$$\chi(k,\omega) \sim \frac{1}{(c^2k^2-\omega^2)^{1-\eta/2}}\ ;\ T = 0,\ g = g_c \tag{14}$$

The most important property of equation (14) is the absence of a quasiparticle pole in the spectral density. Instead, $\mathrm{Im}\,(\chi(k,\omega))$ is nonzero for all $\omega > ck$, reflecting the presence of a continuum of critical excitations. Thus the stable quasiparticles found at low enough energies for all $g \neq g_c$ are absent at the quantum critical point.

We now briefly discuss the nature of the phase diagram for $T > 0$ with g near g_c. In general, the interplay between quantum and thermal fluctuations near a quantum critical point can be quite complicated (Sachdev, 1999), and we cannot discuss it in any detail here. However, the physics of the quantum Ising chain is relatively simple and also captures many key features found in more complex situations and is summarized in Figure 5. For all $g \neq g_c$ there is a range of low temperatures ($T \lesssim |g - g_c|$) where the long-time dynamics can be described using a dilute gas of thermally excited quasiparticles. Further, the dynamics of these quasiparticles is quasiclassical, although we reiterate that the nature of the quasiparticles is entirely distinct on opposite sides of the quantum critical point. Most interesting, however, is the novel *quantum critical* region $T \gtrsim |g - g_c|$ where neither a quasiparticle picture nor a quasiclassical description are appropriate. Instead, we have to understand

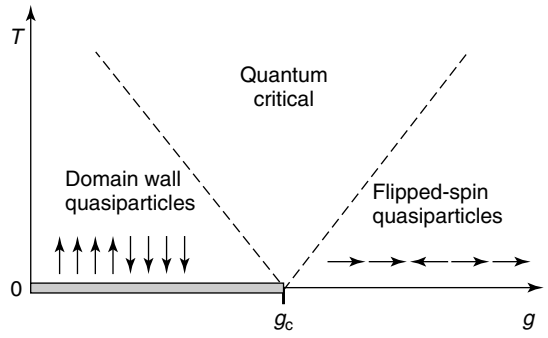

Figure 5. Nonzero-temperature phase diagram of H_I. The ferromagnetic order is present only at $T = 0$ on the shaded line with $g < g_c$. The dashed lines at finite T are crossovers out of the low T quasiparticle regimes where a quasiclassical description applies. The state sketched on the paramagnetic side used the notation $|{\rightarrow}\rangle_j = 2^{-1/2}(|{\uparrow}\rangle_j + |{\downarrow}\rangle_j)$ and $|{\leftarrow}\rangle_j = 2^{-1/2}(|{\uparrow}\rangle_j - |{\downarrow}\rangle_j)$.

the influence of temperature on the critical continuum associated with equation (14). This is aided by scaling arguments, which show that the only important frequency scale that characterizes the spectrum is $k_B T/\hbar$, and the crossovers near this scale are universal, that is, independent of specific microscopic details of the lattice Hamiltonian. Consequently, the zero-momentum dynamic susceptibility in the quantum critical region takes the following form at small frequencies:

$$\chi(k=0,\omega) \sim \frac{1}{T^{2-\eta}} \frac{1}{(1-i\omega/\Gamma_R)} \tag{15}$$

This has the structure of the response of an overdamped oscillator, and the damping frequency Γ_R is given by the universal expression

$$\Gamma_R = \left(2\tan\frac{\pi}{16}\right)\frac{k_B T}{\hbar} \tag{16}$$

The numerical proportionality constant in equation (16) is specific to the quantum Ising chain; other models also obey equation (16), but with a different numerical value for this constant.

4 BEYOND LGW THEORY

The quantum transitions discussed so far have a critical theory identical to that found for classical thermal transitions in $d+1$ dimensions. Over the last decade, it has become clear that there are numerous models of key physical importance for which such a simple classical correspondence does not exist. In these models, quantum *Berry phases* are crucial in establishing the nature of the phases and of the critical boundaries between them. In less technical terms, a signature of this subtlety is an important simplifying feature that was crucial in the analyses of Section 2: both models had a straightforward $g \to \infty$ limit in which we were able to write down a simple, nondegenerate, ground-state wave function of the 'disordered' paramagnet. In many other models, identification of the 'disordered' phase is not as straightforward: specifying absence of a particular magnetic order as in (2) is *not* enough to identify a quantum state, as we still need to write down a suitable wave function. Often, subtle quantum interference effects induce new types of order in the 'disordered' state, and such effects are entirely absent in the LGW theory.

An important example of a system displaying such phenomena is the $S = 1/2$ square-lattice antiferromagnet with additional frustrating interactions. The quantum degrees of freedom are identical to those of the coupled dimer antiferromagnet, but the Hamiltonian preserves the full point-group symmetry of the square lattice:

$$H_s = \sum_{j<k} J_{jk}\left(\hat{\sigma}_j^x\hat{\sigma}_k^x + \hat{\sigma}_j^y\hat{\sigma}_k^y + \hat{\sigma}_j^z\hat{\sigma}_k^z\right) + \ldots \tag{17}$$

Here the $J_{jk} > 0$ are short-range exchange interactions that preserve the square-lattice symmetry and the ellipses represent possible multiple spin terms. Now imagine tuning all the non-nearest-neighbor terms as a function of some generic coupling constant g. For small g, when H_s is nearly the square-lattice antiferromagnet, the ground state has antiferromagnetic order as in Figure 4 and equation (11). What is the 'disordered' ground state for large g now? One natural candidate is the spin-singlet paramagnet in Figure 2. However, because all nearest-neighbor bonds of the square lattice are now equivalent, the state in Figure 2 is degenerate with three other states obtained by successive 90 °C rotations about a lattice site. In other words, the state in Figure 2, when transferred to the square lattice, *breaks* the symmetry of lattice rotations by 90 °C. Consequently it has a new type of order, often called *valence-bond-solid* (VBS) order. It is now believed (Senthil *et al*., 2004a, b) that a large class of models like H_s do indeed exhibit a second-order quantum phase transition between the antiferromagnetic state and a VBS state (Figure 6). The existence of VBS order in the paramagnet and a second-order quantum transition are both features that are not predicted by LGW theory: these can only be understood by a careful study of quantum interference effects associated with Berry phases of spin fluctuations about the antiferromagnetic state.

We will now review the manner in which Berry phases lead to a breakdown of LGW field theory. We begin with the field theory $\mathcal{Z}_\phi$ in equation (12) for the coupled dimer antiferromagnet and modify it to include Berry phases of the spin. For each spin, the partition function acquires a

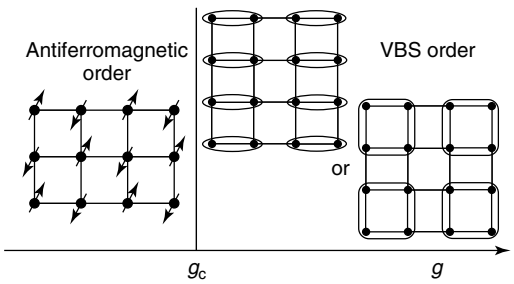

Figure 6. Phase diagram of H_s. Two possible VBS states are shown: one that is the analog Figure 2 and the other in which spins form singlets in a plaquette pattern. Both VBS states have a fourfold degeneracy due to breaking of square-lattice symmetry. So the novel critical point at $g = g_c$ (described by $\mathcal{Z}_z$) has the antiferromagnetic and VBS orders vanishing as it is approached from either side: this coincident vanishing of orders is generically forbidden in LGW theories.

phase factor $e^{iA/2}$, where A is the area enclosed by the world line of the spin on the unit sphere in spin space. To include this contribution, it is necessary to rewrite equation (12) in terms of a 'hard-spin' unit vector field $\mathbf{n}$, rather than the soft-spin field ϕ_α. The direction of $\mathbf{n}$ then represents the local orientation of the antiferromagnetic order parameter. Furthermore, the Berry phase contributions oscillate rapidly from site to site, and, so, we have to write them down on the underlying lattice and cannot directly take the continuum limit. In this manner, we obtain from equation (12)

$$\mathcal{Z}_{\mathbf{n}} = \int \mathcal{D}\mathbf{n}(r,\tau)\delta(\mathbf{n}^2(r,\tau)-1) \times \exp\left[\frac{i}{2}\sum_j \eta_j \int \mathrm{d}\tau \mathcal{A}_\tau(\mathbf{n}(r_j,\tau)) - \frac{1}{2gc}\int \mathrm{d}^2 r \mathrm{d}\tau \left((\partial_\tau \mathbf{n})^2 + c^2(\nabla_r \mathbf{n})^2\right)\right] \quad (18)$$

Excluding the first Berry phase term, this is the action of the so-called O (3) nonlinear sigma model in three space–time dimensions. Here, we are primarily interested in the consequences of the Berry phases: $\mathcal{A}_\tau(\mathbf{n}(\tau))\mathrm{d}\tau$ is defined as the oriented area of the spherical triangle defined by $\mathbf{n}(\tau)$, $\mathbf{n}(\tau+\mathrm{d}\tau)$, and an arbitrary reference point $\mathbf{n}_0$ (which is usually the north pole).

The theory in equation (18) can be considered as the 'minimal model' of quantum antiferromagnets on the square lattice. At small g there is the conventional magnetically ordered 'Néel' phase with $\langle\mathbf{n}\rangle \neq 0$, while at large g there is a 'quantum-disordered' paramagnetic phase, which preserves spin rotation invariance with $\langle\mathbf{n}\rangle = 0$. We are especially interested here in the nature of this paramagnetic state.

The key to an analysis of the large-g regime is a better understanding of the nature of $\mathcal{A}_\tau$. We will see that $\mathcal{A}_\tau$ behaves in many respects like the time component of a compact U(1) gauge field, and, indeed, this accounts for the suggestive notation. All physical results should be independent of the choice of the reference point $\mathbf{n}_0$, and it is easy to see by drawing triangles on the surface of a sphere that changes in $\mathbf{n}_0$ amount to gauge transformations of $\mathcal{A}_\tau$. If we change $\mathbf{n}_0$ to $\mathbf{n}_0'$, then the resulting $\mathcal{A}_\tau'$ is related to $\mathcal{A}_\tau$ by

$$\mathcal{A}_\tau' = \mathcal{A}_\tau - \partial_\tau \phi(\tau) \quad (19)$$

where $\phi(\tau)$ measures the oriented area of the spherical triangle defined by $\mathbf{n}(\tau)$, $\mathbf{n}_0$, and $\mathbf{n}_0'$. Furthermore, as we will discuss more completely in the subsequent text, the area of any spherical triangle is uncertain modulo 4π, and this accounts for the 'compactness' of the U(1) gauge theory.

We proceed with our analysis of $\mathcal{Z}_{\mathbf{n}}$. First, we discretize the gradient terms of the O (3) sigma model. We will limit our considerations here to antiferromagnets on the square lattice, but similar considerations apply to other bipartite lattices. We also discretize the imaginary-time direction, and (by a slight abuse of notation) use the same index j to refer to the sites of a three-dimensional cubic lattice in space–time. On such a lattice we can rewrite (18) as

$$\mathcal{Z}_{\mathbf{n}} = \int \prod_j d\mathbf{n}_j \delta(\mathbf{n}_j^2 - 1) \times \exp\left(\frac{1}{2g}\sum_{j,\mu} \mathbf{n}_j \cdot \mathbf{n}_{j+\hat{\mu}} + \frac{i}{2}\sum_j \eta_j \mathcal{A}_{j\tau}\right) \quad (20)$$

where the sum over μ extends over the three space–time directions, and $\mathcal{A}_{j\mu}$ is defined to equal the oriented area of the spherical triangle formed by $\mathbf{n}_j$, $\mathbf{n}_{j+\mu}$, and the arbitrary (but fixed) reference point $\mathbf{n}_0$. We have also dropped unimportant factors of the lattice spacing and the spin-wave velocity in (20).

The theory equation (20) is still cumbersome to work with because $\mathcal{A}_{j\tau}$ is a complicated function of $\mathbf{n}_j$. However, a purely local formulation can be found by reexpressing $\mathbf{n}_j$ in terms of *spinor* variables. We write

$$n_{j\alpha} = z_{ja}^* \sigma_{ab}^\alpha z_{jb} \quad (21)$$

where σ^α are the Pauli matrices, the z_{ja} are two-component complex spinor fields residing on the sites of the cubic lattice, and a is a *spinor* index that extends over $\uparrow$ and $\downarrow$. It is an interesting classical result in spherical trigonometry that the area of a spherical triangle can be expressed quite simply in terms of the spinor coordinates of its vertices. We will not explicitly review this analysis here, but refer the reader to a separate review (Sachdev, 2004). Using this result, it is not difficult to show that equation (20) is very closely related to the following partition function on the cubic lattice

$$\mathcal{Z}_z = \prod_{j\mu}\int_0^{2\pi} \frac{\mathrm{d}A_{j\mu}}{2\pi} \prod_{ja}\int \mathrm{d}z_{ja} \prod_j \delta\left(|z_{ja}|^2 - 1\right) \times \exp\left(\frac{1}{g}\sum_{j\mu}\left(z_{ja}^* e^{-iA_{j\mu}} z_{j+\mu,a} + \text{c.c.}\right) + i\sum_j \eta_j A_{j\tau}\right) \quad (22)$$

Note that we have introduced a new field $A_{j\mu}$ on each link of the cubic lattice, which is integrated over. This is a compact U(1) gauge field, which has replaced $\mathcal{A}_{j\mu}$ in equation (20): it can be shown (Sachdev, 2004) that the integral over $A_{j\mu}$ in equation (22) is dominated by values $A_{j\mu} \approx \mathcal{A}_{j\mu}/2$, and the resulting action differs

from equation (20) only in unimportant details. The crucial advantage of equation (22) is, of course, that there are no constraints between the z_{ja} and the $A_{j\mu}$, and we now have to deal with a purely local lattice gauge theory.

The theory $\mathcal{Z}_z$ now allows us to address the key questions linked to the breakdown of LGW theory. At small g, we have, as before, a Néel state with $\langle z_a \rangle \neq 0$, and hence from equation (21) $\langle \mathbf{n} \rangle \neq 0$. We will now describe the nature of the large g paramagnetic phase and of the transition between the small- and large-g phases in the subsections in the following text.

4.1 Nature of the paramagnet

For large g, there are strong fluctuations of the z_{ja}, and it therefore pays to integrate out the z_{ja} from $\mathcal{Z}_z$ and obtain an effective theory for the $A_{j\mu}$. This can be done order by order in $1/g$ in a 'high-temperature' expansion. The powers of $1/g$ yield terms dependent upon gauge-invariant U(1) fluxes on loops of all sizes residing on the links of the cubic lattice. For our purposes, it is sufficient to retain only the simplest such term on elementary square plaquettes, yielding the partition function

$$\mathcal{Z}_A = \prod_{j\mu} \int_0^{2\pi} \frac{\mathrm{d}A_{j\mu}}{2\pi} \times \exp\left(\frac{1}{e^2} \sum_{\square} \cos\left(\epsilon_{\mu\nu\lambda} \Delta_\nu A_{j\lambda} \right) + i \sum_j \eta_j A_{j\tau} \right) \tag{23}$$

where $\epsilon_{\mu\nu\lambda}$ is the totally antisymmetric tensor in three space–time dimensions. Here the cosine term represents the conventional Maxwell action for a compact U(1) gauge theory: it is the simplest local term which is consistent with the gauge symmetry and periodic under $A_{j\mu} \to A_{j\mu} + 2\pi$. The sum over $\square$ in (23) extends over all plaquettes of the cubic lattice, Δ_μ is the standard discrete lattice derivative ($\Delta_\mu f_j \equiv f_{j+\mu} - f_j$ for any f_j), and e^2 is a coupling constant. We expect the value of e to increase monotonically with g.

The properties of a pure compact U(1) theory have been described by Polyakov (1987). Here we need to extend his analysis to include the all-important Berry phases in $\mathcal{Z}_A$. The Berry phase has the interpretation of a $\int J_\mu A_\mu$ coupling to a static matter field with 'current' $J_\mu = \delta_{\mu\tau}$, that is, static charges ± 1 on the two sublattices. It is this matter field that will crucially control the nature of the paramagnet.

Polyakov showed that the quantum fluctuations of the pure compact U(1) gauge theory were controlled by *monopole* tunneling events at which the U(1) gauge flux changed by 2π. In particular, at all values of the coupling e, the monopoles eventually proliferate at long enough distances and lead to confinement of 'electric' charges: here these electric charges are the $S = 1/2$ z_a quanta (also known as *spinons*).

For our purposes, we need to understand the influence of the Berry phase terms in $\mathcal{Z}_A$ on the monopoles. This is a subtle computation (Haldane, 1988; Read and Sachdev, 1990) that has been reviewed elsewhere (Sachdev, 2004). The final result is that each monopole can also be associated with a Berry phase factor. If $m_j^\dagger$ is the monopole creation at site j, then this appears in the partition function as

$$m_j^\dagger \zeta_j \tag{24}$$

where ζ_j is a fixed field taking the values 1, i, -1, $-i$ on the four square sublattices as shown in Figure 7.

An important consequence of these Berry phases is that the monopole operator now transforms nontrivially under the operations of the square-lattice space group. Indeed, the partition function of the antiferromagnet must be invariant under all space group operations, and, so, by demanding the invariance of equation (24), we deduce the transformation properties of the monopole operator. A simple analysis of equation (24) then shows that

$$\begin{aligned} T_x &: m \to i m^\dagger \\ T_y &: m \to -i m^\dagger \\ R^{\mathrm{dual}}_{\pi/2} &: m \to m^\dagger \\ I^{\mathrm{dual}}_x &: m \to m \\ \mathcal{T} &: m \to m \end{aligned} \tag{25}$$

Here $T_{x,y}$ are translations by one lattice spacing along the x,y axes, $R^{\mathrm{dual}}_{\pi/2}$ is a rotation by $\pi/2$ about a site of the dual lattice, I^{dual}_x is reflection about the y axis of the dual lattice, and $\mathcal{T}$ is time reversal.

The transformation properties in equation (25) now allow us to relate the monopole operator to physical observables by searching for combinations of spin operators that have

1	i	1	i
$-i$	-1	$-i$	-1
1	i	1	i
$-i$	-1	$-i$	-1

Figure 7. The values of the fixed field ζ_i that specify the Berry phase of the monopole tunneling events. The monopoles are assumed to be centered on the sites of the dual lattice.

the same signature under space group operations. It turns out that the monopole operator is connected to the VBS order parameter (Read and Sachdev, 1990). From Figure 6, we note that VBS order is associated with modulations in the value of the nearest-neighbor spin-singlet correlations. So we can define a complex order parameter, $\psi_{\rm VBS}$, such that

$$\begin{aligned} {\rm Re}\left[\psi_{\rm VBS}\right] &= (-1)^{j_x} \sum_\alpha \hat{\sigma}^\alpha_j \hat{\sigma}^\alpha_{j+x} \\ {\rm Im}\left[\psi_{\rm VBS}\right] &= (-1)^{j_y} \sum_\alpha \hat{\sigma}^\alpha_j \hat{\sigma}^\alpha_{j+y} \end{aligned} \tag{26}$$

It is now easy to work out the space group transformations of $\psi_{\rm VBS}$. These lead to the important correspondence (Read and Sachdev, 1990; Senthil *et al*., 2004a, b)

$$m \sim e^{-i\pi/4}\psi_{\rm VBS} \tag{27}$$

We have now assembled all the ingredients necessary to describe the interplay between the monopole dynamics and the Berry phases in the paramagnetic phase. Using a mapping from the compact U(1) gauge theory to a dual effective action for monopoles, the proliferation of monopoles can be argued (Sachdev, 2004) to be equivalent to their 'condensation' with $\langle m_j \rangle \neq 0$. This argument also applies in the presence of Berry phases although cancellations among the phases now leads to a significantly smaller value of $\langle m_j \rangle$. Nevertheless, it can be shown that $\langle m_j \rangle$ is nonzero in the paramagnetic phase. Because of the nontrivial transformation properties of m_j under the square-lattice space group noted in the preceding text, it is then clear that a nonzero $\langle m_j \rangle$ spontaneously breaks the space group symmetry. Indeed, the connection in equation (27) shows that this broken symmetry is reflected in the appearance of VBS order. The precise configuration of the VBS order depends on the value of Arg$[\langle m \rangle]$. Using equation (27) and the space group transformations in the preceding text, the two VBS configurations shown in Figure 6 appear for Arg$[\langle m \rangle]$ equal to $\pi/4, 3\pi/4, 5\pi/4, 7\pi/4$ or $0, \pi/2, \pi, 3\pi/2$.

We have now established the breakdown of LGW theory induced by the Berry phases in $\mathcal{Z}_{\mathbf{n}}$ in equation (18). A theory of the quantum fluctuations of the LGW antiferromagnetic order parameter $\mathbf{n}$ does not lead to a featureless 'quantum disordered' paramagnetic state. Rather, subtle quantum interference effects induce a new VBS order parameter and an associated broken symmetry.

4.2 Deconfined criticality

We now turn to a brief discussion of the quantum phase transition between the small-g Néel phase with $\langle \mathbf{n} \rangle \neq 0$ and $\langle \psi_{\rm VBS} \rangle = 0$ and the large-g paramagnetic phase with $\langle \mathbf{n} \rangle = 0$ and $\langle \psi_{\rm VBS} \rangle \neq 0$. The two phases are characterized by two apparently independent order parameters, transforming very differently under spin and lattice symmetries. Given these order parameters, LGW theory predicts that there can be no direct second-order phase transition between them, except with fine tuning.

Recent work by Senthil *et al*. (2004a, b) has shown that this expectation is incorrect. Central to their argument is the demonstration that at a possible quantum critical point the monopole Berry phases in equation (24) lead to complete cancellation of monopole effects even at the longest distance scales. Recall that in the $g > g_c$ paramagnetic phase, Berry phases did lead to a partial cancellation of monopole contributions, but a residual effect was present at the longest scales. In contrast, the monopole suppression is complete at the $g = g_c$ quantum critical point.

With the suppression of monopoles, the identification of the continuum critical theory turns out to be quite straightforward. We simply treat $A_{j\mu}$ as a noncompact U(1) gauge field and take the naive continuum limit of the partition function $\mathcal{Z}_z$ in equation (22) while ignoring the monopoles and their Berry phases. This leads to the field theory

$$\begin{aligned} \mathcal{Z}_{zc} = \int \mathcal{D}z_a(x,\tau)\mathcal{D}A_\mu(x,\tau) \\ \times \exp\Bigg(-\int d^2x d\tau \Bigg[|(\partial_\mu - iA_\mu)z_a|^2 + s|z_a|^2 \\ + \frac{u}{2}(|z_a|^2)^2 + \frac{1}{2e^2}(\epsilon_{\mu\nu\lambda}\partial_\nu A_\lambda)^2\Bigg]\Bigg) \end{aligned} \tag{28}$$

In comparing $\mathcal{Z}_{zc}$ to the continuum theory $\mathcal{Z}_\phi$ for the coupling dimer antiferromagnet, note that the vector order parameter ϕ_α has been replaced by a spinor z_a, and these are related by $\phi_\alpha \sim z^*_a \sigma^\alpha_{ab} z_b$, from equation (21). So the order parameter has *fractionalized* into the z_a spinons. A second novel property of $\mathcal{Z}_z$ is the presence of a U(1) gauge field A_μ: this gauge field emerges near the critical point, even though the underlying model in equation (17) has only simple two-spin interactions.

Studies of fractionalized critical theories like $\mathcal{Z}_{zc}$ in other models with spin and/or charge excitations is an exciting avenue for further theoretical research and promises to have significant applications in a variety of correlated electron systems (Senthil, Sachdev and Vojta, 2005; Balents *et al*., 2005).

Theory of Magnetocrystalline Anisotropy and Magnetoelasticity in Transition-metal Systems

Ruqian Wu
University of California, Irvine, CA, USA

1 INTRODUCTION

The application of innovative experimental tools and the desire to grow nanostructures and novel materials in a controlled manner have produced an urgent need for highly reliable, robust, and predictive theoretical models and tools to achieve a quantitative understanding of their growth dynamics and the size, shape, and process dependencies of their physical properties. It has been recognized in many fields of materials science that state-of-the-art *ab initio* electronic structure calculations based on the density-functional theory (DFT) (Hohenberg and Kohn, 1964; Kohn and Sham, 1965) have been enormously successful, in both explaining existing phenomena and, more importantly, in predicting the properties of new systems. For example, the prediction of enhanced magnetic moments with lowered coordination numbers at clean metal surfaces has stimulated both theoretical and experimental explorations for new magnetic systems and phenomena in man-made nanostructures (Freeman and Wu, 1991; Freeman, 2002). Synergistic applications of theory and experiment, as demonstrated repeatedly in many areas of materials science, become a 'must' to further advance our understanding of magnetism in reduced dimensions.

It is known that the magnetism of ultrasmall entities is not stable due to super paramagnetism (Mermin and Wanger, 1966). Thermal fluctuation is the major obstacle for further size reduction of magnetic devices and has become an urgent issue for fundamental research. Innovative strategies to block thermal fluctuation with high magnetic anisotropy energy (MAE) have attracted enormous attention in recent years. Moreover, it is preferred to have the easy axis aligned along the perpendicular direction, a stipulation for the next generation high-density magnetic recording media (Weller and Moser, 1999; Weller *et al*., 2000; Wood, 2000; Bertram and Williams, 2000; Bertram and Shimizu, 2003). Experimental studies for spin reorientation transition (SRT) in various magnetic thin films have been very fruitful (Allenspach and Bischof, 1992; Li *et al*., 1994; Durr *et al*., 1997; Farle, 1998; Hope, Gu, Choi and Bland, 1998; Bland, Hope, Choi and Bode, 1999; Sander, 2004). Many possible tactics have been found to tailor magnetic anisotropies of nanostructured magnetic materials by manipulating lattice strains, compositions, capping layers, growth procedures, and surface adsorbates (Qiu, Pearson and Bader, 1993; Kawakami, Escorcia-Aparicio and Qiu, 1996; O'Brien, Droubay and Tonner, 1996; Millev and Kirschner, 1996; Oepen, Speckmann,

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

Millev and Kirschner, 1997; Farle *et al*., 1997; van Dijken, Vollmer, Poelsema and Kirschner, 2000; Baberschke, Donath and Nolting, 2001; Yin *et al*., 2006), and the underlying electronic mechanism has been extensively explored through density-functional calculations (Johnson, Bloemen, den Broedert and de Vries, 1996; Wu and Freeman, 1999; Weinberger and Szunyogh, 2000; Hong *et al*., 2004). Furthermore, the strain dependence of MAE is the origin of another important magnetic phenomenon: magnetostriction (Gibbs, 2001; Engdahl, 2002). Anisotropic magnetostriction is generally described as the deformation of a body in response to a change in its direction of magnetization through the application of a magnetic field. Strongly magnetostrictive materials are widely utilized in various MEMS, sensor, actuator, and transducer applications. On the other hand, materials with extremely small magnetostrictive coefficients, λ (defined as $\lambda \propto \Delta l/l$, here l denotes the length of a sample), are desired in electric transformers, motor shielding, and magnetic recording. Innovative magnetic materials that have strong magnetostrictive yet ductile mechanical properties attract renewed attention for the miniaturization of operation devices (Clark *et al*., 2000; Clark, Wun-Fogle, Restorff and Lograsso, 2001). Owing to its intrinsic complexity, however, magnetostriction in transition-metal systems has rarely been tackled theoretically until very recently (Wu and Freeman, 1999).

In this chapter, I will review the current status of theoretical determination for magnetic anisotropy and magnetostriction of transition-metal systems. Examples used here, mainly from our own work, will elucidate the main challenges, solutions, and prospects of these vigorous research fields.

2 THEORETICAL BACKGROUND

Magnetic anisotropy depends on two factors: the spin-orbit coupling (SOC, the contribution from this part is called *magnetocrystalline anisotropy*, E_{MCA}) and the magnetostatic dipole–dipole interaction (this part of the anisotropy is called *shape anisotropy*). The shape anisotropy can be evaluated through summing up over discrete lattice

$$E_{\mathrm{shape}} = A \sum_{i \neq j} \left[\frac{(\vec{m}_i \cdot \vec{m}_j)}{|r_{ij}|^3} - \frac{3}{|\vec{r}_{ij}|^5} (\vec{m}_i \cdot \vec{r}_{ij})(\vec{m}_j \cdot \vec{r}_{ij}) \right] \tag{1}$$

Here A is a unit-dependent constant; $\vec{m}$ and $\vec{r}$ are local magnetic moments and position vectors, respectively. The determination of E_{MCA}, on the other hand, was a major challenge for theoretical calculations in the last two decades. The reliable determination of E_{MCA} for a given material requires highly accurate electronic structures and proper treatment of the weak SOC Hamiltonian. The single-particle energy (ε) and wave function (Ψ), the bases for predictions of almost all physical properties of real materials, can be obtained by solving the Kohn–Sham equation

$$\left[-\frac{1}{2}\nabla^2 + V_{\mathrm{ext}} + V_{\mathrm{c}} + V_{\mathrm{xc}} \right] \Psi = \varepsilon \Psi \tag{2}$$

Here, V_{ext} and V_{c} are the external potential and the Coulomb potential among electrons, while V_{xc} is the exchange-correlation potential that takes into account all the complexities of many-body interactions. In practical calculations, the local spin density approximation (LSDA) and the more advanced generalized gradient approximation (GGA) are usually adopted for V_{xc}. By using different basis functions, equation (2) is typically solved as a generalized matrix diagonalization problem of $H - \varepsilon S = 0$, where H and S are the matrices of Hamiltonian and overlap. In the implementation of the all-electron full-potential linearized augmented plane wave (FLAPW) method (Wimmer, Krakaur, Weinert and Freeman, 1981; Weinert, Wimmer and Freeman, 1982), the space is divided into three regions, namely, the near nucleus muffin-tin region, the vacuum region, and the remaining interstitial region. The wave function, potential, and charge density are expended in a 'natural' way without any artificial shape approximations. The spin-orbit coupling term is usually omitted in most of the DFT calculations hitherto. The so-called scalar-relativistic or semirelativistic (Koelling and Harmon, 1977) approaches significantly reduce computational demands but still provide good results for various physical properties such as optimized geometry, spin magnetic moment, and magnetic ordering. For the determination of E_{MCA} and λ, the relativistic SOC is essential. To the order of $(v/c)^2$, the SOC Hamiltonian is expressed as

$$H^{\mathrm{SOC}} = \frac{\hbar^2}{4m^2c^2} \frac{\partial V(r)}{r\,\partial r} \vec{l} \cdot \vec{S} = \xi(\vec{l} \cdot \vec{S}) \tag{3}$$

In practical calculations, the SOC Hamiltonian is expressed in a matrix format in the spin space (the two states are denoted as $\uparrow$ and $\downarrow$, respectively) as,

$$\vec{l} \cdot \vec{S} = \begin{pmatrix} \dfrac{A_+ + A_-}{2} \sin\theta + L_z \cos\theta & \left(A_- \cos^2\dfrac{\theta}{2} - A_+ \sin^2\dfrac{\theta}{2} - L_z \sin\theta \right) \mathrm{e}^{-i\phi} \\ \left(A_+ \cos^2\dfrac{\theta}{2} - A_- \sin^2\dfrac{\theta}{2} - L_z \sin\theta \right) \mathrm{e}^{i\phi} & -\dfrac{A_+ + A_-}{2} \sin\theta - L_z \cos\theta \end{pmatrix} \tag{4}$$

Here θ and ϕ are for polar and azimuthal angles of magnetization and $A^+ = e^{-i\phi}(L_x + iL_y)$ while $A^- = e^{i\phi}(L_x - iL_y)$. For 3d transition metals, it has been shown that involvement of H^{SOC} alters charge density, spin density, and spin moment negligibly (Wu and Freeman, 1999). In contrast, H^{SOC} has to be invoked in the self-consistence loop for the solution of the Kohn–Sham equations when heavy elements are involved, especially in nanoentities in which 4d and 5d elements are also magnetic.

In low dimensions, the leading term in E_{MCA} is the uniaxial anisotropy, $E_{MCA} = K\sin^2\theta + O(\sin^4\theta, \sin^4\phi)$. For the determination of K, the magnetocrystalline anisotropy force theorem (Daalderop, Kelly and Schuurmans, 1990; Wang, Wang, Wu and Freeman, 1996a)

$$E_{MCA} \equiv E(90^\circ) - E(0^\circ) \approx \sum_{occ'} \varepsilon_i(90^\circ) - \sum_{occ''} \varepsilon_i(0^\circ) \quad (5)$$

was adopted in most previous *ab initio* calculations. Because the sets of occupied states, that is, {occ′} and {occ″}, were determined through the Fermi filling scheme, which relies on very limited information from ε_i alone, a huge number of k points (>10 000 in the two dimensional Brillouin zone for thin films) are needed to restrain the numerical fluctuation (Gay and Richter, 1986; Daalderop, Kelly and Schuurmans, 1990). This hurdle was overcome in the last decade by using various broadening techniques (Trygg, Johansson, Eriksson and Wills, 1995; Hjortstam *et al*., 1997) and the state-tracking (Wang, Wu and Freeman, 1993) and the torque (Wang, Wang, Wu and Freeman, 1996b) schemes. Particularly, the torque method circumvents the need to differentiate energies. Instead, E_{MCA} is evaluated through the expectation values of the angular derivative of H^{SOC} with wave function at a magic angle $\Psi'(\theta_m, \phi_m)$. Here the prime indicates that the SOC is taken into account.

$$E_{MCA} = \sum_{i\in occ} \langle \Psi_i'(\theta_m, \phi_m)| \frac{\partial H^{SOC}}{\partial \theta} |\Psi_i'(\theta_m, \phi_m)\rangle \quad (6)$$

The magic angle (θ_m, ϕ_m) can be found from the symmetry, or more explicitly the form of angular dependence of total energy. For a uniaxial system, it can be proved that $\theta_m = 45^\circ$ and $\phi_m = 0^\circ$. Very stable results of uniaxial E_{MCA} have been obtained with a manageable number of k points, as elucidated in examples in the subsequent text.

The determination of magnetostrictive coefficients for real materials is another difficult problem for modern electronic structure theory (Wu and Freeman, 1999; Fahnle, Komelj, Wu and Guo, 2002; Komelj and Fahnle, 2006). In general, the size of the magnetoelastic strain induced by rotation of the magnetization depends on the directions of the measured strain and the spin moment. For a cubic material, the directional dependence of the fractional change in length can be expressed in terms of the direction cosines of the magnetization (α) and of the strain measurement (β) with respect to the crystalline axes

$$\frac{\Delta l}{l_0} = \frac{3}{2}\lambda_{001}\left[\sum_{i=1}^{3}\alpha_i^2\beta_i^2 - \frac{1}{3}\right] + 3\lambda_{111}\sum_{i\neq j}^{3}\alpha_i\alpha_j\beta_i\beta_j \quad (7)$$

If the measurement is carried out along the (001) direction, for example, $\alpha_x = \alpha_y = 0$ and $\alpha_z = 1$, then equation (7) can be simplified as $\Delta l/l_0 = 3/2\lambda_{001}[\alpha_z^2 - 1/3]$ or further, for systems with a single domain,

$$\lambda_{001} = \frac{1}{3}\frac{l_0(\theta = 0^\circ) - l_0(\theta = 90^\circ)}{l_0(\theta = 0^\circ) + l_0(\theta = 90^\circ)} \quad (8)$$

Clearly, λ_{001} represents the change in length along (001) when the magnetization turns from the x, y plane to the z direction. As a normal practice, the equilibrium lengths, $l_0(\theta)$, can be obtained by fitting the calculated total energies in a quadratic form

$$E(\theta = 0^\circ) = al^2 + bl + c; \quad \text{and}$$
$$E(\theta = 90^\circ) = al^2 + bl + c + E_{MCA} \quad (9)$$

From equation (8), one can get

$$\lambda_{001} = -\frac{2}{3}\frac{\frac{dE_{MCA}}{dl}}{b} \quad (10)$$

Since b is negative (a and l_0 are positive), λ and $\frac{dE_{MCA}}{dl}$ should *always* have the same sign. Obviously, the major challenge for first-principles calculations is the determination of $\frac{dE_{MCA}}{dl}$, which is typically very small.

3 MAGNETIC ANISOTROPY OF THIN FILMS

In most of the magnetic thin films, large uniaxial MAEs are induced not only by the surface and interface effects but also by lattice strains due to lattice mismatches and the presence of step edges (Baberschke, 1996; Kawakami, Escorcia-Aparicio and Qiu, 1996). The surface and interface contributions sensitively depend on the atomic relaxations, chemisorptions, and growth morphologies. Well-optimized structures are hence prerequisites for the determination of E_{MCA} through DFT calculations. Fortunately, most of the modern DFT packages can directly calculate atomic forces to expedite the structural optimization procedures. Nevertheless, one should note that while GGA significantly

improves the results of atomic structures for 3d transition metals over LSDA, it overestimates the volume of 4d and 5d elements as well as oxides. Extra care is thus needed to handle systems with mixing building blocks.

To understand complex magnetic films, it is instructive to first analyze the electronic origin of the E_{MCA} for a free-standing magnetic monolayer. The k distributions of E_{MCA} and the band structures of a Co monolayer, for example, are plotted in Figure 1 along the high-symmetry directions in the 2D Brillouin zone. Obvious correlation between the abrupt changes in E_{MCA} and the locations where bands cross the Fermi level discloses simple physics. Clearly, the large negative E_{MCA} for the Co monolayer (-1.34 meV/atom) mainly stems from contributions around the M point. This can be further traced to SOC interaction(s) between the occupied $d_{xz,yz}$ states ($m = \pm 1$, denoted as state 5 in Figure 1) and the unoccupied d_{z^2} state ($m = 0$, denoted as state 1 in Figure 1). Note only the pair across E_{F} with the same (different) magnetic quantum number(s) leads to a positive (negative) contribution to E_{MCA}. By knowing the origin of E_{MCA} of simple systems, one can tailor magnetic anisotropy by engineering the bands of the magnetic layer. For example, owing to the Co–Cu d-band hybridization, the Co-$d_{xz,yz}$ states are lowered in energy in Co/Cu(001) and Cu/Co/Cu(001). As a result, E_{MCA} becomes less negative in Co/Cu(001)and is positive in Cu/Co/Cu(001) (Gavrilenko and Wu, 1999), in good accordance with experimental data (Krams *et al*., 1992). Many calculations have been done in the last decade to study the effects of metal substrates or capping layers on the E_{MCA} of ultrathin magnetic thin films (Wu and Freeman, 1999; Weinberger and Szunyogh, 2000). It is now well established that values of K for magnetic films can be determined through high-quality DFT calculations with satisfactory accuracy; some of the calculations also give atom-resolved contributions from different layers (Uiberacker *et al*., 1999).

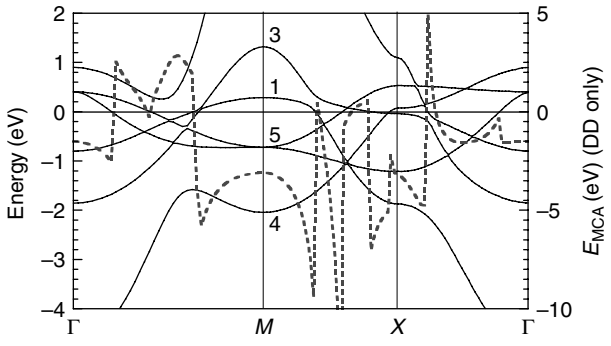

Figure 1. The band structure (thin solid lines, for minority spin only) and the EMCA (bold dashed line) of the Co(001) monolayer ($a = 4.8$ au) through LSDA calculations.

Interestingly, E_{MCA} of Fe, Co, and Ni films can be tuned by surface chemisorptions of O, CO, and H (Baek, Lee, Kim and Vescovo, 2003; Vollmer *et al*., 1999; Vollmer and Kirschner, 2000; van Dijken, Vollmer, Poelsema and Kirschner, 2000; Matsumura *et al*., 2002; Sander *et al*., 2004), and the underlying electronic mechanism has been actively explored through theory and experiment interplays. Figure 2 illustrates theoretical and experimental results of MAEs for O/Ni/Cu(001) from different regions, namely, the y interception of the $K(1/d)$ line is for bulk and its slope is for surface/interface (Hong *et al*., 2004). For O/Ni/Cu(001), the bulk contribution is 27 meV/atom, primarily caused by the tetragonal distortion in the Ni films grown on Cu(001) (Farle *et al*., 1997; Wu, Chen and Freeman, 1997a; Hjortstam *et al*., 1997). Contributions from the Cu/Ni and O/Ni interfaces are -59 and $-17\,\mu$eV/atom, respectively. The dramatic decrease in magnitude at the O/Ni interface leads to a shift of critical thickness for SRT from 10 Ni MLs in vacuum/Ni/Cu(001) to 5 Ni MLs in O/Ni/Cu(001), as given by the interception between the K(1/d) line with the horizontal line of $2\pi M^2$ in Figure 2(a). This brings the optimum record up to date for SRT in Ni/Cu(001), as compared to cases using Cu, hydrogen, or CO. Theoretical calculations reproduced the trend of experimental data very well, indicating the appropriateness of models. Analyses in electronic structures furthermore attributed the O-induced change in E_{MCA} to the new surface state with the d_{xz} feature caused by the O adlayer. O- and H-induced relaxation and buckling in the second layer also play a role. Surprisingly, the presence of O does not purge the magnetization in the surface region (Hong *et al*., 2004). Instead, the Ni surface magnetic moments are significantly enhanced (by more than 5% for Ni alone), especially when the sizable spin polarization of oxygen ($m_{\mathrm{O}} = 0.18\,\mu_{\mathrm{B}}$) is included. However, the magnetic moments of both O and Ni are significantly reduced if the atomic structure is optimized with LDA that produces better agreement with experimental X-ray magnetic circular dichroism data (Sorg *et al*., 2006).

4 MAGNETIC ANISOTROPY OF WIRES AND CHAINS

Ultrasmall monatomic chains, the smallest possible magnetic recording units (for 100–1000 TB in.$^{-2}$), are grown on vicinal substrates (Gambardella *et al*., 2002) or built by Scanning Tunnelling Microscope (STM) tip manipulation (Nilius, Wallis and Ho, 2002). Investigations of MAEs of magnetic clusters including molecule magnets are getting extensive attention for spintronics applications in the future (Sessoli, Gatteschi, Caneschi and Novak, 1993; Respaud,

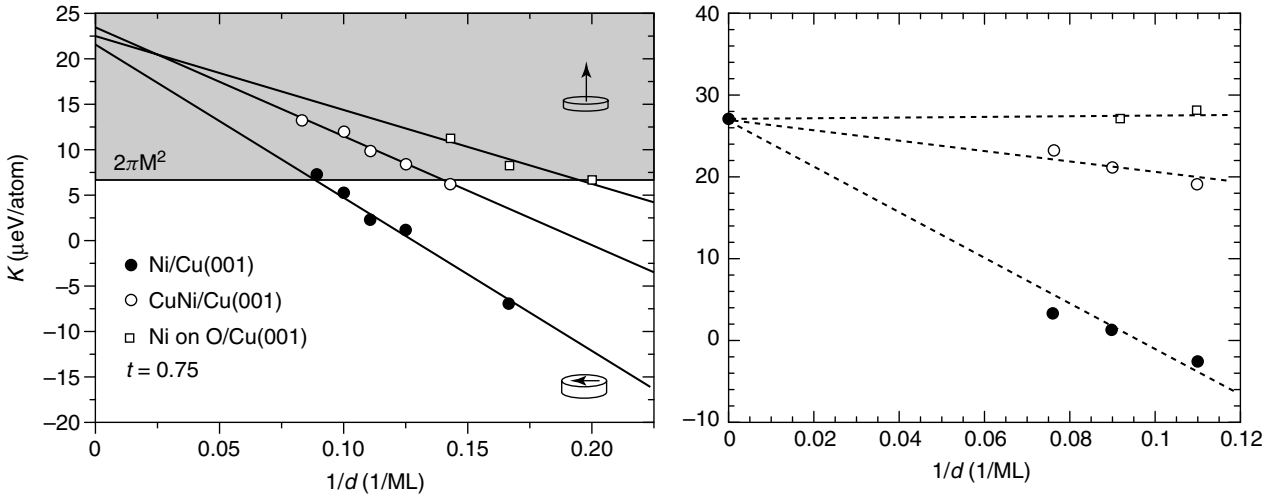

Figure 2. The experimental and theoretical results of magnetic anisotropy energies for Ni/Cu(001), Cu/Ni/Cu(001), and O/Ni/Cu(001).

1998; Caneschi *et al*., 1999; Waldmann *et al*., 2001). The bottleneck for exploitation of nanomagnets is thermal fluctuation, which produces super paramagnetism at finite temperature. A high MAE barrier is vital to maintain ferromagnetic ordering or hold up the magnetic relaxation. Experimentally, Jamet *et al*. studied magnetic anisotropy in a 3-nm cobalt cluster embedded in a niobium matrix and found the dominating role of atoms on the cluster surface (Barra, 1999; Jamet *et al*., 2001, 2004). Gambardella *et al*. reported giant MAEs of Co particles on Pt(111) (Gambardella *et al*., 2003, 2004). They also found that the easy axis of magnetization, the MAE, and the coercive field oscillate as a function of the transverse width of the Co wires on Pt(997). Rusponi *et al*. (2003) attempted to separate contributions of differently coordinated atoms in Co patches deposited on Pt(111) and concluded that the edge atoms play the dominant role in the perpendicular uniaxial anisotropy. Pratzer *et al*. studied Fe stripes on stepped W(110) and found an extremely narrow domain wall, as thin as 6 Å, presumably due to large MAE (Pratzer *et al*., 2001; Pratzer and Elmers, 2003).

Figure 3 displays magnetic phase diagram for a 10-atom monatomic chain, obtained through classical Monte Carlo simulations based on a classical model Hamiltonian. To have high blocking temperature (e.g., 300 K), below which the magnetization of each atom aligns along the easy axis and hence forms a ferromagnetic structure, stringent conditions are required, namely, $J = 320–420$ meV and $K = 30–50$ meV/atom. Such a large E_{MCA} cannot be achieved in nanoentities solely with 3d elements. For the free-standing or supported Co monatomic chains, for example, the amplitude of E_{MCA} is still a few tenths meV/atom (Hong and Wu, 2003). For Co chains on Pt(111), Lazarovits, Szunyogh, and Weinberger (2003). found that the easy axis is perpendicular to the surface, independent of the length of the chains. Fe_n

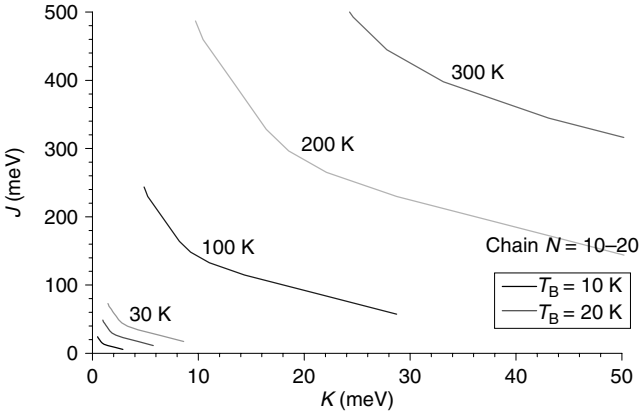

Figure 3. The phase diagram for a free-standing chain of 10 atoms, generated through classical Monte Carlo simulations.

chains grown on Cu(001), Cu(111) as well as embedded in the bulk Cu were also studied (Hong and Wu, 2003). Shick *et al*. found that a quasi-one-dimensional Co chain at the Pt(111) step edge has an easy axis at an odd angle of 20° toward the Pt step (Shick, Gornostyrev and Freeman, 1999; Shick, Maca and Oppeneer, 2004). In addition, the spin and orbital magnetic moments are noncollinear. The proportionality between MAE and the anisotropy of the orbital moment, a conjecture that is adopted for the measurement of E_{MCA} through the X-ray magnetic circular dichroism technique, was also examined for several systems (Ederer, Komelj and Fahnle, 2003; Hong and Wu, 2004).

Intriguingly, giant K up to 30–50 meV/atom was found possible through our recent DFT calculations as illustrated in Table 1. Model calculations for 3d–5d trimers, especially FeOsFe and FeIrFe, revealed large E_{MCA} up to 108 meV, due to both the high spin polarization of Fe and the strong SOC from the 5d atoms. In addition, all 5d atoms possess

Table 1. The calculated K, spin, and orbital magnetic moments distributed in different atoms. The easy axis for positive (negative) E_{MCA} is along (perpendicular to) the chain.

System and magnetic ordering	M_s (μ_B)		M_L (μ_B)		E_{MCA} (meV)
	3d	5d	3d	5d	
FeTaFe (↑↓↑)	2.99	−1.96	−0.16	0.30	−21
FeWFe (↑↓↑)	2.93	−2.85	0.10	0.13	−31
FeReFe (↑↑↑)	3.22	2.94	−0.03	−0.04	−31
FeOsFe (↑↑↑)	3.32	3.21	0.60	0.57	−75
FeIrFe (↑↑↑)	3.36	1.58	0.00	1.53	+108
FePtFe (↑↑↑)	3.34	0.69	0.20	0.34	−27

extraordinarily large spin and in some cases also orbital magnetic moments. In all the trimers, the Fe spin moment is stable and remains 2.99–3.36 μ_B. The spin moments of Ta and W align in an antiparallel manner to that of the adjacent Fe. The maximum induced spin moment occurs for Os, whereas the maximum induced orbital moment occurs for Ir. As indicated by the resonant features in their density of states, strong hybridization is found between Fe and 5d elements. For the FeIr trimer, analyses suggests that the contribution from spin-orbit interaction among the majority spin states, $E_{MCA}(\uparrow\uparrow)$, is negligible compared to $E_{MCA}(\downarrow\downarrow)$. Giant values of 30–60 meV/atom were also reported for stretched Ru or Rh wires by Mokrousov, Bihlmayer, Heinze and Blugel (2006) through FLAPW calculations.

5 MAGNETOSTRICTION OF TRANSITION-METAL BULKS AND ALLOYS

Despite the tremendous advances in modern electronic structure theory for studies in materials science, magnetostriction has been rarely tackled until very recently, due to its intrinsic complexity (Wu and Freeman, 1996; Wu, Chen and Freeman, 1997b, 1998). Benchmark calculations for cubic bulk Fe, Co, and Ni resulted in a good agreement when compared to experiment for λ_{001}. In contrast, the calculated λ_{111} ($+12 \times 10^{-6}$) differs in sign from the experimental data (-23×10^{-6}) (Fahnle, Komelj, Wu and Guo, 2002). This discrepancy was attributed to the incapability of LSDA, but the reliability of experimental data was also questioned with possible involvement of Si impurities. Komelj and Fahnle (2000, 2001, 2002, 2006) investigated the high-order magnetoelastic coefficients of bulk Fe, Co, and Ni. Burkert *et al.* also found that the MAE of FeCo alloy can be exceedingly large when the lattice is tetragonally distorted to a certain c/a ratio (Burkert, Nordstrom, Eriksson and Heinonen, 2004; Burkert *et al.*, 2004; Andersson *et al.*, 2006). One of the most interesting examples is the determination of λ for $Fe_{1-x}Ga_x$ alloys. It was recently found by Clark and collaborators (Clark *et al.*, 2000; Clark, Wun-Fogle, Restorff and Lograsso, 2001; Guruswamy *et al.*, 2000; Cullen *et al.*, 2001; Kellogg *et al.*, 2002) that Ga, when substituted for Fe in the common bcc Fe structure, increases the tetragonal magnetostriction, λ_{001}, over 10-fold above the magnetostriction of the pure bcc bulk Fe ($\lambda_{001} \approx 20 \times 10^{-6}$). As shown in Figure 4, λ_{001} increases with the Ga concentration monotonically when $x < 0.19$; decreases thereafter for $0.19 < x < 0.25$; and increases again if more Ga is added. This promises a possibility of achieving strong magnetostriction in ductile metallic materials, instead of in brittle rare-earth metal compounds (e.g., TERFENOL-D, etc.) (Engdahl, 2002). Strikingly, recent experiments revealed substantial softening in this alloy (Clark *et al.*, 2003). The value of its tetragonal shear elastic constant, $c' = (c_{11} - c_{12})/2$, decreases to 6.8 GPa at $x = 0.27$. Meanwhile, the magnetostrictive coefficients also depend on the quenching history, which indicates that the large magnetostriction is likely to associate with metastable geometries rather than the ground state one (Clark, Wun-Fogle, Restorff and Lograsso, 2001). Nonetheless, the mechanism of such an extraordinary enhancement is unclear.

While the structural phase diagram for $Fe_{1-x}Ga_x$ is rather complex, it is helpful to explore three basic simple structures for $x = 0.25$, namely, DO_3, B_2 like (or L_{60}), and $L1_2$. To determine magnetostrictive coefficients, lattice strain along the z axis (c/c_0) is used as a parameter. Explicitly, the constant-volume mode was adopted in lattice distortion for the $L1_2$ and DO_3 structures, whereas constant-area mode was adopted for the B_2-like structure. The calculated results of

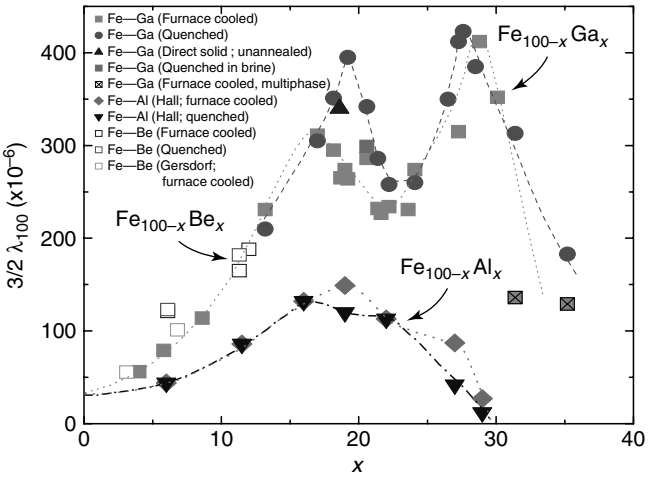

Figure 4. Magnetostrictive coefficients of $Fe_{1-x}Ga_x$ measured by A.E. Clark *et al.*

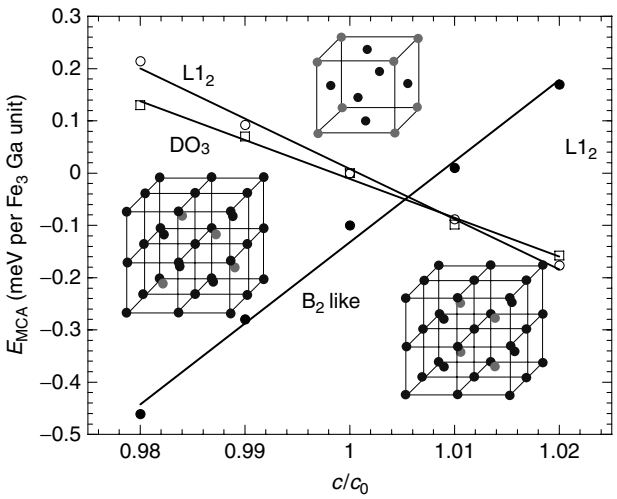

Figure 5. The calculated strain dependence of E_{MCA} of $Fe_{0.75}Ga_{0.25}$ in simple structures.

strain-dependent E_{MCA} are plotted in Figure 5. Interestingly, the calculated slope of E_{MCA} is positive only for the B_2-like structure. Quantitatively, the calculated values of λ_{001} are -107×10^{-6}, -298×10^{-6}, and $+380 \times 10^{-6}$ for the DO_3, $L1_2$, and B_2-like structures, respectively. Overall, the magnitude of λ_{001} for all these three structures is much larger than that for the pure bcc bulk Fe (20×10^{-6}), due to the stronger magnetoelastic coupling as well as the smaller Young's modulus. Experimentally, λ_{001} for $Fe_{1-x}Ga_x$ is $+150 \sim +200 \times 10^{-6}$ when x is 0.25. This indicates that the local B_2-like structure plays a key role in the strong positive magnetostriction of FeGa alloys (Wu, 2002). The change in sign of λ_{001} from the DO_3 structure to the B_2-like structure is very fascinating, since only the second-neighbor arrangement is altered. The calculated magnetic moments in the B_2-like structure ($2.48\,\mu_{\mathrm{B}}$ for Fe(1) in the mixed layer, $2.08\,\mu_{\mathrm{B}}$ for Fe(2) in the pure layer, and $-0.08\,\mu_{\mathrm{B}}$ for Ga) are very close to those in the DO_3 structure ($2.41\,\mu_{\mathrm{B}}$ for Fe(1), $1.96\,\mu_{\mathrm{B}}$ for Fe(2), and $-0.07\,\mu_{\mathrm{B}}$ for Ga). The difference originates from very subtle changes in their band structures. In the DO_3 structure, the negative magnetostriction is associated with strain dependence of the d_{z^2} and $d_{x^2-y^2}$ states in the unoccupied regime. Meanwhile, some of the Fe(2)-$d_{xz,yz}$ and -d_{xy} states become nonbonding states and they lie around the Fermi level in the minority spin channel. This enhances the SOC interaction between occupied t_{2g} states and the unoccupied e_g states and leads to large negative magnetostriction. For the B_2-like structure, the Fe(2)-$d_{xz,yz}$ states in the minority spin band become nondegenerate and some of them are unoccupied because of lower symmetry. Since they have the same magnetic quantum numbers ($m = \pm 1$), the SOC interaction between them leads to a positive magnetostriction.

Unfortunately, the B_2-like structure in the small cell is unstable under tetragonal distortion and one thus needs to consider more complex geometries. Our recent calculations found that the B_2-like structure can be stabilized either by mixing with the DO_3 structure or by removing some Ga atoms from the lattice. For the latter case, large magnetostrictive coefficient, $\lambda_{001} = +188 \times 10^{-6}$, is found for the $Fe_{0.81}Ga_{0.19}$ alloy in the B_2-like structure (by substituting one Ga atom with Fe in a 16-atom unit cell). In contrast, the DO_3-like structure still contributes a negative λ_{001} (-70×10^{-6}). Calculations using a large unit cell for $Fe_{0.75}Ga_{0.25}$ that combines the B_2-like and DO_3 structure result in a positive magnetostriction, $\lambda_{001} = +90 \times 10^{-6}$. Obviously, involvement of the B_2-like geometry is very important for attaining large positive magnetostriction. Total energy calculations also indicate that Ga atoms tend to distribute away from each other. Furthermore, the random alloy is less favorable in energy than those that retain pure Fe layers adjacent to the mixed layers.

6 CONCLUSIONS

As discussed through several examples in the preceding text, high-quality density-functional calculations can provide reliable results for magnetocrystalline anisotropy and magnetostriction in transition-metal systems. The insights revealed through analyses of electronic structures are imperative in guiding experimental procedures for the design of novel nanomagnetic materials. To determine E_{MCA} of nanostructures, a general treatment including noncollinear ordering is necessary, as was done in several recent studies (Nordstrom and Singh, 1996; Nakamura *et al*., 2004). The correlation and orbital polarization effects on E_{MCA} should also be examined, especially when the system has only a few atoms (Yang, Savrasov and Kotliar, 2001; Solovyev, 2005). Furthermore, *ab initio* treatment for spin relaxation, spin waves, and spin transport has been developed recently to explain experimental observations (Vomir *et al*., 2005; Steiauf and Fahnle, 2005) but more efforts are needed to enhance the capability and reliability of theoretical tools. Some of these topics are discussed more extensively in other chapters in this handbook.

Theory of Magnetocrystalline Anisotropy and Magnetoelasticity in 4f and 5f Metals

Børje Johansson and Michael S.S. Brooks
Uppsala University, Uppsala, Sweden

1 INTRODUCTION

The differences in the nature of the chemical bonding in the d, 4f, and 5f series is illustrated by the atomic volumes shown in Figure 1. The parabolic decrease in volumes across the transition-metal series is mirrored by the early part of the 5f series as each added electron changes the bonding. The lanthanide contraction across the 4f series is relatively small and monotonic except for the anomalous divalent elements, Eu and Yb, and the actinide contraction of the heavy 5f elements is similar to that of the rare-earth series with a large expansion for the divalent element, Es. The difference in volume between the divalent and trivalent metals is approximately due to one extra bonding d electron and it is evident that the f electrons are not bonding. Most elements lose their magnetic moments in the metallic state. The exceptions are a few transition metals, some actinides, and most rare earths. The 3d transition metals Fe, Co, Ni, and Mn order magnetically. Otherwise transition metals are paramagnets with enhanced susceptibilities, the enhancement being mostly due to exchange interactions between the d electrons that are also involved in cohesion and the determination of structure (Friedel, 1969; Pettifor, 1970; Skriver, 1985). Nearly all of the rare-earth metals are magnetically ordered at low temperatures. The 4f shell is chemically inert, the bonding and structure being due to the conduction electrons (Duthie and Pettifor, 1977; Skriver, 1983). The rare-earth metals are therefore 5d transition metals with about two 5d electrons. The origin of the magnetism is the localized 4f shell (Jensen and Mackintosh, 1991). However, there is little in the way of direct magnetic interaction between the 4f shells on different atoms, and if the 4f electrons on their own were responsible for the magnetism, the rare earths would be paramagnets down to the lowest temperatures. Exchange interactions between 4f and conduction electrons provide the mechanism for indirect interaction between 4f shells that is finally responsible for magnetic order. The actinide metals are more complex. The light actinides are 5f transition metals, whereas the heavy actinides are 6d transition metals since their 5f shell is chemically inert (Skriver, 1985). The light actinide metals are Pauli paramagnets but magnetic order is to be found in many of their compounds, as is the case for transition metals.

The absence of magnetic order in light actinide elemental metals has changed the way magnetism has been studied in light actinides. Studies of magnetism in transition metals and rare earths began with the elemental metals, and models for their compounds were built on that basis. Fundamental studies of magnetism in light actinides begin with their compounds. Perhaps the most basic empirical result is that there are critical An–An interatomic distances in actinide compounds above which magnetic order occurs. The systematic absence of

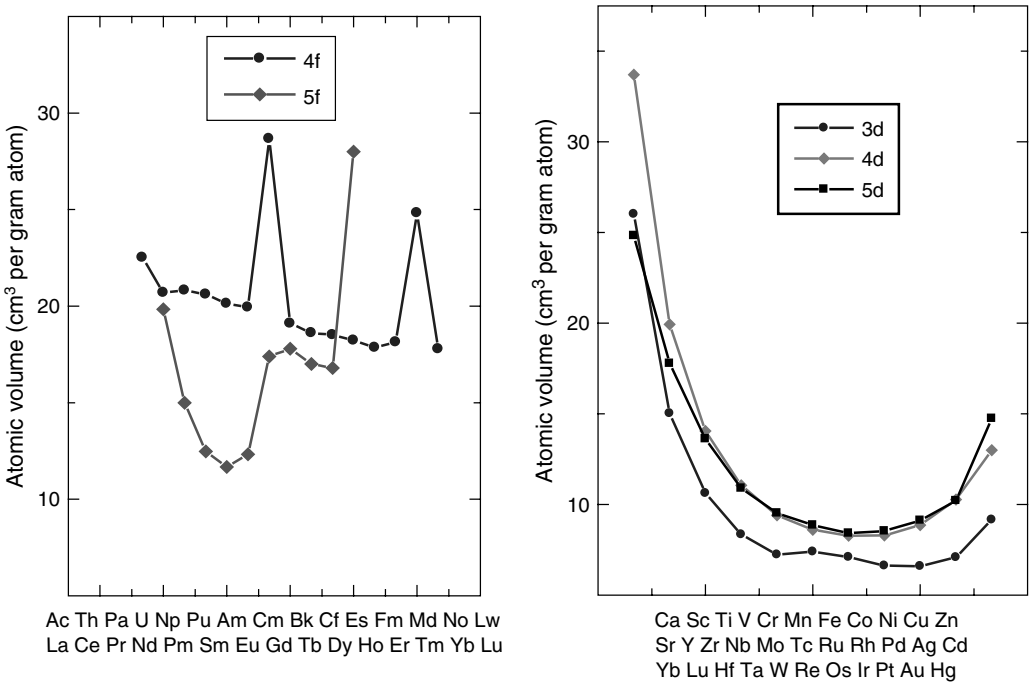

Figure 1. Atomic volumes of the 3d, 4d, 5d, 4f, and 5f elemental metals in the solid state.

magnetism in compounds with small An–An separation (Hill, 1970) suggests that magnetic ordering is due to the competition between kinetic and magnetic energies as in transition metals. However magnetic actinide compounds have, in contrast to transition metals, large orbital magnetic moments – a property that is normally associated with rare earths.

1.1 Free lanthanide and actinide atoms

The single electron wave functions, ψ_{nlm}, are products, $R_{nl}(r)Y_{lm}$, and 4f and 5f atoms have the same angular properties. The radial part of the wave functions differs, Figure 2, because not only are the actinides larger atoms but also the radial 5f wave functions have an extra node and are more extended. The more extended 5f radial densities are responsible for major differences in the magnetic properties of 4f and 5f metals. The densities in Figure 2 are the result of self-consistent field atomic calculations. Exact solutions to the Schrödinger or Dirac equations for large atoms are not achievable but the effect of the Coulomb interactions between electrons can be approximated by a self-consistent field (See also **Density-functional Theory of Magnetism, Volume 1**). The single electron wave equation is solved at a given potential for each of the occupied states and the resulting wave functions used to calculate the electron density. The density is then used to recalculate the potential and the process repeated until the calculated electron density differs from the electron density in the previous iteration by less than a specified amount. The iterative procedure in self-consistent field calculations allows the effect of screening of the Coulomb interactions to be approximated reasonably accurately. For example, the contraction of the f shell across the 4f and 5f series is reproduced, due to incomplete screening of nuclear potential as each f electron is added. For free atoms, the number of electrons is fixed and an issue occurs for 4f and 5f atoms since the f shells are not full. In self-consistent field calculations, the energy is minimized when the energies of the outermost occupied orbitals are equal, and this rarely leads to integral occupation numbers for the different orbitals. In practice, the occupation number of the 4f and 5f states is fixed to its known integer value and the calculation made subject to this constraint. When the f states are truly localized, as in most of the rare earths, the constraint may also be used in the solid state although there are other ways to ensure that the number of f states remains approximately integral (Svane and Gunnarsson, 1990; Anisimov, Aryasetiawan and Lichtenstein, 1997) (See also **Dynamical Mean-field Theory of Itinerant Electron Magnetism, Volume 1**).

The angular properties of the ground state of f shells are obtained from the Russell–Saunders coupling scheme in which direct Coulomb and exchange interactions are the largest parts of the electron Hamiltonian. Since electron–electron interactions are unchanged by simultaneous rotations of all the electrons, the total spin, $\boldsymbol{S}$, and orbital angular

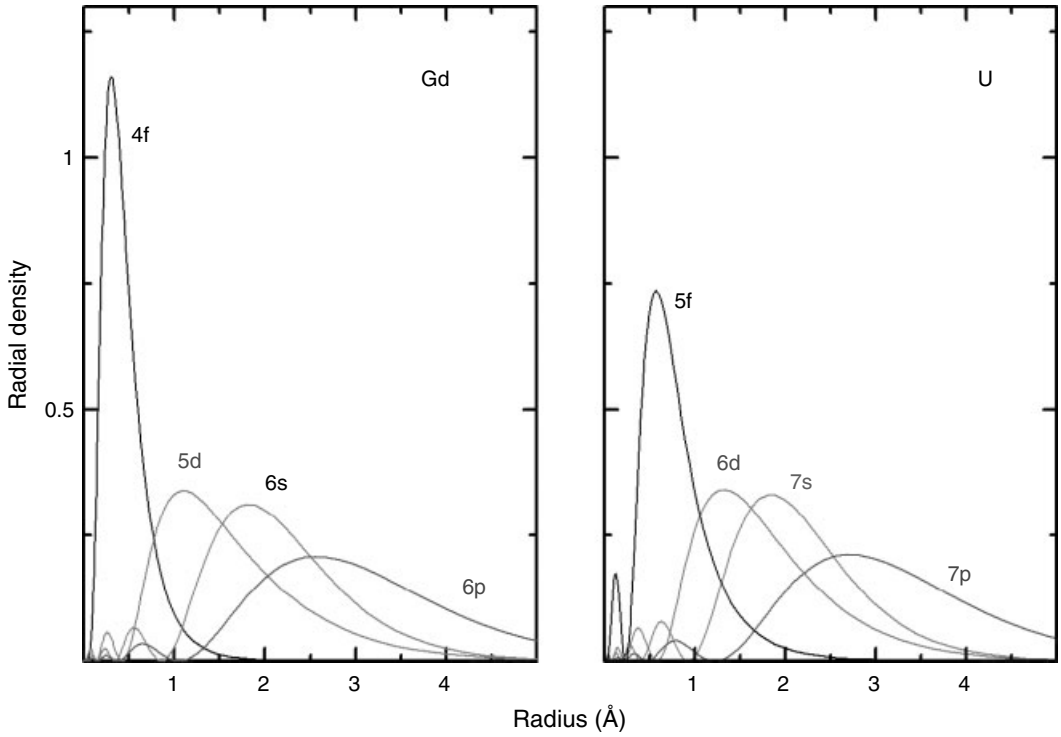

Figure 2. Calculated radial densities ($= 4\pi r^2 R_n^2(r)$) of the valence electrons in Gd and U.

momentum, $\boldsymbol{L}$, are conserved. The smaller spin-orbit interaction is a perturbation that couples $\boldsymbol{L}$ and $\boldsymbol{S}$ to a total angular momentum $\boldsymbol{J}$. It is a consequence of the strong coupling of the electrons to first $\boldsymbol{S}$ and $\boldsymbol{L}$, and then $\boldsymbol{J}$, involving a high degree of electron correlation that the matrix elements of all operators in the ground state are proportional to those of $\boldsymbol{J}$

$$\boldsymbol{O} = \frac{\langle J||\boldsymbol{O}||J\rangle}{\langle J||\boldsymbol{J}|J|\rangle}\boldsymbol{J} \tag{1}$$

where $\langle||\cdots||\rangle$ denotes a reduced matrix element. For example, the saturated ground state f moment, $\boldsymbol{\mu} = \boldsymbol{L} + 2\boldsymbol{S}$, is a product of $\boldsymbol{J}$ with the Landé factor, g_J, that is just the ratio of the reduced matrix elements of $\boldsymbol{\mu}$ and $\boldsymbol{J}$. Equation (1), a consequence of the Wigner–Eckart theorem, becomes particularly useful when the crystal field is added to the electron Hamiltonian.

1.2 Electronic structure of 4f and 5f metals

The standard model for the rare-earth metals (Jensen and Mackintosh, 1991) approximates the rare-earth atoms in the solid by retaining the free atom properties of the open 4f shell and allowing either two or three electrons to enter the conduction (or valence) bands resulting in a solid of divalent or trivalent ions immersed in a sea of conduction electrons. In practice, the orbital degeneracy of the 4f ground state is partially or fully removed in the solid by the crystalline electric field (CEF), which has crystal point group rather than full rotational symmetry. The CEF is therefore an origin of magnetocrystalline anisotropy energy (MAE) for the 4f magnetism. Anisotropic interion interactions (AII) may also play a role. The volume and strain dependence of the CEF and AII produce magnetoelastic effects special to the 4f electrons. Both the CEF and conduction electron–mediated AII depend on the electronic structure of the conduction electrons, primarily 5d electrons. The magnetic properties of 4f metals therefore depend on the electronic structure of both localized and itinerant electrons and the interactions between them.

At temperatures high enough that all crystal-field levels are populated, the Curie–Weiss law for the paramagnetic susceptibility is obeyed with an effective moment of $g_J\sqrt{J(J+1)}$. The Russell–Saunders coupling scheme provides a direct relationship between the number of 4f electrons, the magnitude of the total angular momentum, $\boldsymbol{J}$, and the paramagnetic moment. These relationships are less reliable in actinide compounds where, due to the more extended 5f wave functions, the effects of the CEF are far larger or the 5f electrons are even involved in chemical bonding. A thorough knowledge of the conduction electron wave functions, usually including the 5f wave functions, is required to describe 5f magnetism.

While localized electrons in their ground state always have a maximum spin moment, this is not the case for itinerant electrons. When the energy bands spin polarize, the kinetic energy of the occupied majority spin states increases more rapidly than the kinetic energy of the minority spin states decreases. As a consequence, the total kinetic energy is increased and must be compensated by a gain in exchange energy. The increase in kinetic energy, ΔT_s, is smaller for narrow bands and vanishes in the atomic limit. The balance is quantified by the Stoner criterion, $ID(E_F)/2 > 1$, for the appearance of magnetism, where I is the exchange integral and $D(E_F)$ is the density of states at the Fermi energy. Typically the exchange integral is about 1 and 0.5 eV in 3d transition metals and actinide metals, respectively. The lighter actinide metals and some actinide compounds, for example, UC, with small lattice constants are Pauli paramagnets, and have been found not to satisfy the Stoner criterion (Brooks, 1984; Trygg *et al*., 1995).

The 4f bandwidths in the actinides (typically 3 eV) are less than the 3d bandwidths in transition metals (typically 6 eV), whereas the spin-orbit splitting of 0.7 eV in U is an order of magnitude larger than in Fe where it is about 0.05 eV. The spin-orbit interaction mixes an orbital moment into the ground state. The mixing is from states across the energy bands, and when the bandwidth is large compared to the spin-orbit splitting, the mixing is small; hence the orbital moment is almost entirely quenched in 3d transition metals. The large spin-orbit interaction in light actinide compounds is responsible for large orbital moments in itinerant actinide magnets and concomitantly large MAE (Brooks and Kelly, 1983).

Hohenberg and Kohn (1964) proved that the ground state energy of a system of interacting electrons is a functional of the single electron density and derived a variational principle for the ground state energy. The general theory is known as *density-functional theory* (*DFT*) (See also **Density-functional Theory of Magnetism, Volume 1**). The variational principle was converted to a computationally viable form for self-consistent electron density calculations for atoms and solids by Kohn and Sham (1965). The essence of the Kohn and Sham (1965) procedure is to subdivide the total energy into large contributions that are either well-known functionals, such as the Hartree and kinetic energies and a much smaller remainder, E_{xc}, the exchange and correlation energy. Approximations to E_{xc} *hopefully* produce reasonably small errors. Calculations may then be made without adjustable parameters. A numerically tractable formulation is provided by the Kohn and Sham (1965) equations

$$\left(-\frac{1}{2}\nabla^2 + V_{\text{eff}}\right)\phi_i = \varepsilon_i \phi_i \tag{2}$$

with the effective potential

$$V_{\text{eff}} = V(\boldsymbol{r}) + \int \mathrm{d}\boldsymbol{r}\, \frac{n(\boldsymbol{r}')}{|\boldsymbol{r} - \boldsymbol{r}'|} + \mu_{\text{xc}} \tag{3}$$

consisting of external, Hartree, and exchange-correlation potentials. The latter is given by $\mu_{\text{xc}} = \delta E_{\text{xc}}/\delta n$. The density is reconstructed from solutions to these equations forming a nonlinear system of integrodifferential equations that are solved by iteration. Due to the complexity of the Kohn–Sham equations, more than one stationary solution may exist, for example, metastable magnetic states such as low and high-spin states. The simplest approximation for E_{xc} is the local spin density approximation (LSDA),

$$E_{\text{xc}}^{LSDA}[n_\uparrow, n_\downarrow] = \int \mathrm{d}\boldsymbol{r}\; n(\boldsymbol{r})\epsilon_{\text{xc}}\left(n_\uparrow(\boldsymbol{r}), n_\downarrow(\boldsymbol{r})\right) \tag{4}$$

where ϵ_{xc} is the exchange-correlation energy per electron of the homogeneous electron gas, and $n_\uparrow(\boldsymbol{r})$ and $n_\downarrow(\boldsymbol{r})$ are the spin-up and spin-down electron densities.

2 MAGNETIC INTERACTIONS AND MAGNETOCRYSTALLINE ANISOTROPY ENERGY

2.1 Exchange interactions

The simplest possible exchange interaction between the localized 4f shell and the conduction electrons at rare-earth sites is isotropic

$$\mathcal{H}_{\text{4f-c}} = -\frac{1}{g_j \mu_B^2}\tilde{j}\boldsymbol{\mu}_{\text{4f}}^s \cdot \boldsymbol{\mu}_{\text{c}} = -2\tilde{j}\boldsymbol{S}_{\text{4f}} \cdot \boldsymbol{S}_{\text{c}} \tag{5}$$

where $\boldsymbol{S}_{\text{c}}$, $\boldsymbol{S}_{\text{4f}}$, $\boldsymbol{\mu}_{\text{c}}$, and $\boldsymbol{\mu}_{\text{4f}}^s$ are the conduction electron and 4f spin and spin moments, respectively, and g_j is the 4f g-factor. The local exchange interaction, $\tilde{j}$, depends on the local electron density in LSDA (See also **Density-functional Theory of Magnetism, Volume 1**). More generally, direct and exchange interactions between 4f shell and conduction electrons leads to scattering of conduction electrons accompanied by transitions within the lowest J manifold of the localized 4f electrons. The annihilation and creation operators for the latter transitions may be reexpressed in terms of irreducible tensor operators, $\tilde{O}_K^Q$, so that the Hamiltonian is expanded in multipoles (Teitelbaum and Levy, 1976)

$$\mathcal{H}_{\text{4f-c}} = -\sum_{knLk'n'L'KQ} \tilde{j}_{knLk'n'L'K}^Q \tilde{O}_K^Q(\boldsymbol{J}_j) c_{k'n'L'}^\dagger c_{knL} \tag{6}$$

where the c's are conduction band creation and annihilation operators, n labels the band, and the elements of $\tilde{j}$ are constructed to make $\mathcal{H}_{4f-c}$ symmetry invariant (Hirst, 1978). Another way to view equation (5) is that the conduction electrons interact with an effective inhomogeneous magnetic field $\boldsymbol{H}_i = \tilde{j}_i \boldsymbol{S}_i/\mu_B$ provided by the spin of the 4f shell. The conduction electron moment induced by the field at a site $\boldsymbol{R_j}$ in the crystal is given by

$$\boldsymbol{\mu}_j = \boldsymbol{\chi}_{ji}(\boldsymbol{R})\cdot\boldsymbol{H}_i \tag{7}$$

where $\boldsymbol{\chi}$ is the conduction electron susceptibility tensor and $\boldsymbol{R} = \boldsymbol{R_j} - \boldsymbol{R_i}$. The interaction between the induced moment and the 4f spin at site $\boldsymbol{R_j}$ produces an effective interaction between the f shells at the two sites

$$\mathcal{H}_{ij} = -\frac{\tilde{j}^2}{\mu_B^2}\boldsymbol{S}_i\cdot\boldsymbol{\chi}_{ij}(\boldsymbol{R})\cdot\boldsymbol{S}_j \tag{8}$$

If the conduction electrons were free electrons,

$$\chi(\boldsymbol{R}) = \chi(R) = -4\pi^3\frac{k_F}{R^2}j_1(2k_F R) \tag{9}$$

where j is a spherical Bessel function. The Fourier transform of $\chi(R)$ is the Lindhard function

$$\chi(\boldsymbol{q}) = \sum_{\boldsymbol{k}}\frac{f_{\boldsymbol{k}} - f_{\boldsymbol{k}-\boldsymbol{q}}}{E_{\boldsymbol{k}-\boldsymbol{q}} - E_{\boldsymbol{k}}} \tag{10}$$

where f is the Fermi–Dirac distribution function. The wave-vector-dependent susceptibility may be calculated if the energy band structure is known (Lindgård, Harmon and Freeman, 1975). However it is already clear from the free electron approximation to $\chi(\boldsymbol{q})$ that the main contributions come from pairs of states, one filled and one empty, close to the Fermi energy and separated by wave vector $\boldsymbol{q}$. The peaks in $\chi(\boldsymbol{q})$, or Kohn anomalies, correspond to Friedel oscillations in the real space $\chi(\boldsymbol{R})$. For a real band structure the susceptibility tensor is anisotropic.

More generally, the coupling between the 4f shells on different sites may be expanded in multipole–multipole interactions (Elliott and Thorpe, 1968)

$$\mathcal{H}_{ij} = -\sum_{KLL'}\mathcal{J}^K_{LL'}(\boldsymbol{R})\langle\tilde{O}_K\rangle\tilde{O}_L(\boldsymbol{J}_j)\tilde{O}_{L'}(\boldsymbol{J}_i) \tag{11}$$

where $L = (lm)$ and $K = (kn)$. The $\tilde{O}_L$ are Racah operator equivalents and the effect of the environment has been approximated by a mean field (Jensen, Houmann and Møller, 1975). If all of the $\mathcal{J}_{LL'}$ were zero except for $l = 1$ then $\mathcal{J}_{mm'} = \mathcal{J}_{1,0} = -\mathcal{J}_{1,1} = -\mathcal{J}_{1,-1} = \mathcal{J}$,

$$\mathcal{H}_{ij} = -\mathcal{J}\sum_m(-)^m\tilde{O}_{1,m}(\boldsymbol{J}_j)\tilde{O}_{1,-m}(\boldsymbol{J}_i) = -\mathcal{J}\boldsymbol{J}_j\cdot\boldsymbol{J}_j \tag{12}$$

and isotropic exchange is recovered. The origins of the anisotropic direct and exchange interactions have been studied in detail by Kaplan and Lyons (1963), Specht (1967), Elliott and Thorpe (1968), and Levy (1969). The conduction electron wave functions may be expanded in multipoles about any given site. The monopole is responsible for the $\boldsymbol{s}_c\cdot\boldsymbol{S}_{4f}$ interaction but higher multipoles are responsible for anisotropic exchange (Kaplan and Lyons, 1963; Specht, 1967). Kaplan and Lyons (1963) estimated a pseudodipolar interaction of about 10% of isotropic exchange. An effective spin Hamiltonian such as equation (11) contains the effects of the conduction band MAE and spin-orbit interaction but it *appears* as a part of the anisotropic 4f–4f interaction. Direct electric multipole–multipole interactions between the ions are also present, although probably small in metals due to screening of the Coulomb interactions by conduction electrons. More important are probably the multipole–multipole interactions propagated by lattice strain.

The predominant approximation now used to compute the electronic charge and spin densities in solids from first principles is LSDA (See also **Density-functional Theory of Magnetism, Volume 1**). Gunnarsson (1976) showed how to extract *local* exchange integrals from LSDA, and the variational principle of DFT was used by Brooks and Johansson (1983) to extract local exchange integrals for transition metals, rare earths, and actinide atoms. The 4f–5d and 5d–5d exchange integrals are 94 meV and 0.5 eV, respectively, in gadolinium. The 5f–5f, 5f–4d, and 5d–5d exchange integrals are 0.44, 0.15, and 0.35 eV, respectively, for uranium. Since the ions and ionic magnetic moments in a metal move far more slowly than the conduction electrons, it is a good approximation to assume that the conduction electrons adjust instantaneously to any given ionic moment configuration. The spin-wave dispersion relations in Gd metal, calculated by Lindgård, Harmon and Freeman (1975), were in good agreement with measurements as regards the dispersion, suggesting that the results for the wave-vector-dependent susceptibility were good. However, the exchange interactions were calculated using unscreened Coulomb integrals – a method that predated LSDA – and were too large. The exchange integrals obtained from LSDA, if used in the analysis, would have yielded good agreement with measurements. Indirect exchange interactions may also be extracted from self-consistent energy band calculations where the total energy is calculated for different spiral configurations (Sandratskii, 1998; Kurz *et al*., 2004). It is also possible to extract interionic exchange interactions by using the magnetic force theorem (Liechtenstein, Katsnelson and Gubanov, 1984; Liechtenstein, Katsnelson, Antropov and Gubanov, 1987; Bruno, 2003).

It is evident from the foregoing that if the local exchange interactions between the 4f shell and the conduction electrons

can be obtained reasonably accurately from LSDA, the remaining task is to calculate the conduction band interatomic susceptibility, and various methods for doing this have been devised (Cooke, Lynn and Davis, 1980; Callaway, Chatterjee, Singhal and Ziegler, 1983; Savrasov, 1998; Antropov, Katsnelson, van Schilfgaarde and Harmon, 1995). Application has been to magnetic 3d transition metals, but since the rare earths are 5d transition metals, the same techniques should be even more effective as the 5d bands are very broad and their magnetism is induced, reducing the problems of electron correlation. How this may be done has been illustrated by Perlov, Havilov and Eschrig (2000) who have calculated magnon spectra for the heavy rare-earth metals from a Hamiltonian that contained, apart from the crystal fields, parameters evaluated *ab initio* from LSDA. They also found that the conduction electron spin density is not always necessarily collinear with the 4f spin density at a rare-earth site.

Indirect exchange interactions between the rare and transition-metal sublattices in rare-earth intermetallics were calculated from the difference in total energy between ferromagnetic and ferrimagnetic alignment of the sublattices by Liebs, Hummler and Fähnle (1992). Examples of how the local exchange integrals may be used to determine the indirect exchange coupling between rare earth and transition-metal ions in rare earth–transition metal intermetallics have been given by Brooks, Nordström and Johansson (1991).

2.2 The crystalline electric field

Although known as the *crystalline electric field*, or *CEF*, it is the potential and the potential energy that are the subject of calculations. The potential due to a charge distribution, $\rho(\boldsymbol{r}')$, is

$$V_{\text{cef}}(\boldsymbol{r}) = \int \frac{\rho(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|}\,\mathrm{d}\boldsymbol{r}' = \sum_{nm} B_{nm}(r)C_{nm}(\hat{\boldsymbol{r}}) \tag{13}$$

where

$$B_{nm}(r) = \left(\frac{2n+1}{4\pi}\right)^{1/2}\left[r^n a_{nm} + r^{-n-1}a'_{nm}\right] \tag{14}$$

with

$$a_{nm} = \frac{4\pi}{2n+1}\int_r^\infty \mathrm{d}\boldsymbol{r}'\rho(\boldsymbol{r}')\left(\frac{1}{r'}\right)^{n+1} Y_{nm}(\hat{\boldsymbol{r}}')$$
$$a'_{nm} = \frac{4\pi}{2n+1}\int_0^r \mathrm{d}\boldsymbol{r}'\rho(\boldsymbol{r}')(r')^n Y_{nm}(\hat{\boldsymbol{r}}') \tag{15}$$

and

$$C_{nm}(\boldsymbol{r}) = \tilde{Y}_{nm}(\boldsymbol{r}) = \left(\frac{4\pi}{2n+1}\right)^{1/2} Y_{nm}(\boldsymbol{r}) \tag{16}$$

is a tensor operator.

If the charge distribution in the solid is known, the integrals in equation (15) may be calculated. Then the potential is a linear combination of products of spherical harmonics and CEF parameters. The ground state electron density is therefore used to calculate the parameters, a_{nm}, and the radial integrals $\langle r^n\rangle$ and $\langle(1/r)^{n+1}\rangle$.

The matrix elements of the potential for a localized state characterized by L, S, J may be reduced by the Wigner–Eckart theorem and evaluated. Alternatively, since the matrix elements of the CEF are proportional to those of operator equivalents (Stevens, 1952) written in terms of the total angular momentum, $\boldsymbol{J}$, the CEF Hamiltonian may be replaced by a Hamiltonian expressed in terms of the operator equivalents, $\tilde{O}_{nm}(\boldsymbol{J})$.

In the single electron basis, $i^l R_l Y_{lm}\chi = |m\sigma\rangle$ and the N-electron state $|LSJM\rangle$ is (Judd, 1967)

$$|LSJM\rangle = a_N^\dagger \ldots a_1^\dagger|0\rangle \tag{17}$$

where the $a_i^\dagger$ are electron creation operators and $i = (nlm_l m_s)$. A spin-independent single electron operator, $F = \sum_i f_i$, in this basis is

$$F = \sum_i f_i = \sum_{mm'\sigma} a^\dagger_{m'\sigma}\langle m'\sigma|f|m\sigma\rangle a_{m\sigma} \tag{18}$$

where, for $f(\boldsymbol{r}) = B_{nm}(r)C_{nm}(\hat{\boldsymbol{r}})$

$$\langle m'\sigma|f|m\sigma\rangle = \int Y^*_{lm'}(\hat{\boldsymbol{r}})C_{nm}(\hat{\boldsymbol{r}})Y_{lm}(\hat{\boldsymbol{r}})\,\mathrm{d}\hat{\boldsymbol{r}} \times \int r^2 R_l^2(r)B_{nm}(r)\,\mathrm{d}r = \langle B_{nm}\rangle\langle m'|C_{nm}|m\rangle \tag{19}$$

Since the radial wave function, R_l, is the same for all localized electrons of a given l, the $\langle B_{nm}\rangle$ are factorized out and only the matrix elements of the tensor operator

$$A_{nm} = \sum_{mm'\sigma} a^\dagger_{m'\sigma}\langle m'\sigma|C_{nm}|m\sigma\rangle a_{m\sigma} \tag{20}$$

in the basis $|LSJM\rangle$ are required. Then the CEF contribution to the Hamiltonian is

$$V_{\text{cef}} = \sum_{nm}\langle B_{nm}\rangle A_{nm} \tag{21}$$

If the Wigner–Eckart theorem is applied to A_{nm}

$$\langle LSJM'|A_{nm}|LSJM\rangle = (-1)^{J-M'}\begin{pmatrix} J & n & J \\ -M' & m & M\end{pmatrix} \times \langle LSJ||\boldsymbol{A}^{(n)}||LSJ\rangle \tag{22}$$

where $\boldsymbol{A}^{(n)}$ is a reduced operator. Since $\boldsymbol{A}^{(n)}$ operates only on the spatial variables, the reduced matrix element may be further factored

$$\langle LSJ||\boldsymbol{A}^{(k)}||LSJ\rangle = (-1)^{L+S+J+n}(2J+1) \times \langle L||\boldsymbol{A}^{(n)}||L\rangle \begin{Bmatrix} J & J & n \\ L & L & S \end{Bmatrix} \quad (23)$$

The remaining reduced matrix element may be evaluated by observing that in the basis $|LM_LSM_S\rangle$, the state $|LLSS\rangle$ is a single Slater determinant for which the matrix elements of A_{mn} are easy to evaluate. Then

$$\langle L||\boldsymbol{A}^{(n)}||L\rangle = (2l+1)\frac{\begin{pmatrix} l & n & l \\ 0 & 0 & 0 \end{pmatrix}}{\begin{pmatrix} L & n & L \\ -L & 0 & L \end{pmatrix}} \times \sum_{m=l+1-N}^{l} (-1)^m \begin{pmatrix} l & n & l \\ -m & 0 & m \end{pmatrix} \quad (24)$$

The matrix elements of the crystal field are then evaluated from equation (22) by substituting from equations (23) and (24) for the reduced matrix elements (Colarieti-Tosti, 2004).

The matrix elements of the tensor operator equivalent, $\tilde{O}_{nm}(\boldsymbol{J})$, for the manifold $|JM\rangle$ are, from the Wigner–Eckart theorem,

$$\langle JM'|\tilde{O}_{nm}(\boldsymbol{J})|JM\rangle = (-1)^{J-M'} \begin{pmatrix} J & n & J \\ -M' & m & M \end{pmatrix} \times \langle J||\tilde{\boldsymbol{O}}^{(n)}||J\rangle \quad (25)$$

The operator equivalents are functions purely of the operators J_z and $J_\pm$, and may be obtained from the generating function

$$\sum_m \tilde{O}_{nm}(\boldsymbol{J})\frac{2^n n! t^m}{[(n+m)!(n-m)!]^{1/2}} = \left[-J_+ t + 2J_z + J_-/t\right]^n \quad (26)$$

Consequently, it may be shown that the reduced matrix element of $\tilde{O}_{nm}(\boldsymbol{J})$ is given by (Egami and Brooks, 1975)

$$\langle J||\tilde{\boldsymbol{O}}^{(n)}||J\rangle = \frac{1}{2^k}\left[\frac{(2J+n+1)!}{(2J-n)!}\right]^{1/2} \quad (27)$$

The ratios

$$f_N^n = \frac{\langle LSJM'|A_{nm}|LSJM\rangle}{\langle JM'|\tilde{O}_{nm}(\mathbf{J})|JM\rangle} = (-1)^{L+S+J+n}(2J+1)\begin{Bmatrix} J & J & n \\ L & L & S \end{Bmatrix}\frac{\langle L||\boldsymbol{A}^{(n)}||L\rangle}{\langle J||\tilde{\boldsymbol{O}}^{(n)}||J\rangle} \quad (28)$$

are the Stevens factors used to replace the crystal-field matrix elements by operator equivalents. The matrix elements of the crystal field may be written in terms of either set of tensor operators

$$\langle LSJM'|V_{\text{cef}}|LSJM\rangle = \sum_{nm}\langle B_{nm}\rangle\langle LSJM'|C_{nm}|LSJM\rangle = \sum_{nm} f_N^n\langle B_{nm}\rangle\langle LSJM'|\tilde{O}_{nm}|LSJM\rangle \quad (29)$$

CEF excitations may be observed directly by inelastic scattering of neutrons, and their single-ion nature is evident from their lack of energy dispersion (See also **X-ray and Neutron Scattering by Magnetic Materials, Volume 1**).

Since the self-consistent electron density used to evaluate the CEF is obtained from energy band calculations, it is useful to set this treatment in the context of DFT. An expression similar to equation (13) has been derived from LSDA by Fähnle (1995) who considered the change of energy due to rotations of the 4f shell. The aspherical electron density of a 4f crystal-field state may be thought of as a small impurity charge, $t(\mathbf{r})$ (which integrates to zero), added to the electron density obtained from a self-consistent calculation. The conduction electron density in the crystal will relax to screen the impurity. The energy functional may be partitioned into a part depending on the original density and a part depending on both the original density and the test charge. Since the original density, $\overline{n}$, was at a variational minimum with respect to variations in the density due to the self-consistent nature of the original energy band calculation, the changes in energy due to the screening density cancel to $O(\delta n)$. In addition, the change in kinetic energy of the 4f shell is zero due to Russell–Saunders coupling, leaving a residual energy change of

$$\delta E = E[\overline{n}, t] = \int \overline{V}(\mathbf{r})t(\mathbf{r})\,\mathrm{d}\mathbf{r} \quad (30)$$

where

$$\overline{V}(\mathbf{r}) = V_N(\overline{n}) + V_H(\overline{n}) + \mu_{\text{xc}}(\overline{n}) \quad (31)$$

is the total potential due to all of the charge except for the nonspherical 4f density (Fähnle, 1995), and it includes an exchange contribution.

2.3 Magnetocrystalline anisotropy energy

The free energy of a magnetic crystal depends on the direction of the magnetic moment but must be invariant under the symmetry operations of the lattice which imposes

conditions on the MAE coefficients, κ_{nm}, in the expansion

$$F(\theta, \phi) = \sum_{n,m} \kappa_{nm} Y_{nm}(\theta, \phi) = \sum_{n,m} K_n^m \sin^n \theta \cos m\phi \quad (32)$$

where θ and ϕ are the angles that magnetization makes with a crystal axis and Y_{nm} are the spherical harmonics. The set of K_n^m are MAE constants and it is straightforward to evaluate κ_{nm} in terms of K_n^m. In a general sense, the origin of MAE is the spin-orbit interaction since there is no other interaction in the electron Hamiltonian coupling the spin direction to the crystal lattice. In 4f metals the spin-orbit interaction is responsible for coupling $\boldsymbol{L}$ and $\boldsymbol{S}$ in the 4f shells. The orientation of an aspherical 4f shell is then related to the direction of the total magnetic moment. One source of MAE is the interaction between the CEF and the multipole moments of the 4f shell. Another is the classical dipole–dipole interaction between the magnetic moments that is particularly important in Gd where the 4f shell is half filled. Although the dipole–dipole interaction energy is usually far smaller than the CEF energy it has a very long range and is responsible for the demagnetization field. Indirect exchange interactions – mediated by conduction electrons – between the 4f ions are also anisotropic, due to both multipolar interaction with the conduction bands and spin-orbit coupling in the conduction electron bands, and may be expanded in two-ion multipole–multipole interactions, equation (11). The Coulomb interactions between the 4f aspherical charge clouds may also be expanded in multipole–multipole interactions, again leading to MAE. In addition, multipole–multipole interactions between the 4f shells may be mediated by lattice strain. Despite the multiplicity of ways that MAE can be produced, it is believed that the CEF is the largest source in rare-earth metals.

Similar considerations should apply to the heavy actinides although there are no measurements available. The origin of MAE in compounds of light actinides is more complex and depends on whether the 5f electrons are itinerant or localized. There is strong evidence that the light actinide dioxides, which are semiconductors, have a localized 5f shell and crystal-field excitations have been observed (Amoretti *et al*., 1989; Fournier *et al*., 1991a; Kern *et al*., 1990). Sharp crystal-field excitations have been observed in one metallic compound, UPd_3. In these cases multipolar interactions are also important. In many compounds, such as the NaCl compounds US and UN, evidence is that the 4f electrons are itinerant, and in these cases the spin-orbit interaction enters at the single electron level, coupling spin and orbit in the conduction bands (Brooks and Kelly, 1983). The spin-orbit splitting between $j = l \pm 1/2$ states ranges from 0.7 to 0.9 eV from U to Pu compared with 0.4 eV in Ce. The MAE is an order of magnitude larger than in 4f metals and 4 orders of magnitude larger than in 3d transition metals (Lander *et al*., 1990).

2.4 Magnetoelastic interactions

All magnetic crystals have some type of MAE and magnetoelastic interactions. By the latter, we mean that a magnetic field affects the elastic properties and that stress affects the magnetic properties. In particular, anomalies in magnetic and elastic properties are produced by structural and magnetic phase transitions, respectively. The MAE originates in the coupling of magnetic moments to the directional properties of the crystal lattice, and the magnetoelastic interactions arise because the MAE *always* changes with changes in the lattice. A change in magnetic state produces a change in the (static) homogeneous strain known as *magnetostriction*. If the MAE is expanded for small strains, the leading term – linear in strain and magnetic variables – is responsible for magnetostriction. The term *quadratic in strain* is responsible for a magnetic contribution to the elastic constants and thus the sound velocity. The dynamic effects of the interaction between inhomogeneous strain and magnetic variables include magnetoelastic waves and magnon–phonon scattering.

When the magnetic interion interactions are large compared to the ion–lattice interactions, phase transitions are driven by the magnetic interactions and the accompanying lattice distortion is magnetostriction. When the ionic ground state has an unquenched orbital moment and ion–lattice interactions are larger than the magnetic interion interactions, local Jahn–Teller (JT) distortions can interact to drive a cooperative structural phase transition known as the *cooperative Jahn–Teller* (*CJT*) *effect*. The magnetic transition then often occurs at a lower temperature to a phase of lower symmetry. A CJT transition is characterized by the softening of one or more elastic constants, whereas in a magnetic transition the effect of magnetostriction on the elastic properties is relatively small (Lines, 1979). The interaction between JT ions, T, is usually quadrupolar (Sivardière and Blume, 1972). Large magnetic interion interactions, M, lead to a second-order magnetic dipole transition ($M \gg T$) where the quadrupolar interactions produce magnetostriction in the ordered phase. The sound velocity remains finite. As M/T decreases, the still magnetic transition changes to first order with both dipolar and quadrupolar order parameters discontinuous at the transition. For $T \gg M$, there are two transitions with decreasing temperature, the first being either a first- or second-order CJT transition for the latter of which an elastic constant softens; the second being the magnetic transition which occurs at a lower temperature and is first or second order depending on its closeness to the CJT transition.

Magnetoelastic coupling manifests itself in quite different ways in 4f and 5f metals and compounds. In the heavy rare earths, the large molecular fields due to the large 4f spin moments mean that magnetic effects dominate, but MAE and magnetostriction are very important, influencing the spin-wave energies and producing magnon–phonon interactions. In some compounds of light actinides, particularly small moment antiferromagnets, JT-induced quadrupolar coupling is large.

2.5 Anisotropy and magnetic structure

In the absence of MAE, the magnetic structure is determined by the isotropic exchange interaction, since in the paramagnetic phase, $1/\chi(\boldsymbol{q}) = 1/\chi^0(\boldsymbol{q}) - \mathcal{J}(\boldsymbol{q})$, and the magnet will order with a $\boldsymbol{Q}$ vector corresponding to a maximum in $\mathcal{J}(\boldsymbol{q})$ that will not necessarily be commensurable with the crystal lattice. In the heavy rare earths, $\boldsymbol{Q} = \boldsymbol{Q}_\parallel$ is parallel to the c axis of the hcp structure. The MAE determines the direction of the magnetic moment and also favors commensurable magnetic structures since the MAE is lower when the magnetic moments lie along easy directions. The sign of the dominant axial CEF parameter, $\langle B_{20}\rangle$ (equation (14)), produces an MAE that confines the magnetic moments of Tb and Dy to the hexagonal plane of the hcp structure. This leads to incommensurable *helical magnetic structures* with the magnetic moments parallel within the hexagonal planes but changing in direction along the c axis with wave vector $\boldsymbol{Q}$. The Stevens factor (equation (28)), is of opposite sign for Tm – reversing the sign of the MAE and confining the magnetic moments to the c axis. The resulting incommensurable *c-axis modulated structure* is described by

$$J_\parallel(\boldsymbol{R}_i) = J\cos(\boldsymbol{Q}\cdot\boldsymbol{R}_i + \phi) \tag{33}$$

with the wave vector $\boldsymbol{Q}$ parallel to the c axis, whereas the helical structure has two oscillating components in the hexagonal plane. For larger MAE, as in Ho at low temperature, the hexagonal plane MAE is large enough to force the helical magnetic order to become commensurable. Apart from these simple examples, the rich variety of magnetic structures observed for the rare-earth metals is due to this competition between isotropic exchange and single- and two-ion anisotropic interactions as explained in detail by Jensen and Mackintosh (1991).

The magnetic structure described by equation (33) is known as a *single-q structure* since only a single $\boldsymbol{Q}$ vector is involved. If, however, $\boldsymbol{Q} = \boldsymbol{Q}_\perp$ is in the hexagonal plane there are three distinct values of $\boldsymbol{Q}$ that are equivalent by symmetry, therefore a possible multiple-$\boldsymbol{Q}$ ($m > 1$) magnetic structure is

$$\boldsymbol{J}(\boldsymbol{R}_i) = \sum_m \boldsymbol{J}_m \mathrm{e}^{i(\boldsymbol{Q}_m\cdot\boldsymbol{R}_i + \phi_m)} \tag{34}$$

where the set of vectors $\{\boldsymbol{Q}\}$ lie in the star of $\boldsymbol{Q}_1$. In Nd, where the MAE (as a result of both CEF and anisotropic two-ion interactions) is relatively larger than in the heavy rare earths, the magnetic order is multi-$\boldsymbol{Q}$ (Bak and Lebech, 1978; Forgan, 1982; Walker and McEwen, 1983; McEwen and Walker, 1986).

The Landau expansion of free energy for the set $\{\boldsymbol{Q}\}$ in powers of the magnetic moment is (Jensen and Mackintosh, 1991; Rossat-Mignod, 1987)

$$F\{\boldsymbol{Q}\} = F_0 + a_{\boldsymbol{Q}} \sum_m J_{\boldsymbol{Q}_m} J_{-\boldsymbol{Q}_m} + b_{\boldsymbol{Q}} \sum_m J^4_{\boldsymbol{Q}_m} + b'_{\boldsymbol{Q}} \sum_{m\neq m'} J^2_{\boldsymbol{Q}_m} J^2_{\boldsymbol{Q}_{m'}} + \cdots \tag{35}$$

and at least fourth order terms are required to remove the degeneracy between multiple-$\boldsymbol{Q}$ structures. Consequently, higher order crystal-field terms or quadrupolar coupling are important in the stabilization of multiple-$\boldsymbol{Q}$ structures.

3 RARE EARTHS

3.1 Crystalline-electric-field anisotropy

Since the CEF is the simplest and usually the principal origin of MAE in 4f metals, we establish the relationship between the CEF parameters (equations (13) and (29)), and the MAE coefficients (equation (32)), in the expansion of the free energy (Callen and Callen, 1965; Brooks and Egami, 1973; Jensen and Mackintosh, 1991). Some care should be taken with regard to the balance between the torque from the applied field and the torque from the MAE (Kanamori and Minatono, 1962; Brooks and Egami, 1973), especially when the MAE is large, but the argument is briefly as follows. Since $F = -\ln Z/\beta$ where $Z = Tre^{-\beta\mathcal{H}}$, the change of free energy on rotation of the moments is $\delta F = \langle\delta\mathcal{H}\rangle$. The CEF Hamiltonian has been expressed in terms of operator equivalents with the direction of magnetic moment (and therefore $\boldsymbol{J}$) along the c axis. Each operator equivalent becomes a linear combination of operator equivalents with the direction of the angular momentum specified by polar angles (θ, ϕ). When the CEF is small enough, the system has cylindrical symmetry about the magnetic moment axis and the only surviving thermal averages of $\tilde{O}_{lm}(\boldsymbol{J})$ are for $m = 0$. Hence

$$\langle\tilde{O}_{lm}(\boldsymbol{J}')\rangle = \tilde{Y}_{lm}(\theta,\phi)\langle\tilde{O}_{l0}(\boldsymbol{J})\rangle \tag{36}$$

The thermal average of the crystal field, (equations (13) and (29)) becomes

$$\langle V_{\text{cef}}\rangle = \sum_{nm} f_N^n \langle B_{nm}\rangle \langle \tilde{O}_{n0}(\boldsymbol{J})\rangle \tilde{Y}_{lm}(\theta,\phi) \tag{37}$$

and comparison with equation (32) yields

$$\kappa_{nm} = f_N^n \langle B_{nm}\rangle \left(\frac{4\pi}{2n+1}\right)^{1/2} \langle \tilde{O}_{n0}\rangle \tag{38}$$

There have been a number of attempts to calculate CEF parameters from first principles. Schmitt (1979a,b) calculated the crystal-field parameters from the aspherical charge density at a rare-earth site although this work predated self-consistent calculations of the charge density. Subsequently LSDA was used to calculate the crystal-field parameters from the self-consistent aspherical charge density (Steinbeck, Richter, Nitzsche and Eschrig, 1996; Richter, Oppeneer, Eschrig and Johansson, 1996; Hummler and Fähnle, 1996a,b; Uebele, Hummler and Fähnle, 1996; Divis and Kuriplach, 1995). The consistency of the application of equation (30) when a nonspherical 4f density is added to the aspherical density of the valence electrons has been investigated by Hummler and Fähnle (1996b) and Fähnle and Buck (1997).

The effects of valence electron screening were included by Brooks, Eriksson, Wills and Johansson (1997) by total energy calculations of the different crystal-field states in PrSb and TmSb. A constrained 4f density corresponding to a particular CEF state was added to the valence electron density and the valence electron density calculated self-consistently, thus allowing it to screen the 4f density. The energies of the crystal field excitations were then obtained as energy differences, as observed in experiments, without the necessity to evaluate CEF parameters. The conditions under which it is necessary to include screening in a total energy calculation have been discussed by Fähnle and Buck (1993) and Brooks, Eriksson, Wills and Johansson (1993).

3.2 Magnetostriction

When the lattice is strained, the magnetic interactions are modified leading to a magnetoelastic coupling between the strain and magnetic moments that is linear in the strain (See also **Magnetostriction and Magnetoelasticity Theory: A Modern View, Volume 1**). The elastic energy, quadratic in the strain, is most conveniently formed from the strains that transform according to the irreducible representations, Γ_n of the chemical point group of the lattice. The hcp lattice occurs frequently for rare earths, in which case the irreducible representations are $\Gamma_\alpha(2)$, $\Gamma_\gamma(2)$, and $\Gamma_\epsilon(2)$ in the notation of Callen and Callen (1965). The elastic energy, invariant under symmetry operations of the crystal, is then

$$\mathcal{H}^e = \frac{1}{2}\sum_{n,m} c_m^n (\varepsilon_m^n)^2 \tag{39}$$

where the c_m^n are elastic constants and the ε_m^n are the irreducible homogeneous strains and m runs over the components of the irreducible representation n. The single-ion magnetoelastic contributions to the Hamiltonian are obtained by forming invariant products of the irreducible strains with linear combinations of tensor operator equivalents transforming according to the irreducible representation Γ_n for the site i

$$\mathcal{H}_i^{me} = -\sum_{n,m} M_m^n \varepsilon_m^n \overline{O}_{nm} \tag{40}$$

where the bar over O denotes the appropriate linear combination. When the magnetoelastic coupling is due to the strain dependence of the CEF it is a single site coupling. There is a similar strain dependence of the interionic interactions leading to two-ion magnetoelastic coupling. Since $\mathcal{H}_i^{me}$ is linear in the strain, the equilibrium strains are never zero when there is magnetic order. The equilibrium strains are obtained by minimizing the free energy with respect to strain. To first order one may use $\partial F/\partial\varepsilon = \langle \partial\mathcal{H}/\partial\varepsilon\rangle = 0$ and the spin Hamiltonian will therefore contain, in addition to the contribution from the unstrained MAE, additional terms arising from equilibrium strains proportional to $M_m^n\langle\overline{O}_{nm}\rangle/c_m^n$. The magnetoelastic contribution to the spin Hamiltonian can be quite large in 4f metals. In the heavy rare-earth metals, where the molecular field is far larger than the crystal field, magnetic dipole order dominates. The magnetostrictive contribution to the spin Hamiltonian has a significant influence on the spin wave energies, especially if the magnetization axis is in the hexagonal plane of the hcp structure (Jensen, Houmann and Møller, 1975), as it is in the ferromagnets Tb and Dy. When the easy axis lies in the hexagonal plane, the energy of the uniform spin-wave mode (or ferromagnetic resonance frequency) in the absence of magnetostriction would be simply proportional to $(K_1 K_3' \cos 6\phi)^{1/2}$, where K_1 and K_3' are the axial and hexagonal plane MAE constants, and ϕ is the angle in the hexagonal plane between the magnetization direction and an easy axis. This is to be expected on physical grounds since the ferromagnetic resonance frequency is proportional to $(F_{\theta\theta}F_{\phi\phi})^{1/2}$, that is, the uniform spin-wave mode just samples the MAE. A magnetic field applied in the hexagonal plane could be used to cancel the hexagonal plane contribution, reducing the resonance frequency to zero. The uniform (static) magnetostrictive strains in these metals prevent the uniform mode frequency from going soft since they add another term to the hexagonal plane contribution to the resonance frequency which is independent

of the direction of magnetic moment in the plane (Cooper, 1968; Brooks, 1970). The strain does not, however, make the same contribution in a static MAE experiment since the uniform strain then adjusts to the direction of magnetization. The effective hexagonal plane MAE is therefore different in dynamic and static experiments. Initially it was believed that the uniform strains could sometimes follow the spin precession dynamically (Vigren and Liu, 1972) partially because the frequency of the uniform mode in Dy was far less than seemed to be obtained from static measurements of MAE and magnetostriction constants. The anomaly, however, is actually due to a renormalization of the planar MAE constant in Dy as a result of zero point fluctuations induced by elliptical spin precession (Egami, 1972). A complete treatment includes both coupled magnon and phonon excitations and the effects of zero point motion (Chow and Keffer, 1973; Jensen and Mackintosh, 1991).

Ab initio calculation of the giant magnetostriction in Tb and Er has been made by Buck and Fähnle (1998) who found that it is dominated by the single-ion 4f contribution and obtained good agreement with experiment. The same authors (Buck and Fähnle, 1999) calculated a large magnetostrictive MAE in $TbFe_2$ arising from the intrinsic electronic structure. A model, based on a rigid band Stoner model, has been used successfully by Kulakowski and Moral (1994) for Y_2Fe_{17}.

3.3 Multipole interactions in 4f Metals

The magnetoelastic interaction causes lattice distortion but may do so in different ways. Magnetic interactions break time reversal symmetry, and when they are larger than higher multipole–multipole interactions, the material undergoes a magnetic phase transition that is *accompanied but not driven by* a lattice distortion due to magnetostriction. It can happen that higher, nonmagnetic, multipole–multipole interactions –usually quadrupole–quadrupole ones – are larger than the magnetic interactions, even when the lattice is rigid. In this case, multipolar ordering (which does not break time reversal symmetry) occurs and is *accompanied but not driven by* a lattice distortion – named *quadrupolar striction* by Levy, Morin and Schmitt (1979) – due to magnetoelastic coupling. If the magnetoelastic interactions are larger than the magnetic and quadrupolar interactions, they can drive a phase transition that is *accompanied but not driven by* multipolar ordering. In this case the transition is caused by a CJT effect. Rare-earth compounds in which quadrupolar ordering with quadrupolar striction occurs before magnetic ordering are TmCd and TmZn (Levy, Morin and Schmitt, 1979). In DySb, the JT, magnetic, and quadrupolar interactions are of comparable size (Levy, 1973).

3.4 Conduction electron magnetocrystalline anisotropy energy in rare earths

Typical MAE energies of rare-earth metals are of the order of millielectron volts per atom. The MAE in Gd metal is 2 orders of magnitude smaller than in other rare earths but of the same order of magnitude as in Co, the most anisotropic of the 3d metals. The first approximation to the ground state of Gd is a half-filled shell with $\boldsymbol{L} = 0$ and zero MAE. It is possible that residual interactions would mix enough orbital moment into the S state to explain this MAE. Another alternative has been explored by Colarieti-Tosti *et al.* (2003). Dipole–dipole interactions between the large spins make a significant contribution (Brooks and Goodings, 1969; Jensen and Mackintosh, 1991) and they contribute an MAE of the form $K_1^0 sin^2\theta$, where θ is the angle between the magnetic moment and the c axis with $K_1^0 = 10.3\,\mu$eV per atom. However, the total MAE measured from experiment is $35.4\,\mu$eV per atom (Franse and Gersdorf, 1980), requiring an additional contribution of $25.1\,\mu$eV per atom. The easy direction is observed to lie at an angle of about 20° to the c axis at low temperatures (Cable and Wollan, 1968), which would not be possible without $sin^n\theta$ contributions ($n > 2$) to the MAE. Colarieti-Tosti *et al.* (2003) suggested that the MAE in Gd is due to a combination of the dipole–dipole interaction and the MAE of the conduction electrons. The 4f spin polarizes the conduction electrons via exchange interaction, which transfers the MAE of the conduction electrons to the 4f spin. They tested the hypothesis with LSDA total energy calculations as a function of the direction of the Gd moment between the hexagonal plane and c axis, obtaining reasonable agreement with the measurements of Franse and Gersdorf (1980). According to this theory, Gd is a 5d transition metal with a large 4f spin and the MAE calculation is very similar to those for Fe, Ni, or Co. This mechanism for the MAE must be present in all of the elemental rare-earth metals and the heavy actinides, but since it is far smaller than the MAE arising from the interaction between the CEF and the electric multipole moments of the 4f charge cloud, it is only important for S state ions. In rare earth–transition metal compounds, the transition metal may also make a contribution to the MAE and this would be expected to be largest for cobalt (Steinbeck, Richter and Eschrig, 2001).

4 ACTINIDES

The elemental light actinide metals do not order magnetically. The complexity of the magnetic and magnetoelastic properties of compounds of light actinides derives from the fact that the 5f orbitals are more extended than the 4f

orbitals in rare earths (Figure 2), but are not so extended that the orbital magnetic moments are quenched, as in many transition metals. The existence of a finite orbital angular momentum is not only responsible for the MAE but it also leads to coupling between charge degrees of freedom and lattice vibrations. The simplest consequence of the more extended 5f orbitals is that the effects of the CEF in actinide compounds are larger than in the corresponding rare earths. It is customary to say that the CEF is larger in actinides although, of course, the electric field itself is not. However the matrix elements of the CEF between 5f states are larger, leading to larger splitting of energy levels by the CEF. Also, CEF excitations have been difficult to find in metallic actinide compounds (Holland-Moritz and Lander, 1994) but they have been unambiguously observed in UPd_3 (McEwen, Steigenberger and Martinez, 1993; McEwen, Steigenberger, Martinez and Abell, 1990) and in actinide dioxides (Amoretti *et al*., 1989; Fournier *et al*., 1991b; Kern *et al*., 1999; Kern *et al*., 1990).

The closeness of the actinide 5f states to delocalization, apart from larger CEF effects, is responsible for other differences between anisotropic and magnetoelastic interactions in actinides and rare earths. Firstly, interactions between 5f and conduction electrons frequently require multipole expansions, rather than the simpler RKKY interaction, leading to indirect multipole–multipole interactions. Although also present in some rare-earth compounds, such interactions are more prevalent in actinide compounds. The larger magnetoelastic interactions that accompany larger CEF splittings produce stronger phonon-mediated indirect interactions between 5f shells, and these interactions are also multipolar. An immediate and important effect of large CEF and higher multipole–multipole interactions in actinides is that multiple-$\boldsymbol{Q}$ structures are often the ground states. Multiple-$\boldsymbol{Q}$ structures are stable only if terms higher than quadratic in the magnetization are present in the Landau expansion of free energy, equation (35), and such terms are present due to the CEF and multipole–multipole interactions (Monachesi and Weling, 1983; Rossat-Mignod, 1987; Sandratskii, 1998). When the 5f states are itinerant, the MAE is due to spin-orbit interaction in the energy bands, and the MAE can be very large.

4.1 Light actinide compounds with localized 5f electrons

Band structure calculations (Kelly and Brooks, 1980; Dudarev, Nguyen-Manh and Sutton, 1997) for UO_2 indicate that, if the 5f states are treated as itinerant, the calculated volumes are far too small, a result consistent with a wealth of experimental evidence that the 5f electrons are localized. A more systematic treatment for the light actinide dioxide series (Kelly and Brooks, 1987) found that the valence band electronic structure varies little across the series, suggesting that the strength of magnetic interactions would also not vary too much apart from small effects due to actinide contraction. This indicates that the strength of the CEF and exchange interactions may therefore be scaled across the actinide oxide series, a simplification confirmed by experiment (Amoretti *et al*., 1992). Even though the actinide dioxides are CEF compounds, their electronic structure is by no means simple, since the CEF, exchange, quadrupolar, and magnetoelastic interactions are all involved with equal magnitude.

The uranium ions in UO_2 are tetravalent with a $5f^2$ configuration. The Γ_1, Γ_3, and Γ_4 CEF states in UO_2 lie between 150 and 170 meV above the Γ_5 ground state (Amoretti *et al*., 1989). UO_2 undergoes a first-order antiferromagnetic phase transition at 30.8 K (Leask, Roberts, Walter and Wolf, 1963; Frazer, Shirane, Cox and Olsen, 1965; Faber and Lander, 1976; Lander, Faber, Freeman and Desclaux, 1976). The correlation length increases below T_N (Buyers and Holden, 1985) without diverging and the elastic constants are discontinuous at T_N (Brandt and Walker, 1967), although, within 50 Å of the surface, the magnetic scattering intensity decreases continuously as the bulk Néel temperature is approached from below (Watson *et al*., 1996). Allen (1968a,b) suggested that the magnetoelastic interaction would mediate quadrupole–quadrupole interactions, since the CEF ground state Γ_5 triplet may have both magnetic dipole and electric quadrupole moments. Resonant X-ray scattering experiments at the uranium M_4 absorption edge have confirmed antiferroquadrupolar (AFQ) ordering of the electric quadrupoles (Wilkins *et al*., 2006). Allen's model is consistent with a softening of the C_{44} elastic constant, which is related to the quadrupolar susceptibility, and neutron diffraction (Faber and Lander, 1976) confirmed the presence of a lattice distortion, albeit not the $\boldsymbol{q} = 0$ optical phonon postulated by Allen. Further, Allen assumed a single-$\boldsymbol{Q}$ magnetic structure, whereas measurements (Burlet *et al*., 1986) were more consistent with a triple-$\boldsymbol{Q}$ structure. Recently, Blackburn *et al*. (2005) have established beyond doubt from the spin-wave polarization that the magnetic structure of UO_2 is triple-$\boldsymbol{Q}$. Additional efforts to explain the magnetic structure (Siemann and Cooper, 1979; Solt and Erdös, 1980; Giannozzi and Erdös, 1987) actually found the single-$\boldsymbol{Q}$ structure to be more stable. The magnon–phonon interaction is observed to be strong in the ordered phase (Cowley and Dolling, 1968) and the spin-wave spectrum (Caciuffo *et al*., 1999) is roughly consistent with theory (Giannozzi and Erdös, 1987) except that three branches are observed over most of the Brillouin zone, whereas only two are expected. Neutron scattering measurements (Amoretti *et al*., 1989) showed that the excited

crystal-field states are split above T_N when theory suggests that they should be degenerate in the paramagnetic phase. However a dynamic JT effect, with proper vibronic states, might well resolve the inconsistencies.

The Np ions in NpO_2, tetravalent with a $5f^3$ configuration, are Kramers ions with a magnetic doublet or quadruplet ground state. Heat capacity (Osborne and Westrum, 1953) and magnetic susceptibility measurements (Erdös *et al*., 1980) indicate a phase transition in NpO_2 at 25 K but there was evidence neither for magnetic ordering nor for lattice distortions (Caciuffo *et al*., 1987). Any ordering with an order parameter even under time reversal does not suppress a diverging magnetic susceptibility at low temperature. The absence of magnetic order in NpO_2 was therefore something of a mystery. Superlattice reflections in resonant X-ray scattering at the Np $M_{4,5}$ absorption edges were observed (Mannix *et al*., 1999; Wilkins *et al*., 2004) and attributed to longitudinal triple-$\boldsymbol{Q}$ antiferromagnetic ordering. It seemed that the magnetic moments ($<0.1\,\mu_B$) were too small to be detectable in the neutron experiments. Further theory (Santini and Amoretti, 2000a,b) and experiments (Paixào *et al*., 2002) revealed quite a different picture in which the superlattice Bragg peaks were due to long-range triple-$\boldsymbol{Q}$ ordering of electric quadrupoles. The absence of magnetic dipole order is consistent with the ordering of magnetic octupoles of Γ_5 symmetry that removes the degeneracy of the ground quartet, producing a singlet ground state with no magnetic dipole moment, and drives the ordering of the electric quadrupoles.

The Pu ions in PuO_2 are tetravalent with a $5f^4$ configuration, and if the CEF and exchange parameters are scaled from those of UO_2 and NpO_2, a Γ_1 ground state, about 110 meV below a Γ_4 triplet, would be expected (Colarieti-Tosti *et al*., 2002). The lowest exited CEF state detected by inelastic neutron scattering (Kern *et al*., 1990, 1999) is at 120 meV. No phase transition has been observed in PuO_2 and the magnetic susceptibility is temperature independent at low temperature (Raphael and Lallement, 1968). The gap between ground (Γ_1) and first excited (Γ_4) CEF states required to fit the temperature independent susceptibility (Raphael and Lallement, 1968) is inconsistent with that measured in the neutron scattering experiments (Kern *et al*., 1990, 1999) by a factor of about two. The inconsistency may be removed (Colarieti-Tosti *et al*., 2002) by antiferromagnetic exchange enhancement scaled from the antiferromagnetic exchange interactions in UO_2, assuming an identical electronic structure apart from the correlated 5f states.

CEF excitations have also been observed in UPd_3 (Buyers and Holden, 1985; McEwen, Steigenberger and Martinez, 1993; McEwen, Steigenberger, Martinez and Abell, 1990). UPd_3 has a double hexagonal close-packed structure with uranium ions at sites with local hexagonal and quasicubic symmetry. Early experiments (Walker *et al*., 1994; McEwen *et al*., 1988) revealed that there are at least three transitions in UPd_3. Quadrupolar order first develops at 7.8 K followed by an AFQ transition at 6.8 K and magnetic antiferromagnetic ordering at 4.4 K. AFQ ordering between 7.8 and 6.8 K was observed by resonant X-ray scattering (McMorrow *et al*., 2001) although below 6.8 K an unambiguous identification of the ordered structure was not possible. Subsequently, ultrasound experiments (Lingg, Maurer, Müller and McEwen, 1999) confirmed that in addition to the magnetic phase transition at 4.4 K, orbital ordering occurs at 7.6 K accompanied by a symmetry change from hexagonal to orthorhombic. The quadrupolar transition at 6.8 K was found to split into a second-order transition at 6.9 K and a first-order transition at 6.70 K. McEwen, Park, Gipson and Gehring (2003) have produced a CEF model based on all the available evidence. The CEF at the hexagonal sites has a singlet ground state and a first excited doublet at 15 meV as also deduced by Buyers and Holden (1985). The CEF at the cubic sites has a ground doublet and a first excited singlet at 4 meV with a doublet CEF ground state and a first excited singlet at 4 meV and antiferromagnetic exchange. The phase transition at 7.8 K is second order with the primary order parameter $Q_{x^2-y^2}$. At 6.9 K there is a second-order transition to a phase with order parameters $Q_{x^2-y^2}$ and Q_{yz}. Then, at 6.7 K there is a first-order transition to a phase with order parameters $Q_{x^2-y^2}$, Q_{zx} and Q_{yz}. Finally, the phase below 4.4 K is AFQ with four sublattices, order parameters $Q_{x^2-y^2}$ and Q_{zx}, and a small magnetic moment.

4.2 Other light actinide compounds

The magnetism of the actinide pnictides and chalcogenides with rock salt structure has been studied thoroughly. It has been found that the MAE is extremely large for cubic compounds (Vogt, 1980) and that multiple-$\boldsymbol{Q}$ magnetic structures are common (Rossat-Mignod *et al*., 1984). Theories incorporating parameterized anisotropic bilinear exchange and CEF interactions (Monachesi and Weling, 1983; Monachesi, 1986) are able to reproduce the multiple-$\boldsymbol{Q}$ magnetic ordering in the uranium pnictides and a hybridization mediated anisotropic two-ion interaction has been derived by Cooper and his collaborators (Thayamballi and Cooper, 1985).

The MAE in the uranium chalcogenides has been calculated from self-consistent DFT calculations under the assumption that the 5f electrons are delocalized. Early calculations (Brooks, Johansson, Eriksson and Skriver, 1986) found the difference in energy between the (100) and the (111) directions of magnetization, ΔE_a to be 180 meV per atom (for $\Delta E_a > 0$, the easy axis is (111)). The comparable

MAE for $TbFe_2$, the most magnetically anisotropic cubic rare-earth compound, is of the order of 10 meV per atom. Subsequent calculations yielded lower, but still very large MAE. The magnitude of the MAE is related to the size of the orbital magnetic moment (Bruno, 1989). Conventional LSDA treatments of orbital magnetism tend to yield orbital magnetic moments that are too small (Brooks, 1985) and therefore an MAE that is also too small. Such calculations should therefore set a lower limit on the MAE. Kraft (1997) obtained values for ΔE_a of about 9, 10 and 16meV for US, USe, and UTe, respectively, whereas Shishidou and Oguchi (2000) obtained values of 14, 7, and 8 meV for the same compounds. Trygg (1995), using conventional, full potential linear muffin-tin orbital (LMTO) calculations, obtained $\Delta E_a = 15$ meV for US. He made additional calculations with orbital polarization corrections (Eriksson, Brooks and Johansson, 1990a) that produced orbital magnetic moments close to those deduced from the analysis of experiments (Wedgwood, 1972) and obtained $\Delta E_a = 55$ meV for US. Measurements of the MAE energy of US are difficult since the MAE is so large that it is not possible to move the magnetic moment away from the easy axis (Vogt, 1980). However, working at higher temperatures where the MAE is smaller, and estimating the temperature dependence of the MAE constants from theory, Lander *et al*. (1990) estimated ΔE_a to be about 100 meV per atom.

There have been a few attempts to calculate the CEF parameters in actinides. Apart from the work on PuO_2 by Colarieti-Tosti *et al*. (2002) in actinides, Divis, Richter, Eschrig and Steinbeck (1996) calculated the CEF parameters for UGa_2, and from them, the anisotropy of the magnetic susceptibility.

The MAE of the laves phase compound UFe_2 (Popov, Levitin, Zelený and Andreev, 1980) was measured to be only a little larger than that of metallic Fe ($K_1 \approx 10^6$ ergs cm^{-3}). Nevertheless it was clear that something more interesting was happening in this compound since Popov, Levitin, Zelený and Andreev (1980) also observed a large magnetoelastic distortion that contributed to K_1, an amount equal to about minus the measured K_1. K_1^0, for the unstrained lattice, was deduced to be $\approx 10^7$ ergs cm^{-3}. Evidently, the small value of the total MAE is due to a cancellation of far larger unstrained and magnetoelastic contributions neither of which would be expected to be due to the Fe alone. The magnetic moment of uranium in UFe_2 is negligible (Wulff, Lander, Lebech and Delapalme, 1989) but that is due to the almost complete cancellation of small spin and orbital moments at the uranium sites (Eriksson, Brooks and Johansson, 1990b; Brooks, 2004). The origin of the large anisotropic magnetoelastic coupling is probably the spin–orbit interaction in uranium and the small orbital moment of uranium. It is quite possible that only the Fe moment is rotated in a torque experiment and that there is a large MAE associated with the U moment. Owing to the cancellation of orbital and spin moments on uranium, no anisotropy in the magnitude of the magnetic moment would be observed. If this were the case the measured unstrained torque would be mostly due to the coupling between Fe and U moments. However no detailed theory has been produced to date.

Neutron diffraction experiments on $PuFe_2$ (Wulff *et al*., 1988) determined the easy direction of magnetization to be (100). It appeared that the magnetic moment could not be moved away from the easy direction in achievable magnetic fields. Since $PuFe_2$ has a relatively high Curie temperature of 564 K, the indications are that it has a very large MAE for a cubic compound.

Magnetostriction and Magnetoelasticity Theory: A Modern View

A. del Moral

Universidad de Zaragoza and Instituto de Ciencia de Materiales de Aragón (CSIC), Zaragoza, Spain

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*.

ISBN: 978-0-470-02217-7.

1 INTRODUCTION: MAGNETOELASTIC (MEL) COUPLING AND MAGNETOSTRICTION (MS); CRYSTAL SYMMETRY-BASED PHENOMENOLOGICAL THEORY; ROTATIONAL STRAINS AND NONLINEAR MEL THEORY

Magnetostriction (MS) is the deformation (denoted by $\lambda = \Delta l/l$ for linear distortion and $\omega = \Delta V/V$ for volume dilatation), of a material body when it is magnetized, either when crossing down the magnetic ordering temperature (spontaneous MS) or a magnetic field, **H**, is applied. However MS is also observed in the paramagnetic (PM) regime (*parastriction*, *PS*), and is useful when we want to remove exchange effects, leaving only the *crystal electric field* (CEF) effect. MS is usually expressed in terms of Cartesian *symmetric* strains $\varepsilon_{ij} = (1/2)(u_{ij} + u_{ji})$, where $\mathbf{u} = \mathbf{x} - \mathbf{X}$ is the point displacement of a point $\mathbf{X}$ for a new position $\mathbf{x}$ and $u_{ij} = \partial u_i/\partial X_j$, the *distortion*. The inverse MS effect (*inverse Wiedemann effect* (*IWE*)) consists in the change of magnetization vector, **M** (by rotation or $|\mathbf{M}|$ variation, mainly in itinerant magnets) when a mechanical stress is applied. In the *direct Wiedemann effect* (DWE) a *rotational strain* (*RS*) *MS*, $\omega_{ij} = (1/2)(u_{ij} - u_{ji})$ is produced under application of a helicoidal **H** to a wire or ribbon (Hernando and Bariandarán, 1980), such that it is antisymmetric ($\omega_{ij} = -\omega_{ji}$). However, introduction of RS is paramount in the propagation of an elastic wave (EW) in a magnetized crystal (*magnetoacoustic* (*MA*)

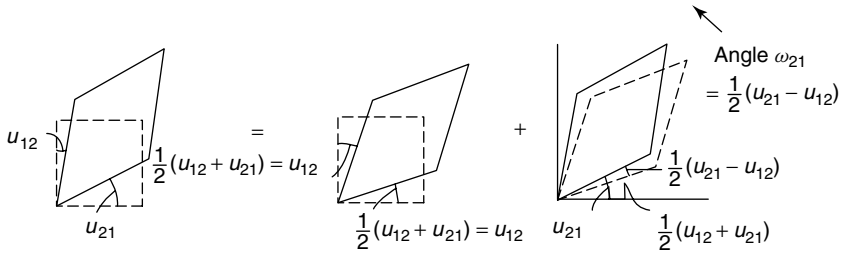

Figure 1. Decomposition of a general deformation in pure strain, ε_{12} and rotation, ω_{12} (Nye, 1976).

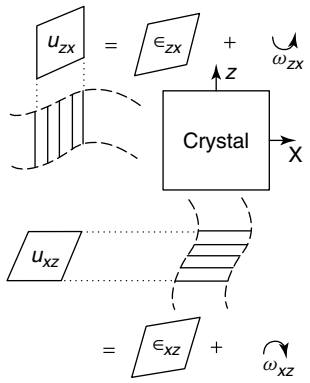

Figure 2. Unequivalence of u_{zx} and u_{xz} shear elastic waves propagating along Z and X axes, due to their antisymmetric rotations, $\omega_{xz} = -\omega_{zx}$, added to otherwise symmetric $\varepsilon_{xz} = \varepsilon_{zx}$ strains (Lüthi, 1976).

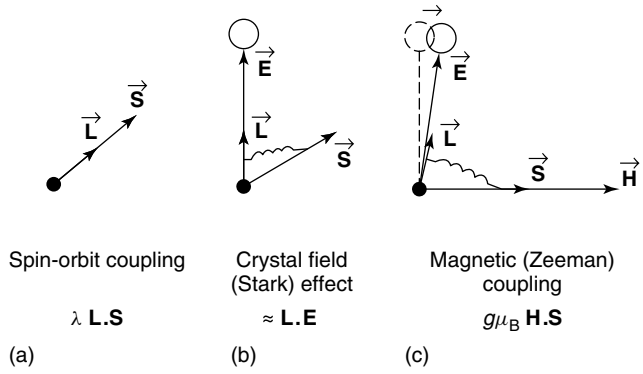

Figure 3. The physical origin of CEF magnetostriction: (a) spin-orbit (SO) coupling; (b) CEF, **E** overrides SO between **L** and **S**; (c) magnetic anisotropy requires stronger **H** to align **S**. Rotation of residual unquenched **L** through SO coupling causes *magnetostrictive* rotation of **E** (Dionne, 1979).

wave), since then, only one distortion is singled out and ω_{ij} is manifested, since $u_{ij} = \varepsilon_{ij} + \omega_{ij}$ (Figures 1 and 2). MS, being an ubiquitous effect in solids, has been observed in every kind of magnetic material (del Moral, 2007). MS is the result of an internal *magnetoelastic* (MEL) *stress*, here denoted as $\overline{\mathrm{M}}_{ij}$ ($\equiv B_{ij}$ in Kittel's notation, see del Moral, 2007) and has its origin in the variation in volume and/or change in shape when the atomic magnetic moment, $\boldsymbol{\mu}$ is modified, either by rotation or by $|\boldsymbol{\mu}|$ variation (this latter called *paraprocess*, manifested in itinerant ferromagnets (FMs)). Effectively, when an atom or ion is magnetized it changes its shape, so modifying the surrounding lattice for accommodating the distortion (*shape or anisotropic magnetostriction* (*AMS*)), or just its volume (*volume or isotropic magnetostriction* (*VMS*)). The mechanism for AMS (but there can also be VMS of this kind) is as sketched in Figure 3.

1. In a free atom the spin-orbit (SO) coupling (Hamiltonian $H_{\mathrm{so}} = \lambda \mathbf{L} \cdot \mathbf{S}$) aligns the orbital, **L** and spin, **S** angular momenta (AM).
2. When the atom is within the solid the highly inhomogeneous CEF, $\mathbf{E}_{\mathrm{CEF}}$, aligns **L** with it (via Stark coupling of energy $\propto \mathbf{L} \cdot \mathbf{E}_{\mathrm{CEF}}$), so overriding the SO coupling. As consequence the expected $\langle\psi|\mathbf{L}|\psi\rangle$ ($|\psi\rangle$ is the magnetic ion wave function within the solid) is usually reduced (*quenching*), that is, some SO coupling survives (except for a singlet where $\langle\psi|\mu|\psi\rangle = 0$).
3. When **H** is applied, this tries to align **S** (via Zeeman coupling, $H_Z = -\boldsymbol{\mu}_S \cdot \mathbf{H}$, with $\boldsymbol{\mu} = \boldsymbol{\mu}_{\mathrm{L}} + \boldsymbol{\mu}_{\mathrm{S}}$, the total magnetic moment), which in turn pulls **L** (atom/ion charge aspherical cloud, $\mathrm{e}\langle\psi|\psi\rangle$) *via* SO coupling, **L** which again pulls $\mathbf{E}_{\mathrm{CEF}}$ and so the ions lattice (which create $\mathbf{E}_{\mathrm{CEF}}$) are displaced. This AMS is called *CEF-MS* (although those mechanisms can also produce VMS). So MS is basically a relativistic (SO) and quantum-mechanical effect.

When a magnetic-order phase transition occurs (or also **H** is applied), usually an isotropic variation of the lattice cell parameter is produced (manifested as an *anomalous thermal expansion* (TH.E.)), so modifying the exchange coupling constant, $J(H_{\mathrm{EX}} = -2J(\mathbf{R}_j - \mathbf{R}_i)\mathbf{S}_i \cdot \mathbf{S}_j$ is the isotropic exchange Hamiltonian between two spins at sites i, j) and we talk of *exchange magnetostriction* (EX-MS) (if exchange is anisotropic, that is $J_x \neq J_y \neq J_z$, an AMS is instead

Table 1. Isomorphisms of spherical harmonics, elastic strain components, one-ion spin operators, two-ion spin operators, and $\alpha_i^{\mu,2}$ polynomials. (From Callen and Callen, 1965.)

Classical polynomials or spherical harmonics[a]	Strain functions	One-ion operators of spherical tensor operators[b]	Two-ion spin operators	Bilinear direction cosines
$1 = (4\pi)^{1/2} Y_0^0$	$\epsilon^{\alpha,1} = \epsilon_{xx} + \epsilon_{yy} + \epsilon_{zz}$	$1 = (2S+1)^{1/2} \Upsilon_0^0$	$\mathrm{S}_f \cdot \mathrm{S}_g$	1

$(1/2)(x^2 - y^2) = (c/\sqrt{2})\lfloor Y_2^2 + Y_2^{-2} \rfloor$	$\epsilon^{\gamma,2} = (1/2)[\epsilon_{zz} - \epsilon_{yy}]$	$(1/2)[(S^x)^2 - (S^y)^2] = (1/2n_2)[\Upsilon_2^2 + \Upsilon_2^{-2}]$	$1/2\lfloor S_f^x S_g^y - S_f^y S_g^x \rfloor$	$(1/2)\lfloor \alpha_x^2 - \alpha_y^2 \rfloor$
$xy = (-ic/\sqrt{2})\lfloor Y_2^2 - Y_2^{-2} \rfloor$	$\epsilon^{\varepsilon,1} = \epsilon_{xy}$	$(1/2)\lfloor S^x S^y + S^y S^x \rfloor = (-i/2n_2)\lfloor \Upsilon_2^2 - \Upsilon_2^{-2} \rfloor$	$(1/2)\lfloor S_f^x S_g^y + S_f^y S_g^x \rfloor$	$\alpha_x \alpha_y$
$yz = (ic/\sqrt{2})\lfloor Y_2^1 + Y_2^{-1} \rfloor$	$\epsilon^{\varepsilon,2} = \epsilon_{yz}$	$(1/2)\lfloor S^y S^z + S^z S^y \rfloor = (-i/2n_2)\lfloor \Upsilon_2^1 + \Upsilon_2^{-1} \rfloor$	$(1/2)\lfloor S_f^y S_g^z + S_f^z S_g^y \rfloor$	$\alpha_y \alpha_z$
$xz = -(c/\sqrt{2})\lfloor Y_2^1 - Y_2^{-1} \rfloor$	$\epsilon^{\varepsilon,3} = \epsilon_{zx}$	$(1/2)\lfloor S^x S^z + S^z S^x \rfloor = (-i/2n_2)\lfloor \Upsilon_2^1 - \Upsilon_2^{-1} \rfloor$	$(1/2)\lfloor S_f^z S_g^x + S_f^x S_g^z \rfloor$	$\alpha_z \alpha_x$

[a] Here $c = (4\pi/15)^{1/2}$.

[b] In Stevens–Buckmaster's notation these operators are denominated $\widetilde{O}_0^0$, $\widetilde{O}_2^0$, $\overline{O}_2^2$, $\widehat{O}_2^2$, $\overline{O}_2^1$, $\widehat{O}_2^1$ respectively, n_2 is a normalization factor.

produced); *quadrupolar* (*QP*) interaction $\overset{\leftrightarrow}{O}{}^{\eta}_{2,i}$ $\overset{\leftrightarrow}{O}{}^{\eta}_{2,j}$ instead manifests in PS. Therefore MS is a *fundamental* effect in condensed matter physics (either in crystalline or amorphous materials), and the order of magnitude of the associated MEL free energy $F_{\rm mel} = (1/2)c\lambda^2$ (where c is an *elastic constant* (EC)) amounts $\approx 1\,\mu$eV/atom in 3d metals (Fe) and 1–10 meV/ion in a rare-earth (RE) metals (e.g., Dy and Tb metals).

Experimentally it is found that MS depends on the direction of the magnetization, $\boldsymbol{\alpha}$, and that of measurement, $\boldsymbol{\beta}$ with respect to the chosen crystal axes, this means that it is a property related to crystal symmetry. Therefore the natural way to derive the MEL free energy, $F_{\rm mel}$ is making it invariant against the point symmetry group (PSG) operations of the magnetic ion in the crystal. For this we define the *irreducible strains* (*ISs*), ε_i^{μ} which form the bases (i is the basis component index) for the irreducible representations (IRs) of the PSG (Γ^{μ}) and multiply them by polynomials of the direction cosines $\boldsymbol{\alpha}$ (α_i) pertaining to the same representation, in order to obtain products invariant against the symmetry operations of the PSG (i.e., pertaining to the fully symmetric representation Γ^{α}) (Callen and Callen, 1964, 1965). The ISs, ε_i^{μ} are of the same form for all PSG (although with different μ denomination) and for the cubic (CUB) PSGs are given in the second column of Table 1. The forms of these ISs for cubic symmetry are displayed in Figure 4, and those for hexagonal (HEX) ones are shown in Figure 5 (here assuming cylindrical symmetry for the hexagonal unit cell). For some representations, for instance for cubic PSGs, the $\mu = \alpha, \gamma$, and ε correspond to externally manifested strictions, meanwhile for $\mu = \beta', \delta'$ the ISs are internal, and can be only externally manifested if they couple to external

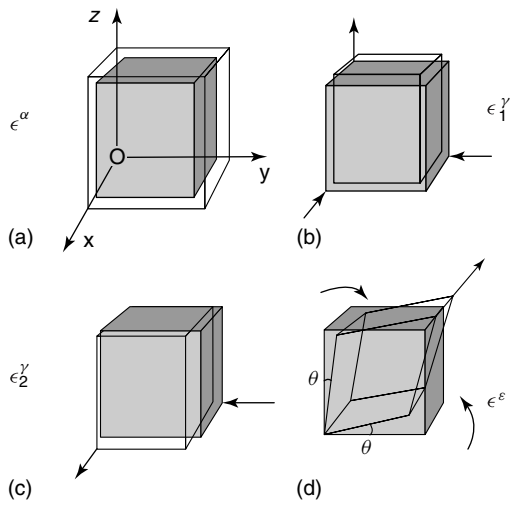

Figure 4. Irreducible strains for cubic symmetry (de Lacheisserie, 1993).

ones, as it happens for example in the cubic Laves-phase intermetallic $DyFe_2$ (Cullen and Clark, 1977); and H_0/Lu superlattices (del Moral, 2007). But before continuing, MS strains can be small (infinitesimal, ε_i^{μ}) or finite, $\mathcal{E}_i^{\mu}$. A kind of *finite* (Brown, 1965) normal ISs are the *Lagrangian strains*, η_{ij} (Eastman, 1966), which include rotations, up to order 2, as well as the local *RSs*, $\mathcal{R}_{ij}$ and which are respectively of the forms (in Cartesian strains),

$$\eta_{ij} = \left(\frac{1}{2}\right)(u_{ij} + u_{ji} + \Sigma_k u_{ki}u_{kj}) = \varepsilon_{ij} + \left(\frac{1}{2}\right) \times \Sigma_k(\varepsilon_{kj} + \omega_{kj})(\varepsilon_{ki} + \omega_{ki}) \cong \varepsilon_{ij} + \left(\frac{1}{2}\right)\Sigma_k \varepsilon_{ki}\varepsilon_{kj} \tag{1}$$

$$\mathcal{R}_{ij} = \omega_{ij} + \left(\frac{1}{2}\right)\Sigma_k(\varepsilon_{jk} + \omega_{jk})(\varepsilon_{ik} - \omega_{ik}) \cong \omega_{ij} - \left(\frac{1}{2}\right)\Sigma_k \omega_{ki}\omega_{kj} \tag{2}$$

(pure RSs ω_{xy}, ω_{zx}, ω_{yz}, bases of $\Gamma^{\delta'}$ are internal). Last expressions for $\eta_{ij}(\mathcal{R}_{ij})$ apply for infinitesimal ω_{ij} (ε_{ij}) strains. We will call all those strains (45 in number) as the ISs π_{ij}^{μ}. These ISs pertain to the same IRs mentioned earlier, where j is the basis-IS number within the basis i for Γ^{μ} IRs (see for a systematic description del Moral, 2007 or Rouchy and de Lacheisserie, 1979). They are of the kinds: purely quadratic in ε_{ij} (21 in number, e.g., $\pi_{11}^{\alpha} = (1/3)(\varepsilon_{xx}^2 + \text{c.p.})$, $\pi_{11}^{\gamma} = (\sqrt{3}/2)(\varepsilon_{zz}^2 - \pi_1^{\alpha})$, $\pi_{11}^{\varepsilon} = \varepsilon_{xx}\varepsilon_{yy}$, etc.); other in ω_{ij} (6 in number, e.g., $\pi_{41}^{\alpha} = \omega_{xy}^2 + \text{c.p.}$, $\pi_{41}^{\gamma} = (\sqrt{3}/2)(\omega_{xy}^2 - \pi_{14}^{\alpha}/3)$, $\pi_{61}^{\varepsilon} = \omega_{zx}\omega_{xy}$, etc.); and remainder are in products $\varepsilon_{ij}\omega_{kl}$ (e.g., $\pi_{14}^{\varepsilon} = (\varepsilon_{yy} - \varepsilon_{zz})\omega_{yz}$, $\pi_{15}^{\gamma} = (\sqrt{3}/2)(\varepsilon_{xy}\omega_{xy} - (1/3)(\varepsilon_{xy}\omega_{xy} + \text{c.p.}))$, etc.). According to the aforesaid we write the MEL free energy for the normal ISs as,

$$F_{\rm mel} = \Sigma_{\mu,l}\overline{\rm M}^{\mu,l}\Sigma_i \alpha_i^{\mu,l}\varepsilon_i^{\mu} \tag{3}$$

where $\overline{\rm M}^{\mu,l}$ are the irreducible *MEL constants* ($\equiv {\rm B}^{\mu,l}$ in popular *Kittel's notation*) and $\alpha_i^{\mu,l}$ are polynomials of $\boldsymbol{\alpha}$ of l-degree bases of Γ^{μ}, isomorphous of ε_i^{μ} and given for $l = 2$ in Table 1 (polynomials of higher order are possible). The MEL free energy then adopts the forms, for cubic and hexagonal symmetries, respectively,

$$F_{\rm mel}^{\rm CUB} = \Sigma_{\ell=0,4,6,\ldots}\overline{\rm M}^{\alpha,\ell}\varepsilon^{\alpha}K^{\alpha,\ell} + \Sigma_{\ell=2,4,6}\overline{\rm M}^{\gamma,\ell} \times \Sigma_{i=1,2}\varepsilon_i^{\gamma}K_i^{\gamma,\ell} + \Sigma_{\ell=2,4,6,6'}\overline{\rm M}^{\varepsilon,\ell}\Sigma_{i=1,2}\varepsilon_i^{\varepsilon}K_i^{\varepsilon,\ell} \tag{4}$$

$$F_{\rm mel}^{\rm HEX} = \Sigma_{\ell=0,2,4,4',\ldots}\Sigma_{i=1,2}\overline{\rm M}_i^{\alpha,\ell}\varepsilon_i^{\alpha}H^{\alpha,\ell} + \Sigma_{\ell}\Sigma_{\mu=\gamma,\varepsilon}\overline{\rm M}^{\mu,\ell}\Sigma_{i=1,2}\varepsilon_i^{\mu}H_i^{\mu,\ell} \tag{5}$$

where $K_i^{\mu,\ell}(\boldsymbol{\alpha})$ and $H_i^{\mu,\ell}(\boldsymbol{\alpha})$ are cubic and hexagonal harmonics, which are tabulated (del Moral, 2007). In order

to obtain the equilibrium strains we have to add the elastic energy, which is of the general diagonal form $F_{\rm el} = (1/2)\Sigma_\mu c^\mu \Sigma_i (\varepsilon_i^\mu)^2$, and minimize the full F (i.e., making $\partial(F_{\rm mel} + F_{\rm el})/\partial\varepsilon_i^\mu = 0$), so obtaining the MSs, which for example, for cubic symmetry have the expressions,

$$\varepsilon^\alpha = -\Sigma_\ell \left(\frac{\overline{\rm M}^{\alpha,\ell}}{c^\alpha}\right) K^{\alpha,\ell},\ \varepsilon^\gamma_{i=1,2} = -\Sigma_\ell \left(\frac{\overline{\rm M}^{\gamma,\ell}}{c^\gamma}\right) K_i^{\gamma,\ell},$$

$$\varepsilon^\varepsilon_{i=1,2,3} = -\Sigma_\ell \left(\frac{\overline{\rm M}^{\varepsilon,\ell}}{c^\gamma}\right) K_i^{\varepsilon,\ell} \qquad (6)$$

and similarly for other classes of symmetry, and where c^μ are the *symmetry ECs*. If we now define the *Clark's MS constants* as $\lambda^{\mu,\ell} = -(\overline{\rm M}^{\mu,\ell}/c^\mu)$ (Clark, DeSavage and Bozorth, 1965; see Figure 5) and notice that for the $\boldsymbol{\beta}$ direction of MS measurement we have to multiply by $\boldsymbol{\beta}$–polynomials, $\beta_i^{\mu,\ell}$, isomorphous to the $\boldsymbol{\alpha}$ ones (of Table 1), we have that,

$$\lambda(\boldsymbol{\alpha}, \boldsymbol{\beta}) = \Sigma_{\mu=\alpha,\gamma,\varepsilon} \Sigma_\ell \lambda^{\mu,\ell} \Sigma_i \beta_i^{\mu,\ell} K_i^{\mu,\ell} \qquad (7)$$

In the same way we can write the MEL free energy in the Lagrangian strains, obtaining $F_{\rm mel}^{\rm 2nd-order} = \Sigma_{i,\mu,\ell,j} \overline{\rm N}^{\mu,\ell} \pi_{ij}^\mu K_i^{\mu,\ell}$, for the cubic PSGs, where $\overline{\rm N}_j^{\mu,\ell}$ are the second-order MEL constants, or *morphic* constants of MS, since they linearly modify the $\overline{\rm M}^{\mu,\ell}$ (*morphic* effect of MEL coupling) ones in the ISs. Now to get the equilibrium finite strains we have to introduce an elastic energy in the third rank (contracted) ECs, C_{ijk} and third-order finite ISs. The importance of higher order than one in u_{ij} MEL coupling is mainly manifested in *EW* propagation in magnetic materials where for a

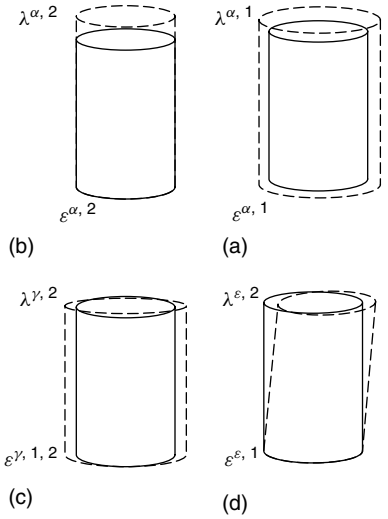

Figure 5. Irreducible strains (down corners) and Clark's MS constants (up corners) for uniaxial symmetry (Clark, DeSavage and Bozorth, 1965).

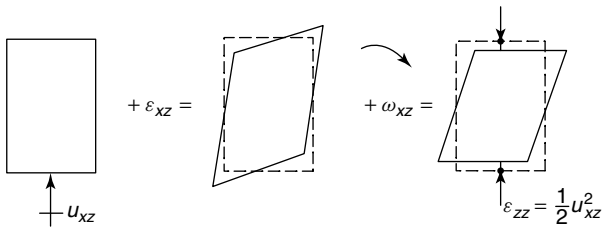

Figure 6. A finite shear gradient u_{xz} is equivalent to a finite strain $\mathcal{E}_{zz}$. (From Bonsall and Melcher, 1976.)

plane wave impressed distortion $u_{xz} = \varepsilon_{xz} + \omega_{xz}$ we end up with a finite Cartesian strain $\mathcal{E}_{zz} = (1/2)u_{xz}^2$ (Figure 6).

To conclude with this phenomenological study of MS sometimes it is better to work with Cartesian strains, and for cubic symmetry we obtain (Lee, 1955),

$$\lambda(\boldsymbol{\alpha}, \boldsymbol{\beta}) = (3/)\lambda_{100}\left(\Sigma_i \alpha_i^2 \beta_i^2 - \frac{1}{3}\right) + 3\lambda_{111}(\alpha_1\alpha_2\beta_1\beta_2 + \text{c.p.}) + \lambda_v\left(\alpha_1^2\alpha_2^2 + \text{c.p.} - \frac{1}{3}\right) \qquad (8)$$

and where the two Kittel's MS constants are $\lambda_{100} \equiv h_1 = -(2/3)\overline{\rm M}_1/(c_{11} - c_{12})$ and $\lambda_{111} \equiv (2/3)h_2 = -(1/3)(\overline{\rm M}_2/c_{44})$, which respectively are the MSs measured along [100] for $\mathbf{M}\|[100]$ and along [111] for $\mathbf{M}\|[111]$ and $\lambda_v \equiv h_3$ the anisotropic volume MS constant, independent of $\boldsymbol{\beta}$ (h_i are the classical *Becker and Döring MS constants*). When the material is polycrystalline or amorphous a number of approaches have been followed to average equation (8) over the 'crystallites' (averages at constant stress, constant strain, fluctuating MS, (Fähnle *et al*., 1990)). A good approximation used for cubic and amorphous materials for AMS being $\lambda_\parallel - \lambda_\perp \equiv \lambda_t = (3/2)(\cos^2\theta - 1/3)$, where θ is the angle

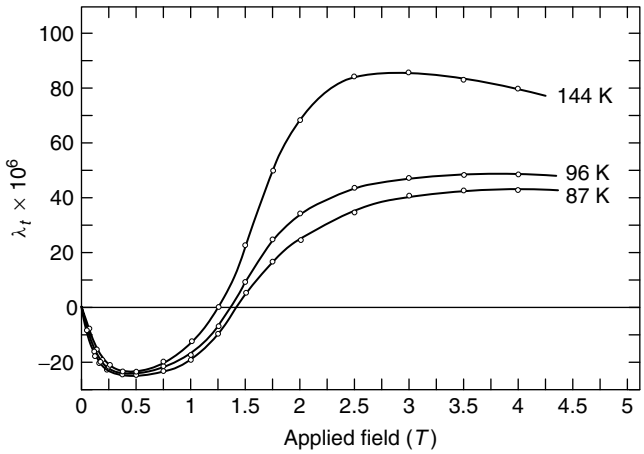

Figure 7. Isotherms of λ_t (H) for polycrystalline MnAs (Choudhury, Lee and Melville, 1974).

($\mathbf{M}$, $\boldsymbol{\beta}$) and λ_s the *saturation MS*. In fact MS adequately maps the different magnetization processes (in fact, MS is superior since it has a sign), that is, domain wall (DW) displacement (MS appears if those are different of 180°), rotation of $\mathbf{M}_s$, and approach to saturation. The $\lambda_t(H)$ isotherms for the hexagonal FM MnAs ($T_c = 393$ K) are portrayed in Figure 7, where the initial decrease is due to DW displacements, the minimum is $\lambda^{\gamma,2}$ (Figure 4c), and the saturation value is $\lambda^{\alpha,2}$ (Figure 4b), the latter two being the MSs due to $\mathbf{M}_s$ rotation.

2 STANDARD THEORY OF MAGNETOELASTIC COUPLING AND MAGNETOSTRICTION (STM): ONE-ION AND TWO-ION MSS; ANTIFERROMAGNETS; SPIN-WAVE APPROACH; PARASTRICTION; MEL PARAMETERS CALCULATION; MS OF RE INTERMETALLICS

The phenomenological theory of MS is firmly based in a microscopic quantum-mechanical one, called *Standard Theory of Magnetostriction* (*STM*), mainly due to Callen and Callen (1964, 1965), which follows the same group theory arguments used before, for obtaining now the *MEL Hamiltonians*. We will distinguish between single-ion CEF and two-ion (bilinear and QP exchanges) MEL couplings.

2.1 Single-ion CEF-MS

MS reduces the point symmetry and therefore, with new terms, adds or modifies the highly inhomogeneous CEF potential, $V(\mathbf{r})$ which can be expanded around the probe ion (i) in the multipolar expansion, either in terms of Cartesian coordinates (x, y, z) polynomials, $f_{n,m}(x, y, z)$ or in terms of spherical harmonics (SH), $Y_n^m(\theta, \phi)$ with coefficients which are proportional to the $V(\mathbf{r})$ *CEF gradients*, A_n^m, that is,

$$V(\mathbf{r}) = \Sigma_{n,m} A_n^m r^n f_{n,m}(x, y, z) = \Sigma_{n,m} A_n^m r^n Y_n^m(\theta, \phi) \quad (9)$$

It is far better to work in terms of so-called *Stevens* AM, $\mathbf{J}$ *operators*, $O_n^m(\mathbf{J})$ by application of the Wigner–Eckart (W–E) theorem to $V(\mathbf{r})$, so obtaining the equivalence $\Sigma_i f_{n,m}(x_i, y_i, z_i) \equiv \theta_n \langle r^n \rangle O_n^m(\mathbf{J})$, where $\mathbf{r}_i$ are the magnetic electron coordinates, $\langle r^n \rangle$ a radial average and θ_n the W–E reduced matrix elements, depending on J (i.e., on the 3d, 4f, 5f ions). Therefore the CEF Hamiltonian can be written as,

$$H_{\mathrm{CEF}} = \Sigma_{n,m} B_n^m O_n^m \quad (10)$$

The Stevens operators (S.Op.) are tabulated (Hutchings, 1964). When the solid is distorted under MS, so it is H_{CEF},

$$H_{\mathrm{CEF}} = \Sigma_{\Gamma,\ell,i,j} \left\{ B^0_{\Gamma,\ell} + \left(\frac{\partial B^{\Gamma,\ell}}{\partial \varepsilon_i^\Gamma} \right)_0 \varepsilon_i^\Gamma + \left(\frac{1}{2} \right) \left(\frac{\partial B^{\Gamma,\ell}}{\partial \pi_{ij}^\Gamma} \right)_0 \pi_{ij}^\Gamma + \cdots \right\} O_i^{\Gamma,\ell} \quad (11)$$

where H_{CEF} is now written in an irreducible form ($\{i, j\}$ span the IR bases) and $M^\Gamma_{n,m} = (\partial B^\Gamma_{n,m}/\partial \varepsilon_i^\Gamma)_{\varepsilon_i^\Gamma = 0}$ are the microscopic *MEL parameters* (first order) whose determination (theoretical or experimentally) is a paramount issue. $N^{\Gamma,\ell} = (1/2)(\partial B^{\Gamma,\ell}/\partial \pi_{ij}^\Gamma)_{\pi_{ij}^\Gamma = 0}$ are the *nonlinear* (*NL*) MEL parameters (second order), which are essential in the magnetoacoustic wave propagation. Now, the single-ion CEF-MEL *coupling* Hamiltonian, $H^{\mathrm{I}}_{\mathrm{mel}}$ is formed as the MEL free energy, just multiplying the strains and AM operators pertaining to the same representation, and therefore the products being invariant against the PSG operations (i.e., pertaining to Γ^α). Although by the deformation the PSG is changed (symmetry lowering by MS) in a first approximation we neglect this effect (it cannot be like that if the strains are finite, thus having the *morphic effect* of MS upon the MEL parameters). Therefore, $H^{\mathrm{I}}_{\mathrm{mel}}$ adopts the *general* form (for any PSG and several ions, f as the lattice point motif; note the negative sign),

$$H^{\mathrm{I}}_{\mathrm{mel}} = -\Sigma_f \Sigma_{\Gamma,\ell} \Sigma_i M^{\Gamma,\ell}(f) \varepsilon_i^\Gamma \mathcal{J}_i^{\Gamma,\ell}(f) \quad (12)$$

where the Racah AM operators $\mathcal{J}_i^{\Gamma,\ell}$ (Kubic Tensor Operator, KTO of cubic PSG, $\mathcal{K}_i^{\Gamma,\ell}$) of order l, are linear combinations of the spherical tensor operators, $\Upsilon_n^{\pm m}$ (isomorphous of the SH), of the form shown in Table 1 for second order (however, we will use the Stevens–Buckmaster's notation (Buckmaster, 1966), shown at the bottom of the table, and where the AM operators are denoted by $\tilde{\mathrm{O}}_n^m$). For finite strains we have to add to the equation (12) the NL-MEL Hamiltonian, of the form $H^{\mathrm{NL}}_{\mathrm{mel}} = -\Sigma_f \Sigma_{\Gamma,\ell} \Sigma_{ij} N^{\Gamma,\ell}(f) \pi_{ij}^\Gamma \mathcal{J}_i^{\Gamma,\ell}(f)$, where $N^{\Gamma,\ell}$ are the NL-MEL parameters. For the most frequent cubic and hexagonal symmetries up to $l = 2$ the MEL Hamiltonians read,

$$H^{\mathrm{CUB}}_{\mathrm{mel}} = -M^{\alpha,0} \mathbf{J}^2 \varepsilon^\alpha - M^{\gamma,2} \left(\varepsilon_1^\gamma \tilde{\mathrm{O}}_2^0 + \left(\frac{1}{\sqrt{2}} \right) \varepsilon_2^\gamma \overline{\mathrm{O}}_2^2 \right) - M^{\gamma,2} \left(\varepsilon_1^\varepsilon i \overline{\mathrm{O}}_2^1 - \varepsilon_2^\varepsilon i \hat{\mathrm{O}}_2^1 + \varepsilon_3^\varepsilon i \hat{\mathrm{O}}_2^2 \right) \quad (13)$$

$$H^{\mathrm{HEX}}_{\mathrm{mel}} = -M_1^{\alpha,2} \varepsilon_1^\alpha \tilde{\mathrm{O}}_2^0 - M_2^{\alpha,2} \varepsilon_1^{\alpha,2} \tilde{\mathrm{O}}_2^0 - M^{\gamma,2} \left(\varepsilon_1^\gamma \overline{\mathrm{O}}_2^2 + i \varepsilon_2^\gamma \hat{\mathrm{O}}_2^2 \right) - M^{\varepsilon,2} \left(\varepsilon_1^\varepsilon i \hat{\mathrm{O}}_2^1 + \varepsilon_2^\varepsilon \overline{\mathrm{O}}_2^1 \right) \quad (14)$$

For lower symmetries the number of independent MEL parameters just increases. To obtain the equilibrium MS

strains, $\overline{\varepsilon}_i^{\Gamma}$ we take the thermal average $\langle H_{\rm mel}\rangle$, add $F_{\rm el}$ and minimize, obtaining for *all* symmetries that

$$\overline{\varepsilon}_i^{\mu} = (1/c^{\mu})\Sigma_{\ell} M^{\mu,\ell}\langle \mathcal{J}_i^{\Gamma,\ell}\rangle \tag{15}$$

where $\langle \mathcal{J}_i^{\Gamma,\ell}\rangle$ has to be substituted by the corresponding Stevens operators of for example, equations (13 and 14).

2.2 Thermal dependence of MS

We are now going to obtain one of the most significant characteristics of MS, which is its *thermal dependence*, which allows one to distinguish between CEF and EX-MSs. For this investigation we consider the cubic symmetry (for remainder ones is the same) and expand $\langle \mathcal{K}_i^{\mu,\ell}\rangle = \sum_m a_{i,m}^{\mu,\ell}\langle \Upsilon_{\ell}^{m}\rangle$. Next we perform the frame rotation (x, y, z)-> (ξ, η, ζ) so that the axis $O\zeta \| \mathbf{M}_{\rm s}$ spontaneous magnetization (Figure 8). Taking into account how the SH are transformed under rotation and the isomorphism between Υ_l^m and Y_l^m, it is easy to show that $\langle \Upsilon_l^m\rangle = \sum_{\mathbf{m}'}\langle Y_{l(\boldsymbol{\zeta})}^{m'}|Y_l^m\rangle\langle \Upsilon_{l(\boldsymbol{\zeta})}^{m'}\rangle$, where $\Upsilon_{l(\zeta)}^{m'}$ refer to the rotated frame. Now under a rotation φ about $\boldsymbol{\zeta}$, $\Upsilon_{l(\zeta)}^{m'}$ transforms as $\mathrm{e}^{im'\varphi}$ and since the spin system (or $\mathbf{M}_{\rm s}$) has cylindrical symmetry around $\boldsymbol{\zeta}$ (keeping only the exchange interaction), $\langle \Upsilon_{l(\zeta)}^{m}\rangle = 0$, except for $m' = 0$. Therefore we have $\langle \mathcal{K}_i^{\mu,l}\rangle = \langle \Upsilon_{l(\zeta)}^{0}\rangle \mathrm{K}_i^{\mu,l}(\zeta)$ and accordingly we end up with $\langle \mathcal{K}_i^{\mu,l}\rangle = \langle \Upsilon_{l(\boldsymbol{\zeta})}^{0}\rangle \Sigma_m a_{i,m}^{\mu,l} = \mathrm{K}_i^{\mu,l}(\zeta)\langle \Upsilon_{l(\boldsymbol{\zeta})}^{0}\rangle$, which provides for the thermal dependence of the MEL constants, being defined as $\overline{\mathrm{M}}^{\Gamma,\ell} \equiv M^{\Gamma,\ell}\langle \Upsilon_{\ell(\boldsymbol{\zeta})}^{0}\rangle_T$. For lowest order $l = 2$, $\Upsilon_{2(\zeta)}^{0} \propto O_{2(\boldsymbol{\zeta})}^{0} = (\sqrt{3}/2)(3J_{\zeta}^2 - J(J+1))$ and if the temperature is low enough only the two first levels of the J manifold will be populated. Expressing $J_{\zeta} = J - \sigma = J - a^{+}a$, with σ, the deviations number operator, we obtain for the eigenvalues $\sigma = 0, 1$ and cutting the expansion that $(1 - \sigma/J)^3 \cong 1 - 3/J$. Therefore, we obtain $\langle \Upsilon_{2(\boldsymbol{\zeta})}^{0}\rangle \approx (2J - 1)J\left[1 - 3\langle\sigma\rangle/J\right] \approx (M/M_0)^3 = m(T)^3$, which for any l adopts the general form

$$\overline{\mathrm{M}}_{j,l}^{\mu}(T)\big/\overline{\mathrm{M}}_{j,l}^{\mu}(0) = \frac{\langle \Upsilon_l^0(\mathbf{J}')\rangle_T}{\langle \Upsilon_l^0(\mathbf{J}')\rangle_0} = \left(\frac{M(T)}{M(0)}\right)^{l(l+1)/2} \tag{16}$$

which is the famous *Akulov–Zener–Callen l(l+1)/2 power law* (AZC) of thermal variation of MS, applicable to FM insulators. This law can be generalized considering that the full J manifold $(-J \le m' \le J)$ is populated (high temperatures). In this case, using the density matrix technique for getting the thermal averages, we have that

$$\langle \Upsilon_l^0(J')\rangle = \sum_{-J}^{J}\langle m'\left|\Upsilon_l^0\right|m'\rangle \frac{\exp[Xm']}{\sum_{-J}^{J}\exp[Xm']} \tag{17}$$

and taking into account that $\int_{-1}^{1} Y_l^0(m')\exp\left[Xm'\right]\mathrm{d}m' = I_{l+1/2}(X)$, where $I_{\ell+1/2}(X)$ is a Bessel function, and defining the reduced Bessel function as $\hat{I}_{\ell+1/2}(X) \equiv I_{\ell+1/2}(X)\big/ I_{1/2}(X)$, we end up with

$$\overline{\mathrm{M}}_{j,l}^{\Gamma}(T) = \overline{\mathrm{M}}_{j,l}^{\Gamma}(0)\hat{I}_{l+1/2}(L^{-1}(m)) \tag{18}$$

where $L^{-1}(m)$ is the inverse Langevin function. However his law is quite general, including all theories based on quasiparticle collective excitations, of which the mean-field approximation (MFA) is a particular case and where the variable $X = ng\mu_{\rm B}\langle m'\rangle/k_{\rm B}T$ (n is the mean-field (MF) constant). Now the reduced magnetization, $m(T)$ along $\boldsymbol{\zeta}$, adopts the form $m(T) = \langle\cos\theta'\rangle = \langle Y_l^0(\mathbf{J}')\rangle_{\rm T}/\langle Y_l^0(\mathbf{J}')\rangle_0 = \hat{I}_{3/2}(X)$. In Figure 9 are shown the reduced $\langle\tilde{\Upsilon}_2^0\rangle(m)$ versus m for several J $(= S)$ values and in Figure 10 the fits of $\lambda^{\gamma,2}\big/2$ and $-\lambda^{\gamma,4}$ thermal variation for Tb metal; also in Figure 11 is shown how the general AZC law is well accomplished for Dy and Er metals (See also **Theory of Magnetocrystalline Anisotropy and Magnetoelasticity in 4f and 5f Metals, Volume 1**). Substituting now equation (15) (for cubic symmetry) into $F_{\rm mel} = \langle H_{\rm mel}\rangle$ we obtain again the same expression for the free energy of equation (3), and if we add $F_{\rm el}$ and the magnetocrystalline anisotropy (MCA) energy, of the form $F_{\rm K} = \Sigma_{\ell}\kappa_{\ell}K^{\alpha,\ell}$, we see that a MEL contribution to the MCA constants, κ_l appears (or *MEL anisotropy* energy), of the form

$$\overline{\kappa}_1^{\rm eff} = \kappa_1 - \left(\frac{1}{2}\right)\Sigma_{\mu}\Sigma_j\left(\frac{1}{c_{\mu}^{\mu}}\right)\Sigma_{l_1,l_2}k_{l_1l_2}^{\mu,l}\overline{\mathrm{M}}_j^{\mu,l_1}\overline{\mathrm{M}}_j^{\mu,l_2} \tag{19}$$

where the k numbers are tabulated (see del Moral, 2007).

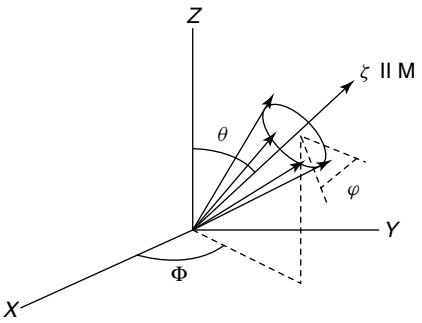

Figure 8. Cylindrical symmetry spin directions distribution around magnetization **M**, at finite temperature (del Moral, 2007.)

2.3 Two-ion (exchange) MS

We will now consider the afore mentioned exchange interaction MS and consider that an exchange interaction exists

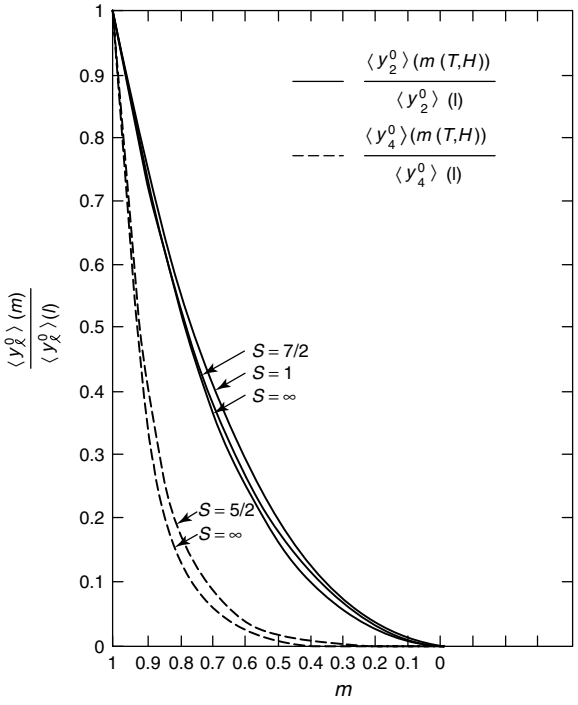

Figure 9. Thermal dependence of longitudinal spin-correlation functions $\ell = 2, 4$, versus reduced $m(T)$ for several spin values, S (Callen and Callen, 1965).

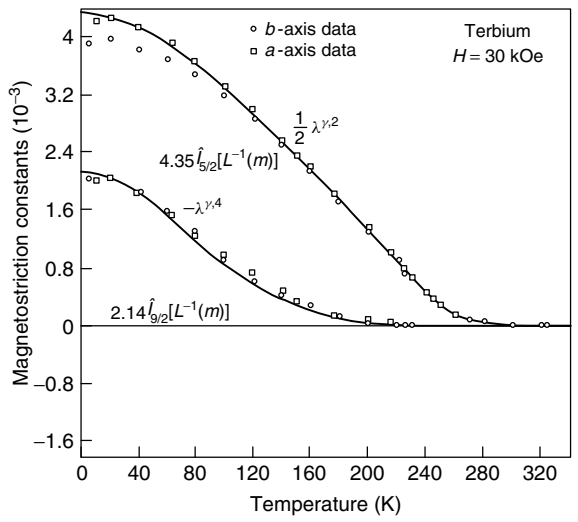

Figure 10. Clark's MS constants, $\lambda^{\gamma,2}$ and $\lambda^{\gamma,4}$ (tetragonal strain) thermal dependence for Tb metal; lines are the STM theoretical fits by reduced Bessel functions $\hat{I}_{\ell+1/2}$ (L^{-1}(m)) with $\ell = 2, 4$ respectively (Rhyne and Legvold, 1965).

between the ion pairs (f, g) of the forms mentioned in Section 1. Now the *two-ion MEL Hamiltonian* takes the form,

$$H_{\rm me}^{\rm II} = -\Sigma_{(f,g)}\Sigma_\Gamma \Sigma_{jj'} D_{jj'}^\Gamma(f,g)\Sigma_i \varepsilon_i^{\Gamma,j}\mathcal{J}_i^{\Gamma,j'}(f,g) \qquad (20)$$

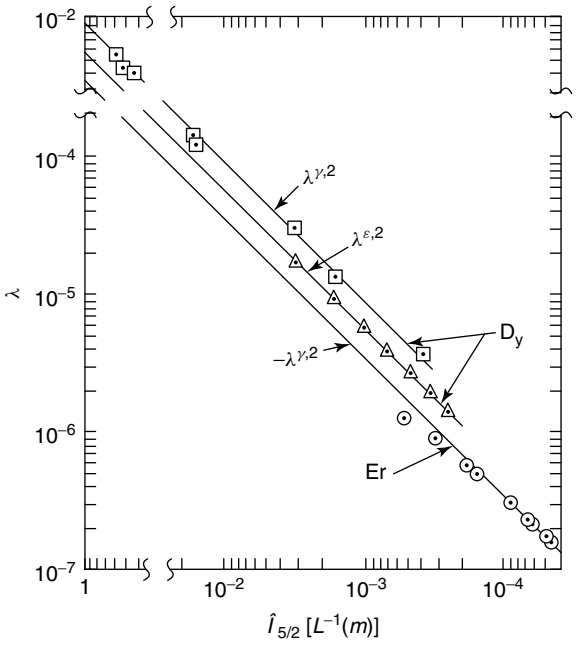

Figure 11. The linear dependence of Clark's MS constants $\lambda^{\gamma,2}$ and $\lambda^{\varepsilon,2}$ with reduced Bessel function $\hat{I}_{5/2}$ (L^{-1} (m)) confirms the STM equation (18) (Tsuya, Clark and Bozorth, 1964).

$D_{JJ'}^\Gamma$ are the EX-MEL parameters and $\mathcal{J}_i^\Gamma(f,g)$, two-ion AM operators, isomorphous of the Stevens operators (see Table 1), and where first correspond to isotropic EX-MS (independent of $\mathbf{M}_s$ orientation) and the remainder to anisotropic EX-MS. In the case of cubic and hexagonal symmetries, $H_{\rm mel}^{\rm II}$ is simply obtained by substituting $J^2 \to J_f \cdot J_g$ and the squared components J_i^2 $(i = x, y, z)$ by $J_f^i J_g^i$ in equations (13 and 14). Now there are four MEL parameters for Γ^α strains, D_{i1} $(i = 1, 2)$ for the isotropic exchange and D_{i2} $(i = 1, 2)$ for the anisotropic one. In this way we obtain three *spin-correlation functions* (SCFs): one-ion longitudinal ($\mathcal{L}_f \sim \langle S_z^2 - (1/3)S(S+1)\rangle$), and two-ion longitudinal ($\mathcal{L}_{fg}(T, H) \sim \langle S_f^z S_g^z - (1/3)S_f S_g\rangle$), and two-ion isotropic ($I_{fg}(T, H) \sim \langle \mathbf{S}_f \cdot \mathbf{S}_g\rangle$), which provide for the thermal dependence of the EX-MSs. In the same way as before the MEL free energy is obtained by taking the thermal average $\langle H_{\rm EX}^{\rm II}\rangle$ and therefore the equilibrium MS becomes $\overline{\varepsilon}_i^\Gamma = (c^\Gamma)^{-1}\Sigma_{(f,g)} D^\Gamma(f,g)\langle \mathcal{J}_i^\Gamma(f,g)\rangle$.

Other theories than the MFA have been developed for explaining the thermal dependence of CEF-MS, such as the one based on a generalization of the Brillouin function theory (Kuz'min, 1992) and including CEF splitting (i.e., unevenly spaced levels), well applicable to RE intermetallics, and the one based on the spin-wave approximation (del Moral and Brooks, 1974). Also a number of techniques have been developed to calculate the two-ion SCFs, such as the cluster one (Bethe–Peierls–Weiss, BPW) and the one based on

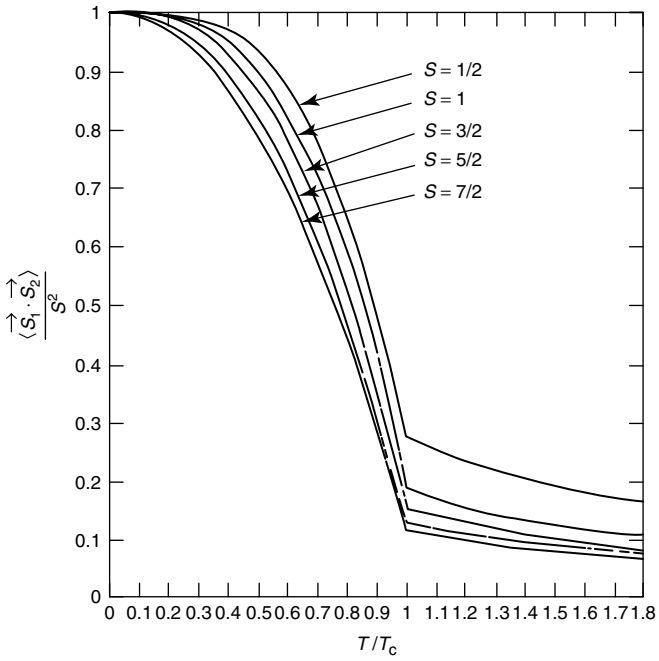

Figure 12. Thermal dependence of isotropic two-ion spin-correlation functions (Callen and Callen, 1964).

the thermodynamic Green function technique. In Figure 12 is shown the thermal variation of $I_{fg}(T)$ for several S values calculated according to the two-atom cluster theory, meanwhile $\mathcal{L}_{fg}(T, H)$ changes as m^2, which distinguishes EX-MS from the CEF-MS, changing as m^3 at low T.

At the Curie temperature, T_c, in FMs, MS manifests *spontaneously*, giving rise to *anomalies* in the volume and anisotropic TH.E.s. For example, for hexagonal symmetry the Γ^α IR anomalous strictions are for volume and tetragonal distortions respectively of the forms,

$$\overline{\epsilon}^{\alpha,1} = \frac{\Delta V}{V} = \lambda_{11}^{\alpha}(T, H) + \lambda_{12}^{\alpha}(T, H)\left(\frac{\sqrt{3}}{2}\right)\left(\alpha_z^2 - \left(\frac{1}{3}\right)\right)$$

$$\overline{\epsilon}^{\alpha,2} = \left(\frac{\sqrt{3}}{2}\right)\left(\overline{\epsilon}_{zz} - \left(\frac{1}{3}\right)\overline{\epsilon}^{\alpha,1}\right) = \lambda_{21}^{\alpha}(T, H) + \lambda_{22}^{\alpha}(T, H)\left(\frac{\sqrt{3}}{2}\right)\left(\alpha_z^2 - \left(\frac{1}{3}\right)\right) \quad (21)$$

where $\lambda_{ij}(T, H) = (1/\Delta_\alpha)\Sigma_{(f,g)}[c_{jj}^{\alpha} D_{ij}^{\alpha}(f, g) - c_{ij}^{\alpha} D_{ji}^{\alpha}(f, g)] I_{f,g}(T, H)$, $i, j = 1, 2$, meanwhile, λ_{12}^{α} and λ_{22}^{α} depend on both $\mathcal{L}_f$ and $\mathcal{L}_{fg}$ (c_{ij}^{α} are symmetry ECs and $\Delta_\alpha \equiv c_{11}^{\alpha} c_{22}^{\alpha} - (c_{12}^{\alpha})^2$). In Figure 13 is shown the *magnetic TH.E.*, $(\Delta V/V)_{\text{isotr}} = \lambda_{11}(T)$, for the cubic Laves-phase polycrystalline $GdNi_2$ compound, with the anomaly

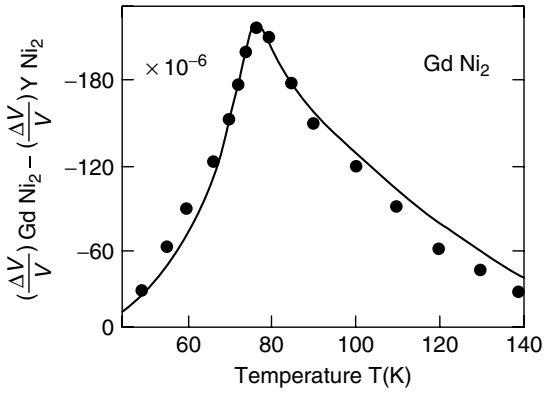

Figure 13. Volume thermal expansion of $GdNi_2$; $\left(\frac{\Delta V}{V}\right)YNi_2$ is the lattice contribution; the line is the theoretical fit (del Moral and Ibarra, 1985).

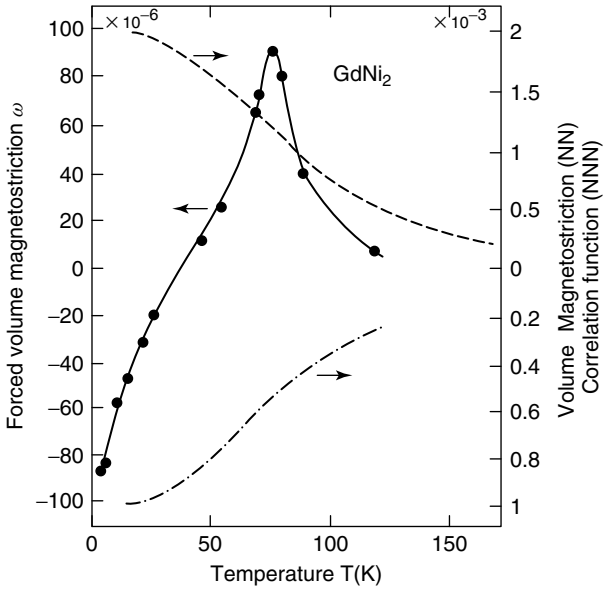

Figure 14. Forced volume MS of $GdNi_2$ and NN and NNN spin-correlation functions (del Moral and Ibarra, 1985).

at $T_c = 75$ K. Also, the volume *forced magnetostriction* (*FMS*), $\partial\omega/\partial H$ is shown to be given by $(\partial\omega/\partial H) = (2/c^{\alpha})\Sigma_{j(f,g)} D_{11}^{\alpha}(f, g)\langle S_j^z \mathrm{S}_f \cdot \mathrm{S}_g\rangle$, with a triple SCF (solved e.g., by decoupling $\langle S_j^z\rangle\langle \mathrm{S}_f \cdot \mathrm{S}_g\rangle$), and in Figure 14 it is shown $\omega(H)$ for $GdNi_2$, together with the *two-spin cluster* BPW theoretical fit. This theory, extended to nearest-neighbours (NN) and next-nearest-neighbour (NNN), explains well the T and H dependencies for archetypal FMs such as EuO, EuS, and the magnetic semiconductor EuSe (del Moral, 2007). Finally note that MS shows critical behavior at T_c with critical exponents $2\beta, 2/\delta$ (FM regime), and -2γ (PM one), as expected (Vázquez, Hernando and Kronmüller, 1986).

2.4 Antiferromagnets

MS in collinear antiferromagnets (AFMs) can be obtained just by applying the STM to each sublattice and adding the contributions. However a phenomenological Landau–Ginzburg (L–G) theory, based on *Dzyaloshinskii's* magnetic symmetry group (MSG) theory arguments (Wolf and Huan, 1988a,b), is more physical and powerful. In those canted AFMs, such as the tetragonal halides MnF_2 and CoF_2 ($T_N = 67.5$, 38 K) and the cubic garnet DyAlG ($T_N = 2.54$ K), instead of $\mathbf{M} = (2M_0)\mathbf{m} = \mathbf{M}_1 + \mathbf{M}_2$ ($= 0$ at 0 K and without canting), the order parameter is $(2M_0)\boldsymbol{\eta} = \boldsymbol{l} = \mathbf{M}_1 - \mathbf{M}_2$, or Néel AFM vector (always non-null, see Figure 15, and where $\mathbf{M}_i$ are the sublattice magnetizations). The MEL free energy must be invariant against the MSG operations and for the simplest case of cubic symmetry (MSG for DyAlG is $Ia3d \times R$, where R is the time inversion operator) the MEL plus elastic free energy is,

$$F_{\text{mel}} + F_{\text{el}} = \overline{D}_1 l^2 \varepsilon + \left(\frac{1}{2}\right)\overline{G}_1 l^2 \varepsilon^2 + \overline{D}_2 m^2 \varepsilon + \overline{D}_3 lm\varepsilon + \cdots + \left(\frac{1}{2}\right) c_0 \varepsilon^2 \qquad (22)$$

where terms odd in $\boldsymbol{\eta}$ are only allowed if $\boldsymbol{\eta}$ is translationally invariant, which only happens if the AFM is commensurate. From the minimization, $\partial(F_{\text{mel}} + F_{\text{el}})/\partial\varepsilon = 0$, we obtain,

$$\overline{\varepsilon} = -\frac{(\overline{D}_1 l^2 + \overline{D}_2 m^2 + \overline{D}_3 ml)}{(c_0 + \overline{G}_1 l^2)} \qquad (23)$$

Without $\mathbf{M}_i$ canting, $\mathbf{m} = 0$ and the MS is determined by $\boldsymbol{l}$ (also $\boldsymbol{l}$ gives rise to an *MEL effect* on the 'bare' EC c_0). In Figure 16a is shown $\overline{\varepsilon}_{xy}$ versus $\mathbf{H}_\perp \| [1\ \overline{1}\ 0]$ for tetragonal CoF_2 (at 4.2 K), noticing a quadratic dependence, and noticing also the dominance of $\boldsymbol{l}$ *rotation* within the [110] plane (term in $\overline{D}_1$). Instead for $\mathbf{H}_\parallel \| [1\ \overline{1}\ 0]$, $\overline{\varepsilon}_{xy}$ changes linearly (Figure 16b), indicating the dominance of the l^2 term, if induced canting is neglected. A similar study has been performed for AFM MnF_2 ($T_N = 67.3$ K) (Shapira, Yacovicht and Nelson, 1975).

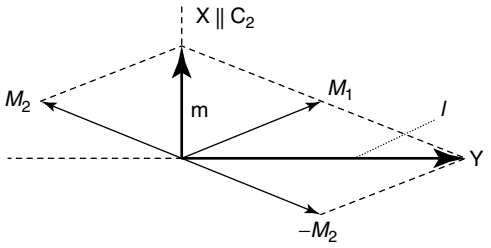

Figure 15. Magnetization, $\mathbf{m}$ and Néel AFM vector, $\boldsymbol{l}$ for AFM; C_2 is a twofold axis (del Moral, 2007).

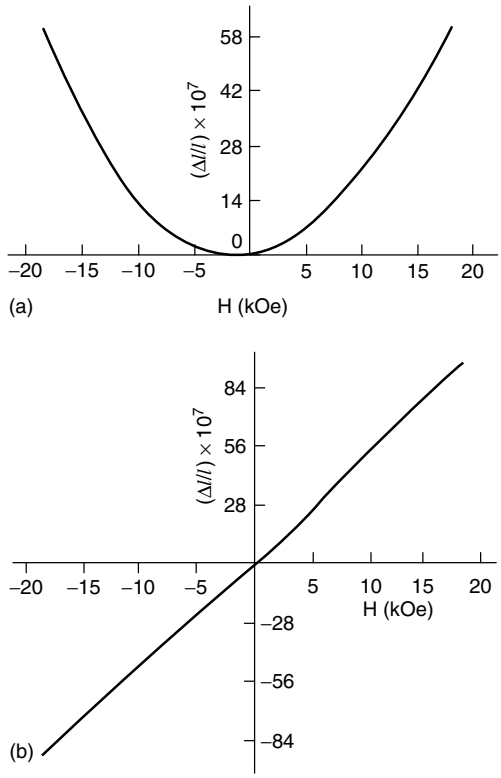

Figure 16. MS $\lambda([1\overline{1}0], [110])$ (a) and $\lambda([001], [110])$ (b) for CoF_2 at 4.2 K (Prokorov and Rudashevskii, 1969).

2.5 Spin-wave approximation for MS

This model is of interest because it provides the MS field dependence in cubic FMs, AFMs, and ferrimagnets (for helical phases in hcp rare-earth metals (REMs) the situation is more complicated). Transformation $S_l^{\pm} \cong \sqrt{2S}a_l^{\pm}$ ($\boldsymbol{l}$ is a lattice site) to boson creation and annihilation operators, immediately yields $\langle \tilde{O}_n^0 \rangle = Q[1 - (n(n+1)/2)(1/M_{\text{so}})g\mu_{\text{B}}\Sigma_l \langle a_l^+ a_l^- \rangle]$, where Q is a constant and $M_{\text{so}} = NgS\mu_{\text{B}}$, or 0 K spontaneous sublattice magnetization. The excited magnon number, at T and applied field H is then $\langle n \rangle_{T,H} = \Sigma_l \langle a_l^+ a_l^- \rangle = (g\mu_{\text{B}})^{-1}[M_{so} - M(T, H)]$. Calling $\Delta m = 1 - m$, we obtain $\langle \tilde{O}_n^0 \rangle = Q[1 - (n(n+1)/2)\Delta m] \approx Q[1 - \Delta m]^{n(n+1)2} = \mathrm{Q}m^{n(n+1)2}$, which again constitutes the AZC power law. Transforming now to magnon operators $a_k^{\pm}$ by Fourier expansion, we obtain $\langle \tilde{O}_n^0 \rangle = Q[1 - (n(n+1)/2NS)\Sigma_k \langle n_k \rangle]$, where $\langle n_k \rangle = \{\exp[\beta E(\mathbf{k}) - 1]\}^{-1}$, or $\mathbf{k}$-magnon number. In a similar way we can calculate the two-ion MS. Assuming a quadratic magnon dispersion $E(\mathbf{k})$ we obtain for the general full MS the expansion,

$$\lambda = \lambda_0 + \lambda_1(T)\sqrt{H} + \lambda_2(T)H + \lambda_3(T)H^{3/2} + \lambda_4(T)H^2 + \lambda_5(T)H^3 + \cdots \qquad (24)$$

The leading term in H applies for α mode (as well as $H^{3/2}$), being of exchange origin. For CEF γ and ε strictions the leading CEF term is in $\sqrt{H}$, that is, nonanalytic (however, exchange α mode has also a $\sqrt{H}$ contribution). Therefore for AMS, $\sqrt{H}$ dependence singles out the CEF-MS origin, as does the H dependence for exchange origin in the volume MS, ω.

Another important aspect manifested by MS is the *spin dimensionality* (Callen, 1982). The AZC law has been derived for spatial $d = 3$ dimension and Heisenberg spins ($D = 3$). We will consider now what happens when the moments are constrained to a plane ($d = 2$, the possible case of ultrathin films, monolayers, and interfaces (IFs) in superlattices (SLs)) and also $D = 2$ (XY magnet), and in general for any D, as we know that MFA is exact for $D = 4$ (for fixed $|\boldsymbol{\mu}|$ the degrees of freedom (DOF) are reduced to $D - 1$). Considering $2D$ spins, the DOF is the angle θ of $\langle \mathbf{S} \rangle$, formed with the MCA *easy direction* (ED), and we will perform a classical calculation of MEL energy. This will be expanded in Legendre polynomials $P_l(\cos\theta)$, where l should be even. In order to obtain $\langle P_l(\cos\theta)\rangle$ we write the partition function as $Z_0 = \int_0^\pi \mathrm{e}^{a\cos\theta} d\theta$, with $a \equiv \langle E\rangle / k_\mathrm{B}T$, where $\langle E\rangle$ is the unperturbed ionic MF energy. Noticing that needed $\langle \cos^n\theta\rangle \sim \partial^n Z_0/\partial a^n$, and that for low-T $\theta = \varepsilon$ is small we perform the expansion, $Z_0 \cong \varepsilon \mathrm{e}^a(1 - a\varepsilon^2/6)$ and therefore we obtain $m = (Z_1/Z_0) \cong 1 - \varepsilon^2/6$, and therefore we obtain $\langle \cos^n\theta\rangle = (Z_n/Z_0) = 1 - n\Delta m$. Then for any l we obtain,

$$\frac{\overline{\mathrm{M}}_i^{\Gamma,l}(T)}{\overline{\mathrm{M}}_i^{\Gamma,l}(0)} = 1 - l^2\Delta m \cong m^{l^2} \tag{25}$$

giving a quite different dependence for $d = D = 2$ than for $D = 3$ spins, that is, an m^4 dependence (or $(l + 0)/1$ power for DOF $n = 2 - 1$). In order to generalize to n DOF, we notice that for $D = 3$ ($n = 3 - 1 = 2$) the power is $l(l + 1)/2$, which by induction gives a general power $l(l + n - 1)/2$. A general proof of the preceding conjecture for all l, all symmetries, and all D does not exist, as the corresponding mathematics does not exist. The exceptions are uniaxial crystals in d dimensions.

2.6 Parastriction

The STM also provides a description of the PS, although a direct calculation of the strictions, through the diagonalization of the full Hamiltonian (including QP exchange interaction), and using perturbation theory has provided a good explanation of PS in cubic-CsCl REM (M = Zn, Ag, Cu, Sb, Cd, P, As) intermetallics, showing FM, AFM, QP, and anti ferro-quadrupolar (AFQP) orderings, in cubic Laves-phase REM_2 (M = Al, Ni, Cu) and hexagonal RENi_5 (del Moral, 2007). We have no space here to develop such a detailed theory (Morin, Schmitt and de Lacheisserie, 1980), and we take recourse to the usual STM, where CEF effects are disregarded (instead in CEF-PS theory we end up, after a perturbation expansion of F, with MSs $\overline{\varepsilon}^\Gamma = (M^{\Gamma,2}/c_0^\Gamma)\chi_Q^\Gamma H^2$, $\Gamma = \gamma(\varepsilon)$, where $\chi_Q^\gamma = \partial Q/\partial(H)^2$ is the QP-field susceptibility, for QP moment $Q = \langle \tilde{O}_2^0\rangle$ ($\langle \overline{O}_2^2\rangle$, etc. for χ_Q^ε). Effectively, in PM regime ($T > T_\mathrm{c}$ or T_N), $X = \beta\mu(H_\mathrm{MF} + H)$ is small and therefore the small $m(T, H) = \hat{I}_{3/2}(X) = (1/3)X + \cdots$ expansion is also allowed, as well as $\hat{I}_{l+1/2}(X) = [1/(2l + 1)!!]X^l + \cdots$, $X \ll 1$. Therefore we obtain $\hat{I}_{l+1/2}(X) \approx 3^l m^l(T, H)/(2l + 1)!!$, $m \gg 1$, and for order $l = 2$ we deduce that

$$\frac{\overline{\mathrm{M}}_{j,2}^\Gamma(T)}{\overline{\mathrm{M}}_{j,2}^\Gamma(0)} = \hat{I}_{5/2}(X) = \left(\frac{9}{15}\right) m^2(T, H) = \left(\frac{9\chi^2(T)}{15M_0^2}\right) H^2, T \gg T_\mathrm{c} \tag{26}$$

where $\chi(T)$ is the first-order PM (Curie) susceptibility and $M_0 = M(0, 0)$. This H^2 dependence is the finger point for a true paramagnet (although higher even powers appear for $T \cong T_\mathrm{c}$). For higher order MEL constants the dependence is as m^ℓ indeed.

Finally we have to mention that in AFM helical systems such as hcp RE metals, MS should be in principle *nonuniform*, the lattice deforming in each crystal plane along the local magnetization. But if we assume such a strain and call by (ξ, η, ζ) the local frame attached to the rotating spin, with turn angle ψ between NN spins along c axis, we obtain the expression for the (l, m, n) site displacement, $u_{lmn} = \int A(\xi, \eta, \zeta) e^{i(\xi l + \eta m + \zeta n)}\, \mathrm{d}\xi\mathrm{d}\eta\mathrm{d}\zeta$ and also the condition $\cos\eta = 2 - \cos 2\psi > 1$, which means that η is imaginary and therefore u is damped as moving away from the crystal surface. This means that for instance, the ε^γ modes are clamped within the lattice, and that the crystal is only strained within a thin surface layer (few lattice constants) (Evenson and Liu, 1969). For a bulk crystal this is insignificant but not for a very thin film (TF).

2.7 Magnetoelastic parameters calculation and MS of RE intermetallics

MEL parameters $M_i^{\Gamma,\ell}$ are the best piece of information about MEL coupling at a microscopic level, and therefore their experimental determination and theoretical calculation are paramount. The simplest way to calculate them is assuming that the ligand ions producing the CEF are point charges, q_i

(*point charge model*, PCM), although PCM is so simplified that it seldom agrees with experiment. A better way is to use the *superposition model*, which assumes axial symmetry along each bond axis, and from A_n^0 build the remaining CEF parameters (Newman and Ng, 1989). The way to proceed is by writing the undistorted CEF gradient (even if it is zero by, e.g., cubic symmetry), and expanding it in the corresponding strain. For instance let us calculate $M^{\gamma,2}$ (for orthorhombic basal plane distortion, $\varepsilon_1^\gamma = (1/2)(\varepsilon_{xx} - \varepsilon_{yy})$) for hexagonal symmetry. We start with the CEF parameter

$$B^{\gamma,2} = +\left(\frac{3}{4}\right) Z|\mathrm{e}|\alpha_J \langle r^2\rangle \Sigma_i q_i \left(\frac{(x_i^2 - y_i^2)}{R_i^5}\right) \tag{27}$$

where (x_i, y_i, z_i) are the point ligand positions (of charge $Z|\mathrm{e}|$) and R_i their distances to the probe ion. $\alpha_J \equiv \theta_2$ is the second-order W–E coefficient. If we now distort the coordinates as $x_i \to x_i(1+\varepsilon_{xx})$, $y_i \to y_i(1+\varepsilon_{yy})$, $z_i \to z_i$ and preserve the volume (i.e., $\varepsilon_{xx} = -\varepsilon_{yy} = \varepsilon_1^\gamma$) we obtain the lattice summation $S = 2\varepsilon_1^\gamma \Sigma_i[(x_i^2 + y_i^2)/R_i^5] - 5\varepsilon_1^\gamma \Sigma_i[(x_i^4 - y_i^4)/R_i^7]$, plus B_2^0. In this form the MEL parameter becomes,

$$M^{\gamma,2} = \left(\frac{3}{4}\right) Z|\mathrm{e}|\alpha_J \langle r^2\rangle \left[\frac{2\Sigma_i\left(x_i^2 + y_i^2\right)}{R_i^5} - 5\Sigma_i \frac{(x_i^4 - y_i^4)}{R_i^7}\right] \tag{28}$$

We can proceed in similar way with other ISs and other symmetries and even with more complex structures (polyatomic motives; the lattice summations are well known, del Moral, 2007). The results of this model can be compared with the measured MEL parameters, obtained from MS measurements, the best way being by studying $\overline{\mathrm{M}}^{\gamma,\ell}$ temperature dependence. This has been performed with the RE metals (hcp structure), many RE intermetallics, such as REM_2 (Laves phases), REM_5 (hexagonal) (M is a metallic atom), and RE impurities in nonmagnetic hosts, a good way to avoid MS exchange contribution. Considering only NN ligands, for the REM_2 the tetragonal distortion, ε_1^γ MEL parameter becomes, $M^{\gamma,2} = \sqrt{6}\mathrm{e}^2\alpha_J\langle r^2\rangle \left\{\frac{4}{3}\left[Z(\mathrm{RE})/R^3(\mathrm{RE})\right] - (156/121)\left[Z(\mathrm{M})/R^3(\mathrm{M})\right]\right\}$, where Z is the ligand charge.

We present an example to show how to proceed for the derivation of the MEL parameter, studying the thermal variation of ISs in the archetypal FM Laves-phase REAl_2, in concrete the *saturation* (spontaneous after DW displacements) tetragonal $\varepsilon_1^\gamma(\varepsilon_{xx} = \varepsilon_{yy} = -\varepsilon_{zz}/2)$ distortion in Pr Al_2 ($T_\mathrm{c} = 33\,\mathrm{K}$; $\langle 100\rangle$ EDs) (Abell, del Moral, Ibarra and Lee, 1983; see del Moral *et al.*, 1986), for $\mathrm{Gd}_{1-x}\mathrm{Tb}_x\mathrm{Al}_2$, where exchange is tailored). The same kind of study has been performed in dilute $\mathrm{Y}_{1-x}\mathrm{RE}_x$ (Pureur, Creuzet and Fert, 1985) and noble metal–rare earth (NMRE) alloys (Creuzet and Campbell, 1981). The thermal variation of the MSs difference giving $\overline{\varepsilon}_1^\gamma$ is shown in Figure 17, together with the theoretical fit by $\overline{\varepsilon}_1^\gamma = (M^{\gamma,2}/c_0^\gamma)\langle\tilde{\mathrm{O}}_2^0\rangle + (M^{\gamma,4}/c^\gamma)\left[\langle\tilde{\mathrm{O}}_4^0\rangle - (14/5)\langle\overline{\mathrm{O}}_4^4\rangle\right]$, where $c_0^\gamma = c_{11}^0 - c_{12}^0 = 4.52 \times 10^5$ K/ion. The thermal averages are calculated by the diagonalization of the unperturbed Hamiltonian $H = H_\mathrm{EX} + H_\mathrm{CEF} + H_\mathrm{Z}$, expressing $H_\mathrm{EX} = g\mu_\mathrm{B}\mathbf{J}\cdot\mathbf{H}_\mathrm{MF}$ within the MFA, obtaining the Pr^{3+} ion energy levels and eigen functions, those mixtures of pure $|\mathrm{J}M_J\rangle$ ones. From the fit we obtain the $M^{\gamma,2}$ value given in Table 2, but a better fit is obtained adding the fourth-order MEL contribution (M_4^γ term in the MEL Hamiltonian). In this table the MEL parameters for other REAl_2 together with PCM calculated parameters are given. As we can see the PCM generally fails, either in magnitude or sign (less). This is because of the neglecting of the *screening* of the CEF by the *distorted* conduction band electrons (CEs) charge density, which is very strong, since the proximity of CE to the probe ion can produce a CEF even *stronger* than the NN ions. However ratios such as $M^{\varepsilon,2}/M^{\gamma,2}$ are dictated *only* by symmetry, being model independent (e.g., $-4/3$ for the RE^{3+} diamond lattice in REM_2).

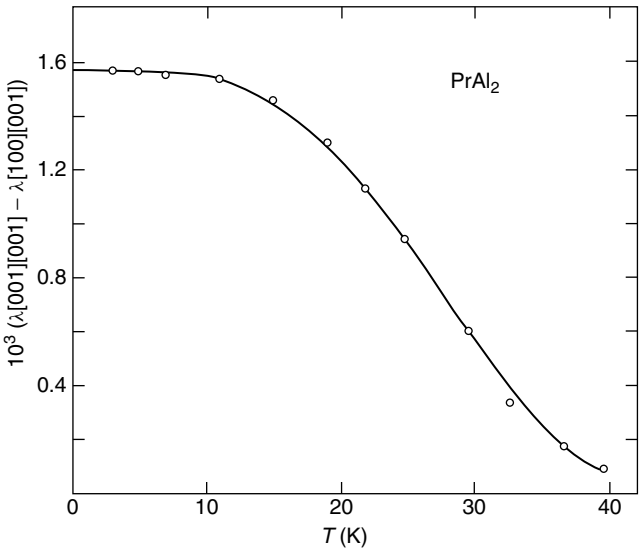

Figure 17. Spontaneous MS ε_1^γ (T) variation for cubic Pr Al_2; line is the theoretical fit (see text) (Abell, del Moral, Ibarra and Lee, 1983).

There are two models to introduce screening in the MEL parameters, both distorting the electronic charge density, $\rho(\mathbf{r} - \mathbf{R}_i)$: one calculates the distortion of the reciprocal space ($\mathbf{q}$) and of the Lindhard's dielectric constant of CE, $\varepsilon(\mathbf{q})$, introducing exchange and correlation between CE, and assumes an spatial charge distribution (Gaussian) for the ligands (del Moral, Echenique and Corrales, 1983); the other just considers the distorted $\rho(\mathbf{r} - \mathbf{R}_i)$, after a previous

undistorted band structure calculation (Morin and Schmitt, 1981). It has been shown that the first approach is superior, the second one failing in the sign and/or order of magnitude. For instance in the case of $NdAl_2$, introduction of CE exchange is essential (positive Fermi holes introduction) and the experimental values are well reproduced (same happens for RE = Pr, Tb).

3 ITINERANT ELECTRON MAGNETOSTRICTION; BAND MODELS; HUBBARD FORCED MAGNETOSTRICTION; STRONGLY CORRELATED SYSTEMS MAGNETOSTRICTION; SPIN-FLUCTUATIONS THEORY; ITINERANT WEAK FERROMAGNETS; *AB INITIO* MS CALCULATION METHODS

Calculation of MS and MEL effects in metals, semiconductors, and alloys is the most difficult task of MS theory. Several theories have been proposed so far (del Moral, 2007): the *Stoner model* of spontaneous magnetovolume (MV), ω_s developed below T_c, and of forced VMS, $\partial\omega/\partial H$ (near saturation); the use of *Hubbard model* (HM); the *band models* (BMs, one of which is the pioneering *Brooks–Fletcher–Katayama* (BFK) one (Fletcher, 1954); see also Tatebayashi, Ohtsuka, Ukai, and Mori (1986)), based on *MS perturbation of tight binding approximation* (*TBA*) *bands* (Mori, 1969a,b; Kondorskii and Straube, 1973; Mori, Fukuda and Ukai, 1974; Otha and Shimizu, 1982), and a simplified BM (band-degeneration and Brillouin zone symmetry (BD-BZS)) of it; and the *ab initio* (AI) calculations (based on first-principles calculations) will be considered. The Stoner model is developed in many text books, and therefore we focus on the BMs (for CEF-MS) and the HM for two-ion MS, as well as in AI methods. In all BMs some conditions to get MS are required: (i) the band must be *orbitally degenerated* to have $\langle \mathbf{L}\rangle \neq 0$ and so non-null SO coupling; (ii) $\mathbf{k}$ points of high symmetry (HS) within the Brillouin zone (BZ) are the main contributors to MS (e.g., Γ point in fcc and bcc-BZs), since only in this case moving out the HS $\mathbf{k}$ point some degeneracy is retained; (iii) only bands near E_F which are partially occupied, yield $\langle \mathbf{L}\rangle \neq 0$ and $\langle \mathbf{S}\rangle \neq 0$; (iv) the SO coupling finally splits the degenerate CEF levels (centers of bands) and mixes the t_{2g} and $e_g\langle \mathbf{L}\rangle = 0$ orbitals (see subsequent text), in this way giving $\langle \mathbf{L}\rangle \neq 0$.

3.1 Band-degeneration (BD) and Brillouin zone symmetry model (BZS)

In the BD-BZS model (Kulakowski and del Moral, 1994) one considers rigid bands within the TBA (with wave functions $\psi_{\mathbf{k},\lambda}(\mathbf{r}) = \Sigma_l a_l \varphi_\lambda(\mathbf{r}-\boldsymbol{l})e^{\mathbf{k}\cdot\boldsymbol{l}}$), centered around the CEF 3d-electron energy levels, E_λ, with density of states (DOS) $D(E-E_\lambda)$. The bands are taken to be of elliptical or Lorentzian shape, obtained by fitting the real DOS band calculations. Also few $\mathbf{k}$ points near the Fermi surface (FS) are considered. Under MS and the MF field, $\mathbf{H}_{MF} = n\mathbf{M}$ (proportional to the Stoner spin-polarized band splitting), there is a rigid band shift $\Delta E_\lambda(\varepsilon_i^\Gamma, \mathbf{H}_{MF})$, and electron number variation, Δn_λ, by transference to other 3d bands ($e_g : \varphi_\lambda = \{3z^2 - r^2, x^2 - y^2\}$; $t_{2g} : \varphi_\lambda = \{xy,yz,zx\}$ for cubic symmetry). Since $\Sigma_\lambda \Delta n_\lambda = 0$, there must be a ΔE_F variation, such that $\Delta n_\lambda = D_\lambda(\mu)\Delta\mu - D_\lambda(\mu)\Delta E_\lambda$, from where ΔE_F is obtained under the preceding constraint. The energy variation is therefore given by $\Delta F(\mathbf{H}_{eff}, \varepsilon_i^\Gamma) = \Sigma_\lambda(\Delta F_\lambda^{(1)} + \Delta F_\lambda^{(2)} + \Delta F_\lambda^{(3)})$, where $\Delta F_\lambda^{(1)} = -n_\lambda \Delta E_\lambda$, or energy gain under rigid sub-band shift; $\Delta F_\lambda^{(2)} = E_F D_\lambda(E_F)\Delta E_\lambda$, or energy cost to keep E_F constant for the exchange polarized bands; $\Delta F_\lambda^{(3)} = -E_F \Delta E_F D_\lambda(E_F)$, or gain under E_F modification ($\mathbf{H} = \mathbf{H}_{app} + \mathbf{H}_{MF}$). Introducing ΔE_F in the total ΔF, we obtain the net variation, $\Delta F_m(\mathbf{H}_{eff}, \varepsilon_i^\Gamma) = -\Sigma_\lambda n_\lambda \Delta E_\lambda$, from where for instance for α strains,

$$\frac{\partial F_m}{\partial \varepsilon_i^\alpha} = -\Sigma_{\lambda=1}^{10}\left(\frac{\partial E_\lambda}{\partial \varepsilon_i^\alpha}\right) \quad (i = 1, 2) \tag{29}$$

which allows the MS calculation, just minimizing, that is, making $\partial(F_m + F_{el})/\partial\varepsilon_i^\Gamma = 0$. The free energy is calculated in itinerant FMs as $F_m = \Sigma_\lambda \int_{-\infty}^{\mu}(E-E_\lambda)^\nu D_\lambda(E-E_\lambda) f_{FD}(\beta(E-E_\lambda))dE$ (with $\nu = 1$) and the band filling, n taking $\nu = 0$.

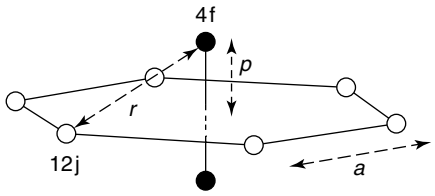

Figure 18. Fe pair atoms (4f sites) in uniaxial Y_2Fe_{17} intermetallic (Kulakowski and del Moral, 1995).

This model has been successfully applied to iron-rich *uniaxial* intermetallics and to Ni and Fe. In the former, for example, for the Y_2Fe_{17} (2–17), with hexagonal structure formed out of pairs of magnetostrictive Fe atoms ('dumbbells') (see Figure 18), **a** ED and with two magnetostrictive doublets ($\{|xz\rangle, |yz\rangle\}$ and $\{|xy\rangle, |x^2 - y^2\rangle\}$), these produced by the CEF splitting. The MEL Hamiltonian is equation (14). From the preceding considerations we immediately obtain for the spontaneous $\overline{\varepsilon}_i^{\alpha}$ MSs ($i = 1, 2$) that

$$\overline{\varepsilon}_i^{\alpha} = \Delta_{\alpha}^{-1}\left[c_{jj}^{\alpha}\left(-\frac{\partial \mathrm{F}_m}{\partial \varepsilon_i^{\alpha}}\right) - c_{12}^{\alpha}\left(-\frac{\partial F_m}{\partial \varepsilon_j^{\alpha}}\right)\right]$$
$$i, j = 1, 2;\ j \neq i \tag{30}$$

By applying field we rotate $\mathbf{M}\|\mathbf{a}$ to $\mathbf{M}\|\mathbf{c}$, and we obtain the rotational or CEF-MSs $\Delta\varepsilon_i^{\alpha} = \varepsilon_i^{\alpha}(\mathbf{c}) - \varepsilon_i^{\alpha}(\mathbf{a})$, where the thermal variation of shape MS $\Delta\varepsilon_2^{\alpha}$ is shown in Figure 19, where we notice a nonmonotonous or non-STM variation, as a consequence of a population of the first doublet, $\langle \mathbf{L} \rangle$ becoming quenched and MS decreasing for $T < 150$ K, as the numerical calculation shows. Same happens with volume MS $\Delta\varepsilon_1^{\alpha}$. The fitted MEL parameters are (in 10^3 K/Fe atom) $M_1^{\alpha,2} = -9.0$ and $M_2^{\alpha,2} = -1.8$, much larger than for RE intermetallics ($\approx 10 - 100$ K/RE^{3+}), due to the much weaker CEF screening in 3d metals. Therefore this model gives a good account of the complicated MS thermal variation (also shown by $Y_2Fe_{14}B$ (2–14), with Tetragonal (TETR) structure and **c** ED) and has been also successful in explaining the maximum shown by $-\lambda^{\gamma,2}$ in iron, below T_c. In iron the use of localized STM gives an AZC exponent $a = 4.9$, which means a breaking of $m^3(T)$ law (Kulakowski and de Lacheisserie, 1989).

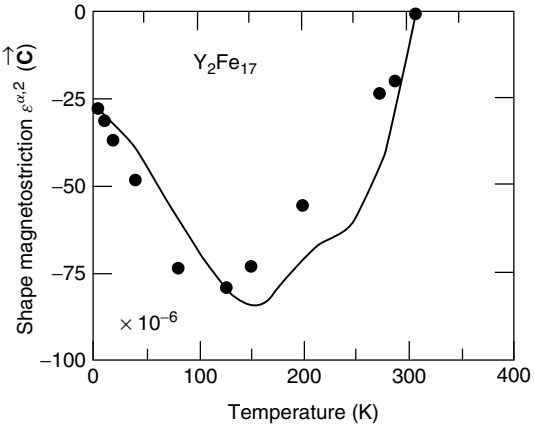

Figure 19. Irreducible ε_2^{α} (**c**) thermal variation in Y_2Fe_{17}; line is the theoretical fit ($\varepsilon_2^{\alpha}(\mathbf{a}) \approx 0$)(Kulakowski and del Moral, 1994).

3.2 Hubbard forced MS

In the preceding Fe intermetallics the magnetostrictive atom pairs are well 'separated' *via* electron hopping from the surroundings, and so the FMS can be calculated in a rather exact way (in fact those systems MS recall the classical *pair-atom* Néel MS model). The important fact is that this simple system shows up that FMS is a consequence of the 3d-electron repulsion, U within the pair. The pair Hamiltonian is the Hubbard one, $H_h = \Sigma_{i=1,2}\Sigma_{\rho,\rho',\sigma} t_{12}(\rho, \rho') c_{i\rho\sigma}^{+} c_{3-i\rho'\sigma} + U_{\mathrm{int}}$, where $|\rho\rangle$ and $|\rho'\rangle$ are t_{2g} states, i the dumbbell sites, $t_{12}(\rho, \rho')$ the hopping matrix elements (Slater–Koster overlapping integrals, depending on the direction cosines of the atoms bond) and U_{int} the intra-atomic electron coulomb repulsion. The preceding Hamiltonian can be transformed to one where the *effective* coulomb interaction depends on the electrons' distance, $U_{\rho\rho'}^{\mathrm{eff}}(r)$, and takes the many-body form $H = U^{\mathrm{eff}}\Sigma_{i=1,2} n_{i,\sigma} n_{i,-\sigma}$ ($n_{i,\sigma}$ is the occupation operator) with a quasi-ground state (QGS) energy level $E_{\mathrm{QGS}} = U^{\mathrm{eff}}$ and

$$U^{\mathrm{eff}} = \left(\frac{U}{2}\right)\left(1 + \frac{r}{2} - \left[1 + (1-r)^2 - 16\left(\frac{t_i}{U}\right)^2\right]^{1/2}\right)$$
$$r \equiv \frac{3J}{4U} \tag{31}$$

strongly reduced from the bare U value ($\cong$1 eV for Y_2Fe_{17}), that is, to 0.1 and 3 meV for 2–17 and 2–14 compounds. But this reduction is only accomplished if t_{12} (= 0.24 and 0.15 eV) is taken as purely *imaginary*, that is, the Bloch pair state QGS is bonding. It can be shown from equation (29) that the FMS, $\chi_{\mathrm{mel}}^{\alpha,i} = \partial\varepsilon_i^{\alpha}/\partial H$ has a contribution such that $\chi_{\mathrm{mel}}^{\alpha,i} = \chi_{\mathrm{mel},0}^{\alpha,i} - (1/c_{ii}^{\alpha})(U_n^{\mathrm{eff}}/4)(\partial/\partial\varepsilon^{\alpha,i}\left[\chi_{hf}(T)m(T)\right])_{\mathrm{T}}$, $i = 1, 2$ (del Moral, Abadia and Garcia-Landa, 2000), which allows to derive U^{eff} from the slopes of the plots of Figure 20 (χ_{hf} is the paraprocess susceptibility, $\partial M_s/\partial H$, and $\chi_{\mathrm{mel},0}^{\alpha,i}$ the combined CEF and Fe–Fe exchange, J, FMS) (del Moral *et al.*, 2007).

3.3 Spin-fluctuations theory of MS

There are RE intermetallics, notably the $REMn_2$ (including Y) and some alloys such as $ZrZn_2$, MnSi and Sc_3In where

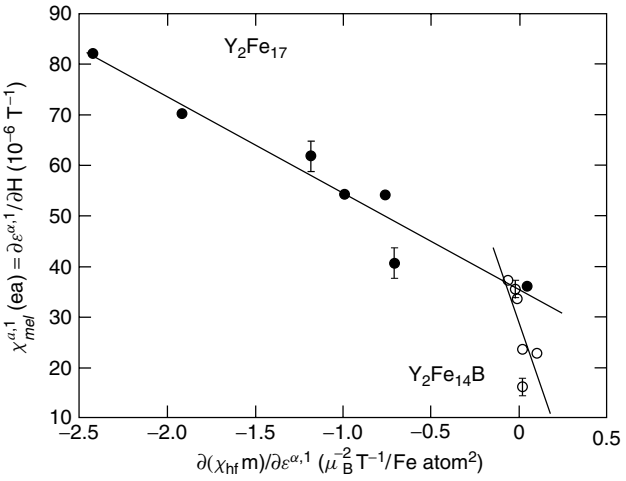

Figure 20. Strain susceptibility for iron intermetallics; see text (del Moral *et al*., 2007).

the Stoner and BM of MS do not work, needing the *spin-fluctuation* (SF) theory of MS for weak ferromagnet (WFM) and weak antiferromagnet (WAFM). In SF theory (Moriya, 1985) we work in the reciprocal $(\mathbf{k}, \omega)$ space as follows. The spin fluctuation is given by $\delta\mathbf{S} = \mathbf{S} - \langle\mathbf{S}\rangle_T$ and there will exist a correlation $S(\mathbf{r}, \mathbf{r}', t - t') = \langle\delta\mathbf{S}(\mathbf{r}, t) \cdot \delta\mathbf{S}(\mathbf{r}', t')\rangle$, which when adequately Fourier transformed gives rise to a dynamical susceptibility $\chi(\mathbf{k}, \omega)$, whose imaginary part can be measured by inelastic neutron scattering. Moreover in spin-localized magnets SFs are spatially localized, and therefore delocalized in *reciprocal* space, around $\mathbf{k} = 0$ or $\mathbf{k} = \mathbf{K}$ in WAFMs ($\mathbf{K}$ is the magnetic structure propagation vector). In SF systems just the opposite occurs, fluctuations are localized around $\mathbf{k} = 0$ (or $\mathbf{K}$) but spatially *extended*. In itinerant magnets those SFs are mainly longitudinal, due to the up and down fluctuation of the spin-polarized subbands. These SFs are therefore the very existing local average spin (local moment), whose mean-squared local amplitude, $S_L^2(T)$ must be T dependent (it is not a true moment $\boldsymbol{\mu} = g\mu_B\mathbf{S}$), that is, self-sustained by thermal fluctuations only. The main result of SF theory for PM regime is that there exists the relationship $S_L^2(T) - S_L^2(T_c) = (3/5)gN^2(1/\chi)$, so that $S_L^2(T)$ increases with T (from 3/5 of its 0 K value; g is a factor function of the DOS slope and curvature at E_F), (see Figure 21). With this background the TH.E. MV can be obtained, just writing $F_{mel} = -\omega\Sigma_{\mathbf{k}}D_{\mathbf{k}}\left[\langle S_{\mathbf{k}}^2\rangle_T - \langle S_{\mathbf{k}}^2\rangle_0\right]$ (Moriya and Usami, 1980). Adding the elastic energy $F_{el} = (1/2)B\omega^2$ (where B is the bulk modulus) and minimizing full F we obtain

$$\omega_s(T) = N^2\left(\frac{D_0}{B}\right)\left[S_L^2(T) - S_L^2(0)\right] \qquad (32)$$

which follows the variation shown in Figure 21, having at T_c^+ (or T_N^+) a discontinuity in the MV of

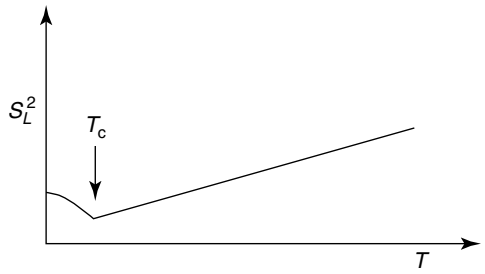

Figure 21. Local spin for spin fluctuation weak FM and AFM (Shiga, 1988).

$\omega_s(T_c) = -(2/5)(D_0/B)[M(0)]^2$, which means that the *atom volume expands* when it acquires a magnetic moment, an interesting result (we assume that the MEL constant is for $\mathbf{k} = 0$, due to the small electron kinetic energy involved). A renormalization of the SFs, long and complicated, transforms equation (32) in an interpolated expression useful for experimental comparison and valid for $T < T_c$, obtaining

$$\omega_s(T) = -\left(\frac{2}{5}\right)\left(\frac{D_0}{B}\right)\left\{[M(0)]^2 - [M(T)]^2\right\},$$

$$\omega_{mel}(T) - \omega_{mel}(T_c) = \left(\frac{3D_0}{5Bg}\right)\frac{1}{\chi(T)} \quad (T > T_c) \qquad (33)$$

and since $1/\chi(T)$ increases with T at PM regime, VMS increases. In Figure 22 is shown the volume TH.E. for the SF Laves-phase series $Y(Mn_{1-x}Ni_x)_2$, where we notice the first-order MV jump, and how small Ni addition suppress the WFM phase, due to the strong SF suppression of μ_{Mn}.

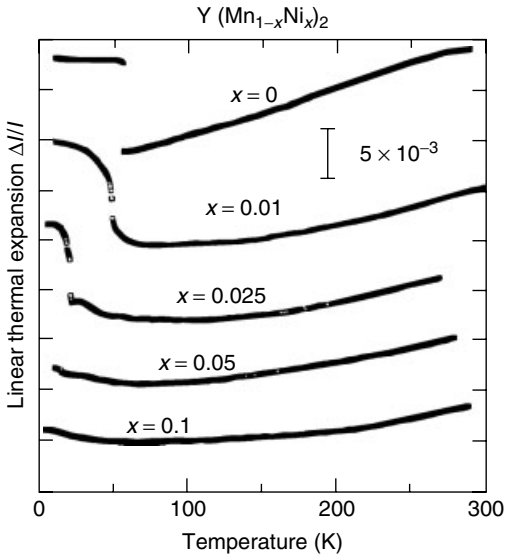

Figure 22. Thermal expansion of cubic $Y(Mn_{1-x}Ni_x)_2$ intermetallics (Ibarra, Garcıa-Olza and del Moral, 1992).

This theory also explains well the MS mentioned in the WFMs, as we will see in the subsequent text.

3.4 Itinerant weak FM magnetostriction

Several theories have been put forward for explaining MS in WFMs such as the archetypal $ZrZn_2$, Sc_3In, MnSi, Ni_3Al, the alloys Fe_xNi_{1-x}, Ni_xAl_{1-x}, and $TiBe_{2-x}Cu_x$, the transition metal (TM)-rich intermetallics, Y_nTM_m(TM = Fe, Ni) and many other alloys. Many of them show the *invar effect*, consisting in the very weak temperature dependence of MV, ω_s below T_c. Others show the *elinvar effect* or constancy also of B bulk modulus below T_c (and other ECs). Of those theories we will consider the Stoner–Wohlfarth–Edwards (SWE) one (Edwards and Wohlfarth, 1968; Mathon and Wohlfarth, 1968) and the SFs one (Moriya, 1985), quite similar to the preceding SF theory; the Shiga's model (Shiga, 1981) based on local spin-polarized bands (of rather clear physical picture) and the field theoretic one (Kakehashi–Liberman–Pettifor, more complex, (Kakehashi, 1981)) may be found elsewhere (del Moral, 2007). In SWE model the free energy, $F(M, \omega)$ adopts a L–G expansion in M, and if the material deforms (either spontaneously or forced by H), the coefficient $A(\omega) = A(\omega_0) - 2\overline{D}^{\alpha}(\omega - \omega_0)$, and therefore,

$$F = F_{00} + \left(\frac{1}{2}\right) AM^2 + \left(\frac{1}{4}\right) BM^4 - HM + \left(\frac{1}{2\kappa}\right) \omega^2 - \overline{D}^{\alpha}\left(M^2 - M_0^2\right)\omega + p\omega \qquad (34)$$

where $F_{00} = F(0, 0)$, $\kappa = 1/B$ is the compressibility, $M = M(T, H)$, $M_0 = M(T, 0)$ (spontaneous magnetization for $T < T_c$), and therefore $\overline{D}^{\alpha}$ is the *MV constant* (p is the applied pressure). Minimizations $\partial F/\partial M = \partial F/\partial \omega = 0$, in particular yield,

$$\omega(H, T) = \kappa \overline{D}^{\alpha}(M^2(H, T) - M_0^2) - \kappa p \qquad (35)$$

where the first term is the *MV* effect. Therefore for $H = 0$, a *spontaneous MV* $\omega_s = \kappa \overline{D}^{\alpha}(M(T, 0)^2 - M(0, 0)^2)$ appears below T_c, and a minimum at T_c (see such a behavior in Figure 23). This appears as an anomalous TH.E. in WFMs, superposed to the lattice one. $\overline{D}^{\alpha}$ is determined from $A(T_c) = 0$ in a second-order transition, that yields $\partial T_c/\partial \omega = -2\overline{D}^{\alpha}\chi_0 T_c$, where $\chi_0 = \left[\partial M(H, 0)/\partial H\right]$ is the 0 K paraprocess (high field) susceptibility at FM regime. It can be also shown that $\overline{D}^{\alpha}_{FM} = -(1/4\chi_0^2)(\partial \chi/\partial \omega) = (1/2)\overline{D}^{\alpha}_{PM}$. Also the forced MS becomes $(\partial \omega/\partial H)_{T\to 0} = 2\kappa \overline{D}^{\alpha} M \chi_0$. The calculation of $\overline{D}^{\alpha}$ is paramount in this theory, and many-body interactions influence it, through the U enhancement of χ_0, yielding at FM regime and 0 K,

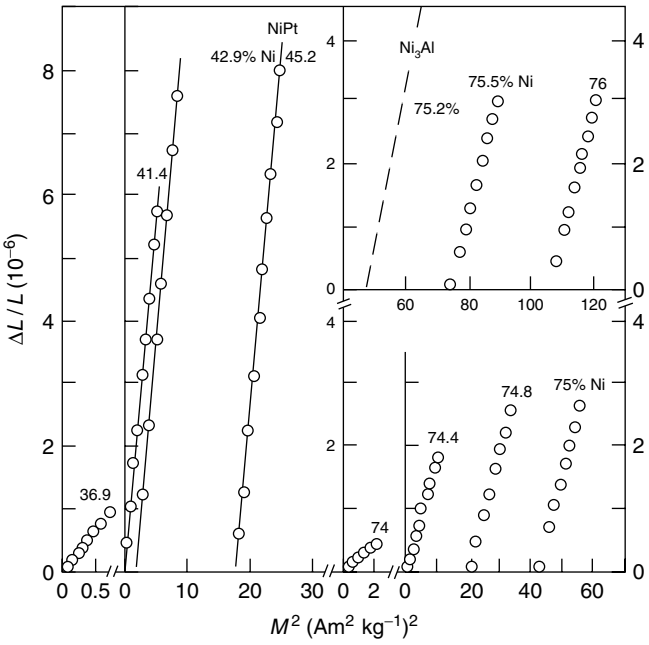

Figure 23. Linear TH.E. Vs M^2 for several weak FMS; see text (Brommer and Franse, 1990).

$$\overline{D}^{\alpha} = \left(\frac{1}{4ND(E_F)\mu_B^2}\right)\left(\frac{\partial \ln D(E_F)}{\partial \ln \omega} + \overline{U}\left(\frac{\partial \ln U}{\partial \omega}\right)\right) \qquad (36)$$

where $\overline{U} = UD(E_F)$ ($\cong 1$ is the Stoner criterion for FM). An important consequence from equation (36) is that $\overline{D}^{\alpha}$ is positive and decreases with increasing T.

In SWE theory we have single-particle excitations, without spin-fluctuations allowance. In fact a strong discrepancy of this theory with experiment is observed, as shown in Table 3. If SFs are taken into account, we obtain in similar way as in the preceding SF theory $\omega_s = \Sigma_{\mathbf{k}}(D_{\mathbf{k}}/B)\left[\langle M_{\mathbf{k}}^2\rangle - \langle M_{\mathbf{k}}^2\rangle_0\right]$, which can be transformed to $\omega_s = (D_0 M_0^2/B)(\eta - 1)$, where $\eta = \langle M_{loc}^2\rangle/M_0^2$, where M_{loc} and M_0 are the local and uniform magnetizations respectively. If we now compare with SWE theory where for $T < T_c$, $\eta_{SW}(T) = (M_T/M_0)^2 = 1 - (T/T_c)^2$ (= 0, for $T > T_c$) and expand $1 - \eta(T) \approx [1 - \eta(T_c)]\,(1 - M(T)/M_0)$, we obtain that $\langle M_{loc}^2\rangle_{T_c} = (3/5)M_0^2$ and therefore the important relation $\omega_s^{SF}/\omega_s^{SWE} = 2/5$, in qualitative agreement with Table 3. Moreover, for $T > T_c$, $\omega_s^{SWE} = 0$, whereas in the SF theory $\omega_s(T) - \omega_s(T_c) = (3D_0/5\gamma)(1/\chi) > 0$ increases with temperature, as observed experimentally. When $\omega_{nm}(T) + \omega_s(T) = 0$, where ω_{nm} is the lattice TH.E., we have the *invar effect* for $T < T_c$ (see Figure 24 for the alloys $Fe_{65}(Ni_{1-x}Mn_x)_{35}$).

Table 3. Experimental values for ω_{exp} thermal expansion relative to ω_{SWE} and other related magnitudes. (From Moriya and Usami, 1980.)

	T_c(K)	M_0 (emu g^{-1})	D_0/B(emu g^{-1})$^{-2}$	$\omega_{exp}/\omega_{SWE}$
Sc_3In	7.5	≈ 3	$1- \approx 1.6 \times 10^{-6}$	$0.3- \approx 0.5$
$ZrZn_2$	18	3	5	≈ 0.6

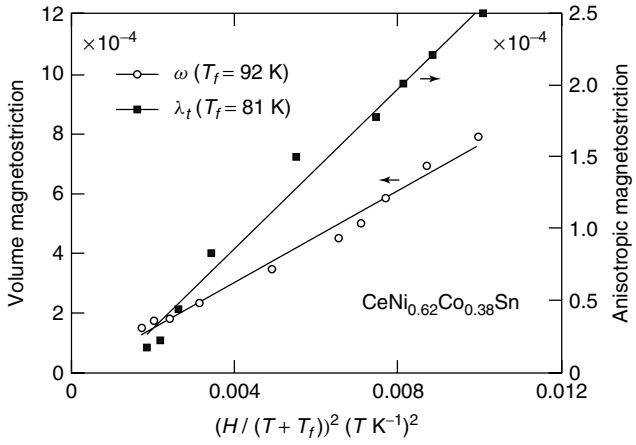

Figure 25. See text for meaning (Adroja *et al.*, 1995).

3.5 Strongly correlated systems (SCS)-MS

Several models have been proposed to explain MS in strongly correlated systems (SCS), where its main characteristic is the instability of the ion f shell, giving rise to Kondo (K), fluctuating valence (FV) and heavy fermion (HF) behaviors (see also **Heavy Fermions: Electrons at the Edge of Magnetism, Volume 1** and **The Kondo Effect, Volume 1**). Of those models we will consider the *interconfigurational* (ICF) one (Zieglowski, Häfner and Wohlleben, 1986), consisting in assuming that $4f^n$-shell valence, ν fluctuates between $4f^n \leftrightarrow 4f^{n\pm1}$ (−:Ce,Eu; +: Yb), so that with macroscopic probes the valence appears as intermediate. One of characteristics of susceptibility and MS in FV materials is that they show a broad maximum around the fluctuation temperature, T_f, and that the H-dependence is quadratic. In the case of ω, we assume the Vegard's ansatz $\Delta V/V = V^{-1}(\partial V/\partial \nu)\Delta\nu(H)$, where $\Delta\nu(H)$ is consequence of the E_F reduction for the higher moment configuration. Assuming the two configurations (separated by energy E_{exc}) with probabilities ε and $(1-\varepsilon)$, and their CEF manifold levels, it is easy to obtain the partition function, $Z_i(H) = \sum_k \exp\left[-E_{ik}(0)/k_B T^*\right]\left[\exp(-\mu_{ik}H/k_B T^*) + \exp(\mu_{ik}H/k_B T^*)\right]$, where $T^* = T + T_f$, E_{ik} are the CEF levels for i-configuration, and μ_{ik} the corresponding moments. From an expansion of $Z_i(H/T^*)$ and preceding considerations the VMS is given by

$$\frac{\Delta V}{V} \equiv \omega = \left[\pm\left(\frac{\nu_0(1-\nu_0)}{2}\right)\left(\frac{(V_{n+1}-V_n)}{V}\right)\left(\frac{\mu_z^2}{k_B^2}\right)\right] \times \frac{H^2}{(T+T_f)^2} \tag{37}$$

This kind of dependence is well manifested in Figure 25 for ω and also λ_t of $Ce(Ni_{1-x}Co_x)Sn$ intermetallics and it is also well followed at high enough field by many SCS (Häfner, 1985).

3.6 *Ab initio* MS calculation methods

First-principles calculations based on the determination of the electronic structure for the MS distorted solid provide a very accurate MEL energy obtention, and have been used

for MS calculation in TMs (Wu and Freeman, 1999; Wu, Gravilenko and Freeman, 2001; Komelj and Fähnle, 2000) and also in REMs and RE intermetallics (Buck and Fähnle 1998, 1999; Wu, 1999). They are based on the powerful nonrelativistic (i.e., without spin consideration) *density-functional approximation* (*DFA*) (Hohenberg and Kohn 1964; Kohn and Sham, 1965) and the relativistic *spin-density* (*functional*) *approximation* (*SDA*) (von Barth and Hedin, 1972), together with some added practical modifications, the *local-density approximation* (*LDA*), *local spin-density approximation* (*LSDA*), the *generalized gradient approximation* (*GGA*), the *full potential linearized augmented plane wave* (*FLAPW*) (Weinert, Wimmer and Freeman, 1982), *force theorem* (*FT*) and *state tracking* (*ST*) methods, and the very practical *torque method* (*TQ*), required to calculate MCA and MEL energies as tiny as respectively $\approx 0.1-1$ and $\approx 0.01\,\mu$eV/atom respectively in TM and alloys. Those theories take resort to **k** space, in order to introduce **k** points of low symmetry, which are also magnetostrictive, and because 'Fermi energy filling' of levels, $\varepsilon(\mathbf{k})$ can introduce some **k** states below E_F in detriment of others contributing more to MEL energy (and MCA). However, it is tried to reduce **k** points to a minimum ($\leq 10^3$), and therefore these methods are more accurate for calculating MS in standing monolayers, overlayers, and very thin multilayers (MLs) (see Section 6). Here, we can only very briefly treat all those approximations (see **Theory of Magnetocrystalline Anisotropy and Magnetoelasticity in Transition-metal Systems, Volume 1** for further details): DFA, and its local (**r** dependent) LDA, consist in writing electrons nonrelativistic Hamiltonian, H in second quantized field operator form and then $H = T + V_{CEF} + E_{EX} + U$ terms as integral *functionals*, $F\,[n(\mathbf{r})]$ of the electron density, $n(\mathbf{r})$, the system becoming an inhomogeneous *quantum liquid* of single-particles (e.g., kinetic energy $T \equiv (1/2)\int \nabla\psi^+(\mathbf{r})\nabla\psi(\mathbf{r})d\mathbf{r}$ in terms of *field* operators, ψ^+, ψ, afterwards transformed to $T[n]$). When H is the relativistic Dirac Hamiltonian, we end up with the FLAPW method, where the functionals are $F\,[n(\mathbf{r}), \mathbf{m}(\mathbf{r})]$, with $\mathbf{m}(\mathbf{r})$ being the local magnetization. In augmented plane wave APW + LSDA + FT *brute force* method, introduction of H_{SO} and H_{CEF} allows calculation of MCA and CEF-MEL energies in terms of the *total* electronic energy ($\approx 1 - 10$ eV) difference when $\mathbf{M}_s$ is rotated from ED (1) to another hard one (2), that is,

$$\Delta E_{MEL} = \sum_{i,\boldsymbol{k}}^{occ} \varepsilon_i^0(\hat{\mathbf{m}}_1, \mathbf{k}) - \sum_{i,\boldsymbol{k}}^{occ} \varepsilon_i^0(\hat{\mathbf{m}}_2, \mathbf{k}) \qquad (38)$$

or *FT* (Daalderop, Kelly and Schuurmans, 1990) (occ. means states occupied up to E_F; i is the band index; superindex 0 means without SO coupling; $\hat{\mathbf{m}}_i$, unitary vector). One must insure that for both directions large direct-Coulomb and intra-atomic-exchange energies are the same, because of the *very weak* MEL energy compared with the band one, therefore requiring the use of a large number of **k** points: $\approx 10^6$ for bulk 3d metals and $\approx 10^4$ for monolayers and overlayers. Results with this method for Ni are only qualitative, $\lambda_{100} = -245$ and $\lambda_{111} = -107$ (in 10^{-6}), about three times the values at 0 K, although results improve for fcc Co.

Calculation of MS much improves with the *tour de force* FLAPW + LSAD + GGA + ST + TQ method, which avoids the use of total energy and FT (Wu and Freeman, 1999). GGA briefly consists in expanding $E_{EX}\,[n]$ as shown in $E_{EX}[n] = \int n(\mathbf{r})\varepsilon_{xc}(n(\mathbf{r}))d\mathbf{r}$, where ε_{xc} is the exchange plus correlation, energy per electron, keeping only $n(\mathbf{r})$ and $\nabla n(\mathbf{r})$, but indeed separating out up and down spins (Perdew *et al*., 1992). But the core of the method is: (i) the mentioned ST, by which the levels filling is done keeping charge and spin densities practically constant, energy difference of equation (38) reflecting certainly the MEL (or MCA) energy; the name is because the initially FLAPW calculated basis state $|\psi_i\rangle$ can be 'tracked' when forming new basis states due to the perturbation introduced by H_{SO} and H_{mel} ('Fermi **k** filling'). The practical consequence is the *large reduction* in the number of **k** states needed ($\approx 0.5 - 1 \times 10^3$) for good energy convergence. (ii) Since MEL energy is the strain dependence of MCA energy, TQ method comes into its calculation, in terms of MCA torque $T(\theta)$. This is calculated using *Feynman–Hellman* theorem, that is, $T(\theta) = \sum_{occ}\langle\psi^{so}_{i,\boldsymbol{k}}\,|\partial H_{so}/\partial\theta|\,\psi^{so}_{i,\boldsymbol{k}}\rangle$, which again avoids calculation of total energy, since SO interaction is introduced from the beginning of the calculation. Those methods have been developed for calculation of MS and MEL constants in 3d metals, RE metals, and RE intermetallics, summarizing the results in Table 4, and comparing with experiment, from where we can realize the degrees of agreement attained, still not quite the experimental values (see **Theory of Magnetocrystalline Anisotropy and Magnetoelasticity in Transition-metal Systems, Volume 1** for further details).

4 MAGNETOELASTICITY DYNAMICS: MAGNETOACOUSTIC (MA) WAVES AND BIREFRINGENCE; ELASTIC CONSTANTS MAGNETOELASTIC CONTRIBUTION; SIMON EFFECT; ROTATIONAL INVARIANCE THEORY; FARADAY EFFECT

Another as powerful a way as MS for studying the MEL coupling and magnetoelasticity is through the ECs or elastic moduli (EM) (polycrystals), because the EWs in magnets are modified by MEL energy (*MA waves*), giving rise to a variety

Table 4. MS (in 10^{-6}, except when quoted otherwise) and MEL constants for 3d metals, RE metals, and RE intermetallics. The main step(s) in the calculation method are indicated (Wu and Freeman, 1999; Wu *et al*., 2001; Komelj and Fähnle, 2000; Buck and Fähnle, 1998, 1999; Wu 1999).

of interesting effects, all of them of the kind of *inverse MEL effects* (see del Moral, 2007). Well known are the ΔE and Δc_{ij} effects related to the DW magnetization process. Let us consider the Δc_{ij}*-effect* in cubic crystals (de Lacheisserie, Morin and Rouchy, 1978), at the end of the DW magnetization process (usually at weak H), before the intradomain $\mathbf{M}_s$ rotation toward applied $\mathbf{H}$. The MCA and MEL energies add to

$$F_m = \kappa_4\left(\alpha_1^4+\alpha_2^4+\alpha_3^4-\frac{3}{5}\right)+\overline{M}^{\gamma,2}\Big[\varepsilon_{xx}\left(\alpha_1^2-\frac{1}{3}\right) + \varepsilon_{yy}\left(\alpha_2^2-\frac{1}{3}\right)+\varepsilon_{zz}\left(\alpha_3^2-\frac{1}{3}\right)\Big] \tag{39}$$

where $\overline{M}^{\gamma,2}$ is the tetragonal MEL constant, and minimizing against $\boldsymbol{\alpha}$, if $K_1 = -2\kappa_4 + c^{\gamma}(\lambda^{\gamma,2})^2 < 0$ ($\langle 111\rangle$ EDs), the $\mathbf{M}_s$ direction under strain becomes $\alpha_i^2 = 1/3 - (\overline{M}^{\gamma,2}/2\kappa_4)(2\varepsilon_{ii}-\varepsilon_{jj}-\varepsilon_{kk})/3$, $i\neq j\neq k$ and bringing them to F_m, we obtain the *MEL contribution* to the effective elastic energy, $\Delta F_{\rm el} = -\big[(\overline{M}^{\gamma,2})^2/6\kappa_4\big]\big\{(\varepsilon_{xx}^2+\varepsilon_{yy}^2+\varepsilon_{zz}^2) - (\varepsilon_{yy}\varepsilon_{zz}+\varepsilon_{zz}\varepsilon_{xx}+\varepsilon_{xx}\varepsilon_{yy})\big\}$. Therefore the EC variations are ($\Delta c_{ij} = c_{ij}^M - c_{ij}^0$, with c_{ij}^0 the without interactions (bare) EC),

$$\Delta c_{11} = -\frac{(\overline{M}^{\gamma,2})^2}{3\kappa_4}, \quad \Delta c_{12} = \frac{(\overline{M}^{\gamma,2})^2}{6\kappa_4} \tag{40}$$

and therefore $c^{\gamma} = c_{11} - c_{12}$ *decreases* (the material softens for $\mathbf{H}\perp\mathbf{u}$, Figure 27) under magnetization, typical of the ΔE effect for low applied fields (DW displacements) in soft magnetic alloys such as Fe_xNi_{1-x} (Carr, 1966).

4.1 Simon effect

The Simon effect (Simon, 1958) is the modification of ECs during the intradomain $\mathbf{M}_s$ rotation process, manifested in the different EW velocity for $\mathbf{H}\|\boldsymbol{\varepsilon}$ and $\mathbf{H}\perp\boldsymbol{\varepsilon}$, where $\boldsymbol{\varepsilon}$ is the shear EW strain (in Voigt's notation), as seen in

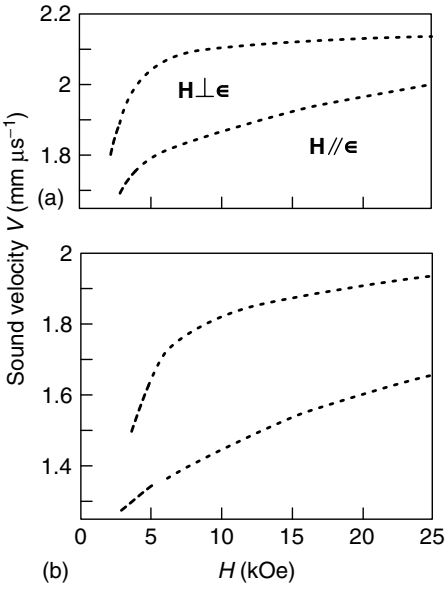

Figure 26. Magnetoacoustic birefringence in $Tb_{0.3}Dy_{0.7}Fe_2$ (a) and $Sm_{0.88}Dy_{0.12}Fe_2$ (b). The saturation sound velocity is unmodified when magnetic field $\mathbf{H}\perp\boldsymbol{\in}$ (polarization), but it is strongly reduced when $\mathbf{H}\|\boldsymbol{\in}$ (Cullen, 1978).

Figure 26 for the 'giant' (≈1%) AMS $Tb_{0.3}Dy_{0.7}Fe_2$ (Terfenol) and $Sm_{0.7}Ho_{0.3}Fe_2$ polycrystalline materials. We will first consider our FM material to be isotropic (polycrystalline or amorphous), where a shear EW ($\boldsymbol{\varepsilon} \perp \mathbf{k}$) is propagating and where $\mathbf{H}$ is set for the preceding two geometries. It is observed that when the angle $\theta = \widehat{\boldsymbol{\varepsilon}, \mathbf{H}}$ is 0 or $\pi/2$ a single wave propagates but for intermediate θ two waves with different velocities, v_T are observed, the faster ($\mathbf{H} \perp \boldsymbol{\varepsilon}$) with small $\mathbf{H}$ dispersion (except at the beginning due to the DW ΔG *effect*; G is the shear modulus), but with strong dependence for the slower ($\mathbf{H} \| \boldsymbol{\varepsilon}$), this effect being known as *MA birefringence* (Figure 26). We write $F_{\text{mel}} = \overline{\text{M}}^{\text{is}} \Sigma_{ij} \varepsilon_{ij} (m_i m_j - (1/3)\delta_{ij})$, where $\overline{\text{M}}^{\text{is}}$ is the isotropic MEL constant and $\mathbf{m} = \mathbf{M}/M_s$. If we set $\mathbf{M} \| \mathbf{H} \| \text{OZ}$, $\mathbf{k} \| \text{OY}$ and the EW displacement $\mathbf{u} \perp \mathbf{k}$, the only nonzero strains are ε_{xz} and ε_{xy}, and since $m_z \cong 1$, the other $\mathbf{m}$ components are of the same order as the strains and therefore only ε_{xz} couples to $\mathbf{M}$, so we have $F_{\text{mel}} = \overline{\text{M}}^{\text{is}} m_z m_x \varepsilon_{xz}$. Now $m_x = \chi_\perp H_x^{\text{mel}}/M_s$, where $\mathbf{H}^{\text{mel}}$ is the *MEL anisotropy field* (defined as $M_s H_x^{\text{mel}} = -\partial F_{\text{mel}}/\partial m_x = -\overline{\text{M}}^{\text{is}} m_z \varepsilon_{xz}$) and therefore we have for the total energy, $F_t = (1/2)G_0(\varepsilon_{xz}^2 + \varepsilon_{xy}^2) - (\overline{\text{M}}^{\text{is}}/M_s)^2 m_z^2 \chi_\perp \varepsilon_{xz}^2$, where G_0 is the zero-field (bare) shear modulus. Therefore the EM for the two strains ε_{xz} and ε_{xy} are different,

$$G = G_0 - (\overline{\text{M}}^{\text{is}})^2 (\chi_\perp M_s^2) m_z^2, \quad G = G_0 \tag{41}$$

respectively, a result that embodies the *Simon effect* of EM, giving rise to the waves with different velocities $v_T = \sqrt{G/\rho}$, the slower being the MA wave. Therefore $\mathbf{H}$ application breaks the isotropy of G in the isotropic medium. This result also applies to cubic crystals within the elastically isotropic {100} planes, since $\overline{\text{M}}^{\text{is}} = 2\overline{\text{M}}_2$.

Extension of the preceding theory to crystals complicates calculations, but not the physics. Then if $\mathbf{M}$ rotates under $\mathbf{H}$ application against MCA field $\mathbf{H}_K$, we have the experimental picture of Figure 27 for a Terfenol crystal, for $c^\gamma = (1/2)(c_{11} - c_{12})(\mathbf{u} \| [1\bar{1}0])$ and $c^\varepsilon = c_{44}(\mathbf{u} \| [001])$, with enormous softening of c_{44} under $\mathbf{H}$ rotation from $\perp \mathbf{u}$ to $\| \mathbf{u}$ within the elastically anisotropic [110] plane. The effect is larger for c^ε than for c^γ because $\overline{\text{M}}_2 >> \overline{\text{M}}_1$ and according to equation (8) $\overline{\text{M}}_2$ couples shear strains ε_{ij} to $\mathbf{M}$ (c_{44} mode), meanwhile $\overline{\text{M}}_1$ does it for linear ε_{ii} strains (c^γ mode). The case of c_{44} mode is the more difficult mathematically (del Moral, 2007) and therefore we will consider a shear ε_{xy}, consisting in a wave with $\mathbf{u} \| [100]$ (OX) and propagation $\mathbf{k} \| [010]$ (OY) and with $\mathbf{H} \| \text{OX}$, so that $\mathbf{M}_s$ is near to OX ($\alpha_x \cong 1$). Now we will consider first the strains as dependent variables and minimize full energy $F = F_K + F_Z + F_{\text{mel}} + F_{\text{el}}$ against ε_{ij}, obtaining the equilibrium strains, $\varepsilon_{ij}^{\text{eq}}$ (or MS) in terms of fixed $\boldsymbol{\alpha}$. In this case the free energy becomes

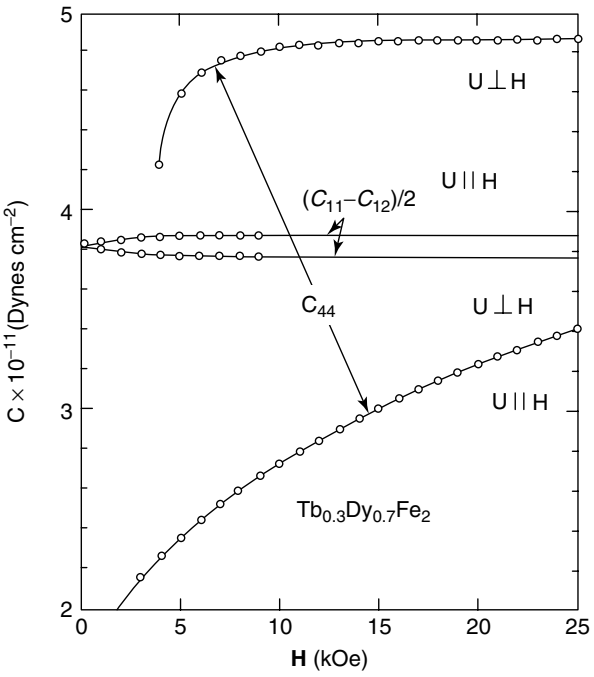

Figure 27. Magnetoacoustic birefringence in Terfenol single crystal for symmetry ECs $(1/2)(c_{11} - c_{12})$ and c_{44}, similarly to Figure 26 ($\mathbf{U} \equiv \boldsymbol{\epsilon}$) (Cullen, Rinaldi and Blessing, 1978).

$$\begin{aligned} F = {} & K_1(\alpha_x^2\alpha_y^2 + \alpha_y^2\alpha_z^2 + \alpha_z^2\alpha_x^2) - HM_s\alpha_x \\ & + \overline{\text{M}}_2\alpha_x\alpha_y \in_{xy} + \left(\frac{1}{2}\right) c_{44}^0 \in_{xy}^2 + \overline{\text{M}}_2(\alpha_y\alpha_z \in_{yz}^{\text{eq}} \\ & + \alpha_z\alpha_x \in_{zx}^{\text{eq}}) + \left(\frac{1}{2}\right) c_{44}^0((\in_{yz}^{\text{eq}})^2 + (\in_{zx}^{\text{eq}})^2) + \cdots \end{aligned} \tag{42}$$

Conversely if we set ε_{ij} as independent (externally *impressed* by a transducer) we find the equilibrium $\boldsymbol{\alpha}$, by making $(\partial F/\partial \alpha_k)_\varepsilon = 0$. From the equivalent zero anisotropy torque $\Gamma_z = M_y \partial F/\partial M_x - M_x \partial F/\partial M_y$ we obtain $\alpha_x^{\text{eq}}\alpha_y^{\text{eq}} = (-\overline{M}_2/(2K_1 + MH) \in_{xy}$, and from $\Gamma_y = 0$, $\alpha_z^{\text{eq}} = 0$. Using the constraint $\alpha_x^2 + \alpha_y^2 \cong 1$, we obtain $\alpha_x^{\text{eq}} \cong 1 - (1/2)(\alpha_y^{\text{eq}})^2 = 1 - (1/2)\left[\overline{\text{M}}_2^2/(2K_1 + MH)^2\right] \in_{xy}^2$, and substituting α^{eq} in equation (42) we obtain the equilibrium energy $F^{\text{eq}} = (1/2)(c_{44}^0 - \overline{\text{M}}_2^2/(2K_1 + MH)) \in_{xy}^2 - M_s H$. Therefore c_{44}^{eff} (the coefficient of $(1/2)\varepsilon_{xy}^2$) becomes (Clark, 1980),

$$c_{44}^{\text{eff}} = c_{44}^0 - \frac{\overline{\text{M}}_2^2}{(2K_1 + M_s H)} = c_{44}^0 - \frac{\overline{\text{M}}_2^2}{M_s(H + H_K)} \tag{43}$$

where $H_K = 2K_1/M_s$ is the [100] *anisotropy field* (in metallic materials and high-frequency ultrasound the skin effect eddy currents (within the surface [100] plane) produces a dipolar demagnetizing field, $H_D = 4\pi M_s$ which adds

to $H + H_K$). Therefore a decrease (*softening*) of c^{ε} is always expected under magnetization rotation when $\mathbf{H}\|\mathbf{u}$ with respect to the unmagnetized crystal, whereas for $\mathbf{H} \perp \mathbf{u}$, $c_{44}^{\text{eff}} \cong c_{44}^{0}$ (if DW process Δc_{44} is excluded). Also, when the effect is larger the stronger is the MS, as for example, in Terfenol where it is gigantic, of $\approx$100%. Moreover under H increase c_{44}^{eff} increases, approaching c_{44}^{0} for $H \gg H_K$, the opposite to the low field Δc_{ij} effect discussed in the preceding text. This is a way of distinguishing between the two magnetization processes, based on magnetoelasticity.

4.2 Magnetoacoustic Faraday effect

This effect consists in the polarization rotation of an ultrasound wave under **H** rotation in FM crystals, more accused in strongly magnetostrictive ones (Rinaldi and Cullen, 1978). For cubic crystals an initially polarized, $\mathbf{u}_T$ shear wave in the elastically anisotropic [110] planes splits in two waves with polarizations **u** along [100] and $[\bar{1}10]$ directions, which are the normal modes, $\mathbf{u}_I$ and $\mathbf{u}_{II}$ (Figure 28). Therefore the MEL coupling can not fully tilt $\mathbf{u}\,\|[001]$ parallel to $\mathbf{M}\|\mathbf{H}$, then the normal mode $\mathbf{u}_I$ forming an angle Φ with [001], which increases with the **H** rotation, the material becoming *magnetoacoustically active*. This angle is weak in weakly magnetostrictive materials, but it is large when MS is gigantic. We will now calculate Φ, and for that we set the EW (*Christoffel's*) (plane, $\mathbf{u} = \mathbf{u}_0 \exp i(\mathbf{k}\cdot\mathbf{r} - \omega t)$) and **M** (*Larmors's*) motion equations in the respective forms (ρ is the density),

$$-\rho\omega^2 \mathrm{u}_i = \Sigma_j \left(\frac{\partial}{\partial x_j}\right)\left(\frac{\partial F}{\partial \varepsilon_{ij}}\right) \tag{44}$$

$$\frac{\partial \mathbf{M}}{\partial t} = \gamma\left(\mathbf{M} \times \left(\frac{\partial F}{\partial \mathbf{M}}\right)\right) \tag{45}$$

which are coupled via the MEL coupling (*MA wave equations*). For $\mathbf{k}\|[110]$ and for sufficiently low frequencies such that $\dot{\mathbf{M}} \cong 0$, the coupled equations are,

$$\rho\omega^2 u_t = k^2 u_t \left(\frac{(c_{11} - c_{12})}{2} - \left(\frac{\overline{\mathrm{M}}_1^2 M_x^2}{M_s^3 H}\right)\right) - k^2 u_z \overline{\mathrm{M}}_1 \overline{\mathrm{M}}_2 \left(\frac{M_x M_z}{M_s^3 H}\right) \tag{46}$$

$$\rho\omega^2 u_z = k^2 u_z \left(c_{44} - \left(\frac{\overline{\mathrm{M}}_2^2 M_z^2}{M_s^3 H}\right)\right) - k^2 u_t \overline{\mathrm{M}}_1 \overline{\mathrm{M}}_2 \left(\frac{M_x M_z}{M_s^3 H}\right) \tag{47}$$

where $u_t \equiv u_x - u_y$ and $H = H_{\text{app}} + H_K + 4\pi M_s$. We notice that the equations coupling is *via* $\overline{M}_1\overline{M}_2$. Setting now $u_t = u_0 \sin\Phi$, $u_z = u_0 \cos\Phi$ and $M_z/M_s = \sin\theta$, we obtain from equations (46 and 47) a linear system of equations in $(\sin\Phi, \cos\Phi)$, whose secular determinant yields $(\omega/k)^2$, and therefore the phase velocities ($v = \omega/k$), $\rho v_{\pm}^2 = \frac{1}{2}(C' + C) \pm \left\{\left[\frac{1}{2}(C' - C)\right]^2 + B^2\right\}^{1/2}$, where C and C' are constants related to the problem parameters, depending on field as $1/H$, B being the coupling constant. We also obtain the polarization angles of rotation for the two normal modes,

$$\tan\Phi_{\pm} = -B\left\{\frac{1}{2}(C - C') \pm \left[\frac{1}{2}(C' - C)^2 + B^2\right]^{1/2}\right\}^{-1} \tag{48}$$

which embodies the *MA Faraday effect*. $B \equiv \overline{\mathrm{M}}_1\overline{\mathrm{M}}_2(\sin 2\theta / 2HM_s)$, where θ is the angle (**M**, [001]), introducing a NL dependence. In Figure 29 is shown the calculated Φ_- versus θ for Terfenol. Another prediction is the interference between the two normal modes, when projected into the reception transducer axis, $\hat{\mathbf{u}}_R$, the maximum occurring for an angle $\theta_R(H)$, which decreases with H, as observed.

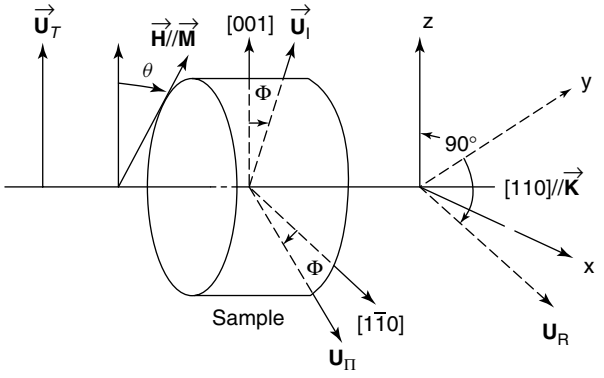

Figure 28. Magnetoacoustic Faraday rotation geometry (Rinaldi and Cullen, 1978).

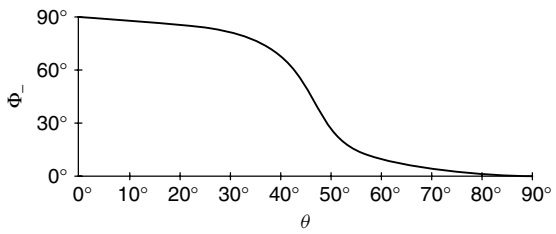

Figure 29. Magnetoacoustic Faraday rotation angle, Φ_- versus **H** rotation angle, θ (Rinaldi and Cullen, 1978).

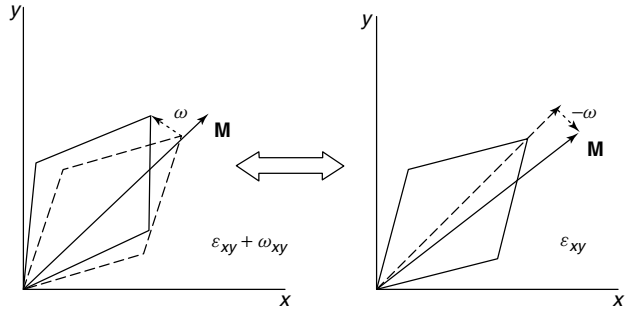

Figure 30. Rotational invariance principle of magnetoelasticity (del Moral, 2007).

4.3 General magnetoelasticity dynamics; rotational invariance

A general theory of magnetoelasticity dynamics has been developed, which includes as a central part the quantum-mechanical *rotational invariance* principle (Brown, 1965; Melcher, 1972; Dohm and Fulde, 1975; Wang and Lüthi, 1977), based on the invariance of angular momentum under spatial rotation. In the most general form the theorem is expressed in terms of *finite* strains (or Lagrangian, η_{ij} if the strains are small) and states that the MEL Hamiltonian for a magnetized crystal under pure strains, $\overleftrightarrow{\mathcal{E}}$ and rotational ones, $\overleftrightarrow{\mathcal{R}}$ is the same if the crystal is only $\overleftrightarrow{\mathcal{E}}$ strained and the AM **J** and applied **H** are rotated back by $\mathcal{R}^{-1}(=\mathcal{R}^t)$ ($\overleftrightarrow{\mathcal{E}}$ is rotationally invariant) (see Figure 30). Therefore we write

$$\hat{H}\left(J_i, H_i, \frac{\partial x_i}{\partial X_j}\right) = H(J_k^*, H_k^*, \mathcal{E}_{kl}) \tag{49}$$

where

$$\begin{aligned} J_k^* &= J_i \mathcal{R}_{ik}, \quad H_k^* = H_i \mathcal{R}_{ik}, \\ \mathcal{E}_{kl} &= \left(\frac{1}{2}\right)\left[\left(\frac{\partial x_i}{\partial X_k}\right)\left(\frac{\partial x_i}{\partial X_l}\right) - \delta_{kl}\right] \end{aligned} \tag{50}$$

where $\partial x_i/\partial X_j$ in $\hat{H}$ mean pure strains. If the RSs, $\boldsymbol{\omega}(\omega_{yz}, \omega_{zx}, \omega_{xy})$ are small this theorem adopts this other more manageable form, which also allows the derivation of the rotational part of Hamiltonian, $H_{\rm rot}$ and where $\hat{H}_{\rm Spin} = \hat{H}_{\rm CEF} + \hat{H}_{\rm strain}$,

$$\begin{aligned} &\exp[-i\hbar^{-1}\boldsymbol{\omega}\cdot\mathbf{J}]\hat{H}_{\rm Spin}(\mathbf{J})\exp[i\hbar^{-1}\boldsymbol{\omega}\cdot\mathbf{J}] \\ &\quad = H_{\rm CEF}(\mathbf{J}) + H_{\rm strain}(\mathbf{J}) + H_{\rm rotation}(\mathbf{J}) \end{aligned} \tag{51}$$

There are some dramatic consequences of this theorem, the most spectacular one is the inequivalence of the EWs shown in Figure 2 when the crystal is magnetized for example,

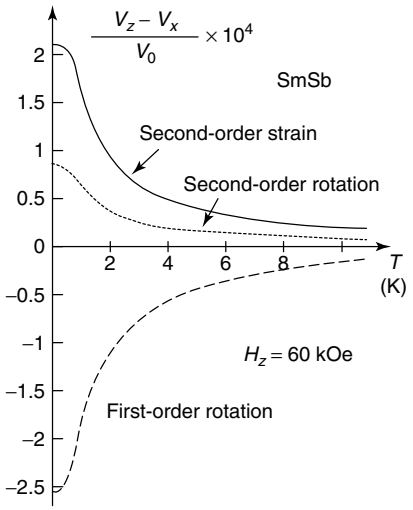

Figure 31. Magnetoacoustic birefringence contributions (Dohm, 1976).

along OZ‖[001] in a cubic crystal, which constitutes in fact the birefringence at *PM regime* (however, it remains at FM regime if $H_{\rm EX}$ is expressed in the MFA). This result has been applied to hcp RE metals, cubic RE intermetallics and to the archetypal RE vanadates ($REVO_4$) (see del Moral, 2007). Let us study in detail the case of cubic (CsCl structure) pnictides RESb, which show a rich variety of magnetic and QP structures, and magnetostructural transitions. From transformation of equation (51) we immediately obtain, after $e^{\pm i\omega_{zx}J_y}$ expansion, $H_{\rm rotation}(c_{44}) = -20B_4\omega_{xz}\Lambda_{xz} + 40B_4\omega_{xz}^2\lambda_{xz} + 2G_3\varepsilon_{xz}\omega_{xz}(J_x^2 - J_z^2)$, where $\Lambda_{zx} = i[H_{\rm CEF}, J_y]$, $\lambda_{zx} = (i/2)[\Lambda_{zx}, J_y]$, plus a 2nd-order term in the strains $H_{\rm str}^{(2)}(c_{44})$ if finite pure strains $\mathcal{E}_{xx}, \mathcal{E}_{zz}$ are considered (see Figure 31). Calculating the full H energy levels, the free energy and using the EC expression variations $\Delta c_{ij}(T, \mathbf{H}) = (\partial^2 F/\partial u_{ij}^2)_T$ we obtain velocity shifts, $\Delta v_{xz}/v_0$ and $\Delta v_{zx}/v_0$, different for the two modes (k_z, u_x) and (k_x, u_z), and respectively

$$\begin{aligned} \Delta v_{\substack{zx \\ xz}}/v_0 = \left(\frac{N}{2\rho v_0^2}\right)\Big\{\left(\frac{1}{4}\right)\chi\{G_3(J_xJ_z + J_zJ_x) \\ \mp 20B_4\Lambda_{xz}\} + 20B_4\langle\lambda_{xz}\rangle + G_3\langle J_x^2 - J_z^2\rangle\Big\} \end{aligned} \tag{52}$$

where $G_3 \equiv -M^{\varepsilon,2}/2$. $\chi\{\ldots\}$ is the *dynamical strain* susceptibility, appearing also in the PS calculation, and calculated using the thermodynamic Green function technique (del Moral, 2007). This susceptibility is defined as $\chi_2^{\varepsilon} = (1/M^{\varepsilon,2})(\partial\langle\tilde{O}_2^0\rangle_{\rm T}/\partial\varepsilon_{xz})$, taking into account the strain dependence of the RE^{3+} QP moment, $\langle\tilde{O}_2^0\rangle$, and for a doublet GS (of splitting Δ), $\chi\{\hat{O}_2^1, \omega\} = -(160/3)p(T)(\Delta/(\Delta^2 - \omega^2))$,

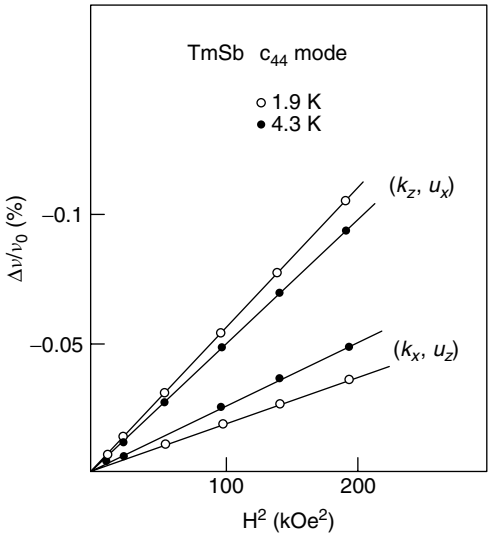

Figure 32. RI breaking of cubic degeneration in TmSb (Wang and Lüthi, 1977).

where $p(T)$ is the high level atom population. In Figure 31 the calculated thermal variations of the different contributions to the velocity birefringence in cubic SmSb (1^{st}-order strain contribution does not appear in birefringence) are shown. In Figure 32 the T and H^2 dependencies of the velocity shifts for TmSb, split by the field, which breaks the cubic axes degeneration are shown. Therefore the birefringence has a quantum-mechanical origin.

5 MAGNETOSTRICTION OF MAGNETICALLY DISORDERED MAGNETS: RANDOM MAGNETIC ANISOTROPY (RMA) AND AMORPHOUS MATERIALS

Disordered magnets, with structural (amorphous) and/or spin disorder (spin glasses and random magnetic anisotropy (RMA) ones) show peculiar characteristics in their MS behaviors and pose difficult problems to MS calculation.

5.1 RMA magnets MS

In the case of RMA (del Moral and Arnaudas, 1989) hard magnets, the local CEF easy axis, $\hat{\mathbf{a}}(\mathbf{r})$ changes randomly through the lattice and the exchange and CEF Hamiltonian has the form $H_{\mathrm{EX+CEF}} = -J_0 \Sigma_{(\mathbf{r},r)} \mathbf{S}(\mathbf{r}) \cdot \mathbf{S}(\mathbf{r}') - D_0 \Sigma_{\mathbf{r}} [\hat{\mathbf{a}}(\mathbf{r}) \cdot \mathbf{S}(\mathbf{r})]^2$. An order parameter, q (of *Edwards–Anderson*) is defined at each site i which takes into account the time autocorrelation instead of the nonexistent spatial one, of the form $q = \lim_{t\to\infty} \langle \langle S_i(0) S_i(t) \rangle_T \rangle_r$, where the average r is over the structural disorder. From the use of statistical mechanics *replica technique* it can be shown that

$$p = \int_{-\infty}^{\infty} \left(\frac{dx}{\sqrt{2\pi}} \right) e^{-x^2/2} \langle S_z^2 \rangle, \; q = p - \left(\frac{1}{\gamma} \right) \times \int_{-\infty}^{\infty} \left(\frac{\mathrm{d}x}{\sqrt{2\pi}} \right) x \mathrm{e}^{-x^2/2} \langle S_z \rangle$$
$$M = \int_{-\infty}^{\infty} \left(\frac{\mathrm{d}x}{\sqrt{2\pi}} \right) \mathrm{e}^{-x^2/2} \langle S_z \rangle \tag{53}$$

where $\gamma = (2/5)^{1/2} \beta \sqrt{q} D_0$, and therefore q, p (QP moment) and M must be solved self-consistently. The effect now of the MEL coupling of probe ion $\mathbf{S}$ to its local CEF is assumed to rearrange the local environment, modifying D_0, but keeping fixed $\hat{\mathbf{a}}(\mathbf{r})$ as in crystalline FMs. If the local strain projected along $\hat{\mathbf{a}}(\mathbf{r})$ is $\varepsilon_{\hat{\mathbf{a}}\hat{\mathbf{a}}}$, the simplest MEL Hamiltonian takes the form, $H_{\mathrm{me}} = -M_2 \Sigma_{\mathrm{r}} [\hat{\mathbf{a}}(\mathbf{r}) \cdot \mathbf{S}(\mathbf{r})]^2 \varepsilon_{\hat{\mathbf{a}}\hat{\mathbf{a}}}(\mathbf{r})$, where the MEL parameter is $M_2 = (\partial D_0 / \partial \varepsilon_{\hat{\mathbf{a}}\hat{\mathbf{a}}})$. Under field application $\mathbf{H} \| \mathrm{OZ}$, where OZ is the macroscopic MS strain, ε_{zz} measurement axis and $\varepsilon_{\hat{\mathbf{a}}\hat{\mathbf{a}}} = \varepsilon_{zz} \cos^2 \theta(\mathbf{r})$, where $\theta(\mathbf{r})$ is the angle formed by $\mathbf{S}(\mathbf{r})$ with OZ. Using the 'replica trick' where the free energy is given by $F = -(k_{\mathrm{B}} T) \lim_{n\to 0} (1/n) (T r_n \mathrm{e}^{-\beta H_{\mathrm{mel}}} - 1)$, where we assume an n-times replicated spin system for taking the trace, it is possible to show from preceding H_{mel} that the effective MEL Hamiltonian takes the form,

$$\tilde{H}_{\mathrm{me}} = -\left(\frac{3M_2}{5} \right) \varepsilon_{zz} \Sigma_{\mathrm{r}} \Sigma_{\alpha} [S_z^{\alpha}(\mathbf{r})]^2 - \left(\frac{2 D_0 M_2}{105} \right) \varepsilon_{zz} \times \Sigma_{\mathbf{r}} \Sigma_{\alpha,\beta} \Sigma_{i,j} S_i^{\alpha}(\mathbf{r}) S_j^{\alpha}(\mathbf{r}) S_i^{\beta}(\mathbf{r}) S_j^{\beta}(\mathbf{r}) \tag{54}$$

The replica trick free energy is too long to be presented here, but from the minimization $\partial (F_{\mathrm{mel}} + \frac{1}{10} N c_{\mathrm{el}} \varepsilon_{zz}^2) / \partial \varepsilon_{zz} = 0$ it is finally obtained that the macroscopic shape MS (Figure 33) becomes,

$$\lambda_t = \left(\frac{M_2}{3 c_{\mathrm{e}}} \right) \left[p - \frac{S(S+1)}{3} \right] = \left(\frac{M_2}{c_{\mathrm{e}}} \right) \int_{-\infty}^{\infty} \left(\frac{\mathrm{d}x}{\sqrt{2\pi}} \right) \mathrm{e}^{-x^2/2} \langle \tilde{\mathrm{O}}_2^{\mathrm{o}} \rangle \tag{55}$$

which takes the usual form for ordered FMs but on top of the thermal average we have to perform the average over the spin disorder (integral). This theory has been applied to a series of RE metallic glasses such as a-$\mathrm{RE}_{40}\mathrm{Y}_{23}\mathrm{Cu}_{37}$, a-$\mathrm{Tb}_2\mathrm{Fe}_{1-x}\mathrm{Ni}_x$ and a-$(\mathrm{Gd}_{1-x}\mathrm{Tb}_x)_2\mathrm{Cu}$ and crystalline $\mathrm{Tb}_x\mathrm{Y}_{1-x}\mathrm{Al}_2$, where in the latter Y substitutions produces the RMA (del Moral, 2007). In Figure 34 the MS thermal variation for RE = Dy (with $T_{\mathrm{SG}} = 23$ K, $D_0 = 1.25$ K, $J_0 = 0.66$ K), together with

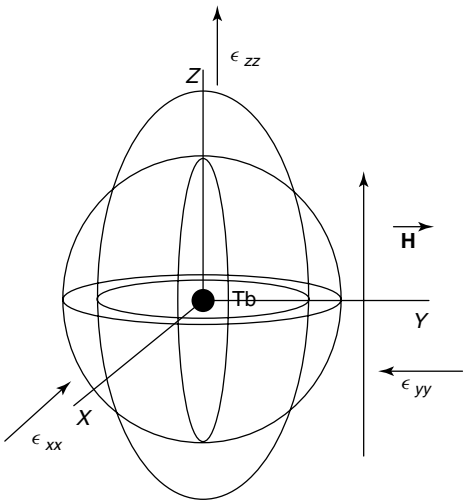

Figure 33. Tetragonal distortion of spherical symmetry in amorphous material (de la Fuente, unpublished).

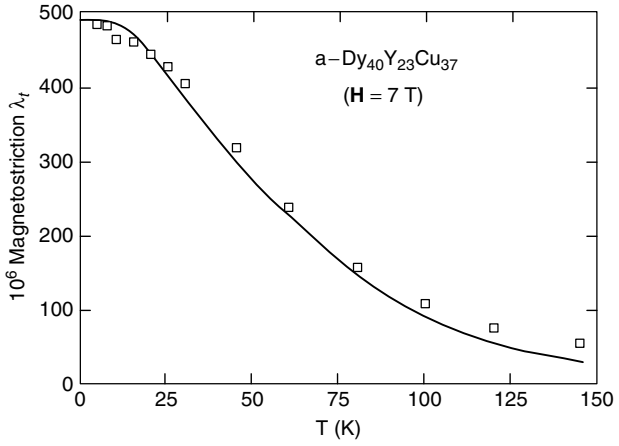

Figure 34. Shape MS thermal variation for a-$Dy_{40}Y_{23}Cu_{37}$; line is the replica model fit (del Moral and Arnaudas, 1989).

the good fit by equation (55), which yields $M_2/c_{\rm el} = 9.2 \times 10^{-6}$, is shown.

5.2 Breaking of AZC law in RMA magnets

We will consider for RMA magnets (del Moral, de la Fuente and Arnaudas, 1996), the ferromagnetic wandering axis regime, where long-range FM order is formed along applied **H**, but the transverse order is limited to a length $R_\perp = (\mathrm{H_{EX}}/\mathrm{H})R_\mathrm{a}$, where R_a is the structural correlation length (SCL) (Chudnovsky, Saslow and Serota, 1986). Therefore we will assume that the system $\mathbf{M}\|\mathbf{H}$ is almost saturated and therefore spin-wave excitations are proper. Instead of only using dynamic magnon operators (α_l, α_l^+ at site $\boldsymbol{l}$), to diagonalize H we will use the transformations (del Moral and Cullen, 1995) $a_l = (1+u_l)\alpha_l + v_l\alpha_l^+ + c_l$ and c.c., c_l, c_l^+ being the disorder spin deviations ('frozen'-in SWs) and u_l, v_l Fourier transforms of the magnon scattering matrices due to RMA disorder. Now we use the same calculation as for FMs, but we have $M(0,H)/gJ\mu_\mathrm{B} = 1 - J^{-1}\{\langle c_l^+ c_l\rangle_r + \langle v_l^+ v_l\rangle_r\}$ and $\langle\langle Y_2^0(\boldsymbol{J})\rangle_\mathrm{T}\rangle_\mathrm{r} = 3J^2 - J(J+1) - 3(2J-1)\langle\langle a_l^+ a_l\rangle_\mathrm{T}\rangle_\mathrm{r} + 3\langle\langle a_l^+ a_l^+ a_l a_l\rangle_\mathrm{T}\rangle_\mathrm{r}$, obtained from the preceding transformations, and from where we have after some easy calculations that order $l = 2$ MS becomes,

$$\frac{\lambda_2(T,H)}{\lambda_2(0,H)} = 1 - 3\xi(1 - m(T,H)) \cong m(T,H)^p \qquad (56)$$

where $p = 3\xi = 3[J(2J-1) - 6J\delta + \delta(1+4\delta)]/[J(2J-1) - 6J\delta + 3\delta(1+2\delta)]$, with $\delta = J\Delta m(0,H)$, and $\Delta m(0,H)$ the *zero-point* magnetization defect, due to the static disorder. Therefore p exponent becomes smaller than 3, which constitutes a *quantum effect*. In Figure 35 we show the double-log plots of $\lambda_2(T)$ versus $M(T)$ at $H = 3\mathrm{T}$ for $\mathrm{Tb}_x\mathrm{Y}_{1-x}\mathrm{Al}_2$ intermetallics, from the straight line slopes obtaining p, which becomes much smaller than 3 (see inset), in agreement with the model. Also p increases toward 3 with H increasing (12 T), as expected.

5.3 Soft metallics glasses MS models

Soft (low MCA) magnetic glasses are rather important materials for technological applications, as seen in other chapters of this Handbook (e.g. in **Magnetostrictive Materials and Magnetic Shape Memory Materials, Volume 4**). For some alloys $\lambda_\mathrm{s}(T)$ shows the same single-ion CEF $\hat{\mathrm{I}}_{l+1/2}(m)$ dependence of crystalline FMs with *localized* moments. The reason is that, although they are RMA materials, the magnetic correlation length (MCL), $L \cong 0.02(l_{ex}^4/l^3)$ (where $l_\mathrm{ex} = \pi\sqrt{A/D_0}$ is the DW width (A is exchange stiffness

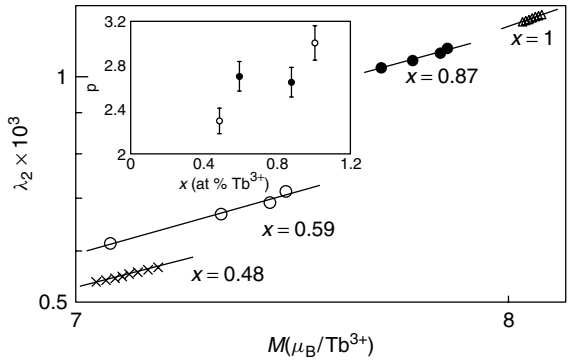

Figure 35. Magnetostriction of $\mathrm{Tb_x\ Y_{1-x}\ Al_2}$ interuetallic vs. magnetization; see text (del Moral, de la Fuente and Arnaudas, 1996).

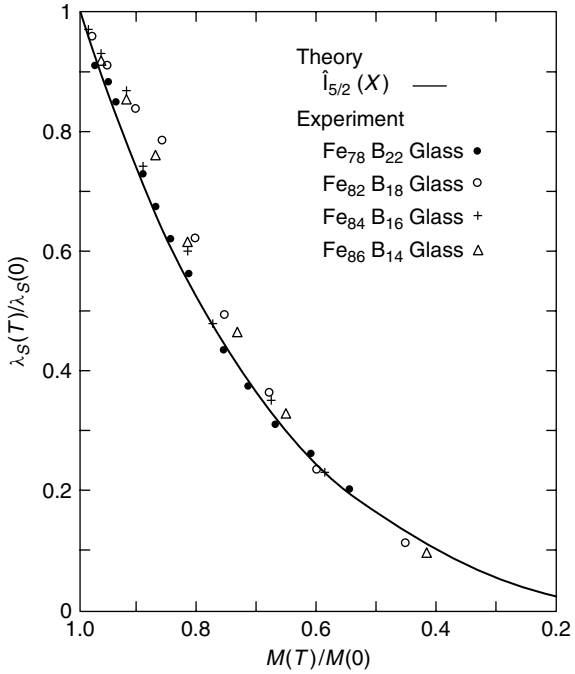

Figure 36. Shape MS thermal variation for a-$Fe_{100-x}B_x$ (O'Handley, Narasimham and Sullivan, 1979).

constant) and l the short range SCL) is so large that the material is quasi-FM. This is the case of the a-$Fe_{1-x}B_x$ alloys shown in Figure 36. However for other more complex alloys $\lambda_s(T)$ shows broad maxima or even changes the sign (see Figure 37). In this case two models can explain such a behavior. In the first one (O'Handley, 1978a) a competition in sign is assumed between the CEF and two-ion MSs, in such a way that

$$\lambda_s(T) = \left(\frac{\overline{M}^s(0)}{c^\gamma}\right)\hat{I}_{5/2}(X) + \left(\frac{\overline{D}^s(0)}{c^\gamma}\right)m^2 \equiv C_1\hat{I}_{5/2}(X) + C_2m^2 \qquad (57)$$

Since the CEF-MS evolves more rapidly ($\propto m^3$) with temperature than the exchange one, this is predominant near T_c, and if $C_1 < 0 < C_2$ and $|C_1| > |C_2|$ a sign variation of λ_s is possible, as it happens for the alloys shown in Figure 37, where the lines are the fits by equation (57). But another explanation is found within the itinerant moment BD-BZS model studied in Section 3, now assuming that we have a RMA, that also explains the broad maxima shown by $\lambda_s(T)$ (see Figure 38 for a pseudobinary alloy, where the continuous line is the theory). In the calculation the random CEF is represented by a random matrix, $R_{\mu\nu}(c)$, where c points to the CEF energy variation with the local atom cluster tetragonal deformation, ε_2^α (e.g., a Bernal polyhedron tetragonally deformed along OZ), and $H_{\text{CEF+mel}} = \Sigma_{i,\mu,\nu,\sigma}R_{\mu\nu}(c)a^+_{i\mu\sigma}a_{i\nu\sigma} + M^{\alpha,2}\varepsilon_2^\alpha[3\delta_{\mu,xy} - 1]$, where i are sites, μ, ν orbitals (t_{2g} with a magnetostrictive doublet $\{xz, yz\}$ near to E_F and the preceding xy singlet or conversely) and $\sigma = \pm 1/2$ is the spin, H_{CEF} giving the d-electron scattering by the disorder. The remainder Hamiltonian is the same as for a crystalline material (del Moral *et al.*, 1998a).

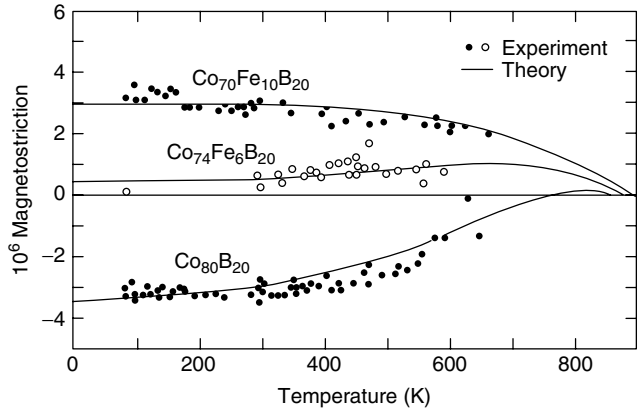

Figure 37. Shape MS thermal variation for a-$(Co_{1-y}Fe_y)_{80}B_{20}$ (O'Handley, 1978a).

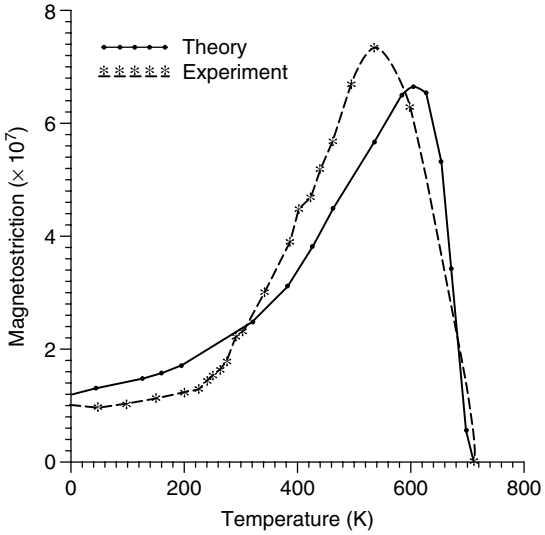

Figure 38. Shape MS thermal variation for a-$Fe_5Co_{71}Si_{12}B_{12}$, experiment and itinerant theory (Kulakowski, Maksymowicz and Magdón, 1993).

5.4 Zero-λ_s alloys; split-band model

Some alloys of technological use, crystalline, and amorphous, show zero λ_s for certain compositions. Generally within the 3d metals and alloys λ_s *oscillates* with band electron filling, n a property well explained using the simplified

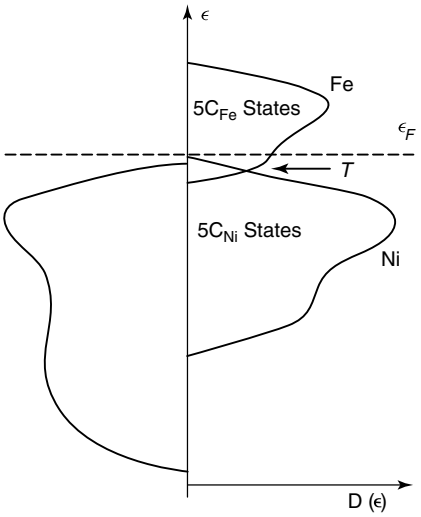

Figure 39. Split bands for binary $Fe_{1-x}Ni_x$ alloys (Berger, 1977).

Berger's *split-band model* (SBM, Berger, 1977) (a Green function theory of itinerant MS does the same, Heine, Kox and Nex, 1984), quite suitable for alloys where a TBA or *AI* MS calculation is difficult. In the SBM one assumes that the bands DOS and their centers, E_p for the alloy partners (e.g., crystalline (c-)Fe_xNi_{1-x} or a $-$ $(Fe_xNi_{1-x})_{80}B_{20}$) do not modify on alloying, the alloy DOS being just the addition of partner DOS (see Figure 39 for c-Fe_xNi_{1-x}, where $E_{Fe} > E_{Ni}$, because the Fe nuclear charge is smaller than Ni one; on the left is the added DOS for down spins ($\downarrow$), on the right the spin up ($\uparrow$) individual bands). Let us assume the existence of a DOSs crossing point T and see at which x E_F traverses T, where $\lambda_s = 0$, as the hole number, n_h in the $\downarrow$ band is zero (strong-FM). In c-Fe_xNi_{1-x}, clearly $n_h = 0.55 + 2C_{Fe}$ in the alloy ($C \equiv x$). Because the Fe state number in the minority band (mB, $\downarrow$) is $5C_{Fe}$, crossing occurs when $n_h = 5C_{Fe}$, that is, when the Ni band holes are filled by the Fe-band electrons, giving $x_0 = 0.18$, or concentration for zero-MS. In this case the total orbital momentum (OM), $\langle L_z\rangle_{alloy} = \Sigma_b \langle b|L_z|b\rangle$ must be zero at E_F (b are band states), since $\lambda_s \propto \langle L_z(E_F)\rangle_{alloy}$. A second-order perturbation calculation upon H_{SO} yields

$$\langle L_z^t\rangle = \sum \langle L_z\rangle = \left(\frac{1}{n_{at}}\right) \Sigma_{i,j,m,n} f_m^i \times \left(\frac{\xi\left(\frac{1}{2}\right) |\langle L_z\rangle_{mn}^{ij}|^2}{(E_m^i - E_n^j)}\right) \tag{58}$$

where $i(j)$ are Fe and Ni bands, $m(n)$ unperturbed $\downarrow$ Bloch states of energy E_m^i, f_m^i the Fermi–Dirac function, $\langle L_z\rangle_{mn}^{ij} = \langle mi|L_z|nj\rangle$ and n_{at} the atom number. Passing equation (58) to continuous DOS, the calculated $\langle L_z\rangle_{alloy}$ is shown in Figure 40, where α_{NiFe} is the $\langle \mathbf{L}\rangle$ quenching parameter and z

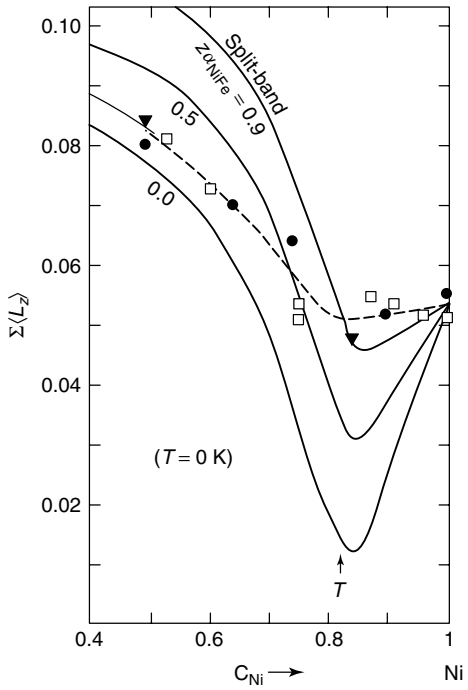

Figure 40. $Fe_{1-x}Ni_x$ alloys, see text for meaning (points are from different probes) (Berger, 1977).

the NN number. We see that $\langle L_z\rangle_{alloy}$ is minimum at T point or for $x_0 = 0.18$, as experimentally observed from different probes. For a $-$ $(Fe_xNi_{1-x})_{80}B_{20}$ alloys, the $\lambda_s = 0$ condition is $5C_{Fe} = 2.55C_{Fe} + 0.55_{Ni} - 1.6C_B$ with $C_{Fe} + C_{Ni} = 0.8$, $C_B = 0.2$, since there is a charge transfer of 1.6 e/B-atom to the TM bands, yielding $x_0 = 0.06$, that is, a strong shifting down. For a-$(Fe_xCo_yNi_{1-x\cdot y})_{80}B_{20}$ pseudoternary alloys the $\lambda_s = 0$ 'point' transform in a $\lambda_s = 0$ 'line' when we trace a triangular MS phase diagram (O'Handley, 1978b) (see **Magnetostrictive Materials and Magnetic Shape Memory Materials, Volume 4**).

6 SURFACE, INTERFACE, AND MAGNETIC THIN FILMS AND SUPERLATTICES MAGNETOSTRICTIONS

Nanostructured materials in the form of TFs, MLs, and SLs encounter increasing technological applications (see **Hard Magnetic Films, Volume 4**, **Ferromagnetic Manganite Films, Volume 5**). However the knowledge of MS in those structures is also important because the reduction to $2d$ (ultrathin films; see **Magnetic Ultrathin Films, Volume 4**) and because the existence of highly perfectioned surfaces (SF) and IFs reveal magnetic properties different

to the bulk. For instance depending on (l, m, n) indices, SF crystal symmetry is reduced (see Figure 41 for bulk fcc lattice) and therefore $H_{\rm CEF}$ becomes modified; in SFs moment is enhanced (to 0.73 and 2.98 $\mu_{\rm B}$ in [100] Ni and Fe SFs respectively); and MCA anisotropy can become perpendicular to SF. In ML or SL the mismatch, $\eta = (a_{\rm m} - a_{\rm nm})/a_{\rm nm}$ between blocks (magnetic and nonmagnetic) lattice parameters gives rise to a *misfit strain*, which for epitaxial growth is $\varepsilon_{\rm mf} \cong \eta(t_{\rm nm}/(t_{\rm m} + t_{\rm nm}))$, although it can be partially released by IF dislocations. Let us first consider the *surface MEL coupling*, where the MCA and MEL free energy is written as $F_{\rm mel}(z) = K^s_{ij}\delta(z)\alpha_i\alpha_j + \overline{\rm M}^{*s}_{ij}\,\delta(z)\alpha_i\alpha_j\varepsilon_{ij}$, where z is the distance from the SF ($z = 0$) and $\overline{\rm M}^*_{ij} = \overline{\rm M}_{ij} + \overline{\rm N}_{ijkl}\varepsilon_{kl}$, introducing NL-MEL coupling due to the large $\varepsilon_{\rm mf}$ (O'Handley and Sun, 1992). Adding the bulk MCA and averaging $F(z)$ over the crystal thickness, t we obtain

$$\langle F\rangle = \left(\frac{1}{t}\right)\int_0^t F(z){\rm d}z = K_{ij}\alpha_i\alpha_j + \left(\frac{K^s_{ij}}{t}\right)\alpha^0_i\alpha^0_j + \overline{\rm M}^*_{ij}\alpha_i\alpha_j\varepsilon_{ij} + \left(\frac{\overline{\rm M}^{*s}_{ij}}{t}\right)\alpha^0_i\alpha^0_j\varepsilon^{s,0}_{ij} \qquad (59)$$

where we see that the SF MCA and MEL constants show a $1/t$ dependence (consequence of converting them to bulk like constants, Néel's assumption). $\boldsymbol{\alpha}^0$ is the unstrained film $\mathbf{M}_{\rm s}$ direction at the SF and $\varepsilon^{s,0}_{ij}$ the SF strains (misfit and MS). Therefore for a crystal block in a ML or SL (two SFs), the MEL constant becomes, $\overline{\rm M}^{\rm eff} = \overline{\rm M}^{v} + 2\overline{\rm M}^{*s}/t$. This Dirac δ(z) approximation is not very realistic as the 'surface' monolayers (ML) extend beyond $z = 0$. For thin blocks and $\varepsilon_{\rm mf} \approx 1\%$ ($\varepsilon_{\rm mf} >> \lambda_{\rm s}$ for 3d metals, but becomes comparable for RE materials), SF-MS can be comparable to bulk (v) one, for example in Ni/Ag MLs, $\lambda^{\rm v}_{\rm s} = -34$ and $\lambda^{\rm sf}_{\rm s} = -35.4/t(\times 10^{-6}$, t in nm) (Zuberek *et al.*, 1998). SF MEL constants can be directly measured using the SESPA technique.

If we now introduce crystal symmetry, the rules for building the MEL Hamiltonian, $H^{\rm sf}_{\rm mel}$ are the same as for the bulk crystal seen in the STM, but reducing the symmetry accordingly with the SF (l, m, n) indices, and the same applies to $F^{\rm sf}_{\rm mel}$. Therefore the MEL constants for a [110] SF (ORTH) of a BCC film have the form $\overline{\rm M}^{\Gamma,l}_{\rm f} = \overline{\rm M}^{\Gamma,l}_{\rm v} + (2/t)\overline{\rm M}^{\Gamma,l}_{\rm s}$, where there are for $l = 2$, three bulk MEL constants ($\Gamma = \alpha, \gamma, \varepsilon$), but four for the SF ($\Gamma = \alpha 1, \alpha 2, \varepsilon, \varsigma$). We will now apply this MEL theory to 3d-metal films and RE SLs.

6.1 Cu/Ni/Cu trilayers

In this structure we have a substrate onto which the magnetic Ni film is deposited, and it is capped with another Cu film to avoid corrosion. The misfit strain in the Ni TF is biaxial, that is, $\varepsilon_{xx} = \varepsilon_{yy} = \varepsilon_{\rm mf}$ in plane and if stress $\sigma_{zz} = 0$, $\varepsilon_{zz} = \nu\varepsilon_{\rm mf}$ with $\nu = -2(c_{11}/c_{12})$, or Poisson ratio (Figure 42). Therefore the misfit MEL energy easily becomes,

$$F^{\rm t}_{\rm me} \cong -(\overline{\rm M}_{11} + \overline{\rm M}_{12} + \overline{\rm M}_{13})\varepsilon_{\rm mf}\cos^2\theta \qquad (60)$$

which adds to the MCA energy $F_{\rm K} = K_1\cos^2\theta$, where θ is the angle of $\mathbf{M}_{\rm s}$ with the film normal OZ. Therefore the effective MA constant takes the form,

$$K^{\rm eff}t = 2(K^{\rm s} + \overline{\rm M}^{\rm s}\varepsilon_{\rm mf} + \overline{\rm N}^{\rm s}\varepsilon^2_{\rm mf}) + \left(\overline{\rm M}^{\rm v}_1\left(\frac{1 + 2c_{11}}{c_{12}}\right) + \overline{\rm N}^{\rm v}\varepsilon_{\rm mf}\right)\varepsilon_{\rm mf}t - 2\pi M^2_{\rm s}t \qquad (61)$$

where NL-MEL energy is included, for volume (v) and SFs (s) (Ni/Cu IFs), as well as the demagnetizing energy (last term) trying to keep $\mathbf{M}_{\rm s}$ in plane. In Figure 43 are shown $K^{\rm eff}t$ for three trilayers prepared under different conditions, where we see that in the range $t \cong 20$–135 Å, the ED is perpendicular to plane (PMA) ('window' effect), a property quite used in magnetic recording to reduce the domain size.

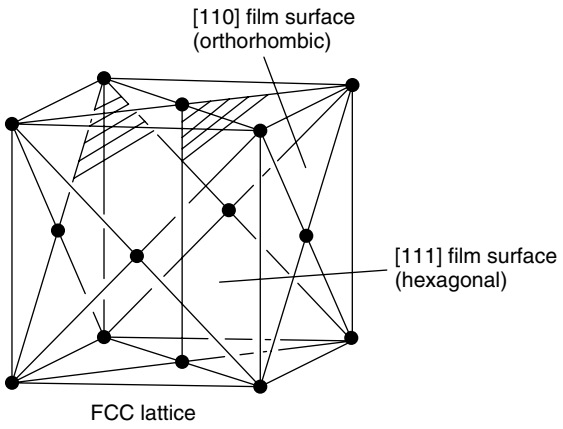

Figure 41. Surface symmetry reductions for fcc lattice (del Moral, 2007).

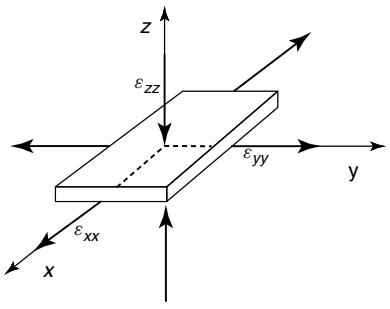

Figure 42. Biaxial strain in a thin film (O'Handley, Sun and Ballentine, 1993).

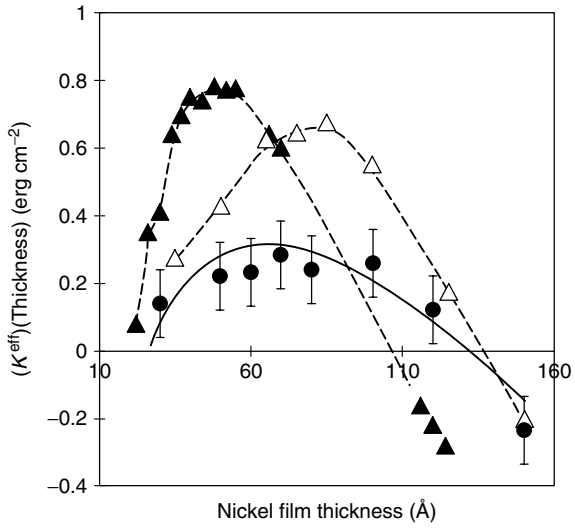

Figure 43. Effective MA in Cu/Ni/Cu trilayers (Ha and O'Handley, 1999).

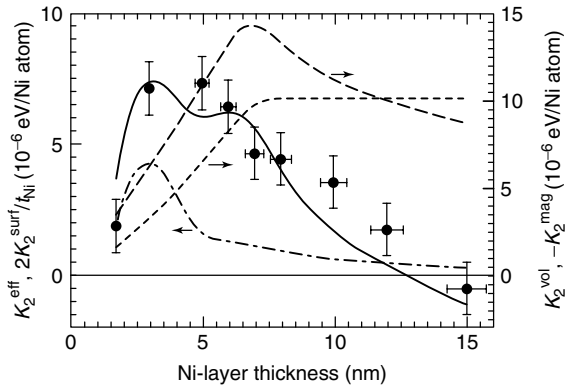

Figure 44. MA constant K_{eff} (•; plain line, theory) ant its contributions, K_2^{vol} (dash), surface (dash-dot), K_2^{mag} (dot) (del Moral *et al.*, unpublished).

The fit by equation (61) (continuous line) is attained with, $K_1 \cong 0$, $K^s = 0.76$, $\overline{M}^s = -1.22$ (erg cm^{-2}), $\overline{N}^v = -1.11 \times 10^{10}$, $2\pi M_s^2 = 1.5 \times 10^6$ (erg cm^{-3}) and $\overline{N}^s = -1.97$ erg cm^{-1}. Since $K^s > 0$ the *spin reorientation* for $t > \approx 20$ Å is due to the bulk NL contribution, which contributes negatively to K^{eff}, whereas the $\overline{M}^s$ contribution is negligible. Assuming that the film is tetragonally distorted, the itinerant BD-BZS model of Section 3 yields the contributions and kind of fit shown in Figure 44 with only $K_2^{eff} = K_2^{vol} + (2K_2^{sf}/t_{Ni}) - 2\pi M_s^2$ contributions (del Moral *et al.*, unpublished). This model also explains the t dependence of $\overline{M}^{\gamma,2}$, due to the SF $2\overline{M}_{sf}^{\gamma,2}/t$ contribution, for $t < 100$ Å, for above the concourse of NL $\overline{N}^{\gamma,2}\varepsilon_{1,mf}^{\gamma}$ being needed, in order to explain the observed 'window'of $\overline{M}^{\gamma,2}$ with t (Ciria *et al.*, 2004).

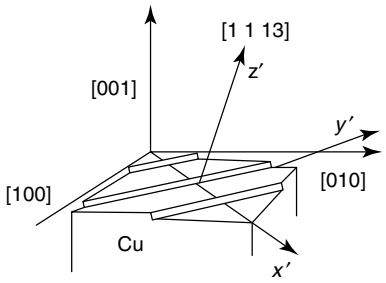

Figure 45. Vicinal surface [1113] terraces (Oepen *et al.*, 1993).

The growth of a SF 'vicinal' to a [001] one, with normal [1113] in fcc Co/Cu ultrathin films (few ML) gives rise to the appearing of steps (Figure 45), which allows study of MEL coupling in one dimension, since a MEL anisotropy is developed along the terrace line. The Néel's *pair-atom MEL model* mentioned explains well the observations, the anisotropy energy density becoming, $E_{film} = E_{bulk} - 2E_{sf}/t - 2E_{step\ edge}/td - 2E_{step\ corner}/td$, where d is the steps distance (an *AI* calculation does exist, Victora and MacLaren, 1993).

6.2 RE superlattices

In RE/Y, RE/Lu, and RE/Sc SLs the oscillatory RKKY exchange interaction is propagated through the NM blocks, the ordering temperatures (T_N, T_c) are strongly modified, a *finite size* effect is manifested for very thin RE blocks in the helical structure and new magnetic phases appear in the (H, T) diagram (Jehan *et al.*, 1993). Since the moments are now truly localized we can write for the orthorhombic MS in basal plane, ε_1^{γ} that thickness and T dependencies respectively are,

$$\overline{M}_{th}^{\gamma} = \overline{M}_{v0}^{\gamma} + \left(\frac{2\overline{M}_s^{\gamma}}{t_{Ho}}\right) + \overline{N}_v^{\gamma}\eta\left(\frac{t_{Lu}}{(\alpha t_{Ho} + t_{Lu})}\right) \qquad (62)$$

$$\overline{M}_{th}^{\gamma}(m) = (\overline{M}_{v0}^{\gamma} + \overline{N}_v^{\gamma}\varepsilon_{mf})\hat{I}_{5/2}(L^{-1}(m)) + \left(\frac{2\overline{M}_s^{\gamma}}{t_{Ho}}\right)m^{\alpha} \qquad (63)$$

In equation (63) the last term is the thermal variation for the IF-MS, which according to STM for $d = D = 2$, gives $\alpha = 4$ at low T ($\alpha = 2$ at high T), our case. In Figure 46 $\overline{M}_{th}^{\gamma,2}$ given by equation (62) is adequately compared with the saturation ($H = 12$ T) and 10 K $\overline{M}_{exp}^{\gamma,2}$ for $[Ho_n/Lu_{15}]_{x50}$ [0001] SLs where the Ho ML number is $n = 8 - 80$ (plus bulk films, o symbol), the Lu block thickness being constant (Ho block in under misfit compression, opposite to Y spacer SLs). From the fit we obtain that $\overline{M}_{v0}^{\gamma,2} = -0.89$, $\overline{M}_{sf}^{\gamma,2}/(c/2) = 7$, $N_v^{\gamma,2} = 185$ (all in GPa), with $\eta = -1.44\%$. In Figure 47 are shown the $\overline{M}^{\gamma,2}(T)$

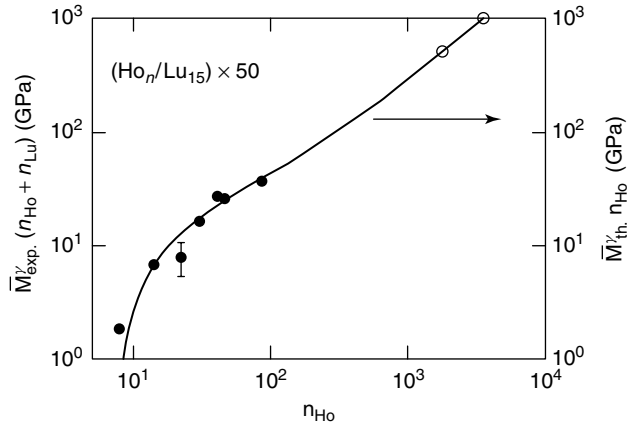

Figure 46. See text for meaning (del Moral *et al*., 1998b).

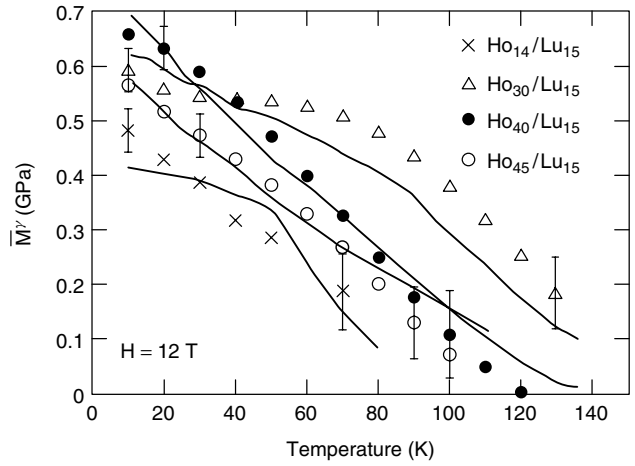

Figure 47. $\overline{M}^{\gamma,2}$ (T) thermal variations for Ho_n/Lu_{15} superlattices; lines are the theory (del Moral *et al*., 1998b).

variations together with the fits by equation (63), using the *same* MEL parameters, the opposite sing IF contribution being needed. Therefore STM is as well behaved in RE SLs as in bulk REMs.

Exchange Coupling in Magnetic Multilayers

David M. Edwards[1] and Andrey Umerski[2]

[1] *Imperial College London, London, UK*
[2] *Open University, Milton Keynes, UK*

1 INTRODUCTION

The recent intensive investigation of magnetic layered structures followed advances in molecular-beam epitaxy (MBE) techniques for preparing samples with atomically flat interfaces between layers. Antiferromagnetic (AF) exchange coupling between ferromagnetic (FM) films across a nonferromagnetic metallic spacer was first clearly observed in Fe/Cr/Fe(001) structures by Grünberg *et al*. (1986). About the same time, the study of exchange coupling in rare-earth-based multilayers also began (Majkrzak *et al*., 1986; Salamon *et al*., 1986). Work on transition metal (TM)-based multilayers intensified following the discovery of the giant magnetoresistance (GMR) effect in antiferromagnetically coupled Fe/Cr systems (Baibich *et al*., 1988; Binasch, Grünberg, Saurenbach and Zinn, 1989). In this chapter, we confine ourselves to the discussion of interlayer exchange coupling (IEC) in TM-based systems.

An important early development in the study of IEC was the discovery by Parkin, More and Roche (1990) that the nature of the coupling oscillates between AF and FM alignments, as the thickness of the spacer is varied. In samples with AF coupling, the strength of the coupling was measured by the magnetic field required to saturate the total moment of the system. In the case of FM coupling, all the moments are aligned parallel, and only a small field, unrelated to the coupling strength, is required for saturation. The first measurements of oscillatory exchange coupling, made on sputtered Fe/Cr/Fe and Fe/Ru/Fe multilayers, were followed by similar ones with a wide range of 3d, 4d, and 5d TM spacers (Parkin, Bhadra and Roche, 1991). Surprisingly, all samples exhibited only long-wavelength oscillations with the same period of about 10 Å, with the exception of Cr where the observed period was about 18 Å. These results were clearly inconsistent with the emerging Ruderman–Kittel–Kasuya–Yosida (RKKY) (Bruno and Chappert, 1991, 1992) and quantum well (QW) (Edwards and Mathon, 1991; Edwards, Mathon, Muniz and Phan, 1991a,b) theories. As discussed later, in these theories, oscillation periods are related to spanning vectors of the spacer Fermi surface and should therefore vary from metal to metal. The source of this discrepancy must lie in the sputtering method of preparing the multilayers. This technique is quick and relatively inexpensive, as required for production of GMR devices, but the resultant structure is not well known. It has been

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

suggested that polycrystallinity with different grain orientations could lead to an averaging effect which might produce Parkin's almost universal 10 Å period. The result still remains mysterious.

The MBE technique has several advantages over sputtering, including generally sharper interfaces, with less interdiffusion, and epitaxial growth with known crystal orientation. The greater speed of deposition by sputtering is offset, in studies of oscillatory exchange coupling, by the ability of MBE to produce samples with a wedged shaped spacer layer. Measurements of the IEC can then be carried out for many different spacer thicknesses on a single sample. The wedge geometry is obtained by moving a shutter in front of the sample during deposition of the spacer material. The gradient of the sloping face of the wedge can be as small as 1 monolayer (ML) per mm with sample sizes of up to 10 mm. Local measurements of the IEC for many different spacer thicknesses are then not affected by the wedge geometry. The wedged-spacer technique was pioneered by Grünberg's group using Fe/Cr/Fe samples grown on GaAs substrates (Demokritov, Wolf and Grüunberg, 1991), where they found only strongly damped long-wavelength oscillations of the IEC with a period of about 12 ML ($\simeq$17 Å).

A major breakthrough in the study of IEC occurred with the discovery of short-wavelength oscillations in Fe/Cr/Fe(001). The NIST group (Unguris, Celotta and Pierce, 1991; Unguris, Pierce, Celotta and Stroscio, 1993; Pierce, Unguris and Celotta, 1994) found oscillations of the exchange coupling with Cr thickness, with a period of about 2 ML. In these samples, a Cr wedge was grown on an atomically flat Fe whisker substrate at a raised temperature ($>$250 °C). Measurements on samples grown at lower substrate temperatures revealed only the long 12 ML period. It was concluded that the IEC is the sum of two components with long and short periods. These results demonstrate the importance of having smooth interfaces for a complete study of IEC. It is, of course, not surprising that local variations in spacer thickness will wash out 2 ML period oscillations. The NIST work made use of a scanning electron microscope with polarization analysis (SEMPA) which detects the sign of the coupling but not its magnitude. In later work on Fe/Au/Fe(001), the same group combined this technique with magneto-optical Kerr effect (MOKE) measurements which additionally determine the magnitude of the coupling (Unguris, Celotta and Pierce, 1997). These measurements are discussed later in Section 7.1, since they represent one of the very few cases where a meaningful comparison can be made between experiment and theoretical calculations based on perfect interfaces.

We present this brief history of IEC as a background to the theoretical work, which is the main concern of this chapter. It is clear that one must beware of too naive a comparison between theory and experiment.

So far, we have only considered coupling between magnetic layers that is either FM or AF, leading to parallel or antiparallel orientations of the two magnetizations. In fact, 90° coupling with magnetizations at right angles is also observed. To describe this possibility, it is conventional to introduce a phenomenological coupling energy, per unit interfacial area, of the form

$$\begin{aligned} E(\theta) &= -J_1 \mathbf{m}_1.\mathbf{m}_2 - J_2(\mathbf{m}_1.\mathbf{m}_2)^2 \\ &= -J_1 \cos\theta - J_2 \cos^2\theta \end{aligned} \tag{1}$$

where $\mathbf{m}_1$ and $\mathbf{m}_2$ are unit vectors in the directions of the two magnetizations and θ is the angle between them. The parameters J_1 and J_2 determine the type and the strength of the coupling. If the term J_1 dominates, the coupling is FM (AF) for positive (negative) J_1, respectively. If the term J_2 dominates and J_2 is negative, the energy is a minimum for $\theta = \pi/2$, so that 90° coupling is stable. The J_2 term is called *biquadratic coupling* and the J_1 term is sometimes called *bilinear coupling*. In much of the theoretical work the quantity calculated is $E(0) - E(\pi) = E_{\mathrm{FM}} - E_{\mathrm{AF}} = -2J_1$.

It is expected that some readers of this chapter will not wish to explore the finer details of the theory. Section 2 is therefore intended to give a broad overview of exchange coupling between magnetic layers and its relation to the existence of QW states and resonances in the spacer region. In Section 3, we describe a simple free-electron model which demonstrates many important features with explicit analytic formulas. These features include the oscillations of the bilinear and intrinsic biquadratic coupling as a function of spacer thickness, the temperature dependence of these couplings, and the nature of the induced moment within the spacer. In Section 4, we sketch the methods used for obtaining quantitative results for the IEC in real systems. Section 5 is concerned with intrinsic and nonintrinsic mechanisms for biquadratic coupling, with particular reference to the role of interface roughness. In Section 6, it is shown how temperature dependence of the IEC arises from both single-particle and spin-wave excitations. Theory and experiment are brought together in Section 7 for systems with spacers classified as noble metal, TM, and AF metal (particularly chromium) or insulator. In the final section, the current status of the IEC is summarized and the outlook for future work is discussed.

2 QUANTUM WELL STATES AND EXCHANGE COUPLING

In this section, we discuss some of the basic theoretical ideas behind the QW theory of the IEC. In Section 2.1,

we apply the free-electron model to a simple QW. We calculate the density of states for this system and observe that this oscillates both as a function of the well width and as a function of the electron energy relative to the bottom of the well. Although this model is simple, it contains many of the essential features of more sophisticated models, and we can compare it qualitatively to results obtained from photoemission experiments. In Section 2.2, we discuss two methods of calculating the exchange coupling between magnetic layers, and show how its oscillations, as a function of spacer thickness, are related to QW states, with periods determined by extremal points of the spacer Fermi surface. Finally in Section 2.3, we describe a quantitative calculation of exchange coupling in a Co/Cu/Co(001) trilayer (Mathon *et al*., 1995, 1997). We interpret the results on the basis of our findings in the earlier two subsections, and compare with experiment.

2.1 QW states in a trilayer

Consider a simple free-electron model of an A/B/A trilayer. The potential energy is depicted in Figure 1(a), where y is the electron coordinate perpendicular to the layers. The thickness of the B layer is l and the depth of the well is V. Electron states Ψ satisfy the Schrödinger equation

$$\frac{-\hbar^2}{2m}\nabla^2\Psi + V(y)\Psi = E\Psi \tag{2}$$

and, owing to in-plane translational symmetry, are classified by a Bloch wave vector $\boldsymbol{k}_\parallel = (k_x, 0, k_z)$. Thus,

$$\Psi = e^{i\boldsymbol{k}_\parallel\cdot\mathbf{r}}u(y) \tag{3}$$

where the electron position $\mathbf{r} = (x, y, z)$. On substituting equation (3) in equation (2) we find that $u(y)$ satisfies the one-dimensional (1D) Schrödinger equation

$$\mathcal{H}u \equiv \frac{-\hbar^2}{2m}\frac{d^2u}{dy^2} + V(y)u = E'u \tag{4}$$

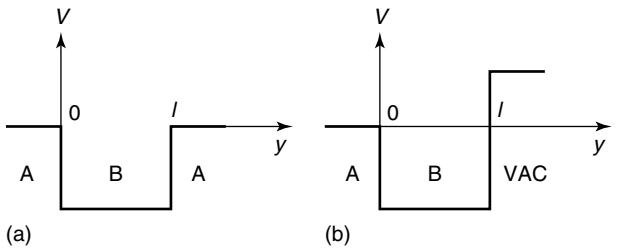

Figure 1. Potential energy $V(y)$ of an electron in (a) an A/B/A trilayer (b) an A/B/VAC system corresponding to a B overlayer on an A substrate.

with $E' = E - \hbar^2\boldsymbol{k}_\parallel{}^2/(2m)$. For a given $\boldsymbol{k}_\parallel$, we take the zero of energy to be such that $E' = 0$ corresponds to the bottom of the well. Thus if E_F is the actual Fermi energy measured from the bottom of the well, electrons fill states in the 1D well up to $E'_\mathrm{F} = E_\mathrm{F} - \hbar^2\boldsymbol{k}_\parallel{}^2/(2m)$. If $E'_\mathrm{F} \le 0$, there are no occupied states with the given $\boldsymbol{k}_\parallel$. Figure 1(b) shows the potential $V(y)$ for the system A/B/VAC, where an overlayer B of thickness l separates the semi-infinite layer A from the vacuum. This is the potential corresponding to angle-resolved photoemission (ARPES) from an overlayer in which electrons are emitted from states of definite $\boldsymbol{k}_\parallel$, for example, $\boldsymbol{k}_\parallel = 0$. The measurement probes the density of states $\rho(E, l)$ of the 1D well. For the present simple discussion, it is sufficient to consider the symmetric well of Figure 1(a).

In general, the eigenstates of the 1D well consist of a number of discrete bound states with $E' < V$ and a continuum of states with $E' > V$. As $\boldsymbol{k}_\parallel$ is varied, we may have a change in the nature of states near the effective Fermi level from continuum for $\boldsymbol{k}_\parallel = 0$ to bound states for some finite $\boldsymbol{k}_\parallel$. The density of states in the region of the well is given by

$$\rho(\mathrm{E}', l) = \int_0^l \mathrm{d}y \sum_i |u_i(y)|^2\,\delta(E' - E_i) \tag{5}$$

$$= -\frac{1}{\pi}\mathrm{Im}\int_0^l \mathrm{d}y\; G(y, y, E'_+) \tag{6}$$

Here $u_i(y)$ and E_i are the eigenfunctions and eigenvalues of the Hamiltonian $\mathcal{H}$ in equation (4) and $G(y, y', E'_+)$ is the one-particle Green function $\langle y\,|(E' - \mathcal{H})^{-1}|\,y'\rangle$. E'_+ signifies that E' has an infinitesimal positive imaginary part. The Green function is straightforward to calculate and we find that, in the continuum region $E' > V$,

$$\pi V\rho(E', l) = \frac{d(2\varepsilon - 1)(\varepsilon - 1)^{1/2}}{\sin^2(d\sqrt{\varepsilon}) + 4\varepsilon(\varepsilon - 1)} \tag{7}$$

where $\varepsilon = E'/V$ and $d = l(2mV/\hbar^2)^{1/2}$ are dimensionless energy and well-width variables. Now

$$d\sqrt{\varepsilon} = l\sqrt{\frac{2E'm}{\hbar^2}} = k_y l \tag{8}$$

where $E = (\hbar^2/2m)(\boldsymbol{k}_\parallel{}^2 + k_y^2)$. Thus $k_y(\boldsymbol{k}_\parallel, E)$ is the k_y coordinate of a point on the constant energy surface of energy E and with a given $\boldsymbol{k}_\parallel$. Clearly, from equation (7), $l^{-1}\rho(\mathrm{E}', l)$ is a periodic function of l with period π/k_y. In the later development, this periodicity property of the density of states turns out to be very useful, and even for nonspherical energy surfaces, the period is found to be determined by the same dimension k_y of the constant energy surface.

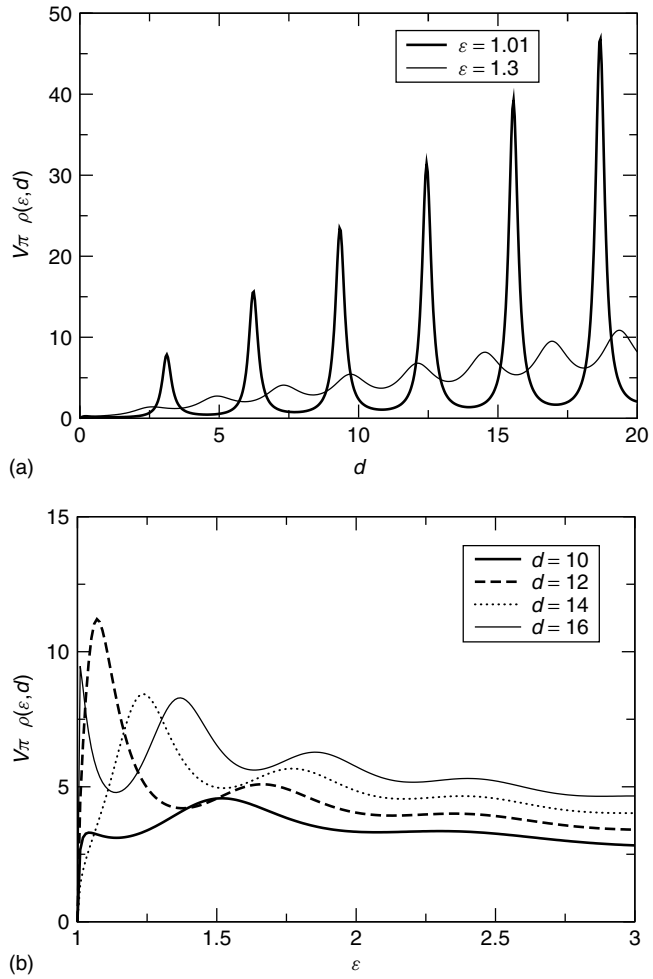

Figure 2. (a) Scaled density of states in the well region (RH side of equation (7)), as a function of dimensionless well width d, for reduced energies $\varepsilon = 1.01$ (thick line) and $\varepsilon = 1.3$ (thin line). (b) Same scaled density of states as in (a), as a function of reduced energy ε for $d = 10, 12, 14, 16$.

In Figure 2(a), the right-hand (RH) side of equation (7) is plotted as a function of d, the dimensionless width of the well, for two energies $\varepsilon = 1.01$ and 1.3. The first case corresponds to an energy E' just above the top of the well and sharp resonances, corresponding to nearly bound states, pass through this energy as d is varied. For $\varepsilon = 1.3$ the resonances are much broader. For E' below the top of the well ($\varepsilon < 1$) the resonances would become δ-functions, corresponding to bound states. In Figure 2(b), the RH side of equation (7) is plotted as a function of ε ($\varepsilon > 1$) for various values of d. This shows how the resonances seen in the density of states shift in energy with changing well width.

Figure 2(a) and (b) may be compared qualitatively with the spectral density observed by Ortega, Himpsel, Mankey and Willis (1993), in ARPES and inverse photoemission with $\boldsymbol{k}_\parallel = 0$, from Cu overlayers on Co(001) or Fe(001). The results of Ortega, Himpsel, Mankey and Willis (1993) shown in Figure 3(a), corresponding to electrons emitted from the Fermi level, are similar to the plots in Figure 2(a). This shows that QW resonances exist in the Cu overlayer and the relation of the oscillation period to the Cu Fermi surface is discussed later. The simple linear increase in amplitude is not observed since not all the photoemitted electrons originate in the overlayer, and in any case, emission is not uniform throughout the overlayer. The spectra shown in Figure 3(b) may be compared with Figure 2(b) with a similar upward shift in resonances as the Cu thickness increases.

Electrons in a ferromagnet such as Co and Fe have a spin-dependent potential energy, the difference in energy between that for minority and majority spin corresponding to an exchange splitting of 1 or 2 eV. Consequently, the QW in a nonmagnetic overlayer has a different depth for the two spin orientations. The effect of this is seen in the spin-resolved photoemission results of Garrison, Chang and Johnson (1993), shown in Figure 3(c), where QW resonances are seen clearly only for minority spins. In general, oscillations in the spectral density of large amplitude are associated with QW states strongly confined in the nonmagnetic layer.

2.2 Relation of QW states to exchange coupling

There are two starting points for a quantitative calculation of exchange coupling. The first proceeds directly from the definition of exchange coupling between two semi-infinite magnetic layers across a nonmagnetic spacer layer of thickness $l = Nd$. Here, d is the interplane spacing and N is the number of atomic planes in the spacer. Thus, we define the exchange coupling as

$$J(l) = \Omega_{\uparrow\uparrow} - \Omega_{\uparrow\downarrow} \tag{9}$$

where $\Omega_{\uparrow\uparrow}$ and $\Omega_{\uparrow\downarrow}$ are thermodynamic potentials of the trilayer per unit cross-sectional area for the parallel and antiparallel configuration of the magnetic moments of the magnetic layers, respectively. The first method of calculating $J(l)$, which we use in this section, is to calculate this energy difference directly.

A second method, which we discuss later, is the torque method in which we consider the nonequilibrium situation where the magnetic moments of the two magnetic layers make an arbitrary angle θ with each other. If the corresponding thermodynamic potential is $\Omega(\theta)$ we define

$$J(l, \theta) = \Omega(0) - \Omega(\theta) = \int_0^\theta -\frac{\mathrm{d}\Omega}{\mathrm{d}\theta}\,\mathrm{d}\theta \tag{10}$$

The integrand $-\mathrm{d}\Omega/\mathrm{d}\theta$ is the torque exerted on one magnetic moment by the other and is related to the spin current flowing across the spacer in the nonequilibrium configuration considered. We discuss this in Section 3. Clearly, from equations (9) and (10), $J(l) = J(l, \pi)$ so that $J(l)$ can be calculated by integrating torque instead of taking the energy difference. Both methods have been used and are known to be equivalent (Umerski unpublished; and see Edwards, Robinson and Mathon (1995) for the one-band case). The torque method was first used by Slonczewski (1989) for the case of an insulating spacer.

To evaluate equation (9) we make two approximations. The first is the so-called force theorem (Pettifor and Varma, 1979), which states that a good approximation to a total energy difference between different structures (in this case, magnetic) is obtained by comparing sums of one-electron energies, using atomic potentials which are independent of the magnetic configurations. The second approximation is to neglect the dependence of the local densities of states within the magnetic layers on the magnetic configuration. This approximation can be checked and is found to be a good one, at least for spacer thicknesses that are not too small. Thus, at temperature $T = 0$,

$$J(l) = \sum_{\boldsymbol{k}_\parallel} \int_{-\infty}^{\mu} (E - \mu) \left\{ [\rho_\uparrow + \rho_\downarrow]_{\mathrm{FM}} - [\rho_\uparrow + \rho_\downarrow]_{\mathrm{AF}} \right\} \mathrm{d}E \tag{11}$$

where μ is the chemical potential. Here $\rho_\sigma = \rho_\sigma(\boldsymbol{k}_\parallel, E, l)$ is the density of states within the spacer for a given wave vector $\boldsymbol{k}_\parallel$ and spin $\sigma = \{\uparrow, \downarrow\}$; these densities of states are calculated for the FM and AF configurations as indicated. At finite temperature T, the factor $E - \mu$ is replaced by $-k_\mathrm{B}T \ln(1 + \exp((\mu - E)/k_\mathrm{B}T))$.

Now, as pointed out in Section 2.1, $l^{-1}\rho_\sigma(\boldsymbol{k}_\parallel, E, l)$ is a periodic function of l with period π/k_y where $k_y = k_y(\boldsymbol{k}_\parallel, E)$ defines the bulk spacer constant energy surface with energy E. This periodicity property has been rigorously proved by Umerski (1997). Thus, we may introduce the Fourier series

$$l^{-1}\rho_\sigma(\boldsymbol{k}_\parallel, E, l) = \sum_n c_{n\sigma}(\boldsymbol{k}_\parallel, E) e^{2inlk_y(\boldsymbol{k}_\parallel, E)} \tag{12}$$

and substitute into equation (11). This is very convenient because for large l we may use the stationary phase approximation (SPA) to evaluate the integrals over $\boldsymbol{k}_\parallel$ and E in

equation (11). The dominant contribution arises from $E \sim \mu$ and from points $\boldsymbol{k}_\parallel = \boldsymbol{k}_\parallel{}^0$ where the function $k_y(\boldsymbol{k}_\parallel, \mu)$ is stationary. Thus oscillations in $\rho_\sigma(\boldsymbol{k}_\parallel{}^0, \mu, l)$, which arise from QW states passing through the Fermi level μ as spacer thickness l varies, give rise to corresponding oscillations in the exchange coupling $J(l)$. Oscillations of large amplitude are associated with strongly confined QW states, as pointed out in Section 2.1, so that one of the terms in equation (11), for example, $[\rho_\downarrow]_{\mathrm{FM}}$ in the case of Co/Cu/Co(001), may be the most significant. We discuss the Co/Cu/Co example further in the next section.

2.3 Co/Cu/Co(001) trilayers

Figure 4 shows a sketch of a cross section of part of the Cu Fermi surface. k_y is in the (001) direction and $\boldsymbol{k}_\parallel$ in the (110) direction. The dashed line is the zone boundary $k_y = \pi/d$. The two stationary points of $k_y(\boldsymbol{k}_\parallel, \mu)$ are indicated: $k_y = k_y^B$ occurs at $\boldsymbol{k}_\parallel = \boldsymbol{0}$ and the other $k_y = k_y^N$ at a finite value $\boldsymbol{k}_\parallel{}^0$. The corresponding oscillation periods are influenced by the discrete nature of the lattice, which we have not considered before. Thus $l = Nd$ where N is an integer, and in this case d is the interplanar Cu distance, so that $\exp(2inlk_y) = \exp(2inl(k_y - \pi/d))$. When $\pi/d - k_y < k_y$ the observed period, considering the function of l only at discrete points Nd, is $\pi/(\pi/d - k_y)$ rather than π/k_y (this is known as the *aliasing effect*). The stationary point at $\boldsymbol{k}_\parallel = \boldsymbol{0}$ therefore corresponds to a long period, in fact 5.9 ML, which is the one seen in Figure 3(a). The other stationary point corresponds to a shorter period of 2.6 ML (∼4.7 Å) and contributions with both periods should occur in the exchange coupling. Recently, the shorter period has been observed (Klässges *et al*., 1998) in ARPES from Cu overlayers on Co(001) with $\boldsymbol{k}_\parallel \sim \boldsymbol{k}_\parallel{}^0$.

Mathon *et al*. (1995, 1997) calculated the exchange coupling in Co/Cu/Co(001) trilayers using a fully numerical method, based on the torque (or 'cleavage') formalism, as well as the semi-analytic SPA described above. Both methods use a tight-binding model, with nine orbitals (3d, 4s, 4p) and parameters fitted to first-principles calculations for the bulk metals. Given this model, the fully numerical method relies further only on the force theorem, and the stationary phase method should give the same results for large l. Here, we just discuss the results since more detail is given in Mathon *et al*. (1995, 1997) and in Section 4 of this chapter.

In Figure 5, we show a comparison between the numerical results for exchange coupling J and the SPA. As expected, the latter is very accurate when the number N of Cu planes is large. Clearly the oscillatory exchange coupling is dominated by the short-period contribution. The SPA, which has the advantage of being able to separate the two contributions, shows that the long-period contribution is less than 1% of the total. The reason for this is easy to understand in terms of confinement of QW states.

Figure 6(a) shows the energy bands for bulk Co (majority and minority spin) and for Cu, along a line in **k** space in the k_y direction with $\boldsymbol{k}_\parallel = \boldsymbol{k}_\parallel{}^0$ corresponding to a short-period Fermi-surface extremum (see Figure 4). There is a good match between the sp-like bands for Cu and Co majority spin where they cross the Fermi level $\mu = E_{\mathrm{F}}$. However, for Co minority spin, the Fermi level falls in an almost

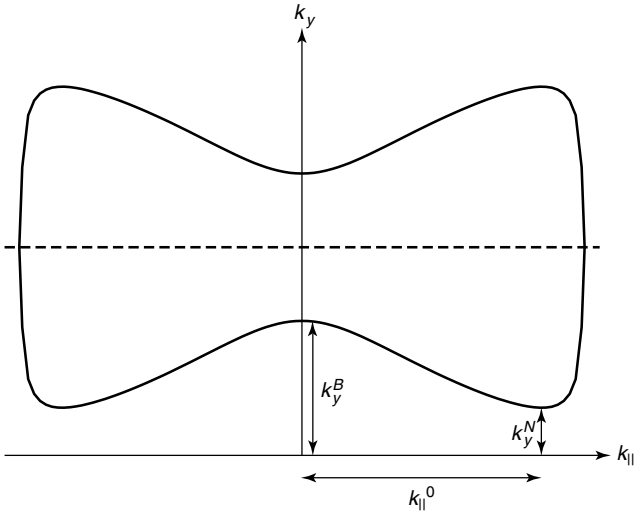

Figure 4. Sketch of a cross section of part of the Cu Fermi surface, showing two extreme values of k_y, namely, k_y^B and k_y^N, which occur at $\boldsymbol{k}_\parallel = 0$ and $\boldsymbol{k}_\parallel = \boldsymbol{k}_\parallel{}^0$ respectively.

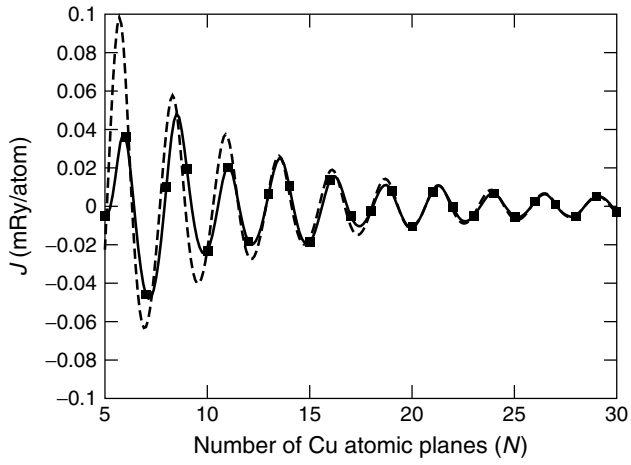

Figure 5. Exchange coupling in a Co/Cu/Co(001) trilayer calculated as a function of Cu thickness, fully numerically (full line) and using SPA (dashed line). (Reprinted figure Mathon, J. *et al*., 1997, *Phys. Rev. B*, **56**, 11797–11809. © 1997 by the American Physical Society.)

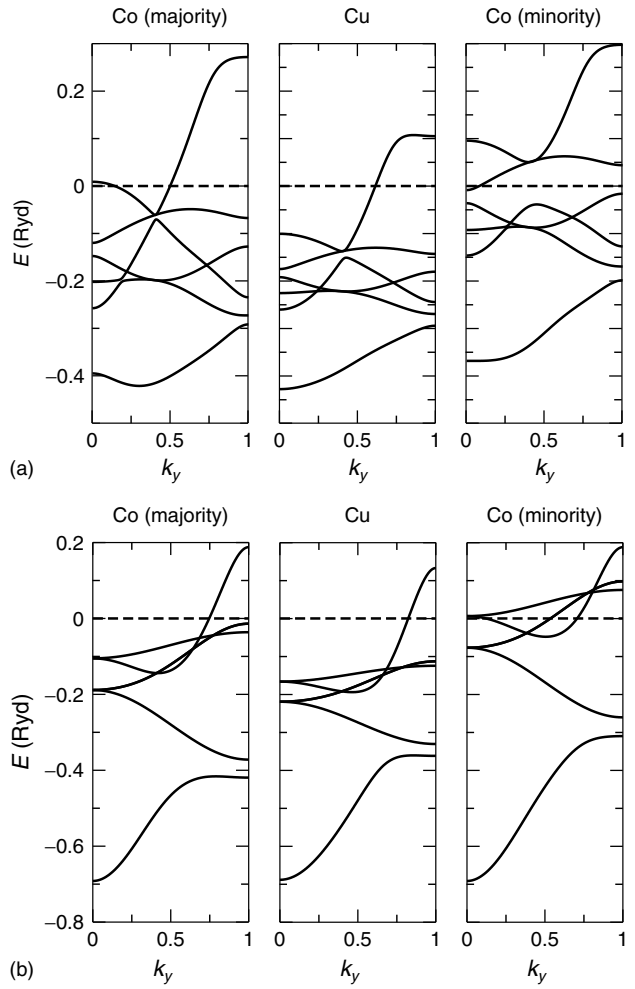

Figure 6. (a) Energy bands for Cu and FM fcc Co along a line in the k_y direction with $\boldsymbol{k}_\parallel = \boldsymbol{k}_\parallel{}^0$ corresponding to a short-period Fermi-surface extremum (see Figure 4). (Reprinted figure Mathon, J. *et al*., 1997, *Phys. Rev. B*, **56**, 11797–11809. © 1997 by the American Physical Society.) (b) Energy bands as in (a) but with $\boldsymbol{k}_\parallel = 0$ corresponding to the long-period Fermi-surface extremum. (Reprinted figure Mathon, J. *et al*., 1997, *Phys. Rev. B*, **56**, 11797–11809. © 1997 by the American Physical Society.)

complete hybridization gap. Thus, in the FM configuration of the Co/Cu/Co trilayer, minority spin electrons at the Fermi level are strongly confined in the Cu layer, which therefore acts like a deep QW in the simple free-electron picture we used in Section 2.1. However, the majority spin electrons are hardly confined at all and will make only a small contribution to QW oscillations in photoemission and exchange coupling. In the AF configuration, electrons of both spin are free to escape into one of the Co layers and therefore contribute weakly to QW oscillations. Thus, the short-period oscillations of Figure 5 arise largely from the minority spin spectral density $[\rho_\downarrow]_{\mathrm{FM}}$ in equation (11). The situation is quite different for $\boldsymbol{k}_\parallel = 0$, corresponding to the long-period Fermi-surface extremum. The sp-like band crosses E_{F} at very similar values in both spin bands of Co and in Cu, as shown in Figure 6(b). Thus, there are no strongly confined QW states of either spin for $\boldsymbol{k}_\parallel = 0$. Consequently, the long-period oscillations in J are much weaker than the short-period ones, as found in the calculations. Nevertheless, the long-period oscillations can be seen in photoemission, at least for minority spin electrons, as described earlier.

The experimental situation is complicated by interfacial roughness. For an oscillation period close to 2 ML, the sign of the exchange coupling is changed by adding a spacer atomic layer. Thus, the presence of steps will tend to reduce the amplitude of this component when averaged over the sample. The short-period oscillation in Cu is clearly much more susceptible to this effect than the long-period one. Johnson *et al*. (1993) and Bloemen *et al*. (1993) found in their experiments that the amplitudes of the short- and long-period oscillations are comparable. Their value of J at the first AF peak ($0.4\,\mathrm{mJ\,m^{-2}}$) is about three times smaller than that found by Mathon *et al*. (1997), which may well be attributed to roughness. Kawakami *et al*. (1999) also concluded that the amplitude ratio is about 1 and discuss their results in terms of QW states observed in ARPES (see also Qiu and Smith, 2002). Weber, Allenspach and Bischof (1995), using a SEMPA, estimate that, in their 'best' samples, the amplitude of the short-period oscillation is at least a factor 7 larger than that of the long-period oscillation. This is more in accord with the predictions of Mathon *et al*. (1997). Unfortunately, SEMPA does not give the absolute values of the exchange coupling.

3 CALCULATION OF THE EXCHANGE COUPLING AND INDUCED MAGNETIZATION IN A PARABOLIC BAND MODEL

In this section, we consider a particularly simple free-electron model (Hathaway and Cullen 1992; Edwards, Ward and Mathon, 1993) of a magnetic trilayer, consisting of two FM metallic layers separated by a nonmagnetic metallic spacer layer. We assume infinite exchange splitting in the ferromagnets, so that minority spin electrons do not penetrate them at all and assume that majority spin electrons experience the same constant potential (taken as zero) as the spin independent potential in the spacer. The advantage of this somewhat idealized model is that it is fully solvable, and contains much of the physical behavior observed in more sophisticated tight-binding or *ab initio* calculations of realistic systems (Edwards, Ward and Mathon, 1993; Mathon *et al*., 2000).

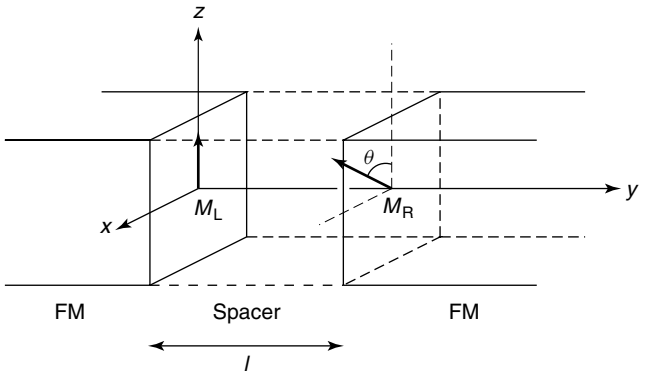

Figure 7. Schematic representation of a trilayer, showing left and right semi-infinite ferromagnets separated by a nonmagnetic spacer layer of width l. The magnetization in the LH ferromagnet is along the z axis while that in the RH ferromagnet makes an angle θ with the z axis. The growth axis is along y.

The geometry of the system is depicted in Figure 7. We select a Cartesian system of coordinates with the x and z axes in the plane of the layers and the y axis along the growth direction. We suppose that the spacer has width l and occupies the region $|y| < l/2$, whereas the ferromagnets occupy the regions $l/2 < |y| < L$. We also assume that the potential is infinite for $|y| > L$, but eventually let $L \to \infty$ so that the ferromagnets become semi-infinite. The magnetizations of the left-hand (LH) and RH ferromagnets are constrained to be in the directions shown in Figure 7, making an angle θ with each other.

The electron eigenstates ψ are classified by a wave vector $\boldsymbol{k}_\parallel$ parallel to the layers and either an energy E or a wave vector k_y in the spacer, such that $E = \hbar^2(k_\parallel^2 + k_y^2)/2m$. The spin current $j(\boldsymbol{k}_\parallel, k_y)$ carried by an electron in this state is given by

$$\mathbf{j}(\boldsymbol{k}_\parallel, k_y) = \frac{i\hbar^2}{4m}\left(\frac{\mathrm{d}\boldsymbol{\psi}^\dagger}{\mathrm{d}y}\boldsymbol{\sigma}\boldsymbol{\psi} - \boldsymbol{\psi}^\dagger\boldsymbol{\sigma}\frac{\mathrm{d}\boldsymbol{\psi}}{\mathrm{d}y}\right) \qquad \text{where}$$
$$\boldsymbol{\psi} = \begin{pmatrix}\psi_\uparrow \\ \psi_\downarrow\end{pmatrix} \tag{13}$$

and $\boldsymbol{\sigma} = (\boldsymbol{\sigma}_x, \boldsymbol{\sigma}_y, \boldsymbol{\sigma}_z)$ are Pauli matrices with spin quantized with respect to the z axis. Note that if $\hbar/2\boldsymbol{\sigma}$ is replaced by the unit matrix, we recover the usual expression for the particle current. The spin current in the spacer is independent of position y, owing to spin conservation, and the only nonzero component of $\mathbf{j}$ is the y component j_y. On summing $j_y(\boldsymbol{k}_\parallel, k_y)$ over all occupied states (such that $E < \mu$ at $T = 0$), one obtains the rate of transfer of the y component of spin angular momentum across the spacer, and hence the torque $-\mathrm{d}\Omega/\mathrm{d}\theta$ which enters equation (10) for the exchange coupling $J(l, \theta)$. The reason for the torque to be in the y direction in the present geometry is that the constrained RH ferromagnet, for example, is trying to precess about an effective field in the z direction arising from the LH magnet.

The integration over θ in equation (10) is done by expanding $j(\boldsymbol{k}_\parallel, k_y)$ in a Fourier series in k_y. Eventually, one obtains an exact result for the exchange coupling at $T = 0$ and for spacer thickness l

$$J(\theta) = \frac{N_{2\mathrm{d}}E_\mathrm{F}^2}{\pi k_\mathrm{F}^2 l^2}\sum_{s=1}^{\infty}\frac{1}{s^3}\left[1 - \cos^{2s}\left(\frac{\theta}{2}\right)\right] \times\left[\left(1 - \frac{3}{(2sk_\mathrm{F}l)^2}\right)\sin(2sk_\mathrm{F}l) + \frac{3}{2sk_\mathrm{F}l}\cos(2sk_\mathrm{F}l)\right] \tag{14}$$

Here, k_F is the Fermi wave vector in the spacer, E_F is the corresponding Fermi energy, and $N_{2\mathrm{d}}$ is the constant density of states per unit area of the electron gas in two dimensions.

The $s = 1$ term in equation (14) gives the fundamental oscillation in $J(\theta)$ as a function of the spacer thickness l with period π/k_F. If J is only observed at discrete thicknesses $l = Nd$, a longer period of $\pi/|k_\mathrm{F} - \pi/d|$ may be observed owing to the 'aliasing effect', as described in Section 2.3. Subsequent terms $s = 2, 3, \ldots$ give higher harmonics with dependencies on angle θ of increasing complexity. The angular factor may be written as $(1 - \cos\theta)/2$ for the $s = 1$ term and as $(3 - 2\cos\theta - \cos^2\theta)/4$ for the $s = 2$ term. So the biquadratic exchange first occurs in the $s = 2$ harmonic, and generally a $\cos^s\theta$ term first occurs in the sth harmonic.

It is straightforward to include Fermi factors in the sum of the spin current over occupied states, in order to investigate the temperature dependence of the exchange coupling. The result in the limit of large spacer thickness l is

$$J(\theta) = \frac{N_{2\mathrm{d}}E_\mathrm{F}}{\beta\pi k_\mathrm{F} l}\sum_{s=1}^{\infty}\frac{1}{s^2}\left[1 - \cos^{2s}\left(\frac{\theta}{2}\right)\right] \times\left[\frac{\sin(2sk_\mathrm{F}l)}{\sinh(s\pi k_\mathrm{F}l/\beta E_\mathrm{F})}\right] \tag{15}$$

where $\beta = (k_\mathrm{B}T)^{-1}$. Clearly, the sth harmonic is damped exponentially for $T > T_s$, where $k_\mathrm{B}T_s = \hbar v_\mathrm{F}/2s\pi l$, v_F being the Fermi velocity. Thus higher harmonics, including the biquadratic exchange, decay more rapidly than the fundamental oscillation with $s = 1$. Impurity scattering in the spacer also damps the oscillations in the IEC exponentially (see e.g., Levy, Maekawa and Bruno, 1998). The analogy between IEC oscillations and de Haas van Alphen oscillations, where similar damping occurs, has been pointed out by Edwards, Mathon, Muniz and Phan (1991a). In order to make the temperature dependence of the exchange coupling explicit, it is

instructive to write equation (15) as

$$J(T,\theta) = \sum_{s=1}^{\infty} J_s(T,\theta) \qquad \text{where}$$

$$J_s(T,\theta) = J_s(0,\theta)\frac{T/T_s}{\sinh(T/T_s)} \tag{16}$$

The temperature dependence exhibited in this simple free-electron model closely resembles the temperature dependence of the exchange coupling for very general spacer band structures which we explore in Section 6.

The nonmagnetic spacer between the two magnetic layers acquires an induced magnetic moment due to the different confinement conditions of up- and down-spin electrons (Mathon *et al.*, 2000). The wave function ψ introduced in the preceding text can be used to calculate this spin density. It is found that the induced magnetization $\boldsymbol{P}(y)$ is coplanar with the magnetizations of the two magnetic layers. Thus $\boldsymbol{P}(y) = P(y)(\sin\phi(y), 0, \cos\phi(y))$, where the 'twist angle' $\phi(y)$ determines how the induced magnetization rotates about the y axis in the spacer. The components of $\boldsymbol{P}(y)$ oscillate with the same period π/k_F as the exchange coupling.

When the magnetizations of the two FM layers are collinear ($\theta = 0$ or π), the twist angle $\phi(y) = 0$, so that the induced moment is also collinear. In the general case when $\theta \neq 0$, Mathon *et al.* (2000) have shown, both for the simple free-electron model considered here and for a multiorbital tight-binding calculation of a Co/Cu/Co(001) trilayer, that the induced moment rotates along a complex three-dimensional spiral and can undergo many complete 360° rotations. Figure 8 displays $\phi(y)$ as a function of y for spacers of thicknesses $l = 8, 10, 14, 16$, with $\theta = \pi/2$. For $l = 8$, the induced moment rotates straightforwardly from 0 to $\pi/2$ with most of the rotation occurring near the middle of the spacer. For $l = 10$, the behavior is already strikingly different. Rather than a rotation from 0 to $\pi/2$, the induced moment reaches $\pi/2$ at $y = l$ by undergoing a slow rotation through an angle of $-3\pi/2$. For $l = 14, 16$, we now reach the typical behavior of induced moment. It rotates through $\pi/2$ several times before finally aligning itself with the magnetization in the right ferromagnet. Not only does this mean that the induced moment rotates by more than 2π but the manner of rotation is itself remarkable. The angle ϕ shows almost constant plateaus, followed by sharp variations.

Several factors probably contribute to this rather bizarre behavior. Firstly, the induced moment is very small and, secondly, electron–electron interactions in the spacer have been neglected. One can imagine a different situation with a spacer such as Pd, which is a paramagnet on the verge of ferromagnetism owing to electron interaction. The induced moments would be larger and would possess an exchange stiffness, which would inhibit rapid rotation. A rather uniform simple twist might be expected as in a domain wall of a ferromagnet. Similar behavior is discussed in Section 7.3 for an AF spacer. The actual behavior of the induced moment in noble metal and TM spacers deserves further consideration.

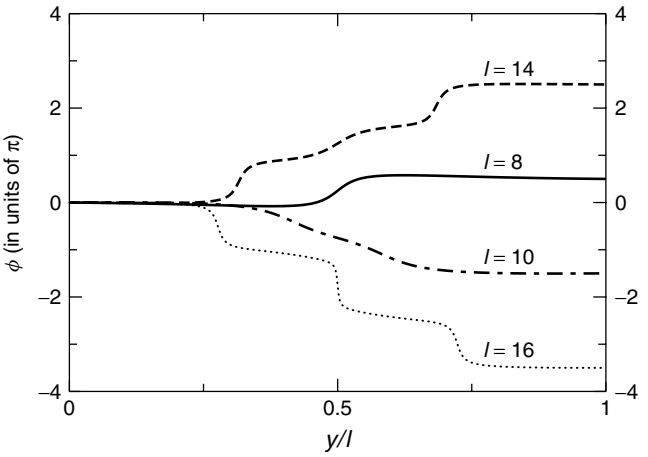

Figure 8. Dependence of the twist angle $\phi(y)$ on the distance from the left ferromagnet/spacer interface for spacer thicknesses $l = 8, 10, 14, 16$ and $\theta = \pi/2$.

4 CALCULATION OF IEC IN MODELS OF REAL SYSTEMS

The standard approach to realistic calculation of the ground state properties of an electronic system makes use of density-functional theory within the local spin-density approximation (LSDA). For a magnetic trilayer or superlattice the total energies of the FM and AF configurations may be calculated and the IEC must then be obtained as the small difference between these two large energies. The one-electron spin-dependent potentials are determined self-consistently in each configuration. This is a computationally slow and difficult task, since typically 10^4 k-points in the in-plane Brillouin zone must be summed over to achieve the required accuracy (Mathon *et al.*, 1997). So the method is usually restricted to relatively thin spacers, where fewer k-points may be used. A much more practical approach is to use the force theorem or frozen potential approximation. Both of these closely related approaches approximate the total energy difference by the difference of sums of one-electron energies over occupied states. In frozen potential approximation, the local one-electron potentials are frequently taken as those corresponding to the bulk magnetic and spacer metals. (For further details and comparison of these methods see Szunyogh, Újfalussy, Weinberger and Sommers, 1996.)

One-electron energies in the given potentials are usually determined by the Korringa–Kohn–Rostocker (KKR) method, the related tight-binding linear muffin tin orbital (TB-LMTO) method or by a straightforward multiorbital tight-binding method. The last method has the advantage of conceptual simplicity and we shall use this approach to sketch the formalism for calculating the IEC in real trilayers. An explicit formula for the IEC is obtained in Section 4.2 which is exact for thick spacers and separates clearly the various oscillatory components.

4.1 The cleavage formula for IEC

The general method is most easily described for a multiorbital tight-binding model with s, p, d orbitals whose one-electron parameters are fitted to first-principles bulk band structure or obtained within an *ab initio* LMTO-tight-binding formulation. Within the one-electron approximation of Section 2.2, we write the Hamiltonian for the magnetic trilayer of Figure 7, in the form

$$H = H_0 + H_P \tag{17}$$

where the one-electron hopping term H_0 is given by

$$H_0 = \sum_{\boldsymbol{k}_\parallel \sigma} \sum_{m\mu,n\nu} t_{m\mu,n\nu}(\boldsymbol{k}_\parallel) c^\dagger_{\boldsymbol{k}_\parallel m\mu\sigma} c_{\boldsymbol{k}_\parallel n\nu\sigma} \tag{18}$$

and H_P contains on-site potentials. These are independent of spin in the spacer, but contain exchange splitting in the ferromagnets. The spin dependence of the exchange potentials in the two ferromagnets is chosen appropriately for their different directions of magnetization. In equation (18), $c^\dagger_{\boldsymbol{k}_\parallel m\mu\sigma}$ creates an electron in a Bloch state, with in-plane wave vector $\boldsymbol{k}_\parallel$ and spin σ, formed from a given atomic orbital μ in plane m. The easiest method of deriving an expression for the IEC within this formulation is to consider a pair of neighboring planes in the spacer (labeled by say n and $n-1$) and to initially 'switch off' the hoppings between them, so that the trilayer is 'cleaved' into two semi-infinite systems. The final expression for the IEC is independent of the position of the 'cleavage plane' within the spacer. Then the Hamiltonian may be written as follows:

$$\begin{aligned} H(\lambda) &= H_{\mathrm{L}} + H_{\mathrm{R}}(\theta) + \lambda H_{\mathrm{LR}} \qquad \text{where} \\ H_{\mathrm{LR}} &= \sum_{\boldsymbol{k}_\parallel \sigma} \sum_{\mu,\nu} t_{n-1\mu,n\nu}(\boldsymbol{k}_\parallel)\; c^\dagger_{\boldsymbol{k}_\parallel n-1\mu\sigma}\; c_{\boldsymbol{k}_\parallel n\nu\sigma} \end{aligned} \tag{19}$$

and H_{L} is the Hamiltonian for the LH semi-infinite system, with the magnetization of the LH ferromagnet in the (0, 0, 1) direction, and H_{R} is the Hamiltonian for the RH semi-infinite system, with the magnetization of the RH ferromagnet in the $(\sin\theta, 0, \cos\theta)$ direction (see Figure 7). The parameter λ represents a coupling constant between the LH and RH systems, so that $H(0)$ corresponds to a cleaved system with no hopping across the cleavage plane, and $H(1) = H$ is the original Hamiltonian.

There are a number of ways in which a formula for the IEC can be derived. One can use a generalization of the energy difference method given in Mathon *et al*. (1997) or the torque method described in Section 3 of this chapter (see also Edwards, 2002) or a method based on Lloyd's formula (Drchal, Kudrnovsky, Turek and Weinberger, 1996). Alternatively, the coupling constant integration method may be used (e.g., Doniach and Sondheimer, 1998). In this case, the change in thermodynamic potential between the cleaved and uncleaved system, obtained by turning on the coupling constant λ, is given by $\delta\Omega = \int_0^1 \langle H_{\mathrm{LR}}\rangle_\lambda \, \mathrm{d}\lambda$, where $\langle H_{\mathrm{LR}}\rangle_\lambda$ denotes the thermal average in the grand canonical ensemble, calculated using the Hamiltonian $H(\lambda)$. The thermodynamic potential of the cleaved system is independent of θ so that the IEC can be written (see equation (10))

$$J(\theta) = \Omega(0) - \Omega(\theta) = \delta\Omega(0) - \delta\Omega(\theta) \tag{20}$$

which after some algebra can be expressed in the form

$$\begin{aligned} J(\theta) = \frac{-1}{\pi} \sum_{\boldsymbol{k}_\parallel} \mathrm{Im} \int dE f(E-\mu) \\ \times \mathrm{Tr} \ln \left(1 - \frac{1-\cos\theta}{2}\mathbf{M}\right) \end{aligned} \tag{21}$$

where

$$\begin{aligned} \mathbf{M} = \mathbf{1} - (\mathbf{1} - \boldsymbol{g}_{\mathrm{R}}^{\uparrow}\boldsymbol{t}^\dagger \boldsymbol{g}_{\mathrm{L}}^{\uparrow}\boldsymbol{t})^{-1}(\mathbf{1} - \boldsymbol{g}_{\mathrm{R}}^{\uparrow}\boldsymbol{t}^\dagger \boldsymbol{g}_{\mathrm{L}}^{\downarrow}\boldsymbol{t})(\mathbf{1} - \boldsymbol{g}_{\mathrm{R}}^{\downarrow}\boldsymbol{t}^\dagger \boldsymbol{g}_{\mathrm{L}}^{\downarrow}\boldsymbol{t})^{-1} \\ \times(\mathbf{1} - \boldsymbol{g}_{\mathrm{R}}^{\downarrow}\boldsymbol{t}^\dagger \boldsymbol{g}_{\mathrm{L}}^{\uparrow}\boldsymbol{t}) \end{aligned} \tag{22}$$

Here, $f(E-\mu)$ is the Fermi function with chemical potential μ, and $\boldsymbol{g}_{\mathrm{L}}^{\sigma}$ and $\boldsymbol{g}_{\mathrm{R}}^{\sigma}$ are surface Green's functions (SGF) for the LH and RH cleaved systems with Hamiltonians H_{L} and H_{R}, respectively. These are matrices with elements $g_{\mu,\nu}$, where μ, ν label the orbitals, and the trace is over these indices. The spin index $\sigma = \uparrow, \downarrow$ refers to the majority and minority spin directions of the corresponding ferromagnet. $\boldsymbol{t}$ is a matrix with μ, ν elements $t_{n-1\mu,n\nu}$ and $\boldsymbol{t}^\dagger$ is its hermitian conjugate.

This form of the IEC was first given by Drchal, Kudrnovsky, Turek and Weinberger (1996), and when $\theta = \pi$ it reduces to the formula of Mathon *et al*. (1997). It is a particularly convenient expression, since the θ dependence is explicit, and does not occur in the calculation of $\mathbf{M}$. The

expansion of this formula in powers of $1-\cos\theta$ to determine the bilinear and biquadratic coupling has been discussed by Drchal, Kudrnovsky, Turek and Weinberger (1996).

Alternative expressions for the IEC have been given by Bruno (1995) and Stiles (1996b, 1999) in terms of reflection and transmission coefficients at interfaces, rather than Green's functions. The form for the IEC, which is usually considered in this approach is one valid in the limit of weak confinement. This approximation amounts to replacing a $\ln(1-X)$ term, similar to that in equation (21), by the leading term X in its power series expansion. The method is not very well adapted to accurate calculation of the IEC in real systems. Quantitative work along these lines for a real trilayer such as Co/Cu/Co(001) is usually restricted to calculation of reflection coefficients (Bruno, 1995), possibly followed by an uncontrolled estimate of the IEC using the weak-confinement approximation (Stiles, 1996b).

4.2 The stationary phase approximation (SPA)

Consider the integrand $F(E,\boldsymbol{k}_\parallel,\theta,l)=Tr\ln(1-\mathbf{M}(1-\cos\theta)/2)$ of equation (21). For each value of $E,\boldsymbol{k}_\parallel,\theta$, it can be shown that (see Umerski, 1997; Mathon and Umerski, 2006; Edwards, 2002) this can be expanded in a Fourier type series:

$$F(E,\boldsymbol{k}_\parallel,\theta,l)=\sum_{\vec{s}} c_{\vec{s}}\,e^{il\phi_{\vec{s}}} \qquad \text{where}$$
$$\phi_{\vec{s}}\equiv 2(s_1k_{y1}+\cdots+s_Pk_{yP}) \qquad (23)$$

where $s_1,\ s_2,\ \ldots,\ s_P$ are integers and $\{\pm k_{y1},\pm k_{y2},\ldots\pm k_{yP}\}$ are the $2P$ solutions of the perpendicular wave vector obtained from the bulk spacer dispersion relation $E(\boldsymbol{k}_\parallel,k_y)=E$. To simplify the present discussion, we restrict ourselves to the case of Fermi surfaces which are symmetric about the $k_y=0$ plane, but see Edwards (2002) for the general case. When the Fermi surface has a single sheet, there are just two solutions $\pm k_y$, and so $\phi_s\equiv 2sk_y$. In this case, $F(E,\boldsymbol{k}_\parallel,\theta,l)$ is a periodic function of the spacer thickness l, with period π/k_y, and the expansion is a standard Fourier series. This case is closely related to the periodicity of the integrand of equation (11), and the expansion corresponds to that of equation (12).

For multisheet Fermi surfaces, the integrand F is said to be a quasiperiodic function of the spacer thickness l, with periods $\pi/k_{y1},\pi/k_{y2},\ldots,\pi/k_{yP}$. Evaluation of the Fourier-like coefficients in this case requires use of the matrix Möbius transformation (Umerski, 1997), and we refer the interested reader to the review articles of Mathon and Umerski (2006) and Edwards (2002). Equation (23) can be substituted into equation (21) for the IEC, and the same argument following that of equation (12) of Section 3 can be applied to obtain a SPA of the IEC. The result is a formula for the exchange coupling, which is asymptotically exact in the limit of large spacer thickness ($l\to\infty$):

$$J(l)=-\frac{(2\pi)^2k_BT}{2lA_{BZ}}\sum_{\vec{s}}\sum_{\mathbf{k}^0_{\parallel\vec{s}}}\mathrm{Re}$$
$$\times\left(\frac{\tau c_{\vec{s}}e^{il\phi_{\vec{s}}}}{|\det(\partial^2\phi_{\vec{s}})|^{1/2}\sinh(\pi k_BT[l\phi'_{\vec{s}}+\psi'_{\vec{s}}])}\right)\Bigg|_{\mu,\mathbf{k}^0_{\parallel\vec{s}}} \qquad (24)$$

Here, $(\partial^2\phi_{\vec{s}})$ is the 2×2 Hessian matrix $(\partial^2\phi_{\vec{s}})_{\alpha,\beta}\equiv\partial^2\phi_{\vec{s}}/\partial k_{\parallel\alpha}\partial k_{\parallel\beta}$, and $\tau=i$ when both eigenvalues of the Hessian matrix are positive, $\tau=-i$ when they are negative, and $\tau=1$ when they have opposite signs. $\phi'_{\vec{s}}\equiv \mathrm{d}\phi_{\vec{s}}/\mathrm{d}E$, $\psi'_{\vec{s}}$ is the derivative of the phase of $c_{\vec{s}}$ with respect to E, and A_{BZ} is the area of the in-plane Brillouin zone. All quantities in equation (24) are evaluated at the chemical potential of the spacer $E=\mu$, and the sum over $\{\mathbf{k}^0_{\parallel\vec{s}}\}$ is over the set of points in the two-dimensional in-plane Brillouin zone at which $\phi_{\vec{s}}(\mathbf{k}_\parallel)$ is stationary.

In the case of a single sheet Fermi surface which is symmetric about the $\boldsymbol{k}_\parallel$ plane, these stationary points coincide with the stationary points of the spacer Fermi surface (i.e., where $k_y(E=\mu,\boldsymbol{k}_\parallel)$) is stationary), and the periods are related to the spanning vectors of the Fermi surface. In the case of Co/Cu/Co(001), these are k_y^B and k_y^N depicted in Figure 4, and equation (24) was used to determine the dashed SPA to Figure 5. For multisheet Fermi surfaces, the stationary points of $\phi_{\vec{s}}$ will include all RKKY periods derived from the extrema of Fermi-surface spanning vectors. However, additional periods arising from more complex linear combinations of Fermi-surface wave vectors are also obtained. In general, these are not merely harmonics of RKKY periods. Such non-RKKY periods even occur in simple models, for example, in a single orbital fcc (110) tight-binding model (Ferreira, d'Albuquerque e Castro, Edwards and Mathon, 1996), as well as in more complex realistic systems such as Fe/Mo/Fe(001) (Edwards, 2002).

It should be noted that a fundamental assumption of the SPA is that the coefficients $c_{\vec{s}}$ of equation (23) are slowly varying functions of the energy, near E_F. Whereas this is found to be true for many realistic systems, Costa, d'Albuquerque e Castro and Muniz (1999) have found that this is not the case for Fe/Au/Fe and Fe/Ag/Fe(001), since electrons at the Fermi energy are very close to deconfinement, and hence their wave functions vary rapidly as a function of energy. As a result, the SPA only becomes an accurate approximation in these systems for extremely thick spacer layers.

5 BIQUADRATIC EXCHANGE COUPLING

5.1 Measurement

Consider two coupled magnetic layers with, for simplicity, the same thickness and magnetization M_0. The magnetocrystalline anisotropy is assumed to have fourfold symmetry and a magnetic field of magnitude H is applied in the plane of the layer (zx plane) along an easy axis (z axis). The magnetic moments of the two layers lie in plane in directions $\mathbf{m}_1 = (\sin\theta_1, 0, \cos\theta_1)$ and $\mathbf{m}_2 = (\sin\theta_2, 0, \cos\theta_2)$. The total energy per unit interfacial area may be written as

$$E_{\text{tot}} = -M_0 D(\cos\theta_1 + \cos\theta_2)H - \frac{KD}{8}(\cos 4\theta_1 + \cos 4\theta_2) - \bar{J}_1\cos(\theta_1 - \theta_2) - \bar{J}_2\cos^2(\theta_1 - \theta_2) \tag{25}$$

where K is the anisotropy constant, $\bar{J}_1$, $\bar{J}_2$ are the bilinear and biquadratic couplings and D is the ferromagnet thickness. In this section, we distinguish between the quantities $\bar{J}_1$, $\bar{J}_2$ which enter E_{tot} for a real, generally imperfect, sample and the couplings J_1, J_2 which pertain to an ideal system with perfect interfaces. For $\bar{J}_2 < 0$ the biquadratic term favors noncollinear alignment of the magnetizations, whereas for $\bar{J}_2 > 0$ it merely reinforces collinear alignment and has essentially no influence on the magnetic properties of the system. Consequently, only negative values of $\bar{J}_2$ are measurable. Following Demokritov (1998), we assume that anisotropy is dominant, this being a common experimental situation. In this case, $\mathbf{m}_1$ and $\mathbf{m}_2$ cannot deviate from the easy axes and only three ground state configurations are possible: FM, AF, and perpendicular (90° coupling). For $H \geq 0$, the corresponding energies E_{tot} are (ignoring the constant term $-KD/4$) $E_{\text{FM}} = -\bar{J}_1 - \bar{J}_2 - 2M_0DH$, $E_{\text{AF}} = \bar{J}_1 - \bar{J}_2$ and $E_{90^\circ} = -M_0DH$, respectively. The most important case is when $\bar{J}_1 < \bar{J}_2 < 0$ so that $\bar{J}_1 - \bar{J}_2 < 0$ and $-\bar{J}_1 - \bar{J}_2 > 0$. The energies E_{FM}, E_{AF}, E_{90° for this case are plotted schematically as functions of H in Figure 9. Here $H_1 = -(\bar{J}_1 + \bar{J}_2)/M_0D$ and $H_2 = -(\bar{J}_1 - \bar{J}_2)/M_0D$. As H increases, transitions occur from the AF configuration to the 90° one at $H = H_2$ and then to the FM configuration at $H = H_1$. The corresponding steps in the normalized magnetization component $M_{||}/M_s$ in the direction of the field, where M_s is the saturation value in the FM state, are shown for a real Fe/Ag/Fe structure in Figure 10 (Schäfer *et al.*, 1995).

The length of the plateau with $M_{||} = M_s/2$ is $H_p = H_1 - H_2 = -2\bar{J}_2/M_0D$ and both $\bar{J}_1$ and $\bar{J}_2$ can be deduced from the observed fields H_1 and H_2.

If $\bar{J}_2 < 0$, $|\bar{J}_1| < -\bar{J}_2$ it is easily seen that the ground state is the 90° one. In this case, only one step occurs, at $H = H_1$, so that only the sum $\bar{J}_1 + \bar{J}_2$ is determined.

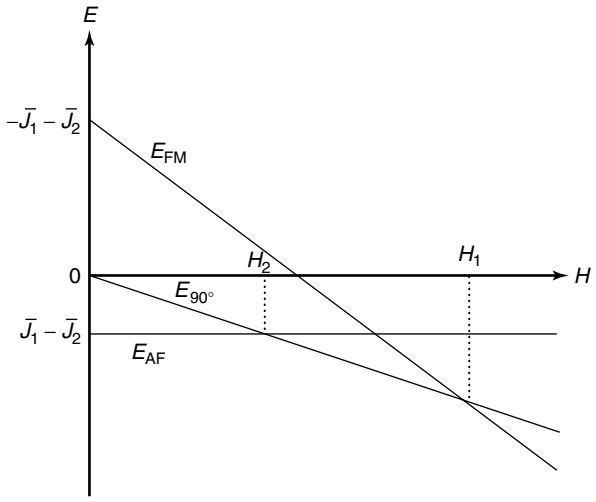

Figure 9. The energies E_{FM}, E_{AF}, E_{90°, defined in the text, schematically plotted as a function of the applied field H, for the case $\bar{J}_1 < \bar{J}_2 < 0$.

5.2 Mechanisms

There is no general theory of biquadratic coupling, which can be applied to all systems. We shall consider four different mechanisms and discuss their limits of applicability.

5.2.1 The intrinsic mechanism

In Section 3, we presented an exact expression (equation (14)) for the exchange energy of a trilayer, as a function of the angle θ between the magnetizations of the magnetic layers, for a simple free-electron model with perfect interfaces. The $s = 1$ term in equation (14) gives the

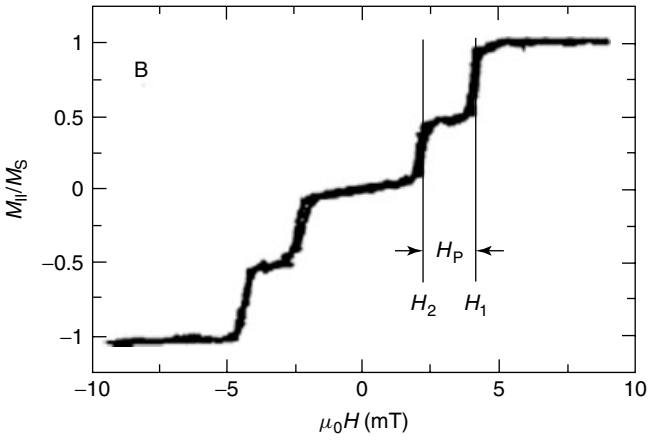

Figure 10. A $M(H)$ loop with hysteresis effects removed (anhysteretic measurement), for an antiferromagnetically coupled Fe/Ag/Fe structure with Ag thickness of 18.5 Å. (Reprinted with permission from Schäfer *et al.*, 1995, © 1995, American Institute of Physics.)

fundamental oscillation of the exchange coupling as a function of the spacer thickness with period π/k_F, where k_F is the Fermi wave vector in the spacer. The biquadratic exchange first occurs in the $s = 2$ harmonic, and, consequently, is much smaller than the bilinear coupling (Edwards, Ward and Mathon, 1993). The same result is obtained in several other model calculations (Erickson, Hathaway and Cullen, 1993; Slonczewski 1993a; d'Albuquerque e Castro, Ferreira and Muniz, 1994). This feature of simple models seems to be a general property and appears in first-principles calculations for real systems (Drchal, Kudrnovsky, Turek and Weinberger, 1996). One may conclude that for ideal multilayers with perfect interfaces, the biquadratic coupling is an order of magnitude smaller than the bilinear coupling. Thus observation of biquadratic coupling $\bar{J}_2$ with magnitude comparable to that of the bilinear coupling $\bar{J}_1$ is indicative of deviations from an ideal structure, for example, interface roughness.

In this section, we shall discuss how interface roughness can result in intrinsic biquadratic coupling becoming much more important owing to the observed bilinear coupling being strongly reduced from its intrinsic value. In the next section, we describe Slonczewski's (1991) 'fluctuation mechanism' of biquadratic coupling, which also relies on interface roughness. The couplings, which arise from intrinsic and fluctuation mechanisms are considered additive. For both mechanisms, it is important that the oscillatory intrinsic bilinear coupling $J_1(N)$, where N is the spacer thickness in MLs, has a dominant short-period component, the period being close to 2 ML. Strong biquadratic coupling is most commonly observed in systems with Cu, Au, Ag, and Cr spacers (Demokritov, 1998) of which all except Ag have such a dominant short-period component. Another exception seems to be Fe/Al/Fe which is discussed in Section 5.2.3.

Drchal, Kudrnovsky, Turek and Weinberger (1996) calculated the intrinsic bilinear and biquadratic coupling, $J_1(N)$ and $J_2(N)$, respectively, for Co/Cu/Co(001) trilayers with Cu thickness N ranging from 1 to 50 ML, and with Co thicknesses of 5 ML and infinity. We shall concentrate on the case of thick Co layers. The bilinear coupling $J_1(N)$ is dominated by a short-period (2.53 ML) oscillation, and the results are in close agreement with those of Mathon *et al*. (1997). The long-period contribution associated with the belly part of the Cu Fermi surface is negligible for thick Co layers. The intrinsic biquadratic coupling $J_2(N)$ is an order of magnitude smaller that $J_1(N)$ and oscillates about zero with a period of about 5 ML. This period is easily understood as follows. $J_2(N)$ oscillates as an $s = 2$ harmonic so its period should be $2.53/2 = 1.27$ ML. However, since N is an integer, an oscillatory term $\sin(2\pi N\lambda^{-1}) = -\sin(2\pi N(1-\lambda^{-1}))$, which corresponds to an actual period of $\lambda/(\lambda-1) = 4.7$ ML for $\lambda = 1.27$. This effect of a discrete lattice on the observed period is known as the *aliasing effect*, and is also described in Section 2.3. To model the effect of interfacial roughness Drchal, Kudrnovsky, Turek and Weinberger (1996), following Kudrnovsky *et al*. (1996), introduced a discrete probability distribution $w(N-P)$ specifying the probability that the spacer layer is P ML thick for a nominal thickness N. Thus, the observed bilinear and biquadratic couplings are related to the intrinsic ones by

$$\bar{J}_{1,2}(N) = \sum_P w(N-P) J_{1,2}(P) \tag{26}$$

Kudrnovsky *et al*. (1996) assumed a distribution of the form $w(0) = (1-2r)^2 + 2r^2$, $w(\pm 1) = 2r(1-2r)$, $w(\pm 2) = r^2$ and $w(m) = 0$ for $|m| > 2$. This corresponds to each Co/Cu interface deviating from its nominal position by ± 1 ML, each with probability r, the steps on the two interfaces being uncorrelated. For the averaging process in equation (26) to be valid, the terrace widths between the steps must not be too small, certainly not less than the spacer thickness. On the other hand, the terrace widths must not be larger than the width of a domain wall in the Co layers ($\sim$100 nm). If this condition is not satisfied the Co magnetizations will adopt the energetically favorable AF or FM configurations locally and the concept of exchange coupling between magnetic layers with essentially uniform magnetization breaks down.

The averaging process of equation (26) essentially washes out the fundamental short-period oscillation of $J_1(P)$, but the $s = 2$ harmonic with period 4.7 ML is largely unaffected. The same applies to $J_2(P)$ so that $\bar{J}_2(N) \approx J_2(N)$. Kudrnovsky *et al*. (1996) calculated $\bar{J}_1(N)$ with a reasonable roughness parameter $r = 0.25$ and it is found to oscillate with a period of about 5 ML, as expected, and with an amplitude about one-fifth of the short-period amplitude in $J_1(N)$ (actually the calculation was performed for Co thickness of 5 ML where the long-period oscillation in $J_1(N)$ is not completely negligible, as it is for thick Co layers. Thus, $\bar{J}_1(N)$ has a contribution from the long-period oscillation period 5.7 ML, in addition to that from the short-period harmonic). Clearly, the effect of interface roughness is to reduce the intrinsic bilinear coupling $J_1(N)$ by a substantial factor to its observable value $\bar{J}_1(N)$; $J_2(N)$ is hardly affected so that $\bar{J}_1(N)$ and $\bar{J}_2(N)$ become comparable in magnitude. Drchal, Kudrnovsky, Turek and Weinberger (1996) investigated the total exchange energy for thick Co layers and found that the 90° coupling is never the ground state configuration for $r \leq 0.1$. However, for $r = 0.2$ and $r = 0.25$, 90° coupling occurs for some Cu thicknesses.

The general belief that intrinsic biquadratic coupling is too small to account for observed values is based on results for simple models with ideal interfaces. The calculations of Drchal, Kudrnovsky, Turek and Weinberger (1996) for Co/Cu/Co(001) with the effect of rough interfaces taken into

account, show that this is not always the case. In fact it is interesting to return to the free-electron model of Section 3, but consider the effect of a lattice with interplanar spacing d. Then $J(\theta)$ is only observed at discrete spacer thicknesses $l = Pd$ taking values $J(P, \theta)$. The fundamental period of the bilinear coupling is π/k_F, where k_F is the Fermi wave vector, and suppose that this is close to $2d$ so that the $s = 1$ term in equation (14) oscillates with a period close to 2 ML. The $s = 2$ term has a long period when observed at discrete spacer thicknesses Nd, due to the aliasing effect. Suppose that roughness subjects $J(P, \theta)$ to an averaging of the type specified in equation (26). The $s = 1$ term in $J(P, \theta)$ is thus largely eliminated and the observed exchange energy $\bar{J}(N, \theta)$ is dominated by the $s = 2$ term with angular dependence $(3 - 2\cos\theta - \cos^2\theta)/4$. Hence $\bar{J}_1(N) = 2\bar{J}_2(N)$ and for spacer thicknesses N with $\bar{J}_1(N) < 0$, corresponding to AF coupling, we have $\bar{J}_1(N) < \bar{J}_2(N) < 0$ which leads to a $M(H)$ curve of the type shown in Figure 10. Further work, both experimental and theoretical, is required on biquadratic coupling as a function of spacer thickness.

5.2.2 *The fluctuation mechanism*

We once again consider a trilayer in which the intrinsic bilinear coupling $J_1(N)$ oscillates with a dominant short period of approximately 2 ML. At a ML step on an interface J_1 therefore changes sign taking values $\pm\Delta J$. Suppose that the terrace width L between steps is considerably less than the width of the domain wall in a magnetic layer. The magnetization in each magnetic layer can therefore only respond to the changing sign of the bilinear coupling by small deviations from its average direction. Slonczewski (1991) showed that the energy of the system is minimized when these average directions are at right angles, that is, 90° coupling is favored.

Figure 11 shows a section of the trilayer where the FM layers have thicknesses D and D'. The corresponding magnetization vectors $\mathbf{M}$ and $\mathbf{M}'$ are oriented in the $x - z$ plane at angles $\theta(y, z)$ and $\theta'(y', z)$ measured from a common axis. For simplicity a periodic structure is assumed with ML steps on one interface of the spacer creating terraces of constant width L. The intrinsic bilinear coupling $J_1(z)$ is therefore a periodic step function of the form

$$J_1(z) = \Delta J \ \ \mathrm{sgn}\left[\sin\left(\frac{\pi z}{L}\right)\right] \approx \frac{4\Delta J}{\pi}\sin\left(\frac{\pi z}{L}\right) \quad (27)$$

The last expression approximates $J_1(z)$ by the first term in its Fourier expansion and only leads to a small error in the final result (Slonczewski, 1991). The sum of the exchange energies per unit area due to interlayer coupling and intralayer FM stiffness may be written as

$$W = \frac{1}{2L}\int_0^{2L} \mathrm{d}z\Big(-J_1(z)\cos(\theta(0,z) - \theta'(0,z)) + A\int_0^D \mathrm{d}y \times(\theta_y^2 + \theta_z^2) + A'\int_0^{D'} \mathrm{d}y'\left(\theta'^2_{y'} + \theta'^2_z\right)\Big) \quad (28)$$

where A, A' are the Bloch wall stiffnesses of the magnetic layers. At the outer surfaces $y = D$ and $y' = D'$ the magnetizations are free so that we have boundary conditions $\theta_y(D, z) = \theta'_{y'}(D', z) = 0$. Minimization of W with respect to variations in $\theta(y, z)$, $\theta'(y', z)$ leads to two-dimensional Laplace equations for θ, θ' with boundary conditions relating $\theta_y(0, z)$, $\theta'_{y'}(0, z)$ to $J_1(z)$. The boundary conditions are

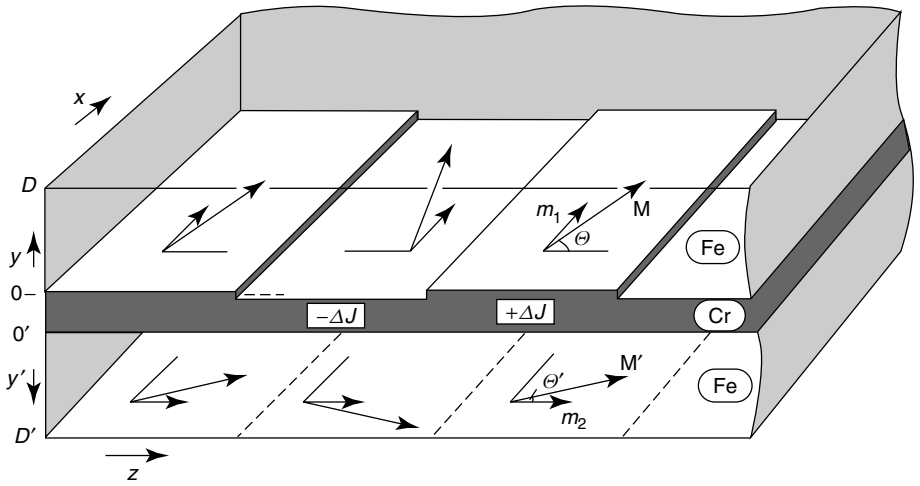

Figure 11. Section of an epitaxial magnetic trilayer, with periodic ML interface terraces. Arrows schematically indicate the fluctuations in magnetizations $\mathbf{M}(y, z)$ and $\mathbf{M}'(y', z)$ in the $x - z$ plane due to fluctuations in the exchange coupling $J(z)$. (Reprinted figure from Slonczewski, J.C., (1991), *Phys. Rev. Lett.*, **67**, 3172–3175. © 1991, by the American Physical Society.)

linearized by assuming that deviations of θ, θ' from their average values $\bar{\theta}$, $\bar{\theta'}$ are small. The result for $\theta(y, z)$ is

$$\theta = \overline{\theta} - \frac{2L\Delta J}{\pi^2 A \sinh\left(\frac{\pi D}{L}\right)} \sin\left(\frac{\pi z}{L}\right) \cosh\left(\frac{\pi}{L}(D-y)\right) \times \sin(\overline{\theta} - \overline{\theta}') \tag{29}$$

with a similar expression for θ'. On introducing these expressions into equation (28) we obtain an energy of the biquadratic form $W = \bar{J}_2[1 - \cos^2(\overline{\theta} - \overline{\theta}')]$ with

$$\bar{J}_2 = -\frac{4(\Delta J)^2 L}{\pi^3 A} \coth\left(\frac{\pi D}{L}\right) \tag{30}$$

We have assumed here equivalent FM layers with $A = A'$, $D = D'$. We note that $\bar{J}_2 < 0$ so that 90° coupling is always favored by the fluctuation mechanism. It is important to stress that ΔJ is the amplitude of the short-period *intrinsic* bilinear coupling J_1 which is not observable in the presence of the roughness responsible for the observed $\bar{J}_2$. Slonczewski (1991) pointed out that measurement of $\bar{J}_2$ in specimens with rough interfaces can therefore give information about the short-period coupling in the ideal system, as long as the terrace width L can be reasonably estimated and the fluctuation mechanism makes the dominant contribution to $\bar{J}_2$. The idea has been cleverly implemented by Heinrich and Cochran (1993) to deduce $J_1(N)$ for bcc Fe/Cu/Fe(001) from the observed $\bar{J}_1(N)$, $\bar{J}_2(N)$. In deriving equation (29) and hence (30), it was required that $\theta - \overline{\theta} \ll \pi/2$ which implies $|\bar{J}_2| \ll \Delta J$. Clearly until this condition breaks down, $|\bar{J}_2|$ is an increasing function of the terrace width L. If $D \ll L$, $|\bar{J}_2| \propto L^2$ and the condition $|\bar{J}_2| \ll \Delta J$ implies $L \ll \pi l$ where $l = \frac{\pi}{2}\sqrt{AD/\Delta J}$ is the domain wall width in the FM layer, interlayer coupling playing the role of anisotropy (Pierce, Unguris, Celotta and Stiles, 1999). Ribas and Dieny (1993) have carried out a numerical study of the fluctuation mechanism, with magnetocrystalline anisotropy included in the magnetic layers. For a model of Fe/Cr/Fe in which one of the Fe layers is thin ($D = 10$ nm) they find a crossover from 90° coupling of the Slonczewski type when $L = 25$ nm, to the appearance in this layer of domains, in which the Fe magnetization adopts the energetically favorable AF or FM configurations locally, for $L = 125$ nm. This is in accordance with a domain wall width of about 50 nm. Moser, Berger, Margulies and Fullerton (2003) have studied this type of crossover experimentally. If the magnetic layers are both thick ($D \gg L$), $|\bar{J}_2| \propto L$ with a condition for validity of equation (30) of the form $L \ll \pi^2 A/(4\Delta J)$. It follows from equation (29) that the magnetization only deviates from a uniform direction within a distance L of the interface with the spacer.

5.2.3 *'Loose spin' model*

Some measurements of $\bar{J}_2$ in Fe/Al/Fe (Gutierrez, Krebs, Filipkowski and Prinz, 1992) and Fe/Au/Fe (Fuss, Wolf and Grünberg, 1992) have shown that it decreases much more rapidly with increasing temperature than can be easily understood within the intrinsic or fluctuation mechanisms. In an attempt to explain this behavior Slonczewski (1993b) proposed that the source of the biquadratic coupling was the polarization of magnetic impurities located in the spacer. A given impurity with spin $\mathbf{S}$ ('loose spin') has an effective Hamiltonian $(\mathbf{U}_1 + \mathbf{U}_2).\mathbf{S}/S$ where $\mathbf{U}_1 = U_1\mathbf{m}_1$, $\mathbf{U}_2 = U_2\mathbf{m}_2$ are the exchange fields due to coupling with the magnetic layers. $\mathbf{m}_1$ and $\mathbf{m}_2$ are unit vectors in the magnetization directions of the magnetic layers. U_1 and U_2 are fields of the RKKY type and therefore fluctuate in sign as the spatial position of the impurity is varied. The energy levels of the impurity are $-mU(\theta)/S$ with $m = -S, -S+1, \ldots, S$, and

$$U(\theta) = |\mathbf{U}_1 + \mathbf{U}_2| = (U_1^2 + U_2^2 + 2U_1U_2\cos\theta)^{1/2} \tag{31}$$

where θ is the angle between $\mathbf{m}_1$ and $\mathbf{m}_2$ as usual. It follows that the free energy of the loose spin at temperature T is

$$f(T,\theta) = -k_B T \ln\left(\frac{\sinh\left([1+(2S)^{-1}]U(\theta)/(k_B T)\right)}{\sinh\left(U(\theta)/(2Sk_B T)\right)}\right) \tag{32}$$

and at $T = 0$, $f(0, \theta) = -U(\theta)$. Slonczewski does not carry out a configurational average over impurity positions, but assumes that each impurity experiences the same exchange fields U_1, U_2. The macroscopic free energy F per unit area is then $F(T, \theta) = \rho f(T, \theta)$, where ρ is the areal density of the impurities. This may be written approximately in the usual form

$$F(T,\theta) = F(T,\pi/2) - \bar{J}_1^{LS}\cos\theta - \bar{J}_2^{LS}\cos^2\theta \tag{33}$$

either by expanding in powers of $\cos\theta$, for small $\cos\theta$, or by choosing $\bar{J}_1^{LS}$, $\bar{J}_2^{LS}$ so as to reproduce $F(T, 0)$ and $F(T, \pi)$ correctly. Either way, at $T = 0$, we find that the sign of $\bar{J}_1^{LS}$ is that of U_1U_2, whereas $\bar{J}_2^{LS}$ is always positive. Hence the failure to take a configurational average is qualitatively not so serious for $\bar{J}_2^{LS}$, the main object of interest. On the other hand, $\bar{J}_1^{LS}$ fluctuates in sign for different impurity positions so will tend to average to zero.

Slonczewski fitted his theory to the observed temperature dependence of $\bar{J}_2$ in Fe/Al/Fe and Fe/Au/Fe in two ways. He first assumed that most of the impurities were positioned far from the interface with $|U_1| \approx |U_2|$. However, exchange fields $|U_{1,2}|/k_B \sim 250 - 400$ K were required, which is unrealistically large. Slonczewski's second type of fit is based on the assumption that the loose spins actually comprise the

last atomic layer of the ferromagnets. Then one exchange field is very large and the other small. The concept of independent loose spins at the surface of an itinerant electron ferromagnet is of doubtful validity.

Slonczewski (1993b) pointed out that a system to which the loose spin model would apply could be constructed by deliberate deposition of magnetic impurities in an atomic layer within the spacer. Following earlier work by Heinrich and Cochran (1993) this has been achieved by Schäfer *et al*. (1995) in Fe/Ag/Fe with a submonolayer of Fe in the center of the Ag spacer. A contribution to biquadratic coupling proportional to the Fe concentration and rapidly decreasing in temperature was observed.

Heinrich and Cochran (1993) proposed an alternative source of strongly temperature dependent biquadratic coupling in Fe/Al/Fe. Interfaces in this structure are known to be rough (Gutierrez, Krebs, Filipkowski and Prinz, 1992), and, with spacer thicknesses of 6–8 ML, magnetic bridges or pinholes are possible. If these exist the exchange coupling would vary between FM through the pinholes and AF elsewhere (the overall bilinear coupling is observed to be AF). If the spacing between pinholes is less than a domain wall width in an Fe layer, the Slonczewski (1991) fluctuation mechanism for 90° coupling could operate. The rapid decay of $\bar{J}_2$ with increasing temperature would be associated with the decay of magnetization in the thin magnetic bridge.

5.2.4 *Magnetic-dipole mechanism*

The magnetic-dipole mechanism is a variant of the fluctuation mechanism where the spatially fluctuating coupling between rough magnetic layers is not due to exchange coupling but due to a magnetic field. A perfect infinite magnetic layer produces a magnetic field outside itself only within a range of the order of the lattice constant (Heinrich *et al*., 1988). However, a rough magnetic layer, with a periodic array of terraces of width L (as in Figure 11), produces a magnetic field which oscillates about zero with lateral periodicity $2L$ and which has a range of the order of $2L$ (Demokritov, Tsymbal, Grünberg and Zinn, 1994). The effect on the magnetization of a smooth magnetic layer, separated from the rough layer by a spacer of thickness t with $t < L$ is therefore similar to that of the fluctuating exchange field in the fluctuation mechanism. Thus a positive contribution to $\bar{J}_2$ is obtained which increases with L until the theory breaks down for L of the order of a domain wall width, just as in the fluctuation mechanism. The two mechanisms may sometimes be difficult to distinguish in practice. Rücker *et al*. (1995) claim to have shown that the magnetic-dipole mechanism is the source of the biquadratic coupling in their rough Fe/Au/Fe trilayers. However, they eliminate the fluctuation mechanism on the grounds that the predicted $\bar{J}_2$ is too small. It is now known (Unguris, Celotta and Pierce, 1997) that the amplitude of the short-period oscillation in J_1 (ΔJ in equation (27)) is at least five times larger than their estimate, which increases their estimate of the contribution of the fluctuation mechanism to $\bar{J}_2$ by a factor of 25. It is thus of the same magnitude as their estimated magnetic-dipole contribution.

6 TEMPERATURE DEPENDENCE OF INTERLAYER EXCHANGE COUPLING

In earlier sections, we noted the temperature dependence of IEC owing to single-particle excitations around the Fermi level. The bulk spacer Fermi surface is given by $E(\boldsymbol{k}_\parallel, k_y) = \mu$, where $E(\boldsymbol{k}_\parallel, k_y)$ defines the bulk band structure with $\boldsymbol{k}_\parallel$ in the plane of the layers and k_y in the perpendicular direction. Consider the simplest case where, for a given $\boldsymbol{k}_\parallel$, there are just two points $k_y = \pm k(\boldsymbol{k}_\parallel)$ on the Fermi surface. In the limit of large l, where l is the spacer thickness, the bilinear exchange coupling is a sum of oscillatory terms with periods determined by extremal values of k_y (see equation (24)). For each period λ there is a series of harmonics $s = 1, 2, \ldots$. The bilinear exchange coupling may be written as

$$J_1(l, T) = \sum_{\lambda, s} J_{1\lambda s}(l, 0)\, f_{\lambda s l}(T) \tag{34}$$

where

$$f_{\lambda s l}(T) = \frac{T/T_{\lambda s l}}{\sinh(T/T_{\lambda s l})} = 1 - \frac{1}{6}\left(\frac{T}{T_{\lambda s l}}\right)^2 + \cdots \tag{35}$$

with

$$k_{\mathrm{B}} T_{\lambda s l} = \pi^{-1}(2 l s k'_{y\lambda} + \psi'_{\lambda s})^{-1} \tag{36}$$

Here $k'_{y\lambda} = \mathrm{d}k_y/\mathrm{d}E = (\hbar v_{\mathrm{F}\lambda})^{-1}$ where $v_{\mathrm{F}\lambda}$ is the Fermi velocity at the relevant extremal point of the Fermi surface. The $\psi'_{\lambda s}$ term, which is the energy derivative of the phase of the relevant coefficient in the Fourier expansion of the spectral density, is zero for the simple parabolic band model with infinite exchange splitting in the ferromagnets, considered in Section 3 (compare equation (36) with equation (16)). In that case there is only one period and $T_{\lambda s l}$ is determined entirely by the spacer Fermi-surface velocity v_{F}. However, d'Albuquerque e Castro, Mathon, Villeret and Umerski (1996) showed that $\psi'_{\lambda s}$ can become large when the condition for confinement of electrons of one spin is just satisfied. They showed that this 'confinement mechanism' for decreasing $T_{\lambda s l}$, which depends on the spacer-ferromagnet interface, operates importantly in Co/Cu/Co(001). They also

showed that for a parabolic band model with perfect matching for one spin-channel, and complete confinement for the other spin-channel, $\psi'_{\lambda s} = s\psi'_{\lambda 1}$, and that this relationship is also satisfied to a good approximation in Co/Cu/Co. (In fact it can be proved rigorously that for nonmagnetic spacers with a single Fermi surface, this condition is exactly satisfied when there is exact matching between one of the spin bands in the ferromagnet and the spacer.) Hence, even in the presence of the confinement mechanism, $T_{\lambda sl} \simeq s^{-1} T_{\lambda 1 l}$. This means that an $s = 2$ harmonic of the oscillatory IEC varies more rapidly with temperature than the corresponding fundamental ($s = 1$). Consequently, the intrinsic biquadratic coupling varies more strongly with temperature than the bilinear coupling.

Combining equations (34) and (35) we find

$$J_1(l, T) = J_1(l, 0) f_e(T) = J_1(l, 0) \left[1 - \frac{1}{6} (T/T_l)^2 \ldots \right] \quad (37)$$

where

$$T_l^{-2} = \frac{\sum_{\lambda s} T_{\lambda s l}^{-2} J_{1\lambda s}(l, 0)}{\sum_{\lambda s} J_{1\lambda s}(l, 0)} \quad (38)$$

If the sign of the term $J_{1\lambda s}(l, 0)$ varies, cancellation can occur in the denominator of equation (38), so that T_l^{-2} can be much larger than any of the $T_{\lambda s l}^{-2}$. Hence T_l can be much smaller than one would expect from any of the Fermi velocities. In addition, it is possible for T_l^{-2}, the coefficient of T^2 in equation (37), to be negative so that the coupling increases with temperature. This occurs in calculations by Costa, d'Albuquerque e Castro and Muniz (1997a) for bcc Fe/Cu/Fe(001) with l corresponding to 13 ML. In this case, terms with three different periods and comparable amplitudes contribute to the coupling. In the usual experimental situation with rough interfaces T_l may differ markedly from its value for ideal interfaces when the ideal couplings $J_{1\lambda s}$ are replaced by averages of the type given by equation (26). The range of temperature over which an expansion like that in equation (35) is valid can be extended by using $x/\sinh x \simeq 1 - 0.15x^{1.82}$, which is an excellent approximation for $0 < x < 1$, in the above analysis. Another discussion of the temperature dependence of the IEC due to single-electron excitation is given by Drchal *et al.* (1999).

Cullen and Hathaway (1993) first pointed out another source of temperature dependence in IEC owing to thermal excitation of spin waves. They considered an effective Heisenberg model in which two FM films are coupled by a weak nearest-neighbor IEC J_I. They also considered a superlattice case of an infinite number of coupled films, but we shall restrict our attention here to the model of the trilayer. Cullen and Hathaway adopted a thermodynamic approach, involving the free energy of the system in different magnetic configurations, and recently Schwieger and Nolting (2004) have followed the same line. Almeida, Mills and Teitelman (1995), using the same model, adopted a dynamic approach involving a Hartree–Fock type of decoupling of the equation of motion for spin waves. Here, we use the method of coupling constant integration (e.g., Doniach and Sondheimer, 1998) to obtain a result which we can relate to those of Cullen and Hathaway (1993) and Almeida, Mills and Teitelman (1995).

The model Hamiltonian is $\mathcal{H}(1)$ where

$$\mathcal{H}(\gamma) = \mathcal{H}_0 - \gamma J_I \sum \mathbf{S}_{\mathrm{L}} \cdot \mathbf{S}_{\mathrm{R}} \quad (39)$$

and the sum is over nearest-neighbor pairs with site L in the interface plane of the LH magnet and site R in the interface plane of the RH magnet. We suppose that the magnetizations of the two magnetic layers are constrained to make an angle θ with each other. The change in free energy when J_I is turned on from zero is given exactly by

$$\delta F(\theta) = F(J_I) - F(J_I = 0) = -J_I \sum \int_0^1 \mathrm{d}\gamma \langle \mathbf{S}_{\mathrm{L}} \cdot \mathbf{S}_{\mathrm{R}} \rangle_\gamma \quad (40)$$

where the thermal average is to be calculated using the Hamiltonian equation (39). In the case of thick magnetic films and $J_I \ll J$, the bulk exchange parameter, the spins $\mathbf{S}_{\mathrm{L}}$ and $\mathbf{S}_{\mathrm{R}}$ are very weakly correlated, except at very low temperature where $k_{\mathrm{B}}T < J_I$. Hence $\langle \mathbf{S}_{\mathrm{L}} \cdot \mathbf{S}_{\mathrm{R}} \rangle_\gamma \simeq \langle \mathbf{S}_{\mathrm{L}} \rangle_{\gamma=0} \cdot \langle \mathbf{S}_{\mathrm{R}} \rangle_{\gamma=0}$ and $\delta F(\theta) = -J_I S^2 \cos\theta \;\; m_{\mathrm{L}}(T) m_{\mathrm{R}}(T)$, where $m_{\mathrm{L}}(T)$, $m_{\mathrm{R}}(T)$ are the reduced magnetizations in the free surface planes of the two ferromagnets, which may be of different materials. If, as assumed by Almeida, Mills and Teitelman (1995), the magnetic films are thick, $m_i(T) = 1 - c_i T^{3/2}$ $(i = L, R)$ and it is well known that $c_i = 2c'_i$, where the bulk magnetization varies as $M_i(T) = M_i(0)(1 - c'_i T^{3/2})$, in the spin-wave regime (Mills and Maradudin, 1967). This simple relation between surface and bulk T dependence breaks down if there is significant variation in the exchange parameters within the ferromagnet near its surface (Mathon, 1988). Thus for thick FM layers, the temperature dependence of IEC due to spin-wave excitations is approximately given by a factor $1 - 2\bar{c}T^{3/2}$, where $\bar{c} = (c_{\mathrm{L}} + c_{\mathrm{R}})/2$. The coefficient of $T^{3/2}$ is twice that found by Almeida, Mills and Teitelman (1995) using the equation of motion method. It appears that the quantity appearing in the equations of motion is different from the thermodynamical IEC, which would be measured by saturation fields (Schwieger and Nolting, 2004). When $k_{\mathrm{B}}T < D\pi^2/t^2$, where D is the spin-wave stiffness and t the thickness of a FM layer, two-dimensional behavior appears and the $T^{3/2}$ law does not apply. Cullen

and Hathaway (1993) consider thin FM layers where J_1, and dipolar coupling within each layer, play an important role in stabilizing two-dimensional ferromagnetism at finite T. Referring to equation (40) they effectively take $\langle \mathbf{S}_L.\mathbf{S}_R\rangle_\gamma = \langle \mathbf{S}_L.\mathbf{S}_R\rangle_{\gamma=1}$. They find that for ferromagnets with a thickness of one or two ML the IEC decreases linearly with T, except at extremely low temperature. If a phenomenological biquadratic coupling $-J_{12}\ (\mathbf{S}_i.\mathbf{S}_j)^2$ is introduced into the Heisenberg model, a similar analysis yields a temperature dependent biquadratic coupling $-J_{12}S^4\cos^2(\theta)\ (1-6\bar{c}T^{3/2})$ due to spin-wave excitations in thick FM layers.

Finally, we comment on how the two contributions to the T dependence of the IEC are to be combined. Since at low temperatures one-electron excitations and spin waves are essentially independent we expect, as proposed by Almeida, Mills and Teitelman (1995), that the total T dependence is determined by a product of an electronic factor $f_e(T)$ and a suitable spin-wave factor.

The attribution of experimentally observed T dependence of IEC to electronic or spin-wave factors is sometimes confused by the fact that $x/\sinh x \simeq 1.025 - 0.175x^{3/2}$ is an excellent approximation for $0.4 < x^{3/2} < 2$. An important distinction is that the spin-wave factor $1-2\bar{c}T^{3/2}$ is independent of spacer thickness, whereas the electronic factor $f_e(T)$ has, in general, a strong dependence on l (equations (36)–(38)). Thus in work on IEC in $Ni_7/Cu_N/Co_2/Cu(001)$ trilayers, Lindner and Baberschke (2003a,b) found a much more rapid temperature dependence for $N = 9$ than for $N = 5$. Nevertheless, on the basis of linear $T^{3/2}$ plots, they ascribe the main source of the T dependence to spin-wave excitation. Actually pure $T^{3/2}$ behavior is not expected for such a thin Co layer. The authors dismiss a reasonable fit of the $(T/T_l)/\sinh(T/T_l)$ type, with $T_l = 120\,\mathrm{K}$ for $N = 9$, on the grounds that T_l is much smaller than expected from Fermi velocities in Cu. A similar problem is reported by Persat and Dinia (1997). However, we have discussed how T_l may be strongly reduced both by the confinement mechanism and by cancellations in the sums of equation (38). Such cancellation may be strongly influenced by roughness which, as in the case of Co/Cu/Co(001), discussed in Section 5.2.1, can suppress a strong contribution with short period λ leaving a weaker $s = 2$ harmonic with an intrinsically smaller characteristic temperature $T_{\lambda 2l}$ (cf. equation (36)).

Clearly much more experimental and theoretical work on the temperature dependence of IEC, particularly its dependence on spacer thickness, is required for a full understanding. A fully satisfactory theory, in which both the single-electron and spin-wave excitations are treated within a tight-binding model with interacting electrons, is not yet available.

7 THEORY AND EXPERIMENT

7.1 Noble metal spacers

In general, agreement between theory and experiment is good with regard to the periods of oscillation of IEC as a function of spacer thickness. This is to be expected since these periods are determined entirely by the nature of the spacer Fermi surface. The situation regarding amplitude and phase of the oscillations is much less satisfactory where wide discrepancies frequently exist not only between theory and experiment but also between different calculations. Observed IEC is invariably smaller than that calculated and this can be understood qualitatively to be due to interface roughness and interfacial diffusion (Kudrnovsky *et al*., 1996; Costa, d'Albuquerque e Castro and Muniz, 1997b; Inoue, 1994). Comparison between theory and experiment is then difficult because the exact nature of roughness and interfacial diffusion in an experiment is largely unknown. Possibly, the only system where direct comparison is possible between experiment and calculations for ideal interfaces is Fe/Au/Fe(001). Unguris, Celotta and Pierce (1997) made SEMPA and MOKE measurements on wedge structures grown on single crystal Fe whiskers, which provide very flat substrates. The angle of the Au wedge is about 0.001° so that the Au thickness increases by 1 ML over steps which are about 10 μm apart. Owing to a dominant short-period contribution to the coupling ($\simeq$2.5 ML), these steps are signaled in SEMPA measurements by a reversal of the magnetization in the top Fe layer. The magnitude of the AF peaks in the coupling was measured by MOKE as shown in Figure 12.

Ninety degree coupling is observed in SEMPA at the transition regions, between regions which are ferromagnetically

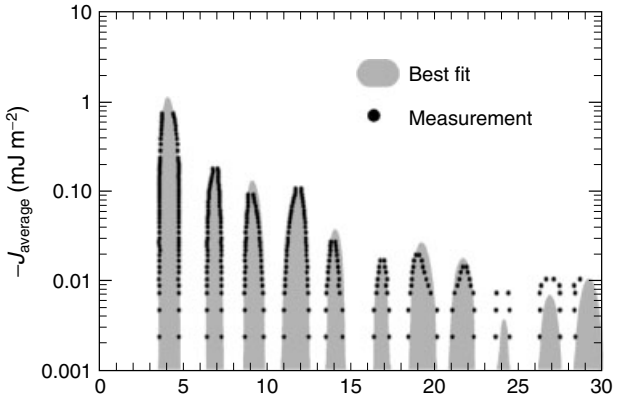

Figure 12. Measured values of coupling strength on Fe/Au/Fe(100) whiskers, as a function Au thickness (in monolayers). (Reprinted figure from Unguris, J., Celotta, R.J., and Pierce, D.T., (1997), *Phys. Rev. Lett.*, **79**, 2734–2737. © 1997 by the American Physical Society.)

and antiferromagnetically coupled. These transition regions are too wide to be merely due to Néel-type domain walls and indicate the existence of weak, but observable biquadratic coupling. Unfortunately, measurements of the magnetization curve $M(H)$ to determine its strength were not carried out. Such measurements would be very valuable because the biquadratic coupling in these samples with very smooth interfaces is presumably intrinsic. One indication that this is indeed the case is an apparent reduction in its strength, reflected in reduced transition region widths, on capping the top Fe layer with a Au layer. In fact, Unguris, Celotta and Pierce (1997) tentatively ascribe this to 'changes in boundary conditions of the spin-dependent quantum well'. The effect of a capping layer on bilinear coupling has been investigated experimentally and theoretically for a Co/Cu/Co structure by de Vries *et al*. (1995). Results of calculations of IEC in Fe/Au/Fe(001) differ widely. Opitz, Zahn, Binder and Mertig (2000), in LSDA calculations within the frozen potential approximation, report couplings an order of magnitude larger than observed by Unguris, Celotta and Pierce (1997). Hafner, Spišák, Lorentz and Hafner (2002), in total energy LSDA calculations, report results four times larger than Opitz, Zahn, Binder and Mertig (2000) and attribute the difference to the use of the frozen potential approximation by the latter authors. Much more reasonable results were obtained by Costa, d'Albuquerque e Castro and Muniz (1997b) using the tight-binding formulation described in Section 4.1. Although $J_1(N)$ does not agree with experiment in detail, as a function of Au thickness N, the order of magnitude is correct. Thus a calculated AF maximum at $N = 8$ ML with $J_1 = -0.5$ mJ m^{-2} may be compared with a measured $J_1 = -0.2$ mJ m^{-2} at the corresponding maximum of $N = 7$ ML. Costa, d'Albuquerque e Castro and Muniz (1997b) show how interplanar distance relaxation at the Fe/Au interface could reduce the calculated J_1 by a factor of 3. These authors also find that the short-period component of the IEC is completely dominant, which agrees with the large ratio of short-period to long-period amplitudes of 7 in experiment (Unguris, Celotta and Pierce, 1997). Stiles (1996b) estimated the size of the two components of J_1 from calculated reflection amplitudes at interfaces; he obtained reasonable magnitudes but an amplitude ratio of 2.

Costa, d'Albuquerque e Castro and Muniz (1997b) also calculated the IEC in Fe/Ag/Fe(001) trilayer and found that $J_1(N)$ exhibited the expected long period of about 5.3 ML. A short period (2.4 ML) of comparable amplitude is also present but produces no sign alternations on the 2 ML scale. The agreement with measurements of Celinski, Heinrich and Cochran (1993) and Unguris, Celotta and Pierce (1993) is excellent apart from theory being four times larger than experiment. The absence of sign alternations in $J_1(N)$ corresponding to a 2 ML period, in calculations for ideal interfaces precludes the Slonczewski fluctuation mechanism for biquadratic coupling. The biquadratic coupling observed by Schäfer *et al*. (1995) and Unguris, Celotta and Pierce (1993) is relatively weak ($J_1/J_2 \simeq 6$ at low T for an Au thickness of 1.8 nm) and is probably intrinsic, contrary to the interpretations of Schäfer *et al*. These authors find that J_1 is strongly temperature dependent, as in the calculations of Costa *et al*., with J_2 even more so. This is as expected for a J_2 of intrinsic origin.

The case of Co/Cu/Co(001) has already been discussed in Sections 2.3 and 5.2.1. We now briefly discuss some systems with TM spacers.

7.2 Transition-metal spacers

TM spacers have not been studied experimentally or theoretically as thoroughly as the noble metal spacers. Theoretical analysis of the IEC is complicated by multisheet Fermi surfaces associated with a partially filled d band. Parkin (1991) measured the IEC of multilayers $(\text{Co}(15\,\text{Å})/\text{TM})_{16}$ for nearly all TM spacers of the 3d, 4d, and 5d series. However, his failure to observe any oscillations with spacer thickness of period less than 10 Å suggests that the sputtered samples suffered from considerable interface roughness and interdiffusion. It is therefore uncertain how much significance should be attributed to Parkin's remarkable observation of an exponentially increasing coupling strength as one moves from left to right along each TM series. Nevertheless Mathon, Villeret and Edwards (1993) presented a plausible explanation of this effect on the basis of QW theory, with variable matching of the Co and spacer d bands as the latter band fills on moving along the series. Stoeffler and Gautier (1990) made more detailed calculations for Co/Ru and Fe/V superlattices. These were based on tight-binding calculations involving d orbitals with on-site electron interactions treated within the unrestricted Hartree–Fock approximation. They could consider only thin spacers and found large coupling strength, for example, about 30 mJ m^{-2} for a bcc $\text{Fe}_3\text{V}_2(001)$ superlattice. One important result is that the effect of electron interaction is to increase the coupling strength by only about 50% above its value for noninteracting electrons.

Realistic calculations for Fe/Mo/Fe(001) have been carried out by Mirbt, Niklasson, Johansson and Skriver (1996), using the LSDA approximation, and by Umerski and Mathon (unpublished, but see Edwards (2002)), using the method of Section 4.1. Umerski and Mathon find a large coupling strength, with $|J_1| \simeq 5$ mJ m^{-2} for a Mo thickness of 10 ML. Mirbt *et al*. find a somewhat larger coupling, which might be expected since electron interaction is included in the LSDA calculations. Both groups find a dominant 2 ML period associated with nesting of the Mo Fermi surface,

similar to that which gives rise to antiferromagnetism in the corresponding 3d metal Cr. Experimentally Qiu, Pearson, Berger and Bader (1992) and Qiu, Pearson and Bader (1993) found a coupling strength nearly 2 orders of magnitude smaller than the theoretical one and with a period of about 3 ML. A large discrepancy between theoretical and experimental coupling strength is also found for the AF spacer Cr, as discussed in the next section.

7.3 Antiferromagnetic Spacers

A huge body of experimental work exists involving trilayers and multilayers with AF Cr as the spacer. Excellent reviews exist on the Fe/Cr system (Pierce, Unguris, Celotta and Stiles, 1999; Fishman, 2001) and here we have space only for a few salient points. Antiferromagnetism in bulk bcc Cr takes the form of a spin-density wave (SDW) which is incommensurate (I) with the lattice, having a wave vector $\mathbf{q} = (2\pi/a)(1 \pm \delta')\hat{\mathbf{y}}$ where a is the lattice constant and $\hat{\mathbf{y}}$ is a unit vector along a cubic axis. The parameter δ' is temperature dependent and $0 \leq \delta' \leq \delta$ where $\pm\delta$ ($\simeq$0.05) corresponds to nesting wave vectors which link planar parts of the paramagnetic Cr Fermi surface. The spin on a site with coordinate y in the I SDW is given by

$$\mathbf{S}_{\mathrm{Cr}}(y) = (-1)^{2y/a}\hat{\mathbf{m}}g(T)\cos((2\pi/a)y\delta' + \theta) \qquad (41)$$

where $\hat{\mathbf{m}}$ is a unit vector perpendicular or parallel to $\hat{\mathbf{y}}$, corresponding to transverse (T) or longitudinal (L) phases, respectively, and θ is an arbitrary phase. Bulk Cr undergoes a Néel transition at $T_{\mathrm{N}}^{\mathrm{bulk}} = 311$ K, into a T SDW phase which changes to a L SDW state below 123 K. At low temperatures, the SDW amplitude $g(T)$ corresponds to a maximum Cr moment of about $0.6\,\mu_{\mathrm{B}}$. Doping with 0.2% Mn or 2.4% Fe drives δ' to zero so that the SDW becomes commensurate (C). Another type of SDW, which does not occur in bulk Cr but may appear in trilayers and multilayers, is a noncollinear helical (H) one with

$$\mathbf{S}_{\mathrm{Cr}}(y) = (-1)^{2y/a}g(T)(\hat{\mathbf{z}}\cos((2\pi/a)y\delta' + \theta) \pm \hat{\mathbf{x}}\sin((2\pi/a)y\delta' + \theta)) \qquad (42)$$

A simple picture of IEC in a Fe/Cr/Fe(001) trilayer combines a strong AF coupling $J_i\mathbf{S}_{\mathrm{Fe}}.\mathbf{S}_{\mathrm{Cr}}$ at the interfaces with a C SDW ($\delta' = 0$) in the Cr layer. For a Cr thickness of N ML this clearly leads to FM coupling between the Fe layers for N odd and to AF coupling for N even. The picture of alternating FM and AF coupling is valid for $9 \leq N < 24$ except that the sign is reversed in SEMPA measurements (Pierce, Unguris, Celotta and Stiles, 1999). Freyss, Stoeffler and Dreyssé (1997) have shown theoretically how this sign reversal may occur because of interface diffusion. Using a tight-binding d-band Hamiltonian, with electron interaction treated in an unrestricted Hartree–Fock approximation, they show that a Cr plane containing more than 20% of Fe acts as if it were part of the FM Fe layer rather than acting as part of the Cr spacer layer. Heinrich, Cochran, Monchevsky and Urban (1999) point out that interfacial mixing occurs at the relevant temperatures when Cr is deposited on Fe but is unimportant for deposition of Fe on Cr. Consequently, interfacial mixing occurs at only one interface, thus effectively reducing N by 1. The work of Freyss, Stoeffler and Dreyssé (1997) also indicates that interfacial alloying is the cause of the delayed onset of the clear 2 ML period in IEC which is only established for $N > 8$ (Pierce, Unguris, Celotta and Stiles, 1999; Heinrich, Cochran, Monchevsky and Urban, 1999).

SEMPA measurements (Pierce, Unguris, Celotta and Stiles, 1999) show that at room temperature the C SDW gives way to a I SDW for $N > 24$. The IEC is FM for both $N = 24$ and 25, so that a phase slip occurs in the alternation between FM and AF coupling. Further phase slips are observed at $N = 44$–45 and 64–65. The phase slips move to larger N as temperature T increases, the first phase slip occurring at $N = 38$–39 at 550 K. It is remarkable that the IEC associated with the Cr SDW persists far above the bulk Néel temperature. A good account of these phenomena is afforded by a phenomenological model based on a free energy expression which is a sum of interfacial couplings $J_i\mathbf{S}_{\mathrm{Fe}}.\mathbf{S}_{\mathrm{Cr}}$ and a free energy corresponding to the bulk SDW of equation (41) (Shi and Fishman, 1997; Fishman and Shi, 1998, 1999). The latter energy is calculated for interacting electrons with nested bands within the random phase approximation and the total free energy is minimized with respect to g, δ', and θ for given N and T. The calculated bilinear coupling $|J_1| \simeq 10$ mJ m^{-2} at $N = 10$ which is about 15 times larger than observed for good samples grown on an Fe whisker (Heinrich, Cochran, Monchevsky and Urban, 1999). Tight-binding d-band calculations which include electron–electron interaction (Stoeffler and Gautier, 1991) give $|J_1| \simeq 25\,\mathrm{mJ\,m^{-2}}$. First-principles calculations based on LSDA (Mirbt, Niklasson, Johansson and Skriver, 1996) also give a large coupling $|J_1| \simeq 30\,\mathrm{mJ\,m^{-2}}$ for $N = 10$. Mirbt *et al.* simulated a Cr spacer without exchange enhancement due to electron interaction and found that the Cr moments were reduced by a factor of 20 from the interacting case while the IEC retained a 2 ML period and was reduced only by a factor of 3 with $|J_1| \simeq 10\,\mathrm{mJ\,m^{-2}}$. This is only slightly larger than the value obtained by standard methods assuming Cr to be paramagnetic with noninteracting electrons (Costa, d'Albuquerque e Castro and Muniz, 1999). Costa *et al.* investigated the

effect of interfacial alloying on the IEC but were unable to account for the very large discrepancy between theory and experiment.

In samples where terrace lengths are short enough for the 2 ML period coupling to be averaged out, a long-period component with a period of about 12 ML is observed (Unguris, Celotta and Pierce, 1991; Demokritov, Wolf and Grüunberg, 1991). The origin of this long period is still controversial. The general consensus is that it is associated with the spanning vector of a small ellipsoidal part of the paramagnetic Cr Fermi surface surrounding the N-point in the Brillouin zone (Stiles, 1996a, 1999; Tsetseris, Lee and Chan, 1997; Bürgler, Grünberg, Demokritov and Johnson, 2001). This part of the Fermi surface should not be much disturbed by the existence of an SDW.

In the work discussed in the preceding text it is assumed that, when the angle θ between the magnetizations of the magnetic layers is equal to 0 or π, the Cr moments are collinear. This is not necessarily the case, as shown schematically for an ideal Fe/Cr_{10}/Fe trilayer in Figure 13.

For $N = 10$ the Fe magnetizations are antiparallel ($\theta = \pi$) in the stable configuration. The figure illustrates the parallel ($\theta = 0$) configuration, which would occur in a saturating magnetic field, and shows three possible SDW states in the Cr layer. The C SDW is the stable one for $\theta = \pi$ and is ruled out for $\theta = 0$ in the presence of strong AF Fe/Cr interfacial coupling. The magnitude of the IEC is determined by the energy difference between the energy of

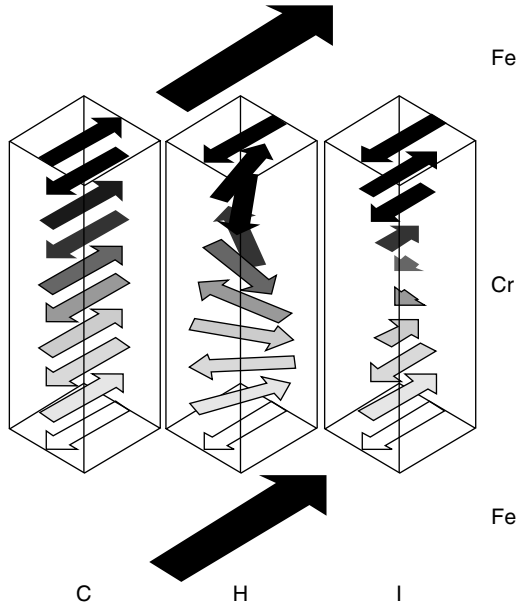

Figure 13. Three possible SDW states in Fe/Cr_{10}/Fe with parallel Fe magnetizations. (Reproduced from Fishman, R.S. (2001), *J. Phys.: Condens. Matter*, **13**, R235–R269, with permission from IOP Publishing Ltd. © 2001.)

the H SDW or I SDW – whichever is lower – and that of the C SDW. Stoeffler and Gautier (1993a,b), using a d-band tight-binding model which apparently favors C over I SDWs in bulk Cr, find that the H SDW has a lower energy than the I SDW for $N \geq 24$. Allowing a nonuniform twist in the helix stabilizes the noncollinear state for $N \geq 20$. The energy of the I SDW, relative to that of the C SDW, tends to a positive constant as $N \to \infty$ owing to the continuing presence of a magnetic defect in the center of the Cr layer where Cr moments are suppressed due to frustrated antiferromagnetism. The energy of the H SDW relative to that of the C SDW tends to zero as $1/N$. Slonczewski (1995) pointed out that, for N not too small, the energy of a H SDW for general θ may be written as $J_+(N)(\pi - \theta)^2$ for even N, as considered above, and as $J_-(N)\theta^2$ for odd N. Here, $0 \leq \theta \leq \pi$ and J_+, J_- are positive stiffness constants such that $J_\pm \propto N^{-1}$. Slonczewski proposed a torsion model for Fe/Cr/Fe in which these energy expressions replace the standard $-J_1 \cos\theta - J_2 \cos^2\theta$ expression. From the work of Stoeffler and Gautier (1993a,b) one would expect this to be valid only for $N \geq 24$ when the H SDW is stable for all θ. But surprisingly Freyss, Stoeffler and Dreyssé (1996) found a stable noncollinear state, with energy $J_+(\pi - \theta)^2$ for $0 \leq \theta \leq \pi$, even for $N = 6$. However, recent, improved tight-binding calculations by Cornea and Stoeffler (2000), which include s, p, and d orbitals, show that for even (odd) N the central Cr moments in a H-type SDW are suppressed as $\theta \to 0(\pi)$. The SDW then becomes incommensurate and collinear and the calculated energies are fitted excellently over the whole range $0 \leq \theta \leq \pi$ by the standard expression, and not by the torsion model, for the cases $N = 4, 5, 10, 11$ considered. For $N = 10$ and 11 it is found that the intrinsic biquadratic coupling $J_2 \simeq |J_1|/3$ in agreement with the measurements of Heinrich, Cochran, Monchevsky and Urban (1999) on trilayers with smooth interfaces. For interfacial terrace lengths less than the domain wall width in Fe the Slonczewski fluctuation mechanism comes into play with a further tendency toward 90° coupling. In Fe/Cr/Fe(001) multilayers with short terraces, Schreyer *et al.* (1995) found a noncollinear orientation of the moments of Fe layers, with a slow approach to saturation in an applied field, which they interpret in terms of the torsion model. This interpretation is challenged by Heinrich, Cochran, Monchevsky and Urban (1999) and by Cornea and Stoeffler (2000).

The torsion model has been used successfully to interpret IEC in systems with Mn spacers (Yan *et al.*, 1999; Filipkowski, Krebs, Prinz and Guttierez, 1995; Krebs, Prinz, Filipkowski and Gutierrez, 1996). Mn is another AF metal, which normally exhibits a C SDW. For rough interfaces, the coupling energy for a given nominal spacer thickness takes the form $c_+(\pi - \theta)^2 + c_-\theta^2$. Here $c_+ = p_+\bar{J}_+$, $c_- = p_-\bar{J}_-$ where p_+, p_- are the fractions of the cross-sectional area

with, respectively, even and odd numbers of planes in the spacer ($p_+ + p_- = 1$) and $\bar{J}_+$, $\bar{J}_-$ are the relevant average stiffness constants. The minimum energy in zero field, with anisotropy neglected, occurs for $\theta = \pi c_+/(c_+ + c_-)$ which gives 90° coupling for $c_+ = c_-$. Yan *et al.* (1999) deduce from $M(H)$ curves that this is the case in Fe/Mn/Fe trilayers with the Mn thickness in the range 1.2–2.45 nm.

7.4 IEC with insulating and semiconducting spacers

Slonczewski (1989) introduced the torque method to calculate the IEC for a free-electron model of two FM metals separated by a potential barrier. Bruno (1995) solved the same problem using the energy difference method. The main result is that the IEC, which may be FM or AF, decays exponentially with increasing barrier width (spacer thickness) at a rate determined by the height of the barrier. This contrasts with the slowly decaying oscillatory coupling for metal spacers. In the latter case, the amplitude of the oscillations decreases with increasing temperature owing to smearing of the Fermi surface (see Section 6). For the insulating barrier case, Bruno (1995) found that the coupling strength increases with temperature owing to the enhanced tunneling of thermally occupied states above the Fermi level. The experimental situation, reviewed by Bürgler, Grünberg, Demokritov and Johnson (2001), is quite confused. Possibly some light is shed on the matter by the very recent theoretical work of Zhuravlev, Tsymbal and Vedyayev (2005). They consider the same free-electron barrier model used by Slonczewski and Bruno, but with the addition of an impurity potential well within the barrier. This creates an impurity level below the top of the potential barrier. A strong resonant AF peak in the IEC appears as the impurity level passes through the Fermi level. The peak reduces slightly with increasing temperature so that the IEC weakens. This temperature dependence contrasts with Bruno's result for the pure barrier and agrees with some experiments. However, the success of the model depends on having a sufficient number of impurity states close to the Fermi level of the ferromagnets.

No quantitative calculations for the IEC on real materials such as epitaxial Fe/MgO/Fe(001) have been made; they are perfectly feasible using the same methods as for existing calculations of tunneling magnetoresistance in this system (Mathon and Umerski, 2001). A large AF coupling ($J_1 \simeq -0.26$ mJ m^{-2}) has been observed in this system with a thin MgO layer of 6 Å (Faure-Vincent *et al.*, 2002). Multiorbital tight-binding calculations for valence-band electrons in all-semiconductor IV-VI magnetic/nonmagnetic superlattices have yielded values for the IEC (Blinowski and Kacman, 2001). J_1 has been calculated for EuS/PbS(001) with PbS thicknesses of $N = 1$–8 ML; it is negative and decreases exponentially with N. Experimental estimates of J_1 exist for $N = 1, 2, 3$ and the calculated values of $-J_1 = 0.77, 0.33, 0.18$ mJ m^{-2}, respectively, follow them closely apart from being larger by an almost constant factor of 10.

8 OUTLOOK

The essential theoretical concepts for understanding IEC were in place soon after its experimental discovery. Ten years ago quantitative calculations of IEC for real systems were already being made. At this time, the emphasis on magnetic multilayer research changed to nonequilibrium phenomena such as tunneling magnetoresistance and, most recently, current-induced switching of magnetization. This has left many issues concerning IEC unresolved. One important issue is the order-of-magnitude discrepancy between theory and experiment for systems with TM spacers (see Section 7.2). Another open topic is the unambiguous observation of intrinsic biquadratic exchange, with evidence for its oscillatory behavior as a function of spacer thickness. This should be possible in systems such as Fe/Au/Fe and Fe/Ag/Fe (see Section 7.1). We expect that work on these and other issues will progress steadily and that maybe there are still some surprises in store.

ACKNOWLEDGMENTS

The authors wish to thank J. Mathon, M. Villeret, J. d'Albuquerque e Castro, and R.B. Muniz for many years of enjoyable collaboration in this subject. We are grateful to the UK Engineering and Physical Sciences Research Council (EPSRC) for continuous support.

Enhanced Magnetoresistance

Peter Zahn and Ingrid Mertig
Martin Luther University, Halle, Germany

1 INTRODUCTION

Magnetoresistance (MR) effects are known since the discovery of the anisotropic magnetoresistance (AMR) in metals in 1857 by William Thomson where the resistance depends on the direction of the current with respect to the material's magnetization. A revival of the MR effect occurred in the late 1980s with the discovery of giant magnetoresistance (GMR). GMR is related to nanofabrication technology. Artificially layered structures, so-called magnetic multilayers, show a drastic change of resistance as a function of relative orientation of layer magnetization. The high potential of future application was realized in the 1990s and a large effort in basic and applied research was initiated. Thereby, two major application areas are in the focus of commercial interests – magnetoresistive sensors and information technology. Read heads in magnetic hard disk drives and nonvolatile memory are expected to beat conventional systems with respect to performance and costs.

The discovery of the GMR effect is a result of up-to-date solid state physics at the nanometer scale. The microscopic understanding of the effect is based on quantum mechanics starting from the atomic level and combines modern concepts of transport theory with material-specific *ab initio* calculations. The main idea of this chapter is to introduce the basic components of the theoretical description and to elucidate the macroscopic phenomenon by means of qualitative microscopic pictures confirmed by quantitative *ab initio* electronic structure calculations.

1.1 Limiting cases

While measuring the resistance of a sample, two regimes have to be distinguished (see Figure 1). In the diffusive limit the mean free path Λ of the electrons is much shorter than the dimension of the sample. The mean free path is a measure of the distance an electron travels in the sample without being affected by the scattering processes.

In the diffusive regime the resistance R is given by Ohm's law and is proportional to the length L and the cross section A of the sample assuming current and voltage measurement in the same direction

$$R = \rho \frac{L}{A} \tag{1}$$

A material-specific proportionality constant ρ, the resistivity, is defined. In general the resistivity is a tensor $\underline{\underline{\rho}}$, which reflects the anisotropy of the crystal in different spatial directions.

A similar relation holds for the conductance g and the conductivity σ

$$g = \sigma \frac{A}{L} \tag{2}$$

Conductance and resistance are related to each other by $g = R^{-1}$. As a consequence, conductivity and resistivity are also inversely proportional $\sigma = \rho^{-1}$ in the diffusive limit. In general, conductivity is also a tensor $\underline{\underline{\sigma}}$.

In the ballistic limit, the dimensions of the sample are shorter than the mean free path of the electrons and the transport cannot be characterized by a material-specific constant only. The resistance and conductance can change in a nonmonotonic way with the length of the sample. This is the nonohmic limit.

1.2 Magnetoresistance

Owing to the general definition the resistivity, ρ can be expressed as a three-dimensional tensor of rank 2. For systems with time-reversal symmetry this tensor can be diagonalized with components ρ_{xx}, ρ_{yy}, and ρ_{zz}

$$\underline{\underline{\rho}} = \begin{pmatrix} \rho_{xx} & 0 & 0 \\ 0 & \rho_{yy} & 0 \\ 0 & 0 & \rho_{zz} \end{pmatrix} \tag{3}$$

This is valid for vanishing spin-orbit coupling and without magnetic field. In isotropic and cubic systems the material-specific resistivity is a single scalar $\rho = \rho_{xx} = \rho_{yy} = \rho_{zz}$.

If one direction is preferred by a symmetry breaking field, two components $\rho_{\parallel}$ and $\rho_{\perp}$ for the transport parallel and perpendicular to the corresponding axis have to be distinguished. This is, for example, the case in hexagonal systems and causes the so-called resistivity anisotropy.

Another way of breaking the symmetry is by means of an external magnetic field. An external magnetic field of strength B can influence the resistivity by the acting Lorentz force. The increase of the diagonal elements of the resistivity caused by the Lorentz force is called *longitudinal and transversal magnetoresistance* according to the relative orientation of the current and the external magnetic field, respectively.

The relative change in resistance (MR ratio) characterizes the enhanced MR

$$\frac{\Delta R}{R} = \frac{R(B) - R(B=0)}{R(B=0)} \tag{4}$$

In the diffusive limit this is equivalent to the relative change in resistivity

$$\frac{\Delta \rho}{\rho} = \frac{\rho(B) - \rho(B=0)}{\rho(B=0)} \tag{5}$$

In magnetic systems the role of an external magnetic field is replaced by the internal magnetization. Crystal anisotropy causes a preferred orientation of the magnetization along the so-called easy axes. Resistances measured parallel or perpendicular to the magnetization direction are different. The ratio is called *anisotropic magnetoresistance*.

Finally, an external magnetic field can be used to change the magnetic order in the sample which can be accompanied by a drastic change of the resistance.

A well-known example is GMR. The effect occurs in magnetic multilayers. Ferromagnetic layers are separated by non(ferro)magnetic metallic layers. The relative change of the layer magnetizations with respect to each other causes an enormous change of the resistance at considerably small fields. This effect is much stronger than the Lorentz force effect.

If the metallic layers are replaced by insulating layers so-called tunneling magnetoresistance (TMR) is obtained (Julliere, 1975; Moodera, Kinder, Wong and Meservey, 1995; Meservey and Tedrow, 1994), (see also **Theory of Spin-dependent Tunneling, Volume 1**).

In colossal magnetoresistance (CMR) systems (von Helmolt *et al*., 1993) the action of the external field causes a magnetic phase transition which is accompanied by a metal–insulator transition. This changes the resistance by orders of magnitude but the strength of the required fields prevent, until now, application in sensor and information technology.

1.3 Giant magnetoresistance

1.3.1 GMR ratio

The discovery of GMR in magnetic multilayer systems (Baibich *et al*., 1988; Binasch, Grünberg, Saurenbach and Zinn, 1989) initiated a variety of experimental and theoretical investigations to elucidate the microscopic origin of the phenomenon. The effect was first discovered in metallic multilayers made up of magnetic layers separated by non(ferro)magnetic layers. The effect is closely linked to the effect of interlayer exchange coupling (IEC) which was discovered some years earlier by Grünberg *et al*. (1986) (see also **Exchange Coupling in Magnetic Multilayers, Volume 1**). In those samples a magnetic coupling of adjacent magnetic layers occurs which is mediated by the electrons of the nonmagnetic layer. The strength J_{AF} and the sign of the coupling depend on the thickness of the nonmagnetic layer (Parkin, 1991; Bruno and Chappert, 1991).

If the layer magnetizations are antiparallel in the ground state, the relative orientation of the layer magnetizations can be changed by means of an external magnetic field. In systems without an intrinsic coupling of the magnetic layers the switching of the magnetic layers can be triggered by their magnetic anisotropy caused by different layer thicknesses, crystal structures, and alloying. The change of magnetic

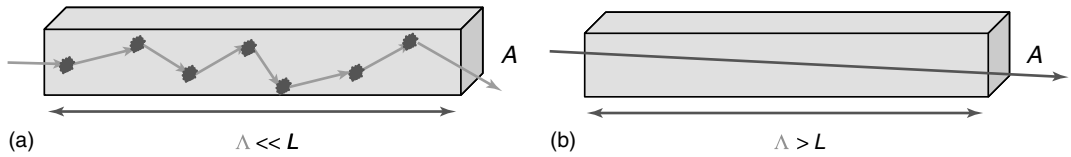

Figure 1. Transport measurements in the diffusive limit (a) and the coherent limit (b). The cross section of the sample is A and the length along the current directions is L, Λ denotes the mean free path.

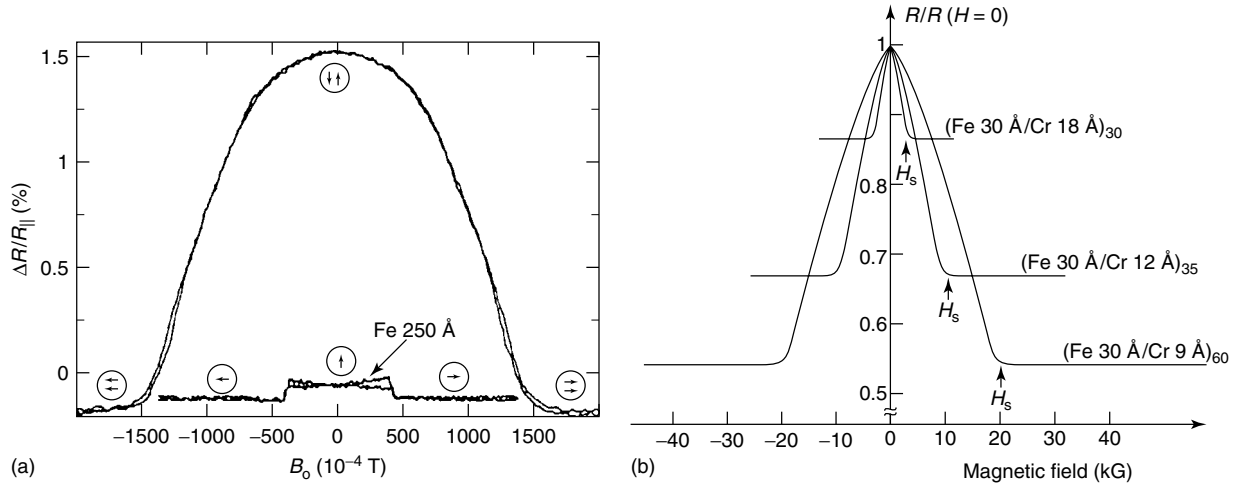

Figure 2. First experimental GMR results obtained in Fe/Cr/Fe systems: trilayer result from Binasch, Grünberg, Saurenbach and Zinn (1989) (a), multilayer result from Baibich *et al*. (1988) (b). (Reproduced from Binasch *et al*., 1989/Baibich *et al*., 1998, with permission from the American Physical Society. © 1989/1998.)

order is accompanied by a drastic change of resistance. The first experiments were carried out at Fe/Cr multilayers and changes up to 50% were achieved, see Figure 2. The close link of the behavior of resistance and magnetization is sketched in Figure 3.

To quantify the GMR effect the following ratio was introduced

$$GMR = \frac{R^{\mathrm{AP}} - R^{\mathrm{P}}}{R^{\mathrm{P}}} = \frac{\rho^{\mathrm{AP}} - \rho^{\mathrm{P}}}{\rho^{\mathrm{P}}} = \frac{\sigma^{\mathrm{P}}}{\sigma^{\mathrm{AP}}} - 1 \qquad (6)$$

This definition is the so-called optimistic one, because it can reach values much larger than 1. It will be used throughout this chapter. Some authors prefer to use the pessimistic definition, which is limited in cases of positive GMR ($\rho^{\mathrm{AP}} > \rho^{\mathrm{P}}$) to values smaller than 100%, and is given by

$$GMR' = \frac{\rho^{\mathrm{AP}} - \rho^{\mathrm{P}}}{\rho^{\mathrm{AP}}} = 1 - \frac{\sigma^{\mathrm{AP}}}{\sigma^{\mathrm{P}}} \qquad (7)$$

It was shown by several authors (Oguchi, 1993; Zahn, Mertig, Richter and Eschrig, 1995; Schep, Kelly and Bauer, 1995; Butler, MacLaren and Zhang, 1993) that GMR in magnetic multilayers is strongly influenced by the electronic structure of the layered system as a function of the magnetic configuration. That is, the differences in Fermi velocities of the multilayers for parallel or antiparallel alignment of magnetic moments in adjacent magnetic layers cause GMR by themselves. Since this effect is a result of Bragg reflection in ideal multilayers, it might be less important in dirty samples that still have remarkable GMR amplitude. Consequently, spin-dependent scattering (Camley and Barnaś, 1989; Levy, Zhang and Fert, 1990; Inoue, Oguri and Maekawa, 1991; Hood and Falicov, 1992; Valet and Fert, 1993; Levy, 1994) is assumed to play a crucial role for GMR. Experiments (Parkin, Modak and Smith, 1993; Enders *et al*., 2001; Santamaria *et al*., 2001) and corresponding calculations (Schep *et al*., 1997; Zahn *et al*., 1998; Zahn, Binder and Mertig, 2003) demonstrated that spin-dependent interface scattering is especially important for the size of the effect.

The idea of the review is to present an overview of the material-specific trends for the standard systems of magnetoelectronics. The general trends are elucidated by a detailed analysis of the spin-dependent scattering cross sections in layered structures.

1.3.2 Geometry

For GMR measurements two geometrical arrangements can be distinguished with respect to the direction of the current relative to layer orientation. The current-in-plane (CIP)

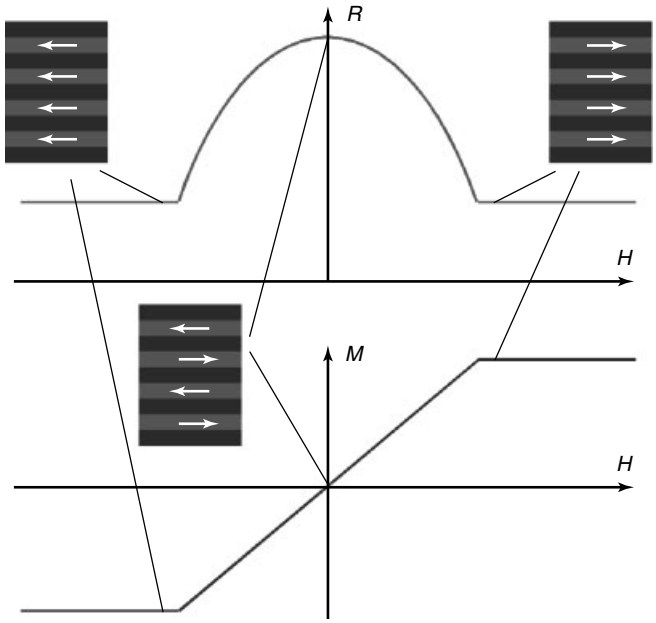

Figure 3. Multilayer structure, resistivity, and magnetization as a function of the external magnetic field.

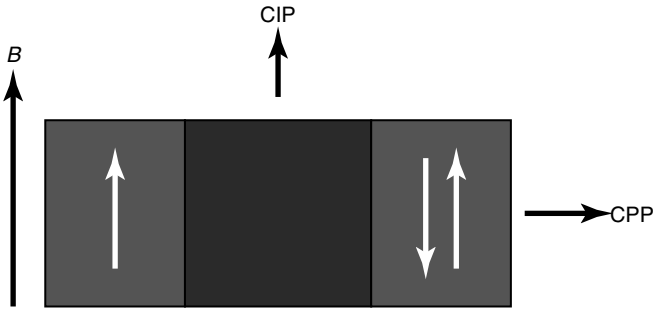

Figure 4. Geometries for GMR transport measurements.

geometry is characterized by a current flowing parallel to the layers. Contrarily, in the current perpendicular to the planes (CPP) geometry the current is driven perpendicular to the planes, as sketched in Figure 4.

In CIP geometry trilayers and multilayers are used. In trilayers one of the magnetic layers, the hard layer, is pinned to a natural or artificial antiferromagnet (Nogues and Schuller, 1999; van den Berg *et al*., 1999). The soft magnetic layer is often made from an alloy to reduce the magnetocrystalline anisotropy. In multilayers the different coercivities of the magnetic layers are obtained by different layer thicknesses or by exploiting the effect of magnetic IEC.

In CPP geometry, several configurations have been used for transport measurements. Planar junctions (Gijs, Lenczowski and Giesbers, 1993), sawtooth samples, which allow measurements in CIP and CPP at one and the same sample (Pratt *et al*., 1991), and multilayer pillars grown in polymer foil holes with a large number of bilayers have been investigated (Piraux, Dubois and Fert, 1996; Piraux *et al*., 1997).

Owing to the symmetry of crystalline layered systems the conductivity tensor $\underline{\underline{\sigma}}$ consists of two different diagonal elements. If the current flows perpendicular to the layers that is, parallel to the crystal z axis

$$\sigma_{\mathrm{CPP}} = \sigma_{zz} = \sigma_{\perp} \tag{8}$$

is obtained and

$$\sigma_{\mathrm{CIP}} = \sigma_{xx} = \sigma_{yy} = \sigma_{\parallel} \tag{9}$$

is observed if the current flows in the layer direction.

2 TRANSPORT THEORY

Starting from density-functional theory (DFT), the one-electron wave functions have to fulfill a Schrödinger equation with an effective one-particle Hamiltonian (Hohenberg and Kohn, 1964; Kohn and Sham, 1965)

$$H(\mathbf{r})\psi_k(\mathbf{r}) = E_k\psi_k(\mathbf{r}) \tag{10}$$

with $H(\mathbf{r}) = -\nabla_r^2 + V_{\mathrm{eff}}(\mathbf{r})$ and the eigenfunctions $\psi_k(\mathbf{r})$. The effective potential $V_{\mathrm{eff}}(\mathbf{r})$ contains by construction all exchange and correlation effects. k is a shorthand notation for Bloch vector $\mathbf{k}$, band index ν and for magnetic systems all properties are spin dependent. Throughout this section the spin quantum number σ will, however, be omitted for reasons of clarity. All equations are given in real-space representation. Atomic units are used by setting $\hbar = 2m = \epsilon^2/2 = 1$.

The starting point is an unperturbed system which might be translational invariant in certain directions and is described by the Hamiltonian $\mathring{H}(\mathbf{r}) = -\nabla_r^2 + \mathring{V}_{\mathrm{eff}}(\mathbf{r})$.

A potential perturbation $\Delta V(\mathbf{r})$ defines a new system $H(\mathbf{r}) = -\nabla_r^2 + V_{\mathrm{eff}}(\mathbf{r}) = \mathring{H}(\mathbf{r}) + \Delta V(\mathbf{r})$.

Both systems can be equivalently described by means of Green's functions defined as

$$(E - H(\mathbf{r}))\, G(\mathbf{r}, \mathbf{r}', E) = \delta(\mathbf{r} - \mathbf{r}') \tag{11}$$

$$\left(E - \mathring{H}(\mathbf{r})\right) \mathring{G}(\mathbf{r}, \mathbf{r}', E) = \delta(\mathbf{r} - \mathbf{r}') \tag{12}$$

instead of Schrödinger equations.

The advantage of Green's functions is that they are related to each other by the Dyson equation

$$G(\mathbf{r}, \mathbf{r}', E) = \mathring{G}(\mathbf{r}, \mathbf{r}', E) + \int \mathrm{d}\mathbf{r}'' \mathring{G}(\mathbf{r}, \mathbf{r}'', E) \times \Delta V(\mathbf{r}'') G(\mathbf{r}'', \mathbf{r}', E) \tag{13}$$

Using cell-centered coordinates for the description of the local potentials and scattering solutions this results in a system of linear equations which can be solved very efficiently (Zeller and Dederichs, 1979; Mertig, Mrosan and Ziesche, 1987).

The local density of states (LDOS) is obtained from the diagonal part of the Green's function

$$n(\mathbf{r}, E) = -\frac{1}{\pi} Im\, G(\mathbf{r}, \mathbf{r}, E) \tag{14}$$

which can be used to calculate the charge density

$$\begin{aligned} n(\mathbf{r}) &= \int_{-\infty}^{E_\mathrm{F}} \mathrm{d}E\, n(\mathbf{r}, E) \\ &= \sum_{E_k \le E_\mathrm{F}} |\psi_k(\mathbf{r})|^2 \end{aligned} \tag{15}$$

and the density of states (DOS)

$$n(E) = \int \mathrm{d}\mathbf{r}\, n(\mathbf{r}, E) \tag{16}$$

with E_F being the Fermi level.

It has been shown that the variational principle of DFT can be reformulated for the case of magnetic systems by introducing the charge and magnetization density, respectively (von Barth and Hedin, 1972)

$$n(\mathbf{r}) = n^{\uparrow}(\mathbf{r}) + n^{\downarrow}(\mathbf{r}) \tag{17}$$

$$m(\mathbf{r}) = n^{\uparrow}(\mathbf{r}) - n^{\downarrow}(\mathbf{r}) \tag{18}$$

$\sigma = \uparrow, \downarrow$ denotes the spin directions 'up' for majority states and 'down' for minority states. The total magnetization of the system is given by

$$M = \int \mathrm{d}\mathbf{r}\, m(\mathbf{r}) \tag{19}$$

In the following $\mathring{V}_\mathrm{eff}(\mathbf{r})$ describes the unperturbed system with periodicity in certain directions and $\Delta V(\mathbf{r})$ describes point defects or, more generally, spatially localized potential perturbations.

2.1 Boltzmann theory

The Boltzmann theory is a quasiclassical theory and combines quantum-mechanical information of the electronic structure with a classical description of the transport. The solution of the Boltzmann equation is a classical distribution function $f_k(\mathbf{r}, t)$ which determines the number of carriers in phase-space volume characterized by k, and the position in real space $\mathbf{r}$. k is related to the wave vector $\mathbf{k}$, the band index ν, and for magnetic systems the spin σ. In the following derivations the spin is neglected for the sake of simplicity and an explicit dependence of the distribution function on time and magnetic field is excluded. The real-space dependence vanishes because of the restriction to homogeneous systems. In the steady state the total rate of change has to vanish, and from the conservation of phase-space volume a master equation for the distribution function is derived

$$\dot{\mathbf{k}} \frac{\partial f_k}{\partial E_k} \frac{\partial E_k}{\partial \mathbf{k}} - \left.\frac{\partial f_k}{\partial t}\right|_\mathrm{scatt} = 0 \tag{20}$$

with the Fermi velocity

$$\mathbf{v}_k = \frac{\partial E_k}{\partial \mathbf{k}} \tag{21}$$

The field term is determined by the external electric field $\mathbf{E}$ with e the electron charge $e = -|e|$ and $\dot{\mathbf{k}} = e\mathbf{E}$. The second term in equation (20) describes the change of carriers in state k due to scattering and is determined by the microscopic transition probability $P_{kk'}$ via equation (22). These scattering processes can be caused, for example, by lattice defects, imperfections, or thermally activated quasiparticles.

The microscopic transition probability $P_{kk'}$ is given by Fermi's golden rule

$$P_{kk'} = 2\pi c N |T_{kk'}|^2 \delta(E_k - E_{k'}) \tag{22}$$

$T_{kk'}$ describes the scattering at one impurity. cN is the total number of impurities in the sample where c is the relative concentration of defects and N is the total number of atoms in the system.

In the framework of a Korringa-Kohn-Rostoker (KKR) Green's function formalism the transition matrix elements $T_{kk'}$ can be calculated without an adjustable parameter using the self-consistently determined impurity potentials in an otherwise perfect matrix (Mertig, Zeller and Dederichs, 1993; Mertig *et al.*, 1995).

Exploiting the microscopic reversibility $P_{kk'} = P_{k'k}$, considering only elastic scattering processes, and introducing a small deviation $g_k = f_k - \mathring{f}_k$ from the equilibrium distribution function $\mathring{f}_k$, the change of the distribution function due to scattering is given by

$$\left.\frac{\partial f_k}{\partial t}\right|_\mathrm{scatt} = \sum_{k'} P_{kk'}(g_{k'} - g_k) \tag{23}$$

In the limit of linear response, the proportionality of g_k and the external field $\mathbf{E}$ is given by the vector mean free path $\mathbf{\Lambda}_k$ using the ansatz

$$g_k = -e \frac{\partial \mathring{f}_k}{\partial E} \mathbf{\Lambda}_k \mathbf{E} \tag{24}$$

The Fermi surface average of the vector mean free path $\mathbf{\Lambda}_k$ is related to the mean free path Λ discussed in Section 1. Using the relaxation time $[\tau_k]^{-1} = \sum_{k'} P_{kk'}$ one obtains with equations (20) and (23) the linearized Boltzmann equation

$$\mathbf{\Lambda}_k = \tau_k \left[\mathbf{v}_k + \sum_{k'} P_{kk'} \mathbf{\Lambda}_{k'} \right] \tag{25}$$

The first term on the rhs describes the mean free path in the relaxation time approximation $\mathbf{\Lambda}_k = \tau_k \mathbf{v}_k$ known from textbooks. The second term on the rhs is the so-called scattering-in term which counts the scattering events from states k' back to the considered state k. It causes the vertex corrections of the mean free path. In the limit of zero temperature, the integration of equation (25) has to be performed for electronic states on the anisotropic Fermi surface of the system under consideration. For magnetic systems the spin degeneracy is lifted and the spin variable σ has to be included explicitly. As a result equation (25) becomes a set of integral equations for majority and minority electrons, separately.

Introducing a diagonal matrix τ containing the Boltzmann relaxation times $\tau = \{\delta_{\mathbf{kk}'} \tau_{\mathbf{k}}\}$ an exact solution for a (super)vector containing the group velocities can be given

$$\mathbf{\Lambda} = [1 - \tau P]^{-1} \tau \mathbf{v} \quad \text{or} \tag{26}$$

$$\mathbf{\Lambda}_k = \sum_{k'} [1 - \tau P]^{-1}_{kk'} \tau_{k'} \mathbf{v}_{k'} \tag{27}$$

The required number of k points to sample the Fermi surface properly prevents a direct evaluation of this equation. Nevertheless this formal solution clearly shows the equivalence of the Boltzmann and Kubo formalisms in the weak scattering limit (see also Butler, 1985). To calculate the residual resistivity, that is the resistivity at zero temperature caused by scattering at defects only, the current density is expressed by the deviation g_k of the distribution function

$$\mathbf{j} = -\frac{e}{V} \sum_k \mathbf{v}_k g_k \tag{28}$$

The contribution of the equilibrium occupation function $\mathring{f}$ vanishes. In the limit of zero temperature and linear response, the nonzero contributions of g_k are restricted to the Fermi surface and the current density can be expressed by a Fermi surface integral, using the ansatz in equation (24)

$$\sigma_{ij} = \frac{e^2}{V} \sum_k \delta(E_k - E_\mathrm{F})\, v_{k,i} \Lambda_{k,j} \tag{29}$$

with i and j as the Cartesian coordinates. For ferromagnetic systems a sum over the spin directions has to be performed which results in a factor 2 for nonmagnetic systems.

Applying the relaxation time approximation for the evaluation of the vector mean free path, the Fermi surface integral for the conductivity contains the tensor of the Fermi velocities scaled by the state-dependent relaxation time

$$\sigma_{ij} = \frac{e^2}{V} \sum_k \delta(E_k - E_\mathrm{F}) v_{k,i} v_{k,j} \tau_k \tag{30}$$

The Fermi surface integral contains information about the band structure of the unperturbed system only and τ_k contains information about the scattering properties. This approximation will be used later on to explain the origin of intrinsic and extrinsic GMR since the band structure and the scattering properties can be nicely separated.

2.2 Landauer theory

For mesoscopic systems where the system size plays a crucial role for transport properties the Landauer–Büttiker theory is an established method (Landauer, 1970; Landauer, 1988; Büttiker, 1988; Datta, 1995). The considered device contains a scattering region, which is connected to electron reservoirs by ideal leads which feed the current in and take it out. The measurement geometry is illustrated in Figure 5 and determines the assumption to be made in the application of the formalism. A two-terminal device is characterized by two reservoirs and current as well as voltage are measured at the same leads. In the case of zero temperature and within linear response, the Landauer conductance becomes

$$g = \frac{e^2}{h} \sum_{\substack{k_\mathrm{L}, k_\mathrm{R} \\ E_{k_\mathrm{L}} = E_{k_\mathrm{R}} = E_\mathrm{F}}} T_{k_\mathrm{L} k_\mathrm{R}} \tag{31}$$

with $T_{k_\mathrm{L} k_\mathrm{R}}$ the quantum-mechanical probability for a state k_L incident from the left reservoir to be transmitted into state k_R of the right-hand side reservoir. k_L and k_R are the quantum numbers of the eigenstates in the left- and right-hand side electrode, respectively, which are normalized to carry a unit current.

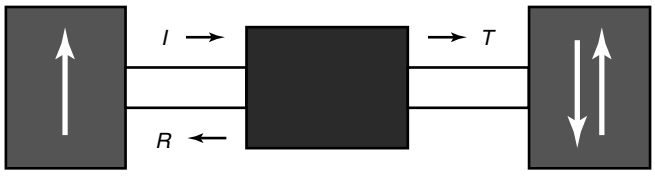

Figure 5. Geometry for the conductance measurement in mesoscopic systems with magnetic electrodes: a scattering region is connected by ideal leads to electron reservoirs (bath), which determine the voltage drop at the junction.

This formula was empirically derived for one-dimensional systems. Fisher and Lee have later shown that equation (31) can be extended to systems of higher dimensions using the transmission matrix t connecting the incident flux in the various channels k_L to the outgoing flux in the channels k_R on the other side (Fisher and Lee, 1981).

For planar tunnel junctions with an in-plane translational invariance and magnetic electrodes, k_L and k_R are shorthand notations for $(\mathbf{k}_\parallel, \nu, \sigma)$, the in-plane wave vector $\mathbf{k}_\parallel$, band index ν, and spin σ in the left or right lead, respectively.

The transmission as introduced by Landauer can be computed by means of the Green's function of the semi-infinite system (Baranger and Stone, 1989). The conductance g for planar junctions with an in-plane translational invariance is obtained by a two-dimensional integration in the surface Brillouin zone (Mavropoulos, Papanikolaou and Dederichs, 2004)

$$g = \frac{e^2}{h} \int \mathrm{d}^2\mathbf{k}_\parallel T_{\mathbf{k}_\parallel}(E_\mathrm{F}) \tag{32}$$

$$T_{\mathbf{k}_\parallel}(E) = \mathrm{tr}\left[J_\mathrm{L}(E) G_\mathrm{LR}(\mathbf{k}_\parallel, E) J_\mathrm{R}(E) G_\mathrm{RL}(\mathbf{k}_\parallel, E)\right] \tag{33}$$

The planes L and R are situated on both sides of the barrier in the unperturbed electrode regions. $J_\mathrm{L}(E)$ and $J_\mathrm{R}(E)$ are the current operator matrices and $G_\mathrm{LR}(\mathbf{k}_\parallel, E)$ are the Green's function elements connecting both sides of the junction. The transmission $T_{\mathbf{k}_\parallel}(E)$ contains as eigenvalues of the matrix the transmission coefficients T_m of the states fed by the reservoirs as introduced by Büttiker, Imry, Landauer and Pinhas (1985).

Transforming equation (31) for a three-dimensional electron gas and perfect transmission to a Fermi surface integral the ballistic or Sharvin conductance (Sharvin, 1965) is obtained

$$g(\mathbf{n}) = \frac{e^2}{h} \frac{A}{4\pi^2} \frac{1}{2} \sum_k \delta(E_k - E_\mathrm{F}) \, |\mathbf{n} \cdot \mathbf{v}_k| \tag{34}$$

$A/4\pi^2$ denotes the density of states of transverse modes and $|\mathbf{n} \cdot \mathbf{v}_k|$ is the Fermi velocity projection on the current direction $\mathbf{n}$. The factor $1/2$ accounts for the electrons moving in the direction of the current. It describes the conductance of a narrow region with cross section A which is connected to two electrodes. It is referred to as ballistic point contact when the diameter of the narrow region is much smaller than the mean free path and much larger than the electron wavelength. In multilayer geometry the vector $\mathbf{n}$ perpendicular to the planes describes the CPP geometry and $\mathbf{n}$ parallel to the planes of the CIP geometry. Although in most experiments this situation is not realized, the formalism was applied to elucidate the microscopic origin of intrinsic GMR (Schep, Kelly and Bauer, 1995; Gijs and Bauer, 1997).

2.3 Kubo formalism

A method of evaluating the response of a quantum mechanical system to an external potential was developed by Kubo in the 1950s, in particular, the current in response to an electric field (Kubo, 1957). In the linear response the two are related by a conductivity which is given in terms of the equilibrium properties of the system, that is, in zero field. Therefore, to calculate the conductivity it is necessary to start from the Hamiltonian that describes the ground state of the conduction electrons. Also we are primarily interested in transport at $T = 0\,\mathrm{K}$, so processes that occur at finite temperature are omitted. Using the Kubo formalism conductivity is evaluated entirely quantum mechanically by the current–current correlation function for the ground state (Kubo, 1957). It is a form of the fluctuation-dissipation theorem (Kubo, 1966), relating a transport coefficient, which characterizes a dissipative process, to the fluctuations at equilibrium. It gives the transport coefficient in the linear response regime and there are no restrictions concerning the strength of the scattering occurring in the system.

First, the expression for the conductivity will be derived starting from the Kubo–Greenwood formula and using the one-particle Green's function. Zero temperature conductivity can be obtained from the current operator by the commonly used expression (Kubo, 1957; Greenwood, 1958; Velický, 1969)

$$\sigma_{ij} = \frac{\pi}{N\Omega} \langle \mathrm{Tr}\, \mathcal{J}_i \delta(E - \mathcal{H}) \mathcal{J}_j \delta(E - \mathcal{H}) \rangle_\mathrm{conf} \Big|_{E=E_\mathrm{F}} \quad \text{with}$$

$$\mathcal{J}_i = -2\imath e \frac{\partial}{\partial x_i} \tag{35}$$

It can be considered in terms of nonlocal conductivities connecting the external field in direction i at one site to the induced current in direction j at another site. N denotes the number of atoms in the sample, Ω is the volume per atom. For systems with a basis it is replaced by the normalization volume $V_\diamond$ of the wave function. In the following the formalism will be given for a bulk system with one atom per unit cell. For systems with a layered structure as considered in Weinberger *et al.* (1996) or bulk systems with an atomic basis a thorough bookkeeping of the layer, unit cell, and atomic indices has to be performed. We consider a sample containing defects μ at random positions $\mathbf{r}_\mu$ with relative concentrations c_μ which give the number of defects per normalization volume. $\mathcal{H}$ is the Hamilton operator of one configuration of the random potential. The large brackets $\langle\rangle_\mathrm{conf}$ denote the configurational average. x_i is a Cartesian coordinate of the real-space vector $\mathbf{r} = (x_1, x_2, x_3)$. For simplicity a compact operator representation is used in this chapter. By means of the Green's function the δ functions

can be replaced by

$$\delta(E-\mathcal{H}) = -\frac{1}{\pi} Im\mathcal{G}(E^+) = -\frac{1}{2\pi\imath}\left[\mathcal{G}(E^+)-\mathcal{G}(E^-)\right], \text{ with } E^\pm = E \pm \imath 0 \tag{36}$$

and the expression from equation (35) splits into four parts

$$\sigma_{ij} = \frac{1}{4}\left(\sigma_{ij}^{++} + \sigma_{ij}^{--} - \sigma_{ij}^{-+} - \sigma_{ij}^{+-}\right), \quad \text{with}$$

$$\sigma_{ij}^{\pm\pm} = -\frac{1}{\pi N\Omega}\,\langle \mathrm{Tr}\ \mathcal{J}_i\ \mathcal{G}(E^\pm)\mathcal{J}_j\ \mathcal{G}(E^\pm)\rangle_{\mathrm{conf}}\big|_{E=E_\mathrm{F}} \tag{37}$$

To evaluate the configurational average over the Green's function $\mathcal{G}(E^\pm)$ the coherent-potential approximation (CPA) first proposed by Velicky and others (Velický, 1969; Gyorffy, 1972; Butler, 1985) might be used. Using the Green's function of the coherent medium and the transition matrices of the single defects, the correspondence of the exact solution of the Boltzmann equation (27) can be demonstrated and the criteria for the applicability of the Boltzmann approach can easily be deduced.

2.4 Magnetic systems

The basic output of a self-consistent electronic structure calculation is the local electron density. In addition, the energy bands E_k and eigenstates Bloch functions ψ_k defined by the Kohn–Sham equation (10) are obtained (Kohn and Sham, 1965). As before, the index k is a shorthand notation for the wave vector $\mathbf{k}$, the band index ν, and the spin index σ. In systems with a net magnetization, the spin degeneracy is lifted and at a given energy eigenstates of rather different character can be found. A prominent example is the relative shift of the spectra in both spin channels, which is obvious for the spin-dependent DOS for Co and Fe in Figure 6.

The properties at the Fermi level are of special interest in the following transport calculations, since they are the main ingredients to calculate the transport coefficients within the chosen approximation. The Fermi velocities are defined by the derivative of the energy bands given in equation (21). The Fermi surface contains all k points with an eigenvalue of the energy E_k^σ equal to the Fermi level E_F. Examples for Fermi surfaces are given in Figure 6 and can be found on the web at http://www.physik.tu-dresden.de/∼fermisur (1998) together with the corresponding Fermi velocity distribution and at http://www.phys.ufl.edu/fermisurface (2005).

For magnetic systems the properties of both spin channels differ quite strongly, which is illustrated by the spin-dependent Fermi surface of Co and the spin-dependent DOS for Co and Fe in Figure 6. For some material combinations the properties of one spin channel coincide to a large extent. This is the case for the majority channels of Co and Cu, which can be seen from the Fermi surfaces and from the DOS in Figure 6. The similarities in the minority channel in Cr, which is actually antiferromagnetic, and Fe can be deduced from the comparison of the LDOS in Figure 6.

In magnetic systems with negligible spin-flip scattering, both spin channels contribute to the current in parallel applying Mott's two-current model, see Figure 7 (Mott, 1964). This applies to systems with collinear magnetic order in the nonrelativistic case. This causes spin-dependent scattering events which change the momentum $\mathbf{k}$ but keep the spin unchanged, so that the scattering probability becomes diagonal in spin space

$$P_{kk'}^{\sigma\sigma'} = \delta_{\sigma\sigma'} P_{kk'} \tag{38}$$

The neglected transition probability amplitudes $P_{kk'}^{\sigma\overline{\sigma}}$ are marked by dashed lines in Figure 8. As a consequence, the conductivity or resistivity are split in majority and minority contributions

$$\sigma = \sigma^\uparrow + \sigma^\downarrow \tag{39}$$

$$\frac{1}{\rho} = \frac{1}{\rho^\uparrow} + \frac{1}{\rho^\downarrow} \tag{40}$$

A similar separation of the spin contributions holds for the conductance or resistance in this case

$$g = g^\uparrow + g^\downarrow \tag{41}$$

$$\frac{1}{R} = \frac{1}{R^\uparrow} + \frac{1}{R^\downarrow} \tag{42}$$

To quantify the contribution of the spin channels, the spin-anisotropy ratio

$$\alpha = \frac{\rho^\uparrow}{\rho^\downarrow} = \frac{\sigma^\downarrow}{\sigma^\uparrow} \tag{43}$$

is defined. In nonmagnetic systems α equals unity and strong deviations from one point to the dominance of one spin channel. For a given host material, the spin anisotropy can vary strongly with the type of defects considered. This is discussed in Mertig (1999) for bulk systems and illustrated in Section 4, Figure 25 for layered structures.

The anisotropy of scattering is characterized by the ratio

$$\beta = \frac{\tau^\uparrow}{\tau^\downarrow} \tag{44}$$

which gives the differences in the averaged electron momentum lifetimes for both spin channels.

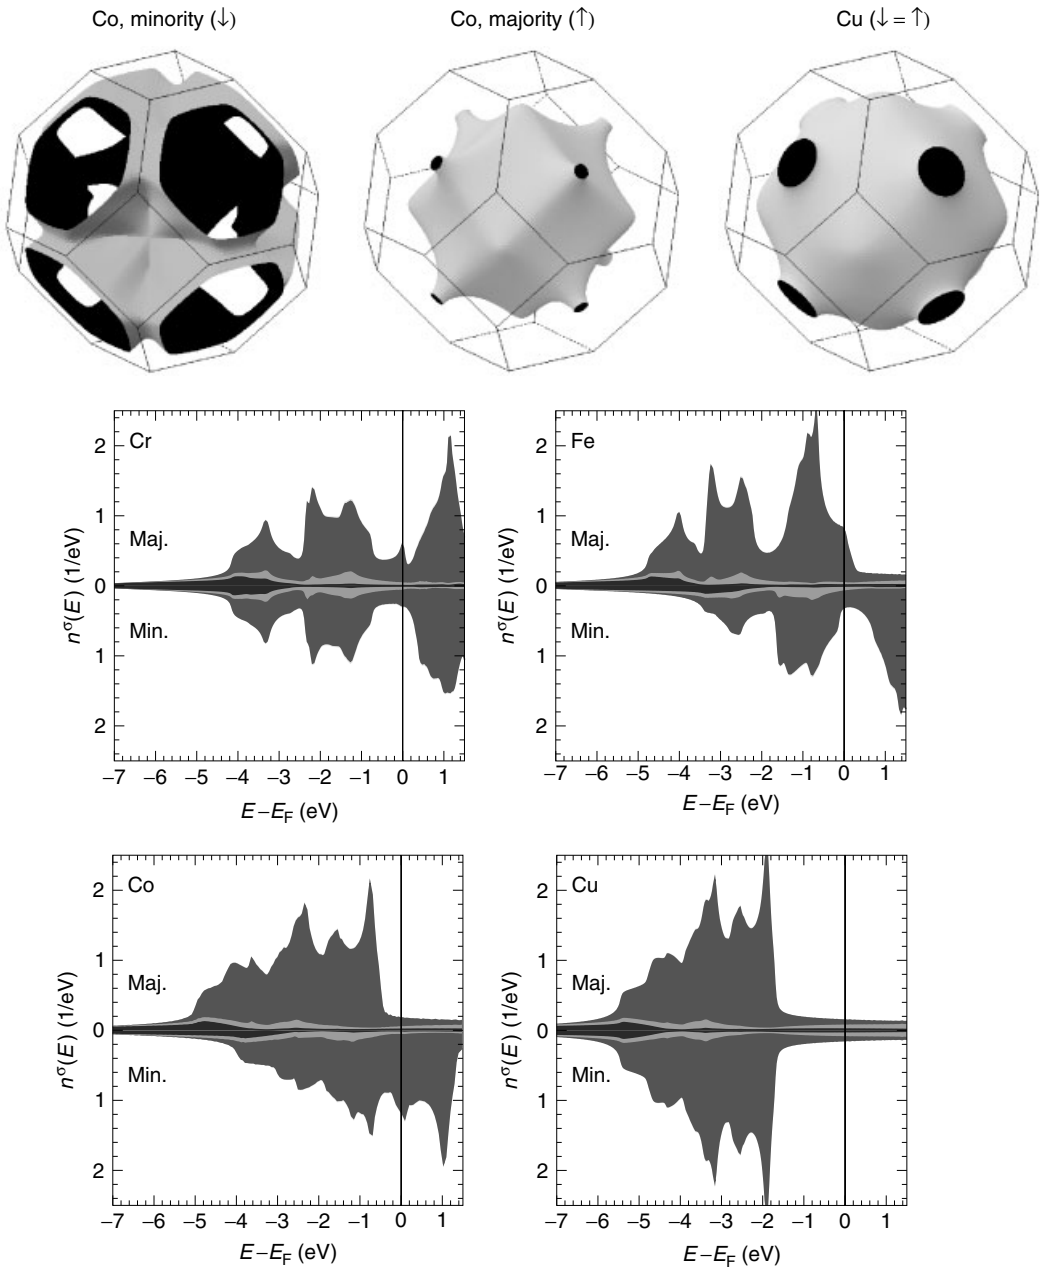

Figure 6. Spin dependence of eigenvalue spectra: Fermi surfaces for Co minority electrons (contribution from the fifth band), Co majority electrons and Cu electrons (top row from left) and spin-dependent density of states for Cr, Fe, Co, and Cu; the colors indicate the amount of s electrons (black), p electrons (light gray), and d electrons (dark gray).

In the above discussion we neglected spin-flip scattering. If one includes spin-flip scattering, the two spin currents are mixed, that is, they are not independent of each other any more. At low temperature, the primary source of spin-flip scattering comes from impurities with spin-orbit coupling or paramagnetic ones for which spin flip is an elastic process. As most of the scattering encountered in magnetic multilayers at low temperature does not flip spin as this costs energy, that is, it is inelastic, the spin diffusion length is usually much longer than the mean free path (Valet and Fert, 1993), so that for CIP where transport is controlled by Λ the presence of spin-flip processes and the subsequent breakdown of the two-current model is not perceived. However for CPP, where Λ does not control GMR, spin-flips limit the distance over which the two spin currents are independent, and concomitantly reduce the GMR in this geometry. This has been nicely demonstrated in a series of experiments in which the amount of spin-flip scatterers, spin-orbit coupled and paramagnetic impurities,

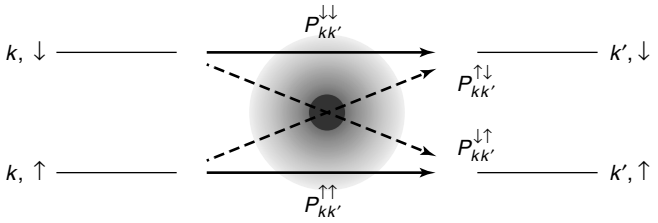

Figure 7. Two-current model: spin-dependent resistors in parallel.

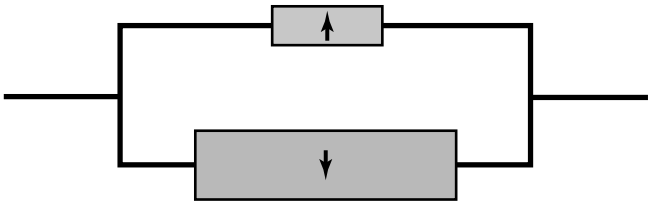

Figure 8. Spin-flip and spin-conserving transition probabilities in magnetic systems.

has been shown to mix the two currents and significantly reduce the GMR (Bass *et al*., 1994; Yang *et al*., 1994). At higher temperatures inelastic spin-flip processes occur. Without introducing impurities, for example, electron–magnon scattering, however, the resistivity assigned to each channel does not increase since momentum is conserved (Fert, 1969; Fert and Campbell, 1976; Campbell and Fert, 1982).

The basis for the simple parameterization of transport in the two-current model is usually assigning one scattering rate τ^{σ} to all the currents with one spin direction. While this may have some validity for homogeneous materials it is not correct for multilayers, except for the local limit which is attained in magnetically layered nanowires (Piraux, Dubois and Fert, 1996; Piraux *et al*., 1997; Piraux, Dubois, Fert and Belliard, 1998). As we show in Section 4 scattering depends on momentum as well as spin; there are as many scattering rates as there are states in a multilayered structure. Parenthetically, as transport is primarily confined to the Fermi surface, by momentum we mean the Fermi momentum. While it is nigh impossible for toy models to account for this, *ab initio* calculations are ideally suited for this task (Binder *et al*., 1998; Blaas *et al*., 1999). Calculations which are completely *ab initio* include the two-current model automatically; however, these calculations have been found to be extremely time consuming. One compromise has been to perform *ab initio* calculations of the band structure and assign different spin-dependent scattering rates to layers and interfaces that are independent of the electron's momentum (Butler *et al*., 1999). This provides a convenient way to include the effects of band structure and a parameterization of the scattering in the different regions with a reasonable number of unknown constants that are determined by fits to experimental data. The concern one might have is that the neglect of the dependence of scattering rates on momentum yields unrealistic scattering rates.

One final source for breakdown of the independence of the up-and-down spin currents is the noncollinearity of the spin structure. For noncollinear structures the eigenstates are not pure spin states, so that when electrons undergo non-spin-flip scattering they nonetheless mix the currents being conducted in eigenstates. This mixing has been identified as a source of resistivity of walls between oppositely oriented magnetic domains (Levy and Zhang, 1997; Brataas, Bauer and Kelly, 2006).

3 MICROSCOPIC SCATTERING THEORY

This section is addressed to the properties of point defects, including the perturbation of the electron density, the perturbed wave functions, and the transition matrix elements. Defects with finite dimensions in all directions, so-called point defects or zero-dimensional defects are considered in the following. The unperturbed system we start from will be a superlattice, a system with three-dimensional periodicity. One single defect will be considered in the following neglecting the interaction of defects and limiting the considerations to the case of dilute alloys. The position of the defect in the unperturbed system is essential for the scattering properties and all derived quantities. For example, in layered systems described by a large unit cell, there are quite different positions for defects, for example, inside the different layers or with respect to the interfaces Figure 9.

The Green's functions of the perturbed system and the unperturbed system are connected by a Dyson equation, see equation (13). The unperturbed system $\mathring{G}$ is now the periodic system without defects and G describes the system with one defect at a specific position μ. The difference of the effective potential $\Delta V^{\mu}(\mathbf{r})$ describes the potential perturbation caused by the defects. Owing to the effective

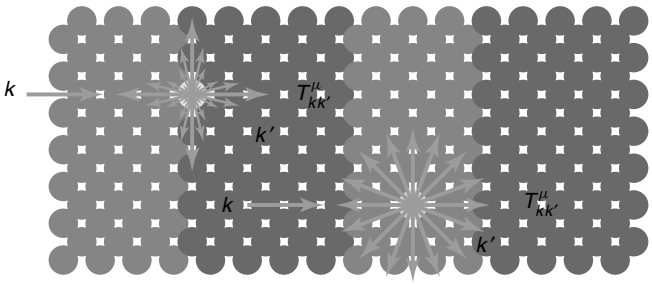

Figure 9. Source of resistance: scattering from a state k into possible states k' at impurities in a multilayer at different positions μ and μ'.

screening of the perturbation in metallic systems, the charge and magnetization relaxation are mainly restricted to the vicinity of several coordination spheres around the defect. The solution of equation (13) can be restricted to a number of neighboring sites next to the defect. Using the Green's function G of the perturbed system the changes in charge and magnetization density can be calculated self-consistently.

The perturbation of the potential $\Delta V^{\mu}(\mathbf{r})$ causes scattering processes of the unperturbed Bloch states which keep the spin and the energy unchanged. The neglect of spin-flip processes is justified by experimental results that in 3d transition metals the scattering cross section for these processes is about 2 orders of magnitude smaller than that for spin-conserving processes (Fert and Campbell, 1976). The scattering at the potential perturbation $\Delta V^{\mu}(\mathbf{r})$ can be expressed by the transition matrix T

$$T^{\mu}_{kk'} = \left(\mathring{\psi}_k(\mathbf{r})|\Delta V^{\mu}(\mathbf{r})|\psi_{k'}(\mathbf{r})\right) = \int \mathrm{d}\mathbf{r}\mathring{\psi}^{*}_k(\mathbf{r})\Delta V^{\mu}(\mathbf{r})\psi_{k'}(\mathbf{r}) \tag{45}$$

which is the quantum-mechanical matrix element.

Providing that the wave functions $\psi^{\mu}_{k'}(\mathbf{r})$ of the perturbed systems can be calculated from the unperturbed ones $\mathring{\psi}_k(\mathbf{r})$ by a Lippman–Schwinger equation

$$\psi^{\mu}_{k'}(\mathbf{r}) = \mathring{\psi}_k(\mathbf{r}) + \int \mathrm{d}\mathbf{r}'\mathring{G}(\mathbf{r},\mathbf{r}',E)\Delta V^{\mu}(\mathbf{r}')\psi^{\mu}_k(\mathbf{r}) \tag{46}$$

the transition matrix can be expressed using only the eigenstates of the unperturbed system and the potential perturbation. By multiple scattering theory, the full perturbation series can be included by inversion, so that the theory is restricted to the dilute limit, which means noninteracting impurities, but is not restricted to weak scattering (Mertig, Mrosan and Ziesche, 1987; Mertig, 1999).

4 MICROSCOPIC THEORY OF GMR

4.1 Intrinsic GMR

The GMR ratio equation (6) calculated within the relaxation time approximation $\mathbf{\Lambda}_k = \tau_k \mathbf{v}_k$ (compare equation (25)) assuming a k-independent relaxation time becomes (Zahn, Mertig, Richter and Eschrig, 1995)

$$GMR = \frac{\sum_k \delta(E^{\uparrow}_k - E_{\mathrm{F}})\, v^{\uparrow}_{k,i}{}^2 + \sum_k \delta(E^{\downarrow}_k - E_{\mathrm{F}})\, v^{\downarrow}_{k,i}{}^2}{2\sum_k \delta(E^{\mathrm{AP}}_k - E_{\mathrm{F}})\, v^{\mathrm{AP}2}_{k,i}} - 1 \tag{47}$$

where $v_{k,i}$ with $i = (\parallel, \perp)$ are the Cartesian components of the velocity parallel and perpendicular to the layers. As we have not considered the spin dependence of the relaxation times, they cancel out, and the GMR ratio is only determined by the intrinsic electronic structure of the system. For concreteness, but without loss of generality, we focus on a Co/Cu multilayered structure. A detailed analysis of the GMR ratio depending on the spacer thickness (equation (47)) for $\mathrm{Co}_n\mathrm{Cu}_m$ multilayers is shown in Figure 10. The CPP-GMR is always larger than the CIP-GMR, and the ratios decrease with increasing Cu-layer thickness (see also Levy, 1994). For a better understanding of these results we can approximate the GMR ratio by using the density of states at the Fermi level $n^{\sigma}(E_{\mathrm{F}}) = \sum_k \delta(E^{\sigma}_k - E_{\mathrm{F}})$, and a Fermi surface average of the square of the velocity components

$$\overline{v^{\sigma}_{k,i}{}^2} = \frac{\sum_k \delta(E^{\sigma}_k - E_{\mathrm{F}})\, v^{\sigma}_{k,i}{}^2}{\sum_k \delta(E^{\sigma}_k - E_{\mathrm{F}})} \tag{48}$$

this leads to

$$GMR \approx \frac{n^{\uparrow}(E_{\mathrm{F}})\,\overline{v^{\uparrow}_{k,i}{}^2} + n^{\downarrow}(E_{\mathrm{F}})\,\overline{v^{\downarrow}_{k,i}{}^2}}{2\, n^{\mathrm{AP}}(E_{\mathrm{F}})\,\overline{v^{\mathrm{AP}2}_{k,i}}} - 1 \tag{49}$$

4.1.1 *Electronic structure of the multilayer*

The electronic structure of the majority bands of Co and Cu are very similar (see also Figure 6). The majority d bands are fully occupied and lie below the Fermi level. However, since Co has two electrons less than Cu, the minority band of Co is less occupied and the electronic structure of the minority band at the Fermi energy is very different for both

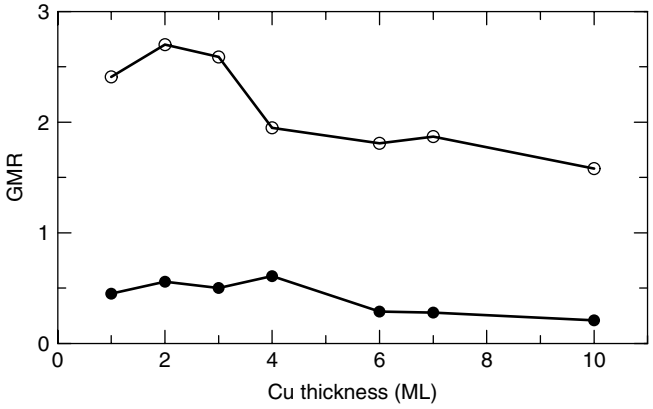

Figure 10. Calculated GMR ratios for Co/Cu(100) multilayers as a function of the Cu layer thickness, CIP-GMR (filled circles) and CPP-GMR (open circles).

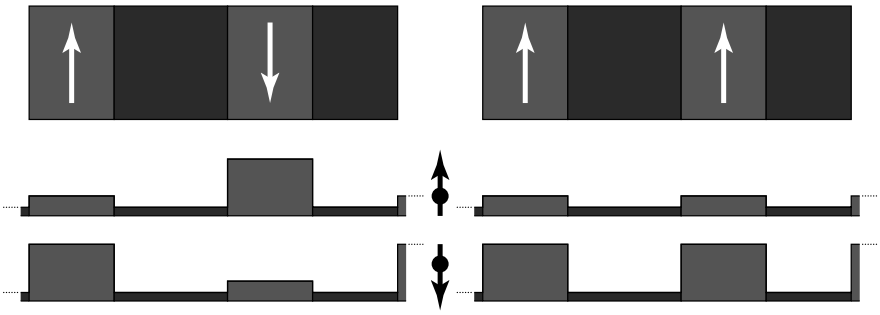

Figure 11. Spin-dependent potentials in a magnetic multilayer for the AP and P configurations for majority and minority electrons.

metals. The majority electrons of a multilayer at E_F with their moments aligned in parallel traverse easily through the system; the reason is that the potential landscape is very flat (see Figure 11) since the bandwidth is nearly the same in each layer. On the contrary, minority electrons at E_F experience high potential steps and are reflected at the Co/Cu interfaces. As a result, the Fermi velocity of the majority electrons is much larger than the Fermi velocity of the minority electrons, $v_F^{\uparrow} \gg v_F^{\downarrow}$ (see also Figure 13). A multilayer with antiparallel moments consists of a potential with a potential well in alternate layers since the spin character of the electrons (majority, minority) changes in every other layer (see Figure 11); also both spin channels are degenerate. The velocity of the electrons is mainly determined by the largest potential step. For this reason the Fermi velocity of the electrons in an AP-ordered multilayer is nearly the same as for the minority electrons, $v_F^{\uparrow} \gg v_F^{AP} \geq v_F^{\downarrow}$ (see also Figure 13).

The densities of states at the Fermi level for P and AP configurations as a function of Cu-layer thickness are shown in Figure 12. When one adds the majority and minority density of states in P configuration they are quite close to the density of states in AP configuration, so that they are neither responsible for the positive GMR ratios nor account for the differences between the CIP- and CPP-GMR; rather these result from differences of the averaged velocities as a function of the magnetic configuration (Figure 13).

If we compare the averaged velocities of the majority and minority electrons in the parallel configuration with those in

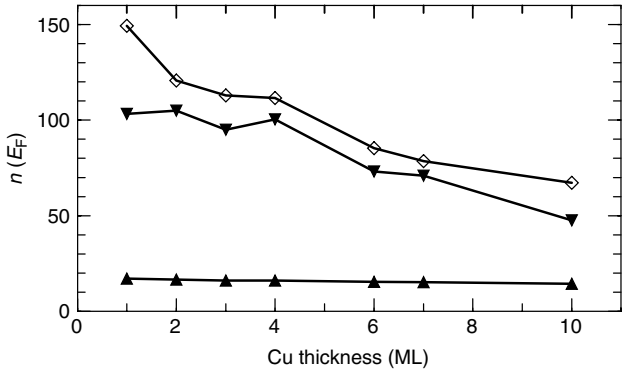

Figure 12. Densities of states at the Fermi energy for Co/Cu(100) multilayers as a function of Cu-layer thickness for majority electrons (triangle upwards) and minority electrons (triangle downwards) in P configuration and in AP configuration (diamonds). (Reproduced from I. Mertig, P. Zahn, M. Richter, H. Eschrig, R. Zeller & P.H. Dederichs: 'Ab initio calculation of residual resisistivity in dilute Fe alloys and giant magnetoresistance in Fe/Cr multilayers', *J. Mag. Mag. Mat.* **151** (1995), copyright © 1995, with permission from Elsevier.)

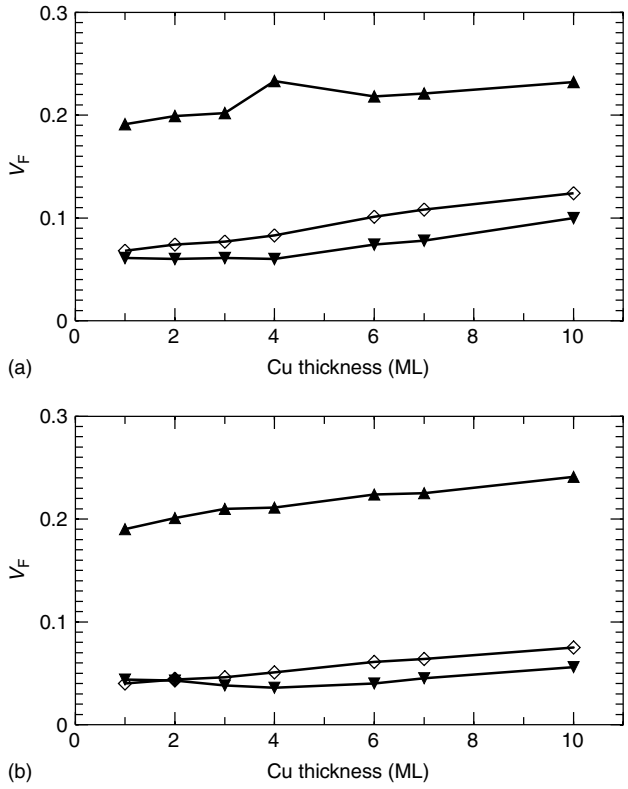

Figure 13. The average of the Fermi velocities in the plane of the layers $\sqrt{\overline{v_{\parallel}^2}}$ (a) and perpendicular to the layers $\sqrt{\overline{v_{\perp}^2}}$ (b) for majority (triangle upwards) and minority (triangle downwards) electrons in P and in AP configuration (diamonds) (Zahn, Mertig, Richter and Eschrig, 1995, 1998; Mertig *et al*., 1995).

the antiparallel configuration we notice that this would lead to a positive GMR ratio. For the components in the plane of the layers $v_{\parallel}$, the CIP-GMR is obtained, whereas $v_{\perp}$ leads to CPP-GMR. When we compare the in-plane components of the velocity with the components perpendicular to the plane (Figure 13) we can even explain the differences of the CIP- and CPP-GMR. Similar conclusions have been drawn by Oguchi (1993) and Butler, MacLaren and Zhang (1993, 1996).

The same result was obtained by calculating the GMR of point contacts in the ballistic limit of transport by using the conductance of equation (34) (Schep, Kelly and Bauer, 1995; Gijs and Bauer, 1997).

4.1.2 Eigenstates of the multilayers

An important ingredient to the microscopic understanding of the conductivity is the layerwise decomposed density of states. The LDOS is calculated from the diagonal part of the spin-dependent one-particle Green's function of the multilayer system (see equation (14)). They can be resolved by means of the spectral representation of the Green's function into a superposition of probability amplitudes of all eigenstates at energy E_{F}.

The LDOS at E_{F} of the P configuration is shown in Figure 14(a) and is nearly the same at all monolayers in the majority channel. The minority electrons are characterized by a very inhomogeneous profile. The LDOS in Co layers is much higher than that in Cu layers. The largest values are obtained for the Co layers at the interface. This is a general behavior independent of Co- or Cu-layer thicknesses. This profile can easily be interpreted by means of probability amplitudes of the eigenstates. Owing to a smooth potential profile most of the eigenstates in the majority bands are extended with a constant probability amplitude for all layers (Figure 14b). In contrast, the minority electrons move in a multiwell potential with a periodicity perpendicular to the layers (z direction). For this reason quantum well states appear which are well localized in z direction but extended in plane. Besides quantum well states with a localization in the center of the Co and Cu layers (Figure 14c,d) pronounced interface states in the Co layers are formed as shown in Figure 14(e). The interface state can be understood in terms of resonant scattering and compares to the virtual bound state (VBS) of a Co impurity in a Cu matrix (Dederichs and Zeller, 1981).

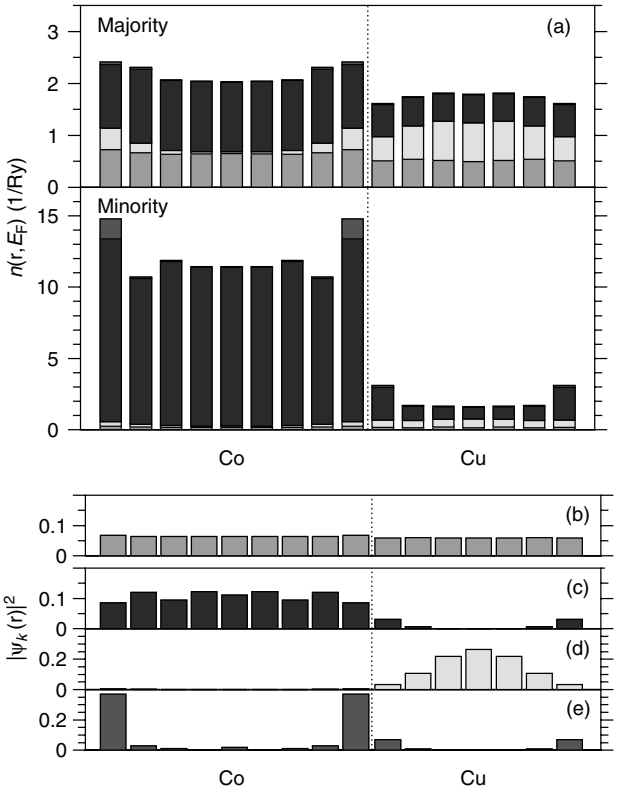

Figure 14. Co_9Cu_7 in P configuration: spin-resolved local density of states at E_{F} in (au) (a), probability amplitude of an extended majority state (b) and of different quantum well and interface states in the minority band (c–e). (Reproduced from Zahn *et al*., 1998, with permission from the American Physical Society. © 1998.)

4.2 Extrinsic GMR

It was shown in the last section that the GMR effect has an intrinsic origin determined by the electronic structure of the magnetic multilayer. Since the intrinsic effect is based on the coherent electronic structure, the samples have to be of high quality. Another rather robust mechanism is spin-dependent scattering in magnetic multilayers. The scattering properties of impurities in magnetic systems exhibit a spin anisotropy (Mertig, 1999). That is, majority and minority electrons undergo a scattering process of different strength. As a measure, the so-called scattering anisotropy of the resistivity (equation (43)) is used. This property, namely, spin-dependent impurity scattering in multilayers causes the GMR effect. The mechanism is illustrated in Figure 15. Let us consider an impurity atom with a scattering anisotropy $\alpha < 1$. The majority electrons are weakly scattered by the impurity in the magnetic layer and cause a small resistance $R^{\uparrow}$ and a large current. The minority electrons, however, are scattered strongly at the same impurities in the magnetic layer which results in a large resistance $R^{\downarrow}$ and a small current. The total resistance R^{P} is small since the fast majority channel determines the transport. In the AP configuration both channels have the same resistance. Strong and weak scattering alternate from layer to layer for the electrons of both spin directions and produce a resistance $R^{\mathrm{AP}} > R^{\mathrm{P}}$ which corresponds to a positive MR effect.

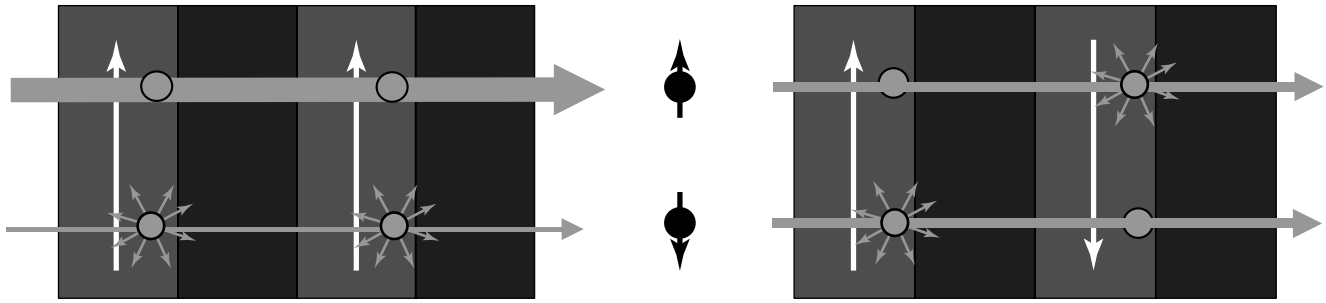

Figure 15. Extrinsic GMR: spin-dependent scattering in magnetic multilayers.

The qualitative picture discussed above will be manifested in a quantitative analysis of the scattering properties of impurities in magnetic multilayers. The results are based on *ab initio* electronic structure calculations. The data demonstrate the diversity of the considered systems, explain obtained experimental trends, and can be understood as instructions to tailor GMR systems of desired properties. Combination of impurities with opposite spin anisotropy can even cause inverse GMR.

4.2.1 Electronic structure of impurities in magnetic multilayers

Impurities are a perturbation of the host material and cause charge and magnetization relaxation. As a result of a self-consistent impurity calculation, the density of states at the impurity site includes all the necessary information. Impurities in a multilayer show a strong dependence on their position with respect to the interfaces. If the impurities are situated in the center of a layer, the LDOS is similar to the corresponding bulk system. At the interfaces the properties are changed.

In this section the LDOS of the 3d transition-metal impurities in Co/Cu multilayers are presented in Figure 16. The data are for impurities in the center and at the interface of the magnetic and of the nonmagnetic layer to demonstrate the differences as a function of the impurity position in the multilayer. Co in Co and Cu in Cu characterize the corresponding host properties, that is, the LDOS in the center and at the interface of the Co and Cu layer. Obviously, the Co and Cu density of states in the center of the Co layer is the same as in bulk (see also Figure 6). Co is magnetic with a moment of $1.64\,\mu_B$. The Co moment at the interface is reduced to $1.55\,\mu_B$. The Cu interface layer is also magnetic with a very small moment parallel to the Co moments of $0.01\,\mu_B$. The central Cu layer is nonmagnetic. The LDOS are shown from left to right corresponding to their position in the unit cell: central Co layer, Co and Cu interface layers, and the central Cu layer. The LDOS in the central layers coincides with the respective properties of bulk defects (for comparison see Stepanyuk, Zeller, Dederichs and Mertig, 1994; Braspenning, Zeller, Lodder and Dederichs, 1984; Mertig, 1999).

In the central Cu layer all defects show a tendency to form VBSs. Their positions shift according to the band filling and for Co, Fe, Mn, Cr, and V a magnetic moment is formed. This tendency is enhanced when the defects are moved closer to the Co layer. In the Cu interface layer in close contact to the Co layer all 3d defects possess a magnetic moment. The orientation of the moment is opposite to the adjacent Co moment for Cr, V, Ti, and Sc in accordance with the less-than-half-filled 3d band. For Cr, V, and Ti an interesting feature is obtained: two VBSs at the upper band edges of the 3d states of the adjacent Co and Cu atoms, which are below and above the Fermi level are formed in the minority channel. The influence on the local magnetic moment and the DOS at the Fermi level is quite small and a smooth transition from the Co central position to the Cu central position is obtained.

The behavior of the 3d impurities in the Co central layer is dominated by the competition of the local electrostatic potential at the defect site which is weaker in the beginning of the row and larger for Ni and Cu. For Ni the reduced moment causes a reduction of the exchange energy which acts in the opposite direction to the Coulomb potential shift in the majority band and in the same direction for the minority electrons. So, the moment at the Ni impurities is suppressed, and the same holds for Cu atoms in the Co layer. The opposite shift, which is connected with a large local moment, is obtained for the minority states of Fe defects. For Mn and the earlier 3d elements the weakening of the electrostatic potential can no longer be counterbalanced by an increasing exchange potential, since the local moment cannot increase sufficiently. So, at Mn a VBS is formed in the majority channel just below the Fermi energy destabilizing the ferromagnetic solution. For Mn, Cr, V, Ti, and Sc an antiferromagnetic alignment of the local magnetic moment relative to the surrounding Co sites is obtained. This tendency is maintained for all sites in the Co layer, as can be recognized from the LDOS of the impurities at the Co interface position.

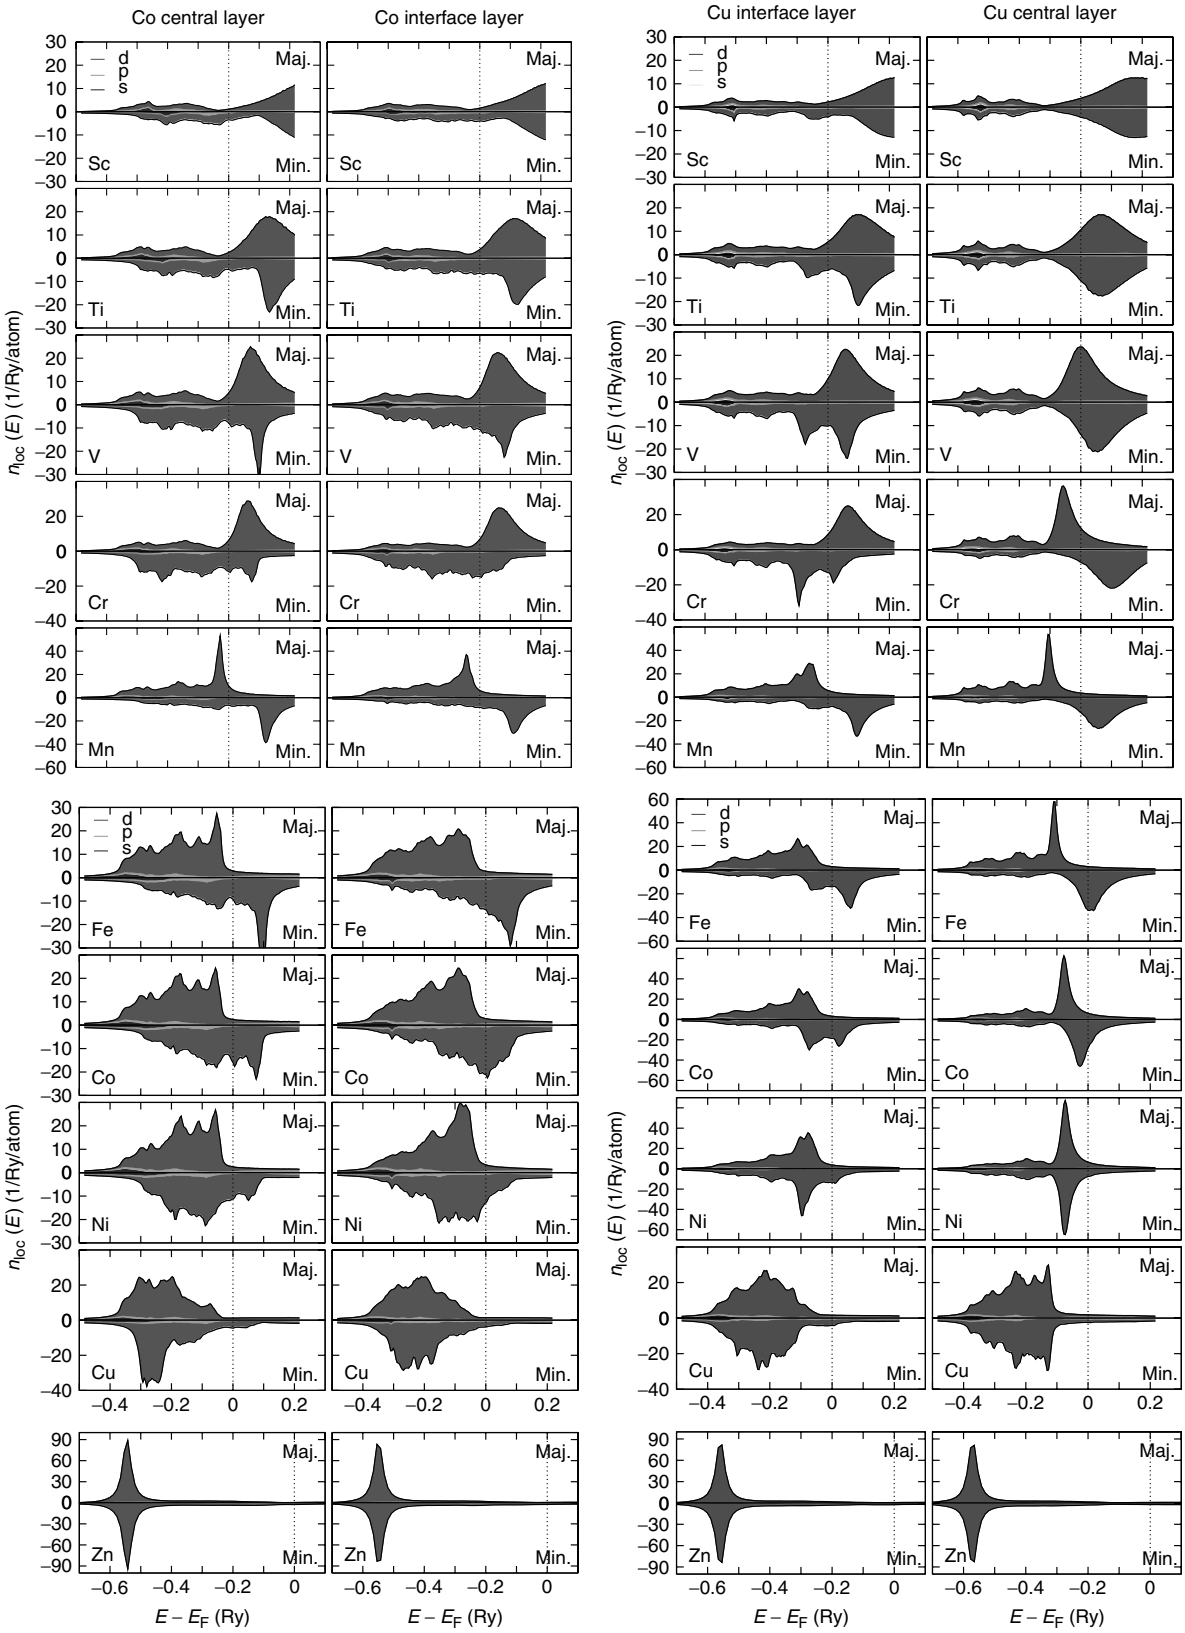

Figure 16. Local partial density of states for 3d transition-metal impurities at the central and interface sites of the Co and Cu layers of a $Co_9Cu_7(001)$ multilayer in P configuration; the color code is the same as in Figure 6.

4.2.2 Scattering anisotropy in bulk materials

The scattering properties of an impurity atom in a bulk system are highly anisotropic, that is, the relaxation times τ_k^σ vary strongly for different states. As an example, the relaxation time anisotropy is shown for a Cu impurity in Co bulk at the Fermi surface (Figure 17). The relaxation times of the minority electrons (Figure 17a) are on average shorter by 1 order of magnitude in comparison to those of the majority electrons (Figure 17b). Shorter relaxation times mean stronger scattering and, in principle, cause larger resistance. The relaxation times per Fermi surface sheet vary by a factor of 2 in bulk systems.

The scattering anisotropy in general is, however, hidden in the microscopic scattering probability $P_{kk'}$, which is an enormous amount of data. An example of a magnetic Co impurity in Cu bulk is given in Figure 18. The spin-conserving scattering probabilities of one initial state $\mathbf{k}$ fixed to (100) into all other states $\mathbf{k}'$ is visualized as a function of the scattering angle (a) or at the Fermi surface (b and c) for majority and minority electrons separately.

Assuming that the system without and with defects is invariant under time-reversal symmetry, one obtains

$$\mathbf{v}_{-k} = -\mathbf{v}_k \quad \text{and} \tag{50}$$

$$\mathbf{\Lambda}_{-k} = -\mathbf{\Lambda}_k \tag{51}$$

where $-k$ should denote the state with a reversed wave vector $-\mathbf{k}$ but the same band index ν. Using the symmetric and antisymmetric part of the transition probability matrix

$$P_{kk'}^{\mathrm{S}} = \frac{P_{kk'} + P_{k-k'}}{2} \quad \text{and} \tag{52}$$

$$P_{kk'}^{\mathrm{A}} = \frac{P_{kk'} - P_{k-k'}}{2} \tag{53}$$

one can rewrite the Boltzmann equation (25) as

$$\mathbf{v}_k = \sum_{k'} \left(P_{kk'}^{\mathrm{S}} \mathbf{\Lambda}_k - P_{kk'}^{\mathrm{A}} \mathbf{\Lambda}_{k'} \right) \tag{54}$$

From this equation it is evident that the Boltzmann relaxation time is determined by the symmetric part of $P_{kk'}$ and the vertex corrections in equation (25) by the antisymmetric contribution

$$\tau_k = \left[\sum_{k'} P_{kk'}^{\mathrm{S}} \right]^{-1} \quad \text{and} \tag{55}$$

$$\sum_{k'} P_{kk'} \mathbf{\Lambda}_{k'} = \sum_{k'} P_{kk'}^{\mathrm{A}} \mathbf{\Lambda}_{k'} \tag{56}$$

To quantify these contributions, the following anisotropies will be defined. The anisotropy α_k^{P} of forward and backward scattering is determined by the ratio of P_{kk} and P_{k-k} and is closely related to the ratio α_k^{A} of the antisymmetric scattering probability to the probability of forward scattering

$$\alpha_k^{\mathrm{P}} = \frac{P_{kk}}{P_{k-k}} \quad \text{and} \tag{57}$$

$$\alpha_k^{\mathrm{A}} = 1 - \frac{1}{\alpha_k^{\mathrm{P}}} = 2\frac{P_{kk}^{\mathrm{A}}}{P_{kk}} \tag{58}$$

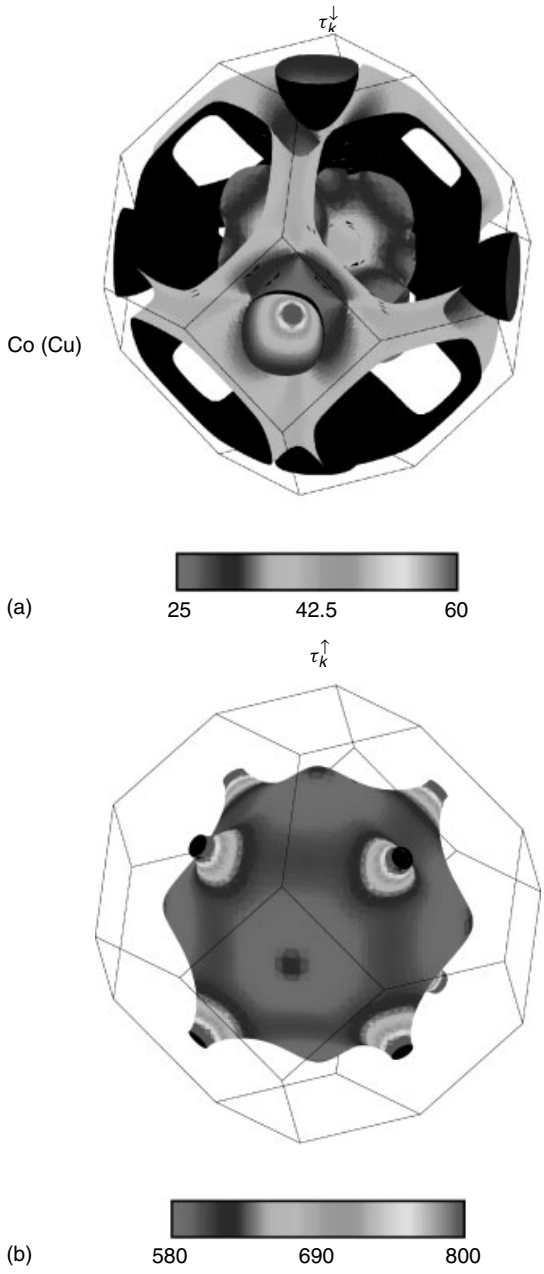

Figure 17. Anisotropic relaxation times τ_k^σ for Cu defects in a magnetic Co host.

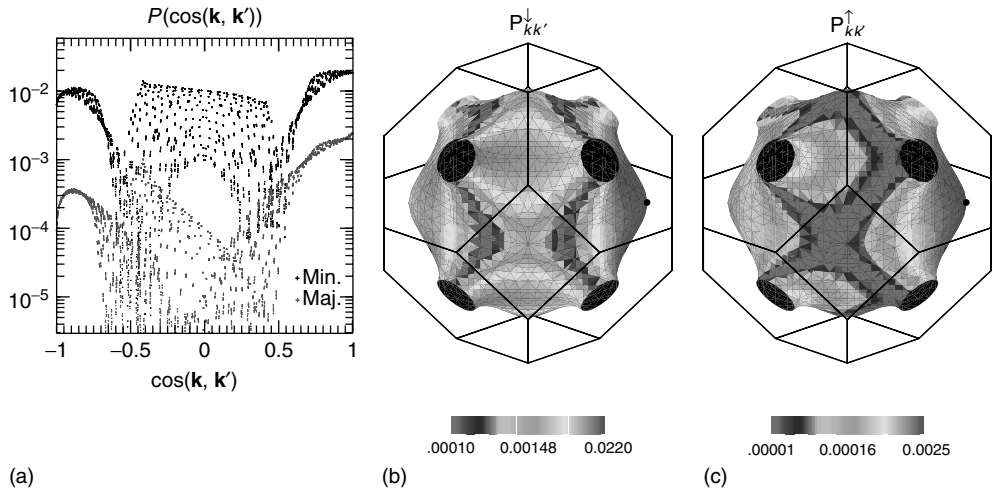

Figure 18. Microscopic transition probability $P_{kk'}$ for magnetic Co defects in a Cu matrix (a); $P_{kk'}$ as a function of the angle between **k** and **k**′ (b and c); $P_{kk'}$ for minority and majority channel, respectively. The initial state **k** is fixed to (100) and is marked by a black dot on the right-hand side.

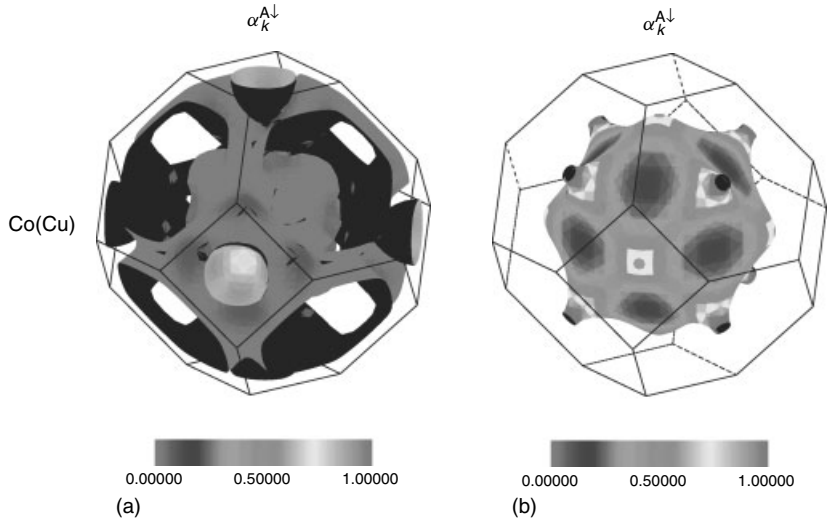

Figure 19. Scattering asymmetry of transition probability α_k^{A} for Cu defects in a magnetic Co matrix (a) minority electrons and (b) majority electrons.

These quantities are state dependent and characterize in short the anisotropy of the scattering and allow for an estimate of the importance of the vertex corrections in equation (25).

The results for a Cu impurity in Co are shown in Figure 19. The scattering asymmetry of the minority electrons is rather low in comparison to the majority electrons which predicts that the vertex corrections will be negligible for the minority electrons but rather important for the majority electrons. Quantitative results are discussed in Section 4.2.4.

4.2.3 Variation of relaxation times

Besides the state and spin dependence of the relaxation times in bulk systems (see discussion above), the relaxation times of impurity states in a multilayer are determined by the relative position of the impurity atom with respect to the interfaces. The interplay of the quantum size effects of the multilayer wave functions (see Section 4.1.2) and the properties of the impurity potential in different positions in the multilayer (see Section 3 and Figure 20) cause variations of the relaxation time.

All Bloch states with a finite probability amplitude at the impurity site are strongly scattered and have a relatively short relaxation time. On the other hand, states with a nearly zero probability amplitude at the impurity site undergo a weak scattering and cause extremely large relaxation times. The state-dependent relaxation times are distributed over several orders of magnitude. This occurs especially for defects inside

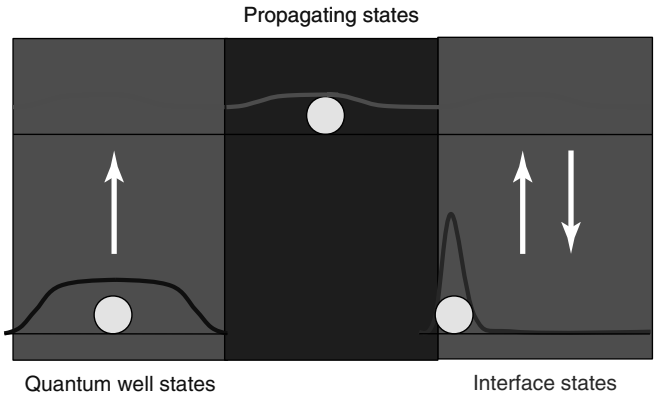

Figure 20. Quantum confinement of eigenstates in a metallic multilayer and characteristic defect positions: the electronic states are described by their probability amplitude.

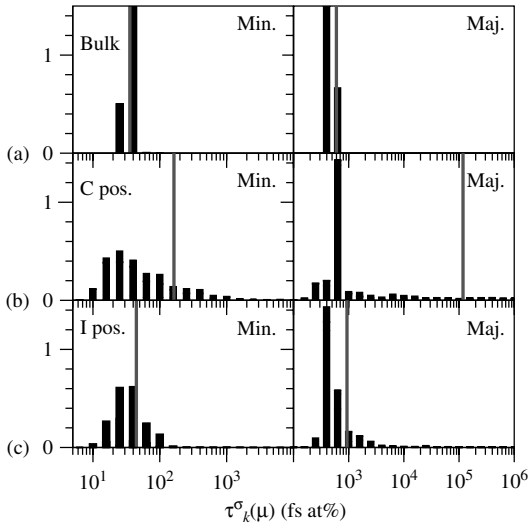

Figure 21. Histogram of spin-dependent, anisotropic relaxation times of Cu impurities in Co_9Cu_7 multilayers for P alignment; bulk impurities (a) are compared with impurities in the center (b) and at the interface (c) of the Co layer (Zahn, Binder and Mertig, 2005). The Fermi surface average of the relaxation times is indicated by a dark gray line. (Reproduced from Zahn *et al*., 2005, with permission from the American Physical Society. © 2005.)

the metallic layers (see Figure 21). This is a new effect that does not happen in bulk systems. Figure 21 shows the relative amount of relaxation times τ_k for the states at the Fermi level for Cu impurities in Co bulk and in the center and at the interface of the Co layer of a Co_9Cu_7 multilayer.

For defects inside the magnetic layer, the maximum of the distribution coincides with that in the bulk material. In addition, a long tail for high values occurs caused by states which have a small probability amplitude at the defect position, for example, quantum well states in the nonmagnetic layer or interface states. This fact is also reflected by the Fermi surface average of the relaxation times indicated by a dark grey line. The averaged relaxation times of bulk impurities and impurities at the interface are nearly the same since all states have a finite probability amplitude at the interface. The averaged relaxation times for impurities in the center of the magnetic layer, however, are quite different. This fact should be borne in mind for the evaluation of theoretical results calculated with constant relaxation times. Comparing the electronic properties of bulk impurities with impurities in a multilayer we can conclude that the electronic structure of impurities in the center of the layer are the same as in bulk; the scattering properties are, however, different. Because of quantum size effects the averaged relaxation times for impurities in the center of the layer are much larger than for bulk impurities in contrast to impurities at the interface, which are comparable.

The states with large relaxation times, although not numerous, are highly conducting and nearly provoke a short circuit. This is the case for Cu impurities in the Co layer of the Co/Cu multilayer, compare Figure 21. This effect is mainly obtained for impurities in the center of the layers and is related to the fact that in-plane transport is mostly driven by quantum well states (Zahn *et al*., 1998). This peculiar behavior is in agreement with the results of Blaas *et al*. (1999) who found higher resistivities for Co/Cu multilayers with interdiffusion restricted to the interface layers than for alloying with Cu atoms in the Co layers.

The multilayer modulation of the relaxation times is quite a robust effect, which was experimentally confirmed for the conductivity and the GMR effect (Marrows and Hickey, 2001).

4.2.4 Vertex corrections in multilayers

The influence of the vertex corrections in the solution of the Boltzmann equation was investigated for the $Co_9Cu_7(100)$ multilayer. The resistances obtained by evaluation of the vector mean free path by equation (25) $\mathring{\rho}_{\parallel}$ and with $\mathbf{\Lambda}_k$ in relaxation time approximation $\rho_{\parallel}$ are compared in Figure 22.

In general the vertex corrections are less important for the minority electrons in comparison to the majority electrons. The scattering anisotropy of the minority electrons is much lower (see also Figure 6) than that for the majority electrons which is related to the character of the electronic states. Scattering of s and p states is highly anisotropic, whereas scattering of the d state is isotropic. The largest deviations occur in the minority channel for a Cr defect and in the majority channel for the defects from Fe to Zn. The latter is caused by the dominating sp scattering since the d states are fully occupied. The large deviation for the Fe defect is comparable to the case of Cu defects in a Co host with large asymmetries of the scattering probability. Compare

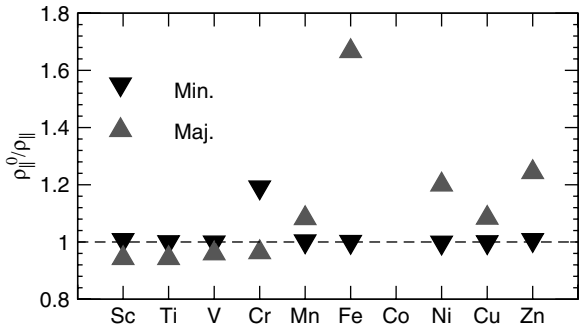

Figure 22. $Co_9Cu_7(100)$: different defects at the Co interface site are treated to consider the ratio $\mathring{\rho}_{\|}/\rho_{\|}$ of CIP conductivities calculated with and without vertex corrections, respectively.

also the bottom panel in Figure 19(b). For pure d scattering or dominating d character of the states (minority channel) the corrections due to the vertex term are small. Zhang and Butler (2000) proposed a simplified scheme to treat the vertex corrections. The main purpose was to increase the scattering probabilities to account for the asymmetry of the scattering, which was determined by the anisotropy of the bulk relaxation times.

4.3 Resistivity and spin anisotropy

4.3.1 Spin anisotropy of resistivity

In the following, the trends of the residual resistivities and the corresponding spin anisotropy of resistivity defined in equation (43) are discussed for $Co_9Cu_7(001)$ multilayers with 3d impurities in the Cu (Figure 23) and the Co layer (Figure 24) in the central and in the interface position in comparison with bulk results. Besides the spin-resolved results for the systems, the total resistivities of the P and AP configurations are presented. The idea of this section is to discuss some general trends that are confirmed by the quantitative results. First, the spin-resolved and total resistivities of the bulk systems are largest in comparison to the multilayer results (P configuration). Second, the general trend of the resistivities for interface impurities in multilayers is very similar to the trend for the bulk systems. Third, the resistivities for impurities in the central position of the Cu or Co layer are very small which is related to the quantum confinement of the wave functions in the multilayer and the large relaxation times of quantum well states. The effect was discussed in Section 4.2.3. The trend of the total resistivity in P configuration is determined by the trend of the spin channel with lower resistivity. The resistivities in the AP configuration are for all systems larger than the resistivities in the P configuration which leads to positive GMR (see Section 4.4.1).

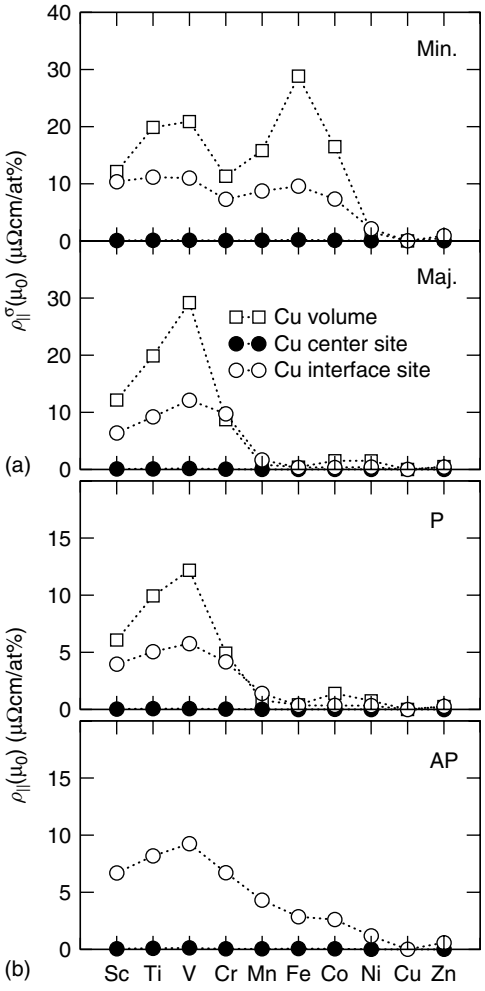

Figure 23. CIP resistivities of $Co_9Cu_7(001)$ multilayers with 3d defects in the Cu layer (central and interface position) in comparison with bulk results, (a) spin-resolved contributions for the P configuration and (b) total resistivities for P and AP configurations.

To understand the physics behind the trend we have to examine the LDOS (Figure 16). The trend is determined by resonance scattering. As soon as the VBS formed by the impurity approaches the Fermi level resonance scattering occurs and causes a large resistivity.

Considering the spin-anisotropy ratio α (equation (43), Figure 25): The trend obtained for bulk impurities coincides with the trend for the corresponding impurities at the interfaces of the layers. A strong shift of the anisotropy to values of $\alpha < 1$ is found for impurities in the central position of the Co layer. The spin-anisotropy ratio is decreased because of the channeling states in the Cu layer $\rho^{\uparrow} << \rho^{\downarrow}$. Strong anisotropy is found for defects with a nuclear charge close to the host material. Since the impurity potential is nearly degenerated with the host potential in one of the spin channels, the corresponding scattering cross section vanishes.

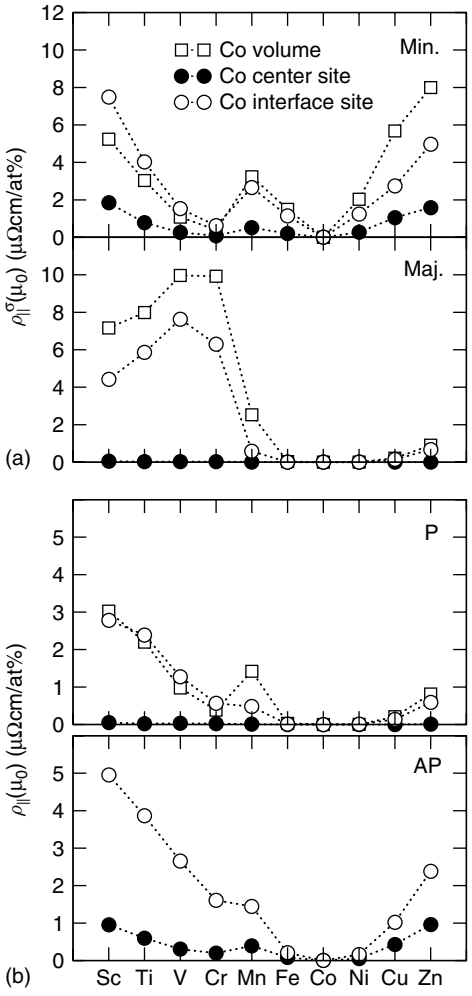

Figure 24. CIP resistivities of $Co_9Cu_7(001)$ multilayers with 3d defects in the Co layer (central and interface position) in comparison with bulk results, (a) spin-resolved contributions for the P configuration and (b) total resistivities for P and AP configurations.

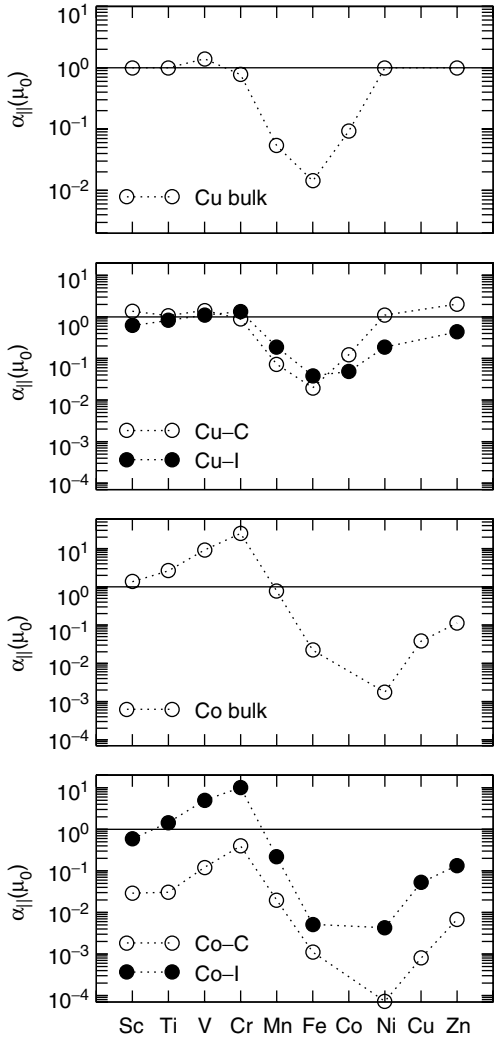

Figure 25. Spin anisotropy α (equation (43)) of the CIP resistivities of $Co_9Cu_7(001)$ multilayers with 3d defects in the Co or Cu layer (central and interface position) in comparison with corresponding bulk results.

4.3.2 Inverse GMR

On the basis of the strong differences in the spin anisotropy it became clear that the amplitude of the GMR effect can be tailored by the chemical composition of the multilayer with appropriate impurity atoms. In particular the GMR ratio could be inverted by combination of impurities with opposite spin-anisotropy ratio (George *et al*., 1994). The mechanism is illustrated in Figure 26. Two types of defects with opposite spin-anisotropy ratio are deposited in adjacent magnetic layers. So that the scattering for electrons with one spin direction changes from strong to weak in the P configuration of the magnetic multilayer. As a result the resistivity of the two spin channels is comparable. In the AP configuration, however, the opposite spin-anisotropy ratio of the impurity atom is counterbalanced by the change of the magnetization direction. As a result a channel with low resistivity is created so that $\rho^{AP} < \rho^{P}$ and the inverse GMR effect is created.

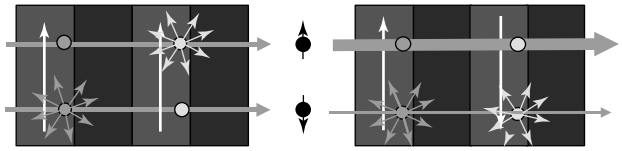

Figure 26. Inverse GMR: spin-dependent scattering.

To simulate a system with inverse GMR, impurities with opposite spin-anisotropy ratio β (see equation (46)) are combined.

To describe a multilayer with two types of noninteracting impurities (A and B), we use the following ansatz for the

microscopic transition probability per spin direction in the parallel alignment

$$P_{kk'}^{\sigma\,\mathrm{P}} = x\,P_{kk'}^{\sigma\,\mathrm{A}} + (1-x)\,P_{kk'}^{\sigma\,\mathrm{B}} \tag{59}$$

and in the antiparallel alignment

$$P_{kk'}^{\sigma\,\mathrm{AP}} = x\,P_{kk'}^{\sigma\,\mathrm{A}} + (1-x)\,P_{kk'}^{-\sigma\,\mathrm{B}} \tag{60}$$

Correspondingly, the electron lifetime becomes

$$\frac{1}{\tau_{\mathrm{P}}^{\sigma}} = x\,\frac{1}{\tau_{\mathrm{A}}^{\sigma}} + (1-x)\frac{1}{\tau_{\mathrm{B}}^{\sigma}} \tag{61}$$

in the parallel configuration and

$$\frac{1}{\tau_{\mathrm{AP}}^{\sigma}} = x\,\frac{1}{\tau_{\mathrm{A}}^{\sigma}} + (1-x)\,\frac{1}{\tau_{\mathrm{B}}^{-\sigma}} \tag{62}$$

in the antiparallel configuration. The parameter x determines the concentration of impurities A relative to B. In the limit $x = 1$ the relaxation time of impurity A with an anisotropy ratio β_{A} and in the limit $x = 0$ the relaxation time of impurity B with an anisotropy ratio β_{B} is reached.

In our calculations A is associated with V impurities in the Fe layers (denoted by Fe(V)) and B is either a Cu impurity in Co layers (Co(Cu)) or a magnetic Co impurity in Cu layers (Cu(Co)). The inverse relaxation times and the anisotropy ratios are shown in Table 1. The spin-anisotropy ratio of Co(Cu) and Cu(Co) is smaller than 1. Both defects cause, in principle, the same scattering behavior of the wave function. The anisotropy ratio of Fe(V) is opposite, that is, in parallel configuration the majority electrons (spin up, ↑) are strongly scattered at the V impurities in the Fe layers and are weakly scattered at the Cu impurities in the Co layers or in the Co-containing Cu layers whereas the minority electrons (spin down, ↓) are weakly scattered at V impurities in Fe layers but strongly scattered at Cu impurities in Co or Co-containing Cu layers. For the antiparallel configuration the scattering channels are mixed. The majority electrons are scattered strongly in each layer and the minority electrons are scattered weakly in each layer. Consequently, a slow and a fast channel occur which results in a low resistivity.

The results of the calculation as a function of impurity concentration and Fe layer thickness are shown in Figure 27. As expected from the simple model, the GMR ratio switches from positive to negative values as a function of the relative impurity concentration x.

Table 1. Anisotropy ratios β (equation (46)) and Fermi surface average of the relaxation times per spin direction τ^{σ} in arbitrary units for the dilute bulk alloys Co(Cu), Cu(Co), and Fe(V).

Impurity	Co(Cu)	Cu(Co)	Fe(V)
β	0.0701	0.1413	21.55
$\tau^{\downarrow}$	2.52	0.42	38.0
$\tau^{\uparrow}$	35.9	2.95	1.76

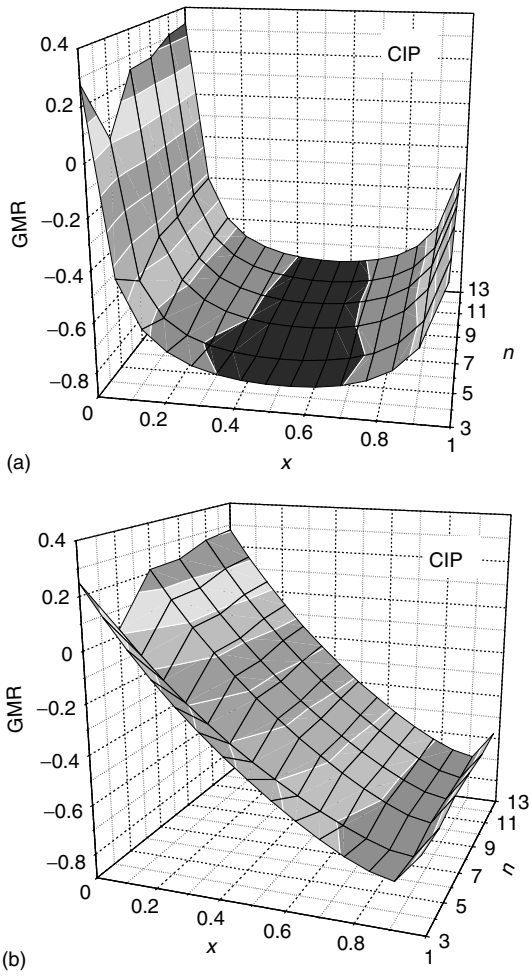

Figure 27. Calculated CIP-GMR of $Fe_n Cu_6 Co_2 Cu_6$ versus Fe layer thickness n and relative defect concentration x; (a) for V impurities in Fe layers combined with Cu impurities in Co layers, (b) for V impurities in Fe layers combined with magnetic Co impurities in Cu layers.

4.4 GMR: defect dependence

4.4.1 Position dependence

The GMR ratios derived from the resistivity calculation of Figures 23 and 24 are shown in Figure 28. The trends

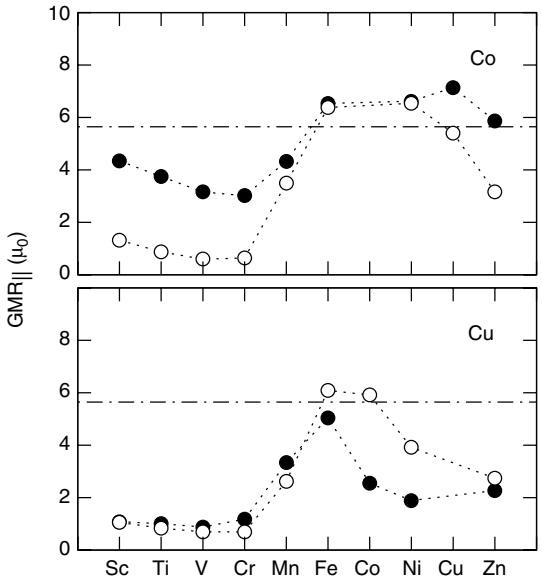

Figure 28. GMR ratio of $Co_9Cu_7(100)$ multilayers for δ layers of 3d transition-metal impurities in the center and at the interface of the Co or Cu layers; the symbols of each subpanel denote the δ layer position; closed symbols: center of the layer and open symbols: interface position; the dashed line indicates the GMR value caused by interface scattering only.

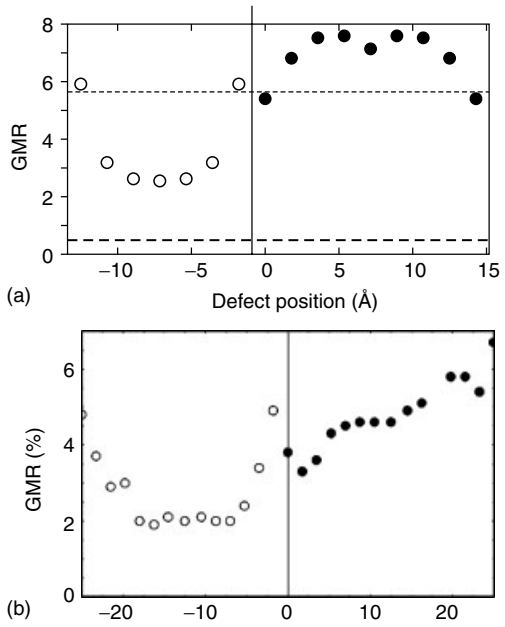

Figure 29. Dependence of the GMR in $Co_9Cu_7(100)$ multilayers on the position of Co impurities in the Cu layer and Cu impurities in the Co layer assuming δ layer scattering and interface scattering with equal weights. The thick dashed line indicates the intrinsic GMR and the thin dashed line the GMR value caused by interface scattering only, from Zahn, Binder and Mertig (2003), (b) shows the experimental results by Marrows and Hickey (2001). (Reproduced from Zahn *et al*., 2003/Marrows & Hickey 2001, with permission from the American Physical Society. © 2001/2003.)

imply that the larger the spin anisotropy α (see Figure 25) the larger the GMR ratio. Although defects in the center of the layers cause a much smaller resistivity than defects at the interfaces (see Figures 23 and 24), they are equally efficient like defects at the interface to induce large GMR. Dependence of the GMR in $Co_9Cu_7(100)$ multilayers on self defects in any of the multilayer position is presented in Figure 29. For the calculation, δ layers of Cu impurities in the Co layer or δ layers of Co impurities in the Cu layer and interface scattering are taken into account with equal weights. The thin dashed line is the GMR value caused by interface scattering only, from Zahn, Binder and Mertig (2003). This value would correspond to the reference value in the experiments of Marrows and Hickey without the δ layer (Marrows and Hickey, 2001). The thick dashed line in Figure 29 gives the GMR value obtained with the assumption of a constant relaxation time without any spin or state dependence (intrinsic GMR). In comparison to this case of isotropic scattering the insertion of an additional δ layer increases GMR, mostly at the interfaces.

Comparing the trend of GMR an excellent agreement with the experiment (Figure 29b) is obtained for the Co/Cu system which is a confirmation of the microscopic picture.

The very good agreement with experimental results is not limited to self defects. Investigations of all the 3d transition-metal impurities deposited as δ layers in the Co/Cu spin valve have been performed, (Marrows and Hickey, 2001) and they substantiate the basic concept of spin-dependent scattering in magnetic multilayers (see Figure 30) (Zahn, Binder and Mertig, 2003).

We still have to mention, that the calculated values are 2 orders of magnitude larger than the experimental ones. The reason is the restriction to substitutional point defects. In addition to these, other scattering processes occur in real samples. Assuming self-averaging, the results could be corrected toward the experimental ones by an additional spin- and state-independent relaxation time τ (thick dashed line in Figure 29) (Zahn *et al*., 1998). In contrast to Zahn *et al*. (1998), the present results were obtained assuming only the impurity distribution described above and are focused on the impurity scattering rates only. Another difference from the experimental setup in Marrows and Hickey (2001) is the geometry. The experimentally investigated samples have been Co/Cu/Co spin valves grown on a buffer layer and protected by a cap layer. As a consequence, the GMR ratios are nearly symmetric as a function of the impurity position in the Cu layer but asymmetric for defects in the Co layer. The calculations are performed in supercell geometry and this is reflected in the symmetry of the results with respect to the defect position in both layers, Cu and Co. A possible

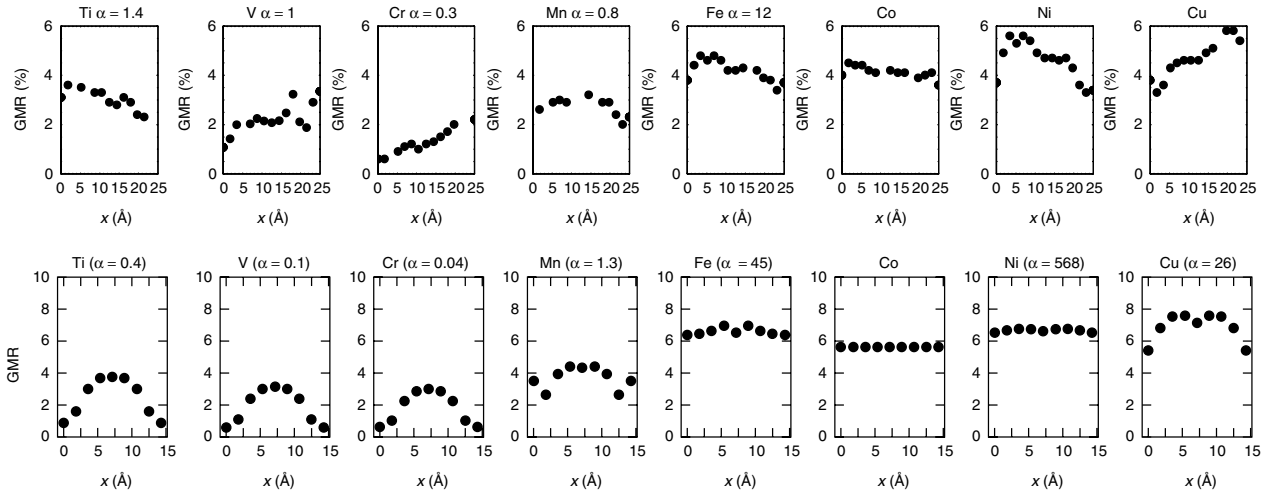

Figure 30. Dependence of the GMR on the position of 3d impurities in the Co layer; upper row: experimental results by Marrows and Hickey (Figure 1 reproduced from Marrows & Hickey 2001, with permission from the American Physical Society. © 2001.); lower row: our calculation (Zahn, Binder and Mertig, 2003). $x = 0$ corresponds to the position of the Cu/Co interface. α values are calculated for the corresponding impurities in bulk Co.

influence of superlattice effects in metallic multilayers was shown to be negligible (Erler, Zahn and Mertig, 2001).

4.5 CPP-GMR

In contrast to the CIP geometry, where the current is flowing parallel to the layers, the CPP geometry is characterized by a current perpendicular to the layers. Owing to the reduced device dimension in current direction microfabrication or even nanofabrication technologies have to be used to enhance the resistivity and resistivity changes. This is necessary to allow for a reliable detection of the effect. The effect was first measured with superconducting contacts (Pratt *et al.*, 1991), which unfortunately implies that the low-temperature regime is accessible only, but allows for a simultaneous measurement of the CIP and CPP effect on the same sample, see Figure 31. Other setups which avoid this restriction are microstructured pillars (Gijs, Lenczowski and Giesbers, 1993), a growth on structured substrates (Ono and Shinjo, 1995; Gijs *et al.*, 1995), and electrodeposition of nanowires into pores of a polymer foil (Blondel, Meier, Doudin and Ansermet, 1994; Piraux *et al.*, 1994). Surveys about the experimental and theoretical achievements are given in (Levy, 1994; Gijs and Bauer, 1997; Barthélémy, Fert and Petroff, 1999; Tsymbal and Pettifor, 2001; Brataas, Bauer and Kelly, 2006).

From a theoretical point of view, the CPP-GMR effect is less complex than the CIP equivalent, because the high symmetry of the former reduces the effort by approximations using model Hamiltonians.

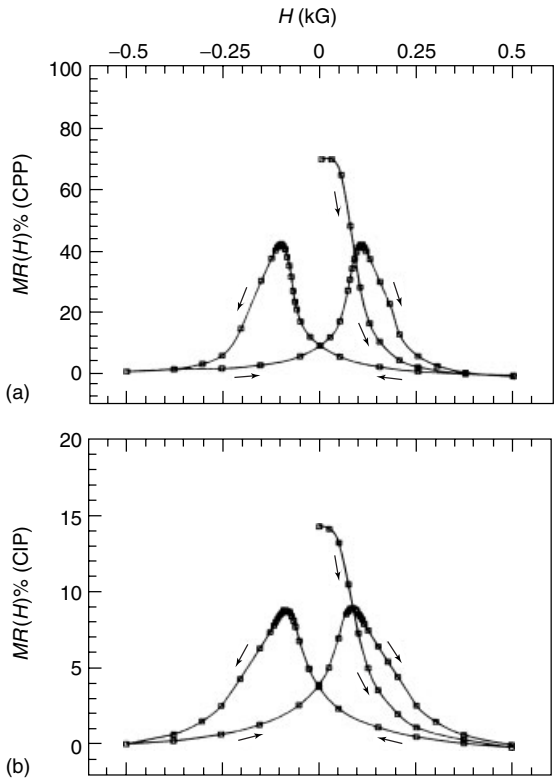

Figure 31. $MR(H) = (R(H) - R_{\mathrm{satt}})/R_{\mathrm{satt}}$ for a Ag (6 nm)/Co (6 nm) multilayer with Nb cross strips simultaneously measured for CPP geometry (a) and CIP geometry (b). (Figure 2 reproduced from Pratt *et al.*, 1991, with permission from the American Physical Society. © 1991.)

The models applied are aimed at the linear response of the system and are based on a quasiclassical approach using the Boltzmann equation and a fully quantum-mechanical

description starting from the Kubo–Greenwood approach, respectively. In the following, considerations are restricted to calculational schemes applied to the CPP geometry. Valet and Fert treated bulk, interface, and spin-flip scattering on the same footing starting from the quasiclassical distribution function (Valet and Fert, 1993). They have shown that the correct treatment of the spin accumulation caused by the spin-dependent bulk and interface resistivities is necessary to describe systems with layer thicknesses of the order of the spin diffusion length. That is the length scale at which the currents in both spin channels are equilibrated by spin-flip scattering processes.

For multilayer systems, the global solution of the Boltzmann equation is obtained by an appropriate coupling of the piecewise solutions inside the layers analogous to the Fuchs–Sondheimer theory (Fuchs, 1938; Sondheimer, 1952), as was shown by Falicov and Hood for the CIP geometry (Falicov and Hood, 1993). Zhang and Levy have demonstrated that the interface resistance and the CPP-GMR are very sensitive to the scattering at the interfaces and that diffusive scattering can assist or suppress the effect depending on the interface reflectivity (Zhang and Levy, 1998). This is illustrated in Figure 32. $(1 - S)$ measures the diffusive scattering and T characterizes the transmission. This quasiclassical approach was later generalized by Butler and coworkers to include the bulk and interface resistivities from *ab initio* calculations (Zhang and Butler, 1995; Butler, Zhang and MacLaren, 2000). Transmission coefficients across a ferromagnet/nonmagnet interface which are essential ingredients for CPP-GMR were first obtained by matching the generalized Bloch states of the two semi-infinite crystals (Stiles, 1996), or from a surface embedding Green's function technique (Schep *et al*., 1997).

A quasiclassical approach including the coherent scattering by the *ab initio* band structure of the multilayer and the diffuse scattering by appropriate spin-dependent relaxation times was developed by the authors. The presented results are, however, limited to the very special case that the mean free path Λ is much larger than the unit cell. Since the CPP geometry is characterized by an alignment of the current and the direction of the quantum confinement effects that occur in this limit because of coherent scattering at the interfaces, the obtained CPP-GMR is much larger than CIP-GMR ratio, both in theory (Zhang and Levy, 1991; Zahn, Mertig, Richter and Eschrig, 1995; Zahn *et al*., 1998) and in experiment (Pratt *et al*., 1991). Compare Figures 33 and 31(a,b), respectively.

To describe the transport in the linear response regime on the basis of quantum mechanics alone the Kubo formula is well suited and it is explained in great detail in text books (Mahan, 1981). The correspondence of the quantum approach starting from the Kubo formula (Kubo, 1957) and the quasiclassical approach for the case of multilayers was shown by Camblong and Levy (1992). Following the description of the CIP-GMR (Levy, Zhang and Fert, 1990), it was applied to the CPP geometry by Zhang and Levy (1991). To include typical features of the electronic structure of the metals forming the multilayer, tight-binding Hamiltonians were included in the consideration to elucidate the role of defects and layer thickness on the MR effect (Tsymbal and Pettifor, 2000; Mathon, 1996). An oscillatory

behavior similar to the IEC was predicted for the coherent limit of very high quality samples (Mathon *et al*., 1995). The generalization of the Kubo formula to inhomogeneous layered systems was derived (Butler, Zhang, Nicholson and MacLaren, 1994; Weinberger *et al*., 1996), but the highly demanding vertex corrections within the CPA to describe defects and interdiffusion prevented a numerical evaluation of the CPP transport coefficients.

A fully *ab initio* level of description was reached by Kudrnovský *et al*. taking advantage of a supercell approach to model the influence of disorder and interdiffusion (Kudrnovský and Bruno, 2000; Xia *et al*., 2001; Drchal *et al*., 2002). This method allows for the description of specular and diffuse scattering at the interfaces and inside the layers on an equal footing. By this approach, the evaluation of the resistivity of a single interface between two metals was performed, which provides parameters for a simplified resistor model of the structure (Bauer *et al*., 2001).

The Berry Phase in Magnetism and the Anomalous Hall Effect

Patrick Bruno
Max-Planck-Institut für Mikrostrukturphysik, Halle, Germany

1 INTRODUCTION

In 1983, Berry made the surprising discovery that a quantum system adiabatically transported round a closed circuit $\mathcal{C}$ in the space of external parameters acquires, besides the familiar dynamical phase, a nonintegrable phase depending only on the geometry of the circuit $\mathcal{C}$ (Berry, 1984). This Berry phase, which had been overlooked for more than half a century, provides us a very deep insight into the geometric structure of quantum mechanics and gives rise to various observable effects. The concept of the Berry phase has now become a central unifying concept in quantum mechanics, with applications in fields ranging from chemistry to condensed-matter physics (Shapere and Wilczek, 1989; Bohm *et al*., 2003).

The aim of this article is to give an elementary introduction to the Berry phase, and to discuss its various implications in the field of magnetism, where it plays an increasingly important role. The reader is referred to specialized textbooks (Shapere and Wilczek, 1989; Bohm *et al*., 2003) for a more comprehensive presentation of the field of geometrical phases. Particular emphasis will be given to the discussion of the anomalous Hall effect, the theory of which has been considerably renewed recently, on the basis of the concept of Berry phase.

2 PARALLEL TRANSPORT IN GEOMETRY

The importance of the Berry phase stems from the fact that it reveals the intimate geometrical structure underlying quantum mechanics. It is therefore appropriate to start with an introduction to the fundamental concept of *parallel transport* in a purely geometrical context; here, we follow the discussion given by Berry (1990).

This is best illustrated by means of a simple example. Consider a surface Σ (e.g., a plane, a sphere, a cone, etc.) and a vector constrained to lie everywhere in the plane tangent to the surface. Next, we wish to transport the vector on the surface, *without rotating it around the axis normal to the surface*, as illustrated in Figure 1. We are interested, in particular, in the case, in which the arrow is transported round a closed circuit $\mathcal{C} \equiv (1 \rightarrow 2 \rightarrow 3 \rightarrow 1)$. We may encounter two different situations: (i) if the surface is flat,

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

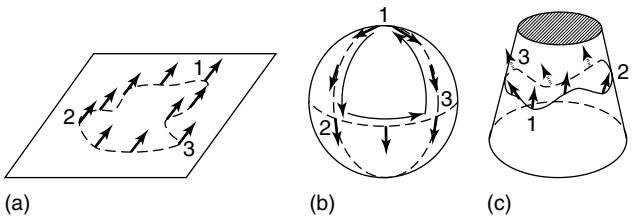

Figure 1. Sketch of parallel transport on (a) a plane, (b) a sphere, and (c) a cone.

as in Figure 1(a), then the arrow always remains parallel to its original orientation, and is, therefore, unchanged after completion of the circuit $\mathcal{C}$; (ii) if, however, the surface Σ is curved as in Figure 1(b) and (c), the arrow, being constrained to lie in the local tangent plane, cannot remain parallel to its original orientation, and after completion of the circuit $\mathcal{C}$, has clearly undergone a rotation by an angle $\theta(\mathcal{C})$, a phenomenon referred to as *anholonomy*.

Let us now formalize this procedure. The arrow is represented by a tangent unit vector $\mathbf{e}^1$, transported along a circuit $\mathcal{C} \equiv \{\mathbf{r}(t)|t = 0 \to T\}$ on the surface. Defining $\mathbf{n}(\mathbf{r})$ as the unit vector normal to the surface at point $\mathbf{r}$, we define a second tangent unit vector $\mathbf{e}^2 \equiv \mathbf{n} \times \mathbf{e}^1$, which is also parallel transported on the surface along $\mathcal{C}$. The three unit vectors $(\mathbf{n}, \mathbf{e}^1, \mathbf{e}^2)$ form an orthonormal reference frame. As $\mathbf{e}^1$ and $\mathbf{e}^2$ are transported, they have to rotate with an angular velocity $\boldsymbol{\omega}$ (to be determined) if the surface is not flat, that is, the equation of motion of $\mathbf{e}^1$ and $\mathbf{e}^2$ is

$$\dot{\mathbf{e}}^r = \boldsymbol{\omega} \times \mathbf{e}^r \quad (r = 1, 2) \tag{1}$$

where the overdot indicates the time derivative. One can easily see that in order to fulfill the requirements that $\mathbf{e}^1$ and $\mathbf{e}^2$ remain tangent unit vectors (i.e., $\mathbf{e}^r \cdot \mathbf{n} = 0$, $(r = 1, 2)$) and never rotate around $\mathbf{n}$ (i.e., $\boldsymbol{\omega} \cdot \mathbf{n} = 0$), the angular velocity has to be given by

$$\boldsymbol{\omega} = \mathbf{n} \times \dot{\mathbf{n}} \tag{2}$$

The law of parallel transport is therefore,

$$\dot{\mathbf{e}}^r = (\mathbf{n} \times \dot{\mathbf{n}}) \times \mathbf{e}^r = -(\mathbf{e}^r \cdot \dot{\mathbf{n}})\mathbf{n} \tag{3}$$

This law can be expressed in a form more suitable for generalization to the case of quantum mechanics, by defining the complex unit vector,

$$\boldsymbol{\phi} \equiv \frac{\mathbf{e}^1 + \mathrm{i}\mathbf{e}^2}{\sqrt{2}} \tag{4}$$

with

$$\boldsymbol{\phi}^\star \cdot \boldsymbol{\phi} = 1 \tag{5}$$

The law of parallel transport now reads,

$$\boldsymbol{\phi}^\star \cdot \dot{\boldsymbol{\phi}} = 0 \tag{6}$$

In order to express the rotation of the unit vectors $(\mathbf{e}^1, \mathbf{e}^2)$ as they move around $\mathcal{C}$, we need to choose a *fixed* local orthonormal frame $(\mathbf{n}(\mathbf{r}), \mathbf{t}^1(\mathbf{r}), \mathbf{t}^2(\mathbf{r}))$ on the surface. The normal unit vector $\mathbf{n}(\mathbf{r})$ is, of course, uniquely determined by the surface, but we have an infinity of possible choices for $\mathbf{t}^1(\mathbf{r})$ (we simply impose that it is a smooth function of $\mathbf{r}$), which corresponds to a gauge freedom; once we have made a choice for $\mathbf{t}^1(\mathbf{r})$, then $\mathbf{t}^2(\mathbf{r})$ is of course uniquely determined. We next define the complex unit vector,

$$\mathbf{u}(\mathbf{r}) \equiv \frac{\mathbf{t}^1(\mathbf{r}) + \mathrm{i}\mathbf{t}^2(\mathbf{r})}{\sqrt{2}} \tag{7}$$

with, of course,

$$\mathbf{u}^\star(\mathbf{r}) \cdot \mathbf{u}(\mathbf{r}) = 1 \tag{8}$$

The relation between the parallel transported frame and the fixed one is expressed as

$$\boldsymbol{\phi}(t) = \exp[-\mathrm{i}\theta(t)]\ \mathbf{u}\,(\mathbf{r}(t)) \tag{9}$$

where $\theta(t)$ is the angle by which $(\mathbf{t}^1, \mathbf{t}^2)$ must be rotated to coincide with $(\mathbf{e}^1, \mathbf{e}^2)$. We obtain the equation satisfied by $\theta(t)$ by inserting the preceding definition in the equation of parallel transport (6), and obtain

$$0 = \boldsymbol{\phi}^\star \cdot \dot{\boldsymbol{\phi}} = -\mathrm{i}\,\dot{\theta}\mathbf{u}^\star \cdot \mathbf{u} + \mathbf{u}^\star \cdot \dot{\mathbf{u}} \tag{10}$$

Since $\mathbf{u}^\star \cdot \mathbf{u} = 1$ and $\mathbf{u}^\star \cdot \dot{\mathbf{u}}$ is imaginary, we get

$$\dot{\theta} = \mathrm{Im}(\mathbf{u}^\star \cdot \dot{\mathbf{u}}) \tag{11}$$

so that

$$\theta(\mathcal{C}) = \mathrm{Im} \oint_{\mathcal{C}} \mathbf{u}^\star \cdot \mathrm{d}\mathbf{u} \tag{12}$$

$$= -\oint_{\mathcal{C}} \mathbf{t}^2 \cdot \mathrm{d}\mathbf{t}^1 \tag{13}$$

If we choose a coordinate system (X_1, X_2) on our surface Σ and define the vector field $\mathbf{A}(\mathbf{r})$ (usually called a *connection*) on Σ as

$$A_i(\mathbf{X}) \equiv \mathrm{Im}\left[u_j^\star(\mathbf{X})\frac{\partial u_j(\mathbf{X})}{\partial X_i}\right] \tag{14}$$

where we have used Einstein's convention of summation over repeated indices, we get

$$\theta(\mathcal{C}) = \oint_{\mathcal{C}} \mathbf{A}(\mathbf{X}) \cdot \mathrm{d}\mathbf{X} \tag{15}$$

which constitutes the *1-form* expression of the anholonomy angle $\theta(\mathcal{C})$. The connection $\mathbf{A}(\mathbf{X})$ depends on our particular gauge choice for $\mathbf{t}^1(\mathbf{X})$: if we make a new choice $\mathbf{t}^{1'}(\mathbf{X})$ which is brought in coincidence with $\mathbf{t}^1(\mathbf{X})$ by a rotation of angle $\mu(\mathbf{X})$, that is, if we make the gauge transformation

$$\mathbf{u}(\mathbf{X}) \rightarrow \mathbf{u}'(\mathbf{X}) \equiv \exp\left(-\mathrm{i}\mu(\mathbf{X})\right) \mathbf{u}(\mathbf{X}) \tag{16}$$

we obtain a new connection

$$A'_i(\mathbf{X}) \equiv \mathrm{Im}\left[u^{\star}_{j'}(\mathbf{X}) \frac{\partial u_{j'}(\mathbf{X})}{\partial X_i}\right] = A_i(\mathbf{X}) - \frac{\partial \mu(\mathbf{X})}{\partial X_i} \tag{17}$$

However, since

$$\oint_{\mathcal{C}} \nabla\mu(\mathbf{r}) \cdot \mathrm{d}\mathbf{r} = \oint_{\mathcal{C}} \mathrm{d}\mu(\mathbf{r}) = 0 \tag{18}$$

we can see that the expression (15) for the anholonomy angle $\theta(\mathcal{C})$ is indeed gauge invariant, as it should be.

A more intuitive understanding of the anholonomy angle may be obtained if we use Stokes' theorem to express it as a surface integral. In doing so, however, we should pay attention to the possible existence of holes in the surface Σ. If this is the case, Σ is said to be nonsimply connected. An example is sketched in Figure 2, where the surface Σ has two holes limited by the contours $\mathcal{C}_1$ and $\mathcal{C}_2$ (hatched areas in Figure 2). Applying Stokes' theorem, we then obtain

$$\theta(\mathcal{C}) = \iint_{\mathcal{S}} B(\mathbf{X}) \mathrm{d}X_1\, \mathrm{d}X_2 \; + \sum_i N_i(\mathcal{C}) \theta(\mathcal{C}_i) \tag{19}$$

where the surface $\mathcal{S}$ is the subset of the surface Σ that is limited by the circuit (dotted area in Figure 2), $\mathcal{C}$, $N_i(\mathcal{C})$ is the winding number of circuit $\mathcal{C}$ around the hole i (i.e., the difference between the number of turns in counterclockwise and clockwise directions),

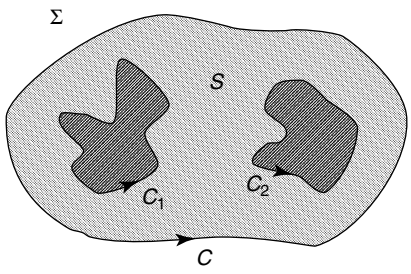

Figure 2. Sketch of a nonsimply connected surface Σ, with two holes (hatched areas), limited by the contours $\mathcal{C}_1$ and $\mathcal{C}_2$.

$$\theta(\mathcal{C}_i) \equiv \oint_{\mathcal{C}_i} \mathbf{A}(\mathbf{X}) \cdot \mathrm{d}\mathbf{X} \tag{20}$$

is the anholonomy angle of circuit $\mathcal{C}_i$ and

$$B(\mathbf{X}) \equiv \left(\frac{\partial A_2}{\partial X_1} - \frac{\partial A_1}{\partial X_2}\right) = \mathrm{Im}\left[\frac{\partial \mathbf{u}^{\star}}{\partial X_1} \cdot \frac{\partial \mathbf{u}}{\partial X_2} - \frac{\partial \mathbf{u}^{\star}}{\partial X_2} \cdot \frac{\partial \mathbf{u}}{\partial X_1}\right] \tag{21}$$

Equation (19) constitutes the *2-form* expression of the anholonomy angle $\theta(\mathcal{C})$. One can see immediately that, unlike the connection $\mathbf{A}(\mathbf{X})$, the quantity $B(\mathbf{X})$ is gauge invariant. The geometrical meaning of $B(\mathbf{X})$ stems from its relation to the *Gaussian curvature* K of Σ at point $\mathbf{X}$, that is,

$$B(\mathbf{X}) \mathrm{d}X_1 \mathrm{d}X_2 = K\, \mathrm{d}S \equiv \frac{\mathrm{d}S}{R_1(\mathbf{X})\, R_2(\mathbf{X})} \tag{22}$$

where $R_1(\mathbf{X})$ and $R_2(\mathbf{X})$ are the principal curvature radii at point $\mathbf{X}$. In the case of the sphere, this is easily checked by explicit calculation, taking the usual spherical angles (θ, φ) as variables (X_1, X_2). Since the Gaussian curvature is related to the solid angle Ω spanned by the normal unit vector $\mathbf{n}$ by

$$B = \frac{\mathrm{d}^2\Omega}{\mathrm{d}X_1\, \mathrm{d}X_2} \tag{23}$$

we finally get

$$\theta(\mathcal{C}) - \sum_i N_i(\mathcal{C}) \theta(\mathcal{C}_i) = \iint_{\mathcal{S}} \frac{\mathrm{d}^2\Omega}{\mathrm{d}X_1\, \mathrm{d}X_2} \mathrm{d}X_1\, \mathrm{d}X_2 = \iint_{\mathcal{S}} \mathrm{d}^2\Omega = \Omega(\mathcal{S}) \tag{24}$$

where $\Omega(\mathcal{S})$ is the solid angle described by the normal vector $\mathbf{n}$ on the surface $\mathcal{S}$. That the above results hold not only for a sphere but also for any surface can be understood easily from the following argument: Equation (3) shows that the trajectory of the parallel transported tangent vectors is entirely determined by the trajectory of the normal unit vector $\mathbf{n}$ along $\mathcal{C}$. We can therefore map the trajectory $\mathcal{C}$ on the surface Σ to a trajectory $\mathcal{C}'$ on the sphere of unit radius S^2, by mapping each point of Σ onto the point of S^2 with the same normal vector $\mathbf{n}$. This implies that we can restrict ourselves to studying the case of parallel transport on S^2 and obtain conclusions valid for parallel transport on any surface Σ.

Let us examine these results for the examples sketched in Figure 1. For the case of the plane, the anholonomy of course trivially vanishes. For the sphere, the anholonomy angle is

given by the solid angle $\Omega(\mathcal{S})$ and is therefore a *geometric* property of the circuit $\mathcal{C}$; this can easily be checked through the following experiment: take your pen in you left hand, and raise your arm above you head, the pen pointing in front of you; then rotate your arm until it is horizontal in front of you, without twisting your hand; then rotate it by 90° to your left; finally rotate your arm back to the vertical (pay attention to never twist your hand in whole process); the pen is now pointing to your left, that is, it has rotated by $4\pi/8 = \pi/2$. For the case of the cone, the Gaussian curvature vanishes everywhere (a cone can be fabricated by rolling a sheet of paper), so that the anholonomy angle is in fact a *topological* property of the circuit $\mathcal{C}$, given by the winding number of the circuit $\mathcal{C}$ around the cone (multiplied by the solid angle of the cone).

3 PARALLEL TRANSPORT IN CLASSICAL MECHANICS: FOUCAULT'S PENDULUM AND THE GYROSCOPE

Let us now consider the famous experiment of Foucault's pendulum that demonstrated the earth's rotation. If the pendulum trajectory is originally planar (swinging oscillation), the vertical component of the angular momentum vanishes. Since forces exerted on the pendulum (gravity and wire tension) produce a vanishing vertical torque, the vertical component of the angular momentum has to be conserved. The absence of any vertical torque imposes that the swing plane has to follow a law of parallel transport as the direction of gravity slowly changes because of the earth's rotation. Therefore, within 1 day it rotates by an angle equal to the solid angle described by the vertical $2\pi(1 - \cos\theta)$, where θ is the colatitude.

The parallel transport may also affect the phase of the periodic motion of the Foucault pendulum or the rotation phase of a gyroscope. Let us consider a gyroscope whose rotation axis is constrained to remain parallel to the axis $\mathbf{n}$; let us now move the rotation axis $\mathbf{n}$ round a closed circuit $\mathcal{C}$. The rotation angle of the gyroscope will be the sum of the *dynamic rotation angle* ωt and the *geometric anholonomy angle* $\theta(\mathcal{C})$ equal to the solid angle described by the rotation axis. Thus if we have two synchronous gyroscopes and perform different circuits with the rotation axes, they will eventually be dephased with respect to each other, an effect that could easily be observed by stroboscopy. This geometric anholonomy angle is known as *Hannay's angle* (Hannay, 1985; Berry, 1985). If the Foucault pendulum is given a conical oscillation instead of a planar swing, then we have exactly the same situation as described in the preceding text for the gyroscope, and the rotation angle will have an anholonomy excess angle given by the solid angle described by the vertical. Thus, two identical Foucault pendula (i.e., of same length) with circular oscillations in opposite directions will have slightly different oscillation frequencies and will progressively get dephased with respect to each other. The swinging motion of the usual Foucault may be viewed as the superposition of circular motions in opposite directions, so that the rotation of the swinging plane may be viewed as resulting from the previously mentioned frequency shift.

4 PARALLEL TRANSPORT IN QUANTUM MECHANICS: THE BERRY PHASE

Let us now consider a quantum mechanical system described by a Hamiltonian controlled by a set of external parameters $(R_1, R_2, \ldots)$, which we describe collectively as a vector $\mathbf{R}$ in some abstract parameter space. Physically, the external parameters may be magnetic or electric fields, and so on. For each value $\mathbf{R}$ of the external parameters, the Hamiltonian $H(\mathbf{R})$ has eigenvalues $E_n(\mathbf{R})$ and eigenvectors $|n(\mathbf{R})\rangle$ satisfying the independent Schrödinger equation, that is,

$$H(\mathbf{R})\,|n(\mathbf{R})\rangle = E_n(\mathbf{R})\,|n(\mathbf{R})\rangle \tag{25}$$

The eigenvectors $|n(\mathbf{R})\rangle$ are defined up to an arbitrary phase, and there is *a priori* no particular phase relation between eigenstates corresponding to different values of the parameter $\mathbf{R}$. We make a particular choice for the phase of the eigenstates, simply requiring that $|n(\mathbf{R})\rangle$ varies smoothly with $\mathbf{R}$ in the region of interest. It may happen that the eigenstates we have chosen are not single-valued functions of $\mathbf{R}$. If this happens, special care must be given to this point.

Let us perform an adiabatic closed circuit $\mathcal{C} \equiv \{\mathbf{R}(t)|t = 0 \to T\}$ in the parameter space. The adiabatic theorem (Messiah, 1991) tells us that if the rate of variation of the external parameters is low enough, a system that is initially in the nth stationary state $|n\rangle$ (assumed nondegenerate) of the Hamiltonian will remain continuously in the state $|n\rangle$. The condition of adiabaticity is that the stationary state under consideration remains nondegenerate, and the rate of variation of the Hamiltonian is low enough to make the probability of transition to another state $|m\rangle$ vanishingly small, that is,

$$\hbar|\langle m|\dot{H}|n\rangle| \ll |E_m - E_n|^2 \quad \forall\, m \neq n \tag{26}$$

Then of course, if one performs a closed adiabatic circuit $\mathcal{C}$, the system has to return to its original state.

Berry (1984) asked the following question: what will be the phase of the state after completion of the circuit $\mathcal{C}$? It may be difficult at first sight to realize that this question may be of any interest. Indeed, the expectation value of any observable quantity A,

$$\langle A\rangle \equiv \langle\psi|A|\psi\rangle \tag{27}$$

does not depend on the phase of $|\psi\rangle$. This lack of interest is certainly the main reason why the Berry phase was (almost) completely overlooked for more than half a century of quantum mechanics. One should mention here that there has been, prior to Berry's seminal paper (Berry, 1984), a number of precursor works on effects related to the Berry phase, including, notably, Pancharatnam's work on optical polarization (Pancharatnam, 1956), Aharonov and Bohm's work on the phase due to the electromagnetic potential vector (Aharonov and Bohm, 1959), and Mead and Truhlar's work on the molecular Aharonov–Bohm effect in the Born–Oppenheimer theory of molecular vibrations (Mead and Truhlar, 1979). However, Berry (1984) was the first to point out the geometric significance and the generality of the adiabatic geometric phase. After the publication of Berry's paper, the generality and the fecundity of this new concept has been widely recognized, soon leading to a considerable amount of developments (Shapere and Wilczek, 1989; Bohm *et al*., 2003).

So, following Berry, taking

$$|\psi(t=0)\rangle \equiv |n(\mathbf{R}(t=0))\rangle \tag{28}$$

we express the state $|\psi(t)\rangle$ at a latter time t as

$$|\psi(t)\rangle \equiv \exp\left[\frac{-\mathrm{i}}{\hbar}\int_0^t \mathrm{d}t'\, E_n(\mathbf{r}(t'))\right]|\phi_n(t)\rangle \tag{29}$$

that is, we introduce an auxiliary wave function $|\phi_n(t)\rangle$ with a zero dynamical phase. Using the time-dependent Schrödinger equation,

$$\mathrm{i}\hbar|\dot{\psi}(t)\rangle = H(t)|\psi(t)\rangle \tag{30}$$

and projecting it on $\langle\psi(t)|$, we get

$$\begin{aligned} 0 &= \langle\psi(t)|\left(H(t) - \mathrm{i}\hbar\frac{\partial}{\partial t}\right)|\psi(t)\rangle \\ &= \langle\phi_n(t)|\dot{\phi}_n(t)\rangle \end{aligned} \tag{31}$$

where we have used the relation

$$\langle\psi(t)|H(t)|\psi(t)\rangle = E_n(t) \tag{32}$$

which follows from the adiabatic theorem. Equation (31) shows that the wave function $|\phi_n(t)\rangle$ obeys a quantum mechanical analog of the law of parallel transport (6).

In complete analogy with the problem of parallel transport on a surface, we now express the parallel transported state $|\phi_n(t)\rangle$ in terms of the fixed eigenstates $|n(\mathbf{R})\rangle$ as

$$|\phi_n(t)\rangle \equiv \exp((\mathrm{i}\gamma_n(t))\,|n(\mathbf{R})\rangle \tag{33}$$

where the phase $\gamma_n(t)$ plays the same role as the angle $-\theta(t)$ for the problem of parallel transport on a surface. We then immediately get the equation of motion of $\gamma_n(t)$, that is,

$$\dot{\gamma}_n(t) = \mathrm{i}\langle n|\dot{n}\rangle = -\mathrm{Im}\langle n(\mathbf{R}(t))|\frac{\mathrm{d}}{\mathrm{d}t}n(\mathbf{R}(t))\rangle \tag{34}$$

which is analogous to equation (11).

Finally, the answer to the question originally asked by Berry is

$$|\psi(T)\rangle = \exp\left[\mathrm{i}(\delta_n + \gamma_n(\mathcal{C}))\right]|\psi(0)\rangle \tag{35}$$

where

$$\delta_n \equiv \frac{-1}{\hbar}\int_0^T E_n(\mathbf{R}(t))\,\mathrm{d}t \tag{36}$$

is the dynamical phase, and

$$\gamma_n(\mathcal{C}) \equiv -\mathrm{Im}\left[\oint_{\mathcal{C}}\langle n(\mathbf{R})|\partial_{\mathbf{R}}|n(\mathbf{R})\rangle\cdot\mathrm{d}\mathbf{R}\right] - \alpha_n(\mathcal{C}) \tag{37}$$

is the Berry phase. The last term in the latter equation arises when the states $|n(\mathbf{R})\rangle$ are not a single-valued function of $\mathbf{R}$ in the region of interest of the parameter space and is given by

$$\alpha_n(\mathcal{C}) = \mathrm{i}\ln\left[\langle n(\mathbf{R}(0))|n(\mathbf{R}(T))\rangle\right] \tag{38}$$

Note that this term was absent in Berry's original paper (Berry, 1984), because the basis states $|n(\mathbf{R})\rangle$ were assumed to be single valued. We shall omit this term in the subsequent text, and consider only the case of single-valued basis states.

We note the very close analogy between the results obtained for quantum and classical systems. The dynamical phase of a quantum system is analogous to the rotation angle ωT in classical mechanics, whereas the Berry phase is analogous to Hannay's angle (they both arise from the anholonomy of parallel transport).

Defining the connection $\mathbf{A}^n(\mathbf{R})$ as

$$\mathbf{A}^n(\mathbf{R}) \equiv -\mathrm{Im}\left[\langle n(\mathbf{R})|\partial_{\mathbf{R}}n(\mathbf{R})\rangle\right] \tag{39}$$

we reexpress the Berry phase as

$$\gamma_n(\mathcal{C}) \equiv \oint_{\mathcal{C}} \mathbf{A}^n(\mathbf{R}) \cdot \mathrm{d}\mathbf{R} \tag{40}$$

which constitutes the 1-form expression of the Berry phase. The latter clearly depends only on the geometry of the circuit $\mathcal{C}$. The connection $\mathbf{A}^n(\mathbf{R})$ is not gauge invariant – if we make a new choice for the phase of the reference state, that is,

$$|n(\mathbf{R})\rangle' = \exp(-i\,\mu(\mathbf{R}))|n(\mathbf{R})\rangle \tag{41}$$

with a single-valued function $\mu(\mathbf{R})$, we obtain a different connection

$$\mathbf{A}^{n\prime}(\mathbf{R}) = \mathbf{A}^n(\mathbf{R}) + \partial_{\mathbf{R}}\mu(\mathbf{R}) \tag{42}$$

However, the Berry phase $\gamma_n(\mathcal{C})$ is gauge invariant, as it should be.

As for the geometric parallel transport on surfaces, we may obtain a gauge-invariant and more transparent expression by transforming the preceding result to a surface integral using Stokes' theorem. Here too, we have to pay attention to the existence of holes in the parameter space – if the parameter space is multiply connected, and if the circuit $\mathcal{C}$ cannot be continuously deformed to a point (i.e., it is not *homotopic* to a point), we must take into account terms associated with the winding of $\mathcal{C}$ around holes of the parameter space.

The formulation of the Berry phase as a surface integral in a form that is independent of a particular choice of coordinates of the parameter space generally requires the use of mathematical formalism of differential forms (Bohm *et al*., 2003), which is beyond the scope of this article. We can nevertheless obtain a useful result without resorting to any advanced mathematics if we make a suitable choice of coordinates of the parameter space. Let us choose a surface $\mathcal{S}$ in the parameter space which is bound by the circuit $\mathcal{C}$, and a parameterization (R_1, R_2) of the surface $\mathcal{S}$. Using Stokes' theorem, we then get

$$\gamma_n(\mathcal{C}) = \iint_{\mathcal{S}} B^n(\mathbf{R})\mathrm{d}R_1\,\mathrm{d}R_2 + \sum_i N_i(\mathcal{C})\gamma_n(\mathcal{C}_i) \tag{43}$$

where $\mathcal{C}_i$ are the circuits bounding the holes of the parameter space and N_i, the corresponding winding numbers of the circuit $\mathcal{C}$ around them, and where

$$\begin{aligned} B^n(\mathbf{R}) &\equiv \left(\partial_{R_1} A_2^n - \partial_{R_2} A_1^n\right) \\ &= -\mathrm{Im}\left[\langle \partial_{R_1} n(\mathbf{R})|\partial_{R_2} n(\mathbf{R})\rangle - \langle \partial_{R_2} n(\mathbf{R})|\partial_{R_1} n(\mathbf{R})\rangle\right] \end{aligned} \tag{44}$$

is the *Berry curvature*. In the case where the parameter space is three-dimensional, we can use the familiar language of vector calculus, as in electrodynamics, and Stokes' theorem yields

$$\gamma_n(\mathcal{C}) = \iint_{\mathcal{S}} \mathbf{B}^b(\mathbf{R}) \cdot \mathbf{n}\,\mathrm{d}S + \sum_i N_i(\mathcal{C})\gamma_n(\mathcal{C}_i) \tag{45}$$

$$\begin{aligned} \mathbf{B}^n(\mathbf{R}) &\equiv \nabla \times \mathbf{A}^n(\mathbf{R}) \\ &= -\mathrm{Im}\left[\langle \nabla n(\mathbf{R})| \times |\nabla n(\mathbf{R})\rangle\right] \qquad (46) \\ &= -\mathrm{Im}\sum_{m\neq n} \langle \nabla n(\mathbf{R})|m(\mathbf{R})\rangle \times \langle m(\mathbf{R})|\nabla n(\mathbf{R})\rangle \qquad (47) \end{aligned}$$

Making use of the relation

$$\langle m|\nabla n\rangle = \frac{\langle m|\nabla H|n\rangle}{E_n - E_m} \tag{48}$$

one eventually gets

$$\begin{aligned} \mathbf{B}^n(\mathbf{R}) = -\mathrm{Im}&\sum_{m\neq n} \\ &\times \frac{\langle n(\mathbf{R})|\nabla H(\mathbf{R})|m(\mathbf{R})\rangle \times \langle m(\mathbf{R})|\nabla H(\mathbf{R})|n(\mathbf{R})\rangle}{(E_m(\mathbf{R}) - E_n(\mathbf{R}))^2} \end{aligned} \tag{49}$$

Obviously, the Berry curvature is gauge invariant. As the notation suggests, the Berry curvature $\mathbf{B}^n$ plays the role of a magnetic field in the space of parameters, whose vector potential is the Berry connection $\mathbf{A}^n$.

The energy denominator in equation (49) shows that if the circuit $\mathcal{C}$ lies in a region of the parameter space that is close to a point $\mathbf{R}^\star$ of twofold degeneracy involving the two states labeled $+$ and $-$, the corresponding Berry connections $\mathbf{B}_+$ and $\mathbf{B}_-$ are dominated by the term involving the denominator $(E_+ - E_-)^2$ and the contribution involving other states can be neglected. So, to first order in $\mathbf{R} - \mathbf{R}^\star$, one has

$$\begin{aligned} \mathbf{B}_+(\mathbf{R}) = -\mathbf{B}_-(\mathbf{R}) = -\mathrm{Im}&\\ &\times \frac{\langle +(\mathbf{R})|\nabla H(\mathbf{R}^\star)| -(\mathbf{R})\rangle \times \langle -(\mathbf{R})|\nabla H(\mathbf{R}^\star)| +(\mathbf{R})\rangle}{(E_+(\mathbf{R}) - E_-(\mathbf{R}))^2} \end{aligned} \tag{50}$$

The general form of the Hamiltonian $H(\mathbf{R})$ of a two-level system is (without loss of generality, we may take $\mathbf{R}^\star = 0$)

$$H(\mathbf{R}) \equiv \frac{1}{2}\begin{pmatrix} Z & X - \mathrm{i}Y \\ X + \mathrm{i}Y & -Z \end{pmatrix} \tag{51}$$

with eigenvalues

$$E_+(\mathbf{R}) = -E_-(\mathbf{R}) = \frac{1}{2}R \tag{52}$$

This illustrates a theorem due to von Neumann and Wigner (1929), stating that it is necessary to adjust three independent parameters in order to obtain a twofold degeneracy from a Hermitian matrix. The gradient of the Hamiltonian is

$$\nabla H = \frac{1}{2}\boldsymbol{\sigma} \tag{53}$$

where $\boldsymbol{\sigma}$ is the vector matrix whose components are the familiar Pauli matrices. Simple algebra then yields

$$\mathbf{B}_+ = -\mathbf{B}_- = -\frac{\mathbf{R}}{R^3} \tag{54}$$

The preceding Berry curvature $\mathbf{B}_\pm$ is the magnetic field in parameter space generated by a Dirac magnetic monopole (Dirac, 1931) of strength $\mp 1/2$. Thus, the Berry phase $\gamma_\pm(\mathcal{C})$ of a circuit $\mathcal{C}$ is given by the flux of the monopole through the surface $\mathcal{S}$ subtended by the circuit $\mathcal{C}$, which, by Gauss' theorem, is nothing but $\mp\Omega(\mathcal{C})$, where $\Omega(\mathcal{C})$ is the solid angle described by $\mathbf{R}$ along the circuit $\mathcal{C}$.

The corresponding vector potential (or Berry connection) $\mathbf{A}_\pm$ (not calculated here) has an essential singularity along a line (Dirac string) ending at the origin and carrying a 'flux' of magnitude $\pm 2\pi$. The position of the Dirac string can be moved (but not removed!) by a gauge transformation, as sketched in Figure 3. If the Dirac string happens to cross the surface $\mathcal{S}$, the Berry phase remains unchanged (modulo 2π), so that the result is indeed gauge invariant.

5 EXAMPLES OF BERRY PHASE

5.1 Spin in a magnetic field

As the first example, we consider the case of a single spin (of magnitude S) in a magnetic field, which is both the most immediate application of the formal theory presented in the preceding text and one of the most frequent cases encountered in experimentally relevant situations. The Hamiltonian considered is

$$H(\mathbf{b}) \equiv -\mathbf{b}\cdot\mathbf{S} \tag{55}$$

with the magnetic field $\mathbf{b}$ being the external parameter. The eigenvalues are

$$E_n(\mathbf{b}) = -nb \tag{56}$$

with $2n$ integer and $-S \le n \le S$. For $\mathbf{b} = 0$, the $2S+1$ eigenstates are degenerate, so the circuit $\mathcal{C}$ has to avoid the origin. The Berry connection can be calculated using equation (49) and well-known properties of the spin operators, and one gets

$$\mathbf{B}^n(\mathbf{b}) = -n\frac{\mathbf{b}}{b^3} \tag{57}$$

which is the 'magnetic field' (in parameter space) of a monopole of strength $-n$, located at the origin. The Berry phase is thus

$$\gamma_n(\mathcal{C}) = -n\Omega(\mathcal{C}) \tag{58}$$

where $\Omega(\mathcal{C})$ is the solid angle described by the field $\mathbf{b}$ along the circuit $\mathcal{C}$. For $S = 1/2$, this of course reduces to the result obtained in the preceding text for the two-level problem. Note that the Berry phase $\gamma_n(\mathcal{C})$ depends only on the quantum number n (projection of $\mathbf{S}$ on $\mathbf{b}$) and not on the magnitude S of the spin. Note also, that while $H(\mathbf{b})$ is the most general Hamiltonian for a spin $S = 1/2$, this is not the case for a spin $S \ge 1$; in the latter case, we restrict ourselves to a subspace of the full parameter space. If a more general Hamiltonian and a wider parameter space is considered, the simple result obtained in the preceding text would not hold any more.

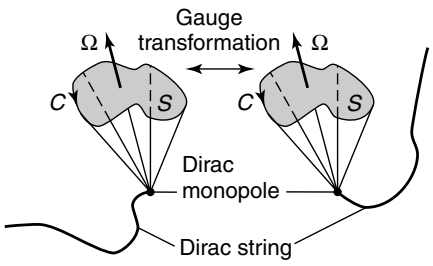

Figure 3. Sketch showing the flux of the Dirac monopole through the circuit $\mathcal{C}$, and the effect of a gauge transformation.

5.2 Aharonov–Bohm effect

Another example that is of great interest, both conceptually and experimentally is the well-known Aharonov–Bohm effect (Aharonov and Bohm, 1959). We follow here the presentation of the Aharonov–Bohm effect given by Berry (1984).

Let us consider the situation depicted in Figure 4, namely, a magnetic field confined in a tube with flux Φ and a box, located at $\mathbf{R}$, in which particles of charge q are confined. The magnetic field vanishes everywhere outside the flux tube and, in particular, inside the box. Let $\mathbf{A}(\mathbf{r})$ be the corresponding vector potential. The latter generally does not vanish in the regions of vanishing field (unless the flux Φ is a multiple of the flux quantum $\Phi_0 \equiv h/e$).

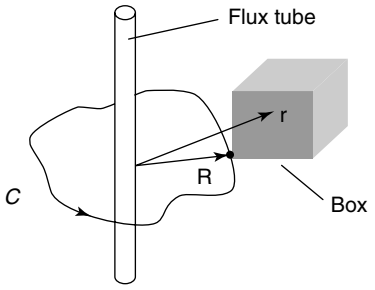

Figure 4. Sketch describing the Aharonov–Bohm effect.

Let the Hamiltonian describing the particles in the box be $H(\mathbf{p}, \mathbf{r}-\mathbf{R})$; the corresponding wave functions, for a vanishing vector potential, are of the form $\psi_n(\mathbf{r}-\mathbf{R})$, with energies E_n independent of $\mathbf{R}$. When the flux is nonzero, we can choose as basis states $|n(\mathbf{R})\rangle$, satisfying

$$H(\mathbf{p}-q\mathbf{A}(\mathbf{r}), \mathbf{r}-\mathbf{R})|n(\mathbf{R})\rangle = E_n|n(\mathbf{R})\rangle \tag{59}$$

whose solutions are given by

$$\langle \mathbf{r}|n(\mathbf{R})\rangle = \exp\left[\frac{\mathrm{i}q}{\hbar}\int_{\mathbf{R}}^{\mathbf{r}} \mathrm{d}\mathbf{r}'\cdot\mathbf{A}(\mathbf{r}')\right]\psi_n(\mathbf{r}-\mathbf{R}) \tag{60}$$

where the integral is performed along a path contained in the box. The energies E_n are independent of the vector potential, because it is always possible to find a gauge transformation that would make it zero in the box (but not everywhere in space!).

The Hamiltonian depends on the position $\mathbf{R}$ of the box via the vector potential. Thus, our parameter space, in this example, is nothing but the real space, with exclusion of the region of the flux tube. If we transport the box around a closed circuit $\mathcal{C}$, the Berry phase will be given by

$$\gamma_n(\mathcal{C}) \equiv \oint_{\mathcal{C}} \mathbf{A}^n(\mathbf{R})\cdot\mathrm{d}\mathbf{R} \tag{61}$$

with the Berry connection

$$\begin{aligned}\mathbf{A}^n(\mathbf{R}) &\equiv -\mathrm{Im}\left[\langle n(\mathbf{R})|\partial_{\mathbf{R}} n(\mathbf{R})\rangle\right] \\ &= -\mathrm{Im}\iiint \mathrm{d}^3\mathbf{r}\psi_n^\star(\mathbf{r}-\mathbf{R}) \\ &\quad\times\left[\frac{-\mathrm{i}q}{\hbar}\mathbf{A}(\mathbf{R})\psi_n(\mathbf{r}-\mathbf{R}) + \partial_{\mathbf{R}}\psi_n(\mathbf{r}-\mathbf{R})\right] \\ &= \frac{q}{\hbar}\mathbf{A}(\mathbf{R})\end{aligned} \tag{62}$$

The Berry curvature $\mathbf{B}^n(\mathbf{R}) = \nabla\times\mathbf{A}^n(\mathbf{R}) = (q/\hbar)\mathbf{B}(\mathbf{R})$ is just given by the magnetic field and vanishes everywhere outside the flux tube. But because the tube region is excluded from the allowed parameter space, the latter is multiply connected, and the Berry phase is purely topological, given by the winding number $N(\mathcal{C})$ of the circuit $\mathcal{C}$ around the flux tube, and by the flux Φ

$$\gamma_n(\mathcal{C}) = 2\pi N(\mathcal{C})\frac{q}{h}\Phi \tag{63}$$

The Aharonov–Bohm effect was confirmed experimentally by electron holography by Tonomura *et al*. (1986) in a configuration where the magnetic field truly vanishes, and plays an outstanding role in the physics of mesoscopic systems; here, it gives rise to conductance oscillations and to persistent currents in mesoscopic metallic rings threaded by a magnetic flux (Olariu and Popescu, 1985; Aronov and Sharvin, 1987; Washburn and Webb, 1992).

5.3 Thomas precession and spin-orbit coupling

In relativistic kinematics, space–time coordinates perceived by observers in different inertial frames are related to each other by Lorentz transformations. The latter may consist of pure Lorentz boosts, pure rotations, or combinations of a boost and a rotation. As is well known, Lorentz boosts with different velocity axes do not commute with each other, and the product of two pure Lorentz boosts with different axes is not a pure Lorentz boost but the product of a Lorentz boost and a rotation. This effect gives rise to the phenomenon of Thomas precession (Thomas, 1926, 1927), which is one of the contributions to the spin-orbit coupling (the other contribution being the result of the Lorentz transformation of the electric field).

Recently, it has been pointed out that the Thomas precession may be understood as an anholonomy associated with the parallel transport on the manifold Lorentz boosts (Jordan, 1988; Aravind, 1997; Rhodes and Semon, 2004). This important result is briefly outlined here.

For simplicity, we restrict to Lorentz boosts in the xy plane and rotations around the z axis. A Lorentz boost of velocity $\mathbf{v}\equiv(v_x, v_y)$ can be characterized by a point (ct, x, y) on the hyperboloid $(ct)^2-(x^2+y^2)=1$ $(t\geq 0)$, such that $(v_x, v_y) = (x/t, y/t)$. Thus a closed trajectory in the space of Lorentz boosts is characterized by a closed loop on the hyperboloid. One can show (Jordan, 1988; Aravind, 1997; Rhodes and Semon, 2004) that upon such a closed loop the system does not return to the initial inertial frame but to an inertial frame that differs from the initial one by a rotation around the z axis, of angle $\theta = -A$, where A is the area enclosed by the loop on the hyperboloid. This rotation is precisely the Thomas precession (Thomas, 1926, 1927), the geometrical nature of which appears clearly from the present formulation. For a quantum spin, a Berry phase

results from the Thomas precession. Another contribution (for charged particles) arises from the Lorentz transformation of the electric field and combines with the Thomas precession to give the familiar spin-orbit coupling of the electron.

For velocities much smaller than the velocity of light, the Berry phase corresponding to a closed loop $\mathcal{C}$ in the (v_x, v_y) plane due to the spin-orbit coupling (including both the Thomas precession contribution and the Lorentz transformation of the electric field) is given by the simple expression

$$\gamma_\sigma(\mathcal{C}) = -\sigma \oint_{\mathcal{C}} \frac{\mathbf{v} \times \mathrm{d}\mathbf{v}}{4c^2} = -\sigma \frac{A(\mathcal{C})}{4c^2} \tag{64}$$

with $\sigma = \pm 1$ for $s_z = \pm 1/2$, respectively, and where $A(\mathcal{C})$ is the area swept in the (v_x, v_y) plane.

The geometric character of the spin-orbit coupling appears clearly from the preceding expression. For an electron in a periodic orbit, the Berry phase accumulates linearly in time, which amounts to an additional term in the dynamical phase, that is, to the spin-orbit coupling term of the Hamiltonian, which is given by the following expression (for velocities much smaller than c):

$$H_{\mathrm{SO}} = \hbar \mathbf{s} \cdot \left(\frac{\mathbf{v} \times \mathbf{a}}{2c^2} \right) \tag{65}$$

where **a** is the acceleration.

The preceding formulation of the spin-orbit coupling allows us to understand qualitatively why electrons with group velocities much smaller than c may nevertheless have a spin-orbit splitting, several orders of magnitude larger than that of free electrons with equivalent velocity. In a quasiclassical picture, the motion of electrons in a solid may be viewed as consisting mostly of periodic orbital motion around nuclei, combined with a hopping interatomic motion. The hopping frequency from atom to atom, which determines the average electron velocity, is typically much smaller than the frequency of the intra-atomic orbital motion around the nuclei. The Berry phase accumulated between two successive hopping events, determined essentially by this intra-atomic orbital motion, is considerably larger than the one accumulated in the interatomic hopping motion, so that the effective spin-orbit coupling of Bloch electrons in a solid may be enhanced by a factor of the order of 10^4 as compared to the spin-orbit coupling of free electrons.

5.4 Experimental observations of the Berry phase for a single spin

Let us now discuss how the Berry phase could be detected experimentally. As already mentioned, this is not immediately clear since the expectation value of any observable would be independent of the phase of the system. As always, when considering phases, some kind of interference has to be observed. There are various ways in which this can be done.

- Berry's original proposal (Berry, 1984) was as follows: A monoenergetic polarized beam of particles in the spin state n along the magnetic field **b** is split into two beams. For one of the beams, the field **b** is kept constant in magnitude and direction, whereas for the second beam, the magnitude of **b** is kept constant and its direction is slowly varied along a circuit $\mathcal{C}$ subtending a solid angle Ω. The two beams are then recombined to interfere, and the intensity is monitored as a function of the solid angle Ω. Since the dynamical phase is the same for both beams, the phase difference between the two beams is given purely by the Berry phase (plus a propagation factor is determined by the phase shift for $\Omega = 0$). Although conceptually possible, it seems unlikely that such an experiment would be feasible in practice. In particular, it would be extremely difficult to ensure that the difference between the dynamical phases of the two beams is smaller than the Berry phase one wants to detect, unless some physical principle enforces it. This kind of experiment may be said to be of type 'one state – two Hamiltonians'. This kind of experiment, being based on interferences, is truly quantum mechanical.
- An alternative approach, more amenable to an experimental test, is to prepare the system into a superposition of two states, that is,

$$|\psi(t=0)\rangle = \alpha |n(\mathbf{R}(t=0))\rangle + \beta |m(\mathbf{R}(t=0))\rangle \tag{66}$$

with $m = n - 1$ and $|\alpha|^2 + |\beta|^2 = 1$, for example, by polarizing it along a direction perpendicular to the field **b**. The orientation of the transverse component of the spin is given by the angle $\theta(t=0) \equiv \arg(\beta) - \arg(\alpha)$. The spin of course precesses at around **b** at the Larmor frequency $\omega_L = b/\hbar$. After completion of the circuit $\mathcal{C}$, the system state has evolved to

$$|\psi(T)\rangle = \alpha \exp[\mathrm{i}(\delta_n + \gamma_n(\mathcal{C}))] |n(\mathbf{R}(t=0))\rangle + \beta \exp[\mathrm{i}(\delta_m + \gamma_m(\mathcal{C}))] |m(\mathbf{R}(t=0))\rangle \tag{67}$$

and the polarization angle has evolved to $\theta(T) = \theta(t=0) + \Delta\theta$ with

$$\Delta\theta = \Delta\theta_{\mathrm{dyn}} + \Delta\theta_{\mathrm{B}} \tag{68}$$

$$\Delta\theta_{\mathrm{dyn}} \equiv \delta_m - \delta_n = \omega_L T \tag{69}$$

$$\Delta\theta_{\mathrm{B}} \equiv \gamma_m(\mathcal{C})) - \gamma_n(\mathcal{C})) \tag{70}$$

Here the angle $\Delta\theta_{\mathrm{dyn}}$ gives the polarization rotation due to the Larmor precession (dynamic phase), while $\Delta\theta_{\mathrm{B}}$ is the polarization rotation due to the Berry phase accumulated along the circuit $\mathcal{C}$. Thus by investigating how the polarization varies as the circuit $\mathcal{C}$ is modified, the Berry phase can be detected. Such an experiment may be said to be of the type 'two states – one Hamiltonian'. Note that this type of experiment can be interpreted in purely classical terms (Cina, 1986) (it bears a clear analogy to the rotation of the swinging plane of the Foucault pendulum); this is related to the fact that only Berry phase differences between two states, and not the absolute Berry phase of a given state, are detected.

- A further possibility consists in repeating the circuit $\mathcal{C}$ in a periodic manner. Thus, the Berry phase is accumulated linearly in time, just as the dynamical phase, and leads to an apparent energy shift for the state n,

$$\Delta E_n = \frac{\hbar}{T}\gamma_n(\mathcal{C}) \tag{71}$$

which gives rise to an observable shift of the transition between two levels n and m. Such an experiment too is of type 'two states – one Hamiltonian'. It can also be interpreted in classical terms and has close analogy to the period shift of a Foucault pendulum with circular oscillation.

The Berry phase has been observed for neutrons ($S = 1/2$) by Bitter and Dubbers (1987), who used the experiment shown in Figure 5. A slow ($v \simeq 500\,\mathrm{ms}^{-1}$), monochromatic beam of neutrons polarized ($P \simeq 0.97$) along an axis perpendicular to the beam axis z is injected in a cylinder with a helical magnetic field with longitudinal component B_z and transverse component B_1 making a right-handed turn of 2π. Depending on the values of B_z and B_1, various values of the solid angle Ω may be achieved.

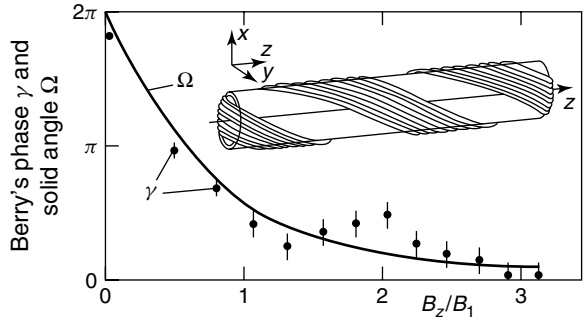

Figure 5. Measurement of Berry phase of neutrons. The inset shows the arrangement of the coil giving a helical field; the neutron beam is along z; length: 40 cm, diameter: 8 cm; an axial coil (not shown) produces a field B_z. The curve shows the Berry phase (more precisely $\gamma_{-1/2} - \gamma_{1/2}$) and solid angle Ω as a function of the ratio B_z/B_1. (Reproduced from Bitter & Dubber 1987, with permission from the American Physical Society. © 1987.)

After having traversed the cylinder, the polarization of the beam is measured, from which the Berry phase can be extracted. The comparison of the measured Berry phase (or more precisely the difference of Berry phase between states $S_z = +1/2$ and $S_z = -1/2$) and of the solid angle is shown in Figure 5. The observation is in good agreement with the theoretical prediction.

The Berry phase has also been confirmed for photons ($S = 1$) by Tomita and Chiao (1986) using an experimental procedure proposed by Chiao and Wu (1986); for protons ($S = 1/2$) by Suter, Chingas, Harris and Pines (1987) following a proposal of Moody, Shapere and Wilczek (1986); and for ^{35}Cl nuclei by Tycko (1987).

6 ANOMALOUS HALL EFFECT

The Berry phase plays an important role in the modern understanding of the anomalous Hall effect. Therefore this problem will be discussed here in a detailed manner.

6.1 Brief historical sketch and survey of the state of the art

The history of the anomalous Hall effect has been quite a turbulent one, rich in misconceptions and controversies, and the reader approaching the corresponding literature without a sufficient overview of the historical developments might easily get lost in details of controversial debates. Therefore, it appears useful to briefly sketch the main stages in the historical development of the field.

Soon after his discovery of the Hall effect of normal metals subject to an external magnetic field (Hall, 1880a), Erwin H. Hall discovered that ferromagnetic metals may exhibit a spontaneous (i.e., in the absence of an external magnetic field) Hall effect (Hall, 1880b, 1881). Toward the end of the nineteenth century and in the first half of the twentieth century, extensive experimental and phenomenological investigations of the anomalous Hall effect of ferromagnetic metals and alloys were carried out (Kundt, 1893; Smith, 1910; Perrier, 1930a,b; Pugh, Rostoker and Schindler, 1950; Smit and Volger, 1953; Pugh and Rostoker, 1953).

From these early studies, the following phenomenological description emerged. In linear response regime, the electric field $\mathbf{E}$ is linearly related to the current density $\mathbf{j}$ by

$$\mathbf{E} = \boldsymbol{\rho}\mathbf{j} \tag{72}$$

with a resistivity tensor $\boldsymbol{\rho}$ (for a magnetic field and/or magnetization parallel to the z-axis) of the form

$$\boldsymbol{\rho} = \begin{pmatrix} \rho_{xx} & \rho_{xy} & 0 \\ -\rho_{xy} & \rho_{xx} & 0 \\ 0 & 0 & \rho_{zz} \end{pmatrix} \tag{73}$$

The Hall effect is given by the antisymmetric part of the resistivity tensor, giving rise to a voltage that is transverse to both the current and the magnetic field (or magnetization). In a ferromagnet, the Hall resistivity $\rho_H = -\rho_{xy}$ is experimentally found to be of the form

$$\rho_H = R_0 H + R_S M \tag{74}$$

where H is the magnetic field, M, the magnetization, R_0, the normal Hall coefficient, and R_S, the anomalous Hall coefficient (the quantity of interest here). Alternatively, the Hall effect may be expressed in terms of the conductivity tensor, $\boldsymbol{\sigma} \equiv \boldsymbol{\rho}^{-1}$. Another important quantity measuring the Hall effect is the Hall angle θ_H (the angle between the electric field and the current) given by

$$\tan\theta_H \equiv \frac{-\sigma_{xy}}{\sigma_{xx}} = \frac{\rho_{xy}}{\rho_{xy}} \tag{75}$$

For values of the magnetic field usually available experimentally, the spontaneous contribution is usually much larger than the normal contribution in ferromagnets. In many cases, it has been found that as the temperature varies, the anomalous Hall resistivity varies as ρ_{xx}^2, which implies that the Hall conductivity σ_{xy} is essentially independent of the relaxation time.

Various mechanisms contribute to the anomalous Hall effect of homogenously magnetized systems:

- the Karplus–Luttinger mechanism (Karplus and Luttinger, 1954)
- the skew-scattering mechanism (Smit, 1955)
- the side-jump mechanism (Berger, 1970).

All three mechanisms rely on the combined effect of exchange and spin-orbit interactions. This can be easily understood from the following considerations. From the Onsager–Casimir symmetry relations (Onsager, 1931; Casimir, 1945), it follows that the antisymmetric part of the resistivity (or conductivity) tensor, that is, the Hall effect, is antisymmetric with respect to time-reversal invariance. In ferromagnets, time-reversal invariance is spontaneously broken by the appearance of the exchange splitting of the band structure. This fact, however, is not sufficient to explain the existence of the Hall effect; indeed, in the absence of spin-orbit interaction, the spin (magnetization) and orbital (electronic motion) degrees of freedom are completely independent of each other. This implies that all properties of the system (including the resistivity tensor) would be invariant under a continuous uniform rotation of the magnetization, resulting in a vanishing Hall effect. This state changes, however, when the electron motion and spin are coupled to each other via the spin-orbit coupling, so that the physical properties are no longer invariant under a global rotation of the magnetization, resulting in the possibility of a nonzero spontaneous Hall effect.

Although sharing a common microscopic origin, the three mechanisms mentioned in the preceding text are quite different in the way they depend on the electronic structure and/or on the impurities present in the ferromagnet.

The Karplus–Luttinger mechanism (Karplus and Luttinger, 1954) results from a velocity correction (the anomalous velocity) due to interband matrix elements of the velocity operator. It yields a Hall conductivity that is essentially a property of the pure Ferromagnet and (for low impurity concentration) is independent of the nature and concentration of impurities, that is, to a Hall resistivity proportional to ρ_{xx}^2, as observed in many cases. The original derivation by Karplus and Luttinger is quite involved and not really physically transparent. This, together with various other theoretical difficulties, led to misunderstanding and controversies that could be definitely lifted only quite recently, through the reinterpretation of the Karplus–Luttinger mechanism in terms of the Berry phase (Chang and Niu, 1996; Sundaram and Niu, 1999; Jungwirth, Niu and MacDonald, 2002). Interestingly, this important progress emerged from concepts developed in the context of the quantum Hall effect (Thouless, Kohmoto, Nightingale and den Nijs, 1982; Avron, Seiler and Simon, 1983; Simon, 1983; Thouless, 1984, 1994; Niu and Thouless, 1984; Niu, Thouless and Wu, 1985; Kohmoto, 1985,1993), which allowed the interpretation of the quantized Hall conductance as a topological invariant, expressed as the integral of a Berry curvature over a closed manifold.

The skew-scattering mechanism (Smit, 1955) arises from the Mott scattering (Mott, 1929) at impurities, that is, from the fact that, owing to spin-orbit interaction, the scattering amplitude depends on the relative orientation of the spin with respect to the scattering plane. An illustrative picture of this mechanism is given in Figure 6(a) (Crépieux and Bruno, 2001). Consider an incident plane wave characterized by a wave vector **k**, which is scattered by a central potential owing to, for example, impurity. In the presence of spin-orbit coupling, the amplitude of the wave packet becomes anisotropic in the sense that it depends on the relative directions of the scattered and incident waves and the spin. After a succession of scattering events, the average trajectory of the electron is deflected by a spin-dependent angle,

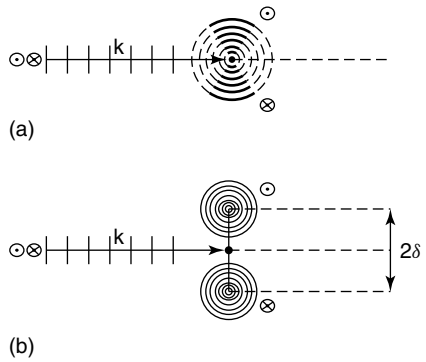

Figure 6. Sketch of the skew-scattering (a) and side-jump (b) mechanisms. (Reproduced from Crepieux & Bruno, 2001, with permission from the American Physical Society. © 2001.)

which is typically of the order of 10^{-2} rad. Because the skew scattering yields an *angular* deflection of scattered electrons, it induces a Hall angle that is *independent* of the impurity density (for sufficiently low impurity density), or in other words, a Hall resistivity that is proportional to the longitudinal resistivity.

The side-jump mechanism (Berger, 1970) arises from the fact that as a plane wave is scattered at an impurity, the outgoing scattered wave is generally not centered exactly at the impurity, but may be slightly shifted away from the impurity, as depicted in Figure 6(b) (Crépieux and Bruno, 2001). This shift can be transverse and/or longitudinal (with respect to the incident wave vector). The longitudinal shift is not directly relevant to the Hall effect and will be ignored here. The transverse shift (side jump) is due to the effect of the spin-orbit coupling and changes sign as the spin component perpendicular to the scattering plane is reversed. The existence of the side jump may be easily understood by examining the reflection of a free electron on a potential barrier under the influence of the spin-orbit coupling (Crépieux and Bruno, 2001). For free electrons, the magnitude of the side jump is of the order of $k\lambda_C{}^2/4 \simeq 10^{-15}$ m, where $\lambda_C \equiv \hbar/(mc)$ is the Compton wavelength. As pointed out by Berger (1970), and discussed in Section 5.3 in the preceding text, band-structure considerably enhance the effective spin-orbit coupling experienced by electrons in solids, and yield an enhancement factor of the order of 10^4 of the magnitude of the side jump. The side jump contributes to the Hall current in two ways: (i) the side jumps experienced at each collision add up to yield a transverse current, and (ii) in the presence of an external electric field, the side jump induces a shift of the electron distribution function away from the Dirac distribution, yielding another contribution to the transverse current (Berger, 1970). The two contributions can be shown to be identical. The most important feature of the side-jump contribution is that it yields a Hall conductivity that is independent of the impurity concentration (and, at least for s-scattering, independent of the sign and magnitude of the scattering potential). Thus, it is essentially an *intrinsic* contribution to the total Hall conductivity just like the Karplus–Luttinger term, and, therefore, yields a contribution to the Hall resistivity that is proportional to ρ_{xx}^2 (Berger, 1970).

Until recently, it was believed that spin-orbit coupling is an essential ingredient to obtain a nonvanishing anomalous Hall effect. This belief is indeed correct in uniformly magnetized ferromagnets for the reasons explained in the preceding text. However, the argument put forward to justify the necessity of the spin-orbit coupling does not hold any more for magnetic systems with noncollinear magnetization. In fact, in general, a time-reversed magnetic configuration (i.e., with all magnetic moments flipped) cannot be obtained by a global rotation of the magnetic moments, unless the magnetization is collinear or coplanar. Therefore, from symmetry considerations, a nonvanishing anomalous Hall effect may be expected, even without spin-orbit coupling, in a magnetic system with a chiral spin texture. Quite recently, it has been proposed that the chiral textured magnetic system may exhibit anomalous Hall effect not (directly) related to the spin-orbit coupling (Ye *et al*., 1999; Ohgushi, Murakami and Nagaosa, 2000; Chun *et al*., 2000; Taguchi and Tokura, 2001; Taguchi *et al*., 2001, 2003, 2004; Lyanda-Geller *et al*., 2001; Shindou and Nagaosa, 2001; Yanagihara and Salamon, 2002; Tatara and Kawamura, 2002; Onoda and Nagaosa, 2002, 2003a,b; Bruno, Dugaev and Taillefumier, 2004; Onoda, Tatara and Nagaosa, 2004; Baily and Salamon, 2005; Kézsmárki *et al*., 2005). The mechanism responsible for the anomalous Hall effect, in this case, relies on the Berry phase accumulated as an electron moves in a textured exchange field. If the exchange splitting is large enough and the electron velocity small enough, the electron spin must adiabatically follow the direction of the local exchange field as it moves through the lattice. In the reference frame where the electron is at rest, it experiences an adiabatically moving exchange field, and the associated geometrical phase in turn generates a fictitious Aharonov–Bohm phase as the electron moves through the lattice. The electron's orbital degree of freedom is coupled to the fictitious field in exactly the same way as to a real magnetic field, and therefore also responds in the same way. In particular, it experiences a Lorentz force that can give rise to a nonvanishing anomalous Hall effect if a net chirality is present.

It is worth pointing out that the theory of the anomalous Hall effect involves the Berry phase in two distinct ways:

1. In the anomalous Hall effect of homogenous ferromagnets, the Karplus–Luttinger contribution can be interpreted as a Berry phase in momentum space.

2. In chiral textured ferromagnets, the anomalous Hall effect arises from the Berry phase due to the exchange field texture in real space.

In the following text, we shall discuss in more detail the interplay of the Berry phase and anomalous Hall effect in these two different contexts.

6.2 Berry phase and the anomalous Hall effect in homogenous ferromagnets

From Kubo's linear response theory, the conductivity tensor for independent electrons is given by Luttinger (1969)

$$\sigma_{ij} = \frac{\mathrm{i}e^2\hbar}{\Omega}\lim_{s\to 0^+} \times \left\langle \sum_{n,m} \frac{f(\varepsilon_n) - f(\varepsilon_m)}{\varepsilon_m - \varepsilon_n} \frac{\langle n|\, v_j\, |m\rangle \langle m|\, v_i\, |n\rangle}{\varepsilon_n - \varepsilon_m + \mathrm{i}s} \right\rangle_c \quad (76)$$

In this equation, n, m label the eigenstates, the thermodynamic limit is implied (volume Ω tending to infinity), and $\langle \ldots \rangle_c$ indicates averaging over impurity configuration. For metals, particular care is needed to perform the limit $s \to 0^+$. Simply setting $s = 0$ yields the Karplus–Luttinger term. The remaining contributions arise from the vicinity of the Fermi level and yield the skew-scattering and side-jump contributions. Here, we are interested in the Karplus–Luttinger term. Disorder is usually considered to be of minor importance for the Karplus–Luttinger term and will be neglected from now on, so that the eigenstates are labeled by the band index n and the wave vector $\mathbf{k}$ in the first Brillouin zone. We thus get

$$\sigma_{ij}^{KL} = -e^2\hbar \int_{1BZ} \frac{\mathrm{d}^D\mathbf{k}}{(2\pi)^D} \sum_{n\neq m} (f(\varepsilon_n(\mathbf{k})) - f(\varepsilon_m(\mathbf{k}))) \times \frac{\mathrm{Im}\left[\langle n\mathbf{k}|\, v_j\, |m\mathbf{k}\rangle \langle m\mathbf{k}|\, v_i\, |n\mathbf{k}\rangle\right]}{(\varepsilon_n(\mathbf{k}) - \varepsilon_m(\mathbf{k}))^2} \quad (77)$$

Using the fact that, for $m \neq n$,

$$\langle n\mathbf{k}|\, H\, |m\mathbf{k}\rangle = 0 \quad (78)$$

one obtains

$$\langle \partial_{\mathbf{k}}(n\mathbf{k})|\, m\mathbf{k}\rangle\, \varepsilon_m(\mathbf{k}) + \langle n\mathbf{k}|\, \partial_{\mathbf{k}}(m\mathbf{k})\rangle\, \varepsilon_n(\mathbf{k}) + \langle m\mathbf{k}|\, \frac{\partial H(\mathbf{k})}{\partial \mathbf{k}}\, |n\mathbf{k}\rangle = 0 \quad (79)$$

Similarly, $\langle n\mathbf{k}|\ m\mathbf{k}\rangle = 0$ implies that

$$\langle \partial_{\mathbf{k}}(n\mathbf{k})|\, m\mathbf{k}\rangle + \langle n\mathbf{k}|\, \partial_{\mathbf{k}}(m\mathbf{k})\rangle = 0 \quad (80)$$

so that

$$\frac{\langle n\mathbf{k}|\, v_j\, |m\mathbf{k}\rangle}{\varepsilon_n(\mathbf{k}) - \varepsilon_m(\mathbf{k})} = \frac{1}{\hbar} \langle \partial_{k_j}(n\mathbf{k})|\ m\mathbf{k}\rangle \quad (81)$$

Finally, we get

$$\sigma_{ij}^{KL} = -\frac{2e^2}{\hbar} \int_{1BZ} \frac{\mathrm{d}^D\mathbf{k}}{(2\pi)^D} \sum_n f(\varepsilon_n(\mathbf{k}))\, \mathrm{Im} \times \left[\langle \partial_{k_j}(n\mathbf{k})|\ \partial_{k_i}(n\mathbf{k})\rangle\right] \quad (82)$$

Defining the Berry curvature in band n as

$$\mathbf{\Omega}^{(n)} \equiv -\mathrm{Im}\left(\langle \partial_{\mathbf{k}}(n\mathbf{k})| \times |\partial_{\mathbf{k}}(n\mathbf{k})\rangle\right) \quad (83)$$

we finally obtain

$$\sigma_{ij}^{KL} = -\frac{e^2}{\hbar} \int_{1BZ} \frac{\mathrm{d}^D\mathbf{k}}{(2\pi)^D} \sum_n f\left({}^{(n)}\varepsilon_n(\mathbf{k})\right) \varepsilon_{ijk}\Omega_k(\mathbf{k}) \quad (84)$$

where ε_{ijk} is the fully antisymmetric tensor. This result is best understood for two-dimensional systems ($D = 2$), where only σ_{xy} and $\Omega_z^{(n)}$ are of interest. There the contribution of the band of index n to the Karplus–Luttinger term is simply determined by the Berry phase associated with parallel transport (with the $\mathbf{k}$-plane playing the role of the parameter space) around the Fermi surface (which is a line in two dimensions).

The case of an insulating system is of particular interest. In this case, there are no Fermi surface contributions (skew scattering and side jump) to the Hall conductivity, and the latter thus reduces to the Karplus–Luttinger term. The contribution of the occupied bands is thus given by an integral over the whole first Brillouin zone (empty bands do not contribute). Because the first Brillouin zone may be viewed as a closed surface (torus), the conductance is topologically quantized in multiples of the quantum of conductance, e^2/h. Since the longitudinal conductance vanishes, we obtain the integer quantum Hall effect without an external magnetic field. This result is completely analogous to the quantum Hall effect obtained in the problem of the Hofstadter butterfly (Hofstadter, 1976; Thouless, Kohmoto, Nightingale and den Nijs, 1982; Avron, Seiler and Simon, 1983).

It is completely similar to the Bonnet theorem in differential geometry (Nakahara, 1990), which relates the integral of the Gaussian curvature (which is a local geometrical property) over a closed surface to its Euler index (which is a global topological invariant).

The simplest example for the Berry phase formulation of the Karplus–Luttinger term is given by the two-dimensional electron gas in the presence of Rashba spin-orbit coupling

and exchange splitting. It is described by the following Hamiltonian:

$$\mathcal{H} = \frac{\hbar^2 \mathbf{k}^2}{2m^*} + \alpha \left(\sigma_x k_y - \sigma_y k_x\right) - M\sigma_z \tag{85}$$

The eigenvalues (shown in Figure 7) are

$$E^{\pm}_{\mathbf{k}} = \frac{\hbar^2 k^2}{2m^*} \mp \lambda(k) \tag{86}$$

with

$$\lambda(k) \equiv \sqrt{M^2 + \alpha^2 k^2} \tag{87}$$

The eigenstates $|\mathbf{k}, \pm\rangle$ are polarized along (resp. against) the unit vector

$$\mathbf{n}(\mathbf{k}) \equiv \left(\frac{\alpha k_y}{\lambda(k)}, \frac{-M}{\lambda(k)}, \frac{\alpha k_y}{\lambda(k)}\right) \tag{88}$$

Thus, as one performs a closed loop around the Fermi line, the spin quantization axis describes a cone, the solid angle of which determines the Berry phase, and, hence, the Karplus–Luttinger contribution to the anomalous Hall effect. We have

$$\sigma^{KL}_{xy} = -\frac{e^2}{h}\frac{1}{4\pi}\int \mathrm{d}^2\mathbf{k}\left[f(E^+_{\mathbf{k}}) - f(E^-_{\mathbf{k}})\right]\varepsilon_{\alpha\beta\gamma} n_\alpha \frac{\partial n_\beta}{\partial k_x}\frac{\partial n_\gamma}{\partial k_y} \tag{89}$$

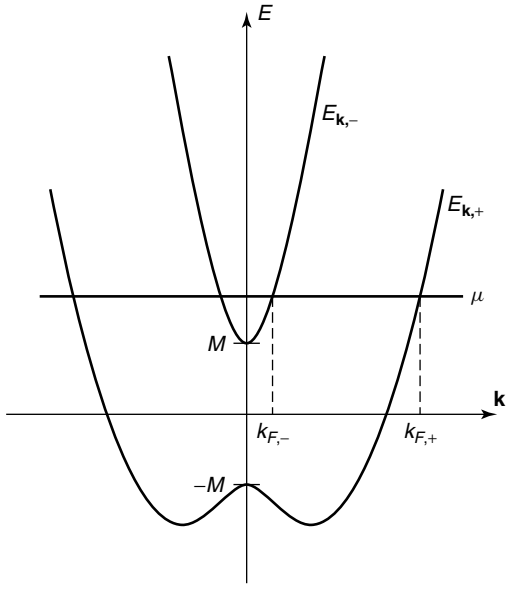

Figure 7. Energy spectrum of electrons in a two-dimensional ferromagnet with Rashba spin-orbit interaction (schematically). (Reproduced from Dugaev *et al*., 2005, with permission from the American Physical Society. © 2005.)

which, for weak spin-orbit coupling ($\alpha k_F \ll M$), finally yields

$$\sigma^{KL}_{xy} \simeq \frac{e^2}{h}\frac{m^*\alpha^2}{M}\left[\theta(M - \varepsilon_F)\frac{\varepsilon_F + M}{2M} + \theta(\varepsilon_F - M)\right] \tag{90}$$

For more extensive discussions, the reader is referred to original publications (Jungwirth, Niu and MacDonald, 2002; Fang *et al*., 2003; Culcer, MacDonald and Niu, 2003; Yao *et al*., 2004; Lee *et al*., 2004; Haldane, 2004; Sinova, Jungwirth and Černe, 2004; Dugaev *et al*., 2005; Sinitsyn, Niu, Sinova and Nomura, 2005).

6.3 Berry phase and the anomalous Hall effect in chiral textured ferromagnets

Let us consider here a system with the Hamiltonian

$$\mathcal{H} \equiv \frac{\mathbf{p}^2}{2m^*} - \mathbf{\Delta}(\mathbf{r})\cdot\boldsymbol{\sigma} \tag{91}$$

where $\mathbf{\Delta}(\mathbf{r}) \equiv \Delta(\mathbf{r})\mathbf{n}(\mathbf{r})$ is a spatially varying exchange potential. Here the quantization axis is chosen to be along z everywhere. This choice is arbitrary, however (it is in fact a gauge choice), and any other choice could be made. In particular, the exchange term becomes simpler if we choose a gauge such that the quantization axis is everywhere along $\mathbf{n}(\mathbf{r})$, that is, if we perform the unitary transformation

$$\mathcal{H} \to \tilde{\mathcal{H}} \equiv \mathcal{T}^\dagger \mathcal{H} \mathcal{T} \tag{92}$$

with

$$\mathcal{T}^\dagger(\mathbf{r})\left[\mathbf{n}(\mathbf{r})\cdot\boldsymbol{\sigma}\right]\mathcal{T}(\mathbf{r}) = \sigma_z \tag{93}$$

However, we should pay attention to the fact that the unitary operator $\mathcal{T}(\mathbf{r})$ does not commute with the momentum operator $\mathbf{p} \equiv -\mathrm{i}\hbar\partial/\partial\mathbf{r}$. Thus, the price to pay for the simplification of the exchange term is a more complicated expression of the kinetic energy term, and the transformed Hamiltonian reads

$$\tilde{\mathcal{H}} = \frac{1}{2m^*}\left(\mathbf{p} + e\mathbf{A}(\mathbf{r})\right)^2 - \Delta(\mathbf{r})\sigma_z \tag{94}$$

where $\mathbf{A}(\mathbf{r})$ is a nonabelian (2×2-spinor) gauge potential given by

$$A_i(\mathbf{r}) \equiv 2\mathrm{i}\pi\phi_0 \mathcal{T}^\dagger(\mathbf{r})\partial_i \mathcal{T}(\mathbf{r}) \tag{95}$$

Note that in the definition of the gauge potential $\mathbf{A}(\mathbf{r})$, we have introduced the flux quantum $\phi_0 \equiv h/e$ for convenience, in order to be able to express the gauge potential in the same

units as a usual vector potential. It is important to realize, however, that this is merely a convention – the electron charge (being absent from the original Hamiltonian) plays no role here, and we would have obtained the same result for a neutral particle, such as the neutron.

It may seem at first sight that we have made no real progress by changing to a new gauge – the exchange has been simplified, but the kinetic energy has taken a more complicated form. However, if the exchange splitting is large enough compared to the rate of variation of $\mathbf{n}(\mathbf{r})$ (as seen in the reference frame in which the electron is at rest), spin flip terms due to the kinetic energy term become negligible, and the spin has to adiabatically follow the local direction of $\mathbf{n}(\mathbf{r})$. More precisely, the condition of adiabaticity (for an electron at the Fermi level) reads:

$$\alpha \equiv \frac{\hbar^2 k_F}{m^* \xi \Delta} \ll 1 \tag{96}$$

where ξ is the typical length on which the direction of $\mathbf{n}(\mathbf{r})$ makes a change of the order of π. If the adiabaticity condition is satisfied, the two-spin channels decouple and one gets:

$$\tilde{\mathcal{H}} = \begin{pmatrix} \tilde{\mathcal{H}}_\uparrow & 0 \\ 0 & \tilde{\mathcal{H}}_\downarrow \end{pmatrix} \tag{97}$$

with

$$\tilde{\mathcal{H}}_\sigma \equiv \frac{1}{2m^*} \left(\mathbf{p} + \sigma e \mathbf{a}(\mathbf{r})\right)^2 - \sigma \Delta(\mathbf{r}) + V(\mathbf{r}) \tag{98}$$

with $\sigma = +1$ (-1) for $\uparrow$ $(\downarrow)$, respectively, and where the effective vector and scalar potentials are respectively given by

$$a_i(\mathbf{r}) = \pi \phi_0 \frac{n_x \partial_i n_y - n_y \partial_i n_x}{1 + n_z} \tag{99}$$

and

$$V(\mathbf{r}) \equiv \frac{\hbar^2}{8m^*} \sum_{i,\mu} \left(\partial_i n_\mu\right)^2 \tag{100}$$

Thus, we have mapped the original problem onto that of spinless particles subject to spin-dependent vector and scalar potentials. The effective magnetic field associated with the effective vector potential is defined as usual by

$$\mathbf{b} = \nabla \times \mathbf{a} \tag{101}$$

and is given in terms of $n(\mathbf{r})$ by

$$b_i = \frac{\phi_0}{8\pi} \varepsilon_{ijk} \varepsilon_{\mu\nu\lambda} n_\mu (\partial_j n_\nu)(\partial_k n_\lambda) \tag{102}$$

where Einstein's convention of summation over repeated dummy indices is implied. One can check that the effective Aharonov–Bohm phase associated with a closed path in space corresponds exactly with the Berry phase for a spin $1/2$ for the corresponding path in $\mathbf{n}$ space, that is, $\pm\Omega/2$, where Ω is the solid angle described by $\mathbf{n}$. This observation establishes the link between the effective magnetic field experienced by the electron because of the exchange field texture and the concept of the Berry phase.

The electron couples to the effective vector potential in exactly the same way as it would couple to a real vector potential, and therefore the same physical consequences are expected, and obtained. These effects can be classified into two categories:

- nonlocal effects due to quantum interferences, such as the Aharonov–Bohm effect and associated persistent currents; intrinsically, these effects are of quantum mechanical nature and require phase coherence.
- local effects such as the Lorentz force and it consequences like the Hall effect; these effects are *not* quantum mechanical in essence, but classical, and do not rely on phase coherence. An insightful paper by Aharonov and Stern (1992) beautifully explains how the effective Lorentz force arises in a classical description.

A good example of the anomalous Hall effect due to a chiral texture is provided by the pyrochlore compound $Nd_2Mo_2O_7$ (Taguchi *et al.*, 2001). The structure and magnetic ordering are displayed in Figure 8. The electronic transport takes place on Mo sites, which adopt a chiral 'umbrella' spin texture owing to the exchange coupling to the Nd moments. The hopping of an electron around any Mo triangle gives rise to a Berry phase related to the solid angle described by the magnetic moments, and hence to a chirality-induced anomalous Hall effect. This is corroborated by the fact that the application of a large magnetic field closes the 'umbrella' texture, thereby suppressing the solid angle and the anomalous Hall effect.

7 OUTLOOK AND CONCLUSIONS

Besides the applications that have been discussed in the preceding text, the concept of Berry phase has been of great importance to a number of topics in solid-state physics. In the theory of the fractional quantum Hall effect, the occurrence of excitations with fractional charges comes naturally out of a Berry phase argument and gives rise to the concept of *anyon* (Wilczek, 1990). In quantum Hall ferromagnets, the Berry phase gives rise to topological excitations, called *skyrmions*

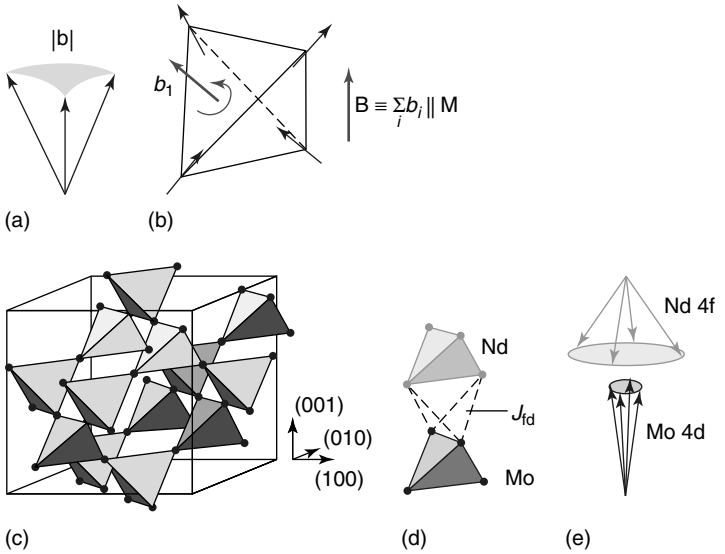

Figure 8. Schematic magnetic and crystal structures of pyrochlore. (a) Spin chirality, that is, the solid angle subtended by the three spins. (b) 'Two-in, two-out' spin structure, in which each spin points along the line that connects the center of the tetrahedron and the vertex. The total fictitious magnetic field is the vector sum of each fictitious magnetic flux that penetrates each plaquette. (c) The B sublattice of pyrochlore structure $A_2B_2O_7$. The A sublattice is structurally identical with this one, but is displaced by half a lattice constant. (d) Relative position of Nd tetrahedron (gray circles) and Mo tetrahedron (black circles) in $Nd_2Mo_2O_7$ pyrochlore. (e) The 'umbrella' structure observed for $Nd_2Mo_2O_7$ (A = Nd, B = Mo) by a neutron diffraction study. A magnetic unit cell contains four inequivalent Nd 4f moments $\mathbf{n}_i$ and four Mo 4d moments $\mathbf{m}_i$. In the umbrella structure, $(\mathbf{m}_i - \mathbf{m}) \perp \mathbf{m}$ and $(\mathbf{n}_i - \mathbf{n}) \perp \mathbf{n}$ for each $\mathbf{m}_i$ and $\mathbf{n}_i$, where $\mathbf{m}$ and $\mathbf{n}$ are the average moments of four $\mathbf{m}_i$ and four $\mathbf{n}_i$, respectively. (Reproduced from Y. Taguchi *et al*: Spin chirality, Berry phase, and anomalous Hall effect in a Frustrated Ferromagnet. *Science* **29**, (2001) 2573–76, with permission from AAAS.)

(Girvin, 1999) with novel properties. In one- and two-dimensional quantum spin systems, the physical properties depend, in a crucial manner, on whether the spin is integer or half-integer (Haldane, 1983, 1988), a phenomenon that is best understood in terms of Berry phase considerations (Loss, 1998). In molecular magnets, the Berry phase can induce destructive interferences of macroscopic tunneling between classically degenerate states, giving rise to the occurrence of *diabolical points* (Loss, DiVincenzo and Grinstein, 1992; von Delft and Henley, 1992; Garg, 1993; Wernsdorfer and Sessoli, 1999; Villain, 2003; Bruno, 2006).

The concept of the Berry phase appears as one of the most profound and insightful concepts in quantum mechanics. This article aimed at giving an introduction to this topic and illustrating its importance and versatility by means of a number of examples in the field of magnetism.

1 INTRODUCTION

Spin is an intrinsic property of elementary particles and participates in magnetic interactions. An electron is an elementary particle that carries a negative electric charge $-e$ and a spin $1/2$ corresponding to the magnetic moment of $e\hbar/(2mc) = 9.285 \times 10^{-24}$ $(\mathrm{J\,T^{-1}})$. We cannot separate a spin from a charge when we deal with electrons. When the electric current flows in a wire, both charge and spin are carried by electrons. In contrast to the electric charge, the spin of an electron has two directions, up or down. In nonmagnetic conductors such as Cu, Al, and Au, spin-dependent phenomena are not observed, since the same number of spin-up and spin-down electrons are present. However, in magnetic materials such as Fe, Co, and Ni, the number of electrons with spin up is different from that with spin down. Therefore, the transport properties of magnetic materials are spin dependent. We can vary the resistance by applying a magnetic field to change the direction of magnetization. This phenomenon is called *magnetoresistance* (MR) and is applied to magnetoresistive devices such as hard-disk drives.

Electron tunneling is a basic phenomenon in quantum mechanics by which electric current can pass from one electrode through a thin insulating barrier layer into a second electrode. The recent nanofabrication technology enables us to control single-electron tunneling through a small island called a *quantum dot*. Electron tunneling is one of the key concepts in nanotechnologies and has many technological applications: the Schottky diode is a basic element of semiconductor heterostructures, the superconducting quantum interference device (SQUID) is a high-sensitivity magnetic sensor, and the scanning tunneling microscope (STM) is an atomic-resolution microscope in which an electron tunnels through a vacuum instead of an insulating barrier. However, all these devices utilize charge degrees of freedom – rather than spin degrees of freedom – of electrons.

Recently, spin-dependent tunneling in magnetic tunnel junctions has attracted enormous attention because of its potential applications in high-density magnetic recording devices and nonvolatile magnetic random access memory (MRAM). Spin-dependent tunneling is also important from a scientific point of view, since it provides much information about the physical properties of magnetic materials. In fact, the concept of spin-dependent tunneling has a long history in physics. In the early 1970s, Meservey and Tedrow (1994) developed a spin-polarized electron tunneling technique that used special properties of the superconducting states to probe spin-dependent features of the electron density of states

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

of ferromagnets (FMs). Applying this technique to various FMs in FM/Al_2O_3/Al tunnel junctions, they showed that the tunneling electrons from FMs are spin polarized, and obtained detailed information about the spin polarization of the conduction electrons near the Fermi level.

The first experiment on spin-dependent tunneling in magnetic tunnel junctions was reported by Julliere (1975). He measured the tunnel conductance of Fe/Ge/Co junctions and showed that it was dependent on the relative orientation of the magnetizations of electrodes. This effect is now called the *tunnel magnetoresistance* (TMR) effect. Subsequently, Maekawa and Gäfvart Maekawa and Gäfvert (1982) demonstrated a strong correlation between the tunnel conductance and magnetization process in Ni/NiO/FM junctions with Ni, Fe, or Co as the counterelectrode. However, these pioneering works on TMR did not attract much attention until the mid-1990s, since the measured TMR values remained very small at room temperature.

In 1995, the first breakthrough for large TMR was brought about by Miyazaki and Tezuka (1995) and Moodera, Kinder, Wong and Meservey (1995), who developed superior fabrication methods for magnetic tunnel junctions with an amorphous Al_2O_3barrier. In the last decade, much effort has been devoted to improving the TMR ratio of magnetic tunnel junctions with an amorphous Al_2O_3barrier. Currently, the record for the largest TMR ratio of the magnetic tunnel junctions with amorphous $Al_2O_3$is 70.4 % at room temperature (Wang *et al*., 2004). The second breakthrough was the discovery of a high TMR in epitaxial magnetic tunnel junctions with MgO barrier (Bowen *et al*., 2001). In 2001, Bowen *et al*. fabricated Fe(001)/MgO(20 Å)/FeCo(001) single-crystal epitaxial junctions and observed a 27% TMR at 300 K, which increased to 60% at 30 K. Although the observed TMR was much smaller than the values predicted by Butler, Zhang, Schulthess and MacLaren (2001) and Mathon and Umerski (2001), it was larger than that obtained on the (001)-oriented Fe/amorphous Al_2O_3/FeCo junction by Yuasa *et al*. (2000). The predicted values of TMR for Fe(100)/Mg(100)/Fe(100) were in excess of 1000% (Butler, Zhang, Schulthess and MacLaren, 2001; Mathon and Umerski, 2001). Owing to the rapid progress in fabrication techniques, the TMR of the epitaxial magnetic tunnel junction has increased rapidly, as shown in Figure 1. The record for the largest TMR ratio of a magnetic tunnel junction with an MgO barrier is 410% at room temperature (Yuasa, 2006).

In the early studies on spin-dependent tunneling, the theoretical interpretation was based on a simple model in which the spin is conserved in the tunneling process and the conductance of each spin direction is proportional to the densities of states of that spin in each electrode. In this model, the tunnel current is larger when the magnetizations of the two electrodes are parallel than when they are antiparallel, which explains the strong dependence of the tunneling current on the relative orientation of the magnetizations of the ferromagnetic electrodes. However, the model does not explain the experimental results that the TMR exhibits rather large bias and temperature dependencies.

Another approach based on the single-electron Schrödinger equation was proposed by Slonczewski (1989). By extending the free-electron model of tunneling in nonmagnetic tunnel junctions (Burstein and Lundqvist, 1969) to magnetic tunnel junctions, Slonczewski found that the polarization of tunneling electrons depends not only on the electronic density of states of FMs but also on the potential height of the tunnel barriers (Slonczewski, 1989). In this approach, the electrodes and the insulating barrier are treated as a single quantum-mechanical system and the wave functions of up and down electrons are constructed by solving the Schrödinger equation in the whole system. While the free-electron model captures some essential features, their predictions for TMR are quantitatively unreliable because the lattice structure of the electrodes and the variation of the band structure near the insulating barrier are overlooked (Zhang and Levy, 1999).

The tight-binding model gives more realistic descriptions for TMR (Zhang and Levy, 1999; Moodera and Mathon, 1999; Asano, Oguri and Maekawa, 1993; Mathon, 1997; Tsymbal and Pettifor, 1998; Mathon and Umerski, 1999; Itoh *et al*., 1999; Itoh, Ohsawa and Inoue, 2000). This approach allows one to distinguish electronic structures at interfaces from that in the bulk and to study the effect of the interface roughness, although it contains some empirical parameters. One can easily see that the single-band tight-binding model reduces to the free-electron model. It is also shown that the conductance of the tight-binding method reduces to the usual expression for the conductance obtained in the classical theory of tunneling when the electron hopping between the electrodes is weak and the coherence across the barrier is completely lost.

A nonempirical description of spin-dependent tunneling of epitaxial magnetic tunnel junctions is provided by the first-principles methods based on density-functional theory within the local spin-density approximation (LSDA) for the electronic structure and the Landauer–Büttiker formula for the conductance (MacLaren *et al*., 1990; MacLaren, Zhang, Butler and Wang, 1999; Butler, Zhang, Schulthess and MacLaren, 2001). Butler, Zhang, Schulthess and MacLaren (2001) studied the spin-dependent tunneling in epitaxial Fe/MgO/Fe magnetic tunnel junctions by using the layer Korringa–Kohn–Rostoker (LKKR) method based on the first-principles method, and predicted a TMR ratio as high as 6000%. They showed that the high TMR ratio in epitaxial magnetic tunnel junctions with an MgO barrier is due to the symmetry of the evanescent wave in the barrier. The symmetry of the current carrying state in the barrier is Δ_1 and

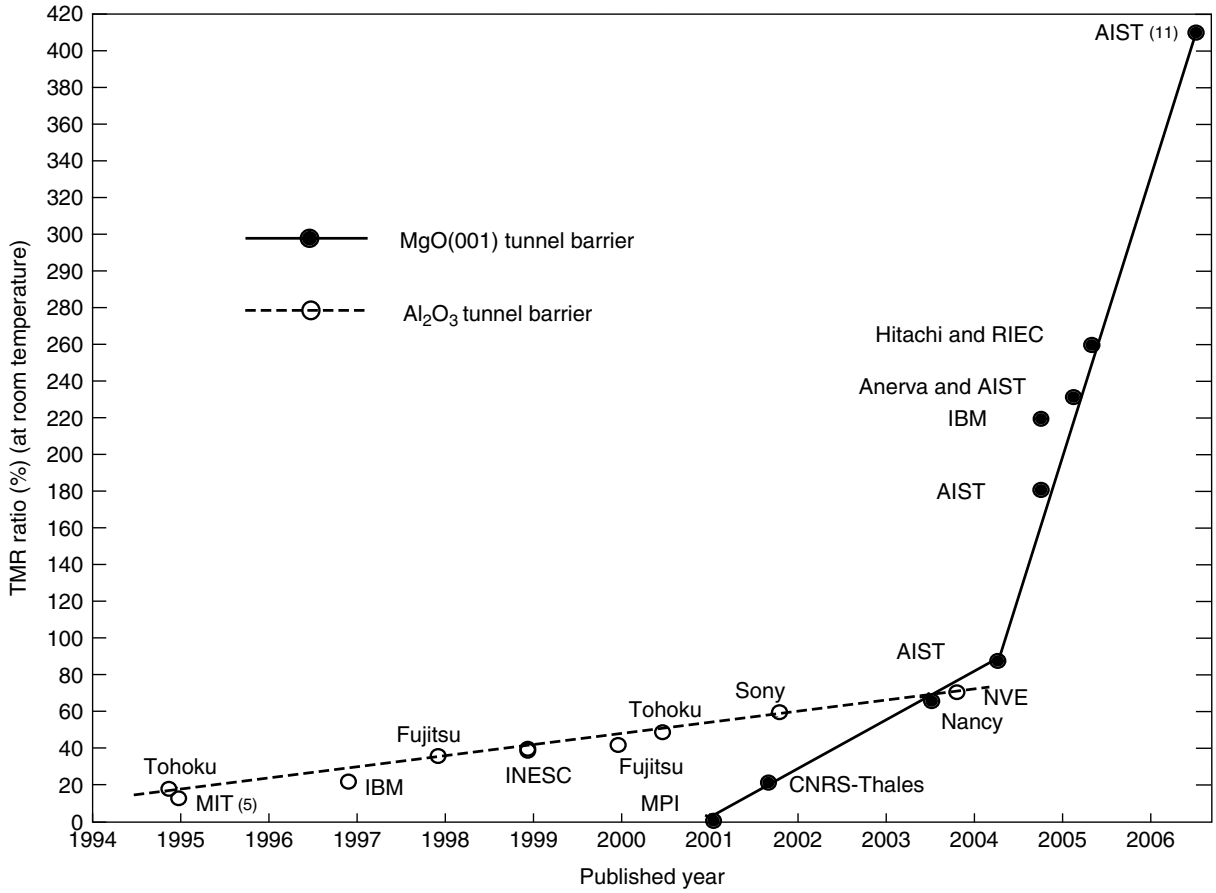

Figure 1. Evolution of the magnetoresistance of magnetic tunnel junctions with Al_2O_3(open circles) and MgO (filled circles) tunnel barriers at room temperature.

the spin polarization of the Δ_1 band in the Fe electrodes is 100%, that is, half-metallic. Mathon and Umerski (2001) arrived at qualitatively identical conclusions independently by using the multiband tight-binding model.

In this chapter, we provide a review of the theories of spin-dependent tunneling in magnetic tunnel junctions. The chapter is organized as follows. The tunneling Hamiltonian model is described in Section 2. We explain the basic ideas for dealing with the electron tunneling and derive the expression of the tunneling current and TMR. We also show some recent advances in the theory of spin-dependent tunneling in a Coulomb blockade regime. In Section 3, we provide a brief review of the free-electron model and show that the TMR is not a monotonic function of the barrier height. In Section 4, we review the theory of spin-dependent tunneling based on the tight-binding model and its application to various magnetic tunnel junctions. The first-principles model and its applications to the epitaxial magnetic tunnel junctions with MgO barriers are described in Section 5.

2 TUNNEL HAMILTONIAN MODEL

Let us consider a tunnel junction where two metallic electrodes are separated by a thin insulating barrier as shown in Figure 2. In the classical mechanics picture, the electrodes cannot exchange electrons through the barrier because the potential of the barrier is higher than the Fermi energy of the electrodes. However, quantum mechanics tells us that there is a nonzero probability of charge transfer by quantum-mechanical tunneling of electrons. The basic idea of the tunnel Hamiltonian model is to write the Hamiltonian of the system as

$$\mathcal{H} = \mathcal{H}_{\mathrm{L}} + \mathcal{H}_{\mathrm{R}} + \mathcal{H}_{\mathrm{T}} \tag{1}$$

where $\mathcal{H}_{\mathrm{L}}$ and $\mathcal{H}_{\mathrm{R}}$ are the Hamiltonians of the left and right electrodes, respectively, and the tunneling process is described by the tunnel Hamiltonian $\mathcal{H}_{\mathrm{T}}$. The tunneling probability decreases exponentially with the thickness of the barrier and is dependent on the characteristics of the

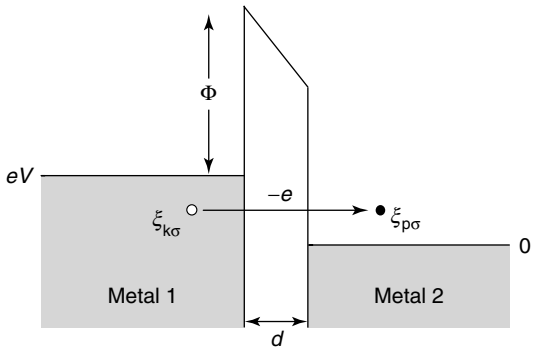

Figure 2. Electron tunneling between two normal metals. The arrow indicates the electron with spin σ transferred through the oxide barrier.

insulating material, but these aspects are absorbed in the phenomenological tunneling matrix elements $\hat{T}^{\sigma}_{\boldsymbol{pk}}$. Thus we write the effective tunnel Hamiltonian in the form

$$\mathcal{H}_{\mathrm{T}} = \sum_{\boldsymbol{kp}\sigma} \hat{T}^{\sigma}_{\boldsymbol{pk}} a^{\dagger}_{\boldsymbol{p}\sigma} a_{\boldsymbol{k}\sigma} + \mathrm{h.c} \tag{2}$$

where $a_{\boldsymbol{k}\sigma}$ is the annihilation operator of an electron with wave vector $\boldsymbol{k}$ and spin σ on the left electrode, $a^{\dagger}_{\boldsymbol{p}\sigma}$ is the creation operator of an electron with wave vector $\boldsymbol{p}$ and spin σ on the right electrode, and no spin flip is assumed in the tunneling process.

When the bias voltage V is applied to the tunnel junction, the tunneling rate $\vec{\Gamma}_{\sigma}(V)$ at which electrons with spin σ are transferred from the left to the right electrodes is calculated by Fermi's golden rule as

$$\vec{\Gamma}_{\sigma}(V) = \frac{2\pi}{\hbar} \sum_{\boldsymbol{k},\boldsymbol{p},\sigma} |\hat{T}^{\sigma}_{\boldsymbol{pk}}|^2 f(\xi_{\boldsymbol{k}\sigma}) \left[1 - f(\xi_{\boldsymbol{p}\sigma})\right] \times \delta(\xi_{\boldsymbol{k}\sigma} - \xi_{\boldsymbol{p}\sigma} + eV) \tag{3}$$

where $\xi_{\boldsymbol{k}}$ and $\xi_{\boldsymbol{p}}$ are one-electron energies measured from the Fermi levels and $f(\xi_{\boldsymbol{k}\sigma}) = \langle a^{\dagger}_{\boldsymbol{k}\sigma} a_{\boldsymbol{k}\sigma} \rangle = 1/[\exp(\xi_{\boldsymbol{k}\sigma}/k_{\mathrm{B}}T) + 1]$ is the Fermi distribution function.

The steady-state current through the junction is determined by the difference between the forward and backward tunneling rates:

$$I_{\sigma}(V) = e\left[\vec{\Gamma}_{\sigma}(V) - \overleftarrow{\Gamma}_{\sigma}(V)\right] \tag{4}$$

where $\overleftarrow{\Gamma}_{\sigma}(V)$ is the tunneling rate at which electrons with spin σ are transferred from the right to the left electrodes and is related to $\vec{\Gamma}_{\sigma}(V)$ by $\overleftarrow{\Gamma}_{\sigma}(V) = \vec{\Gamma}_{\sigma}(-V)$. Substituting equation (3) into equation (4), the tunnel current I_{σ} for the spin channel σ becomes

$$I_{\sigma}(V) = \frac{2\pi e}{\hbar} \langle |\hat{T}^{\sigma}_{\boldsymbol{pk}}|^2 \rangle \int_{-\infty}^{\infty} \mathcal{D}_{1\sigma}(\xi - eV)\mathcal{D}_{2\sigma}(\xi) \times \left[f(\xi - eV) - f(\xi)\right] \mathrm{d}\xi \tag{5}$$

where $\mathcal{D}_{1\sigma}(\xi)$ and $\mathcal{D}_{2\sigma}(\xi)$ are the *tunneling* densities of states with spin σ in the left and right electrodes, respectively, and $\langle |\hat{T}^{\sigma}_{\boldsymbol{pk}}|^2 \rangle$ is the averaged tunneling probability and taken to be a constant proportional to $\exp(-2\kappa d)$, where $\kappa = \sqrt{2m\Phi}/\hbar$ is the decay constant of the evanescent wave in the barrier and Φ is the barrier height. The total current I is given by the sum of the currents in the up- and down-spin channels: $I = I_{\uparrow} + I_{\downarrow}$.

Electron tunneling from ferromagnetic transition metals and alloys into a superconducting Al electrode through an insulating Al_2O_3barrier is one of the most powerful tools for studying the spin-polarized electronic states of FMs. In the early 1970s, Meservey and Tedrow (1994) found that, in a thin film of superconducting Al, the BCS density of states splits into up and down states by application of a magnetic field. This splitting originates from the Zeeman splitting in the quasiparticle dispersion in a magnetic field H:

$$E_{\boldsymbol{k}\sigma} = \left(\xi^2_{\boldsymbol{k}} + \Delta^2\right)^{1/2} - \sigma\mu_{\mathrm{B}}H \tag{6}$$

where Δ is the superconducting energy gap. In the absence of spin-flip scattering, the spin-dependent densities of states of quasiparticles in superconductor (SC) is given by

$$\begin{aligned} \mathcal{D}_{i\uparrow}(E) &= \mathcal{D}_{\mathrm{BCS}}(E - \mu_{\mathrm{B}}H), \\ \mathcal{D}_{i\downarrow}(E) &= \mathcal{D}_{\mathrm{BCS}}(E + \mu_{\mathrm{B}}H) \end{aligned} \tag{7}$$

where i represents the index of electrodes and $\mathcal{D}_{\mathrm{BCS}}(E)$ is the BCS density of states defined as

$$\frac{\mathcal{D}_{\mathrm{BCS}}(E)}{\mathcal{D}_{\mathrm{N}}} = \mathrm{Re}\left[\frac{|E|}{\sqrt{E^2 - \Delta^2}}\right] \tag{8}$$

where $\mathcal{D}_{\mathrm{N}}$ is the density of the state of SC in the normal state. Figure 3(a) illustrates the splitting of the BCS density of states in a magnetic field H.

The Zeeman splitting in the density of states of SC enables one to extract the spin polarization of various FMs using ferromagnet/insulator/superconductor (FM/I/SC) junctions. In magnetic fields, the densities of states of the up- and down-spin bands in FM correspond to those of the majority and minority spin bands, $\mathcal{D}_{1\uparrow} = \mathcal{D}_{\mathrm{M}}$ and $\mathcal{D}_{1\downarrow} = \mathcal{D}_{\mathrm{m}}$, respectively, while those in the SC electrode $\mathcal{D}_{2\sigma}$ are given by equation (7). Then, from equation (5), the conductance

$G = \mathrm{d}I/\mathrm{d}V$ of the junction is given by the sum of the conductance for the two independent spin directions:

$$G(V)/G_{\mathrm{N}} = \left(\frac{1+P}{2}\right)\int_{-\infty}^{\infty}\frac{\mathcal{D}_{\mathrm{BCS}}(E-\mu_{\mathrm{B}}H)/\mathcal{D}_{\mathrm{N}}}{\cosh^2\left[(E-eV)/2k_{\mathrm{B}}T\right]}\frac{\mathrm{d}E}{4k_{\mathrm{B}}T} + \left(\frac{1-P}{2}\right)\int_{-\infty}^{\infty}\frac{\mathcal{D}_{\mathrm{BCS}}(E+\mu_{\mathrm{B}}H)/\mathcal{D}_{\mathrm{N}}}{\cosh^2\left[(E-eV)/2k_{\mathrm{B}}T\right]} \times \frac{\mathrm{d}E}{4k_{\mathrm{B}}T} \tag{9}$$

where $G_{\mathrm{N}} = G_{\mathrm{N}}^{\uparrow} + G_{\mathrm{N}}^{\downarrow}$ ($G_{\mathrm{N}}^{\sigma} = (2\pi e^2/\hbar)\langle|\hat{T}_{\boldsymbol{pk}}^{\sigma}|^2\rangle\mathcal{D}_{\sigma}\mathcal{D}_{\mathrm{N}}$) is the conductance when SC is in the normal state and P is the tunneling spin polarization defined by the relative conductance between the spin-up and spin-down channels:

$$P = \frac{G_{\mathrm{N}}^{\uparrow} - G_{\mathrm{N}}^{\downarrow}}{G_{\mathrm{N}}^{\uparrow} + G_{\mathrm{N}}^{\downarrow}} = \frac{\mathcal{D}_{\mathrm{M}} - \mathcal{D}_{\mathrm{m}}}{\mathcal{D}_{\mathrm{M}} + \mathcal{D}_{\mathrm{m}}} \tag{10}$$

If $\langle|\hat{T}_{\boldsymbol{pk}}^{\sigma}|^2\rangle$ is spin independent, then P is expressed in terms of the densities of states of FM as in the third term of equation (10). In Figure 3(b), the conductance G_{σ} for each spin direction (dashed or dotted) and the total conductance $G = G_{\uparrow} + G_{\downarrow}$ (solid curve) are shown for $P = 0.5$ and $T/T_{\mathrm{c}} = 0.15$. The most striking feature of G is its asymmetry around $V = 0$. The degree of the asymmetry is directly related to the value of P through the weighted factors $\frac{1}{2}(1+P)$ and $\frac{1}{2}(1-P)$ in equation (9).

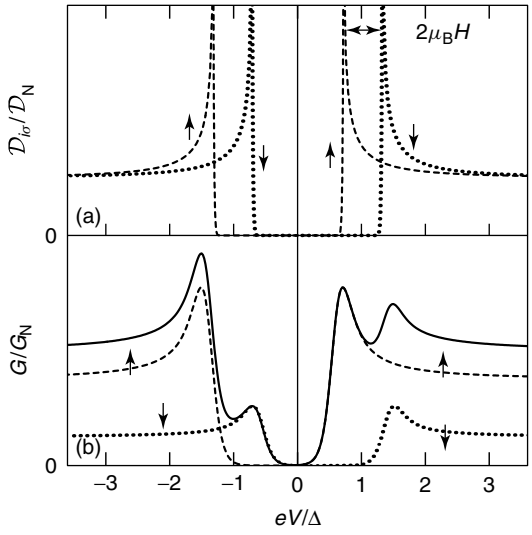

Figure 3. (a) Zeeman splitting of the BCS density of states into spin-up (dashed) and spin-down (dotted) densities of states in a magnetic field H, showing a splitting of $2\mu_{\mathrm{B}}H$. (b) Spin-up conductance (dashed), spin-down conductance (dotted), and total conductance (solid curve).

In the experiments of Tedrow and Meservey, electron tunneling between Al and ferromagnetic metals and alloys in high magnetic fields are used to measure the tunnel conductance. An analysis of the measured conductance based on equation (9) yields the spin polarization P for various FMs. In Table 1, the spin polarization P is listed for various ferromagnetic materials (Moodera and Mathon, 1999; Monsma and Parkin, 2000; Worledge and Geballe, 2000) recently measured by using improved junction preparation conditions, including samples grown by molecular-beam epitaxy (MBE).

As seen in Table 1, the values of the tunneling spin polarization P are positive, that is, $P > 0$, for all of the 3d ferromagnetic metals; the majority spin electrons are predominant in the tunnel current in all cases. From the tunneling experiments, it has been established that the tunnel currents from FM into other metals through the Al_2O_3barrier are dominated by majority spins for Ni, Co, Fe, and their alloys, and the tunneling spin polarization is correlated with the magnetic moment of the electrode. However, the positive sign of P is surprising, especially for metals such as Co and Ni, in which a negative polarization is expected owing to the smaller density of states of the majority spin band at the Fermi level, since the majority d band is below the Fermi level.

Various theoretical explanations have been proposed to explain the positive value of the spin polarization. Stearns (1977) explained this tendency by observing that the ferromagnetic transition metal has a large fraction of d electrons of free-electron-like character at the Fermi surface. Hertz and Aoi argued that the s electrons are responsible for the tunneling and the tunnel currents are proportional to the density of s states at the Fermi level, despite the much higher density of d states in 3d ferromagnetic metals (Hertz and Aoi, 1973). Recent first-principle band calculations support the idea that tunneling is dominated by electrons of s or p character; for Al_2O_3barriers and Co electrodes, the positive spin polarization might be explained by the strong bonding between the d orbitals of Co and the sp orbitals of Al (or the p orbitals of O) at the interface, which results in an almost unoccupied

Table 1. Spin polarization P for various ferromagnetic metals and alloys.

minority sp density of states on Al (or the minority p density of states on O) (Nyugen-Mahn *et al*., 1998; Tsymbal and Pettifor, 2000).

Now we consider the spin-dependent tunneling of magnetic tunnel junctions and derive the TMR ratio. In the low bias regime, where the bias voltage V is much smaller than the bandwidth (of order of eV) and the density of states is nearly constant, the conductance $G_\sigma = \mathrm{d}I_\sigma/\mathrm{d}V$ for each spin channel is given from equation (5) as

$$G_\sigma(V) \approx \frac{2\pi e^2}{\hbar}\langle|\hat{T}^\sigma_{\boldsymbol{pk}}|^2\rangle \mathcal{D}_{1\sigma}\mathcal{D}_{2\sigma} \tag{11}$$

where $\mathcal{D}_{1\sigma}$ and $\mathcal{D}_{2\sigma}$ are the densities of states of the spin σ band at the Fermi levels in the ferromagnetic electrodes.

Assuming that the magnetic moments of the electrodes FM1 and FM2 are aligned to be ferromagnetic (F) in applied magnetic fields, and aligned to be antiferromagnetic (A) in zero magnetic field, the total conductance $G = G_\uparrow + G_\downarrow$ in the F alignment is given by

$$G_\mathrm{F} = G^\uparrow_\mathrm{F} + G^\downarrow_\mathrm{F} \propto \mathcal{D}_{\mathrm{M}1}\mathcal{D}_{\mathrm{M}2} + \mathcal{D}_{\mathrm{m}1}\mathcal{D}_{\mathrm{m}2} \tag{12}$$

and in the A alignment it is given by

$$G_\mathrm{A} = G^\uparrow_\mathrm{A} + G^\downarrow_\mathrm{A} \propto \mathcal{D}_{\mathrm{M}1}\mathcal{D}_{\mathrm{m}2} + \mathcal{D}_{\mathrm{m}1}\mathcal{D}_{\mathrm{M}2} \tag{13}$$

where $\mathcal{D}_{\mathrm{M}i}$ and $\mathcal{D}_{\mathrm{m}i}$ are the densities of states for the majority and minority spin bands in the ith electrode, respectively (see Figure 4a and b). The TMR ratio is defined as

$$\begin{aligned} TMR &= \frac{\Delta R}{R_\mathrm{F}} = \frac{R_\mathrm{A} - R_\mathrm{F}}{R_\mathrm{F}} = \frac{G_\mathrm{F} - G_\mathrm{A}}{G_\mathrm{A}} \\ &= \frac{2P_1P_2}{1 - P_1P_2} \end{aligned} \tag{14}$$

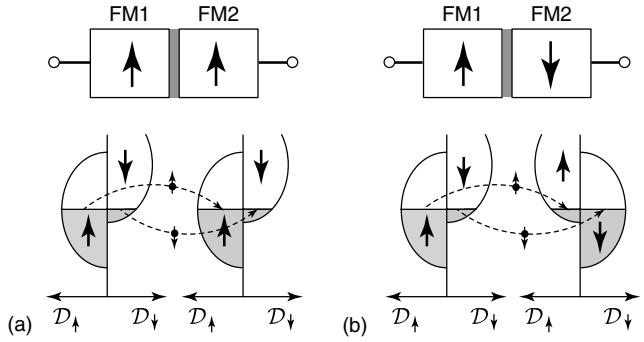

Figure 4. Ferromagnet/insulator/ferromagnet (FM1/I/FM2) tunnel junction and corresponding densities of states of FM1 and FM2 in the ferromagnetic (a) and antiferromagnetic (b) alignments of magnetizations.

where P_i is the spin polarization of the ith electrode defined by

$$P_i = \frac{\mathcal{D}_{\mathrm{M}i} - \mathcal{D}_{\mathrm{m}i}}{\mathcal{D}_{\mathrm{M}i} + \mathcal{D}_{\mathrm{m}i}} \tag{15}$$

Note that another definition, $TMR = \Delta R/R_\mathrm{A} = 2P_1P_2/(1 + P_1P_2)$, is also used in the literature.

One of the advantages of the tunnel Hamiltonian model is that the charging effect, that is, the Coulomb interaction, can be treated easily within this model. The charging energy plays an important role when we consider the charge transport through a very small island. If an electron tunnels into or out of a small island, the electrostatic charging energy changes by $e^2/2C$, where e is the electronic charge and C is the capacitance of the island. The capacitance is proportional to the size of the island and the charging energy $e^2/2C$ can take a high value for a very small island. Therefore, unless the charging energy is overcome by bias potential (eV) or thermal energy ($k_\mathrm{B}T$), an electron is not able to propagate between the electrodes. This is called the *Coulomb blockade* (CB). Since the CB is caused by the charge degrees of freedom of electrons, little attention has been paid to the spin degrees of freedom. However, in the late 1990s, improvements in nanofabrication technology enabled us to fabricate magnetic tunnel junctions in which CB phenomena were observed.

Ono *et al*. have measured the TMR in the Ni/NiO/Co/NiO/Co double junctions and observed Coulomb oscillations in the R_α versus V_g curves (Ono, Shimada and Ootuka, 1997). They found that off resonance the TMR ratio, $\Delta R/R_\mathrm{F} = (R_\mathrm{A} - R_\mathrm{F})/R_\mathrm{F}$, is enhanced to 40%, which is larger than the value of 17.5% expected from $P_\mathrm{Co} = 0.35$ and $P_\mathrm{Ni} = 0.23$ in the absence of the CB effect. The cotunneling theory (Takahashi and Maekawa, 1998) explains this enhancement, since $\Delta R/R_\mathrm{F} = 4P_\mathrm{Co}P_\mathrm{Ni}/(1 - P_\mathrm{Co}P_\mathrm{Ni})^2 = 0.38$, that is, the TMR is 38%. However, they found a TMR of $\sim$4% at resonance, which is considerably smaller than the expected TMR of 17.5%. A reduction in TMR at resonance may occur in the case of a strong tunneling of $R^\alpha_\mathrm{T} < R_\mathrm{K}$, where $R_\mathrm{K} \equiv (h/e^2) \simeq 25.8\,\Omega$ is the quantum resistance.

Recent experiments and theories for the single electron transistor (SET) have shown that the conductance in the strong tunneling case significantly deviates from that in the weak tunneling case $R^\alpha_\mathrm{T} \gg R_\mathrm{K}$. According to the theory of König and Schön (1997), on resonance the bare values of the parameters, E_c and R^s_T, are renormalized so that the conductance becomes logarithmic temperature-dependent, yielding a TMR at low temperatures

$$\left(\frac{\Delta R}{R_\mathrm{F}}\right)_\mathrm{on} = \frac{2P^2}{(1 - P^2)}\left\{1 - \frac{R_\mathrm{K}}{2\pi^2 R^{(\mathrm{F})}_\mathrm{T}}\left[\gamma_\mathrm{E} + \ln\left(\frac{E_\mathrm{c}}{\pi T}\right)\right]\right\} \tag{16}$$

where γ_E is Euler's constant. Therefore, the value of TMR at low temperatures ($k_B T \ll E_c$) is considerably reduced from that at high temperatures. If this is the case for the Ni/NiO/Co/NiO/Co double junctions, we can explain the small value of TMR mentioned above. In contrast, the TMR off resonance remains unaltered (Schoeller and Schön, 1994).

3 FREE-ELECTRON MODEL

In the tunnel Hamiltonian model in the preceding section, we assumed that the tunneling matrix elements and the spin-up and spin-down electrons can be treated as constants. In other words, the wave function in the barrier region is assumed to be independent of the wave vector and spin. However, it is not obvious that the above assumptions are justified. In 1989, Slonczewski proposed another approach for the spin-dependent tunneling based on the free-electron model, where the exact wave function in the barrier region is used (Slonczewski, 1989). He showed that TMR is determined not only by the spin polarization of FM electrodes, P, but also by the potential height of the insulating barrier. Introducing the effective spin polarization of the ferromagnetic electrode, P_{eff}, which ranges from $-P$ to P depending on the potential height of the barrier, the TMR is expressed using the same formula as that derived from the tunnel Hamiltonian model.

Before studying the spin-dependent tunneling in ferromagnetic tunnel junctions, it is convenient to consider the nonmagnetic tunnel junctions and derive an approximate form of the tunnel conductance in weak transmitting limit (Burstein and Lundqvist, 1969). When the bias voltage V is applied, electrons incident from the left electrode tunnel through the insulating barrier, resulting in a tunnel current, as shown in Figure 5(a) and (b). We assume that the system has translational symmetry in the transverse (x and y) direction and therefore the wave vector parallel to the barrier surface $\boldsymbol{k}_\parallel = (k_x, k_y)$ is conserved during the tunneling. We also assume that the temperature is zero. The number of electrons incident from the left electrode per unit time with wave vector $\boldsymbol{k}_\parallel$ is given by

$$N(\boldsymbol{k}_\parallel) = 2 \times \frac{1}{2} \int_0^{eV} \mathrm{d}E\, v_z(E, \boldsymbol{k}_\parallel) \frac{1}{\pi \hbar v_z(E, \boldsymbol{k}_\parallel)} = 2\frac{eV}{h} \tag{17}$$

where $v_z(\boldsymbol{k}_\parallel)$ is the velocity along the z direction and $1/\pi\hbar v_z(\boldsymbol{k}_\parallel)$ is the corresponding 1D density of states for the one spin channel. The factor 2 in equation (17) is due to the spin-degeneracy of the energy bands in the nonmagnetic electrode. Note that the number of incident electrons is independent of the wave vector $\boldsymbol{k}_\parallel$. The tunnel current density

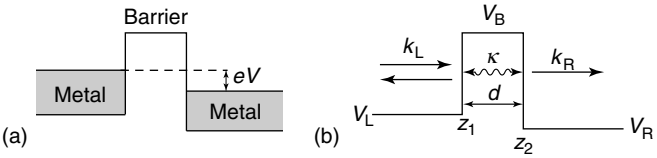

Figure 5. (a) Potential energy diagram for a metal/insulator/metal tunnel junction with the bias voltage V. The shaded area represents the occupied states of electrons at zero temperature. Electrons are transmitted from the occupied states in the left electrode to the unoccupied states in the right electrode. (b) The geometry of one-electron potential for the Hamiltonian given by equation (20). The left and right boundaries of the insulating barrier are indicated by z_1 and z_2, respectively.

is obtained by summing up the number of electrons tunneling through the barrier:

$$I = e \int \frac{\mathrm{d}k_\parallel^2}{(2\pi)^2} N(\boldsymbol{k}_\parallel) T(\boldsymbol{k}_\parallel) = 2\frac{e^2 V}{h} \int \frac{\mathrm{d}k_\parallel^2}{(2\pi)^2} T(\boldsymbol{k}_\parallel) \tag{18}$$

where $T(\boldsymbol{k}_\parallel)$ is the transmission probability defined as the ratio between the probability current densities of incident and transmitting waves. Here we assume the bias voltage V is so small that we can neglect the energy dependence of the transmission probability. The differential conductance per unit area is written in terms of the transmission probability as

$$G \equiv \frac{\mathrm{d}I}{\mathrm{d}V} = 2\frac{e^2}{h} \int \frac{\mathrm{d}k_{\parallel^2}}{(2\pi)^2} T(\boldsymbol{k}_\parallel) \tag{19}$$

The transmission probability $T(\boldsymbol{k}_\parallel)$ is obtained by solving the 1D Schrödinger equation:

$$-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial z^2}\psi(z) = \left(E - V(z) - \frac{\hbar^2}{2m}\boldsymbol{k}_\parallel^2\right)\psi(z) \tag{20}$$

in the geometry shown in Figure 5(b). The general solutions of equation (20) in the left (L) electrode, barrier (B), and right (R) electrode are, respectively, of the forms

$$\begin{aligned} \psi_L(z) &= a_L e^{ik_L z} + b_L e^{-ik_L z}, && \text{for } z \le z_1 \\ \psi_B(z) &= a_B e^{\kappa z} + b_B e^{-\kappa z}, && \text{for } z_1 < z \le z_2 \\ \psi_R(z) &= a_R e^{ik_R z} + b_R e^{-ik_R z}, && \text{for } z > z_2 \end{aligned} \tag{21}$$

where the z components of the wave numbers are defined as

$$\begin{aligned} k_L &= \sqrt{(2m/\hbar^2)(E - V_L) - \boldsymbol{k}_\parallel^2} \\ \kappa &= \sqrt{k_\parallel^2 - (2m/\hbar^2)(E - V_B)} \\ k_R &= \sqrt{(2m/\hbar^2)(E - V_R) - \boldsymbol{k}_\parallel^2} \end{aligned} \tag{22}$$

The scattering wave in the whole system is given by the combination of eigen functions in equation (21). The

coefficients a_L, b_L, a_B, b_B, a_R, and b_R are determined by matching the slope and value of the wave function across the interface (Burstein and Lundqvist, 1969). The matching conditions at $z = z_1$ are conveniently described as a 2×2 matrix R_1 operating on the 2D vectors as

$$\begin{pmatrix} a_L \\ b_L \end{pmatrix} = R_1 \begin{pmatrix} a_B \\ b_B \end{pmatrix} \tag{23}$$

where

$$R_1 = \frac{1}{2k_L} \times \begin{pmatrix} (k_L - i\kappa)e^{(-ik_L+\kappa)z_1} & (k_L + i\kappa)e^{(-ik_L-\kappa)z_1} \\ (k_L + i\kappa)e^{(ik_L+\kappa)z_1} & (k_L - i\kappa)e^{(ik_L-\kappa)z_1} \end{pmatrix} \tag{24}$$

In the same manner, the matching conditions at $z = z_2$ are written as

$$\begin{pmatrix} a_B \\ b_B \end{pmatrix} = R_2 \begin{pmatrix} a_R \\ b_R \end{pmatrix} \tag{25}$$

where

$$R_2 = \frac{i}{2\kappa} \times \begin{pmatrix} (k_R - i\kappa)e^{(ik_R-\kappa)z_2} & -(k_R + i\kappa)e^{-(ik_R+\kappa)z_2} \\ -(k_R + i\kappa)e^{(ik_R+\kappa)z_2} & (k_R - i\kappa)e^{-(ik_R-\kappa)z_2} \end{pmatrix} \tag{26}$$

Since the quantity that we wish to compute is the transmission probability for the electron incident from the left electrode, only a transmitted wave exists in the right electrode and $b_R = 0$. The relation between the coefficients a_L, b_L, and a_R is

$$\begin{pmatrix} a_L \\ b_L \end{pmatrix} = R_1 R_2 \begin{pmatrix} a_R \\ 0 \end{pmatrix} \tag{27}$$

Thus, the transmission probability is

$$T(\boldsymbol{k}_\parallel) = \frac{|a_R|^2 k_R}{|a_L|^2 k_L} = \frac{k_R}{k_L} \frac{1}{|(R_1 R_2)_{11}|^2} \simeq \frac{16 k_L \kappa^2 k_R}{(k_L^2 + \kappa^2)(k_R^2 + \kappa^2)} e^{-2\kappa d} \tag{28}$$

where $d = z_2 - z_1$ is the thickness of the barrier. In the last equality of equation (28), we use the condition $e^{-2\kappa d} \ll 1$ because we are interested in the weak transmitting limit $T(\boldsymbol{k}_\parallel) \ll 1$. Substituting equation (28) into equation (19), the conductance is written as

$$G = 2\frac{e^2}{h} \int \frac{dk_\parallel^2}{(2\pi)^2} \frac{16 k_L \kappa^2 k_R}{(k_L^2 + \kappa^2)(k_R^2 + \kappa^2)} e^{-2\kappa d} \tag{29}$$

We introduce the symbols k_{L0}, k_{R0} and κ_0 to represent the wave numbers with $\boldsymbol{k}_\parallel = 0$. In equation (29), the value of $\boldsymbol{k}_\parallel$ is limited to the range of $0 \le \boldsymbol{k}_\parallel < \min[k_{L0}, k_{R0}]$. For the high barrier, $\kappa_0 \gg \boldsymbol{k}_\parallel$, and the wave number κ can be expressed as

$$\kappa = \kappa_0 \left[1 + \frac{1}{2} \left(\frac{\boldsymbol{k}_\parallel}{\kappa_0} \right)^2 \right] = \kappa_0 + \frac{\boldsymbol{k}_\parallel^2}{2\kappa_0} \tag{30}$$

Since we consider an elliptical energy band, it is often convenient to use

$$\int \frac{d^2 \boldsymbol{k}_\parallel}{(2\pi)^2} = \int \rho_\parallel(E_\parallel)\, dE_\parallel \tag{31}$$

where $E_\parallel = (\hbar^2/2m)\boldsymbol{k}_\parallel^2$ and the 2D density of states $\rho_\parallel(E_\parallel) = (m/2\pi\hbar^2)$. Therefore, the conductance can be written as

$$G = 2\frac{e^2}{h} \rho_\parallel \int_0^{\frac{\hbar^2}{2m}\min(k_{L0}^2, k_{R0}^2)} T(E_\parallel)\, dE_\parallel \tag{32}$$

where

$$T(E_\parallel) = \frac{16 e^{-2\kappa_0 d}}{(V_L - V_B)(V_R - V_B)} \times \sqrt{\frac{\hbar^2}{2m}k_{L0}^2 - E_\parallel} \sqrt{\frac{\hbar^2}{2m}k_{R0}^2 - E_\parallel} \times \left(\frac{\hbar^2}{2m}\kappa_0^2 + E_\parallel \right) \exp\left(-\frac{d}{\kappa_0} \frac{2m}{\hbar^2} E_\parallel \right) \tag{33}$$

For large d, the important region in the integral of equation (32) is $E_\parallel \simeq 0$, and we have

$$G = 2\frac{e^2}{h} \frac{\kappa_0}{4\pi d} T(0) = 2\frac{e^2}{h} \frac{4\kappa_0}{\pi d} \frac{k_{L0} \kappa_0^2 k_{R0}}{(k_{L0}^2 + \kappa_0^2)(k_{R0}^2 + \kappa_0^2)} e^{-2\kappa_0 d} \tag{34}$$

The conductance for spin-up and spin-down electrons is given by half of the total conductance in equation (34) as

$$G_\uparrow = G_\downarrow = \frac{e^2}{h} \frac{4\kappa_0}{\pi d} \frac{k_{L0} \kappa_0^2 k_{R0}}{(k_{L0}^2 + \kappa_0^2)(k_{R0}^2 + \kappa_0^2)} e^{-2\kappa_0 d} \tag{35}$$

Next, let us consider the magnetic tunnel junctions, where the conductance is spin-dependent. In the magnetic electrodes, spin-up and spin-down electrons feel the different exchange potentials h_0 and $-h_0$, respectively. The matching condition depends on the relative angle between the magnetization vectors of left and right electrodes. For simplicity, we

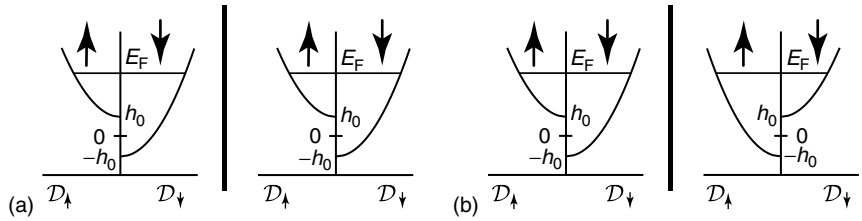

Figure 6. Densities of states for spin-up ($\mathcal{D}_\uparrow$) and spin-down ($\mathcal{D}_\downarrow$) electrons in the F alignment (a) and those in the A alignment (b).

consider two types of alignments of magnetization vectors, ferromagnetic (F) and antiferromagnetic (A) alignments, as shown in Figure 6(a) and (b). The spin quantization axis is taken to be parallel to the magnetization vector in the left electrode. For the F alignment, where the magnetization vectors are parallel, we have two tunneling processes: electrons incident from the left majority (minority) spin band tunnel to the right majority (minority) spin band. Potential diagrams for these two tunneling processes are shown in Figure 7(a) and (b), respectively. The wave numbers of electrons in the majority and minority spin bands are

$$k_{\mathrm{M}} = \sqrt{(2m/\hbar^2)(E - h_0) - \boldsymbol{k}_\parallel^2} \quad \text{(majority)} \tag{36}$$

$$k_{\mathrm{m}} = \sqrt{(2m/\hbar^2)(E + h_0) - k_\parallel^2} \quad \text{(minority)} \tag{37}$$

The conductance for spin-up (spin-down) electrons is obtained from equation (35) by setting $k_{\mathrm{L0}} = k_{\mathrm{R0}} = k_{\mathrm{M0}}(k_{\mathrm{m0}})$, where $k_{\mathrm{M0}}(k_{\mathrm{m0}})$ is the wave number for the electrons in the majority (minority) spin band with $k_\parallel = 0$:

$$G_\uparrow^{\mathrm{F}} = \frac{e^2}{h}\frac{4\kappa_0^3}{\pi d}\frac{k_{\mathrm{m0}}^2}{(k_{\mathrm{m0}}^2 + \kappa_0^2)^2}\mathrm{e}^{-2\kappa_0 d},$$

$$G_\downarrow^{\mathrm{F}} = \frac{e^2}{h}\frac{4\kappa_0^3}{\pi d}\frac{k_{\mathrm{M0}}^2}{(k_{\mathrm{M0}}^2 + \kappa_0^2)^2}\mathrm{e}^{-2\kappa_0 d} \tag{38}$$

The total conductance for the F alignment takes the form

$$G^{\mathrm{F}} = G_\uparrow^{\mathrm{F}} + G_\downarrow^{\mathrm{F}}$$

$$= \frac{e^2}{h}\frac{4\kappa_0^3}{\pi d}\left[\frac{k_{\mathrm{m0}}^2}{(k_{\mathrm{m0}}^2 + \kappa_0^2)^2} + \frac{k_{\mathrm{M0}}^2}{(k_{\mathrm{M0}}^2 + \kappa_0^2)^2}\right]\mathrm{e}^{-2\kappa_0 d} \tag{39}$$

In contrast, for the A alignment where the magnetization vectors are antiparallel, electrons incident from the left majority (minority) spin band tunnel to the right minority (majority) spin band. The potential diagrams for spin-up and spin-down electrons are depicted in Figure 7(c) and 7(d), respectively. The conductance for the A alignment is given by

$$G_\uparrow^{\mathrm{A}} = G_\downarrow^{\mathrm{A}} = \frac{e^2}{h}\frac{4\kappa_0^3}{\pi d}\frac{k_{\mathrm{m0}}k_{\mathrm{M0}}}{(k_{\mathrm{m0}}^2 + \kappa_0^2)(k_{\mathrm{M0}}^2 + \kappa_0^2)}\mathrm{e}^{-2\kappa_0 d}$$

$$G^{\mathrm{A}} = G_\uparrow^{\mathrm{A}} + G_\downarrow^{\mathrm{A}}$$

$$= \frac{e^2}{h}\frac{4\kappa_0^3}{\pi d}\frac{2k_{\mathrm{m0}}k_{\mathrm{M0}}}{(k_{\mathrm{m0}}^2 + \kappa_0^2)(k_{\mathrm{M0}}^2 + \kappa_0^2)}\mathrm{e}^{-2\kappa_0 d} \tag{40}$$

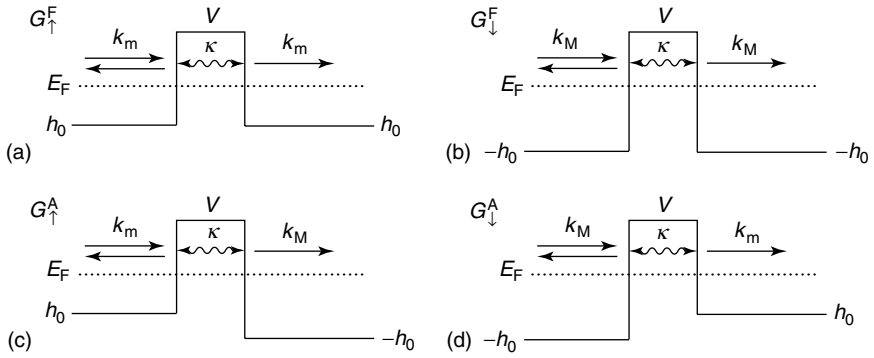

Figure 7. Geometries of the potentials for spin-up and spin-down electrons in the F alignment are shown in panels a) and (b), and those in the A alignment are shown in (c) and (d), respectively.

Using equations (39) and (40), the TMR is expressed as (Slonczewski, 1989)

$$TMR = \frac{G^{\mathrm{F}} - G^{\mathrm{A}}}{G^{\mathrm{A}}} = \frac{(k_{\mathrm{m0}} - k_{\mathrm{M0}})^2(\kappa_0^2 - k_{\mathrm{m0}}k_{\mathrm{M0}})^2}{2k_{\mathrm{m0}}k_{\mathrm{M0}}(k_{\mathrm{m0}}^2 + \kappa_0^2)(k_{\mathrm{M0}}^2 + \kappa_0^2)} = \frac{2P_{\mathrm{eff}}^2}{1 - P_{\mathrm{eff}}^2} \tag{41}$$

where P_{eff} is the effective spin polarization defined as

$$P_{\mathrm{eff}} = \frac{\kappa_0^2 - k_{\mathrm{m0}}k_{\mathrm{M0}}}{\kappa_0^2 + k_{\mathrm{m0}}k_{\mathrm{M0}}} P \tag{42}$$

in which $P = (k_{\mathrm{M0}} - k_{\mathrm{m0}})/(k_{\mathrm{M0}} + k_{\mathrm{m0}})$ is the spin polarization of the ferromagnetic electrode with an elliptical energy band.

Since the wave number in the barrier region κ_0 ranges from 0 (low barrier limit) to ∞ (high barrier limit), we have $-P < P_{\mathrm{eff}} < P$. In the high barrier limit, the TMR is the same as that obtained by the tunneling Hamiltonian method. One interesting result of the free-electron model is that P_{eff} is diminished, and therefore the TMR for values of the barrier height ($\kappa_0 \sim k_{\mathrm{m0}}k_{\mathrm{M0}}$) is diminished. This variation of the TMR has been experimentally observed by Tezuka and Miyazaki (1998) as shown in Figure 8.

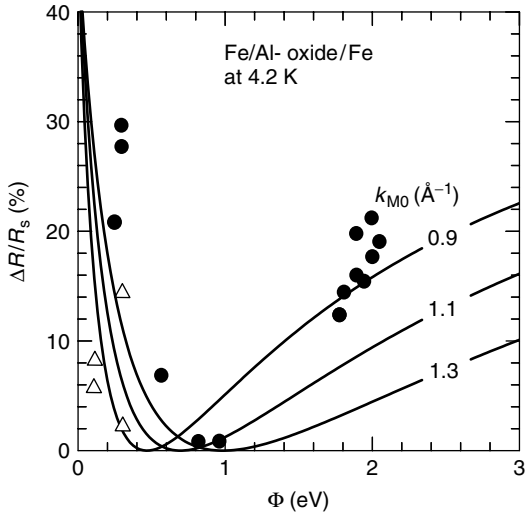

Figure 8. Dependence of TMR on the barrier height Φ at 4.2 K. The horizontal axis is the barrier height obtained by fitting the I–V curves to Simmon's relation (Simmons, 1963). The solid curves are the calculated values using the free-electron model. (Reproduced from N. Tezuka and T. Miyazaki, *J. Magn. Magn. Mater.* **177-181**, 1998, 1283, copyright © 1998, with permission from Elsevier.)

4 TIGHT-BINDING MODEL

Recently, more realistic calculation methods based on the tight-binding Hamiltonian and the Kubo–Landauer formula have been developed by several authors (Zhang and Levy, 1999; Moodera and Mathon, 1999; Asano, Oguri and Maekawa, 1993; Mathon, 1997; Tsymbal and Pettifor, 1998; Mathon and Umerski, 1999; Itoh *et al.*, 1999; Itoh, Ohsawa and Inoue, 2000). The tight-binding model is of great use both in dealing with multiorbital systems having a realistic band structure and in studying the effect of the disorder and roughness of the insulating barrier on the spin-dependent tunneling. In order to understand the basic formalism of the conductance calculation in the tight-binding model, we first consider the 1D chain shown in Figure 9, which is expressed by the following 1D Hamiltonian:

$$\mathcal{H} = -t \sum_{\langle n,n' \rangle} c_n^\dagger c_{n'} + \sum_n \varepsilon_n c_n^\dagger c_n \tag{43}$$

where t is the hopping matrix element and ε_n is the on-site energy at the nth site. The spin indices are dropped for simplicity. In the low bias regime, the conductance G at zero temperature is given by the Kubo formula as

$$G = \frac{\pi\hbar}{N^2} \sum_{\alpha\beta} \left| \sum_{n=1}^{N} \langle \alpha | J(n) | \beta \rangle \right|^2 \times \delta(E_{\mathrm{F}} - E_\alpha)\delta(E_{\mathrm{F}} - E_\beta) \tag{44}$$

where $|\alpha\rangle$ and $|\beta\rangle$ are the eigenstates of the system with energies E_α and E_β, respectively, and the current operator at site n is defined as

$$J(n) = \frac{ie}{\hbar} \left[t c_{n+1}^\dagger c_n - t c_n^\dagger c_{n+1} \right] \tag{45}$$

In the stationary state of the system, the current conservation requires that $J(n)$ is independent of n, and thus the

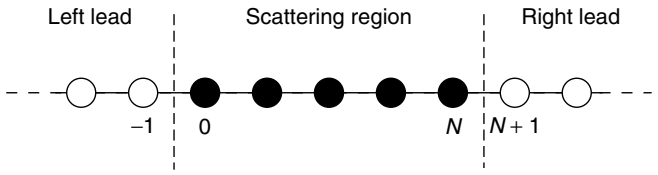

Figure 9. Schematic of the 1D chain including the scattering region, which is indicated by filled circles. The scattering region is connected with the left and right ideal leads.

conductance reduces to

$$\begin{aligned} G = \frac{\pi e^2}{\hbar} t^2 \sum_{\alpha\beta} \Big[& \langle n+1|\alpha\rangle\langle\alpha|n+1\rangle\langle n|\beta\rangle\langle\beta|n\rangle \\ & - \langle n|\alpha\rangle\langle\alpha|n+1\rangle\langle n|\beta\rangle\langle\beta|n+1\rangle \\ & - \langle n+1|\alpha\rangle\langle\alpha|n\rangle\langle n+1|\beta\rangle\langle\beta|n\rangle \\ & + \langle n|\alpha\rangle\langle\alpha|n\rangle\langle n+1|\beta\rangle\langle\beta|n+1\rangle \Big] \\ & \times \delta(E_{\mathrm{F}} - E_\alpha)\delta(E_{\mathrm{F}} - E_\beta) \end{aligned} \tag{46}$$

where $|n\rangle$ is the one-particle state created by the operator $c_n^\dagger$. Let us introduce the Green function:

$$\begin{aligned} \tilde{\mathcal{G}}(n,n') &= \frac{i}{2}\left[\mathcal{G}^+(n,n') - \mathcal{G}^-(n,n')\right] \\ &= \pi \sum_\alpha \langle n|\alpha\rangle\langle\alpha|n'\rangle \delta(E - E_\alpha) \end{aligned} \tag{47}$$

where $\mathcal{G}^+$ and $\mathcal{G}^-$ are the retarded and advanced one-electron Green functions expressed as

$$\mathcal{G}^\pm(n,n') = \left\langle n \left| \frac{1}{E - \mathcal{H} \pm i\delta} \right| n' \right\rangle \tag{48}$$

Here, $\mathcal{H}$ is the total Hamiltonian and δ is a small positive number. Using the Green function defined by equation (47), the conductance can be written as

$$\begin{aligned} G = \frac{4e^2}{h} \Big[& t\tilde{\mathcal{G}}(n,n) t\tilde{\mathcal{G}}(n+1,n+1) \\ & - t\tilde{\mathcal{G}}(n,n+1) t\tilde{\mathcal{G}}(n,n+1) \Big] \end{aligned} \tag{49}$$

The advanced and retarded Green functions are easily obtained by the recursion method (Thouless and Kirkpatrick, 1981; Lee and Fisher, 1981). In the matrix form, the Hamiltonian is given by

$$\mathsf{H} = \begin{pmatrix} \cdots & -t & 0 & 0 & 0 \\ -t & \varepsilon_0 & -t & 0 & 0 \\ 0 & -t & \varepsilon_1 & -t & 0 \\ 0 & 0 & -t & \varepsilon_2 & -t \\ 0 & 0 & 0 & -t & \cdots \end{pmatrix} \tag{50}$$

where the dimension of the matrix is infinite since we consider an open system. Let us define the Green function for the system in which all sites $n > n_0$ are deleted as

$$\mathsf{G}_{n_0}^{\mathrm{L}\pm} = \left[(E \pm i\eta)\mathsf{I} - \mathsf{H}_{n_0}^{\mathrm{L}} \right]^{-1} \tag{51}$$

where the Hamiltonian $\mathsf{H}_{n_0}^{\mathrm{L}}$ consists of sites $n \geq n_0$. The Green function for the system $H_{n_0+1}^{\mathrm{L}}$ satisfies the following equation:

$$\left[(E \pm i\eta)\mathsf{I} - \mathsf{H}_{n_0+1}^{\mathrm{L}} \right] \mathsf{G}_{n_0+1}^{\mathrm{L}\pm} = \mathsf{I} \tag{52}$$

$$\begin{aligned} & \begin{pmatrix} (E \pm i\eta)\mathsf{I} - \mathsf{H}^{\mathrm{L}}(n_0) & -t \\ -t^\dagger & E \pm i\eta - \varepsilon_{n_0+1} \end{pmatrix} \\ & \times \begin{pmatrix} \mathsf{A}_1 & \mathsf{A}_2 \\ \mathsf{A}_3 & \mathcal{G}_{n_0+1}^{\mathrm{L}\pm}(n_0+1, n_0+1) \end{pmatrix} = \mathsf{I} \end{aligned} \tag{53}$$

where $t^\dagger = (0, \cdots, 0, t)$. It follows that the Green function $\mathcal{G}_n^{\mathrm{L}\pm}(n,n)$ satisfies the following recursive relation:

$$\mathcal{G}_{n_0+1}^{\mathrm{L}\pm}(n_0+1, n_0+1) = \left[g^\pm(n_0+1)^{-1} - t\mathcal{G}_{n_0}^{\mathrm{L}\pm}(n_0,n_0)t \right]^{-1} \tag{54}$$

where $g^\pm(n) = (E \pm i\eta - \varepsilon_{n_0+1})^{-1}$ is the Green function for the isolated site $n_0 + 1$. Starting from the left semi-infinite ideal lead, where the exact Green function is analytically given, we can evaluate the Green function $\mathcal{G}_n^{\mathrm{L}\pm}(n,n)$ at arbitrary site $n \geq 1$.

The Green function for the whole system satisfies

$$\begin{aligned} & \begin{pmatrix} (E \pm i\eta)\mathsf{I} - \mathsf{H}_{n-1}^{\mathrm{L}} & -t & 0 \\ -t^\dagger & E \pm i\eta - \varepsilon_n & -t \\ 0 & -t^\dagger & (E \pm i\eta)\mathsf{I} - \mathsf{H}_{n+1}^{\mathrm{R}} \end{pmatrix} \\ & \times \begin{pmatrix} \mathsf{A}_1 & \mathsf{A}_2 & \mathsf{A}_3 \\ \mathsf{A}_4 & \mathcal{G}^\pm(n,n) & \mathsf{A}_5 \\ \mathsf{A}_6 & \mathsf{A}_7 & \mathsf{A}_8 \end{pmatrix} = \mathsf{I} \end{aligned} \tag{55}$$

where $\mathsf{H}_{n_0}^{\mathrm{R}}$ is the Hamiltonian for the semi-infinite system in which all sites $n < n_0$ are deleted. The Green function for the isolated right electrode is calculated by using the following recursive relation:

$$\mathcal{G}_{n_0}^{\mathrm{R}\pm}(n_0,n_0) = \left[g^\pm(n_0)^{-1} - t\mathcal{G}_{n_0+1}^{\mathrm{R}\pm}(n_0+1, n_0+1)t \right]^{-1} \tag{56}$$

The diagonal element of the advanced and retarded Green function for the whole system $\mathcal{G}^\pm(n,n)$ is given by

$$\begin{aligned} \mathcal{G}^\pm(n,n) = \big[& g^\pm(n)^{-1} - t\mathcal{G}_{n-1}^{\mathrm{L}\pm}(n-1,n-1)t - t \\ & \times \mathcal{G}_{n+1}^{\mathrm{R}\pm}(n+1,n+1)t \big]^{-1} \end{aligned} \tag{57}$$

It is also easy to show that the off-diagonal element is given by

$$\mathcal{G}^\pm(n,n+1) = \mathcal{G}^\pm(n,n)t\mathcal{G} \pm {}^{\mathrm{R}}{}_{n+1}(n+1,n+1) \tag{58}$$

Finally, the total conductance for each spin direction is calculated by using equations (49)–(58).

The tight-binding model described above is easily generalized to a 3D junction with a multiorbital system. The Hamiltonian is given by

$$\mathcal{H} = -\sum_{\langle n,n'\rangle,\alpha,\beta,\sigma} t_{n\alpha,n'\beta} c^{\dagger}_{n\alpha\sigma} c_{n'\beta\sigma} + \sum_{n,\alpha,\sigma} \varepsilon_{n\alpha\sigma} c^{\dagger}_{n\alpha\sigma} c_{n\alpha\sigma} \tag{59}$$

where the lattice sites are labeled by indices n and n', and $c^{\dagger}_{n\alpha\sigma}(c_{n\alpha\sigma})$ is the creation (annihilation) operator of an electron with spin σ and orbital α on the lattice site n. The hopping energy is $t_{nn'\alpha\beta}$, and the summation $\langle n, n'\rangle$ runs over nearest-neighbor sites. The spin-dependent on-site potential $\varepsilon_{n\alpha\sigma}$ includes the exchange potential in the FM, and the disorder and roughness of the insulating barrier are described by the variation of the hopping $t_{n\alpha,n'\beta}$ and on-site energy $\varepsilon_{n\alpha\sigma}$ (Itoh *et al*., 1999).

Mathon has studied the continuous transition from the current-perpendicular-to-plane giant magnetoresistance (CPP-GMR) of metallic systems to the TMR of tunnel junctions with a vacuum gap and an insulating barrier (Mathon, 1997). The tunnel junction with a vacuum gap is obtained by gradually turning off the overlap matrix elements between the ferromagnetic electrodes. The insulating barrier is obtained by varying the on-site potentials in the spacer so that the Fermi level in the spacer layer moves into the band gap. It is shown that the tunneling across the vacuum gap and through an insulating barrier leads to the same TMR provided the barrier is at least as high as the conduction bandwidth and the barrier is narrow, not wider than a few atomic planes. It is also shown that the tunneling current across the vacuum gap is carried only by the s−p electrons in the tunneling regime, though a significant proportion of the current in the magnetic metal (Co) is carried by d electrons that are highly spin polarized. The switching from d electrons to s−p electrons can explain the value of the TMR ratio and the change in the sign of spin polarization P of tunneling electrons.

The effect of disorder and roughness of the insulating barrier on TMR has been studied by several authors (Zhang and Levy, 1999; Mathon, 1997; Tsymbal and Pettifor, 1998; Mathon and Umerski, 1999; Itoh *et al*., 1999). Figure 10 shows the TMR ratio R_{MR} of the magnetic tunnel junctions with and without interface roughness calculated by Itoh *et al*. (1999). The interface roughness is treated with the help of the coherent potential approximation (Soven, 1967; Velický, 1969). One can see that R_{MR} for $E_{\mathrm{F}} = -5t$ is enhanced by the interface roughness while that for $E_{\mathrm{F}} = 0$ is suppressed. They found that the diffusive conductance originating from the interface roughness was highly dependent on the shape of the Fermi surface.

The tight-binding model has also been used to study the TMR for half-metallic systems by using the double exchange

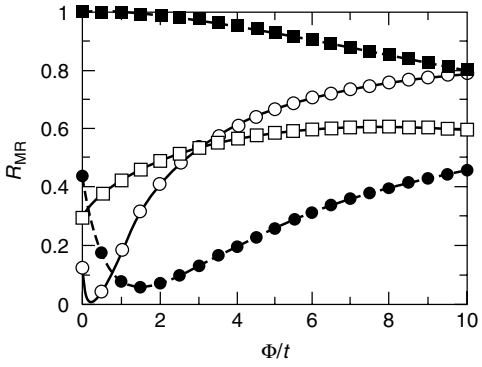

Figure 10. TMR ratio R_{MR} as a function of the barrier height Φ for $E_{\mathrm{F}} = -5t$ (solid and open circles) and $E_{\mathrm{F}} = 0$ (solid and open squares). Solid and open symbols denote the results without (c = 0) and with (c = 0.5) randomness, respectively. The average barrier thickness is taken to be 11 atomic layers. (Reproduced from H. Itoh, A. Shibata, T. Kumazaki, J. Inoue, and S. Maekawa, *J. Phys. Soc. Jpn.* **68**, 1632 (1999), with permission from the Physical Society of Japan.)

model (Itoh, Ohsawa and Inoue, 2000). It is shown that the strong exchange coupling in the double exchange model plays an important role in the temperature dependence of both P and the TMR ratio; their values can be less than the maximum values expected for half-metallic systems at low temperatures, and the TMR ratio decreases more rapidly than P with increasing temperature. The calculated results, however, indicate that the TMR ratio may still be large at high temperatures near the Curie temperature.

The TMR of an epitaxial Fe/MgO/Fe(001) junction was calculated by Mathon and Umerski (2001) and independently by Butler, Zhang, Schulthess and MacLaren (2001). Mathon and Umerski used the tight-binding model with the bands fitted to an *ab initio* band structure of Fe and MgO. The calculated TMR ratio is 1200% for 20 atomic planes of MgO. As mentioned earlier, the larger TMR ratio in epitaxial magnetic tunnel junctions has been observed by several groups (Bowen *et al*., 2001; Faure-Vincent *et al*., 2003); Parkin *et al*., 2004; Yuasa *et al*., 2004; Djayaprawira *et al*., 2005; Hayakawa *et al*., 2005; Yuasa, 2006). The most powerful method to study the spin-dependent tunneling in an epitaxial magnetic tunnel junction is given by the first-principles model, as discussed in the next section.

5 FIRST-PRINCIPLES MODEL

In 1999, MacLaren, Zhang, Butler and Wang (1999) developed a calculation technique for spin-dependent tunneling in magnetic tunnel junctions based on the LKKR method (MacLaren *et al*., 1990). The LKKR method is a self-consistent electronic structure method, based on the LSDA or on some other approximation to density-functional theory,

which may be used to calculate the electronic structure of a three-dimensional solid without requiring the usual constraint of three-dimensional translational symmetry. The LKKR calculation for an interface proceeds as follows: first, a bulk calculation is performed to find the self-consistent potentials for the two leads far from the interface. Then, the whole system with the interface is set up, and the spin-up and spin-down potentials on atomic layers within the sample and within the leads near the interface are allowed to relax through the iterative procedure until electrostatic self-consistency is achieved through the system. Since the plane-wave reflection and transmission coefficients are generated by the LKKR method, the reflection and transmission coefficients for Bloch waves incident on the sample from one of the leads can be obtained easily after a few algebraic steps (MacLaren, Zhang, Butler and Wang, 1999). Then the conductance is obtained by using the Landauer–Büttiker formalism.

MacLaren *et al*. applied the LKKR-based first-principles method to the spin-dependent tunneling in Fe/ZnSe/Fe(100) tunnel junctions and predicted that the TMR ratio reaches as high a value as about 2000%. However, it is difficult to fabricate the epitaxial magnetic tunnel junction with ZnSe showing a larger TMR ratio. Gustavsson, George, Etgens and Eddrief (2001) fabricated an epitaxial Fe/ZnSe/FeCo junction on ZnSe(001)-buffered GaAs(001) substrates by MBE. The transport measurement on microfabricated tunnel junctions yielded up to 16% at 10 K. Butler, Zhang, Schulthess and MacLaren (2001) studied the spin-dependent tunneling in Fe/MgO/Fe junctions by using the LKKR-based first-principles method (MacLaren, Zhang, Butler and Wang, 1999), and predicted a TMR ratio of as high a value as 6000%. As mentioned in the preceding section, Mathon and Umerski (2001) arrived at qualitatively identical conclusions by using the multiband tight-binding description for the electronic structure. Soon after the publication of these two theoretical papers, Bowen *et al*. (2001) reported that a TMR ratio of 27% was observed at 300 K in Fe/MgO/FeCo(001) epitaxial junctions. Encouraged by this work, many groups (Faure-Vincent *et al*., 2003); Parkin *et al*., 2004; Yuasa *et al*., 2004; Djayaprawira *et al*., 2005; Hayakawa *et al*., 2005; Yuasa, 2006) have made substantial efforts for developing epitaxial magnetic tunnel junctions with an MgO barrier having a high TMR ratio, as shown in Figure 1.

The key to understanding the origin of the high TMR ratio observed in the MgO system is the evanescent gap state in the MgO barrier. The decay rate of the evanescent waves in the MgO barrier depends strongly on the symmetry of the wave function. Figure 11 shows the dispersion $k^2(E)$ for MgO in the vicinity of the gap along Δ (100) (Butler, Zhang, Schulthess and MacLaren, 2001). There are three kinds of evanescent waves with different symmetries within the gap, Δ_1, $\Delta_{2'}$, and Δ_5. The horizontal axis is $(k\Delta z)^2$, where k is in the (001) direction and Δz is the interplanar spacing for MgO(001). Negative values of $(k\Delta z)^2$ determine the exponential decay rates for various Bloch states. As shown in Figure 11, the weakest decay is for the state with Δ_1 symmetry, which implies that the evanescent wave with Δ_1 symmetry gives the dominant contribution to the tunneling current. The proportion of the tunneling current carried by the Δ_1 states increases with increasing barrier thickness.

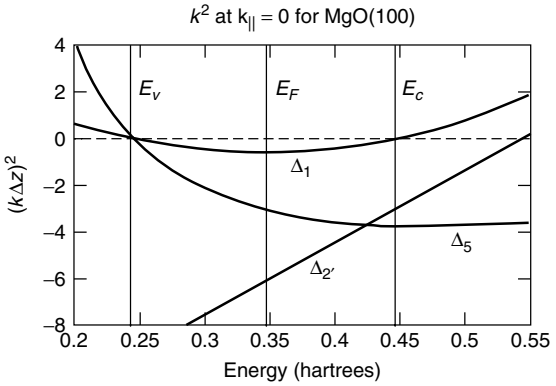

Figure 11. Dispersion $k^2(E)$ for MgO in the vicinity of the gap along Δ (100). k is in the (001) direction and Δz is the interplanar spacing for MgO(001). E_F is the Fermi energy. E_v is the top of the valence band. E_c is the bottom of the conduction band. (Reproduced from Butler *et al*. 2001, with permission from the American Physical Society. © 2001.)

Figure 12 shows the energy band structure of Fe(001) calculated by the LKKR method (Nagahama, Yuasa, Tamura and Suzuki, 2005). The majority and minority spin bans are represented by thin and thick lines, respectively, and the energy bands with Δ_1 symmetry are plotted with solid lines. One can see that the minority spin band with Δ_1 symmetry is absent at the Fermi energy. In contrast, there are majority spin states with Δ_1 symmetry at the Fermi energy. Therefore, the tunneling of electrons with majority spin dominates the current, which yields a high TMR ratio for sufficiently thick barriers. The situation is clearly shown by the tunneling density of states (TDOS) plotted in Figure 12 (b). The TDOS is defined as the density of electronic states subject to the following boundary conditions: on the left-hand side of the interface, there is an incoming Bloch state with unit flux and the corresponding Bloch state with unit flux and the corresponding reflected Bloch states; on the right-hand side are the corresponding transmitted Bloch states (Butler, Zhang, Schulthess and MacLaren, 2001). The states with Δ_2, $\Delta_{2'}$, Δ_5 symmetry decay much faster than that with Δ_1 symmetry. When the magnetizations of Fe electrodes are aligned so as to be antiparallel, only one electrode has the state with Δ_1 symmetry. Therefore, the current is much suppressed than in the case with the parallel alignment, and we have a high TMR ratio.

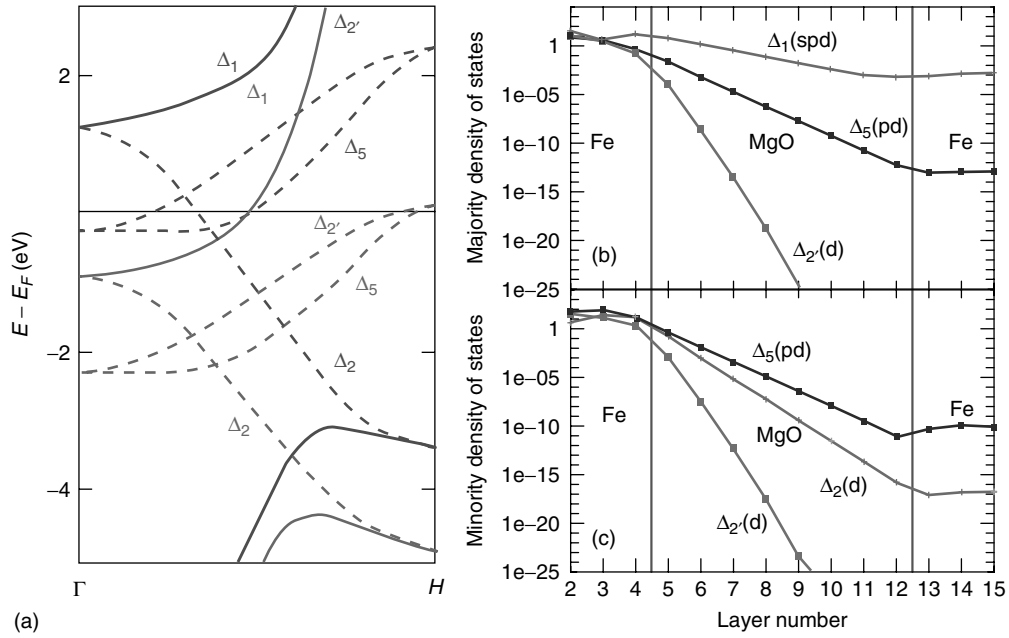

Figure 12. (a) Band structure of Fe(001) calculated by the LKKR method. Solid lines indicate the Δ_1 band, and broken lines indicate other bands. Thick curves represent the band of minority spin, and thin curves the band of majority spin. The majority spin has a Δ_1 band at the Fermi level. (Reproduced from Nagahama *et al*., 2005, with permission from the American Physical Society. © 2005.) (b) Tunneling density of states (TDOS) of the majority spin band for Fe(100)/MgO/Fe(100). (c) TDOS of the minority spin band for Fe(100)/MgO/Fe(100). (Reproduced from Butler *et al*., 2001, with permission from the American Physical Society. © 2001.) Each TDOS curve is labeled by the symmetry of the incident Bloch state in the left Fe electrode, and the magnetizations of Fe(100) electrodes are aligned so as to be parallel.

The transmission electron microscope (TEM) image of a single-crystal magnetic tunnel junction with Fe(001)/MgO (001)(1.8 nm)/Fe(001) fabricated by Yuasa's group (AIST) and the observed TMR ratio are shown in Figure 13(a) and (b), respectively (Yuasa *et al*., 2004). In the TEM image the lattice dislocations are indicated by circles. The lattice of the top Fe electrode is slightly expanded along the [110] axis. The existence of the lattice dislocations is the clear difference between the theoretical model and the real system, and should be considered if we want to construct a more accurate theoretical model of epitaxial tunnel junctions. If we treat the effect of the lattice dislocation on the spin-dependent tunneling in an appropriate way, the quantitative disagreement of the TMR ratio between the theoretical prediction and experimental results will be settled. The predicted TMR ratio is more than 10 times larger than the experimentally observed one. As mentioned before, as the thickness of the MgO barrier increases, the contribution from the states with Δ_1 symmetry increases and therefore the TMR ratio increases, as shown in Figure 13(b). One surprising finding is that the TMR ratio exhibits clear oscillatory behavior as a function of the thickness of the MgO barrier, t_{MgO}. The period of the oscillations (0.30 nm) is independent of temperature and bias voltage, but the amplitude of the oscillation decreases with increasing bias voltage. The origin of the oscillation might be an interference effect, since the period is inconsistent with the thickness of a monoatomic MgO(001) layer (0.22 nm). However, this is still an open question, and further development of the theoretical understanding of this system is required.

6 CONCLUSION

In this chapter, we have described the theoretical models of spin-dependent tunneling in magnetic tunnel junctions, that is, the tunneling Hamiltonian model, free-electron model, tight-binding model, and first principles model. Each model has its own merits and demerits and we should choose the right model for each system. The tunneling Hamiltonian model is a phenomenological model that introduces a crude approximation of constant values for the tunneling matrix elements. However, it gives an intuitive picture of tunneling and a quite useful expression of the TMR ratio. The free-electron model is the simplest of the models that include the quantum coherence. It can explain the anomalous dependence of the TMR ratio on the barrier height, although it cannot handle the multiorbit effect and the scattering due to the disorder. The tight-binding model is a very powerful tool that can treat the complex band structure of materials and

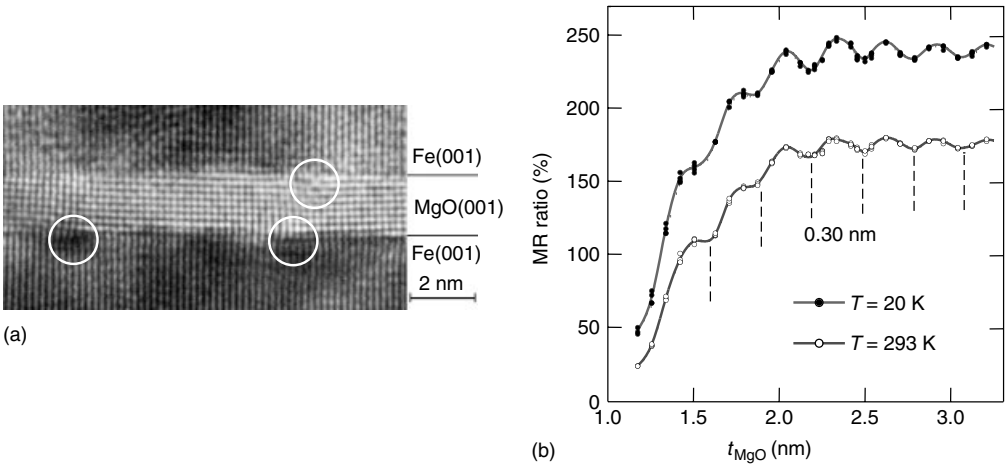

Figure 13. (a) High-resolution TEM image of a single-crystal magnetic tunnel junction with Fe(001)/MgO(001)(1.8 nm)/Fe(001) structure. The vertical and horizontal directions respectively correspond to the MgO[001](Fe[001]) axis and MgO[100](Fe[110]) axis. Lattice dislocations are circled. (b) TMR ratio at T = 293 and 20 K (measured at a bias voltage of 10 mV) versus t_{MgO}. (Reproduced from Yuasa, T. Nagahama, A. Fukushima, Y. Suzuki, and K. Ando, *Nature Materials* **3**, 868 (2004), with permission from Nature Publishing Group.)

disorder at the interface. The model can be applied to both the magnetic tunnel junctions with an amorphous Al_2O_3barrier and those with an epitaxial MgO barrier. However, the model has many parameters that must be determined empirically by fitting the first-principles calculation. The first-principles model has no empirical parameters by definition. However, its computational cost is expensive and it requires two-dimensional translational symmetry.

In order to develop efficient spin-electronic devices, the materials and device designs based on the appropriate theoretical model are required. One successful example is the high TMR ratio realized in the epitaxial magnetic tunnel junctions with MgO barrier, as described in Section 5. The theoretical understanding of the physics of spin-dependent tunneling promises further development of spin electronics and related fields. Further improvements in our theoretical understanding of the physics of spin-dependent tunneling will lead to advances in spin electronics and related fields.

1 INTRODUCTION

Many elements in the periodic table show a magnetic moment as free atoms. However, only iron, cobalt, nickel, and a few rare-earths and their alloys exhibit ferromagnetic properties in bulk compounds. The evolution of the atomic magnetic moments, their mutual coupling (which ultimately produces macroscopic magnetism), and the appearance of magnetic anisotropy in molecules, nanosized aggregates, and solids are the subjects of intense investigation. Besides being of fundamental interest, such questions bear on the design of novel magnetic devices with one or more dimensions reduced to the length scale of interatomic cooperative magnetic behavior. Understandably, we have good theoretical models and plenty of experimental data that tell us how magnetism works in free atoms and crystalline solids. However, as we explore the realm in between these two limits, we face a remarkable paucity of experimental information. The relevant length scale of the exchange interaction in most magnetic materials is only a few atomic spacings. This is the reason why the exploration of magnetic nanostructures has traditionally lagged behind the semiconductor field. Whereas in semiconductors the dimensions of the system influence the charge carriers' behavior already for typical lengths of tens of nanometers, magnetic materials must be engineered down to the Angstrom scale. It is only in the last two decades that advances in growth and characterization methods have allowed us to investigate and produce artificial structures with magnetic properties controlled with nanometer precision. Such progress has given rise to a wealth of technological applications, such as magnetic sensors and hard disk read heads making use of giant magnetoresistance effects, spin-based electronics, and new magnetic media.

Here, we are concerned with fundamental issues that govern the magnetic behavior of nanostructured materials as well as that of magnetic alloys down to the ultimate atomic scale. We describe the fabrication and the magnetic properties of zero-dimensional (0D), one-dimensional (1D), and two-dimensional (2D) nanostructures of Co and Fe, outlining the governing principles for self-organized growth of metallic nanostructures on crystalline substrates. By exploiting the hierarchy of diffusion processes on flat and stepped metal surfaces, we are able to construct low-dimensional magnetic systems almost atom-by-atom, which gives us an unprecedented view on the evolution of magnetization, magnetic anisotropy,

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

and magnetic order from atoms to solids. Starting from individual impurities, we let ensembles of dimers, trimers, and larger clusters self-assemble by controlling their coverage and substrate temperature. Surfaces with regular arrays of monatomic steps are used to induce the formation of 1D atomic chains. With increasing coverage the chains evolve into stripes in a row-by-row fashion, and finally into 2D atomically thin layers. The investigation of such structures has revealed exciting and unexpected properties. As one important result we demonstrate how the superparamagnetic limit – encountered in samples too small to provide sufficient long-term stability of ferromagnetic order and a well-known limit to the increase of the bit density in magnetic memories – can be elegantly circumvented in nanostructures. The key is in the very large magnetic anisotropy of some of the nanostructures, which results from their reduced atomic coordination on one hand, and the electronic hybridization with substrate atoms on the other hand. The discussed examples demonstrate how nanoscale structures can provide practical solutions to elude classical difficulties in the use of magnetic materials as well as fundamental input to our understanding of magnetic phenomena.

2 SELF-ORGANIZED GROWTH OF METALLIC NANOSTRUCTURES

Common to all bottom-up strategies for the fabrication of metallic nanostructures at surfaces is that they are essentially based on growth phenomena. Atoms are deposited on the substrate in vacuum, and nanoscale structures evolve as the result of a multitude of atomistic processes. This is inherently a nonequilibrium phenomenon. Any growth scenario is governed by the competition between kinetics and thermodynamics. In thermodynamic equilibrium, detailed balance requires that all atomistic processes proceed in opposite directions at equal rate. Hence, at finite temperature, the system fluctuates around equilibrium configurations and no net growth occurs – a situation well described by statistical mechanics. The formation of nanostructures at surfaces requires nonequilibrium. A measure for the degree of nonequilibrium is the supersaturation, defined as the actual adatom/admolecule density normalized to the equilibrium adatom/admolecule density $(\rho - \rho_e)/\rho_e$. The supersaturation describes to which extent the evolving structures will be determined by the growth kinetics or by thermodynamic parameters, such as the surface and interface free energy. The larger the supersaturation, the more decisive the kinetic processes.

In a growth experiment, where atoms are deposited at a surface with a constant rate F, the diffusivity D determines the average distance l an adatom has to travel to meet another one to nucleate a new aggregate or to attach to an already formed island. In the nucleation stage at very low coverage this length decreases rapidly and eventually becomes constant, typically at coverages above a few percent of a monolayer (Brune, Roder, Boragno and Kern, 1994). In this saturation regime any further deposition will exclusively lead to the growth of existing islands. The average diffusion length l, and correspondingly the nucleation density at saturation, only depends on the ratio D:F (Pimpinelli, Villain and Wolf, 1992). The ratio of deposition to diffusion rate is thus the key quantity characterizing the growth kinetics and a measure for the supersaturation. If the deposition is slow with respect to the diffusivity, the supersaturation is low and growth takes place close to equilibrium conditions; that is, adatoms or admolecules have enough time to explore the potential energy surface to reach a minimum energy configuration. If the deposition is fast with respect to the diffusivity, the individual atomistic processes become increasingly important and the growth scenario is essentially determined by kinetics.

2.1 The hierarchy of activated motion

Of particular interest within this chapter are metal nanostructures on metal surfaces. At low substrate temperature, the growth of such a system is a prototype for the kinetically dominated growth regime. The shape and size of the nanostructures are largely determined by the competition of the active diffusion processes and can be controlled by the external parameters temperature and deposition flux and by the appropriate choice of the substrate symmetry (Röder *et al*., 1993). The central atomic processes are surface diffusion processes of single adatoms, comprising diffusion on terraces (characterized by the diffusion barrier E_d), over steps (E_s), along edges (E_e), and across corners (E_c). All these diffusion processes are thermally activated, with the respective rate depending exponentially on the potential energy barrier. To first order, these barriers scale with the local coordination; that is, terrace diffusion has a lower barrier than edge diffusion and corner crossing (Stumpf and Scheffler, 1994). Edge descend is often more costly than terrace diffusion due to an extra barrier at the edge of an island, known as the *Schwoebel–Ehrlich barrier* (Ehrlich and Hudda, 1966). For a given material system we have thus a natural hierarchy of the relevant diffusion barriers. By selective activation/freezing of a certain diffusion process we can shape the growing aggregates.

As already mentioned, the terrace diffusion barrier determines the mean free path of a diffusing adatom on the substrate surface and also on top of islands, which build up during deposition. The barrier for crossing a step fixes the average number of attempts necessary for an adatom

to descend the edge. It is the interplay between these two parameters, which determines whether an aggregate grows 2D or three-dimensionally (3D). If atoms nucleate on top of islands without having visited their edge at all, or after they have visited it too few times to descend, the aggregates grow 3D. Otherwise, the downward flux of adatoms is large enough so that no nucleation occurs on top of an island and the aggregates grow only laterally.

If the Schwoebel–Ehrlich barrier is not too large, one can always find growth conditions where the interlayer diffusion is fast enough to prevent any 3D growth. The aggregates then grow in 2D or 1D shape depending on the interplay of the various intralayer diffusion processes. Even 1D growth of aggregates can be easily initiated by choosing a substrate with an intrinsic diffusion anisotropy (Röder *et al*., 1993; Mo, Kleiner, Webb and Lagally 1991). The fcc(110) surface is such a substrate. Due to the particular structure of this surface with troughs along the [1–10] direction, diffusion is much faster along this direction than in the orthogonal [001] direction. This diffusion anisotropy and the fact that corner crossing is also anisotropic can be exploited for the growth of 1D chains (Li *et al*., 1997) (Figure 1a). Another, particularly intriguing way to promote the formation of 1D atomic chains is the use of substrate steps, as will be discussed later in this section.

On substrates with no terrace diffusion anisotropy, aggregates show 2D with the shape determined by the competition between terrace and edge diffusion. On close-packed surfaces large compact islands can only be grown at sufficiently high temperature, where edge diffusion is active and island corners can be crossed (Röder *et al*., 1993; Michely and Comsa, 1991; Morgenstern, Rosenfeld and Comsa, 1996) (Figure 1b). At low temperature, the mobility of adatoms attached to island edges is limited or frozen and the aggregates grow in ramified island shapes (Hwang, Schroder, Gunther and Behm, 1991; Brune, Romainczyk, Roder and Kern, 1994) (Figure 1c). The metal aggregation on fcc(111) surfaces at low temperature is thus a nice model system for fractal growth in the diffusion limited aggregation scenario (Witten and Sander, 1981). The branches can be randomly ramified or grow into crystallographic well-determined directions. The latter is termed *dendritic growth* and the dominant atomistic process here is the anisotropy in the corner crossing (Brune *et al*., 1996). For square lattices, on the other hand, edge and terrace diffusion are too close in energy leading to compact island shapes even at low temperature (Zhang, Chen and Lagally, 1994).

The size of nanostructures formed in the diffusion limited regime can be controlled directly by temperature, flux, and coverage. Owing to the inherent stochastic nature of the nucleation and growth process, however, the possibility of tuning the size distribution is somewhat limited. Narrowed size distribution can be obtained by either Ostwald ripening, confined nucleation, or self-limiting processes. The nucleation regime is ideally suited to synthesize very small clusters comprising just a few atoms. The size distribution achieved here is characterized by a standard deviation roughly scaling with $<n>^{1/2}$, where n is the number of atoms. Larger particle sizes with substantially narrowed size distribution, $0.3<n>$, can be synthesized by the Ostwald ripening technique (Röder *et al*., 1993). Such size distributions are, however, often sufficiently narrow to explore the size dependence of the physical and chemical properties of metallic nanostructures, such as their magnetism.

2.2 Steering and positioning

Any application of magnetic nanostructures requires the fabrication of ordered nanostructure arrays with individually

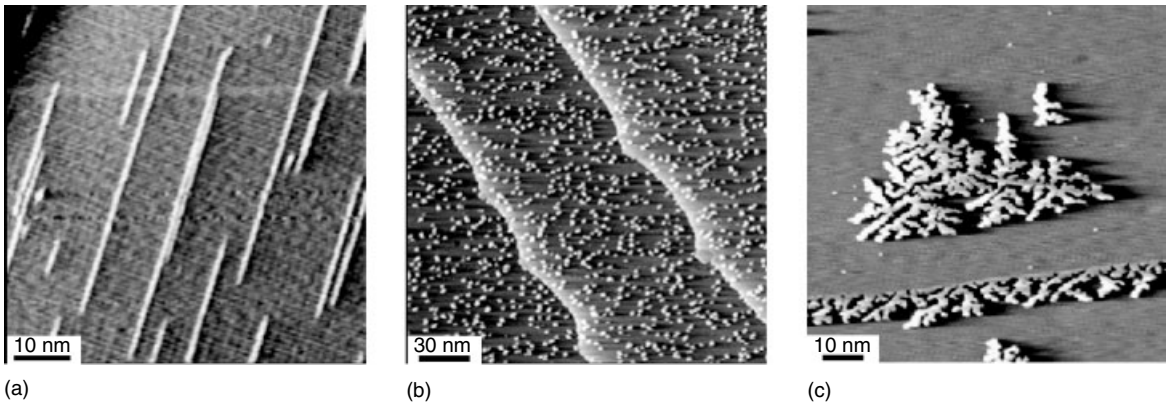

Figure 1. Atomic architecture at surfaces by control of growth kinetics. (a) Formation of monatomic Cu chains on the anisotropic Pd(110) substrate. (b) and (c) Ag nanostructures on Pt(111); size and shape are determined by controlling the kinetic growth parameters deposition flux and temperature.

addressable units. Moreover, uniformity in position and spacing are important considerations because the properties of the nanostructures may not only depend on their size and shape but also on their mutual interactions. Thus, growth strategies need to be developed providing nearly monodisperse nanostructures, which are organized in regular arrangements.

Lateral ordering of the nanostructures can be achieved by (i) self-ordering due to mutual long-range interactions and (ii) directed growth on patterned substrates. The latter approach turned out as particularly successful for guiding nanostructure formation. The patterned surfaces serve as nanotemplates with predefined nucleation sites or energetic sinks (Brune, Giovannini, Bromann and Kern, 1998; Nötzel, 1996; Temmyo, Kuramochi, Kamada and Tamamura, 1998). With this directed self-ordering strategy, the position of each nanostructure is exactly defined by the template, thus yielding nucleation sites predictable with nanometer accuracy. Depending on the required length scale, artificially or naturally structured surfaces can be employed. Natural nanotemplates are surfaces with reconstructions (Barth, Brune, Ertl and Behm, 1990), periodic dislocation networks (Brune, Roder, Boragno and Kern, 1994), or regularly spaced steps (Hahn *et al*., 1994; Kirakosian *et al*., 2001). In these systems periodic spacings ranging from a few angstroms up to a few nanometers are provided. If larger spacings are needed, the usual top-down fabrication techniques can be applied for the fabrication of prestructured substrates (Nötzel, 1996).

Important progress in the fabrication of 2D nanostructure arrays could be made by employing substrates with dislocation networks. These dislocation networks occur naturally on some surfaces (Barth, Brune, Ertl and Behm, 1990) and can also be produced in a controlled way in thin epitaxial films (Brune, Roder, Boragno and Kern, 1994) or by wafer bonding (Leroy, Eymery, Gentile and Fournel, 2002). Typical periodicities range between 2 and 20 nm. The dislocation lines are in general found to be repulsive toward diffusing atoms (Brune, Giovannini, Bromann and Kern, 1998; Fischer *et al*., 1999), while dislocation elbows can act as sinks for mobile atoms (Chambliss, Wilson and Chiang, 1991). For a well-defined set of growth parameters, the adatoms are, therefore, in the first case confined within the dislocation network unit cells, exactly nucleating one island per unit cell. In the second case, islands preferentially nucleate at the attractive defects. These techniques have successfully been applied in the growth of metal or semiconductor nanostructure arrays and even magnetic nanopillars (Fruchart, Klaua, Barthel and Kirschner, 1999). A valuable side effect of the nucleation and growth on such patterned substrates is the typically enhanced size uniformity. In this case, the size distribution becomes binominal and the size uniformity is determined by the statistical fluctuations in the deposition process. As the homogeneity increases with the size of the atom collecting area, the monodispersity becomes better with increasing island distance (Brune, Giovannini, Bromann and Kern, 1998).

As mentioned earlier, regularly stepped surfaces can serve as natural nanotemplates for the self-organized growth of 1D nanoarrays. The step edges act as preferential nucleation sites for the deposited material due to the increased coordination with respect to the terrace sites. A row-by-row decoration of the steps can be achieved if (i) the terrace mobility is high enough that all adatoms can reach the steps and (ii) the mobility of the atoms once attached to the steps is still sufficient to ensure 1D nucleation and growth (Gambardella *et al*., 2000). At appropriate deposition temperatures, the width of the adlayer chains can be changed discretely from monatomic to diatomic, triatomic and so on, simply by controlling the total coverage. Perfect 1D nanotemplates are for example, the (557) surface of Si and the (997) surface of Pt, which had been proven to show highly ordered step structures (Hahn *et al*., 1994; Kirakosian *et al*., 2001). As an example, the Pt(997) surface composed of (111) oriented terraces of 20.2 Å in width, separated by monatomic steps, is shown in Figure 2(a). The regular step ordering is mediated by the repulsive step–step interactions, which suppress step meandering. As examples for nanotemplate supported growth, arrays of 1D Co and Fe chains fabricated on Pt(997) will be discussed within this chapter (see Figure 2b and inset in Figure 8a).

3 MAGNETISM OF ZERO- AND ONE-DIMENSIONAL STRUCTURES

3.1 Magnetic atoms on nonmagnetic substrates

In this chapter, we are concerned with fundamental issues that govern the intrinsic magnetic properties of low-dimensional metal systems fabricated by molecular beam epitaxy on nonmagnetic substrates. We define as *intrinsic* those properties that depend on atomic scale magnetism and crystalline structure, such as the magnetic moment, the magnetocrystalline anisotropy, and magnetic order, as opposed to the *extrinsic* properties that depend on the microstructure and magnetostatic interactions (Kronmüller, 2003; Skomski and Coey, 1999). The main focus will be on 0D and 1D systems, where the influence of size and dimensionality effects on the intrinsic magnetization parameters is largest. For a thorough treatment of 2D systems such as magnetic thin films and multilayers, we refer to the extensive monographs published on the subject (Gradmann, 1993; Schneider and Kirschner, 2000; Bland and Heinrich, 2005) and to other chapters of

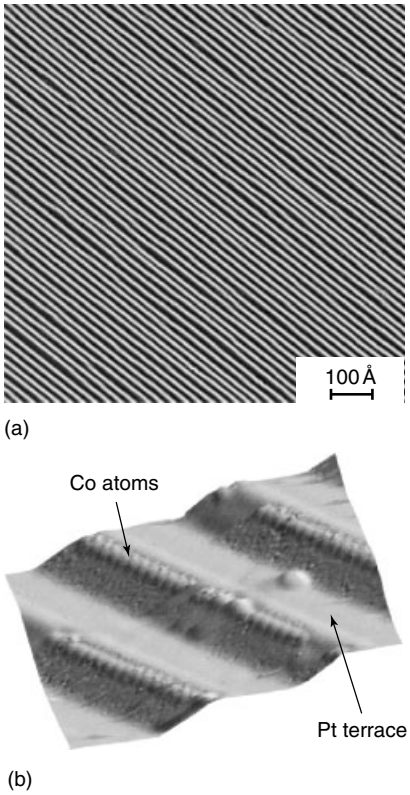

Figure 2. (a) The STM image of a Pt(997) surface shows (111)-oriented terraces of 20 Å width, separated by monatomic steps. The high degree of order makes this substrate an ideal nanotemplate for nanostructure fabrication. (b) Formation of monatomic chains of Co atoms by substrate step decoration.

this handbook (see **Magnetism of Low-dimensional Systems: Theory, Volume 1** and **Magnetic Ultrathin Films, Volume 4**).

The fabrication of magnetic nanostructures and thin films by molecular beam epitaxy (MBE) methods is typically initiated by the deposition of magnetic atoms from the vapor-phase onto a nonmagnetic substrate, as discussed in the preceding text. A first point of fundamental and practical interest, in this context, is the extent to which the local magnetic moment of a transition metal impurity is modified by the interaction with the supporting substrate. The role played by magnetic/nonmagnetic interfaces in determining the magnetization and particularly the anisotropy fields in ultrathin films has been widely investigated in the past (Gradmann, 1993; Sander, 2004). With the aim of controlling the magnetic behavior of structures with ever reducing dimensions, however, our knowledge must progress toward the atomic size level. Identifying and distinguishing local substrate-impurity hybridization effects from coordination and magnetoelastic effects in thin films, for instance, provide useful guidelines to tailor the intrinsic magnetization parameters in finite-sized supported particles, optimize sensitive interface properties that govern electron transport in magnetoelectronic devices (Jansen and Moodera, 1998), and test current theoretical models of low-dimensional magnetic systems (see also **Magnetism of Low-dimensional Systems: Theory, Volume 1**).

Most transition metal atoms in the gas phase possess large spin (m_S) and orbital (m_L) magnetic moments due to the incomplete filling of the d-shell and the atomic correlation effects exemplified by the Hund's rules. In the solid state, electron delocalization and crystal field effects compete with intra-atomic Coulomb interactions causing a substantial or total decrease of m_S and quenching of m_L. Theoretical calculations, however, predict such effects to be strongly reduced at surfaces owing to the decreased coordination of transition metal impurities (see also **Magnetism of Low-dimensional Systems: Theory, Volume 1**; Stepanyuk *et al*., 1996; Nonas *et al*., 2001). As a case experimental system, we consider the magnetic properties of Co. As free atom in the ground state d^7 configuration, Co displays significant spin and orbital magnetism with $m_S = m_L = 3\,\mu_B$, and Brillouin-like isotropic magnetization (Figure 3a). In the bulk hexagonal close-packed structure Co is a strong ferromagnet with $m_S = 1.52$ and $m_L = 0.15\,\mu_B$ and exhibits a fairly large magnetocrystalline anisotropy energy (MCA) compared to bulk Fe and Ni, with a uniaxial anisotropy energy constant $K = 0.05$ meV per atom (Bonnenberg, Hempel and Wijn, 1986).

Once deposited onto a metal surface, we expect the magnetic moment of Co atoms to vary according to the degree of d-orbital hybridization with the conduction electron states of the substrate (Gambardella *et al*., 2002b; Song and Bergmann, 2001). This will depend on the reduced number of neighbors around the impurity as well as on the host band structure, similar to dilute alloys with nonmagnetic metals (Mydosh and Nieuwenhuys, 1980). In dealing with surface impurities, the experimental challenge lies in probing extremely reduced amounts of magnetic atoms (typically the order of 10^{14} atoms cm^{-2} or less, deposited at cryogenic temperature to avoid cluster formation) on a macroscopic metal surface with nonnegligible para- or diamagnetic response. To achieve the required element-specific sensitivity, the method of choice is the absorption of circularly polarized light in the soft X-ray range, described in the chapters **Magnetic Spectroscopy, Volume 1** and **Synchrotron Radiation Techniques Based on X-ray Magnetic Circular Dichroism, Volume 3**. The lineshape of the X-ray absorption spectra (XAS) at the $L_{2,3}$ edges of 3d transition metals ($2p^6 3d^n$ to $2p^5 3d^{n+1}$ excitations) contains information about the electronic configuration of the impurities (van der Laan and Thole, 1991). Simultaneously, as the X-ray absorption cross-section depends on the orientation of the spin and orbital moment of the 3d electrons relative to the X-ray polarization direction, magnetic sensitivity is achieved

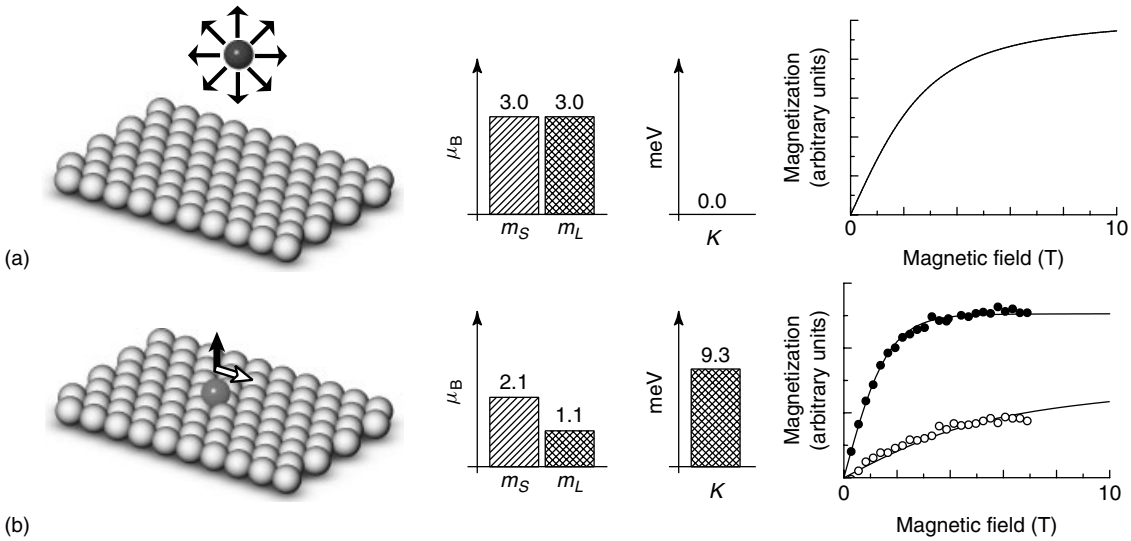

Figure 3. (a) Spin and orbital magnetic moment of a gas phase Co atom as given by the Hund's rules for the d^7 electronic configuration. The magnetic anisotropy energy equals zero due to the spherical symmetry of the system. The isotropic magnetization is represented by a Brillouin function for the d^7 state calculated at $T = 5.5$ K. (b) Spin and orbital magnetic moment and magnetic anisotropy energy of an individual Co atom deposited on the Pt(111) surface. The anisotropic magnetization is measured at $T = 5.5$ K by recording the XMCD intensity at the Co L_3 edge as a function of applied field in the easy (out-of-plane, filled circles) and hard (in-plane, empty circles) direction.

by taking the difference of the XAS spectra for parallel (I_+) and antiparallel (I_-) alignment of the X-ray polarization with respect to the sample magnetization. The X-ray magnetic circular dichroism (XMCD) spectra obtained in this way allow to identify the magnetization direction and strength of a given element (Stöhr, 1999), and to estimate quantitatively m_S and m_L by means of the so-called *XMCD sum rules* (Thole, Carra, Sette and Van der Laan, 1992; Carra, Thole, Altarelli and Wang, 1993; Chen *et al*., 1995).

As an example of a strongly interacting substrate we present data obtained for the Pt(111) surface. The XAS of isolated Co impurities deposited in ultra-high-vacuum on Pt(111) (Figure 4a) reveals broad features typical of Co metal (Figure 4b) that are drastically different from the XAS calculated for the atomic d^7 configuration (Figure 4c) and observed in the vapor-phase (Martins, Godehusen, Richter and Zimmermann, 2003). The spectrum of Co/Pt(111) differs also from that of Co impurities deposited on free-electron metals, such as K, where the narrow XAS multiplet structure indicates that the Co ground state has d^8 atomic-like character (Figure 4c). In the latter case s-d charge transfer takes place, but the Co 3d states remain essentially localized with both m_S and m_L close to the integer Hund's rule limit (Gambardella *et al*., 2002b). On a transition metal surface such as Pt, on the other hand, the electron density is much larger and the impurity 3d-states can hybridize with both the s- and d-states of the substrate. This leads to a strong reduction of m_S and m_L compared to the vapor-phase. Owing to its reduced coordination, the impurity magnetic moment

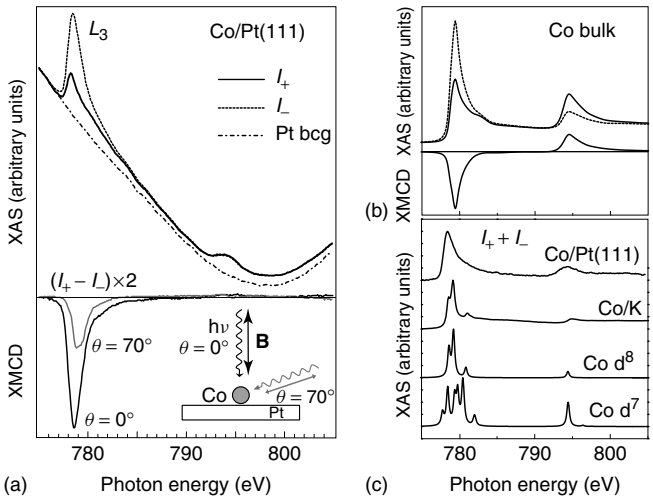

Figure 4. (a) $L_{3,2}$ XAS spectra of Co impurities (0.03 ML) deposited on Pt(111) recorded at $T = 5.5$ K, $\mathbf{B} = 7$ T with parallel (I_+) and antiparallel (I_-) alignment of the photon helicity with respect to $\mathbf{B}$ at an angle $\theta = 0^\circ$ relative to the surface normal. The Co XAS appears superimposed on the background signal of the Pt substrate (dotted line). The XMCD ($I_+ - I_-$) is shown at the bottom for $\theta = 0^\circ$ and 70°. (b) XAS and XMCD spectra of bulk Co. (c) Comparison between the total XAS ($I_+ + I_-$) after background subtraction for Co impurities on Pt(111), Co impurities on a K film, and the calculated XAS for atomic-like d^8 and d^7 configurations.

is nonetheless significantly enhanced with respect to 2D films (Tischer *et al*., 1995; Weller *et al*., 1995), supported nanoparticles (Dürr *et al*., 1999; Koide *et al*., 2001), and 1D

atomic chains (Gambardella *et al.*, 2002a). According to the XMCD sum rules, the vanishing intensity of the XMCD at the L_2 edge in Figure 4(a) compared, for example, to Figure 4(b) indicates that the largest enhancement is that of the orbital component of the magnetic moment, for which we get $m_L = 1.1 \pm 0.1\,\mu_B$.

The presence of strong orbital magnetism allows unusually large MCA through the spin-orbit interaction (Bruno, 1989; Dürr *et al.*, 1997). The MCA energy can be determined by means of XMCD by measuring the magnetization of the Co atoms in an external field applied along different directions with respect to the substrate normal, as shown in Figures 3(b) and 4(a). The solid lines represent fits of the data by means of numerical integration of the equation that describes the impurity magnetization in the presence of the applied field and uniaxial anisotropy energy (Gambardella *et al.*, 2003). For isolated impurities we have $K = 9.3 \pm 1.6$ meV per atom, a remarkable value compared to typical systems with high MCA such as $SmCo_5$ ($K = 1.8$ meV per Co atom Weller and Moser, 1999), Co/Pt and Co/Au multilayers ($K = 0.3$ meV, Nakajima *et al.*, 1998; Weller *et al.*, 1995). Different effects combine in establishing the giant MCA of Co atoms on the Pt surface. The main point is the reduced atomic coordination, which results into narrow 3d-electron bands localized at the impurity sites with augmented spin-orbit interaction due to the increase of the local density of states near the Fermi level (Bruno, 1989; Dürr *et al.*, 1997) and 3d–5d hybridization. Further, the Pt atoms close to Co are magnetically polarized and present an additional MCA due to the strong spin-orbit coupling of the Pt 5d-states. Theoretical calculations indicate the first effect to be dominant (Gambardella *et al.*, 2003) although the two contributions cannot be separated experimentally because of exchange coupling between the Co and Pt magnetic moments.

3.2 Magnetic moment and magnetic anisotropy in finite-sized particles

It is well-known that size effects in metal particles containing a nonnegligible ratio of surface to volume atoms influence the saturation magnetization and MCA properties in cluster beams (Billas, Chatelain and de Heer, 1994; Apsel, Emmert, Deng and Bloomfield, 1996; Knickelbein, 2001) as well as in surface-supported systems (Dürr *et al.*, 1999; Edmonds *et al.*, 1999; Koide *et al.*, 2001; Ohresser *et al.*, 2001; Lau *et al.*, 2002; Rusponi *et al.*, 2004; Bansmann *et al.*, 2005). Such effects become dominant as we reach down to nanometer dimensions. In this critical size regime, key questions are: how the MCA evolves from single atoms to finite-sized particles; how it correlates to atomic magnetic moments; and how both depend on the details of the atomic coordination. By exploiting the energetic hierarchy and temperature dependence of surface diffusion and nucleation processes, the bottom-up approach described in Section 2 allows us to study the development of the magnetization and MCA in magnetic particles constructed on a nonmagnetic substrate starting from isolated magnetic atoms and increasing the particle size almost in an atom-by-atom fashion. Following the previous section, we consider monolayer Co particles grown on Pt(111) as model system. While m_S is expected to vary in a fairly restricted range between 2.1 and 2.2 μ_B for an individual impurity (Gambardella *et al.*, 2003; Lazarovits, Szunyogh, Weinberger and Újfalussy, 2003) to 1.8–1.9 μ_B for a continuous 2D layer (Wu, Li and Freeman, 1991), since the majority spin band is almost filled in all cases, m_L is shown to be much more sensitive to changes in the atomic coordination, reflecting its closer link with the symmetry and

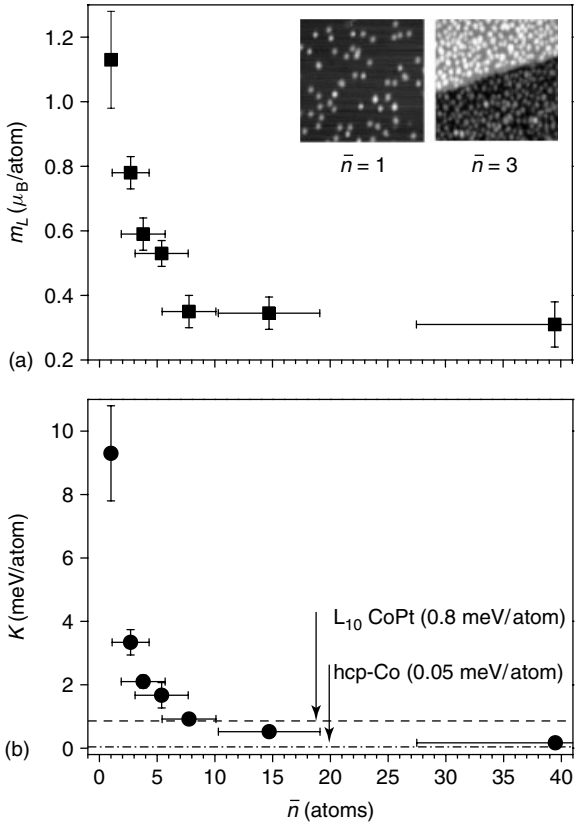

Figure 5. (a) Orbital magnetic moment of monolayer Co nanoparticles deposited on Pt(111) as a function of their average size measured along the easy magnetization direction ($\theta = 0^\circ$). (b) Magnetic anisotropy energy as a function of average particle size. The dashed and dashed-dot lines indicate the magnetic anisotropy energy per Co atom of the CoPt $L1_0$ alloy and *hcp*-Co, respectively. The error bars on the horizontal scale in (a) and (b) represent the standard deviation of the size distribution as determined by STM. The inset shows $180 \times 180\,\text{Å}^2$ STM images of Co impurities and particles with average size $\bar{n} = 1 \pm 0.1$ and 3 ± 1 atoms.

relative filling of different d-orbitals. Figure 5(a) reports the progressive quenching of m_L as a function of average particle size $\overline{n}$. Remarkably, the largest changes of m_L are observed for the smallest particles: for $\overline{n} = 3$ and 4 atoms, m_L has already reduced to 0.78 and 0.59 μ_B, respectively. The MCA energy, due to its spin-orbit origin (Bruno, 1989; Dürr *et al*., 1997), is found to be strongly correlated to the decrease of m_L (Figure 5b). Similar to m_L, drastic changes of K are observed for one-atom variations of the atomic coordination: for $\overline{n} = 3$ atoms, $K = 3.3$ meV amounts to only 30% of the individual impurity value, while already for $\overline{n} > 10$, K drops below the anisotropy energy of the equi-atomic CoPt alloy.

The trend evidenced in Figure 5(b) shows that a huge gain in MCA with respect to bulk or 2D films can be obtained by reducing the size of magnetic particles to a few tens of atoms or less on suitable substrates. Whereas this holds on a per atom basis, it is obvious that the overall stability of the particle magnetization is governed by the sum of the atomic MCA contributions. As more atoms are assembled together to fabricate particles with a large total magnetic moment and total MCA strong enough to stabilize ferromagnetic behavior against thermal fluctuations, this gain is countered by the decrease of K with increasing $\overline{n}$. The problem, however, can be circumvented by noting that the atomic coordination rather than the absolute particle size is the key parameter that governs the magnitude of K, m_L, and m_S. Nanostructures where the shape and composition are tuned so as to control the coordination of the magnetic atoms and maximize useful interface effects, such as in nanowires (Gambardella *et al*., 2002a, 2004) and core-shell particles (Rusponi *et al*., 2004), offer very interesting opportunities to exploit the effects highlighted in this section.

3.3 Magnetic moment and magnetic anisotropy in 1D atomic chains

The dependence of intrinsic magnetization properties on the atomic coordination gives rise to a very diverse magnetic behavior in metal systems that span the 1D–2D limit. As described in Section 2, epitaxial growth on stepped surfaces can be employed to fabricate arrays of nanowires whose thickness and separation are independently adjusted by controlling the coverage and vicinal angle of the substrate. A large number of parallel nanowires are obtained using this method, which allows to use spatially integrating techniques with magnetic sensitivity such as Kerr magnetometry and XMCD. This approach was first explored by Elmers *et al*. (1994) and Pratzer *et al*. (2001) in the study of Fe monolayer stripes grown on stepped W(110). This system presents in-plane anisotropy, scaling of the ordering temperature of each Fe stripe typical of a finite-sized 2D Ising lattice, and a relaxation-free ferromagnetic phase transition due to dipolar coupling across adjacent stripes (Hauschild, Elmers and Gradmann, 1998). Shen *et al*. (1997a,b) found a pronounced temperature- and time-dependent magnetic relaxation for mono- and bilayer Fe stripes on stepped Cu(111) with out-of-plane anisotropy, due to the formation of 1D Ising-coupled spin blocks. Fe stripes on vicinal Pd(110) also present perpendicular anisotropy (Li *et al*., 2001), but the magnetization was found to be time-independent. Recently, Co wires of monatomic thickness have been grown at the step edges of Pt(997) (Figure 2) (Gambardella *et al*., 2000, 2002a) and along the close-packed atomic rows of Pd(110) (Yan *et al*., 2005).

In the limit of atomically thin metal chains, *ab initio* electronic calculations predict large exchange splittings and strongly increased m_S and m_L relative to those of the bulk and 2D monolayers (Weinert and Freeman, 1983; Komelj, Ederer, Davenport and Fähnle, 2002; Ederer, Komelj and Fähnle, 2003; Spisák and Hafner, 2002; Lazarovits, Szunyogh and Weinberger, 2003; Shick, Máca and Oppeneer, 2004) as well as MCA energies exceeding 1 meV per atom (Lazarovits, Szunyogh and Weinberger, 2003; Hong and Wu, 2003, 2004; Újfalussy *et al*., 2004; Shick, Máca and Oppeneer, 2004). Similar to the case of individual impurities, these variations are attributed to the reduced overlap between the d-orbitals in 1D structures. Angle-resolved photoemission experiments on Co monatomic chains grown along the step edges of Pt(997) corroborate the prediction of large exchange splitting of the Co 3d states (2.1 eV Dallmeyer *et al*., 2000) compared to thin films (1.4–1.9 eV) and bulk Co (1.4 eV) (Schneider *et al*., 1990; Clemens *et al*., 1992), suggesting that m_S is of the order of 2 μ_B (Himpsel, Ortega, Mankey and Willis, 1998). XMCD measurements on the same system show that m_L is 0.68 μ_B in the monatomic chain limit, more than twice the value found for a Co monolayer on Pt(997), but drops already to 0.37 μ_B per atom in chains with biatomic thickness (Gambardella *et al*., 2002a). Such values can be rationalized within the trend framed in the previous section, where the average coordination among Co atoms determines large differences of m_L. On the basis of Figure 5(a), for instance, we expect $m_L \approx 0.7\,\mu_B$ per atom for $\overline{n} = 3$, that is, for Co atoms with an average of two Co neighbors, which corresponds to the Co coordination in the monatomic chains.

The sensitivity to the transverse structure of the chains concerns also the orientation of the easy axis and the magnitude of the MCA (Gambardella *et al*., 2004). In Figure 6, we report the magnetization of Co chains with different thickness measured in the plane perpendicular to the chain axis. The magnetization, measured near-remanence at angles θ with respect to the (111) direction, is typical of a uniaxial system and presents a sinusoidal behavior whose maximum indicates the orientation of the easy axis.

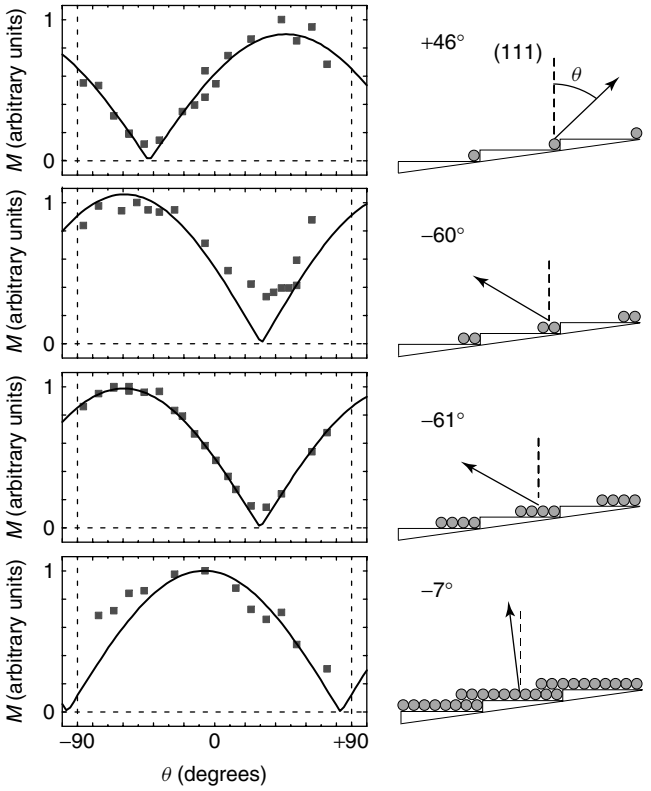

Figure 6. Near-remanence magnetization of Co chains deposited on Pt(997) as a function of the angle θ between the incident photon beam and (111) direction in the plane perpendicular to the chain axis. The data points represent the XMCD signal at the L_3 Co edge. The solid lines fit a $|\cos(\theta - \theta_0)|$ behavior as expected for uniaxial anisotropy. The diagrams indicate the chain thickness and the easy axis direction given by the maximum of the $|\cos|$ function.

In the monatomic chains the easy axis is canted toward the step-up direction due to the reduced symmetry at the Pt step edges, an effect that has been reproduced by first principles relativistic calculations (Újfalussy *et al*., 2004; Shick, Máca and Oppeneer, 2004). With increasing chain thickness unusual oscillations of the easy magnetization direction are observed in the plane perpendicular to the chains (Gambardella *et al*., 2004). The easy axis rotates abruptly from $\theta = +46^\circ$ in the monatomic chains to -60° in the biatomic chains and reverses back toward the surface normal in the monolayer limit as shown in Figure 6. The analysis of the easy and hard magnetization curves reported in Figure 7 reveals further that the magnitude of the MCA has a nonmonotonic behavior with chain thickness. In the monatomic limit $K = 2$ meV per atom at $T = 45$ K, a value enhanced by 1–2 orders of magnitude compared to 2D films (Gradmann, 1993), but in line with expectations based on theoretical calculations (Dorantes-Dávila and Pastor, 1998; Félix-Medina, Dorantes-Dávila and Pastor, 2002; Lazarovits, Szunyogh and Weinberger, 2003; Hong and Wu, 2003, 2004; Újfalussy *et al*., 2004; Shick, Máca and Oppeneer, 2004) and the experiments presented in the previous section. Given that in nanoparticles K is a rapidly decreasing function of the local coordination (Figure 5b), it is not surprising that K reduces to 0.33 meV per atom in the biatomic chains. In triple chains, however, K shows a significant and unexpected increment, upto 0.45 meV per atom, before decreasing again in the monolayer limit. These oscillations as well as the sign inversion of the MCA represented by the rotation of the easy axis appear to be due to thickness-dependent changes in the electronic band structure of the chains rather than to extrinsic (dipolar) effects (Gambardella *et al*., 2004; Vindigni *et al*., 2006), as shown also by tight binding calculations of both free-standing and Pd-supported Co chains one to three atoms thick (Dorantes-Dávila and Pastor, 1998; Félix-Medina, Dorantes-Dávila and Pastor, 2002). Reducing the dimensions of a magnetic layer down to 1D, therefore, reveals a nontrivial magnetic behavior and new opportunities to tune the magnetization properties in metal nanostructures. Examples include the high anisotropy of the 1D-modulated FePt surface alloy presented in Section 4 and the emergence of magnetism in chains of 4d and 5d metals (Bellini, Papanikolaou, Zeller and Dederichs, 2001; Spisák and Hafner, 2003; Rodrigues, Bettini, Silva and Ugarte, 2003).

3.4 Magnetic order in 1D atomic chains

The dimensionality of a magnetic lattice is known to affect not only local properties such as the magnetic moments and MCA but also its thermodynamic properties and in particular order–disorder magnetic phenomena. Ferromagnetism in 2D films is typically more sensitive to temperature-induced fluctuations of the magnetization compared to 3D systems due to the reduced number of atoms contributing to the total exchange interaction (Gradmann, 1993; Schneider and Kirschner, 2000; Poulopoulos and Baberschke, 1999). In the well-known case of the Heisenberg and Ising models, the thermodynamic limit of a 1D spin chain of infinite length is characterized by the absence of long-range magnetic order at any nonzero temperature (Ising, 1925; Mermin and Wagner, 1966; Bruno, 2001). In the past, quasi-1D insulating inorganic crystals have been investigated as Heisenberg model systems to test predictions about magnetism in 1D (De Jongh and Miedema, 1974; Hone and Richards, 1974); typical examples include tetramethylammonium copper and manganese chloride compounds, where Cu^{2+} and Mn^{2+} ions couple ferromagnetically or antiferromagnetically, respectively, along weakly interacting linear chains separated by intervening nonmagnetic complexes (Dingle, Lines and Holt, 1969; Landee and Willett, 1979; Dupas, Renard, Seiden

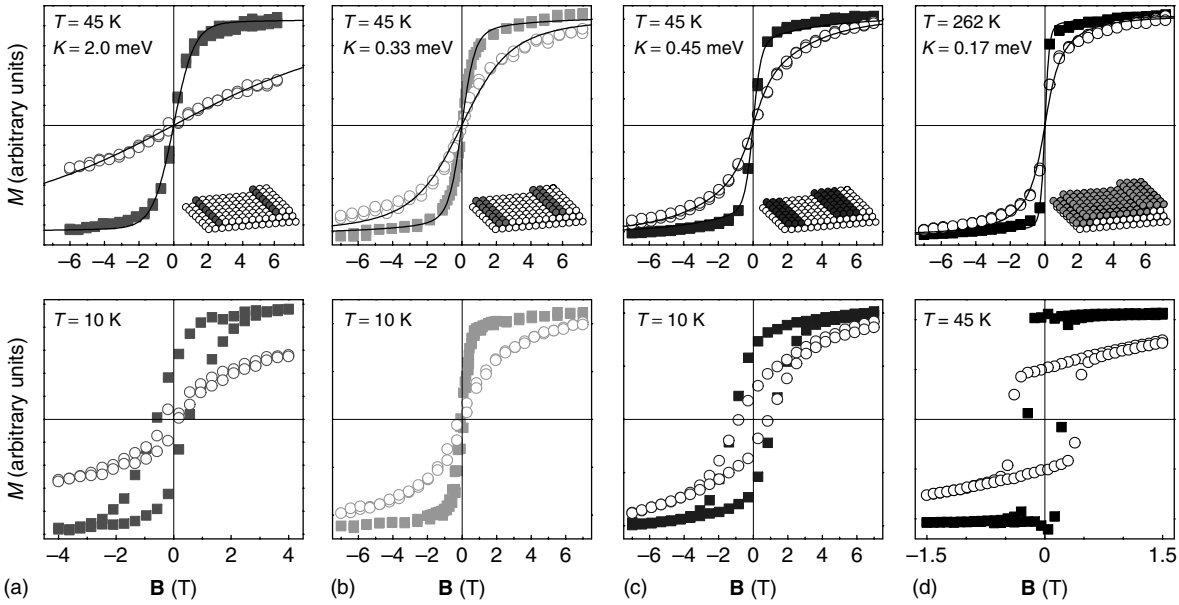

Figure 7. Magnetization of (a) monatomic Co chains, (b) double chains, (c) triple chains, (d) 1.3 monolayers in the easy (filled squares) and hard direction (empty circles). The data points represent the XMCD intensity at the Co L_3 edge as a function of applied field. The solid lines in the top panels are fits of the data in the superparamagnetic regime as described in Gambardella *et al*. (2002a).

and Cheikh-Rouhou, 1982). More recently, the synthesis of molecular ferri- and ferromagnetic chainlike compounds containing magnetically anisotropic ions has allowed to realize 1D Ising model systems where the absence of permanent magnetic order is accompanied by the slow relaxation of the magnetization (Caneschi *et al*., 2001; Bogani *et al*., 2004; Clérac, Miyasaka, Yamashita and Coulon, 2002; Lescouëzec *et al*., 2003) as predicted by Glauber more than 40 years ago (Glauber, 1963). The fabrication of 1D chains of magnetic atoms deposited on a nonmagnetic substrate with the methods described in Section 2 opens up the possibility of extending the investigation of 1D magnetic behavior to metal systems.

The magnetic response of a set of monatomic Co chains at $T = 45$ K (Figure 7a) reveals zero remanent magnetization and the absence of long-range ferromagnetic order. The shape of the magnetization curves, however, indicates the presence of short-range order, that is, of significant interatomic exchange coupling in the chains (Gambardella *et al*., 2002a; Vindigni *et al*., 2006). The observed behavior is that of a 1D superparamagnetic system, that is, a system composed by segments, or spin blocks, each containing N exchange-coupled Co atoms, whose resultant magnetization orientation is unstable due to thermal fluctuations. Fitting the magnetization curves assuming uniaxial MCA and a Boltzmann distribution of the energy states accessible by the system (solid lines) gives the average value $N = 15$ atoms, smaller than the average length of the Co chains, which is estimated to be about 80 atoms from the extension of the atomically straight sections of the Pt steps that act as deposition template. A simple argument of Landau (Landau and Lifshitz, 1959) shows that this result does not contradict the predicted absence of magnetic order in 1D by spin lattice models as long as $N \leq e^{2J/kT}$, where J represents the exchange interaction among adjacent spins ($J \approx 15$ meV Frôta-Pessoa, Muniz and Kudrnovský, 2000; Pratzer *et al*., 2001). However, by lowering the sample temperature below 15 K, we observe a transition to a ferromagnetically ordered state with long-range order and finite remanence at zero field (Figure 7a, bottom panel). This order transition is not dominated by the exchange interaction as in 3D crystals, but rather by the presence of large MCA energy barriers that effectively inhibit the spin fluctuations that lead to the zero remanence thermodynamic limit expected for 1D systems. Below the blocking temperature the magnetization of each spin segment aligns along the common easy axis direction and the system becomes ferromagnetic on a macroscopic scale. Long-range order in 1D metal chains therefore appears as a metastable state, thanks to slow magnetic relaxation. It is interesting to note that as the system evolves toward a 2D film and the number of exchange-coupled Co atoms increases (Figure 5b), we would expect a stronger tendency toward magnetic order. Contrary to expectations, however, in the biatomic chains we observe vanishing long-range magnetic order even at low temperature (Figure 5b). In this case, the tendency toward order is counteracted by the drastic reduction of the MCA energy per Co atom. Paradoxically, therefore, the 1D character of the monatomic chains favors rather than disrupts

ferromagnetic order owing to the minimal coordination of the Co atoms and related enhanced MCA.

4 TOWARD TWO-DIMENSIONAL MAGNETIC STRUCTURES

It is commonly believed that, of all 3d elements, the magnetism of Fe based nanostructures depends the most on the local atomic environment and the interaction with the underlying substrate. This is due to the fact that Fe is a 'borderline ferromagnet' with an exchange interaction sensitively depending in magnitude and sign on the structure at the atomic level (Pajda *et al*., 2000, 2001; Bruno and Sandratskii, 2005). Being a weak ferromagnet, the presence of empty states at the Fermi energy in the minority and majority subband results in a complex dependency of the magnetic properties on the d-band width and occupation, which are controlled by the local atomic coordination. As constructed from Hund's rules, free Fe atoms in the $3d^6 4s^2$ ground state possess spin- and orbital moments of $m_S = m_L = 2\,\mu_B$. In the bulk phase the electron hybridization quenches the orbital moment to $m_L = 0.1\,\mu_B$ (Chen *et al*., 1995). Low-dimensional Fe nanostructures at surfaces are useful to address open questions about the magnetic anisotropy on the atomic level. Of particular interest in the following sections are changes in the magnetism with dimensionality during the crossover from 1D Fe monatomic wires to a 2D Fe or FePt monolayer. As seen in Section 3, the interaction with the substrate has also a decisive influence on the magnetism and can be exploited to tune many of the magnetic properties in low-dimensional structures. The traits of Pt – large Stoner-enhanced susceptibility together with the strong spin-orbit coupling of the 5d states – make it an attractive substrate material for magnetic nanostructures. In contact with 3d magnetic elements Pt acquires a sizable magnetic polarization and gives an important contribution to the magnetocrystalline anisotropy. The role of the substrate will be discussed in the following for all investigated Fe structures, but becomes most apparent for FePt surface alloy layers.

4.1 Fe on Pt – from atomic chains to layered films

Since the early experiments on Fe stripes of finite width prepared on W(110) by Elmers *et al*. (1994) 1D linear Fe nanostructures have been prepared successfully also on vicinal Au (Kawagoe, Sogabe, Kondoh and Narusawa, 1998; Shiraki, Fujisawa, Nantoh and Kawai, 2004, 2005), Cu (Shen *et al*., 1997b; Boeglin *et al*., 2002; Fruchart *et al*., 2004) or Si substrates (Lin *et al*., 2001), on reconstructed Ir surfaces (Klein, Schmidt, Hammer and Heinz, 2004), or by organic patterning (Ma *et al*., 2004). Also on the vicinal Pt(997) surface, Fe shows a strong tendency toward substrate step decoration. Fe atoms arrange themselves to segments of atomic chains at the step edges at growth temperatures between 200 K and 450 K (Lee, Sarbach, Kuhnke and Kern, 2006). Extended monatomic chains of Fe are thus formed at a coverage of $\Theta_{Fe} = 0.13$ monolayer (ML) limited in length only by kinks at step edges or by point defects. The wire formation is, hence, in analogy to the Co chains described in the previous chapter. After complete step decoration, the growth proceeds in the step flow mode until the first Fe monolayer is completed. The layer-wise growth is promoted by the presence of the dense array of substrate steps (Lee, Sarbach, Kuhnke and Kern, 2006).

The evolution of the magnetic anisotropy of Fe stripes with increasing stripe width shows distinctive differences to the Co chains presented in the previous section. The XMCD data in Figure 8 reveal that for a coverage corresponding to 1 atomic row in (a) the preferred magnetization direction is perpendicular to the wire axis, but close to the substrate surface. With increasing coverage the magnetization axis reorients gradually toward the out-of-plane direction. For a coverage corresponding to 3 atomic rows in (b) no distinctive difference between out-of-plane and in-plane magnetization loops is visible, while for 6 rows in (c) the easy magnetization axis points out of the surface plane. For all samples investigated, the in-plane axis along the wire represented the hard magnetization direction. The comparison with Co allows for two important conclusions: (i) In both systems

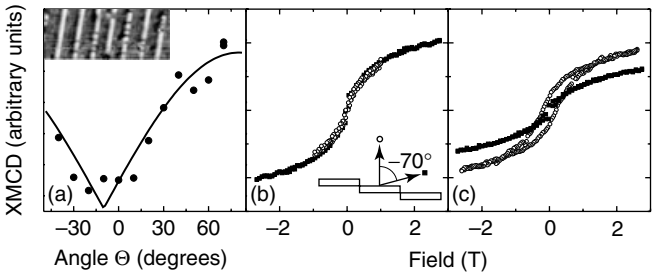

Figure 8. XMCD measurements taken at the Fe L_3 absorption edge as a function of field at 10 K of (a) 0.13 ML Fe (monatomic Fe chain) as a function of polar angle Θ in a constant magnetic field of 1 T. The solid line is a $|\cos(\Theta - \Theta_0)|$ – fit to the data. (b) Hysteresis loops of 0.38 ML Fe (3 atomic stripe), and (c) 0.8 ML (6 atomic stripe). Measurements are taken along the surface normal (o) and under a polar angle of 70° in the direction perpendicular to the step edges (■). A reorientation of the preferred magnetization axis from in-plane perpendicular to the step edges (a) toward perpendicular to the surface (c) occurs with increasing Fe coverage. Inset: STM image of 0.11 ML Fe/Pt(997) showing the wire formation by step decoration.

a preferred magnetization perpendicular to the chain axis is found. Whereas Co chains exhibit an oscillatory reorientation of the magnetization with increasing width, Fe chains rather show a gradual transition from in-plane to out-of-plane magnetization. Complete Fe and Co monolayers have an easy axis close to the sample normal. (ii) The MCA in Fe single atomic chains is 0.56 meV per atom, as determined from fits to angular dependent hysteresis loops. This value is significantly enhanced with respect to the Fe bulk value, but smaller compared to Co chains of equal thickness ($\sim$2 meV per atom, see previous section). Unlike in Co, the MCA of monatomic Fe chains is not sufficient to stabilize remanent magnetization at 10 K, in contrast to Co. In both systems the enhanced MCA goes along with an increase of the orbital moment per atom with respect to bulk, as will be discussed later in this section.

Ab initio electron theory suggests strong similarities in the physics of Co and Fe monatomic chains (Ederer, Komelj and Fähnle, 2003; Shick, Máca and Oppeneer, 2005). The observed ferromagnetic ordering and the enhanced magnetic moments have been predicted theoretically for free and supported atomic chains of Fe (Spisák and Hafner, 2002; Dorantes-Dávila and Pastor, 1998; Lazarovits, Szunyogh, Weinberger and Újfalussy, 2003; Jin, Kim and Lee, 2004). The easy magnetization axis is found perpendicular to the wire axis in all published calculations, as a result of strong Fe–Fe bonds along the chains and the resulting intrachain exchange coupling in this direction. However, the calculated tilt angle of $+30^\circ$ to the surface normal (Shick, Máca and Oppeneer, 2005) is in contrast to our experiment. The calculated tendency of the magnetization to be perpendicular to the Fe–Fe bonding direction may explain the reorientation of the easy axis toward out-of-plane when increasing the Fe coverage above the monochain coverage. Already for chains of 2 atoms in width the intrawire coupling strength perpendicular to the wire axis is of the same order of magnitude as found along the wire (Lazarovits, Szunyogh, Weinberger and Újfalussy, 2003). The intra- and interchain magnetic coupling exceed the dipolar interaction by 2 orders of magnitude and thus dominate the magnetic anisotropy (Spisák and Hafner, 2002). The dipolar interaction would favor ferromagnetically ordered arrays of wires with an in-plane magnetization direction along the wires, which is clearly not observed.

It is important to note that the interaction with the substrate affects the MCA of the wires. This can be seen from a comparison of the experimental data with calculations on free wires which show preferred magnetization *along* the wire axis (Dorantes-Dávila and Pastor, 1998). The role of the substrate is to contribute its spin-orbit coupling to the whole system, thus increasing the total MCA (Dorantes-Dávila and Pastor, 1998), to alter the density of states at the Fermi level (Lazarovits, Szunyogh, Weinberger and Újfalussy, 2003), and possibly to establish interchain coupling by RKKY interaction via intervening substrate sp-electrons (Spisák and Hafner, 2002). The induced magnetic moment in the substrate surface, and thus the substrate contribution to the overlayer magnetism, is one order of magnitude larger for Pt substrates than for Cu substrates (Ederer, Komelj and Fähnle, 2003; Lazarovits, Szunyogh and Weinberger, 2003). Details of the film-substrate interaction will be discussed in the next section.

Further investigation of the magnetism of Fe/Pt(997) in the thickness range between 0.5 and 5 atomic layers shows the evolution of the anisotropy for this system during the transition toward 2D layers (Figure 9). The system has a perpendicular easy magnetization axis up to a film thickness of 3 ML. The reorientation of **M** into the film plane occurs gradually between 2.6 and 3 ML via a canted magnetization state. The spin reorientation is accompanied by a structural transition from fcc(111) to bcc(110) layers with Kurdjumov–Sachs orientation to the substrate. Above 3 ML coverage the easy axis is found within the plane in the direction along the substrate steps. Perpendicular to the steps only hard axis loops with no remanence are found. The strong in-plane anisotropy is attributed to peculiarities of the bcc

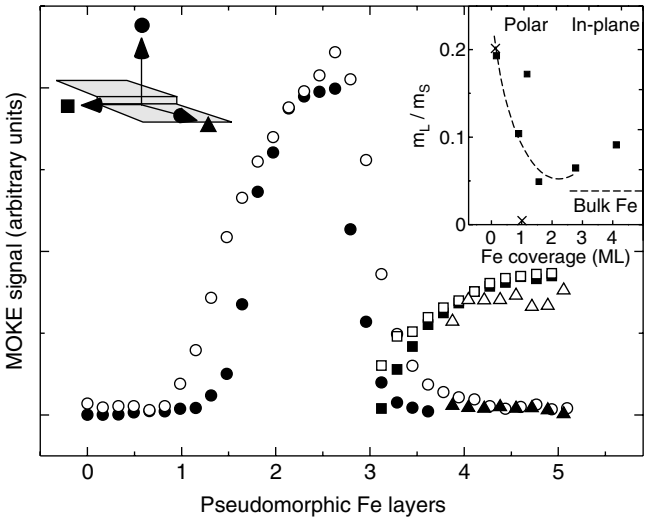

Figure 9. Evolution of the easy magnetization axis for 2D Fe films on Pt substrates with Fe coverage. Open and solid symbols correspond to the saturation and remanent magnetization as obtained from MOKE hysteresis loops at 300 K. A spin reorientation from perpendicular to in-plane direction is observed at the critical thickness of $t_{crit} = 2.8$ atomic layers. Above t_{crit} the films show pronounced in-plane anisotropy with the easy axis along the step edges. Inset: For films thinner than 1 atomic layer the ratio m_L/m_S (from XMCD measurements) increases in favor of larger m_L values, in qualitative agreement with calculations ($\times$, from reference Ederer, Komelj and Fähnle, 2003).

structure of the film in this thickness range (Repetto *et al*., 2006). It is interesting to note that Fe films on Pt(100) substrate, in contrast, do not show perpendicular magnetization at any thickness (He *et al*., 2005). The occurrence of perpendicular magnetization in the monolayer thickness range is commonly ascribed to anisotropy contributions arising at the film's interfaces (see recent overview articles on this field, such as Gradmann, 1993; Shen and Kirschner, 2002; Sander, 2004). More detailed analysis connects the perpendicular magnetic anisotropy of this system with the strong film–substrate interaction. The bonding to the substrate in surface normal direction – which is particularly large for Pt substrates – disturbs orbital motion of the electrons perpendicular to the film plane and significantly increases the bandwidth in this direction, thus promoting perpendicular magnetization (Wang, Wu and Freeman, 1994; Stöhr, 1999). The choice of substrate material and the local atomic arrangement within the nanostructures has decisive influence on the magnetic anisotropy, a fact that will be illustrated more profoundly in the following section.

The measurement of the ratio of orbital to spin magnetic moment reveals an enhancement of the ratio m_L:m_S by a factor of 5 when going from bulk to monatomic chains (see inset in Figure 9). This increase is completely attributed to m_L since below 1 ML Fe coverage m_S is expected to change only slightly (Ederer, Komelj and Fähnle, 2003). In analogy to the discussion of Co clusters in the previous chapter the large m_L is explained by the unquenching of orbital electron motion due to decreased coordination. The latter results in more localized d-bands, and therefore in an increased density of states at E_F and in enhanced moments of the d-electrons. In addition, the exchange splitting between majority and minority electrons is large not only for d-bands but also for sp-bands (Spisák and Hafner, 2002), which may result in sizeable additional contributions to the overall magnetic moment. The minimum in m_L:m_S observed for 1 ML Fe is in qualitative agreement with first principles calculations for Pt-supported fcc(111) Fe monolayers which predict a minimal m_L at this coverage (Ederer, Komelj and Fähnle, 2003).

4.2 High coercivity FePt surface alloy

In Section 3, we elaborated on the importance of high magnetocrystalline anisotropy energy for establishing ferromagnetism in low-dimensional systems. Indeed, nanostructured materials with MCA beyond $10^8\,\mathrm{erg\,cm^{-3}}$ (>1 meV per atom) are being considered for upcoming high-density storage media. Thin films (Yan, Zeng Powers and Sellmyer, 2002; Kanazawa, Lauhoff and Suzuki, 2000; Okamoto *et al*., 2002), multilayers (Johnson, Bloemen, den Broeder and de Vries, 1996), and nanoparticles (Sun *et al*., 2000; Okamoto *et al*., 2002) of intermetallic phases exhibiting the $L1_0$ structure, such as the FePt alloy, fulfill this requirement and are currently in the focus of experimental and theoretical research (2005). The $L1_0$ structure is obtained by alternative stacking of fcc(100) oriented layers of two different materials, such as 3d and 5d elements. Currently, the high anisotropy of FePt alloy is described as the result of 3D coordination of Fe atoms with Pt neighbors. The exchange interaction between Fe atoms across adjacent fcc(100) layers, and hence the 3D nature of the alloy, is considered to be important for large MCA. A key role is played by the induced magnetism in Pt which gives additional MCA contributions due to its large spin-orbit interaction (Ravindran *et al*., 2001). Tetragonal lattice distortion and chemical disorder are found to give access not only to the magnetic anisotropy energy but also to the Curie temperature T_C, exchange interaction J, or saturation magnetization M_S. In this section, we demonstrate on the example of 2D $Fe_{50}Pt_{50}$ surface alloys that the $L1_0$ structure is not required to obtain a large anisotropy. The coordination of Fe with Pt atoms in monolayer thin films increases the MCA so that values close to bulk FePt could be measured (Honolka *et al*., unpublished).

$Fe_{50}Pt_{50}$ surface alloys are obtained by deposition of 0.5 atomic layers of Fe on the Pt(997) substrate at 525 K. The thermally activated diffusion of Fe into the Pt terraces results in the formation of monatomic chain segments of Fe embedded in the Pt surface (Lee, Sarbach, Kuhnke and Kern, 2006), similar to surface alloying of Fe on Pt(111) (Schmid and Varga, 2002). The average spacing between Fe chain segments depends on the amount of deposited Fe and is 5.54 Å (two Pt row spacings) for the idealized $Fe_{50}Pt_{50}$ surface alloy. The element specificity of the XMCD is ideal for probing the magnetism of the Fe and Pt sublattices separately. Typical XAS and XMCD spectra at the Fe $L_{3,2}$ and the Pt $N_{7,6}$ absorption edges are displayed for $Fe_{50}Pt_{50}$ in Figure 10(a). A large dichroic signal was detected at both absorption edges. The presence of a dichroic signal for Pt is the result of an induced magnetic moment due to the hybridization between Fe 3d and Pt 5d states. The existence of a magnetic moment in Pt evidences ferromagnetic coupling between the Fe chains. Antiferromagnetic ordering of the Fe moments would rather result only in negligible Pt moments (Skomski, Kashyap and Sellmyer, 2003; Skomski, Kashyap and Zhou, 2005). The sign relationship of the XMCD signals at the Fe $L_{3,2}$ and the Pt $N_{7,6}$ absorption edges reveals parallel spin alignment of the Fe and Pt sublattices (Shishidou *et al*., 1997). The coupled magnetization of Fe and Pt results in congruent *M-H* magnetization loops which are obtained at each constituent's absorption edge (Figure 10b and c). The preferential magnetization axis is along the surface normal. The large coercive field of $H_C = 0.71$ T is of the same order

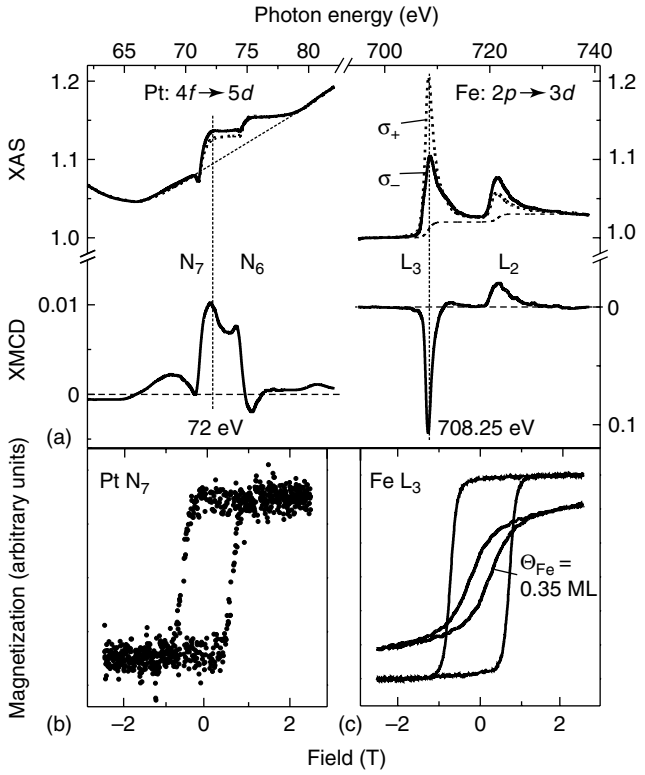

Figure 10. (a) X-ray absorption and XMCD spectra at the Pt $N_{7,6}$ and the Fe $L_{3,2}$ absorption edges of a single, two-dimensional $Fe_{50}Pt_{50}$ surface alloy layer. (b) and (c) The dichroic signal was used to obtain element-specific hysteresis loops of the Fe and Pt sublattice of the same film at 12 ± 1 K. The hysteresis loop of the Fe sublattice is compared to the Fe L_3 loop of a diluted $Fe_{35}Pt_{65}$ monolayer.

of magnitude as the values found for the bulk FePt $L1_0$ phase and demonstrates the presence of a considerable anisotropy energy barrier.

From the XMCD spectrum in Figure 10(a) a total spin moment of $(2.4 \pm 0.2)\mu_B$ per Fe atom is determined. This experimental value is 18% smaller than theoretically predicted Fe moments of $2.93\,\mu_B$ (Staunton *et al.*, 2004a) and $2.92\,\mu_B$ (Kashyap *et al.*, 2004). The determination of the Pt moment from the N-edge dichroism provides a challenge to theorists since the interaction between discrete-like and continuum states during the 4f → 5d dipole transition leads to a Fano-type interference effect and have to be treated accordingly (Shishidou *et al.*, 1997). As a lower limit, a Pt moment of $>0.2\,\mu_B$ per Pt atom is estimated from a comparison of the normalized XMCD signals with $CoPt_3$ bulk samples where the Pt moment is known (Menzinger and Paoletti, 1966). This value is close to calculated Pt spin moments of $0.24\,\mu_B$ per atom in the top layer of Pt(111) covered by one monolayer of Fe (Ederer, Komelj and Fähnle, 2003), and of $0.29\,\mu_B$ (Staunton *et al.*, 2004a) and $0.35\,\mu_B$ (Kashyap *et al.*, 2004) in $L1_0$ ordered FePt. However, at Co/Pt interfaces an induced spin moment as large as $0.53\,\mu_B$ per Pt atom has been determined from XMCD measurements at the Pt $L_{2,3}$ edge (Suzuki *et al.*, 2005).

The MCA of the surface alloy is calculated from angular dependent XMCD measurements to $K = 0.42$ meV per formula unit. Strikingly, this value for the alloyed monolayer is only about a factor of 2–3 smaller than 0.6–1 meV per atom which is typically found for FePt-$L1_0$ bulk samples (Shima, Moriguchi, Mitani and Takanash, 2002; Shima, Takanashi, Takahashi and Hono, 2002; Farrow *et al.*, 1996). As was mentioned already in the preceding text, the MCA is usually related to the orbital moment anisotropy, Δm_L (Bruno, 1989). For the $Fe_{50}Pt_{50}$ surface alloy we determined $\Delta m_L^{alloy} = m_L^{\perp} - m_L^{||} = 0.025 \pm 0.004\,\mu_B$ per hole. This value is close to the measured orbital anisotropy of nonalloyed Fe adlayers on Pt(997) of similar Fe content, $\Delta m_L^{stripe} = 0.035 \pm 0.009\,\mu_B$ per hole. This experimental observation has important implications for the interpretation of the origin of the MCA in alloys, as will be shown in the following text. It is worth to note that both experimental values are by a factor of 2 larger than calculated values, as for instance, in Solovyev, Dederichs and Mertig (1995).

The comparison of the hysteresis loop of $Fe_{50}Pt_{50}$ with those of nonalloyed submonolayer Fe stripes in Figure 8 shows that the alloy has a much stronger tendency toward magnetic ordering, together with a significantly enhanced coercivity. A key role for the conservation of the saturation magnetization in remanence observed for the 2D alloy, and more importantly for the large anisotropy, is obviously played by the magnetism of the Pt atoms. Although the induced exchange splitting in Pt is much weaker than in bulk Fe, its spin-orbit coupling is one order of magnitude larger ($\xi_{Pt} = 0.6$ eV Misemer, 1988 vs $\xi_{Fe} = 0.07$ eV Mackintosh and Andersen, 1980). In result, the Pt orbital moments are expected to be comparable to those of Fe (comparable also to induced Pt orbital moments in the vicinity of Fe chains, $m_L \approx 0.04\,\mu_B$ Ederer *et al.*, 2003). In this simple but quite instructive picture the Fe acts only as the source of magnetization, whereas the Pt sublattice, owing to its large spin-orbit interaction, provides the main contribution to the large MCA. Attempts have been made to express the MCA of binary and multicomponent systems by the sum of the magnetic anisotropy of each constituent (Ravindran *et al.*, 2001; Solovyev, Dederichs and Mertig, 1995). This means that the total MCA is made large by the spin-orbit coupling of the Pt, while the orbital anisotropy of Fe alone remains unchanged – something that our experimental values in the preceding text show. Support of this viewpoint comes from calculations, showing that suppressing the spin-orbit interaction in the 4d/5d constituent reduces the calculated

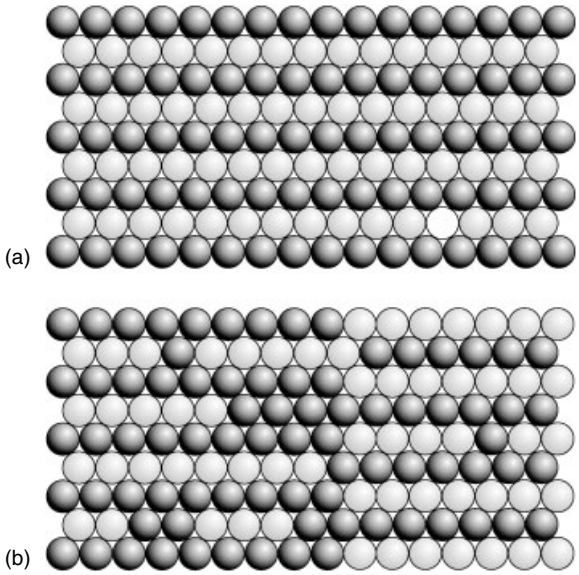

Figure 11. Ordered (a) and disordered (b) structure of a linear, two-dimensional FePt surface alloy. Fe and Pt atoms are represented by dark and bright colors. Deviations from the ideal structure result mostly in ferromagnetic interchain bridges, which promote ferromagnetism in the Fe sublattice and reduce the in-plane anisotropy.

total anisotropy (Burkert *et al*., 2005; Daalderop, Kelly and Schuurmans, 1990).

As has been discussed by several authors, the description of MCA is complicated by chemical disorder (Brown *et al*., 2003; Skomski, Kashyap, Zhou 2005; Okamoto *et al*., 2002; Staunton *et al*., 2004b; Sun *et al*., 2000; Burkert *et al*., 2005), tetragonal distortion (Ravindran *et al*., 2001; Brown *et al*., 2003; Burkert *et al*., 2005), dimensionality, local atomic coordination, and crystal field asymmetry (Ravindran *et al*., 2001). For the surface alloys in this section the chemical disorder, that is, 3d and 5d substitutions as schematically shown in Figure 11(b), plays an important role. Fe atoms in antisite positions bridge the Pt chains and are found to stabilize ferromagnetic ordering of the Fe sublattice, which is predicted to be antiferromagnetic in the ideal structure as in Figure 11(a) (Brown *et al*., 2003). Such disorder can also be assumed to reduce the in-plane magnetic anisotropy of the alloy drastically, as was found experimentally (Honolka *et al*., unpublished).

The experiments point out that the coordination of Fe atoms with Pt, along with strong covalent 3d–5d hybridization, is necessary to achieve large MCA. The importance of Fe-Pt coordination is demonstrated by comparing the hysteresis loop of the $Fe_{50}Pt_{50}$ surface alloy with that of a Fe-poor, diluted $Fe_{35}Pt_{75}$ surface alloy (Figure 10c). Reducing of the Fe concentration by only 30% results in S-shaped loops with the remanence reduced by 78% and the coercivity by 68%. The shape of the loop is similar to the magnetization curve of the nonalloyed Fe stripe in Figure 8(c), for which full spin alignment has only been achieved in external fields of $H > 6$ T. One can say that the increased average spacing between Fe atoms destabilizes the magnetization. It leads on the one hand to narrower Fe d-bands, and in consequence to reduced hybridization and smaller anisotropy. On the other hand, separation of Fe chains by more than one Pt covalent radius significantly decreases the induced net moment in Pt (Ederer, Komelj and Fähnle, 2003) and hence diminishes the Pt's contribution to the magnetism of the surface layer. This is consistent with the observation that Fe-poor FePt bulk alloys exhibit reduced stability of the ferromagnetic order (Brown *et al*., 2003).

5 CONCLUSION

With the ability to control the fabrication of 0D, 1D, and 2D structures of 3d metals by self-organized growth we are capable to study magnetic phenomena in solid-state systems with atomic scale control over their size and crystalline structure. Co and Fe structures of reduced dimensionality reveal a strikingly rich magnetic behavior. Impurity atoms of Co on Pt surfaces have extraordinarily large MCA values and spin and orbital moments halfway between the values of free atoms and bulk Co. The MCA is decreasing with increasing Co coordination when forming small clusters or chains, but still sufficiently large in monatomic Co chains to stabilize a ferromagnetic long-range ordered state at finite temperature. The effect of local atomic coordination on the magnetism of Co and Fe manifests itself in the observed fluctuations of the easy axis with increasing stripe width, as well as in strong orbital magnetism. In all structures investigated a key role is played by the supporting substrate. Pt is found to contribute to the nanostructure's MCA via strong electronic hybridization and even dominates the magnetic anisotropy in the FePt surface alloy. An important consequence of the hybridization is the induced magnetization in Pt.

The basic experiments presented in this chapter contribute to a fundamental understanding of the magnetic properties of finite-sized particles. These results further elucidate the interplay between local coordination, orbital magnetism, and magnetic anisotropy. The link is provided by the electronic structure of the d-states, which sensitively responds to the local atomic arrangement, that is, the number and the electronic nature of the neighboring atoms as well as their interatomic spacing. This knowledge is not only of importance for testing detailed theoretical models used in the prediction and interpretation of magnetic phenomena but also for the conceptual design of nanosized magnetic structures that elude the superparamagnetic limit. In this context, our data show that particles containing only about 400 Co atoms

can behave as ferromagnets at room temperature. Besides the geometry of the atomic arrangement, additional leverage on the magnetic properties is obtained from the choice of the material of the coordinating atoms. When forming a binary alloy the overall magnetism strongly depends also on the nonmagnetic constituent. This is particularly true for nanostructures, such as for the FePt surface alloy, where the low-coordinated Pt atoms acquire a sizeable magnetic moment and contribute with their large spin-orbit coupling to the total magnetic anisotropy.

The work presented in this chapter has only just opened the door toward complex and functional nanostructure networks. Expanded and highly ordered 2D and even 3D networks of nanoscale building blocks can be fabricated by self-organized growth, aided by functionalized molecules, biotemplates or in combination with top-down approaches. It is expected that magnetic nanostructures will play a key role to add functionality to such structures by exploiting their magnetic moments and magnetic ordering associated with magneto-transport or quantum effects. Future experiments may show and exploit ferromagnetism in nanostructures of elements which are nonmagnetic in the bulk, thus opening up additional possibilities. At the frontiers to atomic and nanometer scale structures we will enjoy virtually unlimited avenues for research and promising chances for applications in the near future.

Magnetism of Low-dimensional Systems: Theory

Stefan Blügel and Gustav Bihlmayer
Institut für Festkörperforschung, Jülich, Germany

1 INTRODUCTION

We explore the magnetic ground-state properties of low-dimensional systems to investigate which systems are magnetic, what is the magnetic ground-state structure, and what is the orientation of the magnetization with respect to the crystal lattice.

In this article we focus on the dimensional aspect of itinerant magnetism, in particular, of those systems including d electrons, as relevant for the magnetic ground-state properties of metallic interfaces, multilayers, ultrathin films, step edges, wires or chains, or magnetic clusters deposited on surfaces. Considering the vast number of possible systems – a number growing fast with the number of constituent atoms – the surface or interface orientation, the chemical and structural roughness at interfaces, and the electronic nature of the substrate (metal, semiconductor, insulator), an exhaustive review is unattainable. Instead we discuss chemical trends in order to develop an intuition helpful to understand new systems or envisage new effects that have not been investigated yet.

The simplest low-dimensional systems are isolated atoms, whose spin moments as a function of the number of d electrons are well described by Hund's first rule: the spins of all electrons are aligned in parallel up to a maximum value of $S_z = 5/2$. Thus, nearly all of the 30 transition-metal atoms have magnetic spin moments. The largest possible d moments occur at the center of each series, that is, $5\,\mu_B$ for Cr and Mn in the 3d series. On the other hand, it is well known that only 5 of 30 transition metals remain magnetic in their bulk crystalline phase: Co and Ni are ferromagnetic (FM), Cr is antiferromagnetic (AFM), and Mn and Fe are FM or AFM depending on their crystal structure (cf. Figure 1). Low-dimensional transition metals should fall in between these two extremes. A magnetic material that is nonmagnetic as bulk metal but magnetic as nanostructure may be envisaged. Although these arguments do apply, band narrowing, charge transfer, lift of degeneracies, structural, morphological, or thermodynamical changes mire the interpolation and it took about 10 years to settle the 'relatively simple' problem of the surface magnetism of Ni(100) (Donath, 1994). The magnetic coupling between the moments of atoms in systems of reduced dimensions is totally unclear, in particular if the frustration of the magnetic interactions comes into play as for example in exchange-bias systems.

The magnetic ground-state properties may be divided into (i) the formation of local spin and orbital moments of different sizes, (ii) the interaction between the local moments responsible for the formation of the magnetic order, the magnetic coupling at interfaces or across spacer layers, and (iii) the magnetic anisotropy energy (MAE), which couples the direction of the magnetization to the lattice and determines the easy and hard axes of the magnetization. At this point it may be useful to put the magnetic energies involved

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

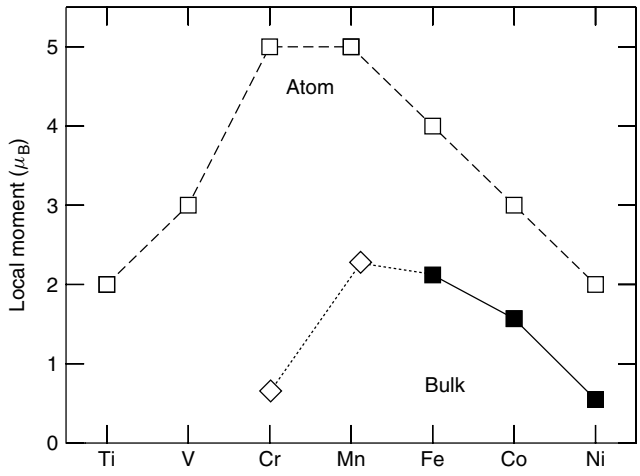

Figure 1. Local spin magnetic moments of isolated 3d atoms (empty squares connected by dashed line), ferromagnetic (solid squares connected by solid line) and antiferromagnetic (diamonds connected by dotted line) 3d bulk metals. The magnetism of the atom includes only the moment due to the d electrons. For the bulk metals, the experimental spin moments are shown.

Table 1. Typical ground-state energies E in eV/atom for 3d metal films.

	E (eV/atom)
Cohesive energy	5.5
Local moment formation	1.0
Alloy formation	0.5
Magnetic order	0.2
Structural relaxation	0.05
Magnetic anisotropy	$0.0001 \div 0.002$

in (i)–(iii) into a general perspective by comparing them in Table 1 with the structural and compositional ground-state energies.

From the relative importance of the different energies it is evident that the local moment formation has a considerable influence on stability, alloy formation, atom arrangement, and atom relaxation at the interface. Since the local moments may change quite substantially at the interface, materials with new and unknown phases (Blügel, 1996), crystal structures, and magnetic structures (Kurz, Bihlmayer, Hirai and Blügel, 2001) are to be expected. Obviously, the anisotropy energy is a rather small quantity, energetically nearly decoupled from the rest and can therefore be treated separately. In magnetism, tiny energies can matter. The anisotropy energy is, technologically speaking, the most important quantity in magnetism as it determines the bimodal state of the magnetization, which can for example be related to bit '0' or '1' and it is an important quantity determining the finite temperature properties of thin films. The anisotropy energy, which depends on all structural and electronic details of a low-dimensional system, is the origin of the magnetostriction, but otherwise does not have much influence on structural aspects. In this sense the problem of the magnetic anisotropy can be tackled after all other aspects of the low-dimensional system have been completely determined.

There are several low-dimensional systems and phenomena that are not covered in this chapter. To these belong the *magnetic nanoparticles* and *magnetic clusters* in the gas phase. The *molecular magnets* and the *Kondo-effect* at surfaces are discussed in detail in **Molecular Magnets: Phenomenology and Theory, Volume 1** and **The Kondo Effect, Volume 1**. When the growth of thin films is repeated to form multilayers, in particular, those of thin magnetic films separated by nonmagnetic spacer layers, an exchange interaction between the films across the spacer layer occurs, which is known as the *interlayer exchange coupling* (see **Exchange Coupling in Magnetic Multilayers, Volume 1**). Here, we do not include the thermodynamic properties of low-dimensional systems, which are partly discussed in **Theory of Magnetic Phase Transitions, Volume 1** and **Electron Theory of Finite Temperature Magnetism, Volume 1**. The works that we present here are basically predictions, analyses, and understanding of the magnetic spin and orbital moment, the magnetic structure and the magnetic orientation on the basis of the electronic structure – results obtained from the density-functional theory are introduced in **Density-functional Theory of Magnetism, Volume 1**. The experimental counterpart can be found in the chapter **Magnetism of Low-dimensional Metallic Structures, Volume 1**

2 THEORY AND MODELS

In this section, the reader is reminded about the theoretical concepts used to predict and analyze the results. The theories have been introduced in other chapters. Further, simple models are discussed to rationalize the results.

2.1 Density-functional theory: noncollinear magnetism

Density-functional theory (Hohenberg and Kohn, 1964) in the local spin-density approximation (LSDA) (von Barth and Hedin, 1972; Kübler, 2000) or the more recent generalized gradient approximation (GGA) (Perdew *et al*., 1992) has been the main underlying basis for the first-principles electronic structure calculations of magnetic systems in reduced dimensions. The theory has been introduced in **Density-functional Theory of Magnetism, Volume 1**. It is based on the Hohenberg–Kohn theorem stating that the ground-state

energy E of a many-body system is a unique functional of the charge density $n(\vec{r})$ and the vector-magnetization density $\vec{m}(\vec{r})$ and is minimal for the true ground-state densities.

In many applications, for example, in FM and AFM solids, there is a common magnetization axis for all atoms. For these collinear cases, a global z axis can be chosen along the direction of the magnetic field. In this case, the energy and all other physical observables become functions of the electron density and the magnetization density $m(\vec{r}) = (\vec{m}(\vec{r}))_z$ rather than $\vec{m}(\vec{r})$, or, equivalently, of the spin-up and spin-down electron densities $n_\uparrow(\vec{r})$ and $n_\downarrow(\vec{r})$. As an example of such computational results we compare in Table 2 the calculated magnetic moments of the elemental bulk ferromagnets with the experimental ones.

This formalism also allows the calculation of complex magnetic structures such as noncollinear magnets, in general, or systems with incommensurate spiral spin-density waves (SSDW) in particular. Such magnetic structures exist in a great variety of systems. They often occur in topologically frustrated antiferromagnets (e.g., antiferromagnets on a triangular lattice or antiferromagnets in contact with ferromagnets with atomically rough interfaces as in exchange-bias systems) or in materials with competing exchange interactions as for example in fcc Fe or Mn.

Non collinear magnets are characterized by a set of magnetization axes $\{\hat{\vec{e}}\}$, which may change from atom to atom in order to minimize the energy functional $E[n(\vec{r}), \vec{m}(\vec{r})|\{\hat{\vec{e}}\}]$ and determine the magnetic structure. The spin spiral is a particular noncollinear magnetic structure with moments that are rotated by a constant angle from atom to atom along a certain direction of the crystal. It can be described by the propagation vector of the spin-spiral $\vec{q}$, the rotation axis (which, in the absence of the spin-orbit or dipole–dipole interaction, is not fixed with respect to the lattice) and the relative (cone-)angle ϑ between the local quantization axis and the rotation axis. The rotation angle of the magnetic moment of an atom at the position $\vec{R}_i$ is then given by $\varphi = \vec{q}\cdot\vec{R}_i$. For a rotation around the z axis the magnetic moment of an atom at the position $\vec{R}_i$ is given by

$$\vec{M}_i = M(\cos(\vec{q}\cdot\vec{R}_i)\sin\vartheta, \sin(\vec{q}\cdot\vec{R}_i)\sin\vartheta, \cos\vartheta) \quad (1)$$

The great value of this type of noncollinear calculations rests in determining from $E[n(\vec{r}),\ \vec{m}(\vec{r})|\{\hat{\vec{e}}\}]$ or $E[n(\vec{r}), \vec{m}(\vec{r})|\{\vec{q}\}, \{\vartheta\}]$ the magnetic ground state as well as the exchange parameters J_{ij}. They enter the Heisenberg model, giving access to magnon spectra, spin-wave stiffness constants, magnetic phase diagrams, finite temperature properties, and magnetic excitations of the low-dimensional system at hand (Sandratskii, 1998; Pajda, *et al*., 2001; Turek, Kudrnovský, Drchal and Bruno, 2006).

Table 2. Magnetic moments M_{LSDA} in μ_{B}/atom for Fe, Co, and Ni calculated using the local spin-density approximation (LSDA) (Moruzzi, Janak and Williams, 1978). Values are compared with experimental data for the pure spin moment M_{spin} and with the total moment M_{tot} including orbital contributions.

Metal	M_{LSDA}	M_{spin}	M_{tot}
Fe	2.15	2.12	2.22
Co	1.56	1.57	1.71
Ni	0.59	0.55	0.61

2.2 Heisenberg model and beyond

Predicting the magnetic ground state of a low-dimensional magnetic system can be a highly nontrivial problem. In cases, for example, where competing exchange interactions between neighboring atoms cannot be satisfied, exchange interactions are frustrated giving rise to a multitude of possible spin structures. In the past, the magnetism of complex spin structures of itinerant magnets was discussed almost exclusively within the framework of model Hamiltonians, for example, the classical Heisenberg Hamiltonian,

$$H_{2\text{-spin}} = -\sum_{i,j} J_{ij}\ \vec{S}_i \cdot \vec{S}_j \quad (2)$$

The spins localized on the lattice sites i, j are considered as classical vectors $\vec{S}$, with the assumption that the spins on all lattice sites have the same magnitude S:

$$\vec{S}_i^2 = S^2, \text{ for all } i \quad (3)$$

The exchange interaction between the spins is isotropic and is described by the pair interaction J_{ij}. In localized spin systems the J_{ij} can be safely approximated by the FM ($J_1 > 0$) or AFM ($J_1 < 0$) nearest-neighbor (nn) interaction, that is, $J_{ij} = 0$ for all i, j, except for $J_{\mathrm{nn}} = J_1$. Also in itinerant magnets J_1 often dominates over the rest of the more distant pairs, however, an attempt to reproduce the Curie temperature T_{C} solely from J_1 produces results of limited quality. In many cases interactions between atoms as distant as 20 sites need to be included to give reliable results.

Exchange interactions beyond the classical Heisenberg model can be motivated from a perturbation expansion of the Hubbard model (Takahashi, 1977). Expanding the Hubbard model into a spin model and replacing the spin operators by classical spin vectors, a second-order perturbation expansion reproduces the classical Heisenberg model. The fourth-order

perturbation treatment (the third order is zero in the absence of spin-orbit interaction) yields two additional terms of a different form. One is the four-spin exchange interaction:

$$H_{4\text{-spin}} = -\sum_{ijkl} K_{ijkl}\big[(\vec{S}_i\vec{S}_j)(\vec{S}_k\vec{S}_l) + (\vec{S}_j\vec{S}_k)(\vec{S}_l\vec{S}_i) - (\vec{S}_i\vec{S}_k)(\vec{S}_j\vec{S}_l)\big] \quad (4)$$

The four-spin interaction arises from the hopping of electrons over four sites, that is, the process $1 \to 2 \to 3 \to 4 \to 1$. The second term, resulting from the hopping $1 \to 2 \to 1 \to 2 \to 1$, is the biquadratic exchange:

$$H_{\text{biquadr}} = -\sum_{ij} B_{ij}(\vec{S}_i \cdot \vec{S}_j)^2 \quad (5)$$

The exchange parameters J_{ij}, K_{ijkl}, and B_{ij} depend on the details of the electronic structure and it is known (Terakura, Hamada, Oguchi and Asada, 1982) that for transition metals the sign and magnitude are rapidly varying functions of the d-band filling. In thin films, the nearest-neighbor exchange constants scaled by the appropriate power of the magnetic moment, S^4K_1 and S^4B_1, are about one order of magnitude smaller than S^2J_1, which is for example for Mn/Cu(111) about 30 meV (Kurz, Bihlmayer, Hirai and Blügel, 2002). The higher-order spin interactions have then the effect, depending on the sign and value, of lifting the degeneracy of magnetic states that are degenerate in the Heisenberg model.

In itinerant magnets, the electrons that are responsible for the formation of the magnetic state do participate in the formation of the Fermi surface and hop across the lattice. Thus, it is by no means clear how far a short-ranged nn interaction or even how far the Heisenberg model, and models beyond that, can go in giving a sufficiently good description of the physics of itinerant magnets at surfaces and films. We believe that the interplay of *ab initio* calculations with model Hamiltonians provides a powerful approach to investigate the magnetic structures of complex magnetic systems such as low-dimensional magnets and to deal with their thermodynamical properties.

For our purpose here, the value of the Heisenberg model lies in two facts: (i) to construct a zero-temperature phase diagram of relevant spin states as a function of the exchange parameters J_{ij} and (ii) that a spin-spiral state, SSDW, with a propagation vector $\vec{q}$ in the first Brillouin zone (BZ) is a fundamental solution of the Heisenberg model for a Bravais lattice. On a Bravais lattice it is convenient to write the spin on lattice sites in terms of their discrete Fourier components $\vec{S}_{\vec{q}}$. The Heisenberg Hamiltonian can then be written in the simple form

$$H_{2\text{-spin}} = -N\sum_{\vec{q}} J(\vec{q})\ \vec{S}_{\vec{q}} \cdot \vec{S}_{-\vec{q}} \quad (6)$$

The summation goes over the reciprocal lattice vectors $\vec{q}$. N denotes the number of lattice sites in the crystal.

$$J(\vec{q}) = \sum_{i,j} J_{i-j}\ \mathrm{e}^{-i\vec{q}(\vec{R}_j-\vec{R}_i)} = \sum_{\vec{0}-\vec{R}_i} J_{\vec{0}-\vec{R}_i}\ \mathrm{e}^{-i\vec{q}(\vec{0}-\vec{R}_i)} = J(-\vec{q}) = J(\vec{q})^* \quad (7)$$

are the Fourier transformed exchange constants and $\vec{R}_i$ is the real-space coordinate of lattice site i. The lowest energy

$$E(\vec{Q}) = -NS^2J(\vec{Q}) \quad (8)$$

is found for the magnetic ground state $\vec{S}_{\vec{Q}}$ of the SSDW with wave vectors $\pm\vec{Q}$ (as well as symmetry-related $\vec{Q}$ vectors) which are obtained by minimizing the energy equation (6) under the condition equation (3). The corresponding spin structures are helical spin spirals (equation (1) for $\vartheta = 90^\circ$) and $\vec{M}_i = -g\mu_B\vec{S}_i$. For particular $\vec{Q}$ vectors, for example, $\vec{Q} = \pm 2\pi/a(0, 0, 1/2)$, one may find the *uudd* state as ground state, a collinear bilayer AFM state of FM double layers (DLs), which couple antiferromagnetically. This state, for example, was found in calculations for regime II of fcc-Fe films on Cu(001) (Asada and Blügel, 1997b).

In two dimensions, $\vec{Q}$ is typically located at high-symmetry points (lines) of the two-dimensional (2D) Brillouin zone, where the energy equation (8) as function of the $\vec{q}$-vector should have an extremum, a maximum, a minimum (or a saddle point), depending on the exchange constants J_{ij} and the symmetry of the high-symmetry point. In principle, one cannot rule out that the minimum of the energy will be located at any arbitrary point along the high-symmetry lines, representing an incommensurate spiral spin-density wave. In practice, we perform first-principles total energy calculations, that is, we study $E\left[n(r), m(r)|\{q\}\right]$ of flat spin spirals along the high-symmetry lines to gain an overview of possible minimum energies $E(\vec{Q})$. The role of higher-order spin interactions is then investigated, carrying out constraint calculations of the total energy $E[n(\vec{r}), \vec{m}(\vec{r})|\{\hat{\vec{e}}\}]$ for particular paths of magnetic configurations. Zero-temperature phase diagrams in the $J_{01} \cdots J_{0i}$ space are very helpful to reduce the relevant phase space of possible spin structures. This method is followed in Sections 3.1.2 and 3.2.2 to explore the magnetic ground state of thin films. The previously described mapping of *ab initio* calculations to spin models relies on the assumption that the magnetic moment does not depend

on the relative difference of the magnetization axis between atoms. For itinerant systems this is not necessarily guaranteed. The change of the moment with respect to the relative quantization axis can be mapped on spin models introducing higher-order spin interactions as well.

2.3 Critical temperature

It is well known that magnetic excitations in itinerant ferromagnets are basically of two different types, namely, the Stoner excitations, associated with longitudinal fluctuations of the magnetizations, and the spin waves or magnons, which correspond to collective transverse fluctuations of the magnetization direction. Near the bottom of the excitation spectrum, the density of states (DOS) of magnons is considerably larger than that of the Stoner excitations, so that the thermodynamics in the low-temperature regime is completely dominated by magnons. Stoner excitations can be safely ignored. Thus, it seems reasonable to extend this approximation up to the critical temperature, T_C, to neglect the Stoner excitation systematically, and to describe the transversal fluctuations by the Heisenberg model expressed in equation (2) with exchange parameters determined from first principles. An overview of the current applications along this line of mapping first-principles results on Heisenberg-type Hamiltonians to study the thermodynamical properties of bulk and low-dimensional magnets can be found in the paper of Turek, Kudrnovský, Drchal and Bruno (2006).

Below the critical temperature, the so-called Curie temperature T_C for ferromagnets, or the Néel temperature, T_N, for magnets with more complex magnetic phases, the spontaneous magnetization remains finite, while it is zero above T_C. The phase transition is of second order, that is the spontaneous magnetization which is the order parameter characterizing the phase transition, vanishes continuously at T_C. A second-order phase transition is governed by the principle of universality, where a system close to the phase transition does not depend on details of the system such as its material parameters or the geometry of the sample, but rather on the symmetry of the underlying model and the dimension of the spin, which is three for the Heisenberg model. In this chapter we are interested in estimating the critical temperatures as these are nonuniversal quantities and are of great practical importance. It is certainly important to know whether cryogenic, room temperature, or elevated temperatures are required to observe particular phenomena.

A first simple estimate of the Néel temperature for a three-dimensional system exhibiting a helical spin-spiral ground state with wave vector $\vec{Q}$ is given by the mean-field approximation (MFA) to the Heisenberg Hamiltonian, which leads to

$$k_B T_N^{MFA} = \frac{2}{3} S^2 J(\vec{Q}) \quad \text{and} \quad k_B T_C^{MFA}(\text{n.n.}) = \frac{2}{3} S^2 N_{nn} J_1 \tag{9}$$

where k_B is the Boltzmann constant. For the FM state, $\vec{Q} = (0, 0, 0)$, the left equation (9) gives the Curie temperature in the MFA, T_C^{MFA}, expressed explicitly in the equation on the right in the nearest-neighbor approximation to the exchange interaction. N_{nn} is the coordination number of nearest neighbor atoms and J_1 is the interaction strength as introduced in Section 2.2. The MFA gives the right proportionality of T_C with respect to the number of neighbors, but also has a few deficiencies. Besides overestimating T_C for three-dimensional systems by typically about 20%, T_C^{MFA} does not depend on the lattice structure or the dimensionality of the system. These shortcomings are remedied by treating the Heisenberg model in the random phase approximation (RPA) (Tyablikov, 1967; Turek *et al*., 2003), which gives for the critical temperatures,

$$\frac{1}{k_B T_N^{RPA}} = \frac{3}{4} \frac{1}{N S^2} \sum_{\vec{q}} \left[\frac{1}{J(\vec{Q}) - J(\vec{q})} + \frac{1}{J(\vec{Q}) - \frac{1}{2} J(\vec{q} + \vec{Q}) - \frac{1}{2} J(\vec{q} - \vec{Q})} \right]$$

$$\text{and } k_B T_C^{RPA}(\text{n.n.}) = \frac{2}{3} S^2 N_{nn} J_1 \cdot \begin{cases} 0.660 & \text{sc} \\ 0.718 & \text{bcc} \\ 0.744 & \text{fcc} \end{cases} \tag{10}$$

The RPA gives weight to the low-energy magnon excitations $E(q) \propto J(\vec{Q}) - J(\vec{q})$ in the summation over all modes. This provides estimates of T_C in close vicinity to the numerical analysis using classical Monte Carlo simulations (Metropolis *et al*., 1953) discussed in detail in the book of Landau and Binder (2000).

Both approximations show that the Curie and Néel temperatures depend on the number of nearest neighbors, and one expects that the critical temperature T_C decreases if the dimensionality of the system is reduced. But both approximations show a qualitatively different behavior for low-dimensional magnets. MFA overestimates the tendency for long-range order and predicts always a phase transition to FM order in the Heisenberg model, regardless of whether we have a one-, two-, or three-dimensional system, whereas $T_C^{RPA} = 0$ already for 2D systems. This is consistent with the theorem of Mermin and Wagner (1966), which states that in two dimensions there is no spontaneous long-range FM order for isotropic Heisenberg models with short-range interaction ($\sum_j J_{ij} r_{ij}^2 < \infty$) at finite temperature. In thin films, the long-range order at finite temperature is stabilized by the magnetic anisotropy, which is practically always present. It

opens a gap Δ in the excitation spectrum of the spin waves, $E(q) \propto \Delta + J(\vec{Q}) - J(\vec{q})$, and suppresses low-energy long-wavelength fluctuations, which occur for low temperatures. According to a renormalization group analysis by Erickson and Mills (1991) and Mills (1994), the transition temperature in two dimensions, $T_C^{(2D)}$, scales with the transition temperature of the three-dimensional Heisenberg model which is renormalized by a logarithmic factor,

$$T_C^{(2D)} = T_C^{(3D)} \frac{2}{\ln\left(\frac{3\pi}{4}\frac{k_B T_C^{(3D)}}{K}\right)} \tag{11}$$

which contains the strength of the uniaxial magnetic anisotropy in terms of a constant K (see Section 2.6). This result is displayed in Figure 2. T_C vanishes in the isotropic limit ($K \to 0$) in accordance with the Mermin–Wagner theorem. Interestingly, for finite K there is a rapid increase of T_C reaching reasonable values, of say 20% of the critical temperature in three dimensional systems, for anisotropy values of less than a percent of the FM coupling constant. Consider for example Fe, with a shape anisotropy of 0.140 meV, which corresponds to 1.63 K on the temperature scale. This is only 0.14% of the Curie temperature of Fe, $T_C^{(3D)}(\text{Fe}) = 1183\,\text{K}$, but already causes a Curie temperature for an Fe film of $T_C^{(2D)}(\text{Fe}) = 0.27 \cdot T_C^{(3D)}(\text{Fe}) = 320\,\text{K}$.

Thus at any finite anisotropy, there is a critical temperature, where the spin degree of freedom is frozen out owing to the presence of the anisotropy, that is the dimension of the spin is reduced from three for the Heisenberg model to one – spin up and down. In terms of universality, the Heisenberg model with any finite anisotropy value is in the universality class of the Ising model, and the Ising model shows a phase transition in two dimensions.

In one dimension even the Ising model does not show long-range order at finite temperatures. Although for quasi-one-dimensional magnetic chains – these are chains of finite size – there is, strictly speaking, no remanent magnetization

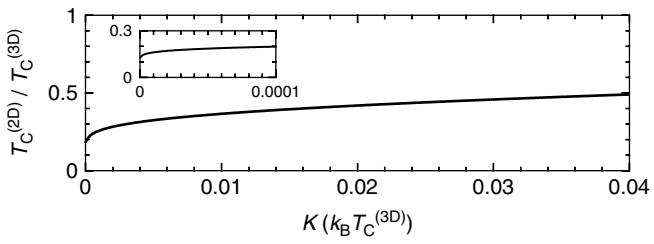

Figure 2. Critical temperature of a two-dimensional magnet as a function of the uniaxial anisotropy following equation (11). The function starts at zero for $K = 0$. Note its rapid growth in the vicinity of the origin as shown in the inset at magnified scale.

or long-range order, but there is a temperature, known as *blocking temperature*, below which a finite chain seems to a have a spontaneous and remanent magnetization, with long-range order in the chain. In reality, this magnetic order is accompanied by a slow relaxation (Glauber, 1963). The relaxation rate depends on the magnetic anisotropy and can be of macroscopic times, such that a quasi-one-dimensional chain appears as a ferromagnet as occurs in the experiments of Gambardella *et al*. (2002).

2.4 Stoner model

The occurrence of ferromagnetism can be studied on the basis of the Stoner criterion introduced in **Density-functional Theory of Magnetism, Volume 1**:

$$I\, n(E_F) > 1 \tag{12}$$

The Stoner criterion is an instability condition that expresses the competition between the exchange interaction in terms of the exchange integral I, which drives the system into ferromagnetism for large I, and the kinetic energy in terms of the nonmagnetic density of states (DOS), $n(E_F)$ at the Fermi energy E_F. The kinetic energy rises if the system becomes magnetic. This effect will be most pronounced for systems with wide bandwidth or low density of states. A big exchange integral and a large nonmagnetic DOS at the Fermi energy favors ferromagnetism. When ferromagnetism occurs, the double degeneracy of the energy bands $\varepsilon_{\vec{k}}$ is lifted, and majority states $\varepsilon_{k\uparrow}$ and minority states $\varepsilon_{k\downarrow}$ are rigidly shifted in energy by the exchange splitting IM, where M is the value of the local magnetic moment,

$$\varepsilon_{k\uparrow} = \varepsilon_{\vec{k}} - \frac{1}{2}IM \quad \text{and} \quad \varepsilon_{k\downarrow} = \varepsilon_{\vec{k}} + \frac{1}{2}IM \tag{13}$$

The rigid band shift is a good model if the shift is small as in the case of bulk ferromagnets. Deviations can be found for thin films, as the magnetic moments and thus the exchange splitting is large.

The Stoner criterion in equation (12) can be generalized, describing the instability against the formation of a frozen spin wave of wave vector $\vec{q}$,

$$I\, \chi_{\vec{q}}(E_F) > 1 \tag{14}$$

Obviously the local DOS was replaced by the $\vec{q}$-dependent susceptibility $\chi_{\vec{q}}$, a quantity that is expressed in the Heisenberg model by $J(\vec{q})$. Within equation (14), antiferromagnetism is just a special case. While the DOS at E_F can be easily assessed by experiment or electronic structure calculations, the static susceptibilities $\chi_{\vec{q}}(E_F)$ are more difficult to

measure. To make use of equation (14), an approximate criterion for antiferromagnetism is derived which makes explicit use of the local DOS. Small magnetic moments with the same magnitude M, but possibly different directions $\widehat{\vec{M}_j}$ at different sites j, induce in linear response theory local moments $\vec{M}_i$ at sites i

$$\vec{M}_i = \sum_j \chi_{ij}(E_\mathrm{F})\, M\, \widehat{\vec{M}_j} \tag{15}$$

The staggered susceptibility describing a particular magnetic state (M) is then expressed as

$$\chi_\mathrm{M} = \sum_i \chi_{0i}\, \widehat{\vec{M}_0}\cdot\widehat{\vec{M}_i} \tag{16}$$

Particular examples of this staggered susceptibility are the FM (χ_FM)

$$\chi_\mathrm{FM} = n = \sum_i \chi_{0i} \tag{17}$$

and the AFM (χ_AFM)

$$\chi_\mathrm{AFM} = \sum_i (-1)^{(i)}\, \chi_{0i} \tag{18}$$

susceptibilities. Assuming that for 3d metals the nearest-neighbor interaction is the most dominating one, χ_{0i} can be neglected for all sites beyond nearest neighbors ($\chi_{0i} = 0$ for $i > 1$), and χ_FM and χ_AFM are given approximately by

$$\begin{aligned} n(E) &\approx \chi_{00}(E) + \chi_{01}(E), \quad \text{and} \\ \chi_\mathrm{AFM}(E) &\approx \chi_{00}(E) - \chi_{01}(E) \end{aligned} \tag{19}$$

where $\chi_{00}(E)$ is the local or atomic susceptibility, respectively, at the energy E. The energy dependence of χ_{00} is fairly simple. It follows from atomic Hund's rule–type arguments: the maximum spin M occurs for half-band filling, hence the atomic (local) susceptibility $\chi = \partial M/\partial H$ will also be largest. From equation (19), we can obtain an approximate form for χ_AFM using only DOS information. This is illustrated in Figure 3. As function of the d-band filling, from V to Ni, the Fermi energy sweeps from the left to the right through the DOS. If the Fermi energy is positioned at the center of the band as for Cr, the DOS is low but the AFM susceptibility is high and antiferromagnetism is expected. If the Fermi energy is closer to the end of the band, the AFM susceptibility is small but the DOS is large and ferromagnetism is expected as for Fe, Co, and Ni. Mn and Fe are at the edge of both magnetic states and, depending on circumstances, different magnetic ground states can be found. Compare also to the calculated DOS, Figure 9 in Section 3.1.1

2.5 Role of coordination number

As discussed in Section 2.4 the Stoner criterion for ferromagnetism, equation (12), depends on (i) the Stoner parameter I and (ii) the DOS $n(E_\mathrm{F})$ at the Fermi energy E_F.

(i) The exchange integral I is an intra-atomic, element-specific quantity, and in the simplest approximation it is independent of the local environment, the structure, and the site of a given atom, for example, surface atom or bulk atom. According to Gunnarsson (1976) and Janak (1977) a global trend

$$I_\mathrm{3d} > I_\mathrm{4d} > I_\mathrm{5d} \tag{20}$$

was found for the exchange integrals of the 3d, 4d, and 5d transition-metal series.

(ii) Focusing on the d electrons as relevant electrons for itinerant magnetism, the DOS depends on both the coordination number N_nn and the hopping matrix elements h_d between the d electrons. This can be understood as follows: The energy integral $\int_W n_\ell(\varepsilon)\,\mathrm{d}\varepsilon = 2\ell + 1$ over the bandwidth, W, of the local DOS of the angular momentum quantum number $\ell(= 2)$ is normalized to $2\ell + 1$ states. Thus, in the simplest approximation possible (e.g., rectangle-shaped

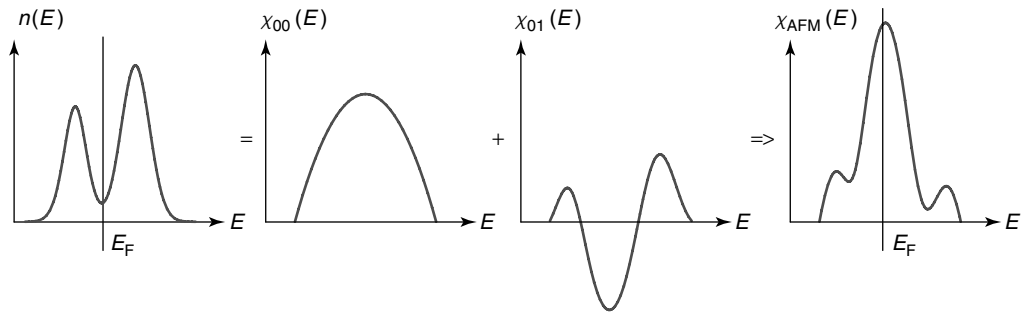

Figure 3. Graphical illustration of equation (19) for a DOS typical for transition-metal monolayers on (001)-oriented noble-metal substrates.

DOS), one can assume that the local DOS scales inversely proportional to the bandwidth, W,

$$n(E_{\mathrm{F}}) \sim \frac{1}{W} \tag{21}$$

At the atomic limit, the bandwidth converges to zero, the Stoner criterion is always fulfilled, and moments in accordance with Hund's first rule will be found. In general the DOS consists of contributions from electrons in s, p, d, and f states. For transition metals, by far the largest contribution comes from the d electrons, and the d–d hybridization determines the shape of the density of states. Therefore, in the following discussion we restrict ourselves to d electrons and write

$$n(E_{\mathrm{F}}) \approx n_{\mathrm{d}}(E_{\mathrm{F}}) \sim \frac{1}{W_{\mathrm{d}}} \tag{22}$$

The average local bandwidth $\overline{W_{\mathrm{d}}}(\vec{R}_i)$ for an atom i at position $\vec{R}_i$ can be estimated in a nearest-neighbor tight-binding model – applicable for the itinerant but tightly bound d electrons of transition-metal atoms – to be

$$W_{\mathrm{d}} \approx \overline{W_{\mathrm{d}}}(\vec{R}_i) = 2\sqrt{N_{\mathrm{nn}}(\vec{R}_i)}h_{\mathrm{d}}(R_{\mathrm{nn}}) \tag{23}$$

According to equation (23) the bandwidth depends on two quantities: (i) the hopping matrix element h_{d} of the d electrons and (ii) the number of nearest-neighbor atoms or coordination number N_{nn}.

(i) The hopping matrix element depends on the overlap of the d wave functions. It decreases with increasing lattice constant or distance R_{nn} to the nearest-neighbor atom, and for a given lattice constant it increases with the extension of the wave function or, equivalently, the number of nodes. In Figure 4 the bandwidths of 3d, 4d, and 5d bulk transition metals are schematically shown, together with the bandwidths of rare earths and actinides. In line with the arguments of increasing number of nodes from 3d to 5d wave functions, a clear 'macro trend' is visible for the transition-metal series, and it is summarized as follows:

$$h_{3\mathrm{d}} < h_{4\mathrm{d}} < h_{5\mathrm{d}} \Rightarrow W_{3\mathrm{d}} < W_{4\mathrm{d}} < W_{5\mathrm{d}} \Rightarrow n_{3\mathrm{d}} > n_{4\mathrm{d}} > n_{5\mathrm{d}} \tag{24}$$

Additionally, within each transition-metal series there exists a 'micro trend' due to the incomplete screening of the Coulomb potential of the nucleus by the d electrons. The d wave functions at the beginning of the transition-metal series are more extensive than at the end of the series, thus the hopping matrix element at the beginning of the series is larger than at the end, with well-known consequences for the bandwidth W and the DOS $n(E_{\mathrm{F}})$.

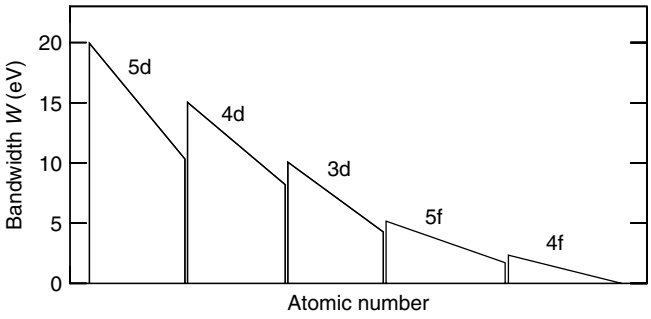

Figure 4. Schematic illustration of the bandwidth W of the transition metals together with rare earths (4f) and actinides (5f), all in the bulk phase. The 5f electrons of the early actinides and the 3d electrons of transition metals from the middle to the end of the 3d series (Cr to Ni) show itinerant magnetism, while the magnetism of the late actinides and the rare earths is best described as localized magnetism, and their magnetic properties can in good approximation be explained in terms of Hund's rule.

(ii) The smaller the coordination number N_{nn} the smaller the d–d hybridization and the smaller the bandwidth. Let us consider for example the coordination number of an atom in the environment of an fcc crystal ($N_{\mathrm{fcc}} = 12$), of an atom in the (001) surface of the fcc crystal ($N_{(001)} = 8$), located in a two-dimensional (001) monolayer (ML) film ($N_{\mathrm{ML}} = 4$) and of an atom in a monatomic chain ($N_{\mathrm{chain}} = 2$), keeping the nearest-neighbor distance ($R_{\mathrm{nn}} = \text{constant}$) and the bonding strength fixed ($h_{\mathrm{d}} = \text{constant}$). Under these circumstances, one obtains for the ratio of the bandwidths

$$W_d{}^{\mathrm{chain}}{:}W_d{}^{\mathrm{ML}}{:}W_d^{(001)}{:}W_d^{\mathrm{fcc}} = 0.41{:}0.58{:}0.82{:}1$$

or that of the local DOS

$$n_d^{\mathrm{chain}}{:}n_d^{\mathrm{ML}}{:}n_d^{(001)}{:}n_d^{\mathrm{fcc}} = 2.45{:}1.73{:}1.22{:}1 \tag{25}$$

Thus, the reduction of the coordination number leads to less d–d hybridization, which consequently leads to band narrowing, and in low-dimensional structures the tendency towards magnetism is considerably boosted. Accordingly, one can expect that transition metals, which are nonmagnetic as bulk metals, may become magnetic at surfaces or as ultrathin films. A nice manifestation of these arguments was recently reported for the size and shape dependence of the local magnetic moments in Fe clusters on the Ni(100) surface (Mavropoulos, Lounis, Zeller and Blügel, 2006) summarized in Section 5.2. The arguments put forward here for the increased ferromagnetism in reduced dimensions can be carried over directly to the increased AFM susceptibility.

The magnetic properties are expected to depend on the surface or film orientation also, because the coordination number N_{nn} (cf. Table 3) as well as the nearest-neighbor

Table 3. Coordination number N_{nn}, interlayer distance d, point symmetry S, and packing density ρ (fraction of the area of the surface unit cell, covered by atoms with an atom radius of touching bulk atoms) for an fcc lattice. Only the three low-index surfaces (001), (011), and (111) are considered. a is the lattice parameter of the simple cubic unit cell.

	N_{nn}	S	d/a	ρ
(111)	9	C_{3v}	0.5774	0.9068
(001)	8	C_{4v}	0.5000	0.7854
(011)	7	C_{2v}	0.3536	0.5554

distance $R_{\parallel}$ between the surface atoms and $R_{\perp}$ between the surface atoms and the atoms in the next layer change along with a change of the surface orientation. For an fcc lattice, the (111) surface is the most densely packed one, and we expect for it the smallest enhancement of the magnetic moments. Among the three low-index surfaces, with the orientation (001), (011), and (111), the (011) surface leads to the most open surface. For the latter we expect the largest magnetic moments. At surfaces or ultrathin films of bcc lattice type the trend should be exactly the opposite. The most densely packed surface is the (011) surface for which we expected the smallest enhancements of the magnetic moments. The (111) surface is the most open one. This surface is already close to a stepped one.

The implication of the coordination number, discussed so far, is an important aspect in interface magnetism but it is not the whole story. Further important aspects, neglected so far, have to be taken into account in order to give a qualitatively correct description of the magnetism at interfaces.

Point symmetry: The disruption of the translational symmetry due to a given interface reduces, in general, the point symmetry. Degeneracies typical for cubic bulk metals may be lifted. One example is the threefold degenerate t_{2g} bulk state, which is split at a (001) surface into a twofold degenerate state and a singly degenerate state. This symmetry break induces a splitting or broadening of the DOS and makes magnetism unfavorable. A famous victim of this scenario is Pd. Bulk Pd has a large DOS at the Fermi energy which contributes to a large exchange enhanced susceptibility. Thus, bulk Pd is nearly FM. The band narrowing experienced at the surface because of the reduction of the coordination number should drive the surface of Pd into the FM state. But this is not the case. Instead, the change of the surface symmetry splits the states at the Fermi energy, broadens the DOS, and counteracts the band narrowing. The surface of Pd(001) remains nonmagnetic.

Shift of the d band relative to the sp band: Compared to a single isolated atom, the d electrons in a solid are in a state of compression. Therefore, in a solid their energy levels are positioned at a much higher energy than in an atom. At the surface, the charge density of the d electrons can relax and their energy levels move downwards. They are situated closer to the bottom of the sp band and the number of d electrons is increased, or the d holes are decreased. This downward shift is often facilitated by a significant hybridization of the d electrons with sp electrons or holes for example, of the substrate. As depicted in Figure 5 this leads to a Lorentzian tail of the DOS. If this tail is positioned close to the Fermi energy, magnetism can be drastically reduced as for example, for a single Ni monolayer on Cu(100), for which the local Ni moment amounts to $0.33\,\mu_B$ as compared to the magnetic Ni moment at the Ni(100) surface ($0.72\,\mu_B$). For a monolayer Pd on Ag(100) magnetism is even absent. In both cases we would expect an increase of the moment due to the reduction of the coordination number by a factor 2 when compared to the respective (100) surface. On the other hand, elements at the beginning of the transition-metal series, such as V, profit from this effect and magnetism is more likely to appear.

sp–d dehybridization: The main carriers of itinerant magnetism are the d electrons. For atoms, we know that the number of d electrons are integer numbers. In metallic systems, this is not the case, the number of d electrons is a noninteger number and depends on the hybridization with the s and p electrons, besides depending on the dominating d–d hybridization. Owing to the hybridization of the d electrons with the sp electrons, d states below the Fermi energy are hybridized into unoccupied sp hybrids and the number of d electrons is reduced when compared to the isolated atom. This so-called sp–d dehybridization changes, as a function of the coordination number or the nearest-neighbor distance, the fractional number of d electrons without any topological change of the DOS. This is illustrated in Figure 6. Surfaces and monolayers with their smaller coordination numbers have, therefore, a higher number of d electrons favorable for magnetism. For an illustration, in a computer experiment we investigated the

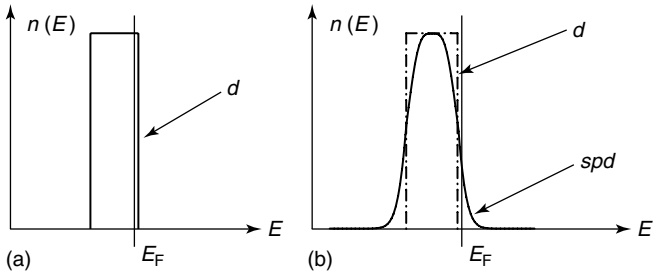

Figure 5. Schematic illustration of the hybridization of the overlayer d electrons with the sp electrons for example, of the substrate, on the density of states, (a) without and (b) with hybridization.

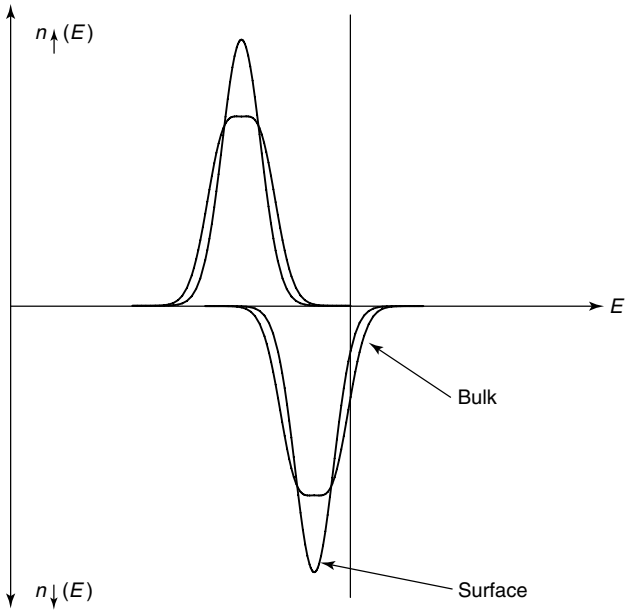

Figure 6. Schematic illustration of the role of the sp–d dehybridization on the density of states of the d electrons $n_d(E)$. The integrated density of d states for the surface is larger than that for the bulk.

Table 4. Calculated magnetic moments in units of μ_B for Ni(001) as an unsupported, freestanding monolayer (coordination number $N_{nn} = 4$), as a function of the lattice constant: $a_{Ag} = 7.79$ au, $a_{Pd} = 7.42$ au, $a_{Cu} = 6.76$ au, and $a_{Ni} = 6.65$ au. $N_{nn} = 8$ indicates the local magnetic moment of the Ni(001) surface and $N_{nn} = 12$ indicates the bulk value. The local magnetic moment of the Ni(011) surface ($N_{nn} = 7$) is also included.

N_{nn}	Lattice parameter			
	Ag	Pd	Cu	Ni
4	1.02	0.96	0.87	0.85
7	–	–	–	0.74
8	–	–	–	0.72
12	–	–	–	0.59

magnetic moment of one layer of Ni for various lattice parameters and coordination numbers. In Table 4 one finds that with decreasing coordination number and increasing atom separation, the magnetic moment increases although the Ni majority band is always completely filled.

Charge neutrality: The local charge neutrality has to be fulfilled in order to avoid the strong Coulomb forces that appear otherwise. It again induces a band alignment. Band narrowing (at interfaces) automatically means that the number of electrons must change. To avoid charged interfaces, a realignment of the center of gravity of the bands occurs. The d band, which moved to lower energy in order to relax the compression, now moves upward again. Owing to an upward shift in the energy, the minority and majority electrons become depopulated differently, and together with the change of the number of majority electrons due to the sp–d dehybridization the magnetic moment increases. All together we find a complex alignment of all the bands, individually, for each symmetry of the electrons.

Strong and weak ferromagnets: Despite the drastic change of the coordination number and the lattice parameter, the Ni moment in Table 4 changes only in the range of $\pm 20\%$. This is typical for strong ferromagnets (magnets with filled majority band). In general, one can say that the magnetism of strong ferromagnets is rather robust against any environmental changes. Weak ferromagnets (magnets with partly occupied majority bands) are sensitive to any environmental changes, and their moments collapse easily.

Using model Hamiltonians, these interwoven effects were frequently neglected. However, they are readily included in self-consistent first-principles results.

2.6 Orbital moment and magnetic anisotropy

A piece of magnetic material is typically magnetically anisotropic. This means that besides the isotropic exchange interaction there are additional interactions, which make the total energy depend on the orientation of the magnetization as measured with respect to the crystal axes and the sample shape. This orientation-dependent energy contribution is called the *magnetic anisotropy energy* (*MAE*), E_{MAE}, given in units of energy/atom throughout this article. Without this effect of the magnetic anisotropy, magnetism would have been hard to discover and possibly useless. In some way or the other, almost all applications of magnetic materials hinge on the fact that it is easier to magnetize a magnetic material in one direction than in another. The magnetic anisotropy is responsible for the occurrence of easy and hard axes, stabilizes magnetic order against thermal fluctuations in dimensions where the exchange interaction alone would not suffice (see Section2.3), and limits the width of a magnetic domain wall. It is, for example, responsible for the bimodal stability of magnetic domains with uniaxial symmetry, which allows the two possible magnetization directions in space to be interpreted in terms of bit '0' or '1'. This makes magnetism very valuable for magnetic storage media. Since the magnetic anisotropy is strongly related to the crystalline symmetry and the shape of the samples, a general expression of E_{MAE} will be a complex function of the orientation of the magnetization relative to the crystal axes. In low-dimensional

systems twofold symmetries are the most relevant ones and the magnetic anisotropy is then expressed as

$$H_{\mathrm{MAE}} = \sum_i \vec{S}_i \cdot \vec{\vec{K}}_i \cdot \vec{S}_i \tag{26}$$

where the tensor of single-site anisotropy constants, $\vec{\vec{K}}$, determines the strength of the anisotropy as well as the direction of minimal and maximal energy, named *easy* and *hard axes*, respectively. In perfect thin films and wires, the presence of a surface is then responsible for a uniaxial anisotropy energy normal to the surface, that is all components of $\vec{\vec{K}}_i$ are zero except $K_i^{zz} = K\delta^{zz}$ for perfect films and $K_i^{xx} = 1/2K\delta^{xx}$ and $K_i^{yy} = 1/2K\delta^{yy}$ for isolated wires. After expressing $\vec{S}_i$ in the form of equation (1), the uniaxial MAE takes the angular dependence

$$E_{\mathrm{MAE}}(\theta) = -K\cos^2\theta \tag{27}$$

θ denotes the angle between the magnetization and the film or wire normal and $K = \Delta E_{\mathrm{MAE}} = E_{\mathrm{MAE}}^{(\parallel)} - E_{\mathrm{MAE}}^{(\perp)}$ is the uniaxial anisotropy constant also given in energy/atom. The total MAE, $E_{\mathrm{MAE}}^{(\mathrm{tot})} = N_{\mathrm{A}} E_{\mathrm{MAE}} = V\mathcal{E}_{\mathrm{MAE}}$, of the system depends then on the number of atoms, N_{A}, in it. Frequently, the MAE is also expressed in terms of an energy density $\mathcal{E}_{\mathrm{MAE}}$. By definition, $K > 0$ ($K < 0$) describes the case of a preferred direction of the magnetization perpendicular, $\perp$, (parallel, $\parallel$) to the film plane or wire axis. Additional higher symmetries in place, for example a fourfold symmetry in a (100)-oriented film plane, corresponds to anisotropy contributions that are smaller in energy than the uniaxial anisotropy and are neglected here. The anisotropy constant depends sensitively on the chemical elements involved, structural details, details of the electronic structure, and the dimensionality of the system.

The microscopic origins of the magnetic anisotropy are the magnetic dipolar interaction and the spin-orbit interaction. The dipolar interaction is of long range and senses the outer boundaries of the sample. This results in shape anisotropy. Discussing long-range contributions, the underlying atomistic lattice describing the crystallinity of the system can be neglected and the shape anisotropy is described in terms of a continuum theory. Any contribution to the MAE, that is due to effects beyond continuum theory and explicitly takes the crystallinity of the system into account, is summarized as magnetocrystalline anisotropy energy (MCA). Both the dipolar and the spin-orbit interaction contribute to the MCA and the total anisotropy constant K,

$$K = K_{\mathrm{shape}} + K_{\mathrm{MCA}}^{(\mathrm{dip})} + K_{\mathrm{MCA}}^{(\mathrm{so})} \tag{28}$$

is just a linear superposition of the different contributions.

The shape anisotropy constant, K_{shape} in atomic Rydberg units/atom of a perfectly flat film of infinite extension or an infinitely long perfectly cylindrical wire is given by the local magnetic moment m and the atomic volume V as

$$K_{\mathrm{shape}}^{\mathrm{film}} = -2\pi\frac{2}{c^2}\frac{m^2}{V} \quad \text{and} \quad K_{\mathrm{shape}}^{\mathrm{wire}} = -\pi\frac{2}{c^2}\frac{m^2}{V} \tag{29}$$

all expressed in atomic units (au), m in μ_{B}/atom, V in au^3, and the speed of light, c, by the inverse of the fine-structure constant α, $c = 2/\alpha$. The negative sign denotes that the shape anisotropy pulls the magnetization into the film plane or along the wire axis. For bcc Fe, for instance, with a bulk magnetic moment of 2.215 μ_{B}/atom and a lattice constant of 5.42 au, $K_{\mathrm{shape}}^{\mathrm{film}}$ is equal to -0.140 meV/atom. The long-range interaction also senses the interface or surface roughness that is always present in real films. According to Bruno (1988) the roughness gives rise to an effective perpendicular contribution to the shape anisotropy the order of magnitude of which depends on the parameters characterizing the roughness. Obviously $K_{\mathrm{shape}}^{\mathrm{film}}$ and $K_{\mathrm{shape}}^{\mathrm{wire}}$ are the same for all atoms irrespective of their position and K is thus homogeneous across the film or wire. The same is true for any finite ellipsoidal structure, for any other finite structure, for example, a nanopattern structure on a surface, K_{shape} becomes inhomogeneous and typically much smaller at the boundary of the structure. For bulk samples, thick films, patterned nanostructures, and wires, the shape anisotropy is frequently the most important of the anisotropies.

For thin films and wires of a few atomic layers, the assumption that the magnetization can be treated as a continuous magnetic medium is no longer valid. Instead, the magnetic dipole-dipole energy has to be evaluated explicitly. In transition metals, the magnetization distribution around the atom is almost spherical and can thus be treated to a good approximation as a collection of discrete magnetic dipoles that are regularly arranged on a crystalline lattice. The dipolar energy E_{dip} per atom experienced by a dipole at site i because of the presence of ferromagnetically aligned dipoles on all other sites j can then be expressed as

$$E_{\mathrm{dip}}^{(i)}(\theta) = K_{\mathrm{dip}}^{(i)}\cos^2\theta = \frac{2}{c^2}\frac{1}{2}\sum_{j(j\neq i)}\frac{m_i m_j}{R_{i,j}^3}\left(1 - 3\cos^2\theta_{ij}\right) \tag{30}$$

θ_{ij} is the angle between the direction of the magnetic moment m of the dipoles at sites i or j given in units of μ_{B} and the vector $\vec{R}_{i,j}$ connecting atoms i and j. $R_{i,j}$ denotes the relative distance between these dipoles or atoms, respectively. The θ dependence explicitly expresses the fact that the dipole–dipole interaction contributes to the magnetic anisotropy. Obviously, in thin films and wires the anisotropy

energy depends on the position of the atom i normal to the surface or wire axis, respectively, and as such explicitly on the film thickness or wire diameter (in contrast to K_{shape} where all atoms have the same value). For crystalline thin wires and films, the sum in equation (30) can be evaluated straightforwardly with fast-converging summation techniques (Topping, 1927; Szunyogh, Újfalussy and Weinberger, 1995). Draaisma and de Jonge (1988) have worked out in detail the layer-dependent dipolar anisotropy $K_{\text{dip}}^{(i)}$. In general, the outer atoms experience values of K_{dip} that are appreciably smaller than those of the inner layers, which finally approach K_{shape}. The inner atoms reach 95% of K_{shape} after about 15 Å below the surface. The exact details depend on the crystal structure and surface orientation, for example, a reduction between 25 and 45% of K_{shape} was reported for a (100)-oriented fcc or bcc monolayer, respectively. The deviation of K_{dip} from K_{shape} gives $K_{\text{MCA}}^{(\text{dip})}$ in equation (28), the dipolar contribution to the MCA which occurs here owing to the presence of a surface or interface and is sometimes also called the *surface contribution* of the dipolar anisotropy. If the MAE is expressed in terms of energy densities $\mathcal{E}$, this $K_{\text{MCA}}^{(\text{dip})}$ is expressed in terms of an areal density. The dipolar energy contributes to the MCA of bulk systems or thick films or wires also, if the underlying lattice structure has a twofold symmetry. For this three-dimensional case more sophisticated summation techniques such as the Ewald summation method (Ewald, 1921) are required to obtain reliable results for equation (30).

The spin-orbit interaction, treated typically by a Pauli-type addition to the Hamiltonian as:

$$H_{\text{so}} = \vec{\sigma}\cdot(\vec{E}(\vec{r}) \times \vec{p}) = \vec{\sigma}\cdot(\nabla V(r) \times \vec{p}) \tag{31}$$

provides the essential contribution to the MCA. This Pauli approximation derives naturally from the Dirac equation and is normally sufficient for treating relativistic effects in transition-metal magnets. For a radially symmetric potential we can rewrite equation (31):

$$H_{\text{so}} = \frac{1}{r}\frac{\mathrm{d}V(r)}{\mathrm{d}r}\vec{\sigma}\cdot(\vec{r} \times \vec{p}) = \frac{1}{r}\frac{\mathrm{d}V(r)}{\mathrm{d}r}(\vec{\sigma}\cdot\vec{L}) = \xi(\vec{r})\vec{\sigma}\cdot\vec{L} \tag{32}$$

where $\vec{L}$ is the angular momentum operator. Since the radial derivative of the potential in a crystal will be largest in the vicinity of a nucleus, we can expect that the major contribution to the spin-orbit interaction will come from this region. Furthermore, since for small r the potential will be Coulomb-like, $(V = -\frac{Z}{r})$, the radial expectation value of $\xi(r)$ leads to a material-dependent spin-orbit coupling constant ξ, which is roughly proportional to the square of the nuclear number Z, $\xi \propto Z^2$. In low-dimensional systems the MCA dominates over the shape anisotropy. The anisotropy depends crucially on the symmetry of the system.

In a solid, where the symmetry of the states is determined by the crystal field, spin-orbit coupling can now introduce orbital moments and magnetocrystalline anisotropies by coupling states that carry no orbital momentum, for example, a d_{xy} and a $\mathrm{d}_{x^2-y^2}$ orbital, such that the combination forms an orbital moment in the z direction. In second-order perturbation theory the expectation value of the orbital moment operator $\mu_{\text{B}}\vec{L}$ can be written as:

$$m_{\text{l}} = \mu_{\text{B}}\langle\vec{L}\rangle = \mu_{\text{B}}\sum_{i,j}\frac{\langle\psi_i|\vec{L}|\psi_j\rangle\langle\psi_j|H_{\text{so}}|\psi_i\rangle}{\varepsilon_i - \varepsilon_j} \times f(\varepsilon_i)\left[1 - f(\varepsilon_j)\right] \tag{33}$$

where f is the Fermi function ensuring that the wave function ψ_i is occupied and ψ_j is unoccupied. In a metal, where several bands are crossing the Fermi level, E_{F}, it is basically the sum of all contributions from bands near E_{F} that determines the orbital moment. van der Laan (1998) has shown, that in the absence of spin-flip terms (i.e., when the majority and minority bands are well separated by the exchange interaction), the spin-orbit coupling changes the total energy of a system in second-order perturbation theory as:

$$\delta E = \sum_{i,j}\frac{\langle\psi_i|H_{\text{so}}|\psi_j\rangle\langle\psi_j|H_{\text{so}}|\psi_i\rangle}{\varepsilon_i - \varepsilon_j}f(\varepsilon_i)\left[1 - f(\varepsilon_j)\right] \approx -\frac{\xi}{4\mu_{\text{B}}}\widehat{m}_{\text{s}}\cdot\left[\vec{m}_{\text{l}}^{\downarrow} - \vec{m}_{\text{l}}^{\uparrow}\right] \tag{34}$$

where $\widehat{m}_{\text{s}}$ is the direction of the spin moment and $\vec{m}_{\text{l}}^{\downarrow}$ and $\vec{m}_{\text{l}}^{\uparrow}$ are the orbital moment vectors of the spin-down and spin-up bands, respectively. If the spin-up band is completely filled, we see that energy change, δE, is proportional to the size of the orbital moment and the MCA, that is, the difference of δE for two different magnetization directions will be proportional to the difference in the orbital moments. This relation between orbital moment anisotropy and MCA was first derived by Bruno (1989).

We have discussed that the reduced coordination number in low-dimensional systems favors the increase of the spin moment. But it also enables the formation of large orbital moments, as can be seen from most atoms. Also in the case of the orbital moment, the hybridization with some neighboring orbitals 'locks' the electrons in place and quenches the orbital moment. Imagine a Sc atom with only one d electron: as an atom, according to Hund's rules, the orbital moment will be maximized and antiparallel to the spin moment. But when Sc atoms are assembled in a square lattice, orbitals with $m = -2$ and $m = +2$ will form linear combinations to build d_{xy} and $\mathrm{d}_{x^2-y^2}$ orbitals of which the latter will be occupied. The more

these two levels are split in energy, the more difficult it will be for the electron to 'circle' around the atom and, therefore, to form an orbital moment.

In Table 5 some representative values of spin and orbital momentum have been collected. These calculations yield very small orbital moments: $0.05\,\mu_B$, $0.08\,\mu_B$, and $0.05\,\mu_B$ for bcc Fe, hcp Co, and fcc Ni, respectively (and about twice the value if the orbital polarization (OP) proposed by Brooks (1985) is included). It is well known that the orbital moments are quenched in the bulk because of the strong hybridization with neighboring atoms. Larger orbital moments are obtained for the (111)-oriented unsupported 3d monolayers. For Fe, Co, and Ni the values are 2–3 times larger than the corresponding bulk values. Thus, in monolayer films the quenching of the orbital moments is less pronounced because of the reduced hybridization. However, it is important to realize that these enhanced orbital moments are still an order of magnitude smaller than the corresponding free-atom values, as given by Hund's second rule (last row in Table 5). Consequently, we expect for atomic-scale magnetic structures such as wires, small clusters, and adatoms strong changes in the orbital moment and, in turn, large values of the MCA. In practice, these films are deposited on substrates. This will once more quench the values, especially for the orbital moments. But the spin polarization of the substrate can lead to additional large contributions to the MCA in particular for substrates with large Z, such as Pt or Ir.

Typically, first-principles calculations based on the LSDA or GGA underestimate the orbital moments. In the literature several methods have been discussed as to how this deficiency can be overcome (Brooks, 1985; Solovyev, Liechtenstein and Terakura, 1988; Solovyev, 2005). For example, the orbital moments of the bulk magnets are about twice the value if Brooks' OP is applied (Eriksson, Brooks and Johansson, 1991b; Hjortstam *et al*., 1996). The effect of OP is much more drastic in low dimensions (Nonas *et al*., 2001). A systematic comparison of LSDA results for Pt-supported and unsupported Fe and Co magnets in various dimensions can be found in the works of Komelj, Ederer, Davenport and Fähnle (2002) and Ederer, Komelj and Fähnle (2003).

In order to interpret *ab initio* results on thin films we discuss the case of an unsupported, (100)-oriented d-metal monolayer, in terms of a simple model following Stöhr (1999). Assume that the d band is substantially exchange split and more than half filled, so that we only have to consider the (partially filled) minority band. The d orbitals at each atom site experience in the monolayer plane a crystal field V, that leads to a splitting of these levels: if the surface normal is assumed to be in z direction, the d_{xy} and $d_{x^2-y^2}$ levels will experience a stronger field than the out-of-plane directed d_{zx}, d_{yz}, and d_{z^2} orbitals. The crystal field leads to a splitting of $2V_\parallel$ for the in-plane oriented orbitals and $2V_\perp$ for the out-of-plane oriented ones. In a band picture, these splittings can be translated into bandwidths W, which will then be twice as large (cf. Figure 7). Normally, $V_\parallel$ will be larger than $V_\perp$, so that $R = V_\perp / V_\parallel < 1$. (If, however, the monolayer is sandwiched between two slabs of nonmagnetic material the situation could be changed.)

Assume that – like in the case of Co – the minority band is half filled; the d_{xy} and $d_{x^2-y^2}$ states will split symmetrically by $\pm V_\parallel$ around the Fermi level, the (d_{zx}, d_{yz}) and d_{z^2} states by $\pm V_\perp$. In a band-picture, these splittings will of course depend on the considered $\vec{k}_\parallel$ point. Now we can use perturbation theory equation (33) to calculate the orbital moments. The result (Stöhr, 1999)

$$m_l^\parallel = \frac{\xi \mu_B}{2V_\parallel}\left(\frac{3}{R} + \frac{2}{R+1}\right) \quad \text{and} \quad m_l^\perp = 4\frac{\xi \mu_B}{2V_\parallel} \tag{35}$$

Table 5. Local spin (m_s) and orbital (m_l) magnetic moments in units of μ_B of Fe, Co, and Ni atoms in bulk materials ($n = 3$), unsupported thin films ($n = 2$), wires ($n = 1$), and as isolated atoms ($n = 0$). For bulk crystals the variation of the orbital moment with direction is small, but for films and wires the orbital moments parallel ($\parallel$) and perpendicular ($\perp$) to the film plane or wire axis are given. The geometry is chosen as if the film or wire would have been grown epitaxially on a Pt(111) substrate. The column $|K_{MCA}|$ indicates the order of magnitude of the MCA for different dimensions. The results were obtained in the GGA to the density-functional theory.

	Fe			Co			Ni			$\lvert K_{MCA}\rvert$
n	m_s	m_l		m_s	m_l		m_s	m_l		(meV/atom)
		$\parallel$	$\perp$		$\parallel$	$\perp$		$\parallel$	$\perp$	
3	2.05	0.05		1.59	0.08		0.62	0.05		0.01
2	3.07	0.07	0.10	2.09	0.20	0.19	0.94	0.18	0.14	1.00
1	3.22	0.72	0.27	2.32	0.98	0.77	1.18	0.84	0.44	10.00
0	4	2		3	3		2	3		-

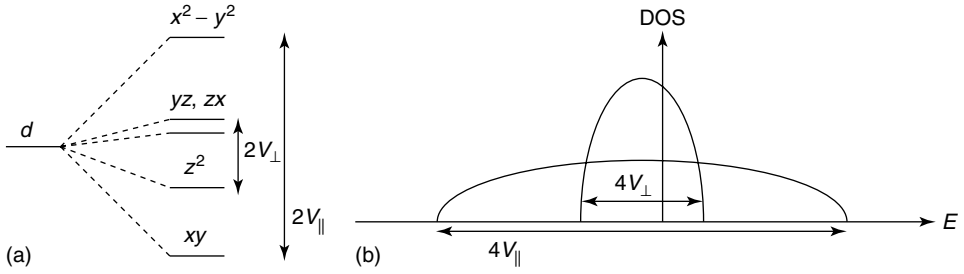

Figure 7. d-level splittings shown in (a) at a given **k** point due to a crystal field in a square monolayer result in a density of states, shown in (b).

shows that only the in-plane orbital moment, $m_l^\parallel$ depends on the splitting of the out-of-plane oriented states, while the out-of-plane orbital moment is only quenched by the in-plane crystal field. This is intuitively clear, since $m_l^\perp$ corresponds to an in-plane motion of the electron, that is, a hopping between the d_{xy} and $d_{x^2-y^2}$ states that are separated by $V_\parallel$. For the calculation of the magnetocrystalline anisotropy energy we can use equation (34), which gives:

$$K_{\mathrm{MCA}} = E_{\mathrm{MCA}}^\parallel - E_{\mathrm{MCA}}^\perp = -\frac{\xi}{4\mu_{\mathrm{B}}}\left(m_l^\parallel - m_l^\perp\right)$$
$$= -\frac{\xi^2}{8V_\parallel}\left(\frac{3}{R} + \frac{2}{R+1} - 4\right) \qquad (36)$$

From this equation we see that, as long as $R < 1$, an in-plane magnetization is obtained, while for $R > 1$ an out-of-plane easy axis is possible. Indeed it is observed that Co monolayers on a weakly interacting substrate (like Cu(001)) have an in-plane easy axis, while a Co layer sandwiched in Pt has a perpendicular magnetization. Taking typical values for 3d-metal monolayers, a spin-orbit coupling strength $\xi \approx 75\,\mathrm{meV}$ and bandwidths $W^\parallel \approx 3\,\mathrm{eV}$ and $W^\perp \approx 2\,\mathrm{eV}$, one arrives at orbital moments of $m_l^\parallel = 0.285\,\mu_{\mathrm{B}}$ and $m_l^\perp = 0.200\,\mu_{\mathrm{B}}$ and the MCA per atom of $K_{\mathrm{MCA}} = 1.6\,\mathrm{meV}$, values in the range of the *ab initio* results given in Table 5.

2.7 Dzyaloshinsky–Moriya interaction

Magnets in low dimensions frequently face a structure inversion asymmetric environment. Consider for example a thin magnetic film on a substrate with the vacuum potential on one side and the potential to the substrate on the other side. This inversion asymmetry leads to a gradient of the potential that can be interpreted in first approximation as an electric field normal to the film surface. In the rest frame of moving electrons, the electric field $\vec{E}$ appears by Lorentz transformation as a magnetic field $\vec{B} \propto \vec{p} \times \vec{E}$, which interacts then with the spin $\vec{\sigma}$ of the electron, giving rise to an additional term in the Hamiltonian, which was already encountered in equation (31) in the context of spin-orbit coupling. Here, instead of an orbital motion, a linear motion of an electron with momentum $\vec{k}$ in an electric field oriented along $\vec{e}_z$ is considered. This can be described by a Hamiltonian $H = \alpha_R \vec{\sigma} \cdot (\vec{k} \times \vec{e}_z)$, known as the *Rashba term* (Bychkov and Rashba, 1984). The strength described by the Rashba parameter, α_R, is determined for example, by the asymmetry of the wave function due to the asymmetry of the potential or the electric field, respectively, and the spin-orbit interaction of the electrons involved.

The magnetic interaction between the spin $\vec{S}_i$ at lattice site i and $\vec{S}_j$ at lattice site j is caused by electrons which hop from site i to site j and back. Electrons in a magnetic film propagate in an exchange field $\pm 1/2IM$ (cf. equation (13)), the bands are exchange split, and the time-inversion symmetry is lost. Owing to the spin-orbit interaction caused by the Rashba term, electrons experience a kinetic energy with an additional weak spin-dependent potential, which depends on the propagation direction $\vec{p}$ of the electrons. Thus, the motion from site i to j and the back motion from j to i is slightly different. The same is true for the time inverse hopping process, the electron hopping first from site j to i and then back. At first sight, both processes look identical and indeed both contribute equally to the isotropic Heisenberg exchange equation (2). But owing to the presence of the spin-orbit interaction, the inversion asymmetric environment, and the lack of time-inversion symmetry, the interference of both processes does not cancel out completely. Instead, it gives rise to an additional antisymmetric exchange interaction between these sites, known as the *Dzyaloshinsky–Moriya* (*DM*) (Dzyaloshinsky, 1958; Moriya, 1960) interaction

$$H_{\mathrm{DM}} = \sum_{i,j} \vec{D}_{ij} \cdot \left(\vec{S}_i \times \vec{S}_j\right) \qquad (37)$$

where $\vec{D}$ is a constant vector, which depends on the symmetry of the system and on the real-space direction given by two sites i and j. For example, for typical (100) and

(110) low-index surfaces of metals, $\vec{D}$ lies in the film plane and points perpendicular to the direction (i, j) connecting two surface atoms, if the two surface atoms are placed along a high-symmetry line. The DM interaction arises as the first-order perturbation in the spin-orbit interaction, and might for this reason be stronger than the magnetocrystalline anisotropy. This chiral interaction tends to orient the spin S_i and S_j orthogonal to each other and to $\vec{D}$, destabilizing a uniform FM or AFM order and can cause, depending on the strength D, a canting of the magnetization at different atoms, a helical or cycloidal spin wave. The sign of $\vec{D}$ defines the chirality of the canting. The DM interaction is practically unknown in metallic bulk magnets, since most metals crystallize in structures with centrosymmetric symmetries. Surprisingly, after 20 years of research on low-dimensional magnetism, the magnitude of $\vec{D}$ has not been established so far and there is currently active research going on to clarify its relevance for the magnetic order in nanomagnets.

3 ULTRATHIN FILMS

The transition-metal monolayers on noble-metal substrates are the classical systems exhibiting two-dimensional magnetism. Because of the reduced coordination number of nearest-neighbor transition-metal atoms in a monolayer film, the d bandwidth in two dimensions is considerably smaller and correspondingly the local density of states (LDOS) at the Fermi energy E_F is considerably larger than in the bulk situation. Thus, magnetism should occur for a much wider variety of transition-metal elements. Following this line of argument it is clear that the strength of the d–d hybridization between monolayer and substrate is an additional parameter which controls the d bandwidth of the monolayer. For instance, a large-band-gap material, for example, MgO(100), used as a substrate allows the formation of two-dimensional monolayer bands within the band gap of the substrate material. In this case the impact on the magnetization of the monolayer due to the substrate is expected to be small. The same is true for noble-metal substrates, which have d bands well below the Fermi energy. The width of the monolayer d band is not significantly broadened by the monolayer–substrate d–d interaction, and magnetism is restricted to the monolayer. Increasing the d–d hybridization by choosing appropriate nonmagnetic transition-metal substrates, for example, Pd(100) or W(110), will lead to a considerable broadening of the monolayer bands and introduce a significant spin polarization of the substrate until we have changed from the two-dimensional limit to the semi-infinite regime. Choosing a magnetic substrate an additional complexity arises owing to the competition of the magnetic coupling in the monolayer and between monolayer and substrate.

3.1 (100)-oriented monolayers on nonmagnetic substrates

3.1.1 Ferromagnetic monolayers

A systematic investigation of the magnetism of all possible 3d, 4d, and 5d transition-metal monolayers on Ag(001) is collected in Figure 8 and in Table 6. One finds that all 3d-metal monolayers (Ti, V, Cr, Mn, Fe, Co, Ni) on Ag(001) substrate show FM solutions. Tc, Ru, and Rh are FM among the 4d metals, and Os and Ir are FM among the 5d metals on Ag(001). The local magnetic moments are partly very large, not only for the 3d monolayers but surprisingly also for the 4d and 5d ones. In the 3d series the overall trend of the local moments follows Hund's first rule. The largest local moment of about $4\,\mu_B$ was found for Mn and from Mn to Ni the magnetic moment decreases in steps of $1\,\mu_B$. The latter is a consequence of the strong ferromagnetism in

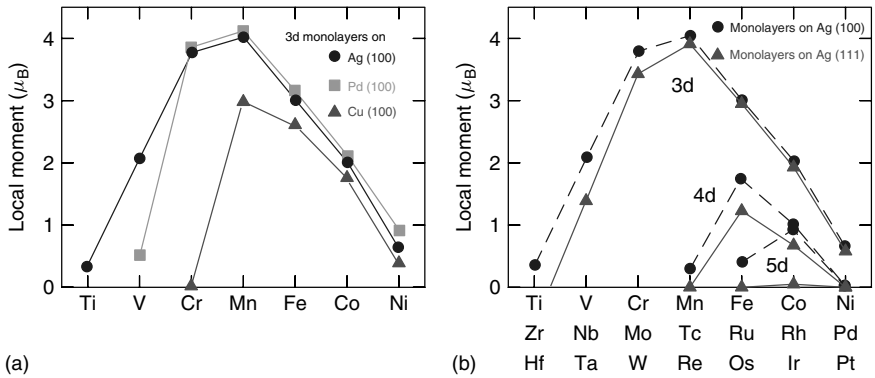

Figure 8. Local magnetic moments as calculated for ferromagnetic (a) 3d-metal monolayers on Ag(100) (Blügel and Dederichs, 1989) (dots), Pd(100) (Blügel, 1988) (squares), and Cu(001) (Blügel, 1996) (triangles), and (b) 3d, 4d (Blügel, 1992a), and 5d (Blügel, 1992b) monolayers on Ag(001) (dots) and Ag(111) (Redinger, Blügel and Podloucky, 1995) (triangles).

Table 6. Local magnetic moments in μ_B/atom for 3d transition-metal atoms as ferromagnetic (F) and antiferromagnetic (AF) 3d monolayers on Ag(001) (Blügel and Dederichs, 1989), Pd(001) (Blügel, 1988), W(001) (Ferriani, Heinze, Bihlmayer and Blügel, 2005), and on Cu(001) (Blügel, 1996; Asada and Blügel, 1997a); compared with results for 3d monolayers as interlayers (IL) in Cu(001) (Blügel, 1996), unsupported (001) monolayers (UL) in the lattice constant of Cu(111), Ag(001) (Blügel, Drittler, Zeller and Dederichs, 1989) and W(001) (Ferriani, Heinze, Bihlmayer and Blügel, 2005), and with results for ferromagnetic 3d monolayers on Cu(111) and Ag(111) (Redinger, Blügel and Podloucky, 1995) as well as on W(110) (Nie, Heinze, Bihlmayer and Blügel, 2007a). '–' indicates that no calculation was performed for this system. '0' indicates that the calculated moment was smaller than the numerical accuracy estimated to be about $0.02\,\mu_B$/atom. '?' indicates a system, for which the calculation was not finished up to self-consistency, but the result is approximately correct.

				Ti	V	Cr	Mn	Fe	Co	Ni

these monolayers. The magnetic moments of Ti, V, and Cr monolayers show a pronounced dependence on the substrate: Ti is magnetic on Ag, but nonmagnetic on Pd; the magnetic moment of V is reduced by more than $1.5\,\mu_B$ when changing the substrate from Ag to Pd; and for Cr the magnetic moment changes from $3.8\,\mu_B$ as an adlayer on Ag or Pd to zero as an adlayer on Cu. Although not as dramatic, the reduction is also visible for Mn. We attribute the drastic reductions of the monolayer moments to the reduction of the lattice constants in the sequence Ag to Pd to Cu.

When comparing the results of the local moments between 3d, 4d, and 5d monolayers on Ag(001) an interesting trend is observed: the element with the largest magnetic moment among each transition-metal series is shifted from Mn to Ru (isoelectronic to Fe) and at last to Ir (isoelectronic to Co), respectively. Following these trends we do not expect ferromagnetism for any other 4d or 5d metal on noble-metal (001) substrates, and indeed Mo and Re remained nonmagnetic. The overall picture of monolayers on Ag and Au is the same, but the different substrate interactions cause Tc and Os on Au to be nonmagnetic and lead to a slightly larger moment for Rh. Pd and Pt are predicted to be nonmagnetic. With the exception of Ru, for which a rather small magnetic moment of 0.2 μ_B was calculated, no monolayer magnetism was found for 4d metals on Pd(100). Investigations (Újfalussy, Szunyogh and Weinberger, 1995) taking into account the spin-orbit interaction have shown that the spin-orbit interactions significantly reduces the magnetic spin moment of the 5d-metal monolayers, and depending on the interlayer relaxation the spin moment might be suppressed.

3.1.2 Antiferromagnetic monolayers

It is by no means clear whether the FM state is actually the magnetic ground state. Looking at the LDOS of the 3d monolayers in Figure 9 and considering the analysis of the AFM susceptibility equation (19) we expect an AFM phase for Cr and possibly also for V and Mn monolayers. In reality, various AFM states as well as noncollinear spin configurations could be anticipated. Studying an Heisenberg model equation (2) for a square lattice as formed by the (001) monolayers up to the second-nearest-neighbor interaction (J_1, J_2) the situation becomes relatively simple. As

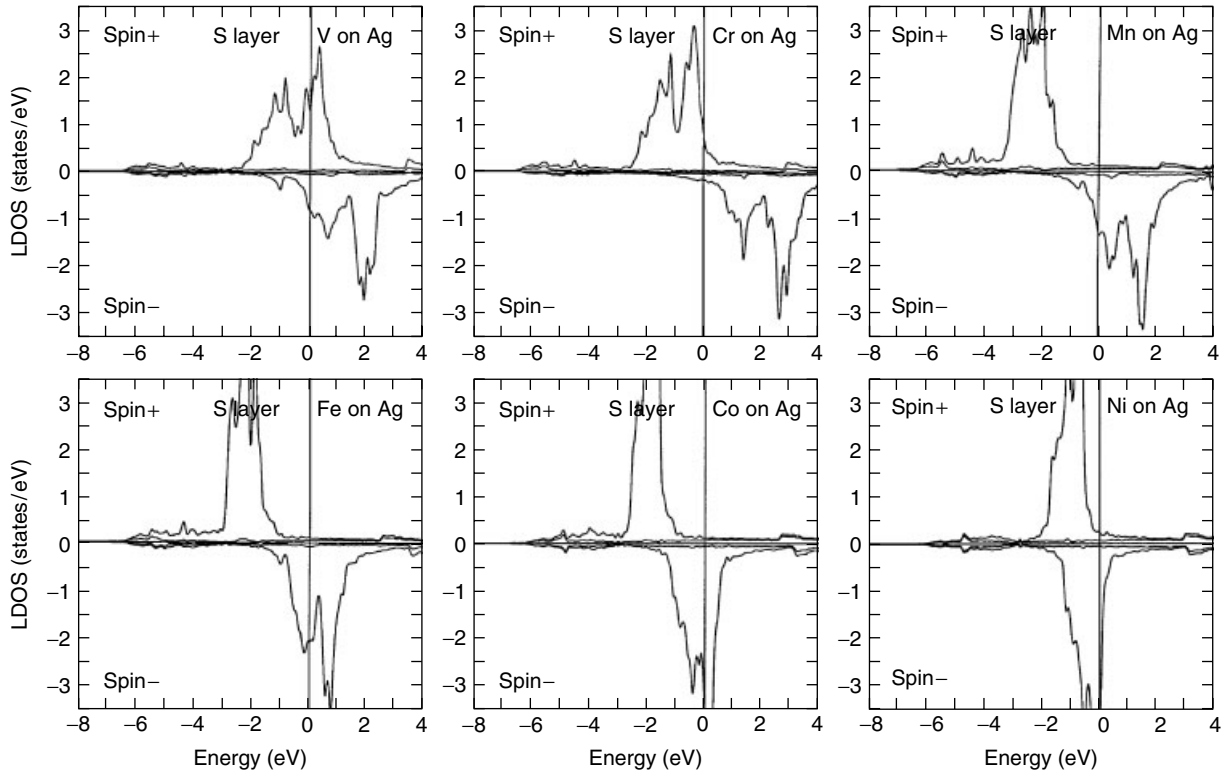

Figure 9. Local density of states (LDOS) of ferromagnetic 3d-metal monolayers on Ag(100). The Fermi energy defines the origin of the energy scale, separating occupied (at negative energies) from unoccupied states (at positive energies). Majority (minority) states are indicated by positive (negative) values of LDOS.

long as the nearest-neighbor interaction is the dominating one, there are only two phases to be considered: the FM p(1 × 1) structure ($J_1 > 0$) discussed in the previous section and the AFM c(2 × 2) superstructure ($J_1 < 0$, a checkerboard arrangement of up and down spins similar to the c(2 × 2) ferrimagnetic (FI) structure in Figure 17, but with moments of identical size on both sublattices). The c(2 × 2) structure corresponds to the $\overline{\mathrm{M}}$ point in the two-dimensional Brillouin zone (2DBZ) of the square lattice. If the next-nearest-neighbor interaction is AFM, $J_2 < 0$, and sufficiently strong, $|J_1| < 2|J_2|$, then the magnetic structure with a 2D $\vec{Q}_{\parallel}$ vector of the $\overline{\mathrm{X}}$ point in the 2DBZ, corresponding to an AFM p(2 × 1) or p(1 × 2) structure (FM rows of atoms along the [100] or [010] direction coupling antiferromagnetically from row to row) becomes the magnetic ground state.

Figure 10 shows the local moments for the FM and c(2 × 2) AFM phase of 3d monolayers on Cu(001). It becomes evident that, for many systems (see also Table 6) both configurations exist with moments of similar values. Depending on the in-plane lattice constant, differences in the local moments for the two magnetic phases develop for earlier transition metals, for example, for Cr on Cu(001), for V on Pd(001), or for Ti on Ag(001). Figure 10 also shows the energy differences $\Delta E = E_{AFM} - E_{FM}$ per atom between the c(2 × 2) AFM and the FM configuration for 3d-metal monolayers on Cu(001) and Ag(001). A clear trend emerges: the Ni, Co, and Fe overlayers ($\Delta E > 0$) prefer the FM configuration and the Mn, Cr, and V ones favor the AFM one. From the strong similarities of the monolayer trends for these two substrates we conclude that this is a general trend: Fe, Co, and Ni favor the p(1 × 1) ferromagnetism on the (001) surfaces of Pd, Pt, and the noble metals Cu, Ag, and Au (Freeman and Fu, 1987); whereas V, Cr, and Mn monolayers prefer the c(2 × 2) AFM configuration. The same trend was recently found for monolayers on W(110) (Nie, Heinze, Bihlmayer and Blügel, 2007a) and is expected for Al substrates although V and Ni might then be nonmagnetic. Since $\Delta E \approx 8S^2 J_1$, ΔE reflects basically the change of J_1 as a function of the band filling (number of d electrons) or how E_{F} moves through the LDOS in Figure 9. For Mn on Ag(001), where ΔE or J_1, respectively, is relatively small, the J's between more distant pairs may determine the picture. We investigated by total-energy calculations the stability of the possible p(2 × 1) structure and found that the c(2 × 2) structure is indeed the magnetic ground state.

The c(2 × 2) AFM phase was first predicted by theory. After the prediction several experiments indicated that the c(2 × 2) state may indeed exist: no FM long-range order was

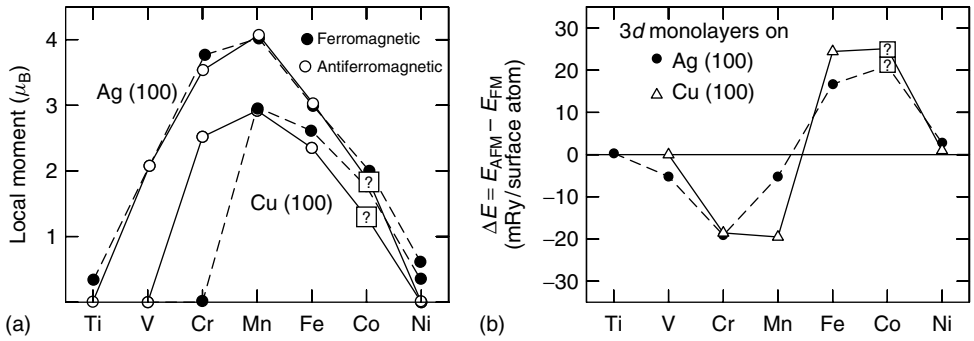

Figure 10. (a) Local magnetic moments of 3d monolayers on Cu(100) (Blügel, 1996) and Ag(100) (Blügel and Dederichs, 1989) calculated for the p(1 × 1) ferromagnetic (solid circles connected by dashed line) and the c(2 × 2) antiferromagnetic configuration (open circles connected by solid line). (b) Total energy difference $\Delta E = E_{AFM} - E_{FM}$ per 3d atom between the c(2 × 2) antiferromagnetic and p(1 × 1) ferromagnetic phase for 3d monolayers on Cu(100) (triangle connected by full line) and Ag(001) (solid circles connected by dashed line). $\Delta E > 0$ (< 0) means the ferromagnetic (antiferromagnetic) configuration is the most stable one. '?' indicates a result that is not fully converged.

found at low temperatures for a V monolayer on Ag(100) (Stampanoni *et al*., 1988), but a local exchange splitting was found for V, Cr, and Mn monolayers on Ag(100) (Ortega and Himpsel, 1993). More than 10 years after the theoretical prediction a direct proof of the c(2 × 2) AFM state became for the first time possible by using the spin-polarized scanning tunneling microscopy in the constant-current mode (Heinze *et al*., 2000; Bode *et al*., 2002). The experiments were carried out for a Mn monolayer on W(110).

3.1.3 Strongly hybridizing substrates

Strong interfacial d-band hybridization between adlayers and transition-metal substrates can modify or even destroy the adlayer magnetization. In the case of strong hybridization, the electronic structure of an interface cannot be deduced from the individual constituents, but rather the interface itself must be considered as a new material that determines the magnetic properties. Strongly hybridizing substrates are for example 4d (Nb, Mo, Ru, Rh, Pd) or 5d (Ta, W, Re, Os, Ir, Pt) metals.

As an example we present here a case study of 3d-metal monolayers on W(001) (Ferriani, Heinze, Bihlmayer and Blügel, 2005). The large surface energy of W leads to experimental conditions that permit an almost perfect preparation of ideal adlayer systems that exhibit pseudomorphic growth at the monolayer range with very little propensity to segregation. The results are summarized in Figure 11. On W(001), we find that the ground state is FM for V, Cr, and Mn, while it is c(2 × 2) AFM for Fe and Co with large energy differences between the two magnetic solutions. The observed trend across the 3d series is rather surprising as it is

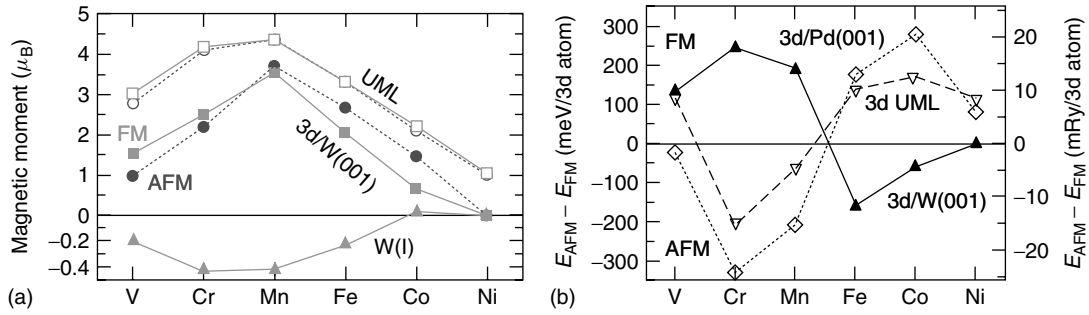

Figure 11. (a) Local magnetic moments of 3d monolayers on W(001) (Ferriani, Heinze, Bihlmayer and Blügel, 2005) and unsupported 3d monolayer (UML) in the lattice constant of W(001) calculated for the p(1 × 1) ferromagnetic (squares connected by full lines) and the c(2 × 2) antiferromagnetic configuration (circles connected by dotted lines). For the FM case, the magnetic moment of interface W atoms is given by triangles. (b) Total energy difference $\Delta E = E_{AFM} - E_{FM}$ per 3d atom between the c(2 × 2) antiferromagnetic and p(1 × 1) ferromagnetic phase for 3d monolayers on W(001), (solid triangles connected by full line), Pd(001) (Blügel, Weinert and Dederichs, 1988) (open squares connected by dotted line), and UML(001) (open triangles connected by dashed line). $\Delta E > 0$ (< 0) means the ferromagnetic (antiferromagnetic) configuration is the most stable one.

exactly opposite to the one expected from the discussion in Section 3.1.2. The theoretical predictions (Ferriani, Heinze, Bihlmayer and Blügel, 2005; Wu and Freeman, 1992b; Qian and Hübner, 2003; Sandratskii, Şaşıoğlu and Bruno, 2006) of an AFM Fe monolayer on W(001) has recently been confirmed experimentally by spin-polarized scanning tunneling microscopy (SPSTM) (Kubetzka *et al*., 2005).

Transition-metal monolayers without substrate, so-called unsupported monolayers (UMLs) and those on Pd(001) have been included for comparison. These monolayers behave as ideal two-dimensional magnets. Their trends in the magnetic phases are indeed inverted with respect to the W(001) substrate, with energy differences of similar magnitude. The results exhibited in Figure 11 are also surprising in comparison to the results of 3d-metal monolayers on W(011), showing exactly the same behavior as on noble metal substrates or Pd. This clearly gives evidence that results on W(001) are an interface effect. In the case of strong overlayer–substrate hybridization, the coordination number, symmetry, and interlayer distance is decisive in the determination of the magnetic properties of the system.

A closer look reveals a significant difference between a bcc substrate such as W and a fcc substrate such as Cu, Pd, Ag, or Au. For a bcc substrate, each transition-metal atom has four nearest W atoms at the interface, while the surrounding transition-metal atoms in the overlayer are only next-nearest-neighbor atoms. Considering that the 5d orbitals of W are more extended than the 3d ones of the overlayer and taking the additional interlayer relaxation into account, we can conclude that here the overlayer–substrate hybridization is more important than the 3d hybridization between the transition metals in the monolayer plane. Thus, the nature of the 3d–5d bond determines the physics. The chemical trend discussed here for the W(001) substrate should also hold for Mo(001), but the magnetic order of 3d metals on other bcc(001) surfaces such V, Nb, Ta is not yet clear.

The strong 3d–5d hybridization also affects the magnetic moments, displayed in Figure 11. As in previous sections the overall trend of the spin moments across the 3d series follows Hund's first rule. This atomic-like behavior indicates that the magnetism is dominated by the local intra-atomic contribution. A comparison with UMLs in the experimental W lattice constant shows that the interaction with the substrate reduces the magnetic moment of the 3d overlayer, a consequence of the 3d–5d hybridization. The magnetism of the overlayer also polarizes the substrate. For the FM configuration, W atoms at the interface are antiferromagnetically coupled to the monolayer (apart from the case of Co) and carry a moment that is roughly proportional to that of the 3d TM. The induced polarization decreases rapidly with distance from the interface into the bulk and is already one order of magnitude lower at the second W layer. The sign of the magnetization oscillates from one W layer to the next, indicating a layered antiferromagnetic (LAF) susceptibility of W(001). For AFM monolayers, the W moments are suppressed owing to symmetry.

3.1.4 Magnetointerlayer relaxation

In order to give the reader an impression (i) how strongly the formation of large monolayer moments may affect the interlayer relaxation and (ii) what is the influence of the magnetic order on the interlayer distance, total-energy calculations as a function of the interlayer distances are presented for two selected systems: Mn/Ag(001) and Mn/Cu(001). Prior to these calculations we determined the in-plane lattice constants, which are taken to be the bulk lattice constants of the substrate; we found a value of $a_0^{Cu} = 6.65\,\text{au}$ for Cu and $a_0^{Ag} = 7.58\,\text{au}$ for Ag. Clearly, the Mn monolayers show the largest magnetic moments on any substrate and the magnetovolume effects should be most substantial.

Figure 12 shows the total energy as a function of the interlayer distance for a Mn monolayer on Cu(001) and Ag(100) for three different magnetic states: nonmagnetic, FM, and c(2×2)AFM. We find, as already discussed in Section 3.1.2 that the nonmagnetic solution is the highest in energy and the AFM one is the lowest-energy magnetic state. Second, we find a substantial change of the minimum-energy interlayer distances with change of the magnetic state. On Cu(100) the most contracted minimum-energy distance was found for the nonmagnetic solution with $\Delta z_N = 1.39\%$. For the FM state a relaxation of $\Delta z_F = 4.02\%$ and for the AFM state a relaxation of $\Delta z_{AF} = 5.41\%$ was determined. We find that the effect of the long-range magnetic ground state on the relaxation is as important as the formation of moments itself: the formation of a magnetic moment expands the interlayer distance by about 2.6% and the change in the magnetic state changes the interlayer distance by 1.4%. This coincides with the energy differences between the FM state and the nonmagnetic state, which is comparable to the energy difference between the AFM state and the FM one.

On Ag(001), the interlayer relaxations for the nonmagnetic, FM, and AFM Mn monolayers are determined to be $\Delta z_N = -13.4\%$, $\Delta z_F = -6.75\%$, and $\Delta z_{AF} = -5.94\%$, respectively. The lattice constant of Ag is 14% larger than the lattice constant of Cu. Consequently the Mn atoms relax inwards on these substrates. Owing to the large Mn moments, around $4\,\mu_B$ on these substrates (recall that the moment of Mn on Cu is slightly below $3\,\mu_B$), the magnetovolume effect is very large. The FM Mn monolayers experience a large expansion of their minimum-energy interlayer distance of about 7%, much larger than for Cu and the magnetic configuration modifies this expansion by an other 1–2%. The

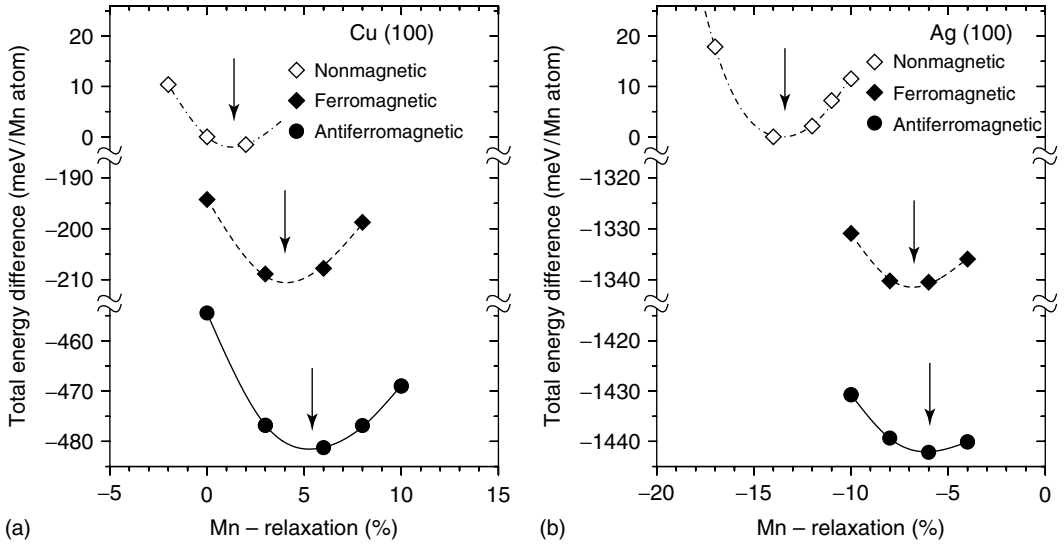

Figure 12. Total energies as a function of the interlayer relaxation for nonmagnetic (open diamonds), ferromagnetic (solid diamonds), and c(2 × 2) antiferromagnetic (solid circles) Mn monolayers on Cu(001) and Ag(001). The energy of the nonmagnetic monolayer at 0% relaxation was chosen as the origin of the total energy scale. The interlayer relaxation is given in relative units with respect to the interlayer distance of the substrate. The vertical arrows indicate the minimum-energy interlayer relaxation.

impact of the magnetic order on the interlayer distance is within about 2%, but the magnetovolume effect due to the formation of large magnetic moments is much larger for Mn on Ag than for Mn on Cu. This is in line with the arguments based on energy differences. The energy difference between the AFM state and the FM state is for all Mn systems in the same range of about 300 meV/Mn atom (cf. Table 1), while the formation energy of local moments is at large difference: about 200 meV for Mn on Cu but 1300 meV for Mn on Ag. This explains the large difference in the magnetovolume effects between Mn on Cu and Mn on Ag. In all cases the relaxations stabilize the FM and AFM phases, respectively.

In conclusion, the atomic volume depends on the magnetism, mostly on the size of the moment and to a smaller extent on the magnetic state. An extreme example of this is the experimentally observed unusually large atomic buckling of the c(2 × 2)MnCu/Cu(001) (Wuttig, Knight, Flores and Gauthier, 1993b) and c(2 × 2)MnNi/Ni(001) (Wuttig, Knight, Flores and Gauthier, 1993b) surface alloys. In these alloys a buckling of the surface atoms of 0.30Å (MnCu) (Wuttig, Knight, Flores and Gauthier, 1993b) and 0.25Å (MnNi) (Wuttig, Knight, Flores and Gauthier, 1993b) was found. Although the atomic radii of Pd and Au are much larger than for Mn, the buckling of the c(2 × 2)CuPd/Cu(001) and c(2 × 2)CuAu/Cu(001) atoms was observed to be just 0.02 Å (Wu *et al.*, 1988) and 0.10 Å (Wang *et al.*, 1987), respectively. It was shown that this buckling was a consequence of the magnetovolume effect due to the large moments of Mn (3.75 μ_B) in Cu (Wuttig, Gauthier and Blügel, 1993a) and Ni (3.55 μ_B) (Rader *et al.*, 1997).

3.2 (111)-oriented monolayers on nonmagnetic substrates

3.2.1 Ferromagnetic monolayers

The (0001) surface of an hcp crystal and the (111) surface of an fcc crystal establish a triangular lattice. Compared to the (100) surface, the coordination number changes from 4 to 6 and the symmetry changes from fourfold to threefold or sixfold, respectively. Moreover, the differences in the magnetic properties between films on a square lattice and on a triangular lattice give an estimate of the importance of the pseudomorphic growth condition for the magnetism of the films.

Figure 8 exhibits the general trend that the magnetic moments of the sixfold coordinated monolayers on Ag(111) are smaller in magnitude than those of the fourfold coordinated ones on Ag(001). On the Ag(111) surface we found magnetism for all 3d metals with the exception of Ti, the magnetism of which was very small anyway. There is nearly no difference between the monolayer moments of Mn, Fe, Co, and Ni on the differently oriented Ag substrates. A comparatively larger reduction of the magnetic moments is found at the beginning of the 3d series where the wave function is more extended than it is at the end of the series. Thus, changing the coordination number from 4 to 6, does not significantly change the local moments. One consequence of this

result is that for monolayers that do not grow pseudomorphically on any substrate but keep an average distance between monolayer atoms similar to the pseudomorphic films, no dramatic difference in the formation of large local moments is expected.

With the exception of Ru ($1.23\,\mu_B$) and Rh ($0.67\,\mu_B$) and a tiny moment for Ir ($0.05\,\mu_B$) among the 5d metals, no ferromagnetism was found for any other 4d and 5d monolayers on Ag(111). For the 4d-metal monolayers Ru and Rh, the moments are reduced to about 70% of the (001) values, and for the 5d metal Ir only a tiny magnetic moment of $0.05\,\mu_B$, about 15% of the (001) value, remains. Obviously, the degree of the reduction of the magnetic moments due to the increase of the hybridization with the increase of the coordination number from 4 to 6 simply follows the increasing degree of delocalization of the d wave function when moving from the 3d to the 4d and 5d transition-metal wave functions.

3.2.2 Monolayers with complex spin structures

AFM interactions on a triangular lattice are the origin of frustrated spin systems. The epitaxial growth of such ultrathin films has been studied intensively by various experimental techniques. In particular, pseudohexagonal c(8×2)Mn films on Cu(100) (Flores, Hansen and Wuttig, 1992), Mn films on the (111) surfaces of fcc Pd (Tian *et al*., 1992b); Ir (Andrieu *et al*., 1996); Cu (Tian, Begley and Jona, 1992a; Grigorov and Walker, 1997; Grigorov *et al*., 1998), and MgO (Grigorov, Fitzsimmons, Siu and Walker, 1999), and on the (0001) surface of Ru (Arrott *et al*., 1987) and Co (Ounadjela *et al*., 1994) have been prepared and analyzed. But also other ultrathin hexagonal films, for example, Cr and V on Pt(111) and Ru(0001) (Zhang, Kuhn and Diebold, 1997; Albrecht *et al*., 1998; Sambi and Granozzi, 1999), or Fe on Ir(111) (von Bergmann *et al*., 2006) have been investigated.

To obtain an overview of all relevant spin structures we develop first a zero-temperature phase diagram in the context of the Heisenberg model. As discussed in Section 2.2 the magnetic ground states are SSDWs, most likely with a commensurate propagation vector $\vec{q}_\parallel$ located at the high-symmetry points in the first 2DBZ of a 2D Bravais lattice. For the 2DBZ of the triangular (hexagonal) lattice, displayed in Figure 13 (a), the high-symmetry points are the corner points $\overline{\Gamma}$, $\overline{\mathrm{K}}$, and $\overline{\mathrm{M}}$ of the irreducible wedge of the 2DBZ (I2DBZ). The $\overline{\Gamma}$ point corresponds to the FM solution. The $\overline{\mathrm{K}}$ point corresponds to a 120° Néel state (Figure 13c), a 2D coplanar spin structure with three atoms in a $(\sqrt{3} \times \sqrt{3})$ R30° unit cell for which the relative angle between the spins at the different sites is always 120°. The $\overline{\mathrm{M}}$ point corresponds to a row-wise antiferromagnetic (RW-AFM) configuration (Figure 13b), which can be described by a rectangular unit cell with two antiferromagnetically aligned atoms. Magnetic ground states with incommensurate $\vec{q}_\parallel$ vectors are also possible preferentially with $\vec{q}_\parallel$ vectors from the connecting high-symmetry lines $\overline{\mathrm{M}}$-$\overline{\Gamma}$-$\overline{\mathrm{K}}$-$\overline{\mathrm{M}}$.

Along the line $\overline{\mathrm{M}}$-$\overline{\Gamma}$-$\overline{\mathrm{K}}$-$\overline{\mathrm{M}}$ we investigated the energetics within the Heisenberg model up to the second-nearest-neighbor interaction, that is, including the exchange constants J_1, J_2. The results are summarized in Figure 14 in terms of a zero-temperature phase diagram.

Depending on the signs and values of J_1 and J_2, four kinds of possible magnetic ground states exist: FM, RW-AFM, 120° Néel, and SSDW. If J_2 is zero or positive (FM) than there are only two possible magnetic ground states, determined by the sign of J_1 – the FM and the Néel state. But small values of J_2 are already sufficient to change the magnetic ground state and an infinite number of

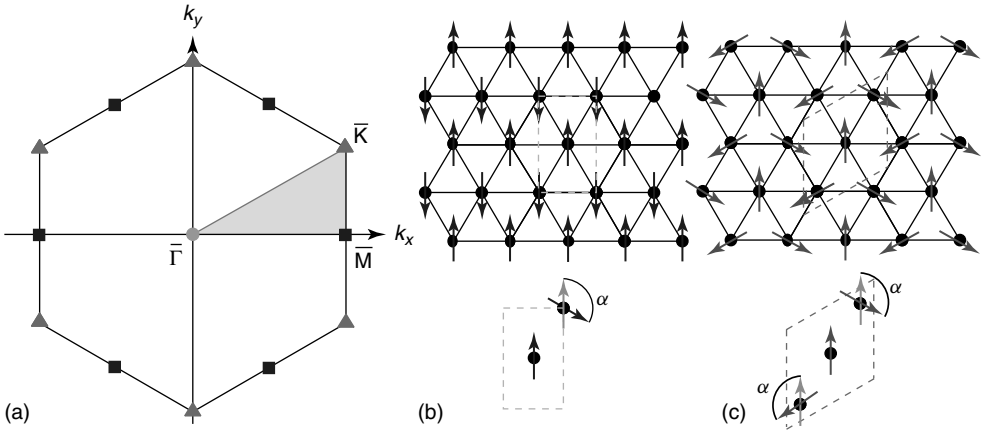

Figure 13. (a) The hexagon shows the first BZ of the 2D hexagonal Bravais lattice. The gray-shaded area indicates the irreducible part. (b) The RW-AFM structure. (c) The coplanar noncollinear Néel (120°) structure. Indicated are the corresponding two- and three-atom unit cells and the continuous paths, which connect the corresponding magnetic structure to the FM state.

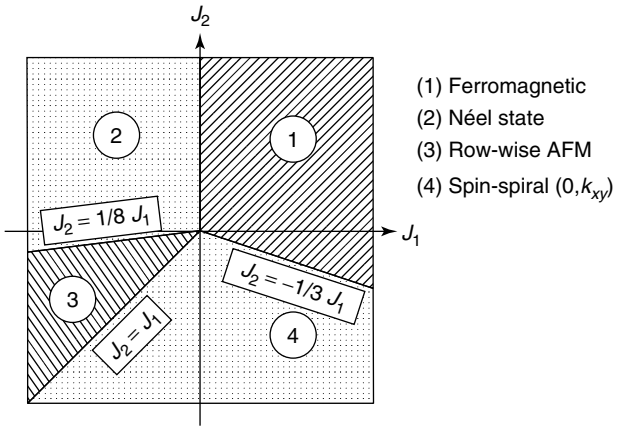

Figure 14. Zero-temperature phase diagram in the (J_1, J_2) space for the triangular lattice indicating the regions of the four possible magnetic states.

magnetic states becomes possible, the RW-AFM state or the incommensurable SSDW at any possible wave vector $\vec{q}_\parallel$ at the high-symmetry line $\overline{\Gamma}$-$\overline{\mathrm{M}}$. Extending the model by also including J_3, a magnetic state with a $\vec{q}_\parallel$ at any high-symmetry line can become a ground state.

Since the J's are rapidly varying functions of the number of d electrons, *ab initio* calculations are carried out to determine the element-specific ground states. Since the calculations are very time consuming, the full overview has been worked out only for unsupported, freestanding monolayers (UMLs). Figure 15 shows for the UMLs with the Cu lattice constant the total energy $E(\vec{q}_\parallel)$ and the magnetic moments $M(\vec{q}_\parallel)$ calculated for a discrete set of the spin spiral $\vec{q}s_\parallel$ vectors along the high-symmetry lines. Among all the SSDWs calculated, the high-symmetry points have the lowest energies: the 120° Néel state ($\overline{\mathrm{K}}$ point) for Cr(111), the RW-AFM state ($\overline{\mathrm{M}}$ point) for Mn(111), and the FM state ($\overline{\Gamma}$ point) for Fe(111). For Fe and Mn, the $M(\vec{q}_\parallel)$ are nearly a constant, but the Cr moments change drastically, as no FM solution could be found for Cr(111). Another interesting observation is the local minimum of $E(\vec{q}_\parallel)$ for Mn on the line $\overline{\Gamma}$-$\overline{\mathrm{K}}$, which is only 21 meV higher in energy than the RW-AFM state. We expect that a small change in the d-band filling, for example, due to alloying with Fe, may change the energetics and an incommensurate SSDW may become the magnetic ground state.

For Mn, the lowest-energy magnetic state found so far is the RW-AFM state, which corresponds to the commensurate SSDW state with one single $\vec{Q}_\parallel$ vector at the $\overline{\mathrm{M}}$ point of the 2DBZ, and the RW-AFM is also called *single-*$\vec{Q}_\parallel$ (1Q) *state*. In the 2DBZ there are three $\overline{\mathrm{M}}$ points corresponding to the three possible directions of the long axis of the RW-AFM unit cell on a triangular lattice. They are equivalent in symmetry but are different from each other with $\vec{Q}_\parallel$ vectors, $\vec{Q}_\parallel^{(k)}$, for

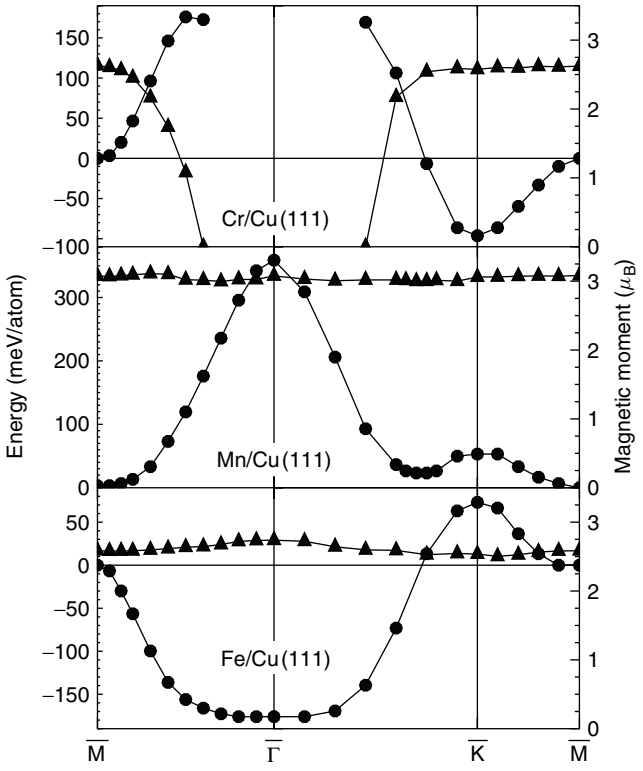

Figure 15. Calculated total energies (circles, left scale) and magnetic moments (triangles, right scale) for spin-spiral states in 3d UMLs with the Cu(111) geometry as function of the 2D wave vector $\vec{q}_\parallel$ along the high-symmetry lines of the 2DBZ. The energy is shown relative to the energy of the RW-AFM state.

$k = 1, 2, 3$. Within the Heisenberg model, the energy of each SSDW denoted by one of the three wave vectors $\vec{Q}_\parallel^{(k)}$ or any SSDW being an orthogonalized linear combination of these vectors is degenerate. Higher-order spin interactions (equations (4) and (5)) may lift this degeneracy and a so-called triple-$\vec{Q}_\parallel$ (3Q)-state, may become lower in energy. The 3Q state is a three-dimensional noncollinear spin structure on a 2D lattice (see Figure 16) with four chemically identical atoms per surface unit cell, where the relative angle between all nearest-neighbor spins is given by the tetrahedron angle of 109.47°. The 3Q state is formed as a linear combination of the three RW-AFM (1Q) structures orthogonal in spin space, each having one of the three $\vec{Q}_\parallel^{(k)}$ vectors of the $\overline{\mathrm{M}}$ points:

$$\vec{m}(\vec{r} + \vec{R}_i) = m(\vec{r}) \times \frac{1}{\sqrt{3}} \sum_{k=1}^{3} e^{i\,\vec{Q}_\parallel^{(k)}\,\vec{R}_i}\,\vec{e}^{(k)} \qquad (38)$$

where the $\vec{e}^{(k)}$ are orthogonal unit vectors in spin space. We see that in the nearest-neighbor approximation to the higher-order exchange contributions, the sign of K_1 and B_1 determine the sign of the energy difference $\Delta E = E_{3Q} - E_{1Q} = 16/3S^4(2K_1 + B_1)$ and thus whether the 3Q or the

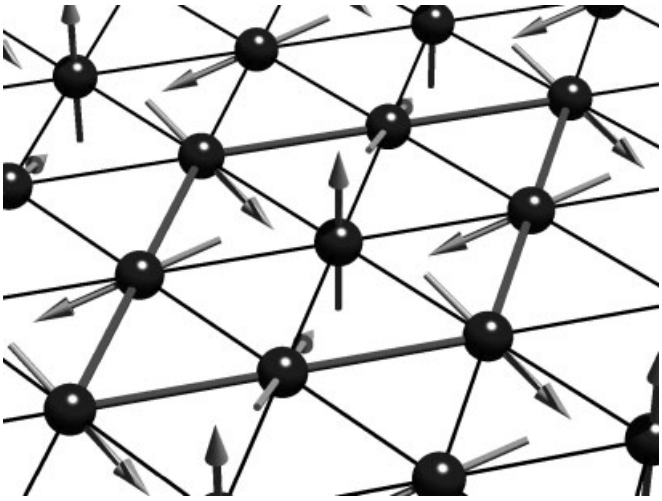

Figure 16. An image of the magnetic 3Q structure, with spins pointing in all three directions of the spin space. Note that, because the spin-orbit interaction is neglected, only the relative orientation of the moments is specified.

1Q state becomes the magnetic ground state. From the *ab initio* calculations for the Mn UML in the geometry of Cu(111) we (Kurz, Bihlmayer, Hirai and Blügel, 2001) found that the 3Q state is 15 meV/atom lower in energy than the 1Q state.

Calculations including the Cu(111) substrate show that the energy differences between different magnetic states change because of the presence of the substrate, but the magnetic ground state remains unaltered: Cr/Cu(111) exhibits the 120° Néel state ($2.35\,\mu_B$), Mn/Cu(111) the 3Q structure ($2.74\,\mu_B$), which is 17 meV lower in energy than the 1Q state ($3.00\,\mu_B$), and Fe/Cu(111) is FM ($2.63\,\mu_B$). On the Ag(111) substrate (Heinze *et al*., 2002) the overall picture is the same, but two differences were noticed: V/Ag(111) is magnetic ($2.19\,\mu_B$) and exhibits as Cr/Ag(111) ($3.65\,\mu_B$) the 120° Néel state and the magnetic ground state of Mn/Ag(111) is the RW-AFM state ($3.91\,\mu_B$) and not the 3Q state ($3.88\,\mu_B$). Fe/Ag(111) is FM ($3.02\,\mu_B$). We believe that the complex spin structures presented here can be resolved using the SPSTM in the constant-current mode (Wortmann *et al*., 2001; Heinze *et al*., 2002). In fact, recent SPSTM results (von Bergmann *et al*., 2006) of an Fe monolayer on the strongly hybridizing Ir(111) substrate yielded a very surprising and unprecedented nanometer-size spin structure exemplifying again that the arguments on the magnetic structure developed for weakly interacting substrates cannot be carried over easily for strongly hybridizing substrates. Since strongly hybridizing substrates have been investigated only recently, great surprises on the magnetic spin structures can be expected in the future.

3.3 Magnetic substrate: magnetic exchange coupling of 3d metals on Fe(001)

3.3.1 Monolayers

3d-metal monolayers on Fe(001) are prototypical systems where the in-plane magnetic interactions, described by the exchange coupling parameter $J_\parallel$, compete with the strong magnetic interactions $J_\perp$ between the monolayer and the substrate. Depending on the signs and values of $J_\parallel$ and $J_\perp$, complex spin structures as ground states can be anticipated. Finally, total-energy calculations are required to determine the minimum-energy magnetic state among the various metastable solutions. We recently carried out calculations (Handschuh and Blügel, 1998; Asada *et al*., 2000) which considered three competing spin structures: the p(1 × 1) FM, the p(1 × 1) LAF and the c(2 × 2) FI spin configurations displayed in Figure 17.

Figure 18 summarizes the results from calculations for structurally unrelaxed monolayers, that is, where the monolayer atoms are located at the ideal, bulk truncated, pseudomorphic Fe atom sites. For most 3d-metal overlayers (Cr, Mn, Fe, Co) on Fe(001) all three configurations exist and are energetically stable. Only the V and Ni monolayers were found to couple exclusively layered antiferromagnetically or ferromagnetically, respectively, to the Fe(001) substrate. Surprisingly, the FM ($M > 0$), the LAF ($M < 0$), and the two different magnetic moments ($M_1 > 0$ and $M_2 < 0$) for the FI phase are all similar in size. The largest magnetic moment of about 3 μ_B was found for Mn, and then the magnetic

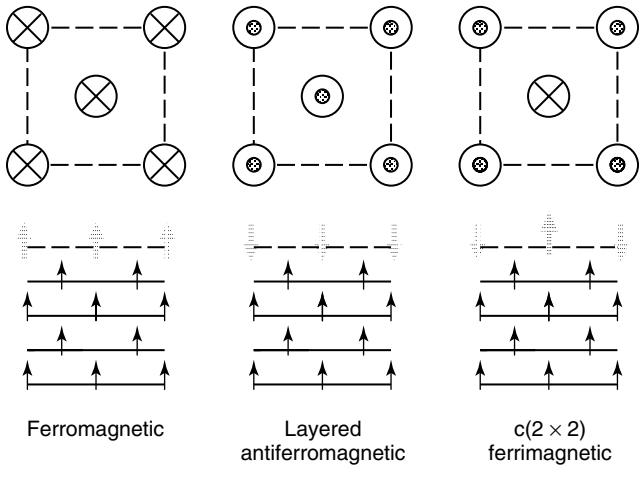

Figure 17. Schematic representation of a ferromagnetic, a layered antiferromagnetic, and a c(2 × 2) (anti)ferrimagnetic superstructure of a monolayer film (broken line) grown as overlayer on a magnetic substrate (full line). Upper panel shows view onto the surface, lower panel shows side view. Arrows indicate the relative spin direction at the positions of the atoms.

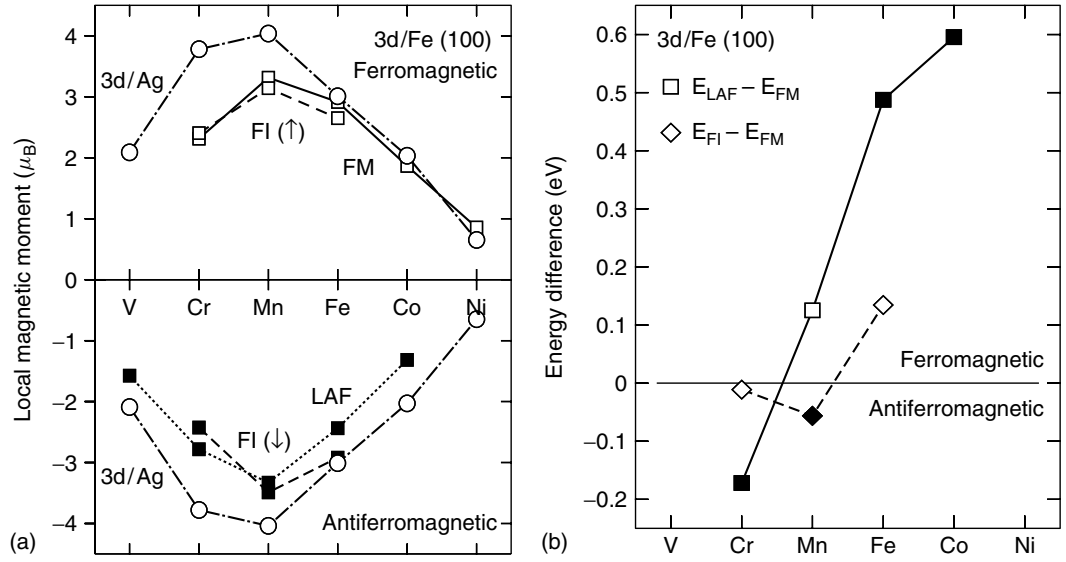

Figure 18. (a) Local magnetic moments of unrelaxed 3*d* transition-metal monolayers on Fe(001). Positive (negative) sign of moments indicates an (anti)ferromagnetic, FM (AF), spin alignment to the Fe substrate, emphasized by open filled) symbols. Shown are results of three different spin configurations: p(1 × 1) FM (solid line), p(1 × 1) LAF (dotted line), and the c(2 × 2) FI (dashed lines) for positive and negative moments. The figure is complemented with results for 3d monolayers on Ag(001) (◯ connected by dash-dotted line). As the Ag substrate is nonmagnetic, ferro-, and antiferromagnetic spin alignment is indistinguishable and moments are identical and are shown twice, once for positive and negative sign. (b) Total energy difference $\Delta E_1 = E_{\mathrm{LAF}} - E_{\mathrm{FM}}$ between the p(1 × 1) layered antiferromagnetic and the ferromagnetic coupling (squares connected by solid lines) and $\Delta E_2 = E_{\mathrm{FI}} - E_{\mathrm{FM}}$ between the c(2 × 2) ferrimagnetic and the p(1 × 1) ferromagnetic coupling (diamonds connect by dashed lines) of 3d transition-metal monolayers with Fe(001). The ferromagnetic (layered antiferromagnetic or ferrimagnetic) coupling has lower energy for $\Delta E > 0$ (<0) and is therefore favored. The layered antiferromagnetic coupling is preferred over the ferrimagnetic one if $\Delta E_1 < \Delta E_2$. Filled squares or diamonds indicate the magnetic ground state. For V and Ni only one magnetic state has been found.

moments drop for elements to the left and right of Mn, reminiscent of the behavior on the noble-metal substrates.

In order to see the effect of the hybridization between the substrate and the overlayer on the size of the local moments, the local magnetic moments of 3d-metal monolayers on Ag(001) (Blügel and Dederichs, 1989) are included for comparison. Fe ($a_{\parallel} = 5.33$ au) and Ag ($a_{\parallel} = 5.51$ au) have very similar in-plane lattice constants and thus very similar in-plane d–d hybridizations may be expected for the monolayer, but the d–d hybridization across the interface is largely different. From Figure 18(a) one infers that the magnetic moments for the Fe, Co, and Ni monolayers are rather independent of the substrate, but increasing deviations are obtained for the monolayer moments in the sequence from Mn to V. The extent of the 3d wave function increases for chemical elements from the end of the 3d series to the beginning of the series. Accordingly, the d–d hybridization within the monolayer and between the monolayer and the Fe substrate increases. As a consequence, the magnetic moments for Mn, Cr, and V overlayers are visibly reduced.

Since the local magnetic moments of the three different magnetic states for Cr, Mn, Fe, and Co monolayers on Fe(001) are very similar in size, total-energy calculations have been performed to determine the minimum-energy magnetic configuration. The energy difference $\Delta E_1 = E_{\mathrm{LAF}} - E_{\mathrm{FM}}$ between the LAF and FM configurations and $\Delta E_2 = E_{\mathrm{FI}} - E_{\mathrm{FM}}$ between the c(2 × 2) FI and the FM configurations, ignoring again any monolayer relaxation, are shown in Figure 18(b). For V and Ni monolayers, which show only one magnetic solution, no data points are included. As reported in the literature (Mirbt, Eriksson, Johansson and Skriver, 1995; Handschuh and Blügel, 1998; Wu and Freeman, 1995) we find with the exception of Cr, that the FM coupling ($\Delta E_1 > 0$) is energetically always more favorable than the LAF one and that for Cr and Mn the FI coupling ($E_2 < 0$) is energetically preferred over the FM one. For Fe, Co, and Ni, the FM solution is the most stable one. When we compare for Cr or Mn the energies among the three different magnetic phases, we find that for Cr the LAF coupling is the magnetic ground state, energetically followed by the FI and the FM coupling, which are metastable phases. The calculated total-energy differences between FM and LAF configurations and between FM and FI show some differences from those of Handschuh *et al.* (Handschuh and Blügel, 1998) mostly due to the different choice of the in-plane lattice constant. Summarizing, (i) the magnetic ground-state structures

are LAF for V and Cr, FI for Mn, FM for Fe, Co, and Ni; (ii) for the Mn monolayer we find a second spin configuration with an energy of about 55 meV/Mn above the ground-state structure.

Therefore, extending the search for the magnetic ground state of Mn to larger surface unit cells may lead to a more complicated ground-state spin structure. Elmouhssine, Moraïtis, Demangeat and Parlebas (1997) and Asada *et al*. (1999) investigated the possibility of additional low-energy Spin structures in the p(2 × 2) surface unit cell containing four Mn surface atoms. Two additional spin structures were included: the p(2 × 2) FM magnetic structure with three Mn atoms out of four coupling ferromagnetically to the Fe substrate and one Mn atom coupling antiferromagnetically, as well as the p(2 × 2) AF structure, which is the LAF version of p(2 × 2) FM, where three Mn atoms couple antiferromagnetically and one atom couples ferromagnetically to Fe. Indeed the calculations reveal that on Fe(001), the Mn c(2 × 2) FI, and the p(2 × 2) FM are nearly degenerate ground states. This is obvious from Figure 19, which displays the energies of the different configurations relative to the c(2 × 2) FI state energy. Tight-binding linear muffin-tin orbital calculations by Elmouhssine *et al*. found that the p(2 × 2) FM superstructure is 15 meV higher in energy than the c(2 × 2) one, while Asada *et al*. found by full-potential linearized augmented planewave (FLAPW) calculations that the total energy of the p(2 × 2) FM superstructure is slightly lower (∼6.4 meV/Mn) than the c(2 × 2) FI structure. The interlayer distances of relevant magnetic configurations had been fully optimized by the use of force calculations; however this is not shown here and these relaxations do not change this picture. The energy differences are comparable to the thermal energy at room temperature. Thus, surface roughness and thermal excitations in true experimental situations could lead to the coexistence of these two magnetic configurations and thus the appearance of magnetic domains within the Mn monolayer. At present one cannot exclude the possibility of magnetic states with even lower energy that have not been investigated yet.

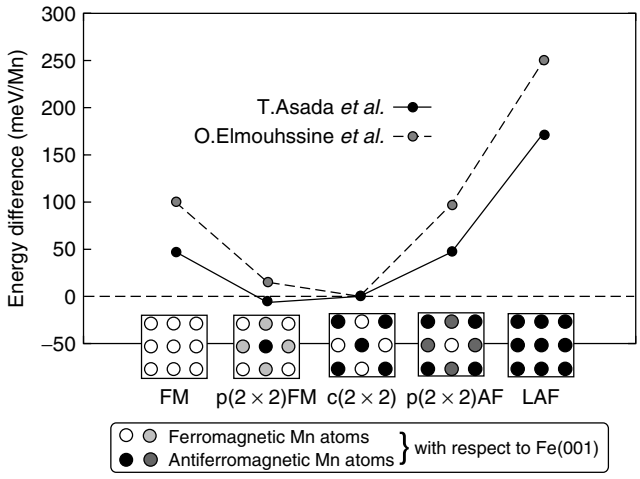

Figure 19. Relative energy $E - E_{c(2\times2)}$ for the five magnetic configurations. The small energy difference between the c(2 × 2) FI state and the p(2 × 2) FM configurations indicates that the two solutions are nearly degenerate ground states.

3.3.2 *Double layers*

In order to demonstrate the complexity of the systems we show here the results of the 3d metal bilayers on Fe(001) as well. For the double layer systems, we have examined all possible magnetic configurations within the c(2 × 2) unit cell. With the exception of Mn all stable magnetic configurations found have the magnetic p(1 × 1) structure. The magnetic ground states are the p(1 × 1) LAF one for V, Cr, and Mn, and the p(1 × 1) FM one for Fe, Co, and Ni bilayers on Fe(001). For Mn we found in addition to the p(1 × 1) LAF ground-state structure also the superstructure ($[\uparrow\downarrow]_S$ $\downarrow_{S-1}$ | ↑ Fe) as a stable solution with a total energy of 43.2 meV/Mn higher than the LAF structure. The magnetic moments for the bilayer systems are collected in Figure 20. Please note for the case of the LAF Mn double layer the almost vanishing magnetic moment of the subsurface atom. Furthermore, for the Mn bilayer, in addition to those two configurations, the ground state ($\uparrow_S$ $\downarrow_{S-1}$ | ↑ Fe) and the

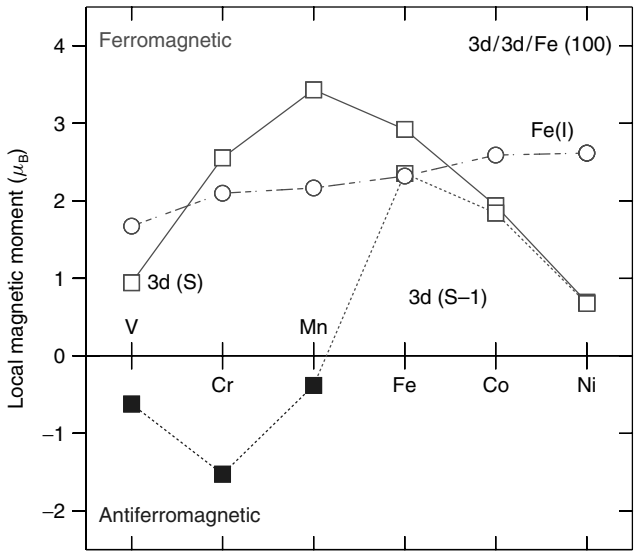

Figure 20. Local magnetic moments (M) for the ground-state spin configurations of unrelaxed 3d transition-metal double layers on Fe(001). The solid line denotes the 3d surface atoms (3d(S)) aligned parallel ($M > 0$) to the Fe substrate, the dotted line denotes the 3d subsurface atoms (3d (S − 1)), whose coupling changes from LAF ($M < 0$) to FM ($M > 0$) from early to late 3d elements. The chained line denotes the interface Fe atoms (Fe(I)).

superstructure stated in the preceding text, we also found a third configuration, ($\downarrow_S \uparrow_{S-1} \mid \uparrow$ Fe), which is about 9 meV/Mn higher in energy than the ground state. Thus, there exist three states within an energy range corresponding to about 400 K. We believe that this gives already a glimpse of the difficulties involved in dealing with thicker Mn overlayers on Fe(001) (Pfandzelter, Igel and Winter, 1997).

For a Cr monolayer the measured magnetic moment was found to be at most 1 μ_B (Hillebrecht *et al*., 1992; Jungblut, Roth, Hillebrecht and Kisker, 1991), which is less than half of the theoretical prediction (Mirbt, Eriksson, Johansson and Skriver, 1995; Handschuh and Blügel, 1998). It was also reported that the layer-by-layer growth leads to a strong intermixing with the substrate Fe layers (Venus and Heinrich, 1996; Pfandzelter, Igel and Winter, 1996; Davies, Stroscio, Pierce and Celotta, 1996). Mn overlayers seem to be even more involved. There is a general experimental consensus that for Mn around 1 ML coverage, the signals related to the magnetization disappear. The microscopic origin for this observation is under strong debate. One explanation supported by theory (Handschuh and Blügel, 1998; Wu and Freeman, 1995) is a possible onset of the in-plane FI coupling. On the other hand, strong interfacial alloying has been observed (Igel, Pfandzelter and Winter, 1998), which may lead to the same results. A third option is the possibility of a double layer growth mode, which may also lead to the disappearance of magnetic signals. The difficulty in controlling and characterizing the morphology of the interface seems to be intimately related to the difficulties in understanding the interfacial magnetism of those systems. A complete picture requires additional theoretical investigations including the possibility of interdiffusion and surface alloying.

3.4 Orbital moment and magnetic anisotropy

3.4.1 Trends in unsupported (100) monolayers

The orbital magnetic moments (m_l) and the MCA are fairly small quantities compared to spin moments and exchange energies. This holds at least for 3d transition metals. These quantities depend on fine details of the electronic structure which changes with lattice constant, film thickness, choice of substrate, and surface orientation. Although it is important to know the actual values of the m_l and the MCA for particular systems, in this subsection we try to provide insight and intuition into the behavior of these quantities by studying the chemical trend of these properties across the transition-metal series. We focus on (100)-oriented unsupported 3d, 4d, and 5d transition-metal monolayers in the lattice constant of Ag(100) ($a_0/\sqrt{2} = 5.459$ au). In order to proceed with a fine scale analysis of these properties as function of the electronic structure or the band filling, respectively, the relativistic density-functional calculations are carried out for films of hypothetical atoms with noninteger nuclear numbers. The rationale behind this *modus operandi* is the idea that owing to the required charge neutrality, the nuclear number and the number of electrons are the same. Thus, a fine change of the nuclear number is followed by a fine change of the number of electrons, caused by the adjustment of the Fermi energy. This facilitates a fine scan of m_l and the MCA as a function of the band filling across the transition-metal series. For example, for the 3d monolayers we have varied the nuclear number Z from the beginning to the end of the transition-metal series, for example, from $Z = 21$ with $N_V = 3$ valence electrons till Cu, $Z = 29$ with $N_V = 11$ valence electrons, in steps of approximately $\Delta Z = 0.10 \sim 0.15$.

The results are summarized in Figure 21. For each Z, two self-consistent relativistic *ab initio* calculations have been carried out, one with the magnetization direction perpendicular to the film plane, $\widehat{m} = \uparrow$, and one with the magnetization parallel to the film plane along the [100] direction, $\widehat{m} = \rightarrow$. The results obtained are the orientation-dependent spin moments, $m_s(\uparrow)$ and $m_s(\rightarrow)$, orbital moments, $m_l(\uparrow)$ and $m_l(\rightarrow)$, and electronic total energies, $E(\uparrow)$ and $E(\rightarrow)$. Here we focus on the FM phase.

The magnetic spin moments exhibited in Figure 21(a), follow the trend discussed in Section 3.1.1: The 3d monolayers behave according to Hund's first rule with a maximum moment of more than 4 μ_B in the center of the series. Also 4d- and 5d-metal monolayers are magnetic for elements between Mo till close to Pd and between W till close to Pt. The magnetic moments decrease from the 3d to the 4d and 5d series and at the same time the element with the maximum magnetic moment in each series shifts to the right in the series. The anisotropy of the spin moments, $\Delta m_s = m_s(\uparrow) - m_s(\rightarrow)$, is very small, for example the calculation of an Ir monolayer yields $m_s(\uparrow) = 1.044\,\mu_B$ and $m_s(\rightarrow) = 1.012\,\mu_B$ and is therefore not further considered. However, for 5d elements, relativistic calculations have an impact on the size of the spin moments. For example, the spin-orbit interaction reduces the magnetic moment of Ir by 0.5 μ_B to about 1 μ_B.

According to equation (30), E_{dip} is proportional to m_s^2 and inversely proportional to third power of the lattice constant, a. Since the lattice constants of all systems are fixed to the one of Ag, Figure 21(a) mirrors the functional behavior of the dipole energy E_{dip} with respect to the band filling. Since the dipolar anisotropy or shape anisotropy in the continuum limit, respectively, $K_{dip} = \Delta E_{dip} = E_{dip}(\rightarrow) - E_{dip}(\uparrow)$, always favors a magnetization in the film plane, the shape anisotropy is strictly negative according to our sign convention for the magnetic anisotropy. The largest value is obtained for a film with elements

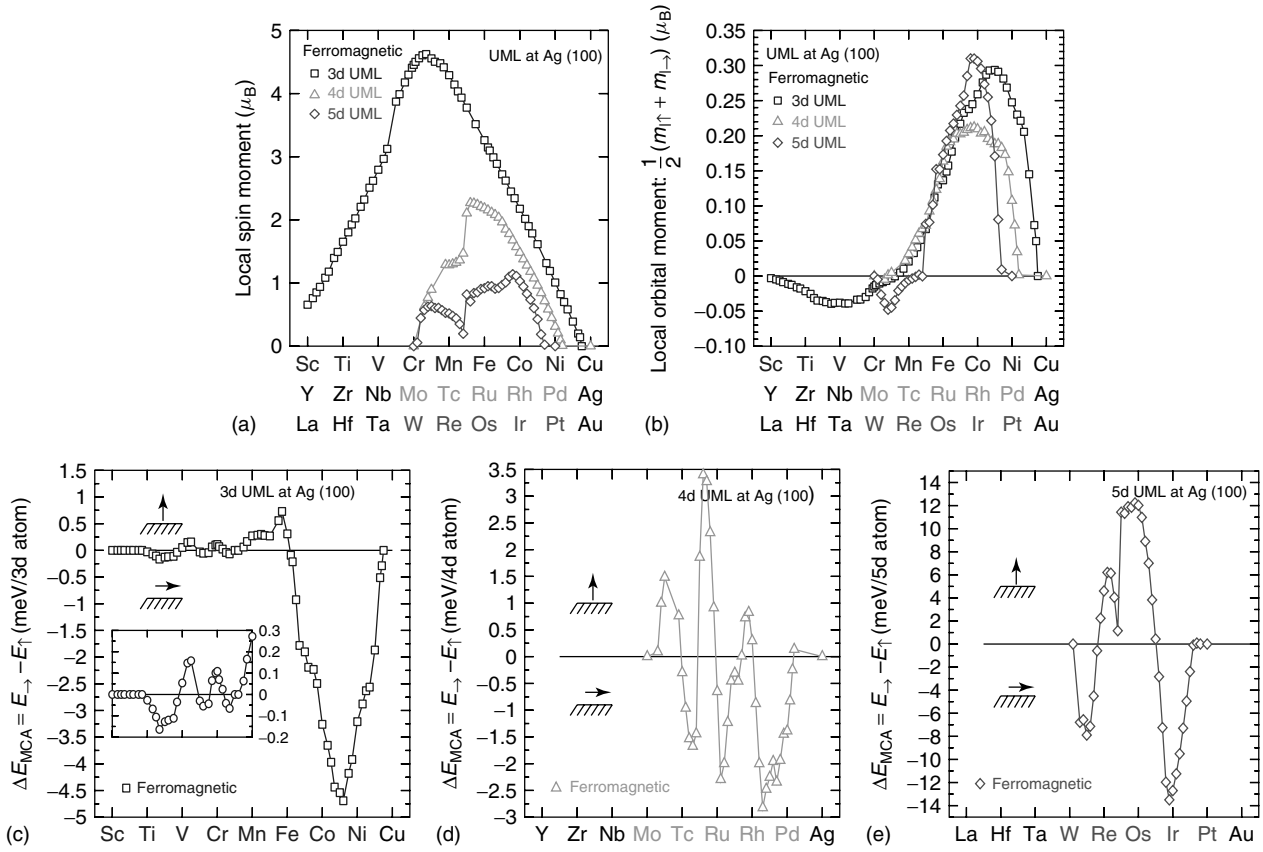

Figure 21. Local magnetic spin moments (a) and orbital moments (b), magnetocrystalline anisotropy constant $K_{MCA} = \Delta E_{MCA}$ calculated as energy difference between two magnetization directions, the magnetization in the film plane ($\rightarrow$) and out of the film plane ($\uparrow$), calculated for ferromagnetic, freestanding, unsupported 3d- (squares) (c), 4d- (triangles) (d), and 5d- (diamonds) (e) metal monolayers (UML) in the (100) surface orientation and in the lateral lattice constant of the Ag(100) substrate (Nie, Bihlmayer and Blügel, 2006). In (b) the average orbital moments between those of the out-of-plane, $m_{l\uparrow}$, and in-plane, $m_{l\rightarrow}$, magnetization directions are shown. The difference of the spin moments on the magnetization direction is difficult to distinguish on the scale of (a) and is not shown. Positive energies in (c)–(e) mean that the out-of-plane magnetization is energetically preferred.

between Cr and Mn and the dipolar anisotropy amounts to $K_{dip} = -0.32$ meV/atom. This is about 30% of the value of K_{shape} as calculated according to equation (29) using continuum theory, in good agreement with the results of Draaisma and de Jonge (1988).

Also the orbital moments, collected in Figure 21(b) exhibit a clear trend: the orbital moments are negative in the first half of the transition-metal series, for example, between Sc and Mn, and positive in the second half of the transition-metal series. The change in sign is reminiscent of Hund's third rule which governs the coupling of the spin and orbital moment. A negative (positive) sign of the orbital moment means that the orbital moment couples opposite (parallel) to the spin moment. The orbital moments of elements in the second half of the transition-metal series are an order of magnitude larger than in the first one. It is surprising that the orbital moments in films made of the 3d, 4d, or 5d elements in the second half of the corresponding transition-metal series show very similar values although the spin moments are substantially different. We recall from equation (35) that for uniaxial symmetry as present in thin films, the orbital moment scales as $m_l \propto \xi \propto Z^2$, which explains the increase of m_l for a given spin moment m_s when switching from the 3d to the 4d and 5d transition-metal series. The anisotropy of the orbital moments, Δm_l, has maximum values of about $\pm 0.07\,\mu_B$ in each series and cannot be neglected. Therefore, in Figure 21(b) the average moments are shown. Δm_l is a rapidly varying function with respect to the band filling and relates according the equation (36) to the corresponding rapid oscillation of the magnetocrystalline anisotropy.

The uniaxial magnetocrystalline anisotropy constants $K_{MCA} = \Delta E_{MCA} = E(\rightarrow) - E(\uparrow)$, calculated as total energy differences for magnetizations in and out of the film plane are exhibited in Figure 21(c–e). Indeed, results show a continuous and very rapidly varying behavior as function of the band filling. We focus first on the 3d-metal monolayers

(Figure 21c). Between Fe and Cu the MCA is negative and the magnetization lies in the film plane. Between Mn and Fe the magnetization normal to the film plane is energetically most favorable. A closer look reveals several changes of sign as a function of the band filling. The large variation of the value of K as function of band filling from 4.75 meV for a band filling between Co and Ni ($N_V = 9.5$) and 0.15 meV for V is surprising. Noninteger band filling is not only of theoretical interest but has a concrete meaning in the spirit of the virtual crystal approximation. For example, we calculated an ordered c(2×2) CoNi UML film, which also has a band filling of $N_V = 9.5$ per atom. K is practically on the spot of the curve Figure 21(c). Adding K_{dip} on top of K_{MCA} one finds that with the exception of a small interval between Mn and Fe, where the positive K_{MCA} exceeds the negative K_{dip}, the magnetization is energetically most favorable to be in the film plane. Thus, among the 3d-metal monolayers (integer nuclear number) only the Fe(100) UML has a magnetization direction out of plane.

Comparing the K_{MCA} values of the 3d, 4d, and 5d monolayers, remarkable results are observed. The most spectacular results are the gigantic K_{MCA} values for the 5d UMLs, which reach values of 12.32 meV for Os and -13.50 meV for Ir. Although the maximum magnetic spin moment within each transition-metal series drops from $4.6\,\mu_{\mathrm{B}}$ in the 3d series to $2.3\,\mu_{\mathrm{B}}$ and $1.1\,\mu_{\mathrm{B}}$ in the 4d and 5d series, respectively, and the orbital moments are roughly the same between the transition-metal series, K_{MCA} varies from -4.69 to 0.73 meV in the 3d series, and from 3.40 to 2.82 meV in the 4d series and to truly gigantic values of -13.50 to 12.32 meV in the 5d series. One further notices that the latter is accompanied by a rapid change of K_{MCA} of about 25 meV when going from Os to its chemical neighbor Ir. One further notices that the functional characteristics of K_{MCA} shows a much more oscillatory behavior in the 4d and 5d series, both exhibiting two maxima and three minima, than in the 3d one with one minimum, one maximum, and then several small rapidly oscillating peaks.

These results can be interpreted on the basis of the corresponding band structures and the second-order perturbation theory of the MCA as presented in Section 2.6. As an example, the Fe monolayer in the Ag(100) lattice constant is analyzed: as can be inferred from Figure 9, the majority d band of Fe on Ag(100) is filled, so that these states will not contribute to equation (34), where only pairs of occupied and unoccupied states near the Fermi level can contribute significantly. Therefore, we can focus on the minority states, and the corresponding band structure is shown in Figure 22. The matrix elements in equation (34) depend on the symmetry of the states, ψ, and the spin-orbit operator (van der Laan, 1998). The spatial part of H_{so} has the symmetry of the orbital moment operator,

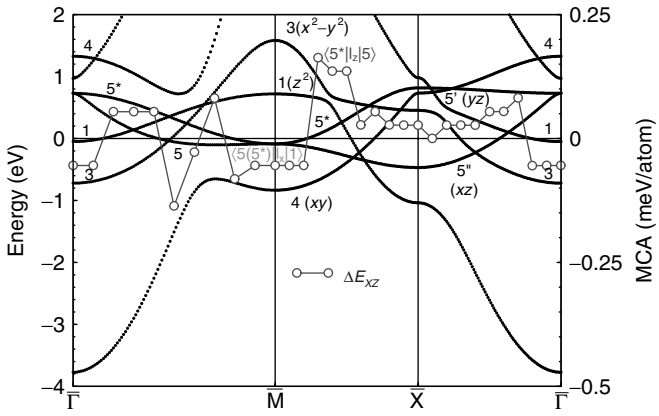

Figure 22. Minority-spin band structure (black) and statewise contribution to K_{MCA} (circles) calculated by perturbation theory for Fe(100) UML in the lattice constant of Ag. The symmetry of the bands is indicated as well as some matrix elements which contribute to K_{MCA} (see text).

for example, l_x or l_z. Therefore it is possible to find out which pairs of states can lead to nonzero matrix elements in equation (34), depending of course on the magnetization direction. For an estimate of the MCA, at each $\vec{k}$ point $K_{\mathrm{MCA}} = \delta E(l_x) - \delta E(l_z) = \Delta E_{xz}$ can be calculated individually, as shown in Figure 22. For example, near the M point, states of d_{xz}, $\mathrm{d}_{yz}(5, 5^*)$ symmetry are just below the Fermi level and states of $d_{z^2}(1)$ symmetry are above it. These states are coupled by the l_x operator, therefore the bands in this region will contribute more to $\delta E(l_x)$ than to $\delta E(l_z)$, favoring an in-plane magnetization. Between $\overline{\mathrm{M}}$ and $\overline{\mathrm{X}}$, a coupling of states with 5 and 5^* symmetry favors an out-of-plane magnetization. After summation over the whole Brillouin zone, the latter contributions dominate and, in accordance with Figure 21(c), Fe/Ag(100) has an out-of-plane magnetization.

If the Fermi level is shifted to higher energies (or the band filling increases), the band with 5^* symmetry gets more occupied and the coupling of the 5 and 5^* states is no longer possible. The contribution of the $\langle 5(5^*)|l_x|1\rangle$ matrix elements near M gets stronger. Finally, K_{MCA} changes sign (see Figure 21c) and the Co UML is in-plane magnetized. As can be inferred from Figure 22, the contributions to the MCA oscillate strongly in $\vec{k}$ space and for an accurate summation a fine resolution in reciprocal space, that is, a fine $\vec{k}$-point mesh, is necessary. It should also be noticed that the decoupling of majority and minority bands used above can only be applied for 3d metals. In 4d or 5d monolayers, the exchange splitting is much smaller and both spin channels give contributions to the MCA. Therefore, a much more complex behavior of the anisotropy as function of the band filling can be seen in Figure 21(d) and (e).

These results give an excellent overview of the trends of the uniaxial anisotropy K of magnetic monolayers. However, the substrate also plays an important role. For weakly magnetically polarizing substrates, for example, Cu and Ag, the same trend is expected although the actual values will change. Substrates with large nuclear numbers and thus large spin-orbit interactions, which have in addition a large Stoner-enhanced susceptibility, for example, W or Pt, and can thus be easily magnetically polarized, may in the end determine the magnetic anisotropy of these systems. For example, in the light of the experimental results of ultrathin Co films in contact with other metal films, as sandwiches or as multilayers, for example, Co/Pd(100) (den Broeder, Kuiper, Donkersloot and Hoving, 1989) or Co/Pt(100) (Lin *et al.*, 1991) the large negative K_{MCA} value of the unsupported Co monolayer, which is in accordance with results of Bruno (1989) based on perturbation theory, is a fairly surprising result. In order to get a better understanding of the influence of the substrate on the magnetocrystalline anisotropy, we compared the uniaxial K_{MCA} for a Co monolayer with and without substrate and found, $K_{\mathrm{MCA}} = -4.75\,\mathrm{meV}$ for a UML(100) in the lattice constant of Ag and $K_{\mathrm{MCA}} = -1.39\,\mathrm{meV}$ on Ag(100), $K_{\mathrm{MCA}} = -1.33\,\mathrm{meV}$ for an UML(100) in the lattice constant of Cu, and $K_{\mathrm{MCA}} = -0.32\,\mathrm{meV}$ on Cu(100). This can be understood in the spirit of the model of Stöhr (1999), introduced in Section 2.6, realizing that the presence of a substrate quenches predominantly the in-plane orbital moment. Therefore, we observe a clear reduction of K_{MCA} due to the presence of the substrate, but the general trend across the transition-metal series will still hold. At arbitrary substrates 4d- and 5d-metal monolayers will be nonmagnetic. But thin films show a significant Stoner-enhanced susceptibility. In contact with 3d transition metals they may develop a magnetic moment, an electronic structure, and a uniaxial K_{MCA} comparable to the isolated monolayers. In turn, strongly spin-polarized substrates with large nuclear number change even the sign of the MCA from in plane to out of plane and will be discussed in Section 3.4.3.

3.4.2 Magnetic reorientation transition: Ni/Cu(100)

If more than one or two layers of magnetic material are deposited as thin film, the layers that are not forming an interface (to the vacuum or the substrate) will show more bulklike properties. It is common to separate the volume-like contributions to the effective anisotropy constants, K^V (energy/unit volume), from the surface term K^S and interface term K^I (energy unit/area). This yields for the effective magnetic anisotropy K of a magnetic layer of thickness t

$$K^{\mathrm{eff}} = K^V + \frac{(K^S + K^I)}{t} \tag{39}$$

All three anisotropy constants K contain contributions of the dipolar and the spin-orbit-derived anisotropy. On phenomenological grounds the dipolar anisotropy is also split into a volume term, K^V_{shape}, namely the shape anisotropy due to the average dipolar energy as obtained by the continuum theory and the contribution due to the reduction of the dipole anisotropy field experienced by the atoms in the surface and interface region, $K^{S\,(\mathrm{dip})}_{\mathrm{MCA}} + K^{I\,(\mathrm{dip})}_{\mathrm{MCA}}$. Thus, we can write for the volume term $K^V = K^V_{\mathrm{shape}} + K^V_{\mathrm{MCA}}$, and for the surface term $K^S = K^{S\,(\mathrm{dip})}_{\mathrm{MCA}} + K^{S\,(\mathrm{so})}_{\mathrm{MCA}}$ and analogously for the interface term. While for smaller thicknesses K^S_{MCA} and K^I_{MCA} can dominate, for thick films the negative shape anisotropy which has a constant value per atom and thus increases with thickness of the film can determine the easy axis.

If these terms have different signs, a reorientation transition of the easy axis can occur. A well investigated example is the system Ni/Cu(001) (Baberschke, 1996): For up to seven layers Ni, an in-plane easy axis of the Ni film is found. Then a reorientation to perpendicular magnetization sets in and only very thick films (more than 50 ML) show again in-plane magnetization. Here K^S is negative, about $-85\,\mu\mathrm{eV/atom}$ at room temperature, while K^V_{MCA} is positive, approximately $30\,\mu\mathrm{eV/atom}$. So we expect a reorientation between 5 and 6 ML, but actually the shape anisotropy contributes another $-10\,\mu\mathrm{eV/atom}$ to K^V (the shape anisotropy in thin films always favors in-plane magnetization). Therefore, the transition sets in after 7 ML thicknesses as illustrated in Figure 23. But we have to realize, that the value of K^V is much larger than the bulk value of fcc Ni. In fact, low energy electron diffraction (LEED) measurements demonstrated that Ni grown on Cu(001) is actually strained, the in-plane lattice constant is 1.6% larger than in fcc Ni. To compensate this strain, the spacing between the Ni layers is smaller than in the bulk. From the arguments put forward in the last paragraph we would now suppose that $V_\perp > V_\parallel$, therefore $R > 1$ and, indeed, K^V favors perpendicular magnetization (although the band filling of Ni does not correspond to the assumptions underlying equation (36)). In very thick films, the structure of Ni relaxes back to fcc and the size of K^V decreases until the influence of the shape anisotropy once more brings the easy axis back in plane.

3.4.3 Monolayers on early transition metals: Fe/W(110)

In the previous sections trends of the magnetic anisotropy of transition-metal layers as a function of band filling and layer thickness were discussed. On weakly interacting, late transition-metal substrates – like Cu or Ag – these results are more or less transferable from one substrate to another. But for early transition-metal substrates, also the influence of the

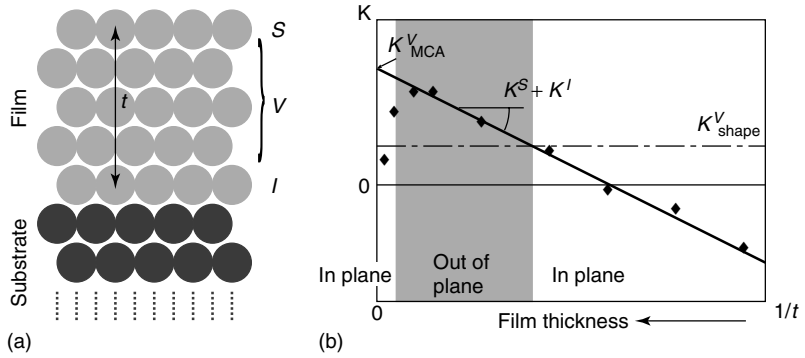

Figure 23. (a) Schematic illustration of a 5 ML Ni film on a Cu substrate; the bulklike, surface and interface regions are marked as V, S, and I, respectively. (b) Schematic plot of the anisotropy (K) versus inverse film thickness (t): the volume-like contribution, K^V, is given by the intersection with the ordinate, the surface- and interface-like term, $K^S + K^I$, can be deduced from the slope of the curve. Together with the (volume) shape anisotropy, K^V_{shape}, these values determine the in-plane/out-of-plane/in-plane transition of the easy axis for Ni films on Cu(001).

substrate has to be taken into account, as demonstrated in this section.

Fe films on W(110) are one the most intensively studied systems (Przybylski and Gradmann, 1987; Hong, Freeman and Fu, 1988; Elmers *et al*., 1994; Weber *et al*., 1997; Sander *et al*., 1997; Qian and Hübner, 1999), as they exhibit unique structural and magnetic properties. It was found that ultrathin Fe films grow pseudomorphically and without intermixing in a layer-by-layer growth mode up to 1.2 ML on the flat W(110) surface and up to 1.8 ML on a vicinal surface. Thus, it developed into a model system of two-dimensional magnetism. The magnetic easy axis switches from in plane for 1 ML Fe coverage to out of plane for a DL Fe coverage, and back to in plane for films grown beyond the pseudomorphic DL (Elmers, Hauschild and Gradmann, 1999). The sequence of the magnetic reorientation transition as function of the film thickness between 1 and 2 ML is rather unique and serves to illustrate the influence of the tungsten substrate on the magnetic anisotropy.

Ab initio calculations (Galanakis, Alouani and Dreyseé, 2000) find in agreement with experiment the reorientation transition between 1 and 2 ML: at 1 ML Fe coverage the easy axis is in the substrate plane and for 2 ML Fe coverage the easy axis switches to the out-of-plane direction. Irrespective of the structural relaxations, the shape anisotropy determines the magnetization direction for thicknesses beyond 2 ML Fe coverages, and the easy axis returns to an in-plane direction.

Interestingly, an unsupported Fe (110) monolayer, with the same lattice constants as in Fe/W(110) shows an out-of-plane magnetization. When put on the W substrate, two things happen: (i) the Fe–W hybridization changes the magnetic properties of Fe (like for Fe/W(100) as discussed in Section 3.1.3) and (ii) Fe induces a considerable spin moment (about $-0.1\ \mu_B$) in the W atoms at the interface and smaller, but finite moments in deeper substrate layers. Since W is a rather heavy element, relativistic effects – like the magnetocrystalline anisotropy – can be large even if the spin- and orbital moments are small. To separate the importance of (i) and (ii) for the MCA of Fe/W(110), a comparison to the system Fe/Mo(110) is helpful: Since in the periodic table Mo is just above W, the Fe–Mo hybridization should be similar to Fe–W. But relativistic effects are much smaller in the light Mo ($Z = 42$) than in the heavy W ($Z = 74$). Both experimentally (Bode, Pietzsch, Kubetzka and Wiesendanger, 2004) and theoretically (Nie, Heide, Bihlmayer and Blügel, 2007b) Fe/Mo(110) was found to have an out-of-plane magnetization. So it is likely that the (induced) magnetic anisotropy of tungsten at the interface is decisive for the in-plane magnetization of Fe/W(110). Layer-resolved *ab initio* calculations (Nie, Heide, Bihlmayer and Blügel, 2007b), which can separate the contribution of each layer to the total MCA, confirm this picture. These calculations also show, that a second Fe layer on W(110) quenches the orbital moment of the interface W from about 0.020 μ_B for the monolayer case to 0.007 μ_B in the double layer one (these values are for out-of-plane magnetization, for other directions of the magnetization they follow a similar trend). Thus, tungsten's influence on the MCA decreases and a double layer Fe on W(110) has out-of-plane magnetization (the same is found for Mo(110) covered with a double layer of iron).

Ab initio calculations show that a similar reorientation transition can be obtained when a capping layer of Au or Ag is put on top of the single Fe monolayer on W(110). Also here, it is the quenching of the interface W orbital moment that is responsible for the change of the easy magnetization axis. Experimentally, Fe islands on W(110) covered with Ag have been reported to have out-of-plane magnetization (Röhlsberger *et al*., 2001). Although stress effects can be important in this system and alter the MAE, it is likely that

the Ag overlayer will also contribute to the observed easy axis by the mechanism explained in this section.

4 WIRES AND CHAINS

Simple in their structure and seemingly easy to understand, metallic monowires not only present a great challenge for experimentalists, but are also an exciting playground for theory. Particularly significant are the consequences of the novel one-dimensional (1D) physics for magnetism in these systems. Electrons, restricted in their dynamics to only one dimension, compensate the lack of hopping between the nearest neighbors by giving *carte blanche* to exchange. This leads to a nonzero magnetization not only in the monowires for most transition metals but also for sp-metals (Zabala, Puska and Nieminen, 1998), for instance Al (Auyela, Raebiger, Puska and Nieminen, 2002). Typically, monowires are created on a substrate by atomic manipulation or self-assembly, allowing the creation of stable artificial structures for further investigations. The hopping and consequently the magnetic properties can change significantly upon structural changes such as dimerization, the formation of zigzag chains, or the stretching of wires. The latter is possible by pulling chains off the surface after a, scanning tunneling microscopy (STM) tip was rammed into the surface and pulled out again. Further, monowires present perhaps the most elementary bridge between the physics of itinerant electrons and molecular physics, and are doubtlessly a fruitful playground for testing the validity and limitations of the models, characteristic in both fields.

Starting from the early pioneering work by Weinert and Freeman (1983) on the magnetic properties of Fe and Ni linear chains, the variety of intriguing properties and aspects of the magnetism in metallic monowires investigated grows every year, spanning over the freestanding (Dorantes-Dávila and Pastor, 1998; Spišák and Hafner, 2003; Delin and Tosatti, 2003; Delin, Tosatti and Weht, 2004; Mokrousov, Bihlmayer, Heinze and Blügel, 2006), as well as substrate-deposited configurations. Among those are predominantly Fe or Co chains on Cu(100) (Spišák and Hafner, 2002), Pd(110) (Robles, Izquierdo and Vega, 2000), Pt(111) (Komelj, Ederer, Davenport and Fähnle, 2002; Ederer, Komelj and Fähnle, 2003; Shick, Maca and Oppeneer, 2004; Újfalussy *et al*., 2004; Baud, Bihlmayer, Blügel and Ramseyer, 2006a,b; Komelj, Steiauf and Fähnle, 2006) and W(110) (Spišák and Hafner, 2004) substrates, Rh (Bazhanov *et al*., 2000) and other 4d metals (Bellini, Papanikolau, Zeller and Dederichs, 2001) on Ag(100) substrate and on insulating substrates such as NaCl (Zabala, Puska and Nieminen, 1998; Auyela, Raebiger, Puska and Nieminen, 2002; Calzolari and Nardelli, 2005), where the hybridization is particularly small.

In this respect, the latest experiments by Hirjibehedin, Lutz and Heinrich (2006), where imaging and manipulation capabilities of the STM were used for studying the spin excitation spectra in linear chains of Mn atoms on CuN insulator, are worth mentioning as they bring the practical realization of spin-based computational schemes and atomic-scale storage devices, stemming from the fascinating abilities of low-dimensional magnetism, one step closer. It is important to notice that the future use of this atomic-scale magnetism in the context of spin-manipulation hinges directly on one quantity: the MCA. In the case of the linear chains, where each atom has only two nearest neighbors, the MCA appears to reach values unattainable in the physics of higher dimensions. The first tight-binding model calculations of the MCA were reported for bare Co and Fe chains (Dorantes-Dávila and Pastor, 1998) and a Co chain deposited on a Pd surface (Robles, Izquierdo and Vega, 2000). In the following subsections, we discuss the *ab initio* values of the MCA and orbital magnetic moments for Co chains deposited on Pt and report on freestanding chains of 4d and 5d transition metals.

4.1 Co on stepped Pt(111)

In the last years, the controlled growth of stripes and wires on step edges (Dallmeyer *et al*., 2000) and semiconductor surfaces (Segovia, Purdie, Hengsberger and Baer, 1999) allowed the investigation of 1D structures. Experimentally, ferromagnetism was reported in Co chains deposited on Pt(997) step-edges: Gambardella *et al*. (2002) found an orbital moment for Co chains on Pt(997) of 0.68 μ_B, the easy axis being tilted by 43° to the surface normal with an MCA of about 2 meV/atom at 45 K. Depositing more than one strand of Co on this surface leads to an oscillation of the easy axis in the plane perpendicular to the wire direction (Gambardella *et al*., 2004) (see also Chapter **Magnetism of Low-dimensional Metallic Structures, Volume 1**

Let us first discuss the magnetic properties of a single, infinite, unsupported FM Co chain following Weinert and Freeman (1983). The local magnetic moment amounts to 2.33 μ_B. The shape anisotropy of a chain has already been discussed in Section 2.6. For an understanding of the orbital magnetism and the spin-orbit coupling in this system we start from a Co dimer. The schematic energy-level diagram is shown in Figure 24. For simplicity we only consider the minority 3d levels and their hybridization: Assuming that the dimer axis is in the z direction, we expect that the d_{z^2} orbitals will form σ bonds, the d_{zx} and d_{yz} orbitals will combine to form π bonds, while the d_{xy} and $d_{x^2-y^2}$ orbitals will be mainly nonbonding (since they are directed perpendicular to the dimer axis). But since these nonbonding states are only singly occupied, now more 'atomic-like' linear combinations

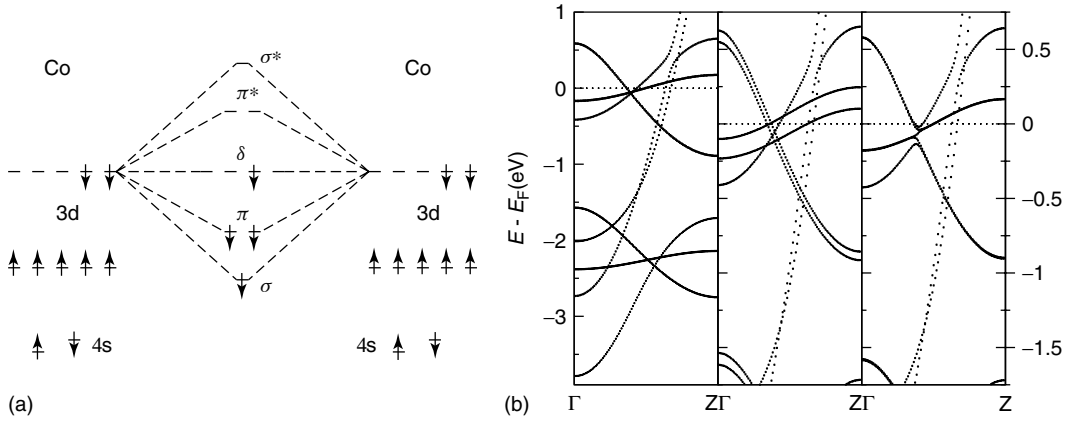

Figure 24. (a) Schematic energy-level diagram of a Co dimer. Only the hybridization between the minority 3d levels is indicated. (b) LSDA band structure of an unsupported Co monowire without (left panel) and with spin-orbit coupling included with the spin-quantization axis parallel (middle panel) or perpendicular (right panel) to the chain direction. Note the different energy scales for the band structure calculation without spin-orbit coupling (left panel), which shows the separation between majority and minority bands, and the middle and right panels, where mainly the spin-orbit splitting of the minority bands can be seen.

can be formed. Remember, that the d_{xy} and $d_{x^2-y^2}$ orbitals are linear combinations of the atomic $m = +2$ and $m = -2$ levels. This means, that a $m = 2$ orbital can be formed, and, if occupied, an orbital moment of 2 can be obtained.

If we look now at the spin-split band structure of such an infinite Co monowire (Figure 24b), we can more or less identify the bands corresponding to the Co dimer levels: Bands with strong positive dispersion correspond to σ bonds, those with negative dispersion to π bonds. But most prominent at the Fermi level is the very flat minority band with small positive dispersion; this is the equivalent of the nonbonding minority δ states. Notice that without spin-orbit coupling (left band structure) this band is doubly degenerate: there are no contributions in the LSDA functional that lead to an OP. But with spin-orbit coupling included, these bands can be seen to split: if the spin-quantization axis is parallel to the wire direction (middle band structure), one of the bands gets preferentially occupied. This is the band that – if fully occupied – leads to an orbital moment of $m_l = +2\,\mu_B$. Actually a smaller orbital moment of $0.9\,\mu_B$ is obtained. When the spin-quantization axis is perpendicular to the chain direction, other bands are mixing and the orbital moment is even smaller. As we know from our previous discussion, the anisotropy in the orbital moment is approximately proportional to the magnetocrystalline anisotropy and, therefore, the easy axis is parallel to the wire direction.

According to experimental findings, a Co chain on Pt(111) has an easy axis perpendicular to the chain direction. This seems to have its origin in the interactions with the Pt substrate. Apart from its two nearest Co neighbors and the reduction of the magnetic moment to about $2.1\,\mu_B$ per Co atom, a Co atom in a chain deposited on a (997) surface actually has five nearest Pt neighbors. Recent calculations (Shick, Maca and Oppeneer, 2004; Újfalussy *et al.*, 2004; Baud, Ramseyer, Bihlmayer and Blügel, 2006b) indeed confirm an easy axis that has a large component perpendicular to the surface. A detailed analysis shows that the Co atoms magnetically polarize the Pt atoms. Consequently, they produce large orbital moments because of their large spin-orbit interaction, which can then dominate the total magnetization direction. The strength of the Pt polarization, and as such the magnetization direction, depends sensitively on the structural relaxation of the Co chain (Baud, Ramseyer, Bihlmayer and Blügel, 2006b). For a Co monowire on a stepped Pt surface a rather large MCA of almost 2.5 meV and an easy axis that is tilted by $\theta = 51^\circ$ were determined with respect to the surface normal in the direction of the upper terrace. Both, the experimentally observed MCA and the orbital moment are smaller than the LSDA results for an unsupported chain, but the orbital moment of a supported wire is severely underestimated in LSDA (and GGA) calculations. In the literature several methods to overcome this deficiency have been discussed (Solovyev, Liechtenstein and Terakura, 1988; Solovyev, 2005). A systematic comparison of LSDA results with and without OP for unsupported and Pt-supported Fe and Co magnets in various dimensions can be found in the papers of Komelj, Ederer, Davenport and Fähnle (2002) and Ederer, Komelj and Fähnle (2003).

The first-principles study (Baud, Bihlmayer, Blügel and Ramseyer, 2006a) of Co chains of different widths, $n = 1, \ldots, 6$ strands, at the stepped Pt surface results, in accordance with experimental observations, in oscillations of the easy axis as a function of chain width around the terrace

normal, and the MCA shows a nonmonotonic behavior. For example, in sharp contrast to the result of the deposited Co monowire the Co double-wire shows a much smaller magnetic anisotropy (0.15 meV) and an easy axis with an angle $\theta = -19^\circ$, that is, pointing away from the upper terrace. This drop of MCA is also accompanied by a decrease of orbital moment anisotropy, that is, the average orbital moment of the double chain is almost constant as a function of the angle θ. The n chains with $n = 3 - 5$ show again larger magnetic anisotropies and the direction of the easy axis varies from -15° for the three-wire to -40° and $+14^\circ$ for the four- and five-wires. As we increase the number of strands beyond three, the MCA decreases again, from 0.99 meV for the three-wire to 0.82 meV and 0.50 meV/Co atom for the four- and five-wires, respectively. We attribute these findings to the individual contributions of the Co chains to the MCA and the total orbital moment. Depending on the position of the Co atom in the chain (at the step edge, in the terrace, in the innermost strand), these contributions can be very different due to the different number of Co and Pt neighbors, even of different sign, and can cancel each other, resulting in this complex behavior of the magnetic properties.

4.2 4d and 5d transition-metal monowires

A large number of metals that are nonmagnetic in the bulk can become magnetic in an 1D arrangement. Since the spin-orbit constant ξ (see equation (32)) increases approximately proportional to the square of the nuclear number, the magnetic anisotropy of unsupported, isolated 4d and 5d transition-metal chains has been investigated in detail. The results (Mokrousov, Bihlmayer, Heinze and Blügel, 2006) are summarized in Figure 25. FM ground states are found for Zr, Ru, Rh, and Pd, and AFM ones for Mo and Tc. Y and Nb wires, being borderline cases, are nonmagnetic. This is in agreement with the results of Spišák and Hafner (2003).

As seen in Figure 24 including the spin-orbit interaction results in a removal of band degeneracies and orbital moments arise (see Figure 25b). For the early 4d metals, left part of the 4d row, the values of m_l are rather small since most occupied bands are involved in chemical bonding. At the same time, Tc, Ru, and Rh monowires exhibit values of 0.2–0.4 μ_B. This is in the range of 0.2–0.3 μ_B obtained for an Fe monowire (Mokrousov, Bihlmayer and Blügel, 2005). For the latter chains we observed a strong dependence of the orbital moment on the magnetization direction. Typically, the axial magnetization leads to values $m_l(\vec{z})$, that are significantly larger than those for the radial magnetization, $m_l(\vec{r})$.

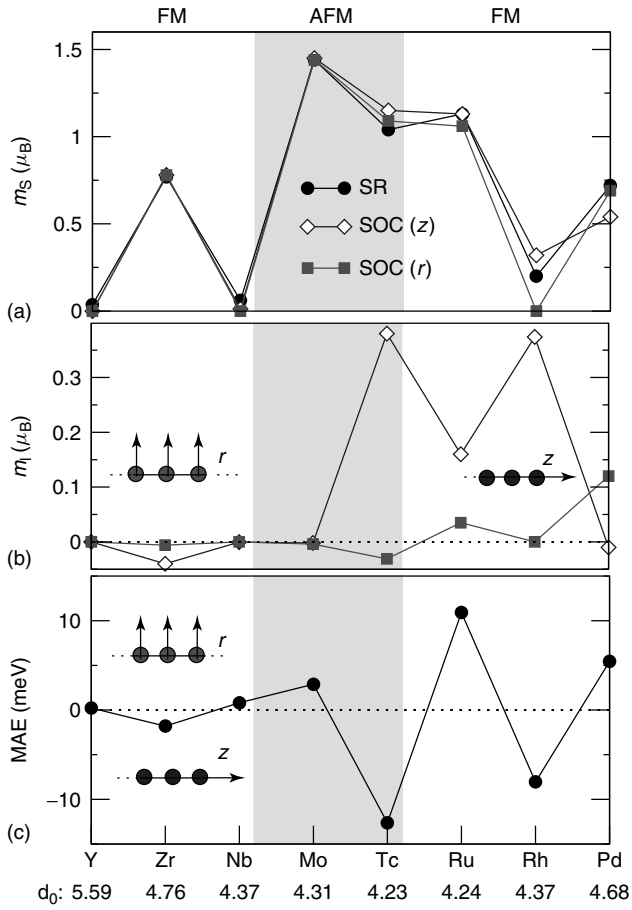

Figure 25. Magnetism in 4d transition-metal monowires at the equilibrium interatomic distance d_0 (Mokrousov, Bihlmayer, Heinze and Blügel, 2006): (a) total (for elements with FM ground state) and muffin-tin (for AFM ground states) magnetic moment without and with spin-orbit interaction (for both magnetization directions), (b) orbital magnetic moments for both magnetization directions, (c) magnetocrystalline anisotropy energy. SR stands for the scalar-relativistic approximation, that is, calculations without spin-orbit interaction. The equilibrium (SR) interatomic distances d_0 are given in atomic units. (Reproduced from Mokrousov *et al*., 2006, with permission from the American Physical Society. © 2006.)

The MCA (Figure 25c) as a function of the nuclear number or of the band filling, respectively, follows roughly the same trend as the orbital moment $m_l(\vec{z})$. The argument that the energy induced by spin-orbit interaction can be assumed to be proportional to the projection of the spin on the orbital momentum $-\vec{S}\cdot\vec{L}$, leading to an easy magnetization axis in the direction of maximum orbital moment, is hardly anymore applicable for heavier 4d transition-metal chains. Here, the spin-orbit interaction becomes stronger and the exchange splitting smaller than in 3d metals. Nevertheless, we observe that in the case when $m_l(\vec{z}) \gg m_l(\vec{r})$ the easy magnetization axis always points along the chain. On the other hand, whenever the difference $|m_l(\vec{z}) - m_l(\vec{r})|$ approaches 0.1 μ_B,

no predictions on the preferred magnetization direction can be made *a priori*. The calculated values of the MCA at the equilibrium interatomic distance d_0 are in the range of 6-12 meV/atom and thus much larger than those for the 3d transition-metal monowires.

Bare infinite monowires do not exist in nature. They are either deposited on a surface or created in a break junction or may be filled in a tubular structure. In either case, monatomic metallic chains would have an interatomic distance, d, different from the calculated equilibrium values for freestanding wires. In the work of Spišák and Hafner (2003) and Mokrousov, Bihlmayer, Heinze and Blügel (2006) it was found that Ru, Rh, and Pd monowires exhibit an FM ground state over a large range of interatomic distances. For Ru and Rh, already for $d > 5$ au, the spin moments saturate at their atomic-like values. The orbital moments gradually rise with d. For $d > 6.3$ au giant values of 1.5 μ_B for $m_l(\vec{z})$ and 0.7 μ_B for $m_l(\vec{r})$ for both monowires are reached. An increase of d leads to a narrowing of the δ-state- and π-state-derived bands in Figure 24, and, eventually, bands with different angular momentum, m_l, become almost fully occupied or fully unoccupied, giving rise to a large value of the orbital moment. In case of Pd, for large distances, the s electron is transferred into the d shell and closes the d shell with 10 electrons, and spin and orbital moments disappear (Delin, Tosatti and Weht, 2004). The combination of high values for spin and orbital moments with the large difference between $m_l(\vec{r})$ and $m_l(\vec{z})$ results in giant values of the MCA (Bruno, 1989). For example, already at $d = 5.5$ au, the MCA of the Rh chain reaches -40 meV/atom and gets as large as -60 meV/atom for $d = 6.3$ au.

As compared to 4d chains, the magnetism of 5d transition-metal monowires is characterized by an even larger spin-orbit strength but generally smaller or even suppressed magnetic moments (Delin and Tosatti, 2003) due to the larger overlap of the 5d wave functions. For example, among the late 5d metals at their respective equilibrium lattice constants we found the largest MCA value for an Os monowire reaching only 2 meV/atom and a spin moment $m_s(\vec{z})$ of 0.36 μ_B. At a strained interatomic distance of 6.3 au, where the values of the spin moments of FM Os, Ir, and Pt chains are already well saturated to 3.53 μ_B, 2.39 μ_B, and 1.13 μ_B, respectively, the respective MCA values of 115, -60, and 44 meV/atom are – at least for Os – colossal in size and can exceed the record value of the Rh chain.

5 ATOMIC-SCALE STRUCTURES

5.1 Adatoms

Single transition-metal adatoms adsorbed on (100) substrates of Cu, Ag, Au (Lang *et al*., 1994; Nonas *et al*., 2001), Pd, and Pt (Stepanyuk *et al*., 1996) have been investigated by first-principles calculations. When the 3d overlayer and adatom moments on Ag(100) are compared as shown in Figure 26, a surprising similarity in the general trend and the magnitude of the magnetic moments is found. Obviously the local moments of monolayers follow Hund's first rule of the adatoms. In other words, if we decompose the DOS according to equation (17) in terms of the local (χ_{00}) and the interatomic nonlocal susceptibilities ($\chi_{0i}, i > 1$), then for the adatoms the nonlocal susceptibilities are basically zero, by definition, but also for the monolayers χ_{00} dominates over χ_{0i}. Fe, Co, and Ni monolayers and adatoms have in each case about the same maximally possible magnetic moments. This will not change for other atomic-scale structures such as chains. For example recent calculations of one-atomic Fe, Co, Ni wires along the ⟨111⟩-type step edge of the Pt(111) surface discussed in Section 4.1 exhibit local moments of 3.18 μ_B, 2.12 μ_B, and

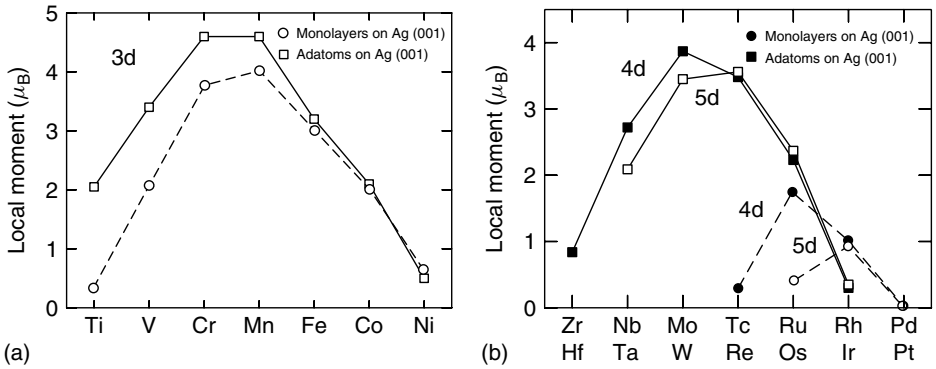

Figure 26. Local magnetic moments calculated for 3d (Nonas *et al*., 2001) (a), 4d (b, solid symbols), and 5d (b, empty symbols) transition-metal adatoms at the hollow-site of Ag(100) (squares connected by full lines) (Lang *et al*., 1994) and monolayers as overlayers on Ag(100) (Blügel, 1992b) (circles connected by dashed lines).

0.83 μ_B, respectively. From Mn to Ti, monolayer and adatom moments deviate systematically because of the increasing extent of 3d wave function and the respective increase of the d–d hybridization in the monolayer.

For the 4d and 5d transition-metal adatoms the comparison to the monolayers on Ag(100) looks radically different. While the adatoms still follow Hund's first rule with maximal moments at the center of each series, the magnetism of monolayers is obviously largely determined by the nonlocal susceptibilities χ_{0i}, which add an essential contribution to χ_{00} necessary to fulfill the Stoner criterion, equation (12). This is a consequence of the large extent of the 4d and 5d wave functions. Since χ_{0i} depends on all details of the local environment, each atomic-scale structure of 4d and 5d metals will have a different collection of magnetic moments. This observation motivated the work on atomic-scale clusters.

5.2 Clusters

Small atomic clusters on surfaces constitute very interesting subjects, as their electronic structure and subsequently their magnetic properties depend, in addition to other factors mentioned in the preceding text, on the individual cluster shape and size. In order to explore the consequences of this statement we explore the spin moment of Fe on a Ni(100) surface (Mavropoulos, Lounis, Zeller and Blügel, 2006). The clusters considered are shown schematically in Figure 27(a), viewed from the top (all atoms lie on the surface). The view is adapted to the surface geometry, meaning that it is rotated by 45° with respect to the in-plane fcc cubic axes of the underlying substrate lattice. The smallest cluster is a single Fe adatom, while the largest consists of nine Fe atoms. On each atom, the calculated spin moment is written, and the average (per atom) moment of each cluster is also given. The Fe moment is always ferromagnetically coupled to the Ni substrate moment. Already, at a first glance it is obvious that the average moment of the clusters depends on the cluster size. The single adatom has manifestly the highest moment (3.24 μ_B), while the nine-atom cluster shows a lower average moment of 2.85 μ_B.

From what has been said in Section 2.5 this behavior is expected on the grounds of hybridization of the atomic d levels with the neighbors. Atoms in larger clusters have, on the average, higher coordination, thus their d wave functions are more hybridized; this leads to lesser localization and lesser tendency to magnetism.

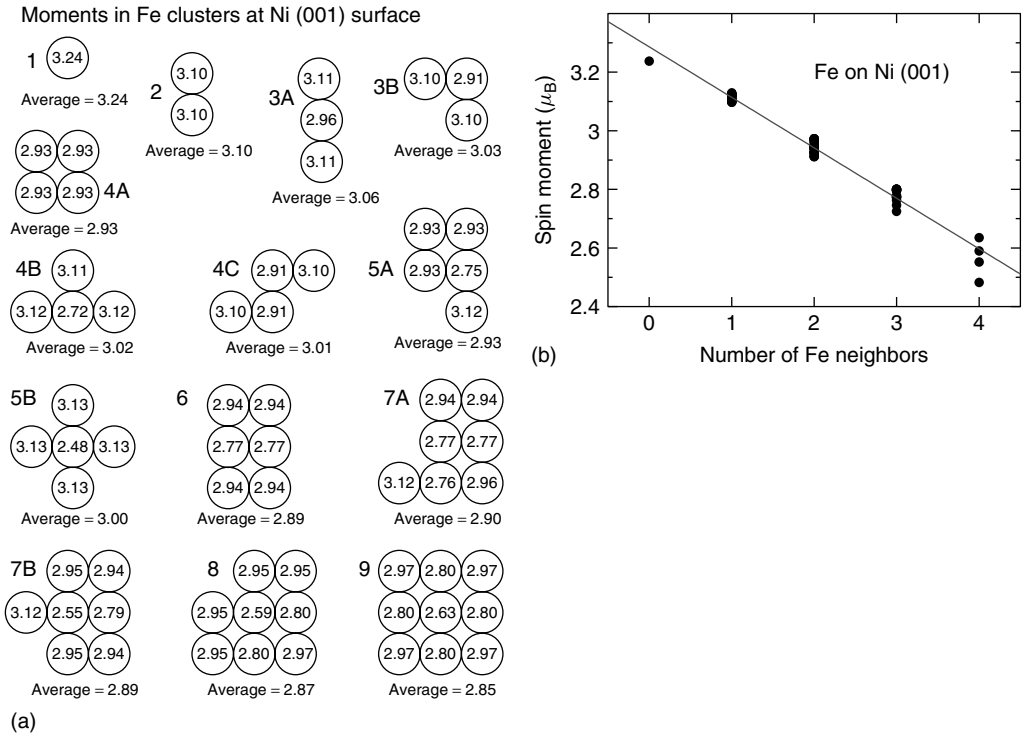

Figure 27. (a) Spin moment (in μ_B) of atoms of Fe clusters at Ni(001) surface, and average (per atom) moment of the clusters (the view is surface adapted, that is, rotated by 45° with respect to the in-plane fcc cubic axes; the clusters are viewed from the top, that is, all atoms lie on the surface). (b) Linear trend for the atomic Fe spin moment as function of the coordination to Fe neighbors. (Reproduced from P. Mavropoulos, S. Lounis, R. Zeller and S. Blugel: Fe clusters on Ni and Cu: size and shape dependence of the spin moment, *Appl. Phys. A* **82**, 2006, 103–107, with permission from Springer Science and Business Media.)

To pursue this idea further, we tried to correlate the local atomic spin moment to the coordination N_c of each atom in the cluster, irrespective of the form or size of the cluster. For instance, let us focus on all Fe atoms which have only one first Fe neighbor, that is, $N_c = 1$ (the coordination to the substrate is the same, $N_s = 4$, for all Fe atoms). Such atoms appear in the clusters with size 2, 3, 4, 5, and 7; there are, in total, 10 such examples (having excluded cases which are trivially equivalent by symmetry). *All* of them have spin moments ranging in the small interval between 3.10 and 3.13 μ_B. Similarly, for the Fe atoms with two Fe neighbors the spin moment ranges from 2.91 to 2.97 μ_B. Collecting all possible cases, from $N_c = 0$ (single adatom) to $N_c = 4$, we present the results in Figure 27(b). One finds an almost linear dependence of the spin moment on the coordination number, $M = -aN_c + b$, with $a = 0.17\,\mu_B$ and $b = 3.29\,\mu_B$. In accordance with the analysis of the 3d transition-metal films, Fe has a strong intra-atomic exchange field, arising from rather localized 3d wave functions resulting in strong intra-atomic susceptibility. Such a linear relation was also found for Fe clusters (Mavropoulos, Lounis, Zeller and Blügel, 2006) on Ni(111), Cu(100), and Cu(111) and for Co clusters on Ni(100). The local magnetic moments of Ni atoms in clusters on Cu surfaces cannot be described by such a simple linear relationship, because the hybridization of the Ni d states with substrate sp electrons enters as an additional important factor (see Figure 5).

In many cases for homo-atomic and mass-selected FM clusters, it is very difficult to address experimentally the magnetic properties of each individual cluster or even each atom in a cluster. Often just the average magnetic moment of clusters of particular sizes or the average local magnetic moment per atom averaged over an ensemble of clusters of the same size but different shapes can be determined. Using this scaling behavior it is possible to estimate the magnetic moments of clusters if the shape is known.

In light of what has been said in Section 5.1 for the 4d and 5d adatoms on surfaces, this rule will not apply to the general case of arbitrary atoms. For example, the magnetism of small 4d and 5d clusters on Ag(100) shows highly nonlocal susceptibilities, resulting even in an increase of the spin moment with coordination. This is connected to the larger extent of the 4d states compared to the 3d of Fe. The magnetic properties of several linear chains (C) and plane islands (I) of 4d (Wildberger *et al*., 1995) and 5d atoms have been calculated in structures as shown in Figure 28. In particular, linear chains of two (dimers, C2), three, and four adatoms (C3 and C4) have been considered, oriented in the [110] direction, in addition to three compact islands with four, five, and nine adatoms (I4, I5, and I9).

Figure 29 shows the calculated moments per adatom for these nanostructures. Since several nonequivalent atoms exist for the clusters C3, C4, I5, and I9, only the average moment is given. For the linear chains quite large moments are obtained, but the behavior with size is nonregular. While the C2 and C4 moments are very similar, the C3 moments of Mo and Tc are much smaller. In this context it is interesting to compare the moments of the inner and outer chain atoms.

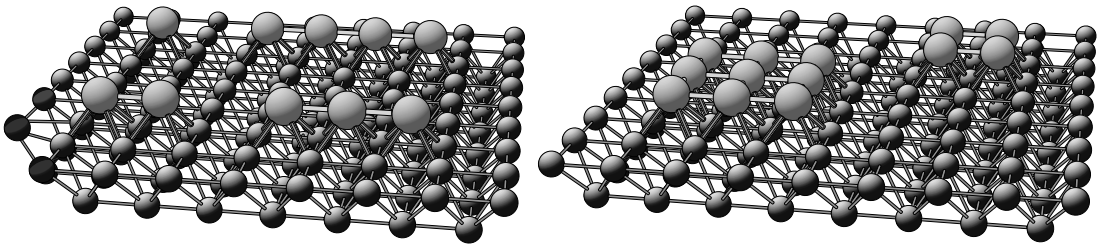

Figure 28. Magnetic clusters of a particular transition metal deposited on an (100)-oriented Ag substrate.

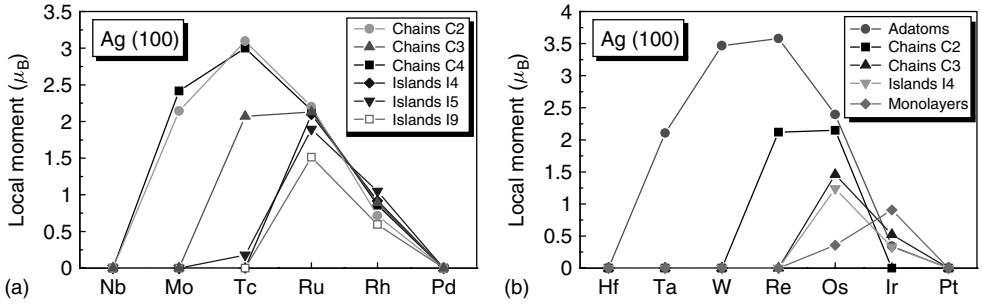

Figure 29. Average magnetic moment per adatom for ferromagnetic 4d (Wildberger *et al*., 1995) (a) and 5d (b) clusters. (Reproduced from Wildberger *et al*., 1995, with permission from the American Physical Society. © 1995)

For Mo and Tc the outer atoms of C3 and C4 have larger moments than the inner ones. In the C4 chain, for instance, the two inner Mo atoms have moments of $1.85\,\mu_B$, while the outer atoms carry moments of $3.00\,\mu_B$. Moving to Ru and Rh the situation changes. In the Ru chains both types of atoms have about the same moments, whereas in the case of Rh the inner atoms carry larger moments. In the Rh C4 chain the inner atoms have moments of $0.96\,\mu_B$ but the outer ones only $0.76\,\mu_B$. This is because the higher coordination of the inner atoms tends to enhance the moments for Rh while Ru is an intermediate case being insensitive to environmental changes. The large moments obtained for all three chain structures indicate that infinite chains of these atoms should also show appreciable moments.

For the considered linear structures also AFM solutions (not shown in Figure 29) have been obtained, which are the most stable configurations for elements in the middle of the transition-metal series. The local moments can be quite large. For instance, for the Mo chains C2, C3, and C4 the local atomic moments are larger than $3\,\mu_B$.

For the compact islands (I4, I5, and I9) the hybridization effects within the cluster are even larger. Similar to the magnetic monolayers (Blügel, 1992a; Eriksson, Albers and Boring, 1991a; Wu and Freeman, 1992a) discussed in Section 3.1.1 appreciable moments are found only for the Ru and Rh nanostructures, whereas zero or very small moments are found for Mo and Tc. This is a consequence of the large spatial extent of 4d wave functions being more important for the compact islands than for the chain structures. Within the Ru structures I5 and I9 we observe that the outer atoms carry a larger moment than the inner ones, the same effect as the one found earlier for the linear structure of Mo and Tc. For Rh the situation is more complicated. For the I5 island the inner moment ($1.00\,\mu_B$) is larger than the outer one ($0.66\,\mu_B$), in agreement with the preceding rule, while the central atom in the I9 cluster has a very small moment of $0.16\,\mu_B$, and the outer atoms have moments of $0.62\,\mu_B$ and $0.64\,\mu_B$. Thus, by comparing the islands with the chain structures, not only is the peak of the moment curve shifted to even larger valences, that is, from Tc to Ru, but the transition from surface enhancement of the moments to surface suppression is also shifted: for the chains this turnover occurs at Ru, but for the more compact islands it occurs at about Rh. The very small moment obtained for the central atom of I9 seems to be in conflict with the results of monolayers for a Rh overlayer on Ag(100) which should have a moment of about $1\,\mu_B$. Calculations for larger Rh islands lead for the inner Rh atoms to considerably larger moments ($0.66\,\mu_B$). Thus, we conclude from these calculations, as well as from the strong difference obtained for the different linear chains C2, C3, and C4, that the moments of the 4d clusters show an unusual and oscillatory dependence on the cluster size.

Preparing clusters with constituent atoms that are subject to an AFM exchange interaction can lead to complex noncollinear magnetism inside the cluster in order to avoid magnetic frustrations due to competing interactions caused by cluster shape and substrate interactions. Obvious examples are Cr and Mn clusters with triangular shapes or those deposited on FM substrates. The actual magnetic structure depends, besides on the cluster shape, on the relative strength of the intracluster exchange interaction of the Cr and Mn atoms versus the cluster–substrate interaction, which can be AFM for Cr and FM for Mn, depending on the substrate. Recent first-principles calculations on Cr and Mn dimers on Ni(100) (Lounis, Mavropoulos, Dederichs and Blügel, 2005) verify the presence of a noncollinear ground state for nearest-neighbor Mn dimers. We see in Figure 30(a) the antiferromagnetically aligned Mn moments are symmetrically tilted under the presence of the FM exchange interaction of the Ni substrate by $\approx \pm 72.6^\circ$ with respect to the direction of the underlying substrate moments. Also the nearest-neighbor Ni moments are tilted by 7.4°. The magnetic ground state of larger Mn compact clusters on Ni(100) remains collinear while Mn chains have a noncollinear ground state similar to the magnetic configuration of the Mn dimer. Cr and Mn clusters on Fe and Co substrates are subject to much larger cluster–substrate interactions and one expects noncollinear magnetism in Cr and Mn clusters of larger size. For example, a Mn trimer on fcc Fe, shown in Figure 30(b) is nearly collinear within the Mn cluster, but is not collinear with respect to the magnetic moments of the underlying Fe substrate. The two outer Mn moments are rotated by 170° and have a value of $3.61\,\mu_B$. The central moment is rotated by 20° and has a value of $3.14\,\mu_B$. This leads to an uncompensated total magnetic moment in the Mn cluster of $-4.16\,\mu_B$ in the direction parallel to the Fe moments, but with opposite sign, and a moment of $0.18\,\mu_B$ normal to the Fe moments. Figure 30(c) shows the ground-state configuration for the Mn tetramer. All neighboring Mn moments are antiferromagnetically aligned and share one plane, which is roughly perpendicular to the substrate magnetization. For clusters on Fe substrates we found that fairly reliable ground-state structures can be obtained from a nearest-neighbor Heisenberg model

Figure 30. Side view of the magnetic ground-state configuration of a Mn dimer on Ni(100) (Lounis, Mavropoulos, Dederichs and Blügel, 2005) (a), of a Mn trimer (b), and tetramer (c) on fcc Fe(100). In (b), moments of two Mn atoms are pointing down (the second one cannot be seen) and one moment is pointing up.

(equation (2)) with exchange parameters obtained from *ab initio* results, where the nearest-neighbor exchange constants for the atoms in the cluster and the interaction between the atoms in the cluster and the substrate enter. This works much less reliably for the Ni substate, as the size of the Ni moment changes dramatically with respect to the relative orientation between the Ni moment and the moments in the cluster.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the valuable discussions and collaborations with Drs P.H. Dederichs, P. Ferriani, M. Heide, S. Heinze, Ph. Kurz, M. Ležaić, S. Lounis, Ph. Mavropoulos, Y. Mokrousov, I. Turek, and X. Nie that made this contribution possible.

Molecular Magnets: Phenomenology and Theory

Mark R. Pederson[1] and Tunna Baruah[2]

[1] *Naval Research Laboratory, Washington, DC, USA*
[2] *University of Texas at El Paso, El Paso, TX, USA*

1 INTRODUCTION

The field of molecular magnetism is indeed quite broad and much has been written on many aspects of this field. Discussions, by many of the pioneers and practioners in this field, including Kahn, Barbara, Verdaguer and others may be found in References Kahn, 1993; 2000; Barbara and Gunther, 1999; Ferlay *et al*., 1995; Turnbull, Sugimot and Thompson, 1996; Postnikov, Kortus and Pederson, 2006; Pederson, Park and Baruah, 2006. A single concise definition is difficult and would probably not satisfy all researchers in this field. Further, it is not possible to review all aspects of this interdisciplinary field, especially given the diverse set of scientific skills and expertise needed to look at all aspects. Before focusing the attention on the theoretical study of one class of molecular magnets, it is useful to give a slightly broader overview of all the molecular systems that may be referred to as *molecular magnets* and give some discussion as to how they are related and different. In general, molecular magnetism deals with any molecular system or collection of atoms that is finite, unreactive, and contains at least one but probably two or more unpaired electrons. However, there is another class of related bulk magnetic materials, assembled from transition-metal molecules, that exhibit interesting magnetic and photomagnetic effects such as the Prussian-blue analogs (Ferlay *et al*., 1995) and spin crossover compounds (Gaspar *et al*., 2003). Although unpaired electrons exist in both molecular magnets and radicals, the distinction between these two systems is that on-site exchange effects in a molecular magnet inhibit unpaired electrons from forming bonds with unpaired electrons on neighboring molecules. This unreactive behavior is generally accomplished by intramolecular charge transfer between the moment-carrying sites and the nominally spin-unpolarized part of the molecule. Rather than forming covalent bonds, the resulting sites are more likely to coordinate with an oppositely charged closed-shell entity such as an O^{2-} anion, a dehydrogenated acidic molecule, or the lone pair on a threefold coordinated nitrogen atom. Within this class of systems, one must distinguish between purely organic systems (Palacio and Markova, 2006) and those containing metal ions.

In the former class for which the molecular oxygen may be the simplest example, the moments are generally more delocalized, less likely to be centered on a single ion, and can have distances between neighboring local moments that are small since they are controlled by covalent bonding. These

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*.

characteristics lead to magnetic or paramagnetic behavior that is governed by different interactions than those that contain metal ions. The combination of the short bond lengths and small spin-orbit splitting leads to multiplet structures exhibiting smaller zero-field splittings. Further, because the spin-orbit splitting is small and the distance (R) between moments is small, the dipolar interaction, which scales as $1/R^3$, leads to an anisotropy energy that depends on both second-order spin-orbit effects and classical dipolar interactions. Excluding the intramolecular dipolar interactions in these systems is expected to lead to errors in the magnetic anisotropy. However, even with the inclusion of these effects, it appears that the role of magnetic anisotropy in organic molecular magnets is small and most of the physics is related to energetics associated with changes in spin ordering between neighboring localized spins rather than global changes in spin projections. While the remainder of this chapter does not directly pertain to this subclass of molecular magnets, some of the physics associated with one class of transition-metal-based molecular magnets coincides with this class of molecules. There are excellent reviews on this subject as well as many recent papers. The interested reader is referred to these (Palacio and Markova, 2006) references.

For the class of molecular magnets that contain transition-metal ions, (see Fig. 1) exclusion of the intramolecular dipolar interactions is at least the best starting point due to the larger distances between neighboring moments. These systems are unreactive because they have a relatively large energy gap between the occupied and unoccupied electronic states. The local filling of the d electrons is determined by relatively strong Jahn–Teller distortions of the sixfold coordinated environment around a given transition-metal atom. Under these conditions, the lowest-energy excitations in these systems are governed by a combination of the interionic exchange interactions, which govern spin ordering, and the spin-orbit interaction. For cases where the spin-orbit interaction is small, the only low-energy excitations are between different spin manifolds each of which would have a degeneracy given by $2S + 1$. The so-called V_{15} molecule exemplifies this type of molecular magnet (Gatteschi *et al*., 1991; Kortus, Hellberg and Pederson, 2001). The spin excitations in these systems can be studied in a straightforward manner from the perspective of Heisenberg Hamiltonians and their extensions. Although straightforward, the computational problem is indeed challenging due to the high dimension of the matrices that need to be diagonalized. For the purpose of discussion, we refer to these molecules as spin systems and put forth the viewpoint that referring to these systems as a 'molecular magnet' is indeed a misnomer despite the fact that the properties of these systems are quite interesting.

For cases where the spin-orbit interaction is large, a simple and very interesting collective behavior emerges if the on-molecule interionic exchange interactions are very large. For discussion in this chapter, we refer to this class of molecular magnets as anisotropic molecular magnets (AMMs) (Friedman *et al*., 1996; Thomas *et al*., 1996; Barra *et al*., 1996; Sangregorio *et al*., 1997; Wernsdorfer and Sessoli, 1999; Wernsdorfer *et al*., 1999). The Mn_{12}-acetate molecule, synthesized by Lis (1980) is the quintessential example of an AMM. Ten years ago, two groups (Friedman *et al*., 1996; Thomas *et al*., 1996) independently observed a phenomenon, now known as *resonant tunneling of magnetization*, in this molecule. It is this class of molecular magnets that most of the discussion will be devoted to. The experiments on these systems will be discussed and the phenomenological Hamiltonian that describes their behavior will be introduced. Then we will discuss how a first-principles theory such as the density-functional theory (Hohenberg and Kohn, 1964; Kohn and Sham, 1965; Perdew *et al*., 1992; Perdew, Burke and Ernzerhof, 1996) may be used to determine the phenomenological Hamiltonian without any adjustable parameters (Pederson and Khanna, 1999).

It should be noted that there is certainly no guarantee that the relative energy scales associated with electronic excitations, spin-ordering changes, and spin-orbit couplings will always lead to a situation that gives rise to a simple collective behavior in an arbitrary molecular material containing transition-metal ions. Because of this, a significant effort will be made to fully discuss the derivations of the computational and theoretical methods that lead to the two simplified extremes. In addition, an attempt is made to identify additional interactions that could lead to a quantitative theory that describes more complicated molecular magnetic materials. It is possible, even likely, that simplified collective behavior appears in these systems as well. However, the theoretical and computational tools that need to be developed to quantify the behavior in this general range are quite significant.

The key experiments, mentioned in the preceding text, have motivated many new experimental and theoretical developments. Because this chapter is being written with some hindsight, an attempt will be made to discuss the problem as to how it may have evolved in the most orderly way, which necessarily means that the chronology of how the field has actually evolved will be primarily apparent from the references. This chapter is not aimed at experts in the field of molecular magnetism. Rather, it is hoped that this chapter will be useful to two audiences. First, it should serve as a good starting point for a researcher who wishes to learn about the fundamental questions in molecular magnets. Second, the derivation for the first-principles determination of the magnetic anisotropy Hamiltonian is aimed at practitioners

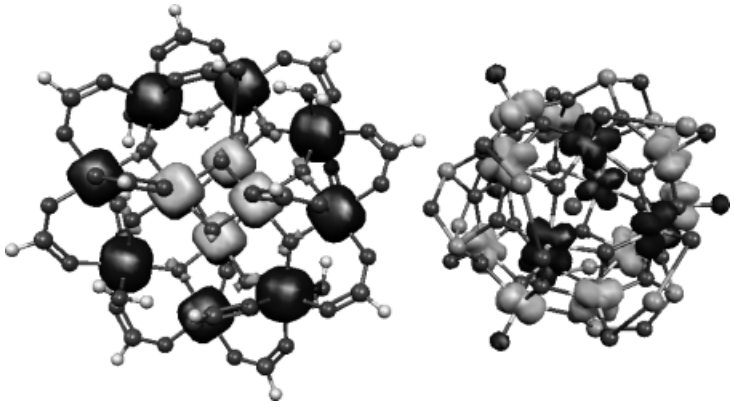

Figure 1. Two types of transition-metal coordinated complexes. On the left is the Mn_{12}-acetate molecular magnet and on the right is the V_{15} spin system. The low-energy excitations in these systems are governed by magnetic anisotropy and spin excitations, respectively.

in electronic structure who are interested in improving the theory or converting a standard electronic structure program into one that can determine magnetic anisotropies. In the first section, the phenomenology of a simple spin system will be discussed. This will include consideration of the Hamiltonians that are most relevant to the spin molecular magnets (SMMs)- and AMMs. With regard to AMMs, we describe the effects of longitudinal resonant tunneling of magnetization, transverse Berry's phase oscillations (Garg, 1993) and the suppression or complication of the latter effect due to higher-order terms in the Hamiltonian (del Barco *et al*., 2004). With regard to the SMMs, we discuss the simplest Heisenberg Hamiltonian that can be used for describing the spin excitations.

After reviewing the fundamental physics that comes out of the spin Hamiltonians, we discuss the first-principles determination of these phenomenological Hamiltonians from a point of view of density-functional theory or other mean-field methods. The derivation of the phenomenological anisotropy Hamiltonian presented here includes additional details and discussion that have not appeared in the original or subsequent work of the NRL group. In doing so, it is hoped that new efforts will be made to improve upon the current computational schemes. There have been two other very complete reviews on applications of the existing formalism published recently. In addition to directing the reader to this work, we briefly discuss more recent theoretical studies of molecular magnets within density-functional theory.

2 PHENOMENOLOGY

2.1 Hamiltonian for a spin molecular magnet

The introduction of spin into electronic wave functions leads to several different effects related to spin polarization. Owing to the nature of fermions, the electronic wave function must be antisymmetric. Because of this, in addition to the repulsive coulomb interaction between electrons, an additional attractive term, between same-spin electrons arises and is referred to as the *electronic exchange interaction*. In an open-shell system, the spin is maximized for cases containing well-localized electronic wave functions that are orthogonal and degenerate, usually, due to orbital symmetry. If two wave functions are orthogonal by symmetry, there is no kinetic energy penalty associated with placing them in parallel spin states and the exchange term will stabilize the high-spin state relative to the lower-spin-state exchange interaction. While this effect is generally referred to as *ferromagnetic behavior*, we emphasize here that it is only one of two necessary conditions to achieve a magnetic state.

Another manifestation of spin polarization arises when we consider two well-separated open-shell atoms or ions (hereafter referred to as a *center*). For this case, the phenomenon referred to as *antiferromagnetic behavior* may be observed. On-site coulomb exchange dictates that each center prefers to have a net moment. However, as the wave function overlap between the two centers increases, the Pauli principle requires orthogonality between all states to be satisfied. The system may accomplish this by choosing antiparallel moments which are orthogonal in spin space. In the antiparallel arrangement, the states associated with a given site tend to delocalize slightly so their positive kinetic energy decreases. This decrease in kinetic energy is partially countered by a decrease in the on-site coulomb exchange energy. The alternative is to choose parallel moments derived from localized wave functions that are orthogonal to those on neighboring atoms. In the parallel arrangement, additional orthogonality constraints cause an increase in the systems' kinetic energy since wiggles in the wave function tails are required to achieve spatial orthogonality. The increase in kinetic energy is partially compensated by an increase in coulomb exchange

energy due to overlap between states on different sites. In a mean-field picture with one fully occupied wave function for each electron, the configuration with the lowest energy depends on the precise characteristics of the occupied wave functions. Often, the lowest-energy configuration leads to a symmetry that is lower than would be expected on the basis of the symmetry of the molecule. The parallel and antiparallel arrangements of neighboring sites are commonly, and again slightly inappropriately, referred to as *ferromagnetic* and *antiferromagnetic spin ordering*. Pictured in Figure 1 are two systems that lead to spin-ordered states.

To systematically determine the classical spin ordering of such systems the energy is parameterized according to:

$$E_{\text{spin}} = \sum_{(\mu,\nu)} J_{\mu\nu} \mathbf{S}_\mu \cdot \mathbf{S}_\nu \tag{1}$$

where S_μ and S_ν are localized spins at site ν and μ respectively and $J_{\mu\nu}$, the exchange coupling constants, are usually only nonnegligible for nearest-neighbor centers. To calculate these parameters, one needs to calculate energies as a function of different spin orderings, know the local moments, and then invert the expression to obtain the exchange couplings. Once the exchange coupling constants are known, the expression may be 'requantized' leading to a spin Hamiltonian of the form:

$$H_{\text{spin}} = \sum_{(\mu,\nu)} J_{\mu\nu} \mathbf{S}_\mu \cdot \mathbf{S}_\nu \tag{2}$$

By constructing all possible product states of the form $\Pi_\nu |S_\nu M_\nu\rangle$, and constructing a very large Hamiltonian matrix, the ground state of the Hamiltonian may be determined. This prescription has been carried out for both the V_{15} spin system (Kortus, Hellberg and Pederson, 2001) and the Mn_{12}-acetate molecular magnet using the density-functional theory described in the subsequent text. In both cases, the lowest-energy spin configuration and low-energy spin excitations were found to be in qualitative accord with experiment. For example, for the case of Mn_{12}-acetate, the wave function consisted of a sum of 10^8 possible configurations. The lowest energy $S = 10$ configuration had 13 states that had reasonably large coefficients (Park, Pederson and Hellberg, 2004). The ferrimagnetic configuration pictured in Figure 1 had an amplitude of 0.6. This configuration agrees qualitatively with the classical ordering determined experimentally (Robinson *et al*., 2000; Mirebeau *et al*., 1999; Petukhov *et al*., 2004).

Assuming that the spin excitations obtained from a Heisenberg Hamiltonian lead to a large gap between the lowest-energy spin multiplet and the first excited spin-multiplet, the system may behave as an AMM. For this case, each spin manifold exhibits zero-field splittings which breaks a $2S + 1$ degenerate multiplet into a set of lower-degeneracy multiplets. Symmetry plays a significant role in determining the size of these zero-field splittings and the number of submanifolds. An $S = 10$ system with uniaxial symmetry would break into S doublets and 1 singlet. The size of these zero-field splittings is also mandated by symmetry. For an O_h system, the barrier would scale as $\frac{1}{16c^8}$ with c the speed of light. For a system without symmetry or with uniaxial symmetry the splittings would scale as $\frac{1}{4c^2}$. Symmetry considerations suggest that magnets with lower symmetry should be stronger. However, there is also a scaling with nuclear charge that could reverse this trend for centers that are heavy enough.

2.2 Hamiltonian for an anisotropic molecular magnet

2.2.1 The second-order Hamiltonian

To the degree that a given system behaves as a single quantum-mechanical spin, the most general second-order anisotropy Hamiltonian for this spin, in the presence of a magnetic field, is given by:

$$H = \sum_i B'_i S'_i + \sum_{ij} \gamma_{ij} S'_i S'_j \tag{3}$$

(with $i, j = x, y, z$). Here, $\mathbf{S}'$, $\mathbf{B}'$ are the standard total spin operators and externally applied magnetic-field components with respect to an arbitrary coordinate system. In the preceding expression, γ_{ij} is referred to as the *second-order anisotropy tensor*. Here, we assume an isotropic g tensor and absorb this term into the definition of the applied magnetic field. Further, it should be noted that general arguments, discussed later, tell us that the phenomenological anisotropy Hamiltonian scales as $\frac{1}{4c^4}$ where c is the speed of light. In atomic units $c = 137$. The preceding Hamiltonian can be immediately simplified by diagonalizing this tensor to find the eigenvalues (λ_i) and eigenvectors which effectively determine the principal axes of magnetization. The Hamiltonian is then most commonly expressed according to:

$$H = \mathbf{B} \cdot \mathbf{S} + \sum_i \lambda_i S_i S_i, \tag{4}$$

$$= AS^2 + DS_z^2 + E(S_x^2 - S_y^2) + \mathbf{B} \cdot \mathbf{S} \tag{5}$$

with $A = \frac{\lambda_x + \lambda_y + \lambda_z}{3}$, $D = \frac{\lambda_z - (\lambda_y + \lambda_x)/2}{3}$, and $E = \frac{\lambda_x - \lambda_y}{2}$. Once the preceding Hamiltonian is adopted, the parameter A is generally taken to be zero since it is isotropic. In the next section, we discuss a means for calculating A, D, and E from

the density-functional theory. The constant, AS^2, is probably very weakly dependent on spin ordering (based on results from Baruah *et al*. 2004). However, some investigation into possible shifts in spin-manifold gaps due to this constant term should be investigated at some point. The parameters D and E are referred to as the *second-order longitudinal and transverse anisotropy parameters*, respectively. Classically, the difference in energy, or energy barrier, for the spin aligned along the z axis rather than the y and x axes would be $(D + E)S^2$ and $(D - E)S^2$, respectively.

Several points should be made. A large barrier for an actual molecular magnet is currently found to be approximately 60–70 K. Before continuing, it is worthwhile dispelling one incorrect notion that can be concluded from the preceding phenomenological Hamiltonian. Examination of this Hamiltonian incorrectly suggests that such barriers could be enhanced by simply engineering larger spin systems and further suggests that an antiferromagnetically ordered molecular magnet, devoid of a net spin, would observe no energy barrier associated with spin reversal. On the contrary, the results of the first-principles derivation, discussed in the subsequent text, show that the barrier scales roughly as $(N_{\text{sites}} \times N_{\text{occ}} \times N_{\text{virt}})$ where N_{sites} are the number of atoms or ions with unpaired localized electrons, and N_{occ} and N_{virt} are characteristic numbers of unpaired states in the occupied and unoccupied manifolds. The derivation shows a hidden inverse square dependence of the γ tensor on the magnitude of the local moments. Thus, an antiferromagnetically ordered set of spins could indeed have an anisotropy and could, for example, be useful for an exchange-biasing application when coupled to a weak paramagnetic molecule with a net spin. The same line of derivation shows that the phenomenological Hamiltonian shown in the preceding text is quantitatively valid only for a given spin manifold. While difficult to prove, it is more likely that the D parameter for two different low-lying spin manifolds would differ by the ratio of $(S_1/S_2)^2$ rather than a factor of unity. However, this Hamiltonian contains all the physics necessary to understand the essence of resonant tunneling of magnetization and oscillations in tunnel splittings. Before considering additional complexities, we consider these two effects.

2.2.2 *Resonant tunneling of magnetization*

To determine the eigenvalues of the above Hamiltonian, it is necessary to construct the $(2S + 1) \times (2S + 1)$ Hamiltonian matrix $\langle SM|H|SM'\rangle$. Setting $A = 0$ and considering the case for $E = 0$ first, it is easy to verify that the eigenvalues of this Hamiltonian, as a function of longitudinal field, are given by

$$E(M) = DM^2 + B_z M \tag{6}$$

At zero field, it is readily apparent that the $(2S + 1)$ levels are split into S doublets (M and $-M$) and one singlet (for an integer spin case). If a longitudinal field is turned on, the S doublets split. However, $S - n$ quasi-doublet degeneracies are restored whenever the magnetic field is chosen such that $B_z = nD$ (with $n = 0, 1, \ldots, S - 1$). With this understanding it is possible to discuss one aspect of the resonant tunneling of magnetization experiments (Friedman *et al*., 1996; Thomas *et al*., 1996).

For the situation where $D < 0$, one may apply a large enough magnetic field so that the spin relaxes to the state $M = S$. If the field were suddenly turned off and then replaced by an infinitesimal field in the opposite direction, the $M = -S$ state would be the new ground state of the system. Classically, the time constant governing relaxation from the $M = S$ to $M = -S$ state would be given by an Ahrrenius behavior:

$$\frac{1}{\tau} = \nu \times e^{(-U/kT)} \tag{7}$$

where ν is referred to as an *attempt frequency* and $U = |D|S^2$ is the activation barrier at zero magnetic field. Given a lattice of noninteracting spins, an experiment which measured magnetization or other observables that depend on the moment projection would allow for the determination of the longitudinal anisotropy constant. For the classical moment, if the antiparallel field is now slowly increased, the energy barrier in the exponential changes continuously according to $U = (|D|S^2 - |BS|)$ and the time constant would also be expected to change continuously with field. However, for a quantum-mechanical spin, the relaxation rate exhibits a much richer dependence on the magnetic field. When the magnetic field is chosen such that the occupied and/or virtual M state aligns perfectly with a state of different M on the other side of the barrier (e.g., $B_z = nD$ for some integer $n < S - 1$), the possibility of tunneling through the barrier, rather than classically jumping over the barrier, exists as well. This leads to a near discontinuity in the tunneling rate and describes the underlying physics observed by Friedman *et al*. and Sessoli *et al*. For the perfect second-order case, multiple state alignments occur simultaneously. Thus, multiple pathways exist for tunneling phenomena and the fastest pathway determines the overall relaxation time. This argument shows the magnetic fields at which tunneling will be allowed based on the consideration of energetics. However, it neither describes the complicated dynamics which lead to resonant tunnelling of magnetization (RTM) nor allows us to directly determine a blocking temperature. However, it is clear from equation (7) that the blocking temperature will be larger if the activation barrier, or magnetic anisotropy, can be increased.

2.2.3 *Tunnel-splitting oscillations*

If the transverse anisotropy (E) is nonzero, an additional quantum-mechanical phenomena can occur for a single quantum-mechanical spin interacting with a magnetic field. This phenomenon was originally predicted by Garg (1993) and subsequently observed by Wernsdorfer and Sessoli (Wernsdorfer and Sessoli, 1999).

Pictured in the upper panel of Figure 2 are the energy levels of an $S = 10$ molecular magnet or quantum spin with anisotropy parameter of $D = -0.25$K and $E = 0.05$ K respectively as a function of a magnetic field applied along the x axis. Following Garg's analytic formula, the units of the magnetic field are given by $B_x^o = [2E(|D| + E)]^{1/2}$. The energy levels as a function of applied field show a series of fascinating crossings or avoided crossing at values of $(N + \frac{1}{2})B_x^o$ and (NB_x^o), respectively. Also pictured in the lower panel of Figure 2 is the logarithm of the energy difference between the two lowest-energy states as a function of magnetic field. There are a total of six different calculations as a function of angle between the in-plane magnetic field and the x axis. This picture shows that the tunnel splittings depend strongly on perfect alignment between the x-axis and the applied magnetic field.

2.2.4 *Effects of higher-order contributions to the anisotropy Hamiltonian*

When higher-order terms are added to the Hamiltonian, for example, terms like $BS_z^4 + C(S_+^4 + S_-^4)$, several effects occur. The S_z^4 term adds a perturbation to the different M states and prevents perfect simultaneous alignments of energy levels in the longitudinal tunneling experiments. The transverse term breaks the perfect periodicity of the tunnel-splitting oscillations in the transverse experiments. Also the relative orientation between the transverse second-order terms and the transverse fourth-order terms changes the orientation of the magnetic fields required for observation of these splittings. This provides a very useful diagnostic tool for the symmetry around a quantum spin and these effects have been observed experimentally and theoretically in relation to the Mn_{12}-acetate molecule. For this case, Cornia identified a weak symmetry-breaking term in the crystal containing these molecules. Weak hydrogen bonds between space-filling acetic acids of crystallization were predicted to lead to three types of spin Hamiltonians with $E = 0, 0.008$, and 0.016 (Cornia *et al.*, 2002; Park, Baruah, Bernstein and Pederson, 2004). Further Pederson, Bernstein and Kortus (Pederson, Bernstein and Kortus, 2002) showed qualitatively from calculations that Raman-active vibrations lead to interactions in the Mn_{12}-acetate which cause an additional transverse term and identify the intrinsic fourth-order axis. The misalignment between the intrinsic transverse axes and those determined from the actual placement of the acetic acids of crystallization provide a system where the tunnel-splitting oscillations can be used as a probe of the local structure around a quantum spin. This has been investigated experimentally and is now quite well understood (del Barco *et al.*, 2004; Hill *et al.*, 2003; Park *et al.*, 2005).

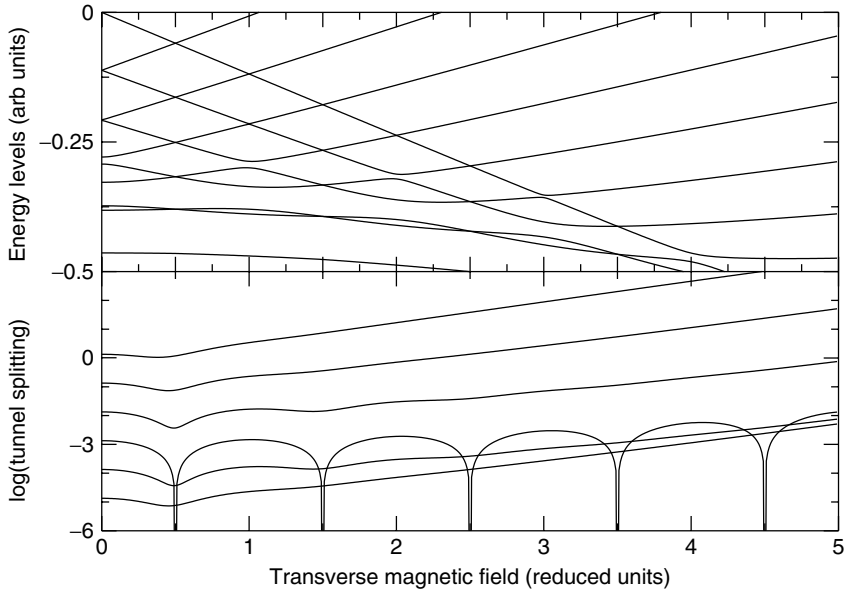

Figure 2. Uppermost energy levels (upper panel) and log (tunnel splittings) of two most stable states for an $S = 10$ quantum spin. The Hamiltonian is field $H = -DS_z^2 - E(S_x^2 + S_y^2) + BS_x$ with $D = -0.25$ and $E = 0.05$. The physical reduced units of the transverse magnetic field are $[2|E|(|D| + |E|]^{1/2}$ as shown by Garg.

2.3 Heisenberg Hamiltonians with anisotropy

As discussed in the subsequent text, the origin of the spin-orbit interaction leads to anisotropy in a molecular system. A general feature of the spin-orbit interaction is that the expectation value of this operator is zero for any wave function that is purely real. This is known as *time-reversal symmetry* but follows immediately if we believe that the expectation value of a physical operator, that is purely imaginary, must be real. Simply appending the phenomenological Hamiltonian to a Heisenberg Hamiltonian leads to splittings in the multiplets; however, there are two main problems with this approximation. First, as already stated, the derivation presented in the subsequent text shows that the anisotropy tensor contains hidden dependencies on the spin of the system. There is not a single phenomenological Hamiltonian that is equally applicable to each state. Second, the operator itself is real and at least quadratic in spin operators. The expectation value of this operator for an arbitrary real wave function is nonzero, which indicates that such a Hamiltonian has some basic physics missing. Alternative approaches have been to include local anisotropy terms (e.g., $\sum_i D_i S_z^i S_z^i$). While these terms describe the energetics of a localized uncoupled spin flip correctly, it has been shown that the energy associated with the simultaneous flipping of a collection of these spins is not equal to the sum of the energies. This is unphysical. Katsnelson, Dobrovitski and Harmon (1999) discuss the use of the Dzyaloshinskii-Moriya (DM) interaction in the Mn_{12}-acetate molecule to build in some of the anisotropic effects.

3 DENSITY-FUNCTIONAL-BASED DERIVATION OF ANISOTROPY HAMILTONIANS

The purpose of this section is to show how to determine the previously discussed phenomenological model from an all-electron mean-field theory. The original derivation of some of the equations here appears in Pederson and Khanna (1999). In that paper, the discussion concentrated on how the change in eigenvalue sum, or trace, was considered when the spin-orbit interaction was included in a quantum-mechanical treatment. The derivation is exact for a collection of electrons moving in an external Hamiltonian. However, if the total energy of the system depends self-consistently on the electronic wave functions, it is really the change in total energy, rather than the change in eigenvalue sum, that one should be interested in addressing. Electric polarizabilities represent a well-known example where a perturbative expression based on the perturbation of a trace gives very different polarizabilities than the correct self-consistent polarizabilities. More generally, in a mean-field theory, the sum of the eigenvalues is not the total energy due to the so-called *double counting* of the coulomb and exchange interactions in the Hamiltonian. Indeed, the electron–electron coulomb contributions to the total energy are exactly half as large in the total energy as they are in the eigenvalue sum. For the spin-orbit interaction, the response of the eigenvalue sum is a very good approximation to the response of the total energy rather than a factor of 2 overestimate. This point is neither immediately obvious nor general to all possible types of perturbations. We discuss the method carefully to show why the method works as well as it does and to aid in identifying the regime of validity.

It should be emphasized that the phenomenological Hamiltonian can in principle be determined numerically using standard self-consistent field (SCF) methods that include the spin-orbit interaction in the energy. However, it has long been recognized that the spin-orbit contribution is the primary interaction leading to magnetic anisotropy. The spin-orbit operator, in atomic units, has a $\frac{1}{2c^2}$ prefactor which leads to lowest-order contributions to the magnetic anisotropy of order $\frac{1}{4c^4}$. These are small numbers which immediately raise questions about the use of an inexact self-consistent numerical treatment. For example, it is well known that the spin-orbit interaction felt by a given electron depends on the electric field observed by that electron. This electric field depends on all charges in the problem including those associated with the other electrons. In the subsequent text, using the proper many-electron wave function and Hamiltonian, we derive the expression for the contributions to the spin-orbit energy due to the electronic coulomb potential. It is not surprising that this exactly reproduces the term one expects from the expression one would derive based on a classical electron moving through an arbitrary coulomb potential. The complication in using this exact expression arises when one invokes the standard variational principle to derive the self-consistent Hamiltonian. Performing this exercise leads to an SCF Hamiltonian that has both the intuitive spin-orbit term and a more complicated term due to the variation of the electric field or coulomb potential of the electronic wave functions. Ignoring this nonlocal term, which has a $\frac{1}{2c^2}$ prefactor in the Hamiltonian, will introduce an error in the total energy that scales as $\frac{1}{2c^4}$ which is the same size as the anisotropy term.

There are two additional problems associated with using a full numerical variational approach. The first is related to the need for a noncollinear treatment of the electronic wave functions because the spin-orbit interaction mixes states of different spin projection. This means that the spin-density matrix is not diagonal and must in principle be rediagonalized at each point in space to construct the energy within a density-functional approach. Noncollinear SCF methods have been used and represent an additional important modification

to a standard SCF procedure that must be performed to obtain energies that are correct to the order of $\frac{1}{4c^4}$. The second problem in relation to the calculation of magnetic anisotropies is that one is not only interested in minimizing the total energy of the system with the spin-orbit interaction turned on. Since the magnetic anisotropy of a molecular magnet or nanoparticle is the target, one is actually interested in minimizing the total energy subject to the constraint that the axis of quantization, which defines the 'z' axis for the spinors, is in an arbitrary but fixed position relative to the molecular axes. Constrained minimizations are also very difficult to do.

Although the numerical determination of magnetic anisotropy is challenging, an entirely analytic approach to a complicated many-electron system is probably futile. Even for the simple triplet state of molecular oxygen, the analytic expressions derived from the magnetic anisotropy are sufficiently complicated that it is difficult to guess whether the molecule is easy axis or easy plane by staring at the formula. Because of these difficulties, we have relied on a partially analytical and partially numerical approach. The approach allows one to derive expressions for the magnetic anisotropy that are variational with respect to a single parameter and alleviates the need for the calculation of some of the more complex terms that would occur in the exact self-consistent Hamiltonian. Further, it leads to a formalism that is easily incorporated into standard codes based upon density-functional theory. We discuss the general idea. First, it is assumed that one has found the occupied and unoccupied electronic wave functions that self-consistently minimize a mean-field energy expression (such as that found in density-functional theory or Hartree-Fock). Second, we append the spin-orbit energy to this expression. Third, we assume that we have a physically motivated means for guessing the form of the wave functions that minimize the energy with the spin-orbit interaction turned on. The starting point for the expression of the new wave functions will correspond to those determined from exact perturbation theory using the full, but not self-consistent, coulomb contributions to the spin-orbit interaction but multiplied by a variational parameter γ. The energy of this expression as a function of γ will then be minimized leading to a variational bound on the energy as a function of a given axis of quantization.

Neglecting spin-orbit effects, in a mean-field theory the part of the total energy of a system of electrons that depends on the electronic wave functions may be written according to:

$$E_{\text{elec}} = \sum_{n\sigma} \langle \psi_{n\sigma} | -\frac{1}{2}\nabla^2 + V_{\text{nuc}} | \psi_{n\sigma} \rangle + \frac{1}{2} \int \mathrm{d}^3 r \times \int \mathrm{d}^3 r' \frac{\rho(\mathbf{r})\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} + \int \mathrm{d}^3 r \, \rho(\mathbf{r}) \epsilon_{xc}(\rho_\sigma, \rho'_\sigma) \quad (8)$$

$$\rho_\sigma(\mathbf{r}) = \sum_n |\psi_{n\sigma}(\mathbf{r})|^2 = \sum_n |\phi_{n\sigma}(\mathbf{r})|^2 \quad (9)$$

$$\rho_\sigma(\mathbf{r}) = \rho_\sigma(\mathbf{r}) + \rho'_\sigma(\mathbf{r}) \quad (10)$$

For the purpose of simplicity, the above equation refers specifically to the local-density approximation. The first three terms represent the electronic kinetic energy, the coulomb interaction of the electrons with the nuclei and the electronic coulomb energy, respectively. The last term represents the local-density approximation to electron correlation and exchange effects. The first three terms are common to most, if not all, mean-field expressions while the last term changes depending on which level of density-functional theory is being used or if one is using exact exchange. The details of the exchange-correlation function do not affect the formalism discussed here. However, the accuracy of the results will of course depend, albeit mildly, on how well the exchange-correlation effects are represented. Requiring that the energy is minimized with respect to the choice of spin orbitals leads to the following Schroedinger-like equation, which must be solved self-consistently.

$$\langle \delta\psi_{n\sigma} | -\frac{1}{2}\nabla^2 + V_{nuc} + \int \mathrm{d}^3 r' \frac{\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} + \mu^\sigma_{xc}(\mathbf{r}) - \epsilon_{n\sigma} | \psi_{n\sigma} \rangle = \langle \delta\psi_{n\sigma} | H_o - \epsilon_{n\sigma} | \psi_{n\sigma} \rangle = 0 \quad (11)$$

where μ^σ_{xc} is the exchange-correlation potential determined from the functional derivative of the exchange-correlation energy. For further details on the self-consistent field method, density-functional theory, and other mean-field approximations, the interested reader is referred to the references. There are many different numerical strategies for solving the preceding equations. One can expand the wave functions in terms of many different types of basis functions including Gaussian-type orbitals, plane waves, augmented plane waves, or linear-muffin-tin orbitals. Discussion of the basis-set dependent numerical details can be found in many places and will not be repeated here. Suppose both the occupied and unoccupied wave functions which satisfy equation (11) have been determined. In preparation for the following perturbative arguments, let us assume that we define a new set of orthonormal wave functions $\{\psi^\gamma_{n\sigma}\}$ which depend continuously upon a variational parameter γ and coincide exactly with the solutions to equation (11) when $\gamma = 0$. An additional constraint on this set of functions will be that $\langle \frac{\mathrm{d}\psi_{n\sigma}}{\mathrm{d}\gamma} | \psi_{m\sigma} \rangle = 0$ for $m = n$. However, without loss of generality it is convenient to make this constraint true for all pairs of occupied wave functions. The energy for this set of orthonormal wave functions $\psi^\gamma_{n\sigma}$ can be expressed in terms

of a Taylor's series in γ. At $\gamma = 0$, the wave functions satisfy equation (10) so there is no first-order change in the energy. Therefore, to second order in γ, the change in energy is given by:

$$\delta E = \frac{\gamma^2}{2}\sum_{n\sigma}\left\{\left\langle\frac{\mathrm{d}^2\psi_{n\sigma}}{\mathrm{d}\gamma^2}|H|\psi_{n\sigma}\right\rangle + \frac{1}{2}\left\langle\frac{\mathrm{d}\psi_{n\sigma}}{\mathrm{d}\gamma}|H|\frac{\mathrm{d}\psi_{n\sigma}}{\mathrm{d}\gamma}\right\rangle + \left\langle\frac{\mathrm{d}\psi_{n\sigma}}{\mathrm{d}\gamma}|\frac{\mathrm{d}H}{\mathrm{d}\gamma}|\psi_{n\sigma}\right\rangle\right\} + c.c \tag{12}$$

The right-most term in the preceding equation is not generally zero but is small for the case of current interest. Neglecting this term, the second-order change in the mean-field energy becomes:

$$\delta E = \frac{\gamma^2}{2}\sum_{n\sigma}\left\{\left\langle\frac{\mathrm{d}^2\psi_{n\sigma}}{\mathrm{d}\gamma^2}|H|\psi_{n\sigma}\right\rangle + c.c\right\} + \left\langle\frac{\mathrm{d}\psi_{n\sigma}}{\mathrm{d}\gamma}|H|\frac{\mathrm{d}\psi_{n\sigma}}{\mathrm{d}\gamma}\right\rangle \tag{13}$$

Now, consider the energy of the γ-dependent choice of wave functions when a very small purely imaginary perturbation ($\mathrm{i}\Delta$) of the form,

$$E(i\Delta) = E'_{\mathrm{elec}} + \sum_{n\sigma}\langle\psi'_{n\sigma}|i\Delta|\psi'_{n\sigma}\rangle \tag{14}$$

is added. For the above energy, the task is to determine very good approximations for the orthonormal wave functions ($\psi'_{n\sigma} = \psi_{n\sigma} + \delta\psi_{n\sigma}$) that minimize the above expression for a given Δ.

As noted in the preceding text, the primed wave functions that minimize equation (14) can be found by the same variational procedure that one uses to perform standard self-consistent field equations. However, for an arbitrary choice of a purely imaginary perturbation operator, $\mathrm{i}\Delta$, it may be that a standard off-the-shelf electronic structure code does not have the necessary numerical techniques to solve the new set of SCF equations. This is especially true when $i\Delta$ becomes the exact spin-orbit interaction. In this case, the electronic coulomb potential appears in the expression for $i\Delta$ and the functional derivative of this term leads to a term in the one-electron Hamiltonian that is cumbersome. For the case that $i\Delta$ is small, such as spin orbit where it has a prefactor of $\frac{1}{2c^2}$, the self-consistent procedure can, to an excellent approximation, be performed *analytically* by adopting the following physically motivated and nearly exact *ansatz* for the perturbation of each occupied wave functions $\psi_\alpha = \phi_m\chi_\sigma$.

$$|\delta\psi_\alpha\rangle = \gamma\sum_\beta|\psi_\beta\rangle\frac{\langle\psi_\beta|i\Delta|\psi_\alpha\rangle}{\epsilon_\alpha - \epsilon_\beta} - \frac{\gamma^2}{2}|\psi_\alpha\rangle\sum_\beta\frac{|\langle\psi_\beta|\Delta|\psi_\alpha\rangle|^2}{(\epsilon_\alpha - \epsilon_\alpha)^2} \tag{15}$$

where the sum over β includes only the unoccupied states. It is easily verified that the preceding wave function remains normalized to second order to the term that is quadratic in γ and that the derivatives satisfy the necessary constraints discussed in the preceding text. Note that Δ or the other factor containing $1/c^2$ is the small parameter in the preceding equation. For a noninteracting collection of electrons it follows immediately that $\gamma = 1$. With respect to the energy for the $\Delta = 0$ limit, (ΔE) for this set of wave functions is to order $(\Delta 2)$ given by:

$$\Delta E = \delta E + \sum_\alpha[(\langle\delta\psi_\alpha|i\Delta|\psi_\alpha\rangle + c.c) + \langle\psi_\alpha|i\Delta|\psi_\alpha\rangle] \tag{16}$$

Now, *if and only if* the perturbing operator $\mathrm{i}\Delta$ yields a vanishing expectation value for each occupied orbital, that is, $\langle\psi_\alpha|i\Delta|\psi_\alpha\rangle = 0$, to second order in γ, the above energy reduces to:

$$\Delta E = -\gamma^2\sum_{\alpha\beta}\frac{|\langle\psi_\alpha|\Delta|\psi_\beta\rangle|^2}{\epsilon_\alpha - \epsilon_\beta} + 2\gamma\sum_{\alpha\beta}\frac{|\langle\psi_\alpha|\Delta|\psi_\beta\rangle|^2}{\epsilon_\alpha - \epsilon_\beta} \tag{17}$$

Since $\epsilon_\beta > \epsilon_\alpha$ for all pairs of occupied and unoccupied states, differentiating the preceding equation with respect to the self-consistency parameter (γ) leads to the conclusion that $\gamma = 1$ for this specific case. Therefore, an upper bound to the second-order energy for a given δ is given by:

$$\Delta E = \sum_{\alpha\beta}\frac{|\langle\psi_\alpha|\Delta|\psi_\beta\rangle|^2}{\epsilon_\alpha - \epsilon_\beta} \tag{18}$$

Now, to connect the preceding formalism to the determination of a phenomenological magnetic anisotropy Hamiltonian, we must start by deriving the spin-orbit energy of a Slater determinant composed of a set of orthonormal single-particle spin orbitals $(\psi_{1\sigma}, \ldots, \psi_{N_\sigma\sigma}, \psi_{1\sigma'}, \ldots, \psi_{N'_\sigma\sigma'})$ where N_σ and N'_σ are the number of electrons for each spin type. Each of these orbitals is a product of a spatial function and a spinor according to:

$$|\psi_{n\sigma}\rangle = \phi_n(\mathbf{r})|\chi_\sigma\rangle \tag{19}$$

$$\langle\phi_{n\sigma}|\phi_{m\sigma}\rangle = \delta_{mn} \tag{20}$$

$$\langle\chi_\sigma|\chi_{\sigma'}\rangle = \delta_{\sigma\sigma'} \tag{21}$$

Note that there is no constraint assumed about the orthonormality of the spatial functions with a different spin index. However, with the exception of the unpaired electrons, the spatial wave functions for antiparallel spin orbitals are nearly identical especially for the core states. Further, we have not yet specified an axis of quantization for the spinors. For now, this choice is assumed to be arbitrary. It is convenient and physically useful to specify the axis of quantization of the spinors with respect to one particular spinor-choice, or alternatively molecular axis, according to:

$$|\chi_1\rangle = \cos\frac{\theta}{2}|\uparrow\rangle + e^{i\phi}\sin\frac{\theta}{2}|\downarrow\rangle$$
$$|\chi_2\rangle = -e^{-i\phi}\sin\frac{\theta}{2}|\uparrow\rangle + \cos\frac{\theta}{2}|\downarrow\rangle \tag{22}$$

The many-electron spin-orbit operator may be written in terms of single-particle operators, corresponding to spin-orbit interactions between the electrons and the coulomb potential of the nuclei and two-particle operators, corresponding to spin-orbit interactions between an electron and the coulomb potential of the other electrons. We discuss the two-particle term in detail and merely give the results of the more-commonly discussed one-electron contributions. The exact two-electron spin-orbit operator may be written in a manifestly symmetric form according to:

$$G_{ls} = \frac{1}{4c^2}\sum_{i,j\neq i}\left[S_i\cdot\nabla_i\frac{1}{r_{ij}}\times p_i + S_j\cdot\nabla_j\frac{1}{r_{ji}}\times p_j\right] \tag{23}$$

$$G_{ls} = \sum_{i,j\neq i} g_{ij} \tag{24}$$

Given an antisymmetrized many-electron Slater determinant composed of the preceding single-particle orbitals, the expectation value of this operator can be evaluated following standard analytic procedures outlined by Slater. The energy is found to be:

$$\langle\Psi|G_{ls}|\Psi\rangle = C_{ls} + E_{ls} \tag{25}$$
$$C_{ls} = \sum_{\alpha\beta}\langle\psi_\alpha(1)\psi_\beta(2)|g_{12}|\psi_\alpha(1)\psi_\beta(2)\rangle \tag{26}$$
$$E_{ls} = -\sum_{\alpha\beta}\langle\psi_\alpha(1)\psi_\beta(2)|g_{12}|\psi_\beta(1)\psi_\alpha(2)\rangle \tag{27}$$

with C_{ls} and E_{ls} the coulomb and exchange contributions to the spin-orbit energy, respectively. Note that the above term is zero if all the above wave functions are real or if there is a set of real wave functions that are related to the above wave functions by a unitary transformation. The constraint of real unperturbed wave functions is important here and in other parts of the derivation. In the preceding equation the summation indices (α, β) include both spatial and spin indices (e.g., $\alpha = n, \sigma$). The exchange contribution manifests itself from the Pauli principle. The coulomb contribution to the spin-orbit term reduces to

$$C_{ls} = \frac{1}{2c^2}\sum_\alpha\langle\psi_\alpha|\mathbf{S}\cdot\boldsymbol{\nabla}\boldsymbol{\Phi}_{\mathrm{e-e}}(\mathbf{r})\times\mathbf{p}|\psi_\alpha\rangle \tag{28}$$

where $\Phi_{\mathrm{e-e}}(\mathbf{r})$ is the electronic coulomb potential. Since we are interested in determining quantities such as $\frac{\mathrm{d}C_{ls}}{\mathrm{d}\gamma}$, we note here that for real zeroth order wave functions it is the explicit dependencies on ψ_α in preceding equation. The coulomb potential changes but since it remains real (i.e., not complex), the change in electronic coulomb potential does not contribute to the first derivative of the coulomb contributions to the spin-orbit energy if the zeroth order wave functions are real.

However, when the single-electron operators associated with the spin-orbit coupling with the nuclei are included, one finds an expression identical to that above, with Φ_{nuc}, the coulomb potential of the nuclei or other applied coulomb field, replacing the electronic coulomb term. Thus, the spin-orbit interaction due to the entire coulomb field Φ is simply

$$C_{ls} = \frac{1}{2c^2}\sum_\alpha\langle\psi_\alpha|\mathbf{S}\cdot\boldsymbol{\nabla}\boldsymbol{\Phi}(\mathbf{r})\times\mathbf{p}|\psi_\alpha\rangle \tag{29}$$

The exchange contributions will be discussed further in the following section. In all of the previous calculations by the NRL group and in most calculations the author is aware of the exchange term has been neglected.

Now that the spin-orbit energy and the perturbative expression for the anisotropy have been developed, it is possible to discuss how these two techniques can be used to derive the phenomenological Hamiltonians that describe molecular magnets. We start by noting that the momentum operator $\mathbf{p} = -i\nabla$ and combine equations (18) and (29) to yield a bound on the second-order spin-orbit energy for a specific set of angles (θ, ϕ). We find:

$$\Delta E = \frac{1}{4c^4}\sum_{\alpha\beta}\frac{\langle\psi_\alpha|\mathbf{S}\cdot\boldsymbol{\nabla}\boldsymbol{\Phi}\times\boldsymbol{\nabla}|\psi_\beta\rangle\langle\psi_\beta|\mathbf{S}\cdot\boldsymbol{\nabla}\boldsymbol{\Phi}\times\boldsymbol{\nabla}|\psi_\alpha\rangle}{\epsilon_\alpha - \epsilon_\beta} \tag{30}$$

$$\Delta E = \frac{1}{4c^4}\sum_{ij}\sum_{\sigma\sigma'}\langle\chi'_\sigma|S_i|\chi_\sigma\rangle\langle\chi_\sigma|S_j|\chi'_\sigma\rangle \times\sum_{nm}\frac{\langle\phi_{n\sigma}|V_i|\phi_{m\sigma}\rangle\langle\phi_{m\sigma}|V_j|\phi_{n\sigma}\rangle}{\epsilon_{n\sigma} - \epsilon_{m\sigma'}} \tag{31}$$

$$V_j = (\mathbf{S}\cdot\boldsymbol{\nabla}\boldsymbol{\Phi}\times\boldsymbol{\nabla})_j \tag{32}$$

To simplify the notation, it is useful to make the following definition for the matrix $M_{ij}^{\sigma\sigma'}$ and note the following

simplification for the matrix elements $\langle\phi_m|V_i|\phi_n\rangle$.

$$M_{ij}^{\sigma\sigma'} = \frac{1}{4c^4}\sum_{nm}\frac{\langle\phi_n|V_i|\phi_m\rangle\langle\phi_m|V_j|\phi_n\rangle}{\epsilon_{n\sigma}-\epsilon_{m\sigma'}} \tag{33}$$

$$S_i^{\sigma\sigma'} = \langle\chi_\sigma|S_i|\chi'_\sigma\rangle \tag{34}$$

$$\langle\phi_{n\sigma}|V_x|\phi_{m\sigma'}\rangle = \left\langle\frac{\mathrm{d}\phi_{n\sigma}}{\mathrm{d}z}|\Phi|\frac{\mathrm{d}\phi_{m\sigma'}}{\mathrm{d}y}\right\rangle - \left\langle\frac{\mathrm{d}\phi_{n\sigma}}{\mathrm{d}y}|\Phi|\frac{\mathrm{d}\phi_{m\sigma'}}{\mathrm{d}z}\right\rangle \tag{35}$$

The matrix elements V_x and V_y are determined from cyclical permutations of the preceding equations. This equation can be derived from the more standard expression of the spin-orbit interaction through an integration by parts (see (Pederson and Khanna, 1999)). With these definitions, the anisotropy energy as a function of spin quantization axis takes the following form

$$\Delta E = \sum_{ij}\sum_{\sigma\sigma'} M_{ij}^{\sigma\sigma'} S_i^{\sigma\sigma'} S_j^{\sigma'\sigma} \tag{36}$$

The final step in understanding magnetization in a molecular magnet is to notice that equation (37) still depends on the angles (θ, ϕ) in the unitary transformation (equation (22)). Therefore, the energy ΔE explicitly depends on these values of angles. Conceptually, one would be interested in mapping out the energy as a function of these two angles. It is worth mentioning that with the specific parameterization of the unitary transformation (equation (22)), the angles correspond to the two rotation angles used in a spherical coordinate system. One approach is to calculate $\Delta E(\theta, \phi)$ and find the vectors/angles which find the critical points of the second-order spin-orbit interaction. For the case of a uniaxial molecule, this was worked out in detail by Pederson and Khanna. However, there is a more elegant way to rewrite the preceding equations in terms of the usually physically meaningful expectation values of $\langle S_i\rangle$. Following (Postnikov, Kortus and Pederson, 2006), we note:

$$\langle S_i\rangle = \sum_{n\sigma}\langle\psi_{n\sigma}|S_i|\psi_{n\sigma}\rangle \tag{37}$$

$$= [N_\sigma - N_{\sigma'}]\langle\chi_\sigma|S_i|\chi_\sigma\rangle = \Delta N\langle\chi_\sigma|S_i|\chi_\sigma\rangle \tag{38}$$

$$= [N_{\sigma'} - N_\sigma]\langle\chi'_\sigma|S_i|\chi'_\sigma\rangle = -\Delta N\langle\chi'_\sigma|S_i|\chi'_\sigma\rangle \tag{39}$$

where ΔN is the total moment of the molecule. In addition, it can be shown, for $\sigma \neq \sigma'$, that:

$$\langle\chi_\sigma|S_i|\chi'_\sigma\rangle\langle\chi'_\sigma|S_j|\chi_\sigma\rangle = \langle\chi_\sigma|S_iS_j|\chi_\sigma\rangle - \langle\chi_\sigma|S_i|\chi_\sigma\rangle\langle\chi_\sigma|S_j|\chi_\sigma\rangle \tag{40}$$

$$= \frac{\delta_{ij}}{4} - \frac{\langle S_i\rangle\langle S_j\rangle}{\Delta N^2} \tag{41}$$

Substituting these expressions for $\langle\chi_\sigma|S_i|\chi'_\sigma\rangle$ in equation 37 gives the second-order spin-orbit energy as a function of $\langle S_i\rangle$. It is:

$$\Delta E = \sum_{ij}\langle S_i\rangle\langle S_j\rangle\frac{1}{\Delta N^2}[M_{ij}^{11} + M_{ij}^{22} - M_{ij}^{12} - M_{ij}^{21}] + \frac{1}{4}\sum_i(M_{ii}^{12} + M_{ii}^{21}) \tag{42}$$

From this, it follows that the effective anisotropy tensor is defined according to:

$$\gamma_{ij} = \frac{1}{\Delta N^2}[M_{ij}^{11} + M_{ij}^{22} - M_{ij}^{12} - M_{ij}^{21}] \tag{43}$$

and we arrive at the final expression for the second-order spin-orbit energy as a function of spin projection. It is:

$$\Delta E = \sum_{ij}\gamma_{ij}\langle S_i\rangle\langle S_j\rangle \tag{44}$$

For any vector of length $|\mathbf{S}| = \frac{\Delta N}{2}$ the spin-orbit energy may be found as a function of orientation. It seems reasonable to requantize this expression and write the phenomenological Hamiltonian as

$$H = \sum_{ij}\gamma_{ij}S_iS_j \tag{45}$$

By diagonalizing the anisotropy tensor, it is possible to recast the preceding equation in the phenomenological form given in equation (1). The division by ΔN^2 in equation (44) is convenient except for the case that an antiferromagnetic system, with zero net spin, is being studied. Under this condition, the expression for the energy as a function of angles in the unitary transformation, or possibly Neel vector, would be a better way of representing the physics.

4 RECENT APPLICATIONS

Two very good reviews on applications of density-functional theory to molecular magnets are about to be published (Postnikov, Kortus and Pederson, 2006; Pederson, Park and Baruah, 2006). However, most of the applications discussed in this work were published prior to 2003. In this section, we primarily give a survey of work that has been completed since then that does not appear in the other reviews.

The method described in the preceding text has been implemented in the NRLMOL code (Pederson and Lin, 1987; Pederson and Jackson, 1990, 1991; Jackson and Pederson, 1990; Quong, Pederson and Feldman, 1993; Pederson, Broughton and Klein, 1988; Porezag and Pederson,

1996, 1999; Briley *et al*., 1998) a few years ago. Since then it has been used to study the anisotropy parameters, local anisotropy axes, and parameters. The first calculations carried out on the Mn_{12}-acetate could correctly predict the anisotropy parameter D within less than 1% error. Since then several different types of molecular magnets have been studied. The density-functional parameters of the spin Hamiltonian, that is, the D and E parameters in equation 5 for various molecular magnets are listed in Table 1 and compared with the available experimental values.

The density-functional theory (DFT) studies on Mn_{12}, Fe_8, Mn_{10}, Co_4, and Mn_4 have been discussed extensively in previous articles (Pederson and Khanna, 1999; Kortus, Pederson, Hellberg and Khanna, 2001; Pederson, Kortus and Khanna, 2002; Baruah *et al*., 2004; Kortus, Hellberg and Pederson, 2001; Kortus, Baruah, Bernstein and Pederson, 2002; Baruah and Pederson, 2002; Baruah and Pederson, 2003; Kortus *et al*., 2003). The energy band gap in the system plays an important role in determining the parameters, which are obtained through a perturbative treatment. However, surprisingly, in Mn_{12}, the DFT calculation gives a very good agreement with experiment for the D parameter. In Mn_{12}, which has S_4 symmetry, the E parameter turns out to be zero by symmetry. However, experiments show tunneling which violates the selection rules applicable to S_4 symmetry. The presence of a small E contribution can possibly arise due to the presence of symmetry-breaking ligands or presence of an extra electron. Incorporation of these effects yields an E parameter 0.016 K (Park, Baruah, Bernstein and Pederson, 2004). The other cases where the DFT calculations give very good agreement with experiment are $[Mn_{10}O_4(2,2'\text{-biphenoxide})_4Br_{12}]^{4-}$, $[Mn_4\ O_3Cl_4(O_2CCH_3CH_2)_3(C_5H_5N)_3]$, and Fe_4 (Kortus, Baruah, Bernstein and Pederson, 2002; Park *et al*., 2003; Kortus *et al*., 2003). The disagreement for the Co_4 molecule is controversial in the sense that there is a lack of reliable experimental data (Yang *et al*., 2002) to compare with. When compared to Co_6 (Murrie, Teat, Stoeckli-Evans and Güdel, 2003) which also has the same cubane structure at the center, the calculated values of the anisotropy barrier agrees well with experimental values. Among all the tabulated systems, the most glaring discrepancy is seen for the $Fe_8O_2OH_{12}(tacn)_6]^{8+}Br_87(H_2O)$ molecule. The Fe_8 molecule is very well studied experimentally and the experimental D parameter is -0.29 K. The Br–Fe_8 molecule has C_1 symmetry but in most calculations which are done at the all-electron level, some symmetry is enforced to make the calculations tractable. This is not unreasonable considering the fact that the calculations are done on the core molecule in the $+2$ charged state without the accompanying symmetry-breaking water molecules and the bromine ions. The calculated gap is small in the Fe_8 and further corrections due to self-interaction may be required. Another example where theory and experiment differ is the Ni_4 analog of Co_4. The Ni_4 molecule has been synthesized with different ligands such as CH_3, CH_2CH_3, or $(CH_2)_2C(CH_3)_3$. The measured electron paramagnetic resonance (EPR) spectra yield values of D between 0.72 and 1.03 K but the calculations found D to be between 0.25 and 0.37 K. Interestingly, DFT finds the $S = 0$ state as the lowest-energy state.

The organic ligands compensate the charges of the transition-metal centers. However, the role of the ligands does not stop there. They also produce the crystal field, and changing the type of ligands can lead to an enhancement of the effective barrier. One example of such barrier enhancement is the $Fe_4(OMe)_6(dpm)_6$ and $Fe_4(thme)_6(dpm)_6$ molecules (Figure 3). The $Fe_4(OMe)_6(dpm)_6$ has C_2 symmetry and four iron atoms lie on a plane such that three of the atoms form an isosceles triangle and the C_2 axis passes through the central iron and one of the apical ones. The

Table 1. Calculated and experimental magnetic anisotropy parameters for different molecular magnets.

Molecular magnet system	Symmetry	Spin S	Gap (eV)	D (K)	E (K)	Experiment D(K), E(K)

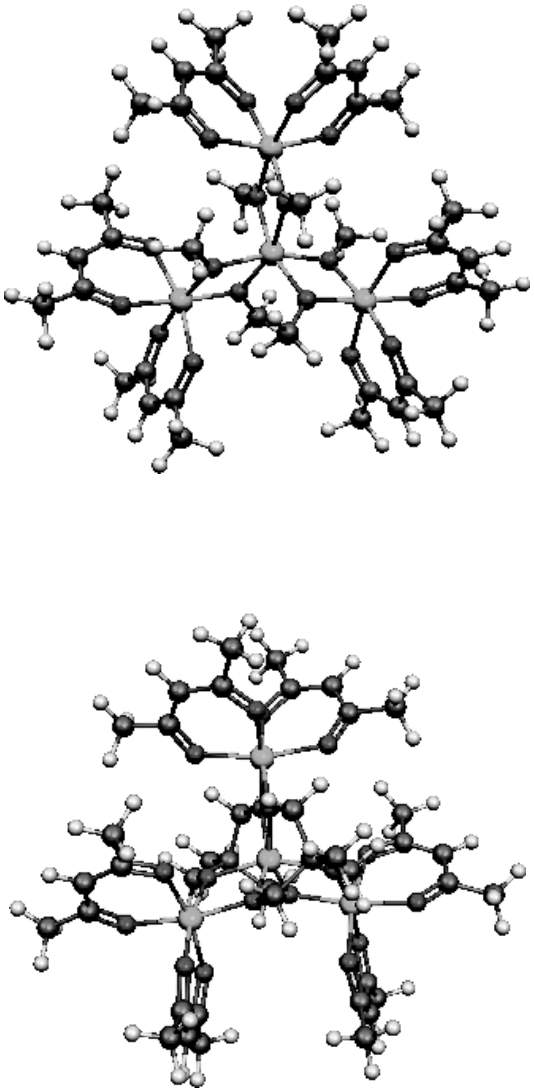

Figure 3. The molecular structures of $Fe_4(OMe)_6(dpm)_6$ and $Fe_4(thme)_6(dpm)_6$.

$Fe_4(thme)_6(dpm)_6$ molecule possesses D_3 symmetry with three iron atoms forming an equilateral triangle with the fourth at the center. Both the molecules have total spin $S = 5$, but the magnetic anisotropy barrier in the $Fe_4(thme)_6(dpm)_6$ is 15.6 K while that of the $Fe_4(OMe)_6(dpm)_6$ is 3.5 K.

The spin interaction between the iron atoms shows similar characteristics in both the molecules – ferromagnetic interaction between the peripheral atoms and antiferromagnetic interaction between the pheral and central atom. Both the molecules are uniaxial with the easy axis coinciding with the C_2 and C_3 axes of symmetry. The main structural difference between the two systems is seen at the position of the central atom. However, elongation of bonds or rotation of the ligands pertaining to the central atom does not fully explain the difference in magnetism between the two molecules. The atom-projected anisotropies show that the orientation of the projected local anisotropy axes are completely different in the two systems. It is the collinear alignment of the local easy axes that leads to a global easy axis system in $Fe_4(thme)_6(dpm)_6$.

The other two Fe_4 compounds are remarkable in that both have a Fe_4O_4 cubane structure but the ligands are slightly different. The $(sap)^{-2}$ has a six-membered ring while the $(sae)^{-2}$ contains a five-membered ring thus leading to different steric strains on the Fe(II) ions. The consequences are that the one with the five-membered ring shows single-molecule magnet behavior while the other does not. This is another example of the ligand changing the magnetic behavior of the molecule.

The calculations on these series of molecules are preliminary, but conclusively show that the π-back donation from the Fe(II) to the ligands allows control of the sign and magnitude of the D parameter. In the $Fe_4(sae)_4(MeOH)_4$ the local easy axes are nearly orthogonal ($\sim 73^\circ$) to the S_4 symmetry axis. In the $Fe_4(sap)_4(MeOH)_4$ cluster, which has nearly S_4 symmetry, the local easy axis has more overlap on the pseudo-S_4 axis leading to a global easy axis system. Further, switching the positions of the imine fragment and a hydroxyl ligand can enhance the barrier by a factor of 6, which is remarkable. This study shows that the steric strains and the orientation of the local axes can enhance or reduce the global SMM behavior.

5 SUMMARY

During the last eight years, the ability to perform calculations on molecular magnets has grown due to new algorithms, faster computers, and an increasing number of researchers interested in this field. This chapter has discussed the basic phenomenological Hamiltonians and a formalism for developing these Hamiltonians from a first-principles methodology such as density-functional theory. There is now a large set of calculated results, which are generally in qualitative accord and often in quantitative accord with experiment. It is hoped that additional work will be performed to further improve computational methodologies for molecular magnets.

Future improvements in the computational methods are likely to concentrate on several different problems. First, pursuit of an improved description of exchange and correlation within a density-functional framework should be one area of concentration. Second, the formalisms discussed here concentrate on two extremes in transition-metal-containing molecules. In one case, the low-energy excitations are determined entirely from exact diagonalization of a many-spin Hamiltonian. In the other case, it is assumed that the leading term from this exact diagonalization will provide a good

anisotropy Hamiltonian. Discussions as to why this is *sometimes* the case have been recently held. However, it is most desirable to develop a formalism that can account directly for multiconfiguration contributions to the magnetic anisotropy. Finally, there is still not much success in quantitatively understanding the higher-order corrections to the magnetic anisotropy Hamiltonian. Future efforts aimed at this problem will be both challenging and useful. It is quite possible that such efforts will require a self-consistent constrained solution to the electronic Hamiltonian. This calls for strong efforts at extending many different electronic structure methods.

ACKNOWLEDGMENTS

This work was supported in part by ONR and NSF. The authors thank Prof. S.N. Khanna, J. Kortus, S. Hellberg, N. Bernstein, K. Park, and J. Ribas for many interesting collaborations on molecular magnetism. It should also be noted that without early developmental efforts by K.A. Jackson, D.V. Porezag, and D. Patton on the nonmagnetic code, it would have been difficult to convert the preceding formalism into an efficient code for understanding molecular magnetism. We thank the editors of this handbook for encouraging us to complete this chapter and for their patience.

Interplay of Superconductivity and Magnetism

Saburo Takahashi and Sadamichi Maekawa
Tohoku University, Sendai, Japan

1 INTRODUCTION

The interplay of superconductivity and magnetism is a long-standing and fascinating research subject in condensed-matter physics (Buzdin, 2005; Golubov, Kupriyanov and Il'ichev, 2005; Bergeret, Volkov and Efetov, 2005; Izyumov, Proshin and Khusainov, 2002). It is widely recognized that superconductivity and magnetism are mutually exclusive because of their essentially different ordered states. Superconductivity in conventional superconductors is due to Cooper pairs of two electrons with opposite spin and momentum ($k\uparrow, -k\downarrow$). The attractive interaction between electrons creates Cooper pairs in a singlet state. In contrast, the ferromagnetic exchange interaction forces electron spins to align in parallel and produces ferromagnetism. Therefore, when the Zeeman energy of an electron pair in the exchange field $h_{\rm ex}$ exceeds the condensation energy of the pair, which is measured by the superconducting gap Δ, the superconducting state is destroyed. The corresponding depairing exchange field is $h_{\rm ex} \sim \Delta/\mu_{\rm B}$, where $\mu_{\rm B}$ is the Bohr magneton. It was predicted a long time ago that a spatially inhomogeneous order parameter with Cooper pairs of nonzero-momentum state appears near the depairing field. This state is called the *Fulde–Ferrell–Larkin–Ovchinnikov* (*FFLO*) state (Fulde and Ferrel, 1964; Larkin and Ovchinnikov, 1965). However, there has been no clear observation in bulk materials with the possible exception of the heavy-fermion superconductor $CeCoIn_5$ (Bianchi *et al*., 2003; Kakuyanagi *et al*., 2005).

For the preceding reasons, the coexistence of superconducting order and ferromagnetic order is quite unlikely in bulk materials. However, recent advances in nanofabrication techniques make it possible to study the interplay of superconductivity and ferromagnetism by artificially preparing ferromagnet/superconductor (F/S) systems consisting of ferromagnetic and superconducting layers in the form of bilayers, trilayers, multilayers, and other structures. In these hybrid structures, the superconducting order parameter penetrates into the F layer owing to the proximity effect. Numerous theoretical and experimental studies on F/S structures (Figure 1) revealed a nonmonotonic temperature dependence of the superconducting transition temperature $T_{\rm c}$ on the thickness of the ferromagnetic layer due to the proximity effect (Radovic *et al*., 1991; Jiang, Davidović, Reich and Chein, 1995; Mühge *et al*., 1996; Aarts *et al*., 1997; Tagirov, 1999; Gu *et al*., 2002; Krunavakarn, Sritrakool and Yoksan, 2004; Obi, Ikebe and Fujishiro, 2005; Moraru, Pratt and Birge, 2006).

Of particular interest is a Josephson junction containing a ferromagnet, in which novel phenomena due to the competition between ferromagnetism and superconductivity arise. When Cooper pairs penetrate from a superconductor

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

into a ferromagnet across the interface of an F/S junction, the Cooper pairs in a clean F have a finite momentum $q \sim h_{\rm ex}/v_{\rm F}$ ($v_{\rm F}$ is the Fermi velocity), because of the exchange splitting $h_{\rm ex}$ between the up-spin and the down-spin bands (Bulaevskii, Kuzii and Sobyanin, 1977; Buzdin, Bulaevskii and Panyukov, 1982; Demler, Arnold and Beasley, 1997; Kontos, Aprili, Lesueur and Grison, 2001). Consequently, the superconducting pair amplitude oscillates as $\cos(2qz)$ along the direction perpendicular to the interface. Recently, it has been demonstrated that such oscillation can be induced in a weak ferromagnet sandwiched between two superconductors, in which the current-phase relation in the Josephson current is shifted by π compared to the conventional Josephson relation (Ryazanov *et al*., 2001; Kontos *et al*., 2002; Blum, Tsukernik, Karpovski and Palevski, 2002; Sellier, Baraduc, Lefloch and Calemczuk, 2003; Frolov *et al*., 2004; Oboznov *et al*., 2006; Weides *et al*., 2006). The π state offers a new route for studying the interplay of superconductivity and magnetism and is also important to superconducting electronics, for example, quantum computing.

The spin injection technique offers a new type of F/S device (spin switching) based on the interplay of superconductivity and spin accumulation created in S. This technique allows us to electronically control the mutual influence between superconductivity and magnetism in hybrid structures, leading to spin electronics applications (Maekawa, 2006; Maekawa and Shinjo, 2002; Žutić, Fabian and Das Sarma, 2004).

2 PROXIMITY EFFECT IN S/F STRUCTURES

Let us consider the interplay of superconductivity and magnetism in a hybrid structure consisting of a superconductor and a ferromagnet, as shown in Figure 1, in which the proximity effect plays a central role. For simplicity, we concentrate on the proximity effect near the superconducting transition temperature $T_{\rm c}$, and derive a basic equation for the superconducting pair amplitude in F/S structures. The self-consistency equation for the superconducting order parameter $\Delta(\mathbf{r})$ near $T_{\rm c}$ is linearized in the form (de Gennes, 1966; Takahashi and Tachiki, 1986; Ketterson and Song, 1999)

$$\Delta(\mathbf{r}) = V(\mathbf{r}) k_{\rm B} T \sum_{\omega} \int {\rm d}\mathbf{r}' Q_{\omega}(\mathbf{r}, \mathbf{r}') \Delta(\mathbf{r}') \tag{1}$$

where $\omega = (2n+1)\pi k_{\rm B} T$, with n being an integer, $V(\mathbf{r})$ is the position-dependent pairing interaction, and $Q_{\omega}(\mathbf{r}, \mathbf{r}')$ is a

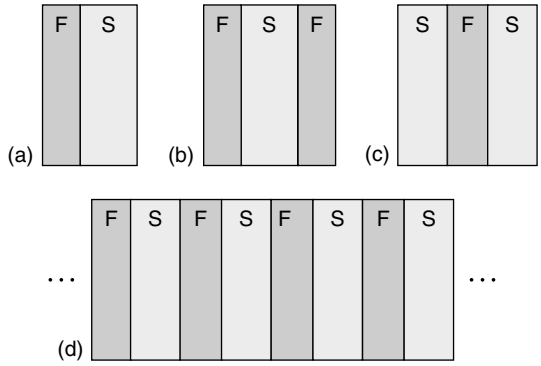

Figure 1. Various types of F/S structures. (a) F/S bilayer, (b) F/S/F trilayer, (c) S/F/S trilayer, and (d) F/S multilayer.

kernel defined by

$$Q_{\omega}(\mathbf{r}, \mathbf{r}') = \frac{1}{2} \sum_{\sigma} \sum_{m,n} \frac{\phi^*_{n\sigma}(\mathbf{r}') \phi_{n\sigma}(\mathbf{r}) \phi^*_{m-\sigma}(\mathbf{r}') \phi_{m-\sigma}(\mathbf{r})}{(i\omega - \xi_{n\sigma})(i\omega + \xi_{m-\sigma})} \tag{2}$$

where $\phi_{n\sigma}(\mathbf{r})$ is the one-electron wave function with energy $\xi_{n\sigma}$ and spin σ in the normal state. The motion of one-electron in a diffusive conductor is described by the one-electron correlation function $g_{\sigma}(\mathbf{r}', \mathbf{r}, t)$ satisfying

$$\left[\hbar \frac{\partial}{\partial t} - \hbar D(\mathbf{r}) \nabla^2 + 2i h_{\rm ex}(\mathbf{r}) \hat{\sigma}_z^{\sigma\sigma} \right] g_{\sigma}(\mathbf{r}', \mathbf{r}, t) = 0 \tag{3}$$

where $D(\mathbf{r})$ is the diffusion constant and $h_{\rm ex}(\mathbf{r})$ is the exchange potential (Zeeman energy) acting on conduction electrons, and $\hat{\sigma}_z$ is the Pauli spin operator. For $t \to 0$, $g_{\sigma}(\mathbf{r}', \mathbf{r}, t)$ reduces to the initial condition $g_{\sigma}(\mathbf{r}', \mathbf{r}, 0) = (1/2)\delta(\mathbf{r} - \mathbf{r}') N_{\sigma}(\mathbf{r})$, where $N_{\sigma}(\mathbf{r})$ is the density of states of the spin-σ band. The kernel $Q_{\omega}(\mathbf{r}, \mathbf{r}')$ and its auxiliary kernel $R_{\omega}(\mathbf{r}, \mathbf{r}')$ are written as (Takahashi and Tachiki, 1986)

$$Q_{\omega}(\mathbf{r}, \mathbf{r}') = 2\pi \int_0^{\infty} {\rm d}t \left[g_{\uparrow}(\mathbf{r}', \mathbf{r}, t) + g_{\downarrow}(\mathbf{r}', \mathbf{r}, t) \right] e^{-2|\omega|t} \tag{4}$$

$$R_{\omega}(\mathbf{r}, \mathbf{r}') = 2\pi \frac{\omega}{|\omega|} \times \int_0^{\infty} {\rm d}t \left[g_{\uparrow}(\mathbf{r}', \mathbf{r}, t) - g_{\downarrow}(\mathbf{r}', \mathbf{r}, t) \right] e^{-2|\omega|t} \tag{5}$$

If we introduce the quantities

$$\mathcal{F}^{(e)}_{\omega}(\mathbf{r}) = \int {\rm d}^3 r' Q_{\omega}(\mathbf{r}, \mathbf{r}') \Delta(\mathbf{r}'),$$
$$\mathcal{F}^{(o)}_{\omega}(\mathbf{r}) = \int {\rm d}^3 r' R_{\omega}(\mathbf{r}, \mathbf{r}') \Delta(\mathbf{r}') \tag{6}$$

we have the coupled equations (Takahashi and Tachiki, 1986; Usadel, 1970):

$$\left[2|\omega| - \hbar D(\mathbf{r})\nabla^2\right] \mathcal{F}_\omega^{(e)}(\mathbf{r}) + 2ih_\omega(\mathbf{r})\mathcal{F}_\omega^{(o)}(\mathbf{r}) = \pi N(\mathbf{r})\Delta(\mathbf{r}) \tag{7}$$

$$\left[2|\omega| - \hbar D(\mathbf{r})\nabla^2\right] \mathcal{F}_\omega^{(o)}(\mathbf{r}) + 2ih_\omega(\mathbf{r})\mathcal{F}_\omega^{(e)}(\mathbf{r}) = 0 \tag{8}$$

where $h_\omega(\mathbf{r}) = (\omega/|\omega|)h_{\rm ex}(\mathbf{r})$ and $N(\mathbf{r}) = N_\uparrow(\mathbf{r}) + N_\downarrow(\mathbf{r})$ is the electronic density of states [1]. Note that $\mathcal{F}_\omega^{(e)}(\mathbf{r}) = \mathcal{F}_{-\omega}^{(e)}(\mathbf{r})$ and $\mathcal{F}_\omega^{(o)}(\mathbf{r}) = -\mathcal{F}_{-\omega}^{(o)}(\mathbf{r})$, so that $\mathcal{F}_\omega^{(e)}(\mathbf{r})$ and $\mathcal{F}_\omega^{(o)}(\mathbf{r})$ correspond to the spin-singlet and spin-triplet components of pair amplitudes with the even- and odd-frequency dependence, respectively (Bergeret, Volkov and Efetov, 2005).

Since the pair function $F(\mathbf{r}) = \Delta(\mathbf{r})/V(\mathbf{r})$ is written as

$$F(\mathbf{r}) = k_{\rm B}T \sum_\omega \mathcal{F}_\omega^{(e)}(\mathbf{r}) \tag{9}$$

equations (7)–(9) yield the self-consistent equations for $F(\mathbf{r})$. In order to solve the self-consistent equation, we introduce the eigenfunction ψ_n and the eigenvalue ϵ_n, which satisfy

$$-\hbar D(\mathbf{r})\nabla^2\psi_n(\mathbf{r}) = \epsilon_n\psi_n(\mathbf{r}) \tag{10}$$

with the boundary conditions that $F(\mathbf{r})/N(\mathbf{r})$ and $D(\mathbf{r})$ $(\hat{\mathbf{n}}\cdot\nabla)F(\mathbf{r})$, $\hat{\mathbf{n}}$ being the unit vector normal to the interface, are continuous at the interfaces. These boundary conditions are applicable to the case that the boundary resistance is negligible [2]. Using the expansion $F(\mathbf{r}) = \sum_n a_n\psi_n(\mathbf{r})$ in the self-consistent equation, we derive the secular equation that determines the superconducting transition temperature $T_{\rm c}$ in a F/S system (Takahashi and Tachiki, 1986)

$$\det\left|\delta_{nn'} - 2\pi k_{\rm B}T\sum_\omega\sum_m \Gamma_{nm}^{-1}\langle m|VN|n'\rangle\right| = 0 \tag{11}$$

where Γ_{nm}^{-1} is the inverse of the matrix Γ with the element

$$\Gamma_{nm} = \left(|\omega| + \frac{1}{2}\epsilon_n\right)\delta_{nm} + \sum_l \frac{\langle n|h_{\rm ex}|l\rangle\langle l|h_{\rm ex}|m\rangle}{|\omega| + \frac{1}{2}\epsilon_l} \tag{12}$$

and $\langle n|VN|n'\rangle$ and $\langle n|h_{\rm ex}|n'\rangle$ are the matrix elements defined by

$$\langle n|\mathcal{O}|n'\rangle = \int {\rm d}^3r\,\psi_n^*(\mathbf{r})\mathcal{O}(\mathbf{r})\psi_n(\mathbf{r}) \tag{13}$$

The superconducting transition temperature $T_{\rm c}$ of F/S structures is determined as the highest temperature among the solutions of equation (11).

2.1 F/S interface

We consider an F/S system where the left side is occupied by S and the right side by F, as shown in Figure 2. In the F region, $\Delta(z) = 0$ $(V(z) = 0)$, so that equations (7) and (8) become

$$\left(\left[2|\omega| - \hbar D_{\rm F}\nabla^2\right]^2 + 4h_\omega^2\right)\mathcal{F}_\omega^{(e)}(z) = 0 \tag{14}$$

which has the solution $\mathcal{F}_\omega^{(e)}(z) \propto \exp(ikz)$ with the wave number k,

$$\left(2|\omega| + \hbar D_{\rm F}k^2\right)^2 + 4h_\omega^2 = 0 \tag{15}$$

yielding $k = \pm\sqrt{(-2|\omega| \mp ih_{\rm ex})/\hbar D_{\rm F}} = \pm\xi_{\rm F1}^{-1} + i\xi_{\rm F2}^{-1}$:

$$\begin{aligned}\xi_{\rm F1} &= \xi_{\rm F}^0\left[\sqrt{1 + \omega^2/h_{\rm ex}^2} - |\omega|/h_{\rm ex}\right]^{1/2}\\ \xi_{\rm F2} &= \xi_{\rm F}^0\left[\sqrt{1 + \omega^2/h_{\rm ex}^2} + |\omega|/h_{\rm ex}\right]^{1/2}\end{aligned} \tag{16}$$

where $\xi_{\rm F}^0 = \sqrt{\hbar D_{\rm F}/h_{\rm ex}}$ and $D_{\rm F}$ is the diffusion constant of F. Therefore, in the F region of the F/S interface, we have

$$\mathcal{F}_\omega^{(e)}(z) \propto \exp\left(\pm iz/\xi_{\rm F1}\right)\exp\left(-z/\xi_{\rm F2}\right) \tag{17}$$

Near $T_{\rm c}$, one can make a lowest-frequency approximation by replacing $|\omega|$ with $\pi k_{\rm B}T$, so that the pair function (9) becomes (Ryazanov *et al.*, 2001)

$$F(z) \propto \cos\left(z/\xi_{\rm F1}\right)\exp\left(-z/\xi_{\rm F2}\right) \tag{18}$$

where $(\xi_{\rm F1}, \xi_{\rm F2}) = \xi_{\rm F}^0[\sqrt{1 + (\pi k_{\rm B}T/h_{\rm ex})^2} \mp (\pi k_{\rm B}T/h_{\rm ex})]^{1/2}$. The main consequence of the complex wave number in the F region is that $F(z)$ oscillates with the period of $\xi_{\rm F1}$ and decays on the scale of $\xi_{\rm F2}$, as depicted in Figure 2. When F is a strong ferromagnet, that is, $h_{\rm ex} \gg k_{\rm B}T$, like a transition-metal ferromagnet (Fe, Co, Ni), both length scales are nearly equal, $\xi_{\rm F1} \approx \xi_{\rm F2} \approx \xi_{\rm F}^0$, and very short. On the other hand, when F is a weak ferromagnet, like a diluted

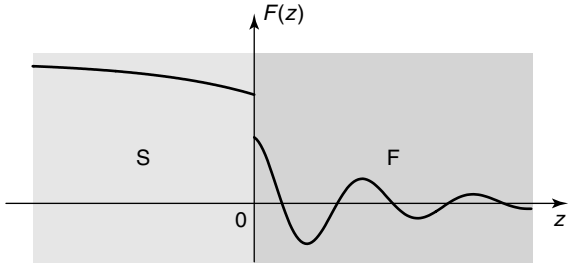

Figure 2. Superconducting pair function $F(z) = \Delta(z)/V(z)$ across the F/S interface.

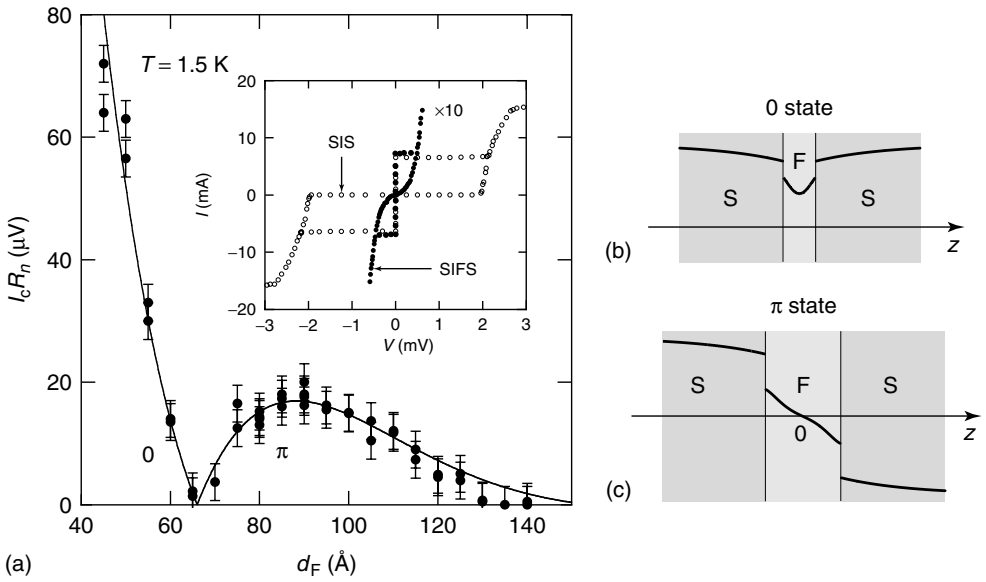

Figure 3. (a) Josephson critical current I_c as a function of thickness d_F of palladium nickel (PdNi) layer (Kontos *et al*., 2002). (Reproduced from Kontos *et al*., 2001, with permission from the American Physical Society. © 2001.) The solid curve is a theoretical fit (Kontos *et al*., 2002). I_c has a zero crossing at $d_F \approx 65$ Å, indicating the transition between the 0 and π states. Inset shows typical I–V characteristics of junctions with (full circles) and without (empty circles) PdNi layer. Spatial variation of the pair amplitude $F(z)$ in the 0 state (b) and in the π state (c).

ferromagnetic alloy (PdNi, CuNi, $\cdots$), in which the exchange field and temperature are the same order of magnitude, $h_{ex} \sim k_B T_c$, both length scales become of the order of tens of nanometers (nm), and, in addition, have a significant temperature dependence.

3 FERROMAGNETIC π JUNCTION

One of the most novel phenomena caused by the interplay of ferromagnetism and superconductivity is the 'π state', which appears in S/F/S junctions and F/S multilayers. It was predicted (Bulaevskii, Kuzii and Sobyanin, 1977; Buzdin, Bulaevskii and Panyukov, 1982) that the Josephson coupling energy takes a minimum at the phase difference equal to π. This state is called the π *state*, and the Josephson junction with the π state is called the π *junction*. In a π junction, the phase in the current-phase relation is shifted by π from that of a conventional Josephson junction (0 junction), so that the Josephson current in the π junction is opposite in sign to that in the 0 junction.

The π state in an S/F/S junction originates from the oscillation of the superconducting pair amplitude $F(z)$ in the presence of the exchange field h_{ex} in F. As shown in Figure 2, at the interface in the S/F junction, the pair amplitude penetrates into F in an oscillatory fashion $F(z) \propto \cos(z/\xi_{F1}) \exp(-z/\xi_{F2})$ in the direction perpendicular to the interface. When the thickness d_F of F in an S/F/S junction is about half the period of the oscillation, that is, $d_F \sim \pi\xi_{F1}$, the pair amplitude of the left and right S's has opposite signs, as shown in Figure 3(c). As a result, the system is stable with the phase difference equal to π, and the current-phase relation is shifted by π from that of the 0 junction in Figure 2(b).

Recent experimental observation of the π state in S/F/S Josephson junctions has opened new research fields. Ryazanov *et al*. have revealed the evidence for the π state by measuring the temperature dependence of the Josephson critical current I_c in Nb/CuNi/Nb junctions (Ryazanov *et al*., 2001), in which the zero crossing of I_c takes place, indicating the transition between the 0 and π states. Kontos *et al*. have measured the dependence of the Josephson current on the thickness of PdNi in a Nb/PdNi/Nb junction as shown in Figure 3(a) (Kontos *et al*., 2002). The transition between the 0 and π states occurs at the zero crossing point ($d_F \approx 65$ Å) of the critical current. In addition, the π state has been observed in a superconducting quantum interference device (SQUID)-type structure with insulating and ferromagnetic Josephson junctions as a π shift in the magnetic field dependence of the critical current (Guichard *et al*., 2003), and in a relatively large superconducting loop with a ferromagnet Josephson junction as a spontaneous current flowing in the loop (Bauer *et al*., 2004. It has been reported recently that, using strong ferromagnets (Co, Ni, and $Ni_{80}Fe_{20}$), multiple 0–π transitions with a short period occur in the thickness dependence of the critical current

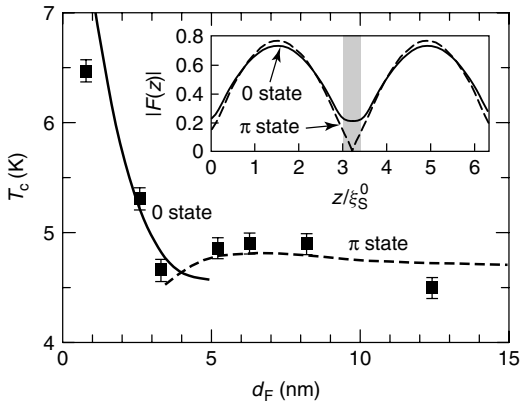

Figure 4. Superconducting transition temperature T_c of the 0 and π states as a function of F-layer thickness d_F for the exchange field $h_{ex} = 10k_B T_{cS}$ and $T_{cS} = 8.8$ K (Kuboya and Takanaka, 1998). The symbols are the experimental data of Nb/CuMu multilayers (Mercaldo *et al*., 1996). The inset shows the spatial variation of the absolute value of the pair amplitude $|F(z)|$. The shaded area is the F layer.

(Robinson *et al*., 2006), and are explained in terms of clean limit results with the oscillation period $\xi_{F1} \sim v_F/2h_{ex}$ and the decay length $\xi_{F2} \sim v_F/2k_B T$, the length scales of which are independent of each other (Born *et al*., 2006), in contrast to the dirty limit results.

The 0–π transition has been observed in F/S multilayers (Jiang, Davidović, Reich and Chein, 1995; Mercaldo *et al*., 1996; Shelukhin *et al*., 2006). In an F/S multilayer system, in addition to the boundary conditions at the interfaces, we impose the Bloch condition $\psi_n(z + L) = \pm\psi_n(z)$, where $L = d_S + d_F$ is the period of the multilayer, and '+' and '−' signs correspond to the 0 state and the π state respectively. Under these boundary conditions, equation (11) is solved numerically (Kuboya and Takanaka, 1998). Figure 4 shows the superconducting transition temperature T_c of the 0 and π states as a function of d_F for $h_{ex} = 10k_B T_{cS}$, $T_{cS} = 8.8$ K, $d_S/\xi_S^0 = 3$, and $\xi_S^0 = 8$ nm, where ξ_S^0 is the coherence length of the bulk S at zero temperature. As d_F is increased, T_c changes from the 0 state to the π state at the thickness $d_F \sim 4$ nm. The symbols are the experimental data of T_c in Nb/CuMn multilayers with fixed Nb layer thickness (∼250 Å) (Mercaldo *et al*., 1996).

4 ANDREEV REFLECTION AT F/S POINT CONTACTS

Andreev reflection (AR) is a fundamental process that occurs at the interface between a normal metal and a superconductor (Andreev, 1964; Blonder, Tinkham and Klapwijk, 1982). In the normal side of the interface, an incident electron with spin σ takes another electron with opposite spin $-\sigma$ to enter the superconductor in the form of a Copper pair, thereby reflecting a positively charged hole. This process allows the current to flow across the N/S interface for bias voltages below the superconducting gap Δ. Recently, a new technique based on AR has been used in F/S point contacts to determine the spin polarization of various ferromagnetic metals (Soulen *et al*., 1998; Upadhyay, Palanisami, Louie and Buhrman, 1998). Figure 5(b) shows experimental results for Andreev reflection for several ferromagnetic materials placed in contact with a superconducting Nb (Soulen *et al*., 1998).

The AR at the interface of a ferromagnetic metal and a superconductor is strongly modified because the incident electrons and the reflected holes occupy the states of the opposite spin bands with different values of the densities of states in the ferromagnet (see Figure 5a). de Jong and Beenakker (de Jong and Beenakker, 1995) have given an intuitive and simple argument for the conductance through a ballistic F/S point contact at zero temperature. A ferromagnet contacts a superconductor through a small area, where the number of up-spin channels $N_\uparrow$ is larger than that

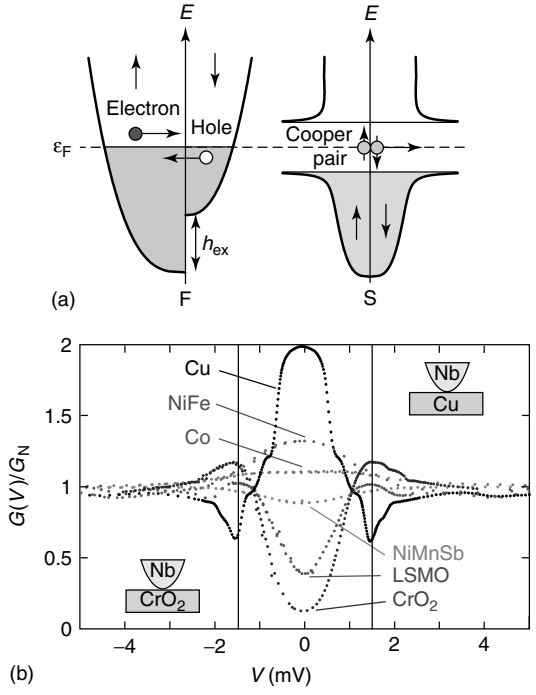

Figure 5. (a) Andreev reflection in a ferromagnet/superconductor (F/S) junction. The up- and down-spin bands are split by the exchange field h_{ex}. (b) Normalized conductance versus bias voltage in normal metal/superconductor (N/S) and ferromagnet/superconductor (F/S) point contacts. (Reproduced from fig 2 in R.J. Soulen Jr., J.M. Byers, M.S. Osofsky, B. Nadgorny, T. Ambrose, S.F. Cheng, P.R. Broussard, C.T. Tanaka, J. Nowak, J.S. Moodera, A. Barry, and J.M.D. Coey, *Science* **282**, (1998) 85, with permission from AAAS.)

of down-spin channels $N_\downarrow$, that is, $N_\uparrow \geq N_\downarrow$. When the superconductor is in the normal state, all scattering channels (transverse modes in the point contact at the Fermi level) are fully transmitted, yielding the conductance

$$G_N = (e^2/\hbar)\left(N_\uparrow + N_\downarrow\right) \tag{19}$$

In the superconducting state, the down-spin electrons in the $N_\downarrow$ channels are all reflected as the Andreev holes, making the conductance double, since $2e$ is transferred at each AR. However, only a fraction $(N_\downarrow/N_\uparrow)$ of up-spin electrons in the $N_\uparrow$ channels is allowed for the AR, because the density of states in the down-spin band is lower than that in the up-spin band in ferromagnets. Therefore, the conductance at zero bias ($V = 0$) is

$$G = (e^2/h)\left[2N_\downarrow + 2(N_\downarrow/N_\uparrow)N_\uparrow\right] = 4(e^2/h)N_\downarrow \tag{20}$$

The ratio of equation (20) to equation (19) gives the normalized conductance

$$G/G_N = 2\,(1 - P_c) \tag{21}$$

where P_c is the point-contact spin polarization

$$P_c = \frac{(N_\uparrow - N_\downarrow)}{(N_\uparrow + N_\downarrow)} \tag{22}$$

The spin polarizations P_c of various ferromagnets can be estimated directly from the conductance values at $V = 0$ by applying equation (21) to experimental results, for example, those of Figure 5. The measured P_c of various ferromagnets are $P_c = 42\%$ for Co (Soulen *et al.*, 1998), $P_c = 42$–46% for Fe (Soulen *et al.*, 1998), $P_c = 43$–46% for Ni (Soulen *et al.*, 1998), $P_c = 49.5\%$ for permalloy ($Ni_{80}Fe_{20}$) (Osofsky *et al.*, 2000), $P_c = 85\%$ for $La_{0.7}Sr_{0.3}MnO_3$ (Braden *et al.*, 2003), and $P_c = 96\%$ for CrO_2 (Ji *et al.*, 2001; Parker, Watts, Ivanov and Xiong, 2002). The role of a point contact and a base electrode can be interchanged between F and S, which brings about no significant difference in the measured $G(V)$ curves or in the estimated value of P_c.

Let us consider a pedagogical mode for the AR in a point contact with S occupying the right half space and an F wire of width w. The wave functions of quasiparticles (QPs) with excitation energy E in the electrodes are calculated from the Bogoliubov–de Gennes equation. For simplicity, the calculation is restricted to the case where only the lowest subband is occupied by electrons or holes in the wires. When an electron with energy E in the majority band (symbol '0' in Figure 6) is incident from the F lead into S, the wave

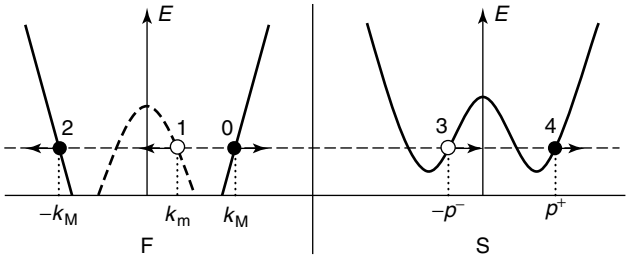

Figure 6. Andreev reflection process at the F/S interface. The open and filled circles represent hole and electron respectively, and the arrows represent the direction of the group velocity. The symbol '0' denotes an incident electron, '1' a reflected Andreev hole, '2' a reflected electron, and '3' and '4' are transmitted holelike and electron-like quasiparticles in S.

function in the lead is given by

$$\Psi_F(x, y) = \left(\begin{bmatrix} 1 \\ 0 \end{bmatrix} e^{ik_M x} + r^{ee}_{MM}\begin{bmatrix} 0 \\ 1 \end{bmatrix} e^{-ik_M x} + r^{eh}_{Mm}\begin{bmatrix} 0 \\ 1 \end{bmatrix} e^{ik_m x}\right)\chi(y) \tag{23}$$

where k_M and k_m are the wave numbers of electron and hole in the majority and minority bands, respectively, $k_\alpha = [2mE + k^2_{F,\alpha} - (\pi/w)^2]^{1/2}$ ($\alpha = M,m$), $k_{F,\alpha}$ is the Fermi momentum of the α band, $\chi(y) = (2/w)^{1/2}\sin\left[(\pi/w)\,(y + w/2)\right]$ is the transverse wave function of the wire, and r^{ee}_{MM} and r^{eh}_{Mm} are the amplitudes of the normal reflection (NR) and the AR, respectively. A similar treatment is made for an incident electron from the minority band. Since $(E, \Delta) \ll \epsilon_{F,\alpha}$, we put $k_\alpha \approx k_{F,\alpha}[1 - (\pi/k_{F,\alpha}w)^2]^{1/2}$ in the following.

Making use of the Andreev approximation (Blonder, Tinkham and Klapwijk, 1982), where $p^\pm$ in Figure 6 is replaced by $(p_F^2 - p_y^2)^{1/2}$, we put the wave function in S as follows:

$$\Psi_S = \int_{-p_F}^{p_F} t_s^{ee}(p_y)\begin{bmatrix} \Delta \\ E - \Omega \end{bmatrix} e^{i\sqrt{p_F^2 - p_y^2}\,x} e^{ip_y y}\mathrm{d}p_y + \int_{-p_F}^{p_F} t_s^{eh}(p_y)\begin{bmatrix} \Delta \\ E + \Omega \end{bmatrix} e^{-i\sqrt{p_F^2 - p_y^2}\,x} e^{ip_y y}\mathrm{d}p_y \tag{24}$$

where $t_s^{ee}(p_y)$ and $t_s^{eh}(p_y)$ are the transmission coefficients and $\Omega = \sqrt{E^2 - \Delta^2}$. The barrier potential at the interface between the wire and S is taken into account by the δ-function-type potential with the amplitude $(\hbar^2 p_F/2m)Z$, Z being a dimensionless barrier-height parameter (Blonder, Tinkham and Klapwijk, 1982). The matching conditions for the wave functions at the interfaces are $\Psi_S(0, y) = \Psi_F(0, y)$ and $[\partial_x\Psi_S(x, y) - \partial_x\Psi_F(x, y)]_{x=0} = p_F Z\Psi_F(0, y)$ appropriate for the $\delta(x)$ barrier potential. The matching technique

to the boundary conditions (Szafer and Stone, 1989) yields the reflection and transmission coefficients.

When the bias voltage V is applied to the wire, the conductance G at zero temperature ($T = 0$) is calculated by putting $E = eV$ as

$$G(V) = \frac{e^2}{h}\left(1 - |r^{ee}_{\mathrm{MM}}|^2 + |r^{eh}_{\mathrm{Mm}}|^2\right) + \frac{e^2}{h}\left(1 - |r^{ee}_{\mathrm{mm}}|^2 + |r^{eh}_{\mathrm{mM}}|^2\right) \tag{25}$$

where h is the Planck's constant and $h/e^2 \approx 25.8\,\mathrm{k\Omega}$ is the quantum resistance.

In the normal state, the transmission probability $\mathcal{T}^{\alpha}_{\mathrm{N}} = 1 - |r^{ee}_{\alpha\alpha}|^2$ ($\alpha = \mathrm{M,m}$) of the majority and minority electrons is

$$\mathcal{T}^{\alpha}_{\mathrm{N}} = 4k_{\alpha}\frac{\Lambda}{[(k_{\alpha} + \Lambda)^2 + Z^2]} \tag{26}$$

where $\Lambda = \int_0^{p_{\mathrm{F}}} (\mathrm{d}q/\pi)\sqrt{p_{\mathrm{F}}^2 - q^2}\,|\langle q|\chi\rangle|^2$ ($0 \le \Lambda \le p_{\mathrm{F}}$) with the overlap integral $\langle q|\chi\rangle$ between e^{ipy} and $\chi(y)$: $\langle q|\chi\rangle = \sqrt{8w/\pi^2}\cos(qw/2)/\left[1 - (qw/\pi)^2\right]$. The spin polarization of the point contact is introduced as

$$P_{\mathrm{c}} = \frac{(\mathcal{T}^{\mathrm{M}}_{\mathrm{N}} - \mathcal{T}^{\mathrm{m}}_{\mathrm{N}})}{(\mathcal{T}^{\mathrm{M}}_{\mathrm{N}} + \mathcal{T}^{\mathrm{m}}_{\mathrm{N}})} \tag{27}$$

For the special case of $\mathcal{T}^{\mathrm{M}}_{\mathrm{N}} = 1$ ($Z = 0$, $k_{\mathrm{M}} = \Lambda$), the conductance for $eV < \Delta$ is calculated as

$$G/G_N = 2(1 - P_{\mathrm{c}}) \tag{28}$$

which is exactly the same as equation (21).

Figure 7 shows the conductance G of F/S point contact as a function of bias voltage V for the barrier heights of $Z = 0$ and $Z = 0.4$ at $T = 0$. The conductance is normalized to the normal-state value $G_N = G(\Delta = 0)$. As can be seen in Figure 7(a), the normalized conductance is flat inside the gap and follows the relation equation (28) for the special case of the perfect transmission of the majority electrons. However, when a small interfacial barrier potential is introduced, as in Figure 7(b), the conductance curves show the peak structure at the gap edge for smaller P_{c}, while they show the dip structure without such peaks for larger P_{c}. These features in the conductance curves have been observed in F/S point-contact experiments.

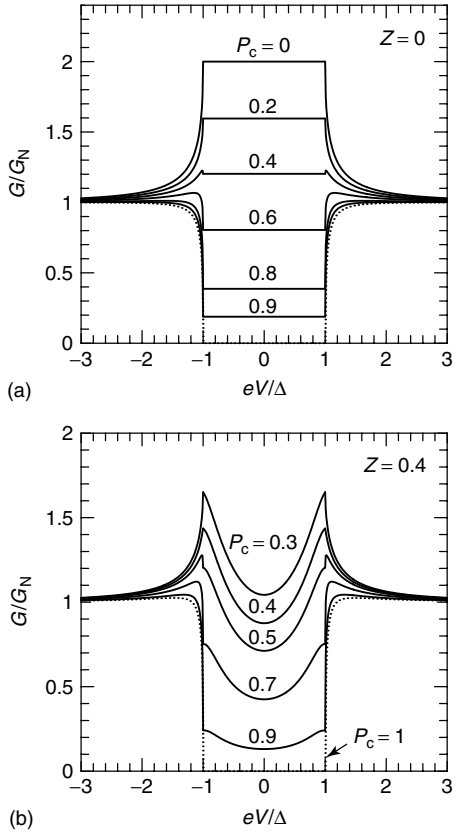

Figure 7. Conductance for the F/S point contacts as a function of bias voltage at $T = 0$. The barrier height is taken to be $Z = 0$ for panel (a) and $Z = 0.4$ for panel (b), for various values of the spin polarization P_{c} at $T = 0$.

5 SUPERCONDUCTING π QUBIT

In quantum computers, information is stored in a basic element called the *qubit*, which is a quantum coherent two-level system. The superposition of the two-level states is utilized in the processing of quantum computing. For physical realization of the qubit, various systems have been proposed, for example, ion traps, nuclear spins, and photons. Among them, solid-state qubits have the advantage of large-scale integration and flexibility of layout. Recently, several qubits based on the Josephson effect have been proposed. One of the proposals is a charge qubit, which uses the charging effect of excess Cooper pairs in a box (Nakamura, Pashkin and Tsai, 1999). Another example is a flux qubit, which uses the superconducting phase. Mooij *et al*. have proposed a flux qubit, which consists of a superconducting loop with three Josephson junctions (Mooij *et al*., 1999). In the flux qubit, degenerate double minima appear in the superconducting phase space under the external magnetic field at which the loop flux corresponds to half the unit magnetic flux. The bonding and antibonding states are formed because of the tunneling between these degenerate states, and are used as the coherent two-level states. Experimentally, the microwave-induced transition between the two-level states, the entanglement of the states,

and the coupling between two qubits have been observed (van der Wal *et al*., 2000; Chiorescu, Nakamura, Harmans and Mooij, 2003; Ciuhu and Lodder, 2001; Majer *et al*., 2005; Izmalkov *et al*., 2004; Chiorescu *et al*., 2004).

Recent advances in nanofabrication techniques have brought a variety of spin-electronic devices. In F/S structures, novel quantum phenomena, such as the π state in ferromagnetic Josephson junctions, arise from the interplay of ferromagnetism and superconductivity. In this respect, recent experimental observations of the π state in those junctions are quite promising for the practical development of superconducting π-shift devices.

Here, we consider a qubit of a superconducting loop consisting of a π junction and a 0 junction (Yamashita, Tanikawa, Takahashi and Maekawa, 2005; Yamashita, Takahashi and Maekawa, 2006). In this system, the potential energy has double minima in the phase space without external magnetic fields because of spontaneous magnetic flux generated by the π junction. The bonding and antibonding states (coherent states), which are formed because of the quantum tunneling between the two degenerate states, are used as a bit in the qubit. A small external magnetic field is enough to manipulate the state of the qubit. These features lead to a smaller size of qubit that is resistant to the decoherence by the external noise.

5.1 Two-junction π qubit

We consider a qubit of a superconducting loop with an S/I/S Josephson junction (0 junction) and an S/F/S Josephson junction (π junction), as shown in Figure 8. In the loop, the 0 junction has the Josephson energy

$$U_0(\theta_0) = -E_{\mathrm{J}}^0 \cos\theta_0 \tag{29}$$

where E_{J}^0 is the Josephson coupling energy and θ_0 is the phase difference in the 0 junction. The current-phase relation is $I = I_0 \sin\theta_0$ with the critical current $I_0 = (2e/\hbar)E_{\mathrm{J}}^0$. On the other hand, the S/F/S junction is a clean and metallic π junction with negligible interface resistance, for which the Josephson energy is well described in the form (Yamashita, Tanikawa, Takahashi and Maekawa, 2005)

$$U_\pi(\theta_\pi) \approx -E_{\mathrm{J}}^\pi \left|\cos\frac{1}{2}(\theta_\pi + \pi)\right| \tag{30}$$

where E_{J}^π is the Josephson coupling energy and θ_π is the phase difference in the π junction. This particular form is realized if appropriate values are chosen for $h_{\mathrm{ex}}/\epsilon_{\mathrm{F}}$ and $k_{\mathrm{F}}d_{\mathrm{F}}$, and leads to the current-phase relation $I \approx -(I_\pi/2)\sin\left[(\theta_\pi + \pi)/2\right]$ for $0 < \theta < 2\pi$ with the critical current $I_\pi = (2e/\hbar)E_{\mathrm{J}}^\pi$.

The total Hamiltonian of the loop is written as $H = K + U_0 + U_\pi + U_L$, where $K = -4E_{\mathrm{c}}^0\left(\partial^2/\partial\theta_0^2\right)$ is the electrostatic energy, $E_{\mathrm{c}}^0 = e^2/(2C_0)$ is the charging energy with the capacitance C_0 of the 0 junction, and U_L is the magnetic energy stored in the loop. The electrostatic energy in the π junction is neglected. The magnetic energy U_L is given by $U_L = (\Phi - \Phi_{\mathrm{ext}})^2/(2L_{\mathrm{s}})$, where Φ is the total flux, L_{s} is the self-inductance of the loop, and Φ_{ext} is the external magnetic flux. The total flux and the phase differences satisfy the relation

$$\theta_\pi + \theta_0 = 2\pi\,(\Phi/\Phi_0) - 2\pi l \tag{31}$$

where $\Phi_0 = hc/2e$ is the unit flux and l is an integer. The total Hamiltonian H is analogous to that describing the motion of a particle with kinetic energy K and in a potential $U = U_0 + U_\pi + U_L$. Minimizing U with respect to θ_0 and

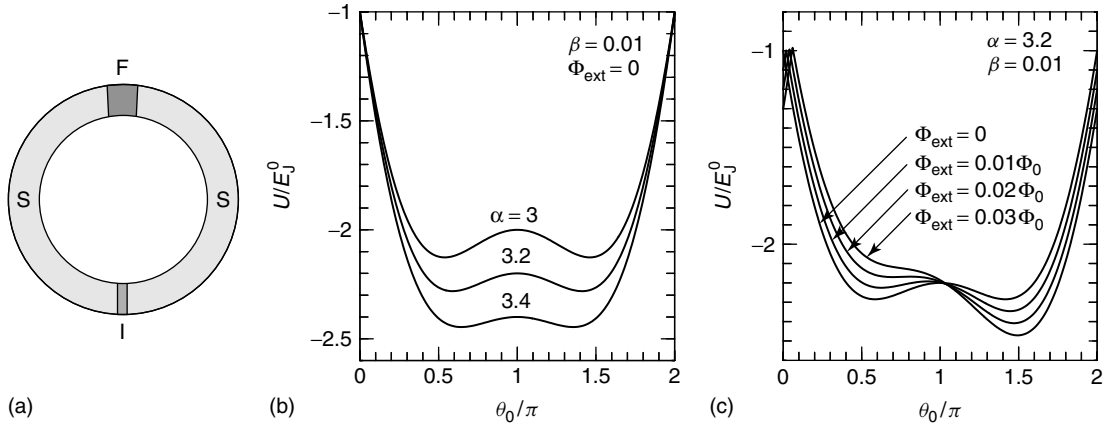

Figure 8. (a) Schematic diagram of a superconducting loop with an insulator and a ferromagnet. The S/I/S junction is a 0 junction (a conventional Josephson junction), and the S/F/S junction is a metallic π junction. (b) Normalized U versus phase θ_0 for $\beta = 1 \times 10^{-2}$ in zero external magnetic field ($\Phi_{\mathrm{ext}} = 0$). (c) Normalized U versus phase θ_0 under the external magnetic fields of $\Phi_{\mathrm{ext}}/\Phi_0 = 0.0$–$0.03$.

θ_π, and eliminating θ_π and Φ from U, we obtain

$$U/E_J^0 = -\cos\theta_0 + \frac{\beta}{2}\sin^2\theta_0 - \alpha\left|\sin\left(\frac{\theta_0}{2} + \frac{\beta}{2}\sin\theta_0 + \pi\frac{\Phi_{\rm ext}}{\Phi_0}\right)\right| \quad (32)$$

where $\alpha = I_\pi/I_0$ and $\beta = (2\pi/\Phi_0)^2 I_0 E_J^0 L_s$, and $\Phi(\theta_0) = \Phi_{\rm ext} + (\Phi_0/2\pi)\beta\sin\theta_0$.

Figure 8(b) shows the θ_0 dependence of U in zero external magnetic field ($\Phi_{\rm ext} = 0$) for several values of α and $\beta = 0.01$. The value $\beta = 0.01$ corresponds to the loop with the inductance $L_s = 2\times10^{-12}$ H with a diameter 2 μm and $I_0 = 500$ nA. As seen in Figure 8(b), the potential has double minima at $\theta_0 \approx \pi/2$ and $3\pi/2$, and the barrier height between the two degenerate states, $|\uparrow\rangle$ ($\theta_0 \approx \pi/2$) and $|\downarrow\rangle$ ($\theta_0 \approx 3\pi/2$), is controlled by α. The value of α can be adjusted by changing the thickness of the insulating barrier or of the ferromagnet. In the $|\uparrow\rangle$ and $|\downarrow\rangle$ states, the supercurrent flows in the clockwise and counterclockwise directions, respectively, inducing flux $\Phi = L_s I \approx \pm 4.8\times10^{-4}\,\Phi_0$.

In the loop, the bonding $|0\rangle \propto |\uparrow\rangle + |\downarrow\rangle$ and the antibonding $|1\rangle \propto |\uparrow\rangle - |\downarrow\rangle$ states are formed via the quantum tunneling between $|\uparrow\rangle$ and $|\downarrow\rangle$, yielding a two-level quantum system. For an alumina barrier with junction area 0.1 μm^2 and thickness 1 nm, $E_c^0 \approx 0.01$ meV and $E_J^0/E_c^0 \approx 96$. In this case, a numerical simulation for $\alpha = 3$ gives the energy gap $\Delta E \approx 0.02$ meV ($\Delta E/h \approx 5$ GHz) between the ground state $|0\rangle$ and the first excited state $|1\rangle$. Microwave absorption is used to measure this two-level quantum state.

Figure 8(c) shows the θ_0 dependence of U in different external magnetic fields and for $\alpha = 3$. The degeneracy of the states $|0\rangle$ and $|1\rangle$ is lifted by applying an external magnetic field. In a small external magnetic field $\Phi_{\rm ext} = \pm0.01\Phi_0$, the double-well potential becomes asymmetric, and one of the components ($|\uparrow\rangle$ or $|\downarrow\rangle$) is lower than the other in the ground state $|0\rangle$, and vice versa in the first excited state $|1\rangle$. In a larger external magnetic field $\Phi_{\rm ext} = \pm0.03\Phi_0$, the double-well potential disappears and the ground state is either $|\uparrow\rangle$ or $|\downarrow\rangle$. Therefore, the currents flow in opposite directions for the $|0\rangle$ and $|1\rangle$ states, when an external magnetic field is applied. As a result, the $|0\rangle$ and $|1\rangle$ states are detected by measuring the current flowing in the loop with a SQUID placed around the loop.

Here, we discuss the dissipation in the metallic π junction. In a small metallic π junction, the discrete Andreev bound states are formed. When the thickness d_F of F is much less than the coherence length, only one Andreev bound state appears in the gap Δ for each spin state σ. The energy, E_σ, of the Andreev bound is gapless ($E_\sigma \approx 0$) at $\theta_\pi = 0$ and 2π, where noise due to thermally excited QPs increases. However, in the π qubit discussed in the preceding text, the quantum tunneling occurs between $\theta_0 \approx \theta_\pi \approx \pi/2$ and $\theta_0 \approx \theta_\pi \approx 3\pi/2$ (Figure 8), for which the Andreev bound state lies near the gap energy. This indicates that the metallic π junction is well gapped in the relevant phase region where the quantum tunneling occurs. Therefore, the QP tunnel dissipation is strongly suppressed at low temperatures and low voltages.

5.2 Three-junction π qubit

Let us next consider a qubit with two 0 junctions and one π junction shown in Figure 9(a) (Yamashita, Takahashi and Maekawa, 2006). The three-junction qubit also does not need an external magnetic field for the formation of the coherent two-level states and is manipulated by a small external field. In addition, this qubit does not require a clean and metallic S/F/S junction, as in the case of the two-junction qubit in the previous section, and works for π junctions with a tunnel barrier between S and F, which are underdamped tunnel π junctions and are robust for decoherence due to thermally excited quasiparticles (Weides *et al*., 2006).

In the three-junction qubit, the first and second 0 junctions have the phase differences θ_1 and θ_2, and the π junction has the phase difference θ_π. The total energy of the system consists of the electrostatic energy and the potential energy of the junctions. The electrostatic energy K is written as

$$K = \frac{4E_c^0}{E_c^\pi + 2E_c^0} \times\left[\left(E_c^\pi + E_c^0\right)\left(\frac{\partial^2}{\partial\theta_1^2} + \frac{\partial^2}{\partial\theta_2^2}\right) - 2E_c^0\frac{\partial^2}{\partial\theta_1\partial\theta_2}\right] \quad (33)$$

where $E_c^0 = e^2/(2C_0)$ and $E_c^\pi = e^2/(2C_\pi)$ are the charging energies of the zero and π junctions, and C_0 and C_π are the capacitances of those junctions. The potential energy U is

$$U = -E_J^0(\cos\theta_1 + \cos\theta_2) - E_J^\pi\cos(\theta_\pi + \pi) + (\Phi - \Phi_0)^2/(2L_s) \quad (34)$$

where E_J^0 and E_J^π are the Josephson coupling energies of the 0 and π junctions, Φ is the total flux in the loop, $\Phi_{\rm ext}$ is the external flux, and L_s is the self-inductance of the loop. A single-valuedness of the wave function along the loop gives the relation

$$\theta_1 + \theta_2 + \theta_\pi = 2\pi(\Phi/\Phi_0) - 2\pi l \quad (35)$$

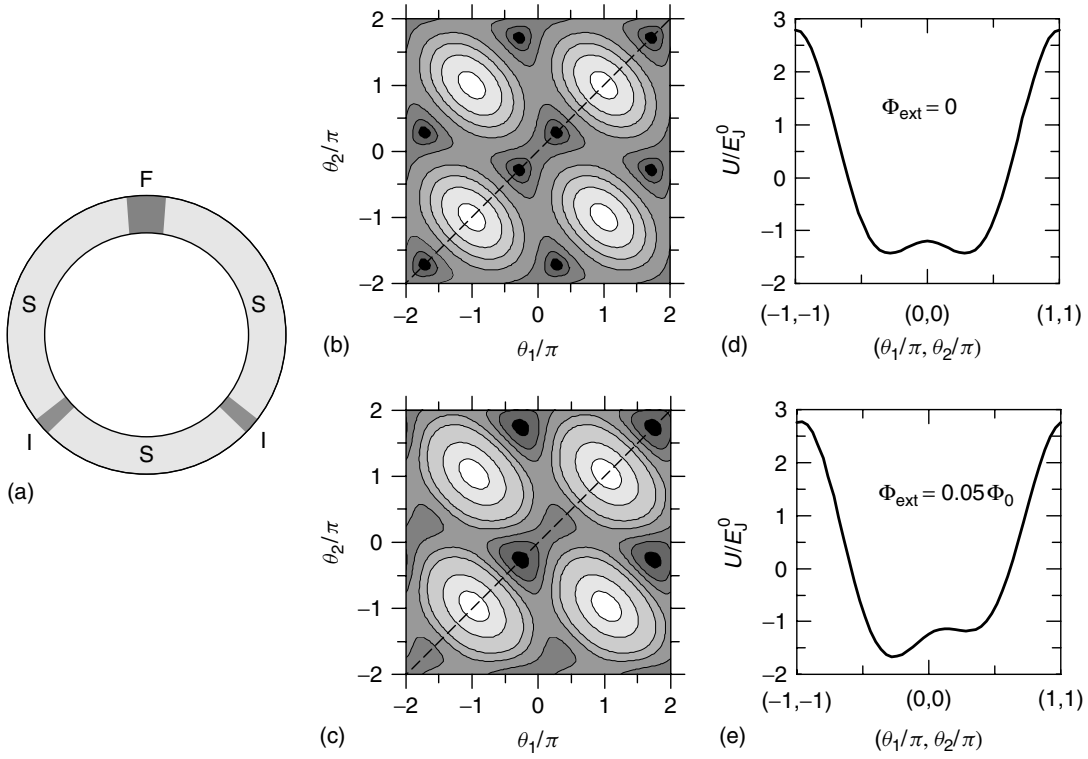

Figure 9. (a) Schematic diagram of a superconducting loop with a π junction and two 0 junctions. Contour plot of the total potential U/E_J^0 in the θ_1–θ_2 plane in zero external magnetic field (b) and in a small external magnetic field of $\Phi_{ext} = 0.05$ (c) for $\alpha = 0.8$ and $\beta = 3.0 \times 10^{-3}$. The phase dependence of U along the dashed lines in (b) and (c) in zero external magnetic flux (d) and in the external magnetic flux $\Phi_{ext} = 0.05\Phi_0$ (e), respectively.

where Φ_0 is the unit flux and l is an integer. Using equation (35) in equation (34), we obtain

$$U = -E_J^0(\cos\theta_1 + \cos\theta_2) - E_J^\pi \cos\left(2\pi\frac{\Phi}{\Phi_0} - \theta_1 - \theta_2\right) + \frac{(\Phi - \Phi_0)^2}{2L_s} \tag{36}$$

Minimizing U with respect to Φ, we obtain the self-consistent equation

$$\alpha\beta \sin\left[2(\Phi/\Phi_0) - \theta_1 - \theta_2\right] = 2\pi(\Phi - \Phi_{ext})/\Phi_0 \tag{37}$$

where $\alpha = E_J^\pi/E_J^0$ and $\beta = 4\pi^2 E_J^0 L_s/\Phi_0^2$. The numerical solution $\Phi = \Phi(\theta_1, \theta_2)$ of equation (37) is used to calculate $U = U(\theta_1, \theta_2)$ as a function of θ_1 and θ_2. In the following, we assume $E_c^0/E_c^\pi = E_J^\pi/E_J^0$, and take $\alpha = 0.8$ and $\beta = 3.0 \times 10^{-3}$. The value of α is controllable by changing the junction area, the barrier height, and the thickness of the ferromagnet. The value of β is suitable for the micrometer-size loop and the Josephson junction with several hundred nanoamperes of the critical current.

Figure 9(b) and (d) shows the potential energy U in the θ_1–θ_2 plane in zero external magnetic flux ($\Phi_{ext} = 0$). As seen in Figure 9, $U(\theta_1, \theta_2)$ has double minima in the phase space. The degenerate $|\uparrow\rangle$ and $|\downarrow\rangle$ states at the minima have the circulating supercurrents of magnitude $\approx 0.8I_0$ in the clockwise and anticlockwise directions, respectively, where I_0 is the critical current in the 0 junctions. Quantum tunneling between the degenerate $|\uparrow\rangle$ and $|\downarrow\rangle$ states creates the bonding $|0\rangle \propto |\uparrow\rangle + |\downarrow\rangle$ and the antibonding $|1\rangle \propto |\uparrow\rangle - |\downarrow\rangle$ states, which are used as a quantum bit. The $|0\rangle$ and $|1\rangle$ states are the states of vanishing circulating current because of the superposition of $|\uparrow\rangle$ and $|\downarrow\rangle$ with equal weight, and have the energy gap ΔE between the $|0\rangle$ and $|1\rangle$ states due to the quantum tunneling. The gap is measured by microwave resonance. From the numerical calculation, the resonance frequency $\Delta E/h \approx 4.4\,\mathrm{GHz}$ for $E_J^0/E_c^0 = 30$.

Figure 9(c) and (e) shows the potential energy U in the θ_1–θ_2 plane in the external magnetic flux $\Phi_{ext} = 0.05\Phi_0$. As seen in the Figure 9(e), the degeneracy of the $|\uparrow\rangle$ and $|\downarrow\rangle$ states is lifted by small external magnetic fields. In the bonding $|0\rangle$ state, the $|\uparrow\rangle$ component increases and the $|\downarrow\rangle$ component decreases, while in the antibonding $|1\rangle$ state the components change in a reversed way. Therefore,

spontaneous circulating currents flow in the clockwise and anticlockwise directions at the $|0\rangle$ and $|1\rangle$ states respectively, producing the spontaneous magnetic flux in the loop. One can detect the states of the qubit through the measurement of the spontaneous flux by a SQUID placed around the loop.

The common features of the two-junction and three-junction π qubits are the formation of the coherent two-level states without external magnetic fields; thus, a small external magnetic field is enough to manipulate and detect the states as compared to the external half unit flux $\Phi_0/2$ required in the proposal of Mooij *et al*. (1999). For example, for a small qubit with the dimensions of several hundred nanometers, a small magnetic field of the order of millitesla is enough for manipulating our qubit. This feature allows us to make qubits of smaller size, which is advantageous in large-scale integration. This type of qubit is also resistant to external noise and has longer decoherence time.

6 SPIN INJECTION INTO SUPERCONDUCTORS

Johnson and Silsbee (1985) first reported that nonequilibrium spins injected from ferromagnets diffuse into Al films over the spin-diffusion length of the order of 1 μm. Johnson (1993) proposed a spin injection technique in an F1/N/F2 structure (F1 is an injector and F2 a detector). Recent experimental studies have demonstrated that the spin-polarized carriers injected from F (NiFe, Co, CoFe,$\cdots$) into N (Cu, Al, Ag,$\cdots$) (Jedema, Filip and van Wees, 2001; Jedema *et al*., 2002; Kimura, Hamrle and Otani, 2004, 2005, 2006; Garzon, Žutić and Webb, 2005; Godfrey and Johnson, 2006; Valenzuela and Tinkham, 2006) and into S (Al,$\cdots$) (Chen *et al*., 2002; Johansson, Urech, Haviland and Korenivski, 2003; Wang and Lu, 2005; Daibou, Oogane, Ando and Miyazaki, unpublished; Urech *et al*., 2006; Miura, Kasai, Kobayashi and Ono, 2006) create a spin accumulation in nonmagnetic metals. Using tunnel devices consisting of a high-T_c cuprate and a ferromagnetic manganite, strong suppression of superconductivity by spin injection has been reported (Vas'ko *et al*., 1997; Dong *et al*., 1997; Yeh *et al*., 1999).

In this section, we discuss nonequilibrium spin accumulation created by a spin-polarized tunnel current and its competition with superconducting condensate in S sandwiched between two ferromagnets (F1/S/F2) (Takahashi, Imamura and Maekawa, 1999, 2000; Takahashi and Maekawa, 2003; Johansson, Korenivski, Haviland and Brataas, 2004). A particular emphasis is placed on the spin-dependent effect, that is, the dependence of the transport properties on the relative orientation of the magnetizations in the F electrodes. In the following, we describe how the spin density is accumulated in S and suppresses the superconductivity, depending on the relative orientation of the magnetizations.

We consider an F1/S/F2 double tunnel junction, as shown in Figure 10(a). The left and right electrodes are made of the same ferromagnets and the central one is a superconductor with thickness d_S. The magnetization of F1 is chosen to point up and that of F2 is either up or down. We assume a symmetric junction, which is characterized by the same tunnel conductance of the tunnel barriers. In the following, we restrict ourselves to the case that the thickness d_S of S is much smaller than the spin-diffusion length $\lambda_S = \sqrt{D\tau_S}$, D being the diffusion constant, so that the spin density accumulated in S is spatially uniform in S.

We calculate the tunnel current using a phenomenological model for tunneling. If S is in the superconducting state, it is convenient to write the electron operators $a_{\mathbf{k}\sigma}$ in S in terms of the QP operators $\gamma_{\mathbf{k}\sigma}$ using the Bogoliubov transformation (Tinkham, 1996)

$$a_{\mathbf{k}\uparrow} = u_{\mathbf{k}}\gamma_{\mathbf{k}\uparrow} + v^*_{\mathbf{k}}\gamma^\dagger_{-\mathbf{k}\downarrow}, \quad a^\dagger_{-\mathbf{k}\downarrow} = -v_{\mathbf{k}}\gamma_{\mathbf{k}\uparrow} + u^*_{\mathbf{k}}\gamma^\dagger_{-\mathbf{k}\downarrow}$$

where $|u_{\mathbf{k}}|^2 = 1 - |v_{\mathbf{k}}|^2 = \frac{1}{2}(1 + \xi_{\mathbf{k}}/E_{\mathbf{k}})$ with the QP dispersion $E_{\mathbf{k}} = \sqrt{\xi^2_{\mathbf{k}} + \Delta^2}$ of S, $\xi_{\mathbf{k}}$ being the one-electron energy relative to the chemical potential and Δ being the gap parameter. Using the golden rule formula, we obtain the spin-dependent currents $I_{i\sigma}$ across junction 1 and 2 (Takahashi,

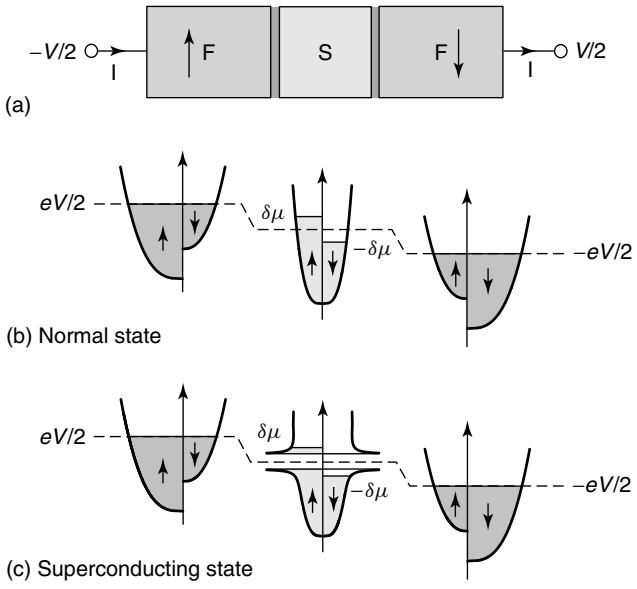

Figure 10. (a) Double-tunnel junction consisting of two ferromagnets (F) and a superconductor (S) separated by insulating barriers. The densities of states of F's (left and right) and S (middle) in the antiparallel magnetizations of F's in the normal state (b) and the superconducting state (c). $\delta\mu$ denotes the chemical-potential shift in S.

Imamura and Maekawa, 1999):

$$I_{1\uparrow} = (G_{1\uparrow}/e)\,(\mathcal{N} - \mathcal{S})\,, \quad I_{1\downarrow} = (G_{1\downarrow}/e)\,(\mathcal{N} + \mathcal{S}) \quad (38)$$

$$I_{2\uparrow} = (G_{2\uparrow}/e)\,(\mathcal{N} + \mathcal{S})\,, \quad I_{2\downarrow} = (G_{2\downarrow}/e)\,(\mathcal{N} - \mathcal{S}) \quad (39)$$

where $G_{i\sigma}$ is the normal-state tunnel conductance of ith junction for electrons with spin σ. Here, the nonequilibrium charge imbalance (Clarke, 1972; Pethick and Smith, 1980) is neglected because it has little effect on the spin-dependent effect in the symmetric junction (Takahashi, Imamura and Maekawa, 2000). The quantity $\mathcal{N}$ is given by (Tinkham, 1972)

$$\mathcal{N}(V) = \frac{1}{2}\int_{-\infty}^{\infty} \mathrm{d}\xi_{\mathbf{k}}\Big[f_0\big(E_{\mathbf{k}} - eV/2\big) - f_0\big(E_{\mathbf{k}} + eV/2\big)\Big] \quad (40)$$

where $f_0(E) = 1/[\exp(E/k_{\mathrm{B}}T) + 1]$ is the Fermi distribution function and $V/2$ is the voltage drop at the barriers. In the normal state, $\mathcal{N}(V) = eV/2$. The quantity $\mathcal{S}$ is the spin density normalized by the normal-state density of states N_{S} in S, and is calculated on the basis of the semiconductor model (Tinkham, 1996):

$$\mathcal{S} = \frac{1}{2}\int_{-\infty}^{\infty} \mathrm{d}\xi_{\mathbf{k}}\Big[f_0\,(E_{\mathbf{k}} - \delta\mu) - f_0\big(E_{\mathbf{k}} + \delta\mu\big)\Big] \quad (41)$$

where the electrochemical potentials of up and down spins are shifted by $\pm\delta\mu$ from equilibrium (see Figure 10).

The injected spin density is determined by balancing the spin injection rate $N_{\mathrm{S}}\,(\mathrm{d}\mathcal{S}/\mathrm{d}t)_{\mathrm{inj}} = [(I_{1\uparrow} - I_{1\downarrow}) - (I_{2\uparrow} - I_{2\downarrow})]/2e$ with the spin relaxation rate $N_{\mathrm{S}}\mathcal{S}/\tau_{\mathrm{S}}$, where τ_{S} is the spin-relaxation time. The result for the parallel (P) and the antiparallel (AP) alignment of magnetizations is

$$\mathcal{S}_{\mathrm{P}} = 0, \quad \mathcal{S}_{\mathrm{AP}} = \frac{P}{1 + \Gamma_{\mathrm{s}}}\mathcal{N}_{\mathrm{AP}} \quad (42)$$

where $P = |G_{i\uparrow} - G_{i\downarrow}|/(G_{i\uparrow} + G_{i\downarrow})$ $(i = 1, 2)$ is the tunnel spin polarization, $\Gamma_{\mathrm{s}} = (\tau_t/\tau_{\mathrm{S}})$ is a spin relaxation parameter, $\tau_t = e^2 N_{\mathrm{S}} R A d_{\mathrm{S}}$ is a characteristic dwell time of an electron in S, A is the junction area, and $R = 1/(G_{i\uparrow} + G_{i\downarrow})$ is the tunnel resistance. The tunnel spin polarization ranges around 30–40% for alumina barriers (Meservey and Tedrow, 1994), and $P \sim 85\%$ for MgO barriers (Parkin *et al.*, 2004). The result (42) indicates that spins accumulate in the AP alignment, while no spins accumulated in the P alignment in the symmetric junction. Therefore, we expect the suppression of superconductivity by spin accumulation in the AP alignment. In the normal state, $\mathcal{S}_{\mathrm{AP}} = P_{\mathrm{eff}} eV/2$ with the effective spin polarization $P_{\mathrm{eff}} = P/(1 + \Gamma_{\mathrm{s}})$.

The superconducting gap Δ in S is determined by $f_{\mathbf{k}\sigma}$ through the BCS gap equation (Tinkham, 1996)

$$\frac{1}{N_{\mathrm{S}} V_{\mathrm{BCS}}} = \int_0^{\omega_{\mathrm{D}}} \frac{\mathrm{d}\xi_{\mathbf{k}}}{2E_{\mathbf{k}}}\left[\tanh\left(\frac{E_{\mathbf{k}} - \delta\mu}{2k_{\mathrm{B}}T}\right) + \tanh\left(\frac{E_{\mathbf{k}} + \delta\mu}{2k_{\mathrm{B}}T}\right)\right] \quad (43)$$

where V_{BCS} is the attractive interaction between electrons and ω_{D} is the Debye frequency in S.

The self-consistent equations, (42) and (43), are solved in terms of Δ and $\delta\mu$ for the P and AP alignments. The results are used to calculate the tunnel current $I = I_\uparrow + I_\downarrow$ as a function of V for the P and AP alignments:

$$I_{\mathrm{P}} = \frac{\mathcal{N}_{\mathrm{P}}(V)}{eR}, \quad I_{\mathrm{AP}} = \left(\frac{1 - P^2 + \Gamma_{\mathrm{s}}}{1 + \Gamma_{\mathrm{s}}}\right)\frac{\mathcal{N}_{\mathrm{AP}}(V)}{eR} \quad (44)$$

In the current bias, $\mathcal{S}_{\mathrm{AP}}$ is directly connected to the injection current I

$$\mathcal{S}_{\mathrm{AP}} = \frac{P}{1 - P^2 + \Gamma_{\mathrm{s}}} eRI \quad (45)$$

It is interesting to note that the spin current $I_{\mathrm{spin}} = I_{i\uparrow} - I_{i\downarrow}$ flows through S with $I_{\mathrm{spin}}^{\mathrm{P}} = PI$ in the P alignment, while $I_{\mathrm{spin}}^{\mathrm{AP}} = 0$ in the AP alignment.

A key parameter for the efficient spin injection into S is the effective spin polarization $P_{\mathrm{eff}} = P/(1 + \Gamma_{\mathrm{s}})$; it depends strongly on the spin relaxation parameter Γ_{s}, which is reexpressed as $\Gamma_{\mathrm{s}} = (1/2)(RA/\rho_N\lambda_{\mathrm{S}})(d_{\mathrm{S}}/\lambda_{\mathrm{S}})$, where RA is the specific (area) tunnel resistance, ρ_N the resistivity, and λ_{S} the spin-diffusion length. For an efficient spin injection into S, it is crucial to make Γ_{s} as small as possible by using a junction with very small RA, a large $\rho_N\lambda_{\mathrm{S}}$, and thin d_{S}. The parameter RA is variable in a wide range by changing the barrier thickness, ranging from $RA \sim 1\,\Omega\mu\mathrm{m}^2$ to $10^4\,\Omega\mu\mathrm{m}^2$. For an Al with thickness $d_{\mathrm{S}} \sim 5\,\mathrm{nm}$, $\rho_N \sim 5\,\mu\Omega\mathrm{cm}$, and $\lambda_{\mathrm{S}} \sim 700\,\mathrm{nm}$ (Jedema *et al.*, 2002; Valenzuela and Tinkham, 2006), we have a condition $RA < 15\,\Omega\mu\mathrm{m}^2$ for realizing that Γ_{s} is comparable to or smaller than unity ($\Gamma_{\mathrm{s}} < 1$). This condition is fulfilled by using a thin MgO barrier with low tunnel resistance and a CoFe-electrode with high P (Parkin *et al.*, 2004), so that a CoFe/MgO/Al/MgO/CoFe structure is most suitable for exploring the effect of spin injection on superconductivity (Yang, H., Yang, S.-H. and Parkin, S.S.P. private communications).

Figure 11(a) shows the superconducting gap Δ_{AP} in the AP alignment as a function of voltage V for $P = 0.4$ (Meservey and Tedrow, 1994) and $\Gamma_{\mathrm{s}} = 0$. The quantity Δ_0 denotes the value of Δ at $V = 0$ and $T = 0$. The gap Δ_{AP} decreases with increasing V and vanishes at

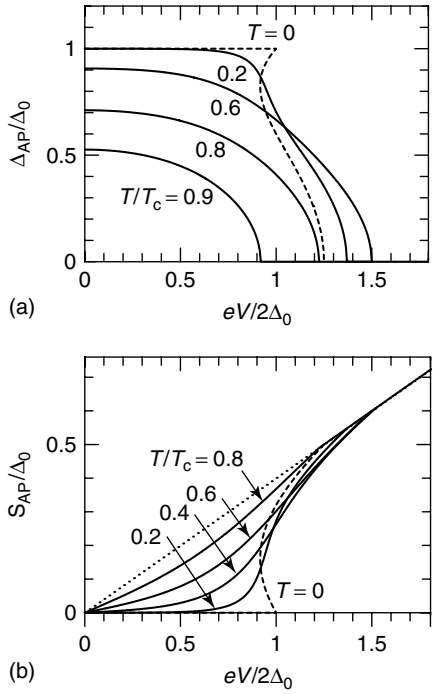

Figure 11. (a) Energy gap Δ_{AP} in S as a function of voltage V for different temperatures in the AP orientation of magnetizations. (b) Spin accumulation $\mathcal{S}_{AP}$ in S as a function of V.

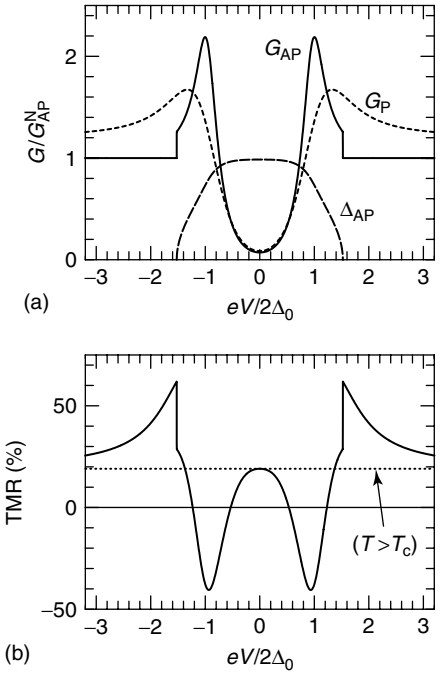

Figure 12. (a) Tunnel conductance as a function of bias voltage. The dashed and solid curves indicate the conductances G_P and G_{AP} for the P and AP alignments respectively, and the long-dashed curve indicates the superconducting gap parameter Δ in the AP alignment. (b) Tunnel magnetoresistance (TMR) as a function of bias voltage. The dotted line indicates TMR $= P^2/(1-P^2)$ in the normal state.

the critical voltage V_c. At very low temperatures, Δ_{AP} becomes multivalued in a certain range of eV; at $T = 0$, it has three solutions: $\Delta_{AP} = \Delta_0$ and $\Delta_{AP} = \Delta_0[1 - 2P^2 \pm 2P\sqrt{(eV/2\Delta_0)^2 + P^2 - 1}]^{1/2}$ for $0.92 < eV/2\Delta_0 < 1$. This suggests that a spatially inhomogeneous FFLO state appears in the narrow range of V at $T \sim 0$. Figure 11(b) shows the voltage dependence of the spin density $\mathcal{S}_{AP}$ in the AP alignment. The dotted line indicates the value of $\mathcal{S}_{AP} = \frac{1}{2}PeV$ in the normal state. As T is lowered below T_c, $\mathcal{S}_{AP}$ is suppressed below V_c by opening of the energy gap. At and near $T = 0$, $\mathcal{S}_{AP}$ shows the S-shaped anomaly around $eV_c \sim 2\Delta_0$, which corresponds to the multiplicity of Δ_{AP} in Figure 11(a). In the P alignment, Δ_P is independent of V and $\mathcal{S}_P = 0$ in the symmetric junction.

Figure 12(a) shows the voltage dependence of the differential conductance G_P and G_{AP} for the P and AP alignments at $T/T_c = 0.4$ and $\Gamma_s = 0$. The G_P shows the ordinary dependence on V expected for the constant gap Δ. In contrast, because of the decrease in Δ_{AP} with increasing voltage, G_{AP} increases with voltage more rapidly than G_P, forming a higher peak than G_P, and then decreases steeply. At the critical voltage V_c, G_{AP} jumps to the conductance G^N_{AP} in the normal state. The TMR is calculated by the formula: TMR $= (G_P/G_{AP}) - 1$. Using the values of Figure 12(a), we obtain the V dependence of TMR shown in Figure 12(b). At $V = 0$, TMR takes the same value as in the normal state. A deep negative dip appears at $eV/2\Delta_0 \sim 1$, where Δ_{AP} steeply decreases, exhibiting an inverse TMR effect ($G_{AP} > G_P$), and is followed by the discontinuous jump at V_c above which TMR is highly enhanced compared to that in the normal state. When the effect of spin relaxation in S is taken into account, the TMR value is reduced roughly by the factor $1/(1 + \Gamma_s)$ because of the reduction of the effective spin polarization $P_{eff} = P/(1 + \Gamma_s)$.

The suppression of the superconducting gap Δ by spin injection is detected by measuring the superconducting critical current I_c. According to the Ginzburg–Landau theory, I_c is proportional to Δ^3 because $I_c \propto \Delta^2 v_c$ with the critical superfluid velocity $v_c \propto \Delta$ (Tinkham, 1996). Figure 13 shows the normalized critical current (I_c/I_{c0}) as a function of injection current I at $T/T_c = 0.9$ for $P_1 = 0.8$, $P_2 = 0$, 0.4, 0.8, and $\Gamma_s = 0$. In the case of symmetric junction, the same spin polarizations (Figure 13a), the critical current I_c in the AP alignment steeply decreases and vanishes at a small value of I, whereas I_c in the P alignment shows no dependence on I. In the case of an asymmetric junction with different spin polarizations (Figure 13b), the critical current decreases with increasing injection current in both alignments but in a different way; I_c decreases more slowly in the P alignment than in the AP alignment.

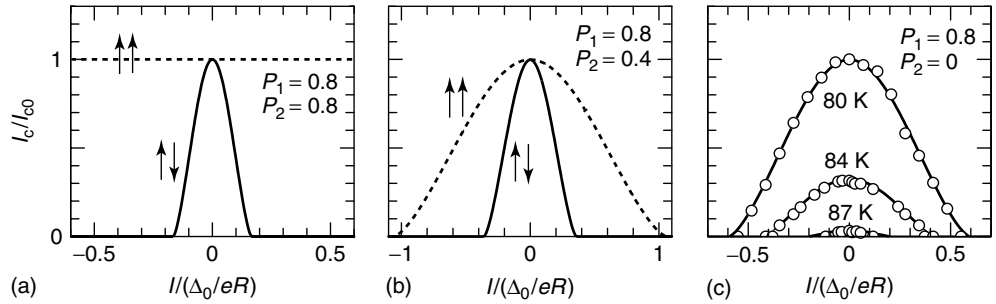

Figure 13. Dependence of the critical current I_c on the injection current I for the spin polarization $P_1 = 0.8$ of F1 and different values of P_2 of F2. The open circles indicate the critical current measured at $T = 80$, 84, and 87 K ($T_c \sim 89$ K) by Dong *et al.* (1997) in a F/S/N junction made of a high-T_c S and ferromagnetic manganite with $P \sim 100\%$.

If one of the ferromagnets, F2, is replaced by a normal metal (N), we have a heterostructure F1/S/N junction with $P_2 = 0$ (Figure 13c). The critical current suppression by spin injection observed in heterostructure junctions consisting of a high-T_c cuprate and a ferromagnetic manganite with a large spin polarization is reproduced well by the calculated result (Vas'ko *et al.*, 1997; Dong *et al.*, 1997; Yeh *et al.*, 1999).

7 SUMMARY AND DISCUSSIONS

In this chapter, we have discussed the novel phenomena arising from the interplay between superconductivity and ferromagnetism in hybrid F/S structures. The most striking consequence due to the proximity effect in the F/S structures is a damped oscillatory behavior of the Cooper-pair wave function in ferromagnets, leading to the formation of the π state in S/F/S Josephson junctions and F/S multilayers. Applications of π junctions to quantum computing devices (qubits) open up a new possibility in the research field of superconducting spin electronics.

AR is a spin-sensitive scattering process at the F/S interface, which provides a powerful tool for probing the spin polarization of various ferromagnets. This spin sensitivity of AR is also capable of probing nonlocality of AR by using the crossed AR between two ferromagnetic leads in contact with a superconductor (Deutscher and Feinberg, 2000; Beckmann, Weber and Löhneysen, 2004).

There is rapidly growing interest in the Josephson current through strong ferromagnets, such as transition-metal ferromagnets or oxide ferromagnets. As shown in Section 2, the Cooper-pair wave function in the spin-singlet state is quickly decayed in strong ferromagnets, and the penetration of singlet pairs into strong ferromagnets is at most only $\sim$1 nm. However, recent observation of the Josephson supercurrent through a half-metallic ferromagnet CrO_2 (Keizer *et al.*, 2006) over several hundreds of nanometers strongly suggested that spin-triplet superconductivity is induced in the half-metallic ferromagnet. The underlying mechanism for occurring spin-triplet superconductivity is a conversion from spin-singlet to spin-triplet pairs due to the spin-mixing or spin-flip scattering at the interface (Bergeret, Volkov and Efetov, 2001; Eschrig, Kopu, Cuevas and Schön, 2003 Asano, Tanaka and Golubov, unpublished).

The dynamics of magnetization and its effect on the proximity effect in S/F structures will offer a new research field. In particular, the effects of spin dynamics (spin-wave emission and absorption, and precession of magnetization) on the proximity effect, the AR (McCann and Fal'ko, 2001), and the Josephson effect (Zhu, Nussinov, Shnirman and Balatsky, 2004; Takahashi *et al.*, unpublished) are important issues to be explored in this fascinating field. The interplay between superconductivity and magnetism provides new electronics devices based on spin and supercurrent.

NOTES

[1] The right-hand side of equation (8) is $\pi[N_\uparrow(\mathbf{r}) - N_\uparrow(\mathbf{r})]\Delta$, which vanishes in F/S structures with the sharp boundaries, because $N_\uparrow(\mathbf{r}) = N_\downarrow(\mathbf{r})$ in N and $\Delta = 0$ in F.

[2] In the presence of boundary resistance, the boundary conditions (Kupriyanov and Lukichev, 1988) are $D(\mathbf{r})\partial F(\mathbf{r})/\partial z\big|_{\mathbf{r}_i^+} = D(\mathbf{r})\partial F(\mathbf{r})/\partial z\big|_{\mathbf{r}_i^-} = (1/e^2R_b)[F(\mathbf{r}_i^+)/N(\mathbf{r}_i^+) - F(\mathbf{r}_i^-)/N(\mathbf{r}_i^-)]$, where R_b is the specific (area) boundary resistance and $\mathbf{r}_i^\pm = \mathbf{r}_i \pm 0$ is the position of the boundaries.

1 INTRODUCTION

Two fundamental properties of the superconducting (SC) state are the zero electrical resistance and the Meissner-Ochsenfeld effect (the expulsion of the magnetic field from the volume of a superconductor). Similarly, superconductivity can be destroyed by applying a magnetic field exceeding some critical value. This demonstrates the antagonistic character of superconductivity and magnetism, and explains the interest to their possible coexistence. Such a problem was first addressed theoretically by Ginzburg (1956) in the framework of the model of the electromagnetic (orbital) interaction between superconductivity and ferromagnetism. After the advent of the microscopic theory of the superconductivity by Bardeen, Cooper and Schrieffer (1957) it became clear that the singlet superconductivity could also be destroyed by an exchange mechanism. The exchange field in the ferromagnetic (FM) state tends to align spins of Cooper pairs in the same direction, thus preventing pairing. This is the so-called Pauli paramagnetic effect which is related with the Zeeman energy of electron spins – the magnetic field favors the orientation of the electron spins along the field direction. The Cooper pair is formed with two electrons with opposite spins (singlet superconductivity), and when the gain of the energy due to the spin reorientation ($\mu_B H$) becomes comparable with the Cooper pair superconducting coupling energy (which is of the order of the superconducting critical temperature T_c), the singlet superconductivity is destroyed. Therefore we obtain the following estimate (see, e.g., Abrikosov, 1988) for the paramagnetic limit of singlet superconductivity existence $H_p \approx 1.24 T_c/\mu_B$ or, in Tesla, $1.8 T_c$ (K). However, in usual superconductors the orbital effect is more important for superconductivity destruction by the magnetic field. In ferromagnetic superconductors the situation is different. The internal magnetic induction does not exceed several kilo-oersted which is smaller than the typical upper critical field in type II superconductors, and then is not harmful for superconductivity. On the other hand, the effective internal field h (which plays the role of Zeeman energy $\mu_B H$) acting on the electron spins due to the exchange interaction is very high. Typically, if expressed in the energy units $h \sim 100$–1000 K, which substantially exceed the superconducting critical temperature T_c, it makes the exchange interaction the main mechanism of superconductivity destruction. This strong exchange interaction is at the origin of very strong suppression of superconductivity by

the magnetic impurities. The early experiments (Matthias, Suhl and Corenzwit, 1958) demonstrated that even a very small concentration (several percents) of magnetic atoms is enough to completely destroy the superconductivity. The influence of magnetic impurities on superconductivity was described by the now classical Abrikosov–Gorkov theory (Abrikosov and Gorkov, 1960).

The small allowed concentration of magnetic atoms in superconducting alloys was not enough to produce the FM ordering. The first regular superconducting single crystals with a regular sublattice of rare earth magnetic atoms have been discovered in 1976, which produced the real breakthrough in studies of magnetism and superconductivity coexistence. They are ternary rare earth (RE) compounds, (RE)Rh_4B_4 and (RE)Mo_6S_8, (RE)Mo_6Se_8; for a review, see, for example, Maple and Fisher (1982) and Fisher (1990) and Kulić (2006). It turned out that in many of these systems superconductivity coexists with antiferromagnetic (AF) order with the Néel temperature $T_N < T_c$. The peaceful coexistence of superconductivity with antiferromagnetism is understandable because, on average, the exchange and orbital fields are zero at distances of the order of superconducting coherence length ξ. Recently, the coexistence of superconductivity and antiferromagnetism was discovered in the series of quaternary intermetallic compounds (RE)Ni_2B_2C. The properties of these compounds are discussed in the reviews (Müller and Narozhnyi, 2001) and (Bud'ko and Canfield, 2006).

The question about FM and SC coexistence appears to be much more fascinating. Such a situation is realized in $ErRh_4B_4$ and $HoMo_6S_8$ compounds. In the superconducting phase below the Curie temperature, instead of the FM ordering, the long period modulated magnetic structure appears. Further cooling provokes the reentrant transition into the normal ferromagnetic phase. The nonuniform magnetic structure in superconductors was predicted a long time ago by Anderson and Suhl (1959), and the theory of the coexistence phase is discussed in detail by Bulaevskii, Buzdin, Kulić and Panjukov (1985).

The example of $ErRh_4B_4$ and $HoMo_6S_8$ shows that ferromagnetism does not coexist with superconductivity in these compounds, instead it is transformed into the modulated magnetic structure in the narrow temperature interval of magnetism and superconductivity coexistence. The first truly ferromagnetic superconductors UGe_2 (Saxena *et al*., 2000) and URhGe (Aoki *et al*., 2001) were discovered only recently, and attracted a lot of interest. Apparently these systems display the triplet superconductivity with parallel spin orientation of electrons in Cooper pair, thus withdrawing the paramagnetic limit. Another interesting problem is the interplay between superconductivity and itinerant-like magnetism in heavy-fermion matter, in the compounds like URu_2Si_2, UPd_2Al_3, UBe_{13}, and so on – for the recent review see Flouquet *et al*. (2006).

The coexistence of superconductivity and ferromagnetism may be easily achieved in artificially fabricated superconductor/ferromagnet heterostructures. Due to the proximity effect, the Cooper pairs penetrate into the F layer and we have the unique possibility to study the properties of superconducting electrons under the influence of the huge exchange field. Moreover, varying in the controllable manner the thicknesses of the ferromagnetic and superconducting layers it is possible to change the relative strength of two competing ordering. The Josephson junctions with ferromagnetic layers reveal many unusual properties quite interesting for applications, in particular, the so-called π-Josephson junction (with the π-phase difference in the ground state) was fabricated (Buzdin, 2005; Bergeret, Volkov and Efetov, 2005).

2 INTERACTION BETWEEN CONDUCTING ELECTRONS AND LOCALIZED MOMENT: ANTIFERROMAGNETIC SUPERCONDUCTORS

2.1 Role of magnetic scattering

The strong pair-breaking effect of magnetic impurities on superconductivity is illustrated in Figure 1 where it is clearly seen that the concentration more than 0.6 at% of Gd

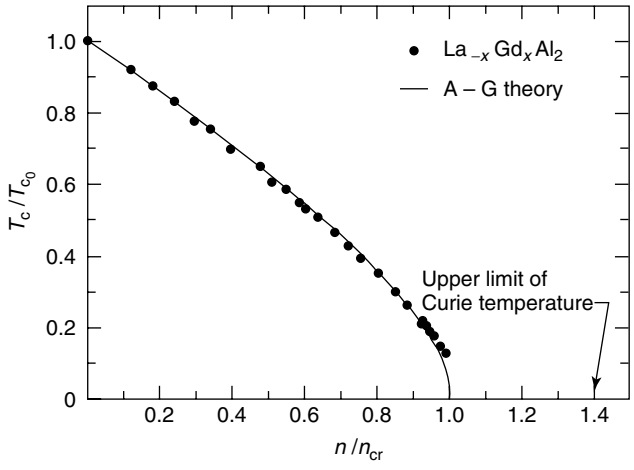

Figure 1. The critical temperature variation versus the concentration n of the Gd atoms in $La_{1-x}Gd_xAl_2$ alloys (Maple, 1968). $T_{c_0} = 3.24$ K and $n_{cr} = 0.590$ at % Gd. (Reprinted from *Physics Letters A*, Vol 26A, 1968, Page 513, Maple, with permission from Elsevier.)

completely destroys the superconductivity in $La_{1-x}Gd_xAl_2$ alloys (Maple, 1968).

The exchange interaction between the spin of the magnetic impurities and spin of electron of the Cooper pairs leads to the spin-flip scattering destroying pair. The theory of this phenomenon was proposed by Abrikosov and Gorkov (1960).

This Abrikosov–Gorkov theory provided an excellent description of the properties of superconductor with magnetic impurities.

The Hamiltonian of the interaction between RE magnetic moments localized in the sites $\vec{r}_i$ and the electron spins is

$$H_{\text{int}} = \int \mathrm{d}^3 r \Psi^+(\vec{r}) \left\{ \sum_i I(\vec{r} - \vec{r}_i)(g_J - 1)\vec{J}_i\vec{\sigma} \right\} \Psi(\vec{r}) \quad (1)$$

where $\Psi(\vec{r})$ is the electron spinor operator, $\vec{\sigma} = \{\sigma_x, \sigma_y, \sigma_z\}$ are the Pauli matrices, $I(\vec{r})$ is the exchange integral, and we take into account that for the RE atoms the total angular momentum $\vec{J}_i$ is quenched and g_J is the Landé g-factor for the Hund's rule ground state of RE. Following the A–G theory (Abrikosov and Gorkov, 1960) the decrease of the critical temperature T_c with the concentration n of magnetic impurities follows the law

$$\frac{\mathrm{d}T_c}{\mathrm{d}n} = -\frac{\pi^2}{2} N(0) \langle I^2(p_F) \rangle (g_J - 1)^2 J(J+1) \quad (2)$$

where $\langle I^2(p_F) \rangle$ is averaged value of the square of the Fourier transform of the exchange interaction over the Fermi surface, $N(0)$ is the electron density of the state at the Fermi energy. The pair-breaking strength of the magnetic scattering occurs to be proportional to the so-called De Gennes factor $\mathrm{d}G = (g_J - 1)^2 J(J+1)$. If all magnetic atoms substitute the nonmagnetic ones, they form a regular lattice and their concentration reaches the same order of magnitude as the concentration of the electrons. The most common mechanism of magnetic ordering in metal RE compounds is the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction and then the magnetic transition temperature may be estimated as $\Theta_m \approx \mathrm{d}G \frac{I^2}{E_F}$. Following equation (2), the decrease of the T_c being $\frac{\mathrm{d}T_c}{\mathrm{d}x} \approx -\Theta_m x$, where x is the relative concentration of the magnetic atoms. Therefore, the addition of the magnetic atoms of iron (having high Curie temperature) usually destroys superconductivity at a very small concentration (less than 1%). The very informative approach is the comparative studies of the properties of ternary $(RE)Rh_4B_4$ and $(RE)Mo_6S_8$ or quaternary $(RE)Ni_2B_2C$ compounds with different RE atoms and with nonmagnetic RE atoms partially substituted by the magnetic ones. Such substitution practically does not perturb the host matrix responsible for superconductivity but permits to vary the magnetic scattering in a controllable manner. An interesting example of the influence of the magnetic scattering on T_c in the $(Lu_{1-x}Dy_x)Ni_2B_2C$ series (Cho, Canfield and Johnston, 1996) is presented in Figure 2. For low Dy concentration we have the quite expected decrease of T_c, which vanishes at $x \approx 0.7$.

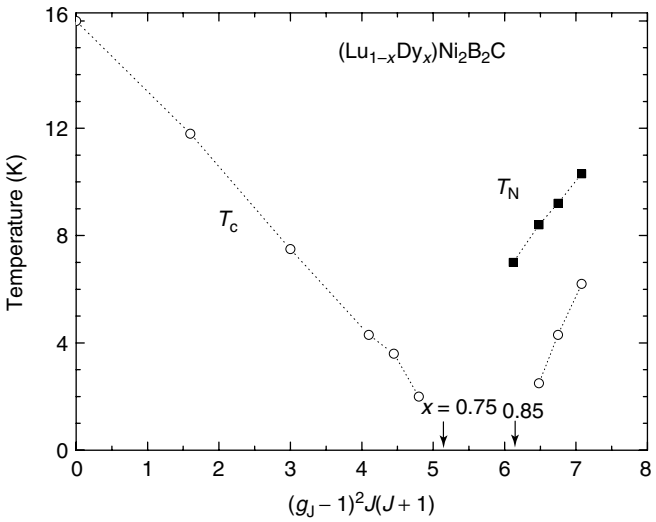

Figure 2. The variation of the critical temperature T_c in the $(Lu_{1-x}Dy_x)Ni_2B_2C$ series. (Reprinted figure with permission from Cho *et al.*, *Phys. Rev. Lett.* Vol 77, 163 (1996) Copyright 1996 by the American Physical Society.)

For $x = 1$ in $DyNi_2B_2C$ the Néel temperature $T_N = 11\,\mathrm{K}$ and superconductivity appears in the antiferromagnetic phase below $T_c = 6.2\,\mathrm{K}$. In the antiferromagnetic state the RE magnetic moments are ordered which decreases the magnetic scattering. They may be considered as magnetic impurities only above the Néel temperature when the RE magnetic moments chaotically change their directions with time. Below T_N they freeze out and the magnetic scattering may occur only via the electrons interaction with the spin waves. On the other hand the average exchange and orbital fields in the antiferromagnetic state are absent and superconductivity appears at lower temperature. The decrease of Dy concentration introduces the disorder in the magnetic sublattice which decreases T_N, and at the same time increases the magnetic scattering and decreases T_c. $DyNi_2B_2C$ only superconducts because the antiferromagnetic ordering reduces the magnetic scattering (Cho, Canfield and Johnston, 1996).

2.2 Antiferromagnetic superconductors

Neutron scattering experiments have shown that usually in ternary $(RE)Rh_4B_4$ (Maple, Hamaker and Woolf, 1982), $(RE)Mo_6S_8$ and $(RE)Mo_6Se_8$ (Thomlinson, Shirane, Lynn and Moncton, 1982), or quaternary $(RE)Ni_2B_2C$ (Müller and

Narozhnyi, 2001) compounds there is the long-range antiferromagnetic order that appears in the superconducting phase. The mutual influence of superconductivity and magnetism in antiferromagnetic superconductors occurs to be rather weak. Indeed, in the case of antiferromagnetism, an average value of magnetic induction and an exchange interaction (exchange field) are practically zero on the scale of Cooper pair size. On the other hand, the Meissner screening of the magnetic field, oscillating on the atomic distance is vanishing. The London penetration depth λ is the characteristic length of the magnetic field screening and typically $\lambda \sim 100–10\,000$ Å, and then it is much larger than the period of antiferromagnetic ordering, which makes its screening impossible. Then we may conclude that the coexistence of superconductivity and antiferromagnetism is quite peaceful – for T_c and T_N of typical antiferromagnetic superconductors see Table 1.

Interestingly, the appearance of magnetic ordering below T_N is at the origin of the anomalous temperature dependence of the upper critical H_{c_2}(T) in antiferromagnetic superconductors. Some typical examples of the H_{c_2}(T) curves measured for the $TmNi_2B_2C$ and $ErNi_2B_2C$ are presented in Figure 3 (Bud'ko and Canfield, 2006). The increase of the H_{c_2} below T_N in $ErNi_2B_2C$ may be related with the decrease of magnetic scattering. It is interesting that the anisotropy of the magnetic subsystem induces the anisotropy of the upper critical field. As it may be seen from Figure 3 near T_c the H_{c_2} along *a* and *c* axis is practically the same. At lower temperature the critical fields are smaller for the orientations corresponding to the easy magnetization directions.

For $TmNi_2B_2C$ it is *c* axis and for $ErNi_2B_2C$ it is the *ab* plane. The decrease of the upper critical field comparing with its value extrapolated from the initial slope near T_c is due to the internal exchange field h created by the polarized magnetic atoms. This field is $\vec{h} = I(g_J - 1)\langle\vec{J}_i\rangle$, where $\langle\vec{J}_i\rangle$ is the moment induced by the applied field which is proportional to the magnetic susceptibility of the RE compound. Then the internal exchange field reflects the anisotropy of magnetic susceptibility and induces the corresponding anisotropy of the H_{c_2} (for more information on the critical fields of the antiferromagnetic superconductors see Buzdin and Bulaevskii (1986)).

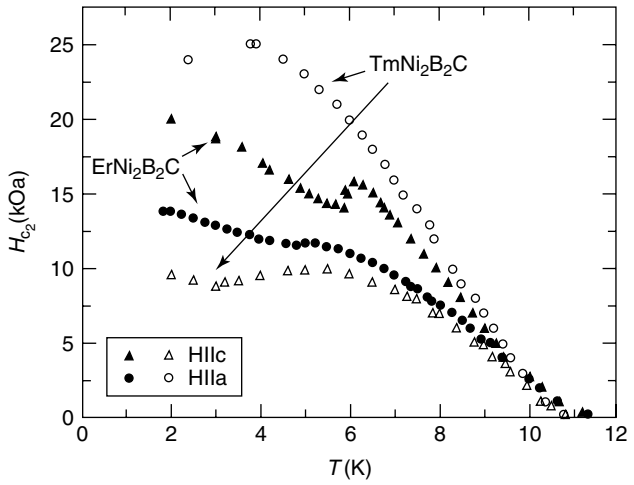

Figure 3. Anisotropic upper critical field $H_{c_2}(T)$ in antiferromagnetic superconductors $TmNi_2B_2C$ and $ErNi_2B_2C$. (Bud'ko and Canfield, 2006. Magnetism and superconductivity in rare earth-nickel-borocarbides. *Comptes Rendus Physique*, **7**, 56–67, with permission from Elsevier.)

Table 1. Antiferromagnetic superconductors.

	T_c (K)	T_N (K)
$NdRh_4B_4$	5.3	1.31
$SmRh_4B_4$	2.7	0.87
$TmRh_4B_4$	9.8	0.4
$GdMo_6S_8$	1.4	0.84
$TbMo_6S_8$	2.05	1.05
$DyMo_6S_8$	2.05	0.4
$ErMo_6S_8$	2.2	0.2
$GdMo_6Se_8$	5.6	0.75
$ErMo_6Se_8$	6.0	1.1
$DyNi_2B_2C$	6.2	11
$ErNi_2B_2C$	10.5	6.8
$TmNi_2B_2C$	11	1.5
$HoNi_2B_2C$	8	5

The data for (RE)Ni_2B_2C compounds are taken from the reviews (Müller and Narozhnyi, 2001) and (Bud'ko and Canfield, 2006) and for (RE)Rh_4B_4 – (Maple, Hamaker and Woolf, 1982) and (RE)Mo_6S_8, (RE)Mo_6Se_8 – (Thomlinson, Shirane, Lynn and Moncton, 1982).

2.3 Field induced superconductivity

A long time ago Jaccarino and Peter (1962) pointed out the possibility of the compensation of Zeeman field by the internal field created by magnetic moment. The total field acting on the electrons spin is $\vec{h}_{tot} = \mu_B\vec{H} + I(g_J - 1)\langle\vec{J}_i\rangle$, and if the sign of the exchange integral I is negative, the compensation Jaccarino–Peter effect occurs. Such behavior was indeed observed in an extremely unusual way in the compound $Eu_{0.75}Sn_{0.25}Mo_6S_{7.2}Se_{0.8}$ (Meul *et al.*, 1984)-Figure 4. The very high orbital critical field in this compound makes it essential to take into account the paramagnetic effect. The presence of localized Eu magnetic moments with negative exchange integral I leads to the possibility of the cancellation of this paramagnetic effect. In a magnetic field, the Eu moments orient along the field, which leads by virtue of the exchange interaction with electrons to the destruction of superconductivity. At low field, the exchange field dominates in $\vec{h}_{tot}$. A further increase of the magnetic field has only a

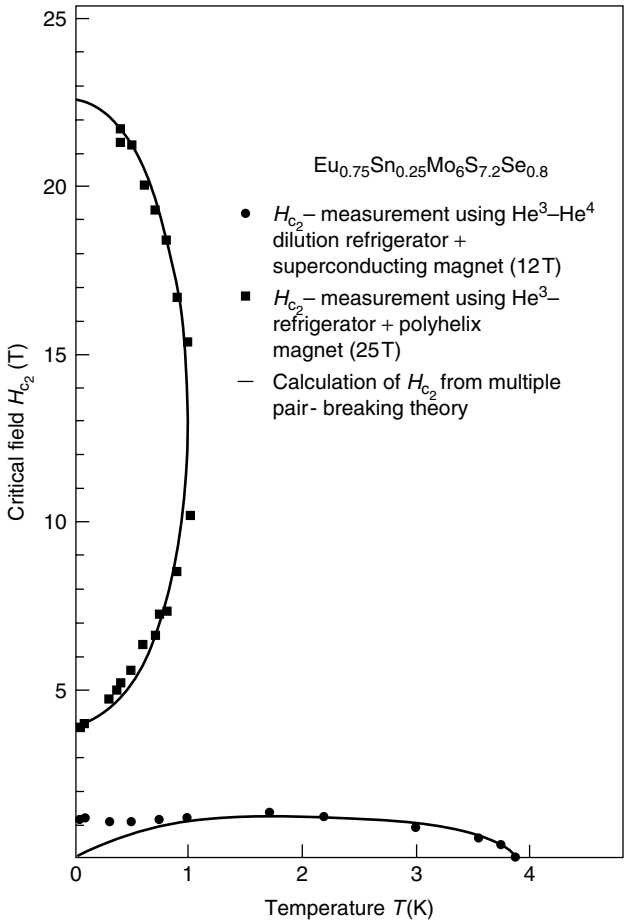

Figure 4. Field induced superconductivity in $Eu_{0.75}Sn_{0.25}Mo_6S_{7.2}Se_{0.8}$ compound (Meul *et al*., 1984). The unusual shape of the (H, T) diagram is a consequence of the Jaccarino–Peter mechanism, that is, the cancellation of the paramagnetic effect by the exchange field produced by polarized Eu atoms. (Reprinted figure from Meul *et al*., *Phys. Rev. Lett.* Vol. 53, 497 (1984). Copyright (1984) by the American Physical Society.)

slight effect on the exchange field of the Eu atoms, since their moment tends toward saturation. On the other hand the Zeeman field linearly increases with H and then finally compensates exchange field. At low temperature the condition of superconductivity existence is $|\vec{h}_{\rm tot}| < 1.24\,T_{\rm c}$ which leads to the restoration of superconductivity when the field is increased. Superconductivity is destroyed again at fields at which the orbital effect becomes important or there is the overcompensation of the exchange field.

Note that recently the magnetic-field-induced superconductivity has been observed in the quasi-two-dimensional organic conductor λ-(bis(ethylenedithio)tetraselenafulvalene, $BETS)_2$ $FeCl_4$ (Uji *et al*., 2001). However at zero magnetic field the superconductivity in this compound is absent due to the antiferromagnetic ordering of Fe^{3+} provoking the metal–insulator transition. A magnetic field above 10 T restores the metal phase. Further increase of the magnetic field induces the superconductivity at $H \approx 17$ T because of the partial compensation of the exchange field of aligned Fe^{3+} spins through the Jaccarino–Peter effect.

2.4 Magnetic high temperature superconductors

The question about the magnetism and superconductivity interplay in high $T_{\rm c}$ superconductor is well beyond the scope of this article. The mechanism of high temperature superconductivity still remains open though many theoretical approaches to handle this problem were proposed (see, e.g., Carlson, Emery, Kivelson and Orgad, 2004; Chubukov, Pines and Schmalian, 2004; Bonn, 2006).

In the $(RE)Ba_2Cu_3O_{6+x}$ and $(La_{2-x}Sr_x)CuO_{4-\delta}$ compounds the oxygen concentration is a very important parameter controlling the Cu ions magnetism. For small x and δ the compounds are insulators and Cu ions order antiferromagnetically with $T_{\rm N} \sim (300–500)$ K (see, e.g., Lynn, 1990). For optimally doped compounds the Cu antiferromagnetic transition is absent, and $T_{\rm c}$ is around 40 and 95 K for $(La_{2-x}Sr_x)CuO_{4-\delta}$ and $(RE)Ba_2Cu_3O_{6+x}$ respectively. The trivalent RE have very little effect on the superconducting properties of $(RE)Ba_2Cu_3O_{6+x}$ compounds. The REorder antiferromagnetically at low temperature $T_{\rm N} \sim (0.5–2)$ K (Lynn, 1990). The RE are very weakly coupled with superconducting Cu–O planes and the exchange interaction between RE and electrons is small (the magnetodipole and RKKY mechanisms give comparable contribution to the antiferromagnetic ordering energy). The condition $T_{\rm N} \ll T_{\rm c}$ ensure quite weak interplay of magnetic and superconducting subsystems in $(RE)Ba_2Cu_3O_{6+x}$.

Nowadays several types of layered compounds, where superconducting and magnetic layers alternate, are known. For example in $Sm_{1.85}Ce_{0.15}CuO_4$ (Sumarlin *et al*., 1992), which reveals superconductivity at $T_{\rm c} = 23.5$ K, the superconducting layers are separated by two ferromagnetic layers with opposite orientations of the magnetic moments and the Néel temperature is $T_{\rm N} = 5.9$ K. Several years ago, a new class of magnetic superconductors based on the layered perovskite ruthenocuprate compound $RuSr_2GdCu_2O_8$ comprising CuO_2 bilayers and RuO_2 monolayers has been synthesized (McLaughlin *et al*., 1999), and as a recent review see Nachtrab *et al*. (2006). In $RuSr_2GdCu_2O_8$, the magnetic transition occurs at $T_{\rm M} \sim 130–140$ K and superconductivity appears at $T_{\rm c} \sim 30–50$ K. Apparently, it is a weak ferromagnetic order, which is realized in this compound. Though the magnetization measurements give evidence of the small ferromagnetic component, the neutron diffraction data on $RuSr_2GdCu_2O_8$ (Lynn *et al*., 2000) revealed the dominant antiferromagnetic ordering in all three directions. Later,

the presence of ferromagnetic in-plane component of about $(0.1-0.3)\mu_B$ has been confirmed by neutron scattering on isostructural $RuSr_2YCu_2O_8$ (Tokunaga *et al.*, 2001).

3 FERROMAGNETIC CONVENTIONAL SUPERCONDUCTORS

As it has been already noted the antiferromagnetism and superconductivity are not in fact incompatible and may easily coexist. The question about ferromagnetism and superconductivity interplay appears to be much more fascinating. Such a situation is realized in $ErRh_4B_4$ and $HoMo_6S_8$ compounds, and leads to the destruction of the superconductivity. For example, in $ErRh_4B_4$ the superconductivity appears below $T_c = 8.7\,K$ and at the Curie temperature $\Theta \approx 0.9\,K$ instead of the ferromagnetic ordering the long period modulated magnetic structure appears. The appearance of this structure has been detected by neutrons scattering experiments (Sinha, Crabtree, Hinks and Mook, 1982), and its period occurs to be around 100 Å. However, a further cooling provokes at the temperature $T_{cr} \approx 0.7\,K$, a first-order phase transition into (or to) a ferromagnetic phase with simultaneous destruction of superconductivity. The transition at $T = T_{cr}$ is called *reentrant transition* because the superconductor goes back into the normal phase. The temperature dependence of the resistivity in the reentrant superconductor $ErRh_4B_4$ is presented in the Figure 5 (Fertig *et al.*, 1977). Similarly in $HoMo_6S_8$ superconductivity appears below $T_c = 1.8\,K$ and in the narrow temperature interval between 0.7 and 0.64 K the nonuniform magnetic structure coexists with superconductivity (Lynn *et al.*, 1981). Further

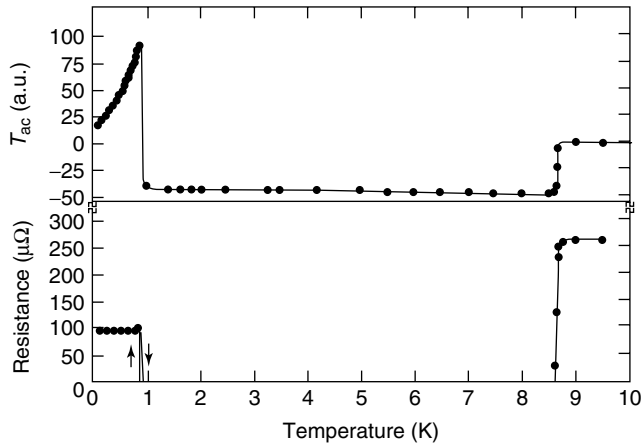

Figure 5. A.C. (alternate current) susceptibility and resistance versus temperature in $ErRh_4B_4$. (Reprinted figure from Fertig *et al.*, *Phys. Rev. Lett.* Vol. 38, 987, 1977. Copyright 1977 by the American Physical Society.)

cooling provokes the destruction of the superconductivity below $T_{cr} \approx 0.64\,K$ and the transition to the ferromagnetic state. Note that the ferromagnetic superconductors give a very rare example of the superconductivity destruction with lowering temperature.

The compound $HoMo_6Se_8$ is quite similar to $HoMo_6S_8$ but has a higher $T_c = 5.5\,K$, and in the superconducting phase also the nonuniform magnetic structure with wave vector $Q \approx 0.09\,Å^{-1}$ appears at $\Theta \approx 0.53\,K$ (Lynn *et al.*, 1984). Unlike $HoMo_6S_8$, however, the superconductivity is not destroyed in $HoMo_6Se_8$, and the nonuniform magnetic structure coexists with it. At low temperature the wave vector decreases down to $Q \approx 0.06\,Å^{-1}$.

What is the origin of such behavior and what is the nature of the coexistence phase in the temperature interval between Θ and T_{cr}? Let us start first with the estimate of the characteristic energy of magnetic interaction. In the case of the RKKY interaction it is the electronic spin susceptibility χ that is responsible for the magnetic ordering and the energy of this interaction may be written as

$$E_m = -\sum_Q \frac{\chi(Q)}{2}|h_Q|^2 \tag{3}$$

where $\chi(Q)$ and h_Q are the Fourier components of the electronic spin susceptibility and exchange field respectively. It is convenient to write $h(\vec{r}) = h_0 S(\vec{r})$, introducing the normalized magnetization $S(\vec{r}) = M(\vec{r})/M_0$, where M_0 and h_0 are the saturated magnetization and the exchange field at $T = 0\,K$. For the ferromagnetic ordering we may easily estimate from (3) the characteristic energy per one magnetic moment (or electron as the electrons' concentration is of the same order of magnitude as the magnetic atoms concentration) as $|E_m| \propto \Theta_{ex} = \frac{N(0)}{2}h_0^2 \propto \Theta$, where $N(0)$ is the electron density of state at the Fermi energy. On the other hand the energy of the superconducting condensation (Abrikosov, 1988) $E_s = -\frac{N(0)}{2}\Delta^2$, and Δ is the superconducting gap. The energy gain per one electron is very small $|E_s| \propto T_c\frac{T_c}{E_F} \ll T_c$. The reason is that the formation of the Cooper pairs modifies the electronic spectrum only in the immediate vicinity near the Fermi surface.

The factor $\frac{T_c}{E_F} \ll 1$ made the superconducting condensation energy very small compared to the magnetic energy. Even in the case $\Theta < T_c$ we have $|E_s| \ll |E_m|$, and so we must conclude that magnetism is a very robust phenomenon compared to superconductivity. Therefore, superconductivity cannot prevent the magnetic ordering and may only modify it. On the contrary, ferromagnetism can easily destroy superconductivity.

Let us address now the question of the type of magnetic transition in superconducting phase. Near the Curie temperature we may describe the magnetic transition in the

framework of Landau functional. For ferromagnetic transition in the normal metal it reads

$$F_{\mathrm{m}} = \tilde{\Theta} \sum_{Q} \lfloor \tau |S_Q|^2 + Q^2 a^2 |S_Q|^2 \rfloor \tag{4}$$

where $\tau = \frac{T-\Theta}{\Theta}$, the energy constant $\tilde{\Theta} \propto \Theta$ and the constant a is the magnetic stiffness being of the order of the interatomic distance. The functional (4) is very general one and its coefficients describe the entropy as well as magnetic energy contributions. The form (4) corresponds to the case of ferromagnetic transition because, namely, $Q = 0$ gives the highest transition temperature Θ. This transition temperature and the wave vector Q are readily determined from (4) as the condition of the vanishing of the coefficient on the $|S_Q|^2$ harmonic.

The question about the type of the magnetic ordering in the superconducting state in the presence of the exchange interaction was first addressed by Anderson and Suhl (1959). In the superconducting state the electronic susceptibility $\chi_{\mathrm{s}}(Q)$ changes comparing with that of normal metal $\chi(Q)$, and to take this into account we need to add to the functional (4) the corresponding term

$$F_{\mathrm{int}}^{\mathrm{ex}} = -\sum_{Q} \frac{\chi_{\mathrm{s}}(Q) - \chi(Q)}{2} |h_Q|^2 \tag{5}$$

The dispersions of the electronic spin susceptibility in normal and superconducting states are schematically presented in Figure 6. The main difference is the vanishing of $\chi_{\mathrm{s}}(Q)$ for $Q = 0$. For large wave vectors $Q\xi_0 \gg 1$ the spin susceptibilities in the superconducting and normal states practically coincide. This explains why superconductivity has no effect

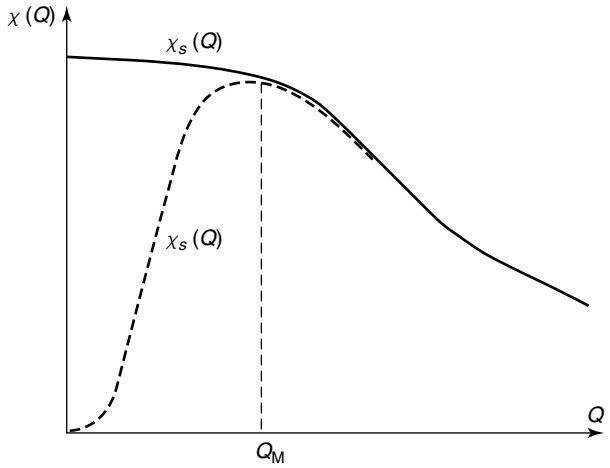

Figure 6. Schematic behavior of the spin susceptibility in normal $\chi(Q)$ and superconducting $\chi_{\mathrm{s}}(Q)$ states.

on the appearance of antiferromagnetic ordering with wave vectors $Q \approx a^{-1}$.

In the superconducting phase the magnetic functional (the energy is calculated per one magnetic atom) becomes

$$\begin{aligned} F_{\mathrm{m}}^{\mathrm{s}} &= F_{\mathrm{m}} + F_{\mathrm{int}}^{\mathrm{ex}} \\ &= \tilde{\Theta} \sum_{Q} \left[\tau + Q^2 a^2 - \frac{\chi_{\mathrm{s}}(Q) - \chi(Q)}{\chi(0)} \frac{\Theta_{\mathrm{ex}}}{\tilde{\Theta}} \right] |S_Q|^2 \end{aligned} \tag{6}$$

At $T = 0$ and $Q\xi_0 \gg 1$ following (Anderson and Suhl, 1959) $\frac{\chi_{\mathrm{s}}(Q)-\chi(Q)}{\chi(0)} = \frac{\pi}{2Q\xi_0}$ and we readily find from (6) the maximum critical temperature corresponds to the nonuniform magnetic structure with $Q_{\mathrm{M}} \approx (a^2\xi_0)^{-1/3}$ (Anderson and Suhl, 1959). The transition temperature Θ_{M} is only slightly smaller than the Curie temperature Θ in the absence of superconductivity: $\frac{\Theta-\Theta_{\mathrm{M}}}{\Theta} \approx (\frac{a}{\xi_0})^{2/3} \ll 1$. Anderson and Suhl called this magnetic structure *cryptoferromagnetic*.

In addition to the exchange mechanism there always exists the electromagnetic mechanism of superconductivity and magnetism interaction which is related with Meissner screening of the magnetic induction created by the magnetization $M(\vec{r}) = M_0 S(\vec{r})$. This mechanism also favors the nonuniform magnetic structure instead of ferromagnetic one (Krey, 1973; Blount and Varma, 1979; Ferrell, Bhattacharjee and Bagchi, 1979; Matsumoto, Umezawa and Tachiki, 1979). The contribution to the free energy from the screening may be readily written as

$$F_{\mathrm{int}}^{\mathrm{em}} = \sum_{Q} \frac{K(Q)}{2} |A_Q|^2 \tag{7}$$

where $K(Q)$ is the electromagnetic kernel in superconductor (see, e.g., Abrikosov, 1988), and A is the vector potential of the magnetic induction in superconductor. Assuming $Q\lambda_L \gg 1$ the vector potential satisfies $i[\vec{Q}\vec{A}_{\vec{Q}}] = 4\pi n M_0 \vec{S}_{\vec{Q}}$, the energy (7) per one magnetic atom reads

$$F_{\mathrm{int}}^{\mathrm{em}} = \Theta_{\mathrm{em}} \sum_{Q} \frac{|S_Q|^2}{Q^2 \lambda_L^2} \tag{8}$$

where $\Theta_{\mathrm{em}} = 2\pi n M_0^2$ and the expression for the kernel $K(Q) = \frac{1}{4\pi\lambda_L^2}$ in the local limit was used. The parameter Θ_{em} describes the strength of the magnetodipole interaction between magnetic atoms, and does not exceed 1 K in the ternary and quaternary magnetic superconductors. Combining (8) and (4) we find the magnetic transition occurs into the nonuniform state with $Q_{\mathrm{M}} \approx \left(\frac{\Theta_{\mathrm{em}}}{\tilde{\Theta}}\right)^{1/4} (a\lambda_L)^{-1/2}$.

The sinusoidally modulated magnetic coexistence phase perfectly resolves an antagonism problem between superconductivity and ferromagnetism. Indeed, from the 'point

of view of superconductivity' such a magnetic structure is like an antiferromagnetic one as $Q_M\lambda_L \gg 1$ and $Q_M\xi_0 \gg 1$. On the other hand, it is like a ferromagnetic one from the 'point of view of magnetism' as $Q_M a \ll 1$. Then it is really a compromise structure. Further lowering of the temperature will favor the structure with the constant modulus of magnetic moment, which is close to its value in the ferromagnet. The full theoretical description of the coexistence phase needs to take into account the magnetic anisotropy and both mechanisms of superconductivity and magnetism interaction (Bulaevskii, Buzdin, Kulić and Panjukov, 1985). The conclusion is that the sinusoidal modulation transforms into the domain phase with the period $d \approx \sqrt{a\xi_0}$ and the main role in the real compounds is played by the exchange interaction. The relative strength of electromagnetic and exchange interaction is controlled by the parameter $r = \frac{F_{\text{int}}^{\text{em}}}{F_{\text{int}}^{\text{ex}}} = \frac{\Theta_{\text{em}}}{\Theta_{\text{ex}}} \frac{1}{Q^2\lambda_{L^2}}$. Due to the large value of $Q\lambda_L \gg 1$ in all ternary ferromagnetic superconductors, the exchange interaction dominates in the formation of the domain coexistence phase. The superconductivity will be destroyed when the additional energy associated with the domain phase will compensate the superconducting condensation energy. This gives the following condition for the transition into the normal ferromagnetic state $S_c(T) \approx \frac{T_c}{h_0}(\xi_0/a)^{1/4}$. If $S_c > 1$ it simply means that the domain phase will be stable till 0 K without the reentrant superconducting transition. This situation is realized in $HoMo_6Se_8$ where the transition into the ferromagnetic state is lacking.

The unambiguous experimental evidence of the existence of the nonuniform magnetic structures were obtained in the neutron diffraction measurements in $ErRh_4B_4$ (Sinha, Crabtree, Hinks and Mook, 1982), $HoMo_6S_8$ (Lynn *et al*., 1981), and $HoMo_6Se_8$ (Lynn *et al*., 1984). For example in Figure 7 it is demonstrated that in $ErRh_4B_4$ (Sinha, Crabtree, Hinks and Mook, 1982) just below the Curie temperature in the superconducting phase the satellite neutron Bragg scattering appears in the narrow temperature interval around (0.1–0.2) K below the magnetic transition. Further lowering of the temperature provokes the transition into the ferromagnetic state with the simultaneous destruction of superconductivity.

Recently the coexistence of superconductivity and nuclear magnetic order has been reported in $AuIn_2$ (Rehmann, Herrmannsdörfer and Pobell, 1997). The superconducting critical temperature of this compound is $T_c = 0.207$ K and the magnetic transition temperature $\Theta \approx 35\,\mu$K though the type of the nuclear magnetic order is not yet known. The hyperfine interaction may play the same role as the exchange interaction and in superconducting $AuIn_2$ nonuniform nuclear magnetic ordering could be expected (Kulić, Bulaevskii and Buzdin, 1997). Coexistence of superconductivity with magnetism gives an interesting opportunity for studying these phenomena when the electronic temperature could be very different from the nuclear one.

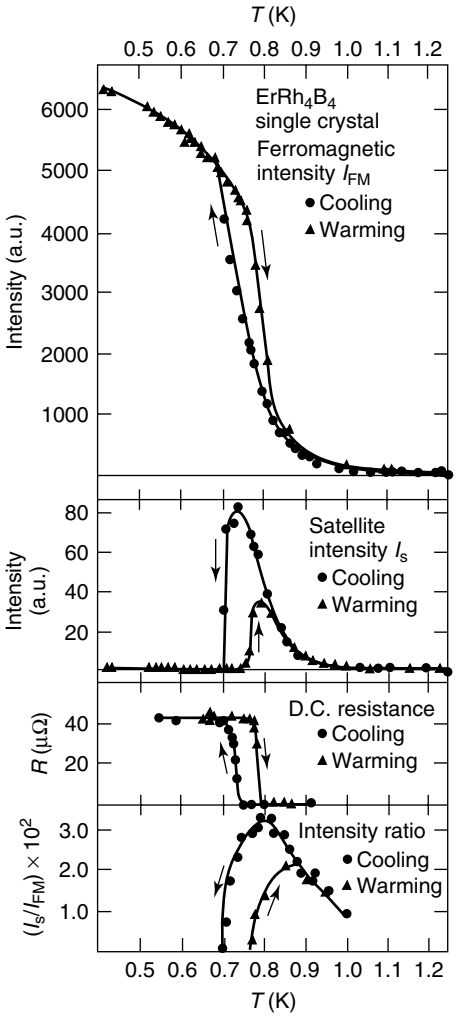

Figure 7. Intensity of the neutron Bragg scattering and resistance as a function of temperature in an $ErRh_4B_4$ (Sinha, Crabtree, Hinks and Mook, 1982). The satellite position corresponds to the wavelength of the modulated magnetic structure around 92 Å. (Reprinted figure from Sinha *et al*., *Phys. Rev. Lett.* Vol. 48, 950, 1982. 4 UNCONVENTIONAL SUPERCONDUCTIVITY: CASE OF HEAVY FERMION COMPOUNDS

In the previous examples, two separated baths exist: one with the localized magnetic centers, another with the Fermi sea. In strongly correlated electronic systems as high T_c oxide, organic conductor, or HFCs this separation is not justified. The spin dynamics and the electronic motion are strongly

coupled; the effective mass m^* of the itinerant electron depends on the proximity to instability points of the magnetism, the valence, or the charge. We will focus here on HFCs, which are intermetallic compounds of 4f or 5f electron (often cerium or uranium atoms). On cooling, the remaining large magnetic entropy ($S = R$ Log 2 for a doublet) is transferred to the Fermi sea for the creation of heavy quasiparticles; m^* is often 2 orders of magnitude larger than the bare electronic mass m_0. The weak delocalization of the 4f or 5f electrons from its site is produced by its hybridization with the other light electrons of the Fermi sea. The corresponding small effective Fermi temperature $T_F \sim 100\,K$ is mainly given by the Kondo temperature T_K of the single 4f or 5f ion. For example, at high temperature ($T > T_K$), the 4f electron of the Ce site behaves as a paramagnetic center with a local Kondo energy. Below T_K, each Ce site is no more independent from the others; heavy quasiparticles are formed in a strongly renormalized band (Flouquet, 2005).

The duality between the localized and itinerant character of the 4f (or 5f) electrons leads to the competition between the long-range magnetic order (AF or FM) and paramagnetism (PM). In Ce HFC, as T_K increases under pressure, the critical magnetic temperature T_N or T_{Curie} collapses at a critical pressure P_C. If the magnetism disappearance occurs continuously through a second-order phase transition (the collapse of T_N is associated with that of the sublattice magnetization M_o), P_C is referred to as the *magnetic quantum critical point*. In the vicinity of P_C, the standard Fermi liquid properties such as temperature dependence of the resistivity in AT^2 can only be observed below a characteristic temperature T_I which collapses right at P_C (Figure 8a).

4.1 Heavy-fermion antiferromagnets and superconductivity

In various cerium HFCs which are AF below P_C, a superconducting dome appears between $P_{+S} - P_{-S}$ tight to P_C (Figure 8b). The quasicoincidence of the pressure of maxima of T_c with P_C suggests a magnetic origin for the pairing. Early theoretical works on superconductivity mediated by AF fluctuations can be found in Emery (1983), Hirsch (1985), and Miyake, Schmitt-Rink and Varma (1986). Recent reviews can be found in Moriya (2003) and Chubukov, Pines and Schmalian (2004). Another source of pairing can originate from valence fluctuations near the pressure P_V where large fluctuations may occur in the occupation number n_f of the 4f shell (Onishi and Miyake, 2000). In Ce HFC, the valence is equal to $v = 4 - n_f$ while T_K is proportional to $1 - n_f$. The evidence of this extramechanism is mainly given by the observation of a maxima of T_c at a pressure far higher than P_C in $CeCu_2Si_2$ and $CeCu_2Ge_2$ (Holmes, Jaccard and Miyake, 2004), and near the pressure P_V where strong valence fluctuations are expected. Quite often P_C and P_V coincide as the collapse of AF corresponds to a strong increase of T_K which drives the system through P_V (Flouquet, 2005).

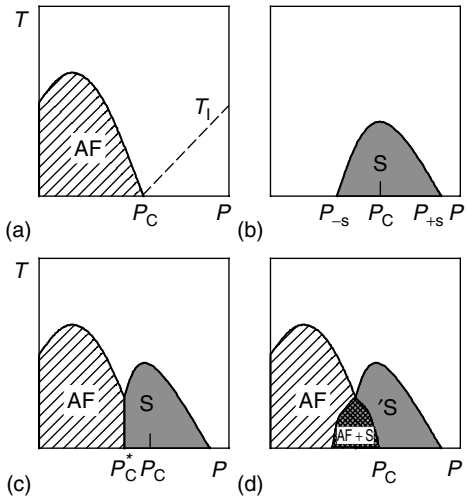

Figure 8. (a) P variation of the Néel temperature (T_N) and the temperature T_I below which Fermi liquid properties are observed without SC. (b) P variation of the superconducting critical temperature T_c neglecting AF order parameter. (c) Possibility of bicritical point if AF and SC expel each other. (d) Coexistence of AF and SC with a tetracritical point.

4.2 Unconventional superconductivity

Due to the strong on-site repulsion among the f electrons, the existence of a previous s-wave superconductivity with finite amplitude of the Cooper pair on a given site is precluded. An anisotropic pairing either a triplet like the p wave of ^3He or a single d wave occurs. In this unconventional superconductor, another symmetry other than the gauge one is broken: point group, odd parity, or time reversal. Often, the order parameter $\Delta(k)$ vanishes on point nodes or line nodes on the Fermi surface (Mineev and Samokhin, 1999). That leads to low energy excitations highly sensitive to any type of impurities and also to the Doppler shift produced by a magnetic field. In these unconventional superconductors, the clean limit is required, that is, the electronic mean free path ℓ must be higher than the superconducting coherence length ξ. Increasing ℓ leads to optimize T_c and $H_{c_2}(0)$.

The consequence of a huge m^* is a large orbital limit, proportional to the product $H_{c_2}^{orb}(0) \sim m^{*2} T_c$. If the zero component of the spin of the Cooper pair exists, the Pauli–Zeeman effect is efficient to break the Cooper pair. In case of equal spin pairing (ESP) between $\uparrow\uparrow$ and $\downarrow\downarrow$ spins, no Pauli

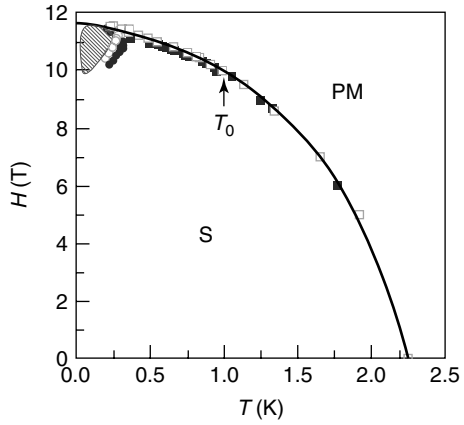

Figure 9. H, T phase diagram of $CeCoIn_5$ with H//110 (filled symbols) and H//100 (open symbols). The hatched domain is the new mixed superconducting phase which may be a FFLO state. (Reprinted figure from Bianchi *et al.*, *Phys. Rev. Lett.* Vol. 91, 187004, 2003. Copyright 2003 by the American Physical Society.)

limit occurs. An interesting possibility, as discussed later, is the appearance of a Fulde–Ferrell–Larkin–Ovchinnikov (FFLO) phase at high magnetic and low temperature (Larkin and Ovchinnikov, 1964; Fulde and Ferrell, 1964). This is possible if the Pauli limit dominates the behavior of H_{c_2} at low temperature. Such a possibility seems realized in $CeCoIn_5$ (Radovan *et al.*, 2003; Bianchi *et al.*, 2003) as an extra phase exists in this limit (Figure 9); however, other mechanisms can occur as reentrant long-range magnetism. A FFLO state was claimed for UPd_2Al_3 (Gloss *et al.*, 1993), and was also suggested for UBe_{13} (Glémot *et al.*, 1999), but with no further confirmation.

4.3 Ce heavy-fermion superconductors

After the unexpected discovery of superconductivity in $CeCu_2Si_2$ (Steglich *et al.*, 1979) at $P = 0$ (almost near the quantum critical pressure P_c), the main steps were:

- the pressure variation of T_C in $CeCu_2Si_2$ and the evidence of similar phenomena in $CeCu_2Ge_2$ (see Holmes, Jaccard and Miyake, 2004),
- the successive discovery of superconductivity in $CeRh_2Si_2$ (Movshovich *et al.*, 1996), $CePd_2Si_2$ and $CeIn_3$ (Mathur *et al.*, 1998) close to P_C,
- the boost on T_c by increasing the two dimensional characters with the insertion of a TIn_2 block ($T =$ Co, Rh, Ir) in the cubic structure of $CeIn_3$; T_c jumps by 1 order of magnitude (Thompson *et al.*, 2001),
- the possibility of SC in the noncentrosymmetric crystal of $CePt_3Si$ (Bauer *et al.*, 2004),
- the direct observation of long-range incommensurate AF order on a $CeCu_2Si_2$ crystal (Stockert *et al.*, 2004), which suggests a spin density wave instability for the origin of its quantum criticality (see Thalmeier *et al.*, 2004).

As an illustrating example let us focus on the interplay between antiferromagnetism and superconductivity in the 1, 1, 5 compound $CeRhIn_5$ with the possibility to tune through the different phases by the two P and H external variables. The increase in the two dimensional character leads to the favorable situation of quite comparable values in the maxima of their transition temperature $T_c = 2.4\,K$ and $T_N = 4\,K$: an ideal example for the study of the interplay between AF and SC (Figure 10).

A key question is the domain of the coexistence of AF and SC. If SC will not appear, the popular view of Ce HFC is that T_N collapses almost linearly with the pressure at P_C as shown in Figure 8(a). Neglecting the AF boundary, SC will appear between P_{-S} and P_{+S} with a temperature maxima T_c near P_C (Figure 8b). For the interference of both AF and SC order parameter, the simple approach is to consider an extra coupled term β in the Landau energy. If $\beta > 0$, superconductivity and magnetism compete. A bicritical point exists with a first-order separation between AF and SC phases at P_C^* (Figure 8c). If $\beta < 0$ a tetracritical point appears and each phase enhances the other (Figure 8d) (Flouquet *et al.*, 2006). Of course in this correlated system, β may depend on P.

At $P = 0$, $CeRhIn_5$ is a AF with $T_N = 3.8\,K$. In this AF state the normal state persists down to 0 K up to 0.8 GPa. Zero resistivity SC anomalies are detected between 0.8 and 1.5 GPa. Only above 1.5 GPa up to $P_C^* \sim 2\,GPa$,

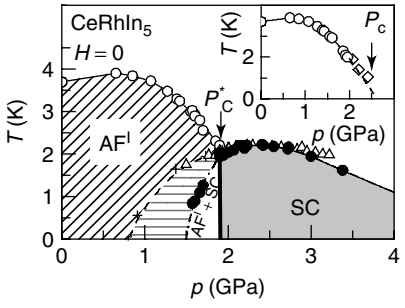

Figure 10. P, T phase diagram of $CeRhIn_5$ from specific heat (○, ●) susceptibility (Δ), and resistivity (X) measurements. Below 1.5 GPa $CeRhIn_5$ is an incommensurate AF in a normal state, the hatched region indicates an inhomogeneous SC state, the white one is the region ($AF^I + SC$) where a SC specific heat anomaly is detected below T_N for $P < P_c^*$. A pure SC without AF is realized for $P > P_c^*$. The inset show the extrapolation of T_N to zero at P_C in absence of SC, the (◇) indicates the temperature where above P_c^*, T_N (H) crosses T_c (H) (Knebel *et al.*, 2006). (Reprinted figure from J. Flouquet *et al.*, *Phys. Rev. B* Vol. 74, 020501 (2006).)

a broadened specific heat appears below T_N linked to SC, however, its temperature maxima T_c(C) is higher than the one detected in susceptibility $T_c(\chi)$ or in resistivity $T_c(\rho)$ (Knebel *et al*., 2004). At least, the SC phase transition is inhomogeneous. Surprisingly, NMR experiments lead to the conclusion of homogeneous gapless superconductivity below $T_c(P)$ (Kawasaki *et al*., 2003). At the opposite end above P_C^*, only a sharp specific heat anomaly characteristic of SC is detected on cooling for $H = 0$. The reason is that, just below P_C^*, where $T_N > T_c$, only few parts of the Fermi surface are involved by AF, and SC is not precluded below T_N. While, above P_C^*, when T_c will be greater than T_N, a large part of the FS is gapped, and thus, AF cannot appear. At first glance, AF and SC are antagonist (Figure 10) but these qualitative arguments do not exclude the possibility of a narrow P domain of a coexistence of SC and AF with a tetracritical point. At least, without SC, AF will collapse at higher pressure P_C than P_C^* defined by $T_c(P_C^*) = T_N\ (P_C^*)$.

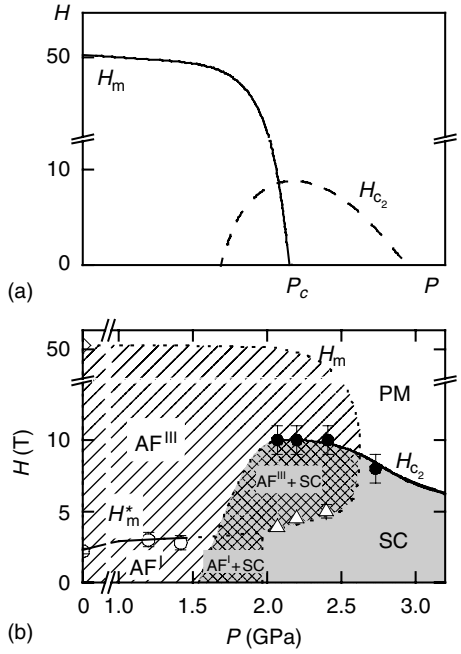

Figure 11. (a) At $T = 0$ K, expected pressure dependence of the magnetic critical field H_m between AF and PM states and the uppercritical field $H_{c_2}(0)$. (b) At $T = 0$ K, the extrapolated phase diagram of $CeRhIn_5$ for H in the basal plane. At zero pressure, the AF is incommensurate (AF^I); above $H_m^* = 2.5$ T, it becomes commensurate (AF^{III}). For $P > P_C^*$ and H H_m^*, SC and AF are suspected to coexist. $AF^I + SC$ and $AF^{III} + SC$ are the coexistence regimes of AF^I and AF^{III} with SC, respectively. SC represents a pure superconducting phase (●) and (○) indicates to $T = 0$ extrapolated values of H_{c_2} and H_m^* from the experiment of Knebel *et al*. (2006), respectively. (Δ) gives the lowest field at which the induced transition at TM is observed (◇) is the value of H_m at $p = 0$ (Takeuchi *et al*., 2001).

The magnetic field can modify the AF–SC boundary. As indicated Figure 11(a), in $CeRhIn_5$, the critical magnetic field H_m between AF and PM domain is high: $H_m \sim 50$ T (Takeuchi *et al*., 2001) for $H//a$ axis while $H_{c_2}(0)$ between P_C and P_C^* is around 8 T. Furthermore, it is expected that H_m will depend weakly on P for $P < P_C^*$. Thus applying a magnetic field can lead to recover the situation where T_N $(P, H) > T_c$ (P, H), and thus, of H reentrance of AF. At first approximation between P_C and P_C^*, T_c (P, H) depends strongly on H but weakly on P, while T_N (P, H) depends weakly on H and strongly on P:

$$T_N(P, H) = T_N(P_C^*)\frac{P_C - P}{P_C - P_c^*} \quad T_c(P, H) \sim T_c(P_C^*)\frac{H_0 - H}{H_0} \tag{9}$$

H reentrance of AF will appear for $H_{1,2}$ equal to

$$H_{1,2} = H_0 - H_0\frac{P_C - P}{P_C - P_C^*} \tag{10}$$

Specific heat experiments have been realized recently in Los Alamos (Park *et al*., 2006) and Grenoble (Knebel *et al*., 2006). Outside differences in the values of P_C^* 1.8 and 1.95 GPa respectively, both measurements show the H emergence of another phase below a pressure around P_C. Figure 12 shows at 2.4 GPa the two phase transitions already for $H > 4$ T: the first one is purely SC, the second one at lower temperature implies presumably an order parameter where SC and AF are coupled. Above P_C, for example,

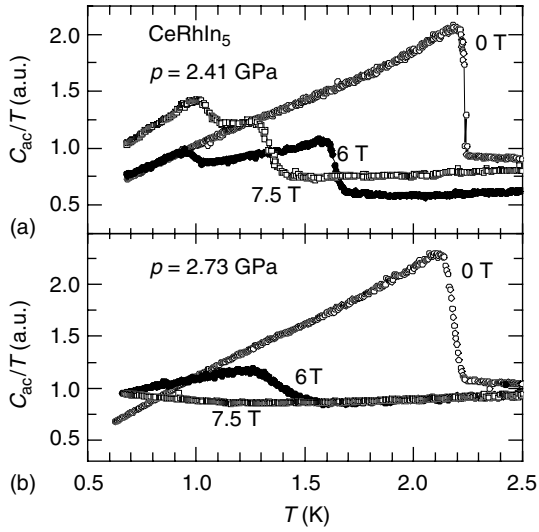

Figure 12. Results of ac microcalorimetry experiments: (a) C/T in arbitrary unit at 2.41 GPa ($P < P_C$) with the appearance of the second phase transition in the SC phase and (b) at 2.73 GPa ($P > P_C$) with the disappearance of the second phase transition (Knebel *et al*., 2006). (Reprinted figure from J. Flouquet *et al*., *Phys. Rev. B* Vol. 74, 020501 (2006).)

at 2.7 GPa, this anomaly disappears and only a unique SC phase transition is observed. As H_c^* is lower than $H_{1,2}$, AF may reappear in a dense vortex matter. One of the peculiarity of the system close to P_C is that, here, superconducting (ξ_0) and magnetic coherent (ξ_m) lengths have a comparable nanometer scale in contrast to previous normal RE intermetallic compounds where ξ_m ($T = 0$ K) corresponds to atomic distances. The Figure 11(b) shows an extrapolation of the H, P phase diagram at $H = 0$ K for H in the basal plane. Above H^*m, the AF structure has switched from incommensurate to commensurate.

At $H = 0$, SC precludes to reach the magnetic quantum critical point, however, the magnetic field can restore its vicinity. That may be the situation for $CeCoIn_5$ with the magnetic field applied along the c axis (Paglione *et al.*, 2003). For the superconductors $CeIn_3$, $CeRh_2Si_2$, $CeCu_2Si_2$, $CePd_2Si_2$, and $CePtSi_3$, AF looks to collapse via a first-order transition. Table 2 lists for different Ce HFC superconductors the value of T_N (max), T_c (max), and the corresponding pressures P_C and $P(T_c$ (max)), as well as the estimated value of the T linear coefficient γ of the specific heat in its normal state at $P = 0$. Table 3 shows the parameter for the uranium HFC which becomes superconductor (see Flouquet, 2005). These observations after the discovery of SC in $CeCu_2Si_2$ have boosted the studies of SC. As excellent crystals can be obtained, for the superconductors already at zero pressure careful experiments have largely contributed to progress on unconventional superconductivity.

Table 2. Parameters of some Ce heavy-fermion superconductors: T_N (max) and T_c (max) in Kelvin, the temperature maxima of their Néel and superconducting temperatures. P_c the critical pressure where T_N is suspected to collapse, $P(T_c$ (max)) the pressure (in GPa) where T_c reaches its maxima in pressure. The linear T term (γ) of the specific heat at $P = 0$ in mJ mol^{-1} K^{-2}. The superconducting coherence length ξ_0 is between 30 and 200 Å.

	T_N (max)	T_c (max)	P_C	$P(T_c$ (max))	$\gamma(P = 0)$

4.4 Ferromagnetic superconductors: UGe2 and URhGe

The discovery of superconductivity in UGe_2 under pressure (Saxena *et al.*, 2000), deep inside its ferromagnetic phase, was unexpected. At $P = 0$, UGe_2 is a ferromagnet with $T_{Curie} = 54$ K and a sublattice magnetization $M_o = 1.48\,\mu_B$/U atom; its γ term is 35 mJ mol^{-1} K^{-2}. The 5f electrons of the U atom are considered to be itinerant. As reported now for many itinerant ferromagnets, FM disappears at $P_C = 1.6$ GPa through a first-order transition characterized by a jump ΔM_o of M_o equal to $0.8\,\mu_B$/U atom. P studies show two FM phases, FM_1 and FM_2 (Figure 13). The FM_2–FM_1 boundary terminates at P_X ($T = 0$) ~ 1.2 GPa at $T = 0$ K, and the first-order line (P_X, T_X) seems to end up at a critical point around $T_X^c \sim 15$ K and $P_X^c \sim 0.7$ GPa (Huxley *et al.*, 2001). Superconductivity appears above 1.0 GPa when T_{Curie} is still high and M_o large ($\sim 1\,\mu_B$); T_c (max) ~ 700 mK for $P = P_X$. The estimation of the exchange field (100 T) seems to preclude a singlet component. Furthermore triplet ESP is suspected with even the possibility of only majority spin pairing. Flux flow experiments have supported the bulk

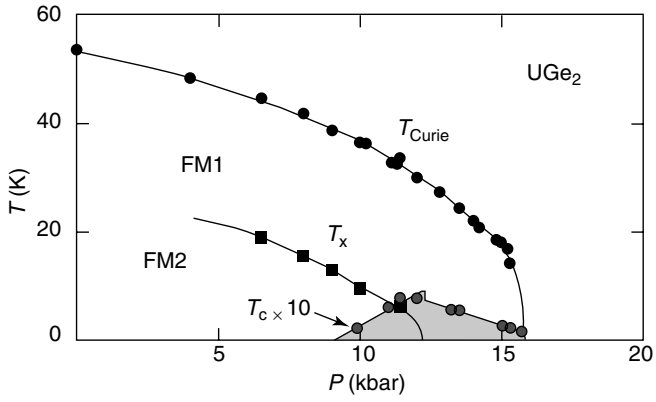

Figure 13. T, P phase diagram of the ferromagnetic superconductors UGe_2. The Curie temperature T_{Curie} (●), the supplementary temperature T_X (■) which leads to first-order transition at $T \to 0$ K and the superconducting temperature T_c (●) are shown. (Reprinted figure from Huxley *et al.*, *Phys. Rev. B* Vol. 63, 144519, 2001. Copyright 2001 by the American Physical Society.)

nature of superconductivity which were confirmed by direct specific heat measurements (Tateiwa *et al*., 2004). The coexistence of superconductivity and ferromagnetism was verified by neutron scattering and recently by NQR measurements on Ge sites (Harada *et al*., 2005). The nuclear relaxation rate T_1^{-1} exhibits a peak at T_{Curie} and a change of slope at T_c from a Korringa law to a T^3 law compatible with unconventional superconductivity with ESP.

Open questions are the mechanism of superconductivity and the variation of the SC order parameter on both side of the first-order line (T_X, P_X). An appealing possibility is that a charge-density wave plays a major role (Watanabe and Miyake, 2002). However, no extra reflections have been detected in neutron diffraction experiments; evidence may have been found in careful calorimetric measurements (Lashley *et al*., 2006).

Applying a magnetic field along the easy axis of the orthorhombic crystal above P_X leads to jump at H_X from FM_1 to FM_2, and even from PM to FM_1 and FM_2 above P_C. The interesting feature is that just above P_X for $P = 1.35$ GPa, the metamagnetic jump from FM_1 to FM_2 at $H_X \sim 1$ T modifies the SC properties, $H_{c_2}(0)$ jumping from 2 to 3 T: *de facto* it corresponds to two different T_c. A recent spectacular example is given later with the H reentrance of SC in URhGe.

A progress in ferromagnetic superconductors seems to be achieved with the observation of SC already at $P = 0$ in the ferromagnet URhGe with $T_c \sim 300$ mK for $T_{\text{Curie}} = 10$ K and $M_o = 0.4\,\mu_B$/U atom (Aoki *et al*., 2001). SC specific heat jump $\frac{\Delta C}{\gamma T_c} \sim 0.45$ was detected on polycrystals. Under pressure, T_{Curie} increases linearly with P reaching 20 K at 12 GPa while $P_{+S} \sim 4.5$ GPa. The growth of small clean crystals allows H_{c_2} measurements along the three a, b, c axis of the orthorhombic crystal; the easy magnetization axis is c (Figure 14) (Hardy and Huxley, 2005). Good fits are obtained with only the orbital limit. Taking into account the relative temperature variation of $H_{c_2}^a$, $H_{c_2}^b$, $H_{c_2}^c$, it was proposed as an ESP between the majority spin paired of the $k_a|\uparrow\uparrow\rangle$ state.

The surprise was the observation of H reentrant SC for $H//b$ associated with a field reorientation of the ordered magnetization M_o from c to b axis at $H_R \sim 12$ T (Figure 15) (Levy *et al*., 2005). In this strongly correlated system, a field reorientation of the magnetic structure is presumably associated with a modification of the spin fluctuation spectrum, which may react on the pairing mechanism. The jump of the b component of M_o is reminiscent of the metamagnetic phenomena extensively studied in the HFC $CeRu_2Si_2$ and URu_2Si_2 with the consequence on the dressing of the quasiparticles (m^*) (see Flouquet, 2005).

Progress in ferromagnetic superconductors requires a new generation of crystals. Up to now, the attempts to discover Ce ferromagnetic SC have failed. The fast claim of

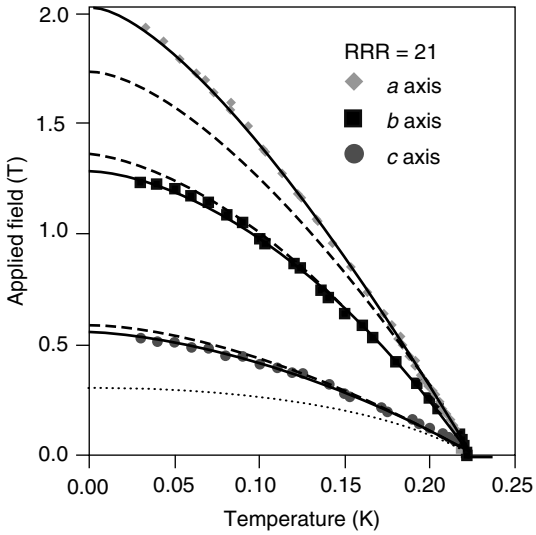

Figure 14. In URhGe, temperature variation of the upper critical field $H_{c_2}(T)$ measured along the a, b, and c axis of a simple crystal with residual resistivity ratio RRR = 21. The solid line show the prediction of the polar state $k_a|\uparrow\uparrow\rangle$. The dotted line is the BCS dependence for the c axis including the paramagnetic limitation and the dashed lines the calculated BCS dependence without paramagnetic limitation (Hardy and Huxley, 2005). (Reprinted figure from Hardy *et al*., *Phys. Rev. Lett.* Vol. 94, 247006, 2005. Copyright 2005 by the American Physical Society.)

superconductivity in the $ZrZn_2$ ferromagnet appears erroneous (Pfleiderer *et al*., 2001; Flouquet, 2005).

On the theoretical side, classification of the SC order parameter was made on general symmetry arguments (Samokhin and Walker, 2002; Mineev, 2002). The stabilization of superconductivity on the FM_1 side ($P < P_C$) was discussed on the basis of a positive feedback between magnetic moments of the Cooper pair and the magnetization density (Walker and Samokhin, 2002; Mineev, 2002). An alternative idea, if the magnetic anisotropy is weak, is the enhancement of T_c due to the coupling of the magnons to the longitudinal magnetic susceptibility (Kirkpatrick, Belitz, Vojta and Narayanan, 2001). As mentioned, an interesting proposal is that CDW are associated with FM. A phenomenological twin peak electronic structure was also developed to explain the maxima of T_c at P_X in UGe_2 (Sandeman, Lonzarich and Schofield, 2003). Possibility of s-wave superconductivity was pointed out by Suhl (2001) and Abrikosov (2002), but ferromagnetism needs to be localized. In UGe_2, the 5f electrons are considered to be itinerant and the reported preliminary experiments favor a triplet pairing.

With a SC order parameter coupled with M_o, one may ask if domain walls are weak links (Machida and Ohmi, 2001; Fomin, 2001), the occurrence of domain wall superconductivity (Buzdin and Mel'nikov, 2003), and finally the evolution of the FM domain structure through SC (Faure and

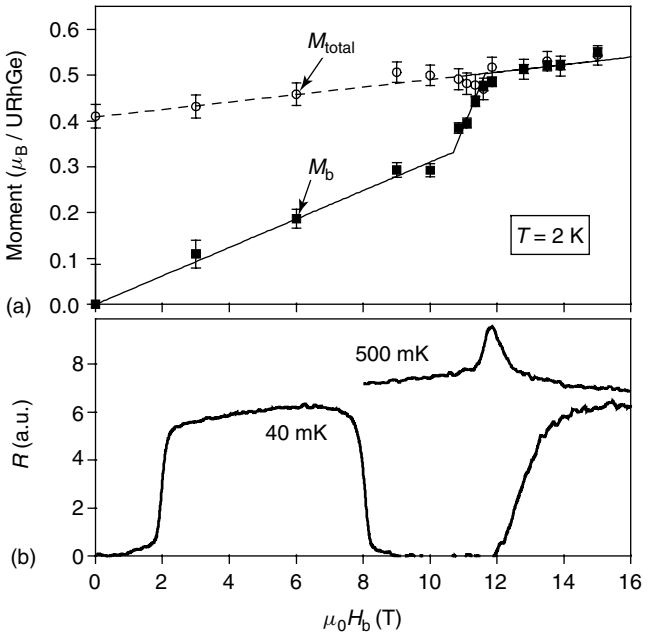

Figure 15. In (a) The total magnetic moment M total and the component Mb measured for H//to the b axis. In (b), variation of the resistance at 40 and 500 mK with the field reentrance of SC between 8 and 12 T (Levy, Sheikin, Grenier and Huxley, 2005). (From Levy *et al*., SCIENCE 309: 1343 (2005). Reprinted with permission from AAAS.)

Buzdin, 2005). A shrinkage of the domain width below T_c is proposed with, furthermore, quite a different T behavior between singlet and triplet pairing.

5 SUPERCONDUCTOR/FERROMAGNET HETEROSTRUCTURES

5.1 Proximity effect in ferromagnets

The coexistence of singlet superconductivity with ferromagnetism was not observed in bulk compounds, but it may be easily achieved in artificially fabricated layered ferromagnet/superconductors (F/S) systems. Due to the proximity effect, the Cooper pairs can penetrate into the F layer and induce superconductivity there. This provides the unique possibility to study the properties of superconducting electrons under the influence of a huge constant exchange field acting on the electron spins. In addition, it is possible to study the interplay between superconductivity and magnetism in a controlled manner, since by varying the layer thicknesses and magnetic content of F layers we change the relative strength of two competing orderings. The behavior of the superconducting condensate under these conditions is quite peculiar (see as reviews Buzdin, 2005; Bergeret, Volkov and Efetov, 2005).

Long time ago Larkin and Ovchinnikov (1964) and Fulde and Ferrell (1964) demonstrated that in a pure superconductor at low temperature the paramagnetic effect leads to the nonuniform superconductivity (it is the so-called FFLO or LOFF state). The appearance of modulation of the superconducting order parameter in FFLO state is related to the Zeeman's splitting of the electron's level under magnetic field acting on electron spins. To demonstrate this, we may consider the simplest case of the 1D superconductor. In the absence of the field, a Cooper pair is formed by two electrons with opposite momenta $+k_F$ and $-k_F$ and opposite spins ($\uparrow$) and ($\downarrow$) respectively. The resulting momentum of the Cooper pair $k_F + (-k_F) = 0$. Under a magnetic field, because of the Zeeman's splitting, the Fermi momentum of the electron with spin ($\uparrow$) will shift from k_F to $k_1 = k_F + \delta k_F$, where $\delta k_F = \mu_B H/v_F$ and v_F is the Fermi velocity. Similarly, the Fermi momentum of an electron with spin ($\downarrow$) will shift from $-k_F$ to $k_2 = -k_F + \delta k_F$ (see Figure 16). Then, the resulting momentum of the Cooper pair will be $k_1 + k_2 = 2\delta k_F \neq 0$, which just implies the space modulation of the superconducting order parameter with a resulting wave vector $2\delta k_F$.

Due to the incompatibility of ferromagnetism and superconductivity, it is not easy to verify this prediction on experiment. Moreover the electron scattering on the impurities destroys the FFLO state very quickly and its observation is possible only in the clean limit (Aslamazov, 1968). It happens that in a ferromagnet in contact with a superconductor the Cooper pair wave function has a damped oscillatory behavior (Buzdin, Bulaevskii and Panjukov, 1982), which may be considered in some sense as an analogy with the decaying nonuniform FFLO superconducting state. Indeed,

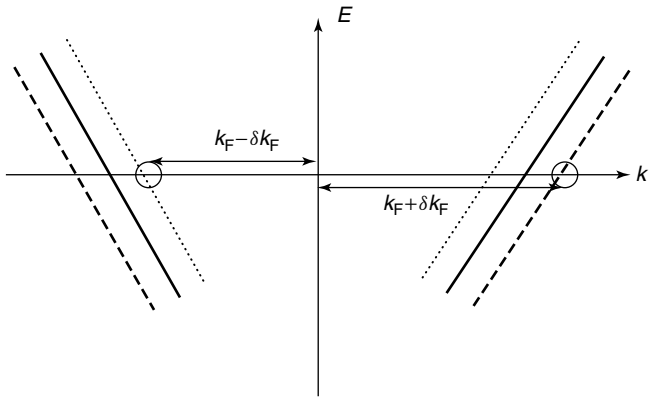

Figure 16. Energy band of the 1D superconductor near the Fermi energy. Due to Zeeman splitting, the energy of the electrons with spin orientation along the magnetic field ($\uparrow$) decreases, dotted line, while the energy of the electrons with the opposite spin orientation ($\downarrow$) increases, dotted line. For more details see text.

when a superconductor is in a contact with a normal metal the Cooper pairs penetrate across the interface at some distance inside the metal. A Cooper pair in a superconductor comprises two electrons with opposite spins and momenta. In a ferromagnet the up spin electron (with the spin orientation along the exchange field) decreases its energy by h, while the down spin electron increases its energy by the same value. To compensate this energy variation, the up spin electron increases its kinetic energy, while the down spin electron decreases it. In the result, the Cooper pair acquires a center of mass momentum $2\delta k_{\mathrm{F}} = 2h/v_{\mathrm{F}}$ which implies the modulation of the order parameter with the period $\pi v_{\mathrm{F}}/h$. The direction of the modulation wave vector must be perpendicular to the interface, because only this orientation is compatible with the uniform order parameter in the superconductor. This phenomenon, however, is quite general and must be present in both the clean and dirty limits (Buzdin and Kuprianov, 1990). It results in many interesting effects: the spatial oscillations of the electron's density of states, the nonmonotonous dependence of the critical temperature of S/F multilayers and bilayers on the ferromagnet layer thickness, the realization of the Josephson 'π' junctions in S/F/S systems. The interplay between the superconductivity and the magnetism in S/F structures occurs at the nanoscopic range of layer thicknesses and the observation of these effects became possible only recently due to the great progress in the preparation of high-quality hybrid F/S systems.

Let us consider the question of the proximity effect for a weak ferromagnet described by the decay of the superconducting correlations in a ferromagnet ($x > 0$) in contact with a superconductor ($x < 0$). If the electron scattering mean free path l is small (which is usually the case in S/F systems), the most natural approach is to use the Usadel equations (Usadel, 1970) for the Green's functions averaged over the Fermi surface. The linearized Usadel equation for the anomalous Green function F_{f} in the ferromagnet reads

$$\left(|\omega| + ih\,\mathrm{sgn}(\omega) + \frac{1}{\tau_{\mathrm{s}}}\right) F_{\mathrm{f}} - \frac{D_{\mathrm{f}}}{2}\frac{\partial^2 F_{\mathrm{f}}}{\partial x^2} = 0 \qquad (11)$$

where $\omega = (2n+1)\pi T$ are the Matsubara frequencies, and $D_{\mathrm{f}} = (1/3)v_{\mathrm{F}}1$ is the diffusion coefficient in the ferromagnet. The parameter $\frac{1}{\tau_{\mathrm{s}}}$ describes the magnetic scattering in the ferromagnetic alloys used as F layers. Note that this form of the Usadel equation in the ferromagnet implies a strong magnetic uniaxial anisotropy, when the magnetic scattering in the plane (xy) perpendicular to the anisotropy axis is negligible (Buzdin, 2005). In the F region, we may neglect the Matsubara frequencies compared to the large exchange field ($h \gg T_{\mathrm{c}}$). Also assuming first that the magnetic scattering is weak, we readily obtain the decaying solution for F_{f}

$$F_{\mathrm{f}}(x, \omega > 0) = A \exp\left(-\frac{1+i}{\xi_{\mathrm{f}}}x\right) \qquad (12)$$

where $\xi_{\mathrm{f}} = \sqrt{D_{\mathrm{f}}/h}$ is the characteristic length of the superconducting correlations decay (with oscillations) in F layer. Due to the condition $h \gg T_{\mathrm{c}}$, this length is much smaller than the superconducting coherence length $\xi_{0\mathrm{s}} = \sqrt{D_{\mathrm{s}}/(2\pi T_{\mathrm{c}})}$ (where D_{s} is the diffusion constant in the superconductor), that is, $\xi_{\mathrm{f}} \ll \xi_{0\mathrm{s}}$. In a ferromagnet, the role of the Cooper pair wave function is played by Ψ that decays as

$$\Psi \propto \sum_{\omega} F_{\mathrm{f}}(x, \omega) \propto \Delta \exp\left(-\frac{x}{\xi_{\mathrm{f}}}\right)\cos\left(\frac{x}{\xi_{\mathrm{f}}}\right) \qquad (13)$$

The presented analysis brings in evidence of the appearance of the oscillations of the order parameter in the presence of an exchange field. The different behavior of the superconducting order parameter in S/F and S/N systems is illustrated schematically in Figure 17.

The damping oscillatory behavior of Ψ is the fundamental difference between the proximity effect in S/F and S/N systems, and it is at the origin of many peculiar characteristics of S/F heterostructures. In the absence of the magnetic scattering the scale for the oscillation and decay of the Cooper pair wave function in a ferromagnet is the same. If we

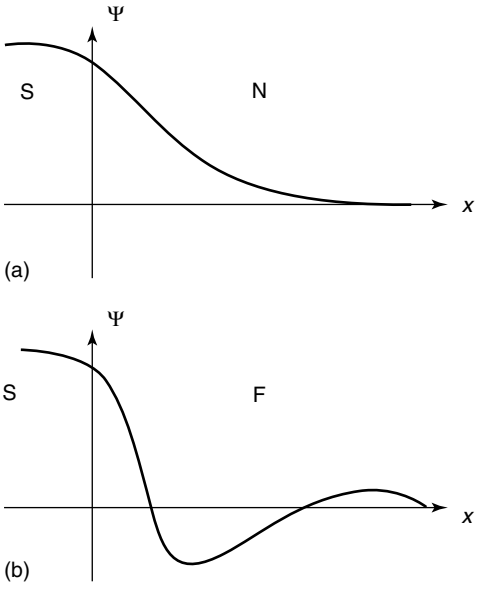

Figure 17. Schematic behavior of the superconducting order parameter near the (a) superconductor–normal metal and (b) superconductor–ferromagnet interfaces. The continuity of the order parameter at the interface implies the absence of the potential barrier. In the general case at the interface the jump of the superconducting order parameter occurs.

take into account the magnetic scattering, then the decaying length ξ_{f1} becomes smaller than the oscillating length ξ_{f2}. Namely $\xi_{f1} = \frac{\xi_f}{\sqrt{\sqrt{1+\alpha^2}+\alpha}}$ and $\xi_{f2} = \frac{\xi_f}{\sqrt{\sqrt{1+\alpha^2}-\alpha}}$, where the parameter $\alpha = \frac{1}{\tau_s h}$ characterizes the relative strength of the magnetic scattering. The damped oscillatory behavior of the order parameter may lead to the electronic density of states oscillations in a ferromagnet in contact with a superconductor (Buzdin, 2000). This prediction has been confirmed by the experiment by Kontos, Aprili, Lesueur and Grison (2001), which up to now remains the only experimental observation of the density of states oscillations in the F layer. The magnetic scattering effect complicates this type of experiment, strongly reducing the amplitude of the oscillations.

5.2 Oscillatory superconducting transition temperature in S/F multilayers and bilayers

The damped oscillatory behavior of the superconducting order parameter in ferromagnets may produce the commensurability effects between the period of the order parameter oscillation (which is of the order of ξ_{f2}) and the thickness of a F layer. This results in the striking nonmonotonous superconducting transition temperature dependence on the F-layer thickness in S/F multilayers and bilayers. Indeed, for a F-layer thickness smaller than ξ_{f2}, the pair wave function in the F layer changes a little and the superconducting order parameter in the adjacent S layers must be the same. The phase difference between the superconducting order parameters in the S layers is absent and we call this state the '0' phase. On the other hand, if the F-layer thickness becomes of the order of ξ_{f2} the pair wave function may go through zero at the center of the F layer providing the state with the opposite sign (or shift of the phase) of the superconducting order parameter in the adjacent S layers, the so-called 'π' phase. The increase of the thickness of the F layers may provoke the subsequent transitions from '0' to 'π' phases, which superpose on the commensurability effect and results in a very special dependence of the critical temperature on the F-layer thickness (Buzdin and Kuprianov, 1990; Radovic *et al*., 1991). The experimental observation (Jiang, Davidović, Reich and Chien, 1995) of this unusual dependence in Nb/Gd was the first strong evidence in favor of the 'π'-phase appearance – see Figure 18.

For the S/F bilayers, the transitions between '0' and 'π' phases are impossible; nevertheless, the commensurability effect between ξ_{f2} and the F-layer thickness also leads to the nonmonotonous dependence of T_c on the F-layer thickness. Processes of the normal quasiparticle reflection at the free F-layer boundary and Andreev reflection at SF interface interfere and this results in T_c minima that is

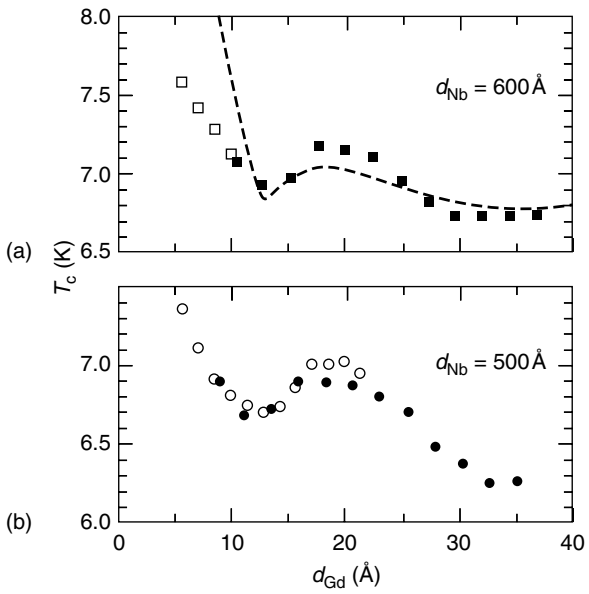

Figure 18. Oscillatory-like dependence of the critical temperature of Nb/Gd multilayers versus thickness of Gd layer (Jiang, Davidović, Reich and Chien, 1995). Dashed line in (a) is a fit using the theory (Radovic *et al*., 1991). (Reprinted figure from Jiang *et al*., *Phys, Rev. Lett.* Vol 74, 314, 1995. Copyright 1995 by the American Physical Society.)

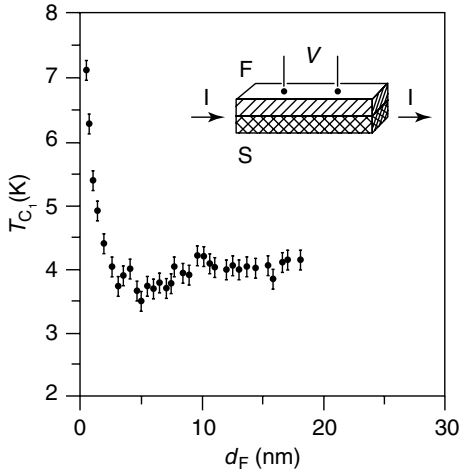

Figure 19. Critical temperature of $Nb/Cu_{0.43}Ni_{0.57}$ bilayer versus the thickness of the ferromagnetic layer (Ryazanov *et al*., 2004). (With kind permission of Springer Science and Business Media: *Journal of Low temp. Physics.*, v 136, 2004, 385, Ryazanov *et al*., figure 3.)

reached when the F-layer thickness is close to a quarter of the spatial oscillation period. The dependence of the T_c of $Nb/Cu_{0.43}Ni_{0.57}$ bilayer on the F-layer thickness (Ryazanov *et al*., 2004) is presented in Figure 19.

5.3 Superconductor-ferromagnet-superconductor 'π' junction

The experiments on the critical temperature of the S/F multilayers and bilayers attracted a lot of interest to the proximity effect in S/F systems but their interpretations were controversial due to the very small value of the characteristic length ξ_{f2} (only several nanometers). The most direct proof of the 'π'-phase observation would be the observation following the theoretical predictions (Buzdin, Bulaevskii and Panjukov, 1982; Buzdin and Kuprianov, 1991) of the vanishing of the critical current at the '0'- to 'π'-phase transition. The first experimental evidence of a '0'–'π' transition in S/F/S (Nb–Cu_xNi_{1-x}–Nb) Josephson junction was obtained in Ryazanov *et al*. (2001) from the measurements of the temperature dependence of the critical current. The '0'–'π' transition was signaled by the vanishing of the critical current with the temperature decrease. Such a behavior is observed for a F-layer thickness d close to some critical value d_c. In fact, it simply means that the critical thickness d_c slightly depends on the temperature. The temperature variation serves as fine tuning and permits one to study this transition in detail. Later, the damped oscillations of the critical current as a function of the F-layer thickness were observed in Nb/Al/Al_2O_3/PdNi/Nb (Kontos *et al*., 2002) and Nb/Cu/Ni/Cu/Nb (Blum, Tsukernik, Karpovski and Palevski, 2002) junctions. Very recent experiments (Oboznov *et al*., 2006) have enabled observation of the two-node thickness dependence of the critical current in Josephson SFS junctions with a ferromagnetic interlayer, that is, both direct transition into π state and reverse one from π into 0 state (Figure 20).

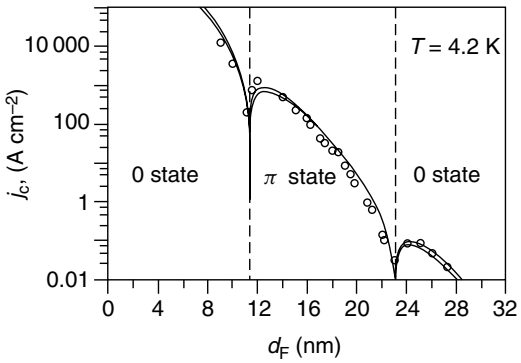

Figure 20. The double-reversal F-layer thickness dependence of the critical current density for Nb/$Cu_{0.47}Ni_{0.53}$/Nb junctions at temperature 4.2 K (Oboznov *et al*., 2006). The open circles present experimental results, the dashed line shows the fit using equation (14). (Reprinted figure from Oboznov, Buzdin *et al*., *Phys. Rev. Lett.* Vol. 96, 197003, 2006. Copyright 2006 by the American Physical Society.)

This revealed that the observed in Ryazanov, Oboznov, Veretennikov and Rusanov (2001) the '0' to 'π' transition with the F-layer thicknesses was the second one. The first transition occurs for F-layer thickness around 10 nm. The temperature dependences of the critical current near the first and the second '0' to 'π' transitions are presented in Figure 21.

The complete quantitative analysis of the S/F/S junctions is rather complicated, because the ferromagnetic layer may strongly modify superconductivity near the S/F interface. In addition, the boundary transparency and electron mean free path, as well as magnetic scattering, are important parameters affecting the critical current. In the case of small conductivity of the F layer or small interface transparency, the 'rigid boundary' conditions (Golubov, Kupriyanov and Il'ichev, 2004) are applied, and the influence of the ferromagnet on the superconducting order parameter in the electrodes may be neglected. This solution of (11) describes the $F(x)$ behavior near the critical temperature and gives the sinusoidal current-phase dependence $I_s(\varphi) = I_c \sin(\varphi)$ where φ is the phase difference on the junction. The critical current I_c passes through zero and changes its sign with the increase of the F-layer thickness.

In the most interesting limit from the practical point of view, when the F-layer thickness is $d_f > \xi_{f1}$ the universal expression for the $I_c(d_f)$ dependence is (Buzdin, 2005)

$$I_c \infty \exp\left(-\frac{d_f}{\xi_{f1}}\right) \sin\left(\frac{d_f}{\xi_{f2}} + \alpha\right) \tag{14}$$

where the angle $\pi/4 < \alpha < \pi/2$ depends on the magnetic scattering amplitude and the boundary transparencies.

Bulaevskii, Kuzii and Sobyanin (1977) pointed out that 'π' junction incorporated into a superconducting ring would generate a spontaneous current, and a corresponding magnetic flux would be half a flux quantum $\Phi_0 = h/2e$. The appearance of the spontaneous current is related to the fact that the ground state of the 'π' junction corresponds to the phase difference π and so, this phase difference will generate a supercurrent in the ring which short circuits the junction. Naturally the spontaneous current is generated if there is any odd number of 'π' junctions in the ring. This circumstance has been exploited in an elegant way (Ryazanov, Oboznov, Veretennikov and Rusanov, 2001) to provide unambiguous proof of the 'π'-phase transition. The observed half-period shift of the external magnetic field dependence of the transport critical current in triangular S/F/S arrays was observed on the '0–π' transition occurred with temperature variation.

The current-phase relation for Josephson junction is sinusoidal $I_s(\phi) = I_1 \sin(\phi)$ only near the critical temperature T_c (Abrikosov, 1988). At low temperature the higher harmonic terms appear. However, in the diffusive limit at $d_f > \xi_{f1}$

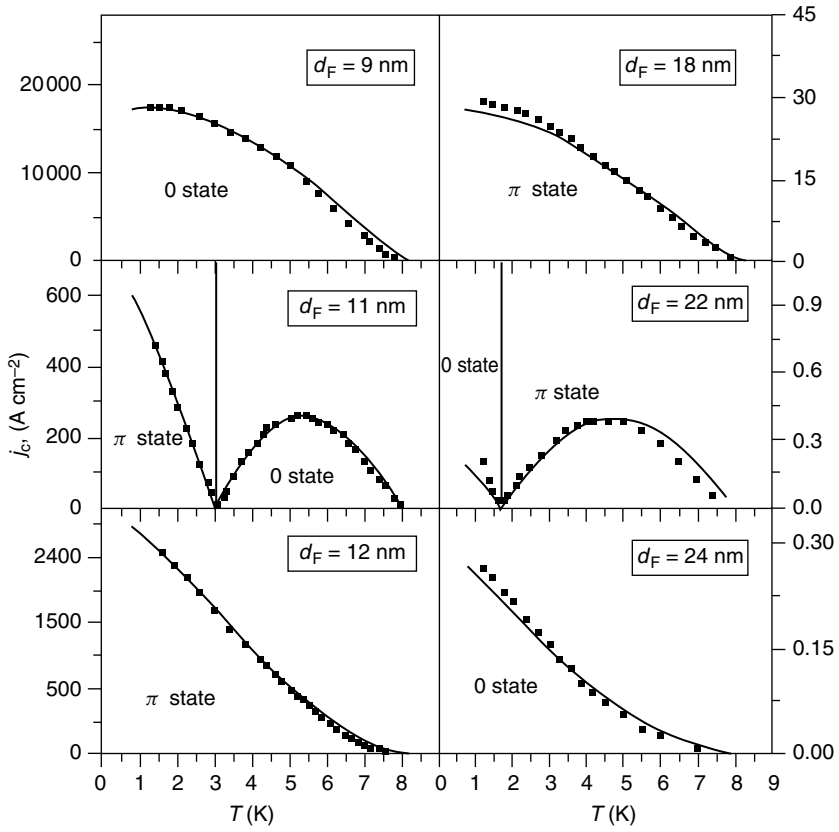

Figure 21. Temperature dependence of the Nb/$Cu_{0.47}Ni_{0.53}$/Nb junctions critical current density at several F-layer thicknesses close to the critical ones (Oboznov *et al*., 2006). The dashed lines show the calculation results based on the solution of the nonlinear Usadel equation. (Reprinted figure from Oboznov, Buzdin *et al*., *Phys. Rev. Lett.* Vol. 96, 197003, 2006. Copyright 2006 by the American Physical Society.)

they are very small and in the usual junctions their presence is hardly to be observed. In S/F/S junctions in general in the dirty limit $I_1 \sim \exp(-d_f/\xi_{f1})$ and the second harmonic contribution happens to be very small and positive $\sim \exp(-2d_f/\xi_{f1})$. The peculiarity of the situation with the '0'–'π' transition is that in the transition region the first harmonic term changes its sign passing through zero and then the role of the second harmonic contribution becomes predominant! To study the scenario of the '0'–'π' transition let us address the general current-phase relation

$$j(\varphi) = I_1 \sin(\varphi) + I_2 \sin(2\varphi) \tag{15}$$

which corresponds to the following phase dependent contribution to energy of the Josephson junction

$$E_J(\varphi) = \frac{\Phi_0}{2\pi c}\left[-I_1 \cos(\varphi) - \frac{I_2}{2}\cos(2\varphi)\right] \tag{16}$$

If we neglect the second harmonic term, then the 0 state occurs for $I_1 > 0$. Near a '0'–'π' transition $I_1 \to 0$ and the second harmonic term becomes important. The critical current at the transition $j_c = |I_2|$ and if $I_2 > 0$, the minimum energy always occurs at $\varphi = 0$ or $\varphi = \pi$.

In the opposite case ($I_2 < 0$) the transition from 0 to π state is continuous, and there is region where the equilibrium phase difference takes any value $0 < \varphi_0 < \pi$. The characteristics of such a 'φ junction' are very peculiar but at the moment there are no experimental evidences of its observation.

5.4 F /S /F spin-valve sandwiches

The strong proximity effect in superconductor-metallic ferromagnet structures could lead to the phenomenon of spin-orientation-dependent superconductivity in F/S/F spin-valve sandwiches. A long time ago De Gennes (1966) considered theoretically the system consisting of a thin superconducting layer in between two ferromagnetic insulators. He argued that the parallel orientation of the magnetic moments is more harmful for superconductivity because of the presence of the nonzero averaged exchange field acting on the surface of the superconductor. This prediction has been confirmed on

experiment by Hauser on In film sandwiched between two Fe_3O_4 films (Hauser, 1969), and on a In film between oxidized FeNi and Ni layers (Deutscher and Meunier, 1969).

A similar effect has been predicted for metallic F/S/F sandwiches (Tagirov, 1999; Buzdin, Vedyayev and Ryzhanova, 1999) and later observed on experiment in CuNi/Nb/CuNi (Gu *et al*., 2002) and Ni/Nb/Ni (Moraru *et al*., 2006) systems.

In the diffusive regime the proximity effect in S/F structures with local inhomogeneity of the magnetization may be rather special (Bergeret, Volkov and Efetov, 2005). The varying in space magnetization generates the triplet component of the anomalous Green's function $\sim \langle \Psi_\uparrow \Psi_\uparrow \rangle$ which may penetrate in the ferromagnet at distances much larger than ξ_f. It is not, however, the triplet superconductivity itself because the corresponding triplet order parameter would be equal to zero, unlike the superfluidity in He^3, for example. In general, the triplet components of the anomalous Green's function always appear at the description of the singlet superconductivity in the presence of rotating in space exchange field. An important finding (Bergeret, Volkov and Efetov, 2005) was the demonstration that in some sense the triplet component is insensitive to pair breaking by the exchange field and can generate the triplet long-range proximity effect. The special long-range triplet proximity effect was predicted to exist in the dirty limit. In the clean limit it disappears, the spin-orbit and magnetic scattering also destroy this effect. Up to know there are no reports on its experimental observation.

The proximity effect is related to the passing of electrons across the superconductor/ferromagnet interface. In addition to this effect if the magnetic field created by the ferromagnet penetrates into a superconductor, it switches on the orbital mechanism of superconductivity and magnetism interaction. The situation when it is the only one mechanism of superconductivity and magnetism interaction is naturally realized in the case, when the ferromagnet is an insulator or the buffer oxide layer separates the superconductor and the ferromagnet. The ferromagnet in such a case plays the role of the additional source of the local magnetic field. In particular the nucleation of superconductivity in the presence of domain structure occurs near the domain walls (Buzdin and Mel'nikov, 2003; Moshchalkov, Ducan, Gobulovic and Mathieu, 2006). The hybrid S/F systems have been intensively studied in connection with the problem of the controlled flux pinning. Enhancement of the critical current has been observed experimentally for superconducting films with arrays of submicron magnetic dots and antidotes (as a review on this subject see Lyuksyutov and Pokrovsky, 2005).

During the last 5 years an enormous progress in the controllable fabrication of the superconductor-ferromagnet heterostructures has been achieved. The peculiar effects predicted earlier were observed in experiments and we have a general understanding of the mechanism of the superconductivity and ferromagnetism interplay in S/F systems. Now this domain of research enters into a period where design of new types of devices becomes feasible and we may expect a lot of interesting findings in the near future.

6 CONCLUSION AND PERSPECTIVES

The RE ternary and quaternary compounds display a rich physics of magnetism and singlet superconductivity coexistence. The reentrant superconductivity and the nonuniform magnetic structure formation in $ErRh_4B_4$ and $HoMo_6S_8$ compounds may be very well described in the framework of the existing theoretical background. It exists a good understanding of the physics of the antiferromagnetic superconductors with localized magnetic moment. On the other hand, a substantial theoretical progress is needed to attend a breakthrough in the problems of the interplay between the itinerant magnetism and superconductivity and heavy-fermion superconductivity.

The studies of HFC have opened the field of unconventional superconductivity. The domain which had been in a shadow during the rush on high T_c superconductors knows again a new boost with the discovery of new materials (the 1,1,5 cerium family, uranium ferromagnetic superconductors, the interplay of superconductivity with multipolar ordering), and also with the necessity to make precise the role of quantum critical points on superconductivity with fine P or H tuning (conditions often easy achieved in HFC). For the general problems under debate on the unconventional superconductivity and its links with normal phase properties, HFCs are excellent systems to observe in great detail SC interplay with the magnetic and valence phase diagrams. Key questions are:

- the evolution of the Fermi surface in the vicinity of P_C^* or P_C,
- the role of impurities on the magnetic and SC boundaries,
- direct observation of first order transition (search for discontinues in volume or sublattice magnetization),
- unambiguous evidence of a valence transition (progress in the resolution of high energy spectroscopy are promising) for the mechanism
- the development of a new generation of measurements for the determination of the order parameter under pressure.

Finally the artificial superconductor-ferromagnet heterostructures provide a possibility to study the interplay between

superconductivity and magnetism in a controlled manner. The oscillatory behavior of the Cooper pair wave function in ferromagnet permits fabrication of the new type of Josephson junction – 'π junction' which opens an interesting perspective for the potential applications of these S/F heterostructures.

General Micromagnetic Theory

Helmut Kronmüller
Max-Planck-Institut für Metallforschung, Stuttgart, Germany

1 INTRODUCTION

The continuum theory of micromagnetism, which was developed in the 1930s and 1940s, was intended to bridge the gap between the phenomenological Maxwell's theory of electromagnetic fields and quantum theory based on atomic backgrounds. In Maxwell' s theory material properties are described by global permeabilities and susceptibilities valid for macroscopic dimensions. On the other hand quantum theory allows a description of magnetic properties on the atomistic level. Both theories are not suitable to describe cooperative and interactive phenomena such as macroscopic magnetization processes or hysteresis loops of ordered spin structures. The requirement to bridge the gap between Maxwell's theory and quantum theory became very urgent after Barkhausen's experiment known as *Barkhausen's jumps* (Barkhausen, 1919) and Sixtus' and Tonks' experiment on the domain wall velocity (Sixtus and Tonks, 1931).

A further landmark that proved the existence of the so-called Weiss domains (Weiss, 1907) was the Bitter experiment (Bitter, 1931), where by using the dipolar interactions between magnetic ferrofluids and the magnetic stray fields exerting from domain walls the domain patterns were clearly visible.

After the explanation of ferromagnetism by Heisenberg (1928) and Dirac (1928) on the basis of exchange interactions, the door was wide opened toward a mesoscopic theory of magnetism combining Maxwell's and quantum theory. A first attempt to treat inhomogeneous magnetic states is due to Bloch (1932) who showed that as a consequence of exchange interactions the transition regions between the Weiss domains have a finite width. Actually Bloch considered a type of domain wall, today called *Néel wall*; however, Bloch neglects the dipolar stray field energy, thus obtaining the result of the stray field free domain wall, now called the *Bloch wall*. The different type of domain walls have been outlined later by Néel (1955a,b), who gave a first approximate calculation of the so-called Néel wall.

The breakthrough toward a continuum theory of magnetism is due to Landau and Lifshitz (1935), who derived a continuum expression for the exchange energy and gave a first interpretation of domain patterns. In this context, the work by Akulov (1928–1931) should be mentioned, who derived continuum expressions for the magnetocrystalline energy. For a further development of the mesoscopic theory, the book by Becker and Döring (1939) became very important. Here for the first time the interaction between magnetization and the microstructure has been considered by the derivation of the so-called magnetoelastic coupling energy for cubic crystals.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

It was the progress made in the 1930s with respect to microstructures, for example, the definition of dislocations as the sources of internal strains, which inspired W. F. Brown to publish in 1940 and 1941 two basic papers from which the modern theory of micromagnetism emerged (Brown, 1940, 1941). Brown in these papers for the first time considered the effect of local perturbations of the direction of magnetization on the law of approach to ferromagnetic saturation in order to find an explanation for the 1/H term usually found experimentally. There were further papers by Kittel, Stoner–Wohlfarth, Néel, Aharoni, Strikman, Treves and of course also Brown in the 1950s, who established the theory of micromagnetism as an efficient tool to describe magnetization processes and the characteristic properties of the hysteresis loop.

Whereas in the second half of the twentieth century micromagnetism was applied mainly to the classical problems of ferromagnetic materials in the twenty-first century the problems of magnetoelectronics and spintronics became relevant. Here the recent developments in computational micromagnetism play an important role. These techniques allow solutions of the nonlinear micromagnetic equations, determination of spin distribution of magnetic ground states, the determination of single-domain configurations and vortex states as well as the investigation of the dynamics of magnetization processes. These theories represent the content of different articles of Volume II.

2 MAGNETIC GIBBS FREE ENERGY

2.1 General remarks

Within the framework of micromagnetism the magnetic state is fully described if for given temperature, applied field, and elastic stresses the distribution of the spontaneous polarization $\boldsymbol{J}_\mathrm{s}(\boldsymbol{r})$, or of the spontaneous magnetization, $\boldsymbol{M}_\mathrm{s}(\boldsymbol{r})$ are well defined by the modulation and their direction cosines $\gamma_i(\boldsymbol{r})$. The spontaneous polarization

$$\boldsymbol{J}_\mathrm{s}(\boldsymbol{r}) = \mu_0 \boldsymbol{M}_\mathrm{s}(\boldsymbol{r}) = |J_\mathrm{s}(\boldsymbol{r})| \sum_{i=1}^{3} \boldsymbol{i}_i \gamma_i(\boldsymbol{r}) \tag{1}$$

is related to the z-component of S_z, of the spin, $\boldsymbol{S}$, of the magnetic ion at position, $\boldsymbol{r}$, by

$$\boldsymbol{J}_\mathrm{s}(\boldsymbol{r}) = \mu_0 \boldsymbol{M}_\mathrm{s}(\boldsymbol{r}) = g\mu_\mathrm{B} S_z(\boldsymbol{r})/\Omega(\boldsymbol{r}) \tag{2}$$

with g the Landé factor given by $\simeq 2$ in case of metal systems with quenched orbital moments, μ_B the Bohr magneton and $\Omega(\boldsymbol{r})$ the local atomic volume per magnetic ion. The local magnetic moment being given by $g\mu_\mathrm{B} S_z(\boldsymbol{r})$.

Micromagnetism in general deals with the determination of the polarization vector $\boldsymbol{J}_\mathrm{s}(\boldsymbol{r})$. Depending on the type of problem either the direction cosines $\gamma_i(\boldsymbol{r})$ or spatial average $\langle \gamma_i(\boldsymbol{r}) \rangle_\mathrm{r}$ or even the spatial and the thermal averages $\langle \langle \gamma_i(\boldsymbol{r}) \rangle_\mathrm{r} \rangle_\mathrm{T}$ have to be determined. The basis for these calculations is the Gibbs free energy with the free variable temperature T, elastic stress tensor $\boldsymbol{\sigma}$, and applied magnetic field $\boldsymbol{H}_\mathrm{ext}$. In terms of energy densities the total Gibbs free energy density is given by

$$\phi'_\mathrm{t} = U - TS - \boldsymbol{\sigma} \cdot \cdot \boldsymbol{\varepsilon} - \boldsymbol{J}_\mathrm{s} \cdot \boldsymbol{H}_\mathrm{ext} \tag{3}$$

Here U, S, $\boldsymbol{\varepsilon}$, and $\boldsymbol{\sigma}$ denote the internal energy density, the entropy per unit volume, the strain tensor, and the stress tensor, respectively. The free energy $U - TS$ includes the exchange, magnetocrystalline, dipolar and magnetoelastic energies as well as the Ginzburg–Landau ordering energy. The last two terms denote the elastic and magnetostatic interaction energies. In the thermodynamic equilibrium the total Gibbs free energy corresponds to a minimum, that is,

$$\delta\phi_\mathrm{t} = \delta \int_V \phi'_\mathrm{t} \, \mathrm{d}V = 0 \tag{4}$$

where at constant T, $\boldsymbol{\sigma}$ and $\boldsymbol{H}_\mathrm{ext}$ the variation has to be performed with respect to the internal magnetic variables of the system. In case where only the angular distribution of $\boldsymbol{J}_\mathrm{s}$ is of interest, the variation of ϕ_t is taken with respect to the direction cosines γ_i or the components $J_{\mathrm{s},i}$ where $|\boldsymbol{J}_\mathrm{s}|$ or $|\boldsymbol{M}_\mathrm{s}|$ are kept constant. Considering the magnetic phase transition at the Curie temperature, T_C, the variation is taken with respect to the components $J_{\mathrm{s},i}$ or $M_\mathrm{s,i}$ leading to the well-known results of the Landau theory (Landau and Lifshitz, 1971), for example, the critical exponents of the molecular field theory (Kronmüller and Fähnle, 1980; Fähnle and Kronmüller, 1980; Herzer, Fähnle, Egami and Kronmüller, 1980; Fähnle, 1981).

Micromagnetism is based on continuum theoretical expressions for the intrinsic energy terms contained in the internal energy U. These terms are either derived from symmetry considerations or by a continuation of quantum theoretical expressions by replacing, for example, localized spins S_z by $\boldsymbol{J}_\mathrm{s}$ according to equation (2). In the following we summarize all continuum theoretical expressions required for the theory of micromagnetism.

2.2 Exchange energy

In order to derive the continuum expression for the exchange energy, Landau and Lifshitz (1935) calculated the exchange energy for small deviations of the magnetization from a homogeneously magnetized ground state. Because only

inhomogeneous magnetic states increase the exchange energy the first deviations, $\nabla\gamma_i$ of the direction cosines γ_i must occur quadratically in the energy expression. Both considerations are fulfilled by the differential operators $(\mathrm{grad}\boldsymbol{J})^2$, $(\mathrm{div}\boldsymbol{J})^2$ and $(\mathrm{curl}\boldsymbol{J})^2$. Kittel and Herring (1951) discussed that $(\mathrm{grad}\boldsymbol{J}_\mathrm{s})$ is the correct description of the excess exchange energy because $\mathrm{div}\boldsymbol{J}_\mathrm{s}$ and $\mathrm{curl}\boldsymbol{J}_\mathrm{s}$ would lead to zero exchange energies in case of $\mathrm{div}\boldsymbol{J}_\mathrm{s} = 0$ or $\mathrm{curl}\boldsymbol{J}_\mathrm{s} = 0$ in spite of the fact that in both cases an inhomogeneous magnetization exists.

In the case of cubic crystals or amorphous materials accordingly the exchange energy density may be written as

$$\phi'_\mathrm{ex} = A\left\{(\nabla\gamma_1)^2 + (\nabla\gamma_2)^2 + (\nabla\gamma_3)^2\right\} \tag{5}$$

The exchange stiffness constant A is related to the exchange integral $J_{i,j}$, between spin $\boldsymbol{S}_i$ and $\boldsymbol{S}_j$ at position $\boldsymbol{r}_i$ and $\boldsymbol{r}_j$. This relation may be derived by calculating the continuum expression (5) from the Heisenberg exchange Hamiltonian (Heisenberg, 1928)

$$H_\mathrm{ex} = -2\sum_{i\neq j} J_{ij}\left(\boldsymbol{r}_{ij}\right)\boldsymbol{S}_i\left(\boldsymbol{r}_i\right)\cdot\boldsymbol{S}_j\left(\boldsymbol{r}_j\right) \tag{6}$$

where J_{ij} denotes the exchange integral between the ions of spin $\boldsymbol{S}_i$ and $\boldsymbol{S}_j$ with distance $\boldsymbol{r}_{ij} = \boldsymbol{r}_j - \boldsymbol{r}_i$.

2.2.1 Short-range exchange interactions

In the case of localized electrons with small changes of the spin orientations between neighboring ions and only nearest neighbor interactions, J_0, the exchange energy density may be written as (Figure 1)

$$\phi'_\mathrm{ex} = -2S^2 J_0 \frac{1}{\Omega}\sum_{j\neq i}^{\mathrm{nn}} \cos\varphi_{ij} \tag{7}$$

where within the framework of the vector model φ_{ij} denotes the angle between neighboring spins. The expression (5) is

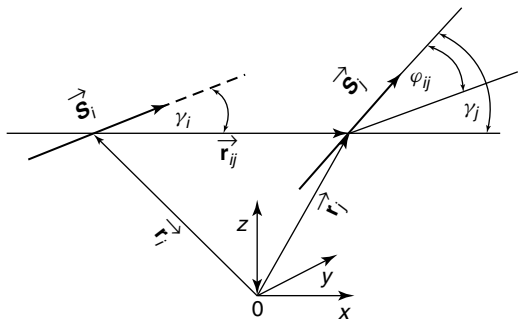

Figure 1. Spacial and angular coordinates of two neighboring spins (Kronmüller and Fähnle (2003)).

obtained from equation (7) by replacing $\cos\varphi_{ij}$ by $\cos\varphi_{ij} = \sum_{n=1}^{3}\gamma_{n,i}(r_i)\gamma_{n,j}(r_j)$ and developing $\gamma_{n,i,j}$ into the Taylor series. In the case of cubic lattices the summation over nearest neighbor ions leads to

$$A = \frac{2J_0S^2}{a}\cdot c \tag{8}$$

where the constant c is given by $c = 1$ for the cubic primitive lattice, $c = 2$ for the bcc lattice and $c = 4$ for the fcc lattice. If in the case of finite temperatures S is replaced by its thermal average $\langle S\rangle$ and necessarily by the spontaneous magnetization $M_\mathrm{s}(T)$ the exchange constant is

$$A = \frac{2J_0M_\mathrm{s}^2}{N^2g^2\mu_\mathrm{B}^2a}\cdot c \tag{9}$$

According to equation (9) the temperature dependence of A follows that of $M_\mathrm{s}^2(T)$. Since the exchange integral J_0 is related to the Curie temperature T_C, within the framework of the molecular field theory (see e.g., Morrish, 1965; Jiles, 1990) the exchange constant is given by

$$A = \frac{3k_\mathrm{B}T_\mathrm{C}S\cdot c'}{2\alpha(S+1)} \tag{10}$$

with $c = 1/6$, 1/4, 1/3 for sc, bcc, and fcc lattices. In the case of uniaxial crystals as tetragonal, trigonal, or hexagonal crystals the exchange energy is

$$\phi'_\mathrm{ex} = A_\perp\sum_{i=1,2}(\nabla\gamma_i)^2 + A_\parallel(\nabla\gamma_3)^2 \tag{11}$$

where $i = 1, 2$ refer to the coordinates perpendicular to the preferred trigonal, quaternary, or hexagonal axis (see Kronmüller and Fähnle, 2003). The exchange stiffness constants determined by equation (10) in general lead to somewhat small values because the molecular field theory neglects the low-energy spin-wave extension. Therefore, values of A either determined from the spin wave dispersion law $E = Dk^2$ as measured by inelastic neutron scattering or from specific domain wall energies are more reliable. In Table 1 experimental results for A are summarized as obtained by the latter two methods.

2.2.2 Long-range exchange interactions

The continuum expression (5) may be clarified from the Heisenberg-type exchange interaction between nearest neighbor atoms. However, in the metallic ferromagnets besides the nearest neighbor interaction exchange interaction also the so-called indirect exchange interaction may be important. This type of indirect exchange interactions originally has been

Table 1. Intrinsic magnetic material constants of transition metals, intermetallic compounds and oxides at room temperature. Values taken from Kronmüller and Fähnle (2003). (Reproduced from H. developed by Zener (1951a,b), Ruderman and Kittel (1954), Kasuya (1956), and Yosida (1957) (RKKY-interaction). The indirect exchange interaction is based on the interaction of localized spin of d or f electrons and the sea of delocalized s electrons. Localized spin moments induce an oscillating spin polarization of the s electrons. Other localized spin moments will interact with this polarization cloud. Accordingly, distant spin moments become magnetically exchange coupled via the oscillating polarization of the s electrons. If the s–d- or s–f interaction corresponds to a δ-function the effective exchange integral between the localized spin moments of distance $|\boldsymbol{r}_{ij}| \, | \, |\boldsymbol{r}_j - \boldsymbol{r}_i| = r$ according to Ruderman and Kittel (1954) is given by

$$J(r) = \frac{J_{sf}^2}{(2k_F r)^4}(2k_F r \cos 2k_F r - \sin 2k_F r) \qquad (12)$$

where k_F denotes the modulus of the Fermi wave vector and J_{sf} the exchange integral between s- and f electrons. Due to the long-range exchange interaction the energy density ϕ'_{ex} is given by the following integral:

$$\phi'_{ex}(\boldsymbol{r}) = -\frac{2}{(g\mu_B)^2} \int J\left(|\, \boldsymbol{r} - \boldsymbol{r}' \,|\right) M(\boldsymbol{r}) \cdot M(\boldsymbol{r}') \, \mathrm{d}^3\boldsymbol{r}' \quad (13)$$

where we have replaced $\boldsymbol{S}(\boldsymbol{r})$ by $\boldsymbol{M}(\boldsymbol{r})$ of equation (2). Introducing Fourier transforms

$$\begin{aligned} J(\boldsymbol{k}) &= \int J(\boldsymbol{r}) e^{i\boldsymbol{k}\cdot\boldsymbol{r}} \, \mathrm{d}^3\boldsymbol{r} \\ M(\boldsymbol{k}) &= \int M(\boldsymbol{r}) e^{i\boldsymbol{k}\cdot\boldsymbol{r}} \, \mathrm{d}^3\boldsymbol{r} \end{aligned} \qquad (14)$$

and applying the convolution theorem we obtain

$$\phi'_{ex}(\boldsymbol{r}) = -\frac{2}{(2\pi)^3 (g\mu_B)^2} \frac{1}{\Omega} \int J(\boldsymbol{k}) M(\boldsymbol{k}) \cdot M(-\boldsymbol{k}) \, \mathrm{d}^3\boldsymbol{k} \qquad (15)$$

where according to Ruderman and Kittel (1954) in case of pointlike localized spins $J(\boldsymbol{k})$ is given by

$$J(\boldsymbol{k}) = \frac{3\Omega z J_{sd}^2}{16 E_F} \left\{ 1 + \frac{4k_F - k^2}{4k_F k} \ln \frac{2k_F + k}{2k_F - k} \right\} \qquad (16)$$

(z = number of s electrons per atom, E_F = Fermi energy), J_{sd} = exchange integral between s and d electrons. Within the framework of Ruderman–Kittel's approximation $J(r)$ becomes infinite at $r \to 0$. Since the s–d or s–f interaction actually has a finite range, instead a constant J_{sd} in equation (16) a k-dependent $J_{sd}(k)$, which decreases with increasing k should be introduced. According to Yosida (1957) a suitable Ansatz for $J(k)$ is

$$\begin{aligned} J(\boldsymbol{k}) &= J(0) \qquad \text{for} \quad k \le 2k_F \\ J(\boldsymbol{k}) &= 0 \qquad\quad \text{for} \quad k > 2k_F \end{aligned} \qquad (17)$$

For $k < k_F$ we obtain from equation (16), $J(0) - J(\boldsymbol{k}) \frac{z J_{sd}^2 \Omega}{32 E_F} \frac{k^2}{k_F^2}$. Figure 2 shows the k-dependence for the Ruderman–Kittel and the Yosida model.

2.3 The magnetocrystalline anisotropy energy

The magnetic properties of spin-ordered crystals in general reveal a marked anisotropy. For example, depending on the

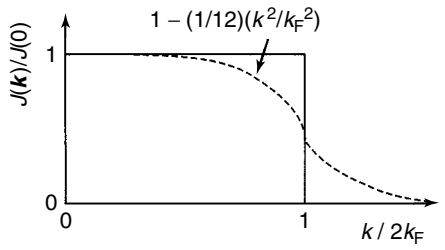

Figure 2. Fourier transform $J(\mathbf{k})$ of the indirect exchange integral for the model according to Yosida (1957) and according to Ruderman and Kittel (1954) (Kronmüller and Fähnle (2003)). (Reproduced from Ruderman & Kittel, 1954, with permisison from Cambridge University Press. © 1954.)

orientation of single crystals the saturation magnetization is approached by small or large magnetic fields. Therefore it is common to speak of hard and easy magnetic directions. The magnetocrystalline energy originates from the coupling between spin and orbital moments (L-S coupling) and the interaction between the ions and the crystal field. In 3d transition metals the orbital moments are nearly completely quenched and consequently the coupling between the orbital moments and the crystal field remains small leading to moderate magnetocrystalline energies. In contrast, in the case of intermetallic compounds, where rare-earth metals are involved, the 4-f electrons are characterized by strong L-S coupling and Hund's rules are valid, the anisotropic charge cloud of 4f electrons interacts strongly with the crystal field resulting in the largest anisotropies measured so far.

The angular dependence of the magnetocrystalline energy was derived for the first time by Akulov (1928–1931) for cubic crystals. Because the magnetocrystalline energy must be invariant with respect to rotations of $\boldsymbol{M}_\mathrm{s}$ by 180° the energy expression must be an even function of the direction cosines γ_i, which have to be taken with respect to the symmetry axes of the point group of the crystal under calculation. A general expression for the magnetocrystalline energy density is (Birss, 1964)

$$\phi'_\mathrm{k}(\boldsymbol{r}) = k_0(\boldsymbol{r}) + \sum_{i\neq j} k_{ij}(\boldsymbol{r})\gamma_i(\boldsymbol{r})\gamma_j(\boldsymbol{r}) + \sum_{i,j,k,l} k_{ijkl}(\boldsymbol{r})\boldsymbol{\gamma}_i(\boldsymbol{r})\gamma_j(\boldsymbol{r})\gamma_h(\boldsymbol{r})\gamma_l(\boldsymbol{r}) + \cdots \quad (18)$$

With diagonalized property tensors $\boldsymbol{k}\phi'_\mathrm{k}$ becomes

$$\phi'_\mathrm{k}(r) = k_0(\boldsymbol{r}) + \sum_i k_i(\boldsymbol{r})\gamma_i^2(r) + \sum_i k_{2i}(\boldsymbol{r})\gamma_i^4(\boldsymbol{r}) + \sum_{i\neq j} k_{3ij}(\boldsymbol{r})\gamma_i^2(\boldsymbol{r})\gamma_j^2(\boldsymbol{r}) + \cdots \quad (19)$$

By specifying the property tensors $\boldsymbol{k}$ to the symmetry requirements of the point groups of a crystal we may derive anisotropy expressions for cubic, hexagonal, tetragonal and orthorhombic crystals.

1. *Cubic symmetry*: (γ_i refer to cubic axes)

$$\phi'_\mathrm{k}(\boldsymbol{r}) = K_0(\boldsymbol{r}) + K_1(\boldsymbol{r})\sum_{i\neq j}\gamma_i^2(\boldsymbol{r})\gamma_j^2(\boldsymbol{r}) + K_2(\boldsymbol{r})\gamma_1^2(\boldsymbol{r})\cdot\gamma_2^2(\boldsymbol{r})\gamma_3^2(\boldsymbol{r}) \quad (20)$$

2. *Hexagonal symmetry*: Here we introduce the angle φ between $\boldsymbol{M}_\mathrm{s}$ and the hexagonal c axis (z axis) and the angle ψ of the projection of $\boldsymbol{M}_\mathrm{s}$ on the hexagonal plane taken with respect to the x axis. Equation (19) now may be rearranged as

$$\phi'_k(\boldsymbol{r}) = K_0(\boldsymbol{r}) + K_1(\boldsymbol{r})\sin^2\varphi(\boldsymbol{r}) + K_2(\boldsymbol{r})\sin^4\varphi(\boldsymbol{r}) + K_3(\boldsymbol{r})\sin^6\varphi(\boldsymbol{r}) + K_4(\boldsymbol{r})\sin^6\varphi(\boldsymbol{r})\cos(6\psi(\boldsymbol{r})) \quad (21)$$

3. *Tetragonal symmetry*: With a similar definition of the angles φ and ψ as in the hexagonal crystal we obtain

$$\phi'_\mathrm{k}(\boldsymbol{r}) = K_0(\boldsymbol{r}) + K_1(\boldsymbol{r})\sin^2\varphi(\boldsymbol{r}) + K_2(\boldsymbol{r})\sin^4\varphi(\boldsymbol{r}) + K_3(\boldsymbol{r})\sin^4\varphi(\boldsymbol{r})\cos(4\psi(\boldsymbol{r}) + \cdots \quad (22)$$

4. *Orthorhombic symmetry*: Equation (19) describes ϕ'_k for orthorhombic symmetry with the direction cosines $\gamma_i(\boldsymbol{r})$ taken with respect to the three two-fold symmetry axes.

   The so-called easy directions are determined by the extrema conditions $\partial\phi'_\mathrm{k}/\partial\gamma_i = 0$ and $\partial^2\phi'_\mathrm{k}/\partial\gamma_i^2 > 0$. Taking into account the anisotropy constants K_1 and K_2 only the easy directions for cubic crystals are the following ones:

   1. $\langle 100\rangle$ directions, $K_1 > 0, K_2 > 0; K_1 > -\frac{1}{9}K_2, K_2 < 0$.
   2. $\langle 111\rangle$ directions, $K_1 < -\frac{1}{9}K_2; K_2 < 0, K_1 < -\frac{4}{9}K_2; K_2 > 0$.
   3. $\langle 110\rangle$ directions, $-\frac{4}{9}K_2\langle K_1 < 0; K_2\rangle 0$.

   For α-Fe at RT Case 1 holds and for Ni Case 2.
   In the case of hexagonal uniaxial crystals also three types of easy directions have to be distinguished:

   1. $\langle 0001\rangle$ - directions ($\pm$c axis): $K_1 > 0; K_1 > -K_2, K_2 < 0, K_{3,4} = 0$
   2. All directions within the basal plane, $K_1 < -K_2, K_2 < 0; K_1 < -2K_2, K_2 > 0; K_{3,4} = 0$
   3. All directions on the surface of a cone with angle $\sin\varphi\sqrt{-K_1/2K_2}$; $-2K_2 < K_1 < 0; K_{3,4} = 0$.

For Co case 1 holds for $T < 520\,\mathrm{K}$, case 2 for $T > 605\,\mathrm{K}$ and case 3 for $520\,\mathrm{K} < T < 605\,\mathrm{K}$. In the case of the hard magnetic compound $Nd_2Fe_{14}B$ the c axis throughout is easy direction in spite of the fact that $K_1 < 0$ holds below 125 K because always $2K_2 > (-)K_1$ holds.

Phase diagrams of the easy directions for cubic and uniaxial crystals as function of K_1 and K_2 are shown in Figure 3.

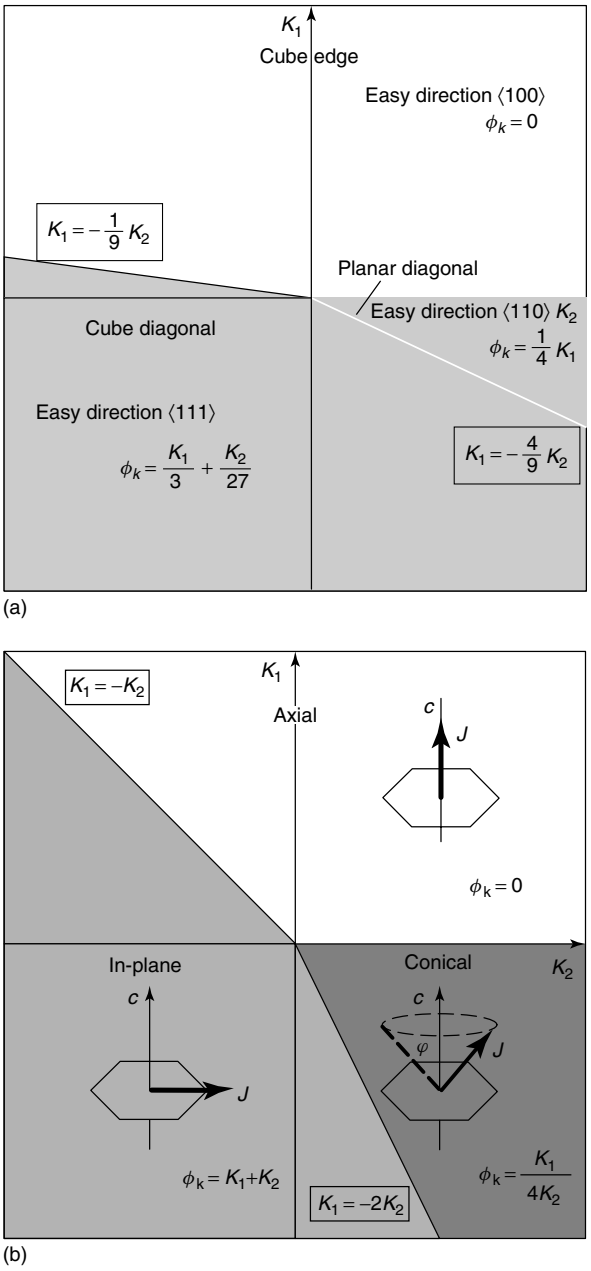

Figure 3. Phase diagrams of easy directions in (a) cubic and (b) uniaxial crystals. (Reproduced with permission from Cambridge University Press.)

2.4 Magnetostatic energies

2.4.1 External field

The magnetostatic energies are related to tow different sources of magnetic fields: The external or applied magnetic field, $\boldsymbol{H}_{\mathrm{ext}}$, and the so-called dipolar fields, $\boldsymbol{H}_{\mathrm{s}}$, resulting from magnetization $\boldsymbol{M}_{\mathrm{s}}$. The magnetostatic energy of the external field, the so-called Zeemann energy may be written as the sum of the interaction energies of local moments $\mu_i g \mu_{\mathrm{B}} \boldsymbol{S}_i(\boldsymbol{r})$ with the external magnetic flux density $\boldsymbol{B}_{\mathrm{ext}}$ giving

$$\phi'_{\mathrm{h}} = -g\mu_{\mathrm{B}} \sum_i \boldsymbol{S}_i(\boldsymbol{r}) \cdot \boldsymbol{B}_{\mathrm{ext}} = g\mu_{\mathrm{B}}\mu_0 \sum_i \boldsymbol{S}_i(\boldsymbol{r}_i) \cdot \boldsymbol{H}_{\mathrm{ext}} \tag{23}$$

By using equation (2) the magnetostatic energy density is,

$$\phi'_{\mathrm{h}} = -\mu_0 \boldsymbol{H}_{\mathrm{ext}}(\boldsymbol{r}) \cdot \boldsymbol{M}_{\mathrm{s}}(\boldsymbol{r}) = -\boldsymbol{H}_{\mathrm{ext}}(\boldsymbol{r}) \cdot \boldsymbol{J}_{\mathrm{s}}(\boldsymbol{r}) \tag{24}$$

2.4.2 Dipolar fields

The role of dipolar fields in magnetism and in particular for the formation of domain patterns has been outlined by Landau and Lifshitz (1935) and Kittel and Galt (1956). Brown (1962) considered the role of dipolar fields, also denoted as stray fields, in the case of micromagnetic problems. In particular, Brown (1962) gave an extensive description of magnetostatic principles. Within the framework of an atomistic description of magnetic moments $\boldsymbol{\mu}_i(\boldsymbol{r})_i = g\mu_{\mathrm{B}} \boldsymbol{S}_i(\boldsymbol{r}_i)$ the macroscopic stray field is determined by a sum over all dipole fields of the magnetic moments $\mu_i(\boldsymbol{r}_i)$.

$$\boldsymbol{H}_{\mathrm{s}}(\boldsymbol{r}) = \frac{1}{4\pi} \sum_i \left(\frac{\boldsymbol{\mu}_i(\boldsymbol{r}_i)}{R^3} - \frac{3\left(\boldsymbol{\mu}_i(\boldsymbol{r}_i) \cdot \boldsymbol{R}\right) \cdot \boldsymbol{R}}{R^5} \right) \tag{25}$$

with $\boldsymbol{R} = \boldsymbol{r} - \boldsymbol{r}_i$. In the continuum theory of micromagnetism the calculation of stray fields starts from the Maxwell equation

$$\mathrm{div}\boldsymbol{B} = 0 \tag{26}$$

where in the case of $\boldsymbol{H}_{\mathrm{ext}} = 0$ the magnetic flux density $\boldsymbol{B}$ is given by

$$\boldsymbol{B}(\boldsymbol{r}) = \mu_0 \boldsymbol{H}_{\mathrm{s}}(\boldsymbol{r}) + \mu_0 \boldsymbol{M}_{\mathrm{s}}(\boldsymbol{r}) = \mu_0 \boldsymbol{H}_{\mathrm{s}}(\boldsymbol{r}) + \boldsymbol{J}_{\mathrm{s}}(\boldsymbol{r}) \tag{27}$$

Since $\boldsymbol{H}_{\mathrm{s}}$ derives from magnetic dipoles the condition curl $\boldsymbol{H}_{\mathrm{s}} = 0$ holds, and $\boldsymbol{H}_{\mathrm{s}}$ derives from a scalar potential $U(\boldsymbol{r})$ according to

$$\boldsymbol{H}_{\mathrm{s}}(\boldsymbol{r}) = -\nabla U(\boldsymbol{r}) \tag{28}$$

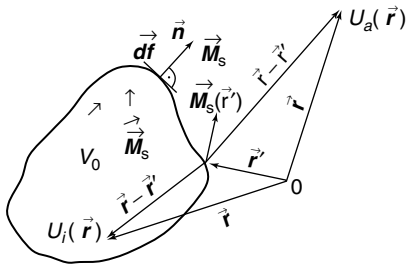

Figure 4. Spacial coordinates and integration variables for the internal potential $U_i(\boldsymbol{r})$ and the external potential $U_a(\boldsymbol{r})$ due to surface charges $\sigma(\boldsymbol{r}') = \boldsymbol{M}_s(\boldsymbol{r}') \cdot \boldsymbol{n}$.

With equation (26) $U(\boldsymbol{r})$ derives from the Poisson equation

$$\Delta U = \text{div } \boldsymbol{M}_s(\boldsymbol{r}) = \frac{1}{\mu_0}\text{div}\boldsymbol{J}_s(\boldsymbol{r}) = -\rho(\boldsymbol{r}) \qquad (29)$$

where we have introduced the magnetic charge density $\rho(\boldsymbol{r}) = -\text{div}\boldsymbol{M}_s(\boldsymbol{r})$. The notation stray field for $\boldsymbol{H}_s$ becomes evident from the Poisson equation, which shows that $\boldsymbol{H}_s$ exists only in cases of a spatially inhomogeneous $\boldsymbol{M}_s$ either in orientation or in the modulus $\mid \boldsymbol{M}_s(\boldsymbol{r}) \mid$. The general solution of Poisson's equation is written as the sum of a volume (V_0) and a surface S integral

$$U(\boldsymbol{r}) = \frac{1}{4\pi}\int_{V_0}\frac{\rho(\boldsymbol{r}')}{\mid \boldsymbol{r}-\boldsymbol{r}' \mid}\text{d}^3\boldsymbol{r}' + \frac{1}{4\pi}\int_S \frac{\boldsymbol{\sigma}(\boldsymbol{r}')\cdot\text{d}f'}{\mid \boldsymbol{r}-\boldsymbol{r}' \mid} \qquad (30)$$

The first term in equation (30) takes care of the volume charges and the second term takes into account the surface charges $\sigma(\boldsymbol{r})\boldsymbol{n} \cdot \boldsymbol{M}_s(r')$ as shown presented in Figure 4.

The magnetostatic strayfield is related with a magnetostatic self-energy density, also denoted as dipolar energy given by

$$\phi'_s(r) = \frac{\mu_0}{2}\cdot\boldsymbol{H}_s^2(\boldsymbol{r}) \qquad (31)$$

In the case of discrete magnetic moment, $\boldsymbol{\mu}_i(\boldsymbol{r}_i)$, its interaction energy with all other magnetic dipoles is given by

$$\phi'^{(i)}_s(r_i) = -\mu_0\boldsymbol{\mu}_i(\boldsymbol{r}_i)\sum_{j\neq i}\boldsymbol{H}_s^{(j)}(r_i) \qquad (32)$$

where the sum extends over all field contributions $\boldsymbol{H}_s^{(j)}$ at $\boldsymbol{r}_i$ of all other dipoles j. The total stray field energy now is given by

$$\phi_s = \frac{1}{2}\sum_i \phi_s^{(i)} = -\frac{1}{2}\mu_0\sum_{j\neq i}\boldsymbol{\mu}_i(\boldsymbol{r}_i)\cdot\boldsymbol{H}_s^{(j)}(\boldsymbol{r}_i) \qquad (33)$$

where the factor 1/2 takes into account that the interaction energy between two dipoles has to be counted only once because $\boldsymbol{\mu}_i(\boldsymbol{r}_i)\boldsymbol{H}_s^{(j)}(\boldsymbol{r}_i) = \boldsymbol{\mu}_j(\boldsymbol{r}_j)\boldsymbol{H}_s^{(j)}(\boldsymbol{r}_j)$ holds. Replacing the magnetic moments by the continuum variables $\boldsymbol{M}_s$ by

$$\boldsymbol{\mu}(\boldsymbol{r}) = \boldsymbol{M}_s(\boldsymbol{r})\,\text{d}V \qquad (34)$$

equation (33) transforms into the integral

$$\phi_s = -\frac{1}{2}\int_{V_0}\boldsymbol{H}_s(\boldsymbol{r})\cdot\boldsymbol{J}_s(\boldsymbol{r})\ \text{d}^3\boldsymbol{r} = \frac{1}{2}\mu_0\int_V \boldsymbol{H}_s^2(\boldsymbol{r})\ \text{d}^3\boldsymbol{r} \qquad (35)$$

It is of interest to note that the first integral extends only over the volume of the magnet and the second one over the total space. By means of Green's theorems equation (35) may be transformed into a surface and a volume integral:

$$\phi_s = \frac{1}{2}\int_S U(\boldsymbol{r})\boldsymbol{J}_s(\boldsymbol{r})\cdot\text{d}\boldsymbol{f} - \frac{1}{2}\int_{V_0}U(\boldsymbol{r})\text{div}\ \boldsymbol{J}_s(\boldsymbol{r})\,\text{d}^3\boldsymbol{r} \qquad (36)$$

$$= \frac{1}{2}\mu_0\int_S \sigma(\boldsymbol{r})\cdot U(\boldsymbol{r})\ \text{d}f + \frac{1}{2}\mu_0\int_{V_0}U(\boldsymbol{r})\rho(\boldsymbol{r})\ \text{d}^3\boldsymbol{r}$$

In the case of a multiconnected homogeneously magnet, that is, $\rho = 0, \phi_s$ is given by a double integral

$$\phi_s = \frac{1}{8\pi}\int_s\int_S\frac{\sigma(\boldsymbol{r})\cdot\sigma(r')}{\mid \boldsymbol{r}-\boldsymbol{r}' \mid}\ \text{d}f'\text{d}f \qquad (37)$$

where the integrals extend over the surfaces f and f'. For $f = f'$ equation (37) describes the self-energy of surface charges.

2.5 Magnetostrictive energy terms

2.5.1 Strain tensors in magnetic materials

Magnetostrictive interactions between elastic stresses and the spontaneous magnetization are one of the main sources of the influence of microstructures on magnetic properties. These interactions are the origin of the pinning of domain walls, the arrangement of domains and deviations from magnetic saturation. First treatments of magnetostrictive interactions are due to Becker (1930; 1932; 1934) and Becker and Döring (1939). These results are one of the basis for the micromagnetic continuum theory as developed by Brown (1940; 1941) who introduced the concept of lattice imperfections into micromagnetism. More recent self-consistent elasticity theories of magnetostrictive interactions have been published by Brown (1966), Rieder (1959), Kronmüller (1967), and Kléman (1980). Elasticity problems in magnetostrictive materials in general are rather complex because not only the intrinsic spontaneous magnetization as described in chapter **Magnetostriction and Magnetoelasticity Theory: A Modern View, Volume 1** play a role

but also rotations of volume elements that result from magnetic torques due to the magnetocrystalline energy in the case of rotational magnetization processes. The role of these rotational processes concerning induced elastic stresses in general can be neglected (Kronmüller and Fähnle, 2003). Therefore, in the following we neglect magnetic torques that contribute to the asymmetric part of the strain tensors. The symmetric part of the strain tensor is composed of four contributions

$$\boldsymbol{\varepsilon}^{\mathrm{T}} = \boldsymbol{\varepsilon}^{\mathrm{ext}} + \boldsymbol{\varepsilon}^{\mathrm{def}} + \boldsymbol{\varepsilon}^{\mathrm{Q}} + \boldsymbol{\varepsilon}^{\mathrm{el}} \tag{38}$$

with the following origins:

1. $\boldsymbol{\varepsilon}^{\mathrm{ext}}$ = external strain tensor of applied stresses.
2. $\boldsymbol{\varepsilon}^{\mathrm{def}}$ = internal strain tensor due to defects.
3. $\boldsymbol{\varepsilon}^{\mathrm{Q}}$ = spontaneous magnetostrictive strain tensor due to spin ordering.
4. $\boldsymbol{\varepsilon}^{\mathrm{el}}$ = elastic strain tensor due to inhomogeneous magnetostrictive strain $\boldsymbol{\varepsilon}^{\mathrm{Q}}$.
5. $\boldsymbol{\varepsilon}^{\mathrm{m}} = \boldsymbol{\varepsilon}^{\mathrm{Q}} + \boldsymbol{\varepsilon}^{\mathrm{el}}$ = total strain tensor due to magnetostriction.

2.5.2 *Determination of stress tensors*

The different contributions of the strain tensors to the elastic stresses have to be determined by different methods because the spontaneous magnetostrictive strains correspond to so-called quasiplastic strains. Within the framework of linear elasticity theory Hoock's law holds:

$$\boldsymbol{\sigma} = \boldsymbol{c} \cdot \cdot \boldsymbol{\varepsilon} \tag{39}$$

where $\boldsymbol{c}$ denotes the fourth rank tensor of elastic constants. The stress tensor, $\boldsymbol{\sigma}$, is determined by the mechanical equilibrium surface conditions ($\boldsymbol{n}$ = surface normal)

$$\left.\begin{array}{ll} \mathrm{Div}\ \boldsymbol{\sigma} + \boldsymbol{f} & = 0 \\ \boldsymbol{n} \cdot \boldsymbol{\sigma}^{\mathrm{ext}}|_{\mathrm{surface}} & \boldsymbol{F}_{\mathrm{surface}} \end{array}\right\} \tag{40}$$

where $\boldsymbol{f}$ corresponds to the volume forces and $\boldsymbol{F}_{\mathrm{surface}}$ to the surface forces. The elastic strain and stress fields $\boldsymbol{\varepsilon}^{\mathrm{def}}$ and $\boldsymbol{\sigma}^{\mathrm{def}}$ of defects are well known. For example, in case of linear dislocations the stress field components vary as $1/r$ and in case of point defects as $1/r^3$. External stresses in general lead to homogeneous stress states if the samples shape is prismatic or cylindrical.

The calculation of the elastic strain fields due to inhomogeneous spontaneous magnetostrictions $\boldsymbol{\varepsilon}^{\mathrm{Q}}$, requires special considerations because just these strains usually are omitted in micromagnetic problems.

The spontaneous magnetostrictive strains $\boldsymbol{\varepsilon}^{\mathrm{Q}}$ have been derived by Becker and Döring (1939) with the components

$$\varepsilon_{ij}^{\mathrm{Q}} = \lambda_{ijkl}\gamma_k\gamma_l \tag{41}$$

where Einstein's sum convention holds (summation from $i = 1$ to 3 if a suffix appears twice). The fourth rank tensor, $\boldsymbol{\lambda}$, possesses the symmetry of the atomic structure, that is, the crystal symmetry or short-range order in otherwise disordered materials. For cubic crystals $\boldsymbol{\varepsilon}^{\mathrm{Q}}$ is given by:

$$\boldsymbol{\varepsilon}^{\mathrm{Q}} = \begin{pmatrix} \frac{3}{2}\lambda_{100}\left(\gamma_i^2 - \frac{1}{3}\right) & \frac{3}{2}\lambda_{111}\gamma_i\gamma_2 & \frac{3}{2}\lambda_{111}\gamma_i\gamma_3 \\ \frac{3}{2}\lambda_{111}\gamma_1\gamma_2 & \frac{3}{2}\lambda_{100}\left(\gamma_2^2 - \frac{1}{3}\right) & \frac{3}{2}\lambda_{111}\gamma_2\gamma_3 \\ \frac{3}{2}\lambda_{111}\gamma_1\gamma_3 & \frac{3}{2}\lambda_{111}\gamma_2\gamma_3 & \frac{3}{2}\lambda_{100}\left(\gamma_3^2 - \frac{1}{3}\right) \end{pmatrix} \tag{42}$$

The magnetostriction constants λ_{100} and λ_{111} have the following meaning: λ_{100} corresponds to the fractional length change upon saturation in ⟨100⟩-direction and λ_{111} has the same meaning for saturation in ⟨111⟩-direction. In the case of hexagonal crystals we deal with four magnetostriction constants and a magnetostriction tensor given by:

$$\boldsymbol{\varepsilon}^{\mathrm{Q}} = \begin{pmatrix} \left(\lambda_{11}\gamma_i^2 + \lambda_{12}\gamma_2^2\right) & \left(\lambda_{11} - \lambda_{12}\right)\gamma_i\gamma_2 & \frac{1}{2}\lambda_{44}\gamma_i\gamma_3 \\ & \left(\lambda_{12}\gamma_1^2 + \lambda_{11}\gamma_2^2\right) & \frac{1}{2}\lambda_{44}\gamma_2\gamma_3 \\ & & \lambda_{33}\gamma_3^2 \end{pmatrix} \tag{43}$$

Isotropic or amorphous materials are characterized by diagonal components

$$\varepsilon_{ii} = \frac{3}{2}\lambda_{\mathrm{s}}\left(\gamma_i^2 - \frac{1}{3}\right), \quad i = 1, 2, 3 \tag{44}$$

and off-diagonal components

$$\varepsilon_{ij}^{\mathrm{Q}} = \frac{3}{2}\lambda_{\mathrm{s}}\gamma_i\gamma_j, \quad i \neq j \tag{45}$$

with λ_{s} the isotropic magnetostrictive constant. The elastic stresses $\boldsymbol{\sigma}^{\mathrm{m}}$ due to the elastic strains $\boldsymbol{\varepsilon}^{\mathrm{el}}$ follow from the condition that the total strain $\boldsymbol{\varepsilon}^{\mathrm{m}}\boldsymbol{\varepsilon}^{\mathrm{Q}} + \boldsymbol{\varepsilon}^{\mathrm{el}}$ can be derived from a displacement field, $\boldsymbol{s}^{\mathrm{m}}$, according to

$$\boldsymbol{\varepsilon}^{\mathrm{m}} = \mathrm{Def}\ \boldsymbol{s}^{\mathrm{m}} \tag{46}$$

where the definition of the operator Def follows from

$$\varepsilon_{ij}^{\mathrm{m}} = \frac{1}{2}\left(\frac{\partial s_i^{\mathrm{m}}}{\partial x_j} + \frac{\partial s_j^{\mathrm{m}}}{\partial x_i}\right) \tag{47}$$

and the elastic stress due to magnetostriction is given by

$$\boldsymbol{\sigma}^{\mathrm{m}} = \boldsymbol{c} \cdot \cdot \boldsymbol{\varepsilon}^{\mathrm{el}} \tag{48}$$

$\boldsymbol{\sigma}^{\mathrm{m}}$ obeys the mechanical equilibrium condition

$$\mathrm{Div}\ \boldsymbol{\sigma}^{\mathrm{m}} = 0 \tag{49}$$

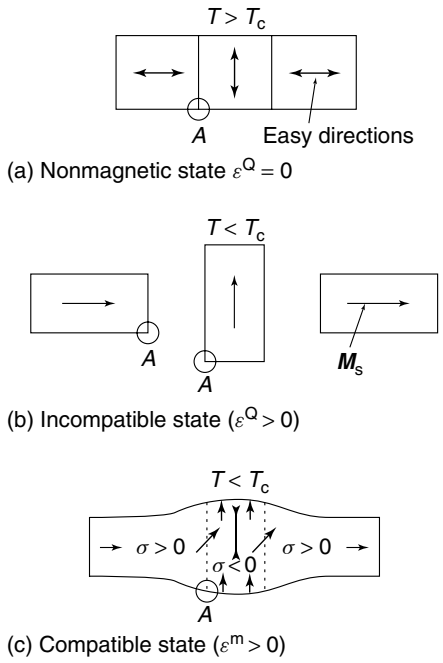

Figure 5. Formation of elastic strains by inhomogeneous spontaneous magnetostrictive strains. The cutting model demonstrates the existence of elastic strains due to the connection of the sites A. (Reproduced with permission from Cambridge University Press.)

and since equation (47) holds

$$\text{Div}\ (\boldsymbol{c}\cdot\cdot\boldsymbol{\varepsilon}^{\text{el}}) = \text{Div}\ \boldsymbol{c}\cdot\cdot\text{Def}\,\boldsymbol{s}^{\text{m}}) - \text{Div}\ (\boldsymbol{c}\cdot\cdot\boldsymbol{\varepsilon}^{\text{Q}}) = 0 \tag{50}$$

The three sets of equations (50) do not allow the determination of the six components $\varepsilon_{ij}^{\text{m}}$. Since $\boldsymbol{\varepsilon}^{\text{m}}$ derives from $\boldsymbol{\varepsilon}^{\text{m}}\text{Def}\boldsymbol{s}^{\text{m}}$, additional relations hold for $\boldsymbol{\varepsilon}^{\text{m}}$, which may be written in the comprehensive form

$$\text{Ink}\ \boldsymbol{\varepsilon}^{\text{m}} = \nabla\times\boldsymbol{\varepsilon}^{\text{m}}\times\nabla = 0 \tag{51}$$

Equation (51) takes into account that the total strain tensor $\boldsymbol{\varepsilon}^{\text{m}}$ describes a compatible continuous deformation without discontinuities. The combination of equations (51) and (50) leads to the so-called Beltrami equations (Kröner, 1958), which for elastic anisotropy is written as (G = shear modulus, ν = Poisson ratio, $\delta_{ij} = 0$ for $i \neq j$, $\delta_{ij} = 1$ for $i = j$, $\sigma_{kk} = \sum_{i=1}^{3}\sigma_{ii}^{\text{m}}$):

$$\Delta\sigma_i + \frac{\nu}{1+\nu}\left(\nabla_i\,\nabla_j\sigma_{kk}^{\text{m}} - \Delta\sigma_{kk}^{\text{m}}\right) = 2G\eta_{ij}^{\text{Q}} \tag{52}$$

where the incompatibility tensor $\boldsymbol{\eta}^{\text{Q}}$ is defined as

$$\boldsymbol{\eta}^{\text{Q}} = (-)\text{Ink}\ \boldsymbol{\varepsilon}^{\text{Q}} = \text{Ink}\boldsymbol{\varepsilon}^{\text{el}} \tag{53}$$

Equation (52) clearly shows that the sources of the elastic magnetostrictive stresses are inhomogeneous spontaneous magnetostrictions. In order to obtain a direct understanding of the formation of elastic magnetostrictive strains the magnetoelastic potential is magnetized homogeneously. Starting from a hypothetical nonmagnetic material with $\boldsymbol{\varepsilon}^{\text{Q}} \equiv 0$ above the Curie temperature, below the Curie temperature spontaneous magnetostrictive strains $\boldsymbol{\varepsilon}^{\text{Q}}$ are formed. In the case of a homogeneously magnetized specimen with $\boldsymbol{\varepsilon}^{\text{Q}} = \text{const}$ no elastic stresses are induced. As shown in Figure 5, in the case of an inhomogeneous magnetization, the different parts of the specimen suffer incompatible spontaneous deformations which develop freely of the specimen is cut into individual parts. According equation (46), however, the displacement field should be continuous without any cracks. According to Figure 5, the individual parts have to be fitted together in order to keep up a continuous displacement field.

This fitting is performed by the application of the elastic strains $\boldsymbol{\varepsilon}^{\text{el}}$, which guarantee the compatible state fulfilling the condition $\text{Ink}\,\boldsymbol{\varepsilon}^{\text{m}} = 0$. This consideration gives a direct insight into the stress-producing role of the incompatibility tensor $\boldsymbol{\eta}^{\text{Q}} = -\text{Ink}\,\boldsymbol{\varepsilon}^{\text{Q}}$.

2.5.3 The magnetoelastic potential – stress tensors in domain walls

In the following the magnetic Gibbs free energy is taken with respect to a hypothetical nonmagnetic state, that is, $\boldsymbol{\varepsilon}^{\text{Q}} = 0$. Below the Curie temperature $\boldsymbol{\varepsilon}^{\text{Q}}$ and its elastic stresses $\boldsymbol{\varepsilon}^{\text{el}}$ appear and the Gibbs free energy according to equation (3) is given by

$$\phi_{\text{t}} = \int\left(\phi_0 + \frac{1}{2}\ \boldsymbol{\varepsilon}^{\text{T}}\cdot\cdot\boldsymbol{c}\cdot\cdot\boldsymbol{\varepsilon}^{\text{T}} - \boldsymbol{\sigma}\cdot\cdot\boldsymbol{\varepsilon}^{\text{T}}\right)\text{d}^3\,\boldsymbol{r} \tag{54}$$

where ϕ_0 contains ϕ_{ex}', ϕ_k' and ϕ_{s}' which are assumed to be independent of strains, minimization of ϕ_{t} with respect to $\boldsymbol{\varepsilon}^{\text{T}}$ leads to Hook's law, $\boldsymbol{\sigma} = \boldsymbol{c}\cdot\cdot\boldsymbol{\varepsilon}^{\text{T}}$, and which allows to rewrite ϕ_{t} as follows:

$$\phi_{\text{t}} = \int\left(\phi_0 - \frac{1}{2}\ \boldsymbol{\varepsilon}^{\text{T}}\cdot\cdot\boldsymbol{c}\cdot\cdot,\boldsymbol{\varepsilon}^{\text{T}}\right)\text{d}^3\,\boldsymbol{r} \tag{55}$$

Inserting for $\boldsymbol{\varepsilon}^{\text{T}}$ equation (39) we may derive the different types of magnetostrictive energy terms. Excluding energy terms, which vanish after integration and taking into account only terms of magnetic origin the magnetic elastic potential is written as

$$\phi_{\text{el}} = -\frac{1}{2}\int\left\{\boldsymbol{\varepsilon}^{\text{Q}}\cdot\cdot\boldsymbol{c}\cdot\cdot\boldsymbol{\varepsilon}^{\text{Q}} - \boldsymbol{\varepsilon}^{\text{el}}\cdot\cdot\boldsymbol{c}\cdot\cdot\boldsymbol{\varepsilon}^{\text{el}}\right\}\text{d}^3\,\boldsymbol{r} - \int\left\{\boldsymbol{\varepsilon}^{\text{def}} + \boldsymbol{\varepsilon}^{\text{ext}}\right\}\cdot\cdot\boldsymbol{c}\cdot\cdot\left(\boldsymbol{\varepsilon}^{\text{Q}} + \boldsymbol{\varepsilon}^{\text{el}}\right)\ \text{d}^3\,\boldsymbol{r} \tag{56}$$

Here the first two terms correspond to self energies of the free spontaneous magnetostrictive strains and of the elastic magnetostrictive strains induced by inhomogeneous spontaneous magnetization. The third term describes interactions between external and defect stresses and the magnetostrictive strains. In order to understand this complex situation we consider three characteristic cases:

1. *Ideal homogeneously magnetized ferromagnet without defects*: In this case no elastic stresses exist, $\boldsymbol{\varepsilon}^{\mathrm{ext}}$, $\boldsymbol{\varepsilon}^{\mathrm{def}}$, $\boldsymbol{\varepsilon}^{\mathrm{el}} = 0$).

$$\phi_{\mathrm{el}} = -\frac{1}{2}\int \boldsymbol{\varepsilon}^{\mathrm{Q}} \cdot\cdot \boldsymbol{c} \cdot\cdot \boldsymbol{\varepsilon}^{\mathrm{Q}}\ \mathrm{d}^3 r \tag{57}$$

   This energy term corresponds to a contribution to the magnetocrystalline energy ϕ_{k}. Inserting $\boldsymbol{\varepsilon}^{\mathrm{Q}}$'s for cubic crystals gives for the elastic energy density

$$\phi'_{\mathrm{el}} = \left\{\frac{9}{4}\ (\mathrm{c}_{11} - \mathrm{c}_{12})\ \lambda_{100}^2 - \frac{9}{4}\ \mathrm{c}_{44}\ \lambda_{111}^2\right\}\ \sum_{i\neq j}\gamma_i^2\,\gamma_j^3 \tag{58}$$

   where c_{ij} corresponds to the cubic elastic constants in Voigt's notation. ϕ_{el} has the symmetry of the magnetocrystalline energy and therefore adds to ϕ_k.
2. *Inhomogeneous magnetization without defects*: Inhomogeneous states of magnetization exist in domain walls, in small particles and in the form of vortices and at the edges and corners of polyhedral small particles. If no defects and external stresses are present, the elastic potential is given by

$$\phi_{\mathrm{el}} = -\frac{1}{2}\int \left\{\boldsymbol{\varepsilon}^{\mathrm{Q}} \cdot\cdot \boldsymbol{c}, \cdot\cdot\ \boldsymbol{\varepsilon}^{\mathrm{Q}} - \boldsymbol{\varepsilon}^{\mathrm{el}} \cdot\cdot \boldsymbol{c} \cdot\cdot \boldsymbol{\varepsilon}^{\mathrm{el}}\right\}\ \mathrm{d}^3\,\boldsymbol{r} \tag{59}$$

   In equation (59) the elastic magnetostrictive self-energy appears, which is of particular interest for domain walls that otherwise would split up into two partial domain walls (e.g., (100)–180°-walls in α-Fe, or the (100)–109°-walls in Ni). For the most important domain walls in α-Fe, Ni, and Co the strain terms $\boldsymbol{\varepsilon}^{\mathrm{el}}$ have been determined. Solution of the elastic equations leads for the (001)–180° wall of the cubic α-Fe to the following stress and stress components using the coordinate system of Figure 6(a):

$$\begin{aligned}
\sigma_{11}^{\mathrm{m}} &= \frac{3}{2}\lambda_{100}(c_{11} - c_{12})\sin^2\varphi,\\
\sigma_{22}^{\mathrm{m}} &= -\frac{3}{2}\lambda_{100}(c_{11} - c_{12}\sin^2\varphi)\\
\sigma_{12}^{\mathrm{m}} &= -\frac{3}{2}\lambda_{111}c_{44}\sin 2\varphi\\
\varepsilon_{11}^{\mathrm{el}} &= \frac{3}{2}\lambda_{100}\sin^2\varphi;\ \varepsilon_{22}^{\mathrm{el}} = -\frac{3}{2}\lambda_{100}\sin^2\varphi,\\
\varepsilon_{12}^{\mathrm{el}} &= -\frac{3}{4}\lambda_{111}\sin 2\varphi
\end{aligned} \tag{60}$$

The magnetostrictive elastic self-energy density for the (100)–180° wall is given by

$$\begin{aligned}
\phi'_{\mathrm{el}} = -\frac{1}{2}\,\sigma_{ij}^{\mathrm{m}}\,\varepsilon_{ij}^{\mathrm{el}} &= \frac{9}{4}\ \lambda_{100}\ (c_{11} - c_{12})\sin^2\varphi\\
&\quad -\frac{9}{4}(\lambda_{100}(c_{11} - c_{12}) - 2\lambda_{111}c_{44})\sin^2\varphi\cos^2\varphi
\end{aligned} \tag{61}$$

In the case of an elastically and magnetically isotropic material ϕ'_{el} is found to be

$$\phi'_{\mathrm{el}} = \frac{9}{2}\,\mathrm{G}\,\lambda_{\mathrm{S}}\ \sin^2\ \varphi \tag{62}$$

These results may be used to determine specific domain wall energies in crystalline and isotropic materials.

Whereas in the case of the (100)–180° dw in α-Fe the elastic strains and stresses vanish within the domains

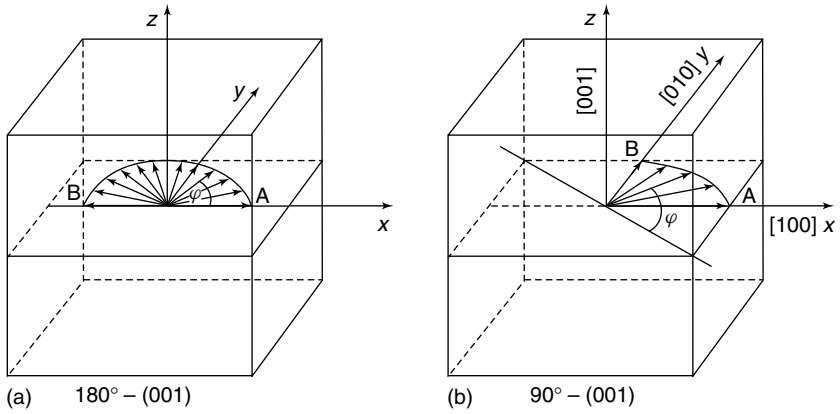

Figure 6. Coordinate systems used for the (001)–180° walls and the (001)–90° walls in cubic α-iron.

for $\varphi = 0$ and $\varphi = \pi$ the situation is different for the (001)–90° wall the geometry of which is shown in Figure 6(b). The rotation of $\boldsymbol{J}_S$ from A to B is described by the direction cosines $\gamma_1 = +\cos(\varphi - \frac{\pi}{4})$, $\gamma_2 \sin(\varphi - \frac{\pi}{4})$, $\gamma_3 = 0$. Strain and stress components are given by

$$\begin{aligned}
\varepsilon_{11}^{\mathrm{el}} &= -\frac{3}{4}\lambda_{100}\,\sin 2\varphi;\ \varepsilon_{22}^{\mathrm{el}} = \frac{3}{4}\lambda_{100}\sin 2\,\varphi;\\
\varepsilon_{12} &= -\frac{3}{4}\lambda_{111}\cos 2\varphi\\
\sigma_{11}^{\mathrm{m}} &= -\frac{3}{4}\lambda_{100}(c_{11}-c_{12})\sin 2\varphi,\\
\sigma_{22}^{\mathrm{m}} &= \frac{3}{4}\lambda_{100}(c_{11}-c_{12})\sin 2\varphi\\
\sigma_{12}^{\mathrm{m}} &= -\frac{3}{2}\lambda_{111}c_{44}\cos 2\varphi
\end{aligned} \tag{63}$$

Within the domains at $\varphi = \frac{\pi}{4}$ and $\varphi = \frac{3\pi}{4}$ the stress components are

$$\begin{aligned}
\sigma_{11}^{\mathrm{m}} &= -\frac{3}{4}\lambda_{100}\,(c_{11}-c_{12}) = -\sigma_{22}^{\mathrm{m}};\quad \sigma_{12}^{\mathrm{m}} = 0\\
\sigma_{11}^{\mathrm{m}} &= \frac{3}{4}\lambda_{100}\,(c_{11}-c_{12}) = -\sigma_{22}^{\mathrm{m}};\quad \sigma_{12}^{\mathrm{m}} = 0
\end{aligned} \tag{64}$$

According to equation (64) the elastic magnetostrictive stresses are finite within the domains. As a consequence this type of dws = domain walls are exposed to strong interactions with stress centers as, for example, dislocations. Therefore 90°-walls in general are less mobile than 180°-walls.

3. *Homogeneous magnetization and external* $\boldsymbol{\sigma}^{\mathrm{ext}}$ *or internal,* $\boldsymbol{\sigma}^{\mathrm{def}}$*, stresses:* In the case of a homogeneously magnetized ferromagnet exposed to external or internal stresses the elastic potential is written as

$$\phi_{\mathrm{el}} = -\frac{1}{2}\int \boldsymbol{\varepsilon}^{\mathrm{Q}}\cdot\cdot\boldsymbol{c}\ \cdot\cdot\boldsymbol{\varepsilon}^{\mathrm{Q}}\ \mathrm{d}^3\boldsymbol{r} - \int \boldsymbol{\sigma}\cdot\cdot\boldsymbol{\varepsilon}^{\mathrm{Q}}\ \mathrm{d}^3\boldsymbol{r} \tag{65}$$

where $\boldsymbol{\sigma}$ means either $\boldsymbol{\sigma}^{\mathrm{ext}}$ or $\boldsymbol{\sigma}^{\mathrm{def}}$ or the sum of both. Here again the first term corresponds to the contribution of the spontaneous magnetization to the magnetocrystalline energy and the second term describes the interaction energy, $\boldsymbol{\varepsilon}^{\mathrm{Q}}$, with external stresses. This latter term was originally developed by Becker and Döring (1939) and is known as the so-called magnetoelastic coupling energy, which for cubic crystals is given by

$$\phi'_{\sigma} = -\frac{3}{2}\,\lambda_{100}\,\sum_{i=1}^{3}\sigma_{ii}\,\gamma_i^2 - \frac{3}{2}\,\lambda_{111}\,\sum_{i\neq j}\sigma_{ij}\gamma_i\gamma_j \tag{66}$$

where $\boldsymbol{\sigma}$ and the γ_i refer to the cubic coordinate system. For isotropic materials as for example, amorphous alloys equation (66) is

$$\phi_{\sigma} = -\frac{3}{2}\lambda_{\mathrm{S}}\left\{\sum_{i=1}^{3}\sigma_{ii}\gamma_i^2 + \sum_{i\neq j}\sigma_{ij}\gamma_i\gamma_j\right\} \tag{67}$$

The stress tensor $\boldsymbol{\sigma}$ in equation (66) and equation (67) either may correspond to external or internal stresses. Equation (67) is the basis for investigating the influence of stresses on the arrangement of domain patterns or the determination of spontaneous magnetization in the neighborhood of stress-active defects. Some examples of this type of interactions will be given in chapter 5.

2.6 Summary

According to the results of Sections 2.1–2.5 the total magnetic Gibbs free energy density is composed of five terms

$$\phi'_{\mathrm{t}} = \phi'_{\mathrm{ex}} + \phi'_{\mathrm{k}} + \phi'_{\mathrm{el}} + \phi'_{\mathrm{s}} + \phi'_{\mathrm{h}} \tag{68}$$

Depending on the problem to be solved in many cases not all of these energy terms have to be taken into account. For example, for the treatment of Blochwall ϕ'_{s} and ϕ'_{H} may be omitted whereas in the case of soft magnetic materials ϕ_{k} plays only a minor role. In the treatment of internal stresses ϕ'_{el} has to be replaced by ϕ'_{σ}. For a crystal of cubic symmetry, the total magnetic Gibbs free energy density in this case is written as

$$\begin{aligned}
\phi'_{\mathrm{t}} = {} & A\sum_i(\nabla\gamma_i)^2 + K_1\sum_{i\neq j}\gamma_i^2\gamma_j^2 + K_2\gamma_1^2\gamma_2^2\gamma_3^2\\
& - \frac{3}{2}\lambda_{100}\sum_{i=1}\sigma_{ii}\gamma_i^2 - \frac{3}{2}\lambda_{111}\sum_{i\neq j}\sigma_{ij}\gamma_i\gamma_j\\
& - \frac{1}{2}\boldsymbol{H}_{\mathrm{s}}\cdot\boldsymbol{J}_{\mathrm{s}} - \boldsymbol{H}_{\mathrm{ext}}\cdot\boldsymbol{J}_{\mathrm{s}}
\end{aligned} \tag{69}$$

where γ_i and $\boldsymbol{\sigma}$ refer to the cubic coordinate system.

Each of these energy terms has a specific influence on the distribution of the directions of the spontaneous magnetization, which will be outlined in the following section.

It is of interest to remember that the continuum expressions (69) for ϕ'_{t} has a quantum theoretical analogon in the

Hamiltonian

$$H = -2\sum_{i\neq j} J_{ij}\, \boldsymbol{S}_i \cdot \boldsymbol{S}_j + \lambda_{\mathrm{SO}} \sum_i \boldsymbol{L}_i \cdot \boldsymbol{S}_i - \frac{\mu_0 (g\mu_{\mathrm{B}})^2}{4\pi} \sum_{i\neq j} \left(\frac{\boldsymbol{S}_i \cdot \boldsymbol{S}_j}{R_{ij}^3} - \frac{3(\boldsymbol{S}_i \cdot \boldsymbol{R}_{ij})(\boldsymbol{S}_j \cdot \boldsymbol{R}_{ij})}{R_{ij}^5} \right) - g\mu_0\mu_{\mathrm{B}} \sum_i \boldsymbol{S}_i \cdot \boldsymbol{H}_{\mathrm{ext}} \tag{70}$$

Here the second term denotes the spin-orbit coupling energy as one of the sources of the magnetoelastic energy is included in equation (70) by the strain dependence of the spin-orbit coupling constant λ_{SO}. The third term corresponds to the dipolar stray field energy and the last term is known as the Zeeman energy.

3 MICROMAGNETIC EQUILIBRIUM EQUATIONS

Micromagnetic equilibrium conditions usually are derived with respect to the orientation of the vector of spontaneous polarization or magnetization. Accordingly, the magnetic Gibbs free energy is mimimalized with respect to the direction cosines γ of $\boldsymbol{J}_{\mathrm{s}}$, where the modulus of $\boldsymbol{J}_{\mathrm{s}}$ is kept constant, that is, the condition

$$\sum_{i=1}^{3} \gamma_i^2 = 1 \quad \text{or} \quad \sum_{i=1}^{3} J_{\mathrm{s},i}^2 = J_{\mathrm{s}}^2 \tag{71}$$

holds. Presenting the results of the following considerations the static equilibrium equations are written as a torque equation

$$\boldsymbol{L} = [\boldsymbol{J}_{\mathrm{s}} \times \boldsymbol{H}_{\mathrm{eff}}] = 0 \tag{72}$$

Here, $\boldsymbol{H}_{\mathrm{eff}}$ denotes the so-called effective field, which is composed of four contributions: external field, dipolar field (stray field), magnetocrystalline field, magnetoelastic field. A trivial solution of equation (72), of course, is $H_{\mathrm{eff}} \equiv 0$. The torque equation for an isotropic medium also may be interpreted as

$$\boldsymbol{J}_{\mathrm{s}} = \mu_0(\mu - 1)\boldsymbol{H}_{\mathrm{eff}},\ \boldsymbol{M}_{\mathrm{s}} = \chi\ \boldsymbol{H}_{\mathrm{eff}}$$

or

$$\mu - 1 = \frac{J_{\mathrm{s}}}{\mu_0 |\boldsymbol{H}_{\mathrm{eff}}|}, \quad \chi = \frac{M_{\mathrm{s}}}{|\ \boldsymbol{H}_{\mathrm{eff}}\ |} \tag{73}$$

In the general case the permeability μ and the susceptibility χ correspond to tensors of second order. In order to derive the micromagnetic equilibrium equations the magnetic Gibbs free energy ϕ_{t} has to be minimized with respect to γ_i taking into account the constraint (71). This leads to the variational equation

$$\delta_{\gamma_i}\phi_{\mathrm{t}} = \delta_{\gamma_i} \int \left\{ \phi'_{\mathrm{ex}} + \phi'_{\mathrm{k}} + \phi'_{\mathrm{el}} + \phi'_{\mathrm{s}} + \phi'_{\mathrm{H}} + \lambda \left(\sum_{i=1}^{3} \gamma_i^2 - 1 \right) \right\} \mathrm{d}^3\boldsymbol{r} = 0 \tag{74}$$

The last term in equation (74) takes care of the constraint (71) by a Lagrange parameter λ. Performing the variational operation of equation (74) gives

$$\delta_{\gamma_i}\phi_{\mathrm{t}} = \int \left\{ 2A \sum_{i=1}^{3} \nabla\gamma_i\ \delta\left(\nabla\gamma_i\right) + \sum_{i=1}^{3} \left(\frac{\partial \phi'_{\mathrm{k}}}{\partial \gamma_i} + \frac{\partial \phi_{\mathrm{el}}}{\partial \gamma_i} - J_{\mathrm{s}} H_{\mathrm{ext},i} - 2\lambda\gamma_i \right) \delta\gamma_i - \frac{1}{2}\left(\boldsymbol{H}_{\mathrm{s}} \cdot \delta \boldsymbol{J}_{\mathrm{s}} + \boldsymbol{J}_{\mathrm{s}} \cdot \delta \boldsymbol{H}_{\mathrm{s}}\right) \right\} \mathrm{d}^3\,\boldsymbol{r} \tag{75}$$

Interchanging the operator $\partial_i = \frac{\partial}{\partial x_i}$ and the variation δ and applying Gauss's theorem the variation of the exchange energy gives

$$\int 2A \sum_{i=1}^{3} \nabla\gamma_i\ \delta\nabla\gamma_i\ \mathrm{d}^3\,\boldsymbol{r} = 2A \int_S \nabla\gamma_i\ \delta\gamma_i\ \mathrm{d}\,\boldsymbol{f} - 2A \int_V \Delta\gamma_i\ \delta\gamma_i\ \mathrm{d}^3\,\boldsymbol{r} \tag{76}$$

where the first term on the right side extends over the surface S of the magnet. Concerning the variation of the dipolar energy according to Brown (1962) because of $\mathrm{div}\boldsymbol{B} = 0$ and rot $\boldsymbol{H}_{\mathrm{s}} = 0$ the relation

$$\int \boldsymbol{H}_{\mathrm{s}} \cdot \delta\, \boldsymbol{J}_{\mathrm{s}}\ \mathrm{d}^3\,\boldsymbol{r} = \int \boldsymbol{J}_{\mathrm{s}} \cdot \delta\, \boldsymbol{H}_{\mathrm{s}}\ \mathrm{d}^3\,\boldsymbol{r} \tag{77}$$

holds. Inserting equations (76 and 77) into equation (75) gives

$$\delta_{\gamma_i}\phi_{\mathrm{t}} = \int_V \left\{ -2A\,\Delta\gamma_i + \left(\frac{\partial \phi'_{\mathrm{k}}}{\partial \gamma_i} + \frac{\partial \phi'_{\mathrm{el}}}{\partial\, \gamma_i} \right) - H_{\mathrm{s},i}\ J_{\mathrm{s}} - H_{\mathrm{ext},i}\ J_{\mathrm{s}} + 2\,\lambda\gamma_i \right\} \delta\gamma_i\ \mathrm{d}^3\,\boldsymbol{r} + 2A \int_S \nabla\gamma_i \delta\gamma_i \cdot \mathrm{d}\,\boldsymbol{f}\,\delta\gamma_i = 0 \tag{78}$$

According to equation (78) the variations $\delta\phi_t$ vanishes if the integrands of the volume and of the surface integrals vanish. The differential equations obtained by this procedure still contain the Lagrange parameter λ. Elimination of λ is performed by multiplying the differential equation for γ_i by γ_j and vice versa and subtracting the corresponding expressions of the type $J_{s,j}H_{eff,i} - J_{s,i}H_{eff,j} = 0$, which correspond to the components of the vector product of $\boldsymbol{J}_s$ and an effective field, $\boldsymbol{H}_{eff}$. Accordingly, the equilibrium condition in the volume is

$$[\boldsymbol{J}_s \times \boldsymbol{H}_{eff}] = 0 \tag{79}$$

and

$$[\boldsymbol{J}_s \times \nabla_n \boldsymbol{M}_s] = 0$$

on the surface. The components of the effective field are given by

$$\begin{aligned} H_{eff,i} = -\frac{1}{J_s}\frac{\partial \phi'_t}{\partial \gamma_i} = \frac{2A}{J_s}\Delta\gamma_i + H_{k,i} \\ + H_{\sigma,i} + H_{s,i} + H_{ext,i} \end{aligned} \tag{80}$$

Here we have introduced the effective fields of the anisotropy and magnetoelastic energy

$$H_{k,i} = -\frac{1}{J_s}\frac{\partial \phi'_k}{\partial \gamma_i}, \quad H_{\sigma,i} = -\frac{1}{J_s}\frac{\partial \phi'_{el}}{\partial \gamma_i} \tag{81}$$

In addition to the above, micromagnetic equilibrium conditions the Maxwell equation $\mathrm{div}\,\boldsymbol{B} = 0$ has to be fulfilled. This leads to the Poisson equation inside the volume

$$\begin{aligned} \Delta U^{(i)} &= \mathrm{div}\ \boldsymbol{M}_s(r) = -\rho(\boldsymbol{r}) \\ \text{with } \boldsymbol{H}_s^{(i)} &= -\nabla\ U^{(i)} \end{aligned} \tag{82}$$

and the Laplace equation

$$\begin{aligned} \Delta U^{(0)} &= 0 \\ \boldsymbol{H}_s^{(0)} &= -\nabla\ U^{(0)} \end{aligned} \tag{83}$$

outside the volume. $U^{(1)}$ and $U^{(0)}$ have to fulfill the following boundary conditions

$$U^{(i)}(\boldsymbol{r}) = U^{(a)}(\boldsymbol{r}) \tag{84}$$

at the surface. Furthermore, the normal component of $\boldsymbol{B}$ at the surface (o) has to be continuous, that is:

$$\left.\begin{aligned} H_{s,0}^{(i)} + M_{s,n} &= H_{s,0}^{(0)} \\ -\nabla_n U_0^{(i)} + M_{s,n} &= -\nabla_n U_0^{(0)} \end{aligned}\right\} \tag{85}$$

In the most general case also the elastic equilibrium conditions has to be taken into account in the volume and at the surface with surface forces $\boldsymbol{F}$, respectively

$$\left.\begin{aligned} \mathrm{Div}(\boldsymbol{c}\cdot\cdot\boldsymbol{\varepsilon}^{el}) &= -\mathrm{Div}(\boldsymbol{c}\cdot\cdot\boldsymbol{\varepsilon}^{Q}) \\ \boldsymbol{n}\cdot\boldsymbol{\sigma} &= \boldsymbol{F} \end{aligned}\right\} \tag{86}$$

In order to formulate equilibrium equations free from the Lagrange parameter and the condition (71) spherical angular coordinates φ and θ are introduced where φ denotes the azimuthal and θ the polar angle. The direction cosines γ_i are replaced by

$$\gamma_1 = \sin\theta\ \cos\varphi,\ \ \gamma_2 = \sin\theta\ \sin\varphi,\ \ \gamma_3 = \cos\theta \tag{87}$$

Now the equilibrium conditions write:

$$\begin{aligned} &2A\Delta\theta - A\ \sin 2\theta(\nabla\varphi)^2 \\ &\quad - \frac{\partial}{\partial\theta}\left(\phi'_k + \phi'_{el} + \phi'_s - \boldsymbol{J}_s\cdot\boldsymbol{H}_{ext}\right) = 0 \\ &2A\left\{\sin^2\theta\Delta\varphi + \sin 2\theta\ (\nabla\varphi)\cdot(\nabla\theta)\right\} \\ &\quad - \frac{\partial}{\partial\varphi}\ \left(\phi'_k + \phi'_{el} + \phi'_s - \boldsymbol{J}_s\cdot\boldsymbol{H}_{ext}\right) = 0 \end{aligned} \tag{88}$$

The micromagnetic equations given by equations (79)–(88) correspond to a system of coupled differential equations for the unknown variables γ_i. Since the stray fields $\boldsymbol{H}_s$ and the elastic tensor $\boldsymbol{\varepsilon}^{el}$ in principle can be represented as integrals (e.g., see equation (30)), it becomes obvious that the micromagnetic equation correspond to a rather complicated system of coupled nonlinear integro-differential equations.

Explicit solutions of the micromagnetic equations have been obtained for a number of fundamental problems as domain walls in bulk materials and thin films (Kronmüller and Fähnle, 2003; Riedel and Seeger, 1971; Lilley, 1950; Rieder, 1959) for nucleation problems (Frei, Shtrikman and Treves, 1957; Aharoni and Shtrikman, 1958; Kronmüller, 1987) the high-field susceptibility in the approach to ferromagnetic saturation (Brown, 1940, 1941; Becker and Döring, 1939; Seeger and Kronmüller, 1960; Kronmüller and Seeger, 1961).

4 SOLUTIONS OF MICROMAGNETIC EQUATIONS

There are only a few cases where explicit solutions of the micromagnetic equations are available. Some of them will be summarized in the following. Many micromagnetic problems have to be solved numerically by the recently developed methods of computational micromagnetism that are summarized in **Numerical Micromagnetics: Finite Difference**

Methods, Volume 2 and **Numerical Methods in Micromagnetics (Finite Element Method), Volume 2**. Explicit solutions have been obtained for a number of fundamental micromagnetic problems as domain walls, nucleation problems, domain patterns, and the law of approach to ferromagnetic saturation. Many problems dealing with the interaction between magnetic and microstructural problems have been solved approximately.

4.1 Domain walls

4.1.1 Bloch walls

The spin distribution in planar Bloch walls in general is described by the spherical angles φ and θ, where θ is kept as a constant and the angle of φ describes the rotation of the spontaneous magnetization along the z-coordinate, which is taken as the domain wall normal $\boldsymbol{n}$ (see Figure 7). Bloch walls are characterized by a vanishing stray field ($\operatorname{div} \boldsymbol{M}_s = 0$), that is, the component of $\boldsymbol{J}_s$ with respect to the wall normal, $\boldsymbol{n}$, is constant

$$\boldsymbol{J}_s \cdot \boldsymbol{n} = J_s \cos\theta = \text{constant} \tag{89}$$

Owing to the vanishing stray field energy, the basic equation for planar Bloch walls according to equation (88) is

$$2A \sin^2\theta \frac{d^2\varphi}{dz^2} - \frac{\partial}{\partial\varphi}\left(\phi'_B\right) = 0 \tag{90}$$

where $\phi'_B = \phi'_k + \phi'_{el}$ includes anisotropy energy and magnetoelastic energies. Integration of equation (90) leads to

$$A \sin^2\theta \left(\frac{d\varphi}{dz}\right)^2 - \left(\phi'_B(\varphi) - \phi'_B(\varphi_i)\right) = 0$$

$$z = \sqrt{A}\sin\theta \int_{\varphi_i}^{\varphi} \frac{d\varphi}{\left(\phi'_B(\varphi) - \phi'_B(\varphi_i)\right)^{1/2}} \tag{91}$$

where $\phi'_B(\varphi_i)$ denotes the value of ϕ'_B in the domain for $z \to -\infty$ where $\varphi = \varphi_i$ holds.

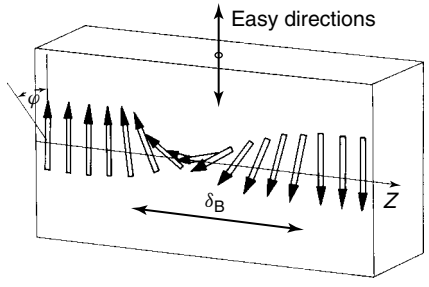

Figure 7. Distribution of magnetization within a 180° wall.

For uniaxial crystals with $\phi'_B = K_1 \sin^2\varphi$ and $\theta = \frac{\pi}{2}$ (180°-wall), the solution is

$$\operatorname{tg}\frac{\varphi}{2} = e^{-z/\delta_0} \text{ or } \sin\varphi = \frac{1}{\operatorname{ch}\left(\frac{z}{\delta_0}\right)}, \quad \cos\varphi = \operatorname{th}\left(\frac{z}{\delta_0}\right) \tag{92}$$

with

$$\delta_0 = \kappa_k^{-1} = \sqrt{\frac{A}{K_1}} \tag{93}$$

which denotes the so-called Bloch wall parameter. In spite of the fact that a domain wall extends from $z = -\infty$ to $z = +\infty$ according to Lilley (1950), Hubert and Schäfer (1998), and Kronmüller and Fähnle (2003) a domain wall width δ_B is defined by the distance between the intersections of the tangent with the largest slope at the $\varphi(z)$ curve with the lines for $\varphi = \varphi_i, \varphi_{ii}$ (see Figure 8):

$$\delta_B = \frac{(\varphi_{ii} - \varphi_i)}{(d\varphi/dz)_{max}} \tag{94}$$

In the case of the 180°-wall in uniaxial materials this gives

$$\delta_B = \pi\delta_0 = \pi\sqrt{\frac{A}{K_1}} \tag{95}$$

and $\delta_B = \sqrt{A/(K_1 + K_2)}$ if the second anisotropy constant is taken into account. For the specific wall energy defined as

$$\gamma_B = 2\sqrt{A}\sin\theta \int_{\varphi_i}^{\varphi_{ii}} \left(\phi'_B(\varphi) - \phi'_B(\varphi_i)\right)^{1/2} d\varphi \tag{96}$$

for the 180° wall with $\varphi_i = 0, \varphi_{ii} = \pi, \theta = \frac{\pi}{2}$

$$\gamma_B = 4\sqrt{A\ K_1} = 4K_1\delta_0 \tag{97}$$

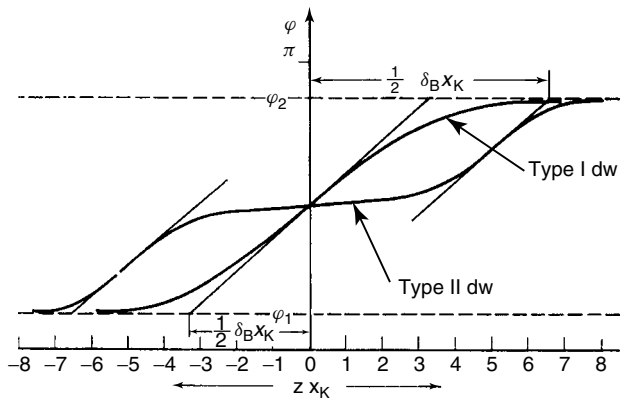

Figure 8. Wall width defined as the intersections of tangents at the steepest slope of φ(z)-curve (Kronmüller and Fähnle (2003)). (Reproduced with permmission from Cambridge University Press.)

is obtained. Whereas in uniaxial crystals the dws are characterized by a single point of inflection of the $\varphi(z)$ curve the situation is more complex in the case of some 180° walls in cubic crystals. For example, the following walls split into two 90° walls if the magnetoelastic energy term ϕ_{el} is neglected: α-Fe: (011)–180°, Ni: (110)–180°, (001)–109,47°. As shown in Figure (8) in this case three points of infliction exist and the $\varphi(z)$-curve is described by

$$\operatorname{ctg}\varphi = -A\cdot \operatorname{sh}\frac{z}{\alpha\delta_0} + \rho \tag{98}$$

Values for A and ρ are given by Lilley (1950) and Kronmüller and Fähnle (2003). In the special case of the (001)–180° wall in α-Fe A, α and ρ are given by

$$A = \frac{3}{2}\lambda_{100}\alpha\sqrt{\frac{c_{11}-c_{12}}{K_1}},$$
$$\alpha = \left(1+\frac{9\lambda_{111}^2 c_{44}}{2K_1}\right)^{-1/2}, \quad \rho = 0 \tag{99}$$

($A = 2.94\cdot 10^{-2}$, $\alpha \approx 1$, $\rho = 0$).

The constricting role of the magnetoelastic energy ϕ_{el} becomes obvious from equation (61) where a term $\propto \sin^2\varphi$ appears, whereas in ϕ_k only terms $\sin^2 2\varphi$ appear that result in a splitting of the 180° wall.

Another important feature of the different types of domain walls in cubic materials is the existence of elastic stresses. In the type I dws there exist long-range stresses within the domains (α-Fe: (100)–90°, (111)–90°. Nickel: (100)–70.53°, (110)–70.53°, (110)–109.47°, (111)–109.47. In the type II dws magnetoelastic stresses exist only within the dws (α-Fe: (001)–180°, (110)–180°, (110)–90°. Nickel: (001)–109.47°, (110)–180°. Kobalt: (001)–180°). As a consequence type I dws have a strong interaction with stress sources, whereas type II dws have a much weaker interaction and therefore are much more mobile than type I dws.

4.1.2 Néel walls

Besides the so-called Bloch walls there exist another type of dws, the so-called Néel walls characterized by the existence of dipolar fields because in this case $\theta = \theta(z)$ and $\varphi =$ const holds. Accordingly there exist volume charges $\rho(z) = -\boldsymbol{M}_s \operatorname{div}\theta(z)$. In bulk materials in general no Néel walls exist. It is the merit of L. Néel (1955a,b), who has shown that in thin films the Bloch walls become instable because of their large dipolar energy due to magnetic surface charges (see Figure 9), which are avoided by the Néel wall type at the expense of volume charges, which, however, lead to a smaller dipolar stray field energy than the surface charges of the Bloch-type wall.

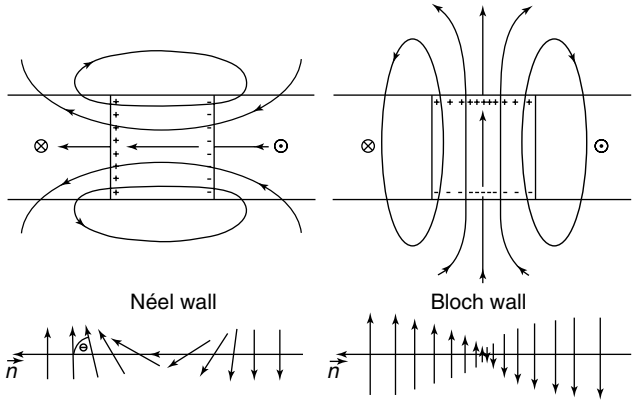

Figure 9. Distribution of magnetization and stray field of Bloch and Néel walls in thin films. (Reproduced with permmission from Cambridge University Press.)

In order to reveal the differences between Bloch and Néel walls in bulk materials we consider a planar 180° Néel wall where the polar angle θ varies from $\theta = \frac{\pi}{2}$ to $\theta = -\frac{\pi}{2}$ (see Figure 9). Solution of the Poisson equation (29) with $\rho = -M_s \operatorname{div}\cos\theta(z)$ gives $H_{z,s} = -M_s\cos\theta(z)$ and $\phi_s = \frac{1}{2}M_s J_s \cos^2\theta(z)$. The differential equation of the Néel wall is obtained from equation (88) for $\varphi = 0$ giving after integration

$$A\left(\frac{\mathrm{d}\theta}{\mathrm{d}z}\right)^2 = \left(\phi_k' + \phi_s'\right) \tag{100}$$

and

$$\operatorname{tg}\left(\frac{\theta}{2}+\frac{\pi}{4}\right) = \exp\left[-z\left(\frac{K_1}{A}+\frac{\mu_0 M_s^2}{2A}\right)^{1/2}\right] \tag{101}$$

For the wall width this gives

$$\delta_{Né} = \frac{\pi}{\left(\frac{K_1}{A}+\frac{\mu_0 M_s^2}{2A}\right)^{1/2}} \tag{102}$$

and the specific wall energy is found to be

$$\gamma_{Né} = 4\ \cdot\sqrt{A\left(K_1+\frac{1}{2}\,\mu_0 M_s^2\right)} \tag{103}$$

From these results it has to be concluded that in bulk materials the Neel wall always has a larger specific wall energy than the Bloch wall, however, its wall width is found to be smaller owing to the constricting role of the dipolar stray field energy.

As mentioned above the situation is different in the case of thin films. Here no rigorous analytical solution of the micromagnetic equation is possible. After the pioneering work by

Néel (1955a,b) numerous approximate and numerical solutions have been published (Dietze and Thomas, 1961; Brown and LaBonte, 1965; Kirchner and Döring, 1968; Holz and Hubert, 1969; Riedel and Seeger, 1971; La Bonte, 1969; Aharoni, 1973, 1975; Aharoni and Jacubovics, 1990). In thin films Néel walls became energetically favored because of their smaller dipolar energy. The distribution of magnetization within a one-dimensional Néel wall depends on the so-called quality parameter $Q = 2K_1/M_s J_s$ and the thickness of the film. The cosine of the rotation angle θ as shown in Figure 10 follows three stages:

1. Kernel region: $\cos\theta(z) \propto \Delta_N^2/(\Delta_N^2 + z^2)$
2. Logarithmic region: $\cos\theta(z) \propto \ln(z)(D)$
3. Dipolar tail: $\cos\theta(z) \propto 1/z^2$.

In stage I the magnetocrystalline energy determines $\cos\theta$ whereas in stage II the local stray field is dominant and in stage III $\cos\theta$ is governed by the long-range dipolar field exerted from stages I and II. According to Aharoni the wall parameter Δ_N and $\gamma_{Né}^{180^\circ}$ approximately are given by

$$\Delta_N = 2\sqrt{\frac{(\sqrt{2}-1)A\ (K_1 - J_s^2 D^2)}{(96\mu_0 K_1)}}$$

$$\gamma_{Né}^{180^\circ} = 2\pi\sqrt{\sqrt{2}-1}\ \sqrt{A\ K_1} + \frac{\pi}{16}\ J_s\ M_s\ D \quad (104)$$

For $D \to 0$ $\gamma_{Né}^{180^\circ}$ approaches the wall energy of the Bloch wall $4 \cdot \sqrt{A\ K_1}$. As analyzed by Hubert (1974) and Hubert and Schäfer (1998) in thin films a large multitude of different types of dws exist, depending on the film thickness, the wall angle and the applied field. The phase diagram shown in Figure 11 shows the ranges where Néel, Bloch, and intermediate wall types are stable in the case of permalloy

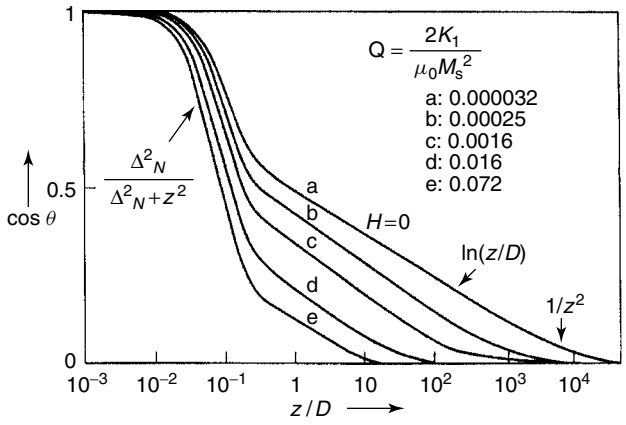

Figure 10. Rotation angle θ of a one-dimensional symmetric Néel wall for different quality parameters $Q = 2K_1/(M_s J_s)$ in reduced length scale $z' = z/D$ (D = film thickness).

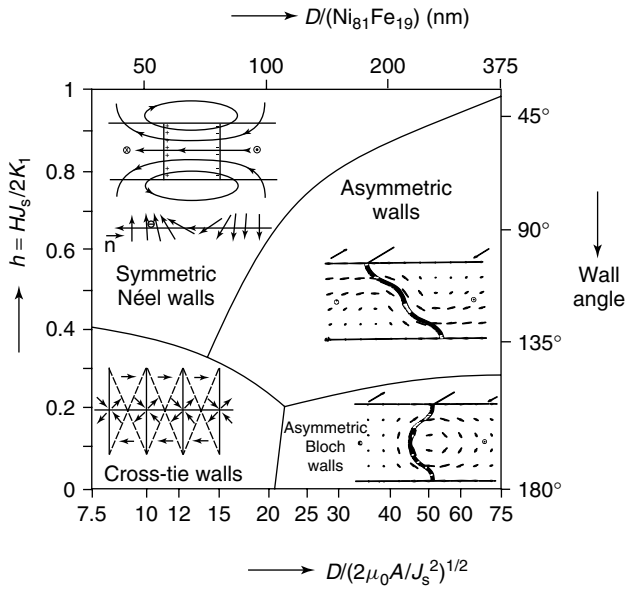

Figure 11. Phase diagram of the main wall types in permalloy with $Q = 0.00025$ according to Hubert and Schäfer (1998).

with $Q = 0.00025$, that is, an extremely soft magnetic material.

4.2 Nucleation fields

Single-domain particles with uniaxial anisotropy in general are characterized by a rectangular hysteresis loop. The critical field under which the spontaneous magnetization reverses spontaneously its direction is called the *nucleation field*, which in case of hard magnetic materials is given by $H_N = 2K_1/(\mu_0 M_s)$. It was W. F. Brown (Brown, 1945, 1963) who pointed out the discrepancy between theory and experiment (Brown's paradox) concerning the nucleation fields, which were found to be a factor of 3 to 4 smaller than predicted. Later on, it has been shown that demagnetization fields and reduced anisotropies at the surface of particles are responsible for these discrepancies (Kronmüller, 1987). Reversal of magnetization in small particles may take place by different types of magnetization modes: homogeneous rotation, curling, buckling, or even more complex nucleation processes at the surfaces. In the following the results for homogeneous rotation and the curling mode are outlined.

4.2.1 Homogeneous rotation in cylindrical particles

The total Gibbs free energy density for homogeneous rotation in the case of a uniaxial anisotropy with the easy axis parallel to the cylinder axis and an applied field under an angle ψ_0

with respect to the negative easy axis is given by

$$\phi'_{\mathrm{t}} = K_1 \sin^2\varphi + K_2 \ \sin^4\varphi + \frac{1}{2}\mu_0 \ M_{\mathrm{s}}^2 \ N_\perp \sin^2\varphi + \frac{1}{2} \ \mu_o \ M_{\mathrm{s}}^2 \ N_\parallel \ \cos^2\varphi + \mu_0 H_{\mathrm{ext}} M_{\mathrm{s}} \cos(\psi_0 + \varphi) \tag{105}$$

where φ denotes the angle between $\boldsymbol{M}_{\mathrm{s}}$ and the positive easy axis. The conditions for a spontaneous rotation of $\boldsymbol{M}_{\mathrm{s}}$ into the opposite direction are a vanishing derivative $\mathrm{d}\phi_{\mathrm{t}}/\mathrm{d}\varphi = 0$ and a second derivative $\mathrm{d}^2\phi_{\mathrm{t}}/\mathrm{d}\varphi^2 \leq 0$. These conditions write

$$\frac{\mathrm{d}\phi'_{\mathrm{t}}}{\mathrm{d}\varphi} = (K_1 + K_{\mathrm{d}}) \sin \ 2\varphi + 2K_2 \sin^2\varphi \sin 2\varphi - \mu_0 \mathrm{M}_{\mathrm{s}} H_{\mathrm{ext}} \ \sin(\psi_0 + \varphi) = 0 \tag{106}$$

and

$$\frac{\mathrm{d}^2\phi'_{\mathrm{t}}}{\mathrm{d}\varphi^2} = 2 \ (K_1 + K_{\mathrm{d}}) \cos \ 2 \ \varphi + 4 \ K_2 \left(3 \sin^2\varphi \cos^2\varphi - \sin^4 \ \varphi\right) - \mu_0 M_{\mathrm{s}} H_{\mathrm{ext}} \cos\left(\varphi + \psi_0\right) \leq 0 \tag{107}$$

Here the magnetostatic dipolar anisotropy constant

$$K_{\mathrm{d}} = \frac{1}{2} \ \mu_0 M_{\mathrm{s}}^2 \ \left(N_\perp - N_\parallel\right) \tag{108}$$

has been introduced, where $N_\perp$ and $N_\parallel$ denote the demagnetization factors of the cylinder perpendicular and parallel to the cylinder axis. The nucleation field for $\psi_0 = 0$ follows from equation (106) by linearization

$$\left[2 \ (K_1 + K_{\mathrm{d}}) - \mu_0 \ M_{\mathrm{s}} H_{\mathrm{ext}}\right] \ \varphi = 0 \tag{109}$$

Taking care of the stability condition (107) the solutions of (107) are $\varphi = 0$ for $H_{\mathrm{ext}} \leq H_{\mathrm{N}}$ and $\varphi \geq 0$ for

$$H_{\mathrm{ext}} = H_{\mathrm{N}} = \frac{2 \ K_1}{\mu_0 \ M_{\mathrm{s}}} + (N_\perp - N_\parallel) \ M_{\mathrm{s}} \tag{110}$$

Taking care of the stability relation (107), it turns out that for $K_1 + K_{\mathrm{d}} \geq 4K_2$ the spontaneous magnetization rotates spontaneously into the opposite direction. However, for $K_1 + K_{\mathrm{d}} \leq 4K_2$ the condition $\mathrm{d}^2\phi_{\mathrm{t}}/\mathrm{d}\varphi^2 \geq 0$ holds and therefore at $H_{\mathrm{ext}} = H_{\mathrm{N}}$, $\boldsymbol{M}_{\mathrm{s}}$ starts to rotate reversibly out of the c axis. The spontaneous reversal of $\boldsymbol{M}_{\mathrm{s}}$ in this case occurs at (Herzer, Fernengel and Adler 1986; Kronmüller, 1985, 1991) a second nucleation field

$$H'_{\mathrm{N}} = \frac{4}{3 \cdot \sqrt{6}} \frac{K_2}{\mu_0 \ M_{\mathrm{s}}} \ \left[1 + \frac{K_1 + K_{\mathrm{d}}}{K_2}\right]^{3/2} \tag{111}$$

According to equation (110) the nucleation field is independent of the particle and the second anisotropy constant K_2 and only depends on the ratio of the ellipsoidal particle axes by $N_\perp$ and $N_\parallel$. From equation (110) we obtain a lower bound of H_{N} for a plate with perpendicular easy axis ($N_\perp = 0$, $N_\parallel = 1$)

$$H_{\mathrm{N}}^{\mathrm{min}} = \frac{2 \ K_1}{\mu_0 \ M_s} - M_{\mathrm{s}} \tag{112}$$

and an upper bound for an in-plane easy axis

$$H_{\mathrm{N}}^{\mathrm{max}} = \frac{2 \ K_1}{\mu_0 M_{\mathrm{s}}} + M_{\mathrm{s}} \tag{113}$$

An intermediate nucleation field is obtained for a sphere ($N_\parallel = N_\perp = 1/3$)

$$H_{\mathrm{N}}^{\mathrm{sph}} = 2K_1/\mu_0 M_{\mathrm{s}} \tag{114}$$

For a cylindrical particle ($N_\perp = \frac{1}{2}$; $N_\parallel = 0$) equation (110) gives

$$H_{\mathrm{N}}^{\mathrm{cyl}} = \frac{2 \ K_1}{\mu_0 \ M_{\mathrm{s}}} \ \pm \frac{1}{2} \ M_{\mathrm{s}} \tag{115}$$

where the (+) and (−) signs hold for an easy axis parallel or perpendicular to the cylinder axis.

4.2.2 The Stoner–Wohlfarth model

For oblique applied magnetic field the basic equation (106) and (107) have been solved by Stoner and Wohlfarth for vanishing higher order anisotropy constants. An extension of their results including the second anisotropy constant has been given by Kronmüller, Durst and Martinek (1987), for K_1, $K_2 \geq 0$ leading to

$$H_{\mathrm{N}}(\psi_0) = \frac{2(K_1 + K_{\mathrm{d}})}{\mu_0 M_{\mathrm{s}}} \frac{1}{\left[(\cos\psi_0)^{2/3} + (\sin\psi_0)^{2/3}\right]^{3/2}} \times \left\{1 + \frac{2 \ K_2}{K_1 + K_{\mathrm{d}}} \frac{(\sin\psi_0)^{2/3}}{\left[(\cos \ \psi_0)^{2/3} + (\sin\psi_0)^{2/3}\right]}\right\} \tag{116}$$

The angle φ_{N} at which a spontaneous nucleation takes place is given by

$$\varphi_{\mathrm{N}} = \mathrm{arctg} \ \sqrt[3]{\mathrm{tg}\psi_0} + \frac{2}{3} \ \frac{K_2}{K_1 + K_{\mathrm{d}}} \tag{117}$$

Figure 12 shows the angular dependence of $H_{\mathrm{N}}(\psi_0)$ for the material constants of $Nd_2Fe_{14}B$ as determined by Hock and Kronmüller (1987). It should be noted that the asymmetry of

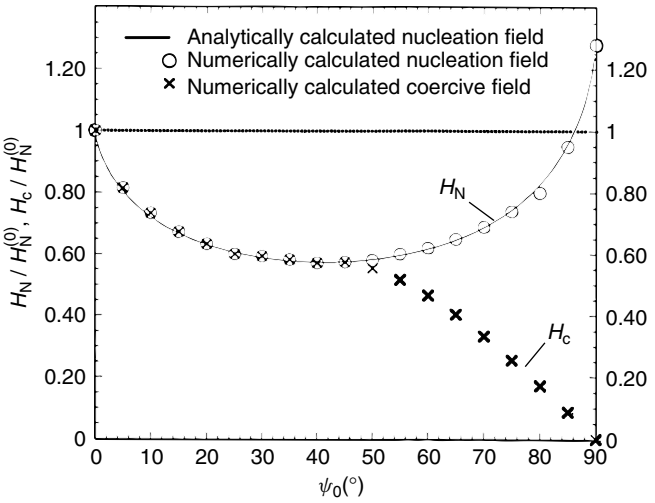

Figure 12. Angular dependence of the nucleation field and the coercive field of $Nd_2Fe_{14}B$ according to equation (116).

the $H_N(\psi_0)$ curve is due to the K_2-term in equation (116). Alternative to Figure 12 the angular dependence of H_N over 2π may be represented in the so-called Stoner–Wohlfarth asteroid where $H_N(\psi_0)$ is plotted as a function of the field components parallel or perpendicular to the c axis. Experimental results of this kind are shown in the article by Kläui and Vaz.

4.2.3 Inhomogeneous rotation by curling

Whereas in the homogeneous rotation mode the reversal of M_s is governed by crystal anisotropy and surface charges the curling mode is governed by exchange energy. Volume charges $\mathrm{div}\boldsymbol{M}_s$ and surface charges $\boldsymbol{n} \cdot \boldsymbol{M}_s$ vanish with the exception of charges at the front sides of a finite cylinder.

In cylindrical polar coordinates the linearized micromagnetic equations give

$$2A \left\{ \frac{\mathrm{d}^2\varphi(r)}{\mathrm{d}r^2} + \frac{1}{r} \frac{\partial\varphi}{\partial r} - \frac{1}{r^2} \varphi(r) \right\} - (2K_1 - \mu_0 M_s H_{ext} - N_\parallel \mu_0 M_s^2)\, \varphi(r) = 0 \quad (118)$$

The solution of equation (118) corresponds to the Bessel function of first order

$$\varphi(r) = \varphi_0 J_1 \left[r \cdot \left(\frac{\mu_0 M_s H_{ext} - N_\parallel \mu_0 M_s^2 - 2K_1}{2A} \right)^{1/2} \right] \quad (119)$$

The nucleation field follows from the boundary condition $\mathrm{d}\varphi/\mathrm{d}r|_{r=R=0}$, which leads to

$$J_1'(R) = 0 \quad (120)$$

The smallest zero of $J_1'(\mathrm{R})$ gives the largest nucleation field (Aharoni and Shtrikman, 1958; Aharoni, 1997)

$$H_N = \frac{2K_1}{\mu_0 M_s} - N_\parallel M_s + \frac{2A}{\mu_0 M_s} \left(\frac{1.84}{R} \right)^2 \quad (121)$$

Here the last term is due to the exchange energy. This term exceeds the nucleation field of the homogeneous rotation at a radius of ($N_\perp = 1/2$)

$$R_{crit}^{nuc} = 3.68 \sqrt{\frac{A}{\mu_0 M_s^2}} = 2.60 l_s \quad (122)$$

($l_s = \sqrt{2A/\mu_0 M_s^2}$, see equation (133)). As a consequence the nucleation fields at small radii are determined by homogeneous rotation and at larger radii by the curling mode. Typical values of R_{crit}^{nuc} are 10–20 nm in the case of soft and hard magnetic materials (like permalloy or $Nd_2Fe_{14}B$). At very large radii, the nucleation field approaches the value of the crystal field $2K_1/(\mu_0 M_s)$.

4.2.4 Critical diameters of small particles

Besides the critical diameter R_{crit}^{nuc} for the transition between nucleation modes there exist two further critical diameters related to superparamagnetism and to multidomain formation.

For the application of small particles as permanent magnets or magnetic recording their thermal stability for time intervals of decades of years is an absolute prerequisite. At a critical diameter D_{crit}^{th} the nucleation fields as given by equations (110) and (121) no longer govern the reversal of magnetization. Reversal of magnetization is initiated by thermal fluctuation. The thermal energy kT is large enough to overcome the effective anisotropy energy $K_{eff} = K_1 + \frac{1}{2}(N_\perp - N_\parallel)\, \mu_0 M_s^2$. The average lifetime of a particle of volume V is given by the Arrhenius law (Néel, 1949a; 1949b, 1950)

$$\tau = \tau_0 \exp\left[-K_{eff}\, V/(kT) \right] \quad (123)$$

where the pre-exponential factor τ_0 is determined approximately by $\tau_0^{-1} = (2\pi)^{-1} \gamma H_{eff}$ (γ gyromagnetic ratio, $H_{eff} = 2K_{eff}/(\mu_0 M_s)$. The lifetime τ depends sensitively on the particle volume as demonstrated by Figure 13 for a material with $K_{eff} = 10^5\,\mathrm{J\,m^{-3}}$, $\tau_0 = 10^{-8}\,\mathrm{s}$, $T = 300\,\mathrm{K}$ and a spherical particle of $V = \frac{\pi}{6} D^3$. For a diameter of 11.5 nm the lifetime is $\tau = 0.1\,\mathrm{s}$, whereas for $D = 14.5\,\mathrm{nm}$ a lifetime of $10^8\,\mathrm{s}$ is obtained. Accordingly there exists a very narrow range of diameters where the transition from a stable configuration to an unstable configuration takes place. For the

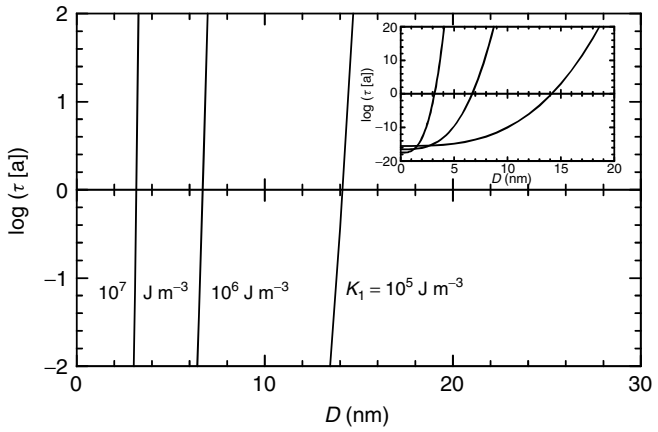

Figure 13. Lifetime of magnetization of a spherical particle of diameter, D, for $K_{\text{eff}} = 10^5$ J/m^{-3}, $\tau_0 = 10^{-8}$s, $T = 300$ K.

material parameters of Co and lifetimes of 0.1 and 10^{10} s the critical diameters are 3.7 and 4.8 nm.

A further critical diameter is determined by the formation of domains due to the increasing magnetostatic stray field energy. For the transition from a single-domain state to a two-domain state the critical diameter for a spherical particle is given by

$$D_{\text{crit}}^{\text{do}} = \frac{9\gamma_{\text{B}}}{(1-\alpha)\mu_0 M_{\text{s}}^2} = \frac{36\sqrt{AK_1}}{(1-\alpha)\mu_0 M_{\text{s}}^2} \qquad (124)$$

where α denotes the factor by which the stray field energy of the homogeneously magnetized single-domain particle is reduced by the formation of a two-domain state. For a sphere, this reduction parameter is found to be $\alpha = 0.4725$ (Goll, Berkowitz and Bertram, 2004), which is very near to the approximate value of $\alpha = 0.5$ as given by Kittel (1949). Table 2 gives a summary of critical diameters $D_{\text{crit}}^{\text{do}}$. Figure 14 shows the dependence of $D_{\text{crit}}^{\text{do}}$ as

Table 2. Critical single-domain diameters of spherical particles according to equation (124). Values for Fe_3O_4, CrO_2 and MnBi were taken from Kronmüller (1991).

Magnet	$\mu_0 M_{\text{s}}^{-2}$ (MJ m^{-3})	γ_{B} (mJ m^{-2})	$D_{\text{crit}}^{\text{do}}$ (nm)
α-Fe	3.82	2.1	9.7
Co	2.54	7.84	55.5
Ni	0.31	0.39	22.6
Fe_3O_4	0.29	2.0	12.4
CrO_2	0.20	2.0	180
MnBi	0.45	12	480
$Nd_2Fe_{14}B$	2.06	24	210
$SmCo_5$	0.88	57	1170
Sm_2O_{17}	1.33	31	420
FePt	1.44	32	340
$BaFe_{12}O_{19}$	0.183	6.3	62

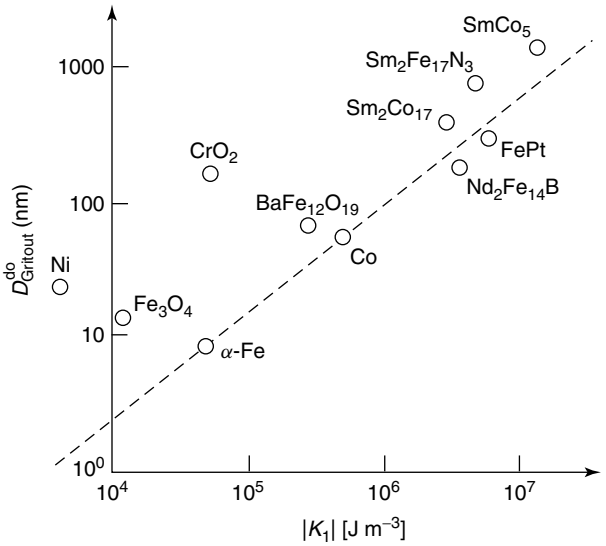

Figure 14. Critical diameters according to equation (124) as a function of K_1.

a function of the anisotropy constant. The low remanence materials do not fit into the empirical law $D_{\text{crit}}^{\text{do}} = (K_1/2.5 \times 10^3\,\text{J m}^{-3})^{0.77}$ (nm). Here it is noteworthy that small critical radii are obtained for α-Fe with $D_{\text{crit}}^{\text{do}} \approx 10$ nm and largest diameter for Co_5Sm with $D_{\text{crit}}^{\text{do}} = 1.17\,\mu$m. Single-domain configurations also have been investigated by the methods of computational micromagnetism. Hertel and Kronmüller (2002) have shown that in cube particles with a quality factor $2K_1/(\mu_0 M_{\text{s}}^2) = 0.1$ (permalloy) the transition from a so-called twisted flower state to a vortex state takes place at an edge length of $8.56\sqrt{2A/(\mu_0 M_{\text{s}}^2)}$ Similarly, Goll, Schütz and Kronmüller (2003) have shown that a square of edge length 1 µm transforms from a four domain Landau structure into a single domain structure at a thickness of 1.5 nm in the case of permalloy and at 2.5 nm and 4 nm in the case of α-Fe and Co, respectively. Hertel (2002) performed similar calculations for rectangular platelets of permalloy of aspect ratio 2:1 and determined the phase diagram of C-state, Landau state, and diamond configurations. It should be noted that these numerical calculations support the analytical calculations of Aharoni (1996) who determined upper and lower bounds for the single domain diameter.

5 LINEARIZED MICROMAGNETIC EQUATIONS

5.1 Brown's equations and the exchange lengths

In cases where the spontaneous magnetization deviates only slightly from a preferred direction the micromagnetic

equations may be linearized in γ_i. This condition exists at large applied fields H_{ext} and large magnetocrystalline energies. Linearization leads to differential equations of second order with constant coefficients. In the following we choose the y axis as the preferred direction either corresponding to the direction of the applied field $H_{\text{ext},2}$ or to an easy direction. Within this coordinate system denoted as Brown's coordinate system the direction cosines follow the conditions

$$\begin{aligned} &\gamma_{1,3} \ll 1; \gamma_2 \sim 1 \\ &\gamma_2 = \sqrt{1-\gamma_1^2-\gamma_2^2} \sim 1 - \frac{1}{2}(\gamma_1^2+\gamma_2^2) \end{aligned} \quad (125)$$

With the condition $\gamma_2 \simeq 1$ the constraint (71) is fulfilled leading to the equilibrium condition

$$\begin{aligned} H_{\text{eff},1} &- \gamma_1 \left(\frac{\partial \phi'_{\text{k}}}{\partial \gamma_2} + \frac{\partial \phi'_{\text{el}}}{\partial \gamma_2} + H_{\text{ext},2} \right) = 0 \\ H_{\text{eff},3} &- \gamma_3 \left(\frac{\partial \phi'_{\text{k}}}{\partial \gamma_2} + \frac{\partial \phi'_{\text{el}}}{\partial \gamma_2} + H_{\text{ext},2} \right) = 0 \end{aligned} \quad (126)$$

To obtain more explicit expressions we develop ϕ'_k and ϕ'_{el} into Taylor series with respect to Brown's coordinates and retain only terms up to the second order in γ_i. With

$$\begin{aligned} \phi'_k(\gamma_i) &= g_0^{\text{k}} + g_i^{\text{k}}\gamma_i + \frac{1}{2} g_{ij}^{\text{k}} \gamma_i \gamma_j \\ &\quad i, j \neq 2 \\ \phi'_{\text{el}}(\gamma_i &= g_0^{\text{el}} + g_i^{\text{el}}\gamma_i + \frac{1}{2}\, g_{ij}^{\text{el}}\, \gamma_i\, \gamma_j \end{aligned} \quad (127)$$

we obtain from equation (127) the linearized micromagnetic equations

$$\begin{aligned} &2A\Delta\gamma_i - J_{\text{s}}(H_{\text{ext}} + H_{\text{s},2})\gamma_i - (g_{ii}^{\text{k}} + g_{ii}^{\text{el}})\gamma_i \\ &-(g_{ij}^{\text{k}} + g_{ij}^{\text{el}})\, \gamma_j + J_{\text{s}} H_{\text{s},i} = g_i^{\text{k}} + g_i^{\text{el}};\ i, j = 1, 3 \end{aligned} \quad (128)$$

and the surface condition

$$\nabla_n \gamma_i = 0, \quad i = 1, 3 \quad (129)$$

Within the framework of linearized equations Poisson' s equation Is written as

$$\Delta U = M_{\text{s}} \left(\frac{\text{d}\gamma_1}{\text{d}x} + \frac{\text{d}\gamma_3}{\text{dz}} \right) \quad (130)$$

A solution of these linearized second-order differential equations is easily obtained by introducing Fourier transforms. With the Fourier transform

$$\left.\begin{aligned} \tilde{\gamma}_i(\boldsymbol{k}) &= \frac{1}{(2\pi)^{3/2}} \int \gamma_i(r) e^{-i\boldsymbol{k}\cdot\boldsymbol{r}}\ \text{d}^3\boldsymbol{r} \\ \gamma_i(\boldsymbol{r}) &= \frac{1}{(2\pi)^{3/2}} \int \tilde{\gamma}_i(k) e^{i\boldsymbol{k}\cdot\boldsymbol{r}}\ \text{d}\boldsymbol{k} \end{aligned}\right\} \quad (131)$$

and the corresponding ones for $U(\boldsymbol{r})$ and $g_i^{\text{k,el}}(\boldsymbol{r})$ the solutions of equations (128) and (130) write (neglecting the terms in g_{ii} and g_{ij}):

$$\left.\begin{aligned} \tilde{\gamma}_i(\boldsymbol{k}) &= -\tfrac{1}{2A}\tfrac{\tilde{g}_i}{k^2+\kappa_{\text{H}}^2} + \tfrac{\kappa_{\text{s}}^2}{2A} \times \tfrac{k_i}{k^2+\kappa_{\text{H}}^2} \times \tfrac{\tilde{g}_x k_x + \tilde{g}_z k_z}{k^4 + (\kappa_{\text{H}}^2+\kappa_{\text{s}}^2)k^2 - \kappa_{\text{s}}^2 k_y^2} \\ \tilde{U}(\boldsymbol{k}) &= -\tfrac{M_{\text{s}}}{k^2}(ik_x\tilde{\gamma}_1 + ik_z\tilde{\gamma}_3) \\ \tilde{H}_{\text{s}}(\boldsymbol{k}) &= -i\boldsymbol{k} \times \tilde{U}(\boldsymbol{k})/(2\pi)^{3/2} \end{aligned}\right\} \quad (132)$$

In the case of long-range RKKY exchange interactions the term Ak^2 has to be replaced by $(J(0) - J(\boldsymbol{k}))M_{\text{s}}^2/(g\mu_{\text{B}})^2$. Equations (132) contain the so-called exchange lengths of the external and of the dipolar fields:

$$l_{\text{H}} = \kappa_{\text{H}}^{-1} = \sqrt{\frac{2A}{J_{\text{s}} H_{\text{ext}}}} \quad l_{\text{s}} = \kappa^{-1} = \sqrt{\frac{2A}{J_{\text{s}} M_{\text{s}}}} \quad (133)$$

If we take into account the magnetocrystalline and the magnetostrictive energy terms in equation (128) two further exchange lengths may be derived. The so-called domain wall parameter and the stress exchange length

$$l_{\text{k}} = \kappa_{\text{k}}^{-1} = \sqrt{\frac{A}{K_1}}, \quad l_\sigma = \kappa_\sigma^{-1} = \sqrt{\frac{2A}{3\lambda_{100}\sigma_{ii}}} \quad (134)$$

The physical meaning of the exchange lengths becomes obvious if we consider δ-function like planar perturbations of the type $g_i \cdot \delta(x)$ and taking into account the torque exerted by only one of the magnetic energies. In the case of a planar perturbation in the (x, z)-plane and a preferred easy axis in y-direction the solution of equation (128) is given by

$$\gamma_i(y) = \gamma_0\, e^{-|y|/l_i}\ (i = 1, 3) \quad (135)$$

where for l_i the dominant exchange length has to be inserted. Values for exchange lengths at room temperature are given in Table 3 together with the wall widths and energies using the characteristic values for A, $J_{\text{s}}, M_{\text{s}}, K_i, \lambda_{ijk}, \delta_{\text{B}}, T_{\text{C}}$ of Table 1. According to equation (135) a local perturbation of the spin orientation leads to an extended deviation of the spin system governed by the exchange lengths as shown in Figure 15. There exist rather large variations of the exchange lengths l_{k} because the K_1-values may vary over 6 orders of magnitude, whereas l_{s} varies only between

Table 3. Exchange lengths, wall widths (in nm) and specific wall energy of transition metals, intermetallic compounds, and oxides at room temperature (l_H determined for $H = 1000\,Oe = 10^6/4\pi$ [A/m], l_σ determined for $\sigma = 10$ MN/m^2).

3 and 10 nm because the interesting magnetic materials have similar polarizations from 0.5 to 2 T and also similar exchange constants between 10 and 30 pJ m^{-1}. In general, that exchange length dominates the spin distribution which leads to the lowest energy state, that is, either the spin system avoids excitation of the high energy modes and if this is not possible owing to boundary conditions the spin inhomogeneities become extended or constricted.

5.2 Applications of Brown's equations

5.2.1 Nucleation processes

The determination of nucleation fields of single-domain configurations has been one of the big successes of the linearized micromagnetic equations. Brown (1945) raised the problem that the coercive fields of real materials in general is much smaller than the nucleation fields as discussed in Section 4.2. There are many experimental efforts to solve this so-called Brown's paradox. Lubersky and Morelock (1964) showed that by the use of Fe-whiskers with diameters larger than 10 nm the nucleation field of the curling mode (see equation (121)) may be approached. Also for Ni-wires the curling modes have been realized by Lederman *et al.* (1995). Measurements of the Stoner–Wohlfarth asteroids have been performed for two-fold anisotropy as Co (Bonet *et al.*, 1999) and for four-fold anisotropy by Thirion *et al.* (2006). Details of these experiments are discussed in **Magnetization Configurations and Reversal in Small Magnetic Elements, Volume 2**.

A further problem treated by Brown's equations is the nucleation in inhomogeneous materials where there exist a local perturbation of the crystal anisotropy constant. The nucleation fields for planar Gaussian perturbations $K_1(z) = K_s + \Delta K(1 - e^{-z^2/r_0^2})$ and hyperbolic perturbations, $K_1(z) = K_1(\infty) - \Delta K/\mathrm{ch}^2(z/r_0)$. ($K_s$ = anisotropy at the center of the planar perturbation, $K_1(\infty) = K_s + \Delta K$, anisotropy constant in the unperturbed matrix) have been determined (Kronmüller, 1987; Kronmüller and Fähnle, 2003) leading to a modified nucleation field

$$H_N = \frac{2K_1}{\mu_0 M_s}\,\alpha_k - N_{eff}\,M_s \tag{136}$$

where the microstructural parameters α_k and N_{eff} depend on the properties of the perturbation, that is, r_0 and ΔK, as well as on the geometry of the perturbation. In the special case where $\Delta K = K_1(\infty)$, the α-parameter for inhomogeneities of average thickness $r_0 > \delta_B$ corresponds to

$$\alpha_k = \frac{\delta_B}{\pi r_0} \tag{137}$$

Experimental values for α_k and N_{eff} are discussed in details by Kronmüller and Fähnle (2003) and in **Micromagnetism–Microstructure Relations and the Hysteresis Loop, Volume 2**. Of course there exist further deteriorating effects as misaligned particles or exchange coupled particles the effects of which are taken into account by microstructural parameters α_ψ and α_{ex} (see Kronmüller and Fähnle, 2003 and **Micromagnetism–Microstructure Relations and the Hysteresis Loop, Volume 2**).

5.2.2 Law of approach to ferromagnetic saturation (LAFS)

Modern theory of micromagnetism has been born by Brown's attempt to explain the so far unexplained $1/H$ term in the law of approach to ferromagnetic saturation (LAFS) (Brown, 1940, 1941). The conventional LAFS $J(H) = J_s - a_1/H - a_2/H^2$ later on has been found to contain also broken

exponents (Kronmüller, 1959; 1967)

$$J(H) = J_s - \frac{a_{1/2}}{H^{1/2}} = \frac{a_1}{H} - \frac{a_{3/2}}{H^{3/2}} - \frac{a_2}{H^2} + \frac{a_3}{H^3} + \alpha T\sqrt{H} + \chi_p \mu_0 H \tag{138}$$

The existence of the field dependent terms in equation (138) makes it difficult to determine the spontaneous polarization J_s for $H = 0$ and any temperature. Furthermore it has to be noted that the coefficients $a_{n/2}$ result from intrinsic and extrinsic properties. In particular, the term $\propto \sqrt{H}$ results from the field dependence of the spectrum of spin-wave excitations (Holstein and Primakoff, 1940; Kronmüller and Fähnle, 2003). The linear term is due to the Pauli paramagnetism, which is described in ferromagnetic materials by an enhanced parasusceptibility χ_p. Whereas these latter two terms have to be determined on the basis of quantum mechanics the $a_{n/2}$ terms are determined by the concepts of micromagnetism. Which one of the $a_{n/2}$ terms dominates depends on the material parameters and the microstructure of the material.

1. *Intrinsic effects*:
   (a) *Uniaxial and cubic crystals*: In uniaxial and cubic crystals the LAFS is described by $1/H^2$ and $1/H^3$ terms if the magnetic field is misaligned with respect to one of the main crystal axes: $\langle 1000\rangle$ in hexagonal crystals and $\langle 100\rangle$, $\langle 110\rangle$ and $\langle 111\rangle$ in cubic crystals. In the case of uniaxial crystals for large fields $H > 2K_1/J_s$, the LAFS is

$$J(H) = J_s\left(1 - \left(\frac{K_1 \sin 2\psi_0}{2K_1 \cos 2\psi_0 + HJ_s}\right)^2\right) \tag{139}$$

where ψ_0 corresponds to the angle between H and the [0001] axis. By averaging over all possible easy directions of the upper half sphere and taking into account the second anisotropy constant the LAFS is (Néel, Pauthenet, Rimet and Giron, 1960)

$$J(H) = J_s\left(1 - \left[\frac{4K_1^2}{15J_s^2} - \frac{64}{105}\frac{K_1K_2}{J_s^2} - \frac{128}{315}\frac{K_2^2}{J_s^2}\right]\frac{1}{H^2}\right) \tag{140}$$

The LAFS of cubic crystals has been treated by Akulov (1928–1931), Gans (1932), and Becker and Döring (1939). The latter authors have determined the full angular dependence of the LAFS. In the case of a polycrystal the averaging over all possible orientations of crystal grains gives

$$J(H) = J_s\left(1 - \frac{8}{105}\frac{K_1}{J_s^2}\frac{1}{H^2} - \frac{192}{5005}\frac{K_1^3}{J_s^3}\frac{1}{H^3}\right) \tag{141}$$

According to equations (140 and 141) from measurements of the high-field polarization the anisotropy constant K_1 can be determined.

   (b) *Amorphous alloys*: In amorphous alloys the intrinsic material parameters are fluctuating quantities as

$$\left.\begin{aligned} J_2(\boldsymbol{r}) &= \langle J_2(\boldsymbol{r})\rangle + \delta J_2(\boldsymbol{r}) \\ g_{ij}^k(r) &= \langle g_{ij}^k(\boldsymbol{r})\rangle + \delta g_{ij}^K(\boldsymbol{r}) \end{aligned}\right\} \tag{142}$$

where $\langle J_2(\boldsymbol{r})\rangle = J_s$, $\langle g_{ij}^k\rangle = 0$, $\langle \delta J_2(\boldsymbol{r})\rangle = 0$.
The effect of these fluctuations has been treated by Kronmüller and Ulner (1977) and by Fähnle and Kronmüller (1978) under the assumption of uncorrelated fluctuations of the material properties. Fluctuations in the polarization result in volume charges, $\mathrm{div}\delta\boldsymbol{J}$ and the exerted dipolar fields produce further inhomogeneities of the orientation of the local magnetization. The micromagnetic equation for the case of magnetostatic fluctuations and a large applied field, H, parallel to the γ-direction, are given by ($i = 1, 3$):

$$\begin{aligned} 2A\ \Delta\gamma_i + \langle J_2(\boldsymbol{r})\rangle\ H_{s,i}(\boldsymbol{r}) - \langle J_2(\boldsymbol{r})\rangle H\ \gamma_i &= 0 \\ \Delta U = \frac{1}{\mu_0}\,\mathrm{div}\ \boldsymbol{J}_2(\boldsymbol{r}) = \frac{1}{\mu_0}\frac{\partial}{\partial y}\ (\delta \boldsymbol{J}_2(\boldsymbol{r})) & \end{aligned} \tag{143}$$

For a spatially random distribution of magnetizations the fluctuations $\delta\boldsymbol{J}_2(\boldsymbol{r})$ obey the following relation

$$\langle \delta \boldsymbol{J}_2(\boldsymbol{r})\ \delta \boldsymbol{J}_2(r')\rangle = \Omega_0 J_s(\boldsymbol{r}) \cdot \delta\left(\boldsymbol{r} - \boldsymbol{r}'\right) \tag{144}$$

where Ω_0 denotes the atomic volume and $\langle \boldsymbol{J}\rangle = \boldsymbol{J}_s$ holds. According to Kronmüller and Ulner (1977) the solutions for γ_i lead to the following LAFS:

$$\begin{aligned} J(H) = J_s 1 - \Omega_0 \frac{(2A/J_s)^{1/2}}{120\pi}\kappa_s^4 \\ \times\left(\frac{1}{H^{1/2}} - \frac{1}{2}\frac{M_s}{H^{3/2}}\right) \\ \text{for } \kappa_H^2 > \kappa_s^2, \text{ and} \\ J(H) = J_s\left(1 - 14 \cdot 10^3\, \Omega_0 \kappa_s^3\right) \end{aligned} \tag{145}$$

for $\kappa_H^2 \geq \kappa_s^2$. The latter equation shows that the dipolar fluctuations in the ground state at $H = 0$

reduce the spontaneous polarization by 10–20%. Taking into account magnetocrystalline fluctuations

$$\langle g_{i2}^{\mathrm{k}}\ (\boldsymbol{r}) \cdot g_{i2}^{\mathrm{k}}\ (\boldsymbol{r}')\rangle = \langle(\delta\ g_{i2}^{\mathrm{k}}(\boldsymbol{r}))^2\rangle\delta(\boldsymbol{r}-\boldsymbol{r}') + \langle g_{i2}(\boldsymbol{r})\rangle^2 \quad (146)$$

the result for the LAFS is

$$J(H) = J_{\mathrm{s}} - \frac{a_{1/2}}{H^{1/2}} - \frac{a_2}{H^2} \quad (147)$$

where the $a_{1/2}$ term results from short-range fluctuations and the $1/H^2$ term takes care of a long-range anisotropy $k_{i2} \neq 0$.

2. *Extrinsic effects*:

(a) *Elastic stress sources in crystalline materials*: Originally Brown (1940, 1941) developed the continuum theory of micromagnetism in order to explain the $1/H$ terms in the LAFS. The basis for this type of calculations was the linearized micromagnetic equation ($i = 1, 3$)

$$2A\Delta\gamma_i - J_{\mathrm{s}}H_{\mathrm{ext}}\gamma_i = g_i^{\mathrm{el}}(\boldsymbol{r}),$$
$$\text{where } g_i^{\mathrm{el}} = \frac{\partial\phi'_{\mathrm{el}}}{\partial\gamma_i}\Big|_{\gamma_{i,1,3}\ll 1}^{\gamma_2=1} \propto \sigma_{\mathrm{kl}} \quad (148)$$

Equation (148) has been applied to all types of stress sources leading to characteristic field dependences of the LAFS:

– Atomic spherical defects and dislocation loops for small radii $\kappa_{\mathrm{H}}r_0 < 1$
These types of defects corresponds to elastic dipoles:

$$\sigma \propto \frac{1}{r^3} \quad J(H) = J_{\mathrm{s}} - \frac{a_{1/2}}{H^{1/2}} \quad \text{for } \kappa_{\mathrm{H}}r_0 < 1$$
$$J(H) = \boldsymbol{J}_{\mathrm{s}} - \frac{a_1}{H} - \frac{a_2}{H^2} \quad \text{for } \kappa_{\mathrm{H}}r_0 \gg 0 \quad (149)$$

– Straight dislocation lines:

$$\sigma \propto \frac{1}{r}; \quad J(H) = J_{\mathrm{s}} - \frac{a_2}{H^2} \quad (150)$$

– Straight dislocation dipoles:

$$\sigma \propto \frac{1}{r^2}: \ J(H) = J_{\mathrm{s}} - \frac{a_1}{H} \quad (151)$$

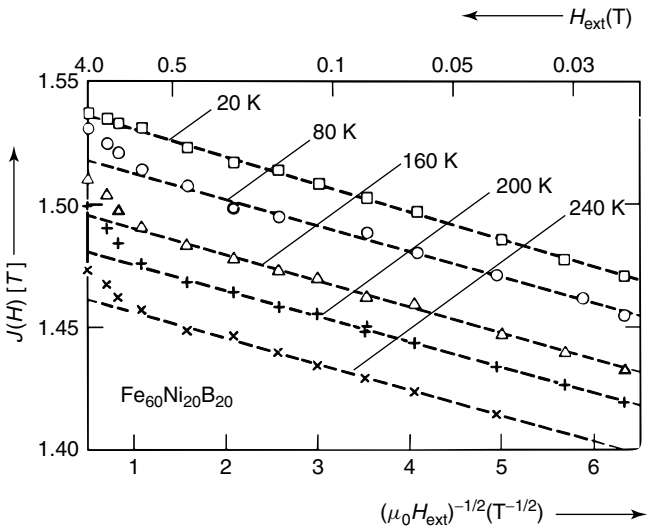

Figure 16. High-field polarization as a function of $1/(\mu_0 H)^{1/2}$ of amorphous thin films of $Fe_{60}Ni_{20}B_{20}$ for different temperatures.

(b) *Spherical nonmagnetic inclusions of radius* r_0:

$$J(H) = J_{\mathrm{s}} - \frac{a_{1/2}}{H^{1/2}} \text{ for } 1 < 8\kappa_{\mathrm{H}}r_0 < 17 + \kappa_{\mathrm{s}}^2 r_0^2$$
$$J(H) = J_{\mathrm{s}} - \frac{a_{3/2}}{H^{3/2}} \text{ for } 8\kappa_{\mathrm{H}}r_0 \gg 17 + \kappa_{\mathrm{s}}^2\ r_0^2 \quad (152)$$

Measurements of the LAFS have revealed the $a_{1/2}, a_1, a_2$ terms in crystalline and amorphous materials. As on example Figure 16 shows the $a_{1/2}$-term for sputtered thin films of amorphous $Fe_{80}B_{20}$ for different temperatures between 20 K and 240 K (Lenge and Kronmüller, 1986). A detailed analysis of these results considering magnetocrystalline fluctuations and the presence of pointlike defects have been performed previously (Kronmüller, Durst and Martinek, 1987; Kronmüller and Fähnle, 2003) showing that both contributions, magnetocrystalline fluctuations as well as pointlike stress centers contribute to $a_{1/2}$. The existence of the $1/H$-term has been detected in as-quenched and plastically deformed amorphous alloys of $Fe_{40}Ni_{40}P_{14}B_6$ (Grimm and Kronmïller, 1980, 1983; Kronmüller *et al.*, 1979). This $1/H$-term results from small linearly extended elastic dipoles due to the agglomeration of vacancy type so-called free volumes (Kronmüller and Fähnle, 2003; Kronmüller, Lenge and Habermaier, 1984). The $1/H^2$-term, which is the result of long-range stresses or magnetocrystalline anisotropies, and also induced anisotropies is the dominant term in crystalline materials, and, in particular, in plastically deformed materials (Kronmüller, 1959; Köster, 1967; Grimm and Kronmüller, 1983; Domann, Grimm and Kronmüller, 1979). Examples of this kind are presented in contributions

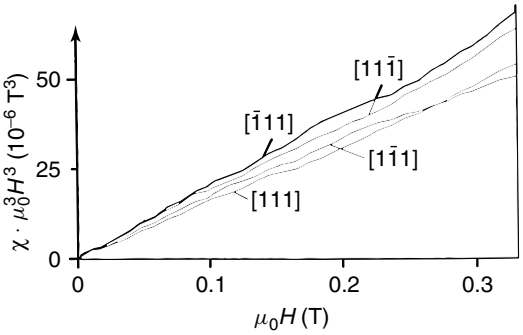

Figure 17. Analysis of the high-field susceptibility of a cyclically deformed Ni single crystal. χH^3 measured parallel to the four ⟨111⟩-directions. Accumulated plastic strain $a_{\mathrm{pl}} = 50$, amplitude per cycle 0.075, flow stress 56.6 MPa (Kronmüller and Fähnle (2003)). (Reproduced with permmission from Cambridge University Press.)

Micromagnetism–Microstructure Relations and the Hysteresis Loop, Volume 2. As a further example Figure 17 shows the analysis of the high-field susceptibility of a cyclically deformed Ni single crystal. In this case the quantity χH^3 follows a linear relation in H thus pointing to the presence of dislocation dipoles. The existence of dense linear clusters of dipole bundles has been proven by transmission electron microscopy (Kronmüller and Fähnle, 2003).

The analysis of the LAFS allows the determination of the temperature dependence of the spontaneous magnetization at $H = 0$. From the $T^{3/2}$-Bloch law the spin-wave stiffness constant and the related exchange energy can be determined if the $1/H^{n/2}$- plots are extrapolated to $H \to 0$. Furthermore from the existence of the $a_{n/2}$ parameters the kind of microstructures can be analyzed (dislocations, dislocation dipoles, point defects, para-, and diamagnetic precipitations).

Extended reviews of this type of analysis have been previously given (Kronmüller and Fähnle, 2003; Kronmüller, 1979, 1981; Umakoshi and Kronmüller, 1981; Grimm and Kronmïller, 1980, 1983; Domann, Grimm and Kronmüller, 1979; Vasquez, Fernengel and Kronmüller, 1989; Kronmüller *et al*., 1979).

6 MICROMAGNETISM OF DOMAIN PATTERNS

6.1 Laminar domain patterns

Analytical determinations of domain patterns by solving the integro-differential equations as derived in Section 3 so far do not exist owing to the complexity of the nonlinear differential equations, which are combined with the differential equations for the long-range dipolar fields. The usual procedure to determine the parameters of domain patterns therefore is based on four steps in order to approximate the true magnetic structure:

1. The existence of dws characterized by their specific wall energy, γ_{B}, is presupposed.
2. Assumptions are made concerning the arrangements of dws.
3. The total Gibbs free energy of dws arrangement is minimized with respect to the geometry of the dws arrangements.
4. Different arrangements of dws are compared with each other. First attempts to determine the size of Weiss domains are due to Landau and Lifshitz (1935) and (Kittel and Galt, 1956).

Several authors have given extended presentations of the state-of-the-art (Hubert and Schäfer, 1998; Hubert, 1974; Chikazumi, 1997; and Kronmüller and Fähnle, 2003). The subdivision of ferro- or ferrimagnetic materials into domains establishing a global demagnetized state results form the magnetostatic energy. For example, the magnetostatic energy of a platelet magnetized perpendicular to the surface per unit surface area is given by $\frac{1}{2}\mu_0 M_{\mathrm{s}}^2 \cdot T$, where T denotes the thickness of the platelet. By means of the formation of domains magnetized parallel or antiparallel to the easy directions this magnetostatic energy can be drastically reduced. On the other hand, however, owing to the formation of domains the total wall energy increases. Therefore an equilibrium domain width exists where the total magnetic Gibbs free energy corresponds to a minimum. In general, the magnetostatic stray field energy is reduced by the formation of so-called closure domains at the surface of the specimen. The type of closure domain is governed by the quality parameter

$$Q = \frac{2K_1}{\mu_0 M_{\mathrm{s}}^2} \tag{153}$$

For $Q > 1$ the closure structure of these hard magnetic materials is governed by the stray field energy, whereas for $Q < 1$ the magnetization deviates from the easy directions and the magnetocrystalline energy determines the energy of closure domains. Several examples of laminar domain patterns are shown in Figure 18 where the Landau structure for $Q < 1$ and the Kittel structure for $Q > 1$ are presented. Of special interest are Landau-type structures with vortices as shown in Figure 19. In the case of laminar domain patterns the total energy per unit area is given by

$$\phi_{\mathrm{tot}} = \gamma_{\mathrm{B}} \frac{T}{D} + \phi_{\mathrm{cl}} \cdot D \tag{154}$$

The first term on the right side of equation (154) corresponds to the specific dw energy, increasing with decreasing domain width D, and the second term corresponds to the energy per

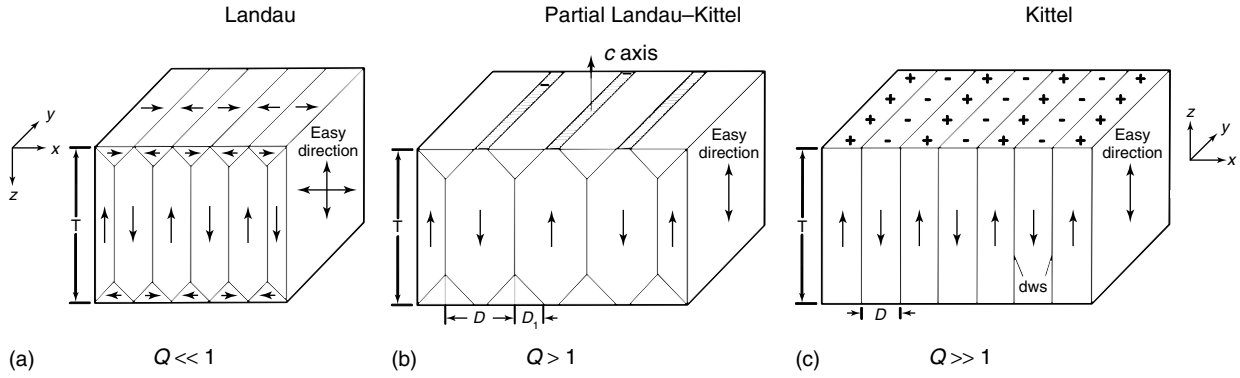

Figure 18. Characteristic laminar domain pattern of platelets for different Q-parameters. (a) Landau structure in ⟨100⟩-α-Fe platelets. (b) Partial Landau–Kittel structure for intermediate Q values (Co). (c) Open Kittel structure for hard magnetic uniaxial crystals with $Q \geq 1$ (FeNdB) (Kronmüller and Fähnle (2003)). (Reproduced with permmission from Cambridge University Press.)

unit area of the closure domains. The equilibrium domain width is obtained from a minimization of ϕ_{tot} with respect to D, giving

$$D = \sqrt{\frac{\gamma_{\text{B}}\, T}{\phi_{\text{cl}}}} \tag{155}$$

Without considering the details of the calculation of ϕ_{el} the results are the following ones:

1. Landau structure of α-Fe with easy directions perpendicular and in-plane. In this case, the closure domain energy is determined exclusively by the magnetoelastic energy, which leads to

$$D = \sqrt{\frac{\gamma_{\text{B}} T}{\frac{9}{16} c_{11} \lambda_{100}^2}} \tag{156}$$

2. Landau structure of a uniaxial soft magnetic materials ($Q \leq 1$) with closure domains magnetized in hard direction

$$D = \sqrt{\frac{\gamma_{\text{B}} T}{\frac{1}{2} K_1}} \tag{157}$$

3. Kittel structure in hard magnetic materials ($Q \geq 1$), with easy direction perpendicular to the platelet.

$$D = \sqrt{\frac{\gamma_{\text{B}} T}{\left(\frac{1.7}{4\pi}\right) M_{\text{s}} J_{\text{s}}}} \tag{158}$$

Equations (156–158) may be used to determine relevant magnetic parameters. For example, from equation (157) we derive:

$$K_1 = 64AT/D^4;\ \gamma_{\text{B}} = 32AT/D^2;\ \delta_{\text{B}} = \frac{\pi}{8} D^2/T \tag{159}$$

So far we have considered domain patterns with discrete orientation of magnetization in the bulk and in the closure domains. In soft magnetic materials, however, the transition from the Kittel structure to the Landau structure with vanishing stray fields takes place continuously as discussed by Hubert and Schäfer (1998) as well as Kronmüller and Fähnle (2003).

In order to describe this process Williams, Bozorth and Shokley (1949) introduced an effective permeability μ^* that takes care of the fact that in materials $Q \leq 1$ the magnetization inclines parallel to the surface not taking care of the easy directions in order to reduce the surface charges. This effect may be taken into account by introducing the effective permeability

$$\mu^* = 1 + \frac{J_{\text{s}}^2}{2\mu_0 K_1} = 1 + Q^{-1} \tag{160}$$

If equation (160) is introduced into equation (158) by replacing μ_0 by $\mu_0 \mu^*$ for a rotation angle of 45° in this closure domains the domain width is given by

$$D = \sqrt{\frac{\gamma_{\text{B}}\, T(1 + Q^{-1})}{\frac{1.7}{4\pi} M_{\text{s}} J_{\text{s}}}} \tag{161}$$

Equations (161) describes fairly well the transition from the Kittel structure ($Q \geq 1$) to the Landau structure ($Q \leq 1$).

6.2 Landau structures with vortices

Domain patterns with vortex structures exist mainly in thin films where the geometry and the distribution of easy directions allows a reduction of the stray field energy only by the formation of vortices at the crossing points of the dws. Typical examples are shown in Figure 19.

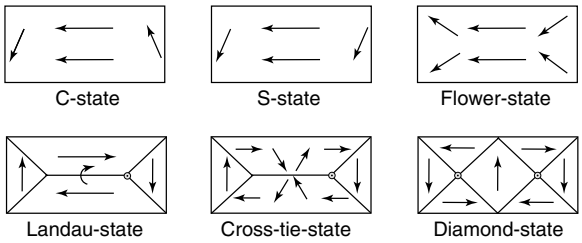

Figure 19. Typical domain patterns in rectangular platelets with vortices in the case of low remanence configurations ($Q \leq 1$) (Kronmüller and Fähnle (2003)). (Reproduced with permmission from Cambridge University Press.)

According to Feldtkeller and Thomas (1965), a vortex corresponds to a region where the magnetization rotates by 360° around a singular point where the magnetization is oriented perpendicular to the film. This configuration is due to the fact that an in-plane magnetization rotating by 360° in the center of the configuration leads to a singularity of the exchange energy because $(\nabla\gamma_i)^2$ becomes infinite. To avoid this singularity the magnetization rotates out of the plane thus producing stray field energy, however, avoiding the singularity of exchange energy. Figure 20 shows the four domain Landau structures in a square platelet with the vortex in the center and Figure 21 shows the spin distribution in the center of the vortex. Different attempts have been made in order to describe the distribution of magnetization within the vortex (Feldtkeller, 1965; Usov and Peschany, 1993, 1994).

These authors use the Ritz method assuming a functional distribution of J_s and minimizing the total magnetic energy. Feldtkeller' s Ansatz for the angle ϑ between $\boldsymbol{J}_s$ and the

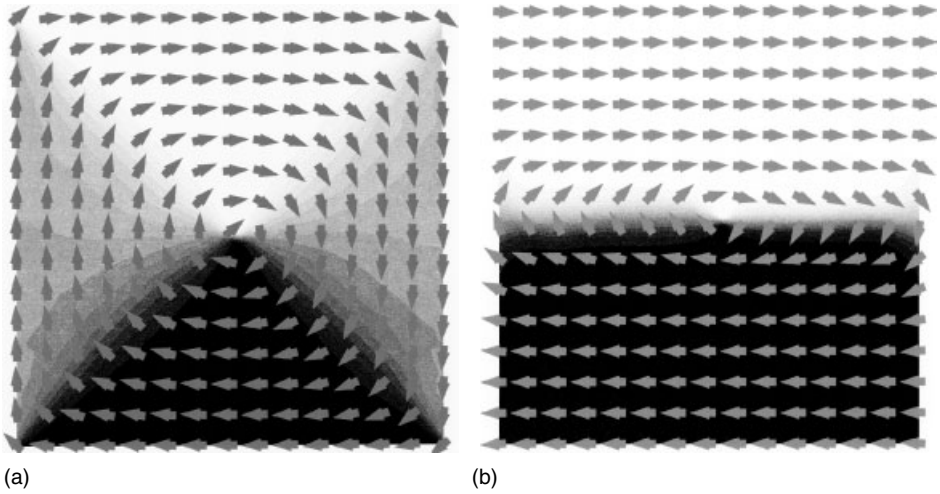

Figure 20. Four and two-domain Landau structures in a square platelet with vortex in the center for Permalloy (a) and Co (b) (Goll, Schütz and Kronmüller, 2003). (Reproduced from Goll *et al*., 2003, with permission from the American Physical Society. © 2003.)

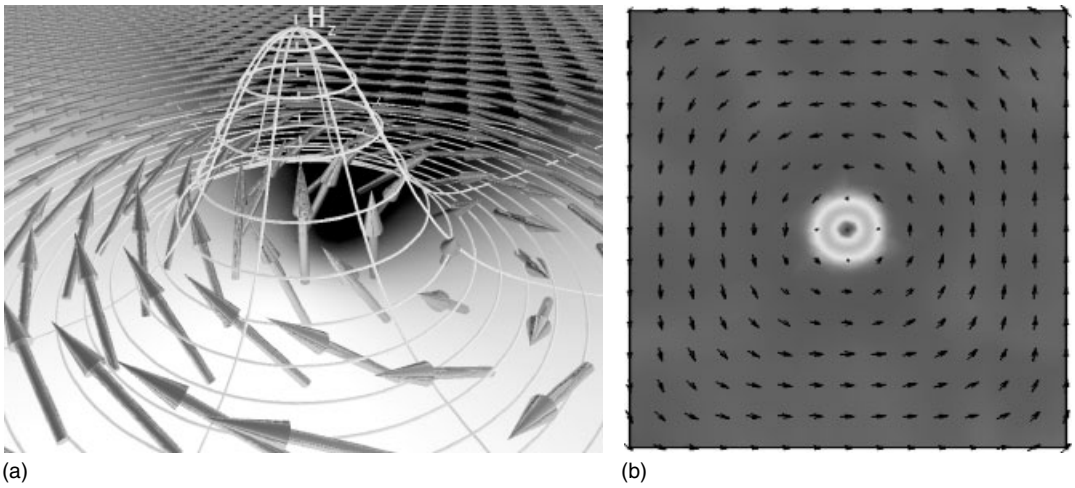

Figure 21. Distribution of magnetization in the center of a vortex. (Courtesy of S. Macke.)

vortex axis is given by $\vartheta(r) \propto \cos[\exp(-2\beta^2 r^2)]$, whereas Usov uses

$$\sin\vartheta = \frac{2\,b\,r}{b^2 + r^2}, \quad \text{for } 0 < r < b, \qquad (162)$$
$$\sin\vartheta = 0 \qquad \text{for } b < r < R$$

where R denotes the radius of the platelet. The parameters β and b in the Feldtkeller and the Usov model have to be determined from the minimization of the total energy. Figure 22 shows the distribution of the reduced z-component, M_z/M_s for the Feldkeller and the Usov model in the case of permalloy. The vortex radius in the case of the model Feldtkeller (1965) varies between 1.5 l_s and 3 l_s for film thicknesses ranging between zero and 20 l_s. Similar results were obtained by Usov and Peschany (1993, 1994) with variation from 2.2 to 4.5 l_s.

Numerical calculations by the finite element technique give further information on the details of the vortex structure. In particular, it turns out that there exists a negative M_z component for distances larger than the vortex radius (see Figure 23). This negative component is of the order of 2% for a platelet of thickness of 25 nm and vanishes nearly for thicknesses $< l_s$.

It is of interest to compare the vortex energy with the total magnetic energy stored in a square platelet of dimensions $250 \times 250 \times 25\,\text{nm}^{-3}$. For permalloy with $A = 13\,\text{pJ m}^{-1}$, $J_s = 1\,\text{T}$, $K_1 = 5.0 \times 10^2\,\text{J m}^{-3}$, $l_s = 5.7\,\text{nm}$ the total magnetic energy of the platelet, composed of ϕ_{ex}, ϕ_k and ϕ_s is 19.83×10^{-18} J, whereas the total magnetic energy

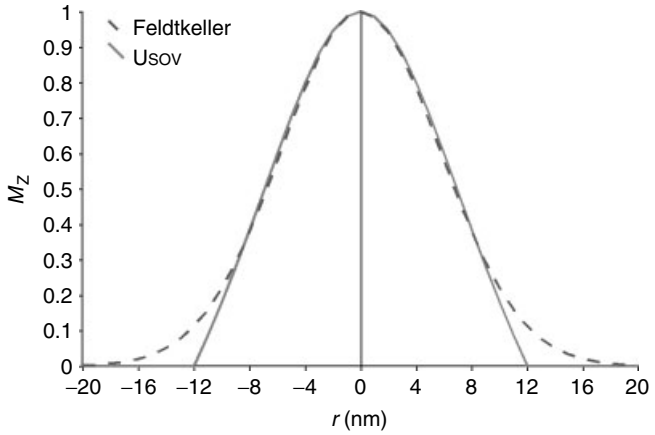

Figure 22. Distribution of M_z/M_s for the Feldtkeller and the Usov Ansatz for permalloy for a film thickness of 5 nm $\approx 1.5 l_s$. (Courtesy of D. Goll and S. Macke.)

stored in the vortex kernel (vortex extension limited by the radius where $m_z = 0$) amounts only to 5.63×10^{-18} J. From these results it becomes obvious that in macroscopic domain patterns the energy stored in vortex arrangements remains rather small in comparison to the dw energies of nm, μm, and cm dimensions. Therefore vortices determine the spin arrangement only in particles of small dimensions.

Many investigations on-line structures in domain walls have been performed on the basis of micromagnetism such as Néel lines, in Bloch walls and Bloch lines and Hubble domains (Thiaville *et al.*, 1991; Miltat, Thiaville and Trouilloud, 1989).

7 MICROMAGNETISM OF DYNAMIC MAGNETIZATION PROCESSES

7.1 The Landau–Lifshitz–Gilbert (LLG) equation

The micromagnetic theory of dynamic magnetization processes deals with the problems of reducing energy losses, with small switching times in demagnetization processes of small particles and thin films and the calculation of resonance frequencies and spin-wave spectra. A first description of the time-dependent motion of magnetic moments is due to Bloch (1932) who considered uncoupled and undamped magnetic moments. Equations for the damped motion of the magnetic polarization at first were published by Landau and Lifshitz (1935).

Starting from the classical mechanical equation for the rotational motion of a rigid body, $\mathrm{d}\boldsymbol{P}/\mathrm{d}t = \boldsymbol{L}$, where $\boldsymbol{P}$ is the angular momentum and $\boldsymbol{L}$ the torque acting on the body, the equation of motion of the magnetic polarization is obtained by using the magneto-mechanical analogue $\boldsymbol{J}_\mathrm{s} = \gamma \boldsymbol{P}$ and inserting the magnetic torque $\boldsymbol{L} = [\boldsymbol{J}_\mathrm{s} \times \boldsymbol{H}_\mathrm{eff}]$, which gives for the undamped rotational motion

$$\mathrm{d}\boldsymbol{J}_\mathrm{s}/\mathrm{d}t = \gamma\,[\boldsymbol{J}_\mathrm{s} \times \boldsymbol{H}_\mathrm{eff}] \tag{163}$$

Here γ denotes the gyromagnetic ratio, $\gamma = -g\,|e|\,/2m = -1.1051g$ $(\mathrm{sA/m})^{-1}$. Landau and Lifshitz have expanded equation (163) by introducing a damping term according to

$$\frac{\mathrm{d}\boldsymbol{J}_\mathrm{s}}{\mathrm{d}t} = \gamma_\mathrm{L}\ [\boldsymbol{J}_\mathrm{s} \times \boldsymbol{H}_\mathrm{eff}]\ - \frac{\alpha_\mathrm{L}}{J_\mathrm{s}}\ [\boldsymbol{J}_\mathrm{s} \times [\boldsymbol{J}_\mathrm{s} \times \boldsymbol{H}_\mathrm{eff}]] \tag{164}$$

Dividing equation (164) by μ_0 and introducing M_s the equation of motion of the spontaneous magnetization is obtained

$$\frac{\mathrm{d}\boldsymbol{M}_\mathrm{s}}{\mathrm{d}t} = \gamma_\mathrm{L}\ [\boldsymbol{M}_\mathrm{s} \times \boldsymbol{H}_\mathrm{eff}] - \frac{\alpha_\mathrm{L}}{M_\mathrm{s}}\ [\boldsymbol{M}_\mathrm{s} \times [\boldsymbol{M}_\mathrm{s} \times \boldsymbol{H}_\mathrm{eff}]] \tag{165}$$

The first term on the right side of equation (165) describes a precessional rotation of $\boldsymbol{M}_\mathrm{s}$ with frequency $\omega = -\gamma H_\mathrm{eff}$. The minus sign in ω means that in the case of a positive effective field the precessional motion takes place anticlockwise. The second term rotates $\boldsymbol{M}_\mathrm{s}$ toward the direction of the effective field, that is, after some time the precessional motion of $\boldsymbol{M}_\mathrm{s}$ finally stops (Figure 24). Equation (165) describes a motion of $\boldsymbol{M}_\mathrm{s}$, which accelerates with increasing damping parameter α_L. Gilbert (1955) pointed out that equation (165) can only be used for small damping. In order to describe the strong damping in thin films (Gilbert and Kelly, 1955) Gilbert

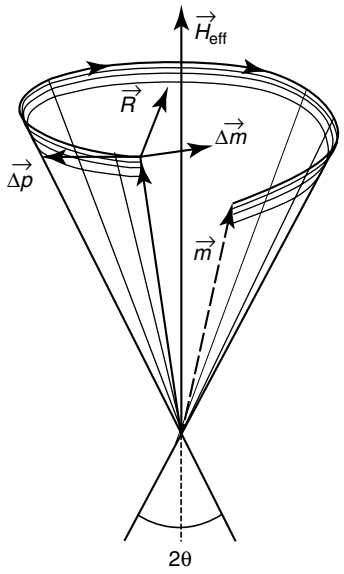

Figure 24. Precessional movement of magnetization around the effective field showing the directions of precessional and damped component.

(1955) proposed an alternative equation, which is written as

$$\frac{\mathrm{d}\boldsymbol{M}_\mathrm{s}}{\mathrm{d}t} = \gamma_\mathrm{G}\ [\boldsymbol{M}_\mathrm{s} \times \boldsymbol{H}_\mathrm{eff}] + \frac{\alpha_\mathrm{G}}{\boldsymbol{M}_\mathrm{s}}\left[\boldsymbol{M}_\mathrm{s} \times \frac{\mathrm{d}\boldsymbol{M}_\mathrm{s}}{\mathrm{d}t}\right] \tag{166}$$

The subscripts L and G in equations (165) and (166) point to the Landau–Lifshitz (LL) and the Gilbert equation. In order to compare the LL and the Gilbert equation the term $\mathrm{d}\boldsymbol{M}_\mathrm{s}/\mathrm{d}t$ on the right side of equation (166) is replaced by the Gilbert equation itself. This leads to the so-called Landau–Lifshitz–Gilbert (LLG) equation:

$$\frac{\mathrm{d}\boldsymbol{M}_\mathrm{s}}{\mathrm{d}t} = \frac{\gamma_\mathrm{G}}{(1+\alpha_\mathrm{G}^2)}\,[\boldsymbol{M}_\mathrm{s} \times \boldsymbol{H}_\mathrm{eff}] + \frac{\alpha_\mathrm{G}\gamma_\mathrm{G}}{(1+\alpha_\mathrm{G}^2)M_\mathrm{s}}\ [\boldsymbol{M}_\mathrm{s} \times [\boldsymbol{M}_\mathrm{s} \times \boldsymbol{H}_\mathrm{eff}]] \tag{167}$$

where the following replacements have taken place

$$\gamma_\mathrm{L} \to \frac{\gamma_\mathrm{G}}{1+\alpha_\mathrm{G}^2}; \quad \alpha_\mathrm{L} \to \frac{\alpha_\mathrm{G}\ \gamma_\mathrm{G}}{1+\alpha_\mathrm{G}^2} \tag{168}$$

The LL and the LLG equation have a similar form, however, the dependences of the precessional and of the damping terms on the parameters $\gamma_{\mathrm{L,G}}$ and $\alpha_{\mathrm{L,G}}$ are quite different.

This becomes obvious if we consider the dependence of the precessional and of the damping term on the $\alpha_{\mathrm{L,G}}$ parameters as presented in Figure 25. The precessional term $\boldsymbol{P} \propto [\boldsymbol{M}_\mathrm{s} \times \boldsymbol{H}_\mathrm{eff}]$, remains constant in the case of the LL equation and decreases in the case of the LLG equation. The damping term increases linearly with α_L in the case

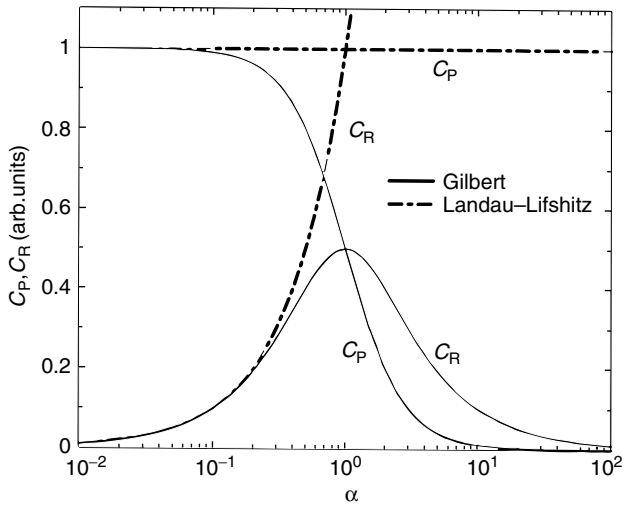

Figure 25. Components of $\mathrm{d}\boldsymbol{M}/\mathrm{d}t$ as a function of α. Precession $C_\mathrm{P} \propto \boldsymbol{M}_\mathrm{s} \times \boldsymbol{H}_\mathrm{eff}$ and damping term $C_\mathrm{R} \propto [\boldsymbol{M}_\mathrm{s} \times [\boldsymbol{M}_\mathrm{s} \times H_\mathrm{eff}]]$ in arbitrary units for the Landau–Lifshitz equation (LL) and the Gilbert equation (LLG). (Reproduced with permmission from Cambridge University Press.)

of the LL equation and runs through a maximum for the LLG equation. It is of interest that in the case of the LLG equation the precession as well as the damping vanishes for large α_G values. This behavior is expected from a physical point of view, whereas the LL equation leads to an unphysical behavior.

7.2 Landau–Lifshitz–Gilbert equations in Cartesian and spherical polar coordinates

7.2.1 Cartesian coordinates

For numerical and analytical calculations it is useful to formulate the LLG equations in terms of reduced dimensionless properties defined as:

$$\tau = \omega t = \gamma H_\mathrm{N} t, \;\; \boldsymbol{h}_\mathrm{eff} = \frac{\boldsymbol{H}_\mathrm{eff}}{H_\mathrm{N}}, \;\; \boldsymbol{m}_\mathrm{s} = \frac{\boldsymbol{M}_\mathrm{s}}{M_\mathrm{s}}$$
$$H_\mathrm{N} = 2K_1/J_\mathrm{s}, \quad \omega = \gamma H_\mathrm{N} \tag{169}$$

where $\boldsymbol{H}_\mathrm{eff}$ is given by equation (80). The motion of the three components m_x, m_y and m_z of $\boldsymbol{m}_\mathrm{s}$ then is described by the following differential equations:

$$\frac{\mathrm{d}\boldsymbol{m}_i}{\mathrm{d}\tau} = \frac{1}{1+\alpha^2}\left[m_j \mid h_{\mathrm{eff},k} \mid -m_\mathrm{k} h_{\mathrm{eff},j}\right] - \frac{\alpha}{1+\alpha^2}\left[m_j\left\{m_i h_{\mathrm{eff},j} - m_j h_{\mathrm{eff},i}\right\} - m_k\left\{m_\mathrm{k} h_{\mathrm{eff},i} - m_i h_{\mathrm{eff},k}\right\}\right] \tag{170}$$
$$i = 1, 2, 3;\; j, k \text{ by cyclic transformation}$$

The differential equation for m_j and m_k are obtained by cyclic transformation. The components of the effective field are obtained from equations (80) and are especially simple in the case of a homogeneous precessional motion, where the exchange field vanishes and $h_{\mathrm{eff},i}$ is given by

$$h_{\mathrm{eff},i} = \frac{1}{H_\mathrm{N}}\left\{-\frac{1}{J}\frac{\partial \phi'_\mathrm{k}}{\partial \gamma_i} + H_{\mathrm{s},i} + H_{\mathrm{ext},i}\right\} \tag{171}$$

$$\text{with} \qquad \boldsymbol{H}_\mathrm{s} = -\begin{pmatrix} N_{xx} & M_\mathrm{s} \\ N_{yy} & M_\mathrm{s} \\ N_{zz} & M_\mathrm{s} \end{pmatrix} \tag{172}$$

if we deal with a specimen of ellipsoidal shapes and demagnetization factors N_{ii}.

7.2.2 Spherical coordinates

In order to get rid of the constraint $\sum_{i=1}^{3} \gamma_i^2 = 1$ spherical coordinates θ and φ (Figure 26) according to equation (71) are introduced. The Gilbert equation (166) then is writen as

$$-\frac{\mathrm{d}\theta}{\mathrm{d}t}\,\sin\theta = -\gamma_\mathrm{G}\, H_{\mathrm{eff},\varphi} + \alpha_\mathrm{s}\,\frac{\mathrm{d}\varphi}{\mathrm{d}t}\sin\theta \tag{173}$$

$$\frac{\mathrm{d}\varphi}{\mathrm{d}t}\,\sin\,\theta = \gamma_\mathrm{G}\, H_{\mathrm{eff},\theta} \;\pm\; \alpha_\mathrm{G}\frac{\mathrm{d}\theta}{\mathrm{d}t}$$
$$\text{with } H_{\mathrm{eff},\varphi} = -\frac{1}{J_\mathrm{s}}\,\frac{\partial \phi_\mathrm{tot}}{\partial \varphi}; \quad H_{\mathrm{eff},\theta} = -\frac{1}{J_\mathrm{s}}\frac{\partial \phi_\mathrm{to}}{\partial \theta} \tag{174}$$

Here $\mathrm{d}\theta/\mathrm{d}t$ described the relaxation of the magnetization into the equilibrium state and $\mathrm{d}\varphi/\mathrm{d}t$ describes the precessional rotation around the orientation of $\boldsymbol{H}_\mathrm{eff}$.

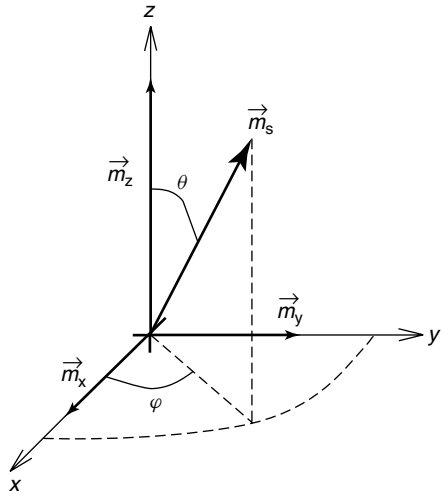

Figure 26. Definition of spherical coordinates θ and φ of the reduced magnetization $\boldsymbol{m} = \boldsymbol{M}/\boldsymbol{M}_\mathrm{s}$.

In the particular case of homogeneous precession in an uniaxial spherical particle the LLG equations are given by ($\boldsymbol{h}_{\text{eff}} = \boldsymbol{h}_{\text{k}} + \boldsymbol{h}_{\text{ext}}$).

$$\frac{\mathrm{d}\theta}{\mathrm{d}\tau} = -\frac{\alpha_{\text{G}}}{1+\alpha_{\text{G}}^2}\ \sin\theta(\cos\theta + h_{z,\text{ext}})$$
$$\frac{\mathrm{d}\varphi}{\mathrm{d}\tau} = \frac{1}{1+\alpha_{\text{G}}^2}\ \left(\cos\ \theta + h_{z,\text{ext}}\right) \tag{175}$$

Here the magnetostatic stray field exerts no torque on the magnetization because it is always oriented antiparallel to the magnetization.

In the case of a thin platelet, the stray field may not be neglected. With demagnetization factors $N_{xx} = N_{yy}$ and N_{zz}, $\boldsymbol{H}_{\text{s}}$ is written as

$$\boldsymbol{H}_{\text{s}} = -M_{\text{s}} \begin{pmatrix} N_{xx} & \sin\theta & \cos\varphi \\ N_{yy} & \sin\theta & \sin\varphi \\ N_{zz} & \cos\theta & \end{pmatrix} \tag{176}$$

and the LLG equations for a uniaxial crystal are given by

$$\sin\theta\frac{\mathrm{d}\varphi}{\mathrm{d}\tau} = \frac{1}{1+\alpha_{\text{G}}^2}\left[F_1 + \alpha_{\text{G}}F_2\right]$$
$$\frac{\mathrm{d}\theta}{\mathrm{d}\tau} = \frac{1}{1+\alpha_{\text{G}}^2}\left[-F_2 + \alpha_{\text{G}}F_1\right] \tag{177}$$

with

$$\begin{aligned} F_1 = {} & [-(k_x + n_{xx})\ \cos^2\varphi - (k_y + n_{yy})\sin^2\varphi \\ & + (k_z + n_{zz})]\sin\theta\cos\theta \\ & + (h_{\text{ext},x}\cos\varphi + h_{\text{ext},y}\sin\varphi)\cos\theta - h_{\text{ext},z}\sin\theta \\ F_2 = {} & \left[(k_x + n_{xx}) - (k_y + n_{yy})\right]\sin\theta\sin\varphi\cos\varphi \\ & - h_{\text{ext},x}\ \sin\varphi + h_{\text{ext},y}\cos\varphi \end{aligned} \tag{178}$$

Here the vectors $\boldsymbol{k}$ are given by

$$\boldsymbol{k} = \begin{pmatrix} 1 \\ 1 \\ 0 \end{pmatrix}, \quad k = \begin{pmatrix} 0 \\ 1 \\ 1 \end{pmatrix} \tag{179}$$

for in-plane and out of plane direction of $\boldsymbol{H}_{ext}$, respectively. The tensor n_{ii} is related to the demagnetization tensor $\boldsymbol{N}$ by

$$\boldsymbol{n} = \frac{1}{Q}\begin{pmatrix} N_{xx} & & \\ & N_{yy} & \\ & & N_{zz} \end{pmatrix} \tag{180}$$

where $Q = 2K_1/(\mu_0 M_{\text{s}}^2)$ denotes the so-called quality factor.

7.3 Magnetization dynamics by spin-polarized electrical currents

In papers by Slonczewski (1996, 1999) and Berger (1996) it has been shown that spin-polarized electrical currents exert torques on $\boldsymbol{M}_{\text{s}}$ producing spin waves at microwave frequencies. This effect is due to the indirect exchange interaction of s electrons with d or f electrons, which are responsible for the spin ordering in transition or rare-earth metals. Similar to the Heisenberg model the s–d and s–f interaction is described by the Hamiltonian

$$H_{\text{s,f,d}} = -2J_{\text{s,f}} \cdot \boldsymbol{s} \cdot \boldsymbol{S} \tag{181}$$

where s denotes the spin of the conduction electrons and S that of the d or f electrons and J_{sd} corresponds to the sd or sf exchange integral. In a continuum theoretical micromagnetic description the current-induced phenomena are described by an extended LLG equation (neglecting the damping term)

$$\begin{aligned} \frac{\partial \boldsymbol{M}_{\text{s}}}{\partial t} = {} & \gamma\ [\boldsymbol{M}_{\text{s}} \times \boldsymbol{H}_{\text{eff}}] + \frac{\propto}{M_{\text{s}}}\left[\boldsymbol{M}_{\text{s}} \times \frac{\mathrm{d}\boldsymbol{M}_{\text{s}}}{\mathrm{d}t}\right] \\ & - \frac{\sigma_j}{M_{\text{s}}^2}\boldsymbol{M}_{\text{s}} \times \left[\boldsymbol{M}_{\text{s}} \times (j \cdot \nabla)\boldsymbol{M}_{\text{s}}\right] \\ & - \xi\frac{\sigma_j}{M_{\text{s}}}\left[\boldsymbol{M}_{\text{s}} \times (j \cdot \nabla)\boldsymbol{M}_{\text{s}}\right] \end{aligned} \tag{182}$$

where j denotes the spin polarized current. The parameter σ_j according to Slonczewski (1996), Berger (1996) and Krüger *et al*. (2007) is defined as

$$\sigma_j = \frac{\epsilon\mu_B}{eM_s(1+\xi^2)} \tag{183}$$

where e denotes the spin polarization efficiency (Slonczewski, 1996; Berger, 1996) and $\xi = \tau_{\text{ex}}/\tau_{\text{sf}}$ the ratio of exchange and spin-flip relaxation times. On the basis of equation (182) a nonlinear theory of microwave generation in magnetic nanocontacts has been developed (Slavin and Kabos, 2005) and the role of current-induced torques for the motion of domain walls has been considered by several authors. There exists an increasing number of publications on this subject dealing with theoretical (Tatara and Kono, 2004; Li and Zhang, 2004; Waintal and Viret, 2004; Thiaville, Nakatami, Miltat and Vernic, 2004; Thiaville, Nakatami, Miltat and Suzuki, 2005) and experimental investigations (Grollier *et al*., 2003; Tsoi, Fontana and Parkin, 2003; Kläui *et al*., 2003, 2005 Kimura, Otami, Tsukagoshi and Aoyagi, 2003; Yamaguchi *et al*., 2004; Vernier *et al*., 2004). The idea to manipulate dws by electrical currents in order to improve the functions of spintronic devices has been outlined by Versluijs, Bari and Coey (2001) and Allwood, Xiong, Cooke and Locatelli (2002).

7.4 Applications of the LLG equations

7.4.1 Effective domain wall mass

As shown in Section 4.1.1 a static 180° dw in a uniaxial crystal is fully described by the rotation angle φ within the dw plane with normal parallel to the z axis. In the case of a moving dw, the spontaneous magnetization due to its precessional rotation has to be described by the rotation angle φ as well as by the angle θ with respect to the dw normal. As shown by Doering (1948), Walker and Dillon (1963), and Slonczewski (1972) at small velocities the wall energy is given by

$$\gamma_B = 4\sqrt{A\ (K_1 + \frac{1}{2}\mu_0 M_s^2 \sin^2\theta)} \tag{184}$$

From a solution of the LLG equation the angle θ is found to increase linearly with velocity v of the dw leading to a quadratic dependence of γ_B on velocity v. Thus γ_B may be written as

$$\gamma_B(v) = \gamma_B(0) + \frac{1}{2} m_w v^2$$
$$\text{with} \quad \gamma_B(0) = 4\sqrt{A\ K_1} \quad \text{and} \tag{185}$$

$$m_w = \frac{1}{2}\mu_0 \gamma_B(0) / \left(A\gamma_G^2\right) = \frac{2\pi\mu_0}{\delta_B \gamma_G^2} \tag{186}$$

A detailed analysis shows that the wall mass is a consequence of the stray field energy resulting from the precessional rotation of $\boldsymbol{M}_s$ within the dw. No simple explicit result exists for two-dimensional dws as they exist in thin films. In particular the role of Bloch lines in dws has been considered by Malozemoff and Slonczewski (1979) and O'Dell (1981).

7.4.2 Switching times in spherical particles

An analytical solution of the LLG equation has been obtained for spheres with uniaxial anisotropy and an external field applied antiparallel to the positive easy direction, which also is parallel to the spontaneous magnetization. In the case of a homogeneous rotation process in a sphere the demagnetization field is always strictly antiparallel to $\boldsymbol{M}_s$ and therefore no torque is exerted on $\boldsymbol{M}_s$ by the demagnetization field. The effective field in reduced units of H_N is given by

$$\boldsymbol{h}_{eff} = \frac{\boldsymbol{H}_{eff}}{H_N} = \begin{pmatrix} -m_x \\ -m_y \\ H_{z,ext}/H_N \end{pmatrix} \tag{187}$$

In terms of spherical coordinates as defined in Figure 26 the LLG equation are given by equations (175). Kikuchi (1956) has integrated equations (175) for $h_{z,ext} = -1$ and given the implicit solution for the time-dependent z-component $m_z = \cos\theta$:

$$\tau = -\frac{1+\alpha_G^2}{4\alpha_G} \times \left[\ln\left(\frac{(m_z(\tau)+1)(m_0-1)}{(m_z(\tau)-1)(m_0+1)} \right) - \frac{2}{m_z(\tau)-1} + \frac{2}{m_0-1} \right] \tag{188}$$

where m_0 corresponds to the z-component of $\boldsymbol{m}$ at $\tau = 0$. For $m_0 = 1$ the torque on $\boldsymbol{m}$ vanishes and no precession would take place. Figure 27 shows the time dependence of $m_z(\tau)$ as determined numerically from equation (188) for $m_0 = 0.99$. Figure 27 shows two time ranges. In a range I strongly dependent on m_0 the magnetization m_z doesn't change strongly. The time τ_R, elapsing until m_z becomes zero is given by

$$\tau_R = \frac{1+\alpha_G^2}{4\alpha_G}\left[\ln\frac{1+m_0}{1-m_0} - \frac{2}{m_0-1} - 2\right] \tag{189}$$

In a range II m_z changes its orientation by almost 180°. The corresponding switching time is given by

$$\tau_s = 2\frac{1+\alpha_G^2}{\alpha_G} \tag{190}$$

Figure 28 shows the characteristic times τ_R and τ_s as a function of the damping constant α_G. Both characteristic times show a minimum at $\alpha_G = 1$, however, their absolute values differ by a factor of 20, depending on the chosen value of m_0. According to the results τ_s always is rather

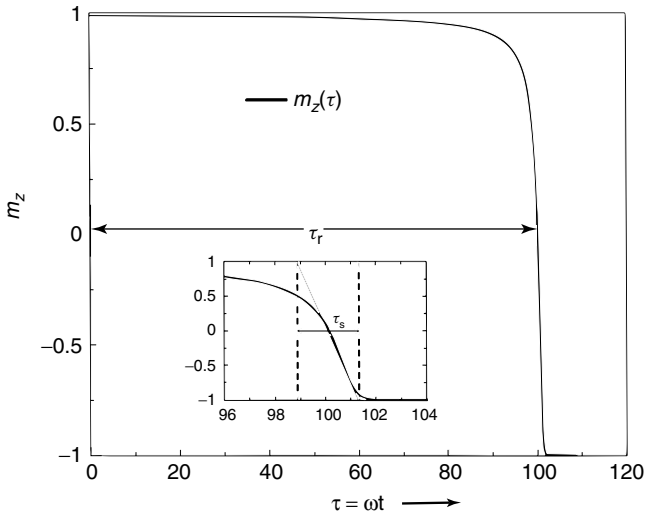

Figure 27. Time evaluation of m_z of a sphere in a reversed field $H_{ext} = -H_N$ for $\alpha = 1$ and $m_0 = 0.99n$ (Kikuchi, 1956) with definition of τ_R and τ_s. (Reproduced with permmission from Cambridge University Press.)

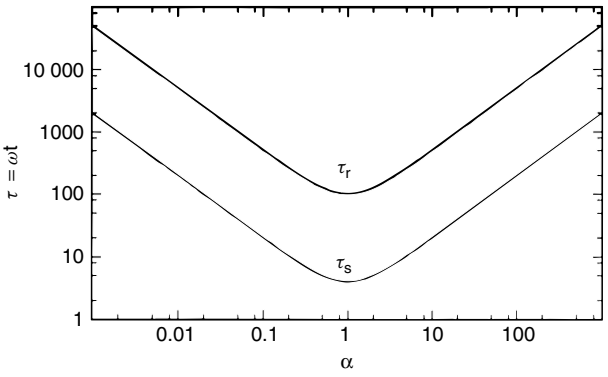

Figure 28. Characteristic switching times τ_R and τ_s of a sphere as a function of α for $m_0 = 0.99$ and $H_{ext} = -H_N$ (Kronmüller and Fähnle (2003)). (Reproduced with permmission from Cambridge University Press.)

small. To reduce the total switching time lower m_0 values and optimum α-values are required. Actually the measured α-values are much lower than the $\alpha = 1$ and are rather of the order of 0.001–0.05.

7.4.3 Switching times in thin platelets and small parallelepipeds

Whereas in spherical particles the magnetic stray fields play no role, in the case of platelets the stray fields cannot be anymore neglected. With the stray field given by equations (27–28) the LLG equations are given by

$$\begin{aligned}\frac{\mathrm{d}\varphi}{\mathrm{d}\tau} &= \frac{1}{1+\alpha_G^2}\left[\left\{1-\frac{1}{Q}(N_\parallel - N_\perp)\cos^2\varphi\right\}\cos\theta\right.\\ &\quad \left. + k_{ext,z} - \frac{1}{Q}(N_\parallel - N_\perp)\sin\varphi\cos\varphi\right]\\ \frac{\mathrm{d}\theta}{\mathrm{d}\tau} &= \frac{-1}{1+\alpha_G^2}\left[\alpha_G\left\{1-\frac{1}{Q}(N_\parallel - N_\perp)\cos^2\varphi\right\}\right.\\ &\quad \times \sin\theta\cos\theta + \alpha_G h_{ext,z} - \sin\theta\\ &\quad \left. -\frac{1}{Q}(N_\perp - N_\parallel)\sin\theta\sin\varphi\cos\varphi\right] \qquad (191)\end{aligned}$$

The demagnetization factors $N_\parallel$ and $N_\perp$ of square parallelepipeds are obtained from Aharoni's results (Aharoni, 1998c). In equation (191) $N_\parallel$ are the demagnetization factors parallel to the in-plane edges of the square platelet and $N_\perp$ corresponds to that perpendicular to the platelet plane.

Switching times haven been determined for square platelets of edge length 12.5 nm and varying thickness with aspect ratios 0.02:1 (cubic particles). The materials investigated are FePt and Co at room temperature with the following material parameters for FePt: $K_1 = 6.6 \times 10^6\,\mathrm{J\,m^{-3}}$, $J_s = 1.43\,\mathrm{T}$, $A = 10\,\mathrm{pJ\,m^{-1}}$ (Hai *et al.*, 2003) and for Co: $K_1 = 0.4 \cdot 10^6\,\mathrm{J\,m^{-3}}$, $J_s = 1.8\,\mathrm{T}$, $A = 13\,\mathrm{pJ\,m^{-1}}$. The ground state of platelets with in-plane easy axis parallel to the edges corresponds to the so-called butterfly state. The reversal of magnetization therefore starts at the corners of the square where $\boldsymbol{J}_s$ reveals a slight inhomogeneity. Figure 29 shows the dependence of the switching time as a function of the damping parameter α for different aspect ratios p of the square platelets. These results were obtained from a numerical solution of equations (191). The inversely applied magnetic field of $1.5H_k$ is strictly parallel to the edges of the square. With decreasing aspect ratio the minimum switching time shifts to smaller α-values, and also τ_s as a whole decreases. The increase of τ_s for larger α-values, $\alpha > \alpha_{min}$, is due to the strongly damped aperiodic relaxation process of $\boldsymbol{M}_s$. For $\alpha < \alpha_{min}$, the switching time again increases owing to reversal processes, which are governed by the precessional process with many precessions before reversal takes place (Goll, Schütz and Kronmüller, 2006).

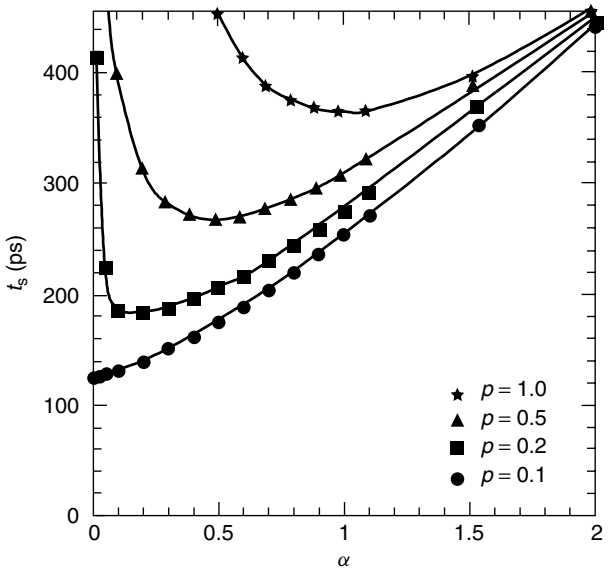

Figure 29. Dependence of the switching time on the damping parameter α for different aspect ratios of a square platelet of Cobalt of edge length 12.5 nm obtained by applying a magnetic field of $H_{ext} = -1.5H_k$ to the remanent quasi-homogeneous equilibrium state (flower state). (Courtesy of D. Goll and S. Macke.)

Figure 29 shows the switching time τ_s as a function of α for the case allowing inhomogeneous rotational processes using the FEM = Finite Element Method method. In this case the reversal process starts from the corners of the platelets by the displacement of a domain wall (Néel walls in thin films) moving to the center of the platelet.

It is of interest to note that the switching times in the case of the flower state are larger than in the case where the field is applied under a misalignment angle of 5° to an ideally

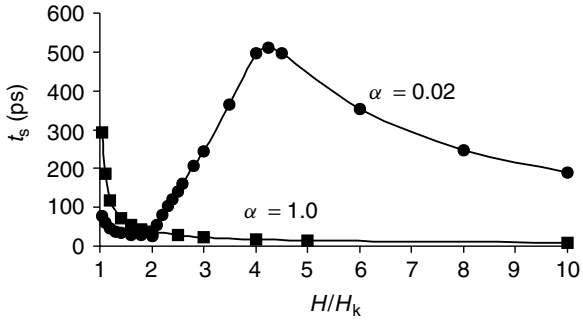

Figure 30. Field dependence of the switching time of a square Cobalt platelet of edge length 12.5 nm (aspect ratio 0.1 and $\alpha = 1$ and 0.01). (Reproduced from D. Goll, G. Schütz and H. Kronmüller: 'Analysis of switching times of inhomogenous magnetization processes in thin platelets', *Physica B* **372**, 2006, copyright © 2006, with permission from Elsevier.)

homogeneous state. This result is due to the fact that the inhomogeneities of $\boldsymbol{J}_s$ at the corners are smaller than 5°.

Another interesting feature of the switching times is their field dependence. Figure 30 shows τ_s for Co as a function of H_{ext}/H_N for $p = 0.01$ and $\alpha = 0.02$ and $\alpha = 1.0$. As for large applied fields $H_{ext} > 1.5H_N$ the switching process takes place quasi–homogeneously the LLG equation is solved assuming homogeneous rotation of $\boldsymbol{M}_s$. For small α-values we may distinguish three stages of τ_s. In stage I up to $H_{ext}/H_N = 2.0$, τ_s decreases. In stage II $2 < \alpha < 4$, τ_s increases up to a maximum value at $H_{ext}/H_N \approx 4$. For larger fields, stage III, τ_s decreases monotonously over the whole field range. Also $Nd_2Fe_{14}B$ show a similar field dependence of τ_s. In the case of large damping parameters the switching time decreases throughout.

The existence of the three field stages is found to be related to the different types of ringing modes as shown in Figure 31 for the three stages. In stage I the ringing amplitude are rather large and therefore the configuration with $\langle J_x \rangle = 0$ is achieved at small times. At larger fields the ringing amplitudes become small leading to larger τ_s values. For large α values τ_s also decreases monotonously over the whole field range.

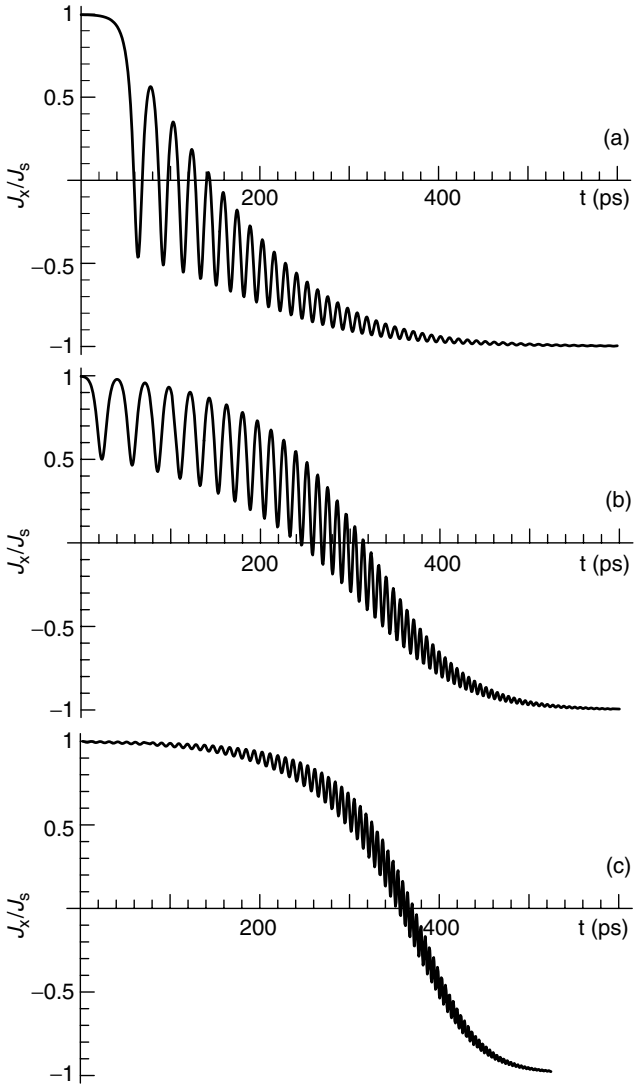

Figure 31. Time dependence of the in-plane x-component of $\boldsymbol{M}_s$ for $\alpha = 0.02$ of the three stages shown for Cobalt in Figure 30. (Reproduced from D. Goll, G. Schütz and H. Kronmüller: 'Analysis of switching times of inhomogenous magnetization processes in thin platelets', *Physica B* **372**, 2006, copyright © 2006, with permission from Elsevier.)

7.4.4 Dynamic nucleation field

Within the framework of the Stoner–Wohlfarth theory (Stoner and Wohlfarth, 1948) and its extension by Kronmüller, Durst and Martinek (1987) the static field follows a hyperbolic curve described by equation (28). An important feature of the asteroid is the rise of the nucleation field for misalignment angles around 90°. Taking into account the precessional movement of $\boldsymbol{M}_s$ it turns out that the nucleation field depends on the damping constant α and the field rate dH_{ext}/dt. Numerical calculations are due to Leineweber and Kronmüller (1999) and Fidler *et al.* (2001). Results obtained for a sphere of $Nd_2Fe_{14}B$ with a rather small radius of 4.2 nm (single-domain particle) with the material parameters $K_1 = 4.3 \times 10^6\,\mathrm{J\,m^{-3}}$, $K_2 = 6.5 \times 10^5\ \mathrm{J/m^{-3}}$, $A = 7.7\,\mathrm{pJ\,m^{-1}}$, $J_s = 1.61\,\mathrm{T}$, $H_N(0) = 5.34 \cdot 10^6\,\mathrm{A\,m^{-1}}$, $\gamma = 2.21 \times 10^5$ 1/sA are shown in Figure 32 for infinite switching field rates. Owing to the precession of $\boldsymbol{M}_s$ the nucleation field over the whole angular range, from $\varphi = 0$ to $\psi = 90°$ is reduced and the reduction is the larger the larger the damping constant α. In particular for angles of $\psi = 90°$ the nucleation field is reduced by nearly a factor of 2, whereas for $\psi = 0°$ no reduction takes place.

7.4.5 Thermal fluctuations and dynamics of magnetization processes

In magnetic recording it is generally accepted that the data stored remain in their state and can be read out reproducibly over many years. Actually, however, the magnetic configuration of a magnetic bit corresponds only to a special minimum of many possible local minima of the Gibbs free energy. Magnetic stability can only be achieved if thermal fluctuations are too weak to overcome the energy barrier to neighboring minima. Pioneering investigations are due to Néel (1949) and Brown (1963, 1979) who gave a first insight into the reversal of magnetization of small particles by thermal fluctuations. According to Brown thermal effects can be included in the LLG equation by adding a stochastically fluctuating field $H_\mathrm{f}(t)$ to the effective field H_eff. The statistical properties of this random field are the following ones:

$$\langle H_{\mathrm{f,i}}(t)\rangle = 0$$
$$\langle H_{\mathrm{f,i}}(t) H_{\mathrm{f,j}}(t+t')\rangle = \mu\delta_{ij}\delta(t') \qquad (192)$$

Equation (192) is a consequence of the fluctuation dissipation theorem (Brown, 1963; Chantrell, Hannany, Wongsam and Lyberatos, 1998), which guarantees that the fluctuating fields are uncorrelated in space and time. The parameter μ corresponds to a temperature dependent constant, which corresponds to the variance of the Gaussian variable $\boldsymbol{H}_\mathrm{f}$ and is given by

$$\mu = \frac{2k_\mathrm{B}T\alpha}{|\gamma_0|M_\mathrm{s}V} \qquad (193)$$

where V denotes the volume of the particle or the discretization volume of finite elements (see also **Magnetization Dynamics Including Thermal Fluctuations: Basic Phenomenology, Fast Remagnetization Processes and Transitions Over High-energy Barriers, Volume 2** and **Magnetization Dynamics: Thermal-driven Noise in Magnetoresistive Sensors, Volume 2**). Inserting $\boldsymbol{H}_\mathrm{f}$ into the LLG equation we obtain a Langevin-type equation for the motion of $\boldsymbol{M}_\mathrm{s}$:

$$\frac{\mathrm{d}\boldsymbol{M}_\mathrm{s}}{\mathrm{d}t} = \frac{\gamma_\mathrm{G}}{1+\gamma_\mathrm{G}^2}\left[\boldsymbol{M}_\mathrm{s}\times(\boldsymbol{H}_\mathrm{eff}+\boldsymbol{H}_\mathrm{f})\right] - \frac{\alpha_\mathrm{G}\gamma_\mathrm{G}}{(1+\alpha_\mathrm{G}^2)\boldsymbol{M}_\mathrm{s}} \qquad (194)$$
$$\times\left[\,\boldsymbol{M}_\mathrm{s}\times\left[\,\boldsymbol{M}_\mathrm{s}\times(\boldsymbol{H}_\mathrm{eff}+\boldsymbol{H}_\mathrm{f})\,\right]\right] \qquad (195)$$

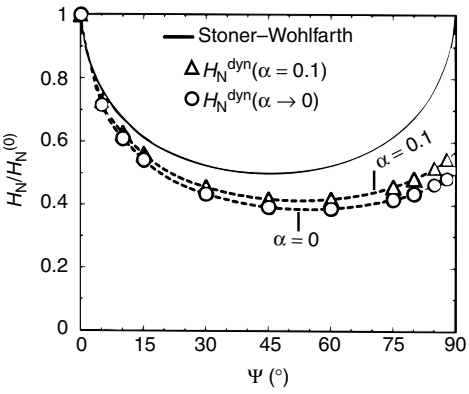

Figure 32. Dynamic nucleation field of a spherical Stoner–Wohlfarth particle of $Nd_2Fe_{14}B$ (diameter 8.4 nm) $H_\mathrm{N}^\mathrm{dyn}$ determined for infinite switching field rates as a function of orientation ψ of H_ext with respect to the easy axis (−) Stoner–Wohlfarth result, $(-0-0-\alpha=0)$, $(-\triangle-\triangle-\alpha=0.1)$. (Reproduced with permmission from Cambridge University Press.)

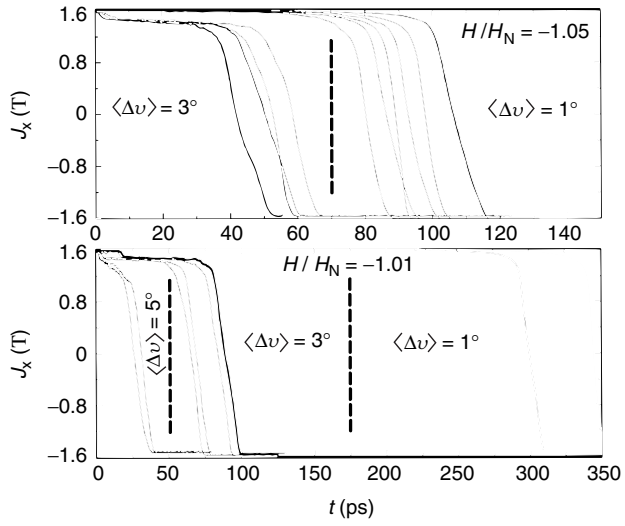

Figure 33. Switching curves of a sphere (diameter 8.4 nm) of $Nd_2Fe_{14}B$ for different applied fields and different strengths $\langle\Delta\vartheta\rangle$ of thermally induced fluctuations. (Reproduced with permmission from Cambridge University Press.)

Thermal excitations described by $\boldsymbol{H}_{\mathrm{f}}$ cause a deviation of $\boldsymbol{M}_{\mathrm{s}}$ from the local equilibrium direction determined by $\boldsymbol{H}_{\mathrm{eff}}$. The effect of $\boldsymbol{H}_{\mathrm{f}}$ in the damping term of equation (194) may be neglected because its effect is of higher order than that of the first term. Equation (194) describes of course the gyromagnetic damped precessional motion of $\boldsymbol{M}_{\mathrm{s}}$, but also the thermally driven spectral noise exerted in small magnetic particles, for example, magnetic dots. Problems of this kind are treated in **Magnetization Dynamics Including Thermal Fluctuations: Basic Phenomenology, Fast Remagnetization Processes and Transitions Over High-energy Barriers, Volume 2** and **Magnetization Dynamics: Thermal-driven Noise in Magnetoresistive Sensors, Volume 2**. A further important effect of $\boldsymbol{H}_{\mathrm{f}}$ is the thermally reduced coercive field of hard magnetic materials as well as the reduction of the switching times by thermal fluctuations (Chantrell, Hannany, Wongsam and Lyberatos, 1998; Leineweber and Kronmüller, 1999; Kronmüller, Leineweber and Bachmann, 2000).

As discussed in Section 7.4.2 in the case of an ideal homogeneously magnetized particle a precession of $\boldsymbol{M}_{\mathrm{s}}$ only takes place if the magnetic field is applied under a misalignment angle θ. Owing to the action of $\boldsymbol{H}_{\mathrm{f}}$ misalignments of $\boldsymbol{M}_{\mathrm{s}}$ occur by thermally activated spin waves. At a temperature T the average misalignment for $T < T_{\mathrm{C}}/2$ is given by $\langle \Delta\theta \rangle = \sqrt{2}(T/T_0)^{3/4}$, where T_0 is the characteristic temperature of Bloch's $\mathrm{T}^{3/2}$ law ($T_0 \approx T_{\mathrm{C}}$). Figure 33 shows switching curves for average misalignment angles $\langle \Delta\theta \rangle$ of $1^\circ, 3^\circ$, and 5° under ideally oriented applied fields of $H_{\mathrm{ext}} = -1.01 H_{\mathrm{N}}$ and $-1.05 H_{\mathrm{N}}$ for the hard magnetic alloy $\mathrm{Nd_2Fe_{14}B}$ (Kronmüller and Fähnle, 2003). These results have been obtained by the dynamic finite element method assuming a Boltzmann distribution $p(\Delta\theta) \propto \exp\left[-\Delta\theta/\langle\Delta\theta\rangle\right]$for the probability of the local misalignment within each cell of the FEM grid. According to Figure 33 the switching relaxation times are considerably reduced by thermal fluctuations. Owing to the assumption of uncorrelated statistical fluctuations switching curves determined successively show a moderate fluctuation.

Numerical Micromagnetics: Finite Difference Methods

Jacques E. Miltat[1] and Michael J. Donahue[2]

[1] *Université Paris XI Orsay and CNRS, Orsay, France*
[2] *National Institute of Standards and Technology, Gaithersburg, MD, USA*

The first two-dimensional numerical simulation of a domain wall structure was published in 1969. In his celebrated work, LaBonte (1969), showed that the structure of a domain wall in an infinite magnetically soft thin film with thickness in the 100 nm range was neither Bloch nor Néel type, but somehow a mixture of both. Some 35 years later, numerical micromagnetics has become ubiquitous and rather unavoidable a tool in the study of magnetic nanostructures. Rather unexpectedly, LaBonte's pioneering work remains modern because of the immense progress made in the elaboration and observation of magnetic nanostructures. Suffice it to say that three-dimensional numerical micromagnetics unravels much hidden complexity and yet firm underlying logics in the wall structures and magnetization distribution within faceted iron nanocrystals, in agreement with the most demanding experiments (Hertel *et al*., 2005). The present chapter deals with numerical micromagnetics using finite difference methods and is organized as follows. Section 1 captures the essentials of micromagnetics, a continuum theory of ferro- or ferrimagnetic bodies, and thus provides the necessary background for the understanding of the following sections. Sections 2 and 3 are devoted to numerical implementations of the micromagnetic continuum theory with primacy given to the field acting on the magnetization and energy, respectively. Section 4 addresses the issue of accuracy in the time domain. Lastly, on the basis of a single but demanding example, a brief comparison between the two approaches is attempted in Section 5.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

1 BACKGROUND

If solely referring to the number of lattice sites in a micron-size magnetic element with thickness in the range of a few nanometers, it becomes immediately clear that fully *ab initio* methods aimed at defining the local value of the magnetic moment and its direction are out of reach. Micromagnetics is a continuum theory of ferro or ferrimagnetic materials, which allows for the computation of magnetization distributions in samples of arbitrary shape (Brown, 1963; Aharoni, 1996; Hubert and Schäfer, 1998). Its basic assumptions consist in considering the magnetization modulus to remain constant ($\mathbf{M} = M_s\mathbf{m}$, $\mathbf{m}\cdot\mathbf{m} = 1$) and all vector quantities (the magnetization $\mathbf{M}$, the exchange $\mathbf{H}_{\text{exch}}$, and demagnetizing $\mathbf{H}_{\text{d}}$ fields, especially) to vary slowly at the atomic scale.

The components of **m** are the direction cosines of the magnetization **M**. Micromagnetics is based on the one hand on the notion of an effective field acting on the magnetization (Brown, 1963; Miltat, 1994; Aharoni, 1996; Hubert and Schäfer, 1998; Kronmüller and Fähnle, 2003), on the other hand on an equation depicting magnetization dynamics known as the *Landau–Lifshitz* or *Landau–Lifshitz–Gilbert* (*LLG*) equation, depending on the exact formulation of damping. According to Brown's theory (Brown, 1963), the effective field is the functional derivative of the energy density ε, w.r.t. magnetization:

$$\mathbf{H}_{\text{eff}} = -\frac{1}{\mu_0 M_{\text{s}}}\frac{\delta\varepsilon}{\delta\mathbf{m}} \tag{1}$$

As shown earlier in this volume (see also **General Micromagnetic Theory, Volume 2**), the effective field usually contains contributions stemming from the exchange, anisotropy, applied field or Zeeman, and demagnetizing energy densities, namely

$$\begin{aligned}\mathbf{H}_{\text{eff}} &= -\frac{1}{\mu_0 M_{\text{s}}}\frac{\delta\varepsilon}{\delta\mathbf{m}} \\ &= \frac{2A}{\mu_0 M_{\text{s}}}\nabla^2\mathbf{m} - \frac{1}{\mu_0 M_{\text{s}}}\frac{\delta\varepsilon_K}{\delta\mathbf{m}} + \mathbf{H}_{\text{app}} + \mathbf{H}_{\text{d}}\end{aligned} \tag{2}$$

corresponding to the following micromagnetic energy:

$$\begin{aligned}E = \int_{\text{V}} \Big[& A\,(\boldsymbol{\nabla}\mathbf{m})^2 + \varepsilon_K - \mu_0 M_{\text{s}}\left(\mathbf{H}_{\text{app}}\cdot\mathbf{m}\right) \\ & -\frac{1}{2}\mu_0 M_{\text{s}}\left(\mathbf{H}_{\text{d}}\cdot\mathbf{m}\right)\Big]\mathrm{d}^3 r\end{aligned} \tag{3}$$

where, A is the exchange constant (units $\mathrm{J\,m^{-1}}$), ϵ_K the anisotropy energy density (units $\mathrm{J\,m^{-3}}$), $\mathbf{H}_{\text{app}}$ and $\mathbf{H}_{\text{d}}$ the applied and demagnetizing field (units $\mathrm{A\,m^{-1}}$), respectively. As noted as early as 1949 by Kittel (1949), the exchange energy may, by combining the constraint $\mathbf{m}^2 = 1$ with the vector relation $|\nabla f|^2 = \nabla\cdot(f\nabla f) - f\nabla^2 f$, be expressed in either of the following forms:

$$\begin{aligned}E_{\text{exch}} &= \int_{\text{V}} \left[A\,(\boldsymbol{\nabla}\mathbf{m})^2\right]\mathrm{d}^3 r \\ &= -\int_{\text{V}} \left[A\mathbf{m}\cdot\left(\frac{\partial^2\mathbf{m}}{\partial x^2} + \frac{\partial^2\mathbf{m}}{\partial y^2} + \frac{\partial^2\mathbf{m}}{\partial z^2}\right)\right]\mathrm{d}^3 r\end{aligned} \tag{4}$$

Additional energy terms may be included in the energy, for example, terms arising from magnetostriction, or longer range exchange coupling across nonmagnetic spacer layers in spin valves (Kools, Rijks, de Veirman and Coehoorn, 1995; Wei and Bertram, 1996); such terms will not be considered in the following.

When considering an energy density functional solely involving exchange and magnetostatic interactions (the ideally soft magnetic material limit), dimensional arguments soon lead to the definition of a characteristic length known as the (*magnetostatic*) *exchange length*

$$\Lambda = \sqrt{\frac{2A}{\mu_0 M_{\text{s}}^2}} \tag{5}$$

a quantity labeled l_s in **General Micromagnetic Theory, Volume 2**. The exchange length rarely exceeds a few nanometers in 3d ferromagnetic materials or their alloys, thereby imposing severe constraints on the mesh size in numerical simulations.

The effective field (see equation (2)) exerts a torque on the magnetization that is proportional to $\mathbf{M}\times\mathbf{H}$. In full analogy with classical mechanics, the rate of change of the magnetization – angular momentum – is, in the absence of damping, equal to the torque, namely

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathbf{m}(t) = -\gamma_0\left[\mathbf{m}(t)\times\mathbf{H}_{\text{eff}}(t)\right] \tag{6}$$

It follows from equation (6) that as long as the torque is zero, the angular momentum is conserved. For a free electron, γ_0 is equal to $\approx 2.21\times 10^5\,\mathrm{A^{-1}ms^{-1}}$. Still in the absence of damping, magnetization motion reduces to a precession of the magnetization around the effective field, with frequency:

$$\omega_0 = \gamma_0\mathbf{H}_{\text{eff}} \tag{7}$$

that is, $\approx$28 MHz/(mT) in units of $\mu_0\mathbf{H}_{\text{eff}}$ for a free electron spin.

Gilbert damping (Gilbert, 1955, 1956, 2004) is most simply introduced by adding to the effective field an Ohmic type dissipation term, namely

$$\mathbf{H}_{\text{eff}} = \mathbf{H}_{\text{eff}} - \alpha\frac{1}{\gamma_0 M_{\text{s}}}\frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} \tag{8}$$

where, α is the (dimensionless) Gilbert damping parameter. Introducing equation (8) into equation (6) leads to the so-called LLG equation,

$$\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = -\gamma_0\left(\mathbf{m}\times\mathbf{H}_{\text{eff}}\right) + \alpha\left[\mathbf{m}\times\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t}\right] \tag{9}$$

or its numerically more tractable and mathematically equivalent form

$$\left(1+\alpha^2\right)\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = -\gamma_0\left[\mathbf{m}\times\mathbf{H}_{\text{eff}} + \alpha\left[\mathbf{m}\times\left(\mathbf{m}\times\mathbf{H}_{\text{eff}}\right)\right]\right] \tag{10}$$

Given a magnetization distribution $\mathbf{m}(\mathbf{r},\mathbf{t}) = \mathbf{M}(\mathbf{r},\mathbf{t})/M_{\text{s}}$, the LLG equation specifies the magnetization distribution at

time $t + \mathrm{d}t$ provided due respect of boundary conditions is maintained. Alternatively, if a sole magnetization distribution at equilibrium is sought for, the only condition that needs to be satisfied reads:

$$\mathbf{m} \times \mathbf{H}_{\text{eff}} = \mathbf{0} \tag{11}$$

Because the exchange energy involves the square of the gradient of the magnetization components, its variation gives rise not only to the exchange contribution to the effective field in equation (2) but also to boundary conditions (BCs). BCs that arise from the sole symmetry breaking of exchange interactions at surfaces are referred to as *free* BCs. Their mathematical expression in the continuum limit reads

$$A\left(\mathbf{m} \times \frac{\partial \mathbf{m}}{\partial \mathbf{n}}\right) = 0 \tag{12}$$

which is equivalent to the Neumann BC

$$\frac{\partial \mathbf{m}}{\partial \mathbf{n}} = 0 \tag{13}$$

since $\mathbf{m}^2 = 1$. In the presence of surface anisotropy, energy density

$$\varepsilon_{K\text{S}} = K_{\text{S}}\left(1 - (\mathbf{n}\cdot\mathbf{m})^2\right) \tag{14}$$

and interlayer exchange, energy density

$$\varepsilon_{\text{J}} = J_1\left(1 - \mathbf{m}\cdot\mathbf{m}'\right) + J_2\left(1 - \left(\mathbf{m}\cdot\mathbf{m}'\right)^2\right) \tag{15}$$

where $\mathbf{m}'$ defines the exchange-bias direction at the interface with the ferro- or ferrimagnetic body, BCs may be expressed (Labrune and Miltat, 1995) either as

$$2A\left(\mathbf{m} \times \frac{\partial \mathbf{m}}{\partial \mathbf{n}}\right) - 2K_{\text{S}}\left(\mathbf{m}\cdot\mathbf{n}\right)\left(\mathbf{m} \times \mathbf{n}\right) - J_1\left(\mathbf{m} \times \mathbf{m}'\right) - 2J_2\left(\mathbf{m} - \mathbf{m}'\right)\left(\mathbf{m} \times \mathbf{m}'\right) = 0 \tag{16}$$

or as

$$\frac{\partial \mathbf{m}}{\partial \mathbf{n}} = \frac{K_{\text{S}}}{A}\left(\mathbf{m}\cdot\mathbf{n}\right)\left(\mathbf{n} - \left(\mathbf{m}\cdot\mathbf{n}\right)\mathbf{m}\right) - \left(\frac{J_1}{2A} + \frac{J_2}{A}\left(\mathbf{m}\cdot\mathbf{m}'\right)\right)\left(\left(\mathbf{m}\cdot\mathbf{m}'\right)\mathbf{m} - \mathbf{m}'\right) \tag{17}$$

See also references Brown (1963), Rado and Weertman (1959) and Guslienko and Slavin (2005).

Altogether, as long as the exchange parameter A is independent of position $\mathbf{r}$, a magnetization continuum owing to micromagnetics is at zero temperature governed by the set of equations:

$$\begin{aligned}
\mathbf{m} &= \mathbf{m}(\mathbf{r}, t)\\
\mathbf{H}_{\text{eff}} &= \mathbf{H}_{\text{eff}}(\mathbf{r}, t)\\
\mathbf{H}_{\text{d}} &= \mathbf{H}_{\text{d}}(\mathbf{r}, t)\\
\mathbf{H}_{\text{eff}} &= \frac{2A}{\mu_0 M_{\text{s}}}\nabla^2\mathbf{m} + \mathbf{H}_{\text{app}} + \mathbf{H}_{\text{d}} - \frac{1}{\mu_0 M_{\text{s}}}\frac{\delta\varepsilon_K}{\delta\mathbf{m}}\\
\frac{\partial \mathbf{m}}{\partial \mathbf{n}} &= \frac{K_{\text{S}}}{A}\left(\mathbf{m}\cdot\mathbf{n}\right)\left[\mathbf{n} - \left(\mathbf{m}\cdot\mathbf{n}\right)\mathbf{m}\right]\\
&\quad - \left[\frac{J_1}{2A} + \frac{J_2}{A}\left(\mathbf{m}\cdot\mathbf{m}'\right)\right]\left[\left(\mathbf{m}\cdot\mathbf{m}'\right)\mathbf{m} - \mathbf{m}'\right]
\end{aligned} \tag{18}$$

augmented with the LLG equation of magnetization motion (9) or the equilibrium condition (11).

In case the exchange constant would be position dependent, an additional term would appear in the exchange components of the effective field. In the following, the exchange constant is assumed to remain constant, that is, a sole function of the ferro- or ferrimagnetic material composition. It has also been implicitly assumed that the system under study was free of surface-specific damping. On the other hand, the saturation magnetization, the anisotropy as well as the damping constant may be modulated according to position without introducing modifications in the set of equations (18).

This chapter considers the finite difference approach to solving these equations, where the magnetization is sampled on a uniform rectangular mesh at points $(x_0 + i\Delta_x, y_0 + j\Delta_y, z_0 + k\Delta_z)$. The computational cell is centered about the sample point with dimensions $\Delta_x \times \Delta_y \times \Delta_z$. The main advantages of the finite difference approach are ease of implementation, simplicity of meshing, efficient evaluation of the demagnetizing energy (via, e.g., fast Fourier transform (FFT) methods), and the accessibility of higher-order methods. A main disadvantage of this approach is that sampling curved boundaries with a rectangular mesh results in a 'staircase-type' approximation to the geometry, which can produce significant errors in the computation. Corrections for this artifact are possible (Parker, Cerjan and Hewett, 2000; Porter and Donahue, 2001; García-Cervera, Gimbutas and Weinan E, 2003), but are not discussed in the present text. The next two sections present two approaches to the problem of discretizing the continuous equations discussed in the preceding text. The first, Section 2, treats equation (2) as fundamental, and focuses primarily on computing an accurate value of $\mathbf{H}_{\text{eff}}$ directly from $\mathbf{m}$. We call this the field-based approach. The alternative energy-based approach, presented in Section 3, is directed first at computing the micromagnetic energy, equation (3). The effective field $\mathbf{H}_{\text{eff}}$, which is needed in the LLG equation (9), is computed from the energy

via the discrete analog of equation (1). The $\mathbf{H}_{\text{eff}}$ computed in this manner is the field value averaged across the corresponding discretization cell. Results using the two methods on a sample problem are compared in Section 5.

2 FINITE DIFFERENCE MICROMAGNETICS: FIELD-BASED APPROACH

As stated in the preceding text, in a field-based approach (Labrune and Miltat, 1995; Albuquerque, 2002; Toussaint *et al*., 2002), one is seeking a numerical solution to the LLG equation (18) on the basis of a direct evaluation of the effective field components under the constraint of problem specific BCs. In this approach, the energy (density) plays a role only to the extent that the effective field is the gradient of the former.

Looking at equation (18) it is immediately seen that a number of derivatives will require evaluation, namely first- and second-order derivatives of the magnetization components in order to define the divergence of the magnetization ($\nabla\cdot\mathbf{m}$) and the components of the exchange field ($\nabla^2\mathbf{m}$), respectively. The magnetization components along boundaries also need to be evaluated in order to define surface charges ($\mathbf{m}\cdot\mathbf{n}$) that do contribute to the demagnetizing field. BCs need to be incorporated in the evaluation of the effective field without loss of accuracy. Finally, solution of the LLG equation does require both stability and accuracy. This section is organized as follows: in a first step we describe the various steps to be taken in order to provide a numerical estimate of the demagnetizing field. In the next step, starting with an evaluation of the exchange field in the bulk, it is first shown how BCs may be included without too heavy a cost in accuracy, at least for so-called free BCs. The third step explains how general BCs may be introduced. Because the problem of an accurate solution of the LLG equation is common to both the field-based and energy-based finite difference methods, it is treated separately (see Section 3).

2.1 Demagnetizing field evaluation

For a magnetization continuum, the demagnetizing field, in full similarity to electrostatics, arises from volume and surface charges

$$\begin{aligned} \lambda_{\text{V}} &= -\mu_0 M_{\text{s}}\,(\nabla\cdot\mathbf{m})\,, \qquad \text{in the volume} \\ \sigma_{\text{S}} &= +\mu_0 M_{\text{s}}\,(\mathbf{m}\cdot\mathbf{n})\,, \qquad \text{at free surfaces} \end{aligned} \tag{19}$$

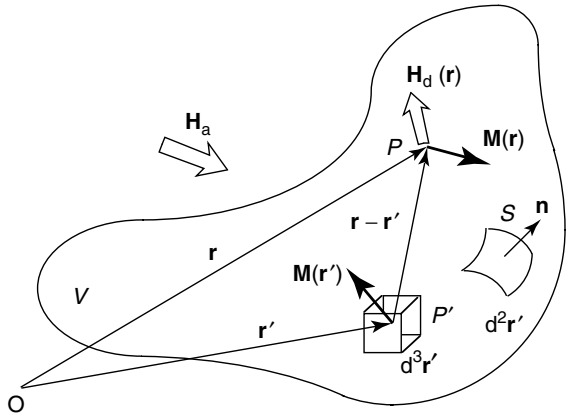

Figure 1. Geometry attached to equation (20).

and derives from the scalar potential expressed as follows:

$$\begin{aligned} \mathbf{H}_{\text{d}}(\mathbf{r}) &= -\nabla\Phi_{\text{d}}(\mathbf{r}) \\ \Phi_{\text{d}}(\mathbf{r}) &= \frac{1}{4\pi\mu_0}\left[\int_V \frac{\lambda_{\text{V}}(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\,\text{d}^3r' + \int_S \frac{\sigma_{\text{S}}(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\,\text{d}^2r'\right] \end{aligned} \tag{20}$$

Figure 1 illustrates the geometrical relations between vectors in equation (20).

It follows from equations (19) and (20) that the demagnetizing field may be directly expressed as

$$\begin{aligned} \mathbf{H}_{\text{d}}(\mathbf{r}) = \frac{1}{4\pi\mu_0}\Bigg[&\int_V \frac{(\mathbf{r}-\mathbf{r}')\,\lambda_{\text{V}}(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|^3}\,\text{d}^3r' \\ &+ \int_S \frac{(\mathbf{r}-\mathbf{r}')\,\sigma_{\text{S}}(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|^3}\,\text{d}^2r'\Bigg] \end{aligned} \tag{21}$$

$\mathbf{H}_{\text{d}}$ derives from the energy density

$$\varepsilon_{\text{demag}} = -\frac{1}{2}\mu_0\,(\mathbf{H}_{\text{d}}\cdot\mathbf{M}) = -\frac{1}{2}\mu_0 M_{\text{s}}\,(\mathbf{H}_{\text{d}}\cdot\mathbf{m}) \tag{22}$$

where the $1/2$ prefactor stems from the fact that $\mathbf{M}$ is the source of $\mathbf{H}_{\text{d}}$.

Four remarks ought to be made here. First, charges must sum up to zero because of the fundamentally dipolar nature of magnetism. Second, contrary to the Zeeman contribution to the total energy, the magnetostatic energy, obtained through summation over the volume and external surface of the element of the energy density equation (22), is necessarily positive or nil. It follows that, in a soft magnetic material, where the magnetostatic energy becomes the leading term, energy may only be minimized by the pole avoidance principle. This means that, whenever possible, the magnetization will tend to be parallel to external boundaries and adopt configurations satisfying $\nabla\cdot\mathbf{m} = 0$ in the volume. Clearly, this may only be achieved at the expense of exchange energy

as well as anisotropy energy when present. Third, because of the long-range decay of magnetostatic interactions, large errors are inevitably made when truncation of the integrals is attempted. Last, but not least, one easily recognizes in the integrals of equation (20) a convolution product. Therefore, from a numerical point of view, much of the computation load may be relieved via an extensive use of FFTs.

Decomposing the magnetic volume into cells (index i', j', k') with *constant* magnetization divergence and the outer surface into tiles (index l', m', n') with *constant* charge density (see Figure 2) immediately leads to an easy and yet accurate numerical estimate of the demagnetizing field at location $\mathbf{r}$. Equation (21) then reduces to a finite sum, namely,

$$\mathbf{H}_{\mathrm{d}}(\mathbf{r}) = \frac{1}{4\pi\mu_0}\sum_{i',j',k'}\left[\lambda_{\mathrm{V}}(i',j',k')\int_{V'(i',j',k')}\frac{(\mathbf{r}-\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|^3}\,\mathrm{d}^3r'\right] + \frac{1}{4\pi\mu_0}\sum_{l',m',n'}\left[\sigma_{\mathrm{S}}(l',m',n')\int_{S'(l',m',n')}\frac{(\mathbf{r}-\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|^3}\,\mathrm{d}^2r'\right] \tag{23}$$

where $\mathbf{r}'$ now spans either the volume of cell i', j', k' or the area of tile l', m', n'. The integrals in equation (23) therefore reduce to purely geometrical coefficients that only need to be computed once. Equation (23) may thus be rewritten as follows

$$\mathbf{H}_{\mathrm{d}}(\mathbf{r}) = \frac{1}{4\pi\mu_0}\sum_{i',j',k'}\lambda_{\mathrm{V}}(i',j',k')\,C_{\mathrm{V}}(\mathbf{r},i',j',k') + \frac{1}{4\pi\mu_0}\sum_{l',m',n'}\sigma_{\mathrm{S}}(l',m',n')\,C_{\mathrm{S}}(\mathbf{r},l',m',n') \tag{24}$$

Note that such a decomposition is achieved if the magnetization is assumed to be a trilinear function of the coordinates

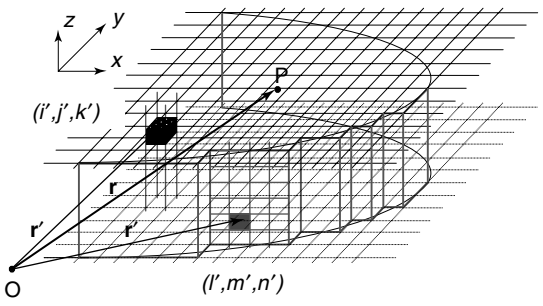

Figure 2. The demagnetizing field at point P($\mathbf{r}$) is built-up from contributions arising from volume cells with constant magnetization divergence and surface tiles with constant charge density. In this drawing, the physical frontier consists in the top and bottom planes, and the continuous rim boundary (in black). The numerical rim boundary is staircase-like (light gray).

x, y, z within the magnetic volume while being constant over the area of a tile. All interaction coefficients C_{V} and C_{S} are definite integrals with kernels $\frac{x-x'}{|\mathbf{r}-\mathbf{r}'|^3}$, $\frac{y-y'}{|\mathbf{r}-\mathbf{r}'|^3}$, $\frac{z-z'}{|\mathbf{r}-\mathbf{r}'|^3}$ for the x, y, and z demagnetizing field components, respectively. For instance, the x component of the demagnetizing field arising from a volume cell is given by equation (24) with

$$C_{\mathrm{V}}^{x} = \int_{x_1'}^{x_2'}\int_{y_1'}^{y_2'}\int_{z_1'}^{z_2'}\frac{x-x'}{|\mathbf{r}-\mathbf{r}'|^3}\mathrm{d}x'\mathrm{d}y'\mathrm{d}z' \tag{25}$$

Similarly, the z component of the demagnetizing field arising from a tile parallel to the xy plane is given by equation (24) with

$$C_{\mathrm{S}xy}^{z} = \int_{x_1'}^{x_2'}\int_{y_1'}^{y_2'}\frac{z-z'}{|\mathbf{r}-\mathbf{r}'|^3}\mathrm{d}x'\mathrm{d}y' \tag{26}$$

For parallepipedic volume cells and rectangular surface tiles, all interaction coefficients may be evaluated with the help of the integrals listed in Appendix A. H^{111} integrals apply to constant divergence volume cells, whereas H^{110}, H^{011}, and H^{101} integrals apply to tiles parallel to the xy, yz, and xz planes, respectively.

Lastly, for both a regular meshing and a regular sampling of the field (volume cells centers or apexes seem natural choices), translational invariance of the interaction coefficients allows for the use of FFTs in the evaluation of the demagnetizing field (Eastwood, Hockney and Lawrence, 1980; Hockney and Eastwood, 1981; Yuan and Bertram, 1992; Berkov, Ramstöck and Hubert, 1993; Ramstöck, Leibl and Hubert, 1994). FFTs considerably reduce the computational load in numerical micromagnetics. However, because the magnetization distribution is not usually periodic, zero-padding techniques need to be implemented (Press, Teukolsky, Wetterling and Flannery, 2001). Further discussion on the use of FFTs in numerical micromagnetics is deferred to Section 3.4. We note in closing this section that a direct evaluation of the field at the apexes of the volume cells leads to weak divergences of the demagnetizing field (Shtrickman and Treves, 1960). It has been shown both numerically (Rave, Ramstöck and Hubert, 1998) and analytically (Thiaville, Tomáš and Miltat, 1998) that the log-type divergence of the demagnetizing field along the edges and at the apices of a uniformly magnetized parallelepiped are balanced via tiny rotations of the magnetization close to boundaries that take place over distances smaller than the exchange length. Methods relying on the direct evaluation of the demagnetizing field therefore practically restrict the choice of the field sampling points to cell centers.

2.2 Derivatives evaluation

Consider a regular, differentiable one-dimensional scalar function $f(x)$ sampled at regular intervals, a (see Figure 3a). Second-order Taylor expansion readily yields expressions for the first and second central derivatives that are widely used in numerics, namely $\frac{\mathrm{d}f}{\mathrm{d}x} = \frac{f_{i+1}-f_{i-1}}{2a}$ and $\frac{\mathrm{d}^2 f}{\mathrm{d}x^2} = \frac{f_{i+1}-2f_i+f_{i-1}}{a^2}$, respectively.

However, the numerical derivation of the structure of a simple Bloch wall using such expressions soon reveals that second-order Taylor expansion leads to restricted accuracy. Fourth-order expansion has actually been found to prove much superior (Trouilloud and Miltat, 1987; Miltat, Thiaville and Trouilloud, 1989; Berkov, Ramstöck and Hubert, 1993; Labrune and Miltat, 1995). Taylor expansion of function $f(x)$ around $x = x_i$ reads as follows:

$$f(x) = \sum_{k=0}^{\infty} \frac{(x-x_i)^k}{k!} f^{(k)}(x_i) = \sum_{k=0}^{\infty} \frac{(x-x_i)^k}{k!} f_i^{(k)} \tag{27}$$

where, $f^{(k)}(x) = f(x)$ if $k = 0$ and $\frac{\mathrm{d}^k f}{\mathrm{d}x^k}$ otherwise. Application of equation (27) to nearest and next nearest neighbors to grid point i and truncation to the fourth order yields a set of four equations, namely

$$\begin{bmatrix} -2a & \frac{(-2a)^2}{2!} & \frac{(-2a)^3}{3!} & \frac{(-2a)^4}{4!} \\ -a & \frac{(-a)^2}{2!} & \frac{(-a)^3}{3!} & \frac{(-a)^4}{4!} \\ +a & \frac{(+a)^2}{2!} & \frac{(+a)^3}{3!} & \frac{(+a)^4}{4!} \\ +2a & \frac{(+2a)^2}{2!} & \frac{(+2a)^3}{3!} & \frac{(+2a)^4}{4!} \end{bmatrix} \begin{bmatrix} f_i^{(1)} \\ f_i^{(2)} \\ f_i^{(3)} \\ f_i^{(4)} \end{bmatrix} = \begin{bmatrix} f_{i-2} - f_i \\ f_{i-1} - f_i \\ f_{i+1} - f_i \\ f_{i+2} - f_i \end{bmatrix} \tag{28}$$

The set of linear equations (28) provide numerical estimates for the first, second, third, and fourth derivatives of f at grid point i. In particular, the general form of the first and second derivative based on second nearest-neighbors expansion reads

$$\begin{aligned} f_i^{(1)} &= \frac{f_{i-2} - 8f_{i-1} + 8f_{i+1} - f_{i+2}}{12a} \\ f_i^{(2)} &= \frac{-f_{i-2} + 16f_{i-1} - 30f_i + 16f_{i+1} - f_{i+2}}{12a^2} \end{aligned} \tag{29}$$

respectively.

2.3 Boundary conditions implementation: 'free' boundary conditions

Expressions in the preceding text cease to be valid when the grid point becomes closest or next-to-closest to the boundary of the magnetic volume. Specific, accuracy preserving expansions need to be worked out. The general principle in the present approach is to replace equations that are missing because of the lack of grid point(s) outside the magnetic volume by equations including explicit reference to BCs, equation (17).

Consider first a point second to closest to boundary (see Figure 3b). Grid point $i + 2$ is missing for this particular geometry. However, defining x_R as the right boundary coordinate along the x axis, the last equation in equation (28) may, assuming $f^{(1)}(x_R)$ to be known along the boundary, be

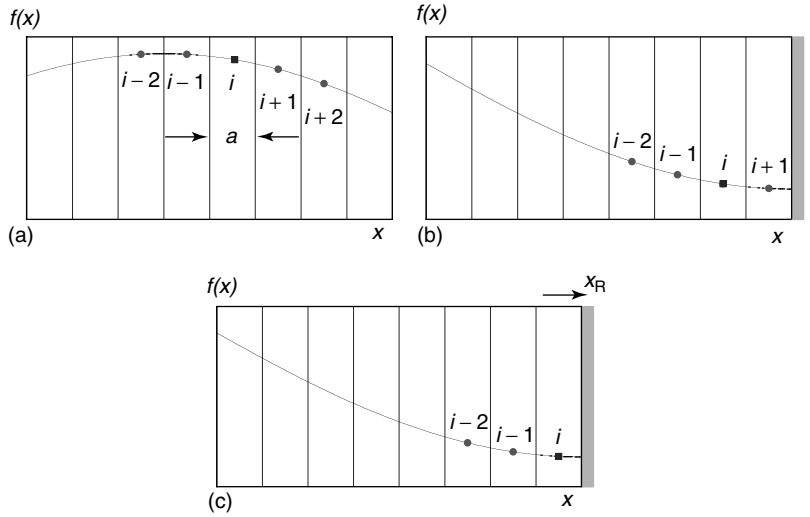

Figure 3. Mesh geometry. (a) Function of the sole scalar x. (b) Mesh points second to closest to boundary. (c) Mesh points closest to boundary.

replaced by

$$f^{(1)}(x_{\mathrm{R}}) = f_i^{(1)} + (x_{\mathrm{R}} - x_i) f_i^{(2)} + \frac{1}{2!}(x_{\mathrm{R}} - x_i)^2 f_i^{(3)} + \frac{1}{3!}(x_{\mathrm{R}} - x_i)^3 f_i^{(4)} \quad (30)$$

which is a result stemming directly from the derivation of Taylor's expansion (27), namely

$$f^{(1)}(x) = \sum_{k=1}^{\infty} \frac{(x - x_i)^{k-1}}{(k-1)!} f^{(k)}(x_i) \quad (31)$$

For the geometry depicted in Figure 3(b), $x_{\mathrm{R}} - x_i = 3a/2$ and equation (28) becomes

$$\begin{bmatrix} -2a & \frac{(-2a)^2}{2!} & \frac{(-2a)^3}{3!} & \frac{(-2a)^4}{4!} \\ -a & \frac{(-a)^2}{2!} & \frac{(-a)^3}{3!} & \frac{(-a)^4}{4!} \\ +a & \frac{(+a)^2}{2!} & \frac{(+a)^3}{3!} & \frac{(+a)^4}{4!} \\ 1 & \left(\frac{+3a}{2}\right) & \frac{(+3a/2)^2}{2!} & \frac{(+3a/2)^3}{3!} \end{bmatrix} \begin{bmatrix} f_i^{(1)} \\ f_i^{(2)} \\ f_i^{(3)} \\ f_i^{(4)} \end{bmatrix} = \begin{bmatrix} f_{i-2} - f_i \\ f_{i-1} - f_i \\ f_{i+1} - f_i \\ f^{(1)}(x_{\mathrm{R}}) \end{bmatrix} \quad (32)$$

Similarly, for a point closest to boundary (see Figure 3c), grid points $i+1$ and $i+2$ are missing. The two first equations of equation (28) now need to be replaced by a single equation, while the two remaining equations need to be truncated to the third order. For the geometry illustrated in Figure 3(c), the minimal set of equations now reads

$$\begin{bmatrix} -2a & \frac{(-2a)^2}{2!} & \frac{(-2a)^3}{3!} \\ -a & \frac{(-a)^2}{2!} & \frac{(-a)^3}{3!} \\ 1 & \left(\frac{+a}{2}\right) & \frac{(+a/2)^2}{2!} \end{bmatrix} \begin{bmatrix} f_i^{(1)} \\ f_i^{(2)} \\ f_i^{(3)} \end{bmatrix} = \begin{bmatrix} f_{i-2} - f_i \\ f_{i-1} - f_i \\ f^{(1)}(x_{\mathrm{R}}) \end{bmatrix} \quad (33)$$

where, $x_{\mathrm{R}} - x_i = a/2$. In both cases, the first and second derivatives are fully determined provided $f^{(1)}(x_{\mathrm{R}})$ is known along the boundary. The implementation of BCs is, however, not unique. For instance, equation (33) could include four internal mesh points instead of only three. Donahue and Porter (2004) have evaluated the accuracy of several numerical schemes allowing for the evaluation of the exchange energy equation (4) and the enclosed derivatives. Their general conclusion is that the so-called 12-neighbors scheme, that is, 4 neighbors along each axis of the Euclidian space, is accuracy preserving up to order 4, at least for 'free' BCs. The derivation in the preceding text belongs to the '12-neighbors' class.

Equation (32) or equation (33) may be applied *mutatis mutandis* to the left boundary $x = x_{\mathrm{L}}$. Altogether, equation (28) and equations akin to equations (32) and (33) fully specify the first, second, and third derivatives of function $f(x)$ within the interval $]x_{\mathrm{L}}, x_{\mathrm{R}}[$, provided boundary values of the first derivatives versus x are known. For 'free' BCs, $f^{(1)}(x_{\mathrm{L}}) = f^{(1)}(x_{\mathrm{R}}) \equiv 0$, or more generally, $\frac{\partial m_{x_{\mathrm{S}}}}{\partial x} = \frac{\partial m_{y_{\mathrm{S}}}}{\partial x} = \frac{\partial m_{z_{\mathrm{S}}}}{\partial x} = 0$ for a flat boundary perpendicular to x located at position x_{S}. Generalization to three dimensions in the Euclidian space proves straightforward. Even for 'free' BCs, however, an evaluation of the relevant magnetization components along boundaries is still required in order to compute the contribution of surface charges to the demagnetizing field. Referring to Figure 3(c), Taylor expansion (equation (27)) up to, for example, the third order yields

$$f(x_{\mathrm{R}}) = f_i + (x_{\mathrm{R}} - x_i) f_i^{(1)} + \frac{1}{2!}(x_{\mathrm{R}} - x_i)^2 f_i^{(2)} + \frac{1}{3!}(x_{\mathrm{R}} - x_i)^3 f_i^{(3)} \quad (34)$$

where i here is the index of the mesh point closest to boundary. Assuming a constant charge density for the surface element centered on x_{R}, the surface charge $+\mu_0 M_{\mathrm{s}}\,(\mathbf{m}\cdot\mathbf{n})$ is simply $+\mu_0 M_{\mathrm{s}} m_{x_{\mathrm{R}}}$ with $m_x(x) = f(x)$ in equation (34). Here also, generalization to three dimensions in the Euclidian space is straightforward.

Summarizing at this point, knowing the distribution $\mathbf{m}(\mathbf{r})$ inside a magnetic volume bounded by flat boundaries, all necessary derivatives of the magnetization components as well as estimates of surface charges are available through Taylor expansion and explicit use of BCs reading $\frac{\partial \mathbf{m}}{\partial \mathbf{n}} = 0$ in the case of 'free' BCs. High accuracy (up to $O(h^4)$) may be preserved in this process.

As an example, the magnetization distribution within a soft and thin rectangular platelet is displayed in Figure 4. The initial state was uniformly magnetized along the diagonal of the rectangle. At remanence, the magnetization becomes essentially uniform and parallel to the element's long edges, thus avoiding both volume and surface charges along the most part of the latter. Close to the extremities, however,

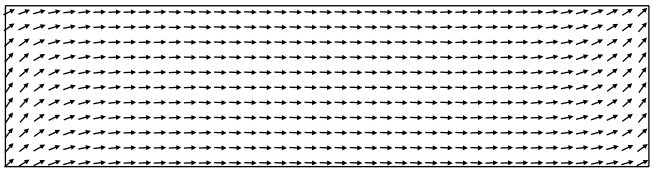

Figure 4. Magnetization distribution characteristic of a so-called S-state in a thin-film element: the magnetization keeps parallel to the long edges of the element, thus avoiding both volume and surface charges along the most part of the latter. Close to the extremities, however, a gradual bending of the magnetization distribution allows for a decrease of surface charges along the element short edges at the expense of exchange and volume magnetostatic energy. $Ni_{80}Fe_{20}$ like materials parameters (exchange constant: $A = 1.3 \times 10^{-11}\,\mathrm{J\,m^{-1}}$, saturation magnetization $M_{\mathrm{s}} = 800\,\mathrm{kA\,m^{-1}}$); dimensions: $500 \times 125 \times 3\,\mathrm{nm}^3$; Meshing: $256 \times 64 \times 1$ (one-layer-of-cells type simulation).

the magnetization distribution is bending in such a way as to allow for a decrease of surface charges along the element short edges at the expense of exchange and volume magnetostatic energy. Actually, in submicron size thin soft magnetic elements, the number of possible magnetization states becomes discrete (Yuan, Bertram, Smyth and Schultz, 1992; Zheng and Zhu, 1997; Rave and Hubert, 2000; Miltat, Albuquerque and Thiaville, 2001; Hertel, 2002). The magnetization state shown in Figure 4 is called an *S state*. Platelets displaying S states may be found in four variants according to the direction of the magnetization in the main section of the element ($\approx +x$ or $\approx -x$), and the magnetization component along the element short edges ($+y$ or $-y$). Reversing the magnetization rotation direction close to one extremity would lead to a so-called C state with, again, four possible variants characterized by a single energy.

Although the thickness in that particular element remains smaller than the exchange length for the material considered (3 vs 5.68 nm), the decomposition of the element into three layers of cells reveals interesting features of the magnetization distribution at equilibrium. The minute splay

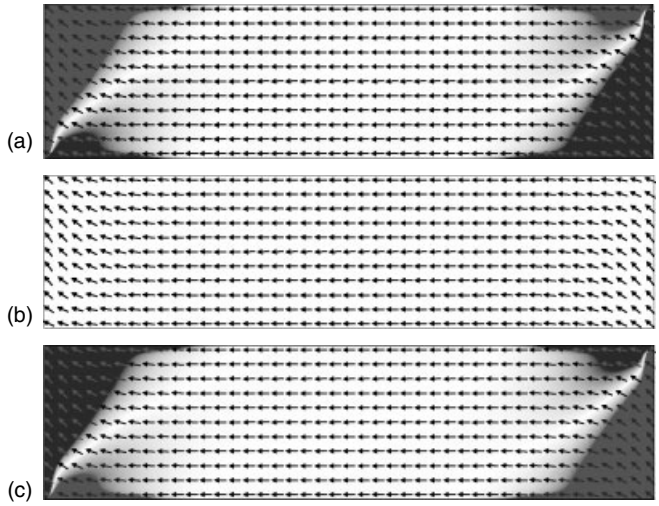

Figure 5. Magnetization distribution characteristic of a so-called S state in a thin-film element owing to three-dimensional micromagnetics. Close to the upper left boundary, the in-plane magnetization is fanning-in, leading to positive volume charges; in the top and bottom computation cell-layers (a and c respectively), the z-component (out-of-plane) of the magnetization is positive and negative, respectively. The fanning-out of the magnetization along the normal to the magnetic element allows for charge compensation between the in-plane and out-of-plane magnetization distributions, leading to an overall reduction of both the exchange and demagnetizing field energy. The magnetization distribution around the bottom right corner behaves symmetrically (in-plane fanning-out, out-of-plane fanning-in). $Ni_{80}Fe_{20}$ like materials parameters (exchange constant: $A = 1.3 \times 10^{-11}\,\mathrm{J\,m^{-1}}$, saturation magnetization $M_s = 800\,\mathrm{kA\,m^{-1}}$); dimensions: $500 \times 125 \times 3\,\mathrm{nm}^3$; meshing: $511 \times 127 \times 3$.

across the thickness of the magnetization displayed in Figure 5 actually leads to a decrease of both the exchange and the magnetostatic energies (see the caption of Figure 5 for details). Figure 5 emphasizes the stringent need for rather small mesh sizes (a relatively small fraction of the exchange length) if the fine features of the magnetization distribution are to be revealed with a satisfying accuracy.

2.4 Boundary conditions implementation: extended boundary conditions

Additional work needs to be performed when dealing with general boundary conditions (17). General BCs are expressed in terms of boundary values for the magnetization. Boundary magnetization values (refer to equation (34)) are functions of derivatives defined at given mesh points that themselves depend on specific derivatives along boundaries (see equations (32) and (33)). It ensues that for each boundary point where an estimate of a boundary derivative is required, an implicit equation needs to be solved. Consider again the boundary point in Figure 3(b) or (c). The requested boundary derivatives read as $\frac{\partial m_x(x_R)}{\partial x}$, $\frac{\partial m_y(x_R)}{\partial x}$, $\frac{\partial m_z(x_R)}{\partial x}$. In components form, neglecting the J_2 biquadratic exchange term, extended BCs for the right boundary (normal along $+x$) read as

$$\begin{aligned}
\frac{\partial m_x^R}{\partial x} &= \frac{K_S}{A} m_x^R \left[1 - m_x^{R2}\right] - \frac{J_1}{2A}\left[\left(\mathbf{m}^R \cdot \mathbf{m}'\right) m_x^R - m_x'\right] \\
\frac{\partial m_y^R}{\partial x} &= -\frac{K_S}{A} m_x^{R2} m_y^R - \frac{J_1}{2A}\left[\left(\mathbf{m}^R \cdot \mathbf{m}'\right) m_y^R - m_y'\right] \\
\frac{\partial m_z^R}{\partial x} &= -\frac{K_S}{A} m_x^{R2} m_z^R - \frac{J_1}{2A}\left[\left(\mathbf{m}^R \cdot \mathbf{m}'\right) m_z^R - m_z'\right]
\end{aligned} \tag{35}$$

where $\mathbf{m}^R = \mathbf{m}(x_R)$. Combined with relations akin to (34) and (32) or (33), equation (35) provides a set of nonlinear equations (third order in the general case) in the variables m_x^R, m_y^R, m_z^R that may easily be solved via, for example, Newton's method. A proper numerical implementation ensures that extended BCs are strictly equivalent to 'free' BCs if $K_S = J_1 = 0$.

2.5 Energy

The energy to be evaluated embodies the exchange, anisotropy, Zeeman, and demagnetizing field energies that sum up to the total energy expressed in equation (3). Additional energy terms do arise from extended BCs, namely $E_{K_S} = \int_S \varepsilon_{K_S}\,\mathrm{d}S$ and $E_J = \int_S \varepsilon_J\,\mathrm{d}S$. Owing to the numerical scheme outlined in the preceding text, both the magnetization and the effective field are meant to be continuous functions of position sampled at regularly spaced volume

mesh points. The magnetization also needs to be evaluated at the center of surface tiles in order to satisfy to BCs and allow for the computation of surface charge densities. Whenever the magnetization is evaluated, its unit norm ($\mathbf{m}\cdot\mathbf{m} = 1$) must be enforced.

2.5.1 Zeeman, anisotropy, and exchange energy

Consider the right-hand expression of the exchange energy in equation (4). Its discrete counterpart reads as

$$E_{\text{exch}} = -A\, V_{\text{Cell}} \sum_{i,j,k} \left[\langle \mathbf{m} \rangle \cdot \left(\left\langle \frac{\partial^2 \mathbf{m}}{\partial x^2} \right\rangle + \left\langle \frac{\partial^2 \mathbf{m}}{\partial y^2} \right\rangle + \left\langle \frac{\partial^2 \mathbf{m}}{\partial z^2} \right\rangle \right) \right] \tag{36}$$

where, $\langle \mathbf{V} \rangle$ is the average value of $\mathbf{V}$ within a given cell. As discussed in Section 3, however, the cell-averaged value of any variable is equal to its value at cell center, be it a volume cell or a surface tile, to order 2, because all nearest order corrective terms sum up to zero. Although higher-order corrections may be worked out, such corrective actions have almost no incidence on the numerical estimate of the relevant energy, as exemplified in Figure 6(a). The same conclusion holds true for the estimate of the Zeeman (applied field) and anisotropy energies as demonstrated in Sections 3.1 and 3.2, respectively. Similar arguments also apply to energy terms linked to specific BCs for which the energy densities in the continuum limit are given by equations (14) and (15).

2.5.2 Demagnetizing field (or magnetostatic) energy

In the present field-based scheme, quantities that are constant per cell or tile are the magnetization divergence and the surface charge density. It is therefore natural to seek an expression for the energy that embodies these quantities. An expression for the energy is readily available if assuming the scalar potential equation (20) to be known (up to this point, only the field has been evaluated at discrete points). If either the magnetization divergence or the surface charge density is piecewise constant, the scalar potential is not. Therefore,

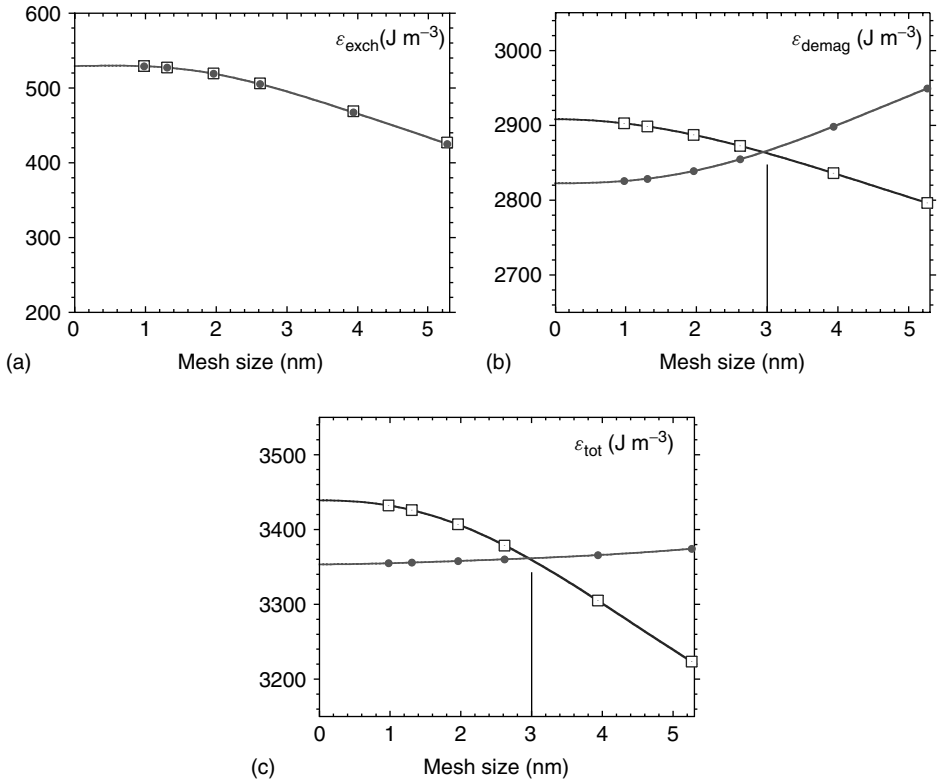

Figure 6. Energy per unit volume versus in-plane mesh size for the S-state magnetization distribution shown in Figure 4. (a) Exchange, (b) magnetostatic, and (c) total energy per unit volume. Open and full symbols refer to direct and cell-averaged summation, respectively. The magnetostatic energy is approximated by equations (41) and (38) for direct and cell-averaged summation, respectively. The fitting curves should be viewed as mere guides to the eye. $Ni_{80}Fe_{20}$ like materials parameters (exchange constant: $A = 1.3 \times 10^{-11}\,\text{J m}^{-1}$, saturation magnetization $M_s = 800\,\text{kA m}^{-1}$); dimensions: $500 \times 125 \times 3\,\text{nm}^3$; one-layer-of-cells type simulation.

the transcription of the continuous energy expression

$$E_{\text{demag}} = \frac{1}{2}\int_V \lambda_V(\mathbf{r})\Phi_d(\mathbf{r})\,d^3r + \frac{1}{2}\int_S \sigma_S(\mathbf{r})\Phi_d(\mathbf{r})\,d^2r \tag{37}$$

into a discrete summation requests the evaluation of the average value of the potential $\langle\Phi_d\rangle$ over each cell or tile (see Section 3.4 where a similar procedure is applied to the evaluation of the average field within a cell). Equation (37) thus becomes

$$E_{\text{demag}} = \frac{1}{2}\sum_{i,j,k}\left[\lambda_V(i,j,k)\langle\Phi_d(i,j,k)\rangle\right] + \frac{1}{2}\sum_{l,m,n}\left[\sigma_S(l,m,n)\langle\Phi_d(l,m,n)\rangle\right] \tag{38}$$

where,

$$\begin{aligned} &4\pi\mu_0 V_{\text{Cell}}\langle\Phi_d(i,j,k)\rangle \\ &= \sum_{i',j',k'}\lambda_V(i',j',k')\int_{V(i,j,k)} d^3r \int_{V(i',j',k')}\frac{1}{|\mathbf{r}-\mathbf{r}'|}\,d^3r' \\ &+ \sum_{l',m',n'}\sigma_S(l',m',n')\int_{V(i,j,k)} d^3r \int_{S(l',m',n')}\frac{1}{|\mathbf{r}-\mathbf{r}'|}\,d^2r' \end{aligned} \tag{39}$$

for volume cells, and

$$\begin{aligned} &4\pi\mu_0 S_{\text{Tile}}\langle\Phi_d(l,m,n)\rangle \\ &= \sum_{i',j',k'}\lambda_V(i',j',k')\int_{S(l,m,n)} d^2r \int_{V(i',j',k')}\frac{1}{|\mathbf{r}-\mathbf{r}'|}\,d^3r' \\ &+ \sum_{l',m',n'}\sigma_S(l',m',n')\int_{S(l,m,n)} d^2r \int_{S(l',m',n')}\frac{1}{|\mathbf{r}-\mathbf{r}'|}\,d^2r' \end{aligned} \tag{40}$$

for surface tiles. Cell or tile average scalar potential evaluation requires integrals of type F^{222}, F^{221} plus circular permutations, F^{220} plus circular permutations, where $F^{000} = \frac{1}{r}$, $F^{100} = \int F^{000}dx$, $F^{110} = \int F^{000}\,dx\,dy$, and so on, (Hubert and Schäfer, 1998). All necessary integrals are tabulated in Appendix B. For instance, the contribution of a tile belonging to the ($xy \equiv [110]$) surface to the averaged potential within a volume cell ($\equiv [111]$) involves the F^{221} integral, and so on. All interaction integrals are positive definite so that interactions between charges of similar sign, whether volume or surface, contribute positively to the energy, whereas interactions between opposite sign charges contribute negatively.

Although potential theory is the only approach to energy evaluation consistent with the present field-based model, a rough estimate of the magnetostatic energy may still be gained from the numerical equivalent of equation (3), namely

$$E_{\text{demag}} = -\frac{1}{2}\mu_0 V_{\text{Cell}}\sum_{i,j,k}(\mathbf{H}_d(i,j,k))\cdot(\mathbf{M}(i,j,k)) \tag{41}$$

where it is implicitly assumed that the magnetization and the demagnetizing field are constant within each volume cell.

Results pertaining to the S state in Figure 4 are displayed in Figure 6. The exchange energy per unit volume versus mesh size (Figure 6a) is seen to depend very little on the use or not of cell-averaged variables in equation (36). Convergence of the exchange energy, on the other hand is only attained for rather small mesh sizes. Markedly different behaviors for the demagnetizing field energy are obtained when using cell-averaged potential theory (equation (38)) or the rough estimate (41) (Figure 6b). In both cases, small mesh sizes are required in order to define the asymptotic value of the magnetostatic energy thus following a trend similar to that of the exchange energy. More surprising at first sight is the fact that both estimates of the magnetostatic energy do not converge to the same value for a vanishing mesh size. It ought to be noted that the best agreement between the two kinds of estimates is obtained for cubic cells (size 3 nm, here). It may therefore be concluded that the rough estimate (41) becomes particularly poor for cell aspect ratios markedly departing from unity. The total energy per unit volume versus mesh size consistent with the assumptions of the present numerical model is shown as full symbols in Figure 6(c). It appears relatively independent of mesh size although this result is physically meaningless: only the respective asymptotic values (Rave, Fabian and Hubert, 1998) of the energy contributions are representative of the physical reality. The exchange and magnetostatic energies actually display opposite curvature convergence behaviors, pointing at a subtle change in the balance between exchange and magnetostatic interactions with decreasing mesh size.

3 FINITE DIFFERENCE MICROMAGNETICS: ENERGY-BASED APPROACH

In an energy-based approach, the magnetic energy is given primacy and is computed directly from the discretized magnetization, whereas the effective field is derived from the resultant energy. The effective field obtained in this manner is a cell-averaged field. This method is obviously convenient if one is interested in finding equilibrium magnetization patterns via direct energy minimization (using, e.g., conjugate-gradient methods), but also has the advantage that the energy, being an integral quantity, has less

variation than the field and is therefore more easily approximated. As noted in Section 2.1, the demagnetizing field can diverge at corners of a sample, yet this logarithmic divergence is integrable, so that the energy contained in any discretization cell remains finite. This effect is seen also in Figure 6(b), where the result using equation (41) leads to an incorrect result, even in the small cell limit. Although the discretization in this example is sufficient to represent variations in the magnetization, it does not pick up variations in the demagnetizing field along the film normal (Parker, Cerjan and Hewett, 2000; Donahue, Porter, McMichael and Eicke, 2000). To correct for this one has to either move to a multilayer simulation or use a potential averaging approach as in equation (38) or as discussed in this section.

3.1 Zeeman energy

As stated before, Zeeman energy is the magnetostatic energy from the interaction of a given magnetization state with an external field,

$$E_{\mathrm{Z}} = -\mu_0 \int_V \mathbf{M}\cdot\mathbf{H}_{\mathrm{app}}\,\mathrm{d}^3 r \tag{42}$$

Here $\mathbf{H}_{\mathrm{app}}$ includes fields directly applied, and also fields resulting from currents inside the device, that is,

$$\mathbf{H}_{\mathrm{current}} = \frac{1}{4\pi}\int_V \mathbf{J}(\mathbf{r}') \times \frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|^3}\,\mathrm{d}^3 r' \tag{43}$$

Assuming that both $\mathbf{M}$ and $\mathbf{H}_{\mathrm{app}}$ are twice differentiable, we can write

$$\mathbf{M}(\mathbf{r}) = \mathbf{M}(\mathbf{r}_i) + B\,(\mathbf{r}-\mathbf{r}_i) + O(\|\mathbf{r}-\mathbf{r}_i\|^2) \tag{44}$$

$$\mathbf{H}_{\mathrm{app}}(\mathbf{r}) = \mathbf{H}_{\mathrm{app}}(\mathbf{r}_i) + C\,(\mathbf{r}-\mathbf{r}_i) + O(\|\mathbf{r}-\mathbf{r}_i\|^2) \tag{45}$$

where B and C are the 3×3 matrices corresponding to the partial derivatives of $\mathbf{M}$ and $\mathbf{H}_{\mathrm{app}}$, respectively, and $\mathbf{r}_i$ is an arbitrary point suitably close to $\mathbf{r}$. Consider this simple approximation to the Zeeman energy:

$$E_{\mathrm{Z}} \approx -\mu_0 \sum_i \mathbf{M}(\mathbf{r}_i)\cdot\mathbf{H}_{\mathrm{app}}(\mathbf{r}_i)|V_i| \tag{46}$$

where the index i runs over all cells in the simulation, $\mathbf{r}_i$ denotes the center of the rectangular cell i, and $|V_i|$ is the volume of cell i. Given equations (44) and (45), we estimate the error in equation (46) as

$$\left| E_{\mathrm{Z}} - (-\mu_0)\sum_i \mathbf{M}(\mathbf{r}_i)\cdot\mathbf{H}_{\mathrm{app}}(\mathbf{r}_i)|V_i| \right|$$

$$\leq \mu_0 \sum_i \left| \int_{V_i} \mathbf{M}(\mathbf{r})\cdot\mathbf{H}_{\mathrm{app}}(\mathbf{r}) - \mathbf{M}(\mathbf{r}_i)\cdot\mathbf{H}_{\mathrm{app}}(\mathbf{r}_i)\,\mathrm{d}^3 r \right| \tag{47}$$

$$\leq \mu_0 \sum_i \left| \int_{V_i} \mathbf{M}(\mathbf{r}_i)^{\mathrm{T}} C\,(\mathbf{r}-\mathbf{r}_i) + \mathbf{H}_{\mathrm{app}}(\mathbf{r}_i)^{\mathrm{T}} B\,(\mathbf{r}-\mathbf{r}_i) + O(\|\mathbf{r}-\mathbf{r}_i\|^2)\,\mathrm{d}^3 r \right| \tag{48}$$

where T denotes the vector transpose. Since $\mathbf{r}_i$ is at the center of the rectangular cell V_i,

$$\int_{V_i} (\mathbf{M}(\mathbf{r}_i)^{\mathrm{T}} C + \mathbf{H}_{\mathrm{app}}(\mathbf{r}_i)^{\mathrm{T}} B)(\mathbf{r}-\mathbf{r}_i)\,\mathrm{d}^3 r = 0 \tag{49}$$

because the integrand is an odd function with respect to $\mathbf{r}_i$. Thus we see that

$$\left| E_{\mathrm{Z}} - (-\mu_0)\sum_i \mathbf{M}(\mathbf{r}_i)\cdot\mathbf{H}_{\mathrm{app}}(\mathbf{r}_i)|V_i| \right|$$

$$\leq \mu_0 \sum_i \int_{V_i} O(\|\mathbf{r}-\mathbf{r}_i\|^2)\,\mathrm{d}^3 r \tag{50}$$

$$\leq O(\Delta^2)|V| \tag{51}$$

where $|V| = \sum_i |V_i|$ is the total volume of the space, and Δ is the maximum cell dimension.

In this approximation, all of the $\mathbf{M}(\mathbf{r}_i)\cdot\mathbf{H}_{\mathrm{app}}(\mathbf{r}_i)$ terms are weighted equally. Higher-order methods can be obtained by varying the weights, similar to the well-known Simpson's rule (Davis and Rabinowitz, 1984; Stoer and Bulirsch, 1993).

The discretized field expression derived from this approximation to the energy is simply

$$\mathbf{H}_{\mathrm{Z},i} = \mathbf{H}_{\mathrm{app}}(\mathbf{r}_i) \tag{52}$$

3.2 Magnetocrystalline anisotropy energy

Magnetocrystalline anisotropy energy models the preferential magnetization orientation in a material, and depends chiefly on the crystalline structure of the material. For uniaxial materials the energy is given by

$$E_{K,\mathrm{uniaxial}} = -\int_V K_1(\mathbf{m}\cdot\mathbf{u})^2\,\mathrm{d}^3 r \tag{53}$$

where K_1 is the material anisotropy coefficient (in $\mathrm{J\,m^{-3}}$), $\mathbf{m}$ is the unit magnetization direction ($\mathbf{M}/M_{\mathrm{s}}$), and $\mathbf{u}$ is the (unit)

anisotropy axis. If K_1 is positive, then $\mathbf{u}$ is the easy axis, while if K_1 is negative then $\mathbf{u}$ is normal to the easy plane. For some materials, a second term $K_2 \sin^4 \phi$ is important, where K_2 is a second anisotropy coefficient and ϕ is the angle between $\mathbf{m}$ and $\mathbf{u}$. This equation should be modified at material interfaces and defects (Moschel, Hyman, Zangwill and Stiles, 1996).

For cubic materials with crystal axes oriented parallel to the coordinate axes, the energy takes the form

$$E_{K,\text{cubic}} = \int_V K_1(m_x^2 m_y^2 + m_y^2 m_z^2 + m_z^2 m_x^2) + K_2(m_x^2 m_y^2 m_z^2)\, \mathrm{d}^3 r \tag{54}$$

For a rotated crystal orientation, m_x should be replaced with the projection of $\mathbf{m}$ onto the first coordinate axis, m_y with the projection onto the second (orthogonal) axis, and m_z with the projection onto the remaining axis.

If we assume that $\mathbf{m}$, $\mathbf{u}$, K_1, and K_2 are twice differentiable, at least within each cell, then we can expand the integrands in equations (53) and (54) in the manner of equations (44) and (45) and obtain an analogous discrete approximation for the magnetocrystalline anisotropy energy. In the uniaxial case this is

$$E_{K,\text{uniaxial}} \approx -\sum_i K_1(\mathbf{r}_i)\ (\mathbf{m}(\mathbf{r}_i)\cdot\mathbf{u}(\mathbf{r}_i))^2\, |V_i| \tag{55}$$

and for the cubic we have

$$E_{K,\text{cubic}} \approx \sum_i \big[K_1(\mathbf{r}_i)\left(\mathbf{m}_x^2(\mathbf{r}_i)\mathbf{m}_y^2(\mathbf{r}_i) + \mathbf{m}_y^2(\mathbf{r}_i)\mathbf{m}_z^2(\mathbf{r}_i) + \mathbf{m}_x^2(\mathbf{r}_i)\mathbf{m}_z^2(\mathbf{r}_i)\right) + K_2(\mathbf{r}_i)\ \left(\mathbf{m}_x^2(\mathbf{r}_i)\mathbf{m}_y^2(\mathbf{r}_i)\mathbf{m}_z^2(\mathbf{r}_i)\right)\big]|V_i| \tag{56}$$

Using the same argument as in the Zeeman energy section, these approximations are also seen to be of order Δ^2.

The discretized field expressions derived from the discretized energies are

$$H_{K,\text{uniaxial},i} = 2K_1(\mathbf{r}_i)\ (\mathbf{m}(\mathbf{r}_i)\cdot\mathbf{u}(\mathbf{r}_i))\,\mathbf{u}(\mathbf{r}_i)/\mu_0 M_\text{s} \tag{57}$$

$$H_{K,\text{cubic},i} = -2\,D(\mathbf{r}_i)\mathbf{m}(\mathbf{r}_i)/\mu_0 M_\text{s} \tag{58}$$

where D is the diagonal matrix with entries

$$D_{11} = K_1(\mathbf{r}_i)\left(m_y^2(\mathbf{r}_i) + m_z^2(\mathbf{r}_i)\right) + K_2(\mathbf{r}_i)m_y^2(\mathbf{r}_i)m_z^2(\mathbf{r}_i) \tag{59}$$

$$D_{22} = K_1(\mathbf{r}_i)\left(m_x^2(\mathbf{r}_i) + m_z^2(\mathbf{r}_i)\right) + K_2(\mathbf{r}_i)m_x^2(\mathbf{r}_i)m_z^2(\mathbf{r}_i) \tag{60}$$

$$D_{33} = K_1(\mathbf{r}_i)\left(m_x^2(\mathbf{r}_i) + m_y^2(\mathbf{r}_i)\right) + K_2(\mathbf{r}_i)m_x^2(\mathbf{r}_i)m_y^2(\mathbf{r}_i) \tag{61}$$

3.3 Exchange energy

As noted in Section 1, the exchange energy may be represented using either of the expressions in equation (4). In practice, the latter relation,

$$E_\text{exch} = -\int_V A\,\mathbf{m}\cdot\left(\frac{\partial^2\mathbf{m}}{\partial x^2} + \frac{\partial^2\mathbf{m}}{\partial y^2} + \frac{\partial^2\mathbf{m}}{\partial z^2}\right)\mathrm{d}^3 r \tag{62}$$

is somewhat easier to work with and is the form used in the following discussion.

The first step in providing a numerical approximation to equation (62) is to find a discrete form for the second derivative operator. As mentioned in Section 2.2, the simplest approximation, which holds if $\mathbf{m}$ is four times differentiable, is

$$\frac{\partial^2\mathbf{m}}{\partial x^2}(\mathbf{r}) = \frac{1}{\Delta_x^2}\big(\mathbf{m}(\mathbf{r}+\Delta_x\hat{x}) - 2\mathbf{m}(\mathbf{r}) + \mathbf{m}(\mathbf{r}-\Delta_x\hat{x})\big) + O(h^2) \tag{63}$$

where Δ_x is the discretized cell dimension along the $\hat{x}$ direction. The analogous equations for $\partial^2\mathbf{m}/\partial y^2$ and $\partial^2\mathbf{m}/\partial z^2$ (involving Δ_y and Δ_z), lead to a seven point approximation to the integrand in equation (62), involving $\mathbf{M}$ at the point $\mathbf{r}_i$ and its six closest neighbors:

$$E_\text{exch} \approx -\sum_i |V_i| A \sum_j \mathbf{m}(\mathbf{r}_i)\cdot\big(\mathbf{m}(\mathbf{r}_i+\boldsymbol{\epsilon}_j) - \mathbf{m}(\mathbf{r}_i)\big)/|\boldsymbol{\epsilon}_j|^2 \tag{64}$$

Here $\mathbf{r}_i + \boldsymbol{\epsilon}_j$, varying over j, specifies each of the six nearest neighbors to $\mathbf{r}_i$ in the discretized mesh. By the same argument used in the previous two sections, this estimate will be of $O(\Delta^2)$. The corresponding expression for the discretized exchange field is

$$H_\text{exch} = \frac{2A}{\mu_0 M_\text{s}} \sum_j \big(\mathbf{m}(\mathbf{r}_i+\boldsymbol{\epsilon}_j) - \mathbf{m}(\mathbf{r}_i)\big)/|\boldsymbol{\epsilon}_j|^2 \tag{65}$$

One may be tempted to replace $\mathbf{m}(\mathbf{r}_i)\cdot\mathbf{m}(\mathbf{r}_i)$ in equation (64) with $|\mathbf{m}|^2 = 1$, obtaining

$$E_\text{exch} \approx -\sum_i |V_i| A \sum_j \big(\mathbf{m}(\mathbf{r}_i)\cdot\mathbf{m}(\mathbf{r}_i+\boldsymbol{\epsilon}_j) - 1\big)/|\boldsymbol{\epsilon}_j|^2 \tag{66}$$

or to drop the '-1' altogether, which shifts E_exch by a constant amount without affecting the exchange field. Either way, however, leads to numerical problems because the term $\mathbf{m}(\mathbf{r}_i)\cdot\mathbf{m}(\mathbf{r}_i+\boldsymbol{\epsilon}_j)$ effectively loses significant precision in the common case where $\mathbf{m}(\mathbf{r}_i)$ and $\mathbf{m}(\mathbf{r}_i+\boldsymbol{\epsilon}_j)$ are nearly parallel. This can be seen by realizing that $\mathbf{m}(\mathbf{r}_i)\cdot\mathbf{m}(\mathbf{r}_i+\boldsymbol{\epsilon}_j) = \cos\theta$, where θ is the angle between $\mathbf{m}(\mathbf{r}_i)$ and

$\mathbf{m}(\mathbf{r}_i + \boldsymbol{\epsilon}_j)$, and $\cos\theta \approx 1 - \theta^2/2$. The torque depends on the component perpendicular to $\mathbf{m}(\mathbf{r}_i)$, which is represented by the θ^2 term. If $|\theta| \ll 1$, then when stored with a finite number of digits the expression $1 - \theta^2/2$ loses a great deal of the precision in θ^2. On the other hand, if one first subtracts $\mathbf{m}(\mathbf{r}_i)$ from $\mathbf{m}(\mathbf{r}_i + \boldsymbol{\epsilon}_j)$ as in equation (64) then the dot product will be between two nearly perpendicular vectors, and precision is significantly retained (Donahue, Porter, McMichael and Eicke, 2000).

Large angles between neighboring spins $\mathbf{m}(\mathbf{r}_i)$ and $\mathbf{m}(\mathbf{r}_i + \boldsymbol{\epsilon}_j)$ also cause problems, but of a rather different nature. Here the problem arises because equation (64) always underestimates the exchange energy, and the larger the neighboring spin angle θ, the larger the underestimate. As a result, magnetization configurations with regions of high exchange energy that are located between grid points tend to have overall smaller total exchange energy than otherwise identical configurations shifted so that the points of high exchange energy are on or near grid points. This can cause artificial, discretization-induced pinning of high exchange energy structures such as vortices (Donahue and McMichael, 1997) or induce a Peierl's like friction for Bloch points motion (Thiaville *et al*., 2003). Figure 7 illustrates this problem on a small, vortex bearing thin plate. In this example, maximum pinning is 18 mT, which occurs with an in-plane cell size of just under 7 nm. Moreover, the pinning is found to be non-monotonic with Δ, at first worsening as Δ is decreased, only abating after the vortex core is resolved.

A related issue can occur in undermeshed 180° Néel walls (Donahue, 1998). If the angle between neighboring spins across the center of the wall is too large, then the wall demagnetizing field can overwhelm the coarse mesh–weakened exchange field and force the Néel wall to collapse into a structure where the entire wall is squeezed between adjacent spins, as illustrated in Figure 8(a). The problem is fixed when a sufficiently fine mesh is used, as in Figure 8(b).

Simulations in Figures 7 and 8 were performed using the OOMMF public code (Donahue and Porter, 1999).

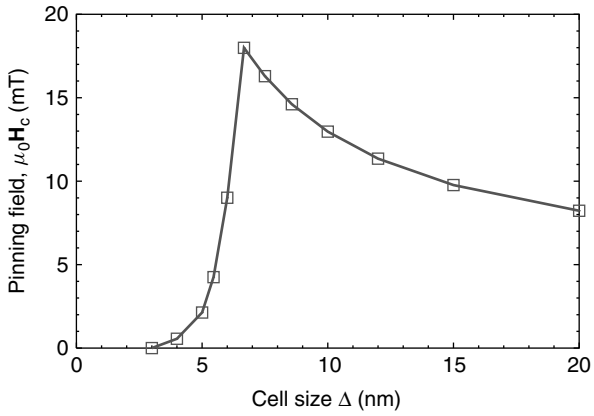

Figure 7. Discretization-induced vortex pinning fields for a $120 \times 120 \times 3\,\text{nm}^3$ $Ni_{80}Fe_{20}$ ($M_s = 800\,\text{kA m}^{-1}$, $A = 13\,\text{pJ m}^{-1}$, $K = 0\,\text{J m}^{-3}$) plate, as a function of in-plane discretization cell size (one-layer-of-cells type simulations). Initial zero-field magnetization configuration is an equilibrium-centered vortex state. Field is applied in plane, parallel to plate edge, and gradually increased until vortex jumps from one discretization cell to the next.

3.4 Self-magnetostatic energy

Self-magnetostatic, or demagnetization energy, is the energy associated with dipole–dipole magnetostatic interactions of material within itself. It is described by

$$E_{\text{demag}} = -\frac{\mu_0}{2} \int_V \mathbf{M} \cdot \mathbf{H}_{\text{d}}\, \mathrm{d}^3 r \tag{67}$$

where the demagnetization field $\mathbf{H}_{\text{d}}$ at position r is

$$\mathbf{H}_{\text{d}}(\mathbf{r}) = -\frac{1}{4\pi} \int_V \nabla \cdot \mathbf{M}(\mathbf{r}') \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3}\, \mathrm{d}^3 r' + \frac{1}{4\pi} \int_S \hat{\mathbf{n}}(\mathbf{r}') \cdot \mathbf{M}(\mathbf{r}') \frac{\mathbf{r} - \mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|^3}\, \mathrm{d}^2 r' \tag{68}$$

Equation (68) is identical to equation (21) and displayed here anew for convenience. Note that E_{demag} involves long-range interactions, and in terms of $\mathbf{M}$ requires integration over $V \times V$.

If we let $\mathbf{g}(\mathbf{r}) = \mathbf{r}/|\mathbf{r}|^3$, then integration by parts allows one to rewrite equation (68) as

$$\mathbf{H}_{\text{d}}(r) = -\frac{1}{4\pi} \int_V \nabla \mathbf{g}(\mathbf{r} - \mathbf{r}') \mathbf{M}(\mathbf{r}')\, \mathrm{d}^3 r' \tag{69}$$

From this formulation it is clear that an approximation to $\mathbf{M}$ of the form (44) is sufficient to produce an approximation to $\mathbf{H}_{\text{d}}$ of second order, and moreover that at this level of

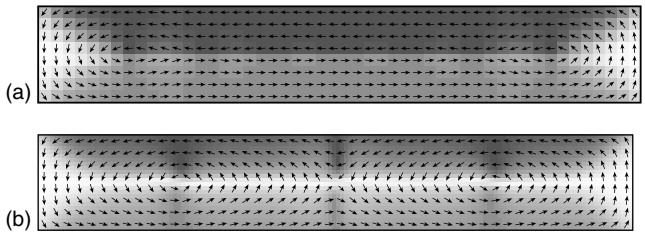

Figure 8. Néel wall in $750 \times 120 \times 30\,\text{nm}^3$ $Ni_{80}Fe_{20}$ rectangle, equilibrium states. (Same material parameters as quoted in Figure 7.) (a) Wall collapses in coarse grid simulation ($\Delta = 15\,\text{nm}$), as compared to (b) fully resolved wall using fine grid ($\Delta = 5\,\text{nm}$). Shade indicates x-axis component of the magnetization. Multilayer cubic cells used in both simulations.

approximation the linear portion of $\mathbf{M}$ can be ignored. Thus we have

$$\mathbf{H}_{\mathrm{d}}(\mathbf{r}) = -\frac{1}{4\pi}\sum_i \int_{V_i} \nabla \mathbf{g}(\mathbf{r}-\mathbf{r}')\mathbf{M}(\mathbf{r}_i')\,\mathrm{d}^3 r' + O(\Delta^2) \tag{70}$$

$$= \frac{1}{4\pi}\sum_i \int_{S_i} \hat{\mathbf{n}}(\mathbf{r}')\cdot\mathbf{M}(\mathbf{r}_i')\frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|^3}\,\mathrm{d}^2 r' + O(\Delta^2) \tag{71}$$

This shows that, to second order, the demagnetization field at point $\mathbf{r}$ can be computed by treating each cell in the discretization as a uniformly magnetized block. Likewise, second-order accuracy can be maintained in equation (67) by replacing $\mathbf{M}$ in each cell with its value at the center, so we have

$$E_{\mathrm{demag}} \approx -\frac{\mu_0}{8\pi}\sum_{i,j}\int_{V_i}\mathbf{M}(\mathbf{r}_i)\cdot\int_{S_j}\mathbf{M}(\mathbf{r}_j')\cdot\hat{\mathbf{n}}(\mathbf{r}')\frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|^3}\,\mathrm{d}^2 r'\,\mathrm{d}^3 r \tag{72}$$

$$\approx -\frac{\mu_0}{8\pi}\sum_{i,j}\mathbf{M}^{\mathrm{T}}(\mathbf{r}_i)\left(\int_{V_i}\int_{S_j}\frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|^3}\hat{\mathbf{n}}^{\mathrm{T}}(\mathbf{r}')\,\mathrm{d}^2 r'\,\mathrm{d}^3 r\right)\mathbf{M}(\mathbf{r}_j) \tag{73}$$

This can be rewritten as

$$E_{\mathrm{demag}} \approx \frac{\mu_0}{2}\sum_{i,j}|V_i|\,\mathbf{M}^{\mathrm{T}}(\mathbf{r}_i)N(\mathbf{r}_i,\mathbf{r}_j)\mathbf{M}(\mathbf{r}_j) \tag{74}$$

where $N(\mathbf{r}_i,\mathbf{r}_j)$ is the 3×3 matrix arising from the fivefold integration in equation (73) divided by $-4\pi|V_i|$. The term $(\mu_0|V_i|/2)\,\mathbf{M}^{\mathrm{T}}(\mathbf{r}_i)N(\mathbf{r}_i,\mathbf{r}_j)\mathbf{M}(\mathbf{r}_j)$ is seen to be the (exact) magnetostatic energy arising between uniformly magnetized cells at positions $\mathbf{r}_i$ and $\mathbf{r}_j$. It is clear from the definition that N depends only on the difference $\mathbf{r}_i-\mathbf{r}_j$, so $N(\mathbf{r}_i,\mathbf{r}_j) = N(\mathbf{r}_i-\mathbf{r}_j) = N_{i-j}$.

If we compute the effective demagnetization field from equation (74), we obtain

$$\mathbf{H}_{\mathrm{d},i} = -\sum_j N_{i-j}\mathbf{M}_j \tag{75}$$

Note that as elsewhere in Section 3, $\mathbf{H}_{\mathrm{d},i}$ is computed from the energy expression (73) rather than the field expression (71), so that $\mathbf{H}_{\mathrm{d},i}$ can be interpreted as being the average value for the demagnetization field in cell i arising from a cell j having uniform magnetization $\mathbf{M}_j$.

We must now compute N_i. It follows from the magnetic reciprocity theorem (Brown, 1963) that N_i must be symmetric. (Newell, Williams and Dunlop, 1993 also discuss additional properties of N_i). This means that the 3×3 matrix N_i holds only six independent entries,

$$N_i = \begin{bmatrix} N_{xx,i} & N_{xy,i} & N_{xz,i} \\ N_{xy,i} & N_{yy,i} & N_{yz,i} \\ N_{xz,i} & N_{yz,i} & N_{zz,i} \end{bmatrix} \tag{76}$$

The entries, $N_{xx,i}$, and so on, can be evaluated analytically (Schabes and Aharoni, 1987; Newell, Williams and Dunlop, 1993; Fukushima, Nakatani and Hayashi, 1998). First, define

$$f(x,y,z) = \frac{1}{2}y(z^2-x^2)\sinh^{-1}\left(\frac{y}{\sqrt{x^2+z^2}}\right) + \frac{1}{2}z(y^2-x^2)\sinh^{-1}\left(\frac{z}{\sqrt{x^2+y^2}}\right) - xyz\arctan\left(\frac{yz}{xR}\right) + \frac{1}{6}(2x^2-y^2-z^2)R \tag{77}$$

$$g(x,y,z) = xyz\sinh^{-1}\left(\frac{z}{\sqrt{x^2+y^2}}\right) + \frac{1}{6}y(3z^2-y^2)\sinh^{-1}\left(\frac{x}{\sqrt{y^2+z^2}}\right) + \frac{1}{6}x(3z^2-x^2)\sinh^{-1}\left(\frac{y}{\sqrt{x^2+z^2}}\right) - \frac{1}{2}y^2z\arctan\left(\frac{xz}{yR}\right) - \frac{1}{2}x^2z\arctan\left(\frac{yz}{xR}\right) - \frac{1}{6}z^3\arctan\left(\frac{xy}{zR}\right) - \frac{xyR}{3} \tag{78}$$

where $R=\sqrt{x^2+y^2+z^2}$, and $\sinh^{-1}$ is the inverse hyperbolic sine, $\sinh^{-1}(x)=\log(x+\sqrt{1+x^2})$. Note that $f(x,y,z)$ and $g(x,y,z)$ are identical to $F^{022}(x,y,z)$ and $F^{112}(x,y,z)$ defined in Appendix B. They describe magnetostatic interactions between parallel and perpendicular charged tiles, respectively. Then

$$4\pi\Delta_x\Delta_y\Delta_z N_{xx,i} = 8f(x_i,y_i,z_i) - 4\sum_{v\in A}f(v) + 2\sum_{v\in B}f(v) - \sum_{v\in C}f(v) \tag{79}$$

$$4\pi\Delta_x\Delta_y\Delta_z N_{xy,i}(x,y,z) = 8g(x_i,y_i,z_i) - 4\sum_{v\in A}g(v) + 2\sum_{v\in B}g(v) - \sum_{v\in C}g(v) \tag{80}$$

where A is the set of 'nearest neighbors' to (x_i,y_i,z_i), B is the set of next nearest neighbors, and C is the set of corners

of the 3×3 cube about (x_i, y_i, z_i):

$$A = \{(x_i \pm \Delta_x, y_i, z_i), (x_i, y_i \pm \Delta_y, z_i), (x_i, y_i, z_i \pm \Delta_z)\} \tag{81}$$

$$B = \{(x_i \pm \Delta_x, y_i \pm \Delta_y, z_i), (x_i \pm \Delta_x, y_i, z_i \pm \Delta_z), (x_i, y_i \pm \Delta_y, z_i \pm \Delta_z)\} \tag{82}$$

$$C = \{(x_i \pm \Delta_x, y_i \pm \Delta_y, z_i \pm \Delta_z)\} \tag{83}$$

so that $|A| = 6$, $|B| = 12$, and $|C| = 8$. The other four elements of N_i are computed analogously, by permuting x, y, z and Δ_x, Δ_y, Δ_z, with $N_{yy,i}$ and $N_{zz,i}$ using equation (79) and $N_{xz,i}$ and $N_{yz,i}$ using equation (80).

If we let ϕ represent the operator on f and g in the right-hand side of equations (79) and (80), we see that $\phi/|V|^2$ is a second-order discrete approximation to the differential operator $-\partial^6/\partial x^2 \partial y^2 \partial z^2$ (Abramowitz and Stegun, 1970). If we define ψ_x/Δ_x^2 to be the second-order discrete approximate to $-\partial^2/\partial^2 x$, $\psi_x(f)(x) = -f(x - \Delta_x, y, z) + 2f(x, y, z) - f(x + \Delta_x, y, z)$ (and likewise ψ_y and ψ_z), we see that ϕ can be decomposed as $\psi_x \circ \psi_y \circ \psi_z$. This admits a relatively efficient approach to the evaluation of N_{xx} for the entire range of (x, y, z) of interest. First, evaluate f at each point on the mesh. Then, evaluate $\psi_z(f)$ at each point on the mesh, which can be done essentially in place. If there are n points in the mesh, evaluating $\psi_z(f)$ requires $2n$ subtractions. Then, evaluate ψ_y on the new values, and finally ψ_x, for a total of $6n$ subtractions (as compared to $26n$ additions/subtractions in a direct implementation of equation (79)). The other five terms of N_i can be evaluated using the same method.

As can be seen from equation (75), $\mathbf{H}_{\mathrm{d},i}$ is a discrete (three dimensional) convolution of N_i with $\mathbf{M}_i$, so it can be computed efficiently using FFT techniques (Stockham, 1966). A few details of the application of the FFT in this case bear mentioning (Donnelly and Rust, 2005a,b).

The basics of the technique are to take the FFT of the N_i and $\mathbf{M}_i$ sequences, say $\tilde{N}_k$ and $\tilde{\mathbf{M}}_k$, multiply these together pointwise to obtain $\tilde{\mathbf{H}}_{\mathrm{d},k}$, and then take the inverse FFT of $\tilde{\mathbf{H}}_{\mathrm{d},k}$ to obtain $\mathbf{H}_{\mathrm{d},i}$. Since the FFT and inverse FFT can be computed with operation count of $O(n \log n)$ (where n is the size of the set $\{i\}$), the computation of the entire set $\{\mathbf{H}_{\mathrm{d},i}\}$ can be computed in $O(n \log n)$, as opposed to $O(n^2)$ resulting from a direct evaluation of equation (75).

However, the magnetization data in equation (75) should be interpreted as being finite in extent but lying in an infinite space. Since convolution by FFT produces a cyclic (periodic) convolution, the magnetization data need to be zero-padded to double length in each of the x, y, and z directions to remove wraparound artifacts. Note that this results in an eightfold increase in the number of points. The interaction coefficient sequence N_i also needs to be extended to this size, however, it is not zero-padded but rather is extended through the origin into 'negative' territory, where, following the usual FFT conventions, index $-i = (-i_x, -i_y, -i_z)$ is stored at the index corresponding to $(n_x - i_x, n_y - i_y, n_z - i_z)$.

Since the interaction coefficient sequence N_i is determined by the geometry of the problem, the FFT of this sequence, $\tilde{N}_k$, can be computed once during program initialization and saved for subsequent use. Moreover, the various symmetries of the terms N_{xx}, N_{xy}, and so on (Newell, Williams and Dunlop, 1993), and the fact that these sequences are real (as opposed to complex), result in the transformed sequences $\tilde{N}_{xx,k}$, $\tilde{N}_{xy,k}$, and so on, having the same symmetries and also being purely real. As a result, only one octant of $\tilde{N}_k$ needs to be stored and that storage can be as real (as opposed to complex) values.

The $\mathbf{M}_i$ sequence is also real; this property can be used to accelerate the FFT by almost a factor of 2 and reduce the storage requirements for $\tilde{\mathbf{M}}_k$ by half. ($\tilde{\mathbf{M}}_k$ is complex valued, but is conjugate symmetric with respect to the origin, so only one half-space needs to be stored.) The fact that large portions of the zero-padded $\mathbf{M}_i$ array are zero can also be used to significantly speed up the FFT.

3.5 Boundary conditions

As discussed in Sections 2.3 and 2.4, at grid points where the stencil for an expression extends beyond the boundaries of the part being simulated, the stencil will need to be adjusted. Typically this involves replacement of missing magnetization values (i.e., points corresponding to stencil values outside the part boundary) with relations involving BCs and possibly additional points inside the part. These considerations apply not just to part boundaries but across any interface where the magnetization fails to fulfill the smoothness requirements for the given expression. We consider in this subsection only the 'free' BCs arising in the case of no surface anisotropy. As discussed in Sections 1 (equations (14)–(17)) and 2.4, other constraints are possible.

In general, BCs may influence any of the energy terms. However, for the second-order relations discussed here (Section 3), only the exchange energy is directly affected. Indeed, expressions (46) and (52) for the Zeeman term, expressions (55–58) for anisotropy, and (74) and (75) for demagnetization may be used unaltered at boundaries or in situations where $\mathbf{M}$ is discontinuous across cell faces.

However, examination of equation (64) reveals that the formula is undefined at boundaries; for example, if $\mathbf{r}_i$ is on the leftmost edge of the discretized mesh, then $\mathbf{r}_i - \Delta_x \hat{x}$ is outside the mesh, so we have no value for $\mathbf{m}$ there.

The most common solution to this problem is to introduce a 'ghost' spin at the missing location, with value the same

as the nearest spin inside the boundary, that is define $\mathbf{m}(\mathbf{r}_i - \Delta_x\hat{x}) = \mathbf{m}(\mathbf{r}_i)$. Here we implicitly assume that the boundary runs along the discretization cell surfaces, and is therefore exactly halfway between $\mathbf{r}_i - \Delta_x\hat{x}$ and $\mathbf{r}_i$. With this definition, the interpolated magnetization $\mathbf{m}(\mathbf{r})$ satisfies the usual Neumann BC $\partial\mathbf{m}/\partial\mathbf{n} = \mathbf{0}$. This approach is sometimes referred to as using 'mirror boundary conditions', because the magnetization is in some sense reflected across the boundary. It should be noted that this simple scheme for defining the value of the ghost spin only works for the second-order method. The relations are more complicated when higher-order methods are involved (Donahue and Porter, 2004). Also, the computed value for the field (65) at the edge spin $\mathbf{r}_i$ is only first-order accurate in Δ_x. However, the boundary region has narrow width Δ_x, so in the energy computation (64) a factor of Δ_x is introduced into the $|V_i|$ term; therefore the computed value for the total energy remains second order in Δ_x (Donahue and Porter, 2004).

The usual artifact of applying an incorrect BC is a loss in accuracy arising from a reduction in method order. This effect is shown in Figure 9, where a uniform magnetization spiral is impressed upon a one-dimensional rod. The magnetization pattern is not relaxed but rather held fixed while the exchange energy is computed for different discretization scales. For this reason the usual 'free' BCs, $\partial\mathbf{m}/\partial\mathbf{n} = \mathbf{0}$ do not hold. To obtain full method accuracy it is necessary to apply the correct boundary conditions, which in this case are of the Dirichlet type.

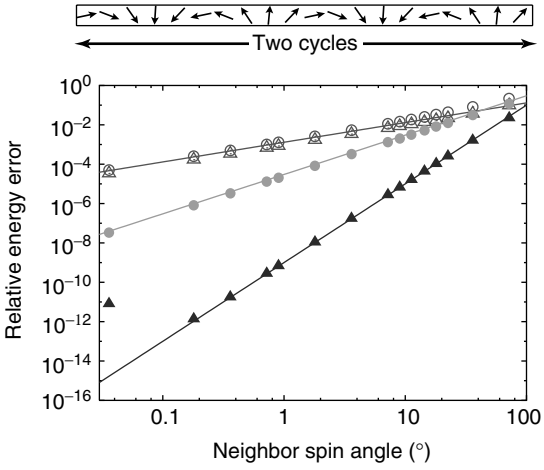

Figure 9. One-dimensional convergence study of exchange energy on an impressed magnetization spiral. Horizontal axis is the (constant) angle between neighboring spins, i.e. 720° divided by the number of spins. Circles represent second-order exchange method discussed in Section 3.3, triangles are a fourth-order method presented in Donahue and Porter (2004). Open symbols (top line) are results using 'free' boundary condition, $\partial\mathbf{m}/\partial\mathbf{n} = \mathbf{0}$; these show only first-order convergence because the magnetization spiral does not obey this boundary condition. Closed symbols (bottom two lines) use the correct Dirichlet boundary conditions and recover the quoted convergence rates, second and fourth order, respectively. The leftmost point on the lowest curve shows the limit of numeric accuracy imposed by round-off errors.

4 SOLVING THE LLG EQUATION

When attempting to solve the LLG equation, accuracy needs to be preserved both in space and time. To look for time accuracy monitoring tools that might easily be implemented in a given code, let us first take the vector product of the right-hand side of the LLG equation (9) with $\mathrm{d}\mathbf{m}/\mathrm{d}t$. One gets

$$\mathbf{h}_{\mathrm{eff}} \cdot \frac{\mathrm{d}\mathbf{m}}{\mathrm{d}\tau} = \alpha \left(\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}\tau} \right)^2 \tag{84}$$

where, $\tau = \gamma_0 M_s t$, $\mathbf{m} = \mathbf{M}/M_s$, $\mathbf{h}_{\mathrm{eff}} = \mathbf{H}_{\mathrm{eff}}/M_s$. Equation (84) is local. Alternatively, starting from the general expression of the system's free energy functional, its rate of change may, provided the applied field be time independent, be written as (Brown, 1963)

$$\frac{\mathrm{d}\int \varepsilon_{\mathrm{T}}}{\mathrm{d}\tau} = -\mu_0 M_s^2 \int \left(\mathbf{h}_{\mathrm{eff}} \cdot \frac{\mathrm{d}\mathbf{m}}{\mathrm{d}\tau} \right) \tag{85}$$

There exists no local counterpart to this expression, owing to the nonlocal nature of magnetostatic interactions. It follows from equations (84) and (85) that the damping parameter is related to the rate of change of the total free energy and the rate of change of the magnetization through

$$\alpha = -\frac{1}{\mu_0 M_s^2} \left[\frac{\int \mathrm{d}\varepsilon_{\mathrm{T}}/\mathrm{d}\tau}{\int (\mathrm{d}\mathbf{m}/\mathrm{d}\tau)^2} \right] \tag{86}$$

As expected, the damping parameter may stay positive only if the overall energy decreases as time elapses. Two numerical equivalents to this important relation may be written down, namely

$$\langle \alpha \rangle = \frac{\gamma_0 \Delta t}{\mu_0 M_s} \left[\frac{-\sum_{i=1}^{N} \Delta\varepsilon_i}{\sum_{i=1}^{N} \Delta\mathbf{m}_i^2} \right] \tag{87}$$

where i is the node index, N the total node number, and the reduced time has been replaced by the physical time step in the calculation, and

$$\alpha_{\mathrm{MS}} = N \frac{\gamma_0 \Delta t}{\mu_0 M_s} \left[\frac{-\sum_{i=1}^{N} \Delta\varepsilon_i}{\left(\sum_{i=1}^{N} \Delta\mathbf{m}_i \right)^2} \right] \tag{88}$$

which represents a transcription of equation (86) for the average magnetization, that is, for the macrospin equivalent to the magnetization distribution. Because of Schwartz' inequality, one always finds

$$\alpha_{\mathrm{MS}} \geq \langle \alpha \rangle \tag{89}$$

This seemingly innocuous relation contains a deep meaning: any experiment that measures the time evolution of some average of the magnetization distribution is bound to yield a value larger than the true Gilbert damping parameter. On the other hand, it turns out that equation (87) provides an extremely sensitive tool when evaluating the accuracy of the numerical time integration of the LLG equation (Albuquerque, Miltat and Thiaville, 2001). Note in passing that the variational form $\Delta\varepsilon_i = -\mathbf{H}_{\mathrm{eff},i} \cdot \Delta\mathbf{M}_i$ provides the most accurate estimate of the energy change within the time step Δt.

A typical calculation of the kind is illustrated in Figure 10 dealing with the effect of a spin-polarized current flowing through a submicron size elliptical element. Momentum transfer from the conduction electrons to the magnetization induces magnetization motion for large enough current densities and may lead to the existence of precessional states (Slonczewski, 1996; Sun, 2000; Miltat, Albuquerque, Thiaville and Vouille, 2001; Stiles, Xiao and Zangwill, 2004; Stiles and Miltat, 2006, references therein; and see also **Theory of Spin-transfer Torque, Volume 2**). Shortly after switching the current on, magnetization motion proves undistinguishable whether using a semi-implicit Crank–Nicholson integration scheme or the fourth-order explicit Runge–Kutta algorithm (Figure 10a). At longer times, however, magnetization trajectories would prove somewhat different. Energy dissipation, on the other hand, as monitored via equation (87), proves distinctively different (Figure 10b) for the two time integration schemes. The Runge–Kutta algorithm leads to a numerical damping parameter equal to the nominal value in this calculation to a better than 10^{-6} relative accuracy for the 25 fs time step considered. Rather large fluctuations in the numerical damping parameter $\langle \alpha \rangle$ are seen to arise from the implicit integration scheme in spite of its unconditional stability. Generally speaking, $\langle \alpha \rangle$ is seen to be significantly depressed whenever the magnetization becomes stationary, a result ascribed to residual numerical noise in the solution of a large set of linear equations (sparse matrix) by means of iterative methods. Such considerations become particularly important when dealing with long time integrations such as requested in spin-transfer problems.

5 COMPARING METHODS

Numerical methods outlined in Sections 2 and 3 do differ in the order of approximations for exchange interactions and

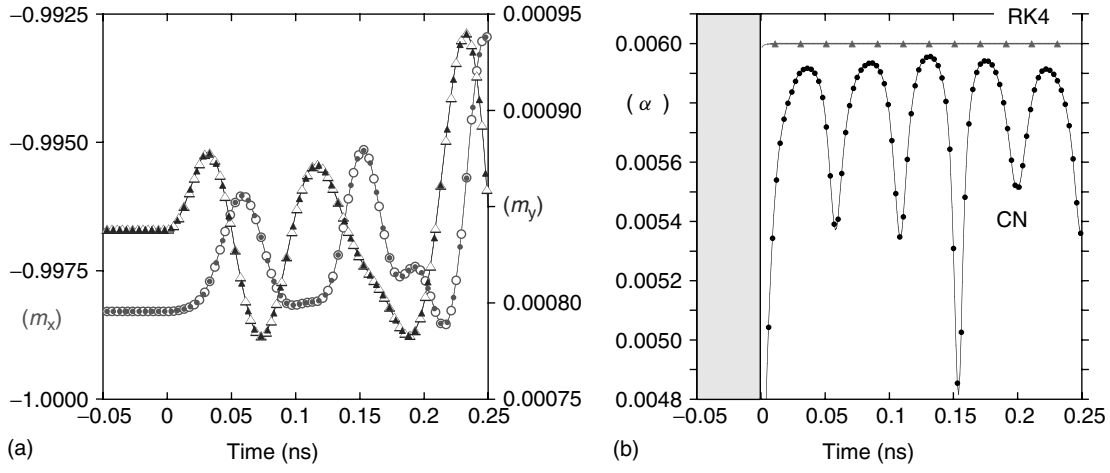

Figure 10. Onset of magnetization motion under the influence of a spin-polarized current flowing across a submicron size elliptical element. The magnetization distribution at rest is stabilized by a field applied along the ellipse long axis and equal to $1.5H_K$, where H_K is the shape anisotropy field of the elliptical platelet. Current density: $J = 0.5\,\mathrm{A\,\mu m^{-2}}$ flowing from time $t = 0$ on. A tiny constant field ($80\,\mathrm{A\,m^{-1}}$ or 1 Oe) is applied along the short ellipse axis, hence the nonzero value of the average m_y component prior to current application. (a) Element-averaged magnetization components versus time along the long (m_x) and short (m_y) elliptical axes, respectively. Open symbols refer to the Crank–Nicholson solution with an implicit character restricted to exchange interactions; full symbols refer to a fourth-order Runge–Kutta time integration. (b) Volume-averaged damping parameter (equation (87)) owing to the semi-implicit Crank–Nicholson (time step 12.5 fs) or explicit fourth-order Runge–Kutta (time step 25 fs) time integration schemes. Co-like materials parameters (exchange constant: $A = 1.3 \times 10^{-11}\,\mathrm{J\,m^{-1}}$, saturation magnetization $M_s = 1500\,\mathrm{kA\,m^{-1}}$, damping coefficient $\alpha = 0.006$); dimensions: $170 \times 80 \times 2.5\,\mathrm{nm}^3$; one-layer-of-cells type simulation.

BCs. More significantly, perhaps, they differ in the evaluation of the demagnetizing field, direct evaluation at nodes in the first case, field averaged over the cell volume in the second. The approach described in Section 3 uses constant magnetization cells, that is, zero-order expansion for the magnetization $\mathbf{m}(\mathbf{r})$. Note, however, that cell averaging, or indeed more complex integration approaches, may equally be applied to cells with a constant divergence (first-order expansion for the magnetization). The real question that arises from the different modeling options is the degree of coherence in approximation levels. Magnetization dynamics raises an additional issue, namely, is there a best numerical implementation for the LLG equation? In other words, should a mapping of the magnetization and the effective field onto the nodes of a regular mesh be preferred to motion involving a cell-averaged magnetization and a cell-averaged field or vice versa? The point being that in general, $\langle \mathbf{m}(t) \times \mathbf{H}_{\text{eff}}(t) \rangle \neq \langle \mathbf{m}(t) \rangle \times \langle \mathbf{H}_{\text{eff}}(t) \rangle$. We do not provide general answers to these questions in the following but, rather, analyze the convergence proper to each approach when dealing with the reversal of a rectangular platelet under the action of a slightly off-axis magnetic field applied at time $t = 0$. The specifics of the test problem considered here, which is the second part of μMAG Problem No. 4 (Micromagnetic Modeling Activity Group, 2005), are shown in Figure 11. At time $t = 0$ a uniform field is applied in-plane at 190° counterclockwise from the positive x axis. The applied field causes the spins in the middle portion of the sample to rotate clockwise, and the spins on either end to rotate counterclockwise. The differing rotation directions results from the relative angle of the applied field with respect to the initial position of the spins in the middle of the plate in contrast to the spins at the ends, but the origin of the motion is perhaps not immediately obvious. The damping parameter α is relatively small, so the spin evolution is dominated by precessional motion. In the middle part of the sample, $\mathbf{H} \times \mathbf{m}$ is directed upward ($+z$), so the initial motion of the spins in the middle is up and out of the film plane. In response, a large opposing demagnetization field is generated directed into the film plane ($-z$). Precession about this demagnetizing field results in the clockwise rotation of these spins, as seen in Figure 11(b). At the ends, the initial spin motion is in the $-z$ direction, the resulting demagnetizing field points along $+z$, and so the rotation of the spins at either end is counterclockwise.

After approximately 0.16 ns, the respective rotations generate two 360°-character domain walls, one on either end (Figure 11c), which are gradually pushed off the sample as the center domain expands (Figure 11d). As the walls are forced off the ends, the confined geometry leads to very tight magnetization structures containing vortices and cross-ties

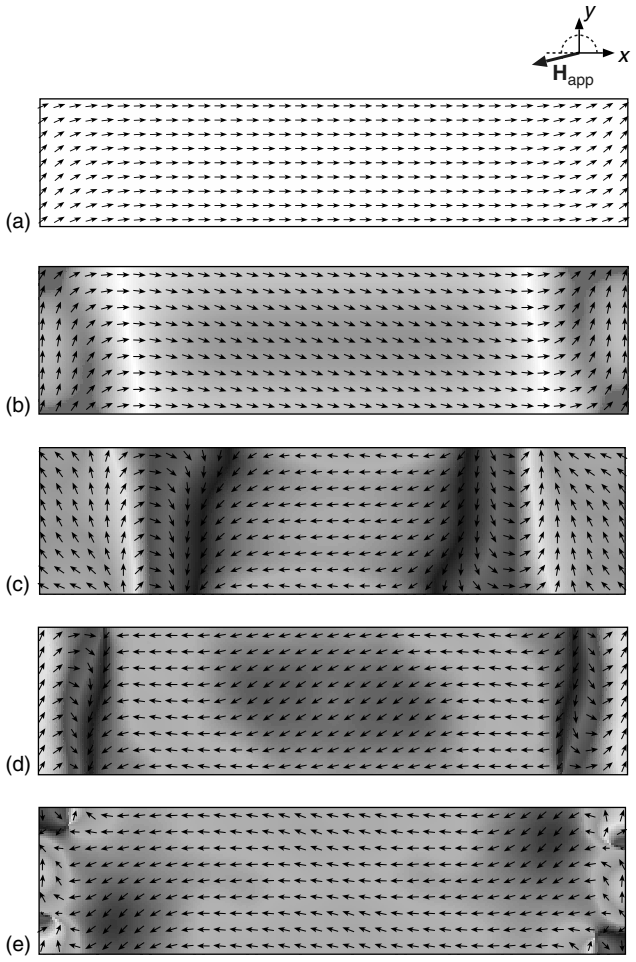

Figure 11. Magnetization states for μMAG Problem 4b (Micromagnetic Modeling Activity Group, 2005). Sample is a $Ni_{80}Fe_{20}$ slab with dimensions $500 \times 125 \times 3\,\text{nm}^3$, material parameters $A = 13\,\text{pJ m}^{-1}$, $M_s = 800\,\text{kA m}^{-1}$, $K = 0\,\text{J m}^{-3}$, $\alpha = 0.02$, $\gamma_0 = 2.211 \times 10^5\,\text{m A}^{-1}\text{s}^{-1}$. Dynamic simulation, starting in a zero-field equilibrium 'S'-state (a). At time $t = 0$ fs a uniform applied field, $\mu_0 \mathbf{H}_{\text{app}} = (-35.5, -6.3, 0)$ mT, is instantaneously applied. By 60 fs (b), domain rotation has begun. Large angle (≈360°) domain walls are formed by 160 fs (c), which are slowly pushed outwards (450 fs, (d)) and off the ends by 520 fs (e). In (b), the shade indicates the z-component of the magnetization, which is $+z$ (out of the page) in the central region, and $-z$ (into the page) at the ends. In (c–e), shade indicates in-plane magnetization angle. These images taken from a simulation using the energy-based method, with $255 \times 63 \times 1$ cell count.

(also called *antivortices*), which require a very fine mesh to properly resolve (Figures 11e and 12).

These effects are reflected in the simulation results displayed in Figures 13 and 14. The simulations all agree fairly well until some time after 0.4 ns, corresponding to the annihilation of the 360° domain walls. After that, although the features described in Figures 11 and 12 prove qualitatively similar in all simulations, discretization effects are clearly

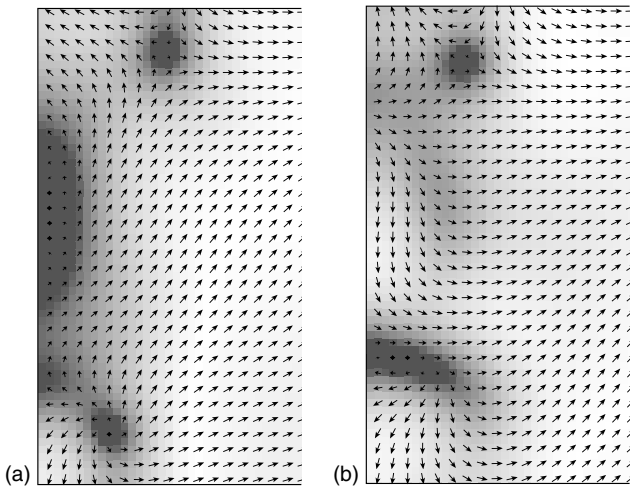

Figure 12. Details at left edge of simulation in Figure 11, at times $t = 500$ fs (a) and $t = 520$ fs (b). Cross-tie (or antivortex) at top and distorted vortex at bottom form from ends of 360° wall. The half-vortex visible in the middle of the left edge in (a) is a remanent of the 360° wall, which is pushed off the edge by 520 fs (b) as the cross-tie and distorted vortex move inward. Shade indicates the z-component of the magnetization, which is primarily out of the page ($+z$).

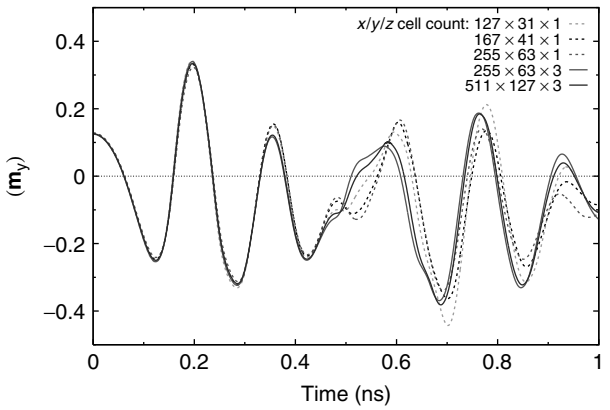

Figure 13. Average m_y versus time results for test problem from Figure 11 using the field-based method of Section 2, with different $x/y/z$ cell counts as indicated. In-plane counts 127×31 yields $\approx$4 nm square cells, $167 \times 41 \approx 3$ nm square cells, $255 \times 63 \approx 2$ nm square cells. Single-layer simulations (z cell count $= 1$) appear to converge toward a different limit than the multilayer simulations (z cell count $= 3$).

evident, especially in the field-based simulations shown in Figure 13. In this figure, the single-layer simulations do not appear to be converging toward the same limit as the three-layer simulations, although the $127 \times 31 \times 1$ solution proves rather close to the converged $500 \times 125 \times 3$ energy-based solution (see Figure 15). Whether this result is purely coincidental is hard to say. We note, however, that the most compact set of initial $\langle \mathbf{m}_y \rangle$ values including both approaches

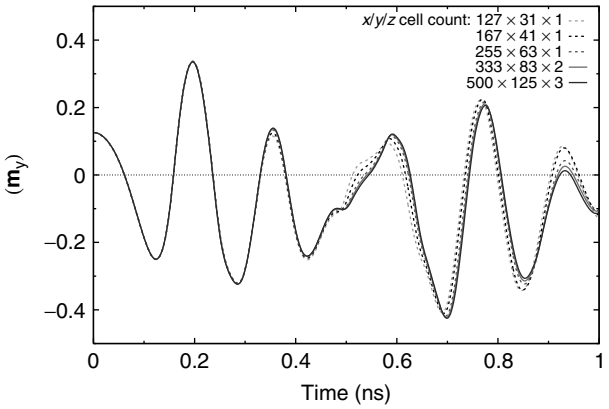

Figure 14. Average m_y versus time results for test problem from Figure 11 using energy-based method of Section 3, with various $x/y/z$ cell counts as indicated. Single-layer and multilayer simulations converge to same limit. Single-layer $500 \times 125 \times 1$ results (not shown) are indistinguishable from multilayer $500 \times 125 \times 3$ results.

is obtained for the extreme meshing conditions, with $\langle \mathbf{m}_y \rangle = 0.12472109$ (field-based), 0.12526786 (energy-based) for the $127 \times 31 \times 1$ discretization, and 0.12567210 (field-based) and 0.12599484 (energy-based) for the $\approx$1 nm cubic mesh size. The larger variability in initial conditions in the field approach is undoubtedly responsible in part for the sizable differences in time integration observed at later times and it is not even certain that three layers suffice for full convergence. In contrast, the results from the energy-based approach shown in Figure 14 do in this test manifest only minor z-layer discretization effects and appear to converge in a relatively straightforward manner. As noted in the preceding text, this is probably more due to the effect of using a cell-averaged demagnetizing field as opposed to any intrinsic property of the energy-based approach, and presumably indicates that the midplane (midcell) demagnetizing field samples are not generally truly representative of the field profile through the thickness of the film (cell), an effect alluded to earlier.

The important point from this comparison, as seen in Figure 15, is that both methods converge toward similar limits, and either way a very small cell size is required to approach that limit. It must be stressed that the cell size required here, $\approx$1 nm, is much smaller than the exchange length for this material, which by equation (5) is about 5.7 nm. This illustrates the importance of always checking for discretization effects in micromagnetic simulations, especially in confined geometries with small magnetic structures such as vortices and cross-ties. We note in closing that a subtle influence of the approximation order in the exchange interactions and BCs may not at this stage be ruled out.

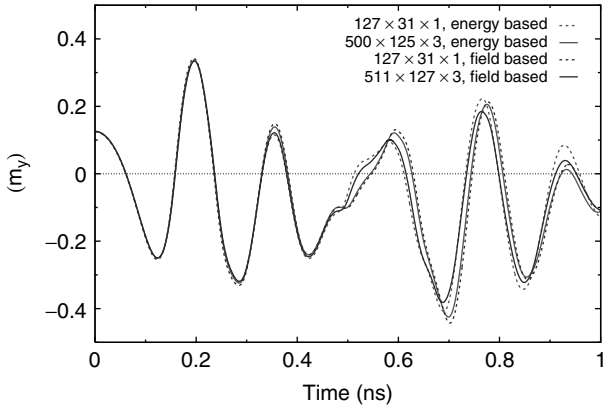

Figure 15. Test problem results comparing field-based (dark gray curves) and energy-based (light gray curves) approaches. Cell count $500 \times 125 \times 3$ corresponds to discretizing with 1 nm cubes.

6 CONCLUSION

This short review of finite difference methods applied to micromagnetics provides the reader with all the necessary ingredients to develop his or her own code. Different approximations have been discussed for exchange interactions and BCs. Ways to include general BCs have also been indicated. The appendices provide all required integrals for the definition of magnetostatic interaction coefficients due to one's own choice regarding discretization. Provided care is taken in the choice of a proper meshing and time integration step, the field- or energy-based methods described in the preceding text lead to comparable meshing sensitivity as evidenced in Figure 15. On the whole, numerical micromagnetics relying on finite difference methods has reached a high maturity level. As already stated, however, available data do not show convergence toward a single $\langle \mathbf{m}_y \rangle(t)$ trajectory for this particular problem. Lastly, if finite difference methods prove extremely efficient in terms of computation time due to an extensive use of FFTs, they display excessive discretization artifacts when dealing with curved geometries. Although that dependence needs to be quantified more precisely, work continues on the issue and practical solutions are expected in the near future.

APPENDICES

A DEMAGNETIZING FIELD: USEFUL INTEGRALS

For parallepipedic volume cells and rectangular surface tiles, defining $\rho = \sqrt{(u^2 + v^2 + w^2)}$, $L_u = \frac{1}{2}\ln(\frac{\rho+u}{\rho-u})$, $P_u = \arctan(\frac{vw}{u\rho})$, and L_v, L_w, P_v, P_w through permutation in the variables u, v, w, all interaction coefficients allowing for a direct evaluation of the demagnetizing field at any position in space (except corners) may be evaluated with the help of the following integrals (Tomáš, 1999):

$$
\begin{aligned}
H_u^{111} &= \iiint \frac{u}{\rho^3}\mathrm{d}u\mathrm{d}v\mathrm{d}w = +uP_u - vL_w - wL_v \\
H_v^{111} &= \iiint \frac{v}{\rho^3}\mathrm{d}u\mathrm{d}v\mathrm{d}w = +vP_v - wL_u - uL_w \\
H_w^{111} &= \iiint \frac{w}{\rho^3}\mathrm{d}u\mathrm{d}v\mathrm{d}w = +wP_w - uL_v - vL_u \\
H_u^{110} &= \iint \frac{u}{\rho^3}\mathrm{d}u\mathrm{d}v = -L_v \\
H_v^{110} &= \iint \frac{v}{\rho^3}\mathrm{d}u\mathrm{d}v = -L_u \\
H_w^{110} &= \iint \frac{w}{\rho^3}\mathrm{d}u\mathrm{d}v = +P_w \\
H_u^{011} &= \iint \frac{u}{\rho^3}\mathrm{d}v\mathrm{d}w = +P_u \\
H_v^{011} &= \iint \frac{v}{\rho^3}\mathrm{d}v\mathrm{d}w = -L_w \\
H_w^{011} &= \iint \frac{w}{\rho^3}\mathrm{d}v\mathrm{d}w = -L_v \\
H_u^{101} &= \iint \frac{u}{\rho^3}\mathrm{d}u\mathrm{d}w = -L_w \\
H_v^{101} &= \iint \frac{v}{\rho^3}\mathrm{d}u\mathrm{d}w = +P_v \\
H_w^{101} &= \iint \frac{w}{\rho^3}\mathrm{d}u\mathrm{d}w = -L_u
\end{aligned}
\tag{A1}
$$

B POTENTIAL: USEFUL INTEGRALS

Defining $\rho = \sqrt{(u^2 + v^2 + w^2)}$, $L_u = \frac{1}{2}\ln(\frac{\rho+u}{\rho-u})$, $Q_u = u\arctan(\frac{vw}{u\rho})$, and L_v, L_w, Q_v, Q_w through permutation in the variables u, v, w, the necessary integrals for the computation of the cell- or tile-averaged scalar potential are as follows (Tomáš, 1999):

$$
\begin{aligned}
F^{220} &= \frac{1}{2}u(v^2 - w^2)L_u + \frac{1}{2}v(u^2 - w^2)L_v \\
&\quad -uvQ_w + \frac{1}{6}\rho(2w^2 - u^2 - v^2) \\
F^{202} &= \frac{1}{2}w(u^2 - v^2)L_w + \frac{1}{2}u(w^2 - v^2)L_u \\
&\quad -wuQ_v + \frac{1}{6}\rho(2v^2 - w^2 - u^2) \\
F^{022} &= \frac{1}{2}v(w^2 - u^2)L_v + \frac{1}{2}w(v^2 - u^2)L_w \\
&\quad -vwQ_u + \frac{1}{6}\rho(2u^2 - v^2 - w^2) \\
F^{211} &= uvwL_u + \frac{1}{6}w(3u^2 - w^2)L_v + \frac{1}{6}v(3u^2 - v^2)L_w \\
&\quad -\frac{1}{6}u(uQ_u + 3vQ_v + 3wQ_w) - \frac{1}{3}\rho vw \\
F^{112} &= uvwL_w + \frac{1}{6}v(3w^2 - v^2)L_u + \frac{1}{6}u(3w^2 - u^2)L_v \\
&\quad -\frac{1}{6}w(wQ_w + 3uQ_u + 3vQ_v) - \frac{1}{3}\rho uv \\
F^{121} &= uvwL_v + \frac{1}{6}u(3v^2 - u^2)L_w + \frac{1}{6}w(3v^2 - w^2)L_u \\
&\quad -\frac{1}{6}v(vQ_v + 3wQ_w + 3uQ_u) - \frac{1}{3}\rho wu
\end{aligned}
$$

$$
\begin{aligned}
F^{221} &= \frac{1}{6}uw(3v^2 - w^2)L_u + \frac{1}{6}vw(3u^2 - w^2)L_v \\
&\quad + \frac{1}{24}(6u^2v^2 - u^4 - v^4)L_w \\
&\quad - \frac{1}{6}uv(uQ_u + vQ_v + 3wQ_w) \\
&\quad + \frac{1}{24}\rho(2w^3 - 3w(u^2 + v^2)) \\
F^{212} &= \frac{1}{6}wv(3u^2 - v^2)L_w + \frac{1}{6}uv(3w^2 - v^2)L_u \\
&\quad + \frac{1}{24}(6w^2u^2 - w^4 - u^4)L_v \\
&\quad - \frac{1}{6}wu(wQ_w + uQ_u + 3vQ_v) \\
&\quad + \frac{1}{24}\rho(2v^3 - 3v(w^2 + u^2)) \\
F^{122} &= \frac{1}{6}vu(3w^2 - u^2)L_v + \frac{1}{6}wu(3v^2 - u^2)L_w \\
&\quad + \frac{1}{24}(6v^2w^2 - v^4 - w^4)L_u \\
&\quad - \frac{1}{6}vw(vQ_v + wQ_w + 3uQ_u) \\
&\quad + \frac{1}{24}\rho(2u^3 - 3u(v^2 + w^2)) \\
F^{222} &= \frac{1}{24}u(6v^2w^2 - v^4 - w^4)L_u \\
&\quad + \frac{1}{24}v(6w^2u^2 - w^4 - u^4)L_v \\
&\quad + \frac{1}{24}w(6u^2v^2 - u^4 - v^4)L_w \\
&\quad - \frac{1}{6}uvw(uQ_u + vQ_v + wQ_w) \\
&\quad + \frac{1}{60}\rho(u^4 + v^4 + w^4 - 3(u^2v^2 + v^2w^2 + w^2u^2))
\end{aligned}
\tag{B1}
$$

All of these integrals are equal to their counterparts in Hubert and Schäfer (1998). The F^{200} integral in Hubert and Schäfer (1998) proves, however, erroneous; it should read: $F^{200} = uL_u - \rho$.

Numerical Methods in Micromagnetics (Finite Element Method)

Thomas Schrefl[1], Gino Hrkac[1], Simon Bance[1], Dieter Suess[2], Otmar Ertl[2] and Josef Fidler[2]

1 INTRODUCTION

The design and development of magnetic materials and devices requires a precise understanding of both the influence of a material's microstructure on the macroscopic magnetic properties and the influence of the magnetostatic interactions on the functional behavior of a device. A prominent example for the former is the remanence enhancement in exchange spring permanent magnets (Kneller, 1991), while an example for the latter is the case of single pole write heads in perpendicular magnetic recording (Kanai *et al*., 2005). In the following we review these two examples and explain why the finite element method (FEM) is an effective technique to treat these systems quantitatively.

Both the calculation of the remanence and coercivity of permanent magnets and the simulation of perpendicular magnetic recording involve realistic physical models. The calculation of the magnetic properties of permanent magnets needs a model of the grain structure that takes into account the grain size distribution as well as the shape of the grains. The simulation of perpendicular magnetic recording needs a computer model that takes into account the size, the shape, and the relative motion of the magnetic objects in a recording system. The FEM has been widely used to calculate magnetic fields in magnetic circuits, electric motors, and magnetoelectric devices (Preis *et al*., 1992). The strength of the FEM is its flexibility to model complex geometries and to refine the finite element mesh locally where higher accuracy of the solution is needed. The FEM is a well-established tool that has been used in science and engineering over many decades. Finite element mesh generators that perform the task of dividing complex objects into a computational grid are commercially and freely available (Schneiders, 2007).

In nanocrystalline permanent magnets (Manaf, Leonowicz, Davies and Buckley, 1991; Goll, Seeger and Kronmuller, 1998) exchange interactions between the grains cause a strong coupling between the magnetic moments with the effective coupling range being larger than the grain size. Although the crystallites are randomly oriented the remanence will be larger than expected from the Stoner–Wohlfarth theory (Stoner and Wohlfarth, 1948). When the magnet is saturated all the magnetic moments point parallel to the saturation field. Upon decreasing the external field, the magnetocrystalline anisotropy causes the magnetization in the center of the grains to rotate parallel to its easy axis. However, next to the grain boundaries exchange coupling with the neighboring grain that may have

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

a different anisotropy direction hinders the rotation of the magnetic moments. In a band along the grain boundaries, the magnetic moments remain oriented in a direction that is close to the direction of the saturation field (Schrefl, Fischer, Fidler and Kronmuller, 1994c). Owing to the interplay of exchange interactions and magnetocrystalline anisotropy the magnetic moments will deviate from their local easy axis next to the grain boundaries, giving rise to remanence enhancement. Remanence enhancement occurs in single-phase, nanocrystalline permanent magnets but can be considerably increased in so-called exchange spring permanent magnets, where magnetically soft grains are strongly exchange coupled to magnetically hard grains. In the remanent state, the magnetization direction in the soft magnetic grains is mostly governed by exchange interactions with the neighboring hard magnetic grains. This keeps the magnetization close to the direction of the saturation field. With increasing size of the soft magnetic grains magnetostatic interactions become dominant, vortices form within the soft magnetic grains, and remanence enhancement breaks down (Schrefl and Fidler, 1998). This example clearly shows that the macroscopic magnetic properties arise from the interplay between the intrinsic magnetic properties and the magnet's microstructure. Upon changing the microstructure (grain size, grain shape), the macroscopic properties change. The remanence and the coercivity will have different values although there is little or no change in the chemical composition of the magnet. This change of the macroscopic magnetic properties arises from a different local arrangement of the magnetic moments for different microstructures.

The directions of the magnetic moments can be calculated numerically by minimizing the total Gibbs' free energy of the system (Brown, 1963a). In the physical model, the intrinsic magnetic properties change from grain to grain. In the mathematical model, this is reflected by coefficients in the governing equations that vary locally in space. The grain structure of a magnet can be modeled by a set of polyhedra. Within a grain, the magnetic moments are not uniform. The interplay between exchange interactions and the magnetocrystalline anisotropy cause a nonuniform magnetization distribution. In order to resolve the magnetization distribution on a subgrain level, the computational grid has to be smaller than a grain. A polyhedral grain can be easily subdivided into tetrahedrons. Within the framework of the FEM discrete equations can be formulated on irregular, tetrahedral grids. The problem of finding the magnetization distribution of the remanent state is transformed into an algebraic minimization problem with the help of the FEM. The algebraic minimization problem is usually solved with an iterative method like the Newton method or the conjugate gradient method (Gill, Murray and Wright, 1993). These iterative schemes start from an initial state and proceed in steps toward a local minimum close to the initial state. A magnet has many magnetization states that correspond to a local minimum of the Gibbs' free energy. Thus, in order to compute the remanent state, a sequence of local minima must be computed. Luckily, for the saturated state the magnetization configuration is known since all magnetic moments can be assumed parallel to the external field if the external field is high. Therefore for the first calculation, a high external field is applied, the initial magnetization is assumed to be parallel to the field, and the magnetization configuration of the corresponding local minimum is calculated by solving the algebraic minimization problem. The external field is decreased and the corresponding magnetic state is calculated. This process is repeated until the remanent state (zero external field) is reached. According to Kinderlehrer and Ma (1994), the successive minimization of the total Gibbs' free energy for different external fields is a valid means to calculate the hysteresis loop of a ferromagnetic material. Alternatively, the Landau–Lifshitz–Gilbert (LLG) equation of motion (Gilbert, 1955; Landau and Lifshitz, 1935) for the magnetization can be solved for a time varying external field. This method shows the dynamic response of the magnetization upon application of an external field. The finite element and a proper time discretization method resolve the magnetization in time and in space. Such dynamic micromagnetic simulations are especially important for application where the external field changes fast, as the hysteresis properties are not only dependent on the field strength but also on the frequency of the field (He *et al*., 1996). Generally, the coercivity increases with increasing rate of change of the external field.

With data rates in the gigahertz regime, the rate of change of the external field and its influence on the coercive field play a major role in magnetic recording (Weller and Moser, 1999). Therefore, in magnetic recording simulation the locally acting external field as function of time has to be taken into account. The magnetic field seen by the data layer is created by the moving write head. In perpendicular recording, the magnetostatic interactions among the write pole of the head, the return pole of the head, and the soft underlayer (SUL) lead to the write field which is perpendicular to the recording media. The data layer itself can be seen as being placed in the 'air gap' of a magnetic circuit being composed of the write pole and the SUL. This is in contrast to conventional longitudinal recording where only the fringing field of the air gap can be used for writing. Thus, the maximum write field is higher than in longitudinal recording. The write field can switch highly coercive grains, which in turn enables a higher bit density. In order to optimize the field gradient, or to tilt the field angle for low field switching according to the Stoner–Wohlfarth angular dependence of the switching field, different soft magnetic

shield can be placed next to the write pole (Liu *et al*., 2005). The write field profile and the write field dynamics arise from the complex interaction of different magnetic parts with a particular shape. Again the FEM provides an easy way to model the complex geometries of the different parts involved in perpendicular recording systems (Scholz and Batra, 2005; Takano, 2005). The write field as a function of time as seen be the data layer grains is the result of magnetization dynamics in the yoke of the write head, which is driven by the magnetic field from the current coils and the magnetostatic interactions between the moving write head and the hard disk medium (Schrefl *et al*., 2005). A common numerical method to treat the interactions between distinct parts is the boundary element method (BEM) (Fetzer, Kurz and Lehner, 1997). Hybrid FEMs/BEMs can be used to effectively simulate the recording process taking into account the relative motion of the head with respect to the hard disk medium (Schrefl, Schabes, Suess and Stehno, 2004).

2 MAGNETOSTATIC FIELD CALCULATION

The FEM is useful technique to break down a complicated object into smaller, easily manageable parts. The basic idea of the FEM is to build a complicated object from, or to divide it into, smaller, simple blocks. Whereas it is impossible to describe a physical process for the complicated object, it can easily be done for the simple building block, the so-called FE. The process of creating a mesh, subdividing an object into triangles, tetrahedrons, or hexahedra, and the reformulation of the partial differential equation is called *finite element discretization*. For magnetic field problems, we can mostly use finite element libraries as black box solvers, however, additional input and software development is required if we want to solve the micromagnetic equations. In this section, we will look at the basic concept of the FEM and review the different formulations for the calculation of the magnetostatic field. We will also discuss various techniques to treat the so-called open boundary problem. In order to solve a partial differential equation uniquely, either the solution or its derivative has to be known at the boundary of the problem domain. This is not possible in computational micromagnetics. If we want to calculate the magnetic field inside a magnet, Maxwell's equations only give a jump condition for the magnetic scalar or magnetic vector potential at the magnet's boundary. Special methods are required to take into account the regularity of the potential, the potential vanishes proportional to r^{-1} as r approaches infinity. The application of the FEM to discretize the magnetic Gibbs' free energy will be discussed in Section 3.1.

The FEM is a numerical technique to solve partial differential equations. However, historically the FEM was developed for solving variational problems. The approximation of a minimization problem with a mesh of triangles goes back the Schellbach in the year 1851 (Schellbach, 1851). He proposed a finite element-like solution to the problem of finding a surface with minimum area that is enclosed by a given curve. Experimentally, this problem can be solved easily by putting a wire frame in soap and looking at the resulting 'soap bubble'. The soap wants to reduce the surface tension and forms an area with minimal surface. Schellbach created a mesh of triangles to interpolate the shape of the surface. In a second step, the nodes (corners of the triangles) were moved to minimize the surface area. An early example of the FEM in civil engineering is the design of the roof for Munich 1972 Olympics arena in the late 1960s (Leonhardt and Schlaich, 1972).

2.1 Finite element discretization

A predecessor of the FEM is the Ritz method (Ritz, 1909). Within the framework of the Ritz method a variational problem is solved as follows:

- start from a functional $f(v)$ which has to be minimized (or maximized). The function $u(\mathbf{r})$ is a minimizer (or maximizer) of $f(v)$ if

$$f(v) \geqslant f(u) \text{ for all } v, (\text{or } f(v) \leqslant f(u) \text{ for all } v) \quad (1)$$

- express $u(\mathbf{r})$ by a set of N unknown parameters u_i. If u is a minimizer (or maximizer) of f, we have to satisfy

$$\frac{\partial}{\partial u_i} f(u) = 0, \ i = 1, \ldots, N \quad (2)$$

- solving equation (2) yields an approximation for the minimizer (or maximizer) u of f.

The Ritz method was used by Brown, in order to calculate the magnetostatic energy for a given magnetization distribution (Brown, 1962). We will discuss Brown's method in Section 2.2.1. Now let us continue with the discussion of the FEM.

Within the framework of the FEMs special functions are used to approximate $u(\mathbf{r})$: The minimizer (or maximizer) u is expanded with a set basis functions, $\varphi_i(\mathbf{r})$,

$$u(\mathbf{r}) = \sum_{i=1}^{N} u_i \varphi_i(\mathbf{r}) \quad (3)$$

The basis functions have only local support and are defined by the help of a mesh of FE. If $\mathbf{r}_i$ denotes the vector from the origin to node i, the FE basis functions have the following properties

$$\varphi_i(\mathbf{r}_j) = \delta_{ij} = \begin{cases} 1 \text{ if } i = j \\ 0 \text{ if } i \neq j \end{cases} \tag{4}$$

Using equations (3) and (4), we see that the value of u at node point i is

$$u(\mathbf{r}_i) = u_i \tag{5}$$

It is possible to treat the problem in terms of these globally defined basis functions. However, for practical reasons it is helpful to treat the problem on the level of a single FE. This makes it easy to solve the problem computationally. The governing equations need to be implemented for one element only. For all the other elements of the finite element mesh, the same functions or subroutines can be called.

2.1.1 The linear tetrahedral finite element

Suppose we subdivide the problem domain V into tetrahedral finite elements and let the total number of tetrahedrons be E. If we refer to a particular finite element with the index e, V_e is the volume (domain) of element e. The vertices of a tetrahedron are numbered locally by the index α that runs from 1 to 4. Figure 1 shows a simple finite element mesh composed of three tetrahedrons. Then we can approximate the solution locally, say on element e by

$$u(\mathbf{r}) = \sum_{\alpha=1}^{4} u_\alpha \varphi_\alpha(\mathbf{r}) \tag{6}$$

The functions $\varphi_\alpha(\mathbf{r})$ are called *shape functions* for the finite element V_e. For the case of simplicity we can restrict ourselves to linear basis functions that are defined as follows

$$\varphi_\alpha(\mathbf{r}_\beta) = \delta_{\alpha\beta}, \quad \sum_{\alpha=1}^{4} \varphi_\alpha(\mathbf{r}) = 1 \tag{7}$$

$$\varphi_\alpha(x, y, z) = a_\alpha + b_\alpha x + c_\alpha y + d_\alpha z, \ \alpha = 1, 2, 3, 4 \tag{8}$$

where $\mathbf{r}$ denotes the vector to the point with the coordinates x, y, and z. Equation (7) uniquely defines the coefficients a_α, b_α, c_α, and d_α (Kikuchi, 1986)

$$a_1 = \frac{1}{6V_e} \begin{vmatrix} x_2 & y_2 & z_2 \\ x_3 & y_3 & z_3 \\ x_4 & y_4 & z_4 \end{vmatrix} \tag{9}$$

$$b_1 = -\frac{1}{6V_e} \begin{vmatrix} 1 & y_2 & z_2 \\ 1 & y_3 & z_3 \\ 1 & y_4 & z_4 \end{vmatrix} \tag{10}$$

$$c_1 = -\frac{1}{6V_e} \begin{vmatrix} x_2 & 1 & z_2 \\ x_3 & 1 & z_3 \\ x_4 & 1 & z_4 \end{vmatrix} \tag{11}$$

$$d_1 = -\frac{1}{6V_e} \begin{vmatrix} x_2 & y_2 & 1 \\ x_3 & y_3 & 1 \\ x_4 & y_4 & 1 \end{vmatrix} \tag{12}$$

where x_α, y_α, and z_α denote the coordinates of node α. The other constants follow form the cyclic permutation of the

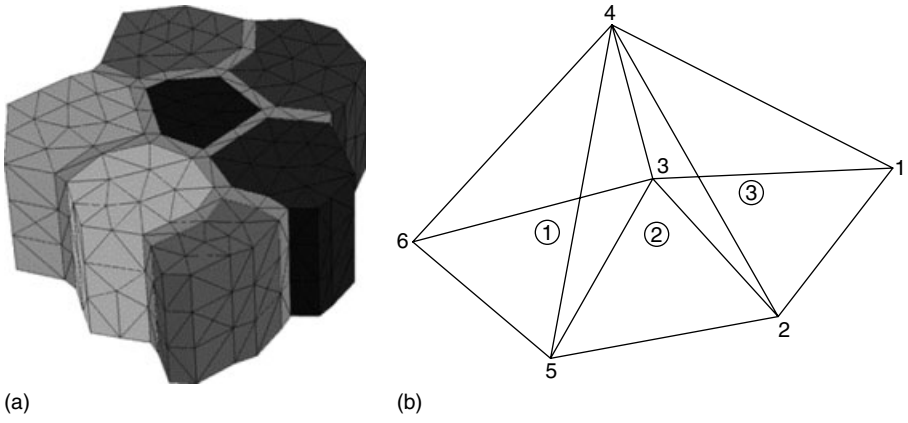

Figure 1. (a) Finite element mesh of the grains in a recording media. Both the grains and the grain boundary phase are subdivided into tetrahedral finite elements. (b) Numbering of nodes and elements in a tetrahedral finite element mesh.

indices 1, 2, 3, and 4. The volume of the element, V_e, can be calculated from

$$6V_e = \begin{vmatrix} 1 & x_1 & y_1 & z_1 \\ 1 & x_2 & y_2 & z_2 \\ 1 & x_3 & y_3 & z_3 \\ 1 & x_4 & y_4 & z_4 \end{vmatrix} \tag{13}$$

Equation (7) has some important consequences. We see that the vector $\mathbf{r}$ can be expressed by the following sum of the shape functions on the finite element

$$\mathbf{r} = \sum_{\alpha=1}^{4} \mathbf{r}_\alpha \varphi_\alpha(\mathbf{r}) \tag{14}$$

or

$$\begin{aligned} x &= \sum_{\alpha=1}^{4} x_\alpha \varphi_\alpha(x, y, z), \quad y = \sum_{\alpha=1}^{4} y_\alpha \varphi_\alpha(x, y, z), \\ z &= \sum_{\alpha=1}^{4} z_\alpha \varphi_\alpha(x, y, z) \end{aligned} \tag{15}$$

Given equation (6), we can easily calculate the gradient of u. This becomes important when we will derive the magnetic field from the magnetic potential. The derivative of u with to x, y, and z can be written as

$$\begin{aligned} \frac{\partial u}{\partial x} &= \sum_{\alpha=1}^{4} u_\alpha \frac{\partial \varphi_\alpha(x, y, z)}{\partial x}, \quad \frac{\partial u}{\partial y} = \sum_{\alpha=1}^{4} u_\alpha \frac{\partial \varphi_\alpha(x, y, z)}{\partial y}, \\ \frac{\partial u}{\partial z} &= \sum_{\alpha=1}^{4} u_\alpha \frac{\partial \varphi_\alpha(x, y, z)}{\partial z} \end{aligned} \tag{16}$$

or

$$\nabla u = \sum_{\alpha=1}^{4} u_\alpha \nabla \varphi_\alpha(\mathbf{r}) \tag{17}$$

Since the basis functions φ_α are linear functions in space within a finite element, the derivative of u are constant within an element. From (8) we can calculate the derivatives of the basis functions

$$\frac{\partial \varphi_\alpha}{\partial x} = b_\alpha, \frac{\partial \varphi_\alpha}{\partial y} = c_\alpha, \frac{\partial \varphi_\alpha}{\partial z} = d_\alpha \tag{18}$$

2.1.2 Approximation of the solution

We can think of f being the energy functional of a problem. The total energy splits into a sum over all elements

$$f(v) = \sum_{e=1}^{E} f^{(e)}(v) \tag{19}$$

where $f^{(e)}$ is the contribution from element V_e to the total energy. Now, the minimizer (or maximizer) of f is expanded with the finite element basis functions. Substituting v in (19) with the right-hand side of equation (3) transforms the variational problem into an algebraic minimization problem. The unknown coefficients u_i correspond to values of the solution at node point $\mathbf{r}_i$ and can be determined by solving

$$\frac{\partial}{\partial u_i} \sum_{e=1}^{E} f^{(e)}(u_1, \ldots, u_N) = 0, \ i = 1, \ldots, N \tag{20}$$

Interchanging the derivation and summation gives

$$\sum_{e=1}^{E} \frac{\partial f^{(e)}(u_1, \ldots, u_N)}{\partial u_i} = 0, \ i = 1, \ldots, N \tag{21}$$

Equation (21) leads to a system of equations that determine the values of u at the node points of the finite element mesh, u_i. The left-hand side of equation (21) is a sum over all the elements of the finite element mesh. Once it is clear how to derive the contributions of one element toward the equations, the contributions from all the other elements can be calculated in a similar way. Computationally this means that the subroutine/function that computes the contribution of an element will be called E times, one time for each element, and the results of the function call are assembled to the global system of equations (see Section 2.2.2). The above-mentioned approach of splitting the total energy of a system into a sum of contributions from each finite element is used in finite element micromagnetic solvers. A well-known example is the finite element solver MAGPAR (Scholz *et al.*, 2003) that computes equilibrium configurations of the magnetization by energy minimization over a set of tetrahedrons.

2.1.3 Notation

In the remainder of this chapter, we use the following conventions for symbols and indices. The indices i and j refer to a node of the finite element mesh. They run from 1 to the total number of nodes, N. The indices l and k refer to the Cartesian coordinates x, y, and z and thus run from 1 to 3. A spatial scalar field $u(\mathbf{r})$ or a vector field $\mathbf{m}(\mathbf{r})$ can be represented on an finite element mesh. u_i is the value of u at the node i with the coordinates $\mathbf{r}_i$, $u_i = u(\mathbf{r}_i)$. The set of all u_i, with $i = 1$ to N, will be the vector $\underline{u}$ over all nodes of the finite element mesh. Similarly, $\mathbf{m}_i$ refers to the vector $\mathbf{m}$ at node i of the finite element mesh. It is the value of the vector field $\mathbf{m}(\mathbf{r})$ at point $\mathbf{r}_i$. The l-th component of the vector $\mathbf{m}$ at node i is given by m_{il}. The vector $\underline{\mathbf{m}}$ has $3N$ components and is the collection of all

m_{il}, $\underline{\mathbf{m}} = (m_{11}, m_{12}, m_{13}, \ldots, m_{il}, \ldots, m_{N3})$. The Greek indices α and β denote the nodes of a given finite element with index e. In tetrahedral finite elements, α and β run from 1 to 4. The finite element basis functions are denoted by φ_i. There are N finite element basis functions, one for each node. The basis function with a Greek subindex, φ_α, is an abbreviation for the basis function at node α of element e, $\varphi_\alpha = \varphi_\alpha^{(e)}$. We use the superscript (e) to denote a quantity given on finite element e. For example, $M_\mathrm{s}^{(e)}$ is the local value of the spontaneous magnetization within finite element e. Matrices are given by uppercase bold-face letters. The transpose of a matrix is denoted by the superscript T. Local matrices, the so-called element matrices, will have the superscript (e). For example, the element stiffness matrix, $\mathbf{K}^{(e)}$, is a 4×4 matrix with the matrix elements $K_{\alpha\beta}^{(e)}, \alpha, \beta = 1, \ldots, 4$.

2.2 The magnetostatic boundary value problem

First, let us consider a ferromagnetic body with spontaneous magnetization, M_s, and a given magnetization distribution

$$\mathbf{M}(\mathbf{r}) = M_\mathrm{s}\mathbf{m}(\mathbf{r}), \text{ with } |\mathbf{m}| = 1 \tag{22}$$

The magnetostatic energy (stray field energy) of the ferromagnetic body with volume V is

$$\Phi_\mathrm{s} = -\frac{\mu_0}{2}\int_V \mathbf{M}\cdot\mathbf{H}_\mathrm{s}\,\mathrm{d}V \tag{23}$$

where μ_0 is the permeability of vacuum. The self-demagnetizing field (stray field), $\mathbf{H}_\mathrm{s}$, may be directly calculated from Maxwell's equations. We split the total magnetic field into a three parts

$$\mathbf{H} = \mathbf{H}_\mathrm{s} + \mathbf{H}_\mathrm{current} + \mathbf{H}_\mathrm{eddy} \tag{24}$$

The stray field, $\mathbf{H}_\mathrm{s}$, is created by the magnetic volume charge density,

$$\rho_\mathrm{m} = -\nabla\cdot\mathbf{M} \tag{25}$$

and the magnetic surface charge density,

$$\sigma_\mathrm{m} = \mathbf{M}\cdot\mathbf{n} \tag{26}$$

where $\mathbf{n}$ denotes the surface normal at the boundary of V. These virtual charges are useful for the calculation of the stray field from a given magnetization distribution. $\mathbf{H}_\mathrm{current}$ is the magnetic field created by a given current distribution. Examples are the current through the driving coil of the write head or the current through the sensing element of a read head. It can be calculated by Bio–Savart's law

$$\mathbf{H}_\mathrm{current}(\mathbf{r}) = \frac{1}{4\pi}\int_V \mathbf{j}\times\frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|^3}\,\mathrm{d}V' \tag{27}$$

where the integral is over the conductor with a current density $\mathbf{j}$. Finally, in conducting magnets we also may want to include a field, $\mathbf{H}_\mathrm{eddy}$, generated by the eddy currents. Equation (24) splits the magnetic field into its nonrotational part, $\mathbf{H}_\mathrm{s}$, and into its solenoidal part, $\mathbf{H}_\mathrm{current} + \mathbf{H}_\mathrm{eddy}$, which can be written as

$$\nabla\times\mathbf{H}_\mathrm{s} = 0 \tag{28}$$

$$\nabla\cdot(\mathbf{H}_\mathrm{current} + \mathbf{H}_\mathrm{eddy}) = 0 \tag{29}$$

The magnetic induction, $\mathbf{B}$, and the magnetic field are related by

$$\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M}) \tag{30}$$

Using (28) we can write the stray field as gradient of a magnetic scalar potential

$$\mathbf{H}_\mathrm{s} = -\nabla U \tag{31}$$

Building the divergence of equation (30) and using $\nabla\cdot\mathbf{B} = 0$, we obtain $\nabla\cdot\mathbf{H} = -\nabla\cdot\mathbf{M}$, which can be rewritten with the help of equations (24), (29), and (31) as

$$\nabla^2 U = -\rho_\mathrm{m} \tag{32}$$

Outside the magnet $\mathbf{M} = 0$ we have

$$\nabla^2 U = 0 \tag{33}$$

At the magnet's boundary the following interface conditions hold

$$U^{(\mathrm{in})} = U^{(\mathrm{out})} \tag{34}$$

$$\left(\nabla U^{(\mathrm{in})} - \nabla U^{(\mathrm{out})}\right)\cdot\mathbf{n} = \sigma_\mathrm{m} \tag{35}$$

Equations (34) and (35) follow from the requirement that at the boundary of the magnet the component of $\mathbf{H}$ parallel to the surface and the component of $\mathbf{B}$ perpendicular to the surface are continuous, respectively. Assuming that the magnetic potential is regular at infinity,

$$U(\mathbf{r}) \to \frac{1}{|\mathbf{r}|} \quad \text{for } |\mathbf{r}| \to \infty \tag{36}$$

the solution of equations (32–35) is

$$U(\mathbf{r}) = \frac{1}{4\pi}\left(\int_V \frac{\rho_\mathrm{m}(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\,\mathrm{d}V' + \oint_{\partial V} \frac{\sigma_\mathrm{m}(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\,\mathrm{d}S'\right) \tag{37}$$

Numerically, the direct calculation of the magnetic scalar potential (37) on a grid of N grid points leads to a computational effort proportional to N^2. This is undesirable, especially when the computation of the magnetic potential is part of an iterative procedure to determine the magnetization distribution $\mathbf{M}(\mathbf{r})$ and many evaluations of the integrals in equation (37) are required. This is the case in numerical micromagnetics. In energy minimization methods, variants of the Newton method or the conjugate gradient method are used. These are iterative techniques and the magnetic potential has to be evaluated at every iteration step, in order to calculate the magnetostatic energy or its gradient. In dynamic micromagnetics, the magnetostatic field has to be evaluated at least once per time step. Therefore, methods are required that scale better than N^2. Traditionally, fast Fourier transform methods are applied in micromagnetics to evaluate the integral (37) (Mansuripur and Giles, 1988). However, Fourier transform techniques require a regular grid. Alternatively, equations (32–36) can be solved with the FEM that reduces the computational effort since special linear solvers for multiple right-hand sides can be used to solve the discretized equations.

In Sections 2.2.1 and 2.2.2, we show how the magnetic scalar potential can be computed using the FEM. As mentioned earlier, the FEM is the most suitable method for solving variational problems. In Section 2.2.1, we derive a variational problem that is equivalent to the equations (32–36). The finite element discretization of the variational problem leads to a system of linear equations for the magnetic scalar potential at the nodes of the finite element mesh. In Section 2.2.2, we discuss how this system of equations can be easily found by first formulating the equation for a single finite element and then assembling the contributions of all elements. The efficient implementation in a computer code using matrix–vector multiplication is discussed in Section 2.2.3.

2.2.1 Magnetic scalar potential formulation

A convenient way to find the finite element equations for the numerical solution of equations (32)–(36) is to derive an equivalent variational problem. For a given magnetization distribution $\mathbf{M}(\mathbf{r})$, the magnetostatic energy can be evaluated by maximizing the functional (Brown, 1962)

$$\Phi_\mathrm{s,H} = -\frac{\mu_0}{2}\int \mathbf{h}^2 \mathrm{d}V - \mu_0 \int_V \mathbf{M}\cdot\mathbf{h}\,\mathrm{d}V \tag{38}$$

with respect to the vector function $\mathbf{h}$, which is required to be regular at infinity and nonrotational everywhere. In equation (38) the first integral is over the entire space and the second integral is over the volume of the ferromagnet. In order to achieve the irrationality, we can derive $\mathbf{h}$ from a potential u, which is a continuous function in space: $\mathbf{h} = -\nabla u$. We now express u in terms of the finite element basis functions as in equation (3). Maximizing $\Phi_\mathrm{s,H}$ with respect to the coefficients u_i will give the finite element approximation to the stray field energy. With increasing numbers of basis functions in the expansion (3) $\Phi_\mathrm{s,H}$ comes closer to the stray field energy. In the limit of large N, $\Phi_\mathrm{s,H}$ will be equal to the stray field energy, Φ_s, and u will be equal to the magnetic scalar potential U.

In order to compute the system of equations (2) for u_i, let us first consider a single finite element. Substituting the finite element ansatz (6) into equation (38) and using equation (17) to express the gradient will give the energy function for the finite element V_e

$$\Phi_\mathrm{s,H}^{(e)} = -\frac{\mu_0}{2}\int_{V_e}\left(\sum_{\alpha=1}^{4} u_\alpha \nabla\varphi_\alpha\right)^2 \mathrm{d}V + \mu_0 \int_{V_e} \mathbf{M}\cdot\left(\sum_{\alpha=1}^{4} u_\alpha\nabla\varphi_\alpha\right)\mathrm{d}V \tag{39}$$

In order to maximize $\Phi_\mathrm{s,H}^{(e)}$with respect to u_α, we have to solve

$$\frac{\partial\Phi_\mathrm{s,H}^{(e)}}{\partial u_\beta} = 0 \quad \text{for } \beta = 1,\ldots,4 \tag{40}$$

Applying the chain rule to the first integral on the right-hand side of equation (39) gives

$$\frac{\partial\Phi_\mathrm{s,H}^{(e)}}{\partial u_\beta} = -\mu_0\int_{V_e}\left(\sum_{\alpha=1}^{4} u_\alpha\nabla\varphi_\alpha\right)\cdot\nabla\varphi_\beta \mathrm{d}V + \mu_0\int_{V_e}\mathbf{M}\cdot\nabla\varphi_\beta\,\mathrm{d}V \tag{41}$$

which gives a linear system of equations for u_α

$$\mathbf{K}^{(e)}\mathbf{u} = \mathbf{g}^{(e)} \tag{42}$$

where $\mathbf{K}^{(\mathrm{e})}$ is a 4×4 matrix, the so-called element stiffness matrix, with the matrix elements

$$K_{\alpha\beta}^{(e)} = \int_{V_e}\nabla\varphi_\alpha\cdot\nabla\varphi_\beta\,\mathrm{d}V \qquad \alpha = 1,\ldots,4 \text{ and } \beta = 1,\ldots,4 \tag{43}$$

and $\mathbf{g}^{(e)}$ is a column vector, the so-called element load vector, with the entries

$$g_\beta^{(e)} = \int_{V_e} \mathbf{M} \cdot \nabla \varphi_\beta \, \mathrm{d}V \;\; \beta = 1, \ldots, 4 \tag{44}$$

In order to compute the element stiffness matrix and the load vector, the integrals in equations (43) and (44) can be evaluated exactly. Since the basis function is linear on the finite element, the integrand in equation (43) is constant and we obtain for the matrix elements of the element stiffness matrix

$$K_{\alpha\beta}^{(e)} = \left(\nabla \varphi_\alpha \cdot \nabla \varphi_\beta\right) V_e$$
$$\alpha = 1, \ldots, 4 \text{ and } \beta = 1, \ldots, 4 \tag{45}$$

For evaluating the element load vector in a micromagnetic simulation, we also interpolate the magnetization vector linearly in each tetrahedron. For element V_e we obtain

$$\mathbf{M}(\mathbf{r}) = M_\mathrm{s}^{(e)} \sum_{\alpha=1}^{4} \mathbf{m}_\alpha \varphi_\alpha(\mathbf{r}) \tag{46}$$

In composite magnetic material the spontaneous magnetization, M_s, may vary in space. There we allow M_s to change from element to element and denote the local spontaneous magnetization with $M_\mathrm{s}^{(e)}$. The integrand in equation (44) varies linearly in space and thus can be evaluated exactly with the midpoint rule

$$g_\beta^{(e)} = M_\mathrm{s}^{(e)} V_e \left(\frac{1}{4}\sum_{\alpha=1}^{4} \mathbf{m}_\alpha\right) \cdot \nabla \varphi_\beta \;\; \beta = 1, \ldots, 4 \tag{47}$$

2.2.2 *Assembling*

Once we have computed the stiffness matrix and the load vector for all finite elements, we can assemble them to the global system of equations for values of the magnetic potential at the nodes of the finite element mesh, u_i. Neighboring finite elements share common nodes. In order to form the global system of equations, we have to add the local contributions associated with these common nodes. For example, in Figure 1, element 2 and element 3 share the nodes with the node numbers 2, 3, and 4. We add entries of the element stiffness matrix to the global system matrix and we add entries of the element load vector to the right-hand side of the equation.

If we give numbers to each node of the tetrahedral mesh, each finite element V_e is uniquely defined by the numbers of its four vertices. Element 2 consists of the four vertices 2, 3, 4, and 5. If we know the coordinates of the four vertices of an element the geometry of the element is defined and we can compute the shape functions, the derivatives of the shape functions, and the element stiffness matrices. These quantities depend on the geometry only and need to be computed only once at the beginning of the simulations.

The element connectivity of an element is the sequence consisting of its four node numbers. The element connectivity defines a mapping $(e, \alpha) \to i$ from the local node α of element e to the global node i. The assembly process can be defined with the help of the connectivity matrix

$$C_{i\alpha}^{(e)} = \begin{cases} 1 \text{ if the global node } i \text{ corresponds to the} \\ \quad \text{local node } \alpha \text{ on element } e \\ 0 \text{ otherwise} \end{cases} \tag{48}$$

The entries of the right-hand side vector of the global system of equations can be formally written as

$$g_i = \sum_{e=1}^{E} \sum_{\alpha=1}^{4} C_{i\alpha}^{(e)} g_\alpha^{(e)} \tag{49}$$

The matrix elements of the stiffness matrix can be formally written as

$$K_{ij} = \sum_{e=1}^{E} \sum_{\alpha,\beta=1}^{4} C_{i\alpha}^{(e)} K_{\alpha\beta}^{(e)} C_{j\beta}^{(e)} \tag{50}$$

The stiffness matrix is a sparse matrix. Its sparsity pattern reflects the structure of the finite element mesh. K_{ij} is nonzero only if node i and node j are connected with an edge.

In the following equation, we denote vectors that gather nodal values by underlining the symbol. Then, the system of equations to calculate the magnetic potential at the nodes of the finite element mesh is

$$\mathbf{K}\underline{u} = \underline{g} \tag{51}$$

where $\underline{u}$ is a vector containing all the nodal values u_i of the magnetic scalar potential. The energy function given by equation (38) forms the basis for the derivation of the linear system of equations for the potential values. The first integral on the right-hand side of equation (38) is in integral over the entire space. Therefore, we have to mesh the ferromagnet and a large region in the exterior of the ferromagnet. In principle, the finite element mesh has to be extended over a wide region outside the ferromagnet, which will increase the total number of equations and complicates the finite element mesh generation. In Section 2.2.4, we will discuss methods to overcome this problem.

2.2.3 Divergence and gradient operators

The linear system of equations (51) is the discrete form of Poisson equation for the magnetic scalar potential. The matrix–vector product of the left-hand side represents the Laplace operator on the irregular finite element grid, whereas the right-hand side represents the divergence of the magnetization. For ease of computation, it will be convenient to compute the right-hand side of equation (51) by a simple matrix–vector multiplication. Similarly, once we have solved the system of linear equation, it will be helpful to calculate the magnetic field on all nodes of the finite element mesh by the multiplication of a matrix with the vector $\underline{u}$. From equations (25) and (32) we see that the right-hand side of (51) corresponds to the divergence of the magnetization. In order to compute the magnetic field, we need the gradient of the magnetic potential. Therefore, let us have a look how we can represent the divergence of a vector field and the gradient of a scalar field on a finite element mesh by matrix–vector multiplications.

Before we derive a matrix–vector representation for the divergence of the magnetization vector on the finite element grid, $\nabla \cdot \mathbf{M}(\mathbf{r})$, we have to define the representation of the vector field $\mathbf{M}(\mathbf{r})$ on the finite element mesh. In micromagnetics we assume that the magnitude of $\mathbf{M}(\mathbf{r})$ is a function of temperature, T, only and does not change with the magnetic field

$$|\mathbf{M}(\mathbf{r})| = M_\mathrm{s}(T, \mathbf{r}) \tag{52}$$

However, the spontaneous magnetization M_s may change with space. For example, this is the case in composite magnets (Kneller, 1991; Schrefl, Fidler and Kronmüller, 1994a,b; Fischer and Kronmuller, 1996; Fischer, Leineweber and Kronmuller, 1998; Suess *et al*., 2005; Victora and Shen, 2005) where magnetically hard and soft phases are combined. After the generation of the finite element mesh we assign $M_\mathrm{s}(T, \mathbf{r})$ to the different finite elements according to the distribution of the different phases. Therefore, it is sufficient to store the unit vector $\mathbf{m}(\mathbf{r})$. Similar to $\underline{u}$, we define a vector $\underline{\mathbf{m}}$ of length $3N$ that contains the unit magnetization vectors $\mathbf{m}_i$ at the nodal points of the mesh. If the index l denotes the Cartesian component of $\mathbf{m}_i$, $\underline{\mathbf{m}}$ can be explicitly written as

$$\underline{\mathbf{m}} = (m_{11}, m_{12}, m_{13}, \ldots, m_{il}, \ldots, m_{N3})^\mathrm{T} \tag{53}$$

Here and in the remainder of the chapter, we denote the transpose of a matrix with the superscript T. Using this definition we can rewrite the equation for the element load vector (47)

$$g_\beta^{(e)} = \sum_{\alpha=1}^{4} \sum_{l=1}^{3} D_{\beta\alpha l}^{(e)} m_{\alpha l} \;\; \beta = 1, \ldots, 4 \tag{54}$$

The matrix elements of the matrix are

$$D_{\beta\alpha l}^{(e)} = \frac{M_\mathrm{s}^{(e)} V_e}{4} \frac{\partial \varphi_\beta}{\partial x_l} \text{ for } \alpha = 1, \ldots, 4 \text{ and } \beta = 1, \ldots, 4 \tag{55}$$

Similar to the stiffness matrix we can assemble the element contributions and obtain

$$\underline{g} = \mathbf{D}\underline{\mathbf{m}} \tag{56}$$

The above product of the $N \times 3N$ matrix $\mathbf{D}$ with the unit magnetization vector over the mesh represents the divergence of the magnetization distribution, $\nabla \cdot \mathbf{M}(\mathbf{r})$. Here, N is the number of nodes within the ferromagnet.

Similarly, we can derive a product of a $3N \times N$ matrix with the magnetic scalar potential over the mesh that will give the magnetic field on each node of the finite element mesh. The solution of (51) gives the magnetic potential at the nodes of the finite element mesh. Using equation (17) we can calculate the gradient of the potential in every finite element and calculate the magnetic field in every element. Since we used a linear interpolation for the magnetic scalar potential within a tetrahedron, the magnetic field will be constant within a particular finite element and discontinuous at element boundaries. A common practice is to smooth the field to the nodes of the finite element mesh (Zienkiewicz, Lyness and Owen, 1977). In order to extrapolate the magnetic field to the nodes of the mesh, we look at the stray field energy of the system. First we define a magnetic moment at each node of the finite element mesh that is evaluated by spatial averaging

$$\boldsymbol{\mu}_i = \left(\frac{1}{4} \sum_{e=1}^{E} \sum_{\alpha=1}^{4} C_{i\alpha}^{(e)} M_\mathrm{s}^{(e)} V_e \right) \mathbf{m}_i \tag{57}$$

The vector $\mathbf{m}_i$ is the unit vector parallel to the magnetization at node point i and the combined terms in brackets have the dimensions of a magnetic moment. The product $M_\mathrm{s}^{(e)} V_e$ is the magnitude of the magnetic moment of element e. We assign one quarter of a tetrahedron's magnetic moment to node i, if one vertex of the tetrahedron has the global number i. With this definition of the magnetic moment on each node of the finite element mesh, the magnetostatic energy (23) can be rewritten as

$$\Phi_\mathrm{s} = -\frac{\mu_0}{2} \underline{\boldsymbol{\mu}}^\mathrm{T} \mathbf{I} \underline{\mathbf{H}}_\mathrm{s} \tag{58}$$

where $\mathbf{I}$ is the identity matrix, $\underline{\boldsymbol{\mu}}$ and $\underline{\mathbf{H}}_\mathrm{s}$are vectors over the finite element mesh that contain the magnetic moments and

the stray field at the node points, respectively. Alternatively, we can write

$$\Phi_s = -\frac{\mu_0}{2}\underline{\mathbf{m}}^T \mathbf{L}\underline{\mathbf{H}}_s \tag{59}$$

with the $N \times N$ matrix $\mathbf{L}$ defined as

$$L_{ij} = \delta_{ij}\left|\boldsymbol{\mu}_i\right| \tag{60}$$

The matrix $\mathbf{L}$ is a diagonal matrix with the moduli of the magnetic moment at the nodes of the finite element mesh as matrix entries.

In order to derive a matrix–vector equation for $\underline{\mathbf{H}}_s$, we compare equation (59) with the usual formulation of the magnetostatic energy which is given by the sum of the magnetostatic energy contributions from each finite element

$$\begin{aligned}\Phi_s &= \sum_{e=1}^{E}\Phi_s^{(e)}, \text{ with } \Phi_s^{(e)} = -\frac{\mu_0}{2}\int_{V_e}(\mathbf{M}\cdot\mathbf{H}_s)\,\mathrm{d}V \\ &= \frac{\mu_0}{2}\int_{V_e}(\mathbf{M}\cdot\nabla u)\,\mathrm{d}V\end{aligned} \tag{61}$$

Within each element we use the magnetic potential to evaluate the stray field, $\mathbf{H}_s$.

Using the finite element expansion for $\mathbf{M}$ and u, we obtain

$$\begin{aligned}\Phi_s^{(e)} &= \frac{\mu_0}{2}\int_{V_e} M_s^{(e)}\left(\sum_{\alpha=1}^{4}\mathbf{m}_\alpha\varphi_a\right)\cdot\left(\sum_{\beta=1}^{4}u_\beta\nabla\varphi_\beta\right)\mathrm{d}V \\ &= \frac{\mu_0}{2}\sum_{l=1}^{3}\sum_{\alpha,\beta=1}^{4} m_{\alpha l}G_{\alpha l\beta}^{(e)}u_\beta\end{aligned} \tag{62}$$

Using the midpoint rule for the integration of over the element V_e we obtain

$$G_{\alpha l\beta}^{(e)} = \frac{M_s^{(e)}V_e}{4}\frac{\partial\varphi_\beta}{\partial x_l} \text{ for } \alpha = 1,\ldots,4 \text{ and } \beta = 1,\ldots,4 \tag{63}$$

for the matrix elements. After summation over all finite elements, equation (62) will have the same structure as equation (59). By comparison we get $\mathbf{L}\underline{\mathbf{H}}_s = -\mathbf{G}\underline{u}$ or

$$\underline{\mathbf{H}}_s = -\mathbf{L}^{-1}\mathbf{G}\underline{u} \tag{64}$$

The $3N \times N$ matrix **G,** which is computed by assembling the element contributions in equation (63), relates the potential values with the stray field values at the nodes of the finite element mesh.

The matrix to compute the right-hand side of the linear system of equations (divergence operator), the system matrix itself (stiffness matrix), and the matrix to compute the stray field from the potential (gradient operator) are all sparse. Using sparse matrix storage techniques and sparse matrix algebra (Saad, 2003), the stray field can be computed efficiently. The matrices depend only on the geometry of the finite element mesh and thus have to be computed only once at the beginning of the simulation. The linear system of equations can be solved by sparse Gaussian elimination with partial pivoting. The matrix factorization needs to be done only once. Special reordering schemes (Amestoy, Davis and Duff, 2004) reduce the number of nonzeros in the factorization and thus lead to fast direct linear equation solvers (Davis, 2005; Schenk and Gärtner, 2004). For successive field computations on an irregular grid, the stray field can be computed faster and with less computational effort by the use of the FEM than by direct evaluation of equation (37).

2.2.4 *The open boundary problem*

In order to impose the regularity of the magnetic potential, equation (36), the finite element mesh has to be extended over a large region outside the magnetic particles. As a rule of thumb the distance between the boundary of the external mesh and the particle should be at least five times the extension of the particle (Chen and Konrad, 1997). Various other techniques have been proposed to reduce the size of the external mesh or to avoid a discretization of the exterior space. Here we review those methods for open boundary problems that have been successfully used in finite element micromagnetics and discuss the implementation of a hybrid FEM/BEM (Fredkin and Koehler, 1990) to calculate the magnetostatic interactions between distinct magnetic bodies.

The use of asymptotic boundary conditions (Yang and Fredkin, 1998) reduces the size of the external mesh compared to truncation. At the external boundary Robbin conditions are applied, which are derived from a series expansion of the solution of the Laplace equation for U outside the magnet and give the decay rate of the potential at a certain distance from the sample (Khebir, Kouki and Mittra, 1990). A similar technique that considerably reduces the size of the external mesh is the use of space transformations to evaluate the integral over the exterior space in equation (38). Among the various transformations proposed to treat the open boundary problem, the parallelepipedic shell transformation (Brunotte, Meunier and Imhoff, 1992), which maps the external space into shells enclosing the parallelepipedic interior domain, has proved to be the most suitable in micromagnetic calculations. The method can be easily incorporated into standard finite element programs transforming the derivatives of the nodal basis functions. This method was applied in static three-dimensional micromagnetic simulations of the magnetic properties of

nanocrystalline permanent magnets (Schrefl, Fischer, Fidler and Kronmuller, 1994c; Fischer and Kronmuller, 1996).

An alternative approach for treating the so-called open boundary problem is a hybrid FEM/BEM (Koehler, 1997; Fredkin and Koehler, 1990). The basic concept of this method is to split the magnetic scalar potential into two parts $U = U_1 + U_2$, where the potential U_1 is assumed to solve a closed boundary value problem. Then the equations for U_2 can be derived from equations (32–35), which hold for the total potential $U = U_1 + U_2$. The potential U_1 accounts for the divergence of the magnetization and U_2 is required to meet the boundary conditions at the surface of the particle. The latter also carries the magnetostatic interactions between distinct magnetic particles. The potential U_1 is defined to solve Poisson's equation inside the ferromagnetic regions and is set to zero in the exterior space

$$\nabla^2 U_1(\mathbf{r}) = \nabla \cdot \mathbf{M}(\mathbf{r}) \qquad \text{for } \mathbf{r} \in V \tag{65}$$

$$U_1 = 0 \qquad \text{for } \mathbf{r} \notin V \tag{66}$$

with V being the volume of the ferromagnetic regions. At the surface of the magnets, natural boundary conditions hold for U_1

$$\nabla U_1 \cdot \mathbf{n} = \mathbf{M} \cdot \mathbf{n} \qquad \text{for } \mathbf{r} \in \partial V \tag{67}$$

Since the total potential $U = U_1 + U_2$ must fulfill equations (32–36) and, U_2 must satisfy the Laplace equation

$$\nabla^2 U_2(\mathbf{r}) = 0 \tag{68}$$

everywhere in space and fulfill the boundary conditions

$$\left(\nabla U_2^{(\text{in})} - \nabla U_2^{(\text{out})}\right) \cdot \mathbf{n} = 0 \tag{69}$$

and

$$U_2^{(\text{in})} - U_2^{(\text{out})} = U_1^{(\text{in})} \tag{70}$$

A standard FEM may be used to solve equations (65) and (67). Fortunately, equations (68–70) describe the magnetic scalar potential of a dipole layer with moment U_1 at the surface ∂V. The scalar potential of such a dipole layer is known and is given by the double layer integral

$$U_2(\mathbf{r}) = \frac{1}{4\pi} \oint_{\partial V} U_1(\mathbf{r}') \nabla' \frac{1}{|\mathbf{r} - \mathbf{r}'|} \cdot \mathbf{n}' \mathrm{d}S' \tag{71}$$

over the dipole density times the derivative of the Green's function (Jackson, 1999). In principle, U_2 can be evaluated everywhere within the magnetic bodies using (71). However, instead of the direct computation of U_2 discretizing (71), we evaluate U_2 at the boundary and then we solve (68) within V using the known boundary values of U_2 as Dirichlet conditions. To compute U_2 on ∂V, we have to take the limit $\mathbf{r} \to \partial V$ of the surface integral from inside V

$$U_2(\mathbf{r}) = \frac{1}{4\pi} \oint_{\partial V} U_1(\mathbf{r}') \nabla' \frac{1}{|\mathbf{r} - \mathbf{r}'|} \cdot \mathbf{n}' \, \mathrm{d}S' + \left(\frac{\Omega(\mathbf{r})}{4\pi} - 1\right) U_1(\mathbf{r}) \tag{72}$$

where $\Omega(\mathbf{r})$ is the solid angle subtended by ∂V at point $\mathbf{r}$. We discretize (72) using piecewise linear functions to interpolate U_1 on a triangular surface mesh. The values of U_2 on the surfaces of the magnets follow from a matrix–vector product

$$\underline{U}_2 = \mathbf{B} \underline{U}_1 \tag{73}$$

The boundary element matrix, $\mathbf{B}$, depends only on the geometry of the problem and has to be computed only once for a given finite element mesh. $\mathbf{B}$ is a fully populated $M \times M$ matrix that relates the M boundary nodes with each other. In order to evaluate the matrix elements of $\mathbf{B}$, let us construct a surface mesh with F triangles and M nodes. The dipole density U_1 is expanded with linear basis function. Within the triangle S_e the expansion is

$$u_1(\mathbf{r}) = \sum_{\alpha=1}^{3} u_{1\alpha} \varphi_\alpha(\mathbf{r}) \tag{74}$$

with φ_α being linear basis functions on a triangle (Kikuchi, 1986), which can be defined similar to the tetrahedral basis functions in equation (7). First, let us evaluate the integral on the right-hand side of (72) for each node point $\mathbf{r}_i$ of the surface mesh. The integral splits into a sum of integrals over triangles

$$I(\mathbf{r}_i) = \sum_{e=1}^{F} I^{(e)}(\mathbf{r}_i) \tag{75}$$

The contribution of triangle S_e to the integral is

$$I^{(e)}(\mathbf{r}_i) = \frac{1}{4\pi} \oint_{S_e} \left(\sum_{\alpha=1}^{3} u_{1\alpha} \varphi_\alpha(\mathbf{r}')\right) \nabla' \times \frac{1}{|\mathbf{r}_i - \mathbf{r}'|} \cdot \mathbf{n}' \mathrm{d}S' \tag{76}$$

Interchanging the summation and integration, we obtain

$$I^{(e)}(\mathbf{r}_i) = \sum_{\alpha=1}^{3} B_{i\alpha}^{(e)} u_{1\alpha} \tag{77}$$

$B_{i\alpha}^{(e)}$ is the contribution of the local node α of triangle S_e to the matrix element B_{ij} of the boundary matrix.

$$B_{i\alpha}^{(e)} = \frac{1}{4\pi} \oint_{S_e} \varphi_\alpha(\mathbf{r}') \nabla' \frac{1}{|\mathbf{r}_i - \mathbf{r}'|} \cdot \mathbf{n}' \mathrm{d}S' \tag{78}$$

Using the element connectivities of the triangular mesh, we can define a mapping from the triangle number and the local node number $(e, \alpha) \rightarrow j$ to the global numbers of the finite element mesh. Similar to the assembly process for the element stiffness matrix (see Section 2.2.2) we can assemble the boundary matrix

$$B_{ij} = \sum_{e=1}^{F} \sum_{\alpha=1}^{3} C_{j\alpha}^{(e)} B_{i\alpha}^{(e)} + \left(\frac{\Omega(\mathbf{r}_i)}{4\pi} - 1 \right) \delta_{ij} \tag{79}$$

Here $C_{j\alpha}^{(e)}$ is the connectivity matrix as defined in equation (48) and $\Omega(\mathbf{r}_i)$ is the solid angle subtended by the surface of the mesh at the node $\mathbf{r}_i$. Lindholm (1984) gives analytic formulae for the evaluation of the integrals in (78).

Since the hybrid FEM/BEM does not introduce any approximations, the method is accurate and effective. The use of the BEM easily treats the magnetostatic interactions between distinct magnetic particles and requires no mesh outside the magnetic particles. Süß and coworkers (1999) applied the hybrid FEM/BEM, in order to simulate the effect of magnetostatic interactions on the reversal dynamics of magnetic nanoelements. This was also successfully used for the computation of the magnetostatic interactions between the write head, the SUL, and the data layer in perpendicular magnetic recording (Schrefl *et al*., 2005).

In summary, we have to perform the following procedure to compute the demagnetizing field. Prior to the time integration of the LLG equation we assemble the system matrices **K**, **D**, and **G**, and compute the Cholesky factorization of the finite element stiffness matrix **K**. This setup phase also involves the computation of the boundary matrix **B**. This matrix is fully populated. Therefore, we apply one of the matrix compression techniques introduced in Section 2.3 to sparsify the matrix. Generally, we are interested on the dynamic response of a system over a time span which is about two orders of magnitude larger than intrinsic precession time. Thus, the CPU time of the setup phase is only a small fraction of the total CPU time. At each iteration step during the time integration, we have to perform the following steps to update the magnetostatic field:

1. Compute the right-hand side of equation (65) (divergence of the magnetization) by matrix–vector multiplication (equation (56)).
2. Solve the linear system for U_1 using the Cholesky factors of the system matrix.
3. Compute the matrix–vector product to obtain U_2 at the boundary of the magnetic bodies (equation (73)).
4. Solve the linear system for U_2 in the interior of the magnets using the Cholesky factors of the system matrix.
5. Sum U_1 and U_2 and build the gradient of the magnetic potential by the matrix–vector multiplication (equation (64)).

All operations in the above-mentioned algorithm are of linear complexity. Thus, the hybrid FEM/BEM provides a means to compute the magnetostatic field of irregularly shaped, spatially distinct magnets efficiently. In Section 4.1, we will discuss how this method can be extended for problems involving the relative motion of ferromagnets while keeping almost optimal scaling of the algorithm.

Long and coworkers (2006) compared the accuracy of the hybrid FE/BE algorithm with the direct computation of the magnetic potential from its surface charges and volume charges (equation (37)). The comparison was done for a granular magnetic recording media, whereby each grain was subdivided into about 148 tetrahedral finite elements. With this mesh density the error of the finite element solution was less than 0.3% when compared with the direct evaluation of the magnetic scalar potential.

One drawback of the above-mentioned scheme is that the linear system of equations that gives U_1 is indefinite. Thus special linear solvers suitable for indefinite systems (Davis, 2005) have to be applied to solve for U_1. An alternative hybrid FEM/BEM was proposed by Garcia-Cervera and Roma (2006). In their method, the potential U_1 is defined by a closed Dirichlet problem. U_1 solves the Poisson equation within the magnet with the boundary condition $U_1 = 0$ at the magnet's surface. Again the Laplace equation holds for the potential U_2 in the entire space. U_2 will be continuous at the magnet's surface, but its normal derivative will show a jump. Then U_2 is given by the single layer integral over the surface of the magnet. The integral is over the product of a virtual charge density times the free space Green's function. The virtual charge density is the normal derivative of U_1 minus the magnetic surface charge. This method has been applied in combination with an adaptive grid refinement technique for the simulation of the magnetic domain configuration in NiFe nanoelements (Garcia-Cervera and Roma, 2006).

2.2.5 *Magnetic vector potential formulation*

In the previous sections, we discussed the calculation of the stray field by using a magnetic scalar potential. We started from a variational problem stated by Brown (1962) that gives the scalar potential by maximizing a function that approximates the magnetostatic energy. This formulation and its finite element implementation are most useful in dynamic micromagnetic simulations where the magnetostatic field has

to be evaluated at each time step. In static micromagnetics, we want to find the magnetization distribution that minimizes the total Gibbs' free energy of a magnetic system. For energy minimization, we do not necessarily need to know the stray field but we need the total energy and its gradient at each iteration step. For this purpose, it is useful to reformulate the magnetostatic boundary value problem as a minimization problem.

The magnetostatic boundary value problem can be reformulated as a minimization problem using a magnetic vector potential. For a given magnetization distribution $\mathbf{M}(\mathbf{r})$, the magnetostatic energy can be evaluated by minimizing the functional (Brown, 1962)

$$\Phi_{\mathrm{s,B}} = \frac{1}{2\mu_0}\int \mathbf{b}^2 \mathrm{d}V - \int_V \mathbf{M}\cdot\mathbf{b}\,\mathrm{d}V + \frac{\mu_0}{2}\int_V \mathbf{M}^2\,\mathrm{d}V \quad (80)$$

with respect to a vector field $\mathbf{b}$, that is required to be regular at infinity and solenoidal. If minimized with respect to $\mathbf{b}$, the functional $\Phi_{\mathrm{s,B}}$ becomes equal to the magnetostatic energy, Φ_{s}, and $\mathbf{b}$ becomes equal to the magnetic induction $\mathbf{B}$. In order to impose the constraint that $\mathbf{b}$ is solenoidal, we express $\mathbf{b}$ in terms of a magnetic vector potential $\mathbf{b} = \nabla \times \mathbf{A}'$. The unknown vector function $\mathbf{A}'$ can now be expanded with the finite element basis functions defined in (7)

$$\mathbf{A}'(\mathbf{r}) = \sum_{i=1}^{N} \mathbf{A}'_i \varphi_i(\mathbf{r}) \quad (81)$$

Now the magnetic vector potential is computed by an algebraic minimization problem. If minimized with respect to the $3N$ coefficients, A_{xi}, A_{yi}, and A_{zi}, $\Phi_{\mathrm{s,B}}$ reduces to the stray field energy and $\mathbf{A}'$ becomes equal to the magnetic vector potential $\mathbf{A}$, $\mathbf{B} = \nabla \times \mathbf{A}$. Numerical techniques similar to those discussed in the previous sections can be applied for the finite element computation of the magnetic vector potential. Brown's method in combination with the linear nodal tetrahedral elements for the Cartesian components of the magnetic vector potential leads to the same algebraic system of equations as the standard finite element discretization (Demerdash, Nehl and Fouad, 1980) of the corresponding partial differential

$$\nabla \times \nabla \times \mathbf{A} = \nabla \times \mathbf{M} \quad (82)$$

The vector potential formulation for the solution of the magnetostatic boundary value problem is especially useful in static micromagnetic simulations (Asselin and Thiele, 1986). Then the functional $\Phi_{\mathrm{s,B}}$ is used to represent the magnetostatic energy. We simply add $\Phi_{\mathrm{s,B}}$ to the other micromagnetic energy terms. Now we can expand both the magnetic vector potential and the magnetization with the FE bases functions that will give an algebraic minimization problem for the equilibrium configuration of the magnetization and the magnetic vector potential that corresponds to the stray field of the equilibrium state. The total energy will be minimized with respect to both magnetization and magnetic vector potential, in order to compute the equilibrium magnetic states. This method has been applied for the calculation of remanence and coercivity in nanocomposite permanent magnets (Schrefl, Fidler and Kronmüller, 1994b).

2.3 Matrix compression techniques

The application of the FEM/BEM as explained in Section 2.2.4 has many advantages. Only the magnetic bodies of the considered domains need to be discretized, open boundary problems pose no additional difficulties, and problems including motion can be treated in a nice way (Kurz, Fetzer, Lehner and Rucker, 1999; Schrefl, Schabes, Suess and Stehno, 2004). However, the application of the FEM/BEM leads to dense matrices. The storage requirements and computational costs for matrix–vector multiplication are of $O(M^2)$, where M is the number of unknowns, respectively the number of boundary nodes. Clearly we will run into problems if we increase the size of the model, because of limitations regarding computational power. One has optimal efficiency if the computational amount of work is $O(M)$. For many situations characterized by a sparse system matrix, one knows optimal solution algorithms. Examples are multigrid or algebraic multigrid methods (Kaltenbacher *et al.*, 2001; Sun and Monk, 2006). In this chapter, we discuss method to obtain nearly optimal efficiency for the computation of the boundary element matrix and the evaluation of the matrix–vector product (73).

Different methods were used to sparsify matrices from boundary element discretization and to achieve an efficiency close to the optimum in BEMs. Among the various methods are multipole expansion schemes, panel clustering methods, wavelet transforms, and methods based on the singular value decomposition of blocks of the interaction matrix. Originally, fast BEMs were introduced for the fast evaluation of capacities and electrostatic forces in interconnects. An overview on the history of the different acceleration schemes is given in Ramaswamy, Ye, Wang, and White (1999). In micromagnetics fast integration methods are traditionally used for modeling granular recording media (Miles and Middleton, 1991) or the fast evaluation of dipole fields (Koehler, 2005). Most of these methods (Blue and Scheinfein, 1991; Brown, Schulthess, Apalkov and Visscher, 2004) aim at the direct calculation of the magnetic field or magnetic potential from its volume and surface charges (see equation (37)). Here, we focus on fast methods to evaluate boundary integrals for

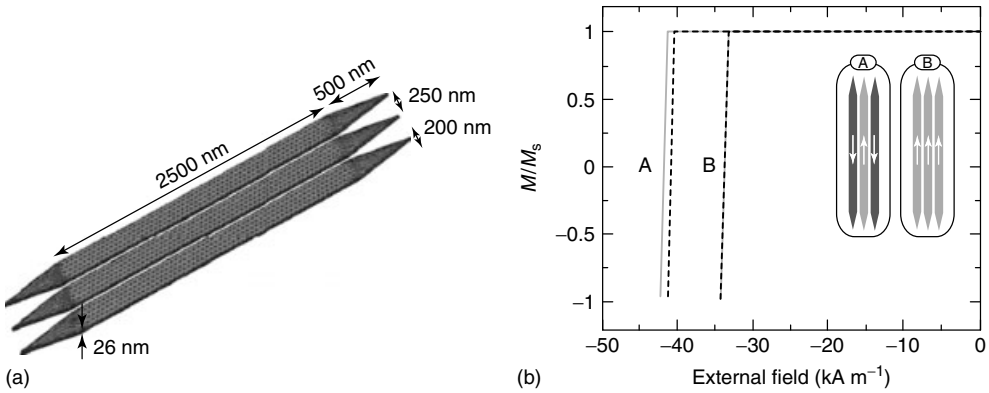

Figure 2. (a) Finite element surface mesh of three interaction NiFe nanoelements. (b) Computed demagnetization curves for the center element for different magnetization configurations of its neighbors. The solid curves use the exact boundary element matrix, the dashed curves use a wavelet compression of the boundary element matrix. In A, the magnetostatic interaction field stabilizes the center element, in B, the magnetostatic interaction field decreases the switching field.

use in hybrid FEM/BEM. All of these methods use the concept of grouping neighboring surface triangles into clusters as proposed originally by Hackbusch and Nowak (1989).

2.3.1 *Wavelet transform*

In numerical methods for partial differential equations, wavelet bases may be used to expand the unknown function such as the magnetization or the magnetic potential. An example for this approach in micromagnetics is the work of Hines, Ridley, and Roberts (2003) and Ridley, Spargo, Hines, and Roberts (2003). Here, we follow a different approach as applied in the computation of capacitance of high speed interconnects (Zheng, Li and Qian, 1999). Rather than expanding the potential with a wavelet basis we first compute the full interaction matrix. Treating the matrix like a two-dimensional discrete image, it is possible to sparsify the matrix applying a wavelet transform (Press, Teukolsky, Vetterling and Flannery, 1997). The matrix–vector product (73) can be evaluated in the wavelet basis. A sparse matrix is obtained after setting small elements of the transformed matrix to zero. Only about 15% nonzero entries remain, which significantly reduces the storage requirements and computation time for the evaluation of the surface integral.

This method was applied to calculate the magnetization reversal mechanisms in magnetic nanoelements (Schrefl, Scholz, Suss and Fidler, 2001). *In situ* observations of magnetization reversal using transmission electron microscopy predict a spread in the switching field due to magnetostatic interactions (Kirk, Chapman and Wilkinson, 1997). Figure 2 shows the surface mesh for three NiFe elements that are 200 nm wide, 3500 nm long and 26 nm thick. The center-to-center spacing is 250 nm. The original boundary element matrix of the system consists of 1.1×10^7 elements. After transformation and thresholding the matrix contains 1.9×10^6 nonzero entries, giving a sparsity of 83%. The demagnetization curve of the center element was calculated for a pair of switched or unswitched neighbors. The magnetization of the neighboring elements was fixed assuming a small uniaxial anisotropy parallel to the long axis. Figure 2 compares the numerically calculated demagnetization curves obtained with the conventional BEM and with wavelet-based matrix compression. In configuration A, the magnetostatic interaction field of the switched neighbors stabilizes the center element. In configuration B, the interaction field of the neighbors favors the reversal of the center element. This comparison shows that the wavelet-based matrix compression method provides accurate results. The spread in the switching field of 8 kA m^{-1} agree well with experimental data obtained on the very same magnetic nanostructures (Kirk, Chapman and Wilkinson, 1997).

2.3.2 *The Barnes and Hut tree code*

Tree codes are algorithms to calculate forces between a large number of particles. They arrange the particles in a hierarchy of clusters, and compute the interaction at a given point by summing over multipole expansions of these groups. In this way the computational requirements can be reduced to a $O(M \log M)$-scaling. A famous implementation of this method is the so-called Barnes and Hut (1986) tree code for the gravitational interaction between stars and galaxies. The domain, which surrounds all particles, is hierarchically partitioned into a sequence of cubes, where each cube contains eight siblings, each with half the side length of the parent cube. These cubes form the nodes of an oct-tree structure. The tree is constructed such that each cube contains either exactly one particle, or is parent to further cubes, in which case the parent cube carries the total mass of all the particles that lie inside this cube. The computation of the

forces at a point **r** proceeds by walking through the tree, and summing up appropriate contributions to the force from the tree elements. The gravitational force of a cell is added if the distance between **r** and the center of mass of the cell is larger than a certain threshold. If a cell fulfills this criterion, the tree walk along this branch can be terminated. Otherwise it is 'opened', and the walk is continued with all its siblings. We can use the same idea to speed up the computation of the surface integral in the hybrid FEM/BEM. The first term of the right-hand side of equation (72) is the potential of a dipole sheet with the dipole density $\mathbf{p} = U_1\mathbf{n}$ (Jackson, 1999). Instead of mass and gravitational potential, we have dipole strength and magnetic potential. After triangulation of the surface into a set of triangles, the surface integral over the surface ∂V can be approximated by a sum over dipoles. There is one dipole per triangle and the dipole strength is U_1 times the triangle area. Using the Barnes and Hut algorithm (Barnes and Hut, 1986), we group the dipoles to clusters and build a tree structure. Then the surface integral can be evaluated by walking through the tree. Dipoles far away from the field point will be grouped together and represented by a larger dipole in the center of the cluster. If the field point is very close to a triangle, the integral over the triangle will be evaluated analytically. As opposed to the wavelet method of Section 2.3.1, the tree code requires only a short setup phase. The matrix–vector product (73) can be evaluated without building the full matrix.

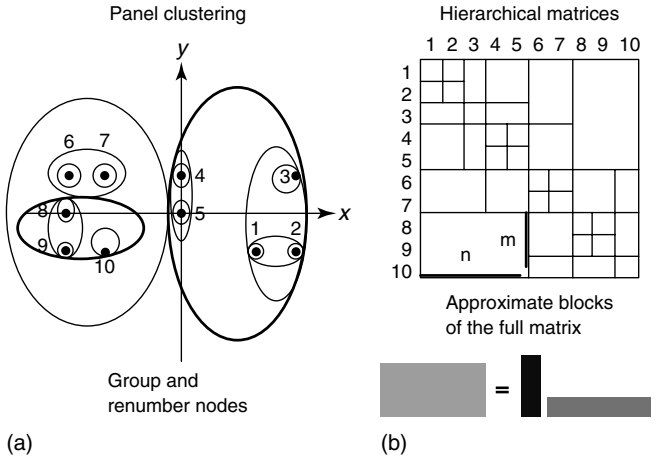

Figure 3. (a) The nodes are renumbered and grouped together so that the nodes with consecutive numbers are located next to each other and form a cluster. (b) Corresponding block structure of the interaction matrix. The large off-diagonal blocks can be approximated by low-rank matrices. (Reproduced from S. Kurz, O. Rain & S. Rjasanow: 'The Adaptive Cross-Approximation Technique for the 3-D Element Method', *IEEE Transactions on Magnetics*, **38**, (2002) copyright © IEEE 2002, with permisison of the IEEE.)

2.3.3 Hierarchical matrices

The idea of clustering the triangles of the surface mesh allows the storage of the boundary matrix in compressed form. The compressed matrix is sparse in a sense that only few data are needed for its representation. The matrix–vector multiplication is of almost linear complexity (Grasedyck and Hackbusch, 2003). Originally, the discretization of boundary integral leads to a large dense matrix that has no explicit structure. However, by suitable renumbering and permuting the boundary nodes, the dense matrix can be written in a block structure so that each block describes the interaction between two clusters of boundary nodes. If the two clusters are far apart, then the corresponding block matrix can be approximated by low-rank matrices. The corresponding two clusters are called *admissible*. If the $n \times m$ matrix **A** is a block matrix that describes the interaction of two admissible clusters, then it can be approximated by the product of two smaller matrices with the dimensions $n \times k$ and $k \times m$

$$A_{nm} = \sum_{i=1}^{k} B_{nk} C_{km} \tag{83}$$

For admissible clusters, k will be much smaller than n and much smaller than m. Therefore both, the storage for the block matrix and CPU time evaluating the product of the block matrix–vector with a vector is only $O(k(n+m))$ instead of $O(nm)$. The renumbering of the nodes is done by geometrical criterions. Consecutive boundary node numbers will be assigned to nodes located close to each other. These nodes are combined in a cluster. Each cluster pair corresponds to a block in the renumbered boundary matrix. Two admissible clusters appearing as a large off-diagonal block matrix can be approximated by a product of two smaller matrices. The off-diagonal blocks represent the far field interactions between nodes.

Figure 3 gives an example for the panel clustering and the block structure for a set of 10 nodes. The cluster with the nodes (8,9,10) and the cluster with the node (1,2,3,4,5) form a pair of admissible clusters. The corresponding block matrix appears in the lower left corner of the boundary matrix.

As with the tree code, there is no need to compute the full matrix in order to evaluate the matrix–vector product (73). First, the boundary nodes are renumbered and arranged into a cluster tree. Then, low-rank approximation of the off-diagonal block matrices can be computed using adaptive cross approximation (Kurz, Rain and Rjasanow, 2002; Grasedyck, 2005; Bebendorf and Grzhibovskis, 2006). This iterative algorithm computes the factorization (83) of the block matrix into two smaller matrices with a complexity of $O(k^2(n+m))$.

We compared the CPU time required for the setup phase and for the evaluation of the boundary integral using the tree code and the hierarchical matrices for matrix compression. The tree code requires the least memory and has the shortest setup phase. The calculation of the tree takes only a quarter of the CPU time that is required to the build the hierarchical matrix. However, the evaluation of the matrix–vector product by walking the tree takes considerable more time than the multiplication of the hierarchical matrix with a vector.

Figure 4 compares the CPU time for matrix–vector multiplication. The CPU time for multiplying the full matrix with a vector scales like M^2, where M is the number of boundary nodes. Whereas both the tree code hierarchical matrix method show an almost linear increase of the CPU time with increasing M, the hierarchical matrix method clearly outperforms the tree code in terms of the slope of the curve. Thus for computationally intensive problems such as magnetic recording simulations that take into account the mutual interactions between the recording head and the data layer, the hierarchical matrix method is the method of choice for matrix sparsification.

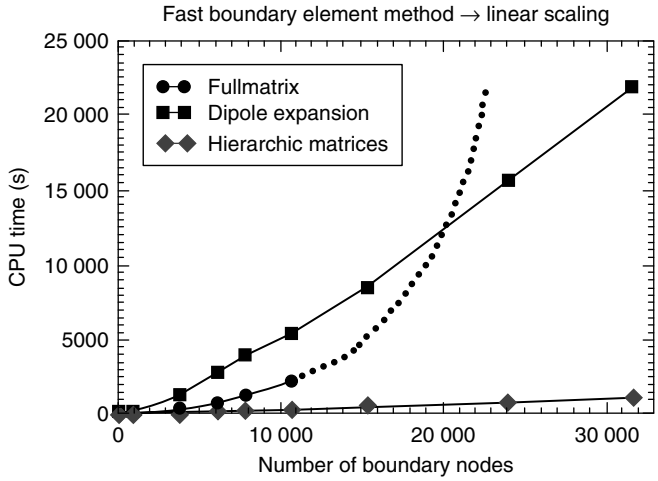

Figure 4. CPU time for the matrix–vector multiplication for different representations of the boundary element matrix.

2.3.4 Multipole expansion

Traditionally, also multipole methods are used to accelerate the BEM. Again this method was originally introduced to speed up the boundary element solution of three-dimensional electrostatic problems (Buchau, Huber, Rieger and Rucker, 2000; Bachthold, Korvink and Baltes, 1996; Nabros and White, 1991). Again we start from a suitable hierarchical clustering of the surface triangles of the boundary mesh. In order to evaluate the surface integral for group of triangles that is located at a large distance, we replace the charge distribution on those triangles by carefully chosen multipoles in the center of a sphere that encloses the triangle cluster. Outside the sphere the multipoles create the same potential field as the original charge distribution. Conventional integration is applied in the near-field of the triangle. Multipole expansion was successfully used to accelerate the evaluation of the surface integral in the hybrid FEM/BEM for micromagnetics (Liu *et al.*, 2006). In this work, almost linear efficiency was achieved with the multipole accelerated hybrid FEM/BEM for simulating the write processes in perpendicular magnetic recording media.

Buchau and coworkers (2003) compared the different boundary acceleration techniques in combination with a hybrid FEM/BEM for nonlinear magnetostatic problems. As compared to the hierarchical matrices, the use of multipole expansion leads to a higher compression rate of the boundary element matrix at the same accuracy. However, the computation of the matrix–vector product was about one order of magnitude faster using a hierarchical matrix.

3 FINITE ELEMENT MICROMAGNETICS

The basic objectives of micromagnetic simulations are the calculation of bulk magnetic properties or the simulation of dynamic magnetization processes. For the optimization and characterization of hard or soft magnetic materials, micromagnetic calculations help understand the correlation between the physical/chemical microstructure and the magnetic properties. In magnetic recording, the simulation of magnetization reversal gives insight into the data rate and area density limits of hard disk storage. Both static micromagnetic calculations and dynamic micromagnetic simulations start from the total Gibbs' free energy of the magnetic system. For the calculation of static hysteresis properties, the total Gibbs' free energy is minimized with respect to the direction cosines of the magnetization for subsequently changing external field. For the simulation of dynamic magnetization processes, the equation of motion is solved for the magnetization vector. The leading term in the equation of motion is the torque term, given by the cross product of the magnetization with the effective field. The effective field is the variational derivative of the total Gibbs' free energy density. A detailed discussion of the micromagnetic energy contributions and the associated effective field terms is given by H. Kronmüller in General Micromagnetic Theory Chapter 1 of Volume II of this Handbook (Kronmüller, 2007). In the following sections, we first discuss the micromagnetic energy contributions and the competitive effects of the different

energy terms on the magnetization configuration upon minimization. Then we introduce the finite element discretization of the energy terms, which leads to a matrix–vector representation of the total Gibbs' free energy and of the effective field. Finally, we briefly discuss time integration techniques for the LLG equation of motion.

3.1 Static hysteresis properties

The minimization of the total Gibbs' free energy of a ferromagnet gives an equilibrium configuration of the magnetization $\mathbf{M}(\mathbf{r})$. Starting from a well defined initial state, initial magnetization curves, hysteresis loops, or recoil curves can be computed by the subsequent calculation of equilibrium states for varying external field. Let us consider the magnetization in a configuration that is a local minimum of the total Gibbs' free energy. A small change in the external field leads to a shift in the position of the local minimum. The total energy can decrease if the magnetization moves toward a new local minimum, which will be attained in the subsequent minimization step. This process is related with a reversible change in the magnetization. The local minimum of the current magnetization state is separated by an energy barrier from any other possible minimum of the system. The barrier height decreases with increasing opposing external field. An irreversible switching event occurs when the energy barrier vanishes. Then the magnetization configuration can relax toward another minimum of the system. This relation of the energy landscape with the quasi-static hysteresis loop obtained in micromagnetic simulations was originally addressed by Schabes (1991).

3.1.1 Total magnetic Gibbs' free energy

Energy minimization methods start from the total Gibbs' free energy

$$\Phi_\mathrm{t} = \Phi_\mathrm{A} + \Phi_\mathrm{K} + \Phi_\mathrm{S} + \Phi_\mathrm{H} \tag{84}$$

which is the sum of the exchange energy, the magnetocrystalline anisotropy energy, the stray field energy, and the Zeeman energy. The energy contributions depend on the magnetization $\mathbf{M}(\mathbf{r})$. Within the framework of micromagnetics, we assume that $|\mathbf{M}(\mathbf{r})| = M_\mathrm{s}$ is a function of temperature only and does not depend on the magnetic field $\mathbf{H}$. Therefore we write the magnetization contributions in terms of the unit vector of the magnetization, $\mathbf{m}(\mathbf{r})$. Any search for a local minimum of the energy with respect to $\mathbf{m}(\mathbf{r})$ has to fulfill the constraint $|\mathbf{m}(\mathbf{r})| = 1$. Upon minimization, the different energy contributions have different effects on the magnetization. The minimization of the ferromagnetic exchange energy

$$\begin{aligned}\Phi_\mathrm{A} &= \int_V \left(A\left((\nabla m_x)^2 + \left(\nabla m_y\right)^2 + (\nabla m_z)^2\right)\right) \mathrm{d}V \\ &= \int_V A \sum_{l=1}^{3} (\nabla m_l)^2 \mathrm{d}V\end{aligned} \tag{85}$$

keeps neighboring magnetic moments parallel to each other. Here m_x, m_y, and m_z are the Cartesian components of $\mathbf{m}(\mathbf{r})$ and A is the ferromagnetic exchange constant. The minimization of the magnetocrystalline anisotropy energy aligns the magnetization along certain crystallographic directions. In uniaxial materials, the magnetocrystalline anisotropy energy is given by

$$\begin{aligned}\Phi_\mathrm{K,uniaxial} = \int_V &\left(K_1\left(1 - (\mathbf{m}\cdot\mathbf{k})^2\right)\right. \\ &\left. + K_2\left(1 - (\mathbf{m}\cdot\mathbf{k})^2\right)^2\right) \mathrm{d}V\end{aligned} \tag{86}$$

whereas in cubic materials

$$\begin{aligned}\Phi_\mathrm{K,cubic} = \int_V &\left(K_1\left(\gamma_1^2\gamma_2^2 + \gamma_1^2\gamma_3^2 + \gamma_2^2\gamma_3^2\right)\right. \\ &\left. + K_2\gamma_1^2\gamma_2^2\gamma_3^2\right) \mathrm{d}V\end{aligned} \tag{87}$$

In equations (86) and (87), K_1 and K_2 are the magnetocrystalline anistropy constants, $\mathbf{k}$ is the unit vector parallel to the magnetocrystalline easy axis, and γ_l is the projection of the magnetization vector on the cubic axis l. In a minimization problem, we may safely neglect terms in the total energy that do not depend on the magnetization. Thus, in the case of vanishing K_2 we may rewrite the first term on the right-hand side of equation (86)

$$\Phi'_\mathrm{K,uniaxial} = -\int_V K_1 (\mathbf{m}\cdot\mathbf{k})^2 \mathrm{d}V \tag{88}$$

The minimization of the stray field energy

$$\Phi_\mathrm{s} = -\frac{\mu_0}{2}\int_V M_\mathrm{s}(\mathbf{H}_\mathrm{s}\cdot\mathbf{m})\,\mathrm{d}V \tag{89}$$

causes the formation of magnetic domains. The minimization of the Zeeman energy rotates the magnetization parallel to the magnetic field, which might be created by an impressed current in a coil or wire,

$$\Phi_\mathrm{H} = -\mu_0\int_V M_\mathrm{s}(\mathbf{H}_\mathrm{current}\cdot\mathbf{m})\,\mathrm{d}V \tag{90}$$

3.1.2 Algebraic minimization

In order to compute the hysteresis loop, we have to minimize the total Gibbs' free energy for different values of the applied field. To accomplish this task, we first discretize the total Gibbs' free energy using the FEM. When the unit vector of the magnetization is expanded with the finite element basis functions

$$\mathbf{m}(\mathbf{r}) = \sum_{i=1}^{N} \mathbf{m}_i \varphi(\mathbf{r}) \tag{91}$$

the energy functional $\Phi_\mathrm{t} = \Phi_\mathrm{t}(\mathbf{M}(\mathbf{r}))$ reduces to an energy function with the nodal values of the unit magnetization vector as unknowns

$$\begin{aligned}\Phi_\mathrm{t} &= \Phi_\mathrm{t}(\mathbf{m}_1, \mathbf{m}_2, \ldots, \mathbf{m}_N) \\ &= \Phi_\mathrm{t}(m_{11}, m_{12}, m_{13}, \ldots, m_{il}, \ldots, m_{N3})\end{aligned} \tag{92}$$

where N is the total number of nodes in the finite element mesh of the magnetic region and l denotes the Cartesian component of $\mathbf{m}$. The minimization of equation (92) with respect to the $3N$ variables, m_{il}, subject to the constraint

$$|\mathbf{m}_i| = \sqrt{m_{i1}^2 + m_{i2}^2 + m_{i3}^2} = 1 \text{ for } i = 1, \ldots, N \tag{93}$$

gives an equilibrium distribution of the magnetization. To satisfy the constraint, equation (93), polar coordinate θ_i, ϕ_i for the unit vector of the magnetization at node i can be introduced such that

$$m_{i1} = \sin\theta_i \cos\phi_i, \;\; m_{i2} = \sin\theta_i \sin\phi_i, \;\; m_{i3} = \cos\theta_i \tag{94}$$

An alternative approach (Koehler, 1997; Chen, Fredkin and Koehler, 1993) to fulfill the constraint (93) is to normalize the unit magnetization vector in the discrete energy function, equation (92), by replacing m_{il} with $m_{il}/|\mathbf{m}_i|$. In both cases, resulting algebraic minimization problem can be solved using a conjugate gradient method (Gill, Murray and Wright, 1993). Conjugate gradient-based minimization techniques require computation of the gradient of the energy, in order to select the search directions. Using polar coordinates, the gradient of the energy can be expressed as

$$\begin{aligned}\frac{\partial \Phi_\mathrm{t}}{\partial \theta_i} &= \sum_{l=1}^{3} \frac{\partial \Phi_\mathrm{t}}{\partial m_l} \frac{\partial m_l}{\partial \theta_i}, \\ \frac{\partial \Phi_\mathrm{t}}{\partial \phi_i} &= \sum_{l=1}^{3} \frac{\partial \Phi_\mathrm{t}}{\partial m_l} \frac{\partial m_l}{\partial \phi_i} \text{ for } i = 1, \ldots, N\end{aligned} \tag{95}$$

After finite element discretization, the total energy of the system in case of uniaxial anistropy may be written in matrix–vector notation

$$\begin{aligned}(\Phi_\mathrm{A} + \Phi'_{\mathrm{K,uniaxial}}) + \Phi_\mathrm{s} + \Phi_\mathrm{H} = \frac{1}{2}\underline{\mathbf{m}}^\mathrm{T}\mathbf{F}_\mathrm{AK}\underline{\mathbf{m}} + \frac{1}{2}\underline{\mathbf{m}}^\mathrm{T}\mathbf{F}_\mathrm{s}\underline{\mathbf{m}} \\ - \underline{\mathbf{F}}_\mathrm{H}^\mathrm{T} \cdot \underline{\mathbf{m}}\end{aligned} \tag{96}$$

where $\underline{\mathbf{m}}$ is the vector containing the nodal values of the unit vector of the magnetization, as introduced in equation (53). The matrix $\mathbf{F}_\mathrm{AK}$ takes into account the exchange energy, Φ_A, and the uniaxial magnetocrystalline anisotropy, $\Phi'_{\mathrm{K,uniaxial}}$. The matrix $\mathbf{F}_\mathrm{AK}$ is sparse, as both energy terms depend only locally on the magnetization. It makes sense to combine both the exchange energy and the magnetocrystalline anisotropy energy into a single term, because the matrix $\mathbf{F}_\mathrm{AK}$ is a function of the finite element basis functions and needs to be computed only once at the beginning of the simulation. The stray field depends on the magnetization distribution over the entire magnetic system. Using equations (31), (37), and (89), the stray field energy can be written as two-fold volume integral over the magnetic particles. As a consequence the demagnetization matrix, $\mathbf{F}_\mathrm{s}$, becomes fully populated. Del Vecchio, Hebbert and Schwee (1989) used equations (95) and (96) to calculate magnetization processes in thin films.

Now we derive the entries of the matrix $\mathbf{F}_\mathrm{AK}$, which is used for the calculation of the sum of the exchange energy and magnetocrystalline anisotropy energy. We use the same approach that is applied to calculate the finite element stiffness matrix in Section 2.2.2. We first compute the energies of one tetrahedron and then sum up the contributions of all finite elements. The exchange energy and the magnetocrystalline anisotropy energy depend only locally on the magnetization. The energies can be computed by summation of the contributions from the finite elements. On the finite element V_e, the exchange energy is given by

$$\begin{aligned}\Phi_A^{(e)} = \int_{V_e} A \sum_{l=1}^{3} \left(\sum_{\alpha}^{4} m_{\alpha l} \nabla \varphi_\alpha \right) \\ \times \left(\sum_{\beta=1}^{4} m_{\beta l} \nabla \varphi_\beta \right) \mathrm{d}V\end{aligned} \tag{97}$$

or in matrix–vector notation

$$\Phi_A^{(e)} = \frac{1}{2} \sum_{k,l=1}^{3} \sum_{\alpha,\beta=1}^{4} m_{\alpha l} F_{\mathrm{A},\alpha k \beta l}^{(e)} m_{\beta l} \tag{98}$$

with the 12×12 matrix

$$F^{(e)}_{\mathrm{A},\alpha k\beta l} = 2A^{(e)} \left(\int_{V_e} \nabla\varphi_\alpha \cdot \nabla\varphi_\beta \mathrm{d}V \right) \delta_{kl} = 2A^{(e)} K^{(e)}_{\alpha\beta} \delta_{kl} \tag{99}$$

$A^{(e)}$ is the local exchange constant in element V_e and $K^{(e)}_{\alpha\beta}$ are the elements of the element stiffness matrix, equation (45). The indices α and β are over the vertices of the tetrahedron and the indices l and k are over the Cartesian coordinates. The uniaxial anisotropy energy of the finite element V_e is given by

$$\begin{aligned} \Phi'^{(e)}_{\mathrm{K,uniaxial}} &= -K^{(e)}_1 \int_{V_e} \left(\sum_{\alpha=1}^{4} \mathbf{m}_\alpha \varphi_\alpha \mathbf{k} \right)^2 \mathrm{d}V \\ &= -K^{(e)}_1 \int_{V_e} \sum_{\alpha,\beta=1}^{4} \sum_{k,l=1}^{3} \left(m_{\alpha l} \varphi_\alpha k^{(e)}_l \right) \\ &\quad \times \left(m_{\beta k} \varphi_\beta k^{(e)}_k \right) \mathrm{d}V \end{aligned} \tag{100}$$

Where $K^{(e)}_1$ is the local magnetocrystalline anisotropy constant in element V_e and $k^{(e)}_l$ is the l-th Cartesian component of the uniaxial anisotropy direction within the finite element. In matrix–vector form equation (100) can be written

$$\Phi'^{(e)}_{\mathrm{K,uniaxial}} = \frac{1}{2} \sum_{k,l=1}^{3} \sum_{\alpha,\beta=1}^{4} m_{\alpha l} F^{(e)}_{\mathrm{K},\alpha k\beta l} m_{\beta l} \tag{101}$$

with the 12×12 matrix

$$F^{(e)}_{\mathrm{K},\alpha k\beta l} = -2K^{(e)}_1 k^{(e)}_l k^{(e)}_k \int_{V_e} \varphi_\alpha \varphi_\beta \mathrm{d}V \tag{102}$$

The integral in equation (102) can be evaluated analytically (Chen, Fredkin and Koehler, 1993)

$$\int_{V_e} \varphi_\alpha \varphi_\beta \mathrm{d}V = (1 + \delta_{\alpha\beta}) \frac{V_e}{20} \tag{103}$$

In a finite element simulation program, the global matrix $\mathbf{F}_{\mathrm{AK}}$ takes into account all local energies. It can be obtained by assembling its finite element contributions $\mathbf{F}^{(\mathrm{e})}_{\mathrm{AK}} = \mathbf{F}^{(e)}_{\mathbf{A}} + \mathbf{F}^{(e)}_{\mathbf{K}}$.

The Zeeman energy can be written by the dot product, $\Phi_{\mathrm{H}} = -\underline{\mathbf{F}}^{\mathrm{T}}_{\mathrm{H}} \cdot \underline{\mathbf{m}}$. The vector $\underline{\mathbf{F}}_{\mathrm{H}}$contains the magnetic field generated by imposed currents at the nodes of the finite element mesh multiplied by the modulus of the local magnetic moment at the nodes

$$(\underline{\mathbf{F}}_{\mathrm{H}})_{ik} = |\boldsymbol{\mu}_i| H_{\mathrm{current},ik} \tag{104}$$

Here the index i runs over all nodes of the finite element mesh, and the index k denotes the Cartesian component of the magnetic field produced by imposed currents. An example is the field exerted on the yoke of the write head created by the write current through the coils during magnetic recording (Schrefl, Schabes, Suess and Stehno, 2004).

The use of the matrix–vector formulation, which is given by equation (96), to compute the total magnetic Gibbs' free energy helps to program micromagnetic solvers. The parallelization of the solver is easy, as the parallelization of matrix–vector operations is straightforward using scientific programming environments (Scholz *et al.*, 2003).

3.2 Dynamics micromagnetics

In Section 3.1, we have shown how the micromagnetic energy contributions can be computed by simple matrix–vector products once a magnetic particle has been discretized by the FEM. The problem of computing the equilibrium states of a magnetic structure then reduces to an algebraic minimization problem. Here, we show how the partial differential equation that describes the magnetization dynamics can be transformed into a system of ordinary differential equations. Only sparse matrices are required to compute the right-hand side of the equations.

The time evolution of the magnetization $\mathbf{M}(\mathbf{r})$ in a ferromagnetic body is given by the LLG equation (Brown, 1963b)

$$\frac{\partial \mathbf{M}}{\partial t} = -\frac{|\gamma|}{1+\alpha^2} \mathbf{M} \times \mathbf{H}_{\mathrm{eff}} - \frac{\alpha}{M_{\mathrm{s}}} \frac{|\gamma|}{1+\alpha^2} \mathbf{M} \times (\mathbf{M} \times \mathbf{H}_{\mathrm{eff}}) \tag{105}$$

where γ is the gyromagnetic ratio, α is the Gilbert damping constant, and $\mathbf{H}_{\mathrm{eff}}$ is the effective field. The effective field is defined as the negative variational derivative of the total Gibbs' free energy density, E_{t}, with respect to the magnetization

$$\mathbf{H}_{\mathrm{eff}}(\mathbf{r}) = -\frac{1}{\mu_0} \frac{\delta E_{\mathrm{t}}}{\delta \mathbf{M}(\mathbf{r})} \tag{106}$$

with the total Gibbs free energy being the integral of E_{t} over the ferromagnetic body

$$\Phi_{\mathrm{t}} = \int_V E_{\mathrm{t}} \mathrm{d}V \tag{107}$$

Similar to the total energy the effective field splits into the exchange field $\mathbf{H}_{\mathrm{A}}$, the anisotropy field $\mathbf{H}_{\mathrm{K}}$, the stray field

$\mathbf{H}_s$, and an applied magnetic field $\mathbf{H}_{\text{current}}$. The exchange field is given by

$$\mu_0 \mathbf{H}_A = \frac{2A}{M_s^2} \Delta \mathbf{M} \tag{108}$$

and the anisotropy field is given by

$$\mu_0 \mathbf{H}_K = \frac{2K_1}{M_s} (\mathbf{m} \cdot \mathbf{k}) \mathbf{k} \tag{109}$$

where A is the exchange constant, K_1 is the uniaxial anistropy constant, and $\mathbf{k}$ is the anisotropy direction. The total effective field is

$$\mathbf{H}_{\text{eff}} = \mathbf{H}_A + \mathbf{H}_K + \mathbf{H}_s + \mathbf{H}_{\text{current}} \tag{110}$$

It is the sum of the exchange field, the anisotropy field, the stray field, and the applied field created by imposed currents. Here we assume small ferromagnetic bodies so that the eddy currents and the magnetic fields created by eddy currents, $\mathbf{H}_{\text{eddy}}$, can be neglected (Kanai, Matsubara, Muraoka and Nakamura, 2001). The components of the exchange field are proportional to the Laplacian of the magnetization. Thus equation (105) has a spatial derivation on its right-hand side and is a partial differential equation. It has to be solved together with an equation that gives the stray field for a certain magnetization distribution. In order to solve the time evolution of the magnetization, we have to solve a system of integro-differential equations.

In the previous sections, we already discussed discretization methods for the effective computation of the stray field. Now we will show how we can discretize the partial differential equation (105). Before going into much detail, let us see how we will proceed for the numerical computation of magnetization dynamics. The main steps are illustrated in Figure 5. First, we discretize the LLG equation and the magnetostatic boundary value problem for a magnetic scalar potential using a hybrid FEM/BEM. This leads to a system of ordinary differential equations. The system of ordinary differential equations describes the dynamics of the magnetic moments at the nodes of the finite element mesh. There are three equations per nodes for the Cartesian components of the magnetic moment. The motion of the magnetic moments is coupled by the exchange field and by the stray field. Together with the anisotropy field and an applied field these files give the total effective field. Similar to the magnetic moments we can define the effective field at the nodes of the finite element mesh. The system of ordinary differential equations is nonlinear. Because the system is stiff (Nakatani, Uesaka and Hayashi, 1989) we need a backward differentiation method for its discretization. This leads to a nonlinear system of equation that has to be solved at each time step. A proper

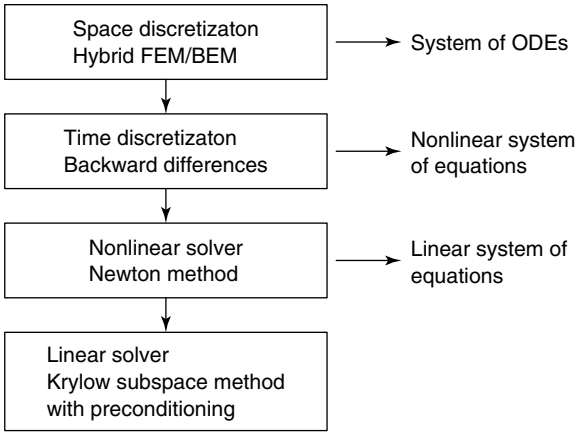

Figure 5. Space and time discretization of the LLG equation. The space discretization transforms the problem into a system of ordinary differential equations. At each time step, a nonlinear system of equations has to be solved which is solved by the Newton–Rapson method. Each Newton step requires the solution of a linear system of equations which is done by a Krylow subspace method (Saad, 2003).

method to solve the nonlinear system is the Newton method that in turn gives a linear system of equation that has to be solved at each Newton step. For the solution of the linear system of equations matrix-free Krylov subspace methods are most appropriate.

In the following text, we will discuss two different methods to evaluate the effective field numerically. The first method uses a physical interpretation of the finite element discretization of the total Gibbs free energy. We assume that a magnetic moment is associated with each node of the finite element mesh as discussed in the paragraph following equation (57). Following the same reasoning, it is possible to define the effective field at the nodes of the finite element mesh. The second method is purely mathematical and uses the concept of mass lumping (Vacus and Monk, 2001) that is commonly used in finite element simulation.

The magnetization $\mathbf{M}(\mathbf{r})$ is a continuous vector field in space. To represent the magnetization distribution, we can subdivide the ferromagnetic body into N distinct control volumes V_i with magnetization $\mathbf{M}_i$. The control volumes have the following properties

$$V = \sum_{i=1}^{N} V_i \text{ and } V_i \cap V_j = 0 \tag{111}$$

Then the effective field at point $\mathbf{r}_i$ can be approximated by

$$\mu_0 \mathbf{H}_{\text{eff}}(\mathbf{r}_i) = \mu_0 \mathbf{H}_{\text{eff},i} \approx -\frac{1}{V_i} \frac{\partial \Phi_t}{\partial \mathbf{M}_i} \tag{112}$$

In equation (112), V_i is the volume surrounding point $\mathbf{r}_i$. In limit of large N, the size each control volume goes to zero and the above equation is exact (Gardiner, 1996). There is also a physical interpretation of this result. Multiplying V_i with $\mathbf{M}_i$ gives the magnetic moment at point $\mathbf{r}_i$. So the effective field can also be written as

$$\mu_0 \mathbf{H}_{\mathrm{eff},i} = -\frac{\partial \Phi_\mathrm{t}}{\partial \boldsymbol{\mu}_i} = -\frac{1}{|\boldsymbol{\mu}_i|}\frac{\partial \Phi_\mathrm{t}}{\partial \mathbf{m}_i} \tag{113}$$

where $\boldsymbol{\mu}_i$ is the magnetic moment at point $\mathbf{r}_i$ and $\mathbf{m}_i$ is the unit vector of the magnetization at point $\mathbf{r}_i$. Now let us consider the finite element discretization of the unit vector of the magnetization $\mathbf{m}(\mathbf{r})$ with linear basis function on a tetrahedral mesh as introduced in Section 2.1 and let the nodes of the finite element mesh coincide with the points $\mathbf{r}_i$. Then equation (113) defines the effective field at the nodes of the finite element mesh. Making use of the matrix–vector notation for the micromagnetic energy (96) we can write the effective field as matrix–vector products

$$\mu_0 \underline{\mathbf{H}}_\mathrm{eff} = -\mathbf{L}^{-1}\mathbf{F}_{AK}\underline{\mathbf{m}} - \mu_0 \mathbf{L}^{-1}\mathbf{G}\underline{\mu} + \mu_0 \underline{\mathbf{H}}_\mathrm{current} \tag{114}$$

where the vector $\underline{\mathbf{H}}_\mathrm{eff}$ is a vector over all nodes of the FE mesh whose definition is similar to the definition of $\underline{\mathbf{m}}$ in equation (53). Here we used equation (64) for the calculation of the stray field $\mathbf{H}_\mathrm{s}$.

Now we will show how to derive the effective field using the FEM. The effective field can be derived using a procedure called *mass lumping* (Vacus and Monk, 2001). The exchange field is given by equation (108). In order to calculate the components of the exchange field, we use the Galerkin method. First, we multiply equation (108) with the saturation magnetization M_s. Secondly, we multiply the resulting equation with test functions φ_i and integrate over the problem domain. This gives a set of $3N$ equations for $H_{\mathrm{A},il}$ where the index i denotes the node number and the index l denotes the Cartesian component of the exchange field. Starting with

$$\int_V M_\mathrm{s}\varphi_i \mu_0 \mathbf{H}_\mathrm{A}\mathrm{d}V = \int_V \varphi_i 2A\Delta\mathbf{m}\,\mathrm{d}V \;\; i = 1, \ldots, N \tag{115}$$

where the integral is over the ferromagnetic body, we now expand both the exchange field with the finite element basis functions (see equation (4)). Within the framework of the Galerkin method the test functions of (115) are identical with the basis functions. On the right-hand side we can reduce the second derivative in space to a first derivative in space using an integration by parts. Then we obtain

$$\int_V M_\mathrm{s}\varphi_i \left(\sum_{j=1}^{N} \mu_0 H_{\mathrm{A},jl}\varphi_j\right)\mathrm{d}V = -2\int_V A\nabla\varphi_i \nabla m_l\,\mathrm{d}V + 2\oint_{\partial V} \varphi_i A\frac{\partial m_l}{\partial n}\,\mathrm{d}S \tag{116}$$

The index i denotes the node number and runs from 1 to N, the index l denotes the Cartesian component of the exchange field and runs from 1 to 3. The second term on the right-hand side of (116) vanishes as the normal derivative of the magnetization components $\partial m_l/\partial n$ vanish according to Brown (1963a). The left-hand side can be written as sum of contributions over the finite elements

$$\int_V M_\mathrm{s}\varphi_i \left(\sum_{j=1}^{N} \mu_0 H_{\mathrm{A},jl}\varphi_j\right)\mathrm{d}V = \sum_{e=1}^{E}\int_{V_e} M_\mathrm{s}^{(e)}\varphi_\alpha \left(\sum_{\beta=1}^{4} \mu_0 H_{\mathrm{A},\beta l}\varphi_\beta\right)\mathrm{d}V \tag{117}$$

The expansion coefficients $H_{\mathrm{A},\beta l}$ are the nodal values of the Cartesian components of the exchange field at the nodes of the tetrahedron. Thus we can write

$$\int_V M_\mathrm{s}\varphi_i \left(\sum_{j=1}^{N} \mu_0 H_{\mathrm{A},jl}\varphi_j\right)\mathrm{d}V = \sum_{e=1}^{E}\sum_{\beta=1}^{4}\left[M_\mathrm{s}^{(e)}\int_{V_e}\varphi_\alpha\varphi_\beta \mathrm{d}V\right]\mu_0 H_{\mathrm{A},\beta l} \tag{118}$$

where we assume that the saturation magnetization, $M_\mathrm{s}^{(e)}$, is constant on each element e. The element matrix

$$M_{\alpha\beta}^{(e)} = \int_{V_e}\varphi_\alpha\varphi_\beta\,\mathrm{d}V \tag{119}$$

is called *mass matrix*. Unfortunately, the matrix contains off-diagonal terms that would require the solution of a linear system of equations to evaluate the exchange field. However, we can compute the value of the exchange field at the nodes of the finite element mesh directly from the right-hand side of equation (116) using mass-lumping technique that is widely used in finite element computation. The matrix elements of $M_{\alpha\beta}^{(e)}$ are given by equation (103). We now approximate $M_{\alpha\beta}^{(e)}$ with a diagonal matrix

$$\widetilde{M}_{\alpha\gamma}^{(e)} = \delta_{\alpha\gamma}\sum_{\beta=1}^{4} M_{\alpha\beta}^{(e)} \tag{120}$$

The diagonal elements of $\widetilde{M}^{(e)}_{\alpha\alpha}$ are the sum of the corresponding rows of the mass matrix. Using (103) we obtain

$$\widetilde{M}^{(e)}_{\alpha a} = \frac{V_e}{20}\sum_{\beta=1}^{4}(1+\delta_{\alpha\beta}) = \frac{V_e}{20}(2+1+1+1) = \frac{V_e}{4} \quad (121)$$

With mass lumping, equation (116) can be written as follows

$$\sum_{e=1}^{E}\sum_{\beta=1}^{4}\left[M_{\mathrm{s}}^{(e)}\frac{V_e}{4}\right]\delta_{\alpha\beta}\mu_0 H_{\mathrm{A},\beta l} = -2\sum_{e=1}^{E}A^{(e)}\int_{V_e}\nabla\varphi_\alpha\sum_{\beta=1}^{4}\nabla\varphi_\beta m_{\beta l}\,\mathrm{d}V \quad (122)$$

Here we expanded the direction cosine of the magnetization, m_l, on the right-hand side of with the finite element basis function and we replaced the integral over the problem domain V with a sum over the integrals over the finite elements V_e. $A^{(e)}$ denotes the local exchange constant within element e. Using the element matrix $F_A^{(e)}$, which was introduced in equation (99) when we calculated the exchange energy, we obtain

$$\sum_{e=1}^{E}\sum_{\beta=1}^{4}\left[M_{\mathrm{s}}^{(e)}\frac{V_e}{4}\right]\delta_{\alpha\beta}\mu_0 H_{\mathrm{A},\beta k} = -F^{(e)}_{A\alpha k\beta l}m_{\beta l} \quad (123)$$

The term in brackets on the left-hand side gives the magnetic moments at the nodes of the finite element mesh. Using the diagonal matrix $\mathbf{L}$, which contains the moduli of the magnetic moments at the nodes (see equation (60)) we obtain

$$\mu_0\mathbf{L}\underline{\mathbf{H}}_{\mathrm{A}} = -\mathbf{F}_{\mathrm{A}}\underline{\mathbf{m}} \quad (124)$$

through assembling the finite element contributions. Thus we can write the exchange field at the finite element mesh as

$$\mu_0\underline{\mathbf{H}}_{\mathrm{A}} = -\mathbf{L}^{-1}\mathbf{F}_{\mathrm{A}}\underline{\mathbf{m}} \quad (125)$$

The last equation has the very same structure as equation (114).

In the last paragraph, we demonstrated the derivation of the exchange field using mass lumping. This method is especially useful when we want to calculate the exchange field in exchange spring magnets or in exchange spring recording media (Suess *et al*., 2005). These magnets are composed of exchange coupled magnetically hard and soft phases. Let us assume that the total volume of the magnet V splits into two exchange-coupled volumes V_1 and V_2 with $V = V_1 \cup V_2$. Further, we denote the saturation magnetization and the exchange constant in V_1 with $M_{\mathrm{s}1}$ and A_1 and in volume V_2 with $M_{\mathrm{s}2}$ and A_2. Then the volume integral on the right-hand side of equation (116) splits into two integrals over the volumes V_1 and V_2, and the surface integral split into a surface integral over the common interface of the two subvolumes, ∂V_{12}, and the two surface integrals on the outer boundaries of the two subvolumes, ∂V_1 and ∂V_2. If $\mathbf{n}_{12}$ denotes the normal vector at the interface pointing from V_1 into V_2 we obtain

$$\begin{aligned}\int_V M_{\mathrm{s}}\varphi_i\left(\sum_{j=1}^{N}\mu_0 H_{\mathrm{A},jl}\varphi_j\right)\mathrm{d}V &= -2\int_{V_1}A_1\nabla\varphi_i\nabla m_l\,\mathrm{d}V \\ -2\int_{V_2}A_2\nabla\varphi_i\nabla m_l\,\mathrm{d}V &+ 2\oint_{\partial V_1}A\varphi_i\frac{\partial m_l}{\partial n}\,\mathrm{d}S \\ +2\oint_{\partial V_2}A\varphi_i\frac{\partial m_l}{\partial n}\,\mathrm{d}S &+ 2\oint_{\partial V_{12}}\varphi_i\left(A_1\frac{\partial m_l}{\partial n_{12}} - A_2\frac{\partial m_l}{\partial n_{12}}\right)\mathrm{d}S\end{aligned} \quad (126)$$

Now we make use of the boundary conditions and the interface conditions, in order to evaluate the surface integrals in equation (126). Using variational calculus, Brown (1963a) showed that $\partial m_l/\partial n = 0$ holds on the surface of a magnet. Similarly, Kronmüller and coworkers (1976) showed that at a materials interface the product of the normal derivative with the exchange constant is continuous. Therefore the interface condition

$$A_1\frac{\partial m_l}{\partial n_{12}} - A_2\frac{\partial m_l}{\partial n_{12}} = 0 \quad \text{on } \partial V_{12} \quad (127)$$

holds. Using the boundary conditions and the interface conditions the surface integrals in equation (126) vanish. Therefore, the exchange field in composite magnets can be derived similar to the exchange field in single-phase magnets by using equations (122–125). In particular, equation (125), which gives the exchange field at the nodes of the finite element mesh, is also valid for composite magnets.

Using the arguments in the preceding text, we can think of individual magnetic moments sitting on the nodes of the finite element mesh. Similarly, we have the vector of the effective field at each node point. We transformed the partial differential equation (105) in a system of ordinary differential equations

$$\frac{\partial\boldsymbol{\mu}_i}{\partial t} = -\frac{|\gamma|}{1+\alpha^2}\boldsymbol{\mu}_i\times\mathbf{H}_{\mathrm{eff},i} - \frac{\alpha}{|\boldsymbol{\mu}_i|}\frac{|\gamma|}{1+\alpha^2}\boldsymbol{\mu}_i \times(\boldsymbol{\mu}_i\times\mathbf{H}_{\mathrm{eff},i}) \quad \text{for } i = 1,\ldots,N \quad (128)$$

However, we do not store the magnetic moment $\boldsymbol{\mu}$ at the node, but interpolate the unit vector of the magnetization $\mathbf{m}$ on the finite element grid. In order to arrive at an equation that is more suitable for computation, we multiply both sides

of equation (128) by the factor $\mu_0/(|\gamma||\boldsymbol{\mu}_i|)$

$$\frac{\partial \mathbf{m}_i}{\partial t'} = -\frac{1}{1+\alpha^2}\mathbf{m}_i \times \mathbf{h}_{\text{eff},i} - \frac{\alpha}{1+\alpha^2}\mathbf{m}_i \times (\mathbf{m}_i \times \mathbf{h}_{\text{eff},i}) \text{ for } i = 1, \ldots, N \tag{129}$$

The index i runs from 1 to the total number of nodes in the finite element mesh. In equation (129), we also introduced the reduced effective field $\mathbf{h}_{\text{eff}} = \mu_0 \mathbf{H}_{\text{eff}}$. As a consequence, all terms in equation (129) are in the order of $O(1)$ which facilitates the numerical solution.

Here we introduced a reduced time

$$t' = \frac{|\gamma|}{\mu_0} t \tag{130}$$

which leads to time steps in the order of $\Delta t' = 10^{-2}$ in the numerical solution scheme. Instead of using the fully populated matrix $\mathbf{F}_s$ to compute the stray field, we can apply the FEM. First, the magnetostatic boundary value problem for the magnetic scalar potential (equations (32–35)) is solved. Secondly, the stray field is computed from the potential using sparse matrix operators on the finite element grid (see equation (64)).

Standard library methods for the solution of stiff ordinary differential equations can be used to solve (129). An example is the backward differentiation scheme as implemented in the CVODE package (Cohen and Hindmarsh, 1996). The package solves an initial value problem for a system of ordinary differential equation given in the following form

$$\frac{\mathrm{d}y_i}{\mathrm{d}t} = f_i(y_1, y_2, \ldots, y_L, t), \; i = 1, \ldots, L \tag{131}$$

Here y_i are the components of the vector $\underline{\mathbf{m}}$ (the collection of the unit vectors of the magnetization vector over all nodes of the finite element mesh, see equation (53). The functions f_i are the components of the right-hand side of the LLG equation as given in (129). The total number of unknowns, L, is three times the number of nodes in the finite element mesh. The user needs to provide an initial state, y_i for $i = 1$ to L at time $t = 0$, and a subroutine for the evaluation of the right-hand side f_i. The computation of the right-hand side involves several steps. Every time the user supplied function for the evaluation of the right-hand side is called, the y_i are treated as components of unit magnetization vectors. Then corresponding effective field is computed using (114) and the right-hand side of (129) is evaluated.

Figure 5 summarizes schematically the approach for the numerical solution of the LLG equation (129). Such an equation cannot be solved directly. However, applying a hierarchy of numerical methods, the problem can be broken down to the solution of a system of linear equations. All but the first task of the following list is done within the time integration package CVODE.

Most of the computation time in finite element programs is spent in solving linear equations. A good choice of the numerical method can shorten the time to solution drastically. The special structure of the system matrices arising from finite element discretization can be used to speed up the simulations. It is used for preconditioning the linear system that has to be solved at each Newton step during time integration (Cohen and Hindmarsh, 1996). We can provide an approximate Jacobian matrix that contains all the short-range interactions (exchange interactions, magnetocrystalline anisotropy, external field) but neglects the long-range magnetostatic interactions. This method speeds up the time integration by orders of magnitude (Suess *et al*., 2002).

4 EXAMPLES

4.1 Write field dynamics in perpendicular recording

Multiscale finite element simulation of the write process in perpendicular media span a length scale of three orders of magnitude (Schrefl *et al*., 2005). The coupled system or partial differential equations for magnetization dynamics (129) is solved simultaneously for the head, the data layer, and the SUL during the motion of the head. All magnetostatic interactions between head, data layer, and SUL are concurrently taken into account. Finite element micromagnetics is combined with fast boundary element techniques to calculate the magnetostatic interactions between the recording head, the data layer, and the SUL in perpendicular magnetic recording. The FEM is highly suitable to model the physical microstructure of the media such as realistic grain shapes and intergranular phases. The fast boundary method provides an efficient and accurate means to simulate the mutual interactions between the moving magnetic parts.

A common approach to include moving parts into electromagnetic finite element simulations is the use of sliding grids and Mortar elements (Buffa, Maday and Rapetti, 2001). An alternative approach is the use of hybrid FEM/BEM techniques (Kurz, Fetzer, Lehner and Rucker, 1999). For magnetic recording simulations, FEMs/BEMs have the advantage that no mesh is needed between the different magnetic parts. In order to avoid the recomputation of the matrix elements of the matrix $\mathbf{B}$ at each time step due to the movement of the head, the superposition principle for the magnetic field is used. The finite element mesh of the entire recording system is split according to the real-world objects. For each object (head, data layer, SUL) its self-demagnetizing field is calculated using the hybrid FEM/BEM (Fredkin

and Koehler, 1990). The magnetic field is the sum of the self-demagnetizing field and the interaction field from other objects. In order to illustrate the computation of the interaction field, let us list the steps required to compute the head field:

1. We compute the magnetic scalar potential created by the head magnetization at the surface of a virtual box, which encloses the data layer. This so-called field box moves together with the head. Therefore the corresponding interaction matrix has to be computed only once.
2. A fast Poisson solver (Swartzentrauber and Sweet, 1979) is used to evaluate the potential within the field box at high spatial resolution on a regular grid.
3. Numerical derivation gives the head field within the field box which is then interpolated at the nodes of the mesh of the data layer.

The above-mentioned procedure, illustrated in Figure 6, is applied for all mutual magnetostatic interactions between the head, data layer, and SUL.

In perpendicular recording, the total write field acting on the data layer is the sum of the field created by the magnetic surface and volume charges in the pole tip of the head and the field created by magnetic surface and volume charges

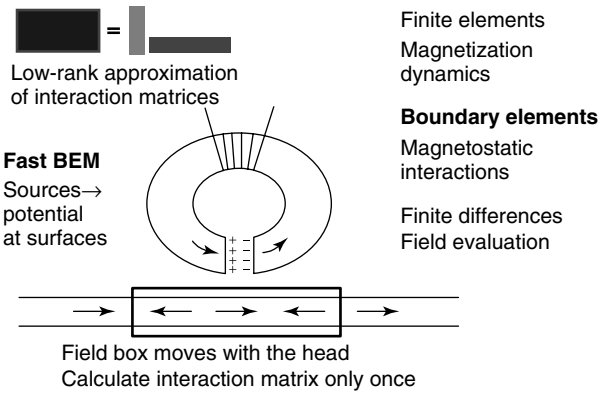

Figure 6. In magnetic recording simulation different numerical methods are combined, in order to achieve optimal performance. The finite element method is used to calculate the magnetization dynamics within the head and within the data layer. A boundary integration technique is used to calculate the magnetostatic interactions between the different parts. Large blocks of the interaction matrix are represented by low-rank approximations, in order to reduce the storage requirements and to speed up the matrix–vector multiplication. Instead of evaluating the potential from the head directly on the nodes of the data layer, the potential is evaluated at the surface of a field box that moves together with the head. Then, a fast Poisson solver is used to evaluate the magnetic scalar potential within the field box. The interaction field is interpolated from the regular grid of the field box onto to nodes of the finite element mesh of the data layer and added to the self-demagnetizing field of the layer.

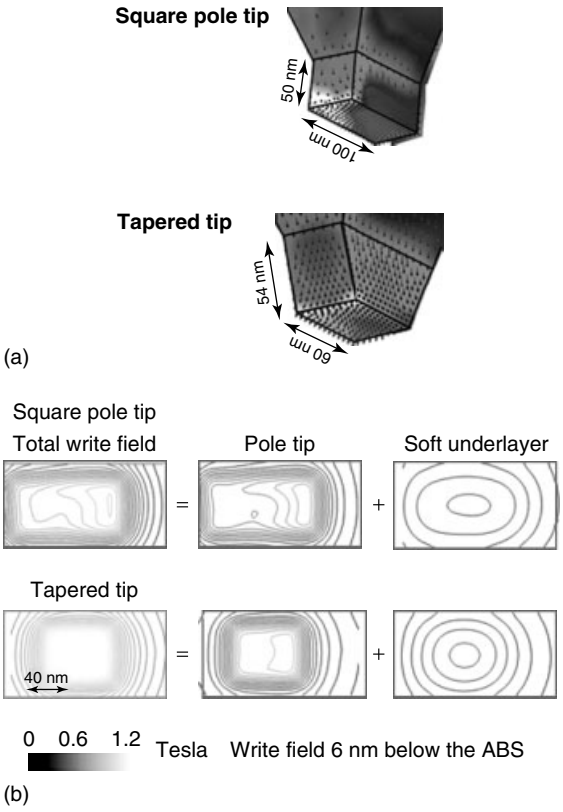

Figure 7. (a) Magnetization distribution in the pole tip of a single pole head. (b) Contour plots of the perpendicular write field. The write field is the sum of the magnetic field created by the pole tip magnetization and the magnetic field created by the soft underlayer magnetization. The magnetization configuration in the square pole tip (top) is a twisted flower state. In the tapered pole tip (bottom) is more uniform than in the square pole tip which in turn increases the perpendicular write field component.

in the SUL. Figure 7 compares the write field contributions for a write head with a square pole tip and a write head with a tapered pole tip. In the square pole tip the interplay of magnetostatic and exchange interaction lead to the formation of a twisted flower state (Hertel and Kronmuller, 2002) at maximum write current. A significant component of the magnetization is parallel to the air bearing surface (ABS) forming a vortex-like state with the center located off axis. In the tapered pole tip, the magnetization aligns almost parallel at an angle of 90° to the ABS at maximum current. For the tapered pole tip the magnetic surface charge density, $\sigma_m = \mathbf{M} \cdot \mathbf{n}$, is higher than for the square pole tip. As a consequence both the perpendicular write field component and the field gradient are higher for the tapered pole tip. Figure 7(b) gives the total write field as sum of the pole tip field and the SUL field. The results show that the tapered pole tip improves both the gradient of the pole tip field and the gradient of the SUL field. The head field gradient is smaller for the SUL field than

for the pole tip field. This result underlines the fundamental differences between the SUL and pole contributions to the total write flux. While the contributions from the pole are generated by a lithographically defined object, the gradients for the SUL contributions are created along a moving domain boundary in the SUL.

A fundamental limit of the data rate in magnetic recording is given by the intrinsic reversal time of the magnetization in head. The reversal speed of the magnetization in pole tip determines the head field rise time. Figure 8(a) compares the write current and the write field as a function of time. The delay between zero crossing of the current and reaching the maximum write field is about 0.8 ns. The time profile of the write field is governed by two characteristic timescales: (i) reversal of the pole tip by vortex motion and (ii) saturation of the pole tip and alignment of the SUL magnetization. Figure 8(b) shows the pole tip magnetization (top) and the corresponding write field (bottom) 0.3, 0.65, and 0.8 ns after zero crossing of the current. The pole tip reversal occurs by vortex motion. After annihilation of the vortex an end domain, which reduces the surface charges, remains for about 0.2 ns. Finally, the pole tip becomes saturated and the maximum write field of 1.2 T is reached.

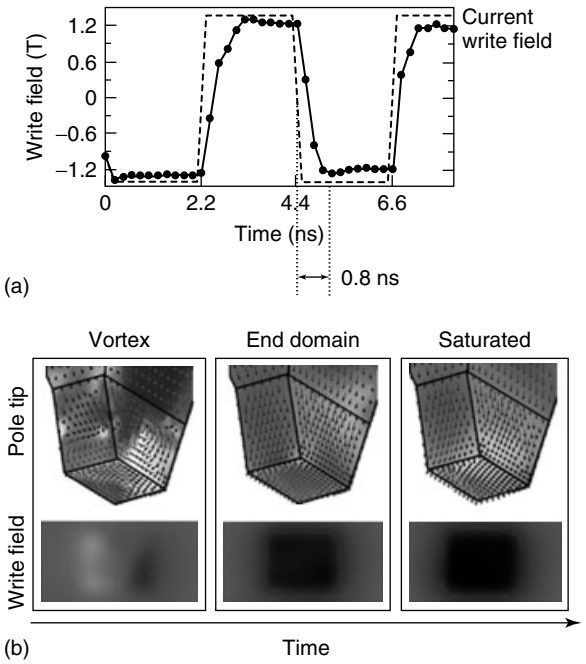

Figure 8. Write field dynamics. (a) Total write field as a function of time at a distance of 6 nm below the ABS. (b) Pole tip magnetization and total write field (color coded) as a function of time. The color code in the pole tip maps the magnetization component parallel to the down track direction (long axis parallel to the ABS). The color code for the write field maps the perpendicular write field component.

4.2 Recording on exchange spring media

The area density of magnetic recording is limited by the so-called superparamagnetic effect (Charap, Lu and He, 1997). With decreasing particle size the particle may switch spontaneously. An increase of the magnetocrystalline anisotropy leads to particles that cannot be switched with the write field. A soft magnetic layer exchange coupled with the hard magnetic grains reduces the switching field with hardly any effect on the thermal stability (Suess *et al*., 2005; Victora and Shen, 2005). Exchange spring media opens the possibility to reach area densities up to 1 Tbit in.$^{-2}$ with conventional perpendicular recording.

Exchange spring media for magnetic recording makes use of the exchange coupling between different magnetic phases at the nanoscale. Similar to nanocomposite permanent magnets, the exchange interactions between a magnetically hard phase and a magnetically soft phase lead to novel magnetic properties that can be tuned by changing the intrinsic magnetic properties of the different phases (Schrefl and Fidler, 1999), by changing the volume fraction of the different phases (Schrefl, Fischer, Fidler and Kronmuller, 1994c), and by changing the strength of the exchange interaction between the different phases (Fukunaga, Kuma and Kanai, 1999). Whereas in permanent magnets we want to increase the remanence while keeping a high coercive field, in recording media we want to reduce the switching field, while keeping a high energy barrier. In permanent magnets, the soft phase increases the remanence and the exchange interactions with the hard phase provides a high coercive field. In domain wall–assisted recording (Dobin and Richter, 2006) the soft magnetic helps to nucleate a reversed domain, the exchange interactions help propagate the reversed domain into the hard magnetic phase, and the hard magnetic phase provides a high thermal stability.

Finite element micromagnetic simulations show that the reversal mode induced by the external write field significantly differs from uniform rotation. A nucleus with oblique magnetization is formed within the soft magnetic part of the grain that helps the reversal of the hard magnetic layer. The switching field is given by the critical value of the external field that is required to expand the nucleus into the hard magnetic phase. In the limit of a thick soft magnetic layer, the switching field of a composite grain corresponds to the domain wall propagation field. Whereas the domain wall propagation field is proportional to the change (gradient) of the domain wall energy, the energy barrier for thermal switching is given by the domain wall energy in the hard phase. Thus, the bilayers can be optimized in order to achieve a high thermal stability without an increase of coercive field. In grains with identical

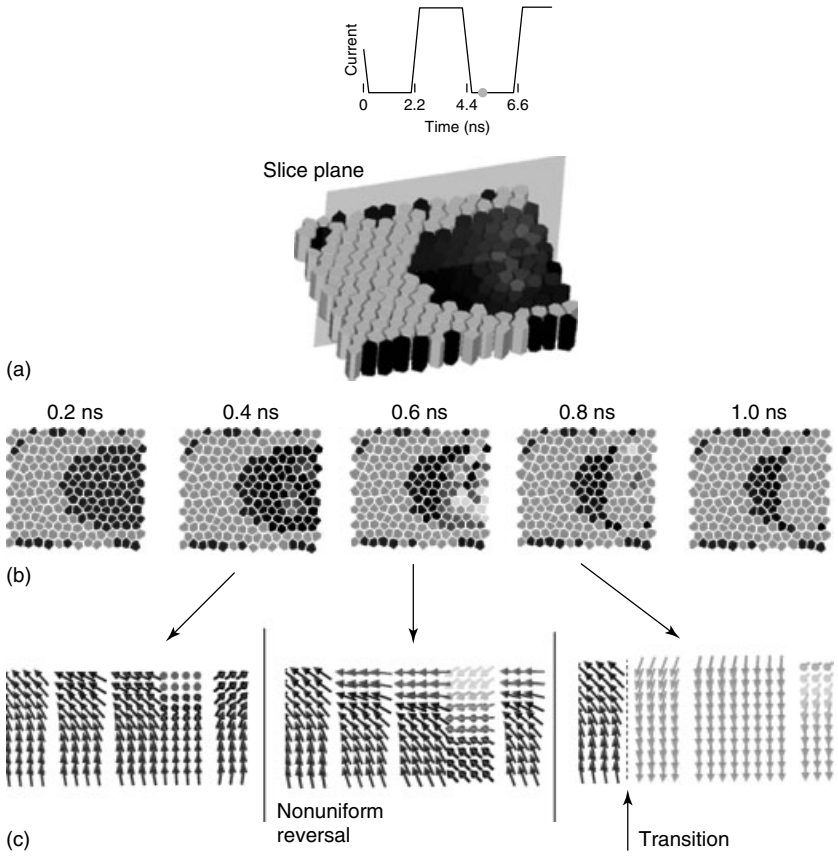

Figure 9. Evolution of the bit pattern during recording on exchange spring media. (a) Write current profile and data layer magnetization 0.4 ns after zero crossing of the current. (b) Top view of the data layer as function of time. (c) Magnetization in a slice through the data layer. The color code maps the perpendicular component of the magnetization. The total layer thickness is 14 nm. The thickness of the soft layer (on top the hard layer) is 5.3 nm, the average magnetic polarization is 0.5 T.

size and coercivity, an optimized bilayer reaches an energy barrier exceeding those of optimized single-phase media by more than a factor of two.

Figure 9 shows the formation of a bit pattern during recording on an exchange spring media. The hard magnetic layer with a thickness of 8.7 nm is perfectly exchange coupled to a soft magnetic layer with a thickness of 5.3 nm. The cross-sectional view clearly shows that switching of the individual grains is nonuniform. If the write field exceeds the critical field for the expansion of the nucleus into the hard phase, the media grains below the pole tip become fully reversed.

4.3 Thermal stability of exchange spring media

In order to estimate the thermal stability of exchange spring media, we have to calculate the energy barrier of composite grain. A micromagnetic system will be close to a local minimum of the total magnetic Gibbs' free energy. Thermal fluctuations of the magnetization cause the magnetization to wander around this minimum. Occasionally, the system will reach a region next to a saddle point. The system may cross the energy barrier and move into the basin of attraction of a different energy minimum. A small single-phase grain reverses by uniform rotation. The energy barrier for uniform rotation is $E_\mathrm{b} = KV$, where K is a uniaxial anisotropy constant that includes the contributions of the magnetocrystalline anisotropy and the shape anisotropy and V is the volume of the grain. The relaxation time is the inverse of probability per unit time for crossing the barrier E_b. It can be approximated using the Néel-Brown theory (Brown, 1963b; Neel, 1949) to

$$\tau = f_0^{-1} e^{E_\mathrm{b}/k_\mathrm{b}T} \tag{132}$$

The attempt frequency, f_0, depends on material parameters, like anisotropy, particle shape, and damping (Braun, 1994). Its value, which ranges from $f_0 = 10^9$ to $f_0 = 10^{12}$ Hz, sets the timescale for thermally assisted magnetization reversal. The Boltzmann constant is $k_\mathrm{B} = 1.3806505(24) \times 10^{-23}\,\mathrm{J\,K^{-1}}$, and T is the temperature.

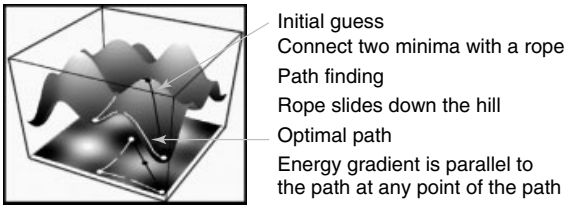

Figure 10. Elastic band method for the computation of the optimal path between two local minima. The left-hand side shows energy landscape of two interacting magnetic particles (Chen, Zhang and Bertram, 1992). The initial path connects the initial state (both particles magnetized up in the center of the graph) with the state final state (both particle magnetized down in the front corner of the graph). This path is changed iteratively until the energy gradient is parallel to the path at any point of the path. This is an optimal path connecting the initial state and the final state via a saddle point. (Reproduced from W. Chen., S. Zhang & H.N. Bertram: 'Energy barriers for thermal reversal of interacting single domain particles'. *Journal of Applied Physics*, **71**, (1992), copyright © 1992 American Institute of Physics, with permission from the AIP.)

In a composite grain of similar size, the magnetization reversal process is nonuniform. Numerical methods are required to calculate the energy barrier. In order to illustrate how the barrier can be obtained numerically, let us start with a simplified system. Figure 10 shows the energy landscape for two interacting magnetic particles (Chen, Zhang and Bertram, 1992). Thermal fluctuations drive the micromagnetic system from the stable region in the center (both particles magnetized up) to another stable region at the corner (both particles magnetized down). The path with the smallest energy barrier is chosen since the population probability decreases exponentially with the energy of the system. To calculate the crossing point with the lowest energy, one needs to find the relevant saddle points between the two stable regions. Starting from an initial guess for the path that connects two local minima of the system, a highly probable path is found by moving the points along the path according to an algorithm that resembles tensioning an elastic band across a mountain. Variants of elastic band methods are commonly used to calculate transition rates in chemical physics (Henkelman and Jonsson, 2000). These so-called string or elastic band methods have been successfully applied for calculating micromagnetic energy barriers by E, Ren and Vanden-Eijnden (2002) and Dittrich *et al*. (2002). Once the energy barrier is calculated, the Neel-Brown theory can be used to calculate the transition probability for energy barrier crossing. Whereas the Neel–Brown theory is commonly used in magnetic recording (Sharrock, 1994), it is interesting to note that in some micromagnetic systems the transition probability follows a Weibull distribution (Kronmüller, Leineweber and Hertel, 2000).

The path connecting the initial state of the system with its final state is represented by a set of images, which are

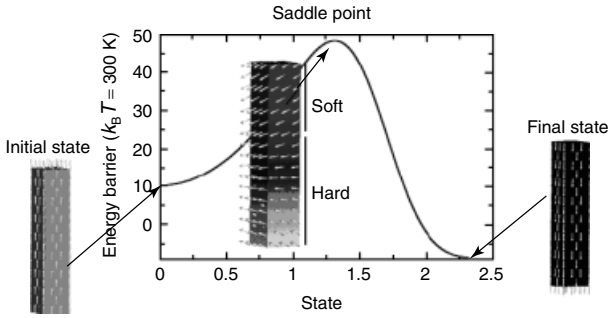

Figure 11. Energy along the minimum energy path for thermally activated switching of a composite grain. The grain is exposed to the mean interaction field of the recording layer that is composed of the demagnetizing field and the intergrain exchange interaction field. Therefore, the energy of the initial state is higher than the energy of the final state. The magnetization configuration of the saddle point configuration is nonuniform.

a small subset of all the magnetic states along the path. The magnetization configuration of an image is represented by the vector $\underline{\mathbf{m}}$, see equation (53), on the finite element grid. A sequence of magnetic states can be constructed in such a way as to form a discrete representation of a path from the initial magnetization state to the final magnetization state. The simplest case of the initial path is a straight-line interpolation in the configuration space between the initial state and the final state (see Figure 10). An optimization algorithm is then applied until at any point along the path the gradient of the energy is only pointing along the path. This path is called *minimum energy path* and means that the energy is stationary for any degree of freedom perpendicular to the path. The set of images along the minimum energy path will be visited during thermally activated reversal of the system.

The elastic band method was applied to calculate the minimum energy path for thermally activated reversal of a composite grain from an exchange spring medium. The interaction field acting in the grain is taken into account using a mean-field approach (Suess *et al*., 2005). It is the sum of the exchange field between the neighboring grains and the demagnetizing field of the film. The comparison of the magnetization configuration of the saddle point (Figure 11) and the intermediate states during recording (Figure 9) shows that the magnetization reversal is nonuniform for both thermally induced switching and field induced switching.

1 DETERMINISTIC LLG EQUATION AND TREATMENT OF THE ENERGY DISSIPATION IN MICROMAGNETICS

1.1 Origin and limitations of the standard LLG equation

An equation of motion for the magnetization of a ferromagnet, known as the Landau–Lifshitz equation

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

$$\frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} = -\gamma_0 \cdot [\mathbf{M} \times \mathbf{H}^{\mathrm{eff}}] - \gamma_0 \cdot \frac{\lambda}{M_{\mathrm{S}}} \cdot [\mathbf{M} \times [\mathbf{M} \times \mathbf{H}^{\mathrm{eff}}]] \quad (1)$$

has been introduced 1935 by L.D. Landau and E.M. Lifshitz in their pioneering work (Landau and Lifshitz, 1935) devoted to the phenomenological evaluation of the permeability tensor of ferromagnets.

The first term in (1) describes the magnetization precession of the total effective field and can be derived in frames of a general phenomenological theory which is based on the assumption that for low temperatures and slowly (in space in time) varying magnetization the magnitude of the magnetization vector $\mathbf{M} = M_{\mathrm{S}}$ is conserved. The latter statement, in turn, follows from the assumption that the equilibrium value of M_{S} is fixed by the exchange interaction, which is assumed to be the strongest interaction in a ferromagnet, which is definitely the case for all 'normal' ferromagnetic materials. Comparison of the equation (1) with the precession equation for a 'free' magnetic moment in the small damping limit provides the value $\gamma_0 = g|e|/2m_{\mathrm{e}}c$ which is the so-called gyromagnetic ratio. The g-factor in this definition, being $g = 2$ for a free electron, may slightly vary around this value dependent on the concrete material. Usually at least the combination $\gamma_0 M_{\mathrm{S}}$ may be measured with a high accuracy using FMR, so that the treatment of the first term in (1) is quite straightforward.

In contrast to the precession term, the handling of the energy dissipation processes in ferromagnets turned out to be a highly complicated issue. The double vector product term in (1) was chosen in the original paper (Landau

and Lifshitz, 1935) basing on the purely phenomenological reason that energy dissipation processes (i) should drive the magnetization toward the effective field direction (in the minimal energy state the magnetization is directed along $\mathbf{H}^{\text{eff}}$), but (ii) the magnetization magnitude M_S should still remain constant. The second term in (1) obviously satisfies these both conditions, being directed toward the effective field and perpendicular to the magnetization.

It was pointed already by the authors of (Landau and Lifshitz, 1935) themselves that the damping form suggested by (1) is by neither the only possible nor the most general one. First of all, it can be seen by a sole inspection of this equation that *if* we understand the coefficient before the damping term λ in a usual way, that is, as a parameter whose value is proportional to the intensity of the energy dissipation processes in our system, then (1) cannot be used to describe the magnetization motion for moderate and large damping. The reason for this limitation can be seen immediately if we consider the overdamped regime ($\lambda \geq 1$) where the magnetic moment motion is dominated by the dissipation term. In this case, the basic equation (1) predicts that the magnetization relaxation is getting *faster* when the damping value *increases* which is in a strong contradiction with a physical picture of damping.

This circumstance was realized already by Landau and Lifshitz themselves, who have pointed out that their equation may be used in the precession-dominated regime ($\lambda \ll 1$) only. The first phenomenological equation which qualitatively, reasonably describes the magnetization motion in the whole dissipation range was suggested by Gilbert (1955):

$$\frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} = -\gamma_0 \left[\mathbf{M} \times \left(\mathbf{H}^{\text{eff}} - \frac{\alpha}{M_S} \cdot \frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} \right) \right] \tag{2}$$

Gilbert has derived this equation starting with the equation of the undamped magnetization precession rewritten in the Lagrangian formalism. In this formalism, the damping can be rigorously added to the system using the so-called Rayleigh dissipation function (Landau Lifshitz, 1981). Transforming the resulting equation back to the force-torque form, Gilbert arrived at the equation (2), where the damping is represented by the second term in the round parenthesis with α being the damping constant.

The dissipation term form introduced in the Gilbert formulation of the magnetization dynamics can also be understood in the following way. First, the energy damping is supposed to slow down the precession of the magnetic moment, so the term describing the energy dissipation can be added directly to the effective field which is responsible for the moment precession and defines its frequency via $\omega = \gamma_0 H^{\text{eff}}$. Second, the magnitude of this term should be proportional to the relaxation speed, analogously to a standard (e.g., hydrodynamical) viscous damping. And finally, the added damping term should still conserve the magnetization magnitude. All these three conditions are satisfied by the dissipation term (2), which is called the *Gilbert* damping. It is straightforward to show (Kikuchi, 1956) that this formulation leads to the intuitively expected dependence of the switching time (relaxation speed) on the damping α, where the switching time is large both for small damping (precession-dominated regime, the moment performs many precession cycles before switching) and large damping (magnetic moment does not precess, but moves slowly owing to a large α value).

The Gilbert equation in its native form (2) is highly inconvenient to use, because it contains the time derivative of the magnetization on both sides. Fortunately, it can be easily cast into an explicit form ($\mathrm{d}\mathbf{M}/\mathrm{d}t$ on the left-hand side only) by multiplying both sides by the vector $\mathbf{M}$, transforming the double vector products using the standard vector algebra rule and utilizing the conservation of the magnetic moment magnitude as $(\mathbf{M}\cdot\mathbf{M}) = M_S^2$. The final result

$$\frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} = -\frac{\gamma_0}{1+\alpha^2} \cdot [\mathbf{M} \times \mathbf{H}^{\text{eff}}] - \frac{\gamma_0}{M_S} \cdot \frac{\alpha}{1+\alpha^2} \cdot [\mathbf{M} \times [\mathbf{M} \times \mathbf{H}^{\text{eff}}]] \tag{3}$$

has the form of the Landau–Lifshitz equation (1) if we replace the gyromagnetic ratio γ_0 by $\gamma_0/(1+\alpha^2)$ and put $\alpha = \lambda$. It is also evident that in the small damping limit both equations coincide if $\alpha = \lambda$, as it should be.

Summarizing, we point out that the two most widely used equations for the description of the damped magnetization motion are formally equivalent. However, the physics involved in the definition of the damping coefficient is quite different: Whereas in the Gilbert form (2) the value of the damping parameter α can be assumed to be proportional to the intensity of the energy dissipation processes which slow down the magnetic moment motion, for the Landau–Lifshitz form it is true only in the small damping limit. Although this issue has been discussed in the past several times (see in addition to the original papers of Landau *et al*. and Gilbert, e.g., also comments in Kikuchi (1956) and Mallinson (1987)), everybody who is familiar with the contemporary literature will surely agree that recalling them once more will at least not harm. The difference mentioned in the preceding text tends to be forgotten simply because for the overwhelming majority of applications (including, but limited to the magnetic random access memory (MRAM) technology and high density storage media) the case of the small damping is of major interest. However, this circumstance detracts no way from the importance of the physical meaning of the parameters entering into these equations.

We conclude this subsection with the following important remark. As soon as we have introduced the restriction $\mathbf{M} = M_S$, the magnetization is allowed only to rotate so that *any* magnetization change $\Delta\mathbf{M}$ should be perpendicular to $\mathbf{M}$ itself. Hence, one can gain the impression, that the equation (1) (or its equivalent forms) is the most general form of the equation of motion in this situation: from a purely mathematical point of view (1) can be considered as an expansion of the magnetization time derivative (which should lie in the plane perpendicular to the magnetization) over the two vectors $[\mathbf{M} \times \mathbf{H}]$ and $[\mathbf{M} \times [\mathbf{M} \times \mathbf{H}]]$ which form an orthogonal basis in this plane. Coefficients γ and λ can then be viewed simply as the expansion coefficients of an arbitrary allowed magnetization change in this basis. However, from the physical point of view the equation (1) and its analogues contain a much stronger assumption than the trivial statement about the existence of such an expansion. Namely, the form (1) means that the expansion coefficients are *time-independent scalar* variables, so that the magnetization motion including damping can be described on a phenomenological level with two *scalar* parameters whose values do *not* depend on the instantaneous magnetization configuration. As we shall see in the subsequent text, this is not necessarily true. However, in many cases the combined Landau–Lifshitz–Gilbert (LLG) equation (3) provides a convenient and at least semiquantitatively adequate description of the damped magnetization precession.

Concluding this subsection, we would like to briefly mention possible extensions of the standard LLG-equation (3) to the case, when the magnetization magnitude is *not* conserved, which may be particularly interesting for temperatures not very far from the Curie point. One of the possibilities to account for a change of the magnetization *value* on the mesoscopic level is the insertion into the LLG equation of the *longitudinal* relaxation term. This question was discussed already by Aharoni in the 1980s. For the recent development, including a more detailed discussion of possible forms of such an additional term, other physical problems concerning this topic (e.g., calculation of the corresponding relaxation time) and some simulation results obtained with such a generalized LLG equation, we refer the reader to the publications (Garanin, 1997; Smith, 2002; Grinstein and Koch, 2003; Garanin and Chubykalo-Fesenko, 2004).

1.2 To the possibility of alternative forms of the damping term

Rigorous *evaluation* of the damping constant entering the LLG equation is one of the most complicated problems of the modern solid-state magnetism not only due to a large variety of the damping mechanisms in ferromagnets, but also because in most cases it is really difficult to separate the contributions of these mechanisms to the energy dissipation rate measured experimentally (e.g., using FMR). To the mechanisms mentioned in the preceding text belong the spin-lattice relaxation (magnon-phonon interaction), two-and many-magnon processes, magnon-impurity interactions, magnon scattering on the surface and interface defects and so on, we refer the interested reader to the contributions in the Volume 1 of this Handbook.

For this reason, aphenomenological approach which could provide nontrivial conclusions about the form of the damping term and supply methods for the evaluation of the damping value beyond the simplest LLG phenomenology, but still valid for a relatively broad class of the energy dissipation processes is in principle highly desirable. However, a development of such an approach is a delicate matter, requiring careful analysis of each step of a corresponding 'general' procedure.

As an example of a such an attempt we would like to analyze a recently developed and meanwhile widely cited approach of Safonov and Bertram (2003) and references therein, who suggested to use the *normal mode analysis* of a magnetic system coupled to a thermal bath. Up to a certain level such an analysis can be performed without specifying the concrete energy dissipation mechanism, but merely employing general assumptions concerning the Hamilton function, which describes the interaction between the magnetization and thermal reservoir.

In the simplest case of a uniformly magnetized ferromagnetic particle, the normal mode analysis starts with the Taylor expansion of the magnetic energy density E/V over small magnetization variations M_x and M_y

$$\frac{E}{V} = \frac{H_{0x}}{2M_S} M_x^2 + \frac{H_{0y}}{2M_S} M_y^2 \tag{4}$$

near the equilibrium moment orientation $\mathbf{M}_0$, whereby the $0z$-axis is directed along $\mathbf{M}_0$. Dimensionless coefficients before the squares of magnetization components $M_{x(y)}$ in (4) can be written in the form $H_{0x(y)}/M_S$, where parameters $H_{0x(y)}$ (which describe the curvature of the energy surface for the equilibrium magnetization state) have the dimension of a field [1].

Any equation of motion which describes the magnetization precession in terms of components M_x and M_y leads to the coupling of their time-dependencies and is thus unsuitable for the identification of the system normal modes. For this reason, Safonov and Bertram proceed by introducing the (complex-valued) functions $a(t) \sim M_x + iM_y$ and $a^*(t) \sim M_x - iM_y$. These functions are fully

analogous to the corresponding quantum-mechanical operators which increase/reduce the z projection of the angular momentum, but the formalism developed by Safonov and Bertram is a purely classical one. The functions $a(t)$ are required to describe the interaction of a magnetic system with a thermal bath, because they appear in the corresponding interaction term of a Hamiltonian; this is the reason why this intermediate transformation should be explicitly introduced. The second transformation $a(t) \sim uc(t) + vc^*(t)$ and $a^*(t) \sim uc^*(t) + vc(t)$ diagonalizes the Hamilton function, which becomes H: $\omega_0 c^* c$, with $\omega_0 = \gamma\sqrt{H_{0x}H_{0y}}$ being the FMR frequency of our system. Equation of motion for these new 'coordinates' are uncoupled, that is, $\dot{c}(t) = -i\omega_0 c(t)$ and $\dot{c}^*(t) = i\omega_0 c^*(t)$.

At the next step the interaction between the *normal modes* of the magnetization oscillations and a thermal bath described *as a set of harmonic oscillators* is introduced via the insertion of a linear coupling between functions $a(t)$ and the thermal bath normal modes b_k into the system Hamiltonian (see Safonov and Bertram, 2003 for details):

$$H \sim E_{\text{mag}} + E_{\text{bath}} + \sum\nolimits_k \left[G_k(ab_k^* + a^* b_k) + F_k(ab_k + a^* b_k^*)\right] \tag{5}$$

where E_{mag} and E_{bath} are the energies of a magnetic system and thermal bath only.

Transformation of the interaction term to the variables $c(t)$ and $c^*(t)$, solution of the resulting dynamic equations for the thermal bath modes b_k and substitution of the expression for b_k into the dynamic equations for $c(t)$ leads to the equation

$$\frac{\mathrm{d}c}{\mathrm{d}t} = -i(\omega_0 + \Delta\omega)c - \eta c + f(t) \tag{6}$$

which describes a damped harmonic oscillator under the influence of a random force (noise) $f(t)$. The damping constant η in this formalism

$$\eta = \pi \left|\tilde{G}_k\right|^2 D(\omega_0) \tag{7}$$

is proportional to (i) the squared interaction coefficient $\tilde{G}_k = uG_k + vF_k$ of a magnetic system with the bath normal mode having the same frequency ω_0 as the undisturbed magnetic system and (ii) the density of states $D(\omega_0)$ of a thermal bath at this frequency.

An important conclusion which can be drawn from the consideration in the preceding text is that in this phenomenological model the magnetization damping present in the Gilbert or Landau–Lifshitz equation of motion for the components of the system magnetization $\mathbf{M}(t)$

$$\frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} = -\gamma_0 \left[\mathbf{M} \times \left(\mathbf{H}^{\text{eff}} - \frac{\hat{\alpha}}{M_{\text{S}}} \cdot \frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t}\right)\right] \tag{8}$$

cannot be reduced anymore to a scalar variable, but is a tensor

$$\hat{\alpha} = \frac{\eta}{\omega_0^2} \begin{pmatrix} H_{0x} & 0 & 0 \\ 0 & H_{0y} & 0 \\ 0 & 0 & 0 \end{pmatrix} \tag{9}$$

where the diagonal components of this tensor are proportional to the parameters $H_{0\text{x(y)}}$ characterizing the energy surface curvature near the equilibrium magnetization state (expression (9) may be verified by rewriting M_x and M_y via the functions $c(t)$ and $c*(t)$ and substituting the resulting expressions into (8), thus arriving at the equation (6)). This tensor reduces to a scalar only for a symmetric energy minimum with $H_{0\text{x}} = H_{0y}$, which is rather an exception.

The formalism outlined in the preceding text can be extended to magnetic systems with arbitrarily nonhomogeneous equilibrium magnetization configuration (Bertram, Safonov and Jin, 2002). After the discretization of a ferromagnetic body into N finite elements the eigenmodes of its magnetization state can be identified using the equation of motion *without* damping $\dot{\mathbf{M}}_i = -\gamma[\mathbf{M}_i \times \mathbf{H}_i^{\text{eff}}]$. Expanding the system state magnetization vector $\mathbf{T} = (\mathbf{M}_1, \ldots, \mathbf{M}_i, \ldots, \mathbf{M}_N)$ the near the equilibrium state one obtains a set of coupled equations $\dot{T} = -\gamma\hat{\mathbf{H}}\cdot\mathbf{T}$ where tensor $\hat{\mathbf{H}}$ consists of corresponding effective field components. Diagonalization of this tensor provides the eigenvectors $\mathbf{c}_i$, which give the spatial distribution of the i-th eigenmode and eigenvalues, which are proportional to the mode oscillation frequencies ω_i. Further analysis proceeds then as in the simplest case discussed in the preceding text.

However, the procedure sketched in the preceding text, which leads to the conclusion that the damping in the LLG equation *should* be a tensor, is incorrect, as shown by Smith (2002). Taking into account that the question about the form of the phenomenological damping term is crucially important for micromagnetic calculations, we shall briefly reproduce here the argumentation of Smith, replacing his simple illustrative example by an even simpler one.

To find out where is the flaw in the argumentation of Bertram and Safonov, we consider the simplest possible mechanical system with more than one eigenmode, that is, two particles of equal masses m, each of which is attached to a wall via a spring with the stiffness constant k. Particles are placed in the *isolated* reservoirs filled with a fluid with

different viscosities (this is the only difference between the particles) and coupled via a spring with the stiffness k_c. If particle coordinates x_1 and x_2 in the mechanical equilibrium are set to zero, the corresponding equations of motion are

$$m\ddot{x}_1 = -\eta_1\dot{x}_1 - kx_1 + k_c(x_2 - x_1) + F_1^L \tag{10}$$

$$m\ddot{x}_2 = -\eta_2\dot{x}_2 - kx_2 - k_c(x_2 - x_1) + F_2^L \tag{11}$$

Here, the friction coefficients η_1 and η_2 are different owing to different fluid viscosities. Random thermal forces F^{L} responsible for the Brownian motion of the particles are obviously *uncorrelated* (because the reservoirs with the particles are isolated from each other), δ correlated in time and their mean-square values are proportional to the system temperature T.

The determination of the system normal modes should be performed in a standard way, using the equations (10) and (11) without dissipative and fluctuation forces. In this very simple case, it is enough to add and subtract these equations in order to find out that the normal modes are $x_+^{\mathrm{n}} = (x_1 + x_2)/\sqrt{2}$ and $x_-^{\mathrm{n}} = (x_1 - x_2)/\sqrt{2}$, so that the transformation matrix U between the vector of the particle coordinates $\mathbf{x}$ and the normal modes of our system $\mathbf{x}^{\mathrm{n}}$ (i.e., $\mathbf{x} = U\cdot\mathbf{x}^{\mathrm{n}}$) is

$$U = \frac{1}{\sqrt{2}}\begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix} \tag{12}$$

Next, we apply this transformation to the initial equations of motion system, (10) and (11), written in the matrix form

$$M\ddot{\mathbf{x}} = -\mathrm{H}\dot{\mathbf{x}} + K\mathbf{x} + F^{\mathrm{L}} \tag{13}$$

where the mass and friction matrices are diagonal ($M = diag(m, m)$, $\mathrm{H} = diag(\eta_1, \eta_2)$), and the stiffness matrix K has both diagonal $K_{11} = K_{22} = -(k + k_c)$ and off-diagonal elements $K_{12} = K_{21} = k_c$. The transformation to the normal modes proceeds in the usual way: we insert the unit matrix in the form $I = U\cdot U^{\mathrm{T}}$ into the matrix-vector products into the equation (13) and multiply it by the matrix U^{T} from the left. Using the relation $U^{\mathrm{T}}\mathbf{x} = \mathbf{x}^{\mathrm{n}}$ and performing the matrix multiplications $\tilde{M} = U^{\mathrm{T}}MU = M$, $\tilde{\mathrm{H}} = U^{\mathrm{T}}\mathrm{H}U$, $\tilde{K} = U^{\mathrm{T}}KU$, we arrive at the *equations of motion for the normal modes*:

$$\begin{bmatrix} m & 0 \\ 0 & m \end{bmatrix}\cdot\begin{bmatrix} \ddot{x}_+^{\mathrm{n}} \\ \ddot{x}_-^{\mathrm{n}} \end{bmatrix} = -\frac{1}{2}\begin{bmatrix} \eta_1 + \eta_2 & \eta_1 - \eta_2 \\ \eta_1 - \eta_2 & \eta_1 + \eta_2 \end{bmatrix}\cdot\begin{bmatrix} \dot{x}_+^{\mathrm{n}} \\ \dot{x}_-^{\mathrm{n}} \end{bmatrix} + \begin{bmatrix} -k & 0 \\ 0 & -(k + 2k_c) \end{bmatrix}\cdot\begin{bmatrix} x_+^{\mathrm{n}} \\ x_-^{\mathrm{n}} \end{bmatrix} + \begin{bmatrix} F_+^{\mathrm{n,L}} \\ F_-^{\mathrm{n,L}} \end{bmatrix} \tag{14}$$

where the vector of fluctuation forces $\mathbf{F}^{\mathrm{n,L}} = U^{\mathrm{T}}\cdot\mathbf{F}^{\mathrm{L}}$ now contains the corresponding forces for the normal modes defined as $F_+^{\mathrm{n,L}} = (F_1^{\mathrm{L}} + F_2^{\mathrm{L}})/\sqrt{2}$, $F_-^{\mathrm{n,L}} = (F_1^{\mathrm{L}} - F_2^{\mathrm{L}})/\sqrt{2}$.

It can be immediately seen from equation (14) that the equations of motion for the normal modes which include the damping term are *correlated* owing to the non-diagonal character of the transformed damping matrix $\tilde{\mathrm{H}} = U^{\mathrm{T}}\mathrm{H}U$. This means that the simple phenomenological addition of the *uncoupled* damping terms like the term $-\eta\cdot c$ in (6) is incorrect. This term in (6) results from writing the equations of motion for the coupled system 'magnetic body + thermal bath' directly in terms of the normal modes (see (5)), which hence turns out to be incorrect at least when the coupling of these modes and correlation properties of corresponding random (fluctuation) forces are important. The conclusion (9) about the obligatory tensor form of the damping in the LLG equation, being a direct consequence of the *uncoupled* damping of *normal modes*, is for this reason erroneous. A detailed extension of this discussion to the case of micromagnetic equations can be found in (Smith, 2002).

Another very important point is that the addition of *uncoupled* fluctuation forces into the equations of motion for *the normal modes* (instead of using corresponding equations for real particles) as it is done in equation (6) is also physically incorrect. Namely, if thermal forces acting on the *normal modes* would be indeed uncorrelated, then the corresponding forces acting on *real* particles (obtained via the backward transformation as $\mathbf{F}^L = U\cdot\mathbf{F}^{\mathrm{n,L}}$) would be correlated, which is completely unphysical. This is evident at least in the case considered in the preceding text where particles are placed into *separate isolated* reservoirs. Taking into account that the random (Brownian) forces are caused by the chaotic motion of the fluid molecules, any correlations between these forces in two separate isolated fluid volumes are obviously absent.

The discussion in the preceding text should remind the reader, that although normal modes of the system are doubtlessly a very useful physical concept, one should not forget that initially dynamical equations must be written for real particles (magnetic moments) where the physical meaning of various terms in such equations can be directly examined.

The last comment in order is that the argumentation line presented here does *not* mean that the tensor form of the damping term is *forbidden*. As already mentioned by Smith (2002), this only means that any conclusion about the specific

form of the damping should be based on the consideration of the corresponding physical mechanism responsible for the energy dissipation.

2 STOCHASTIC LLG EQUATION: CHOICE OF THE STOCHASTIC CALCULUS

2.1 General introduction to the solution of SDEs

Equation-of-motion simulations of the remagnetization dynamics *including* thermal fluctuations require, in contrast to the case $T = 0$, the solution of stochastic differential equations (SDE), which is by far more difficult. A simple example of such stochastic (Langevin) equations arising in the theory of stochastic processes is the equation of motion for a particle in a viscous medium under the influence of a deterministic force F_{det} and thermal fluctuations represented via the random (or Langevin) force ξ_{L}(η denotes the friction coefficient)

$$\dot{x} = \frac{1}{\eta} F_{\mathrm{det}}(t) + a(x,t)\cdot\xi_{\mathrm{L}}(t) \tag{15}$$

$\xi_{\mathrm{L}}(t)$ is usually assumed to be a random Gaussian variable, δ correlated in time:

$$\langle \xi(t) \rangle = 0, \quad \langle \xi(0)\cdot\xi(t) \rangle = 2D\cdot\delta(t) \tag{16}$$

with the noise power $D \sim T$. The 'good' function $a(x,t)$ contains the coordinate- and time-dependencies of the noise characteristics.

The problem with the equations of this kind is that they can *by no means* be interpreted as the 'usual' differential equations (DE). Namely, any attempt to integrate equation (15) as an ordinary DE leads to the integral

$$W(t) = \int_0^t \xi(t')\cdot \mathrm{d}t' \tag{17}$$

which obviously represents a random process, because its integrand is a random variable. From the correlation properties (16) it follows that $W(t)$ is the standard Wiener process (Brownian motion) Gardiner (1997). This process is *not* differentiable – the ratio $(W(t+\Delta t) - W(t))/\Delta t$ diverges in the limit $\Delta t \to 0$ almost surely. Because the derivative $\mathrm{d}W/\mathrm{d}t = \xi(t)$ does not exist, in the usual sense the equation (16) including this derivative *does not exist* also and hence cannot be interpreted as a 'normal' ordinary DE.

The proper way to assign a mathematically correct meaning to the equations like (15) is to introduce the differential of the Wiener process $\mathrm{d}W$ (which is usually viewed by a physicist as a replacement of the product $\xi(t)\mathrm{d}t$) and to define the corresponding integral

$$I = \int a(x,t)\cdot \mathrm{d}W(t) \tag{18}$$

analogously to the standard Riemann–Stieltjes integrals as the limit of partial sums

$$\begin{aligned} I &= \lim_{n\to\infty} \sum_{i=1}^{n} a(x(\tau_i), \tau_i)\cdot \Delta W(\Delta t_i) \\ &= \lim_{n\to\infty} \sum_{i=1}^{n} a(x(\tau_i), \tau_i)\cdot [W(t_i) - W(t_{i-1})] \end{aligned} \tag{19}$$

with the points τ_i where the integrand values are evaluated lie inside the interval $[t_{i-1}, t_i]$.

This limit, being understood in the mean-square sense (see any handbook on stochastic calculus) is convenient enough to develop the complete analysis of such *stochastic* integrals. The real problem is that (in a heavy contrast to the standard analysis) this limit itself – and not just the values of partial sums in (19) – *depends on the choice of the intermediate points* τ_i (see Chapter 3 in Gardiner (1997) for a simple but impressive example).

The only way to cope with this problem is to introduce some standard choices of the intermediate points and to find the best choice from the physical point of view. The two standard choices – (i) $\tau_i = t_{i-1}$ coincide with the *left* points of the intervals (*Ito* stochastic calculus) and (ii) $\tau_i = (t_{i-1} + t_i)/2$ are in the *middle* of the intervals (*Stratonovich* interpretation) – lead to *different* solutions if the noise in a stochastic equation is *multiplicative* – that is, the random term is *multiplied* by some function of the system variables. In this case, usually the *Stratonovich* interpretation provides physically correct results, recovering, for example, some important properties of physical random processes obtained using more general methods (Gardiner, 1997).

In micromagnetics, the most common way to include thermal fluctuation effects into the consideration is the addition of the so-called 'fluctuation field' to the deterministic effective field in equation (LLG). This leads to the *stochastic* LLG equation (Brown, 1963b) for the magnetic moment motion.

$$\begin{aligned} \frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} &= -\gamma\cdot[\mathbf{M}\times(\mathbf{H}^{\mathrm{det}} + \mathbf{H}^{\mathrm{fl}})] - \lambda\cdot\frac{\gamma}{M_{\mathrm{S}}} \\ &\quad \cdot[\mathbf{M}\times[\mathbf{M}\times(\mathbf{H}^{\mathrm{det}} + \mathbf{H}^{\mathrm{fl}})]] \end{aligned} \tag{20}$$

Here, the *deterministic* effective field $\mathbf{H}^{\mathrm{det}}$ acting on the magnetization includes all the standard micromagnetic contributions (external, anisotropy, exchange and magnetodipolar interaction field). Analogous to the random force in

the mechanical equation (15), Cartesian components of the fluctuation field $\mathbf{H}_i^{\mathrm{fl}}$ are usually assumed to be δ correlated in space and time (Brown, 1963b)

$$\langle H_{\xi,i}^{\mathrm{fl}} \rangle = 0 \quad \langle H_{\xi,i}^{\mathrm{fl}}(0) \cdot H_{\psi,j}^{\mathrm{fl}}(t) \rangle = 2D \cdot \delta(t) \cdot \delta_{ij} \cdot \delta_{\xi\psi} \tag{21}$$

where i, j are the discretization cell (magnetic moment) indices and $\xi, \psi = x, y, z$. The noise power D evaluated using the fluctuation-dissipation theorem (see subsequent text for a detailed discussion) is proportional to the system temperature T and depends on γ and the damping constant λ:

$$D = \frac{\lambda}{1+\lambda^2} \cdot \frac{kT}{\gamma M_{\mathrm{S}} \Delta V} \tag{22}$$

We note in passing that the fluctuation field $\mathbf{H}^{\mathrm{fl}}$ in the dissipation term of (20) can be omitted by rescaling correspondingly the noise power D (Garcia-Palacios and Lazaro, 1998; Braun, 2000). We shall use this possibility below by comparing the Ito and Stratonovich interpretations of the LLG equations.

The noise in the Langevin equations 20 is *multiplicative*, because in the vector products the random field projections are *multiplied* by the magnetic moment projections. This fact was pointed out already in the pioneering paper of Brown (1963b), who suggested to use for this reason the Stratonovich interpretation of the equation.

Analytic solution of (20) is possible only in a few simplest cases, so that really interesting magnetic systems can be studied only numerically. For such simulations, the choice of the stochastic calculus is, in principle, of *primary* importance, because different numerical integration schemes converge to different stochastic integrals: The Euler and the simple implicit methods converge to the Ito solution, Heun and Milstein schemes – to the Stratonovich limit (McShane, 1974) and Runge-Kutta methods can converge to both types of the stochastic integrals (including the in-between cases) depending on their coefficients (Rümelin, 1982). Most authors (see, e.g., Garcia-Palacios and Lazaro, 1998; Scholz, Schrefl and Fidler, 2001; Berkov, Gorn and Görnert, 2002) and commercial micromagnetic packages (advanced recording model (ARM), LLG, MicroMagus) use the Heun, Runge-Kutta or modified Bulirsch–Stoer methods converging to the Stratonovich solution, but several groups employ the Ito-converging Euler (Zhang and Fredkin, 2000; Lyberatos and Chantrell, 1993) method and implicit schemes (Nakatani, Uesaka, Hayashi and Fukushima, 1997). These last papers were criticized in Garcia-Palacios and Lazaro (1998) where it has been claimed that only the Stratonovich interpretation ensures the physically correct solution of (20).

Fortunately, we could show that for *standard* micromagnetic models (where $|\mathbf{M}| = M_{\mathrm{S}} = Const$) both Ito and Stratonovich stochastic calculi provide identical results, so that the only criterion by the choice of the integration method is its efficiency by the solution of the LLG stochastic equation for the particular system under study. In the next subsection, we address this question in more detail because of its methodical importance.

2.2 Equivalence of Ito and Stratonovich stochastic calculus for standard micromagnetic models

In this subsection, we shall prove that for the system in which the dynamics is described by the stochastic equation (20) the Ito and Stratonovich versions of the stochastic calculus are equivalent *if the magnetization magnitude (or the magnitude of the discretization cell/single particle) is assumed to be constant* [2]. This is true for many magnetic system models including the classical Heisenberg and related models, spin glasses, fine magnetic particle systems (Dotsenko, 1993; Hansen and Morup, 1998), and in standard micromagnetics (Brown, 1963a).

First, we repeat that the fluctuation field in the dissipation term of (20) that can be omitted by rescaling correspondingly the noise power D (Garcia-Palacios and Lazaro, 1998; Braun, 2000). Thus we can restrict ourselves to the study of a simpler equation

$$\begin{aligned} \frac{\mathrm{d}\mathbf{m}_i}{\mathrm{d}\tau} = &- \left[\mathbf{m}_i \times (\mathbf{h}_i^{\mathrm{eff}} + \mathbf{h}_i^{\mathrm{fl}})\right] \\ &- \lambda \cdot \left[\mathbf{m}_i \times \left[\mathbf{m}_i \times \mathbf{h}_i^{\mathrm{eff}}\right]\right] \end{aligned} \tag{23}$$

To proceed, we recall that by the transition between the Ito and Stratonovich forms of a stochastic differential equation the additional drift term appears: if one adds to a SDE system

$$\frac{\mathrm{d}x_i}{\mathrm{d}t} = A_i(\mathbf{x}, t) + \sum_k B_{ik} \xi_k \tag{24}$$

the *deterministic* drift $D \sum_{jk} B_{jk} (\partial B_{ik} / \partial x_j)$, then the *Ito* solution of this new system

$$\frac{\mathrm{d}x_i}{\mathrm{d}t} = A_i(\mathbf{x}, t) + D \sum_{jk} B_{jk} \frac{\partial B_{ik}}{\partial x_j} + \sum_k B_{ik} \xi_k \tag{25}$$

is equivalent to the *Stratonovich* solution of the initial system (24) (Kloeden and Platen, 1995).

For the LLG equation written in Cartesian coordinates the matrix $\mathbf{B}$ is $B_{ik} = \sum_j \varepsilon_{ijk} m_j$, and the additional drift term reduces to $\mathrm{d}\mathbf{m}_i / \mathrm{d}\tau = -2D\mathbf{m}_i$. This drift is directed *along* the magnetic moment $\mathbf{m}_i$ trying to change its *magnitude*, which is forbidden by the model. Hence, this term *must* be discarded, which leads to the equivalence of the Ito and Stratonovich schemes.

The same result can be obtained (and understood) in a much simpler way rewriting the LLG equation using spherical coordinates (θ, ϕ) of the moment unit vector $\mathbf{m}$ (Cartesian coordinates of magnetic moments are *not* independent: owing to the conservation of a moment magnitude they are subject to the restriction $m_{x,i}^2 + m_{y,i}^2 + m_{z,i}^2 = 1$). In spherical coordinates the part containing the fluctuation (stochastic) field part of (23) which is of interest for us reads (Brown, 1963b; Braun, 2000).

$$\frac{\mathrm{d}\theta}{\mathrm{d}\tau} = h_{\varphi}^{fl}, \quad \frac{\mathrm{d}\varphi}{\mathrm{d}\tau} = -\frac{1}{\sin\theta} h_{\theta}^{fl} \tag{26}$$

so that the matrix $\mathbf{B}$ responsible for the drift mentioned in the preceding text is

$$B = \begin{pmatrix} B_{\theta\theta} & B_{\theta\varphi} \\ B_{\theta\varphi} & B_{\varphi\varphi} \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ -1/\sin\theta & 0 \end{pmatrix} \tag{27}$$

and this drift is exactly zero: $D\sum_{jk} B_{jk}(\partial B_{ik}/\partial x_j) = 0$ ($i, j, k = 1, 2$ and $x_1 = \theta, x_2 = \phi$). Hence, we arrive at the same result that Stratonovich and Ito stochastic integrals are equivalent in this case, which means that *for stochastic dynamics of models with rigid dipoles* (*dipoles with constant magnitudes*) *there is no difference between the Ito and Stratonovich solutions of corresponding stochastic differential equations* (Berkov and Gorn, 2002).

It is interesting to see why the opposite statement made in Garcia-Palacios and Lazaro (1998) is incorrect. Using the Fokker–Planck equation (FPE) which describes the evolution of the probability distribution of the magnetization orientation $P(\mathbf{m}, t)$, the authors of Garcia-Palacios and Lazaro (1998) have shown that an additional drift term $\partial(\mathbf{m}P)/\partial\mathbf{m}$ appears in the FPE derived from the *Ito* interpretation of the Langevin equation. But this term should be excluded from the FPE because it leads to the probability density drift *along* the magnetization vector which would change the moment magnitude (this can be most easily seen in *spherical* coordinates (m, θ, ϕ) where this term reduces to $\partial(mP)/\partial m$).

To support our conclusion about the equivalence of the Ito and Stratonovich integrals for models with constant magnetic moment magnitudes, we have performed numerical experiments simulating equilibrium (density of states) and nonequilibrium (time dependent magnetization relaxation) properties of a disordered system of magnetic dipoles. We have solved the stochastic LLG equation (20) using methods converging either to its Ito (Euler scheme) or Stratonovich (drift-modified Euler and Heun schemes) solutions. Results obtained by all these methods coincide within the statistical accuracy, confirming that Ito and Stratonovich calculi lead, for these systems, to the same physical results despite that the noise in the stochastic LLG equation is *multiplicative*.

However, we point out that the proof in the preceding text *heavily relies* on the *conservation* of the moment magnitude. Hence for models where this is *not* the case – for example, by simulations of the heat assisted magnetic recording (HAMR) or for models attempting to relax the local restriction $\mathbf{M} = M_S = \text{Const}$ (see preceding text) – one should pay close attention to the choice of a numerical method used to solve equation (20).

3 STOCHASTIC LLG EQUATION: THERMAL NOISE CORRELATIONS

3.1 Thermal fluctuations for a single magnetic moment

3.1.1 Introduction

As it was stated in Section 2, the 'standard' way to take into account the thermal fluctuations of the magnetization in micromagnetic simulations is the inclusion of the 'fluctuation field' $\mathbf{H}^{fl}$ into the basic equation (20), which we write out here for a single magnetic moment $\boldsymbol{\mu}$ once more to have it at hand:

$$\frac{\mathrm{d}\boldsymbol{\mu}}{\mathrm{d}t} = -\gamma\cdot\left[\boldsymbol{\mu}\times(\mathbf{H}^{det}+\mathbf{H}^{fl})\right] - \lambda\cdot\frac{\gamma}{\mu}\cdot\left[\boldsymbol{\mu}\times\left[\boldsymbol{\mu}\times(\mathbf{H}^{det}+\mathbf{H}^{fl})\right]\right] \tag{28}$$

Components of the this field $\mathbf{H}_i^{fl}$ are supposed to have δ correlation in space and time

$$\langle H_{\xi,i}^{fl}\rangle = 0 \;\langle H_{\xi,i}^{fl}(0)\cdot H_{\psi,j}^{fl}(t)\rangle = 2C\cdot\delta(t)\cdot\delta_{ij}\cdot\delta_{\xi\psi} \tag{29}$$

where i, j are the discretization cell (or magnetic moment) indices and $\xi, \psi = x, y, z$. The proportionality coefficient before the δ functions in (29) is the noise power C, which can be evaluated as (when the random field is present in both terms on the right-hand side of (20))

$$C = \frac{\lambda}{1+\lambda^2}\cdot\frac{kT}{\gamma\mu} = \frac{\lambda}{1+\lambda^2}\cdot\frac{kT}{\gamma M_S V_p} \tag{30}$$

In the last equality we have used the relation $\mu = M_S V_p$ between the particle magnetic moment μ, saturation magnetization of the particle material M_S and the particle volume V_p.

The question of main interest is whether the properties (29) and (30), introduced by Brown (1963b) for a single-domain particle – actually for a single magnetic moment surrounded by a thermal bath – would survive for a typical micromagnetic system, where complicate interactions between the magnetic moments of the finite elements used to discretize a continuous problem are present.

We start the discussion of this principal problem with the statement that it actually contains two separate question:

1. Whether the correlations between random field components *can be really treated as δ -functional ones* and
2. Whether *the noise power can be evaluated using the universal expression like* (30) which contains *only* the system temperature T, the gyromagnetic ratio γ, the damping constant λ and the magnitude of the cell magnetic moment $\mu = M_S \Delta V$, and thus does not depend on any interaction details and other features of the concrete system under study.

To answer these questions for a micromagnetic system, we first recall how the δ correlations (29) of the random noise are introduced for a single magnetic particle, how the power of this noise (30) can be obtained for this simplest case, and discuss a physical sense of the expression (30).

First of all, in case of a single particle (single magnetic moment) we are not interested in *spatial* correlation properties of the noise. The statement that temporal correlations of the random field components are δ functional is an *assumption* based explicitly on the properties of that physical component of a thermal bath which is responsible for the appearance of thermal fluctuations. The most common point of view is that thermal fluctuations are mainly due to the interactions with phonons. In this case, we are interested in the correlation time associated with typical phonons, which contribute to thermal bath fluctuations. If we study the properties of our system at room temperature, which is of the same order of magnitude as the Debye temperature of typical materials, then we are speaking about phonons with the wavelength about several interatomic distances; typical life time of such room-temperature phonons is about a picosecond or less, so for remagnetization processes on time scales much larger than that we can safely accept the temporal correlation function $\delta(t)$ in (29). We note in passing that for the description of the magnetization dynamics on a much shorter time scales the phenomenology (20) is not valid anyway, because the equilibrium between various subsystems of a magnetic body (electrons, phonons, magnons etc.) cannot be reached. We also point out that the logic presented above to justify the δ-functional character of temporal noise correlations fails for systems at low temperatures, where the decay time of the characteristic (long-wave) phonons may be more than several nanoseconds, especially in pure materials.

3.1.2 *Derivation of the relation between the noise power and system properties for a mechanical Brownian motion*

Let us now examine the derivation of the relation (30). Usually it is quoted as a consequence of a so-called fluctuation-dissipation theorem (see subsequent text), but in many cases it can be obtained in a much simpler way, which also make the physical sense of this relation more transparent. To illustrate this point, we start with the mechanical Brownian motion of a 'normal' free particle described by the Langevin equation

$$m\frac{\mathrm{d}^2 x}{\mathrm{d}t^2} = -\eta\frac{\mathrm{d}x}{\mathrm{d}t} + F^{\mathrm{fl}}(t) \tag{31}$$

where the first term on the right is the friction force and the second term represents the Langevin (fluctuating) force, which has by the assumptions outlined above zero-mean value and the correlation properties $\langle F^{\mathrm{fl}}(0)\cdot F^{\mathrm{fl}}(t)\rangle = 2C\cdot\delta(t)$. Introducing the particle velocity $v = \mathrm{d}x/\mathrm{d}t$, we obtain for v from the equation above a simple first-order differential equation

$$\frac{\mathrm{d}v}{\mathrm{d}t} + \frac{\eta}{m}v = \frac{1}{m}F^{\mathrm{fl}}(t) \tag{32}$$

which explicit solution

$$v(t) = v(0)e^{-\eta t/m} + \frac{1}{m}\int_0^t e^{-\eta(t-t')/m}F^{\mathrm{fl}}(t')\,\mathrm{d}t' \tag{33}$$

allows the straightforward evaluation of the mean-square velocity: writing the velocities for two different time moments $v(t_1)$ and $v(t_2)$ using (33), multiplying these quantities and taking the thermal average, we obtain the expression for the product $\langle v(t_1)v(t_2)\rangle$ which contains only the correlation function $\langle F^{\mathrm{fl}}(t_1)\cdot F^{\mathrm{fl}}(t_2)\rangle = 2C\cdot\delta(t_1 - t_2)$ (all other terms are zero because the velocity values are not correlated with the values of the random force). Putting $t_1 = t_2$ and using the basic property of the δ function, we finally obtain the desired result $\langle v^2\rangle = C/2\eta m$. On the other hand, in the *thermal equilibrium* the average kinetic energy of the particle is $\langle E_K\rangle = m\langle v^2\rangle/2 = kT/2$, so that $\langle v^2\rangle = kT/m$. Equating these two expressions for the mean square of the particle velocity, we obtain the desired result

$$C = \eta\cdot kT \tag{34}$$

which connects the noise power C with the friction coefficient η and system temperature T. Note that by derivation of this relation we have used only the fact that the system (particle) is in a thermodynamical equilibrium with the surrounding thermal bath.

For a particle which moves in an external potential and hence possesses the energy $V(x)$ the situation is more complicate, because no general analytical solution of the corresponding Langevin equation

$$\eta\frac{\mathrm{d}x}{\mathrm{d}t} = -\nabla V(x) + F^{\mathrm{fl}}(t) \tag{35}$$

is available in (35) we have neglected the inertial term for simplicity, which means that we are interested in times much larger than the velocity equilibration time $t_p = m/\eta$. In this situation, the relation between the noise power C and the system features can be established using another principal equation of the theory of stochastic processes – the FPE.

The FPE describes the temporal and spatial evolution of the probability density $w(x,t)$ which gives the probability $w(x,t)\cdot dx\cdot dt$ to find the particle inside the region $[x; x+dx]$ during the time interval $[t; t+dt]$. This equation can be derived in many ways; the most transparent general method to obtain the FPE starts from the so-called Chapman–Kolmogorov (also called *Smoluchovski*) equation. From a physical point of view, this latter equation simply states that the conditional probability $P(x_1,t_1|x_3,t_3)$ to find the particle at x_1 at the time t_1, *if* its position at the time t_3 was x_3, can be obtained by integrating the product of conditional probabilities for the transitions $(x_1,t_1)\to(x_2,t_2)$ and $(x_2,t_2)\to(x_3,t_3)$ over all intermediate particle positions x_2. The derivation of the FPE from the Chapman–Kolmogorov equation is conceptually very simple (see, e.g., Gardiner, 1997) and assumes only the existence of the limits

$$A(x,t) = \lim_{\Delta t\to 0}\frac{\langle x(t+\Delta t)-x(t)\rangle}{\Delta t}$$
$$B(x,t) = \frac{1}{2}\lim_{\Delta t\to 0}\frac{\langle (x(t+\Delta t)-x(t))^2\rangle}{\Delta t} \qquad (36)$$

The resulting FPE reads in a general case

$$\frac{\partial w(x,t)}{\partial t} = -\frac{\partial}{\partial x}[A(x,t)\cdot w(x,t)] + \frac{\partial^2}{\partial x^2}[B(x,t)\cdot w(x,t)] \qquad (37)$$

Here, the first term on the right describes the systematic particle *drift* due to the potential force $F_{pot}(x) = -\nabla V(x)$ and the second term is responsible for the particle *diffusion* due to thermal fluctuations. For each concrete system the limits (36) can be evaluated from the corresponding Langevin equation (Coffey, Kalmykov and Waldron, 2004) in conceptually the same manner as the mean square of the particle velocity was derived from (32). For the simple system described by the equation (35) the result is

$$A = -\nabla V(x)/\eta, \quad B(x) = Const = C/\eta^2 \qquad (38)$$

(C is the noise power from the correlation function $\langle F^{fl}(t_1)\cdot F^{fl}(t_2)\rangle = 2C\cdot\delta(t_1-t_2)$ of the random force) so that the FPE (37) has the form of a standard diffusion equation

$$\frac{\partial w(x,t)}{\partial t} = \frac{\partial}{\partial x}\left[\frac{1}{\eta}\frac{\partial V}{\partial x}\cdot w(x,t)\right] + \frac{C}{\eta^2}\cdot\frac{\partial^2 w(x,t)}{\partial x^2} \qquad (39)$$

which means that the noise power C is equal to the diffusion coefficient.

To establish now the required relation between the noise power and other system properties, we use the statement that in the equilibrium state (where the time derivative $\partial w/\partial t = 0$ the probability distribution function should be given by the (normalized) Boltzmann exponent $w(x) = N\exp(-V(x)/kT)$. Substitution of this expression into the right-hand side of the FPE (39) gives the equation, which is worth to be explicitly written out:

$$\frac{d^2V}{dx^2}\left(\eta - \frac{C}{kT}\right) - \frac{1}{kT}\cdot\left(\frac{dV}{dx}\right)^2\left(\eta - \frac{C}{kT}\right) = 0 \qquad (40)$$

The equation (40) should be satisfied for an arbitrary potential $V(x)$ which leads exactly to the same relation $C = \eta\cdot kT$ between the random noise power and system parameters as the result (34) for a free particle. Now we have proved that this relation *does not* depend on the concrete potential $V(x)$, and thus represent a very general statement. Again, the only physical assumption used to derive this formula was the statement that *the system is in a thermodynamical equilibrium*, so that the Boltzmann distribution for the probability density $w(x,t)$ could be used.

3.1.3 FPE and noise power evaluation for a single magnetic moment

The FPE can be derived for a single magnetic moment in the same way as in the preceding text for a mechanical particle. The resulting equation is, however, much more complicate due to the following reasons: (i) we deal here with a *rotational* diffusion and (ii) the precession term (which is the counterpart of the inertial term in mechanics) in the corresponding Langevin equation (20) cannot be neglected, because this would lead to a *qualitatively* incorrect description of the magnetization dynamics for the overwhelming majority of physically interesting systems.

The first derivation of the corresponding FPE was presented (up to our knowledge) by Brown (1963b), who used the 'physical' or 'intuitive' method, employing the continuity equation for the distribution density $w(\theta,\phi)$ of the magnetic moment directions. This equation relates the time derivative of $w(\theta,\phi)$ and its flux on the (θ,ϕ) sphere, whereby the diffusion term is added to the flux in a phenomenological way using the similarity with the equation describing the mechanical rotational diffusion. The rigorous derivation of this FPE, which uses the functional analysis methods can be found in the Appendix of Garanin (1997). Another derivation of the same FPE from the Langevin equation (20) which employs the relations (known from the general rules of stochastic calculus) between the coefficients of the Langevin

equation and corresponding terms from FPE is contained in Garcia-Palacios and Lazaro (1998). The structure of the resulting equation

$$\frac{\partial w(\mathbf{m},t)}{\partial t} = -\nabla_{\mathbf{m}}\Big\{\gamma[\mathbf{m}\times\mathbf{H}^{\text{eff}}]w - \gamma\cdot\lambda\cdot[\mathbf{m}\times[\mathbf{m}\times\mathbf{H}^{\text{eff}}]]w + D_{\text{rot}}[\mathbf{m}\times[\mathbf{m}\times\nabla_{\mathbf{m}}]]w\Big\} \tag{41}$$

is obviously inherited from the Langevin equation in the LLG form (20) which the FPE (41) has been derived from: the first term in the curved parenthesis describes the drift of the probability density due to the precession term in (20), the second term corresponds to the drift due to the damping torque and the third (diffusion) term also has the structure of the damping term in the original LLG. The operator $\nabla_{\mathbf{m}}$ acting on the vectors on the right-hand side of (41) means the divergence over the components of the vector $\mathbf{m}$, so that, for example, in Cartesian coordinates $\nabla_{\mathbf{m}}\mathbf{a} \equiv \sum_i \partial a_i/\partial m_i (i = x, y, z)$. The coefficient before the rotational diffusion term, expressed in terms of the quantities entering into the LLG equation (20), is

$$D_{\text{rot}} = \gamma^2(1+\lambda^2)\cdot C \tag{42}$$

where C is the noise power of the fluctuating field $\mathbf{H}^{\text{fl}}$.

The procedure for the calculation of the noise power using this FPE is fully analogous to that described in the preceding text for the mechanical translational diffusion. Namely, we substitute the equilibrium probability density $w(x) = N\exp(-V(\theta,\varphi)/kT)$ into the equation (41) with zero left-hand side ($\partial w/\partial t = 0$). Taking into account the effective field definition $\mathbf{H}^{\text{eff}} = -\partial V/\partial\mathbf{m}$ we arrive after a very tedious, but straightforward differentiation at the relation similar to (40), which in this case can be satisfied only if

$$D_{\text{rot}} = kT\cdot\frac{\gamma\lambda}{\mu} \tag{43}$$

Equating the two expression (42) and (43) for D_{rot}, we arrive at the final result which establish the relation (30) between the noise power C and the system parameters:

$$C = \frac{\lambda}{1+\lambda^2}\cdot\frac{kT}{\gamma\mu} = \frac{\lambda}{1+\lambda^2}\cdot\frac{kT}{\gamma M_{\text{S}} V_{\text{p}}} \tag{44}$$

As in the corresponding relation (34) for the mechanical translational Brownian motion, the noise power is proportional to the system temperature kT and to the friction constant λ. Also, fully analogous to the mechanical noise power (34), the value of C in (44) does *not* depend on the concrete potential $V(\theta,\phi)$ acting on the magnetic moment, which can be understood as a first hint that this result will remain unchanged for a system of *interacting* magnetic moments also. The appearance of the gyromagnetic ratio γ in the denominator is due to its presence as a common factor for both drift terms in the initial FPE (41), so that after the substitution of an equilibrium Boltzmann probability density and differentiation it appears in the equality (43). The factor $(1+\lambda^2)$ in the denominator reflects the special structure of the LLG (28), where the fluctuating field $\mathbf{H}^{\text{fl}}$ has been added *both* to the precession and dissipation terms. It is also possible to use an alternative form of this equation – with $\mathbf{H}^{\text{fl}}$ added to the precession term *only*, in which case the factor $(1+\lambda^2)$ in the relation (45) is absent (Garcia-Palacios and Lazaro, 1998).

One aspects of this relation deserve a special discussion, namely, the inverse proportionality of the noise power C to the total particle magnetic moment μ, or – taking into account that the saturation magnetization of the particle material M_{S} is constant – to the particle volume V_{p}. In other words, the noise power, or the dispersion of the fluctuation field $\sigma_{\text{fl}}^2 = \langle(\mathbf{H}^{\text{fl}})^2\rangle decreases$ linearly with the increasing particle volume. This dependence can be understood on an intuitive level in the following way. Let us consider a small magnetic particle consisting of N atoms with magnetic moments $\boldsymbol{\mu}_i$. For each atomic magnetic moment the equation of motion (we neglect damping to simplify the discussion) can be written as

$$\frac{\mathrm{d}\boldsymbol{\mu}_i}{\mathrm{d}t} = -\gamma\cdot\big[\boldsymbol{\mu}_i\times(\mathbf{H}^{\text{det}} + \mathbf{H}_i^{\text{fl}})\big] \tag{45}$$

Here, we have assumed that the particle is so small deterministic effective fields are approximately equal for all elementary moments. Thermal fluctuation field $\mathbf{H}_i^{\text{fl}}$ randomly varies from one atom to another. To obtain the equation of motion for the total particle magnetic moment $\boldsymbol{\mu}_{\text{tot}} = \sum_{i=1}^{N}\boldsymbol{\mu}_i$, we have to sum the equations (45) over all particle atoms:

$$\sum_i \frac{\mathrm{d}\boldsymbol{\mu}_i}{\mathrm{d}t} = \frac{\mathrm{d}\boldsymbol{\mu}_{\text{tot}}}{\mathrm{d}t} = -\gamma\cdot\sum_i\big[\boldsymbol{\mu}_i\times\mathbf{H}^{\text{det}}\big] - \gamma\cdot\sum_i\big[\boldsymbol{\mu}_i\times\mathbf{H}_i^{\text{fl}}\big] \tag{46}$$

Taking into account the independence of $\mathbf{H}^{\text{det}}$ on the elementary moment index, the first sum on right-hand side immediately transforms to $[\boldsymbol{\mu}_{\text{tot}}\times\mathbf{H}^{\text{det}}]$. Situation with the second (random field) term is more complicate, because $\mathbf{H}_i^{\text{fl}}$ is a random quantity. Using again the assumption that the particle is small enough to ensure that due to the exchange interaction atomic magnetic moments are nearly parallel, we

can write the elementary moment on the second sum as $\boldsymbol{\mu}_i = \boldsymbol{\mu}_{\text{tot}}/N$ and factor the i-independent total moment out of the sum. Then the equation (46) takes the desired form of the Langevin equation for the total moment

$$\begin{aligned}\frac{\mathrm{d}\boldsymbol{\mu}_{\text{tot}}}{\mathrm{d}t} &= -\gamma\cdot\left[\boldsymbol{\mu}_{\text{tot}}\times\mathbf{H}^{\text{det}}\right] - \gamma\cdot\left[\frac{\boldsymbol{\mu}_{\text{tot}}}{N}\times\sum_i \mathbf{H}_i^{\text{fl}}\right] \\ &= -\gamma\cdot\left[\boldsymbol{\mu}_{\text{tot}}\times(\mathbf{H}^{\text{det}}+\mathbf{H}_{\text{tot}}^{\text{fl}})\right] \end{aligned} \tag{47}$$

if we *define* the fluctuation field $\mathbf{H}_{\text{tot}}^{\text{fl}}$ acting on the total moment as

$$\mathbf{H}_{\text{tot}}^{\text{fl}} = \frac{1}{N}\sum_{i=1}^{N}\mathbf{H}_i^{\text{fl}} \tag{48}$$

The relation (48) between the total and elementary thermal fields means that the dispersion of the total fluctuation field σ_{tot}^2 can be evaluated as

$$\sigma_{\text{tot}}^2 = \frac{1}{N^2}\cdot\sum_{i=1}^{N}\sigma_i^2 = \frac{1}{N^2}\cdot N\sigma_{\text{at}}^2 = \frac{1}{N}\cdot\sigma_{\text{at}}^2 \tag{49}$$

where we have used the assumption that all fluctuation fields are random *independent* variables with *equal* dispersions $\sigma_i^2 = \sigma_{\text{at}}^2 \forall i = 1,\ldots,N$. The dispersion of the fluctuating field on a single atom σ_{at}^2 does not depend on the system volume, so the equality (49) explains why the dispersion of the total fluctuation field $\mathbf{H}_{\text{tot}}^{\text{fl}}$ which appears in the LLG equation (28) is inversely proportional to the number of elementary magnetic moments in the system, that is, to the system volume.

The relation (30) can also be understood as the statement that with increasing particle volume the importance of thermal fluctuation decreases, in accordance with an intuitive picture of Brownian motion.

Already here we would like to point out, that the increase of the noise power (30) with the decreasing particle volume just discussed has serious consequences for numerical micromagnetic simulations. The random field $\mathbf{H}^{\text{fl}}$ present in the LLG equation of motion is the *main factor*, which limits the simulation time step when an algorithm with the built-in adaptive step-size control is used (which should always be the case). The reason is quite simple: fluctuation field, being a random process, is *not* a smooth function of time and space, which naturally strongly diminishes the efficiency of any numerical integrator. It can be even shown that the order of a numerical integration scheme applied to a stochastic equation is usually a *square root* of the order of the same scheme applied to an ordinary differential equation (Kloeden and Platen, 1995). Hence, the growth of the mean fluctuation field amplitude with the decreasing discretization cell volume (entering into (30) instead of the particle volume) enforced by the relation (30) leads to the *decrease* of the integration time step in micromagnetic simulations on finer grids, which should be always kept in mind by estimating simulation time basing on the data obtained on coarser grids.

3.2 Noise correlations for an interacting system: general theory

The most interesting question concerning the random field concept used to simulate magnetization dynamics under the influence of thermal fluctuations is the following: can the random field components on different spatial locations (different discretization cells) still be considered as *independent* (uncorrelated) random variables, despite the strong interactions between magnetic moments? The hand-waving argument that this interaction should not influence the correlation properties of random fields, because all the interaction kinds are already included in the deterministic part of the effective field $\mathbf{H}^{\text{det}}$ cannot be considered as fully satisfactory. For example, in a system of interacting particles moving in a viscous media, random forces acting on different particles should be treated as correlated ones to ensure correct statistical properties of such systems (see, e.g., Ermak and McCammon, 1978). For this reason, we have to resort to a general theory which allows to evaluate noise correlations in interacting many-particle systems in a rigorous way.

This theory operates with the so-called *thermodynamically* conjugate variables (Landau and Lifshitz, 1980) (which should not be confused with the conjugate variables known from quantum mechanics) and we repeat here briefly the major points of this concept to make this review self-contained. In short, we consider a system which state is fully characterized by a set of N variables $\{\mathbf{x} = x_1, x_2, \ldots, x_N\}$ chosen so that their values at equilibrium are zero: $\mathbf{x}_0 = 0$. If the system fluctuates, that is, the values of system variables deviate from these equilibrium values and change with time, then the time derivatives $\mathrm{d}x_i/\mathrm{d}t$ can be expressed as functions of instantaneous values of $\mathbf{x}(t)$ as $\dot{x}_i = f_i(\mathbf{x})$. If the deviations from the equilibrium are small, we can expand the functions f_i around $\mathbf{x} = 0$ and maintain only the first order terms in small quantities x_i (at equilibrium in the absence of thermal fluctuations $\dot{x}_i = 0$), obtaining a system of first-order differential equations describing the relaxation of the system variables to their equilibrium values as

$$\frac{\mathrm{d}x_i}{\mathrm{d}t} = \sum_k \Lambda_{ik}x_k, \text{ where } \Lambda_{ik} = \frac{\partial f_i}{\partial x_k} \tag{50}$$

To account for thermal fluctuations, we introduce into (50) random forces $\xi_i(t)$ which are assumed to be responsible for

the fluctuations of the system variables:

$$\frac{\mathrm{d}x_i(t)}{\mathrm{d}t} = \sum_k \Lambda_{ik} x_k(t) + \xi_i(t) \tag{51}$$

Assuming that the correlation times of these forces are much less than all characteristic system relaxation times, we can write the correlation functions $K_{\mathrm{ik}}(t)$ of the random forces as $\langle \xi_i(0)\xi_k(t)\rangle = 2C_{ik}\cdot\delta(t)$. The problem is to calculate the correlation coefficients C_{ik} in order to obtain from the system (51) correct statistical properties of the system fluctuations.

It turns out that the correlation matrix C_{ik} can be expressed in the simplest way when the system (51) is rewritten in terms of *thermodynamically conjugate variables* $\{\mathbf{X} = X_1, X_2, \ldots, X_N\}$ defined as derivatives of the system entropy S over the 'initial' variables $\mathbf{x}$: $X_i = -\partial S/\partial x_i$. Near the equilibrium the difference between the system entropy S and its maximum (equilibrium) value $S_{\max}$ can be expanded over small deviations x_i: $S - S_{\max} = -\frac{1}{2}\sum_{i,k}\beta_{ik}x_i x_k$, so that thermodynamically conjugate variables X_i are linear functions of $\{\mathbf{x}\}$:

$$X_i = -\frac{\partial S}{\partial x_i} = \beta_{ik}x_k, \quad \text{or} \quad \mathbf{X} = \hat{\boldsymbol{\beta}}\mathbf{x} \tag{52}$$

where $\hat{\beta} = \{\beta_{ik}\}$. Substituting $\mathbf{x} = \hat{\beta}^{-1}\mathbf{X}$ into the sum on the right-hand side of (51), we obtain the stochastic equations for thermal fluctuations of our system near its equilibrium state in the form

$$\begin{aligned}\frac{\mathrm{d}\mathbf{x}}{\mathrm{d}t} &= -\hat{\Lambda}\mathbf{x} + \boldsymbol{\xi} = -(\hat{\Lambda}\cdot\hat{\beta}^{-1})\mathbf{X} + \boldsymbol{\xi} \\ &= -\hat{\Gamma}\cdot\mathbf{X} + \boldsymbol{\xi}, \ \text{or} \end{aligned} \tag{53}$$

$$\frac{\mathrm{d}x_i}{\mathrm{d}t} = -\sum_k \Gamma_{ik}X_k + \xi_i \tag{54}$$

with the matrix $\hat{\Gamma} = \{\Gamma_{ik}\}$ defined as $\hat{\Gamma} = \hat{\Lambda}\hat{\beta}^{-1}$.

The usefulness of these transformations becomes apparent when we express the correlation coefficients of the random forces C_{ik} in terms of matrices $\hat{\Lambda}$, $\hat{\Gamma}$, and $\hat{\beta}$. Corresponding derivation for the many-variable case is quite tedious, so we restrict ourselves to the system characterized by a single variable x and its conjugate $X = -\partial S/\partial x = \beta x$. Such a system is described by the relaxation equation

$$\frac{\mathrm{d}x}{\mathrm{d}t} = -\Lambda x(t) + \xi(t) \tag{55}$$

The temporal correlation function of x defined as $\varphi(t - t') = \langle x(t)x(t')\rangle$ may depend on the difference $t - t'$ only (stationary fluctuations) and can be easily found multiplying (55) by $x(t')$, performing statistical averaging $\langle\cdots\rangle$ and taking into account that the values of $x(t')$ and $\xi(t)$ are uncorrelated. The result is $\varphi(t) = \langle x^2\rangle\exp(-\lambda|t|) = (1/\beta)\exp(-\Lambda|t|)$, where the mean square of x was evaluated from its probability distribution $w(x)\ \exp\{S(x)\}$ using the above mentioned quadratic expansion $S - S_{\max} = -(\beta/2)x^2$ near its maximum.

Denoting the Fourier transform (FT) of $x(t)$ as $\tilde{x}(\omega)$, we rewrite the definition of $\phi(t)$ as

$$\begin{aligned}\varphi(t - t') &= \langle x(t)x(t')\rangle \\ &= \frac{1}{(2\pi)^2}\iint \langle\tilde{x}(\omega)\tilde{x}(\omega')\rangle e^{-i(\omega t + \omega' t')}\mathrm{d}\omega\mathrm{d}\omega' \end{aligned} \tag{56}$$

The statement that the CF $\varphi(t - t')$ may depend on the time *difference* only (see above) requires that the FT product in (56) has the form $\langle\tilde{x}(\omega)\tilde{x}(\omega')\rangle = 2\pi\cdot P_x(\omega)\cdot\delta(\omega + \omega')$. Here $P_x(\omega)$ is the spectral power of $x(t)$ and is, according to (56), the Fourier transform of its correlation function $\varphi(t) = \langle x(t)x(0)\rangle$ (Wiener–Khinchin theorem). For $\varphi(t) = (1/\beta)\exp(-\Lambda|t|)$ the simple integration gives $P_x(\omega) = 2\Lambda/\beta(\omega^2 + \Lambda^2)$.

Now we apply the same method to calculate the correlation function of the random force. Expressing $\xi(t)$ via its FT $\tilde{\xi}(\omega)$, (due to (55) we have $\tilde{\xi}(\omega) = (\Lambda - i\omega)\tilde{x}(\omega)$), and using the definition $K(t - t') = \langle\xi(t)\xi(t')\rangle$, we obtain

$$\begin{aligned}K_\xi(t - t') &= \frac{1}{(2\pi)^2}\iint \langle\tilde{\xi}(\omega)\tilde{\xi}(\omega')\rangle e^{-i(\omega t + \omega' t')}\mathrm{d}\omega\mathrm{d}\omega' \\ &= \frac{1}{(2\pi)^2}\iint (\lambda - i\omega)(\lambda - i\omega')\langle\tilde{x}(\omega) \\ &\quad \times \tilde{x}(\omega')\rangle e^{-i(\omega t + \omega' t')}\mathrm{d}\omega\mathrm{d}\omega' \\ &= \frac{1}{2\pi}\int (\lambda^2 + \omega^2)P_x(\omega)e^{-i\omega t}\mathrm{d}\omega \end{aligned} \tag{57}$$

where by the last transformation the property $\langle\tilde{x}(\omega)\tilde{x}(\omega')\rangle = 2\pi\cdot P_x(\omega)\cdot\delta(\omega + \omega')$ was used. Equation (57) means that the spectral power of the random noise fluctuations $P_\xi(\omega)$ is related to the spectral power $P_x(\omega)$ of the x-fluctuations via $P_\xi(\omega) = (\omega^2 + \Lambda^2)P_x(\omega)$. Hence the random force spectrum $P_\xi(\omega) = 2\Lambda/\beta$ is frequency independent, as it should be for the quantity with the CF $K(t) = \langle\xi(t)\xi(0)\rangle = (2\lambda/\beta)\cdot\delta(t)$.

In terms of the conjugate variable the relaxation equation for a single-variable system reads $\mathrm{d}x/\mathrm{d}t = -\Gamma\cdot X(t) + \xi(t)$, so that $\tilde{\xi}(\omega) = \Gamma\cdot\tilde{X}(\omega) - i\omega\tilde{x}(\omega)$. The procedure identical to (57) results in the relation $P_\xi(\omega) = \omega^2 P_x(\omega) + \Gamma^2 P_X(\omega)$ between the spectral powers of the random noise, $x(t)$ and its conjugate $X(t)$. The spectrum $P_X(\omega) = 2\beta\Lambda/(\omega^2 + \Lambda^2)$ can be found from the equation $\mathrm{d}X/\mathrm{d}t = -\Lambda X(t) + \xi(t)/\beta$ for $X(t)$ (it follows from (55) and $X = \beta x$). Combining $P_x(\omega)$

and $P_X(\omega)$ into the noise spectrum $P_\xi(\omega)$ and using the relation $\Gamma = \Lambda/\beta$ (analogue of matrix relation $\hat{\Gamma} = \hat{\Lambda}\hat{\beta}^{-1}$), we obtain $P_\xi(\omega) = 2\Gamma$, so that $\langle \xi(t)\xi(0)\rangle = 2\Gamma\cdot\delta(t)$.

The whole exercise presented in the preceding text makes real sense only for the many-variable case (random noise correlations as a function of Γ can be obtained for a single-variable system immediately from the equation $\mathrm{d}x/\mathrm{d}t = -\Lambda x(t) + \xi(t)$ and the relation $\Gamma = \Lambda/\beta$). For a system described by *many* variables, however, we need a set of CF's $\varphi_{ik}(t) = \langle x_i(t)x_k(0)\rangle$ and their FT's $P_{ik}^{(x)}(\omega)$. The *system* of differential equations for these CF's $\mathrm{d}\varphi_{ik}(t)/\mathrm{d}t = \sum_l \lambda_{il}\varphi_{ik}(t)$ is transformed into the system of linear algebraic equations for $P_{ik}^{(x)}(\omega)$. Solving this and analogous system for spectral powers $P_{ik}^{(X)}(\omega)$ of the conjugates, using of the relations between the FT's of noise components, initial and conjugate variables $\tilde{\xi}_i(\omega) = \sum_k \Gamma_{ik}\tilde{X}_k(\omega) - i\omega\tilde{x}_i(\omega)$ (which follows from $\mathrm{d}x_i/\mathrm{d}t = -\sum_k \Gamma_{ik}X_k(t) + \xi_i(t)$) we obtain the result $P_{ik}^{(\xi)}(\omega) = \Gamma_{ik} + \Gamma_{ki}$. Hence the required correlation properties of the random noise components are

$$\langle \xi_i(t)\xi_k(0)\rangle = (\Gamma_{ik} + \Gamma_{ki})\cdot\delta(t) \tag{58}$$

which is a direct generalization of the single-variable relation $\langle \xi(t)\xi(0)\rangle = 2\Gamma\cdot\delta(t)$.

The simplicity of the relation (58) which gives the correlation coefficients of the random noise matrix directly in terms of the elements of $\hat{\Gamma}$-matrix is the reason to use equation (54) where the stochastic motion of a system near its equilibrium state is described using the *conjugate* variables $\{\mathbf{X}\}$.

The relation (58) can be used to derive correlation properties of the random noise in a very important particular case, which includes also micromagnetic models. To do this, we begin with the important remark that our starting point, namely the relaxation equations (50) for the system variables are *not* the equation of motion derived from some physical formalism (like Newton laws or Lagrange mechanics), but are merely a direct consequence of the mathematical assumption that the relaxation rates $\mathrm{d}x_i/\mathrm{d}t$ of the system variables near its equilibrium state can be expanded in terms of small deviations $\{\mathbf{x}\}$ from their equilibrium values. Equations (50) maintain only the first-order terms of this expansion.

For many physical system the expansion coefficients Γ_{ik} may be given in a more specific form, which allows further progress by evaluating the correlation matrix $\langle \xi_i\xi_k\rangle = (\Gamma_{ik} + \Gamma_{ki})$. First we note, that the entropy change by the system deviation from its equilibrium state may be expressed via the *minimal work* $A_{\min}$ required to transfer the system from equilibrium into the state with the entropy S as $S - S_{\max} = -A_{\min}/kT$ (see, e.g., Landau and Lifshitz, 1980). This allows us to calculate conjugate variables as derivatives of this work: $X_i = -\partial S/\partial x_i = (1/kT)\cdot(\partial A_{\min}/\partial x_i)$.

Further, for a wide class of physical systems this minimal work $A_{\min}$ is equal to the energy difference $E - E_0$ between the system energy in the equilibrium state E_0 and in the given state E, which can be also expanded near the equilibrium state as

$$E - E_0 = \frac{1}{2} + \sum_{i.k} a_{ik}x_i x_k \tag{59}$$

so that

$$X_i = \frac{1}{kT}\frac{\partial A_{\min}}{\partial x_i} = \frac{1}{kT}\frac{\partial E}{\partial x_i} = \frac{1}{kT}\sum_k a_{ik}x_k \tag{60}$$

which means that the matrix $\{\beta_{ik}\}$ from the definition (52) in this case is $\hat{\beta} = \hat{a}/kT$.

If the deterministic motion of the system can be described by the Newtonian equations with the inertial term neglected, that is, in the form $\eta_i\cdot\mathrm{d}x_i/\mathrm{d}t = F_i$, then, evaluating the forces as $F_i = -\partial E/\partial x_i = -\sum_k a_{ik}x_k$, introducing particle mobilities as inverses of the corresponding friction coefficients $\kappa_i = 1/\eta_i$, and adding random forces to the right-hand side of the equation of motions, we obtain these equations in the form

$$\frac{\mathrm{d}x_i}{\mathrm{d}t} = -\kappa_i\sum_k a_{ik}x_k + \xi_i \tag{61}$$

where the random forces ξ_i are related to the forces F_i used in (35) via $\xi_i = F_i/\kappa_i$. Comparing this system to the relaxation equations (51), we find that in this case $\hat{\Gamma} = \hat{\kappa}_{\mathrm{diag}}\hat{a}$, where the diagonal matrix $\hat{\kappa}_{\mathrm{diag}}$ contains mobilities κ_i on its main diagonal. Substituting $\hat{\Gamma} = \hat{\kappa}_{\mathrm{diag}}\hat{a}$ and $\hat{\beta} = \hat{a}/kT$ into the definition of the matrix $\hat{\Gamma} = \hat{\Lambda}\hat{\beta}^{-1}$, we arrive at the important result

$$\hat{\Gamma} = kT\cdot\hat{\kappa}_{\mathrm{diag}} \tag{62}$$

This means that for a system where (i) the minimal work required to bring it out of the equilibrium is equal to the corresponding energy change and (ii) the relaxation of the system coordinates can be expressed via the damped equations of motion, the correlation matrix of random forces acting on different variables

$$\begin{aligned}\langle \xi_i(t)\xi_k(0)\rangle &= (\Gamma_{ik} + \Gamma_{ki})\cdot\delta(t)\\ &= 2\kappa_i\cdot kT\cdot\delta_{ik}\cdot\delta(t)\end{aligned} \tag{63}$$

is *diagonal*. This property is *independent* on the specific expression of the interaction energy $E\{\mathbf{x}\}$ between the particles, which means that for such a system random noise components are uncorrelated despite the presence of an interparticle interaction.

3.3 Noise correlations for an interacting system: application to micromagnetic simulations

Using the formalism developed above, we shall rigorously demonstrate in this subsection that *physical* correlations between the random fields on *different* cells or between the random field components on *one and the same* cell are absent.

The formalism from the previous subsection may be applied directly to micromagnetic Langevin dynamics simulations of magnetization fluctuations in a thermodynamic equilibrium. Although the situation in micromagnetics is slightly more complicate than for systems discussed in Section 3.2 (due to the presence of a *precessional* term), a complete description of random field correlation properties is nevertheless possible.

For a micromagnetic system the variables $\{\mathbf{x}\}$, which determine its state are the magnetization projection. Here we consider a system which is already discretized into finite elements (cells) and denote the projections of the magnetization inside the i-th cell as $M_i^\alpha, \alpha = x, y, z$. The most important step now is the establishing of the corresponding conjugate variables. Comparing the definition of the deterministic effective field

$$\mathbf{H}_i^{\text{det}} = -\frac{1}{\Delta V_i}\frac{\partial E}{\partial \mathbf{M}_i}, \text{ or}$$
$$H_{i,\alpha}^{\text{det}} = -\frac{1}{\Delta V_i}\frac{\partial E}{\partial M_i^\alpha}(\alpha = x, y, z) \tag{64}$$

appearing in the LLG equation for a discretized system

$$\frac{\mathrm{d}\mathbf{M}_i}{\mathrm{d}t} = -\gamma\cdot\Big[\mathbf{M}_i \times (\mathbf{H}_i^{\text{det}} + \mathbf{H}_i^{\text{fl}})\Big] - \lambda\cdot\frac{\gamma}{M_{\text{S}}}\cdot\Big[\mathbf{M}_i \times \Big[\mathbf{M}_i \times (\mathbf{H}_i^{\text{det}} + \mathbf{H}_i^{\text{fl}})\Big]\Big] \tag{65}$$

with the definition (60) of the conjugate variables $X_i = (1/kT)(\partial E/\partial x_i)$, we immediately see that the variable X_i^α conjugate to the projection M_i^α is simply proportional to the corresponding effective field projection:

$$X_i^\alpha = -\frac{\Delta V_i}{kT}\cdot H_{i,\alpha}^{\text{det}} \tag{66}$$

The direct consequence of this proportionality is the absence of correlations between the random field projection on *different* discretization cells, because in the LLG equation of motion for the magnetization of the i-th cell only the effective field projections *for the same cell* (and hence – conjugate variables with the same index i) do appear. This means that the matrix elements $\Gamma_{ik}^{\alpha\beta}$ from the system (54) with different cell indices $i \neq k$ are automatically zero, ensuring the absence of intercell correlations according to (58).

To find out, whether any correlations between the random field components on *one and the same* cell do exist, some technical work should be done. To simplify the treatment, we assign to each cell its own coordinate system with the $0z$-axis parallel to the equilibrium direction of the cell moment. The quadratic energy expansion around the equilibrium magnetization state

$$E - E_0 = \frac{1}{2}\sum_{i,j}\sum_{\alpha,\beta=x,y} a_{ik}\cdot\Delta M_i^\alpha \Delta M_j^\beta \tag{67}$$

will then include small deviations $\Delta M_i^\alpha \ll M_i^z \approx M_{\text{S}}$ (from zero) of the x and y magnetization components only, because the magnitude of the cell magnetic moment should be conserved. The deterministic effective field evaluated according to (64) will have on each cell also only x and y components $H_i^{x(y)}$ which will be of same order of magnitude as ΔM_i^α. Writing the LLG equations of motion (65) for ΔM_i^x and ΔM_i^y, neglecting the terms $\Delta M_i^{x(y)}\cdot H_{i,z}^{\text{fl}}$ which are small compared to $M_i^z\cdot H_{i,x(y)}^{\text{fl}}$ (because $\Delta M_i^\alpha \ll M_i^z$) and linearizing the resulted equations with respect to small deviations $\Delta M_i^x \equiv M_i^x$ and $\Delta M_i^y \equiv M_i^y$, we obtain the system

$$\frac{1}{\gamma M_{\text{S}}}\frac{\mathrm{d}M_i^x}{\mathrm{d}t} = +(H_{i,\text{det}}^y + H_{i,\text{fl}}^y) + \lambda(H_{i,\text{det}}^x + H_{i,\text{fl}}^x) \tag{68}$$

$$\frac{1}{\gamma M_{\text{S}}}\frac{\mathrm{d}M_i^y}{\mathrm{d}t} = -(H_{i,\text{det}}^x + H_{i,\text{fl}}^x) + \lambda(H_{i,\text{det}}^y + H_{i,\text{fl}}^y) \tag{69}$$

It is evident from these equations that the coefficients $\Gamma_{ik}^{\alpha\beta}$ for $\alpha \neq \beta$ obey the relation $\Gamma_{ii}^{xy} = -\Gamma_{ii}^{yx}$, so that the cross-correlation coefficients of the fluctuation field projections on the given cell are identically zero: $C_{ii}^{xy} = C_{ii}^{yx} \sim (\Gamma_{ii}^{xy} + \Gamma_{ii}^{yx}) = 0$. This property, being obtained in our specific coordinate system, should remain the same in any other coordinates due to the space isotropy. *Hence there are no physical correlations neither between the random fields on different cells nor between the random field components on one and the same cell*. This result was obtained also in Chubykalo *et al*. (2003) with a somewhat more complicated method.

Note that this statement does not apply to artificial (having nonphysical nature) correlations between the random fields on different cells that appear due to the finite-element discretization of an initially continuous problem. This topic is discussed in the next subsection.

* * *

A very interesting theme is the discussion of the correlation properties of the random thermal fields in micromagnetics

from a point of view of the fluctuation-dissipation theorem (FDT). Due to the space limitations we preferred not to include this topic into the current review, because it requires a careful and detailed discussion supplemented by a substantial amount of the readers theoretical knowledge. A very transparent and clear discussion of this topic at a high scientific level can be found in Smith (2001).

4 DISCRETIZATION EFFECTS IN DYNAMIC MICROMAGNETIC SIMULATION

4.1 Discretization effects for $T = 0$

In this subsection, we discuss the influence of a finite-element representation of the continuous micromagnetic problem (discretization) on the magnetization dynamics observed in numerical simulations performed *without* taking into account thermal fluctuations, that is, for $T = 0$.

To demonstrate the importance of the discretization effects we have chosen the following problem: we study the switching dynamics of a nanoelement with lateral sizes $L_x \times L_z = 400 \times 600\,\text{nm}$, thickness $h = 5\,\text{nm}$ (our $0xz$-plane coincides with the element plane), $M_S = 1000\,\text{G}$ and exchange stiffness $A = 10^{-6}\,\text{erg cm}^{-1}$. To simplify our task, we have set the magnetocrystalline anisotropy to zero. The switching of this element is simulated integrating the LLG equation (1) using an optimized Bulirsch–Stoer algorithm with the adaptive step-size control. We start from the S-type remanent state applying at $t = 0$ the external field $\mathbf{H} = H_z\mathbf{e}_z$ with $H_z = -200\,\text{Oe}$; this field is well beyond the corresponding quasistatic switching field $H_{sw} \approx -80\,\text{Oe}$. To study the discretization effects *s*imulations were done for five sequentially refined grids ($N_x \times N_z = 40 \times 60, 60 \times 90, 80 \times 120, 120 \times 180, 200 \times 300$) with the same (1:1) aspect ratio of the grid cell.

The switching process for the most interesting low damping case $\lambda = 0.01$ is shown in Figure 1(a) (grid $N_x \times N_z = 120 \times 180$): it starts with the reversal of closure domains near the short element borders, proceeds via the reversal of the central domain and is completed by the 'flip' of narrow domains near the long sides.

To emphasize the importance of the discretization effects we have compared results for several grids listed above. In Figure 1(b) we present corresponding $m_x(t)$ dependencies, because in our geometry the influence of the discretization effects can be most clearly seen on this projection. It can be clearly seen that the remagnetization curves do *not* converge to any limiting curve up to the finest grid $N_x \times N_z = 200 \times 300$. The effect is even *qualitative*, as it can be seen from the comparison of final states (m_x-gray-scale maps on the right in Figure 1(b)) for all discretizations $N_x \times N_z \leq 120 \times 180$ and for $N_x \times N_z = 200 \times 300$.

This discrepancy can not be attributed to an insufficient discretization of the interaction (energy) terms, because already for a moderate grid $N_x \times N_z = 80 \times 120$ the cell sizes $\Delta_x = \Delta_z = 5\,\text{nm}$ are smaller than our characteristic micromagnetic length $l_{\text{dem}} = (A/M_S^2)^{1/2} = 10\,\text{nm}$. We have also verified starting from the grid $N_x \times N_z = 60 \times 90$ quasistatic hysteresis loops did not change when the grid was refined further.

The reason for a significant modification of the switching process by the grid refinement is a strong influence

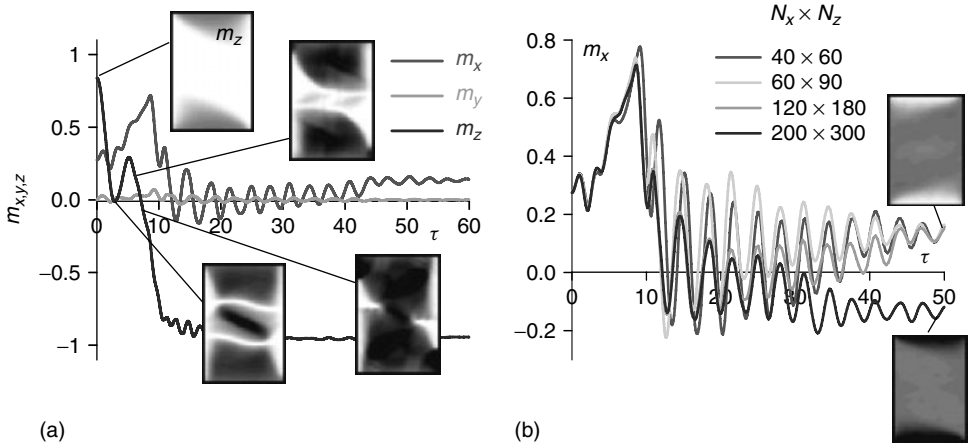

Figure 1. Switching of a thin 'soft' magnetic element ($400 \times 600 \times 5\,\text{nm}$) with a *low* damping ($\lambda = 0.01$) in a field $H_z = -200\,\text{Oe}$ starting from the S-type remanent state: (a) time-dependencies of all magnetization projections for the discretization $N_x \times N_z = 120 \times 180$($m_z$-grey-scale maps for several times $\tau = t\gamma M_S$ are shown). (b) m_x time dependencies simulated using various grids as shown in the legend. (Reproduced from D.V. Berkov *et al*., 2002. © 2002 with permission from IEEE.)

of magnetic excitations with a short wavelength. For the static case, it is sufficient to discretize the system using the mesh size somewhat smaller than the characteristic (exchange or demagnetizing) magnetic length of the material. For dynamics it is, generally speaking, not true. Even if the mesh is fine enough to represent all the features of the starting magnetization state, during the remagnetization process magnons with the wavelengths shorter than the grid cell size may play an important role, so that magnons with decreasing wavelengths appear when the remagnetization proceeds. As soon as the grid is unable to support these magnons, simulations became inadequate (Berkov, 2002a). This means that in such situations *dynamical* simulations on a given lattice are valid up to some *maximal* time duration.

The problem emphasized in this subsection requires further thorough investigation, because recently the so-called spin-injection driven magnetization dynamics was predicted theoretically and discovered experimentally (see the review of Miltat, Albuquerque and Thiaville, 2001 in this Volume). It has been shown that when the magnetization dynamics is excited by a spin polarized current, both (i) large deviations of the magnetization from its equilibrium position and (ii) quasichaotic magnetization dynamics (where spatial variations of the magnetization are very fast) are possible and even represent quite common features of corresponding remagnetization processes. This rapidly developing topic with potentially very rich applications makes the study of numerical artifacts due to the interplay of the discretization grid with short-wavelength magnons really important.

For systems with *larger* dissipation the effect demonstrated above may be absent due to a much smaller decay times of the short-wave magnons (so that they do not play any significant role by switching).

4.2 Influence of the discretization on the random field correlations

We proceed with the consideration of discretization effects on the magnetization dynamics simulated at finite temperatures, that is, with the fluctuation field $\mathbf{H}^{\mathrm{fl}}(\mathbf{r}, t)$ included into the LLG equation. The standard assumption (29) that this field is δ correlated in space and time may become invalid due to the following effect: as pointed above, by discretizing a continuous magnetic film we exclude all magnons with the wavelength smaller than the grid cell size $\Delta = \min(\Delta x, \Delta z)$. However, these magnons can still have a mean free path *much larger* than the grid cell size, thus causing substantial correlations especially of the exchange fields on neighboring cells. Although these excitations cannot be included into simulations on the given grid explicitly, it is possible to take them into account as an additional contribution to the fluctuation field $\mathbf{H}^{\mathrm{fl}}$ with the corresponding correlation properties.

To compute the correlation function (CF) of the effective field produced by such short-wave magnons, we have first performed simulations (with the white noise only) solving LLG equations at the grid which was finer than the 'actual' grid intended to be used for final simulations. Then from the total effective field produced at this fine grid all contributions with the wavelength *larger* than the cell sizes of the 'actual' grid Δ were cut out, so that only magnons with short wavelengths $\lambda_{\mathrm{mag}} \leq \Delta$ remained. Afterwards magnetic field generated by these short-wave magnons was calculated and averaged over all subcells inside the given cell of the actual simulation grid. Finally, the correlation properties of *this averaged field* were evaluated (Berkov and Gorn, 2004).

The resulting CF has a quite complicated form both in space (Figure2a) and time (Figure 2b) and can be roughly described as exponentially decaying oscillations. Both the

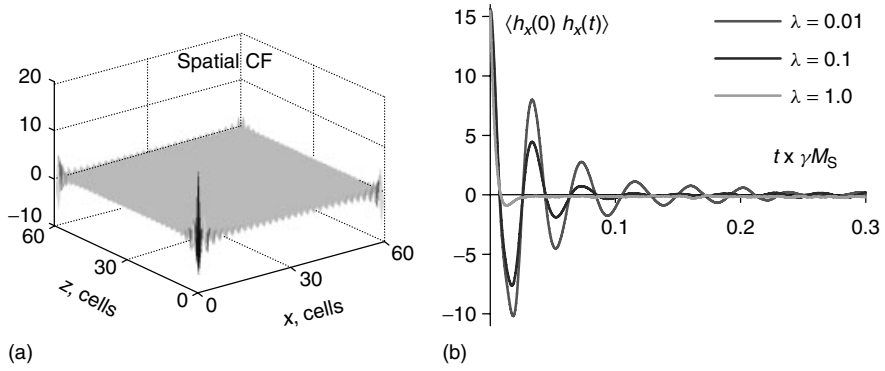

Figure 2. Correlation functions (CF) of the x component of the random field $\mathbf{H}^{\mathrm{fl}}$ resulting from the short-wave magnons. (a) 2D spatial CF, (b) Temporal CF on one and the same cell for various dissipation constants λ. (Reproduced from Berkov *et al*., 2004, with permission from Elsevier. © 2004.)

time and space oscillation periods are determined by the corresponding properties of the magnons with the shortest wavelength available for the 'actual' grid. The *space* decay length depends mainly on the 'quasistatic' magnetic system parameters like the saturation magnetization and exchange constant, whereas the decay *time* is determined by the damping λ.

To take into account the influence of the short-wave magnons which are cut off by the given grid, one should, strictly speaking, perform simulations on this grid by solving the SDE system (20) with both the standard white noise term and an additional colored noise with correlations imposed by *the field of these short-wave magnons*. For this purpose it is necessary to implement an algorithm, which could generate a Gaussian random noise with any given correlation function.

Several methods for generation of such a noise are available. Matrix methods (James, 1980) can generate random sequences with arbitrary given CF, but are very time and storage consuming. Linear Langevin equation (Garcia-Ojalvo and Sancho, 1994) or the so-called 'physical' methods (simulation of a simplified system without long-range interactions) are fast, but can generate only noise with monotonously or regularly oscillating exponentially decreasing CFs. These methods may be in principle applied to micromagnetic systems, because correlations caused by the short-wave magnons are mostly oscillating and exponentially decreasing.

However, correlation functions like those shown above still exhibit significant irregularities, which cannot be reproduced by 'physical' method. In this case, some version of a spectral method (Romero and Sancho, 1999) should be used, because this method can generate arbitrarily correlated random numbers. The method is based on the usage of the temporal and spatial FT of the required correlation function which after the multiplication with the so-called anticorrelated (in the Fourier space) random numbers gives the Fourier image of the random number field with requested correlations. Their inverse FT provides the requested random numbers themselves (Romero and Sancho, 1999). The important disadvantage of the method is that the complete correlation matrix should be stored (for a spatially 2D system our the dimension of the this matrix would be $N_x \times N_z \times L_t$, where L_t is the number of time steps), requiring large memory resources. For this reason, in most cases the usage of so-called 'external storage' of the Fourier transform is unavoidable (Press, Teukolsky, Vetterling and Flannery, 1992).

4.3 Discretization and the density of magnon states

Finite-element discretization of a micromagnetic system *qualitatively* affects the spectral power its thermal excitations, so this question should be addressed here in detail. To present the main point as transparent as possible, we consider a simplest model: a square region of an extended thin film (periodic boundary conditions are assumed) in an external field perpendicular to the film plane and neglect anisotropy and magnetodipolar interactions.

A spectrum of *equilibrium* thermal magnetic excitations can be efficiently computed using the Langevin dynamics (Berkov and Gorn, 2005). Starting from the saturated state along the external field we integrate the SDEs (20) till the total energy does not change systematically with time (equilibrium is reached). From this time moment we save the trajectories of every cell magnetization during a sufficiently long time (which depends on the desired accuracy and

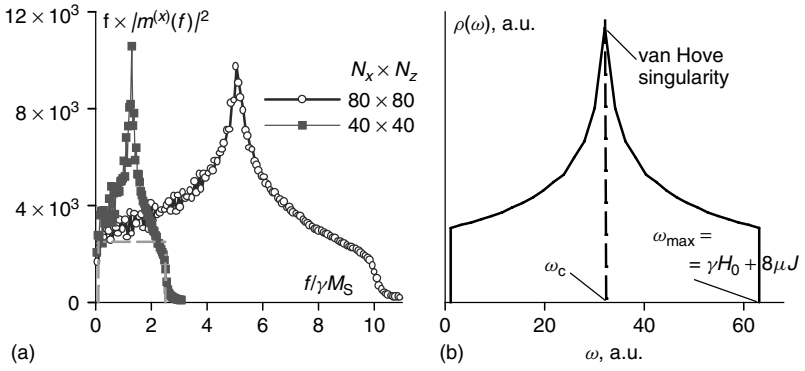

Figure 3. (a) Power spectrum of m_x-oscillations for various discretizations. Cusps are the manifestations of the magnon DoS singularity (right panel). The dashed rectangle represents the spectrum expected in the limit of very fine discretization for a low frequency region available for the 40×40 discretization; (b) density of magnon states for the model (70). The cusp by $\omega_c = \omega_{min} + \omega_{max})/2$ is the van Hove singularity common for all 2D models with the cosine like $\omega(\mathbf{k})$ dependence. (Reproduced from Berkov *et al*., 2005, with permission from Elsevier. © 2005.)

frequency resolution of the spectral power finally obtained). Finally we perform the temporal FT of these trajectories and averaging over several thermal noise realizations.

Corresponding results for a thin-film region with lateral sizes 400×400 nm, thickness $h = 5$ nm, $M_S = 1000$ G, $A = 10^{-6}$ erg cm^{-1} placed in an external field $H_{ext} = 100$ Oe are presented in Figure 3(a), where oscillation power spectra of m_x projection at $T = 10$ K are shown for two different discretizations. The most striking features of these spectra are (i) sharp cusps in the middle and (ii) a shift of this cusp towards higher frequencies when the grid is refined.

This result can be easily understood as follows. After the in-plane discretization of the film into $N_x \times N_y$ cells with the sizes Δx and Δy and volumes ΔV the system energy $E = E_{\text{ext}} + E_{\text{exch}}$ is converted into the sum over cells i, j

$$E = -\mu \sum_{i,j=1}^{N_{x(y)}} \mathbf{m}_{ij} \mathbf{H}_{ij}^{\text{ext}} - \frac{1}{2} J \mu^2 \sum_{\langle i,j \rangle} (\mathbf{m}_i \mathbf{m}_j) \qquad (70)$$

where μ is the cell magnetic moment. The exchange constant J in (70) depends on the exchange stiffness A and the grid cell parameters as

$$J = \frac{A}{M_S^2 \cdot \Delta V} \left(\frac{1}{\Delta x^2} + \frac{1}{\Delta y^2} \right) \qquad (71)$$

As usual, the total oscillation power for the given frequency ω in a thermal equilibrium is directly proportional to the number of modes contributing to this frequency, that is, to the magnon density of states $\rho(\omega)$. For a typical *lattice* model described by the energy (70) this density of states is well known. Namely, the quadratic expansion of (70) over small magnetization deviations from the ground state (small temperature or large external field limit) leads to the eigenfrequencies $\omega_{pq} = \gamma \cdot (H_{\text{ext}} + \mu J \cdot f_{pq})$ depending on the eigenmodes wave vector indices p and q via the sum of cos functions as $f_{pq} = 2 \cdot (2 - \cos(2\pi p / N_x) - \cos(2\pi q / N_z))$, which is common for all 2D lattice models with the nearest-neighbors harmonic interaction. If the eigenfrequencies depend on the wave vectors in a cosine like manner, then the density of states (Figure 3b) contains the famous van Hove singularity in its middle, which is clearly visible in both spectra in Figure 3(a) as a cusp. The spectrum shift toward higher frequencies when the discretization is refined follows simply from the fact that the eigenfrequencies $\omega_{pq} = \gamma \cdot H_{\text{ext}} + \mu J \cdot f_{pq})$, being proportional to the exchange constant J, increase according to (71) as an inverse square of a cell size when a mesh is refined.

The actual excitation spectrum of a real system (which we attempt to simulate) also contains such a cusp (a real system is discrete at the atomic level) but for frequencies determined by the interatomic distances and thus absolutely unavailable for simulations. This means that the correct spectrum of the continuous thin film model in the frequency region available for micromagnetic simulations is nearly flat as shown by the dashed rectangle in Figure 3(a). Hence, in order to obtain adequate results for equilibrium system properties using such simulations, one should either work in the frequency region where the spectrum is still approximately flat ($\omega \ll \omega_c$) or use a *colored* noise to correct the excitation spectrum of the corresponding lattice model.

5 MAGNETIZATION RELAXATION OVER HIGH ENERGY BARRIERS

For system with high energy barriers $\Delta E \gg kT$ direct simulation of the magnetic moment trajectories using the Langevin dynamics is fairly impossible. Such simulations simply mimic the time-dependent system behavior so that the simulation time necessary to overcome the barrier *exponentially* growths with its height following the Arrhenius–Van't Hoff law (probability to overcome the barrier is $p \sim \exp(-\Delta E / T)$)–exactly as for real systems.

Nevertheless, methods for numerical simulations allowing to study transitions over large barriers are highly desirable from the practical point of view: they are the only way to predict the long-time stability of the information storage devices. To evaluate the transition probability p over such barriers we must in the first place find the *lowest* saddle point between the two metastable state of interest. Its height gives us the corresponding energy barrier ΔE between these states, allowing to estimate p from the Arrhenius–Van't Hoff law. Analytical methods for the saddle-point search exist only for relatively simple magnetic systems (Braun, 1994, 2000; Klik and Gunther, 1990). In principle, such a saddle point can be found by solving a system of nonlinear equations $\partial E / \partial x_i = 0$ (where x_i denote the variables of a system configuration space), because at a saddle point *all* energy derivatives $\partial E / \partial x_i$ should be zero, but neither an energy maximum nor a minimum should be achieved. However, general methods for the solution of such systems are not available, and there exist even arguments that there will never be any (Press, Teukolsky, Vetterling and Flannery, 1992). For this reasons numerical methods based on other principles are required.

5.1 Time-temperature scaling method

The time-temperature scaling method (Xue and Victora, 2000) quantifies the rough idea that in some cases simulations of the transition over high energy barriers involving

macroscopically long waiting times at *low* temperatures can be replaced by simulations over the same energy barrier, but at a much *higher* temperature so that the transition time (and hence – the simulation time) is much smaller and is accessible for simulations.

To make this idea applicable in numerical simulations, we need the quantitative relation between the time and temperature scales. To establish such a relation, we start from the simplest version of the Arrhenius–Van't Hoff law which states that the average transition time τ_{av} depends on the energy barrier height ΔE and the system temperature T mainly exponentially via their ratio as

$$\tau_{\mathrm{av}} = \frac{1}{\nu_0} \exp\left(\frac{\Delta E}{kT}\right) \tag{72}$$

where the prefactor is defined using the so-called 'attempt frequency' ν_0. If the temperature dependence of this frequency is weak compared to the exponent $\exp(-\Delta E/kT)$ then the product $kT{\cdot}\log(\tau_{\mathrm{av}}{\bullet}\nu_0)$ remains constant for the transition over this barrier. This means that if a transition over some barrier takes on average a long time τ_{long} at a (low) temperature T_{long}, then in order to observe the same transition during a desired short time τ_{short} we need to increase the temperature up to the value $T_{\mathrm{s/l}}$ which is related to the quantities introduce above via

$$T_{\mathrm{s/l}} \log(\nu_0 \tau_{\mathrm{short}}) = T_{\mathrm{long}} \log(\nu_0 \tau_{\mathrm{long}}) \tag{73}$$

To calculate from this equation, the scaled temperature $T_{s/l}$ which we should use in simulations if we would like to reduce our simulation time from the inaccessible value τ_{long} down to τ_{short}, we need to determine the attempt frequency ν_0 for the system under study. Analytical formulae for ν_0 are available only for the simplest systems like a single-domain particle (Brown, 1963b). For this reason Xue and Victora (2000) have proposed the following trick. They have introduced a new time τ_{ref} which is much larger than the short time τ_{short} (which we would like to use for final simulations), but still small enough so that simulations during this time are possible and the desired transition occurs during the time τ_{ref} at some intermediate temperature T_{ref}. The first step for the determination of the attempt frequency ν_0 (and hence – the temperature $T_{\mathrm{s/l}}$) is the simulation of a system at the temperature T_{ref} during the time τ_{ref}, whereby some physical property of the system is determined or some dynamical process in the system is recorded. Then one should perform several simulation runs at different temperatures during the short time τ_{short} and *find the temperature* $T_{\mathrm{s/r}}$ for which the process recorded at T_{ref} during the time τ_{ref} *proceeds as similar as possible* to the process observed during the short time τ_{short}. This means, that the corresponding times and temperatures are connected via the same relation as (73), namely

$$T_{\mathrm{s/r}} \log(\nu_0 \tau_{\mathrm{short}}) = T_{\mathrm{ref}} \log(\nu_0 \tau_{\mathrm{ref}}) \tag{74}$$

This latter relation can be used to extract the attempt frequency ν_0, because all other quantities here are known. Determination of ν_0 from (74) and its substitution into (73) leads to the following expression for the required high simulation temperature $T_{\mathrm{s/l}}$:

$$T_{\mathrm{s/l}} = T_{\mathrm{long}} + (T_{\mathrm{s/r}} - T_{\mathrm{ref}}) \cdot \frac{T_{\mathrm{long}} \log(\tau_{\mathrm{long}}/\tau_{\mathrm{short}})}{T_{\mathrm{ref}} \log(\tau_{\mathrm{ref}}/\tau_{\mathrm{short}})} \tag{75}$$

Simulations at this temperature during the time τ_{short} should now reproduce the behavior of the system under study at the low temperature T_{long} during the time τ_{long} which is exponentially larger than τ_{short} due to the relation (73).

Xue and Victora have applied their algorithm to the simulations of the hysteresis loops at various field sweep rates R (which served as inverse time scales τ_{short} etc.). A remarkable agreement between the two numerically calculated loops for the sweep rates 0.5 and 50 Oe nsec^{-1} was obtained and the loop measured experimentally at $R = 50\,\mathrm{Oe\,sec^{-1}}$ (i.e., nine orders of magnitude slower) could be successfully predicted (Xue and Victora, 2000). They have also simulated the process of a bit decay in magnetic recording media (Xue and Victora, 2001) over a macroscopically long time scale, which is highly interesting for the development of high-density magnetic storage.

Concluding this subsection, we note that the method outlined above probably is not able to reproduce correctly the magnetization dynamics for a system with *low* dissipation, when the precession term in the LLG equation is really important (results of Xue and Victora were obtained on systems with moderate damping). The reason is that actual simulations in this method are performed at temperatures much higher that the actual system temperature, so that the relation between the random (fluctuation) field and the deterministic field is wrong. Another limitation of this formalism is the usage of the relation (72), which is valid only when the entropic contribution to the transition probability (curvature of the energy landscape in the vicinity of a saddle point and energy minima) can be neglected.

5.2 Rigorous evaluation methods for the energy barrier height

In this subsection, we describe general numerical methods for the evaluation of the energy barrier height between the two metastable states. All methods aim to evaluate some

kind of an optimal trajectory between these states and the required energy barrier can then be calculated as the barrier along this trajectory. The transition probability between the energy minima in question can then be evaluated using the general transition-rate theory (Hoenggi, Talkner and Borkovec, 1990), whereby the features of the energy surface near critical points may be also taken into account.

5.2.1 *Minimization of a thermodynamical action (Onsager–Machlup functional)*

General idea

This method is based on the search for the *most probable transition path* between the two energy minima by minimizing the corresponding *thermodynamical action* derived from the path-integral formulation of the problem. The underlying idea (Onsager and Machlup, 1953) can be explained considering a system of N particles with coordinates $x_i (i = 1, \ldots, N)$ and the interaction energy $V(\mathbf{x})(\mathbf{x} = (x_1, \ldots, x_N))$ in a viscous fluid. Langevin equations for this system are

$$\dot{x}_i = -\frac{\partial V(\mathbf{x})}{\partial x_i} + \xi_i(t), \quad i = 1, \ldots, N \tag{76}$$

where we have neglected the inertial term for simplicity and absorbed the friction constant into the time scaling. Langevin forces ξ_i are again assumed to be independent Gaussian δ-correlated random variables: $\langle \xi_i(0)\xi_j(t)\rangle = 2D\delta_{ij}\delta(t)$.

Due to these simple correlation properties the probability of some *particular* noise realization $\{\xi_i(t)\}, i = 1, \ldots, N$ for the time period $[0, t_\mathrm{f}]$ is (Onsager and Machlup, 1953); (Bray and McKane, 1989)

$$P[\boldsymbol{\xi}(t)] = A \exp\left[-\frac{1}{4D}\int_0^{t_\mathrm{f}} \sum_i \xi_i^2(t)\mathrm{d}t\right] \tag{77}$$

Rewriting the system (76) as $\xi_i(t) = \mathrm{d}x_i/\mathrm{d}t + \partial V(\mathbf{x})/\partial x_i$ and introducing the Jacobian $J[\mathbf{x}(t)]$ of the transformation $\mathbf{x} \to \boldsymbol{\xi}$, we immediately obtain that the probability to observe a *given trajectory* $\mathbf{x}(t)$ for the transition $A \to B$ during the time t_f $(\mathbf{x}_A(0) \to \mathbf{x}_B(t_\mathrm{f}))$ is

$$P[\mathbf{x}(t)] \sim J[\mathbf{x}] \exp\left[-\frac{S(\mathbf{x}(t), t_\mathrm{f})}{4D}\right] \tag{78}$$

where the *thermodynamical action* $S(\mathbf{x}(t))$ is defined as

$$S(\mathbf{x}(t), t_\mathrm{f}) = \int_0^{t_\mathrm{f}} \mathrm{d}t \sum_i \left(\frac{\mathrm{d}x_i}{\mathrm{d}t} + \frac{\partial V(\mathbf{x})}{\partial x_i}\right)^2 \tag{79}$$

It is obvious that the trajectory which minimizes the action $S(\mathbf{x}(t))$ provides the most probable (optimal) transition trajectory $\mathbf{x}_\mathrm{opt}(t)$, along which the energy barrier for this transition can be found: $\Delta E(A \to B) = E_\mathrm{max}(\mathbf{x}_\mathrm{opt}) - E_A$. The minimization of the functional $S(\mathbf{x}(t))$ can be performed using various numerical methods which employ the discretization of the transition path $\mathbf{x}(t)$ thus reducing the task of minimizing (79) to the problem of the minimization of a many-variable function (see Berkov, 1998 for detail).

Unfortunately, the minimization of the functional (79) by itself, being technically quite complicate, does *not* represent a main problem when searching for an optimal physical transition path. The main problem is the presence of many 'false' local minima of the functional (79), that is, the existence of many trajectories between the states A and B *which minimize* (79) *but do not provide any information about the corresponding energy barriers*.

To explain why this is almost always the case we note that for *any* path for which the conditions $\mathrm{d}x_i/\mathrm{d}t = \pm\partial V(\mathbf{x})/\partial x_i$ are fulfilled (the plus/minus sign correspond to the downhill/uphill trajectory parts) provides an extremum to the action (79) (Bray and McKane, 1989). This means that the extremal trajectories for the action functional (79) go *along the gradient lines* of the energy surface.

On a very simple 2D energy landscape shown in Figure 4(a) *both* the solid line $M_1 \to M_2$ and the dashed line $M_1 \to P_2 \to M_2$ deliver local extrema to the action for the transition $M_1 \to M_2$, because both paths proceed along the gradient lines of the energy surface. Moreover, these both extrema are local *minima* of the action; in fact, they were obtained by minimizing (79) with the potential shown in Figure 4 as a gray-scale map simply starting from different initial trajectories. However, the solid line trajectory passes through the saddle point, giving the correct energy barrier height (the 'true' optimal trajectory), whereas the dashed line $M_1 \to P_2 \to M_2$ goes via the energy *maximum* supplying no useful information whatsoever ('false' optimal trajectory). The next example shown in Figure 4(b) demonstrates that even the *value* of the action (given by the sum of heights which an optimal trajectory has to climb over) along the 'false' optimal path $(M_1 \to P_2 \to M_2)$ may be smaller than the corresponding value along the 'true' optimal trajectory. Hence without a *reliable* algorithm able to distinguish between these two kinds of optimal paths the whole method is absolutely useless, because the number of 'false' optimal trajectories exponentially growth with the complexity of system.

An apparently straightforward possibility to discriminate between these two cases is the analysis of the *curvature tensor* of the energy surface at the points where the energy along the optimal trajectory has local *maxima*: if the corresponding matrix of the second energy derivatives has exactly *one*

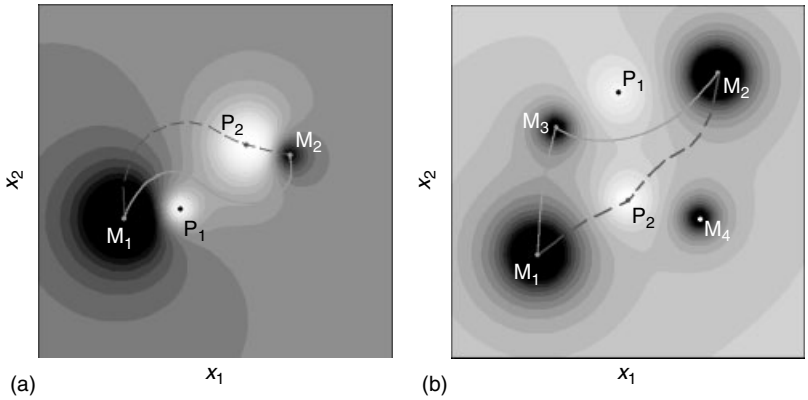

Figure 4. (a) 'True' (solid line) and 'false' (dashed line) optimal trajectories for a simple energy landscape. (b) An example of an energy landscape, where the action (79) along the 'false' optimal path $M_1 \to P_2 \to M_2$ may be even smaller than along the 'true' path $M_1 \to M_3 \to M_2$ (see text for details). (Reproduced from Berkov *et al.*, 1998, with permission from Elsevier. © 1998.)

negative eigenvalue, then this point indeed corresponds to a transition saddle. This method, however, is not sufficiently reliable due to a discrete representation of the continuous trajectory and a finite accuracy by the determination of an 'optimal' path. An alternative algorithm based on small 'jumps' away from the trajectory point with the highest energy in a random direction and subsequent minimization of the system energy starting from this new position, is described in detail in (Berkov, 1998).

Another problem arises due to the presence of the transition time t_f in the action (79) as the upper integral limit, which should be known in advance to set the time step and/or the number of time slices in the discretized action version; this transition time is of course not known. Fortunately, the barrier *height* determined from the discretized action turned out to depend on the t_f-value only slightly. For this reason sufficiently accurate results could be obtained by minimizing the discretized action using the small constant time step and simply doubling the number of time slices until the relative difference between the two barriers heights obtained for the subsequent action minimizations becomes less than a certain small threshold.

Implementation for magnetic systems

To apply this method to systems of interacting magnetic moments we have to start with the magnetic counterpart to the Langevin equation (76), namely, with the stochastic Landau–Lifshitz–Gilbert equation of motion for magnetic moments (20). The precession term in this equation affects, of course, the optimal transition *trajectory*, but does not change the system energy and hence it is reasonable to assume that it does not change the barrier *height* for this transition (see also our discussion of the string method below). For this reason we neglect the precession term in (20) and obtain the equation of motion for the magnetization unit vectors $\mathbf{m}_i$

$$\frac{\mathrm{d}\mathbf{m}_i}{\mathrm{d}t} = -\Big[\mathbf{m}_i \times \Big[\mathbf{m}_i \times (\mathbf{h}_i^{\mathrm{det}} + \mathbf{h}_i^{\mathrm{fl}})\Big]\Big] = -\mathbf{m}_i \cdot (\mathbf{m}_i \cdot \mathbf{h}_i^{\mathrm{tot}}) + \mathbf{h}_i^{\mathrm{tot}} \tag{80}$$

where all constants are again absorbed in the time unit, the total field is $\mathbf{h}^{\mathrm{tot}} = \mathbf{h}^{\mathrm{det}} + \mathbf{h}^{\mathrm{fl}}$ and the normalization $m_i = 1$ was used by the last transformation.

The conservation of the magnetic moment magnitude enforces the transition to spherical coordinates (θ, ϕ) of $\mathbf{m}$, because only the random field components perpendicular to $\mathbf{m}$ should be taken into account. Transforming all vectors to the new coordinates with the z'-axis along $\mathbf{m}$ and the x'-axis in the meridian plane of the initial spherical coordinates (so that in the initial system $m_x = \sin\theta\cos\varphi$, $m_y = \sin\theta\sin\varphi$, $m_z = \cos\theta$), we obtain equations of motion for the magnetization angles

$$\frac{\partial\theta_i}{\partial t} = -\frac{\partial E\{\Omega\}}{\partial\theta_i} + h^{\mathrm{fl}}_{i,x'},$$
$$\sin\theta_i \cdot \frac{\partial\phi_i}{\partial t} = -\frac{1}{\sin\theta_i} \cdot \frac{\partial E\{\Omega\}}{\partial\phi_i} + h^{\mathrm{fl}}_{i,y'} \tag{81}$$

where $h^{\mathrm{fl}}_{x'}$ and $h^{\mathrm{fl}}_{y'}$ are Cartesian components of the fluctuation field $\mathbf{h}^{\mathrm{fl}}$ in the new coordinate system. Deterministic effective field $\mathbf{h}^{\mathrm{det}}$ is already contained in corresponding angular derivatives of the magnetic energy E{Ω} (where {Ω} denotes the set of all angles (θ_i, φ_i)), which may include also the interaction energy of any kind (i.e., exchange, dipolar, RKKY, etc.).

The system (81) is fully analogous to (76) so that under the same assumptions (Langevin field components are independent Gaussian δ-correlated random variables) the magnetization path in the Ω space which minimizes the

thermodynamical action S for a magnetic system

$$S[\Omega(t)] = \int_0^{t_f} \mathrm{d}t \sum_i \left[\left(\frac{\mathrm{d}\theta_i}{\mathrm{d}t} + \frac{\partial E\{\Omega\}}{\partial \theta_i} \right)^2 + \left(\sin\theta_i \cdot \frac{\mathrm{d}\phi_i}{\mathrm{d}t} + \frac{1}{\sin\theta_i} \cdot \frac{\partial E\{\Omega\}}{\partial \phi_i} \right)^2 \right] \qquad (82)$$

provides the information about the energy barrier separating the states Ω_A and Ω_B.

Application for magnetic nanocomposites

With this method we have calculated the distribution of the energy barriers in a system of single-domain magnetic particles (embedded in a nonmagnetic matrix) with the uniaxial anisotropy and magnetodipolar interaction between the particles. The most intriguing question for this system is the influence of the magnetodipolar interaction on the distribution density of the energy barriers $\rho(E)$ (Hansen and Morup, 1998; Dormann, Fiorani and Tronc, 1999), which controls both the reversible and irreversible thermodynamics of the system. To solve this question, we have computed $\rho(E)$ for various volume concentrations of the magnetic phase, thus varying the interaction strength.

Calculations were performed for systems with high ($\beta = 2K/M_S^2 = 2.0$), moderate ($\beta = 0.5$) and low ($\beta = 0.2$) single-particle anisotropies. The energy barrier distributions were accumulated from $N_{conf} = 8$ realizations of the particle disorder; for each configurations about $N_{trans} = 200$ transitions between metastable states were analyzed. Corresponding results are shown in Figure 5 were the distribution of the reduced energy barriers $\varepsilon = E/M_S^2 V$ are presented.

First of all, it can be seen that for low particle concentrations ($\leq 1\%$)$\rho(\varepsilon)$ consists of the relatively narrow peak positioned at the value corresponding to the energy barrier $\varepsilon_{sp} = \beta/2$ for a single particle moment flip, as it should be for a weakly interacting system. The position of this single-particle flip barrier is shown both in Figure 5 with the dashed line. As expected, with increasing concentration the energy barrier density broadens, but for the systems with the low and high anisotropy this broadening occurs in a qualitatively different ways. For the high-anisotropy case (Figure 5, right column) the broadening of $\rho(\varepsilon)$ with increasing concentration is accompanied by its shift toward *lower* energy barriers, so that already for moderate particle concentration ($\geq 4\%$) almost all barriers lie below the value for a single particle.

For the system of particles with the low anisotropy (Figure 5, left column) barriers both higher *and* lower than a single particle barrier arise. However, the overall

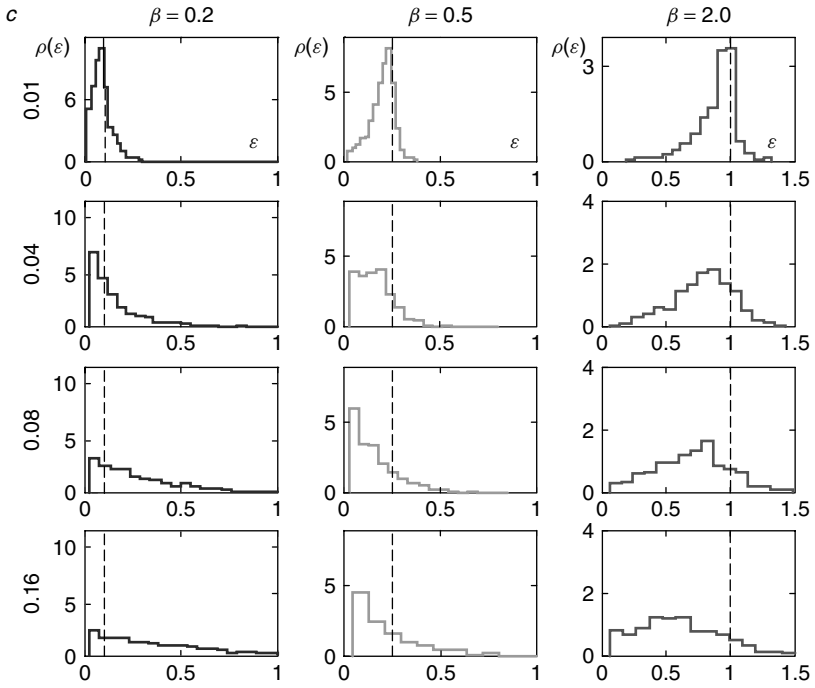

Figure 5. Density of the energy barriers for transitions between randomly chosen energy minima in a disordered magnetic particle system with the low ($\beta = 0.2$, left column), moderate ($\beta = 0.5$, middle column) and high ($\beta = 2.0$, right column) single-particle anisotropies for various particle volume fractions c. Dashed lines show positions of the energy barriers for a single particle with the corresponding anisotropy.

energy barrier spectrum clearly shifts toward *higher* energies with increasing particle concentration. Detailed physical explanation of this behavior can be found in Berkov (2002b).

It is also important to keep in mind that different transitions cause different moment changes. The key question is whether the magnitude of the moment changes is *correlated* with the height of the corresponding energy barrier. If, for example, the moment change tends to zero when the energy barrier height for this particular transition decreases, small energy barriers would not play any significant role in the system thermodynamics, because corresponding magnetization changes would be nearly undetectable. For this reason we need a 2D *mutual* distribution of the energy barriers and moment changes $\rho(E,\Delta m)$. Corresponding contour plots for a system with the low anisotropy $\beta = 0.2$ and two different concentrations are shown in Figure 6. For the low concentration $c = 0.01$ the density $\rho(E, \Delta m)$ consists of a single sharp peak positioned near the point ($\varepsilon = 0.1$, $\Delta m = 2.0$), which corresponds to a single-particle flip. From $\rho(E, \Delta m)$ for the high concentration $c = 0.16$ it can be seen that, although the moment changes for the low barriers are concentrated at somewhat smaller values than Δm for the higher ones, they do *not* tend to zero. Hence all transitions provide approximately equivalent contributions to the system thermodynamics.

5.2.2 The string method

General idea

To explain the main idea of the string method (Ren and Vanden-Eijnden, 2002), we start with the same basic equation

$$\dot{x}_i = -\nabla V(\mathbf{x}) + \xi_i(t), \quad i = 1, \ldots, N \tag{83}$$

as for the action minimization method. It is intuitively clear, that for a system which time evolution is described by this

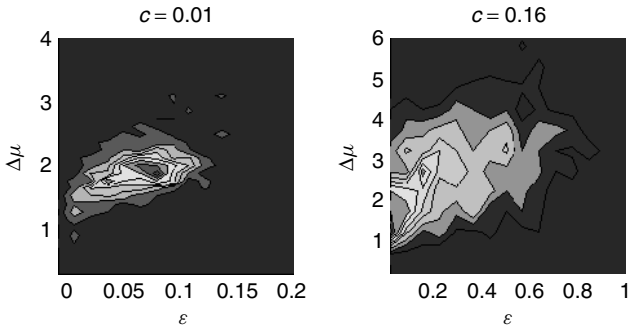

Figure 6. Mutual 2D distribution density $\rho(E, \Delta m)$ of the energy barriers and moment changes for dilute ($c = 0.01$, left panel) and concentrated ($c = 0.16$, right panel) system of magnetic particles with $\beta = 0.2$. (Reproduced from D.V. Berkov *et al.*, 2002. © 2002 with permission from IEEE.)

equation, the path $\phi_{opt}(\mathbf{x})$ which connects the two given metastable states A and B of the potential $V(\mathbf{x})$ and goes via a saddle point with the minimal energy barrier, satisfies the condition

$$(\nabla V)_\perp(\phi_{\text{opt}}) = 0 \tag{84}$$

In this notation $(\nabla V)_\perp(\phi)$denotes the component of the energy gradient, which is perpendicular to a curve ϕ. The physical sense of the statement (84) is that at any point of the optimal transition path the energy gradient is perpendicular to this path, with other words, the transition path proceeds along the energy gradient lines (see also our discussion of the action minimization method given above). A rigorous proof of this statement can be found in (Freidlin and Wentzell, 1998).

Although the equation (84) is only the necessary, but by no means the sufficient condition that the path ϕ goes through the lowest energy barrier between A and B (see, e.g., Figure 4a, where for the dashed line curve the condition $(\nabla V)_\perp(\phi) = 0$ is also fulfilled everywhere), this equation provides a useful hint how to find ϕ_{opt} starting from some arbitrary path ϕ: one can simply 'move' this path with the 'velocity'$\mathbf{u} = (\nabla V)_\perp(\phi)$which is normal to the path curve, until the stationary state of the system (given by the condition $\mathbf{u} = 0$) is reached.

To implement this idea, it is necessary to introduce some parameterization of a path ϕ, so that the coordinates of a point along the curve ϕ (in the N-dimensional configuration space of our system) are represented as functions of some parameter α: $x_1 = x_1(\alpha), \ldots, x_N = x_N(\alpha)$. Then, treating the evolution of ϕ with the velocity $\mathbf{u} = (\nabla V)_\perp(\phi)$ as a 'motion' in a fictitious time t, so that the instantaneous position of the path is given by the functions $\phi(\alpha, t) = (x_1(\alpha, t), \ldots, x_N(\alpha, t))$, we can write the corresponding 'dynamical' equation for $\phi(\alpha, t)$ as (Ren and Vanden-Eijnden, 2002)

$$\frac{\partial \phi(\alpha, t)}{\partial t} = -(\nabla V)_\perp(\phi) = -[\nabla V(\phi) - (\nabla V, \mathbf{e}_\tau)\mathbf{e}_\tau] \tag{85}$$

where the vector $\mathbf{e}_\tau$ is the unit tangent vector ϕ and thus its components at the curve point characterized by the parameter value α are

$$e_\tau^{(l)} = \frac{1}{\|\mathbf{x}_\alpha\|} \cdot \frac{\partial x^{(l)}(\alpha, t)}{\partial \alpha}, \quad \|x_\alpha\| = \sqrt{\sum_{l=1}^{N} \left(\frac{\partial x^{(l)}}{\partial \alpha} \right)^2} \tag{86}$$

so that the expression in the square brackets on the right-hand side of (85) is, as required, the component of the energy gradient vector normal to ϕ.

Numerical solution of (85) requires the discretization of the path ϕ using some concrete parametrization. A significant advantage of the string method is that this parametrization can be chosen arbitrarily basing on the considerations of either simplicity, or stability of a numerical method used to integrate (86), or required accuracy for the energy barrier value etc. The simplest choice is the 'natural' parametrization of a curve using the parameter α equal to its normalized arclength. In this case for a path starting at the point A with the coordinates $(x_A^{(1)}, \ldots, x_A^{(N)})$ and ending at $B(x_B^{(1)}, \ldots, x_B^{(N)})$ we have $\alpha(A) = 0$ and $\alpha(B) = 1$. Starting from some smooth curve between A and B, we discretize it into $K+1$ points equally spaced along the curve (for this kind of parametrization!) where the k-th point along the curve with coordinates $\mathbf{x}_k$ is characterized by the parameter value $\alpha_k = k/K (k = 0, \ldots, K)$. Calculating the derivatives of the coordinates as functions of α by some finite-difference approximation method, we compute the components of the unit tangent vector (86) for the given position of a string (at the given 'time' t) and make a 'time' step integrating numerically equations (85).

Application to micromagnetic systems

By implementation of this formalism for a micromagnetic system we encounter the same question as in the action minimization method: the dissipation term in the stochastic LLG-equation indeed represents the gradient of the micromagnetic energy (or, to be more precise, projection of this gradient into the hyperplane normal to all magnetic moment vectors), but the precession term does not. In their paper (Ren and Vanden-Eijnden, 2003) devoted to the usage of the string method in micromagnetism E *et al*. mention that they could prove that the local minima and saddle points remain the same after neglecting the precession term (unfortunately, this result is cited in (Ren and Vanden-Eijnden, 2003) as 'unpublished').

E *et al*. have demonstrated the applicability of the string method to micromagnetism in the papers (Ren and Vanden-Eijnden, 2002, 2003), where they have studied the remagnetization of a thin Permalloy nanoelement ($200 \times 200 \times 10\,\mathrm{nm}^3$ nanoelement, discretized in-plane only) choosing the two remanent S states with opposite magnetization orientations as initial and final states of the transition over a barrier (an external field was assumed to be absent). They could show that there exist at least two possible paths for this transition. The first path correspond to the magnetization switching via the intermediate S states (rotated by 90° relative to the initial and final S states) flower state, flower states (which were identified as saddle points) and the C state which was the lowest energy minimum visited during the transition process. The second transition path corresponded to the formation of the two vortices, which propagation through the nanoelement governed the switching process. The energy barriers for this second path were found to be significantly higher than for the first one. Another example briefly considered in (Ren and Vanden-Eijnden, 2003) deals with the remagnetization of a rectangular prism with a square cross-section ($200 \times 50 \times 50\,\mathrm{nm}^3$, discretized in 3D), where also two possible transition paths for the switching between the two states with the magnetization oriented (on average) along the two opposite directions of the long prism axis have been found.

From the methodical point of view, the string method has two significant advantages compared to the action minimization. First, a thermodynamical action itself already contains the first derivatives of the system energy (forces or torques). Hence its minimization with any method employing the *derivatives* of the function to be minimized (and only such methods provide a reasonable convergence speed) requires the evaluation of second derivatives of the system energy, that is, its Hessian matrix. By the string method which is based on the 'equation of motion' like (85), only the first energy derivatives are required, so that computational cost should be lower and the stability of the method higher than for the action minimization. The second important issue is the appearance of many undesired local maxima of the action, as discussed in the previous subsection. In the string method these maxima will probably play no significant role, because each point of the string is moved according to the equation (85) in the direction toward *lower* values of the system energy, so that it is highly unlikely that the string gets stuck at some 'false' metastable state like that shown in Figure 4, because such a 'false' path always goes through at least one energy *maximum*.

5.2.3 The elastic band method

Description of the method

The elastic band method, belonging to the so-called 'chain-of-states' method for searching the saddle points in complicate energy landscapes, is closely related to the string method discussed above. The main initial idea (exactly as in the discretized version of a string method) was to represent the continuous path in the configuration space of a system under study as a number of discrete states $\{\mathbf{S}_k\}(kd = 0, \ldots, K)$ and to build up an 'object function' of a type

$$Q = \sum_{k=1}^{K} V\{\mathbf{S}_k\} + \kappa \sum_{k=1}^{K-1} (\mathbf{S}_k - \mathbf{S}_{k-1})^2 \qquad (87)$$

Keeping the initial ($k = 0$) and final ($k = K$) states fixed and minimizing this function with respect to the set of states $\{\mathbf{S}_k | k = 1, \ldots, K-1\}$ should, on the one hand, lead to the decrease of the energies of the states involved (given by the terms $V\{\mathbf{S}_k\}$ in the first sum). On the other hand, the second sum should prevent the neighboring states (along the path) to

'run away' from each other (because the terms $(\mathbf{S}_k - \mathbf{S}_{k-1})^2$ give the distances between the states in the configuration space), thus keeping the discretized path reasonably smooth. Together these two tendencies should provide the sequence of closely positioned states (second sum) with the energy being as low as possible (first sum), which from the qualitative point of view obviously corresponds to the path over a saddle point between the fixed initial and final states. The method was named an 'elastic band' method, because the second term in (87) exactly corresponds to the energy of elastic bands (springs) with zero natural length and elastic constant κ 'built in between' the neighboring states of the chain $\{\mathbf{S}_k\}$.

In practice, this idea does not work really well: if the elastic constant κ is chosen too large (elastic term dominates) then the chain of states tends to 'round the corners' of the energy landscape, trying to reduce the length of the chain (distances between the neighboring states) on the cost of increasing the potential energy of the chain states. If κ is too small, then the elastic term is not able to prevent the states from sliding into the potential minima (initial and final states), so that the saddle point can be located with a reasonable accuracy. The region of intermediate κ values where the saddle point position of a continuous transition path is reproduced by the chain (87) well enough, is usually very narrow or may even not exist (see an excellent review contained in Jónsson, Mills and Jacobsen, 1998). For this reason the elastic band method, introduced in the middle of the 1980th, was considered as unreliable a decade long.

The solution of both problems was suggested by Mills and Jonsson (1994) (see Jónsson, Mills and Jacobsen, 1998 for a detailed explanation), who noted that both effects were due to the 'too physical' understanding of the model (87). Namely, by the minimization of the object function (87) both the potential (due to the first sum) and elastic (second sum) forces were fully taken into account using the straightforward differentiation of the object function Q. By its constructed Q fully mimics the energy of a set of 'particles' (states) connected via springs with elastic constants κ and moving in a potential landscape V. But the actual purpose of this function is quite different from simply imitating the behavior of the physical system just described: Q should be constructed so that the chain of 'particles' (states) reproduces as good as possible the *optimal continuous* path between the two given energy minima, which goes from the starting to the final state *along the gradient lines* of the potential $V\{\mathbf{x}\}$. Hence, Q fulfills its purpose well enough if (i) the first term would move the states *perpendicular* to the gradient lines (grad(V) is normal to the optimal path, see above) and (ii) the second term would produce only the force *parallel* to the path (to ensure that the states stay close to each other, it is sufficient to apply a force along the line connecting the states). For this reason we can *separate* the effects of the first (potential) and the second (elastic) terms by taking into account (i) only that projection of the potential force which is *perpendicular* to the path and (ii) only that projection of the elastic force which is *parallel* to the path.

This leads to the 'nudged elastic band'(NEB) model with the 'equation of motion' for the state i in the form similar to that of (85)

$$\frac{\partial \mathbf{S}_k}{\partial t} = -[\nabla V - (\nabla V, \mathbf{e}_\tau)\mathbf{e}_\tau]_{\mathbf{S}_k} + (\mathbf{F}_k^{\mathrm{el}}, \mathbf{e}_\tau)\mathbf{e}_\tau \qquad (88)$$

where the first term in square brackets is fully analogous to the corresponding term in equation (85) thus 'moving' each state in the direction normal to the transition path and the second term represents the tangential projection of the elastic force $\mathbf{F}^{\mathrm{el}}$ (derivative of the second sum in (87)) which takes care that the states remain close to each other in the configuration space. During to the fact that the two terms on the right-hand side of (88) are perpendicular to each other, that is, fully decoupled, there exist now a wide range of the elastic constants κ where the position of the saddle point along the transition path can be reproduced with a nearly arbitrary accuracy just by increasing the number of states used to discretize a path.

Finally, we note that the quality of decoupling of the two force contributions in (88) and thus – the quality of the saddle point determination and the stability of the method as a whole – crucially depend on the calculation accuracy of the tangent vector direction $\mathbf{e}_\tau$. For this reason large effort has been devoted to the development of improved method for the tangent determination for discretized curves (Jonsson and Henkelmaan, 2000).

Micromagnetic simulations using the elastic band method

Up to our knowledge, first application of the NEB method to micromagnetic simulations is due to Dittrich *et al*., (2002,2003a,b), Dittrich, 2003 and Dittrich, Thiaville, Miltat and Schrefl (2003). In their first paper, Dietrich *et al*. (Dittrich *et al*., 2002) describe their concrete implementation of the general NEB algorithm for micromagnetics, which involves a transition to the spherical coordinates of magnetic moment (as really independent variables, see the discussion above) and a proper finite-difference approximation of the tangent vector for the discretized transition path.

In this first study Dittrich *et al*. (2002) noted that for some simple systems the method works well even without the spring force, that is, without the second term in (88). This means that one can sometimes obtain a good approximation to a saddle-point path simply by moving the states of the discretized initial guess for the transition path along the energy gradient projection perpendicular to the instantaneous trajectory configuration (we note in passing that this simplified method has nothing to do anymore with the

'NEB'). In particular, in Dittrich *et al*. (2002) the energy barriers calculated numerically for the system of two interacting single-domain particles with uniaxial anisotropies were found to agree well with the analytical results available for this system. The ability of the method to find energy barriers for (i) a coherent switching of a small ($5 \times 5 \times 1\,\mathrm{nm}^3$) rectangular nanoelement, (ii) a switching of an elongated slab (typical cross-section size 13 nm, length 70 nm) via the domain wall motion, and (iii) magnetization reversal of a piece of a granular magnetic media was also demonstrated.

Later Dittrich *et al*. have implemented also a complete elastic band method (Dittrich *et al*., 2003a), including the second (elastic) term into their 'equation of motion' for the states in the chain. As expected, they have observed that for every concrete problem there exist a broad range of the elastic constant values where the height and position of a saddle point is reproduced with a sufficiently high accuracy, although for each new problem this region must be found afresh. With this improved algorithm Dittrich *et al*. could rigorously evaluate energy barriers arising due to the shape anisotropy in triangular and square nanoplatelets, investigate the increase of the energy barrier in a ferromagnetic grain coupled to an antiferromagnet (a promising candidate for a high-density recording media with improved thermal stability) and identify several possible reversal modes in a MRAM cell (Dittrich *et al*.,2003a,b; Dittrich, Thiaville, Miltat and Schrefl, 2003).

More details about micromagnetic simulations performed with this method can be found in the contribution **Numerical Methods in Micromagnetics (Finite Element Method), Volume 2** of T. Schrefl to this volume.

An interesting topic which has been pursued by several research groups in the last few years is the applicability of the Monte-Carlo (MC) methods (Binder, 1986) for dynamic micromagnetic simulations at finite temperatures. The major *advantage* of modern MC schemes when applied to the magnetization transition between various metastable states is evident: The corresponding computation time does *not* depend exponentially on the height of the energy barrier separating these states, as it is the case for the Langevin dynamics. However, there exist also several principal problems by the dynamical application of the MC methods. The two most serious of them are: (i) the difficulty to establish a relation between a MC step and a physical time and (ii) proper inclusion of the magnetization precession, which is also a highly nontrivial task, because the precession does not lead to the change of the system energy and hence does not affect the probability to accept a MC step. Recent methodical progress on this area can be found in Nowak, Chantrell and Kennedy (2000), Chubykalo *et al*. (2003), and Cheng, Jalil, Lee and Okabe (2005, 2006) and is reviewed in the contribution of U. Nowak to this volume.

NOTES

[1] Note however, that the effective field itself $\mathbf{H}^{\mathrm{eff}} = (1/V)\cdot\partial E/\partial\mathbf{M}$ is of course zero at equilibrium – up to the component along the magnetization vector which can be neglected because the magnetization magnitude is assumed to be constant

[2] The *deterministic* Landau–Lifshitz–Gilbert equation conserves the moment magnitude anyway. However this is *not* automatically the case for its stochastic analogue.

ACKNOWLEDGMENTS

The author greatly acknowledges many useful discussions on the topics treated in this chapter with J. Miltat, N. Smith, M. Stiles, A. Slavin, T. Schrefl, and U. Nowak.

1 INTRODUCTION

The theoretical study of magnetization dynamics has been the focus of considerable research for many years (Landau and Lifshitz, 1935; Gilbert, 1955, 2004; Kikuchi, 1956; Callen, 1958; Mallinson, 1987; Wigen, 1994). Traditionally, this study has been driven by the ferromagnetic resonance problems (Damon, 1953; Suhl, 1957; Walker, 1957; Skrotskii and Alimov, 1959a) in which the main part of magnetization is pinned by a strong constant magnetic field, whereas only a small transverse component of magnetization executes resonance motions caused by radiofrequency (rf) fields. These small magnetization motions are studied by linearizing the magnetization dynamics equation and, for this reason, the literature on magnetization dynamics has been mostly concerned with the linear magnetization dynamics studies. Recently, new directions of research have emerged that deal with large motions of magnetization and require the analysis of the nonlinear dynamics magnetization. These new directions are mainly connected to the recent advance in magnetic storage technologies. The enormous increase in data storage density and transfer rate has required the design and the realization of magnetic devices in the nanoscale spatial range. In these devices, the magnetization dynamics modes are usually approximately spatially uniform but undergo motions which appreciably deviate from equilibrium. The study of nonlinear quasi-coherent magnetization motion is particularly relevant in such research as fast precessional switching (Acremann *et al*., 2000; Bauer, Fassbender, Hillebrands and Stamps, 2000; Crawford, Kabos and Silva, 2000; Schumacher *et al*., 2003) of magnetization in thin films and magnetization dynamics induced by spin-polarized current injection (Berger, 1996; Slonczewski, 1996; Sun, 2000; Grollier *et al*., 2001; Kiselev *et al*., 2003; Rippard *et al*., 2004), and ferromagnetic resonance in nanomagnets and ultrathin magnetic films.

In this chapter, we will systematically apply and review the methods and concepts of nonlinear dynamical system theory relevant to the analysis of large magnetization motions governed by the commonly used magnetization evolution equation: Landau–Lifshitz equation. Precessional and damping switchings of magnetization and nonlinear ferromagnetic

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

dynamics driven rf field are treated as very important applications. However, many results obtained for those applications are of considerable interest in their own right. The chapter is organized as follows.

Sections 2 and 3 deal with the theoretical aspects of Landau–Lifshitz dynamics. First, the Landau–Lifshitz equation is introduced as dynamical generalization of micromagnetic Brown's equation and its general property are considered. Then, Landau–Lifshitz dynamics is treated as a nonlinear dynamical system defined on a sphere and the problem of equilibria and geometric representation of dynamics is discussed. Special attention is paid to the conservative Landau–Lifshitz dynamics and analytical expressions are derived for this dynamics in terms of elliptic-type integrals.

Sections 4 deals with precessional and damping magnetization switchings. Analytical treatment of the damping switching and the precessional switching for uniaxial magnetic particle is illustrated in details and a comparison of the two switching techniques is presented in terms of switching speed. Then, a novel approach, based on the averaging technique, to the analysis of magnetization relaxation to equilibrium is presented. This approach is and results in a differential equation for the free energy.

In Section 5, we will address the problem of the existence of spatially uniform magnetization modes under far-from-equilibrium conditions driven from an external rf field. In the case of systems with uniaxial rotational symmetry subject to a circularly polarized rf, remarkable conclusions can be drawn (Skrotskii and Alimov, 1959a,b; Khapikov, 1992; Träxler, Just and Sauermann, 1996). Indeed, the presence of rotational symmetry has far-reaching consequences because the equivalent dynamical system on the unit sphere is reduced to autonomous form and the basic physical aspects of the dynamics can be recast into corresponding topological and geometric properties of the phase portraits of the Landau–Lifshitz equation (Bertotti, Serpico and Mayergoyz, 2001). The phase portraits of the dynamics and the associated bifurcation diagrams exhibit an extremely rich and interesting structure, and provide some nontrivial predictions concerning periodic and quasiperiodic types of dynamical response as well as nonlinear ferromagnetic resonance mechanisms.

2 MICROMAGNETICS AND LANDAU–LIFSHITZ EQUATION

2.1 Fundamental equations

2.1.1 Brown's equations and their dynamical generalization

The study of magnetization dynamics in ferromagnetic media is based micromagnetic Brown's equations and their dynamical generalizations (Brown, 1962, 1963; Aharoni, 1996; Bertotti, 1998; Hubert and Schäefer, 1998; Kronmueller and Faehnle, 2003; Landau and Lifshitz, 1984). This material has been broadly discussed in another chapter (**General Micromagnetic Theory, Volume 2**) of this handbook and here we shall limit ourselves to a brief introduction of the main equations.

Micromagnetics is an highly nonlinear continuum theory which takes into account effects on rather different spatial scales: short-range exchange forces and long-range magnetostatic effects. The state of the ferromagnetic body is described by the magnetization vector field $\mathbf{M}(\mathbf{r})$ which, for temperature considerably below the Curie temperature, satisfies the following condition

$$|\mathbf{M}(\mathbf{r})| = M_{\mathrm{s}}(T) \tag{1}$$

which means that the magnitude of $\mathbf{M}(\mathbf{r})$ is spatially uniform and equal to the saturation magnetization $M_{\mathrm{s}}(T)$ at the given temperature T. The constraint expressed in equation (1) reflects the fact that, at the smallest spatial scale compatible with the continuum hypothesis, the strong exchange interaction prevails over all other types of force.

The direction of $\mathbf{M}(\mathbf{r})$ is in general nonuniform and, at equilibrium, is determined by minimizing an appropriate Gibbs–Landau free energy functional $G_{\mathrm{L}}(\mathbf{M}(.);\ \mathbf{H}_{\mathrm{a}})$ (Brown, 1962, Brown, 1963; Aharoni, 1996; Landau and Lifshitz, 1984). The minimization of $G_{\mathrm{L}}(\mathbf{M}(.);\ \mathbf{H}_{\mathrm{a}})$ under the constraint given by equation (1), leads to the Brown's equations:

$$\mathbf{M} \times \mathbf{H}_{\mathrm{eff}} = 0 \tag{2}$$

where the effective field $\mathbf{H}_{\mathrm{eff}}$ is defined as (minus) the variational derivative of the free energy functional with respect to the magnetization vector field: $\mathbf{H}_{\mathrm{eff}} = -\delta G_{\mathrm{L}}/\delta\mathbf{M}$. The effective field $\mathbf{H}_{\mathrm{eff}}$ takes into account all the information about the geometry and the magnetic properties of the system. When magnetoelastic effects are neglected, it is given by:

$$\mathbf{H}_{\mathrm{eff}} = \mathbf{H}_{\mathrm{a}}(t) + \mathbf{H}_{\mathrm{S}} + \mathbf{H}_{\mathrm{EX}} + \mathbf{H}_{K} \tag{3}$$

where $\mathbf{H}_{\mathrm{a}}(t)$ is the applied field, $\mathbf{H}_{\mathrm{S}}$ is the magnetostatic (demagnetizing) field produced by the magnetization $\mathbf{M}(\mathbf{r})$, $\mathbf{H}_{\mathrm{EX}} = (2A/\mu_0 M_{\mathrm{s}}^2)\nabla^2\mathbf{M}$ is the exchange field (A is the exchange stiffness constant and μ_0 is the vacuum permeability) (Bertotti, 1998), which describes exchange forces which tend to oppose magnetization nonuniformities, and $\mathbf{H}_K$ is the crystal anisotropy field, a purely local term which depends on the magnetization vector at the point considered and on some constants characterizing the local anisotropy. In the case of uniaxial materials, it has the following form

$$\mathbf{H}_K(\mathbf{M}) = \mathrm{H}_K(\mathbf{e}_K \cdot \mathbf{M}/M_{\mathrm{s}})\mathbf{e}_K \tag{4}$$

where H_K is an anisotropy parameter, and $\mathbf{e}_K$ is the unit vector along the easy axis direction.

The minimization of $G_L(\mathbf{M}(.);\ \mathbf{H}_a)$ also leads to boundary conditions on $\mathbf{M}(\mathbf{r})$ which, in the simplest case, are

$$\frac{\partial \mathbf{M}}{\partial \mathbf{n}} = 0 \tag{5}$$

at the body surface ($\mathbf{n}$ denotes the surface normal unit vector). This condition is expected when no surface anisotropy is present which is the case we shall treat here.

It is also important to underline two additional assumptions implicitly contained in the equation in the preceding text. First, the use of magnetostatic field $\mathbf{H}_S$ implies that we are in fact neglecting any propagation effect, which means that the electromagnetic wavelength must be much larger than the linear dimensions of the body under study. Second, eddy currents have been neglected and thus no eddy currents term has been included in $\mathbf{H}_{\text{eff}}$.

When $\mathbf{M} \times \mathbf{H}_{\text{eff}} \neq 0$, the system is not at equilibrium and evolves according to some appropriate dynamic equation. The most used dynamic equation is the Landau–Lifshitz equation (Landau and Lifshitz, 1935) based on the idea that in a ferromagnetic body the effective field $\mathbf{H}_{\text{eff}}$ induces a precession of the local magnetization $\mathbf{M}(\mathbf{r}, t)$ of the form

$$\frac{\partial \mathbf{M}}{\partial t} = -\gamma \mathbf{M} \times \mathbf{H}_{\text{eff}} \tag{6}$$

where $\gamma > 0$ is the absolute value of the gyromagnetic ratio. Equation (6) gives rise to magnetization dynamics in which the value of the saturation magnetization $M_s = |\mathbf{M}|$ is locally preserved, because $\partial|\mathbf{M}|^2/\partial t = 2\mathbf{M}\cdot\partial\mathbf{M}/\partial t = 0$. In this respect, equation (6) is consistent with the fundamental micromagnetic constraint (1). However, this equation cannot describe any approach to equilibrium, because $\mathrm{d}G_L/\mathrm{d}t = -\mathbf{H}_{\text{eff}}\cdot\partial\mathbf{M}/\partial t = 0$, which means that the dynamics is nondissipative.

Energy relaxation mechanisms can be taken into account by additional phenomenological terms, chosen through heuristic considerations. In their original paper, Landau and Lifshitz (1935) introduced an equation of the following form

$$\frac{\partial \mathbf{M}}{\partial t} = -\gamma_L \mathbf{M} \times \mathbf{H}_{\text{eff}} - \frac{\alpha_L \gamma_L}{M_s} \mathbf{M} \times (\mathbf{M} \times \mathbf{H}_{\text{eff}}) \tag{7}$$

where γ_L is a gyromagnetic-type constant and α_L is a dimensionless damping parameter. The value of α_L is always very small, of the order of $10^{-4}/10^{-3}$. The parameter γ_L is usually assumed to be equal to the gyromagnetic ratio γ. In addition to the Landau–Lifshitz equation, another equation broadly used in the description of magnetization dynamics is the one proposed by Gilbert (1955, 2004):

$$\frac{\partial \mathbf{M}}{\partial t} = -\gamma_G \mathbf{M} \times \left(\mathbf{H}_{\text{eff}} - \frac{\alpha_G}{\gamma_G M_s} \frac{\partial \mathbf{M}}{\partial t} \right) \tag{8}$$

where again γ_G is a gyromagnetic constant and α_G a dimensionless damping constant. The Gilbert form is equivalent to subtracting from the effective field a viscouslike term proportional to the time derivative of magnetization and this type of dissipative terms can be introduced by using the method Rayleigh dissipation function in the framework of Lagrangian dynamics (Gantmacher, 1975; Gilbert, 1955, 2004).

By using appropriate algebraic manipulations (Aharoni, 1996), equation (8) can be transformed in the following form:

$$\frac{\partial \mathbf{M}}{\partial t} = -\frac{\gamma_G}{1+\alpha_G^2} \mathbf{M} \times \mathbf{H}_{\text{eff}} - \frac{\alpha_G \gamma_G}{(1+\alpha_G^2) M_s} \mathbf{M} \times (\mathbf{M} \times \mathbf{H}_{\text{eff}}) \tag{9}$$

from which it is clear that equations (7) and (8) are mathematically equivalent to provided that:

$$\alpha_G = \alpha_L = \alpha, \qquad \gamma_G = \gamma_L (1+\alpha^2) \tag{10}$$

The above relations shows that the two gyromagnetic constants γ_L and γ_G cannot be simultaneously equal to the gyromagnetic ratio γ. In addition, while in equation (7) the damping term is proportional to α_L, the damping term in equation (9) is a nonmonotonic function of α_G which, after reaching a maximum at $\alpha_G = 1$, monotonically decreases. This is the behavior physically expected for large damping parameters.

These facts suggest that equations (7) and (8) are not physically equivalent, and this raises the interesting question of which is the most appropriate magnetization dynamics equation. This issue acquires particular relevance whenever α is expected to be a nontrivial function of the state of the system. In fact, this issue is part of the more general and relatively open problem of what are the limits under which the phenomenological introduction of damping is acceptable and is in agreement with microscopic models of spin dynamics (Callen, 1958; Suhl, 1998). It is also important to notice that the difference between equations (7) and (8) are of second order in the damping parameters and accordingly, for typical values of α_G and α_L, are expected to be quantitatively not very relevant. In the rest of this chapter, we describe magnetization dynamics by means of equation (8). We take $\gamma_G = \gamma$ and we will denote α_G simply as α. We refer to this equation as the Landau–Lifshitz–Gilbert (LLG) equation.

2.1.2 Spatially uniform solutions

In this chapter, we investigate magnetization dynamics in nanomagnets in which the magnetization is expected to be, with good approximation, spatially uniform. LLG equation admits indeed spatially uniform solutions under the following conditions: (i) the ferromagnetic body is of ellipsoidal shape; (ii) no surface anisotropy is present, so equation (5) is valid at the body surface; (iii) the parameters (e.g., anisotropy constants, anisotropy axis direction) which characterize the local anisotropy field $\mathbf{H}_K$ are spatially uniform; (iv) the applied field $\mathbf{H}_\mathrm{a}$ is spatially uniform; (v) the initial distribution of magnetization is spatially uniform.

The first condition guarantees that internal demagnetizing fields is spatially uniform. Indeed, $\mathbf{H}_\mathrm{S}$ inside uniformly magnetized ellipsoidal bodies is spatially uniform and can be expressed in terms of the demagnetizing factors. By choosing a system of unit vectors ($\mathbf{e}_x$, $\mathbf{e}_y$, $\mathbf{e}_z$) along the principal axes of the ellipsoid, one obtains:

$$\mathbf{H}_\mathrm{S}(\mathbf{M}) = -N_x M_x \mathbf{e}_x - N_y M_y \mathbf{e}_y - N_z M_z \mathbf{e}_z \qquad (11)$$

where N_x, N_y, N_z are the demagnetizing factors and $N_x + N_y + N_z = 1$ (Osborne, 1945). The second condition is necessary because the presence of surface anisotropy could produce pinning of magnetization at the body surface, which could induce spatial magnetization nonuniformities. The third condition guarantees that the anisotropy field $\mathbf{H}_K$ is spatially uniform when $\mathbf{M}$ is spatially uniform.

Under these conditions, the effective field associated with a spatially uniform magnetization state is itself spatially uniform and can be written as:

$$\mathbf{H}_\mathrm{eff}(\mathbf{M}, t) = \mathbf{H}_\mathrm{a}(t) + \mathbf{H}_K(\mathbf{M}) - N_x M_x \mathbf{e}_x - N_y M_y \mathbf{e}_y - N_z M_z \mathbf{e}_z \qquad (12)$$

This result is tantamount of the fact that the LLG equation admits spatially uniform solutions. Indeed, consider the initial-value problem for equation (8) under the condition of spatially uniform initial distribution: $\mathbf{M}(\mathbf{r}, t = 0) = \mathbf{M}_0$. It can be readily verified that a spatially uniform vector field $\mathbf{M}(t)$ is the unique solution of LLG equation (8), provided that it is the solution of the ordinary differential equation:

$$\frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} = -\gamma \mathbf{M} \times \left(\mathbf{H}_\mathrm{eff}(\mathbf{M}, t) - \frac{\alpha}{\gamma M_\mathrm{s}} \frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} \right) \qquad (13)$$

with the initial condition $\mathbf{M}(t = 0) = \mathbf{M}_0$.

Once we have recognized this important property of LLG magnetization dynamics in ellipsoidal particles, the issue of stability of spatially uniform modes naturally arises. The question is whether small nonuniform perturbations of the initial uniform magnetization distribution would increase during the time evolution or would remain small. The quantitative theory for studying this issue has not been completely established yet. The problem has been investigated in detail for certain particular cases such as nucleation theory, magnetostatic mode analysis and spin-wave analysis (Brown, 1963; Aharoni, 1996; Suhl, 1956, 1957; Walker, 1957). In qualitative terms, the smaller the magnetic body the more stable the spatially uniform solutions are expected to be. In this respect, in the remaining part of this article, we assume that the dimensions of the body are small enough that magnetization state can be considered as, with good approximation, spatially uniform. As a final remark, we also observe that the analysis presented can be also applied to nonspheroidal nanomagnets (as thin films or cubes) if one can assume *a priori* that the magnetization is spatially uniform within the magnetic body (and this again is physically reasonable for very small bodies). In this case, one can prove that equations (11) and (12) are still valid, provided that the left-hand sides of these two equations are interpreted as the spatial averaged (over the magnetic body) magnetostatic field and effective field, respectively (Aharoni, 1996). In conclusion, one can write the LLG equation in uniformly magnetized nonspheroidal bodies equation as the ordinary differential equation (13).

2.1.3 LLG equation in dimensionless form

It is useful to rewrite the LLG equation in dimensionless form to reveal the natural scales in the problem. In this respect, fields and magnetization are naturally measured in units of M_s. Accordingly, we introduce the dimensionless vectors $\mathbf{m} = \mathbf{M}/M_\mathrm{s}$ and $\mathbf{h}_\mathrm{eff} = \mathbf{H}_\mathrm{eff}/M_\mathrm{s}$. In addition, a natural timescale is provided by $(\gamma M_\mathrm{s})^{-1}$ and thus we normalize the time as $t \to \gamma M_\mathrm{s} t$ (in permalloy, with $\gamma = 2.2 \times 10^5\,\mathrm{A^{-1}\,m\,s^{-1}}$ and $M_\mathrm{s} = 8 \times 10^5\,\mathrm{A\,m^{-1}}$, one finds $\gamma M_\mathrm{s} = 176\,\mathrm{GHz}$, that is, $(\gamma M_\mathrm{s})^{-1} \simeq 6\,\mathrm{ps}$). By using these normalizations equation (13) can be written as follows:

$$\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = -\mathbf{m} \times \left(\mathbf{h}_\mathrm{eff}(\mathbf{m}, t) - \alpha \frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} \right) \qquad (14)$$

where $\mathbf{h}_\mathrm{eff}(\mathbf{m}, t) = \mathbf{H}_\mathrm{eff}/M_\mathrm{s} = \mathbf{h}_\mathrm{a}(t) + \mathbf{h}_\mathrm{S}(\mathbf{m}) + \mathbf{h}_K(\mathbf{m})$, $\mathbf{h}_\mathrm{a}(t) = \mathbf{H}_\mathrm{a}(t)/M_\mathrm{s}$, $\mathbf{h}_\mathrm{S}(\mathbf{m}) = \mathbf{H}_\mathrm{S}(\mathbf{M})/M_\mathrm{s}$, and $\mathbf{h}_K(\mathbf{m}) = \mathbf{H}_K(\mathbf{M})/M_\mathrm{s}$. According to equation (11) one has that

$$\mathbf{h}_\mathrm{S}(\mathbf{m}) = -N_x m_x \mathbf{e}_x - N_y m_y \mathbf{e}_y - N_z m_z \mathbf{e}_z \qquad (15)$$

Regarding the anisotropy field, we assume that it has the form as in equation (4) and thus we have

$$\mathbf{h}_K(\mathbf{m}) = \kappa (\mathbf{e}_K \cdot \mathbf{m}) \mathbf{e}_K \qquad (16)$$

where $\kappa = \mathrm{H}_K/M_\mathrm{s}$ is the normalized anisotropy constant (if K_1 is the physical anisotropy constant $\kappa = 2K_1/\mu_0 M_\mathrm{s}^2$, this dimensionless constant is often denoted by Q and it is referred to as *quality factor* (Kronmueller and Faehnle, 2003; Hubert and Schäefer, 1998)). If we further assume that $\mathbf{e}_K$ is along one of Cartesian unit vectors, the normalized effective field can be written in the following simple form:

$$\mathbf{h}_\mathrm{eff} = -D_x m_x \mathbf{e}_x - D_y m_y \mathbf{e}_y - D_z m_z \mathbf{e}_z + \mathbf{h}_\mathrm{a}(t) \quad (17)$$

where the parameters D_x, D_y, D_z include the effects of both demagnetizing fields and crystal anisotropy fields. In the case that $\mathbf{e}_K = \mathbf{e}_x$, they are given by:

$$D_x = N_x - \kappa, \quad D_y = N_y, \quad D_z = N_z \quad (18)$$

In the sequel, except when otherwise specified, we assume that the parameters D_x, D_y, D_z are ordered as follows:

$$D_x \leq D_y \leq D_z \quad (19)$$

which can be always achieved by an appropriate permutation of the Cartesian axes. When inequality (19) is fulfilled then the axis $\mathbf{e}_x$ is the easy axis of the magnetic particle.

The free energy associated with the magnetic body is expressed in normalized form as:

$$g_\mathrm{L}(\mathbf{m}; \mathbf{h}_\mathrm{a}) = \frac{G_\mathrm{L}(\mathbf{M}; \mathbf{H}_\mathrm{a})}{\mu_0 M_\mathrm{s}^2 V} = \frac{1}{2} D_x m_x^2 + \frac{1}{2} D_y m_y^2 + \frac{1}{2} D_z m_z^2 - \mathbf{h}_\mathrm{a}(t) \cdot \mathbf{m} \quad (20)$$

where V is the volume of the body and $G_\mathrm{L}(\mathbf{M}; \mathbf{H}_\mathrm{a})$ is the micromagnetic free energy. The effective field is related to the energy through the expression:

$$\mathbf{h}_\mathrm{eff} = -\frac{\partial}{\partial \mathbf{m}} g_\mathrm{L}(\mathbf{m}; \mathbf{h}_\mathrm{a}) \quad (21)$$

where $\partial/\partial\mathbf{m}$ denotes the gradient with respect to $\mathbf{m}$. Equation (14) can be transformed in the following equivalent form

$$\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = -\frac{1}{1+\alpha^2}\mathbf{m} \times \mathbf{h}_\mathrm{eff}(\mathbf{m}, t) - \frac{\alpha}{1+\alpha^2}\mathbf{m} \times (\mathbf{m} \times \mathbf{h}_\mathrm{eff}(\mathbf{m}, t)) \quad (22)$$

which is the normalized version of equation (9).

2.2 General aspect of LLG dynamics

2.2.1 Conservation of magnetization amplitude

It can be readily seen, by dot multiplication of both sides of equation (14) by $\mathbf{m}$, that the quadratic form $m_x^2 + m_y^2 + m_z^2$ is an integral of motion of LLG dynamics. By taking into account equation (1) and the normalization introduced in the previous section, one can conclude that under all circumstances

$$m_x^2 + m_y^2 + m_z^2 = 1 \quad (23)$$

which means that equation (14) defines a dynamical system evolving on the surface of the unit sphere. The evolution of this dynamical system proceeds along the lines of the vector field:

$$\mathbf{v}(\mathbf{m}, \alpha, t) = -\frac{1}{1+\alpha^2}\mathbf{m} \times \mathbf{h}_\mathrm{eff}(\mathbf{m}, t) - \frac{\alpha}{1+\alpha^2}\mathbf{m} \times (\mathbf{m} \times \mathbf{h}_\mathrm{eff}(\mathbf{m}, t)) \quad (24)$$

given by the right-hand side of equation (22). These lines are tangential to the unit sphere for all $\mathbf{m}$, α and t.

In the interesting particular case where the applied field is constant ($\mathrm{d}\mathbf{h}_\mathrm{a}/\mathrm{d}t = 0$), the dynamical system defined by equation (14) or (22) is autonomous, since the effective field does not depend explicitly on time anymore. Accordingly, the vector field in equation (24) is stationary: $\mathbf{v} = \mathbf{v}(\mathbf{m}, \alpha)$. The fact that the evolution of magnetization is driven by a stationary vector field tangential to the unit sphere has some remarkable consequences of a topological nature:

- There must exist equilibrium states for the system (points where $\mathbf{v} = 0$), because a stationary vector field on the sphere necessarily has singular points (Perko, 1996). In general, singular points of a vector field can be either zeros or poles where the magnitude of the vector field tends to infinity. However, the LLG vector field $\mathbf{v}$ is continuous and, consequently, it cannot have poles.
- The number of equilibria is at least two and is even under all circumstances. This conclusion is derived from Poincaré index theorem (Perko, 1996), which asserts that the number of nodes, foci, and centers minus the number of saddles of any autonomous dynamics on the sphere is equal to two. The distinctive qualitative features of saddles, nodes, foci, and centers are shown in Figures 1(a–d) (see Perko, 1996; Wiggins, 1990; Hubbard and West, 1995 for more details on the classifications of equilibria in nonlinear dynamical systems).
- Chaos is precluded, because the phase space is two dimensional (Wiggins, 1990; Hubbard and West, 1995).

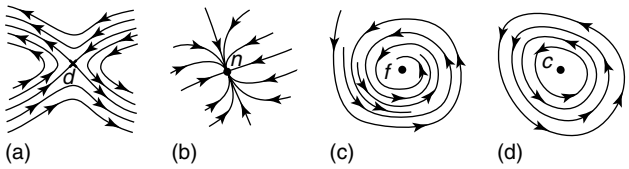

Figure 1. Qualitative sketches of magnetization dynamics on small portions of the unit sphere in neighborhoods of equilibrium points of different nature. (a) Saddle equilibrium; (b) stable node (the sketch for the unstable node can be obtained by inverting the arrows); (c) stable focus (the sketch for the unstable focus can be obtained by inverting the arrows); (d) center (this kind of equilibrium is generally present only in conservative (undamped) systems).

This is the consequence of the generalized version of the Poincaré-Bendixson theorem, which states that on two-dimensional manifolds the only possible steady states are either stationary states associated with equilibria or self-oscillations (periodic steady states) associated with limit cycles of the dynamics. The distinctive features of limit cycles are shown in Figure 14.

2.2.2 *Energy balance in LLG dynamics*

The equation describing the time evolution of the free energy can be readily obtained from the LLG equation written in the form (14). Dot multiplication of both sides of the equation by $\mathbf{h}_{\text{eff}}(\mathbf{m}, t) - \alpha \mathrm{d}\mathbf{m}/\mathrm{d}t$ yields $(\mathbf{h}_{\text{eff}}(\mathbf{m}, t) - \alpha \mathrm{d}\mathbf{m}/\mathrm{d}t) \cdot \mathrm{d}\mathbf{m}/\mathrm{d}t = 0$. Then, by using the fact that $\mathbf{h}_{\text{eff}} = -\partial g_{\text{L}}/\partial \mathbf{m}$, one arrives at the energy balance equation:

$$\frac{\mathrm{d}}{\mathrm{d}t} g_{\text{L}}(\mathbf{m}; \mathbf{h}_{\text{a}}) = -\alpha \left| \frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} \right|^2 - \mathbf{m} \cdot \frac{\mathrm{d}\mathbf{h}_{\text{a}}}{\mathrm{d}t} \tag{25}$$

The two terms on the right-hand side respectively represent the power dissipated because of intrinsic damping and the power supplied through the action of the time-varying applied field.

When the applied field is constant, the energy balance equation is reduced to the simpler form:

$$\frac{\mathrm{d}g_{\text{L}}}{\mathrm{d}t} = -\alpha \left| \frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} \right|^2 \tag{26}$$

which has the following important consequences:

- The dynamics of the system is such that the free energy $g_{\text{L}}(\mathbf{m}(t); \mathbf{h}_{\text{a}})$ is always a decreasing function of time.
- The time derivative of $g_{\text{L}}(\mathbf{m}(t); \mathbf{h}_{\text{a}})$ is zero only when $\mathrm{d}\mathbf{m}/\mathrm{d}t = 0$, namely, when the system reaches equilibrium points. Since equilibrium points are stationary points for the energy, the dynamics is directed away from energy maxima and toward energy minima.
- No self-oscillations (periodic solutions) are admissible. Indeed, the necessary condition for the existence of a nonconstant periodic solution is that $g_{\text{L}}(\mathbf{m}(t); \mathbf{h}_{\text{a}})$ is a periodic (nonmonotone) function of time. This requirement is in contradiction with the monotone time decrease implied by equation (26).

The considerations in the preceding text also apply to the case when $\mathbf{h}_{\text{a}}(t)$ has only a transient variation and, after a finite interval of time, becomes a constant vector (this is the typical case in magnetization switching under pulsed field). When the applied field becomes constant the energy balance expressed by equation (26) precludes the appearance of self-oscillations in the system dynamics: the magnetization will always evolve toward one of the stable equilibria. In the case of coexisting stable equilibria, which will be the final equilibrium state is determined by the applied field history and by the initial magnetization state.

On the other hand, when the vector field $\mathbf{v}(\mathbf{m}, \alpha, t)$ is not stationary, LLG dynamics becomes much more complicated, and quasiperiodic or chaotic solutions may appear (Wigen, 1994; Alvarez, Pla and Chubykalo, 2000).

We should mention here that there is a special case of nontransient and periodic variation of the applied field in which magnetization dynamics can, nevertheless, be reduced to autonomous form. This is the case when the magnetic body has uniaxial symmetry and the applied field is time harmonic and circularly polarized. By taking advantage of the symmetry of the problem, one can introduce a reference frame in which the applied field is constant and the dynamics is reduced to an autonomous dynamical system on the unit sphere (Bertotti, Serpico and Mayergoyz, 2001; Bertotti, Mayergoyz and Serpico, 2006b). This case is treated in details in Section 5.

3 MAGNETIZATION DYNAMICS ON THE UNIT SPHERE

3.1 Equilibria

3.1.1 *The general problem*

The first step in the analysis of magnetization dynamics is the determination of the equilibrium points and the study of their stability. We will focus our attention on the study of equilibria in the case of constant applied field. Equilibrium states are found by solving the equation:

$$\mathbf{m} \times \mathbf{h}_{\text{eff}} = 0 \tag{27}$$

under the constraint $|\mathbf{m}| = 1$. Notice that due to the viscous-like nature of damping in LLG dynamics (damping proportional to $\mathrm{d}\mathbf{m}/\mathrm{d}t$), the equilibrium states are not affected by the value of α and thus the problem of finding equilibria can be formulated in terms of the free energy only. If we take into account the constraint $|\mathbf{m}| = 1$, equation (27) can be rewritten in spherical coordinates as two scalar equations:

$$\frac{\partial g_{\mathrm{L}}}{\partial \theta} = 0, \frac{\partial g_{\mathrm{L}}}{\partial \phi} = 0 \tag{28}$$

which means that LLG equilibria are always critical points of the free energy $g_{\mathrm{L}}(\mathbf{m}; \mathbf{h}_{\mathrm{a}})$ with $\mathbf{m}$ restricted to vary on the unit sphere. In this respect, equilibria can be classified as energy maxima (which will be indicated with the label 'u'), energy minima (indicated by the letter 's') and energy saddles (indicated by the letter 'd'). If the magnetic body is invariant with respect to the angle ϕ, the second equation in equation (28) can be ignored. This is the case corresponding to the Stoner–Wohlfarth model (Stoner and Wohlfarth, 1948) reviewed briefly below. For more general magnetic systems, it is necessary to consider some appropriate extension of the Stoner–Wohlfarth theory. In this respect, a rather general approach is to solve the following system of equations:

$$\mathbf{h}_{\mathrm{eff}}(\mathbf{m}) = \lambda \mathbf{m}, \qquad |\mathbf{m}|^2 = 1 \tag{29}$$

which is equivalent to four scalar equations for the four unknowns represented by λ and the three components of $\mathbf{m}$. This approach was proposed in Donahue and Porter (2002) and leads to the determination of *two*, *four*, or *six* equilibrium points, depending on the value and the orientation of the applied field. This treatment is, however, based on the assumption of uniaxial crystalline anisotropy. A comprehensive treatment of equilibrium magnetization states in uniformly magnetized particles for an arbitrary crystalline anisotropy can be found in Thiaville (2000).

The classification of equilibria in terms of the free energy is also instrumental for the understanding of their stability properties under constant applied field. In this case, according to equation (26), if the system is not at equilibrium, magnetization motion is such that the free energy decreases in time for $\alpha > 0$ and remains constant for $\alpha = 0$. Thus, for $\alpha > 0$, the dynamics will always bring magnetization away from energy maxima and toward energy minima. On the other hand, for $\alpha = 0$ the magnetization will keep on precessing around an energy minimum or maximum if it is initially close to it. We conclude that for $\alpha > 0$ energy maxima are unstable nodes or foci and energy minima are stable nodes or foci of the dynamics (see Figure 1b and c, respectively). Conversely, for $\alpha = 0$ energy maxima and minima are all centers of the dynamics (see Figure 1d). The energy saddles are also unstable. Indeed, in any neighbor of a saddle there are magnetization states with energy lower than the energy of the saddle. Thus, in the case $\alpha > 0$, magnetization will be directed away from the saddle. In the case $\alpha = 0$ the magnetization trajectories follow Constant-energy lines and since the dynamics around the saddle is like the one depicted in Figure 1(a), almost all trajectories tend to go away from the saddle.

3.1.2 Stoner–Wohlfarth model

The Stoner–Wohlfarth theory applies to spheroidal particles with rotational symmetry. We assume that the symmetry axis and the magnetocrystalline easy axis are both along the x axis. This implies that $N_y = N_z$ and $\mathbf{e}_K = \mathbf{e}_x$, and parameters D_x, D_y, D_z are given by:

$$D_x = N_x - \kappa, \quad D_y = D_z = D_\perp \tag{30}$$

where the notation '$\perp$' indicates the direction perpendicular to $\mathbf{e}_x$. By using the latter equations and the condition $|\mathbf{m}|^2 = 1$, the free energy of the particle (20) can be easily recast in the following form:

$$g_{\mathrm{L}}(\mathbf{m}; \mathbf{h}_{\mathrm{a}}) = -\frac{1}{2}(D_\perp - D_x)m_x^2 + \frac{1}{2}D_\perp - \mathbf{h}_{\mathrm{a}} \cdot \mathbf{m} \tag{31}$$

where $D_\perp - D_x$ is a positive quantity. We observe that, for symmetry reasons, at equilibrium, the magnetization lies in the plane defined by the easy axis $\mathbf{e}_x$ and the applied field $\mathbf{h}_{\mathrm{a}}$. By introducing the spherical angle θ between $\mathbf{m}$ and $\mathbf{e}_x$, one has $m_x = \cos\theta$ and equation (31) can be transformed into:

$$g_{\mathrm{L}}(\theta; \mathbf{h}_{\mathrm{a}}) = \frac{1}{2}D_x + \frac{1}{2}\kappa_{\mathrm{eff}} \sin^2\theta - h_{ax}\cos\theta - h_{a\perp}\sin\theta \tag{32}$$

where

$$\kappa_{\mathrm{eff}} = D_\perp - D_x \tag{33}$$

is the effective anisotropy constant, h_{ax} and $h_{a\perp}$ are the components of the applied field parallel and perpendicular to the x–axis, respectively. The equilibria can be found by means of the first of equation (28) which, after simple algebraic manipulations, becomes

$$\frac{h_{a\perp}}{\sin\theta_0} - \frac{h_{ax}}{\cos\theta_0} = \kappa_{\mathrm{eff}} \tag{34}$$

For given values of h_{ax} and $h_{a\perp}$, equation (34) returns the angles θ_0 such that the free energy has an extremum. It is interesting to notice that equation (34) can be transformed

into a polynomial equation. Indeed, after appropriate algebraic manipulations, one readily derives the following quartic equation in $m_x = \cos\theta$:

$$h_{a\perp}^2 m_x^2 = (h_{ax} + \kappa_{\text{eff}} m_x)^2 (1 - m_x^2) \tag{35}$$

which admits either two real solutions or four real solutions depending on the values of the parameters $h_{ax}, h_{a\perp}, \kappa_{\text{eff}}$. Each of these solutions corresponds to a stable or unstable equilibrium.

Qualitatively speaking, one can easily see from equation (32) that for small values of the applied field (e.g., consider the case $h_{ax} = 0, h_{a\perp} = 0$) the anisotropy energy prevails and the free energy has two minima (near the states $\mathbf{m} = \pm\mathbf{e}_x$) while, for sufficiently strong applied fields, the linear term $-\mathbf{h}_a \cdot \mathbf{m}$ prevails and the free energy has only one minima characterized by a magnetization direction approximately aligned with the applied field. Thus, there exists a region around the origin of the control plane $(h_{ax}, h_{a\perp})$ in which there are two minima of the free energy whereas, outside this region, there is only one minimum.

A more systematic study of energy maxima and minima can be carried out by computing $\partial^2 g_{\text{L}}/\partial\theta^2$ at the equilibria, that is, at values θ_0 which are solutions of equation (34). This is given by:

$$\left.\frac{\partial^2 g_{\text{L}}}{\partial\theta^2}\right|_{\theta_0} = \frac{\kappa_{\text{eff}} \cos^3\theta_0 + h_{ax}}{\cos\theta_0} = \frac{h_{a\perp} - \kappa_{\text{eff}} \sin^3\theta_0}{\sin\theta_0} \tag{36}$$

The boundary between the region with two minima and region with one minima is a bifurcation line which can be found by searching equilibria with $\partial^2 g_{\text{L}}/\partial\theta^2 = 0$, that is, inflection points. These points correspond to the critical condition expected when a minima disappears (this process correspond to the so-called saddle-node bifurcation (Kuznetsov, 1995)). By using this condition in equation (36), one arrives to the parametric representation of the bifurcation line which is referred to as the *Stoner–Wohlfarth astroid*:

$$\begin{cases} h_{ax} = -\kappa_{\text{eff}} \cos^3\theta_0 \\ h_{a\perp} = \kappa_{\text{eff}} \sin^3\theta_0 \end{cases} \tag{37}$$

which can be expressed in implicit form by the following equation:

$$h_{ax}^{2/3} + h_{a\perp}^{2/3} = \kappa_{\text{eff}}^{2/3} \tag{38}$$

The Stoner–Wohlfarth asteroid is the curve labeled as A_{sw} in Figure 2.

The Stoner–Wohlfarth asteroid has remarkable geometrical properties which permit one to graphically derive the directions of admissible magnetization equilibria. To discuss these proprieties, we first notice that the equation (34), which gives magnetization equilibria, can be interpreted in the following way: given an equilibrium state $\mathbf{m}$, that is, assigned the value θ_0, this equation gives the set of excitation conditions $(h_{ax}, h_{a\perp})$ which produce such $\mathbf{m}$. Since (34) is linear in $(h_{ax}, h_{a\perp})$, this set is a straight line in the $(h_{ax}, h_{a\perp})$ plane, and it has slope $\text{tg}\theta_0$. This line touches the Stoner–Wohlfarth asteroid in the point of the (h_{ax}, h_{ay}) plane given by equation (37). One can easily check that the tangent to the asteroid, at the point given by the angle θ_0, is given by

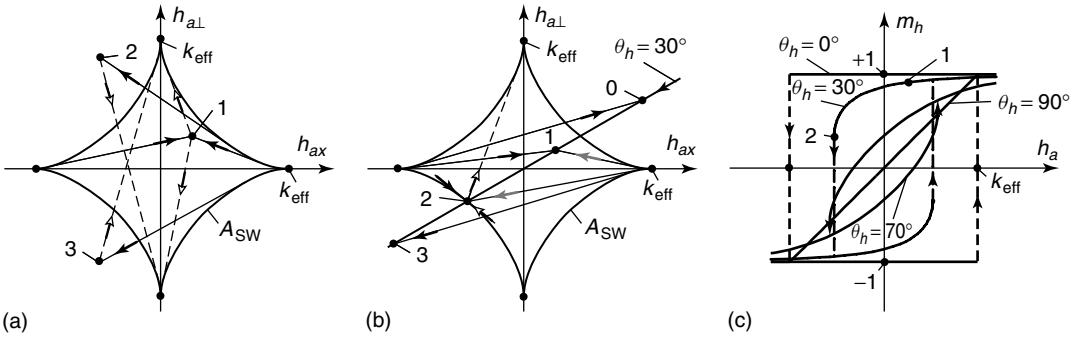

Figure 2. Illustration of Stoner–Wohlfarth tangent construction and hysteresis loops of m_h versus h_a. (a) Points 1, 2, 3 in the control plane and associated tangent lines to the Stoner–Wohlfarth asteroid. Black arrows and white arrows along the tangent lines represent stable and unstable equilibria, respectively. (b) The applied field point $(h_{ax}, h_{a\perp})$ moves along the straight line, with slope $\theta_h = 30°$, going through points 0, 1, 2, 3. This line represents applied fields $h_{ax} = h_a \cos\theta_h$, $h_{a\perp} = h_a \sin\theta_h$ with decreasing amplitude h_a and fixed direction. The evolution of magnetization is given by the black arrows (stable equilibrium) which are obtained by the tangent construction. Notice that when the field point is inside the asteroid, there is a second stable equilibrium, which is represented with a gray arrow. At the point 2 (where all equilibria are represented), the equilibrium represented by the black arrow annihilates with an unstable equilibria (white arrow) and the magnetization 'jumps' toward the remaining stable equilibrium. (c) Hysteresis loop in the plane (m_h, h_a) for different values of θ_h; m_h is the component of $\mathbf{m}$ along the direction of $\mathbf{h}_a$. The points 1 and 2 correspond to the points 1, 2 in (b). Jumps of magnetization are represented by dashed lines.

$dh_{a\perp}/dh_{ax} = (dh_{a\perp}/d\theta)(d\theta/dh_{ax}) = \mathrm{tg}\theta_0$. This means that the straight line (34), for $\theta = \theta_0$, is a tangent at the point of the Stoner–Wohlfarth asteroid which corresponds to θ_0. This geometrical property suggests the following construction: given a point in the control plane we can draw the tangent lines to the asteroid emanating from this point. The slope of each of these lines identifies a possible magnetization equilibrium. According to equation (37), the upper half of the asteroid corresponds to $0 < \theta_0 < \pi$, while the lower half corresponds to $-\pi < \theta_0 < 0$. Thus, tangent lines to the upper half correspond to magnetization equilibrium directions pointing upward, while tangent lines to the lower half correspond to magnetization equilibrium directions pointing downward (see Figure 2a). One also can see that, while only two tangent lines can be drawn from points external to the asteroids (see points 2, 3 in Figure 2a), four tangents can be drawn from points inside it (see points 1 in Figure 2a). Each of these tangents may identify either a stable or an unstable state and the stability can be discussed using equation (36). Let us use the last expression in this equation. One can see that when a tangent to the asteroid drawn from the point $(h_{ax}, h_{a\perp})$ touches the upper half of the asteroid $(0 < \theta_0 < \pi, \sin\theta_0 > 0)$ the corresponding equilibrium is an energy minimum $(\partial^2 g_L/\partial\theta^2|_{\theta_0} > 0)$ or an energy maximum $(\partial^2 g_L/\partial\theta^2|_{\theta_0} < 0)$ depending on if $h_{a\perp} > \kappa_{\mathrm{eff}} \sin^3\theta_0$ (i.e., $(h_{ax}, h_{a\perp})$ is above the tangency point) or $h_{a\perp} < \kappa_{\mathrm{eff}} \sin^3\theta_0$ (i.e., $(h_{ax}, h_{a\perp})$ is below that the tangency point), respectively. On the other hand, when the tangent line touches the lower half of the asteroid $(-\pi < \theta_0 < 0,\ \sin\theta_0 < 0)$, the opposite occurs, and the equilibrium is an energy minimum or an energy maximum depending if $h_{a\perp} < \kappa_{\mathrm{eff}} \sin^3\theta_0$ or $h_{a\perp} > \kappa_{\mathrm{eff}} \sin^3\theta_0$, respectively. According to this rule, only one stable equilibrium exists when the applied field point $(h_{ax}, h_{a\perp})$ is outside the asteroid. Conversely, two stable equilibria exist when $(h_{ax}, h_{a\perp})$ is inside the asteroid (see Figures 2a and b).

The asteroid properties discussed in the preceding text are the basis for the analysis of magnetization process taking place when the applied field is slowly varied over time. This variation has to occur on a time scale much larger than the timescale of the transient necessary to let magnetization relax to a stable equilibrium state. This condition corresponds to static hysteresis processes. Let us consider the case when $\mathbf{h}_a$ oscillates between opposite values along a fixed direction. The $\mathbf{m}$ orientation at each point is obtained by the tangent construction discussed in the preceding text. Inside the asteroid two orientation are possible, and the one which is actually realized depends on past history (see Figure 2b). If the field oscillation were all contained inside the asteroid, the magnetization would reversibly oscillate around the orientation initially occupied. A qualitatively different behavior occurs when the field amplitude is large enough to cross the asteroid boundary. The state occupied by the system may lose stability when the field point $(h_{ax}, h_{a\perp})$ exits the asteroid and the magnetization jumps discontinuously to a new equilibrium state (see point 2 in Figure 2b). This irreversible jumps are also referred to as Barkhausen jumps. In Figure 2(b) it is shown the magnetization half cycle where the field intensity decrease from positive to negative values. The process related to the increasing-field half cycle can be easily derived by symmetry. The hysteresis process can be clearly shown by representing the component $m_h = \cos(\theta_0 - \theta_h)$ of $\mathbf{m}$ along the applied field direction (θ_h is the angle between $\mathbf{h}_a$ and $\mathbf{e}_x$). By using different values of θ_h, one obtains static hysteresis loops as drawn in Figure 2(c). Note, in particular, that no loop at all is obtained when the field is exactly perpendicular to the anisotropy axis ($\theta_h = 90^\circ$).

3.1.3 Equilibria when one component of the applied field is zero

In many cases relevant to applications, one can assume that the applied field $\mathbf{h}_a$ lies in one of the coordinate planes, namely, that one of the Cartesian components of $\mathbf{h}_a$ is zero. In this situation, the analysis of equilibria can be substantially simplified. In the following, we will assume that $h_{az} = 0$, but the theory can be extended to the other cases by an appropriate reorientation of the Cartesian axes. In the case $h_{az} = 0$, by using the fact that $m_z^2 = 1 - m_x^2 - m_y^2$, m_z can be eliminated from the expression of the free energy, equation (20). This leads to the following formula:

$$g_L(\mathbf{m}; \mathbf{h}_a) = -\frac{D_z - D_x}{2} \times \left[(m_x - a_x)^2 + k^2 \left(m_y - a_y\right)^2 - p_0^2\right] \quad (39)$$

where:

$$a_x = -\frac{h_{ax}}{D_z - D_x}, a_y = -\frac{h_{ay}}{D_z - D_y}, k^2 = \frac{D_z - D_y}{D_z - D_x} \quad (40)$$

$$p_0^2 = a_x^2 + a_y^2 + \frac{D_z}{D_z - D_x} \quad (41)$$

Equation (39) is written in a particularly simple form because it already includes the constraint $|\mathbf{m}|^2 = 1$. This form permits one to readily recognize the nature of equilibria, namely, whether they are energy maxima, minima, or saddles.

Let us start our discussion by writing the equation for equilibria. By using the constants defined in equation (40) and (41), the components of equation (27) along the three

Cartesian axes can be written as

$$\left(D_z - D_y\right) m_z \left(m_y - a_y\right) = 0 \tag{42}$$

$$-\left(D_z - D_x\right) m_z \left(m_x - a_x\right) = 0 \tag{43}$$

$$\left(D_z - D_x\right) m_y \left(m_x - a_x\right) - \left(D_z - D_y\right) m_x \left(m_y - a_y\right) = 0 \tag{44}$$

Due to the form of equations (42–44), it is convenient to divide equilibria in two families: equilibria with $m_z \neq 0$ and equilibria with $m_z = 0$.

- Equilibrium points with $m_z \neq 0$
  In this case, equations (42–43) immediately lead to $m_x = a_x$ and $m_y = a_y$. The value of m_z can be then determined from the constraint $|\mathbf{m}| = 1$. This leads to two equilibrium points:

$$m_x = a_x, m_y = a_y, m_z = \pm\sqrt{1 - a_x^2 - a_y^2} \tag{45}$$

  which are symmetric with respect to the (m_x, m_y) plane. Notice that solutions of this type are possible only when the field lies inside the region confined by:

$$a_x^2 + a_y^2 = 1 \tag{46}$$

  that is:

$$\frac{h_{ax}^2}{\left(D_z - D_x\right)^2} + \frac{h_{ay}^2}{\left(D_z - D_y\right)^2} = 1 \tag{47}$$

  The expression (39) of the free energy shows that these equilibria are always energy maxima.
- Equilibrium points with $m_z = 0$
  This class of equilibria is characterized by the condition $m_x^2 + m_y^2 = 1$. Thus, their positions on the unit circle of the (m_x, m_y) plane can be described by the angle coordinate ϕ_0: $m_x = \cos\phi_0$, $m_y = \sin\phi_0$. The angle ϕ_0 associated with the equilibrium points is obtained by solving equation (44) rewritten in the form:

$$\left(D_y - D_x\right) \sin\phi_0 \cos\phi_0 + h_{ax} \sin\phi_0 - h_{ay} \cos\phi_0 = 0 \tag{48}$$

  In order to interpret the meaning of equation (48), it is useful to express the system free energy $g_{\mathrm{L}}(\mathbf{m}; \mathbf{h}_{\mathrm{a}})$ (see equation (20)) for $m_z = 0$ in terms of the angle ϕ_0:

$$g_{\mathrm{L}}\left(m_z = 0, \phi_0; \mathbf{h}_{\mathrm{a}}\right) = \frac{1}{2} D_x + \frac{1}{2}\left(D_y - D_x\right) \sin^2\phi_0 - h_{ax} \cos\phi_0 - h_{ay} \sin\phi_0 \tag{49}$$

  This energy expression is identical to equation (32) considered in the Stoner–Wohlfarth model, with $(D_y - D_x)$, h_{ay}, and ϕ_0 playing the role of κ_{eff}, $h_{a\perp}$ and θ_0, respectively. Equation (48) coincides with the equation $\partial g_{\mathrm{L}}/\partial\phi_0 = 0$. It can be inferred from this fact that all the results known for the Stoner–Wohlfarth model can be extended to the equilibrium points characterized by $m_z = 0$. In particular, one immediately concludes that there will be either four equilibrium points, two of which will be energy minima, or two equilibrium points, one of which will be an energy minimum. The bifurcation line where the number of energy minima changes from one to two or vice versa is given by the asteroid curve in the (h_{ax}, h_{ay}) control plane shown in Figure 3:

$$h_{ax}^{2/3} + h_{ay}^{2/3} = \left(D_y - D_x\right)^{2/3} \tag{50}$$

In conclusion, there are four qualitative different situations, separated by the two bifurcation lines given by equations (47) and (50) (see Figure 3).

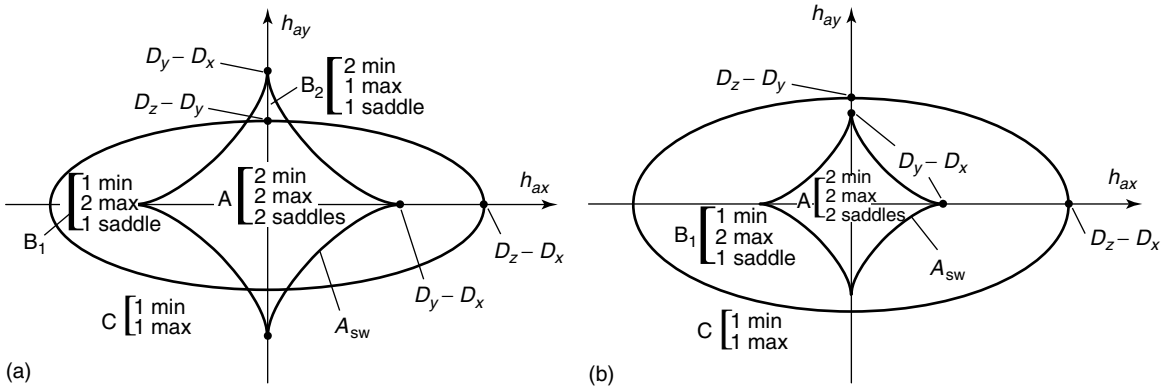

Figure 3. Bifurcation lines in the (h_{ax}, h_{ay}) control plane. (a) $D_z - D_y < D_y - D_x$; (b) $D_z - D_y > D_y - D_x$. The label A_{sw} indicates Stoner–Wohlfarth asteroid.

- Region A, 6 equilibrium points: 2 minima, 2 maxima, 2 saddles
- Region B_1, 4 equilibrium points: 1 minimum, 2 maxima, 1 saddle
- Region B_2, 4 equilibrium points: 2 minima, 1 maximum, 1 saddle
- Region C, 2 equilibrium points: 1 minimum, 1 maximum.

In this classification, the number of saddles has been indirectly determined on the basis of Poincaré index theorem: the number of maxima and minima minus the number of saddles must be equal to two. Let us notice that for certain values of the parameters D_x, D_y and D_z the region B_2 may not exist (see Figure 3b). The condition for the existence of region B_2 is that $D_y - D_x > D_z - D_y$.

3.2 Geometrical and analytical descriptions of conservative LLG dynamics

3.2.1 Unit-circle representation

As we have already discussed in a previous section (see Section 3.1.3), due to the viscouslike nature of the damping, equilibria of the system are given by critical points of the free energy $g_L(\mathbf{m}; \mathbf{h}_a)$. In addition, since the damping constant α is usually a small quantity, on short timescales, LLG dynamics is approximately conservative. In this respect, detailed information of the nature of dynamics can be obtained from the configuration of constant-energy lines, that is, the lines given by $g_L(\mathbf{m}; \mathbf{h}_a) = g_0$ on the unit sphere. It turns out that, in the case when one of the components of the applied field is zero (in the following we will assume $h_{az} = 0$), it is possible to give a two-dimensional representation of constant-energy lines. Indeed, by taking into account equation (39) and setting the energy equal to g_0 we end up with the equation:

$$(m_x - a_x)^2 + k^2 \left(m_y - a_y\right)^2 = p^2 \tag{51}$$

where:

$$p^2 = a_x^2 + k^2 a_y^2 + \frac{D_z - 2g_0}{D_z - D_x} \tag{52}$$

Equation (51) shows that the projection of magnetization trajectories on the (m_x, m_y) plane is described by a family of self-similar elliptic curves with aspect ratio k (which, according to equation (40), depends only on the anisotropy factors), all centered at the point (a_x, a_y). The family of ellipses is generated by varying the free energy value g_0 within an appropriate interval. Indeed, for a given value of $\mathbf{h}_a$, the constant g_0 controls the size of the ellipses through equation (52). It must be underlined that the only admissible portions of the ellipses are obtained by taking those parts of equation (51) which lie inside the circle $m_x^2 + m_y^2 \leq 1$. Although this representation involves only two components of magnetization, information on the third component m_z can be immediately obtained by using that $m_z^2 = 1 - (m_x^2 + m_y^2)$. For example, $m_z = \pm 1$ when $(m_x, m_y) = (0, 0)$ while $m_z = 0$ when (m_x, m_y) lies on the unit circle. The unit-circle representation can be interpreted as a top view of the unit sphere. In this sense, only the upper hemisphere $m_z > 0$ is immediately represented. However, when the applied field lies in the (x,y) plane, the free energy has a mirror symmetry with respect to the (m_x, m_y) plane and this implies that constant-energy lines (or parts of the same constant-energy line) with given energy g_0, belonging to different hemispheres, are projected into the same ellipse (or portion of ellipse) in the (m_x, m_y) plane. In other terms, the unit circles representation consists of lines, each of which represents two constant-energy (conservative) trajectories or two parts of the same trajectory with opposite values of m_z. The ellipses originating from the energy saddles (bold lines passing through the point indicated with d) are either homoclinic trajectories, that is, trajectories starting and ending on a saddle equilibrium, or heteroclinic trajectory, that is, trajectories starting from a saddle equilibrium and ending at a different saddle equilibrium. Trajectories, homoclinic, and heteroclinic, passing through saddles are also referred to as separatrices because they create a natural partition of the phase portrait into different 'central regions' (regions spanned by a continuum of nested closed lines on the unit sphere). Examples of unit-circle representation are reported in Figure 4(a–c). The three figures correspond to zero applied field, field applied along x axis, and field applied along y axis, respectively.

3.2.2 Integrability of conservative dynamical equations

We already mentioned in Section 3.2.1 that the family of trajectories with constant energy gives important information about LLG dynamics on short timescale owing to the fact that the damping constant is normally a small parameter. In this section, we show that conservative LLG dynamics can be studied analytically. The starting point for the analytical solution of the conservative dynamics is equation (51), which shows that the projection of the magnetization trajectory onto the (m_x, m_y) plane is an arc of the ellipse. Therefore, the trajectory can be expressed in the parametric form:

$$m_x = a_x - p\cos u, \quad m_y = a_y + \frac{p}{k}\sin u \tag{53}$$

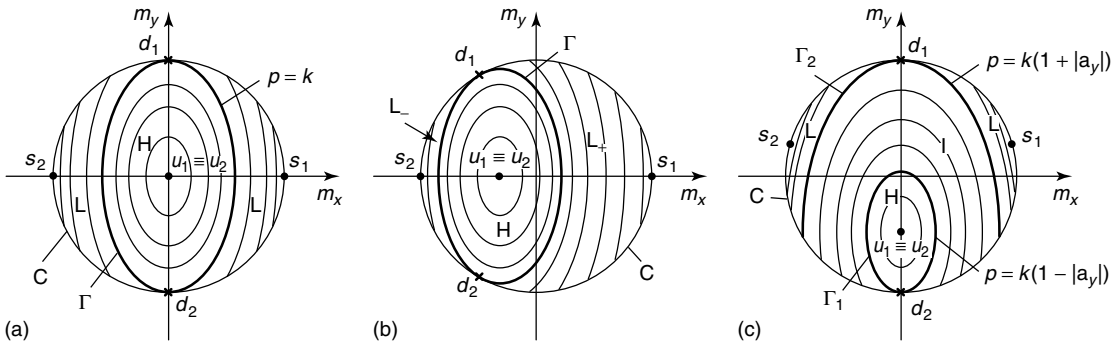

Figure 4. Sketches of the unit-circle representation for three different values of $\mathbf{h}_a$: (a) $\mathbf{h}_a = 0$, (b) $\mathbf{h}_a = h_{ax}\mathbf{e}_x$, (c) $\mathbf{h}_a = h_{ay}\mathbf{e}_y$. Magnetization trajectories are obtained from the intersection of the ellipses given by equation (51) with the unit circle $m_x^2 + m_y^2 \leq 1$. The following notation is used to indicate equilibrium points: 's' denotes energy minima, 'u' denotes energy maxima, and 'd' denotes energy saddles. The thicker lines (indicated by Γ) denote separatrices (homoclinic and heteroclinic trajectories). Letters H, L, I are used to label 'central regions': H denotes 'high-energy regions', L denotes 'low-energy regions', and I denotes 'intermediate energy regions'.

where the connection between the parametric variable u and time is to be determined. Equation (53) implies that the remaining magnetization component m_z will be given by:

$$m_z = \pm\sqrt{1 - (a_x - p\cos u)^2 - (a_y + (p/k)\sin u)^2} \quad (54)$$

By inserting equation (53) into the x component of equation (14) with $\alpha = 0$, one finds:

$$\frac{\mathrm{d}u}{\mathrm{d}t} = k\,(D_z - D_x)\,m_z \quad (55)$$

Since m_z depends on u only, one obtains the desired equation for $u(t)$ by using the method of separation of variables:

$$\frac{\mathrm{d}u}{\sqrt{1 - (a_x - p\cos u)^2 - \left(a_y + (p/k)\sin u\right)^2}} = k\,(D_z - D_x)\,\mathrm{d}t \quad (56)$$

where the '$\pm$' signs are no longer indicated because the last equation is to be interpreted as an equation for multibranch analytical functions in the complex plane.

Equation (56) is solvable in terms of elliptic integrals. This can be shown by carrying out the substitution $w = \tan(u/2)$, which transforms equation (56) into the equation:

$$\frac{\mathrm{d}w}{\sqrt{P(w)}} = \frac{k}{2}\,(D_z - D_x)\,\mathrm{d}t \quad (57)$$

where $P(w)$ represents the fourth-order polynomial:

$$P(w) = \left(1 + w^2\right)^2 - \left[a_x(1 + w^2) - p(1 - w^2)\right]^2 - \left[a_y(1 + w^2) + (2p/k)w\right]^2 \quad (58)$$

Equation (57) is precisely of the form permitting integration in terms of elliptic integrals and elliptic functions (Hancock, 1958; Smirnov, 1989). However, the integration is based on the knowledge of the roots of the polynomial $P(w)$, which are generally given by rather complicated formulas.

3.2.3 Solution under zero field

The study of equation (56) in all its complexity is carried out in Bertotti, Mayergoyz and Serpico (2006a), here we limit ourselves to the case of zero applied field, which gives some first insight into the properties of conservative magnetization dynamics. This case is simple enough to be solved without excessive technical complications. Under zero field, conservative LLG equation (see equation (14) with $\alpha = 0$, and equation (17) with $\mathbf{h}_a = 0$) becomes formally identical to Euler equation for the angular momentum of a rigid body (Landau and Lifshitz, 1976). The unit-circle representation of conservative magnetization trajectories is, in this case, the one in Figure 4(a): the unit sphere is partitioned into four central regions, two symmetric high-energy regions (indicated by H and projected into the same region of the unit circle) and two symmetric low-energy energy regions (indicated by L). The magnetization components (equations (53) and (54)) can be expressed as functions of $w = \sin u$ only, since $a_x = a_y = 0$ (see equation (40)) and one finds that:

$$m_x = \mp p\sqrt{1 - w^2}, \quad m_y = \frac{p}{k}w,$$
$$m_z = \pm\frac{k'p}{k}\sqrt{w_0^2 - w^2} \quad (59)$$

where:

$$w_0 = \frac{k}{k'p}\sqrt{1 - p^2} \quad (60)$$

$k'^2 = 1 - k^2$, and p^2 is linearly related to the system energy through equation (52), which for zero field is reduced to:

$$p^2 = \frac{D_z - 2g_0}{D_z - D_x} \tag{61}$$

By making the change of variable $w = \sin u$ in equation (56), one obtains the following equation:

$$\frac{\mathrm{d}w}{\sqrt{\left(1 - w^2\right)\left(1 - k_H^2 w^2\right)}} = \Omega_H \mathrm{d}t \tag{62}$$

where:

$$k_H = \frac{1}{w_0} = \frac{k'p}{k}\frac{1}{\sqrt{1 - p^2}} \tag{63}$$

$$\Omega_H = k\sqrt{1 - p^2}\,(D_z - D_x) \tag{64}$$

The solution of equation (62) is the Jacobi 'sin-type' elliptic function (Hancock, 1958):

$$w = \mathrm{sn}\,(\Omega_H t, k_H) \tag{65}$$

By inserting equation (65) into equation (59) and by using Jacobi elliptic function transformation rules one obtains the magnetization components:

$$m_x = \mp p\,\mathrm{cn}\,(\Omega_H t, k_H) \tag{66}$$

$$m_y = \frac{p}{k}\mathrm{sn}\,(\Omega_H t, k_H) \tag{67}$$

$$m_z = \pm\sqrt{1 - p^2}\mathrm{dn}\,(\Omega_H t, k_H) \tag{68}$$

One finds two sets of solutions, depending on the choice made for the sign of m_z. The corresponding sign of m_x is determined by using LLG equation. Equations (66)–(68) depend on the energy g_0 of the conservative motion through the parameter p defined by equation (61). The parameter p has an intuitive geometrical meaning. As shown by equation (51), it measures the size of the ellipse along which the magnetization motion takes place. The energy of the system takes values in the interval (see equation (39)):

$$\frac{D_x}{2} \le g_0 \le \frac{D_z}{2} \tag{69}$$

that is, $0 \le p^2 \le 1$. When g_0 is varied in this interval, the first two equations in equation (59) generate the unit-circle representation of the conservative phase portrait shown in Figure 4(a). The energy maxima ('u_1', 'u_2' in in Figure 4a) correspond to $p = 0$, where the constant-energy ellipse given by equation (51) is reduced to a point, whereas $p = 1$ represents the energy minima ('s_1', 's_2' in Figure 4a), where the ellipse is tangent to the unit circle from outside. The heteroclinic separatrix trajectories (bold lines Γ connecting the two saddles 'd_1', 'd_2' in Figure 4a) divide the portrait into the high-energy (H) and low-energy (L) regions.

- *Region H:* This region actually consists of two separate regions symmetric with respect to the (m_x, m_y) plane. The system energy varies in the interval $D_y/2 \le g_0 \le D_z/2$, that is:

$$0 \le p^2 \le k^2 \tag{70}$$

According to equation (63), $0 \le k_H \le 1$ in this region, so one immediately concludes from equations (66)–(68) that the magnetization motion is a precessional motion about the hard z axis. By taking into account the properties of Jacobi elliptic functions, one obtains for the precession period:

$$T_{g_0} = \frac{4\mathbf{K}(k_H)}{\Omega_H} \tag{71}$$

where $\mathbf{K}(k_H)$ represents the complete elliptic integral of the first kind (Hancock, 1958; Smirnov, 1989).

- *Region L:* This region consists of two regions symmetric with respect to the (m_y, m_z) plane, in which the energy varies in the interval $D_x/2 \le g_0 \le D_y/2$. Therefore:

$$k^2 \le p^2 \le 1 \tag{72}$$

which implies $1 \le k_H \le \infty$. The nature of the corresponding magnetization motions is made clear by observing that the role of cn and dn Jacobi functions is exchanged when their modulus exceeds 1. By using known transformation rules for Jacobi functions one can write equations (66)–(68) in the equivalent form:

$$m_x = \mp p\mathrm{dn}\,(\Omega_L t, k_L) \tag{73}$$

$$m_y = \frac{1}{k'}\sqrt{1 - p^2}\mathrm{sn}\,(\Omega_L t, k_L) \tag{74}$$

$$m_z = \pm\sqrt{1 - p^2}\mathrm{cn}\,(\Omega_L t, k_L) \tag{75}$$

where:

$$\Omega_L = k_H \Omega_H = k'p\,(D_z - D_x) \tag{76}$$

$$k_L = \frac{1}{k_H} = \frac{k}{k'p}\sqrt{1 - p^2} \tag{77}$$

It can be verified that $0 \leq k_L \leq 1$, so equations (73)–(75) describe a precessional motion about the x axis. The precession period is:

$$T_{g_0} = \frac{4\mathbf{K}(k_L)}{\Omega_L} \tag{78}$$

In the following two sections, we discuss in some detail the solution of equation (56) under a nonzero field in two cases of particular physical interest, namely, when the field is perpendicular or parallel to the easy axis of the system.

4 NONLINEAR MAGNETIZATION DYNAMICS UNDER CONSTANT AND PULSED APPLIED FIELDS

The problem of nonlinear magnetization dynamics under constant and pulsed applied fields arises especially in magnetization switching of magnetic particles and thin films. This topic has received considerable attention in connection with the enormous advances in the magnetic storage technologies and spintronics (Bauer, Fassbender, Hillebrands and Stamps, 2000; Mallinson, 2000).

Traditionally, the study of magnetization reversal has been carried out by using the classical Stoner–Wohlfarth model (Stoner and Wohlfarth, 1948). As we have discussed in Section 3.1.2, this model is static in nature and does not take into account any magnetization dynamics. However, in the frequency range relevant to magnetic storage applications, magnetization precession has a crucial influence on magnetization dynamics and therefore has to be appropriately taken into account. Despite the nonlinear nature of the dynamics it is possible to develop a systematic and rigorous analysis of the LLG equation by using the methods of nonlinear dynamical system theory. These techniques have been outlined in the previous sections of this article and turn out very effective in the analysis of magnetization switching. In particular, these techniques yield detailed information about the parameters which enter in the design of devices (e.g., critical fields for switching, pulse duration, frequency of precessional motion, relaxation time in 'ringing' processes).

4.1 Switching under rectangular field pulses

4.1.1 Damping switching in uniaxial magnetic body

The traditional mode of switching in uniaxial particles (damping switching; Mallinson, 2000) is shown in Figure 5(a). The switching is realized by applying a field opposite to the initial magnetization orientation. If the field

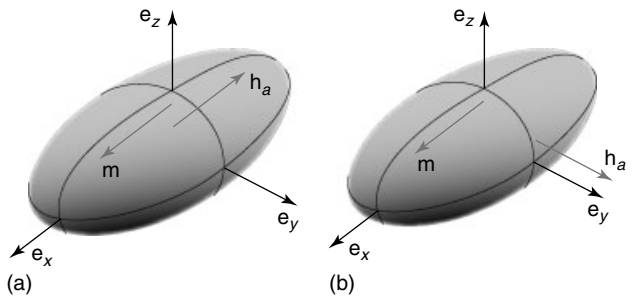

Figure 5. (a) Damping switching mode of operation. the applied field is opposite to the initial magnetization; (b) Precessional switching mode of operation: the applied field is orthogonal to the initial magnetization.

is strong enough, the initial state becomes unstable and the magnetization relaxes toward the energy minimum in the direction of the applied field. We analyze this mechanism by using the LLG equation in the Landau–Lifshitz form (see equation (22)):

$$\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = -\frac{1}{1+\alpha^2}\mathbf{m} \times \mathbf{h}_{\text{eff}} - \frac{\alpha}{1+\alpha^2}\mathbf{m} \times (\mathbf{m} \times \mathbf{h}_{\text{eff}}) \tag{79}$$

Exact analytical solutions of this equation can be obtained in the special case where the magnetic body exhibits uniaxial symmetry and the external field is applied exactly along the symmetry axis, which we choose as the x axis (see Figure 5a). Under these assumptions, the effective field is given by the formula:

$$\mathbf{h}_{\text{eff}} = -D_\perp(m_y\mathbf{e}_y + m_z\mathbf{e}_z) - D_x m_x \mathbf{e}_x + h_{ax}\mathbf{e}_x \tag{80}$$

where $D_\perp = D_y = D_z$ and h_{ax} is assumed to be constant during the pulse duration. Kikuchi (1956) considered a similar problem for an isotropic ferromagnetic sphere, where the effective field is defined by the formula:

$$\mathbf{h}_{\text{eff}} = -\mathbf{m}/3 + h_{ax}\mathbf{e}_x \tag{81}$$

The difference in the mathematical forms of equations (80) and (81) leads to a profound difference in the physics of magnetization switching. In the case of equation (81), there exists an infinite set of equilibrium states for $h_{ax} = 0$ and no critical field is required to switch from one equilibrium state to another. In contrast, in the case of equation (80) there are only two equilibrium states for $h_{ax} = 0$, namely, $m_x = \pm 1$, and the switching from one equilibrium state to the other is only possible if the applied field h_{ax} exceeds some critical field. The problem when the effective field is given by equation (80) has been treated in Mallinson (2000), and Leineweber and Kronmueller (1999) where the analysis is based on the solution of the LLG equation

in spherical coordinates. Our approach will exploit the rotational symmetry of the problem (the treatment below closely follows the one in Bertotti, Mayergoyz, Serpico and Dimian (2003)).

When the effective field is given by equation (80), the LLG equation becomes invariant with respect to rotations of coordinate axes y and z around the x axis. As a result of this rotational symmetry, it is expected that $\mathrm{d}m_x/\mathrm{d}t$ depends only on the x component of $\mathbf{m}$. Indeed, by using simple algebra, one finds that:

$$(\mathbf{m}\times\mathbf{h}_{\mathrm{eff}})\cdot\mathbf{e}_x = 0,$$
$$[\mathbf{m}\times(\mathbf{m}\times\mathbf{h}_{\mathrm{eff}})]\cdot\mathbf{e}_x = -\kappa_{\mathrm{eff}}\left(\tfrac{m_x+h_{ax}}{\kappa_{\mathrm{eff}}}\right)(1-m_x^2) \qquad (82)$$

where $\kappa_{\mathrm{eff}} = D_\perp - D_x$ (as in equation (33) of the Stoner–Wohlfarth theory). From equation (22) and the first of equation (82), we derive the following equation:

$$\frac{1}{\kappa_{\mathrm{eff}}}\frac{\mathrm{d}m_x}{\mathrm{d}t} = \frac{\alpha}{1+\alpha^2}\left(m_x + \frac{h_{ax}}{\kappa_{\mathrm{eff}}}\right)\left(1-m_x^2\right) \qquad (83)$$

Equation (83) shows that the magnetization switching from the state $m_x = 1$ to the state $m_x = -1$ (or vice versa) is driven exclusively by damping: in the conservative case ($\alpha = 0$) the x component of magnetization simply remains constant. In this sense, this switching can be regarded as 'damping' switching. On the other hand, the equation shows that anisotropy affects the switching only in the form of scale factors for field and time. Indeed, if one expresses equation (83) in terms of the rescaled time $\kappa_{\mathrm{eff}}t$ and rescaled field $h_{ax}/\kappa_{\mathrm{eff}}$, anisotropy disappears completely from the description. This means that damping switching will follow a law of correspondent states when represented in terms of these rescaled variables.

It seems from equation (83) that no switching is possible if the magnetization is initially in the equilibrium state $m_x = 1$. However, owing to thermal effects, the vector $\mathbf{m}$ slightly fluctuates around the above equilibrium state. As a result, the value of m_x at the instant when the applied field is turned on will be slightly different from 1 and the switching process is initiated. This argument justifies the solution of equation (83) with the initial condition:

$$m_x(t=0) = m_{x0} \qquad (84)$$

where m_{x0} is close to 1. It is apparent from equation (83) that if $h_{ax} < -\kappa_{\mathrm{eff}}$, then $\mathrm{d}m_x/\mathrm{d}t < 0$ and the switching to the equilibrium state $m_x = -1$ will proceed for any m_{x0}. On the other hand, if $h_{ax} \geq -\kappa_{\mathrm{eff}}$, then, for m_{x0} sufficiently close to 1, $\mathrm{d}m_x/\mathrm{d}t > 0$ and no switching is possible. This clearly reveals that κ_{eff} plays the role of critical switching field. In the sequel, it is assumed that $h_{ax} < -\kappa_{\mathrm{eff}}$.

By separating variables in equation (83), we obtain:

$$\int_{m_{x0}}^{m_x}\frac{\mathrm{d}m_x}{(1-m_x^2)(m_x - |h_{ax}|/\kappa_{\mathrm{eff}})} = \frac{\alpha\kappa_{\mathrm{eff}}}{1+\alpha^2}t \qquad (85)$$

and, after integration:

$$t = \frac{1+\alpha^2}{2\alpha(\kappa_{\mathrm{eff}}-|h_{ax}|)}\ln\frac{1-m_{x0}}{1-m_x} + \frac{1}{2(\kappa_{\mathrm{eff}}+|h_{ax}|)} \times \ln\frac{1+m_{x0}}{1+m_x} + \frac{\kappa_{\mathrm{eff}}}{\kappa_{\mathrm{eff}}^2 - h_{ax}^2}\ln\frac{|h_{ax}|-\kappa_{\mathrm{eff}}m_x}{|h_{ax}|-\kappa_{\mathrm{eff}}m_{x0}} \qquad (86)$$

By using the last equation, the minimal pulse time needed for switching can be found. Indeed, if the duration of the field pulse is such that a negative value of m_x is reached, then the magnetization will be in the basin of attraction of the reversed state $m_x = -1$, and the switching will be achieved. Thus, the minimal pulse duration T_{ds} (ds stands for damping switching) can be found by substituting $m_x = 0$ in equation (86):

$$T_{\mathrm{ds}} = \frac{1+\alpha^2}{\alpha}\left[\frac{\ln(1-\cos\phi_0)}{2(\kappa_{\mathrm{eff}}-|h_{ax}|)} + \frac{\ln(1+\cos\phi_0)}{2(\kappa_{\mathrm{eff}}+|h_{ax}|)} + \frac{\kappa_{\mathrm{eff}}}{\kappa_{\mathrm{eff}}^2 - h_{ax}^2}\ln\frac{|h_{ax}|}{|h_{ax}|-\kappa_{\mathrm{eff}}\cos\phi_0}\right] \qquad (87)$$

where ϕ_0 is the angle formed by the initial magnetization with the x axis. For the typical case of small ϕ_0, the minimal pulse time T_{ds} given by equation (87) is very close to the actual switching time at which m_x reaches a value almost equal to -1. Indeed, equation (83) shows that m_x decreases much faster when it is close to zero than when it is close to its initial equilibrium value. This conclusion is supported by the calculations shown in Figure 6, made by using equation (86). It is interesting to notice that T_{ds} tends to infinity both for $\alpha \to 0$ and $\alpha \to \infty$. Indeed, for $\alpha \to 0$, we have conservative dynamics and the system oscillates around the initial state. While for $\alpha \to \infty$, as a result of the viscous nature of Gilbert damping, dynamics become slower and slower. In addition, one can easily see that the minimum of T_{ds} as function of α, is obtained for $\alpha = 1$, which is the optimum value of damping to achieve fast damping switching. However, most materials used in applications have a damping constant appreciably smaller than 1.

Figure 7 presents the field dependence of the inverse pulse time $1/T_{\mathrm{ds}}$ calculated from equation (87). The curves are approximately linearly dependent on the field except for field values very close to the critical field κ_{eff}. Indeed, for small values of the initial angle ϕ_0, the first term in the right-hand side of equation (87) is dominant. By neglecting the two

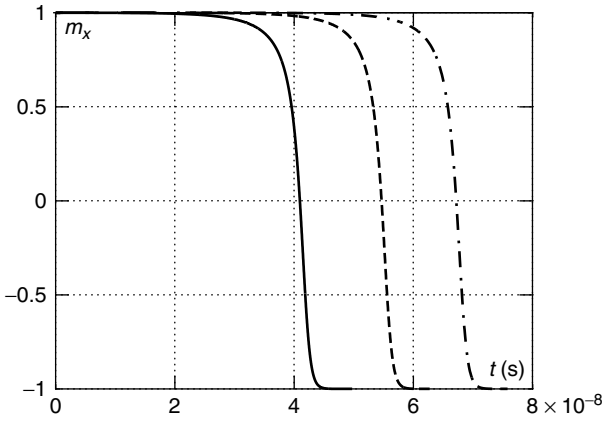

Figure 6. Evolution of m_x with time (measured in s) calculated from equation (86), with $m_{x0} = \cos\phi_0$. Continuous line: $\phi_0 = 1^\circ$; dashed line: $\phi_0 = 0.3^\circ$; dash-dotted line: $\phi_0 = 0.1^\circ$. Parameter values: $\alpha = 0.01$, $\kappa_{\rm eff} = 0.25$, $h_{ax} = -1.2\kappa_{\rm eff}$, $(\gamma M_{\rm s})^{-1} = 6\,{\rm ps}$ (permalloy).

other terms, one obtains the approximate law:

$$\frac{1}{T_{\rm ds}} \simeq \frac{\alpha}{(1+\alpha^2)\ln(\sqrt{2}/\phi_0)}(|h_{ax}| - \kappa_{\rm eff}) \qquad (88)$$

which is indeed linear in the field. Equation (88) shows that the dynamic (short-time) coercivity appreciably exceeds the static coercivity $\kappa_{\rm eff}$. This behavior is similar to that observed in Thornley (1975), Doyle and He (1993), and Rizzo, Silva and Kos (2000).

The switching time given by equations (87) and (88) depends on the value of the initial angle ϕ_0. The expected value of this angle can be evaluated by using statistical mechanics arguments. If the fluctuations are so weak that no thermally induced switching can occur within the timescale of observation of ϕ_0, then, one can approximate the behavior of $g_{\rm L}(\mathbf{m}; \mathbf{h}_{\rm a} = 0)$ around $\phi_0 = 0$ by a parabolic potential well. This leads to the following distribution function:

$$\rho(\phi_0) \approx c\phi_0 \exp\left[\frac{\mu_0 M_{\rm s}^2 \kappa_{\rm eff} V}{2k_{\rm B}T}\phi_0^2\right] \qquad (89)$$

where $k_{\rm B}$ is Boltzmann constant, T is the temperature, c is an appropriate normalization constant, μ_0 is vacuum permeability, and V is the volume of the magnetic body. For a permalloy film with dimensions 0.1 µm, 0.1 µm, 10 nm at room temperature ($T = 300^\circ K$), the expected value of ϕ_0 is in the order of $\sqrt{k_{\rm B}T/(\mu_0 M_{\rm s}^2 \kappa_{\rm eff} V)} \approx 0.8^\circ$.

4.1.2 *Precessional switching in uniaxial magnetic body and comparison with damping switching*

In this section, we will present an alternative technique to obtain the switching of a nanomagnet which is commonly

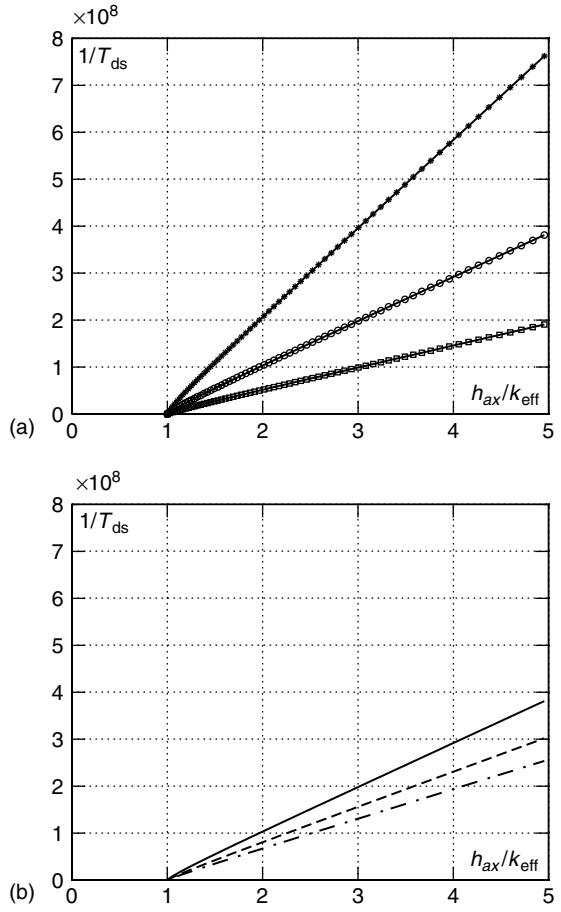

Figure 7. Inverse of minimum pulse duration $1/T_{\rm ds}$ (measured in s^{-1}) versus ratio between applied field and critical switching field $\kappa_{\rm eff}$, calculated from equation (87)) for damping switching ($\alpha = 0.01$, $(\gamma M_{\rm s})^{-1} = 6\,{\rm ps}$ (permalloy)). (a) $1/T_{\rm ds}$ versus $h_{ax}/\kappa_{\rm eff}$ for $\phi_0 = 1^\circ$ and different values of $\kappa_{\rm eff}$: '□': $\kappa_{\rm eff} = 0.125$; '○': $\kappa_{\rm eff} = 0.25$; '∗': $\kappa_{\rm eff} = 0.5$. (b) $1/T_{\rm ds}$ versus $h_{ax}/\kappa_{\rm eff}$ for $\kappa_{\rm eff} = 0.25$ and different values of ϕ_0: continuous line: $\phi_0 = 1^\circ$; dashed line: $\phi_0 = 0.3^\circ$; dash-dotted line: $\phi_0 = 0.1^\circ$.

referred to as *precessional switching*. The mode of operation of precessional switching is depicted in Figure 5(b). The magnetization is initially along the easy axis and a field approximately orthogonal to the easy axis is applied on the magnetic body. The field produces a torque which tilts the magnetization from its initial position and drives a precessional oscillation. Magnetization reversal is realized by switching the field off when the magnetization is close to its reversed orientation.

We notice that, while in damping switching the role of dissipation is crucial, precessional switching is accomplished by controlling the magnetization precession within a time interval which is usually so short that the role of dissipation is negligible. This type of switching can be considerably faster and it may require lower applied fields in comparison

with traditional switching. However, the switching is realized only if the field pulse duration is accurately controlled in such a way that the field is switched off precisely when the magnetization is close to its reversed orientation.

For the sake of comparison with damping switching we will consider precessional switching in a spheroidal particle rotationally symmetric with respect to the anisotropy easy axis $\mathbf{e}_x$ (Mayergoyz, Dimian, Bertotti and Serpico, 2005). The case of generic ellipsoidal particle can be treated by means of appropriate generalization of the following derivation (Bertotti, Mayergoyz and Serpico, 2006a). Owing to the uniaxial symmetry of the system, the effective field (17) can be written in the following form:

$$\mathbf{h}_{\text{eff}} = -D_{\perp}(m_x\mathbf{e}_x + m_y\mathbf{e}_y) - D_x m_x\mathbf{e}_x + h_{ax}\mathbf{e}_x + h_{ay}\mathbf{e}_y \tag{90}$$

where $D_{\perp} = D_y = D_z$. It is interesting to notice that the expression (90) can be written as $\mathbf{h}_{\text{eff}} = (D_{\perp} - D_x)m_x\mathbf{e}_x + h_{ax}\mathbf{e}_x + h_{ay}\mathbf{e}_y - D_{\perp}\mathbf{m}$, and the last term $D_{\perp}\mathbf{m}$ is proportional to $\mathbf{m}$ and thus has no effect on the torque $\mathbf{m} \times \mathbf{h}_{\text{eff}}$. For this reason, in the case of uniaxial particles, one can assume the following alternative expression of the effective field

$$\mathbf{h}_{\text{eff}} = \kappa_{\text{eff}} m_x\mathbf{e}_x + h_{ax}\mathbf{e}_x + h_{ay}\mathbf{e}_y \tag{91}$$

where, as in the previous section, $\kappa_{\text{eff}} = D_{\perp} - D_x$ (see equation (33)). The magnetic free energy corresponding to the above effective field has the form:

$$g_{\text{L}}(\mathbf{m}; \mathbf{h}_{\text{a}}) = -\frac{\kappa_{\text{eff}}}{2}m_x^2 - h_{ax}m_x - h_{ay}m_y \tag{92}$$

It can be easily observed that in the case of zero applied field there are two stable equilibria $\mathbf{m} = \pm\mathbf{e}_x$ surrounded by two energy wells separated by the boundary $m_x = 0$ (the circle corresponding to $m_x = 0$ on the unit sphere has the role of the separatrix between the two energy well). Since the dissipation results in the decrease in magnetic free energy, it can be concluded that the time evolution of magnetization within each energy well inevitably leads to the stable equilibrium inside this well. Thus, the essence of the precessional switching is to move the magnetization by the applied pulsed magnetic field from one energy well to another. As soon as the target potential well is reached, the applied field can be switched off and magnetization will relax to a new equilibrium as a result of damping.

In the following, we analyze the dynamics in the time interval when the field is applied. In this interval, we assume that the effect of damping is negligible and thus we solve conservative LLG equation.

By using conservation of the free energy (92) and $m_x^2 + m_y^2 + m_z^2 = 1$, one can easily prove that magnetization

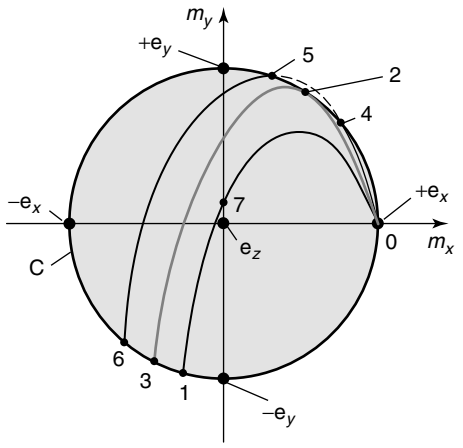

Figure 8. Unit-circle representation of trajectories for precessional switching in uniaxial particle.

trajectories in the (m_x, m_y) plane, starting from the point $(m_x = 1, m_y = 0)$ (point ('0' in Figure 8), are described by the following equation

$$-\frac{\kappa_{\text{eff}}}{2}m_x^2 - h_{ax}m_x - h_{ay}m_y = -\frac{\kappa_{\text{eff}}}{2} - h_{ax} \tag{93}$$

Thus, on the (m_x, m_y) plane, the precessional magnetization motion occurs along the parabola (93) that is confined within the unit disk $m_x^2 + m_y^2 \leq 1$. The fact that, in the present case, we do not have arcs of ellipses (as it is generally the case according to the discussion in Section 3.2.1), is a consequence of the rotational symmetry of the magnetic body.

Several examples of parabolic magnetization trajectories on (m_x, m_y) plane are shown in Figure 8.

Next, we want to investigate the different types of parabolic trajectories that can be generated by (93) in a function of the values of h_{ax} and h_{ay}. Our purpose is to find the region in the (h_{ax}, h_{ay}) control plane which corresponds to trajectories of the family (93) which, starting from the point $(m_x = 1, m_y = 0)$ and remaining inside the unit circle

$$m_x^2 + m_y^2 = 1 \tag{94}$$

eventually enters in the $m_x < 0$ half circle (e.g., trajectory '0-7-1' in Figure 8) . A necessary condition for this is that the trajectories admit an intersection with the line $m_x = 0$ with $|m_y \leq 1|$. By substituting $m_x = 0$ in (93) we arrive to the following equation:

$$m_y = \frac{(h_{ax} + \kappa_{\text{eff}}/2)}{h_{ay}} \tag{95}$$

From the last equation one obtains that the intersection of the parabola (93) with the line $m_x = 0$ occurs inside the unit

circle ($m_y \leq 1$) under the following condition

$$\left|h_{ax} + \frac{\kappa_{\text{eff}}}{2}\right| \leq |h_{ay}| \tag{96}$$

The region in the (h_{ax}, h_{ay}) control plane corresponding to the inequality (96) is represented in gray in Figure 9(a).

Next, we have to analyze the conditions on (h_{ax}, h_{ay}) to rule out situations like the one corresponding to the trajectory 0-4-5-6 sketched in Figure 8 in which the parabola passing through the point ($m_x = 1, m_y = 0$) (point '0' in the figure) corresponds to two disjoint pieces of magnetization trajectories (0-4 and 5-6). In this condition, there can be no precessional switching since the magnetization evolution starting from $\mathbf{e}_x$ remains trapped in the half plane $m_x > 0$ (between the points 0 and 4 in Figure 8). The family of parabolas similar to 0-7-1 and the family of parabolas similar to 0-4-5-6 are separated by the critical trajectories 0-2-3 which is tangent to the $m_x > 0$ portion of the unit circle. This case corresponds to values of (h_{ax}, h_{ay}) for which there is a saddle point in 2 and the initial state $\mathbf{e}_x$ is on the corresponding homoclinic trajectory 0-2-3. Small deviations from this critical condition lead to trajectories consisting of one piece of parabola (for instance, trajectory 0-7-1 in Figure 8) or to trajectories consisting of two disjoint pieces of the same parabola (for instance, trajectory 0-4 and 5-6 in Figure 8). Let us investigate the conditions under which we have the critical case.

By imposing the condition of tangency of the curves represented by equations (94) and (93), one arrives at the following relation:

$$\kappa_{\text{eff}} m_x m_y + h_{ax} m_y - h_{ay} m_x = 0 \tag{97}$$

At point 2 (Figure 8), three equations (94), (93), and (97) are satisfied. These three equations define the curve h_{ay} versus h_{ax} that separates the values of h_{ax} and h_{ay} which correspond to the first and second classes of parabolic trajectories, respectively. This h_{ay} versus h_{ax} curve can be easily found in parametric form by introducing the polar angle ϕ_0 such that:

$$m_x = \cos\phi_0, \qquad m_y = \sin\phi_0 \tag{98}$$

By substituting (98) into (93) and (97) and solving these equations with respect to h_{ax} and h_{ay}, we arrive at the following parametric equation for the 'separating' curve:

$$\begin{aligned} h_{ax} &= -\kappa_{\text{eff}} \cos\phi_0 \cos^2(\phi_0/2), \\ h_{ay} &= \kappa_{\text{eff}} \sin\phi_0 \sin^2(\phi_0/2) \end{aligned} \tag{99}$$

(similar formulas were derived by using different reasoning in Porter, 1998). We observe that, by varying the parameter ϕ_0 in equation (99) in the interval $[-\pi/2, \pi/2]$, we

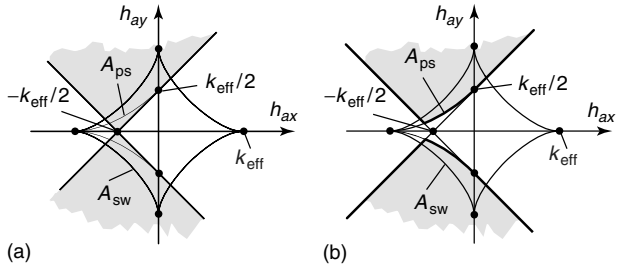

Figure 9. Regions in the (h_{ax}, h_{ay}) control plane related to the conditions for precessional switching. The curves labeled by A_{sw} and A_{ps} correspond to the Stoner–Wohlfarth model asteroid (see equation (37)) and to equation (99), respectively. (a) The shaded region correspond to equation (96)). (b) The shaded region correspond to the condition of precessional switching.

generate two arcs of the asteroid (curve A_{ps} in Figures 9a and b) which are inside the Stoner–Wohlfarth asteroid (curve A_{sw} in Figures 9a and b). These two arcs of the asteroid along with the vertical segment, defined by conditions $h_{ax} = 0$ and $-\kappa_{\text{eff}}/2 \leq h_{ay} \leq \kappa_{\text{eff}}/2$, define the boundary of a closed region in the control plane (h_{ax}, h_{ay}) completely inside the Stoner–Wohlfarth asteroid. When the applied field is inside this region, according to the discussion in the preceding text, there is an intersection of the parabolic trajectory (93) with $m_x > 0$ portion of the unit circle and the trajectory starting from $\mathbf{e}_x$ remains trapped in the $m_x > 0$ half plane (like trajectory $0 - 4$ in Figure 8b). By removing the above region from the gray region corresponding to condition (96) (see Figure 9a), one obtains the switching region for precessional switching in Stoner–Wohlfarth particles depicted in Figure 9(b).

Now we will focus on the duration of the applied field pulse which guarantees successful switching. In this respect, we will assume that magnetization evolves on a trajectory similar to trajectory '0-7-1' in Figure 8. To find the evolution of magnetization, one can consider that the x component of LLG equation, in this case, reads

$$\frac{\mathrm{d}m_x}{\mathrm{d}t} = h_{ay} m_z \tag{100}$$

By using (93) and the condition $m_z^2 = 1 - m_x^2 - m_y^2$, one can expressed m_z^2 as a fourth-order polynomial in m_x. Thus in this case, by using equation (100), the time windows for switching the field off is $t_7 < t < t_1$, where:

$$t_7 = -\int_1^0 \frac{\mathrm{d}m_x}{|h_{ay} m_z(m_x)|} \tag{101}$$

and

$$t_1 - t_7 = -2\int_0^{m_{x2}} \frac{\mathrm{d}m_x}{|h_{ay} m_z(m_x)|} \tag{102}$$

and $m_x = 1$, $m_x = 0$ and $m_x = m_{x2}$ correspond to points 0, 7, and 1 in Figure 8, respectively. The value of m_{x2} can be found by solving simultaneous equations (94) and (93).

Let us determine the duration of the field pulse necessary to switching in the case of applied field along the y axis ($\mathbf{h}_\mathrm{a} = h_{ay}\mathbf{e}_y$). In the case of Stoner–Wohlfarth particle it can be shown that, after appropriate integration of equation (56), m_y can be expressed in the following form:

$$m_y(t) = \frac{D}{2h_{ay}}\mathrm{sn}^2(h_{ay}t, k_s) \tag{103}$$

where $\mathrm{sn}(u, k)$ is the 'sin-type' Jacobi elliptic function of argument u and modulus k, and $k_s = D/(2h_{ay})$. It can be readily inferred that m_x will reach the value -1 after one period of the function $\mathrm{sn}^2(h_{ay}t, k_s)$ (which is half of the period of the function $\mathrm{sn}(h_{ay}t, k_s)$). This period can be expressed, in physical units, as

$$T_\mathrm{ps} = \frac{1}{\gamma M_\mathrm{s}}\frac{2K(k_s)}{h_{ay}} \tag{104}$$

where $K(k)$ is the complete elliptic integral of the first kind of modulus k.

It has been previously discussed that in the case of precessional switching the field pulse duration must be tuned with attention, in the sense that complete switching is achieved only if the field is switched off in a certain time window. No such timing is required for damping switching, because any field pulse of duration exceeding the minimum time T_ds will lead to switching. Precessional switching is thus more difficult to realize. On the other hand, it has clear advantages with respect to damping switching, because the critical field is lower and the switching time is much shorter. In fact, it is instructive to compare switching times for precessional and damping switching for the same value of the ratio r_c between applied fields and corresponding critical fields, that is, $h_{ay}/\kappa_\mathrm{eff}$ for damping switching and $2h_{ay}/\kappa_\mathrm{eff}$ for precessional switching. For T_ps, we will use the formulas for Stoner–Wohlfarth particles, since they were obtained for the same symmetry assumed for damping switching, namely, uniaxial symmetry around the $\mathbf{e}_x$ direction. One can express the ratio $T_\mathrm{ps}/T_\mathrm{ds}$ in the form:

$$\frac{T_\mathrm{ps}}{T_\mathrm{ds}} = \frac{\alpha}{1+\alpha^2}F(r_\mathrm{c}) \tag{105}$$

where the function $F(r_\mathrm{c})$ is obtained from equations (87) and (104). The graph of the function $F(r_\mathrm{c})$ is shown in Figure 10 for different values of the angle ϕ_0 involved in damping switching. It is clear from this figure and equation (105) that precessional switching is (for $\alpha \ll 1$) approximately $1/\alpha$ times faster than damping switching. For applied fields close to their respective critical fields (i.e., r_c close to 1), this difference is even more pronounced.

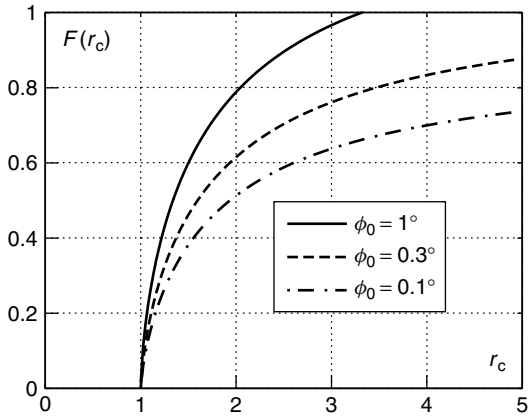

Figure 10. Comparison between precessional and damping switching times. Plot of the function $F(r_\mathrm{c}) = T_\mathrm{ps}/T_\mathrm{ds}$ versus the ratio r_c between applied field and corresponding critical field, that is, $h_{ay}/\kappa_\mathrm{eff}$ for damping switching and $2h_{ay}/\kappa_\mathrm{eff}$ for precessional switching. The function is plotted for different values of the initial angle ϕ_0 characterizing damping switching. Continuous line: $\phi_0 = 1^\circ$; dashed line: $\phi_0 = 0.3^\circ$; dash-dotted line: $\phi_0 = 0.1^\circ$.

4.2 Relaxation to equilibrium

The analysis of magnetization relaxation to equilibrium is instrumental for the interpretation of the 'ringing' phenomena (Back *et al.*, 1998, 1999; Schumacher *et al.*, 2003; Kaka and Russek, 2002) that occur in precessional switching whenever the magnetization is not exactly in the desired equilibrium state at the moment the external field is switched off. The relaxation process exhibits two distinct timescales: the fast timescale of precessional dynamics and the relatively slow timescale of relaxation dynamics controlled by the damping constant α. The free energy g_L varies significantly only on the slow timescale. In other words, the free energy is a 'slow' variable whose dynamics is not obscured by 'ringing' and thus reveals the actual rate of relaxation to equilibrium. For this reason, it is desirable to derive the differential equation for the free energy and use it for relaxation studies instead of the Landau–Lifshitz equation. It turns out that this equation can be derived by using the averaging technique. This technique is conceptually related to the Poincaré–Melnikov method presented in Section 5.2.3 in the description of magnetization dynamics driven by time-harmonic fields.

Our starting point for the analysis of relaxation toward equilibrium is equation (26), discussed in Section 2.2.2:

$$\frac{\mathrm{d}g_\mathrm{L}}{\mathrm{d}t} = -\alpha\left|\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t}\right|^2 \tag{106}$$

This equation shows that the magnetization dynamics under constant applied field is such that the free energy is monotonically decreasing until some equilibrium state is reached. Since the damping constant is a small quantity, $\alpha \ll 1$, the magnetization dynamics during one period of the precessional motion closely mimics the conservative dynamics corresponding to $\alpha = 0$. The free energy is decreased appreciably only over many precession periods and remains practically constant during one period. For this reason, no essential information on relaxation is lost if equation (26) is averaged over one precession period and the conservative solution is used for $\mathrm{d}\mathbf{m}/\mathrm{d}t$. By denoting the averaged energy as $\overline{g}_{\mathrm{L}}$, we have:

$$\frac{\mathrm{d}\overline{g}_{\mathrm{L}}}{\mathrm{d}t} = -\frac{\alpha}{T_{\overline{g}_{\mathrm{L}}}} \int_0^{T_{\overline{g}_{\mathrm{L}}}} \left| \frac{\mathrm{d}\mathbf{m}_{\overline{g}_{\mathrm{L}}}}{\mathrm{d}t} \right|^2 \mathrm{d}t \tag{107}$$

where $\mathbf{m}_{\overline{g}_{\mathrm{L}}}(t)$ corresponds to the conservative dynamics with energy $\overline{g}_{\mathrm{L}}$ and $T_{\overline{g}_{\mathrm{L}}}$ is the associated precession period. Explicit expressions for these quantities have been derived in Section 3.2. Each precession trajectory is fully determined by the value of its free energy, so the right-hand side of equation (107) is a function of energy only and equation (107) can be solved by the method of separation of variables.

Let us apply this approach to the description of 'ringing' phenomena. The derivations in the sequel are valid for arbitrary values of D_x, D_y, D_z and uniaxial symmetry is not assumed. We denote by g_{off} the energy of the system immediately after the external field has been switched off. We assume that the field pulse is such that magnetization switching is guaranteed. This means that after the field is switched off the system is inside the energy region around the final equilibrium state of interest (see Figure 8). In terms of energy, this means that $D_x/2 < g_{\mathrm{off}} < D_y/2$. This energy value represents the initial condition for the integration of equation (107). The solution is obtained once the right-hand side of equation (107) is explicitly calculated. This can be done by introducing the variable w (see equation (59)) and by taking advantage of the fact that $|\mathrm{d}\mathbf{m}/\mathrm{d}t|^2 = |\mathrm{d}\mathbf{m}/\mathrm{d}w|^2 |\mathrm{d}w/\mathrm{d}t|^2$. By using equation (59) one finds:

$$\left| \frac{\mathrm{d}\mathbf{m}}{\mathrm{d}w} \right|^2 = \frac{p^2}{1-w^2} + \frac{k'^2}{k^2} \frac{w_0^2 p^2}{w_0^2 - w^2} \tag{108}$$

where w_0 and p^2 are respectively given by equations (60) and (61), with $\overline{g}_{\mathrm{L}}$ in the place of g_0. It can be verified that $w_0^2 < 1$ in the zero-field energy region under study. The derivative $\mathrm{d}w/\mathrm{d}t$ is obtained from equations (62)–(64):

$$\frac{\mathrm{d}w}{\mathrm{d}t} = \pm k' p \left(D_z - D_x\right) \sqrt{\left(1-w^2\right)\left(w_0^2 - w^2\right)} \tag{109}$$

Therefore:

$$\left| \frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} \right|^2 \mathrm{d}t = k' p^3 w_0^2 \left(D_z - D_x\right) \times \left(\sqrt{\frac{1-w^2/w_0^2}{1-w^2}} + \frac{k'^2}{k^2} \sqrt{\frac{1-w^2}{1-w^2/w_0^2}} \right) \frac{\mathrm{d}w}{w_0} \tag{110}$$

By inserting equation (110) into equation (107), the integral in the latter equation can be reduced to canonical elliptic integrals of the first and second kind. By taking into account that the variable w spans the interval $(0, w_0)$ four times in one precession period and by using equation (78) for $T_{\overline{g}_{\mathrm{L}}}$, one obtains the desired equation for the energy:

$$\frac{\mathrm{d}\overline{g}_{\mathrm{L}}}{\mathrm{d}t} = -\alpha \left(D_z - 2\overline{g}_{\mathrm{L}}\right) \left[\left(2\overline{g}_{\mathrm{L}} - D_x\right) + \left(D_y - D_x\right) \times \frac{\mathbf{E}(k_{\mathrm{L}}(\overline{g}_{\mathrm{L}})) - \mathbf{K}(k_{\mathrm{L}}(\overline{g}_{\mathrm{L}}))}{\mathbf{K}(k_{\mathrm{L}}(\overline{g}_{\mathrm{L}}))} \right] \tag{111}$$

where $\mathbf{K}$ and $\mathbf{E}$ respectively represent the complete elliptic integrals of the first and second kind, while:

$$k_{\mathrm{L}}^2 = w_0^2 = \frac{D_z - D_y}{D_y - D_x} \frac{2\overline{g}_{\mathrm{L}} - D_x}{D_z - 2\overline{g}_{\mathrm{L}}} \tag{112}$$

Equation (111) is a first-order separable differential equation that can be solved numerically. However, a useful approximate analytical solution can be obtained by observing that $k_{\mathrm{L}}^2 < 1$ during the entire relaxation. Hence, the elliptic integrals $\mathbf{K}$ and $\mathbf{E}$ can be expressed in simpler form by using the expansions:

$$\mathbf{K}(k_{\mathrm{L}}) = \frac{\pi}{2} \left(1 + \frac{k_{\mathrm{L}}^2}{4}\right) + \mathcal{O}(k_{\mathrm{L}}^4) \tag{113}$$

$$\mathbf{E}(k_{\mathrm{L}}) = \frac{\pi}{2} \left(1 - \frac{k_{\mathrm{L}}^2}{4}\right) + \mathcal{O}(k_{\mathrm{L}}^4) \tag{114}$$

As a result, equation (111) is reduced to:

$$\frac{\mathrm{d}\overline{g}_{\mathrm{L}}}{\mathrm{d}t} = -\alpha \left(2\overline{g}_{\mathrm{L}} - D_x\right) \left(D_{yz} - 2\overline{g}_{\mathrm{L}}\right) \tag{115}$$

where $D_{yz} = (D_y + D_z)/2$. Equation (115) can be easily integrated by the method of separation of variables. The result is:

$$\overline{g}_{\mathrm{L}}(t) = \frac{D_x}{2} + \frac{\left(D_{yz} - D_x\right)\left(g_{\mathrm{off}} - D_x/2\right)}{\left(2g_{\mathrm{off}} - D_x\right) + \left(D_{yz} - 2g_{\mathrm{off}}\right) \exp\left[2\alpha \left(D_{yz} - D_x\right) t\right]} \tag{116}$$

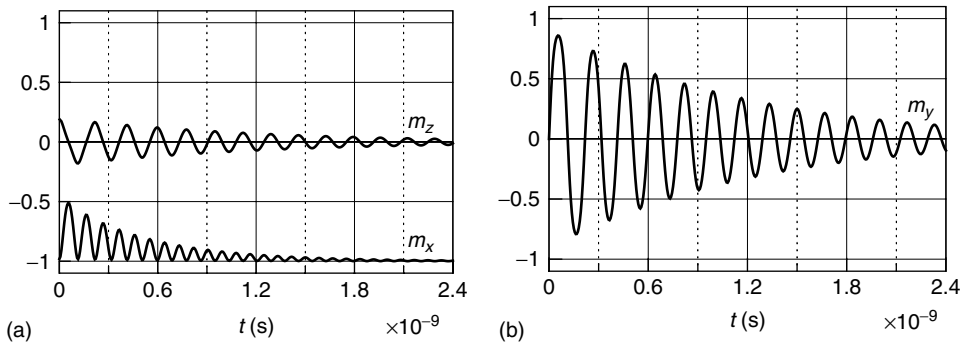

Figure 11. Magnetization components versus time obtained by numerical integration of LLG equation. Parameters: $\alpha = 0.01$, $D_x = -0.05$, $D_y = 0$, $D_z = 1$, $g_{\text{off}} = -0.005$, $(\gamma M_s)^{-1} = 6\,\text{ps}$.

Figure 11 shows an example of magnetization relaxation to equilibrium, computed by direct numerical integration of the LLG equation (equations (14) and (17). The system is a thin film with in-plane anisotropy along the x axis ($D_x = -0.05$, $D_y = 0$, $D_z = 1$). The magnetization is initially inside the central energy region around $m_x = -1$. The energy varies in this region from $g_{\text{L}} = D_y/2 = 0$ (energy of heteroclinic trajectories) down to $g_{\text{L}} = D_x/2 = -0.025$ (energy minimum at $m_x = -1$). The initial energy is $g_{\text{off}} = -0.005$, relatively close to the upper boundary of the region. By inserting the numerically computed magnetization components in the equation for the free energy (equation (20)), one obtains the time behavior of the instantaneous energy $g_{\text{L}}(t)$. The result is shown by the continuous line in Figure 12. The wavy behavior of the energy reflects the precessional magnetization dynamics taking place on the fast timescale. The dashed line represents the averaged energy $\overline{g}_{\text{L}}(t)$ obtained by numerical integration of equation (111).

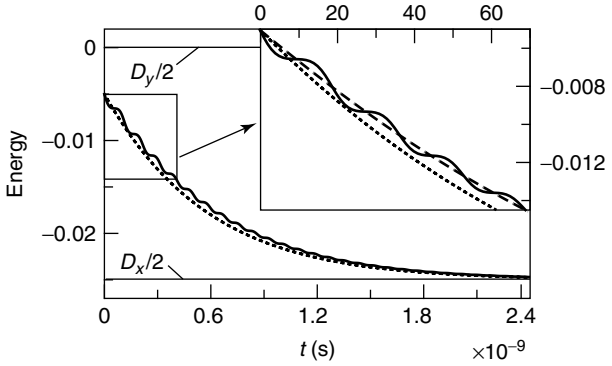

Figure 12. Comparison between numerically and analytically computed energy relaxation to equilibrium. Continuous line: numerical integration of LLG equation; dashed line (omitted in the main diagram for the sake of clarity but shown in the inset): numerical integration of equation (111); dotted line: equation (116). Parameters: $\alpha = 0.01$, $D_x = -0.05$, $D_y = 0$, $D_z = 1$, $g_{\text{off}} = -0.005$, $(\gamma M_s)^{-1} = 6\,\text{ps}$.

Finally, the dotted line represents the approximate analytical solution given by equation (116). It is apparent that the description of the relaxation in terms of the averaged energy $\overline{g}_{\text{L}}(t)$ leads to quite accurate results. The analytical approximation is quite satisfactory as well, if one takes into account that the initial value of the elliptic-integral modulus k_{L} is as large as $k_{\text{L}} \simeq 0.89$.

We remark in conclusion that the averaging technique discussed in this section is general and can be applied to relaxation phenomena under nonzero field as well, provided that one has sufficient information about the solution $\mathbf{m}_{g_0}(t)$ of the conservative dynamics for the field considered.

5 NONLINEAR MAGNETIZATION DYNAMICS UNDER CIRCULARLY POLARIZED FIELD

5.1 LLG dynamics in rotationally invariant systems

In nanometer-scale magnetic bodies, appropriately applied microwave fields can drive spatially uniform magnetization motions very far from static equilibrium conditions. In this situation, it is not possible to treat the problem through linearization of the equations of motion around a reference static equilibrium state and one has to study the magnetization dynamics taking fully into account nonlinear effects such as nonlinear resonance, bifurcations, quasiperiodic, or even chaotic dynamics. In this section, we consider nanomagnets with uniaxial anisotropy and subject to circularly polarized microwave applied fields. The problem is rotationally invariant around the disk axis and this permits one to analytically determine all admissible single-domain dynamical regimes (Bertotti, Serpico and Mayergoyz, 2001). The possibility of deriving exact solutions of the nonlinear problem is very important since give the possibility to treat, by
