depicted in Figure 19 [18]. The lateral size of domains was estimated by the evaluation of the Q_x extension of Bragg sheets within the framework of the BA (Section 2.10).

After applying a magnetic field, the AF coupling is removed and the diffuse scattering is now spread over larger parts of the reciprocal space. Two types of magnetic diffuse scattering can therefore be recognized. One is due to correlated domains giving rise to the Bragg sheets. The other originates from uncorrelated domains. The correlated AF domains yield a diffuse peak in the transverse direction at the half-order position, whose width is inversely proportional to the average lateral domain size. The featureless diffuse scattering is due to uncorrelated magnetic domains and likely from spin disorder at the interfaces.

Langridge *et al*. (2000) have also investigated the magnetic roughness in Co/Cu multilayers. In remanence the half-order peak is widely spread out, indicating an AF domain structure, which is vertically correlated throughout the multilayer. After applying a magnetic field, the AF coupling is removed and the diffuse scattering is now spread over larger parts of the reciprocal space. Two types of magnetic diffuse scattering can therefore be recognized. One is due to correlated domains giving rise to the Bragg sheet. The other one originates from uncorrelated spins at the interfaces. These two parts have been analyzed and quantified in detail in Langridge *et al*. (2000) in the kinematic approximation. The magnetic roughness and how it reveals itself in X-ray and neutron scattering experiments is presently of high interest to experimentalist as well as theorists.

4.2.2 Fe/Cr multilayers

As already mentioned, Fe/Cr superlattices are more complex than other exchange-coupled superlattices owing to the spin-density wave magnetism of the Cr spacer layer. The competition between the interlayer coupling and the antiferromagnetism of Cr often results in a noncollinear coupling, that is the magnetization vectors in adjacent magnetic layers may deviate considerably from F (coupling angle 0°) or AF (coupling angle 180°) alignment. Early studies of Fe/Cr superlattices therefore have concentrated on the exploration of the coupling angle. Adding a biquadratic coupling term to the bilinear exchange coupling predicts under certain conditions a coupling angle of 90°.

However, extensive PNR work has convincingly demonstrated that the coupling angles are neither collinear nor biquadratic but take values in-between. This finding favored Slonczewski's proximity magnetism model (Slonczweski, 1995), which includes both, the interlayer exchange coupling between the Fe layers and the topological antiferromagnetism of the Cr spacer layer together with long-range lateral thickness fluctuations. With this model any angle between 0° and 180° can be realized depending on the relative strength of the F and AF coupling terms J_+ and J_-, respectively (Slonczweski, 1995):

$$E(\phi) = J_+ \left(\frac{\phi}{\pi}\right)^2 + J_- \left(\frac{\pi - \phi}{\pi}\right)^2 \qquad (144)$$

Figure 32 shows a typical result from an exchange coupled [Fe(5.7 nm)/Cr(1.7 nm)]×9 superlattice grown in [001] direction. A magnetic half-order peak can be recognized in the NSF as well as in the SF cross sections. Furthermore, a F component can be discerned at the first-order Bragg peak by the intensity splitting of the R^{++} and R^{--} reflectivities. This unusual reflection pattern, which contains signatures of a F- and an AF orientation of the Fe layers, can be best explained by Fe layer magnetization vectors enclosing an angle of about 50° between adjacent planes, as shown schematically in the lower left corner (Schreyer *et al*., 1995a,b). Nontrivial

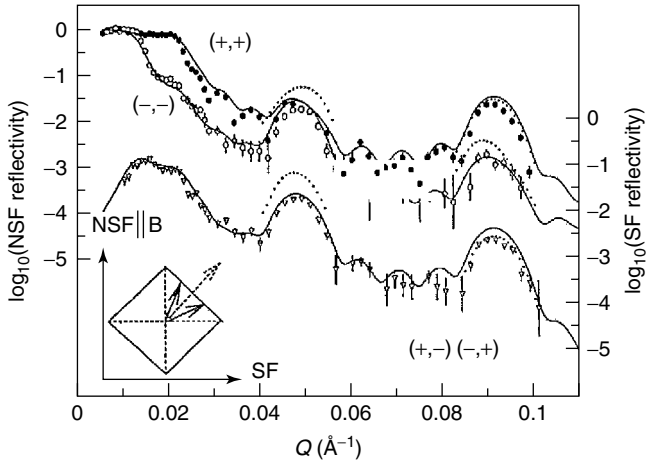

Figure 32. Polarized neutron measurements from a 10 bilayer Fe/Cr superlattice. In all four cross sections a half order Bragg peak can be recognized indicating an antiferromagnetic doubling of the magnetic periodicity, as well as a ferromagnetic splitting of the first-order Bragg peak in the NSF cross sections. From the coexistence of half-order antiferromagnetic peaks and ferromagnetic splitting of the integer Bragg peaks, a noncollinear coupling angle of the magnetization vectors in adjacent Fe layers was discerned. (Reprinted figure with permission from Schreyer *et al*., *Phys Rev. B* Vol 52, 16066 (1995). © 1995 by the American Physical Society.)

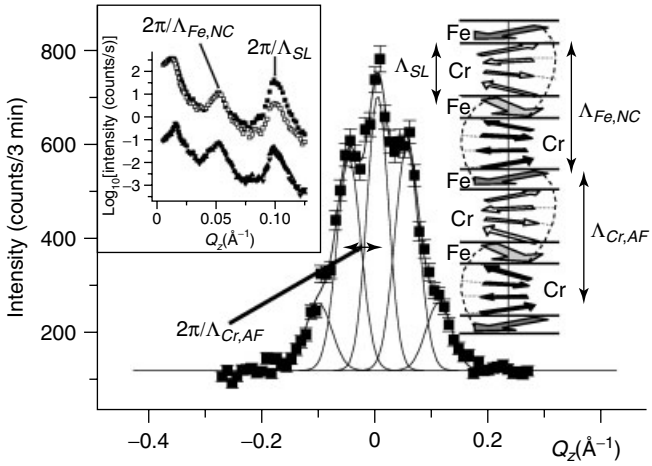

Figure 33. Polarized neutron measurements from Fe/Cr superlattice revealing the correspondence between a twisted Fe magnetization and twisted Cr spin structure. The sample studied is a 200 repeat $Fe_{19}/Cr_{42}(001)$ superlattice. The left inset shows PNR results of all four cross sections. The splitting of the first order Bragg peak together with the presence of a half-order peak in the NSF and SF reflectivities indicates a noncollinear (NC) coupling of the Fe layers with a period twice the superlattice period: $\Lambda_{Fe,NC} = 2\Lambda_{SL}$. The main part shows a scan through the high angle (010) peak in the [00*l*] direction. The bcc forbidden (010) peak is a fingerprint of the commensurate AF Cr spin structure. This peak is surrounded by satellite peaks, which indicate the same doubling of the superlattice period as observed in the PNR measurement at low angles, however, here $\Lambda_{Cr,AF} = 2\Lambda_{SL}$. Thus the AF Cr structure is modulated by the same period as the Fe backbone. The right inset shows a schematic of the Fe and Cr magnetic structures as deduced from the scattering data fulfilling the condition $\Lambda_{Cr,AF} = \Lambda_{Fe,NC} = 2\Lambda_{SL}$. The empty and filled small arrows indicate an opposing sense of rotation of the Cr moments between the NC coupled Fe layers (large arrows). (Reprinted figure with permission from Schreyer *et al*., *Phys Rev. Lett.* Vol. 79, 4914 (1997). © 1997 by the American Physical Society.)

coupling angles were later confirmed by Abbe *et al*. (2004) with nuclear resonant scattering using circular polarized synchrotron radiation.

The interplay between exchange coupling, SDW order, and interface roughness was further investigated for thicker Cr spacer layers. For an ideally flat Fe/Cr interface an antinode of the transverse and incommensurate SDW order is expected to be placed next to the interface. Then the AF Fe–Cr interface coupling is strong and the phase information controlling parallel or antiparallel alignment of successive Fe layers is transmitted through the Cr spacer (Fullerton, Bader and Robertson, 1996). By decreasing the Cr layer thickness below a critical value, the incommensurate SDW order collapses and is replaced by a commensurate AF order with an enhanced Néel temperature (Fullerton *et al*., 1995; Schmitte *et al*., 1999). In Figure 33 polarized neutron data are reproduced for a Fe/Cr superlattice with a Cr thickness of 42 Å (Schreyer *et al*., 1997). The low angle reflectivity measurements again reveal a noncollinearly coupled superlattice, while the high angle data confirm that for this thickness the Cr spin structure is in a commensurate state with AF order. In addition, the superlattice periodicity is imprinted not only on the structure factor of the Fe layers but also on the Cr layers. Thus both, the F and AF layers are modulated by the same superlattice periodicity. Together with the reflectivity data this implies that the Fe as well as the Cr spin structure must be twisted, providing a noncollinear exchange coupling between the Fe layer magnetization vectors. This at first glance surprising noncollinear spin arrangement can be best explained within the frame of the proximity exchange model introduced by Slonczweski (1995), described already above. Assuming that thin Cr layers are in a commensurate SDW state, lateral thickness fluctuations of monatomic high steps require the Cr spin structure to twist counterclockwise on either side of a step in order to couple to a homogeneous Fe layer magnetization. The combination of left and right turning Cr spin springs, representing the spin stiffness of the Cr layer, mediates a noncollinear Fe magnetization.

Further progress on the understanding of Fe/Cr superlattices has been achieved by mapping out the off-specular diffuse scattering in addition to the specular polarized neutron reflectivity (Lauter-Pasyuk *et al*., 2001, 2002). Figure 34 shows the reciprocal-space map [19] taken from a [Fe(6.7 nm)/Cr (0.9 nm)]×12 superlattice in an applied field

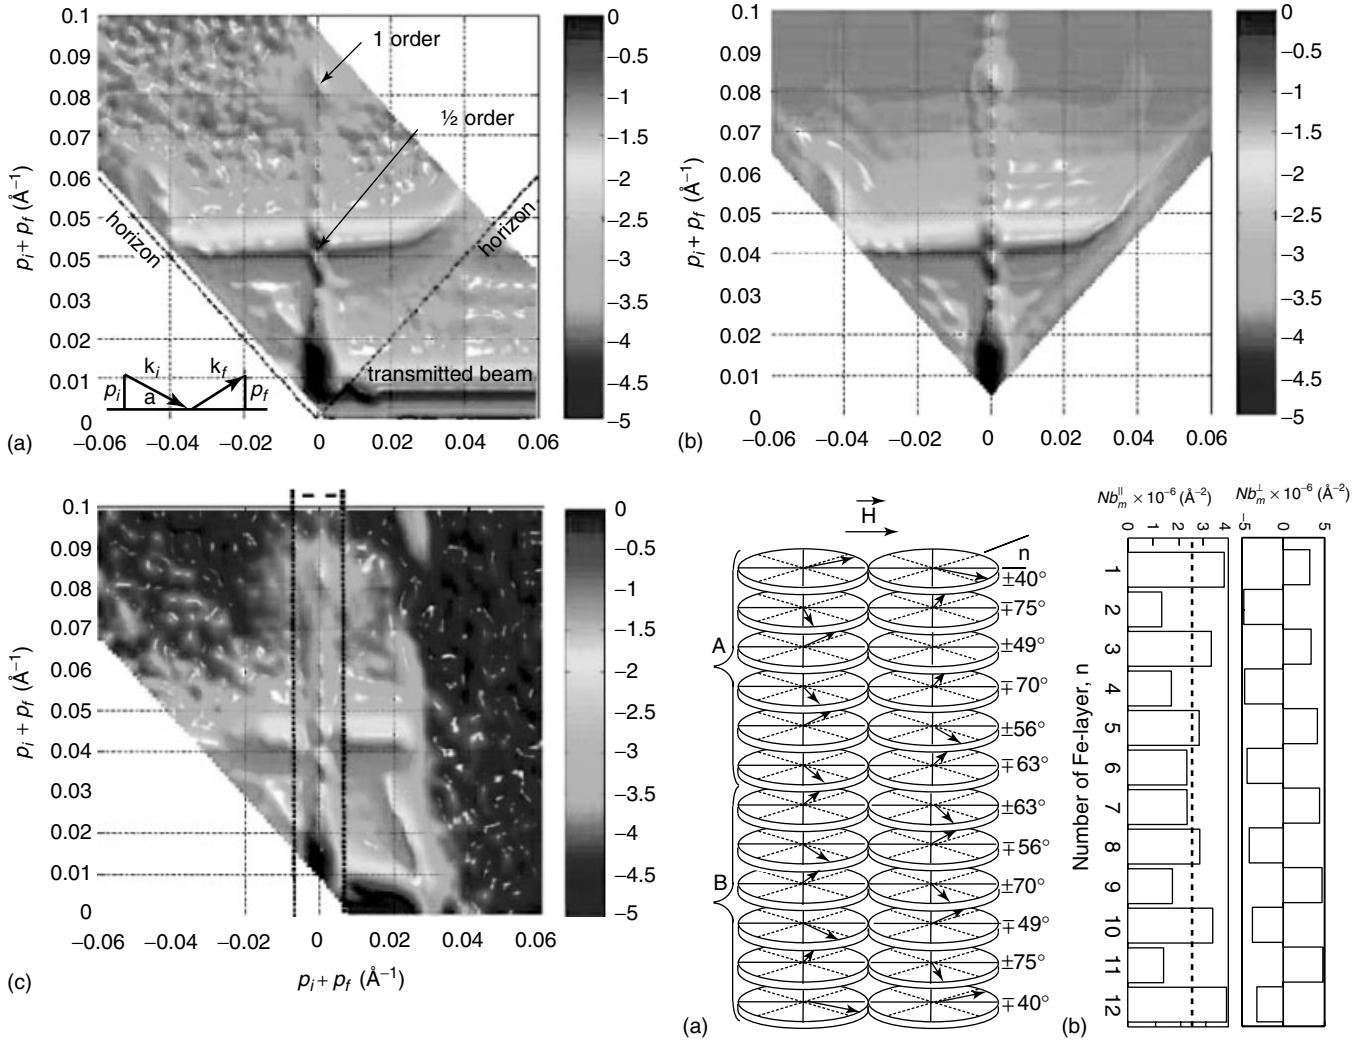

Figure 34. Left panel: (a) Experimental 2D map of the intensity scattered from the Fe/Cr(001) superlattice as a function of the momentum transfer $Q_z = (p_i + p_f)$ versus $(p_i - p_f)$, where p_i and p_f are the components of the incoming and the outgoing wave vector perpendicular to the sample surface, respectively, defined in Figure 2. The logarithmic intensity color scale is shown on the side. The incoming neutrons are in the $(-)$ state. No polarization analysis of the outgoing beam is applied. (b) 2D model fit to the experimental data in (a) using the distorted wave Born approximation. (c) Same map as in (a), however, now recorded with a $(-)$ analyzer turn-on within the region marked by vertical dashed lines. Right panel: (a) Configuration of the magnetization vectors in the Fe layers of the Fe/Cr superlattice in the external field **H** applied in plane along one of the easy axes; dashed lines mark the hard axes. Only Fe layers are shown. The only possible two types of domains (left and right) are depicted. Brackets A and B indicate the two transverse antiphase parts of one lateral domain. The canting angles ϕ_n between $\mathbf{M}_n$ and **H** are shown on the right-hand side. (b) Magnetic parts of the layer resolved neutron scattering length density for the parallel and perpendicular projection of the magnetization with respect to the magnetic field $Nb_m^{\parallel}$ (left) and $Nb_m^{\perp}$ (right), respectively. The dashed line indicates the average value for $Nb_m^{\parallel}$ parallel to the field direction. For more details see text. (Reprinted figure with permission from Lauter-Pasyuk *et al.*, *Phys. Rev. Lett.* Vol. 89, 167203 (2002) © 2002 by the American Physical Society.)

of 19.5 mT. The specular ridge running vertically is crossed by an extensive Bragg sheet at the position of the AF half-order Bragg peak, while no appreciable off-specular scattering is seen around the first-order Bragg peak. Polarization analysis has shown that the specular reflectivity is of completely non-spin-flip nature, while the SF Bragg sheet is produced by in-plane domains with magnetization components normal to the net magnetization and perfect AF correlation across neighboring magnetic layers. The most prominent feature of the NSF reflectivity is the fact that it shows a dip instead of a peak at the position of the half-order AF Bragg peak. The origin of the dip is a stacking fault defect in the mean magnetization distribution over layers as discussed in the subsequent text.

The maps in Figure 34 demonstrate a number of remarkable features due to the optical effects accounted for in DWBA as described in the Section 2.11. One of those effects is the appreciable asymmetry of the maps with respect to an interchange of the incident and scattered wave vectors, as is clearly seen in Figure 34. This effect can be explained as follows: neutrons with the incident momentum enter the sample with one spin state, then undergo a SF process in the sample and leave with a different spin state. Accordingly, the optical potentials and the critical angles for the neutrons entering and exiting the sample are different. From this asymmetry, the mean magnetization averaged over the coherence length can be determined. The intensity of the SF Bragg sheet is, on the other hand, proportional to the mean square fluctuation of the magnetization projection perpendicular to the polarization analysis axis.

This example shows that the off-specular diffuse magnetic and SF scattering is very rich in information, allowing a complete analysis of domain structures and coupling angles in magnetic multilayers. Figure 34(b) shows a calculation of the intensity map, taking into account not only the layer structure of the superlattice but also the magnetic domain structure, displayed in the panel to the right. The calculated map reproduces very well the recorded intensity map, showing that the Fe/Cr superlattice contains a twisted domain state [20]. The canting of the magnetization vectors in each of two possible lateral domains is nonuniform across the multilayer stack. The canting angles are maximal in the end layers due to missing neighbors and therefore weaker exchange coupling. The canting angles progressively relax toward the middle of the multilayer from both sides. The magnetization vectors in the top and bottom layers are tilted in an antiphase fashion, which creates an unavoidable stacking fault in the middle. This is a specific feature of multilayers with an even number of bilayers and by symmetry reasons cannot be avoided in a canted state. The stacking fault causes a dip in the half-order Bragg peak at the specular position due to destructive interference between the neutron waves reflected from the sequence of layers on either side of the stacking fault.

4.2.3 Heusler multilayers

Heusler compounds have attracted recent interest as electrodes in spintronic devices (Hillebrands and Felser, 2006). Due to a half-metallic splitting of the d band at the Fermi level, the spin polarization is predicted to be 100%. The full Heusler compounds have a composition of the type X_2YZ, (X = Co,Ni; Y = Mn, Z = Si,Ge) and a L_{21} structure, which consists of 4 interpenetrating fcc lattices. Only compounds with long-range structural order exhibit a F order parameter. Site disorder has detrimental effects on the polarization, the average magnetic moment, and the Curie temperature. Film growth of ordered Heusler alloys and proper epitaxy to adjacent metal or semiconductor layers is still a challenge. Often a cluster type ferromagnetism is observed below a blocking temperature. Neutron reflectometry has been used to investigate the magnetization profile in the Heusler layers and interlayer coupling effects across non-magnetic interlayers. In particular Bergmann *et al*. have studied the structural and magnetic properties of a series of sputter-deposited [Co_2MnGe/V] multilayers (Bergmann *et al*., 2005). Those measurements have revealed a magnetic phase transition at a Néel temperature T_N that is characterized by an onset of simultaneous F intralayer order in the Co_2MnGe layers and AF interlayer order between adjacent Co_2MnGe layers. In Figure 35 the experimental results obtained by specular PNR and reciprocal-space maps are shown, together with a structural model, which applies to the low temperature coupled state. Above T_N the magnetic layers are in a superparamagnetic state. The observed AF interlayer ordering is attributed to magnetic stray fields arising from the granular Heusler layers. The interlayer dipolar interactions cause a reversible magnetic phase transition of the magnetic clusters with weak AF order between the layers and for thin enough V spacer spacers. For V thicknesses more than 3 nm, the AF coupling vanishes.

The remanent state of the [Co_2MnGe(3 nm)/V(3 nm)] multilayer is particularly interesting as the PNR results reproduced in Figure 35(c) cannot be described by a single-domain state. The half-order AF Bragg peak is seen in the NSF and SF reflectivities, indicating that the AF coupled domains are canted with respect to the polarization axis. At the same time there is a F component clearly visible at the first-order Bragg peak. This requires the AF domains to have a F projection onto the y-axis parallel to the guiding field direction. The specular PNR data can well be simulated using a model, which assumes a coherent AF coupling through the multilayer stack, the AF sublattice having the magnetic moments m_1 and $-m_2$ with $|m_1| = |-m_2|$, respectively. In order to provide both SF and NSF reflections at the AF peak position, the model assumes that the sublattice magnetizations have projections parallel and perpendicular to the applied field.

However, the results of the PNR simulations are based on the hypothesis that the layers are homogeneously magnetized over the neutron coherence area: specular reflectivity does not provide any direct information on the lateral length scales of the film, completely ignoring their crystalline structure and possible large-scale inhomogeneities. A transverse scan of the AF peak in zero field at 15 K as well as the 2D map in Figure 35(a) reveal the presence of magnetic off-specular scattering. In fact, the transverse scan through the half-order AF peak has no resolution-limited Gaussian profile

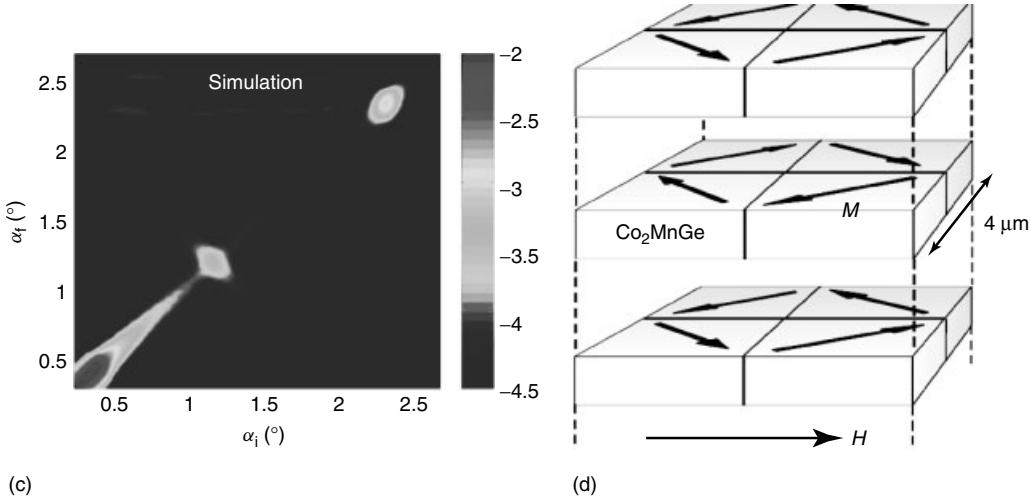

Figure 35. Left column: 2D maps of the specular and off-specular scattering from a Heusler alloy multilayer with a vanadium spacer layer and 50 repeats: Co_2MnGe(3 nm)/V(3 nm). The specular ridge stretches along the diagonal. The angles α_i and α_f refer to the incident an exit angles as defined in Figure 1. The top panel (a) shows the experimental results at remanence and at 15 K and without polarization analysis, the lower panel (b) is a simulation of the scattering pattern with a superiterative-based version of the Distorted Wave Born Approximation as explained in the Section **2.10**. In this simulation the domain state shown in panel (d) was assumed, which obviously can reproduce the data very well. There is a clear AF coupling in this multilayer, expressed by the half-order peak, which also exhibits some streaking due to the breakdown of the magnetic layers in domains. The half order peak is also observed in the specular reflectivity scans shown in panel (c). The AF peak is entirely diffuse, indicating that the domains are smaller than the longitudinal projection of the neutron lateral coherence length. The estimated domain size according to the simulation in (b) is 2.1 μm. (Reprinted figure with permission from A. Bergmann *et al*., *Phys. Rev. B*, Vol. 72, 214403 (2005). © 2005 by the American Physical Society.)

and can well be described by a Lorentzian line shape. This gives a strong hint that the AF peak seen in the specular reflectivity is mainly due to a contribution of off-specular scattering to the specular reflection within the range of their overlap. The presence of magnetic off-specular scattering indicates that the magnetization in the single layers is broken up into domains, the size of which being smaller than the longitudinal projection of the neutron coherence length $L_{\|} = L/\sin\alpha$, where the neutron coherence length L is given by $L = 1/\Delta Q$, and ΔQ is the uncertainty in the wave vector transfer due to experimental resolution. The longitudinal projection of the lateral coherence length is estimated to be about 60 μm. Hence, simulating the specular data only leads to false results for this sample. A complete simulation of both, the specular and off-specular intensity using the superiterative-based version of the distorted wave Born approximation, presented in the Section 2.11, can account for all features of the scattering map. The results are shown in Figure 35(b). In the fit it was assumed that the magnetic films break up into a Landau type of pattern with four possible types of domains with perfect AF coupling and an average lateral size of 2.1 μm with magnetic moments of the layers set to 50% of the bulk value. The model is sketched in Figure 35(d).

The domain state of the Heusler alloy multilayer is particular illustrative for the analysis of PNR data from magnetic multilayers. It clearly shows that a correct picture on the state of the sample can only be gained by recording both, specular and off-specular intensity. For all present and future PNR experiments this has now become a standard.

4.2.4 Tuning of exchange coupling with hydrogen

Usually the IEC is explored by varying the thickness of the mediating paramagnetic layer. A new twist is added if the IEC can be varied solely by changing the electronic properties of the interlayer without changing its thickness. This can be achieved in various ways via alloying, temperature change, photoconductance, and so on, but most effectively, reversibly and nondestructively by loading the interlayer with hydrogen. Hydrogen in metals adds an electron and creates new states at the Fermi level, thereby changing the quantum well states drastically. Change of the interlayer exchange coupling with hydrogen has been demonstrated for Fe/Nb (Klose *et al*., 1997) and Fe/V superlattices (Hjörvarsson *et al*., 1997), and a change from ferro- to AF coupling has been observed by the development of a half-order peak as a function of hydrogen concentration. The development of the half order AF peak as a function of hydrogen concentration is illustrated in Figure 36 for Fe/Nb (Klose *et al*., 1997) and in Figure 37 for Fe/V (Hjörvarsson *et al*., 1997). Interstitial hydrogen in the metal matrix also expands the host lattice. However, the observed IEC effects are more drastic than can be explained by a comparatively small lattice

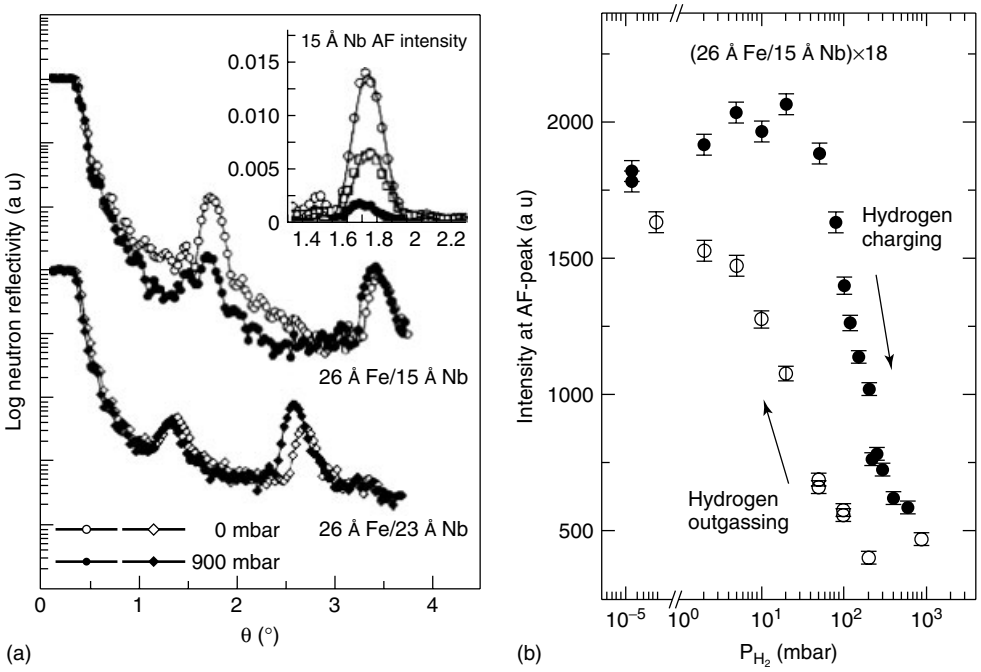

Figure 36. (a) Neutron reflectivity results from two Fe/Nb multilayers with different Nb spacer thicknesses. Both multilayers exhibit antiferromagnetic coupling in remanence and before hydrogen loading as recognized by the half-order peak at the scattering angles $\theta = 1.2^{\circ}$ and 1.5°, respectively. The exchange coupling of the multilayer with a Nb thickness of 15 Å changes with increasing hydrogen concentration and becomes more ferromagnetic. Note that all peaks shift to smaller angles due to the expanding multilayer period upon hydrogen loading. (b) Intensity of the half-order antiferromagnetic peak as a function of the hydrogen concentration for a complete cycle of loading and degassing of the Nb spacer. (Reprinted figure with permission from F. Klose *et al*., *Phys Rev. Lett.* Vol. 78, 1150 (1997). © 1997 by the American Physical Society.)

expansion. In the work of Leiner *et al*. (2003) the concept of IEC was combined with issues of intra- ($J_{\parallel}$) and interlayer ($J_{\perp}$) exchange coupling. By fine tuning the hydrogen concentration, $J_{\perp}$ changes the sign from positive or F exchange coupling to negative or AF exchange coupling. At the crossover point the quasitwo- dimensional magnetic layers are not coupled in the perpendicular direction. With zero coupling, there is no interaction between the magnetic sheets and each layer becomes an isolated two-dimensional magnet. Griffiths (1970) presented the properties of this system as a 'phase diagram' plotting the Curie temperature and the Néel temperature as a function of varying interlayer exchange coupling $J_{\perp}$ (inset of Figure 38). This reveals that as adjacent layers decouple, the critical temperature also drops toward a minimum value at zero coupling. Therefore, according to Griffiths for $J_{\perp} = 0$ the system should display a strongly reduced but finite ordering temperature. This phase diagram could largely be confirmed by Leiner *et al*. (2003) using hydrogen in Fe/V superlattices to effectively decouple the Fe layers. With decreasing $J_{\perp}$ one expects an increasing in-plane fluctuation of the magnetization. This could, however, not yet been observed and remains a challenge for the future.

A significant change of the interlayer exchange coupling was also found in Fe/LaH_x multilayers with varying hydrogen concentration (Lohstroh *et al*., 2001). Even small amounts of additional hydrogen atoms dissolved in metallic LaH_x may invert the sign of the coupling, similar to Fe/V(H), asserting that the main effect is due to a change of the electronic structure of the host lattice. In contrast, in Fe/Ce multilayers the Fe layers are magnetically decoupled, but become weakly coupled when Cerium is hydrogenated. The weak AF coupling can only be discerned by the half-order peak in NR experiments (Lohstroh *et al*., 2000).

Hydrogen in Ho/Y superlattices penetrates preferentially into the Y layers and breaks the coupling between the Ho magnetic spirals from one layer to the next. Without hydrogen and for Y layer thicknesses below 5 nm, the Ho spin spiral penetrates through the Y layer with a fixed phase relationship from one Ho layer to the next. With hydrogen in the Y spacer layer, the Y polarization and the exchange coupling is interrupted. This is because between the compositions of YH_2 and YH_3 a metal insulator transition takes place (Huiberts *et al*., 1996).

With neutron reflectometry at small angles the $(000 + \tau)$ peak was measured as a function of temperature and hydrogen concentration (Leiner, Ay and Zabel, 2004). The integrated intensity of the peak yields the order parameter,

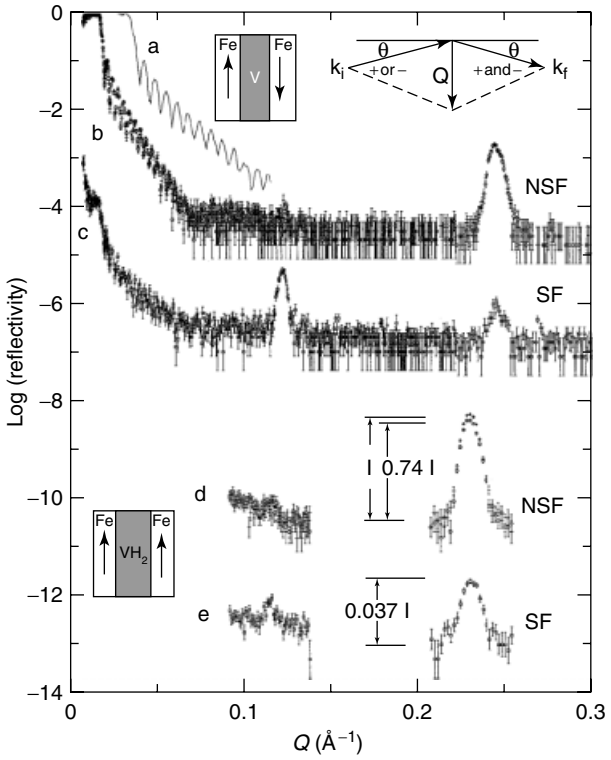

Figure 37. Polarized neutron reflectivity at room temperature for a Fe(3 ML)/V(14 ML) superlattice before and after hydrogen loading. The inset in the upper right corner shows the neutron scattering geometry for the polarized beam. NSF and SF refers to non-spin-flip and spin-flip reflectivity, respectively. After hydrogen loading the half-order peak in the SF channel has vanished. The shift of the first-order Bragg peak to smaller scattering vectors is due to the lattice expansion from the hydrogen in the vanadium spacer. (Reprinted figure with permission from B. Hjörvarsson *et al*., *Phys Rev. Lett.* Vol. 79, 901 (1997). © 1997 by the American Physical Society.)

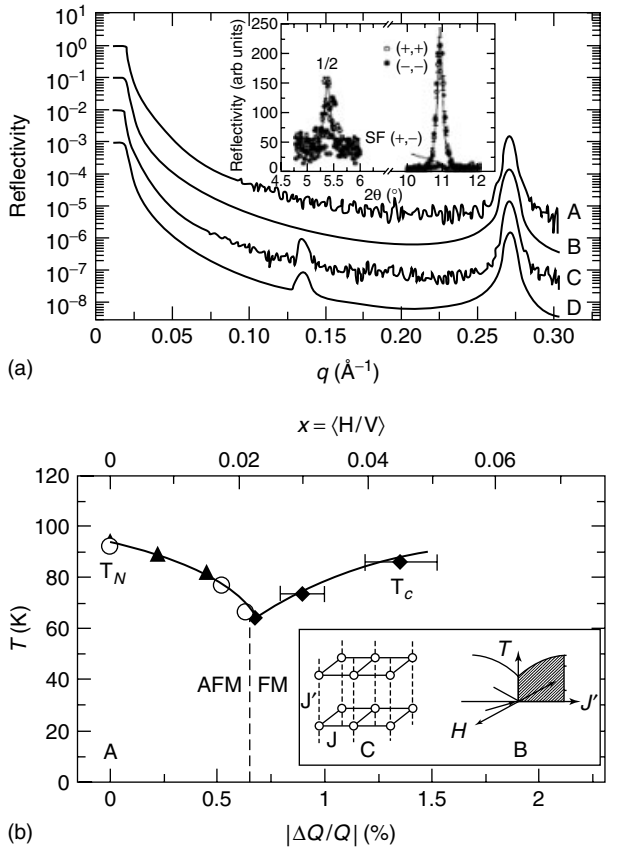

Figure 38. (a) Neutron reflectivity from a Fe(2 ML)/V(13 ML) at high and low temperatures. In the low temperature scan a half-order becomes visible, indicative for an antiferromagnetic coupling of the adjacent Fe layers, separated by V spacer layers. (b) The experimental phase diagram of an iron–vanadium Fe(2 ML)/V(13 ML) multilayer as a function of hydrogen concentration and temperature. Inset: Schematic magnetic phase diagram by Griffiths (1970) of a model system of spins on a cubic lattice (T is the temperature, J' is the interlayer coupling strength and H is the external magnetic field). (Reprinted figure with permission from V. Leiner *et al*., *Phys. Rev. Lett.* Vol. 91, 037202 (2003). © 2003 by the American Physical Society.)

whereas the width contains the information on the coherence length of the spin spiral in Ho. Figure 39 reproduces maps of the $(000 + \tau)$ peak before hydrogen loading and as a function of temperature. The peak is split into several satellite peaks due to the folding of the $(000 + \tau)$ peak with the superlattice reflections. In Figure 40 a radial scan through the τ peak clearly shows that the original splitting of the τ peak into several side peaks diminishes with increasing hydrogen content in the Y spacer layers and a broad τ peak remains, representative for a short Ho spiral in a single layer. Once this state is reached, the Néel temperature for the Ho layer drops dramatically. This is more pronounced for thinner Ho layers. Thus for a Ho(11 ML)/Y(23 ML) superlattice the Néel temperature drops from initially 93 to 75 K with increasing hydrogen concentration. This Néel temperature is identical to the one measured for a single Ho film of the same layer thickness, which is reduced compared to the bulk value of 131 K due to finite size effects.

4.2.5 Dilute magnetic semiconductors

Dilute magnetic semiconductors (DMS) are of tremendous present interest for spintronic applications. They usually consist of II-VI or III-V compounds doped with magnetic ions. The prototype DMS is $Ga_{1-x}Mn_xAs$, which exhibits ferromagnetism for Mn concentrations up to $x \approx 7\%$ and a Curie temperature as high as 170 K (Matsukuraa, Ohnoa and Dietl, 2002). Kepa *et al*. (2001) have studied a superlattice of alternating GaAs and $Ga_{1-x}Mn_xAs$ layers by PNR to investigate the magnetic ordering with a Mn concentration

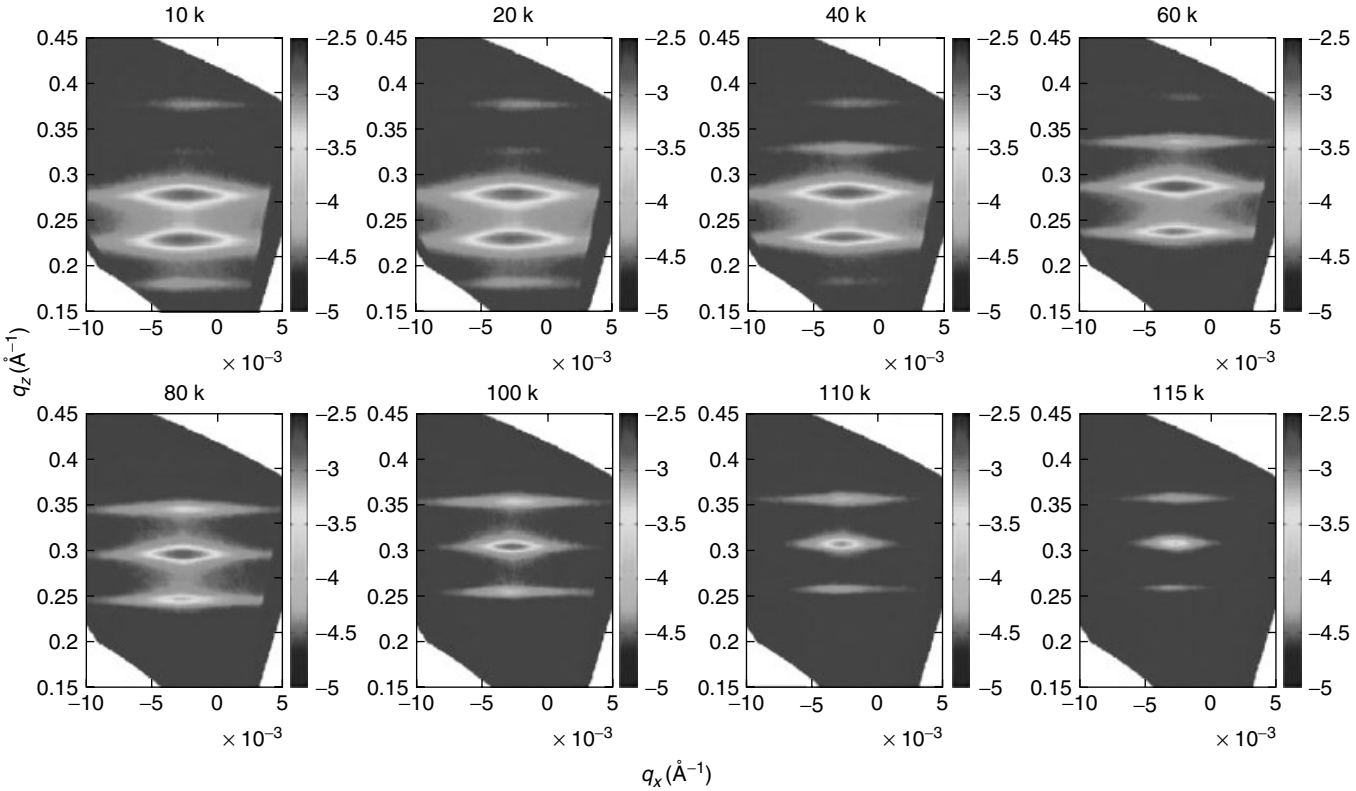

Figure 39. Reciprocal-space maps around the position of the magnetic $(000 + \tau)$ peak of a (Ho(27 ML)/Y(17 ML)) superlattice before hydrogen uptake in the Y spacer layer and for different temperature up to the Neel temperature of 91 K. (Reprinted figure with permission from V. Leiner *et al*., *Phys Rev. B* Vol. 70, 104429 (2004). © 2004 by the American Physical Society.)

of 6% in the magnetic layers. Below the Curie temperature of about 30 K the NSF reflectivities $\mathcal{R}^{++}$ and $\mathcal{R}^{--}$ split at the first-order Bragg reflection, clearly indicating F ordering Figure 41. This ordering persist even in essentially zero field, which is a clear sign for a single-domain state throughout the superlattice. As the single-domain state occurs by zero field cooling, Kepa *et al*. suggest that a long-range interlayer exchange interaction must be responsible for the perfect F alignment of all GaMnAs layers in the superlattice. Modeling of the reflectivities confirm that all Mn atoms contribute to the F single domain state and that Mn is in $S = 5/2$ state.

In contrast to Kepa *et al*. (2001), Kirby *et al*. (2004) have studied single $Ga_{1-x}Mn_xAs$ layers by PNR in the as deposited state and after annealing. The main interest in this work was to analyze the magnetization profile in the GaMnAs layer, which is a direct measure of the Mn-concentration distribution in the z direction. GaMnAs layers are used for spin injection into GaAs and therefore the magnetization or the polarization should be high at the GaMnAs/GaAs interface. Indeed, before annealing the magnetization profile is rather asymmetric with a low Mn concentration at the interface and a high concentration close to the surface. After annealing at 280 °C for 1 h the concentration distribution and magnetization increased and the profile becomes much more homogeneous. Annealing therefore has not only the effect of Mn redistribution in the z direction but also to change the occupancy from interstitial to substitutional sites. PNR yields an amazingly rich insight in the magnetization distribution even for thin alloy films and low concentrations.

Primus *et al*. (2005) have recently studied the magnetization reversal mechanism of $Ga_{1-x}Mn_xAs$ layers on GaAs substrates with PNR methods. A SF peak at the coercive field is observed for one sample, while for a second sample no SF peak is observed. Therefore it is concluded that in the second sample the reversal takes place via 180° domain wall nucleation and propagation, while in the first sample the magnetization reversal may proceed by an incoherent rotation mechanism through 90° domains. Both samples differ in their growth temperature and show different in-plane anisotropies. The first sample exhibits an in-plane biaxial anisotropy, while the second sample has an in-plane uniaxial anisotropy. Thus, magnetic anisotropy and reversal mechanism are intimately related.

A very interesting PNR study has recently been performed by (Diwekar *et al*., 2004) on GaAs films. During MBE

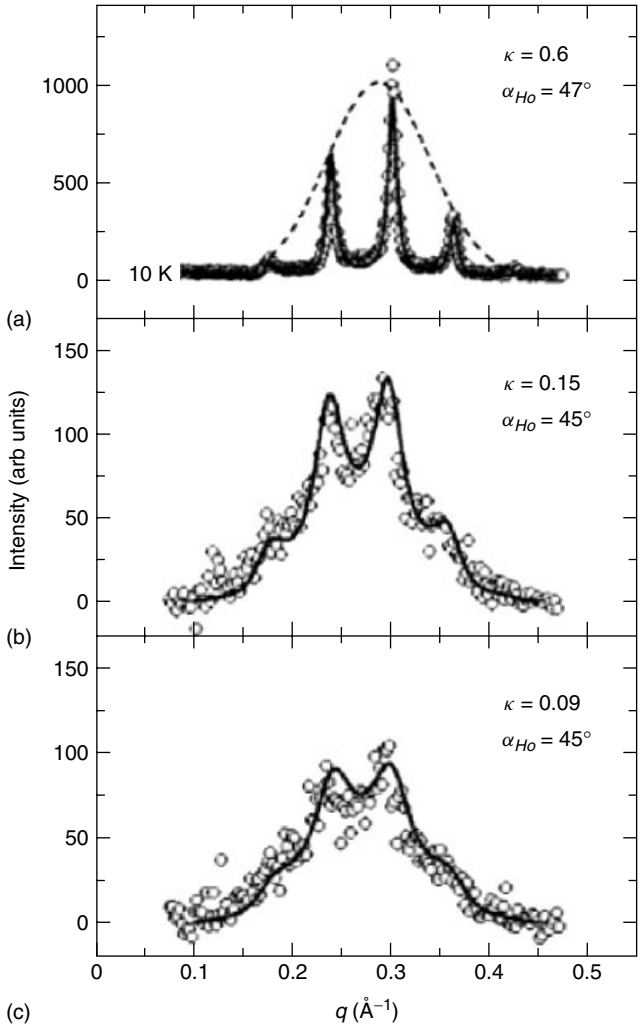

Figure 40. Specular diffraction patterns of a (Ho(11 ML)/Y(23 ML)) superlattice taken for the pristine sample (a) and with two different deuterium concentrations in the yttrium interlayers (b) and (c). Due to the reduced thickness of the individual holmium films the width of the τ peak, plotted as a dashed line in panel (a), is increased. Before hydrogen loading the diffraction pattern shows sharp peaks of an exchange-coupled superlattice. Through exposure to hydrogen at two different pressures, the interlayer correlation is successively lost and the shape of the diffraction pattern approaches the envelope function for the τ peak of an individual thin Ho film. The parameter κ characterizes the interlayer correlation where $\kappa = 1$ defines perfect order. (Reprinted figure with permission from V. Leiner *et al*., *Phys Rev. B* Vol. 70, 104429 (2004). © 2004 by the American Physical Society.)

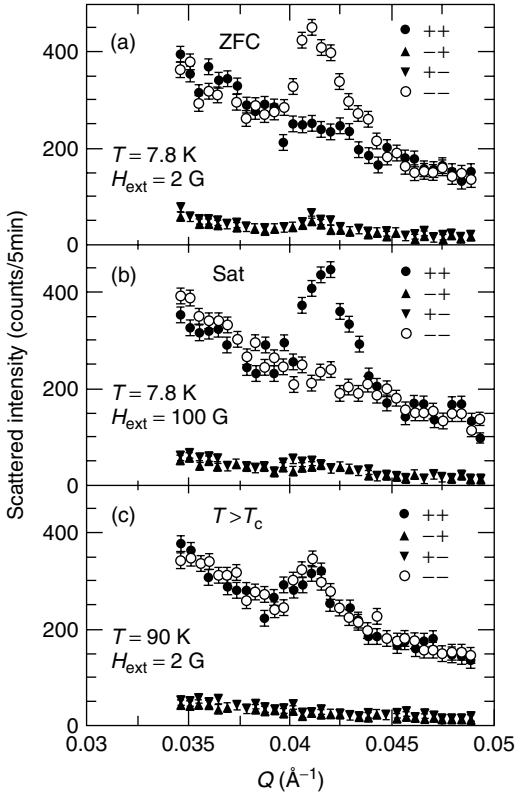

Figure 41. Polarized neutron reflectivity from a GaMnAs/GaAs superlattice. The first-order Bragg peak exhibits the same $\mathcal{R}^{++}$ and $\mathcal{R}^{--}$ splitting after zero field cooling (a) and field cooling (b), showing that the GaMnAs layers are in a ferromagnetic state at low temperatures and that the magnetization vectors in all layers are parallel aligned. The SF reflectivity is negligible. Such a behavior is usually only observed in case of interlayer exchange coupling, which is also invoked here to explain the reflectivity results. In (c) the reflectivity is shown for temperatures above the ordering temperature, where no splitting of the NSF Bragg peak is observed. (Reprinted figure with permission from H. Kepa *et al*., *Phys Rev. B* Vol. 64, 121302 (2001). © 2001 by the American Physical Society.)

growth the GaAs layers were interlaced with partially filled MnAs layers in discrete and periodic distances, forming a digital ferromagnetic heterostructure (DFH). Owing to the alignment of the Mn moments even in a weak external field, the superlattice shows F Bragg peaks below the ordering temperature of about 40 K (see Figure 42). In contrast to the studies by Kepa *et al*. (2001), the DFH exhibits a sizable difference for the saturation and remanent magnetization, which becomes even more pronounced when comparing PNR and SQUID data. The PNR data from the F Bragg peak focus on those magnetic moments which follow the DFH periodicity, while the SQUID data take an average over all moments. This difference indicates that in the superlattices magnetic clusters must be present, which align in the external field even at temperatures far above the spontaneous ordering temperature. Diwekar *et al*. have made another interesting observation. Below 100 K, magnetic moments within each MnAs layer first order locally, but long-range order is developed along the growth direction only below $T_c = 40 < 100$ K. This two-step ordering mechanism can be attributed to fluctuations in the interlayer exchange interactions.

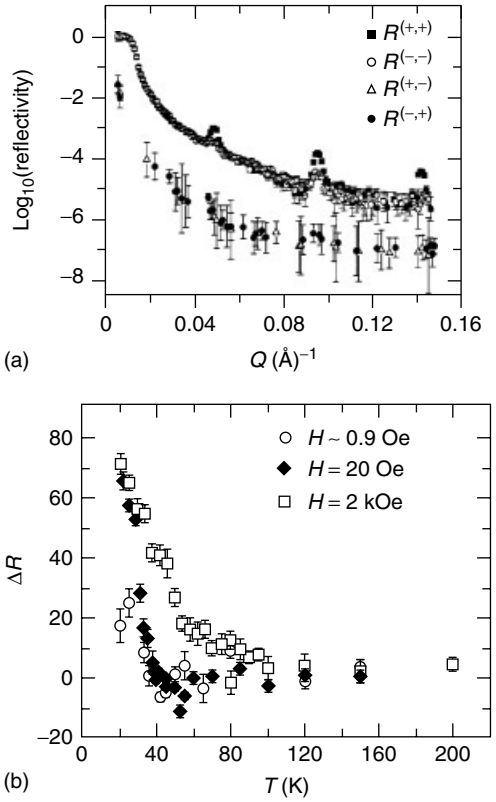

Figure 42. (a) Polarized neutron reflectivity from a digital superlattice of 50 ML GaAs interlaced with a half-filled MnAs layer and repeated 60 times. The half-filled monolayer with Mn atoms provides enough contrast to clearly recognize the superlattice periodicity. (b) Temperature dependence of the magnetization determined from integrated intensity difference $\Delta R = R^{+,+} - R^{-,-}$ between the NSF cross sections at the first-order SL Bragg peak position. The strong field dependence of the data is indicative for a cluster type magnetism. ΔR is only sensitive to magnetization contributions that have the periodicity of the SL. In contrast, magnetometer measurements average over all moments, periodic and random. (Reproduced from M. Diwekar *et al*., with permission from American Institute of Physics. © 2004.)

5 LATERALLY PATTERNED MAGNETIC ARRAYS

Laterally patterned and periodic magnetic arrays have recently attracted much scientific interest because the interplay between exchange and shape anisotropy allows to control the magnetic domain state within the magnetic elements in remanence such as dipoles and vortices, and their spatial separation controls the dipolar interaction and correlation during reversal. A number of experimental techniques has been employed to characterize the domain state and the magnetization reversal of these new lateral nanostructures. Among those PNR may not be the obvious experimental tool because of a combination of low intensity and diminishing scattering volume. Nevertheless, in recent years PNR has been shown to be a rather powerful method for the investigation of some of their fundamental properties. In contrast to imaging methods, such as Kerr microscopy and magnetic force microscopy, neutrons simultaneously probe the whole magnetic array and hence are sensitive to cooperative effects within the array. On the other hand, being a depth sensitive probe, PNR measurements disclose information hidden in buried magnetic layers and interfaces. This may become especially important in the near future when for the information storage in magnetic media the third dimension will be used, for example, via the layer-by-layer patterning in multilayered systems.

Quantitative evaluation of PNR data allows to recover the vectorial magnetization profile and also to receive rather detailed information on magnetization vector fluctuations and correlations within the magnetic array. However, it should be kept in mind that the lateral resolution element, that is the area from which a coherent scattering can be observed, is highly anisotropic and covers only a small fraction of the sample surface illuminated by the neutron beam. The effect of coherent and incoherent summation of the scattering signal from lateral stripe arrays is discussed in Section 2.8 and can be used to obtain information that is complementary to methods which use a different averaging method such as MOKE. Similar to the case of continuous thin magnetic films the complementarity of PNR and MOKE can effectively be used for characterizing the magnetization reversal mechanisms and for discriminating between rotation and domain nucleation.

There are three possible sources of information on the magnetic state in a periodic array as can be seen from a model simulation of a magnetic stripe array in Figure 43: specular neutron reflectivity, Bragg diffraction from the lateral period and off-specular diffuse scattering from domains smaller than the coherence range. The simulations were carried out by use of the DWBA routine described in the Section 2.11 and highlight some particular features not accounted for in Figure 12. The simulations shown in Figure 43 have been performed for an 80-nm-thick Co stripe array (stripe width 3 μm and periodicity 4 μm). The stripes are oriented perpendicular to the scattering plane and parallel to the y-axis. The mean magnetization within the stripes is assumed to be tilted by 25° away from y-axis (i.e., the neutron polarization axis). Furthermore fluctuations are allowed around the mean magnetization orientation. The specular reflection ridge runs along the diagonal, where $\alpha_i = \alpha_f$. In Figure 43 the splitting of the NSF reflectivities $\mathcal{R}^{++}$ and $\mathcal{R}^{--}$ is well visible due to the assumption of a high sample magnetization. SF reflectivities $\mathcal{R}^{+-}$ and $\mathcal{R}^{-+}$ are due to the orientation of the mean magnetization away from the polarization axis of the

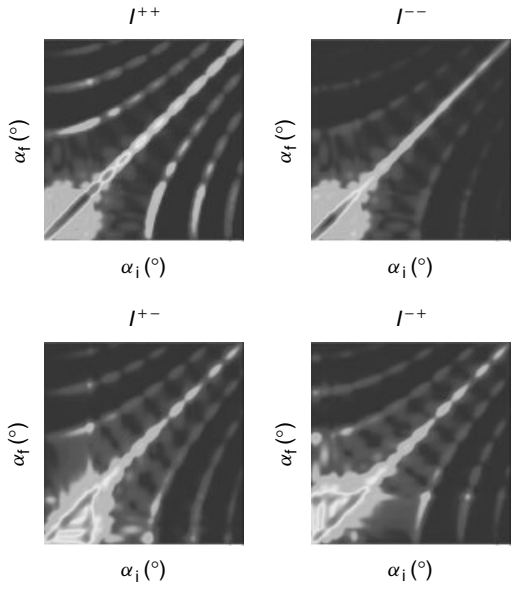

Figure 43. Model simulation of intensity maps of all four cross sections for an 80-nm thick Co stripe array with a stripe width of 3 µm and a periodicity of 4 µm. The mean magnetization is assumed to be oriented about 25° away from the neutron polarization axis which is equivalent to the orientation of the ridge of the stripes. It is further assumed that the stripes are not in a single-domain state but exhibit fluctuations around the mean magnetization within the coherence area.

neutrons. The other two features occur in the intensity maps at $\alpha_i \neq \alpha_f$. The first one is the intensity of Bragg diffraction concentrated along curved lines $\cos\alpha_i - \cos\alpha_f \approx n(\lambda/\Lambda)$, where n denotes the order of diffraction and Λ is the period. It is caused by the periodic variation of nuclear and magnetic potentials across the striped pattern. Equivalent to the specular reflection splitting occurs between the NSF diffraction lines. SF Bragg diffraction in the off-specular scattering range can be observed due to rotation of the stripe magnetization away from the stripe ridge which is assumed to be parallel to the polarization axis of the neutrons. The second feature is a well-structured diffuse intensity observed at low angles of incidence α_i and/or scattering angles α_f. This intensity distribution is asymmetric with respect to the main diagonal in the bottom panels of Figure 43. The I^{+-} off-specular intensity is mostly disposed at $\alpha_f < \alpha_i$, while the I^{-+} off-specular intensity is concentrated at $\alpha_f > \alpha_i$ such that the left image becomes identical to the right one if α_i and α_f are interchanged. Correspondingly, there is also an antisymmetry between the off-specular scattering intensities in the same SF maps if simulated for fields below and above the coercive field. The asymmetry is a direct consequence of optical effects accounted for in DWBA (Section 2.11). NSF diffuse scattering is, in contrast, symmetric. SF and NSF scattering together are sensitive to magnetization fluctuations of both longitudinal and transverse components. Both features are due to the lateral magnetization variation on a scale smaller than the coherence range.

For a complete determination of the magnetization state of a lateral magnetic array it is important to simultaneously evaluate the specular reflectivities, the off-specular Bragg diffractions, and the diffuse scattering. This is due to the fact that the information these different scattering contributions contain are not independent but rather are interrelated. Sometimes, due to a lack of magnetic material in the patterned sample or due to other reasons, it may even be the case that no splitting of the NSF reflectivities can be observed while splitting still occurs along the Bragg diffraction lines in the off-specular scattering range.

Such a case is described by Temst, Van-Bael and Fritzsche (2001) where 20-nm-thick circular Co disks with a diameter of 4 µm are arranged in a 2 × 2 cm large square lattice with a 10 µm period as seen in Figure 44(a). The authors could not observe a splitting at the specular reflectivity but were able to extract qualitative magnetic information from field dependent intensity measurements of all four cross sections at the Bragg positions. From missing SF Bragg diffraction they concluded that the disks pass through a multidomain state during magnetization reversal.

In Figure 45 similar measurements of Temst *et al.* and Fritzsche *et al.* using rectangular bars are shown (Temst *et al.*, 2003a,b; Fritzsche, Van Bael and Temst, 2003). In both cases the bars were saturated in a negative field parallel to the long side of the bars and parallel to the NSF direction [21]. For the PNR experiment, a magnetic field H was applied along the positive NSF axis (x direction in Figure 44b), that is, opposite to the direction of the remanent magnetization.

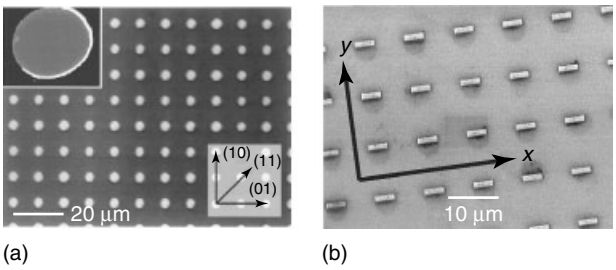

Figure 44. (a) Optical microscopy picture of a periodic array of Co disks on a square lattice with a 10 µm period (Temst, Van-Bael and Fritzsche, 2001). The length of the white bar corresponds to 20 µm. The inset (upper left corner) shows an AFM image of a single disk. In the lower right corner the in-plane directions are defined. (Reproduced from K. Temst *et al.*, with permission from the American Institute of Physics. © 2001.) (b) SEM picture of an array of Co bars (Temst *et al.*, 2003a). The white marker corresponds to 20 µm. (Reproduced from K. Temst *et al.*, 2003, with permission from Elsevier. © 2003.)

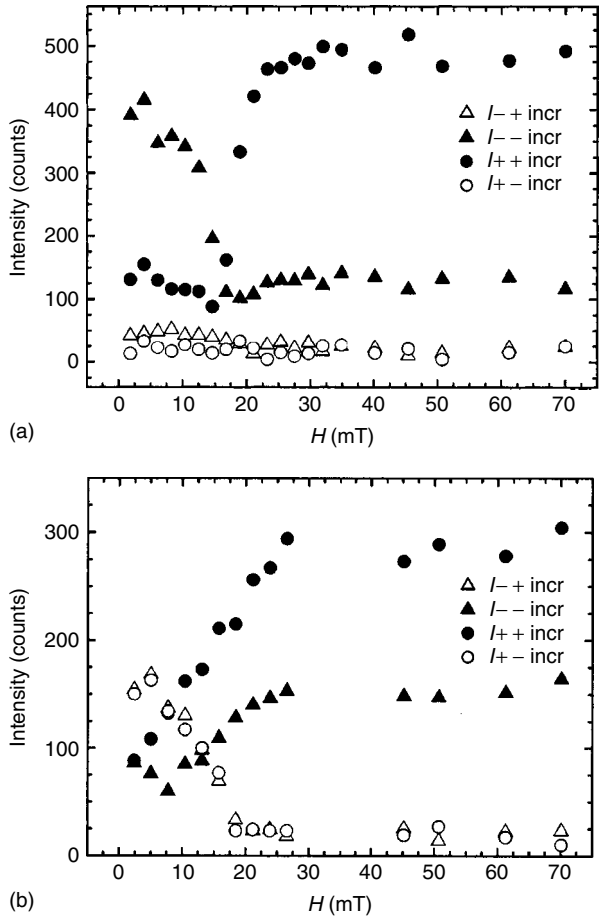

Figure 45. Intensity of the first-order off-specular Bragg peak as a function of decreasing field H applied along the easy axis (a) and along the hard axis of rectangular Co bars (b) (Figure 44b). Prior to this experiment, the bars were saturated along the negative x direction, that is along the easy axis. (Reproduced from K. Temst *et al*., 2003, with permission from Elsevier. © 2003.)

Figure 45(a) shows the intensity of the off-specular first-order Bragg peak as a function of magnetic field. The SF contribution is very small, indicating that there are negligible magnetization components perpendicular to the neutron polarization axis. Figure 45(b) reproduces the NSF and SF Bragg intensities as a function of magnetic field after the sample has been saturated along the easy axis and rotated by 90°, such that the easy axis magnetization is parallel to the SF axis. In this case, a strong SF signal can be observed, since the remanent magnetization is now perpendicular to the neutron polarization. As the field is increased parallel to the hard axis, that is the short side of the bars, the SF signal fades away and the NSF intensities increase.

PNR studies were also performed on a Co/CoO stripe array of about 1 µm width and with a periodicity of 15 µm exhibiting the EB effect (Temst *et al*., 2005a). Similarly Temst *et al*. studied Co/CoO bars with a length of 4 µm and a width of 1 µm placed on a square lattice with a periodicity of 10 µm. (Temst *et al*., 2005b). For the stripes Temst *et al*. present specular PNR measurements with full polarization analysis. The measurements were performed at the two different coercive fields characteristic for EB systems and with the stripes aligned either parallel or perpendicular to the neutron polarization axis (i.e., the applied magnetic field direction). Information was gained from the SF specular reflectivity. In case of the parallel orientation the authors did not observe SF specular intensity during both reversals, whereas in case of perpendicular orientation a specular SF signal was observed at one of the coercive fields. In accordance with the measurements by Radu *et al*. (2003a) on continuous and exchange-biased Co/CoO bilayers, the absence of SF specular reflectivity is explained by nucleation of domains smaller than the coherence length of the neutron beam, while enhanced SF specular reflectivity during magnetization reversal is a sign for magnetization reversal through rotation.

The magnetization state of the Co/CoO bars (Temst *et al*., 2005b) again was determined by field dependent intensity measurements at the off-specular first-order Bragg peak. Similar to the Co/CoO stripe array, for the Co/CoO rectangular bars SF scattering could not be observed when the field was applied along the long side of the bars, indicating a reversal by domain wall nucleation and motion. The polarized neutron scattering (PNS) measurements were supported by micromagnetic simulations using the object orientated micromagnetic framework (OOMMF) of the Division of the Information Technology Laboratory at the National Institute of Standards and Technology (Donahue and Porter, 1999).

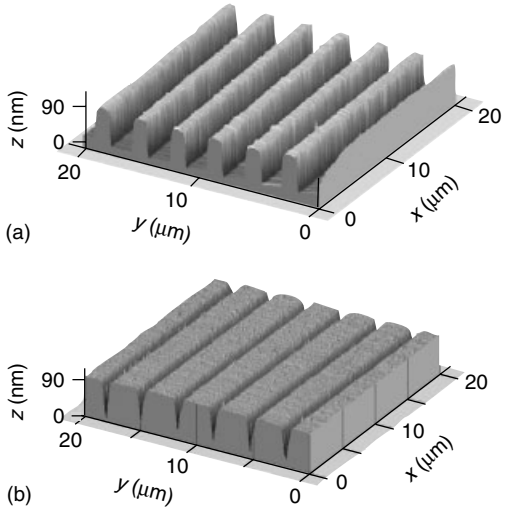

Figure 46. Surface topography of arrays of $Co_{0.7}Fe_{0.3}$ stripes obtained with an atomic force microscope shown in a 3D surface view. The displayed area is $20 \times 20\,\mu m^2$. (a) Narrow stripes with a width of 1.2 µm and (b) wide stripes with a width of 2.4 µm.

From these simulations NSF intensities were calculated and compared to the experimentally observed field dependent intensities from the Bragg peak.

Theis-Bröhl and coworkers have studied the magnetization reversal of various stripe arrays with main emphasis on the analysis of the scattering contributions from specular and off-specular intensities and from Bragg peaks (Theis-Bröhl, Schmitte, Leiner and Zabel, 2003; Theis-Bröhl *et al*., 2003; Theis-Bröhl, 2003). In (Theis-Bröhl *et al*., 2003) an array of 90-nm thick and 1.2 µm wide CoFe stripes with a periodicity of 3 µm (Figure 46a) has been analyzed. A splitting of the specular $\mathcal{R}^{++}$ and $\mathcal{R}^{--}$ reflectivity was not observed. Instead information could be gained from the intensity of the first-order Bragg peak as a function of applied magnetic field. The

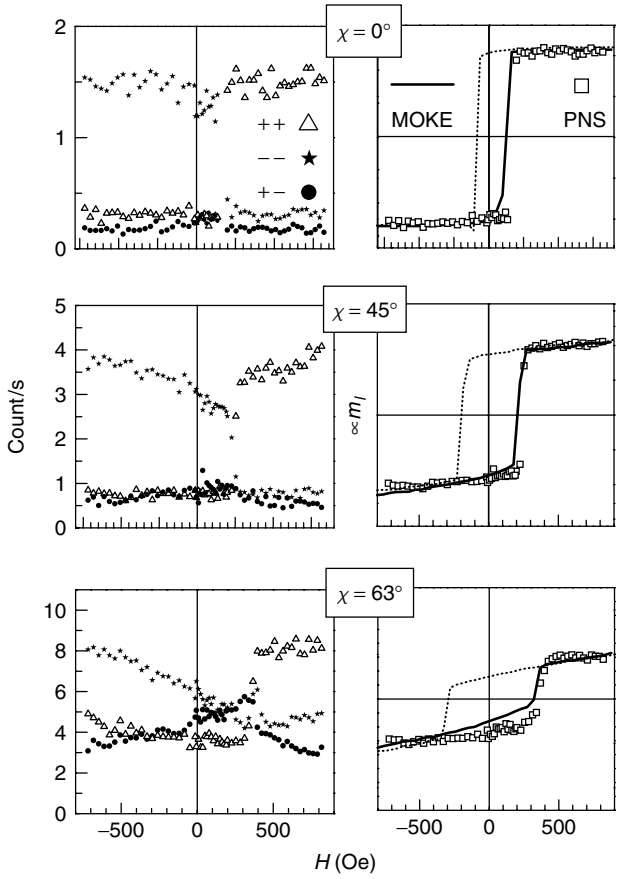

Figure 47. Magnetization reversal measurements performed at the first-order Bragg peak for three different cross sections (left column) and calculated magnetization curves from the polarized neutron measurements (right column). The neutron spin asymmetry (open square) is compared to longitudinal MOKE hysteresis loops (solid and dotted lines). The top row depicts measurements at a sample rotation of $\chi = 0^{\circ}$, the middle row measurements at a sample rotation of $\chi = 45^{\circ}$ and the bottom row measurements at a sample rotation of $\chi = 63^{\circ}$. (Reprinted figure from K. Theis-Bröhl *et al*., *Phys Rev. B.* Vol 67, 184415 (2003). © 2003 by the American Physical Society.)

Bragg intensities were converted into spin asymmetry (SA) curves and compared to longitudinal MOKE hysteresis loops as shown in Figure 47.

It should be noted here that reciprocal lattice spots from lateral stripe arrays occur along the x-axis when the stripes are oriented parallel to the y-axis (see sample geometry in Figure 48). Rotating the stripes by an angle χ causes a rotation of the reciprocal lattice points from the x-axis to the x−y plane by the same angle. Due to a poor resolution in the wave vector transfer projection q_y, as compared to a high resolution in the projection q_x, Bragg reflections still can be observed at $q_x \approx n(2\pi/d)\cos\chi$; where n is an integer and d is the lattice spacing (Toperverg *et al*., 2000; Dorner and Wildes, 2003). This fact was used in (Theis-Bröhl, Schmitte, Leiner and Zabel, 2003; Theis-Bröhl *et al*., 2003; Theis-Bröhl, 2003) for analyzing the magnetization state of stripe pattern as a function of sample rotation. The stripe array displayed in Figure 46(a) and discussed above showed a relatively simple remagnetization process dominated by a single-domain state with domain nucleation and wall movement restricted to a small field range around the coercive field. The case $\chi = 0$ is the easy axis configuration without rotation of magnetization and reversal purely takes place through domain nucleation and DW movement at the coercive field. In all other cases with $\chi \neq 0$ rotation of the magnetization within a single-domain state occurs for fields $H \neq H_c$ while the reversal through domain nucleation and DW movement is restricted to fields $H \approx H_c$. The comparison between MOKE and PNR showed a good agreement between both methods revealing that this simple qualitative method can be applied in case that a single-domain magnetic state predominates over most of the field range.

Comprehensive data analysis was performed on a pattern with CoFe stripes having a larger width of 2.4 µm (Figure 46) (Theis-Bröhl *et al*., 2005; Theis-Bröhl, McCord, Zabel and Toperverg, 2005). Between $H = 0$ and the $H = H_c$ the

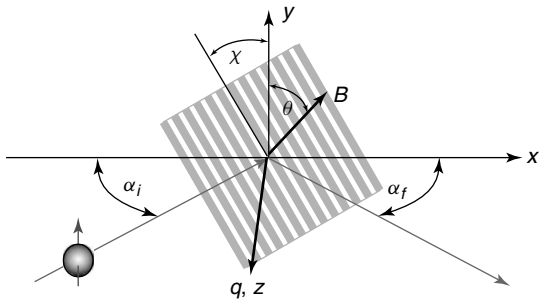

Figure 48. Sketch of the neutron scattering geometry. χ is the angle of the sample rotation with respect to the applied field (same definition as in Figure 1). The magnetic field $\vec{H}$ is applied perpendicular to the scattering plane. α_i and α_f refer to the incident and exit angles of the neutrons to the sample surface.

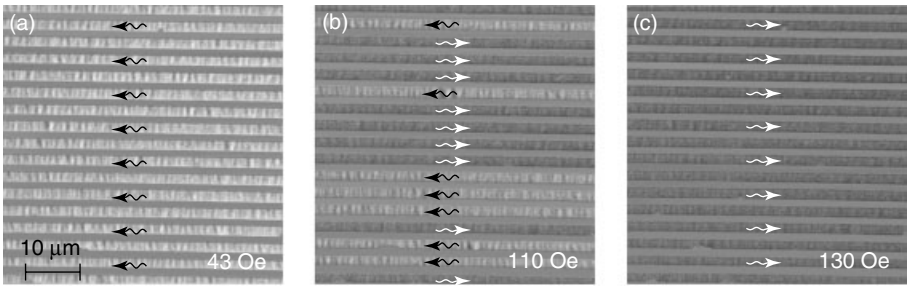

Figure 49. Kerr microscopy images taken below H_c (a), at H_c (b), and above H_c (c) with the magnetic field aligned parallel to the stripes. The plane of incidence results in a top–down magneto-optical sensitivity axis perpendicular to the stripes. The curly arrows indicate the mean magnetization direction as well as the presence of ripple domains. (Reprinted figure from K. Theis-Bröhl *et al*., *Phys Rev. B.* Vol 71, 020403 ® (2005) © 2005 by the American Physical Society.)

wide stripes decompose into a multidomain state as can be seen from Kerr microscopy measurements in Figure 49. Polarized neutron measurements without polarization analysis in the off-specular scattering range and respective simulations of the intensity maps are shown in Figure 50. The maps contain all three features described above. The specular reflectivity reveals oscillations due to the thickness of the stripes and splitting between R^+ and R^-. In the off-specular scattering range Bragg diffraction occurs and asymmetric diffuse scattering is seen indicative for a multidomain

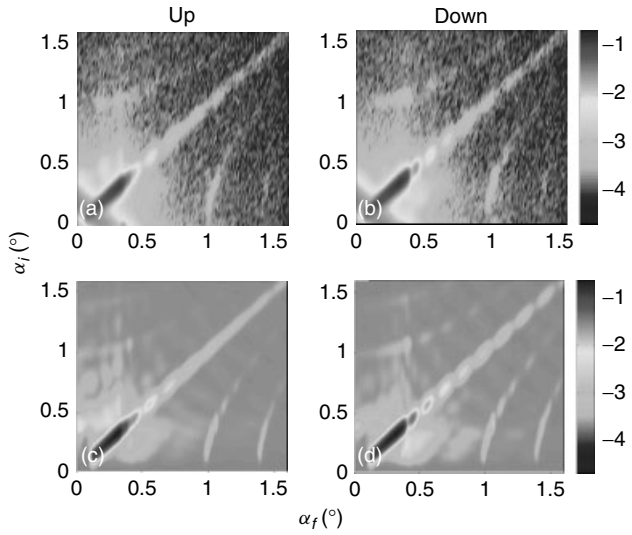

Figure 50. Experimental maps of the polarized neutron intensity on a logarithmic scale from a periodic stripe array measured at a magnetic field of 43 Oe and plotted as a function of the angles of incidence α_i, and the scattering angles α_f (a) and (b). Calculated intensity maps (c) and (d). (a) and (c) correspond to the incident neutron polarization parallel to the stripes and parallel to the external field, while in (b) and (d) the polarization and the field directions are antiparallel. (Reprinted figure from K. Theis-Bröhl *et al*., *Phys Rev. B.* Vol 71, 020403 ® (2005) © 2005 by the American Physical Society.)

state. Simulations of polarized intensity maps and specular reflectivity with full polarization analysis were performed by using a routine on the basis of DWBA. With this comprehensive study including all features occurring in the intensity maps it was shown that polarized specular and off-specular neutron scattering provide a detailed picture of the mean domain magnetization vectors in a magnetic stripe array, including longitudinal and transverse fluctuations about the mean magnetization direction and correlation effects between magnetic domains across different stripes. As a result of the quantitative analysis it was found that the domain magnetization vectors are heavily correlated not only parallel to the stripe direction, but also over a large perpendicular distance between them. This correlation creates an inherent instability of the system with respect to the formation of large domains as observed during the magnetization reversal.

Lateral magnetic structures were also measured by Lee *et al*. using time-of-flight polarized neutron reflectometry (Lee, Klose, Yin and Toperverg, 2003). The sample studied was an array of permalloy ($Ni_{80}Fe_{20}$) bars, with dimensions 10-nm thick, 2 µm wide, 10 µm long, and separated by 2 µm. As displayed in Figure 51 the authors present spin-up and spin-down intensity maps containing specular reflection, off-specular Bragg reflections and diffuse scattering. They explain the observed features qualitatively on the basis of DWBA and discuss how to obtain the F domain dispersion from polarized neutron data.

An attempt to exit into the third dimension via lateral structuring the top iron layer of an antiferromagnetically coupled Fe/Cr multilayer is illustrated by the study of Ziegenhagen *et al*. (2003). The top two-dimensional pattern consists of 15-nm-thick Fe stripes with a period of 1 µm. The array was examined by specular reflection and off-specular scattering using polarized neutrons. A schematic outline of the stripe pattern and the experimental results are shown in Figure 52. The measurements were performed with a magnetic field parallel to the Fe stripes and at a

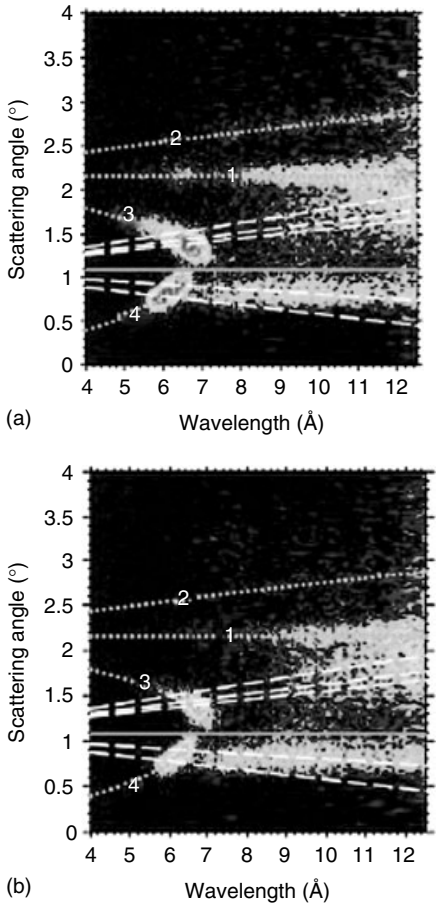

Figure 51. Log-scale intensity map for (a) spin-up and (b) spin-down incident neutrons scattered from an array of micron-sized magnetic elements on a silicon surface. The solid line at 1.08° is the horizon. The dotted lines are calculated locations of: (1) specular reflection; (2,3) off-specular reflections; and (4) diffraction. The dashed lines are the critical edges (from the horizon to higher/lower angles): the silicon edge (above the horizon only) and the permalloy edges corresponding to SLD Nb_{c+} and Nb_{c-}. level below the exchange coupling of the Fe layers in order to maintain the AF state of the Fe/Cr superlattice. The intensity maps are rather complex as they contain Bragg peaks from the chemical and magnetic perpendicular periodicity of the Fe/Cr superlattice superimposed on the intensity from the lateral stripe pattern. In detail, the maps contain specular reflectivity with half- and full-order peaks due to the perpendicular magnetic and the structural periods of the multilayer, respectively. Furthermore, intense off-specular diffuse scattering together with Bragg sheets at the half-order positions can be recognized, indicating domain formation with a strong AF correlation across the multilayer stack. Furthermore, first-order lateral Bragg diffraction peaks are visible at positions where the intensity becomes enhanced due to the AF Bragg sheet. This can be attributed to the fact that the top layer lateral magnetic structure is replicated into the inner layers.

A lateral magnetic array does not necessarily require a patterned structure by itself. Using an ion based method, such as ion bombardment induced magnetic patterning (IBMP) or focused ion-beam treatment, magnetic properties of thin magnetic films can locally be altered without changing the structural properties. Such methods are interesting with respect applications because of their high surface smoothness compared to lithographically patterned structures. Theis-Bröhl *et al*. (2006) investigated the magnetization arrangement of a smooth and continuous layer with a purely magnetic in-plane stripe pattern created by alternating EB to an AF substrate. The stripe pattern was produced by IBMP using He^+ ions, which locally changed the EB direction at the ferromagnet/antiferromagnet interface, but not the magnetic or AF properties of the $Co_{70}Fe_{30}$ and $Mn_{83}Ir_{17}$ layers, respectively. For the analysis of the magnetic domain structure evolution along the hysteresis loop a combination of experimental techniques, for example, magneto-optical Kerr effect, Kerr microscopy, polarized neutron reflectometry, and off-specular scattering of polarized neutrons with polarization analysis, was used.

For the demagnetized state antiparallel alignment of magnetization in neighboring stripes would be an ideal case. But due to the competition between EB, exchange interaction between neighboring F regions, and anisotropy, the perfect antiparallel alignment can be found only in the case that the EB dominates the others effects. For the model system studied in Theis-Bröhl *et al*. (2006) it was found that for magnetic fields parallel to the stripes and below saturation the magnetization in neighboring stripes is periodically canted with respect to the stripe axis so that the net magnetization of the F film turns almost perpendicular to the stripes. At the same time the projection of the magnetization vector onto the stripe axis has a periodically alternating sign. All this information was gained on a quantitative basis. Specular reflectivities were fitted by using an originally developed least-squares software package, which allows simultaneous evaluation of all four measured reflectivities in one cycle (Figure 53b) and simulations of intensity maps measured with full polarization analysis were performed on the basis of DWBA. The longitudinal Kerr-hysteresis loop in Figure 53(a) shows steps on both branches corresponding to the 'antiparallel' orientation of magnetization in neighboring regions. PNR measurements were performed at different fields along the hysteresis loop. Three representative cases on both branches are represented in Figure 53(b): one measured around the first coercive field $H_{c,1}$ (top row), one measured at the step of the hysteresis loop in the 'antiparallel' state (middle row) and one measured in saturation (bottom row).

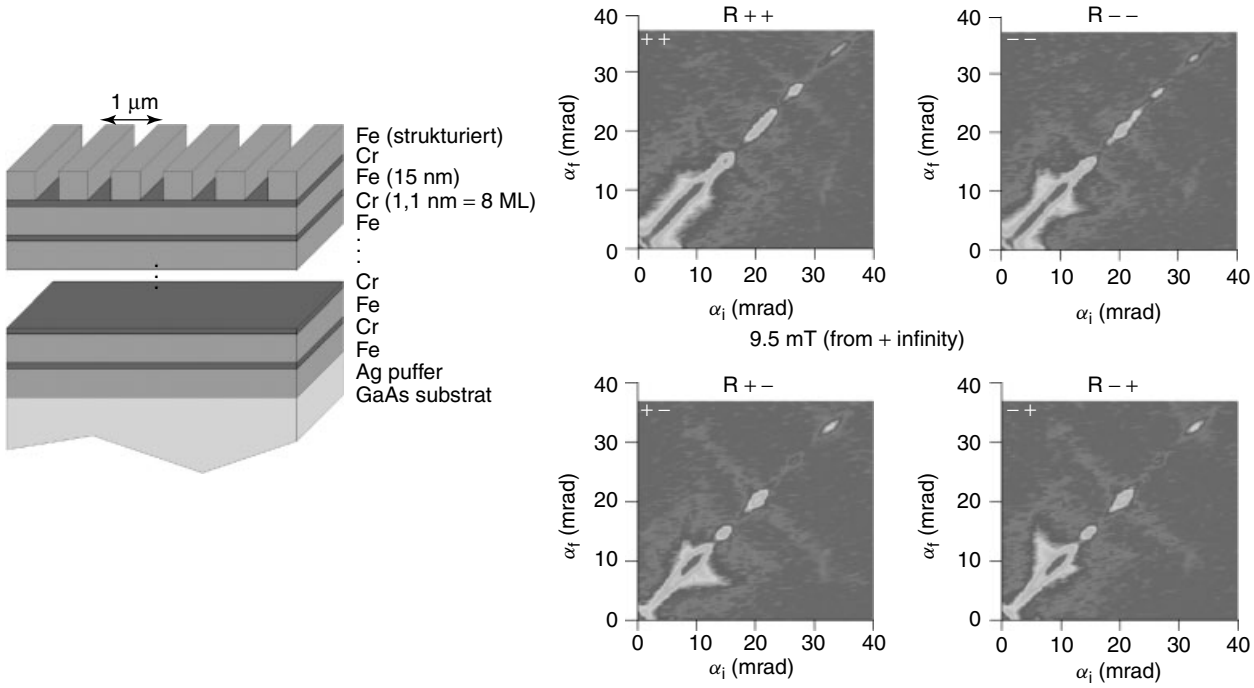

Figure 52. Specular reflection and off-specular scattering from a Fe/Cr superlattice. The top Fe layer has been lithographically structured into stripes with a 1 µm lateral period. The specular ridge contains half and full-order peaks from the perpendicular chemical and magnetic superlattice period. Patterning creates off-specular Bragg peaks and diffuse scattering forming Bragg sheets. The latter cross the specular ridge at the AF superstructure peaks on the reflectivity ridge. Diffraction signal from the lateral structure is only seen in regions of the reciprocal space where the intensity is enhanced due to the Bragg sheet scattering. (Reproduced from N. Ziegenhagen *et al*., 2003. With permission from Elsevier. © 2003.)

Telling *et al*. used IBMP for magnetic patterning of a Co/Pt multilayer and for rotating the easy axis magnetization direction in certain sample regions from out-of-plane to in-plane (Telling *et al*., 2003). The sample was irradiated through a grid stencil with a period of 13 µm assuming the sample properties do not change underneath the stencil. Specular polarized neutron reflectivity measurements performed in remanence and at saturation yield the magnetization state of the in-plane moments. Out-of-plane magnetization is not accessible to PNR. Off-specular intensity was measured as a function of q_z and the off-specular scattering angle. At remanence the authors observe Bragg diffraction peaks around the specular reflection from which the lateral long-range magnetic order in the sample can be inferred. Similar peaks cannot be observed at saturation when all domains of the sample are magnetized in-plane. Off-specular diffuse scattering was found to be small due to the smooth and uncorrelated interfaces of the sample.

In conclusion, up to now only in a few cases PNR has been applied to laterally patterned magnetic arrays. PNR and PNS was either used to qualitatively describe the remagnetization process and to discriminate between magnetization rotation on the one hand and domain nucleation and DW movement on the other hand, or for a quantitative analysis of the magnetization reversal process. Unlike PNR studies of magnetic thin films, in PNR studies of lateral patterns often no splitting between specular NSF reflectivities can be observed but qualitative information can still be gained from off-specular Bragg diffraction. Quantitative data analysis successfully can be performed within the framework of DWBA. In order to apply DWBA, the magnetization distribution within the coherence volume is decomposed into several components as discussed in Section 2.11. For lateral structures these are three components: the mean value of the magnetization, periodic perturbation of the mean magnetization due to periodic alterations of the longitudinal magnetization projection in the lateral array of magnetic elements, and random fluctuations in the magnetization due domains smaller than the coherence length. The basic features in polarized intensity maps from lateral arrays (specular NR, Bragg diffraction from the lateral period and off-specular diffuse scattering) can very well be described within this model. With this tool comprehensive PNR studies can be performed for a complete quantitative description of the magnetization state including correlations between the magnetic elements.

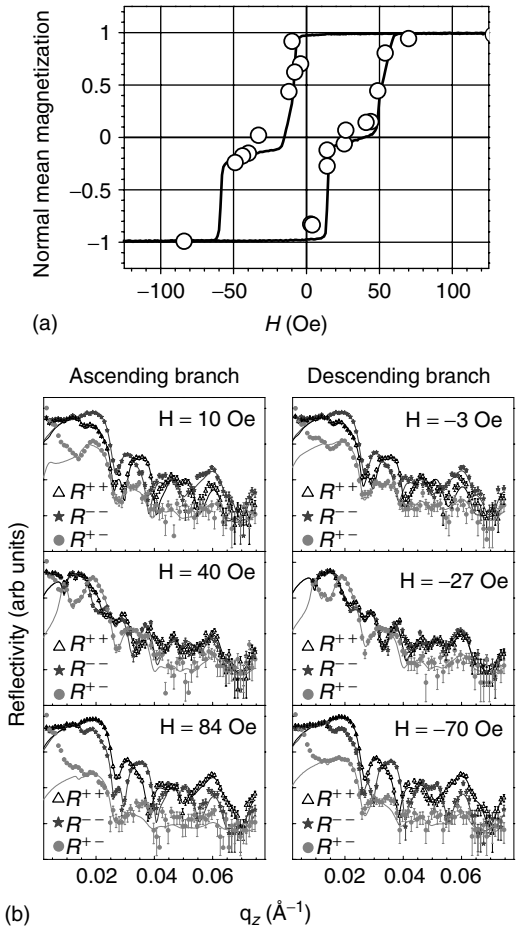

Figure 53. (a) Longitudinal MOKE hysteresis loop (line) and results of fits to the specular PNR data (symbols) of a sample magnetically patterned into stripes by ion bombardment induced magnetic patterning and measured with the field applied along the EB axis. (b) Polarized neutron reflectivity measurements performed at different applied magnetic fields. The symbols present measurements of non-spin-flip reflectivities $\mathcal{R}^{++}$ and $\mathcal{R}^{--}$ and one spin-flip reflectivity $\mathcal{R}^{+-}$. The lines represent fits to the data points. (Reprinted figure from K. Theis-Bröhl *et al.*, *Phys. Rev. B* Vol. 73, 174408 (2006) © 2006 by the American Physical Society.)

6 SUMMARY AND CONCLUSIONS

PNR is a new method in solid state physics and materials research for the analysis of magnetic thin films, magnetic heterostructures, magnetic superlattices, and lateral magnetic structures available for only some 15 years. During this time not only the magnetic systems to be studied have steadily been improved and have become more complex, also the PNR method has been appreciably developed from analyzing specular reflectivity only to a complete analysis of the specular and off-specular scattering using the distorted wave Born approximation (DWBA). Furthermore, the PNR method is now being employed at many different neutron sources using increasingly sophisticated neutron optics, neutron detectors, and sample environments. All this helps making PNR a very powerful method to meet the future challenges. Those lie in even more complex systems and smaller samples with less magnetic material. Furthermore, the time domain will likely to be explored in more detail in the future. Aside from the nano- to picosecond region investigated by time-resolved light and synchrotron experiment, there are rich physical phenomena in the subsecond to minute region which are amenable to the PNR method, such as training effects in exchange bias systems, magnetic viscosity, and spin glass relaxations.

The benefits of PNR and scattering for the investigation of magnetic nano- and heterostructures can be summarized as:

- Direct probe of atomic moments and magnetic induction;
- Cross section is known accurately;
- Both F and AF structures can be studied easily;
- Sensitivity to spin disorder and spin fluctuations;
- Magnetic correlation lengths can be probed on different length scales and in different depth below the surface.

The competition with other methods for the investigation of magnetic heterostructures is strong, in particular, with other scattering techniques such as X-ray resonant magnetic scattering (Kortright *et al.*, 2003) and diffraction MOKE (Bragg-MOKE) (Grimsditch and Vavassori, 2004; Westphalen *et al.*, 2006). The use of PNR can only be justified if the sample in question is already thoroughly characterized by other methods and if PNR can add information not available otherwise. This is indeed the case whenever the complete magnetization state including correlations between the magnetic elements need to be analyzed even in deeply buried layers.

NOTES

[1] NSF reflectivity must turn to zero along with the phase difference χ_{+-} at either $p_0 = 0$ and at $p_0 \geq p_{c+}$ just due to the fact that in the first limit $\chi_+ = \chi_- = \pi$, while in the second one $\chi_+ = \chi_- = 0$. Therefore NSF reflectivity cannot be a monotonous function of p_0 and should show at least one maximum in the range $p_{c-} \leq p_0 \leq p_{c+}$.

[2] In the following the unit matrix will be omitted and the quantities without 'hat' are be assumed to be proportional to $\hat{1}$.

[3] This consideration does not take into account that actually the identity $\mathcal{R} \equiv 1$ is achieved only in the limit $\alpha_i \to 0$. Otherwise some intensity lost from the

specular reflection channel due to off-specular scattering has to be recovered via the optical theorem (Toperverg, Schärpf and Anderson, 2000; Toperverg, 2003). This loss is, however, negligible far below the total reflection edge, where the neutron wave does not penetrate deep into the matter.

[4] To the best of our knowledge such kind of GIND was observed for the first time by Ioffe, Turkevitch and Drabkin (1981) from Ni grating with the lateral period of $a = 21\,\mu\text{m}$.

[5] Generally speaking, the coherence area is the lateral cross section of the 3D coherence volume (Sinha, Tolan and Gibaud, 1998) which also includes the uncertainty $\Delta Q_z \sim (2\pi/\lambda)\sqrt{(\Delta\alpha_i)^2 + (\Delta\alpha_f)^2}$. The latter smears out the interference of waves reflected from different interfaces. The resolution function also includes the spread $\Delta\lambda$ over the neutron wavelengths λ, which may affect the resolution in Q_y and Q_z, but is not important for the coherence volume anisotropy discussed here. In real PNR experiments the collimation in ϑ_y is quite relaxed so that an uncertainty $\Delta\vartheta_y$ is by 1–2 orders of magnitude higher than that in α_i and α_f. This is responsible for the anisotropy of the coherence volume in all three direction and also increases the anisotropy of the coherence area.

[6] Strictly speaking, the long axis of the coherence ellipsoid is usually smaller than the sample size. Therefore $\overline{Nb}$, in principle, depends on both, the y and the x coordinates. However, if the long axis crosses many structural elements then relative deviations in their number within different ellipsoids shifted along the x-axis are small and can be neglected.

[7] This result of BA is incorrect. In the more consistent DWBA approach Bragg diffraction contains both: SF and NSF contribution

[8] This linear combination serves instead of well-known equation for the scattering amplitude written as a product $T^f S(\boldsymbol{Q}) T^i$, where T^f and T^f are transmittances of incoming and scattered wave and $S(\boldsymbol{Q})$ is the scattering function. This equation is often used to describe off-specular scattering from roughness (Sinha, Sirota, Garoff and Stanley, 1988) and surface diffraction (Dosch, 1993) in the case of semi-infinite systems. However, it does not properly take into account refraction effects and ignores scattering of waves reflected from the mean potential. Both types of effects are of the crucial importance in the case of neutron scattering from patterned magnetic films and multilayers.

[9] Similar experimental maps have recently been obtained by (te Velthuis *et al*., 2006) on the Co/CoO system exhibiting EB effect (see also **Domain States Determined by Neutron Refraction and Scattering, Volume 3**).

[10] Let us to remind that the dispersion signifies fluctuations of the angle of domain magnetization rotation. In the case of a binary distribution of these angles, that is, if for instance, the domain magnetization is randomly turned for only angles $\pm\Delta\gamma$, then the dispersion equals zero.

[11] The negative SLD of the Co layer forms a potential well in front of the positive barrier of the substrate. The neutron wave passing through the well interferes with that reflected from the substrate. As a result, such a potential profile condenses the neutron wave field in the film if the corresponding wave number matches the width of the well. This brings new features (Seregin, 1977; Kentzinger, 2003; Feygenson *et al*., 2004) into the off-specular intensity distribution. However, the resonance levels are usually very narrow and quite difficult to observe with PNR.

[12] Similar maps were obtained experimentally (Radu *et al*., 2003b) for a slightly more complicated stack of layers.

[13] Features similar to those displayed in Figure 17 were recently observed experimentally (Radu *et al*., 2005a)

[14] A more complete review on the general aspects of EB systems can be found in this Handbook, and more PNR work on EB systems is covered by Felcher and Hoffmann, **Domain States Determined by Neutron Refraction and Scattering, Volume 3**.

[15] In the paper of Lee *et al*. (2002) the notation is $\gamma = \varphi$ and $\Delta = \chi^2$.

[16] In both systems the main scattering features are due to the Co layer before (Figure 25) and after (Figure 29) EB with the AF CoO layer.

[17] The aim of Figure 15 was not to reproduce exactly the experimental results in Figure 29, but rather to illustrate different contributions of the magnetic scattering from domains. In particular, off-specular SF scattering in the upper maps can easily be eliminated via suppression of the domain magnetization fluctuations in the direction parallel to net magnetization.

[18] In Figure 19 the scattering intensity maps are presented in the coordinates p^i versus p^f. Then the specular ridge runs parallel to $p^i = p^f$, which is the diagonal of the map. The Bragg sheets are perpendicular oriented and cross the specular ridge at normal angle. In the case of rocking scans the natural coordinates are $Q_x \approx \frac{1}{2}(\alpha^f - \alpha^f)Q_z$ versus $Q_z = p^i + p^f$. These coordinates are nonlinear with respect to the angles of incidence and scattering, but they are especially convenient if the Born (kinematic) approximation holds, for example, if optical effects are not important.

[19] These maps are plotted in the rectangular coordinate system with the axis $p^i + p^f = Q_z$ versus $p^i - p^f$.

This system is just turned by 45° with respect to that in Figure 19.

[20] Noncollinear magnetization arrangement was already noticed by Schreyer *et al*. (1997) as discussed above in view of the nonlinear interlayer coupling. Here the effect of magnetization canting is different in origin. It occurs only in an applied field and does not require nonlinear exchange coupling. The former conclusions of Schreyer *et al*. (1997) are based on the analysis of solely specular reflectivity assuming sublayer magnetization homogeneous over the range greater than the coherence length. This assumption holds if off-specular scattering is negligible and SF specular reflection is ascribed to the canting of mean magnetization. The same assumption was also made for other superlattices, such as in Co/Cr(001) (Zeidler *et al*., 1995) and in Fe/Cr(211) (te Velthuis *et al*., 2002) superlattices. In theses studies it was, however, suggested that the tilt angle of magnetization varies from layer to layer due to the surface spin-flop transition. With increasing field a DW formed first at the surface and then penetrated into the superlattice, thus splitting the SL into two antiphase, AF domains.

[21] In Figure 44(b) the x corresponds to the NSF y-axis.

ACKNOWLEDGMENTS

The authors would like to acknowledge fruitful discussions with Florin Radu, Andreas Schreyer, Chuck Majkrzak, and Julie Borchers. This work was supported by DFG, SFB 491 and by the BMBF under contract O3ZA6BC1.

APPENDIX

A AMPLITUDE OF NUCLEAR SCATTERING FROM A GRATING

In BA, $F_l^0(\boldsymbol{Q}) = F_l^N(\boldsymbol{Q})$ and for the case of patterned layers the function $F_l^0(Q_z, Q_x; y)$ is given by the equation

$$F_l^0(Q_z, Q_x; y) = F_l^z(Q_z, y) \sum_j \boldsymbol{e}^{i Q_x x_j} F_{lj}^L(Q_x, y) \quad \text{(A1)}$$

where $x_j = x_j(y)$ are coordinates of the lateral structure elements. The function $F_l^z(Q_z, y)$ is simply a form-factor of the l^{th} layer

$$F_l^z(Q_z, y) = \boldsymbol{e}^{i Q_z z_{l-1}} \frac{\boldsymbol{e}^{i Q_z d_l} - 1}{i Q_z} \quad \text{(A2)}$$

and $d_l = d_l(y)$ is the height of the structural element at a fixed coordinate y. As shown in the bottom panel of Figure 8, it may be happened that for some choice of y that $d(y) = 0$, while $d(y) = d$ for the other value of y. The function $F_{lj}^L(Q_x, y)$ in equation (A1),

$$F_{lj}^L(Q_x, y) = \int_0^{a_j} \mathrm{d}x\, \boldsymbol{e}^{i Q_x x} \Delta(Nb)_l^N(x, y) \quad \text{(A3)}$$

is the Fourier transform of the lateral SLD deviations profile $F_{lj}^L(x, y)$ of a single structural element j along the x-axis at fixed coordinate y. In the case of a regular pattern, $a_j = a(y)$ is the structural period in the lateral direction parallel to the x-axis. If each of the lateral periods contains n_x elements in a unit cell, then from equation (A3) it follows that $F_{lj}^L(Q_x, y) = F_l^L(Q_x, y)$, and

$$F_l^L(Q_x, y) = \sum_{m=1}^{n_x} \Delta(Nb)_l^{(m)} \boldsymbol{e}^{i Q_x x_l^{(m-1)}} \frac{\boldsymbol{e}^{i Q_x a_l^{(m)}} - 1}{i Q_x} \quad \text{(A4)}$$

where $\Delta(Nb)_l^{(m)} = (Nb)_l^{(m)} - \overline{(Nb)}_l^N$, $(Nb)_l^{(m)}$ is the nuclear SLD, while $a_l^{(m)} = x_l^{(m)} - x_l^{(m-1)}$ is the width of the m^{th} element in the l^{th} layer, and $x_l^{(0)} = 0$. Due to fact that

$$\overline{Nb}_l^N = \sum_{m=1}^{n} \frac{a_l^{(m)}}{a_l} (Nb)_l^{(m)} \quad \text{(A5)}$$

$F_l^L(Q_x, y) = 0$ at $Q_x = 0$ and does not contribute to specular reflection. For the stripe array the SLD in Figure 10 $\overline{(Nb)}^N = (a^{(1)}/a)(Nb)^N$, where $a = a^{(1)} + a^{(2)}$, and $\Delta(Nb)^{(1)} = (a^{(2)}/a)(Nb)^N$ at $0 \le x < a^{(1)}$, and $\Delta(Nb)^{(2)} = -\overline{Nb}^N$ if $a^{(1)} \le x < a$.

Synchrotron Radiation Techniques Based on X-ray Magnetic Circular Dichroism

Gisela Schütz, Eberhard Goering and Hermann Stoll

Max-Planck-Institut für Metallforschung, Stuttgart, Germany

1 INTRODUCTION

The use of X-rays in the investigation of matter started with Röntgen's discovery in 1895. The very first application was the imaging of density distributions of human bodies and solids. The observation of the element-specific absorption edges has provided an effective method to measure the density of a certain atomic species, so a new tool for material analysis was born. With the support of commercially available intense X-ray tubes and effective monochromators, it was possible to resolve details of the absorption edges (Stumm von Bordwehr, 1989). In a range of several electron volts close to the absorption edge, the observed structures in the absorption coefficient could be related to the density of the unoccupied states at the absorbing atom site. This gives a new opportunity to get insight into the electronic structure of the absorbing media. A breakthrough for the interpretation of oscillatory features, observed up to several 100 eV above the transition threshold, has been achieved by Sayers, Lytle and Stern (1970) and Sayers, Stern and Lytle (1971) by a Fourier analysis technique. This provides direct information of the short-range order close to the absorbing atom.

With the advent of synchrotron X-ray sources in the 1980s, highly intense and collimated X rays of variable well-defined polarization became available. This caused the development of new powerful techniques as well as a significant improvement of the conventional ones. In the early 1980s first anomalous reflectivity studies were reported as a means to study the structure of buried interfaces and, more generally, nontransparent samples (Bremer, Kaihola and Keski-Kuha, 1980). The development of X-ray microscopy on the basis of Fresnel optics started at HASYLAB/DESY by pioneering work led by Schmahl *et al*. (1996).

Since the first experimental proof of the existence of X-ray magnetic circular dichroism (XMCD) by Schütz *et al*. (1987) at HASYLAB a new field was opened to study the magnetic characteristic of solids by various spectroscopic X-ray methods. As initially expected, these effects occur for energies close to an inner-shell absorption edge and are intimately related to the polarization of the symmetry-selected empty density of states (DOS). The subsequent theoretical development of sum rules results in a quantitative determination of local magnetic spin and orbital moments in an element-specific manner. Owing to large magnetic contributions to the absorption and scattering cross sections – up to 50% at the transition metal $L_{2,3}$ edges and the rare-earth (RE) $M_{4,5}$ edges – a magnetic moment below $10^{-5}\,\mu_B$ can be detected. In this contribution the basis of the experimental aspects and the underlying physics are presented and discussed. Selected, X-ray-related technologies

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

such as magnetic extended absorption fine structures (MEXAFS), magnetic reflection, and time-resolved scanning X-ray microscopy are introduced in more detail.

2 EXPERIMENTAL ASPECTS

2.1 Synchrotron radiation

2.1.1 Circular polarized X rays from bending magnets and helical undulators

Since the discovery of X rays by Röntgen at the end of the nineteenth century, Bremsstrahlung of electrons accelerated by high voltage to several kiloelectron volts is used in X-ray tubes and later for higher energies in particle accelerators. With the advent of modern electron storage rings in the 1970s, these new powerful X-ray sources have initiated a breakthrough in the application of X rays in a wide field of science and technology. The synchrotron radiation is emitted by highly relativistic electrons with energies in the gigaelectron volt range, that is, $E/m_e c^2 > 1000$, which are radially accelerated when bended onto a circular motion. The spectrum of the emitted radiation is a very broad continuum of highly collimated X rays with extremely large intensity several orders higher compared to the best X-ray tubes. The radiation has well-defined polarization, as sketched in Figure 1, for the radiation emitted from a simple bending magnet device (Schwinger, 1949). The radiation emitted in the plane of the electron orbit is linearly polarized, while viewing from above and below the center of the beam the intensity drops significantly off, but the degree of circular polarization P_C of the radiation increases drastically. Taking into account a decrease of about a factor 5, one can achieve a large value of $P_C > 90\%$.

To overcome the intensity reduction by the inclined view methods today, insertion devices such as helical wigglers and undulators are used, where an additional oscillating motion of the electrons is induced inside the special magnet structure arrangement (Sasaki, 1994). Thus, additional synchrotron radiation is emitted in the case of undulators with coherent overlap of each motion period. The polarization is adjustable by the relative horizontal position of the upper and lower magnet structure (Figure 2) (Bahrdt *et al*., 2001). In Figure 3, the brilliance of various X-ray sources is shown as a function of energy (Thompson *et al*., 2001). Typical values for bending magnets, undulators, and wigglers (the less coherent version of an undulator) are given for 1.7 GeV (like BESSY II in Berlin) and 7 GeV (like Spring 8 in Japan) electron storage rings.

2.1.2 Quarter-wave plates for fast polarization switching

In the case of visible optics, quarter-wave plates are usually used to provide circular polarized light. Typically the light beam with linear polarized **E**-vector is oriented at 45° to the two principal axes of the single crystal which provides birefringence. The **E**-vector is then split 50:50 along two different principal axes. For the correct crystal thickness one half is delayed in phase by 90° with respect to the other half, giving perfectly circular polarized light. For hard X rays, this is realized by a dynamical scattering approach and is excellently suited to provide switchable polarizations (Giles *et al*., 1994a,b; 1995; Justen, 2000; Leitenberger, 1997; Pizzini *et al*., 1998; Richter, 1992). For the generation of circular polarized X rays, the Bragg transmission mode is typically used. Such an arrangement is shown in Figure 4(a), where the quarter-wave plate is placed in the monochromatic beam just before the sample. In a simple consideration close to a Bragg condition, the interaction of the light is enhanced due to standing waves phenomena resulting in a reduction of the phase propagation, which is different for electrical polarization directions in the scattering plane and perpendicular. If

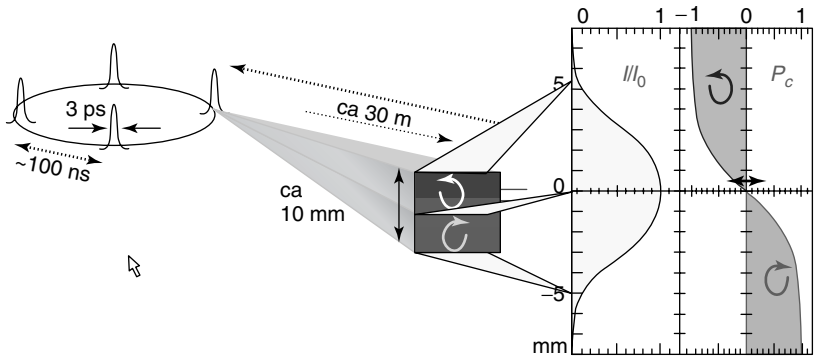

Figure 1. Synchrotron radiation emitted from a bending magnet and its polarization characteristics. Owing to the filling of the electron storage ring with electron packages this synchrotron radiation has a defined and adjustable time structure in the picosecond range.

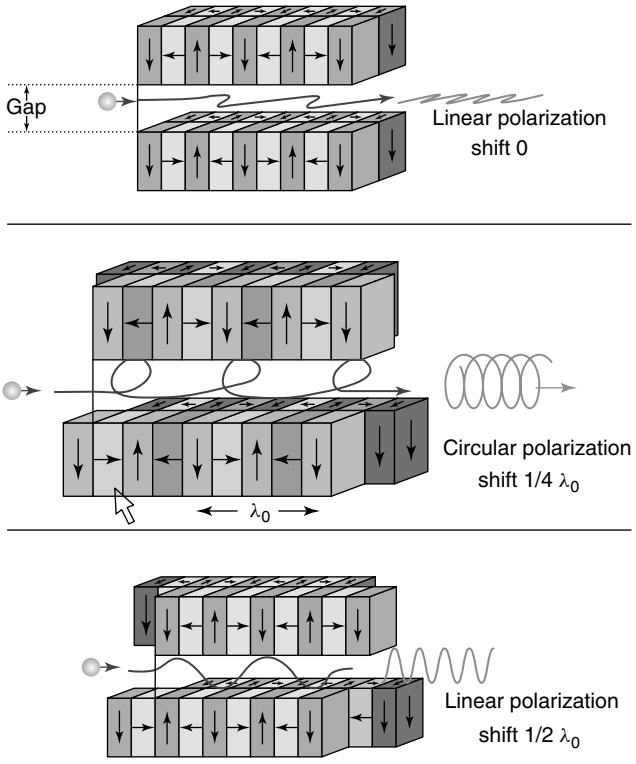

Figure 2. Magnet structure and emission characteristics of a helical undulator. The polarization can be varied by a horizontal shift of the arrangement of the permanent magnets. (Reproduced from Wende *et al*. (2004) *Reports on Progress in Physics* **67**, 2105–2181.)

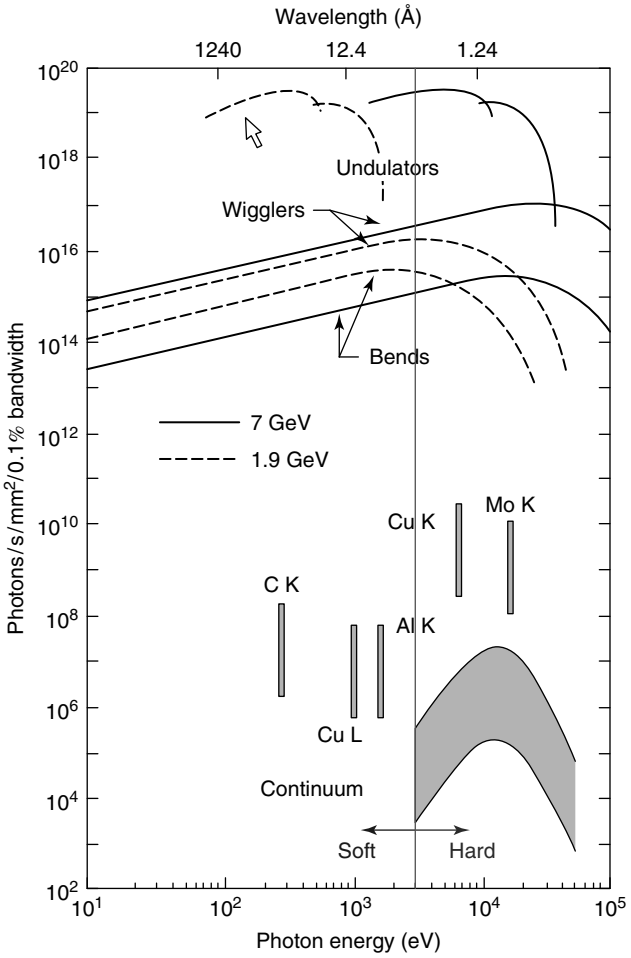

Figure 3. Brilliance in photons/s/mm^2/0.1% bandwidth for various X-ray sources in the soft X-ray range below approximately 2 keV and hard X-ray range above 2 keV. (Reproduced from Thompson *et al*. (2001) *X-ray data booklet*. LBNL.)

the scattering plane is tilted by 45° respective to the electrical field vector, a similar condition is present as for conventional quarter-wave plates as sketched in Figure 4(b). The electrical field vector is oriented parallel to the bisector between π and σ polarization [1]. The phase difference $\Delta\Phi$ between the π and σ and polarizations can be expressed analytically (Justen, 2000) by

$$\Delta\Phi(\Delta\theta) = \frac{k\chi_{\vec{h}}\chi_{-\vec{h}}\sin(2\theta)}{4} \cdot \frac{1}{\Delta\theta} \cdot \frac{\mathrm{d}}{\sin(\theta)} \qquad (1)$$

where the dielectric susceptibility

$$\chi_{\vec{h}} = \left(\frac{r_e\lambda^2}{\pi V_{EZ}}\right)^2 F_{\vec{h}} \qquad (2)$$

describes the scattering strength at a Bragg reflex $\vec{h}$ as a function of the wavelength z and $\mathrm{V}\theta_2$. $F_{\vec{h}}$ is the corresponding structure factor, normalized to the volume of the unit cell $F_{\vec{h}}$. $\Delta\theta$ is the difference angle to the corresponding Bragg condition, and d is the effective crystal thickness as shown in Figure 4(b).

As shown in Figure 4(c) $\Delta\theta$ diverges at the Bragg condition and is proportional to the thickness d. $\Delta\theta$ determines the degree of circular polarization P_C. The calculated values for equal π and σ intensities are presented in the center part of Figure 4(c). Close to the Bragg condition the circular polarization shows strong oscillations which, in reality, is smeared out due to the finite beam divergence as shown in the lower part of Figure 4(c) in combination with a measurement of the circular polarization [2]. It should be noticed that no free parameters have been used for the simulation.

To optimize the quarter-wave plate, a balance has to be found for minimal absorption realized by very thin crystal and the polarization increasing with the thickness. A careful simulation is required to determine the parameters of the set of crystals appropriate for the different energy ranges. Usually the Bragg condition will be roughly tuned by a goniometer, to the appropriate Bragg condition. The sign of $\Delta\Phi$ for off-center conditions and thus the sign of

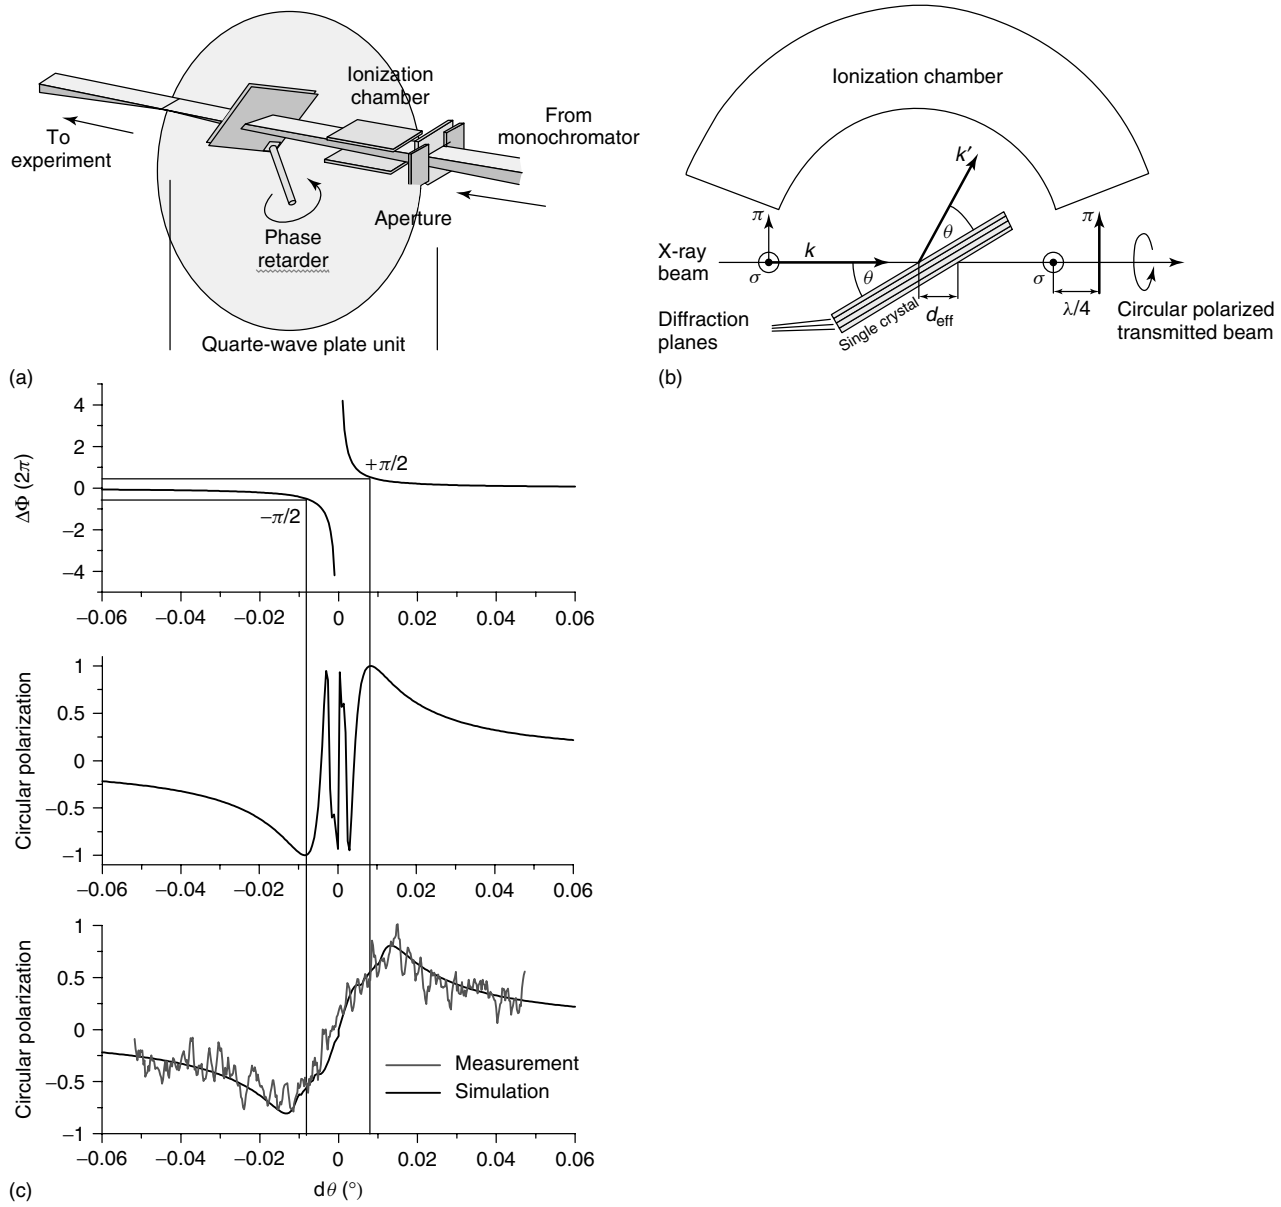

Figure 4. (a) Principle of a quarter-wave plate for the hard X-ray range. Linear polarized X rays, which are monochromatized at the Si(111)-double-crystal monochromator. The quarter-wave arrangement is positioned just before the XMCD (XRMS) experiment. (b) Principle of the function of a X-ray quarter-wave plate creating circularly polarized X-ray owing to dynamical scattering. (c) Polarization characteristics in dependence of the deviation of the Bragg angle.

the circular polarization can be changed by a fast switching piezo driver, where frequencies of 100 Hz and higher can be realized providing the opportunity to measure the XMCD effect by a lock-in technique. If the scattered Bragg intensity is also measured simultaneously [3], the exact Bragg angle could also be used to permanently retune the angle to its optimal center position. This is absolutely necessary for energy dependent measurements (Justen, 2000; Weigand, 2003) due to dynamical scattering dependent variations of the quarter-wave plate X-ray absorption (abnormal absorption (Borrmann, 1951, Borrmann, Hildebrandt and Wagner, 1955)).

2.2 XAS and XMCD: experimental aspects

2.2.1 General aspects

The interaction of photons with matter exhibits several interaction channels whose contributions vary strongly with

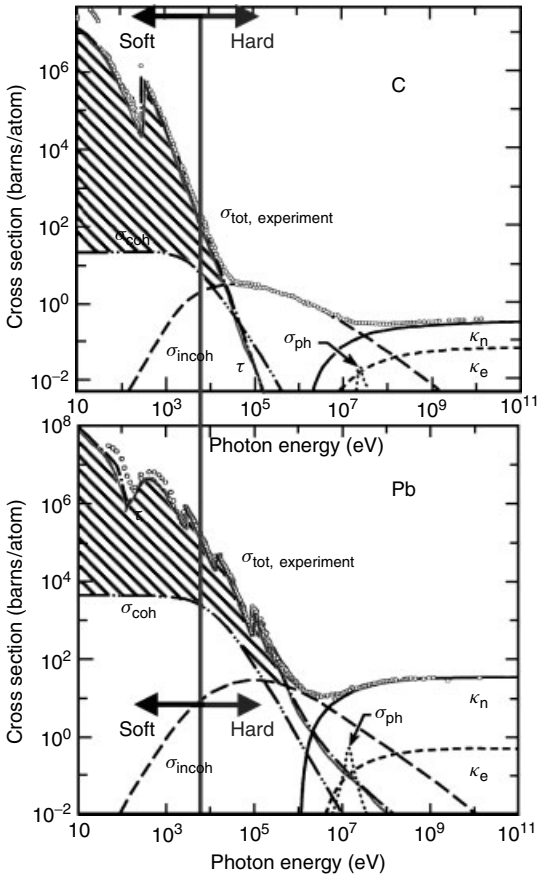

Figure 5. Carbon and lead cross section of various interaction channels of photon with matter in the energy range of 10–100 GeV. σ_{tot}: total photon cross section; τ: atomic photoeffect; κ_n: pair production (nuclear field); κ_e: pair production (electron field). (Reproduced from Thompson *et al*. (2001) *X-ray data booklet*. LBNL; Hubbell *et al*. (1980) *J. of Phys. and Chem. Ref. Data* **9**, No. 4, 1023–1047.)

energy. This is demonstrated in Figure 5, where the interaction cross sections of photons with matter from the 10 eV (VUV–range) to 100 GeV (extremely hard X rays) for the light element carbon and the heavy element lead is illustrated (Hubbell, Gimm and Overbo, 1980). For X rays in the energy range below 100 keV down to 0.1 keV, the photoeffect related absorption τ is the prominent interaction channel. In the soft X-ray range the photoeffect exceeds the Thomson scattering cross section by more than two orders of magnitude and τ drops with $E^{-7/2}$ to the credit of an increasingly inelastic scattering cross section (Bransden and Joachain, 1983).

In general, the absorption cross section σ_τ exhibits element-specific absorption edges which originate from an additional absorption possibility, if the X-ray energy reaches the element-specific binding energy of an inner atomic electron level. The off-resonant absorption edge heights are well-known tabulated values (Henke, Gullikson and Davis, 1993, 2002). The measured step feature in an absorption spectrum marks the optical density of an atomic species in a sample, and absorption spectroscopy can be used as an effective method to identify optical density of the different components of each element in a sample separately. The edges are defined as K, L, and M edges with respect to the initial atomic shell, that is, the 1s (K), 2s and 2p (L), and 3s, 3p, and 3d (M) states. In addition, the spin-orbit quantum number j is labeled, that is, $2p_{1/2}$ for the L_2 edge, $2p_{3/2}$ for the L_3 edge, $3d_{3/2}$ for the M_4 edge, and $3d_{5/2}$ for the M_5 edge. As seen in Figure 5, the photo cross section contributes only for nonrelativistic energies. Here it is set in advance to the theoretical considerations in Section 3 that in this case the dipole approximation is valid and the orbital quantum number l of final states f are changed by $l_f = l_i \pm 1$.

The formulation for the description of circular magnetic dichroism or magnetic absorption in analogy to the corresponding effects is well known for spin-dependent Compton scattering which is introduced by an additive dichroic or magnetic part of the cross section in the Klein–Nishina formula $\sigma_\tau \rightarrow \sigma_\tau \pm \Delta\sigma_\tau$. In a real experiment, the degree of circular polarization P_C is smaller than 1 and the sample magnetization $\mathbf{M}$ not fully aligned along the photon propagation direction and the experimentally determined magnetic cross section scales with the scalar product $\mathbf{P} \cdot \mathbf{M}$ resulting in $\sigma_\tau \rightarrow \sigma_\tau \pm \mathbf{P} \cdot \mathbf{M} \cdot \Delta\sigma_\tau$.

2.2.2 *Transmission method for hard X rays*

Following Lambert–Beer's law

$$I(E)/I_0(E) = e^{-\mu(E)\cdot x} \tag{3}$$

the absorption coefficient

$$\mu(E) = \sum_i \frac{N_A}{A_i} \cdot \sigma_{\mathrm{tot,i}},(E) \cdot \rho_i \tag{4}$$

which is correlated to the inverse penetration depth, can be related to the ratio between incident $I_0(E)$ and transmitted intensity $I(E)$ through a sample with thickness x as sketched in Figure 5(a). For a real target it is a summation over all elements i with atomic weight A and density ρ (g cm^{-3}), and directly correlated to the energy dependent absorption cross section as drawn in Figure 5.

Hard X rays can penetrate samples of thicknesses of typical several μm, where the mean free path strongly decreases with the atomic number by Z^5. Appropriate samples are free-standing polycrystalline foils, possibly covered with evaporated thin target films, or powder targets fixed on tapes consisting of soft matter such as Kapton or hard Si_3N_4. To take a circular dichroic spectrum, which requires in a

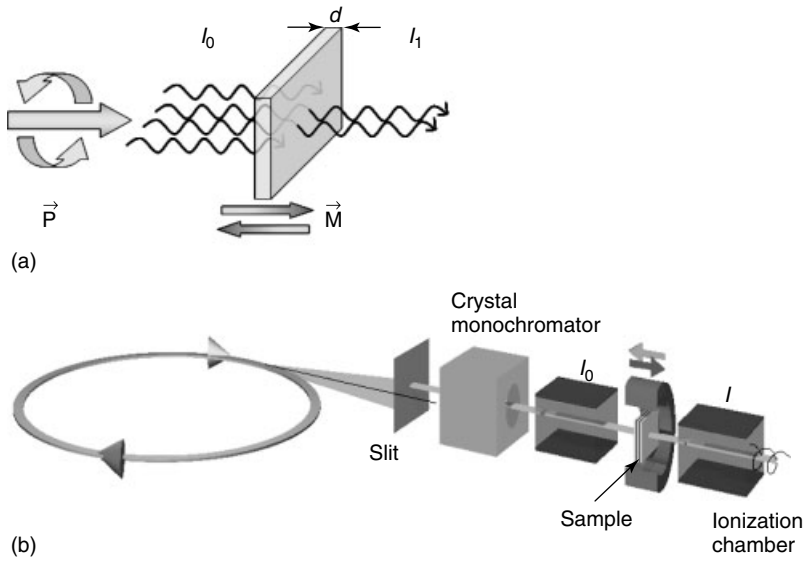

Figure 6. (a) Principle of the measurement of XMCD in the transmission mode for hard X rays. (b) Experimental realization of (a) for hard X rays emitted from a bending magnet by the inclined view method. Formed by a proper deposited slit and monochromatized by a crystal monochromator (Si111/Si311/Ge111) the incident and transmitted intensity is monitored by ionization chambers. The magnetization of the sample mounted inside an electromagnet is periodically reversed.

simplest way the reverse of the sample magnetization, the radiation is monochromatized by a crystal monochromator and the incident and transmitted intensity I is monitored by ionization chambers as a function of the photon energy. The magnetic sample can be mounted inside a solenoid, providing a reversible magnetic external field. In the case of a thin polycrystalline foil, where in general, the magnetization lies in plane, the sample has to be tilted with respect to the photon beam direction resulting in a nonvanishing projection of the magnetization along the photon beam direction. A typical arrangement is shown in Figure 6(b), where a magnetic multilayered sample has an easy direction perpendicular to the plane.

2.2.3 *Soft X rays*

In the case of soft X rays the absorption is stronger by 1 to 2 orders of magnitude and the corresponding exponential penetration depth decreases down to the nanometer range. Therefore, a conventional transmission experiment is very hard to accomplish. For this type of conventional absorption measurement it is necessary to prepare thin-film samples, quite similar to the techniques known from transmission electron microscopy. In the case of thin-film systems it is an established method to prepare samples on extreme window-like thinned substrates, typically made of SiN. Owing to this relative complex sample preparation, the absorption coefficient is usually measured indirectly by two secondary processes called *total electron yield* (*TEY*) and *total fluorescence yield* (*TFY*). In the case of TEY the basic physical process is the excitation of Auger electrons, which thermalize by creating a large number of secondary electrons by inelastic e–e scattering processes. For TFY the characteristic fluorescence light emitted by the de-excitation of the core hole is detected. These intensities are proportional to the number of absorption events per volume and therefore proportional to the absorption process itself. This proportionality is quite good in terms of TEY and less reasonable in cases of TFY. A sketch of the experimental setup is shown in Figure 7(a).

Total electron yield (TEY)

Owing to the very short escape length of the Auger electrons the secondary electrons of lower energies are the dominant fraction of the total electron current and as seen in Figure 7(b) the escape depth increases from 50 eV to lower energy (Zangwill, 1988). Only Auger electrons close to the surface (a few angstroms) have the possibility to leave the sample without being involved in an inelastic electron–electron scattering process. The scattered electrons will excite many other electrons resulting in a shower of low-energy electrons, so-called secondary electrons, where a large fraction will migrate from a region of a few nanometers to the surface. Electrons with an energy above the electron work function, that is, the energy needed to leave the surface, have the possibility to escape into the vacuum (Figure 7c). The circular polarized synchrotron radiation hits the sample and excites electrons inside the sample. The total electron drain

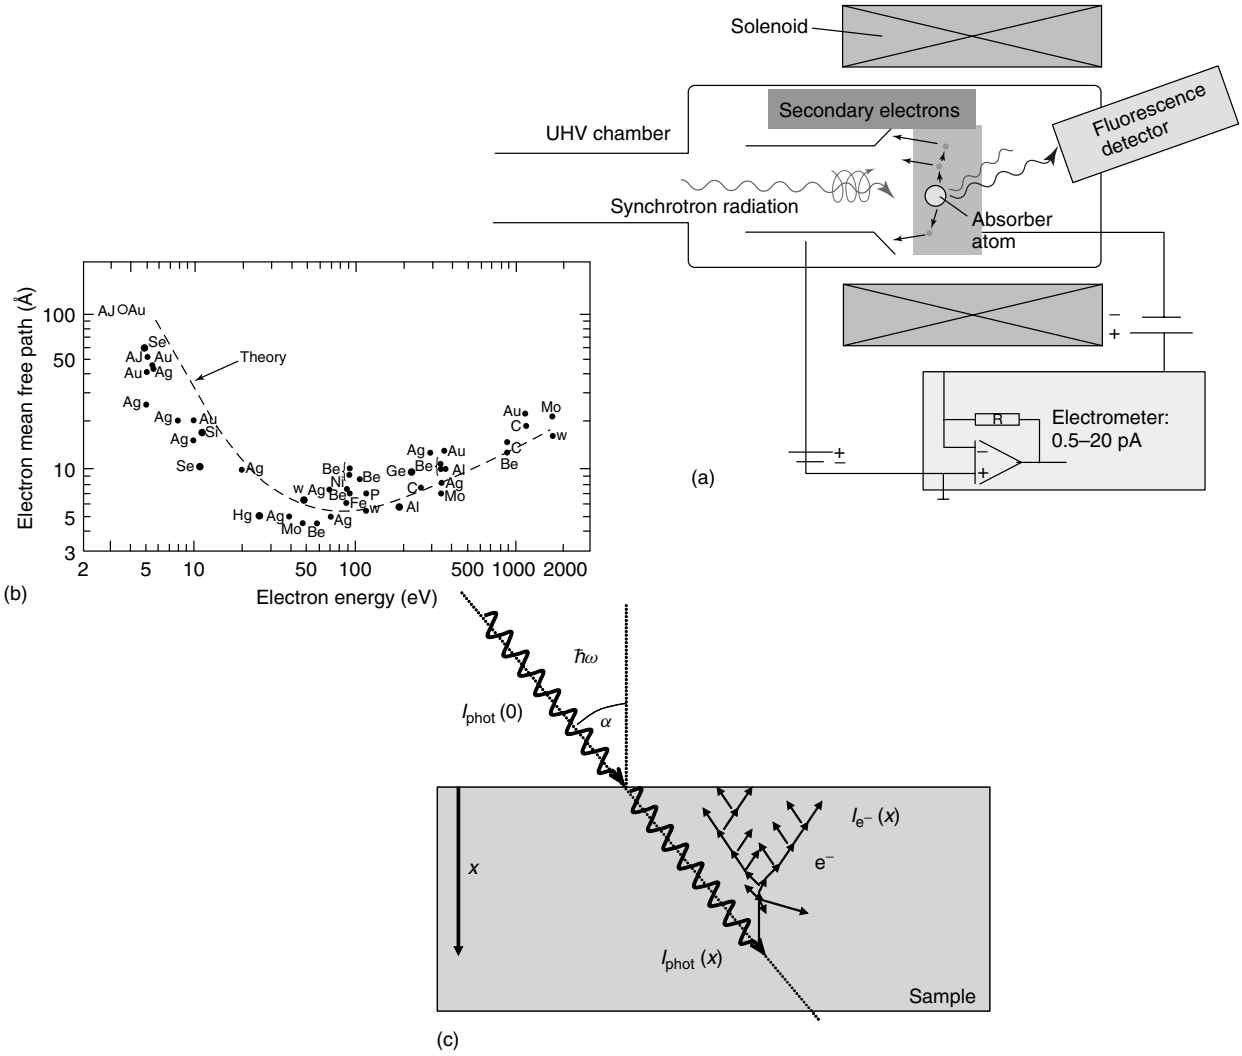

Figure 7. (a) Principle of measurement of XMCD in the soft X-ray range. The absorption coefficient can be detected via the fluorescence radiation of the sample current after emission of the secondary electrons the sample surface, (b) mean-free electron scattering length as a function of energy (Reproduced from Zangwill (1988) *Physics at surfaces*, Cambridge Univ. Press, Cambridge.), (c) important values for the estimation of the relation of the sample current and the absorption coefficient.

current (TEY signal) is measured by a very sensitive electrometer connected to the ground or by an external electron detector like channeltrons, channelplates, or similar detectors. For magnetic absorption measurements, the sample should be magnetized preferentially parallel and antiparallel along the photon beam direction by using a switchable magnet (permanent or current driven).

As quantitatively discussed in the appendix, the electron current is in good approximation proportional to the absorption coefficients

$$I_{e^-}(x) = k \cdot I_{\text{phot}}(0) \cdot \frac{\mu(E)}{\cos\alpha}\xi \qquad (5)$$

where ξ is an effective exponential decay length of the secondary electrons, α is the angle respective to the surface normal, $\mu(E)$ is the energy dependent absorption, and $I_{\text{phot}}(0)$ is the photon beam intensity at the surface. The effective exponential decay length ξ is in a first approximation an energy average over the electron scattering length curve as shown in Figure 7(b), and well known in photoemission spectroscopy.

Nevertheless, for a very short photon absorption length – compared to the electron escape length – the resonant absorption is damped by the so-called saturation or self-absorption effect. A detailed discussion is also given in the Appendix.

In reality the electrons will perform spiral-like traces in an applied magnetic field, where some of the electrons can even be redirected to the sample, reducing the total measured electron current. To reduce this effect, the sample is usually

set to a negative bias voltage by a nearly noise-free DC power supply. This reduces the backscattering probability and enhances the overall performance, especially when measuring the difference between opposite field directions to measure XMCD.

Total fluorescence yield (TFY)

In the case of TFY, the core-hole excitation is monitored by the emitted fluorescence photons. The strength of this decay channel is determined by the fluorescence yield, strongly increasing with the atomic number and is less than 1% for K edge at oxygen and L edges at 3d elements and 20% for 3d K edges and L edges. This small number of events dramatically modifies the statistical quality of the X-ray absorption spectra (XAS) (XMCD) data especially in the soft X-ray range. Therefore, it is typically necessary to probe a significant number of absorption processes using TFY, which could be realized by intensive undulator radiation from second generation synchrotron sources like ESRF and BESSY II. On the other hand, fluorescence photons have much higher decay lengths compared to the secondary electrons in the TEY, providing less surface sensitivity and more reliable bulk information. TFY is therefore more appropriate for systems with buried layers compared to the electron escape length, or systems where the main interest is related to probe the bulk properties, whereas TEY provides more surface-sensitive information on intrinsic-like surface variations or chemical or structural modifications.

Nevertheless, for a quantitative XAS and XMCD analysis TFY is quite problematic due to the strongly enhanced self-absorption processes. In principle, this could be handled numerically similar to the above described TEY self-absorption correction, but the typical systematic error is much higher. In this case the mathematical procedure needs the attenuation lengths for both photon types, the primary beam and the fluorescence. The latter could be quite problematic, especially when the energy distribution of all TFY decay channels is not simple or even known, for example, if the TFY photons have a main distribution in the X-ray region and an additional contribution in the UV region [4]. In this case, two different escape length scales are present, preventing the simple analysis.

2.3 Circular magnetic X-ray dichroism spectra

2.3.1 History

As theoretically outlined in Section 3 in the vicinity of the absorption edges the occurrence of X-ray magnetic circular dichroism is expected as a universal effect and experimentally verified. XMCD was initially measured as the difference of the absorption coefficient for circularly polarized X rays for reversed magnetization of the absorber. The circular dichroic or magnetic absorption profile $\mu_C(E)$ or $\Delta\mu(E)$ are related to the measured differences for projection of the saturation magnetization parallel (μ^+) and antiparallel (μ^-) onto propagation direction of the circularly polarized photon beam by $\mu^+(E) - \mu^-(E) = P_C \cdot \boldsymbol{M(T)/M(0)} \cdot \mu_C\ (E)$. These values are deduced from the experimental data by a rescaling of the difference, taking into account the incomplete circular polarization, the sample magnetization alignment with respect to the photon beam and the achieved degree of saturation magnetization at the finite temperature.

First evidence of the existence of XMCD or magnetic absorption was found in the hard X-ray range at the K edge of iron metal (Schütz *et al*., 1987). The effect is smaller than 1% as sketched in Figure 8 where the original data provides an experimental accuracy of 10^{-4}. This was high enough to manifest the occurrence of the effect in the near edge and the extended absorption X-ray fine structure (Schütz *et al*., 1987). Also in the hard X-ray range it has been found that at the Gd and Tb metal $L_{2,3}$ edges (Schütz *et al*., 1988, 1989) and subsequently at the corresponding absorption in 5d impurities much stronger XMCD signals up to more than 20% have been measured as shown again by the original data (see original data from Schütz *et al*. (1988, 1989) in Figure 9). One year later the corresponding experiments were performed at the $L_{2,3}$ edges in the 3d transition metals (TMs) (Chen, Sette, Ma and Modesti, 1990) as shown in Figure 10.

In the meantime, XMCD studies for a large number of elements in various systems have been performed and the method is established as an important tool to address element-specific magnetic structures and a large variety of phenomena and aspects in magnetism.

2.3.2 Systematics of XAS and XMCD at the L edges in 3d metal systems

The XMCD spectra at the $L_{2,3}$ edge of the 3d TMs are the most important phenomena studied as can be understood by the theoretical consideration in Section 3. The energy region, in which these edges occur, is located in the soft X-ray energy range between 400 and 1000 eV. To give an overview a typical 3d metal series of the $L_{2,3}$ edge XAS and XMCD spectra are shown in Figure 11. The visible XMCD effect is strong and pronounced and could achieve about 50% of the white line intensity, reflecting the strong and intensive magnetic cross sections. General trends in the 3d metal series could be observed. For the nonmagnetic XAS, the observed total linewidth is increasing for the light TMs. This is in contrast to the behavior of the lifetime broadening (Fuggle and Alvarado, 1980), but reflecting the increase in

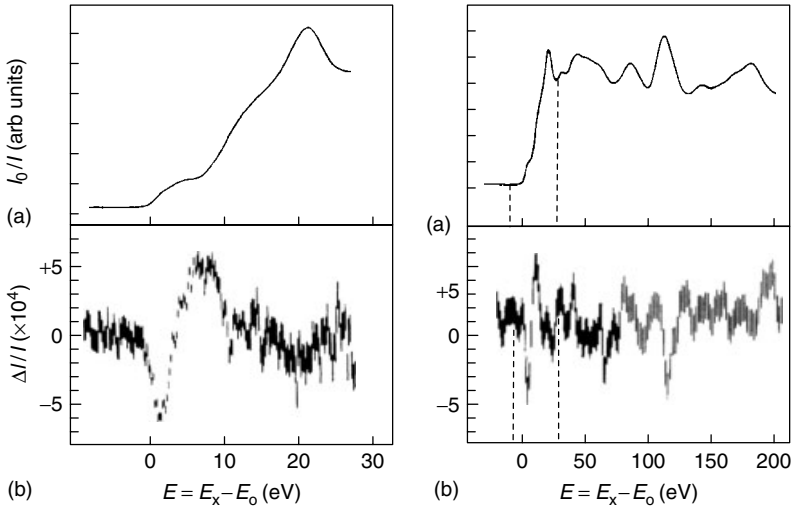

Figure 8. First experimental proof of the existence of magnetic absorption of XMCD found in the hard X-ray range at the K edge at 7111 in an iron foil corresponding to the origin of the energy scale. The transmission I_O/I (a) and the difference for opposite magnetization of the sample $\Delta I/I$ (b) was detected in a similar arrangement as sketched in Figure 4(b) but with the cold rolled Fe foil tilted with 30° with respect to the photon beam. (Reproduced from Schütz *et al*. (1987) *Physical Review Letters* **58**, 737–740.)

the number of unoccupied states. So, for the heavy TM the 3d shell is nearly filled up and only a fraction of typical e_g character is available for resonant core level excitations. For the light TM the major part of the 3d shell is empty, providing a large number of possible excitation channels and broader XAS structures, according to the broader unoccupied fraction of the DOS. General trends are also observable for the XMCD spectra. For the heavy TM the XMCD spectra reveal a simple structure, with a 'down peak' at the L_3 edge and an 'up peak' at the L_2 edge. For the light TM, the shape of the XMCD spectra becomes more complicated.

Without discussing all the details of the spectra, which are based on complicated band structure details, two predominant features could be identified. The simple 'up–down structure' is now superimposed by a peak derivative-like structure, and at the threshold of the transition another relative sharp feature appears. The first mentioned derivative-like structure has been identified by an increase in the number of unoccupied states, providing a related ground-state moment feature with peak derivative-like structures (van der Laan, 1997a,c,d), while the second feature represents the partial empty t_{2g} states.

2.3.3 XAS and XMCD in rare-earth metals

The RE elements, that is the lanthanide series, also play an important role in the field of magnetism. This is related to the unusual properties of the 4f shell electrons. Owing to the fact that the $4f^n$ state is of atomic character the 4f electrons exhibit well-known magnetic states following Hund's rules. Relatively large effects at the $L_{2,3}$ edges, found in the hard energy range between 5 and 10 keV, are shown in Figure 9. They can be observed in any RE metals system as demonstrated by a systematic study of the RE_2Co_{17}-system (Fischer, Schütz and Wiesinger, 1990). The absorption edge itself, which is energetically split by several 100 eV, is a clear step function superimposed by the so-called white line feature. In its vicinity, the XMCD signals in the order of percent are found. Especially at the low-energy side of the $L_{2,3}$ edges, except for Ce and Gd, pronounced negative contributions are visible (see Figure 12).

In contrast to the L edge of the RE metals, in which a photoelectron transition $2p \rightarrow 5d$ is involved, the $M_{4,5}$ edge absorption, located in the soft-energy range, probe the magnetic 4f state which is highly polarized. Both spin-orbit states are separated by 20–50 eV and the strong absorption lines, which exhibit a pronounced fine structure, are superimposed on a very small step function. The XMCD signal also shows sharp derivative-like features. Typical spectra of the Gd and Sm $M_{4,5}$ edges are shown in Figure 13.

3 THEORETICAL MODELS AND NEW INSIGHTS INTO MAGNETISM

3.1 XANES and its relation to local electronic structures

Following Fermi's golden rule, the one electron absorption cross section is described by Bransden and Joachain (1983)

and Cowan (1981)

$$\mu(\hbar\omega) \propto \sum_{\mathrm{f}} \left|\left\langle \psi_{\mathrm{f}} \left| \vec{p} \cdot \vec{A} \right| \psi_{\mathrm{i}} \right\rangle\right|^2 \delta(E_{\mathrm{f}} - E_{\mathrm{i}} - \hbar\omega)$$
$$= |M_{\mathrm{fi}}(E)|^2 \cdot \rho(E) \qquad (6)$$

Thus, the absorption coefficient is directly proportional to the square of the dipole transition matrix element times the density of the final states. The dipole selection rules $\Delta l = \pm 1$ allows only transitions from initial s to a final p state. Thus, the K-edge absorption near edge structure represents the density of the unoccupied p states with an energy spread of

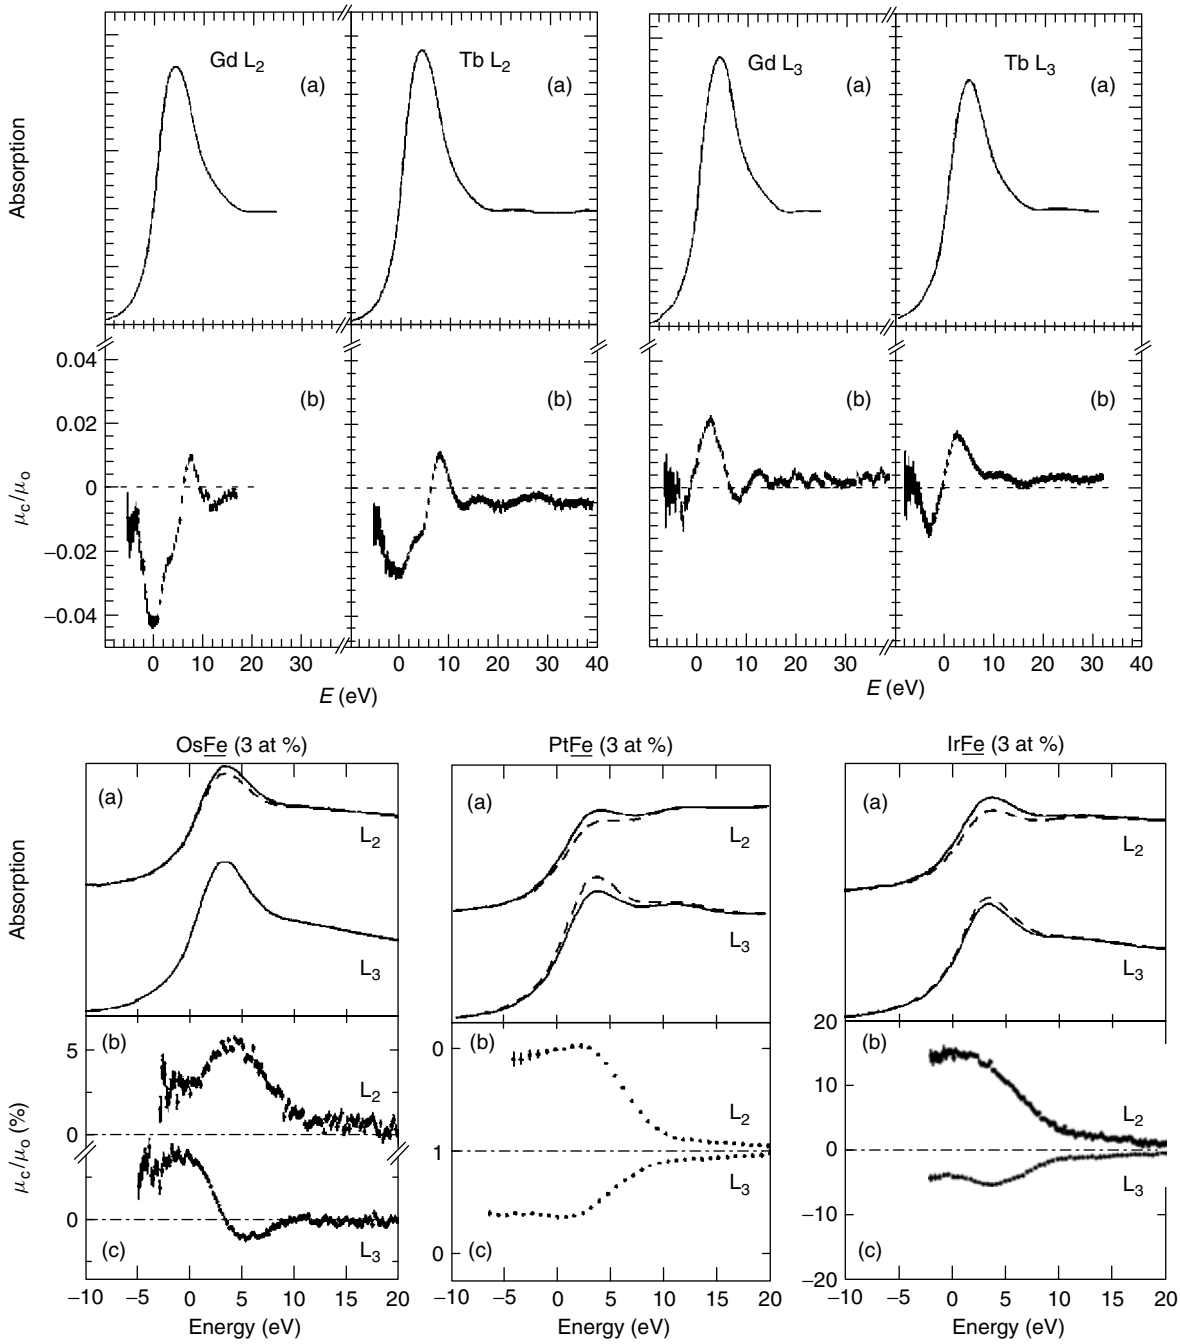

Figure 9. $L_{2,3}$ dichroic signals at Gd and Tb metal (Reproduced from Schütz *et al*. (1988) *Zeitschrift für Physik B: Condensed Matter* **73**, 67–75.) and Os, Ir, and Pt impurities in iron (Reproduced from Schütz *et al*. (1989) *Zeitschrift für Physik B: Condensed Matter* **75**, 495–500.), where the giant effects of larger than 20% have been observed. The absorption and the relative magnetic absorption coefficients $\mu_{\mathrm{C}}/\mu_{\mathrm{O}}$ have been measured in the same experimental arrangement as in Figure 6 (Schütz *et al*., 1988).

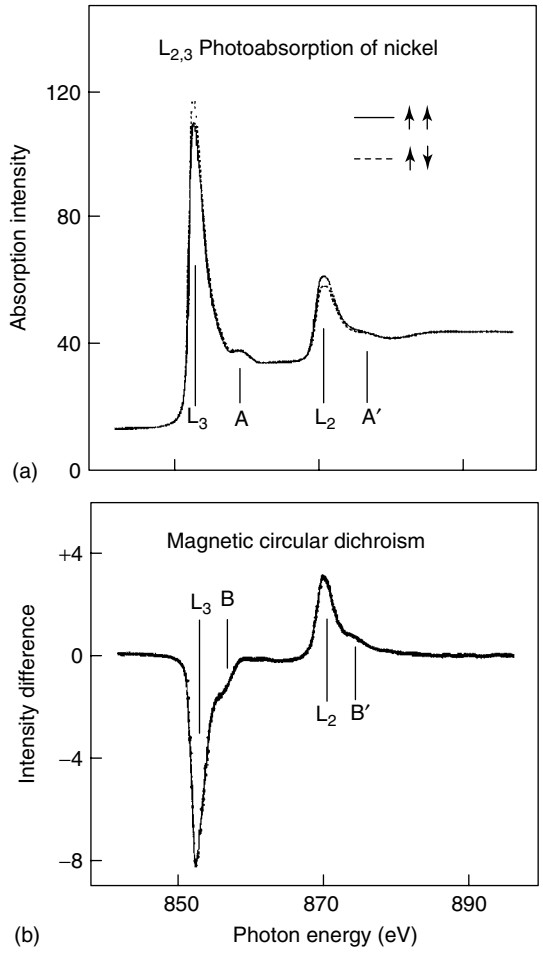

Figure 10. First evidence of soft X-ray XMCD observed at the Ni $L_{2,3}$ edge in the pure metal studied by TEY measurements using the inclined view method and the experimental setup as shown in Figure 7. (a) XAS and (b) XMCD of Ni. (Reproduced from Chen *et al*. (1990) *Physical Review B* **42**, 7262–7265.)

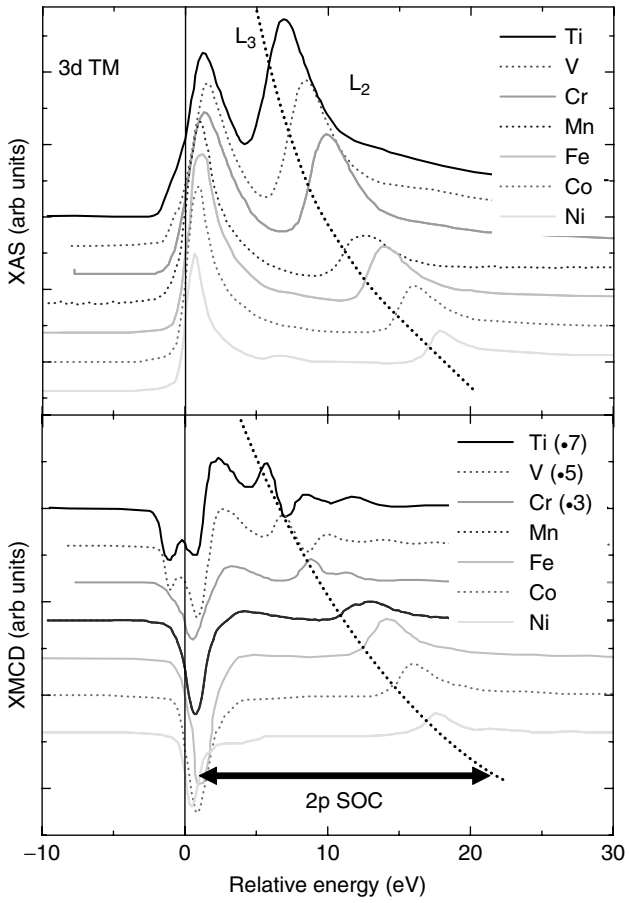

Figure 11. XAS and XMCD spectra of the whole 3d series. The splitting between the L_3 and L_2 edges increases with nuclear charge and the related 2p spin-orbit split energy (SOC), as indicated by the dotted line. All spectra have been aligned in energy at the half height of the L_3 edge. All spectra have been extracted from (Scherz, 2003), except the Mn spectra are from (O'Brien and Tonner, 1994).

several electron volts. For atoms with a large nuclear charge, the information of the fine structure is smeared out by the strong lifetime broadening effects, due to the fast decay of the core hole (Krause and Oliver, 1979). It is about 1 eV at the K edge of 3d transition elements with energies between 5 and 9 keV due to the fast decay of the created core hole. After excitation of a $2p_{1/2}$ and $2p_{3/2}$ electron, corresponding to the $L_{2,3}$ edges, final s and d states are populated, whereby the strengths of the matrix elements is, for the $p \rightarrow s$ transition, weaker by a factor 100 and often neglected [5]. At the 3d L edges of 3d transition element with energies in the soft X-ray range between 400 and 1000 eV the lifetime widths are smaller. Owing to the stronger radial overlap of the 2p level with the final more localized d states, the matrix element has a resonance-like character resulting in prominent white line features and for the 3d elements very fine details of the final state density are measured and splitting is directly observable. For 4d and 5d L edges this broadening is of the order of 5 eV. This is demonstrated in Figure 14 showing a comparison of the final p and d projected DOS to the corresponding K and L X-ray absorption near edge spectroscopy (XANES) spectra.

Owing to fast decay, via Koster–Kronig radiationless transitions, the p levels of M and N states are too broad and not suitable for XANES analysis.

The final state structure for the $M_{4,5}$ edges of the RE elements is not related to band structure-like features, due to the small Coulomb interaction of the 4f electrons and the valence band, where the 4f energy could be considered as atomically sharp. Therefore, the transition from the 3d shell to the 4f shell could be treated in an atomic multiplet calculation, where on-site 4f correlations and 3d–4f hole interactions are relevant for the shape of the spectra.

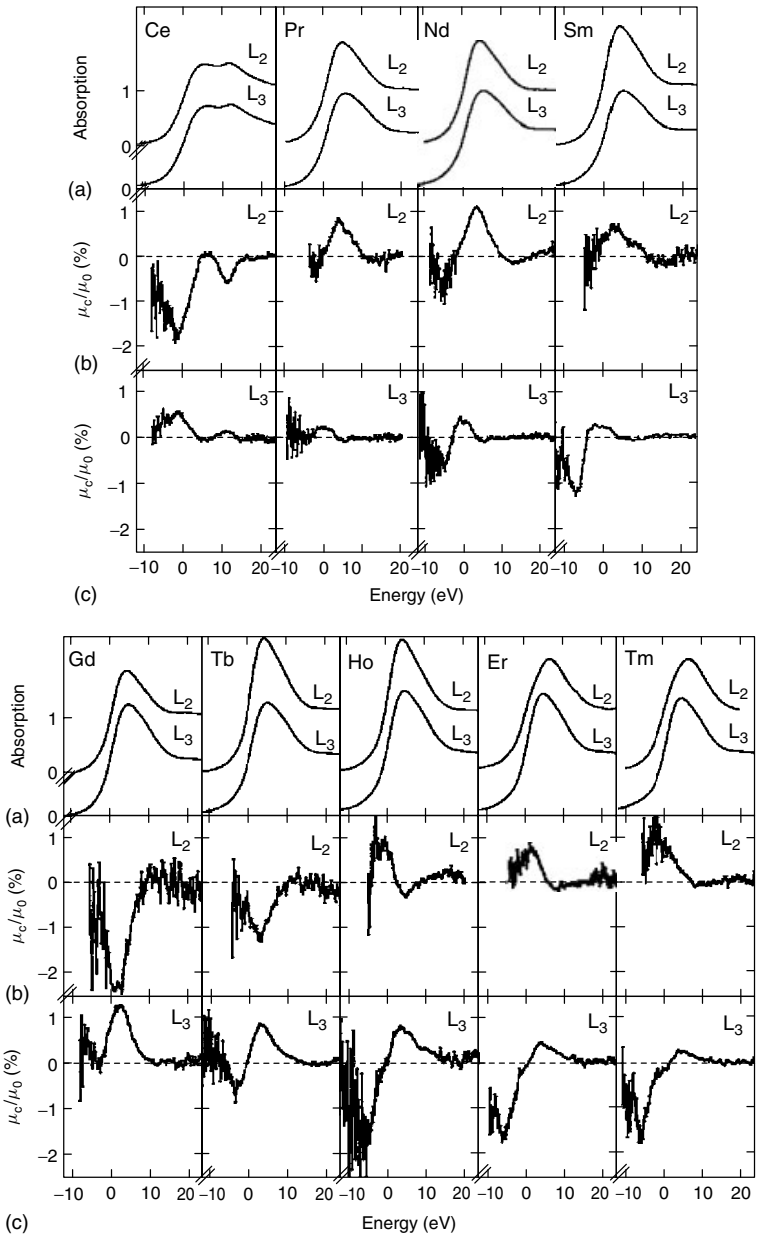

Figure 12. XAS and XMCD spectra at the $L_{2,3}$spectra of a series of rare-earth elements in the compound RE_2Co_{17}. (Reproduced from Fischer *et al*. (1990) *Solid State Communications* **76**, 772–781.)

3.2 The two-step model for XMCD

Step 1: The origin of the occurrence of XMCD as a universal effect is simply explained by basic quantum-mechanical vector coupling rules. When a circularly polarized photon beam is absorbed, an additional constrain is that the magnetic orbital quantum number has to be changed by $\Delta m = +1$ or -1 for right or left-handed photons [6]. The consequence for an absorption of a right circular polarized photon beam in an initial $p_{1/2}$ state is illustrated in Figure 15(a), where the initial level is separated for the different m components of the $j = 1/2$ and their statistical weight. Taking into account that the Clebsch–Gordon coefficients for the coupling of an initial electron state photon beam to the initial and final d state, prefer strongly the $m_i = 1$ to the $m_f = 2$ state transition to the credit of the transition $m_{il} = -1$ to the $m_{fl} = 0$. This shows that the spin character of the photoelectron in the final state is negative. The polarization of its angular momentum is, on the other hand, strongly positive since $m_l = +1$ and m final states are populated. The expectation values of the spin and orbital polarization with respect to the quantization axis z, that is, the photon **K** vector, are $\langle \sigma_z \rangle = -1/2$ and

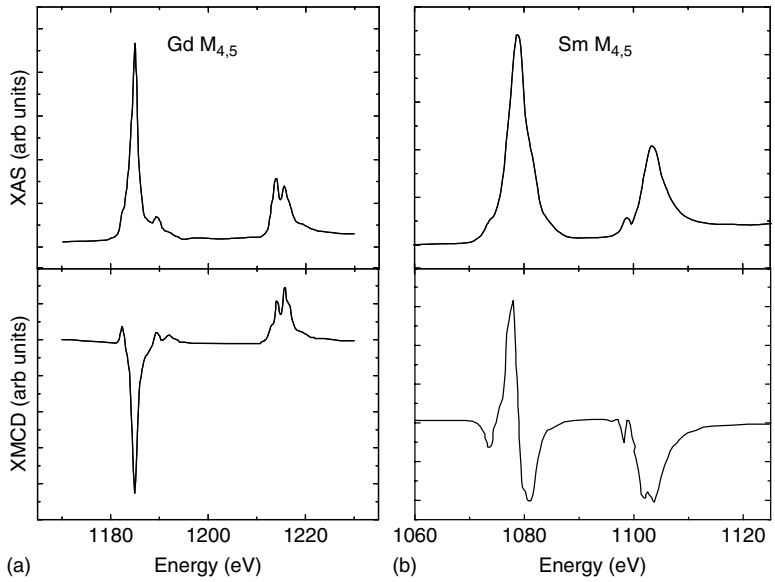

Figure 13. (a) Shows the nonmagnetic and the magnetic absorption spectra at the Gd $M_{4,5}$ edges of a GdFe thin-film system (From Peters *et al*., 2004.) and (b) shows the corresponding Sm $M_{4,5}$ spectra of a Sm_4As_3 sample. (From Suga and Imada, 1996.)

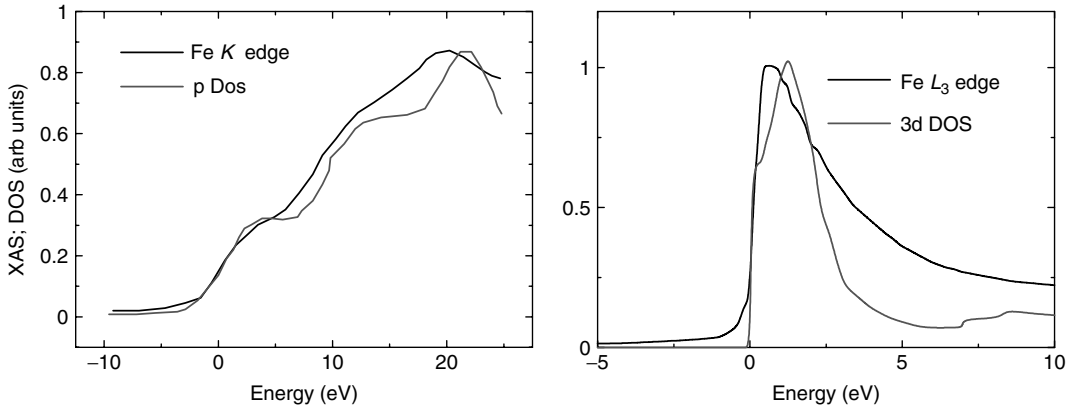

Figure 14. Relation of the Fe K- (Stähler, Schütz and Ebert, 1993)and L_3 - (Chen *et al*., 1995) absorption coefficient in Fe to the p- (Stähler, Schütz and Ebert, 1993) and d-projected density of the final unoccupied states at the Fermi level.

$\langle l_z \rangle = +3/4$. The analogous calculation for an initial $p_{3/2}$ level results in opposite spin but identical orbital polarization $\langle \sigma_z \rangle = +1/4$ and $\langle l_z \rangle = +3/4$.

In the transition $s \rightarrow p$ for a right circularly polarized photon the only transition possible is the transition $m_i = 0$ to $m_f = +1$ creating a final photoelectron with $\langle \sigma_z \rangle = 0$ and $\langle l_z \rangle = 1$. This implies that in the absorption process of a circularly polarized photon beam, only an orbital polarized photoelectron without spin polarization is created. The corresponding values can be seen in Figure 15(b).

This phenomenon of the creation of spin-polarized electrons is only a result of simple quantum-mechanical vector coupling rules where magnetic states play no role at all. On the basis of the same effect, the excitation of a selected $p_{3/2}$ occupied band state close to the Fermi level in GaAs photocathode (Pierce and Meier, 1976) to a $s_{1/2}$ vacuum level by a circular polarized 1.42 eV light is commonly used as an effective source for spin-polarized electrons.

Step 2: The magnetism in this model is introduced by the fact that, in the vicinity of an absorption edge in a magnetic material, the final state DOS is spin split in a simple band structure model. Therefore, the excitation probability of polarized excited electrons depends on the spin-polarized DOS of the final state atom, and the strength of the absorption depends on the polarization of the empty states available in the absorption process following Pauli's exclusion principle [7]. This results in a difference in the absorption coefficients for flipping the light helicity of the photon beam with respect to the sample magnetization. For spin-only systems this fact can be simply implemented into Fermi's golden rule

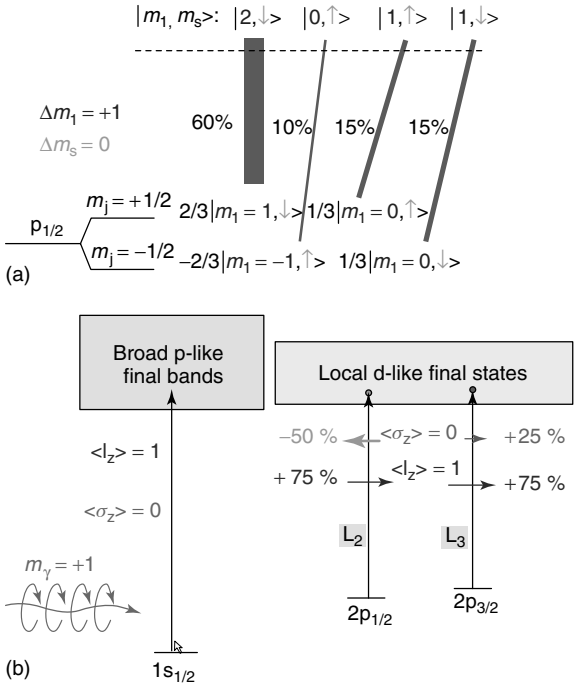

Figure 15. (a) Transition probabilities from the different $m_j = \pm 1/2$ configuration (energetically identical) of the $p_{1/2}$ spin–orbit coupled level separated into the two possible $m_l m_s$ configurations to a final d state in an L–S coupling scheme of initial and final states. The numbers before the sets indicate their statistical weights corresponding to the square of the Clebsch–Gordon coefficients. (b) Spin and orbital polarization of the photon in an initial $1s_{1/2}$, $2p_{1/2}$, and $2p_{3/2}$ atomic level corresponding to a K, L_2, and L_3 absorption.

$$\mu_{\pm}(E) = \mu_0(E) \pm \mu_C(E) \propto \sum_{|f\rangle |i\rangle} |\langle f| \mathbf{W}(E) |i\rangle|^2 \times \left(\rho_{|f\rangle}(E) \pm \langle \sigma_z \rangle \cdot \Delta\rho_{|f\rangle}(E)\right) \tag{7}$$

or simplified to

$$\frac{\mu_C(E)}{\mu_0(E)} = \langle \sigma_z \rangle \cdot \frac{\Delta\rho_{spin}(E)}{\rho(E)} \tag{8}$$

Thus, the measured signal in this simple model is directly correlated to the spin density difference of the unoccupied states.

To illustrate how the information on the spin density difference is related to the local magnetic spin moment, see Figure 16, a simple model of the formation of local magnetic d moments in the band structure picture is drawn. The magnetic d moment corresponds to the spin density difference of the occupied part $m^{occupied}(\mu_B) = \int_{-10\,eV}^{0} \Delta\rho(E)dE$ integrated from the lower band edge at about -10 eV edge to the Fermi level $E = 0$, which is nonzero due to the energy shift of the majority and minority contribution with respect to the Fermi level. It is assumed that the complete d band,

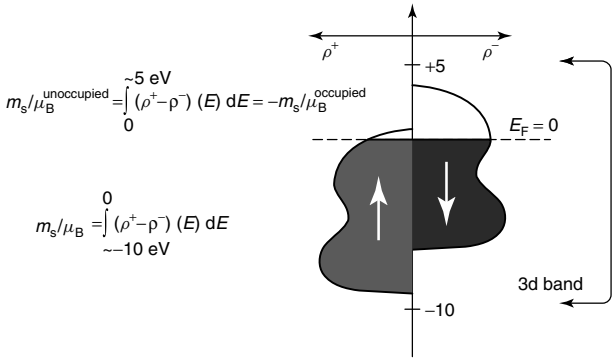

Figure 16. Correlation of the integrated density of the unoccupied state to the local moment carried by the occupied spin-split 3d states.

consisting of the occupied part and the unoccupied part, contains five up and five down electrons. An integral covering the whole d band has to vanish

$$m^{total}(\mu_B) = \int_{-10\,eV}^{+5\,eV} \Delta\rho(E)\,dE = 0 \tag{9}$$

Thus, the 'hole' moment carried by the spin density difference of the unoccupied part is given by $m^{unoccupied}(\mu_B) = \int_0^{+5\,eV} \Delta\rho(E)\,dE = -m^{occupied}(\mu_B)$. On the basis of this simple picture one can find a simple relation of the integrated XMCD signal to the local magnetic spin moment following equation (9)

$$m^{occupied}(\mu_B) = -\int_0^{+5\,eV} \Delta\rho(E)\,dE = -\langle \sigma_z \rangle \frac{\int \mu_C(E)\,dE}{\int \mu_0(E)\,dE} \cdot \int \rho(E)\,dE \tag{10}$$

where $\int \rho(E)\,dE$ is the 'number' of holes.

If an orbital polarization has to be taken into account one can show that, on the basis of the L–S coupling scheme of initial and final state, an additive contribution occurs

$$\frac{\mu_C(E)}{\mu_0(E)} = \langle \sigma_z \rangle \cdot \frac{\Delta\rho_{spin}}{\rho} + \langle l_z \rangle \cdot \frac{\Delta\rho_{orbit}}{\rho} \tag{11}$$

with $m_{spin}(\mu_B) = -\int \Delta\rho_{spin}(E)\,dE$ and $m_{orbit}(\mu_B) = -\int \Delta\rho_{orbit}(E)\,dE$.

Since the sensitivity on the spin moment has a different sign at both edges, but the sensitivity to the orbital moment is identical, a comparison of the dichroic profiles at L_2 and L_3 XMCD by a proper addition/subtraction is able to cancel either spin or orbital moment sensitivity. This is the basis of the sum rules developed in a more complex theoretical framework, which are discussed in the following chapter, but resulting in the same final formulae for cubic symmetry.

3.3 Sum rules

3.3.1 General formulation

The phenomenon of XMCD has been described by a more sophisticated theory, resulting in the 'sum rules', providing a separation of the spin and orbital contributions to the absorption difference. This has been derived by the pioneering work of Carra, Thole, Altarelli and Wang (1993) and Thole, Carra, Sette and van der Laan (1992), who investigated theoretically the transition probabilities of the core electrons depending on different ground-state properties of the sample, providing spin orbital and magnetic dipole term projections. One key issue was the elimination of the radial matrix elements using the ratio of magnetic and nonmagnetic absorption profiles. The first experimental verification of the sum rules have been done for the $L_{2,3}$ edges in the work of Chen *et al.* (1995). This was the starting point, where the number of papers using XMCD sum rules exploded during the following years. In this correct description an important new aspect in magnetism has to be taken into account: the aspheric spin contribution, described by the so-called magnetic dipole term T_z, which might occur in noncubic systems. Similar to the simple two-step model, described above, to deduce the spin and orbital momentum and the T_z term, the areas of the nonmagnetic absorption spectra (XAS) and the corresponding magnetic difference (XMCD) have to be analyzed.

Here too, the ground-state number of the unoccupied states of the final state shell has to be known.

The expressions as developed by Thole and Carra are given here:

$$\frac{-\int_{j_+ + j_-}\left(\mu^+(E)-\mu^-(E)\right)\cdot \mathrm{d}E}{\int_{j_+ + j_-}\left(\mu^+(E)+\mu^-(E)+\mu^0(E)\right)\cdot \mathrm{d}E} = a\cdot\frac{\langle \mathrm{L}_z\rangle}{n_h}$$
$$\frac{-\left(\int_{j_+}\left(\mu^+(E)-\mu^-(E)\right)\cdot \mathrm{d}E - b\cdot\int_{j_-}\left(\mu^+(E)-\mu^-(E)\right)\cdot \mathrm{d}E\right)}{\int_{j_+ + j_-}\left(\mu^+(E)+\mu^-(E)+\mu^0(E)\right)\cdot \mathrm{d}E}$$
$$= \frac{c\cdot\langle \mathrm{S}_z\rangle + \mathrm{d}\cdot\langle \mathrm{T}_z\rangle}{n_h} \qquad (12)$$

Here, $n_h = 4l_\mathrm{f} + 2 - n$ is the number of holes present in the final state shell.

l_f and l_i are the orbital angular momentum quantum numbers of the final and initial states, which are connected to each other by the dipole selection rule as $l_\mathrm{f} = l_\mathrm{i} \pm 1$. $\langle \mathrm{S}_z\rangle$, $\langle \mathrm{T}_z\rangle$, and $\langle \mathrm{L}_z\rangle$ are the expectation values of the spin, dipole term, and orbital moment projection along the z (photon beam) direction. The values for the prefactors a–d are shown in Table 1.

Table 1. Sum-rule related prefactors.

l_i	l_f	a	b	c	d
s:0	p:1	1	–	–	–
p:1	d:2	1/2	2	2/3	7/3
d:2	f:3	1/3	3/2	2/3	2

It is important to mention that for s-shell absorption ($l_\mathrm{i} = 0$) without spin-orbit splitting (SOC) in the initial state, no spin and no dipole term contributions are observable with XMCD. On the other hand, the spin moment could not be extracted without the contribution of the dipole term $\langle \mathrm{T}_z\rangle$, which will be discussed later.

Usually, the absorption is just measured for the left and right circular polarized light, and the absorption of z-polarized light is not known. This part is approximated by the average of the two circular polarized absorption coefficients. Therefore, the integral in the denominator reduces to

$$\mu^+(E) + \mu^-(E) + \mu^0(E) \approx \mu^+(E) + \mu^-(E) + \left(\mu^+(E) + \mu^-(E)\right)/2 = 3/2\left(\mu^+(E) + \mu^-(E)\right) \qquad (13)$$

This approximation is valid for systems with cubic symmetry and powder samples, but even for reduced symmetry the approximated integral is not differing significantly from the measured sum over all three different polarization vectors.

The situation for Fe metal is shown in Figure 17 illustrating the magnetic Fe $L_{2,3}$ absorption, measured in transmission mode, for parallel and antiparallel aligned sample magnetization with respect to the photon beam helicity. The energy is located at the resonant absorption profile of the Fe $2\mathrm{p} \rightarrow 3\mathrm{d}$ excitation. In all spectra, the backgrounds of the less bound electrons have been subtracted by the same straight line for both magnetization (helicity) directions. A clear and pronounced difference is observable. The difference, which is the XMCD signal, is plotted in Figure 17, where the dark shaded curve is related to the L_3-edge absorption (2p shell: $j = 3/2$) and the light shaded curve to the L_2-edge absorption (2p shell: $j = 1/2$). The magnetic effect is quite dramatic.

According to the sum rules of Thole and Carra we have to gather three different integrals, that is the XAS, dark shaded, and light shaded areas. In the case of the XAS signal (Figure 17c) a background must be subtracted, which results from an excitation into higher unoccupied d states (as 4d, 5d, etc.), which are typically nonmagnetic, less localized and broader in energy. The step height for the background approximation is 2/3 of the full edge jump at the L_3 edge and 1/3 at the L_2 edge, according to the degeneracy of the spin-orbit split 2p shell initial states (L_3: $m_j = -3/2; -1/2;$ 1/2; 3/2 and L_2: $m_j = -1/2;$ 1/2).

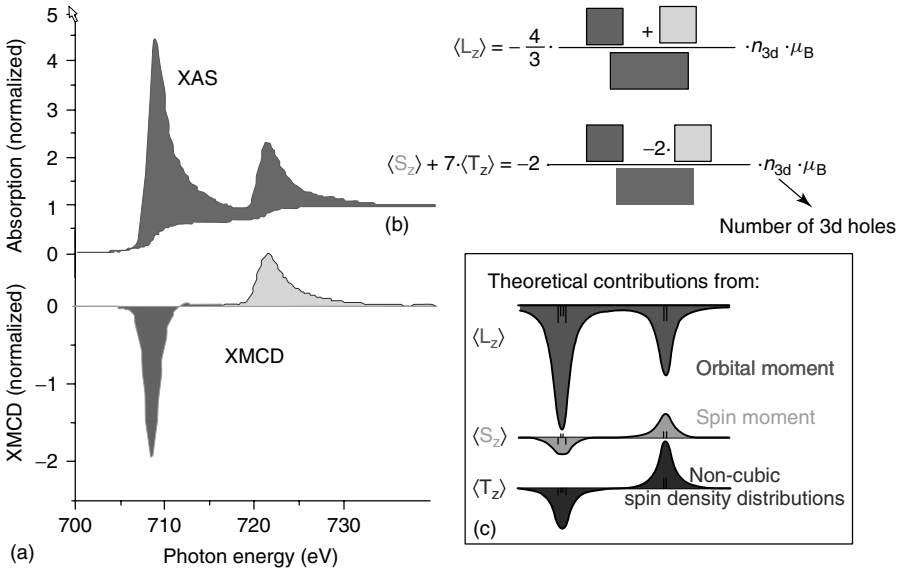

Figure 17. (a) Fe $L_{2,3}$ XAS and XMCD spectra and the (b) analysis via the sum rules on the basis of the theoretical contributions (c) to the XMCD by the orbital, spin and magnetic dipole moment.

Using the coefficients given in Table 1, we can give the corresponding sum rule expressions

$$\begin{aligned}\langle \mathrm{L}_z\rangle &= -n_h \cdot 2\frac{\int_{j_+ + j_-}\left(\mu^+(E)-\mu^-(E)\right)\cdot \mathrm{d}E}{\frac{3}{2}\cdot\int_{j_+ + j_-}\left(\mu^+(E)+\mu^-(E)\right)\cdot \mathrm{d}E}\\ &= -n_h\cdot\frac{4}{3}\cdot\frac{\text{dark gray}+\text{light gray}}{\text{XAS}}\frac{2}{3}\langle \mathrm{S}_z\rangle+\frac{7}{3}\langle \mathrm{T}_z\rangle\\ &= -2\cdot\frac{\int_{j_+}\left(\mu^+(E)-\mu^-(E)\right)\cdot \mathrm{d}E - 2\cdot\int_{j_-}\left(\mu^+(E)-\mu^-(E)\right)\cdot \mathrm{d}E}{\int_{j_+ + j_-}\left(\mu^+(E)+\mu^-(E)+\mu^0(E)\right)\cdot \mathrm{d}E}\cdot n_h\\ &= -n_h\cdot 2\cdot\frac{\text{dark gray}-2\cdot\text{light gray}}{\text{XAS}} \qquad (14)\end{aligned}$$

For the magnetic moments, one gets one Bohr magnetron for each projected orbital moment [8] and two for each spin value, due to the g factors.

As a consequence the 2p → 3d XMCD sum rule is as follows:

$$\begin{aligned}\langle m_l\rangle &= -2\frac{\int_{j_+ + j_-}\left(\mu^+(E)-\mu^-(E)\right)\cdot \mathrm{d}E}{\frac{3}{2}\cdot\int_{j_+ + j_-}\left(\mu^+(E)+\mu^-(E)\right)\cdot \mathrm{d}E}\cdot n_h\cdot\mu_\mathrm{B}\\ &= -\frac{4}{3}\cdot\frac{\text{dark gray}+\text{light gray}}{\text{XAS}}\cdot n_h\cdot\mu_\mathrm{B}\langle m_s\rangle+7\langle \mathrm{T}_z\rangle\\ &= -2\cdot\frac{\int_{j_+}\left(\mu^+(E)-\mu^-(E)\right)\cdot \mathrm{d}E - 2\cdot\int_{j_-}\left(\mu^+(E)-\mu^-(E)\right)\cdot \mathrm{d}E}{\int_{j_+ + j_-}\left(\mu^+(E)+\mu^-(E)\right)\cdot \mathrm{d}E}\cdot n_h\cdot\mu_\mathrm{B}\\ &= -2\cdot\frac{\text{dark gray}-2\cdot\text{light gray}}{\text{XAS}}\cdot n_h\cdot\mu_\mathrm{B} \qquad (15)\end{aligned}$$

The left part $\langle m_s\rangle + 7\langle \mathrm{T}_z\rangle$ is called the *effective XMCD spin*. The sign of the integrals must be carefully taken into account. Negative XMCD signals provide negative integrals and positive signals positive integrals.

One very important point is the necessity to know the number of holes in the final state shell before the excitation of the 2p electron. The nominator provides a magnetic XMCD signal and the denominator the nonmagnetic part, both are proportional to the number of 3d holes. While for the XAS part the resonant intensity is directly proportional to the number of unoccupied states, the ratio is proportional to the magnetism per 3d hole. To get the full magnetic moment, the number of 3d holes which can usually be deduced from local density band structure calculations (LDA) must be known and are usually not critical. If not known, simple chemical estimates of typical electron configurations provide a first approximation. In addition, sum rules contain only integral information. An additional insight into the magnetic character of different unoccupied parts of the 3d shell could be deduced from the fine structure present in the XMCD spectra.

Note that the two-step model, as well as the sum rules, implies some important premises for the application, given as follows:

1. The absorption into final states with reduced orbital moments, like 2p → 4s, must be negligible as compared to the absorption for increased orbital moments, as 2p → 3d.
2. The radial matrix elements should not be varying as a function of the energy of the final state. This happens if final state electrons are less bound and more delocalized

compared to final state excitations close to the absorption threshold.

3. Relativistic corrections to the radial matrix elements should be negligible. Or, in other words, the radial matrix element should not be different for the $l_i + 1/2$ and the $l_i - 1/2$ excitations.
4. The dipole approximation should be a good approximation, or higher terms in the expansion, like the quadrupolar transition, should have spectral weight less than the error bar.
5. For the effective spin sum rule the $l_i + 1/2$ and the $l_i - 1/2$ excitations, for example. The L_2 and L_3 resonances, must be separable in terms of energy. This includes spectral overlap and quantum-mechanical mixing, that is a mixture of $l_i + 1/2$ and $l_i - 1/2$ excitations of the same energy induced by an additional interaction, for example, 2p–3d Coulomb interaction.

3.3.2 *Atomic multiplet description for $M_{4,5}$ edges*

In RE metals the 4f electrons carrying large magnetic moments, which are well localized and the small Coulomb interaction of the 4f electrons with all outer electrons, can be treated in a perturbative atomic model (de Groot, Fuggle, Thole and Sawatzky, 1990). The XAS and XMCD at the $M_{4,5}$ edges can be successfully calculated in a so-called atomic multiplet approach taking into account all dipole allowed transition strengths and the variety of all possible final states. The final $4f^{n+1}$ and the $3d^9$ states consist of a large number of possible electron configurations and related symmetries. Owing to the 3d–4f Coulomb interaction, these final states usually have a different energy, which could be excited preferentially, if the corresponding photon energy is applied in the absorption process. It is beyond the scope of this chapter to explain all the theoretical details about multiplet theory, but it has been demonstrated that this many-particle approach is able to provide theoretical spectra, which are in nearly perfect agreement with available experimental data as shown for the nonmagnetic $M_{4,5}$ spectra of the whole series (Thole *et al*., 1985) and for linear and circular magnetic dichroism. As shown in Figure 19, Goedkoop *et al*. (1988a,b) have successfully described the experimental Gd $M_{4,5}$-edge spectra from Peters *et al*. (2004) and the Sm $M_{4,5}$ spectrum (Suga and Imada, 1996). The origin of the XMCD effect is also shown in Figure 18(b), where all atomic transitions from different m_j are shown, including the strength of the corresponding transition.

The excellent agreement between the experimental curves and theoretical spectra is obvious. Usually the 4f spectra are not significantly altered in different chemical environments. The determination of orbital and spin moments via sum rules is not essential, because Hund's rule values are usually a good estimate. Nevertheless, XMCD provides the unique opportunity to give sublattice magnetizations in complex systems containing many different magnetic elements, for example, in the RE–Iron–Garnets (Goering, Gold and Schütz, 2001; Knülle, Ahlers and Schütz, 1995; Rudolf *et al*., 1991, 1992).

One additional aspect in the $M_{4,5}$ edges arises for some 4f systems with mixed valent 4f states. On the other hand, it is possible to have the same valency with different 4f J states present, which are not strict Hund's rule J values. Those systems could be nicely probed by XAS and XMCD.

Figure 19 shows experimental XAS and XMCD results of ultra thin layers of α-Ce at the $M_{4,5}$ edges and the corresponding multiplet calculations for Ce^{3+} in $4f^1_{J=5/2}$ and $4f^1_{J=7/2}$ (Finazzi *et al*., 1995). Similar to the results of the $M_{4,5}$ edges shown earlier, a clear fingerprint structure for different J states of Ce is observable, which is well reproduced by a weighted superposition of the two $4f^1_{J=5/2}$ and $4f^1_{J=7/2}$ related spectra giving the ratio of the spectral weights between $J = \frac{7}{2}$ and $J = \frac{5}{2}$ of 0.12 ± 0.03 (Finazzi *et al*., 1995).

3.3.3 *The quadrupolar spin density described by the T_z term*

The magnetic dipole term T_z, which was not addressed in magnetism prior to the development of the sum rules, is a quadrupolar spin distribution resulting from lower than noncubic symmetry of the surrounding charge density. The left side of Figure 20 shows an absorber atom (light gray center) with its surrounding atoms (dark gray) in noncubic symmetry with a fourfold symmetry. If this environment is now uniaxially squeezed [9], as indicated by the vertical arrows on the left side, the charge distributions will be modified and rearranged, as schematically sketched on the right. The atoms on the left and right side will move away from the central atom. Thus the charge density is higher above and below the central atom, and reduced at the left and right side. Without symmetry breaking, the total charge distribution at the central atom is predominantly characterized by a radially dependent monopolar charge distribution. With symmetry breaking, an additional quadrupolar charge distribution is necessary to describe the whole charge distribution correctly. If the sample is fully magnetically saturated, the spin expectation value is always aligned along the external field. Owing to the fact that each electron provides a spin, a quadrupolar charge distribution directly corresponds to a quadrupolar spin distribution, which is exactly the T_z term. As shown in Figure 20, the increased charge along the z direction is exactly the part which is reduced along the x and y directions. Mathematically this could be described by

the magnetic dipole term $\mathbf{T} = \mathbf{S} - 3\hat{r} \cdot (\hat{r} \cdot \mathbf{S})$, as known for a dipole field in electrostatics. If the spin is aligned along the axis α, T_z could be expanded in terms of the mentioned quadrupolar charge tensor $Q_{\alpha\beta}$ (Stöhr and König, 1995; van der Laan, 1998b) [10].

$$T_\alpha = \sum_\beta Q_{\alpha\beta} S_\beta \tag{16}$$

Measuring with a high field aligned parallel to the photon beam direction provides full sample saturation and a constant isotropic spin related XMCD signal. Measuring along the x and y axis provides a T_z projection, which is half of the value measured along the z direction and of opposite sign, corresponding to the charge distribution. Thus, an angular averaging XMCD measurement provides the full cancellation of crystallographic T_z moment contributions formulated as the sum rule $\sum_\alpha \langle T_\alpha \rangle \approx 0$, where the 'approximate' symbol is related to the part of the T_z term induced by the spin-orbit interaction of the final state shell (Stöhr and König, 1995).

As discussed above, a uniaxial force will introduce a magnetic dipole term. If this is purely related to the crystal structure itself, the average over all three crystallographic directions will provide the pure spin moment, where all dipole term contributions are canceled. Another possible 'uniaxial force' is related to the spin moment itself, aligned along one preferred direction. In this case, the charge distribution is altered by the spin-orbit interaction in the magnetic shell, and the uniaxial symmetry breaking is oriented along the direction of the sample magnetization. The related T_z term will not cancel since it aligns along the spin moment direction. Rotating the spin along different directions will also rotate the T_z contribution, and the absolute value of the effective spin moment always includes the spin-orbit induced dipole term contribution. Stöhr and König have discussed this influence and they found only minor contributions (Stöhr and König, 1995). Nevertheless, with

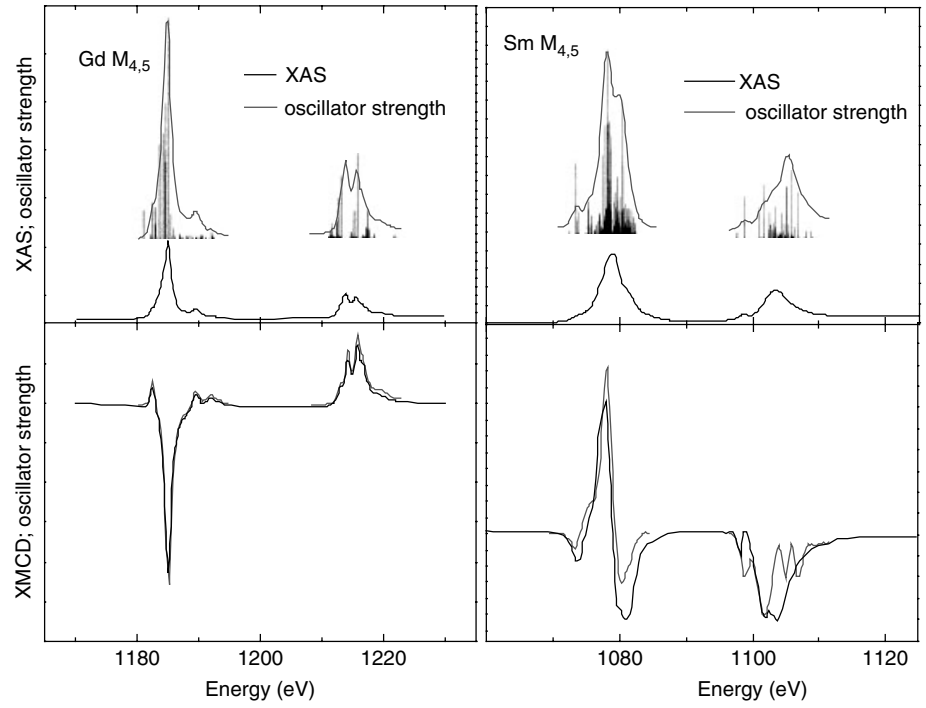

Figure 18. (a) Comparison of the Gd and Sm $M_{4,5}$ spectra, already shown in Figure 13, with the oscillator strength derived by atomic multiplet theory. The left side shows the nonmagnetic and the magnetic absorption spectra (black line) at the Gd $M_{4,5}$ edges of a GdFe thin-film system, while the gray curves are the related multiplet theory based oscillator strength reproduced from Peters *et al*. (2004). The right side shows the corresponding spectra of a Sm_4As_3 sample (from Suga and Imada, 1996) and the theoretical curves extracted from Goedkoop *et al*. (1988b) for Sm^{3+}. The upper part shows additional line intensities for Gd^{3+} and Sm^{3+} reproduced from Goedkoop *et al*. (1988b). The energy of the theoretical data has been adapted to the experimental results. To improve visibility, the experimental and theoretical spectra are shifted along the ordinate. (b) Atomic model for $3d^{10}4f^{13} \rightarrow 3d^9 4f^{14}$ transition in the rare earth element Yb^{3+}. The left (right) part shows the transition in the nonmagnetic (magnetic) case, respectively. The vertical arrows indicate the dipole allowed transitions for the various m_j states of the atom for left, linear and right polarized light. The polarization dependent relative intensities, due to the angular parts of the matrix elements, are indicated below by the small dots. (Reproduced from Goedkoop *et al*. (1988a) *Journal of Applied Physics* **64**, 5595–5597.)

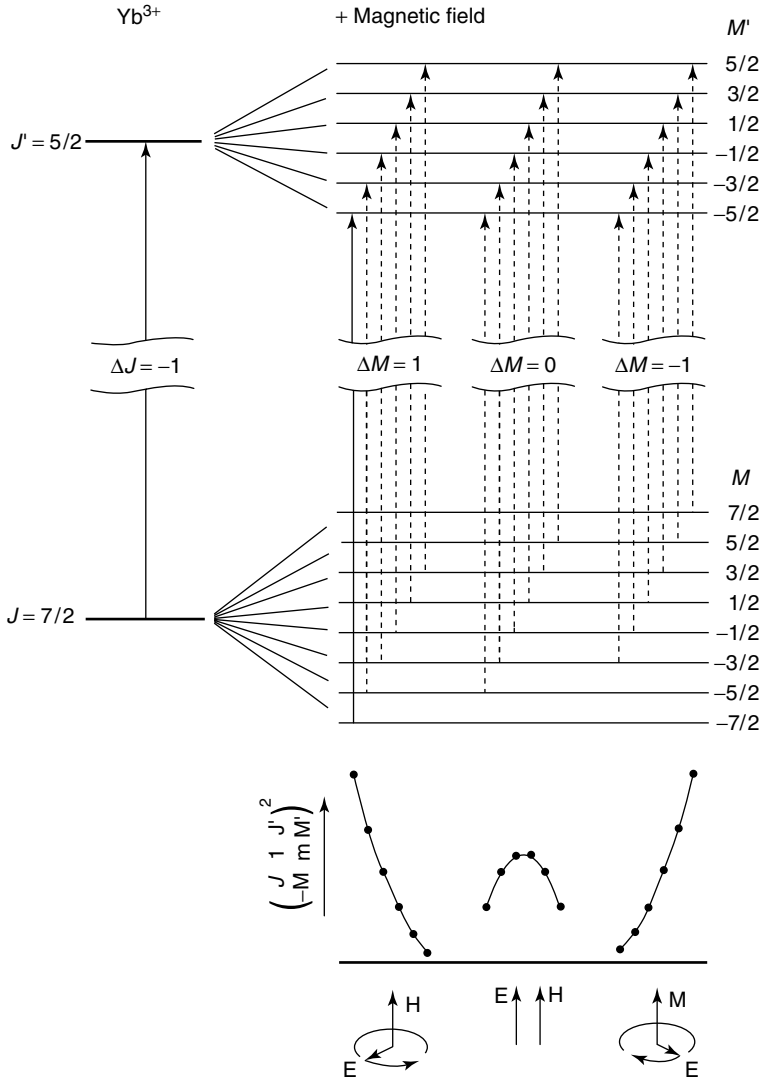

Figure 18. *Continued.*

increased spin-orbit interaction this part of the T_z term could not be separated from the spin moment consequently. Usually the absolute error in spin moment determination is in the range of 10% or slightly above, while relative errors are much smaller, for example, angular dependencies. Therefore, for 3d metal systems the spin-orbit induced T_z contribution should be in the error bar of the absolute value.

3.3.4 Moment analysis

A recent approach to go beyond the sum rules is provided by the moment analysis generally based on the findings of Gerrit van der Laan. The general shape modifications, found for the 3d TM series shown in Figure 21 could be understood by a single particle approach, which takes into account the important 2p–3d Coulomb and exchange interaction (van der Laan, 1997b,c,d, 1999a,b). The spectral XMCD shape of the heavy 3d TM as Fe, Co, and Ni consist roughly of simple down and up structures at the L_3 and L_2 edges respectively, as shown in Figure 11. This shape changes to a more peak derivative-like shape while going to light TMs. This has been explained in terms of a change in band filling, nearly empty for the light 3d TM as Ti and V, and nearly filled for the heavy ones such as Fe, Co, and Ni. Different ground-state expectation values provide different spectral shapes as shown in Figure 21. In the spectral analysis the complex XMCD profile is treated as a superposition of these spectral shapes, where the relevant intensity is proportional to various ground-state expectation values of tensor operators $\langle \underline{w}^{xyz} \rangle$. The underscore describes that the ground-state moment is related to the unoccupied part of the d shell. So, Figure 21 shows the dominating spectral shapes

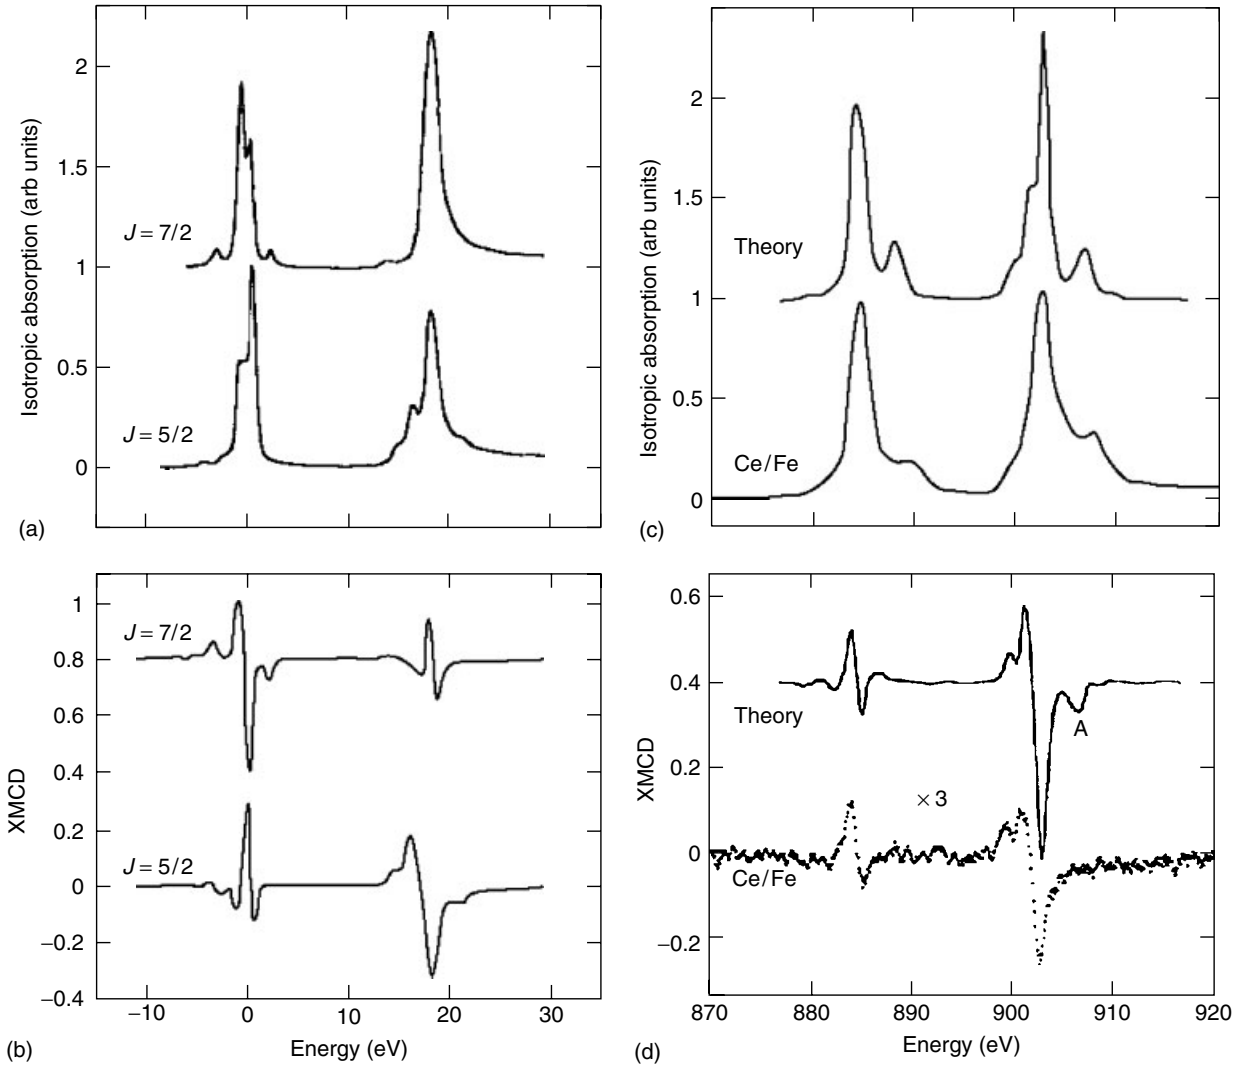

Figure 19. (a) Multiplet calculations of Ce for two different configurations $4f^1_{J=5/2}$ and $4f^1_{J=7/2}$. (b) The corresponding XMCD spectra. (c) Measured M4,5 result for the measured α-Ce and a weighted sum of the two $4f^1_{J=5/2}$ and $4f^1_{J=7/2}$ configurations shown in (a) to provide the best agreement to the experimental data. (d) Shows the XMCD comparison corresponding to (c). (Reproduced from Finazzi *et al*. (1995) *Physical Review Letters* **75**, 4654–4657.)

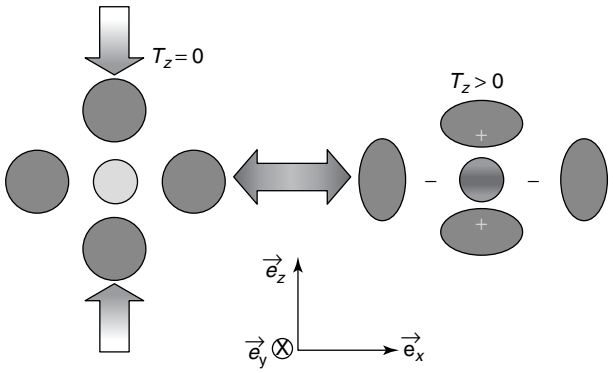

Figure 20. Schematic explanation of the charge and spin distribution, providing a nonvanishing T_z term.

present at the p → d excitation with a given (SOC) of the 2p shell. The following physical expectation values of the unoccupied part of the 3d shell are represented: $\langle \underline{w}^{000} \rangle$ is proportional to the number of holes n_h, $\langle \underline{w}^{110} \rangle$ to the spin-orbit coupling, $\langle \underline{w}^{101} \rangle$ to the orbital moment, $\langle \underline{w}^{011} \rangle$ to the spin, and $\langle \underline{w}^{211} \rangle$ to the magnetic dipole term T_z (van der Laan, 1997c,b).

The spectral shapes in Figure 21 are a sum of Lorentzian broadened line intensities, indicated as vertical lines below the spectra, originating from an energy splitting of various m_j states of the 2p core hole, related to the 2p–3d exchange energy. So, the $2j + 1$ degenerated core-hole states will split in energy into four (L_3:$2p_{3/2}$) and two (L_2:$2p_{1/2}$) channels. The energy splitting respective to the excitation center of

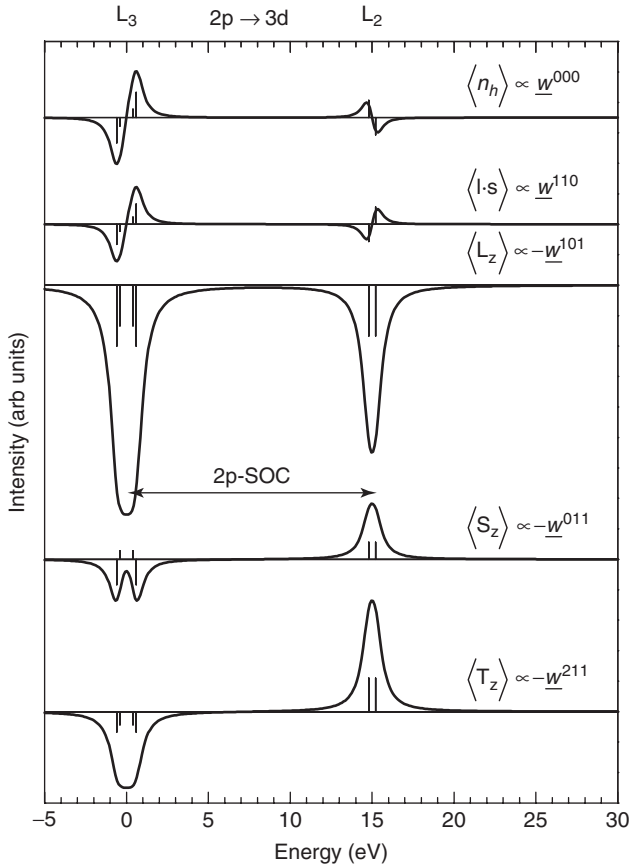

Figure 21. XMCD spectral shape of different ground-state moments $\underline{w}^{xyz}$, which are proportional to the corresponding expectation values.

gravity is

$$E_{jm} = H_s m_j \frac{j(j+1) + s(s+1) - l(l+1)}{2j(j+1)} \qquad (17)$$

where j is the total angular momentum of the p hole, m_j is the z component of j, s, and l are the spin and orbital moments of the p hole and H_s is equal to the effective pd exchange (van der Laan, 1997c,b). This expansion is a direct consequence of the Coulomb interaction between the core hole and the 3d final states and tries to take the dominating parts quantitatively into account. Different 3d final state configurations and possible different final state energies are not covered by this method. For a detailed understanding of this method, the reader is asked to refer to the literature (Goering *et al*., 1999, 2002c; Goering, Gold and Schütz, 2001; Goering, Bayer, Gold and Schütz, 2002; Goering, Gold and Bayer, 2004; van der Laan, 1997a,b,c,d; van der Laan and Thole, 1996).

Although introduced as a phenomenological model to describe complex 3d TM XMCD spectra, the validity was just checked for consistency, but it has recently been proved by theory to be also a correct description, demonstrating a more general character with extended validity (Dörfler and Fähnle, 2006).

The XMCD in Holmium iron garnets formula unit $Ho_3Fe_5O_{12}$ has been analyzed, where two different types of antiferromagnetic coupled Fe^{3+} sublattices, slightly separated in energy because of different chemical coordination, (three tetrahedral and two octahedral Fe ions) are present (Bloch, Chaisse and Pauthenet, 1967; Guillot and Pauthenet, 1967; Pauthenet, 1958). Figure 22 shows the room-temperature (RT) Fe $L_{2,3}$ XMCD spectrum of HoIG, which is much more structured compared to the pure Fe metal spectrum (see Figures 11 and 17). The most evident difference is the strong positive peak at the L_3 edge, directly suggesting an antiparallel ordered Fe sublattice magnetization. Dunaevsky *et al*. have calculated the DOS by a recursive calculation method for YIG, which has a similar 5d hybridization to

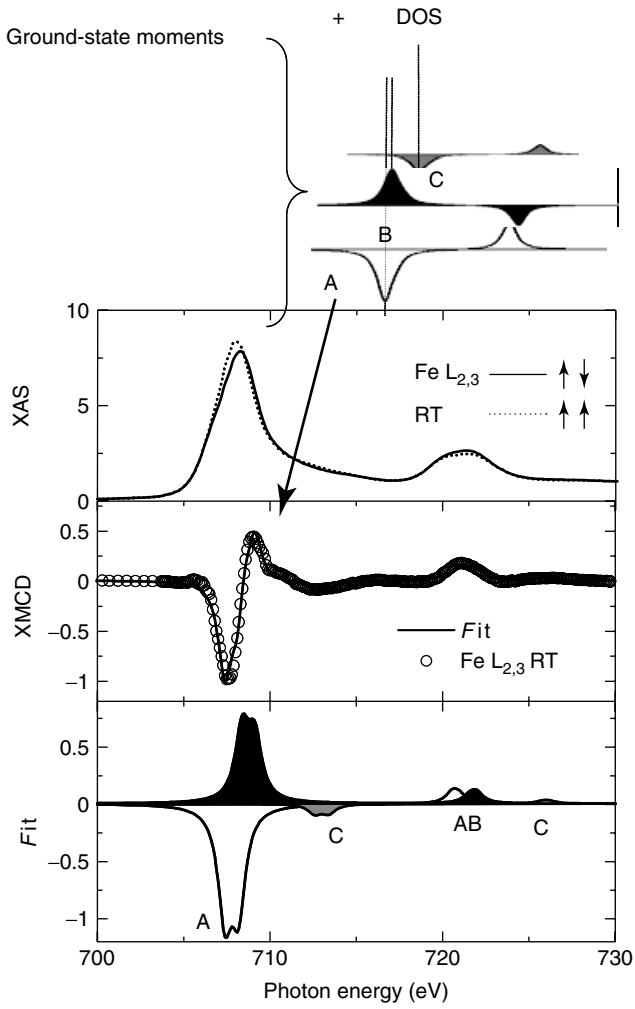

Figure 22. Moment expansion of iron garnets.

Fe 3d compared to the other rare elements like Ho. We have reproduced at the top of Figure 22 the DOS from Dunaevskii and Savel'ev (1989). The white shaded part corresponds to the octahedral (A) and the black shaded part to the tetrahedral (B) oxygen coordinated Fe ions. A clear energy shift between the two Fe sublattices is directly observable. The gray shaded part corresponds to the RE (Y) 5d DOS (C), which is important for the magnetic interaction between the RE and the Fe ions.

For the approximation of the XMCD spectrum, three sets of ground-state moments are generated and located at the three mentioned DOS related energy positions. The fit result and the room-temperature XMCD spectrum are shown in the middle part of Figure 21. The corresponding moment analysis contributions are shown below. All spectral shapes in the XMCD spectrum are nearly perfectly reproduced by the fit. As suggested above, the antiparallel coupling of the Fe sublattices is clearly observable. The extracted ratio of the spin moments A and B is 2.39, which should be 1.5 according to sublattice estimates from the literature (Geller *et al*., 1963), denoting a slightly higher magnetic moment for the Fe^{3+} at tetrahedral sites (B) compared to octahedral sites (A) which has also been predicted by theory (Dunaevskii and Savel'ev, 1989). It should be mentioned that the used linewidth to broaden the line spectra from the ground-state moments is large and dominated by the band structure.

3.4 Magnetic anisotropy and microscopic orbital moments

3.4.1 General aspects

One of the most important and technical relevant issues in magnetism of crystalline solids is the magnetocrystalline anisotropy energy (MAE). This energy provides the controllability of preferred easy axis behavior and influences magnetic switching and the coercivity. Owing to the fact that the spin itself does not interact with the electric crystal, an orbital moment must be present to couple the spin to the crystal lattice by spin-orbit field interaction. In the case of the 3d TM, the orbital moment is usually quenched and quite small compared to the spin moment and could not be addressed properly in the past by experiment [11]. Since XMCD now provides the separate determination of the spin and orbital magnetic moment projections in different crystallographic directions, understanding a new profound anisotropic behavior of 3d metal compounds in a microscopic, element specific, and quantitative way is possible especially in order to prove microscopic models. P. Bruno has formulated a perturbative approach of the MAE to reach a quantitative description for TM systems, which has the favorable effect of being intuitive: On the basis of 3d spin-orbit coupling, an enhanced orbital moment along the easy axis of a uniaxial anisotropic magnetic material is postulated. In such a system, the spin-orbit energy tries to align the spin moment along the direction with enhanced orbital projections. So the anisotropy is microscopically reflected in anisotropic magnetic moment projections (Bruno, 1989), and described quantitatively by $E_{\mathrm{S.O.}} = \frac{\xi}{4}\Delta\langle L\rangle$. This is sketched in Figure 23. While this model has been derived for systems with fully occupied majority spin band, Gerrit van der Laan extended it to include a higher term in perturbation theory of the spin-orbit energy, which includes the magnetic dipole term T_z

$$\begin{aligned}\Delta E &\approx -\frac{\xi}{4}\cdot\hat{S}\cdot\left[\left\langle L^{\downarrow}\right\rangle - \left\langle L^{\uparrow}\right\rangle\right] \\ &\quad + \frac{\xi^2}{\Delta E_{\mathrm{ex}}}\left[\frac{21}{2}\cdot\hat{S}\cdot\langle T\rangle + 2\left\langle (L_\xi S_\xi)^2\right\rangle\right] \\ &= E_{\mathrm{L}}^{\downarrow} + E_{\mathrm{L}}^{\uparrow} + E_{\mathrm{T}} + E_{\mathrm{LS}} \end{aligned} \tag{18}$$

With reduced symmetry the dipole operator term can play an important part. Owing to the fact that the absolute value of the spin moment also changes with chemical and crystallographic environments, the small orbital moment of 3d TM systems could not simply be separated quantitatively from the spin moment. Therefore, understanding their anisotropy was difficult up to now since XMCD gives the integral projected orbital moments. Regarding the formula of van der Laan shown above, the full orbital moment anisotropy could be a mixture of majority and minority orbital anisotropies with opposite signs. Thus, the total orbital anisotropy could be very small due to cancellation of large anisotropies of the minority and the majority band. Quantitative experimental verification of these models needs the presence of either a completely filled majority or an empty minority band. Completely filled or empty sub-bands do not provide an orbital moment and therefore the full anisotropy is only due to the remaining partially filled band as identified by *XMCD measurement*.

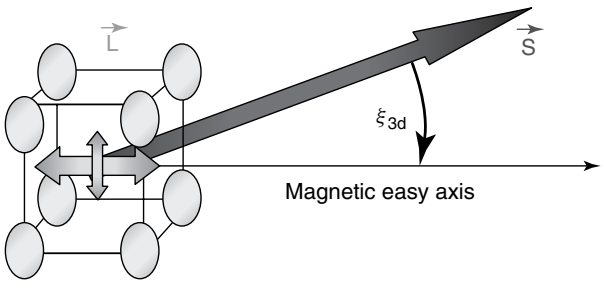

Figure 23. Bruno model of the magneto crystalline anisotropy in relation to spin and orbital moments.

Three examples will be shown which clearly demonstrate the unique possibilities of XMCD providing a deep, clear and unambiguous understanding of the anisotropy in 3d metal compounds.

3.4.2 The Au/Co/Au reorientation transition

One important phenomenon to be addressed is the transition between in-plane and out-of-plane magnetization behavior for ultra thin ferromagnetic films, like Co covered by Au. For thick films the shape anisotropy dominates the whole scenario, while for ultrathin films, just by adding some monolayers of Co, the axis direction is easily flipped from in plane to out of plane. The basic idea behind this phenomenon is the increased influence of the surface: Its symmetry breaking results in enhanced Co orbital magnetic moment projections along the surface normal, and a corresponding spin-orbit energy. The enhanced surface orbital moment interacts with the spin, trying to align the sample magnetization along the surface normal, via 3d shell spin-orbit coupling. It overcomes the shape energy and reduces with thickness; the magnetization rotates to the normal direction.

D. Weller and coworkers have investigated this transition and measured the Co orbital moment projections using XMCD at the Co $L_{2,3}$ edges, as shown in Figure 24 along the surface normal and at more grazing incidence geometry. Despite the fact that they had to face self-absorption phenomena (see above), they found clear thickness dependent orbital- and T_z moment variations at a Co wedge covered in Au. This observation clearly reflects the increased influence of the orbital moment at the surface layer, verifying the ideas of P. Bruno. As mentioned, the self-absorption problem in these studies has prevented reliable quantitative comparisons between the microscopic moment projections given by XMCD and the macroscopic magnetization behavior mediated by the Bruno model.

3.4.3 Co on Pt steps: the reduction of symmetry

An illustrative example of the potential of XMCD has been shown by the studies of Co atom chains and monolayers decorated on Pt(997) surface by Gambardella *et al*. (2003, 2004). While the spin sum rule application is hindered by the large dipole term T_z, the orbital moment can be directly deduced and is listed in Table 2 for different Co systems of reduced symmetry. The L_z values are compared with the magnetocrystalline anisotropy K_1.

The XMCD spectra shown in Figure 25, illustrates a comparison of Co nanoparticles going from the bulk to the atomic chains, monoatomic layers, and bulk Co. The increasing L_3-XMCD effect directly indicates a significant increase of an angular momentum, oriented parallel to the spin moment.

Table 2. Orbital moment projections and its correspondence to uniaxial anisotropy.

System	$\langle L_z \rangle$ (μ_B)	K_1(meV/atom)
Co metal (hcp)	0.14	0.053
Co/Pt(997) ML	0.31	0.14 ± 0.01
Co/Pt(111) ML	0.29	
Co/Pt(997) chain	0.68 ± 0.05	2.0 ± 0.2
Co/Pt(111) adatom	1.1 ± 0.1	9.3 ± 1.6

3.4.4 The magnetic anisotropy of CrO_2

CrO_2 is a classical ferromagnetic oxide, important for magnetism and of significant technological relevance. During recent years its half-metallicity with nearly 100% spin polarization at the Fermi level has attracted the interest of this chalcogenide as a candidate for injection of highly spin-polarized electrons and applications in spintronics, (Das Sarma, Fabian, Hu and Zutic, 2000; Wolf *et al*., 2001). CrO_2 crystallizes in the Rutile structure with a ratio of lattice constants of $a/c = 1.51$ (Porta, Marezio, Reimeika and Dernier, 1972; Swoboda, Arthur and Cox, 1961; Thamer, Douglass and Staritzky, 1957). Magnetometry reveals a magnetic moment of $2\,\mu_B$/fut (Kubota, 1960), which is consistent with two different theoretical approaches: The description of local magnetic moments of Cr^{4+} ions in a $3d^2$ configuration gives the same correct magnetic moment as band structure calculations on the basis of an itinerant picture (Korotin, Anisimov, Khomskii and Sawatzky, 1998; Lewis, Allen and Sasaki, 1997; Mazin, Singh and Ambrosch-Draxl, 1999; Schwarz, 1986). CrO_2 is difficult to access experimentally due to its reconfiguration into the more stable Cr_2O_3 phase. Recently a chemical-vapor-deposition technique has been established, which provides epitaxial single-phase thin films, grown on TiO_2 substrates (Li, Gupta and Xiao, 1999; Spinu *et al*., 2000, 2001) achieving spin polarization close to 100% measured by Andreev reflection (DeSisto *et al*., 2000; Ji *et al*., 2001; Ji, Strijkers, Yang and Chien, 2001; Soulen *et al*., 1998, 1999) and spin-polarized photoemission (Dedkov *et al*., 2002). Using these samples, 2p XAS and XMCD spectra for CrO_2 grown with its rutile *c* axis in plane have been studied for parallel and antiparallel aligned magnetization as shown in Figure 26(b) for $\vartheta = 7^\circ$, 40°, 86° and $\phi = 60^\circ$. The angle $\vartheta = 40^\circ$ represents an intermediate angle between *a*- and *c*-axis projection. The angle of incidence $\phi = 60^\circ$ has been chosen as a good compromise for a significant amount of in-plane sensitivity [12] and reduced self-absorption. The dichroic

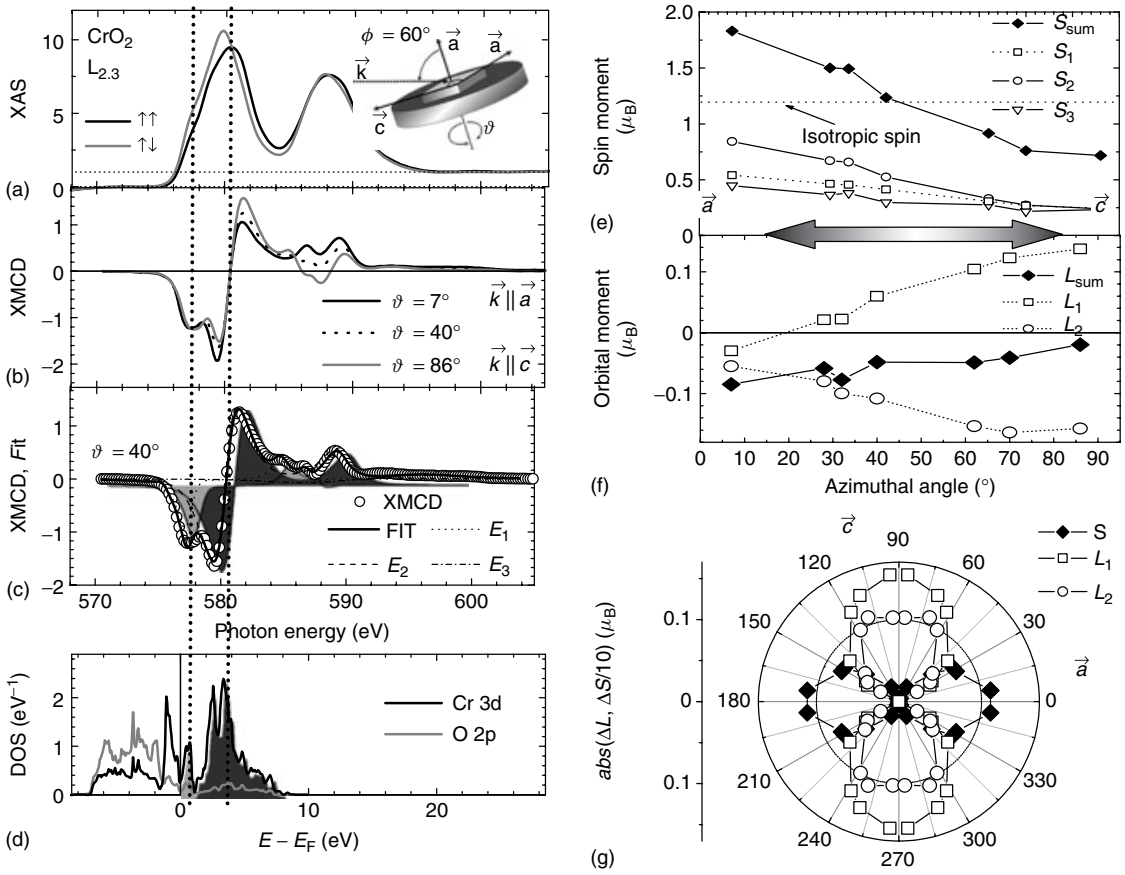

Figure 26. CrO_2 XAS (a) and XMCD (b) results, measured at the Cr $L_{2,3}$ edges at 80 K. (c) XMCD moment-analysis fit at an intermediate angle of 40° and (d) corresponding p and d projected DOS. Anisotropy of the effective spin (e) and the orbital moments (f), also shown as the difference in a polar plot (g).

spectra exhibit many structures with very strong unusual azimuthal variations. For *c*-axis enhanced projection ($\vartheta = 86^\circ$), a direct observable change of sign at 587 eV is present. This negative XMCD intensity suggests a strong increase in a projected orbital moment along the *c* axis (see Section 3.3.4 moment analysis: $\langle L_z \rangle \propto -\underline{w}^{101}$ exhibit only negative contributions) in contradiction to the nearly constant XAS. Owing to the spectral overlap of both L edges, the conventional sum rule analysis cannot be addressed to Cr 3d spin moments. A detailed analysis of the experimental data is based on the spin-up and spin-down DOS for Cr 3d and O 2p states, derived by LSDA $+U$ calculation (shown in Figure 25d (Korotin, Anisimov, Khomskii and Sawatzky, 1998)). Two prominent features are directly observable, a narrow (1-eV wide) fully spin-polarized unoccupied majority t_{2g} band at 0.5 eV and a broader mixture of e_g-majority and t_{2g}/e_g-minority states (Stagarescu *et al.*, 2000) at 3 eV. Two sets on a basis of the DOS (at E_1 and E_2) and one set according to the MEXAFS signal at E_3 (see also Section 4.1) are taken into account in the fitting procedure to separate the spectral overlap of L_3 and L_2 edges (Goering *et al.*, 2002a).

The original XMCD spectrum and the moment-analysis-fit result for an intermediate azimuthal angle are shown in Figure 25(c) ($E_1 = 577.0$ eV (dotted), $E_2 = 580.5$ eV (dashed), and $E_3 = 587.0$ eV (dot dash)). The two mentioned dominating parts E_1 and E_2 are shaded in light and dark gray. To reduce the number of free parameters, the sum over all orbital contributions has been set to the sum rule determined integral value. Peak width and broadening have been held fixed for all fitted XMCD spectra.

All spectral features could be reproduced nearly perfectly by this fitting procedure. The extracted three effective spin and two orbital [13] contributions for the areas E_1, E_2, and E_3 are shown in Figure 26(e, f, and g), indicating a very strong anisotropy. The azimuthal spin anisotropy is clearly related to the strong anisotropic T_z; that is, the quadrupolar spin distribution at the Cr site (Stöhr and König, 1995), which (van der Laan, 1998b) is extremely high compared to previously published experiments (Weller *et al.*, 1995) and theoretical predictions (Crocombette, Thole and Jollet, 1996). Applying the T_z sum rule the total isotropic spin of 1.2 μ_B has been determined and separated from the T_z

part. Figure 26(f) shows the corresponding orbital moment projections, where for E_1 a positive orbital (along the c axis) moment with a strong azimuthal variation, and for the broad part at E_2 a negative contribution with a reduced azimuthal variation are observed. The total orbital moment is negative and maximum along the a axis and a minimum along the c axis.

According to Hund's rules an antiparallel coupling of spin and orbital moments is expected (Ashcroft and Mermin, 1976; Kittel, 1976), which is consistent to the total observed orbital moment, but the total orbital moment has its maximum along the hard axis direction, which is in contradiction to the simple Bruno model. As we have shown, a large T_z term is present for CrO_2 which is included in the MAE model of van der Laan (1998a).

The microscopic moments can be used to test the anisotropy formula of van der Laan. The total orbital change by a rotation of 90° is $\Delta \langle L_z \rangle = (0.065 \pm 0.005)\,\mu_B$, a total dipole term part of $\langle 7T_z \rangle = -3$ and a spin moment of $\langle S_z \rangle = 2.4$ [14]. From the LSDA $+U$ calculation (Korotin, Anisimov, Khomskii and Sawatzky, 1998), an averaged exchange energy of 3 eV is extracted. From the *in situ* XMCD- and superconducting quantum interference device (SQUID)-derived hysteresis curves, a uniaxial anisotropy energy $K_1 = (5.8 \pm 0.5) \cdot 10^4 \mathrm{J\,m^{-3}}$ has been derived.

If we neglect the squared diagonal spin-orbit interaction and take into account the completely empty minority band, the van der Laan formula reduces to $\delta E \approx \frac{\xi}{4} \cdot \hat{S} \cdot \langle \mathbf{L}^{\uparrow} \rangle + \frac{\xi^2}{\Delta E_{ex}} \frac{21}{2} \cdot \hat{S} \cdot \langle \mathbf{T} \rangle$. With the above values the correct correspondence between the macroscopic anisotropy energy K_1 and the microscopic formula is obtained using a spin-orbit coupling energy of $\xi = 14\mathrm{meV}$ [15].

The orbital term favors an a–a plane easy axis behavior, directly observable from the enhanced orbital moment projection, while the dipole term T_z favors the c axis. Both MAE contributions nearly cancel each other, but the dipole term dominates. This is a possible explanation for the observed reorientation transition for ultra thin CrO_2 films (Li, Gupta and Xiao, 1999), which could be interpreted by lattice mismatch-induced changes in the delicate balance between orbital projections and the magnetic dipole term.

3.5 K-edge XMCD

In the K-edge absorption process the initial $1s_{1/2}$ photoelectron populates a final p-like state, which plays a minor role in magnetism in 3d elements. Following the sum rule it is expected that the XMCD effect is only sensitive to the p-projected orbital polarization, which, on the other hand, is generally rather small due to the quenching mechanism. Thus the fascinating possibilities arising from the direct application of sum rules on $L_{2,3}$-XMCD spectra of 3d-transition elements will not be touched by K-XMCD.

From an experimental point of view, the K edges of the 3d elements are energetically located in the hard X-ray range. Thus a large variety of bulk systems and related magnetic problems can be addressed, where soft XMCD studies suffer from the strong surface sensitivity. For example, important classes of materials in magnetism are 3d RE compounds, which exhibit strong surface oxide contamination and can often hardly be addressed by soft XMCD at the 3d L edges or 4f $M_{4,5}$ edges, 3d K edges. Using hard X rays for these systems parallel measurements of the 3d K edges in combination with RE $L_{2,3}$ edges can give interesting complementary information. The simple sample handling and high penetration depth in combination with the highly achievable accuracy allows, in some cases, to monitor changes in the local magnetic properties with external sample conditions such as temperature, external fields, and pressure. Thus, the K-edge XMCD signal can provide information on even small changes in the magnetic orientation of the absorbing atom.

Furthermore, although no direct relation of the K-XMCD and its strength to the local magnetic moment is easily accessible, (Stähler, Schütz and Ebert, 1993) the fine structure which often provides significantly more pronounced characteristics compared to the broad near-edge profile itself, can play the role of a fingerprint of the chemical state. As an example, studies of the Fe K-edge profile in Tb/Fe multilayers are shown in Figure 27 in comparison with the corresponding signal in the pure metal and the binary compound $TbFe_2$. The multilayer XMCD profiles can easily be explained by a mixture of both components (Attenkofer *et al*., 1993) giving interesting insight into the chemical state of the interfaces. An accuracy of 10^{-5} can be achieved and a large number of K-edge XMCD studies have been reported in a variety of 3d TM systems.

Recently, the corresponding signals at the oxygen K edge have gained considerable interest since, at the moment, no other method is able to address the problem of oxygen polarization. As observed in CrO_2 (Goering *et al*., 2002b) large dichroic oxygen K-edge contributions, with a strength up to several percent (Figure 28), are observed, where oxygen has been normally considered to be a nonmagnetic component. Although the understanding of this phenomenon and its quantitative relation to the local magnetic moment is still complicated, it is expected to serve as proof of a significant magnetic polarization at the oxygen site. Systematic comparison of the oxygen K-XMCD signal in different systems might provide some information about the existence of oxygen polarization. A unique possibility arises by studying the hysteresis loop at the oxygen site as shown in the insert of Figure 28. Often

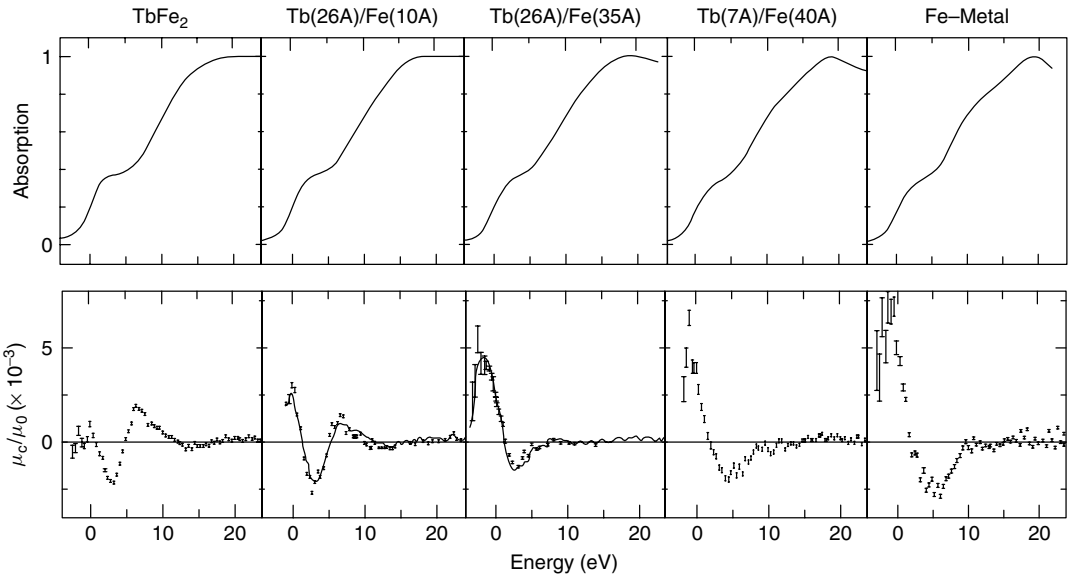

Figure 27. Normalized Fe K-edge XMCD signal of TbFe Multilayers in comparison with the XMCD profile in pure Fe and the binary compound $TbFe_2$. The solid line in lower part of the second and third panel correspond to the modeling of the K-XMCD spectra by an admixture of Fe- and TbFe2-like components in the Fe layer.

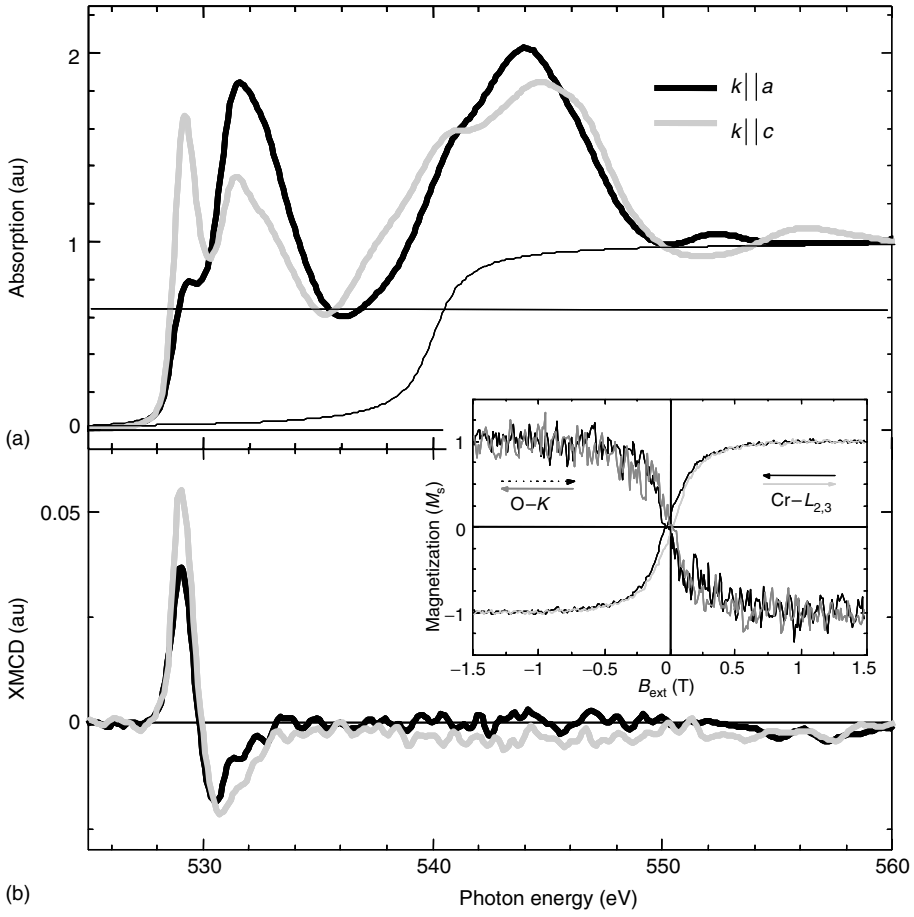

Figure 28. (a) Oxygen K-edge absorption spectra for different crystal orientations. (b) Corresponding dichroic XMCD signal. Inset shows the element specific magnetization curves.

the oxygen K-edge XMCD and the deduced orbital moments are too large compared to the theoretical expected value, a phenomenon which has not yet been understood. Very recently oxygen K-XMCD studies have been addressed to oxide interlayer (Bowen *et al*., 2006). Owing to the absence of a corresponding signal in $Co/Al_2O_3/Co$ and Fe/MgO/Fe tunnel magneto resistance systems with an upper limit of $0.05\,\mu_B$ have been deduced by comparison with the results in $La_{0.7}Sr_{0.3}MnO_3$, where a dichroic O–K edge signal of 1.6% has been associated with a calculated moment of $0.08\,\mu_B$ (Pellegrin *et al*., 1997). This finding is in striking contradiction to the predicted value ranging from 0.07 to $0.2\,\mu_B$. (Bowen *et al*., 2006) since a significant spin moment is present in systems with vanishing or nearly quenched orbital polarization as in cubic systems. In general, the integration of the oxygen XMCD in terms of local moment is doubtful.

3.6 Limits of the sum rules for $L_{2,3}$ edges in rare-earth metals

As demonstrated in Figures 9, 12, and 29 at the $L_{2,3}$ edges in RE metals significant XMCD signals can also be observed. For example in Gd metal, as drawn in Figure 29, the $L_{2,3}$-edges XMCD ratio is -0.87 and close to the value of -1 for spin-only systems, as expected from the sum rules. The deviation suggests the presence of a small orbital contribution in the 5d states, which couple antiparallel to the spin. If one compares the $L_{2,3}$ XMCD signal of Gd metal with the corresponding dichroic profile in iron metal, as shown in Figure 29(b) an opposite sign can be found for both edges. This is in striking contradiction to the experimental macroscopic measurements and theoretical expectations indicating and predicting for Gd a spin moment of $0.47\,\mu_B$ and only a small negative orbital contribution of $-0.05\,\mu_B$ (Sticht and Kübler, 1985). This manifests the 'positive' breakdown of the sum rules for the $L_{2,3}$ edges in RE metals. But on the basis of various *ab initio* theories, it is possible to provide a satisfying description of the XMCD spectra. Theoretical *ab initio* investigations are based either on linearized band structure methods (Carra *et al*., 1991) or on multiple scattering theory (Ankudinov and Rehr, 1995; Ebert, Schütz and Temmerman, 1990) and achieved a good qualitative and quantitative agreement with the experimental findings. The theoretical spectra presented here have been obtained, analogous to those in Ebert (2000b) using a spin-polarized fully relativistic implementation of the Korringa–Kohn–Rostoker Green's function method (Ebert, 2000b). Another complication arises in the case of the RE metals where the $2p \rightarrow 5d$ transition can be superimposed by quadrupolar $2p \rightarrow 4f$ transitions. In Figure 30, the experimental Tb and theoretical $L_{2,3}$-XMCD spectra are shown, proving that these $E2$ transitions can also be treated properly on a theoretical basis (Wende *et al*., 2002). Details of the calculations illuminate furthermore that the spin dependence of the radial matrix elements in these elements accounts for the failure of the sum rules. It has been demonstrated that a proper generalization of the sum rules, taking

this phenomenon into account, allows their application without a change of the sum rules in form or nature (Wende *et al.*, 2002).

4 XMCD-RELATED TECHNIQUES

4.1 Magnetic EXAFS

4.1.1 Experimental aspects

In an energy range of approximately 30 eV to 2 keV above an absorption edge in solid materials, the absorption coefficient exhibits an oscillating contribution. These oscillating structures, called *extended absorption fine structures* (*EXAFS*), show a decaying amplitude as a function of distance to the absorption edge and provide a strength of roughly 10% to the absorption jump height.

The oscillations $\chi(E) = \frac{\mu(E)-\mu_0(E)}{\Delta\mu_0}$ are extracted from the absorption $\mu(E)$ by the subtraction of the atomic-like smooth background $\mu_o(E)$ and normalization to the absorption jump $\Delta\mu_0$. This oscillating absorption is discussed here as a function of the photoelectron wave vector $k = \frac{1}{\hbar}\sqrt{2m(E-E_0)}$, where E_0 denotes the absorption threshold energy and m the electron mass. Viewing Figure 29, the energy range from about 7 to 8.5 keV covering all three Gd metal L absorption edges, it is evident that also an extended X-ray fine structure circular magnetic dichroic contribution is present. In contrast, the conventional corresponding MEXAFS can be detected directly by the circular magnetic absorption difference for reversed sample magnetization, $\chi(E) = \mu^+(E) - \mu^-(E)$ similar to the XMCD effect. In Figure 31, these magnetic oscillations are compared with Gd metal $L_{2,3}$ edges renormalized to each other by a factor 2. These structures appear to be nearly identical, except in the region of about 150 eV, that is, the range where multielectron effects are involved and significant differences from this relation are observed. These contributions result from the complex excitation from an additional 4d $\rightarrow$ 4f electron excitation channel, which is relatively weak but exhibits a large spin dependence since the fully polarized 4f-final state is involved in these magnetic multielectron excitations (MMEE) (Dartyge *et al.*, 1992).

In the meantime, it has been manifested by several MEXAFS studies that their occurrence is a universal effect, which exists even for absorbing atoms with vanishing magnetic moments. In Figure 32, the La L_3 edge in the ferromagnetic perovskite $La_{0.7}Ca_{0.3}MnO_3$ is shown (from Weigand, 2003). Here, the near-edge XMCD can be interpreted in terms of sum rules indicating the existence of a nearly vanishing spin and orbital moment of $m_S \sim +0.043\,\mu_B$ and $m_L \sim +0.003\,\mu_B$ of the La component, which is two orders smaller than the Mn moments of $3.4\,\mu_B$. Taking into account the scaling factor 2, the comparison of the corresponding MEXAFS $L_{2,3}$ edges proves that they are nearly identical within the statistical accuracy achievable today for the MEXAFS investigations in the hard X-ray range. It is evident that for the absorbing La atoms without a 4f occupation, as expected, no MMEE occurs.

As already observed in the first observation of the XMCD at the Fe K edges an extension of the magnetic effects toward the EXAFS range has also been indicated as seen in Figure 8 which is nearly of the same amplitude as the magnetic XANES. Another example for K-edge MEXAFS is given for Co metal in Figure 33 and is more than one order of magnitude smaller than the MEXAFS at $L_{2,3}$ edges. The magnetic part contributes only by less than 1% to the spin-averaged oscillation. Also, here MMEE contributions disturb the oscillating behavior in the

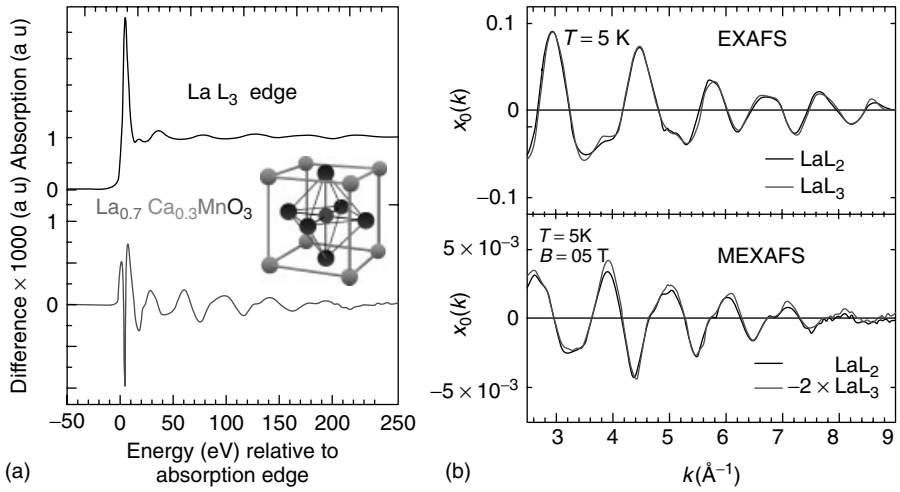

Figure 32. (a) Absorption and XMCD signal taken at the La L_3 edge in the ferromagnetic perovskite $La_{0.7}$ $Ca_{0.3}MnO_3$, (b) La L-EXAFS oscillation $\chi_0(k)$ and corresponding magnetic contributions $\chi_c(k)$ as function of the photoelectron k-number. By rescaling the L_3 MEXAFS by a factor -2 the MEXAFS at both edges are identical.

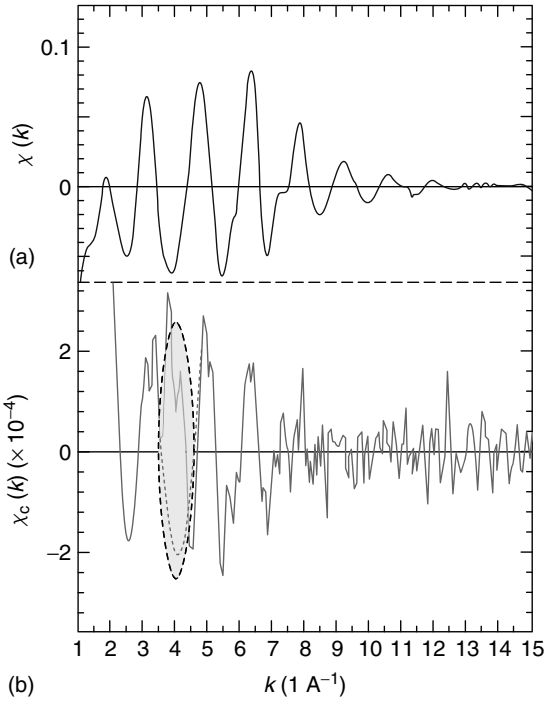

Figure 33. EXAFS (a) and MEXAFS (b) at the Co K edge in fcc Co metal. The shaded area corresponds to the expected energetical position of the 1s3p–4p3d multielectron excitations.

energy range of the 3p binding energy 60 eV, which indicates the occurrence of a strongly spin-dependent additional 3p–3d transition. As generally observed in K-edge MEXAFS a high-frequency fine structure seems to be superimposed to the broader oscillation correlated with conventional EXAFS.

Following the scenario described above one would expect much stronger MEXAFS at the $L_{2,3}$ edges of the 3d transition elements. However, serious complications result from the L_2–L_3-edge overlap of only 10–20 eV spin-orbit split edges, which is just in the order of a typical next neighbor distance-related (0.2–0.4 nm) half-wavelength. Figure 34 shows the experimental results of MEXAFS studies at the $L_{2,3}$ edges in a 30 ML Fe film on Cu(001) taken from Lemke *et al*. (1998),

where the MEXAFS oscillation can be clearly monitored with a relative amplitude of about 3% owing to a partially constructive overlap.

4.1.2 Theoretical description and data analysis

As already suggested by Kronig in 1932, who related the EXAFS to an influence of the next neighbors, and since the breakthrough by Sayers, Lytle and Stern (1970) and Sayers, Stern and Lytle (1971) the EXAFS are a powerful structural tool to study short-range order in an element-specific manner. The EXAFS have been described as an interfering sum of backscattered electron contributions from the next coordination shells j with N_j atoms at the distance r_j, which are smeared locally out by the Debye–Waller factor $\exp(2\sigma_{\mathrm{j}}(\mathrm{k})\mathrm{k}^2)$. These three parameters depend on the local structure of the system. The influence of the emitting atom itself is taken into account by the factor $S_i(k)$

$$\chi(k) = -\sum_j N_j S_i(k) F_j(k)\, \mathrm{e}^{-2\sigma_j^2(k)k^2}\, \mathrm{e}^{-2r_j/\lambda_j(k)} \times \frac{\sin\left(2kr_j + \Phi_{ij}(k)\right)}{kr_j^2} \qquad (19)$$

The electron–electron interaction is introduced by the elastic backscattering amplitude $F_{\mathrm{j}}(k)$, the inelastic mean free path $\lambda_{\mathrm{j}}(k)$ and the phase shifts Φ_{ij} acting on the electron waves.

Following the explanation of the XMCD in the XANES by the simple two-step model in the case of a right (left) circular polarized photon the outgoing photoelectron wave is spin polarized; therefore, one has to distinguish between 'singlet' and 'triplet' scattering indicated in Figure 35. A dependence of the interaction parameter on the relative spin orientation of the magnetic electrons of a neighboring atom polarized in photon beam direction can be introduced in a most simple manner by $F^{\pm}(k) = F_0(k) \pm \sigma_z F_{\mathrm{C}}(k)$ for the elastic backscattering amplitude and

$\Phi^{\pm}(k) = \Phi_0(k) \pm \sigma_z \Phi_{\mathrm{C}}(k)$for the phase shifts, while the inelastic scattering of the spin-dependent effects are of minor importance and can be neglected. Hereby – similar to the description of the spin-dependent Compton scattering – an additive spin-dependent part has been introduced which scales with the photoelectron polarization. Although this picture is very simple, it easily explains the ratio of 2 of the MEXAFS amplitude, which is observed at the L_3 and L_2 edges in magnetic systems.

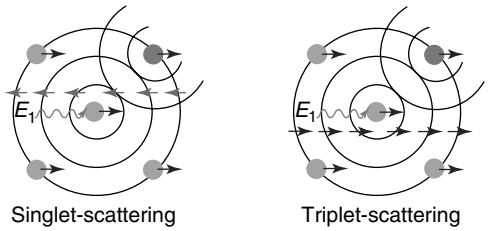

Figure 35. Two-step model of the magnetic EXAFS.

Another similar approach is the ansatz with an energy shift (Wende, 2004). More sophisticated theoretical treatments based on *ab initio* theories have been developed to describe successfully the MEXAFS (Ebert, 2000a).

Following the simple two-step model it is expected that only neighboring atoms account for the occurrence of dichroic signals in the EXAFS oscillations. This can be proved straightforwardly by an analysis of the MEXAFS by a Fourier transform (FT) of the conventional spin-averaged oscillations.

Taking the example shown in Figure 32 into consideration and following the EXAFS formula, the FT of $\chi(k)$ at the La $L_{2,3}$ edges will predominantly appear at distances given by the next neighbor coordination shell, which is slightly modified by the presence of the corresponding phase shift. The strengths of the lines are proportional to the number of atoms at these distances. As a typical result the FT($\chi(k)$) of the example given above is shown in the left panel of Figure 36 where the next neighboring oxygen, manganese, and La/Ca neighbors are clearly visible. In the FT of the corresponding $\chi_{\mathrm{C}}(k)$ spectrum only the line of the next magnetic Mn atoms appears, proving unambiguously that the spin-dependent contribution results only from backscattering

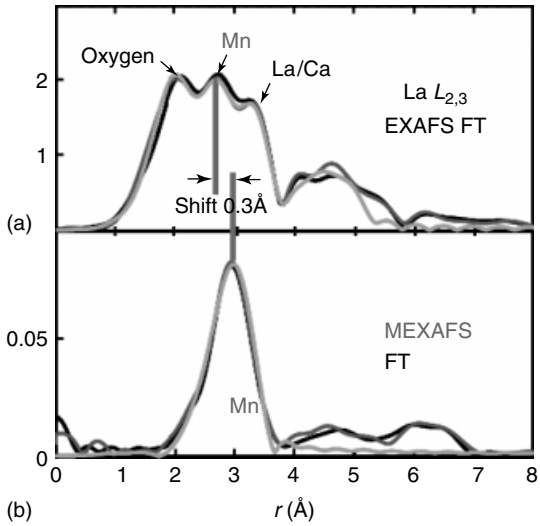

Figure 36. Fourier Transform FT(χ_0(k)) (a) and FT(χ_0(k)) of the La L_2- edges (black) and L_3-edges rescaled by a factor 2 (gray) in comparison with the theoretical spectra calculated with the FEEF8.2 program modified following the equation.

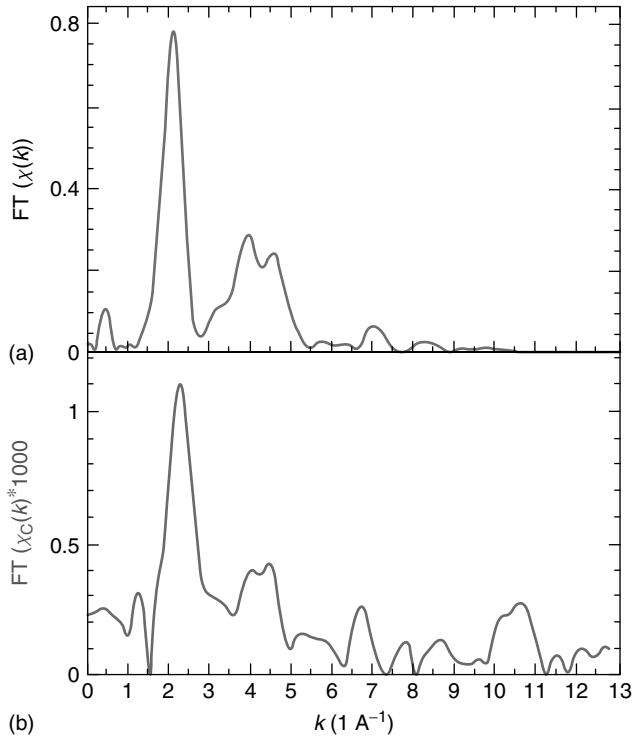

Figure 37. Fourier Transform FT($\chi_0(k)$) (a) and FT($\chi_0(k)$) of the EXAFS and MEXAFS shown in Figure 32.

from the magnetic neighbors. This proves that the MEXAFS is an appropriate method to probe the magnetic short-range order even for nonmagnetic absorbing atoms as the La component in this perovskite. It has been verified in ferrimagnetic iron garnets that the phases in the FT help to distinguish between ferro- and antiferromagnetic coupling of the corresponding sublattices.

On all the sample studies up to now, we found an interesting correlation of the relative strength of the MEXAFS: A rescaling of the ratio maxFT($\chi_C(k)$)/maxFT($\chi(k)$) by the spin polarization of the outgoing photoelectron wave and the magnetic spin moment of the next nearest neighbor in units of Bohr magnetrons seems to be a constant value, indicating a spin-dependent contribution to the backscattering amplitude of 2–3% per spin-polarized electron in the atomic shells of the next neighbors (Figure 37).

Significant effects at the K edge are observed in the MEXAFS as shown in Figure 8 and also at the Co K edge in Figure 33, as expected from the sum rules only the orbital polarization can be addressed. The FT for this pure metal provides the same local information in the spin-averaged and spin-dependent case, but a significant enhancement of the multiple scattering paths is observed. This might be correlated to an increase of the spin polarization of the outgoing photoelectron wave due to the presence of the spin-dependent elastic scattering if the electron is scattered several times.

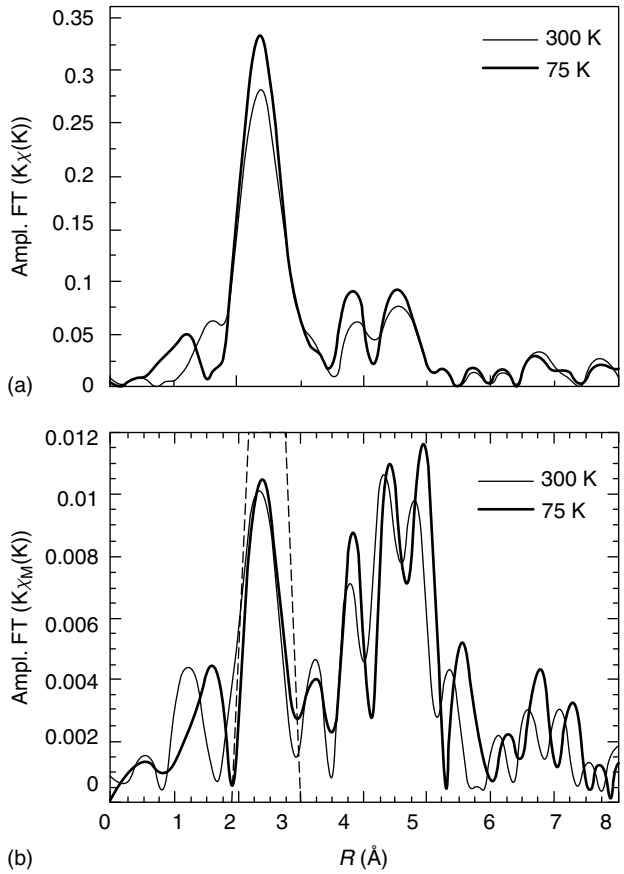

Figure 38. Fourier Transform FT($\chi_0(k)$) (a) and FT($\chi_0(k)$) of the EXAFS and MEXAFS shown in Figure 34. (Reproduced from Lemke *et al*. (1998) *J. of Physics: Condensed Matter* **10**, 1917–1930.)

This phenomenon is prominent at the K edges, where the starting spin polarization is expected to be induced by spin-orbit effects and in the order of only 1%. A more detailed systematic investigation of the MEXAFS may well provide a new direct possibility to study spin–spin interaction of hot electrons with kinetic energies up to several 100 eV. Similar behavior is indicated in the FT of the MEXAFS at the Fe $L_{2,3}$ edges of metallic Fe (Figure 38). Besides the influence of multiple scattering paths, the overlap of the L_2 and L_3 MEXAFS result in additional, obviously unphysical, line features. This demonstrates the general difficulty in analyzing 3d L-MEXAFS in terms of investigating short-range magnet orders.

4.2 Magnetic reflectometry

4.2.1 General aspects

Since the discoveries of Max von Laue and Luis Néel, the use of X-ray scattering for the structural analysis of

condensed matter is well known and highly established. Hereby the momentum transfer in the scattering process provides structural information along its direction.

One special case of structural determination is the investigation of ultrathin films in the thickness range of several monolayers of atoms at relative small momentum transfer ranges by reflectometry, providing information of film thickness and interfacial properties like roughness. For the X-ray scattering processes resulting in the presence of the cross section σ_{coh} drawn in Figure 5 the basic interaction is described by the scattering amplitude f_0 by $\sigma_{\mathrm{coh}}(E) = \int |f_0(E,\theta)|^2 \,\mathrm{d}\Omega$, where θ is the scattering angle as introduced in Figure 4(b).

In the vicinity of an absorption edge additional dispersive (f') and absorptive (f'') scattering factors occur to the elastic scattering amplitude $f(E) = f_0 + f' + f''$, which are related to each other by Kramers–Kronig relations (Hoyt, Warburton and de Fontaine, 1984; Neumann *et al.*, 1998).

$$f'(E) = \frac{2E_0}{\pi} \oint \frac{f''(E)}{E_0^2 - E^2} \mathrm{d}E \tag{20}$$

Following the optical theorem, the absorptive scattering amplitude is directly correlated to the absorption cross section by $\mu_{\mathrm{abs}}(E) = \rho_{\mathrm{a}} 2 r_0 \lambda f''(E)$. This close relationship is explained in Figure 39 where the left part illustrates the absorption process and the right part symbolizes the resonant scattering process into a single intermediate state and results in the emission of an elastically scattered photon with the same energy.

At a circular dichroic active absorption edge – in analogy to the XMCD contributions – a magnetic scattering factor has to be taken into account as expressed in the pioneering work of Hannon, Trammell, Blume and Gibbs (1988)

$$f(q,E) = \underbrace{-\left(\vec{e}_f^{\,*} \cdot \vec{e}_i\right) \cdot \left[f_0 + f'(E) + f''(E)\right]}_{\text{Nonmagnetic Colomb Part}} + \underbrace{i\left(\vec{e}_f^{\,*} \times \vec{e}_i\right) \cdot \vec{b} \cdot \left[m'(E) + i m''(E)\right]}_{\text{Magnetic Part}} + \cdots \tag{21}$$

where $\boldsymbol{q}$ is the scattering vector, $\vec{e}_i$ and $\vec{e}_f$ are the complex polarization vectors of the incident and scattered beam, $\vec{b}$ is the unit vector of the magnetization. The residual resonant scattering amplitude is separated in a charge and magnetic term with different dependencies of the polarization vectors. The complex amplitude of the magnetic term with dispersive part m' and absorptive part m'' changes its sign by reversal of the external magnetic field. The absorptive contribution to the magnetic scattering amplitude is usually derived by XMCD experiments, similar to the dispersive time-even part $f'(E)$ and time-odd part $m'(E)$ of the scattering factor, which are deduced by Kramers–Kronig relations equal to equation (20)

$$m'(E) = \frac{2E_0}{\pi} \oint \frac{m''(E)}{E_0^2 - E^2} \mathrm{d}E \tag{22}$$

To give an example of this procedure, the charge and magnetic scattering factors at the Pt L_3 edge of a $Pt_{20}Fe_{80}$

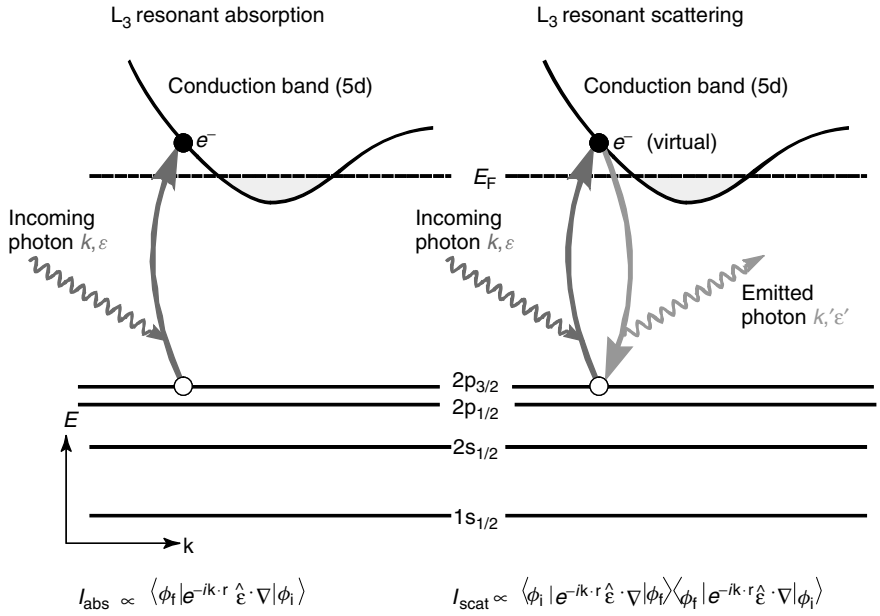

Figure 39. Physical process of the excitation of an inner shell $2p_{3/2}$ electron to a 5d unoccupied conduction band (left side) in comparison with the resonant scattering event.

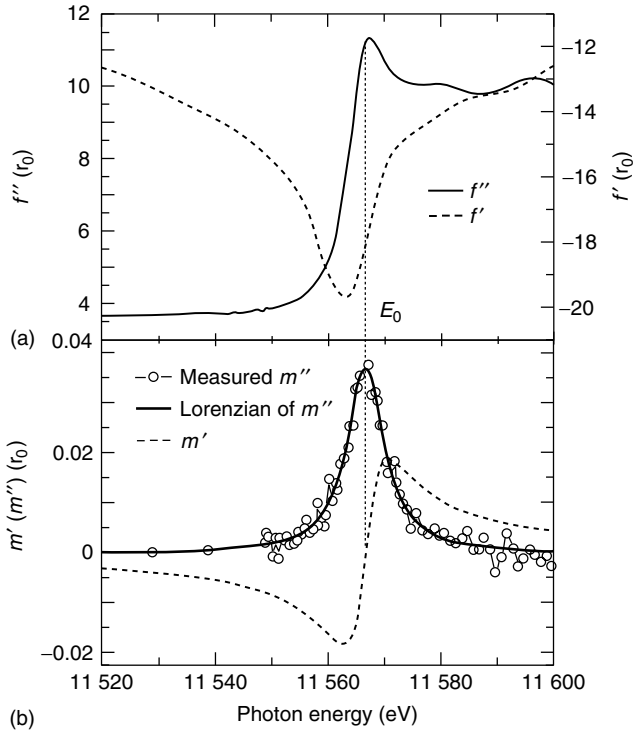

Figure 40. (a) Dispersive f' and imaginary part f'' in the vicinity of the Pt L_3 edge in a $Pt_{20}Fe_{80}$ alloy and (b) the corresponding magnetic contribution m' and m''. (Reproduced from Geissler *et al.* (2002) *Zeitschrift für Metallkunde* **93**, 946–952.)

and the Co $L_{2,3}$ edges of Co metal sample are shown in Figures 40 and 41, respectively.

4.2.2 The description by the complex index of reflection

In grazing incidence conditions the momentum transfer $q_z = 2k_0 \sin\theta$ along the surface normal is small compared to reciprocal lattice vectors and the granular atomic structure of the material can be neglected, providing a description in a continuum approach. The interaction with electromagnetic waves is handled by a complex index of refraction $n = 1 - \delta + i\beta$, where the energy dependent optical constants δ and β are related to the complex scattering amplitude f_j of each site by the well-known optical theorem (Compton and Allison, 1935)

$$n = 1 - \delta + i\beta = 1 - \frac{r_0}{2\pi}\lambda^2 \sum n_j f_j \qquad (23)$$

where n_j is the number of atoms per unit volume, r_0 is the classical electron radius and λ is the wavelength of the incoming electromagnetic wave. Concerning the imaginary contributions a simple relation between β and the absorption coefficient is found by $\beta(E) = \frac{\mu(E)}{4\pi}\lambda$. The reflectivity R_i of each single interface is calculated by the well-known Fresnel equations (Jackson, 1975) for reflection of s- and p-polarized electromagnetic plane waves. This is schematically shown in Figure 42 for a multilayer system. These angular dependent reflectivity spectra are evaluated by the well-known Parratt algorithm (Parratt, 1954), which could be handled even for structures consisting of a sequence of layered media with different indices of refraction

$$R_i = \frac{R_{\mathrm{t,i}} + R_{\mathrm{b,i}} \exp(2i\varphi)}{1 + R_{\mathrm{t,i}} R_{\mathrm{b,i}} \exp(2i\varphi)} \qquad (24)$$

Hereby $R_{\mathrm{t,\,i}}$ and $R_{\mathrm{b,\,i}}$ are the Fresnel reflection amplitudes at the top and bottom surface of the layer i. For rough interfaces, these coefficients must be modified by an exponential damping factor (Névot and Croce, 1980; Holy *et al.*, 1993; Holý, Pietsch and Baumbach, 1999; Sinha, Sirota, Garoff and Stanley, 1988),

$$R_{i\to j}^{\mathrm{rough}} = R_{i\to j}^{\mathrm{flat}} e^{-q_{z,i} q_{z,i+1} \sigma^2} \qquad (25)$$

where $R_{i\to j}$ means the Fresnel coefficient for reflection from the interface and the related transition of light from medium i to j. $q_{z,i}$ and $q_{z,i+1}$ are the components of the complex wave vectors in medium i and $i+1$ perpendicular to the interface.

The phase difference $\varphi = 2\pi / d_i n_i \lambda \sin\theta_i$ is responsible for the interference patterns in the reflectivity curves, containing the thickness d_i and the index of refraction n_i. In an angle dispersive setup, the intensity maxima appear whenever $\exp(2i\varphi) = 1$, which is analogous to the Bragg equation modified by the influence of refraction. All scattered light intensities and phase differences are taken into account, which are essential for a high qualitative and quantitative simulation of experimental data.

Surface imperfections yield to a decrease in reflectivity and an increase of diffuse scattered light. Stearns (1989) has shown that in the case of a smooth or nonabrupt change in the index of refraction, which can be described by an interface profile function $p(z)$, the resultant loss in specula reflectance can be approximated by a simple multiplication of the Fresnel coefficients by the FT $\tilde{w}(q_z)$ of the function $w(z) = \mathrm{d}p/\mathrm{d}z$. Assuming a Gaussian distribution of the atoms of two layers at the interface, corresponding to an error function as $p(z)$, the mean vertical roughness or interdiffusion or a combination of the two cases can be described by the quantity σ, the root mean square (rms) roughness.

Reflectometry at thin layered systems yields to information about layer thickness and interface roughness due to the above mentioned interference phenomena of the reflected intensity at each interface (Holy *et al.*, 1993; Sinha, Sirota, Garoff and Stanley, 1988). Hereby the maxima and minima

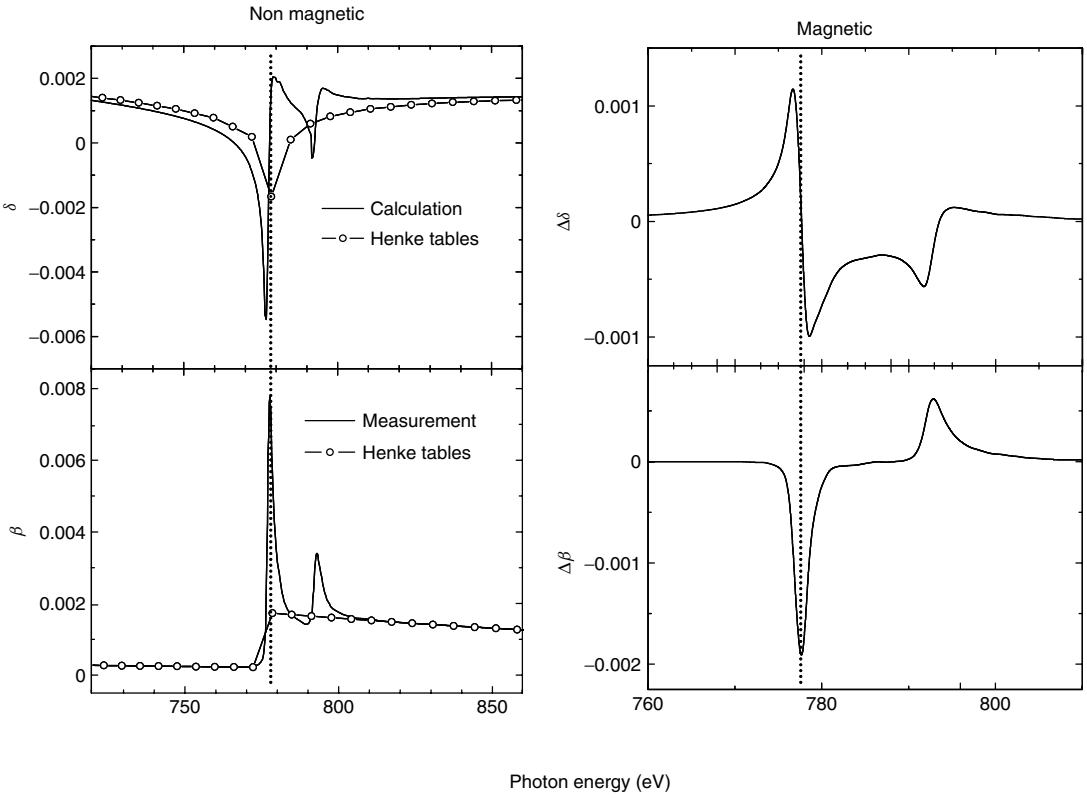

Figure 41. The nonmagnetic and magnetic energy dependent parts of the complex index of refraction. The nonmagnetic (magnetic) absorptive parts are based on corresponding XAS (XMCD) measurements, which have been scaled to nonresonant tabulated values (Henke table). The dispersive parts are calculated by Kramers–Kronig calculation, discussed in chapter.

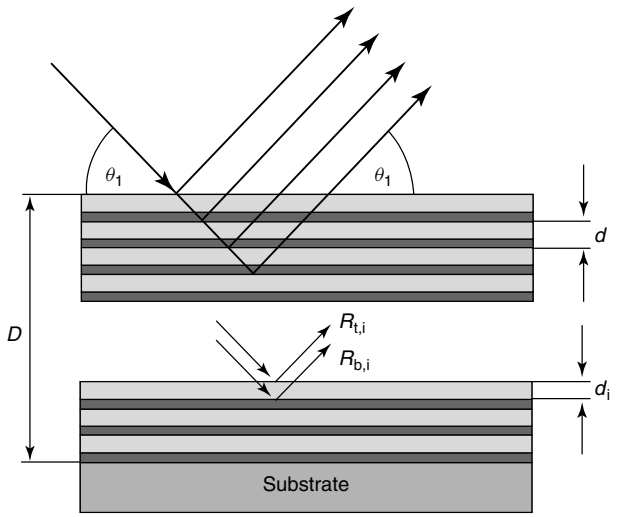

Figure 42. Schematic X-ray reflection in a multilayer structure. (Reproduced from Geissler *et al*. (2002) *Zeitschrift für Metallkunde* **93**, 946–952.)

in the reflectivity curve are caused by the interference of the waves reflected from the upper and lower interfaces of a thin film.

4.2.3 Magnetic reflectometry in multilayers

Multilayer systems provide Bragg peaks related to the superstructure of the multilayer (Ferrer *et al*., 1997) containing information of layer-averaged properties, for example, depth profiles of one component of the whole multilayer system (Jaouen *et al*., 2000; Seve *et al*., 1999; Tonnerre *et al*., 1995). Figure 43 shows the experimental nonmagnetic resonant reflectivity curves of a Ce/Fe multilayer system reproduced from Seve *et al*. (1999), in combination with the simulated reflectance for a multilayer system. The Bragg reflections of the multilayer superstructure of the multilayers are directly observable.

The magnetization induced changes in the reflectivity are measured by the weighted reflectivity difference for reversed sample magnetization

$$A = \frac{R^+ - R^-}{R^+ + R^-} \tag{26}$$

The magnetic asymmetry ratios are also plotted as a function of photon energy (Figure 44), where the scattering angle has been chosen to be at various superstructure Bragg peaks, indicated by the diffraction order. Without

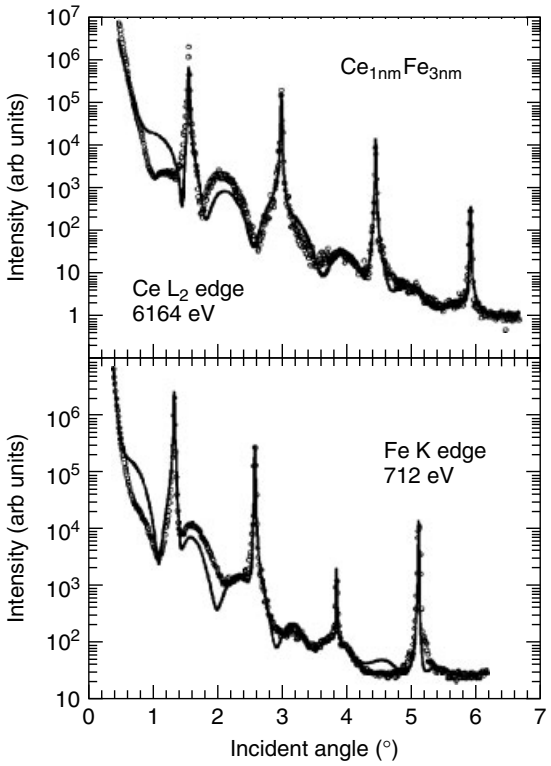

Figure 43. Resonant nonmagnetic reflection curves of a Ce–Fe multilayer system. Clear superstructure Bragg reflections are visible. The shift of the superstructure peaks reflects different the variation of the photon wavelength from the Fe K edge to the Ce L2 edge. (Reproduced from Seve *et al*. (1999) *Physical Review B* **60**, 9662–9674.)

going into details of the analysis, the chemical profile has been extracted from the nonmagnetic spectra, and magnetic counterpart from the magnetic asymmetry. Multilayer systems provide the unique opportunity to extract nonmagnetic and magnetic multilayer information in an analytical way (Seve *et al*., 1999; Tonnerre, 1997). Thus variations and their dependence on the distance of an individual layer from the substrate, important for components with large lattice mismatch, can hardly be addressed. Furthermore, diffuse X-ray resonant magnetic scattering (XRMS) in the soft X-ray region can be applied to investigate correlations between chemical and magnetic roughness in thin films and multilayers (MacKay, Teichert, Savage and Lagally, 1996; Osgood *et al*., 1999). Magnetic resonant reflectivity measurements in the soft X-ray region were performed (Kao *et al*., 1990, 1994; Sacchi and Mirone, 1998; Tonnerre *et al*., 1995, 1998) to measure the energy dependence of the reflected intensity for parallel and antiparallel alignment of the photon helicity and the direction of the magnetization.

4.2.4 Resonant magnetic reflectometry at single layers

Hard X rays

The experimental setup of the magnetic reflectivity experiment in specular geometry, where the incident and reflected intensity has been detected by ionization chambers, is shown in Figure 45. To simplify the analysis the energy of the scattering experiment has been adjusted to the Pt L_3 maximum of the absorptive part m'' where the dispersive part m' nearly vanishes, as shown in Figure 40 (marked with E_0). f'' and m$''$ were derived from the nonmagnetic and magnetic absorption profiles respectively, measured in a separate transmission experiment (Ruegg, Schütz, Fischer and Wienke, 1991). The structural profile information, that is, layer thickness and roughness, is derived by a nonresonant Cu K_α experiment by conventional Parratt simulation (Figure 45). Figure 46(a) shows the magnetic asymmetry and the result of simulations based on a technique called *multislicing* (Geissler *et al*., 2001): The reflectance of a rough interface was initially modeled by the reflectance of a sharp interface, damped by an exponential damping factor, and then approximated by a series of many virtual slices with no roughness in between, providing the same smooth distribution of the corresponding optical constants, which reflects the same optical and chemical profile. For the magnetic profile simulation the magnetic scattering part is added (subtracted) to the optical profile (determined by the chemical profile), providing two different reflectivities R^+ and R^-. Figure 46 shows the simulated magneto-optical profile and the corresponding magnetization per Pt atom. The magnetization per atom has been deduced from the normalization of the magneto-optical profile to the chemical profile, as shown in the inset of Figure 46(b) (Geissler *et al*., 2001; Geissler, Goering, Weigand and Schütz, 2002).

Since for hard X rays the typical scattering angle range is below 4°, the dipole scattering formula can be reduced by the small angle approximation to [16]

$$f_{\mathrm{res},\theta\approx 0}(E) = -r_0\left[\left(f_0 + f'(E) - if''(E)\right) + P_{\mathrm{C}}\left(m'(E) - im''(E)\right)\right] \qquad (27)$$

This provides a strongly reduced numerical effort, necessary for the reflectivity simulations. Since the magnetic effect is in the order of 4%, it does not provide a strong impact to the total reflectance. This conserves the general momentum transfer and the related interference conditions, and the magnetic asymmetry can be considered proportional to the magnetic moment.

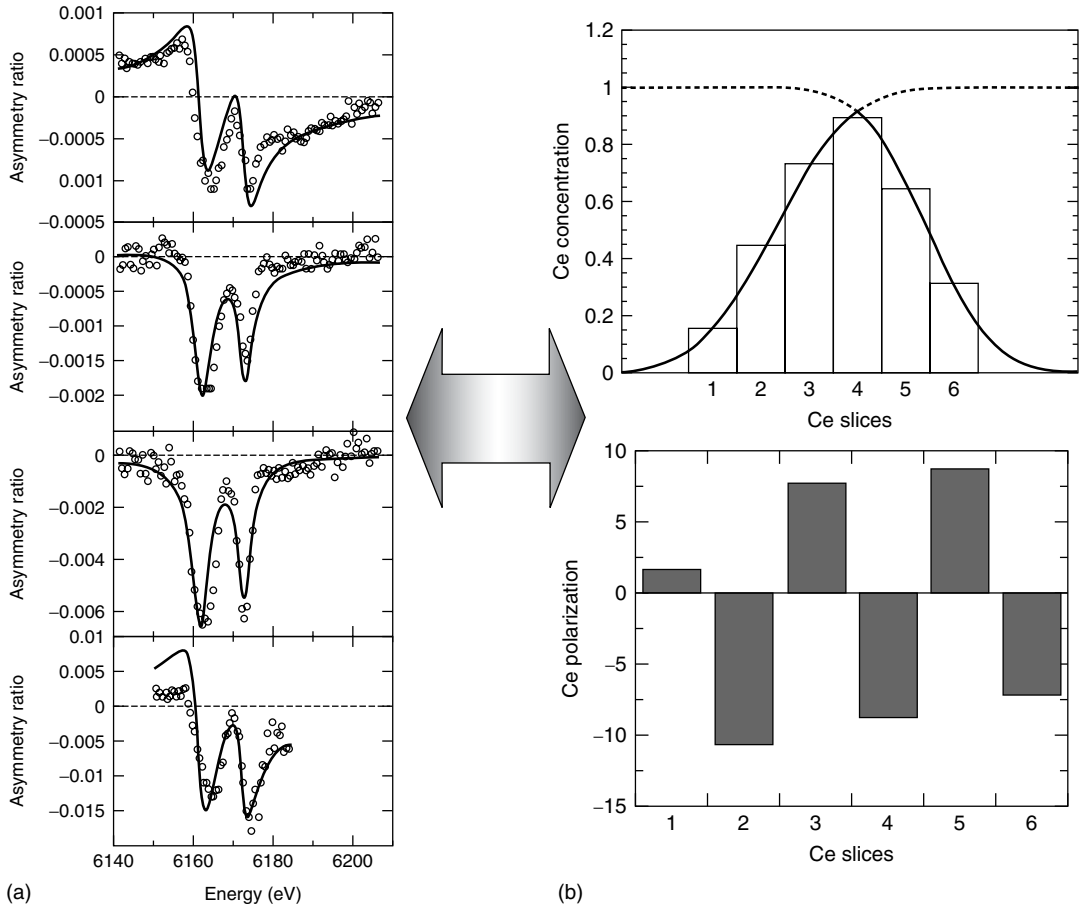

Figure 44. (a) The energy dependent asymmetry ratio measurement (circles) and simulation (line). (b) The upper curve shows the chemical profile, estimated from the nonmagnetic simulation shown in the previous figure. The lower part represents the Ce magnetic polarization, extracted from the asymmetry fit. (Reproduced from Seve *et al*. (1999) *Physical Review B* **60**, 9662–9674.)

Soft X rays

In this energy range, two major difficulties arise owing to the larger scattering range of about to 40–50° and very strong resonant nonmagnetic and magnetic absorption lines. The whole geometry of the magnetic scattering scenario, which is discussed here, is sketched in Figure 47. A typical experimental asymmetry, measured at the Co L_3 edge for the same PtCo sample, is shown in Figure 48 in comparison with the simulations, which provide a very good representation of the experimental data. The principle calculation method is quite comparable to the Pt spectra shown above, but owing to the large range of scattering angles a full treatment of the scalar and cross products of the incoming and scattered polarization vectors separated into σ and π channels is necessary

$$f_{\mathrm{E1},\sigma} = -r_0 \frac{\left(f_0 + f' - if''\right) \pm K \cdot \cos\theta \cdot M \cdot \left(m' - im''\right)}{\left(1 + K^2\right)^{1/2}} \qquad (28)$$

$$f_{\mathrm{E1},\pi} = -r_0 \frac{K \cdot \cos 2\theta \cdot \left(f_0 + f' - if''\right) \pm \cos\theta \cdot M \cdot \left(m' - im''\right)}{\left(1 + K^2\right)^{1/2}} \qquad (29)$$

The degree of circular polarization is described as $P_C = 2K/(1 + K^2)^{1/2}$, and the magnetic part of the scattering amplitude varies with the cosine of the angle of incidence. For the calculation of the asymmetry ratio the intensities of the σ and π components have been added in a kinematic approximation. This approximation breaks down at very small scattering angles owing to the enhanced influence of multiscattering processes. Nevertheless, for systems with a nonmagnetic protective top layer, the asymmetries are usually small at graving incidence conditions, where the interface of the nonmagnetic protective top layer to the vacuum dominates the reflection.

After determination of the resonant optical properties, as shown for the Co $L_{2,3}$ edges in Figure 41, the magnetic profile could be determined by the same general procedure used above, where the interface is artificially sliced into ultra

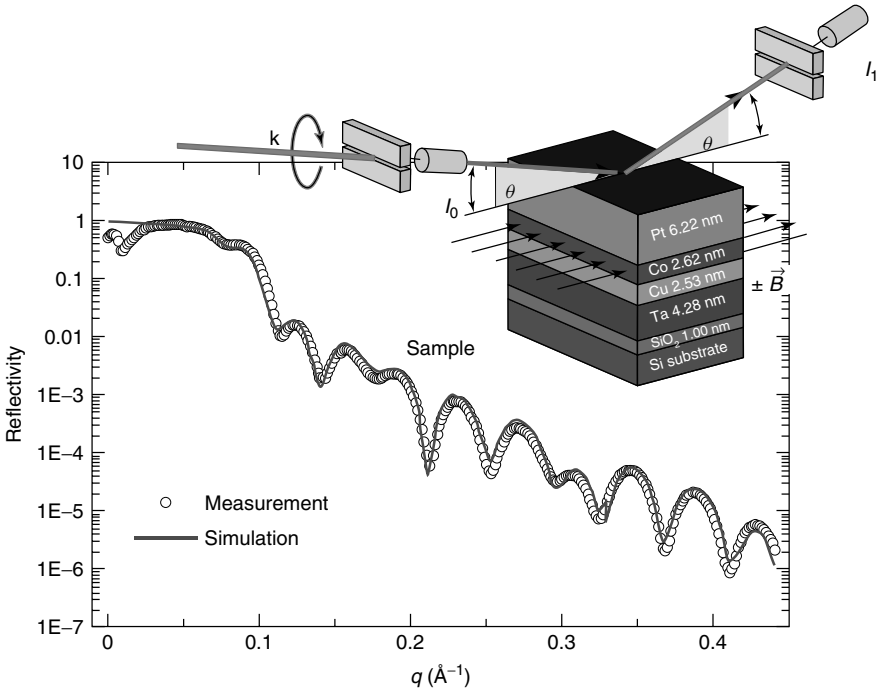

Figure 45. Experimental geometry of a reflection measurement for a Pt/Co/Cu-layered system and a nonresonant reflection curve, performed at the CuK_α energy.

thin layers. The nonmagnetic optical profile corresponds to the roughness determined chemical profile, convoluted with the optical constants as shown in Figure 49. The lighter gray part shows the resonant nonmagnetic absorption profile, clearly reflecting the increase inside the Co layer. For the magnetic simulation the darker gray part is added (as shown) and subtracted from the lighter gray curve, giving two magnetic reflectivity curves and the asymmetry. As for Pt, the element-specific Co magnetization profile could be extracted as shown in Figure 50, which compared to bulk Co is enhanced at the Pt site by a factor of 1.25 and reduced at the Cu site by a factor of 0.7. These results are in very good quantitative agreement with complementary experimental results for Co/Pt layers (Canedy, Li and Xiao, 2000; Nakajima *et al.*, 1998) and Co/Cu (Bland, Daboo, Patel and Fujimoto, 1998; Ney, Poulopoulos and Baberschke, 2001).

4.2.5 Restrictions and limits

- Since XRMS is a conventional scattering method and – in contrast to holography – the absolute phase information is lost, the result is not unambiguous. Thus, it is absolutely necessary to restrict the shape of the magnetization to intentionally reasonable and meaningful profiles.
- The determination of the optical constants and the corresponding energy calibration must be done very carefully. The best way is a simultaneous determination of the absorption coefficient at the same experimental station.
- Measurements at the energy of the maximum XMCD effect provide, in most cases, the opportunity for the magnetic dispersive part to nearly vanish (see Figure 41 for the optical Co profile). This reduces a possible error source from the determination of the dispersive part.
- The determination of the magnetic moment per atom needs the knowledge of the thickness dependent variation in the absorption which must be monitored by XAS/XMCD experiments. Auxiliary sources of information are usually theoretical investigations.
- As demonstrated for Magnetite (Goering, Gold, Lafkioti and Schuetz, 2006). Self-absorption, careful background approximation, long energy range measurements and calibration to the efficiency of the I_0 detector are all necessary to provide good estimates of the absolute resonant absorption coefficients.

4.3 Magnetic X-ray microscopy

4.3.1 General aspects

During the 1980s the availability of high-brilliance synchrotron sources and the fast development in nanotechnology

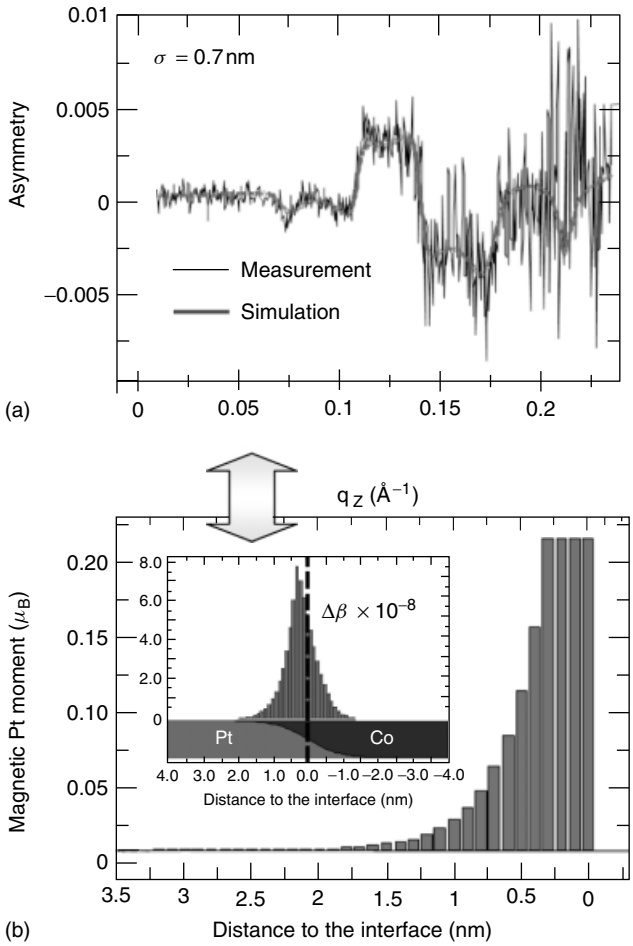

Figure 46. (a) Measured and simulated magnetic reflectivity. (b) Magnetic Pt moment per Pt atom. The inset shows the magneto-optical profile of Pt (slices). The roughness determined chemical profile is indicated by the gray and black shaded areas, shown at the bottom of the inset.

led to new powerful concepts using X rays for imaging of submicron structures by photoemission electron microscopy (PEEM), (Tonner and Harp, 1988) and Fresnel lens-based X-ray transmission microscopes (Attwood, 1999). More recently lensless coherent imaging techniques (Eisebitt *et al.*, 2004) were established.

The basic experimental set ups are sketched in Figure 51(a–d). Using XMCD as a magnetic contrast, all four types of methods can be used to image magnetic structures. Owing to the smaller wavelength of the X rays and the huge magnetic cross sections, especially for prominent absorption edges of the magnetically relevant elements, as shown in Section 2, these magnetic X-ray imaging techniques overcome the commonly used Kerr microscopes (Hubert and Schäfer, 1998) concerning image contrast and lateral resolution. These X-ray imaging techniques cannot provide atomic resolution in contrast to the spin-polarized scanning tunneling microscope (SP-STM) (Bode, 2003; Wachowiak *et al.*, 2002) and the magnetic force microscope (Martin and Wickramasinghe, 1987; Koblischka and Hartmann, 2003). However, the element specificity of magnetic X-ray imaging techniques and the direct correlation of the contrast to local magnetic spin and orbital moments make them unique tools for investigating magnetism of micro- and nanostructures. These systems are important subjects in solid state and material sciences as well as in data storage and sensor technologies.

The PEEM is sketched in Figure 51(a). Secondary electrons, which are commonly emitted after irradiation with monochromatic X rays from an undulator, are imaged by an electron microscope. The lateral resolution is determined by the electron optics and for magnetic applications is in

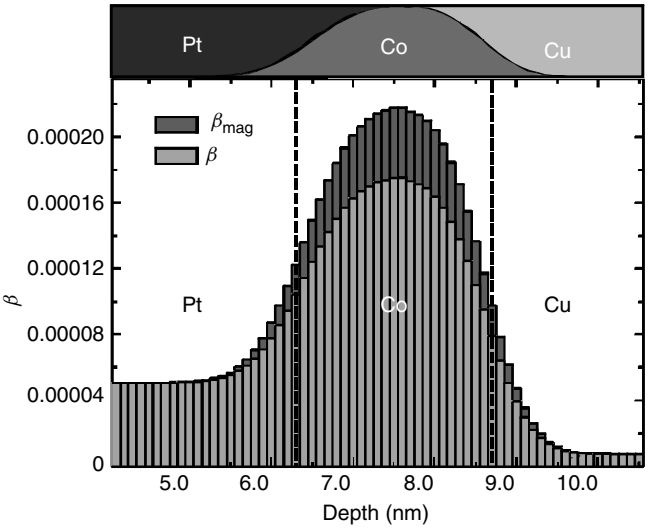

Figure 49. The determined absorptive nonmagnetic dark gray and magnetic light gray amplitudes at the CoPt interface are shown as a function of depth. The dashed lines indicate the average interface position, given by the nonmagnetic Parratt reflectivity simulation.

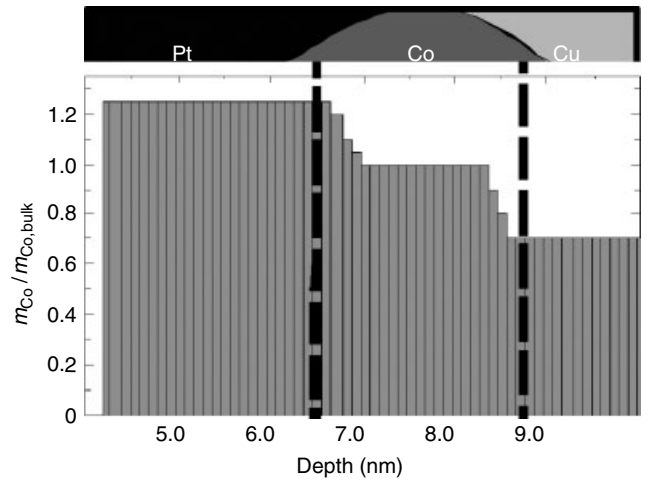

Figure 50. Determined magnetic moment per Co atom, derived from the normalization of the resonant magneto-optical profile by the chemical distribution shown above.

the order of 50–100 nm. Similar to the TEY detection mode for XMCD studies for soft X rays, described in Section 2, this method is inherently strong surface-sensitive to a few atomic layers with the advantage that nontransparent samples and very thin layers can be studied. Since low-energy electrons are involved in this photon-in/electron-out technique, the application of an external magnetic field in the XMCD/PEEM and the high voltage present at the sample, introduce experimental difficulties.

In X-ray microscopy techniques where only photons are involved, Fresnel zone plates (Attwood, 1999) are used as optical elements and the magnetic field is not modifying the image. Both types of microscopes operate in the transmission mode: a full-field X-ray microscope (Figure 51b) and a scanning transmission X-ray microscope (STXM, Figure 51c). The lateral resolution is determined by the width of the outermost ring of the zone plate and is in the order of about 25 nm (record 15 nm (Chao *et al*., 2005)) limited by current electron-beam lithography techniques. Both types of microscopes image the structures of samples with thicknesses in the order of some 100 nm deposited on transparent substrates as Si_3N_4 or on grids as used for transmission electron microscopy. Since the focal length of the Fresnel lenses is proportional to the photon energy for full-field microscopy, the first condenser lens can work as a monochromator with an energy resolution $E/\Delta E$ of 200–1000 by focusing a polychromatic beam from a bending magnet onto a sample spot with a diameter of several micrometers. The micro zone plate images the sample onto an X-ray-sensitive CCD camera. In contrast to this, the STXM uses one micro zone plate to focus the beam onto the sample mounted on a scanning stage and the transmitted intensity is monitored by a typical photomultiplier tube or an avalanche photodiode. More sophisticated detector schemes allow simultaneous imaging in four ways; bright-field and darkfield imaging, as well as differential phase contrast in the x and y direction (Kirz *et al*., 2004).

New paths are treated by lensless imaging with coherent X-ray scattering where, as sketched in Figure 51(d), the images are reconstructed in real space either by iterative phase retrieval schemes using over-sampling techniques. Miao, Charalambous, Kirz and Sayre (1999) or by FT holography. The latter technique has also been applied for imaging magnetic nanostructures (Eisebitt *et al*., 2004) where a resolution of about 50 nm was obtained.

All of these methods have been extended to explore magnetic nanostructures using the XMCD effect. Up to now soft X rays have been used for covering the L edges of 3d elements and M edges for RE elements.

4.3.2 Time-resolved imaging

As an example for third generation synchrotrons, the inherent time structure of the Advanced Light Source (ALS) at Berkeley, CA, is outlined in Figure 52, with its sub-100-ps wide X-ray flashes. This forms the basis for the implementation of stroboscopic pump and probe measurements with subnanosecond time resolution (Stoll *et al*., 2004; Choe *et al*., 2004). In addition to the standard multibunch operation of the synchrotron, a two-bunch mode is provided but this special operation mode is only available for about 10% of an annual beam time. The time structure in a two-bunch mode operation allows 328-ns time-intervals between the magnetic

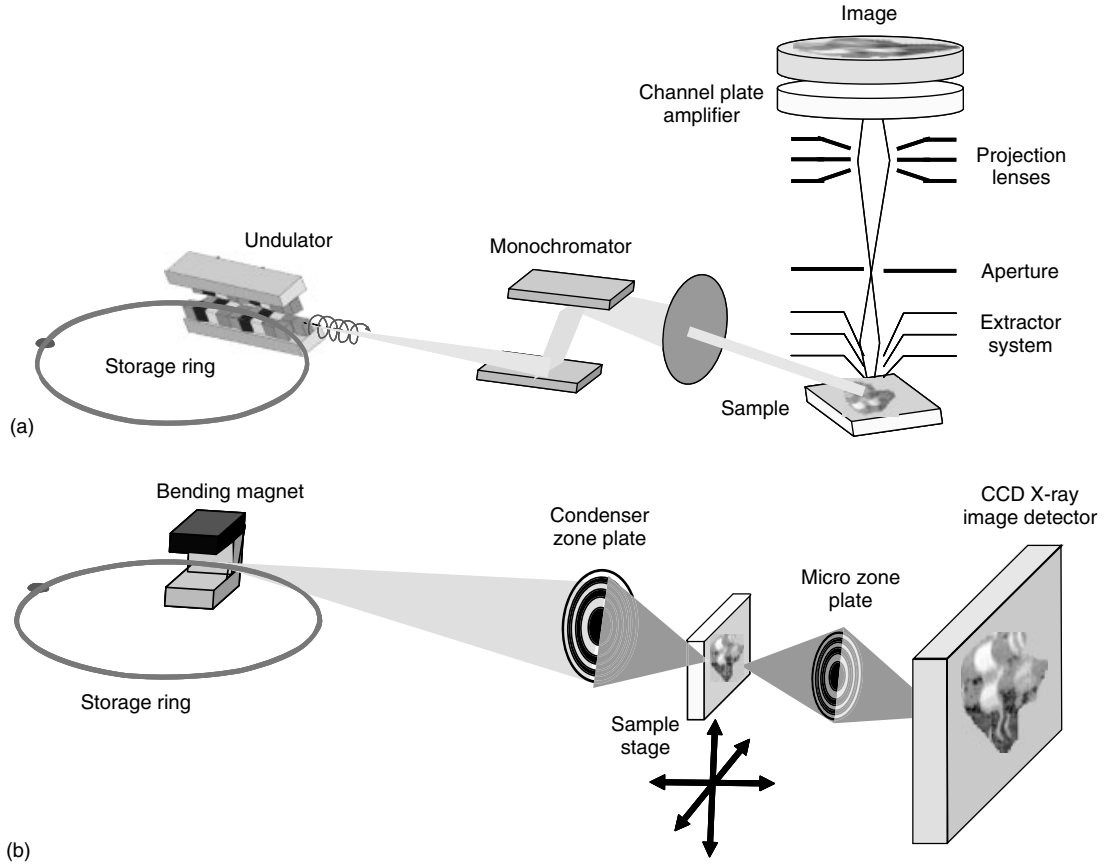

Figure 51. (a) Scheme of the X-ray photoemission electron microscope (X-PEEM). The incident X rays excite secondary electrons in an area of 1–50 µm, which are imaged by an arrangement of electrostatic and magnetic lenses onto a phosphor screen. (b) Scheme of a full-field transmission X-ray microscope. A polychromatic photon beam is focused by a condenser zone plate onto a field of the transparent sample of about 10 µm. The magnified image, generated by a micro zone plate, is thrown onto an X-ray-sensitive CCD camera. (c) Scheme of a scanning transmission X-ray microscope (STXM). A monochromatic photon beam is focused by a Fresnel micro zone plate onto the sample mounted on a piezo driven stage. The transmitted radiation is measured by an X-ray detector as a function of the sample position. (d) Set up for lensless imaging with coherent X rays. Monochromatized undulator radiation is directed to a pinhole. Coherent scattering at the sample causes a fine structure known as 'speckle' in the diffraction pattern which allows reconstruction of the real space image of the sample by an iterative phase retrieval scheme.

excitation pulses of the sample and therefore enables the sample's magnetization to relax and to reach its equilibrium state again, in contrast to the 2-ns interval between successive X-ray flashes in a multibunch mode operation, which is too frequent for most magnetic experiments. A sophisticated data acquisition scheme was built up which overcomes this drawback and allows us to perform time-resolved STXM measurements in multibunch mode with variable relaxation times. A pump pulse is followed by n successive X-ray flashes routed in separate image storage areas (for example, $n = 4$: 'pump' (magnetic excitation) pulses show up every 8 ns, and all X-ray 'probe' flashes in between are used for data acquisition). A similar set up was incorporated for the 'sine-excitation' experiments described later. In this way, by taking advantage of the higher photon flux in multibunch mode compared to the two-bunch mode operation, data acquisition for time-resolved magnetic STXM experiments is speeded up by a factor of about 10.

In order to generate the magnetic field as the pump pulse, an electric current is sent through a Cu wire as sketched in Figure 53(a), which provides a magnetic field parallel to the plane of the micrometer-sized platelet prepared directly on the Cu strip line. A magnetic pulse perpendicular to the sample can be applied by a Cu microcoil, which surrounds the sample on the Si_3N_4 membrane as shown by the scanning electron microscope (SEM) image in Figure 53(b).

For the time-dependent measurements several complementary stroboscopic techniques have been used:

1. 'Time-domain' *pump and probe excitation,* Figure 54(a) (Stoll *et al*., 2004), where current pulses through the microcoil or strip line, synchronized with the storage

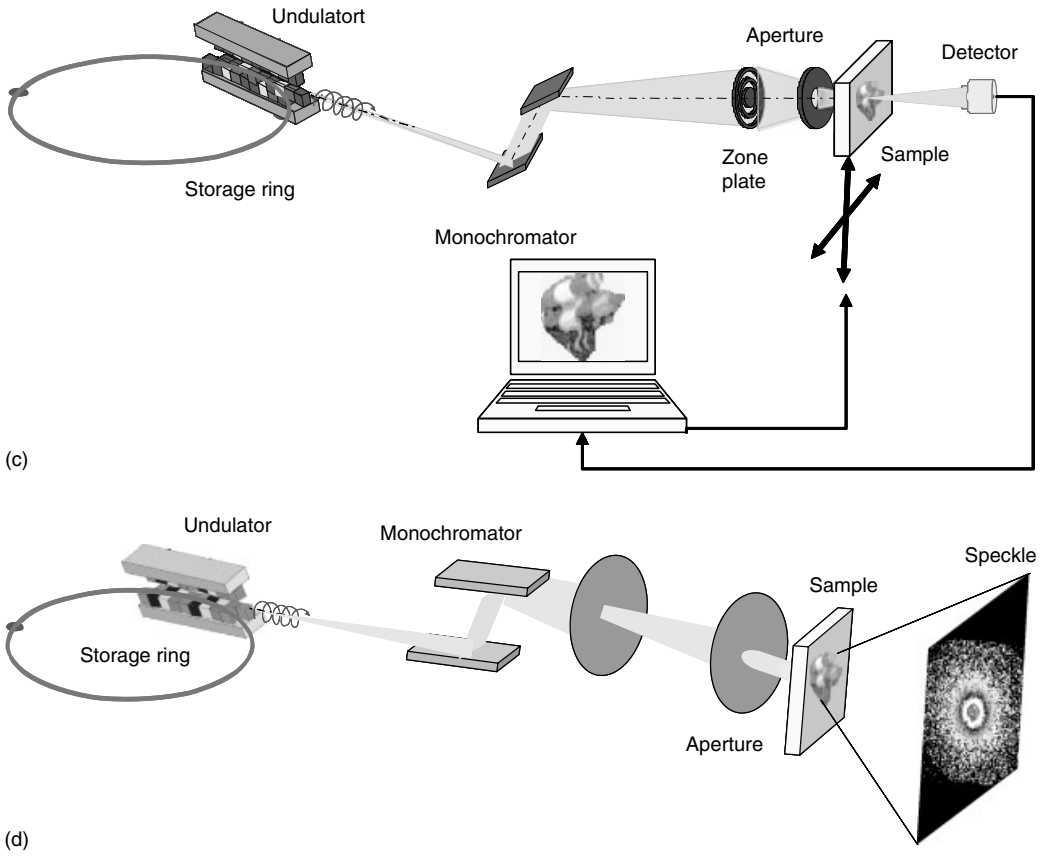

Figure 51. *Continued.*

ring, generate magnetic pulses which act as a 'pump' and the subsequent X-ray flashes, delayed properly, serve as 'probe'.

2. 'Frequency-domain' *sine excitation* or *spatially resolved ferromagnetic resonance* technique, implemented to time-resolved X-ray microscopy by Puzic *et al*. (2005) (Figure 54b), where the sample is excited by a continuous alternating field and the response of the sample's magnetization is determined dependent of the phase of the excitation. Generally speaking, pump and probe performs a broadband excitation of all magnetic modes involved, whereas the sine excitation allows excitation of distinct magnetic eigenmodes by choosing the excitation frequency close to their eigen frequencies.
3. A combination of both techniques above is called a *burst mode excitation* and is sketched in Figure 54(c). The sample is excited by one or several periods of an alternation magnetic field, and although this is a 'resonant' excitation, the sample is excited from its ground state.
4. In addition, an oscillating field with small amplitude can be superimposed to the burst excitation as shown in Figure 54(d).

4.3.3 Investigation of magnetic vortex dynamics by the STXM

It is well known that micrometer- or submicrometer-sized magnetic patterns can minimize their stray field energy by an inhomogeneous magnetization like the formation of domains separated by domain walls. In square-shaped ferromagnetic structures, the competition of the exchange interaction between nearest-neighbor spins and the long-range dipole–dipole energies can result in a vortex structure, or so-called Landau pattern (Hubert and Schäfer, 1998). Uniform magnetized domains form an in-plane flux closure around its center (Figure 55), where the magnetization goes out of the plane because of the short-range exchange interaction forming the vortex core, which is extended over about 20 nm. The direction of the out-of-plane component of the magnetization (up or down, see Figure 55) is defined as the polarization of the vortex core. The stability in an external static magnetic field (Wachowiak *et al*., 2002) has already been investigated and is well understood (Shinjo *et al*., 2000; Cowburn, Koltsov, Adeyeye and Welland, 1999; Novosad *et al*., 2002a; Guslienko *et al*., 2001; Shibata and Otani, 2004). Its dynamics have gained strong interest by magneto-optical techniques

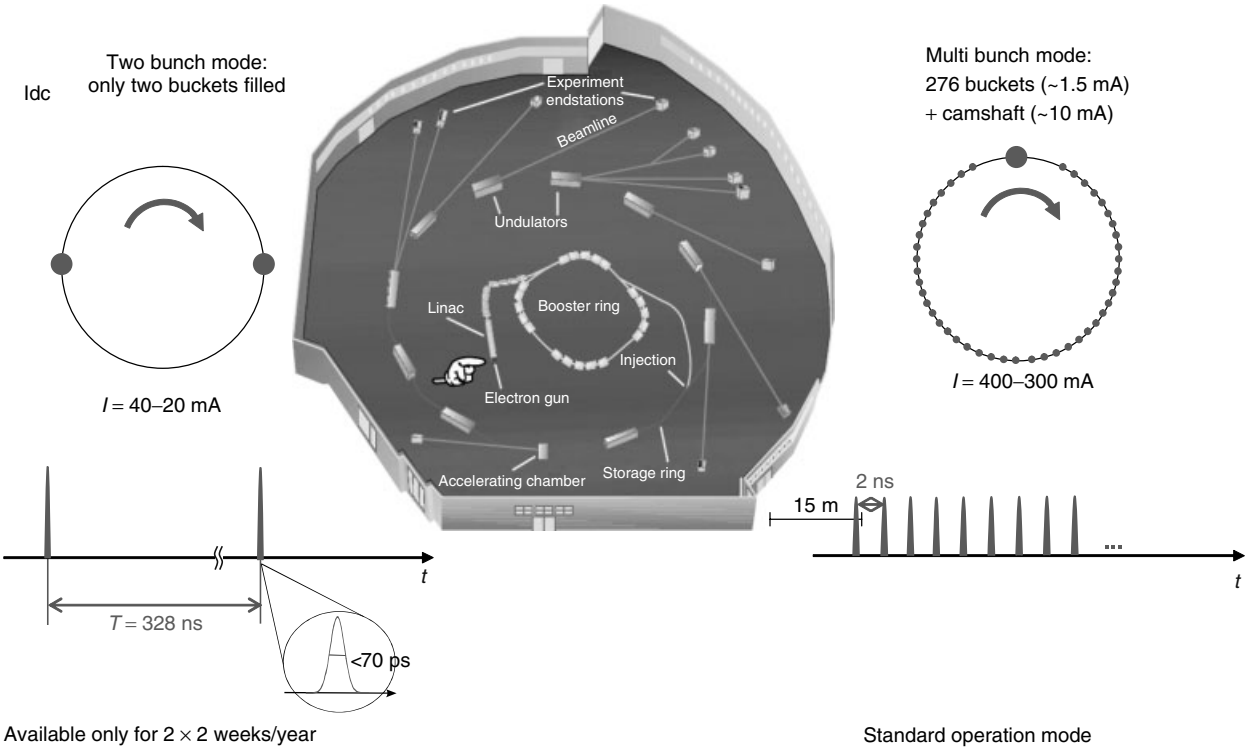

Figure 52. Operation modes at the Advanced Light Source with a sketch of the electron storage ring in the mid-panel. In the standard operation (multibunch mode, right panel) 276 buckets are filled into the storage ring. In a small fraction of the beam time period – especially for time-dependent measurements – only two bunches with a distance of 328 ns are injected into the storage ring. Hereby the current in the accelerator ring and thus the X-ray photon flux is significantly reduced by more than one order of magnitude.

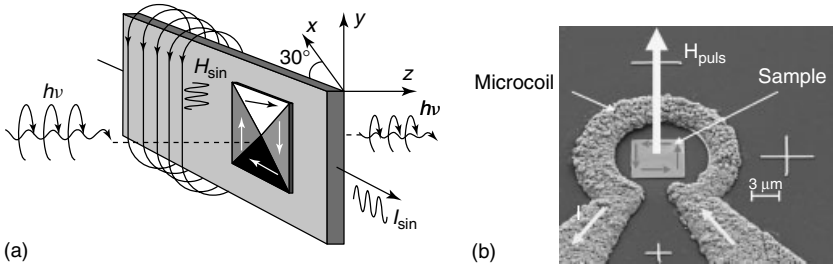

Figure 53. (a) A micrometer-sized Permalloy sample, showing a Landau pattern, is prepared on a Cu strip line. The electric ac current through this strip line generates an oscillating magnetic field parallel to the sample plane. To image the Landau structure, the whole sample arrangement is tilted by 60° with respect to the incident photon beam, creating a net component of the 'in-plane' sample magnetization onto the photon propagation direction. The sample has to be mounted perpendicular to the beam, for imaging the 'out-of-plane' magnetization perpendicular to the surface. (b) To create a magnetic field perpendicular to the sample plane, the electric current is sent through a Cu microcoil.

(Park *et al*., 2003; Cowburn, Koltsov, Adeyeye and Welland, 1999; Novosad *et al*., 2002b), a translational mode in the sub-gigahertz range corresponding to a gyrotropic motion of the vortex core around the structure center (Argyle, Terrenzio and Slonczewski, 1984) was observed. Since lateral dimensions of the vortex structure are in the submicrometer range and its timescales relevant in the subnanosecond range, it is an ideal subject to be addressed by time-dependent magnetic microscopy studies. Hereby, details in the dynamic response of a vortex structure to externally applied magnetic fields as pulsed or sine excitation were gained with time-resolved transmission X-ray microscopy (Puzic *et al*., 2005) and PEEM (Choe *et al*., 2004).

Up to now, very high external magnetic fields of about half a tesla (Okuno *et al*., 2002; Thiaville *et al*., 2003) were required to reverse the vortex core owing to the high stability typical for vortex structures. Recently, vortex-core switching with short bursts of an alternating magnetic field as low

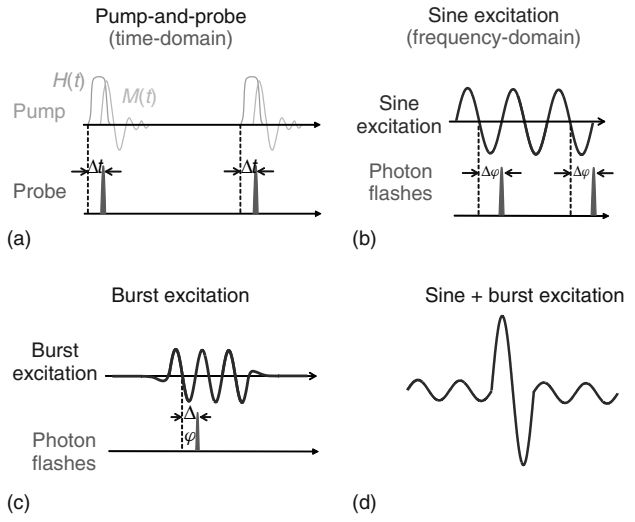

Figure 54. Stroboscopic measurement techniques: (a) 'time-domain' pump and probe technique, (b) 'frequency-domain' sine excitation (spatially resolved ferromagentic resonance), (c) burst excitation, (d) sine excitation combined with a single period burst.

as 1.5 mT was discovered by time-resolved imaging at a scanning transmission X-ray microscope (Van Waeyenberge *et al*., 2006). This dynamic low-field vortex-core reversal scheme is sketched in Figure 56. The sample was excited by a small alternating magnetic field (250 MHz, amplitude: 0.1 mT) parallel to the surface. The sense of gyration of the vortex structure could be reversed by a single period magnetic burst field (amplitude: 1.5 mT, see Figure 56). As the sense of the gyrotropic vortex motion only depends on the polarization of the vortex core (up or down), magnetic vortex-core reversal by excitation with short bursts of an alternating field (1.5 mT) was discovered this way (Van Waeyenberge *et al*., 2006). The Permalloy ($Ni_{80}Fe_{20}$) platelet, prepared on a strip line, was tilted by 60° with respect to the incoming photon beam, which resulted in a net magnetization projection onto the quantization axis (see Figure 53a).

A vortex-core switching mechanism derived from micromagnetic simulations (Van Waeyenberge *et al*., 2006), which was unknown so far, explains this reversal by low alternating fields as a result of the creation of a vortex-antivortex pair as sketched in Figure 57(a). This dynamic switching encounters is illustrated in Figure 57(b) and describes the following steps: (i – iii) excitation of the sample with an external in-plane alternating field generates an increasing out-of-plane polarization opposite to the original vortex, resulting in (iv) the creation a vortex–antivortex pair both with opposite polarization compared to the original vortex which results in (v) the annihilation of the antivortex with the original vortex and at the end (vi) a vortex with opposite polarization remains.

4.3.4 Dynamic imaging of the out-of-plane vortex core

As shown recently, owing to the high magnetic contrast at the dichroic active absorption edge, it is possible to resolve even directly a magnetic vortex core for a sample mounted with its plane perpendicular to the photon beam. Typical contrast images for reversed polarization of the X-ray beam before and after switching the vortex core by an appropriate burst are presented in Figure 58(a). A differential image of optimum statistical accuracy is taken by a proper subtraction of the dichroic images for reversed vortex-core orientation, and is plotted in a 3D image in Figure 58(b). As shown in Figure 58(c) it exhibits a slightly asymmetric shape with a maximum contrast of about 2% and a full width at half maximum (FWHM) in the order of 50 nm. The extension

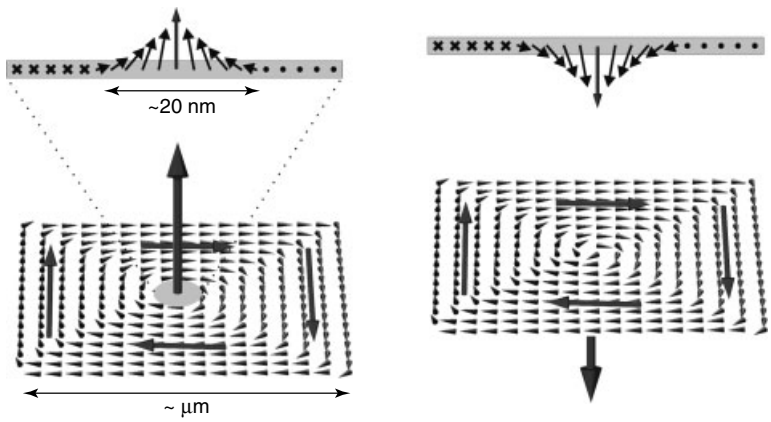

Figure 55. In a Landau pattern, the uniform magnetized domains form an in-plane flux closure around its center. In the center, because of the short-range exchange interaction, the magnetization goes out of the plane creating the vortex core. The direction of the out-of-plane component of the magnetization is defined as the polarization of the vortex core (up or down). Both states are energetically degenerate.

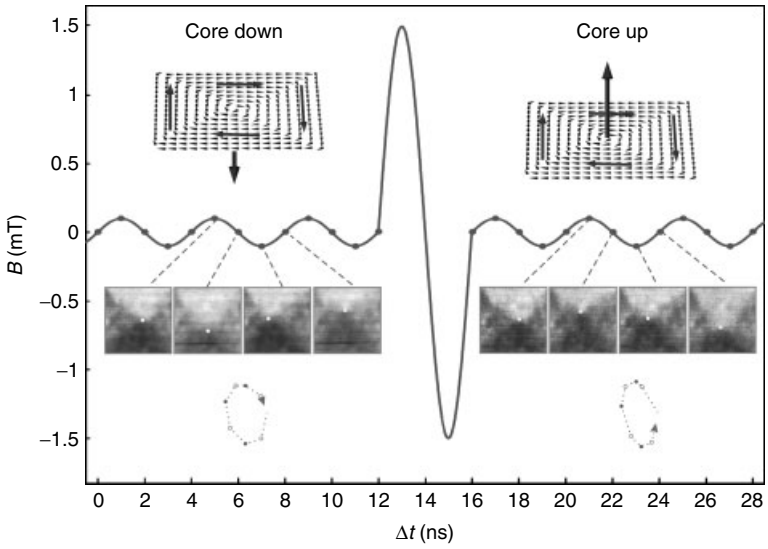

Figure 56. STXM images of the response of the Landau structure on the excitation by an alternating in-plane field (amplitude: 0.1 mT) and an additional alternating field pulse (one period with 1.5 mT amplitude). Since the sense of rotation only depends on the polarization of the vortex core, it is proven that the vortex-core polarization has been switched by the field pulse.

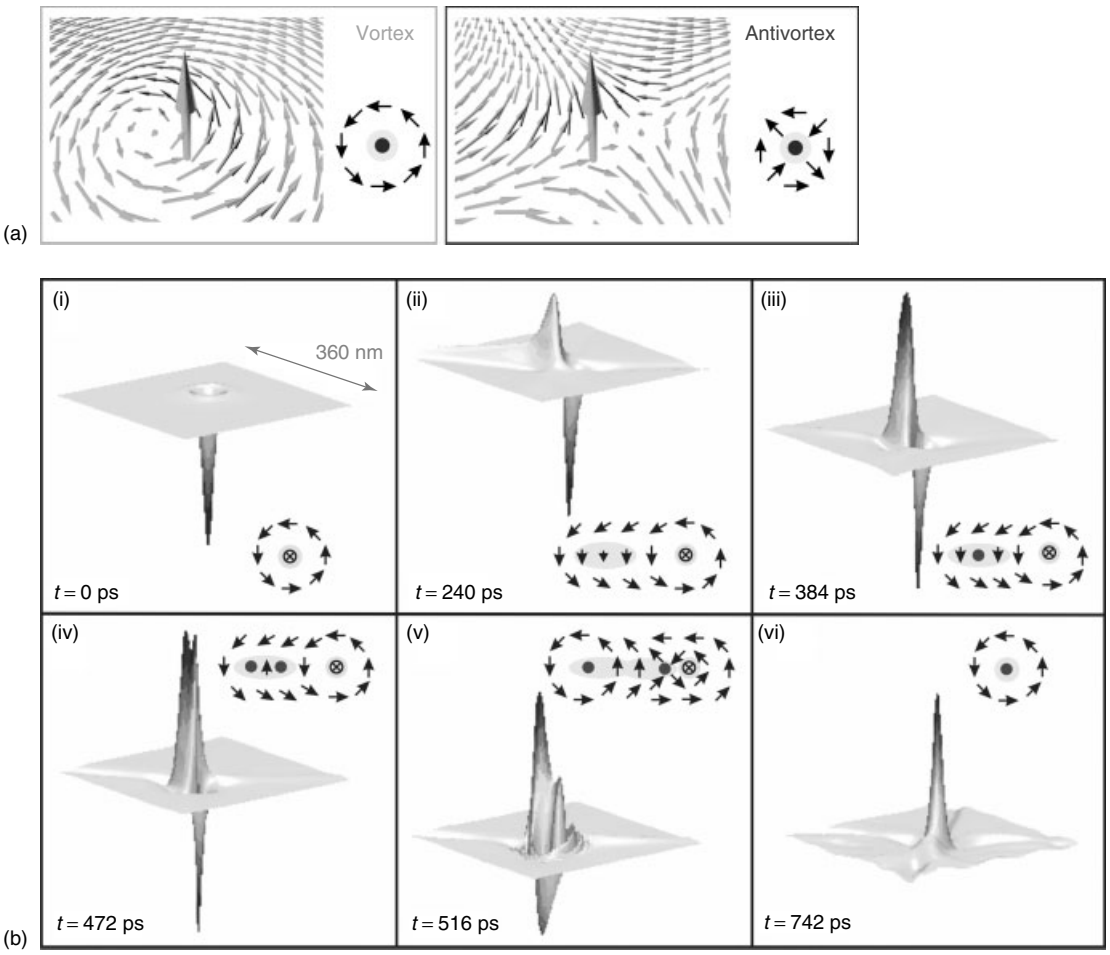

Figure 57. (a) A sketch of a vortex structure compared to an antivortex structure. (b) Details of the switching of the vortex core simulated by the OOMMF (Donahue and Porter, 1999) program showing the formation of a halo with opposite polarization splitting in a vortex and antivortex pair. Finally, the antivortex annihilates with the original vortex by emission of spin waves.

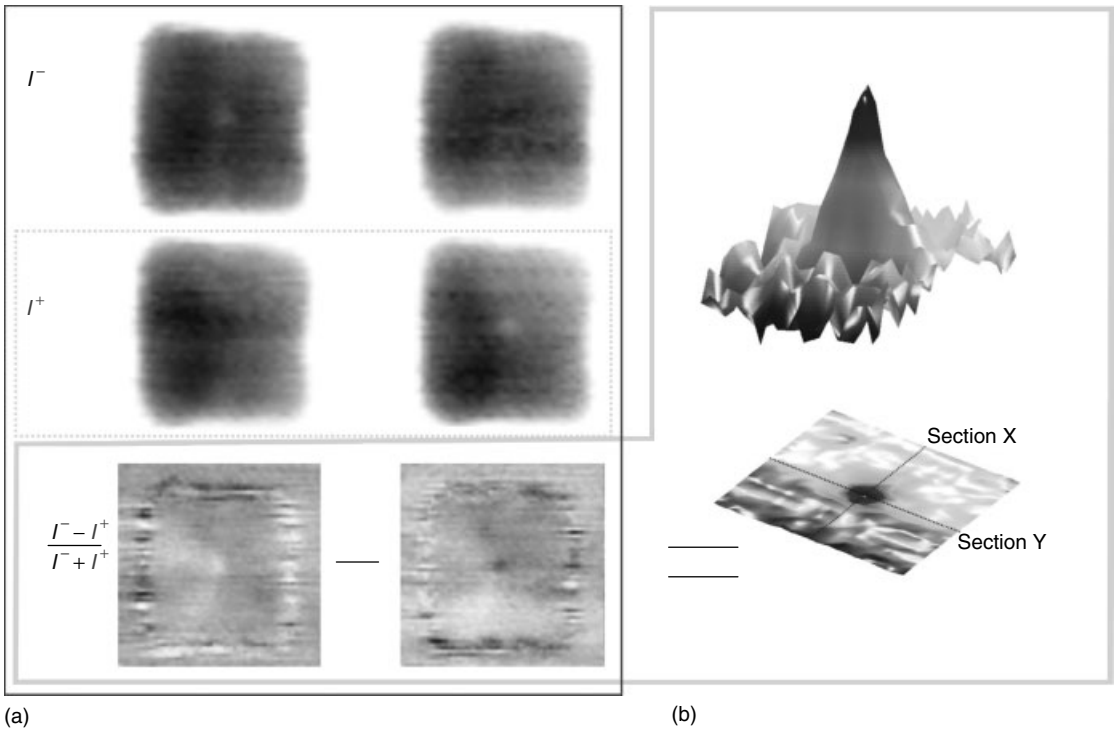

Figure 58. (a) Shows the static configuration of a vortex structure ($500 \times 500\,\mathrm{nm}^2$, 40 nm thick) with a vortex core pointing up (left column) and pointing down (right column). In the first row images were taken for negative polarization of the photons (I^-), while images with opposite polarization (I^+) are shown in the second row. The 'dichroic image' is depicted in the third row. A white or black spot can be observed, corresponding to a vortex-core pointing up or down respectively. The jitter around the vortex structure is an artifact caused by mechanical vibrations. Both 'dichroic images' were subtracted from one another and a 3d image is given in (b) ($200 \times 200\,\mathrm{nm}^2$ cut).

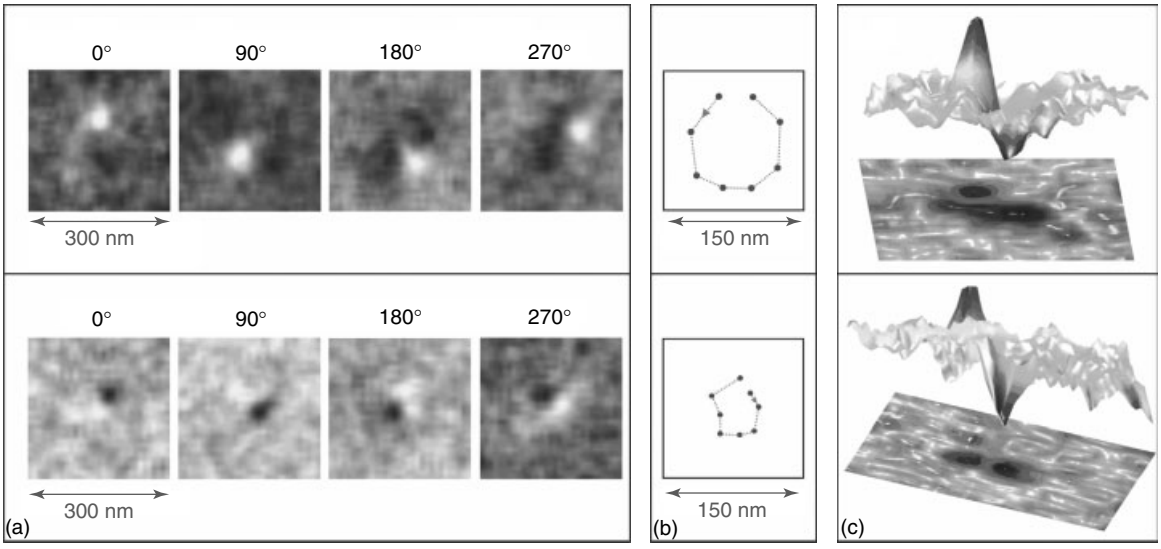

Figure 59. Dynamic response of a vortex structure (sample A: $500 \times 500\,\mathrm{nm}^2$, 40 nm thick) due to an in-plane alternating magnetic field ($f = 437.5\,\mathrm{MHz}$, $H_0 = 710\,\mathrm{A\,m^{-1}}$) with a vortex core pointing up (upper row) and down (lower row). (a) Shows the out-of-plane magnetic contrast of the Landau structure at different phases of the external field (uneven phases are not shown). The images are cuts ($300 \times 300\,\mathrm{nm}^2$) from the complete structure. The position at the different phases is depicted in (b) ($150 \times 150\,\mathrm{nm}^2$), and (c) is a 3D representation of the vortex structure ($300 \times 300\,\mathrm{nm}^2$) at phase 270° (upper row) and phase 135° (lower row).

of the vortex core (about 20 nm) and a maximum value of the XMCD effect at the Ni L_3 edge of about 26%, give exactly the expected magnetic absorption effect owing to the experimentally smeared-out perpendicular magnetization component of the vortex core.

In Figure 59(a), the gyrotropic motion of the vortex core is shown for a $500 \times 500\,\mathrm{nm}^2$ large Permalloy platelet mounted with its normal parallel to the photon beam inside the scanning X-ray microscope. This motion has been studied for the two polarization states of the vortex core, indicating a large difference in the amplitude of the gyrotropic vortex motion for the two cases (Figure 59b). This asymmetry may be attributed to local imperfections in the thin film causing nonuniform magnetization distributions over the sample which have an influence on the motion. The speed of the vortex-core motion was also deduced from the trajectories. For the vortex-core pointing up, a speed of $140\,\mathrm{m\,s}^{-1}$ was calculated, while a much smaller speed of $\approx 80\,\mathrm{m\,s}^{-1}$ was found when the vortex-core is pointing down.

The 3D representations in Figure 59(c) indicate the occurrence of a broad contribution of opposite sign at one side of the vortex core. The procedure used during the data analysis can introduce such a negative contribution as an artifact. On the other hand, it was recently discovered that a vortex core deforms with a similar halo prior to the switching of the vortex core by creation and annihilation of a vortex–antivortex pair (Novosad *et al*., 2005). Today it cannot be excluded that the dynamical vortex deformation, which could up to now not be proved experimentally, is partly responsible for the negative contributions in Figure 59(c). This has to be clarified by future experimental magnetic STXM studies with a significantly enhanced accuracy, especially a better lateral resolution.

NOTES

[1] To be more precise, the Borrmann effect has to be taken into account, which gives different absorption for the two field components. To provide the same intensity for both interfering field components, the angle of incidence must be chosen slightly different from the 45° condition to give 100% circular polarized light.

[2] This has been done by the XMCD effect. So the energy is tuned to the maximum XMCD effect of a magnetized sample. Then the absorption is measured as a function of the Bragg angle, which directly reflects the circular polarization. Other dynamical effects, like the Borrmann, 1951, Borrmann, Hildebrandt and Wagner, 1955) effect have to be cancelled by averaging over different sample magnetizations.

[3] This could be done by measuring the intensity of the scattered beam by an additional ionization chamber.

[4] This could be a problem if the sample provides a band gap, large enough to be transparent for a secondary UV channel.

[5] This is related to the much weaker radial matrix element due to the oscillating radial wave function of the higher s electrons in the radial distribution of the excited core electron.

[6] This is a direct consequence of the dipole approximation in Fermi's golden rule (Bransden and Joachain, 1983).

[7] This assumes forbidden spin flip processes!

[8] In units of $\mu_B \nabla$.

[9] This could be realized by external or internal forces.

[10] The description given here, is close to the discussion of Stöhr and König (1995).

[11] Orbital moments could also be investigated by precise g-factor measurements in ferromagnetic resonance.

[12] As explained in the previous chapters, XMCD is sensitive to the projection of the magnetization along the circular polarized photon beam **K** vector.

[13] The MEXAFS part has been approximated by pure effective spin contributions!

[14] Dipole term and spin moments have been renormalized owing to the $j_{3/2} - j_{1/2}$ mixing, present for reduced spin-orbit splitting of the 2p excitation (Goering, 2005).

[15] This value is smaller than the pure atomic values, reflecting the delocalization and the band character of the 3d electrons in CrO_2.

[16] The polarization dependent prefactors will reduce in small angle approximation for circular polarized light to $\left(\varepsilon'^{\dagger} \cdot \varepsilon\right) = \varepsilon \cdot \varepsilon = 1$ und $\left(\varepsilon'^{\dagger} \times \varepsilon\right) = i\boldsymbol{q}\,P_C$, where $\boldsymbol{q}$ is the wave vector of the photon beam and P_C is the degree of circular polarization.

APPENDIX

Owing to the absorption coefficient $\mu(E)$, which is a function of the photon energy E, the intensity will be reduced as a function of the effective path length $s(x) = x/\cos\alpha$, according to the Lambert–Beer's Law

$$I_{\text{phot}}(x) = I_{\text{phot}}(0) \cdot \exp\left[-\frac{\mu(E) \cdot x}{\cos\alpha}\right] \qquad \text{(A1)}$$

The number of excited electrons per volume fraction is now proportional to the local and depth- dependent intensity of the photon beam and to the absorption coefficient itself, taking into account the local excitation probability. To quantify this we estimate the number of produced electrons, including all secondary electrons, to be proportional to the photon beam intensity. Despite the fact that the generation of the secondary electrons is different as a function of distance to the absorption site, we assume further that the exited electron density, which is able to leave the sample, is exponentially damped by secondary processes. The number of electrons exited at the depth x at photon energy E is

$$n(x, E) = k \cdot I_{\text{phot}}(0) \cdot \exp\left[-\frac{\mu(E)}{\cos\alpha}\right] \cdot \frac{\mu(E)}{\cos\alpha} \qquad \text{(A2)}$$

The 1/cos at the right side is related to the intensity per surface area present at depth x.

So the total number of electrons leaving could be now determined by a simple integration over $n(x, E)$ by a given sample of thickness d

$$I_{\text{e}^-}(x) = \int_0^d n(x, E) \cdot \mathrm{d}x = k \cdot I_{\text{phot}}(0) \cdot \frac{\mu(E)}{\cos\alpha} \times \int_0^d \exp\left[\frac{-\mu(E) \cdot x}{\cos\alpha}\right] \cdot \exp\left[\frac{-x}{\xi}\right] \cdot \mathrm{d}x \qquad \text{(A3)}$$

After integration this reduces to

$$I_{\text{e}^-}(x) = k \cdot I_{\text{phot}}(0) \cdot \frac{\frac{\mu(E)}{\cos\alpha}}{\frac{\mu(E)}{\cos\alpha} + \frac{1}{\xi}} \times \left(1 - \exp\left[-\left(\frac{\mu(E)}{\cos\alpha} + \frac{1}{\xi}\right) \cdot d\right]\right) \qquad \text{(A4)}$$

Assuming a thick sample $d >> 1/\mu(E)$ this reduces to

$$I_{\text{e}^-}(x) = k \cdot I_{\text{phot}}(0) \cdot \frac{\frac{\mu(E)}{\cos\alpha}}{\frac{\mu(E)}{\cos\alpha} + \frac{1}{\xi}} \qquad \text{(A5)}$$

If the photon absorption length is much larger compared to the effective electron escape length, or, in other words, $\mu(E)/\cos\alpha << 1/\xi$, then the description of the TEY current reduces to

$$I_{\text{e}^-}(x) = k \cdot I_{\text{phot}}(0) \cdot \frac{\mu(E)}{\cos\alpha}\xi \qquad \text{(A6)}$$

clearly demonstrating the nice proportionality between the absorption and the observed TEY current. Now we want to discuss what happens if the absorption of light is very strong or the angle of incidence is more grazing. This is mathematically reflected by the condition $\mu(E)/\cos\alpha \gg 1/\xi$. In this case the current reduces to

$$I_{\text{e}^-}(x) = k \cdot I_{\text{phot}}(0) \cdot \frac{\frac{\mu(E)}{\cos\alpha}}{\frac{\mu(E)}{\cos\alpha}} = k \cdot I_{\text{phot}}(0) \qquad \text{(A7)}$$

This shows quite a dramatic effect which could be understood in the following way. If the angle of incidence is quite grazing, all the photons will be absorbed in a very thin top layer close to the surface, because the effective way of traveling through the sample is very large. If this effective length is much longer compared to the absorption length, all photons will be absorbed at the top, no matter what exact energy dependence is given by the absorption length. Therefore, the energy dependent current signal is more or less a straight line. In the range between those two extremes the measured TEY signal exhibits damped high absorption lines, for example, as present at the 2p absorption lines for the 3d TMs.

This resonance damping or saturation effect in the TEY signal is enhanced for high absorption, as present at the 2p ($L_{2,3}$) or 3d ($M_{4,5}$) absorption resonance lines, and for large atomic density, as for pure 3d TM samples and/or at grazing incidence. In contrast a reduced number of atoms per volume, for example, as present for the minority part in alloys or in chalcogenides, give only small self-absorption effects.

Now we discuss the influence of self-absorption for films with reduced thickness d. In this case, we can expand the equation for the thickness dependent TEY signal (equation (A4)) for small thickness d.

$$\begin{aligned} I_{\text{e}^-}(x) &= k \cdot I_{\text{phot}}(0) \cdot \frac{\frac{\mu(E)}{\cos\alpha}}{\frac{\mu(E)}{\cos\alpha} + \frac{1}{\xi}} \times \left(1 - \exp\left[-\left(\frac{\mu(E)}{\cos\alpha} + \frac{1}{\xi}\right) \cdot d\right]\right) \\ &= \frac{k \cdot I_{\text{phot}}(0)}{\frac{\mu(E)}{\cos\alpha} + \frac{1}{\xi}} \cdot \frac{\mu(E)}{\cos\alpha} \times \left(1 - 1 + \left(\frac{\mu(E)}{\cos\alpha} + \frac{1}{\xi}\right) \cdot d + \cdots\right) \\ &= \frac{k \cdot I_{\text{phot}}(0)}{\cos\alpha} \cdot \mu(E) \cdot d \end{aligned} \qquad \text{(A8)}$$

This expansion is valid in the case of extreme thin layers, where $d << \xi$ and $d << \cos\alpha/\mu(E)$. It also reflects the intuitive experimental result. The number of produced electrons increases as more photons are absorbed in a thin layer close to the surface and not in the substrate below.

To correct the saturation effect of reduced resonance line absorption profiles, it is necessary to know the relevant parameters, as the effective electron escape length ξ and the energy dependent photon absorption profile $\mu(E)$. Unfortunately, both parameters are not known, especially the absorption coefficient is unknown until the correction has been performed.

An example of a corrected absorption profile, deduced from the TEY signal by adapting the current profile before and after the resonances to well-known absorption coefficients, is being shown later in Figure 50. In this case, the measured absorption profile has been used to determine the self-absorption corrected signal in an iterative way. This could be done in the case of smooth and polished samples, where the electron escape length can be determined by a self-consistent saturation correction as the function of the angle of incidence or film thickness (Goering, Gold, Lafkioti and Schuetz, 2006; Gold, 2006; Hunter-Dunn *et al.*, 1995; Nakajima, Stöhr and Idzerda, 1999; Weber, 1998).

Ultrafast Magnetodynamics with Lateral Resolution: A View by Photoemission Microscopy

Hermann A. Dürr[1] and Claus M. Schneider[2]

[1] *BESSY GmbH, Berlin, Germany*
[2] *Institut für Festkörperforschung, Jülich, Germany*

1 INTRODUCTION

The dynamic behavior of magnetic systems with a nonuniform magnetization distribution is a complex issue. Individual magnetic structures, such as domains, domain walls, vortices, and other noncollinear configurations each contribute with their specific dynamic response to the overall picture. This is particularly true in the ultrafast regime, that is, on the nanosecond timescale and below. In order to disentangle these contributions, suitable laterally resolving approaches must be employed. Time-resolved photoemission microscopy (TR-PEEM) has been developed into a versatile tool to probe the dynamic response of magnetic systems with high spatial resolution. Two complementary avenues are currently pursued, each probing specific aspects. Soft X-ray pulses are employed to address element-selective aspects of magnetization dynamics down to the picosecond timescale. Photoexcitation with ultrashort laser pulses provides access to the spin dynamics even in the subpicosecond regime. With free-electron laser (FEL) light sources coming on line in the near future, these avenues may converge into a unique approach to magnetodynamic phenomena, combining element and chemical selectivity with a high lateral (∼10 nm) and time resolution (∼100 fs).

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

1.1 Magnetism and photoemission microscopy

Magnetic thin films and nanostructures play a central role for many areas in information technology. First of all, they provide highly specialized functionalities in various elements of a magnetic mass storage device, such as a hard disk. These are still the first choice, if it comes to fast, high-capacity random access memory (Lodder, 1998; Wang, 2005). With the discovery of large magnetoresistive effects (Baibich *et al*., 1988; Binasch, Grünberg, Saurenbach and Zinn, 1989; Meservey and Tedrow, 1994; Moodera, Kinder, Wong and Meservey, 1995) in thin-film systems at room temperature, not only novel applications but also an entire new research field emerged – spinelectronics or spintronics (Prinz, 1998; Wolf *et al*., 2001). Spintronics operates at a crossover of electronics and magnetism by treating the charge and the spin degrees of freedom of electrons in transport processes on an

equal footing. In this way one can hope to combine the best of two worlds, such as the well-established charge control in semiconductors with the nonvolatility of magnetic bits. The first realization of such a spintronics device may be a hybrid, the so-called magnetic random access memory, which is currently in the test phase in many major microelectronics companies (Freescale, 2006).

The breathtaking development in thin film and nanomagnetism has been fostered significantly by the improvement of analytical methods and approaches. In this context, synchrotron radiation adopted a key role (see also **Synchrotron Radiation Techniques Based on X-ray Magnetic Circular Dichroism, Volume 3**). It paved the path for detailed spectroscopic studies of magnetic materials, which largely shaped our understanding of the electronic foundation of magnetism. Milestones along this way were the discoveries of X-ray magnetic dichroism with linearly (van der Laan *et al*., 1986) and circularly polarized light (Schütz *et al*., 1987) (Chen, Sette, Ma and Modesti, 1990). Magnetic x-ray linear (MXLD) and circular dichroism (MXCD) provide a unique combination of magnetic sensitivity and element selectivity, and they laid the foundation to the field of x-ray magneto-optics. Sum rules enabled a quantitative determination of spin and orbital magnetic moments on the basis of spectroscopic investigations (Thole, Carra, Sette and van der Laan, 1992; Carra, Thole, Altarelli and Wang, 1993; Thole and van der Laan, 1993) – at least within certain limits.

Moreover, the access to synchrotron radiation and the discovery of magnetic dichroism, in particular, led to the revival of a very interesting full-field imaging technique – photoelectron emission microscopy (PEEM) – unleashing its full power. Originally invented by Brüche (1933, 1934), photoemission microscopy remained for a long time a specialized technique in surface science, despite some major achievements in the electron-optical concept, such as the low-energy electron microscope and its spin-polarized version introduced by Bauer and Telieps (1988) and Altman *et al*. (1991). With the increasing availability of brilliant soft X-ray sources, however, PEEM was recognized as a technique enabling a high lateral resolution mapping of surfaces with chemical information. Imaging of magnetic domains with threshold PEEM was performed as early as 1957 (Spivak, Dombrovskaia and Sedov, 1957) exploiting the stray field emanating from a ferromagnet's surface as a contrast mechanism. Its enormous potential for magnetic studies with synchrotron radiation was demonstrated by Stöhr *et al*. (1993), Schneider *et al*. (1993), when first domain imaging experiments of magnetic surfaces and thin films were successfully performed. Since then, PEEM has matured into a valuable tool to unravel the magnetic microstructure in complex thin-film systems. Its unique features arise from the fact that the choice of the light polarization permits the study of ferro- and antiferromagnetic components of a system (Stöhr *et al*., 1999; Nolting *et al*., 2000). In this way, in-depth studies of antiferromagnetic systems and their domain structures became available for the first time (Ohldag *et al*., 2001).

1.2 Dynamical aspects of magnetism

Recently, the dynamical aspects of magnetism moved into the focus of interest. From a technical viewpoint, the main topic is the switching speed, that is, the time it takes to flip the magnetization vector from one given orientation to another. This speed issue is at the heart of magnetic data storage, spintronics, and other areas involving high-frequency modulations of a magnetic system. The faster a magnetic system switches, the faster can be the data transfer rate in a memory or the clock speed of a spintronic device. From a more fundamental point of view, however, one would like to understand the physical processes and limitations governing the magnetization reversal, the origin of the damping mechanisms, and the nature and types of the magnetic excitations appearing in a given system. For these reasons, the recent years have witnessed an increasing interest in fast and ultrafast dynamic processes in magnetic systems (Hillebrands and Ounadjela, 2001, 2003, 2006). The relevant timescales dealt with in the experimental studies range from a few nanoseconds down to less than 100 fs, depending on the type of interaction triggering the dynamic response of the magnetic system. In addition to the 'traditional' way of controlling the magnetization reversal by an external magnetic field, spin-polarized currents (Myers *et al*., 1999) or even photons (Kimel *et al*., 2005) have been successfully employed for this purpose recently.

In order to access the microscopic mechanisms and processes, which determine the magnetization dynamics, time-resolving magnetic imaging techniques are mandatory. Most of our knowledge until now was obtained from Kerr microscopy (Freeman and Hiebert, 2001), employing pulsed-laser sources as a 'clock' to provide a time resolution in the nanosecond and subnanosecond regime. Synchrotron radiation also has a well-defined intrinsic time structure due to the very way it is created (Wiedemann, 2003). The width of these light pulses is usually in the picosecond range, whereas their spacing can be adjusted to any value between 1 ns and 1 µs, depending on the storage ring operation mode and filling pattern. This provides an extremely versatile time-resolved access to magnetization dynamics, both laterally integrated and resolved, as has been demonstrated recently (Krasyuk *et al*., 2003; Vogel *et al*., 2003). They allow access to phenomena such as domain nucleation, magnetization rotation,

or precessional switching, which may be described in continuum models, for example, in the Landau–Lifshitz–Gilbert (LLG) framework.

With laser irradiation even shorter light pulses are available, providing a convenient probing of processes on the 100 fs timescale. Usually the wavelength of these light pulses lies in the near infrared region and can be easily transposed into the visible or ultraviolet regime by means of frequency doubling or tripling schemes. This already allows the study of the influence of electronic excitations on the magnetic properties as well as the interactions between spin and electron systems and the lattice, that is, to probe the transfer of energy and angular momentum (Rhie, Dürr and Eberhardt, 2003). An X-ray counterpart is expected to become available soon through new synchrotron radiation sources, the so-called free-electron lasers (DESY, 2006). The perspective for the future will thus be a combination of element selectivity with femtosecond time resolution and the high lateral resolution provided by PEEM.

This chapter addresses the new developments and achievements in magnetization and spin dynamics obtained with the method of photoemission microscopy using picosecond soft X-ray and femtosecond optical laser pulses. We are well aware of the fact that there are many other interesting imaging approaches to magnetization dynamics, such as various types of Kerr microscopy or the techniques of X-ray transmission microscopy, which became available recently (for details see **Synchrotron Radiation Techniques Based on X-ray Magnetic Circular Dichroism, Volume 3**). Other methods, such as magnetic X-ray holography (Eisebitt *et al*., 2004) are currently extended into the time regime. These techniques are addressed in other parts of this book. Here we focus onto a particular subset of experiments performed with photoemission microscopy, in order to illustrate the virtues and future potential of probing magnetization dynamics with lateral resolution down to the nanometer regime.

This contribution is organized as follows. In Section 2 we briefly review the various important timescales playing a role in magnetism. In Section 3 we give a short account of the technical details of time-resolving PEEM experiments. Sections 4 and 5 are devoted to the experimental results obtained on the picosecond and femtosecond timescales, respectively and their discussion. In Section 6 we outline the future development of the PEEM technique with respect to time-resolved studies in and outside of magnetism.

2 TIMESCALES IN MAGNETISM

In the quasistatic limit, each magnetic system assumes a spatial distribution of the magnetization, which is determined by energy minimization principles. In very small particles, that is, far below a size of 1 μm, one often finds a single domain state, where the magnetization is uniformly oriented along one direction throughout the entire particle, creating a sizable magnetic stray field outside the particle. If the particle becomes larger, the stray field increases up to the point where the total energy of the system may be reduced at the expense of exchange energy by the spontaneous formation of domains, domain walls, and noncollinear magnetization distributions (buckling, curling, etc.). The details of the magnetic microstructure depend sensitively on the shape of the magnetic particle and the material parameters, and so does the transition from a single- to a multidomain state as a function of particle size. As a result, one observes a large zoo of magnetic domain structures in the quasistatic case (Hubert and Schäfer, 1998) already. Understanding the formation of these domain structures and their dynamic response to external magnetic fields is at the heart of the technological exploitation of magnetism. The experimental visualization of magnetic structures and magnetization reversal processes provides a major key to this understanding.

It is important to note that the relevant timescales in magnetism cover an extremely wide range of more than 20 orders of magnitude (Figure 1) – determined by both applications and fundamental processes. On the one end of the scale, we find the retention time in magnetic data storage. As the stored information consists essentially of a sequence of well-defined magnetic domains, these magnetic domains have to be extremely stable against thermal fluctuations. Therefore, a value of 10–15 years (10^8 s) is usually considered desirable as retention time. On the other end of the timescale, we are confronted with ultrafast energy and angular momentum transfer processes in magnetic systems on a timescale of 10^{-14} s. These processes are related to nonequilibrium electron distributions and are held responsible for an extremely fast decay of the magnetic order, for example, in the wake of a highly energetic laser pulse. In the intermediate time regime between 10^{-3} and 10^{-12} s we find a wealth of different dynamical processes. These range from relatively slow phenomena, such as magnetization creep and aftereffects, to fast mechanisms, which determine the technological limits of magnetization reversal such as domain nucleation, domain wall propagation, and coherent rotation. It is often overlooked that the ongoing increase in storage density is accompanied by a corresponding increase in the data transfer rates, that is, the read/write speeds, slowly approaching the gigahertz regime. A similar development takes place in the field of magnetic random access memories, where a duty cycle of about 20 ns has already been demonstrated (Freescale, 2006).

The dynamic aspects of a magnetic system are often described as *magnetization dynamics* or *spin dynamics*. It

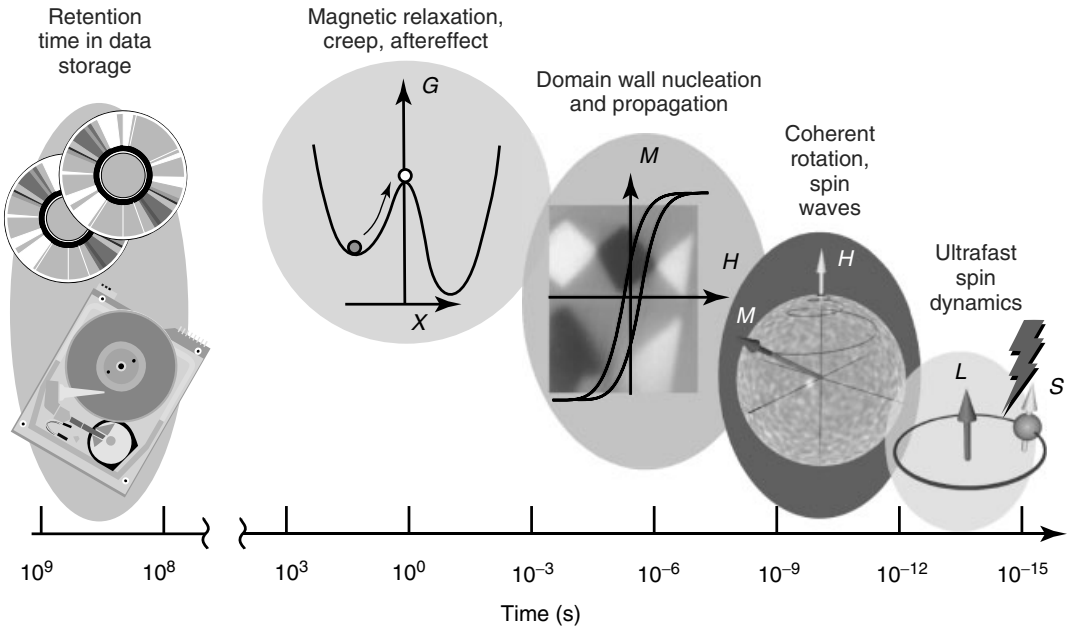

Figure 1. Timescales in magnetism and the associated microscopic processes determining the dynamic behavior of a magnetic system.

should be stated that this terminology contains more than just a semantic difference, but is unfortunately not unambiguous in use. In our view, the term magnetization dynamics refers to the response of a magnetic continuum system, that is, the spins or magnetic moments of the system are strongly coupled by the exchange interaction, to a low-energy excitation, for example, a magnetic field pulse or a spin-polarized current pulse. From a theory point of view, this situation can be rather successfully described in small particles by means of macrospin models within the LLG formalism (Miltat, Albuquerque and Thiaville, 2003). This approach works also – with increased computational efforts – for nonuniform magnetization distributions, such as domains and domain walls. One of the main restrictions of this approach is that locally only the direction of the magnetization $\vec{M}$ is changing, but not its magnitude. In other words, the absolute value of $\vec{M}$ is always preserved in this continuum theory. This continuum picture represents one limiting case and is capable of describing the response of a magnetic system down to the picosecond regime.

The other extreme situation is encountered when an excitation acts directly on the electronic system first. In fact, this can be readily achieved by strong laser pulses, which lead to electronic transitions on the electronvolt scale. The consequence is an electron distribution in strong nonequilibrium – at least on a timescale of several 10 fs. This nonequilibrium state represents a formidable problem for the theoretical treatment and strong efforts are currently devoted to its solution. The physical mechanisms in this temporal regime rather act on the individual electron and, in this way, on the individual spin for that matter. It is thus justified to describe this regime as ultrafast spin dynamics [1]. In subsequent steps, the energy and angular momentum associated with the electronic excitation is then transferred to the magnetic and lattice subsystems. Most of these processes are already terminated during the first few picoseconds. On a longer timescale, however, the system still responds by means of precessional motion of the magnetization. A first interesting attempt has been made recently to connect the processes on the electronic timescale with the magnetodynamic timescale in the 100 ps regime (Koopmans, Ruigrok, Longa and de Jonge, 2005).

In Sections 4 and 5 we discuss results obtained for both regimes.

3 PHOTOEMISSION ELECTRON MICROSCOPY

3.1 Electron-optical layout

The electron-optical system of a standard photoemission electron microscope allows a wide-field imaging of a surface with electrons emitted from this surface. Its basic concept is very similar to that of an optical immersion lens microscope (Bauer and Telieps, 1988; Schönhense, 1999; Bauer, 2001a). The PEEM consists of three main parts: (i) the objective lens, (ii) contrast aperture, and (iii) projective lens system

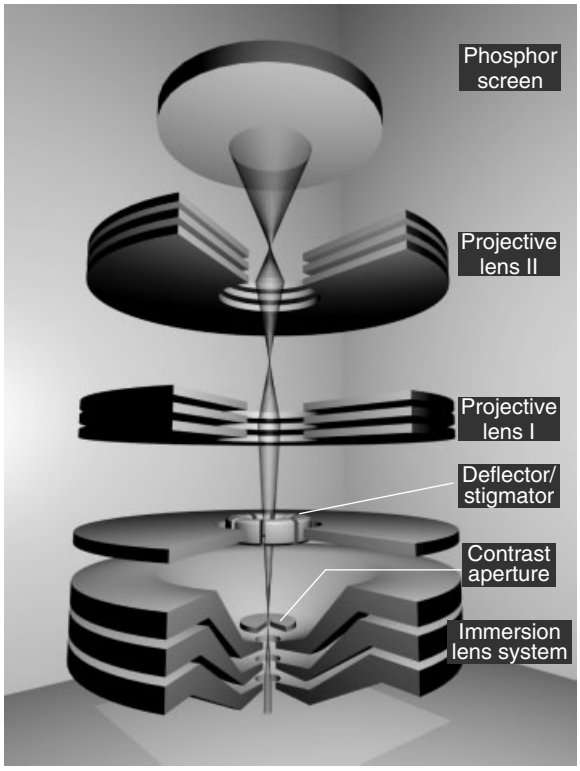

Figure 2. Electron-optical column of a an electron emission microscope.

(Figure 2). The objective lens system is designed to collect the emitted electrons up to large starting angles with respect to the surface normal. For this purpose, a large electrostatic extraction field ($\approx$10 kV mm^{-2}) of axial symmetry $\vec{E}_{\rm ex}(r, \theta, z)$ is applied between the sample and the objective lenses. This approach makes the sample an inherent part of the electron-optical system giving rise to a variety of nonmagnetic contrast mechanisms, induced by the topography, chemical or crystalline heterogeneity of a surface (Bauer *et al*., 1996). As the distance between sample and immersion lens objective is only about 2–3 mm, the light reaches the sample surface usually at a flat angle of 15–25°. A contrast aperture (size of 20–50 µm) in the backfocal plane of the objective lens serves to select the proper trajectories and thus to reduce the influence of lens aberrations. The smaller the contrast aperture, the better the contrast and the lateral resolution that can be obtained. The projective lens system is used to magnify the image onto the image detector, consisting of a multichannel plate and a phosphor screen, which converts the image, so that it can be acquired by a CCD camera. More sophisticated electron-optical configurations may also involve electromagnetic instead of electrostatic lenses, or they may include electrostatic energy filters to further select the electron trajectories and improve the image quality (Bauer, 2001b).

3.2 Magnetic contrast in PEEM

The information about the magnetic state of the sample is contained in the spin polarization *and* the intensity distributions of the electrons emitted from the sample. It can be extracted by various magnetic contrast mechanisms, which fall into two classes. The first class involves a direct analysis of the electron spin polarization vector $\vec{P}$. The second class exploits a difference in the intensity distributions ΔI – a magnetic *dichroism* – for different geometrical configurations of the spin quantization axes describing the system. The physical mechanism underlying magnetic dichroism involves the excitation of spin-polarized photoelectrons due to optical orientation (Meier and Zakharchenya, 1984) into exchange split, that is, spin-polarized final states. The magnitude of the transition matrix element thus depends on the spin character of both photoelectron and final state. As a consequence, the final state effectively serves as an *internal* spin detector, translating the magnetic information carried by the spin into an intensity signal.

The most prominent magnetic contrast mechanisms in X-ray photoemission electron microscopy (XPEEM) exploit soft X-ray magnetodichroic phenomena with circularly or linearly polarized soft X rays in the electron yield mode (Stöhr and Anders, 2000 Schneider and Schönhense, 2002). This holds for the imaging of both static and dynamic magnetization configurations. With circularly polarized light (X-ray magnetic circular dichroism, XMCD), the ferromagnetically ordered state may be probed (Schütz *et al*., 1987), whereas linearly polarized light gives access to the antiferromagnetically ordered state via magnetic linear dichroism (X-ray magnetic linear dichroism, XMLD) (van der Laan *et al*., 1986). This unique feature of XPEEM permits the investigation of composite magnetic systems, comprising ferro- and antiferromagnetic components (Nolting *et al*., 2000; Kuch *et al*., 2006).

Although X-ray magnetic dichroism is sometimes referred to as the *X-ray counterpart of the Kerr effect*, there are important differences. First, the magnetic dichroism directly results in an intensity change, whereas the polar and longitudinal Kerr effects lead to polarization changes in the reflected light. In addition, the X-ray dichroic signal may be rather large (e.g., $\sim$20% intensity change at the Fe L_3 absorption with XMCD). Thus the magnetic microstructure may give rise to a contrast comparable with topographically induced contrast levels. In order to enhance the magnetic contrast, often two images taken at opposite light helicity are subtracted, thereby eliminating the nonmagnetic contrast. The XPEEM approach allows also microspectroscopy studies and thus gives access to quantitative magnetic parameters, such as the spin and orbital magnetic moments via XMCD sum rules (Thole, Carra, Sette and van der Laan, 1992;

Carra, Thole, Altarelli and Wang, 1993; Thole and van der Laan, 1993; Goering, 2005; Goering *et al.*, 2005), or the magnetocrystalline anisotropy energy via XMLD analyses (van der Laan, 1999; Dhesi, van der Laan, Dudzik and Shick, 2001). In metallic systems the information depth is about 2–3 nm. The lateral resolution of the present instruments with respect to soft X-ray-based magnetic imaging is of the order of 50 nm and basically limited by the rather large energy spread of the photoelectrons entering the PEEM. A much more narrow energy spread can be obtained in threshold photoemission, pushing the lateral resolution down to less than 20 nm. Also for threshold photoemission conditions a magnetodichroic contrast mechanism has been reported (Marx, Elmers and Schönhense, 2000), but has not yet found widespread use.

A certain complication arises from the fact that the PEEM operates with electrons, which can easily be deflected in external magnetic fields because of the Lorentz force. On the one hand, this circumstance severely limits the application of a photoemission microscope for the investigation of magnetic structures in an applied magnetic field, as the imaging capabilities are impaired. On the other hand, the sensitivity to magnetic fields can be turned into a virtue. A careful analysis of the electron trajectory changes can yield detailed information about the magnetic field distribution around and above the sample. This can be used, for example, to quantitatively determine the stray fields at the edges of microstructured magnetic elements (Nepijko, Sedov and Schönhense, 2000). In certain cases of hard magnetic materials or permanent magnets with their large stray fields, this Lorentz force deflection can even be used to image the magnetic domain distribution of the surface (Mundschau *et al.*, 1996), although only with moderate lateral resolution. We should also recall that the Lorentz force-related contrast formed the basis for the first ever observation of magnetic domains in a photoelectron emission microscope (Spivak, Dombrovskaia and Sedov, 1957).

When the photoelectrons are excited by ultrashort pulses of a Ti:sapphire laser system operating typically at a photon energy of 1.5 or 3.1 eV, frequency multiplication schemes or multiphoton excitation processes must be involved to overcome the work function. In this case, the magnetic sensitivity is achieved by explicitly analyzing the photoelectron spin polarization $\vec{P}$. The spin polarization analysis can be implemented into a PEEM as shown schematically in Figure 3 (Dürr, Kronast and Eberhardt, 2001). In addition to imaging the lateral photoelectron distribution, the photoelectron beam can be deflected into a spin detector, where its spin polarization is quantified via spin-dependent scattering of low-energy electrons from a W(100) single crystal surface (Kirschner, 1985). The normalized intensity difference between conjugate diffraction beams (marked '1' and '2' in Figure 3) – the scattering asymmetry – is a direct measure of the magnitude of the component of $\vec{P}$ perpendicular to the plane connecting the diffracted beams. Thus, the perpendicular component and one in-plane component of the spin polarization vector with respect to the sample surface can be measured simultaneously. To retain lateral resolution in spin-resolved measurements an adjustable iris aperture mounted in the first image plane of the PEEM is used to define the width of the transmitted photoelectron beam, that is, only photoelectrons emitted from a selected sample area are transmitted into the spin detector, thereby carrying local spin polarization information.

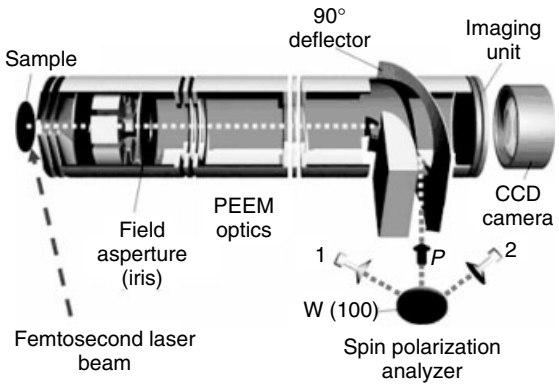

Figure 3. Schematic diagram of the spin-polarized photoemission electron microscope.

3.3 Time resolution in microscopy experiments

Time-resolved studies – or more specifically time-resolved magnetic imaging – may adopt one of the following two procedures. In the *one-shot approach* the entire image is acquired during a single pulse-wise illumination of the sample. The result represents the momentary magnetic state of the sample and is also capable of capturing nonperiodic and stochastic events, such as fluctuations in the vicinity of phase transitions, statistical switching events, or traveling spin waves. In order to be able to perform a one-shot imaging, however, one needs a very bright illumination source (photons or electrons) and a very fast and sensitive image detector. This combination is currently not yet available, and high hopes are set on the upcoming FELs and the associated instrument development.

At present, most of the time-resolved magnetic imaging experiments follow a stroboscopic imaging scheme. In this case, one repeatedly records images of the magnetic system – typically 10^6–10^8 cycles – and adds them up until a sufficient signal-to-noise ratio is achieved. It is obvious that this procedure allows one to only observe the repeatable events in the magnetization reversal process, that is, those

processes that occur during each cycle at the same location of the sample. Fluctuations and statistical switching events will be averaged out. In practice, this requires the magnetic system to be always in the same state when the data are taken. In other words, one needs to carefully control the momentary magnetic configuration of the sample of interest during the experiment by an external magnetic field or by other means. These considerations hold for experiments in the nano-, pico-, and femtosecond regimes.

A photoemission microscopy experiment dedicated to the investigation of time-resolved magnetic processes must thus include two further major ingredients: (i) a time-dependent excitation of the magnetic system and (ii) a time-resolved data acquisition scheme. The first one is usually achieved by short magnetic field pulses or laser light pulses, whereas the second one involves sophisticated synchronization schemes and/or time-resolving imaging detectors.

3.4 Short magnetic field pulses

In order to map the time evolution of the magnetization, the magnetic system is most conveniently 'excited' by an external magnetic field – sometimes called *Oersted field* – with a well-defined time structure. In most cases this time structure is either smoothly periodic (sine wave excitation) or consists of a periodic sequence of short pulses (pulse excitation) provided by a signal generator. Well up into the megahertz regime, these time-dependent magnetic fields can be generated by means of coil/yoke systems similar to the write heads used in present hard disk drives. However, the inductivity of these system limits the rise time of the magnetic field to a few 10 ns.

For faster rise times of the magnetic field pulse one has to resort to alternative approaches. An appropriate way to overcome the inductivity problem is the use of planar thin-film structures as high-frequency transfer lines. These are prepared on insulating substrates and can be appropriately designed for high-frequency applications. The structures are usually defined by optical or electron beam lithography and etching or lift-off procedures in Cu or Au films. The key to a proper control of the time dependence of the magnetic field, that is, avoiding unwanted reflections or damping of the current signal, is a proper impedance matching of the thin-film structure to the current source. Two principal geometries of these thin-film structures are most often used: microcoils and microstrip lines. The choice determines the direction of the magnetic field $\vec{H}$ with respect to the sample. If the thin-film structure and the transfer lines are properly designed taking into account geometry and material parameters, the limiting factor of the rise time of the magnetic field is the pulse generator. In many applications conventional electronic circuits are used to create short current pulses. Commercial pulse generators may provide current pulses with a minimum of about 500 ps pulse width and less than 100 ps rise time. The use of these microcoil or -strip lines requires some lithographic efforts and the structures must be adapted to the specific environment in a photoemission microscope. At present, however, this has proved to be a very successful approach, yielding many interesting results on the magnetodynamics in the nanosecond and subnanosecond regime (Schönhense, Elmers, Nepijko and Schneider, 2006).

If still faster current pulses are required, one has to resort to other means, for example, to photoconductive switches, for example, Auston switches (Keil, Gerritsen, Haverkort and Wolter, 1995) or Schottky barrier approaches (Acremann *et al*., 2001). In these cases, the excitation involves a very short laser pulse (e.g., from a Ti:sapphire laser) and enables rise times of the order of a few picoseconds. A detailed control of the pulse shape may be achieved by combining two Auston switch circuits with opposite current polarities, one of which is illuminated with a short time delay with respect to the other (Gerrits *et al*., 2001). Because of the longer recombination time of the charge carriers, the falling edges of the two current pulses are rather similar on the timescale and very closely compensate each other. In this way, even subpicosecond-width electrical pulses may be generated (Keil, Gerritsen, Haverkort and Wolter, 1995).

3.5 Pulsed light sources

In the visible range of light, lasers are the instruments of choice to generate short light pulses. Most widely employed are solid-state lasers, such as Nd-YAG systems, which deliver pulses in the 10 ps range. Also fast pulsed-laser diodes may reach into this regime. The repetition frequencies are of the order of several 10 MHz. These light sources are used in Kerr microscopy (Chumakov *et al*., 2005) or to trigger optical switches in PEEM (Raabe *et al*., 2005). Still shorter pulses of the order of 30–100 fs are obtained, if these picosecond pulses are used to pump a mode-locked Ti:sapphire oscillator. The resulting femtosecond pulses are emitted with a wavelength of about 800 nm at a repetition frequency of typically around 80 MHz. The majority of the ultrafast time-resolved experiments in the laboratory are carried out with these light sources. The ongoing development of laser sources, however, has already demonstrated the feasibility of creating pulses of several hundred attoseconds width, even at photon energies as high as $h\nu = 100$ eV (Hentschel *et al*., 2001).

For studies with chemical selectivity, the soft X-ray range ($h\nu = 50$–1500 eV) is of particular interest. In third

generation synchrotron radiation laboratories, highly brilliant beams of this light are generated by means of insertion devices, so-called undulators. Depending on the undulator type, the radiation may be linearly or elliptically polarized (Wiedemann, 2003). The emission of synchrotron radiation dissipates energy from the electrons in the storage ring. In order to compensate this energy loss the electrons are accelerated after each cycle in a microwave cavity. As a consequence, the electrons are not distributed evenly along the orbit, but are grouped into packets (bunches), with a separation determined by the microwave frequency. Since synchrotron radiation is generated only at the moment when an electron bunch passes through a bending magnet or undulator, the bunch structure results in a natural time structure of the synchrotron radiation. Depending on the operation mode of the storage ring, that is, the bunch pattern in the ring, the light pulse width ranges between $\Delta t = 1-100$ ps, at repetition frequencies from $\Delta T = 2$ ns–1 μs (Table 1).

Synchrotron radiation with an even shorter pulse width in the 100 fs range may become available soon in a novel type of facility, the FEL (DESY, 2006). The FEL comprises a linear accelerator, which feeds the relativistic electrons into a long undulator. At both ends of the undulator, optical mirrors are placed to form an optical resonator on the undulator axis. The synchrotron radiation generated in the undulator is reflected between the mirrors and can thus more efficiently interact with the electron bunches passing through the undulator. This interaction has two consequences. First, energy is directly transferred from the electrons into the electromagnetic wave field in the resonator. Second, the interaction also modulates the electron density in a bunch along its direction of motion, that is, the bunch will be segmented into short microbunches, each of which generates radiation with a pulse width in the subpicosecond regime. A more advanced concept omits the optical resonator and instead employs two undulators – a *radiator* and an *amplifier*. The light created in the radiator is fed into the amplifier to enhance the interaction between light and electrons. This approach is called *self-amplified spontaneous emission* and yields a much better control of the light pulse width. Pulses as short as 50 fs have already been generated in this mode of operation (Ayvazyan *et al*., 2006).

Table 1. Pulse train characteristics of various synchrotron and laser light sources.

Light source	Pulse width (ps)	Repetition time (ns)
BESSY multibunch	30	2
BESSY single bunch	100	805
BESSY low alpha	3	2 or 805
ESRF multibunch	20	2.8
ESRF 16 bunch	60	176
YAG laser	15	44
Ti:Sapphire	0.01–0.1	12
FEL	0.1	xx

The combination of variable photon energy and light polarization, high brilliance, and well-defined time structure renders synchrotron radiation a unique tool to study static and dynamic aspects of magnetism. It thus forms the basis of the experiments described in Section 3.

3.6 Time-resolving image detection

In the operation modes described in the preceding text, the time resolution in the PEEM is essentially determined by the width of the photon pulse. Moreover, the repetition rate in the experiment also is determined by the timing characteristics of the light source, as each light pulse will contribute to the measured signal. In order to allow for more flexible timing schemes without having to change the bunch pattern in the ring, it is advantageous to introduce some time-resolution capability in the PEEM itself. This can be achieved, for example, by using gated-detector schemes. In some cases, gating the PEEM image detector can be necessary to improve the signal-to-noise ratio and to select the proper events. In the so-called camshaft mode operation provided by several synchrotron radiation facilities, the bunch pattern consists of a multibunch sequence covering, say, about three quarters of the ring circumference. The fourth quarter which can cover a time window of up to 200 ns is empty, except for a singular highly filled bunch ('cam') placed somewhere in the center of this empty region. By ramping the operating voltage of the PEEM image converter (multichannel plate) up only in the vicinity of the cam pulse, the image detector will capture information solely related to the cam pulse, that is, the PEEM is operated in an effectively single-bunch mode (Raabe *et al*., 2005).

A complementary approach involves image detectors with intrinsic time resolution, such as, for example, a delay line detector (DLD) (Oelsner *et al*., 2001). The DLD measures the position of individual counting events in the image plane by means of a crossed-wire system with a time resolution of about 50 ps. This feature can be used to establish a particular 'interleave' operating mode of the PEEM, meaning that only every nth light pulse is used to trigger the magnetic excitation (e.g., field pulse), but a time sequence of $n-1$ images is recorded after each excitation, mapping the response of the system at regular time intervals given by the detector. In this way, the detection efficiency during the time-resolved experiments can be considerably enhanced. At present, however, the maximum counting rates of these DLD systems are still limited to a few megahertz, rendering

them appropriate only for very specialized applications. More on the implementation and use of time-resolving imaging detectors in PEEM, in particular, with respect to time-of-flight applications may be found in a recent review article (Schönhense, Elmers, Nepijko and Schneider, 2006).

3.7 Ultrafast timing configurations

The achievable temporal resolution in stroboscopic time-resolved imaging experiments is given by the duration of pump and probe pulses as well as by the temporal jitter between them. Aiming for picosecond resolution, it is possible to electronically synchronize the sources for pump and probe pulses. The resulting jitter may be of the order of a few up to 10 ps. However, when utilizing subpicosecond laser pulses down to a few femtoseconds, eliminating the jitter is imperative. This is conveniently achieved by generating both pump and probe pulses from the same source, which is then usually a femtosecond laser system. Using this approach, even experiments involving magnetic field pulses generated via an Auston switch can easily reach a temporal resolution of less than 100 fs (Gerrits *et al*., 2001).

A schematic overview of a typical full-optical pump-probe setup is displayed in Figure 4 (Link, Dürr and Eberhardt, 2001). After the first frequency conversion stage, a beam splitter generates two pulses. The reflected part, which contains 70% of the beam intensity is again frequency converted producing UV photons of around 4.5 or 6 eV and serves as the pump pulse. The transmitted part runs through an optical delay stage (retroreflector) and serves as probe pulse. Both pulses are focused onto the sample and are brought into spatial overlap. By physically moving the retroreflector, both pulses can be delayed in time with respect to each other. A retroreflector shift of 1 μm corresponds to a delay of 6.7 fs, so that precise time-resolved measurements are possible. In such a setup each pump pulse is inherently synchronized to a probe pulse. Consequently the time-resolved signal detection requires no special adjustment of the PEEM data acquisition compared to the time averaging mode.

4 MAGNETIZATION DYNAMICS INDUCED BY SHORT MAGNETIC FIELD PULSES

In the following, we will discuss some selected results from recent spatiotemporal investigations of the magnetization reversal and magnetodynamics in microstructured elements. These results illustrate that the detailed dynamic behavior of

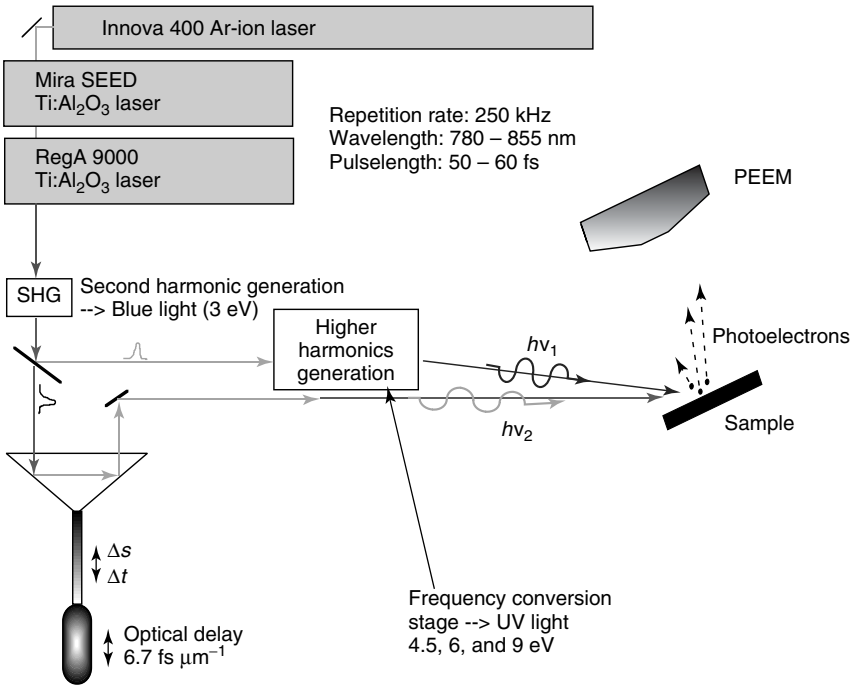

Figure 4. Schematic diagram of a femtosecond laser pump-probe setup (Link, Dürr and Eberhardt, 2001). The infrared femtosecond laser radiation is frequency doubled and split into two parts. The reflected light is again frequency converted while the other part could be delayed in time using a retroreflector. Both beams are focused onto the same spot of the sample mounted in a PEEM. (Reproduced from Link *et al*., 2001, with permission from IOP Publishing Ltd. © 2001.)

the magnetization depends in a complicated manner not only on the magnetic field conditions but also on the geometrical (shape and thickness) and intrinsic magnetic properties (anisotropy and damping) of the elements. Moreover, in the ground state these elements usually exhibit an inhomogeneous magnetization distribution, which may be described by a set of micromagnetic entities of different topology and dimensionality, such as domains, domain walls, vortices, Bloch lines, and so on. Each of these magnetic structures contributes with its individual response on a characteristic timescale to the overall magnetodynamic response. A more extensive description of these phenomena may be found in Schönhense, Elmers, Nepijko and Schneider (2006).

For educational purposes it may be useful to distinguish between small-angle excitations, which are related to spin waves and dynamic magnetization modes, and large-angle motions ($\theta > 90^\circ$) of the local magnetization vector, which are related to magnetization reversal events. By a proper choice of the experimental conditions, a certain type of excitations can be specifically prepared for studies. It should be kept in mind, however, that in a general experimental situation, both small- and large-angle excitations of the magnetization are present and will be interacting in a complex pattern.

4.1 Incoherent versus coherent magnetization rotation

In this section we deal with the most prominent configuration in a magnetodynamic XPEEM experiment. The magnetic field pulse $H_\mathrm{p}(t)$ is applied within the plane of a film with in-plane magnetization. If the field pulse is strong enough, it can initiate large-angle precessions leading to a partial or complete magnetization reversal. Of particular importance for the dynamic behavior is the initial state of the magnetic system, that is, whether the system starts from a magnetically saturated or a domain state. In the following, we will concentrate on experiments starting from an initial state with a well-defined domain configuration. This approach differs from most magneto-optic studies, in which the initial state is usually magnetically saturated (Chumakov *et al.*, 2005).

We consider a set of relatively large rectangular elements (size $20 \times 80\,\mu\mathrm{m}^2$ and $80 \times 80\,\mu\mathrm{m}^2$) of 30-nm-thick permalloy. These elements are placed on a coplanar waveguide similar to the one discussed in Section 3.4. The ground state magnetic configuration (minimal magnetic stray field) takes a characteristic Landau domain pattern (Hubert and Schäfer, 1998), consisting of a geometrical arrangement of triangular and diamond-shaped domains, which closes the magnetic flux within the structure. The domains are separated by 90° Néel walls at this film thickness. At the intersection of two domain walls in the inner part of the sample we find magnetic vortices, which will be discussed in more detail in Section 4.4. This domain pattern is also observed in the leftmost image in Figure 5), corresponding to a time $\Delta t = -1.5$ ns, that is, *before* the onset of the field pulse. The magnetic contrast in these domain images arises from MXCD at the Ni L_3 absorption edges. The arrows in the image mark the direction of the local magnetization $\vec{M}$, as reconstructed from the gray level in the domain on the basis of the angular dependence of the MXCD effect. As the geometry of the experiment is fixed, we are most sensitive to the magnetization directions pointing to the right and to the left, which result in a bright and dark contrast level, respectively.

The image sequence in Figure 5 displays time slices of the response of the magnetic system during a field pulse of 10 ns width, the time profile of which is given in the figure. The time resolution in this experiment is mainly determined by the width of light pulse, that is, $\delta t \simeq 60$ ps (see Table 1). The time slices have been recorded at intervals of $\Delta t = 125$ ps being essentially determined by the minimum increment of the delay generator. The synchronization between magnetic field pulse and synchrotron radiation pulse was achieved by means of a clock signal derived from the frequency of the microwaves used to accelerate the electrons in the storage ring. The solid line in Figure 5 maps the pulse profile at the output of a commercial pulse generator used to drive the coplanar waveguide. The second profile (circles) reflects the pulse shape directly on the waveguide and has been extracted by means of a PEEM-specific procedure making use of the fact that the current pulse on the waveguide is accompanied by an electric-field pulse $\vec{E}_\mathrm{p}(t)$ (for details, see Krasyuk *et al.*, 2003). As we can see, both the rising and the falling edge of the pulse are somewhat broadened as compared to the generator output, but the field pulse still has a well-defined plateau. It takes about 2 ns to reach this plateau value, the limiting factor basically being the capacitance of the waveguide.

Two important aspects must be considered. First, the XPEEM experiment does not involve external magnetic guiding fields, in contrast to what is customary in optical techniques (Freeman, Hiebert and Stankiewicz, 1998). This means that the initial Landau domain pattern can only be restored by the intrinsic anisotropies (dipolar and magnetocrystalline anisotropy) in the microstructure. Second, the measurements have been carried out at a repetition rate of 5.7 MHz, giving the system 176 ns time to relax in between magnetic field pulses. In this stroboscopic experiment, each image is formed by averaging over about 10^8 individual pulse events. The sharpness of the features in the image proves the Landau pattern to be a stable initial state, into which the domain structure reproducibly relaxes back after each field pulse. This reproducibility is a crucial requirement

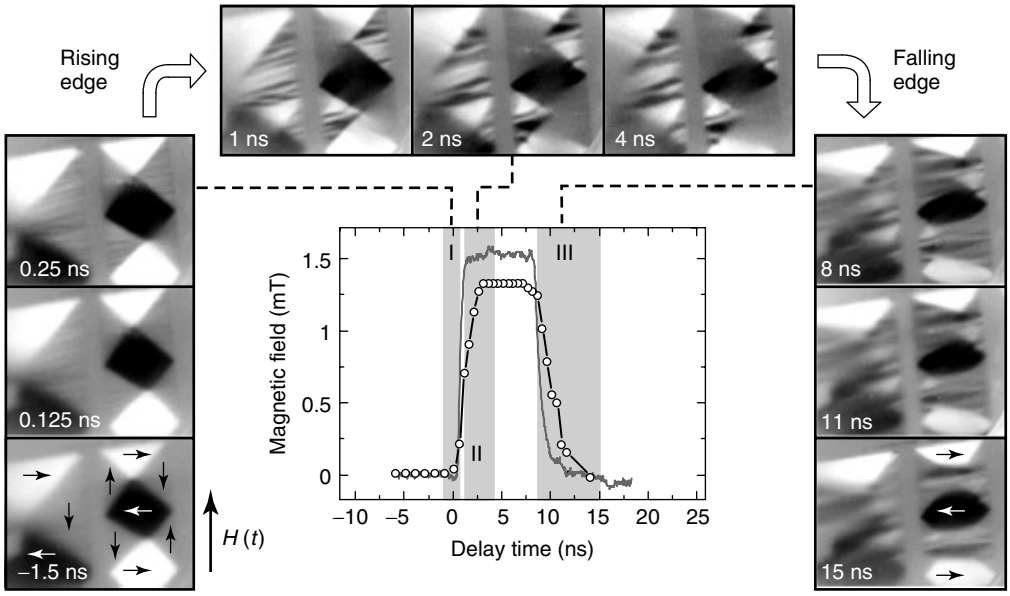

Figure 5. Time evolution of the magnetic domains in a set of rectangular permalloy microstructures (smaller one $20 \times 80\,\mu m^2$) at the rising edge (left, I), plateau region (top, II), and falling edge of a magnetic field pulse (right, III). Pulse profiles (center) measured at the pulser output (- - - -) and on the coplanar waveguide (○). The time stamps refer to the onset of the pulse and arrows give the direction of the local magnetization vector $\vec{M}$ and the pulse field $\vec{H}_p$. (Taken from Schneider *et al.*, 2006.)

in these time-resolved XPEEM experiments. Otherwise, a sampling of different magnetic configurations in subsequent pulse cycles would wash out the information in the averaged image.

During the magnetic field pulse, the transient magnetic field $\vec{H}_p(t)$ is oriented upwards in the images in Figure 5. When the pulse sets in (region I) we start to see the first changes in the magnetization distribution – the formation of a network of fine stripes in those domains, where $\vec{M}$ in the initial state is oriented opposite to the pulse field $\vec{H}_p$. Interestingly, this is a configuration in which no or little torque $\tau \sim \vec{M} \times \vec{H}_p(t)$ on the magnetization is exerted. These stripes become more pronounced with increasing $\vec{H}_p$ ($\Delta t = 0.25$ ns) up to the pulse plateau (region II). From the dark/bright contrast in the stripes we can directly conclude that they must have large components of $\vec{M}$ *perpendicular* to the field $\vec{H}_p$, which are pointing either to the left or the right. This behavior is known to be due to an *incoherent* magnetization rotation (Freeman, Hiebert and Stankiewicz, 1998; Hiebert *et al.*, 2002). This implies that the initial domain breaks up into smaller regions, each of which rotates incoherently in the external field, thereby forming this transient stripe pattern. The reason for the incoherent rotation is a limited domain wall velocity (typically several $100\,ms^{-1}$), prohibiting a response of the domain structure to the fast pulse by simple domain wall motion. It is remarkable, that these fine stripes are apparently formed always at the same location on the sample, otherwise they would not show up as sharp features in the images. This already suggests that the formation mechanism may involve a network of nucleation sites provided, for example, by magnetic inhomogeneities such as magnetization ripple. In the latter case, the local magnetization changes its direction slightly from point to point because of laterally varying magnetic anisotropies. We note that the other domains are not yet affected significantly. In particular, those domains with $\vec{M} \parallel \vec{H}_p(t)$ do not exhibit the stripe pattern.

In region II we can discern further details of the remagnetization process. The previously sharp boundaries between the triangular domains with $\vec{M} \parallel \vec{H}_p$ and $\vec{M} \perp \vec{H}_p$ appear to gradually wash out when moving from the corner of the sample toward the vortex position ($\Delta t = 1$ ns). This can be seen more clearly in Figure 6(b), which displays the upper end of the narrow rectangle in Figure 5 imaged with higher magnification. The reconstructed magnetization distribution is given in Figure 6(e–h), the arrows marking the in-plane direction of the local magnetization vector. From there we can see that the entire area that was initially magnetized opposite to the pulse field is subject to incoherent rotation processes. In particular, the vortices remain at the same positions.

The transient domain walls bounding the incoherently rotated areas resemble to some extent so-called cross-tie walls. This has been noticed in comparable Kerr effect experiments also (Neudert *et al.*, 2005). However, there is a distinct difference from the static cross-tie walls, which are well known for thin-film elements Hubert and Schäfer

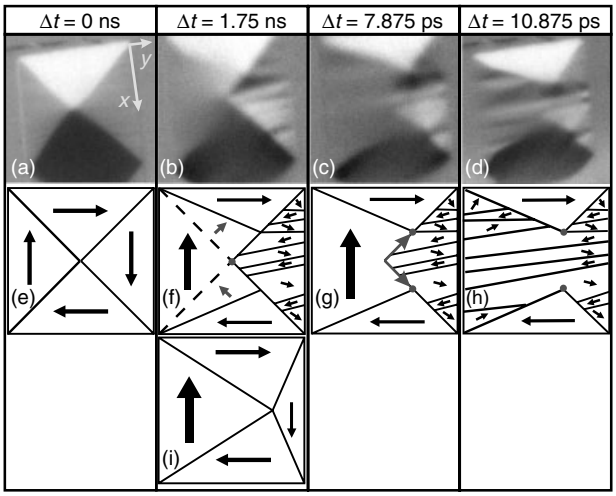

Figure 6. Time evolution of the magnetic domains at the upper end of the rectangular $20 \times 80\,\mu^2$m permalloy microstructure at $\Delta t = 0$ ns (a), $\Delta t = 1.75$ ns (b), $\Delta t = 7.875$ ns (c), and $\Delta t = 10.875$ ns (d). The panels (e–h) display the reconstructed magnetization distribution, reflecting the evolution of the triangular domain with 'up' magnetization into a 'W'-shaped structure via magnetization rotation and formation of vortices (gray circles). (Reproduced from Schneider *et al*., 2004, with permission from the American Physical Society. © 2004.)

(1998) and Kronmüller and Hertel (2000). In the static case, the 90° walls, which intersect a classic 180° Néel wall to form the cross-tie configuration extend to both sides of the 180° wall, that is, the configuration is somehow symmetric with respect to the 180° wall. In the dynamic case described in Figures 5 and 6, the situation is much more asymmetric. The two 90° Néel walls separate the coherently rotated region of the left-hand side from the incoherently rotated region on the right-hand side. Therefore, a direct comparison of these wall types in the static and dynamic cases should be made with great care.

The gradual contrast change in the transition regions between $\vec{M} \parallel \vec{H}_\mathrm{p}$ and $\vec{M} \perp \vec{H}_\mathrm{p}$ can be understood as a *coherent* rotation of $\vec{M}$. This behavior is due to the fact that for the situation $\vec{M} \perp \vec{H}_\mathrm{p}$ the torque acting on the magnetization is highest, and the system can easily respond by simply rotating $\vec{M}$ into the direction of the external field. As a consequence, the triangular domains with $\vec{M} \parallel \vec{H}_\mathrm{p}$ grow on the expense of the neighboring ones with $\vec{M} \perp \vec{H}_\mathrm{p}$ ($\Delta t = 2$ ns). Further studies show that the coherent rotation process starts with the onset of the field pulse and is thus – as expected – faster than the incoherent rotation events. As a consequence, the domain wall, which is still clearly visible, is displaced at very high speeds of up to $1000\,\mathrm{ms}^{-1}$ (Schönhense, Elmers, Nepijko and Schneider, 2006). We also note that these coherently rotated regions narrow down, if we move from the position of the central vortex to the edge of the microstructure, giving rise to a triangular shape of this region (Figure 6b). This is due to the fact that the domain wall is more strongly pinned in the corner of the microstructure. As a general feature of this multidomain state, the response is obviously determined by a competition between coherent and incoherent rotation processes, depending on the orientation of the local magnetization with respect to the pulse field $\vec{H}_\mathrm{p}$.

It is instructive to compare the experimental findings up to this point to the known response of the Landau pattern to a slowly varying field. In this case, the magnetization reversal takes place via domain wall displacement. Upon applying the field, the domain with $\vec{M} \parallel \vec{H}$ grows on the expense of the other domains (Figure 6i). In particular, the position of the vortex moves, in the given example toward the right edge of the sample. As a result the domain in which $\vec{M}$ is oriented antiparallel to the applied field shrinks. This behavior is in clear contrast to our observations and thus cannot describe the highly dynamic situation created by a fast field pulse.

The interplay between coherently and incoherently rotated regions also has another interesting consequence. As the field strength increases, the central vortex retains its position, but the locations where the domain walls meet the incoherently rotated area shift away from the central vortex ($\Delta t = 4$ ns in Figure 5), thereby creating two new vortices. In this course, the domains with $\vec{M} \parallel \vec{H}_\mathrm{p}$ take the shape of a 'W' lying on its side, with the new vortices moving along the long legs of the 'W'. Again, this is seen more clearly in the magnified image in Figure 6(c) and the corresponding graphical reconstruction (Figure 6g). The position of the vortices is marked by the grey circles in Figure 6(e–g).

The microscopic mechanisms determining the magnetization dynamics can also be sensitively influenced by static fields. XPEEM experiments to this issue are still missing. However, Kerr microscopy studies on comparable samples have demonstrated that even a small additional magnetic field – in the transverse direction in this case – may significantly modify the response of the system (Choi *et al*., 2001a,b).

4.2 Blocked relaxation

Finally, in region III of Figure 5 the pulse field drops again and the magnetic system is allowed to relax. This relaxation, however, also exhibits a peculiar behavior. First, we note that the stripe pattern almost instantaneously expands into the domains with $\vec{M} \parallel \vec{H}_\mathrm{p}$ as soon as the field drops ($\Delta t = 8$ ns). Although it may be tempting to invoke domain wall motion as the driving mechanism, this hypothesis must be dismissed because of the limited domain wall velocity. A faster mechanism must involve rotational processes and

can be understood in the following way. On the rather long plateau of the field pulse, the magnetic system has sufficient time to assume a new quasiequilibrium state, which is determined by an effective field H_{eff} including the pulse field. On the trailing edge of the pulse, H_{eff} is reduced and this change ΔH_{eff} acts onto the system like a field pulse into the opposite direction. For the 'W'-shaped area, in particular, this means ΔH_{eff} is directed *opposite* to the local magnetization direction. As a consequence, incoherent rotation events start to take place and can form a stripelike domain structure containing small- and large-angle domain walls in this region. It is thus a local magnetization rotation rather than a domain wall motion that leads to the 'expansion' of the stripe pattern.

After this fast initial change, however, the magnetization configuration remains rather stable. Only marginal changes appear in the images between $\Delta t = 8$ and 15 ns. This means that the relaxation of the 'excited' magnetic state, that is, the decay of the stripelike phase, takes place on a significantly longer timescale (>10 ns) than its buildup ($\simeq$1 ns). Even after $\Delta t = 20$ ns we did not observe a full relaxation of the system. The stability of the stripe domain phase is another consequence of the limited domain wall velocity. In this context, we would like to recall that in the absence of the pulse field, the restoring force that drives the system back to the initial state results only from the demagnetizing field and the anisotropy. Apparently, this restoring force is not strong enough to initiate rotation processes to resolve the domain walls locally. Instead, the walls are removed from the system via domain wall displacement. If there is a pulse field acting in the opposite direction, however, the incoherently rotated regions may be restored much faster. This has been observed in experiments with bipolar pulses (Schneider *et al.*, 2004).

4.3 Transient stray fields

The PEEM is also ideally suited to investigate the issue of transient magnetic stray fields. As stated above, the Landau domain pattern forming the initial state in the experiment (Figure 5) is a consequence of energy minimization. If we inspect the incoherently rotated regions close to the sample edge, we note, however, that this magnetization distribution causes many magnetic poles at the sample edge. This can be seen more clearly at the right-hand side of the structure in Figure 6(h), which displays the graphical reconstruction of the magnetization distribution at $\Delta t \approx 11$ ns after the field pulse onset. These magnetic poles should generate a sizable stray field outside the permalloy microstructure. Considering the fact that the XPEEM image is built up by low-energy electrons, a question arises as to whether this stray field has some influence on the image. Recalling our discussion of the Lorentz force-related contrast in Section 3.2, we can use similar arguments in the present case. Let us assume the sample edge to be ideally straight (Figure 7a). In the absence of a magnetic stray field, the image of the edge will also show a straight line. In the presence of a stray field, the electron trajectories starting in the vicinity of the sample edge and passing through the stray field region will be changed by the Lorentz force, and the image of a straight edge will appear rather as a 'jagged' line. In a realistic sample, this interaction will thus lead to a stray field-induced distortion in the image of the object. Knowing the imaging parameters of the microscope and the exact shape of the object, we can quantitatively determine the stray field (Nepijko, Sedov and Schönhense, 2000). As an example, we take the image recorded at $\Delta t \approx 11$ ns (Figure 7b). In order to visualize the distortion of the sample edge in the image, we have magnified the sample edge in the horizontal direction. The straight edge is imaged into the wavy line A $\longmapsto$ B. From this line we can extract a quantitative value of the trajectory deflection $S_y(x)$ (Figure 7c), which serves as an input for the calculation of the stray field component $B_x(x)$ along the sample edge. As can be seen in Figure 7(d), the stray field at the edge can easily reach values of $B_x > 100$ mT. This result confirms the expectation that the energy minimization may be violated on nanosecond timescales, because it is less important than torque arguments.

4.4 Vortex-core rotation

A particularly interesting structure that occurs in thin films is a magnetic *vortex*. A vortex is an almost singular point in the magnetization distribution. It can be most clearly observed in microstructured systems with an in-plane magnetization. The geometrical shape of the microstructure gives rise to a demagnetizing field, which forces the magnetization into a closed path around the center of the structure. In the center of this magnetization swirl or vortex, however, the magnetization vector turns out of the film plane despite the in-plane magnetic anisotropy in order to meet the constraint $|\vec{M}| = \text{const.}$ and avoid magnetic frustration. This vortex-core structure and particularly the out-of-plane magnetization $\vec{M}_z$ have been experimentally confirmed first by magnetic force microscopy studies (Shinjo *et al.*, 2000). Further details on the internal magnetic structure of the vortex region were revealed by spin-polarized scanning tunnelling microscopy (STM) (Wachowiak *et al.*, 2002). With respect to the film plane, for a given sense of rotation of the vortex, two energetically equivalent configurations are possible, with $\vec{M}_z$ pointing away from or toward the surface. These two configurations differ only by their 'handedness'. This handedness will be of importance for the dynamical behavior.

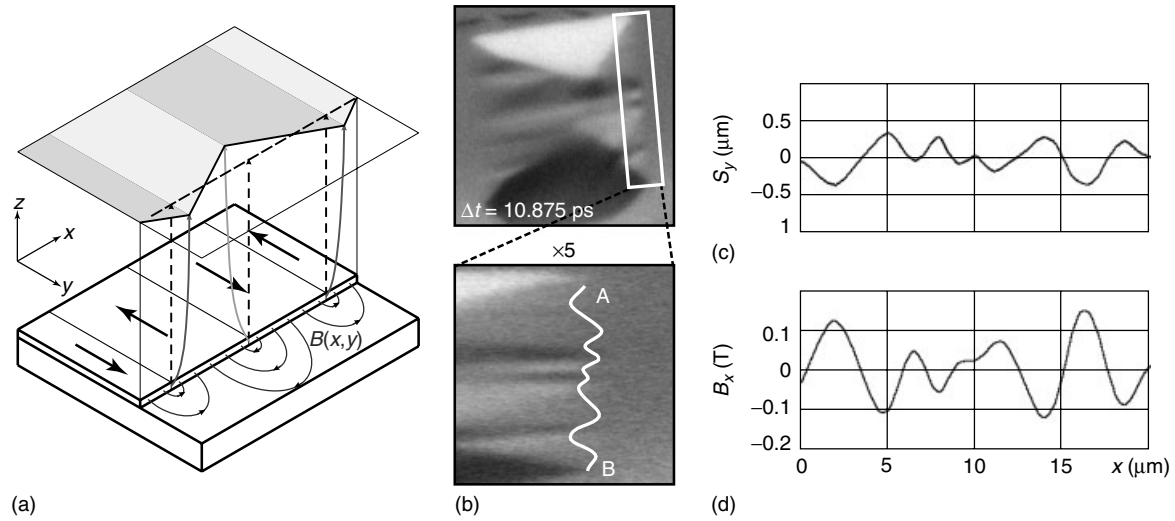

Figure 7. Image distortion due to magnetic stray fields at the sample edge. (a) Change of the electron trajectories due to the Lorentz force. (b) Magnetization configuration at $\Delta t = 10.875$ ns and horizontally magnified (×5) edge region. (c) Quantitative evaluation of the edge shift $S_y(x)$ along the path A $\longmapsto$ B. (d) and resulting magnetic stray field component $B_x(x)$. (Reproduced from Schneider *et al*., 2004, with permission from the American Physical Society. © 2004.)

The question of how such a three-dimensional magnetic object like a vortex behaves dynamically was first addressed by time-resolved Kerr effect investigations on submicrometer-size permalloy disks (Park *et al*., 2003). These experiments probed the polar Kerr effect close to the center of the disk and observed a distinct periodic variation of the polar Kerr signal, when the system was magnetically excited by a short in-plane field pulse. Since most of the polar Kerr signal should originate from the $\vec{M}_z$ component in the vortex core, the periodic signal variation was explained by a motion of the vortex core in and out of the laser spot. The entire vortex core was proposed to undergo a *gyrotropic* motion, that is, to rotate around the geometrical center of the disk. Owing to the small size of the disk, however, a direct imaging was beyond the lateral resolution of Kerr microscopy.

The issue of the gyrotropic motion of the vortex core was also addressed with the better lateral resolution provided by XPEEM (Choe *et al*., 2004). The samples consisted of microstructured elements of a CoFe alloy film of 15 nm thickness, placed on a coplanar waveguide. The current pulse was launched by means of an Auston switch and had a width of around 300 ps full width half maximum (FWHM) at a maximum amplitude of $B_{\max} \sim 15$ mT. The repetition rate of the field pulse was around 125 MHz, giving the magnetic system about 8 ns to relax into the ground state.

We first compare domain image 'snapshots' taken at two different time delays Δt after the exciting field pulse (Figure 8) for rectangles with increasing aspect ratio: (I) $1 \times 1\,\mu m^2$, (II) and (III) $1.5 \times 1\,\mu m^2$, and (IV) $2 \times 1\,\mu m^2$. All rectangles exhibit the simple Landau pattern with two diagonal 90° domain walls and a central vortex. In each image sequence, however, the position of the vortex in the center region shifts more or less strongly between the first and the second image. The most pronounced difference occurs in the rectangle with the largest aspect ratio (IV). In the image taken at $\Delta t = 3.3$ ns the vortex core is shifted from the center to the *left* by around 400 nm, whereas at $\Delta t = 7.7$ ns the core position is located at around 400 nm to the *right* of the geometrical center. Recalling the fact that the magnetic field pulse has a width of less than 1 ns, it apparently has initiated a motion of the vortex core, which continues beyond the field pulse duration.

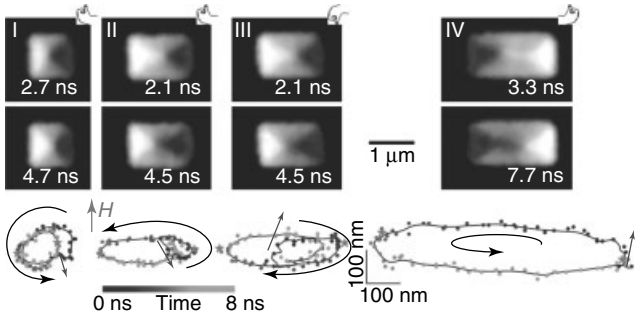

Figure 8. XPEEM domain images of various rectangular CoFe elements (XMCD signal at the Co $L_{2,3}$ edges) with increasing aspect ratio (denoted as I–IV) as a function of the specified time elapsed after the magnetic field pulse. The bottom panels map the respective trajectories of the vortex in 100 ps steps. The progression in time is indicated by the dot greyscale. Hands illustrate the vortex handedness and the direction of the out-of-plane core magnetization. (Taken from Choe *et al*., 2004.)

In order to map this behavior in more detail, the vortex-core position has been determined from subsequent images acquired in time increments of 100ps for the maximum timeline of 8ns. The resulting trajectories of the core movement (bottom part of Figure 8) can be decomposed into two phases. During the field pulse, the vortex core responds by a linear accelerated motion along the direction indicated by the gray arrows. After the field pulse it follows the curved path marked by the black line. Whereas for the quadratic structure (I) this curved trajectory closely approaches a circle, it is strongly elliptical for the $2 \times 1\,\mu m^2$ element. These curved trajectories directly reflect the gyroscopic motion of the vortex cores, which is driven by the magnetostatic field of the moving vortex. A closer inspection of the data in Figure 8, however, reveals two peculiarities. First, there seems to be no common sense of rotation (indicated by the black arrow) or direction of the linear motion. In other words, for two elements with a similar in-plane domain pattern, opposite senses of rotation can occur, for example, clockwise for element (III) and counterclockwise for element (II). As will be discussed below, this difference is related to the chirality of the vortex. Second, the initial linear motion is directed mainly *along* the axis of the pulse field, not perpendicular to it.

For reasons of simplicity, we assume an ideal vortex structure on a square (Figure 9). Together with the in-plane magnetic configuration, the out-of-plane component M_z of the vortex (arrow at the center of the squares in Figure 9a) defines a chirality of the system, being left handed (right handed) for the structure on the left (right) side of the figure. From the results discussed in Section 4.1 we know already, that a nanosecond field pulse may not simply cause a simple domain wall motion resulting in a motion of the vortex perpendicular to the applied field (Figure 6i). If the pulse field $H_p(t)$ is even shorter, the precessional motion of $\vec{M}$ becomes important. $H_p(t)$ generates a torque (indicated by the blue arrows) on those magnetization components with $M_i \perp H_p$. On the subnanosecond timescale, the initial motion is a precession of the magnetic moment around H_p, which is stronger than the damping along the field direction (Choe *et al*., 2004). If we consider the left-hand case in Figure 9(a), the magnetization in domain 3 precesses toward the core magnetization, that is, develops an out-of-plane component, whereas the core magnetization precesses toward domain 1, that is, develops an in-plane component. If we define the position of the vortex core by the maximum M_z component, this concerted precessional motion of the magnetization distribution results in an effective movement of the vortex core antiparallel to the applied field. The same arguments explain the initial movement of the right-handed vortex parallel to $H_p(t)$.

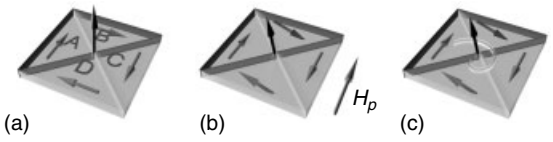

Figure 9. (a) Spin structure of a left-handed vortex structure (vortex core indicated by the vertical arrow). (b) Initial sideways motion of the vortex core due to the magnetization torque exerted by the pulse field. (c) Subsequent trajectory of the vortex core projected onto the surface (spiral line). (After Choe *et al*., 2004.)

This initial linear displacement of the vortex core by $H_p(t)$ is the key process, which starts the subsequent gyrotropic rotation of the core. The displacement is accompanied by an imbalance of the in-plane magnetization components, which in turn causes a magnetostatic field perpendicular to this displacement, trying to restore a balanced configuration. This situation sends the vortex core onto a counterclockwise (Figure 9b) or clockwise spiraling trajectory (Figure 9c). The trajectories plotted in Figure 9(b) and (c) are the result of a micromagnetic simulation, covering the first 3 ns after the field pulse. The magnetic damping in the system causes the trajectory of this gyrotropic motion to spiral inwards again, until the balance of the in-plane magnetization components is restored.

Raabe *et al*. (2005) report a similar experiment with a repetition time of the field pulse of 16 ns. In contrast to a gyrotropic motion, however, they find only a linear displacement of the vortex perpendicular to the applied field. The shorter relaxation period in the experiment of Choe *et al*. (2004) is proposed as a possible explanation for this discrepancy. According to the findings by Raabe *et al*.'s findings, the vortex is still moving with a speed of $\sim 100\,m\,s^{-1}$ by the time the next field pulse arrives in Choe *et al*. experiment. Another difference between these experiments, however, which has not been noted so far, is found in the rise times and peak values of the field pulse. According to the reported values in both publications, the field sweep rate $\delta H/\delta t$ is at least a factor of 5 higher in the approach by Choe *et al*. This difference could also have a significant impact on the dynamic response by virtue of exciting modes in a broader frequency range. These examples demonstrate that the dynamic response of a magnetic system in the subnanosecond regime depends not only on the initial state but also significantly on the details of the experimental procedure.

A vortex is a very stable structure and a high field of the order of $H \sim 0.5\,T$ is required to reverse the direction of the vortex core. In this case, the field is applied opposite to the vortex-core direction. In the fast dynamic case, the situation may be significantly different. It has been shown that a continuous excitation of the vortex by a small periodic in-plane field causes the vortex core to precess on a stable

orbit (Chou *et al*., 2006). Taking this precessional motion as a dynamic ground state of the system, a pioneering experiment by Stoll *et al*. showed a small burstlike increase of the field amplitude by a few millitesla to be sufficient to switch the vortex core (van Waeyenberge *et al*., 2006). Detailed micromagnetic simulations revealed a complex microscopic mechanism, which involves a complex sequence of vortex–antivortex creation and annihilation steps (Hertel and Schneider, 2006).

5 QUASIRESONANT EXCITATIONS

In this section, we discuss the results of an experiment involving a periodic magnetic field excitation (Krasyuk *et al*., 2005). As already demonstrated in Section 4.2, the relaxation of the transient magnetization configuration induced by a field pulse may take several nanoseconds to several tens of nanoseconds, depending on the configuration. On the other hand, it is well known from several studies that the precessional motion in permalloy involves frequencies down to the low gigahertz regime (Choi *et al*., 2001; Park *et al*., 2003; Raabe *et al*., 2005; Neudert *et al*., 2005). If we take a 10–nm-thick rectangular element of $16 \times 32\,\mu m^2$ size, micromagnetic simulation predicts a precessional mode with a frequency of 1.25 GHz (Krasyuk *et al*., 2005). The question is thus, whether the XPEEM imaging is able to pick up the response of such a particular mode.

In the respective experiment, the element was excited with a pulse train at a repetition rate of 500 MHz. As this corresponds to the regular multibunch operation of the storage ring, each field pulse is followed by a soft X-ray pulse for imaging. The sample was adjusted such that the light impinged *perpendicular* to the magnetization of the long domains with the magnetization vector pointing up and down, respectively (Figure 10). In the static image, the contrast arises thus mainly from the top and bottom closure domains of the Landau pattern. In addition, there is a line contrast from the 180° domain wall in the center of the structure. This contrast arises from the fact that in a Néel wall the magnetization vector rotates within the film plane and thus has a component along the direction of light incidence $\vec{q}$ in the center portion of the wall. This wall contrast will become important in the second part of this section.

In the chosen geometry the magnetic contrast in the vertically magnetized domains vanishes in the static case, because of $\vec{M} \perp \vec{q}$. Therefore, this arrangement is very sensitive to small changes in the magnetization direction in these domains, as any component of $\vec{M}$ along $\vec{q}$ will give rise to a change in the contrast level. This property is exploited in the dynamic experiment, where one observes a clear change

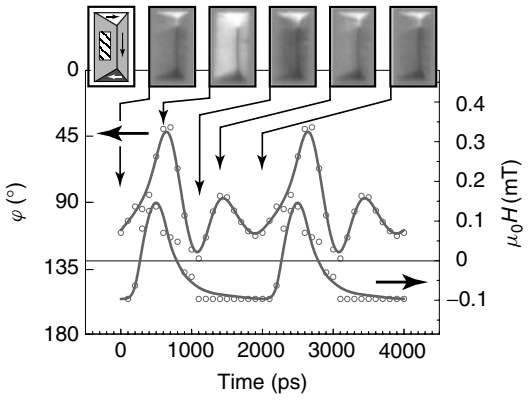

Figure 10. Response of a permalloy microelement to a periodic excitation. (Top) Selected XMCD domain images recorded at the temporal positions indicated. The leftmost sketch depicts schematically the transient domain configuration during the experiment, the shaded area marking the integration area for quantitative contrast evaluation. (Bottom) Experimentally determined field pulse shape $H(t)$ and rotation of the magnetization vector $\varphi(t)$ as calculated from the contrast change in the shaded area. (Taken from Schneider *et al*., 2006.)

of the magnetic contrast in these areas as soon as the field pulse acts on the element (Figure 10).

The pulse field in this experiment is directed in plane and perpendicular to the magnetization direction in the long domains, thus exerting the maximum torque in these domains. We note that the change in contrast is the same in both domains, although the magnetization direction in the long domains is opposite. This contrast change is due to an additional in-plane component of $\vec{M}$, which arises because of the precessional motion started by the field pulse. Initially, the torque acting on the magnetization pulls it out of the film plane in opposite directions for the left and the right domain. This motion is counteracted by the increase in demagnetizing energy and leads to a precessional trajectory with an opposite sense of rotation with a large in-plane magnetization component M_x along $\vec{q}$. The initial part of the precession is basically in phase for both domains, therefore the in-plane components M_x yield a comparable magnetic contrast. The damped precessional nature of the motion is clearly visible by the alternating magnetic contrast levels in selected images of a longer sequence.

From the XMCD signals in the image sequence, one can quantitatively determine the magnitude of M_x and thus the angle φ, by which the magnetization vector $\vec{M}$ is rotated out of the equilibrium position (bottom part of Figure 10). Comparing the results for $\varphi(t)$ to the field pulse shape reveals the damped oscillatory character of the motion of $\vec{M}$. The maximum deflection is reached slightly after the maximum of the field pulse and the period of this oscillation is about 800 ns, being in agreement with the prediction of 1.25 MHz

from the simulation. Therefore, only about two periods are visible, before the next field pulse excites the system again. The numerical values of $\varphi(t)$ prove that the motion involves in fact a large-angle precession of the magnetization within the individual domains.

A closer inspection of the domain images reproduced in Figure 10 reveals another interesting finding, namely, a distinct displacement of the domain wall away from the center of the structure, as compared to the field-free ground state. We verified that this displacement is indeed a transient effect and occurs as a response to the periodic magnetic excitation of the system. In particular, the displacement increases with increasing field pulse amplitude and thus growing precession amplitude (Figure 11). Above a certain critical amplitude, the wall is essentially driven out of the system. In passing, we note that the 180° wall seen in Figure 11 contains a Bloch line across which the sense of the in-plane rotation of the magnetization within the wall changes. Therefore, the upper part of the wall appears bright, whereas the bottom part appears dark.

The reason for the unidirectional shift Δx of the domain wall is a specific resonance phenomenon. A Fourier analysis of the magnetic field pulse sequence reveals significant contributions of higher harmonics of the fundamental frequency of 500 MHz, that is, at 1 and 1.5 GHz. The second and third harmonic components are the most important ones, as the eigenfrequency of the precessional mode is around 1.25 GHz. This means that the magnetic system is driven close to resonance. The system can absorb more energy from the excitation and increase its entropy by moving its eigenfrequency closer to the component of exciting frequency spectrum which has the higher power. In our case this is the 1 GHz component. By increasing the size of the already larger domain, its precessional frequency is lowered and thus moves a little closer to the second harmonic component. This process is counteracted by an increase of the demagnetizing energy, establishing a new quasistationary domain configuration. An increase of the precessional amplitude via the field pulse amplitude thus leads to a further increase of the domain area and shift of the wall. This situation can be modeled more quantitatively (for details, see Krasyuk *et al*., 2005), with the result for the displacement Δx as a function of the precession amplitude being shown by the line in Figure 11(e). The data points I, II, and III correspond to the experimental situation depicted by the images (b–d). The delayed onset is due to domain wall pinning. This example demonstrates that high-frequency excitations may lead to both a high-frequency and a quasistatic response in the same experiment.

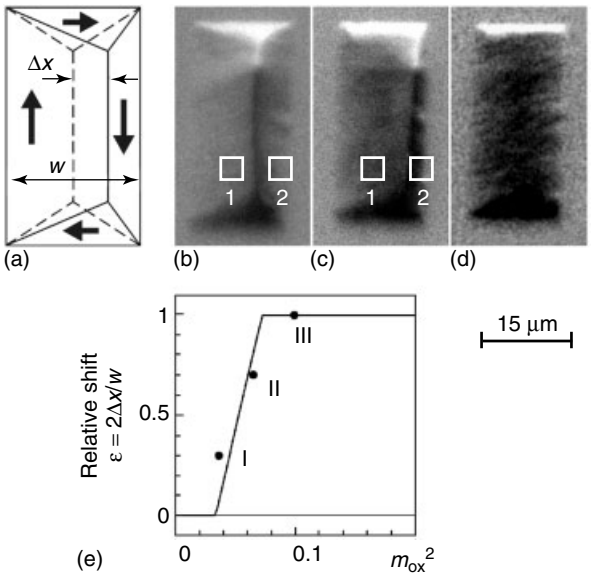

Figure 11. Quasistatic displacement of a domain wall due to resonant excitation. The images (b), (c), and (d) show the transient domain configuration at $\Delta t = 600$ ps for increasing field pulse amplitudes, (a) gives a sketch of the domain structure. (e) Relative domain wall displacement ϵ as a function of precessional amplitude (represented here by the maximum magnetization component m_x occurring during precession). (Taken from Krasyuk *et al*., 2005.)

6 ULTRAFAST EXPERIMENTS

Femtosecond pump-probe studies are of increasing importance for many new research areas such as femtochemistry (Bonn *et al*., 1999), ultrafast magnetization dynamics (Koopmans, van Kampen, Kohlhepp and de Jonge, 2000), ultrafast surface melting (Rousse *et al*., 2001), and coherent excitation of phonons (Sokolowski-Tinten *et al*., 2003), or magnons (Melnikov *et al*., 2003). In such studies the electronic system is excited by the absorption of a femtosecond laser pump pulse. The energy transfer to other degrees of freedom is then measured stroboscopically in real time by a subsequent femtosecond laser probe pulse. Pump-probe studies offer the opportunity to observe changes in the electronic system while the nuclei are practically at rest. Also the influence of other quasiparticles such as spin excitations can be separated since the timescales of these processes is usually different. In all of these cases the optical excitation represents a significant disturbance to the electronic system. For instance in pump-probe investigations of the femtosecond magnetization dynamics on average one electron–hole excitation takes place for about every 10th atom throughout the material (Koopmans, van Kampen, Kohlhepp and de Jonge, 2000; Rhie, Dürr and Eberhardt, 2003). Comparable excitation densities are expected for other applications (Bonn *et al*., 1999; Rousse *et al*., 2001; Sokolowski-Tinten *et al*., 2003; Melnikov *et al*., 2003). The evolution of electronic and magnetic excitations in this regime is a very active research field

(see also **Time-resolved Kerr-effect and Spin Dynamics in Itinerant Ferromagnets, Volume 3**) which will become even more interesting with the availability of X-ray FEL sources in the future.

In addition to femtosecond temporal resolution, probing the system on the nanometer scale is important since electronic and spin excitations typically travel only submicrometer distances on such timescales. It is well known that a dielectric medium can be used to manipulate the properties of light pulses even leading to the trapping of light inside photonic crystals (Mok and Eggleton, 2005). For metals the dielectric material's response to light is mainly determined by the plasmon resonance, that is, by collective oscillation of the electrons. This is utilized in the emerging field of plasmonics for manipulating optical radiation at subwavelength dimensions by metallic nanostructures (Ozbay, 2006). The use of pulsed-laser radiation offers the exciting prospect of tailoring the pulse structure (length, polarization intensity, etc.) by coherent control to optimize the nanoscale system response (Brixner, de Abajo, Schneider and Pfeiffer, 2005). Ultimately it should be possible to use femtosecond pump-probe spectroscopy with optimally shaped laser pulses for exciting one quantum system and observe in real time the nonlocal information transfer to another system (Brixner, de Abajo, Schneider and Pfeiffer, 2005).

In this chapter we review recent attempts to achieve nanometer spatial and femtosecond temporal resolution on magnetic nanostructures. This approach is based on the plasmonic enhancement of the photoemission yield from nanostructures.

6.1 Imaging plasmonic near fields of nanostructures

Surface plasmon enhanced optical fields at microscopically rough surfaces were employed early to explain the chemical sensitivity enhancement in various optical spectroscopies (Wokaun, Gordon and Liao, 1982). Similar plasmon enhancement effects were used in two-photon photoemission spectroscopy to specifically probe laser-induced electronic excitations in Ag nanoparticles although without any lateral resolution (Lehmann *et al*., 2000). The plasmon enhanced optical near fields at the boundaries of Ag nanostructures have been directly imaged using PEEM (Cinchetti *et al*., 2005). The spatial and temporal plasmon propagation was determined in real time using pump-probe PEEM spectromicroscopy (Kubo *et al*., 2005).

Near field enhancements occur also for transition metals which do not display strong plasmon resonances. An example is shown in the following text. Utilizing the light polarization dependent dielectric response of ferromagnetic CoPt nanodots energy is pumped into electron–hole excitations. Femtosecond pump-probe spectroscopy is then employed (see the next section) to probe the real-time energy transfer into spin excitations leading to a reduction of the ferromagnetic spin alignment in the nanodots.

The experimental setup is shown schematically in Figure 3. The sample consisted of $200 \times 200\text{-nm}^2$ wide magnetic structures separated from each other by 100-nm-wide and 100-nm-deep troughs (see Figure 12a) (Dürr, Kronast and Eberhardt, 2001). A multilayer with Pt(1.8 nm)[Co(0.5 nm) Pt(1.8 nm)]$_4$ was sputter deposited on top of a patterned Si substrate. The multilayer structure of the nanodots induces an equilibrium spin alignment along the surface normal owing to a large perpendicular magnetic anisotropy at the CoPt interfaces (Dürr, Kronast and Eberhardt, 2001).

Figure 12 shows typical PEEM images of this sample. The sample was illuminated from the left by 3.1 eV (b) and 6.2 eV photons (c) with s- and p-polarization, respectively. Although the dot structure is resolved in both images there are clear differences. The image taken with 3.1 eV photons shows much better lateral contrast due to the more

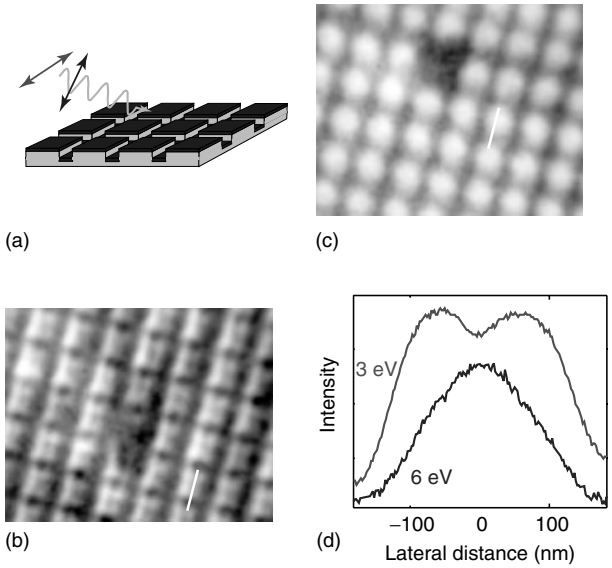

Figure 12. (a) A schematic view of the sample. In all images the light is incident from the left at an angle of 25° to the sample surface. (b) and (c) PEEM images of the same sample area taken with laser excitation at 3.1 eV photon energy for s-polarized (gray double arrows) and 6.2 eV photons for p-polarized (black double arrows) light, respectively. Note that one nanodot is missing near the center of the images. In (d) the linescans over a single nanodot (indicated by the white lines in (b) and (c) illustrate the different emission characteristics for 3.1 eV s- and 6.2 eV p-polarized light as gray and black lines, respectively. Data in (d) have been scaled to equal intensity and are offset for clarity. (Reproduced from Dürr *et al*., 2001, with permission from Springer-Verlag GmnH. © 2001.)

pronounced edges of the dots. This can also be seen in the linescans shown in Figure 12(d). For 3.1 eV photons, the photoemission intensity is concentrated at the edge of the dots while for 6.2 eV emission takes place mainly in the dot center. The images in Figure 12 were normalized to maximum/minimum contrast. In the raw data there are additional differences visible. While for 3.1 eV photons there is almost no photoemission intensity detectable coming out of the troughs, there is a significant contribution from these areas at 6.2 eV.

The photon energy dependence of the PEEM images in Figure 12 is an indication that the nanodot dielectric response modifies the laser field amplitude at the sample surface (Dürr, Kronast and Eberhardt, 2001). This process can be modeled approximating the CoPt nanodots or by ellipsoidal particles with lateral and vertical dimensions of 200 and 10 nm, respectively. Neglecting interactions between the nanodots and using bulk optical constants for Co and Pt the electric-field enhancement, $f(h\nu)$, at the tips of the long and short axis of ellipsoidal nanodots can be calculated for s- and p-polarized light (see Figure 13) (Wokaun, Gordon and Liao, 1982). The curves are dominated by a Mie-plasmon resonance broadened by interband transitions. The resonances depend on the particle shape and are red shifted for plasma oscillations along the long axis of the spheroid (excited by s-polarized light) and blue shifted for oscillations along the short axis (excited by p-polarized light).

This polarization dependence in Figure 3 implies different emission directions for photoelectrons. In photoemission the maximum intensity usually occurs when the light electric-field vector is aligned along the surface normal. This can easily be seen considering the dipole transition matrix element between initial $|i>$ and final $|f>$ states which is $<i|\nabla V|f> \cdot \mathbf{A}$, where $\mathbf{A}$ is the electric-field vector potential and ∇V is the surface potential gradient along the sample normal. Consequently mainly horizontal photoelectron trajectories starting from the nanodot edges are expected with s-polarized light. Such trajectories are indeed observed in Figure 14(a) and (b) when the contrast aperture in the objective lens backfocal plane (see Figure 2) is moved off center. The resulting PEEM images show photoemission only from the upper (lower) nanodot edges when electron trajectories starting upward (downward) are selected in Figure 12(a,b). These structures contribute to the double peaks of the linescan with s-polarized light in Figure 12(a). Their width is determined from Figure 14(a,b) to typically 60 nm (Heitkamp *et al*., 2006).

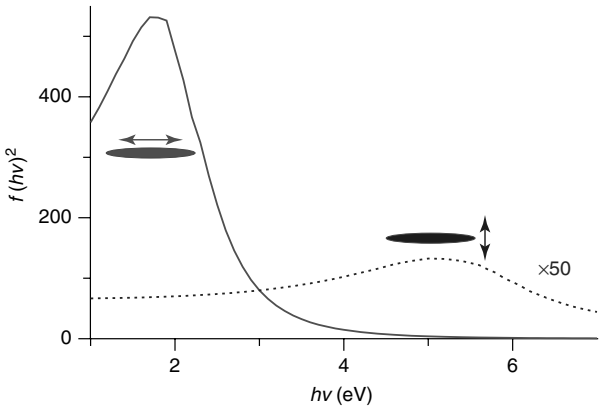

Figure 13. Calculated dielectric response of spheroidal ($10 \times 200\,\mathrm{nm}^2$) Pt particles (schematically shown as insets) as a function of photon energy. (Reproduced from Dürr *et al*., 2001, with permission from Springer-Verlag GmnH. © 2001.)

6.2 Femtosecond electron and spin dynamics of nanostructures

A microscopic description of the processes following the absorption of a femtosecond laser pulse can proceed in terms of energy relaxation between different reservoirs of quasiparticles such as electrons, spins, and phonons. Initially laser heating of the electron system creates a nonequilibrium electron distribution of the available energy levels. This exited state decays and after typical relaxation times the energy is transferred to the other quasiparticle systems such as spin excitations until it is finally dissipated via phonons to an external heat sink. Observing these processes in real time for magnetic materials is presently a very active research field. Although there is agreement on the subpicosecond timescale for energy transfer between electron and spin systems (Beaurepaire, Merle, Daunois and Bigot, 1996; Scholl, Baumgarten, Jacquemin and Eberhardt, 1997; Güdde *et al*., 1999; Koopmans, van Kampen, Kohlhepp and de Jonge, 2000) the microscopic mechanism is still under debate. It has been suggested theoretically that spin-orbit coupling alone may be too weak and that it is rather an interplay between spin-orbit forces and a strong laser field

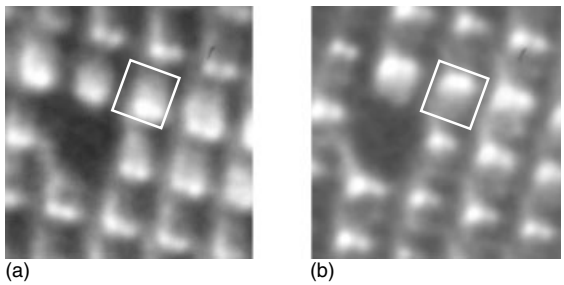

Figure 14. (a) and (b) Images with opposite off-center positions of the contrast aperture in the objective lens backfocal plane (see Figure 2). The white frame indicates the position of the same nanodot in both images.

that leads to an ultrafast sample demagnetization (Zhang and Hübner, 2000). Very recently it was suggested that laser heating might open a very efficient channel for transfer of spin angular momentum to the lattice (Koopmans, Ruigrok, Longa and de Jonge, 2005).

In the following we concentrate on showing that the locally enhanced laser field for s-polarized light described in the last section can induce a transient demagnetization of the nanodots, that is, that it is possible to probe the magnetization dynamics with subwavelength spatial resolution. To investigate the spin dynamics in a pump-probe experiment an area of 5×5 uniformly magnetized nanodots from Figure 12(a) was selected. Time resolution was achieved by splitting each laser pulse in two and introducing a variable time delay, Δt, between them. The work function of the topmost Pt layer was about 5.9 eV. Thus, two 3.1 eV photons have to be absorbed to generate one photoelectron. In a first photoabsorption process, electronic states up to 3.1 eV above the Fermi level become partially populated. A subsequent photoemission process using a second 3.1 eV photon then probes the population of states confined to an energy interval of 2.9–3.1 eV above the Fermi level. For this two-photon photoemission event the absorption of two photons has to occur almost simultaneously since the lifetime of the intermediate states is only a few femtoseconds (Aeschlimann *et al*., 1997;Knorren, Bennemann, Burgermeister and Aeschlimann, 2000).

Typical spectra are shown in Figure 15(b) and (c) where the time delay, Δt, between the two laser pulses was varied (Heitkamp *et al*., 2006). When the laser pulses overlap in time they can interfere. The alternating pattern of high and low two-photon photoemission intensity indicated by the shaded area in Figure 15(b) corresponds to constructive and destructive interference, respectively. From the width of this interference region the laser pulse length can be deduced (Lehmann *et al*., 2000) to 150 fs for the present example.

In Figure 15(c) the relative photoelectron spin polarization signal is shown as a function of Δt (Heitkamp *et al*., 2006), interference near zero time delay also leads in this case to fluctuations in the spin polarization (shaded area in Figure 15c). However, in the adjacent region the two laser pulses are in close enough temporal proximity so that each pulse probes the transient sample demagnetization generated by the other pulse. This pattern is clearly apparent in Figure 15(c) through the transient reduction of the photoelectron spin polarization nearly symmetric around time zero. The photoemission yield, N, measured in a one-color experiment is the sum of that for the indistinguishable individual laser pulses, that is, $N = N_1 + N_2$. The reduction of the spin polarization during the first laser pulse is S_1. That during the second pulse is S_2 if it arrives after the transient demagnetization of the first pulse (red curves in Figure 15a).

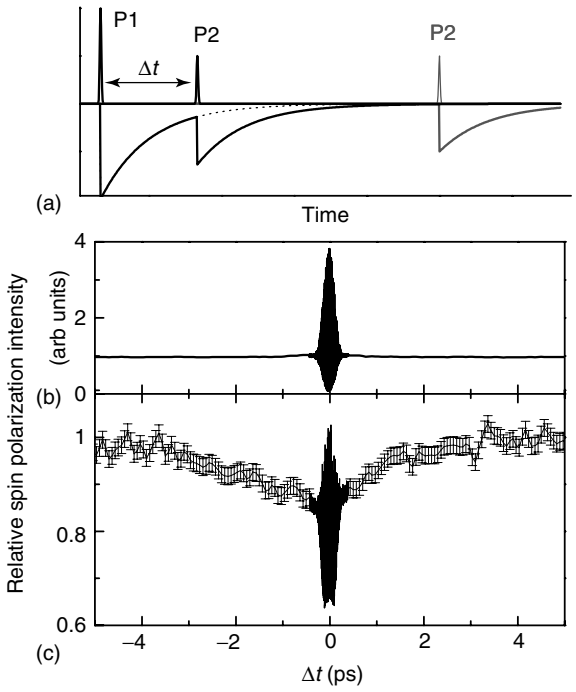

Figure 15. (a) Schematic diagram of the two-photon photoemission intensity (top panel) for two laser pulses P1 and P2 with different intensities (black lines). The gray line shows the laser pulse P2 arriving at a different time delay, Δt, after P1. The lower panel shows the transient change of photoelectron spin polarization due to sample demagnetization. (b) Measured two-photon photoemission intensity versus Δt. (c) Measured photoelectron spin polarization versus Δt.

The reduction in spin polarization during the laser pulses is then given by $S = A(N_1S_1 + N_2S_2)/N$. The scaling parameter A describes the initial sample demagnetization. If the second laser pulse (black P2 in Figure 15a) arrives within the transient demagnetization of the first pulse the spin polarization is given by $S' = [AN_1S_1 + N_2(AS_2 + S_1e^{-\Delta t/\tau})]/N$ with τ being the time constant for remagnetizing the sample. The spin polarization measured in Figure 15(c) is $\Delta S = S' - S = S_1e^{-\Delta t/\tau}N_2/N$, which depends only on the relative photoemission yield of the second and the initial reduction of the spin polarization for the first pulse as well as the exponential remagnetization term. This expression is independent of A since τ is much larger than the initial demagnetization time. The asymmetry in the spin polarization observed in Figure 15(c) for negative and positive time delays, respectively, is due to an intensity difference of 23% for the two laser pulses, that is, for negative time delay the more intense pulse arrives first. This experiment demonstrates that femtosecond laser-induced demagnetization can indeed be probed with nanometer spatial resolution.

7 CONCLUSION AND OUTLOOK

We gave an overview how dynamical magnetic phenomena that evolve on the picosecond and femtosecond timescales can be probed with nanometer spatial resolution. The emphasis of this review was on the application of photoemission microscopy, which has evolved into a state-of-the-art imaging technique. Other techniques such as optical and X-ray microscopy can give similar or complementary insight and are described in other parts of this book.

Section 4 reviewed recent experiments on the picosecond magnetization dynamics which were induced by ultrafast magnetic field pulses. Relevant devices such as magnetic sensors, magnetic random access memory, or spintronic applications demand simultaneous access to high spatial and temporal resolution. We showed for several examples that these requirements can be fulfilled by photoemission microscopy with synchrotron radiation. Parallel magnetic imaging becomes possible due to the strong magneto-optical effects in the X-ray range. This results in a large magnetic contrast for studying dynamical effects such as domain nucleation, domain wall movements, magnetization precession, and vortex-core rotation.

An even faster timescale is assessed in Section 5. The use of femtosecond laser pulses allows heating magnetic elements above their Curie temperature on a subpicosecond timescale. This is of applied interest for magneto-optical storage media where the information is erased by laser heating. The sample magnetization is probed in this regime by analyzing the photoelectron spin. In this case photoemission microscopy is used as a scanning probe technique with typically micrometer spatial resolution. We showed that spatial resolution can be dramatically enhanced by utilizing the dielectric response of nanostructures. This allows focusing optical radiation to subwavelength dimensions and is of interest for the emerging field of plasmonics.

The versatility and the wide range of different magnetic contrast mechanisms enable photoemission microscopy to exploit the full potential of complementary radiation sources such as picosecond synchrotron and femtosecond laser. The availability of FELs in the not too distant future is expected to revolutionize the field of ultrafast magnetization dynamics. When X-ray pulses of femtosecond duration as well as variable photon energy and polarization will become available, parallel magnetic imaging with nanometer resolution presently only feasible with picosecond synchrotron radiation will become possible on the femtosecond timescale. The proven versatility of photoemission microscopy is expected to play a central role also for these light sources also (BESSY, 2004).

NOTE

[1] The term spin dynamics is also often used in the context of spin waves.

ACKNOWLEDGMENTS

Claus M. Schneider would like to thank Alexander Krasyuk, Andreas Oelsner, Sergey Nepijko, Hans-Joachim Elmers, and Gerd Schönhense (all Johannes Gutenberg University, Mainz) for a very fruitful collaboration and many extensive discussions. Thanks are due to Nick Brookes and Céline de Nadaï (European Synchrotron Radiation Facility, Grenoble), Stefan Cramm (Research Center Jülich), Detlev Schmitz (Hahn-Meitner Institute, Berlin), and the staff at BESSY for their support during the beamtimes. The samples have been fabricated and supplied by Rainer Kaltofen and Ingolf Mönch (both Leibniz Institute for Solid State and Materials Research IFW, Dresden).

1 INTRODUCTION

Until the availability of electron microscopes the imaging of magnetic domain structures was limited to the use of optical methods.

For the Bitter decoration technique (Hámos and Thiessen, 1931; Bitter, 1931, 1932; Hubert and Schäfer, 1998), one used fine magnetic grains, which were suspended in a solvent, to visualize areas where a high gradient of the magnetic induction was present at the specimen's surface. After application of the Bitter fluid one had to wait a short period of time until the fluid was dried up fully, leaving the magnetic grains bunched around areas where the gradient was largest. For a sufficiently large concentration of the grains, these agglomerates could be seen rather easily by a simple light-optical microscope. It is needless to say that the resolution achievable by this technique was ultimately limited by the optical resolution of the microscope, while the grains can in principle be finer than a light microscope's resolution. There have been some attempts later to embed the agglomerates into thin, electron transparent carbonaceous films which could then be transferred into an electron microscope to make use of its better resolution.

Another technique of visualization of magnetic surface structures was to employ the magneto-optical Kerr effect (Kerr, 1877), which is based on the rotation of the polarization plane of linearly polarized light when it is reflected from magnetic surfaces. The detection of this effect can be done simply by using a correctly aligned analyzer which will darken areas where due to reflection the polarization plane was rotated, leaving other areas, where no or opposite rotation occurred, relatively bright. Thus, a gray scale image can be observed, where regions of different magnetic orientation show up in different shades of gray. Obviously this technique is also limited basically by the optical resolution of the microscope used and can be as good as 0.15 µm when blue illumination is used.

However, only after the electron microscope was invented in 1934 by Ernst Ruska and his coworker Knoll (Ruska, 1934) further progress in magnetic microstructural observation was possible. From that date it lasted still another 25 years until the first reports of successful attempts to directly visualize the micromagnetic structures which can be found in magnetic materials (Hale, Fuller and Rubinstein, 1959; Boersch and Raith, 1959; Boersch, Raith and Wohlleben, 1960). Shortly thereafter, the new technique was already used to characterize and measure properties of magnetic materials (Fuller and Hale, 1960; Fuchs, 1961;

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

Puchalska and Spain, 1962; Cohen, 1965; Grundy and Tebble, 1968; Wade, 1968; Petrov, Spivak and Pavlyuchenko, 1972a,b). So far, the technique in use was the rather simple-to-use defocused (or Fresnel) imaging, which is highly nonlinear in contrast. Thus, the newly found technique was frequently used to qualitatively characterize micromagnetic structures, but in general lacked the ability to allow quantitative measurements, except for some favorable cases. First measurements of magnetic domain wall widths were performed by Wade (1962), based on a pure geometrical optics approach, improved wave optical calculations allowed a quantum mechanical description as given by (Boersch, Hamisch, Wohlleben and Grollmann, 1960; Boersch, Hamisch, Grohmann and Wohlleben, 1962; Reimer, 1997; Chapman, McFadyen and McVitie, 1997; Hirsch *et al*., 1965).

Electron microscopy can visualize the magnetic induction $\vec{B}$, as there is an interaction between the electrons of charge $q = -e$ and velocity $\vec{v}$ and the magnetic induction, the Lorentz force $\vec{F}_L$,

$$\vec{F}_L = q \cdot \vec{v} \times \vec{B} \tag{1}$$

Equation (1) also emphasizes, that due to the vector product there is no Lorentz force connected with components of the magnetic induction, which are parallel or antiparallel to the electron beam's direction (which coincides with the direction of $\vec{v}$). Therefore, Lorentz microscopy is not sensitive to the out-of-plane component of a specimen's induction. For most cases, this is not a severe constraint, as in thin films, which are mainly under investigation in the transmission electron microscope (TEM), the large demagnetizing fields prevent a perpendicular magnetization anyway.

The theoretical treatments which are given in the subsequent text can only give an impression of the theory involved. Although not false, they are often strongly simplified and contain only the parameters necessary for our purposes. Thus they should not be considered as complete, further interested readers may consult the literature provided in the corresponding section.

2 SPECIMENS SUITABLE FOR INVESTIGATION

2.1 Thin films

Thin magnetic films have been the first magnetic specimens looked at in the TEM by Lorentz microscopy. They are created by means of evaporation, sputtering or similar vacuum deposition techniques. The main advantage of having a thin film lies in the fact that it is already electron transparent. The only preparation step, which is generally rather simple, consists in a liftoff of the film from the substrate onto which it was deposited. This may be achieved by dissolving the substrate in various chemical etchants (which usually have also a tendency to affect the specimen itself) or by using glue or polymers to tear the film off the substrate, before they in turn are dissolved in an agent, which in general is not harmful for the specimen itself. The last step involved is then the deposition of the freely floating specimen onto a metallic grid which then allows the observation in the TEM.

The main advantage of continuous thin films is that there are no boundary or edge effects, provided that the lateral extension of the films is large compared to any micromagnetic structures involved. Thus, thin magnetic films have been extensively studied with respect to their domain configuration, remagnetization behavior, domain structure, and so on.

2.2 Patterned thin films on transparent membranes

The technical ability to decrease the dimensionality of a magnetic specimen has led to a vast field of new and exciting phenomena in the last few years. The size of the specimen has become a very important parameter having a major impact on the magnetic configurations and their switching behavior.

Various methods allow the patterning of thin film, and thus the restriction of the magnetization to a very small volume. Typical dimensions accessible for patterning are laterally from 30 nm upward, with specimen thicknesses from a few monolayers up to more than 100 nm. However, for transmission electron microscopy the substrate has to be considered carefully. As the direction of the electron beam is generally normal to the specimen's plane, it has to be chosen transparent for electrons. This restriction limits the substrate thickness to a few tens of nanometers, which in turn makes these membranes mechanically very sensitive. Widely spread is the use of silicon nitride (Si_3N_4) membranes, which will briefly be introduced in the subsequent text.

The patterning itself is mostly done by electron lithography, less frequently by optical lithography with several possibilities to use lift-off processes. However, recently focused ion beam (FIB) systems became available for the patterning process. This novel possibility, often in combination with 'conventional' techniques allows a very accurate fabrication of structures down to the 10-nm scale.

2.3 Silicon nitride membrane substrates

Membranes for TEM purposes are commercially available, so that most groups abandoned fabricating them themselves. A broad range of different types is offered in the meantime, with membranes of several mm^2 area and thickness down to 20 nm.

Basically, they are prepared by the deposition of Si_3N_4 on both faces of a silicon wafer. On one side of the wafer, the nitride is removed, usually in the shape of a square. Then the wafer is brought into a wet etchant (such as hot KOH or NaOH) which starts a preferential etching process where the etching proceeds much faster (depending on the etchant and crystal orientation) into the wafer rather than in lateral direction. Thus, while the initial square window is hardly widened, an etch pit evolves in the shape of an inverted pyramid. When the top of this pyramid touches the Si_3N_4 layer on the opposite face of the wafer, the vertical etch process is effectively stopped, since this material is removed slower by orders of magnitude. When the wafer is kept in the etchant, only a lateral etching takes place, therefore widening the pyramid's body in lateral dimension. This finally leads to the formation of a truncated pyramid hollow, which at its top is covered by the remaining Si_3N_4 membrane, typically $100 \times 100\,\mu m^2$ wide. A free-standing membrane has formed, which can be used as an electron transparent substrate for transmission electron microscopy experiments.

2.4 Electron lithography

A standard method to pattern magnetic structures on supporting membranes is electron lithography. Different variations of subsequent steps are possible, depending on the respective demands. We describe one of the easiest ways to achieve high quality patterned specimens.

Onto a silicon nitride membrane (Figure 1a) two layers of resists (i.e., polymethylmethacrylate, PMMA) with different molecular weights and thus various sensitivities are spun. The more sensitive resist is deposited first and is capped by the less sensitive resist (Figure 1b).

After that, the structures are transferred to the resist by electron lithography (Figure 1c). For this purpose, a scanning electron microscope in combination with suitable software package is used. In most cases, it is desirable to use a double layer of resist which forms a distinct 'undercut' profile (Figure 1d). This means that the lower layer of resist forms a wider mask than the upper layer. When the material is then deposited into the pattern (by any method of thin film deposition, such as – for example – evaporation or sputtering) the upper (narrower) mask defines the overall dimensions of the structure deposited. Since the underlying mask is hardly in contact with the deposited patterned material, the subsequent lift-off process of the resist is largely facilitated. As many ferromagnetic materials suffer from oxidation it is in general necessary to cap the magnetic structures with a protective layer. Commonly used elements for this purpose are Al or Ti (Figure 1e). After the lift-off process, which dissolves and thereby removes both the resist and the residual deposited material, the patterned structure, supported by the membrane is ready for investigation (Figure 1f).

A critical point in specimen preparation for TEM or scanning transmission electron microscopy (STEM) investigations are charge effects. If the specimen is not conductive, the electron beam charges the specimen during observation. This causes deflections and/or instabilities of the electron

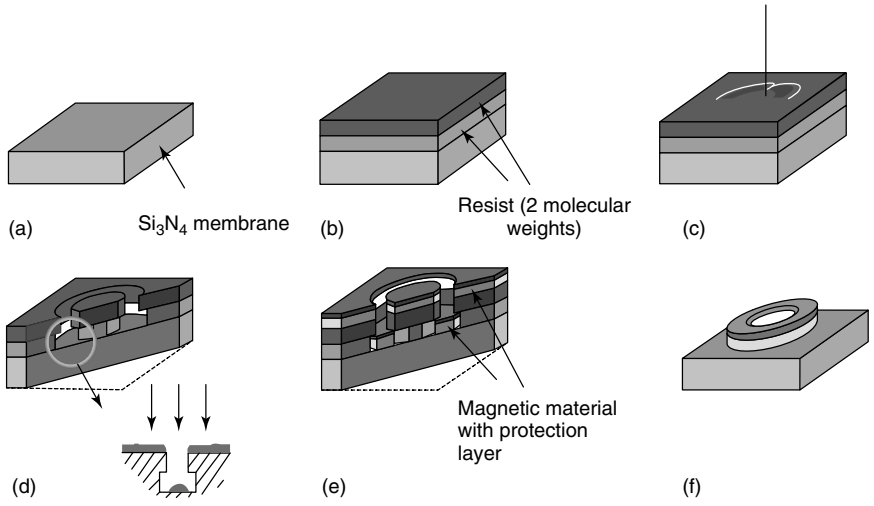

Figure 1. Procedure used to create patterned magnetic structures on electron transparent membranes by electron beam lithography. (See text for details (a–f).)

beam and can in severe cases prevent a proper investigation of the specimen.

To avoid this, it is useful to coat the entire sample, including the membrane, with a thin layer of conductive material like aluminium or carbon.

2.5 Focused ion beam (FIB)

Another technique to prepare patterned specimens of very high quality is given by the FIB technique. FIB Equipment is presently available from basically all manufacturers of electron beam related equipment or electron microscopes. Here, a finely focused beam of Ga ions is scanned across the specimen in the same way as in a scanning electron microscope. The Ga ions, however, sputter away the exposed parts of the specimen, and using a mask generator – usually driven by a computer – it is possible to safely remove unwanted parts of the specimen, leaving behind a patterned layer. Beam diameters down to 10 nm have been achieved and therefore patterning on this level is possible. However, the sputtering process tends to amorphize the vicinity of the irradiated area, and Ga may be implanted into the remaining areas. Especially in the case of very small structures one has to be aware of the creation of magnetically dead layers from the patterning process. On the other hand, the destructive action of ion beams has been shown to be useful for patterning when the material separating the structures is made non-magnetic by irradiation with an ion beam (see, for example, Bernas *et al*., 1999; Terris *et al*., 1999; Toporov, Langford and Petford-Long, 2000a). This is especially useful for Lorentz microscopy since the Fresnel diffraction effects from patterned specimens can be avoided or at least significantly reduced, since the magnetic structures are embedded into a thin film of equal thickness, however nonmagnetic material. Therefore, the electron beam does not experience differences in the electron optic refractive index which would in turn cause Fresnel diffraction, blurring the image at the particle's edges.

2.6 Bulk material, preparation problems

Nowadays it is rather uncommon to use bulk materials, which have to be thinned down to electron transparency prior to investigation, since most areas of interest deal with continuous thin films or particulate materials of very small dimensions which are already electron transparent. There are, however, various thinning techniques, which are well-established in the electron microscopy community (Schimmel and Vogell, 1981; Reimer, 1959; Williams, 1984) which can be used to prepare TEM specimens from bulk samples. In any case, two things have to be kept in mind. Firstly, care has to be taken not to change the magnetic properties by the process of thinning, and secondly it is important to consider the fact that the specimen is sometimes subjected to magnetic fields of typically 1–2 T in the objective lens in standard imaging mode. Although this is of no significance for thin film specimens, for thicker specimens the resulting forces may well lift the specimen out of the specimen holder, leaving the specimen to stick on the microscope's pole pieces.

Electron microscopy has established itself as a very powerful research tool in solid-state physics and instruments of various kinds are wide-spread. Thus, some fundamental facts about these techniques belong meanwhile to the basics of physics. Nevertheless the understanding of Lorentz microscopy, the difficulties and possibilities connected with it demands a fundamental knowledge on how transmission electron microscopy works. Prior to the description of the various techniques of Lorentz microscopy, a short introduction in electron optics and the instrument itself should be given. We restrict this description on the facts necessary to understand what follows.

Then, we introduce the magnetic specimen as a (strong) phase object, before we start to treat the main techniques of Lorentz microscopy, Fresnel and Foucault imaging, differential phase contrast (DPC) microscopy and electron holography in more detail.

3 BASIC IMAGING TECHNIQUES OF LORENTZ MICROSCOPY

3.1 Introduction to electron microscopy

In the subsequent text, a short introduction to an electron microscope is provided. Further information about practical aspects can be found in the textbook of Williams and Carter (1996), the theoretical background is comprehensively treated by Reimer (1997).

3.1.1 Conventional and scanning transmission electron microscopes (CTEM and STEM)

There are two different modes to record an image with a transmission electron microscope.

Similar to a light optical microscope, an image can be generated by illuminating the object and recording the magnified image. In a certain sense, this can be considered as 'parallel' recording and is usually termed as conventional transmission electron microscopy (CTEM).

However, it is also possible to record the image serially. To achieve this, a focused electron probe is scanned across

the specimen, the electron beam passes through the sample and for every point of the sample, the signal of a detector in the subsequent text the specimen is used to characterize the respective point. If the registered signals are plotted according to the current position of the electron probe on the specimen, an image of the sample is generated. This method is termed STEM. It is important to point out that there exists a variety of detectors which are sensitive for different electron-matter interactions. In the subsequent text, a description will be given which detector is suitable to record the local magnetic properties of the specimen and therefore to visualize and measure quantitatively magnetic properties.

It has been shown (Cowley, 1969) that CTEM and STEM have a close relationship and can considered as complementary techniques. It depends on the task to decide, which technique should be chosen.

3.1.2 Components of a TEM

The electrons are provided by an electron gun (see Figure 2). Presently, both thermal and field emission emitters are in use. In a thermal emitter, the filament consists of a tungsten or a LaB_6 crystal, which is electrically heated and accordingly emits electrons. The electrons in a field emission gun (FEG), however, are extracted from an extremely pointed cathode by an electric field. The sharp tip causes a strong electric field at its very end, as the field is inversely proportional to the radius of the tip's curvature. Therefore, electrons are emitted from a very limited area which in turn provides an excellent spatial coherence of the electron wave, a crucial requirement for electron holography.

The emitted electrons are accelerated in a multistage process to reach their final highly relativistic energy of several hundred keV, depending on the microscope. A higher acceleration voltage causes a smaller de-Broglie wavelength λ of the electrons, typically in the pm range ($\approx$1.97 pm for 300 keV electrons). The influence of the wavelength on the resolution of the TEM is not crucial, as it is limited by the lens aberrations rather than by the wavelength. The high energy, however, ensures sufficient penetration power to penetrate thin metallic films with typical thicknesses of $\approx$100 nm. A disadvantage of high energy electrons is the higher beam 'stiffness' compared to electrons of less energy. This can be seen easily from equation (12), where the Lorentz angle of deflection is directly related to the de Broglie wavelength of the electron.

Leaving the gun area, a condenser lens system consisting of at least two lenses and an aperture forms the electron beam. These lenses define the illuminated area on the specimen.

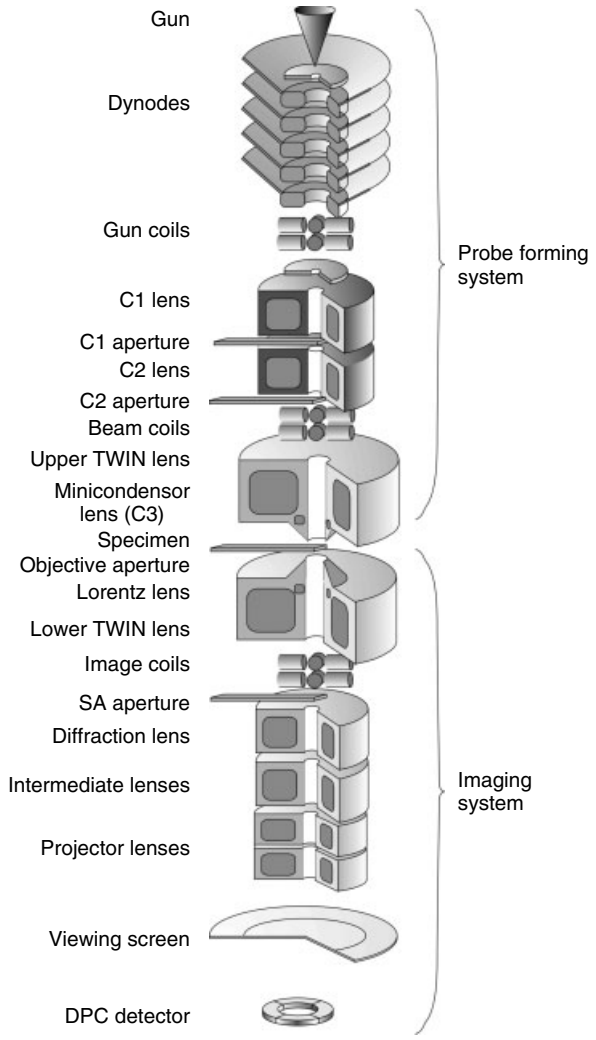

Figure 2. Typical components of a commercial TEM, equipped with a Lorentz lens and a DPC detector.

In CTEM mode, a beam as parallel as possible is of advantage to gain high coherence. In most cases, however, a compromise between high coherence (parallel illumination) and the brightness of the illuminated region (convergent illumination) has to be chosen.

In the STEM case, the condenser system provides an electron beam focused to a point-like electron probe on the specimen. Here, the condenser aperture is of crucial importance, as it defines the illuminated area on the STEM detector.

The specimen itself is inserted into the electron microscope with a specimen holder (Williams and Carter, 1996), which restricts the dimensions of the sample to approximately 2 mm.

In a modern microscope, the sample sits right inside the objective lens, which often acts as a combination of a further condenser lens and an imaging lens. The magnetic field in the

fully excited objective lens exceeds 1 T and would severely influence the micromagnetic configuration of the specimen. Therefore, the objective lens cannot be used for magnetic imaging techniques.

However, a low magnification mode is usually implemented in all microscopes, which operates with the objective lens turned off. Its action is performed by an other lens (called *intermediate* or *diffraction lens*) which is located at a larger distance from the specimen. This requires a long focal length lens, which yields only a very moderate magnification (in the order of 10^3) and at the same time causes only a negligible magnetic field at the specimen's location.

A different approach uses a special Lorentz lens (Zweck and Bormans, 1992), which serves as an objective lens. This Lorentz lens is located at a larger distance from the sample than the objective lens but still closer than the lenses usually in use.

The Lorentz lens allows investigations with virtually zero magnetic field in the sample's region, whereas the optical quality of that lens is worse than the standard objective lens, but better than what can be achieved without it. The magnification is in the 10^5 range, the resolution can reach 2 nm.

Several lenses follow, which magnify the CTEM (and Lorentz TEM) image further.

A fluorescent screen allows the direct observation of the image. It can be recorded with a conventional plate camera, although in the meantime most microscopes are equipped with a CCD camera, which allows a digital acquisition of the image for simple further processing.

A growing number of microscopes has also the ability to generate energy filtered images. This, in terms of Lorentz microscopy, has the advantage to exclude inelastically scattered electrons from the image, which in turn allows to reduce the 'background noise' and opens the opportunity to investigate thicker specimens or samples with weak magnetic inductions.

The energy filter is expected to enable the implementation of a new magnetic imaging technique as well, which is currently under investigation and based on chiral dichroitic effects (Hébért and Schattschneider, 2003; Schattschneider *et al*., 2006).

In the STEM mode the electron beam propagates after the specimen along a certain distance, the camera length, to the detector plane. As the distance between detector and specimen plane is a fixed distance, given by the geometry of the microscope, the imaging lenses are used to generate a 'virtual' camera length from the mm to the several 100 m regime.

In most cases, the STEM signal is recorded subsequently by a solid-state detector, the whose shape determines the imaging conditions, as will be shown in the subsequent text.

3.1.3 Theoretical description

In standard TEM mode the specimen is illuminated with a beam, which is ideally parallel. This ideal case shall for simplicity be treated in the following description. Therefore, the illuminating plane electron wave can be considered to have a uniform (normalized) intensity equal to 1 everywhere in the sample's plane.

In a theoretical treatment (i.e., Cowley, 1995) a specimen's transmission function $T(\vec{r})$ is described by its absorption $U(\vec{r})$ and its phase shift $\varphi(\vec{r})$, both depending on the local properties of the specimen at position $\vec{r}$,

$$T(\vec{r}) = U(\vec{r}) \cdot e^{i\varphi(\vec{r})} \tag{2}$$

The observable image is obtained by a convolution of the specimen function with the point spread function (PSF) $C(\vec{r})$, which is the Fourier transform of the so-called phase contrast transfer function (CTF) $c(\vec{k})$, given in reciprocal space as

$$c(\vec{k}) = p(\vec{k}) \cdot e^{i\chi(\vec{k})} \tag{3}$$

Here, $p(\vec{k})$ describes an aperture in the back focal plane and is in fact a pupil function ($p(\vec{k}) = 1$ for $|\vec{k}| \leqslant k_0$, $p(\vec{k}) = 0$ for $|\vec{k}| > k_0$), while $\chi(\vec{k})$ comprises the defocus term $-\pi \cdot \Delta z \cdot \lambda \cdot k^2$ with the electron wavelength λ and the defocus Δz and other terms of higher order describing spherical aberrations. For simplicity, these terms and also damping terms according to chromatic aberrations and beam convergence have been omitted. Please note that in this treatment we assumed the magnification to be equal to 1 to keep the equations as simple as possible.

The convolution with the PSF is equivalent to a multiplication of the CTF with the Fourier transform of the specimen function

$$t(\vec{k}) = FT[T(\vec{r})] \tag{4}$$

followed by a transformation back to real space. The image intensity is readily obtained from the square modulus of the resulting function

$$I(\vec{r}) = \left| FT^{-1}[t(\vec{k}) \cdot c(\vec{k})] \right|^2 \tag{5}$$

A similar approach is possible when dealing with STEM. Here, the specimen is illuminated with a convergent electron beam. Thus, the STEM image is generated serial rather than in parallel. Having that in mind, the specimen's exit wave function, that is the wave leaving the specimen after transmission, can also be described by a convolution, in this case between the shapes of the convergent probe formed by

the condenser lenses and the specimen function. Since STEM is a scanning technique, this convolution has to be performed on every spot of the specimen which is illuminated by the beam. This can conveniently be described by a laterally shifted δ function. Thus the wave $\Phi(\vec{r})$ emerging from the sample can be described by

$$\Phi(\vec{r}) = T(\vec{r}) \cdot [C(\vec{r}) \otimes \delta(\vec{r} - \vec{r}_0)] \tag{6}$$

where $\vec{r}_0$ is the position of the electron probe on the specimen and $C(\vec{r})$ is again the PSF, this time of the probe forming condenser lens (and the condenser aperture).

The propagation to the detector plane is again the mathematical equivalent of a Fourier transform, which leads to

$$\Phi_{det}(\vec{k}) = t(\vec{k}) \otimes c(\vec{k}) \cdot e^{-2\pi i \vec{k}\vec{r}_0} \tag{7}$$

where we used the Fourier theorems of multiplication and convolution which state that a convolution in real space is equal to a multiplication in Fourier space and vice versa.

The measured signal $S(\vec{r}_0)$ is then the wave intensity integrated over the detector area D and weighted with a detector function $\mathrm{d}(\vec{k})$,

$$S(\vec{r}_0) = \int_D \left|\Phi_{det}(\vec{k})\right|^2 \cdot \mathrm{d}(\vec{k}) \cdot \mathrm{d}\vec{k} \tag{8}$$

Thus, the detector function determines the measured properties in a crucial way and has to be considered carefully when dealing with DPC microscopy in the subsequent text.

For both, CTEM and STEM we would like to emphasize, that the recording media is only able to record the intensity of the incoming wave. The phase of a wave front which hits the detector can in general not be recorded, except when a holographic technique is used, where the phase can be reconstructed from an interference pattern. Unfortunately, magnetic information is phase information of the wave leaving the specimen, as will be shown in the subsequent text. Thus – with the exception of electron holography – the techniques of Lorentz microscopy which are described in the subsequent text aim on converting the phase information of the exit wave into an intensity information of the detected wave front.

3.2 The magnetic specimen as phase object

In geometrical optics it is straightforward to calculate the deflection of the electron beam caused by the Lorentz force according to equation (12) in the subsequent text. This very descriptive treatment allows a first approach to the various methods of Lorentz microscopy. However, this description is usually not sufficient to completely understand the image formation process and the interpretation of image intensities. Therefore another more theoretical formulation is necessary.

3.2.1 Magnetic phase shift

It has been shown by Aharonov and Bohm (1959), that the vector potential $\vec{A}(\vec{r})$ generated by a magnetic induction distribution $\vec{B}(\vec{r})$ manifests itself in a phase shift of a bypassing electromagnetic wave.

The phase shift φ between two different paths γ_a and γ_b which share the same starting and end point can be calculated to be

$$\varphi = \frac{e}{\hbar}\left(\int_{\gamma_b} \vec{A} \cdot \mathrm{d}\vec{s} - \int_{\gamma_a} \vec{A} \cdot \mathrm{d}\vec{s}\right) = \frac{e}{\hbar}\left(\int_{\gamma_b - \gamma_a} \vec{A} \cdot \mathrm{d}\vec{s}\right)$$
$$\overset{(*)}{=} \frac{e}{\hbar}\int_{\Omega} \nabla \times \vec{A} \cdot \mathrm{d}\vec{f} \overset{(**)}{=} \frac{e}{\hbar}\int_{\Omega} \vec{B} \cdot \mathrm{d}\vec{f} \tag{9}$$

where at $(*)$ Stokes rule is applied, leading to an integral over the area Ω limited by γ_a and γ_b. Furthermore at $(**)$ the identity

$$\vec{B} = \nabla \times \vec{A} \tag{10}$$

was used. This is illustrated in Figure 3 where the location where the two different paths enter the specimen are denoted by 'a' and 'b'.

Equation (9) connects the phase shift φ with the magnetic flux that penetrates the area Ω enclosed between the two paths. As a transmission technique measures physical values only integrated along the beam trajectory (z direction), a further modification of equation (9) makes sense,

$$\varphi = \frac{e}{\hbar}\int_{\Omega} \vec{B} \cdot \mathrm{d}\vec{f} = \frac{e}{\hbar}\iint B_{\perp} \cdot \mathrm{d}z \cdot \mathrm{d}x \tag{11}$$

where $\int B_{\perp} \cdot \mathrm{d}z$ can be attributed to the collected phase shift along the electron trajectories. This notation also emphasizes that only the component of $B_{\perp}$ perpendicular to the electron beam's trajectory contributes to φ. For a simple treatment, one can assume that the fields outside the ferromagnetic specimens are negligible, which is often the case for thin and longitudinally extended films. In a further assumption, the induction is considered to be constant over the thickness z of the specimen. Then, it is easily understood that equation (11) describes the total flux contained within a rectangular section of the specimen $\mathrm{d}x \cdot \mathrm{d}z$ which leads to the observable phase shift φ.

This redraft of equation (9) shows, that the integrated magnetic induction which is accessible in the experiment

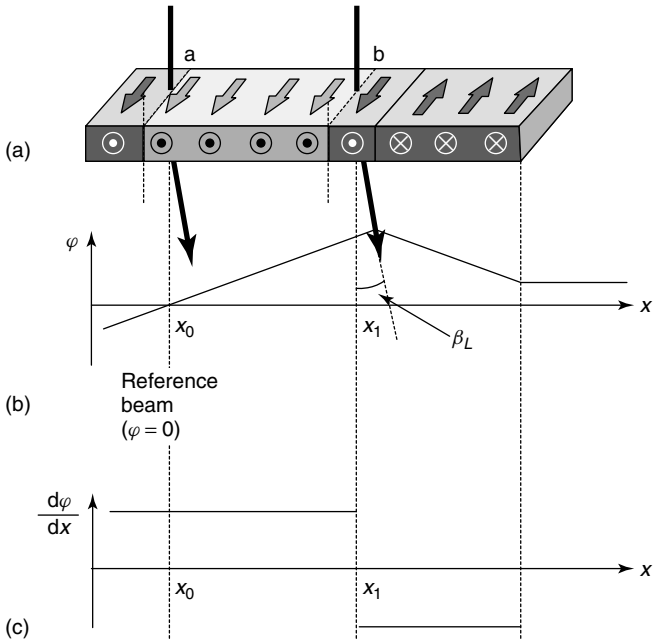

Figure 3. Demonstration of the interrelationship between beam deflections due to the Lorentz force and the corresponding phase shift. (a) Specimen with in-plane induction. (b) Phase shift of electron wave after the magnetic specimen that can also be interpreted as tilting the incoming beam by the Lorentz angle β_L. (c) Course of the signal detected by a DPC detector.

is directly connected with the spatial derivative of the phase ($\mathrm{d}\varphi/\mathrm{d}x$) rather than with the phase φ itself. A fundamental principle, which can be derived from equation (11) is also, that in electron microscopy, as in most measurements, it is the magnetic induction which is detected rather than the magnetization $\vec{M}$ itself. Even though $\vec{B} \sim \vec{M}$, if stray (and internal demagnetizing) fields are neglected for simplicity this is important to keep in mind.

Furthermore, the Lorentz angle for a magnetic induction B_0 can be derived from equation (11), if the x direction is thought to be perpendicular to the B field.

The phase shift φ is connected with a wave propagation of $\frac{\varphi}{2\pi} \cdot \lambda$ for the electron wavelength λ ($\approx 1.97\,\mathrm{pm}$ for 300 keV electrons), which leads in a geometrical optic approach to the Lorentz angle

$$\beta_L = \frac{\lambda e}{2\pi\hbar} \int B_0 \cdot \mathrm{d}z \tag{12}$$

Assuming realistic values the Lorentz angle β_L is in the microradian range, which is small compared to typical Bragg angles of 1–10 mrad for diffraction from crystalline lattice planes.

As a tilt of a parallel beam with respect to the optic axis converts in the back focal plane of a lens into a focal point not centered on the optic axis, in reciprocal space (which is equivalent to the back focal plane of a lens) the beam deflection can be expressed as a distinct point located at

$$\delta\left(\vec{k} - \frac{e}{2\pi\hbar} \int B \cdot \mathrm{d}z \cdot \hat{k}_x\right) \tag{13}$$

where $\hat{k}_x$ is the unit vector in k_x direction within the coordinate system assumed in the preceding text. For a common magnetic specimen that point is located very close to the central beam, because the deflection is usually rather small.

In the case of thin magnetic samples, the specimen's absorption is often neglected, since the effect of magnetism is a pure phase shift, as explained in the preceding text. The specimen's transmission function in equation (2) then simplifies to

$$T(\vec{r}) = e^{i\varphi(\vec{r})} \tag{14}$$

3.2.2 Electrostatic phase shift

In the previous section the phase shift of the electron wave due to magnetic induction was treated, which is the fundamental mechanism for Lorentz microscopy.

However, there exists also a phase shift due to (inner) electrostatic fields. This phase shift occurs in 'real' samples, which have a finite material thickness and thus modify the refractive index for electrons. The effect shall be briefly discussed in the subsequent text.

For Lorentz microscopy it is especially important to distinguish between magnetic and electrostatic phase shifts. Here we will describe several possibilities.

In the absence of external electric fields, the electrostatic phase shift φ_el from a specimen is given by

$$\varphi_\mathrm{el} = \frac{2\pi}{\lambda} \cdot \frac{E + E_0}{E(E + 2E_0)} \cdot \int V \cdot \mathrm{d}z \tag{15}$$

where V is the mean inner potential of the sample, E and E_0 are, respectively, the kinetic energy and the rest energy of the electrons (Reimer, 1997).

Comparing equation (15) with the magnetic phase shift (equation (11)) shows a way to separate the magnetic phase shift from the electrostatic phase shift.

The first method uses the fact that due to the vectorial character of the integration in equation (11) the phase from the magnetic signal will be inverted after a rotation of the specimen around a horizontal axis by 180°, while this is not the case for pure electrostatic phase shifts. Obviously, if two images are taken with the specimen rotated by 0° and 180°, the magnetic and the electrostatic phase shifts can be separated by addition or subtraction of the two images.

An addition of the images (possibly after an inversion and realignment of the images by means of image processing techniques) renders purely the electrostatic phase shift, while from a subtraction one obtains purely magnetic phase shifts. It is important to note for quantitative measurements that the obtained phases are multiplied by a factor of 2 since the corresponding phases add up, while the unwanted ones cancel to zero. These experiments can be performed using a special specimen holder which allows the specimen to be rotated by 180° as in Huhle, Goldberg and Lichte (2000).

Another possibility is the separation by magnetic saturation. This method was proposed by Dunin-Borkowski, McCartney and Smith (1998) and utilizes the fact that a magnetic particle saturated in two antiparallel directions reverses its magnetic contribution to the phase shift. Thus, the electric phase shift can be extracted from two images in antiparallel saturation simply by adding both phases, while the magnetic phases simply cancel out. Once the electric phase is known, it can be subtracted from images of the same particle recorded at arbitrary external field values.

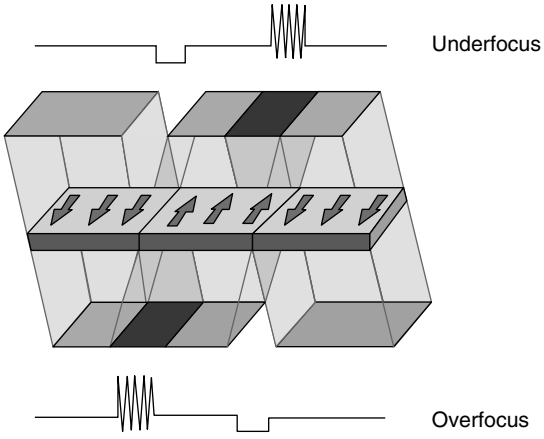

Figure 4. Schematic representation of Fresnel imaging. The electron beam, deflected by the Lorentz force leads to convergent and divergent beams below the specimen (overfocus) which lead to increased or decreased electron intensity in the corresponding areas. In converging areas, interference of the coherent partial waves can be observed, while in divergent areas only a decrease in intensity is observable. If a plane above the specimen is imaged (overfocus), the contrast changes sign.

3.3 Fresnel imaging

3.3.1 Introduction

As pure phase objects magnetic specimens do not produce an in-focus contrast which can be related to the internal magnetic structure of the sample. This can easily be seen in the case of an ideal imaging condition, where one assumes a δ-shaped PSF and also the CTF $c(\vec{k}) \equiv 1$. This yields $I(\vec{r}) = |e^{i\varphi(vecr)}|^2 = 1$ without any spatial information about the object.

The easiest way to obtain images of micromagnetic structures is to defocus the imaging lens by values of micrometers to centimeters, depending on the thickness and induction strength of the specimen, which leads to out-of-focus Fresnel images. In terms of geometric optics this is visualized in Figure 4.

Owing to the Lorentz force the electrons exit from the specimen at certain angles, depending on the direction and strength of the magnetic induction within the specimen. This leads at each domain wall to two neighboring beams, which are convergent or divergent below the sample. If now the lens is not focused on the specimen's exit surface, but on a plane slightly below, a higher (or lower) intensity is recorded owing to the converging (or diverging) beams. Thus, in Fresnel imaging it is the change of the magnetic induction which is imaged rather than the induction itself. Domain walls appear as bright or dark lines, depending on the relative alteration of the magnetization in the two adjacent domains.

This defocusing works both ways, both for the imaging of a plane below and also above the specimen, leaving the location of the visible domain walls unaltered, but changing the contrast from white walls to black walls and vice versa. This is because the deflected electron beams can be considered also to come already tilted by β_L from the area above the specimen, as can be seen in Figure 4 and for a practical example in square-shaped magnetic particles in Figure 5.

The description of the Fresnel mode in terms of wave optics shall be only briefly sketched, as a complete treatment is rather demanding. As shown in equation (13), an area with a certain constant magnetic induction B_0 can be attributed to

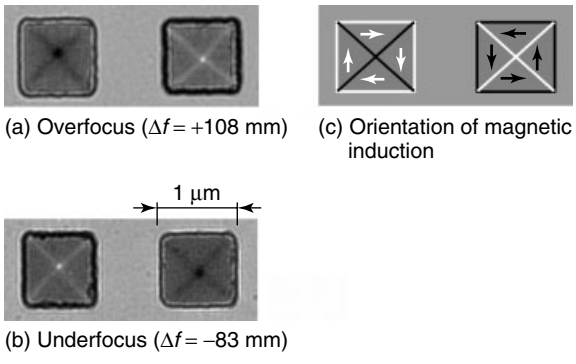

Figure 5. Experimental Fresnel images of square shaped magnetic particles ($Ni_{80}Fe_{20}$), taken in overfocus (a) and underfocus (b) condition. (c) Gives a schematic representation of the specimen's induction (arrows).

a distinct point in the Fourier space of the back focal plane. Defocusing the microscope results in a shift of the phase in the back focal plane due to the multiplication with the phase factor $e^{-i\pi\lambda\cdot\Delta z\cdot k^2}$ in equation (3). This phase factor in reciprocal space in turn causes a spatial shift of the image of the corresponding domain in real space by $\frac{e\lambda}{2\pi\hbar}\cdot\Delta z\cdot\int B_0\,\mathrm{d}z$ and thus an overlap or separation of the images of individual domains. In the region of overlap, one has higher intensity (a bright wall), in regions of separated domains due to the shift the intensity is reduced (a dark wall).

It should be noted here, however, that due to the necessary defocusing to be able to see contrast, one does unavoidable get Fresnel fringes, especially at the borders of the specimen. This is mainly due to electrostatic phase shifts, but also at any region boundary, where the refractive index, that is the phase shifting property of the specimen changes abruptly, one will observe Fresnel fringes. Thus, also black domain walls are usually lined with Fresnel fringes. The same holds for white domain walls. However, in addition to Fresnel fringes one also obtains biprism interferences due to the coherent overlap of partial electron wave fields which have been deflected toward each other below the specimen.

3.3.2 Pros and cons

Fresnel imaging is easy and cheap. On an existing TEM it is not a problem to do magnetic observation using Fresnel imaging, provided the objective lens field does not influence the sample. This can be achieved in most commercial microscopes by switching to the 'low magnification' mode, where the objective lens is usually turned off, and a long focal length intermediate or diffraction lens is used for imaging. However, the interpretation of the images in terms of magnetic induction maps is not straightforward and requires some knowledge, as only induction variations are recorded. Even for experts it is often not possible to reconstruct the magnetization of a sample because continuous rotation of the magnetization causes no detectable contrast.

Furthermore for the defocus value a compromise has to be found. A small defocus causes only small magnetic contrast in the image, while a strong defocus of the microscope – giving bright and clearly visible domain images – results in a large area covered with Fresnel fringes, blurring the details within the specimen. This is equivalent to a decrease of the maximum achievable resolution. Therefore, for structures with lateral extensions smaller than 300 nm it becomes increasingly difficult to gain useful magnetic information.

In the last few years, a new trend in Fresnel microscopy has appeared. As described in Section 5.1, Fresnel images of different defoci are used to reconstruct the exit wave function and thus allow a detailed insight into the interior magnetic structure of the specimen.

3.3.3 Example

As a typical example, Figure 5 shows Fresnel images obtained from a patterned polycrystalline $Ni_{80}Fe_{20}$ alloy. The squares hava a lateral dimension of 1 µm and 30 nm thickness and are supported by an electron transparent Si_3N_4 membrane. Figure 5(a) and (b) show the contrast reversal when changing the defocus from overfocus Figure (a) to underfocus Figure (b). Figure 5(c) schematically shows the induction distribution which is the same for images Figure 5(a) and (b). The domain wall contrast (bright or dark with respect to the specimen's average brightness) shown corresponds to an overfocus condition. It is obvious that for a given defocus it is possible to determine the direction of rotation of the specimen's induction from the wall contrast. It is also worth to note that the bright and dark perimeter of the squares in Figure 5(c) also changes with both the direction of rotation of the induction and with the defocus. In the experimental images, this contrast at the specimen's perimeter is masked by the always present contrast due to Fresnel fringes. Nevertheless, it can be recognized since the appearance of the fringe at the specimen's perimeter is different in gray shade and width for the two different cases.

3.4 Foucault imaging

3.4.1 Standard Foucault imaging

Introduction

In principle not difficult to understand, Foucault imaging needs some experimental skill to yield interpretable results and often suffers from experimental deficiencies.

As pointed out in the preceding text, every Lorentz angle (equation (12)) forms a distinct point in reciprocal space, according to equation (13). Thus, the back focal plane of the imaging lens comprises, in spatial separation, the various magnetic inductions which exist within the specimen. Therefore, if an aperture is introduced into the diffraction plane of the imaging lens, it will allow the selection of particular magnetic inductions by selecting the corresponding focal points to be transmitted through or blocked by the aperture. In this sense, it may be considered to be a 'directional induction filter' (see Figure 6).

An image which is obtained with an aperture in the back focal plane shows dark areas, if the corresponding magnetic induction is blocked by the aperture, otherwise the domains appear bright, with gradual shades in the boundary regions (see Figure 7). It should be noted here that there are bright (upper right corners) and dark (top of particles

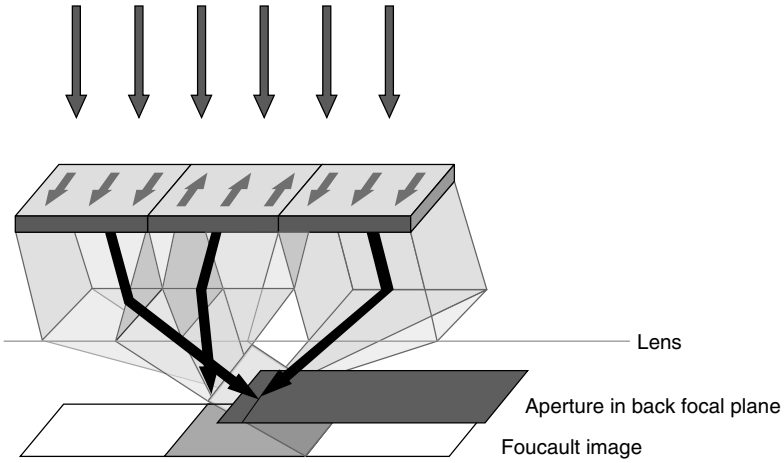

Figure 6. Contrast formation in Foucault imaging mode. The incoming parallel electron beam becomes deflected by the specimen's induction. Differently deflected beams are focused into different spots in the back focal plane of the lens. A semiinfinite aperture can be used to block certain spots to contribute to the final image, that is, certain areas of the specimen which are magnetized in the same direction become dark.

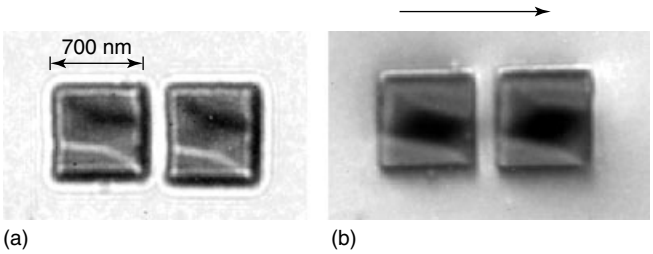

Figure 7. Comparison of (a) a Fresnel image and (b) a Foucault image taken from the same specimen. Whereas in (a) the domain walls are visible as bright and dark features, in (b) areas of sequal induction direction are shown in equal gray shades. The induction direction selected by the aperture position is indicated by an arrow. Please note that stray fields emerging from the specimen can be seen as bright and dark shades surrounding the specimen.

and right lower corner of right particle) shades outside the specimen which are effects of stray fields which emerge locally from the specimens. Although the explanation of contrast formation given in the preceding text was based strictly on geometrical optics it shall be noted that in terms of wave mechanics it is straightforward to modify the aperture function $p(\vec{k})$ in equation (3) in order to build a 'directional induction filter function'.

Pros and cons

Similar to the Fresnel technique, the Foucault mode principally does not need any special equipment, provided the specimen area is magnetic field free. In addition, it is an in-focus technique, which avoids the Fresnel fringes which tend to blur the magnetic information, especially for large defoci and small particle dimensions (i.e., smaller than approximately 300 nm). The crucial point in this case is the aperture – and at the same time the largest problem which in most cases prevents the technique to be used practically. As pointed out in Section 3.4.1, the angles between the magnetically deflected beams and the central beam are very small which in turn means that in the back focal plane of the imaging lens the central beam and the Lorentz deflected beams are very close to each other. This makes the lateral positioning of the aperture a very tedious task, especially as the apertures usually are not confined by smooth boundaries, but are in general rather jagged and rough, which makes it extremely difficult to determine which parts of the Lorentz deflected beams have been blocked by the aperture. In addition to that, the aperture usually is contaminated by more or less insulating debris, which causes intolerable phase shifts due to electrostatic charging. In total, these technical problems presently prevent the Foucault technique from being widely used.

3.4.2 Coherent Foucault imaging

Coherent Foucault imaging is also a Foucault imaging technique as in 3.4.1. In this case, the contrast is not achieved by an absorbing semi-infinite aperture placed in the diffraction plane, but rather by a phase shifting electron transparent membrane. For these operation conditions, areas of equal phase shift, that is equal magnetic flux can be made visible (Chapman *et al*., 1994; Chapman, Johnston and Heyderman, 1994). The technique requires coherent illumination, that is a field emission electron gun and suffers from contamination problems of the phase shifting membranes. Nevertheless, under optimum experimental conditions, meaningful results have been obtained in the past (Johnston and Chapman, 1995; Chapman *et al*., 1994).

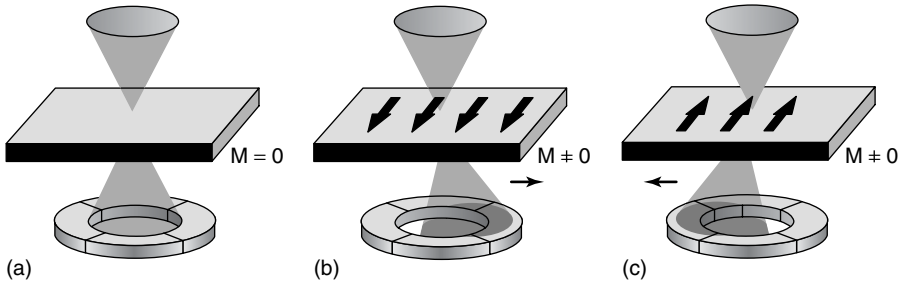

Figure 8. Schematic representation of the beam tilt and corresponding shift of the electron beam cone leaving the specimen in the detector's plane. (a) For a non-magnetic specimen, the beam is not deflected, the segmented detector does not measure any deflection. (b), (c) Owing to a nonzero induction within the specimen, the beam becomes tilted, causing different segments of the detector to record intensity. Thus, the direction of deflection indicates the direction of the induction in the probed spot. The direction and amplitude of deflection can be measured by a four-segment position sensitive device.

3.5 Differential phase contrast (DPC)

3.5.1 Introduction

One of the more advanced and also more demanding techniques of Lorentz microscopy is DPC microscopy. Unlike the previous methods, DPC utilizes a scanning transmission microscope (STEM) and needs a special detector configuration as described in the subsequent text. It should, however, be noted here that it has been shown by McCartney, Kruit, Buist and Scheinfein (1996) that it is also possible to obtain DPC in a modified TEM, when an electron biprism is mounted on a condensor aperture.

For STEM-based DPC, a focused electron beam with a certain convergence semi-angle α_{in} is scanned across the specimen (see Figure 8). The electrons leave the sample in a cone-shaped beam, which causes a disk shaped illumination on a detector located a certain distance from the sample, termed the *camera length*. The Lorentz force causes a tilt of the cone due to beam deflection from the specimen which is usually in the range of $10^{-5} - 10^{-7}$ rad. This results in a shift of the illuminating disk in the detector plane, which is – depending on the camera length used – typically in the µm to mm range. If now the detector has the ability to record the shift with respect to both direction and strength, it is possible to derive information on the magnetic induction of the area which is illuminated by the electron probe.

DPC was first proposed by Dekkers and de Lang (1974). They discovered that an asymmetric detector function in equation (8) can detect the spatial derivative of the phase shift along a particular direction.

Since in the STEM mode only a small area of the specimen around $\vec{r}_0$ is illuminated by the beam, the phase shift acting on the beam from this area can be linearly approximated by

$$\varphi(\vec{r}) \approx \varphi(\vec{r}_0) + (\vec{r} - \vec{r}_0) \cdot \nabla_{\vec{r}-\vec{r}_0}\varphi(\vec{r}_0) \tag{16}$$

This modifies the specimen function (equation (2)) to

$$T(\vec{r}) \approx e^{i\varphi(\vec{r}_0) - i\vec{r}_0 \cdot \nabla\varphi(\vec{r}_0)} \cdot e^{i\vec{r} \cdot \nabla\varphi(\vec{r}_0)} \tag{17}$$

For the action of this linearly approximated phase shift in the detector plane (which again is in reciprocal space) on the intensity distribution of the probe beam one obtains

$$\left|\Phi_{det}(\vec{k})\right|^2 \approx \left| c(\vec{k}) \otimes e^{i\varphi(\vec{r}_0) - i\vec{r}_0 \cdot \nabla\varphi(\vec{r}_0) - 2\pi i\vec{k}\vec{r}_0} \cdot \delta\left(\vec{k} - \frac{1}{2\pi}\nabla\varphi(\vec{r}_0)\right)\right|^2 = p\left(\vec{k} - \frac{1}{2\pi}\nabla\varphi(\vec{r}_0)\right) \tag{18}$$

where Φ_{det} stands for the Fourier transform of the specimen function (17) convoluted with the probe's point spread function $c(\vec{k})$. When the observable intensity $\left|\Phi_{det}(\vec{k})\right|^2$ is calculated one obtains the microscope's aperture function $p(\vec{k})$, however shifted by $-\frac{1}{2\pi}\nabla\varphi(\vec{r}_0)$. This can be interpreted as a shift of the electron beam on the detector by a distance which is proportional to the local phase gradient $\nabla\varphi(\vec{r}_0)$.

These considerations explain the name of this particular method and also show its limits. If the variation of φ occurs at a length scale comparable or smaller than the probe diameter, this simplified treatment is no longer valid. Modern microscopes, however, are capable to form probe diameters of 5–10 nm even without an excited objective lens, when equipped with a field emitter. Therefore, at present this does not impose severe limitations on the method.

3.5.2 Signal detection, four quadrant detector

Various detector configurations have been considered, such as the four quadrant detector (Rose, 1977) and the annular four quadrant detector (Chapman, McFadyen and McVitie, 1997). The latter is superior concerning both the signal to noise ratio and the separation of the magnetic phase shift from other

effects which can also modify the measured intensity, which might falsely be interpreted as an additional magnetic phase (Chapman, McFadyen and McVitie, 1997).

As these position sensitive detectors are not part of the standard detectors delivered with common electron microscopes, the usual commercial bright-/dark-field detector used in a regular STEM has to be replaced by a custom-made four quadrant detector with amplifiers.

To record a DPC image, the specimen is scanned with the electron probe and for every beam position the difference values of two opposite detector segments are recorded, as shown in Figure 9. Here, for simplicity a line scan across a 180° domain wall is chosen for demonstration (a).

The beam position on the detector is shown in (c) as a shaded area for two scanning positions r_1 and r_2. Taking the difference values of two opposite detector segments leads to two recorded values shown in (b) for the complete line scan. For real imaging, not only line scans are recorded. Instead, a two-dimensional scan is performed which leads to a set of two-dimensional arrays of image data. In general, these sets are represented in a gray or color encoded image rather than a graph. Thus, a DPC data set consists of two images representing the x and the y component of the magnetic induction in the specimen plane. A double arrow is shown in the image pairs (Figure 10) to indicate both the mapping direction and the sign and amplitude of the local induction component as indicated by the gray scale given.

In Figure 10(c) an alternative variant of illustration is used. The two measured (gray) values at each scan point (x,y) are combined to locally construct a vector, which gives the direction and amplitude of $\vec{B}(x, y)$. Doing so for every image

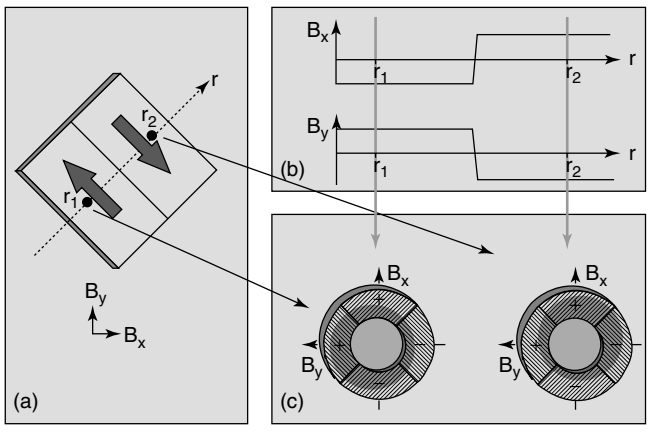

Figure 9. Interrelation of specimen's local induction, beam shift on the detector segments and measurable signal. (a) An electron probe is scanned across a magnetic specimen. The two locations indicated by r_1 and r_2 lead to the beam displacement on the detector segments shown in (c). If the signals of opposing segment are subtracted, positive and negative signals are obtained, indicating the B_x and B_y components at the probe's location.

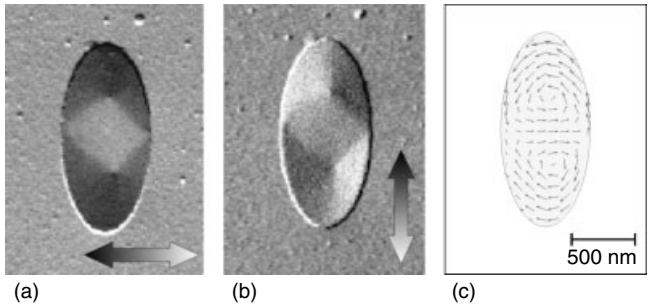

Figure 10. DPC image pair with (a) horizontal and (b) vertical induction component recorded. The double-headed arrow indicated the mapping direction and with its gray scale also the strength of the local induction in that direction. From the individual image points a local induction vector map can be reconstructed as shown in (c) for this example.

point, one is able to reconstruct a vector field, which reflects the magnetic induction. It turns out to be useful to use a threshold value to suppress noise contributions from outside the particle or from the particle's edges. This illustrates the problems of this type of representation. Even contrasts due to edge effects will lead to the creation of local 'induction vectors', which are, however, not meaningful. A misinterpretation can usually be avoided by simple comparison of contrasts in the component images with the reconstructed induction vector map.

As a DPC instrumentation is up to now commercially not available, only custom-made solutions are in use. Though analog recording systems have delivered excellent results, a fully digitized system facilitates the operation (Uhlig and Zweck, 2002). For this purpose, a fast AD/DA (analog-to-digital/digital-to analog) converter is necessary to read out the detectors. The synchronization of the scanning with the detector read out timing is of crucial importance, so it can be advantageous not to use the scan signal generated by the STEM software of the microscope. A good solution is to provide an external scan signal, which is driven by the same computer which also triggers the detector read out. This can be achieved by a corresponding software package which provides the recording functions and image processing routines for vector fields as well. It is of great use if there is also the ability to control further microscope functions with the same software.

3.5.3 Pros and cons

As in every scanning technique, the achievable spatial resolution depends mainly on the diameter of the electron probe. Although in regular STEM imaging probe diameters in the 0.1 nm regime can be achieved (Crewe, 1970), this is not possible for DPC imaging. Since the specimen region is required to be magnetic field free, the probe forming objective lens

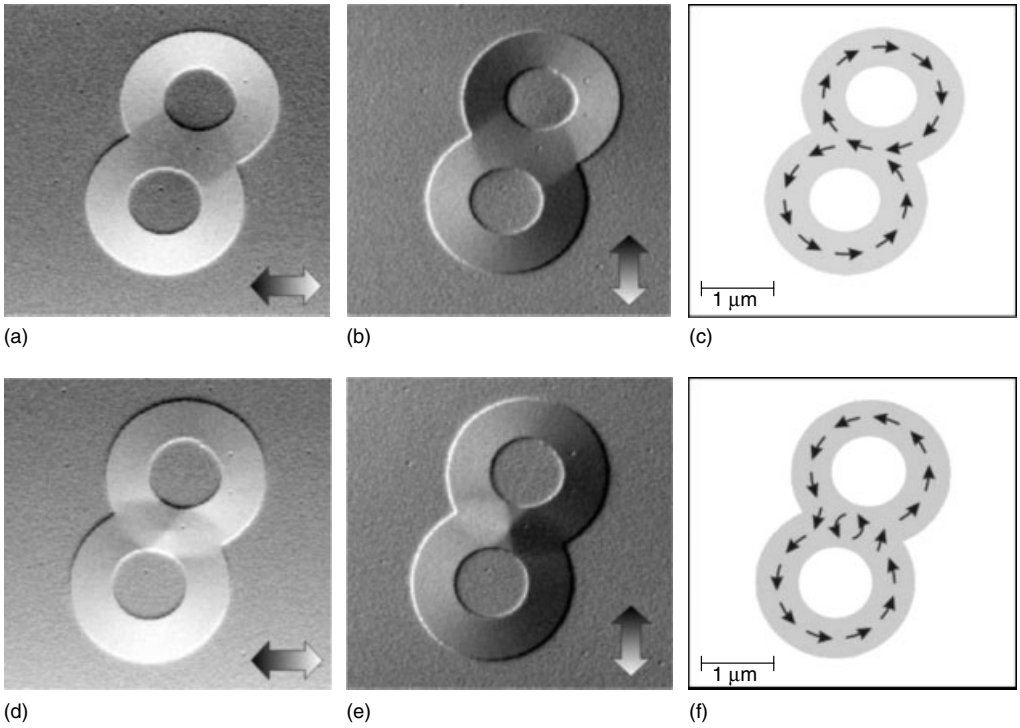

Figure 11. DPC image pairs (a), (b) and (d), (e) for double ring systems which show two different micromagnetic configurations. These configurations are shown in (c) and (f). In (c) the two rings show opposite sense of induction circulation, while in (f) the circulation is in both rings counterclockwise. Obviously, the specimen areas which are common to both rings exhibit a different micromagnetic situation. In (c) the common area is homogenous, while in (f) a vortex is formed in this region.

cannot be used like in standard STEM. A compromise can, however, be made if the probe forming condenser lenses are used in combination with a FEG to form a probe as small as possible. An achievable resolution of 5 nm has been demonstrated.

A disadvantage of DPC – at least for lithographically structured specimens as described in the preceding text – is the comparably high contamination rate of the specimen. Especially after subsequent scans over the same area considerable amounts of contamination are deposited onto the sample rendering it useless in the worst case. This effect is probably due to the impossibility of thoroughly cleaning the specimens after structuring, since the electron transparent membrane would be destroyed by standard procedures. Therefore, residual resist from the e-beam lithography process is the main source for contamination.

3.5.4 Examples

DPC microscopy is capable to image the internal magnetic structure of specimens, even if the change of the induction's direction is not as strong as necessary to create a reasonable contrast in the Fresnel mode. This is demonstrated in magnetic ring structures, as shown in Figure 11.

The double ring system presented in Figure 11 has inner diameters of 1 µm and the outer diameters are 2 µm. The two rings overlap in such a way that in the region of overlap the ring width is identical to the width of each individual ring, that is, the overlap is 100%. The material used is Permalloy ($Ni_{80}Fe_{20}$) with a thickness of 20 nm. The structure, resembling the number '8', shows two different magnetic configurations in remanence. In (a) and (b) the DPC image pair shows a state with different directions of magnetization rotation in the two rings, (c) provides a sketch of the magnetization. The continuous rotation can be seen especially in (b) by the continuous change of the gray scale along the circumference, except in the immediate vicinity of the overlap region of both rings. This intersection area is clearly bordered by a distinct contrast and is of constant color. Differently from the continuous rotation in the rest of the ring, one finds a constant magnetization direction inside that area.

In contrary, Figure (d) and (f) show the same sense of magnetization rotation in both rings. This causes a 180° change in the magnetization direction in the intersection region. Here a vortex-like structure as described in Raabe *et al*. (2000) has formed.

DPC also enables a deeper insight in the internal structure of magnetic configurations. In Figure 12, a Permalloy ring of inner/outer diameters of 2.5/3 µm, respectively

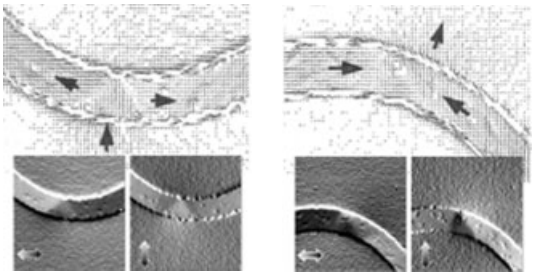

Figure 12. Detailed structure of domain walls in magnetic ring structures. (a) Induction vector map of a transverse wall which consists of two 90° walls, forming a triangular structure. (b) Induction vector map of a vortex domain wall, where a vortex mediates the change of induction between the two opposing parts of the head-to-head wall. Below the induction maps the corresponding DPC component image pairs are displayed.

and a thickness of 20 nm is shown for an external field of $7.9\,\mathrm{kA\,m^{-1}}$ applied in the vertical image direction. The so-called onion state (Rothman *et al*., 2001) which appears here comprises two 180° domain walls, which according to theory can be of two domain wall types, the transverse and the vortex domain wall (McMichael and Donahue, 1997).

In Figure 12(a) a transverse domain wall is imaged by DPC. The region of the wall is shown as a gray scale image pair (bottom) and also as a vector field reconstruction (top). Owing to limitations in hardware, the individual arrows, indicating the local induction direction are hardly distinctly visible. Larger arrows are used to indicate the averaged induction direction in different areas of the structure. The typical theoretically predicted triangular structure is visible, where inside the triangle the magnetization is perpendicular to the structure's edge and also to the magnetization outside the triangular region.

Figure 12(b) visualizes the vortex domain wall type, where the 180° change in magnetization direction is accomplished via a vortex generation.

For the vector field reconstruction threshold values have been used to omit vectors with too small or too large absolute values, which can attributed to structural properties.

3.6 Holography

3.6.1 Introduction

Another technique, capable to give information on magnetic structures, is electron holography (Bromwich *et al*., 2005; Lau and Pozzi, 1978; Tonomura, 1983; Tonomura *et al*., 1980; Dunin-Borkowski, McCartney and Smith, 1998; Lichte, 2002; Lehmann and Lichte, 2002), which was invented by Dennis Gabor in 1948 (Gabor, 1948). Holography was initially proposed as a method to reconstruct the wave field which exits from a specimen both in amplitude and phase. Since, after Aharanov and Bohm (1959), the vector potential of a magnetic specimen influences the phase of an electron wave, it is obvious that the phase shifting action of a magnetic specimen on an initially plane wave can be measured by electron holography.

To record the phase of a wave, an interference experiment has to be carried out. If the electron wave after transmission through the specimen interferes with a coherent reference wave and the corresponding interference pattern is recorded, the phase shift can be recovered by mathematical procedures.

This procedure of two interfering wave fronts, whose wave vectors form an angle $\alpha(\vec{k}_1,\vec{k}_2) \neq 0$ is termed off-axis holography. Is has the advantage that in the reconstruction process the image and its conjugate (twin image) are spatially separated, that is, a mutual influence between the two images can be excluded (Leith and Upatnieks, 1962).

In practice, the region of interest of the sample is placed in one half of the illuminating electron beam, while the second half of the beam is ideally unaffected by the specimen and therefore can act as a reference wave (Figure 13). A positively charged wire with a diameter in the sub-µm range is used as a Möllenstedt biprism (Möllenstedt and Düker, 1956) to tilt the two partial beams toward each other, producing an interference pattern in the recording plane.

In a strongly simplified mathematical model in which the influence of the microscope itself is omitted, the object wave $\Phi_{Obj}(\vec{r})$, that is the primary wave modulated by the specimen's transmission function according to equation (2) can be written as $\Phi_{Obj}(\vec{r}) = U(\vec{r}) \cdot e^{i(\vec{k}_0\vec{r}+\varphi(\vec{r}))}$, while the reference wave would be written as $\Phi_{Ref}(\vec{r}) = e^{i\vec{k}_0\vec{r}}$. If both waves are tilted toward the optic axis by $\pm\vec{k}'$, the resulting two waves can be written as

$$\begin{aligned} &\Phi_{Obj}(\vec{r}) = U(\vec{r}) \cdot e^{i((\vec{k}_0-\vec{k}')\vec{r}+\varphi(\vec{r}))} \quad \text{and} \\ &\Phi_{Ref}(\vec{r}) = e^{i((\vec{k}_0+\vec{k}')\vec{r})} \end{aligned} \tag{19}$$

Then, in the plane of observation the intensity is given by

$$\begin{aligned} I(\vec{r}) &= \left|\Phi_{Obj}(\vec{r}) + \Phi_{Ref}(\vec{r})\right|^2 = \left(U(\vec{r}) \cdot e^{i(\vec{k}_0-\vec{k}')\vec{r}+i\varphi(\vec{r})}\right. \\ &\quad \left. + e^{i(\vec{k}_0+\vec{k}')\vec{r}}\right) \cdot \left(U(\vec{r}) \cdot e^{-i(\vec{k}_0-\vec{k}')\vec{r}-i\varphi(\vec{r})} + e^{-i(\vec{k}_0+\vec{k}')\vec{r}}\right) \\ &= U^2(\vec{r}) + 1 + U(\vec{r}) \cdot \left(e^{-i(2\vec{k}'\vec{r}-\varphi(\vec{r}))} + e^{i(2\vec{k}'\vec{r}-\varphi(\vec{r}))}\right) \\ &= U^2(\vec{r}) + 1 + 2U(\vec{r})\cos(2\vec{k}'\vec{r} - \varphi(\vec{r})) \end{aligned} \tag{20}$$

As is obvious in equation (20), the phase information $\varphi(\vec{r})$ of the magnetic specimen is contained in the interference cosine term. It can, however, be extracted in Fourier space. For this purpose, first the recorded image (i.e., $I(\vec{r})$) is

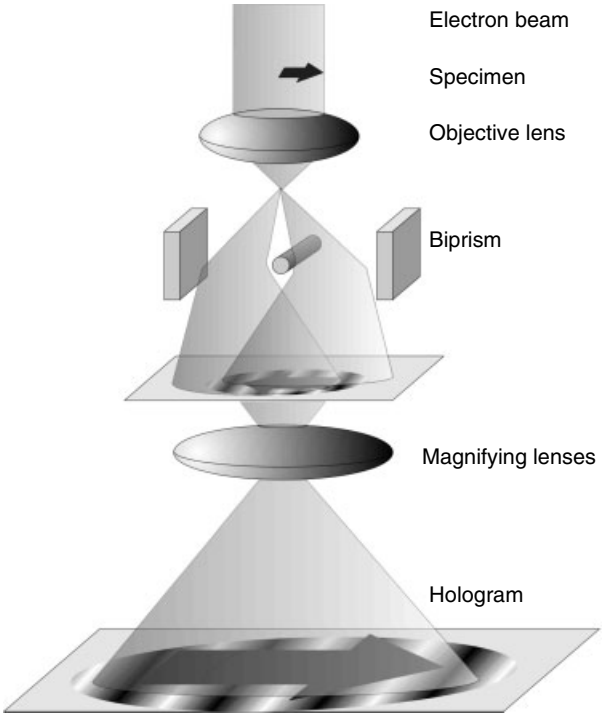

Figure 13. Typical setup for off-axis holography. The specimen is illuminated by one half of the incoming electron beam, the second half acts as the reference wave. The two partial waves are then brought to interference by the electron biprism, a positively charged wire. After further magnification, the hologram can be recorded in the image plane.

Fourier transformed, leading to

$$
\begin{aligned}
FT\left[I(\vec{r})\right] &= FT\left[U^2(\vec{r})\right] + FT\left[1\right] + \int U(\vec{r})\left(e^{-i2\vec{k}'\vec{r}+i\varphi(\vec{r})}\right. \\
&\quad \left. + e^{i2\vec{k}'\vec{r}-i\varphi(\vec{r})}\right)\cdot e^{2\pi i\vec{k}\vec{r}}\mathrm{d}\vec{r} = FT\left[U^2(\vec{r})\right] \\
&\quad + \delta(\vec{k}) + \int U(\vec{r})\left(e^{-i2\vec{k}'\vec{r}+i\varphi(\vec{r})+2\pi i\vec{k}\vec{r}}\right)\mathrm{d}\vec{r} \\
&\quad + \int U(\vec{r})\left(e^{i2\vec{k}'\vec{r}-i\varphi(\vec{r})+2\pi i\vec{k}\vec{r}}\right)\mathrm{d}\vec{r} = FT\left[U^2(\vec{r})\right] \\
&\quad + \delta(\vec{k}) + \int U(\vec{r})\left(e^{i\varphi(\vec{r})}\cdot e^{-i2\vec{k}'\vec{r}}\right)e^{2\pi i\vec{k}\vec{r}}\mathrm{d}\vec{r} \\
&\quad + \int U(\vec{r})\left(e^{-i\varphi(\vec{r})}\cdot e^{-i2\vec{k}'\vec{r}}\right)\cdot e^{2\pi i\vec{k}\vec{r}}\mathrm{d}\vec{r} \\
&= FT\left[U^2(\vec{r})\right] + \delta(\vec{k}) + FT\left[U(\vec{r})\cdot e^{i\varphi(\vec{r})}\right] \\
&\quad \otimes \int\left(e^{2\pi i\vec{k}\vec{r}-i2\vec{k}'\vec{r}}\right)\mathrm{d}\vec{r} + FT\left[U(\vec{r})\cdot e^{-i\varphi(\vec{r})}\right] \\
&\quad \otimes \int\left(e^{i2\vec{k}'\vec{r}+2\pi i\vec{k}\vec{r}}\right)\mathrm{d}\vec{r} = FT\left[U^2(\vec{r})\right] + \delta(\vec{k}) \\
&\quad + FT\left[U(\vec{r})\cdot e^{i\varphi(\vec{r})}\right]\otimes\delta\left(\vec{k}-\frac{\vec{k}'}{\pi}\right) \\
&\quad + FT\left[U(\vec{r})\cdot e^{-i\varphi(\vec{r})}\right]\otimes\delta\left(\vec{k}+\frac{\vec{k}'}{\pi}\right) \qquad (21)
\end{aligned}
$$

The first term describes the Fourier transform of the transmission function of the specimen. For all practical cases, the specimen's dimensions are larger than the resolution of the technique by at least a factor of 10, which leads to Fourier coefficients which are located very close to the center of the Fourier spectrum, compared to the extension of the complete Fourier spectrum out to its resolution limits. The second term also contributes explicitly to the center of the Fourier spectrum. The latter two terms are shifted by $\pm\frac{\vec{k}'}{\pi}$ and contain the specimen's amplitude and phase information and the corresponding complex conjugate.

Since, obviously, the terms $FT\left[U(\vec{r})\cdot e^{\pm i\varphi(\vec{r})}\right]$, which make up the so-called side bands, contain all information about the specimen, one simply has to cut out the part of the Fourier transform and undo the shift by $\pm\frac{\vec{k}'}{\pi}$ before inversely transforming the partial spectrum. This back transformation yields then both the amplitude and phase function, that is, the exit wave function of the specimen under investigation. To prevent artifacts, care has to be taken to ensure that the side band information does not overlap with the central band's information content. This can conveniently be achieved by changing $\vec{k}'$ to the desired value by tuning the biprism's voltage.

As the specimen is not the only source of phase shifts in the electron microscope, these other sources have to be eliminated to reveal the specimen's phase shift only.

For this purpose, the specimen holder is removed from the microscope without changing the imaging conditions after every acquisition and a reference hologram is recorded. This hologram now contains only the parasitic phase shifts caused by the microscope, due to lens aberrations, charging effects, and so on. After identical treatment of this reference hologram, one obtains a reference wave function and consequently the specimen's exit wave function can be calculated by simply taking the difference of the disturbed and reference wave functions (Rau, Lichte, Völkl and Weierstall, 1991; Franke, Herrmann and Lichte, 1988; Lehmann, Völkl and Lenz, 1994).

The mathematical procedures described in the preceding text are commercially available in the meantime, that is the software package HoloWorks (Völkl, Allard and Frost, 1995).

Without going into any details it seems helpful to mention here that for electron holography a highly coherent and bright illumination is essential. Sufficient brightness gives reasonably short exposure times during which typical experimental artifacts such as drift or contamination play no or only a negligible role. For the coherence required, a FEG is required. To further optimize the imaging conditions, the use of a so-called elliptical illumination is common. Detailed experimental procedures are

given in the literature (Speidel and Kurz, 1977; Düker, 1955; Lehmann and Lichte, 2002; Völkl, Allard and Joy, 1999).

4 BASIC EXPERIMENTAL TECHNIQUES

4.1 Application of magnetic fields

To observe not only the remanent state of magnetic samples but also investigate magnetization processes makes it necessary to generate a well-defined magnetic field in the specimen area. As the samples are thin films, especially magnetic in-plane fields are of interest. To generate these fields is possible in some different ways, which are described in more detail in the subsequent text.

4.1.1 Tilting method

The electromagnetic lenses in the TEM generate a vertical magnetic field in the specimen region. Usually one tries to minimize these fields by using a special low-field Lorentz lens, as explained in the preceding text. However, moderate vertical fields and a tilted specimen can be used to generate the magnetic in-plane fields needed in the specimen plane. For this method a fixed vertical field is applied and the strength of the specimen's in-plane field is regulated by the tilting angle. Although simple to use, this method suffers from some disadvantages.

The worst effect is, that in order to create an in-plane field one always has to accept the presence of an even stronger magnetic out-of-plane field. The effect of this field in experiments is difficult to estimate, but a biasing effect on switching processes is probable, especially when areas of perpendicular magnetization are present (i.e., a vortex core structure) in the sample.

A second disadvantage is that the rate of change of the magnetic field is limited by the tilt speed of the holder which means generally a few seconds for a full field sweep from +B to −B. Experiments with fast magnetic pulses are in general not possible. Another possible problem can arise from the different tilt speeds for orthogonal axes in regular double tilt holders, which have to be taken into account if during a change of field strength and direction precise control over the external field at any time rather than simply at the beginning and the end of the process is required.

4.1.2 Special specimen holder

Another solution which was pursued in the last years is to implement small electromagnetic coils on the specimen holder to generate pure magnetic in-plane fields (i.e., Uhlig, Heumann and Zweck, 2003). These coils can be controlled by an external computer device connected to a DA converter (see Figure 14).

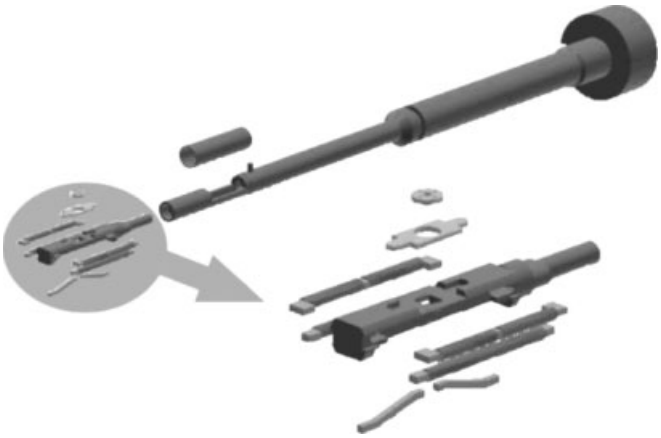

Figure 14. Explosion view of the special holder for magnetic in-plane fields. The specimen sits in the center of two orthogonal magnetic fields, generated by electromagnets. The magnets can be controlled in their strength by an external computer, which allows perfect control over the direction of the local field. The field strength, however, is very limited. (Drawing and construction by Stephan Otto, University of Regensburg.)

The solution with coils on the specimen holder suffers from different problems. Primarily, space on the specimen holder is very limited. Only small coils can be implemented which in turn limits the maximal achievable magnetic field. For example, in an FEI microscope (Tecnai F30) even with a sophisticated coil design effective fields of only about 0.02 T were achieved due to the small specimen holder size. For many magnetization experiments such a holder can only be used in a reasonable way in combination with the tilt technique, but tilting is often not possible because of space restrictions.

Instead of using electromagnetic coils, it is also possible to utilize the magnetic Biot–Savart fields which surround a current carrying wire. To get a reasonable magnetic field strength the specimen must be placed very close to the wires, resulting in another specialized specimen holder (Yi *et al.*, 2004). A big advantage of this design is the predictability of the generated magnetic fields, as the geometry is simple and no magnetic material with hysteretic properties is involved. Furthermore, it was shown, that the tilting of the electron beam due to the horizontal magnetic field is cancelled out by an opposite field of the same strength beneath the sample. However, the problem of limited field amplitudes remains. The fields are only applicable in one in-plane direction.

Both designs have in common the problem of heating of the specimen holder. If a current through the wires is applied, the coils (or wires) heat up (in most cases the devices are operated at their very limit in order to generate sufficient magnetic fields) and thus also the specimen holder itself.

Since this heating causes thermal expansion of the holder, investigations in the μm and nm range may suffer from specimen drift.

Furthermore, the combination with other ways of specimen manipulation is very limited. Cooling or defined heating experiments, tilting (in order to orient the specimen to a special crystallographic direction) or other *in situ* measurements, which require a different specimen holder are not possible with these holders.

4.2 Variation of temperature, *in situ* experiments

It shall be only briefly mentioned that with the availability of various specimen holder which allow the specimen to be at low (LHe, LN_2) temperatures or high temperatures up to 1200 °C, the experimentator has a wide range of experimental possibilities which will be useful for future investigations on magnetic materials. It is also possible to use specimen holders with integrated electrical leads which can serve to contact the specimen and to drive currents through it while under observation.

4.3 Imaging of stray fields, elimination of inner potentials

As was described in the preceding text, especially for patterned magnetic materials it is often a problem that the electron wave's phase shift due to the electrostatic inner potential is generally much stronger than the magnetically caused phase shift. Ways to separate the two effects have been described in the preceding text. In Figure 15(a), two reconstructed holograms are shown. The specimen is in a remanent magnetization state after having been saturated in the direction indicated by the arrows. For further processing, it is necessary to be sure that the remanent states represent as good as possible the state of saturation, because otherwise local deviations from the purely saturated state will lead to artifacts in the final image which can be easily misinterpreted. Equal colors represent equal phase shifts and may, for a simple interpretation, be associated with 'magnetic field lines'. However, the signal is rather noisy, and it is difficult to derive a reasonable micromagnetic pattern from these images. After image processing according to (Dunin-Borkowski, McCartney and Smith, 1998), the images in Figure 15(b) are obtained. The phase shifts caused by the inner electrostatic potential of the specimen (which is due to thickness variations, if a homogeneous composition may be safely assumed) have been removed and the pure magnetic phase shift is visible. In the same way, the pure electrostatic phase shift can be derived, as shown in Figure 15(c), left image. The gray scale variations can be regarded to represent the specimen's thickness fluctuations. The Figure 15(c) right image finally shows equal phase shift contour lines, superimposed by a shadow image of the specimens boundary. The contour lines may be interpreted to be 'magnetic field lines', which also extend outside the specimen.

4.4 Hysteresis loops

In order to determine hysteresis loops from individual particles, the experimenter has to have the ability to control the magnetic field experienced by the specimen under investigation and to measure a quantity which is proportional to the specimen's magnetization or induction. As was shown in Section 4.1, the application of magnetic fields in the microscope is possible by various methods. In the case of DPC it was shown that the signal is given by

$$I \sim \vec{\nabla}\varphi(\vec{r}) = \vec{\nabla}(B_\perp \cdot A) \tag{22}$$

where $\varphi = B_\perp \cdot A$ is the magnetic flux through a specimen cross section A. If the induction is considered to be constant over the specimen's thickness, equation (22) becomes

$$I \sim \left| \frac{\mathrm{d}}{\mathrm{d}(x,y)} (B_\perp \cdot L(x,y) \cdot t) \right| \tag{23}$$

where $L(x, y)$ is a distance along the specimen's plane and t is the specimen's thickness, giving in combination $L(x, y) \cdot t = A$. For the given situation of a position sensitive detector, one is able to decompose the signal strength into two partial signals which correspond to two orthogonal directions

$$I_x(\vec{r}) \propto \frac{\mathrm{d}}{\mathrm{d}x}(B_\perp \cdot L(x,y) \cdot t) \propto \frac{\mathrm{d}}{\mathrm{d}x}(B_\perp \cdot A) \propto \frac{\mathrm{d}}{\mathrm{d}x}(\phi(\vec{r})) \text{ and}$$
$$I_y(\vec{r}) \propto \frac{\mathrm{d}}{\mathrm{d}y}(B_\perp \cdot L(x,y) \cdot t) \propto \frac{\mathrm{d}}{\mathrm{d}y}(B_\perp \cdot A) \propto \frac{\mathrm{d}}{\mathrm{d}y}(\phi(\vec{r})) \tag{24}$$

Electron holography records the electron wave's phase shift due to the flux enclosed between two partial waves a distance $L(x, y)$ apart. Thus, using equations (22) or (24) one can simply calculate the vector components $I_x(\vec{r})$ and $I_y(\vec{r})$ which allow a direct calculation of local induction vectors. Obviously, both DPC and electron holography are techniques capable to reconstruct quantitatively induction maps of micromagnetic configurations within specimens with a lateral resolution down to presently 5 nm.

A state-of-the-art electron microscope with its ability to control the most important functions via a script language allows automatization of time consuming processes. This opens the possibility to generate hysteresis curves of single

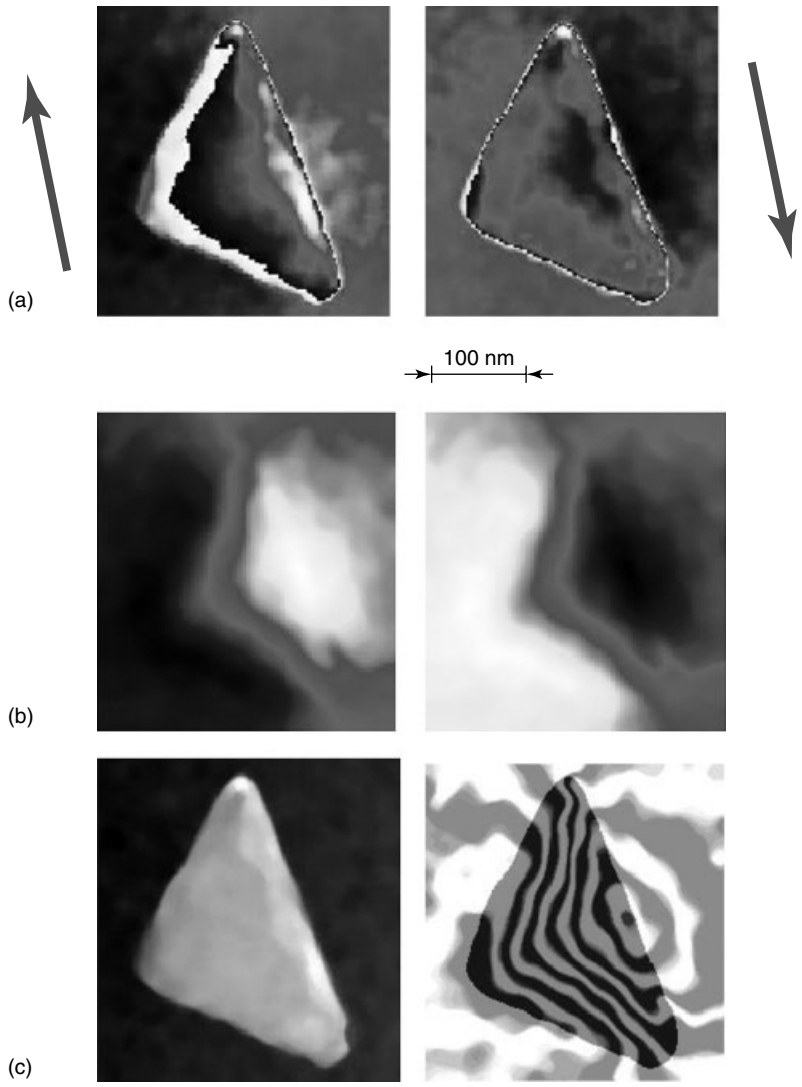

Figure 15. Separation of electrostatic and magnetic phase shifts. (a) Two reconstructed holograms taken in remanent conditions with specimens oppositely magnetized. (b) Pure magnetic phase shifts after subtraction of the electrostatic component. (c) Gray scale image of the electrostatic phase shift (= thickness contours, left image) and magnetic field lines (= lines of equal magnetic phase shift, right image), superimposed with a shade image of the specimen's contour.

particles in the μm- and sub-μm range (Uhlig and Zweck, 2004).

Only a few techniques have the ability to generate true single particle hysteresis curves. An electron microscopy based method can additionally provide the magnetic configuration within the specimen at every point of the loop, which makes it superior to other comparable techniques.

The hysteresis loop in Figure 16 of a 1.5/0.75 μm outer/inner diameter ring structure made of 20-nm thick Permalloy was recorded automatically in approximately 18 h with a fully digitized DPC device attached to a FEI Tecnai F30. The data series consists of 209 images, which were recorded with different external field values by tilting the specimen in the vertical objective lens field. Before each image was recorded, some alignment procedures were done automatically. The images were aligned with respect to each other using a cross correlation procedure. The software then calculates the average magnetic induction inside the specimen in every image and plots its value versus the external field value.

The jumps in the hysteresis loop indicate a switching process, when the initial onion state changes into a flux closure state at a field value of $6.1\,\mathrm{kA\,m^{-1}}$ and into the reversed onion state at $11.6\,\mathrm{kA\,m^{-1}}$. The magnetic field sweep in the opposite direction first provides a switching into the flux closure state at $-2.3\,\mathrm{kA\,m^{-1}}$ and back into the original onion state at $-12.6\,\mathrm{kA\,m^{-1}}$. The fact that the loop is not closed

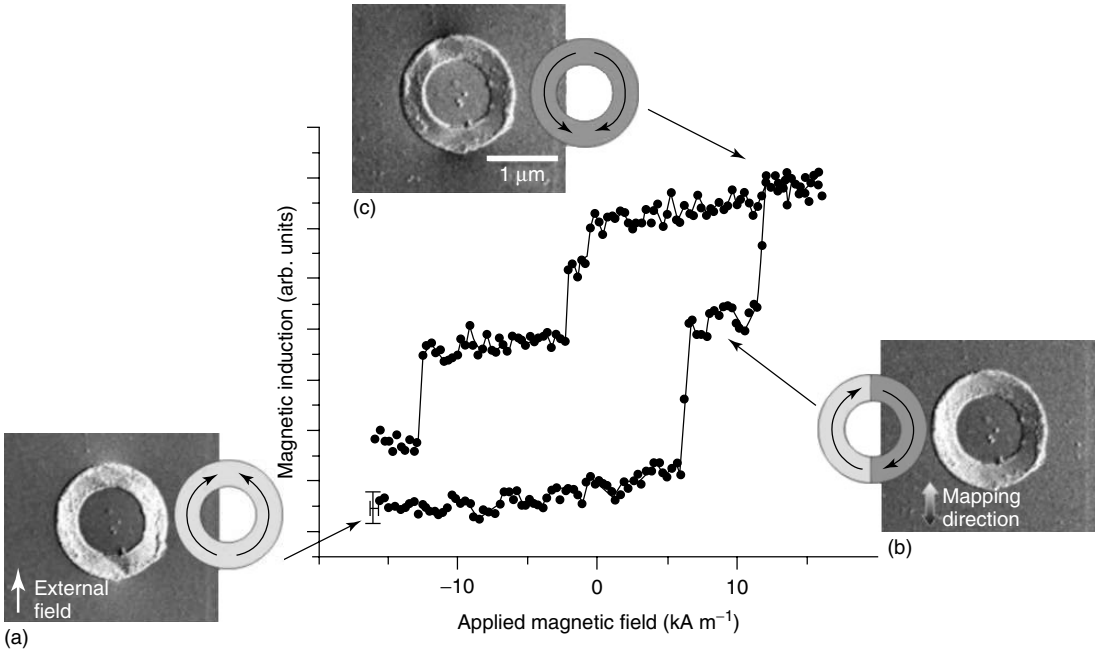

Figure 16. Hysteresis loop of a single magnetic ring. As is obvious from the DPC images, (a), (b) and (c), together with the schematic drawings besides them, the ring switches from an upwards oriented 'onion state' (a) into a 'vortex state' (b) and then into a 'reversed onion state' (c). Each change of magnetic configuration is accompanied by distinct features in the hysteresis loop. The loop is not closed completely, which is due to instrument instabilities and contamination problems during the experiment.

at the left side is due to the fact, that during the long recording time of 18 h contamination of the specimen occurs which changes the experimental conditions slightly.

In Figure 17, a complete hysteresis loop, derived from electron holograms made on a $Ni_{80}Fe_{20}$ specimen is shown. Figure 17(a) shows the geometric shape of the particle investigated, while images (b) through (l) give induction distributions for various stages of the loop. As can be seen clearly, for this specimen the remagnetization starts from a saturated state, until the specimen relaxes into a so-called vortex state (Raabe *et al*., 2000; Shinjo *et al*., 2000). With increasing, however reversed field direction, the vortex core becomes shifted toward the specimen's edge until a new, inversely magnetized saturated state is reached. If the field is now decreased again, first a so-called 'C'-state forms (Figure 17h) as an intermediate state which is then followed by the creation of a vortex with subsequent shift and saturation as before. This series illustrates nicely the tremendous advantage of micromagnetic imaging. For each stage of the hysteresis loop of *one single individual* particle the micromagnetic configuration is known precisely, the mechanisms involved in magnetization reversal become obvious.

Even more impressive is the loop shown in Figure 18 of a 6-nm thick Permalloy ellipse with short and long axis lengths of 155 and 170 nm, respectively. The data for this image were recorded with electron holography (Heumann, Uhlig and Zweck, 2005).

After differentiation of the reconstructed holograms according to equation (24), the local induction vectors can be reconstructed and the average induction of the specimen can readily be calculated for each external field value.

The particle in Figure 18 shows a single domain switching behavior. The switching occurs between 0.24 and 0.32 kA m^{-1}, and does not show any intermediate states as would be expected if there was a nucleation of domain walls or other micromagnetic configurations which might form during the magnetization reversal. The switching can also be seen from the inversion of the grayscale superimposed on the particle's images below the hysteresis loop shown. The gray scale indicates the slope of the electron wave which was generated by the specimen's vector potential acting on the initially plane wave. The induction is directed perpendicular to the gray scale's slope, pointing left or right. Lines of equal phase shift are also displayed which indicate the magnetic field lines within and outside the specimen.

5 IMAGE PROCESSING AND SIMULATIONS

5.1 Transport-of-intensity equation (TIE)

A comparably new approach is the reconstruction of the exit wave phase by using several images with

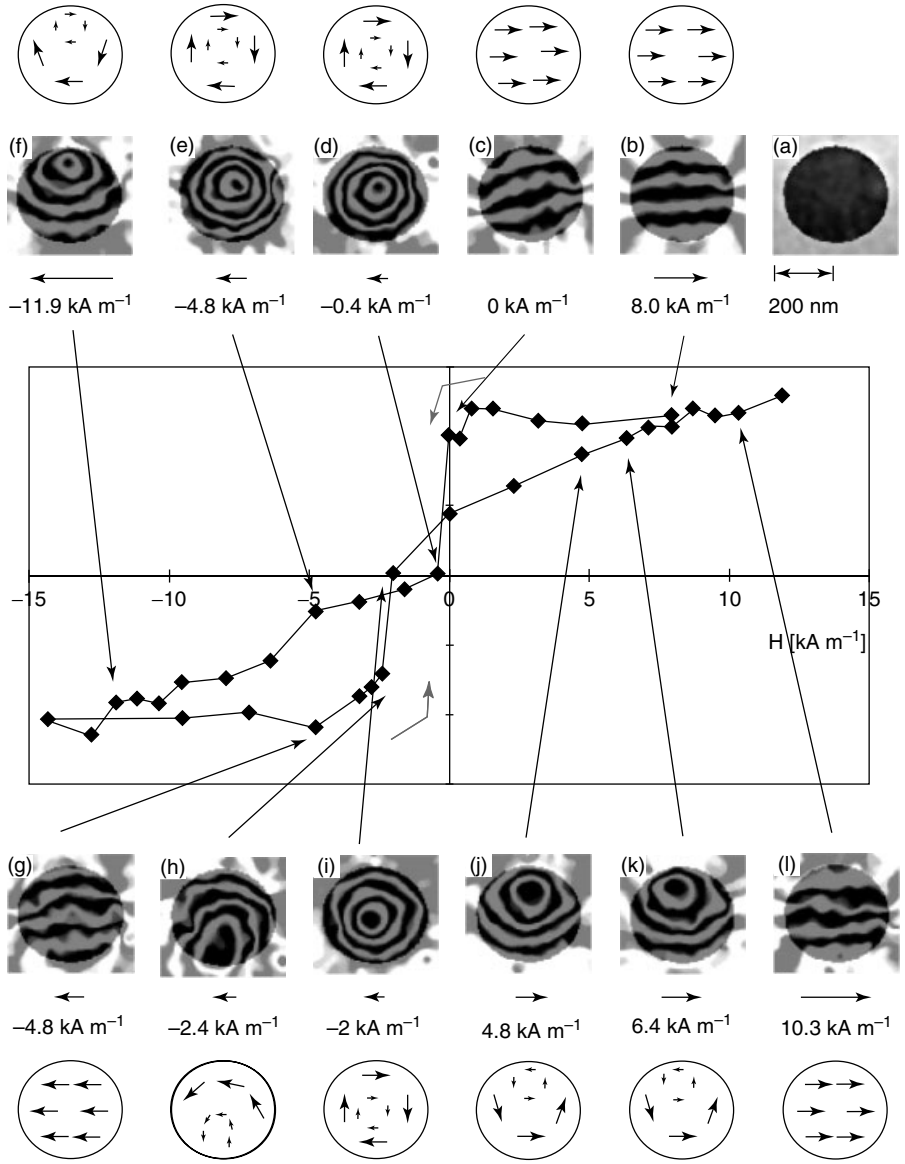

Figure 17. Complete hysteresis cycle derived from electron holograms as described in the preceding text. The experimental images represent the phase shift caused by the magnetic particle on the electron beam for each step of the hysteresis loop. Above and below the experimental images, a schematic view of the induction's course is given.

different focus conditions. Of course this technique is also applicable for magnetic imaging (Volkov and Zhu, 2004; Bajt *et al.*, 2000). To illustrate the background of this method, we follow the calculations of (Allen and Oxley, 2001).

If the wave function of the electrons is considered as a plane wave e^{ikz}, which propagates along the z direction and is perturbed by $\xi(\vec{r}_\perp, z)$,

$$\Phi(\vec{r}_\perp, z) = e^{ikz} \cdot \xi(\vec{r}_\perp, z) \tag{25}$$

where $\vec{r}_\perp$ is a vector in the x-y plane.

The Schrödinger equation for wave propagation in free space

$$(\nabla^2 + k^2)\Phi(\vec{r}) = 0 \tag{26}$$

leads with the paraxial approximation, that is when the second derivative of $\xi(\vec{r}_\perp, z)$ with respect to z is small $\left(\frac{\partial^2}{\partial z^2}\xi(\vec{r}_\perp, z) \approx 0\right)$, to

$$\left(\nabla_\perp^2 + 2ik\frac{\partial}{\partial z}\right)\xi(\vec{r}_\perp, z) \tag{27}$$

with $\nabla_\perp$ operating in the x-y plane.

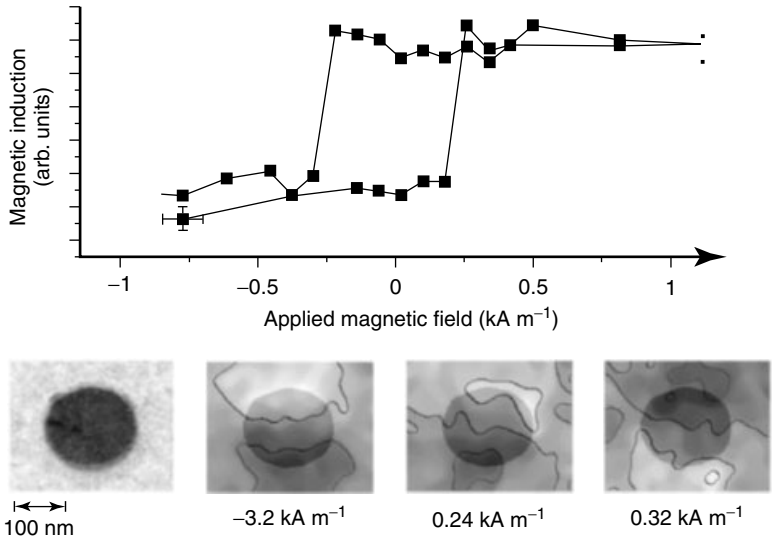

Figure 18. Hysteresis loop of a $Ni_{80}Fe_{20}$ particle with approximately 160-nm diameter. The hysteresis loop has been determined from holograms taken at various applied fields and shows single domain behavior of the specimen, that is, a switching between two magnetic states without any intermediate stages. The micrographs below the hysteresis loop show (left to right) a shadow image of the specimen used to determine the geometrical shape and holographic phase reconstructions of the induction distribution within the specimen vor the applied fields as indicated. Between 0.24 and 0.32 kA m^{-1} a switching occurs as can be seen from the inverted gray scale contrast.

If now the perturbation term is replaced by

$$\xi(\vec{r}_\perp, z) = \sqrt{I(\vec{r}_\perp, z)} \cdot e^{i\varphi(\vec{r}_\perp, z)} \tag{28}$$

which separates the intensity from the phase of the wave, it is possible to obtain the following expression which is termed the transport of intensity equation (TIE),

$$\nabla_\perp \cdot \left[I(\vec{r}_\perp, 0) \cdot \nabla_\perp \varphi(\vec{r}_\perp, z) \right] = -k \frac{\partial_{z=0}}{\partial z} I(\vec{r}_\perp, z) \tag{29}$$

As $I(\vec{r}_\perp, 0)$ is known as the *intensity of the in-focus image* and $\frac{\partial_{z=0}}{\partial z} I(\vec{r}_\perp, z)$ can be calculated from slightly defocused images, the phase can be extracted by mathematical procedures. Principally, this method measures the second spatial derivative of the phase and thus the first derivative of the magnetic induction.

Mathematical methods (Allen and Oxley, 2001) are used to extract the phase information from a series of images taken at various focus distances.

It is obvious from Figure 19 that the TIE technique is capable to generate induction maps similar to those obtained from differential phase contrast and electron holography. One obvious limitation, however, seems to be the same as for regular Fresnel imaging. For thin or weakly magnetic specimens the defocus distance Δz has to be chosen rather large in order to generate sufficient contrast. Especially for patterned materials, the large defocus will in combination with the electrostatic contribution cause strong Fresnel fringes at the perimeter of the specimen. If the specimen is small, that is in the dimension of 300 nm or below, and thin, this will deteriorate the useful signal. Also, owing to a large defocus, the PSF will blur the image and reduce lateral resolution. However, since the TIE technique is still rather new, it will be interesting to observe what new possibilities and advanced data processing techniques will be developed in the future (Belaggia, Schofield, Volkov and Zhu, 2004; de Graef and Zhu, 2001).

5.2 Image simulation from induction distributions

Fresnel images only display the magnetic induction in an indirect way since the contrast shows only the rate of change of the induction (see equations (9) and (11)). Experienced Lorentz microscopists can rather easily deduce a micromagnetic configuration which explains qualitatively the contrasts observed, but sometimes the simple models fail to explain details of the experimental images. To understand all features of an experimental image in detail, it is therefore often necessary to perform image simulations from a given micromagnetic configuration, which precisely take all imaging parameters into account. To do these simulations, a realistic model of the configuration under investigation is needed for a start. Fortunately, there are various computer programs available which are able to calculate the energetically stable arrangement of local magnetic moments, usually by solving the Landau-Lifshitz-Gilbert equation, such as MicroMagus, OOMMF, LLG or by the code written by Hertel and

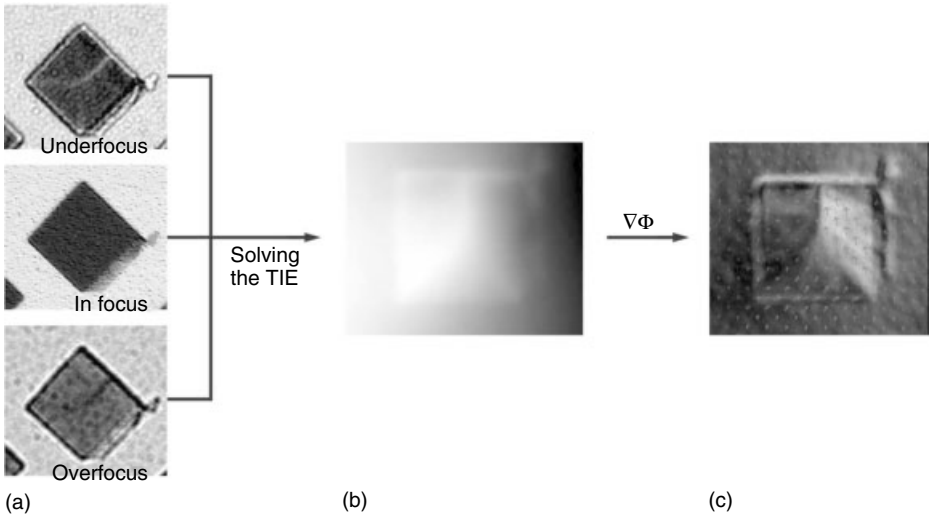

Figure 19. Induction map reconstruction from Fresnel images using the transport-of-intensity-equation (TIE) approach. Three micrographs (a), taken at different defoci, are used as input for the TIE computation and render a Phase map (b) and – after differentiation – an induction vector map. (Images courtesy of Kohn, Petford-Long and Anthony, 2005.)

Kronmüller (1999), which uses a finite element-like mesh and is less susceptible to artifacts which arise from the discretization of edges with square elements. Even for DPC images, which are by far more directly interpretable, and for reconstructed electron holograms these simulations turn out extremely useful, as from the micromagnetic simulations one can calculate not only the phase shift which the electron wave suffers from within the specimen but also due to stray fields which extend outside the specimen. This is especially important for patterned materials, where stray fields become important. The simulations also allow to take into account the stray fields above and below the specimen which are usually simply neglected because they are difficult to deal with.

Once a micromagnetic configuration is available – usually in the form of a three-dimensional matrix of induction vectors – the phase shifting action on an electron wave has to be calculated. This can be done using an algorithm proposed by Mansuripur (1991) which allows a fast calculation. The result is a so-called 'phase plate' which in detail incorporates the local variations of phase shifts which a certain micromagnetic configuration will imprint on an electron wave upon transmission. Using standard electron optical treatment, the phase distribution can then easily be converted to either Fresnel images, DPC image pairs or reconstructed holograms. This task is done by a software package (Haug, Otto, Schneider and Zweck, 2003) which also allows the specimen to be tilted with respect to the electron beam. This is an important feature, since it allows the investigation of specimens which have strong out-of-plane components. These will be observable only if the specimen is tilted to partially project the induction into the plane of observation, that is, create a sufficiently large induction $B_\perp$ which is perpendicular to the electron beam (Köhler *et al*., 2000).

Figures 20 and 21 give an example of the usefulness of these image simulations. Figure 20 shows an experimental image of a Landau structure (a, left) and a so-called

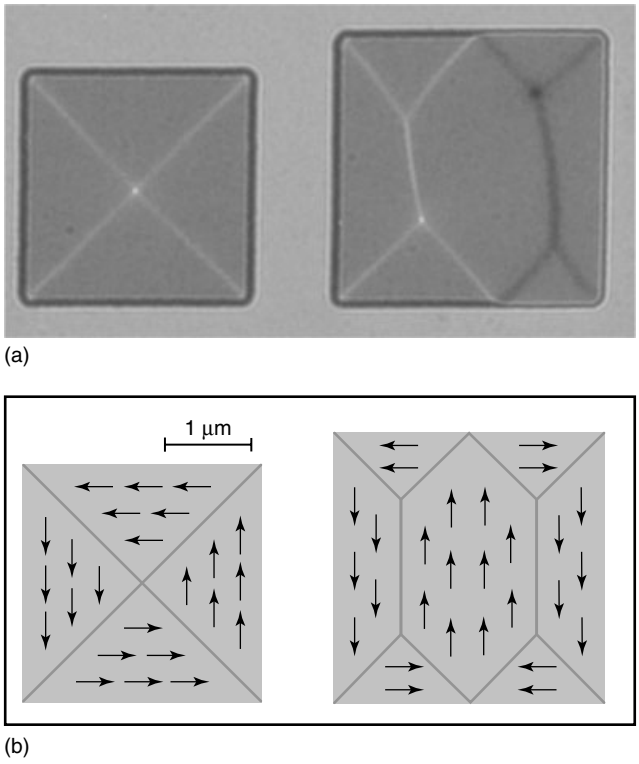

Figure 20. Comparison of experimental Fresnel images (a) with schematic representations of the internal induction distribution (b).

seven-domain structure (a, right), together with simple models (b) for the micromagnetic situation. Although on first glance the model seems to describe all features satisfactorily, on closer inspection it does not. Although the contrast of the walls (white or dark walls) would be correctly deduced from the model, another detail remains unexplained. When looking at the white walls of the 7-domain structure (a, right) only, they appear in the shape of a double fork, which is slightly tilted with respect to the specimen's outer edges. Also, the two forks are different. Whereas in the upper fork the legs join smoothly into the vertical white wall, the lower one forms a rather sharp junction with a bright spot at the center of this junction. The same is observable for the dark walls, but with reversed order. Obviously, the simple model cannot explain these differences.

A micromagnetic simulation gives a more detailed picture of the situation, as shown in Figure 21(a). The two forks show different micromagnetic properties, as on one fork a vortex structure is formed while the other, smoother side is generated by a more gradual change of the direction of the induction. Even the slight tilt with respect to the specimen's edges is reproduced. In Figure 21(b) the phase shifting action of the specimen is shown. Within the specimen, contour lines of equal phase shift are visible, which can be interpreted in terms of magnetic field lines. Outside of the specimen's boundary, white and dark shades indicate the phase shifting action of stray fields which are generated from this configuration. Please note that between subsequent transitions from black to white a phase shift of 2π is included. Figure 21(c) and (d) finally show a comparison of the simulated and the experimental Fresnel images in perfect agreement. (Please note that the two dark spots beneath the walls which appear in the experimental image only are artifacts caused by dirt particles and have no magnetic origin.)

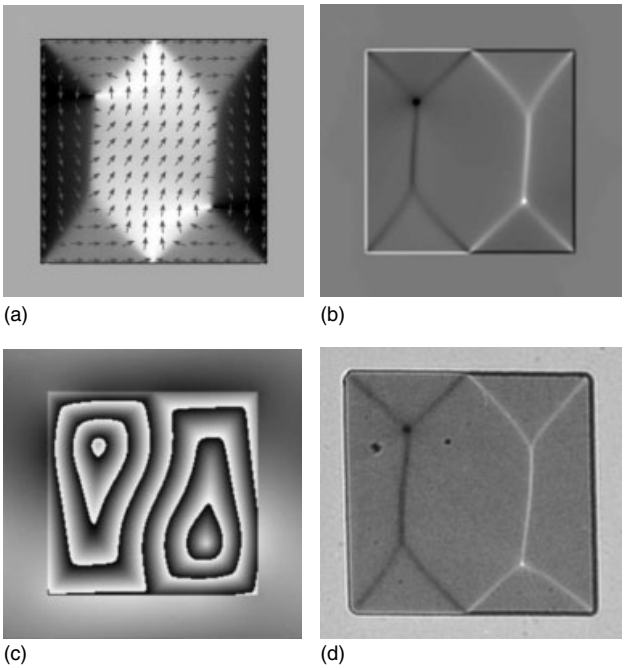

Figure 21. Comparison of an experimental Fresnel image of a so-called 7-domain structure (d) with the result of micromagnetic simulations (a). (b) The phase contour map of the structure in consideration, (c) is the simulated Fresnel image, which reflects all-important features of the true image. Note that two dark spots in (d) stem from dirt particles. Simulation parameters are: FEI Tecnai F30 characteristics, 300 kV, $C_S = 8$ m (Lorentz lens), $C_C = 41$ mm, $\theta_C = 1.6 \times 10^{-6}$ rad, size $= 2 \times 2\,\mu$m, thickness $= 20$ nm. (Images courtesy of T. Haug.)

6 APPLIED LORENTZ MICROSCOPY

In this chapter, it is intended to present an overview of recent published work, which used magnetic imaging by electron microscopy either as the main tool of investigation or as a complementary tool to cross-check results gained from other sources. As it is beyond the scope of this contribution to discuss in detail what has been found by various groups this will be hardly more than a commented list of references which may serve as a first start for a more detailed reading. The intention is to demonstrate that Lorentz microscopy has already been applied to a broad field of problems not only of model specimens but in contrary on many specimens which are of immediate interest both to basic research and industrial applications. Since domain wall movements are the most important process for magnetization reversal processes in extended specimens, it is an obvious task to study the properties of domain walls in various materials (Young and Chapman, 1993; Ploessl *et al*., 1993; McVitie and Chapman, 1990; Gong and Chapman, 1987; Chapman and Morrison, 1983; Chapman, Batson, Waddell and Ferrier, 1978; Akhter *et al*., 1998; Petford-Long, Doole and Donovan, 1993; de Graef, Kishi, Zhu and Wuttig, 2003; Zhu, Volkov and de Graef, 2001; de Graef, Willard, McHenry and Zhu, 2001; Dooley, de Graef and McHenry, 1998; Dooley and de Graef, 1997; Dooley *et al*., 1995; McVitie, 1995; Chapman, McVitie and McFadyen, 1987; Chapman *et al*., 1977; Zweck *et al*., 2001). Since the domain walls can – while moving during a remagnetization process – get pinned at so-called pinning sites, which contributes partially to the hysteretic properties, investigations of these pinning sites or 'domain wall traps' have been conducted by Brownlie, McVitie, Chapman and Wilkinson (2006), Ozkaya, Langford, Chan and Petford-Long (2002) and McVitie, Brownlie, Chapman and Wilkinson (2005). When not only slow, quasi-static magnetization processes have to be considered, the domains exhibit inertia or some sort of viscous properties (Rose *et al*., 1998;

Goodman *et al*., 2000). As domain walls contain energy which is due to increased exchange energy caused by the spatially close location of directionally varying spins within the wall, nature shows a tendency to reduce the domain wall energy by either transforming into a 'single domain state', which is preferred for small particles (Heumann, Uhlig and Zweck, 2005) or by forming a vortex state (Gillies, Chapman and Kools, 1996; Raabe *et al*., 2000; Shinjo *et al*., 2000; Schneider, Hoffmann and Zweck, 2000, 2001, 2003; Schneider *et al*., 2002, 2003; Rahm *et al*., 2001, 2003).

Patterned magnetic elements show under certain conditions properties, which differ from those of bulk material, simply due to the reduction in length scale. These changes may be dipolar interaction (Kundrotaite, Rahman, Aitchison and Chapman, 2001; Ridley *et al*., 2000; Kirk *et al*., 2000; Bromwich *et al*., 2005, 2006), or plainly the formation and behavior of magnetic domains in these patterned media (Liu, Chapman, McVitie and Wilkinson, 2004; Lim *et al*., 2003; Kirk *et al*., 1999, 2000, 2001; Kirk, McVitie, Chapman and Wilkinson, 2001; Kirk *et al*., 2001; McVitie and Chapman, 1997; Kirk, Chapman and Wilkinson, 1999; Gomez *et al*., 1999a,b; Aitchison *et al*., 1998; Gu *et al*., 1998; Kirk, Chapman and Wilkinson, 1997; McVitie, Chapman, Hefferman and Nicolson, 1988; Ross *et al*., 2006; Bromwich, Petford-Long, Castano and Ross, 2006; Petford-Long *et al*., 2006; Bromwich *et al*., 2004; Owen, Hang-Yan and Petford-Long, 2002; Ozkaya, Langford, Chan and Petford-Long, 2002; Hu, Wang, McCartney and Smith, 2005; Dunin-Borkowski *et al*., 2000, 2001; Hefferman, Chapman and McVitie, 1990; McVitie, Chapman, Hefferman and Nicolson, 1988; McVitie and Chapman, 1988). In this context, it is also important to study anisotropy effects (Gentils, Chapman, Xiong and Cowburn, 2005) and to be able to apply *in situ* magnetic fields in order to study the intermediate processes during magnetization reversal (Hefferman, Chapman and McVitie, 1991; McVitie *et al*., 2003; Yu *et al*., 2002; Yu, Petford-Long and Miyazaki, 2001; Shang, Hogwood, Petford-Long and Anthony, 2001; Yu, Petford-Long and Jakubovics, 1999; Hu, Wang, McCartney and Smith, 2005; Yi *et al*., 2004; Kirk *et al*., 2001; McVitie and Chapman, 1997; Uhlig and Zweck, 2002).

In patterned magnetic media, it was found that the edge roughness, rounding of corners of patterned particles and, in general, the geometric shape does significantly contribute to the magnetic behavior, mostly due to increased shape anisotropies or because irregularities at the perimeter of a particle act either as pinning sites or facilitate the formation of domain walls or vortices (Langridge *et al*., 2006; Yi *et al*., 2002; Crawford *et al*., 2002; Herrmann, McVitie and Chapman, 2000).

The broad interest of industry in micromagnetic properties (mostly of patterned media) stems from the possibilities, which arise for technology and production of new devices. Some of these new devices could be patterned hard disks, magnetic memory devices such as the frequently mentioned MRAM (magnetic random access memory), which would be a nonvolatile, but fast, small and energy-efficient computer memory. Other devices are already in use, either as read heads in hard disks, as so-called spin valves for sensor applications (Lim *et al*., 2002a,b, Lim *et al*., 2004; Marrows *et al*., 2001; Murdoch *et al*., 2000; King, Chapman, Kools and Gillies, 1999; King, Chapman and Kools, 1998; Chapman *et al*., 1998; Petford-Long *et al*., 1998, 1999; de Morais and Petford-Long, 2000; Portier and Petford-Long, 1999, 2000; Portier, Petford-Long, Anthony and Brug, 1998, 1999b; Portier *et al*., 1997a,b, 1998; Kasama *et al*., 2005; Ardhuin *et al*., 2000; Warot, Petford-Long and Anthony, 2003; Shang, Hogwood, Anthony and Petford-Long, 2001; Shang, Petford-Long and Anthony, 2002). These sensors always rely on one magnetic layer to be fixed ('hard magnetic') while another layer ('soft magnetic'), which acts as the sensing layer, is free to align its magnetic moment with an externally applied field. To fix the hard layer, it is usually exchange biased to an antiferromagnet underneath. During switching, local stray fields can deteriorate the fixed layer by creation of domain walls, reducing the desired effect (Rickart *et al*., 2005; Gogol, Chapman, Gillies and Vanhelmont, 2002; Fassbender *et al*., 2002; King, Chapman, Gillies and Kools, 2001; Rijks *et al*., 1997; Choi, Petford-Long and Ward, 2003; Wang, Petford-Long and Kief, 2001; Wang and Petford-Long, 2002; O'Grady *et al*., 2001; Portier *et al*., 2000). This is also relevant for magnetic tunnel junctions (Cardoso *et al*., 2006; Shang, Hogwood, Petford-Long and Anthony, 2001; Portier *et al*., 1998; Portier, Petford-Long, Anthony and Brug, 1999a).

Interesting and rather easily experimentally accessible are magnetic media, which have been patterned by ion irradiation. In this case, the ion bombardment and implantation renders the exposed areas nonmagnetic. Thus it is rather simple to obtain patterned magnetic media which during Lorentz imaging do not suffer from the effects of inner electrostatic potentials, since the magnetic and nonmagnetic areas consist of the same material (McGrouther, Nicholson, Chapman and McVitie, 2005; McGrouther and Chapman, 2005; McGrouther, Chapman and Vanhelmont, 2004; Hyndman *et al*., 2001, 2002; Fassbender *et al*., 2002; Warin *et al*., 2001; Owen and Petford-Long, 2003). For patterned magnetic materials in the μm and sub-μm regime, theoreticians perform micromagnetic calculations both for static and dynamic behavior (http://math.nist.gov/oommf/; http://llgmicro.home.mindspring.com/; Hertel and Kronmüller, 1999; http://www.micromagus.de/) which then may be compared to the behavior of real materials (Kirschner *et al*., 2003; Schrefl, Fidler, Chapman and Kirk, 2001;

Suss, Schrefl, Fidler and Chapman, 1999; Schrefl, Fidler, Kirk and Chapman, 1997a,b, 1999; de Graef *et al*., 2006; Saxena *et al*., 2004; de Graef, Nuhfer and McCartney, 1999). Comparisons have also been made between the results from magnetic force microscopy (MFM) and Lorentz imaging of patterned materials (McVitie *et al*., 2001). Patterned magnetic media considerably smaller than approximately 100 nm are expected to reach the superparamagnetic limit, where thermal excitations are sufficient to temporarily overcome the exchange energy. If this happens, the material will in temporal average appear paramagnetic. Therefore, it is important to be able to study thermal effects in magnetic materials in nanometer dimensions (Wang *et al*., 2002; Portier, Petford-Long, Anthony and Brug, 1999a).

Lots of investigations have also been devoted to multilayered thin films and their magnetic properties. Lorentz microscopy proved here also to be of immediate value, since it was possible to directly observe the magnetic configurations and processes (Chapman *et al*., 1999; Weir *et al*., 1999; Aitchison, Chapman, Jardine and Evetts, 1997; Heyderman, Chapman and Parkin, 1994; Hosomi, Petford-Long and Doole, 1999; Ormston, Petford-Long and Teer, 1999; Zimmermann, Zweck and Hoffmann, 1995a,b; Zweck, Zimmermann and Schuhrke, 1997). Lorentz microscopy is even of use when magnetic thin films with a soft magnetic axis perpendicular to the specimen's plane are of interest (Aitchison *et al*., 2001).

As has been shown in the preceding text, Foucault imaging is – just as DPC and holography – capable to image external stray fields leaking from a specimen (Daykin and Petford-Long, 1995; Doole, Petford-Long and Jakubovics, 1993; te Lintelo, Lodder, McVitie and Chapman, 1994). This has been used to characterize the magnetic configuration which one can find in MFM tips (Ruhrig *et al*., 1996; Zhou, McVitie and Chapman, 1995; te Lintelo, Lodder, McVitie and Chapman, 1994). A similar task was attempted with magnetic read/write heads used in data storage technology by DPC in combination with a tomographic 3D reconstruction of the magnetic fields emerging from the gap region (Ferrier, McVitie and Nicholson, 1990; Petri *et al*., 1996).

Electron holography has successfully been applied to study the magnetic crystals which can be found in magnetotactic bacteria (de Graef and Zhu, 2001; Dunin-Borkowski *et al*., 1998).

Extensive research was also conducted on the effect of crystallography and morphology on the magnetic properties of materials (Marrows *et al*., 1999; Thompson, Gutfleisch, Chapman and Harris, 1998, 1999; Thompson *et al*., 1998; Chapman *et al*., 1995; Wong, Chapman, McVitie and Hefferman, 1992; Youhui, Shindo and Petford-Long, 2003; Jackson *et al*., 2000; Kim *et al*., 1994; Kim, Petford-Long and Jakubovics, 1994; Petford-Long *et al*., 1993; Portier *et al*., 1999), which is also of enormous importance in the case of hard magnets (Craig *et al*., 2006)

Certainly it is not surprising that a number of publications deal with the various imaging techniques and their development and interpretation. An overview of the frequently used imaging modes is given in Chapman and Scheinfein (1999), Chapman (1984) and Chapman, Waddell, Batson and Ferrier (1979). Coherent imaging is treated in McVitie and Chapman (1995), Johnston and Chapman (1995), McVitie *et al*. (1995), Chapman, Gillies and Freitas (1996), Chapman, Johnston and Heyderman (1994) and Chapman *et al*. (1977), DPC in Chapman, Ploessl and Donnet (1992), Donnet, Chapman, van Kesteren and Zeper (1992), Zweck, Chapman, McVitie and Hoffmann (1992), Chapman, McVitie and Hefferman (1991), Chapman, McFadyen and McVitie (1990), McVitie and Chapman (1990), Chapman and Morrison (1983), McCartney, Kruit, Buist and Scheinfein (1996) and Ferrier, Morrison and Chapman (1984) .

Further developments imply STEM holography (Mankos *et al*., 1995) of magnetic materials and Fresnel STEM (Chapman, Waddell, Batson and Ferrier, 1979). A new interpretation of the micromagnetic features in terms of amperian currents was given by McVitie and White (2004).

7 FUTURE TRENDS

It is certainly difficult to predict future developments in Lorentz microscopy. Nevertheless, we will try to give an idea of what seems possible in near future in the field of magnetic imaging.

One rather obvious field of research, which already became started, deals with ferromagnetic semiconductors. These materials in general consist of a conventional semiconductor material, where a certain species of atoms has been partially replaced by atoms with a non-vanishing magnetic moment, as for example in (Ga,Mn)As. At present, the Curie temperature is still well below room temperature, and the average magnetic moment per unit volume is rather low. This calls for magnetic imaging techniques which utilize low temperature cooling holders, to go below T_C and lead to an optimum magnetic ordering, yielding a higher detectable induction.

Another possibility for future applications will be dynamic imaging of magnetic Eigen modes. Using stroboscopic illumination and/or a gateable camera will allow the experimentator to repeatedly excite the magnetic modes and then – similar as it is done in magneto-optic pump-probe experiments – record an image at a given instant of time after a defined delay. Early experiments have been done by Bostanjoglo (Bostanjoglo and Rosin, 1981a,b). The techniques developed by him have been recently extended and modernized for biological research (Meurig, 2005; Baum

and Zewail, 2006). Thus, time resolution in the regime of nanoseconds seems to be at reach for magnetic imaging.

The current development of lens correctors for high resolution electron microscopes and their commercial availability leads to the question, what magnetic imaging might profit from them. Especially for STEM imaging modes such as DPC imaging it seems reasonable to expect smaller probe sizes at even higher probe current and in turn higher resolution when a corrected condenser lens is used to focus the beam onto the specimen.

In recent publications (Hébért and Schattschneider, 2003; Schattschneider *et al*., 2004, 2006) it was shown that it is possible to detect a dichroic behavior of magnetic materials with electrons which can be considered to be the electron analog on for X-ray magnetic circular dichroism (XMCD) (Schneider, 1996; Ebert, 1996). This effect is presently investigated and may in the future lead to a new, element specific technique to image the magnetic moment distribution within a specimen. In analogy to XMCD, even a separation of orbital and spin magnetic moments seems possible, in principle.

Finally, as electron microscopic tomography has become a commercially available tool it may make sense to think about magnetic tomography in more detail, where one would be able to reconstruct the three-dimensional magnetic vector fields inside and around magnetic specimens of specific shapes. Pioneering work on this topic has been done in the past (Ferrier, Liu, Martin and Arnoldussen, 1995; Petri *et al*., 1996) and is continued nowadays (Paganin, Lade and Morgan, 2005; Stolojan, Dunin-Borkowski, Weyland and Midgley, 2001). With the availability of better and faster program code as well as much faster computers this seems to be a feasible task.

ACKNOWLEDGMENTS

We are thankful to all persons, who contributed to this publication by providing images, especially Dipl. Phys. St. Otto, Dr. M. Heumann, Dr. M. Schneider and Dr. Th. Haug. The preparation of most of the samples presented here would not been possible without the nanofabrication laboratory of Prof. Dieter Weiss. Further we would like to thank Dr. A. Kohn, whose help and corrections were necessary to present the novel technique of TIE based phase reconstruction in an appealing way.

Electron Holography of Ferromagnetic Materials

Martha R. McCartney and David J. Smith
Arizona State University, Tempe, AZ, USA

1 INTRODUCTION

The transmission electron microscope (TEM) has long been considered to be an indispensable tool for characterizing microstructure. Applications of the TEM span across many scientific disciplines and many different types of material. However, information about magnetic induction cannot easily be obtained. Under normal operating conditions, the magnetic field of the objective lens used for imaging is in the order of 1.5–2.0 T, which would fully saturate most magnetic materials in the vertical direction. Studies of inherent remanent states or magnetization reversal behavior are automatically precluded. The microscopist must either remove the magnetic sample from the normal imaging plane out of the strong lens field or switch off the objective lens current and rely on an auxiliary lens for imaging purposes. The latter approach is nowadays most commonly used for TEM examination of magnetic materials.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

Several TEM techniques suitable for studying magnetic materials have been developed over the years. The well-known Lorentz microscopy takes advantage of the sideways deflection of the incident electrons by the magnetic field within the sample (Chapman, 1984; McVitie and Chapman, 1997). For the in-focus imaging condition, there is no distinct magnetic contrast, but black and white lines become visible, corresponding to the positions of magnetic domain walls, when the lens is defocused. Drawbacks of Lorentz microscopy are that long-range magnetic fields are difficult to visualize, the resolution is somewhat limited except for special variants that are available with a scanning microscope, and absolute quantification of field strengths can be difficult to achieve. Nevertheless, a major attraction of Lorentz microscopy is that domain-wall nucleation, as well as motion, can be observed in real time during magnetization reversal.

Off-axis electron holography is an alternative electron microscopy technique that has proved ideal for studying the magnetic state and response of ferromagnetic materials at length scales approaching the nanometer level (Lichte, 1986, 1991; Tonomura, 1993). By measuring the phase change of the electron wave that has traveled through the sample relative to an unperturbed reference wave, a quantitative measure of the local magnetic field can be obtained. Important micromagnetic properties such as coercivity, magnetization reversal behavior, and remanent states can be extracted following hologram analysis.

There are at least 20 different forms of electron holography (Cowley, 1992), but the off-axis or sideband variant is almost invariably used because it is relatively straightforward to implement in modern TEMs. This particular technique relies on the interference between two coherent electron waves, as illustrated in Figure 1. The field emission electron gun (FEG) provides the essential beam coherence, and the electrostatic biprism, normally located in the selected-area

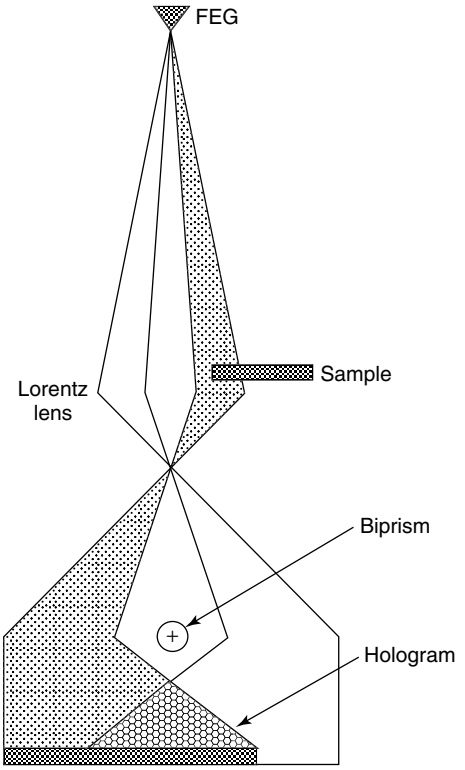

Figure 1. Schematic ray diagram illustrating experimental geometry used for off-axis electron holography in the TEM. Essential components are the field emission electron gun (FEG) used to provide coherent illumination, and the electrostatic biprism, which causes overlap of object and (vacuum) reference waves. Lorentz mini-lens enables field-free observation of specimen at moderate magnification (∼70 000×) and resolution (∼1.4 nm).

aperture plane, is used to overlap the wave scattered by the object with the reference vacuum wave. The resulting interference pattern is then processed in order to retrieve the electron phase, in turn allowing access to the desired information about the magnetic field of the sample. In the next section, the basic theory and experimental practice of off-axis electron holography are outlined. Representative examples that illustrate applications of the technique to magnetic materials, including hard magnets, thin films, and nanostructures, are then described. Finally, future prospects are briefly discussed.

2 OFF-AXIS ELECTRON HOLOGRAPHY

The technique of off-axis electron holography has attracted much recent attention because it enables magnetic materials to be studied at high spatial resolution and sensitivity. One attractive feature relative to other magnetic imaging techniques is that unwanted effects arising from local variations in sample thickness and composition are normally removed relatively easily so that much smaller regions of the sample can be analyzed. The technique can in principle achieve a spatial resolution of better than 1 nm for magnetic materials although there are practical limitations associated primarily with the signal-to-noise ratio available during hologram recording and processing (Harscher and Lichte, 1996). Moreover, the specimen thickness must be restricted to a maximum of perhaps 400 nm, and preferably considerably less, so that elastic and inelastic scattering effects do not adversely affect the hologram quality.

2.1 Basic theory

Off-axis electron holography relies on having a high-brightness electron source to emit a highly coherent beam of electrons onto the sample region of interest. The phase across the electron wave front emerging from the sample will vary according to the local composition and density (i.e., mean inner potential, MIP) in addition to the magnetic field component. Making an assumption of negligible dynamical diffraction, which would impact the phase for crystalline materials that are close to a strongly diffracting condition (Gajdardziska-Josifovska *et al*., 1993), the relative phase change of the object (or scattered) wave compared with the reference (or vacuum) wave can be expressed as

$$\phi(x) = C_E \int V(x,z)\,\mathrm{d}z - \frac{e}{\hbar}\iint B_\perp(x,z)\,\mathrm{d}x\,\mathrm{d}z \qquad (1)$$

where z represents the incident beam direction, x is a direction in the sample plane, V is the MIP, and $B_\perp$ is the magnetic induction component that is perpendicular to both x and z (Reimer, 1989). The constant C_E is given by the expression

$$C_E = \frac{2\pi}{\lambda E}\frac{E+E_0}{E+2E_0} \qquad (2)$$

where λ is the electron wavelength, and E and E_0 are the kinetic and rest mass energies, respectively, of the incident electron.

When neither V nor B vary along the beam direction within the sample thickness t, and assuming that the electric field as well as magnetic fringing fields outside the sample can be neglected, this expression for the phase can be simplified as

$$\phi(x) = C_E V(x)t(x) - \frac{e}{\hbar}\int B_\perp(x)t(x)\,\mathrm{d}x \qquad (3)$$

This latter expression means that the strength of the magnetic signal, as given by the second term, depends on both the thickness and the lateral width of the particular magnetic material(s) present.

Differentiation with respect to x then leads to

$$\frac{\mathrm{d}\phi(x)}{\mathrm{d}x} = C_E \frac{\mathrm{d}}{\mathrm{d}x}\{V(x)t(x)\} - \frac{e}{\hbar}B_{\perp}(x)t(x) \tag{4}$$

The first term in this expression will be zero in the event that the sample has uniform thickness and composition. Thus, the gradient of the phase is directly interpretable in terms of the in-plane magnetic induction. Equiphase contours are easily added to a phase image, and their relative separation provides a convenient way to 'visualize' any local variations in field strength. Indeed, the in-plane field can be quantified on an absolute basis. Extra complications will arise when the sample thickness and/or composition are not uniform: as described later, further processing is necessary before quantitative information can be reliably extracted.

When the object and reference waves are overlapped by the electrostatic biprism to produce an interference pattern or hologram, then the intensity can be written in the form

$$I(x, y) = |\Psi_1(x, y)|^2 + |\Psi_2(x, y)|^2 + |\Psi_1(x, y)|\,|\Psi_2(x, y)| \times (e^{i(\phi_1-\phi_2)} + e^{-i(\phi_1-\phi_2)}) \tag{5}$$

or it can be rewritten in the simpler form

$$I(x, y) = A_1^2 + A_2^2 + 2A_1A_2\cos(\Delta\phi) \tag{6}$$

where Ψ is the electron wave function, $\Delta\phi$ is the relative electron phase change, and the subscripts refer to the reference and object waves. This expression can be interpreted as the normal TEM image in addition to a superimposed cosine function, which represents the interference fringes of the hologram. Shifts in the positions of these interference fringes are caused by local changes in the electrostatic and/or magnetic fields of the sample.

For better comprehension of this technique, the steps involved in hologram recording and processing are illustrated in Figure 2. An electron hologram from part of a chain of magnetic nanocrystals from a magnetotactic bacterial cell, supported on a holey carbon film, is shown in Figure 2(a). Note how the spacings and directions of the fringes change as they cross the crystallites. The hologram is then Fourier transformed to produce a two-dimensional frequency map, as shown in Figure 2(b). The strong side spots correspond to the basic cosine interference, and their separation depends primarily on the biprism voltage. The variations of intensity that are visible in the vicinity of these spots originate from the phase shifts caused by the sample. These sidebands contain the desired phase information about the image wave, which cannot be obtained from the central 'autocorrelation' function. Reconstruction of the complex image wave then utilizes one of these sidebands.

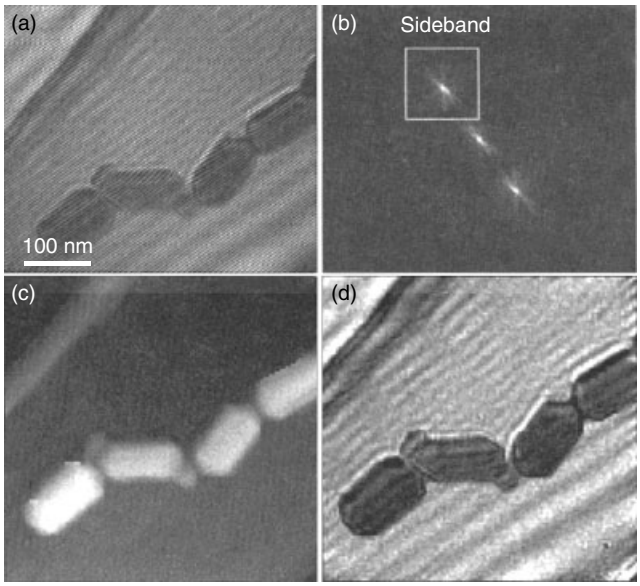

Figure 2. (a) Off-axis electron hologram showing part of a chain of magnetite nanocrystals; (b) Fourier transform of (a) indicating sideband used in phase reconstruction; (c) reconstructed phase image; (d) reconstructed amplitude image.

The actual reconstruction process involves extraction and recentering of one of the sidebands, followed by calculation of its inverse Fourier transform to retrieve the complex image wave function. The phase and amplitude of the complex image are then given by

$$\phi = \arctan(i/r)$$
$$A = \mathrm{sqrt}(r^2 + i^2) \tag{7}$$

where 'r' and 'i' refer to the real and imaginary parts of the wave function, respectively.

This reconstruction process was applied to the hologram shown in Figure 2(a) and the corresponding phase and amplitude, respectively, are shown in Figure 2(c) and (d). Note that the phase is normally calculated modulo 2π so that phase shifts which exceed this amount will cause 2π phase discontinuities at positions in the phase image that are unlikely to be related in any meaningful way to specific specimen features. Thus, the phase should be carefully unwrapped to make sure that the image features are interpreted correctly. In this regard, it is helpful when the hologram is recorded digitally, since this recording mode facilitates the subsequent reconstruction process.

2.2 Experimental geometry

The geometry for carrying out off-axis electron holography studies in the electron microscope has been illustrated

schematically in Figure 1. The FEG provides the defocused illumination onto the sample, which is located in such a way that it covers roughly half the field of view. The electrostatic biprism is used to achieve overlap between the object (scattered) wave and the vacuum (reference) wave. The biprism usually consists of a thin (<1 μm) metallic wire or quartz fiber coated with gold or platinum. Application of an electric potential from a dc power supply or battery results in formation of the interference pattern or hologram. Typical biprism voltages for the medium-resolution studies considered here are between 50 and 200 V. Higher voltages are, however, necessary in order to achieve the subangstrom fringe spacings that are required for high-resolution applications (Orchowski, Rau and Lichte, 1995). Finally, note that a rotatable biprism is highly useful in practice since the direction of the interference fringes should often be aligned preferentially with particular features of the sample.

The usual location for the biprism is in the plane of the selected-area aperture holder, often replacing one of the selected-area apertures. For this geometry, the first image plane must be shifted electron-optically to slightly below the selected-area plane by increasing the excitation of the diffraction or intermediate lens. The spacing of the interference fringes and the amount of fringe overlap will be determined by the voltage on the biprism as well as by the specific lens-specimen geometry (Smith and McCartney, 1999).

Several geometries have been used by electron microscopists to ensure that a magnetic sample is located in a field-free region for observation. By simply turning off the normal objective lens, a low-magnification image and a large field of view can be obtained. The image resolution is relatively poor although a postcolumn image filter, if available, could be used to obtain additional image magnification. Another alternative is to use a weak imaging lens below the normal objective lens. For example, the Philips CM200 FEG-TEM has a special mini-lens, which permits an overall image magnification of up to 70 000×, although the reconstructed phase image has a spatial resolution that is limited by the lens aberrations to about 1.4 nm (McCartney, Smith, Farrow and Marks, 1997). Many of the holography results described later originated from a microscope of this type. Yet another approach is to use a modified specimen holder, whereby the sample is located just outside the field of the immersion objective lens. A far-out-of-focus image is obtained, so that extra phase shifts caused by the lens defocus must be corrected (Mankos, Higgs, Scheinfein and Cowley, 1995). This geometry, unfortunately, is not available with most commercial instruments.

The attachment of a slow-scan charge-coupled-device (CCD) camera at the base of the lens column permits digital recording of electron holograms (de Ruijter, 1995), greatly expediting the reconstruction process (de Ruijter and Weiss, 1993; Smith and McCartney, 1999). The CCD camera is a sensitive electron detector, with linear output versus input over a wide dynamic range. Thus, the nonlinear optical density of the conventional photographic plate is no longer a problem. Subsequent computer processing is also facilitated by the digital hologram acquisition (de Ruijter and Weiss, 1993). Holograms recorded using a CCD camera enable phase shifts to be measured with high accuracy and sensitivity once due correction for phase distortions has been made using the reference hologram.

2.3 Practical factors

The spatial coherence of the incident electron beam is crucial for practical electron holography. It is necessary to minimize the beam convergence angle since poor interference-fringe contrast will otherwise result and weak phase detail will then be lost from the reconstructed hologram. It has become common in off-axis electron holography to use highly elliptical illumination. The condenser lens stigmator settings are adjusted to achieve high illumination aspect ratios: 100:1 is not uncommon (Smith and McCartney, 1999). Note also that the major axis of the elliptical illumination patch must be aligned so that it is perpendicular to the biprism wire direction. The beam coherence, and hence the fringe contrast, will then be maximized (Völkl and Lehmann, 1999).

The reconstruction process is impacted by several additional factors. Smaller fringe spacings are needed for small object dimensions and/or wider regions of fringe overlap, and this in turn necessitates higher biprism voltages. However, the fringe contrast usually drops when the biprism voltage is increased. Moreover, the magnification must be increased to ensure sufficient sampling of the finely spaced interference fringes. Four recording pixels per hologram fringe is commonly considered as the minimum acceptable sampling (Joy *et al.*, 1993), but even greater sampling is recommended when sensitive phase measurements are being made (Smith and McCartney, 1999). Lens aberrations do not usually limit the spatial resolution of the final reconstructed phase image for magnetic materials, which depends instead mainly on the effective size of the sideband selected during hologram reconstruction. The resolution will be limited by the available signal strength and the required phase sensitivity (i.e., the signal-to-noise ratio in the phase image). Phase sensitivities of perhaps $2\pi/100$ can be achieved routinely during holographic studies (de Ruijter and Weiss, 1993), making it possible to detect details in thin magnetic films on a scale of about 5 nm (Harscher and Lichte, 1996). The resolution of smaller features normally requires longer acquisition times or stronger magnetic induction within the sample.

It is usual practice to record reference holograms with the sample removed from the field of view so that any artifacts associated with local imperfections or irregularities of the imaging and recording system can be excluded. Otherwise, phase distortions occur that will limit the accuracy and integrity of the hologram reconstruction process. Finally, note that accurate registration of sample and reference holograms is conveniently achieved when digital recording is used, which is unlike the situation for conventional photographic recording.

2.4 Magnetization reversal and phase contributions

Under normal conditions for off-axis electron holography, the magnetic sample must be located in a field-free environment, which enables its inherent magnetization, or 'remanent state', to be determined. Knowledge of magnetization reversal mechanisms is, however, important for many practical applications. One straightforward way for these processes to be studied via electron holography is to slightly excite the current in the objective lens coil, and then in-plane magnetic fields, as determined by prior calibration, can be applied by tilting the sample by fixed amounts (Dunin-Borkowski *et al*., 2000). Thus, the magnetization reversal behavior can be fully documented over an entire hysteresis cycle by recording holograms throughout the tilting process.

An additional benefit of carrying out *in situ* magnetization reversal is that the MIP and magnetic contributions to the phase, as described in equations (3) and (4), can be conveniently separated. Thus, pairs of holograms that differ only in the magnetization direction during recording can be added to give the MIP term, while subtraction yields the magnetic term. The MIP term can then be subtracted from all of the other phase images recorded during the cycle to retrieve the magnetic signal. An alternative approach, but not really a practical option in many cases, would be to turn the sample upside down, thereby changing the sign of the magnetic contribution. This separation of phase contributions also means that the magnetic fields can then be quantified on an absolute basis. For example, phase contours can be easily added to the reconstructed phase image, where phase differences of 2π correspond to the quantity $(h/e) = 4 \times 10^{-15}$ Wb.

3 APPLICATIONS TO MAGNETIC MATERIALS

Electron holography was originally proposed by (Gabor, 1949) as a means of correcting electron microscope lens aberrations. This goal was not realized for many years due to various factors – especially the poor coherence of the electron sources available then. Using FEG electron sources, conventional microscope resolution limits were finally surpassed for electron holography with both optical reconstruction methods (Tonomura, Matsuda and Endo, 1979) and digital reconstruction (e.g., Orchowski, Rau and Lichte, 1995; Rau and Lichte, 1999). Off-axis electron holography has since been successfully used in a wide variety of applications. The examination of ferroelectric and electrostatic fields has been attracting increasing attention in recent years. However, such topics are beyond the scope of this review, and the interested reader is referred elsewhere to a recent comprehensive review for further details (Dunin-Borkowski, McCartney and Smith, 2004a).

3.1 Early studies

Historically, the early studies of magnetic materials using electron holography were limited by poor spatial resolution (considerably worse than 10 nm), caused mainly by the need to locate the sample in a region of very low magnetic field. Imaging was restricted to the diffraction/projector system of lenses below the sample with the strong objective lens switched off. The total magnification was only in the order of a few thousand times, and reconstruction of the hologram was done optically because photographic film had been used for recording the holograms. Notable results included confirmation of the Aharonov–Bohm effect in superconducting Nb at low temperature (Tonomura *et al*., 1986) and studies of quantized vortex 'lattices' in a superconducting Nb thin film (Bonevich *et al*., 1993). Another interesting example involved examination of a thin magnetized Co film, used for high-density recording media applications: in this particular study, fringing fields were clearly visualized leaking out from the edge of the thin film (Osakabe *et al*., 1983).

3.2 Hard magnets and magnetic domains

Permanent magnets with large remanence and high coercivity have many practical applications so that any information about magnetic microstructure that can be provided by electron holography should be highly useful. Ternary alloys based on Nd–Fe–B (McCartney and Zhu, 1998a; Park and Shindo, 2002) and related nanocomposite materials (Park, Shindo, Kanekiyo and Hirosawa, 2004) have received considerable recent attention. Figure 3 shows some results from a study of magnetic domain structure in sintered $Nd_2Fe_{14}B$ (McCartney and Zhu, 1998b). A pair of overfocus and underfocus Lorentz images are shown in Figure 3(a) and (b): note the contrast

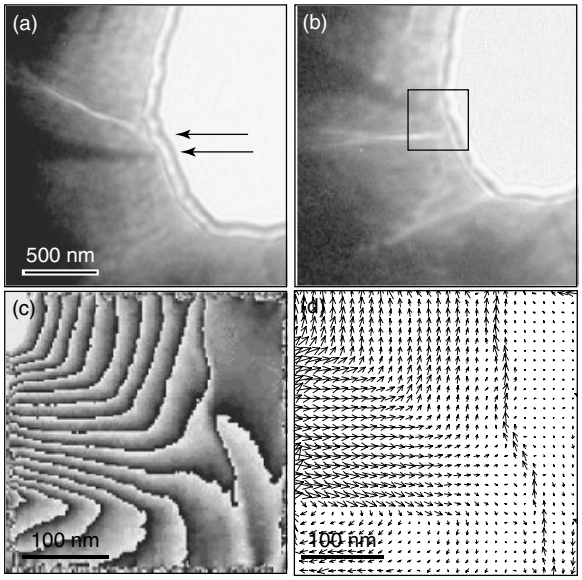

Figure 3. (a, b) Overfocus and underfocus Lorentz micrographs showing domain walls (arrows in a) in sample of $Nd_2Fe_{14}B$; (c) reconstructed phase image from region outlined in (b), contoured at 0.5π radian intervals; (d) induction map derived from phase gradients showing 90° and 180° domain walls. (Reproduced from McCartney & Zhu 1998, with permission from the American Institute of Physics. © 1998.)

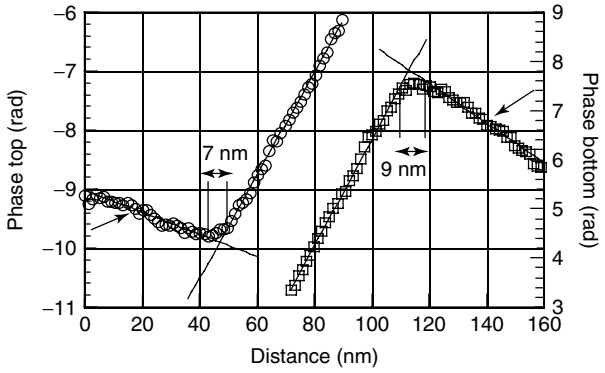

Figure 4. Profile of phase across 90° and 180° domain walls in $Nd_2Fe_{14}B$. Maximum wall widths of 6.7 and 9.2 nm, respectively. (Reproduced from McCartney & Zhu 1998, with permission from the American Institute of Physics. © 1998.)

inversion at the domain walls (arrows). The contoured phase image in Figure 3(c) was reconstructed from an off-axis electron hologram of the region indicated in Figure 3(b). Those regions with equispaced phase contours indicate uniform magnetization giving rise to a constant phase plane, whereas the ridges and valleys correspond to the domain-wall positions visible in the Lorentz images. Phase gradient maps are easily calculated, and by combining two perpendicular gradient images it is possible to produce a vector map, which is a direct image of the magnetic domain structure of the sample. The vector map, shown in Figure 3(d), is divided into $10 \times 10\,\text{nm}^2$ squares. Three distinct domains are visible, with the magnetic induction in the top and middle domains oriented at approximately 90° and oriented at roughly 180° in the middle and lower domains. Moreover, by measuring the distance over which the slope of the phase abruptly changes, estimates of the domain-wall width can be extracted. Figure 4 shows corresponding phase profiles from the 90° and 180° domain walls of Figure 3, and measurements indicate maximum wall widths of 6.7 ± 1.4 and 9.2 ± 1.4 nm, respectively. Finally, it is interesting that, based on estimates for the foil thickness derived from the mean free path for inelastic electron scattering (McCartney and Gajdardziska-Josifovska, 1994), the vector lengths can be used to calculate the corresponding magnetizations of $4\pi M_s = B = 0.8$, 1.2, and 0.5 T for the top, middle, and bottom domains, respectively. The differences may come from undetermined fringing fields immediately above and below the sample surface, or because the technique is insensitive to any out-of-plane components.

The rearrangement of magnetic domains in ferromagnetic shape memory alloys (FMSAs) is an important aspect of developing practical applications. Alloys with stoichiometry close to Ni_2MnGa are of particular interest because of the large shape deformation (~6%) induced by an applied field (Ullakko *et al*., 1996), which has been attributed to rearrangement of twin-related plates of the martensitic material. Electron holography and Lorentz microscopy have been used in recent studies of magnetic domain structure of FMSA Ni_2MnGa, both in thin-film form prepared by sputtering (Murakami *et al*., 2003, 2004), and in spherical particles prepared by spark erosion and annealed to achieve the martensitic phase (Solomon *et al*., 2005). The results shown in Figure 5 are taken from this latter study. The stripes visible in Figure 5(a) correspond to the twin-related martensitic variants, and out-of-focus Lorentz microscopy showed that the twin boundaries corresponded to the positions of the magnetic domain walls. Figure 5(b) shows the reconstructed phase image after electron holography from the area indicated in Figure 5(a), while Figure 5(c) shows the x-phase gradient which is proportional to the in-plane magnetization component. The vector map derived from the phase gradient images is shown in Figure 5(d). Careful measurement reveals that the in-plane projections of the magnetization across the domains are oriented at roughly 60°, corresponding closely to the value expected when the c axes of the twin-related variants are projected onto the sample plane. Finally, Figure 5(e) shows the line profile across the domain indicated in Figure 5(b), and the domain-wall width is measured to be about 17 nm (Solomon *et al*., 2005), consistent with theoretical estimates. These studies of magnetic domains in giant

Figure 5. magnetorestrictive materials indicate that electron holography should play a valuable role toward developing a better understanding of other FMSA materials in future studies.

3.3 Thin films

An important consideration with hard magnets, especially when thinned down to an electron-transparent foil from the bulk form of the material, is the likelihood that magnetic fringing fields will emerge from the top and bottom surfaces. Off-axis electron holography (and Lorentz microscopy) is not sensitive to these out-of-plane field components so that the true three-dimensional nature of the magnetic vector field in and surrounding a magnetic sample may not always be fully determined. Moreover, the magnetic properties could be altered by the actual thinning process. Such issues are obviously less troublesome for the nanostructures that are the topic of the following section. For several reasons, continuous films can be challenging materials for examination by off-axis electron holography. The presence of a hole or edge in the field of view, or at least access to a continuous uniform background, is essential for provision of the requisite vacuum or reference wave. Removal of the substrate, or at least perforation by back-side ion-milling, is likely to cause stress and/or local bending in the film, especially around the edges, which could possibly mask the intrinsic magnetic structure. Our experience is that rapid thickness variations around edges and small holes can make holograms from such areas difficult, or even impossible in some cases, to interpret reliably.

Thin films of ordered Co-Pt and Fe-Pt alloys have the $L1_0$ crystal structure, leading to potentially useful applications for magnetic recording because of the pronounced magnetocrystalline anisotropy. Depending on the substrate used for thin film deposition, the tetragonal c axis will be primarily either in plane or out of plane. Figure 6(a) shows the hologram for a cross-sectional sample of an epitaxial $Fe_{0.5}Pt_{0.5}$ ordered alloy film (thickness ~100 nm) deposited onto an MgO(110) substrate (McCartney, Smith, Farrow and Marks, 1997). The (001) easy axis of the ordered alloy is parallel to the film normal for this growth direction. Magnetic fringing fields are visible outside the material in the reconstructed phase image shown in Figure 6(b), and corresponding induction maps confirmed that adjacent domains within the Fe-Pt film had the expected opposite polarity. Note here that Lorentz imaging was not particularly useful in these studies because of the coarse Fresnel fringes that occurred at the large defocus values that were necessary to achieve appreciable magnetic contrast.

In this application of electron holography to Fe–Pt ordered alloys described in the previous paragraph, no attempt was made, nor was it felt to be necessary, to quantify the strength or extent of the fields within or emerging from the sample. Such a task is quite challenging for multilayered thin films in cross-sectional geometry because of the often rapid and unknown variations in thickness and contrast, which can easily overwhelm any changes in the magnetic signal. Careful consideration of equations (3) and (4) shows, however, that by combining phase profiles and phase gradients for holograms with reversed magnetization directions, it is possible to remove the specimen thickness and composition profiles and thus finally determine the magnetization with some reasonable level of confidence and respectable accuracy (Dunin-Borkowski, McCartney, Smith and Parkin, 1998a). Conversely, failure to properly account for thickness and

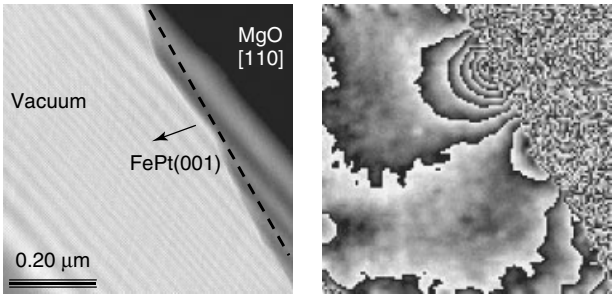

Figure 6. (a) Off-axis electron hologram obtained from epitaxial Fe-Pt/MgO with (001) easy axis parallel to film normal; (b) contoured phase image showing magnetic flux extending into vacuum. (Reproduced from McCartney *et al*., 1997, with permission from the American Institute of Physics. © 1997.)

composition variations will most likely cause erroneous interpretation when studying complex layered structures such as magnetic tunnel junctions in cross section.

3.4 Nanostructures

Interest in magnetic nanostructures is increasing in recent times both for scientific reasons and because of possible applications for magnetic recording. However, a micromagnetic structure becomes increasingly difficult if not impossible to characterize by most imaging techniques as lateral dimensions are reduced. Another concern is that shape irregularities in small magnetic elements are likely to play a more prominent role during magnetization reversal. Domain walls are obviously less likely because of energy considerations to be found in the remanent state of magnetic nanostructures. However, extensive simulations may still be required before quantitative analysis of magnetization can be achieved, especially since interactions between closely spaced adjacent particles can sometimes lead to interesting and unexpected results.

Off-axis electron holography represents a powerful method for probing the magnetic response of individual nanostructures, especially for elements having one or more dimensions on the scale of 100 nm or below. Analysis by holography does, however, become more challenging because the corresponding magnetic phase changes that are produced will decrease with the element width, which is unlike the MIP term that has no such length dependence. Close attention must be given to experimental parameters such as the total signal acquired before reconstruction to compensate for the loss of interference-fringe contrast which, as we noted earlier, decreases with smaller fringe spacing. Some local smoothing of noise fluctuations can be helpful in clarifying any significant features of the reconstructed phase images.

3.4.1 Spheres, rings, and chains

Spherical nanoparticles represent an interesting model system but they are challenging to study because of rapid variations in the projected thickness. Analytical expressions have been derived for the magnetic and electrostatic phase expected for an electron wave passing through uniformly magnetized spherical particles (de Graef, Nuhfer and McCartney, 1999). Figure 7(a) shows an electron hologram from a chain of carbon-coated Co nanospheres and the reconstructed phase image is shown in Figure 7(b). The corresponding phase profile across the center of a 33-nm-diameter particle is shown in Figure 7(c), together with a least-squares-fitted profile generated by varying the particle diameter, the saturation induction, and the MIP. The fitted values of 1.7 T and 26 V for the latter two parameters are in good agreement with expected results, thus establishing confidence that quantitative measurements can be achieved even at the nanoscale using electron holography.

Chains of spherical Fe–Ni nanoparticles have received further attention (Hÿtch *et al*., 2003; Dunin-Borkowski *et al*., 2004b). Perhaps the most interesting result emerging from this study was confirmation that magnetic vortices rather than single domains could be supported in particles above a certain critical size for vortex formation. Moreover, as shown by the examples reproduced in Figure 8, vortex axes could be either parallel or perpendicular to the chain axis. It was also found that flux channeling and vortex formation depended on the Fe–Ni alloy concentration, as well as being strongly influenced by the size and proximity of other particles in the chain. Finally, it is worth noting here that careful comparisons with the results of micromagnetic simulations were essential to a full interpretation and explanation of the experimental contours in these studies.

The flux closure associated with vortex formation is an interesting and potentially useful property for high-density information storage, and several examples will be mentioned in Section 3.4.3. A recent study showed that stable flux closure states could also be achieved at room temperature with self-assembled Co rings formed by nanoparticles with sizes in the range of 27 ± 4 nm and ring diameters of $\sim$100 nm (Tripp, Dunin-Borkowski and Wei, 2003).

3.4.2 Rods and wires

Magnetic rods and nanowires should have a unidirectional remanent state, and their well-defined geometry enables magnetostatic effects to be easily separated from thickness and electrostatic effects. Early holography studies of Co and Ni nanowires indicated that wires of small radius (20–35 nm) behaved like tiny magnetic dipoles with uniform magnetization close to the expected saturation value (Beeli, Doudin,

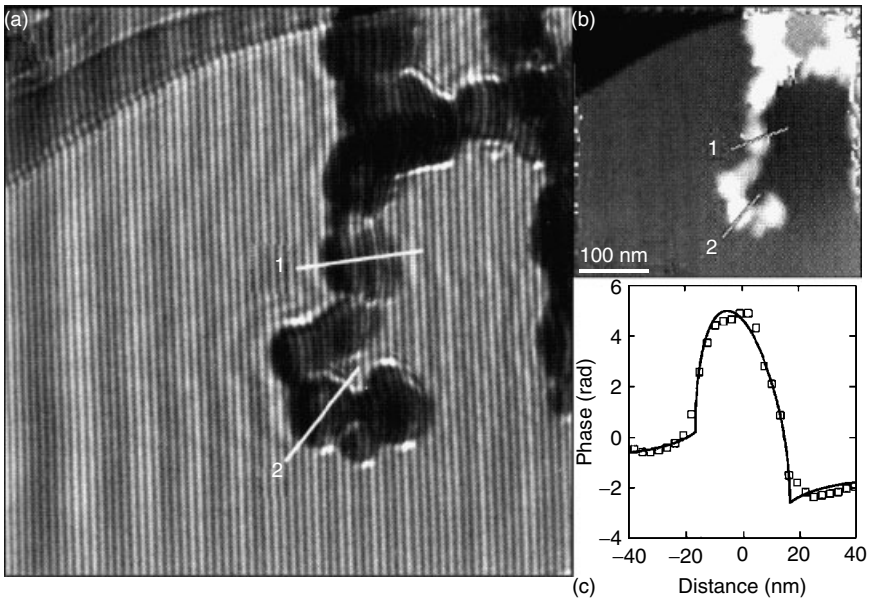

Figure 7. (a) Electron hologram showing chain of Co nanospheres supported over a hole in carbon support film; (b) reconstructed phase image after phase unwrapping; (c) experimental and fitted phase profile for linear trace across spherical Co nanoparticle (de Graef *et al*., 1999). (Reproduced from Hÿtch *et al*., 2003, with permission from the American Physical Society. © 2003.)

Ansermet and Stadelmann, 1996). In contrast, wires with larger radii showed increasing amounts of nonuniform magnetization, and multidomain wires were sometimes observed. Later studies have focused on magnetic nanowires of smaller diameter. For example, Fe-Pt nanorods with diameters of ∼26 nm were grown *in situ* by electron-beam-induced deposition and developed randomly oriented crystallites of the ordered $L1_0$ magnetic phase after annealing at 600 °C (Che *et al*., 2005). Single crystal Co nanowires, with diameters as small as 4 nm, were shown to be fully magnetized, assuming bulk values for Co MIP and magnetization (Snoeck *et al*., 2003). It was also reported in this last study that the phase contrast contours along the wire axes were not always straight, but further work is needed to fully understand this result.

3.4.3 Patterned shapes

Nanostructured shapes enable micromagnetic behavior, especially during hysteresis cycling, to be conveniently investigated in a controlled fashion, both as a function of particle geometry as well as proximity to other particles. Elements with a wide range of shapes, sizes, and separations have been prepared by electron-beam evaporation onto self-supporting 55-nm-thick silicon nitride membranes using standard electron-beam lithography and lift-off processes (Dunin-Borkowski, McCartney, Kardynal and Smith, 1998b). Figure 9 is a low-magnification bright-field image showing part of a typical array of such patterned elements. Some loss of interference-fringe contrast occurs because of the underlying silicon nitride support, but off-axis electron holography can still be successfully carried out using the

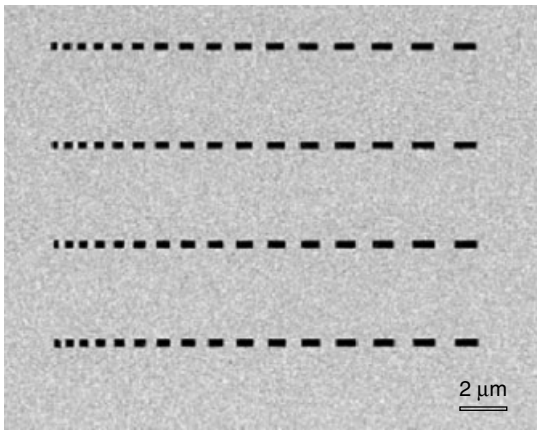

Figure 9. Low-magnification, bright-field image showing typical array of lithographically patterned magnetic elements supported on 55-nm-thick silicon nitride membrane.

Lorentz mini-lens configuration described earlier. Samples are tilted *in situ* within the microscope using the normal objective lens slightly excited to obtain the desired in-plane field. The hysteresis behavior and remanent states of individual elements can then be determined. The featureless silicon nitride regions nearby are used for acquisition of the reference holograms that are needed to remove phase distortions associated with the imaging/recording system.

Our initial studies involved rectangular 30-nm-thick Co elements (Dunin-Borkowski, McCartney, Kardynal and Smith, 1998b), where removal of the MIP phase contribution was accomplished by the aforementioned method of fully reversing the magnetization and then halving the difference between the corresponding pair of holograms. Micromagnetic simulations based on the Landau–Lifshitz–Gilbert equations were also carried out (Dunin-Borkowski *et al*., 1999). Reasonable agreement with the experimental results was obtained, but some important differences were also revealed. For example, simulations showed that the strength and direction of the applied field had a marked impact on the observed domain structure. It was also shown that the magnetization behavior of the adjacent Co elements was affected by their close proximity and interaction, with fringing fields extending between the elements when fully magnetized. This result thus emphasized the need to consider intercell coupling when designing high-density storage devices. The characteristic flux closure associated with a vortex state was invariably seen during hysteresis cycling, while other new and unexpected domain configurations were sometimes observed during investigation of remanent states from different stages of the magnetization cycle (Dunin-Borkowski *et al*., 2000).

Trilayered spin-valve (SV) structures consisting of two ferromagnetic layers separated by a thin metallic spacer layer have recently received much attention because of the large differences in resistance when the magnetization directions of the magnetic layers are aligned parallel or antiparallel – the so-called giant magnetoresistance (GMR) effect. We have studied patterned SV structures based on submicron Co (10 nm)/Au (5 nm)/Ni (10 nm) combinations shaped as rectangles, diamonds, ellipses, and bars and with lateral dimensions on the 100-nm scale (Smith *et al*., 2000; Dunin-Borkowski *et al*., 2000). Figure 10 shows some representative results from a complete hysteresis cycle for elliptical and bar-shaped elements. The arrows within each element indicate the field direction, and the in-plane component of the applied field is aligned along the long axis of each element. The occurrence of two different contour spacings within each element at different applied fields, with corresponding steps in the hysteresis loops was a significant observation of these SV studies. Micromagnetic simulations, described elsewhere (Smith *et al*., 2000), indicated that antiferromagnetic coupling between the Co and Ni layers, due to the strong demagnetization field of the closely adjacent and more magnetically massive Co layer, was the reason for this behavior. Vortex states were not observed in any of the remanent states in further studies of rectangular SV elements, unlike magnetization states sometimes observed during hysteresis cycling. This difference in behavior can presumably again be attributed to the presence of the strong coupling between the Co and Ni layers following removal of the external field. Similar coupling between layers was reported in a more recent study of Co/Cu/NiFe thin-film elements (Kasama *et al*., 2005). The observed variability in switching fields in this case was attributed to slight variations in the shape and size of the elements, as well as microstructural variability.

More recent studies of the remanent states of nanopatterned Co elements have concentrated on thinner elements (Hu, Wang, McCartney and Smith, 2005, 2006; Wang, Hu, McCartney and Smith, 2006). The remanent states of 10-nm-thick triangles, squares, pentagons, and hexagons were found to have a 'twisted' configuration, whereas those of rectangles, ellipses, and 'dumbbells' were basically linear (Wang, Hu, McCartney and Smith, 2006). In contrast, the remanent states of disk- and ring-shaped elements were primarily circular, whereas slotted disks and rings had modified circular states that were highly reproducible and had minimal fringing fields. This latter characteristic is very unlike what is observed for linear shapes such as rectangles and ellipses, which typically display considerable stray fields near their ends. Figure 11 shows some representative examples for sets of slotted disks and rings illustrating the interesting remanent states of these modified circular elements. When the applied field was parallel or nearly parallel to the slot curves, the remanent states appeared to be stable single domains (Wang, Hu, McCartney and Smith, 2006).

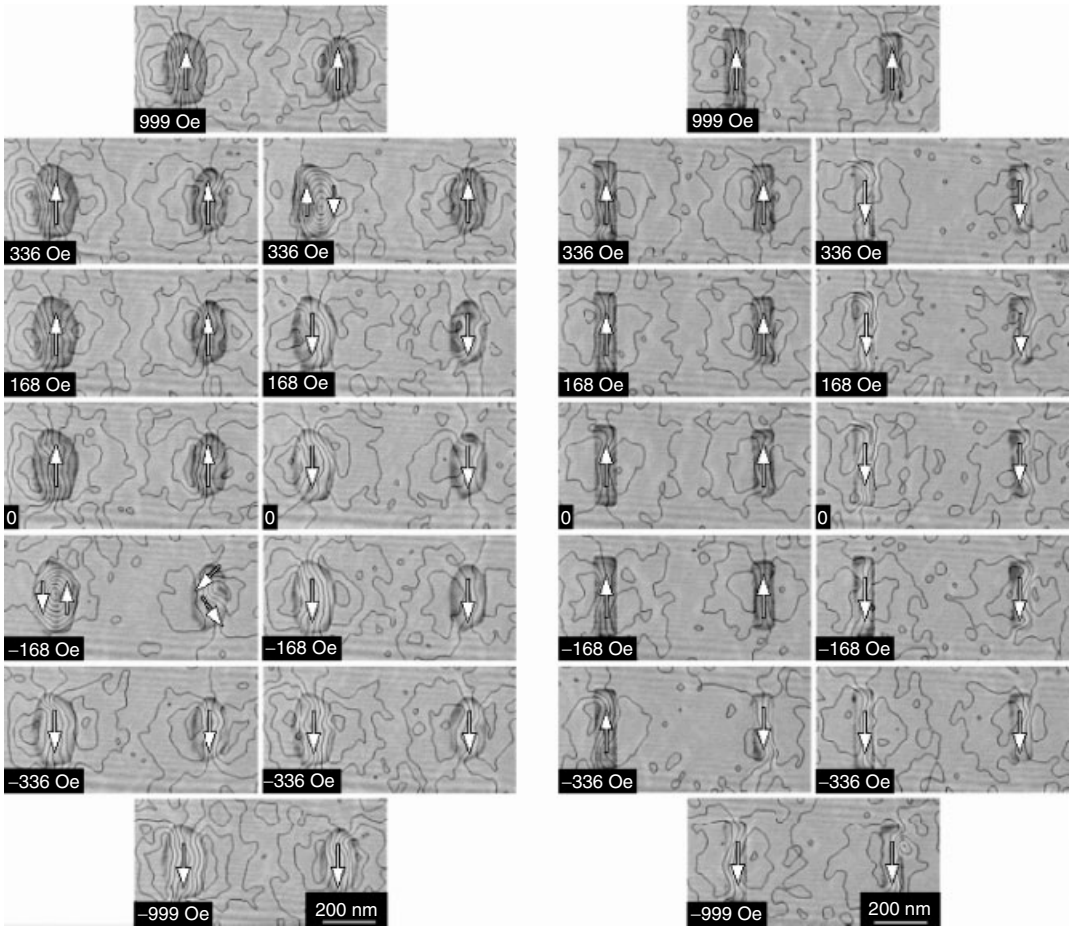

Figure 10. Magnetic contributions to phase for elliptical and bar-shaped Co (10 nm)/Au (5 nm)/Ni (10 nm) spin-valve elements over complete hysteresis cycle. Phase contours of 0.064π rad. Field applied in vertical direction. Loop should be followed counterclockwise. Average out-of-plane field of 3600 Oe directed into the page.

The circular magnetization state of disk- and ring-shaped elements clearly avoids any edge-domain problems, while the flux closure helps to minimize any interelement interactions. Two stable magnetization states have been identified in submicron magnetic ring elements: the so-called onion state with domain walls on opposite sides of the ring, and the vortex state, which has fully enclosed flux (Rothman *et al*., 2001). Electron holography has allowed us to study magnetization reversal processes for nanoscale Co rings into the deep-submicron regime (Hu, Wang, McCartney and Smith, 2005). The most important finding was that the ratio of the outer to the inner diameter of the rings played the major role in determining the actual switching process. Figure 12 shows an example of coherent rotation of domain walls for a ring of 150 nm inner diameter and 400 nm outer diameter.

Our most recent study has involved slotted disks and rings (Hu, Wang, McCartney and Smith, 2006). It was found that both of these shapes had very stable and well-defined remanent states, unlike complete disks and rings of similar dimensions. Representative examples are shown in Figure 13. In the case of slotted disks ('pacman shape'), vortex states were invariably observed during the switching process, whereas rapid switching without vortex formation was the behavior mostly shown by the slotted rings. Because of this nonvortex switching mode for slotted rings, the field at which the magnetization reversed direction was very well defined, typically to within ∼40 Oe. Thus, this modified geometry should be particularly attractive for information storage applications based on circular elements rather than linear elements (Zhu, Zheng and Prinz, 2000).

3.5 Rocks, minerals, and bacteria

Ferromagnetic materials abound in nature but the use of electron holography to study these materials is virtually unexplored. A wealth of valuable information is

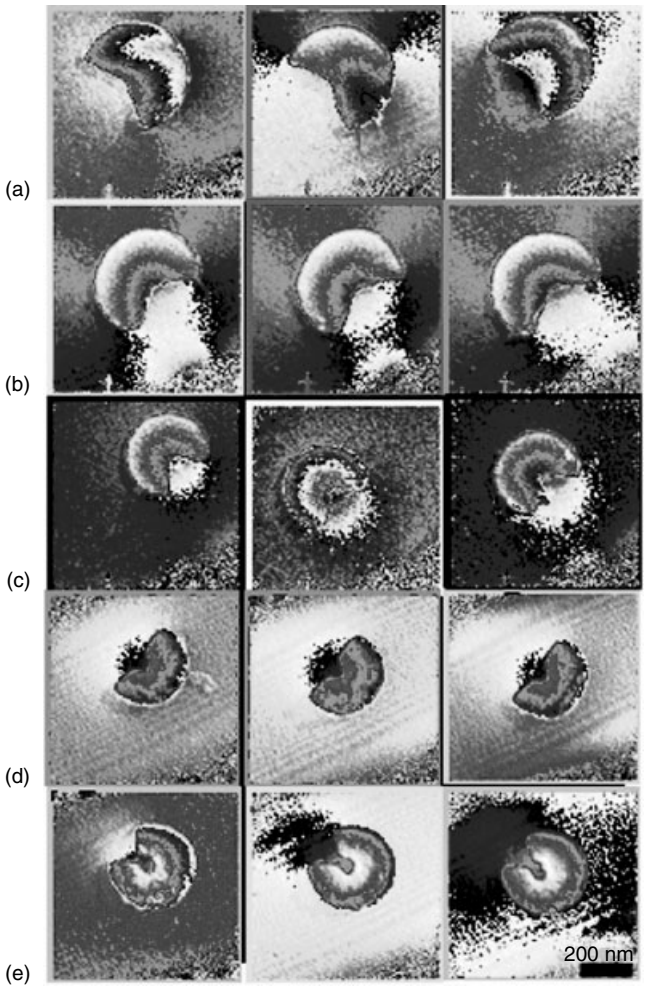

Figure 11. Reconstructed phase images showing remanent states for sets of three identical 10-nm-thick Co elements. (a) 400-nm slotted disk with 120° slot angle (curve perpendicular to magnetic field direction); (b) 400-nm slotted disk with 120° slot angle (curve parallel to magnetic field direction); (c) 300-nm slotted disk with 90° slot angle; (d) 300-nm slotted ring with 180° slot angle; (e) 300-nm slotted ring with 90° slot angle. (Reproduced from Wang *et al*., 2006, with permission from Elsevier. © 2006.)

seemingly waiting to be discovered. In the field of geology, planar arrays of magnetite nanoparticles from titanomagnetite minerals have received recent attention (Harrison, Dunin-Borkowski and Putnis, 2002; Dunin-Borkowski *et al*., 2004b). Unlike the well-controlled geometries of lithographically patterned nanostructures, the roughly equidimensional magnetite nanocrystals display considerable variability in their sizes and spacings. This feature makes for a fascinating case study of nanomagnetism. Some small, closely spaced crystals couple together to form flux closure domains much like the Co rings described earlier, whereas other larger blocks appear to form vortex states with flux closure. The

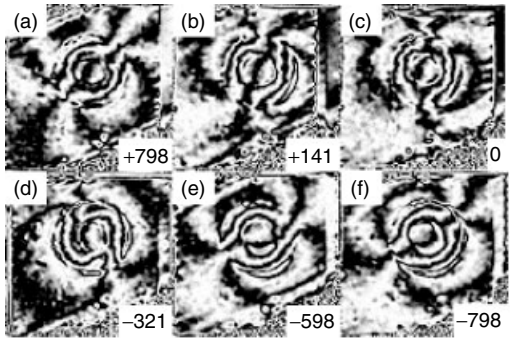

Figure 12. Amplified (8×) phase images showing reversal behavior of 400/150-nm ring during half of hysteresis cycle (in-plane fields indicated under each image: units of Oe). Note two domain walls rotating coherently around the ring. (Reproduced from Hu *et al*., 2005, with permission from the American Institute of Physics. © 2005.)

observed abundance of single-domain states, rather than vortex states prevailing in isolated cubes, was attributed to strong particle interactions based on demagnetizing fields for the local crystal environments.

Ferromagnetic nanomaterials occur naturally in many biogenic systems. Interesting examples are the magnetosomes, composed of magnetite or greigite crystals, found in magnetotactic bacteria. In these organisms, the magnetite crystals are invariably found in chains, as shown in Figure 14(a), which provide an internal navigation aide. Off-axis electron holography has been used extensively to study the individual and collective micromagnetic behavior of these magnetite nanocrystal chains (Dunin-Borkowski *et al*., 1998c; McCartney *et al*., 2001). Figure 14(b) shows the corresponding hologram taken from the area indicated in Figure 14(a). After magnetization reversal and phase addition, the electrostatic phase contribution can be extracted, and the nanocrystallites are revealed to be cubo-octahedral in shape. The magnetic phase contribution is shown in Figure 14(c), where the phase contours have been overlaid onto the MIP contribution so that the positions of the crystals and the magnetic contours can be correlated. Thus, the distribution of magnetic flux within and between the crystallites can be observed. Interestingly, the contour lines do not lie entirely on a continuous curve along the chain axis but rather display slight misalignment from nanocrystal to nanocrystal. It was also found that individual crystals were fully magnetized into single-domain states even though many were below the critical size for superparamagnetism at room temperature. Finally, note that it was possible to determine the total dipole moments of the particle chains (Dunin-Borkowski *et al*., 2001). Further studies of other bacterial strains, and more information about differences in domain structure and magnetic properties of these intriguing nanocrystal ensembles can be found elsewhere (Dunin-Borkowski *et al*., 2001; McCartney *et al*., 2001).

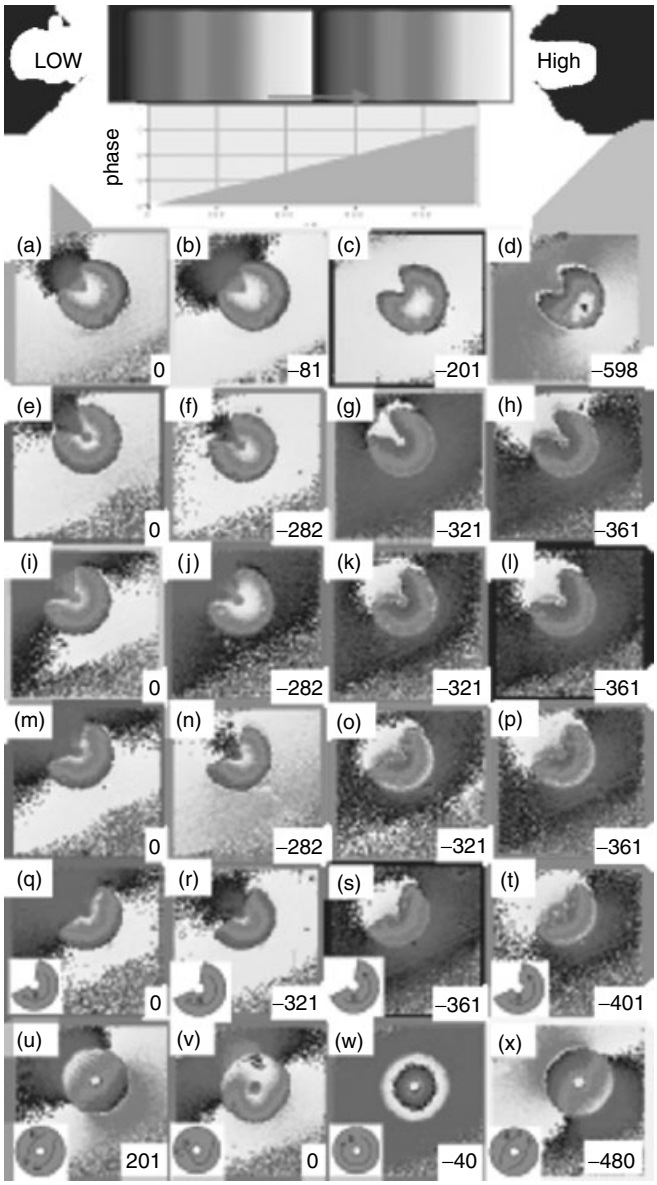

Figure 13. Phase images from 400-nm slotted disks and slotted rings during switching: (a–d) 60° slotted disk. Note the presence of a vortex state; (e–h) 60° slotted ring. Switching occurs rapidly between (f) and (g); (i–l) 90° slotted ring; (m–p) 120° slotted ring; (q–t) 150° slotted ring. Single-domain state illustrated at bottom left of each image; (u–x) vortex switching process in 400/50-nm ring. U-shaped state visible in (v), vortex state visible in (w), with onion states visible in (u) and (x). (Reproduced from Hu *et al*., 2006, with permission from the American Physical Society. © 2006.)

4 FUTURE PROSPECTS

This chapter has introduced the technique of off-axis electron holography and described its development as a tool for characterizing ferromagnets at the nanometer scale. The representative examples described should have clearly demonstrated that off-axis electron holography is already playing a valuable role in understanding the response of magnetic nanostructures. And it can be expected that electron holography will become a more widely used tool for future micromagnetic characterization studies.

Despite this optimistic outlook, there are several challenges that need to be faced. A major problem is that visualization of dynamic effects caused by changes of an applied magnetic field, considered to be necessary for a complete understanding of micromagnetic behavior, is not easily implemented. In our experiments, we have changed the in-plane field component by tilting the sample *in situ* within the field of the weakly excited objective lens, but this process clearly does not allow for real-time observations. Moreover, it has been shown that the out-of-plane component of the applied field imposes switching asymmetries during hysteresis cycling (Dunin-Borkowski *et al*., 1999). The development of a specimen holder with in-built coils capable of applying a horizontal field has been reported (Yi *et al*., 2004). However, the maximum field that can so far be applied is insufficient for many important applications. An alternative approach is to change the applied field of the objective lens, but the electron trajectories through the objective lens will then be affected. This problem could be solved by provision of three sets of auxiliary coils, with one set to apply the field close to the level of the sample, and the subsequent sets to steer the beam back onto the optic axis (Bonevich, Pozzi and Tonomura, 1999). This possibility is tedious to implement in practice and is not

yet generally available. Another problem is that off-axis electron holography is not suited for real-time observations because the recorded holograms are usually processed off-line. As faster computers and better CCD cameras become available, then real-time viewing of reconstructed phase images might just become possible. A third issue relates to the three-dimensional nature of the magnetic vector field, which was not considered for many of the applications described here. This omission is not so serious for objects such as thin films and nanostructures when the fields are constrained by the sample geometry to lie primarily in the plane, although subtle changes during the reversal cycle of the nanopatterned SV shapes were attributable to some out-of-plane rotation effects (Smith *et al*., 2000). For more massive three-dimensional objects such as probes for magnetic force microscopes, the out-of-plane field components must be taken properly into account (Streblechenko, Scheinfein, Mankos and Babcock, 1996; Matteucci, Frost and Medina, 2004).

ACKNOWLEDGMENTS

Much of the electron holography described here was carried out at the John M. Cowley Center for High Resolution Electron Microscopy at Arizona State University. We are grateful to Drs R. E. Dunin-Borkowski, R. F. C. Farrow, R. B. Frankel, H. Hu, B. Kardynal, S. S. P. Parkin, M. Posfai, M. R. Scheinfein, H. Wang, and Y. Zhu for provision of samples and ongoing collaborations.

Spin-polarized Low Energy Electron Diffraction

Hans-Joachim Elmers
Johannes Gutenberg Universität, Mainz, Germany

1 INTRODUCTION

Magnetic properties of surfaces, ultrathin films, and nanostructures are of great interest. A vital precondition for their investigation is an experimental method that is sensitive enough to probe magnetic order in structures consisting of a limited number of atoms and even time-resolved investigation of magnetization dynamics in them. On the other hand, diffraction of low-energy electrons (low-energy electron diffraction, LEED) is one of the most often used versatile methods in surface science for the investigation of structural properties of nanostructures. In the usual energy range up to a few hundred electronvolts, the mean free path of electrons in a solid is of the order of atomic distances. Therefore, the information depth is of this order and the diffracted electrons provide exclusive information on the surface, in contrast, for example, to X-ray or neutron diffraction methods. With comparatively low experimental effort the crystal structure of surfaces can be determined. By providing a polarized incident electron beam and/or a polarization analysis of diffracted electrons, magnetic surface properties can be analyzed. The combination of elastic electron diffraction and polarization analysis, usually called spin-polarized low-energy electron diffraction (SPLEED), is the aim of the present review.

The first experimental approach to spin-polarized electron diffraction was attempted by Davisson and Germer (1929) soon after their pioneering discovery of electron diffraction; however, they found no effect. It took half a century until the first convincing SPLEED data were reported by Celotta *et al*. (1979). Feder (1977, 1985) undertook the first rigorous calculations in order to predict magnetically induced asymmetries for the scattering of spin-polarized electrons at magnetic surfaces. The development of efficient sources for a polarized electron beam (Kirschner, 1985a) immediately boosted the number of experiments using SPLEED. The first path breaking SPLEED experiments were reviewed by Gradmann and Alvarado (1985).

Since then, the development of computational power has stimulated extensive effort in this field. Further development of experimental techniques including a higher spin polarization of the sources (Maruyama *et al*., 1991), a free manipulation of the spin direction (Duden and Bauer, 1995), and imaging with diffracted electrons (spin-polarized low-energy electron emission microscopy, SPLEEM) (Altman *et al*., 1991; Bauer, Duden and Zdyb, 2002) allowed a wide range of applications (**Spin-polarized Low Energy Electron Microscopy, Volume 3**).

Most of the experiments using elastic SPLEED pursue three main aims. The first aim is a quantitative analysis of space-dependent spin densities from quantitative comparison of relativistic dynamical scattering calculations with SPLEED experiments. Secondly, the comparatively large magnetic SPLEED asymmetries are used to detect and analyze magnetic order in nanostructures with a small magnitude of magnetization, particularly in the vicinity of the magnetic

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

phase transition. The third group of experiments addresses the improvement of electron polarization detectors, that still have an efficiency far lower than optical devices.

It is the aim of the present chapter to give a review of physical principles and experimental results, emphasizing the experimental point of view. Section 2 outlines the basic principles of SPLEED, a short discussion of inelastic scattering and comments comprehensive references that are relevant for understanding the theoretical calculations. The experimental methods used for SPLEED are described in Section 3 with a focus on new developments. Section 4 describes applications of SPLEED to the experimental determination of magnetic and structural properties of surfaces and ferromagnetic monolayer (ML) structures. Valence band structure properties of ultrathin films providing a path to more efficient spin detectors are inferred from SPLEED at kinetic electron energies below 10 eV.

2 PRINCIPLES OF SPLEED

2.1 Spin polarization of an electron beam

The spin of an electron is described as an operator ($\mathbf{s} = s_x, s_y, s_z$) satisfying the permutation relation $[s_x, s_y] = -i\hbar s_z$ (and cyclic permutations). In the limit of nonrelativistic interactions, which may be assumed for low-energy electrons, the spin operator is proportional to the operator of the angular momentum:

$$\mathbf{s} = \frac{\hbar}{2}\sigma \tag{1}$$

$$\sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \quad \sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} \quad \sigma_x = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \tag{2}$$

with σ_i being Pauli's spin matrices. For a pure spin state all electrons in the beam obtain the same spin function

$$\chi = a_1 \begin{pmatrix} 1 \\ 0 \end{pmatrix} + a_2 \begin{pmatrix} 0 \\ 1 \end{pmatrix} = \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \tag{3}$$

where $\begin{pmatrix} 1 \\ 0 \end{pmatrix}$ and $\begin{pmatrix} 0 \\ 1 \end{pmatrix}$ are the eigenfunctions of the operator σ_z. At a measurement of the spin component s_z one finds a value of either $+\hbar/2$ or $-\hbar/2$ with the probability $|a_1|^2$ and $|a_2|^2$. Because the components of the angular momentum operator are noncommutative, only one component of the spin of absolute value $|s| = \sqrt{3/4}\hbar$ can be measured simultaneously. The polarization P is a vector, given by the expectation value of the spin operator:

$$P = \frac{\langle \chi | \sigma | \chi \rangle}{\langle \chi | \chi \rangle} \tag{4}$$

The degree of polarization parallel to the quantization axis z is a scalar:

$$P_z = \frac{\langle \chi | \sigma_z | \chi \rangle}{\langle \chi | \chi \rangle} = \frac{|a_1|^2 - |a_2|^2}{|a_1|^2 + |a_2|^2} = \frac{N^{\uparrow} - N^{\downarrow}}{N^{\uparrow} + N^{\downarrow}} \tag{5}$$

with $-1 \leq P_z \leq 1$. $N^{\uparrow}$ ($N^{\downarrow}$) denotes the number of electrons with spin parallel (antiparallel) to the quantization axis. A mixed spin state can be described by a sum over pure spin states with appropriate coefficients. P_z can then be calculated in a similar way as for pure spin states (Kessler, 1976).

2.2 Spin-orbit coupling

For a calculation of electron scattering, one considers as a first step the scattering by a radially symmetric potential $V(r)$. In the vicinity of the atomic nucleus, electrons acquire relativistic velocities. Therefore, the relativistic Dirac equation has to be solved. As a direct consequence, the spin of the electron is always coupled to its orbital momentum. In a nonrelativistic approximation, this spin-orbit interaction can be described by an additional spin-orbit interaction potential (Kessler, 1976)

$$V_{\mathrm{so}} = \frac{1}{2m^2c^2}\frac{1}{r}\frac{\mathrm{d}V}{\mathrm{d}r}(\mathbf{s} \cdot \mathbf{l}) \tag{6}$$

with $\mathbf{s}$ being the spin and $\mathbf{l}$ the orbital moment operator. The sign of this additional spin-orbit potential depends on the path of the electron, that is, whether it passes the nucleus left-hand or right-hand wise, and on the spin direction.

A classical interpretation would be based on the fact that in the system of the electron, the positive charge of the nucleus forming the scattering potential passes by and generates a magnetic field that in turn interacts with the magnetic moment of the electron.

We consider the electron traveling along the x axis, transversally polarized parallel to the z axis and scattered in the $x - y$ plane at a scattering angle θ (thus the orbital moment is parallel to the spin). The spin-orbit interaction results in different differential scattering cross sections for spin-up and spin-down electrons $\sigma^{\uparrow}(E, \theta)$ and $\sigma^{\downarrow}(E, \theta)$. The contribution of the spin-orbit coupling to the total scattering potential is weak. Exclusively for minima of the differential cross sections, a significant difference depending on the spin can be observed. The scattering asymmetry is defined as:

$$A_{\mathrm{so}}(\theta) = \frac{\sigma^{\uparrow}(\theta) - \sigma^{\downarrow}(\theta)}{\sigma^{\uparrow}(\theta) + \sigma^{\downarrow}(\theta)} \tag{7}$$

Since the number of scattered electrons N is proportional to the scattering cross section, an unpolarized electron beam

will be polarized after the scattering according to:

$$P = A_{so}(\theta) = \frac{N^{\uparrow}(\theta) - N^{\downarrow}(\theta)}{N^{\uparrow}(\theta) + N^{\downarrow}(\theta)} \tag{8}$$

with the polarizing power P (Kessler, 1976). If the scattering potential shows a mirror symmetry with respect to the scattering plane, change of sign of the orbital momentum will be equivalent to a change of sign of the polarization: $\sigma^{\uparrow}(-\theta) = \sigma^{\downarrow}(\theta)$ and consequently $A_{so}(\theta) = -A_{so}(-\theta)$. This relation is exploited for a polarization analysis in a Mott detector, where intensities are measured at complementary scattering angles. Considering a totally polarized electron beam one will measure an asymmetry A according to:

$$A = \frac{N^{\uparrow}(\theta) - N^{\uparrow}(-\theta)}{N^{\uparrow}(\theta) + N^{\uparrow}(-\theta)} = \frac{\sigma^{\uparrow}(\theta) - \sigma^{\downarrow}(\theta)}{\sigma^{\uparrow}(\theta) + \sigma^{\downarrow}(\theta)} = P \tag{9}$$

that is, the polarization generated by the scattering of an unpolarized electron beam because of the spin-orbit interaction is identical to the scattering asymmetry generated by a totally polarized electron beam (analyzing power equals polarizing power) (Feder, 1981).

2.3 Exchange coupling

Exchange coupling is a quantum-mechanical effect without any classical analogon. Its origin is the Pauli principle demanding for a spin-1/2 particle a wave function that is antisymmetric with respect to the exchange of two particles. As a direct consequence of this principle, the differential scattering cross section depends on the relative orientation between the spin of the incoming electron and the spin of the target (e.g., a polarized atom). Note that this is not a direct spin–spin dipole interaction, which can be neglected for the energy range of interest here, but a Coulomb interaction (Kessler, 1976).

Let us consider the scattering of polarized electrons $e^{\uparrow\downarrow}$ at polarized atoms $A^{\uparrow\downarrow}$ with a neglection of spin-orbit coupling. Then we have the following scattering channels:

$$e^{\downarrow} + A^{\uparrow} \longrightarrow e^{\downarrow} + A^{\uparrow} \qquad (|f|^2) \tag{10a}$$

$$e^{\downarrow} + A^{\uparrow} \longrightarrow e^{\uparrow} + A^{\downarrow} \qquad (|g|^2) \tag{10b}$$

$$e^{\uparrow} + A^{\uparrow} \longrightarrow e^{\uparrow} + A^{\uparrow} \qquad (|f - g|^2) \tag{10c}$$

In the case of (a) the electron is directly scattered without exchange (scattering amplitude f), case (b) denotes the exchange scattering with amplitude g, and in the case of (c) the electrons cannot be distinguished and one may have exchange or direct scattering.

In a complete experiment where one knows the polarization of electron and atom before and after the scattering, the scattering cross sections can be determined directly. When unpolarized electrons are scattered at a polarized target, the scattered electrons are polarized according to:

$$A_{ex}(\theta) = \frac{|g|^2 + |f - g|^2 - |f|^2}{|f|^2 + |g|^2 + |f - g|^2} = P(\theta) \tag{11}$$

In all cases when electrons are scattered at a polarized target, the exchange scattering provides contributions to the total scattering cross section. This is true even in cases where unpolarized electrons are scattered and no polarization analysis is performed. The total cross section for scattering at a spin-up polarized atom $A^{\uparrow}$ is then given by

$$\sigma_0(\theta) = \frac{1}{2}(|f|^2 + |g|^2 + |f - g|^2) \tag{12}$$

Since the cross section depends only on the relative orientation of electron spin and target spin, one obtains the same cross section for a spin-down polarized target $A^{\downarrow}$. Therefore, a magnetization reversal does not change the intensity of the scattered electron beam along direction θ. The scattered intensity also remains constant when the polarization of an incident polarized beam on an unpolarized target is reversed.

The scattered intensity changes, however, when the incident beam and the target are polarized and the polarization of either the target or the incident beam is reversed. The cross sections for parallel and antiparallel orientations of the incident electron beam and the target is given by:

$$e^{\uparrow} \longrightarrow A^{\uparrow} \qquad \sigma_0^{\uparrow\uparrow}(\theta) = |f - g|^2 \tag{13a}$$

$$e^{\downarrow} \longrightarrow A^{\uparrow} \qquad \sigma_0^{\uparrow\downarrow}(\theta) = |f|^2 + |g|^2 \tag{13b}$$

Obviously, the exchange scattering amplitude g causes a change of the scattered intensity depending on the relative orientation of target and electron spin. One thus obtains information on the exchange scattering mechanism without analyzing the polarization of the scattered electrons. The scattering cross sections do not depend on the scattering angle. In contrast to the case of spin-orbit scattering (see Section 2.2) there is, in particular, no left–right asymmetry for the case of exchange scattering:

$$A_{ex}(\theta) = A_{ex}(-\theta) \tag{14}$$

2.4 Diffraction of spin-polarized electrons at surfaces

In the two preceding subsections, spin-orbit and exchange scattering were treated separately. However, in general both

effects are present simultaneously. An unpolarized electron beam might become polarized via the spin-orbit coupling in the vicinity of a nucleus and then responds to the exchange interaction with conduction electrons far away from the nucleus. Scattering at a solid-state surface may add multiple-scattering and inelastic processes.

Let us consider the scattering of electrons at a solid-state surface in the kinematic approximation. While the total intensity of scattered (unpolarized) electrons is determined mainly by the translational symmetry of the surface (LEED spots), the polarization of the scattered electrons depends only on the atomic scattering amplitudes (Kirschner, 1985b) and not on the lattice periodicity. This can be easily seen considering that the polarization is given by

$$P = \frac{I^{\uparrow\uparrow} - I^{\uparrow\downarrow}}{I^{\uparrow\uparrow} + I^{\uparrow\downarrow}} \tag{15}$$

and the lattice factor is a common factor for both intensities.

Within the kinematic approximation, the polarization carries no information on the crystallographic structure of the surface. As a consequence of the fact that intensity and polarization are decoupled, it should be possible to find scattering conditions with simultaneously high intensity and high polarization. This is in contrast to scattering at atoms where high polarization always occurs at intensity minima (Kessler, 1976) and might be important for the construction of polarization detectors (see Section 3.2). The polarization is also independent of the temperature because the Debye–Waller factor is a common factor for the intensities, too.

The exchange asymmetry observed for scattering at a ferromagnetic surface should depend only on the effective magnetic moment per atom, averaged over the information depth of the low-energy electrons, when only the kinematic approximation is considered.

Kirschner and Feder (1979) showed, however, that the kinematic approximation cannot be used to describe the scattering of low-energy electrons. For constant energy and constant incident angle they measured the polarization of the (00) spot after reflection at a W(100) surface as a function of the azimuthal angle. The scattering vector $(k - k')$ remains constant and therefore intensity and polarization should not vary according to the kinematic approximation. Instead, a strong variation was found for both intensity and polarization, depending on the azimuthal angle. The experimental observation could be simulated by a dynamic LEED theory considering multiple-scattering events.

Because of the inherent interconnection of spin-orbit coupling and exchange coupling, special scattering geometries have to be chosen to separate these two effects. In the longitudinal geometry the electron polarization is in the scattering plane. According to equation (6) the spin-orbit asymmetry vanishes. The scattering asymmetry is then exclusively caused by the exchange coupling and measures the magnetization component parallel to the incident spin direction. In the transversal geometry, the electron spin is perpendicular to the scattering plane. The scattering plane is adjusted to a mirror plane of the scattering surface. Then the electron spin is parallel to the normal $\vec{n}$ of the scattering plane after the scattering event, too Feder, 1981. The exchange asymmetry measures the magnetization component parallel to $\vec{n}$. In this case, the scattering can be described by four independent problems using the scalar scattering potentials:

$$V_\sigma^\mu(\vec{r}) = V_0(\vec{r}) + \sigma\mu V_{\mathrm{ex}}(\vec{r}) + V_{\mathrm{so}}(\vec{r}) \tag{16}$$

(Alvarado *et al.*, 1982) with $\sigma = +(-)$ for spin parallel (antiparallel) to $\vec{n}$ and $\mu = +(-)$ for magnetization antiparallel (parallel) to $\vec{n}$. In the experiment, one determines four scattering intensities I_σ^μ from which one calculates the scattering asymmetries:

$$A_{\mathrm{so}} = \frac{(I_+^+ + I_+^-) - (I_-^+ + I_-^-)}{(I_+^+ + I_+^-) + (I_-^+ + I_-^-)} \tag{17}$$

$$A_{\mathrm{ex}} = \frac{(I_+^+ + I_-^-) - (I_+^- + I_-^+)}{(I_+^+ + I_-^-) + (I_+^- + I_-^+)} \tag{18}$$

$$A_{\mathrm{u}} = \frac{(I_+^+ + I_-^+) - (I_+^- + I_-^-)}{(I_+^+ + I_-^+) + (I_+^- + I_-^-)} \tag{19}$$

The latter asymmetry A_{u} is obtained as the difference between the two magnetization directions after averaging over two spin directions and therefore describes the asymmetry one obtains for unpolarized electrons. It is a direct consequence of the coupling between spin-orbit and exchange interaction. A_{u} can be neglected in the case of $3d$ elements as was first shown by Tamura, Ackermann and Feder (1984) numerically using a scheme of simultaneous calculation of spin-orbit and exchange asymmetry (Ackermann and Feder, 1984; Feder, Rosicky and Ackermann, 1983). Contrarily, in the case of rare-earth elements A_{u} has to be considered (Weller *et al.*, 1985).

The magnetic information depth depends on the mean free path λ_e of the electrons (see Section 2.5) and the angle of incidence θ according to $d_e = \lambda_e \cos\theta$. At the surface of a bulk crystal or a thick film the magnetization deviates from the core of the material. Assuming that the deviation can be described by an exponential behavior with a coherence length $\xi_\perp$ perpendicular to the surface, the contribution n_{s} of the scattering asymmetry evoked by the topmost layer to the total scattering asymmetry is given by

$$n_{\mathrm{s}} = \frac{\xi_\perp}{\xi_\perp + d_e} \tag{20}$$

The temperature dependence of the coherence length $\xi_\perp$ diverges at the Curie temperature T_C according to

$$\xi_\perp(T) = \xi_\perp^0 \left(\frac{T_C}{T_C - T} \right)^\nu \tag{21}$$

Close to T_C the exchange asymmetry A_{ex} thus measures the magnetization of the topmost layer ($n_s = 1$). This fact was used to determine the critical behavior of the surface magnetization of Ni (Alvarado, Hopster and Campagna, 1982). For $T \ll T_C$ the critical lengths $\xi_\perp$ and d_e are of the same order of magnitude and therefore A_{ex} is determined only to some extent by the topmost layer. A detailed comparison of theory and experiment is needed in this case to determine the surface magnetization.

2.5 Inelastic interactions of electrons at surfaces

Inelastic processes to be considered in the low-energy regime are given by plasmon scattering, photoemission from valence states, photoemission of core level states and finally phonon and magnon scattering processes.

Scattering processes with phonons or magnons result in very small energy losses (<100 meV). Without using high resolution electron analyzers these electrons cannot be distinguished from elastically reflected electrons and therefore potentially cause erroneous intensity signals. Phonon scattering does not result in a significant amount of spin-flip processes, that is, the spin of the scattered electron is conserved. However, the momentum is changed and therefore the intensity in an off-specular direction is increased while the intensity in the specular direction is smaller than expected. Inelastic processes including excitation and annihilation of magnons are particularly interesting because they change the electron polarization. These processes have been intensively investigated by Vollmer *et al*. (2003) using spin-polarized electron energy loss spectroscopy (SPEELS). An additional scattered intensity attributed to magnon losses can only be observed for spin parallel to the magnetization of the sample at energy losses up to a few hundred millielectronvolts. The cross section for spin-wave excitation depends very strongly on the energy E_i of the incident electrons. Only below $E_i \approx 10$ eV can the spin wave be observed as a peak in the intensity spectrum for spin parallel to the magnetization. For higher incident electron energy, the contribution to elastically reflected electrons can be neglected.

Contrary to the collective spin-wave excitations, Stoner excitations that are the main contributions for higher incident energy above 25 eV (Kaemper, Abraham and Hopster, 1992) can be described in a single-particle picture: A Stoner excitation consists of an electron above the Fermi energy E_F coupled to a hole below E_F with opposite spin. They can be excited very efficiently by electron scattering, and their properties have been investigated extensively by SPEELS (Venus and Kirschner, 1988). Stoner excitations of majority-hole minority-electron character are much more likely than those of minority-hole majority-electron character with a pronounced maximum at an energy loss of 1–2 eV (Kaemper, Abraham and Hopster, 1992). By a Stoner excitation the spin of the scattered electron is apparently reversed. These spin-flip events were found to be very important in the off-specular, impact scattering regime, where they comprise up to one-third of the total electron–hole excitations and are responsible for the great majority of the observed intensity asymmetry. They are also detected under specular and near specular scattering conditions, but their relative importance decreases compared to strong dipole scattering (Venus and Kirschner, 1988).

Below 50 eV electron–hole excitations of valence electrons dominate all loss processes (Quinn, 1962). Since the momentum space for these processes becomes increasingly smaller with decreasing energy, the mean free path of electrons increases significantly at low energies. Above 50 eV electron–hole excitations are overbalanced by plasmon excitations. At higher energy the excitation of core level states becomes possible, too, although the cross section for these processes is negligibly small. The cross section for both processes, plasmon excitation and electron–hole excitations, decreases with increasing energy since the available time for a scattering process gets smaller.

The mean free path has been determined for a large number of materials (Seah and Dench, 1979; Woodruff and Delchar, 1986). Although individual values may vary by nearly an order of magnitude, the general trend following theoretical considerations (Quinn, 1962) is described by a minimum of the mean free path between 10 and 300 eV. The absolute value of the mean free path in this energy range is of the order of 1 nm. The interaction of low-energy electrons is therefore restricted to a few atomic layers at the surface, which makes electron diffraction an ideal tool for investigating the properties of surfaces and ultrathin films. Below 10 eV the mean free path increases considerably for many materials, particularly for noble metals. Surprisingly, this applies less to transition metals where the mean free path is related to the number of d-holes (Schoenhense and Siegmann, 1993).

2.6 Theory of SPLEED

Unpolarized LEED intensity calculations for various surfaces reproduce experimental data with impressive accuracy (Tong, 1994). A similar calculation concept considering the diffraction of spin-up and spin-down electrons separately has

been developed by Feder (1981, 1985). As explained below in more detail, calculation schemes for electron reflectivities may use as an input self-consistently calculated ground-state potential functions provided by separate program packages (**Density-functional Theory of Magnetism, Volume 1**).

For electron energies of several tens of electronvolts the muffin-tin (MT) approach for calculating the electron reflectivities proves very adequate. Within the core region, one may use spherically symmetric potentials, and bulk potentials generated from *ab initio* electronic-structure calculations are sufficiently accurate to describe electron scattering from atoms in the surface. At sufficiently high beam energy, the electron is scattered by the core region of the potential, and is influenced rather modestly by the details of the potential in the outer portion of the unit cell. Thus, for many materials the approach of using less time-consuming bulk calculations to approximate scattering potential at surfaces is sufficiently accurate. The crystal is divided into nonoverlapping spheres centered at each atomic site. Outside the spheres, the so-called inner potential is assumed to be constant. All inelastic processes are described by an imaginary part of the inner potential V_{i} which simulates the inelastic mean free path (IMFP). The inner potential V_{i} can be chosen in such a way that the mean free path fits the experimentally observed universal curve and is of the order of 4 eV, slightly changing with energy.

Inside the MT spheres, the portion of the ion-core potential in the electron energy range of typical LEED energies is to a large extent determined by the nuclear charge and tightly bound core-state electrons, which are not easily polarizable and retain their atomic character in the solid environment. Therefore, this portion of the potential changes only little as the atom is placed in the surface environment and is, to a good approximation, spherically symmetric. On the other hand, the outer parts of the atom, the valence and conduction electrons, are affected by the neighboring atoms and the surface. These distortions break the spherical symmetry of the ion-core potential. The distortions are important at very low energy (<30 eV) but play a minor role for electron energies >50 eV. Therefore, one may use only the spherical part of bulk potentials which in turn can be generated by *ab initio* electronic-structure calculations.

Electronic-structure calculations can be carried out on different levels of sophistication depending on the particular system and required accuracy. Ordered compounds can be calculated by means of full potential methods. A coherent potential approximation (CPA) may be used to determine the properties of doped compounds and randomly disordered alloys. The most time-consuming and most accurate calculations are given by the fully relativistic calculations.

Several calculation schemes are available and can be run on a personal computer. Self-consistent band structure calculations are useful for well ordered structures using the full potential linearized augmented plane-wave (FLAPW) method provided by Blaha, Schwarz, Sorantin and Tricky (1990) and Schwarz, Blaha and Madsen (2002) (Wien2k 04). In this method, only core states are treated relativistically. The exchange-correlation functional can be taken within the generalized gradient approximation (GGA) in the parameterization of Perdew *et al*. (1992). For comparison, calculations can also be performed using the linear muffin-tin orbital (LMTO) method provided by Savrasov (1996) (LMTART 6.5) on different levels of sophistication from simple atomic sphere approximation (ASA) to full potential plane-wave representation (FP-LMTO-PLW).

For less ordered structures, that is, random alloys, it is appropriate to carry out self-consistent band structure calculations using the Korringa–Kohn–Rostocker (KKR) method provided by Akai (1998) and Kotani and Akai (1996). The random alloys were calculated within the CPA. The program allows to use various types of the exchange-correlation functional, that are, for example, Barth and Hedin (1972), Moruzzi, Janak and Williams (1978), Vosko, Wilk and Nussair (1980) (VWN), and Vosko and Wilk (1980), or the GGA in the parameterization of Perdew and Yue (1986) and Perdew *et al*. (1992), or Engel and Vosko (1993). The program allows also to work in both approximations, MT and ASA.

The ion-core potentials are then used to calculate the various individual atomic t matrices (Feder, 1985). For SPLEED, it is convenient to assemble the atoms into layers and view the crystal as an infinite array of such layers parallel to the surface. Layer diffraction matrices $\tau_i = t_i(1 - Gt_i)^{-1}$ are then constructed that describe multiple scattering within the layer i. G is the intralayer single-particle propagator with complex self-energy. The atomic t matrix and the layer diffraction matrices are calculated usually in the angular momentum representation. The number of partial waves required for a reliable calculation depends on the number of nuclear charges of the contributing atoms. For 3d transition metals partial waves of up to $l = 4$ are sufficient while for 5d transition metals partial waves up to $l = 7$ are required (Plihal, Mills, Elmers and Gradmann, 1995).

The reflected electron intensity is then expressed by the full crystal T matrix. The exact calculation of the T matrix requires matrices too large to be handled conveniently. There are two major methods to deal with the T matrix in an appropriate way, the renormalized forward scattering (RFS) and the layer doubling method. In the RFS scheme, forward interlayer scattering events are iteratively accumulated and back interlayer events are summed sequentially. The summation over successive orders of backscattering events is stopped if numerical convergence to a desired accuracy is reached. Thus, wherever there is convergence of the power-series

expansion of backscattering matrices, the RFS method is fast and can be rapidly carried to a high degree of numerical accuracy. The layer doubling method, on the other hand, induces a larger set of scattering events than RFS. It generates the exact solutions of forward and backward-scattering matrices in the reciprocal space representation for two layers. The procedure is then repeated to scattering matrices for 2^n layers. This process converges in typically three to four iterations. The RFS method is a pertubative expansion and has therefore the virtue of being faster than both the exact T matrix calculation and the layer doubling method; however, it is less stable and diverges for small layer spacings.

3 EXPERIMENTAL METHODS

3.1 Sources

Various sources for spin-polarized electrons have been described in the literature (Kirschner, 1985a, 1985b; Maruyama *et al*., 1991). The most often used GaAs source was first introduced by Pierce and Meier (1976). The principle of the GaAs source is based on spin-polarized photoelectrons emitted from a GaAs surface, that are excited by circular polarized light. At the Γ point, the valence band which has a preferential p character is splitted by the spin-orbit coupling in fourfold degenerated $p_{3/2}$ states and twofold degenerated $p_{1/2}$ states. The conduction band possesses a preferential s character. Absorption of a photon with the gap energy (GaAs, 1.52 eV) induces an efficient dipole-allowed electron transition. For a right (left) circular polarized photon, the z component of the total angular momentum is changed by $+1(-1)$. If only electrons from the $p_{3/2}$ states are excited, right circular polarized light induces the transitions $m_j = -3/2 \rightarrow m_j = -1/2$ and $m_j = -1/2 \rightarrow m_j = +1/2$ with different transition probabilities (3:1). Therefore the expected polarization is $P = 50\%$. Using strained layers grown on substrates with slightly larger lattice constants, the degeneracy of the $p_{3/2}$ states is lifted and an even higher polarization is possible (Maruyama *et al*., 1991).

In order to extract the excited electrons from the conduction band one needs a trick. Using heavily p-doped GaAs charge redistribution in the surface region (10 nm) leads to a band bending toward lower energy. A capping of the surface with a combination of Cs and O pushes the conduction band finally below the vacuum level. Then, the electrons can escape without paying the work function energy (negative electron affinity, NEA). For NEA, the photon energy has to be adjusted to the band gap energy in order to avoid excitation of $p_{1/2}$ states. In this case, the polarization is independent of the level of the vacuum energy, which is easily changed by contamination. Alternatively, one may use photons with higher energy in the visible spectral region. In this case, the vacuum level has to be adjusted higher such that electrons excited from the $p_{1/2}$ states cannot escape (positive electron affinity, PEA).

After escaping the semiconductor surface the electrons are polarized longitudinally. Using electrostatic and/or magnetic deflectors, the polarization can be adjusted in any direction (Duden and Bauer, 1995).

Aulenbacher *et al*. (2002) investigated the limiting factors for the pulse length of electron bunches escaping a GaAs photocathode under the conditions of highly polarized beam production. For GaAs cathodes with layer thickness d that is large in comparison to the optical absorption length the photoemission time response of GaAs was explained by a diffusion model (Hartmann *et al*., 1999), typical response times being about 50–100 ps. For a highly polarized electron source, however, uniaxially strained GaAs or GaAsP cathodes are used. In these cathodes, the active layer thickness is limited to a value of $d = 125 \pm 25$ nm, which is only a fraction of the absorption length of the exciting laser radiation. In addition, the available heavy hole–light hole splitting of the valence band of the strained samples requires that the photoexcitation energy does not exceed the semiconductor band gap by more than 30–60 meV.

Using NEA-GaAs photocathodes, the pulse response of active layers with $d = 200$–1000 nm has been measured to depend quadratically on the layer thickness (Aulenbacher *et al*., 2002). For a thickness below 200 nm, the pulse length decreases to below 2 ps. The response time of a strained layer photocathode with 150 nm active layer thickness and minimized doping concentration in the active region is therefore at least a factor 25 faster than the bulk depolarization time. Therefore, the strained layer photocathodes with their inherent thickness limit of about 150 nm are relatively free from depolarization effects in the bulk of their active region. Thus, strained layer photocathodes offer ultrafast response and high spin polarization which may not only be useful in fundamental science but also for possible optospintronic devices.

3.2 Detectors

The low efficiency of spin detection is a severe experimental obstacle that impedes experimental progress. In terms of spin-detector development, a quantity of great interest is defined as the figure of merit (FOM) and is proportional to the inverse square of the statistical error in an electron counting experiment to measure the polarization of an incident beam (Kessler, 1976). The FOM can be calculated from the square of the total scattering asymmetry multiplied by the reflection coefficient. Conventional spin polarimeters (mini-Mott detectors) have a FOM below 2×10^{-4} (Pierce,

Celotta, Kelley and Unguris, 1988). Detailed investigations of the Fe(110) surface have shown that FOM of the order of 8×10^{-3} can be achieved (Fahsold, Hammond and Kirschner, 1992; Hammond, Fahsold and Kirschner, 1992). Along this direction, different surfaces have been investigated to increase the FOM, the lifetime, and the reproducibility (Hillebrecht *et al*., 2002; Jungblut, Roth, Hillebrecht and Kisker, 1992). Recently, FOM up to 6×10^{-3} have been achieved with a robust system, Fe(001)-p(1 × 1)O (Bertacco and Ciccacci, 1999; Bertacco, Merano and Ciccacci, 1998). A different approach suggested even higher FOM of up to 5×10^{-2} using high-quality ultrathin Co or Fe films on W(110) (Zdyb and Bauer, 2002a, 2002b). For Co/W(110) thin film, it has been shown that a FOM as high as 2×10^{-2} could be obtained for films grown at room temperature and that it is possible to reverse aging effects by moderate annealing (Graf *et al*., 2005).

3.3 SPLEED spectrometers

The standard setup of a SPLEED spectrometer consists of a source of spin-polarized electrons, the sample, and, in the simplest version, a Faraday cup as an electron detector. For the experiments described here (Waller and Gradmann, 1982; Elmers, 1995), the spin-polarized electrons were taken from a GaAs source, irradiated by circularly polarized light from a laser diode with a photon energy of $h\nu = 1.4\,\mathrm{eV}$ ($\lambda = 830\,\mathrm{nm}$). The electrons were electrostatically deflected by 90° resulting in a transversely polarized electron beam. Electron energies E with respect to the Fermi level of the target are given by $E = eU + h\nu$, where eU denotes the energy difference between the Fermi levels of the GaAs source and the target, respectively. The axis of electron polarization $\vec{P}_0$ is parallel to the normal $\vec{n}$ of the scattering plane, coinciding with the measured magnetization component. The magnitude of $\vec{P}_0$ can be calibrated by a comparison of scattering asymmetries obtained from a clean W(100) surface with previous studies, resulting in typical values $P_0 = 20 \pm 2\%$. A_{ex} can be determined for constant energy E as a function of the incident angle θ with respect to the target normal or, alternatively for constant angle as a function of E. The finite width of the electron beam and of the detector results in an averaging of $A(\theta)$ over a finite angle. Therefore, asymmetries are usually underestimated in sharp extrema.

Present day electron spectrometers offer energy resolutions of less than 1 meV (Ibach, 1991). Progress in instrumentation became possible through the development of efficient numerical methods to calculate electron optical properties of energy dispersive devices beyond the limitations of the classical cylindrical and spherical deflectors, and of lens systems which are not radial symmetric. The performance of spectrometers is ultimately determined by the brightness of the available electron sources.

In order to probe spin-flip events in electron energy loss spectroscopy (EELS) sources of spin-polarized electrons as described in the preceding text are used. The orientation of the spin is then longitudinal to the initial electron trajectory of the electrons. For the purpose of measuring the spin asymmetry of surface excitations, the spin should be oriented perpendicular to the scattering plane and therefore transverse to the electron trajectory at the sample position. This requires a deflection of the electron trajectory of 90° between the point of electron emission from the GaAs cathode and the sample. Unfortunately, a 90° deflection is incompatible with the standard deflecting energy dispersive elements such as the cylindrical or spherical deflector which feature 127° and 180° deflection, in the absence of fringe field corrections. Initial approaches to the problem (Kirschner, Rebensdorff and Ibach, 1984), therefore, introduced an additional deflector between the photocathode and electron monochromator on the expense of a current reduction. An optimum design for a spectrometer combines a 90° deflection in the energy dispersive elements with stigmatic imaging of the entrance slit of the first monochromator onto the exit slit of the last analyzer of the entire spectrometer. A realization of this concept was reported by Ibach *et al*. (2003) comprising a two-stage monochromator, the first stage being a 90° deflector which is followed by a 180° deflector. The combination of both deflectors provides a nearly stigmatic image of the entrance slit onto the exit slit in the presence of space charge. The overall performance of this concept was demonstrated by the determination of spin-wave dispersion curves (Vollmer *et al*., 2003).

3.4 SPLEED by SPLEEM

For a direct investigation of band structure properties, it is necessary to reflect electrons at very low energies, that is, below 20 eV. In electron spectrometers, as described above, the sample area is usually well shielded from external magnetic fields and electron diffraction can be studied at kinetic energies of a few electronvolts. An alternative approach is given by the use of a SPLEEM (Altman *et al*., 1991; Zdyb and Bauer, 2002b). In the diffraction mode the microscope allows at normal incidence the observation of the specular reflected beam. An important advantage of this instrument is the simultaneous control of the sample surface properties and the possibility to restrict the area of interest to any sample area thus avoiding an averaging over, for example, inhomogeneous film thicknesses or magnetization structures.

As demonstrated by Zdyb and Bauer (2002b) SPLEEM can be applied to SPLEED, provided that a nearly parallel beam of slow electrons with normal incidence on the sample is produced by focusing a spin-polarized 15 keV electron beam into the back focal plane of a cathode lens. In this lens, the electrons are decelerated to the desired energy at the sample, reaccelerated again after reflection, and used for imaging the surface. This high magnification is necessary in order to measure the intensity reflected from microcrystals. The electron beam was produced by a GaAs source as described in the preceding text.

4 APPLICATIONS

4.1 SPLEED at nonmagnetic surfaces

The 5d element W is not ferromagnetic and therefore one obtains $A_{ex} = 0$. Because of the large atomic number of W its surface exhibits large values of A_{so}. In a famous double scattering experiment Kirschner (1985a) showed how absolute values for A_{so} could be determined without any assumption on the polarization detector or on the electron source.

An unpolarized incident electron beam perpendicular to a W(100) surface (polarizer) generates four (2,0) spots of equal intensity. The two complementary diffracted beams in one of the two scattering planes are oppositely polarized, perpendicular to the corresponding scattering plane. The relations between counting rates $N_1^{\uparrow}$, $N_1^{\downarrow}$ of up- and down-polarized electrons and polarization P are given by

$$\left(\frac{N_1^{\uparrow}}{N_1^{\downarrow}}\right)_{(2,0)} = \frac{1-P}{1+P} \qquad \left(\frac{N_1^{\uparrow}}{N_1^{\downarrow}}\right)_{(\bar{2},0)} = \frac{1+P}{1-P} \tag{22}$$

The (2,0) spot is then diffracted at a second W(100) surface (analyzer) and generates again a (2,0) and $(\bar{2}, 0)$ spot which now have different intensities in addition to their different polarizations:

$$\begin{aligned}\left(\frac{N_2^{\uparrow}}{N_2^{\downarrow}}\right)_{(2,0)} &= \frac{(1-P)(1-A)}{(1+P)(1+A)} \\ \left(\frac{N_2^{\uparrow}}{N_2^{\downarrow}}\right)_{(\bar{2},0)} &= \frac{(1-P)(1+A)}{(1+P)(1-A)}\end{aligned} \tag{23}$$

with the asymmetry A of the second surface. From the different intensities one obtains:

$$R = \frac{I_{(2,0)} - I_{(\bar{2},0)}}{I_{(2,0)} + I_{(\bar{2},0)}} = A \cdot P \tag{24}$$

Because the scattering plane being a mirror plane of the two W(100) surfaces the asymmetries are equal, $A = P$, and the asymmetry can be determined from $P = \sqrt{R}$ (Kirschner, 1985b).

Because of the fact that W(100) can be easily cleaned in a ultrahigh vacuum by flashing and because it provides comparatively large values of P, the W(100) surface is used as a spin detector (SPLEED detector) (compare Section 3.2). Here, P depends strongly on the incident energy and the scattering energy has to be well defined for the application as a spin detector. A commercialized version using four electron counters allows simultaneous detection of two polarization components (Focus-GmbH, 2005).

The usefulness of spin-polarization analysis in LEED for the structure determination of nonmagnetic surfaces and of ordered layers adsorbed at single-crystal surfaces has been successfully demonstrated by experimental and theoretical analysis of SPLEED data (Potthoff *et al.*, 1995; Hilgers, Potthoff, Mueller and Heinzmann, 1995; Venus, 1993), where adsorbate structures and structural parameters could be determined.

Zasada (2002) proposed the interesting idea of measuring the spin-dependent diffuse LEED intensity. He considered the resulting incoherent scattering asymmetries from a single-crystal surface Pt(111) partially covered with CO molecules and calculated values for different parameters characterizing the adsorbate/substrate system. The parameters considered were geometrical parameters related to the local arrangement of molecules near chemisorption sites and order parameters related to the statistical distribution of the occupied chemisorption sites. The impressive sensitivity of the incoherent scattering asymmetries to geometry and local order examined for the CO/Pt(111) system demonstrated the practical use of the theory and implies a challenge to experimental work in this field.

4.2 Surface magnetization of bulk ferromagnets

4.2.1 Critical behavior

In the following, we concentrate on the critical behavior of the magnetization near the Curie temperature T_C. SPLEED will be a convenient experimental tool to analyze the critical behavior, if A_{ex} is proportional to the magnetization with respect to its temperature dependence. This appears reasonable near T_C, as the magnetic coherence length ξ diverges with the reduced temperature $t = (T - T_C)/T_C$ going to zero, and so ξ becomes large in comparison with the information depth of the low-energy electrons. Feder and Pleyer (1982) theoretically confirmed a similar temperature dependence of A_{ex} and magnetization. Considering the finite coherence length, an experimental analysis

using $A_{ex} \propto M$ should be restricted to $t < 0.1$, and the results should be checked by comparing $A_{ex}(T)$ for various energies.

Pioneering work was done by Palmberg, de Wames and Vredevoe (1968) on antiferromagnetic NiO surfaces, using the temperature dependence of half-order LEED spots which are caused by the antiferromagnetic order and therefore disappear at the Néel-temperature. The critical exponent for the surface magnetization was found close to 1, in contrast to $\beta \approx 1/3$ for the bulk. Note that, in this case, no spin analysis is needed and an unpolarized beam can be used, although the effect is caused by the exchange asymmetry.

An experimental study using SPLEED of the critical behavior of Ni(110) and Ni(100) surfaces was given by Alvarado, Campagna, Ciccacci and Hopster (1982) and Alvarado, Campagna and Hopster (1982). They found a critical power law $A_{ex} \propto t^{\beta}$ with a critical temperature identical with the bulk value and determined a critical exponent $\beta = 0.8 \pm 0.02$ for both Ni(100) and Ni(110) differing dramatically from the bulk value $\beta = 1/3$. The value found for the Ni surfaces is in agreement with theoretical models considering local moments and short-range interaction (Heisenberg model).

An interesting case investigated by SPLEED is the inferred existence of a remanent magnetization at the Gd(0001) surface while the bulk magnetization has vanished for temperatures above T_C. The existence of surface magnetic ordering above the bulk Curie temperature for Gd(0001) thin films grown epitaxially on W(110) was first measured by Weller *et al*. (1985) using temperature dependent SPLEED. From theoretical considerations, a pure surface transition can occur if the exchange coupling is enhanced at the surface (Binder, 1985). A spin-polarized energy-resolved photoemission study of Gd(0001) (Weller *et al*., 1985) revealed an antiferromagnetic coupling of the topmost layer to the underlying magnetic layers. The experimental result reported in (Weller *et al*., 1985) provoked a heavy debate in the scientific community because of conflicting experimental results denying a pure surface transition ((Arnold and Pappas, 2000) and references therein). Recently published articles in favor (Denecke *et al*., 2002) or disfavor (Melnikov *et al*., 2004) of an enhanced Curie temperature at the surface suggest that the topic has not been clarified, yet.

4.2.2 *Magnitude of surface magnetization at low temperatures*

The advantages of probing simultaneous A_{ex} and A_{so} in order to evaluate the magnitude of the magnetization at surfaces was first demonstrated in an investigation of the Ni(001) surface (Feder, Alvarado, Tamura and Kisker, 1983). The comparison of experimental and calculated A_{so} values confirmed the adequacy of the used exchange-correlation potential and the topmost atomic layer spacing as bulk like. Experimentally obtained A_{ex} values were compared with different model assumptions for the surface magnetization. Two independent theoretical analyses (Feder, Alvarado, Tamura and Kisker, 1983; Freeman, 1983) concluded on a slightly enhanced surface moment (+5 m%) for the Ni(001) surface.

In the following, we discuss extensively the case of the Fe(110) surface as an example for the determination of magnetization near the surface of well defined systems.

In the work of Waller and Gradmann (1982) and Waller (1986), the total scattered intensity (spin-up plus spin-down current) is measured, for the specular (00) beam and for the (11) beam. They have studied a remarkably wide range of energies. The polarization of the incident beam is parallel to the surface and perpendicular to the scattering plane defined as the plane that contains the incident beam and the normal to the surface. The magnetization of the substrate is also parallel to the surface, and to the [001] direction, which is an easy axis. The scattering plane is perpendicular to the [001] direction in the surface, so in all measurements the incident beam polarization is parallel to or antiparallel to the substrate magnetization. The geometry corresponds to the transversal geometry described in Section 2.4.

In conventional LEED analyses, in comparison between theory and experiment one does not compare the absolute intensity given by theory with the data. Indeed, it is difficult to extract the absolute intensity from the data. One typically adjusts the theoretical intensity to fit experiment at one point, and then compares the two as a function of angle at fixed energy, or energy at fixed incident angle. The exchange and spin-orbit asymmetries are intensity ratios, and the absolute values of these quantities are not affected by the difficulty of extracting a single absolute intensity from data influenced by geometric corrections, spectrometer sensitivities, and so on. Thus, a comparison between theory and experiment provides a severe test of the quality of the potentials used in the theoretical work.

Figure 1(a–c) shows a comparison between calculated and measured total intensity, spin-orbit asymmetry and exchange asymmetry for the specular beam scattered at a Fe(110) surface. The experimental data were first published in Tamura, Feder, Waller and Gradmann (1990). The calculations have been performed using the multiple-scattering theory described in Ormeci, Hall and Mills (1990, 1991). For the analysis *ab initio* self-consistent potentials calculated by Fu and Freeman (1987) for the Fe(110) surface were employed. The enhanced surface moments were simulated by simply scaling up the spin-dependent portion $\Delta V(\vec{r}) = V^{\uparrow}(\vec{r}) - V^{\downarrow}(\vec{r})$ of the self consistent potential by

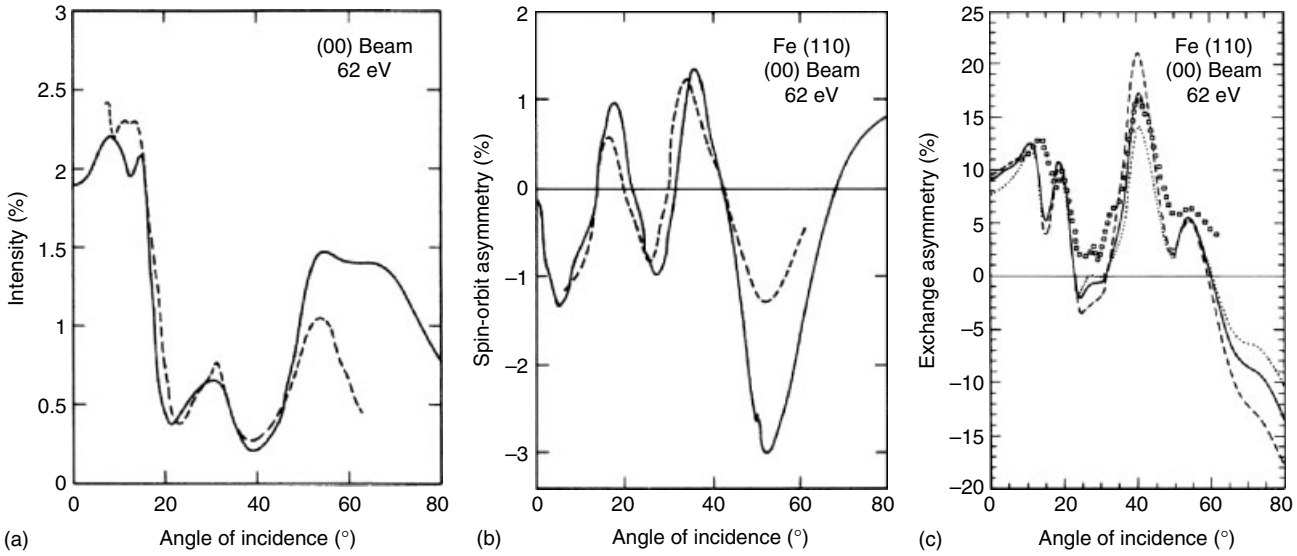

Figure 1. SPLEED from Fe(110). Comparison between theory (full lines) and experimental data (dashed lines in (a) and (b), squares in (c)) for total intensity (a), spin-orbit asymmetry (b), and exchange asymmetry (c) for the (00) spot of a Fe(110) surface at 62 eV beam energy. The measured exchange asymmetry A_{ex} (squares) is compared with theoretical results based on three different assumptions for the surface magnetic moments at the Fe(110) surface: (i) calculations based on the picture of Freeman and Fu (solid line); (ii) calculations based on the model of Tamura, Feder, Waller and Gradmann, 1990; (dashed line); (iii) calculations based on the assumption that the Fe moments assume their bulk value everywhere (dotted line). (Reproduced from A. Ormeci *et al*., 1990, with permission from American Physical Society © 1990.)

an appropriate scale factor. This is the only adjustment that was made to the potential; no adjustment was made to the overall strength of the exchange potential.

The overall agreement between theory and experiment is remarkably good. A certain discrepancy between theory and experiment remains at large angles as was pointed out in Tamura, Feder, Waller and Gradmann (1990) and Ormeci, Hall and Mills (1990). The agreement between theory and experiment for the spin-orbit asymmetry, shown in Figure 1(b), confirms the assumption for the polarization of the incident electron beam ($P = 0.3$), because it is very insensitive to the magnetic-moment profile. The features of the experimental data are reproduced nicely, though the magnitude of the negative dip in A_{so} above 40° is overestimated.

The exchange asymmetry (Figure 1c) at an incident beam energy of 62 eV comprises a considerable sensitivity to the magnitude of the near-surface moments. The solid line denotes calculations for the model of Fu and Freeman (1987), that is, 19.4% enhancement of moment in the surface layer, 6.8% in the second layer, 2.7% in the third layer, and 1.4% in the fourth. The dashed line is the prediction calculated for the model proposed in (Tamura, Feder, Waller and Gradmann, 1990), which has the surface-layer moment enhanced by 35%, and the second-layer moment diminished by 15%. All other moments assume their bulk values. The dotted line shows the exchange asymmetry calculated for a picture which takes the moments equal to their bulk value everywhere.

The prominent peak in A_{ex} near $\theta = 40^\circ$ is quite sensitive to the magnitude of the moments near the surface. The peak in the data has $A_{ex} = 0.17$, extremely close to the value provided by the model of Fu and Freeman (1987). The model of (Tamura, Feder, Waller and Gradmann, 1990) gives a maximum value of $A_{ex} = 0.21$, while the assumption of bulk moments everywhere gives $A_{ex} = 0.14$. The best overall account of the data is provided by the model of (Fu and Freeman, 1987). The finding of an enhanced surface moment at the free Fe(110) surface has been quantitatively confirmed by torsion oscillation magnetometry (TOM) (Wagner, Weber, Elmers and Gradmann, 1997).

As pointed out in Ormeci, Hall and Mills (1990), deviations between theory and experiment may occur particularly at the intensity minima. The minimum in the experimental data may be less deep than that in theory, because defects on the surface may destroy the long-range order needed for the destructive interference between scattered waves generated from various layers of the samples to produce a near zero in the total intensity. This may be a difficulty, even for samples with very high-quality surfaces. In addition, the defects produce an incoherent background of elastically scattered electrons which are collected along with those that contribute to the coherently reflected beam.

4.3 Ferromagnetic monolayer structures

4.3.1 Monolayer Fe(110) on W(110) – critical behavior

As pointed out in the preceding text, SPLEED can be used to analyze the critical behavior of ultrathin films, if A_{ex} is proportional to the magnetization with respect to its temperature dependence. SPLEED is advantageous because of its surface sensitivity, especially if the magnetization is concentrated in an ultrathin film on top of a nonmagnetic substrate (Venus and Cool, 1999). For ultrathin Fe(110)/W(110) films A_{ex} exhibits peak values of polarization up to 40 % for specific scattering conditions (Venus and Cool, 1999).

For ultrathin films, $A_{ex} \propto M$ was used for the interpretation of the data over a large range of temperatures Duerr *et al.* (1989). However, deviations from the proportionality for $t > 0.1$ ($t = (T - T_C)/T_C$) were discussed in detail for surfaces (Kirschner, 1984) and ultrathin films (Elmers and Hauschild, 1994). In (Elmers and Hauschild, 1994), strictly speaking a deviation from the proportionality has not been confirmed, because M has not been measured. But the temperature dependence of A_{ex}, at lower temperatures, deviates so strongly from everything we know about $M(T)$ that this confirms the loss of proportionality at low temperatures. $A_{ex} \propto M$ in the critical range $t < 0.1$ rests on the careful discussion in this chapter.

For a comparison of theoretical models with experiment it is crucial to prepare samples as close as possible to the structures considered by theories. The system Fe on W(110) serves as a favorable model system since it is possible to grow extended monolayers to a high degree of perfection (Przybylski, Kaufmann and Gradmann, 1989). The monolayer Fe(110)/W(110) develops a huge uniaxial magnetic anisotropy favoring an in-plane magnetic easy axis along the [1$\bar{1}$0] direction (Gradmann, Korecki and Waller, 1986; Gradmann, Przybylski, Elmers and Liu, 1989; Elmers and Gradmann, 1990; Fritzsche, Elmers and Gradmann, 1994; Elmers *et al.*, 1994; Pratzer *et al.*, 2001). According to theoretical models, one expects therefore a critical behavior close to the two-dimensional (2d)-Ising model.

2d-Ising behavior can be expected only in a narrow critical temperature region ΔT below and above T_C. As a result of the scaling theory (Pfeuty and Toulouse, 1977) $\Delta T/T_C$ is for a 3d system with anisotropy constant K of the order $K/k_bT_C \approx 10^{-3}$, which would make the critical behavior practically impossible to observe. In 2d systems, however, large regions of correlated spins occur even far from the phase transition (Demokritov, Kreines, Kudinov and Petrov, 1989), effectively broadening the critical region by a factor $J/K \approx 10^2$. For an investigation of the critical region, we therefore concentrate on the temperature region $\Delta T_C/T_C < 0.1$.

For uncovered Fe monolayers, the magnetic order $M(H, T)$ was determined via the exchange asymmetry, $A_{ex}(H, T)$, of reflected spin-polarized electrons (Elmers, 1995). The incident angle and energy of the spin-polarized electrons were chosen such that A_{ex} was maximized. In this experiment, a small field could be applied via the Oerstedt field of a current running through the substrate crystal, thus allowing to determine not only the magnetization but also the magnetic susceptibility. For fields below 2 Oe, the deflection of electrons due to the Lorentz force could be neglected. The result for the temperature dependence of the spontaneous magnetization $M_0(T) \propto A_{ex}(T)$ and of the magnetic susceptibility $\chi(T)$ is shown in Figure 2.

A careful evaluation of $A_{ex}(H, T)$ for very low fields $H \leq 2$ Oe (Elmers, Hauschild and Gradmann, 1995a, 1995b) verified that $M_0(T)$ equals the remanent magnetization $M(H = 0, T)$, which was originally determined in the experiment. Figure 2 shows a steep decrease of $M_0(T)$ near $T = 222$ K, followed by an inflection point at $T_{infl} = 222.5$ K and a final vanishing at $T^* = 223.4$ K. This typical tail is frequently observed for ultrathin films and often associated with finite size effects (Duerr *et al.*, 1989). Note, however, that the extension of the tail, in our case, is of the order of just 0.5% of T_C. We find a satisfying explanation for the tail

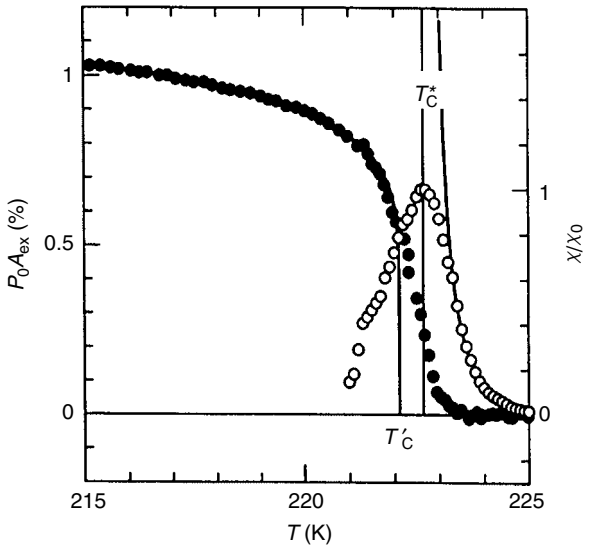

Figure 2. Exchange asymmetry P_0A_{ex} (●) in the remanent state of 0.8-ML Fe on W(110), deposited at 660 K, as a function of temperature. Susceptibility χ/χ_0 (○) versus T for the same sample. Full lines represent power laws $A_{ex} \propto (T'_C - T)^{\beta'}$ and $\chi \propto (T - T'_C)^{-\gamma'}$, with values for the critical temperature $T'_C = 222.1$ K and for exponents $\beta' = 0.124$ and $\gamma' = 3.2$. $T^*_C = 222.6$ K defines the maximum of χ. (Reproduced from H.J. Elmers *et al.*, 1995, with permission from World Scientific. © 1995.)

shown in Figure 2 assuming a small distribution of Curie temperatures in our sample. In fact, the sample consists of monolayer stripes formed adjacent to terrace steps on the substrate. The distribution of the terrace width results in a variation of the stripe widths and consequently of T_C. In this picture, every individual magnetic stripe, as formed in the step flow growth mode, shows a second-order phase transition (no tail) but with slightly different T_C. The averaging over the distribution results in the tail. Even for a single stripe of uniform width a tail has been predicted by Landau (1976) who demonstrated by MC simulations that long-range order in the 2d-Ising model on a finite sized quadratic square lattice shows similar tails above T_C. This minor effect, however, can be neglected in the experiment described here.

For a determination of the critical exponent, $A_{ex}(T)$ was fitted numerically to a power law $A_{ex}(T) \propto (T - T'_C)^{\beta'}$ in the region $0.9 < T/T_C < 0.996$, thus avoiding the temperature region affected by the tail. The fit results in a critical temperature $T'_C = 222.1(1)$ K, which can be appointed to the Curie temperature of the system, and in the critical exponent $\beta' = 0.124(1)$, which is in agreement with the theoretical value $\beta = 1/8$ of the 2d-Ising model. The accuracy of the fit can be estimated from a double logarithmic plot (Figure 3).

As was shown by a more thorough study of the critical behavior (see Elmers, Hauschild and Gradmann (1996)), the magnetization tail above T_C can be interpreted as a result of convolution of the critical power law with the monolayer stripe width distribution. Using an appropriate deconvolution

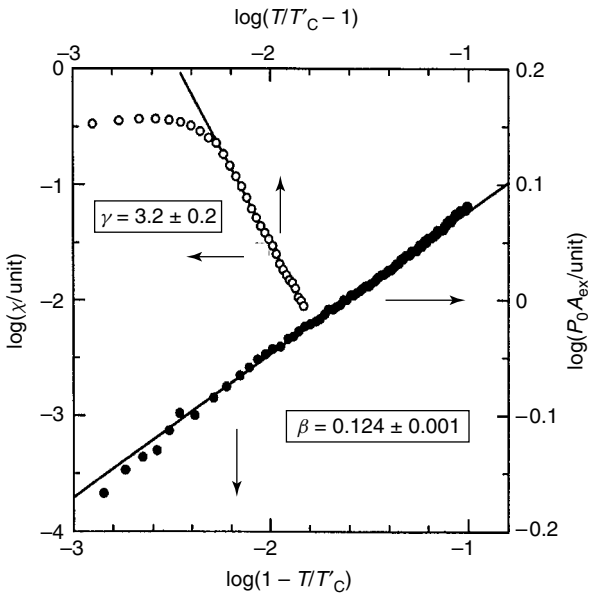

Figure 3. Double logarithmic plot of susceptibility χ (○) and exchange asymmetry A_{ex} (●) versus reduced temperatures (data from Figure 2). Exponents resulting from the slope are $\beta' = 0.124$ and $\gamma' = 3.2$. (Reproduced from H.J. Elmers *et al.*, 1995, with permission from World Scientific. © 1995.)

scheme, critical power laws could be established for both magnetization and susceptibility with critical exponents $\beta = (0.134 \pm 0.003)$ and $\gamma = (2.8 \pm 0.2)$. These values form a small but definite deviation from the 2d-Ising model. The enhanced value of γ can be explained from the fact that the anisotropy energies per atom are smaller than exchange coupling energies. The enhanced value of β is indicative of long-range interactions.

The magnetic susceptibility was determined from the initial increase of A_{ex} with increasing external fields. As shown in Figure 2, $\chi(T)$ exhibits a maximum value χ_0 at a temperature $T^*_C = 222.65$ K well above T'_C ($T^*_C = (1 + 2.5 \times 10^{-3})T'_C$). The deviation of the maximum of the susceptibility from the Curie temperature can be understood from the following argument. It is well known (Essam and Fisher, 1963) that $\chi(T)$ rises much faster when approaching T_C from $T < T_C$ than from $T > T_C$. The rise is limited at T^- (for $T < T_C$) and at T^+ (for $T > T_C$) because of the limited size of the sample (magnetic islands). Now, T^- is much closer to T_C than T^+, and consequently, the maximum will show up at some mean value in between T^- and T^+, which should be above T_C.

A rough estimate of the absolute value of χ_0, assuming bulk magnetization at $T = 0$ K and a proportionality $M \propto A_{ex}$ even for $T \ll T'_C$, results in $\chi_0 \approx 10^3$ (SI units), which is somewhat smaller than previous observations for Fe on W(110) (Back, Wuersch, Kerkmann and Pescia, 1994). As was pointed out by Farle *et al.* (1993), the maximum value of χ observable in an experiment is limited by the in-plane demagnetization factor $1/N_\parallel$, which is roughly given by $1/N_\parallel = \rho/t$ for islands of diameter ρ and thickness t. In turn, the large susceptibility we observed for the Fe(110)/W(110) monolayer, corresponds to magnetic islands with an effective diameter of $\rho = 5\,\mu$m.

At temperatures below the maximum value of the susceptibility, $\chi(T)$ can be approximated by a power law, $\chi(T) \propto (T'_C - T)^{-\gamma'}$. A double logarithmic plot (Figure 3) reveals a linear behavior, resulting in an exponent $\gamma' = 3.2(2)$, which is definitely above the 2d-Ising value $\gamma = 7/4$. Note that we used T'_C for the logarithmic plot. We find that, in contrast to the case of β', the exponent γ' strongly depends on the choice of the critical temperature (without affecting the linear behavior in the double logarithmic plot). If we took, for example, T^*_C as the Curie temperature of the system, the corresponding power-law fit would result in a critical exponent $\gamma' = 1.75(10)$, surprisingly close to the Ising value.

4.3.2 Submonolayer Fe(110) on W(110): ferromagnetic monolayer stripes

Fe grows pseudomorphically from the steps of the W substrate (step flow growth) in continuous stripes of monoatomic

height Elmers *et al*. (1994). The second layer starts only after the completion of the first layer. The width $b = \Theta w$ of the Fe stripes can be controlled by the Fe coverage Θ with w being the width of the W terrace. Certainly, the W substrate will show an arbitrary distribution of terrace widths. Employing mean values for b and w, one may reinterpret Θ in terms of an average stripe width. The mean width of the W terraces in the experiment reported here was $\overline{w} = 40\,\text{nm}$.

Figure 4 shows $P_0 A_{ex}(T) \propto M_0(T)$ for Fe films with decreasing coverage, down to a coverage of only $\Theta = 0.1$. The remarkably high signal-to-noise ratio emphasizes the sensitivity of the SPLEED probe. The magnetic phase transition, which is sharp for Θ close to the complete monolayer, smears out for decreasing Θ, that is, for decreasing stripe width. The Curie temperature $T_C(\Theta)$ was determined operationally from the point of inflection in the $M_0(T)$ curves. The increase of $T_C(\Theta)$ as a function of Θ is shown in Figure 5. It can be interpreted as an increase of $T_C(b)$ as a function of the stripe width b, as explained in the caption.

The dispersion of stripe widths can be estimated from $M(H)$ in the vicinity of T_C. Assuming a Gaussian distribution of the terrace width w with a full width at half maximum of Δw and a mean value $\overline{w} = 40\,\text{nm}$, the distribution of the stripe width then results via $T_C(b)$ (see Figure 5) in a distribution of Curie temperatures with the mean value given by $T_C(\Theta\overline{w})$. In this model, the phase transition of a single stripe follows the ideal power law; however, the averaging causes a tail in the $M_0(T)$ relation with a width ΔT roughly increasing with $\Delta w\, \mathrm{d}T_C/\mathrm{d}b$. A comparison of this simple model with the experimentally observed tails results

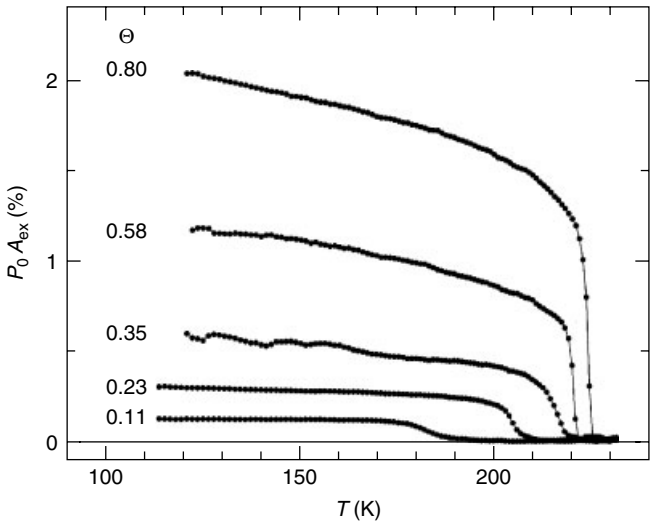

Figure 4. $P_0 A_{ex}(T) \propto M_0(T)$ versus T for electron reflection from Fe(110) films prepared at 660 K on W(110) with total coverage Θ. The spin polarization P_0 of the incident electron beam is roughly 20%. (Reproduced from H.J. Elmers *et al*., 1994, with permission from American Physical Society. © 1994.)

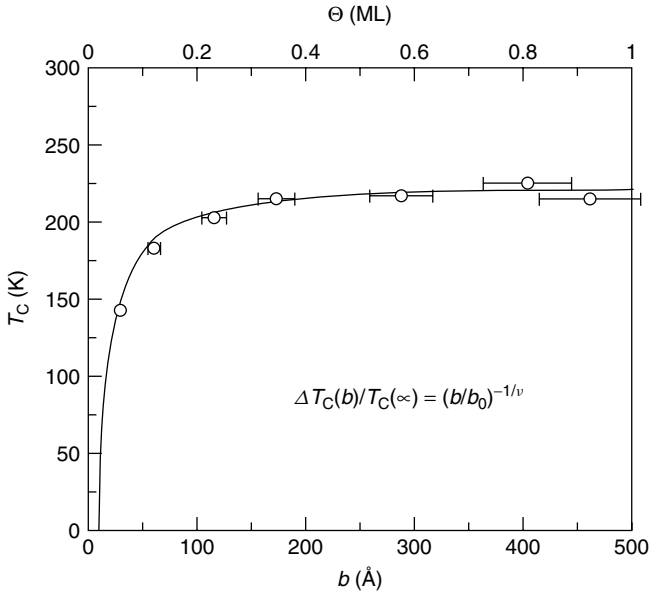

Figure 5. Curie temperature T_C versus coverage Θ for Fe(110) deposited on W(110) at 660 K (○). Stripe width from $b = w\Theta$ with $w = 40\,\text{nm}$. Error bars indicate the mean half width ($0.1b$) of the distribution of Fe stripe widths. The power-law fit as indicated in the figure (full line) results in $\nu = 0.97(14)$, $T_C(\infty) = 230\,\text{K}$, and $b_0 = 0.8\,\text{nm}$. (Reproduced from H.J Elmers *et al*., 1995, with permission from World Scientific. © 1995.)

in a value $\Delta w/\overline{w} = 0.1$, independently of the coverage. An excellent agreement of the model and the experimental data was found for all coverages $0.05 \leq \Theta(\text{ML}) \leq 0.8$.

The decreasing values of T_C for increasing $\Theta > 0.8$ are presumably related to an interaction appearing when the separated stripes are closing in. The finite size scaling for the two-dimensional stripes results in the power law, $1 - T_C(b)/T_C(\infty) = (b/b_0)^{-1/\nu_2}$, with $T_C(\infty)$ denoting the Curie temperature of the extended monolayer. A three-parameter fit to the experimental data (see Figure 5) results in $T_C(\infty) = T_C(\text{ML}) = 230\,\text{K}$, $b_0 = 0.8\,\text{nm}$ and $\nu_2 = 0.97 \pm 0.14$. The critical exponent of the two-dimensional correlation length ν_2 is close to the value $\nu_2 = 1$ predicted for the 2d-Ising model. The stripe width b_0 marks the onset of ferromagnetic order, corresponding to four atomic chains in the stripe.

4.3.3 Bilayer Fe(100) on W(100) – critical behavior of the 2d-XY model

Despite the lack of a full theoretical understanding, spontaneous magnetization was found experimentally in ultrathin films without uniaxial anisotropy (Elmers, 1995). Without uniaxial anisotropy, the spontaneous magnetization M_0 lies in the film plane. In most cases, the anisotropy was not determined explicitly, but can be deduced from the symmetry of

the film. For films of cubic symmetry in the (100) plane, the most significant contribution to the anisotropy energy will be of fourfold symmetry resulting in a biaxial anisotropy which is weak in comparison to the uniaxial anisotropy discussed in the preceding text.

The critical behavior of 2d systems where the magnetization can rotate freely in the film plane (2d-XY model) was discussed in Bramwell and Holdsworth (1993a) with the result of quasispontaneous magnetization and a critical exponent of $\beta = 1/4$. Instead of the power-law behavior regularly found in magnetic systems, the magnetic susceptibility was predicted to increase exponentially (Kosterlitz, 1974) in a 2d-XY model.

Magnetic properties were investigated (Elmers and Hauschild, 1994) for Fe layers on W(100). It was confirmed experimentally that Fe/W(100) films even up to a coverage $\Theta = 2\,\mathrm{ML}$ are thermodynamically stable (Elmers and Hauschild, 1994). Moreover, Fe grows pseudomorphically on the W(100) substrate (Elmers and Hauschild, 1994) with an expansion of 9.4% due to the lattice mismatch, thus forming a promising epitaxial system for studying 2d magnetism.

Using SPLEED, the exchange asymmetry, A_{ex}, was measured as a function of temperature and external field H for an annealed ($T_{\mathrm{a}} = 550\,\mathrm{K}$) Fe(100)/W(100) film. The thickness well below the bilayer ($\Theta = 1.6\,\mathrm{ML}$) guarantees the absence of effects evoked by triple layer islands.

Figure 6 shows the temperature dependence of the spontaneous magnetization $M_0(T)$ and the magnetic susceptibility $\chi(T)$ just in the critical regime. Imperfectnesses of the two-dimensional sample, like finite sized islands or a distribution of island sizes, cause the tail of $M_0(T)$ just above T_{C}. The tail covers only a small temperature region of $\Delta T \approx 1\,\mathrm{K}$ ($0.005\,T_{\mathrm{C}}$). This might be taken as a hint for the good quality of the sample. The power law $M_0(T) \propto (T'_{\mathrm{C}} - T)^{\beta'}$ fits the experimental data $A_{\mathrm{ex}}(T) \propto M_0(T)$, resulting in the critical temperature $T'_{\mathrm{C}} = 207.8(2)\,\mathrm{K}$ (the Curie temperature for this special film) and in an effective exponent $\beta' = 0.217(5)$. The double logarithmic plot (Figure 7) reveals the result $\beta = 0.22(1)$ of the fit. This value is consistent with the theoretical value for the 2d-XY model, $\beta = 3\pi^2/128 \approx 0.23$ (Bramwell and Holdsworth, 1993b).

Here χ was derived from the difference $\Delta M = M(H_1, T) - M(0, T)$, of the magnetization in an external field $H = 0.6\,\mathrm{Oe}$ compared with the magnetization in the remanent state. In the limited temperature interval ($0.98\ T'_{\mathrm{C}}, 1.02\ T'_{\mathrm{C}}$) around T'_{C}, $\Delta M(H)$ showed a nonlinear increase (with decreasing slope) as a function of H, thus providing only a lower limit for χ, only.

For $T < 0.98\ T'_{\mathrm{C}}$ and $T > 1.02\ T'_{\mathrm{C}}$, ΔM turned out to increase linearly with H, thus allowing for a determination of $\chi(T)$. Figure 7 shows a double logarithmic plot of $\chi(T > T'_{\mathrm{C}})$ using the critical temperature T'_{C} determined from the fit of $M_0(T)$ (Figure 6). A fit using the exponential law, $\chi \propto \exp(b/\sqrt{T/T'_{\mathrm{C}} - 1})$, agrees well with the experimental data. The fit results in a parameter $b = 1.6(1)$, which is of the order of magnitude predicted for the pure 2d-XY model with nearest-neighbor interaction, $b(2\mathrm{d} - XY) = 2.6$ (Kosterlitz, 1974).

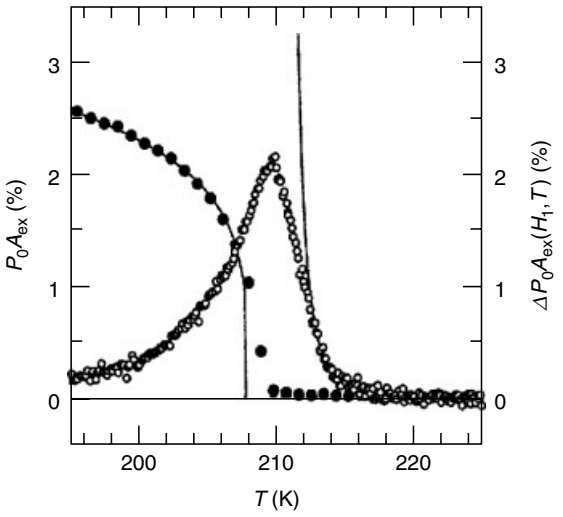

Figure 6. Exchange asymmetry P_0A_{ex} (●) in the remanent state of 1.6-ML Fe on W(100), deposited at 300 K and subsequently annealed at $T = 550\,\mathrm{K}$, as a function of temperature. Increase $\Delta P_0A_{\mathrm{ex}} = P_0[A_{\mathrm{ex}}(H_1, T) - A_{\mathrm{ex}}(0, T)]$ of exchange asymmetry with an external field $H_1 = 0.63\,\mathrm{Oe}$ as a function of temperature (○). The solid lines represent a power law $A_{\mathrm{ex}} \propto (T'_{\mathrm{C}} - T)^{\beta'}$ and an exponential law $\Delta P_0A_{\mathrm{ex}} \propto \exp(b/\sqrt{(T/T'_{\mathrm{C}} - 1)})$, respectively, with values for the critical temperature $T'_{\mathrm{C}} = 207.8\,\mathrm{K}$ and for exponents $\beta' = 0.22$ and $b = 1.6$. (Reproduced from H.J. Elmers *et al.*, 1995, with permission from World Scientific. © 1995.)

4.3.4 *Bilayer Fe(100) on W(100) – magnitude of magnetization*

In this section, an example is given about how magnetic *and* structural information can be gained by a comparison of experimental and theoretical data of SPLEED data (Plihal, Mills, Elmers and Gradmann, 1995). For this purpose, a ferromagnetic bilayer of very high quality is chosen, that is, the pseudomorphic Fe bilayer Fe(100)/W(100) (Elmers and Hauschild, 1994). Another advantage is that this bilayer has been studied theoretically by *ab initio* calculations (Wu and Freeman, 1992).

In order to obtain information on the angular variation of the specular reflectivity, the SPLEED intensities are measured at various energies. Both the spin-orbit asymmetry A_{so} and the exchange asymmetry A_{ex} is evaluated. For comparison with theoretical data, relativistic multiple-scattering theory has been applied according to the scheme outlined in Section 2.6.

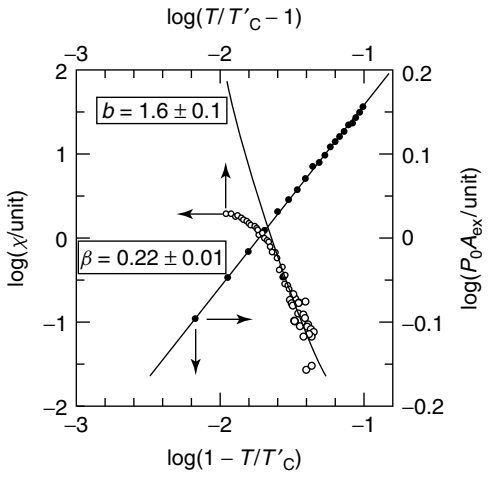

Figure 7. Double logarithmic plot of susceptibility χ (○) and exchange asymmetry A_{ex} (●) versus reduced temperatures. (Data from Figure 6.) Full lines represent fits to the power law and to the exponential law, respectively, with parameters as indicated in the figure. (Reproduced from H.J. Elmers *et al*., 1995, with permission from World Scientific. © 1995.)

The Fe bilayer was magnetized by field pulses of 2 Oe along the [001] axis in the film plane. Asymmetries A^+ and A^- for both magnetization directions were then determined in the remanent state at $T = 115$ K which is below the Curie temperature $T_C = 225$ K of this system. Spin-orbit and exchange asymmetries were separated as described in Section 2.4 neglecting a weak interference correction A_u. In this geometry, A_{ex} is sensitive to the magnetization component parallel to [001]. Plihal, Mills, Elmers and Gradmann (1995) assumed that [001] is the easy axis of this system following previous magnetic studies (Venus and Johnston, 1994; Jones and Venus, 1994; Elmers and Hauschild, 1994). Later, a magnetic easy axis along [011] as reported already in (Mulhollan, Fink, Erskine and Walters, 1991) was confirmed by Wulfhekel *et al*. (2003) using spin-polarized scanning tunneling microscopy (Wulfhekel *et al*., 2003). They observed a switch of the magnetic easy axis from [011] toward [100] with increasing thickness. Therefore, the remanent magnetization assumes in the geometry used for the SPLEED experiment only a value of 0.7.

In order to determine the geometrical structure of the film, experimental and theoretical curves were compared for the spin-orbit asymmetry. In Figure 10, the angular variation of the data (solid circles) are compared with theoretical calculations (solid lines) for various overlayer geometries. Here, a_1 is the distance between the outermost plane of the tungsten nuclei and the first layer of Fe nuclei, and a_2 is the spacing between the two Fe layers. Note that the spin-orbit asymmetries are much larger than those realized on the Fe(110) surface (Waller and Gradmann, 1982). The large values of

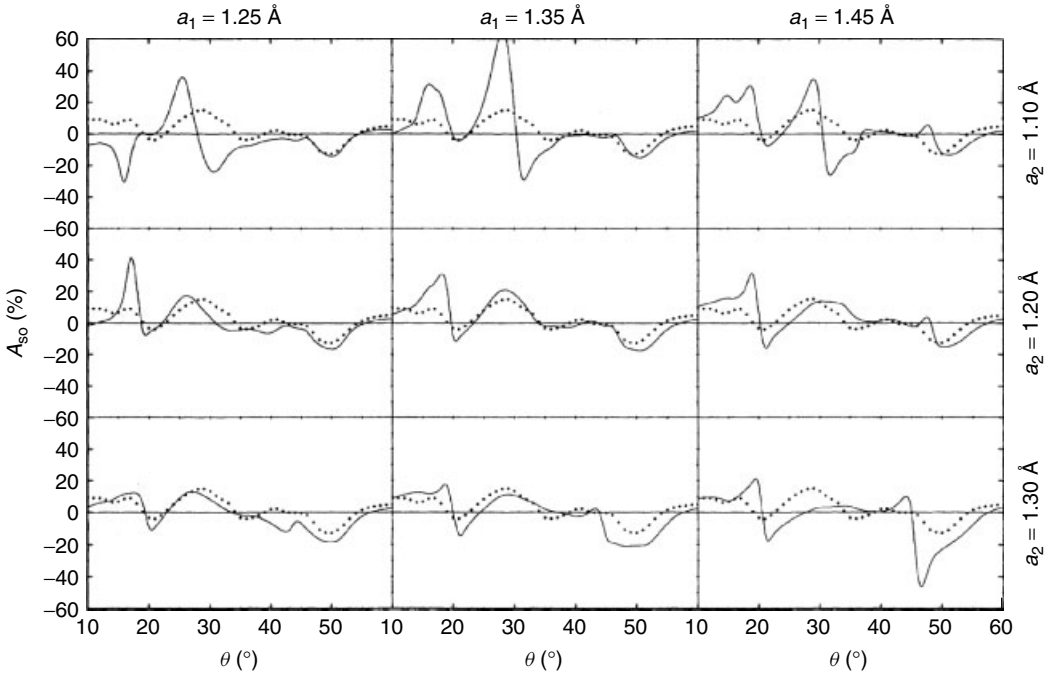

Figure 8. For various values of the layer spacings a_1 and a_2, calculated and measured values of the spin-orbit asymmetry are shown; the electron-beam energy is 90 eV, measured relative to the Fermi level. Here, a_1 is the spacing between the outer layer of W nuclei and the innermost Fe layer, while a_2 is the spacing between the outermost two Fe layers. The solid lines are theoretical results and the dotted line is experimental data. (Reproduced from M. Plihal *et al*., 1995, with permission from the American Physical Society. © 1995.)

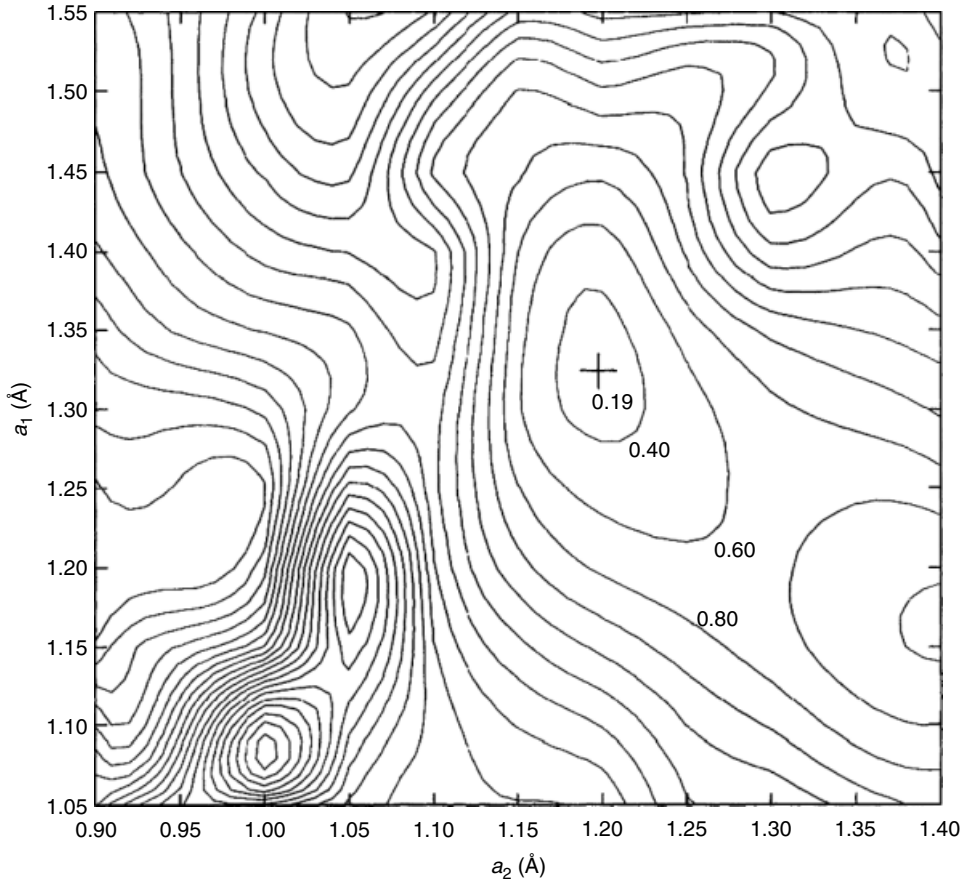

Figure 9. Contours of constant mean-square displacement, associated with the difference between the calculated and measured spin-orbit asymmetry, at 90 eV. The cross marks the absolute minimum. (Reproduced from M. Plihal *et al*., 1995, with permission from the American Physical Society. © 1995.)

A_{so} shown in Figure 10 have their origin in the penetration of the electron wave into the W substrate. The values of A_{so} are smaller than found in pure W, because the electron wave is attenuated by the Fe.

The structural sensitivity of A_{so} is apparent upon scanning the various geometries included in Figure 8. Substantial changes in the angular variations of A_{so} result from displacements of the Fe layers by ± 0.1 Å. In LEED analyses, optimum geometries usually are deduced by minimizing the R factor. Because absolute values are compared for A_{so}, it is useful to simply employ the mean-square deviation between theory and experiment as a measure of goodness of the fit here. In Figure 9, we show contour plots of the mean-square deviation, in the $a_1 - a_2$ plane. There is a clear minimum at the values $a_2 = 1.20$ Å and $a_1 = 1.32$ Å. The remaining extrema in the figure are maxima, though there is another minimum near $a_2 = 0.97$ Å and $a_1 = 1.24$ Å. From similar plots for various energies one finds the latter minimum not significant and the most likely values for the lattice distances of $a_2 = 1.20$ Å and $a_1 = 1.35$ Å. The spacing between the two outermost Fe layers a_1 is in very good agreement with theoretical values found in Wu and Freeman (1992), while for a_2 a much smaller value of 1.09 Å was found. A recent *ab initio* calculation (Qian and Huebner, 2003) considering the W-5p states correctly found a distance of $a_2 = 1.25$ Å for the first monolayer Fe on W(100), thus confirming the SPLEED analysis well.

The exchange asymmetry A_{ex} is analyzed in Figure 10 where a comparison between theory and experiment is shown. Here, μ_2 is the moment in the outermost layer and μ_1 is the moment in the innermost layer and $\mu_{Fe} = 2.2\,\mu_B$ denotes the bulk moment. The chosen moments represent the best fits out of a larger variety of calculated spectra (Plihal, Mills, Elmers and Gradmann, 1995), although the calculated spectra appear not dramatically sensitive to the choice of magnetic moments. Although the theory clearly reproduces the experimental trends, the agreement is less good than found for the spin-orbit asymmetry. Part of the problem may reside in the use of bulk Fe forms for the exchange potential. This may be a problem, particularly for the innermost Fe

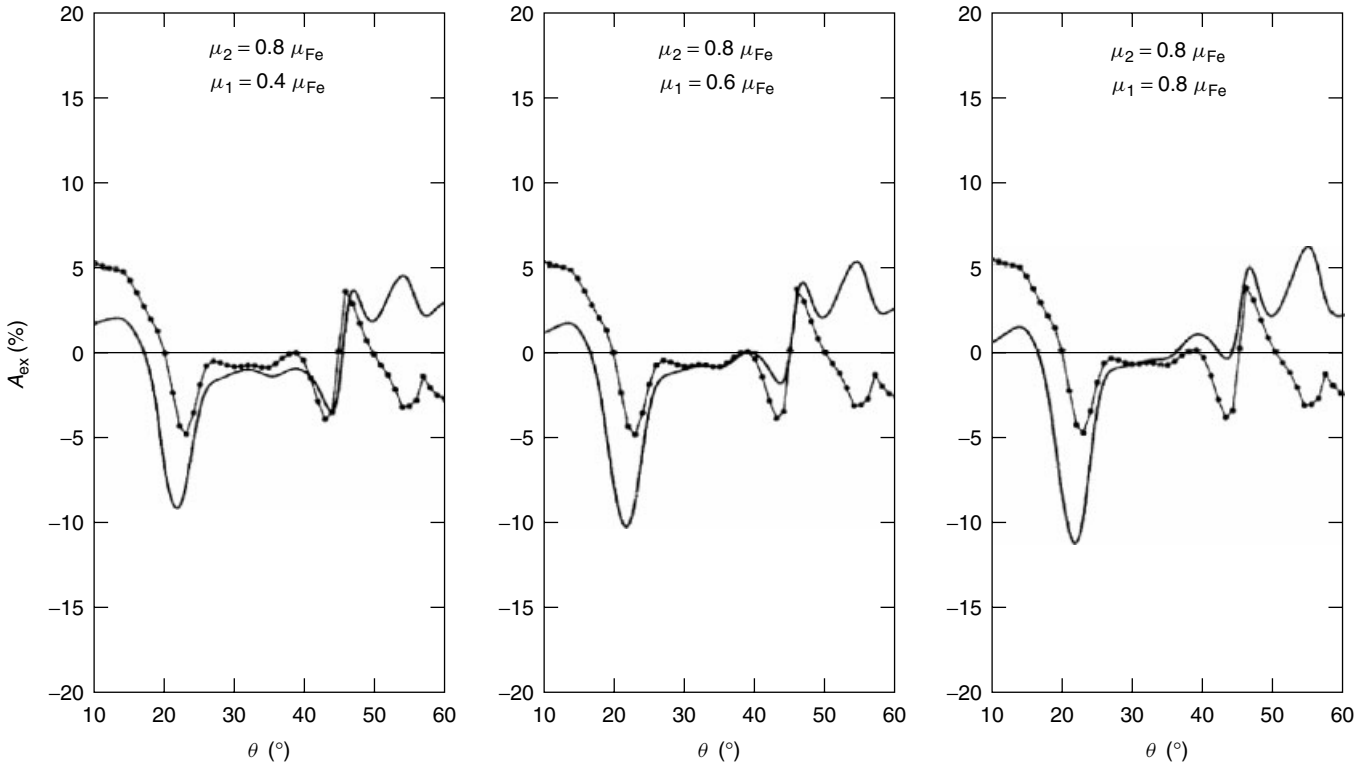

Figure 10. Sensitivity of the exchange asymmetry to the variation of surface moments. The top layer moment $\mu_2 = 0.8\,\mu_{Fe}$ is fixed. The inner Fe layer moment μ_1 is varied between 0.4 and $0.8\,\mu_{Fe}$ where μ_{Fe} is the magnetic moment of bulk Fe. The beam energy is 120 eV. The solid lines are theoretical results, and the dotted line is experimental data. (Reproduced from M. Plihal *et al.*, 1995, with permission from the American Physical Society. © 1995.)

layer, where 3d electrons will hybridize with the W 5d electrons. Indeed, Wu and Freeman (1992) found a very small moment at the outermost W layer in their calculations.

The magnetic moments of $\mu_1 = 1.3\,\mu_B$ and $\mu_2 = 1.8\,\mu_B$ (Plihal, Mills, Elmers and Gradmann, 1995) found here are smaller than magnetic moments predicted theoretically. Wu and Freeman (1992) calculated $\mu_1 = 1.68\,\mu_B$ and $\mu_2 = 2.43\,\mu_B$. Qian and Huebner (2003) found a value of $\mu_1 = 2.1\,\mu_B$ for only 1 ML Fe/W(100). Part of this discrepancy can be attributed to the fact that the experimental asymmetries were presumably measured at a remanent value of 0.7 of the saturation value. Moreover, the measurement was performed at a temperature of $0.5\,T_C$, which might reduce magnetic moments further (Elmers, 1995). Thus, the agreement between theory and experiment is acceptable. The trend of a lower moment at the W interface is correctly reproduced.

4.4 Band structure analysis – toward efficient spin detectors

The mean free path of electrons increases below ca 20 eV in many materials (Seah and Dench, 1979). Moreover, since the only remaining diffraction spot is the (00) spot, the reflected intensity increases considerably. These facts make the regime of very low kinetic energy particularly interesting for application in spin detectors (see Section 3.2) and for the investigation of buried layers. Since spurious magnetic fields easily deflect the electrons of low energy, special diffraction geometries are necessary. In most cases, an immersion lens as part of an electron emission microscope retards the electrons just before the sample surface (Altman *et al.*, 1991) as discussed in Section 3.

As an example (Graf *et al.*, 2005) Figure 11(c) and (d) show the average reflectivity for Co and Fe in a gray-scale plot versus electron energy and film thickness, respectively. The energy dependence of reflectivity for films of different thickness seems to have at least two periodic components. The authors assume (Graf *et al.*, 2005) that the energy independent component visible at low thicknesses (white arrows in Figure 11d) is due to the varying density of steps during deposition. The reflectivity minima (dark) coincide with half completed monolayers (higher surface step density) and the maxima (bright) occur with the completion of each monolayer slow surface step density. These growth oscillations are most clear at small film thickness and are

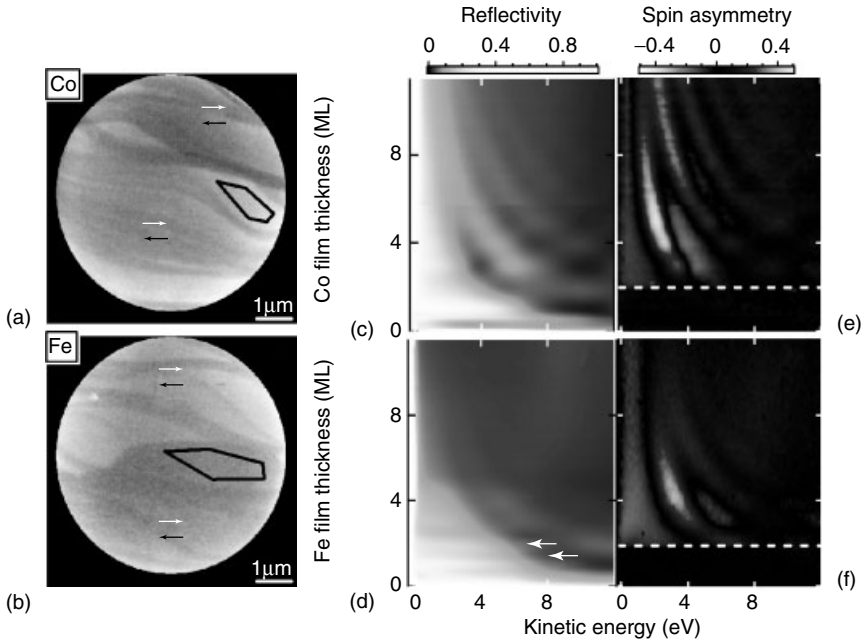

Figure 11. (a and b) Real space image of magnetic domains in Fe/W(110) and Co/W(110) films with indicated areas of uniform magnetization used for the analysis. Gray-scale (c and d) plots of the measured reflectivity as a function of the electron kinetic energy (horizontal axis) and film thickness (vertical axis) for Fe/W(110) and Co/W(110) films. (e and f) Gray-scale plots of the spin asymmetry of the reflectivity. (Reproduced from J. Graf *et al*., 2005, with permission from the American Physical Society. © 2005.)

used to calibrate the film deposition rate. The component of interest is energy dependent and looks like hyperbolic shaped maxima (bright) and minima (dark) in the reflectivity plots. This is a bulk and intrinsic effect known as the quantum size effect (QSE) (Zdyb and Bauer, 2002a, 2002b; Scheunemann *et al*., 1997). More specifically, a ferromagnetic slab acts like a resonant cavity and induces interference patterns. The QSE is more pronounced for Co/W(110) than for Fe/W(110) films. This might be attributed as suggested in Graf *et al*. (2005) to kinetic roughening during room-temperature growth of Fe/W(110) (Albrecht, Fritzsche and Gradmann, 1993).

The spin asymmetry (A_{ex}) versus kinetic energy and film thickness is shown in Figure 11(e) and (f). For the calculation of A_{ex} a polarization of $P = 0.2$ of the incident electron beam was assumed. The white dashed lines at 2 ML film thickness in Figure 11(e) and (f) clearly separate a uniform black region from a modulated red and blue region. The featureless black region indicates $A_{ex} = 0$ for both Fe and Co films. This can be explained by noting that the Curie temperature T_C of Fe/W(110) films is above room temperature only for film thicknesses greater than 2 ML (Elmers *et al*., 1995). A similar decrease of T_C was observed for thin Co films. The measurement above T_C shows a qualitatively similar hyperbolic behavior of the oscillating asymmetry. Figure 12(a) shows energy scans of the spin-dependent reflectivity for different Co film thicknesses. The reflectivity for the antiparallel spin shows a red shift with respect to the case of parallel spin. The reflectivity oscillation in the case of spin parallel are damped with respect to the antiparallel spin.

These observations suggest that two mechanisms contribute to the total spin asymmetry. The spectra for film thickness larger than 5–6 ML are mainly dominated by the damping mechanism. The damping was attributed (Graf *et al*., 2005) to different mean free paths for spin parallel or antiparallel to the majority spin. Indeed it is known that the so-called universal curve (Seah and Dench, 1979) predicts a very large value of the IMFP for transition metals at low energy. Spin-dependent values of the IMFP of the order of a few monolayers have been reported at very low energies (Pappas *et al*., 1991; Passek, Donath and Ertl, 1996; Getzlaff, Bansmann and Schoenhense, 1993). A red shift of the antiparallel spin reflectivity spectra can be clearly observed in Figure 12(b) for the spin-dependent reflectivity for a 4-ML thick Co/W(110) film. The large gradients of the reflectivity induced by the quantum well states (QWS) are slightly shifted for electrons of opposite spin owing to the exchange splitting of the band structure. The minima and the maxima of the reflectivity indicated with the light and dark arrows are shifted by 0.3 and 0.15 eV, respectively. It is the combination of this energy shift with the large gradients in the reflectivity that causes a significant enhancement or reduction of the magnetic asymmetry (Figure 12c). This seems to be the dominant mechanism at small film thickness even in

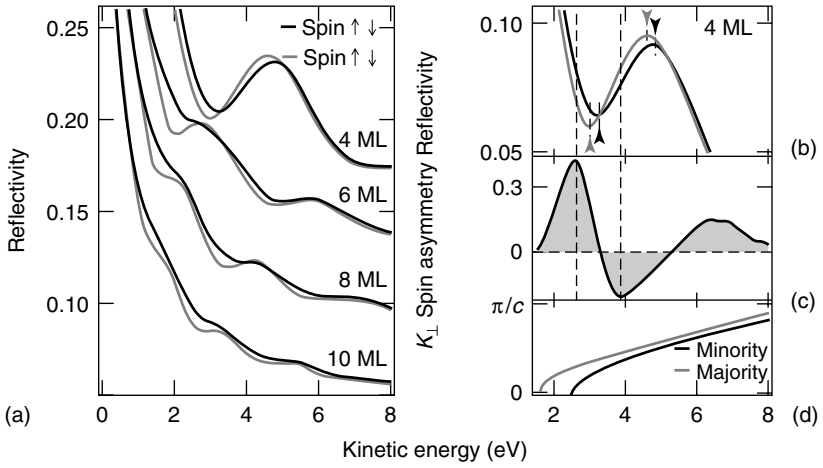

Figure 12. (a) Energy dependence of the reflectivity for spin parallel and antiparallel to the Co/W(110) film magnetization for different film thickness. The energy scans are incrementally shifted by 0.05. (b) Expanded view of the spin dependence of the reflectivity for the 4-ML thick film. (c) Spin asymmetry for a 4-ML thick Co/W(110) film obtained from Figure 11(e). (d) Band structure calculation for a 4-ML thick Co/W(110) film (Scheunemann *et al*., 1997). (Reproduced from J. Graf *et al*., 2005, with permission from the American Physical Society. © 2005.)

the presence of some inelastic damping. Figure 12(d) shows a band structure calculation along the perpendicular direction for a 4-ML Co/W(110) thin film (Scheunemann *et al*., 1997). The first maxima at 2.6 eV of the spin asymmetry may have a contribution from the exchange-split band gap. But there is no band gap at the second maxima at 4.7 eV which is caused by the finite size effects at small film thicknesses. This observation emphasizes that the interference of the electron wave function due to the reflection at both interfaces dominates and the film thus acts as an effective spin-selective interferometer (Zdyb and Bauer, 2002b; Egger, Back, Krewer and Pescia, 1999; Scheunemann *et al*., 1997).

While the example described above concerns the interference of an electron wave in the ferromagnetic film, similar spin-dependent interference patterns can also be observed in a nonmagnetic film if at least one interface is ferromagnetic. For Cu thin films grown on fcc Co/Cu(100), the electron reflectivity from the Cu thin film exhibits Fabry–Pérot type interference (Wu *et al*., 2005). When the Cu thickness increases, the energies of the interference peaks decrease (or increase) for **k** vector greater (or less) than half of the Brillouin zone (BZ) vector. This interference effect results in a spin asymmetry of the electron reflectivity from the Cu film.

Since in a nonmagnetic overlayer the electron wave function is independent of the spin, the spin-dependent reflectivity is only determined by the interfaces. If the complex reflectivities of the electron wave in Cu at the Cu/vacuum and Cu/Co interfaces are $r_B \exp(i\phi_B)$ and $r_C \exp(i\phi_C)$, respectively, where r and ϕ denote the magnitude and phase gain of the electron reflection at the corresponding interface, the total electron reflectivity is given by satisfying the continuity boundary conditions at the two Cu interfaces:

$$R = \frac{r_B^2 + r_C^2 + 2r_B r_C \cos(2kd_{Cu} + \phi_B + \phi_C)}{1 + r_B^2 + r_C^2 + 2r_B r_C \cos(2kd_{Cu} + \phi_B + \phi_C)} \qquad (25)$$

Here, d_{Cu} is the Cu overlayer thickness and k is the electron momentum vector in the Cu film. Equation 25 describes a classical Fabry–Pérot interferometer. The reflection phases for hot electrons at the upper and lower interface of the Cu film are calculated as $\phi_B = 0$ and $\phi_C = \pi - 2\arcsin\sqrt{(E - E_L)/E_U - E_L}$, where $E_U = 9.6$ eV and $E_L = 2.5$ eV are the upper and lower edges of the Co energy gap (Mankey, Willis and Himpsel, 1993; van Gelderen, Crampin and Inglesfield, 1996).

The maximum electron reflectivity takes place at the interference condition of $2kd_{Cu} + \phi_B + \phi_C = 2\pi n$, with an integer n. This is exactly the result of the phase accumulation model (Smith, Brookes, Chang and Johnson, 1994) for QWS below the vacuum level. Therefore, the phase accumulation model describes both the confined QWS below the vacuum level and the interference condition above the vacuum level. In a solid, an electron also experiences the lattice periodic potential which generates an envelope function for the electron Bloch wave (Qiu and Smith, 2002). This condition for constructive interference should be valid as well for $k < k_{BZ}/2$ (k_{BZ} is the Brillouin zone wave vector) as for $k > k_{BZ}/2$. In the latter case, the condition describes the electron envelope function arising from a beating effect between the electron wave and the periodic lattice potential at $k > k_{BZ}/2$. The different interpretation of the maximum condition leads to an opposite energy versus thickness dispersion for QWS

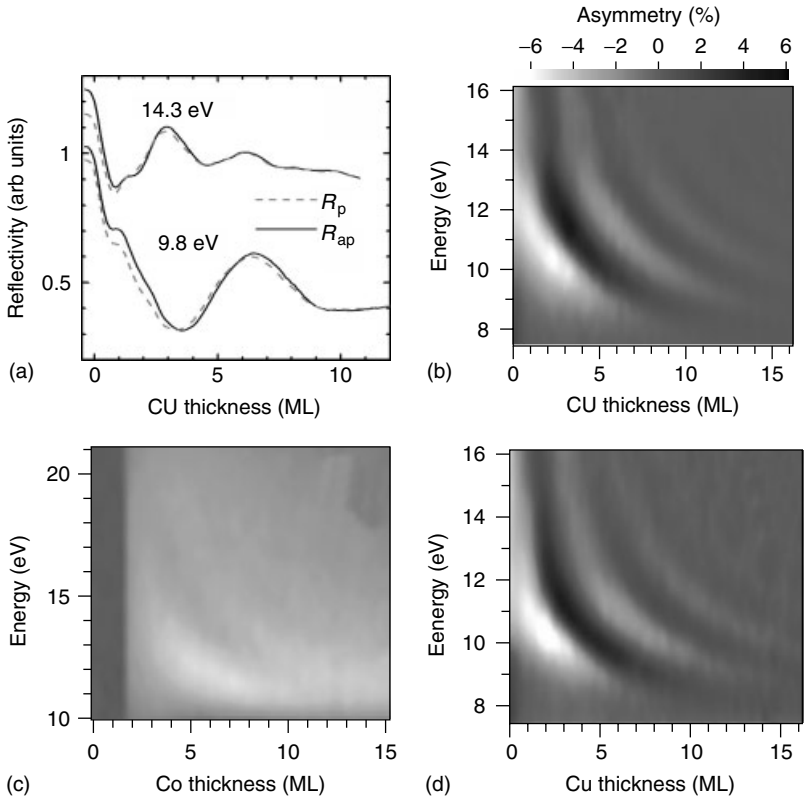

Figure 13. (a) Spin-dependent electron reflectivity from Cu/Co(5 ML)/Cu(001). Asymmetry of the spin-dependent electron reflectivity from (b) Cu/Co(5 ML)/Cu(001), (c) Co/Cu(001), and (d) Cu/Co(15 ML)/Cu(001). (Reproduced from Y.Z.Wu *et al*., 2005, with permission from the American Physical Society. © 2005.)

at $k < k_{BZ}/2$ and $k > k_{BZ}/2$ with a crossover occurring at $k = k_{BZ}/2$ (Egger, Back, Krewer and Pescia, 1999; Wu *et al*., 2005). In the energy range of 8–26 eV above E_F, there is one relevant energy band along the (001) direction (ΓX) Δ_1 symmetry, in which the energy decreases with increasing k and crosses the $k_{BZ}/2$ point at 19 eV (Mankey, Willis and Himpsel, 1993). The corresponding dispersion curves with the crossover at 19 eV were confirmed quantitatively (Wu *et al*., 2005) in the experiment.

For a polarized incident electron beam one has to consider a spin-dependent complex reflectivity (r_C^i, ϕ_C^i) at the Cu/Co interface. Figure 13(a) shows representative spin-resolved electron reflectivity measurements for a 5-ML Co film on Cu(001) capped with a thin Cu layer as a function of the Cu capping film thickness at two incident electron energies, indicating that the electron reflectivity of the Cu film is clearly spin dependent. A spin-dependent reflectivity of a nonmagnetic film was first observed in (Scheunemann *et al*., 1997) and attributed to a spin-dependent phase ϕ_C^i, which can account for the peak position, only. As emphasized in (Wu *et al*., 2005) both the positions and the magnitudes of the reflectivity peaks depend on the incident electron spin direction, indicating that the ferromagnetic Co also causes a spin dependence of r_C^i. The asymmetry of the electron reflectivity, $(R^{\uparrow\uparrow} - R^{\uparrow\downarrow})/(R^{\uparrow\uparrow} + R^{\uparrow\downarrow})$ is shown in Figure 13(b). The spin-dependent reflectivity at the Cu/Co interface results in a spin-dependent Fabry–Pérot interference from the Cu film with the asymmetry oscillating as a function of both the electron energy and the Cu film thickness. The electron reflection asymmetry in Co/Cu(001) as a function of Co film thickness and electron energy, as shown in Figure 13(c), shows a similar behavior as discussed above for Co/W(110). For Co thinner than 1.6 ML, the asymmetry is zero because the Co/Cu(001) film is paramagnetic at room temperature. For Co thicker than 1.6 ML, the reflection asymmetry exhibits a weak interference effect. The asymmetry oscillation amplitude of Cu/Co(5 ML)/Cu(001) is an order of magnitude greater than that of Co/Cu(001), thus clearly indicating that the interference shown in Figure 13(b) is dominated by the Cu film. The asymmetry does not depend significantly on the Co film (Figure 13d). The sign of the asymmetry for Cu/Co(5 ML)/Cu(001) alternates between positive and negative, while the sign of the asymmetry for Co/Cu(001) remains unchanged.

The asymmetry oscillation is damped when d_{Cu} is increased. The damping is due to the electrons retaining

their coherence only up to a finite depth because of inelastic scattering. If d_{Cu} becomes larger than this depth, interference between electrons reflected at the Cu/vacuum boundary and electrons reflected at the Cu/Co boundary is no longer possible.

The spin-dependent complex electron reflectivity at the Cu/Co interface results in a spin-dependent Fabry–Peŕot interference in the Cu film, making it possible to detect magnetic information in the Co underlayer. This observation could be quite interesting for preparing spin detectors that are insensitive to ambient conditions.

5 CONCLUSION AND OUTLOOK

A review was given on our present knowledge of SPLEED, with a main emphasis on experimental findings. We handpicked some experimental examples which are discussed in more detail to illustrate the kind of knowledge that can be gained from SPLEED.

With respect to a theoretical explanation of the observed scattering asymmetries, the calculations show that groundstate potentials generated by common numerical *ab initio* methods provide a very good account of the spin dependencies of the electron-scattering intensities from metallic surfaces, with the use of an inner potential whose real and imaginary parts are comparable with earlier LEED analyses. It turns out that spin-orbit asymmetries can be reproduced quite well by calculations. They respond sensitively to changes in the lattice structure. A comparison of theory and experiment can efficiently be used to determine lattice structures to a high degree of accuracy.

Less good agreement is achieved for the exchange asymmetry, and the extraction of quantitative data on surface magnetization still remains a challenge. The determination of magnetic moments in the surface as inferred from SPLEED rests on the sensitivity to surface moment exhibited by particular prominent regions of scattering parameter. Unfortunately, these regions are often associated with minima in the total intensity and these minima observed on scattering from solid surfaces may be sensitive to the presence of defects.

Definitely, the largest merit of SPLEED is given by its high sensitivity to magnetization in the topmost layers. In particular, close to the magnetic phase transition the critical behavior of the magnetization can be studied in great detail. Using special experimental setups it is even possible to apply small external fields. Fundamental thermodynamic theories could thus be confirmed. The high asymmetry signal can be further exploited to perform magnetic sensitive imaging using SPLEEM.

At very low energies ($<10\,eV$) the scattering probability of electrons shrinks allowing to probe buried interfaces. Because of the lower scattering rate at very low energies multiple scattering effects are less dominant and a theoretical description appears more easy. Interferometric effects similar to the physics of an optical Fabry–Pérot setup were demonstrated. These observations might provide a way to considerably improve present polarization detectors for electrons.

A very interesting future application of SPLEED is provided by the development of an electron source which is capable to produce ultrashort electron bunches of a few picoseconds (Aulenbacher *et al*., 2002). A pulsed electron beam allows a time-resolved investigation of periodic motions via stroboscopic imaging. This can be applied favorably to the investigation of magnetization dynamics at surfaces and in ultrathin films and nanostructures. Ultrafast magnetization reversal processes are presently attracting much attention. Technologically, fast magnetic recording, advanced magnetic memory elements, and spin electronics call for an in-depth understanding and control of fast magnetization reversal processes on the nano- and subnanosecond scale. More fundamental questions are associated with magnetic excitations (eigenmodes) and damping processes in confined magnetic structures. The fundamental timescales for magnetization reversal processes range down to a few femtoseconds, whereas present technologically interesting timescales are on the order of sub-nanoseconds. The time resolution in a stroboscopic experiment is limited by the pulse length of the incident electron beam. The ultrashort pulse lengths of spin-polarized electron bunches already achieved prove to be sufficient for the study of magnetization dynamics and can compete with the shortest X-ray pulses available at a synchrotron. Only optical light pulses from pulsed laser sources are shorter, however, on the expense of surface sensitivity.

The author thanks U. Gradmann and G. Schönhense for stimulating discussions and U. Gradmann for careful reading of the manuscript.

Spin-polarized Low Energy Electron Microscopy

Ernst Bauer
Arizona State University, Tempe, AZ, USA

1 INTRODUCTION

In many applications thin ferromagnetic films are deposited on substrates that are too thick for transmission electron microscopy, so techniques such as Lorentz microscopy or holography cannot be used for imaging of the magnetic properties. Suitable imaging methods are then magnetic force microscopy (MFM), spin-polarized scanning tunneling microscopy (spin-STM), X-ray magnetic circular dichroism photo emission electron microscopy (XMCDPEEM), scanning electron microscopy with polarization analysis (SEMPA), spin-polarized low-energy electron microscopy (SPLEEM) and magneto-optical microscopies. These methods are to certain extent complementary because they give method-specific information and differ frequently in application range. This chapter tries to illustrate where SPLEEM stands among the various magnetic imaging methods. In brief, SPLEEM, SEMPA, and XMCDPEEM have in common that the electrons, which are used for imaging, are very slow. This limits the information depth from several tenths of a nanometer up to several nanometers, depending upon the material and upon the electron energy, which can range from 0 to about 20 eV. In SPLEEM and XMCDPEEM magnetic information is obtained via the spin of the incident particles, and in SEMPA via the spin of the emitted particles. Though differing strongly in the way the magnetic information is obtained, SPLEEM and XMCDPEEM are similar in that they are full-field imaging methods with parallel image acquisition while SEMPA is a scanning method with sequential image acquisition. The feature that XMCDPEEM and SEMPA have in common is that they use secondary electrons for imaging while SPLEEM uses elastically scattered electrons. SPLEEM is a laboratory method while XMCDPEEM requires a synchrotron radiation source with high brilliance. Despite the high brilliance of third-generation synchrotron radiation sources image acquisition times in XMCDPEEM are significantly longer than in SPLEEM. However, XMCDPEEM is generally applicable to surfaces that are not too rough, while SPLEEM is useful mainly for single crystals, epitaxial layers, and highly oriented films.

In order to understand the possibilities and limitations of SPLEEM it is first necessary to understand the elastic and inelastic interactions of very slow electrons with ferromagnetic and nonmagnetic materials. These will be discussed in Section 2. Aspects of the image formation are treated in the experimental part (Section 3). Applications are illustrated by a number of examples in Section 4, which is followed by a brief summary and outlook.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

2 INTERACTION OF VERY SLOW ELECTRONS WITH MATTER

2.1 Elastic scattering

Two aspects of the interaction of very slow electrons with matter are important in the image formation process: the intensity and the magnetic contrast. We consider first the intensity, which determines the image acquisition time and the ability to focus. As will become clear in the experimental section (Section 3), SPLEEM uses electrons that are scattered into a narrow cone around the backward direction. The more concentrated the angular distribution is around $\theta = 180^\circ$, the higher the image intensity and the shorter the image acquisition time. Therefore, single crystalline or highly oriented surfaces are desirable because in these samples the scattered electrons are focused into diffraction beams, in particular into the specular reflected beam ((00) beam in surface crystallography nomenclature). Although the angular distribution of very slow electrons elastically scattered by free atoms has been studied extensively, little is know about the angular distribution in scattering from atoms in polycrystalline samples. Therefore, most information comes from calculations, which are not very accurate at low energies because the energy-dependent exchange and correlation contributions to the effective scattering potential are highly simplified or neglected. Results of these types of calculations indicate that at very low energies the backscattering cross sections of light atoms, for example Cu, can be higher than those of heavy atoms, for example Ag. The nonmonotonic dependence of the backscattering cross section is also true for energies in the LEED range (usually 30 eV to several hundred electronvolts) (Bauer, 1994, 1998, 2006), but at the very low energies this effect is particularly strong. In Cu, the backscattering cross section increases rapidly with decreasing energy near 0 eV and the same is true for the neighboring atoms Ni, Co, and Fe.

Reliable experimental data are available only for single crystal surfaces. As an example, Figure 1 shows the specular reflectivity of the W(110) surface at normal incidence, together with the electronic band structure along the surface normal, which gives a qualitative understanding of the reflectivity. Quantitative understanding requires taking into account the surface barrier (Herlt, Feder, Meister and Bauer, 1981). The reflectivity decreases rapidly with increasing energy as expected from the atomic backscattering cross section but the decrease is modulated by the band structure. In the energy gap between 1 and 6 eV the reflectivity is high because there are no allowed states in this energy range in the crystal. Similarly, in the energy range where the bands are steep (around 15 eV) so that the density of states is small, the reflectivity is enhanced. Fortunately,

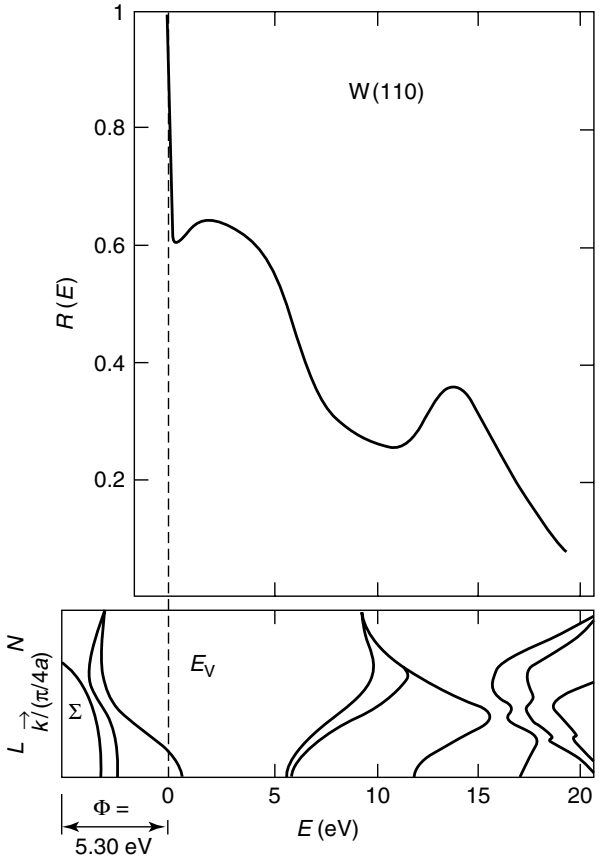

Figure 1. Specular reflectivity of a W(110) surface and comparison with the band structure along the [110] direction. (Reproduced from Herlt *et al.*, 1981, with permission from Elsevier. © 1981.)

for the interpretation of most SPLEEM images, a detailed understanding of the backscattering is not necessary. It is important only in energy regions with strong backscattering. In these regions the information depth is dominated by the elastic attenuation of the incident beam, which is determined by elastic backscattering: the incident wave is then an evanescent wave, and the sample is a reactive medium. In all other cases, the information depth in determined mainly by inelastic scattering, which will be discussed below.

The second aspect of importance for image formation is the contrast. In SPLEEM the contrast mechanisms known from LEEM are spin dependent because of the exchange interaction in which electrons with opposite spin experience a different potential. The interaction of spin-polarized electrons with matter is well described in SPLEED chapter (See also **Spin-polarized Low Energy Electron Diffraction, Volume 3**), so that only the features specific for very slow electrons need to be discussed here. First of all it has to be mentioned that in 180° scattering, which is a special case of the specular scattering described in the SPLEED chapter, only exchange scattering occurs. Because of the

Pauli principle, incident electrons with spin parallel to that of the electrons in the material experience a different potential, sometimes described by the Slater hole, than electrons with antiparallel spin. This exchange potential depends upon the density of the electrons with the same spin and is energy dependent. In crystals it manifests itself in the spin dependence of the energy-dependent band structure. In the free electron gas with electron density ρ, it is given by

$$V_{\mathrm{x}}(\eta) = -4\left[\left(\frac{3}{8\pi}\right)\rho\right]^{\frac{1}{3}} F(\eta) \tag{1}$$

where

$$F(\eta) = \frac{1}{2} + \left[\frac{(1-\eta^2)}{4\eta}\right]\ln\left[\frac{(1+\eta)}{(1-\eta)}\right] \tag{2}$$

and $\eta = k_{\mathrm{F}}/k_{\mathrm{i}} = (E_{\mathrm{F}}/E_{\mathrm{i}})^2$. Here E_{i} is the energy of the incident electron and k_{F}, E_{F} are the somewhat modified Fermi momentum and energy. Figure 2 shows the energy dependence of $F(E_{\mathrm{i}}/E_{\mathrm{F}})$. Although the 3d metals are far from being free electron–like, this dependence allows an estimate of how rapid the spin dependence caused by the exchange potential decreases with energy. With the Fermi energies of Fe, Co and Ni of 10.2, 9.5, and 8.7 eV, and the corresponding work functions of their most densely packed surfaces, the (110), (0001), and (111) surfaces, of 5.1, 5.45, and 5.45 eV, respectively, approximate $F(\eta)$ values for these metals at 1, 10, 20, and 50 eV above the vacuum level of 0.23, 0.13, 0.09, and 0.05, respectively, are obtained. Thus, the exchange potential, on which the spin selectivity of SPLEEM is based, decreases significantly with energy. This, together with the decrease of the reflectivity with increasing energy and with the decreasing spin dependence of the inelastic mean free path (IMFP) with increasing energy, is the reason for using very slow electrons in SPLEEM.

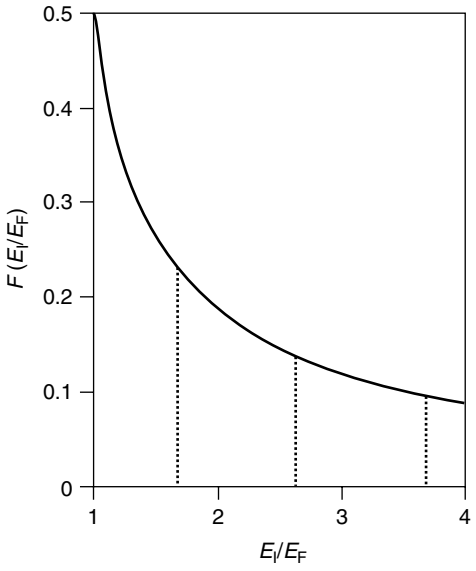

Figure 2. Energy dependence of the exchange energy of the free electron gas. The approximate values of $F(E_{\mathrm{i}}/E_{\mathrm{F}})$ of 0.23, 0.13, and 0.09 at 1, 10, and 20 eV above the vacuum level for Fe, Co, and Ni, respectively, are indicated.

2.2 Inelastic and quasi-elastic scattering

The sampling depth of SPLEEM is determined by the loss of electrons, which are elastically and quasi-elastically backscattered into a narrow cone around the direction of incidence. Both quasi-elastic scattering via phonon and magnon excitation and inelastic scattering via electron–hole pair creation cause this loss. The influence of these processes on SPLEEM intensity and magnetic contrast is determined by the momentum and energy transfer associated with them on the one hand and by the angular aperture and chromatic aberrations of the imaging system on the other. In SPLEEM only a small fraction of the momentum space around the backward direction is used for imaging and the accepted energy range below the elastic peak depends upon the dispersion of the magnetic fields used for separation of the reflected beam from the incident beam. Small energy losses such as those encountered in phonon and magnon excitation are accepted in all cases, but they can nevertheless contribute noticeably to the intensity attenuation because the small angular aperture cuts out only a small part of the momentum distribution. In addition, magnon excitation is spin selective and can influence the magnetic contrast. Little is known at present about the magnitude of these effects. Electron–hole pair creation causes larger energy losses of the order of 1 eV and higher. The resulting inelastically scattered electrons are at least partially eliminated by the chromatic aberration of the beam separation system unless it has been corrected. Hong and Mills (2000) have calculated the probability of the various electron–hole pair creation mechanisms and have found that the process shown in Figure 3a is about twice as probable as that shown in Figure 3b. In the first mechanism, the Stoner excitation, a spin-down electron excites a spin-up electron, causing an apparent spin flip of the reflected electron. In the second mechanism, the direct excitation, the spin of the reflected electron is preserved. Although the probability of Stoner excitations decreases with decreasing momentum transfer, they are still noticeable at zero momentum transfer to the crystal electron (Plihal and Mills, 1998). If the resulting inelastically scattered electrons are accepted by the SPLEEM electron optics, then they cause an increase of the reflection asymmetry due to the exchange potential mentioned above.

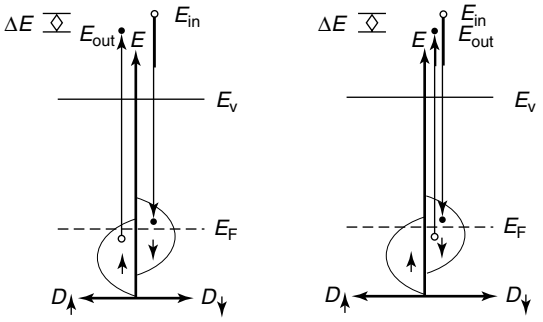

Figure 3. Schematic of electron excitations in a ferromagnet. (a) Stoner ('spin-flip') excitation, (b) direct ('nonspin-flip') excitation. Only the transition for incident spin-down electrons which are more likely than those of spin-up electrons are shown.

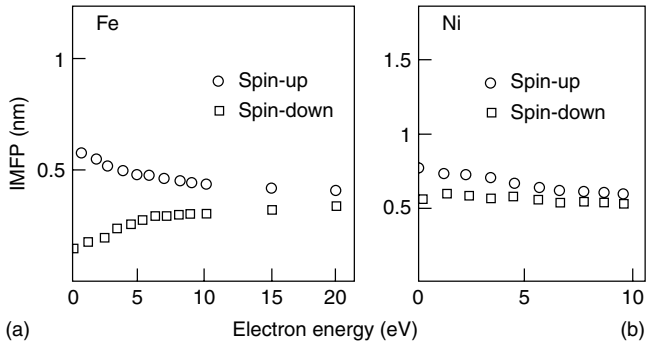

Figure 4. Inelastic mean free paths of spin-up and spin-down electrons in Fe and Ni as a function of energy obtained from explicit calculations. The zero of the energy is the vacuum level. (adapted from Hong and Mills, 2000.)

These considerations, which take into account instrumental aspects, have to be kept in mind in the discussion of the experimental and theoretical IMFPs, which ultimately determine the sampling depth of the electrons. The experimental data of the energy dependence of the spin-averaged IMFPs and their spin dependence are very limited and 'differ' considerably from author to author. A critical compilation has been given by Hopster (1999). Therefore, only theoretical data will be given here. Siegmann (1994) proposed the following relation for the spin dependence of the inelastic cross sections $\sigma_\uparrow$, $\sigma_\downarrow$ of spin-up and spin-down electrons, which determine their IMFP:

$$\sigma_{\uparrow\downarrow} = \sigma_0 + \sigma_d(5 - n_{\uparrow\downarrow}) \tag{3}$$

Here σ_d is the cross section for scattering into an unoccupied d orbital, σ_0 that for scattering into a non–d orbital, and $n_{\uparrow\downarrow}$ are the numbers of occupied majority and minority spin states, respectively. For example, for $n_\uparrow = 4$, $n_\downarrow = 2$ and $\sigma_d \gg \sigma_0$ one gets $\sigma_\uparrow/\sigma_\downarrow \approx 1/3$, so that the IMFPs of electrons with opposite spins differ by a factor of 3. Detailed accurate calculations of the energy dependence of the spin-up and spin-down IMFPs in Fe and Ni (Hong and Mills, 2000) give the results shown in Figure 4. In Fe the spin-up IMFP is larger than the spin-down IMFP by a factor of 4.3, 2.0, and 1.4 at 0, 5, and 10 eV, respectively, in Ni only by a factor of 1.4 at 0 eV and it decreases rapidly to the spin-down value. Accordingly, the magnetic contrast is significantly smaller in Ni than in Fe. Important are also the low absolute values of the IMFPs, for example, 0.2 and 0.55 nm in Fe or 0.5 and 0.7 nm in Ni at 2 eV for spin-down and spin-up IMFPs, respectively. These low values make SPLEEM an ideal tool for the study of surface magnetism.

Summarizing this section, elastic backscattering cross section, elastic exchange asymmetry, and IMFP difference between spin-up and spin-down electrons decrease rapidly with increasing energy. Therefore, optimum conditions for reflected intensity and magnetic contrast are obtained at the lowest energies. Exceptions to this rule occur around exchange-split band edges and in the presence of quantum size effects (QSEs), which will be discussed in Section 4.2.2.

3 SPLEEM INSTRUMENTATION

3.1 Overview

A SPLEEM instrument consists of the electron source, the spin manipulator, the beam separator, which separates incident and reflected electrons, the objective lens, the electron-optical systems on the illumination side and on the imaging side of the separator and finally the channel plate image intensifier–fluorescent screen from which the SPLEEM image or SPLEED pattern is recorded by a CCD camera. The electron-optical system on the illumination side has to produce a demagnified image of the source in the back focal plane of the objective lens; the electron-optical system on the imaging side has to produce a magnified SPLEEM image or SPLEED pattern on the channel plate image intensifier. These goals can be achieved with a variety of designs. Those of the presently operating SPLEEM systems are shown in Figures 5 and 6. In Figure 5 the electron source, which is at −15 kV, is seen on the far left, together with the spin-polarization manipulator, followed by the transfer optics. In the center is the beam separator, which deflects the electron beam 60° upward into the objective lens. In this lens, which includes the sample, the incident electrons are decelerated to the desired low energy and reaccelerated after reflection from the sample. The lens produces the SPLEED pattern in its back focal plane and the first SPLEEM image in the center of the separator. Both the first SPLEEM image and the SPLEED pattern are then magnified by the lens combinations in the imaging system, consisting of a transfer lens, an intermediate lens, and a

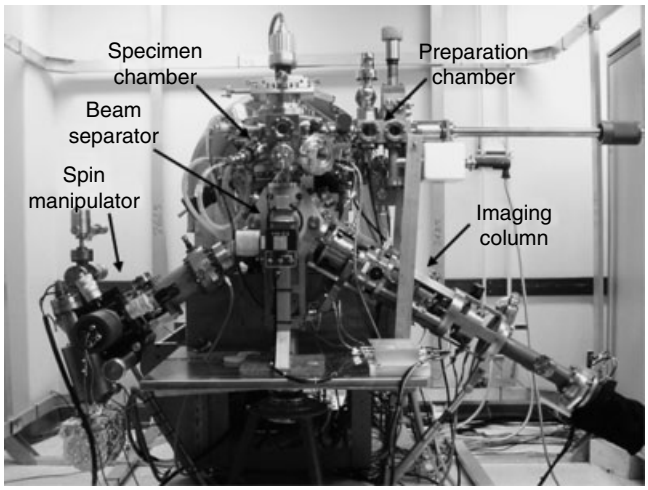

Figure 5. Spin-polarized low-energy electron microscope with 60° beam separator.

projective lens. The transfer lens transfers the first SPLEED pattern into the position of the angle-limiting aperture before the intermediate lens, the intermediate lens images either this plane or the SPLEEM image in front of the projective lens, which produces the final magnification. These lenses can be moved mechanically for rough beam alignment. Fine alignment is achieved with deflectors. An objective stigmator corrects the astigmatism of the objective lens and stigmators before and after the beam separator correct the astigmatism of the beam separator. An aperture in the illumination system limits the size of the illuminated area on the sample and also eliminates stray electrons. The sample manipulator on top allows not only three translations but also tilt so that the sample normal can be brought into coincidence with the optical axis of the objective lens. The sample is at a voltage close to that of the electron source (−15 kV). The voltage difference determines the energy of the incident electrons. The specimen chamber, which also contains the objective lens, has several ports for accessories such as evaporators, a UV light source, gas inlets, and so on, for *in situ* experiments. A small preparation chamber and airlock on the upper right side allow easy sample transfer and precleaning by sputtering, heating, and gas exposure. The whole system is pumped by sputter ion pumps and getter pumps, supported by additional pumps. The critical parts of the instrument (electron source, spin manipulator, objective lens, etc) will be discussed below in detail.

While the SPLEEM instrument shown in Figure 5 uses magnetic lenses except for the objective lens and has the specimen at high voltage, the one shown schematically in Figure 6 uses only electrostatic lenses and has the specimen near ground potential. Illumination and imaging section are parallel, which is achieved with three magnetic deflectors schematically indicated by circles. Focusing in the

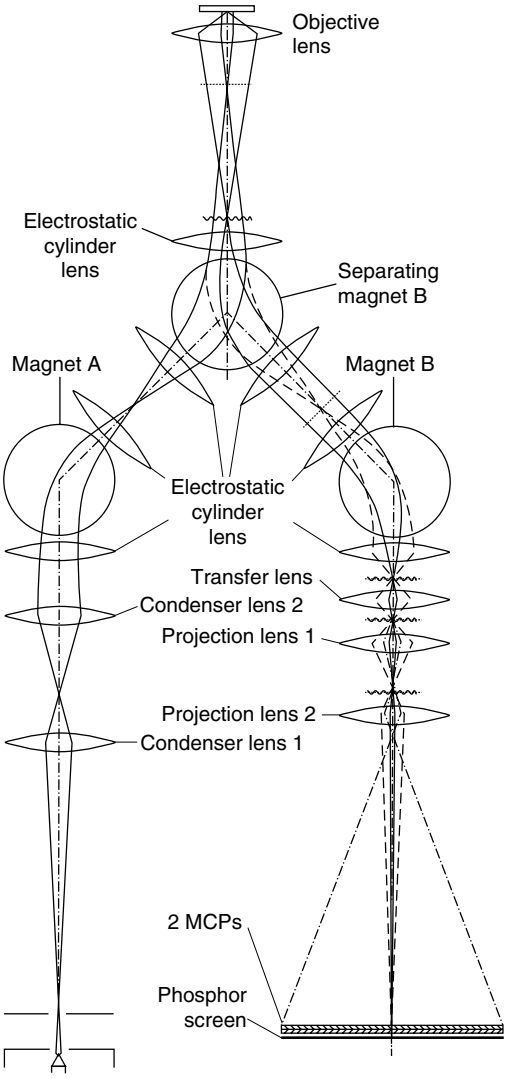

Figure 6. Schematic of a small spin-polarized low-energy electron microscope, which can be mounted on a 6′ diameter flange. The spin-polarized electron gun with spin manipulator at the left bottom is not shown. (Reused with permission from K. Grzelakowski and E. Bauer, *Review of Scientific Instruments*, **67**, 742 (1996). Copyright 1996, American Institute of Physics.)

nonfocusing plane of the magnetic deflectors is achieved by electrostatic cylinder lenses on both sides of the deflectors. The electron optics is floating at −5 kV except for the first electrode of the objective lens, which can be operated up to −15 kV. For details refer Grzelakowski and Bauer (1996).

As most SPLEEM work is done *in situ* the facilities in the sample chamber are important. Many films are grown on refractory substrates that require cleaning at high temperatures; in many SPLEEM studies the temperature must be changed during film growth or during the SPLEEM measurements. The low Curie temperatures of ultrathin films

make cooling very desirable, which has been achieved till now down to 115 K (Tober, Witte and Poppa, 2000). The study of the influence of magnetic fields on the magnetization distribution in the sample is complicated because of the deflection of the electron beam. In-plane fields can in principle be applied with window frame sample holders but to date only perpendicular fields have been used, albeit with some difficulty because the field must be aligned exactly on axis (Poppa, Tober and Schmid, 2002).

3.2 The electron source

The physical basis of photoelectron emission from negative electron affinity GaAs and related surfaces has already been described in the chapter on SPLEED (See also **Spin-polarized Low Energy Electron Diffraction, Volume 3**). There is extensive literature on this subject of which only a few overview papers can be cited (Pierce *et al*., 1980; Pierce, 1995). These give a detailed description of the cleaning of the cathode surface, of the activation procedure for obtaining a high quantum yield and high polarization, of the lifetime of the emission, and of the gun design, as well as ample references to earlier work. Here only more recent studies, in particular those which are important for the source operation in a spin-polarized electron microscope, will be discussed. As far as surface cleaning is concerned, cleaning with atomic hydrogen, long used for oxide removal from GaAs, has become popular (Maruyama *et al*., 2003) but also controversial (Baylac *et al*., 2005). It removes not only the oxide but also carbon-related contaminants, the main detrimental impurities (Petit and Houzay, 1994). Conventional cleaning by heating to about 600–620 °C has to be done very carefully in order to avoid loss of As resulting in Ga droplet formation that inactivates the surface. Atomic hydrogen cleaning, on the other hand, can be done at as low as at 300 °C but is usually done at 400–450 °C. No GaAs decomposition can occur at these temperatures. However, care has to be taken to avoid overdosing with hydrogen, which causes its incorporation into the crystal where it is believed to create yield-reducing defects and to deactivate the high p-doping used for the band bending necessary to achieve negative electron affinity.

The parameters that are important for the operation in SPLEEM are quantum efficiency, degree of spin polarization P, brightness B, and lifetime τ. Energy width ΔE is also of interest but small enough to be not resolution limiting. High polarization requires lifting of the degeneracy of the $P_{3/2}$ band at the Γ point. The band splitting into $m_j = \pm 3/2$ and $m_j = \pm 1/2$ (heavy and light hole) bands that can be achieved by strain or superlattices is usually small so that only a small photon energy range above the $P_{3/2}$ excitation threshold can be used. P values of about 85% and quantum yields of 1.7% have been reported (Maruyama *et al*., 2004). Because of the small photon energy range (<100 meV) the quantum efficiency is small and such cathodes have not been used till now in SPLEEM. Increasing the photon energy above the $P_{1/2}$ threshold causes a further decrease to the P values of 20–30% obtained also with conventional degenerate cathodes whose quantum yields are a factor of 10 or higher. Because high brightness B is needed in imaging, unstrained (nondegenerate) cathodes are, therefore, used in general. The brightness of the cathode is defined by $B = j/\pi\ \alpha^2$, where j is the emitted current density and α is the half-angle of the emission cone. For a given cathode j can be increased by focusing the photon beam into a finer spot and increasing the photon flux up to the space charge limit, α is determined by the ratio of transverse to longitudinal energy. A fine spot is needed in any case because it determines the ultimate diameter of the electron beam in the back focal plane of the objective lens. The diameter of this spot determines the divergence of the beam at the sample. The mean longitudinal and transverse energies (E_l and E_t, respectively) depend on the extraction voltage, upon the energy difference between the photon energy and the band gap, the roughness of the surface and other parameters. E_l may be as large as several 100 meV, E_t can be as small as 25 meV at room temperature (Pastuszka *et al*., 2000). This gives a lower limit of α of about 0.1. Thus, B depends upon many parameters and varies from source to source. Values as high as 1×10^5 A/cm^2-sr have been reported in a scanning electron microscope (Pierce, 1995). In the SPLEEM instruments, B has not been determined. The instrument shown in Figure 5 operates typically with 1 μA emission current at an extraction voltage of 1 kV. Imaging is still possible with several hundred nanoamperes. The lifetime τ is important not only for convenience of operation but in particular for longer experiments. It depends strongly on the pressure in the gun chamber and ranges from several hours at high pressures (10^{-10} mbar (10^{-8} Pa) range) to hundreds of hours at low pressures (10^{-12} mbar (10^{-10} Pa) range) and with continuous slow Cs supply during operation. While it is widely believed that the short lifetime in the absence of Cs supply during operation is caused by desorption of Cs, the pressure influence on the lifetime has been attributed to slow oxygen uptake. Because of the complexity of the phenomena involved, good spin-polarized electron sources are still a work of art and experience, which has to be collected for each individual case.

3.3 The polarization manipulator

In order to obtain magnetic contrast between regions with different directions of the magnetization **M** one must be able

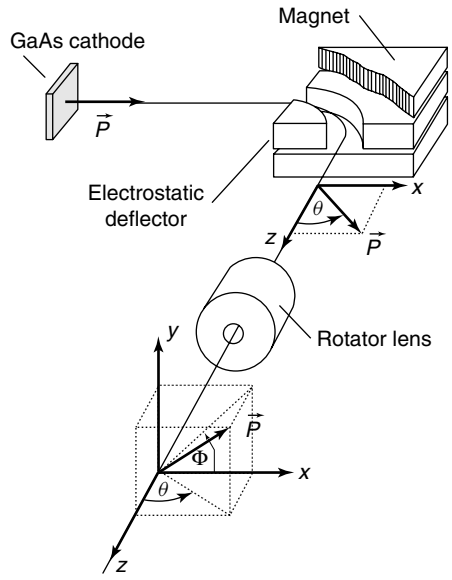

Figure 7. Principle of the spin manipulator used in the SPLEEM instruments shown in Figures 5 and 6 (Grzelakowski, Duden, Bauer *et al*., 1994). (Reprinted from *Surface Review and Letters*, **5** (1998) 12/3. Copyright 1998 with permission from World Scientific Publishing Co. Pte. Ltd, Singapore.)

to rotate the spin-polarization vector **P** of the spin-polarized electron beam, best in any direction in space. Maximum magnetic sensitivity is obtained when the spin of the incident electron is parallel or antiparallel to the spin of the electron in the sample, that is when **P** // ± **M**. In general the sensitivity is proportional to **P**·**M**. An unrestricted rotation of **P** is achieved with a spin manipulator as schematically shown in Figure 7 (Duden and Bauer, 1995; Bauer, 1997). The manipulator consists of a combined electrostatic/magnetic 90° deflector and a rotator lens. The cathode is illuminated at normal incidence through the deflector with circular polarized light from a diode laser and emits electrons with **P** parallel or antiparallel to the surface normal, depending upon the handedness of the helicity. Purely electrostatic deflection leaves **P** unchanged, purely magnetic deflection rotates **P** by 90°. By combining the two fields in the proper ratio any direction in the $x-z$ plane in Figure 7 can be reached. Out-of-plane directions are achieved by rotating **P** around the axis of the magnetic lens. While optimum magnetic contrast can be obtained by rotating **P** parallel and antiparallel to **M**, it is usual to select one or two preferred in-plane directions (magnetic easy or hard axis) and the surface normal. By vectorial addition of the three signal components the direction of **M** can be determined. In order to minimize the voltage and currents in the sector and rotator lens these components float close to the cathode potential, typically 1 kV relative to it, and the final acceleration to the full energy (15 or 5 kV, respectively, in the two instruments discussed in Section 3.1) occurs after the rotator lens.

3.4 The objective lens

The objective lens is the third crucial element of a SPLEEM instrument. In this lens the fast electrons are decelerated to the desired energy at the sample ('cathode'), which is part of the lens. For this reason the objective lens is also called a *cathode lens*. Cathode lenses, whether electrostatic, magnetic, or mixed electrostatic/magnetic, have large chromatic and spherical aberrations, which determine the limiting resolution of the instrument. The chromatic and spherical aberrations depend upon the angular aperture α as the first and third power of α, respectively, and make it necessary to limit α by a small angle-limiting ('contrast') aperture in the back focal plane (or in an image plane of it). This produces a diffraction disc of confusion whose radius is inversely proportional to sin α. The resolution can be optimized by choosing an aperture radius, which produces the smallest disc of confusion. Figure 8 shows the three contributions (b, c, d) to the resolution and the resulting overall resolution (a), together with the optimum radius (r) for the presently most frequently used cathode lenses (Chmelik, Veneklasen

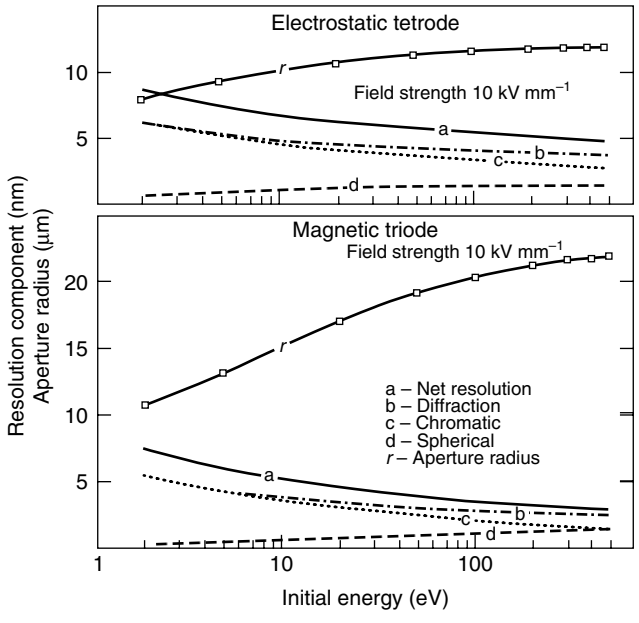

Figure 8. Radii of the resolution-limiting discs of confusion (b, c, d), resulting resolution (a) and optimal aperture radius (r) of cathode lenses. The electrostatic tetrode objective lens is used in the instruments shown in Figures 5 and 6 (Chmelik, Veneklasen and Marx, 1989). (Reprinted from OPTIK, Vol 83, 1989, Page 155, Copyright 1989 with permission from Elsevier.)

and Marx, 1989). Although the calculations are for a higher energy and larger energy width, they indicate that the limiting resolution of these instruments should be less than 10 nm between 2 and 10 eV energy at the sample. This resolution has not been achieved till now in SPLEEM for a number of reasons such as nonoptimal aperture, vibrations, voltage and current instabilities, insufficient shielding of ac fields, sample drift, increased energy width due to inelastically scattered electrons that are accepted by the aperture, and so on. Another important reason is the low signal/noise ratio because of the low **P** value. This will be discussed below. Presently a resolution of several 10 nm can be obtained routinely, under optimum conditions about 20 nm.

Ideally the image of the source in the back focal plane should be a point. Under these conditions the surface is illuminated perfectly perpendicular to the surface. In practice, the image of the source in the back focal plane has a finite extension leading to a corresponding nonperpendicular illumination of the surface. This reduces contrast and to some degree also resolution. The illumination aperture that cuts out far-off axis electrons in the illuminating beam reduces this problem.

3.5 The image acquisition/processing system

As mentioned earlier, the magnetic contribution to the backscattering caused by the exchange potential is small compared to the nonmagnetic part. As a result, the image intensity I may be written as $I = I_{st} + c\ \mathbf{P}\cdot\mathbf{M}$, where I_{st} is the structure-sensitive part seen in ordinary (nonspin-polarized) LEEM and c is a small proportionality constant. In a sample with high magnetic contrast the magnetic contribution is typically less than 10% of the total intensity; with low magnetic contrast it is 1% or less for $P \approx 25\%$. In order to eliminate the structural contrast two images with opposite **P** have to be taken (Figures 9a and 9b) and subtracted pixel by pixel (Figure 9c). Strong magnetic contrast allows image acquisition times of fractions of a second for each helicity image, which can be immediately subtracted from the opposite helicity image with present processing speeds; weak magnetic contrast as observed near the Curie temperature may require seconds per helicity image. The processing software calculates also the sum image in which the magnetic contrast is cancelled and can divide the difference image by the sum image, resulting in the so-called asymmetry image $A = (I\uparrow - I\downarrow)/(I\uparrow + I\downarrow)$. This is usually displayed. Image drifts, for example during studies of temperature-dependent phenomena, have to be corrected off-line. The asymmetry image frequently has low contrast, and is therefore contrast-enhanced, sometimes by more than a factor of 10. In such cases, the signal/noise ratio is the main resolution-limiting factor (Duden and Bauer, 1998). When the magnetic contribution to the signal is large, for example, 10%, then noise limits the resolution to about 20 nm, provided that many difference images are summed.

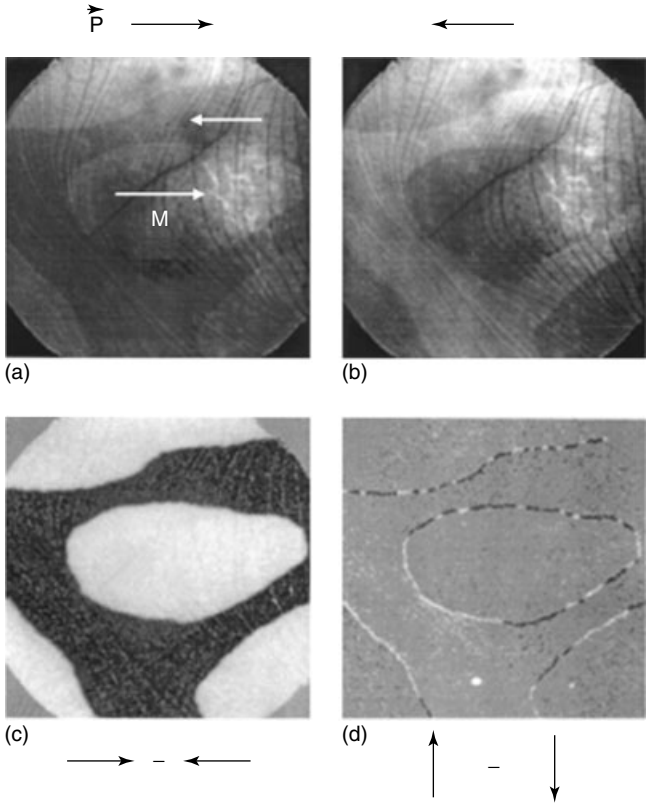

Figure 9. Magnetic contrast in a sample with strong uniaxial in-plane magnetization (6 Co ML on W(110)). (a) and (b) are images taken with **P** parallel and antiparallel to the easy axis, (c) is the contrast-enhanced difference image, and (d) the contrast-enhanced difference image of two images taken with opposite **P** perpendicular to the easy axis. Electron energy 2 eV, field of view 13 µm (Bauer, Duden, Pinkvos *et al*., 1996). (Reprinted from *Journal of Magnetism and Magnetic Materials*, Vol 156, 1991. Copyright 1991 with permission from Elsevier.)

4 APPLICATIONS

4.1 Surfaces of bulk crystals

Bulk crystals have hardly been studied because the low sampling depth of SPLEEM predestines it for the study of ultrathin films. However, SPLEEM is also suited for the study of the surface magnetism of bulk crystals. This is illustrated in Figure 10 (Altman *et al*., 1991), which

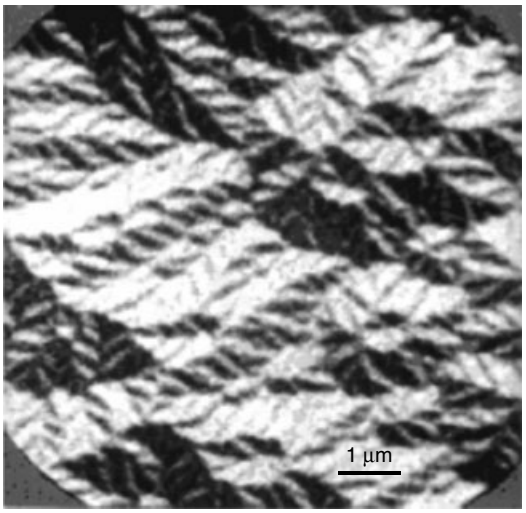

Figure 10. SPLEEM image of a Co(0001) surface. Electron energy 2 eV, field of view 12 μm (Altman, Pinkvos, Hurst *et al.*, 1991). (MRS Symposium Proceedings, 232, (1991) 125.)

shows the magnetic domain structure of a Co(0001) surface after sputter cleaning and annealing. It was taken in the early phase of SPLEEM to demonstrate the capability of this technique by comparison with SEMPA images of the Co(0001) surface in which this 'flower' domain pattern was discovered (Unguris, Scheinfein, Celotta and Pierce, 1989). It shows the sixfold symmetry of in-plane closure domains, terminating the domains in the bulk whose magnetization is perpendicular to the surface. Subsequent work concentrated on ultrathin films for reasons mentioned above.

4.2 Ultrathin films

4.2.1 Single layers, underlayers, and overlayers

Spin order in a thin film decreases rapidly with decreasing film thickness so that in monolayer films the Curie temperature T_C is in general below room temperature. In some cases, T_C is above room temperature so that the temperature dependence of the magnetization can be studied conveniently. An example is the Fe monolayer on a Au double layer on W(110). It shows weak ferromagnetic contrast at room temperature, which can be increased significantly by capping with Au. Figure 11 shows some SPLEEM images taken near T_C (Zdyb and Bauer, 2007). It is clearly seen that near the phase transition ferromagnetic (dark and white) and paramagnetic (gray) regions coexist. The local phase transition temperature decreases with decreasing step distance. In regions with large step distances, which are on large terraces, strong fluctuations of the magnetization direction occur before the transition into the paramagnetic state. These phenomena are averaged out in laterally averaging studies of the phase transition, leading to incorrect critical parameters for thin films on surfaces with varying step density.

In contrast to the Fe monolayer on a Au double layer on W(110), T_C of the Fe monolayer on a thick Au layer on W(110) is below room temperature as it is also on the (111) surface of a bulk Au crystal. The same is true for most other ferromagnetic film–nonmagnetic substrate combinations. In most of these films, the direction of the magnetization changes with thickness, a phenomenon called

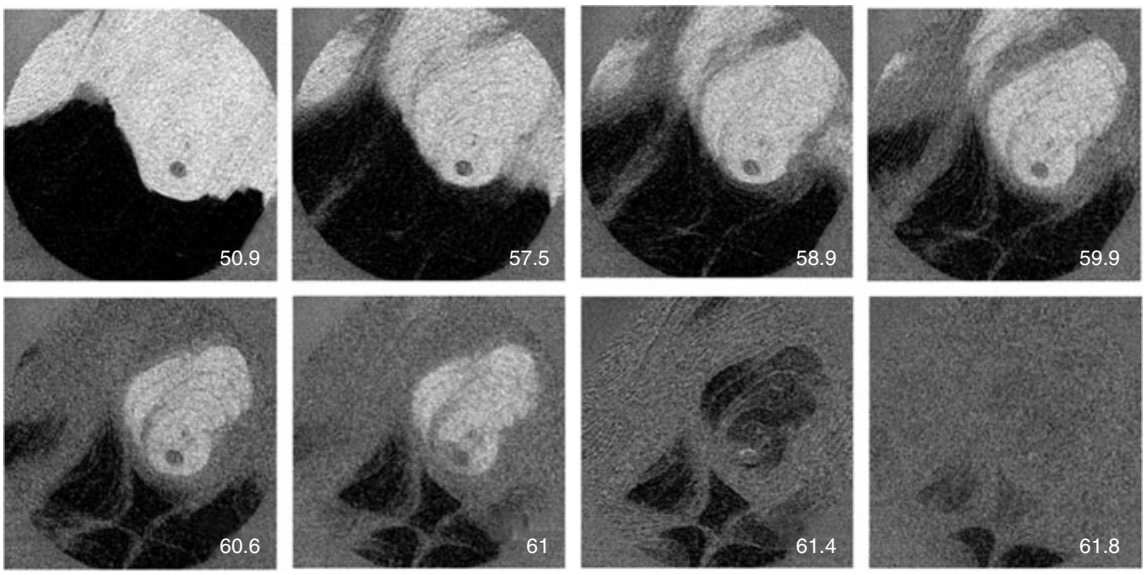

Figure 11. SPLEEM images of a Au-capped Fe monolayer on a Au double layer on W(110) at the temperatures (in °C) indicated in the images. On the large terraces the magnetization disappears at 62.0 °C. Electron energy 2 eV, field of view 14 μm (Zdyb and Bauer, 2007).

spin reorientation transition (*SRT*), which has been studied in considerable detail by SPLEEM. At the same time another phenomenon, the QSE, evolves with increasing thickness and this will be discussed before the SRT will be addressed.

Fe on W(110) and Au(111) produces strong magnetic contrast, because the surface of these films is flat. This is not the case on other substrates due to the different growth modes. For example, Co grows on the W(100) surface not with the equilibrium plane (0001) but with the (11−20) plane parallel to the substrate. The large anisotropic misfit causes growth of rectangular crystals with large aspect ratio and tilted surfaces. As a consequence, the (00) beams are reflected off-axis and there is insufficient intensity on axis at the low energies suitable for SPLEEM. The observed magnetic contrast is more or less buried in the noise (Duden, Zdyb, Altman and Bauer, 2001). On the W(111) surface the large atomic roughness supports metastable pseudomorphic Co growth at room temperature and somewhat higher temperature over a wide thickness range. At 380 K the layer becomes ferromagnetic with in-plane magnetization at 7.6 monolayers (ML). Domain structure and magnetization direction are strongly influenced by surface steps, which indicates that the in-plane anisotropy is weak (Man *et al*., 2003).

While Fe and Co and their alloys have large magnetic moments and, therefore, produce strong magnetic contrast, at least far away from the Curie temperature, Ni with its small magnetic moment is more difficult to study. Nevertheless, some results have also been obtained for Ni layers on Cu(100), for example, the domain wall width (Ramchal, Schmid, Farle and Poppa, 2004a).

Nonmagnetic underlayers are frequently used to vary the anisotropy of the substrate. The case of Au underlayers for the growth on bcc(110) surfaces that have twofold symmetry is a good example. As shown at the beginning of this section a Au double layer on W(110) induces enough uniaxial anisotropy so that an Fe monolayer is ferromagnetic at room temperature. When the Au underlayer is thicker, for example 10 ML thick, then the Fe monolayer is not ferromagnetic at room temperature and develops initially out-of-plane magnetization with a preferred domain wall orientation. The in-plane magnetization that occurs in thicker Fe films again shows uniaxial anisotropy, just like the monolayer on the Au double layer.

Another example is Co on Au on W(110). Up to 4 Au ML the magnetization of the Co layer is in plane at all thicknesses. Above an Au thickness of 4 ML the magnetization of the Co layer is perpendicular to the surface below a critical Co thickness that ranges from 3.3 ML at a Au thickness of 5 to 4.3 ML at a Au thickness of 10 ML. The domain structure changes from a striped phase with domain walls parallel to the W[001] direction to a more isotropic phase as shown in Figure 12. Above the critical Co thickness the films again have uniaxial anisotropy. The influence of underlayers has been attributed to changes in the magnetoelastic anisotropy caused by the misfit strain, but step anisotropy caused by anisotropic growth cannot be excluded, in particular as the films are grown at relative large angles of incidence.

Nonmagnetic overlayers can have a dramatic influence on the magnetization of ferromagnetic layers, as already seen above in the case of the Fe monolayer. Laterally averaging magneto-optical and magnetometric measurements frequently show a considerable enhancement of the magnetic anisotropy. Examples are Au, Ag, Cu, and Pd overlayers on Co layers, which enhance the perpendicular anisotropy strongly, with a peak at around 1 ML. This phenomenon was studied with SPLEEM, using 3−8-ML-thick epitaxial Co films on W(110) (Duden and Bauer, 1999a). As will be discussed in Section 4.2.3, in these layers, **M** is slightly tilted away from in-plane. For Au, the increase of the perpendicular anisotropy with overlayer coverage was largest (from 25 to 70°) for the thinnest film and smallest (from 10 to 25°) for the thickest film, with only a weekly pronounced maximum at 2 ML. In the case of Cu overlayers, a deposition temperature-dependent maximum was

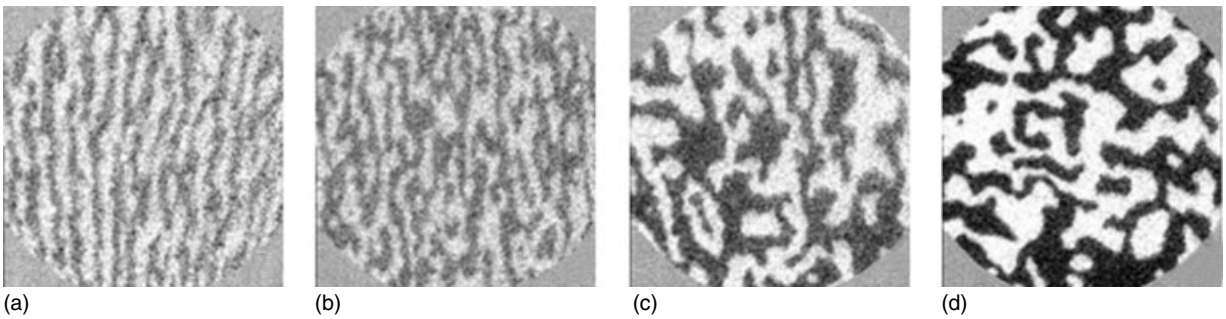

Figure 12. Out-of-plane SPLEEM images of the influence of the thickness of a Au layer on W(110) on the domain configuration of Co layers grown on top of it. Au layer thickness is 5, 6, 8, and 10 ML in a, b, c, and d, respectively. The corresponding Co thicknesses are 2.8, 3.0, 3.3, and 4.0 ML. Electron energy 1.2 eV, field of view 10 μm (from Ph.D. thesis Duden, 1996).

found, which could be connected to a structural effect using LEEM imaging: only the double layer increased the perpendicular anisotropy, which was attributed to strain effects, while the monolayer and triple layer had no noticeable effect. The temperature-dependent coexistence of monolayer and double layer regions seen in the LEEM images then causes temperature-dependent location of the maximum. This is a good example of the power of the combination of SPLEEM and LEEM imaging using difference and sum images.

4.2.2 Spin-dependent quantum size effects

A thin film bounded by parallel surfaces acts for the incident electron wave similar to the Fabry-Perót etalon in light optics: the reflectivity shows maxima and minima as a function of wavelength or film thickness due to constructive and destructive interference between the waves reflected at the two boundaries. The condition for constructive interference is $n\lambda/2 = t + \varphi$, where λ is the wavelength, t the thickness of the film, and φ represents the finite penetration depth of the wave beyond the boundaries. This is the standing wave condition and corresponds to a quantization of the electron wave, therefore the name *quantum size effect (QSE)*. In the bulk of crystals only electron states determined by the band structure E(**k**) are allowed, which in the case of ferromagnetic materials is exchange split as illustrated in Figure 13. As a consequence, at a given thickness t the QSE condition $n\lambda/2 = t + \varphi$ is fulfilled for spin-up and spin-down electrons at different energies E(**k**) because of $k = 2\pi/\lambda$ as indicated in Figure 13 for $k = 0.12$. Therefore, not only the reflectivity but also the asymmetry $A = (I_\uparrow - I_\downarrow)/(I_\uparrow + I_\downarrow)$ should change in an oscillatory manner with increasing thickness and energy. This was first observed in SPLEEM studies of Co layers on W(110) (Scheunemann *et al.*, 1997).

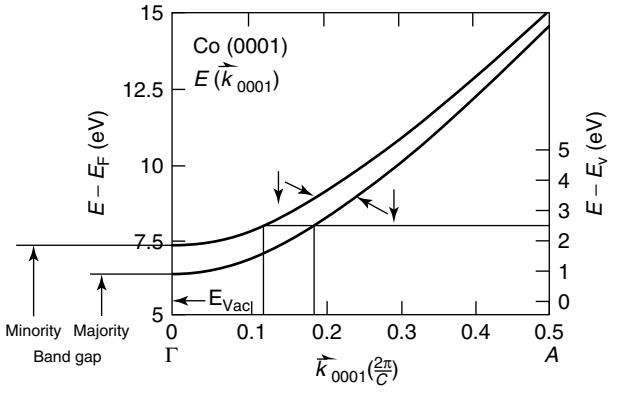

Figure 13. Band structure of Co above the vacuum level in the Γ A direction ([0001]).

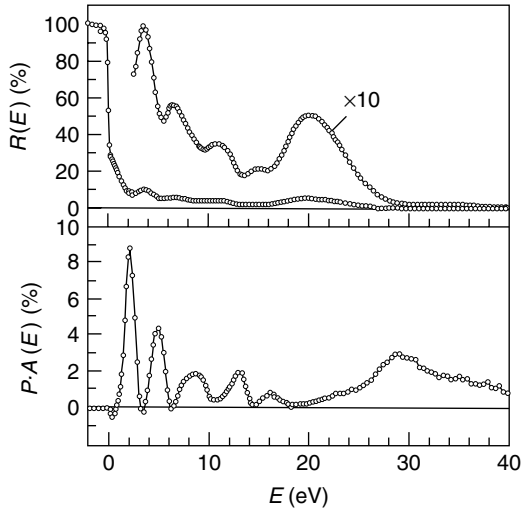

Figure 14. Reflectivity and asymmetry of the reflectivity of a 6 ML thick Co film on W(110) as a function of energy. The true asymmetry is by a factor of about 4–5 higher because of $P \approx 0.2$–0.25. (From M.S. thesis of Wurm, 1994). (Reprinted from *Journal of Magnetism and Magnetic Materials*, Vol 156, 1991. Copyright 1991 with permission from Elsevier.)

The largest asymmetry A was observed at 6 ML of Co (Figure 14).

From Figure 13 it is obvious that by measuring the reflectivity as a function of thickness and energy the exchange-split band structure above the vacuum level can be determined. Early attempts were not successful because the films consisted of small regions differing in thickness resulting in a smearing out of the thickness dependence. With proper growth conditions films with large regions with constant thickness on large substrate terraces can be prepared as illustrated in Figure 15 for Fe films on W(110) (Zdyb and Bauer, 2002a). The images in the top row show the reflectivity at several energies, while those in the lower row show the corresponding asymmetry images in which the contrast is enhanced. Large regions, 6, 7, and 8 ML thick can be seen. Such films have areas large enough for intensity measurements with good signal/noise ratio from which the band structure along the surface normal can be determined with high accuracy (Zdyb and Bauer, 2002b). This technique has been applied more recently to Co films on W(110) also (Graf *et al.*, 2005). In addition to the determination of the unoccupied band structure perpendicular to the surface the QSE has also another promising application: as a spin analyzer or polarizer. The large asymmetry values A that can be achieved when the QSE condition is fulfilled, together with the high reflected current $I = RI_0$, give a large figure of merit $Q = IA^2$ for such devices. In the first measurements on Co films consisting of regions with somewhat different thickness a Q value of about 2×10^{-2} was achieved, while

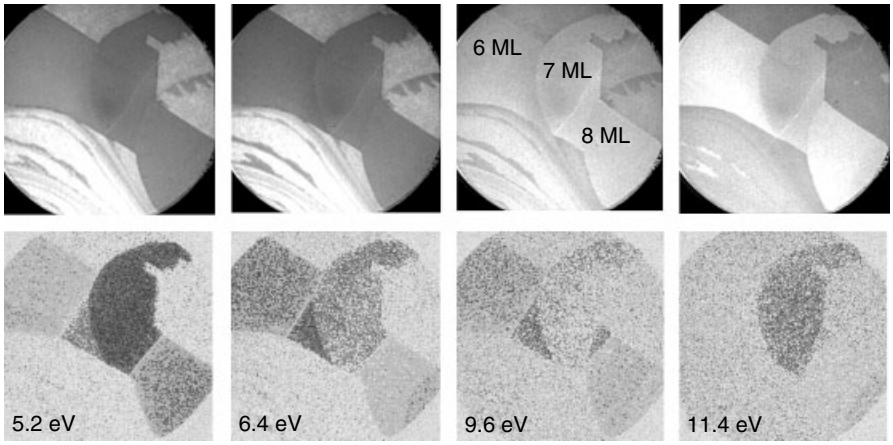

Figure 15. SPLEEM (top) and asymmetry images (bottom) of an Fe layer with large regions of constant thickness on a W(110) surface with large terraces, taken at several energies. When plotted in color, the asymmetry images show the magnitude of the asymmetry and direction of the magnetization. Electron energy 11.4 eV, field of view 9 µm (Zdyb and Bauer, 2002b).

with the constant thickness Fe layers a Q of about 5×10^{-2} (Zdyb and Bauer, 2002a) was achieved. This value can still be enhanced by Au capping, which at the same time reduces the deterioration of Q over time, which was studied in some detail in the more recent study (Graf *et al*., 2005).

Nonmagnetic overlayers have a significant influence on the spin-dependent QSE. This was actually observed before the SPLEEM QSE measurements on Co layers in a study of the influence of Cu overlayers on a Co layer on Cu(100) (Kerkmann, Pescia, Krewer and Vescovo, 1991). In a SPLEEM study (Poppa, Pinkvos, Wurm and Bauer, 1993) a strong modulation of the asymmetry was observed as a function of Cu overlayer thickness on epitaxial Co layers of fixed thickness on W(110). This effect was studied recently in more detail for Cu overlayers on fcc Co(001) on Cu(001) and attributed to the spin-dependent reflectivity of the Cu/Co interface (Wu *et al*., 2005). Overlayers also have additional effects as seen in the Au monolayer (Section 4.2.1), which will be discussed below.

4.2.3 Spin reorientation transitions

With increasing thickness the Curie temperature increases in ultrathin films according to

$$\frac{T_C(n)}{T_C(\infty)} = \frac{(n-1)}{2N_0} \tag{4}$$

where n is the number of monolayers and N_0 the range of the spin-spin coupling. Above N_0 the finite size scaling law

$$\frac{T_C(n)}{T_C(\infty)} = 1 - \left[\frac{2n}{(N_0+1)}\right]^{-1/\upsilon} \tag{5}$$

applies, where υ is the critical exponent for the correlation length for the three-dimensional system (Zhang and Willis, 2001). For Ni, for example, $N_0 \approx 5$ ML and $\upsilon \approx 1$. Thus, at small thickness T_C increases rapidly with thickness and accordingly also magnetization and, therefore, the magnetic contrast. At the same time the influence of the electronic interactions with the substrate, which determines the magnetic anisotropy of the monolayer, decreases and magnetocrystalline and shape anisotropy play an increasing role. In addition, the mismatch between film and substrate introduces magnetoelastic effects, which are particularly evident when the mismatch is anisotropic because it usually produces a well-pronounced easy and hard axis. Steps can also induce magnetic anisotropy, which changes with coverage.

Thus, with increasing thickness not only the magnitude of the magnetization but also its direction changes. This leads to a large variety of so-called SRTs. The first SPLEEM observation of a change of the direction of **M** with coverage was made on Co layers on W(110) (Duden and Bauer, 1996). **M** was not in plane in the thinnest layers as deduced previously from magnetometric measurements but tilted considerably out of plane and tilted into the plane in an apparently oscillatory manner with increasing thickness. The out-of-plane component changed its direction within the large in-plane component domains, preferentially at atomic steps, causing a 'wrinkled' magnetization in the layer.

The most-studied SRT is probably that in Co layers on Au(111) which has been the subject of several SEMPA studies with partially contradicting results. These layers have perpendicular **M** below about 4 ML and in-plane **M** above 5 ML. The SPLEEM study of this SRT, which was not made on a Au single crystal but on epitaxial Au layers of various thickness on W(110), brought additional contradictions

(Duden and Bauer, 1997). Instead of the continuous tilting of **M** into the plane (without or with breakup of the original in-plane domains) that had been deduced from the SEMPA studies, the SRT started with a broadening of the Bloch domain walls, before large in-plane domains developed. This result was later confirmed by laterally averaging magneto-optical measurements (Ding, Pütter, Oepen and Kirschner, 2001). A general theoretical analysis of the SRT (Vedmedenko, Oepen and Kirschner, 2002) finally revealed that both modes of transition, continuous tilt or coexistence of in-plane and out-of-plane regions during the transition, can occur, depending upon the relative magnitude of the various anisotropies involved. Apparently, differences in the substrate topography, in the growth process, and Au segregation to the surface of the Co layer can cause the necessary changes of the relevant anisotropies to produce different SRT modes.

While in the SRT of Co on Au(111) no major structural phase transition occurs with increasing thickness, except possibly a change between fcc and hcp stacking, that of Fe on Au(111) is accompanied by a massive change in structure from a quasi-pseudomorphic fcc layer to an initially distorted bcc (110) layer at about 3 ML (Bulou *et al*., 2004; Dekadjevi *et al*., 2005). Before this structural transition **M** has out-of-plane orientation, after it is in-plane oriented. This transition was studied in detail in $Fe_{1-x}Co_x$ alloy films with $x \leqslant 0.3$, which have bcc structure with nearly the same lattice constant as pure Fe (Zdyb and Bauer, 2003). Contrary to the Fe monolayer on the Au double layer on W(110) discussed in Section 4.2.1 these films were grown on 10 ML thick Au films on W(110) which have already relaxed considerably to the bulk structure but still transfer some of the twofold symmetry of the substrate onto the Fe film. As a consequence, the (110)-oriented bcc films have uniaxial anisotropy with an easy axis in the [001] direction. As seen in Figure 16 below the SRT the magnetization points predominantly out of plane and the domain size increases initially with increasing thickness as usual. A quantitative analysis of the out-of-plane and in-plane contrast shows that **M** is tilted about 15° against the surface normal already from the very beginning. Upon the onset of the SRT the tilt increases and the domain size decreases continuously until **M** abruptly tilts to about 60°, forming large domains when the structural phase transition occurs. With increasing thickness, **M** rotates completely into the plane. Thus, this system shows an SRT, in which the magnetization continuously rotates into the plane, but whose completion is pre-emptied by the structural phase transition. The deposition was made at a grazing angle of incidence so that the SRT occurs earlier on uphill slopes and later on downhill slopes on the terraced surface than on the flat regions. The tilted magnetization even below the onset of the SRT was subsequently also

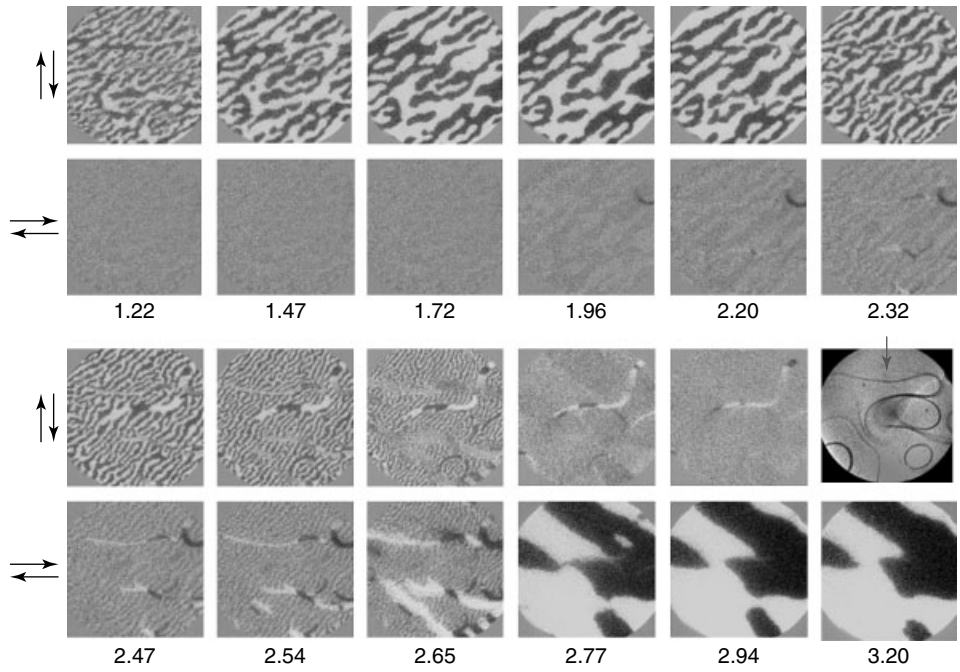

Figure 16. SPLEEM images of the spin reorientation transition (SRT) in an $Fe_{0.7}Co_{0.3}$ layer on 10 ML of Au with (111) orientation on W(110). The top row shows the out-of-plane images, the bottom row the in-plane images. The thickness is given in monolayers. The last out-of-plane image is replaced by a LEEM image to illustrate the topography of the surface. The deposition direction is indicated. Electron energy 2.5 eV, field of view 10 µm (Zdyb and Bauer, 2003).

observed in Fe films with laterally averaging magneto-optical measurements (Toulemonde, Petrov, Naid Abdi and Bucher, 2004).

Several other interesting SRTs have been studied with SPLEEM. One of them is the much studied and controversial out-of-plane to in-plane transition of Fe on Cu(100) which occurs via an apparently nonmagnetic state (Man, Altman and Poppa, 2001a; Man *et al*., 2001b). In this complicated system particular attention was paid to the connection with the film structure and the influence of H_2 on the growth, structure, and magnetic properties of the films and the study was combined with laterally averaging magneto-optical measurements. The magnetization and the domain size decreased with increasing thickness without change of the magnetization direction. This was attributed to the decrease of the Curie temperature from above room temperature at 3 ML to 285 K at about 4 ML. An attempt was made to explain the results in terms of finite size scaling but other explanations are possible too (Bauer, 2005a) in the light of more recent structural STM studies (Biedermann, Tscheliessnig, Schmid and Varga, 2001, 2004). The second part of the SRT, that is the appearance of the in-plane magnetization, was not studied.

SRTs in coupled ferromagnetic layers are of particular interest because they have frequently different anisotropies, which compete with each other. Examples are Fe layers on Ni layers on Cu(100) (Ramchal, Schmid, Farle and Poppa, 2004b). This was studied for 7.2 and 11 ML thick Ni layers, which have perpendicular and canted magnetization, respectively. Up to 2.5 Fe ML the magnetization in the Fe and Ni layers is parallel, but between 2.5 and 2.9 Fe ML the magnetization in the Fe layer rotates in a spiral-like motion into the plane with simultaneous breakup of the originally large domains into stripes with decreasing widths, similar to that seen in Figure 15, before large in-plane domains appear.

4.2.4 Multilayers

The antiferromagnetic and ferromagnetic coupling between ferromagnetic layers through nonmagnetic interlayers plays an important role in magnetoresistive devices. Early unpublished SPLEEM studies of multilayers revealed that no useful additional information could be gained by going beyond a trilayer (sandwich) because with increasing number of layers the surface becomes increasingly rougher. This decreases the intensity and sharpness of the (00) spot and accordingly the signal/noise ratio of the SPLEEM images. Therefore, later trilayers were studied, with emphasis on the influence of interface roughness and of the biquadratic exchange coupling between the layers, which is expressed by the biquadratic coupling 'constant' J_2 in the expression for the interlayer exchange energy

$$E = J_1(1 - \cos\phi) + J_2(1 - \cos^2\phi) \qquad (6)$$

where J_1 is the bilinear coupling 'constant' and ϕ the angle between the magnetization directions in the two layers. Biquadratic coupling is explained in terms of various interface roughness models. Co/Au/Co and Co/Cu/Co trilayers were chosen (Duden and Bauer, 1999b,c). In these studies the short IMFP in Co and the large IMFP in Au and Cu play an important role because the magnetic signal is dominated by the top layer, and a wide thickness range of the nonmagnetic layer can be studied. These studies revealed a complex dependence of the interlayer coupling upon the interlayer thickness as well as upon the top layer thickness.

In films grown at about 300 K, antiferromagnetic coupling occurs at 5 and 4.5 ML of Au and Cu, respectively, independent of the thickness of the top layer, however, nearly always with a strong biquadratic contribution. Bilinear coupling is dominating at 3 Cu ML, at 8 Cu ML the coupling is nearly completely bilinear. While in trilayers with a Cu spacer layer the top layer magnetization is always in-plane, in trilayers with a Au spacer layer the SRT described in Section 4.2.3 occurs in the top Co layer, with antiferromagnetic coupling at 5 Au ML. How the antiferromagnetic coupling changes with the thickness of the top layer is indicated for a few thicknesses in Figure 17; (a) and (b) show images of the Au-covered bottom Co layer which has predominantly in-plane magnetization (b), taken before the deposition of the top Co layer. Image (a) shows, however, that there is also still some out-of-plane **M** component present. (c)–(f) are images of the top Co layer. When it is 3 ML thick (c), **M** is mostly out of plane with antiferromagnetic coupling

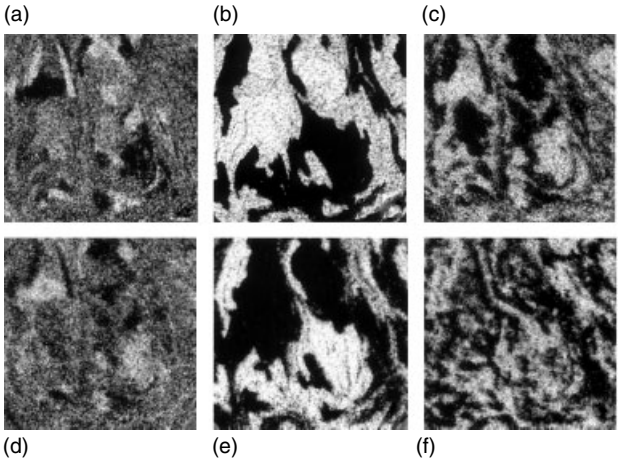

Figure 17. SPLEEM images of antiferromagnetically coupled Co/Au/Co trilayers on W(110). Electron energy 1.2 eV, field of view $6 \times 6\,\mu m^2$. For explanation see text (Duden and Bauer, 1994b).

to the out-of-plane regions in the bottom layer (a). At 4 top Co layers, out-of-plane (d) and in-plane coupling are of comparable strength and at 6 top Co layers **M** is basically only in-plane (e) with some 90° component (f). The strong 90° component in the in-plane magnetization after the SRT is seen also in the ferromagnetic coupling case in the strong domain pattern on the right side of the middle row of Figure 18 where **P** is perpendicular to the easy axis in the bottom layer. In the third row of this figure, **M** is purely out of plane and ferromagnetically coupled to the out-of-plane component in the bottom layer. A quantitative analysis of many SPLEEM images shows that the ratio of J_2/J_1 increases from 4 to 7 Au ML. On the other hand, with the Cu spacers the biquadratic coupling is strongest in the thinner Cu layers and decreases with increasing spacer thickness. These differences between Au and Cu indicate that the interface roughness, which causes biquadratic coupling, decreases in Au spacers with increasing thickness, while it decreases in Cu spacers, probably due to the different growth modes of these layers. Interface roughness is important because with increasing deposition temperature, that is increasing roughness, the correlation between the domain structure in the top and bottom layers rapidly decreases.

Noncollinear coupling, which converts into collinear coupling with increasing spacer thickness, was also observed in a completely different system: in an Fe trilayer with an antiferromagnetic NiO spacer layer (Biagioni *et al*., 2005). In this case there is no correlation between the domain size in top and bottom layers. The domains in the top layer are much smaller than those in the bottom layer and presumably depend on the size of the antiferromagnetic domains in the NiO layer. The critical thickness for the transition from noncollinear to collinear coupling seems to be preparation-dependent, a possible indication of roughness effects.

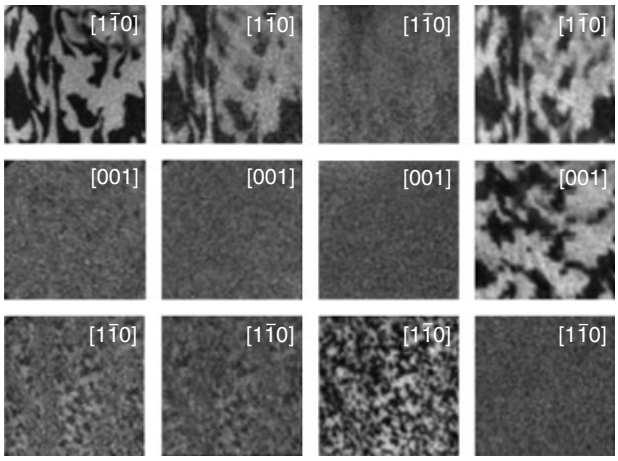

Figure 18. SPLEEM images of ferromagnetically coupled Co/Au/Co trilayers on W(110). The images in the top row are taken with **P** parallel to $\pm$**M** in the bottom layer (W[1$\bar{1}$0] direction), those in the middle row 90° with **P** rotated (W[001] direction) and those in the bottom row with **P** perpendicular to the layer (W[110] direction). The columns show from the left to the right the following layer combinations: the bottom Co layer (7 Co), the Au-covered bottom Co layer (6 Au/7 Co) and the complete sandwiches 3 Co/6 Au/7 Co and 7 Co/6 Au/7 Co, where the numbers give the number of monolayers. Electron energy 1.2 eV, field of view $6 \times 6\,\mu m^2$ (Duden and Bauer, 1994b).

4.2.5 Small particles

The samples discussed in Sections 4.2.1–4.2.4 were continuous films. SPLEEM is also suited for the study of small particles, provided that they are single crystals with the top plane parallel to the substrate. Such studies were already attempted in the early years of SPLEEM. Pinkvos, Poppa, Bauer and Kim (1993) studied small Co particles on W(110), obtained either by growth at elevated temperature or by annealing a thick film at elevated temperature. The particles grown at elevated temperature (790 K) form elongated crystals along the W[001] direction with submicron widths and were all single domain, presumably due to the shape anisotropy. The particles obtained by annealing show a pronounced memory of the original magnetization direction in the continuous film, even in the smallest particles, which are quite irregular-shaped and have a few 100-nm diameter. More recent work aimed at the understanding of the magnetic domain structure of small particles. Fe on W(110) was chosen for this purpose because growth experiments in connection with optimizing conditions for QSE experiments (Zdyb and Bauer, 2002a) had shown a wide variety of growth shapes (Zdyb, Jalochowski, Pavlovska and Bauer, 2006). They range from more or less isometric crystals to ribbons and wires as shown in Figure 19. Several energies compete in these epitaxial crystals to different degrees, depending upon the shape of the particle: stray field energy (shape anisotropy), exchange energy, surface/interface energy, magnetoelastic anisotropy energy, and magnetocrystalline energy. In the small isometric particles the first two energies are dominating, which produces multidomain states, similar to the situation in polycrystalline particles on amorphous substrates (Cherifi *et al*., 2005). In the wires (c, d) shape anisotropy is dominating, in the ribbons all energies are relevant. In the larger flat crystals in (c, d) magnetoelastic energy produces single-domain states. It should be noted that for polycrystalline particles other methods such as X-ray magnetic circular dichroism PEEM are better suited although SPLEEM can be applied to them too, albeit with much longer image acquisition times.

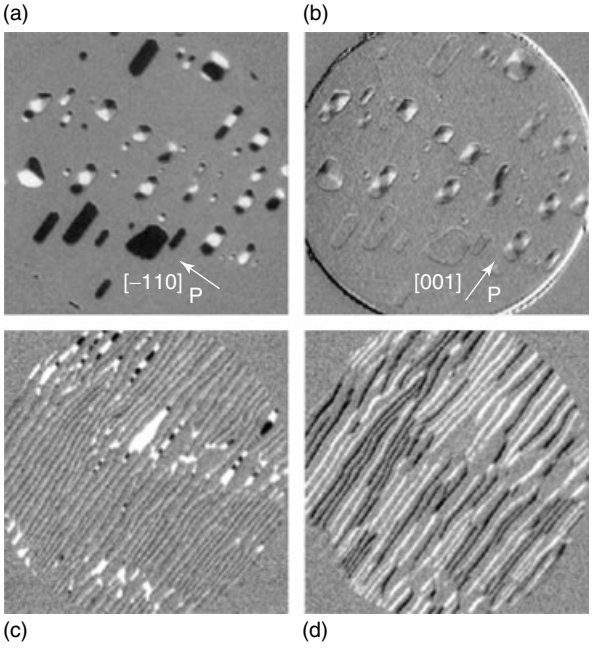

Figure 19. SPLEEM images of small epitaxial Fe crystals (a, b) and wires (c, d) obtained by annealing 5–10-ML thick films at about 700 K. The directions of the polarization and of the axes in the W(110) surface are shown in (a) and (b). Electron energy 3.5 eV, field of view 14 µm (Zdyb, Jalochowski, Pavlovska *et al*., 2006).

Finally, a study at the present resolution limits of SPLEEM should be mentioned. Micromagnetic simulations have predicted the height and thickness ranges in small hexagonal Co particles, in which single-domain and vortex domain states should (co)exist. The coexistence region ranges from about 30–40 nm width to 600–6000 nm width, depending upon thickness in the range from 1 to 10 nm. These widths are partially accessible to SPLEEM with which the thermally activated switching between the two states of Co epitaxial particles on Ru(0001) was studied (Ding *et al*., 2005).

5 SUMMARY AND OUTLOOK

In this chapter a brief overview of the field of SPLEEM was given with the goal to introduce the reader to the method and its application possibilities. Complementary, though partially overlapping, information may be found in two other recent reviews (Bauer, 2005a,b). The qualitative aspects of SPLEEM and its applications only were discussed, which does not mean that it is not possible to obtain quantitative data. Quantitative analysis of sufficiently detailed and accurate SPLEEM measurements allows extraction of many magnetic parameters that determine the direction or relative magnitude of the magnetization. Such parameters are anisotropy constants or critical exponents. It is, however, difficult to determine the absolute magnitude of the magnetization from the magnetic contrast, not only because of the complications caused by QSEs, but generally because the constant c in the magnetic contribution $c\mathbf{P}\cdot\mathbf{M}$ is not known and $|\mathbf{P}|$ is usually not known accurately either.

The strengths of SPLEEM are the high surface sensitivity and the combination of magnetic with structural information obtained in the LEEM mode via diffraction contrast, step contrast and quantum size contrast and in the LEED mode. SPLEEM of course also has its drawbacks when compared to other magnetic low-energy electron imaging methods, which do not provide the structural information. SEMPA and XMCDPEEM can be applied to amorphous and polycrystalline samples with random crystal orientation, while SPLEEM is only of limited use there. In addition, XMCDPEEM images give directly chemical information and in a SEMPA instrument this information can be obtained too if equipped with spectroscopy facilities.

The amount of information obtained till now with SPLEEM is still limited, mainly because only two home-built instruments have been available and operating until recently, partially on-off and with limited resources. The recent installation of two commercial instruments, equipped with both a spin-polarized and a high intensity LaB_6 cathode, should change this situation. The LaB_6 gun can be used for focusing so that the spin-polarized cathode does not have to have high intensity. GaAs cathodes with high polarization, but low intensity can then be used which will improve the magnetic contrast by a factor of 4–5 above the present values. This will increase the signal/noise ratio and, as a consequence, the resolution considerably, possibly to the values obtainable with the energy width-limited resolution of the cathode lens of about 5 nm. Further improvements of the resolution will require correction of the aberrations of the objective lens. While this is theoretically possible it remains to be seen whether or not it is also possible in experiment. The results from the first aberration-corrected low-energy electron microscope, the SMART (Schmidt *et al*., 2002) will have to show this in the future. Some resolution improvement has been achieved already. Another future avenue of research is time-resolved SPLEEM. This has to be done in pulsed operation of the gun, which is quite common already in high-energy physics, synchronized with pulsed changes of the magnetization. It is already used increasingly in XMCDPEEM studies. In this case the high spatial resolution alluded to above probably cannot be achieved; otherwise a too large number of pulse repetitions has to be used because of the low signal per pulse. The method is also limited to processes in which the magnetic state returns within a short time interval into the state before the pulse-induced change.

Besides these future possibilities of SPLEEM there are still many problems in the physics of ultrathin films and small

particles that can be solved with SPLEEM in its present state. Examples are (i) the influence of the lateral inhomogeneity in ultrathin films on magnetic properties, which in many cases have been studied only by laterally averaging methods. This includes the influence of steps and of the step density on SRTs and on the critical behavior; (ii) the micromagnetic aspects of the interlayer coupling; and (iii) the competition between the various anisotropies in small magnetic particles with a wide variety of shapes.

ACKNOWLEDGMENTS

The development of SPLEEM was initially supported by IBM and later by the Deutsche Forschungsgemeinschaft and by the National Science Foundation.

Scanning Electron Microscopy with Polarization Analysis

Hans Peter Oepen and Robert Frömter
Universität Hamburg, Hamburg, Germany

1 INTRODUCTION

'Magnetism goes nano' is the slogan that describes best the activities in research on ferromagnetic systems. Those activities include basic research, as well as the research related to applications in profit oriented industrial development laboratories. As still a big business can be made with storage media, the trend goes toward higher density, that is, smaller bit structures, to compete with new storage devices like flash memories. In basic research, the dimensionality plays a fascinating role, as the size can be reduced to the limits where the collective phenomenon 'ferromagnetism' will be affected. Questions for the transition from atomic via molecular magnetism to ferromagnetism come into the reach of feasibility, promising new and highly interesting insight into collective phenomena. To perform such studies it is equally important to fabricate and to analyze such structures and devices. In this contribution, we will focus on a microscopy technique for magnetic structure analysis that bridges the scales from micrometers to nanometers, that is, spin-SEM (for scanning electron microscopy) or SEMPA (for scanning electron microscopy with polarization analysis). Besides its application in basic research, this technique has developed into a versatile tool for solving problems in development and even production of commercial devices.

With recent improvements in different components of SEMPA and in sample preparation, spin-SEM is now applicable for the investigation of all kinds of ferromagnetic systems. This ensures the technique its importance in competition with the high resolving scanning probe techniques **Scanning Probe Techniques: MFM and SP-STM, Volume 3**. The latter show an ultrahigh sensitivity for surface morphology and chemical composition on the atomic scale, which limits their applicability to systems exhibiting perfect smooth surfaces. This is commonly at variance with fabrication processes of devices. Transmission electron microscopy based techniques, like Lorentz microscopy **Lorentz Microscopy of Thin-film Systems, Volume 3** or electron holography **Electron Holography of Ferromagnetic Materials, Volume 3**, cover a similar range of scales as SEMPA. Utilizing special detector layouts (differential phase contrast technique (Chapman, Batson, Waddell and Ferrier, 1978)), scanning transmission electron microscopes can show a similar suppression of morphological structures like spin-SEM. In comparison to transmission electron microscopy techniques, however, SEMPA needs no massive

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

sample manipulation, like reducing the thickness to some 10 nm. Spin-SEM can be applied to investigate samples or devices in exactly the same setup they are intended for use in commercial systems. Particularly the control of industrial fabrication processes for media and devices will create an increasing demand for spin-SEM investigation in the future.

In this contribution, we will introduce the SEMPA technique with special emphasis on the scientific basics and less on the technical realization. The aim is to make a broader audience familiar with the technique, so that the nonexpert in magnetic microscopy gets information at his hand that helps decide whether the technique is suitable to solve his problems or not.

The chapter is organized as follows: In Section 2, the basics of spin-polarized secondary electron (SE) emission is presented, whereas in the succeeding section, the implications of the physical process for the instrument are discussed and principal design features and properties of SEMPA are worked out. We also discuss some drawbacks that result exclusively from the related physics. A state-of-the-art spin-SEM is presented in the following section, that is, a new generation of SEMPA that has been realized quite recently. The specifications will be given and discussed in the framework of design criteria that were realized. In Section 5, the application of spin-SEM will be demonstrated by means of the results obtained with different samples. Here, we focus on the unique features of the techniques although their limits are also shown.

2 BASICS OF SPIN-POLARIZED SECONDARY ELECTRON EMISSION

When a solid is irradiated by electrons with energies in the range of a few kiloelectron volts, electrons are reemitted showing a well-known energy distribution, which is sketched in Figure 1 (Reimer, 1998). The elastically scattered electrons create a sharp peak at the primary energy (E_0), followed by structures that are due to electrons, which have excited plasmons. On the flat background at lower energies, there are small structures that originate from Auger electrons (100–2000 eV), and finally at very low energies a pronounced intensity maximum is found. Electrons in that energy range are called *true* secondary electrons. While most of the higher-energy electrons that create structures in the distribution are used in solid state and surface physics for investigating the properties of matter, the electrons below 50 eV are used in SEM in general to visualize the morphology of surfaces. Owing to the high SE intensity, good statistics can be achieved and fast image acquisition is possible. These low-energy electrons are created in a cascade process by multiple inelastic scattering of the incident electrons and the inelastic scattering of the excited electrons that are created during preceding inelastic processes. The electrons in the low-energy tail have undergone strong interactions with electronic states around the Fermi energy during their emission process.

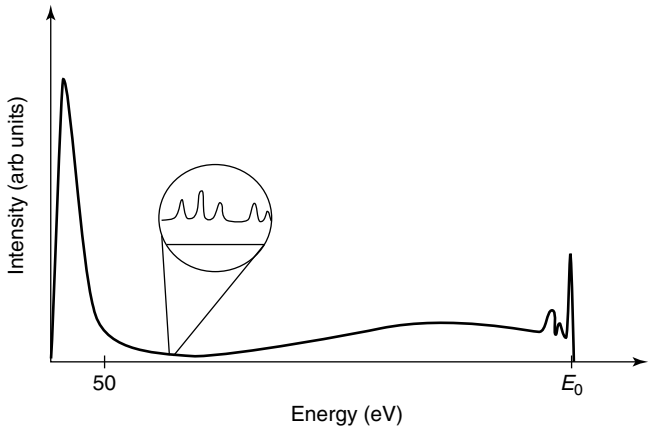

Figure 1. Intensity distribution of electrons leaving a surface, when bombarded by electrons with energy E_0. The small peak at E_0 is due to the elastically scattered electrons. As an inset, the small peaks that appear due to Auger processes are shown enlarged. Those electron energies are determined by energy levels of the atom that was excited by the primary electron. Auger electrons are used to study the chemical composition of surfaces in an energy range from 100 to 2000 eV. At very low energies, the secondary electrons generate a strong maximum. In scanning electron microscopy, the electrons below 50 eV are often called *true secondaries*.

Itinerant ferromagnets show a strong imbalance of the so-called spin-up and spin-down electrons at the Fermi level. In that nomenclature, spin-up/-down means antiparallel/parallel alignment of the electron spin with respect to the sample magnetization. Hence, owing to the aforementioned strong interaction in SE emission, one should expect some signature of this spin imbalance in the low-energy SE. Indeed, in the first investigation of spin-polarized SE emission a strong polarization of those electrons was found (Chrobok and Hofmann, 1976). Subsequent studies of the energy dependence of the spin polarization revealed a polarization enhancement for SE with energies below ∼10 eV, that is, polarization values higher than the averaged electron polarization at the Fermi energy (Figure 2). The polarization decreases with increasing SE energy. Above ∼30 eV the polarization value is that of the average polarization of the electrons at the Fermi energy P_F (Figure 2). The enhancement of the polarization scales roughly with the polarization value at E_F, which means that the polarization at low energies P_0 becomes larger in the row Ni, Co to Fe. For Fe, a polarization $P_0 \sim 48–50\%$ was found (Kisker, Gudat and Schröder, 1982; Unguris, Pierce, Galejs

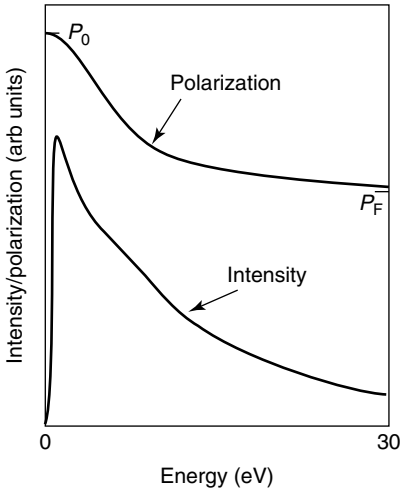

Figure 2. Intensity and polarization distribution of secondary electrons from an itinerant ferromagnet. The polarization is highest at the very low energies where the intensity also peaks. For secondary electron energies above 30 eV, the polarization value merges into the value P_F that is roughly the averaged polarization of electrons at the Fermi level. P_0 values differ for the different itinerant ferromagnets. It is highest for Fe and lowest for Ni.

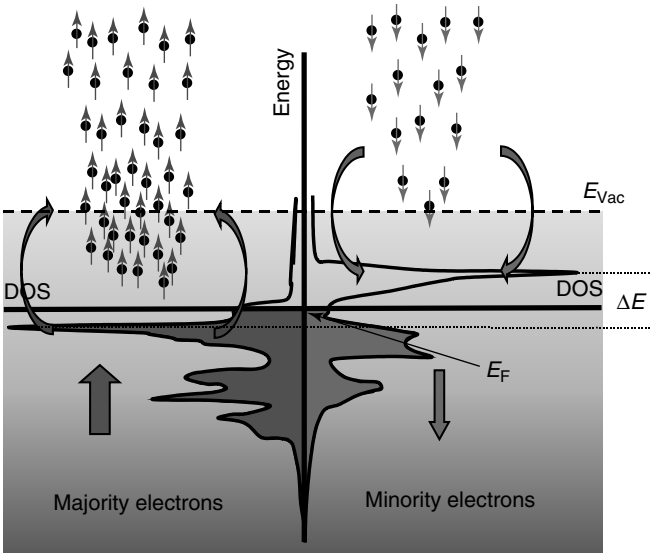

Figure 3. Spin-resolved density of states for a hypothetical itinerant ferromagnet. The electrons with minority spin have a high density of states above the Fermi level while majority spin electrons occupy states below E_F. The shaded energy range indicates the band states below the vacuum level (E_{Vac}). Electrons above E_{Vac} can leave the solid and contribute to the secondary electrons. A rough sketch of the filtering processes that cause the enhanced polarization is given. The energy loss due to Stoner excitations is on the average ΔE.

and Celotta, 1982; Hopster *et al*., 1983; Hammond, Fahsold and Kirschner, 1992; Kirschner, 1988).

The enhancement is commonly believed to originate from the cascade process of SE creation. In an itinerant ferromagnet, a filtering mechanism is effective due to the different density of states for up and down electrons. Roughly speaking, as the inelastic electron/electron scattering can only proceed via states around the Fermi level, the density of states at E_F determines the scattering probability. There are two processes involved in the inelastic scattering: on the one hand, the scattering of electrons with energies well above E_F into lower lying energy states and on the other hand, the simultaneous excitation of electrons into higher states due to energy conservation.

For minority spins, there are a great number of unoccupied states available above E_F, while almost all the majority states around E_F are occupied (see Figure 3). This means that preferably minority spin electrons are scattered into states around E_F and are filtered out of the electrons that will be emitted ($E > E_{Vac}$). For electrons with majority spin the probability for inelastic scattering is very small (Figure 3), due to a negligibly small number of states above E_F. On the other hand, if the energy difference that is available for excitation is in the range of a few electron volts, that is, when electrons with energy slightly above E_F are scattered into lower lying states, the electrons that can be excited will originate exclusively from states close to E_F. Hence, mostly electrons of majority spin character are excited, because close to the Fermi energy the occupied states are mostly majority states. In summary, with decreasing electron energy the possibility to filter out minority and excite majority electrons increases for electron energies around and below the vacuum level. Owing to the multiplication that happens within the emission process, the polarization enhancement is created.

If there is no considerable imbalance of the density of states at E_F for spin-up and spin-down electrons, the SE polarization will be very small if any is found at all. This will happen in the so-called localized ferromagnets, which have a magnetization that is originating from the occupation of inner shell states. The effect of the localized magnetic moments on the spin polarization of the conduction band electrons is generally very small. Hence, when utilizing the SE spin polarization as a tool for investigating ferromagnetism, this class of materials is out of range. This obstacle can be partially overcome when the material is covered with an ultrathin itinerant ferromagnet layer (so-called dusting, see the following text). This layer often mirrors the domain structure of the material underneath while it fulfills the requirements for SEMPA imaging.

The above-sketched process is associated with a net energy loss, as the electron that loses energy falls into states above E_F, while the excited electron comes from states

below E_F. In total, the electron exchange creates electrons with opposite spin and a mean energy loss ΔE. Roughly speaking, ΔE is, on the average, the energy difference of the maxima of the two densities of states (Figure 3). The above described interaction process in ferromagnets is called *Stoner excitation* (for an overview, see Feder, 1985).

The very existence of low-energy losses (in the range <5 eV), particularly in combination with a high scattering cross section, has a strong impact on the information depth for the electron spin polarization. It was found that the polarization is determined by the topmost layers of the ferromagnet, that is, the information depth is extremely small. For 3d ferromagnets, the latter amounts to about 5 atomic layers (Abraham and Hopster, 1987). This finding is puzzling, as it apparently contradicts the general trend, predicted for the so-called mean free path. The master or universal curve (Ibach, 1977; Seah and Dench, 1979) gives a mean free path in the range of 10 nm (30–50 atomic layers) for electrons with energies below 10 eV. As this universal curve is used in electron spectroscopy to estimate escape depths for higher-energy electrons, it only takes energy losses above 10 eV into consideration. This assumption is strongly oversimplifying the physics of electron scattering at energies a few electron volts above E_F. More recent compilations of mean free path data indicate much smaller values for certain transition metals and thus a deviation from a universal-curve behavior at low energies (Powell and Jablonski, 1999). In fact, it has been found that the d holes in 3d transition metals are responsible for strong electron–electron inelastic interaction that gives an appropriately short mean free path for low-energy electrons (Schönhense and Siegmann, 1993). Since in a ferromagnet these d holes are also spin polarized, a strongly spin-dependant mean free path can be expected (Schönhense and Siegmann, 1993; Hong and Mills, 2000). As a matter of fact the low losses and hence the small depth of information are striking when the spin polarization is taken into consideration.

As the quantization axis for the spin is given by the magnetic field **B** inside the sample, the spin polarization of the SE has a well-defined direction in real space and in general reveals the orientation of the magnetization of the ferromagnet (Unguris, Pierce, Galejs and Celotta, 1982; Kirschner and Suga, 1987). As the charge of the electrons is negative by definition, the magnetic moment of electrons is antiparallel to its angular momentum. The polarization that is defined via the angular momentum is thus antiparallel to the magnetization vector.

In conclusion, the physical processes of SE emission give a polarization enhancement at the very low energies, that is, exactly in the range where the SE intensity is high. The polarization is antiparallel to the magnetization. The polarization value is highest for Fe and decreases from Co to Ni. The low-energy losses, that is, the Stoner excitations, dominate the scattering processes and are responsible for the very small depth of information for electron polarization.

3 GENERAL CONSIDERATIONS

The physics of SE emission sets the limits and dictates the prerequisites for the microscopy of magnetic structures utilizing SE. In this paragraph, we will present the general features of a spin-SEM and will work out how the physics of SE emission implies certain solutions. In the conventional SEM, the true SEs, which have the highest intensity in the whole electron energy spectrum, are used for imaging. High intensity is superior for imaging techniques, as it makes quick measurement with high signal-to-noise ratio feasible. The fact that in SE emission from itinerant ferromagnets the highest polarization coincides with highest intensity brought about ideas and conjectures for a new imaging technique for magnetic structures (DiStefano, 1978; Celotta and Pierce, 1982; Kirschner, 1984).

The idea is to use a very narrow primary beam for SE creation and determine the SE spin polarization at the very low energies (Figure 4) to obtain a local information about the magnetization with high spatial resolution. Measuring the orientation of polarization gives the full information about the magnetization vector, as polarization and magnetization are antiparallel (according to the properties of spin-polarized SE emission). The latter proposition makes the vector analysis of the spin polarization desirable. Putting the pieces together, the basic idea is to measure the polarization orientation point

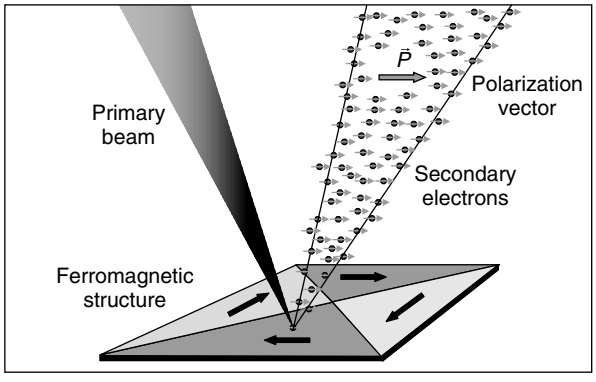

Figure 4. Principle of a spin-SEM. The primary beam creates SE at the sample surface. The SE are spin polarized. The polarization is antiparallel to the magnetization at the emission spot. Measuring the orientation of polarization reveals the magnetization orientation. Scanning the primary beam across the surface gives the lateral distribution of the magnetization orientation, that is, the domain structure.

by point using the smallest possible spot size for the impinging electron beam. The resulting polarization distribution is identical (except for the sign) to the local distribution of the magnetization orientation, that is, the micromagnetic or domain structure of the ferromagnet. From that basic consideration, it is evident that the geometry of the experiment is quite similar to that of SEM. In particular, it means that the experiment is performed in reflection and sample thickness and composition are no matters of concern.

To create the ultrafine, so-called primary, electron beam, it was conjectured to utilize a SEM column and combine a SEM and a spin-polarization analyzer. The result is a new microscope that was called *spin-SEM* or *SEMPA* (for SEM with polarization analysis). The unique feature of this type of microscope is that it gives direct access to the distribution of the magnetization orientation (as vectorial quantity), which is identical to the magnetic structure that is of interest.

The extremely low depth of information, which is synonymous with high surface sensitivity, has strong implications for the realization of a spin-SEM. First of all it means that the surface of the sample under investigation has to be absolutely clean. Therefore, any surface pollution by oxidation, contamination, or any remains of a pretreatment have to be avoided. Even contamination due to handling of samples under ambient conditions can cause the total loss of the polarization signal. In general, this means that surface preparation techniques have to be available in the microscope to produce clean ferromagnetic surfaces *in situ*. Ion milling (or sputtering) is commonly used to remove contamination layers from surfaces. Alternatively, one can deposit a ferromagnetic layer that gives a fresh clean surface. The deposited film usually adopts the magnetic structures of the underlying sample. Even when the sample surface has been perfectly prepared, the surface has to stay clean during investigation. With data acquisition times in the range of minutes, one can estimate the vacuum that is required to perform such investigations. It becomes evident that the microscope has to operate under ultrahigh vacuum (UHV) conditions and has to be equipped with sputtering and evaporation facilities.

Apparently, the high surface sensitivity seems to be a disadvantage of the technique, as it requires the very sophisticated and expensive equipment known from surface science experiments. We will demonstrate, however, in the course of this chapter that this property can be very advantageous as well, because in combination with ultrathin films it gives access to a large class of samples for investigation by SEMPA. To stress the point once more: imaging of magnetic structures utilizing spin-polarized SE emission works only with clean surfaces and experiments have to be performed under UHV conditions.

From the above considerations, the general setup can be easily imagined (Figure 5). The basic components of the instrument are the SEM column and the spin-polarization analyzer. The microscope is run under UHV conditions, which means that all equipment including the SEM column has to be UHV compatible.

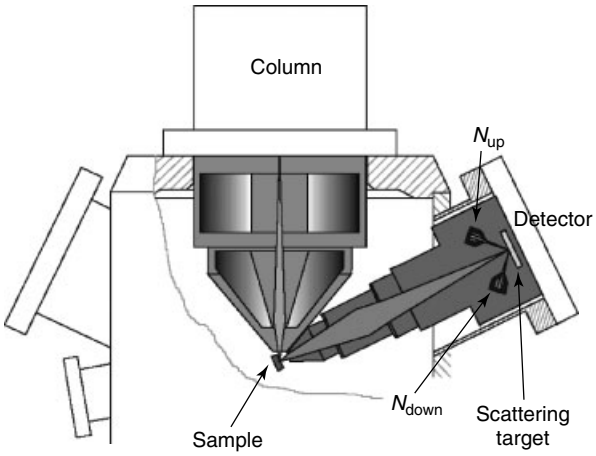

Figure 5. Sketch of a SEMPA setup. Main components are the SEM column and the spin detector, including the electron optics that focuses the SE onto the detector crystal. Two out of four counting facilities are displayed. The oppositely oriented diffracted beams give access to the polarization component perpendicular to the plane of drawing.

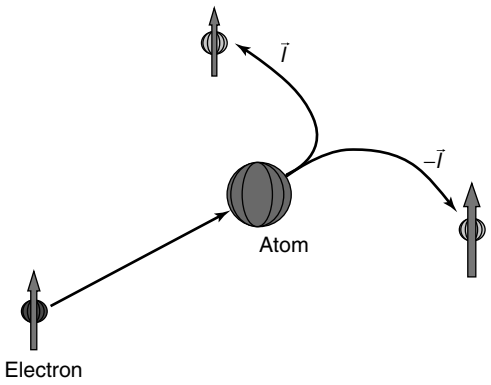

Figure 6. Sketch of the scattering of electrons at atoms. Depending on the direction in which the electrons are scattered, an angular momentum is defined. Scattering into opposite angles gives opposite angular momenta and thus opposite orbital magnetic momenta. The interaction of the electron spin with the orbital momenta is responsible for the increase/decrease of the scattering energy and thus for different cross sections. A scattering asymmetry is found.

The spin polarization of electrons is measured by means of a scattering experiment. Owing to the coupling of the electron spin and the orbital momentum (Figure 6) a right/left asymmetry can be found. It means that the scattering intensities under opposite angles are different. The asymmetry is proportional to the polarization of the incoming electrons. More

precisely, the asymmetry is proportional to the polarization component that is perpendicular to the scattering plane, spanned by the incoming and scattered electron beams. To achieve direct correlation and easy interpretation in polarization detectors, normal incidence geometry is chosen and the scattering intensities are measured under opposite angles. In Figure 5, two scattered beams and corresponding detectors are displayed (named N_{up} and N_{down}). They are used to determine the polarization component that is perpendicular to the plane of drawing, that is, the scattering plane. Additionally, a second scattering asymmetry can be determined in a direction perpendicular to the first one. The according polarization component is in the plane of drawing (parallel to the surface of the scattering target). The corresponding scattered beams point out of or into the plane of drawing.

To maximize the number of SEs that enter the detector, a specifically designed electron optics is mounted in front of the analyzer. This optics focuses the SE into the detector while enlarging the angle of acceptance of the detector. The ultimate aim is to bring all the SEs emitted into the half-space into the analyzer.

All successful realizations of spin-SEM worldwide look pretty much the same and comprise those above-mentioned basic components. For a listing, see for instance in Oepen and Hopster (2005, p. 137). The individual microscopes differ with respect to the SEM columns and the polarization detectors that are used. While the performance and features of the various commercially available SEM columns can be easily obtained from the companies selling SEM, the spin-polarization analyzers are somewhat more exotic and will be briefly discussed next.

The high-energy scattering at the cores of materials with high atomic number is used in Mott detectors for polarization analysis (typical energies 20–100 keV) (Koike and Hayakawa, 1984; Allenspach, 1994; Iwasaki, Takiguchi and Bessho, 1997; Stamm *et al*., 1998; Hopster, 1999). A gold foil is used as scattering target. The scattering angles are 120° with respect to the momentum of the incident electrons (Kessler, 1985; Barnes, Mei, Lairson and Dunning, 1999). Mott detectors are bulky for high-voltage insulation reasons.

The second type of detector is based on the low-energy electron diffraction (LEED detector) at single crystal surfaces (Kirschner and Feder, 1979; Kirschner, 1985). The scattering is performed at a W(001) surface. The (2,0) diffraction beams at 104.5 eV are taken for the polarization analysis (Frömter, Oepen and Kirschner, 2003).

A second low-energy concept is based on the diffuse scattering of electrons at polycrystalline Au films (low-energy diffuse scattering (LEDS) detector) (Scheinfein *et al*., 1989; Hembree, Unguris, Celotta and Pierce, 1987) at a scattering energy of 150 eV.

What is common for all the above-mentioned detectors is a very low efficiency for polarization analysis, that is, in the range of 10^{-4} (Scheinfein *et al*., 1990). In other words, 1 electron in 10 000 contributes to the polarization analysis. This is a disadvantage as it puts strong requirements on the specification of every instrument component and makes an optimized tuning absolutely necessary. In particular, for the SEM column this means that the primary current should be as high as possible, while the lateral resolution must be high at the same time. Some rough estimations reveal that a primary current in the range of 10^{-9} A is desirable to obtain reasonable measuring times (Oepen and Hopster, 2005). Standard thermionic emitters fail as electron source, because currents in that range are available only at the cost of spatial resolution (Reimer, 1998). The best choice under the prerequisite of good spatial resolution and high current is the field emission (FE) column (especially thermally assisted FE or Schottky guns). The number of SEs per incoming electron depends on the primary energy. Particularly at energies above 10 keV the SE yield decreases and drops by more than a factor of 3 with respect to the values at energies around 1 keV (Kirschner, 1988). Hence, it is recommendable to run the SEM column in a low voltage mode. Such working parameters are usually at variance with high spatial resolution and high primary intensities. The best compromise between resolution and SE intensity has to be experimentally found – it usually depends also on the sample under investigation. Again, FE columns can meet the requirements of high resolution, high primary current at low primary energy best.

Secondly, the electron optics and the polarization analyzer have to be optimized in the sense, that all the SE created by the primary current should be collected and focused into the analyzer. For optimization, the convolution of the SE energy distribution of polarization/intensity and the detector analyzing properties, like permissible angle and energy spread, have to be considered (Oepen and Hopster, 2005). The latest generation of a spin-SEM has been realized recently (Kohashi and Koike, 2001; Frömter, Oepen and Kirschner, 2003). We will discuss the obtained performance of our system and compare it with the idealized system in the following paragraph.

As mentioned above, the polarization detector measures the left/right asymmetry of scattered electrons. The spin-orbit coupling is the relevant effect and its contribution is small in comparison to the electrostatic (Coulomb) scattering. To separate the spin-dependent part from the much larger 'background' the normalized intensity difference between right and left scattering intensity is constructed. The scattering asymmetries

$$A_{\mathrm{vert}} = \frac{(N_{\mathrm{right}} - N_{\mathrm{left}})}{(N_{\mathrm{right}} + N_{\mathrm{left}})}, A_{\mathrm{horz}} = \frac{(N_{\mathrm{up}} - N_{\mathrm{down}})}{(N_{\mathrm{up}} + N_{\mathrm{down}})} \quad (1)$$

are proportional to the polarization, that is, the polarization component perpendicular to the respective scattering planes. The proportionality factor is the inverse of the sensitivity S (in Mott scattering called *Sherman function* (Kessler, 1985)). A 100% polarized electron beam gives an asymmetry of S. For Mott and LEED detector the sensitivity is $\sim$25% and considerably higher than S for the LEDS detector ($\sim$11%). As a general rule, one may say that the higher the sensitivity, the easier is the handling of the spin-SEM, as the system is less sensitive to slight misalignments in the detector and electron optics that cause apparatus or device asymmetries. Owing to the normalization procedure, the surface morphology is suppressed and a strong magnetic contrast can be attained.

4 REALIZATION OF A SPIN-SEM UTILIZING A LEED DETECTOR

The preceding section discussed general considerations for the implementation of spin analysis in SEM. In the following, we will exemplarily present the realization and the performance of a particular instrument. The spin-SEM, which has been realized in our laboratory, consists of a modern UHV compatible Schottky-emission SEM column and a LEED spin-polarization detector. The LEED detector has been chosen for several reasons: At first, the compact size guarantees highest flexibility with little space required for the polarization analyzer. Secondly, the angular and energy acceptance of the LEED scattering process can be well matched to the broad energy and angular spread of SE emission. This allows for comparatively high detection efficiency, since a large amount of SE contributes to the spin analysis, while the apparatus asymmetry, caused by scanning of the primary beam, can be kept low. Details will be given below. Not least, the use of the LEED detector for SEMPA has been pioneered in our lab almost 20 years ago (Oepen and Kirschner, 1989; Oepen and Kirschner, 1991). The detector discussed here represents the third generation of ongoing improvement and miniaturization processes.

4.1 Overview

The complete experimental setup consists of two vacuum chambers, one for microscopy and the other for sample preparation, including thin-film fabrication. The whole system can be baked to at least 150 °C and is operated in the low 10^{-10} mbar residual pressure regime. Under these conditions, the magnetic contrast from an iron sample has proved to be useful for several days. Samples can be quickly inserted into the microscopy chamber by means of a load lock and can be further transferred into the preparation chamber under UHV.

One design criterion has been to achieve as much flexibility as possible for applying the high resolving electron beam from the SEM column. For that purpose, several UHV ports have been orientated with straight view onto the sample. On such flanges, there are mounted the spin analyzer, a sputter gun, a hemispherical energy analyzer, and an electron beam evaporator for iron film deposition. In order to achieve high detection efficiency, it is important to keep the distance sample/detector optics small. For that reason the spin detector can be retracted, which maintains unhindered sample access for other devices. The hemispherical analyzer, which is also retractable, can be used for Auger electron spectroscopy. In combination with the SEM column, this opens up the possibility for spatially high resolution chemical analysis, that is, scanning Auger microscopy (SAM).

4.2 The SEM column

The UHV version of the Zeiss Gemini system is used in our microscope. This column was designed as primary source for SAM and SEMPA. It is equipped with a Schottky FE cathode and a combined electromagnetic/electrostatic objective lens. The electron optical properties are superior to conventional microscopes, as the column combines high current with high spatial resolution, even at relatively low primary beam energies. It thus fits very well the requirements for a SEM column to be used in spin-SEM. At a working distance of 8 mm, a resolution of 7.5 nm is specified for a beam current of 1 nA at 3 keV primary energy. This current value fits well into the range that offers good working conditions (Hopster and Oepen, 2005), while the low primary energy is superior as it allows to operate close to the energy range where the SE yield becomes maximum (Hopster and Oepen, 2005).

4.3 Geometric design considerations

As mentioned in the previous sections, the important issue for a good working spin-SEM is to maximize the angular acceptance of the polarization analyzer. For that reason, a normal takeoff geometry is chosen, as illustrated in Figure 7. Additionally, the distance between sample and detector optics is minimized. The SEs are accelerated into the optics by means of high potentials at the first elements of the optics. The first condition puts strong limitations on the geometrical arrangement. The angle between SEM column and detector optics should be much smaller than 90° to maintain an acceptable tilt angle with respect to the column axis. A too large sample tilt would cause a serious deterioration of image

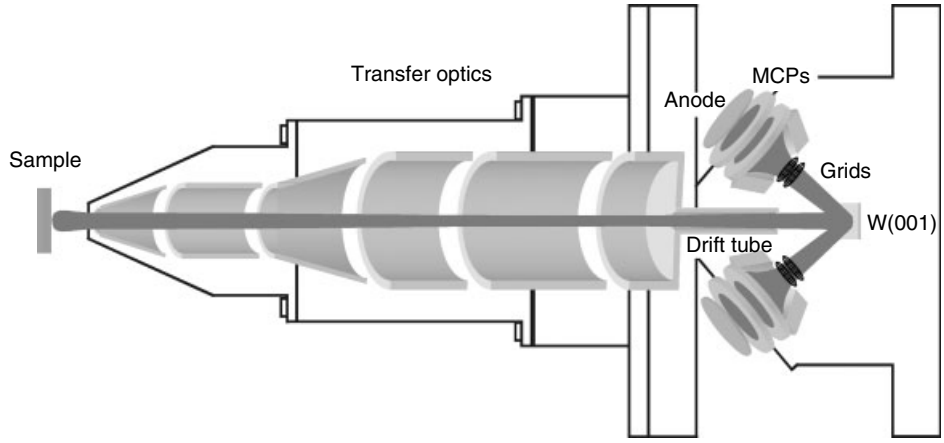

Figure 7. Schematic of the spin detector. Two of the four (2,0) LEED beams are shown in this projection, together with their associated electron counting channels. The first and fourth lenses of the transfer optics are split into quadrupole elements for beam steering.

quality in tilt direction. The small distance between sample and detector optics is a limiting condition for the smallest angle achievable and the size of the extraction optics. The final solution is as follows: straight access to the sample at a collection distance of 8 mm (to front end of detector) for a conical extractor optics with full opening angle of 49°. The sample tilt is 64° with respect to the column axis. The selected geometry is adapted to a column working distance of 8 mm. As consequence of this geometry, the column's working distance is somewhat larger than in conventional SEM applications, which causes a slight decrease in the achievable final resolution.

The objective lens is responsible for a magnetic stray field that declines with increasing working distance. A vertical field component of 2 mT has been measured at the sample position under working conditions. Owing to the fast acceleration of the electrons toward the spin detector by the first elements of the optics, no precessional rotation of the spin-polarization vector could be observed within an error margin of 1°. The electric stray field of the column at the sample surface is quite small and it is easily overcome by the potential gradient of 56 V mm^{-1} at the sample, which is generated by the electrical potentials at the first two lens elements of the transfer optics (in the range of 2–3 kV). Two elements of the electron optics are constructed as steering elements (electrostatic quadrupoles). They serve to align the electron beam with the axis of the optics and compensate for small angular deviations due to electrostatic and magnetic fields of the SEM column and sample tilt.

4.4 The spin detector

The diffraction of electrons at surfaces is a well-established technique in surface science to investigate the structure and quality of surfaces. When electrons with definite energy and low angular spread are scattered at ordered surfaces a perfect diffraction pattern is obtained. Any deficiency from one of those conditions gives a degradation of scattering probability. Surface contamination, for example, can cause superstructures or even the complete destruction of coherent scattering. In the 1980s, much attention was paid to spin effects in LEED. It was found that the scattering at nonmagnetic surfaces, like W(001), can produce diffracted beams of spin-polarized electrons owing to spin-orbit interaction in the scattering. The double scattering experiment was the realization of a self-calibrating experiment that transformed the polarization into an intensity variation (Kirschner and Feder, 1979). With this experiment, the polarization sensitivity could be measured precisely and a new spin detector was suggested and realized. The angle and energy dependence of the sensitivity was investigated for W(001), which was the prerequisite for further optimization of the LEED detector. The most important quantity to characterize the detector efficiency is twice the product of reflectivity R times the square of the polarization sensitivity S, that is, $2RS^2$ (Kirschner, 1985). This so-called Figure of Merit allows for direct comparison with other types of spin detectors, since it is derived from the uncertainty of polarization detection: the statistical error of a single polarization measurement using single electron counting technique is governed by Poisson statistics. It can be expressed as (Kessler, 1985)

$$\Delta P = \frac{1}{\sqrt{NS^2}} \tag{2}$$

For the LEED detector, $N = N(2,0) + N(\overline{2},0)$ is the total number of counts in two opposed beams for a given acquisition time. As N is proportional to R, maximizing RS^2 will minimize ΔP.

In the calibration experiments, the highest Figure of Merit has been found for the second-order diffracted beams and at a kinetic energy of 104.5 eV. With an energy spread of 1.5 eV and an angular spread of 0.5° at normal incidence, the sensitivity was determined to be $S = -0.27$, the reflectivity $R = 0.0011$, and thus the Figure of Merit was calculated to be 1.6×10^{-4} (Kirschner, 1985). In order to achieve an appropriate and reproducible analyzer performance, it is necessary to keep parameters like energy and angular spread in a certain parameter range and the surface in a well-defined condition regarding contamination and structure. Any contamination decreases the polarization sensitivity.

The new detector for the spin-SEM is displayed in Figure 7. Scattering at the W(001) surface is performed in normal incidence. For that geometry and at the chosen nominal scattering energy of 104.5 eV, the (2,0) beams appear at a fixed angle of 49.4° with respect to the normal. To preserve the initial direction of electron scattering, the complete surrounding of the crystal is held at the same potential, the scattering potential. The (2,0) beams can leave the field-free region around the W(001) crystal by traversing grids at the same potential, which separate the scattering from the counting section. A second set of grids (retarding grids) is used to separate the elastically scattered electrons from the SE generated at the W crystal as well as to suppress the inelastic background. The retarding grids act as high-energy pass filters and are set to a potential close to sample ground. An electron, which has passed both grids, is then accelerated into a dual microchannel plate (MCP) assembly for pulse amplification. Between the retarding grid and the MCP entrance, a tapered optical element is mounted. With this electrode, the electron beam is defocused before hitting the front of the first channel plate. Owing to the defocusing, the whole plate area can be illuminated by the electrons. This is important to increase the expected lifetime, that is, to increase the total number of detected events before the MCP quality degrades. In addition, the lowered area intensity reduces the dead time of the plate assembly, as subsequent electrons will not hit exactly the same microchannel. The current pulses generated in the MCP stack are collected with an anode plate and, after high-voltage decoupling, fed into counting electronics.

For cleaning the W(001) surface, the single crystal can be flash heated above 2000 K from its rear by electron bombardment. Within 30 s after flashing the detector is ready again for measuring.

As discussed in the preceding paragraphs, the SE emission is characterized by a wide energy spread with varying polarization and an emission into half-space. The above-mentioned conditions for optimized LEED analyzer spin sensitivity (small angle/energy spread) would mean that only a small portion of the total SEs could be utilized for spin polarization analysis. The limited energy spread reduces the usable number of electrons by a factor of 5 while 5 orders of magnitude are lost due to the extreme limitation of the angular acceptance. In other words, nearly all information is wasted when the detector is run at its optimized performance with respect to polarization sensitivity. The consequence is a dramatic decrease of statistics and image quality for given dwell time. As compensation, one had to increase the measuring time by orders of magnitude. Images with an appropriate number of data points could not be achieved in reasonable times. Hence, the spin polarization analyzer has to work at less favorable conditions in a spin-SEM in order to cover a large part of the SE spectrum. The goal is to find the optimum in the trade-off between degrading polarization sensitivity versus increasing count rates upon increase of the angle and energy acceptance. From general considerations about the SE emission, it was deduced that the detector with best performance (for spin-SEM application) should accept all the SE up to at least 10 eV, while the acceptance angle of the detector should be as large as possible (Oepen and Hopster, 2005). The solution for the latter requirement is to put the sample into the focal plane of the detector system. By this, a large emission angle is transformed into a quasiparallel beam configuration. This means that the majority of all the electrons that are transferred into the detector are scattered at conditions close to normal incidence. In our design (see Figure 7), there is a drift tube at the end of the optics, which is essential for adjusting the beam. The drift tube allows tuning of the electrons into a parallel beam configuration just by maximizing the observed intensities, as it permits only an angular spread of maximum ±5°.

Electrons with different energies are scattered into different angles. Hence, a LEED process gives a discrimination of energy in itself via angular selection of the scattered beams. In our setup, the diaphragms that are used as grid support act as apertures that limit the scattering angle of the diffracted beams (Figure 7). For idealized normal incidence, the apertures define an energy spread of roughly ±10 eV around the nominal scattering energy.

4.5 Performance of the spin detector

In order to quantitatively understand the key properties of the LEED detector, like the obtainable image contrast and the detection efficiency, a best-case calculation has been carried out (Frömter *et al*., subm., 2007). The most simple approach involves a convolution of the spin and intensity distributions of the SE with the calibration curves for the energy-dependent reflectivity and spin sensitivity for scattering at W(001). A more sophisticated and already a quite accurate result can be obtained if the energy and angular

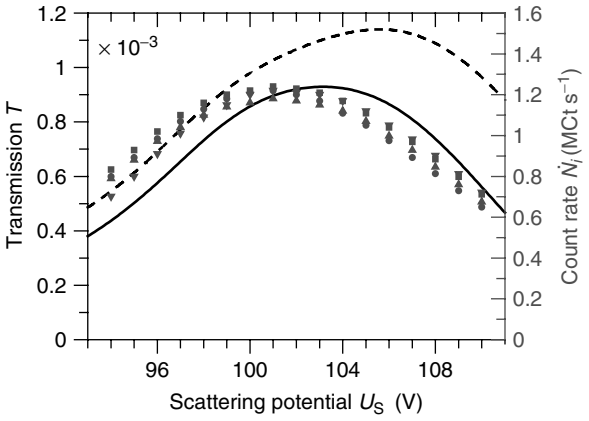

Figure 8. Model of the detector transmission. Measured count rates of all four channels (dots, right scale) from an iron sample and calculated transmission values (lines, left scale) are plotted versus the scattering potential applied to the W(001) crystal. The dashed line is calculated accepting all elastically scattered SE, regardless of their energy. The solid line gives the result for the model that accounts for energy filtering at the entrance apertures in accordance with the real geometry. The transmission in the model is normalized per incoming secondary electron. Details concerning the parameters and model are given in (Frömter *et al*., (subm. 2007)). (Reprinted from Frömter *et al*., Review of Scientific Instruments, submitted. © American Institute of Physics.)

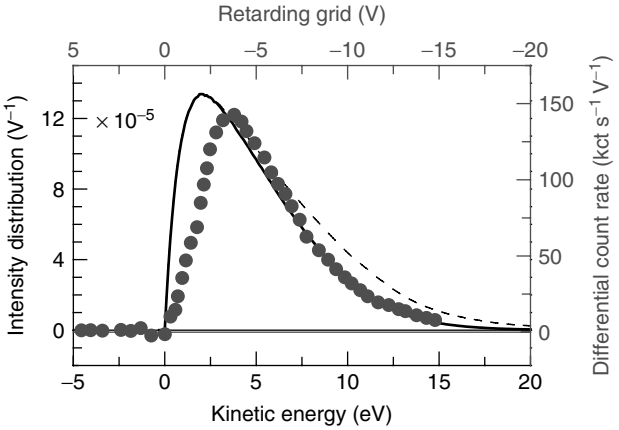

Figure 9. Energy distribution of the SE after scattering at W(001). Dots give the experimental results, when the retarding grid voltage was varied between +5 and −20 V (top axis). The data shown are differentiated with respect to energy (right axis), to obtain the distribution. From the model, we obtain the dashed line as energy distribution (left and bottom axes) if all elastically scattered SE are accepted. The energy filtering at the entrance apertures, which is included in the solid line calculation, is the reason for the gradual cutoff above 5 eV that is in perfect agreement with the measured data. At energies below 4 eV the grid transmission becomes less than unity, so the measured data falls off more rapidly.

dependent transmission properties of the apertures on the diffracted beams are included into the model.

The result for the scattered intensity is shown in Figure 8. Plotted are the calculated detector transmissions for the two conditions described in the preceding text and experimental data from an Fe whisker. The abscissa is the electrostatic potential applied to the scattering crystal with respect to sample and thus gives the variation of the kinetic energy of the scattered electrons. The influence of the energy-determining apertures is obvious from the comparison of the two theoretical curves. A gradual decrease in transmission at energies above 106 eV helps increase the overall performance, since the polarization sensitivity is reduced at these energies. The shape of the theoretical curve that includes the aperture effects (solid line) fits the experimental data quite well. A slight energy shift is found, which is probably caused by some deviation from the exact geometry.

In order to compare the absolute numbers of experiment and model, one has to estimate the number of electrons actually entering the detector. The experiment has been carried out with a primary current of 1 nA at 2 keV energy. If one assumes for these conditions a SE yield of 1, there will be roughly 6×10^9 SE per second entering the detector. Taking the optimum transmission from the theory curve, there should be 5×10^6 electrons per second detectable for each scattered beam. For the five times smaller count rate found in the experiment, several effects are responsible: roughly 20% of the counts are lost at the retarding grids owing to their reduced transmission at lowest energies (Huchital and Rigden, 1972). The magnitude of this effect has been estimated from the spectra in Figure 9. As the structure of the energy dependence is almost the same for theory and experiment, we can conjecture that the remaining effect is mostly of geometrical origin. Appointing the further reduction of count rates to the angular acceptance of the optics, one can calculate an effective full opening angle of SE acceptance. Assuming a Lambert intensity distribution, the remaining transmission of 0.25 corresponds to a full acceptance angle of 60°. This value is well above the geometrical acceptance of 49° and reflects the effectiveness of the accelerating field at the sample. Putting the exact SE yield into the calculation can vary the numbers slightly, but will not change the general result. In summary, from the comparison of the absolute numbers we may conclude that the transfer optics does not focus the SE, which are emitted at very large angles, into the detector. This is in part a consequence of the drift tube, which has been inserted in the electron path to facilitate alignment and that defines the limiting input aperture.

Nevertheless, the obtained count rate well above 1 million counts per second and per channel allows for taking quick overview images from iron samples within less than a minute, or taking high-quality images with only 1% uncertainty in the asymmetry within 5–10 min.

With the same theoretical approach the expected asymmetry can be calculated, taking the SE polarization distribution and the energy-dependent sensitivity of the scattering at W(001) into account. We assume a polycrystalline Fe surface as sample, which represents the situation when decoration with iron is performed. Although the spin polarization at zero SE energy is taken to be 48% in the model, the predicted asymmetry for the experimental setup is just 9%. For polycrystalline Fe films, asymmetries of 8.5% have been found experimentally in our SEMPA. The agreement with the theoretical prediction is perfect. Note that the calculated value is significantly smaller than the product of nominal detector sensitivity times polarization $0.27 \times 48\% = 13\%$. The latter is an ideal quantity that can only be achieved with electrons very close to zero SE energy or with a constant polarization of 48% for all SE.

The energy distribution of the SE can be measured by varying the potential of the retarding grids and differentiating the measured intensities. The obtained energy distribution and a calculation from the above model are displayed in Figure 9. Again a very good agreement is found. At higher energies the transmission of the SE is reduced by the apertures as precisely described by the model. On the low-energy side, the experimental distribution is reduced with respect to the theoretical curve, which is due to a decreased transmission of the retarding grid setup. Measuring the energy distribution of the SE has turned out to be a very useful tool for checking the operation of the LEED detector. From the results one can infer on the quality of the W(001) crystal preparation or charging of the sample.

5 FEATURES OF THE TECHNIQUE

5.1 Application of high surface sensitivity

In Sections 2 and 3, we have already discussed the surface sensitivity of spin-SEM and its implications, that is, the need for the elaborated UHV technique and necessary cleaning of the sample. These can be seen as a real disadvantage for spin-SEM applicability. On the other hand, this particular property of spin-polarized SE emission bears a big potential for SEMPA.

Obviously, the high surface sensitivity gives access to the investigation of magnetic structures in films of ultimately low thickness down to the monolayer (ML) range. Several ultrathin-film systems that exhibit epitaxial, layer-by-layer growth have been investigated *in situ* utilizing spin-SEM. For ferromagnetic films with in-plane easy axes of magnetization, those studies reveal that the films are single domain after growth, which is the state of lowest energy (Robins *et al*., 1988; Oepen *et al*., 1990). It is believed that the single domain state is created during film growth. While growing, the increasing thickness lets the film pass the phase transition from paramagnetism to ferromagnetism. At any stage of film growth, the thickness varies locally by at least ± 1 ML from the mean integer thickness. For thermodynamical reasons, the different heights appear only in larger connected clusters, statistically distributed on the substrate. These thicker parts are called *islands*. On thickness increase, the islands become ferromagnetic first and one can expect a spontaneous alignment of the moments within each island along one of its axes of easy magnetization. In the ideal case, the orientation of magnetization will equally occupy all possible easy axes. Hence, a multidomain state would be stabilized on thickness increase. As the experiment reveals the opposite, we may conclude that a different mechanism is effective: at the phase transition already small magnetic fields can determine the magnetization direction, as the magnetic susceptibility becomes infinite here (Oepen, 1991). Hence, even smallest residual fields can cause the alignment of the magnetic moments in the islands during film growth. Beyond the phase transition, ferromagnetism is stabilized and the state of aligned moments turns into the nearest lying easy axes of magnetization and is frozen in. Thus, a single domain virgin state is created.

In conclusion, the residual fields align all the moments and the easy axis that is closest to the field direction gives the magnetization direction in the ferromagnetic single domain state. It has to be mentioned that there are also stray fields created by the aligned moments of the islands, which could vary the field direction locally. This effect, however, is negligibly small because the stray field of in-plane magnetized ML islands is extremely low.

Interestingly, a stable multidomain pattern can be created in such a film by demagnetizing procedures. The local minima of the energy landscape, which are required for this behavior, are most likely created by small defects that pin extremely localized magnetic features like Bloch lines (Hubert, private communication). In such films, the domain walls have been studied (Berger and Oepen, 1992). Qualitatively, the same wall structures like in considerably thicker films (Fuchs, 1962; Feldtkeller, 1963) were found, that is, Néel walls with long-ranging tails. The domain structure is very irregular and does not reflect any symmetry (in contrast to the known behavior for bulk samples). The reason for this characteristic feature is that the aligning forces on the walls are negligibly small. The aligning forces arise from magnetic stray fields that are created by the magnetic poles, which appear when the wall orientation is such that the component of magnetization normal to the wall is noncontinuous for the two adjacent domains (pole avoidance principle). As the magnetic pole strength scales with the thickness of the film, the force is very small in

the limit of ultrathin films and hence the pole avoidance is not effective. On the contrary, the volume charges that are created due to the Néel-wall structure cause a wall interaction over large distances. This is one driving force for the observed wall bending and the irregularity.

Ferromagnetic films with an out-of-plane easy axis of magnetization behave differently: in general, multidomain structures are found in the virgin state (Allenspach, Stampanoni and Bischof, 1990; Speckmann, Oepen and Ibach, 1995). Again, this is a consequence of the growth process where local thickness variations occur. Around the phase transition, the thicker parts become ferromagnetic and create stray fields that magnetize the film oppositely in the vicinity, as soon as the thickness of those regions increases. Note that the stray fields for perpendicularly magnetized films are much larger than the fields created by in-plane magnetized films of the same thickness.

The temperature dependence of magnetization, namely, the phase transition from ferro- to paramagnetism, has also been studied in ultrathin films by observing the magnetization of oppositely magnetized domains in spin-SEM. With this technique, any influence due to applied probing fields (in hysteresis measurements) and microstructural effects could be ruled out (Kerkmann, Pescia and Allenspach, 1992).

In recent years, the perpendicular magnetic anisotropy that is caused by surface anisotropies has attracted much attention. One particular question arose with the transition from vertical to in-plane magnetization on thickness increase. It was speculated about a loss of long-range order. Spin-SEM investigations could answer that question and reveal that indeed a breakup into tiny domains appears (see Figure 10) around the thickness range where the transition takes place (Allenspach, Stampanoni and Bischof, 1990; Allenspach and Bischof, 1992; Speckmann, Oepen and Ibach, 1995). These domains caused the previously observed decrease of signal in spatially integrating methods. Moreover, it was demonstrated that from SEMPA studies, utilizing its high spatial resolution, the magnetic surface anisotropy could be determined (Speckmann, Oepen and Ibach, 1995; Oepen, Speckmann, Millev and Kirschner, 1997). What is remarkable is the fact that the first-order contribution to the surface anisotropy could be derived from the magnetic microstructure in the regime of vertical magnetization alone.

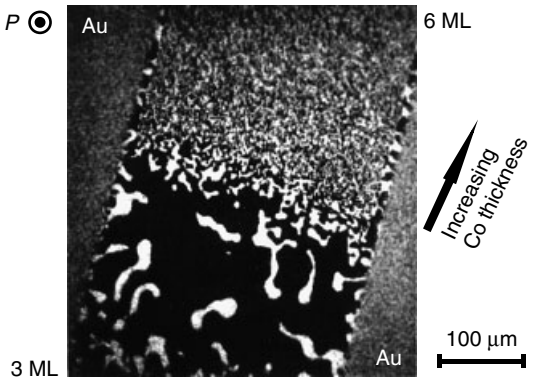

Figure 10. Spin reorientation transition in a Co wedge on Au(111). The spin-SEM image of the vertical magnetization component is shown. The Co wedge was grown *in situ* through a mask. On the left- and right-hand sides the bare Au surface is seen. The thickness increases along the diagonal (left to right) from ∼3 ML to ∼6 ML. At lower Co thickness vertically magnetized domains are found. With increasing thickness, the domains shrink and finally the magnetization reorientates into the film plane (>5 ML). Above 5 ML, the vertical polarization is zero and shows the same contrast as the bare Au surface. Owing to shadowing, the Co thickness gradually increases at the edges from zero to the nominal thickness. Along each edge a domain pattern can be observed as the thickness range with vertical magnetization orientation is contained.

Recently the high surface sensitivity of spin-SEM has been successfully employed for the investigation of the temperature behavior of the layered antiferromagnetism in $La_{1.4}Sr_{1.6}Mn_2O_7$ (Konoto *et al*., 2004), as well as the temperature dependent transitions from antiferromagnetic to ferromagnetic coupling in slightly different manganites (Konoto *et al*., 2005). In those studies, the high surface sensitivity was used to selectively probe the magnetism of the respective top layers in macrostepped surfaces of the complex material.

A very successful story of the application of SEMPA utilizing surface sensitivity was the study of exchange-coupled films (Unguris, Celotta and Pierce, 1991, 1997). A straightforward but intriguing experiment was the investigation of the domain structure that is caused by exchange coupling across a wedge shaped film. In the very first experiments, a Cr wedge was grown on an Fe whisker. On top of the wedge, a thin Fe film was grown and the magnetic structure in this layer observed via SEMPA (Unguris, Celotta and Pierce, 1991) (Figure 11). While the domain structure on the (001) surface of the whisker is very simple and stable, as was investigated before film deposition, the SEMPA investigation of the layered stack reveals a strong oscillatory contrast, which originates exclusively from the Fe film on top. The domain structure shows interlayer thickness dependent stripes that change alternatively from parallel to antiparallel alignment with respect to the whisker magnetization (Figure 11). If the Cr wedge was imaged before Fe deposition, the opposite spin polarization was observed. This is attributed mainly to the magnetization of the topmost Cr layer in the stack, thus indicating an antiparallel coupling between Cr and Fe. From those experiments, two different periods of the oscillatory exchange coupling could be identified and determined very precisely; biquadratic contributions (Pierce, Unguris, Celotta and Stiles, 1999; Tulchinsky, Unguris and Celotta, 2000) and phase slips (Unguris, Celotta and Pierce, 1991) were identified.

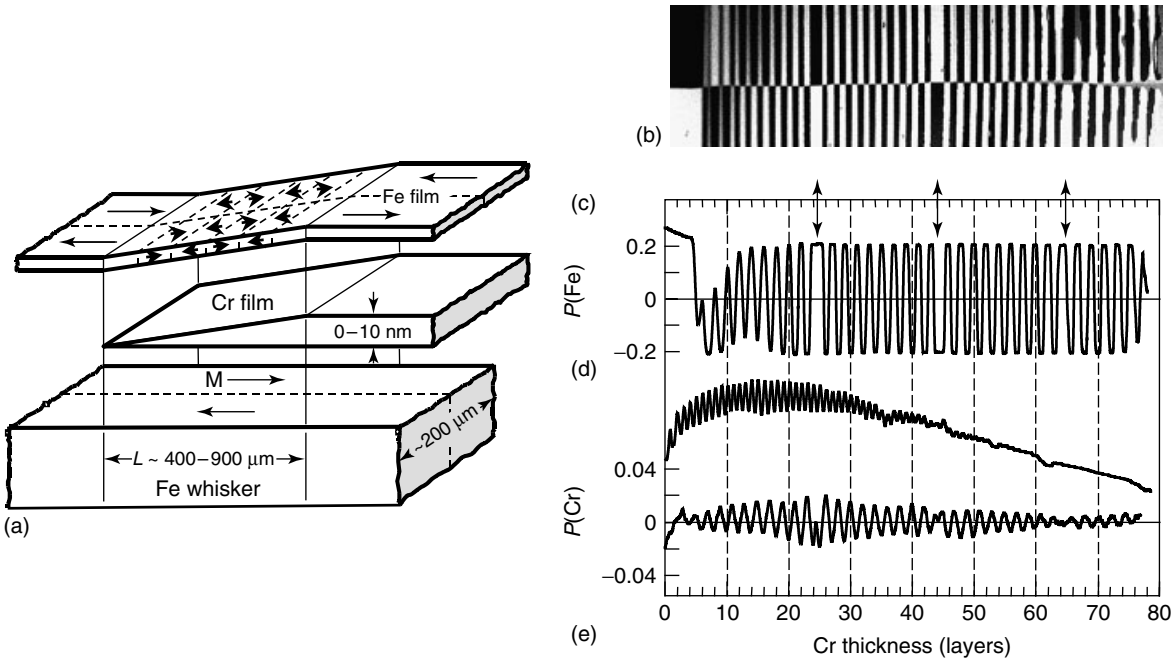

Figure 11. Oscillatory interlayer exchange coupling in Fe/Cr/Fe. (a) Schematic expanded view of Fe/Cr/Fe exchange coupling sample showing the Fe whisker substrate, the Cr wedge, and the Fe overlayer. (b) SEMPA image of the component of magnetization, M_x, in the Fe overlayer along the Fe whisker. The arrows mark the Cr spacer-layer thicknesses where phase slips in the short-period oscillations of the magnetization occur. (c) A line scan through (b) showing the measured spin-polarization profile of the overlayer. (d) Spatial reflection high-energy electron diffraction (RHEED) intensity oscillations along the Cr wedge before depositing the Fe overlayer give an accurate determination of Cr thickness. (e) The spin polarization of the Cr layer P(Cr), before depositing the Fe overlayer, after subtracting the background from the whisker. (Reprinted from *Journal of Magnetism and Magnetic Materials*, 200, Pierce, D.T., Unguris, J., Celotta, R.J. and Stiles, M.D., Effect of roughness, frustration, and antiferromagnetic order on magnetic coupling of Fe/Cr multilayers, 1999, with permission from Elsevier.)

At the very beginning of spin-SEM investigations, a new idea appeared that promised to make SEMPA a universal tool for domain structure and magnetic fine structure analysis, that is, the decoration technique (VanZandt, Browning and Landolt, 1991). It makes use of the pronounced surface sensitivity of the technique, as the main idea is to deposit a very thin layer of an itinerant ferromagnet on top of the sample to be investigated. This layer thus creates a fresh and clean ferromagnetic surface that is accessible for spin-SEM investigation and somehow mirrors the magnetic state below. In the meantime, the decoration or dusting technique has evolved into a standard procedure, whenever sample transfer is necessary at ambient conditions. It works in nearly every case. It is not only that the dusting eliminates the cleaning procedures, it also helps to increase the contrast. To make life easier, it is obvious that Fe, the material that gives the highest contrast in the spin-SEM, is mostly used for dusting. The maximum contrast is already achieved when Fe in the thickness range of a few atomic layers is deposited – independent of the ferromagnet under investigation. For every system, however, it has to be checked whether the magnetic structure is influenced (or even changed) by the dusting layer or not.

An example for magnetic imaging utilizing a dusting layer is shown in Figure 12. The sample is a thin-film Co structure on oxidized Si, fabricated by e-beam lithography. An Fe film (thickness 1 nm) was deposited *in situ* (i) to prevent charging while imaging, as large parts of the sample are insulating SiO_2 and (ii) to spare any cleaning procedure. All three images have been taken simultaneously. On the left-hand side the intensity distribution is shown, which displays the sample morphology like in conventional SEM micrographs. This image was obtained as the sum of all four scattering intensities. It shows the Co rectangle ($10 \times 20\,\mu m^2$, thickness 50 nm) with some remains of the photoresist used for structuring. On the right-hand side, two polarization images are shown, which display two components of the polarization that are perpendicular to each other, as indicated by the arrows. The polarization images show magnetic structures in the film on the bare SiO_2, as well as on top of the Co structure. Obviously, the magnetization pattern differs strongly in these two regions: the Fe film on the SiO_2 shows a uniaxial behavior, which can be seen from the black/white contrast in one component, while the second component does not show any magnetic contrast (except for the regions

of domain walls). Within the Co structure, however, the domain pattern exhibits all possible in-plane magnetization orientations, as is evident from the appearance of all the shades between black and white in both images. The expert reader directly realizes that the domain walls are cross-tie walls that are characteristic for films of soft magnetic materials in a particular thickness range. The coarse structure is a so-called Landau–Lifshitz pattern that minimizes the magnetostatic energy in magnets of limited size. Hence, the appearance of that type of micromagnetic structure and wall indicates that the Fe film indeed mirrors the magnetic structure of the Co beneath.

In the film on the bare SiO_2 the magnetic structure is much simpler; particularly the walls are straight and not as complex as cross-tie walls. The domain pattern, however, seems to be influenced by the magnetic domain structure of the ferromagnetic rectangle. This is due to stray fields leaping out of the structure. The small domains on the right-hand side of the structure obviously cannot provide a complete flux closure and stray magnetic fields are created. The property of dusting, to visualize simultaneously the magnetic pattern of a microstructure and its stray fields, is sometimes very advantageous for the complete understanding and modeling of the magnetic microstructure. If such an effect is not desirable, or if an interaction of film and magnet cannot be ruled out, the deposited film has to be thinner. In principle, the thickness can be reduced below the thickness where the ferromagnetism of an isolated iron film would set in. In that case, when films of high magnetic susceptibility and vanishing remanence are used, it will depend on the coupling if the film reflects the magnetic structure of the ferromagnet or not. A strong coupling can stabilize ferromagnetism in the part of the film where it covers the ferromagnet, whereas in the rest of the film long-range order will be missing. Hence, the film will not have any effect on the ferromagnet under investigation.

The coupling and mechanism behind the decoration technique has not yet been studied systematically. In particular, it depends on the chemical composition, thickness, and structure of the contamination layer. In the case of Figure 12, the surface composition of the microstructure was not analyzed, particularly, the thickness of the adsorbate and oxide layers is unknown.

The decoration technique makes a different class of ordered magnetic materials accessible for spin-SEM, that is, the antiferromagnetic materials. Recently, the domain structure in ferromagnetic films deposited onto antiferromagnets was imaged via SEMPA (Hopster, 1999; Matsuyama, Haginoya and Koike, 2000). The coupling between antiferromagnet and Fe adlayer, as well as the temperature behavior was in the focus of the studies. Those investigations rely upon well characterized and well prepared interfaces between antiferromagnet and film.

As further class of materials, dusting gives access to localized ferromagnets that cannot be investigated otherwise via SEMPA. This was demonstrated by Aeschlimann *et al*. (1990), who studied the bit structure in TbFe magneto-optic storage media. Owing to segregation of Fe to the surface, they obtained a kind of self-dusting layer at the surface that made the investigation feasible.

As in spin-SEM the backward-emitted SE electrons are used, there does not exist any limitation on sample thickness, like in transmission electron microscopes. Hence, SEMPA can also be applied for studying magnetic devices that are developed or produced in industrial laboratories or fabrication facilities. The advantage is that only very mild cleaning or sample manipulations are necessary (ion milling or dusting) for imaging, and surfaces have not to be perfect regarding surface morphology. Many examples of spin-SEM investigations of storage media from industrial research and production facilities have been given in a review article by Koike, recently (Koike, 2005).

In summary, we may conclude that the high surface sensitivity is a big advantage of spin-SEM. That particular property gives access to very different physical questions and systems after appropriate sample preparation. Generally speaking, mild ion milling is the adequate preparation procedure in case of thick magnetic systems, while dusting is advisable in case of thin films, multilayer systems, and nonitinerant ferromagnets. Utilizing SEMPA, however, means that some experience in surface science and the related technology are an absolute necessity for the operator in charge of microscopy.

5.2 Surface morphology

The spin polarization is proportional to the normalized intensity difference, the scattering asymmetry (equation (1)). Owing to the normalization, the sample morphology is strongly suppressed. In literature, examples have been given for strong magnetic contrast despite strong sample morphology (Matsuyama and Koike, 1990). Morphology suppression means, for instance, that surface roughness is irrelevant. This makes the cleaning of surfaces via ion milling possible, without any adverse effect on the magnetic image. The opposite is true when high spatial resolution spin-resolving scanning tunneling microscopy (spin-STM) is used for magnetic imaging. Owing to the strong sensitivity of STM for any changes of the local band structure, strong morphological contrasts, even for structures on the atomic scale (steps, impurities), are observed. High spatial resolution spin-STM requires absolutely flat and well-defined surfaces to resolve the magnetic contrast. As technical samples do not exhibit such ultimately

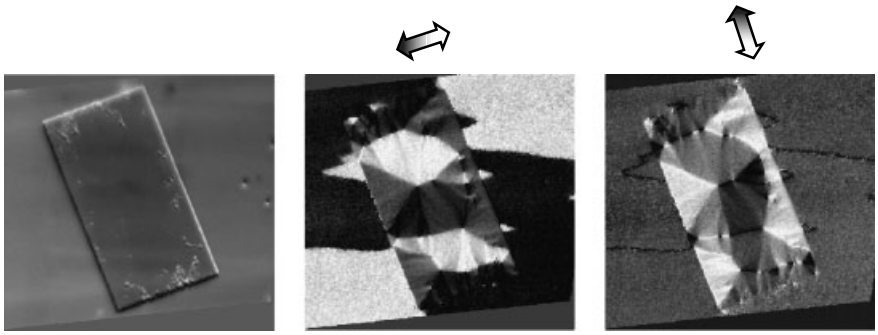

Figure 12. Morphology and domain structure of a thin-film Co structure on SiO_2. The dimensions of the Co rectangle are $10 \times 20\,\mu m^2$ and the thickness is 50 nm. To prevent charging, a 1-nm-thick Fe film was deposited prior to imaging. The picture on the left-hand side gives the topography. The pictures in the center and on the right-hand side show the magnetic structures obtained in two orthogonal in-plane polarization components, as indicated by arrows.

perfect surfaces, they are out of reach for the investigation via spin-STM. Hence, for the magnetic imaging of technical samples spin-SEM (utilizing ion milling or dusting as preparation) is superior to the scanning probe techniques, although one does not achieve the same extreme spatial resolution.

The inherent property of morphology suppression has been demonstrated many times. Nevertheless this feature of spin-SEM needs some further consideration: at first, samples that consist of mesoscopic subsurfaces, which are inclined with respect to each other, can show apparent magnetic contrast. This contrast is due to the surface orientation, which determines largely the initial emission direction of the SE. Different emission directions cause different apparatus or device asymmetries, as the electron beam that is focused into the detector hits the scatter target at a different position or changes its angle of incidence. Hence, on a mesoscopic scale a varying offset appears which is of purely experimental origin. It is like a locally changing device asymmetry. A varying offset is superimposed upon the real polarization structure and is usually difficult to eliminate. This emission cone effect is minimal in one polarization component when the surface's inclination varies only in the direction perpendicular to the scattering plane of the polarization component. The two scattered beams, which determine the scattering plane, are equally affected by the changes of the incoming beam. When calculating the polarization distribution of the component, all the changes cancel out to a large extent. Such a special geometry was chosen, when the domain structure on two macroscopic surfaces of a whisker with surfaces that enclose an angle of 90° have been imaged in one picture (Matsuyama and Koike, 1990).

Device asymmetry becomes a delicate problem in micro- and nanostructures that exhibit a significant aspect ratio of height to lateral extensions. Such structures can show emission cone effects in both polarization components and strong deviations from the true magnetic structure can result. For structures with steep side planes, the effect of varying emission angles can be observed even on the horizontal upper surface around the edges. Here it is the attractive electric field from the first detector electrode, which is no more homogenous but tends to bend the electrons outwards as it gradually follows the sample topography. The emission cone effect is pronounced in the low-energy polarization detectors while it is less important in Mott detectors.

Besides the emission cone effect, the edge effect, well known from SEM, will contribute to the polarization image. While the edge effect gives an enhancement of the edge structures in SEM micrographs owing to an apparently enhanced SE yield, the spatial resolution is not affected for conducting material in most cases (for a detailed discussion, see textbooks about electron microscopy, e.g., (Reimer, 1998)). The enhanced yield comes from the SE emission from the side planes, when the primary beam hits the top

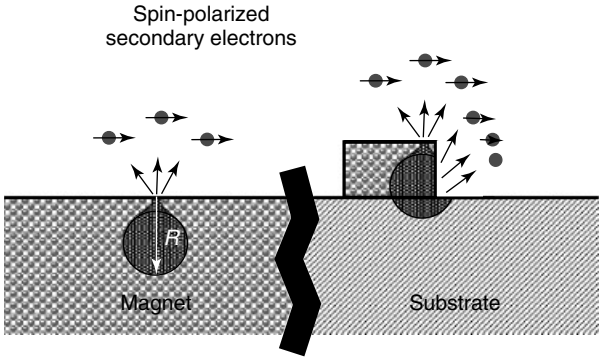

Figure 13. Sketch of the edge effect in a ferromagnetic material. When nanostructures of height that is comparable to the electron range R are analyzed, electrons from the side planes with different polarization might dominate the SE emission. Additionally SE from the bloom can be emitted from the nonmagnetic substrate. The polarization of the SE will change continuously with the distance of the primary beam from the edge. The arrows give the polarization of the SE emitted in the indicated directions.

surface and traverses the structure beneath the side plane (Figure 13). The emission from side planes might influence the polarization image and reduce the lateral resolution if the side planes give a reduced polarization due to imperfect dusting or due to surface contamination that could not be totally removed by ion milling. As the amount of SE that originate from the sidewalls depends on the distance of the primary electron beam from the edge, the polarization will change with distance to the edge and the magnetic structures seem to be washed out, that is, apparently the magnetic resolution is diminished. The edge effect depends strongly on the steepness of the side planes and the height of the nanostructure.

An estimation for the extrapolated range of high-energy electrons in iron gives, based on the phenomenological equation given in Reimer (1998), a value of $>30\,\mathrm{nm}$ for $2\,\mathrm{keV}$ primary electrons. Images from nanostructures with heights comparable to the extrapolated range will show a degradation of resolution owing to the edge effect. Additionally, resolution can be lost owing to the bloom of SEs, which is created in the substrate close to the interface (Reimer, 1998). The SE in the bloom can also create low-energy SEs when the bloom comes close to a surface. Near the edge of a nanostructure this can happen and electrons are created at the substrate surface because the bloom has a larger extent than the primary beam. The measured polarization is altered when the primary beam is approaching the edges of the structure as the number of secondaries from the substrate increases. The magnetic structure starts to fade away even before the primary beam touches the edge of the structure. In very thin nanostructures (height $\ll$ extrapolated range), however, the high-energy electrons penetrate into the substrate and SE are emitted from the topmost layers only. No image degradation is found.

The above-mentioned imperfect or inhomogeneous coverage of side planes with dusting material or contamination is mostly due to shadowing during deposition of dusting material or during sputter cleaning. The extent of the imperfection depends on the steepness and profile of the side planes, the spatial expansion of the evaporation or sputter source and the angular alignment of sample and source. Shadowing can be minimized by sample rotation during preparation. When dusting is applied to nonconducting materials, charging also might occur due to an imperfect coverage. The charging can cause a loss of resolution in the SEM image and even a loss of polarization in the SEMPA image due to the associated energy shift of the SE.

In conclusion, we may summarize that spin-SEM is very well suited for the high lateral resolution investigation of all kinds of samples, particularly technical samples, as surface roughness is not a problem. The SE-emission properties can affect magnetic images, when structures with differently oriented surfaces or steep edges are investigated. Special care has to be paid to the interpretation of the results in these cases.

5.3 Image analysis in spin-SEM

A unique feature of spin-SEM is that the polarization detection can give direct access to the orientation of the magnetization. As explained in the earlier paragraphs, two perpendicular polarization components can be detected simultaneously by one detector. The two components span a plane, which is congruent with the sample surface, if sample and scattering crystal (target) are aligned in parallel – the geometry discussed in the following. It is more complicated to derive the polarization values and finally the local magnetization from the four measured count rates in a real experiment than described so far. While scanning, the data acquisition system calculates and stores point by point a doublet of asymmetry components A_x and A_y according to equation (1). The principal axes in the so-defined asymmetry space are, by nature of the scattering process, aligned with the axes of the corresponding magnetization components M_x and M_y. This correlation is of course only true in the absence of strong magnetic fields along the path of the SE, which rotate the polarization. A well-defined polarization rotation can be used on purpose in polarization rotation devices for spin-SEM, which can give access to the three orthogonal polarization components, utilizing only one detector (Kohashi, Matsuyama and Koike, 1995).

For a qualitative understanding of the magnetization distribution in simple cases, it is sufficient to plot two grayscale images of the asymmetries $A_x(x, y)$ and $A_y(x, y)$, which have been scaled to show the whole range of occurring asymmetry values (Figure 14). The brighter areas can be attributed to a more positive polarization component and the darker to a more negative one. This simple approach is only reliable, if all representative in-plane directions occur within the selected field of view. If one direction is missing, the closest intermediate direction will be scaled to full range and thus be falsely interpreted as domain with full magnetization.

So, the question remains, why are not the exact values of the $\mathbf{A}$ vector used to determine P instead of the relative method described above? In a real spin detector there is no direct proportionality between $\mathbf{A}$ and $\mathbf{P}$, because there is always a significant vectorial offset $\mathbf{A}_0$, the apparatus or device asymmetry, which has to be corrected first:

$$\mathbf{M} \propto \mathbf{P} = S^{-1}(\mathbf{A} - \mathbf{A}_0) \tag{3}$$

The origins for the apparatus asymmetry $\mathbf{A}_0$ are different total sensitivities of the individual counterchannels, which

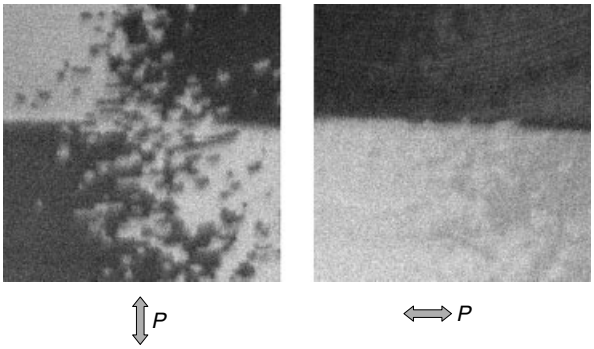

Figure 14. Domain pattern of an Fe whisker surface, obtained in two in-plane polarization-sensitive axes. Both pictures were taken simultaneously. The picture size corresponds to $5.9 \times 5.9\,\mu m^2$.

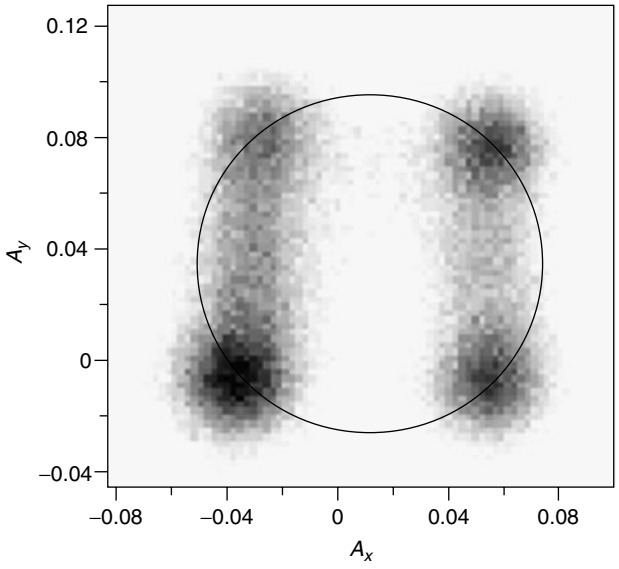

Figure 15. Two-dimensional histogram of the asymmetry corresponding to Figure 14. The number of asymmetry doublets appearing in Figure 14 are coded in gray levels in the A_x,A_y plane. Four accumulation points can be identified, which lie on a circle. This demonstrates that four orientations of domains predominate the domain pattern. The center of the circle gives the total device asymmetry $\mathbf{A}_0$ in the A_x,A_y plane. The magnetization orientation can be directly read from the plot.

are mostly determined by the beam alignment in the transfer optics and the precise sample position, different current amplifications/sensitivities of the four detector channels, or from residual magnetic fields, to name a few. The apparatus asymmetry varies from image to image and has to be determined for each measurement before any quantitative information can be extracted.

In the easiest case, for example, a magnetic nanostructure on nonmagnetic substrate, it is possible to determine the asymmetry on the nonmagnetic region inside the image. This asymmetry gives $\mathbf{A}_0$ directly and can thus be corrected straight away in the magnetic parts of the image. Even in the absence of nonmagnetic areas within the image, it is, in most cases, possible to restore and thus correct for the apparatus asymmetry. The method to employ makes use of the statistical distribution of all measured (A_x, A_y) doublets that occur in one image. In order to access this statistical distribution graphically, one can display the two-dimensional (2D) histogram of all recorded asymmetry doublets from one SEMPA measurement in one intensity graph. Such plot is the important tool to determine the device asymmetry and to cross-check the experiment. Most importantly, the 2D histogram is the prerequisite for any vectorial analysis of the magnetization. Figure 15 displays the 2D histogram of the measured asymmetry values from the image in Figure 15. The histogram exhibits four accumulation points, which indicate predominant anisotropy doublets, that is, dominant orientations of the magnetization. The maxima correspond to the magnetization of the four domains that appear in the magnetic pattern of Figure 15. Under the condition that the absolute value of the magnetization $|\mathbf{M}|$ is constant in homogeneous material, the magnetization vector is lying on the surface of a sphere and can be described by

$$\mathbf{M} = |\mathbf{M}|(\cos\varphi^* \sin\theta, \sin\varphi^* \sin\theta, \cos\theta) \qquad (4)$$

where θ, φ are the polar angles, measured with respect to symmetry adapted axes, for example, [100] and [001] in cubic systems. Depending on the surface orientation of the sample, one obtains a certain cut through that sphere. If easy directions of magnetization exist within the surface, one will find closure domains with orientation along those directions. In Fe, the easy axes of magnetization are the $<100>$ directions. Hence, in a nominal (001) surface of iron (as in the case of Figures 13 and 14) one can expect four different directions of domain magnetization. Consequently, the accumulation points found in Figure 13 have to be elements of a circle with a radius that corresponds to the value of $|\mathbf{M}|$ measured in asymmetry units. Drawing a circle through the four accumulation points, we actually find an almost perfect fit. The center of the circle, however, does not coincide with (0,0) in the asymmetry plane, although it should represent $|\mathbf{M}| = 0$. The location of the center of the circle is therefore identical to the vector of device asymmetry $\mathbf{A}_0$.

The radius of the circle, which is proportional to the value $|\mathbf{M}|$ of the magnetization, is an important quantity that gives hints on detector sensitivity. Generally speaking, the larger the radius, the better the detector works regarding polarization sensitivity. The radius of the circle is also sensitive to contamination of the sample surface.

In a system with in-plane magnetization, a deformation of the circle into an ellipse is most often caused by a tilt of the sample surface with respect to the detector target. If the latter is not the case, the ellipse will indicate some problem with detector adjustment. If out-of-plane components can exist in the system, like in ultrathin films or hard magnetic systems, the deviation of accumulation points from a circle can indicate the presence of a vertical component. The tilt of the magnetization with respect to the surface plane (or surface normal) can be calculated from the position of the accumulation point in the 2D histogram, that is, putting the distance to the center in relation to the expected circle radius. The prerequisite is that the alignment of sample and detector crystals are carefully controlled and accurately known (Frömter *et al*., (subm. 2007)).

From the 2D histogram, one can also extract information about the quality of polarization detection, particularly its statistics. The distribution of the scatter events around the maxima is determined by the uncertainty of the polarization measurement. The fact that the distribution of scattering events is rotationally symmetric (with respect to the accumulation maximum) indicates that no systematical error is influencing the polarization analysis (see Figure 15). The observed width of these accumulation maxima fits well the predicted accuracy calculated according to equation (2).

The contrast-to-noise ratio (CNR) of a micrograph can also be extracted from the 2D histogram. Magnetic structures can be resolved in the domain pattern as long as the distance between maxima is larger than the diameter of the scattering distribution, that is, the uncertainty of the polarization detection. The ratio of distance to diameter is defined as CNR (sometimes also called *contrast*). Taking the full width at half maximum of the scatter points and the distance between the centers (in Figure 13), one obtains a contrast for 180° domains of >3.7 (along the diagonal), while that for 90° is >2.7 (horizontal/vertical spacing of the scatter maxima). Currently, a CNR of 15 is obtained with the same system using a dwell time of 20 ms per pixel.

From the former discussions, it follows that the 2D histogram can be interpreted as the true angular distribution of the orientation of **M** in the sample surface. Hence, the 2D histogram can be used to combine the vector information of the two polarization components into one single domain image. For that purpose, it is useful to change from a gray scale to a color representation. In the 2D histogram, the direction of magnetization is determined as the orientation of the corresponding asymmetry doublet with respect to the circle center. In case of in-plane magnetization, a certain color can be appointed to a direction disregarding the measured polarization value. Such color representation is often used since it gives the complete survey over all magnetization orientations in one image. Owing to black/white reproduction of the book, we go without an example for the color representation.

To summarize, the magnetization vector information cannot be achieved without the investigation of the 2D histogram. The latter is used to find the device asymmetry. The device asymmetry fixes the origin of the polarization vectors, which in turn allows the association of vectors with measured asymmetry doublets.

The details of the 2D histograms are also essential to understand domain images. For instance, in Figure 15, the accumulation points in the horizontal direction are well separated, whereas in the vertical direction the polarization maxima are connected via a line of counted events with reduced frequency. Well-separated maxima appear because the corresponding domains do not have mutual boundaries. The corresponding domains are not adjacent but in opposite edges of the domain pattern. In contrast, the domains that correspond to the accumulation points on the left-/right-hand side share a boundary that is blurred. The fact that the scatter events are exactly lying on the line between the scatter maxima (and thus seem to indicate a reduced magnetization value) reveals that those asymmetry values are composed from a statistical mixture of electrons having one or the other polarization value, which belongs to the two domain orientations. As both domains have about the same A_x component, the x signal is constant, while the y signal is determined by the spread of the primary electron beam, which covers changing portions of the one or the other domain. In other words, the lateral resolution is not good enough to resolve the fine structure between the different domains that intermix at the boundary of the large domains. The same origin, an insufficient resolution, gives a sharp horizontal domain wall (in Figure 14) that shows no trace in the 2D histogram of the whole image.

The above given explanation of the domain image by means of the corresponding 2D histogram strongly supports the arrows indicated in the domain pattern, although the experienced reader with background in micromagnetics would probably insist that the given domain magnetizations were wrong. Indeed, from micromagnetic considerations alone that would be true, but secondary effects (from the magnetic point of view) dominate the magnetic structure. In fact, we find indications for misaligned surfaces and the vertical domain boundary seems to be pinned by a grain boundary that divides most likely twin grains. From the domain pattern on a larger scale (Figure 16), the complexity of the pattern is obvious, including fir tree structures, which are a direct evidence for a slight tilt of the surface out of the (001) orientation. The SEM micrograph (Figure 17) shows step bunches that bend around in the range where the domain image was taken. The different orientation of the steps supports the thesis of adjacent twin grains. Although the overall system seems to be

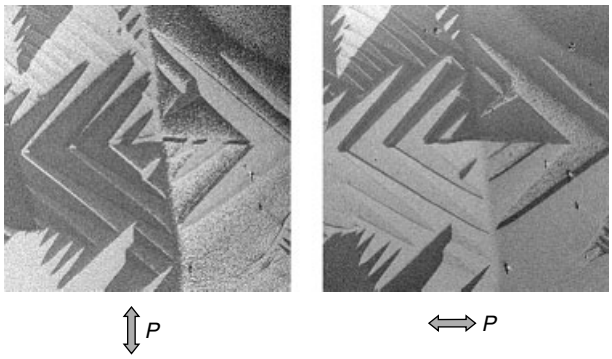

Figure 16. Overview of the domain pattern of the Fe whisker. The pattern shown in Figure 14 is a zoom into the center of this image. Image size is $200 \times 200\,\mu m^2$. The appearance of fir tree structures demonstrates that the imaged subsurfaces are vicinal to {001} surfaces.

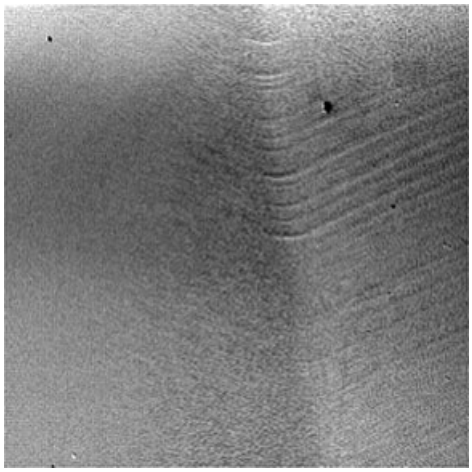

Figure 17. SEM micrograph (sum of four spin channels) of the central region of Figure 16. Image size is $100 \times 100\,\mu m^2$. The lines appearing in the image are most likely step bunches. The orientation of the lines changes going from right to left. This indicates that the whisker has two different surface orientations on the left- and right-hand side, most likely separated by a grain boundary.

very complex, we have chosen the higher resolving domain image for the sake of simplicity to demonstrate the features and strength of the 2D histogram.

Another example is depicted in Figure 18 that shows again the histogram of measured polarization components within the sample surface plane. The corresponding domain structure is shown in Figure 19. In contrast to the previous example, the 2D histogram does not show a pronounced accumulation in individual points. A ring of scattering events is found, the diameter of which is small compared to diameter of the circle drawn through the accumulation points in the previous example. There is a considerable amount of polarization doublets situated within the ring. The sample

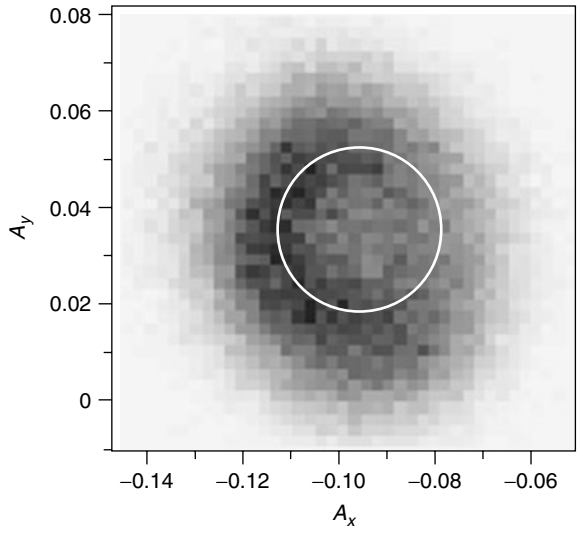

Figure 18. Two-dimensional histogram corresponding to the domain pattern shown in Figure 19. The circle marks the radius of most frequent asymmetry doublets.

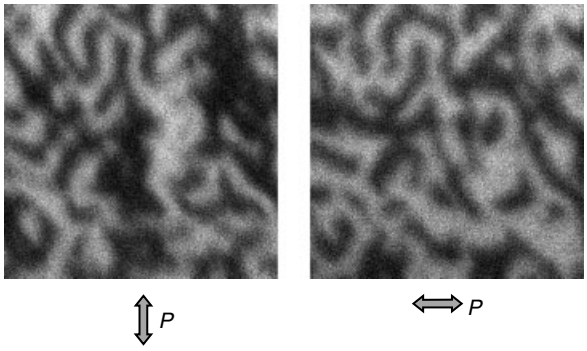

Figure 19. Domain image obtained from a $(Co/Pt)_8$ multilayer on Si wafer. Polarization components within the film plane are shown. The corresponding axes of sensitivity are indicated by the arrows. Image size is $2.35 \times 2.35\,\mu m^2$.

is a Co/Pt multilayer stack that was covered by a Pt cap layer to prevent oxidation of the thin Co layers. This sample was decorated by Fe to perform the spin-SEM investigation. From the dusting with Fe, one would expect almost the same polarization value as before, that is, a larger ring diameter.

The smaller ring diameter as well as the other listed properties can be consistently explained by magnetization canting. The shallow ring structure indicates that there exists a preferred canting angle. The radius of the ring is small, which means that the magnetization is mostly out of plane. The inhomogeneous color of the ring might indicate an anisotropy in the in-plane component, that is, a preferential orientation roughly in one direction. The uneven population can be due to an in-plane magnetic field that had been applied in-plane prior to the SEMPA investigation.

Inside the ring there are also polarization doublets found. Considering a constant value of |**M**|, this means that there are parts in the domain pattern with even less tilting of the magnetization out off the normal direction. A more quantitative examination reveals that those parts come from the transition regions between the domains.

It should be mentioned that for a disc-shaped thin-film element, made from soft magnetic material, a ring (with large ratio of radius/width) was found that did not show any magnetization components in the enclosed area. The corresponding magnetic pattern was a vortex structure in which the area covered by the vertically magnetized singularity is negligibly small (Hopster and Oepen, 2005).

In summary, to achieve a most complete set of information it is important to analyze the asymmetry histogram besides the lateral distribution of measured asymmetries. The histogram allows for the control of the experiment and detector performance. Beyond that, the careful analysis gives further insight into the magnetic behavior of the system under investigation. From the plot, the exact orientation of the local magnetization, a global preferential magnetization orientation, and a possible magnetization tilt can be quantitatively extracted.

6 SUMMARY AND OUTLOOK

In SEMPA, the spin-polarized SE emission is used for the imaging of magnetic structures. Starting from the process of SE creation, the ultimate performance and the requirements on the different components are discussed. The most restrictive property of spin-polarized SE emission is the high surface sensitivity, which demands for the application of UHV technology. The latter makes the technique sophisticated and somehow complex.

The apparently disadvantageous high surface sensitivity can be turned into an advantage, as it allows under certain preparation conditions – dusting – the applicability of SEMPA to almost all classes of materials and samples. With a resolution below the 10-nm mark, dusting makes spin-SEM most attractive for all kind of application laboratories involved in the development of new magnetic devices or storage media. Here, SEMPA can serve for the next 10 years until the lateral dimensions will finally approach the sub-nanometer range.

ACKNOWLEDGMENTS

We are grateful to J. Kirschner (Max Planck Institute of Microstructure Physics, Halle) for his steady interest, helpful discussions, and strong support. Special thanks go to C. Menk, K. Morrison, G. Steierl for their SEMPA work and W. Pfützner for technical assistance. We thank J. Kirschner for the permission to show yet unpublished spin-SEM images from our cooperation. Financial support from the BMBF (Grant No. 13N7484/5) and the Deutsche Forschungsgemeinschaft via SFB 508 and SFB 668 are gratefully acknowledged.

Investigation of Domains and Dynamics of Domain Walls by the Magneto-optical Kerr-effect

Rudolf Schäfer
Leibniz Institute for Solid State and Materials Research, Dresden, Germany

1 INTRODUCTION

The magnetic microstucture, that is, the arrangement of domains and domain walls, forms the mesoscopic link between basic physical properties of a magnetic material and its macroscopic properties. Hysteresis phenomena, energy loss in inductive devises, noise in sensors, or the magnetoresistive properties of modern spintronic devices can be decisively determined by the peculiarities of the underlying magnetic microstructure, especially by irreversibilities in the magnetization process. The development and optimization of magnetic materials therefore requires the knowledge of magnetic domains and their reaction to magnetic fields, which, in most cases, can only be gained by direct imaging.

Although there has been considerable progress in magnetic imaging in recent years, the classical Kerr technique still has unbeatable advantages. The method is based on the magneto-optical Kerr effect, that is, the magnetization-dependent rotation of plane-polarized light on reflection from a nontransparent magnetic sample. By means of an analyzer, in an optical reflection polarization microscope, this rotation is converted into a (in general weak) domain contrast that can be enhanced by digital image processing. Among all observation methods, Kerr microscopy is the most versatile and flexible imaging technique. With image processing, domain contrast is seen on virtually all ferro- and ferrimagnetic samples. Often, no specific surface treatment is required and even coatings may be allowed. Magnetic fields of arbitrary strength and direction can be applied to the sample, making it possible to observe magnetization processes and to simultaneously and locally record magnetization loops. Magnetization dynamics can be studied at arbitrary frequencies, covering the whole range from slow processes (as fast as the eye can follow) to excitations beyond the gigahertz regime by employing time-resolved imaging methods. Samples may be heated and cooled in optical heating stages and cryostats respectively so that magnetic phase transitions or other thermal effects on the magnetic microstructure can be investigated. Mechanic sample deformation during domain observation is easily possible, which makes the study of stress effects on domains possible. In- and out-of-plane magnetization components can be imaged separately, and, for low-anisotropy materials, the magnetization vector field at least on the sample surface can be quantitatively evaluated. The information depth of Kerr microscopy is in the 10-nm regime for metallic materials, allowing the depth-selective observation of magnetization distributions in layered sample systems. The magnification can easily be varied by changing the microscope objective, so that overview observations in the centimeter regime down

to detailed studies of samples of micrometer size are possible. The lateral resolution of optical microscopy with visible light is limited to about 300 nm by the Rayleigh criterion. This can be a drawback for the study of sub-micrometer patterned structures or for certain micromagnetic objects like vortices or stripe domains in very thin films. In bulk samples, only the magnetization of the surface region can be seen, but this limitation also applies to most other imaging techniques.

Since the first application of Kerr microscopy (Williams, Foster and Wood 1951; Fowler and Fryer, 1952), there has been tremendous progress in methodical developments around the traditional Kerr technique. In this article, the mentioned possibilities of modern Kerr microscopy are reviewed, together with physical and technological fundamentals. A comprehensive review on magnetic domains and imaging methods with emphasis on Kerr microscopy is given in the monograph 'Magnetic Domains' (Hubert and Schäfer, 1998), where an extended bibliography can also be found.

2 MAGNETO-OPTICS

Magnetic imaging at optical frequencies employs mainly the magneto-optical Kerr and Faraday effect. Both are rotational effects, that is, plane-polarized light is rotated somewhat on transmission through an optically transparent specimen (Faraday effect) or on reflection from a nontransparent sample (Kerr effect), respectively. Both effects can also be interpreted as circular birefringence (i.e., a birefringence of circularly polarized light) and are described by the same physical laws. Another effect, mostly used for transmission observations in magnetic garnets, is the Voigt or Cotton–Mouton effect, also known as *linear magnetic birefringence* (i.e., a birefringence of linearly polarized light). This effect can also be applied in reflection, together with the magneto-optical gradient effect. All three reflection effects are helpful for domain analysis. Owing to its dominating importance, we focus on the Kerr effect in this article and mention the other effects only briefly.

2.1 Kerr effect

The rotational action of the Kerr effect (Kerr, 1877) is phenomenologically described by the dielectric law $\boldsymbol{D} = \boldsymbol{\varepsilon}\boldsymbol{E}$, in which an antisymmetric $\boldsymbol{\varepsilon}$ tensor (containing the components of the magnetization vector) connects the electrical vector $\boldsymbol{E}$ of an illuminating plane light wave with an induced displacement vector $\boldsymbol{D}$ in the regime of optical frequencies. This relation can be written in the form

$$\boldsymbol{D} = \varepsilon(\boldsymbol{E} + \mathrm{i}Q\boldsymbol{m} \times \boldsymbol{E}) \tag{1}$$

where ε is the regular dielectric constant and Q is a complex material parameter that is roughly proportional to the saturation magnetization of the sample and that describes the strength of the Kerr effect. The $\boldsymbol{D}$ vector can be interpreted as secondary light amplitude being generated by the magneto-optical interaction of $\boldsymbol{E}$ with the magnetization vector $\boldsymbol{m}$ anywhere in the sample.

The cross product in equation (1) reveals the gyroelectric nature of the Kerr effect. Its symmetry can be derived by using the concept of a Lorentz force ($\boldsymbol{m} \times \boldsymbol{E}$) on the electrons set in vibrational motion by the light wave (Figure 1a). If the Lorentz movement v_{Lor} (parallel to the second term in equation (1)) is projected onto the plane perpendicular to the propagation direction of the reflected light wave, the magneto-optic light amplitude $\boldsymbol{K}$ is obtained. This so-called Kerr amplitude is polarized perpendicularly to the regularly reflected amplitude $\boldsymbol{N}$ that is polarized in the same plane as the incident light and that is given by the Fresnel equations. By interference of $\boldsymbol{K}$ and $\boldsymbol{N}$, the polarization vector of the reflected light is rotated by the (small) angle $\Phi_{\mathrm{K}} = KN^{-1}$ (Figure 1b). Here K and N are the effective light amplitudes after the light has passed through the analyzer. For domains with opposite magnetization, the Lorentz force acts in reverse direction, that is, the Kerr amplitude changes sign. A domain contrast is produced if most of the reflected light from one domain type is blocked by the analyzer, as indicated in Figure 1(b), transferring the rotation of the polarization plane to a difference in intensities. The size of the usable signal that also determines the signal-to-noise ratio if video microscopy is applied is important for good domain visibility. The relative signal S, that is, the difference between the intensities of bright and dark domains, is derived as (Hubert and Schäfer, 1998)

$$S \cong 4\beta KN \tag{2}$$

Three properties are noted: (i) The Kerr signal is a linear function of the Kerr amplitude K and therefore of the respective magnetization components according to equation (1). (ii) The Kerr signal can be enhanced by increasing the analyzer angle β beyond Φ_{K}, allowing to increase the signal-to-noise ratio and to adjust to the sensitivity of the detector. (iii) The 'visibility' of domains is determined by the Kerr *amplitude* and not by the Kerr rotation. Although $\boldsymbol{K}$ depends on material constants, it can be enhanced in case of materials where the incoming light is not completely absorbed by magneto-optical interaction, but 'uselessly' reflected to some extent. Antireflection coatings increase the absorbed intensity (based on interference effects that reduce the regularly reflected light component while enhancing the Kerr component – see Hubert and Schäfer (1998) for a review), proportionally raising $\boldsymbol{K}$ and thus the

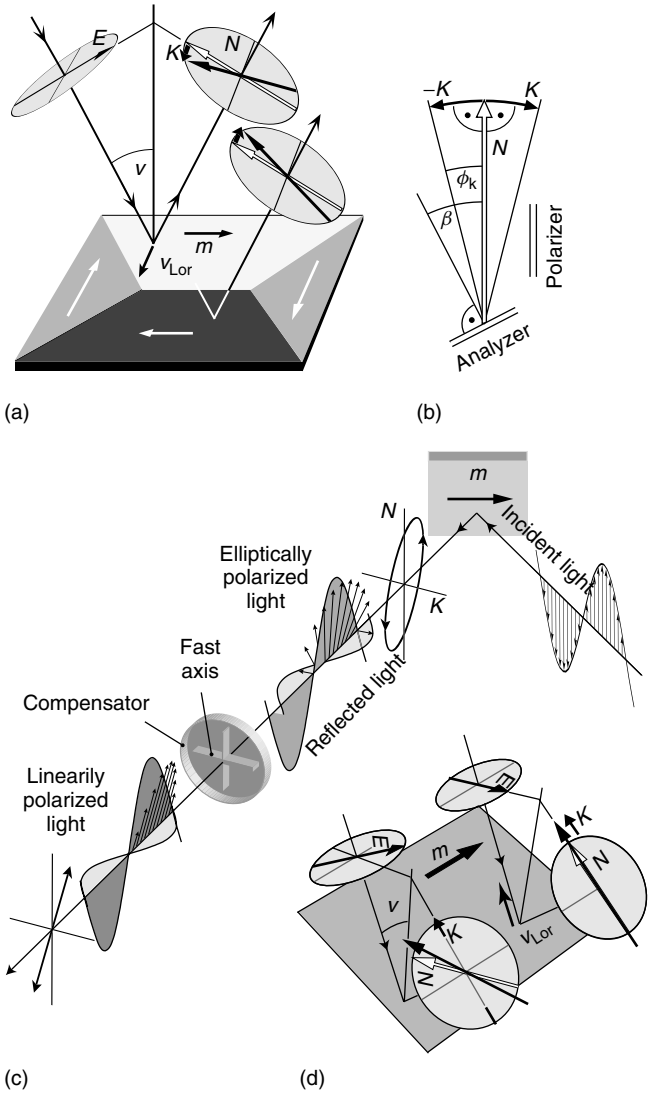

Figure 1. (a) Illustration of the elementary magneto-optical interaction for the longitudinal Kerr effect. The sample with in-plane magnetization is illuminated using light that is polarized parallel to the plane of incidence. The electric field vector $\boldsymbol{E}$ of the incident light, together with the magnetization vector $\boldsymbol{m}$, generates a Lorentz movement of the electrons ('right-hand rule'). If the resulting Lorentz speed v_{Lor} is then projected onto the plane perpendicular to the direction of propagation of the reflected light, the magneto-optical amplitude $\boldsymbol{K}$ is obtained (a similar $\boldsymbol{K}$ component would also be generated if the light would be polarized perpendicular to the plane of incidence). The interference of the normally reflected component $\boldsymbol{N}$ and the Kerr component $\boldsymbol{K}$ results in magnetization-dependent light rotation by a small angle Φ_K, which, by using an analyzer, leads to the domain contrast (b). The analyzer should actually be set at the angle $\beta > \Phi_K$ to optimize the domain visibility. The action of the compensator is illustrated in (c). It converts elliptical light into a linear wave by shifting the two constituent, orthogonal wave components. The symmetry of the transverse Kerr effect is explained in (d). Only light of parallel polarization yields an effect, so that a Kerr rotation is only possible at 45° polarization.

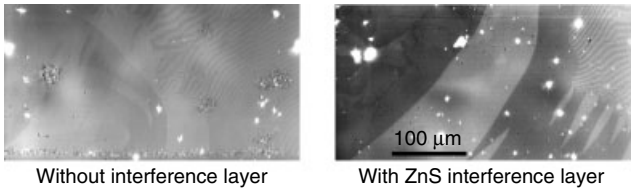

Figure 2. Effect of a dielectric antireflection coating on the Kerr contrast, demonstrated for an amorphous ribbon that is coated in the right image.

useful signal (Figure 2). Effective dielectric coatings are ZnS for metals and MgF_2 for oxides. As the Kerr effect is weak in general, this gain should not be relinquished even if digital image processing (see Section 3.1.3) is applied.

In general, the polarization plane of the reflected light is not just rotated with respect to that of the incident light, but also elliptically polarized. Ellipticity is caused by an 'intrinsic', material-dependent (Oppeneer, 2001) phase shift between the $\boldsymbol{N}$ and $\boldsymbol{K}$ components (also interference layers on top of the sample surface can add a phase shift). If a noticeable ellipticity occurs, the reflected wave is less detectable by the analyzer. This problem can be eliminated by the use of a compensator (see Figure 1c), which should be attached in front of the analyzer. A compensator is an optical device that is based on birefringent materials such as quartz or mica and that is capable of impressing a controllable retardance on a wave, that is, it changes the relative phase of the constituent orthogonal ordinary and extraordinary components of the wave in a variable way. Highest flexibility is obtained by using simple wave plates with a fixed retardance of $\lambda 4^{-1}$, for instance (rather than a regular compensator as, e.g., of the Babinet type, which requires that its optical axes are aligned along and perpendicular, respectively, to the plane of the regularly reflected light – see Figure 1c). A variable phase shift between $\boldsymbol{N}$ and $\boldsymbol{K}$ is obtained by rotating the plate, which leads to a phase shift of both components. By means of such a compensator, a beam that is reflected elliptically from the sample can be converted into a linear wave. The azimuth angle of this wave is different from that of the incident wave, however, requiring an additional analyzer rotation for extinction. In this way, it is possible to extinguish at least the light of one domain thus generating a significant Kerr contrast.

Different basic geometries are distinguished in Kerr microscopy, which can again be derived with the help of the Lorentz concept. To produce a Lorentz movement that leads to detectable Kerr rotation, an appropriate direction of light incidence and polarization has to be selected for a given magnetization direction. As a simple rule, the Kerr rotation is proportional to the magnetization component parallel to the reflected beam of light. This rule implies that

domains that are magnetized parallel to the sample surface (as shown in Figure 1a) require oblique light incidence, and that for maximum rotation the plane of incidence must be parallel to the axis of magnetization with the polarizer set either parallel or orthogonal to the incidence plane (*longitudinal* Kerr effect, $\vartheta \neq 0$). The Kerr amplitude is then proportional to the sine of the angle of incidence ϑ, and therefore disappears for perpendicular incidence. In this case, maximum rotation is exhibited by domains that are magnetized perpendicularly to the sample surface (*polar* Kerr effect, $\vartheta = 0$), while in-plane domains do not cause a Kerr amplitude. At oblique incidence, both in- and out-of-plane magnetization components generate a superimposed Kerr contrast. The separation of the two components is possible by proper difference images that are obtained at different microscope settings, as demonstrated in Figure 3. Also, the *transverse* Kerr effect, illustrated in Figure 1(d), leads to in-plane magnetization sensitivity. Here, the in-plane $\boldsymbol{m}$ vector is normal to the plane of (oblique) incidence. Light with $\boldsymbol{E}$ parallel to this plane generates a Kerr amplitude, but its polarization direction is the same as that of the normally reflected beam. The transverse Kerr effect thus causes an amplitude variation, which can be used for measuring purposes. A rotation that is detectable by an analyzer is obtained when the incident light is polarized at 45° to the plane of incidence. Then, the $\boldsymbol{E}$ component perpendicular to the incidence plane is not affected ($\boldsymbol{E} \,||\, \boldsymbol{m}$), while the parallel component is modulated in its amplitude on reflection, leading to polarization rotation by superposition, as also indicated in Figure 1(d).

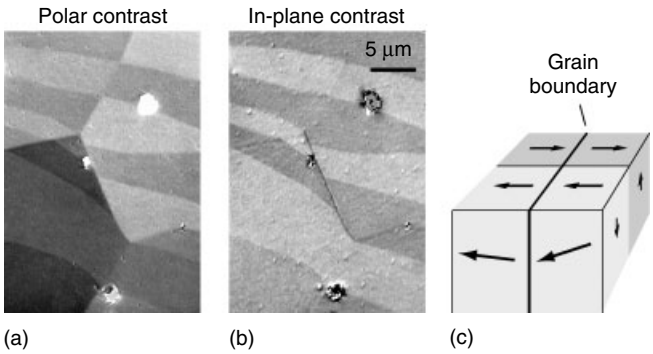

Figure 3. Domains in a coarse-grained NdFeB crystal in which the magnetization axes of the four different grains are misaligned relative to the observed surface as schematically shown in (a). The magnetization components perpendicular to the surface (polar components) can be imaged separately at perpendicular incidence (b). At oblique incidence, polar and in-plane components show up simultaneously (not shown). When the illumination direction is rotated by 180°, the polar Kerr effect does not change sign, whereas the longitudinal effect does (see Figure 13b below). By forming the image difference the polar contrast disappears, leaving just in-plane contrast (c).

2.2 Other magneto-optical effects

Three further magneto-optical effects that can be used for domain observation in a polarization microscope have to be mentioned. Related to the Kerr effect is the Faraday effect (Faraday, 1846). It follows the same symmetry rules, but is restricted to transparent samples such as magnetic garnet films and is observed in transmission experiments (Fowler and Fryer, 1956). The Faraday contrast is much stronger than the Kerr contrast and does not require electronic means for enhancement. In recent years, the Faraday effect found application in magneto-optic indicator films. These are transparent garnet films with in-plane anisotropy that are coated with a mirror layer on one side. If the mirror side is placed in contact with a magnetic specimen, the stray field of the sample induces a polar magnetization component in the active layer, which can be viewed in the polar Faraday effect at reflection. Charged domain walls, for instance, can be indirectly imaged in this way (Nikitenko *et al*., 1998).

The Voigt effect (Voigt, 1898) was mainly applied for transmission observations of in-plane domains in garnets (Dillon, 1958). It is quadratic in the magnetization components, so that only domains magnetized along different axes show a contrast. The effect is strongest at perpendicular incidence (where a Faraday or Kerr contrast of in-plane domains is not possible) and requires a compensator for adjustment. Later, the Voigt effect was also discovered in reflection experiments on metals, together with the magneto-optical gradient effect (Schäfer and Hubert, 1990) that shows up under similar experimental conditions. The gradient effect is a birefringence effect, which depends linearly on magnetization gradients. Both effects (in combination with the Kerr effect) are helpful in the analysis of domains in cubic materials such as epitaxial thin-film systems by considering their contrast laws and depth sensitivities (see Schäfer (1995) for an overview). The gradient effect can also favorably be applied to image fine transitions and domain modulations. The phenomenological differences between Kerr, Voigt, and gradient effect are compared in Figure 4, in which a typical domain pattern of an iron–silicon crystal with two orthogonal easy axes of magnetization in the surface was imaged in an optical polarization microscope under different conditions as indicated.

3 KERR MICROSCOPY

Two types of Kerr microscopes are in use: wide-field (regular) microscopes, which immediately provide an image of a certain sample area, and laser-scanning microscopes, in which a laser spot is scanned relative to the sample surface building up the image sequentially. Both have their drawbacks and advantages, as elaborated in the following

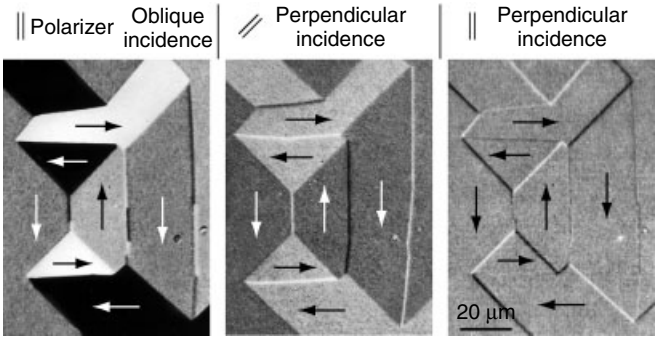

Figure 4. Domains on a (100) surface of silicon–iron (Fe 3 wt% Si, sheet thickness 0.3 mm), imaged in the magneto-optical Kerr (a), Voigt (b), and gradient effect (c). The Kerr effect is linear in the magnetization vector, so the four-domain phases in (a) show up in different colors. The same pattern imaged in the Voigt effect displays only two colors, one for each magnetization axis. This contrast is independent of the magnetization *direction* since the Voigt effect depends quadratically on the magnetization vector. The gradient effect is sensitive to changes in magnetization. Therefore, domain boundaries show up in this effect with a contrast, depending on the relative magnetization directions of the neighboring domains. Both Voigt and gradient effect are strongest at perpendicular incidence of light and require a compensator for contrast adjustment. (Reproduced from Schäfer, R. and Hubert, A. (1990). A new magnetooptic effect related to non-uniform magnetization on the surface of a ferromagnet. *Physica Status Solidi A*, **118**, 271–288 by permission of Wiley-VCH.)

sections. Emphasis is on wide-field microscopy as it is the most commonly applied and most versatile technique.

3.1 Wide-field Kerr microscopy

3.1.1 Microscope

Standard wide-field Kerr microscopes are based on commercial reflected light microscopes with strain-free optics to allow for polarization microscopy. Wide-field microscopes apply the Köhler illumination technique, which was introduced in 1893 by August Köhler from Carl Zeiss corporation, to obtain homogeneously illuminated images at maximum resolution. This technique is explained by ray diagrams in Figure 5, where the illumination and image-formation ray paths are illustrated separately for the purpose of visualization. Light emitted from the lamp is focused onto the plane of the aperture diaphragm by the lamp collector lens, passes through the opening of a variable field iris diaphragm, and is then plane polarized and deflected downward into the objective lens, for example, by a partially reflecting plane glass mirror. After reflection from the specimen, the light is captured by the objective and then passes through the half-mirror again. Modern optical microscopes are built with infinity-corrected objectives, that is, the light rays emerge from the objective in parallel bundles from every azimuth and are projected to infinity. These bundles enter the tube lens, which forms an intermediate image that is further processed toward the eyepiece or camera. In the 'infinity' space, accessories like reflector mirror, analyzer, and compensator are added with simple design and without distortion of the image. Polarizers and analyzers in today's microscopes are made of dichroic polarizing foils. Although the polarization degree (2×10^{-6}) of such sheet polarizers is sufficient for Kerr microscopy, they suffer from a high light absorption of more than 50%. Light intensity by a factor of 2–3 and better extinction can be gained by replacing sheet polarizers with Glan–Thompson prism polarizers.

The field diaphragm is imaged on the specimen and thus determines which part of the sample is illuminated. It does not affect the optical resolution or intensity of illumination. The latter is rather controlled by the *aperture* diaphragm that also determines the angles of incidence and is therefore crucial for Kerr microscopy. Closing or opening the aperture diaphragm varies the angle of the light rays reaching the specimen from all azimuths, with the largest angle of incidence being limited by the numerical aperture of the objective. A centered aperture iris (Figure 5a) results in an illumination cone that hits the sample vertically. Owing to symmetry, the Kerr amplitudes resulting from in-plane magnetization components cancel each other, so that in this case a sole sensitivity to out-of-plane magnetization is given as required for the polar Kerr effect. An off-centered aperture diaphragm (Figure 5c) leads to an obliquely incident bundle of rays (with an angle-of-incidence dispersion ranging between perpendicular and maximum) as necessary for longitudinal and transverse Kerr sensitivity. Oblique incidence is also provided by a Berek prism (Figure 5d), which is a 90° prism constructed in the form of a trapezoid, resulting in a light path where the beam is internally reflected three times before it exits the prism. A Berek prism introduces little depolarization and causes no light loss, contrary to the mentioned glass plate reflectors for which just a quarter of the illuminating light is used for image formation. However, the viewing aperture is restricted by the prism itself, leading to a reduced optical resolution in the direction transverse to the microscope plane. If light intensity poses no problem, a sheet reflector offers optimum resolution and high flexibility in the observation mode (see next paragraph). In recent years, microscope companies have largely eliminated the option of Berek prisms in their product lines. The availability of highly sensitive video cameras can partly compensate for this unfavorable circumstance.

The plane of the aperture diaphragm is conjugate to the back focal plane of the objective lens, also called *diffraction plane* or *pupil* of the objective. As the back focal plane is

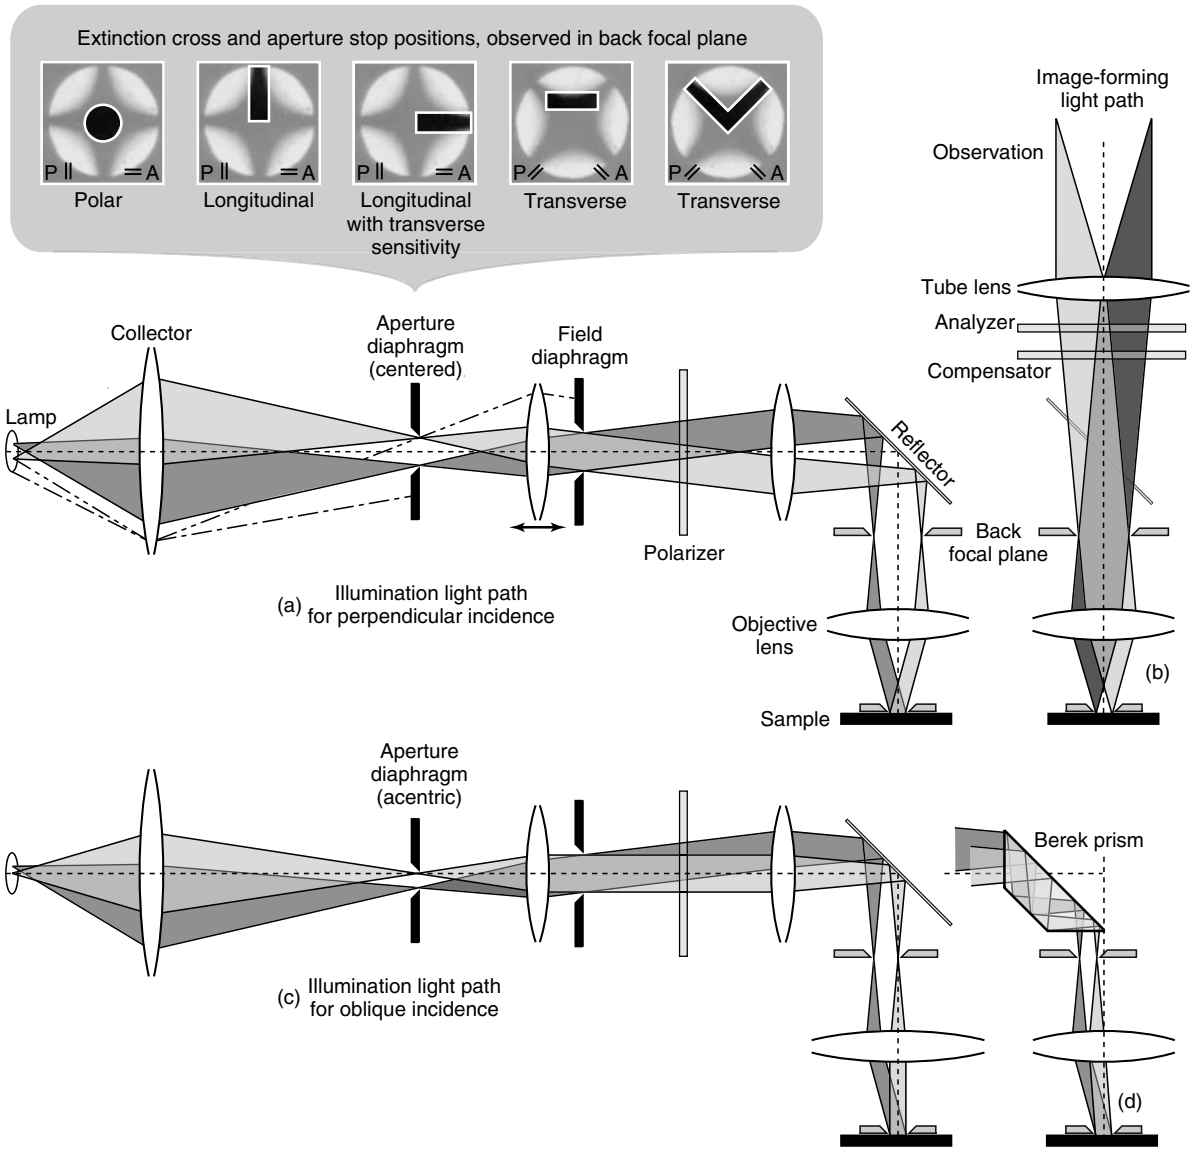

Figure 5. The essential components and ray paths of a wide-field Kerr microscope. (a) Illumination path for perpendicular light incidence, and (b) image-forming path. Oblique incidence (c) requires a displaced aperture slit and can also be obtained with a Berek prism (d). The inset shows the diffraction plane of the microscope for the case of a sheet reflector. Here, the aperture diaphragm can be viewed and adjusted to fulfill the requirements for the polar Kerr effect (centered iris diaphragm) or longitudinal and transverse effects (displaced slit diaphragm). The orientation of the extinction cross depends on the polarizer setting (indicated by P), with the analyzer (A) and eventually the compensator being adjusted for maximum extinction.

not identical for all objectives in conventional microscopes (objectives are rather constructed for identical front focal planes to guarantee identical sample positions), the relevant lens that images the aperture into the pupil has to be moved or supported by additional lenses to exactly provide this condition for all objectives – a feature that is not available in commercial microscopes. If the aperture diaphragm is not imaged exactly to the pupil, it is not effective uniformly for the whole observation field and the points on the sample are not illuminated from the same angular range. This may result in an inhomogeneous image up to a magnetic contrast inversion across the image (see Fig. 2.16 in Hubert and Schäfer (1998)). The diffraction plane can be seen in the so-called conoscopical image of the microscope by replacing the eyepiece by an auxiliary telescope or by a built-in, focusable Bertrand lens. This image is characterized by a cross-shaped extinction zone when the polarizer and analyzer are crossed for maximum extinction (Figure 5, inset), rather than being homogeneously dark as would be the ideal case. The reason for this 'Maltese' cross, which becomes more pronounced

as the numerical aperture of the objective increases, is that a convergent light bundle, rather than a parallel laser beam, is used in wide-field microscopy. All beams not lying in a central incidence plane along or perpendicular to the polarization plane cannot be extinguished by the analyzer as they are reflected in an elliptical and rotated polarization state in general. This is due to differential transmission of the p (***E*** vector parallel to plane of incidence) and s (***E*** vector perpendicular to plane of incidence) components at the steep optical interfaces of lenses. This depolarization results in four bright quadrants, separated by the Maltese cross, in the conoscopic image. For best contrast conditions, the illumination should be restricted to the area of maximum extinction in the conoscopic image by properly positioning the aperture stop, as illustrated in the inset of Figure 5 for the case of a sheet reflector (by using a Berek prism, half of the pupil would be occupied by an image of the prism itself). For the polar Kerr effect, a centered iris diaphragm is used, while the longitudinal effect is preferably adjusted by an off-centered *slit* aperture that is oriented parallel to the plane of incidence. For the transverse Kerr effect, the polarizer and consequently also the extinction cross are rotated by 45° (due to depolarization at the reflector, the use of a compensator is mandatory in this case to obtain a closed extinction cross). Here, a displaced slit perpendicular to the plane of incidence or a V-shaped slit are the best solutions. Both, longitudinal and transverse effects can be adjusted as well by using a Berek prism, while the polar effect requires a sheet reflector. If a sheet reflector is used, the 'true' transverse Kerr effect can be replaced by the longitudinal effect by placing the slit aperture on the sideward branch of the extinction cross, thus causing a transverse plane of incidence, that is, transverse sensitivity.

3.1.2 Lateral resolution

The lateral resolution in optical microscopy is determined by the numerical aperture ($NA = n \sin\alpha$) of the objective lens, where α is half the opening angle of the objective (i.e., half the angle of the cone of light from the specimen that is accepted by the objective) and n is the refractive index of the medium used between objective and object ($n = 1$ for air; $n \approx 1.5$ for immersion oil). The higher α and n, the more orders of diffracted light are collected by the objective, which increases the resolution. The smallest distance between two objects that can be resolved is given by $d_{\min} = 0.5\,\lambda N A^{-1}$ according to the Rayleigh criterion (λ is the wavelength of light, e.g., 550 nm for green light). The highest numerical aperture available is 1.4, obtained with oil-immersion objectives of 100× magnification. Using such an objective and blue light for illumination, domains as narrow as 150 nm can be resolved (Schmidt and Hubert, 1986). Smaller magnetic objects like domain walls down to a size of some 10 nm may also become visible by digital contrast enhancement, but their image is diffraction broadened. Ultraviolet (UV) light would further improve resolution; however, UV light with a wavelength of 400 nm is already absorbed to 50% by conventional lenses (at 360 nm wavelength, the absorption is 100%). UV microscopes with all-quartz optics, permitting resolutions down to about 80 nm at deep-UV wavelengths, have been developed mainly for defect inspection in semiconductors. The implementation of polarization optics in such microscopes, however, appears to be problematic (Yamasaki, 2006, Private communication).

In Figure 6, some examples of high-resolution observations, using white light and oil immersion, are collected. The surface magnetization of asymmetric Bloch walls on bulk soft magnets is well resolved, even in the case of iron–silicon with a surface wall width of just 150 nm (Figure 6a). The same is true for all kinds of domain walls in magnetic films, as shown for the examples of crosstie walls (Figure 6b) in thin films and asymmetric Bloch and Néel walls in thick films (Figure 6c). Also, small-angle magnetization modulations (ripple or patchy modulations) are easily identified. The practical limit for the observation of small particles is demonstrated in Figure 6(d) for cobalt thin-film elements. Faint contrasts are still visible on the 230-nm-wide dot. A reliable judgment on the magnetization distribution, however, requires elements larger than a micrometer (Figure 6e). The images in Figure 6(f) demonstrate an *in situ* observation of current-induced domain wall propagation (Kläui *et al*., 2005) in a NiFe stripe structure with a width close to the resolution limit.

Restrictions in the resolution of Kerr microscopy are outweighed by a highly flexible magnification. Sample areas ranging between 5 mm and 30 µm can be covered by simply changing objective lenses in standard microscopes. Often, a low-resolution overview of domain patterns on a still larger lateral scale is required, even in the research on novel, nanoscale objects such as film systems for spintronics (Schäfer, Hubert and Parkin, 1993). Custom-made Kerr setups with separated illumination and observation paths are suited for this purpose (see Fig. 2.14 in (Hubert and Schäfer, 1998)). An elegant way of realizing such microscopes is to modify an optical stereomicroscope by using one path for illumination and the other for observation. An example for multiscale imaging in shown in Figure 7, which, at the same time, is an example for the possibility of sample manipulation by stress.

3.1.3 Image processing

As the Kerr effect is weak, polarization effects from imperfect surfaces, showing up especially at nearly crossed polarizers, can strongly obscure the magnetic image. Magnetic

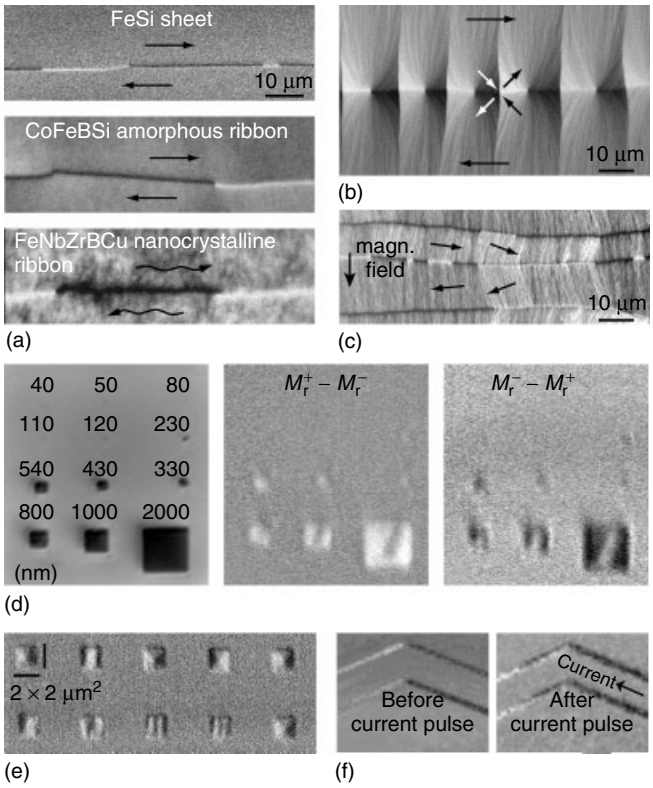

Figure 6. High-resolution Kerr observations. (a) Domain wall imaging on different bulk samples. The surface wall width for the FeSi Goss sheet (300 nm thick) with (110) surface orientation is 150 nm, for the metallic glass (25 µm thick) it is 0.9 µm, and for the nanocrystalline ribbon (20 µm thick) a surface wall width of 1.6 µm is measured, as expected due to the decreasing anisotropy in the order of materials. The black–white contrast of the wall segments is caused by the rotation sense of magnetization (see also Figure 4a). (b) Crosstie wall in a 40-nm-thick Permalloy film, and (c) coexisting asymmetric Bloch- and Néel walls in a 460-nm-thick Permalloy film, the latter being characterized by a double contrast. See (Hubert and Schäfer, 1998) for details. (d) Regular image (left) and difference images between the remanent states after positive and negative saturation (middle) and vice versa (right) on quadratic cobalt elements of various sizes. The saturation field is aligned vertically; the edge length of the elements is indicated in nanometers. (e) Domain patterns in an array of 2-µm-wide Co elements after ac demagnetization. In (f) the head-on domain walls in 500-nm-wide NiFe stripes were shifted by current pulse injection (See also **Current Induced Domain-wall Motion in Magnetic Nanowires, Volume 2**). Figure 7. Demonstration of magnification range and sample manipulation abilities of Kerr microscopy. (a) Low-magnification domain overview on FeSi transformer steel sheet, showing three grains of different misorientation (characterized by the density of lancet domains (Hubert and Schäfer, 1998)) in the demagnetized state. Sixteen images, obtained with a 3.2× objective lens, were combined in this composite picture. Details of the lancet domains are presented in the inset, which was obtained with a 100× oil immersion objective at high resolution. The Kerr sensitivity was rotated by 90°, so that the domain walls are imaged rather than the domains. In (b) an external tensile, a stress of 2 kg mm^{-2} was applied to the sheet in vertical image direction, leading to domain refinement and suppression of the supplementary domains.

contrast enhancement is possible by the interference layers mentioned in Section 2. A much more powerful option, however, is the implementation of video microscopy and digital image processing (Schmidt, Rave and Hubert, 1985; Argyle, Petek and Herman, 1987). Magnetic materials are ideally suited for difference imaging because the magnetic state can be manipulated by external magnetic fields without changing the topography of the specimen. The standard procedure (Figure 8a) starts with a digitized, averaged image of the magnetically saturated state, where in an external dc magnetic field all domains are eliminated. Alternatively, an alternating field of moderate amplitude can be applied, which mixes up the domains during averaging with the advantage that forces on the sample may be smaller than in the high saturating field. This domain-free background (reference) image is then subtracted from a state containing domain information, so that in the difference image a clear micrograph of the domain pattern is obtained, which can be improved by averaging and digital contrast enhancement, free of topographic contrasts. Often, it is desirable to study domains in different aspects, for example, under longitudinal and transverse contrast conditions. This is possible by a combination experiment, as also demonstrated in Figure 8(a). After having created a regular difference image of a certain domain pattern, an image of the same pattern, but under different contrast conditions, is stored as a reference image that is

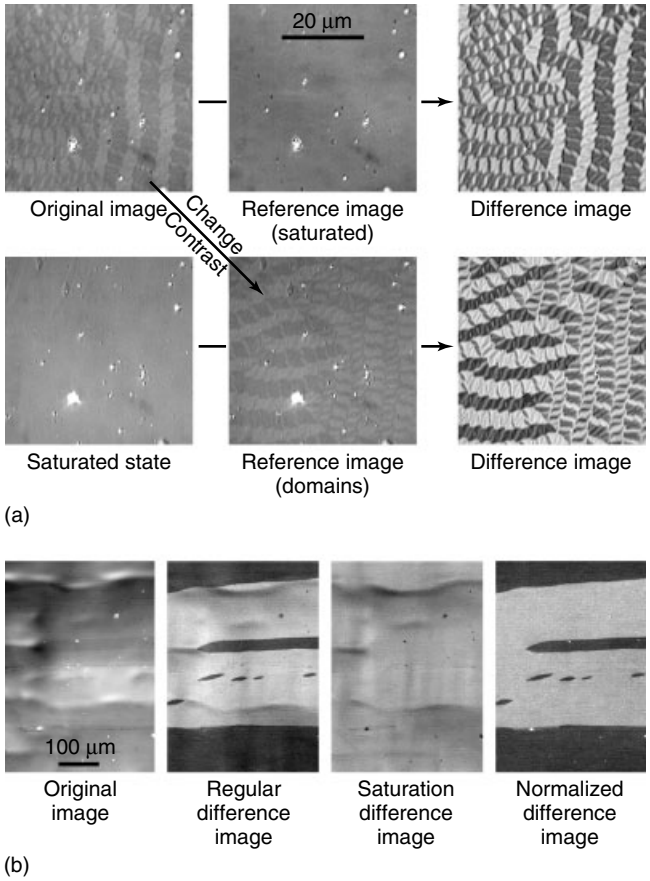

Figure 8. (a) Difference techniques for contrast enhancement, demonstrated for stress-induced domains on an iron-rich metallic glass. In a combination experiment, difference images of the same domain pattern are obtained under longitudinal (upper row) and transverse (lower row) contrast conditions. (b) Nonmagnetic contrast contributions in a 'regular' difference image can be removed by normalization by a 'saturation difference image', which is the difference image between two saturated states along opposite directions. The sample is an amorphous ribbon with a wavy surface.

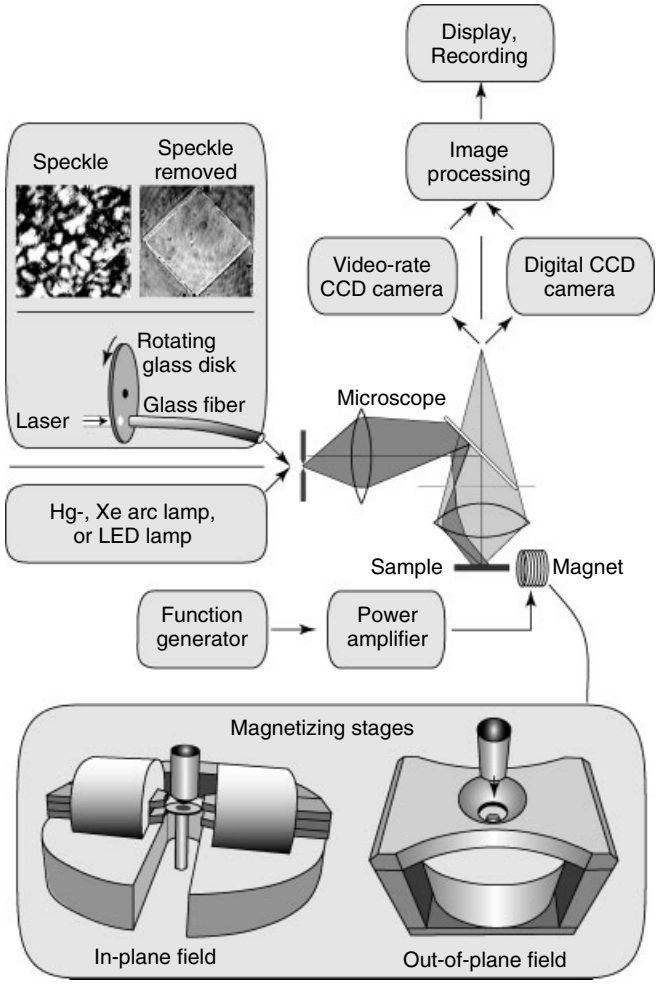

Figure 9. Experimental setup for wide-field Kerr microscopy. Options are shown for illumination, video processing, and magnetizing stages. Also shown is the presence and suppression of interference patterns by laser illumination with and without rotating glass disk respectively on a 28 by 28 μm^2 Permalloy thin-film element. then subtracted from a saturated state obtained under the same contrast conditions. Sometimes, inhomogeneities in the illumination or nonplanar surfaces produce strong contrast in the direct image, which can remain visible as artificial contrast in a 'regular' difference image. An enhanced method (McCord and Hubert, 1999) that normalizes the standard difference image by a 'saturation difference image', thus removing these artifacts, is demonstrated in Figure 8(b). Further experimental possibilities applying difference techniques are shown in Section 4.

3.1.4 Setup

The complete experimental setup for video-enhanced, wide-field Kerr microscopy is schematically shown in Figure 9. As most of the light is thrown away in Kerr microscopy due to the small opening of the polarizer and analyzer, light sources with a high luminous density are mandatory. The best light source in most cases is a high-pressure mercury arc lamp. It offers sufficient brightness and a color spectrum that can be monochromatically used in the yellow-green as well as the blue range by suitable spectral filters. The use of monochromatic light can be useful for the imaging of certain materials, for example, ferrites. Here, the portion of linear Kerr light is largest at 400 nm so that the domains can be imaged without additional means, while at 550 nm the elliptical contribution is strongest, requiring a compensator. The disadvantage of the mercury lamp is its instability and short lifetime. Xenon-arc lamps are more stable and offer white light at a luminous density of just one-quarter of the mercury lamp. This is still sufficient if a Berek illuminator

and prism polarizers are used to avoid light loss, or if loss is compensated by a highly sensitive video camera. In any case, the infrared radiation component of these lamps has to be removed by heat-reflecting filters to protect the specimen and, possibly, sheet polarizers from damage (also video cameras may be sensitive to the near infrared).

Much higher light intensity at better stability is obtained by laser illumination (Argyle, Petek and Herman, 1987) (the luminous density of a 5-mW laser is comparable to that of a 100-W mercury lamp). The laser light is fed into the microscope by a multimode glass fiber of typically some 100 µm diameter, replacing the conventional arc lamp. The image of the fiber output is then focused to a small spot in the back focal plane of the objective by the microscope optics (alternatively, the fiber end can also be directly positioned in the back focal plane). This ensures an almost parallel illumination of the sample. As the laser spot is smaller than the arc image of a conventional lamp, the spot image can be directly placed on the extinction cross so that an aperture stop is not necessary. By moving the fiber output around in the back focal plane, the plane of incidence and the sensitivity axis is adjusted. A variety of different lasers is available that cover a wide range of wavelengths. Traditional argon ion lasers can be replaced by modern diode lasers or diode-pumped solid-state lasers such as Nd:YAG lasers with a wavelength in the infrared that can be shifted to the visible range by frequency doubling. Also, blue solid-state lasers are available. Lasers can be run in continuous wave or pulsed modes, the latter making them suitable for time-resolved imaging (see Section 4). The coherence of the laser light introduces problems in wide-field microscopy. Light scattering and diffraction patterns (speckle) develop because of interference at surfaces and dirt particles in the optics. Such mottle unsteadiness (Figure 9, inset) makes it impossible to observe magnetic responses in real time. These artifacts can be eliminated by temporally scrambling the laser light. If the interference patterns fluctuate substantially faster than the integration time of the detector (e.g., the video frame rate of the camera), the speckle and scattering artifacts disappear in the image. Several methods for despeckling have been developed (Inoué and Spring, 1997; Argyle and McCord, 2000): inserting a spinning glass wedge or a glass disk with a randomly undulated surface in the illumination, sending the light over tumbling and rotating mirrors, or mechanically vibrating the glass fiber and additionally vibrating the tip of the fiber so that its image covers a suitable area in the back focal plane. In any case, satisfactory results with laser-illuminated microscopes are only obtained in multiframe accumulated images where residual laser effects are averaged out. A promising alternative to laser illumination are high-intensity light-emitting diodes (LEDs), which are also fed into the microscope by an optical glass fiber (Kleinefeld, 2006 Private Communication). They combine high stability with the absence of speckle and interference fringes. By cooling the LED in liquid nitrogen, it tolerates higher currents, thus delivering higher intensity.

A sensitive video camera transforms the optical image into an electrical signal that is displayed on a screen, either directly or after image processing. Charge-coupled device (CCD) cameras or highly sensitive complementary metal oxide semiconductor (CMOS) cameras have replaced classical Nevicon tube cameras in recent years. A number of 'regular' integrating video-rate CCD cameras, which have been optimized for bright-field video microscopy, are available. Also, *digital* CCD cameras can be used for Kerr microscopy if their frame rate is fast enough (at least video frequency) to allow real-time imaging. The read-out speed of digital cameras can be enhanced by joining adjacent pixels together into super pixels (binning), though at the cost of resolution. An approximately 1000×1000 pixel resolution at a frame rate of 30 frames per second (fps) are reasonable numbers for standard Kerr microscopy. Owing to the low light level in Kerr imaging, high camera sensitivity is important. Image intensifiers (see Figure 22, below) can further increase sensitivity, and cooling of the CCD chip improves the signal-to-noise ratio. The option of electronic shading correction that allows to improve inhomogeneously illuminated images is advantageous. In practice, the image brightness has to be adapted properly to meet the signal requirements and optimum dynamic range of the video camera. Increasing the analyzer angle β (Figure 1b – the intensity increases with β^2) or opening the aperture stop beyond the width of the extinction cross, thus increasing the background intensity, are practical means to achieve a large signal-to-noise ratio. A possible loss in contrast is not a severe problem, as contrast can easily be enhanced electronically.

Image processing for contrast enhancement requires digital image acquisition. Digital CCD and CMOS cameras directly provide a digitized data stream, while for video-rate CCD cameras the analogous output has to be converted by an analog-to-digital converter. At least 8-bit resolution (meaning that the intensity amplitude of an image is represented by 256 discrete values) is required in the (optimized) original image to avoid visually obvious gray-level steps in the processed image (for digital cameras, this number may be higher). To create a difference image, first an averaged reference image is stored by summation of repeated images (typically 64 or 128 frames) of the same sample state. The digital frame memory, which holds the accumulated images, must have a storage capacity of at least 16 bits to also accommodate the brightest pixels of the sum of digital 8-bit images. The reference image is stored and continuously subtracted

from all following images, being displayed on the monitor at the same time. As the visual observation of domain motion is fundamental for any kind of domain analysis, it is advantageous if the subtraction process is performed in 'real time' at (at least) video frequencies without averaging. For recording and presentation purposes, noise can be reduced by adding each of the digitized images in a recursive procedure to produce a running average of the incoming images. Because noise is random and the signal is not, a running average both reduces the noise contribution and enhances the signal component of the output digital image. The result is an image of constant brightness, the noise of which is continuously reduced with increasing averaging time. Owing to the small magnitude of the Kerr contrast, the resulting difference image may contain relevant information often only in the lower bit levels. The visually meaningful 8 bits are selected and displayed. Domain images in 8-bit resolution are sufficient for pleasing visual observation as the human eye can distinguish, at most, 50 discrete shades of gray within the intensity range of a video monitor. By difference-image processing, the Kerr contrast is typically enhanced by a factor of 30; this means that contrasts below 0.1% can be visualized (the contrast sensitivity of the human eye is some percent at best). Digitized images open the way for further computer processing depending on specific demands.

The free space around the nosepiece of the microscope allows a variety of sample manipulations. The application of mechanical stress, as an example, was already documented in Figure 7. In-plane magnetic fields of arbitrary direction can be applied by rotatable coils or electromagnets. In the design of Figure 9, the specimen is mounted on a stamp that is placed between the pole pieces of an independently pivoted electromagnet. Magnetic fields $\mu_0 H$ up to some tenths of a Tesla can be achieved in such setups, reaching the Tesla regime at proper pole-tip geometry and close pole distance. Sample displacement of centimeters in the X and Y directions is possible and the entire stage unit is capable of precise up and down movement with the conventional coarse and fine focusing mechanism of the microscope. In-plane fields of arbitrary direction may alternatively be created by proper superposition of the fields of two fixed, perpendicular electromagnets. Also, perpendicular magnetic fields (i.e., parallel to the objective) can be generated in a Kerr microscope, either by regular coils or by specially designed electromagnets, as sketched in Figure 9, which provide fields up to the Tesla range. Other applications may require special designs (see Section 4.2.5 on dynamic imaging). Optical cryostats or heating stages, which fit between the pole pieces of an electromagnet, allow temperature-dependent observation of magnetization processes. As vacuum insulation is required for these devices, the sample has to be observed through a glass window. Long-distance objectives have to be used then which suffer from a reduced optical resolution of about 0.5 µm at best, as given by the numerical aperture of these objectives. A problem for the application of stronger fields is parasitical Faraday rotations in the lenses or glass windows of the optical temperature stages that may be much stronger than the Kerr effect. The Faraday contribution can be compensated by rotating the analyzer.

As extremely weak contrasts are enhanced by the difference imaging procedure, a high mechanical, thermal, and electrical stabilization of the microscope and electronics is indispensable to obtain optimal results (at least during the time where the same reference image is used). A stable light source, heat-reflection filters to avoid sample heating, and placing the microscope on a damped table to avoid vibrations are fundamental. Mechanical stabilization is most critical. Rough surfaces cause light scattering that immediately destroys the Kerr contrast in a difference image if the sample is displaced relative to the state where the reference image has been accumulated. Displacements of the order of the resolution limit of the used objective are sufficient to deteriorate a difference image. Considerable sample movement may be caused on larger samples in the gradient of the magnetizing fields. Using stiff sample holders and stiff gluing of the specimen reduces the problem (care has to be taken to avoid unwanted mechanical stress in the samples). All magnetic parts in the sample space should additionally be replaced by nonmagnetic ones as far as possible.

3.1.5 Kerr microscopy and magneto-optical magnetometry

Plotting the average image intensity in a sample area, which is defined by the objective and field diaphragm, as a function of the applied magnetic field yields a local magneto-optical hysteresis curve. At the same time, the domain images can be recorded, thus providing a visualization of the underlying magnetization process. Figure 10 shows an example of such an experiment, performed on an exchange-coupled bilayer system.

3.1.6 Quantitative Kerr microscopy

Owing to its linearity and direct sensitivity to the magnetization, the Kerr effect can be used for a quantitative determination of the magnetization direction (Rave, Schäfer and Hubert, 1987). The principle of quantitative Kerr microscopy is explained in Figure 11(a). The Kerr intensity has a sinusoidal dependence on the direction of the magnetization vector. This sensitivity function, which is used for calibration, is obtained by measuring the intensity of saturated states along different directions. Also, domain intensities can be used for calibration if their magnetization direction is known *a priori*,

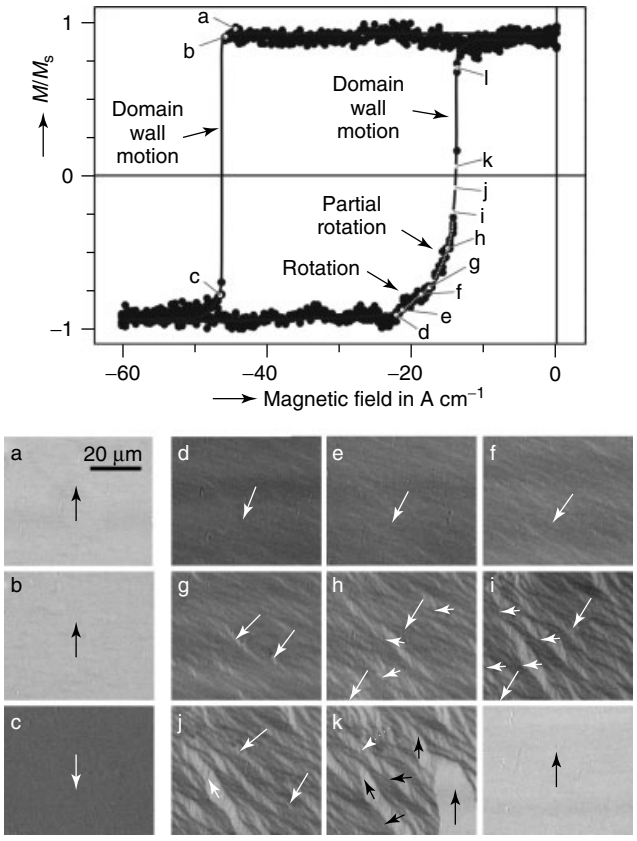

Figure 10. Magneto-optical hysteresis curve, directly measured in a wide-field Kerr microscope, together with domain images on a CoFe (20 nm)/IrMn (10 nm) bilayer film. The domains in the ferromagnetic CoFe film, which is exchange coupled to the antiferromagnetic IrMn film that is responsible for the loop shift (exchange bias effect, See also **Exchange Coupling in Magnetic Multilayers, Volume 1**) are shown. The steep forward branch of the magnetization curve is caused by domain wall motion (a–c), while inhomogeneous rotational processes (d–k) are responsible for the rounded part of the recoil branch. The wall motion along the forward branch is so fast that it cannot be recorded by static images. The magnetization M is normalized to the saturation magnetization M_s in the plot. (Reproduced from J. McCord, R. Schäfer, R. Matthesi, K.-U. Barholz: Observations by permission of American Institute of Physics.)

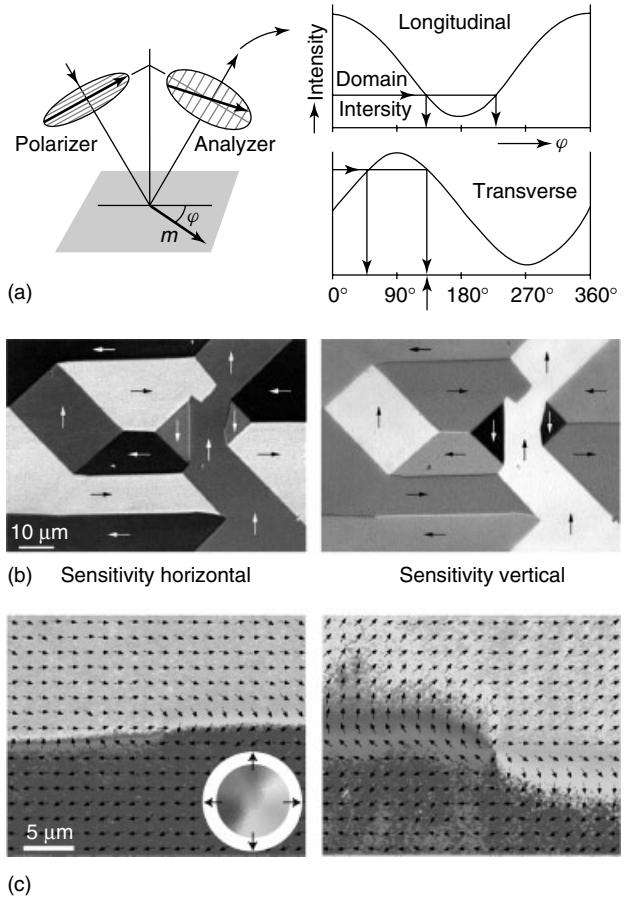

Figure 11. Principle and application of quantitative Kerr microscopy. (a) Calibration functions of the Kerr intensity at longitudinal and transverse sensitivity as a function of magnetization direction (schematically). The intensities of an unknown domain, measured under the same conditions, are compared with the calibration functions, as indicated by arrows. (b) Domain pattern on iron–silicon [100] sheet, imaged under two complementary Kerr sensitivities. (c) Quantitative images on a Co-rich amorphous ribbon. The domain wall width of the as-quenched state (left) is strongly enlarged (right) if residual anisotropies are reduced by annealing in a rotating magnetic field (Schäfer and Herzer, 2001). A vector plot and color code (here shown in black and white) can be used for presentation.

for example, due to crystal anisotropy or at sample edges. The intensity of unknown domains is then compared with the calibration function and so the angle of $\boldsymbol{m}$ in the surface can be measured. The problem is that due to the sinusoidal dependence there are two possible angles for a given domain intensity. To resolve this ambiguity, the domain pattern of interest has to be imaged twice under different sensitivity conditions that should be shifted by 90° (e.g., by choosing longitudinal and transverse Kerr effects). Figure 11(b) shows domains on an iron single crystal with [100] surface orientation that were imaged under these conditions. If the domain magnetization is transverse to the contrast sensitivity, the domain walls show up as black or white contrast, as given by their surface rotation sense. In Figure 11(c), the quantitative method was applied to domain walls in a cobalt-rich metallic glass ribbon. Originally, these images are displayed with a color code, where the in-plane magnetization directions are mapped by a color wheel. The quantitative method can reliably be applied only to soft magnetic materials for which no polar magnetization components are present at the surface, which would otherwise be difficult to calibrate or separate from in-plane contrast.

3.1.7 Depth-selective Kerr microscopy

The magnetic information depth of the Kerr effect is about 20 nm in metals. A quantification of this depth sensitivity has to consider the *phase* of the magneto-optic amplitude (Träger, Wenzel and Hubert, 1992). The total magneto-optical signal can be seen as a superposition of contributions from different depths, which are damped exponentially and which differ in phase as a function of depth according to a complex amplitude penetration function (Figure 12a).

These phase differences can be exploited in Kerr microscopy (Schäfer, 1995). Using a rotatable compensator, the phase of the Kerr amplitude, generated in a certain depth, can be adjusted relative to that of the regularly reflected light amplitude (as shown in Section 2, a detectable Kerr rotation is only possible if $\boldsymbol{K}$ and $\boldsymbol{N}$ are in phase). In this way, light from a selected depth zone may get invisible if its Kerr amplitude is adjusted out of phase with respect to the regular light. In sandwich films, (See also **Exchange Coupling in Magnetic Multilayers, Volume 1**) consisting of ferromagnetic layers that are interspaced by nonmagnetic layers, the zero of the information depth can be put somewhere into the middle of one layer so that the integral contributions of this layer just cancel, leaving only contrast from the other layer (Figure 12b). This kind of layer-selective Kerr microscopy is demonstrated in Figure 12(c) for a Co/Cu/NiFe sandwich sample. Demagnetization in an alternating field leads to a complicated mixture of wide domains in the low-coercivity bottom layer and fine, irregular domains in the high-coercivity top layer. After contrast separation, traces of these fine domains are also seen in the bottom layer, most likely induced by dipolar interaction with the magnetically charged domain walls of the top layer.

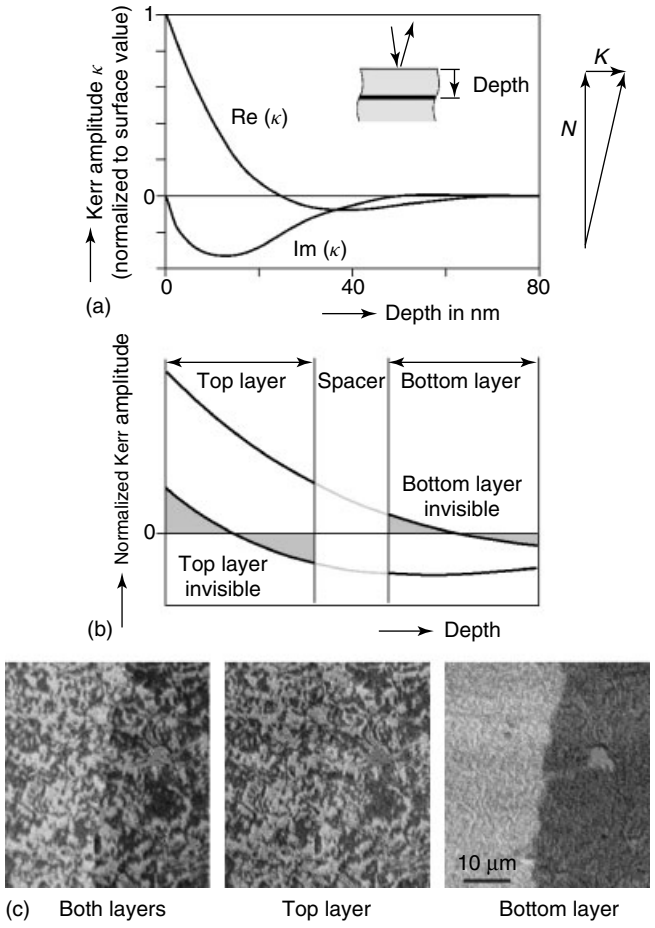

Figure 12. (a) Depth sensitivity of the normalized Kerr amplitude κ in iron. The relative phase of $\boldsymbol{K}$ and $\boldsymbol{N}$ was selected so that $\boldsymbol{N}$ is allowed to interfere with the $\boldsymbol{K}$ generated right at the surface (after Träger, Wenzel and Hubert, 1992). Proper phase selection (b) Proper phase selection (b-schematically) allows layer-selective Kerr imaging on thin-film sandwiches, as demonstrated in (c) for a sputtered Co/Cu/$Ni_{81}Fe_{19}$ (5 nm/5 nm/50 nm) trilayer. (Sample: *D. Bürgler*, FZ Jülich, imaging: *J. McCord*, IFW Dresden.)

3.2 Laser-scanning Kerr microscopy

In a laser-scanning Kerr microscope, a polarized laser beam is scanned relative to the specimen and its polarization state after reflection is analyzed by a photodetector. The early approaches of this technique were stimulated by the interest in the dynamics of magnetization processes in thin-film recording heads (see Section 4.2.1). First measurements, using a fixed laser spot and a line scan of the sample (Re, Shenton and Kryder, 1985), were soon extended to a two-dimensional scanning technique (Kasiraj, Shelby, Best and Horne, 1986). Elimination of nonmagnetic signals (due to nonideal surfaces) was achieved by synchronous detection: the magnetization was modulated by a high-frequency magnetic field. The corresponding modulation in the polarization of the Kerr light was then extracted from the optical detector with a phase-sensitive lock-in technique. Thus, a map of the high-frequency magnetization response (permeability) was obtained, in which the domain structure was revealed owing to domain wall motion. In succeeding developments, the domain information could be directly extracted by advanced detection schemes that even have the capability of vector magnetomery (Egelkamp and Reimer, 1990; Clegg, Heyes, Hill and Wright, 1991; Silva and Kos, 1997; Nagai, Sekiguchi and Ito, 2003).

The principle of such an advanced laser-scanning Kerr microscope is illustrated in Figure 13(a). A collimated and polarized laser beam is focused onto the specimen surface using an infinity-corrected objective lens. Argon lasers are widely used because of their brightness and excellent geometry. The laser spot is then moved across the specimen by

scanning probe and sample relative to each other. In commercial instruments, which have been designed mainly for biological applications, the laser spot is scanned in a TV-raster fashion (beam scanning). For Kerr microscopy, however, moving the sample itself in a rasterlike way by using a precision XY stage is more favorable. Although this stage scanning is relatively slow (the time required to produce an image is of the order of tens of seconds), it ensures that both, the angle of incidence and the polarization state of the illuminating ray bundle, are constant over the entire scan. By scanning, the image is constructed in a point-by-point manner with a lateral resolution that is basically determined by the size of the probing laser beam. Using a 100× oil immersion objective with a numerical aperture of 1.3, a laser spot size of 0.8 µm is obtained. A smaller focused spot size of 0.16 µm is achieved if the beam diameter is first increased by beam expansion to completely fill the objective aperture before it is focused on the sample (Inoué and Spring, 1997).

The reflected light, which is collected by the same objective lens, passes a rotatable quarter-wave plate to compensate ellipticity and finally enters a Thomson polarizing beam splitter. To obtain maximum sensitivity and flexibility, the splitter is set at 45° to the incident (undisturbed) polarization (Freeman and Hiebert, 2002a). Alternatively, the beam splitter can be set at 0° and the polarization plane can be rotated by 45° by using a half-wave plate before the light enters the splitter (Wright, Heyes, Clegg and Hill, 1995). The splitter provides two beams of orthogonal polarization direction (Figure 13a, inset) that hit a pair of quadrant photodiodes. Each pair of opposing quadrants is aligned along the projection of the samples x and y axes, respectively. The two beams are of equal intensity for the case of undisturbed 45° polarization, while any sample-induced polarization rotation leads to equal but opposite intensities (45° is the angle most sensitive to small polarization changes). By suitably combining the outputs of the eight photodiode quadrants, the three orthogonal components of magnetization can be simultaneously detected and separated, provided that they are sampled nearly equally, which is true for objectives with a high numerical aperture. As illustrated in Figure 13(b) (and demonstrated experimentally in Figure 3), the longitudinal Kerr contrast changes sign if excited by two beams of opposite directions of incidence, while the polar contrast remains unchanged. By adding the signals of all four diodes of one quadrant detector, the longitudinal components are cancelled, while the polar components are added. As the total intensity that reaches each detector is reduced and enhanced, respectively, by equal amounts owing to the beam splitting, the pure polar contrast can thus be separated by subtracting the two sum signals (i.e., taking the quadrant combinations $(X_1^+ + X_1^- + Y_1^+ + Y_1^-) - (X_2^+ + X_2^- + Y_2^+ + Y_2^-)$), whereas a nonmagnetic surface-contrast image

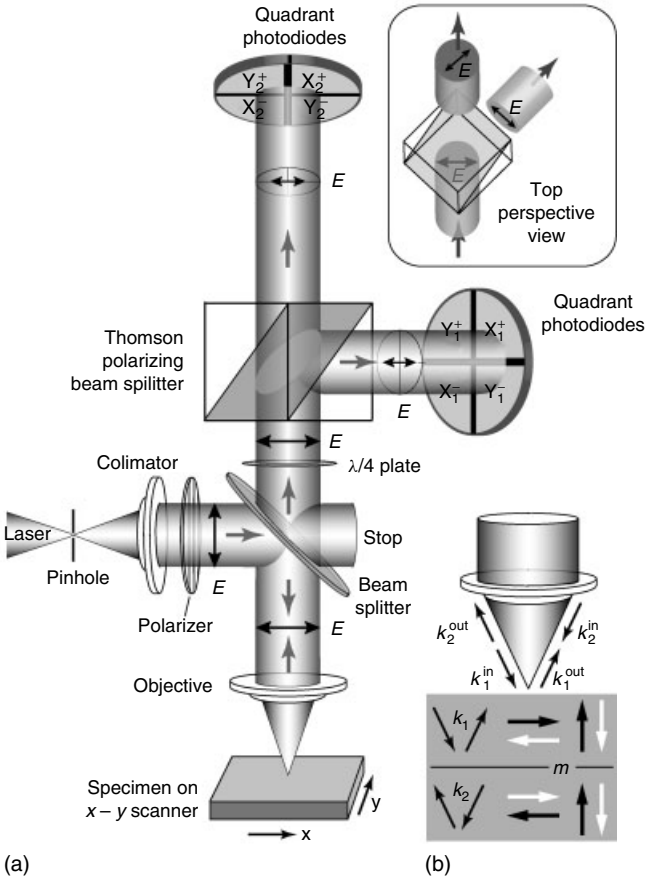

Figure 13. (a) Principle of laser-scanning Kerr microscopy (based on setups realized by Wright, Heyes, Clegg and Hill, 1995, and Freeman and Hiebert, 2002a). The polarization plane of light is indicated by the $\boldsymbol{E}$ vector. The inset shows a perspective view from top to illustrate the orthogonal polarization directions of the two beams leaving the polarizing beam splitter. (b) Contrast of in- and out-of-plane magnetization components depending on the direction of the $\boldsymbol{k}$ vector.

is generated by simply adding the signals. The longitudinal Kerr contrast of magnetization components along the x-axis is revealed by combining $(X_1^+ - X_1^-) - (X_2^+ - X_2^-)$, and that along the y-axis by $(Y_1^+ - Y_1^-) - (Y_2^+ - Y_2^-)$. Since all data are collected from the quadrants simultaneously, the three magnetization components at one sample spot are captured at the same time. This elegant method of vector magnetometry requires a highly symmetrical beam profile so that each quadrant receives the same quarter of the beam (Freeman and Hiebert, 2002a). The longitudinal contrast can be further enhanced by introducing a set of four apertures into the optical path in the back aperture of the objective lens. This restricts the range of the angles of incidence to provide a bundle of rays around an incidence angle of approximately 60°, depending on the used objective's numerical aperture (Wright, Heyes, Clegg and Hill, 1995).

Another advantage of the differential detection technique is the common mode rejection of laser noise while at the same time the signal is doubled. Further enhancement of the signal-to-noise ratio can be achieved by applying lock-in techniques: the illuminating laser beam is modulated by some photoelastic (Silva and Kos, 1997), acousto-optic (Wright, Heyes, Clegg and Hill, 1995), or electro-optic (Egelkamp and Reimer, 1990) device and the reflected light is measured by a phase-sensitive detection amplifier, thus selecting only signals that are proportional to the Kerr amplitude. By using ac detection, contrast arising from nonmagnetic surface structures is suppressed, the $1/f$ noise – inherent in the laser light source – is avoided, and polarization changes can be measured independently of intensity fluctuations in the reflected light. Signal enhancement by the lock-in technique (supported by additional subtraction of a constant background intensity in the preamplified signal) makes it possible for even the small light amplitude modulation of the transverse Kerr effect to be used for imaging purposes (Egelkamp and Reimer, 1990; Acremann *et al*., 2000). The technique, which is not easily possible in conventional Kerr imaging, has the advantage of being sensitive only to one magnetization component. By illumination from two directions, quantitative Kerr images can be obtained (Büscher and Reimer, 1993). Since the spots on the sample are illuminated sequentially in a laser-scanning microscope, interference speckle is less important and can be even completely eliminated by using an aperture (pinhole) in the detection system (Wright, Clegg, Boudjemline and Heyes, 1994). The aperture is placed conjugate to the spot being scanned so that only the light originating directly from the scanned spot is transmitted to the photodetector (such confocal systems also offer three-dimensional imaging capabilities, which is highly attractive in biological studies (Sheppard and Wilson, 1984)). The use of confocal imaging schemes has been shown to enhance the lateral resolution in non-magneto-optical microscopes by a factor of $\sqrt{2}$, which has, however, not been verified in Kerr imaging (Nutter and Wright, 1998).

A disadvantage of laser-scanning Kerr microscopy is its slow speed compared to regular imaging microscopes. The image acquisition time of some tens of seconds in stage-scanning microscopes can be lowered by beam scanning (Ping *et al*., 1995). This requires, however, special optical design to ensure a constant mean angle of incidence across the whole scan. Depolarization errors can be minimized by realizing the scanning with a vibrating single-mode optical fiber (Ping, See and Somekh, 1996). Scan rates of one frame per second can be obtained in this way, which, however, is still not fast enough for live observations of domains at video frequencies.

To conclude, scanning Kerr microscopy falls short in replacing conventional microscopy for 'routine' domain research as real-time imaging of domain motion cannot be realized. The capability to simultaneously image all three magnetization components (vector magnetometry) and to easily eliminate background contrast by lock-in techniques is advantageous. Static Kerr images of satisfactory quality, both of in- and out-of-plane domains, can therefore be obtained. Also, other quantities like permeabilities or magnetization curves can conveniently be measured on a microscopic scale, thus probing the spatial variation of magnetic properties. The biggest potential of laser-scanning microscopes, however, lies in their predestination for *stroboscopic* imaging of fast dynamic processes (see Section 4.2.4).

4 DYNAMIC KERR MICROSCOPY

Dynamic magnetization processes cover a wide range of timescales. Relaxation processes, wall creep, and aftereffect phenomena may last up to minutes and longer, eddy-current-limited processes in thick, electrically conducting specimens last microseconds, and precessional phenomena in metallic films occur in the nano- and sub-nanosecond regime (See also **Magnetization Dynamics Including Thermal Fluctuations: Basic Phenomenology, Fast Remagnetization Processes and Transitions Over High-energy Barriers, Volume 2**). Wide-field Kerr microscopy is suitable for dynamic domain studies in a frequency range from arbitrarily slow to beyond the gigahertz regime. Slow domain dynamics can be observed visually as fast as the eye can follow, either directly in the microscope or on contrast-enhanced images on the video screen if contrast enhancement by real-time image subtraction is used. As an example, domain growth by wall motion in an amorphous ribbon is presented in Figure 14(a–c) by three difference images, each obtained after stopping the field change during the (slow) magnetization cycle. However, on fast magnetization processes also, valuable information can be obtained by regular difference-image processing. In Figure 14(d), the domain state of (c) was excited by a 25-Hz sinusoidal field of small amplitude. Blurred domain boundary contrast in the averaged difference image indicates vibrational domain wall motion. Increasing the field amplitude (e) reveals immobile domains in the middle of the image and strong domain activity on the sides, as evident by the strongly blurred contrast in these areas. After switching off the alternating field (f), the domain pattern differs in details from the initial one (c), indicating irreversible processes. Reversible and irreversible wall displacements can immediately be distinguished in the experiment of Figure 14(g–i). In (g) and (h), the domain state of (f) was subtracted from averaged images of two states in which the sample was subjected to alternating fields (25 Hz) of weak and moderate amplitudes, respectively.

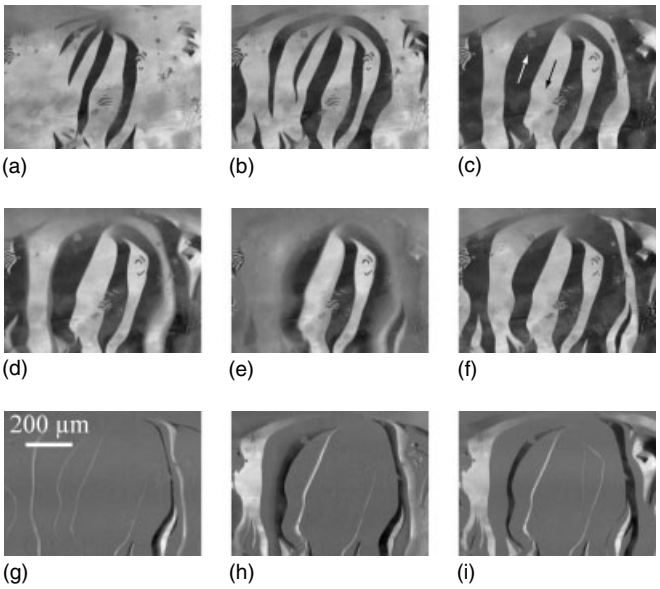

Figure 14. Studying the dynamics of a domain pattern in an amorphous ribbon ($Fe_{78}Si_9B_{13}$, thickness 20 µm) by conventional difference-image processing. The area shown is characterized by 180° domains that change their direction by about 90° at the top owing to stress-induced magnetic anisotropy. (a–c) Growth of dark domains in vertically aligned magnetic field. State (c) is excited by an alternating magnetic field of 25 Hz and increasing amplitude in (d) and (e). The moving parts of the domain pattern get blurred in the averaged difference image. In (g,h), the configuration (f) is subtracted from images with the same alternating fields applied as before. Changes in the domain pattern show up as strong black and white contrast in these dynamically averaged difference images. After switching off the ac field, some walls remain displaced irreversibly as can be seen by residual contrasts in the difference image (i).

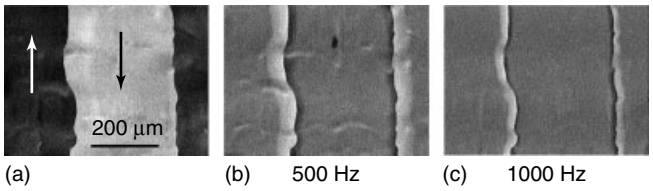

Figure 15. Imaging of periodic wall oscillation processes in a nanocrystalline ribbon ($Fe_{73}Cu_1Nb_3Si_{16}B_7$, thickness 20 µm). The domain state (a) is subtracted from images with a sinusoidal field of 500 Hz (b) and 1000 Hz (c) of same amplitude applied along the domain direction. (Courtesy *S. Flohrer*, IFW Dresden.)

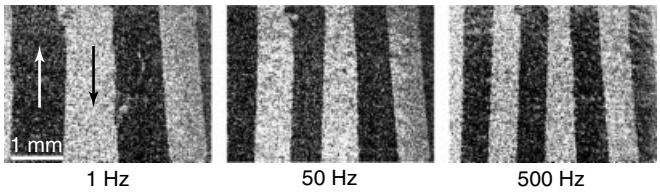

Figure 16. Eddy current–driven domain refinement in an ideally oriented grain on FeSi transformer steel. Three static domain states are shown after the sample was demagnetized with different frequencies as indicated. (Courtesy *S. Flohrer*, IFW Dresden.)

Those parts of the domain pattern that do not move stay gray in the dynamically averaged difference images, while changing parts show up as contrast. After turning down the field (i), contrast in the static difference image is left in those areas where irreversible processes took place. Such difference techniques can also be used to study periodic or quasi-periodic processes, as demonstrated in Figure 15. Here, oscillating domain walls were recorded with long exposure times at different frequencies with the static domain state subtracted. The black and white contrast gives information on the amplitude of wall motion that decreases with increasing frequency due to eddy-current damping. An asymmetry in the wall amplitude is also seen clearly. Two further examples of dynamic studies by regular image subtraction, showing domain multiplication processes as a consequence of dynamic field excitation, are presented in Figures 16 and 17.

Although dynamic effects can be studied by the aforementioned methods, such experiments do not reveal the dynamic processes by themselves because they are either smeared out by averaging procedures (as in Figure 14) or they are already over when images are taken (as in Figure 16). Time-resolved, high-speed imaging is rather required for detailed dynamic investigations. Kerr microscopy offers these possibilities both in the wide field and in the laser-scanning modes, as shown in the following sections.

4.1 Principle of high-speed microscopy

The principle of time-resolved high-speed microscopy is illustrated in Figure 18. The sample is excited by a continuously changing or pulsed periodic magnetic field. At certain time delays relative to the excitation, the magnetization is microscopically probed in a finite time window. Shifting the time delay of the probing window yields a series of time-resolved images of the magnetization process. Time resolution is either obtained by a gated high-speed video camera using a constant light source for illumination, or by a pulsed light source and continuous detection.

An ideal dynamic experiment should deliver a time-delayed series of single-shot images, as indicated in Figure 18(a), each of them representing the momentary magnetic state of the sample during the evolution of the magnetization process within the same excitation cycle. Repeating the imaging sequence in a number of following cycles would allow the study of the most general case that may also include nonreproducible and stochastic magnetization events,

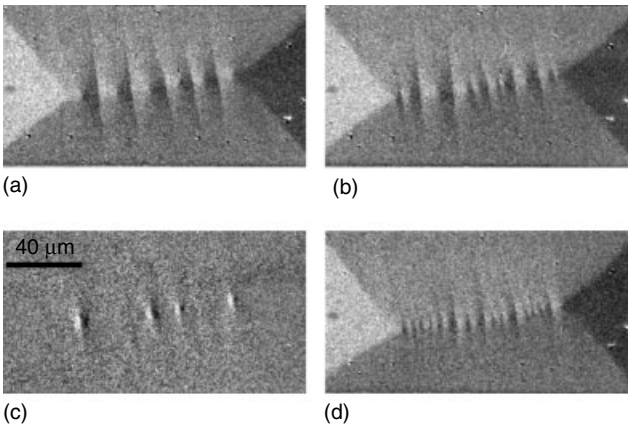

Figure 17. The dynamic multiplication of Bloch lines in a crosstie domain wall of a $Ni_{81}Fe_{19}$-film element of 50-nm thickness, again studied by conventional image processing. Image (a) shows a regular difference image in the demagnetized ground state. Image (b) was acquired after applying a single field pulse (amplitude $400\,A\,m^{-1}$, pulse length 1.2 ns, rise and fall time 120 and 170 ps, respectively) along the short axis of the element, leading to an increasing number of cross-ties, that is, the nucleation of new Bloch lines. The locations of Bloch line generation are evident in (c), where the difference of the two images before and after the field pulse is shown. In (d), a train of field pulses with a repetition rate of 23 MHz is applied. In these experiments, only the domain states before (a) and after pulse-field application (c–d) are displaced – the *mechanism* of Bloch line generation is not seen. (Courtesy *A. Neudert*, IFW Dresden. Reproduced from A. Naudert, J. McCord, R. Schäfer, R. Kaltofen, I. Mönch, H. Vinzelberg, L. Schultz: Bloch line generation in cross-tie walls by fast magnetic field pulses. *Journal of Applied Physics* (2006) by permission of American Institute of Physics.)

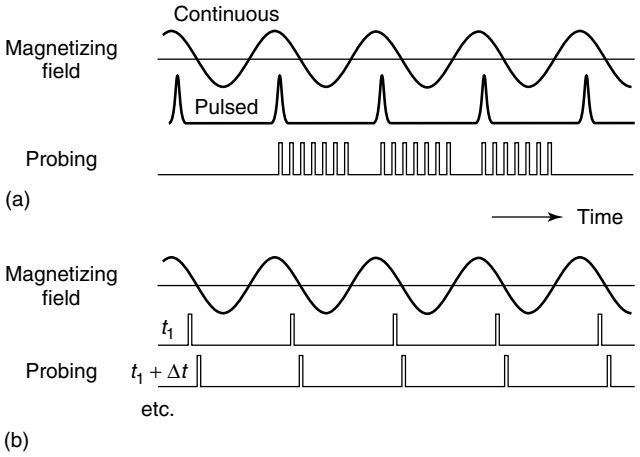

Figure 18. Principle of time-resolved imaging, (a) for an ideal single-shot experiment, and (b) in the stroboscopic mode. The sample is excited either by alternating magnetic fields or a by train of field pulses.

which may change from cycle to cycle. Single-shot imaging, however, requires a sufficient amount of photons to be accumulated in the detector during the probing time in order to obtain a sufficient signal-to-noise ratio. Very bright light sources and highly sensitive image detectors are therefore necessary. Also, the repetition rate of the experiment has to be fast enough to provide adequately short time delays for in-cycle imaging. Both conditions are increasingly difficult to meet with rising excitation frequency or if the magnetization response is too fast after pulse-field excitation.

If the repetition rate is the limiting factor (due to restrictions in the speed of light-pulse sequence, camera trigger, or delay electronics), single-shot imaging can nonetheless be applied as long as the detector sensitivity poses no limitation. By capturing images at identical time delays relative to the field excitation period (Figure 18b), but in different cycles, it is still possible to identify stochastic events. In case of repetitive processes, the full magnetization process may even be recovered by shifting the time delay of probing. If both detector sensitivity and repetition rate of the experiment are limited, time-resolved microscopy has to be performed in a different way, known as *stroboscopic imaging* (though, strictly speaking, the other methods are also of stroboscopic nature). In a strobed system, image acquisition is precisely synchronized to a periodic excitation, so that images are captured in the same time period of successive cycles (like in Figure 18b) and accumulated over many cycles (up to some 10° for fast pulse-field experiments) until a sufficient signal-to-noise ratio is achieved. The time delay is then periodically shifted to temporarily scan along the magnetization process. This accumulation technique, however, requires repetitive magnetization processes during successive cycles. If the process is different for every excitation period, a complicated mixture of contrasts (or even no contrast at all) is seen in the averaged images – in other words: only the repeatable events are seen as sharp features in the accumulated images, statistical events, and fluctuations are averaged out. A possibility to extract stochastic events ('noise') from stroboscopic images of nonrepetitive processes was described in Freeman, Steeves, Ballentine and Krichevsky (2002b).

The limitations of single-shot and stroboscopic imaging are demonstrated in Figure 19 by time-resolved (wide-field) studies on the same location of the amorphous ribbon that was already investigated in Figure 14. The pictures uncover the domain activity hidden in the blurred contrast of Figure 14(e). Time-resolved, stroboscopically obtained pictures at 25-Hz sinusoidal excitation are shown in Figure 19(a). They were recorded at three delay times as indicated, starting from an almost saturated high-field state. About 800 pictures of successive cycles, each with an illumination time of 0.4 ms, were collected and averaged for each image. Repeatable as well as nonrepetitive processes are evident in the probed area, indicated by strong and faint (or even blurred) domain contrast respectively. A strong reversibility

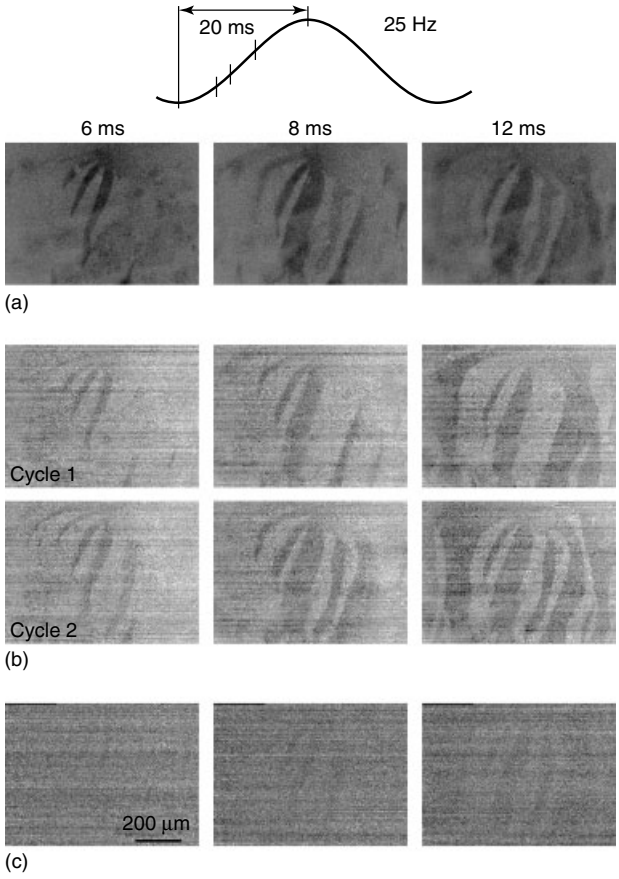

Figure 19. Dynamic studies at 25-Hz sinusoidal excitation on the same sample area as in Figure 14. (a) Stroboscopic images, obtained by a gated image intensifier and a digital CCD camera. Seven hundred and sixty-eight frames of 0.4-ms illumination time have been accumulated for each picture. The time delay relative to the maximum field is indicated. (b) Single-shot images at 2-ms illumination time, obtained by a high-speed CMOS camera with sufficiently large frame rate. The pictures in each row were taken successively within the same cycle. (c) Single-shot images at 0.4-ms illumination time. The difference images in which an averaged image of the saturated state is subtracted are shown in each case (together with *S. Flohrer* and *J. McCord*, IFW Dresden).

in the middle zone is confirmed by this experiment, which was already indicated by domain stiffening in the experiments of Figure 14. By single-shot imaging (Figure 19b) also, the irreversible processes are resolved by sharp contrasts. The two rows of images were recorded in different cycles of excitation, with the images within one row having been obtained subsequently within the same cycle at similar delay times as in Figure 19(a). A comparison of the two rows reveals similar and different domains that appear within the two cycles, indicating reversible and irreversible processes. The reversible domains add up to the strong contrast in the stroboscopic experiment of Figure 19(a). The illumination time for each image in Figure 19(b) was 2 ms, which was obviously sufficient to get a reasonable signal-to-noise ratio, but which occasionally left unsharp boundaries caused by nonnegligible wall movement within this time window. This effect should be strongly reduced if the illumination time of the single shots is reduced to 0.4 ms (Figure 19c) as for the stroboscopic image. However, strongly noisy pictures with almost vanishing domain contrast are obtained then, indicating the limits of single-shot imaging. As the conditions for serial single-shot imaging are (so far) impossible to meet for frequencies above the 50-Hz regime due to the mentioned limitations, most of the time-resolved imaging experiments at power frequencies and beyond have to follow a stroboscopic scheme.

4.2 Experimental setups for time-resolved microscopy

High-speed imaging requires the following main components: microscope (or at least objective lens in case of laser-scanning microscopy), image detection, pulsed light source or triggered video camera to obtain time resolution, power supply connected to a coil or stripe line for magnetic excitation of the sample, and some synchronous means including delay electronics to adjust and shift, respectively, the excitation and probing time. Time resolution and repetition rates of excitation and probing have to be chosen appropriately to meet the specific requirements of the sample and processes to be studied. If, for instance, the relaxation processes in a magnetic thin-film element after pulse-field excitation last 20 ns, the repetition rate of the field pulses should be less than 50 MHz to allow complete relaxation before the next pulse is applied. To provide repetitive conditions for stroboscopic imaging, it also has to be assured that the initial domain state is identically recovered between the excitation periods. For time-resolved imaging, both laser-scanning microscopy with a pulsed laser as well as wide-field microscopy can be used, the latter either based on a pulsed light source or on a triggered video camera. The three methods are compared in this chapter, following a brief historical review on the development of time-resolved Kerr microscopy.

4.2.1 Historical review

First time-resolved Kerr imaging techniques emerged in the early 1960s, based on regular wide-field microscopy and motivated by the interest of that time in the fast reversal of soft magnetic films for memory applications and in the dynamic processes and losses in electrical steel. In 1963, an optical strobing apparatus for imaging the flux reversal in NiFe films was introduced (Conger and Moore, 1963), in which light pulses of about 100-ns duration were generated

using sunlight and a mirror that was fastened to a spinning turbine. Simultaneously, Drechsel (1961) used a xenon flash-lamp to create single light pulses of 1 ms duration that were applied to single-shot imaging of iron crystals after sharply changing the magnetic field. Stroboscopic imaging on Goss sheets with several minutes averaging time at sinusoidal excitation up to 200 Hz was realized by Passon (1963) by adding a rotating disk with holes in the illumination light path of a continuously shining halogen lamp. Pictures were recorded by photographic films in these early experiments. Some years later, high-speed motion-picture cameras with frame rates up to 5000 pictures per second allowed single-shot imaging on transformer steel up to the 100-Hz regime (Houze, 1967; Haller and Kramer, 1970). The motion pictures could be examined frame by frame to analyze the character of domain wall motion. In the experiment of Houze, the high-speed camera was synchronized with a xenon flash lamp, that is, one flash per frame was recorded. In another setup of Passon (1968), time resolution was realized by a commercial television camera, equipped with a sensitive image intensifier that could be gated by trigger pulses. Stroboscopic observation of periodic processes up to 20 kHz with a gating time as low as 2 µs was possible with this system. Wall damping and wall multiplication phenomena with increasing frequency (due to eddy-current effects) were observed in these pioneering experiments. Also found was an increase in the reproducibility of magnetization processes in transformer steel with raising frequency – the precondition for stroboscopic imaging. An excellent review on these findings is given in Shilling and Houze (1974). In the meantime, laser illumination had entered the scene. A Kerr optical 'apparatus' with a Q-switched ruby laser for pulsed illumination was set up by Kryder (Kryder and Humphrey, 1969a). Time resolution of 10 ns was obtained by synchronizing the laser light pulses with the actuation of a Kerr electro-optic shutter in front of the photo camera. The intensity of the laser pulses (of some megawatts) was sufficient to provide single-shot photographs of the dynamic state during flux reversal in permalloy thin films (Kryder and Humphrey, 1969b). Many of these early dynamic Kerr experiments became possible only after contrast enhancement by optical interference layers (see Figure 2).

A decade later, the emerging bubble memories again stimulated interest in dynamic imaging. Most setups of that time (Humphrey, 1975; Kryder and Deutsch, 1976) were based on dye lasers that were triggered by pulsed nitrogen ion lasers, generating light pulses in the 10-ns-duration range at a low repetition rate of about 10 Hz. Owing to the high laser energy, caution had to be taken to avoid sample damage by overheating, for example, by defocusing the laser beam (Malozemoff, 1973). Such effects could be avoided by using continuous illumination and a gated image intensifier to obtain

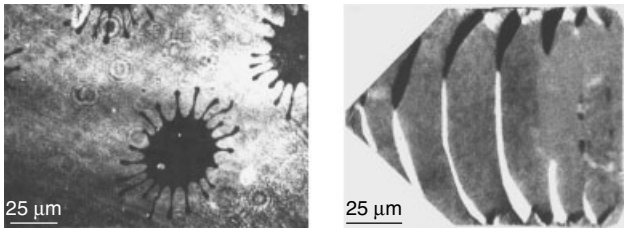

Figure 20. (a) Single-shot picture of 'exploding' magnetic bubbles in a garnet film. (b) Stroboscopic image from the yoke of a thin-film recording head, excited with a 1-MHz drive field. A difference image between two states is shown that were acquired by series of 5-ns laser pulses, where the pulses of the second series are delayed somewhat relative to the pulses of the first series. (Reproduced by permission of Springer from Hubert and Schäfer, 1998, the pictures are courtesy of *F. Humphrey* (a) and *B. Argyle* (b).)

high-speed photographs of bubble devices (Vella-Coleiro and Nelson, 1974). In Kryder's system (Kryder and Deutsch, 1976), the laser pulse frequency corresponded to the trigger rate of a TV camera so that each frame recorded had only one laser pulse for illumination. By recording on a videotape recorder, the repeatability of the magnetization process could be examined by frame-by-frame analysis of the tape. Transient bubble domain shapes during expansion and collapse in pulsed magnetic fields have been observed by high-speed photography (Gál, Zimmer and Humphrey, 1975). A snapshot of 'exploding' bubble domains, as an impressive example, is shown in Figure 20(a). Single-shot imaging in magnetic garnet films profited from strong contrasts due to the polar Faraday effect that can be favorably applied in bubble films.

Dynamic imaging in the following decade focused on the understanding of the sources of wiggle and noise in thin-film recording heads. First measurements were performed in a photometric way (Re, Shenton and Kryder, 1985): an Ar laser spot was focused on the pole tip in a regular optical polarizing microscope. The head was excited by high-frequency currents up to 50 MHz, sent through the drive coil. The reflected light, modulated by the polar Kerr effect, was then recovered with a photomultiplier and a lock-in amplifier detection scheme. By line scanning across the pole tip, the profile of the switching magnetization could be determined. This method was then extended to a two-dimensional scanning technique (Kasiraj, Shelby, Best and Horne, 1986), delivering spatially resolved images of magnetization changes with a time resolution of 50 ns. Since nonmagnetic signals were eliminated by the lock-in technique in this approach, the weak Kerr contrast of permalloy films was greatly enhanced. Different approaches, applied to the imaging of thin-film head yokes, were based on stroboscopic wide-field Kerr microscopy and background subtraction for contrast

enhancement (Petek, Trouilloud and Argyle, 1990; Liu, Schultz and Kryder, 1990; Kryder, Koeppe and Liu, 1990). A time resolution of 5–10 ns was obtained by dye laser pulses, pumped by Nd:YAG and nitrogen lasers, respectively. An example of such a stroboscopic image from the yoke of a thin-film head is presented in Figure 20(b), showing the averaged domain states at different phase positions in a difference image to emphasize wall motion.

A revival of (still ongoing) interest in high-speed imaging began in the late 1990s, owing to increasing demands for higher speeds and densities from data storage technologies, and for newer approaches such as magnetic random access memories (MRAMs) or spin electronics. The switching speeds of magnetization in metallic thin films have approached the sub-nanosecond regime where intrinsic magnetic response times due to spin-precessional effects become the limiting factor in devices, asking for an understanding and control of fast magnetization reversal processes. Motivated by these accumulated interests, dynamic behavior in micro- and nanosized particles is being actively studied in recent years by micromagnetic simulations and direct observation of the magnetization processes with simultaneous spatial and temporal resolution. The necessary breakthrough in terms of time resolution was related to the development of ps- and fs-laser systems that are most frequently applied in scanning Kerr microscopes. The first laser-scanning microscope with a time resolution of 50 ps (Freeman and Smyth, 1996) was applied for polar Kerr measurements of magnetic flux propagation in recording head pole tips. This apparatus was then extended to in-plane sensitivity (Stankiewicz *et al*., 1998) and time-resolved vector magnetometry (Ballentine, Hiebert, Stankiewicz and Freeman, 2000) (see Section 3.2) and used to study the switching behavior of patterned thin-film elements with lateral extensions of some micrometers that were deposited on coplanar transmission lines to create magnetic field pulses (see Section 4.2.5). A strongly modulated, nucleation-dominated magnetization configuration was observed during dynamic switching, which was replaced by domain wall motion if a transverse biasing field was applied, leading to a dramatic enhancement of switching speed at the same time (Choi *et al*., 2001). Excellent reviews of the outstanding work of the Freeman group are found in (Freeman and Hiebert, 2002a; Choi and Freeman, 2004; Choi, Krichevsky and Freeman, 2005b).

Laser-scanning Kerr microscopy with a temporal resolution in the 10-ps regime is now well established and used for a wide variety of time-resolved observations. (See also **Investigation of Spin Waves and Spin Dynamics by Optical Techniques, Volume 3**, **Time-resolved Kerr-effect and Spin Dynamics in Itinerant Ferromagnets, Volume 3**, and **Ultrafast Magnetodynamics with Lateral Resolution: A View by Photoemission Microscopy, Volume 3**). This includes investigations in magnetic recording heads and media (Back, Heidmann and McCord, 1999; Wakana, Nagai and Sakata, 2001; Veerdonk *et al*., 2001; Nagai, Sekiguchi and Ito, 2003), as well as in patterned soft magnetic film elements. 'Precessional switching' as reversal mechanism of small elements could be demonstrated by time-resolved imaging (Hiebert, Ballentine and Freeman, 2002; Hiebert, Lagae and Boeck, 2003b). In this method, a fast-rising field pulse is applied perpendicular to the initial direction of the magnetization, causing a large angle precession that is used to revert the magnetization if the field is stopped exactly after 180° precessional rotation. It could also be demonstrated that post-switching oscillations ('ringing') can be avoided (Krichevsky and Freeman, 2004) by properly combining easy- and hard-axis field pulses in a crossed-wire stripeline geometry (see Section 4.2.5). Other experiments using scanning Kerr microscopy focus onto the spin-wave eigenmodes of magnetization (Acremann *et al*., 2000; Park *et al*., 2002; Barman *et al*., 2004; Buess *et al*., 2004 (See also **Magnetic Modes in Circular Thin Film Elements, Experiment and Theory, Volume 2**)) and the gyrotropic motion of a central vortex in magnetic thin-film elements (Park *et al*., 2003; Park and Crowel, 2005). Though most of the research groups are using laser-scanning microscopy, there was also progress in picosecond wide-field imaging, both based on triggered video cameras (Chumakov *et al*., 2005) as well as on pulsed-laser-illuminated microscopes (Neudert *et al*., 2005).

At the moment, the interest in magnetization dynamics is shifting from field-induced to current-induced switching (Stiles and Miltat, 2006) (See also **Spin Angular Momentum Transfer in Magnetoresistive Nanojunctions, Volume 5** and **Theory of Spin-transfer Torque, Volume 2**), while at the same time the lateral dimensions of the relevant magnetic structures are getting well smaller than micrometer. Microscopy at optical frequencies will therefore meet its lateral resolution limit. Other methods with an order of magnitude higher resolution, based on X-ray dichroism (Choe *et al*., 2004; Kuksov *et al*., 2004; Stoll *et al*., 2004) or X-ray holography (Eisebitt *et al*., 2004), offer an alternative. On the basis of the latter technique, a spatial resolution of 5 nm in conjunction with a time resolution of the order of 20 fs is predicted for imaging at future X-ray free electron lasers, offering the potential for stroboscopic snapshot imaging of extremely fast magnetic switching processes of very small particles in the future.

4.2.2 Camera-based stroboscopic wide-field Kerr microscopy

In camera-based stroboscopic microscopes (Figure 21), the magnetic field excitation of the specimen is exactly synchronized with the exposure time of the video camera.

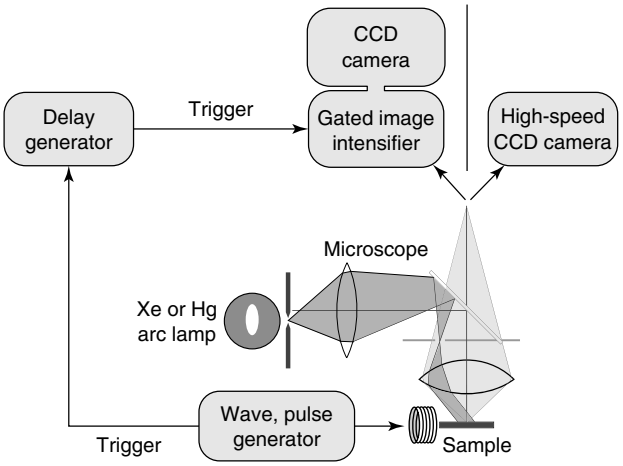

Figure 21. Block diagram for camera-based stroboscopic wide-field Kerr microscopy. Time resolution is provided by triggering a high-speed video camera or a gated image intensifier at constant illumination with precise timing relative to the field excitation.

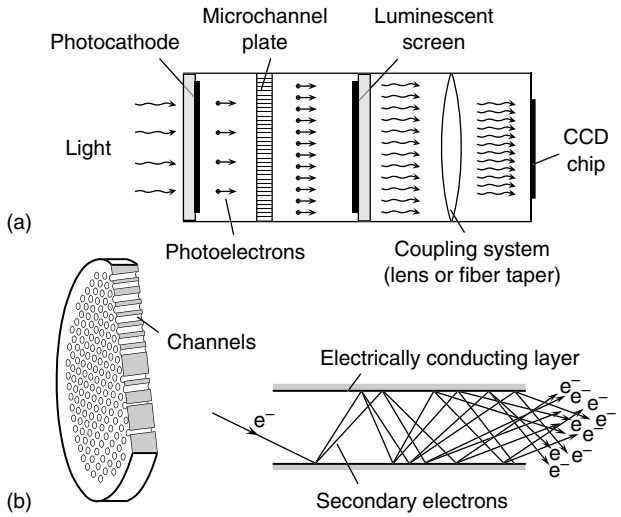

Figure 22. (a) Schematics of an image intensifier (second generation). Significant signal amplification up to four orders of magnitude is due to the microchannel plate (b). It consists of millions of very thin, electrically conducting glass capillaries with typically 10-µm diameter, which act as independent secondary electron multipliers. Their luminous gain ranges from 10 000 Lm/Lm up to 10^7 for intensifiers having two microchannel plates. Beside their gating capability, image intensifiers (combined with a CCD camera) can also be used to enhance low light level images in regular Kerr microscopy.

A function generator, which also provides the signal for the magnetic field, creates trigger pulses that are delayed in a defined way relative to the field excitation by an electric delay generator or optical delay line. These trigger pulses control the moment when the camera is exposed for a short time. The sample may be continuously illuminated in such experiments or in synchronization with a pulsed light source.

Today a variety of digital CCD and CMOS camera systems are available for time-resolved microscopy, which have replaced the traditional high-speed movie cameras of the early days of stroboscopy (see Section 4.2.1). A critical factor is the read-out time of the camera that determines the repetition rate of the experiment. Digital high-speed CCD and CMOS cameras with frame rates ranging between some hundred up to some thousand frames per second (at sufficient pixel resolution) are presently available. For comparison, the high-speed motion-picture camera used by Houze (1967) already offered rates of 5000 pictures per second (see Section 4.2.1). Frame rates up to the megahertz regime are also possible with digital cameras. Such speeds, however, are either reached by pixel binding on cost of resolution or they only allow to capture very few consecutive pictures that are stored in the (limited) memory of the camera head before being transmitted to the computer. The other important criterion is the time resolution given by the electronic or mechanic shutter of the camera, which can typically be varied from seconds down to the sub-100-ns range in present cameras. The smallest opening time in single-shot experiments depends on the sensitivity of the CCD or CMOS chip and the intensity of the light source. Single-shot imaging up to power frequencies is possible with the mentioned cameras. Higher frequencies require stroboscopic imaging and the accumulation of images at given time delays (see Figure 19a). Background subtraction for contrast enhancement is recommended just as in regular wide-field microscopy.

Much higher time resolution at increased sensitivity can be gained by using a gateable image intensifier in combination with a regular CCD camera. The intensifier primarily functions as an electronic shutter (Figure 22). A photocathode in a vacuum tube is permanently exposed to a positive potential, which prevents the emitted photoelectrons from leaving its surface. On the arrival of a trigger signal, an impulse of negative voltage is applied to the photocathode, pushing the photoelectrons into a microchannel plate (MCP) where they are accelerated and multiplied. After leaving the MCP, the multiplied electrons are further accelerated before they finally hit the phosphor layer of the output window generating photons. A regular CCD camera accumulates these photons during integration time. The gating time of the fastest image intensifiers reaches currently the 200-ps regime at a repetition rate of around 100 MHz (or less than 100 ps at kilohertz repetition rates).

Equipped with such modern, highly sensitive CCD or CMOS cameras and fast-image intensifiers, camera-based wide-field strobes have been set up in recent years for dynamic investigation of magnetic films (Chumakov *et al.*,

2005) and bulk soft magnetic materials (Moses, Williams and Hoshtanar, 2005; Flohrer *et al*., 2006). An advantage of camera-based systems is the possibility to vary the effective opening time of the camera or intensifier, respectively, between shortest and continuous exposure (as opposed to laser-based stroboscopes with usually fixed pulse frequencies – see following sections). This gives the opportunity to compare time-resolved data directly with the images acquired by static or quasistatic imaging. This comparison can be helpful in the interpretation of dynamic processes, because the peculiarities of the high-speed magnetization processes can be readily identified.

Examples for camera-based dynamic experiments have already been presented in Figure 19. The single-shot images (Figure 19b,c) were recorded with a high-speed digital CMOS camera, while time resolution in the stroboscopic pictures (Figure 19a) was achieved by a gated image intensifier. Two further examples, again obtained with image intensifiers, show the characteristic features of fast magnetization processes in bulk material (Figure 23) and thin-film elements (Figure 24). In Figure 23 (Flohrer *et al*., 2006), the outermost ribbons of nanocrystalline tape-wound cores with centimeter dimension and different uniaxial anisotropy were imaged at different frequencies of a sinusoidal magnetic field. Domain refinement (wall multiplication) was visible with increasing frequency for all three cores (Figure 23a). In the material with the weakest anisotropy, regular domains were replaced by patches at higher frequency. The partly blurred domain boundary contrast at 50 Hz resulted from domain movement during the exposure time or from slightly nonreproducible wall displacement processes. An increase in the reproducibility of the magnetization process with rising frequency and decreasing anisotropy was observed. Figure 23(b) demonstrates the high-frequency magnetization process of the low-anisotropy material that is dominated by nucleation and growth of patch domains rather than by wall motion.

The thin-film switching process in Figure 24(a) (Chumakov *et al*., 2005) was imaged at a much higher time resolution of 250 ps. A square-shaped film element was switched between two (nearly) saturated states in a sharply rising pulse-field applied along the elements diagonal and generated by a coplanar waveguide (see Section 4.2.5). A 'concertina' pattern developed, which became visible at transverse Kerr sensitivity and consisted of alternating areas of clock- and counterclockwise magnetization rotation. The magnetization was finally reverted by a mixture of rotation and domain boundary motion that lasted several nanoseconds. Two vortices were created and pushed toward the edges during this process. Quasistatic switching in a slowly changing field occured differently (Figure 24b): there was also a concertina formed when the magnetic field was decreased from saturation, which, however, broke down abruptly in the reversed field by the unpinning and fast motion of Bloch lines, leaving the element in a four-domain Landau state with a single vortex.

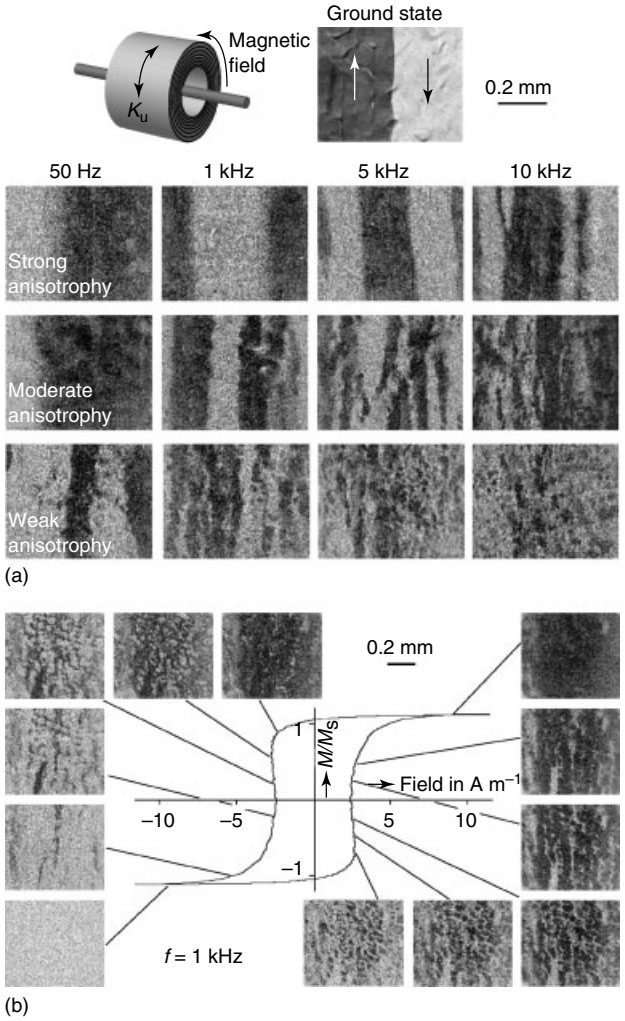

Figure 23. Time-resolved domain observations on $Fe_{73}Cu_1Nb_3Si_{16}B_7$ nanocrystalline tape-wound cores (See also **Soft Magnetic Materials – Nanocrystalline Alloys, Volume 4**) in circumferential magnetic field (core width 20 mm, outer diameter 25 mm, ribbon thickness 20 µm). A gated image intensifier with a gating time of one-hundredth of the magnetic field period was applied for time resolution; several thousand frames of independent events were accumulated for each image. (a) Stroboscopic images, taken around the point of zero induction during sinusoidal excitation with saturating peak induction at different frequencies as indicated. Three cores with different strength of induced anisotropy K_u were studied (top row: 29 J m^{-3}, middle row: 10 J m^{-3}, bottom row: 5 J m^{-3}). The domain ground state, consisting of 180° domains and obtained by static imaging, is shown for comparison. (b) Inductively measured hysteresis loop and stroboscopic images obtained at 1 kHz on the core with weak anisotropy. (Reprinted from Acta Materialia, 2006, Flohrer *et al*., 2006. Magnetization loss and domain refinement in nanocrystalline tape wound cores. *Acta Materialia*, **54** 3253–3259, with permission from Elsevier.)

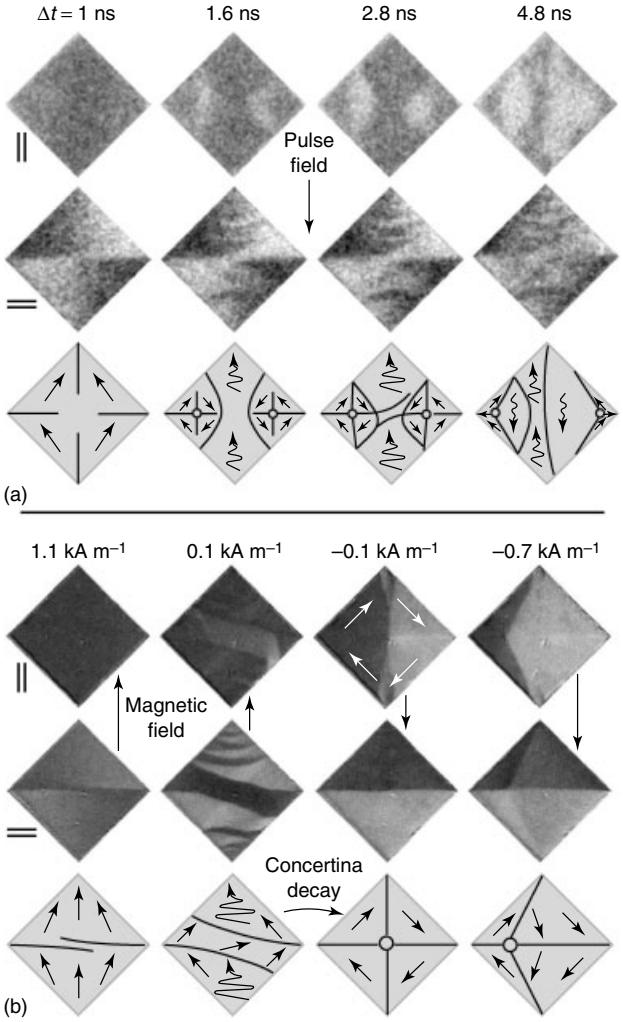

Figure 24. Comparison of magnetization processes in a Permalloy thin-film element (edge length 28 µm, thickness 50 nm) in diagonal magnetic fields. The time-resolved images in (a) were obtained after applying a pulsed magnetic field (rise time several nanoseconds, duration 1000 ns, amplitude 2 kA m^{-1}) opposite to a saturating bias field. A gated image intensifier with a gating time of 250 ps was applied for time resolution. To achieve a reasonable signal-to-noise ratio, the Kerr images of some 10^8 independent events, excited by a train of field pulses that are repeated periodically, were integrated in time. The delay time of recording after onset of the field pulses is indicated. (b) Quasistatic process in slowly changing field that is decreased from saturation and inverted. Similar states are shown at two orthogonal Kerr sensitivities as indicated by double lines. The magnetization vector fields are drawn schematically. (Reprinted with permission from D. Chumakov *et al.*, *Phys Rev. B* Vol. 71, 014410 (2005). Copyright (2005) by the American Physical Society.)

4.2.3 Light-based stroboscopic wide-field Kerr microscopy

The components of a stroboscopic wide-field microscope based on pulsed illumination are shown in Figure 25. The

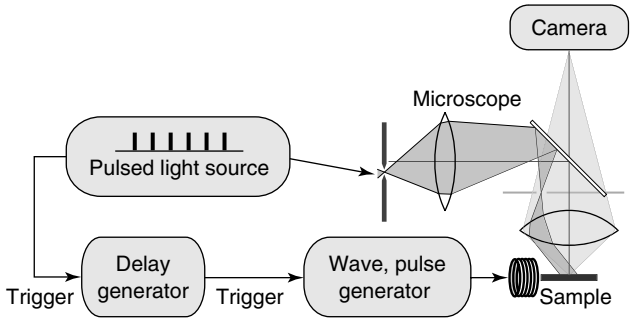

Figure 25. Block diagram for light-based stroboscopic wide-field microscopy. A pulsed light source is employed for time resolution.

wave or pulse generator is triggered by the light source with some intermediate delay electronics. The images, shot at a defined time delay, are accumulated in a regular CCD camera. For comparative (quasi) static imaging, it is advantageous to switch to a steady light source, which can be easily realized in wide-field microscopes. Like in all other wide-field techniques, contrast can be enhanced by background subtraction.

Lasers are most widely employed as a pulsed light source. The laser light is fed into the microscope by a glass fiber after employing proper means to prevent speckle patterns (see Section 3.1.4). A portion of the laser light shines on a photodiode giving the trigger pulses. Today, the traditional dye lasers (see Section 4.2.1) can be replaced by mode-locked solid-state lasers such as Nd-YVO_4 that deliver light pulses with a length in the 10-ps range at visible wavelengths after frequency doubling. The repetition rate of these lasers is fixed at some 10 MHz, and their output power has to be limited to the 100-mW range (e.g., by a rotatable half-wave plate) to match the sensitivity range of the detection CCD camera and to avoid sample damage. Externally triggerable, pulsed laser diodes can be operated in the same time regimes and are also suited for stroboscopic imaging (Wakana, Nagai and Sakata, 2001; Nagai, Sekiguchi and Ito, 2003). Still shorter pulses of 30–100 fs are achieved if the mentioned picosecond lasers are used to pump a mode-locked Ti:sapphire laser. The emitted femtosecond pulses have a wavelength around 800 nm at a repetition frequency of about 80 MHz. At present, most time-resolved experiments are carried out with the mentioned laser light sources. The ongoing progress in laser technology has already brought along sub-femtosecond lasers (Hentschel *et al.*, 2001), which so far have not been employed for imaging. A problem with laser light sources is the repetition rate that is usually fixed at a certain frequency (e.g., some 10 MHz in case of solid-state lasers), limiting the flexibility of the experiment as compared to camera-based systems. Also possible for wide-field microscopy are pulsed xenon-arc flashlamps. They provide light pulses of the typical order of

1 µs at a low repetition rate in the 100 Hz regime, but they are intense enough to allow single-shot imaging, for example, in magnetic films with perpendicular anisotropy and thus strong polar Kerr effect (Romanens *et al*., 2005). Flashlamps are an alternative to lasers if lower time resolution is sufficient. Signal-to-noise ratios like in quasistatic imaging can be obtained, however, at strongly reduced exposure times.

An example for a laser-based wide-field strobing experiment on a NiFe square element is presented in Figure 26, again in comparison with the quasistatic process. Vortex motion and wall displacement are characteristic for slowly changing magnetic fields (Figure 26a). By applying a sharp field pulse (b), fast rotational processes and spike domain nucleation are observed (c), which are slowly resolved after several nanoseconds. The development of small-angle domains with oscillatory behavior in the low-permeability closure domain is also noteworthy.

4.2.4 Stroboscopic laser-scanning Kerr microscopy

The principle components of a stroboscopic experiment based on laser-scanning microscopy are shown in Figure 27. The pulsed laser beam is split into a pump and probe beam. The probe beam is directly used for imaging, as described in Section 3.2, whereas the pump beam triggers the field excitation via an electric delay generator (or optical delay line) and pulse generator. Most of the modern scanning microscopes are based on today's standard laser, the mode-locked and frequency-doubled titanium-sapphire femtosecond laser. 'Pulse picking' may eventually be required to adapt the high repetition rate of the laser to the rates of the delay electronics (unless an optical delay line is applied). To avoid sample damage or unwanted thermal effects on the magnetization, the laser pulses may require attenuation (to an optical power of typically below 100 µW), thereby increasing the number of shots to be accumulated. The suppression of nonmagnetic contrasts and signal enhancement can be achieved by modulating the field excitation at kilohertz frequencies (as indicated in Figure 27 for a train of field pulses that is periodically interrupted) and using lock-in detection (Hicken *et al*., 2002; Buess *et al*., 2004). The time resolution achievable with laser-scanning microscopy is ultimately limited by the laser pulse width, but may practically be limited by trigger jitter from the delay electronics (Freeman and Hiebert, 2002a). A resolution of the order of some 10 ps is typically achieved in present laser-scanning microscopes.

Two stroboscopic operation modes can be employed in a laser-scanning microscope: temporal and spatiotemporal-resolving modes. In the temporal mode, (See also **Investigation of Spin Waves and Spin Dynamics by Optical Techniques, Volume 3**, **Time-resolved Kerr-effect and**

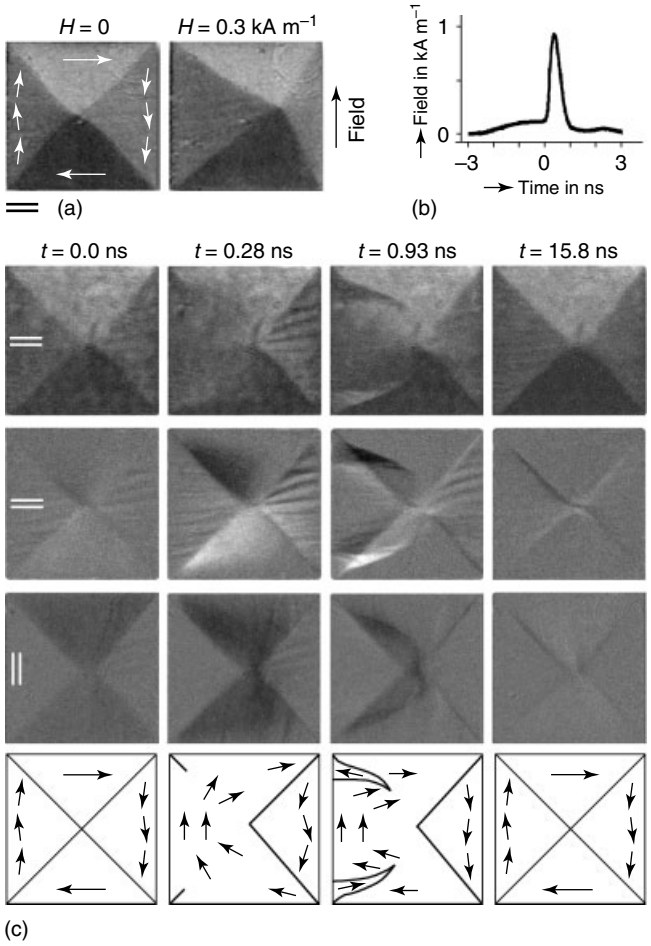

Figure 26. Excitation of a Landau ground state in a permalloy thin-film element (edge length 40 µm, thickness 50 nm) in magnetic fields parallel to the edge. (a) Quasistatic process. The dynamic process (c), excited by a sharp field pulse (b), is completely different. The difference images are shown as follows: In the upper row of (c), an image of the saturated state was subtracted, while images of the Landau ground state were subtracted in the middle and lower row at different Kerr sensitivity directions as indicated, highlighting changes in the magnetization. The time delays where the images have been captured in a stroboscopic way are indicated. The accumulation of some 10^6 single pictures, each of them obtained with a laser pulse of about 20 ps length, was necessary to obtain an image of sufficient contrast. (Reprinted with permission from A. Neudert *et al*., *Phys. Rev. B.* Vol. 71, 134405. Copyright (2005) by the American Physical Society.)

Spin Dynamics in Itinerant Ferromagnets, Volume 3, and **Ultrafast Magnetodynamics with Lateral Resolution: A View by Photoemission Microscopy, Volume 3**), the sample response is measured locally by focusing on a particular place of the sample and changing the time delay. The Kerr signal of a train of light pulses is accumulated after each time step, building up the time-dependent profile for selected magnetization components (see Park *et al*., 2003, e.g., of such

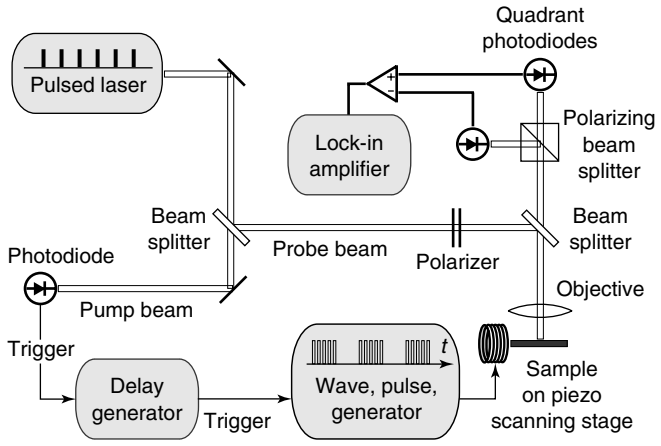

Figure 27. Block diagram of the main components of a typical stroboscopic imaging setup based on laser-scanning Kerr microscopy. Instead of the electronic delay generator, an optical delay line (not shown) may be used for the synchronization of probe beam and magnetic pulse, in which the travel path of the probe beam with respect to the pump beam is computer controlled using mirrors mounted on a slider. (After Choi and Freeman, 2004.)

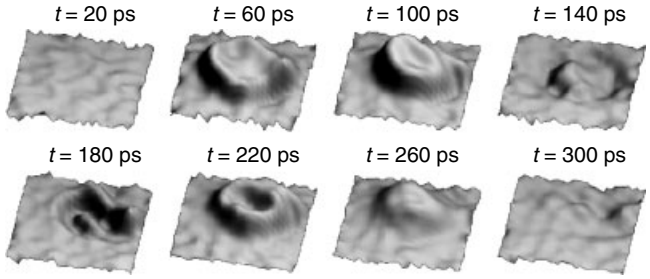

Figure 28. Stroboscopic laser-scanning Kerr microscopy of the polar magnetization component in a cobalt disk with a diameter of 6 µm and a thickness of 20 nm at increasing time delays after pulse-field excitation. Laser pulses with a width of 100 fs were used for imaging, and the magnetic field pulse was created with a photoconductive switch. (Courtesy of *Ch. Bac*k, Regensburg. See Acremann *et al*., 2000, for details.)

local magnetometry). For spatiotemporal imaging, the time-dependent profile is locally measured and then the sample is scanned at a particular fixed time delay to obtain a two-dimensional mapping of the magnetic response. Repeating the procedure at a different time delay leads to a stroboscopic image series of the dynamic process. Like in stroboscopic wide-field microscopy, only repetitive phenomena can be imaged by this technique, while single-shot imaging is not possible at all. A review of stroboscopic laser-scanning Kerr microscopy is given in Freeman and Hiebert (2002a).

An example of a spatiotemporal stroboscopic laser-scanning experiment is presented in Figure 28. A small cobalt disk was excited by sharp magnetic field pulses perpendicular to the film plane. The temporal evolution of the polar magnetization component at various time delays, revealing precessional magnetization oscillations that last several 100 ps is shown in the figure.

To conclude, laser-scanning-based stroboscopes have three main advantages: (i) The time evolution of magnetization can in a convenient and highly sensitive way be measured locally in an area of the laser beam size. (ii) The laser pulse can be used for pumping and probing by employing photoconductive switches (see Section 4.2.5). (iii) Longitudinal, transverse, and polar magnetization components can be recorded simultaneously, as described in Section 3.2. A drawback of the method is clearly related to the scanning procedure that is required to obtain full images, which makes it difficult to obtain static domain images for comparison.

4.2.5 Magnetic field generation

For time-resolved studies, the magnetic system has to be excited by an external magnetic field with a well-defined time structure (in recent years it could be shown that excitation is also possible by spin-polarized electric currents (Stiles and Miltat, 2006), by heating with femtosecond laser pulses (Koopmans, 2003) or by photomagnetic interaction (Hansteen *et al*., 2006)). In most experiments, this time structure is either harmonic (e.g., sine wave excitation) or consists of a train of periodic field pulses of variable shape and duration (pulse-field excitation) provided by a signal generator. The excitation field can be created by magnetic coils or electromagnets if large samples are to be magnetized at power frequencies. For small samples, coil/yoke systems like in magnetic recording heads can be used well up into the megahertz regime. The field rise times in these systems, however, are limited to a few nanoseconds due to inductivity. Much faster rise times are possible by overcoming the inductivity problem in coplanar waveguides (Figure 29) that are fabricated from copper or gold thin films by lithography using etching or lift-off techniques. Such approaches are of course restricted to the excitation of patterned magnetic film samples, which can be deposited onto the conductor line. The impedance of the waveguide has to be carefully matched to the current source to avoid unwanted reflections or damping of the current pulse. Magnetic fields up to the order of $10\,\mathrm{kA\,m^{-1}}$ are possible with such transmission lines. Coplanar waveguides may also be fabricated in cross-wire geometry, which allows, for example, to study precessional switching by exciting along and perpendicular to the easy axis of the deposited film elements (Hiebert *et al*., 2003a), or to control post-switching magnetization oscillations by varying the delay between two orthogonal pulses (Krichevsky and Freeman, 2004).

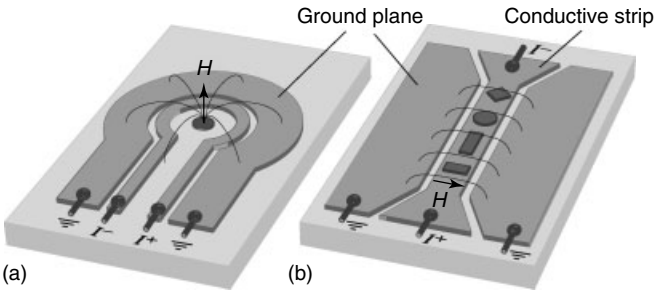

Figure 29. Coplanar waveguides, consisting of a conductor transmission line that is separated from a pair of ground lines (all on the same plane), for the generation of fast magnetic field pulses in small elements. The microcoil in (a) provides perpendicular fields, while the waveguide in (b) generates in-plane fields, as indicated. The sample elements are deposited on top of the conductor line. For wide-field Kerr microscopy, it is advisable to coat the strip by antireflection layers to prevent disturbing light effects on the sample (Chumakov *et al*., 2005). (Reprinted figure with permission from D. Chumakov *et al*., *Phys Rev. B* Vol. 71, 014410 (2005). Copyright 2005 by the American Physical Society.)

Magnetization dynamics is critically determined by the rise time of the excitation pulses (Choi, Ho, Arnup and Freeman, 2005a). Commercial electronic pulse generators may provide current pulses of down to 50-ps rise time with variable pulse width down to about 500 ps and repetition rates of several hundred megahertz. Faster rise times of a few picoseconds are possible by so-called Auston switches (Auston, 1975), which have been adapted from semiconductor physics to the fast excitation of magnetic films (Freeman, 1994). In the Auston switch, an above–band gap optical pulse from a picosecond laser strikes a biased coplanar transmission line structure, fabricated on a semi-insulating semiconductor substrate, to create a transient photoconductivity and launch a current pulse down the transmission line. The decay of the photoexcitation is determined by the recombination rate of the electron–hole pairs and is usually much slower in the nanosecond range, preventing the creation of ultrashort pulses. Laser-scanning microscopes are ideally suited for the application of photoconductive switches in stroboscopic experiments, as the probing laser can simultaneously be used for current launching after employing beam splitting and delay (Choi and Freeman, 2004). The biggest advantage of photoconductive switches is the fact that the sample can be pumped without the introduction of electronic jitter (Hicken *et al*., 2002). Examples for the application of these switches to the study of precessional excitation spectra or localized spin-wave modes in film elements may be found in Acremann *et al*. (2000); Park *et al*. (2002); Park *et al*. (2003); Gerrits *et al*. (2002); Barman *et al*. (2004); Buess *et al*. (2004).

5 OUTLOOK

The classical Kerr technique for magnetic domain observation has strongly gained in efficiency after the introduction of digital image processing in the mid-1980s. By contrast enhancement, domains get visible on virtually all relevant ferro- and ferrimagnetic materials and magnetization directions can be determined quantitatively and even selectively based on depth. The dynamic capability and the compatibility with arbitrary applied magnetic fields make Kerr microscopy ideally suited for the investigation of magnetization processes on arbitrary timescales. On bulk materials, just the surface region can be seen (like in most other domain observation techniques); therefore theoretical arguments combined with domain studies in magnetic fields are required to get a three-dimensional understanding of the magnetic microstructure. The optical resolution limit of about 200 nm limits the application of Kerr microscopy when small objects are to be studied as they are increasingly getting addressed with rising miniaturization of devices. Yet, Kerr microscopy will remain the method of choice for the visualization of moving domains in the laboratory.

ACKNOWLEDGMENTS

The careful reading of the manuscript and supply of images by Jeffrey McCord, Sybille Flohrer, and Andreas Neudert (all IFW Dresden) is highly appreciated. Thanks also to Dmitry Chumakov (IFW Dresden) and Christian Back (Regensburg) for providing images.

Magnetization-induced Second Harmonic Generation

Andrei Kirilyuk and Theo Rasing
Radboud University Nijmegen, Nijmegen, The Netherlands

1 INTRODUCTION

The invention of lasers has radically affected the field of science and technology. Their development led to the discovery and rapid promotion of nonlinear optics (Franken, Hill, Peters and Weinreich, 1961; Akhmanov and Khokhlov, 1964; Boyd, 1965; Shen, 1984). With manifold applications, nonlinear optical phenomena play a vital role in modern optics. Compared with linear optics, nonlinear optical processes reveal novel information about the electronic structure of solids because, based on the involvement of more than a single optical field, additional experimental degrees of freedom are accessible. In the vast field of nonlinear optics second-harmonic generation (SHG), as the lowest-order nonlinear process, plays a particular role. Being a higher-order process, it brings new and complementary information in comparison with linear optics, partly due to the different selection rules for multiphoton processes and the higher-order susceptibilities involved. Another strong point of the technique is it's intrinsic surface and interface sensitivity that is derived from extremely simple yet powerful symmetry constraints. The SHG technique was therefore widely used for studies of surfaces and interfaces (Shen, 1984; Heinz, 1991; Bennemann, 1998).

The breaking of time-reversal symmetry leads to a number of well-known magneto-optical (MO) effects like Faraday rotation in transmission and Kerr rotation in reflection (Zvezdin and Kotov, 1997). For nonlinear optics, in the electric-dipole approximation, even-order effects like SHG are only allowed in media with a broken space inversion symmetry. As a consequence, even-order nonlinear MO effects can only be observed in materials in which both space-inversion and time-reversal symmetry are broken. Though the first predictions of magnetic effects in SHG were made over 40 years ago (Pershan, 1963; Adler, 1964; Lajzerowicz and Vallade, 1967) and discussed in several theoretical publications (Kielich and Zawodny, 1973; Pan, Wei and Shen, 1989; Hübner and Bennemann, 1989), the field of nonlinear magneto-optics really evolved in the past fifteen years by the observation of huge MO effects from magnetic surfaces and interfaces (Reif, Zink, Schneider and Kirschner, 1991; Reif, Rau and Matthias, 1993; Spierings *et al*., 1993). This 'revival' and recent strong development of nonlinear magneto-optics is clearly related to the enormous interest in the study and applications of magnetic multilayers and nanostructures as well as to the development of solid state mode-locked femtosecond lasers that are particularly suitable for these kinds of studies (Keller, 2003).

One of the very important fundamental achievements was the demonstration of the extreme sensitivity of magnetization-induced second-harmonic generation (MSHG)

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

to the slightest modifications of the spin-polarized electronic structure of transition-metal surfaces (Wierenga *et al*., 1995; Straub, Vollmer and Kirschner, 1996; Vollmer, Straub and Kirschner, 1996b; Jin, Regensburger, Vollmer and Kirschner, 1998; Veenstra *et al*., 1999; Veenstra, Petukhov, Jurdik and Rasing, 2000). Even tiny increases in the magnetization of the surface layer, caused by the presence of atoms with low coordination numbers on surfaces with atomic steps, could be detected (Jin, Regensburger, Vollmer and Kirschner, 1998). On the other hand, the possibility to distinguish the contributions from different interfaces (Kirilyuk, Rasing, Haast and Lodder, 1998) showed a way to measure the magnetization of a buried interface and therefore triggered a lot of applied interest. One of the particular intriguing problems attacked with MSHG was the spin-polarization of the interfaces between ferro- and antiferromagnets in exchange-biased structures (Sampaio *et al*., 2003, 2005; Valev, Gruyters, Kirilyuk and Rasing, 2006a,b; Valev *et al*., 2007). In addition, it has been demonstrated that, conform the original predictions, SHG can be used to study antiferromagnetic ordering and even image antiferromagnetic domains, which is very hard or even impossible to do with other techniques (Fiebig, Fröhlich, Krichevtsov and Pisarev, 1994; Fiebig, Fröhlich, Sluyterman and Pisarev, 1995).

This review is organized as follows: first, a general description of MSHG is given followed by a discussion of the theory of MSHG in Section 2. Then, the details of various experimental techniques are given in Section 2. Section 4 discusses the applications of MSHG to magnetic surfaces; Section 5 is concerned with buried magnetic interfaces, followed by a discussion of the unavoidable bulk contributions to the interface MSHG, and the consequences of the electronic quantum-well-state resonances. Further developments of the techniques are briefly outlined in Section 6.

2 THEORY OF MSHG

2.1 General idea

An incident light wave induces a polarization in a medium that serves as a source for the transmitted and reflected light. In the electric-dipole approximation, this polarization $\mathbf{P}$ can be written as an expansion in powers of the optical electric field $\mathbf{E}(\omega)$:

$$\mathbf{P}(\omega, 2\omega, \ldots) = \chi^{(1)}\mathbf{E}(\omega) + \chi^{(2)}\mathbf{E}(\omega)\mathbf{E}(\omega) + \ldots \qquad (1)$$

The tensor $\chi^{(1)}$ is the linear optical susceptibility allowed in all media. SHG is described by the second term with the corresponding nonlinear tensor $\chi^{(2)}$ allowed only in noncentrosymmetric media. The latter is easy to verify by carrying out the inversion operation that changes the sign of every *polar* vector, such as $\mathbf{P}$ or $\mathbf{E}$. Consequently, $\chi^{(2)}$ is allowed at surfaces or interfaces between centrosymmetric media, giving rise to the surface/interface sensitivity of the technique. For crystals with a spontaneous or magnetic field-induced magnetization $\mathbf{M}$, the nonlinear second-order optical polarization of a medium $\mathbf{P}^{\mathrm{nl}}(2\omega)$ can be written as:

$$\mathbf{P}^{\mathrm{nl}}(2\omega) = \chi^{\mathrm{cr}}\mathbf{E}(\omega)\mathbf{E}(\omega) + \chi^{\mathrm{magn}}\mathbf{E}(\omega)\mathbf{E}(\omega)\mathbf{M} \qquad (2)$$

where the first term describes the purely crystallographic contribution while the second one exists only in the presence of a magnetization $\mathbf{M}$ and describes MSHG. Note that $\mathbf{M}$ is an *axial* vector, so that the inversion operation does not change its sign and the surface/interface sensitivity also holds for magnetic materials. Thus these two contributions to the nonlinear polarization $\mathbf{P}^{\mathrm{nl}}(2\omega)$ are of electric-dipole character and simultaneously allowed in noncentrosymmetric media, but their properties are different. The crystallographic contribution is described by a polar tensor χ^{cr} of rank 3, whereas the magnetization-induced contribution is described by an axial tensor χ^{magn} of rank 4. In lossless media χ^{cr} is a real tensor and χ^{magn} is an imaginary tensor, therefore there is no interference between the SHG waves coming from these two sources for linearly polarized fundamental light (Pershan, 1963; Pan, Wei and Shen, 1989). The interference becomes allowed for linearly polarized fundamental light in the absorption region, because both tensors will be complex, or by using circular optical excitation. It is this interference that gives rise to new nonlinear MO effects, which have no counterparts in linear optics (Pavlov, Pisarev, Kirilyuk and Rasing, 1997; Kirilyuk, Pavlov, Pisarev and Rasing, 2000; Gridnev *et al*., 2001).

The expression (2) is general and fully describes MSHG in the electric-dipole approximation. The number of nonzero component of χ^{cr} and χ^{magn} tensors depends on the crystallographic and magnetic symmetry of the sample. For high symmetry systems (the vast majority of thin-film structures studied so far), each of these tensors consists of a few components only. Moreover, these components are not intermixing with each other, that is, the tensor

$$\chi^{(2)} = \chi^{\mathrm{cr}} + \chi^{\mathrm{magn}} \cdot \mathbf{M} \qquad (3)$$

can be written as a single third rank tensor whose components are either *even* or *odd* in $\mathbf{M}$. An important case is that of an isotropic interface (that of a quite standard polycrystalline film, for example, or a (100) surface of a cubic system). In this case, and with xz being the plane of incidence, the nonlinear MO tensor $\chi^{(2)}$ can be written as (Pan, Wei and Shen, 1989): The elements shown to depend on M_i are *odd*

$$\chi^{(2)} = \begin{pmatrix} \chi_{xxx}(M_y) & \chi_{xyy}(M_y) & \chi_{xzz}(M_y) & \chi_{xzy}(M_z) & \chi^{\mathrm{cr}}_{xzx} & \chi_{xxy}(M_x) \\ \chi_{yxx}(M_x) & \chi_{yyy}(M_x) & \chi_{xzz}(M_x) & \chi^{\mathrm{cr}}_{yzy} & \chi_{yzx}(M_z) & \chi_{yxy}(M_y) \\ \chi^{\mathrm{cr}}_{zxx} & \chi^{\mathrm{cr}}_{zyy} & \chi^{\mathrm{cr}}_{zzz} & \chi_{zzy}(M_x) & \chi_{zzx}(M_y) & \chi_{zxy}(M_z) \end{pmatrix} \tag{4}$$

in the corresponding magnetization component (roughly proportional to it–see Pustogowa, Hübner and Bennemann, 1993). Thus the nonlinear MO properties of an isotropic interface with a selected magnetization direction are characterized by up to 10 (complex) numbers.

Here $\mathbf{E}(\omega)$ and $\mathbf{P}(2\omega)$ are *local* fields and polarizations; to relate them to the amplitudes of the incoming and outgoing electromagnetic waves, appropriate Fresnel factors should be used. In fact, the $\chi^{(2)}$ tensor alone determines the geometrical symmetry properties of MSHG; for an extended treatment of these properties, both theoretical and experimental, we refer the reader to Gridnev *et al*. (2001).

The $\chi^{(2)}$ tensor of equation (4) allows one to qualitatively understand the behavior of MSHG as a function of magnetization reversal. In the transverse MO geometry, $\mathbf{M}||y$, (see Figure 1), equation (4) shows that in the case of *S*-polarized incident light (i.e., $\mathbf{E}_{\mathrm{in}} = \mathbf{E}_y$) one even ($\chi_{zyy}$) and one odd ($\chi_{xyy}(M_y)$) tensor element will produce the outgoing SH waves. Both of them lead to the same *P*-polarization of the output. Therefore, the total MSHG output can be written as

$$I^{2\omega}(\pm\mathbf{M}) \propto |E_{\mathrm{in}}|^4(\alpha\chi_{zyy} \pm \beta\chi_{xyy}(\mathbf{M}))^2 \tag{5}$$

where α and β denote the corresponding Fresnel factors (they result, for example, in the angle of incidence dependence of the MSHG signal). Thus the reversal of $\mathbf{M}$ leads to a change in the MSHG intensity.

In contrast, in the longitudinal geometry, with $\mathbf{M}||x$, the corresponding odd element ($\chi_{yyy}(M_x)$) gives rise to an *S*-polarized output. The total output polarization will thus be a vector sum of the two orthogonal vectors, one of them being reversed upon reversal of $\mathbf{M}$. The resulting MO effect is therefore a change of MSHG polarization (Reif, Rau and Matthias, 1993; Koopmans, Groot Koerkamp, Rasing and van den Berg, 1995). In both cases, the relative effects can be quite large, as the odd and even tensor elements are of similar size (see, e.g., Koopmans, Groot Koerkamp, Rasing and van den Berg, 1995). This is in strong contrast to most linear MO effects, where the odd components are generally much smaller than the even ones.

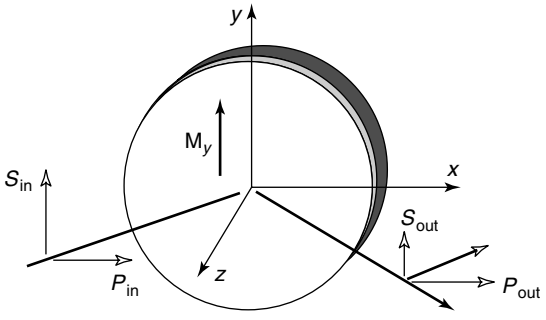

Figure 1. Schematic geometry of the experiment: xz is the plane of incidence, $\mathbf{M}$ is directed along y (transversal geometry) or along x (longitudinal geometry). Input light is either *P* polarized (E_x, E_z) or *S* polarized (E_y).

The problem of calculating the nonlinear (magneto-) optical response of a given medium contains two clearly distinct parts: (i) calculation of the nonlinear susceptibility, and (ii) with known susceptibility, calculate the outgoing MSHG intensity. Both these parts are nontrivial and require a lot of attention: part (i) involves sophisticated electronic structure calculations in a nonperiodic electronic system, while part (ii) contains nontrivial electromagnetic boundary conditions and complicated multiple-scattering processes.

2.2 Nonlinear magneto-optical susceptibility

As a first step in the calculation of the nonlinear MO susceptibility tensor $\chi^{(2)}$, a complete spin-dependent electronic band structure of the sample should be computed, including the corresponding wave functions. As by the 'sample' we mean surface or interface that is a nonperiodic structure, both the band structure and wave functions will be position dependent in the perpendicular to the surface direction.

Next, the electronic structure serves as a background for the calculation of the MO response. This approach was followed by Hübner and Bennemann (1989) and Hübner (1990) using the Heisenberg's equation-of-motion formalism in second-order perturbation theory. The screening of the driving electromagnetic field by the system's electrons were taken into account self-consistently.

The surface or interface susceptibility is then given by:

$$\chi_{ijm}(2\omega) = \frac{e^3\mathbf{q}_{||}a}{\Omega}\frac{\lambda_{s.o.}}{\hbar\omega}\sum_{\mathbf{k},l,l',l'',\sigma} M_i M_j M_m \times \left\{ \frac{\frac{f(E_{\mathbf{k}+2\mathbf{q}_{||}l''\sigma}) - f(E_{\mathbf{k}+\mathbf{q}_{||}l'\sigma})}{E_{\mathbf{k}+2\mathbf{q}_{||}l''\sigma} - E_{\mathbf{k}+\mathbf{q}_{||}l'\sigma} - \hbar\omega + i\hbar\alpha_l} - \frac{f(E_{\mathbf{k}+\mathbf{q}_{||}l'\sigma}) - f(E_{\mathbf{k}l\sigma})}{E_{\mathbf{k}+\mathbf{q}_{||}l'\sigma} - E_{\mathbf{k}l\sigma} - \hbar\omega + i\hbar\alpha_l}}{E_{\mathbf{k}+2\mathbf{q}_{||}l''\sigma} - E_{\mathbf{k}l\sigma} - 2\hbar\omega + i2\hbar\alpha_l} \right\} \tag{6}$$

Here, the symmetry of the wave functions enters through the dipole matrix elements $M_i = \langle \Psi_{k,l,\sigma} | p_i | \Psi_{k,l',\sigma} \rangle$, where p_i is the momentum operator. It is this symmetry that is responsible for the selection rules giving rise to the surface sensitivity of the response. The dependence on the electronic structure results from the eigenvalues $E_{k,l,\sigma}$, which depend on the wave vector $\mathbf{k}$, the band index l, and the spin σ. Note, the matrix elements may involve s-, or d-states, as well as quantum well states (QWS) that appear in ultrathin layers, and will depend on the corresponding wave functions. $f(E_{k,l,\sigma})$ is the Fermi function, α_l is the Lorentzian broadening of the states. Taking into account only vertical transitions, equation (6) already shows how changes of the susceptibility result from modifications in the joint density of states, which is probed by nonlinear optics. Since SHG is generated at the surface and the interface of the film, the summation over the energy eigenvalues has to be performed according to the surface and the interface electronic structure. Thus for a paramagnetic material, the band structure for both spin directions is the same and no spin dependence results. In the case of a ferromagnetic material, the nonlinear tensor $\chi_{ijm}(\mathbf{M})$ will be separated into odd and even components as discussed in the preceding text.

The only attempt to carry out the whole computational procedure in full was made by Andersen and Hübner (2002) who calculated the nonlinear MO response of a single Fe(001) monolayer on top of a 1, 2, 3, or 4 monolayer 'substrate'. The results showed indeed the expected large nonlinear MO effects. Such a sample is close to the limit of modern computation possibilities. Moreover, even in that case the calculation procedure was not entirely stable, as their own tests showed. The problem is that small errors in calculating the wave functions due to a restricted basis set (to save computation time) get amplified when three transition matrix elements are multiplied to obtain the final result.

Another approach based on the first-principles layer Korringa–Kohn–Rostocker method was employed to calculate the MSHG response from the Ni(110) surface. The preliminary results showed the contribution of the surface states to the nonlinear MO susceptibility (Calmels, Crampin, Inglesfield and Rasing, 2001), in good agreement with experimental results (Veenstra, Petukhov, Jurdik and Rasing, 2000).

2.3 Calculation of MSHG from multilayers

To calculate the MSHG response from a multilayer system one realizes that, in fact, the nonlinear susceptibility $\chi^{(2)}$ is expected to quickly decrease on both sides of the interface. As a result, the spatial distribution of $\chi^{(2)}$ can be well approximated by an infinitesimally thin nonlinear sheet between the two non-nonlinear media, see Figure 2 (Bloembergen and Pershan, 1962; Sipe, 1987; Wierenga, Prins, Abraham and Rasing, 1994; Wierenga, Prins and Rasing, 1995). This is even more true because the characteristic length to compare with is the wavelength of light, typically several hundred nanometers. Such an approximation reduces the number of parameters in the problem. A well-known concept in optics is to treat the boundary conditions at an interface, and the propagation of light through a homogeneous slab, in terms of matrices that relate the field components on both sides of the interface and the layer respectively. Describing the full multilayer is thus reduced to a simple matrix multiplication (Palik, 1985).

Owing to the very small nonlinear susceptibility values, the total problem can be split in two. In the first part, the influence of the nonlinearity on the light behavior is totally neglected. The local electric fields and polarizations induced by the incident light inside the structure are derived from the primary electric field through the linear susceptibility tensor. The tensor, in turn, may depend on the layer magnetization, thus giving rise to linear MO effects. The induced polarizations are actually quite small compared to the fundamental electric field and can be considered as a perturbation.

The second part of the problem concerns the electromagnetic waves at the second-harmonic frequency. Here, the fundamental electromagnetic field is absent and the 2ω-polarizations play the role of the only sources. If all the layers of the structure possess a center of inversion, then, within the electric-dipole approximation, there will be no volume polarization. The total second-harmonic yield can thus be related to the interfaces only, each interface being described by its own nonlinear optical tensor $\chi^{(2)}$.

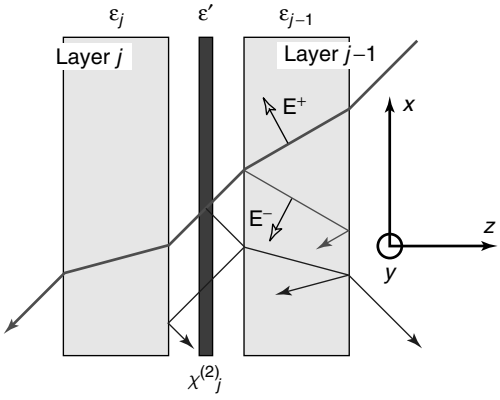

Figure 2. Infinitesimal nonlinear sheet inside an artificial vacuum sheet at an interface.

It should be noted that even in linear optics, the normal component of the electromagnetic field is discontinuous across ideal interfaces. The surface polarizations become radiation sources. The corresponding electric fields can be obtained from Maxwell's equations, which are now accompanied by the unconventional boundary conditions taking into account singular polarizations of ideal interfaces (Shen, 1984). A comprehensive treatment of problems related to a model of both linear and nonlinear MO effects in multilayers has been given by Atkinson and Kubrakov (2002). Most often, however, bulk anisotropy of layers can be neglected together with the linear MO effects that are argued to be small enough.

The parameters accessible experimentally are the MSHG intensity and polarization. In addition, also the phase of the total MSHG output can be determined quite straightforwardly (Veenstra, Petukhov, de Boer and Rasing, 1998; Leute, Lottermoser and Fröhlich, 1999). In order to determine the nonlinear susceptibilities at interfaces, the MSHG output is first measured as a function of some parameters, for example, angle of incidence, magnetization, sample thickness, azimuthal angle, and so on. Then, multiple-scattering calculations are used to fit the obtained data using the nonlinear optical tensor components as fit parameters, provided that the obtained experimental data are sufficient for an unambiguous fit. Various polarization combinations help to distinguish different tensor components by selectively exciting one or another combination of them. An example of such an analysis will be included in Section 5.

The main assumption of the discussed model is that it considers the source of the SH field in the form of an infinitely thin, coherently and homogeneously polarized sheet. Although this assumption is justifiable in many cases investigated experimentally, it is not sufficiently general. Moreover, it is based on a macroscopic-like description of the source of the SH field, which does not provide a direct physical insight into the processes involved in the SHG phenomena.

A different model was discussed recently (Hamrle, Polerecký and Ferré, 2003; see also Sampaio *et al*., 2004), where the problem of MSHG was considered from a different point of view. The SH field was considered to be generated by a point electric dipole oscillating at an angular frequency 2ω, positioned at the layer interface. This is closely related to the symmetry considerations used in the macroscopic models like that discussed in the preceding text.

This approach to the SHG has some advantages. In particular, once the electromagnetic (EM) field generated by the point dipole is known, it can be used to evaluate the SH field generated from a system with arbitrarily spatially distributed dipoles. Furthermore, as it is based on a well understood microscopic quantity (an elementary dipole), it can be more directly related to a quantum-mechanical description of MSHG.

The elegance of the developed model becomes apparent when systems with an inhomogeneous distribution of susceptibility tensors along the interfaces are considered. This is the case when the magnetization of the layers, and thus the interfaces, exhibits variations in the lateral dimension due to, for example, the presence of magnetic domains, propagating spin waves, periodic structures, magnetic nanostructures, and so on, and where the optical properties (layer thicknesses and permittivity tensors) can be assumed to be laterally homogeneous (Hamrle, Polerecký and Ferré, 2003).

2.4 Interface and bulk contributions to MSHG from a superlattice

It would be misleading to state that *all* the MSHG response from centrosymmetric media is generated at interfaces only. Strictly speaking, the surface nonlinear optical tensor χ does not even fulfill the energy conservation law, one of the basic principles of physics. Reexamined closely (Petukhov *et al*., 1998), this paradoxical result can be understood with the aid of an additional bulk contribution to the energy flow, as part of the surface response appears to be determined by the bulk parameters alone.

Having realized that, it is interesting to look more closely at the description of surface and bulk contributions to MSHG from a multilayer. The polarization $\mathbf{P}$ can be written as an expansion in powers of the optical electric field $\mathbf{E}(\omega)$:

$$\mathbf{P}(\omega, 2\omega, \ldots) = \chi^{1,d}\mathbf{E}(\omega) + \chi^{1,q}\nabla\mathbf{E}(\omega) + \chi^{2,d}\mathbf{E}(\omega)\mathbf{E}(\omega) + \chi^{2,q}\mathbf{E}(\omega)\nabla\mathbf{E}(\omega)\ldots \quad (7)$$

The tensor $\chi^{1,d}$ is the linear optical susceptibility allowed in all media. SHG is described by the third and the fourth term where the electric-dipole tensor $\chi^{2,d}$ is allowed only in noncentrosymmetric media and at surfaces and interfaces, while the quadrupole tensor $\chi^{2,q}$ is allowed everywhere. For crystals with a spontaneous or magnetic-field induced magnetization $\mathbf{M}$, expansion of the nonlinear optical polarization of a medium $\mathbf{P}^{\mathrm{nl}}(2\omega)$ can be further written (keeping only terms linear in magnetization) as:

$$\mathbf{P}^{\mathrm{nl}}(2\omega) = \chi^{\mathrm{cr}}\mathbf{E}(\omega)\mathbf{E}(\omega) + \chi^{m}\mathbf{E}(\omega)\mathbf{E}(\omega)\mathbf{M} + \chi^{q,\mathrm{cr}}\mathbf{E}(\omega)\nabla\mathbf{E}(\omega) + \chi^{q,m}\mathbf{E}(\omega)\nabla\mathbf{E}(\omega)\mathbf{M} \quad (8)$$

where the first and third term describe the purely crystallographic contributions while the second and fourth only exists in the presence of a magnetization $\mathbf{M}$.

Although smaller, the last two terms in equation (8) originate from the bulk and therefore may be comparable in magnitude to the strong dipole contribution coming from the very thin interface layer. Experimental results (see Sato *et al*., 2001, and below) confirm this assumption and substantiate the necessity to take this contribution into account in high-quality single-crystalline multilayers.

3 EXPERIMENTAL DETAILS

The strong development of nonlinear magneto-optics in the past decade is also related to the development of solid state mode-locked lasers that combine short pulse lengths with high repetition rates and allow the study of ultrathin magnetic films without destroying them. For most MSHG experiments nowadays, a Ti-sapphire laser (82 MHz × 100 fs pulses) tunable from 750–1100 nm but extendable to 400 nm–3 μm using a parametric amplifier, is used. After proper filtering the generated specular harmonic light can be analyzed.

For each polarization combination, the total MSHG response from a magnetic material can be simplified by

$$\mathbf{P}(2\omega) = (\chi_{\text{eff}}^{\text{even}} \pm \chi_{\text{eff}}^{\text{odd}}(\pm\mathbf{M}))E_{\omega}^{2} \tag{9}$$

where $\chi_{\text{eff}}^{\text{even}}$ and $\chi_{\text{eff}}^{\text{odd}}$ are effective tensor components that are even and odd in the magnetization and describe the crystallographic and magnetic contributions to the total response, respectively. As both these contributions are complex quantities, the total (MSHG) signal is thus given by

$$I^{2\omega} = |\chi_{\text{eff}}^{\text{even}}|^2 + |\chi_{\text{eff}}^{\text{odd}}|^2 \pm 2|\chi_{\text{eff}}^{\text{even}}||\chi_{\text{eff}}^{\text{odd}}|\cos\Delta\Phi \tag{10}$$

where $\Delta\Phi$ is the phase difference between the two contributions. The importance of the latter is obvious: when $\Delta\Phi = \pi/2$, the interference term is zero and changing the magnetization direction will have no effect on the total MSHG signal.

Though generally phase information is lost in intensity measurements, fortunately the phase can be measured quite easily in nonlinear optics by using interference techniques (Stolle *et al*., 1997). The latter can also be exploited in the case where there is only a purely odd response, by adding a nonmagnetic reference signal, as it is the interference between even and odd terms that gives rise to the nonlinear MO effects.

While MSHG signals give large relative MO effects, being a nonlinear optical technique the absolute intensities are rather small (10–10^4 photons/s) but easily detectable with modern photon counting or charge-coupled devices (CCD), though care should be taken to filter out the 2ω signal versus the much stronger fundamental signal at ω (see Figure 3).

Because of the simplicity of the experimental configuration, coupled with the large effects, the transverse geometry is often used for experimental studies. For that situation, one can define a magnetic contrast or asymmetry as:

$$A = \frac{I^{2\omega}(+\mathbf{M}) - I^{2\omega}(-\mathbf{M})}{I^{2\omega}(+\mathbf{M}) + I^{2\omega}(-\mathbf{M})} = \frac{2|\chi_{\text{eff}}^{\text{odd}}|/|\chi_{\text{eff}}^{\text{even}}|}{1 + |\chi_{\text{eff}}^{\text{even}}/\chi_{\text{eff}}^{\text{even}}|^2}\cos\Delta\Phi \tag{11}$$

Because A is normalized with respect to the total SHG intensity, it does not depend on the intensity or shape of the fundamental light pulses, nor on the spectral properties of optical components, such as filters, in the optical set up. Together with the already mentioned simplicity, this makes A a useful parameter for quantitative investigations. One should, however, realize that the appearance of large effects that result from the large magnetic tensor components also means that, in contrast to most linear MO effects, the nonlinear optical effects are often not simply linearly proportional to the magnetization, as directly follows from equations (10) and (11). This can for example strongly affect the shape of an MSHG loop (Pavlov *et al*., 2001; Valev, Gruyters, Kirilyuk and Rasing, 2005).

3.1 MSHG microscopy

It is interesting as well as challenging to employ the nonlinear optical effects in the imaging mode. Owing to the high sensitivity to the symmetry and order, SHG has been used to image ferroelectric domains and domain walls (Uesu, Kurimura and Yamamoto, 1995; Bozhevolnyi *et al*., 1998; Mishina *et al*., 2001), molecular surface ordering (Flörsheimer *et al*., 1997a,b), metal (Pedersen and Bozhevolnyi, 1999) and semiconductor (Erland *et al*., 2000) surface structures. In addition, owing to its high contrast, SHG microscopy could be combined with optical near-field imaging (Smolyaninov, Zayats and Davis, 1997; Bozhevolnyi, Vohnsen and Pedersen, 1998; Zayats and Smolyaninov, 2004) thus expanding the resolution possibilities.

The MSHG technique can be straightforwardly adopted to provide spatial information on the magnetization distribution at interfaces. Owing to its high MO contrast as well as some rather unusual MO effects, it can also be used as a technique complementary to the standard Magneto-optical Kerr effect (MOKE) microscopy.

The latter has been clearly demonstrated in thin films of magnetic garnets where the initial inversion symmetry of the bulk was broken by anisotropic film growth. The arising

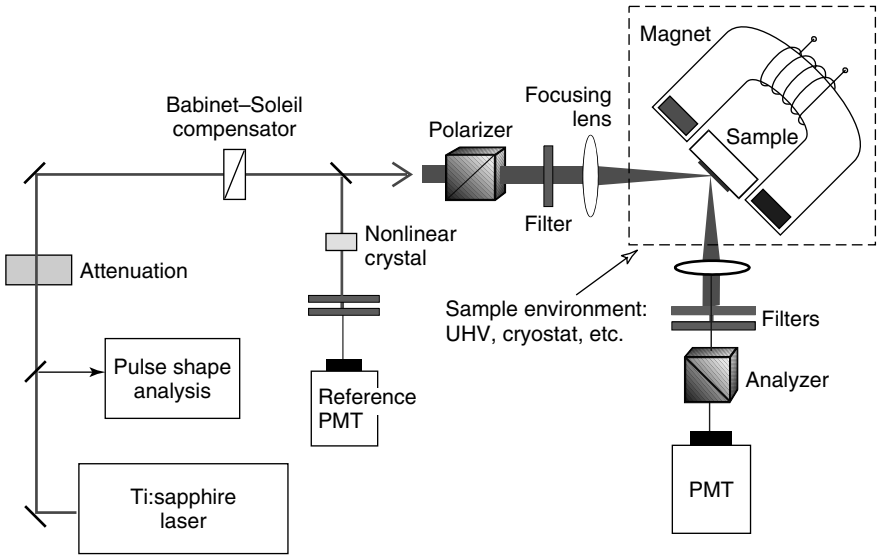

Figure 3. Typical MSHG experimental setup, with an autocorrelator for pulse shape characterization and a reference SHG channel.

strong MSHG response has different symmetry properties than the corresponding linear MO effects and was thus useful in distinguishing the complementary magnetization components, as shown in Figure 4 (Kirilyuk, Kirilyuk and Rasing, 1997).

For imaging, laser light is focused onto a sample. The generated SHG light is used, after proper filtering, for the imaging of the sample with the help of a CCD camera. Owing to the very large contrast, the images could be obtained directly and without any contrast improvement nor background subtraction, a procedure that is usually necessary to obtain the image with linear magneto-optics. The size of the MSHG image is restricted to the diameter of the focused laser beam, approximately 30 μm in this case, whereas the resolution is determined by the standard criteria for the used microscope. The size limitation for the image can be overcome by using a sample scanning procedure. Figure 5 shows a millimeter-size image of an ultrathin stepped film, where owing to electronic quantization effects (QWS) one can observe a strong contrast from monolayer-high steps (Kirilyuk, Rasing, Mégy and Beauvillain, 1996). A more elaborated procedure, demonstrated by Pavlov *et al*. (2001) (see Figure 6), involves a combination of the high-resolution imaging with scanning the sample, and a subsequent reconstruction of the total image from small parts.

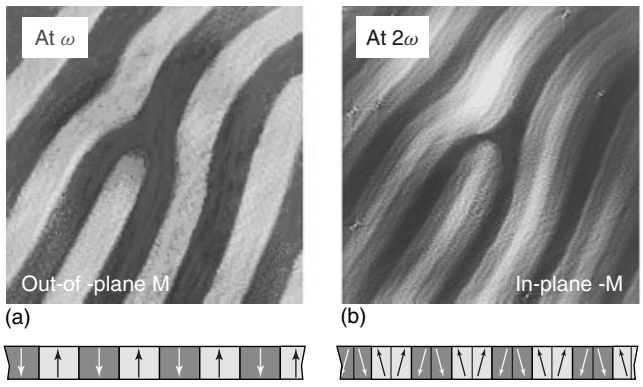

Figure 4. Images of magnetic domain structure in a thin layer of magnetic garnet: (a) linear Faraday effect, (b) MSHG in transmission. Below the images, the domain structure is shown as inferred from the pictures: Faraday effect sees the polar component of **M** only, while MSHG is able to detect also the in-plane component of the magnetization, showing that each up/down domain in the left picture is actually divided in two subdomains with tilted magnetization directions.

For the purposes of the present review, it is more interesting to consider MSHG imaging based on a pure interface response, such as for example that from CoNi/Pt interfaces (Kirilyuk, Kirilyuk and Rasing, 1999), or from Pt/Co/Pt multilayers (Pavlov *et al*., 2001). Such sputtered multilayers were found to be a promising MO material (Bijker, Donnet and Lodder, 1996) because of their low Curie temperature and strong MO effects.

Figure 7 shows the magnetization reversal process in a 9-nm thick CoNi film starting from a fully saturated sample (see Figure 7a). A magnetic field of the same value (60 Oe) was applied for the given time intervals (usually 20 s) followed each time by an image accumulation in zero field (10 min per image). In the MSHG images of Figure 7, there appear some details of the domain structure with a weaker contrast than that of the opposite domains. For example, images (d) and (e) clearly show several faint stripes extending along the diagonal of the images. All of them disappear later, in a completely saturated sample (f). Owing

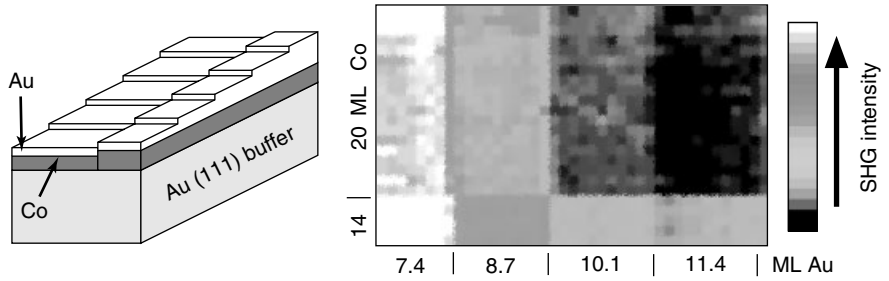

Figure 5. Large-scale image of a stepped Au/Co/Au(111) layer, showing monolayer sensitivity of SHG imaging.

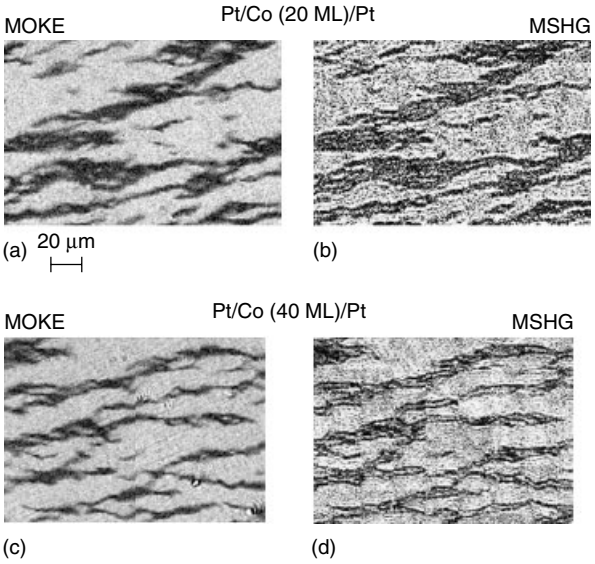

Figure 6. MOKE and MSHG images for Pt/Co(20 ML)/Pt (a and b), and for Pt/Co(40 ML)/Pt films (c and d). The field was previously applied along the easy anisotropy axis. (Reproduced from Pavlov *et al*., 2001, with permission from IOP Publishing Ltd. © 2001.)

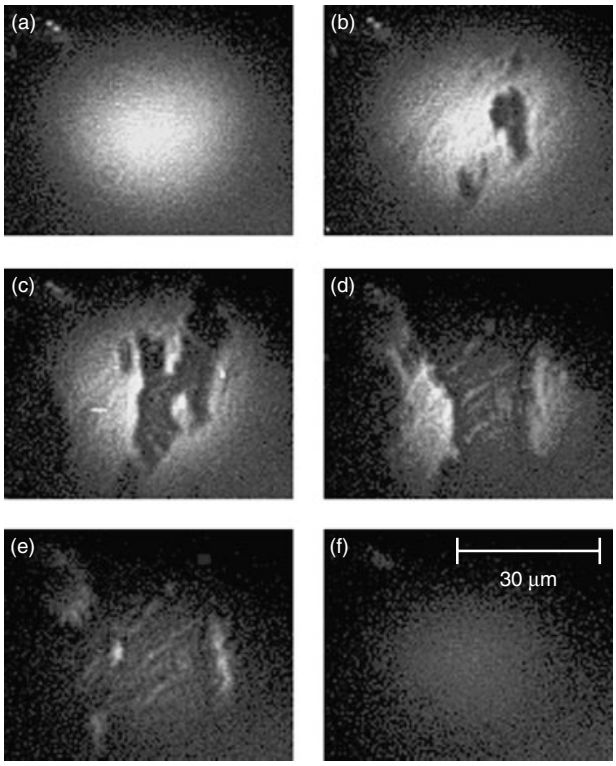

Figure 7. MSHG images of magnetization reversal in a Pt/CoNi/Pt sandwiched layer. Magnetization is saturated 'up' in image (a) and 'down' in image (f). Images (b), (c), (d), and (e) show gradual appearance and growth of opposite magnetic domains. The laser spot diameter is approximately 30 µm. No background subtraction of any kind has been used.

to the low quality of the linear MOKE images in such transversal geometry, a precise comparison of the linear and MSHG images is difficult. Therefore, it is unfortunately impossible to give an unambiguous interpretation to these structures as interface-related.

3.2 Measurements of the optical phase

In most surface, SHG experiments only the intensity of the second-harmonic light is routinely measured. The phase of SHG does, however, contain valuable information for a correct interpretation of the experimental data (Veenstra, Petukhov, de Boer and Rasing, 1998; Veenstra, Petukhov, Jurdik and Rasing, 2000). Furthermore, phase-sensitive measurements are especially useful in surface-specific SHG where the response mainly originates from a thin surface region so that the optical phase is directly related to the phase of the components of the surface nonlinear susceptibility $\chi^{(2)}$. As an example, the phase may give direct information about absolute molecular orientation on surfaces (Kemnitz *et al*., 1986) and in liquid crystals (Stolle *et al*., 1995). For MSHG, the phase between the even and odd susceptibility components is an extremely important parameter, as it determines the actual contrast in the MSHG signal (see equation (11)).

The phase of the SHG response can be determined with an interference technique described in Chang, Ducuing and

Bloembergen (1965). This method is however not compatible with, for example, UHV apparatus when femtosecond lasers are used. The reason is the dispersion of the optical windows ($\Delta n_{glass} \sim 10^{-2}$), causing a too large time delay $\tau \sim 1$ ps) between the fundamental and SHG pulses that destroys the interference. The following alternative approach overcomes this problem in an elegant way (Veenstra, Petukhov, de Boer and Rasing, 1998).

When 2ω and ω pulses propagate through air, the relative phase Φ between them gradually changes,

$$\Phi(d) = \Phi_0 + \delta\Phi = \Phi_0 + \frac{4\pi\,\Delta n_{\text{air}}}{\lambda} d \tag{12}$$

where $\Delta n_{\text{air}} = n(2\omega) - n(\omega) \sim 10^{-5}$ is the dispersion of the ambient air, d is the distance the two pulses have traveled through air, and λ is the fundamental wavelength. By using an additional SHG source (called reference) at position d in the path of the beam, interference can be observed in the detected total intensity

$$I_{2\omega,tot}(d) = I_{2\omega,s} + I_{2\omega,r} + 2\alpha\sqrt{I_{2\omega,s} I_{2\omega,r}}\cos[\delta\Phi(d) + \Phi_0] \tag{13}$$

where $I_{2\omega,s}$ and $I_{2\omega,r}$ are the SHG signals generated by the sample and the reference, respectively. The spatial coherence is described by the coherence parameter α. This interference disappears if the pulses do not overlap in time. As is shown in Figure 7(a), this may happen if the femtosecond fundamental and SH pulses have to travel through a strongly dispersive element like an optical window.

Looking at the problem more closely, in the time domain the optical field at the detector created by two pulses with a delay τ can be described by the function

$$\begin{aligned} E_{2\omega}(t) = {} & E_1 g(t)\exp(-i2\omega_0 t) \\ & + E_2 g(t-\tau)\exp(-i2\omega_0 t + i\Phi) + c.c. \end{aligned} \tag{14}$$

where $E_i g(t)$ describes a slowly varying envelope with amplitude E_i $(i = 1, 2)$. Using the so-called 'time-shifting' identity, $g(t-\tau) \Leftrightarrow G(\Omega)e^{i\Omega\tau}$, where $g(t) \Leftrightarrow G(\Omega)$ is the Fourier transformation, the measured spectrum at the detector is given by

$$\begin{aligned} & I(2\omega_0 + \Omega) \propto |G(\Omega)|^2 \\ & [E_1^2 + E_2^2 + 2\alpha E_1 E_2 \cos(2\omega_0\tau + \Omega\tau + \Phi)] \end{aligned} \tag{15}$$

where Ω denotes the deviation of the frequency from the central frequency $2\omega_0$ within the spectrum of the MSHG output. The second term in the cosine, $\Omega\tau$, leads to beatings in the spectrum of the SH light. The phase of the beatings is directly related to the phase Φ of the response from the sample. Thus the phase information can be easily recovered by using a spectrometer.

In the experimental demonstration, the phase of the MSHG response from an Rh/Co/Cu multilayer was measured. In the longitudinal geometry the *S*-polarized MSHG from this isotropic sample should be *odd* in **M** (see equation (4)) so that reversal of the magnetization must change the phase of the response by 180° (Stolle *et al.*, 1997). A 3-mm thick glass plate was used to introduce a time delay τ between the SHG response from the sample and the reference (a thin poled polymer film with high second-order nonlinearity), see Figure 8(a). The beating part of the SHG spectrum is shown in Figure 8(b) for opposite directions of **M**. The phase change introduced by the magnetization reversal is found to be $\Phi(-M) - \Phi(+M) = 176^\circ \pm 5^\circ$, in excellent agreement with the expected π shift.

In Section 4, we describe the application of this technique to the surface MSHG from Ni(110).

4 MSHG FROM MAGNETIC SURFACES

A clean magnetic surface is the benchmark object for a nonlinear MO experiment. From the theoretical point of view, it is also the simplest one. The experimental study of it, however, requires utmost care mostly devoted to the preparation of a well-defined and clean surface.

4.1 Ni(110) surface: spin-dependent spectroscopy

The spin-dependent electronic structure of ferromagnetic surfaces and interfaces forms the fundamental basis for understanding surface magnetic phenomena. The following example (taken from Veenstra, Petukhov, Jurdik and Rasing, 2000) shows how MSHG can be used to study the electronic surface states on a ferromagnetic metal surface.

Experiments were performed at room temperature on a disk-shaped Ni(110) single crystal placed in UHV conditions between the poles of an electromagnet. In a standard procedure, the sample surface was cleaned by repeated cycles of Ar^+ sputtering and annealing, until no contamination could be traced. The MSHG experiments started with the observation of the influence of the O_2 absorption. Oxygen exposure was done at approximately 3×10^{-9} mbar. Using Auger electron spectroscopy, the coverage of the sample with oxygen was found to be a nonlinear function of exposure that saturated at 45 Langmuir (L). Such saturation coverage corresponds to 1 monolayer (ML) of NiO.

Figure 9 shows the oxygen exposure dependence of the MSHG signal in the $P_{\text{in}}P_{\text{out}}$ polarization combination. It can be seen that when the clean surface is exposed the SHG

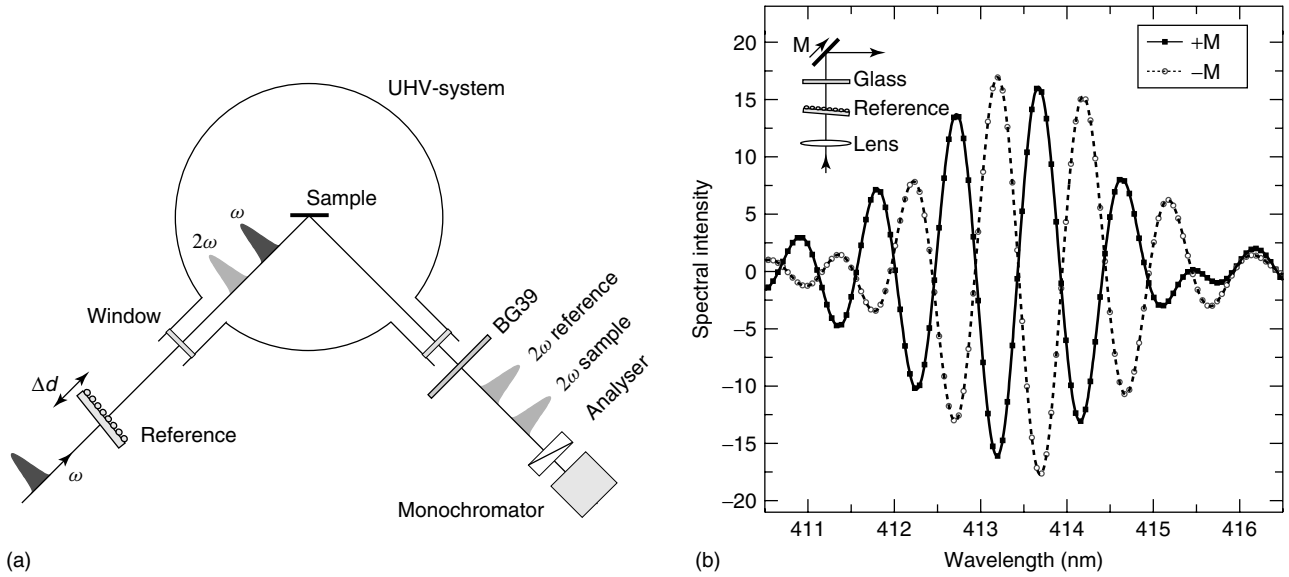

Figure 8. (a) Sketch of the experimental setup for the spectral phase measurements. The SH pulse from the reference is delayed with respect to the fundamental laser pulse due to the dispersion of the window. Figure 9. SHG intensity from Ni(110) surface as a function of oxygen dose for opposite directions of **M** as well as the MSHG asymmetry.

intensity increases and has a maximum at 1 L, and another maximum around 10 L. Close to 20 L, the intensity drops by more than an order of magnitude with further increase to saturate around 45 L. The observed two maxima seem to be well in line with the appearance of the $c(2 \times 1)$ and $c(3 \times 1)$ oxygen induced surface superstructures. These superstructures could be observed, at these same coverages, with low-energy electron diffraction (LEED). The magnetic asymmetry plotted in the same figure, roughly indicates the changes in the ratio $\chi^{\text{magn}}/\chi^{\text{cr}}$. Clearly, very small amounts of oxygen drastically change the asymmetry, including the change of sign. On the other hand, the observed SHG intensity maxima at 1 and 10 L do not visibly correlate with the MSHG asymmetry at all.

Spectroscopic MSHG experiments were carried out on the same surface, with the aim to obtain a better insight in the origin of the nonlinear MO response. A tunable optical parametric amplifier pumped by a Ti:sapphire regenerative amplifier was used to produce the fundamental light pulses in the wavelength range of 750–1000 nm. To normalize the measured second-harmonic intensity from the sample, the SHG intensity from a *c*-cut quartz crystal in the transmission geometry was measured with a second photomultiplier tube. The phase of the SHG was measured using the UHV compatible phase-sensitive detection technique (see preceding text in Section 3.2).

The magnetic asymmetry measured in the $P_{\text{in}}P_{\text{out}}$ polarization combination is plotted in Figure 10(a) as a function of $2\hbar\omega$ photon energy. The open circles represent the response of a clean surface while the solid squares are the response of a surface very slightly contaminated with oxygen (0.5 L). In the inset, the average SHG intensity measured on a clean surface is shown. The magnetic asymmetry has a sharp maximum at 2.7 eV and changes sign at 2.6 and 3.1 eV. This resonant feature completely disappears upon oxidation, clearly proving its surface specific nature. The relation between the effective susceptibilities and the intensity data of Figure 9 is given by

$$4|\chi_{\text{eff}}|^2 = I(+M) + I(-M) \pm 2\sqrt{I(+M)I(-M)}\cos(\Delta\varphi) \tag{16}$$

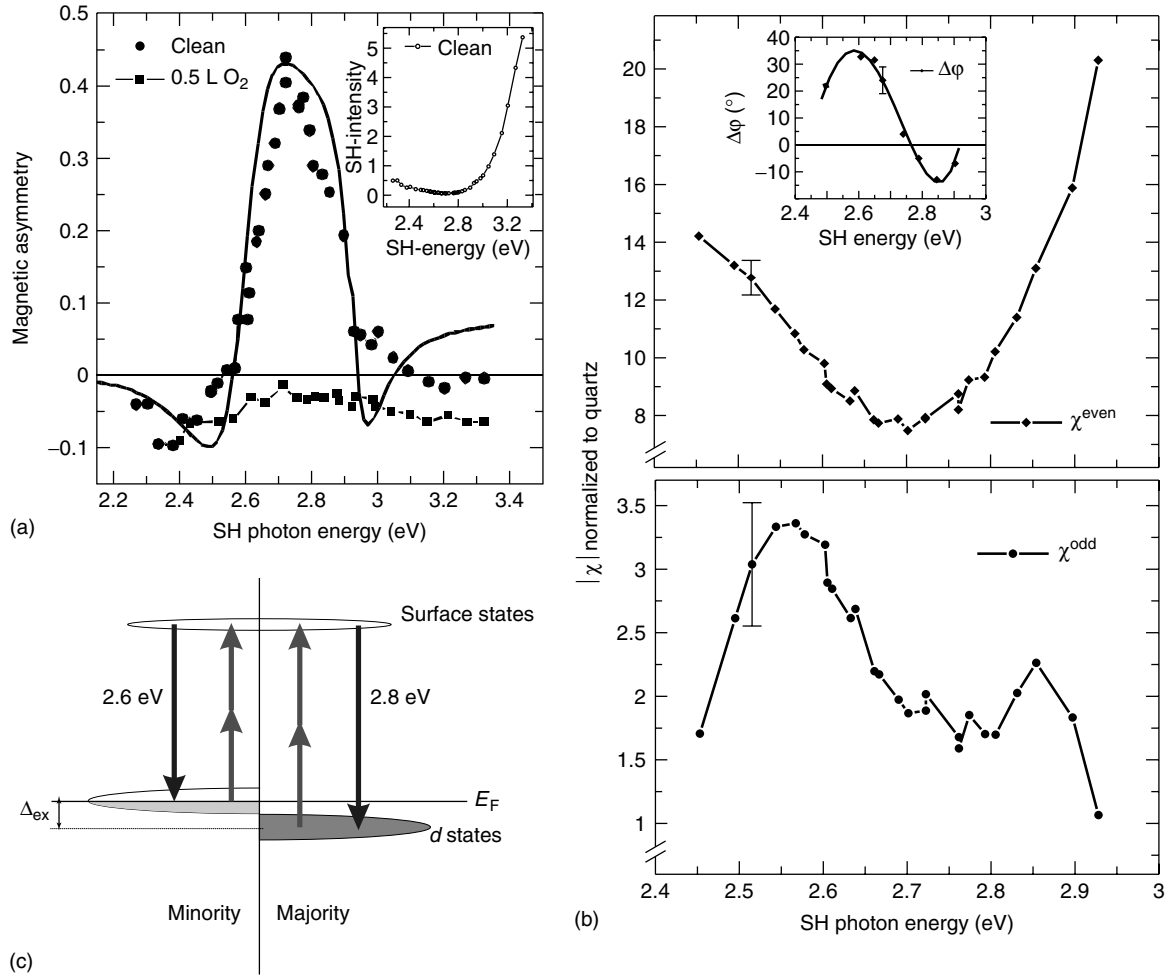

Figure 10. (a) MSHG asymmetry and total intensity (see inset) as a function of 2ω photon energy as measured on a clean and oxidized Ni(110) surface. (b) Amplitude of the effective tensor elements as derived from the measured intensity, asymmetry, and relative phase (inset). (c) Schematic picture of the exchange split density of states and empty surface states in nickel. (Reproduced from Veenstra *et al.*, 2000, with permission from the American Physical Society. © 2000.)

where $\Delta\varphi$ is the phase difference between the SH fields $E(2\omega, +\mathbf{M})$ and $E(2\omega, -\mathbf{M})$. This phase difference was measured as a function of frequency and is shown in Figure 10(b), along with the resulting effective susceptibilities $|\chi_{\text{eff}}^{\text{odd}}|$ and $|\chi_{\text{eff}}^{\text{even}}|$. Surprisingly, the sharp maximum of Figure 10(a) corresponds to the two-peak structure of $|\chi_{\text{eff}}^{\text{odd}}|$ combined with a minimum of $|\chi_{\text{eff}}^{\text{even}}|$.

The resonances as observed in the nonlinear MO spectra of Figure 10(b) can be calculated using equation (6) within a simple model shown in Figure 10(c). The model involves the spin splitting of the d bands around the Fermi energy and an empty surface state around 2.5 eV above E_{F}. The exchange splitting of the d band leads to a maximum density of states for minority spin electrons at the Fermi energy and a maximum for majority spin electrons approximately 250 meV below E_{F}. As this surface state is of nearly pure p_z character, the exchange splitting of this state is much smaller than the splitting of the d states and can be neglected. Including only these d states and a known surface state (Goldmann, Dose and Borstel, 1985) in the summation of equation (6), $|\chi_{\text{eff}}^{\text{odd}}|$ can be written as

$$\chi^{\text{odd}} = A_0 + \frac{A_1}{2\hbar\omega - E_1 + i\hbar\Gamma_1} + \frac{A_2}{2\hbar\omega - E_2 + i\hbar\Gamma_2} \quad (17)$$

where the second term describes the transitions of the minority spin electrons from filled to empty states having energy difference E_1 and the third term includes the transitions of the majority spin electrons. Because of the spin dependence of the resonant contributions to the odd tensor component, the matrix elements A_1 and A_2 should have an opposite sign and be of approximately equal amplitude. Using these relations, the model can be used to fit $|\chi_{\text{eff}}^{\text{odd}}|$ to give $E_1 = 2.58$ eV

and $E_2 = 2.85\,\text{eV}$. Using $|\chi_{\text{eff}}^{\text{even}}|$ from Figure 10(b), it is now possible to calculate the magnetic asymmetry shown in Figure 10(a) by the solid line. The typical features of the asymmetry such as the two sign changes and the maximum are described very well by the model. This proves that these features do indeed arise due to the difference in exchange splitting between the initial d states and the final surface state, which proves that MSHG spectroscopy can be a powerful tool to probe the spin-dependent electronic structure of surfaces.

4.2 Magnetic moments of Co during growth on a Cu surface

The following experiment made direct use of the enormous sensitivity of MSHG to surface magnetism as well as to structure and morphology. Jin, Regensburger, Vollmer, and Kirschner (1998) studied *in situ* the layer-by-layer growth of Co films on Cu(001). During the growth of the Co film (very slow growth with a rate of about 7 ML/h) MSHG signals were measured in the transverse MO geometry.

Figure 11(a) shows the total MSHG intensity for *S*-polarized incident light as a function of the Co film thickness d_{Co} for the two opposite magnetization directions. The MSHG yield from the uncovered Cu surface is much smaller than that from a Co film. Therefore, at the beginning of the Co deposition the MSHG intensity increases almost linearly. The onset of a difference in the $I(+M)$ and $I(-M)$ at $d_{Co} = 1.5\,\text{ML}$ indicates the onset of magnetic order. The corresponding magnetic asymmetry is shown in Figure 11(b), together with the average intensity in Figure 11(c). On top of the overall thickness dependence an oscillation with a one monolayer period is clearly visible up to $d_{Co} = 7$ to 8 ML. The slowly varying part is caused by changes in the electronic structure with increasing film thickness and the appearance of quantum size effects in the SHG.

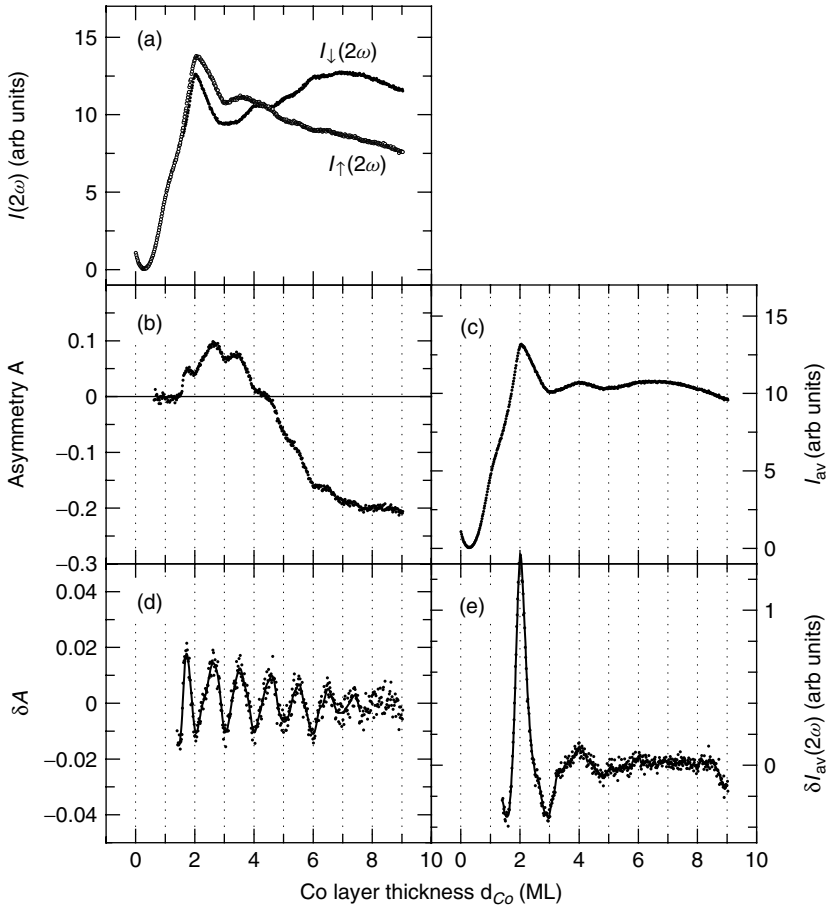

Figure 11. (a) Measured total SHG intensities as a function of the Co film thickness for *S*-polarized incident light in the transversal geometry. (b) Magnetic asymmetry and (c) average SHG intensity calculated from data of (a). In (d) the difference of the magnetic asymmetry and its running average over 50 data points is plotted. (e) Similar as (d) but for the average SHG intensity. (Reproduced from Jin *et al.*, 1998, with permission from the American Physical Society. © 1998.)

However, the one ML period oscillations must rather be related to the morphology of the surface than to the electronic structure. It is well known that SHG is quite sensitive to the surface morphology. For example, on a stepped Al surface the intensity changes by almost two orders of magnitude depending on the step density and step orientation (Janz, Bottomley, van Driel and Timsit, 1991). The enhancement of SHG from this atomic scale roughness is caused by the modified electronic structure of the flat surface. Co grows on Cu in a nearly layer-by-layer growth mode (Schmid and Kirschner, 1992). Periodically Co islands nucleate, grow in size, and coalesce (see Figure 12) causing the total length of step edges to oscillate. Therefore, the observed oscillatory component in the SH intensity may be attributed to the oscillatory varying step density.

The same periodicity is seen not only in the intensity, but in the asymmetry as well. It is very well revealed in the $S_{\text{in}}P_{\text{out}}$ polarization combination (see Figure 11), where the effect of morphology on the average SHG intensity is smaller, compared to the $P_{\text{in}}P_{\text{out}}$ one (Jin, Regensburger, Vollmer and Kirschner, 1998). For clarity, the rapidly varying component of the asymmetry is calculated as the difference of A and its smoothly varying course.

A difficult point in the data treatment was to decide, whether the increase of the measured asymmetry corresponds to the *increase* of the surface magnetization or to its *decrease*. This could be solved by a continuous increase of the film thickness up to 150 ML so that the contribution of the buried interface vanished. It was thus shown that the increase of the magnetization-induced asymmetry at half-filled layers indeed comes from the enhancement of the magnetic *surface* nonlinearity in the whole thickness range.

Though MSHG, similar to the linear MOKE, does not measure the magnetization directly, it has been shown in Pustogowa, Hübner and Bennemann (1993), that to a first approximation, the magnetic tensor elements of the second-order susceptibility depend linearly on the magnetization. Provided the amplitude of the change is small, variations of the asymmetry directly relate to the variations of the tensor elements. Therefore, the observed increase of the asymmetry at half-filled layers suggests the *increase of the magnetic moments* of the atoms at step sites as it is expected from the simple argument of reduced coordination number at these sites. It is by far not easy to estimate the absolute increase of the step magnetic moments as the probing depth of MSHG is not exactly known. Very roughly, the experimental data of Jin *et al*. fall in line with theoretical estimates of an increase in moment of a few percent at the step edges.

These measurements prove the ability of MSHG to detect changes in the magnetic moment at interfaces of the order of $\frac{1}{50}\mu_{\text{B}}$ per atom.

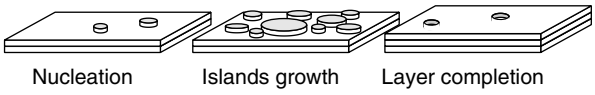

Figure 12. The layer-by-layer growth of a thin film: appearance, growth, and coalescence of islands periodically change the number of step atoms.

5 INTERFACES IN MAGNETIC MULTILAYERS

5.1 Investigation of buried interfaces of CoNi/Pt films with MSHG

This section describes the first successful attempt (from Kirilyuk, Rasing, Haast and Lodder, 1998) to derive the relative nonlinear MO susceptibilities *per interface* from the experimental MSHG data.

The samples for this study were Pt/CoNi/Pt sandwiched layers, prepared in a computer controlled sputtering system, base pressure of 5×10^{-8} mbar, with argon as a sputtering gas. The deposition rates were kept low ($1.7-2.0\,\text{Å}\,\text{s}^{-1}$ for Pt and $0.4-0.6\,\text{Å}\,\text{s}^{-1}$ for CoNi), to assure a smooth layer growth and a good control of layer thickness. A 40-nm thick Pt buffer layer was deposited on a Si(001) substrate followed by a magnetic CoNi layer (thickness varied between 3 and 12 nm) and covered by a 3-nm thick Pt cap layer. Such samples were prepared at different Ar pressures (between 4 and 36 μbar). It was found that the magnetic properties of the samples considerably depend on the growth conditions, in particular on the Ar pressure used for sputtering.

Experimentally, the asymmetry of the MSHG signal A, as defined by equation (11), was measured as a function of the angle of incidence.

In order to determine the $\chi^{(2)}$ tensor for one given interface quality, a set of samples was used with different magnetic layer thicknesses, prepared under exactly the same conditions (including of course the sputtering pressure of $p_{\text{Ar}} = 12\,\mu\text{bar}$). It was therefore assumed that the $\chi^{(2)}$'s are the same for the different samples, and only the local optical fields at the interfaces are changed, owing to absorption and multiple scattering. To fit the data, the transfer matrix technique described in Section 4.2 was employed with nonlinear susceptibilities as fitting parameters.

The results of the measurements together with the fitting curves are shown in Figure 13(a) for the $S_{\text{in}}P_{\text{out}}$ polarization combination. The number of fitting parameters is determined by the polarization used. Thus for $S_{\text{in}}P_{\text{out}}$ one can arbitrarily fix the only tensor component of the cover layer surface zyy_0 (neither the absolute intensity nor the optical phase

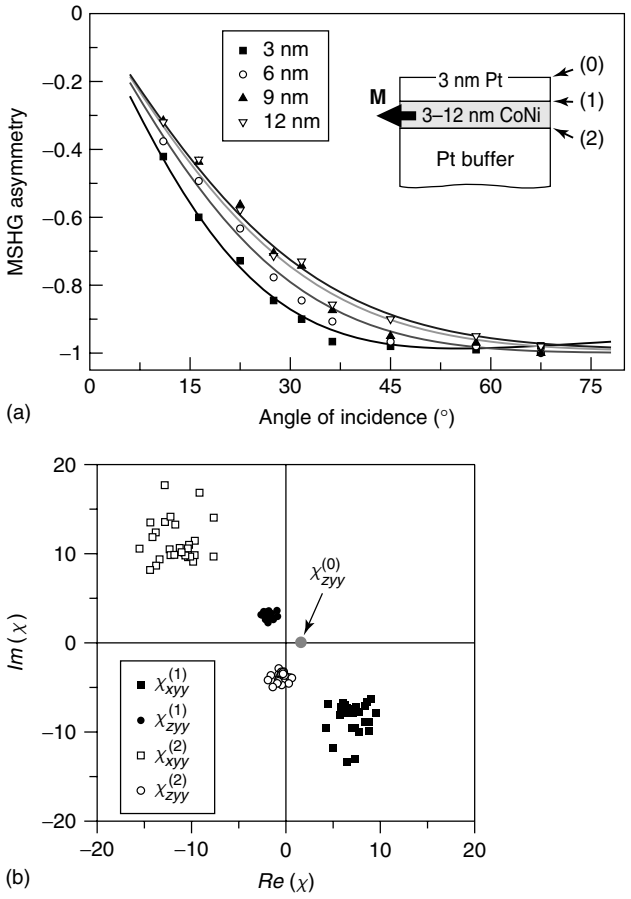

Figure 13. (a) Angle-of-incidence dependencies of the MSHG asymmetry for Pt/CoNi/Pt samples with different CoNi layer thicknesses (indicated in the figure). Lines are the theoretical fit to the experimental points using one single set of tensor elements. (b) The nonlinear tensor components derived from the fits in (a). (Reproduced from Kirilyuk *et al*., 1998, with permission from the American Physical Society. © 1998.)

of the total MSHG signal is taken into account), hence $zyy_{1,2}$ and $xyy_{1,2}$ are the only components left to be determined (inset in Figure 13(a) shows the indexing of the interfaces). This leaves eight parameters (2 interfaces $\times$ 2 complex components) to fully describe these data. The uniqueness of the fits was checked for both $S_{\rm in}P_{\rm out}$ and $P_{\rm in}P_{\rm out}$ polarization combinations by randomizing the initial choice of the fit parameters. Figure 13(b) shows the $\chi^{(2)}$ tensor components obtained from the fits of Figure 13(a). The convergence of the parameters is evident. An interesting point is that the tensor components show opposite signs for the subsequent magnetic layer interfaces (1) and (2). This is an independent experimental confirmation of a strict requirement from symmetry (It is easy to derive by using the mirror symmetry operation with respect to the center plane of the film that the second-order susceptibilities of ideal mirrored interfaces are of equal amplitude but opposite phase.) and provides a strong support for the model used in the calculations. Also, the crystallographic and magnetic contributions to $\chi^{(2)}$ appear to be of the same order of magnitude, in strong contrast to the linear case.

To determine the dependence of $\chi^{(2)}$ on the interface quality, the sample with a 3-nm thick CoNi layer was measured for different Ar sputtering pressures. The assumption was then made that *all* tensor components changed in a similar way, that is, the scaling parameters $\mathcal{M}$ and $\mathcal{C}$ could be defined as

$$\chi^{(2)}_{\rm magn}(p_{\rm Ar}) = \mathcal{M}(p_{\rm Ar}) \cdot \chi^{(2)}_{\rm magn}(p_0) \tag{18}$$

$$\chi^{(2)}_{\rm cr}(p_{\rm Ar}) = \mathcal{C}(p_{\rm Ar}) \cdot \chi^{(2)}_{\rm cr}(p_0) \tag{19}$$

with $p_0 = 12\,\mu$bar. To fit the data for any new sample only the two complex parameters $\mathcal{M}$ and $\mathcal{C}$ are used (actually this only gives three parameters in total because one phase can still be fixed). The possibility to fit the data for any Ar pressure in such a manner supports the assumption that all $\chi^{(2)}$'s are changed in a similar way.

The parameters $\mathcal{M}(p_{\rm Ar})$ and $\mathcal{C}(p_{\rm Ar})$ represent the dependence of the nonlinear MO interface properties on the interface structure (controlled via the sample preparation conditions). The value of $\mathcal{C}$ is proportional to the crystallographic contribution to the MSHG, expressed via the local symmetry breaking induced by the interface. It is incorrect to say, however, that $\mathcal{M}$ represents the purely magnetic part of MSHG. Indeed, all the 'magnetic' elements of $\chi^{(2)}$ are only nonzero in the presence of the crystallographic symmetry breaking, that is, the same factor influences both $\chi_{\rm cr}$ and $\chi_{\rm magn}$. Hence, one may write $\mathcal{M} \propto \mathcal{C} \cdot \mathbf{M}$.

To extract information on the interface magnetic properties, we take the ratio $\mathbf{m} = \frac{\mathcal{M}}{\mathcal{C}}$. In Figure 14, $\mathbf{m}$ is plotted as a function of the sputtering Ar pressure for the $S_{\rm in}P_{\rm out}$ and $P_{\rm in}P_{\rm out}$ polarizations. The precise coincidence of the $\mathbf{m}$ dependency for both polarization combinations once again supports the model used for the derivations.

Figure 14 shows that the crystallographic contribution $\chi_{\rm cr} \propto \mathcal{C}$ increases rapidly above 15 µbar, while staying almost constant below this pressure. The increase of $\chi_{\rm cr}$ indicates an increasing interfacial roughness for higher sputtering pressures. Though the crystallite size is known to stay constant in the whole pressure range, the crystallites may become slightly disoriented (Bijker, Donnet and Lodder, 1996). This increase of $\chi_{\rm cr}$ due to the increasing interface roughness can schematically be understood as being due to the increase of the effective surface area of the interface. For stronger roughness, other mechanisms may play a role (Aktsipetrov *et al*., 1990).

In contrast to the crystallographic one, the magnetic contribution $\mathbf{m}$ shows a clear maximum at pressures of 15–20 µbar.

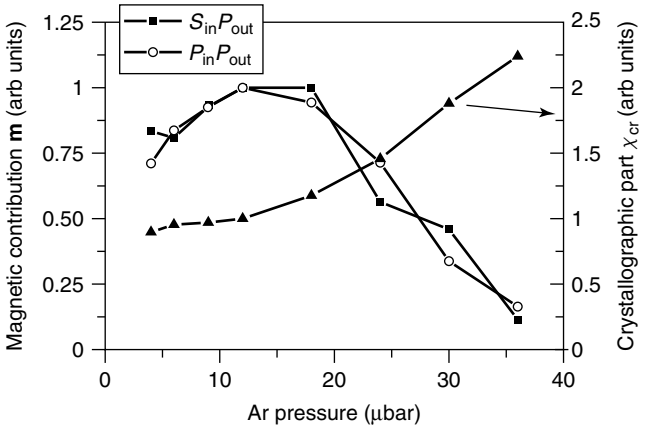

Figure 14. Crystallographic as well as magnetic contributions to the nonlinear MO tensor derived from the two different polarization combination data (indicated in the figure). (Reproduced from Kirilyuk *et al*., 1998, with permission from the American Physical Society. © 1998.)

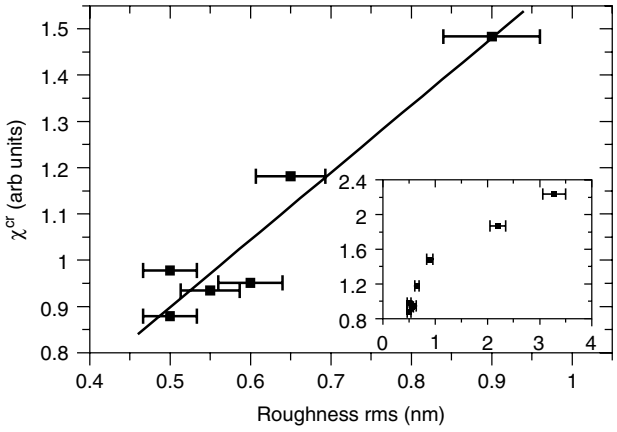

Figure 15. Crystallographic $\chi^{(2)}$ contribution as a function of interface roughness determined from AFM and X-ray scattering experiments. (Reproduced from Bal *et al*., 2001, with permission from the American Institute of Physics. © 2001.)

At very low Ar pressures the interface layers become slightly intermixed due to the high energies of sputtered atoms. This intermixing hardly affects the crystallographic part of MSHG but clearly suppresses the magnetic one. Note that the maximum in the interface magnetization does not have to coincide with the sharpest interface. Evidently, the drop of **m** for large p_{Ar} is related to a decreasing in-plane magnetic moment of the rough interface. A possible explanation here is that the increasing roughness changes the local coordination of the Co atoms, which may even lead to an out-of-plane lifting of the *local* interface magnetic moments. This explanation is supported by the observation of a specular *S*-polarized MSHG output at higher Ar pressures (Bal, van den Berg, Keen and Rasing, 2001). Such an MSHG yield can only be nonzero in the presence of a perpendicular (out-of-plane) magnetization component. In addition, polar MOKE hysteresis loops also showed a small remanence ($\leq$10% of M_s) for the sample sputtered at $P_{Ar} = 36\,\mu$bar, confirming the MSHG results.

It was also measured that up to a roughness rms value of 1.0 nm, the value of χ^{cr} is roughly proportional to the surface/interface roughness measured by other methods, such as atomic force microscopy (AFM) and grazing-incidence X-ray scattering (see Figure 15).

Summarizing, nonlinear magneto-optics is clearly able to follow the (subtle) changes in the interface structure, both crystallographic and magnetic. For the case of Pt/CoNi/Pt, an optimum sputtering pressure is found that yielded a maximum in-plane interface magnetization with only a small change in interface morphology. With further increase of the sputtering pressure, the interface roughness clearly increases while the in-plane interface magnetic moment decreases. It should be underlined that for all studied samples, no difference in the total layer magnetization was observed with either MOKE or vibrating sample magnetometry (VSM).

5.2 Interface versus bulk MSHG in Fe/Au multilayers

In this study, the MSHG technique was applied to Fe/Au superlattices with atomically controlled epitaxial layers. The superlattice with a modulation of mono-atomic layers of Fe and Au has been known to show an artificial order with an $L1_0$ structure that does not exist in nature (Takanashi *et al*., 1995). Such an artificial structure remains at interfaces between Fe and Au layers when the modulation period becomes longer than mono-atomic (Mitani *et al*., 1996). The linear MO spectra of the superlattices modulated by integer and noninteger numbers of atomic layers have been studied intensively, suggesting the formation of a peculiar band structure in such an artificial real-space structure (Sato *et al*., 1996, 1999).

Figure 16 shows the results of a rotational anisotropy measurements for all four polarization combinations in the longitudinal geometry. A sample with lattice period $x = 15$ ML was used. All curves show clear fourfold anisotropy and a clear magnetic contrast.

In Figure 17, the results of all four polarization combinations for the sample with $x = 15$ ML are plotted, for the case of the transverse geometry. Note the different vertical scales for the various data, indicating a substantial difference for the MSHG response for different polarization combinations. It is also obvious that all data involving S_{in} or S_{out} polarization, yield a much stronger anisotropy, which is a direct consequence of the in-plane xy tensor components that contribute

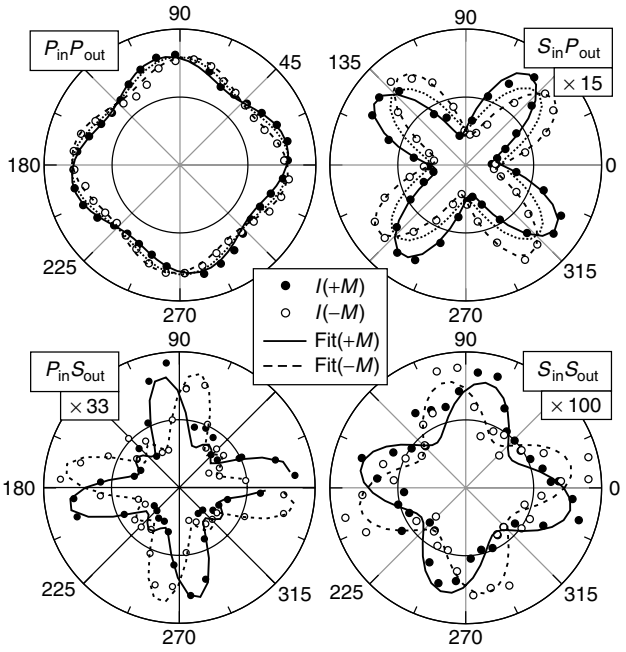

Figure 16. Rotational anisotropy curves (experimental points plus theoretical fits) for the sample with single layer thickness $x = 15$ monolayers in longitudinal geometry. Multiplication factors in three plots show the scaling of the corresponding data in order to reach the same intensity level as with the $P_{in}P_{out}$ polarization combination (this figure and the following one). (Reproduced from Sato *et al*., 2001, with permission from the American Physical Society. © 2001.)

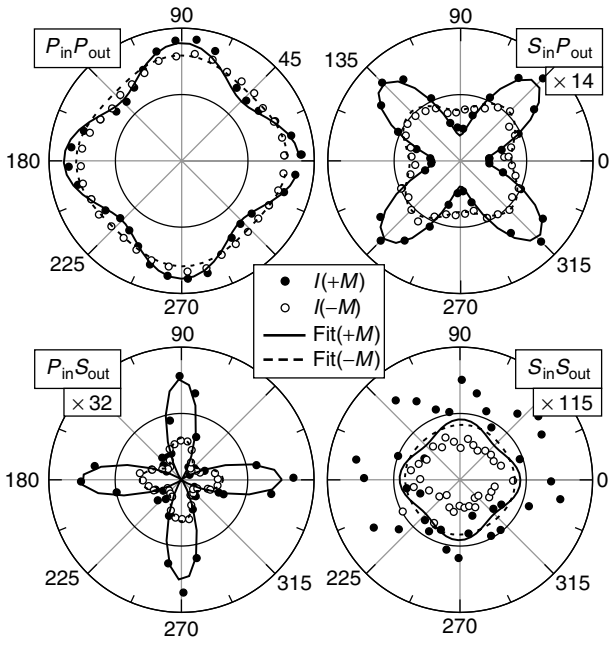

Figure 17. Rotational anisotropy curves for the sample with single layer thickness $x = 15$ monolayers in transversal geometry. (Reproduced from Sato *et al*., 2001, with permission from the American Physical Society. © 2001.)

to these signals (see subsequent text). Even the weakest $S_{in}S_{out}$−curve shows a clear fourfold symmetry pattern.

Usually, an analysis of MSHG results (Pan, Wei and Shen, 1989; Wierenga, Prins and Rasing, 1995; Hübner and Bennemann, 1989) is performed assuming that the top surface and buried interfaces are the only sources of the nonlinear MO response. Their nonlinearity is described in terms of the effective surface/interface dipole-like nonlinear susceptibility $\chi^{(2)}(\mathbf{M})$, which is a third rank tensor. Such contribution yields the azimuthal patterns described by the following formulae (Sato *et al*., 2001):

$$\begin{aligned}
E_{2\omega}^{p,p}(\phi, \pm\mathbf{M}_l) &= A^{p,p} \pm C^{p,p} \sin 4\phi, \\
E_{2\omega}^{s,p}(\phi, \pm\mathbf{M}_l) &= A^{s,p} \pm C^{s,p} \sin 4\phi, \\
E_{2\omega}^{p,s}(\phi, \pm\mathbf{M}_l) &= \pm A^{p,s} \pm B^{p,s} \cos 4\phi, \\
E_{2\omega}^{s,s}(\phi, \pm\mathbf{M}_l) &= \pm A^{s,s} \pm B^{s,s} \cos 4\phi
\end{aligned} \tag{20}$$

where the ± sign indicates those terms which change sign upon magnetization reversal, A, B and C are independent of ϕ and the direction of the longitudinal magnetization $\mathbf{M}_l$. Note that the light intensity is related to the field via $I_{2\omega}^{\alpha,\beta} = c/(2\pi)|E_{2\omega}^{\alpha,\beta}|^2$.

However, these patterns do not yield any effect of magnetization reversal for the $S_{in}S_{out}$ and $P_{in}S_{out}$ MSHG intensity, in contrast to the experimental observation shown in Figures 16 and 17. They are also unable to properly describe the patterns for the other two polarization combinations (see Figure 16, dotted lines on the plots for $P_{in}P_{out}$ and $S_{in}P_{out}$ polarization combinations; also in this case, the equations are not able to fit the magnetic contrast because of different symmetry pattern, see subsequent text). Therefore, one has to take into account additional anisotropic contributions to the second-order nonlinear response. In particular, the nonlocal (quadrupole-allowed) contribution from the bulk of cubic nonmagnetic metals (Cu, Vollmer, Straub and Kirschner, 1996a; Ag, Koos, Shanon and Richmond, 1993; and Al, Pedersen and Keller, 1989) and semiconductors (Si, Tom, Heinz and Shen, 1983) has been shown to lead to a fourfold anisotropy of SHG at their (100) surfaces. Accounting for this additional contribution modifies the rotational patterns to the following ones

$$\begin{aligned}
E_{2\omega}^{p,p}(\phi, \pm\mathbf{M}_l) &= A^{p,p} + B^{p,p} \cos 4\phi \pm C^{p,p} \sin 4\phi, \\
E_{2\omega}^{s,p}(\phi, \pm\mathbf{M}_l) &= A^{s,p} + B^{s,p} \cos 4\phi \pm C^{s,p} \sin 4\phi, \\
E_{2\omega}^{p,s}(\phi, \pm\mathbf{M}_l) &= \pm A^{p,s} \pm B^{p,s} \cos 4\phi + C^{p,s} \sin 4\phi, \\
E_{2\omega}^{s,s}(\phi, \pm\mathbf{M}_l) &= \pm A^{s,s} \pm B^{s,s} \cos 4\phi + C^{s,s} \sin 4\phi
\end{aligned} \tag{21}$$

Using these equations for the theoretical fits to the experimental data of Figures 16 and 17 showed a good agreement between experiment and theory.

Thus, we have shown that the MSHG response of Fe/Au(001) superlattices shows a strong azimuthal anisotropy in both the MSHG intensity as well as in the nonlinear MO Kerr rotation.

5.3 Quantum well states in ultrathin films

An interesting system where the interfaces play an important role are thin metal layers, where due to the electronic potential discontinuities experienced by electron states at interfaces, the perpendicular wave vector can be quantized, giving rise to resonances in the density of electronic states that are usually referred to as QWS (Ortega and Himpsel, 1992; Segivia, Michel and Ortega, 1996; Suzuki *et al*., 1992; Bruno, Suzuki and Chappert, 1996).

In MSHG experiments, QWS are mostly observed on samples consisting of a transition-metal layer with a thin (often wedge-shaped) noble metal overlayer on top. A strong influence of QWS on the second harmonic intensity as well as on the magnetic asymmetry has been observed when measuring the MSHG response as a function of this noble-metal overlayer thickness. It is nevertheless expected that the MSHG output in such systems is generated mostly at the interfaces, even in the case that QWS's are involved (Luce, Hübner and Bennemann, 1996; van Gelderen, Crampin, Rasing and Inglesfield, 1996; Luce *et al*., 1998).

It is shown that quite different experimental MSHG observations on QWS systems could be explained within the same approach (Luce *et al*., 1998). The main difference happened to come from the number of interfaces contributing to the total response: systems where both the surface and the interface are important, behave different than those with the domination of only one of them. The following two sections separately describe these two systems.

5.3.1 MSHG from Cu/Co/Cu(001) and Cu/Fe/Cu(001) layers

Cu/Co/Cu(001) was the first system showing an extremely strong dependence of the MSHG output on the copper overlayer thickness (Wierenga *et al*., 1995; Vollmer *et al*., 1995). In this study, 10 ML Co grown on Cu(001) was used as a substrate, on which a thin Cu overlayer was epitaxially grown. Figure 18 shows the very strong changes of the magnetic asymmetry as a function of the Cu layer thickness. This magnetic asymmetry oscillates between $+0.6$ and -0.6 in the range of 0–10 ML. As a reference, the dashed line on this figure shows the result of multiple-scattering calculations for

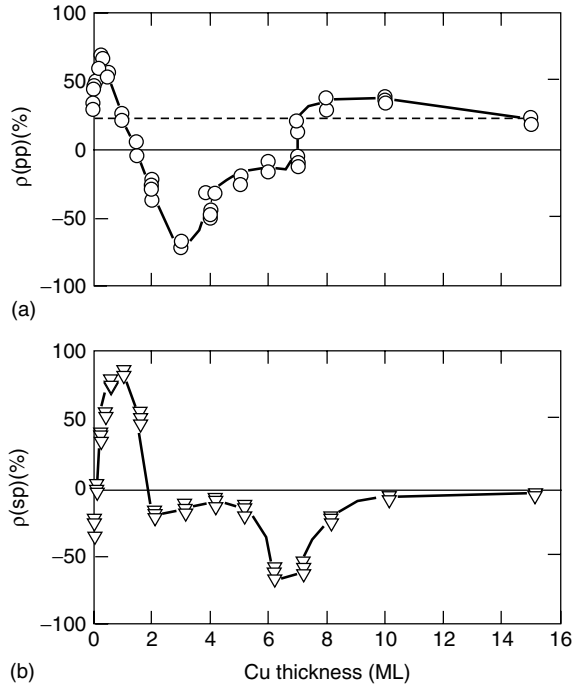

Figure 18. The MSHG asymmetry in $P_{\text{in}}P_{\text{out}}$ (a) and $S_{\text{in}}P_{\text{out}}$ (b) polarization combinations as a function of Cu overlayer thickness on top of a 10 ML Co film on Cu(001). The solid lines are guides to the eye, dashed line is the result of multiple-scattering calculations. (Reproduced from Wierenga *et al*., 1995, with permission from the American Physical Society. © 1995.)

the same system. Obviously the observed MSHG behavior is not of optical but rather electronic origin. Ortega and Himpsel have studied the same system (Ortega and Himpsel, 1992) and found an oscillating behavior of the density of states at the Fermi surface as a function of the Cu film thickness and observed an oscillation period of 5.5 ML. Oscillations of period 2.3 ML can be attributed to QWS as well.

The experimental results seem to indicate that these finite size effects of the Cu film which modulate the electronic structure at the interface can be seen by SHG, in both the magnetic and nonmagnetic parts (see Vollmer *et al*., 1995). It is, however, not clear what is the origin of the observed oscillations. There is no direct relation to the oscillation periods observed for interlayer coupling because not only electronic states close to the Fermi energy contribute but more or less all states within $\pm 2\hbar\omega$ around the Fermi energy. The situation can be described similarly to the case of the linear Kerr effect (Bruno, Suzuki and Chappert, 1996). Optical two-photon transitions from the Cu $3d$ band into the quantized Cu $4s$ band are resonantly enhanced if the energy difference between a discrete d-band state and an s-band state equals the energy of an SH photon. This is schematically illustrated in Figure 19. For films of finite thickness, k_z is no longer a good quantum number and the

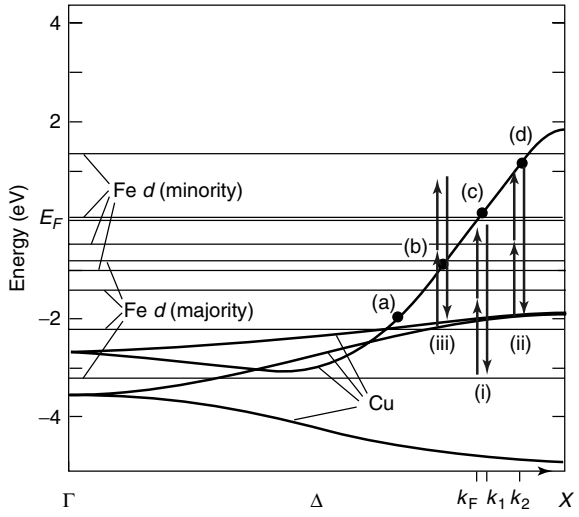

Figure 19. Illustration of the generation of SHG oscillations due to QWS. The electronic structure refers to the case of a *x* Cu/Fe/Cu(001) system. Only the rightmost QWS of a 12 ML Cu film are drawn (solid dots). (Reproduced from Luce *et al*., 1998, with permission from the American Physical Society. © 1998.)

continuous bulk bands along the k_z direction split up into a set of discrete levels, QWS, indicated by dots in the figure. The possible resonant transitions for a given wavelength are also indicated in the figure by vertical arrows. If the thickness of the film is increased, the QWS is moved more toward the X point and the optical transition becomes less resonant. Therefore, from this picture, a maximum of SHG intensity can be expected for the given film thickness D. At the thicknesses of $2D$, $3D$, and so on, there will be again a resonant optical transition into a QWS resulting in a variation of the SHG intensity with a period of D.

Another possible mechanism is related to the appearance of a new final state, due to the change in the film thickness. Each time a QWS shifts though the Fermi energy, it becomes a new possible final state. Generally speaking, this transition is nonresonant for the given wavelength but nevertheless contributes to the total signal. Because this kind of optical transition is related to the Fermi energy, a periodic SHG intensity oscillation with the same period observed for the interlayer coupling is expected.

Thus the periodicity with layer thickness in transitions of the second kind is independent of the photon energy while the period of the first kind of transitions is strongly dependent on it.

As is obvious from the figure, if only a few dominant optical transitions occur, the k selectivity of the optical response is optimal, and the SHG oscillations will be most pronounced. Of course, the strength of the absolute signal depends further on the joint density of states for optical transitions. In the case of a ferromagnetic spacer layer between the substrate and the overlayer film, resonant transitions for minority and majority electrons are possible at different overlayer thicknesses due to the spin-split d states. Thus a phase shift for the $I(+M)$ and $I(-M)$ signals occur. Consequently, one may observe an oscillatory magnetic contrast in the SHG response though a nonmagnetic overlayer is studied.

5.3.2 *Au/Co(0001)/Au(111) system: double oscillation period*

In another case of a QWS system, the interference effects play an essential role in the MSHG response, so that even the oscillatory period can be changed (Kirilyuk, Rasing, Mégy and Beauvillain, 1996). This would require that the primary contribution to $\chi^{(2)}$ comes from the overlayer itself rather than from the (magnetic) substrate. As the total response is the result of interference between the two contributions, the relative phase between the SH waves coming from two different interfaces will be important. This implies in fact that also *the parity* of the QWS wave function may influence the SHG response. Using for simplicity $|\chi^s_{ijm}(2\omega)| \approx |\chi^i_{ijm}(2\omega)|$, one gets

$$I(2\omega) \approx 2|\chi^s_{ijm}(2\omega)|^2 + 2\chi^s_{ijm}(2\omega)\chi^i_{ijm}(2\omega) \qquad (22)$$

For equally weighted contributions one gets obviously a perfect cancellation of the thickness-dependent $\chi(2\omega)$, if the resultant phase of the product of $\chi^s_{ijm}(2\omega)\chi^i_{ijm}(2\omega)$ is -1, like for inversion symmetric films. This may result from the parity of the QWS. For example, if for increasing film thickness d the first unoccupied QWS close to the Fermi energy E_F, which sets the oscillation period, has even parity and if at the interface no phase shift of π occurs, then no SHG results. Thus, in the case where the symmetry of the QWS regulates $I(2\omega, d)$, one should observe in SHG a pronounced period doubling of the oscillation period, since only the QWS with odd parity cause oscillations.

This idea was experimentally verified on step-shaped wedges of Au(111) or Cu(111) epitaxially grown on top of thin (5–20 ML) Co(0001) films on a Au(111) substrate. The copper wedge was covered by 10 ML of gold for protection. The Co films were also grown as steps, with a few different thicknesses. Because of the strong interface-induced perpendicular magnetic anisotropy in this system, it was possible to use different (polar or transversal) MO configurations, depending on the Co thickness.

Figure 20(a) shows that the generated total SH intensity exhibits a strongly oscillatory behavior as a function of the gold overlayer thickness that can be very well described by damped cosines. The slight change of the observed

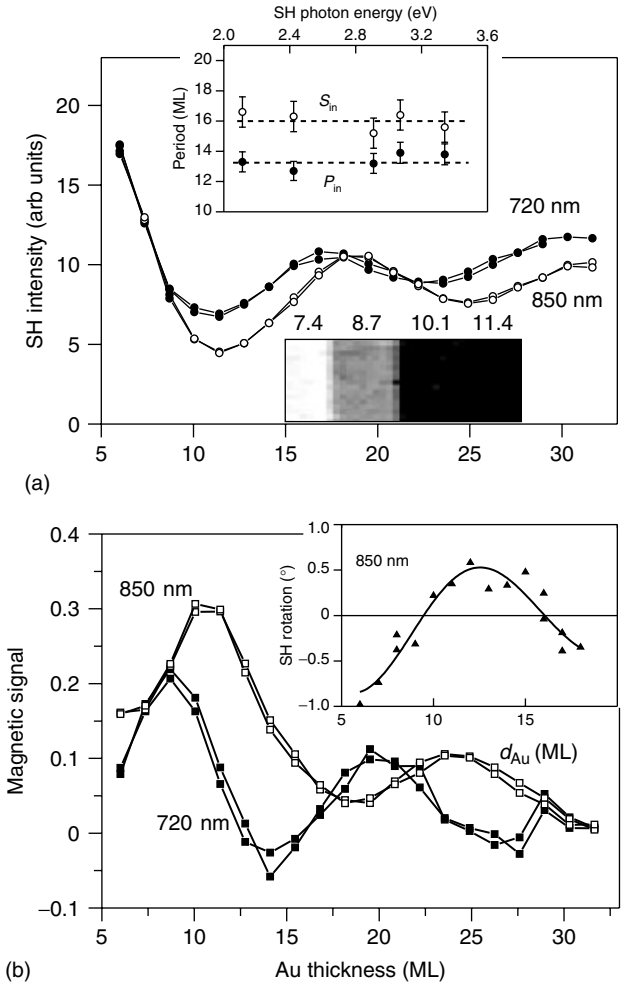

Figure 20. (a) SHG intensity ($P_{in}P_{out}$) as a function of the Au(111) overlayer thickness on a 20 ML thick Co film. Inset shows a photon energy dependence of the oscillation periods for $P_{in}P_{out}$ and $S_{in}P_{out}$ polarization combinations. (b) MSHG asymmetry as a function of the gold layer thickness. (Reproduced from Kirilyuk *et al.*, 1996, with permission from the American Physical Society. © 1996.)

periods for the curves measured with 720 and 850 nm wavelengths appeared not to be significant: in the total range of 720–1170 nm the period is constant ($\Lambda \approx 13$–14 ML) within 10–15% (see inset in Figure 20a).

The same kind of oscillatory behavior has also been found for the magnetization dependent SHG. Figure 20(b) shows the magnetic asymmetry for a 20 ML thick Co layer, while the SH polarization rotation is plotted in the inset for the perpendicularly magnetized 6 ML Co film. All the observed periods are basically the same as given above for the intensities. However, the shape of these curves is more complicated than simple damped oscillations. This is due to the fact that the magnetic signals are calculated as a ratio of different oscillatory terms (see equation (11)).

Linear MOKE studies performed on the same kind of samples (Mégy *et al.*, 1995) reported oscillations of the Kerr rotation with the much shorter period of 7.7 ML. This strong difference with MSHG might be assigned to the different wavelength region used for the MOKE experiments (540–630 nm). To fill this gap, MOKE measurements were done using the same Ti-Sapphire laser at $\lambda = 850$ nm. This resulted in a period of 7 ± 1 ML. That is, in the case of $\lambda_{MOKE} = \lambda_{SH}$, the total excitation energy was equal for the two experiments. Also the situation $2\lambda_{MOKE} = \lambda_{SH}$, was investigated, in order to study possible effects of initial and intermediate or intermediate and final states. However, again the observed MSHG period was *twice* as large as the period detected with MOKE. Hence the difference in periods cannot be explained by the different total excitation energy ($\hbar\omega$ vs $2\hbar\omega$).

It has been already discussed (see Section 5), that for a thin film the corresponding tensor elements on the opposite film interfaces are related to each other by a mirror symmetry and therefore they differ only by a phase factor of 180°. Hence the resulting total SHG signal arises from the competition between the signals from the two film interfaces that mostly cancel each other and does only depend on the difference in their local fields. In other words, the nonlinear polarization $\mathbf{P}(2\omega)$ is an *odd* function with respect to the film symmetry plane.

Within this approach, the influence of QWS on MSHG would be largely cancelled too because every QWS contributes symmetrically (via its local density of states) to the χ tensor elements of both interfaces. Even for the nonsymmetric geometry (like our case – Co/Au and Au/air interfaces) one may still argue that the corresponding electron wave functions are rather symmetric once they form a confined state.

Following these arguments, one may expect no QWS effects on the MSHG signal at all! This is contrary to the experimental observations of a total domination of QWS in the SHG response. That one does observe a (rather strong) signal is partly related to the fact that the local electromagnetic fields at the two interfaces are different (this follows from Fresnel formulae) and partly from the (a-) symmetry of the QWS wave functions. In a simple textbook picture, the confined QWS have alternating odd and even character, that is, the asymmetry of the QWS wave functions is repeated with the double period. This asymmetry can be expressed as a relative phase factor between the two QWS interface contributions (the Co/Au and the Au/air). Because the total SHG response results from a *coherent* superposition of these interface contributions, it will also display a periodic behavior with the double period, despite of the fact that the individual contributions oscillate with the single period. Because the linear MOKE experiment only probes the Co/Au

region, MOKE indeed shows the single period. It should be stressed that it is the wave function phase at a given interface which plays a crucial role and, without interference, the effect would be unobservable.

To test these ideas, the total MSHG signal was decomposed into the contributions from different interfaces, as described in Section 5.1. For this purpose, first the angle-of-incidence dependencies of the MSHG signals were measured for each gold overlayer thickness value. Next, a fit of these data was performed, using the $\chi^{(2)}$ tensor elements as fitting parameters in $S_{\text{in}}P_{\text{out}}$ polarization combination. Figure 21(a) shows the individual $\chi^{(2)}$-components of the two gold layer interfaces as a function of the film thickness, displaying an oscillatory behavior with a mean period of around 6–8 ML that is, the same period as observed by MOKE. However, the resulting SHG intensity and magnetic signal perfectly fit the experimentally observed slowly oscillating behavior with the double period (see Figure 21b). This means that while the local density of states and hence the $\chi^{(2)}$-tensor at each interface show the standard QWS period, the resulting total response includes also the phase between the corresponding elements and therefore allows a slower variation. This is possible, of course, only because the interfaces are not independent as soon as every QWS wave function is located at both interfaces simultaneously. Although it is not exactly correct to talk about 'contributions of different interfaces' in such conditions, it is still possible to formally use this model. One should mention here that the $\chi^{(2)}$-components of different interfaces may be determined accurately only relative to each other. Their absolute values, in contrary, may contain rather large systematic errors. However, the derived fast-oscillatory behavior of the $\chi^{(2)}$-tensor is obtained from the best fit of the (slowly oscillating) experimental data, and may be considered as a strong support of the model.

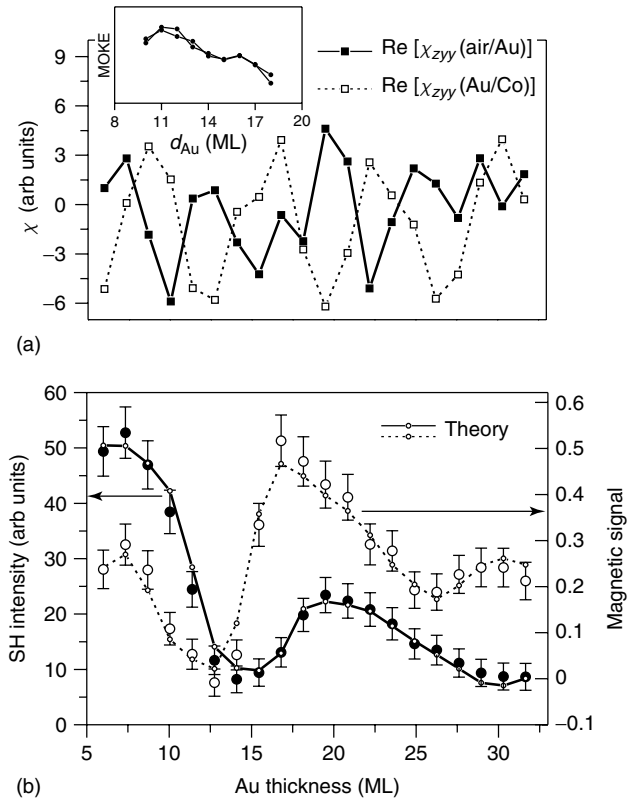

Figure 21. (a) Tensor components of different Au(111) film interfaces as a function of the film thickness. Inset shows the linear MOKE ellipticity for comparison. (b) Theoretical fit of the SHG intensity (solid dots) and MSHG asymmetry (open dots) using the parameters shown in (a). (Reproduced from Kirilyuk *et al.*, 1996, with permission from the American Physical Society. © 1996.)

As for the linear MOKE technique, although it has 'bulk' sensitivity, the oscillatory part of the signal is provided by the narrow region along the Au/Co interface, where the spin-polarization of electrons is affected the most. Therefore, it is related to the local density of states at this interface only, which oscillates with a single QWS period.

Very similar results were obtained for Cu(111) and Ag(111) overlayers, with corresponding periods of 12–14 ML. The main difference was the observed amplitude of the intensity oscillations for both of these metals which was much smaller than for Au(111). The recently detected linear MOKE oscillations on Cu(111) (Bounouh *et al.*, 1997) showed a period of 7 ML. Hence, the period doubling is confirmed also for another system. From the experimental point of view, it would be very interesting to study also a *magnetic* thin film as well as to increase the spectral region of measurements.

5.4 Magnetization reversal at the interfaces

In the discussion of thin magnetic films and multilayers, interfaces play an often dominating role determining the magnetization reversal behavior. To find out the behavior of the magnetization at the film interfaces as opposed to that in the middle of the film, MSHG can be used in combination with the linear MOKE technique. The magnetization reversal hysteresis is thus measured simultaneously, from the same spot on the sample (Zhao *et al.*, 2005). Figure 22 shows an example of such experiment on an amorphous TbFeCo layers that have recently attracted attention as possible MO hybrid-recording media (Awano *et al.*, 2000). MOKE and MSHG hysteresis loops were measured for different sample temperatures across the Curie point $T_C = 465$ K. A clear difference between the results of the two methods was observed that can only be related to the different magnetic behavior in the bulk and at the interfaces of the film. Closer

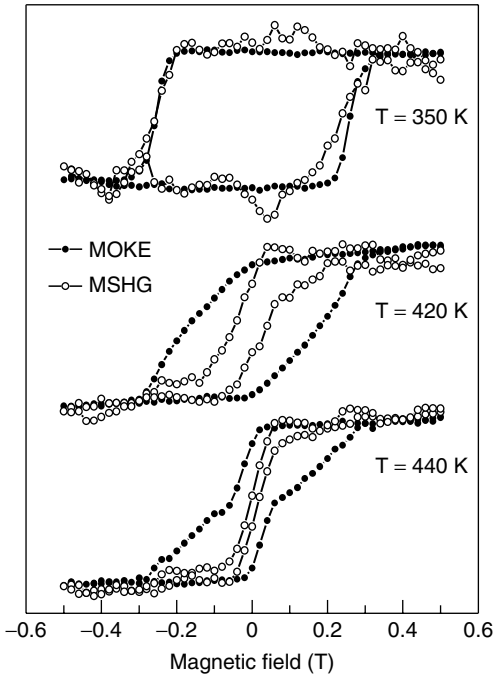

Figure 22. MOKE and MSHG hysteresis loops from a TbFeCo MO recording layer for three different sample temperatures.

inspection of the loops in Figure 22 seems to indicate that the reversal starts at the interfaces but stays somehow pinned in the bulk, thus slowing down the bulk reversal.

6 CONCLUSION

This chapter revises the recent progress and achieved milestones in the newly developed area or nonlinear magneto-optics. By no means pretending of being comprehensive, it focuses on the application of MSHG to *surface and interface* phenomena, such as enhanced magnetic moments, electronic surface states, and correlation between interface structure and magnetism. The extreme surface/interface sensitivity of the MSHG technique manifests itself in every of the considered examples.

On the other hand, various interesting developments of MSHG are not mentioned. Among them is the very extensive work on nonlinear magneto-optics in antiferromagnetic dielectrics (Fiebig *et al*., 2000, 2001; Feibig, Degenhardt and Pisarev, 2002). In addition, one should mention the attempts to study MSHG effects in complex systems such as magnetic photonic crystals (Lyubchanskii *et al*., 2003) and nanoparticles (Aktsipetrov, 2002), as well as a discussion of possible MSHG effects in vacuum (Ding and Kaplan, 1989).

Another area where the MSHG technique is used quite extensively, is for the pump-probe studies of ultrafast magnetization dynamics (Güdde *et al*., 1999; Regensburger, Vollmer and Kirschner, 2000; Silva, Pufall and Kabos, 2002; Gerrits, Hohlfeld, van den Berg and Rasing, 2002). Here, MSHG has some advantage over MOKE, because (i) owing to large *odd* components of the nonlinear optical tensor, different components of **M** can be easily separated, and (ii) it is also quite straightforward to distinguish the electron-temperature relaxation effects from those owing to the transient magnetization behavior, by analyzing the various tensor components. In addition, the MO probe of the ultrafast magnetization dynamics can only be done with femtosecond laser pulses, which makes the measurements of the MSHG response as easy as that of the MOKE. The particular direction where the MSHG probe can be especially interesting is the observation of the *magnetization dynamics at surfaces and interfaces*. The spin-orbit coupling at interfaces would become accessible with this approach.

Investigation of Spin Waves and Spin Dynamics by Optical Techniques

Burkard Hillebrands and Jaroslav Hamrle
Technische Universität Kaiserslautern, Kaiserslautern, Germany

1 INTRODUCTION

Dynamic properties and the eigenmode spectrum of magnetic objects have become a focus of interest in modern magnetism. The fundamentals of this area are covered in several chapters in this handbook [1].

Progress in research in this interesting field is largely determined by the availability of suitable experimental tools. A wide range of tools exists; most of them use optic and electric properties. Here we confine the discussion to optical techniques.

This chapter aims at providing an introduction into the principle of operation and the range of applicability. We discuss time-resolved Kerr effect magnetometry, Brillouin light scattering (BLS) spectroscopy, and second-harmonic generation (SHG) techniques. Emphasis is laid on the introduction and discussion of the various tools and the presentation of characteristic applications.

Optical techniques for the study of spin waves and spin dynamics can be roughly categorized into two fundamental classes. Frequency-domain techniques provide a spectroscopic approach and issues such as the dispersion of spin-wave modes can be directly obtained. The second class comprises techniques working in the time domain, where the magnetic response of a sample is probed, usually stroboscopically, as a function of a stimulating pumping signal, and, in a narrow time window, as a function of the time delay to the excitation. Some experiments have been developed, which combine both classes, such as time-resolved BLS spectroscopy.

In Section 2 the background in spin dynamics and spin−wave modes is sketched. Section 3 contains an introduction to various experimental techniques, such as BLS and its variants, time-resolved Kerr effect microscopy, and SHG techniques. The applications of these techniques to various physical problems are addressed in Section 4 with several examples. In Section 5 conclusions are given.

2 BACKGROUND IN SPIN DYNAMICS AND SPIN-WAVE MODES

The fundamentals of spin dynamics and spin waves are presented in several chapters of this handbook (see also Hillebrands, 2003; Hillebrands and Thiaville, 2006). Here we summarize this background and list the equations necessary to understand the experimental optical techniques.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

In a classical picture, the magnetization precesses around the internal field, described by the Landau–Lifshitz torque equation of motion:

$$\frac{1}{|\gamma|}\frac{\partial \vec{M}}{\partial t} = -\vec{M} \times \vec{H}_{\text{eff}} \tag{1}$$

where $\gamma = \gamma_e g/2$ is the gyromagnetic ratio, $\gamma_e = -1.759 \cdot 10^7\,\text{Hz Oe}^{-1}$ is the value of γ for the free electron and g is the spectroscopic splitting factor. We neglect damping effects. The effective magnetic field acting on the magnetization, $\vec{H}_{\text{eff}}$, is given by

$$\vec{H}_{\text{eff}} = \vec{H}_0 + \frac{2A}{M_s^2}\nabla^2\vec{M} - \frac{1}{M_s}\vec{\nabla}_{\vec{\alpha}} g_{\text{vol}} + \vec{H}_d + \vec{h} \tag{2}$$

On the right-hand side, the first term is the external applied field $\vec{H}_0$. The second term accounts for the exchange interaction, where A is the exchange stiffness constant and M_s is the saturated magnetization. The third term accounts for magnetic anisotropies with the enthalpy density g_{vol} describing the volume anisotropy and the gradient operator $\vec{\nabla}_{\vec{\alpha}}$ for which the differentiation variables are the components of the unit vector $\vec{\alpha}$ pointing into the direction of the saturation magnetization $\vec{M}_s$. The fourth term describes the dipolar stray field. In the case of an in-plane magnetized infinite film, the stray field is zero, $\vec{H}_d = 0$, whereas in the case of an out-of-plane magnetized film it is $\vec{H}_d = -4\pi M_s \hat{n}$ (in CGS units), $\hat{n}$ with pointing into the normal direction of the film surface. The last term $\vec{h}$ accounts for the fluctuating field generated by the precessing moments. It has its origin in the dipolar and exchange interaction.

In a ferromagnetic system, the dipolar and exchange interactions result in the appearance of spin-wave modes. An example of the spin-wave mode is shown schematically in Figure 1. The displayed mode travels from the bottom left to the upper right corner of the square. Phase fronts, characterized by the same precession phase (dashed line in Figure 1) and the wavelength λ can easily be identified as indicated in the figure.

Inspecting equations (1) and (2) it is evident that both dipolar and exchange interactions determine the mode properties. In finite objects such as films, squares, circles, and so on, confinement and localization effects appear and modify the dispension of the spin waves. The mode properties of such confined spin waves are characterized by quantization conditions for the wave vector and by boundary conditions at the sidewalls of the object.

2.1 Exchange and dipolar modes in films

Spin waves investigated by optical techniques usually have wavelengths comparable to or larger than the wavelength of the used light. Thus interatomic distances are small compared to the wavelength, and we can apply continuum models. A good introduction is given in Hillebrands (2000). The description in such a classical picture describe most of the experimental observations. Quantum-mechanical corrections must be taken into account for films thinner than a few monolayers, but here a phenomenological correction of the demagnetizing field still allows for using a classic description (Stamps and Hillebrands, 1991).

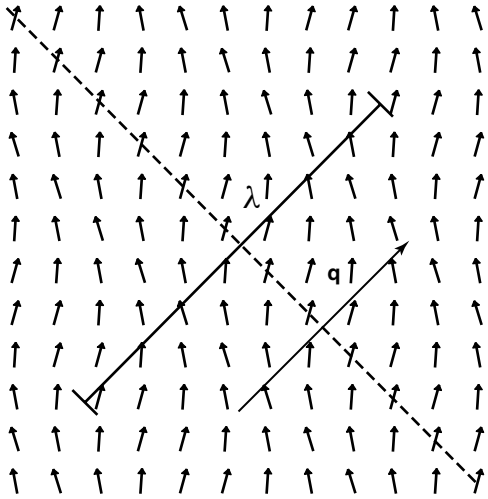

Figure 1. Sketch of a spin wave. The dashed line indicates a phase front.

We need to solve the Landau–Lifshitz torque equation of motion (equation (1)), together with the magnetostatic Maxwell equations,

$$\vec{\nabla} \times \vec{H} = 0 \tag{3}$$

$$\vec{\nabla} \cdot (\vec{H} + 4\pi\vec{M}_s) = 0 \tag{4}$$

From the equation of motion, (equation (1)), six independent partial wave solutions are obtained when exchange interaction is taken into account.

In the presence of surfaces and interfaces, boundary conditions must be fulfilled by a suitable superposition of the partial wave solutions. These are the Maxwell boundary conditions as well as a boundary condition derived from the equation of motion (equation (1)). For the surface of a film or an interface to a nonmagnetic layer this is the so-called Rado–Weertman boundary condition (Rado and Weertman, 1959; Gurevich and Melkov, 1996)

$$\vec{M} \times \left[\vec{\nabla}_{\vec{\alpha}}\sigma_{\text{inter}} - \frac{2A}{M_s}\frac{\partial \vec{M}}{\partial n}\right]\Bigg|_{\text{interface}} = 0 \tag{5}$$

Equation (5) describes the balances of torques acting on the interface where σ_{inter} is the enthalpy density describing a

magnetic interface anisotropy. It is evident that interface anisotropies provide an additional torque to the moments at the interface.

For magnetic films, a number of different spin-wave modes appear, depending on the geometry of the applied field and the wave vector of the spin wave. Both the exchange interaction and the dipolar interaction contribute to the dispersion. However, depending on the specific mode, one or the other can dominate the frequency.

If the wavelength of a spin-wave mode is very short (i.e., the wave vector is very large), exchange interaction dominates the frequency. In bulk materials, these so called modes. Their dispersion is approximately quadratic, that is, proportional to the square of the wave vector,

$$\frac{\omega(q)}{\gamma} \approx H + Dq^2 \tag{6}$$

with $D = 2A/M_s$ denoting the so-called stiffness constant. In films, perpendicular standing exchange modes, also called perpendicular standing spin waves (PSSW), are observed. Here the exchange modes propagate in a direction perpendicular to the film and form a standing wave pattern. The wave vector perpendicular to the film, $q_\perp$, is quantized due to the confinement. In case of both pinned ($\sigma_{\text{inter}} = \infty$) and unpinned ($\sigma_{\text{inter}} = 0$) boundary conditions, the perpendicular wave vector reads $q_{\perp,l} = l(\pi/d)$ where d is the film thickness and $l = 0, 1, 2 \ldots$ for unpinned boundary conditions. In case of a general boundary condition, the expression of $q_{\perp,l}$ is more complicated (Gurevich and Melkov, 1996).

Spin-wave modes investigated by optical techniques and traveling in the film plane usually have a wave vector in the range between the wavelength of the used light and many micrometers, which is much larger than interatomic distances. Thus, exchange interaction is weak and these modes are often governed by dipolar interactions. This can be easily understood by considering the oscillating dipole fields associated with the precessing moments. The local field strength increases with the wavelength as more moments locally contribute to the stray field.

The spin-wave dispersion depends on the direction of the wave vector, $\vec{q}$, and the direction of the magnetization vector, $\vec{M}$, with respect to the film orientation. Figure 2 illustrates the various modes in the so-called magnetostatic limit, where exchange interaction can be neglected. Please note that changes in geometry result in large changes in frequency as well as mode propagation characteristics.

If the magnetization and the wave vector both lie in the film plane and form an angle of $\varphi \approx 90^\circ$, then in the case of negligible anisotropy, the dispersion of the spin waves is

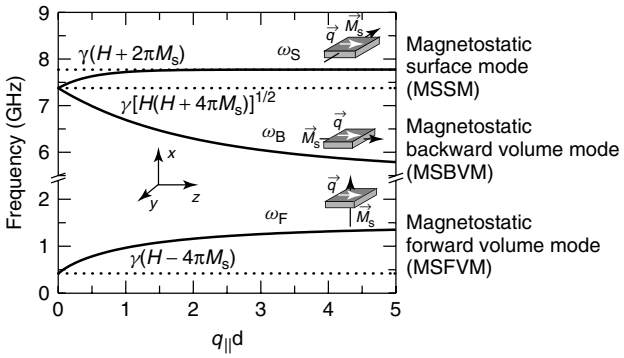

Figure 2. Typology of spin-wave modes as a function of the directions of the magnetization, $\vec{M}_s$, and the wave vector $\vec{q}$ in the dipolar limit. ω_S is the frequency of the surface spin wave when $\vec{q} \perp \vec{M}_s$ and $\vec{q}$, $\vec{M}_s$ lie in the film plane (MSSM, magnetostatic surface mode). ω_B, ω_F are the frequencies of the volume spin waves, with the wave vector parallel (MSBVM, magnetostatic backward volume mode) and perpendicular (MSFVM, magnetostatic forward volume mode) to the sample magnetization $\vec{M}_s$, respectively. Calculated for a 1000-nm-thick Yttrium iron garnet (YIG) film ($4\pi M_s = 1750\,\text{G}$, $\gamma = 17.6\,\text{MHz Oe}^{-1}$, $A = 1.6 \times 10^{-7}\,\text{erg cm}^{-1}$) at $H_0 = 1900\,\text{Oe}$ parallel to $\vec{M}_s$. (Reproduced from B. Hillebrands *et al*., 2006, with permission from Springer-Verlag. © 2006.)

given by Damon and Eshbach (1961):

$$\left(\frac{\omega_S(q)}{\gamma}\right)^2 = H_0\,(H_0 + 4\pi M_s \sin\varphi) + (2\pi M_s)^2\left(1 - e^{-2q_\parallel d}\right) \tag{7}$$

where $q_\parallel$ is the in-plane component of the wave vector, $q^2 = q_\parallel^2 + q_{\perp,l}^2$ and H_0 is the applied magnetic field. This spin-wave mode is called a *magnetostatic surface mode* (MSSM) or, sometimes, a Damon–Eshbach mode.

In the presence of in-plane anisotropy, the direction of magnetization is defined by the energy minimum of the total magnetic enthalpy density

$$g_{\text{tot}} = g_{\text{eff}} - \vec{M}_s \vec{H}_0 \tag{8}$$

which is the sum of the enthalpy density of the magnetic anisotropy and the Zeeman energy. The direction of $\vec{M}_s$ might deviate from the direction of the applied field, $\vec{H}_0$.

If the wave vector and the magnetization are collinear and both lie in the film plane, we obtain the so-called magnetostatic backward volume modes (MSBVM). The slope of the corresponding dispersion and thus the group velocity of these modes is negative, that is, the group and the phase velocity point in opposite directions, giving this mode its name (see ω_B in Figure 2). Without anisotropies and in the long wavelength limit ($q_\parallel d < 1$), the dispersion is given by Demokritov, Hillebrands and Slavin (2001), Kalinikos and

Slavin (1986), and MacDonald (1951)

$$\left(\frac{\omega_{\mathrm{B}}(q)}{\gamma}\right)^2 = H_0\left[H_0 + 4\pi M_{\mathrm{s}}\left(\frac{1-e^{-q_\parallel d}}{q_\parallel d}\right)\right] \tag{9}$$

The qualitatively different dispersions of the magnetostatic surface wave (equation (7)) and the magnetostatic backward volume wave (equation (9)) can be understood as follows: We assume that the film plane is the (y, z) plane. A spin wave propagating in the direction $\vec{q}_\parallel$ in the film plane can be written as

$$\begin{aligned}\vec{M}(\vec{r}, t) &= \begin{pmatrix} 0 \\ 0 \\ M_{\mathrm{s}} \end{pmatrix} + \begin{pmatrix} m_x \\ m_y \\ 0 \end{pmatrix} e^{\mathrm{i}(\omega t - \vec{q}_\parallel \vec{r})} \\ &= \vec{M}_{\mathrm{s}} + \vec{m} e^{\mathrm{i}(\omega t - \vec{q}_\parallel \vec{r})}\end{aligned} \tag{10}$$

with $\vec{M}_{\mathrm{s}} \perp \vec{m}$ and $\left|\vec{M}_{\mathrm{s}}\right| \gg |\vec{m}|$. The out-of-plane component m_x will create dynamic surface charges which alone lead to a reduction of energy (frequency) with decrease of wavelength (or increase of wave vector). However, there exists also an additional energy term based on the magnetic volume charges $\rho_M = -4\pi\nabla \cdot \vec{M} = 4\pi i \vec{q}_\parallel \cdot \vec{m} \exp[i(\omega t - \vec{q}_\parallel \vec{r})]$. For $\vec{q}_\parallel \parallel \vec{M}$ (magnetostatic backward volume waves) it is $\vec{q}_\parallel \cdot \vec{m} = 0$ and thus the volume charges are absent. Hence the only term remaining is the energy based on the surface charges and therefore the dispersion is negative. Contrarily, for $\vec{q}_\parallel \perp \vec{M}$ (surface waves) it is $\vec{q}_\parallel \cdot \vec{m} \neq 0$ and, therefore, this additional energy term increases in frequency with increasing wave vector, and therefore the dispersion is positive.

In most cases, the dispersion can only be calculated numerically; (Hillebrands, 2000; Hillebrands, 1990; Heinrich and Cochran, 1993). A good description of the algorithm is given in Stamps and Hillebrands (1991) for ultrathin films, that is, when the product of the wave vector and the film thickness is small compared to unity, $q_\parallel d \ll 1$. An approximate formula can be used (Stamps and Hillebrands, 1991):

$$\begin{aligned}\left(\frac{\omega(q)}{\gamma}\right)^2 = &\left(\frac{1}{M_{\mathrm{s}}}\frac{\partial^2 g_{\mathrm{eff}}}{\partial\theta^2} + H_0\cos(\varphi - \varphi_H)\right. \\ &\left. + \frac{2A}{M_{\mathrm{s}}}q^2 + 4\pi M_{\mathrm{s}} f\left(1 - \frac{1}{2}q_\parallel d\right)\right) \\ &\times\left(\frac{1}{M_{\mathrm{s}}}\frac{\partial^2 g_{\mathrm{eff}}}{\partial\varphi^2} + H_0\cos(\varphi - \varphi_H)\right. \\ &\left. + \frac{2A}{M_{\mathrm{s}}}q^2 + 2\pi M_{\mathrm{s}} f q_\parallel d\sin^2(\varphi - \varphi_q)\right) \\ &- \frac{1}{M_{\mathrm{s}}^2}\left(\frac{\partial^2 g_{\mathrm{eff}}}{\partial\theta\partial\varphi}\right)^2\end{aligned} \tag{11}$$

with θ and φ denoting the polar and azimuthal angle of the magnetization (using a conventional spherical coordinate system) the saturation magnetization M_{s}, the applied magnetic field H_0, the exchange constant A, the demagnetizing factor f (which may deviate from 1 for very thin films, see (Cochran, Heinrich and Arrott, 1986; Heinrich *et al*., 1988)), and the film thickness d. The angles φ, φ_H, φ_q indicate the directions of magnetization of the external field and of the wave vector with respect to an in-plane reference direction, which is usually chosen along a high-symmetry crystallographic axis. In equation (11) the directional derivatives of the effective anisotropy enthalpy density, g_{eff}, are written as derivatives with respect to the polar and azimuthal angles.

Equation (11) illustrates the applicability of investigating spin waves to determine magnetic anisotropies. The basic underlying equation, the Landau–Lifshitz equation, (equation (1)) is a torque equation and, correspondingly, the second derivatives of the anisotropy enthalpy, which describe torques, enter equation (11).

In the so-called magnetostatic forward volume mode (MSFVM) geometry, the magnetization is perpendicular to the film. The static internal field inside the film can be written as an applied field reduced by a static film magnetization, $H_0 - 4\pi M_{\mathrm{s}}$. Without anisotropies and in the long wavelength limit, the dispersion is given by Kalinikos and Slavin (1986) and Demokritov, Hillebrands and Slavin (2001)

$$\begin{aligned}\left(\frac{\omega_{\mathrm{F}}(q)}{\gamma}\right)^2 = &(H_0 - 4\pi M_{\mathrm{s}}) \\ &\times\left(H_0 - 4\pi M_{\mathrm{s}}\frac{1-e^{-q_\parallel d}}{q_\parallel d}\right)\end{aligned} \tag{12}$$

For the wave vector range considered here, the exchange interaction can be neglected for systems with a weak stiffness constant $D = 2A/M_{\mathrm{s}}$ such as Yttrium iron garnet (YIG). However, in the case of, for example, permalloy, the stiffness constant is about 20 times larger. Therefore, the contribution of exchange to the dispersion relation is not negligible, although it is still the dipolar interaction that governs the shape of the dispersion. This is presented in Figure 3(a), where dispersion relations of a permalloy film are calculated with and without the exchange contribution. We can see that the presence of exchange adds a contribution $\gamma D q^2$, quadratic in q, as described by equation (6). Owing to this contribution, the MSBVM ω_{B} may gain (from a certain value of $q_\parallel$) a positive slope and therefore both the phase and group velocity point in the same direction.

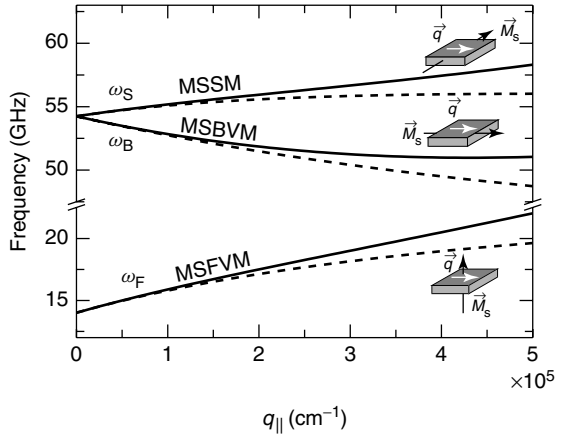

Figure 3. Full lines: The dispersions of a 30-nm thick permalloy film ($4\pi M_s = 10\,\text{kG}$, $\gamma = 17.6\,\text{MHz Oe}^{-1}$, $A = 1.3 \cdot 10^{-6}\,\text{erg cm}^{-1}$) under an applied external magnetic field $H = 15\,\text{kOe}$ parallel to $\vec{M}_s$. Both dipole–dipole and exchange interactions are taken into account. The dashed lines show the dispersions calculated for $A = 0$. ω_S, ω_B, and ω_F are different spin wave modes at different geometries as defined in Figure 2.

2.2 Quantized lateral spin-wave modes and boundary conditions

Of particular interest is the mode spectrum in confined magnetic structures, such as stripes, squares, rectangles, circles, and so on, patterned into a magnetic film. New finite size effects will appear because of the lateral boundaries of these objects. In first approximation, it is useful to address these final size effects by the simple quantization condition:

$$w = n\frac{\lambda_n}{2}; \quad q_{\parallel,n} = \frac{2\pi}{\lambda_n} = \frac{\pi}{w}n \tag{13}$$

where w is the width of the magnetic structure, n is a positive integer, and λ_n is the spin-wave wavelength. This is illustrated in Figure 4. If the magnetization lies statically in the film plane along the structure edge, no stray fields are generated for infinitely extended stripes. However, if the magnetization precesses around this direction, dynamic out-of-plane stray fields appear since the dynamic part of the magnetization has a component perpendicular to the film plane. This is properly taken into account by the Maxwell boundary conditions. In laterally confined structures, the same effect appears at the sidewalls of the objects. In zero-order approximation, we can describe quantized modes using equation (13), but the stray fields at the sidewalls are not considered. They will, however, generate surface torques, since the cross product of the stray field with the surface moments is a torque. This problem can be solved phenomenologically by including a new boundary condition, acting at the lateral edges (Guslienko, Demokritov, Hillebrands and Slavin, 2002; Guslienko and Slavin, 2005).

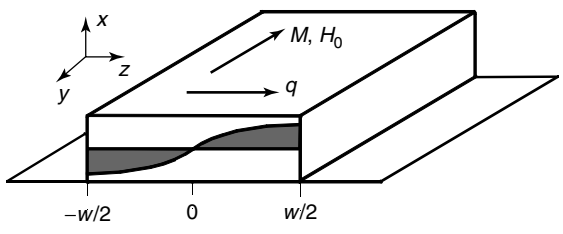

Figure 4. Sketch of a finite object with ($n = 1$) mode. Here n is the mode index and λ_n the corresponding wavelength. We can use these quantized values of the wave vector to evaluate the dispersion equation in first-order approximation.

$$\frac{\partial \vec{m}}{\partial z} + \frac{1}{\xi_D}\vec{m} = 0; \qquad \xi_D = \frac{d}{2\pi}\left(1 + 2\ln\frac{w}{d}\right) \tag{14}$$

with $\vec{m}$ denoting the dynamic part of the magnetization, and d and w the thickness and the width of the object, ($d \ll w$), respectively. Here, z is in-plane direction perpendicular to the edge of the stripe, as sketched in Figure (4). The additional surface torque of the dynamic stray fields is taken into account by the parameter ξ_D.

Finite objects are associated with dipolar stray fields. Unless the objects have an ellipsoidal shape, the internal field is inhomogeneous, and thus we need to discuss the propagation of spin waves in an intrinsically inhomogeneous system. These phenomena are discussed in Section 4.2.2.

3 EXPERIMENTAL TECHNIQUES

In this section we will discuss several optical techniques, which are applied to investigate spin wave and spin dynamic properties.

Two classes of experiments exist. The first class comprises spectroscopic techniques which allow to measure the spin-wave mode spectrum directly. For thin films and patterned structures, this is in particular the BLS spectroscopy. Here, the primary quantity of observation is the frequency of spin waves measured as a function of the wave vector. Another spectroscopic techniques are optical ferromagnetic resonance experiments. Here the fundamental precession mode, the zero wave vector ferromagnetic resonance mode, is excited, often by application of a cw microwave field. The amplitude of the forced magnetization precession is measured stroboscopically. The second class comprises techniques that work on the timescale. Most of these techniques are based on a stroboscopic approach. The sample is excited by a short perturbation, and, with defined time delay, the magnetic response is tested utilizing the magneto-optic Kerr effect

(MOKE) and SHG. For the perturbation, short field pulses or field steps, light pulses, microwave pulses, and so on, can be used. The techniques are discussed in detail in the following.

Other methods involving both spectroscopic and stroboscopic aspects exist. For instance, time-resolved BLS spectroscopy measures the intensity of spin-wave packets; however, in this case the sample is excited with microwave pulses generating spin-wave pulses, whose propagation time is then measured stroboscopically.

3.1 Brillouin light scattering spectroscopy

The fundamental principle of BLS spectroscopy is inelastic scattering of monochromatic, visible light from spin waves (Hillebrands, 2000; Hillebrands and Güntherodt, 1994; Sandercock, 1982). This is illustrated in Figure 5. In a quantum-mechanical picture, a photon of energy $\hbar\omega_L$ and momentum $\vec{q}_L$ creates or annihilates a magnon $(\omega, \vec{q})$, which is the quantum of a spin wave. Consequently, the photon frequency and wave vector are changed. Temporal and translational symmetries correspond to conservation of energy and momentum. If a magnon is created, the scattered photon has the energy $\hbar\omega_L - \hbar\omega$ and momentum $\hbar q_L - \hbar q$. If a magnon is annihilated, the energy of the scattered photon is $\hbar\omega_L + \hbar\omega$ and the momentum is $\hbar q_L + \hbar q$. For finite temperatures ($T \gg \hbar\omega/k_B \approx 5\,\mathrm{K}$) both processes have about the same probability. In a classical description the process can be understood as scattering of light from a propagating phase grating in the dielectric constant generated by the propagating spin wave via spin-orbit coupling. The laser light is Doppler shifted by the frequency of the spin wave, and the periodicity of the phase grating induces a change in the direction of the scattered light. For a detailed discussion see Hillebrands (2000) and references therein.

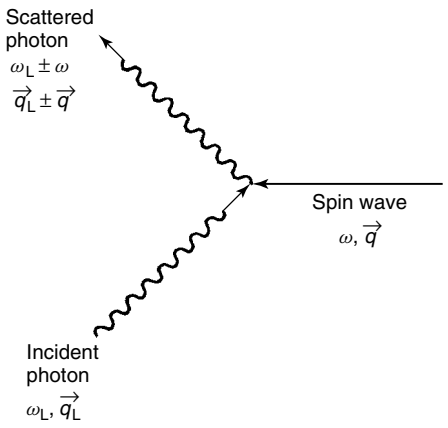

Figure 5. Scattering process of photons from spin-wave excitations (magnons).

For an infinitely extended film, translational invariance exists in the plane of the film. Correspondingly the wave vector components parallel to the film plane are conserved in the scattering process. These components can be varied in an experiment by changing the angle of light incidence. The system is time invariant, and correspondingly the frequency shift measured in the BLS experiments is equal to the frequency of the spin wave.

As BLS is an optical technique, it allows for a local measurement of spin waves with a spatial resolution defined by the diameter of the laser spot. Typically, the spot size is of the order of 40 µm. Techniques have been reported to reduce the diameter down to the optical limit (see Section 3.1.2). BLS can be applied in different environments, such as low and high temperatures, ultrahigh vacuum, and so on.

3.1.1 The Brillouin light scattering setup

A typical BLS setup is shown in Figure 6. Light from a frequency stabilized laser in single mode operation with wavelength λ is focused onto the sample. As a light source a cw laser, such as a solid-state laser or an Ar^+-laser, can be used, a typical linewidth is $\Delta\nu = 20\,\mathrm{MHz}$. From the spin waves, light is inelastically scattered. The direction under which the scattered light is analyzed determines the transferred wave vector in the scattering process and thus the wave vector of the spin wave. Often the backscattering geometry is used because of maximum momentum transfer, in particular for metallic samples, but forward scattering is also applied if spin-wave modes with large wavelengths are investigated and the sample is transparent. The scattered light containing elastic and inelastic contributions is sent through a spatial filter, consisting of two lenses and a pinhole, to suppress background noise, and then enters the monochromator. Commonly a multipass tandem Fabry–Pérot interferometer developed by Sandercock (JRS Scientific Instruments), is used. The light then passes a second spatial filter and a prism to suppress signals from common transmission orders of the two etalons outside of the measured spectrum. The light is detected by a photomultiplier or an avalanche photodiode. Single photon counting must be used, and the dark count rate should be lower than 3 counts/s. A computer or a multichannel analyzer collects the photon signals as a function of the mirror spacing and displays the data.

Optical etalons are commonly used as the frequency-selecting element. They consist of two highly flat ($\lambda/200$) glass plates enclosed with a high reflectivity coating ($R = 92$–96%). The transmission function of an etalon

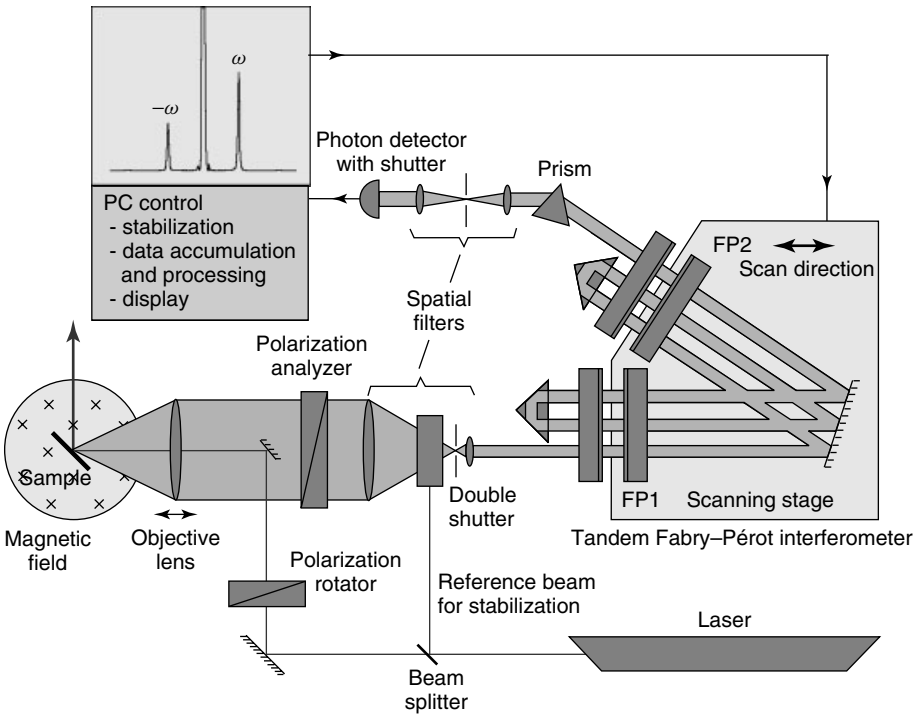

Figure 6. Schematic view of a Brillouin light scattering setup.

is the Airy function

$$I = I_0 \frac{1}{1 + F \sin^2(\Delta\phi/2)} \tag{15}$$

with I denoting the transmitted intensity as a function of the mirror spacing s, $F = 4R/(1-R)^2$ the finesse, R the mirror reflectivity, $\Delta\phi = 2\pi s/\lambda$ the phase shift for one loop (two reflections) in the etalon, and λ the wavelength. Perpendicular incidence of the light is assumed, as it is the case in the experimental setup described here. The etalon transmits all the light if the spacing between the two plates is an integer multiple of half the wavelength. In the experiment one of the two plates is scanned piezoelectrically to allow for resonance conditions for different wavelengths and corresponding frequencies.

To avoid ambiguities in the assignment of inelastic peaks to the respective transmission order, a tandem arrangement is commonly used. Its central part is shown in Figure 7. One mirror of each of the two etalons is mounted on a common translation stage. The axes of the two etalons form an angle Θ. If the translation stage is moved along the normal direction of FP_1 and if the spacing of etalon FP_1 is changed by Δ, the corresponding change in spacing of FP_2 is $\Delta \cos\Theta$.

To understand the operation let us assume that both etalons are in transmission (see Figure 7b). If the spacing of FP_1 is changed by $\lambda/2$ this etalon is again put into transmission. However, since the change in spacing of FP_2 is smaller by the factor $\cos\Theta$, FP_2 is now not in transmission. Since the light is sent through both etalons in series, transmission is only obtained in the common transmission order. Let us now assume that the light from the sample contains an inelastic contribution. The spectrum, shown in the upper left part of Figure 7, consists now of a strong line at frequency ω_L, corresponding to elastically scattered light, and two weaker side bands at $\omega_L \pm \omega$. These side bands appear in the transmission of the etalons at characteristic spacings (see Figure 7b). It is evident that only the signal from the side bands belonging to the common transmission order is transmitted through both etalons. Thus the ambiguity in the mode assignment is removed. In practice, the translation stage is piezoelectrically driven with a feedback for linearization. The frequency range between the central transmission order and the first neighboring order is called the *free spectral range*.

A frequency resolution in the subgigahertz regime and a high contrast of better than 10^{10} (Sandercock, 1982; Mock, Hillebrands and Sandercock, 1987) can be achieved, the latter by multipassing the light beam through the etalons using a system of mirrors and/or retroreflectors (see Figure 6). This sensitivity allows for the observation of spin waves down to magnetic monolayers, although the inelastic light scattering process is rather ineffective (Krams *et al*., 1992).

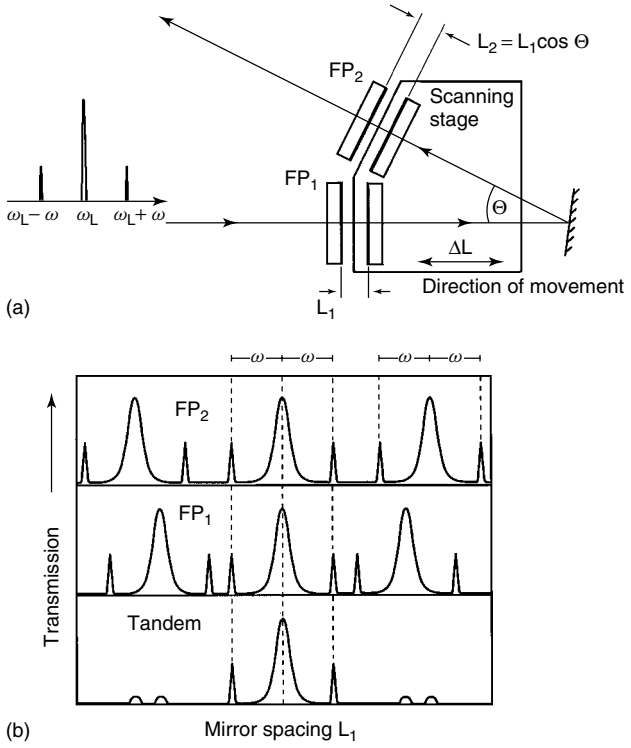

Figure 7. Schematic view of the operation of a tandem Fabry–Pérot interferometer. (a) View of the light pass. (b) Transmitted intensity of first etalon (FP_1), second etalon (FP_2), and both etalons in series. The inelastic contributions due to scattering from spin waves are indicated by ω. (Reproduced from B. Hillebrands *et al.*, 2000, with permission from Springer-Verlag. © 2000.)

To maintain stable operation, the parallelity of the mirror plates must be maintained to a very high degree (a common value is $\lambda/100$). This cannot be achieved statically, and sophisticated dynamic stabilization schemes are applied (Mock, Hillebrands and Sandercock, 1987; Sandercock, 1971; Hillebrands, 1999). Often a shutter system is used to switch between the light from the sample and reference light used for stabilization (see Figure 6). Active stabilization and the data collection can be performed by hardware as well as by software solutions, such as the TFPDAS3 package (Hillebrands, 1999).

The total accessible frequency range in a BLS experiment is in the range of 0.2 GHz–1 THz. In a typical experiment a much smaller range is used, defined by the spacing of the etalon mirror plates. The finesse, that is, the ratio of the free spectral range over the resolution is fixed and is typically of the order of 50. Thus the needed frequency resolution determines the free spectral range. Scanning over several transmission orders can be made to enhance the frequency range. Sensibility down to monolayer thickness has been shown with a good signal-to-noise ratio, for example, 2 ML of Co deposited on Cu(001) (Krams *et al.*, 1992).

3.1.2 Space-resolved Brillouin light scattering spectroscopy

The laser spot size in a standard geometry is of the order of 40 µm. Thus BLS spectroscopy can be used for imaging of spin-wave propagation and spin-wave eigenmodes in confined objects with moderate spatial resolution. A large class of experiments involves the excitation of spin waves in garnet films with wavelengths in the range of 0.1–1 mm. Here a scanning sample stage allows the realization spatial resolution by measuring the intensity of the inelastic scattered light point by point on the sample in a scanning probe fashion. Spatial resolution can be increased down into the submicrometer range using the so-called microfocus technique. Here the full numerical aperture of an objective lens is used for maximum optical resolution. Compared to standard BLS spectroscopy two major modifications are made. First, a microscope objective is used and, for maximum spatial resolution, the incoming laser light is expanded to the output aperture of the objective lens. Second, for practical reasons, an optical microscope setup is integrated to monitor the position of the laser spot on the sample. Figure 8 illustrates the light pass for both BLS spectroscopy and monitoring.

Unfortunately, a price is to be paid for the increased optical resolution, and this is the loss in wave vector resolution, in accordance with Heisenberg's principle of uncertainty. However, in small magnetic objects the excitation spectrum most often consists of quantized, dispersionless modes, so that the loss in wave vector resolution is not a real drawback.

Microfocus BLS spectroscopy has been used to measure the local mode spectra in micrometer sized objects, such as stripes, squares, rectangles, circles, and rings (see Section 4.5 for illustrations).

3.1.3 Time-resolved Brillouin light scattering spectroscopy

The BLS spectroscopy technique has been extended toward time resolution (Slavin, Demokritov and Hillebrands, 2002).

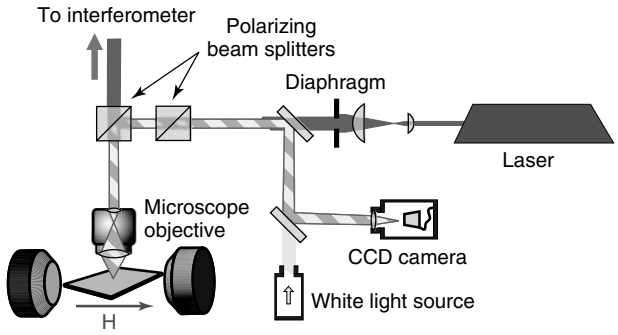

Figure 8. Schematic view of microfocus Brillouin light scattering setup.

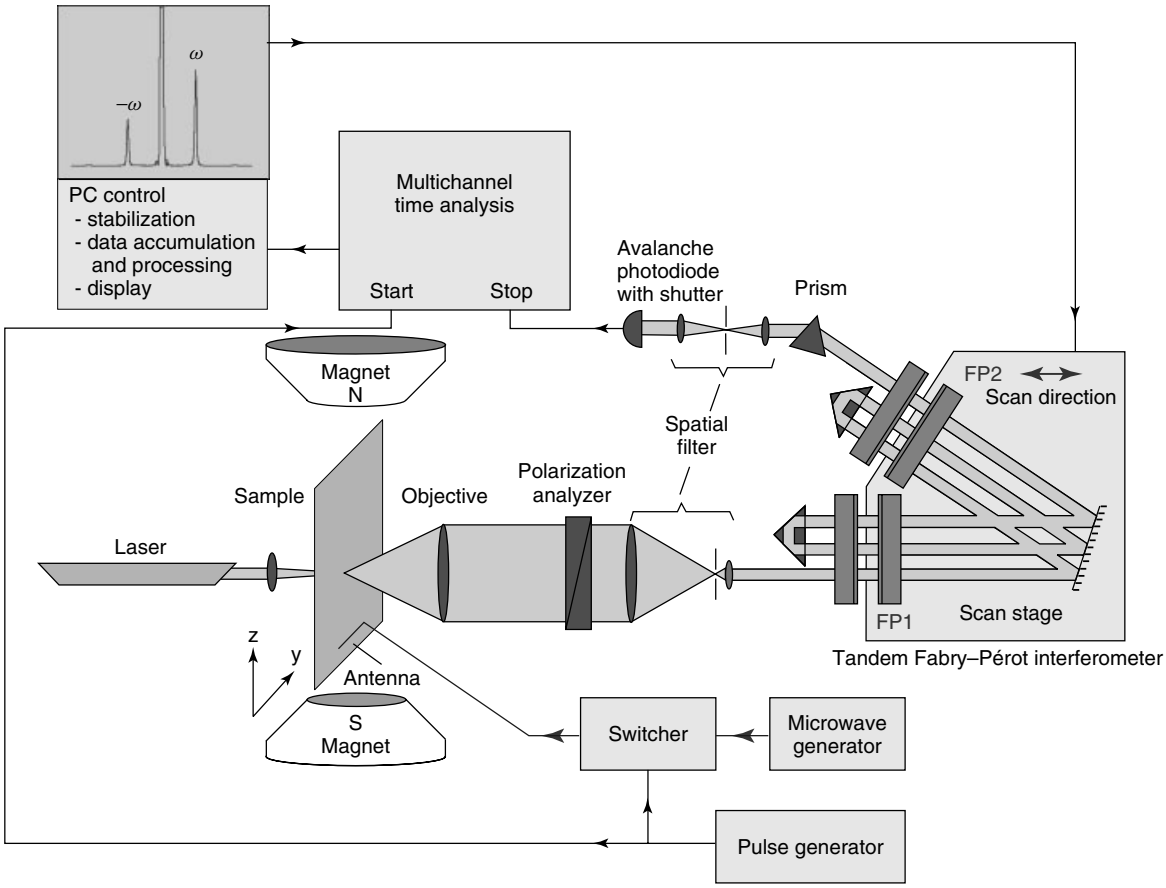

Figure 9. Schematic layout of the Brillouin light scattering apparatus with space and time resolution. For a discussion of the components see text. (Reproduced from A.N. Slavin *et al*., 2002, with permission from Springer-Verlag. © 2002.)

This allows for direct access to spin-wave propagation phenomena by monitoring the propagation of microwave excited spin-wave pulses. In a typical experiment, a spin-wave pulse is launched in a sample by application of a microwave pulse to an antenna structure. Observation of the spin-wave packet is now realized by measuring stroboscopically the time between launch and detection in the area of the laser focus. Most often this technique is combined with space-resolved BLS, enabling the full spatio-temporal observation of the packet propagation.

Figure 9 illustrates the fundamental operation. Spin-wave pulses are excited by an antenna structure connected to a microwave generator with a microwave switcher. The microwave switcher is controlled by a pulse generator, which serves as the central clock. The microwave pulses are typically 10–30 ns long and have a repetition rate upto 1 MHz. The propagating spin-wave pulse is detected in the focus of the laser light. Here, most often a transmission geometry is used because of the small wave vector of the modes to be detected. If spin-wave pulses cross the laser focus, they generate inelastically scattered photons, which are then detected by the photomultiplier. The propagation time is obtained by measuring the time between launch of the spin-wave pulse at the antenna and its detection in the laser focus (the time measurement unit is indicated in Figure 9 by 'multichannel time analysis'). For this purpose a 24-bit reference counter is used, which runs with a time base of 1.2 GHz. The counter is started by the pulse generator and stopped by the detection of an inelastic scattered photon. The content of the counter is thus a measure of the elapsed time of such an event. A memory cell is addressed by the content of the counter and its content is increased by 1. After averaging many of these events the memory contains the temporal distribution of the spin-wave signal in the laser spot. Repeating this measurement point by point by scanning the laser focus across the sample, the full spatio-temporal information of the propagating spin-wave pulse is obtained. The result is usually displayed in an animated movie format.

The time resolution is of the order of 2 ns, limited by the narrow transmission linewidth of the Fabry–Pérot interferometer. In a typical experiment, the measurement at each position on the sample takes about 1–10 s. A complete

measurement of a two-dimensional spin-wave intensity pattern in a YIG-film with a sample area of $2 \times 6\,\mathrm{mm}^2$ and a mesh size of 0.1 mm takes a little bit more than 2 h including the time caused by sample positioning.

3.2 Time-resolved magneto-optic Kerr effect magnetometry and microscopy

This class of experimental tools uses the magneto-optic Kerr effect is used to pick up information on the magnetization and its dynamics (Freeman, 2005; Rasing, van den Berg, Gerrits and Hohlfeld, 2003; Freeman and Hiebert, 2002; Choi and Freeman, 2005). The three standard Kerr effect geometries linear in the magnetization – longitudinal, transverse, and polar Kerr effect geometry – are used, although, particularly for imaging, the polar Kerr effect geometry is most often employed. In the longitudinal (transverse) geometry, the in-plane magnetization component parallel to the (perpendicular) plane of the incidence is probed. In polar geometry, the magnetization component perpendicular to the film plane is tested.

The dynamic part of the magnetization is usually perpendicular to the static part. Consequently, for an in-plane magnetized sample, both the polar Kerr effect as well as one of the two in-plane Kerr effects contribute to the signal. The polar Kerr effect is usually about a factor of 100 larger than the longitudinal or the transverse counter parts. This factor depends on many parameters, such as optical and magneto-optical parameters of the ferromagnetic layer, overlayer, and substrate as well as on the angle of incidence, light wavelength, light polarization, and so on. (Višňovský *et al*., 1995; Qiu and Bader, 1999; Hubert and Schäfer, 1998). For example, in the case of 30-nm-thick permalloy film investigated by s-polarized (p-polarized) light at an incidence angle $\varphi = 45^\circ$ and wavelength $\lambda = 680\,\mathrm{nm}$, the Kerr rotation in the case of polar magnetization is 140 mdeg, (160 mdeg), whereas in the case of longitudinal magnetization it is 6.4 mdeg (2.4 mdeg), respectively. On the other hand, in thin films there is a large ellipticity of the precession of the magnetic moments which must be taken into account. The out-of-plane dynamic component of the magnetization is typically a factor of 100 smaller than the in-plane dynamic component. Therefore, the out-of-plane and in-plane components of the dynamic magnetization contribute more or less equally to the resulting Kerr signal.

Two general classes of techniques are used: In the pump probe approach, the system is excited by a short perturbation, which can be a magnetic field pulse, heating by a light pulse, and so on. With some controlled time delay a probe light pulse is sent to the sample and the Kerr signal of the reflected light is measured. The temporary evolution of the magnetization dynamics is obtained by measuring the Kerr signal as a function of the delay time. In a second experimental approach, the system is subject to a microwave field, which excites a uniform forced precession of the magnetization. Pulsed light, which is synchronized to the microwave frequency, is sent to the sample and the Kerr signal is measured. A measurement of the Kerr amplitude as a function of the microwave frequency, applied field, and so on, yields the dynamic response of the sample. This is the so-called optical ferromagnetic resonance technique, discussed in the next subsection.

Figure 10 shows a schematic setup to measure the dynamics of all three Cartesian components of the magnetization, m_x, m_y, m_z (Freeman, 2005; Freeman and Hiebert, 2002). An electric pulse generator is used to generate current pulses, and thus the sample is stimulated by magnetic field pulses. Commonly the current pulses are sent to the sample using a strip-line geometry for reasons of high-frequency impedance matching. For the detection part, a Ti:sapphire laser system is commonly used, which typically provides 70-fs-long pulses of $\lambda = 800\,\mathrm{nm}$ wavelength and has a repetition rate of 82 MHz. The laser serves as the general clock of the system. Some part of the light and a photodiode are used to generate the electrical clock signal to trigger the electrical pulse generator. A pulse picker is used to reduce this repetition frequency of the laser down to 1 MHz, well adapted to the timing of the magnetization dynamics. Often a frequency doubler is employed to work at shorter wavelengths. Some authors also report the successful use of pulsed diode laser as a light source (Fassbender, 2003).

The laser light is sent to the sample via a beam splitter and an objective lens for focusing. The reflected light is then sent to a polarizing beam splitter and to photodiodes, which work in the geometry of an optical bridge for differential detection of the polarization rotation induced by the MOKE. When quadrant detectors are used (as shown in Figure 10), then linear combinations of signals from proper detector quadrants provide signals proportional to all three Cartesian magnetization components (Freeman, 2005; Freeman and Hiebert, 2002). Such a setup is frequency limited by the rise time of the pulse generator being about 50 ps as well as the jitter of the system. The use of coplanar strip lines and a careful matching of the impedances result in a frequency limit in the 5-GHz range.

An alternative way allowing access to a higher frequency range is to use a photoconductive switch, illuminated by a laser pulse, to generate fast transient electrical current pulses. Figure 11 shows the approach used by the Nijmegen group (Gerrits *et al*., 2001; Rasing, van den Berg, Gerrits and Hohlfeld, 2003). In such a switch the light pulse generates

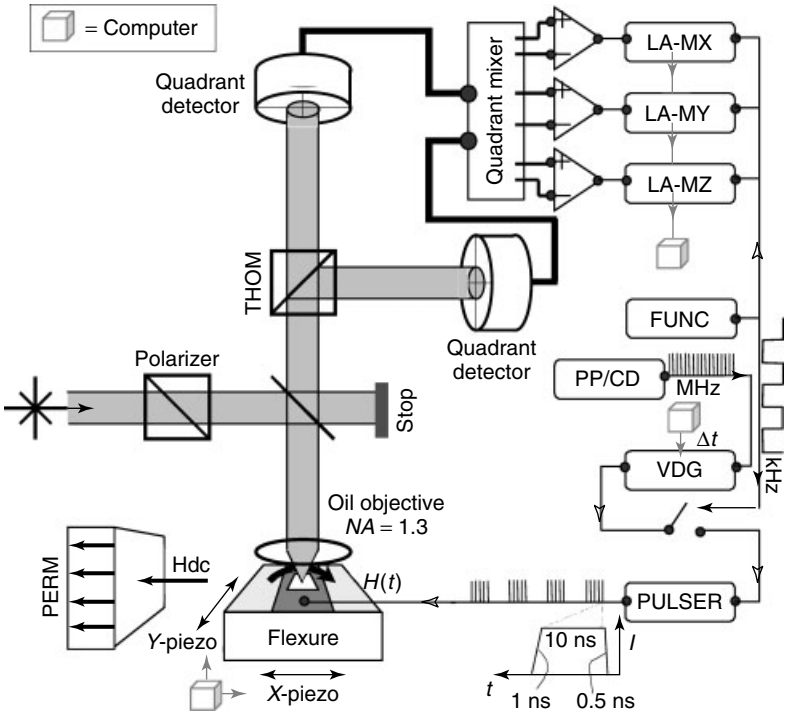

Figure 10. Scheme of the setup of the time-resolved Kerr effect experiment: A polarized pulsed-laser source is split by a beam splitter and focused onto the sample with an oil immersion objective lens (numerical aperture $NA = 1.3$). The reflected light is analyzed by a Thomson polarizing beam splitter (THOM). The light is detected by a quadrant detector that simultaneously acquires all three components of the magnetization. To reduce noise, lock-in amplifiers (LA) are employed. Temporal resolution is achieved by synchronizing the laser pulses through the output of a cavity dumper or pulse picker (PP/CD) triggering an electronic pulser (PULSER) at megahertz frequencies via a variable delay generator (VDG) with computer-controlled variable delay Δt. The pulses provided by the VDG are toggled (gated) by a fast gating switch controlled by a function generator (FUNC) at kilohertz frequency. The gated train of electrical pulses from the pulser (amplitude 50 V, length 10 ns, rise time 0.5 ns, fall time 1 ns) is launched to a coplanar transmission line, creating a transient in-plane magnetic field $\vec{H}(t)$ at the sample. The static magnetic field is generated by a permanent magnet (PERM). The spatial image is built by scanning the sample position underneath the laser spot. (Reproduced from M.R. Freedman *et al.*, 2002, with permission from Springer-Verlag. © 2002.)

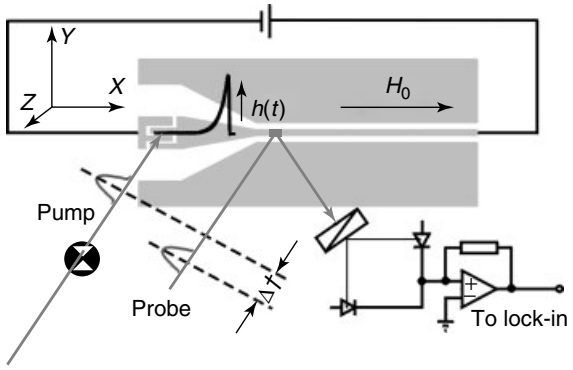

Figure 11. Scheme of the setup of the time-resolved Kerr effect experiment demonstrating the photoconductive switch. The 100-fs pump pulse excites a current pulse, which is concentrated in the taper and launched into the signal line. The response of the magnetic element to the correlated field pulse, $h(t)$, is measured by detecting the Kerr rotation of the 100-fs probe pulse as a function of the pump pulse delay Δt. (Reproduced from T. Rasing *et al.*, 2001, with permission from The Magnetics Society of Japan. © 2001.)

electron hole pairs in doped GaAs and thus increases the conductivity. Photoconductive switches show very fast current raise times (≈10 ps), but however, also slow decay times (≈600 ps). This problem can be circumvented by using two photoconductive switches which are illuminated by two laser pulses with a short delay in between. The output currents of both switches are connected in an antiparallel arrangement and thus will cancel each other in the long tail. Figure 12 demonstrates the principle.

A typical operation voltage is ±30 V and the usual peak power of the laser pulse excitation is 100 MW cm^{-2}. Well-defined magnetic pulses with a peak field strength of 100 Oe a duration of less than 50 ps, and a jitter considerably better than 1 ps can be generated. When using a single photoconductive switch, a frequency resolution of about 15–20 GHz has been achieved (Zhu *et al.*, 2005).

Experiments as described above are very well suited to measure the magnetization dynamics of small magnetic objects. Very often a high spatial resolution is needed. An

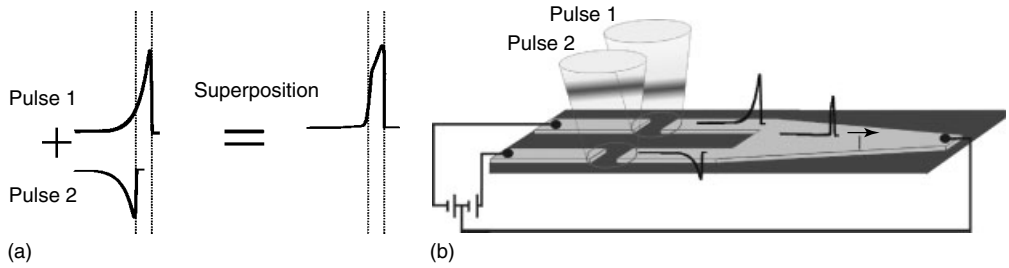

Figure 12. (a) Principle of magnetic field pulse cancellation due to the exponential character of the trailing edge. (b) Schematic drawing of the double photoconductive switch setup that allows for a control of the shape of the field pulse generated. (Reproduced from H.A.M. Gerrits *et al*., 2003, with permission from Elsevier. © 2003.)

objective lens is used to focus the light down to a minimum focus size, which is typically of the order of 1 – 10 μm. A further reduction of the focus size going to the optical limit has been studied. In Freeman and Hiebert (2002), the use of a solid immersion lens is reported and the achieved spatial resolution was 220 nm corresponding to a resolution of $\lambda/2.9$ relative to the wavelength (Rayleigh criterion). By scanning the laser focus across the sample and measuring the time-resolved magnetic response, two characteristic quantities can be obtained from the measurements: First, the dynamic response is measured point by point, as a function of the delay time. Second, images corresponding to a given delay time can be made. Such images can be presented in an animated movie format, and the experimentally determined 'wiggling' of the magnetization can be demonstrated. Furthermore, the time-resolved local magnetization response can be Fourier-transformed for each point on the surface. The Fourier components can be imaged as a function of the position. Thus, the local amplitude of individual modes with a given frequency ω can be displayed. Here the Kerr effect technique meets the microfocus-BLS technique, where the mode amplitude is directly measured locally. Section 4.3 shows a result, where both methods are compared.

A number of related stroboscopic Kerr effect techniques exist. For instance, magnetic anisotropy and an intense light pulse can be used to excite precession, which is then stroboscopically sampled with the techniques described above (van Kampen *et al*., 2002; Hansteen, Kimel, Kirilyuk and Rasing, 2005; Weber *et al*., 2005; Hicken, Barman, Kruglyak and Ladak, 2003). Here the light pulse results in a sudden local heating of the sample. In the presence of a temperature-dependent anisotropy, this may result in a change of the easy direction of magnetization, stimulating a precession of the magnetization. van Kampen *et al*. (2002); Hansteen, Kimel, Kirilyuk and Rasing (2005); Weber *et al*. (2005); and Hicken, Barman, Kruglyak and Ladak (2003) discuss this technique.

Most time-resolved Kerr microscopy setups use a scanning approach. However, for wide-field imaging a conventional Kerr microscope can be used jointly with pulse excitation. Neudert *et al*. (2005) demonstrate this approach.

3.3 Optical ferromagnetic resonance

Tamaru *et al*. (2002, 2004) have pioneered the technique of spatially resolved optical ferromagnetic resonance following early experiments by Petek, Trouilloud and Argyle (1990). They have shown that the uniform mode of a film or the eigenmode spectrum of a small magnetic object can be investigated by driving the system with an applied microwave field, for instance, in a microwave cavity or for a sample mounted on top of a coplanar strip line connected to a microwave source. This optical approach has the advantage that the full optical resolution can be used to obtain spatial information about the mode profiles. Figure 13 shows a typical setup.

A coplanar transmission line is used to apply the microwave signal to the sample, while a Ti:sapphire frequency-doubled laser system is used as a clock. The laser is controlled by a 80-MHz reference clock, which also synchronizes the microwave generator working at 8 GHz with an intervening delay generator for phase adjustment. To increase sensitivity, a lock-in technique is used. A 1-kHz signal generator modulates the microwave signal and is used as a reference signal for a lock-in amplifier used for analysis of the Kerr signal. For this type of experiment, a very precise phase synchronization between the microwave signal and the laser pulses is mandatory. The experiment is conducted in the usual ferromagnetic resonance operation: the applied field is changed and the output signal is measured as a function of the applied field point by point on the sample. In this way, the two-dimensional distribution of the mode profiles are obtained as a function of the applied field.

3.4 Second-harmonic generation techniques

As discussed in Section 3.2, the magneto-optical Kerr effect may be used to determine all three Cartesian components

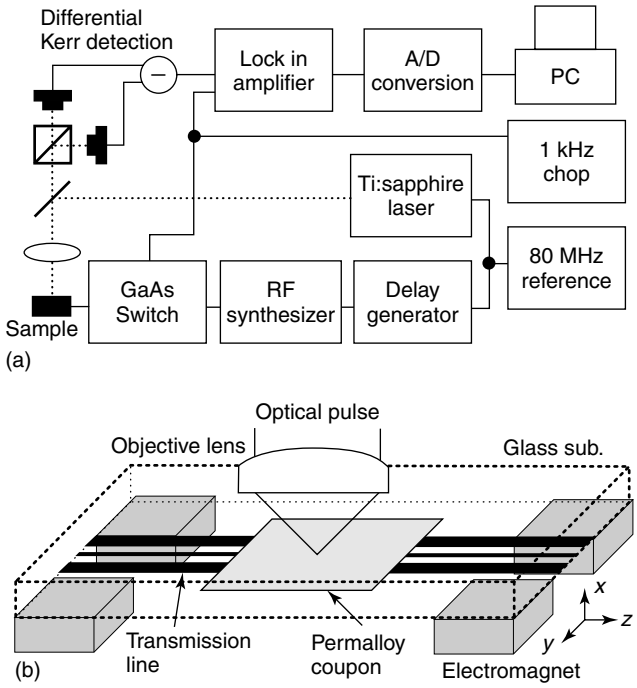

Figure 13. Schematic diagram of a Kerr effect ferromagnetic resonance setup. (a) Entire system and (b) sample with coplanar transmission line. (Reprinted with permission from S. Tamaru *et al*., 2002, © 2002, American Institute of Physics.)

of the magnetization. Therefore it is well suited to pick up the dynamic signal. However, the polar, transverse, and longitudinal Kerr effect contributions are mixed together and often there is a need to separate them (Choi and Freeman, 2005).

The employment of the SHG technique is an alternative elegant way to obtain magnetization information in all three Cartesian directions. For materials with point symmetry (such as most metals), the SHG signal originates only from the interface or surface, because here the point symmetry is broken. Using the SHG technique, the in-plane magnetic contribution can be separated by realizing different orientations of the analyzer (Gerrits *et al*., 2002a; Kabos, Kos and Silva, 2000). When the incident light is p polarized, then the s-polarized SHG yield ($p_{in} - s_{out}$) is an odd function of the longitudinal magnetization. On the other hand, the p-polarized SHG yield ($p_{in} - p_{out}$) is an odd function of transverse magnetization [2]. As the SHG signal only weakly depends on the polar magnetization, this direction was measured by means of the magneto-optical polar Kerr effect (Gerrits *et al*., 2002a; Gerrits *et al*., 2002b). The only disadvantage of this elegant approach is that it mixes surface or interface magnetic signals related to in-plane magnetic directions and the bulk magnetic signal related to the polar direction.

4 APPLICATIONS OF OPTICAL TECHNIQUES

The development of new experimental techniques, as discussed in Section 3, has enabled a large variety of new experimental results. In this section we present a few of these results. They are aimed at demonstrating the specific potentials of some of the optical techniques discussed above and are not meant as an introduction into the underlying physics. As an example of the application of space- and time-resolved BLS spectroscopy we discuss results on the spin-wave tunneling effect. BLS in the 'Fourier microscope' mode also allows to characterize the lateral extensions of confined magnetic modes. This is demonstrated in the investigation of localized modes in rectangular microelements. As a further topic, the investigation of mode patterns in squares using both time-resolved Kerr microscopy and microfocus BLS spectroscopy will be presented. Next, as an example of the optical ferromagnetic resonance technique, we demonstrate the investigation of confined modes using this approach. We finally conclude by presenting a few experiments on the investigation of propagating spin waves using time-resolved optical techniques, which complement BLS experiments.

4.1 Spin-wave tunneling

In a ferro- or ferrimagnetically ordered film spin waves may propagate, characterized by their dispersion. Spin waves can easily be excited using an antenna structure mounted on the surface of the film and connected to a microwave generator. If the antenna structure is driven by microwave pulses, spin-wave pulses are generated. Their carrier frequency is determined by the frequency of the microwave generator $\omega_{\mu W}$, and their wave vector is determined by the dispersion law $\omega(\vec{q})$. The slope in the dispersion is the group velocity of the spin-wave packets, $\vec{v}_g = \nabla_q \omega(\vec{q})$.

The method of space- and time-resolved BLS, as described in Sections 3.1.2 and 3.1.3, is used to study the propagation properties of such spin-wave packets. We demonstrate this for a specific physical problem. We assume that we have a spin-wave waveguide realized by a YIG stripe of typically 6 µm thickness, 1.5 mm width, and 10 mm length. The YIG films are grown on Ga–Gd–garnet (GGG) substrates, which are nonmagnetic. The spin waves are excited by attaching a microfabricated microwave antenna to the film, which is connected to a pulsed microwave generator.

If we inhibit propagation of such a spin wave in certain, narrow (smaller or comparable to spin-wave wavelength) areas of the spin-wave waveguide, the spin-wave tunneling effect may appear. It has been shown recently that a region of lowered magnetic field can act as a tunnel barrier for a

propagating dipolar-dominated backward volume (MSBVM) spin wave (Demokritov *et al*., 2004). In this region, the dispersion curve is shifted down on the frequency scale because of the reduced internal field, and if the dispersion does not allow any more for the propagation of a MSBVM spin wave for the given frequency $\omega_{\mu W}$ determined by the microwave generator, propagation is forbidden. If the forbidden region is small enough, tunneling of spin waves may appear. Here we demonstrate the spin-wave tunneling effect using a different scenario which is in a sample with a narrow mechanical gap cut into the YIG waveguide.

The spin-wave waveguide was fabricated by chemical etching of the YIG-film. While the mechanical gap was realized by a transverse slot of 20 µm width. The waveguide was magnetized along its longitudinal axis. Backward volume magnetostatic spin waves (BVMSW) with a carrier frequency

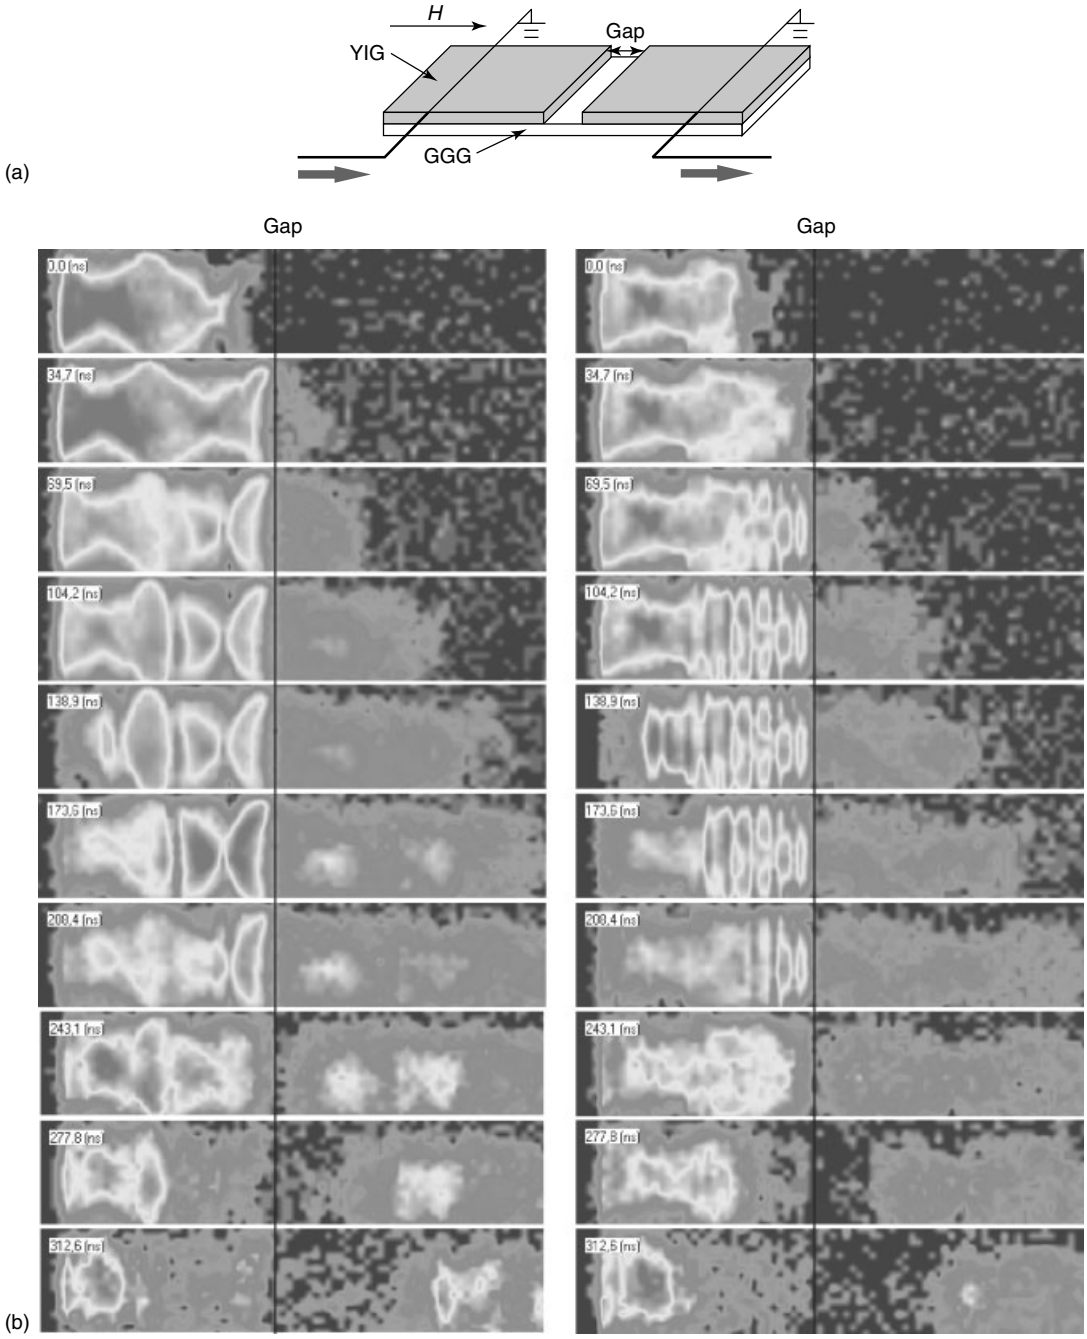

Figure 14. (a) Schema of the setup for spin-wave tunneling measurements. (b) Tunneling of a spin wave through a mechanical gap. The position of the gap is indicated by the black line. Left column: $H = 1835$ Oe, right column: $H = 1846$ Oe.

of $\omega/2\pi$ = 7.125 GHz were excited in the waveguide using a 25-μm-wide microstrip antenna.

Figure 14 shows the experimental results using space- and time-resolved BLS spectroscopy for two different values of the magnetizing field: $H = 1835$ Oe (left) and $H = 1846$ Oe (right), yielding spin waves with $q = 10$ and $4.2\,\mathrm{cm}^{-1}$, respectively. The data are normalized to the maximum value in each picture. The larger magnetic field corresponds to a smaller carrier wave number of the spin-wave packet incident on the gap.

As expected, the main part of the waves is reflected from the gap and forms a standing wave pattern together with the incoming wave. A small part of the wave energy tunnels through the gap and forms a propagating transmitted wave. One can see in Figure 14 that the amplitude of the transmitted pulse is smaller for short carrier wavelengths and larger for long carrier wavelengths.

In the experiment, frames with the spatial information are obtained for each time step, and thus an animated video can be obtained, which shows the propagation of the spin-wave pulse. Follow-up experiments have been performed to measure the wave vector dependence of the tunneling efficiency, and to investigate the trapping of spin waves in so-called spin-wave cavities, made by two gaps cut into the waveguide with a small separation.

4.2 'Fourier mode' Brillouin light scattering spectroscopy: characterization of spatial distributions of the spin-wave intensity and localization of modes

The spin dynamics in patterned magnetic structures is a very important contemporary problem, motivated, apart from basic science aspects, largely by applications in the field of data storage and sensors, where the speed of operation now reaches into the GHz regime. For this frequency regime BLS spectroscopy and time-resolved MOKE techniques are two important characterization techniques.

Let us first understand the spin-wave eigenmode properties in such small elements. The problem is nontrivial, as in many cases both dipole–dipole and exchange interactions must be taken into account simultaneously (see Section 2.1). An additional difficulty comes from the fact that many of the small magnetic elements have a inhomogeneous distribution of the internal field and the saturation magnetization, in particular, if they have a nonelliptical shape.

The complexity of spin waves inside such small magnetic elements results from several physical effects:

- Spin-wave quantization due to spatial confinement, such as in longitudinally magnetic stripes (Jorzick *et al*., 1999; Mathieu *et al*., 1998; Roussigné, Chérif, Dugautier and Moch, 2001; Wang *et al*., 2002) and in ellipsoidal magnetic elements, where the internal magnetic field is homogeneous (Mathieu *et al*., 1997; Hillebrands *et al*., 1997).
- Spin-wave quantization and localization to small regions inside the magnetic object. The inhomogeneous internal magnetic field may form so-called spin-wave wells, which may provide such a localization mechanism (Jorzick *et al*., 2002; Park *et al*., 2002; Bayer *et al*., 2004; Bayer, Demokritov, Hillebrands and Slavin, 2003; Bayer *et al*., 2005).

In Section 3.1 we have derived the fundamental properties of BLS spectroscopy. There it was stated that in the light scattering process the in-plane component of the wave vector is conserved if the film is infinitely extended. The latter is not the case anymore for finite magnetic objects. To understand the consequences we discuss Figure 15.

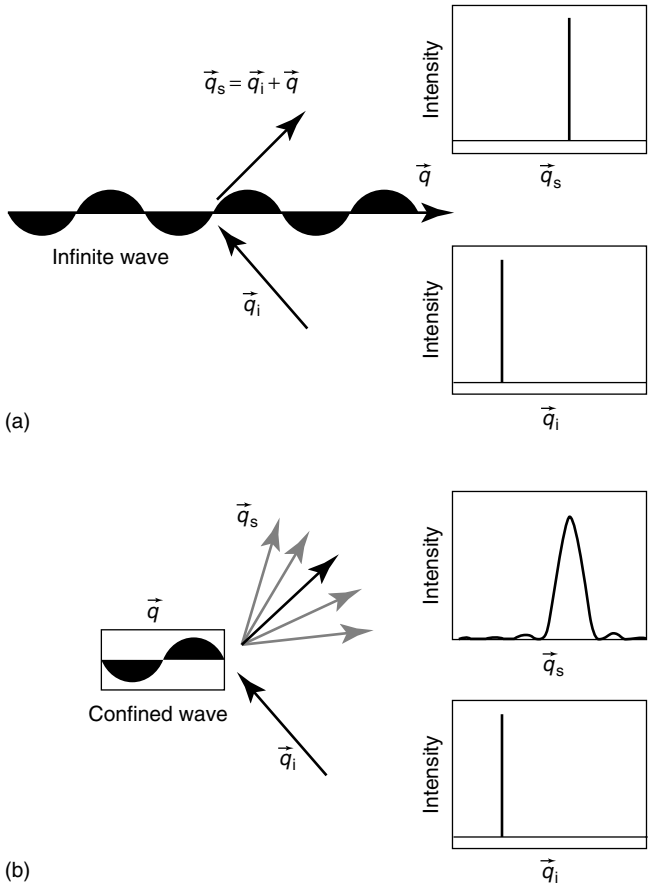

Figure 15. Schematic description of the light scattering process for (a) an infinite scattering volume (plane wave) and (b) a confined scattering volume. q_I and q_S indicate the wave vector of the incoming and scattered light, respectively.

The BLS process in an unconfined medium is illustrated in Figure 15(a): Monoenergetic photons with a frequency ω_I and wave vector $\vec{q}_I$ interact with the elementary quanta of the spin waves, which are the magnons, described by ω and $\vec{q}$. Because of the conservation laws resulting from the time and translational invariance of the system, the scattered photon has an increase or decrease in energy (ω_S and momentum $\vec{q}_S$, as described in Section 3.1). For a laterally confined structure, the in-plane translational invariance is broken. Therefore, there is a given uncertainty in the scattered wave vector $\vec{q}_S$, as is shown in Figure 15(b), where the value of the uncertainty is determined by the lateral size of the element. The intensity of the scattered light as a function of the dynamic magnetization, $m(y)$ [3] of the spin-wave mode confined to the stripe is according to Jorzick *et al.* (1999) and Mathieu *et al.* (1998) proporational to

$$I(q) \sim \left| \int_{-w/2}^{w/2} \vec{m}(y) \exp(-\mathrm{i}qy)\mathrm{d}y \right|^2 \qquad (16)$$

where w is the stripe width, q is the wave vector, and the integration is performed along the stripe width. Thus, the light scattering intensity is proportional to the squared Fourier transform of the dynamic magnetization, $|\vec{m}(y)|^2$. As the integration is performed over the interval $[-w/2, w/2]$ and the dynamic magnetization is essentially a sine function with a wave vector q, the maximum in scattering intensity will be at q and the broadening will be determined by the stripe width w. In the more complicated case of a rectangular element discussed in Section 4.2.2, a two-dimensional Fourier transform is needed.

4.2.1 Modes in longitudinal magnetized stripes

In order to understand the 'Fourier microscope' BLS technique, let us first discuss the modes in a longitudinally magnetized stripe, where the modes propagate in a direction perpendicular to the stripe axis. Since in this geometry the magnetization is parallel to the stripe axis, the magnetic field is homogeneous and equal to the applied external field (neglecting areas close to the stripe ends). These stripes are made from permalloy ($Ni_{81}Fe_{19}$) films of typically 20–40 nm thickness with a typical width in the range of 1–2 µm. Permalloy has the advantage that magnetic anisotropies are small and can be neglected. The geometry studied here supports surface waves (MSSM or Damon–Eshbach modes), which propagate in the film plane perpendicular to the stripes. When the spin wave reaches a lateral boundary of the stripe, it will be reflected and it forms a standing (confined) wave as already discussed in Section 2.2 and shown in Figure 4.

The standing wave patterns will result in quantized spin-wave frequencies. Figure 16 shows the measured results.

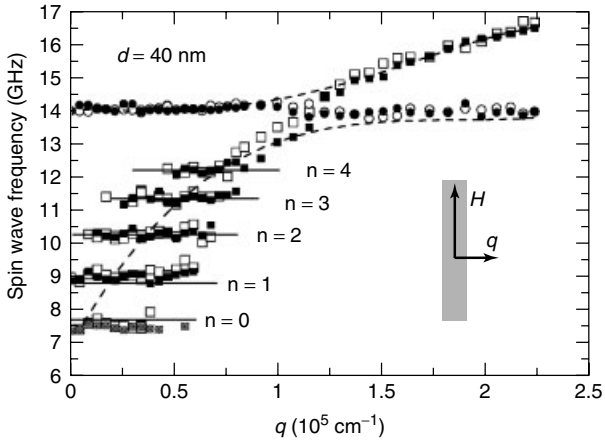

Figure 16. Obtained spin-wave dispersion curve for permalloy stripes with a thickness of 40 nm, a stripe width of $w = 1.8\,\mu m$ and a separation between the stripes of 0.7 µm (open symbols) and 2.2 µm (solid symbols). The external magnetic field along the stripe axis was 500 Oe, being perpendicular to the $\vec{q}$ vector as sketched in the Inset. The solid horizontal lines indicate the results of calculations using effective pinning (Demokritov, 2003). The dashed lines, showing the hybridization between the dispersion of the magnetostatic surface mode (MSSM) and the first perpendicular standing spin-wave mode (PSSW), were calculated numerically for a continuous film of 40 nm thickness. (Reproduced from J. Jorzick *et al.*, 1999, with permission from American Physical Society. © 1999.)

For small wave vectors, the spin-wave dispersion splits, as expected, into several modes, which are laterally standing modes due to the confinement. The mode order is characterized by the number of nodes along the propagation direction. Each mode does not show any dispersion and is observed over a finite but well-defined wave vector range. The separation between the modes decreases with increasing wave vector (increasing frequency) and, for higher order modes, this separation becomes indistinguishable. At 14 GHz, the dispersionless, perpendicular standing spin wave, determined by the exchange interaction and traveling perpendicular to the film, is observed. It intersects the regime of the MSSM modes.

We now discuss the two main properties, namely, the lack of dispersion and the finite wave vector range of observation, in more detail. The discrete nature of the mode spectrum has been already discussed in Section 2.2, so only the results are discussed here. It is important to note that, owing to the stray fields generated by the dynamic excitations outside of the stripe, an additional pinning mechanism is present, since the stray fields interact with the dynamic magnetization. This is discussed in detail in Guslienko, Demokritov, Hillebrands and Slavin (2002). As a result, the quantized values for the parallel wave vector, $q_{\parallel,n}$ are given by $q_{\parallel,n} = n(\pi/w_{\mathrm{eff},n})$, where $w_{\mathrm{eff},n} > w$ is an effective stripe width larger than the real stripe width. This is shown in Figure 17.

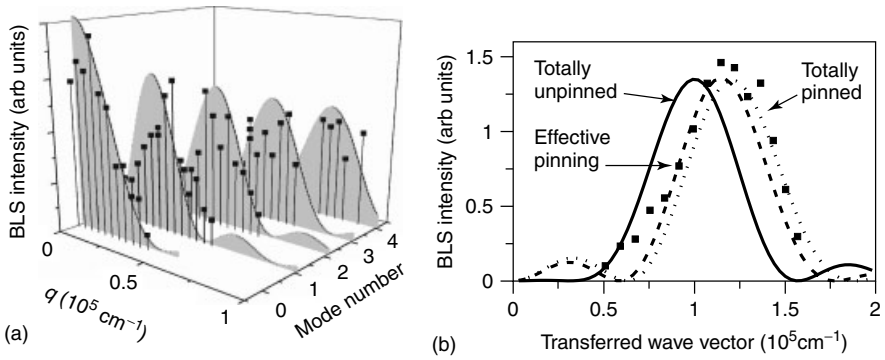

Figure 17. (a) Measured relative Brillouin light scattering intensities of the in-plane quantized spin-wave modes as a function of the wave vector $q_\parallel$ and the mode number n (black squares) compared to calculations as discussed in the text (solid lines). (b) Experimental data for the quantized $n = 3$ mode compared to calculations using three different boundary conditions. (Reproduced from S.O. Demokritov *et al.*, 2003, with permission from IOP Publishing Ltd. © 2003.)

Figure 17(a) shows the detected BLS intensities as a function of the transfer red wave vector $q_\parallel$. The mode intensities are normalized to the perpendicular standing spin-wave mode. The black squares correspond to the experimentally measured intensities, while the gray curves represent calculations based on equation (16).

Figure 17(b) shows the measured and calculated profiles for different boundary conditions. It is evident that the boundary condition determines the highest intensity of the respective mode in the Fourier space, that is, it determines value of the effective stripe width $w_{\mathrm{eff},n}$.

Measurements of intensities as a function of the wave vector, as displayed in Figure 17, provide Fourier space information. The larger the extent of the scattering regime in real space, the smaller the distribution in Fourier space, as measured with BLS. This can be used to estimate the spatial extent of such localized spin-wave modes. However, it should be noted that the BLS spectroscopy is a measurement of intensities not of amplitudes, and thus phase information is lost in this experiment. Consequently information about the lateral extent of modes can be obtained, but not the exact position of the mode amplitudes.

4.2.2 *Characterization of the spatial distribution of the spin-wave intensity and localization of modes in a rectangular element*

In the last section we have learned that information on the spatial distribution of spin waves can be obtained from the wave vector dependence of the BLS cross section of the quantized modes. Now we discuss an application where information on the lateral extent of spin-wave modes is very useful. We examine spin waves in a rectangular structure, as shown in Figure 18 (Inset).

Figure 18 displays the BLS intensity for a given mode as a function of the transferred wave vector $q_\parallel$ and perpendicular to the applied field. This system is a $Fe_{19}Ni_{81}$ rectangular of dimensions $1 \times 1.75\,\mu m^2$. For a transferred wave vector parallel to the applied magnetic field ($q_\parallel$ in Figure 18) a nearly q-independent BLS intensity is observed indicating a strong localization of the mode in real space. Investigations have shown that owing to the strongly varying internal field an additional localization mechanism operates here, which localizes the mode to regions near the two boundaries (Jorzick *et al.*, 2002; Bayer, Demokritov, Hillebrands and Slavin, 2003). Contrarily, for a transferred wave vector perpendicular to the applied field ($q_\perp$ in Figure 18) the peak in intensity shows that the mode is quantized over a much wider spatial length, consistent with the lateral dimensions of the rectangle. These experiments show very clearly that BLS microscopy in the 'Fourier microscope' mode is very useful to characterize spatial extensions of dynamic modes in such structures.

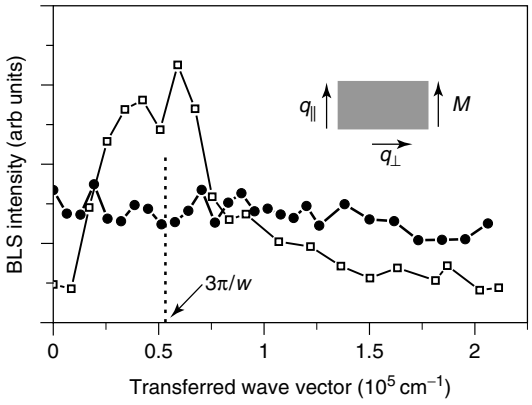

Figure 18. Brillouin light scattering study of a rectangular $Fe_{19}Ni_{81}$ element with dimensions $1 \times 1.75\,\mu m^2$. The intensity of the third localized mode as a function of the transferred in-plane wave vector parallel $q_\parallel$ (circles) and perpendicular $q_\perp$ (Squres) to the applied magnetic field. 4.3 Spin-wave modes in a square with Landau flux-closure domain structure

In this section and discuss the spin waves inside a 16-nm-thick permalloy ($Fe_{19}Ni_{81}$) square with a lateral width $L = 4\,\mu m$ containing a Landau flux-closure domain structure. The structure was produced by e-beam evaporation on a Si-substrate and capped with a 2-nm-thick Al overlayer for corrosion protection.

The domain walls are aligned along the diagonals of the square and the magnetization directions in the four triangular domains are aligned such that the flux is closed in the square. This is indicated in Figure 19(a).

In a time-resolved Kerr microscopy experiment made at the university of Regensburg (Perzlmaier *et al*., 2005), modes were excited using a one-turn microcoil with the sample in the center. A short current pulse was applied to the microcoil generating a magnetic field pulse of duration 300 ps. The time response of the sample was measured stroboscopically with 10-ps time steps. The time response was measured stroboscopically for each point of a two-dimensional mesh across the sample in order to yield spatial information also. The spatial resolution was 300 nm. From this data mode patterns have been reconstructed by Fourier-transforming the temporal response for each point on the sample. The upper parts of the panels in Figure 19 were obtained by plotting the Fourier component values for the respective mode frequencies. As can be seen, at 0.8 GHz, intensity is observed at the positions of the domain walls indicating a domain wall resonance. With increasing frequency several spin-wave modes (indicated by the index n in Figure 19) are observed.

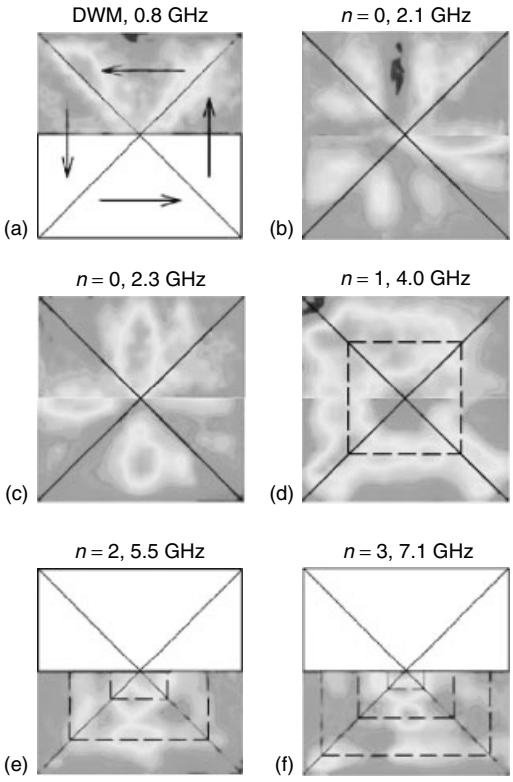

Figure 19. Spatial distribution of the amplitude of the dynamic magnetization corresponding to the eigenmodes in a $4 \times 4\,\mu m^2$ permalloy ($Fe_{19}Ni_{81}$) square. The upper and lower parts of each panel are measured using time-resolved scanning Kerr microscope and microfocus Brillouin light scattering spectroscopy, respectively. Diagonal solid lines indicate the domain walls, whereas the dashed lines indicate the mode maxima for a quantization in a transversal direction. The corresponding transversal quantization numbers n and the measurement frequencies are indicated near the distribution. Arrows in (a) indicate the direction of the static magnetization. DWM stands for domain wall mode. (Reproduced from K. Perzlmaier *et al*., 2005, with permission from American Physical Society. © 2005.)

Microfocus BLS (described in Section 3.1.2) is equally well suited to measure these dynamic modes. The lower halves of the panels in Figure 19 show the results. Here, a Fourier transform of data is not necessary, as the BLS process yields the spectral components directly. Again, using a scanning probe approach, the spectra are measured along a two-dimensional mesh of mesh size 200 nm. For frequencies, where both methods yield results, the agreement is remarkably pronounced. Modes with higher frequencies are better accessed by microfocus BLS spectroscopy, where time-resolved MOKE microscopy reaches its limit because of constraints in the pulsed field excitation. On the other hand, BLS does not access the modes with low frequencies as they are overlapped by elastically scattered light.

Figure 19 shows a clear quantization of the modes in each of the four triangular domains. Whereas a quantization

Tamaru *et al*., 2002, © 2002, American Institute of Physics.)

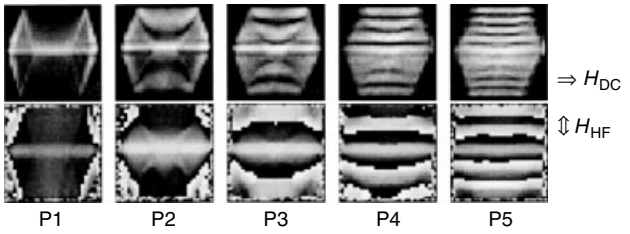

Figure 21. Spatial distribution of magnetization response at each peak. The upper and lower rows are the amplitude and phase distributions, respectively. The amplitude is normalized to the maximum value to give the largest contrast. (Reprinted with permission from S. Tamaru *et al*., 2002, © 2002, American Institute of Physics.)

along the direction of the magnetization can be observed, but not unambiguously assigned to a specific mode order; quantization in the perpendicular direction is very clearly observed. In Figure 19(b) and (c) the mode patterns show one maximum in the transverse direction, in Figure 19(d–f) the higher order modes are clearly observed.

4.4 Experiments with optical ferromagnetic resonance techniques

As shown in Section 3.3, time-resolved Kerr effect magnetometry, synchronized to a driving cw microwave field, can be used to measure spin-wave mode profiles (see Figure 12). Figure 20 shows the measured magnetization response of a 100-nm-thick permalloy film sputter deposited on a glass substrate and patterned into a $50 \times 50\,\mu m^2$ square. On top of the structure a planar transmission line of 750-nm-thick Cu with a center conductor width of 3 µm and an impedance of 50 Ω is mounted. The sample has been first saturated, and then the Kerr response has been measured as a function of the field, as shown in Figure 20. The sample is driven at 7.04 GHz. Five peaks are clearly seen. Figure 21 shows the obtained spatial distribution of the magnetization response at each peak. Standing wave patterns can easily be identified.

4.5 Propagating spin waves observed by optical techniques

The BLS spectroscopy technique is most often the method of choice to study propagating spin-wave modes. This has been demonstrated in Section 4.1, where spin-wave packets tunneling through a forbidden region have been discussed. We conclude this chapter by discussing complementary experiments using time-resolved MOKE microscopy.

Indications for the generation of spin waves have been found in a number of experiments (Silva, Kabos and Pufall,

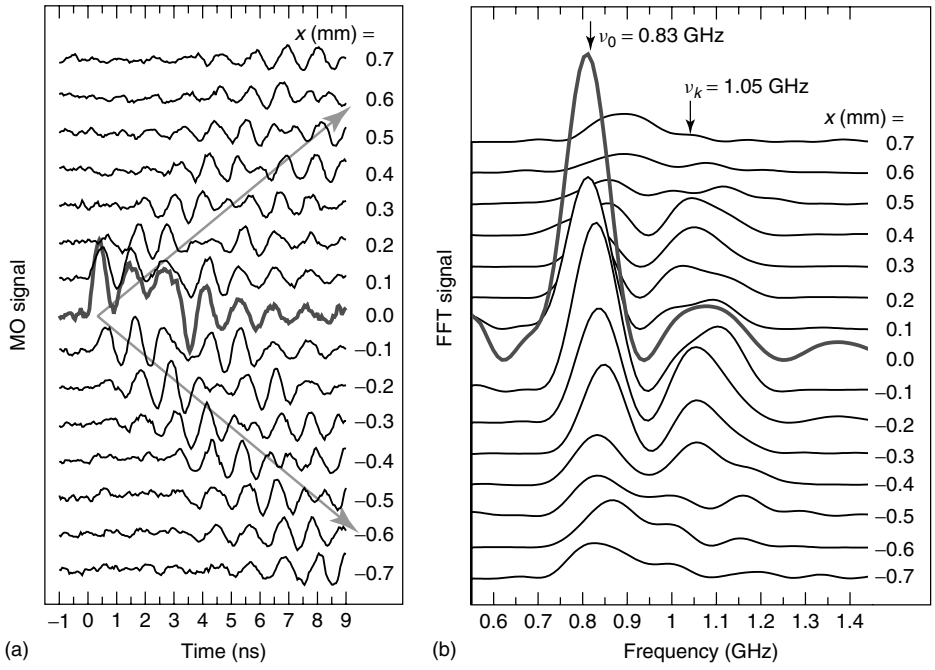

Figure 22. Response of the magneto-optic signal in time (a) and via fast Fourier transformation in frequency space (b). The distance of the investigated area from the transmission line, x, is indicated in both figures. The arrows in (a) correspond to the group velocity $6.6\,cm\,\mu s^{-1}$ as determined from change of the positions of maximum magnetization deviation after a half-precession period. The frequencies of the uniform and the propagating spin-wave mode are $\nu_0 = 0.83$ GHz and $\nu_k = 1.05$ GHz, respectively. (Reproduced from J. Fassbender *et al*., 2003, with permission from Springer-Verlag. © 2003.)

2002; Hiebert, Ballentine and Freeman, 2002; Gerrits, Silva, Nibarger and Rasing, 2004), where a reduction of the absolute value of the magnetization vector was observed. There, the excitation of high wave vector spin waves was confirmed. The direct observation of propagating spin waves using this technique has been reported by Fassbender (2003). Using a pulsed excitation of an infinitely extended film mounted on a strip line, the propagation of well-confined wave packets away from the strip line into the film was observed. Figure 22 shows some obtained results. The magneto-optic response for different distances from the transmission line as a function of time is shown in Figure 22(a), and the corresponding Fourier transforms are shown in Figure 22(b). At $x = 0$, two peaks in the frequency spectrum are observed, identified as a uniform precession mode and a propagating spin-wave mode with frequencies $\nu_0 = 0.83\,\mathrm{GHz}$ and $\nu_k = 1.05\,\mathrm{GHz}$, respectively. For the uniform precession mode the strong decrease in mode intensity in the direction perpendicular to the strip line indicates the localization of this mode to the transmission line. The intensity of the propagating wave, however, is nearly constant over a large range. For larger distances the mode is not observed for reasons of finite group velocity and damping. The propagating spin-wave mode carries energy away and reduces the energy to be dissipated in the transmission line area.

Investigations like these allow the measurement of the phase velocity v_{ph}, the wavelength λ, and the wave vector q, as demonstrated in Figure 23. Here, the magneto-optic signal, averaged along a line parallel to the transmission line, is shown as a function of the distance x from the transmission line for different delay times. The solid arrows indicate the temporal evolution of constant phases. Their slopes allow for the determination of the phase velocity, which is $v_{\mathrm{ph}} = 34 \pm 7\,\mathrm{cm\,\mu s^{-1}}$. The dashed arrow indicates the center of the spin-wave packets, which move at the smaller group velocity v_{g}. From these data a wavelength of $\lambda = 0.03\,\mathrm{cm}$ and a wave vector of $q = 210\,\mathrm{cm^{-1}}$ of the propagating spin wave are obtained. The obtained data indicates that the observed mode is an MSSM (see equation (7)).

5 CONCLUSIONS

This Chapter provides an introduction into the state of the art of optic techniques for investigating magnetization dynamics. Techniques on both the frequency scale and the timescale – BLS spectroscopy and the Kerr effect – have been presented. A few selected experiments have been discussed to demonstrate the specific strengths for each method.

The field of magnetization dynamics is currently advancing very fast. Progress is substantially driven by new experimental techniques. Further advancements in optical techniques will certainly help to push this very interesting field continuously forward.

NOTES

[1] See, for example, **Dissipative Magnetization Dynamics Close to the Adiabatic Regime, Volume 1**, **Nonlinear Magnetization Dynamics in Nanomagnets, Volume 2**, **Guided Spin Waves, Volume 2**, and **Magnetization Dynamics: Thermal-driven Noise in Magnetoresistive Sensors, Volume 2**.

[2] The $p_{\mathrm{in}} - p_{\mathrm{out}}$ SHG configuration also depends on the polar magnetization component (Bennemann, 1998), but this contribution is usually weak.

[3] Recall that the dynamic magnetization $\vec{m} = \vec{M} - \vec{M}_s$ is the difference between the total and the saturation magnetization.

ACKNOWLEDGMENTS

The authors are very thankful to all those who have contributed to the progress in optical techniques, in particular, to the members of the group in Kaiserslautern. They would like to thank specifically Sergej Demokritov, Jürgen Fassbender, and Alexander Serga.

Time-resolved Kerr-effect and Spin Dynamics in Itinerant Ferromagnets

Bert Koopmans
Eindhoven University of Technology, Eindhoven, The Netherlands

1 INTRODUCTION

The time-resolved optical exploration of the ultimate limits of magnetization dynamics in itinerant ferromagnets (FMs) is widely recognized as an intriguing field of research (for reviews, see Zhang, Hübner and Bigot, 2002; Koopmans, 2003; Bennemann, 2004). Clearly, it has been driven by the quest for fundamental understanding of magnetization processes in the strongly nonequilibrium regime – a particularly nontrivial issue. How to understand the magnetism of materials, when by an almost instantaneous perturbation of the material different subsystems, such as electrons and lattice, are no longer in thermal equilibrium? What are the limiting timescales at which we can manipulate the magnetic order? And what are the relevant processes that we need to understand and maybe even can control?

Apart from this fundamental interest, there are two other obvious drivers that have led to an exciting, rapidly progressing field of research. First of all there is the availability since the 1990s of commercial and easy-to-handle systems for producing femtosecond laser pulses, and the development of ultrasensitive magneto-optical (MO) pump-probe schemes with unprecedented time resolution.

Secondly, there is the intimate relation of the field with the booming area of spintronics, and related therewith all applications that require ultrafast control of magnetic materials and devices. Exemplary is the extremely rapid progress in magnetic hard disk recording, where the need for subnanosecond control over media and heads has emerged. A similar driver is provided by the development of magnetic random access memory (MRAM), for which new magnetic switching schemes are being considered. More general, the fundamental exploration of ultrafast magnetization dynamics provides generic insight in elementary spin-scattering phenomena that are of profound interest for many novel spintronic devices.

Finally, technologies that combine the interaction of laser light with magnetic materials within the application itself, such as MO recording, have to be identified as an important stimulus for laser-based studies of fast magnetic processes. Of particular interest from this viewpoint are recent activities striving for laser-based heat-assisted magnetic recording.

In general, pump-probe schemes have been most successful in search for the ultimate timescales. In such a

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

stroboscopic scheme, a first, pulsed perturbation is being applied to the magnetic system under investigation after which a second probe pulse, arriving at a preset delay time, is being used to probe the magnetic state. By scanning the delay time, the full temporal evolution of the magnet state after its initial perturbation can be followed. It has to be emphasized, however, that in general the probe only provides a limited access to the multidimensional character of the strongly nonequilibrium magnetic state, which makes interpretation of such experiments an art itself.

It should be stressed that any perturbation that changes the magnetic ground state will do – although the physics being probed may (and will) be strongly depending on the type of excitation chosen. Also, probing the magnetization dynamics can be achieved by different means; the choice made again affecting the view on the magnetic system being obtained. Although a number of approaches will be explained throughout this chapter, our main focus will be on all-optical approaches, in which femtosecond laser pulses are used both as the perturbation and as the probe.

By now it is generally known that pulsed-laser excitation triggers a rich spectrum of spin dynamical processes. The field started with pioneering experiments by Beaurepaire, Merle, Daunois and Bigot (1996), who addressed the truly nonequlibrium regime of itinerant FMs for the first time. It was found that laser heating of ferromagnetic thin films gives rise to a loss of magnetic order within the first picosecond. This exciting result became soon confirmed by several groups. By now, a general consensus has been achieved on a characteristic 'demagnetization' timescale of a hundred to a few hundreds of femtoseconds.

Apart from the ultrafast loss of magnetic order, the experiments provided access to spin-dependent dynamics in the population of electronic states that could be interpreted as 'artifacts' when striving for resolving the genuine magnetization dynamics, but could be seen as a highly challenging spin-dependent phenomenon on itself as well.

Moreover, in many cases it turned out possible to trigger precessional dynamics by perturbing the magnetic anisotropy on a picosecond timescale by the laser heating. On the one hand, this offered an alternative to pulsed field-induced precessional experiments, on the other hand, it provided a complementary view on the dynamics of the magnetic anisotropy itself. In this respect, a particularly interesting research topic that emerged is the ultrafast manipulation of the interlayer exchange coupling between a FM and a neighboring antiferromagnetic (AF) layer.

Despite the interest in laser-induced loss of magnetic order, from technological point of view it would be of superior interest not only to quench, but also being able to increase or even fully create ferromagnetic order at a subpicosecond timescale. Also this has been recently achieved in pioneering experiments in FeRh thin films, by driving the metamagnetic AF to FM phase transition by pulsed heating.

Today, we have reached the end of the first (extremely successful) decade of laser-induced magnetization dynamics, where the field went through a continuous discovery of new phenomena and development of novel approaches. Theoretical understanding of the processes at a microscopic level is lagging somewhat behind. However, there is a growing awareness being witnessed that these issues should be considered among the major challenges of modern condensed-matter physics. It would be welcomed if this opinion would lead to a significant increase of theoretical efforts.

The scope of this chapter is as follows. In Section 2 we start with a general overview, and introduce basic concepts. In Section 3, experimental approaches, mostly concentrating on all-optical ones, are described in detail. Particular emphasis is on the subtle and nontrivial way the targeted physical parameters are being probed. Then, a number of sections reviewing experimental progress over the past decade can be found. After a brief review of the pioneering, early days (Section 4), sections on population dynamics (Section 5), light-induced orbital momentum transfer (Section 6), demagnetization dynamics (Section 7), anisotropy dynamics induced precession (Section 8), and growth of magnetic order by triggering phase transitions (Section 9) will follow. Finally, concluding remarks will be drawn in Section 10.

2 CLASSIFICATION AND BASICS

Within this section, first the dynamics of the average magnetization vector (orientational or precessional dynamics) and the thermodynamics of spin systems (dealing with the magnitude of the magnetization) are discussed separately. Then, after some considerations regarding conservation of angular momentum, different scattering mechanisms are briefly introduced: electron–electron scattering, electron–phonon scattering, and different types of spin-flip scattering.

2.1 Precessional dynamics

The most elementary spin dynamics process is that of the precession of a single spin in an applied magnetic field H. The field introduces a splitting between spin-up and spin-down states with an energy difference equal to $\gamma\mu_0 H$, where γ is the gyromagnetic ratio. As a consequence, the dynamics of any electron that is in a superposition of the two eigenstates corresponds to a precession of the spin expectation value around the field-axis at the Larmor frequency $\omega_L = \gamma\mu_0 H/\hbar$. The same frequency is found

for an ensemble of spins, or the magnetization $\vec{M}$ of a homogeneous magnetic material. Characteristic frequencies are in the gigahertz regime, as can be estimated from $\gamma/\hbar = 176\,\mathrm{ns}^{-1}\,\mathrm{T}^{-1}$.

Including dissipation will lead to a damped precessional motion, in which a gradual decay toward the lowest energy state is accompanied by the alignment of $\vec{M}$ with the applied magnetic field. Accounting for dissipation in a phenomenological way in the spirit of Gilbert, leads to the well-known Landau–Lifshitz–Gilbert (LLG) equation of motion (Miltat, Albuquerque and Thiaville, 2002)

$$\frac{\mathrm{d}\vec{M}}{\mathrm{d}t} = \gamma\mu_0\left(\vec{M}\times\vec{H}_{\mathrm{eff}}\right) + \frac{\alpha}{M}\left(\vec{M}\times\frac{\mathrm{d}\vec{M}}{\mathrm{d}t}\right) \qquad (1)$$

where we replaced the applied (external) field $\vec{H}$ by the effective field

$$\vec{H}_{\mathrm{eff}} = \vec{H} + \vec{H}_{\mathrm{anis}} = \vec{H} - \frac{1}{\mu_0 M}\vec{\nabla}E_{\mathrm{anis}}(\vec{M}) \qquad (2)$$

Herein, the anisotropy field ($\vec{H}_{\mathrm{anis}}$, related to the gradient of the anisotropy energy E_{anis}) may include contributions from dipolar fields by the system itself (resulting in the 'shape anisotropy'), crystalline anisotropy (mediated by spin-orbit interactions), and others. Note that this effective field depends on the orientation of the magnetization vector itself, and thereby becomes explicitly time-dependent even for a constant external field. Finally, equation (1) can be generalized to a nonhomogeneous magnetization distribution $\vec{M}(\vec{r}, t)$, in which the exchange interaction between noncollinear spins has to be included as well.

It should be noted that the process of energy dissipation is much more complicated than would have been expected from the appearance of a single damping parameter in equation (1). In fact, the value of α depends on almost all details of the (micromagnetic) system; the 'constant' being far more than a materials specific parameter. Exploration of magnetic damping is an active field of research (see e.g., Urban, Woltersdorf and Heinrich, 2001; Tserkovnyak, Brataas and Bauer, 2002; Woltersdorf, Buess and Back, 2005; Buess, Haug, Scheinfein and Back, 2005; Steiauf and Fähnle, 2005).

2.2 Thermodynamics–transfer of energy

After having treated the dynamics of the average magnetization vector, we consider the thermodynamic evolution of spin fluctuations. In general, for an ordinary ferromagnetic system, the thermal equilibrium value of the magnetization (M_{eq}) displays a continuous decrease as a function of increasing temperature. Above the Curie temperature and in the absence of a magnetic field, any long-range magnetic order vanishes. Without loss of generality, one can introduce a spin temperature T_{s}, from the one-to-one relation between M_{eq} and T (Figure 1a); that is, at a spin temperature T_{s} the magnetization equals $M_{\mathrm{eq}}(T_{\mathrm{s}})$ by definition.

Let us next consider a system with interacting lattice (phonons), electronic (excluding spin) and spin degrees of freedom. Within the so-called three-temperature (3T) model (Beaurepaire, Merle, Daunois and Bigot, 1996), each of the subsystems are assumed to be internally in thermal equilibrium, and described by their own temperature (T_{p}, T_{e}, and T_{s}, respectively) and heat capacity (C_{p}, C_{e}, and C_{s}), where in general the latter can be functions of T_{p}, T_{e} and T_{s}, respectively. Given any starting set of temperatures, the evolution of the system is described by a set of three coupled differential equations:

$$C_{\mathrm{e}}\frac{\mathrm{d}T_{\mathrm{e}}}{\mathrm{d}t} = -G_{\mathrm{ep}}(T_{\mathrm{e}} - T_{\mathrm{p}}) - G_{\mathrm{es}}(T_{\mathrm{e}} - T_{\mathrm{s}}) \qquad (3)$$

$$C_{\mathrm{p}}\frac{\mathrm{d}T_{\mathrm{p}}}{\mathrm{d}t} = -G_{\mathrm{ep}}(T_{\mathrm{p}} - T_{\mathrm{e}}) - G_{\mathrm{sp}}(T_{\mathrm{p}} - T_{\mathrm{s}}) \qquad (4)$$

$$C_{\mathrm{s}}\frac{\mathrm{d}T_{\mathrm{s}}}{\mathrm{d}t} = -G_{\mathrm{es}}(T_{\mathrm{s}} - T_{\mathrm{e}}) - G_{\mathrm{sp}}(T_{\mathrm{s}} - T_{\mathrm{p}}) \qquad (5)$$

The mutual coupling constants, G_{ep}, G_{es}, and G_{sp} will strive to balance out any nonequilibrium between the subsystems by exchange of energy (Figure 1b). In laser-heating experiments (see next subsection), absorption of photons leads mostly to electronic excitations, causing a quasi-instantaneous increase of the electron temperature. The successive dynamics has been found to be phenomenologically describable by equations (3–5), as already noted in the original work by Beaurepaire, Merle, Daunois and Bigot (1996). Therefore, the model is extremely useful to parameterize transient experiments, although only limited microscopic insight is being provided.

As another limitation of this description, the three-temperature model does not properly take care of conserving the angular momentum $\vec{J}$ of the total system (Koopmans, 2003; Koopmans, van Kampen and de Jonge, 2003).

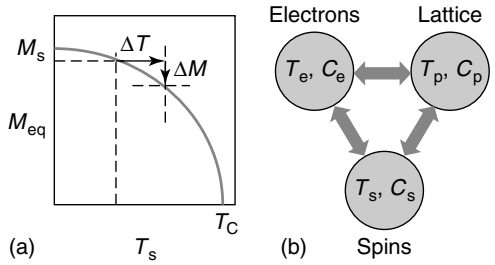

Figure 1. (a) Definition of spin temperature, and representation of a laser-induced magnetization dynamics experiment, and (b) the three interacting reservoirs in the three-temperature model.

At present, angular momentum conservation is being considered as an important ingredient of understanding the ultrafast equilibration process.

2.3 Transfer of angular momentum

At a subpicosecond timescale, it is natural to consider the interacting reservoirs being isolated from the environment. For such a closed system, not only the total energy should be conserved (discussed in Section 2.2), but also the total angular momentum $\vec{J}$. The spin ($\vec{S}_e$) and orbital ($\vec{L}_e$) moment of the electronic system are related to its magnetic moment

$$\vec{\mu} = \mu_B(\vec{L}_e + g\vec{S}_e) \tag{6}$$

where $g \approx 2$ for the materials considered here. In addition, these electronic moments are related to the total angular momentum of the system. When including possible momentum carried by the laser field (photons) and the lattice (phonons), the total angular momentum reads

$$\vec{J} = \vec{L}_e + \vec{S}_e + \vec{L}_{phonon} + \vec{L}_{photon} \tag{7}$$

Since the Hamiltonian of the entire system conserves $\vec{J}$, a change in magnetization of a closed system can only be achieved by exchange among the four contributions at the right-hand side of equation (7). This has interesting consequences not contained within the three-temperature model.

As an example, let us consider the exchange of energy between the electron and the spin reservoir, heating up the spins (lowering M) by cooling down a hot-electron gas. In the absence of interactions with the laser field and lattice this can only be achieved by an exchange of $\vec{S}_e$ and $\vec{L}_e$ as mediated by spin-orbit coupling. One has to realize that in the ground state, the magnetization of ferromagnetic transition metals is strongly dominated by the spin momentum (i.e., $\mu \approx g\mu_B S$) because of quenching of the orbital momentum (Ashcroft and Mermin, 1976). Then, for $g \approx 2$, transferring spin momentum to orbital momentum leads to a reduction of μ by a factor of 2 at most. In particular, it means that this mechanism cannot lead to a full quenching of M, whereas a complete loss of magnetic order has been experimentally observed at high enough fluences (see the discussion on the full quenching regime in Section 7).

2.4 Laser-induced electron and spin dynamics

This section addresses the different scattering processes as of relevance after laser excitation.

2.4.1 Photoabsorption and state filling

The interaction of laser pulses with matter primarily causes electronic excitations. Exploiting light sources in the (near)visible range, with typically photon energies from one to several electron volts, causes thereby excited electrons with energies a hundred times the thermal energy at room temperature. Even if the excitations conserve spin, and thereby $\vec{M}$ is conserved during the excitation, the redistribution of occupied electronic levels will change the MO response of the system (Koopmans, van Kampen and de Jonge, 2003; Oppeneer and Liebsch, 2004). In particular, excitations made by the pump pulse, will block the same transitions to be made by probe photons, a phenomenon denoted 'dichroic bleaching' (Koopmans, van Kampen, Kohlhepp and de Jonge, 2000b).

After laser excitation, the total energy of the electron system has increased. Although at this stage the system is in strong thermal nonequilibrium and thereby a temperature is not unambiguously defined, the excess energy can be used to define an electron temperature, $T_{e,E}$, according to the equilibrium relation between excess energy and electron temperature. For a free-electron system with a constant density of states (DOS) D_F one can derive $E_{ex} = \frac{1}{6}\pi^2 D_F (k_B T_{e,E})^2$, where k_B is the Boltzmann constant. In the weak perturbation limit, treating only small changes in temperature, we thus find:

$$\Delta T_{e,E} = \frac{3}{\pi^2 D_F k_B^2 T_{e,E}} \Delta E_{ex} \tag{8}$$

Alternatively, we could have defined a temperature according to the slope of the electron distribution function $f(E)$ at the Fermi energy E_F. From the analogy with a thermalized electron distribution, one can derive

$$\Delta T_{e,F} = -\left(4k_B \left.\frac{df(E)}{dE}\right|_{E_F}\right)^{-1} \tag{9}$$

Note that laser excitation causes an instantaneous increase of $T_{e,E}$, while $T_{e,F}$ displays a gradual increase in which electronic relaxation is involved.

2.4.2 Electron–electron scattering

The lifetime of 'hot' carriers is very short. Within a free-electron metal, phase space arguments can be used to derive the hot-electron lifetime (Knorren, Bennemann and Burgermeister, 2000; Bennemann, 2004)

$$\tau_{ee}(E) = \frac{1}{K_{ee}(E - E_F)^2} \tag{10}$$

where the electron–electron scattering constant K_{ee}^{-1} is typically 30 fs eV^2 for Ag and 3 fs eV^2 for nickel (Knorren, Bennemann and Burgermeister, 2000). The difference reflects the larger phase space for scattering provided by the high DOS of the Ni d-band near E_F. Note, however, that for such metals, with d-states near the Fermi level, equation (10) is not too accurately fulfilled.

After having started the cascade-like process of e–e scattering, the electron gas rapidly thermalizes (Groeneveld, Sprik and Lagendijk, 1995). Different approximations for the thermalization process lead to an expression of the form

$$\tau_T = \frac{A}{K_{ee} T_e^2} \tag{11}$$

with $A \sim 2\,\mathrm{K}^2\,\mathrm{eV}^2$ for nickel (van Kampen *et al*., 2005a). Taking $K_{ee}^{-1} = 3\,\mathrm{fs\,eV}^2$ leads to a thermalization time $\tau_T \approx 300$ fs for Ni. Significantly lower estimates ($\sim$100 fs) are obtained when correcting for deviations from equation (10), in better agreement with experimental findings (van Kampen *et al*., 2005a).

The simplest way of introducing laser excitation into the 3T-model is by inserting a source term in equation (3) (Beaurepaire, Merle, Daunois and Bigot, 1996):

$$C_e \frac{dT_e}{dt} = -G_{ep}(T_e - T_p) - G_{es}(T_e - T_s) + P(t) \tag{12}$$

where $P(t)$ denotes the power dissipated in the electron system by absorption of photons at time t. This way, however, the process of electron thermalization is not covered since in the strict 3T-model the electron system is considered to be internally in thermal equilibrium from the start ($\tau_T = 0$).

Extended models have been introduced to account for the thermalization by adding an additional bath of nonthermal electrons (Fann, Storz, Tom and Bokor, 1992; Sun *et al*., 1994). The extended 3T model (Koopmans, 2003) is sketched in Figure 2. Within such a 'E3T' model, it is essential to use $T_{e,F}$ to denote the temperature of thermalized electrons. The

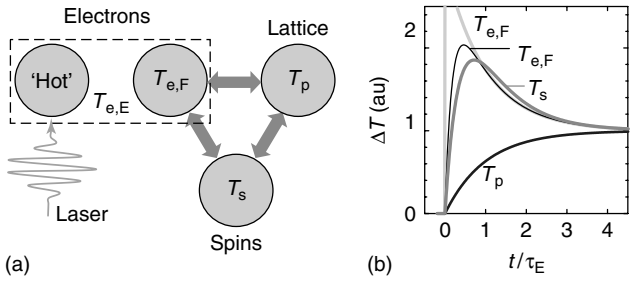

Figure 2. Extended three-temperature model: (a) The four reservoirs, including nonthermalized 'hot' electrons excited by the laser pulse. (b) Schematic transient of the four temperatures, discussed in the text, for a case where $\tau_T = 0.2\tau_E$ and $\tau_M = 0.5\tau_E$.

total energy stored in the system of nonthermal electrons is then

$$E_{\mathrm{nonthermal}} = C_e(T_{e,E} - T_{e,F}) \tag{13}$$

which vanishes after thermal equilibrium has been established, $T_{e,E} = T_{e,F}$. The temporal evolution of the Fermi temperature is often approximated by an empirical relation:

$$\Delta T_e = \Delta T_1 \left[1 - \exp\left(\frac{-t}{\tau_T}\right)\right] \tag{14}$$

where ΔT_1 is the final temperature rise, proportional to the absorbed laser power in the low-fluence limit. Note that in equation (14) we dropped the explicit subscript 'F', as we will keep on doing throughout this chapter.

2.4.3 *Electron–phonon scattering*

Equilibration of electrons with the lattice proceeds via electron–phonon (e–p) scattering (for a review, see e.g., Groeneveld, Sprik and Lagendijk, 1995). The most efficient process is the deformation potential scattering by longitudinal acoustic zone-edge phonons (with an energy of the order of the Debye energy, $\hbar\omega_D$) (van Hall, 2001). If one assumes that the heat capacities C_e and C_p are relatively constant over the temperature range covered, and neglecting the spin system for the moment ($C_s = 0$), equations (3) and (4) can be solved analytically, resulting in an exponentially converging temperature with a time constant

$$\tau_E = \frac{C_e C_p}{C_e + C_p} \frac{1}{G_{ep}} \tag{15}$$

where subscript 'E' denotes 'Energy' equilibration. Typically, $\tau_E \sim 0.5$ ps for the ferromagnetic transition metals (van Kampen *et al*., 2005a).

Incorporating the thermalization process as well, an empirical relation for the electron temperature transient can then be introduced (van Kampen *et al*., 2005a):

$$\begin{aligned}\Delta T_e = {} & \Delta T_1[1 - \exp(-t/\tau_T)]\exp(-t/\tau_E) \\ & + \Delta T_2[1 - \exp(-t/\tau_E)]\end{aligned} \tag{16}$$

where ΔT_2 is the final temperature to which T_e and T_p converge, and $\Delta T_1 \geq \Delta T_2$. It is easy to show that $\Delta T_1/\Delta T_2 = 1 + C_p/C_e$. In the limit $\tau_T \ll \tau_E$, ΔT_e approaches ΔT_1 for times $\tau_T \ll t \ll \tau_E$, and thereby a clear 'overshoot' of T_e is being witnessed.

The simplest *microscopic* approach, on equal footing with the derivation of the free-electron lifetime (10), is obtained by using a simple Einstein model with identical harmonic oscillators representing the phonon system. Matrix elements

for e–e and e–p scattering (λ_{ee} and λ_{ep}, respectively) can then be assigned to the scattering processes, represented in Figure 3. Alternatively, scattering probabilities $K_{ee} \propto \lambda_{ee}^2$ (cf. (10)) and $K_{ep} \propto \lambda_{ep}^2$ entering the Boltzmann equations describing the dynamics of the system, can be introduced. It can be derived that for T_e and T_p well above T_D the phenomenological coupling constant G_{ep} of the 3T-model is independent of temperature, and related to the microscopic parameter K_{ep} according to (Hohlfeld, 1998)

$$G_{ep} = K_{ep} E_p k_B \tag{17}$$

Using the Born–Oppenheimer approximation for the deformation potential scattering, and equations (15) and (17), yields τ_E of the order of 1 ps, in reasonable agreement with experiment (van Kampen *et al*., 2005a).

2.4.4 Spin scattering

Often, it is of relevance to assign a characteristic timescale τ_M to an experimentally obtained MO transient – independent of the microscopic interpretation. Although the full 3T-model can be used for that purpose, here we limit ourselves to a simple approximation that can be treated analytically. We use the following assumptions: (i) the spin specific heat is neglected, (ii) C_e and C_p are considered constant, which can be achieved at low enough fluence, (iii) we assume that the spin dynamics is merely controlled by T_p and $T_{e,E}$ (and *not* $T_{e,F}$), according to:

$$\frac{dT_s}{dt} = \frac{(T_{e,E} - T_s)}{\tau_{M,e}} + \frac{(T_p - T_s)}{\tau_{M,p}} \tag{18}$$

We note that the last assumption lacks a strict, physical motivation, though it is in line with the description of the energy flow in the 2T- and 3T-model. Moreover, it makes sense that the highly excited (nonthermal) electrons have a significant influence on the spin relaxation, as would not be the case if equation (18) were described in terms of $T_{e,F}$. Finally, we use the electron and phonon temperature transients: $\Delta T_{e,E}(t) = T_2 + (T_1 - T_2)\exp(-t/\tau_E)$ and $\Delta T_p(t) = T_2(1 - \exp(-t/\tau_E))$, in agreement with equation (16). Then, we find as a general solution:

$$\Delta T_s(t) = \Delta T_2 + \frac{(\tau_E \Delta T_1' - \tau_M \Delta T_2)\exp(-t/\tau_M)}{\tau_E - \tau_M} + \frac{\tau_E(\Delta T_2 - \Delta T_1')\exp(-t/\tau_E)}{\tau_E - \tau_M} \tag{19}$$

with $\tau_M^{-1} = \tau_{M,e}^{-1} + \tau_{M,p}^{-1}$, and $\Delta T_1' = \Delta T_1 \tau_M / \tau_{M,e}$. An 'overshoot' of T_s is achieved in the case that the e–s channel dominates over the s–p channel, that is $\tau_{M,e} \ll \tau_{M,p}$, unless $\tau_M \gg \tau_E$, all as expected.

The result shows that an overall τ_M (including both contributions via the s–p and s–e channel) can be fitted, without prior knowledge of which of the two channels dominates, and without needing information from transient reflection. If the latter *is* available, and thereby ΔT_1, the ratio of the fitted $\Delta T_1'/\Delta T_1$ can be used to extract $\tau_{M,e}$ and $\tau_{M,p}$ separately.

Often, in literature, an even more empirical fitting function is being used that can be described generally as:

$$\Delta T_s(t) = \left(1 - \exp\frac{-t}{\tau_M}\right)\Delta T_e(t) \tag{20}$$

It should be emphasized that although the shape of the resulting profile $T_s(t)$ can be quite similar to the one produced by (19), the extracted value of τ_M can be off by a factor two! Examples thereof are discussed in Sections 6 and 7.

As to the microscopic origin of the laser-induced demagnetization, quite a number of spin-scattering processes have to be considered. We discuss them in the context of conservation of J. First, the hot-electron lifetime can be spin dependent (Aeschlimann *et al*., 1997; Knorren, Bennemann and Burgermeister, 2000; Bennemann, 2004). Experiments using two-photon photoemission (TPPE) have indeed found significant differences between majority and minority carriers for the ferromagnetic transition metals Co, Fe, and Ni (Aeschlimann *et al*., 1997). The results have been interpreted in terms of the huge difference of phase space for scattering majority and minority carries within the spin-split DOS of these materials. Relevant timescales are in the low-femtosecond regime. It should be emphasized, however, that the spin-dependent lifetime has no relation to a change in magnetic moment of the system.

Secondly, spin scattering by redistribution of angular momentum within the electron system is considered. It has been argued that hot electrons will have high enough energy to overcome the Stoner gap (Scholl, Baumgarten, Jacquemin and Eberhardt, 1997), and thereby create Stoner excitations–changes of the local spin moment. These spin flips would be accompanied by emission (or absorption) of magnons (spin waves). However, also this process does not provide a net change of the magnetic moment of the system.

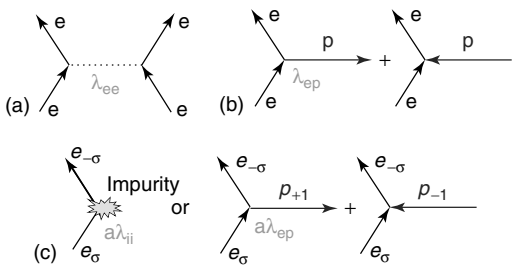

Figure 3. Feynmann diagrams for (a) e–e scattering, (b) e–p scattering, and (c) e–p scattering accompanied with spin flip.

An other purely electronic process to be considered is transfer from spin to orbital momentum as mediated by spin-orbit coupling. From the typical energy scale $\Delta_{\mathrm{exc}} \sim 0.1\,\mathrm{eV}$ fast time scales $\hbar/\Delta_{\mathrm{exc}} \sim 10\,\mathrm{fs}$ could be anticipated indeed. In Section 2.3, however, we already derived that, unlike experimental observations, this mechanism cannot account for a full quenching of M while conserving J. Moreover, the final state would be characterized by a large orbital momentum. Using arguments to be introduced in Section 3.2, this should lead to an increase rather than a decrease of MO signals upon laser heating, again contrary to experimental observations.

Thirdly, transfer of energy between the lattice and spin system can occur (Koopmans, Kicken, van Kampen and de Jonge, 2005; Koopmans, Ruigrok, Dalla Longa and de Jonge, 2005). This can be considered as ordinary spin-orbit mediated spin-lattice relaxation (Yafet, 1963). Angular momentum is being transferred from the spin to the lattice, by absorption or emission of phonons carrying orbital momentum. On a macroscopic scale, this transfer is being witnessed as a finite rotation of a magnetic bar upon changing its magnetic moment, as in the classical De Haas and Einstein experiment (Scott, 1962). For nonmagnetic metals spin-lattice scattering has been well addressed, and described by Eliot–Yafet type of scattering (Yafet, 1963). A finite probability a is assigned for an electron to flip its spin upon momentum scattering with phonons or impurities. This process is schematically represented in Figure 3(c). Although values of a have been tabulated before for some nonmagnetic metals (Beuneu and Monod, 1978), little is known about implications for ferromagnetic transition metals. In passing we not that, in principle, a similar factor a can also be related to the spin diffusion length (l_{sf}), used to describe magneto transport in, for example, current-perpendicular to the plane giant magnetoresistance (GMR) pillars (Dubois *et al*., 2006). However, a comparison between the spin-flip probability in the transport regime and the strongly nonequilibrium laser-heating case is far from trivial – and has not been discussed in literature yet. Therefore, in the present review, we will refrain from such a detailed analysis.

Finally, scenarios including the laser field itself or hybrid mechanism have been proposed, but all have their intrinsic complications. At this stage, the reader may wonder what is causing the demagnetization after all. Although a full understanding has not been achieved yet, a more quantitative discussion of the present insights is discussed in Sections 6 and 7.

3 EXPERIMENTAL APPROACHES

Over the past decade a number of techniques have been developed that give access to the dynamics of spin systems down to femtosecond timescales. Most of them rely on the use of subpicosecond laser pulses. This section provides a detailed description of the relation between magneto-optics and spin dynamics, and discusses different experimental approaches.

3.1 Excitation sources

In order to access subpicosecond magnetization dynamics, extremely short rise time or pulse-lengths should be exploited. From conceptual point of view, magnetization dynamics is triggered in the most straightforward way by short magnetic field pulses. Conventional approaches using electronic pulse generators are limited to a rise time of several tens of picoseconds at least, even when taking utmost care to feed pulses into- and guide them through microscopic strip lines (Elezzabi and Freeman, 1996; Elezzabi, Freeman and Johnson, 1996; Hiebert, Stankiewicz and Freeman, 1997). An exciting alternative has been provided by using picosecond electron bunches from a linear accelerator (Siegmann *et al*., 1995) Experiments so far (Back *et al*., 1998, 1999; Tudosa *et al*., 2004; Stamm *et al*., 2005) have been restricted to static microscopic characterization after single pulse excitation. Time-domain extrapolations of the technique could be imaginable, although stroboscopic approaches are very unlikely. In passing, we also stress the importance of spin-torque induced switching, which recently has been observed spatio-temporally resolved by ultrafast x-ray microscopy (Acremann *et al*., 2006).

Hybrid schemes, using femtosecond optical pulses to produce picosecond rise time magnetic field pulses have been demonstrated in a multitude of configurations. The standard approach employs a photoconductive switch to launch an electrical pulse into a strip line. Typically, around picosecond rise times and – when desired – tunable duration can be produced (e.g., Gerrits *et al*., 2002). An alternative, in which switch and sample are integrated, is the use of laser pulses to trigger breakthrough of a Schottky barrier that supports a thin-film FM sample (Woltersdorf, Buess and Back, 2005).

Integrating pulse generator and sample even further is established in all-optical configurations. In order to study precessional dynamics similar to the field-induced cases, a configuration can be employed in which an internal anisotropy field pulse is being generated by pulsed-laser heating of a magnetic thin-film system (van Kampen *et al*., 2002). We stress that this approach has been demonstrated to be widely applicable. However, it cannot be applied in, for example, magnetic configurations in which the applied and effective field are both along a symmetry axis of the sample. Further details will be discussed in Section 8. The next section will focus on thermodynamic processes triggered by the laser heating.

3.2 Ultrafast probes and time-resolved magneto-Optics

A number of femtosecond laser-based approaches to probe the subpicosecond magnetization dynamics have been developed. Detecting photoemitted electrons has been exploited in different schemes: spin-polarized time-resolved photoemission (SP-TRPE) (Scholl, Baumgarten, Jacquemin and Eberhardt, 1997), time-resolved photoemission (TRPE) probing the evolution of the exchange splitting (Rhie, Dürr and Eberhardt, 2003, 2005; Lisowski *et al*., 2005), or probing the spin dynamics via the image-potential states at FM surfaces (Schmidt *et al*., 2005). With the advance of new generations of synchrotrons, X-ray magnetic circular dichroism – with the unique potential of probing spin and orbital momenta separately – is expected to play an important role in the near future. Within the present chapter, though, we concentrate on all-optical approaches.

The latter are based on the MO-Kerr effect. The key link between the magnetic state of a material and the MO response is provided via the dielectric tensor. As an instructive case, for an optically isotropic material, magnetized along $\hat{z}$, the dielectric tensor reads:

$$\overleftrightarrow{\epsilon} = \begin{pmatrix} \epsilon_{xx} & \epsilon_{xy} & 0 \\ -\epsilon_{xy} & \epsilon_{xx} & 0 \\ 0 & 0 & \epsilon_{xx} \end{pmatrix} \tag{21}$$

Note that ε_{xy} transforms antisymmetrically under reversal of the magnetization, $\vec{M} \leftrightarrow -\vec{M}$, providing the 'magnetic contrast'.

Thus, polarized light experiences a rotation upon transmission (Faraday effect) or reflection (Kerr effect) from a magnetic medium. The resulting complex MO rotation is written as $\tilde{\theta} = \theta + \mathrm{i}\epsilon$, where θ and ϵ are the induced MO rotation and ellipticity, respectively. The relation between MO rotation and $\vec{M}$ can be written as (Koopmans, 2003)

$$\tilde{\theta} = \tilde{F} M \tag{22}$$

where a generalized Fresnel coefficient $\tilde{F}$ has been introduced that involves all details of the experimental configuration and sample layout. We restricted ourselves to the simplified case where $\tilde{\theta}$ depends on the magnitude (or a single component) of $\vec{M}$ only, and refer to (Koopmans, 2003) for the general case.

Measuring $\tilde{\theta}$ in a time-resolved experiment, one should be aware of the possibility that the perturbation does not only modify $\vec{M}$, but also the generalized Fresnel coefficient $\tilde{F}$. This can significantly hinder a simple interpretation solely in terms of $\vec{M}$

Another, even more subtle complication arises because MO experiments are only possible by the sake of spin-orbit coupling, through which the spatial degree of freedom (electric field) is correlated with the spin degree of freedom (magnetic ordering). In fact, it can be stated that optics is merely capable of measuring the *orbital* moments in a material, whereas a prediction about $\vec{M}$ is possible only after assuming a certain fixed ratio of spin ($\vec{S}$) to orbital ($\vec{L}$) momenta. This ratio is not *a priori* conserved upon perturbation of the material. As to the dependency on $\vec{L}$, a sum-rule has been derived that links the frequency integrated absorptive past of the off-diagonal element of the dielectric tensor to a part of the *orbital* momentum (Oppeneer, 1998). Rather than writing equation (22) in terms of $\vec{L}$, we will include those potential deviations within the explicit time dependence of $\tilde{F}$.

In the further analysis we assume the weak perturbation regime, in which changes of the Kerr rotation are relatively small. In that case, the relation $\theta(t) = F(t)M(t)$ can be linearized (Koopmans, 2003):

$$\Delta\theta(t) = M_0 \Delta F(t) + F_0 \Delta M(t) \tag{23}$$

where index '0' denotes unperturbed values (at $t < 0$) and Δ indicates pump-induced values. From equation (23) it is easily seen that, whenever $F(t) = F_0$ independent of t, the relation

$$\frac{\Delta\theta(t)}{\theta_0} = \frac{\Delta\epsilon(t)}{\epsilon_0} = \frac{\Delta M(t)}{M_0} \tag{24}$$

is fulfilled, that is, the normalized transient rotation and ellipticity should be equivalent. Therefore, any deviation from equation (24) demonstrates the presence of an explicit t-dependence of F. A similar identification of 'optical artifacts' can be based on a spectroscopic analyses. Whenever optical artifacts play a role, one may expect the normalized MO transients to depend on the probing frequency ω. If not, the relation

$$\frac{\Delta\theta(\omega_1, t)}{\theta_0(\omega_1)} = \frac{\Delta\epsilon(\omega_2, t)}{\epsilon_0(\omega_2)} = \frac{\Delta M(t)}{M_0} \tag{25}$$

holds for any set of frequencies (ω_1, ω_2).

Complementary to measuring the linear optical response, higher order optical signals can be monitored to acquire information on the magnetization dynamics. A well-known example is provided by magnetization-induced optical second-harmonic generation (MSHG) (See also **Magnetization-induced Second Harmonic Generation, Volume 3**). Also there, the aim is to extract information on those tensor elements that transform odd under reversal of $\vec{M}$. Well-known advantages of MSHG are its interface sensitivity (Pan, Wei and Shen, 1989; Hübner and Bennemann, 1989; Shen, 1989)

and the huge nonlinear Kerr angles that can be achieved (Koopmans, Groot Koerkamp, Rasing and van den Berg, 1995). Disadvantages are the small signals, down to the photon counting regime, and an even less-trivial interpretation. In principle, the analysis in terms of a generalized Fresnel factor $\tilde{F}$ can be extended to the nonlinear case, leading to similar explicit time-dependencies that affect magnetization dynamics studies in the same way as in its linear counterpart (Regensburger, Vollmer and Kirschner, 2000).

3.3 Implementations

The simplest realization of an all-optical time-resolved magneto-optical Kerr effect (TRMOKE) experiment in a *crossed-polarizer configuration* is sketched in Figure 4. Pump and probe pulses are focused to overlapping spots on the sample. The pump pulses pass a mechanical delay line to adjust the time delay. The influence of the pump beam on the polarization state of the reflected probe pulse is measured using an analyzer at an angle α_A and any type of photodetector. Either a measurement of $\tilde{\theta}(t)$ with and without pump pulses is performed, or, to enhance the sensitivity, a mechanical chopper is placed in the pump beam, and a lock-in amplifier is used to directly measure $\Delta\tilde{\theta}(t)$.

It can easily be derived that the pump-induced change in output signal is described in lowest order of $\Delta\tilde{\theta}$ and α_A by (Koopmans, 2003)

$$\Delta I(t) = 2R_0\alpha_\mathrm{A}\Delta\theta(t) + \alpha_\mathrm{A}^2\Delta R(t) \tag{26}$$

where R_0 and $\Delta R(t)$ are the reflectivity and pump-induced transient thereof. Within the basic implementation, no sensitivity on ellipticity is achieved, and care has to be taken to rule out artificial signals due to a $\Delta R(t)$ of nonmagnetic origin. Bigot *et al*. argued that part of the drawbacks of the crossed-polarizer approach are avoided by performing measurements at a multitude of analyzer angles (Bigot, Guidoni, Beaurepaire and Saeta, 2004).

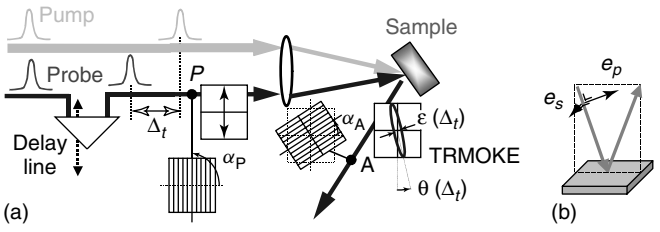

Figure 4. Schematic illustration of a TRMOKE setup. (a) In the crossed-polarizer experiment, a polarizer is inserted at 'P' and an 'analyzer' almost crossed at 'A'. (b) Definition of the polarization vectors $\vec{e}_\mathrm{s}$ and $\vec{e}_\mathrm{p}$.

A particularly attractive, alternative scheme is provided by replacing the analyzer by a polarizing beam splitter, using a pair of balanced photodiodes and generating the difference signal by a differential amplifier (Ju *et al*., 1998b). Thereby, a highly sensitive measure of the MO transient is achieved. When working exactly at the balanced configuration, a dependency on $\Delta R(t)$ can be avoided (Koopmans, 2003):

$$\Delta I(t) = 2R_0\Delta\theta(t) \tag{27}$$

When required, a sensitivity to the complementary ellipticity channel is obtained by using a quarter-wave plate, an option also available for the crossed-polarizer configuration.

A final scheme is achieved by exploiting polarization modulation using, for example, a photoelastic modulator (PEM) placed before the sample (Koopmans, van Kampen, Kohlhepp and de Jonge, 2000a). Then, the detected signal displays oscillating signals I_nf at harmonics nf of the PEM frequency f. A number of configurations has been reported, some of them solely depending on $\Delta\tilde{\theta}(t)$, others also on ΔR (Koopmans, 2003). As an example, having the main axis of the PEM parallel or perpendicular to the plane of incidence, one obtains to a fair approximation (Koopmans, van Kampen, Kohlhepp and de Jonge, 2000a; Koopmans, 2003):

$$\frac{\Delta I_\mathrm{1F}(t)}{I_{0f}} = 2J_1(A_0)\Delta\varepsilon(t) \tag{28}$$

$$\frac{\Delta I_\mathrm{2F}(t)}{I_{0f}} = 2J_2(A_0)\Delta\theta(t) \tag{29}$$

where $J_n(A_0)$ is the nth order Bessel function at the retardation A_0 of the PEM. It is obtained that the $1f$-signal is proportional to the transient ellipticity, whereas the $2f$-signal corresponds to rotation. Thus, the approach is highly applicable when identifying optical artifacts (cf. equation (24)).

Aiming at a full deconvolution of transient dielectric tensor elements of the magnetic materials, rather than just the transient (MO) reflection, a combination of experiments is required. Combining rotation and ellipticity, both in the magnetic and nonmagnetic channel, and/or combining rotation (Kerr) and transmission (Faraday) measurements, have been reported. Examples of such a transient MO ellipsometry can be found in (Guidoni, Beaurepaire and Bigot, 2002). When further striving for parallel detection of a broad spectral range, the simplest configuration, that of the crossed-polarizer, is most appropriate. Bigot introduced such a method of femtosecond spectrotemporal magneto-optics, in which spectrally broadened probe pulses (480–750 nm) were used, and the Kerr and Faraday rotation spectra where measured at a multitude of analyzer angles (Bigot, Guidoni, Beaurepaire and Saeta, 2004).

In the analysis so far, cases were treated where only the magnitude $M(t)$, or one of its vector components, $M_i(t)$, was of relevance. Vectorial schemes, to measure three components of $\vec{M}(t)$, using a high-aperture microscope objective and four-quadrant detection are widespread by now (for details, see Freeman and Hiebert, 2002). While so far being restricted to studies of magnetic field-induced dynamics, very recently, an extension to all-optical investigations down to the femtosecond regime has been reported (Vomir *et al*., 2005).

It has been discussed that dichroic bleaching can hinder a proper view on the ultrafast demagnetization process during the first hundreds of femtoseconds. Attempts to establish a full separation of $\Delta F(t)$ and $\Delta M(t)$ have been reported by van Kampen *et al*. In particular, they suggested to measure the MO transients at different ambient temperatures to establish this separation (Koopmans, van Kampen and de Jonge, 2003; van Kampen, 2003). The key approach is as follows. We start by writing the normalized $M(t)$ in terms of a spin temperature $T_s(t)$,

$$\frac{\Delta\theta(t)}{\theta_0} = \frac{\Delta F(t)}{F_0} + \frac{1}{M_0}\frac{\mathrm{d}M_0}{\mathrm{d}T_0}\Delta T_s(t) \tag{30}$$

We now consider transient experiments at two ambient temperatures ($T_{0,1}$ and $T_{0,2}$) and denote thermal differences by δ. As an important approximation, we assume that *the state-filling effects are relatively independent of temperature*, that is, $\delta\Delta F(t) \approx 0$ and $\delta F_0 \approx 0$, since broadening the Fermi-profile by a few millielectron volts hardly changes the hot-electron ($>$ eV) behavior. Then we obtain:

$$\delta\left(\frac{\Delta\theta(t)}{\theta_0}\right) = \delta\left[\frac{1}{M_0}\frac{\mathrm{d}M_0}{\mathrm{d}T_0}\right]\Delta T_s(t) + \frac{1}{M_0}\frac{\mathrm{d}M_0}{\mathrm{d}T_0}\delta\Delta T_s(t) \tag{31}$$

Note that $|M_0^{-1}\mathrm{d}M_0/\mathrm{d}T_0|$ is strongly T-dependent. In fact, it diverges while approaching T_C, providing further support for the neglect of the term $\delta(\Delta F(t)/F_0)$ in equation (30). In order to proceed, we make a second approximation: *the evolution of the spin temperature is independent of the starting temperature of the experiment*, that is, $\delta\Delta T_s(t) = 0$. Within the 3T-model, for example, this is fulfilled if C_e, C_p, and G_{ep} are T-independent, and C_s can be neglected. Then, the spin dynamics can be derived from

$$\Delta T_s(t) \approx \frac{\delta\left(\Delta\theta(t)/\theta_0\right)}{\delta\left[M_0^{-1}\left(\frac{\mathrm{d}M_0}{\mathrm{d}T_0}\right)\right]} \tag{32}$$

where the numerator is experimentally measured, and the denominator is obtained from the materials specific $M(T)$. Preliminary results of this *thermal difference scheme* have been recently reported by our group (Koopmans, van Kampen and de Jonge, 2003; van Kampen, 2003).

As a final more sophisticated approach, one might want to perform a 'thermal difference scheme' but drop the approximation of constant C_e and C_p. Such an approach has been outlined in Koopmans (2004). While potentially an interesting route for future studies, we refrain from a detailed discussion in the present review.

4 PIONEERING WORK ON LASER-INDUCED DYNAMICS

Early attempts on estimating timescales with laser-induced magnetization dynamics were by Agranat and coworkers in the mid-1980s (Agranat, Ashikov, Granovskii and Rukman, 1984, 1986). The demagnetization of transition metal thin films was studied by measuring the remnant MO contrast with a dc probing laser after pulsed-laser heating with pulses of different duration. It was concluded that the spin relaxation time in the FM lies in the interval $1\text{ns} < \tau_M < 40\text{ns}$.

First real-time experiments were performed using SP-TRPE in the beginning of the 1990's (Vaterlaus, Beutler and Meier, 1991; Vaterlaus *et al*., 1992). Detailed experiments were conducted on the rare-earth FM gadolinium (Gd), yielding $\tau_M = 100 \pm 80\,\text{ps}$, and iron. The accuracy in those experiments was limited, however, by the relatively long duration of the heating pulses ($\sim$10 ns). Nevertheless, the experimentally determined relaxation time τ_M was found to be in good agreement with theoretical estimates based on spin-lattice relaxation by Hübner and Bennemann (1996). Therefore, around 1995, it was concluded that the demagnetization upon laser heating is dominated by spin-lattice relaxation, and proceeds at a typical timescale of $\tau_M \sim 0.1$–1 ns.

In view of the previous context, a surprising result was obtained in 1996 by Beaurepaire, Merle, Daunois and Bigot (1996). They reported on a combined TRMOKE and transient reflection study. The spin temperature, as extracted from TRMOKE, was found to display a maximum around 2 ps, while the initial decay rate was a few tenths of a picosecond only, suggesting $\tau_M < 0.5$ ps (Figure 5). The complete behavior was shown to be described adequately by a 3T-model (equations (12), (4), and (5)). A complete dominance of the spin-electron coupling over the spin-lattice coupling needed to be assumed.

The experimental finding of an ultrafast ($\tau_M < 500$ fs) spin relaxation was confirmed soon thereafter by several groups. Hohlfeld *et al*. exploited time-resolved SHG (Section 3.2) to study $T_e(t)$ and $T_s(t)$ in bulk polycrystalline nickel (Hohlfeld, Matthias, Knorren and Bennemann, 1997). In contrast with the work of Beaurepaire, it was found that already after 300 fs the magnetization is governed by the electron temperature,

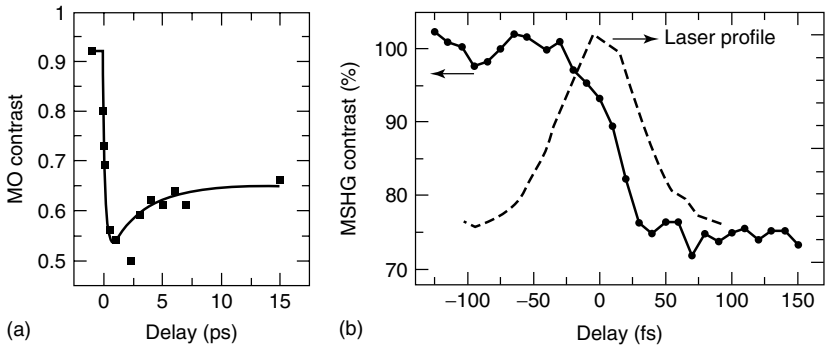

Figure 5. (a) Pioneering experiments by Beaurepaire, showing the loss of MO contrast of a nickel thin film within 1 ps after laser excitation. (Reproduced from Beaurepaire *et al*., 1996, with permission from the American Physical Society. © 1996.) (b) Similar data by Güdde and Hohlfeld, using MSHG, and showing a quasi-instantaneous demagnetization. (Reproduced from J. Güdde *et al*., 1999, with permission from the American Physical Society. © 1999.)

that is, $T_s(t) = T_e(t)$, even before electrons and *lattice* have mutually thermalized, that is, $\tau_M < \tau_E$. For even smaller delay times, $t < \tau_T$, at which the electron thermalization has not set in yet, a break down of the classical magnetization behavior was found. On the basis of this, one could conclude that $\tau_M \approx \tau_T$.

In later experiments, using shorter pulses, even a quasi-instantaneous break down of the MO contrast was found (Güdde *et al*., 1999; Hohlfeld *et al*., 1999); $\tau_M \approx 0 \ll \tau_T$. Within the experimental resolution, the loss of 'magnetic order' was described by the time integral of the absorbed pump power, that is, the absorbed energy was seen to be converted directly to the spin system. Other experiments showed a 100% quenching of M, when using high enough fluence and films with a reduced T_C (Güdde *et al*., 1999; Conrad, Güdde, Jähnke and Matthias, 1999). A similar FM→PM transition was demonstrated in more detail for $CoPt_3$ by Beaurepaire *et al*. (1998).

An alternative confirmation for an ultrafast subpicosecond loss of magnetic order in Ni thin films ($\tau_M = 300$ fs) came from TRPE by Scholl, Baumgarten, Jacquemin and Eberhardt (1997). In contrast with previous work, a second, slower transition of hundreds of picoseconds was reported. The two timescales were assigned to Stoner excitations and ordinary spin-lattice relaxation, respectively. However, such a second process has never been reproduced, despite specific search for it (Hohlfeld, 1998; Hohlfeld *et al*., 1999).

On the basis of these first experiments it was concluded that the loss of MO contrast is extremely fast, at least within a few hundred femtoseconds, that is, well before the electron and lattice system are mutually equilibrated; ($\tau_M < \tau_E$). Speculations were around on a demagnetization directly linked to electron thermalizaton ($\tau_M \approx \tau_T$), or even being quasi instantaneous ($\tau_M \ll \tau_T$), meaning that $M(t) = M_{eq}(T_{e,E}(t))$. Particularly the last claim triggered some concerns as to the simple interpretation of the data, and a potential role of 'optical artifacts'. Such optical effects will be addressed in the next two sections. After that, we will return to the genuine demagnetization process in more detail.

5 POPULATION DYNAMICS

Around the year 2000, a number of groups started to question the simple interpretation of the TRMOKE experiments that seemed to indicate an almost instantaneous demagnetization. Doubting a direct proportionality between MO signal and M is equivalent to considering a potential explicit time dependence of the effective Fresnel coefficient $\tilde{F}$ in equation (22).

First experimental evidence that this was indeed the case came from Koopmans, van Kampen, Kohlhepp and de Jonge (2000a,b), who measured the rotation and ellipticity separately in a TRMOKE experiment on (epitaxial) nickel thin films (Figure 6a). It was found that during the first hundreds of femtoseconds after laser excitation, a profound difference between the two normalized channels arose: $\Delta\varepsilon(t)/\varepsilon_0 \neq \Delta\theta(t)/\theta_0$. Those experiments provided unambiguous proof that, at least in some cases, the MO transient after pulsed-laser heating does not reflect the genuine magnetization dynamics. Effects were attributed to 'dichroic bleaching', or state blocking effects, as introduced in Section 2.4.1.

Similar conclusions were drawn from MSHG experiments on Ni(110) single crystals by Regensburger, Vollmer and Kirschner (2000). MSHG experiments can be performed in several configurations, selecting different (combinations of) second-harmonic susceptibility tensor elements. In one of the configurations, the authors observed a reversal of the MO contrast when pumping at high enough laser fluence, whereas it was carefully excluded to be related to a true magnetization reversal. It was concluded, again, that the fast initial drop of the MO signal cannot be unambiguously attributed to an ultrafast demagnetization.

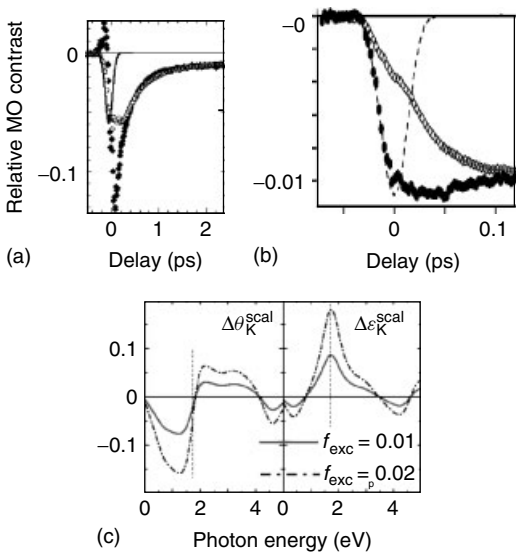

Figure 6. (a) TRMOKE ellipticity and rotation for nickel thin film. (After Koopmans, 2000b.) (b) Complementary channels for $CoPt_3$. (After Guidoni, 2000.) (c) Calculated dichroic bleaching for same excitation density as (a); the laser frequency corresponds to the vertical dashed line. (Reproduced from Oppeneer *et al*., 2004, with permission from IOP Publishing Ltd. © 2004.)

By now, a clear consensus on the explicit time dependence of $\tilde{F}$ has been achieved. However, it has been found also that the relative importance of such 'optical artifacts', as well as the timescale over which they contribute, depends strongly on sample layout and experimental settings. Comin reported results for 50-nm cobalt thin films, observing the strongest differences persisting for a few hundred femtoseconds, very similar to the original nickel work (Comin *et al*., 2004). Pronounced differences in the transients of different MSHG tensor elements of nickel and permalloy thin films were reported by Melnikov, Güdde and Matthias (2002). Beaurepaire performed detailed experiments on $CoPt_3$ (Guidoni, Beaurepaire and Bigot, 2002). It was again found that during electron thermalization ($t < \tau_T$) a difference between the real and imaginary signal exists, however, full overlap was found after thermalization was established (Figure 6b). Finally, van Kampen carefully controlled the 'chirp' (i.e., the time lag between high- and low-frequency components) of the laser pulses to investigate the optical artifacts (van Kampen, 2003; Koopmans, van Kampen and de Jonge, 2003). The MO trace depended on the chirp indeed, in a way that was fully consistent with expectations from simple models. This served as additional proof for the absence of a direct relation between $\tilde{\theta}(t)$ and $M(t)$.

Differences persisting for much longer times, up to several tens of picosecond, were observed both by van Kampen on Cu(001)/Ni (Koopmans, van Kampen, Kohlhepp and de Jonge, 2000b; van Kampen, 2003), and by Kampfrath on iron thin films (Kampfrath *et al*., 2002). In this context, it also noteworthy mentioning similar results for manganites (more specifically PCMO and LCMO) by McGill *et al*. (2004). In that case, artifacts playing a role for nanoseconds could be attributed to contrasting carrier dynamics.

In general, it has been argued that the strongest deviations would occur in cases where either of the two signals strongly dominates the static MO response, that is, cases where $\theta_0 \ll \epsilon_0$ or *vice versa*. In such a case even small changes in the minor channel (e.g., $\Delta\theta(t)$) would yield huge effects in the normalized signal ($\Delta\theta(t)/\theta_0$). In MO spectra such cases would occur near zero crossings of $\theta(\omega)$ or $\epsilon(\omega)$, with obvious divergences at the zero crossings themselves.

In cases where θ_0 and ϵ_0 are of similar magnitude, smaller differences – or even no measurable difference at all – have been reported. Identical traces have been observed, for instance, for nickel films on silicon wafers (Wilks, Hughes and Hicken, 2002) (although subtle differences were reported in Wilks *et al*., 2004), and $Si/Si_3N_4/Ni$ films (van Kampen, 2003). Moreover, Bigot used femtosecond spectroscopy with supercontinuum pulses (spectrum spreading from 480 nm to 750 nm) to demonstrate that for $CoPt_3$ films the identity $\Delta\theta(t)/\theta_0 = \Delta\epsilon(t)/\epsilon_0$) holds for the whole spectral range measured (Bigot, Guidoni, Beaurepaire and Saeta, 2004), although the temporal resolution was somewhat lower ($\geq$200 fs) in this experiment.

Altogether, lots of evidence has been gathered for optical artifacts. The few reports on long lasting effects are not fully understood yet. In contrast, dichroic bleaching during the thermalization phase of the electronic system after optical excitation has been interpreted in a quantitative way. In a naive picture, one would expect the relative change of the MO response $\Delta\theta/\theta_0$ to be of the order of the excitation density f_{exc}, defined as the number of optically excited electrons per atom. Such a behavior can easily be derived for an ensemble of two-level systems. However, effects for dichroic bleaching as reported in the original work (Koopmans, van Kampen, Kohlhepp and de Jonge, 2000b) were as high as $\Delta\theta/\theta_0 \sim 0.1$ for laser fluences corresponding to $f_{exc} = 0.01$. It was conjectured that such an effect could be understood by the fact that because of momentum conservation during optical excitations, the transitions are concentrated in specific parts of the Brillouin zone. As a result, the few states that are involved are much more effective in blocking additional transitions when using probe and pump pulses of the same photon energy (Koopmans, van Kampen, Kohlhepp and de Jonge, 2000b).

Recently, Oppeneer and Liebsch (2004) performed *ab initio* calculations of the magneto-optics for nonequilibrium electron distributions in nickel to put these hand waving arguments on more solid ground. More specifically, they

investigated the MO response right after optical excitation, treating the electronic structure and optical matrix elements within the density-functional theory. They found a quantitative agreement with the experiments, but only when properly taking the momentum conservation during optical excitation into account. At the laser frequency of 1.7 eV the calculated dichroic bleaching corresponded to $\Delta\epsilon/\epsilon_0 \approx 9 f_{\mathrm{exc}}$, in good agreement with experimental results (Figure 6c). It is fair to stress that the calculations represent a worst-case scenario in the sense that electronic relaxation of hot electrons is not included. Such a relaxation is taking place within tens of femtoseconds, most probably leading to a fast decay of the bleaching effects. Detailed calculations thereof would be of considerable interest, but require an enormous numerical effort and have not been reported to date.

Concluding this section, both experimental and theoretical results have demonstrated the nonequivalence of the MO response and the transient magnetization in the regime of the strongly excited state before thermalization has set in. By focusing on the strongest of the complementary MO signals (rotation vs ellipticity) one may hope to obtain a more direct view on the magnetization dynamics. Nevertheless, a full understanding has not yet been achieved, as also evidenced by artifacts remaining for tens of picoseconds of unknown origin that appear in some of the experiments.

6 EXPERIMENTS ON ORBITAL MOMENTUM TRANSFER

In the process of laser-induced loss (or, more generally, modification) of magnetic order, a contribution by the transfer of angular momentum between the laser field and the FM sample cannot be excluded *a priori*. As to emphasize its potential relevance, it is of interest pointing recent developments in optical control of ferromagnetic garnets. It was demonstrated by Kimel and Hansteen *et al*. that circularly-polarized light can be used to nonthermally excite and coherently control the spin dynamics via the inverse Faraday effect in, for example, $DyFeO_3$ (Kimel *et al*., 2005) and $Lu_{3-x-y}Y_xBi_yFe_{5-z}Ga_zO_{12}$ (Hansteen, Kimel, Kirilyuk and Rasing, 2005). Other related work is that on ultrafast modification of the order parameter in AF materials that has been addressed both in theory (Gomez-Abal, Ney, Satitkovitchai and Hübner, 2004) and experiment (Kimel, Pisarev, Hohlfeld and Rasing, 2002; Duong, Satoh and Fiebig, 2004). In the latter case, however, conservation of J does not play a role, since the AF ordered state carries no net M.

The feasibility of the role of the laser field to the demagnetization process in itinerant FMs could be concluded from theoretical work by Zhang and Hübner. They developed a particularly interesting model, in which an ultrafast magnetic response (within ~10 fs) is explained by the dephasing induced by a cooperative effect of spin-orbit coupling and the external laser field (Zhang and Hübner, 2000). Although not stated explicitly, either direct angular momentum transfer from/to the laser field, or laser-enhanced transfer between orbital and spin momentum should be at the basis of the described effect. It is questionable, however, whether the laser-induced mechanism plays a dominant role in the demagnetization after laser heating of the ferromagnetic transition metals, as will be discussed in the subsequent text.

The first experiments on laser-induced angular momentum transfer for itinerant FMs were reported by Ju *et al*. (1998b). They used circularly-polarized pump pulses to study ultrafast spin dynamics in $CoPt_3$. More recently, Wilks and coworkers reported on polarization dependent studies on the ultrafast MO response of nickel thin films (Wilks *et al*., 2004). Whereas linearly polarized pump pulses provided relatively conventional transient demagnetization results ($\tau_{\mathrm{M}} = 130$ fs; minor difference between rotation and ellipticity), pronounced effects showed up in the rotational channel around zero delay when using circularly-polarized pump pulses. Nevertheless, this additional signal was demonstrated to transform even under reversal of the magnetic field, while transforming odd under reversal of the handedness of the polarization. Therefore, it cannot be considered a real magnetic effect, as also becomes clear from the observation of similar features for nonmagnetic materials (Wilks and Hicken, 2004). The additional features are well described by the specular inverse Faraday effect (SIFE) and specular optical Kerr effect (SOKE) (Wilks *et al*., 2004), related to the third-order optical susceptibility tensor, $\chi^{(3)}_{xxyy}$ and $\chi^{(3)}_{xyyx}$.

More recently, Dalla Longa performed additional circularly-polarized pumping experiments on nickel thin films (Dalla Longa, 2007), fully confirming results of Wilks. In the work of Dalla Longa, however, focus was particularly on a potential influence of the handedness of the pump polarization on the demagnetization timescale τ_{M}. It was argued that when the angular momentum of the photon was parallel to the original magnetic moment of the thin film, transfer of angular momentum could never promote a fast demagnetization on itself. Results (Figure 7) showed τ_{M} to be independent of the pump polarization within experimental accuracy ($\tau_{\mathrm{M}} = 135 \pm 10$ fs when using equation (20); $\tau_{\mathrm{M}} = 74 \pm 4$ fs when using equation (19)), ruling out a significant role of the photon angular momentum in the laser-induced ultrafast demagnetization process in nickel. In passing we emphasize that these results are in line with earlier, more qualitative, conclusions on an insignificant role of circular polarization for $CoPt_3$ (Beaurepaire *et al*., 1998).

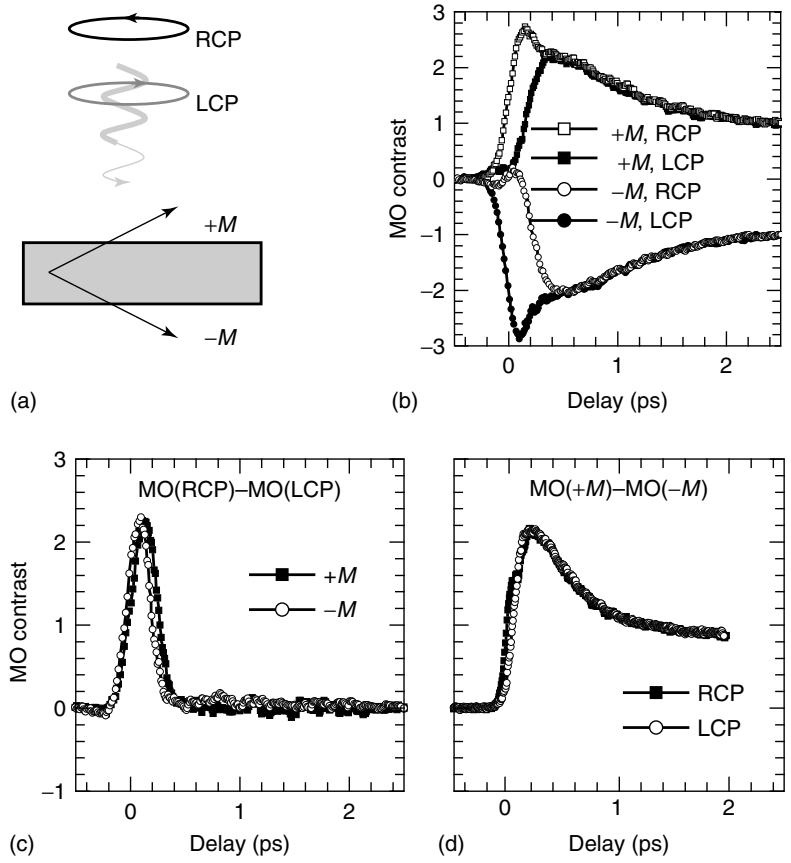

Figure 7. (a) Schematic diagram of the configuration. Applying a field perpendicular to the thin film, causes an upward ($+M$) or downward canting of the magnetization ($-M$). Photon angular momentum in a polar geometry is parallel or antiparallel for right-handed (RCP) or left-handed (LCP) polarized light, respectively. (b) TRMOKE in polar geometry on a 10-nm Ni thin film, using RCP and LCP pump light and canting magnetization upward and downward. (c) Polarization contrast (difference in contrast between RCP and LCP), and (d) magnetic contrast (difference between $+M$ and $-M$) in the same experiment. (After Dalla Longa, 2007.)

The latter conclusion cannot be considered as a complete surprise, because it agrees with earlier predictions: For example, in (Koopmans, van Kampen, Kohlhepp and de Jonge, 2000b) an excitation density $f_{\text{exc}} = 0.01$ led to a maximum demagnetization of 5%. For nickel, with an atomic magnetic moment of $0.6\,\mu_{\text{B}}$. This corresponds to a loss of $0.03\,\mu_{\text{B}}$ per Ni atom. Even if all absorbed photons would have transferred one quantum of angular momentum, the photon flux would have been a factor of 3 too small. Even more strongly, taking into account the quenching of orbital momentum in the transition ferromagnetic metals (Ashcroft and Mermin, 1976), which generally leads to a lowering of MO efficiency by one to two orders of magnitude, fully excludes a possible role of the photon-induced mechanism.

It should be emphasized that the foregoing estimate does not disqualify a photon-induced transfer between orbital and spin momenta, mediated by the laser field. However, in Section 2.3 it was argued that such a mechanism cannot lead to a full quenching of magnetization in the systems considered.

In conclusion, circularly-polarized light triggers interesting processes in the itinerant FMs, but these cannot be considered of relevance for the ultrafast demagnetization process. A simple estimate shows that the amount of photons is too small to account for the observed decrease of magnetic moment. Moreover, the experiments demonstrate that a possibly small transfer does not act as a seed for the process.

7 DEMAGNETIZATION DYNAMICS

After having read Section 5, the reader might have wondered whether TRMOKE is capable of probing the ultrafast magnetic behavior properly, and even whether a genuine demagnetization is occurring within a picosecond at all. Fortunately, the situation is far more positive. At present, it is generally

believed that – in most cases – TRMOKE closely images the genuine $M(t)$ behavior, and agrees on a characteristic timescale well below a picosecond, as based on the following arguments:

1. A loss in MO contrast within a few hundred femtoseconds is observed in almost all itinerant ferromagnetic metals (apart from Ni, e.g., Fe (Kampfrath *et al.*, 2002), NiFe (Melnikov, Güdde and Matthias, 2002), Co (Güdde *et al.*, 1999; Conrad, Güdde, Jähnke and Matthias, 1999; Comin *et al.*, 2004), $CoPt_3$ (Beaurepaire *et al.*, 1998; Guidoni, Beaurepaire and Bigot, 2002), and $Co_{25}Ni_{75}$/Pt multilayers (Wilks, Hicken, Ali and Hickey, 2005)).
2. In almost all experiments, starting with (Hohlfeld, Matthias, Knorren and Bennemann, 1997), it has been found that after approximately 300–500 fs, $\tilde{\theta}(t)$ is consistent with a spin temperature that is approaching the electron temperature, that is, $M(t) \sim M_{\rm eq}[T_{\rm e}(t)]$. From about half a picosecond, the demagnetization transient $\tilde{\theta}(t)$ reflects both the subpicosecond e–p equilibration, as well as the diffusive cooling of the thin film thereafter. Deviations from this behavior only occur in those exceptional cases where differences between $\Delta\theta(t)/\theta_0$ and $\Delta\epsilon(t)/\epsilon_0$ persist for longer times.
3. The *magnitude* of the demagnetization (as measured after a few hundred femtoseconds) displays a temperature dependence that would have been expected from a laser-heating induced change of the *equilibrium* magnetization at different ambient temperatures, that is, $\Delta\tilde{\theta} \propto ({\rm d}M_{\rm eq}(T)/{\rm d}T)\Delta T$, where ΔT is determined by the laser fluence and heat capacity (van Kampen, 2003).
4. Even in cases where differences between $\Delta\theta(t)/\theta_0$ and $\Delta\epsilon(t)/\epsilon_0$ persist for tens of picosecond, the thermal differences of the complementary channels (the real and imaginary part of ${\rm d}\tilde{\theta}/{\rm d}T$) nicely overlap (Koopmans, van Kampen and de Jonge, 2003), as shown in Figure 8.
5. If, in spite of the preceding arguments, at 1 ps the spin system would not have reached thermal equilibrium with electrons and lattice, a second (slower) transient to the final fully equilibrated state should be observed (most probably on a timescale of at most hundreds of picoseconds). Except for initial work by Scholl, Baumgarten, Jacquemin and Eberhardt (1997), in which a slower transition to the fully demagnetized state after a few hundred picosecond was claimed, such a two-step process has never been observed for the elementary itinerant FMs.
6. At large laser fluence (or reduced Curie temperature) and at a reversed bias field (i.e., H antiparallel to M) it has been shown possible to fully quench the MO contrast well within a picosecond, after which recovery is in the opposite orientation (Beaurepaire *et al.*, 1998; Hohlfeld *et al.*, 2001). It is difficult to come up with any interpretation other than a successful magnetization reversal, seeded within the first picosecond. We emphasize that the possibility to achieve full quenching in Ni thin films is not entirely uncontroversial. For example, Cheskis *et al.* claimed to see a saturation of the contrast loss at high excitation densities (Cheskis *et al.*, 2005). However, such a saturation can equally well be explained by the finite penetration depths of the pump light and the relatively thick film thickness (30 nm, i.e., twice the extinction depth) used in that work. Thereby, as a rough estimate, the laser power to heat the bottom part of the film above the Curie temperature is almost ten times higher than needed for the surface.
7. It has been demonstrated that the loss of MO contrast is accompanied by emission of a picosecond terahertz radiation pulse; which is interpreted as being due to the sudden change in magnetic moment within the first picosecond (Beaurepaire *et al.*, 2004; Hilton *et al.*, 2004).

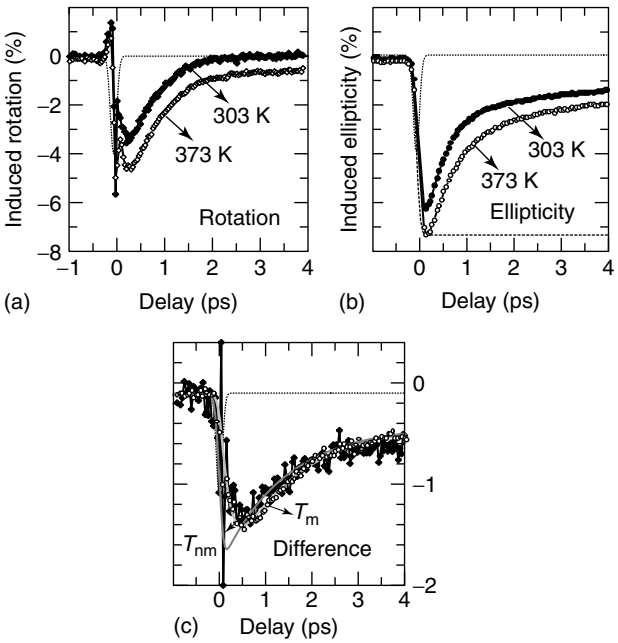

Figure 8. Transient MO response for Cu(001)/Ni/Cu at ambient temperatures of 307 K (filled) and 373 K (open). Normalized rotation (a) and ellipticity (b), respectively. (c) Thermal difference curves for rotation (filled) and ellipticity (open symbols). The line labeled T_{nm} (dark gray) indicates the fitted loss of electron plus phonon excess energy in the Ni layer (in au), the line labeled $T_{\rm M}$ (light gray) represents the fitted spin temperature (in au) (van Kampen, 2003).

8. In addition to the ultrafast demagnetization probed by TRMOKE and TRPE, it has been found from TRPE that also the exchange splitting is being reduced within approximately 300 fs (Rhie, Dürr and Eberhardt, 2003, 2005). Although also the interpretation of the photoemission data is far from trivial, it should be seen as an additional evidence for genuine magnetic effects during the first half a picosecond.
9. Despite the differences between $\Delta\theta(t)/\theta_0$ and $\Delta\epsilon(t)/\epsilon_0$ observed for some systems during the first hundreds of femtoseconds, in many other cases complementary channels do provide the same response. As an example, this has been verified in particular detail for a broad spectrum of laser frequencies in recent studies on $CoPt_3$ (Bigot, Guidoni, Beaurepaire and Saeta, 2004).
10. It has been found that the sudden reduction of magnetic moment can create an 'anisotropy field pulse' (van Kampen *et al*., 2002), its duration being estimated to be typically <2 ps for nickel thin films (cf. Section 8). Thereby, indirectly it provides additional proof of a genuine picosecond magnetic response.
11. In a special material (FeRh, cf. Section 9) a transition from an AF to FM state within 1 ps has been demonstrated unambiguously (Ju *et al*., 2004; Thiele, Buess and Back, 2004). One could well argue: if it is even possible to *generate* magnetism within 1 ps, then there is no reason to disbelieve a *lowering* of the ferromagnetic moment at a similar timescale.

Finally, we would like to stress that equally interesting results have been observed in other FM systems, such as Gd(0001) surfaces (Melnikov *et al*., 2004; Lisowski *et al*., 2005), magnetic semiconductors such as InMnAs (Wang *et al*., 2003, 2005), and several colossally magnetoresitive mangantites and other oxides (e.g., Kise *et al*., 2000; Ogasawara *et al*., 2005).

Altogether, ample of evidence for the loss of magnetic order in the elementary itinerant FMs within hundreds of femtosecond has been gathered by now. In search for the underlying mechanisms, it is of relevance agreeing on a number of relevant timescales. Here we will focus on a set of coherent experiments, both TRMOKE and transient reflection, performed for nickel thin films. Care was taken to have optically transparent films (homogeneously heating the layer), thermally well isolated from the substrate. Thereby, transport of hot electrons and thermal diffusion could be excluded, and a local description in terms of an extended 3T-model will be valid (van Kampen *et al*., 2005a). A set of characteristic data is displayed in Figure 9. It is concluded that the demagnetization time $\tau_M \approx 100$–200 fs (when using equation (20); just below 100 fs when using equation (19) (Dalla Longa, 2007)) is approximately equal or slightly longer than the thermalization time $\tau_T \approx 80$ fs, but shorter than the e−p equilibration $\tau_E \sim 0.4$ ps. Weak temperature dependencies in τ_M have been found in (van Kampen, 2003), but will not be discussed any further here.

Quite a few mechanisms have been proposed to account for such a subpicosecond demagnetization. However, as discussed in Sections 2.3 and 2.4, many of the proposed mechanisms excluding the lattice degree of freedom do not obey conservation of angular momentum. (i) Some interesting theoretical studies demonstrated femtosecond MO response, however, more in the spirit of state-filling effects than a transient $M(t)$ (Hübner and Zhang, 1998; Zhang and

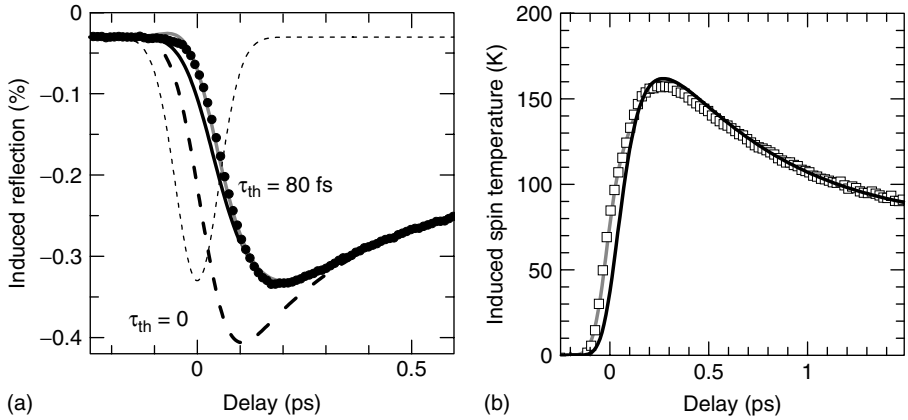

Figure 9. (a) Transient reflection on a nickel thin film, resolving τ_T and τ_E as indicated. Filled circles: measured reflection changes, thin dashed line: pump-probe autocorrelation, fat dashed line: 2T-model fit using infinitely fast thermalization ($\tau_T = 0$), fat line: fit including finite thermalization, and gray line: adding a coherent signal on top (representing weak state-filling effects). A background signal due to lattice expansion is corrected for (van Kampen *et al*., 2005a). (Reproduced from M. van Kampen *et al*., 2005, with permission from IOP Publishing Ltd. © 2005.) (b) TRMOKE data on the same film, resolving τ_M. Open circles display measured data. The black and gray lines represent 3T-model fits without- and with a coherent signal (dichroic bleaching) respectively (van Kampen, 2003).

Hübner, 1999; Vernes and Weinberger, 2005). (ii) In some explanations, the transfer of spin itself was not addressed explicitly, and it was merely stated to be occurring during electron thermalization (Hohlfeld, Matthias, Knorren and Bennemann, 1997; Guidoni, Beaurepaire and Bigot, 2002, and others). (iii) Elsewhere, a link was made with Stoner excitations (Scholl, Baumgarten, Jacquemin and Eberhardt, 1997), or a collapse of the Stoner gap (Cheskis *et al*., 2005), in both cases angular momentum conservation seems not fulfilled. (iv) Spin-orbit scattering in which spin and orbital momenta are exchanged would lead to an enhanced orbital moment upon lowering M. Thereby an increase of the MO contrast rather than a reduction would be expected (MO measuring mostly orbital effects (Oppeneer, 1998)), which has never been observed. (v) Transfer of orbital momentum during laser excitation has been demonstrated to be negligible (Section 6). (vi) Finally, emission of Tera Hertz radiation has been observed to accompany the laser-induced demagnetization (Beaurepaire *et al*., 2004; Hilton *et al*., 2004). The configuration was such, however, that it cannot explain the loss of angular momentum. At this stage, we consider it unlikely that such a scenario will provide the key answer.

Motivated by the controversy that arose, we have readdressed the possibility to include the lattice interactions in order to take care for a potential bath of angular momentum. Let us first restate two general arguments against such a scenario: (i) It is too slow, or, phrased differently, it would require an unrealistically large spin-flip probability a (see subsequent text, and Section 2.4.4). (ii) If the lattice is involved, one would expect the spin temperature to lag behind the lattice temperature that is, $\tau_M > \tau_E$.

A first numerical model including e–p induced spin-flip scattering was published in Koopmans, Kicken, van Kampen and de Jonge (2005). In search for the simplest model that just contained the essential ingredients three reservoirs were defined. A simplified electron and lattice system were defined as introduced in Section 2.4. In addition, the spin system was described as a set of identical two-level systems obeying Boltzmann statistics and with an exchange splitting Δ_{ex} that depends in a self-consistent way on the average spin moment $\overline{S}$, that is, using a mean-field (Weiss) description: $\Delta_{ex} = J\overline{S}$, where the exchange energy J is related to the Curie temperature via $k_B T_C = J/2$. A spin-flip probability a, for an e–p event to be accompanied by spin flip, was introduced. All dynamics was performed within the random-$\vec{k}$ approximation.

Numerically solving the Boltzmann equations after optical excitation of the electron system, revealed traces for T_e, T_p and T_s very similar to the ones obtained by the 3T model (Koopmans, Kicken, van Kampen and de Jonge, 2005). Some results for an arbitrary set of parameters and

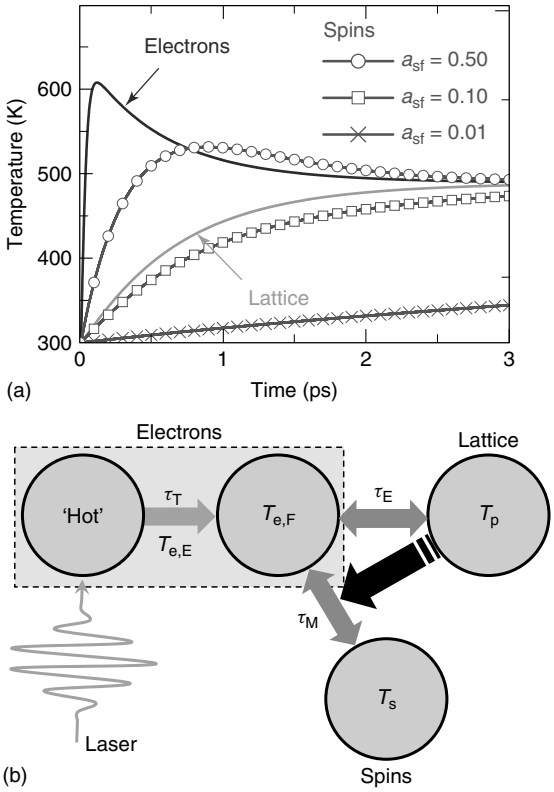

Figure 10. (a) Calculated traces of electron, lattice and spin temperature for different spin-flip probabilities a, according to the model discussed in the text. (Reproduced from B. Koopmans *et al*., 2005, with permission from Elsevier. © 2005.) (b) Schematic flow scheme of the phonon-mediated model.

as a function of spin-flip probability a are displayed in Figure 10(a). As expected, the higher a, the faster the equilibration of the spin temperature. However, as a surprising observation it can be seen that for some sets of parameters it is possible to achieve a spin response faster than the heating of the lattice (i.e) $\tau_M < \tau_E$, even though phonons are involved in the model. This clearly disproves argument (ii) against a phonon-mediated demagnetization.

These numerical efforts were later backed by an analytical approach, both including spin-flip scattering with phonons and with impurities. Equations could be derived for τ_M and τ_E in the limit of infinitely fast thermalization $\tau_T \to 0$ (Koopmans, Ruigrok, Dalla Longa and de Jonge, 2005). More specifically, for the phonon-mediated model, and for temperatures 'well-enough below T_C', a ratio

$$\frac{\tau_M}{\tau_E} = \frac{3c_0 D_s (\hbar\omega_D)^2}{\pi^2 a D_F k_B^3 T^2 T_C} \tag{33}$$

was found. For a reasonable set of parameters for Ni, it required $a \sim 0.1$ to end up with $\tau_M \sim \tau_E$. On the basis of the

band structure considerations – in particular the knowledge that band degeneracies near the Fermi level can enhance a by orders of magnitude (Fabian and Sarma, 1998) – it was concluded that phonon-mediated spin-flip scattering in the spirit of Elliot and Yafet may provide a non-negligible contribution to the subpicosecond magnetic response for realistic values of a. This significantly weakens argument (i) against a phonon-mediated demagnetization.

All of this can be understood diagrammatically as sketched in Figure 10(b): The energy flow from the electron to the spin bath, whereby T_s approaches T_e, is strongly influenced by (the temperature of) the lattice. The fact that even $a = 0.1$ is sufficient to achieve $\tau_M \sim \tau_E$ is related to the fact that it needs many e–p events ($\hbar\omega_q \sim 0.05\,\text{eV}$) to lower the kinetic energy of an optically excited electron ($<1\,\text{eV}$), whereas a single spin flip per atom is more than sufficient to quench all magnetization in nickel (with a magnetic moment of $0.6\,\mu_B$).

Finally, of even more generic interest, a potential link between the demagnetization process and Gilbert damping of precessional dynamics was derived in (Koopmans, Ruigrok, Dalla Longa and de Jonge, 2005). Therefore, the same model Hamiltonian was used to derive an analytical expression for the Gilbert parameter α. The approach followed was quite similar to the spin-flip scattering treated by Kamberský (1970), though did not include ordinary scattering between spin-dependent band levels (Kamberský, 1970; Kunes and Kamberský, 2002). Interestingly, for all mechanisms considered, that is, both the impurity- and phonon-mediated spin-flip scattering, practically the same relation between α and τ_M was found (Koopmans, Ruigrok, Dalla Longa and de Jonge, 2005):

$$\tau_M \approx c_0 \frac{\hbar}{k_B T_C} \frac{1}{\alpha} \tag{34}$$

again valid for T well-enough below T_C. The parameter c_0 is between $1/8$ and $1/4$, slightly depending on details of the models and regimes worked in. Although a strongly simplified model it sets the relevant timescale with surprising accuracy. For example, using $\alpha = 0.02$–0.03 (being the intrinsic value for nickel (Heinrich, Meredith and Cochran, 1979)), and $T_C = 630\,\text{K}$, readily predicts $\tau_M \sim 100\,\text{fs}$, within a factor of 2 of the measured value!

Thus, two major areas of contemporary research in magnetism were linked: (i) the ultrafast (subpicosecond) manipulation of magnetic matter, and (ii) the switching and precessional dynamics in multilayered and micromagnetic systems. Maybe, relating the two fields provides future answers to the origin of the femtosecond-scale magnetization processes in itinerant FMs as triggered by pulsed-laser heating. For sure, the new insight will inspire the community to come up with new and even more dedicated investigations aiming at further unraveling the secrets of ultrafast magnetization dynamics.

8 ANISOTROPY DYNAMICS AND LASER-INDUCED PRECESSION

Magnetic anisotropies arise from a subtle balance of the magnetic energy in an applied field, dipole–dipole interactions (in case of shape anisotropy) and spin-orbit interactions that give rise to coupling to the lattice (magnetocrystalline- and surface anisotropies). It has been found that sudden laser heating of a FM material can perturb the balance between the different anisotropy contributions and the applied field, launching a precessional motion of the magnetization vector. Such an approach provides access to both the precessional dynamics (frequency and damping), as well as the picosecond-dynamics of the magnetic anisotropy itself.

Ju *et al*. demonstrated the ability to use the ultrafast optical modulation of the AF/FM interaction of an exchange-biased (EB) bilayer to launch a precession of $\vec{M}$ (Ju *et al*., 1998a, 2000). In these experiments, such a modulation was obtained by heating a NiFe/NiO bilayer close to the blocking temperature T_B. A more general scheme was introduced by van Kampen *et al*. They found a similar laser-induced precession for a single magnetic layer with a canted equilibrium orientation of $\vec{M}$ (Koopmans, van Kampen, Kohlhepp and de Jonge, 2000b; van Kampen, Koopmans, Kohlhepp and de Jonge, 2001). Initially, the phenomenon was observed for specially engineered systems with a canted ground state orientation of the magnetization, such as epitaxial Cu(111)/Ni/Cu and Cu(001)/Ni/Cu at a proper (intermediate) Ni-layer thickness. Owing to the contrasting temperature dependence of the various anisotropy contributions, the canting angle Θ_c is strongly T-dependent when starting at a nontrivial angle ($\Theta_c \neq 0^\circ$ and $\Theta_c \neq 90^\circ$).

Later, it was reported that the phenomenon was even more general, and could be observed in polycrystalline films with an in-plane anisotropy as well, by pulling $\vec{M}$ to a canted orientation in an applied magnetic field (van Kampen *et al*., 2002) (Figure 11). For such a nickel polycrystalline film, the equivalence of the laser-induced precession with microwave driven magnetization oscillations was verified in a conventional 'FMR' experiment (van Kampen *et al*., 2002).

Many applications of the approach have followed. The dispersion of perpendicular standing spin waves could be resolved (van Kampen *et al*., 2002). In later experiments, discrete modes in artificial spin chains, that is, submicrometer pillars of $[NiFe/Al2O3]_n$ (n repetitions), were investigated (van Kampen *et al*., 2005b). The all-optical approach is

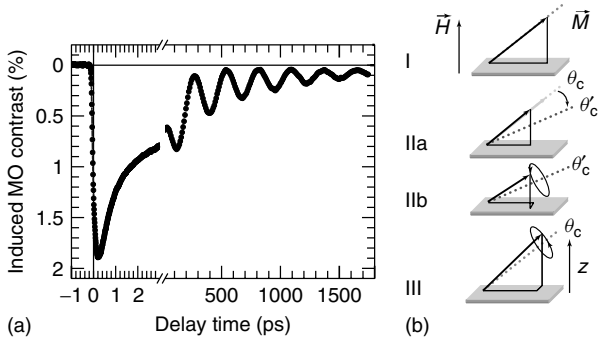

Figure 11. (a) Laser-induced precession in a polycrystalline nickel thin film, showing demagnetization (<2 ps) and successive precession, by measuring the polar component of the canted $\vec{M}$, and (b) schematic explanation: (I) In the external field, $\vec{M}$ is canted out of plane; (II) laser heating changes the equilibrium orientation, thereby triggering a precession; (III) after thermal recovery, the final precession is almost in the original anisotropy field.

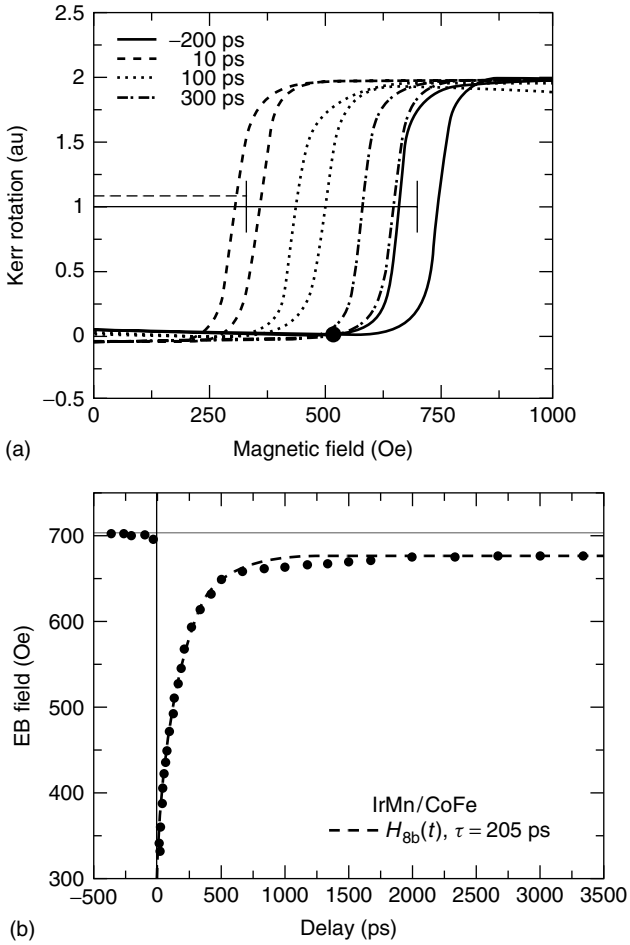

Figure 12. Exchange-bias shift field as a function of pump-probe delay measured for a IrMn/CoFe sample. (a) Easy axis transient hysteresis loops for various pump-probe delays as indicated. particularly convenient for measuring dynamics on wedge-shaped samples, in which one of the film thicknesses is continuously varying over the sample area. Józsa used this configuration to explore correlations between damping and coercivity as well as damping by means of spin pumping (Józsa, 2006). Furthermore, the technique has been used to probe anisotropies, such as in the Fe/AlGaAs(001) system (Zhao *et al.*, 2005). The role of anisotropy on the ultrafast dynamics in cobalt has been addressed by Bigot, Vomir, Andrade and Beaurepaire (2005). Finally, it should be emphasized that the all-optical approach is particularly suited to measure materials with a high anisotropy (thereby a high precessional frequency) and a high damping (where a frequency domain approach is troublesome), such as hard disk recording media (Bergman *et al.*, unpublished).

Returning to the initial 'anisotropy field pulse', it has been demonstrated that the anisotropy is being modified really at the picosecond timescale. This can be concluded qualitatively from the observation of the first rotation of $\vec{M}$ already after several picoseconds. A more accurate estimate is obtained by backtracing the anisotropy field pulse from the complete precessional signal. A scheme therefore has been developed by Józsa (2006). For a nickel thin film, a characteristic timescale of at most 1–2 ps was derived this way.

Finally, a particularly interesting problem, with both scientific and technological aspects, is the quenching of the anisotropy interaction between a FM and an AFM, as originally being explored by Ju *et al.* for NiFe/NiO (Ju *et al.*, 1998a,b, 2000). More recently, Weber and coworkers reported on a collapse of the exchange-bias field H_{EB} within the first 10 ps after laser excitation, for three different EB systems (NiFe/FeMn, IrMn/CoFe and NiMn/CoFe) (Weber, Nembach and Fassbender, 2004; Weber *et al.*, 2005; Weber, Nembach, Hillebrands and Fassbender, 2005), the time scale basically determined by the relatively long pulse duration used (9 ps – see Figure 12). The fast thermal unpinning is followed by a slower heat diffusion dominated recovery of H_{EB}. Using a similar approach and identical samples, Hoffmann *et al.* found that even for 100-fs pulses the collapse of H_{EP} seemed to be just limited by the pulse duration (Hoffmann, 2006) – an observation that is not well being understood by now.

Future studies would certainly profit from the availability of well-defined, epitaxial systems. As a first attempt, Dalla Longa *et al.* started to explore the ultrafast dynamics of the EB effect in epitaxial Co/Mn films (Dalla Longa, Kohlhepp, de Jonge and Koopmans, 2006). This system displays large monolayer oscillations in both coercivity and EB field as a function of the Co thickness (Kohlhepp, Kurnosikov and de Jonge, 2005). First laser-induced precessional effects have been demonstrated for this intriguing system (Dalla Longa, Kohlhepp, de Jonge and Koopmans, 2006).

9 ULTRAFAST PHASETRANSITIONS AND GROWTH OF MAGNETISM

After having established the possibility to quench ferromagnetic order on a subpicosecond timescale, a new challenge is in generating magnetic order. Not only is this of profound fundamental interest it would also open up more serious applications of the laser-induced ultrafast magnetic manipulation.

The simplest approach is provided by cooling down a FM after laser heating above T_C (Figure 13a). Beaurepaire reported on such a laser-induced FM to PM transition within 0.5 ps in $CoPt_3$, and the successive recovery to the original FM state (Beaurepaire *et al*., 1998). Such experiments were extended to the real switching domain by Hohlfeld *et al*. (2001). The material of choice was the recording material GdFeCo, and pairs of set and reset magnetic field pulse allowed to follow the reversal process in a stroboscopic experiment (Figure 13b). However, the growth of M is basically limited by the cool-down time of the magnetic film, a slow diffusion driven process taking tens to hundreds of picoseconds.

A potentially much faster generation of magnetic order could be achieved for materials that display a magnetic phase transition (Figure 13c). A typical example is provided by FeRh. Recently, Ju *et al*. (2004) and Thiele, Buess and Back (2004) demonstrated independently the feasibility of driving therein the AF→FM phase transition within a picosecond by laser heating. When properly prepared, FeRh has the chemically ordered CsCl structure. At low temperatures, the material has an antiferromagnetic spin orientation, with iron local moments of $\pm 3\,\mu_B$ and no appreciable moment on rhodium. At a phase transition temperature of ~370 K, a first-order transition to a ferromagnetic phase takes place, with iron- and rhodium local moments of $3\,\mu_B$ and $1\,\mu_B$, respectively. The fact that the phase transition shows up slightly above room temperature makes it particular attractive for applications. The latter has been recently emphasized by Thiele, Maat and Fullerton (2003). They proposed the use of an exchange spring bilayer FePt/FeRh as a storage medium for heat-assisted recording.

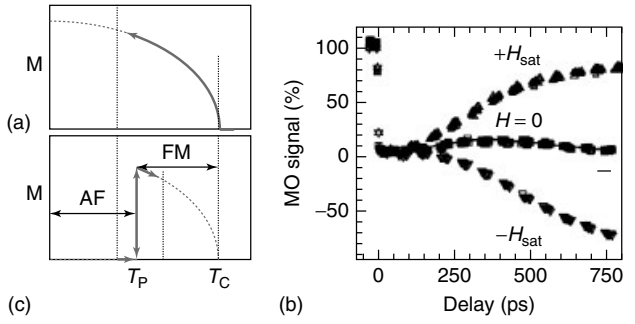

Figure 13. Schematic representation of growth of magnetic moment by cooling down below T_C (a) and by driving a AFM to FM phase transition (c). An experimental realization of the first option is displayed in (b) for a GdFeCo thin film, and applying different external fields. (Reproduced from J. Hohlfeld *et al*., 2001, with permission from the American Physical Society. © 2001.)

A typical time-resolved experiment is displayed in Figure 14(a). Using FeRh thin films, Ju *et al*. observed that about 20% of the final net MO signal establishes within the first picosecond, converging to a full signal after ~50 ps (Ju *et al*., 2004). Different fingerprints have been suggested to decide on a genuine laser-induced phase transition: (i) Appearance of a MO signal when performing the experiments in a magnetic field. (ii) The observation of a 'threshold fluence', as reported by Ju *et al*. (2004), and shown in Figure 14(b). A certain minimum laser fluence is needed to heat up the film above the transition temperature, T_P. Moreover, the higher the fluence, the longer the MO signal persists, because it takes longer to cool down below T_P – all exactly as observed in Figure 14(b). (iii) A 'two-peak feature' in the MO transient, as claimed originally by both teams (Ju *et al*., 2004; Thiele, Buess and Back, 2004). The magnetization may be expected to go twice through a maximum – that is, during heat up as well as while cooling down – since right above T_P the magnetic moment is highest. Also, at increasing laser fluence the time at which the second peak occurs should be larger. This 'two-peak argument' will next be addressed in more detail.

If the magnetic system would be in a constant equilibrium with electrons and lattice, a double pass of the state with highest M would be expected indeed. However, in the nonequilibrium experiment, the electron temperature is almost suddenly raised well above T_P. It is questionable whether in such a case the equilibration of electron and spin system is indeed accompanied by first a buildup of magnetic order, after which it is quenched again. Bergman, Ju *et al*. rephrased this consideration recently in terms of two separate timescales: τ_s to account for a process in which T_s increases monotonically, driving M through an optimum indeed, and τ_M accounting for a process in which the *magnetization* (rather than T_s) grows monotonously from zero to its final value (Bergman *et al*., 2006).

Support for the second model came from magnetic field dependent experiments, in which it was shown that the two features originally observed had to be assigned to the onset of a laser-induced precession, similar to the ones described in Section 8. This behavior was successfully accounted for by an LLG simulation in which both the magnitude and orientation of $\vec{M}$ were described (Bergman *et al*., 2006) – including heat diffusion and a gradual increase of M after passing T_P. More specifically, the effective field

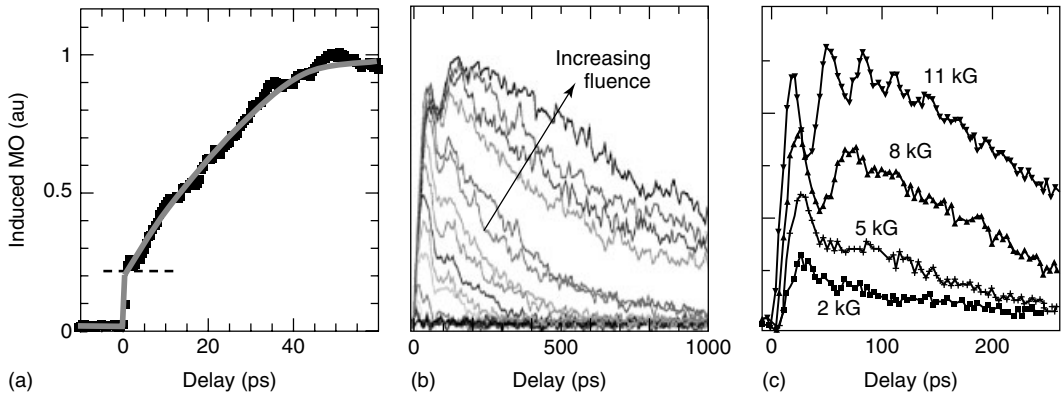

Figure 14. (a) Experimental realization of a subpicosecond growth of FM moment after pulsed-laser heating, demonstrated by TRMOKE on a thin FeRh film. (Reproduced from G. Ju *et al*., 2004, with permission from the American Physical Society. © 2004.) (b) A threshold fluence is needed to reach T_P, and the higher the fluence, the longer the system remains in the FM state. (Reproduced from B. Bergman *et al*., 2006, with permission from the American Physical Society. © 2006.) (c) At higher fields, a precession of $\vec{M}$ can be clearly observed.

($H_{\text{eff}}(t|)$) was calculated from time dependent orientation and magnitude of the magnetization vector throughout the film, $\vec{M}(z,t)|$), (z being the depth coordinate), and used in the LLG equation for the normalized magnetization: $\vec{m}(t) = \vec{M}(z,t)/M(z,t)$ requiring all spins in the system to be parallel:

$$\frac{\mathrm{d}\vec{m}}{\mathrm{d}t} = \gamma\mu_0\left(\vec{m}\times\vec{H}_{\text{eff}}\right) + \alpha\left(\vec{m}\times\frac{\mathrm{d}\vec{m}}{\mathrm{d}t}\right) \qquad (35)$$

For more details we refer to Bergman *et al*. (2006). At higher fields, a faster precession was found indeed as shown in Figure 14(c). This new interpretation shows that a two-peak feature as originally postulated is not observed upon laser heating of FeRh, asking for a description in terms of τ_M.

By observing an ultrafast, subpicosecond component in the MO response, both teams concluded to have solved the long-standing issue whether the magnetic phase transition in FeRh is driven by lattice expansion, or whether it is a purely electronic phenomenon. The observation of a growth of magnetism well before the lattice is expanded (several picoseconds) unambiguously demonstrates the latter (Ju *et al*., 2004; Thiele, Buess and Back, 2004).

The successive growth of the final MO contrast during a period of tens of picoseconds has been addressed in more detail in Bergman *et al*. (2006), exploiting a combined TRMOKE and transient reflectivity approach. It was concluded that all data are consistent with a subpicosecond nucleation of magnetic moments that grow and align during the next tens of picoseconds – driven by effective field and mutual exchange interactions.

Our understanding of the whole process on a *microscopic* scale is still limited. On the other hand, the material with its two coupled spin systems may provide a very efficient playground for acquiring more in-depth understanding of magnetic processes at the subpicosecond timescale. It is anticipated that exploring laser-induced magnetic phase transitions in general, and the FeRh case in particular, will grow toward a very rich and challenging field of research in the forthcoming years.

10 CONCLUDING REMARKS

Within a decade after the first report on femtosecond magnetization dynamics an exciting and active field of research has emerged. Hand in hand with developments in spintronics, ever new phenomena have been discovered. By now, a whole toolkit of methods for manipulating and probing FM matter on a subpicosecond time scale has become available. Main emphasis in this chapter was on all-optical approaches. It was shown that femtosecond laser pulses can demagnetize a ferromagnetic film within a few hundred femtosecond, but also drive an AF to FM phase transition and thereby generate a magnetic moment at a similar timescale. By changing the magnetic anisotropy at the subpicosecond timescale, precessional phenomena can be triggered and probed in an elegant all-optical scheme.

As will have become clear, our understanding of many of the phenomena is still at rather a phenomenological level. While the basic interactions leading to the equilibration of the electron and lattice system after pulsed-laser heating are relatively well understood, no consensus on the microscopic mechanisms underlying the femtosecond quenching and growth of magnetic order has been achieved yet. Nevertheless, the bare fact that a genuine change in magnetic order does occur within a few hundred femtoseconds is generally accepted by now. A larger number of supporting arguments were discussed, although it should be stressed that utmost care remains necessary to interpret optical data in the strong

nonequilibrium regime, where state-filling effects do mix up with the 'magnetic' signal. Within the chapter, the role of transfer of angular momentum has been emphasized, and some of the recently proposed dissipation channels were discussed. Recent approaches seem to point out a potential universal link between dissipation of precessional motion of the magnetization vector (Gilbert damping) with the relaxation time of microscopic spin fluctuations (represented by τ_M). Moreover, a possible role of phonons in the magnetic relaxation process even at picosecond timescale was estimated.

Clearly, a more comprehensive understanding of the underlying physics requires more dedicated theoretical efforts as well as novel, targeted experiments. New insight could be expected, for example, from the rapid development of synchrotron radiation sources, which may open up the possibility of performing element specific measurements of the spin dynamics at subpicosecond timescale, with the potential to discriminate between orbital and spin angular momenta. Also, rapid progress has been witnessed in the use of TRPE. Other routes, such as directly exciting and probing lower energy excitations (such as spin waves) in the system could be anticipated to provide deeper insight, but have not been explored intensively in the picosecond regime yet. Clearly, particular progress is expected from combing several of the aforementioned approaches in a clever way.

Apart from progress by improving our analytical techniques, exciting opportunities arise by engineering novel structures. Experiments on FeRh, but also spin dynamics in oxides that was not explicitly discussed in the present chapter, have shown the exciting phenomena that can be observed when moving to specific alloys and compounds. Also, a growing awareness is being witnessed that new classes of dynamics can be explored when entering the regime of exchange-coupled systems. Finally, the development of nano-structuring techniques opens up a particular challenging route for a combined spatiotemporal manipulation of the flow of energy and angular momentum in the nonequilibrium regime.

Upon completing this chapter, I'm particularly grateful to my (former) PhD and undergraduate students Maarten van Kampen, Csaba Józsa, Jeroen Rietjens, Bastiaan Bergman, Francesco Dalla Longa, Harm Kicken, and Dijon Boesten for their skillful experiments and original contributions to the research program – much of which contributed in an essential way to this chapter. Furthermore, I have profited considerably from instructive discussions and joint projects with many colleagues. Out of them, I specifically want to mention Ganping Ju and coworkers at Seagate Research, and Jaap Ruigrok at Philips Research, for our recent collaborations on FeRh (Section 9) and theory of femtosecond dynamics (Section 7), respectively. Finally, I acknowledge support by the European Communities Human Potential Programme (contract number HRPN-CT-2002-00318 ULTRASWITCH), and by the Netherlands Foundation for Fundamental Research on Matter (FOM).

Investigation of Ultrathin Ferromagnetic Films by Magnetic Resonance

Klaus Baberschke
Freie Universität Berlin, Berlin-Dahlem, Germany

1 INTRODUCTION

When a magnetic dipole moment is subjected to a magnetic field $\vec{H}$, it experiences a torque motion. Its equation of motion is given by

$$\frac{\partial \vec{\mu}}{\partial t} = \gamma \left[\vec{\mu} \times \vec{H}_0\right] \quad \text{with} \quad \gamma = \frac{g\mu_B}{\hbar} = g\frac{(-e)}{2mc} \tag{1}$$

$$\frac{\partial \vec{M}}{\partial t} = -\gamma(\vec{M} \times \vec{H}_{\text{eff}}) \tag{2}$$

The motion of the angular momentum or the magnetic moment consists of a uniform precession about $\vec{H}$ with angular velocity $\vec{\omega}_L = -\gamma \vec{H}$. Without damping, the component of $\vec{\mu}$ along $\vec{H}$ remains fixed in magnitude, so that the 'Zeeman energy' $E = \vec{\mu} \cdot \vec{H}$ is a constant of the motion. Real systems have a finite damping (relaxation). The dissipation of this part of energy can be pumped into the torque motion by means of microwave radiation in resonance with $\omega_{MW} = \omega_L$, yielding a Lorentzian linewidth ΔH (Figure 1b, see Section 4). Electron paramagnetic resonance (EPR) (equation 1) and ferromagnetic resonance (FMR) (equation 2) [1] are based on the same principle – for EPR see (Abragam and Bleaney, 1966; Orton, 1968; Pake, 1962), for FMR see (Vonsovskii, 1966; Heinrich, 1994; Farle, 1998). Historically, they followed very different routes: For EPR H_0, the local and the external field are equal and known with high precision. The only unknown quantity is the g-factor or g-tensor. For FMR it is the opposite, $\vec{H}_{\text{eff}}$ of a ferromagnet is the unknown parameter. It is the vector sum of several anisotropic field contributions (dipole, spin orbit, external, and microwave).

$$\vec{H}_{\text{eff}} = \vec{H}_{\text{dipole}} + \vec{H}_K + \vec{H}_0 + \vec{h}_{\text{MW}} \tag{3}$$

Note that the exchange field in a ferromagnet is always parallel to $\vec{M}$ and does not contribute to the torque. $\vec{M}$ can be seen as the sum of the individual moments per volume $\vec{M} = \sum \vec{\mu}_i$. For ultrathin simple ferromagnetic films (e.g., Fe, Co, Ni), μ is defined per particle.

In this chapter we will give a brief overview of three aspects that are most important for the investigation of novel magnetic nanostructures by means of microwave spectroscopy: The UHV-FMR technique and its monolayer sensitivity and the static parameters of magnetism (e.g., magnetic anisotropy energy (MAE) and interlayer exchange coupling (IEC), both measured with FMR in absolute energy

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

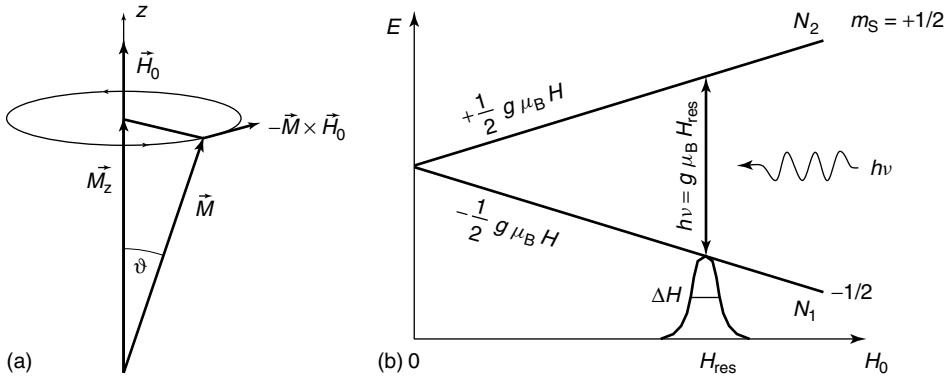

Figure 1. (a) Sketch of the uniform precession of vector $\vec{M}$ about the external field $\vec{H}_0$. (b) Zeeman levels for a spin $m_s = \pm 1/2$ system and the dipole transition for $\vec{h}_{MW}$ being perpendicular to $\vec{H}_0$.

units). Finally in Section 4 we give examples for the spin dynamics determined from the FMR linewidth.

The examples used here, mainly from our own work, will elucidate the strength of FMR and its intimate contact with *ab initio* calculations exactly adapted to FMR experiments.

2 *In situ* UHV-FMR: EXPERIMENTAL DETAILS

Magnetic resonance spectroscopy will be most instructive if external parameters can be varied. One important parameter is the temperature T. The intensity of the magnetic resonance signal (area under the resonance line) is proportional to the static susceptibility (White, 1970). Temperature variation allows us to study the EPR above the Curie temperature T_C and the FMR in the ferromagnetic phase below T_C, cf. Section 4. Other phase transitions such as those in superconductors or crystallographic phase transitions can be studied with paramagnetic impurities as a sensor by means of EPR (Baberschke, 1976; von Waldkirch *et al*., 1973). In ferromagnets, one of the most important quantities is the MAE and its temperature dependence (Heinrich, 1994; Vonsovskii, 1966; Farle, 1998). FMR measures this directly in absolute energy units, cf. Section 3 [2]. Equally important is the measurement of the angular dependence of the resonance signal. Following equation (1), it is a standard procedure in the paramagnetic regime to determine the anisotropic magnetic moment, that is, the g-tensor (Abragam and Bleaney, 1966; Orton, 1968; Pake, 1962). If these experimental requirements can be combined with UHV, the EPR/FMR will be a very powerful experimental tool to study ultrathin ferromagnetic films. The ultimate sensitivity of microwave spectroscopy is in the range of 10^{11} spins. Usually, in standard surface science and UHV technique, molecules are adsorbed with a submonolayer coverage onto a crystalline substrate, for example, a Cu(001) crystal. Equivalently, ferromagnetic monolayers (ML) of Fe, Co, and Ni are epitaxially grown on such a substrate with a surface area of a few square millimeters. This corresponds to $\sim 10^{14}$ lattice sites on the surfaces (Farle *et al*., 1985). Thus the EPR/FMR should be sensitive to submonolayer coverage. This has been demonstrated for 1/100 ML of paramagnetic molecules (Zomack and Baberschke, 1986).

2.1 *In situ* UHV-FMR

Figure 2 shows the combination of a UHV chamber and a microwave EPR/FMR spectrometer. Microwave spectrometers are commercially available (Varian, Bruker). The most popular microwave frequency is 9 GHz (X band). The corresponding microwave cavity usually has a geometric size of $\sim$4 cm $\times$ 4 cm (wavelength of the microwave $\sim$3–4 cm) with a central access hole of 0.5–1 in. diameter for inserting the sample. In this central access hole a quartz finger tip of a UHV chamber is inserted. In other words, the microwave cavity and all other parts of the spectrometer are operated in laboratory air. Only the sample itself is prepared and measured *in situ* under UHV conditions. This offers a very important variety of experiments, for example, to measure ultrathin films, first facing vacuum without protection layer. Then adding a cap layer and monitoring the effect of the capping on the magnetism of the ultrathin ferromagnet, or adding step-by-step *in situ* a second ferromagnetic film and studying IEC, and so on. Figure 2 shows the large electromagnet with external fields of 10–15 kOe and the field axis pointing horizontally in the laboratory frame. The sample itself is mounted on a vertical UHV manipulator with a rotating vertical axis. This allows full angular-dependent measurements varying the magnetic field from in plane to out of

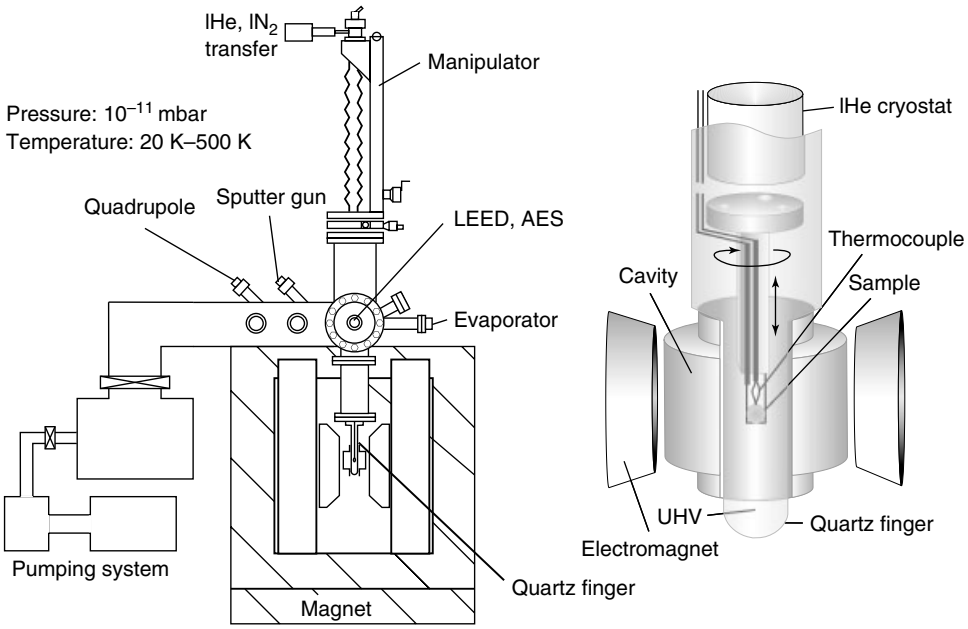

Figure 2. Sketch of the combination of a conventional EPR spectrometer with a large electromagnet and a UHV chamber equipped with all necessary installations for surface science physics (Zomack and Baberschke, 1986; Farle, 1998). The pumping station is mounted on the left-hand side, whereas the bottom part of the UHV chamber is inserted into the electromagnet and the microwave cavity. The electromagnet (being movable on a track) and the microwave cavity are taken away from the UHV chamber for a standard bakeout procedure to reach a base pressure in the 10^{-11} mbar range. For details see text.

plane. The commercial manipulator is equipped with a cooling system for ℓHe or ℓN_2. It has a very large z (vertical) travel of ∼50 cm. This specialty is necessary to move the sample above the electromagnet into the upper part of the UHV chamber for sample preparation. This upper level is equipped with standard surface science UHV instruments such as Auger, LEED, quadrupole, evaporator, sputter gun, and so on. Recording a typical FMR spectrum takes only a few minutes. Thus, a full angular dependence or temperature dependence may be measured within an hour. Afterward, the sample may be moved to the upper position for further sample preparation such as adding a cap layer or a second ferromagnet, adsorbing gas on the surface, and so on. Finally it is moved down again for a second *in situ* experiment.

Figure 3 shows the EPR/FMR of Gd/W(110) as one example. The Curie temperature of bulk Gd equals $T_{\mathrm{Cb}} \approx 292\,\mathrm{K}$, for 1.6 ML Gd/W(110) it is $T_{\mathrm{C}} < 292\,\mathrm{K}$ (open squares) due to the finite size effect. Figure 3(b) convincingly shows the high sensitivity of the FMR. At 316 K, the signal for 1.6 ML is recorded with a very good signal-to-noise ratio. The resonance signal has been monitored from 360 K to below the corresponding Curie temperature for each film (Farle and Baberschke, 1987). The steep increase of the intensity follows the temperature dependence of the susceptibility of the Gd films. The external field $\vec{H}_0$ was applied in plane along the easy axis of the Gd film. Consequently, the external resonance field shifts to lower values at lower temperature because the internal one $\vec{H}_{\mathrm{dipole}} + \vec{H}_K$ increases when the temperature is reduced.

The idea of a fingertip inserted into a microwave cavity has been used before for ^{3}He/^{4}He dilution refrigerators (Nagel *et al*., 1980; Baberschke and Tsang, 1980). The same idea of experimental setup, namely, the combination of UHV technique with magnetic measurements can be used to determine the magnetization with a SQUID (Ney *et al*., 2002) as well as the ac-susceptibility $\boldsymbol{\chi}_{\mathbf{ac}}$ (Stetter *et al*., 1992). All three techniques FMR, SQUID, and $\boldsymbol{\chi}_{\mathbf{ac}}$ combined with state-of-the-art surface physics and UHV technique offer a new insight into the understanding of the fundamentals of the magnetism of ultrathin ferromagnetic films.

2.2 Multifrequency FMR

Following equation (1), we estimate that a typical resonance condition is given for ∼10 GHz and ∼3.5 kOe. Under certain limitations the absorption of electromagnetic waves between two Zeeman levels is proportional to ω^2. Thus EPR microwave spectroscopy is more sensitive by ∼4 orders of magnitude than nuclear magnetic resonance operating in the range of 100 MHz. On the other hand, microwave spectroscopy has some limitations. It operates usually only at one fixed frequency due to microwave oscillators and the waveguide technique. Consequently, the magnetic field has

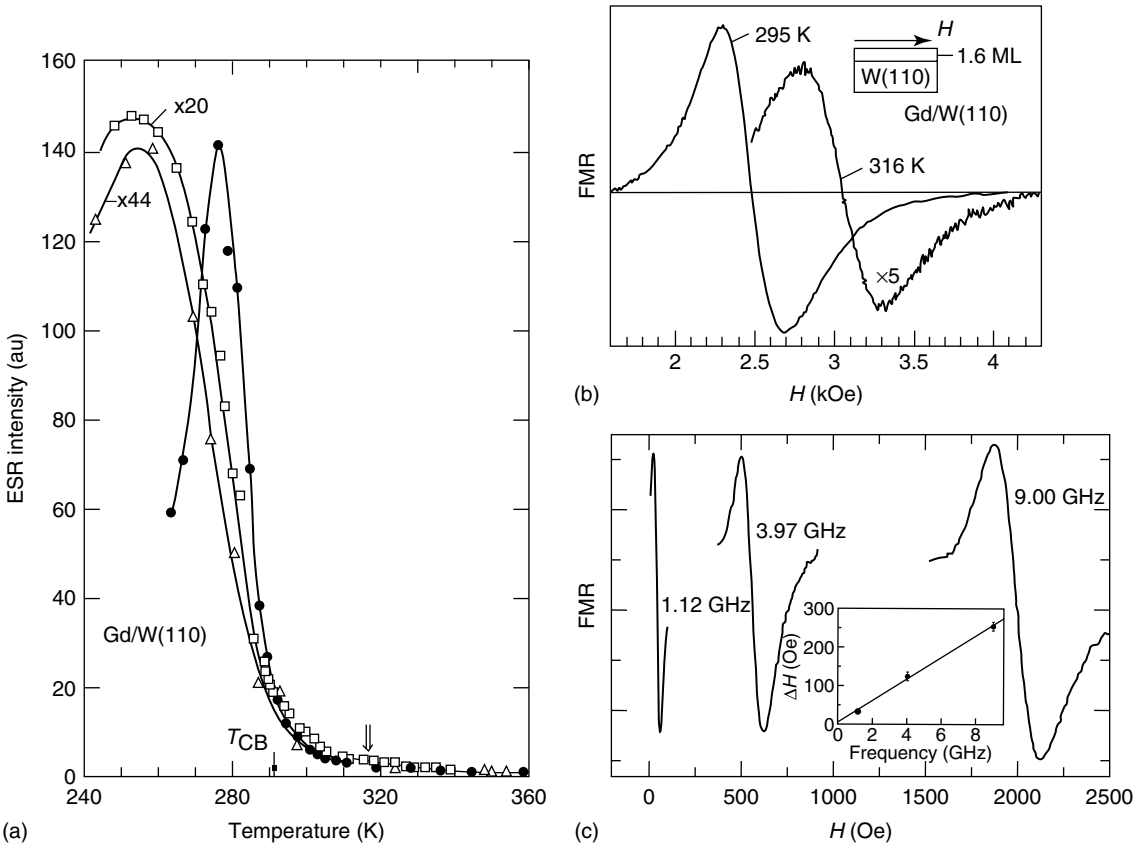

Figure 3. Typical magnetic resonance spectra of ferromagnetic monolayers (Farle and Baberschke, 1987). (a) EPR intensity for different film thickness: 80 Å (full circles), 1.6 ML (open squares), 0.8 ML (open triangles). The arrow at 316 K corresponds to the experimental spectrum given in (b). Note that the spectrum at 295 K in (b) is still above T_C. (c) FMR of 7 ML Ni/Cu(001) at 1, 4, and 9 GHz. The spectra are taken in the ferromagnetic phase. Corresponding to equations (1) and (2) also the external Zeeman field reduces if the microwave frequency is reduced. Note the narrowing of the linewidth – at 1.12 GHz the linewidth is $\Delta H = 15$ Oe only (cf. Section 4). All three spectra are taken *in situ* in UHV without protective layer for the same film, just by replacing the microwave cavities.

to be scanned (see Figure 1b). The majority of experiments are performed in dilute paramagnetic systems. These experiments focus mostly on the determination of the different components of the g-tensor (equation 1). Consequently, the larger the frequency, the better the separation of different components of the g-tensor (slopes in the Zeeman level) for a given linewidth. Field scanning in a ferromagnetic film creates some difficulties. First of all, in contrast to a paramagnet, the ferromagnet has an internal anisotropy field with an easy and a hard axis in the crystallographic frame. Thus, the applied external field and the internal field are usually not collinear. Scanning the external field through the resonance condition means, in principle, dragging the magnetization behind the field direction and, as a consequence, the Lorentzian line shape should be deformed. Fortunately, this effect is very small. More important is the analysis of the measured linewidth itself. If determined at only one frequency, it will not be so easy to interpret this value. In the past, quite frequently some inhomogeneous broadening assuming local field distribution was used for the interpretation of the width. In Figure 3(c) we show the FMR of 7 ML Ni/Cu(001) at 1, 4, and 9 GHz. Obviously, the linewidth is strongly frequency dependent and narrows down to a few oersteds only at low frequencies. This means that frequency-dependent measurements are very important to disentangle relaxation processes and other contributions to the linewidth of the FMR in ultrathin ferromagnetic films. Fortunately, microwave cavities in this lower frequency range (1, 3, 4 GHz) are available with the same geometrical size as the 9 GHz cavity and the same central access hole of 1 in. diameter. This allows us to keep the sample in UHV, only replacing the 9 GHz microwave cavity by a 1 or 4 GHz cavity, and measure the same film. In Section 4 it will be shown that FMR measurements at very high frequencies of 200 GHz and more are also of relevance to investigate the dynamics of magnetic nanostructures. For these frequencies, the wavelength reduces to below the millimeter regime. Different experimental techniques are needed (Silsbee *et al.*, 1979;

Monod and Janossy, 1977). Currently these experiments are not performed in UHV. Here, one still needs a protective cap layer to record the FMR signal.

3 *g*-TENSOR AND MAGNETIC ANISOTROPY ENERGY (MAE)

To solve the equations of motion equations (1) and (2) under the influence of a small oscillatory microwave field $\vec{h}_{\mathrm{MW}}$ with $\vec{h}\tau\perp\vec{H}_0$ and to calculate the resonance condition with ω_{MW} and a given external magnetic field H_0 we refer to standard literature, for example, (Vonsovskii, 1966; Heinrich, 1994; Farle, 1998). It is the advantage of magnetic resonance spectroscopy that the method to calculate the resonance condition and interpret, for example its angular dependence (direction of H_0 with respect to the crystallographic axis of ultrathin films), is well established for a long time. In this section we give a few examples to demonstrate the power and usefulness of FMR to gain information on the intrinsic parameters of ultrathin ferromagnetic structures. The resonance conditions are given below for the polar and azimuthal angular dependence

$$\begin{aligned}\left(\frac{\omega}{\gamma}\right)^2 = \Bigg[& H_0\cos(\theta-\theta_H) \\ & + \left(-4\pi M_{\mathrm{eff}} - \frac{2K_{2\parallel}}{M} + \frac{K_{4\perp}}{M} - \frac{K_{4\parallel}}{2M}\right)\cos 2\theta \\ & + \left(\frac{K_{4\perp}}{M} + \frac{K_{4\parallel}}{2M}\right)\cos 4\theta\Bigg] \times \Bigg[H_0\cos(\theta-\theta_H) \\ & + \left(-4\pi M_{\mathrm{eff}} - \frac{2K_{2\parallel}}{M} + \frac{K_{4\parallel}}{M}\right)\cos^2\theta \\ & + \left(\frac{2K_{4\perp}}{M} + \frac{K_{4\parallel}}{M}\right)\cos^4\theta + \frac{2K_{2\parallel}}{M} - \frac{2K_{4\parallel}}{M}\Bigg] \quad (4)\end{aligned}$$

$$4\pi M_{\mathrm{eff}} := 4\pi M - 2K_{2\perp}/M \quad (5)$$

and for $\theta = \theta_H = 90^\circ$:

$$\begin{aligned}\left(\frac{\omega}{\gamma}\right)^2 = \Bigg[& H_0\cos(\varphi-\varphi_H) + \frac{2K_{2\parallel}}{M}\cos 2(\varphi-\varphi_{\mathrm{u}}) \\ & + \frac{2K_{4\parallel}}{M}\cos 4\varphi\Bigg] \times \Bigg[H_0\cos(\varphi-\varphi_H) + 4\pi M_{\mathrm{eff}} \\ & + \frac{2K_{2\parallel}}{M}\cos^2(\varphi-\varphi_{\mathrm{u}}) + \frac{K_{4\parallel}}{2M}(3+\cos 4\varphi)\Bigg] \quad (6)\end{aligned}$$

where θ_H is the polar angle of the external magnetic field H_0 with respect to the surface normal of the thin film, θ the angle of the magnetization, and φ the azimuthal angle in plane. Only along the easy and hard axis of the magnetization, the vectors $\vec{M}$ and $\vec{H}_0$ are parallel and $\theta = \theta_H$. For all other orientations, the equilibrium angle of θ can be calculated by minimizing the free energy of the system (Smit and Beljers, 1955). Full angular-dependent measurements of the FMR of ultrathin films have shown in numerous cases the dragging of the magnetization, see for example, Figure 38 in (Farle, 1998). Equations (4)–(6) also show the various contributions of anisotropy fields K_i/M (Berghaus *et al.*, 1989). In several cases, the analysis of the experimental results was projected on two mechanisms only as given in equation (5): The dipole or shape anisotropy field $4\pi M$ and the so-called uniaxial out-of-plane anisotropy contribution $K_{2\perp}/M$, also called K_{u}/M. However, equations (4) and (6) show that full angular-dependent FMR measurements also give access to $K_{2\parallel}$. An axial in-plane symmetry is usually caused by steps at the surface or can be observed for vicinal crystal surfaces. Since many of the ultrathin ferromagnets (Fe, Co, Ni) are grown pseudomorphically on nonmagnetic single-crystal substrates like Cu or GaAs, they will not grow in their bulk crystallographic cubic structure but will be tetragonally or trigonally distorted. This can easily be detected by monitoring the $K_{4\perp}$ and $K_{4\parallel}$ contributions – K_4 is a fourth-order term but in most cases not of cubic symmetry. For details of the MAE and its notation, see Appendix B.

As stated in the introduction one focal point of FMR investigations in the past was the determination of anisotropy energies and anisotropy fields in ultrathin ferromagnets. It was often assumed that the g value is close to $g = 2$ for the free electron (Vonsovskii, 1966; Heinrich, 1994). In contrast, equations (4) and (6) offer the opportunity to determine not only anisotropy fields but also, independently, the proper g value as is common practice in standard EPR. Resolving the double parentheses product in equation (4), we see that there exists one term that depends only on the external magnetic field H_0^2. FMR experiments at different frequencies offer the possibility of determining g also from the proportionality of the parabolic behavior of $\omega^2 = f(H)$. This will be discussed in the following subsection.

3.1 *g*-tensor, μ_{L}, μ_{S}

In the past it was often assumed that the orbital magnetic moment is quenched in cubic Fe, Co, and Ni structures and magnetism was explained in terms of the spin magnetic moment only. However, giant orbital magnetic moments have been observed recently in magnetic nanostructures (Gambardella *et al.*, 2003). Even in bulk cubic materials, the survival of large orbital moments for itinerant magnets has been observed (Brewer *et al.*, 2004). Kittel (Meyer and Asch,

1961) has already shown that the departure from $g = 2$ is a measure of the ratio of orbital-to-spin magnetic moment [3].

$$\frac{\mu_L}{\mu_S} = \frac{g-2}{2} \tag{7}$$

For bulk Fe, Co, and Ni, the g value increases from 2.09 to 2.21 (Stearns, 1986). This tells us that in Ni μ_L is already 10% of the spin moment, and μ_L is parallel to μ_S in accordance with the positive sign of the spin-orbit coupling constant. In EPR, it is also well known that the light 3d elements like Cr have g values $g < 2$, the spin-orbit constant is negative and μ_L and μ_S are aligned antiparallel. EPR/FMR have the capability to measure orbital and spin magnetism. As a matter of fact, standard second-order perturbation theory (Abragam and Bleaney, 1966; Orton, 1968; Pake, 1962) shows that the MAE and the anisotropy of the orbital magnetic moment are caused by the same matrix elements mixing excited states into the magnetic ground state.

One example in thin-film magnetism is given in Figure 4. A thick Fe film and ultrathin Fe_n/V_m multilayers were measured by two techniques: FMR and X-ray magnetic circular dichroism (XMCD) (Anisimov *et al.*, 1999). For the same specimen, the ratio of the orbital-to-spin magnetic moment was measured by both techniques. In Figure 4(a), the ratio is given as function of the Fe thickness. A thick Fe film of 40 nm shows $g = 2.09$ corresponding to $\mu_L/\mu_S = 0.045$. When reducing the Fe thickness to 4 and 2 MLs only, the g value increases up to $g = 2.26$, which means an increase of μ_L by a factor of 3. In Figure 4(b), the XMCD spectra for both, the V and Fe $L_{3,2}$ edges are plotted. It is known that at an Fe/V interface a magnetic moment is induced at the V site. Following Hund's rule for V (Fe) spin and orbital moment are antiparallel (parallel) aligned. This leads to an enhancement of the effective orbital moment and a reduction of the total spin moment. FMR measures the total magnetic response of such a multilayer structure, whereas X-ray absorption spectroscopy (XAS) and XMCD (see also **Synchrotron Radiation Techniques Based on X-ray Magnetic Circular Dichroism, Volume 3** and **Magnetic Spectroscopy, Volume 1**) are element-specific methods and are, therefore, in a position to measure the magnetism at the Fe and the V site separately as shown in Figure 4(b). The apparent discrepancy between the determination of μ_L/μ_S by FMR and XMCD can therefore easily be explained. XMCD (full circles) measure only the Fe contribution. For the total response as probed by FMR we note from Figure 4(b) that the spin moment of V is antiparallel to that of Fe. The total spin moment is reduced. In contrast, the orbital moments of Fe and V are aligned parallel. Therefore, the larger value for the ratio (open circles) determined by FMR is completely understandable.

In conclusion, owing to its element-specificity, XMCD measures μ_S and μ_L at the Fe and the V site separately. FMR determines the ratio μ_L/μ_S from the g value. If a second measurement, for example by SQUID, provides the total magnetization ($\mu_L + \mu_S$), spin and orbital contributions may be separated without XMCD.

3.2 MAE in a ferromagnetic monolayer

The *in situ* FMR in ultrathin Ni/Cu(001) films of 3–25 ML has been used to study the spin reorientation transition (SRT) (Schulz and Baberschke, 1994). To analyze the experimentally determined K values properly it is important to notice that when changing the thickness of the ferromagnetic film, the Curie temperature T_C will change, too. It is therefore not advisable to plot $K(1/d)$ at a fixed thermodynamic temperature T but rather at the reduced temperature $t = T/T_C$.

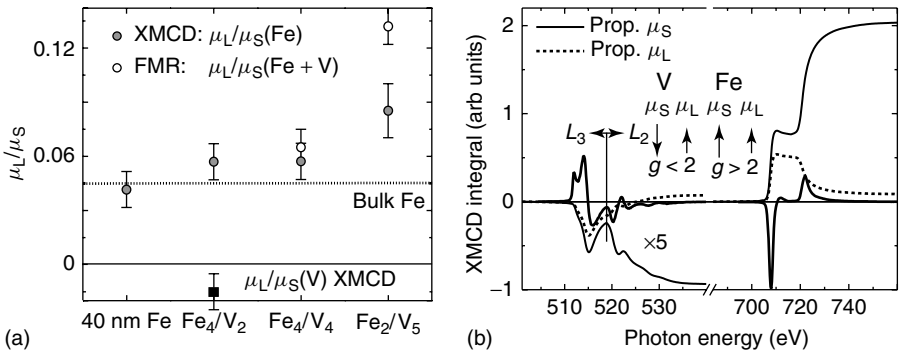

Figure 4. Orbital and spin magnetic moments, μ_L and μ_S, respectively, of Fe/V multilayers measured by FMR and XMCD (Scherz *et al.*, 2001). (a) The ratio μ_L/μ_S increases with decreasing Fe thickness. Note that XMCD measures only the Fe moments (full circles), whereas FMR measures the total (Fe and V) response (open circles). The ratio μ_L/μ_S of V in Fe_4V_2 as obtained from XMCD (full squares) is negative because μ_L and μ_S are aligned antiparallel in V. (b) XMCD spectra (thick solid line) and integrated XMCD signals as they would appear in the spin (thin solid line) and orbital (dotted line) sum rule.

Comparing experimental results only makes sense if the data are taken at the same reduced temperature. The MAE vanishes at T_C, that is, it is zero in the paramagnetic regime. In Figure 5(a) two sets of data are plotted: full circles at $t = 0.56$ and open triangles at $t = 0.74$. That this is an important point is seen in Figure 5(b) in which experimental data are plotted at a fixed temperature of $T = 300\,\mathrm{K}$ as a function of the thickness from $\sim$1 to $\sim$10 ML. At first glance, it seems that as the film becomes thinner the anisotropy K increases with a positive slope. If, however, the data of Farle *et al.* (1999) (full circles) are plotted at a fixed, reduced temperature $t = 0.21$ (Figure 5c) instead of a fixed absolute temperature $T = 300\,\mathrm{K}$, again a linear function of $1/d$ results with negative slope up to $\sim$6 ML. This is the only correct way of analyzing magnetic anisotropy of ultrathin films. Figures 5(a) and 5(c) can be interpreted in the same way: Starting from right to left, at very thin films of $\sim$3 ML we see a linear increase with negative slope of $f(1/d)$ up to a particular value of $\sim$15 ML for Ni and $\sim$6 ML for Co. In the ultrathin limit, the Ni and Co films grow pseudomorphically with tetragonal distortion for Ni(001) (trigonal for Co(111)). At the bending, the pseudomorphic growth stops and the films grow in the natural bulk structure of the specific material, for example, fcc for Ni. These linear dependences of $K(1/d)$ in Figure 5(a) and 5(c) confirm equation (A3), namely, the classical argument by Néel that the surface and interface anisotropies scale down with $1/d$. The diagrams also show the extrapolation of the linear slope to the y axis indicated as K^V. Let us assume for sake of argument that ultrathin films of Ni or Co grew with a rigid perturbed lattice structure (i.e., tetragonally distorted owing to pseudomorphic growth) up to infinite thickness, indeed an extremely large volume anisotropy of 30 or 90 μeV/atom would occur. Of course, ferromagnetic films do not do that. The growth mode collapses back to the natural bulk lattice structure of the material with much lower anisotropy per particle. We did observe that this linear function and bending in $K(1/d)$ is the most sensitive indicator for changes in the growth mode. The crystallographic structure may change only by less than 0.1 Å, which is difficult to measure by diffraction (LEED) but does have large effects on MAE and K.

FMR measures the total M_{eff} (equation (5)). After subtraction of the dipole contribution $2\pi M^2$, the K parameters (Figure 5) can be plotted as a function of $1/d$ or as a function of T (for details see Appendix B). We also see that $2\pi M^2$ has to be scaled with the reduced temperature. It is obvious that because of the small magnetic moment per Ni atom the shape anisotropy for Ni is much smaller ($\sim$10 μeV/atom) than for Co ($\sim$90 μeV/atom) with a large magnetic moment per atom. This is the simple reason why the easy axis of magnetization for ultrathin ferromagnetic films of Co is in most cases in plane. Whereas for Ni the K anisotropy caused by the spin-orbit coupling can exceed the dipole contribution and result in an SRT from in plane to out of plane at $\sim$7–9 ML (e.g., Figure 5a). For details see (Baberschke 1996, 2001; Farle, 1998). Like in bulk ferromagnets, the various K_i parameters have a different temperature dependence. For bulk, see (Stearns, 1986), for ultrathin films, see (Farle, 1998; Baberschke, 2001). In equations (4) and (6) the shift of the external resonance field H_0 as a function of the temperature or angle is measured in absolute field units, that is, Oe. For a given magnetization, this can easily be translated into energy units. Many other spectroscopies discussed in this volume measure magnetic anisotropy usually only in arbitrary units. Determining the absolute MAE is the strength of the FMR. Therefore, a new challenge is to compare FMR experiments with *ab initio* calculations from first principles.

The importance of the temperature dependence of the MAE in ferromagnetic nanoclusters recently became very evident. Various groups have investigated small ferromagnetic particles (e.g., Co) by means of MOKE and XMCD, measuring very large MAE and orbital magnetization.

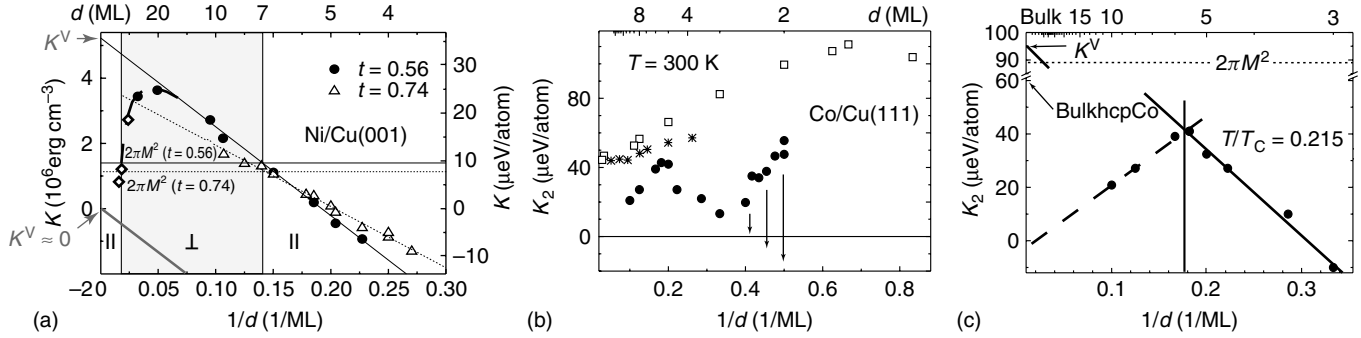

Figure 5. K_2 anisotropy as a function of $1/d$ (a) for Ni/Cu(001) at different reduced temperatures (Schulz and Baberschke, 1994), (b) and (c) for Co/Cu(111). The data in (b) are taken from (Huang *et al.*, 1994) (open squares) and (Kohlhepp *et al.*, 1993) (asterisks). Both were measured at fixed, ambient temperature. The data taken from (Farle *et al.*, 1999) (full circles) are plotted at fixed temperature in (b) and as a function of reduced temperature in (c).

Usually, one assumes a uniaxial anisotropy constant K_u. However, Antoniak *et al*. (2005) measured the temperature dependence $K(T)$ for Fe/Pt nanoparticles with FMR and observed that it changes between 50 and 300 K by one order of magnitude. This explains the whole magnetic behavior of these nanoparticles.

To demonstrate the high sensitivity of the MAE on small crystallographic lattice perturbations, we show in Figure 6(a) *ab initio* calculations for an infinite-sized single Ni crystal. It is an all electron, full relativistic calculation including orbital polarization (full symbols) and without orbital polarization (open symbols). The infinite-sized crystal was chosen to demonstrate the importance of the volume contribution K^v. K^v is defined as the difference in total energy between the hard and easy axis, for bulk Ni the [100] and [111] magnetization directions (Hjortstam *et al*., 1997). The difference in total energy was calculated for different ratios c/a, starting from an fcc lattice ($c/a = 1$), passing through a regime with tetragonal symmetry and ending in a bcc symmetry ($c/a = 1/\sqrt{2}$). For fcc and bcc, K^v almost vanishes, $K^v \ll 1\,\mu$eV/atom. In the tetragonal regime, K^v increases by orders of magnitude up to $K^v \approx 500\,\mu$eV/atom. For the FMR experiments shown in Figure 5, the pseudomorphic growth of the Ni film produces a constant ratio $c/a \approx 0.95$ (gray regime in Figure 6a). The *ab initio* calculations in Figure 6 yield an anisotropy energy of $K^v \approx 100\,\mu$eV/atom. This result is in perfect agreement with the experimental finding after extrapolating the experimental value to $K^v\,(T = 0)$. Comparing experiment and theory, one comes to the conclusion that *changes in the nearest-neighbor distance of* $\sim$*3%, that is,* $\sim$0.05 *Å, may change the MAE by orders of magnitude.*

The Weinberger group (Uiberacker *et al*., 1999) has performed similar calculations for a particular FMR experiment on a 12 ML Ni film grown on a Cu substrate and facing vacuum. Figure 6(b) shows the magnetic part of the difference in total energy per individual Ni layer. For the open triangles, a rigid, unrelaxed fcc lattice was assumed, whereas open squares and open circles are calculations for a relaxed tetragonal Ni structure adapted to the lattice of the Cu substrate. It is obvious that the topmost Ni layer facing vacuum shows a large negative contribution corresponding to the negative slope in Figure 5(a). It is also clear that the first Ni layer on the Cu substrate has a different (smaller) negative energy contribution due to hybridization with the Cu band structure. Such an effect cannot be separated in an FMR experiment – the experiment measures the sum of the two contributions. However, the center part of the 12 ML Ni film is most instructive: For a rigid cubic lattice, their energy contribution is very small. If, however, one puts the real relaxed lattice as determined from experiment into the calculation, we see that the center part of an ultrathin film also contributes to the total MAE in full agreement with the results of Figure 6(a). That is to say, *surface and interface magnetic anisotropy contributions* K^s *are certainly very large following the early argument by Néel, but they usually count only*

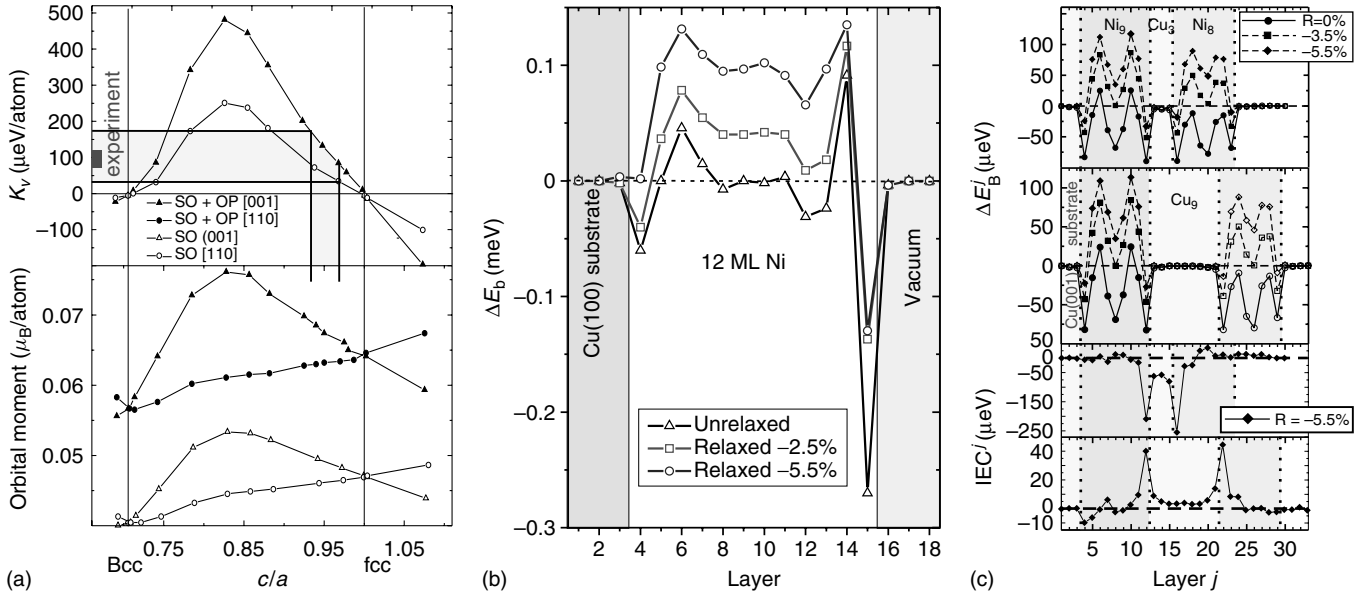

Figure 6. *Ab initio* calculations of MAE and IEC for various Ni structures. (a) The difference in total energy is calculated for an infinite-sized Ni crystal as a function of the ratio c/a. (Taken from Hjortstam *et al*., 1997.) The lower part shows the orbital moment and its anisotropy. (b) Similar *ab initio* calculations for a 12 ML Ni film, layer resolved. (Taken from Hjortstam *et al*., 1997.) (c) Similar calculations for a trilayer also showing the IEC, see Section 3.3. (Taken from Hammerling *et al*., 2003.)

for one layer each, whereas the central part of an ultrathin film counts for $n-2$ *layers.* For the particular example shown here, it is obviously clear that the K^{v} contribution to the total MAE is the dominating one. For the details of the nomenclature, see Appendix B.

3.3 UHV-FMR in a trilayer and interlayer exchange coupling (IEC)

The archetype of a magnetic multilayer structure is the so-called 'trilayer', consisting of two FM films, FM1 and FM2, weakly exchange coupled via a nonmagnetic spacer NM. Two exchange-coupled ferromagnetic films exhibit two eigenmodes of the uniform motion of the magnetizations M_1 and M_2 – like two coupled pendula. Analogous to the notion of phonon branches, they are labeled acoustic (in phase) and optic (π out of phase) modes. The FMR is the technique of choice for investigating these spin-wave dynamics (Lindner and Baberschke, 2003b). It measures both AFM and FM coupling and determines the MAE and IEC parameters. For such a case, $\vec{M}$ has to be replaced by the vector sum $\vec{M}_1 + \vec{M}_2$ in the equation of motion, equation (2). Furthermore, an additional energy contribution of the IEC energy is added to the free-energy density. Following the FMR resonance condition, equations (4–6) also have to be modified. One has to distinguish the individual anisotropy parameters of each FM film, for example, K_i^{Ni} and K_i^{Co} (for details see (Heinrich, 1994; Lindner and Baberschke, 2003a). In theoretical calculations, the IEC usually enters with an IEC constant at $T = 0$. Most of the experiments are analyzed with an effective parameter J_{inter}.

$$F_{\mathrm{ex}} = -J_{\mathrm{inter}} \frac{\vec{M}_1 \cdot \vec{M}_2}{M_1 M_2} \tag{8}$$

The scalar product $\vec{M}_1 \cdot \vec{M}_2$ takes care of the individual orientation of M_i in each film. (Note that in an FMR experiment with an external magnetic field H_0, the orientation of M changes as a function of the orientation and strength of H_0.) In Figure 7, an instructive example is given showing that in a step-by-step experiment the UHV-FMR gives detailed information on all relevant magnetic parameters for such trilayers.

Figure 7(a) and (b) show the experimental and simulated FMR spectra of a $Ni_7/Cu_9/Co_2$ trilayer at two different

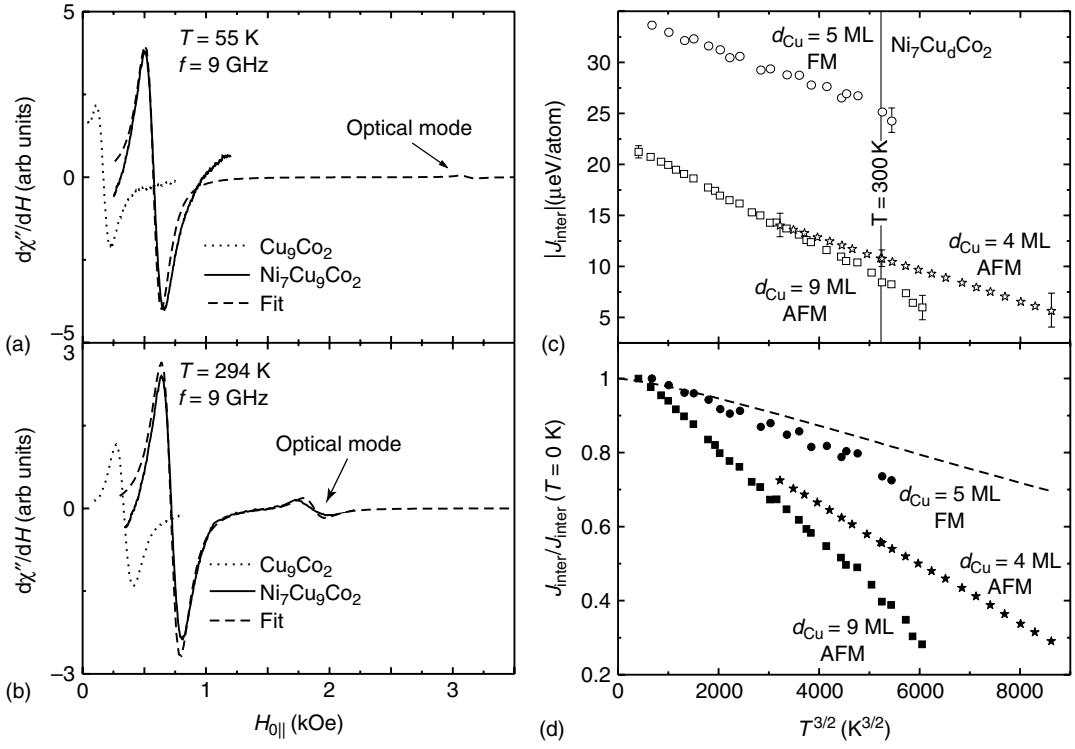

Figure 7. (a) and (b) experimental and calculated FMR spectra of a Ni/Cu/Co trilayer at different temperatures along the in-plane easy axis, taken from (Lindner *et al*., 2002). First the single Co film on Cu(001) was measured (dotted). Subsequently the top Ni film was evaporated. The same type of experiment was carried out for different spacer thicknesses d_{Cu} for AFM and FM coupling. J_{inter} determined from the FMR fitting is plotted in absolute energy units in (c) and normalized to $T = 0$ in (d) as a function of an effective $T^{3/2}$ law (Schwieger *et al*., 2007).

temperatures. First, only the Co_2 film capped with the Cu_9 spacer layer was prepared. A single resonance line (dotted) is recorded. Its intensity and position change because K_i and M are temperature dependent. In a second step, the Ni_7 film is deposited on top. At room temperature, the FMR records two resonance lines: one of the weak optical mode and a second one of the strong acoustical mode. From the intensity and position of the two lines it is immediately evident that this trilayer has an AFM coupling between the two ferromagnetic films (Heinrich, 1994; Lindner and Baberschke, 2003a). The simulation of the coupled resonance lines (dashed) is in perfect agreement with experiment. A full measurement of the dependence on the polar angle and the temperature gives access to all MAE parameters, provided $M(T)$ is known from another experiment. Taking the angular dependences of only the bottom film and the IEC trilayer, all unknown parameters influencing the resonance field of the optical and acoustical mode can be determined. The only parameter left, which determines the resonance shift, is J_{inter} itself. This straightforward way of determining the coupling demonstrates the advantage of *in situ* measurement. The coupling between FM1 and FM2 is an oscillatory function of the spacer thickness (Bruno and Chappert, 1991). For the particular system $Ni_7/Cu_d/Co_2$, this has been observed and determined by UHV-FMR for a spacer thickness in the range of $d_{\text{Cu}} = 2\text{–}9\,\text{ML}$ (Lindner and Baberschke, 2003a). Again, it is documented in textbooks (Heinrich, 1994) that FMR is equally applicable for AFM and FM coupling: for AFM coupling, the intense acoustical mode appears at a lower magnetic field than the weak optical mode; for FM coupling, this reverses such that the optical mode is at a lower magnetic field than the acoustical mode. We note that FM1 and FM2 in trilayers may also consist of the same material, for example, $Ni_8/Cu_d/Ni_9$. For Ni films of different thicknesses, the MAE values and magnetization are different, leading to different eigen resonances of the individual modes.

Another important parameter for understanding the magnetism of coupled ferromagnetic films is the *temperature dependence* of the coupling strength, that is, $J_{\text{inter}} = f(T)$. Two models were proposed in the past:

1. Thermally excited spin waves in the magnetic layers lead to a reduction of the effective IEC. In this model, the characteristic temperature is given by T_{C}. Arias and Mills calculated a $T^{3/2}$ power law (Arias and Mills, 1999, 2000):

$$\frac{J_{\text{inter}}}{J_{\text{inter},0}} = 1 - a\left(\frac{T}{T_{\text{C}}}\right)^{3/2} \tag{9}$$

   Other parameters like the thickness of the spacer layer are hidden in the prefactor a.

2. In the framework of electronic band structure, the smearing of the Fermi edge at elevated temperature makes the coupling less effective, excitations of electron–hole pairs reduce the IEC (Bruno, 1995). This temperature-dependent factor was calculated by Bruno as given in equation (10).

$$\frac{J_{\text{inter}}}{J_{\text{inter},0}} = \frac{T/T_0}{\sinh\left(\frac{T}{T_0}\right)} \tag{10}$$

The characteristic temperature T_0 is controlled by electronic band structure effects, that is, v_{Fermi} and the spacer thickness. The Curie temperature is no explicit parameter but is implicitly included via the intralayer coupling of the ferromagnets.

Lindner *et al*. (2002) have shown for various ultrathin film systems over the full temperature range from $\sim$0 K up to T_{C} that the effective temperature dependence is very close to the $T^{3/2}$ law and can be less well fitted by a $x/\sinh(x)$ function. However, Nolting and coworkers (Schwieger and Nolting, 2004; Schwieger *et al*., 2005) have reinvestigated the origin of the temperature dependence of the IEC yielding an effective functional dependence, which for given intra- and interlayer exchange parameters gets very close to an effective exponent of $\sim 3/2$ but does not follow the exact power law for spin-wave excitations with $T^{3/2}$. For the $Ni_7/Cu_d/Co_2$ trilayer system, the temperature dependence is plotted in Figure 7(c) and (d). Figure 7(c) gives the absolute values for $|J_{\text{inter}}|$. For $d_{\text{Cu}} = 5\,\text{ML}$ the coupling is FM, for $d_{\text{Cu}} = 4\,\text{ML}$ and $d_{\text{Cu}} = 9\,\text{ML}$ the coupling is AFM. In Figure 7(d) the measured values are normalized to $T = 0$, this eliminates the temperature-independent part of $|J_{\text{inter}}|$. Nonmonotonic slopes as a function of d_{Cu} are seen; that is, a nonmonotonic temperature dependence of $|J_{\text{inter}}|$. The temperature dependence for AFM coupling is larger than that for FM. This nonmonotonic behavior clearly indicates that the coupling between spin-wave modes will be more important for the *temperature dependence* of $|J_{\text{inter}}|$, than the smearing of the Fermi edge.

In conclusion, the strength of the effective $T^{3/2}$ dependence of J_{inter} depends on various parameters of the electronic band structure, electron–hole excitations, and spin-wave excitations. Further *in situ* FMR experiments with different Cu thickness and full angular- and temperature-dependent measurements will give the key information to understand the IEC. Recent quantum mechanical calculations based on an extended Heisenberg model give clear evidence that magnon excitations are responsible for about 75% of the temperature dependence of the IEC. The remaining 25% is due to temperature effects in the effective quantum well, formed by the spacer and the spacer/magnet interfaces like

reduced spin asymmetry or softening of the spacer Fermi surface (Schwieger *et al.*, 2007).

Finally, we come back to Figure 6(c) where the Weinberger group has calculated layer resolved the K anisotropy (ΔE_B) and the IEC for an $Ni_8/Cu_d/Ni_9$ trilayer. We see that the anisotropy energy depends strongly on the c/a ratio as discussed in the previous section. We also notice that for $d_{Cu} = 3$ ML and $d_{Cu} = 9$ ML the spacer does not contribute to the MAE. The layer-resolved calculated IEC demonstrates clearly that more or less only the Ni layer contributes to the exchange coupling directly at the interface but for very thin spacers (3 ML) the Cu also makes a finite contribution.

4 DYNAMICS IN THE FMR, THE LINEWIDTH ΔH

Starting from Figure 1 it is obvious that the linewidth in the EPR and FMR is a measure of the spin relaxation, scattering, and spin fluctuations. Two principal relaxation paths are discussed in standard literature: spin–lattice relaxation and spin–spin relaxation. The former is a process in which energy dissipates from the magnetic system to the thermal bath. For the latter, energy is scattered within the magnetic spin system. It depends on the concentration of magnetic moments (dilute ferromagnets) and can be discussed in the framework of spin-wave excitations, magnon–magnon scattering, Stoner excitations, and so on. For both processes, phase transitions (structural or magnetic) are of importance: diverging spin fluctuations as a function of temperature will influence the linewidth. Müller and coworkers have given a nice example for the EPR: $SrTiO_3$ undergoes a structural phase transition at $\approx$105 K. If this crystal is doped with a paramagnetic center, the EPR will show a dramatic divergence of the linewidth at this phase-transition temperature (von Waldkirch *et al.*, 1973). Similar effects were observed for the classical antiferromagnet MnF_2 at the Néel temperature of $T_N = 67$ K (Burgiel and Stranberg, 1964). In both cases, a dramatic divergence of ΔH is observed.

For bulk ferromagnets like Ni and Fe whiskers also a line broadening in the FMR occurs starting from low temperature and approaching the Curie temperature from the T_C^- side.

On the right-hand part of Figure 8, the FMR linewidth $\Delta H(T)$ is shown for bulk Ni. A very sharp peak of only 7 K width is measured at the Curie temperature of $T_C \approx 630$ K. The line broadens from below 200 Oe to more than 1.6 kOe. How can this be understood? Approaching the phase transition from the T_C^- side, one observes a breakdown of the uniform precession of the magnetization. The uniform rotation of the spin waves with infinite wavelength breaks into pieces because of thermal excitations. This increases the FMR

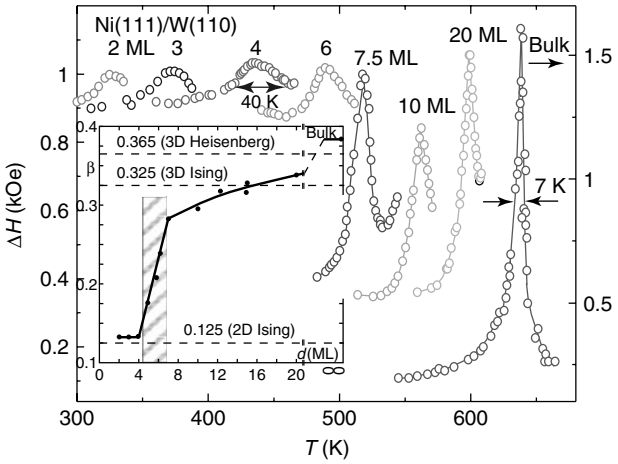

Figure 8. FMR linewidth $\Delta H(T)$ of bulk and ultrathin Ni films $d = 2$–20 ML as a function of the temperature. Note the very sharp peak for thicker films and the very broad peak for the ultrathin 2D film. The inset shows the critical exponent β and the transition 3D $\rightarrow$ 2D. For details see Li and Baberschke (1992).

linewidth. Starting from the paramagnetic side above T_C^+ also a narrow line of 250 Oe width is observed. The susceptibility and spin–spin correlation length ξ increase dramatically owing to Gaussian and critical fluctuations. The sharpness of the peak in the linewidth is surprising. It depends very much on the high perfection of the crystallographic structure of the single crystal. (Since these measurements are performed in an external magnetic field, ξ will not diverge to infinite.) Applying the UHV-FMR to Ni(111) thin films grown on W(110), we observe in the first place a shift of the diverging peak to lower temperature in full agreement with the thickness-dependent Curie temperature of ultrathin films caused by *finite size* effects (Baberschke, 1996). At a certain thickness of $d = 4$–6 ML, the Ni film undergoes a transition from 3D to 2D behavior. Immediately, we observe a broadening of the linewidth peak as indicated by $\sim$40 K in the figure. This can be easily understood because the fluctuations in less than 3D are enhanced and extended over a larger range of temperature. For details see (Li and Baberschke, 1992; Li *et al.*, 1990).

4.1 Gilbert damping and magnon–magnon scattering

In the following text we focus on the analysis of the linewidth in FMR experiments in ultrathin films deep in the ferromagnetic phase $T \ll T_C$. This is of particular importance for the investigation of magnetization dynamics and magnetization reversal in magnetic nanostructures. The commonly used ansatz is to add the so-called Gilbert

damping to the equation of motion, equation (2), that is, the second term in equation (11). This Landau–Lifshitz–Gilbert (LLG) equation has been discussed in great detail in many review articles. For FMR in bulk material see, for example (Sparks, 1964; Vonsovskii, 1966), for ultrathin films see, for example (Heinrich, 1994, 2005). The Gilbert ansatz is based on a double vector product $-\vec{M} \times (\vec{M} \times \vec{H}_{\text{eff}})$ as shown in Figure 9(b) with a resulting vector that is always pointing toward the symmetry axis of the Larmor precession. For small angles β between H_{eff} and M, this can be approximated by the time derivative $\partial \vec{M}/\partial t$.

$$\frac{\partial \vec{M}}{\partial t} = -\gamma(\vec{M} \times \vec{H}_{\text{eff}}) + \frac{G}{\gamma M_S^2}\left[\vec{M} \times \frac{\partial \vec{M}}{\partial t}\right] \quad \text{with}$$
$$\alpha = G/\gamma M \tag{11}$$

Thus it can be interpreted as a velocity-proportional viscous damping like in mechanical (Stokes) friction. The viscosity damps the Larmor precession, and the magnetization spirals into the z axis pointing to the surface of a sphere, that is, the length of $\vec{M}$ stays constant but the expectation value $\langle M_z \rangle$ increases if $\beta \to 0$. This is indicated in Figure 9(b) as relaxation path 1. A uniform motion of the magnetization plus a viscous damping leads to a dissipation of energy into the thermal bath (path 1 in Figure 9(a) – an irreversible process. Two notations are commonly used in equation (11): (i) G, the Gilbert-damping parameter, given as a relaxation rate in s^{-1}, or (ii) the dimensionless parameter α in analogy to the viscous damping. The relaxation rate per second G seems to be more instructive for easier comparison with other relaxation rates in the literature. As discussed in Section 2, standard EPR/FMR experiments use a fixed microwave frequency and scan the external Zeeman field H_0. Under these conditions, the LLG (11) leads to a linewidth ΔH_G depending linearly [4] on ω

$$\Delta H_G(\omega) \approx \frac{2}{\sqrt{3}} \frac{G}{\gamma^2 M} \frac{\omega}{\cos\beta} \tag{12}$$

One example is shown in Figure 3 in which for 1 GHz experiments the linewidth for a 10 ML Ni film is very narrow in the range of 10–20 Oe, whereas for the most commonly used 10 GHz frequency the linewidth increases up to 200–250 Oe.

A second relaxation process is discussed in standard literature and indicated in Figure 9(c): The uniform motion of the magnetization (or switching the magnetization) may scatter into excited states of the magnetic subsystem (spin waves, Stoner excitations, magnon–magnon scattering, etc.) The projection of $\vec{M}$ onto the z axis stays constant since the precessional energy is scattered into the transverse components M_x and M_y. (For details see Sparks, 1964). These processes may be reversible and are indicated in Figure 9(a) as path 2. They are in full analogy with optical spectroscopy. In the long run, these excitations will also decay into the thermal bath as indicated by path 3. One may raise the question: Is there any experimental evidence for the appearance of this second relaxation process, that is, scattering within the magnetic subsystem, in magnetic nanostructures? The theoretical background to study this question is known for a long time. One possible model is described by the Bloch–Bloembergen equation (Bloembergen, 1950; Bloch, 1946)

$$\frac{\partial \vec{M}}{\partial t} = -\gamma(\vec{M} \times \vec{H}_{\text{eff}}) - \frac{M_x}{T_2}\hat{e}_x - \frac{M_y}{T_2}\hat{e}_y - \frac{M_z - M_S}{T_1}\hat{e}_z \tag{13}$$

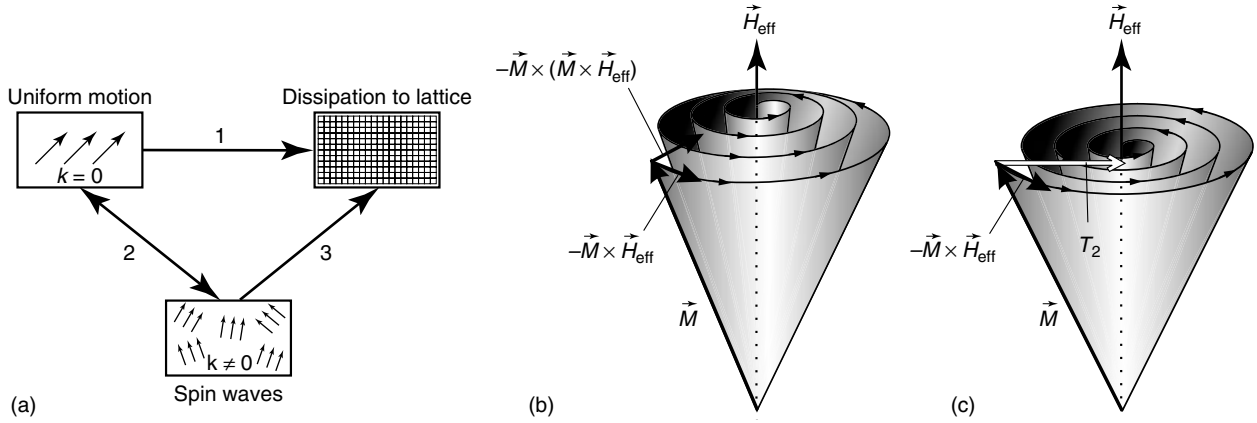

Figure 9. Schematic illustration of different relaxation processes taken from Suhl (1998); Sparks (1964): (a) The uniform motion of the magnetization with $k = 0$ in an FMR experiment may scatter with energy dissipation into the thermal bath (path 1). In path 2 it can also scatter into spin waves with $k \neq 0$ – a reversible process. In the long run, this energy also travels along path 3 into the heat sink. (b) Depicts the LLG scenario from equation (11). (c) Shows the Bloch–Bloembergen process for spin–spin relaxation.

In this case, two different relaxation rates are introduced into the equation of motion (Abragam and Bleaney, 1966): the longitudinal relaxation rate T_1, that is, the direct path into the thermal bath, and the so-called transverse rate, T_2, by which energy is scattered into the transverse magnetization components M_x and M_y. This is depicted in Figure 9(c). The projection of $\vec{M}$ on the effective field $\vec{H}_{\text{eff}}$ stays constant and energy is scattered into the transverse components M_x and M_y. This is a dephasing of the former coherent rotation of the magnetization as discussed in the previous section. This scenario of a transverse relaxation rate is known, for example, Sparks (1964); Mills and Rezende (2003); Suhl (1998). Only very recently, Arias and Mills have calculated this type of magnon–magnon scattering in a quantitative manner for standard FMR experiments in ultrathin films (Arias and Mills, 1999, 2000) (see also **Spin Waves: History and a Summary of Recent Developments, Volume 1**). The result for the FMR linewidth is given below, with Γ as a parameter

$$\Delta H_{2\text{M}}(\omega) = \Gamma \sin^{-1} \sqrt{\frac{\sqrt{\omega^2 + (\omega_0/2)^2} - \omega_0/2}{\sqrt{\omega^2 + (\omega_0/2)^2} + \omega_0/2}} \qquad (14)$$

It is obvious that the frequency dependence of the linewidth for magnon–magnon scattering is by no means linear. It saturates at very high frequency and starts with a steep slope at low frequencies (Figure 10). The first experimental evidence of a nonlinear $\Delta H(\omega)$ was reported for Fe/V nanostructure in Lindner *et al.* (2003) and for Fe/GaAs films, (Woltersdorf and Heinrich, 2004). Recently, the FMR linewidth of Fe/V multilayers has been measured and analyzed over a very large frequency range from 1 to 225 GHz as shown in Figure 10 (Lenz *et al.*, 2006). Key information can be obtained from Figure 10: (i) FMR measurements at very low frequencies (1–4 GHz) unambiguously show that the linewidth narrows dramatically, that is to say ΔH is given by relaxation processes only. A practice used in the literature for earlier experiments between 9 and 36 GHz to *assume* a linear frequency dependence (Celinski and Heinrich, 1991), extrapolating from this, an apparent residual linewidth (the tangent crossing the y axis) does not always seem to be justified. (ii) For all in-plane orientations of the external field ([001] and [110]), one observes a nonlinear frequency dependence. In contrast, for $\vec{H}$ normal to the film plane ([001], full triangles), a 100% linear frequency dependence is observed. This is in perfect agreement with the theoretical prediction in (Arias and Mills, 1999, 2000). The authors of (Lenz *et al.*, 2006) deduce a constant (independent of orientation) Gilbert damping of $\sim 0.7 \times 10^8\ \text{s}^{-1}$ for these multilayers. Fitting equation (14) to the curved frequency dependence yields a magnon–magnon scattering rate of $\gamma\Gamma \approx 10$–50 larger than the Gilbert damping. Thus, experimental evidence is given that both relaxation mechanisms (longitudinal and transverse scattering) are active in magnetic nanostructures. A combination of magnon–magnon scattering, modeled by equations (13) and (14), and a viscous Gilbert damping described by equations (11) and (12) seems to give a better insight into the spin dynamics of ultrathin films. For the particular investigated systems, Fe/V multilayers and Fe films on GaAs, the magnon–magnon scattering of $1/T_2 \approx 10^9\ \text{s}^{-1}$ seems to be about 2 orders of magnitude faster than the viscous Gilbert damping of $1/T_1 \approx 10^7\ \text{s}^{-1}$.

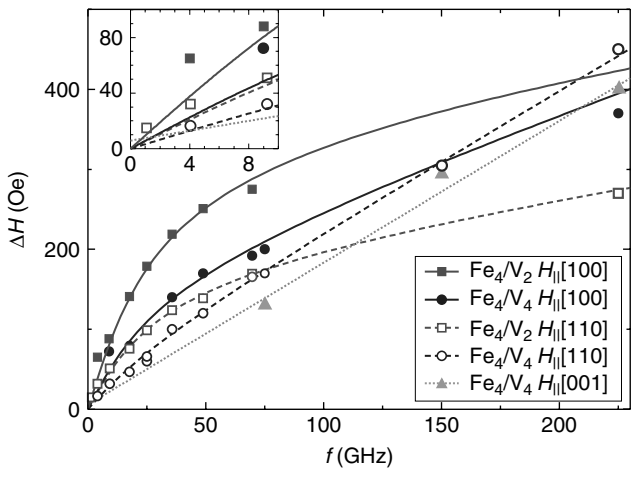

Figure 10. FMR linewidths of two Fe/V-multilayer samples for different in-plane and out-of-plane orientations of the external field as a function of the microwave frequency. The inset is a magnification of the low frequency regime. For details see Lenz *et al.* (2006).

4.2 Spin-pump effects in the FMR

Consider in Figure 11(a) that 3d magnetic moments of the FM are excited by a microwave radiation $h\nu$ and undergo a Larmor precession in an external field, equations (1) and (2). It is standard textbook reasoning that the local 3*d* moments are coupled to the sea of conduction electrons via the classical s–d exchange interaction. In turn, the conduction band of the FM is hybridized with the conduction band of the NM. This classical s–d exchange between spin waves and s electrons has been used by Janossy and coworkers (Silsbee *et al.*, 1979; Monod and Janossy, 1977) to activate and enhance the Larmor precession in the NM conduction band, the so-called conduction electron spin resonance (CESR). Angular momentum is transferred to the conduction band and then transported into the NM. These authors used highest-purity Au as NM and were able to detect the spin current of the Au conduction band through micrometer thick Au. This has been monitored at the right-hand end of Figure 11(a) either as emitted

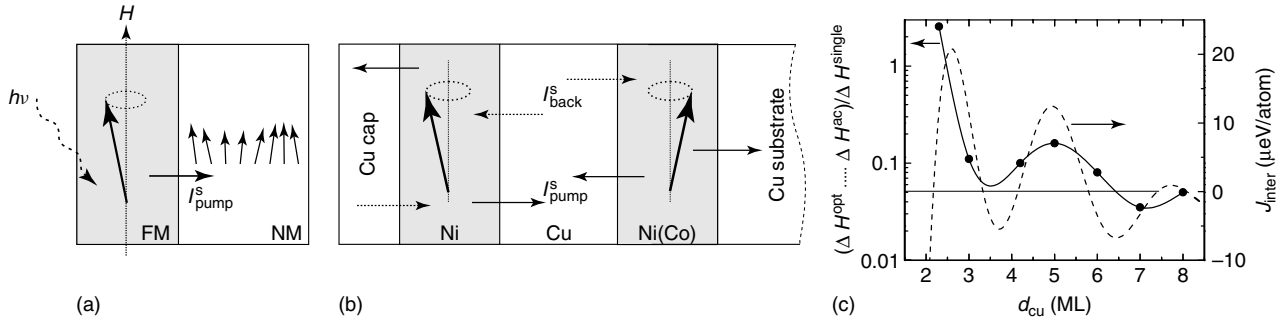

Figure 11. Schematic illustration of the spin-pump effect of (a) a single interface and (b) a trilayer consisting of two different ferromagnetic films and a nonmagnetic spacer. (c) Oscillatory behavior of the linewidth as a function of the Cu spacer. The data are taken from Lenz *et al*. (2004) for a $Ni_8/Cu_x/Ni_9$ trilayer.

microwave radiation or by exciting another magnetic system. This is the basic mechanism called *spin pumping* in our days. Thus, angular momentum and energy are lost from the ferromagnetic film and transported to the NM (metal, semiconductor). In the frame of Figure 9(a), this can be seen as a dissipation of energy like path 1 in Figure 9(a). Recently, such a mechanism became of particular interest for magnetic nanostructures consisting of two ferromagnetic films separated by an NM spacer, see Figure 11(b). Such a scenario has been investigated theoretically in Tserkovnyak *et al*. (2002) and by others. Experimental evidence was given in Heinrich *et al*. (2003) for Fe/40 ML Au/Fe (see also **Magnetic Ultrathin Films, Volume 4**). The thickness of the spacer will be of particular interest. For a larger thickness, like 40 ML Au, there is no IEC between FM1 and FM2 – see Section 3.3. Only ballistic transport is possible for the spin current depending on the perfection of the spacer and its interfaces. For ultrathin spacer films of only a few monolayers, one expects also some IEC (see Section 3.3) influencing the FMR linewidth. Constructive or destructive interference phenomena and quantum well effects should be detectable in the spin current I_{pump}. In Section 3.3 we have seen that a trilayer consisting of two different ferromagnets (Ni and Co or two Ni films with different thickness) has two different (acoustic and optic) FMR modes. In Lenz *et al*. (2004) and Heinrich *et al*. (2003) first evidence is given that indeed the FMR linewidths influence each other when both resonance conditions coincide. Figure 11(c) shows the difference between the optic and acoustic linewidth $\Delta H^{opt} - \Delta H^{ac}$ for $Ni_8/Cu_x/Ni_9$ with an ultrathin spacer thickness of $d_{Cu} = 2–8$ ML. On the left-hand side, the relative change in the linewidth normalized to the linewidth for a single film is plotted on a logarithmic scale, whereas on the right-hand side the energy scale for J_{inter} (dashed line) is shown. The broadening of the optical linewidth is the largest (more than a factor of 2) for the thinnest Cu spacer and the largest J_{inter}. A clear oscillatory behavior for both linewidth and J_{inter} is observed as a function of d_{Cu}.

5 SUMMARY, OUTLOOK

As discussed by several examples, microwave spectroscopy is a very useful technique to investigate ultrathin ferromagnetic films. It covers the ferromagnetic as well as the paramagnetic regime. It is sensitive to ferromagnetic as well as antiferromagnetic IEC in superstructures. The static resonance conditions, its angular and temperature dependence as well as the linewidth, yield reliable information on the static and dynamic parameters of ultrathin film magnetism. If the standard FMR technique is combined with state-of-the-art surface science and UHV technique, the combined UHV-FMR spectroscopy opens a new challenging research field to study the growth and crystallographic modifications, the electronic band structure, and the direct observation of the magnetism in one experiment. Such a complete set of experimental observables is the best input for a better theoretical description of the magnetism of magnetic nanostructures. Standard FMR technique might have one drawback: the spectroscopy has no spatial resolution. The wavelength of the microwave ranges from submillimeters to a few centimeters and the absorbed energy out of the microwave radiation is the macroscopic response of the whole specimen. A recent development to overcome this problem is to combine an STM or AFM tip with FMR. Several groups have developed this technique. A lateral resolution in the range of 10–100 nm was reached (Meckenstock *et al*., 2003; Meckenstock *et al*., 2004). Another interesting new development is the combination of synchrotron radiation and FMR. XMCD has the advantage of being element specific. XMCD also has access to orbital and spin magnetic moments. If this can be used to probe the change in the magnetization induced by the precession of magnetic moments, this X-ray-detected magnetic resonance (XDMR) is the analogue of the well-known optical-detected magnetic resonance (ODMR). First experimental results at the K-edge of Fe in a YIG crystal have been reported recently (Goulon *et al*., 2005). Also, the

combination of an electronic network analyzer with FMR spectroscopy offers the possibility of studying the dynamics of magnetic nanostructures in the frequency as well as in the time (pulsed) domain (Counil *et al*., 2004).

Finally we point out recent advances in the theory of the FMR in ultrathin films: The vast majority uses a classical continuum model to interpret experimental spectra, where the classical LLG equation of motion for the magnetization or an expansion of the free energy is considered. Recently a microscopic Heisenberg Hamiltonian was used to directly calculate for FMR the spin-wave resonance modes and external resonance fields as a function of the field direction and as a function of temperature (Schwieger *et al*., 2005). Future work will provide better microscopic insight into the FMR of ultrathin films.

NOTES

[1] The FMR community uses a positive γ value, whereas in EPR the negative sign of the charge is taken into account.

[2] Note that many other experimental techniques like MOKE, spin-polarized PE, and so on, measure the magnetization in arbitrary units, only. MAE and IEC, for example, measured by FMR are given in absolute energy units per particle. These numbers are of interest for comparison with theory.

[3] This equation is strictly valid only for g-values close to two.

[4] Note that this linear frequency dependence is a consequence of the field-scanning technique in conventional FMR. For other experimental techniques at fixed magnetic field and scanning the microwave frequency or for Brillouin light scattering the analysis of the measured linewidth is different, see (Mills and Rezende, 2003). Caution has to be taken when comparing different experiments.

ACKNOWLEDGMENTS

The idea of EPR and FMR in metals and its combination with UHV technique was brought to our attention by S. Hüfner (FUB) and R. Orbach (UCLA). Discussions with H. Ebert, M. Farle, K. Lenz, J. Lindner, D.L. Mills, and R.Q. Wu are acknowledged. Special thanks is given to C. Sorg, E. Kosubek, and K. Lenz for their assistance in the preparation of the manuscript. Financial support was given over decades by the Deutsche Forschungsgemeinschaft DFG under the research grants Sfb 161, Sfb 6, and Sfb 290.

APPENDICES

A UNITS

The history of ferromagnetism and magnetic anisotropy went different routes and was uncoupled from other areas of solid-state magnetism, unfortunately. As a consequence, the classification of magnetic anisotropy contributions used an expansion different from Legendre polynomial expansion in crystal-field theory. Moreover, as a consequence various units are used in the historical part of magnetoelasticity, namely, erg cm^{-3} and erg cm^{-2}, that is to say energy per volume and area, respectively. Other parts of solid-state physics and, in particular, the theory prefers eV/atom, that is to say energy per particle (see also **Theory of Magnetocrystalline Anisotropy and Magnetoelasticity in Transition-metal Systems, Volume 1**). This newer notation started to be used in surface and thin-film magnetism and we strongly advocate it, since it facilitates communication with theory and gives an easier insight. For example, in thin-film magnetism Fe, Co, and Ni ions contribute equally strongly to the anisotropy energy, be it a surface atom or an atom in the inner part of a nanostructure, namely, $10-100\,\mu eV/atom$. In the older version it would read $1.5-15 \times 10^6\,ergcm^{-3}$ for K^v and $0.03-0.3 \times 10^6\,ergcm^{-2}$ for K^s, which is not so easy to compare. A transformation of the older into the newer notation is simply given by the atomic volume of the individual elements, for example, for fcc Ni, $10^6\,ergcm^{-3}$ corresponds to $6.83\,\mu eV/atom$ or $7.38\,\mu eV/atom$ for bcc Fe, respectively.

B NOTATION OF THE MAGNETIC ANISOTROPY ENERGY

The magnetic part of the free-energy density and its anisotropy in ultrathin ferromagnetic films has only two origins: (i) the dipole–dipole interaction, which depends on M and the shape of the specimen, (ii) all other contributions (crystalline MAE, magnetoelastic MAE, etc.) are caused by spin-orbit interaction or even better by a full relativistic treatment of the free-energy density. We recall that the exchange interaction $\vec{s}_1 \cdot \vec{s}_2$, the Heisenberg Hamiltonian, is completely isotropic, its energy levels do not depend on the direction in space in which the crystal is magnetized (Aharoni, 2000). The so-called anisotropic exchange is nothing but the anisotropy of the orbital magnetism projected to an effective spin space.

1. The dipole contribution: Mostly, a homogeneous dipole density is assumed with a dipolar field of $4\pi M$ and an energy density of $2\pi M^2$. For ultrathin films of a few monolayers only, this may not be completely appropriate. The dipolar field of a discrete lattice sum has been discussed elsewhere (Farle, 1998; Heinrich *et al*., 1987). The discrete sum of point dipoles delivers somewhat smaller values for the dipolar contribution but this may even be an underestimation because it is currently clear that for 3d or 4f ferromagnets a finite distribution of the magnetic moment density has been measured by means of neutron scattering. In conclusion, if the continuous dipole density ansatz is inadequate for magnetic monolayers or nanometer dots, the real value will be somewhat smaller but not as small as calculated from a lattice grid with point dipoles.
2. Spin-orbit effects: The experimentalist measures the total (or effective) magnetic anisotropy field or energy. Subtracting from this measured value a separately determined or calculated dipolar contribution, the remaining part is given by the spin-orbit-caused contribution and is commonly labeled with K_i. We do not advice to analyze the sum of the two contributions with K_{eff} because the temperature dependence of the dipolar contribution and the spin-orbit-caused anisotropy may be completely

different. The latter contribution, which is also called ΔE_{band} in the *ab initio* theory, is calculated from the band structure. It has anisotropic contributions in various spacial directions of the ferromagnet. To facilitate a comparison between different experimental results or comparison to theoretical *ab initio* calculations we list below different notations. Owing to the pseudomorphic growth of ultrathin Fe, Co, Ni, and Gd films on cubic substrate crystals, one hardly has cubic symmetry in the ultrathin film but rather structures of tetragonal or lower symmetry.

$$E_{\text{tetr}} = -K_2\alpha_z^2 - \frac{1}{2}K_{4\perp}\alpha_z^4 - \frac{1}{2}K_{4\parallel}\left(\alpha_x^4 + \alpha_y^4\right) + \ldots \quad \text{(A1a)}$$

$$= -K_2\cos^2\theta - \frac{1}{2}K_{4\perp}\cos^4\theta - \frac{1}{2}K_{4\parallel}\frac{1}{4}\left(3 + \cos 4\varphi\right)\sin^4\theta + \ldots \quad \text{(A1b)}$$

$$= -K_2'\sin^2\theta - K_{4\perp}\sin^4\theta + K_{4\parallel}\cos 4\varphi\sin^4\theta + \ldots \quad \text{(A1c)}$$

$$E_{\text{hex}} = K_2\sin^2\theta + \frac{1}{2}K_{2\parallel}\cos 2\varphi\sin^2\theta + K_4\sin^4\theta + K_{6\perp}\sin^6\theta + K_{6\parallel}\cos 6\varphi\sin^6\theta + \ldots \quad \text{(A2)}$$

In the preceding equations, the free-energy density is expanded in terms of trigonometric functions. Equation (A1a) used by Heinrich (1994) is identical to equation (A1b), which is given as a function of polar and azimuthal angles up to fourth order. Quite often this energy is expanded in a sine function with the same polar angle θ, given in equation (A1c). It is obviously clear that the prefactor K_2' of equation (A1c) is not identical to the one in equations (A1a) and (A1b) ($K_2' = K_2 + K_{4\perp}$). Also, the fourth-order contributions differ. Moreover, quite often the MAE is measured only in two directions: the easy and hard axes. The total energy difference is projected onto the second-order $\cos^2\theta$ term – often labeled with K_{u} for uniaxial MAE. For a proper determination of the various energy contributions, a full angular-dependent measurement is required including the field-dragging effect if the external field H_0 is not aligned parallel to the easy or hard axes. It is well established for ultrathin films that the fourth-order term $K_{4\perp}$ is by no means small. Quite often it is in the same order of magnitude as K_2. Less popular but maybe more instructive is the expansion of the free energy into spherical harmonics (Vonsovskii, 1974; Coqblin, 1977; Farle, 1998). Clearly, the terms with power $\cos^n$ are grouped differently, resulting in different prefactors and their temperature dependence. For bulk ferromagnets the trigonometric expansion has been used mostly and the K_2, K_4, and K_6 contributions as a function of temperature are listed in the literature (Stearns, 1986). This temperature dependence with the oscillatory $\pm$ values and zero crossings of the $K(T)$ parameters will change completely and look different if one expands the measured energy in terms of Legendre polynomials (Farle, 1998).

For ultrathin films of 5–10 atomic layers measured by FMR, for example, each of these K_i parameters can be decomposed into contributions of volume K_i^{v} and surface/interface K_i^{s} (Farle, 1998; Baberschke, 2001) following the reasoning by Néel.

$$K_i = K_i^{\text{v}} + 2K_i^{\text{s}}/d \quad \text{(A3)}$$

Spin-polarized Photoelectron Spectroscopy as a Probe of Magnetic Systems

Peter David Johnson[1] and Gernot Güntherodt[2]

[2] *RWTH Aachen University, Aachen, Germany*

1 INTRODUCTION

Driven by the requirements for new information storage technologies and the potential of 'spintronics' the last two decades have seen a rapid increase in research devoted to studies of low dimensional magnetic systems. New technologies such as molecular-beam epitaxy (MBE), previously developed in the semiconductor industry, are now being applied to the development of new magnetic materials with unique properties. The understanding of the properties of these two-dimensional (2D) systems has provided a number of exciting challenges for the scientific community, both experimental and theoretical.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

On the experimental side, a whole range of electron spectroscopies previously developed for the study of metallic surfaces have been 'spin-sensitized' through the addition of spin polarimeters. Electron-based techniques are particularly suited to the study of surfaces and thin films because the strong Coulomb interaction between electrons results in a relatively short mean-free path and associated probing depth. In this chapter, we examine in detail the recent developments of one such technique, spin-polarized photoemission. Photoemission itself has already seen widespread application to the study of the electronic structure of a range of different materials (Kevan, 1992; Hüfner, 2003). The spin-polarized counterpart has a history spanning a period of time that is almost as long as the 'modern' era of photoemission. However, it has taken several years for the complete angle-resolved, spin-resolved photoemission experiment to be developed to the point where it provides spectra with a signal-to-noise ratio comparable to that of its non-spin-resolved counterpart. Here it should be noted that in a further contribution to the handbook by Dürr and Schneider (See also **Ultrafast Magnetodynamics with Lateral Resolution: A View by Photoemission Microscopy, Volume 3**) the time-resolved photoemission microscopy and its application to ultrafast magnetodynamics is treated in some detail.

Several reviews of spin-polarized photoelectron spectroscopy (SPPES) have already appeared in the literature (Feder, 1985; Kisker, 1987; Johnson, 1997). The present review represents an attempt to provide a perspective on the rapid developments in the last 10 years. We first examine the physics of the photoemission process itself with particular reference to the excitation of spin-polarized electrons. The experimental aspects including the different spin polarimeters

that are currently available and the unique requirements of a polarimetry measurement are discussed. We then examine a whole range of recent experiments. We discuss recent studies of magnetic surface states observed on nonmagnetic materials, spin-polarized quantum-well states that develop in nonmagnetic thin films deposited on ferromagnetic substrates, the measurement of spin-dependent self-energy effects and finally studies of a range of magnetic oxides including both ferromagnetic and antiferromagnetic materials and ferromagnet/oxide interfaces. The properties of the quantum-well states observed in thin films are particularly relevant to the discussion of the giant magnetoresistance (GMR) property observed in magnetic multilayers and studies of the oxides are relevant to the development of new capabilities in spintronics.

2 THE PHOTOEMISSION PROCESS

In studies of condensed matter systems, photoemission represents the excitation of an electron from an initial state below the Fermi level to a final state above the vacuum level. As illustrated in Figure 1, the initial state may fall within the delocalized valence bands or it may represent a more localized core level. In the absence of spin–orbit coupling, it can be shown for linearly polarized incident light that the nonrelativistic Schrödinger equation, with the momentum operator $\boldsymbol{p}$ replaced by $\boldsymbol{p}-(\mathrm{e/c})\boldsymbol{A}$, represents an adequate description of the spin-conserving transitions. Here $\boldsymbol{A} = \boldsymbol{A}_0 e^{i\omega t}$ is the vector potential of the electromagnetic field. From Fermi's Golden rule, the differential cross section $\mathrm{d}\sigma/\mathrm{d}\Omega$ for excitation from some initial state $\left|\psi_\mathrm{i}\right\rangle$ to some final state $\left|\psi_\mathrm{f}\right\rangle$ is given by

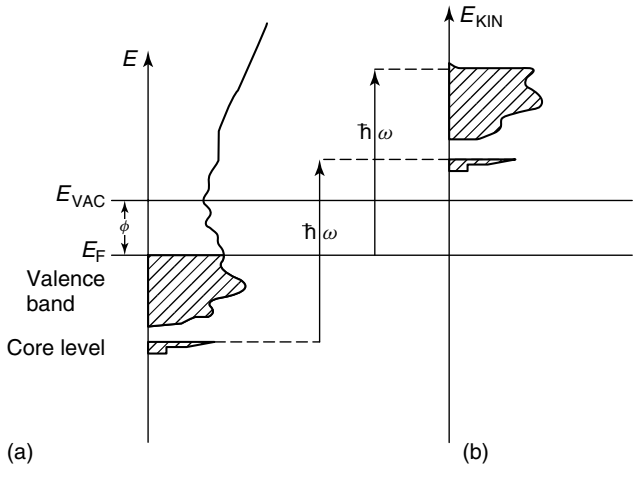

Figure 1. A schematic of the photoemission process. The incident photon with energy $\hbar\omega$ excites an electron from an initial state below the Fermi level E_F to some final state above the vacuum level E_vac. The left panel shows the electron originating either from the valence band or the more localized core level. The right panel displays the excited electron-energy distribution in the final state.

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\left(E_\mathrm{f}, \hbar\omega, k_\mathrm{f}, \boldsymbol{A}\right) \propto \sqrt{E_\mathrm{f}} \sum_\mathrm{i} \left|\left\langle\psi_\mathrm{f}\right| \left(\boldsymbol{A}\cdot\boldsymbol{p} + \boldsymbol{p}\cdot\boldsymbol{A}\right) \left|\psi_\mathrm{i}\right\rangle\right|^2 \times \delta\left(E_\mathrm{i} - E_\mathrm{f} - \hbar\omega\right) \quad (1)$$

where the δ function describes the energy conservation of the process. Measuring the kinetic energy of the electron in the final state E_f and knowing the incident photon energy, $\hbar\omega$, the experimentalist can trace back to the binding energy of the electron in the initial state E_i.

Neglecting the diamagnetic term $|\mathrm{A}|^2$ which is always small and noting that $\nabla.\mathbf{A}$ is nonzero only in the surface region, equation (1) is usually reduced to the simpler form

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} \propto \sqrt{E_\mathrm{f}} \sum_\mathrm{i} \left|\left\langle\psi_\mathrm{f}\right| \left(\boldsymbol{A}\cdot\boldsymbol{p}\right) \left|\psi_\mathrm{i}\right\rangle\right|^2 \delta\left(E_\mathrm{i} - E_\mathrm{f} - \hbar\omega\right) \quad (2)$$

The matrix element introduces selection rules, which can be exploited to determine the symmetry of the initial state. In the nonrelativistic limit, excitation by linearly polarized light between one electron states of the form $|n, l, m_1\rangle$ is restricted to transitions such that $\Delta l = \pm 1$ and $\Delta m_l = 0$. In the event that the incident light is circularly polarized, the second selection rule becomes $\Delta m_l = \pm 1$ dependent on the handedness of the polarization. In the fully relativistic treatment with spin-orbit coupling included, the selection rules become $\Delta j = 0, \pm 1$ and $\Delta m_j = \pm 1$ with j and m_j now referring to the total angular momentum.

A more complete description of the photoemission process will allow for the many-body response of the system to the excitation. Here the δ function of equation (2) is replaced by the single particle spectral function of the hole state $A(\boldsymbol{k}, \omega)$ such that

$$A(\mathbf{k}, \omega) = \frac{1}{\pi} \frac{\Sigma_2(\mathbf{k}, \omega)}{\left[\omega - \varepsilon_\mathrm{k} - \Sigma_1(\mathbf{k}, \omega)\right]^2 + \left[\Sigma_2(\mathbf{k}, \omega)\right]^2} \quad (3)$$

where the real component of the self energy, $\Sigma_1\,(\mathbf{k}, \omega)$, gives a shift in energy and associated mass enhancement and the imaginary component of the self energy, $\Sigma_2\,(\mathbf{k}, \omega)$, gives the lifetime broadening. Note that ω in equation (3) represents the initial-state energy E_i and ε_k represents the bare-band dispersion in the absence of any many-body interactions. In ferromagnetic systems, because of the spin polarization of the electronic structure, we may anticipate a spin dependence in the response of the system.

Extending the technique and measuring the photoemitted current at some emission angle θ, it becomes possible to map the dispersion of the different initial-state bands. As illustrated

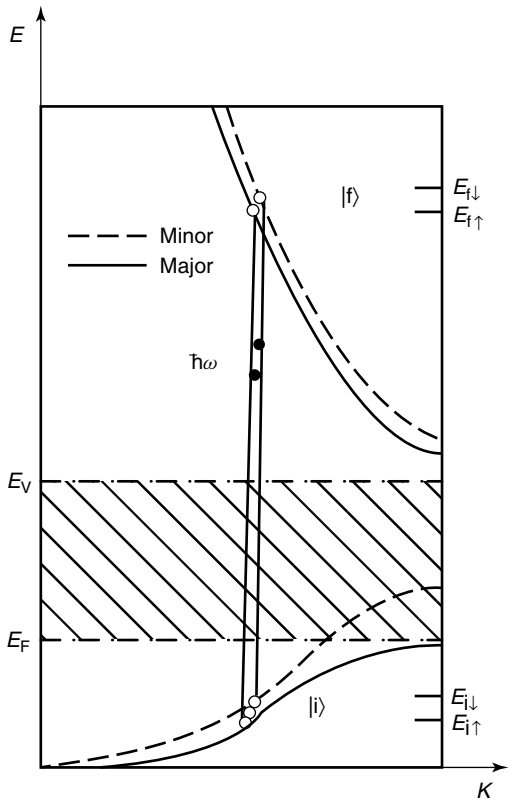

Figure 2. A schematic of the direct k-conserving transition in the photoemission process. The incident photon excites an electron from an initial state E_i below the Fermi level E_F to some final state E_f above the vacuum level E_V. Spin conservation is maintained in the transition.

in Figure 2, at a well-defined $k_{||}$, the process represents a direct transition between two bands of the same spin. In the solid-state environment, momentum conservation is maintained through the mediation of the crystal momentum giving

$$k_f = k_i + G \tag{4}$$

where k_i and k_f are the wave vectors associated with the initial and final states and G represents a suitable lattice vector. If E_{kin} represents the kinetic energy in the final state then to within a reciprocal lattice vector the parallel momentum $k_{||}$ of the photoelectron given by

$$k_{||} = \left(\frac{2m}{\hbar^2}\right)^{1/2} E_{kin}^{1/2} \sin\theta \tag{5}$$

and is conserved on crossing from the solid into the vacuum. Thus a measurement of this component in the vacuum supplies a good measure of the parallel component of the momentum in the solid. The perpendicular component is ill defined due to the breaking of translational symmetry perpendicular to the surface plane.

3 THE EXPERIMENTAL METHODOLOGY

As in any electron spectroscopy, spin-polarized photoemission requires the use of an electron spectrometer. These instruments can take many different forms although, as illustrated in Figure 3, the hemispherical analyzer represents the most commonly used instrument in SPPES at the present time. A more complete discussion of the properties of such an analyzer can be found elsewhere (e.g., Roy and Carette, 1977). Here, we note that in such an instrument the kinetic energy of the electron is measured by retarding electrostatic fields applied between the two hemispheres and the momentum is selected by defining a small angle of collection. As also illustrated in Figure 3, some form of electrostatic lens is required to couple this analyzer to whichever spin polarimeter is selected for the experiment.

An overview of the practicalities of coupling spin polarimeters to electron spectrometers has been given by Pierce, Celotta, Kelley and Unguris (1988). In particular, these authors emphasize the requirement for optimizing the experiment by matching the phase space or acceptances of the source, the electron spectrometer and finally of the spin polarimeter itself. At any point on the pathway of the electron beam the Helmholz–Lagrange law states that there will be a conservation of the product $EA\Omega$, where E is the energy, Ω the solid angle and A the cross-sectional area. In the optimum configuration this product will be matched to the acceptance phase space of the polarimeter. Pierce, Celotta, Kelley and Unguris (1988) have tabulated the latter for a number of different spin polarimeters.

3.1 Measuring the spin polarization

The two principal means of measuring spin polarization involve either the use of spin-dependent scattering via the spin-orbit interaction with a heavy atom or the use of an exchange interaction with a ferromagnetic material. We briefly examine these two different approaches. Much of the pioneering work in spin-polarized photoemission was carried out with spin polarimeters of the high-energy Mott-scattering type (Kisker, Clauberg and Gudat, 1982). Here the electrons to be analyzed are scattered off gold atoms at energies typically of the order of 100 keV. Spin-orbit coupling of the electron in the potential of the gold atom leads to an asymmetry in the scattering, left and right, dependent on the spin of the electron. Because of the high energies involved in the earlier designs, Mott polarimeters tended to be large. However, there have recently been a number of successful modifications that have allowed the polarimeter to be scaled down in size. Figure 4 shows the configuration used in one such device

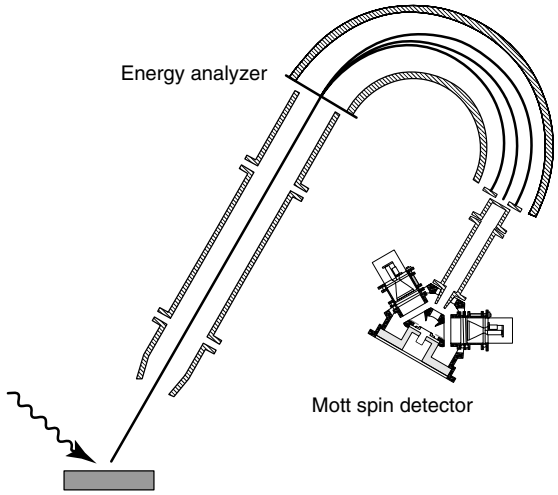

Figure 3. Overview of a spin-resolved spectrometer system. A Mott spin polarimeter is coupled to a hemispherical electron-energy analyzer via an input lens. An electron multiplier array assembly located in the exit plane of the energy analyzer is used for non-spin-resolved multichannel detection.

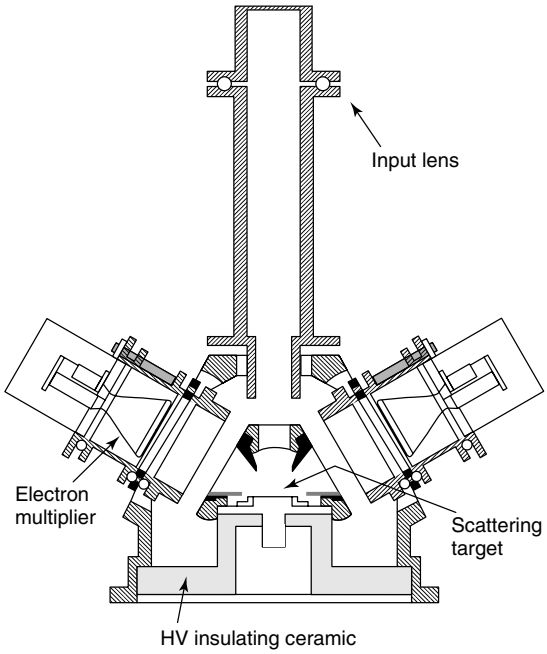

Figure 4. Cross-sectional view of the Mott spin polarimeter with enlarged conic-type collection angle. Only one pair of electron multipliers is shown; the other pair is located in the perpendicular plane.

as described by Huang *et al*. (2002a). After initially passing through a deceleration lens, the incident beam of electrons is accelerated onto the gold foil at an energy of 20 keV. As in the earlier designs (Kisker, Clauberg and Gudat, 1982), those electrons elastically scattered through 120° are detected by two symmetrically opposite channeltrons. Retarding fields in front of the latter collectors remove any electrons that have undergone inelastic losses. The spin polarization P of the incident electron beam is given by

$$P = \frac{1}{S}\frac{I_A - I_B}{I_A + I_B} \tag{6}$$

where S, the Sherman function of the device, is a measure of its ability to distinguish different spins and I_A and I_B represent the intensities measured in opposite channels. Mott polarimeters of this type are now sufficiently small that they can in principle be readily moved inside a vacuum system and, therefore, be used for angle-resolved polarization measurements. The figure of merit (FOM) used in comparing different polarimeters is defined as

$$FOM = S^2\frac{I}{I_0} \tag{7}$$

where again S is the Sherman function, I is the sum of the current collected by the two opposite detectors and I_0 is the incident beam current (Kessler, 1985). The FOM for the traditional Mott polarimeter is typically 10^{-4}; that of the compact low-energy Mott device was initially of the order of 2×10^{-5} (Tang, Zhang, Dunning and Walters, 1988). However, through the use of large area electron detectors and careful optimization of the electron optics, the FOM of the compact devices has gradually been improved. Burnett, Monroe and Dunning (1994) reported an FOM of approximately 1.6×10^{-4}. More recently (Huang *et al*., 2002a) have refined the electron optics further to achieve an FOM of $\sim 2 \times 10^{-4}$. The advantage of the Mott polarimeters, both large and small, is that they are relatively easy to operate in a reproducible fashion.

Originally designed for use in secondary electron microscopy with polarization analysis (SEMPA) studies (Unguris, Pierce and Celotta, 1986; Scheinfein *et al*., 1989), low-energy diffuse scattering from polycrystalline gold films has also proved an excellent device for energy- and angle-resolved spin-polarized photoemission studies (Johnson *et al*., 1992). Rather than the high energies, characteristic of the Mott devices, the electrons to be spin analyzed are now scattered from a polycrystalline gold surface at the much lower energy of 150 eV, an energy at which the Sherman function of gold exhibits a local maximum. The back-scattered electrons pass through retarding grids to remove low-energy secondary electrons, and are then collected by four discrete anodes allowing a measurement of two components of the polarization to be made in parallel. This type of detector has an FOM of the order of 1.0×10^{-4} (Unguris, Pierce and Celotta, 1986), that is, comparable to the traditional Mott detector.

If the scattering surface is a single crystal rather than polycrystalline it is possible to use spin-dependent diffraction to measure the polarization. The spin asymmetry in the scattering again reflects the spin-orbit interaction. Detectors of this type include a low-energy detector, which relies on spin-orbit effects in the diffraction of the electrons from a single-crystal tungsten (001) surface (Kirschner and Feder, 1979). The intensities of the symmetrically opposite (2;0) and ($\bar{2}$;0) diffracted beams are measured with the electrons incident at an energy of 100 eV. The authors report an FOM for this detector of 1.6×10^{-4}.

Spin polarimeters based on an exchange interaction fall into two categories, those employing reflection and those employing transmission. In practice, only the reflection technique has been used in working spin polarimeters to date. A detector based on low-energy reflection from a ferromagnetic film has been described by Tillman, Thiel and Kisker (1989). Here the scattering surface is a 400-Å-thick Fe(001) film grown on an Ag(001) substrate. Reflected intensities are measured when the electrons to be analyzed are incident on a magnetized iron surface at an energy of approximately 10.0 eV. The asymmetry in the scattering, A, in such a detector is given by

$$A = \frac{1}{P}\frac{I^{\uparrow\uparrow} - I^{\uparrow\downarrow}}{I^{\uparrow\uparrow} + I^{\uparrow\downarrow}} \tag{8}$$

where P is the spin polarization in the incident beam and $I^{\uparrow\uparrow}$ and $I^{\uparrow\downarrow}$ are the scattered intensities obtained when the target and primary beam magnetic moments are parallel and antiparallel, respectively. The FOM of such a device is then given by

$$FOM = A^2 \frac{I_R}{I_P} \tag{9}$$

where I_R and I_P are the reflected and primary beam currents, respectively. One difficulty with an instrument of this type is that with the reflecting or analyzing surface being effectively another 'sample', two samples have to be successfully prepared and magnetized. However, at 10.6 eV analyzing energy, the authors report a value of 0.21 for A and an FOM of 3.5×10^{-3}.

More recently the spin-dependent reflectivity of electrons from Fe single-crystal films, 2–8 monolayers (ML) thick, grown on a W(110) substrate has been studied by Zdyb and Bauer (2002). These authors analyzed their data in terms of the quantum-well structure associated with the thin films, that we discuss in detail later. The authors went on to point out the importance of considerations of the quantum-well structure in the design of future spin polarimeters. In a later study, Graf *et al*. (2005) extended these ideas to studies of both Fe and Co thin films grown on W(110). Again by measuring the spin-dependent reflectivities as a function of film thickness the authors determined that a five ML thick film of Co/W(110) represented the optimum configuration for a spin polarimeter. They further indicated that the FOM of such a device would be of the order of 0.02, some two orders of magnitude higher than that achieved in the miniature Mott detectors.

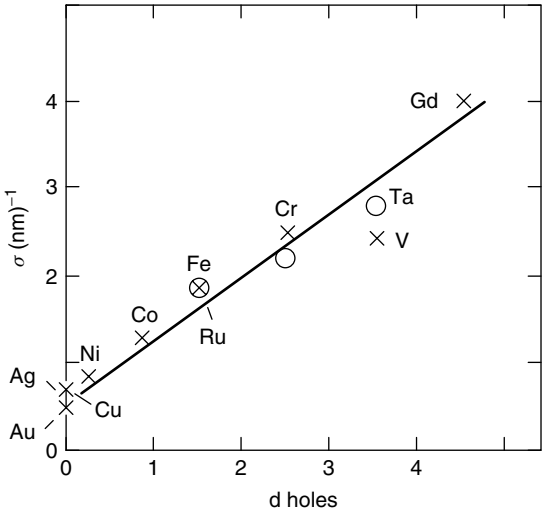

Figure 5. Total scattering cross section $\sigma = 1/\lambda$ in nm^{-1} against the number of unoccupied d orbitals for the transition metals indicated. The data are obtained by analyzing the electron spin polarization in overlayer films and are valid for electron energies within 5 eV of the vacuum level.

Turning to transmission, Schönhense and Siegmann (1993) have suggested the possibility of using the spin-dependent transmission through ferromagnetic thin films as a means of detecting spin polarization. It is evident that such a spin dependence in transmission exists in that the low-energy secondary electron cascade in all electron spectroscopies is known to display an enhanced spin polarization. The latter polarization, which is typically larger than would be expected simply on the basis of the bulk valence band polarization, reflects the spin-dependent mean-free paths of the transmitted electrons. Schönhense and Siegmann examined a number of experiments in detail. As shown in Figure 5 they find that the total scattering cross section $\sigma(E) = 1/\lambda$ is well described by the expression

$$\sigma = \sigma_0 + \sigma_d(5 - n) \tag{10}$$

where σ_d accounts for scattering into the d holes and σ_0 is a constant accounting for other inelastic scattering events. They define a transport polarization α such that an electron beam with small initial polarization P_0 will acquire a polarization after traveling a distance x such that

$$P(x) = P_0 + \alpha(x) \tag{11}$$

The transport polarization α is given by

$$\alpha = \frac{\left[\exp\left(\sigma^- - \sigma^+\right)\, x - 1\right]}{\left[\exp\left(\sigma^- - \sigma^+\right)\, x + 1\right]} \tag{12}$$

with $\sigma^{(\pm)}$ representing the spin-dependent cross sections. In their picture, the spin polarization is, therefore, dominated by the inelastic scattering involving unoccupied states above the Fermi level.

Schönhense and Siegmann note that a spin polarimeter based on the use of spin-dependent transmission will have an FOM given by $\alpha^2 I$ where $I = e^{-\sigma x}$ represents the total spin-integrated transmission through the film and σ is the spin-averaged total cross section. On the basis of their experimental observations, they show that the FOM for an iron film will peak at approximately 7×10^{-2} for film thicknesses of approximately 1.0 nm. For Co they predict an FOM of 6×10^{-2} for a film thickness of approximately 1.5 nm. These ideas have been given some support in studies of the spin-dependent transmission through a free-standing Co film (Lassailly *et al*., 1994; Van der Sluijs *et al*., 1994). The authors of the latter study found that at low energies, close to the surface vacuum level, the transmission coefficient for the minority-spin electrons was 0.7 of that found for the majority-spin electrons. The total transmitted current was of the order of 10^{-5} of the primary beam. By cesiating both sides of the film, this transmission ratio was increased to 3×10^{-4} and a Sherman function of $S = 0.4$ was measured (Van der Sluijs *et al*., 1994).

3.2 Using the spin polarimeter

Before closing our discussion of the experimental details, we offer a brief introduction to the practicalities of a spin-polarization measurement. A more detailed discussion can be found elsewhere (Kessler, 1985).

In order to measure a spin polarization, it is necessary to define a quantization direction for the spin of the electrons. In studies of ferromagnetic or ferrimagnetic systems, this is achieved by ensuring the sample is magnetically saturated. As an example, ferromagnetic thin films can be magnetized by discharging a current pulse through a small coil in close proximity to the film. As we discuss later, it is also possible to perform spin-polarization measurements on antiferromagnetic or even nonmagnetic systems when spin-orbit effects are present. In this case, the quantization direction is defined by the polarization vector of the incident light with the latter being circularly polarized.

To avoid any error being introduced into the measurement by apparatus asymmetries, it is necessary, in the case of ferromagnetic systems, to make two measurements of the spin polarization, one with the sample magnetized 'up' $\left(I_{\mathrm{L}}^+, I_{\mathrm{R}}^+\right)$ and one with the sample magnetized 'down' $\left(I_{\mathrm{L}}^-, I_{\mathrm{R}}^-\right)$. Here I_{L} and I_{R} represent the number of electrons scattered from the target into the left and right channels, respectively. Assuming that the incident beam does not move between the '+' and '−' measurements, any instrumental asymmetry derived from a misalignment of the beam incident on the scattering target can then be removed by combining the four measurements such that the true spin polarization P is given by

$$P = \frac{1}{S}\frac{\sqrt{I_{\mathrm{L}}^+ I_{\mathrm{R}}^-} - \sqrt{I_{\mathrm{L}}^- I_{\mathrm{R}}^+}}{\sqrt{I_{\mathrm{L}}^+ I_{\mathrm{R}}^-} + \sqrt{I_{\mathrm{L}}^- I_{\mathrm{R}}^+}} \tag{13}$$

where as before S represents the Sherman function of the instrument. The measured intensities combined in this manner remove, to first order, any instrumental asymmetry. The two measurements, '+' and '−', may have different count rates without affecting the measured polarization. Assuming that there is not an asymmetry that changes with the two magnetization directions, the instrumental asymmetry A is given by

$$A = \frac{\sqrt{I_{\mathrm{L}}^+ I_{\mathrm{L}}^-}}{\sqrt{I_{\mathrm{R}}^+ I_{\mathrm{R}}^-}} \tag{14}$$

The individual spin-up and spin-down spectra are obtained from the polarization P by

$$I^{\uparrow} = \langle I \rangle\,(1 + P) \quad I^{\downarrow} = \langle I \rangle\,(1 - P) \tag{15}$$

where

$$\langle I \rangle = \frac{I_{\mathrm{L}}^+ + I_{\mathrm{L}}^- + I_{\mathrm{R}}^+ + I_{\mathrm{R}}^-}{4} \tag{16}$$

In studies employing incident circularly polarized light equations (13) and (16) still apply but $(+, -)$ represent the direction of polarization of the incident light.

4 SOME RECENT APPLICATIONS OF SPPES

In the following, we highlight some recent applications of spin-polarized photoemission to problems in condensed matter physics. In particular, we highlight some of the latest developments in the study of spin-polarized surface states and quantum-well states, we examine the application of high-resolution SPPES to the study of spin-dependent

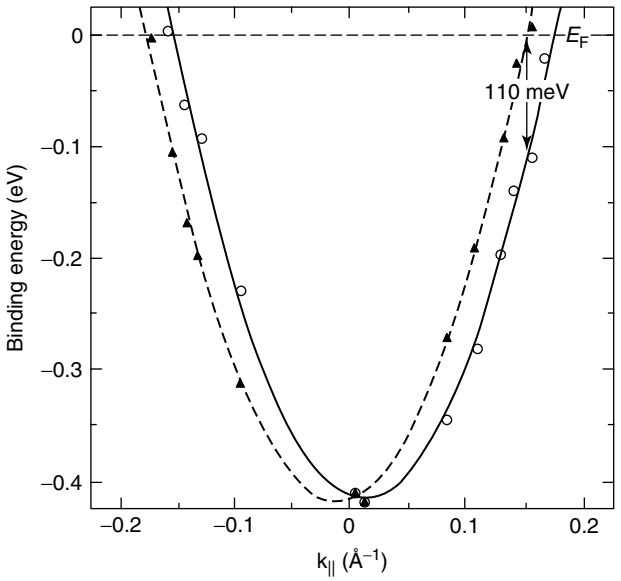

Figure 6. Experimentally determined E vs k dispersion for the surface state at the center of the zone on a Au(111) surface. The measured data points are indicated by the open circles and filled triangles; the solid and dashed lines are parabolic fits. The fit results are (eV and Å^{-1}): $E_1(\mathrm{k}) = 15.2(k - 0.0117)^2 - 0.416$, and $E_2(k) = 15.3(k + 0.0117)^2 - 0.418$. (Reproduced from La Shell *et al*., 1996, with permission from the American Physical Society. © 1996.)

self-energizing effects and finally we review some recent studies of magnetic oxide systems and ferromagnetic/oxide interfaces. The latter oxide systems present a range of exotic phenomena and are currently the subject of intense research activity with respect to spin functionality in spintronics. Primarily, we will restrict our discussion to studies of materials that display magnetic properties. However, we will also review the application of SPPES to the study of the properties of the cuprates, the basis of the high T_c superconductors.

4.1 Spin-polarized surface states

Discussed in detail elsewhere (Johnson, 1997), there have previously been a number of studies of spin-polarized surface states. In general, the spin polarization of the states investigated in those studies reflected the reduced dimensionality present at the surface or solid/vacuum interface of ferromagnetic materials. Examples include states localized on the Fe(001) (Brookes, Clarke, Johnson and Weinert, 1990) and Fe(110) surfaces (Vescovo *et al*., 1993).

It has recently been shown that electronic states at the surface of certain nonmagnetic materials can also display a measurable spin polarization. In this case, the spin polarization reflects a spin-orbit interaction. Shown in Figure 6, a state showing this property was first identified on the surface of Au(111). (LaShell, McDougall and Jensen, 1996). In a high-resolution photoemission study, these authors found that an s–p derived Shockley state displaying parabolic dispersion actually split into two bands as the state moved away from the center of the zone. The authors concluded that the splitting reflected the spin-orbit term in the Hamiltonian given by

$$H_{\mathrm{SO}} = \frac{\hbar}{4m^2c^2}\boldsymbol{\sigma} \cdot (\boldsymbol{\nabla} V x \boldsymbol{p}) \tag{17}$$

where $\boldsymbol{\sigma}$ is the Pauli spin operator and, ∇V is the local potential gradient and $\boldsymbol{p}$ is the electron momentum. The lack of inversion symmetry at the surface allows this spin-orbit interaction to lift the degeneracy between the two spin states. Similar results and hence confirmation were found in a later study of Au(111) but not Ag(111) (Nicolay, Reinert, Hufner and Blaha, 2001).

Examination of equation (17) shows that the energy of an electron depends on its spin direction and its momentum. With a given momentum the effect reverses for different spin directions and for a given spin the effect reverses either side of the zone center. Such effects were confirmed in spin-resolved studies of a surface state on the W(110) surface (Hochstrasser, Tobin, Rotenberg and Kevan, 2002) and for the Au(111) surface state (Hoesch *et al*., 2004). The results of the latter study are shown in Figure 7 where the sign convention (spin up vs spin down) is defined in a spin coordinate axis that is the counterclockwise tangent to the Fermi surface contour. The effect has also been reported in a study of the magnetic Gadolinium (0001) surface state that we discuss in detail later (Krupin *et al*., 2005). In their study, Krupin *et al*. reported the observation of the 'Rashba effect' and reported that it was enhanced upon oxidation of the surface.

As Hoesch *et al*. note, such an effect will be unobservable in the bulk of a material such as gold due to the combined restrictions of the time reversal-symmetry $E^{\uparrow}(\mathbf{k}) = E^{\downarrow}(-\mathbf{k})$ and the inversion symmetry $E^{\uparrow}(\mathbf{k}) = E^{\uparrow}(-\mathbf{k})$ leading to the Kramers degeneracy $E^{\uparrow}(\mathbf{k}) = E^{\downarrow}(\mathbf{k})$.

4.2 Thin films and magnetic multilayers

Magnetic multilayers and related thin films have been an important area of study in magnetism. This interest reflects the many potential technological applications of the GMR property observed in the multilayers. Indeed, this effect first discovered in 1987 by Fert and Grünberg, has already seen widespread use in a number of commercial applications.

GMR is observed in metallic multilayers consisting of ferromagnetic layers separated by nonmagnetic spacer layers.

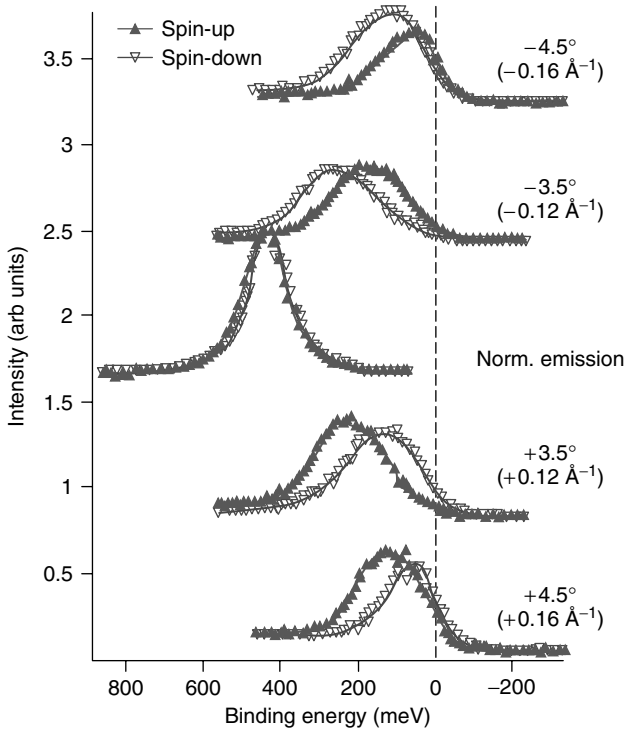

Figure 7. Spin-resolved photoemission spectra from the Au(111) surface state at various polar emission angles. The photon energy was $\hbar\omega = 21.1$ eV. The spin assignment was determined from the transverse in-plane component of the polarization vector. Spin-up and spin-down intensities are marked with filled and open triangles, respectively. (Reproduced from Hoesche *et al*., 2004, with permission from the American Physical Society. © 2004.)

Depending on the thickness of the spacer layer, the adjacent ferromagnetic layers are aligned either ferromagnetically or antiferromagnetically. In the latter configuration, a magnetic field may be applied to realign the magnetic layers and thereby modify the spin-dependent transport or resistance through the system. It is this ability to substantially modify the spin-dependent resistance in these 'GMR' materials that makes them so important.

In order to understand this phenomenon we must first understand the factors that determine the different alignments of the adjacent magnetic layers. In fact, the spacer layer thickness that results in the antiferromagnetic alignment can correspond to several atomic layers. Insight into this property comes from the recognition that the system can be treated as a series of one-dimensional quantum wells. Within these wells the electronic structure will be quantized with an energy separation that reflects the width or thickness of the spacer layer. Let us consider this quantization. In the vicinity of the interface with the adjacent magnetic layer the wave function of the electron state within the well takes the form

$$\Psi = e^{-ik_z} + r_c e^{i\phi} e^{ik_z} \tag{18}$$

where $r_c e^{i\phi_c}$ represents the complex reflectivity at the interface with the substrate and ϕ_c gives the phase change of the wave function. A stationary or bound state exists whenever the total phase change within the well is given by the Bohr–Sommerfeld quantization condition

$$2\phi_c + 2kma = 2\pi n \tag{19}$$

Here, we are considering a well bound by two adjacent magnetic layers and hence two identical interfaces. $2kma$ represents the phase change accumulated on the round trip across a well consisting of m atomic layers with interlayer spacing a. Thus we see that as the number of layers changes, the quantization condition changes and the energy of the stationary state changes to accommodate additional nodes within the wave function. Modifying equation (19) accordingly we obtain

$$\phi_c + (k + \Delta k)\,(m + 1)\,a = \pi\,(n + 1) \tag{20}$$

As we will see later, the spin-dependent scattering at the interface results in quantum-well states showing a strong spin polarization. As the thickness of the nonmagnetic layer changes, the quantum-well states move to lower energy and cross the Fermi level with a well-defined periodicity. The total energy of the system is at a maximum when an occupied quantum-well state is sitting right at the Fermi level. Because the states are spin polarized the system can achieve a lower total energy by having adjacent ferromagnetic layers realign to an antiferromagnetic configuration. By doing so the quantum-well state is allowed to 'leak' away through one interface and the total energy is reduced.

The above represents a quantum well description of the interlayer exchange coupling. In a more detailed analysis of this picture, Smith, Brookes, Chang and Johnson (1994) concluded that the appropriate quantum numbers for classifying the quantum-well states were not n, the number of nodes, or m, the number of layers, but rather $\upsilon = (m - n)$ as illustrated in Figure 8 for silver films deposited on an Fe(001) substrate. In this classification scheme, the thickness against energy relationship may be written

$$\frac{D_\upsilon(E)}{a} = \frac{\frac{\phi_c(E)}{\pi} + \upsilon}{\frac{1-k(E)}{k_{BZ}}} \tag{21}$$

where $k_{BZ} = \pi/a$ represents the zone boundary wave vector and $D = ma$. A quantum-well state crosses the Fermi level each time υ increments by one. It is clear from equation (21) that the Fermi surface will therefore be sampled every Δm layers such that

$$\Delta m = \left(\frac{1 - k_F}{k_{BZ}}\right)^{-1} \tag{22}$$

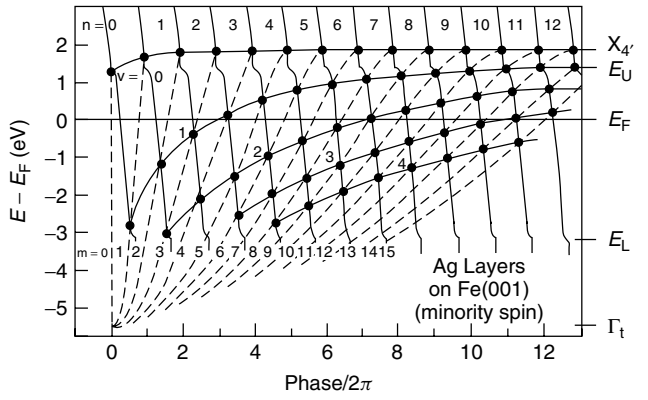

Figure 8. Graphical solutions (full circles) for the energies of quantum-well states of Ag overlayers on Fe(001) using the phase accumulation model. Full bold waves represent the phase $2\pi n - \phi_c - \phi_b$ and dashed curves represent the quantum-well phase accumulation $m2ka$. States characterized by the quantum number $v = (m - n)$ are connected by the full thin curves. (Reproduced from Smith *et al.*, 1994, with permission from the American Physical Society. © 1994.)

where k_F represents the Fermi wave vector. Recognizing that $2(k_{BZ} - k_F)$ gives the associated bulk Fermi surface spanning vectors, q, one immediately retrieves from equation (22) a period length Δma given by 2π/q identical to that obtained by Bruno and Chappert (1991) in an analytical description of the thickness dependence of the oscillatory interlayer exchange coupling in magnetic multilayers.

With a relatively short mean-free path for the escaping electrons photoemission does not lend itself to direct studies of the electronic structure of a multilayer. As such the spin-polarized photoemission studies relevant to these materials are studies that have focused on the properties of the associated overlayers or thin films. Here we refer to, for instance, silver films on Fe(001) substrates and copper films on Co(001) substrates.

The first study that identified the role of spin-dependent interfacial scattering was a study of the quantum-well states that form in silver films deposited on an Fe(001) substrate (Brookes, Chang and Johnson, 1991). In the study, the authors identified an interface state or quantum-well state characterizing a ML thick silver film. With increasing thickness this state evolves into a series of states that move up to and through the Fermi level as shown in Figure 9. The movement to lower binding energy simply reflects the fact that with each new layer the wave function describing the quantum-well state has to gain an extra half wavelength to accommodate the new atomic potential (Smith, Brookes, Chang and Johnson, 1994). We can use the same quantization condition given above for the multilayers but now the ϕ_c of one interface is replaced by the ϕ_b describing the phase shift of the wave function at the solid/vacuum interface. Thus the

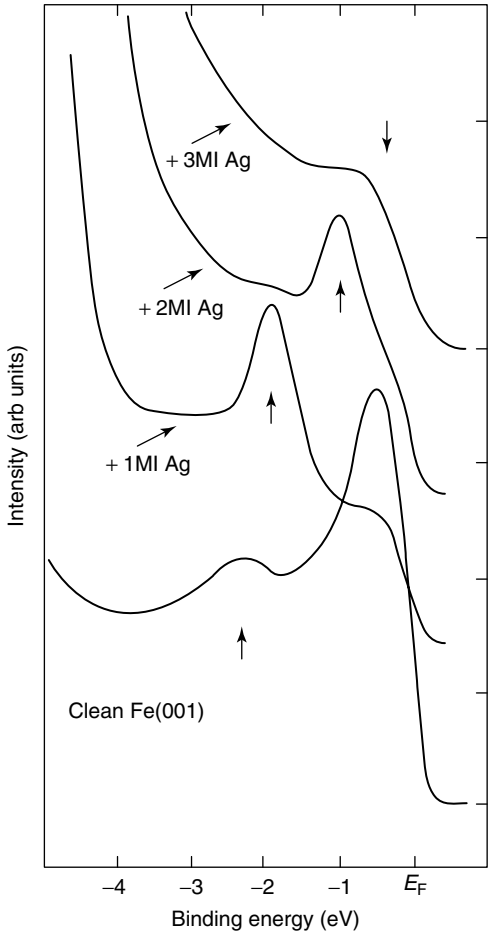

Figure 9. Spin-integrated photoemission spectra recorded from silver films deposited on an Fe(001) substrate. The different film thicknesses are indicated.

quantization condition of equation (19) now becomes

$$\phi_c + 2kma + \phi_b = 2\pi n \tag{23}$$

The spin-polarized photoemission study of Brookes, Chang, and Johnson (1991) revealed that the Ag quantum-well states are highly spin polarized, preferentially with minority spin. As discussed earlier, the observation of a strong spin polarization can be explained in terms of the spin-dependent reflectivities at the interface with the ferromagnetic substrate. If one considers the spin-dependent band structure of iron in the ΓH direction, Figure 10, one observes that in the minority-spin band structure a s–d hybridization gap exists in the vicinity of the Fermi level. At binding energies corresponding to this gap, the propagating waves will be reflected back into the silver layer. Thus, it is the gap that defines the degree of confinement of the minority-spin quantum-well state. In the majority-spin band structure, on the other hand, the hybridization gap is displaced to higher

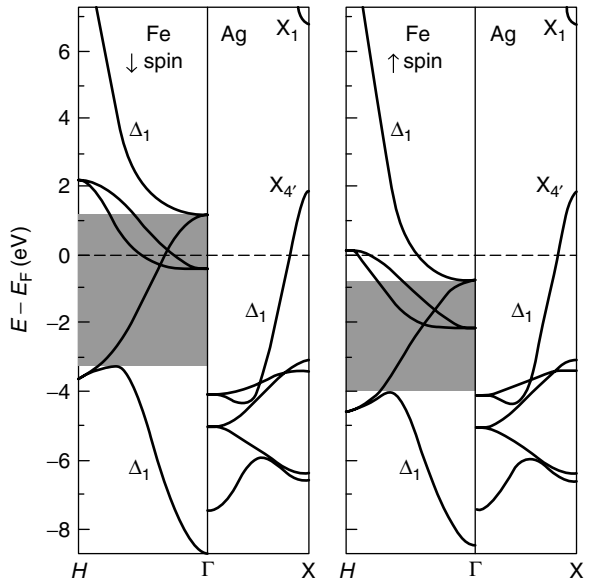

Figure 10. Energy bands of Fe and Ag along the Δ direction for both minority and majority spins. The toned areas indicate the range of the s–d hybridization gap in Fe for states of Δ_1 symmetry.

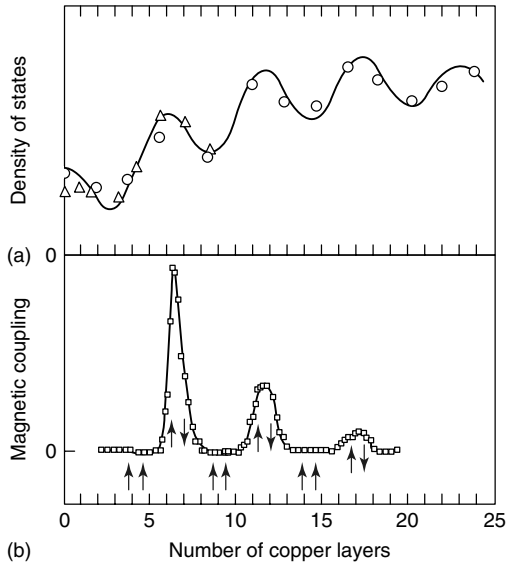

Figure 11. (a) Oscillations in the inverse photoemission intensity at E_F for copper films deposited on a fcc Co(001) substrate from the study of Ortega, Himpsel, Mankey and Willis (1993). (Reproduced from Ortega *et al.* (1993), with permission from the American Physical Society. © 1993.) (b) Results of a Kerr effect study showing the oscillatory antiferomagnetic coupling in Cu/Co(001) multilayers as a function of the copper thickness from the study of Qiu, Pearson and Bader (1992). binding energies and the majority-spin states in the silver layer in the vicinity of the Fermi level will be less strongly confined. The quantum-well states that survive in the silver layer will, therefore, preferentially carry minority spin as observed experimentally.

Subsequent inverse photoemission studies of the Ag/Fe(001) system tracked the quantum-well states as they continued to evolve above the Fermi level eventually converging on the bulk X_4' critical point (Ortega and Himpsel, 1992; Ortega, Himpsel, Mankey and Willis, 1993). These studies clearly demonstrated in this and a number of other systems that the Fermi surface was sampled by the quantum-well states with a frequency identical to that observed for the oscillatory exchange coupling in the associated multilayers. This is illustrated in Figure 11 where the intensity observed at the Fermi level in inverse photoemission studies of copper films deposited on a Co(001) substrate is compared with the oscillatory coupling observed in the associated Cu/Co(001) multilayers.

An interesting question arises as to whether or not majority-spin quantum-well states exist in the spin-polarized photoemission spectra recorded from these films. Examination of Figure 10 shows that in the Fe majority-spin band structure, the top of the s–d hybridization gap falls only 0.8 eV below the Fermi level and the top of the Ag d bands falls 3.0 eV below. Thus one might anticipate seeing strong majority-spin states in the region above the silver d bands up to 0.8 eV below the Fermi level. In fact, such states are predicted in calculations using both the phase model approach of equation (23) and the tight-binding method (Smith, Brookes, Chang and Johnson, 1994) and *ab initio* calculations of the layered KKR type (Crampin, De Rossi and Ciccaci, 1996).

The spin-polarized photoemission study of Ag on Fe(001) (Brookes, Chang and Johnson, 1991) represented a study of the spin-polarization effects in very thin films. Indeed, at the ML limit it is probably more reasonable to describe the induced state as an interface state. Two studies have examined the spin-polarization characteristics of quantum-well states in thicker films. In both cases, the studies were of copper films deposited on a fcc Co(001) substrate (Garrison, Chang and Johnson, 1993; Carbone *et al.*, 1993). As in the earlier Ag/Fe (001) study, the quantum-well states shown in Figure 12 were found to be highly spin polarized with minority spin. However, now the Cu films were grown to thicknesses of the order of six atomic layers or more. In fact in a more recent study Carbone *et al.*, (1996) reported the observation of quantum-well states in copper films of the order of 50 atomic layers thick. At such thicknesses the escape depth of the photoelectrons ensures that the spin-polarization information in the spectrum clearly reflects emission from the Cu film itself rather than the cobalt substrate. In their study, Carbone *et al.* also claimed the observation of majority-spin quantum-well states with considerably less intensity than the minority-spin

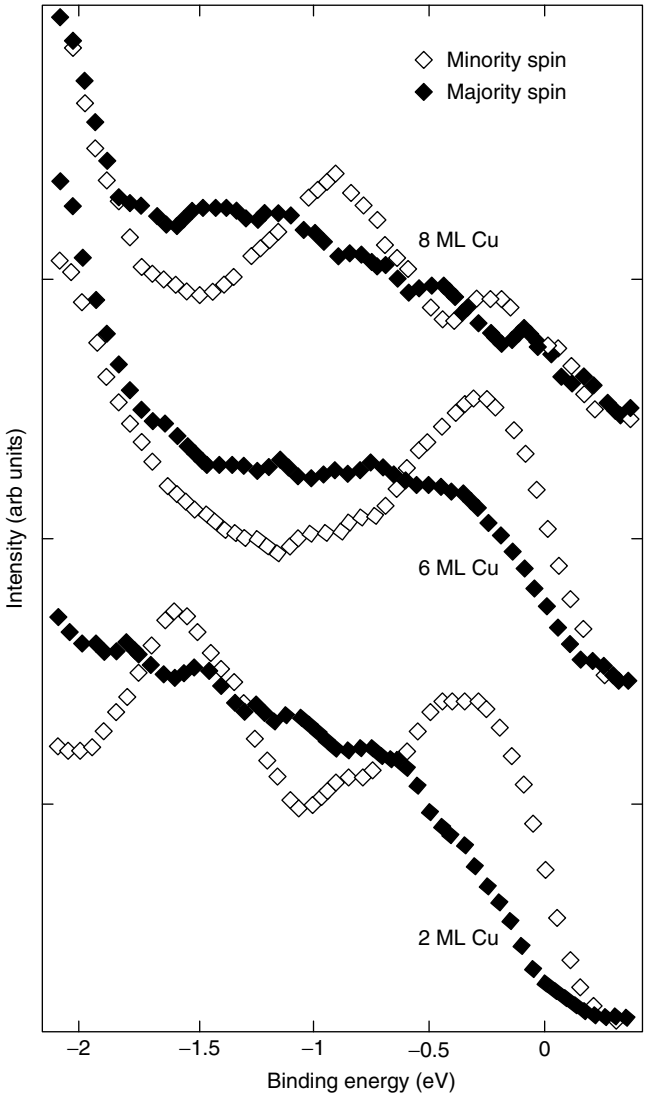

Figure 12. Spin-resolved photoemission spectra recorded from two, six, and eight monolayer thick copper films deposited on a fcc Co(001) substrate. The minority- and majority-spin spectra are represented by the open and full diamonds, respectively. The spectra are recorded for photoelectrons emitted along the surface normal.

counterparts. They determined an exchange splitting of 0.15 eV between the two spin components.

In order to obtain a better understanding of the photoemission spectra in their study Garrison, Chang and Johnson (1993) calculated the electronic structure of the different thickness copper films using a spin-dependent tight-binding scheme in a slab formulation. These tight-binding calculations were carried out using an effective Hamiltonian of the form

$$H = \sum_{\mathbf{k}} E(\mathbf{k})\, n_{\mathbf{k}} + \left(\frac{U}{N}\right) \sum_{\mathbf{k},\mathbf{k}'} n_{\mathbf{k}\uparrow} n_{\mathbf{k}'\downarrow} \qquad (24)$$

Where the first term reflects the nonmagnetic band structure and the second term represents the modification due to the on-site spin-dependent potential U. The latter was simply taken as the effective Stoner parameter. Using such an approach the authors sought a self-consistent solution such that for each layer $\Delta_{\mathrm{l}} = U_{\mathrm{l}} m_{\mathrm{l}}$ where Δ_{l} is the layer-dependent splitting introduced into the d orbitals, U_{l} the layer-dependent Stoner parameter and m_{l} the calculated moment for each layer. On the basis of their calculation Garrison *et al*. concluded that the quantum-well states have significant d as well as sp character. This interesting observation stems from the fact that, within the Cu film, as in bulk Cu, the s-, p bands will hybridize with the d bands of the same symmetry. This hybridization results in a small fraction of the d electrons being carried up to and through the Fermi level and indeed in bulk Cu, approximately 3% of the d-electron manifold is unoccupied. A similar observation has also been made in an *ab initio* layered KKR calculation of copper films deposited on Co(001) (Van Gelderen, Crampin and Inglesfield, 1996).

The observation that there is a small spin polarization in the Cu d band, and further that this band crosses the Fermi level, is a clear indication that a small magnetic moment of d character must exist on the Cu site, an observation that was confirmed in a magnetic circular dichroism (MCD) study of Cu/Co multilayers (Samant *et al*., 1994; Held *et al*., 1996). Here the authors, exploiting the dipole selection rules, studied absorption at the Cu L-edge to obtain site and spin specific information on the unoccupied d bands. The study found a small moment of d character on the copper sites and further concluded that the largest moments exist in the interface where the hybridization with the neighboring Co layers will be strongest. This observation of a localized interfacial magnetic interaction has also been confirmed in numerous other SPPES studies of the d bands in overlayer films deposited on ferromagnetic substrates. As examples, we cite the Pd(111)/Fe(110) interface (Weber, Wesner, Güntherodt and Linke, 1991; Weber, Wesner, Hartmann and Güntherodt, 1992), the Pt/Co(0001) interface (Weber *et al*., 1993), the Ag/Fe(001) interface (Brookes, Chang and Johnson, 1994) and Ru and Rh deposited on Co(0001) (Rampe *et al*., 1995). In general, these studies all identified a moment on the interfacial overlayer atoms but the induced polarization rapidly decayed away with deposition of subsequent overlayers.

More recently Qiu and coworkers have continued to investigate the properties of quantum-well systems and their relationship to the oscillatory exchange coupling (Zhang *et al*., 2000; Qiu and Smith, 2002; Wu *et al*., 2006). In particular, these authors have focused on the thickness dependence of the quantum-well electronic structure (Rotenberg *et al*., 2006) and on the properties of double quantum-well structures (Ling *et al*., 2002; Wu *et al*., 2006).

There is also the possibility of quantizing the electronic structure of d bands in a thin film. The role of this has been explored in a SPPES study of chromium films grown on an Fe(001) whisker with particular reference to the oscillatory exchange coupling in Fe/Cr multilayers (Li *et al*., 1997). In another PES study, Krajl *et al*. examined the quantization of the d bands in silver films grown on an V(001) substrate (Kralj *et al*., 2003). The authors were successfully able to explain the quantum-well structure both in terms of the phase models described in the preceding text and in terms of tight-binding calculations. It is interesting to speculate on the possible role of quantized d bands in the multilayer structures. Indeed it is known that scattering from a d resonance at energy E_d can induce a phase shift δ_l such that (Harrison, 1980)

$$\tan \delta_\mathrm{l} = \frac{\Gamma}{2(E_\mathrm{d} - E)} \tag{25}$$

Thus the scattering induces a phase shift at energy E that increases from 0 to π over the range Γ of the resonance. A phase shift of π will shift the quantum-well states from one thickness dependent branch to the next.

4.3 Collective excitations and self-energizing effects

In recent years, the energy and momentum resolution of angle-resolved photoemission have improved to a degree that allows detailed studies of self-energy effects. Thus it has become routinely possible to study the lifetime and dispersion modifications associated with a variety of collective modes including phonons, spin excitations, and charge density waves. In magnetic systems, with the added complexity of spin detection, the studies of magnetic systems have been considerably more limited. Here we review the only detailed study of spin-dependent self-energy effects, namely a recent study of gadolinium. The spin-dependent electronic structure of this material had previously been studied extensively with spin-resolved photoemission.

The ground state of gadolinium is ferromagnetic with a Curie temperature T_C of 293 K. The (0001) surface of this material has been shown both theoretically (Wu, Li, Freeman and Fu, 1991) and experimentally (Li *et al*., 1991) to support a surface state derived from the Gd 5d orbitals. The state, which is spin polarized through an exchange interaction with the localized 4f orbitals has an important history and indeed it was spin-resolved photoemission studies of the surface state that finally confirmed that the surface moments were ferromagnetically aligned with the bulk of the material (Mulhollan, Garrison and Erskine, 1992).

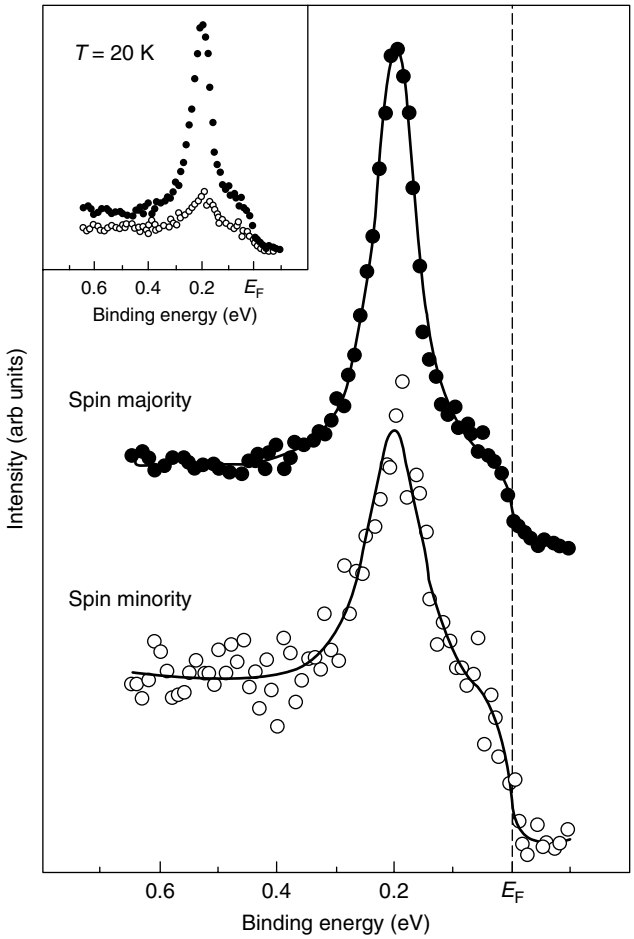

Figure 13. Spin-resolved photoemission spectra recorded from the Gd(0001) surface at 20 K. The upper and lower spectra represent the emission in the majority- and minority-spin channels, respectively. The lines indicate Lorentzian fits to the spectra superimposed on appropriate backgrounds. The inset shows the relative inteansities in the two spin channels.

The results of a more recent photoemission study of this same state held at 20 K with both high energy and spin resolution are illustrated in Figure 13 (Fedorov *et al*., 2002). As noted earlier, both experiment (Mulhollan, Garrison and Erskine, 1992; Li *et al*., 1993) and theoretical calculations (Wu, Li, Freeman and Fu, 1991) indicate that the surface state should be 100% majority spin, reflecting parallel alignment of the surface and bulk moments. The coexistence of both spin components at the same energy in Figure 13 is therefore an intrinsic property of the surface state arising from a combination of spin-orbit and spin-exchange processes. A simple model yields a polarization $P = \Delta/\sqrt{\Delta^2 + \zeta^2}$ for each quasiparticle state. With a spin-orbit parameter $\xi = 0.3$ eV and an exchange splitting $\Delta = 0.7$ eV at 0 K, we get a spin-orbit induced mixing $R = (n/n^-) = (1 - \mathrm{P})/(1 + \mathrm{P}) \sim 5\%$. This increases to 8% at $T = 150$ K as the exchange

splitting between the occupied and unoccupied surface states gets smaller (Fedorov, Starke and Kaindl, 1994; Weschke *et al*., 1996).

Fitting the spectra in Figure 13 with Lorentzian line shapes shows that the minority-spin peak has a larger width than its majority-spin counterpart, 116 meV as opposed to 86 meV. Removing the contribution from the experimental resolution, these widths become approximately 105 meV in the minority-spin channel and 70 meV in the majority channel. Possible decay modes for either spin photohole can involve electron–phonon, electron–magnon and electron–electron scattering. Each of these different mechanisms will give distinct spin-dependent contributions to the scattering rate. Electron–electron scattering by exchange processes favors the two holes in the final state being of opposite spin (Sinkovic, Shekel and Hulbert, 1995). From consideration of the total density of states in the spin channels, the authors of the spin-resolved study estimated the scattering rate from the process to be equal for a majority-spin hole and a minority-spin hole. The electron–phonon and impurity scattering rate are proportional to the density of states at the hole binding energy for the same spin while the electron–magnon rate is proportional to the density of states for the opposite spin. Since the majority-spin density of states is large while the minority-spin part is small and from consideration of the required momentum transfer, impurity and electron–phonon scattering should be more important in the majority-spin channel. The observation that the minority-spin channel is broader suggests electron–magnon scattering is the dominant decay mechanism. At $T = 0\,\mathrm{K}$, the minority-spin component of a photo-hole can scatter to the majority-spin component of a hole state higher in the surface band by emitting a spin wave (tilting the spins of the localized f electrons). The corresponding spin-flip process is not available to the majority-spin component of the photo-hole at $T = 0$ because the localized f spins have saturated magnetization and are not able to tilt upwards when the hole tilts down. At higher temperatures, inelastic scattering can occur back and forth between the two spin channels mediated by the emission or absorption of magnons, but the minority-spin component always has the higher density of final states to scatter into. An approximate treatment (Allen, 2001) using the 's–f' Hamiltonian (Zener, 1951a–c) found the result

$$\frac{\hbar}{\tau\,(\downarrow)} = \frac{\sqrt{3}}{4}\frac{P\,(\uparrow)\,m^*}{S}\left(\frac{2JSa}{\hbar}\right)^2 \tag{26}$$

for the decay of the minority ($\downarrow$) spin component due to spin-flip scattering with magnon emission. Here J is the s–f exchange parameter giving the exchange splitting $2JS = 0.65$ measured for the surface state, $m^* = 1.21$ is the effective mass measured for the surface band, and $P(\uparrow) = 0.87$ is the experimentally measured majority component of the band. With $S = 7/2$ and $a = 3.6\,\text{Å}$, $\hbar/\tau\,(\downarrow) = 0.095\,\mathrm{eV}$. Conversely, replacement of $P(\uparrow)$ by $P(\downarrow) = 1 - P(\uparrow)$ gives $\hbar/\tau(\uparrow) \approx 0.014\,\mathrm{eV}$ for the majority-spin component. Thus at low T, the majority-spin channel is dominated by electron–phonon scattering, whereas the minority-spin channel is dominated by electron–magnon scattering. On the basis of the relative spin-dependent densities of states it is possible to provide estimates of the contribution of phonon scattering in the two spin channels. These would be 46 meV in the majority-spin channel and 10 meV in the minority-spin channel, leaving approximately l0 meV in each channel due to impurity scattering. This system has also been studied by the group of Kaindl using scanning tunneling spectroscopy (Rehbein, Wegner, Kaindl and Bauer, 2003). They arrived at slightly different values for the different contributions but also concluded that the occupied majority-spin surface state preferentially decays via electron–phonon scattering. The important experimental observation in the study described in the preceding text is that the occupied minority-spin component of that state has a shorter lifetime. The only way that can occur is through the participation of magnon scattering.

4.4 Half-metallic ferromagnetic oxides

Half-metallic ferromagnets (HMF) show in the ideal case a 100% spin polarization at the Fermi level E_F. The high polarization reflects a metallic density of states for one spin direction and a band gap for the other spin direction. This class of materials was first discovered via *ab initio* calculations by de Groot, Mueller, van Engen and Buschow (1983) for Mn-based Heusler alloys, such as NiMnSb. Besides the expectation of exceptional magneto-optical properties, these materials have recently attracted considerable attention because of their potential application in the field of spintronics (Pickett and Moodera, 2001). In principle, HMFs are ideal spin injectors and detectors because under moderate voltage they can carry current of only one spin direction. A wealth of theoretical work has been devoted to the spin-dependent electronic structure of metal-based HMF (Kübler, 2003; Wurmehl *et al*., 2005) or zinc-blende chalcogenide HMF (Mavropoulos, Ležaić and Blügel, 2005). Here we focus on transition-metal oxide HMF, the existence of which, again, had all been predicted by *ab initio* electronic structure calculations. Examples include Fe_3O_4 (Yanase and Siratori, 1984; Zhang and Satpathy, 1991), CrO_2 (Schwarz, 1986; Korotin, Anisimov, Khomskii and Sawatzky, 1998), $La_{1-x}Sr_xMnO_3$ (Pickett and Singh, 1996) and Sr_2FeMoO_6 (Kobayashi *et al*., 1998). The experimental challenge ever since has been to prove the half-metallic nature of these ferromagnetic or ferrimagnetic materials. While this task would best be carried

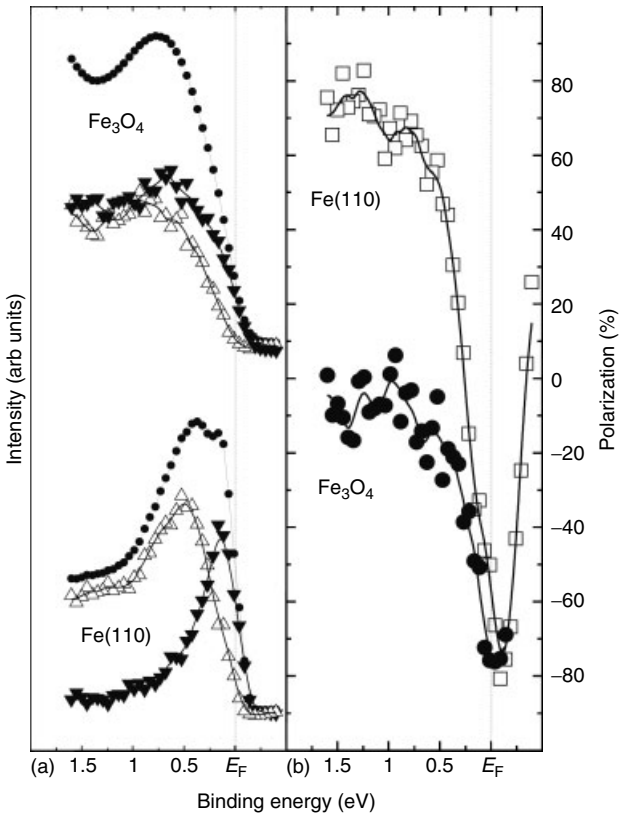

Figure 14. (a) Spin-resolved photoemission intensities (Δ spin up, ▼ spin down) measured at $h\nu = 21.2\,\text{eV}$ together with the total intensity (●) of 5-nm-thick Fe(110) (bottom) and $Fe_3O_4(111)$ (top), obtained by oxidizing Fe(110) in oxygen atmosphere at 250 °C. out using polycrystalline materials to yield an average over all k states of the Brillouin zone, the experimental studies have mostly been aimed at using single crystalline material or thin epitaxial films. This was necessary because the particular experimental techniques used for measuring spin polarization all show a subtle surface sensitivity. Among these are spin-polarized tunneling into superconductors, superconducting point-contact spectroscopy using Andreev reflection, magnetic tunnel junctions (MTJ) and spin-polarized photoemission. While most of the techniques depend critically on interface qualities, photoemission relies particularly on ultraclean surfaces. Another crucial point concerns the different nature of the electronic states probed by transport and by photoemission measurements. In this section, we give an account of the progress made in the field of oxidic HMF using SPPES.

1. $Fe_3O_4(111)$, (100): SPPES studies of magnetite (Fe_3O_4) began in 1975 (Alvarado *et al*., 1975). The interpretation of the valence band photoemission spectra is still a subject of controversial debate (Alvarado, Erbudak and Munz, 1976; Alvarado and Bagus, 1978; Cai, Ritter, Weiss and Bradshaw, 1998; Dedkov, Rüdiger and Güntherodt, 2002a; Dedkov *et al*., 2004; Fonin *et al*., 2005). Alvarado *et al*. performed the first SPPES measurements on cleaved $Fe_3O_4(100)$ single crystals (Alvarado *et al*., 1975; Alvarado, Erbudak and Munz, 1976; Alvarado and Bagus, 1978). The spin polarization of the photoelectrons showing a maximum value of -60% near the Fermi energy E_F was measured at 10 K using an incident photon energy of 5 eV (Alvarado, Erbudak and Munz, 1976). From a single-ion-in-a-crystal-field (SICF) model, a maximum value of $P = -66.6\%$ was obtained for the spin polarization at $T = 0\,\text{K}$ (Alvarado, Erbudak and Munz, 1976; Alvarado and Bagus, 1978). This was considered to be in agreement with the measured value of -60%. However, subsequent spin-polarization measurements on epitaxial thin films of $Fe_3O_4(111)$ and $Fe_3O_4(100)$ yielded at room temperature, values of $-(80 \pm 5)\%$ and $-(40\text{–}55)\%$ near E_F, respectively (Dedkov, Rüdiger and Güntherodt, 2002a; Morton *et al*., 2002; Huang *et al*., 2002b; Fonin *et al*., 2005). Figure 14 shows in (a) the spin-resolved photoemission intensities (▲ spin up, ▼ spin down) together with the total intensity (●) of Fe(110) (bottom) and $Fe_3O_4(111)$ (top). The spin polarization is shown in (b) for Fe(110) (■) and $Fe_3O_4(111)$ (●). In both cases, the spin polarization at E_F is accidentally -80%. For $Fe_3O_4(111)$ this provided evidence closer to the theoretically predicted half-metallic nature of magnetite (Yanase and Siratori, 1984; Zhang and Satpathy, 1991), at least for the [111] direction.

For the interface between a 25-nm-thick $Fe_3O_4(111)$ thin film and a 2-nm-thick γ-$Al_2O_3(111)$ layer a *negative* spin polarization of about -40% was found by SPPES (Bataille *et al*., 2006).

Interestingly, for the (100)-oriented epitaxial thin films of Fe_3O_4 spin-polarization values of only $-(40\text{–}55)\%$ near E_F were obtained (Morton *et al*., 2002; Huang *et al*., 2002b). These values are significantly lower than the -100% predicted by local spin density approximation (LSDA) calculations for the bulk material (Zhang and Satpathy, 1991) as well as the $-(80 \pm 5)\%$ measured at room temperature on the (111)-oriented Fe_3O_4 surface near E_F (Dedkov, Rüdiger and Güntherodt, 2002a). The low value for the (100) surface was ascribed either to surface imperfection (Morton *et al*., 2002) or to strong electron correlation effects (Huang *et al*., 2002b). Recent measurements of SPPES on epitaxial thin films of $Fe_3O_4(100)$ gave a spin polarization of $-(55 \pm 10)\%$ at E_F (Fonin *et al*., 2005). In an effort to explain this result on the basis of density-functional theory (DFT) and *ab initio* thermodynamics calculations it was discovered that the surface electronic structure of $Fe_3O_4(100)$ differs distinctly from the bulk one. A $(\sqrt{2} \times \sqrt{2})R45^0$ wavelike surface atom reconstruction due to a Jahn–Teller effect was found to lead to surface states in the majority-spin band gap, resulting

in a calculated spin polarization of -40% at E_F (Fonin *et al*., 2005). However, for all of these comparisons between experiment and theory it has to be remembered that, except for the latter reference, the electronic structure calculations have been performed for the bulk material without taking account of subtle surface reconstruction and relaxation or charge redistribution effects, particularly for (100) polar surfaces. These surface effects certainly play an important role in VUV-PES and SPPES measurements.

For correlated electron systems, such as Fe_3O_4, an atomic configuration-based approach had initially been chosen for the interpretation of the SPPES data (Alvarado, Erbudak and Munz, 1976; Alvarado and Bagus, 1978). Recent investigations (Cai, Ritter, Weiss and Bradshaw, 1998; Dedkov, Rüdiger and Güntherodt, 2002a), however, showed that band dispersions (Yanase and Siratori, 1984; Zhang and Satpathy, 1991) must be taken into account for the interpretation of photoelectron spectra of Fe_3O_4. In particular, surface symmetry-related band dispersions were identified for $Fe_3O_4(111)$. Angle-resolved PES determinations of the electronic band structure of well-ordered $Fe_3O_4(111)$ surfaces using synchrotron radiation (Dedkov *et al*., 2004) gave direct evidence for surface-Brillouin-zone (SBZ) symmetry-related contributions of the oxygen and iron sublattices. In the $\overline{\Gamma}-\overline{M}$ direction of the $Fe_3O_4(111)$ SBZ, two types of dispersing states were identified. They originate from a periodic multilayered structure of iron and oxygen ions, with Fe^{2+} and Fe^{3+} cations incorporated into the close-packed fcc oxygen sublattice. For $Fe_3O_4(100)$ a 'wavelike' atom pattern observed by STM along the [110] direction (Tarrach *et al*., 1993; Stanka, Hebenstreit, Diebold and Chambers, 2000; Fonin *et al*., 2005) gave the first hint of surface reconstruction effects, which were finally corroborated by DFT calculations (Fonin *et al*., 2005). Over a broad range of oxygen pressures, the modified B-layer bulk termination, consisting of oxygen and iron (Fe_B) in octahedral B sites and showing a pairwise 'wavelike' shift of iron atoms perpendicular to the B rows, was identified as lowest energy configuration. As a consequence of this reconstruction, surface states appear in the band gap of the majority-spin subband leading to a reduction of the spin polarization to about -40% at E_F and a loss of half-metallicity of the $Fe_3O_4(100)$ surface. These surface states are a hybridization of $d_{x^2-y^2}$ states of octahedral iron in the surface layer and p_x, p_y states of the surface oxygen without a subsurface tetrahedral iron neighbor.

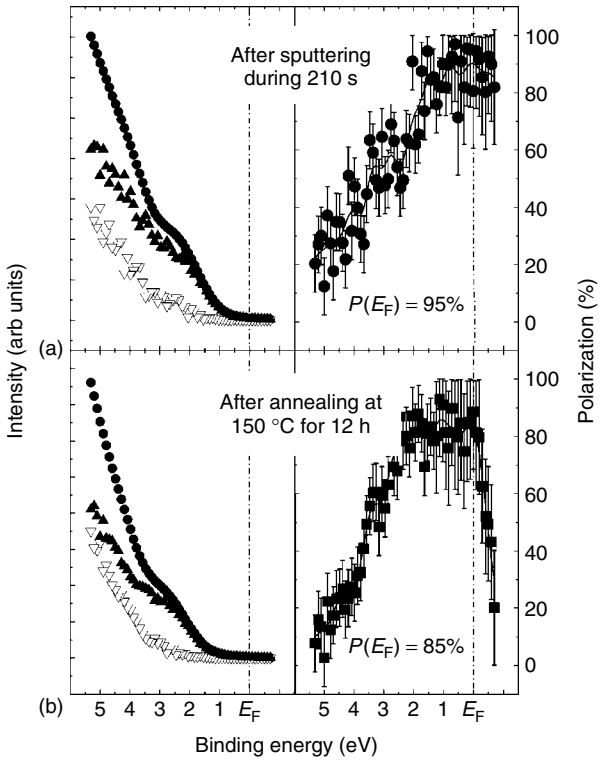

Figure 15. Right panel: spin polarization as a function of binding energy of an epitaxial CrO2(100) film (a) after Ar^+ sputtering for 210 s at 500 eV and (b) after 750 s sputtering and an additional annealing treatment at 150 °C for 12 h. Left panel: corresponding spin-polarized photoemission spectra at $h\nu = 21.2$ eV (▽ spin down, ▲ spin up) and total photoemission intensity (●). (Reproduced from Dedkov *et al*., 2002b, with permission from the American Institute of Physics. © 2002.)

2. $CrO_2(100)$: In spite of applications in magnetic tapes and potential use for magneto-optical storage, the electronic structure of CrO_2 was theoretically predicted only in 1986 using the LSDA to DFT (Schwarz, 1986). The first SPPES investigations revealed a spin polarization of up to 90% near 2 eV binding energy below E_F (Kämper *et al*., 1987). No spin analysis using a 100-kV Mott spin detector (Kisker, Clauberg and Gudat, 1982) was feasible at the time between E_F and 2 eV binding energy because of the low photoemission intensity. The low emission intensity was attributed to oxygen deficiencies. However, high quality epitaxial thin films of $CrO_2(100)$ grown on Ti(100) single-crystal substrates showed a spin polarization of up to 95% at E_F (Dedkov *et al*., 2002b). Figure 15 shows in the right panel the spin polarization as a function of binding energy of an epitaxial $CrO_2(100)$ film (a) after Ar^+ sputtering for 210 s at 500 eV and (b) after 750 s sputtering and an additional annealing treatment at 150 °C for 12 h. The left panel shows spin-polarized photoemission spectra (▼ spin down, ▲ spin up) and total photoemission intensity (●). The value of $P = 95\%$ at E_F in Figure 15(a) agrees with measurements using superconducting point-contact spectroscopy (Soulen, Byers and Osofsky, 1998; Ji *et al*., 2001). The good agreement between spin-polarization values from photoemission and transport measurements has to be attributed to the unusually strong 2p(O)-3d(Cr) hybridization found in electronic structure calculations based

on LSDA + U (Korotin, Anisimov, Khomskii and Sawatzky, 1998). A value of 90% spin polarization for unoccupied states above E_F was also found using spin-resolved O 1s X-ray absorption spectroscopy (Huang *et al*., 2003). These data give evidence that the presence of holes in the oxygen band prevents CrO_2 from being an insulator and supporting the notion that the material is a self-doped or p-type metal (Korotin, Anisimov, Khomskii and Sawatzky, 1998).

The shoulder in the photoemission intensity in Figure 15(a) and (b) which becomes most pronounced after sputtering for 750 s, has been associated with the localized Cr(3d) states. These, however, were found in LSDA + U calculations (Korotin, Anisimov, Khomskii and Sawatzky, 1998) to be near 1 eV binding energy. The photoemission intensity near 2 eV was more recently attributed to emission from the Cr_2O_3 surface layer (Chang *et al*., 2005). This conclusion was reached on the basis of MCD in resonant photoemission studies with hν tuned to the Cr 2p absorption edge. The energy positions of the Cr 3d bands in CrO_2 are then determined with no contribution from antiferromagnetic Cr_2O_3. However, this conclusion contradicts the finding of the peak at 2 eV binding energy after prolonged sputtering (750 s), removing all Cr_2O_3 (Dedkov *et al*., 2002b). Hence the peak at 2 eV is of intrinsic origin, most likely associated with the lower Hubbard band (LHB). The upper Hubbard band (UHB) may be evident in the atomic-like Cr 3d state observed in spin-resolved O 1s X-ray absorption near 0.6 eV above E_F (Huang *et al*., 2003). These observations combined give a Coulomb correlation energy U in agreement with the value $U = 3$ eV used in LSDA + U electronic structure calculations (Korotin, Anisimov, Khomskii and Sawatzky, 1998). Further, in agreement with these calculations, a more localized Cr 3d derived spectral weight near 1 eV is found by MCD in resonant photoemission (Chang *et al*., 2005). In the most recent bulk sensitive board X-ray photoelectron spectroscopy (HAX-PES) measurements using hard X-rays ($h\nu = 7942$ eV) (Suga, 2006) dispersionless Cr(3d) states were found near 1 eV binding energy. Most interesting in the HAX-PES measurements is the rather small spectral weight near E_F, similar to the previous VUV-PES data by Kämper *et al*. (1987). This is in strong contrast to a theoretical study using LSDA + DMFT (dynamic mean-field theory) and applying the iterated perturbation theory (IPT) as 'Anderson-impurity solver' to the multiorbital case (Craco, Laad and Müller-Hartmann, 2003). In this calculation, CrO_2 is found to exhibit a rather unusually high density of states at E_F. The authors stress the importance of dynamical correlation leading to a collective orbital Kondo effect and the emergence of a correlated Fermi liquid scale. However, the puzzle of the low intensity or missing Fermi edge in the earlier surface-sensitive VUV ($h\nu = 21.2$ eV) photoemission data (Kämper *et al*., 1987) has recently been attributed to a surface relaxation of CrO_2(100) deduced from LSDA-based first-principles calculations (Hong and Che, 2006). The distorted tetrahedral oxygen coordination of each surface Cr ion gives rise to an inversion of the $t_{2g} - e_g$ splitting of the Cr 3d orbitals, with E_F lying in a gap between the occupied e_g and unoccupied t_{2g} states for a local electronic structure at the surface. For future photoemission intensity calculations of CrO_2 it appears indispensable to apply computational schemes merging the local density approximation (LDA) with DMFT and using quantum Monte–Carlo simulations (QMC) to solve the effective Anderson-impurity model of DMFT.

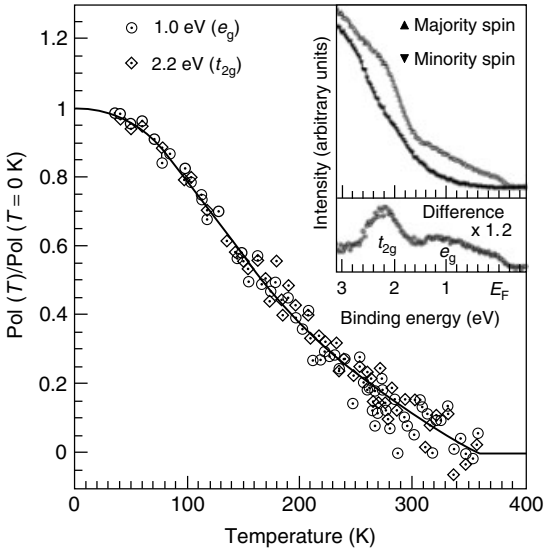

Figure 16. Temperature dependence of spin polarization of Mn 3d states, e_g at 1.0 eV binding energy and t_{2g} at 2.2 eV binding energy obtained with $h\nu = 40$ eV. The inset shows the spin-polarized photoemission spectra for the majority and minority spins and the difference at 40 K. 3. Manganites: The manganite class of materials is unusual not only because of the occurrence of the colossal magnetoresistance (CMR), but also because of its dense granular magnetoresistance, and the development of concepts like double exchange and Jahn–Teller polarons. The rich electronic phase diagrams reflect the fine balance of interactions, which determine the electronic ground state. The different competing, novel phases, including orbital order and orbiton excitations, arise from an interaction between different microscopic degrees of freedom, including charge, spin, orbitals, and lattice. The most straightforward evidence of a minority-spin gap and a concomitant 95% spin polarization near E_F was obtained in $La_{0.7}Sr_{0.3}MnO_3$ at 40 K by means of SPPES (Park *et al*., 1998a,b). This observation was consistent with first principles calculations of $La_{1-x}Ca_xMnO_3$ (Pickett and Singh, 1996). Figure 16 shows the temperature

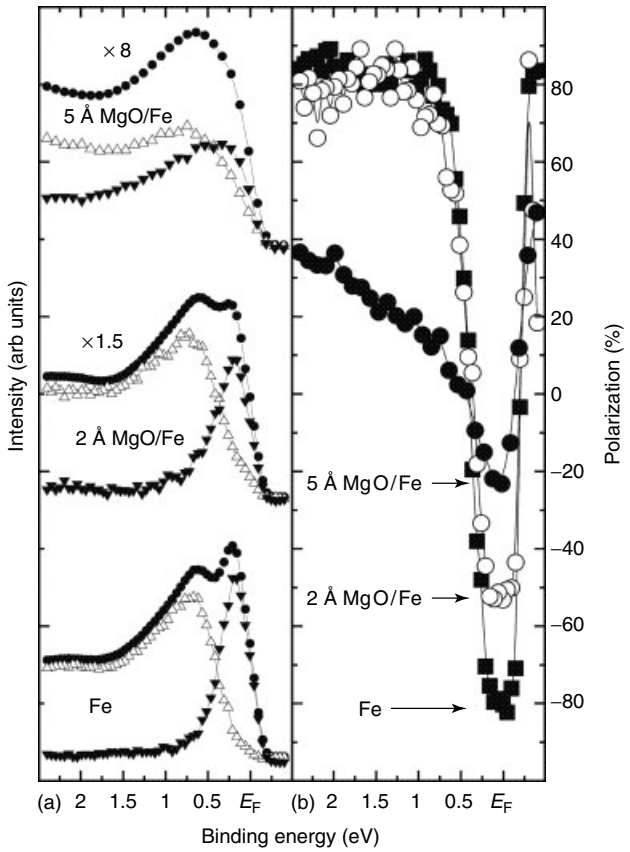

Figure 17. (a) The spin-resolved photoemission spectra (▼ spin down, △ spin up) together with the total emission intensity (●) of Fe(110), 2 Å MgO on Fe(110), and 5 Å MgO on Fe(110) (from bottom to top). (b) The spin polarization as function of binding energy of a 50-Å-thick Fe(110) film (■), 2 Å MgO on Fe(110) (○), and 5 Å MgO on Fe(110) (●). (Reproduced from Dedkov *et al*., 2006, with permission from the American Institute of Physics. © 2006.)

dependence of the spin polarization of the Mn 3d states, e_g at 1.0 eV binding energy and t_{2g} at 2.2 eV binding energy, obtained with $h\nu = 40$ eV (Park *et al*., 1998a,b). The half-metallic nature of $La_{0.7}Sr_{0.3}MnO_3$ had a crucial impact on spin-polarized tunneling into Co through a $SrTiO_3$ tunnel barrier (de Teresa *et al*., 1999).

4.5 Ferromagnet-oxide interfaces

Interfaces between electrodes of itinerant ferromagnets and insulating oxide layers play a decisive role in MTJs, giving rise to the tunnel magnetoresistance (TMR). A most prominent and successful example is Fe(100)/MgO(100)/Fe(100), which was theoretically predicted to yield a TMR of the order of about 1000% (Butler, Zhang, Schulthess and MacLaren, 2001; Mathon and Umerski, 2001). The presently highest TMR values that have currently been achieved experimentally are 220% at room temperature (300% at

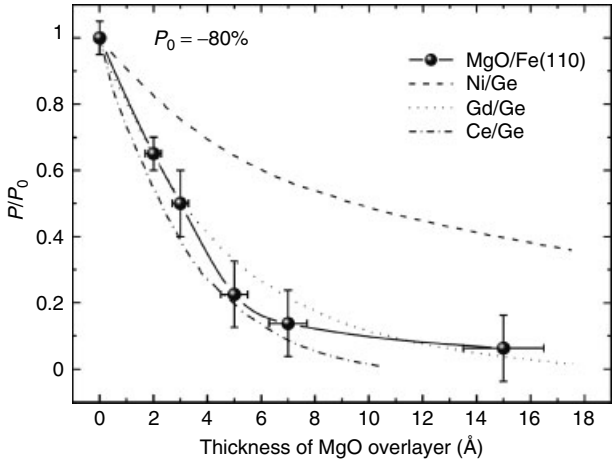

Figure 18. The change of the normalized spin polarization at E_F of the MgO/Fe(110) system with increasing MgO layer thickness. The spline fit to the experimental data is shown by a *solid line*. The reference curves for depolarization of polarized electrons ($P_0 = 23.5\%$) optically excited in germanium after traversing an evaporated overlayer of Ni (*dashed line*), Gd (*dotted line*), and Ce (*dot–dashed line*) are taken from Meier, Bona and Hüfner (1984) and Dedkov, Fonin, Rüdiger and Güntherodt (2006). (Reproduced from Dedkov *et al*., 2006, with permission from the American Institute of Physics. © 2006.)

4 K) for sputtered and textured Fe(100)/MgO(100)/Fe(100) (Parkin *et al*., 2004) and 180% at room temperature for epitaxial, MBE grown Fe(100)/MgO(100)/Fe(100) (Yuasa *et al*., 2004). Other materials combinations yielded 260% at RT (361% after annealing; 403% at 5 K) for CoFeB/MgO/CoFeB (Hayakawa *et al*., 2005; Lee *et al*., 2006) and 410% at room temperature (507% at 20 K) for bcc Co(001)/MgO(001)/Co(001) (Yuasa *et al*., 2006).

1. Fe/MgO: There also appears to be a problem with the formation of a submonolayer of FeO at the Fe/MgO interface (Meyerheim *et al*., 2001, 2002), which may be responsible for reduced TMR values (Zhang, Butler and Bandyopadhyay, 2003). The formation of FeO at the interface of MBE grown Fe(110)/MgO(111) could be identified via STM as well as by SPPES (Dedkov, Fonin, Rüdiger and Güntherodt, 2006). Figure 17 shows the spin-resolved photoemission spectra (a) as well as the spin polarization (b) for clean Fe(110) and the same with 2 Å MgO and 5 Å MgO overlayers (from bottom to top). With increasing overlayer thickness the polarization is attenuated from −80 to −50% and −20%, respectively. This attenuation of the spin polarization as a function of thickness of the MgO overlayer is represented in Figure 18.

In Figure 18, exponential fits to the experimentally observed depolarization of electrons ($P_0 = 23.5\%$) excited by circularly polarized light ($h\nu = 3.05$ eV) in germanium after traversing an evaporated overlayer of Ni (dashed line), Gd (dotted line), and Ce (dot-dashed line) are shown. All

curves show an exponential dependence of the polarization on the thickness of the overlayer possessing valence d electrons in the vicinity of E_F. The mean-free path for spin-flip scattering decreases as a function of the number of unoccupied d states in the valence band from Ni via Gd to Ce (Ni: two unoccupied d orbitals, $4s^2 3d^8$; Gd: nine unoccupied d orbitals, $6s^2 5d^1$; Ce: ten unoccupied d orbitals, $6s^2 5d^0$) (Meier, Bona and Hüfner, 1984). The reference curves for the Gd/Ge and Ce/Ge systems are very close to the experimentally observed sharp decrease of spin polarization in the MgO/Fe(110) system and can qualitatively be used as additional argument for the presence of a depolarizing FeO layer at the MgO/Fe(110) interface, that is, spin scattering into the four unoccupied d orbitals of Fe^{2+} ($3d^6$) in FeO. The comparison is only qualitative with respect to the absolute number of hole states as there may be additional spin scattering at the FeO/MgO interface. The presence of such an FeO interfacial layer and the increase of the FeO layer thickness at the MgO/Fe interface with increasing MgO layer thickness is supported by AES and STM measurements (Dedkov, Fonin, Rüdiger and Güntherodt, 2006). For these MTJs values of the TMR at RT of 32% (54% at 1.5 K) were obtained (Guerrero *et al*., 2005; Hauch *et al*., 2006).

The influence of MgO overlayers deposited on 16 ML Fe grown on GaAs(100) has been investigated for direct transitions between different symmetry Fe bulk and final states by means of SPPES (Matthes, Tong and Schneider, 2004). A spin-dependent attenuation for direct transitions related to Fe bulk initial states has been observed as a function of the MgO thickness.

2. α-Al_2O_3/Fe(110): The optimization of the oxidation process of thin Al films deposited on an Fe(110) surface was characterized in a spin-, angle-, as well as energy-resolved photoemission study (SPARPES) of the valence band (Dedkov, Fonin, Rüdiger and Güntherodt, 2002c). The spin-resolved spectra together with the total intensity and the spin polarization respectively, as a function of the binding energy for W(110), Fe(110), 7 Å Al on Fe(110) as well as α-Al_2O_3/Fe(110) are presented in Figure 19(a) and (b). For the 7 Å-Al/Fe system the spin polarization near E_F is decreased from -80% characteristic of the clean Fe(110) surface to about $-(35 \pm 5)\%$. Aluminum has no d electrons in the valence band and, therefore, the scattering of spin-polarized electrons from the valence band of Fe can be described by the spin-averaged scattering cross section (Siegmann, 1994). The spin polarization of photoelectrons for adlayer/ferromagnet systems can be calculated (Siegmann, 1994) by $P = P_0 \exp(-d \cdot \sigma)$, where $P_0 = -80\%$ is the polarization of the pure Fe(110) film, d the thickness of the adlayer (7 Å for Al and 13 Å for 1 ML of α-Al_2O_3), and σ the total

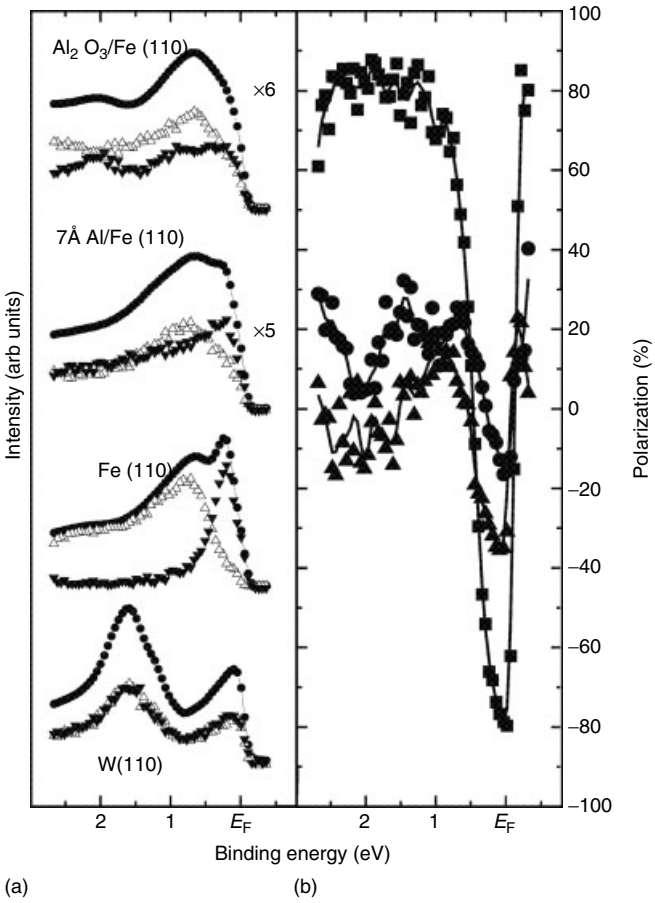

Figure 19. (a) The spin-resolved photoemission spectra (▼ spin down, △ spin up) together with the total emission intensity (●) for W(110), Fe(110), 7 Å Al on Fe(110), and approximately 1 ML Al_2O_3 on Fe(110). (b) The spin polarization as a function of binding energy of a 50-Å-thick Fe(110) film (■), 7 Å Al on Fe(110) (▲), and approximately 1 ML α-Al_2O_3 on Fe(110) (●) (Dedkov, Fonin, Rüdiger and Güntherodt, 2002c).

scattering cross section, which in our case is equal to the spin-independent part of σ, $\sigma_0 = 1/8\,\text{Å}^{-1}$ for both materials (Al and Al_2O_3) without d electrons in the valence band (Siegmann, 1994). In this case, the spin polarization would be attenuated to (-33%) which is in reasonably good agreement with the value of $-(35 \pm 5)\%$ observed experimentally.

The spin-resolved spectra following oxidation of the 7-Å-thick Al layer on Fe(110) via subsequent annealing at 250 °C are presented in Figure 19(a) (top curves). The spin polarization of the α-Al_2O_3/Fe(110) system decreases to $-(15 \pm 5)\%$ near E_F. The reason for the decrease of the spin polarization can be due to additional attenuation of the spin-polarized photoelectrons by the Al_2O_3 layer with an estimated thickness of 11 Å, close to the thickness of 1 ML of α-Al_2O_3. The estimated spin polarization of 1 ML α-Al_2O_3/Fe(110)

is -17%, which is in the range of the experimental value of $-(15 \pm 5)\%$. The spin polarization of -15% in the α-Al_2O_3/Fe(110)/W(110) system obtained by SPARPES is in contrast to the positive value determined by spin-polarized tunneling into superconductors (Meservey and Tedrow, 1994). For the photon energy of $h\nu = 21.2\,\text{eV}$, the cross section of the photoemission process from the valence band of Fe is larger for 3d electrons than for 4s electrons. Therefore, an attenuation of the negative spin polarization of Fe without change in sign, due to the coverage with α-Al_2O_3 can be described by the spin-independent part of the scattering cross section (Siegmann, 1994). In tunneling experiments, 4s electrons from the valence band of Fe have a higher tunneling probability in comparison with 3d electrons. It is the participation of the 4s electrons that explains the positive sign of the spin polarization as calculated (Tsymbal and Pettifor, 1997) and experimentally observed (Meservey and Tedrow, 1994) for tunneling from the ferromagnet into the superconductor.

4.6 The antiferromagnetic cuprates

The origin of the high T_C superconductivity observed in the cuprates presents one of the greatest challenges in condensed matter physics today. As such it is particularly important to understand the nature of the low-energy excitations in these materials. It is generally accepted that the superconductivity in the cuprates evolves from a parent insulating state by doping carriers into the two-dimensional CuO_2 planes. The ground state of the parent compound is an antiferromagnetic Mott insulator. With doping, the systems move from the antiferromagnetic state to a regime where superconductivity is possible. Cluster calculations indicate that the ground state associated with the CuO_2 planes consists of a linear combination of $3d^9$ and $3d^{10}\mathbf{L}$ states, and the photoemission final state as a combination of $3d^8$, $3d^9\mathbf{L}$ and $3d^{10}\mathbf{L}^2$ states, where $\mathbf{L}$ denotes an oxygen ligand hole orbital. Most theories predict that the $3d^8$ states close to the Fermi level are of local singlet character rather than the high spin triplet state favored by Hund's first rule (Zhang and Rice, 1998).

To investigate this possibility Tjeng and coworkers have used incident circularly polarized light and spin resolved the electrons emitted in a resonant photoemission process involving the 2p spin-orbit split core level (Tjeng *et al.*, 1997, 1999; Tjeng, Brookes and Sinkovic, 2001). The authors of these studies point out the critical importance of initially exciting from the spin-orbit split core level. In the absence of such an excitation, the measured polarization from the valence bands would be zero for an antiferromagnetic material. The results of their study of optimally doped $Bi_2Sr_2CaCu_2O_{8+\delta}$ (Brookes *et al.*, 2001) are shown in Figure 20, which shows

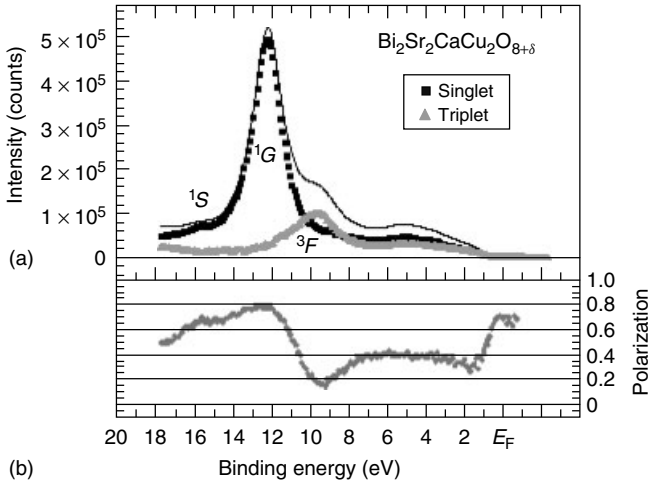

Figure 20. Spin-polarized photoemission spectra from $Bi_2Sr_2CaCu_2O_{8+\delta}$. (a) The spin-integrated resonant photoemission spectra taken at the Cu $L3$ absorption edge (full line). The symbols show the integrated spectra separated into its singlet (■) and triplet (▲) components. (b) The measured spin polarization corresponding to the spectra in panel (a).

the spin-integrated photoemission spectrum, the same spectrum resolved into triplet and singlet contributions and the measured spin polarization. The latter polarization, defined as $(\uparrow\uparrow - \uparrow\downarrow)/(\uparrow\uparrow + \uparrow\downarrow)$ where $\uparrow\uparrow$ refers to parallel alignment of the photon spin and electron spin, $\sigma^+ e^\uparrow + \sigma^- e^\downarrow$, and $\uparrow\downarrow$ refers antiparallel alignment of the same, $\sigma^+ e^\downarrow + \sigma^- e^\uparrow$, is calculated to be 5/6 or 83.3% for pure singlet states and $-1/3 * 5/6$ or -27.8% for triplet states. It is clear from the lower panel of Figure 20 that the measured polarization provides strong evidence for the presence of the so-called Zhang–Rice singlets (Zhang and Rice, 1988) in the vicinity of the Fermi level.

5 SUMMARY AND FUTURE OUTLOOK

We have seen that in the past 20 years the development and application of spin-polarized photoemission has been extensive. Because of its sensitivity to the surface region it has offered a number of new insights into the electronic structure of ferromagnetic surfaces and thin films. Studies of the latter have been particularly relevant to understand the properties of the GMR materials. Further with the increased photon fluxes now available from synchrotron radiation sources it has become possible to develop new methodologies and extend the technique to the study of nonmagnetic and antiferromagnetic materials. We may anticipate still further developments in the future particularly in the area of development of more efficient spin polarimeters. Such developments will allow experiments to be carried out with

higher energy resolution than has been achieved to date. Amongst other things this will make accessible studies of the fine details associated with magnetic anisotropies in thin films. We may also anticipate further developments in the combination of spin-polarized photoemission and microscopy. This will be particularly relevant as detailed studies of nanoscale systems are pursued, particularly with reference to materials investigated for their potential use in spintronics.

ACKNOWLEDGMENTS

Peter Johnson would like to acknowledge the many contributions of collaborators to his own work in this area including A. Clarke, N. Brookes, B. Sinkovic, K. Garrison, Y. Chang, A.V. Fedorov, S.L. Hulbert, M. Weinert, P.B. Allen, and many others. He would particularly like to thank the late Neville Smith for his continued interest and inspiration. Work at Brookhaven National Laboratory is supported by the Department of Energy under Contract No. DE-AC02-98CH10886. Gernot Güntherodt would like to thank his Ph.D. students Yu.S. Dedkov, M. Fonin, J.O. Hauch and C. König as well as his former group assistant and collaborator U. Rüdiger for the fruitful cooperation. The experimental support by P. Turban and the valuable theoretical support and inspiration by R. Pentcheva are gratefully acknowledged. He is also indebted to S. Suga and his team for a most fruitful collaboration.

1 INTRODUCTION

In the last few decades, magnetism at surfaces and in thin films has attracted great attention. These studies are of fundamental interest and some discoveries led to important applications now used in everyday life, for example, magnetoresistance phenomena used in data storage (Jullière, 1975; Binasch, Grünberg, Saurenbach and Zinn, 1989; Baibich *et al*., 1988). Most of the studies have focused on static magnetism but recently dynamics also receives growing interest. The magnetization dynamics is governed by spin waves, which are collective excitations and can be described as quasiparticles, which carry a wave vector q, an energy E, and a magnetic moment of $1\,g\mu_B$ (where g is the gyromagnetic ratio and μ_B is a Bohr magneton), (See also **Spin Waves: History and a Summary of Recent Developments, Volume 1**). The latter places them in the class of bosons. In energy, they range from the μeV range to the 100 meV range, in momentum, from zero (the zone center) to the zone boundary (up to about $2\,\text{Å}^{-1}$). Their lifetimes range from a couple of ten femtoseconds to tens of microseconds, depending on damping. Low-energy spin waves are easily excited by phonon–magnon interaction, that is, by temperature. If a sufficient number of spin waves are excited, the global magnetic moment of a body decreases substantially. Therefore, spin waves play an important role for the magnitude of the Curie temperature, that is, the ferromagnetic versus paramagnetic transition.

The detailed description of the physical nature of these collective magnetic excitations cannot be cast into one single picture because of the many orders of magnitude of dynamic range in energy, momentum, and lifetime. In the limit of long wavelength, low energy, and long lifetime, the usual semiclassical picture of precessing (classical) spins has proved useful. In this case, each spin is only slightly tilted out of its direction along the magnetic easy axis. Thus, the reduction of the magnetic moment by $1\,g\mu_B$ occurs by the concerted action of all spins in the entire crystal. This picture relies on classical spins, because they may adapt any spin orientation continuously, as opposed to the quantum spins being quantized in direction. These 'spin waves' are damped by collisions with phonons, other spin waves, electrons, lattice deformations, and impurities, but they are usually long lived.

Spin waves have a characteristic dispersion, which links their energy to their wave vector. Depending on the wave

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

vector, different magnetic interactions determine the spin-wave energy. The exchange interaction is typically much stronger than other magnetic interactions. Nevertheless, owing to its relatively short range, other interactions, like the long-ranged dipole interaction, can become important at sufficiently small wave vectors. As a rule of thumb, in 3d ferromagnets this so-called dipole regime extends to wave vectors below $q < 10^{-3}\,\text{Å}^{-1}$ (Cottam and Slavin, 1994). For wave vectors above $q > 10^{-2}\,\text{Å}^{-1}$, the exchange interaction can be safely assumed to be the dominating interaction that determines the spin-wave energy (Cottam and Slavin, 1994).

For different regimes, different theoretical approaches are used to describe spin waves. As discussed in the preceding text, for the dipole or small wave-vector regime, a macroscopic continuum model description is sufficient (Mills, 1984). A large number of studies focus on the low wave-vector regime with its macroscopic description. A detailed summary can, for example, be found in Hillebrands and Ounadjela (2002), (See also **Investigation of Spin Waves and Spin Dynamics by Optical Techniques, Volume 3**, **Time-resolved Kerr-effect and Spin Dynamics in Itinerant Ferromagnets, Volume 3**, and **Investigation of Ultrathin Ferromagnetic Films by Magnetic Resonance, Volume 3**). By contrast, deep in the exchange-dominated regime, where the wavelength may become comparable in size to the interatomic distances in a crystal, a true microscopic description is needed. For such high wave vectors the strong exchange interaction leads to high spin-wave energies. These high-energy spin waves are usually short lived, because of their strong interaction with single electron–hole excitations, called *Stoner excitation*. These Stoner excitations consist of an electron excited about E_F and a hole in a filled band with opposite spins of the quasiparticles (adding up to $1\,g\mu_B$!). Electron and hole may have different wave vectors, that is, they reside at different locations in the Brillouin zone, and the wave vector of the Stoner excitation is the vectorial sum of the individual wave vectors. High-energy spin waves couple strongly with Stoner excitations because of their similarity in energy, wave vector, and spin character. This relationship is so intimate that spin wave may even be described as a coherent superposition of Stoner excitations (Majlis, 2001). It has been proved that this concept holds not only for the high-energy, short wavelength spin waves but also for the low energy, long wavelength modes (Edwards and Bechara Muniz, 1985; Bechara Muniz, Cooke and Edwards, 1985). The long lifetime of the latter is understandable because for electrons *and* holes very close to the Fermi energy (i.e., low-energy Stoner excitation) the available phase space for the de-excitation is small.

The different regimes of spin waves have been studied experimentally by various techniques, each having certain strengths and weaknesses. The regions in energy/wave vector/thickness space that are accessible by the established techniques are shown in Figure 1. Spin waves in thin ferromagnetic films have been studied by ferromagnetic resonance (FMR), Brillouin light scattering (BLS), and also by time domain methods (Hillebrands and Ounadjela, 2002). All these methods have in common that only long wavelength spin waves can be studied, having a wave vector of the order of $10^{-2}\,\text{Å}^{-1}$, at most (light gray areas in Figure 1). High wave-vector spin waves can be investigated by inelastic neutron scattering (INS) (dark gray) (Brockhouse, 1957), but the weak interaction of neutrons with matter prohibits measurements on ultrathin films or at surfaces (Schreyer *et al.*, 2000). Owing to the limitation of the established techniques, spin waves in about 99% of the Brillouin zone in ultrathin films remained unexplored experimentally (see Figure 1). This region is, however, of high interest because here the wavelength of spin waves can become comparable to the distances between the atoms in the crystal. Thus, their study allows direct access to magnetic properties at the surfaces on the atomic scale.

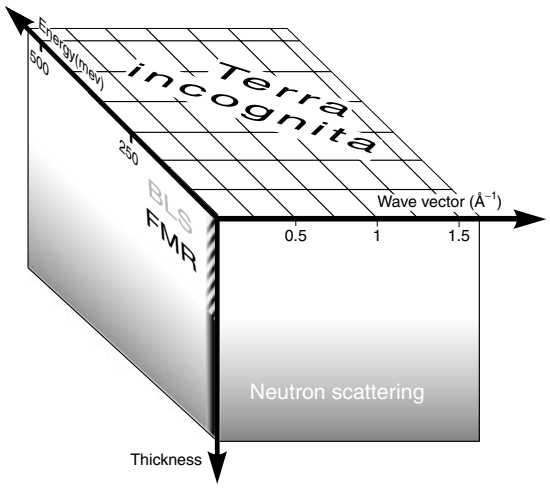

Figure 1. Scheme of the regions in wave vector/energy/thickness space in which spin waves have been studied using established experimental techniques (marked by different gray tones). None of these techniques has been able to measure high wave-vector spin waves in a single thin film or at surfaces, that is, in the 'terra incognita'.

Spin-polarized electron energy loss spectroscopy (SPEELS) is a suitable technique to access the *terra incognita* shown in Figure 1. In the experiment, a monochromatic, spin-polarized electron beam is scattered inelastically from a magnetized sample and the scattered electrons are analyzed for their wave vector and energy transfer during scattering. The use of electrons as scattering particles has certain merits. Because of the strong interaction between low-energy electrons and matter, electron scattering is highly surface sensitive. This has been used for several decades in many surface

sensitive techniques (see, e.g., Henzler and Göpel, 1994). In addition, electron scattering is known for the relatively easy realization of high-energy and high wave-vector transfers. Thus, the basic idea to study spin waves by electron scattering is evident and it has already been proposed decades ago (DeWames and Vredevoe, 1967). The history of the study of spin waves by SPEELS has been a 25 years history of trial and error until, in 1999, the proof of principle of this technique was given (Plihal, Mills and Kirschner, 1999): a spin-polarized electron with its spin antiparallel to the majority spin orientation may create a spin wave by exchanging with another electron in the surface with parallel (majority) spin, coming out with somewhat smaller energy. The energy difference equals the spin-wave energy. The interaction is of the exchange type, that is, electrostatic, no direct magnetic spin–spin interaction is involved. This is puzzling at the first glance, but it is the origin of the extraordinary sensitivity of SPEELS.

We are presently able to study spin-wave excitations with wave-vector transfers up to (and beyond) the surface Brillouin zone boundary on films as thin as 2.5 atomic layers. From the signal-to-noise ratio, one could even speculate that the sensitivity limit for the detection of spin waves by SPEELS is in the submonolayer regime. Up to now, several systems have been investigated by SPEELS (Vollmer *et al*., 2003, 2004a,b,c; Etzkorn *et al*., 2004, 2005). In this chapter, we will discuss the general method and the spectrometer used for these studies, as well as the results of studies on fcc Co on Cu(001), hcp Co on W(110), and Fe on Cu(001). We find that the magnetic excitations are confined to an extraordinarily small volume in space and time. By a Fourier analysis of the energy loss spectra and using the measured group velocity from the dispersion relation, we estimate a linear space–time range of some 10 yocto sm (yocto $\Psi = 10^{-24}$) for wave vectors about halfway to the zone boundary.

1.1 The spin-polarized electron energy loss spectrometer

In the SPEELS experiments, spin-polarized electrons are scattered from a magnetic sample. The energy and momentum transfer of the scattered electrons to the sample is analyzed to obtain information about the inelastic scattering processes. To realize the experiment, a spin-polarized, monochromatic electron beam is needed that hits the sample under controlled conditions. With the help of an analyzer, the intensity of the scattered electrons is counted in a small window in energy and wave-vector space.

The detection of spin waves demands the highest possible electron flux through the SPEEL spectrometer. To accomplish this task, a new type of high performance SPEEL spectrometer has been designed for this particular experiment (Ibach *et al*., 2003). A sketch of the spectrometer is shown in Figure 2. The spectrometer consists of three main parts. In the first part, the spin-polarized electron beam is created by a strained GaAs photocathode (Pierce and Meier, 1976; Drescher *et al*., 1996). When hitting the sample, the spin direction of the incident electrons is parallel or antiparallel to the direction of magnetization of the sample. In the following, we will talk about $I_\uparrow(I_\downarrow)$ if the spin of the incident electron is parallel to the spin of a majority (minority) electron of the sample. The second part, the monochromator, consists of a premonochromator and a main monochromator with deflection angles of 90° and 180°, respectively. The third part of the spectrometer is the analyzer, which is a standard EELS monochromator with a deflection angle of 146° (Ibach, 1993; Ibach, Balden and Lehwald, 1996) followed by a channeltron as detector. The analyzer and the detector are mounted on an arm so that they can be rotated around the sample position in the scattering plane (Figure 2). The dimensions and a detailed description of the design of this SPEEL spectrometer are given in Ibach *et al*. (2003).

In the experiment, the spectrometer was used to measure the intensity of electrons scattered from the sample under a

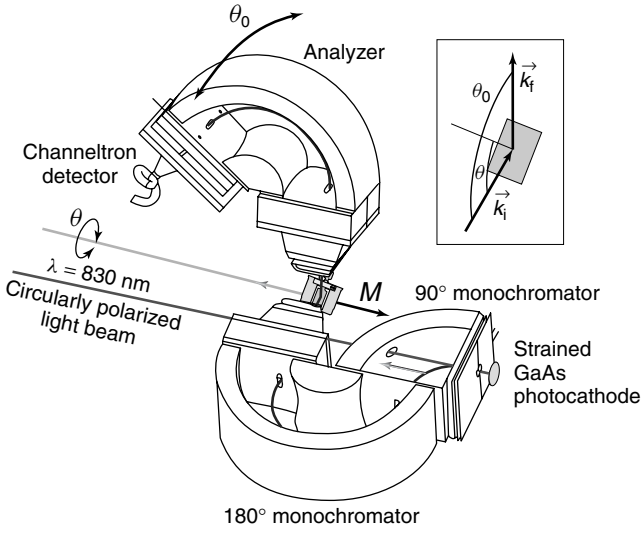

Figure 2. Sketch of the spectrometer under operation with a GaAs photocathode. The circularly polarized light excites a longitudinal spin-polarized electron beam from the cathode (the spin direction is shown by the arrow). After the electrons have traveled through the electrostatic monochromators, the beam is transversely polarized. Electrons having the proper energy then travel through the analyzer into the detector (The full path is shown as a solid line through the entire spectrometer). The inset illustrates the definition of the scattering angles θ and θ_0. (Reproduced from H. Ibach *et al*., 2003. © 2003 with permission from the American Institute of Physics.)

particular angle and with a certain energy transfer. For experimental reasons, the SPEELS measurements were performed in the 'constant wave-vector transfer mode', that is, for each scan, the wave-vector transfer is fixed by the scattering geometry and the electron intensity is measured as a function of the energy loss. The energy losses measured in the experiments are small compared to the primary kinetic energy $E^{\mathrm{i}}_{\mathrm{kin}}$ of the incoming electrons and hence $k_{\mathrm{i}} \approx k_{\mathrm{f}}$. Therefore, one can approximate the wave-vector transfer parallel to the sample surface to $\Delta K_{\parallel} \approx k_{\mathrm{i}}(\sin(\theta_0 - \theta) - \sin(\theta))$. All wave-vector transfers mentioned in the following are calculated within this approximation. Owing to the conservation of energy and momentum parallel to the surface in the scattering event, the measured intensity spectra comprise the information about the inelastic events that occurred in the scattering process.

As an example, Figure 3 illustrates the excitation of a spin wave as a scattering event. To excite a spin wave, energy, momentum, and magnetic moment have to be transferred to the sample. Both the energy and the momentum transfer are detected by the spectrometer and allow conclusions about the spin wave that was excited. Because the total magnetic moment has to be conserved in the scattering process, the excitation of spin waves is only possible if this conservation law is fulfilled. In a simple picture, the creation of a spin wave reduces the magnetization of the sample by $1\,g\mu_{\mathrm{B}}$. Therefore, the incoming electron has to be of $e_{\downarrow}$(minority) character to be able to excite a spin wave (as indicated in Figure 3b). Vice versa, the annihilation of a spin wave is only possible in the $e_{\uparrow}$ channel.

This selection rule can be used in the experiment to separate spin-wave excitations from other excitations. It is sufficient to have a spin-polarized incoming electron beam and a ferromagnetic sample with a defined magnetization direction parallel to the polarization axis. In this particular case, an energy loss caused by the excitation of spin waves is only possible for one spin direction of the incoming electrons and will appear only in $\mathrm{I}_{\downarrow}$. This

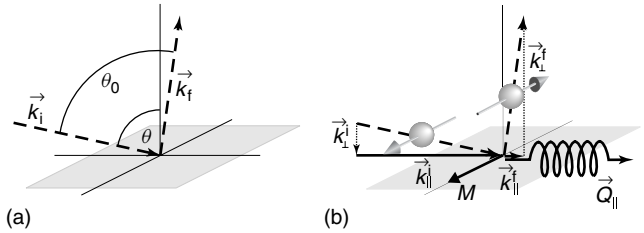

Figure 3. Schematic picture of an electron scattering process in which a spin wave is excited. θ_0 defines the angle between the incoming and outgoing electron path. θ is the angle between the surface normal and the incident beam. The wave-vector component parallel to the surface is conserved in the scattering process; the component perpendicular to it is not. (Note that, by definition, the spin and its magnetic moment point into opposite directions.)

circumvents the necessity of a 'complete' experiment with a spin analysis of the scattered electrons, which is an experimental challenge due to the notoriously inefficient detectors (Kirschner, 1985a).

1.2 Established experimental methods to study spin-wave excitations

Different experimental techniques are suited to study spin-wave excitations. In all scattering techniques (INS, BLS, and SPEELS), the approach to detect spin-wave signals is similar. A particle with known energy is scattered under defined conditions from a sample and is later analyzed with respect to its wave vector and energy transfer during scattering.

A recent example of high wave-vector and high-energy spin-wave excitations investigated by INS is shown in Figure 4 (Perring, Taylor and Squires, 1995). The experiments were performed on hcp Co using a time-of-flight technique. The peaks visible in the spectrum in Figure 4(a) are caused by energy losses due to spin-wave excitations with different wave-vector transfers in different Brillouin zones. The information measured in different Brillouin zones can be backfolded into the first Brillouin zone. The resulting dispersion relation is shown in Figure 4(b). In these measurements, the dispersion could be followed up to about $0.8\,\mathrm{\AA}^{-1}$, that is, about two-thirds of the Brillouin zone. The solid line is a fit to the data using a dispersion relation calculated from a nearest-neighbor Heisenberg model. A good agreement between the measured dispersion and this model was found (Perring, Taylor and Squires, 1995). The INS studies show a broadening of the spin-wave peaks due to itinerant effects. Nevertheless, the spin-wave losses were well defined up to the highest wave vectors investigated.

BLS and FMR are used to study spin waves with long wavelength ($Q_{\parallel} = 10^{-3}\,\mathrm{\AA}^{-1}$). Both techniques probe several similar properties of magnetic materials. They can determine the macroscopic magnetic quantities of a sample, for example, the anisotropy. In addition, in both techniques standing spin-wave modes perpendicular to the surface have been observed in films with thicknesses of several nanometers or thicker (Tannenwald and Weber, 1961; Grimsditch, Malozemoff and Brunsch, 1979). This leads to the possibility to study spin waves with higher wave vectors, up to $q_{\perp} \approx 10^{-2}\,\mathrm{\AA}^{-1}$ (Hillebrands and Ounadjela, 2002).

1.3 Spin waves within the Heisenberg description

The spin-wave dispersion relation for high wave vectors is determined by contributions of the exchange interaction. This interaction can be considered in the Heisenberg model of localized magnetic moments. This description is not expected

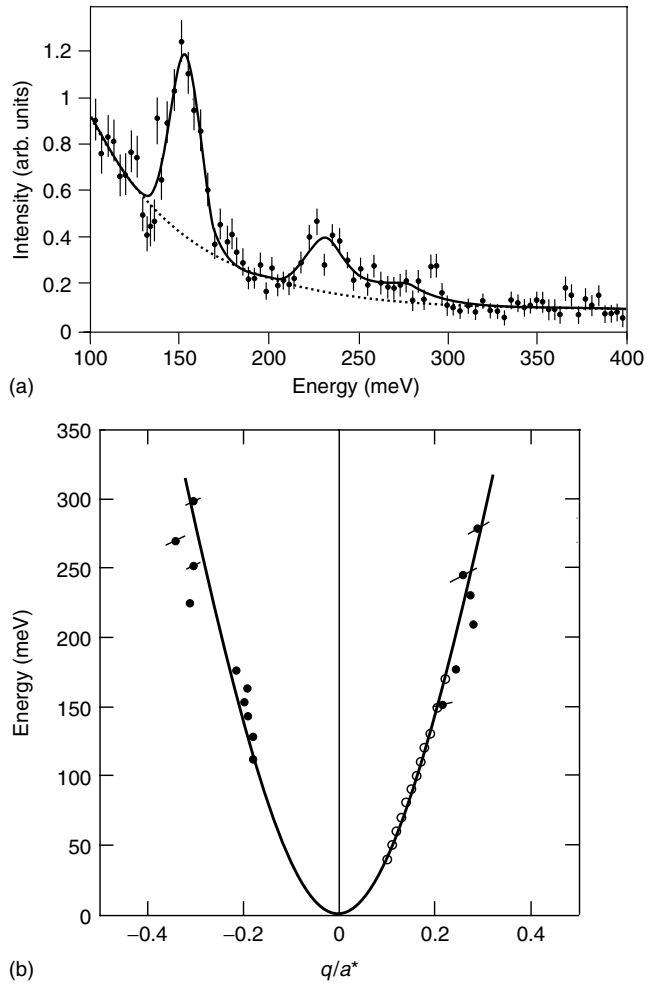

Figure 4. (a) Example of recent neutron scattering measurements of spin-wave excitations in hcp Co (Perring, Taylor and Squires, 1995). The left side shows a time-of-flight spectrum, transformed back into energy space (for details see Perring, Taylor and Squires, 1995). In (b) the resulting spin-wave dispersion is shown. The wave vector is normalized in this graph so that the Brillouin zone boundary is at $q/a^* = 0.5$. The solid line is a fit obtained by a nearest-neighbor Heisenberg model. (Reproduced from Perring *et al.*, 1995. © 1995 with permission from Elsevier.)

to be truly valid for the mobile conduction electrons, which carry the magnetic moments in 3d metals; however, it provides a simple description of the underlying physical properties.

Using the Heisenberg Hamiltonian:

$$H = -\sum_{ij} J_{ij} S_i \cdot S_j \tag{1}$$

the spin-wave dispersion can be calculated. Here, J_{ij} is the exchange-coupling constant between the magnetic moments S_i and S_j. It was found by Bloch that the Heisenberg Hamiltonian allows low-energy collective excitations of spins (Bloch, 1930, 1932). These spin waves are transverse fluctuations of the magnetic moment. As an approximation, a small angle of precession is assumed. In other words, each magnetic moment is only a little tilted out of its equilibrium position. For simplicity, we will consider only nearest-neighbor exchange interactions and a constant value of J and S (not depending on the position, i.e., equal at the surface, interface, and bulk). By considering the exchange interaction as torque acting on each magnetic moment, one obtains the equation of motion from equation (1)

$$i\hbar \frac{\mathrm{d}S_i^+}{\mathrm{d}t} = 2JS \sum_j \left[S_i^+ - S_j^+ \right] \tag{2}$$

For thin films, it is useful to consider solutions in the form of waves in the film plane,

$$S_i^+ = A_i \mathrm{e}^{i(Q_\parallel (R_i - \omega t))} \tag{3}$$

Here A_i is the amplitude of the spin wave at position R_i, $Q_\parallel$ is the wave vector parallel to the surface, and ω is the angular frequency of the spin wave. From this, we find that

$$\hbar\omega A_i = 2JS \sum_j \left[A_i - A_j e^{i(Q_\parallel (R_j - R_i))} \right] \tag{4}$$

This equation can be used as a starting point to derive the spin-wave dispersion in an arbitrary crystalline structure.

For the direction perpendicular to the surface two types of solutions are possible. One is a surface spin-wave mode that has an excitation amplitude, which decays exponentially into the bulk $A_{n+1} = A_n e^{-\alpha \frac{a_0}{2}}$. For the following it is interesting to note that the decay factor α for the surface spin-wave amplitude depends on $Q_\parallel$. The surface localization of the surface spin-wave mode increases with $Q_\parallel$ and is highest at the surface Brillouin zone boundary. The other solutions are bulk spin-wave modes, here $A_{n+1} = A_n e^{iq_\perp \frac{a_0}{2}}$ where $q_\perp$is the wave vector perpendicular to the surface.

For a semi-infinite system, one thus obtains a continuum of bulk modes and one surface mode for each given $Q_\parallel$. For example, the spin-wave dispersion for the surface mode for an face centered cubic (fcc) semi-infinite crystal with (001) surface along the (110) direction calculated from equation (4) is given by

$$\hbar\omega = 8JS \left[1 - \cos\left(Q_\parallel \frac{a_0}{\sqrt{2}} \right) \right] \tag{5}$$

In the experiments shown later, the films under investigation were only a few atomic layers thick. This can be taken into account by considering a slab of n layers with two surfaces. The introduction of a second surface leads to two

surface modes in the system, one acoustic (i.e., the spin-wave energy vanishes as q approaches 0) and one optical surface mode. In addition to the two surface modes, $n-2$ dispersion relations are obtained that belong to modes having a wave-like character perpendicular to the surface (standing waves), that is, of 'bulk' modes.

The results of the above calculations for an 8 ML fcc slab and an fcc semi-infinite crystal are shown in Figure 5(a). In Figure 5(b), the dispersions obtained from similar calculations for hexagonal closed packed (hcp) Co are presented. These systems have been chosen because both have been investigated and are discussed in the following text. The only free parameter in these calculations is the value of JS. For the two dispersions shown, we have chosen $JS = 15$ meV. The eight dispersions of the spin waves in the slab are represented by solid lines. The two surface modes of the slab calculations are the lowest energy branches of the eight modes. The acoustic mode of the surface spin wave of the 8 ML slab falls on a line with the surface spin-wave mode of the semi-infinite crystal. Noticeable differences between both of these surface modes appear only for very thin slabs, as discussed later. The above derivation of the spin-wave dispersions has been done in a classical description. Though the quantum-mechanical derivation is more appropriate, the spin-wave dispersion is one of the cases where both descriptions yield exactly the same results (Nolting, 1986).

The spin-wave energy of the acoustic branch at small wave vectors can be approximated by

$$\hbar\omega = 2JS\,a_0^2 Q_\parallel^2 = D\,Q_\parallel^2 \tag{6}$$

Here, D is the so-called spin-wave stiffness. In many experiments, the wave-vector transfer is limited to small values so that the equation (6) is valid. In these cases, the quantity published in literature is typically the spin-wave stiffness.

The Heisenberg model is valuable, especially because of its simplicity. It has already been mentioned that it is not expected to be applicable to an itinerant electron system. Nevertheless, we will see later that several of our results are described surprisingly well within this model. Other findings, however, can only be understood in an itinerant electron description. Therefore, in the following, an introduction to magnetic excitations in an itinerant electron model is given, with emphasis on the differences to the results mentioned in the preceding text.

1.4 Magnetic excitations in itinerant electron ferromagnets

In the 3d-magnetic metals, the conduction electrons that are the carriers of magnetic moments cannot be considered as localized at a particular position, but as itinerant. The discussion of magnetism in such itinerant electron systems goes back to Stoner (1936, 1938). Magnetic order results in an exchange splitting of the electron bands, which causes a higher occupation of states for electrons of one spin direction (majority electrons) compared to the other spin direction (minority electrons).

The magnetic excitations allowed in the model are the so-called Stoner excitations. The original Stoner model overestimated the Curie temperature for magnetic order substantially, because no collective spin excitations were taken into account. This led to an overestimation of the minimum energy for magnetic excitations. The consideration

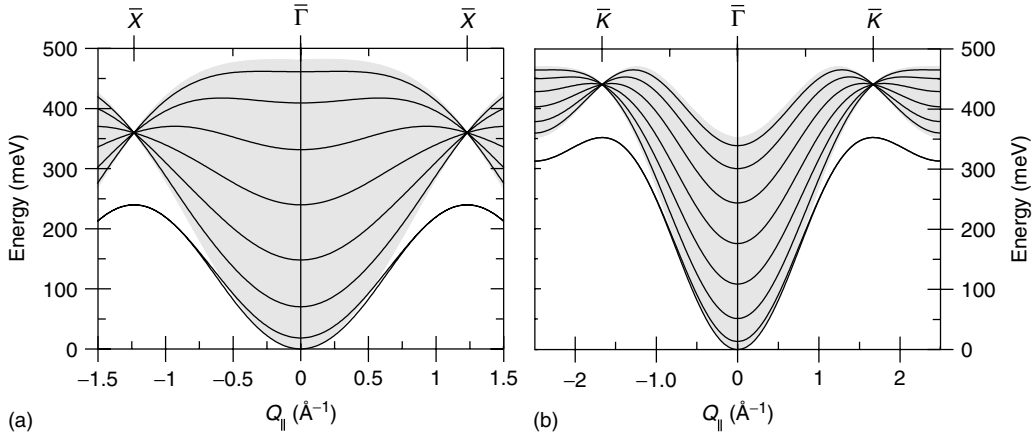

Figure 5. Spin-wave dispersions calculated within a nearest-neighbor Heisenberg model as a function of $Q_\parallel$ for an 8 ML slab (solid lines) and a semi-infinite crystal (gray area). In (a) calculations have been performed for an fcc crystal with a (001) surface and in (b) for a hcp crystal with a (0001) surface. In these calculations $JS = 15$ meV. The symbols on the top axis mark the important points in the surface Brillouin zone.

of low-energy collective excitations within the itinerant electron model is needed to describe the experimentally observed Curie temperature. Collective excitations were introduced by Slater (1937) for an itinerant electron system in which all electron spins in the system are of majority character except for one. He found that the lowest energy magnetic excitations of such a system are of collective nature. This state can be described by the superposition of single particle states and represents the correlated motion of the spin-reversed electron and the hole it left in the sea of aligned electrons (Martin, 1967). It was found that its properties are similar to the spin-wave excitations in the localized model (Slater, 1937). The extension of the model derived by Slater to more realistic itinerant metals has been performed by Herring and Kittel (1951) and Herring (1952). The general finding is that collective excitations exist in an itinerant electron system and that they have similar properties compared to the well-defined spin waves in a localized model in the limit of low wave vectors and low energies. For example, in this limit a quadratic dispersion relation of these excitations was found (Herring and Kittel, 1951), as in the Heisenberg model (see equation (6)). At high wave vectors and energies, Stoner excitations are possible in itinerant electron systems. A correlated electron–hole pair that is created in the region where Stoner excitations are possible can easily decay into such uncorrelated states. Therefore, in the region in which Stoner excitations are possible, the collective excitations are not well-defined long-living spin waves, but they are strongly damped (Herring, 1966). The general concept of magnetic excitations in itinerant ferromagnets is summarized in Figure 6.

As a simple, one-dimensional example, in Figure 6(a) one pair of exchange split bands is shown. The exchange splitting is assumed to be identical to U over the entire Brillouin zone. The majority band lies completely below E_F to represent a strong ferromagnet. The energy and wave-vector transfer needed to excite a Stoner excitation of an electron from an occupied majority state to an unoccupied minority state is shown in Figure 6(b) as a gray area. For strong ferromagnets, the minimum energy for Stoner excitations, the Stoner gap Δ, is given by the distance between the majority band and E_F. A possible acoustic spin-wave branch is also shown in Figure 6(b) as a black line. When the spin-wave branch enters the Stoner continuum it is strongly damped. This range of the dispersion is presented as a dotted line. The real physical situation is only partly described by Figure 6. For example, realistic band structures consist of more than one band, and s bands of both spin characters cross the Fermi edge so that no true overall Stoner gap exists. In our studies, we investigate spin waves at surfaces by electron scattering. In this case, additional effects have to be considered. It has been theoretically predicted that in inelastic electron scattering experiments, the creation of free electron like Stoner excitations is as probable as a creation of d-electron Stoner excitations (Penn and Apell, 1988); the calculations have been performed for Fe; however, it can be assumed that similar effects may also occur in Co. In addition, at the surface the wave vector perpendicular to the surface has not been conserved owing to the loss of translational invariance. Both considerations lead to drastic changes compared to what has been shown in Figure 6. Large parts of the Stoner excitation free area for $Q_\parallel$ are then filled owing to possible excitations having a finite $q_\perp$ (Tang, Plihal and Mills, 1998).

With the advance of theory, it became feasible to calculate the above described magnetic excitation spectrum in bulk itinerant ferromagnets on the basis of *ab initio* calculations (Savrasov, 1998). Such calculations, however, have not been made for surfaces and thin films. Other approaches are used, starting from an *ab initio* calculation of the underlying band structure. One frequently used approach is based on the adiabatic approximation, in which the electron motion is decoupled from the spin motion (see, e.g., Katsnelson and Lichtenstein, 2000; Frota-Pessôa, Muniz and Kudrnovský, 2000; Halilov, Eschrig, Perlov and Oppeneer, 1998; van Schilfgaarde and Antropov, 1999; Pajda *et al*., 2000; Grotheer, Ederer and Fähnle, 2001; Udvardi, Szunyogh, Palotás and Weinberger, 2003; and references therein). Therefore, the damping of spin waves by Stoner excitations is not taken into account. As discussed in the preceding text, this is a good approximation in itinerant electron systems only in the limit of low wave vector and low-energy spin waves. In principle, these calculations map the itinerant ferromagnetism onto a Heisenberg like description. Several publications gave values for the exchange-coupling constants derived this way (Pajda *et al*., 2000; Grotheer, Ederer and Fähnle, 2001; Razee, Staunton, Szunyogh and Györffy, 2002).

The other approach goes beyond the adiabatic approximation. This is a nontrivial extension of the model using the adiabatic approximation, because one has to take into account the full dynamics of the system (Cooke, Blackman and Morgan, 1985; Blackman, Morgan and Cooke, 1985; Trohidou, Blackman and Cooke, 1991; Bass, Blackman and Cooke, 1992; Tang, Plihal and Mills, 1998; Plihal, Mills and Kirschner, 1999; Hong and Mills, 2000a; Muniz and Mills, 2002; Muniz, Costa and Mills, 2003; Costa, Muniz and Mills, 2003, 2004a,b). This description includes the damping of spin waves caused by Stoner excitations and therefore this theory is expected to be valid throughout the Brillouin zone. So far, these calculations were only possible using an empirical tight binding description of the underlying band structure (Trohidou, Blackman and Cooke, 1991; Tang, Plihal and Mills, 1998; Hong and Mills, 2000a; Costa, Muniz and Mills, 2004a). In a recent series of publications, Mills and coworkers applied this theory to magnetic thin films of

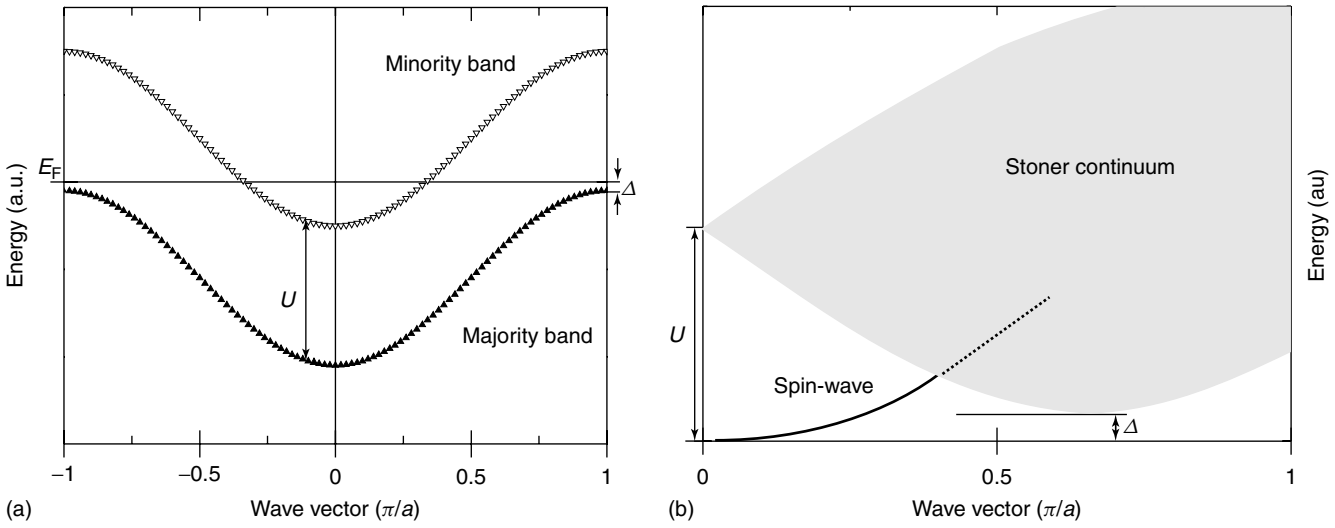

Figure 6. (a) Pair of exchange split bands with the majority band completely below the Fermi energy E_F (by the amount Δ) to represent a strong ferromagnet. The exchange splitting parameter U is assumed to be constant in the entire Brillouin zone. (b) The gray region shows the low-energy part of the Stoner spectrum calculated for the band shown in (a). At $q = 0$ the creation of a Stoner excitation costs an energy which is equal to U. The minimum energy of the Stoner excitations is equal to Δ and is located at some higher wave vector. To give a general idea, a possible spin-wave dispersion (not calculated from the bands shown in (a) is included in (b)).

Fe, Ni, and Co (Plihal and Mills, 1998; Plihal, Mills and Kirschner, 1999; Hong and Mills, 2000a; Muniz and Mills, 2002; Muniz, Costa and Mills, 2003; Costa, Muniz and Mills, 2003, 2004a,b). These calculations showed that the damping of spin waves caused by Stoner excitations is strong in these films. As shown in the last section, within the Heisenberg model one expects as many spin-wave modes at a given $Q_\parallel$ as layers are contained in the film. In the itinerant electron theory that goes beyond the adiabatic approximation, this picture changes drastically. Instead of a number of discrete modes each of zero width, the theoretical calculations show only one broad feature (Costa, Muniz and Mills, 2003, 2004a). This arises from the strong damping and smearing of the different modes. They overlap and can hardly be distinguished from each other (Costa, Muniz and Mills, 2004b).

In this section, two different theoretical concepts of magnetism have been introduced, in which high wave-vector spin waves show a different behavior. In the following, we will concentrate on spin waves in 3d metals, in which the electrons that carry the magnetic moments have itinerant character. Nevertheless, we will discuss our results to some extent in a nearest-neighbor Heisenberg model. Of course, several questions concerning the validity of such a description arise. As discussed in the preceding text, high wave-vector spin waves in this system are expected to be heavily damped. It is expected that this damping not only influences the spectral shape of the spin waves but also effects the dispersion (Costa, Muniz and Mills, 2004b). In addition, a questionable assumption is that only nearest-neighbor interactions are included in our calculations. As is shown later, it seems possible to take some of the above-mentioned criticism into account by an effective nearest-neighbor exchange-coupling constant in the Heisenberg model.

2 EXPERIMENTAL RESULTS

In this section, results of investigations of spin waves by SPEELS are presented. As model examples, the systems fcc Co on Cu(001) and hcp Co on W(110) are discussed. Some of the experimental capabilities of the SPEELS technique are demonstrated using these systems. In addition, some results obtained on tetragonal distorted Fe on Co/Cu(001) are mentioned.

2.1 SPEELS measurements of Co on Cu(001) and Co on W(110)

Figure 7 shows some representative SPEEL spectra of $I_\uparrow$ and $I_\downarrow$ measured on 8 ML fcc Co on Cu(001) (a) and on 8 ML hcp Co on W(110) (c). For the SPEELS measurements of fcc Co on Cu(001), the [110] direction of the Cu crystal was oriented parallel to the scattering plane. Thus, the measured wave-vector transfer was along the $\overline{\Gamma} - \overline{X}$ direction in the surface Brillouin zone (see inset Figure 7b). The magnetization direction of the Co film was perpendicular to the scattering plane, along $[1\overline{1}0]$, if not quoted otherwise.

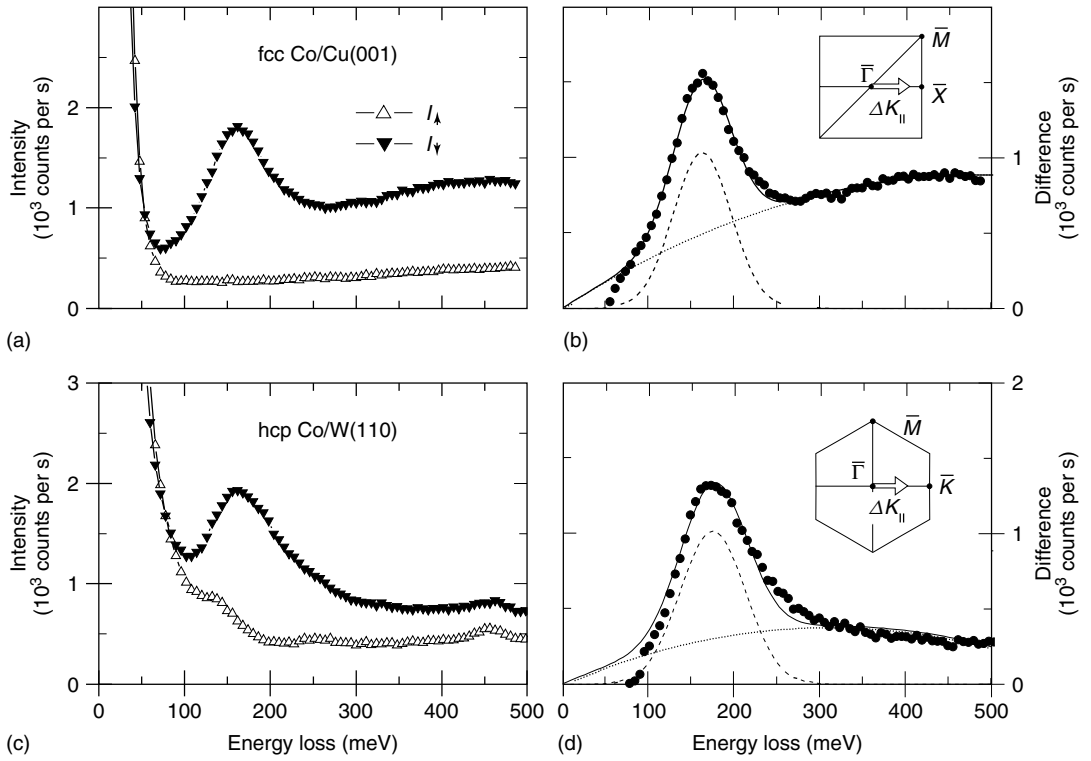

Figure 7. SPEEL spectra of $I_\uparrow$ and $I_\downarrow$ measured on 8 ML fcc Co on Cu(001) (a) and on 8 ML hcp Co on W(110) (c). The spectra have been recorded at a wave-vector transfer of $\Delta K_\parallel = 0.78\,\text{Å}^{-1}$. In Figure 7(b/d) the difference spectra of (a/c) are shown. The solid curves show fits of the difference spectra (see text for details). The insets give the reciprocal space representation of the fcc Co(001) and hcp Co(0001) surface, respectively. The arrows in the insets mark approximately the position of the wave vector at which the spectra were recorded. For the spectra in (a) $E_{\text{kin}} = 7\,\text{eV}$ and $\theta_0 = 90^\circ$ and in (c) $E_{\text{kin}} = 4\,\text{eV}$ and $\theta_0 = 80^\circ$. The energy resolution in these scans was $\Delta E \approx 40\,\text{meV}$.

For the measurements of hcp Co on W(110), the scattering plane was chosen along the Co[11$\bar{2}$0] axis, which is parallel to the W[001] axis. This corresponds to the $\overline{\Gamma} - \overline{K}$ direction in the reciprocal space (see inset Figure 7d).

All spectra plotted in Figure 7 have been recorded at a wave-vector transfer of $\Delta K_{||} = 0.78\,\text{Å}^{-1}$, which corresponds approximately to the reciprocal space position pointed out by the arrows in the insets of Figure 7(b/d). The solid and open triangle symbols mark the measured intensities of $I_\downarrow$ (incoming electron spin of minority character) and $I_\uparrow$ spectrum (incoming electron spin of majority character), respectively. The intensities of these as well as the following spectra have been corrected for the incomplete spin polarization of the incident electron beam (which has been determined in an independent scattering experiment to 0.79 ± 0.1 in this case). In the $I_\downarrow$ spectra, a prominent loss feature centered at about 170 meV is visible. This peak is caused by the excitation of spin waves by the inelastic scattering of electrons, as shown in the following text. In the spectra measured on hcp Co (Figure 7c) additional loss features show up in both spin channels. These can be attributed to the (almost) spin independent scattering processes of vibrational excitations of small amounts of adsorbates as discussed in more detail later.

As can be seen in Figure 7(a/c), the energy loss around 170 meV is only present in the $I_\downarrow$ spectra. This spin-selective excitation can be understood on the basis of the considerations given in the previous section. Since the total magnetic moment is conserved during the scattering process, the incoming electron has to transfer its spin magnetic moment to the crystal to reduce the magnetic moment of the latter. The incident electron has to have minority spin character and the outgoing electron, majority spin character to excite a spin wave and to fulfill the conservation law. Thus, this scattering event is only possible for an incoming electron of minority spin character. This spin-selective excitation process is a fingerprint of spin-wave excitations. Its unique character can be used to improve the spin-wave signal-to-background ratio by looking at the difference spectrum $(I_\downarrow - I_\uparrow)$. The difference spectra obtained from the spectra in Figure 7(a/c) are plotted in Figure 7(b/d). Assuming a spin-wave peak and a background of electron–hole pair excitations we are able to describe the difference spectra. The spin-wave peak is described well by a Gaussian peak and the

background with a second-order polynomial. The resulting fit curves of the spectra are presented in Figure 7(b/d) as solid lines. The two contributions for the spin wave and the background are indicated separately dashed and a dotted line, respectively. The energy resolution for the spectrometer in this scan was $\Delta E \approx 40$ meV full-width at half-maximum (FWHM) and the peak width of the spin-wave signal is about 75 meV (FWHM) for fcc Co and about 90 meV for hcp Co. The measured width is, therefore, not determined by the spectrometer resolution, but the loss features have an intrinsic width (Vollmer *et al*., 2003; Etzkorn *et al*., 2005).

The background is caused by the excitation of electron–hole pairs, which can be assumed to be partially Stoner excitations. Beside the spin-wave excitations, the electron–hole pair excitation processes also depend on the spin direction of the incident electron. It is known that both $I_\downarrow$ and $I_\uparrow$ contain spin flip and nonspin flip processes of electron–hole pair excitations (Hopster, Raue and Clauberg, 1984; Kirschner, Rebenstorff and Ibach, 1984; Kirschner, 1985b; Abraham and Hopster, 1989; Hopster and Abraham, 1989; Kämper, Abraham and Hopster, 1992). The intensity in the different spin channels can often be explained by the spin dependent density of occupied and unoccupied states. In the spectra, Stoner excitations appear as a broad feature with loss energies ranging from very low energies up to several electronvolts. Only little structures as a function of the loss energy have been observed. One study of Stoner excitations using a 'complete' experiment was performed on Co on Cu(001) (Kämper, Abraham and Hopster, 1992). It was found that all the four spin channels contribute strongly to the intensities at energy losses higher than 300 meV. The energy resolution in these experiments was about 300 meV so that the measurements below this loss energy are difficult to interpret. If one assumes that all spin channels contribute to the background also in the low-energy loss range, a significant amount of Stoner excitations should be possible in the energy range of spin-wave excitations. Thus, the damping of the spin waves due to the decay into these Stoner excitations provides a likely explanation for the measured spin-wave width.

Figure 7(a/c) displays the count rate in electron counts per second. The spin-wave intensity measured under these scattering conditions (for details, see figure caption) is about 1.5×10^3 counts per second using a flux of the incident electron beam of the order of 20 nA, that is, $\approx 10^{11}$ electrons per second. With this, the spin-wave intensity is of the order of a few percent of the elastically scattered electron intensity. These high intensities allow relatively short measuring times. The spectra shown in Figure 7(a/c), for example, were measured in about 30 min, only.

The spin-wave energy and shape are rather similar for both spin-wave loss features measured on the two crystalline Co phases (Figure 7), but the background of electron–hole pair excitations is different for the two. Another aspect is the varying amount of vibrational losses present in the spectra. More and stronger vibrational losses caused by small amounts of contaminations (residual gas adsorbed at the surface) are visible in the spectra measured on Co on W(110), though the vacuum conditions were similar in both studies. In the spectra shown in Figure 7(c), the vibrational loss features can be attributed to an H-metal vibration (140 meV) and probably to an H_2O vibration (450 meV). The energy values are in agreement with literature values (Ibach and Mills, 1982). The H vibration was cross-checked by additional adsorption studies. From these adsorption studies, it is also possible to estimate the amount of adsorbates. The H-loss peak in Figure 7(c) corresponds to about 10% of the saturation coverage.

To test the magnetic origin of the spin dependent excitation of the spin-wave loss feature, we use a fundamental symmetry argument. An important consequence of the spin-selective excitation of spin waves is that when the magnetization of the sample is reversed, the peak of the spin-wave loss feature should appear in the 'opposite' spin channel. This is simply because the definition of majority and minority spin reverses. The proof of the magnetic origin of the loss feature is shown in Figure 8. Here, two spectra were measured under identical conditions, except that the sample magnetization was reversed. The spectra indicated with M are measured on a Co film, which had the 'normal' direction of the magnetization. In this case also the normal notation of majority and minority spin character is used. These spectra are presented as triangles and solid circles for the difference. The star symbols in Figure 8(a) and the open circles in Figure 8(b) show the spectra measured on the reversely magnetized Co film ($-M$). For these spectra, the notation majority and minority might be confusing. Therefore, the spectra are assigned as 'the same' channel. The spin direction of the incident electrons (not with respect to the sample magnetization) was the same for the spectra with open and solid symbols in Figure 8(a). The main result of these measurements is that by reversing the magnetization of the sample, the spectra measured for the two incoming spin directions interchange almost ideally. This holds true, in particular, for the spin-wave feature. Thus, we have proved that the spin-selective excitation is of magnetic origin, as expected for a spin-wave excitation. In addition, scattering contributions to this spectra caused by spin-orbit coupling (that do not change the sign upon magnetization reversal) are seen to be negligible in this case. Since the spin-orbit contributions are small, as expected for 3d metals, they will not be considered here.

Another important characteristic of spin waves is their dispersion. Since the measured loss features are attributed

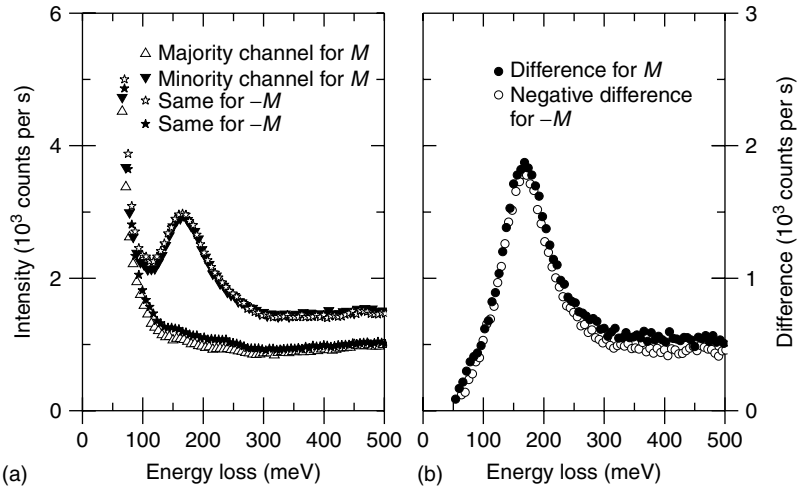

Figure 8. Comparison between SPEEL spectra and their differences measured on oppositely magnetized films. Both measurements were taken on 8 ML Co on Cu(001), with $\Delta K_{\parallel} = -0.81\,\text{Å}^{-1}$, $E_{\text{kin}} = 7\,\text{eV}$, and $\theta_0 = 90^{\circ}$. In the measurements marked with M the magnetization lies in the 'normal' direction, along $[1\bar{1}0]$ (triangles and solid dots). For the measurements labeled as $-M$, the magnetization was rotated by 180° (stars and open dots). Note that for the difference spectrum recorded with $-M$, the negative difference is shown.

to a spin wave, they should move to higher energies for higher wave-vector transfers, assuming an acoustic spin-wave branch.

In Figure 9, SPEEL spectra measured on an 8 ML Co film on Cu(001) at different wave-vector transfers are presented. Here, the measured intensity at each energy loss was divided by the intensity of the elastically scattered electrons to obtain the normalized intensity. Figure 9(a/b) show the normalized intensities for negative and Figure 9(c/d) for positive wave-vector transfers. For low absolute values of the wave-vector transfer, the spin-wave losses appear as a shoulder in the elastic peak. For higher wave-vector transfers, the spin-wave loss feature shifts to higher loss energies as a result of its dispersion.

So far, the presented results were measured on 8 ML Co. Because of the short mean free path of low-energy electrons, this can be considered as a relatively thick film for such an experiment. SPEELS measurements on thinner Co films have been made to investigate the influence of reduced dimensions on the spin waves and to test the capabilities of this method (Etzkorn *et al*., 2004). As an example, SPEEL spectra measured on 5 ML and on 2.5 ML Co films on Cu(001) are shown in Figure 10(a/b) and (c/d), respectively. It is obvious that even for 2.5 ML Co, the spin-wave loss features are clearly visible in the spectra, though the spin-wave intensities are reduced (note that the normalized intensity scales for the two film thicknesses differ by a factor of 2). From the measured signal-to-noise ratio, one may speculate that it should be possible to investigate spin-wave excitations by SPEELS in submonolayer quantities of magnetic films. Beside the spin-wave signal, other loss features are present in the spectra, especially in the spectra of 2.5 ML Co. These losses were excited for both spin directions of the incoming electrons and do not show dispersion. They can be attributed again to vibrational losses caused by traces of adsorbates on the surface. Mainly a loss feature at about 230 meV is visible, which can be assigned to CO vibrations (Ibach and Mills, 1982). We have confirmed this by additional adsorption studies, too.

In the SPEEL spectra given in Figures 9 and 10, a clear dispersion of the spin-wave peak is visible. From these spectra, one can determine the energy position of the spin waves as a function of the wave-vector transfer. The resulting dispersion curves are presented in Figure 11. Additional data have been measured at and beyond the Brillouin zone boundary ($\overline{X}$). They are also plotted in Figure 11 to confirm that the measured spin-wave dispersion obeys the periodicity of the surface Brillouin zone.

In the previous section, the spin-wave dispersion within a nearest-neighbor Heisenberg model was calculated for a semi-infinite fcc crystal along the $\overline{\Gamma} - \overline{X}$ direction. The resulting dispersion relation of the surface spin-wave mode was given in equation (5). We have fitted this dispersion relation to the measured data for 8 ML Co on Cu(001). The result is plotted as a solid line in Figure 11. A surprisingly good agreement is found between the experimental data and the calculated dispersion of the surface spin-wave mode. Note that the shape of the calculated dispersion is fully determined by the crystalline structure and geometry of the system. The only fit parameter used in this model is the product of the exchange-coupling constant and the magnetic moment (JS). It defines the amplitude of the dispersion, in

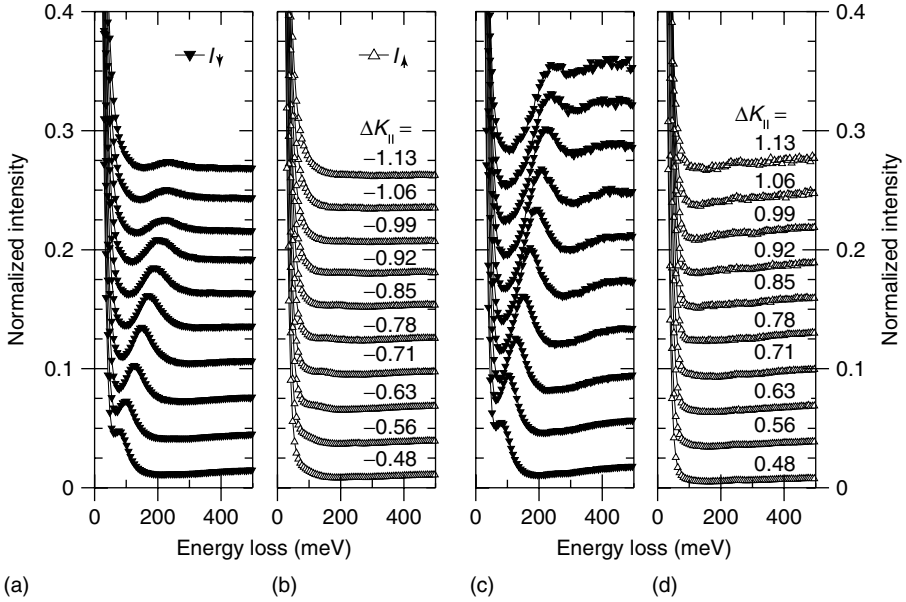

Figure 9. SPEEL spectra of 8 ML Co on Cu(001) with $E_{\text{kin}} = 6.5\,\text{eV}$ and $\theta_0 = 90^\circ$, taken at different wave-vector transfers, which are indicated by the numbers above the spectra. In (a/b) the spectra for negative and in (c/d) the spectra for positive wave-vector transfers are presented. All intensities are normalized with respect to the intensities of their elastic peaks. Each adjacent spectrum has an offset of 0.025 (one minor tick) to allow a better comparison.

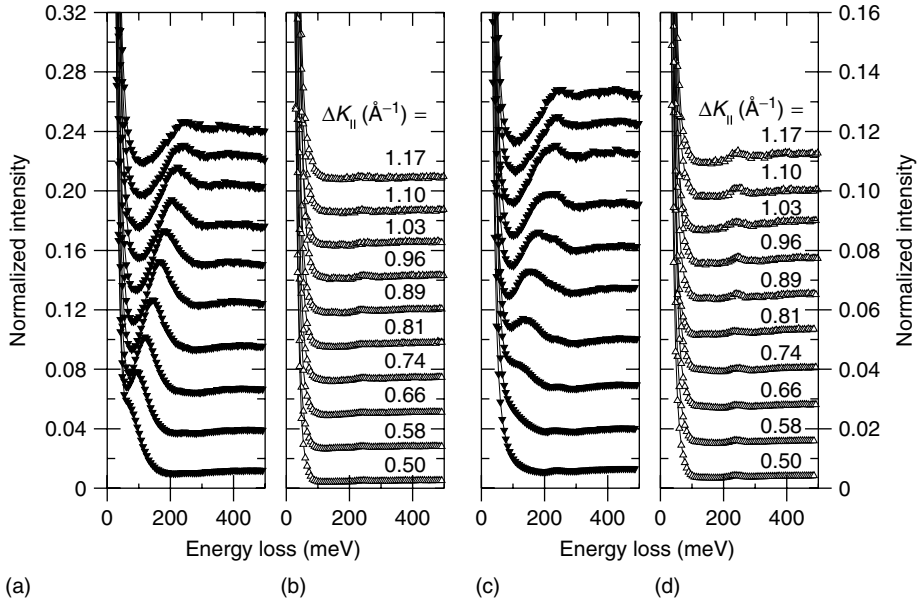

Figure 10. SPEEL spectra measured on 5 ML (a/b) and 2.5 ML (c/d) Co films on Cu(001). The numbers above the spectra indicate the different wave-vector transfers. The intensities are normalized to the intensity of the elastic peaks. Each adjacent spectrum has a vertical offset of 1/16 of the total scale (one minor tick) to allow better comparison. All spectra were taken with $E_{\text{kin}} = 7\,\text{eV}$ and $\theta_0 = 90^\circ$.

other words, the spin-wave energy at the surface Brillouin zone boundary. The value of JS resulting from the fit shown in Figure 11 is $JS = 15 \pm 1\,\text{meV}$. This value is in perfect agreement with the value of $JS = 14.7 \pm 1.5\,\text{meV}$ which was obtained by neutron scattering experiments for bulk spin waves in fcc Co (with 8% Fe to stabilize the fcc phase at room temperature) (Sinclair and Brockhouse, 1960; Pickart *et al.*, 1967).

At first glance, the dispersions of the three different film thicknesses are similar. A closer look, however, reveals

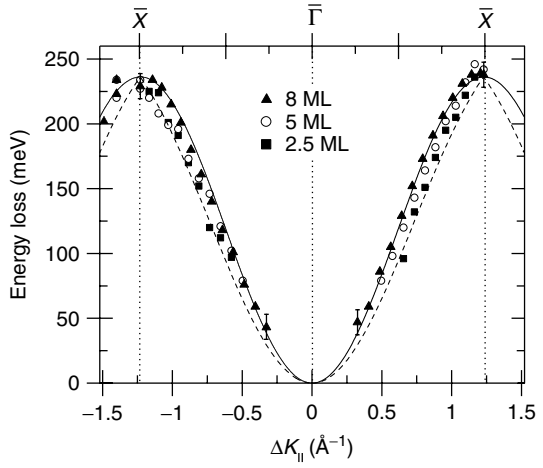

Figure 11. Spin-wave dispersion for 8, 5, and 2.5 ML Co on Cu(001) measured by SPEELS. The data points represent the energy position of the maximum of the spin-wave peaks, as determined from the data presented in Figures 9 and 10. The solid and the dashed lines are dispersions of the surface spin-wave mode calculated within a nearest-neighbor Heisenberg model with $JS = 15$ meV for a semi-infinite film and a 2 ML slab, respectively. Measurement with wave vectors at $\overline{X}$ and at $\Delta K_{\parallel} = -1.40\,\text{Å}^{-1}$ were taken with $E_{\text{kin}} = 7$ eV and $\theta_0 = 80^{\circ}$. The data point at $\Delta K_{\parallel} = -1.49\,\text{Å}^{-1}$ was taken with $E_{\text{kin}} = 8$ eV and $\theta_0 = 80^{\circ}$.

that there are small but noticeable differences between the dispersions of the different films. Although there is some scattering in the data, a clear tendency is visible that the spin-wave energies are reduced for thinner films for wave vectors not too close to the surface Brillouin zone boundary. Close to the surface Brillouin zone boundary, the spin-wave energies are independent on the thickness within the error bars. As a comparison, the calculated dispersion relation of the surface mode of a 2 ML slab is added in Figure 11 as a dashed line. For this calculation, we used a value of $JS = 15$ meV, again. For intermediate wave vectors, the calculated spin-wave energies for the 2 ML slab lie below that for an 8 ML slab (or the semi-infinite crystal). At the surface Brillouin zone boundary, however, both curves meet. This behavior describes the experimental findings very well. Although JS is the same, the calculated dispersions are different because of the surface localization of a surface spin-wave mode and the reduced thickness of the slab. The surface localization increases with increasing wave vector of the spin waves. In the nearest-neighbor Heisenberg model, the spin wave is completely localized in the surface layer at the surface Brillouin zone boundary. Since the interactions in the model are limited to the nearest neighbors, it does not make any difference for $\overline{X}$ whether the film is only 2 ML thick or semi-infinite. For lower wave vectors, the spin wave is less localized at the surface and therefore the absence of magnetic atoms below the second layer in the slab configuration reduces the spin-wave energy.

A compact representation of the main results on spin-wave excitations obtained by SPEELS measurements is a contour plot of the measured intensity of the spin waves as a function of the wave vector and energy transfer. Figure 12 shows such a contour plot of the spin-wave losses obtained from the spectra shown in Figure 9 that were measured on 8 ML fcc Co on Cu(001). The plotted intensities show the difference of the $I_{\downarrow}$ and $I_{\uparrow}$ spectra after the subtraction of the electron–hole pair background. Here, the lines connect points of equal spin-wave intensities in energy and wave-vector space. They are interpolated linearly between the measured points. The underlying grid represents the density of the measured data points.

The contour plot allows one to follow how the spin-wave excitations evolve in the spectra with increasing wave-vector transfers. For low wave vectors, the spin-wave losses start as an intense and relatively narrow feature and they end as low intensity broad humps at high wave vectors. The dispersion derived from the nearest-neighbor Heisenberg model for $JS = 15$ meV is added as a solid line in Figure 12. As already shown, this dispersion matches the measured dispersion well (compare also Figure 11). Deviations between the

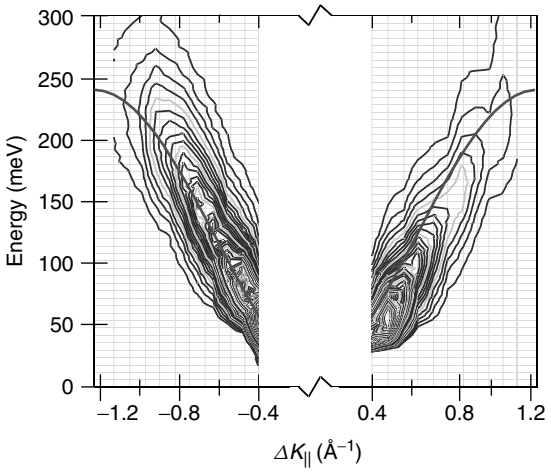

Figure 12. Contour plot of the spin-wave intensities measured by SPEELS. The graph represents the difference spectra measured on 8 ML Co on Cu(001) from which the background of electron–hole pair excitations were subtracted. The original spectra were shown in Figure 9. The contour lines connect points of the same intensity. Between the measured points, the intensity was linearly interpolated. The density of the measured data is illustrated by the underlying grid. Between adjacent dark (light) gray contour lines the intensity changes by 200(1000) counts/second. The outermost contour line marks the intensity of 200 counts per second. The thick solid line represents the surface spin-wave dispersion derived from the nearest-neighbor Heisenberg model for $JS = 15$ meV (see also Figure 11).

experimental data and the calculated dispersion occur mainly for high wave vectors on the negative wave-vector side. In this region, these deviations can be partially attributed to the underestimation of the (subtracted) background of electron–hole pair excitations by the fitting routine (see also Figure 7).

One should note that the interpretation of this graph is rather difficult. For example, the excitation mechanism of the creation of a spin wave by an electron is not fully understood. Therefore, the drop of the spin-wave intensity for higher wave vectors can be related to either a drop of the excitation probability or a drop of the spin-wave intensity itself. As discussed later in more detail, there are arguments to assume the drop to be mainly caused by the scattering process. The unknown excitation process also leads to the difficulty that spectra taken at different scattering conditions cannot be transformed into each other. Therefore, in the graph shown in Figure 12, only spectra are presented which were taken with the same E_{kin} and θ_0. Nevertheless, Figure 12 gives a good summary of the results obtained by the SPEELS measurements.

Also, in the SPEELS measurements on hcp Co on W(110), the spin-wave loss feature shows a well-defined dispersion. As visible in Figure 7, the spin-wave energies at $\Delta K_{\parallel} = 0.78\,\text{Å}^{-1}$ are similar for both the hcp and the fcc Co phase. At higher wave vectors, however, a significant difference between the two spin-wave dispersions occurs. This is illustrated in Figure 13 in which the measured spin-wave dispersions for 8 ML fcc Co and 8 ML hcp Co are plotted together with the measured spin-wave width in both systems. Owing to the different crystallographic orientations in which the spin waves are measured the dispersion relations are different in both cases. The calculated dispersion relation for the hcp crystal within the nearest-neighbor Heisenberg model for the surface mode of a semi-infinite crystal along $\overline{\Gamma} - \overline{K}$ is

$$E_{\mathrm{sw}}(Q_{||}) = \frac{16}{3} JS \left[3 - \cos(a_0 Q_{||}) - 2\cos\left(\frac{a_0 Q_{||}}{2}\right)\right] \quad (7)$$

This dispersion relation has been fitted to the measured data. The result is added as a black line in Figure 13(a). From the fit of the dispersion, we obtain a value of $JS = 14.8 \pm 1\,\text{meV}$. The agreement between the experimental data and the Heisenberg model is again fairly good. The value of JS is similar to the value obtained from the dispersion in fcc Co on Cu(001). We can conclude that the differences in the spin-wave energies in the two dispersions measured on fcc and hcp Co are due to the different crystallographic directions in which the spin-wave energies are measured, whereas the strength of the exchange coupling is similar in both crystallographic lattices. The fact that the value of JS is similar in both cases is not necessarily expected since the crystal structure is different and the nearest-neighbor distance is slightly changed (2.55 Å for fcc Co and 2.51 Å for hcp Co). The value of JS obtained from Co on W(110) is again in relatively good agreement to neutron scattering experiments performed on bulk hcp Co (Perring, Taylor and Squires, 1995) as discussed later.

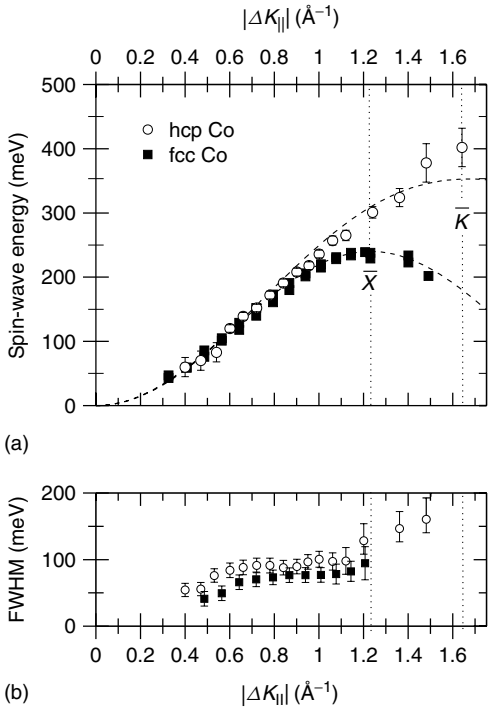

Figure 13. (a) Spin-wave dispersion of 8 ML Co on W(110) measured by SPEELS. The solid line represents a fit to the data with the dispersion of the surface mode of a semi-infinite crystal calculated within a nearest-neighbor Heisenberg model (see text for details). For comparison, data obtained for 8 ML fcc Co on Cu(001) is also plotted. The surface Brillouin zone is marked for both systems. In (b), the width of the spin-wave peak obtained from the SPEEL spectra for both fcc and hcp is given. The width has been corrected for the finite energy resolution of the spectrometer. The large error bars for the highest wave-vector transfers are caused by the low spin-wave intensities in the SPEEL spectra in this region. The low intensity is due to the combined effect of a drop of the excitation probability with both larger E_{kin} and higher wave-vector transfer as discussed later.

In addition to the spin-wave energies, the spin-wave width obtained from the measurements is plotted in Figure 13(b). The width is rather large and has a similar behavior as a function of the wave vector in both cases. The width measured for hcp Co is larger by about 15 meV compared to the width for fcc Co at each wave vector. One can speculate about possible reasons for this increased width. It may result from the different electronic structure, the crystalline quality, or the influence of the substrate. Since, for high wave vectors,

surface spin waves are largely confined in the topmost layers, the influence of the substrate should be rather small for an 8 ML thick film. In addition, we found a very similar spin-wave width for 3 (not shown) and 8 ML Co films on W(110) which suggests that the effect of the substrate may not to be the dominating contribution in this case. Instead, it could well be that the substantially larger amount of crystalline imperfections in hcp Co on W(110) causes an enlarged damping and thus a larger spin-wave width (Etzkorn *et al*., 2005).

2.2 SPEELS measurements of 3 ML Fe on 1 ML Co on Cu(001)

In addition to the studies of spin waves in the two crystallographic orientations of cobalt, we have also examined spin waves in another ferromagnet that is iron. Here, we shortly mention a study of spin waves in Fe on Cu(001). This system is of particular interest in the field of magnetism in thin films, because it has the tendency to be antiferromagnetic for ultrathin films (Li *et al*., 1994; Ellerbrock *et al*., 1995; Keavney *et al*., 1995). Fe is stabilized on Cu(001) in a strongly, rather complex tretragonal distorted lattice below thicknesses of about 12 ML (Thomassen *et al*., 1992; Müller *et al*., 1995; Biedermann, Tschelieβnig, Schmid and Varga, 2001). In the low-thickness regime, up to 3 ML, the Fe orders ferromagnetically, but above, a more complex magnetic order is observed. Above 12 ML thickness, the Fe retains a bulk like bcc phase and also the magnetic properties are bulk like (Thomassen *et al*., 1992).

Ultrathin Fe layers grown on Cu have their easy axis of magnetization perpendicular to the surface plane (Thomassen *et al*., 1992; Li *et al*., 1994). The projection of the spin of the incident electrons onto the magnetization direction for a perpendicularly magnetized sample would be zero in the SPEELS experiments. To exploit the defined spin direction of the incident electron, the easy axis of magnetization of the system must be brought into the surface plane. For that reason, we grew the Fe films on a Cu(001) substrate predeposited with 1 ML Co. This switches the easy axis of

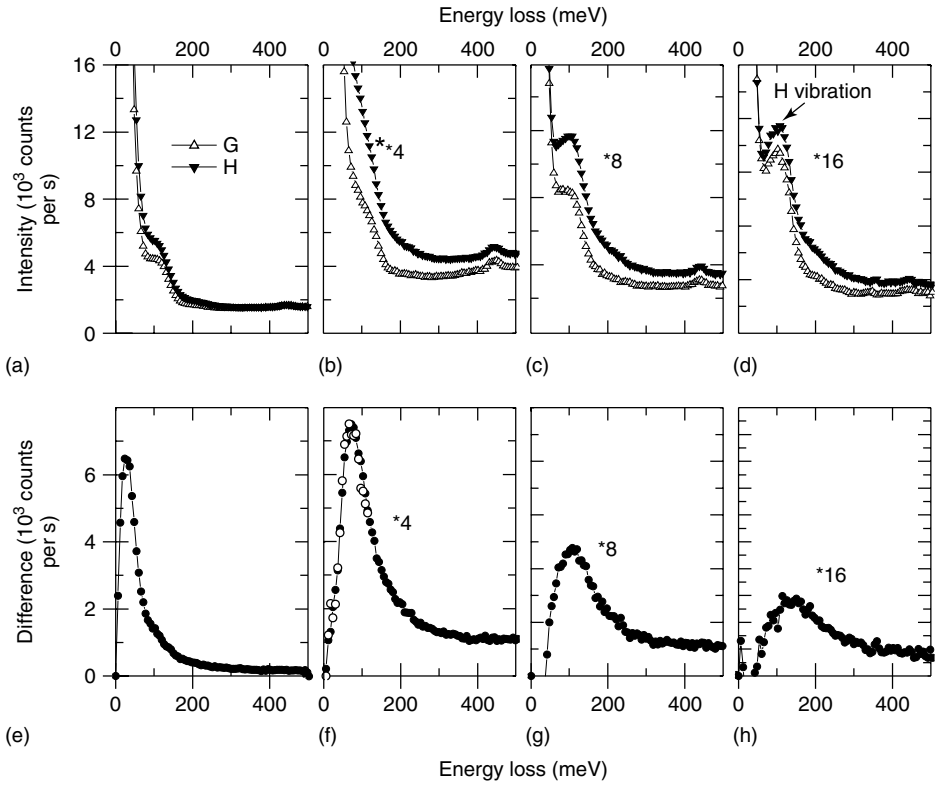

Figure 14. SPEEL intensities and difference spectra measured on 3 ML Fe on 1 ML Co on Cu(001). The wave-vector transfers were 0.5 Å^{-1} (a/e), 0.81 Å^{-1} (b/f), 1.03 Å^{-1} (c/g), and 1.17 Å^{-1} (d/h), respectively. The measured intensity has been multiplied by the number marked in each spectrum. The dominating loss feature in the intensity spectra itself is a vibrational excitation of H. In the difference spectra, however, the spin-wave loss peak is still prominently visible. The difference spectra are calculated as $I_\downarrow - \alpha I_\uparrow$, where α is a weighting factor that is chosen so that the difference vanishes at 0 meV loss energy (see text for details). Spectra have been recorded with $E_{\text{kin}} = 7$ eV, $\theta_0 = 90^\circ$, and an energy resolution of 38 meV.

magnetization of the entire film into the surface plane along a [110] direction but leaves all other properties of the film nearly unchanged (O'Brien and Tonner, 1995; Torija, Pierce and Shen, 2001).

In Figure 14(a–d), the energy loss spectra measured on 3 ML Fe on 1 ML Co on Cu(001) are shown for different wave-vector transfers. The spectra are dominated by contributions of the vibrational excitation of H at about 120 meV loss energy. By exploiting the spin-dependent excitation process of spin waves and calculating the difference of $I_\downarrow$ and $I_\uparrow$, the H contribution vanishes and one still finds a quite pronounced spin-wave feature. The spin-wave energies in this system are rather low and the low-energy side of the spin-wave loss feature might be influenced by spin dependent contributions of the elastic peak. To reduce the influence of these contributions to the difference spectra, the difference has been calculated as $I_\downarrow - \alpha I_\uparrow$. Here, α is a weighting factor which was chosen so that the difference vanished for 0 meV loss energy. For all spectra shown α is a number close to 1, since the spin dependent contributions to the elastic peak are rather weak in these spectra. To ensure that the spin-wave feature in the difference spectra are not altered by remaining contributions of the elastic peak, we have performed measurements with increased energy resolution (23 meV compared to 38 meV). The difference spectra obtained from these high-resolution measurements at 0.81 Å^{-1} are also included in Figure 14(f) as open circles. They have been scaled to match the intensity at the spin-wave maximum. It is obvious from the agreement of the two shapes that the spin-wave loss feature is well resolved at least for wave-vector transfers above 0.81 Å^{-1}.

One can also see that the spin-wave loss feature in this system is very broad and not of Gaussian peak shape. The FWHM of the spin-wave loss peaks are about the same as the spin-wave energy at each wave vector.

The spin-wave dispersion and also the width of the spin-wave loss peak measured on 3 ML Fe film on 1 ML Co on Cu(001) is shown in Figure 15. For this system, the experimental dispersion curve cannot be fitted well by the Heisenberg model using only one value of JS for the entire Fe film. If we assume, however, that the exchange-coupling constant at the surface layer (J_1) is enhanced by a factor of 2, with respect to the J in the interior of the film, the spin-wave mode of the (modified) nearest-neighbor Heisenberg model fits quite well the experimental data with a value of $JS = 5.8$ meV (thick solid line in Figure 15) (Vollmer *et al*., 2004b,c). Such an increased J_1 at the surface is generally expected from theoretical calculations for many magnetic films (Pajda *et al*., 2000; Razee, Staunton, Szunyogh and Györffy, 2002). The experimentally measured results for the Fe film on 1 ML Co on Cu(001) are compatible with theoretical expectations, while for the Co

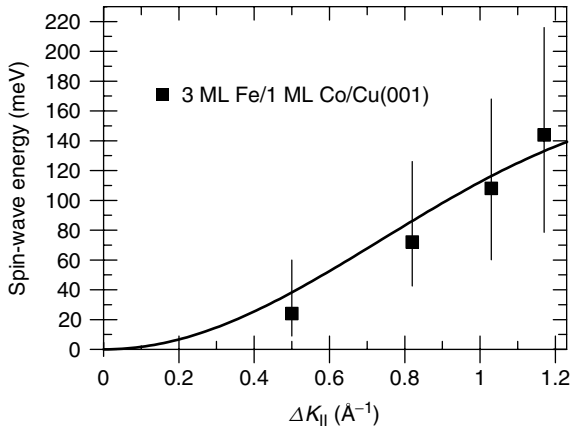

Figure 15. The spin-wave dispersion of the spin waves measured on 3 ML Fe on 1 ML Co on Cu(001). The vertical lines represent the energy range for which the spin-wave peak intensity is larger than half of its maximum intensity. The solid line is a dispersion calculated with a modified Heisenberg model (see text for details).

films, a strongly increased J_1 is in disagreement with the description of the measured dispersion using the Heisenberg model. The large width of the spin-wave excitation in the Fe indicates an extremely strong damping of this excitation, as discussed in more detail in the next section. It might well be that for such a drastic damping in this system the Heisenberg model fails to describe the properties of spin waves. Independent of the model describing the measurements the data show that the spin-wave energies are significantly reduced compared to results from bulk Fe. This reduction can be seen in the spin-wave stiffness of about $D = 150 \pm 10$ meVÅ^2 that can be estimated from our data of the tetragonally distorted Fe. This is much lower than the spin-wave stiffness of 260–280 meV Å^2 measured for bulk bcc Fe (Mook and Nicklow, 1973; Yethiraj *et al*., 1991). The reduction is much stronger than what can be estimated to result from reduced thicknesses or surface mode properties (compare Figure 11). Thus, it may be attributed to the differences in the exchange interaction of the two crystalline phases of Fe.

The spin-wave loss features measured by SPEELS have been typically measured with a low kinetic energy of the incident electrons (typically $E_{\text{kin}} < 10$ eV). At this energy, the spin-wave peaks are relatively intense in the measured spectra. The measured spin-wave intensity, however, strongly depends on the E_{kin}. This is illustrated in Figure 16 for the three systems that have been presented, fcc Co, hcp Co, and Fe on Co/Cu. The key feature in these graphs is the strong enhancement of the spin-wave intensities below $E_{\text{kin}} = 10$ eV. At these low primary energies, the intensity of the spin-wave signal is enhanced by more than an order of magnitude. This enhancement allows the clear detection

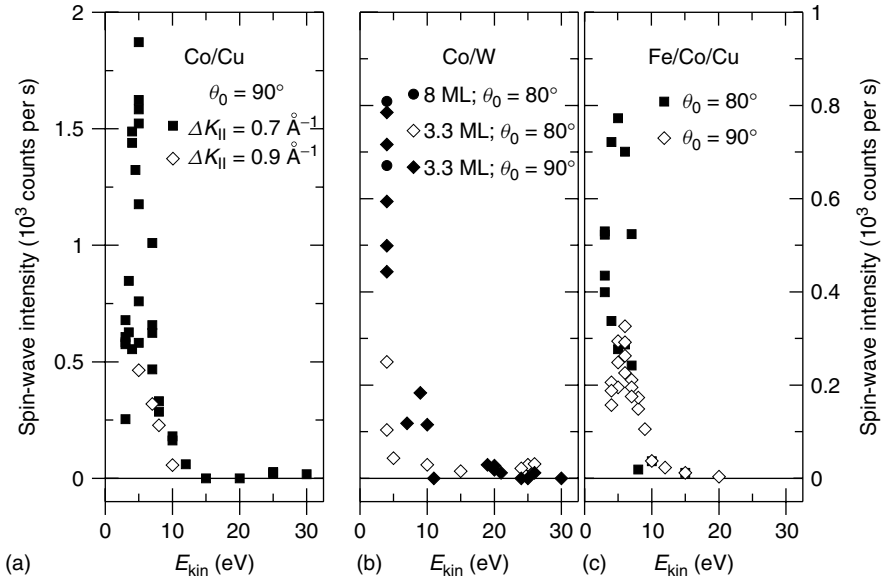

Figure 16. The spin-wave intensity in the SPEEL spectra strongly depends on the kinetic energy of the incoming electrons E_{kin}. In (a), the spin-wave intensity of 8 ML Co on Cu(001) as a function of E_{kin} is given. The solid points are for measurements with $\Delta K_{\parallel} = 0.7\,\text{Å}^{-1}$ and the open symbols for $\Delta K_{\parallel} = 0.9\,\text{Å}^{-1}$. In all measurements shown here, $\theta_0 = 90^{\circ}$. In (b), the data of 8 ML (circles) as well as of 3.3 ML Co on W(110) (diamonds) are shown. Here the measurements were carried out with $\Delta K_{\parallel} = 0.88\,\text{Å}^{-1}$ and with two different θ_0. In (c), the data for 3 ML of Fe grown on 1 ML Co on Cu(001) is given. Here the measurements were carried out with $\Delta K_{\parallel} = 0.81\,\text{Å}^{-1}$ at two different θ_0.

of the spin-wave loss features. Though this enhancement is crucial for the experimental results, its origin is not completely understood. It is, however, presumably caused by the energy dependence of the exchange scattering process. One should note that the measured spin-wave intensities shown in Figure 16 are influenced by both the cross section of the scattering event and the transmission function of the spectrometer. The latter is difficult to take into account precisely because it depends on the potentials applied to the spectrometer (about 40 different potentials) that will be optimized for each scan and thus change. The data shown in Figure 16 have a relatively large scatter, which we mainly attribute to these differences in the optimization of the potentials applied to the spectrometer.

The absolute intensity also depends on the scattering geometry, for example, on the scattering angle θ_0. The enhancement of the spin-wave intensities at low primary energies of the incoming electrons, however, is similar in all three cases shown.

3 DISCUSSION

In the following section, the results presented in the last section are discussed in more detail. We try to extract some of the fundamental magnetic properties of the materials investigated. Later, the results are compared to the experimental data obtained by other techniques and discussed in the light of recent theoretical calculations.

In the last section, we have seen that the spin-wave intensity depends strongly on E_{kin}. To discuss possible underlying reasons, we compare the results to theoretical predictions. The interaction that allows excitation of a spin wave in an electron scattering event is the exchange interaction (Feder, 1985). The probability of an exchange process is known to decrease with increasing incident electron energy (Hopster, Raue and Clauberg, 1984; Kirschner, 1985b). Mills and Hong have calculated the spin dependent inelastic mean free path in ferromagnetic metals. They have explicitly considered exchange processes that lead to the excitation of electron–hole pairs and of spin waves (Hong and Mills, 1999, 2000b). In their calculations, they found a strong increase in the probability of exchange processes for minority electrons at low incoming electron energies. The calculations predict, however, that exchange processes of electrons with energies higher than 5 eV above E_{F} (that is equivalent to $E_{\mathrm{kin}} \approx 0\,\text{eV}$ in our experiments) lead almost exclusively to Stoner excitations. In other words, in these calculations, the spin-wave excitations are probable only for primary energies lower than the work function. This energy regime is not accessible in the SPEELS experiments. Thus, the probability of exciting a spin wave by exchange processes is

underestimated in the theoretical predictions. The general finding of enhanced spin-wave intensities at low E_{kin}, however, is in agreement with the energy dependence of the exchange processes.

In many of the spectra shown, the spin-wave intensities and therefore the observed probability of an electron to scatter from a spin wave was rather large. Typically, the measured spin-wave intensities were of the order of a few hundred to a few thousands of counts per second (see Figure 7). As has been shown by the normalized intensity scale (e.g., in Figure 9), the intensity of the spin-wave signal is typically of the order of a few percent of the intensity of the elastic peak. The total background intensity can be calculated by integrating the background signal over the entire energy range up to the incident electron energy. One finds that the total background intensity is of the same order of magnitude as the intensity of the elastically scattered peak. Therefore, in each measured $I_{\downarrow}$ spectrum about one electron out of 100–1000 detected electrons was scattered from a spin wave. For the moment, we assume that a similar relation holds over the entire wave-vector range. For metals, typically a few percent of the incoming electrons are reflected from the sample. Using these assumptions, we can estimate the probability that an incoming electron of minority character is inelastically scattered by exciting a spin wave to be about 10^{-4}. This estimation should be seen as an upper limit. It will overestimate the scattering probability, because close to the specular condition, other scattering mechanisms play an important role, which will suppress the relative spin-wave intensities. The estimation is also only valid for low primary energies of the incoming electrons. As already shown, at other primary energies, we observed orders of magnitude lower excitation probabilities (see Figure 16).

Another point directly visible from the spectra or from the contour plot shown in Figure 12 is that the measured spin waves are rather broad. For high wave vectors, the ratio of the spin-wave energy to the spin-wave width is about two to three for Co and about one for Fe. This is in agreement with the behavior expected for high wave-vector spin waves in itinerant systems, especially at surfaces (Tang, Plihal and Mills, 1998; Muniz and Mills, 2002). As has been shown, for example, in Figure 7, it is possible to fit the spin-wave loss feature measured on Co by one single broad peak of Gaussian shape. If one assumes that the total width of the spin-wave loss feature is reflecting the damping of a single mode, it is straightforward to calculate, for example, the lifetime of these spin waves. Within this approximation, the behavior of the spin-wave excitations in real space and time can be calculated from the measured spectra by a two-dimensional Fourier transformation: from wave vector to real space and from energy to time. One example for spin waves with $\Delta K_{\parallel} = 0.81\,\text{Å}^{-1}$ measured on 8 ML fcc Co is shown in Figure 17. For the calculations, we assumed a Gaussian peak shape in energy and wave-vector space. The decay in time and space is inversely proportional to the width of the spin wave in energy and wave-vector space. For the example shown in Figure 17, the amplitude of the spin wave in real space drops to e^{-1} of its initial value after about ≈15 Å, only. Since the wavelength is about 8 Å, the spin wave is already damped out after a few oscillations. The lifetime of the spin wave is also short, about 30 fs. From the dispersion, the group velocity v_{G} and the phase velocity v_{P} of the excitation can be calculated by $v_{\mathrm{G}} = (\mathrm{d}E/\mathrm{d}q)$ and $v_{\mathrm{P}} = (E/q)$. For fcc Co at $\Delta K_{\parallel} = 0.81\,\text{Å}^{-1}$, one obtains the values of $v_{\mathrm{G}} \approx 40\,\mathrm{km\,s^{-1}}$ and $v_{\mathrm{P}} \approx 39\,\mathrm{km\,s^{-1}}$. Owing to the similar group and phase velocity and the short lifetime of the spin wave, the spin wave spreads only little in space. By multiplying v_{G} with the lifetime, the distance by which the center of gravity of the spin wave travels can be estimated; it is about 12 Å (Figure 17). Therefore, the high wave-vector spin waves in Co are highly confined in time and space owing to the strong damping and, thus, they are not the well-defined long-living excitations discussed in the introduction. We note in passing that the above-mentioned ratio of the spin-wave energy to the spin-wave width measured for Fe by the same arguments comes from a spin wave that is already damped out after its first oscillation. With this information on lifetime and propagation speed, we may estimate the linear phase

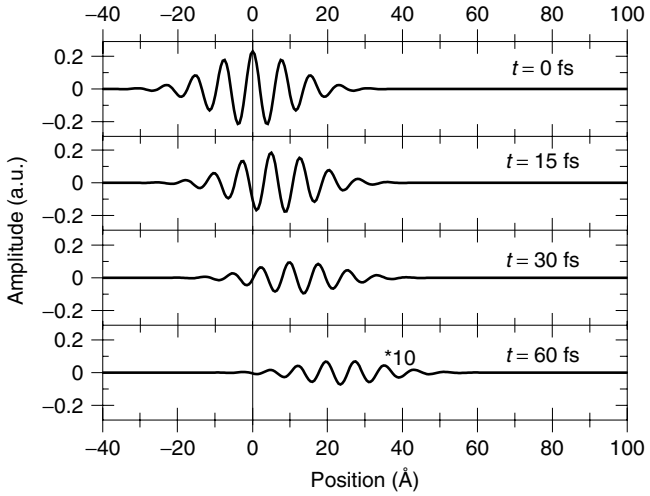

Figure 17. Classical representation of the spin-wave amplitude in real space and time obtained from a Fourier transformation of the wave vector/energy data (see text for details). The graph represents spin-wave data measured with $\Delta K_{\parallel} = 0.81\,\text{Å}^{-1}$ on fcc Co. The spin wave is created at time $t = 0$ and $x = 0$. Its decay length in space is about 15 Å. The decay time is about 30 fs. Note that the amplitude for the curve at $t = 60$ fs has been multiplied by 10.

space of these elementary excitations in terms of time–space coordinates. We find a value of roughly 10×10^{-24} sm, a remarkably small value!

This does not, of course, mean that we obtain this kind of experimental resolution in space and time with our method. It just says that we are able to study objects that are extremely confined in time and space using a method that works in wave vector and energy space. Conversely, this means, for example, for the spatial coordinate, that the high-energy spin-wave characteristics will not change significantly if we measure them on an 'infinite' thin film or on nanoscale islands with a diameter of a few nanometers. Together with the high surface sensitivity of electron scattering, SPEELS may thus be an appropriate tool to study elementary excitations in nanoscale magnets.

3.1 Comparison between the SPEELS data and other experimental results

In the following, the results of this work are compared to other experimental investigations of spin waves. Since SPEELS is a new technique to study spin waves and explores spin waves in a region, which has not been accessible by other techniques, a direct comparison is difficult. INS is the only technique, which allows the study of a similar wave-vector range as the one investigated by SPEELS. Thus, the following comparison will mainly focus on the results obtained by INS. The measurement of spin-wave excitations with high wave-vector transfers by INS is not an easy task in 3d ferromagnets, because of the high spin-wave energies in these systems. Therefore, only a few INS studies have been made.

In the case of fcc Co, which is not stable in bulk at room temperature, no INS experiments that examine very high wave-vector spin waves have been published. One way to compare the results of the low wave-vector transfer regime studied by INS with our data is to use the nearest-neighbor Heisenberg model. The value of JS derived from neutron scattering on bulk fcc Co (using crystals with 8 and 6% Fe) is $JS = 14.7 \pm 1.5$ meV (Sinclair and Brockhouse, 1960; Pickart *et al*., 1967). This is in excellent agreement with the value of $JS = 15 \pm 1$ meV obtained by SPEELS. To illustrate the results of these two experiments, Figure 18(a) shows the dispersion measured by INS (Sinclair and Brockhouse, 1960) and by SPEELS for fcc Co. One should note that strictly speaking the wave-vector axis shows a three-dimensional wave vector in the case of INS whereas it is two dimensional for the SPEELS measurements. Since the SPEELS measurements are dominated by the excitation of surface spin waves (with $q_\perp = 0$); however, both can be compared. To connect the different wave-vector transfers the solid and the dashed lines in Figure 18(a) display the dispersion calculated with the nearest-neighbor Heisenberg model for the surface and the bulk mode, respectively. The values of JS used are the ones given in the publications Sinclair and Brockhouse (1960) and Vollmer *et al*. (2003). The surface and the bulk mode have a different dispersion for similar values of JS (compare Figure 5); however, for the wave-vector range measured by INS the spin-wave energies are very similar in both cases.

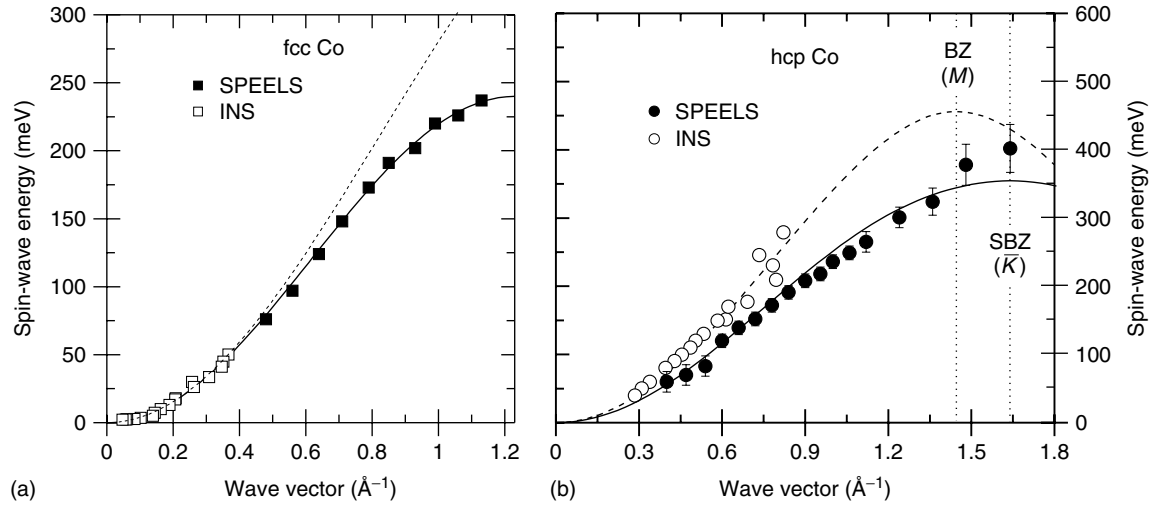

Figure 18. Comparison of the spin-wave dispersions measured with SPEELS (solid symbols) and INS (open symbols) for fcc (a) and hcp (b) Co. The solid and dashed lines are dispersions calculated with the nearest-neighbor Heisenberg model for the surface and the bulk mode of the specific crystals, respectively (for details see text). The vertical dotted lines in (b) mark the two (surface) Brillouin zone boundaries for the specific directions measured. The INS data are taken from Sinclair and Brockhouse (1960) in the case of fcc Co and from Perring, Taylor and Squires (1995) in the case of hcp Co. (Reproduced from Perring *et al*., 1995. © 1995 with permission from Elsevier.)

For bulk hcp Co, only one publication exists, to our knowledge, in which the spin-wave dispersion was measured up to the very high wave-vector transfers (Perring, Taylor and Squires, 1995) (see also Figure 4). In the neutron measurements, the dispersion of the bulk spin-wave mode was obtained along $\Gamma - M$ (Perring, Taylor and Squires, 1995) whereas in the SPEELS data the spin-wave dispersion of the surface mode is measured along $\overline{\Gamma}$-$\overline{K}$. These are the two different high symmetry directions in the basal plane. Figure 18(b) shows the results of both measurements and also indicates the different Brilluoin zone boundaries (vertical lines) of both cases. The spin-wave energies measured by INS are higher than the one measured by SPEELS. To compare the two different modes along the different directions in more detail, we use the nearest-neighbor Heisenberg model, again. A fit of the neutron data with the bulk dispersion yields a value of $JS = 19.2 \pm 0.6$ meV (Perring, Taylor and Squires, 1995) (dashed line in Figure 18b). For the SPEELS data we obtain $JS = 14.8 \pm 1$ meV (solid line) (Etzkorn *et al*., 2005). Within the Heisenberg model, it is also possible to estimate the influence of the different crystallographic directions on the spin-wave dispersion. In the case of an isotropic exchange (this seems to be a reasonable approximation, because the basal plane has a sixfold symmetry and even in fourfold symmetries the anisotropy in the exchanges are typically very small (Mook and Nicklow, 1973)), no drastic changes in the dispersion in any direction within the basal plane are expected for the wave-vector range investigated by INS. Also the bulk and surface modes are at similar energies at these wave-vector transfers. Therefore, within the Heisenberg model the differences between the two data sets are mainly caused by the differences in *JS*. One could speculate about possible reasons for this deviation, like the different properties of thin films and bulk Co. Considering the differences in the two experiments, however, in our view the agreement is rather satisfying. One should note that even within the results obtained by different INS studies on hcp Co (typically for lower wave vectors) the observed values for *JS* range from 17.3 to 20.2 meV (Perring, Taylor and Squires, 1995 and references therein).

Another point that is worth mentioning is the amount of Co used in the experiments to detect spin-wave losses. In the case of INS measurements, about 100 g of single crystalline Co was used to obtain the data shown in Figure 4. As we have seen, high wave-vector spin waves can be studied by SPEELS on a few atomic layers of Co. The electron beam used in the experiments has a lateral extension of about 1 mm^2. Therefore, the amount of material scattered from is about a factor of 10^{10} different between both experiments. For much lower wave vector and energy transfers, it is possible to reduce the amount of material needed in INS drastically. One example is the work of Schreyer *et al*. (2000). They have studied spin waves using only about 10 mg Dy. Nevertheless, this amount of material is still higher by a factor of 10^6 compared to the SPEELS experiments.

By BLS and FMR, the exchange stiffness *D* can be measured in magnetic films. Within the nearest-neighbor Heisenberg model, one can determine *JS* from *D* (see equation (6)). Liu and colleagues performed BLS measurements on about 100-nm-thick Co films of different crystalline structures (Liu *et al*., 1996). The authors found values of $JS = 17.9 \pm 0.6$ meV for fcc and $JS = 17.3 \pm 1.4$ meV for hcp Co. Therefore, in qualitative agreement with our data, no changes of *JS* were found for the different Co structures. The reported absolute values for *JS*, however, are higher than that obtained by SPEELS. Other BLS studies report values of $JS = 13.5 \pm 3$ meV (Vernon, Lindsay and Stearns, 1984) and $JS = 18.3 \pm 2.8$ meV (Grimsditch, Fullerton and Stamps, 1997). The low value reported by Vernon, Lindsay and Stearns (1984) was obtained by BLS measurements on polycrystalline films. In a FMR study also a low value of $JS = 13.5 \pm 0.7$ meV was measured on polycrystalline Co films (Tannenwald and Weber, 1961). One may speculate that these low values are related to the poor film quality. In general, the agreement between the BLS and FMR results and SPEELS data is fairly good, if one considers the difference in the order of magnitude of the investigated wave-vector range (about 2 orders of magnitude) and the uncertainty introduced by the Heisenberg model.

We emphasize again that we have compared surface spin waves to bulk spin waves and results obtained in very different wave-vector regimes. This comparison was made using the nearest-neighbor Heisenberg model. Within this model, fairly good agreement between all experimental results is observed, especially considering possible uncertainties introduced by the model. Typically, the deviations of the literature values to our experimental findings are of the same size as the deviations of literature values among themselves. Generally, the SPEELS values tend to lie slightly below the values obtained by other techniques.

3.2 Comparison to theoretical calculations

In the following, the results of the spin-wave excitations measured by SPEELS are compared to theoretical calculations. It is widely accepted that calculations using the adiabatic approximation may only give a crude estimate for high wave-vector spin waves in 3d ferromagnets (Tang, Plihal and Mills, 1998; Udvardi, Szunyogh, Palotás and Weinberger, 2003). Nevertheless, most calculations are performed within this approximation, because it is nontrivial to go further. Several recent *ab initio* calculations map itinerant magnetism on an

effective Heisenberg model to calculate the spin-wave dispersion. This allows a direct comparison between the calculated exchange-coupling constants and the experimental findings, as well as a comparison between the spin-wave dispersion relations. Because no damping is included in these theories, they must fail to predict the correct broad spectral shape of the spin waves observed experimentally. Calculations that examine spin-wave properties in thin films regularly obtain a strong enhancement of the exchange-coupling constant in the surface layer (see e.g., Pajda *et al*., 2000; Razee, Staunton, Szunyogh and Györffy, 2002; Costa, Muniz and Mills, 2004b). To the best of our knowledge, no calculations for thin hcp Co films have been published. Therefore, the discussion is limited to fcc Co. Pajda and coworkers found in their calculations an enhancement of the nearest-neighbor exchange-coupling constant for one ML Co on Cu(001) of about a factor of 2 compared to the bulk value (Pajda *et al*., 2000, 2001). In calculations by Razee, Staunton, Szunyogh and Györffy (2002), it was observed that this enhancement persists in the surface layer for Co films up to 7 ML thickness. Other exchange-coupling constants, as well as the magnetic moment, are also enhanced close to the surface (Razee, Staunton, Szunyogh and Györffy, 2002). These effects are, however, typically much smaller than a factor of 2. SPEELS seems especially suited to study such effects, because the energy of surface spin waves at high wave vectors strongly depends on the strength of the exchange coupling at the surface. As we have seen earlier, we are able to describe our measured dispersions for both fcc and hcp Co by a nearest-neighbor Heisenberg model using only one value of *JS* throughout the films and for all film thicknesses investigated. Within the description of the Heisenberg model, we therefore do not find any evidence for such an enhancement of the exchange-coupling constant at the Co surface.

As has been discussed in the last section, the spin-wave energies measured by SPEELS are typically slightly below those expected from measurements using other techniques. Following the above argument, we can bring our data in perfect agreement to other experimentally observed values of *JS* by assuming that the exchange-coupling constant is reduced at the surface. If the exchange-coupling constant at the surface is different from the bulk value, then our experimental findings on Co point in the direction of a reduction and not of an enhancement. It was also found that the spin-wave energy does not change for lower temperatures (Etzkorn *et al*., 2004). Hence, the difference between experimental values and theoretical expectations cannot be explained by temperature effects. The entire argumentation is, however, based on the nearest-neighbor Heisenberg model, which limits possible conclusions.

Since the theoretically predicted enhancement of the surface exchange is not observed in Co in the SPEELS experiments, it can be expected that the surface spin-wave energies are overestimated in the calculations that use an enhanced exchange interaction. Calculations of the spin-wave dispersions for bulk crystals do not consider the exchange coupling at surfaces. These calculated dispersions are typically in good agreement to the dispersion that we can calculate in the Heisenberg model using the values of *JS* obtained by SPEELS (Halilov, Eschrig, Perlov and Oppeneer, 1998; Pajda *et al*., 2001; Grotheer, Ederer and Fähnle, 2001).

This is illustrated in Figure 19 in which the dispersions for bulk fcc and hcp Co obtained from recent calculations using the adiabatic approximation are plotted. To compare the SPEELS results with these calculations, the bulk dispersions estimated from the nearest-neighbor Heisenberg model using a value of $JS = 15\,\text{meV}$ is shown as solid lines. Of course, the simple Heisenberg model does not allow a detailed comparison to these highly sophisticated calculations. The general agreement in the spin-wave energies is, however, very good, especially considering that the calculations were performed fully *ab initio*.

So far, the experimental results were compared to theories using the adiabatic approximation. It has already been discussed that this approximation is expected to fail for high wave-vector spin waves in the itinerant electron systems. As was pointed out by Mills and coworkers (Tang, Plihal and Mills, 1998; Costa, Muniz and Mills, 2004b; Muniz and Mills, 2002), the results from calculations within and beyond the adiabatic approximation can differ qualitatively as well as quantitatively.

In the case of Co, only a few theoretical publications are available which treat the spin-wave excitations within a nonadiabatic approach (Trohidou, Blackman and Cooke, 1991; Costa, Muniz and Mills, 2004a,b). All of them are based on an empirical tight binding description of the electronic structure, with parameters chosen by fitting to *ab initio* calculated electronic structures. One of the studies (Trohidou, Blackman and Cooke, 1991) has been performed for hcp bulk Co. The result of this study is that high wave-vector spin waves are significantly damped, as indicated by a broadening of the structures. Nevertheless, the spin-wave energies are similar to the energies which were calculated by theories using the adiabatic approximation (Halilov, Eschrig, Perlov and Oppeneer, 1998; Grotheer, Ederer and Fähnle, 2001). Two recent calculations have been performed for thin fcc Co films on Cu(001) (Costa, Muniz and Mills, 2004a,b). The calculated quantity in these publications is the layer-resolved spectral density of spin fluctuations as a function of the wave vector. The calculations by Costa, Muniz and Mills, (2004b) illustrated the changes in the spectra shape when the calculations were done within and beyond the adiabatic approximation. In the latter case, the spectral shape deviates strongly from the expectations

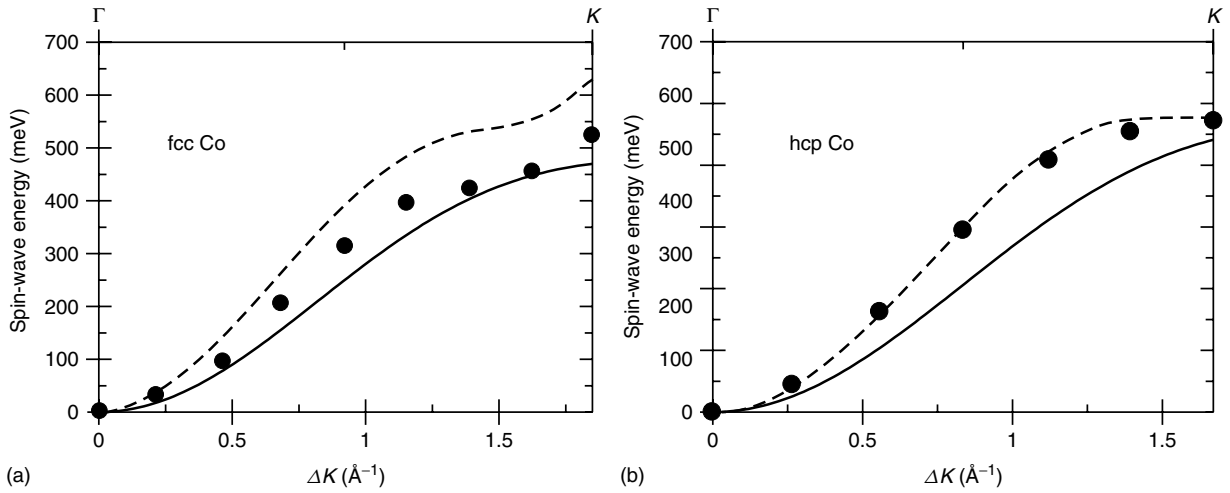

Figure 19. Comparison between the calculations of the spin-wave dispersion (dashed line and solid dots) for fcc (a) and hcp (b) Co using the adiabatic approximation and the estimated bulk dispersion from the SPEELS data using the nearest-neighbor Heisenberg model (solid line). In (a), the calculated data has been taken from Pajda *et al.* (2001) (dashed line) and Halilov, Eschrig, Perlov and Oppeneer (1998) (dots) (reproduced from Pajda *et al.*, 2001 and Halilov *et al.*, 1998, with permission from the American Physical Society. © 1998/2001) and in (b), from Grotheer, Ederer and Fähnle (2001) (dashed line) and Halilov, Eschrig, Perlov and Oppeneer (1998) (dots). (Reproduced from Grotheer *et al.*, 2001 and Halilov *et al.*, 1998, with permission from the American Physical Society. © 1998/2001.)

derived from a Heisenberg model except for very low wave vectors. For higher wave vectors, the spectral density in the nonadiabatic description consists of one single broad feature, instead of several discrete modes as expected from the Heisenberg model (see Figure 5). Only some structure in the broad feature reminds of these modes. This behavior is in qualitative agreement with the spectra measured by SPEELS and provides a quite natural explanation of the broad spin-wave loss features.

In Figure 20, the calculated spectral density in the surface layer for a wave vector of $\Delta K_{\parallel} = 0.85\,\text{Å}^{-1}$ is compared to the measured difference spectrum taken at about the same wave vector. The calculated spectral density has been shifted in the energy and scaled in the intensity axis to allow better comparison between the two shapes. These two shapes of the calculated and measured spectra are in promising agreement. One has to mention that the measured difference spectra cannot directly be related to the calculated spectral density. The calculation considers only the $e^{\downarrow\uparrow}$ spin channel. In the measured difference all spin channels contribute. This is expected to lead to differences especially concerning the background in the two cases. It is also important to mention that the calculated spectral density shown in Figure 20 is a quantity that is solely a property of the spin excitations and does not take into account the actual excitation process. This may lead to considerable effects in the calculated spectra. For example, it has been shown by Mills and coworkers (Plihal and Mills, 1998; Costa, Muniz and Mills, 2003) that the spectral weight of Stoner excitations measured by electron scattering is underestimated in the calculations. The high-energy shoulder in the calculations is slightly higher in intensity than the measured one. The effect is stronger for lower wave-vector transfers (not shown here) and may be attributed to the cross-section dependence of the spin-wave excitation. As has been mentioned by the authors, it is difficult to assign a particular spin-wave mode to a structure in the calculated spectral density (Costa, Muniz and Mills, 2004b). In these

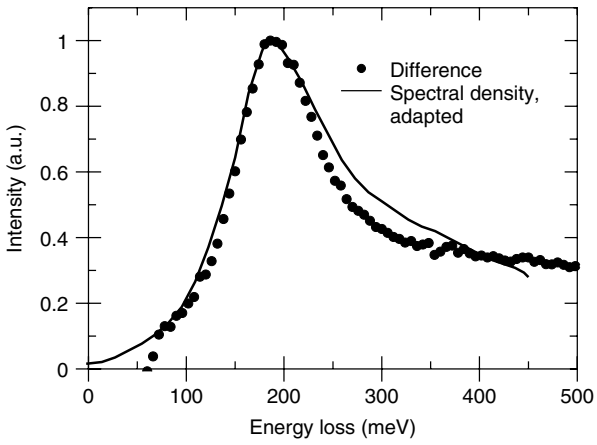

Figure 20. Comparison between the calculated spectral density in the surface layer taken from Costa, Muniz and Mills (2004b) (solid line) and the difference spectra measured by SPEELS (dots). For both, the wave vector was about $\Delta K_{\parallel} = 0.85\,\text{Å}^{-1}$. The calculated spectrum is shifted by 50 meV to lower energies and both quantities are normalized to one at their maximum. (Reproduced from Costa *et al.*, 2004b, with permission from the American Physical Society. © 2004.)

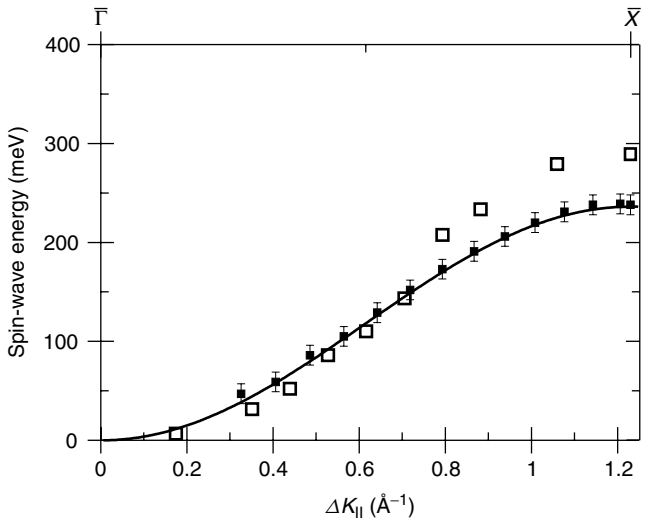

Figure 21. The dispersion obtained by the calculations of the spectral density taken from Costa, Muniz and Mills (2004b) (□) in comparison to the SPEELS data (■). Both results are for 8 ML Co on Cu(001). The open squares of the theoretically calculated dispersion mark the position of the maximum of the calculated spectral density. (Reproduced from Costa *et al*., 2004b, with permission from the American Physical Society. © 2004.)

calculations, however, the lowest energy features are always located in the surface layers. This indicates that a significant part of the low-energy spectral density within the surface layer can be attributed to what has been called a well-defined surface spin-wave mode in the Heisenberg model. Therefore, these calculations at least do not contradict the interpretation that the loss features measured by SPEELS are dominated by contributions of surface spin waves. The good agreement between the theoretical and the experimental results indicates that the effect of damping of spin waves by Stoner excitations seems to be taken into account correctly in the theory.

In addition to the spectral density, Costa, Muniz and Mills (2004b) have also calculated the dispersion of the spin waves. It was obtained by plotting the energy position of the maximum of the spectral density in the surface layer as a function of the wave vector. The resulting calculated dispersion and the dispersion measured by SPEELS are shown in Figure 21. The agreement between the two dispersions is rather satisfactory; however, as has been discussed in detail by Costa, Muniz and Mills (2004b), small changes in the choice of the tight binding parameters can change the calculated spin-wave energies by a factor of 2 (Costa, Muniz and Mills, 2004a,b). Thus, at the current stage of theory, it seems difficult to obtain precise predictions of the spin-wave energies. Here, full *ab initio* calculations going beyond the adiabatic approximation, as they have been done for the bulk (Savrasov, 1998), would be highly desirable for thin films.

4 CONCLUSIONS AND OUTLOOK

In this chapter, studies of high wave-vector spin waves in 3d-ferromagnets using inelastic spin-polarized electron scattering have been discussed. This technique allows a unique access to high-energy spin waves at surfaces. For the two investigated crystalline phases of Co (fcc and hcp) very similar spin-wave properties have been found. In both cases, the measured dispersions agree surprisingly well with the dispersion of surface spin waves calculated in a nearest-neighbor Heisenberg model. The value of the product of the exchange-coupling constant and the spin moment is similar ($JS \approx 15$ meV) in both phases. This value of JS is also in fairly good agreement with the results obtained by other experimental techniques. Although the dispersion relation agrees well with the expectations from the Heisenberg model that does not take the damping of spin waves into account, the measured energy loss features in the spectra have a large intrinsic width, which indicates a strong damping of these excitations. Indeed, recent calculations going beyond the adiabatic approximation, that is, consider the possible decay of spin waves into Stoner excitations, are in promising agreement with the measured spin-wave widths in the SPEEL spectra (Costa, Muniz and Mills, 2004b). In contrast to several theoretical predictions, no enhancement of the exchange coupling at the surface layer was measured in thin Co films.

For 3 ML Fe on 1 ML Co on Cu(001), the measured dispersion does not agree with the dispersion relation derived from the nearest-neighbor Heisenberg model, if only one value of JS for the entire Fe film was considered. The agreement can be improved considerably if an enhanced exchange coupling at the surface is taken into account. The spin-wave features in this system are, however, damped extremely strong (the ratio of spin-wave energy to spin-wave width is about 1). For such a large damping the Heisenberg model itself is expected to fail. The measured spin-wave energies in this strongly distorted Fe system are significantly smaller than that for bulk like Fe. Independent of any model description, this can only be explained by a strong reduction of the exchange interactions in the tetragonal distorted Fe phase compared to bcc Fe.

From the above-mentioned results, two other experimental approaches to study spin waves by inelastic electron scattering seem feasible. The use of a 'standard' non-spin-polarized EELS should to be possible. The higher energy resolution in such experiments may allow studying spin waves with much smaller energies. Owing to the high spin-wave intensities measured, also 'complete' experiments (in which the spin of both the incoming and the outgoing electron is determined) seem feasible. One of the interesting questions yet to be answered is whether inelastic electron scattering can also be

used to study other types of magnetic material, for example, antiferromagnets or rare-earth magnets. In addition, electrons as scattering particles to study spin excitations can be used not only by SPEELS but also, for example, by scanning tunnelling microscopy (STM). In fact, it has already been demonstrated that spin flip excitations of single atoms can be observed using STM (Heinrich, Gupta, Lutz and Eigler, 2004).

It is our hope that the results presented and discussed here stimulate further experimental and theoretical efforts in the field of elementary magnetic excitations at surfaces and in nanostructures.

ACKNOWLEDGMENTS

The authors dedicate this chapter to the memory of the late Rüdiger Vollmer, who has significantly contributed to the presented work on spin-polarized electron energy loss spectroscopy. During the short span of his scientific career, he has excelled in diverse areas of physics adding substantial knowledge to the physics of condensed matter.

We would like to thank H. Ibach for designing the SPEEL-spectrometer. In addition, we thank W. Tang and Y. Zhang for their continued help in running the experiment.

The authors would also like to acknowledge the enlightening and very helpful discussions with D.L. Mills, J. Henk, W. Wulfhekel, L. Udvardi, M. Munoz-Navia, B. Hillebrands, and B. Heinrich.

Scanning Probe Techniques: MFM and SP-STM

Alexander Schwarz, Matthias Bode and Roland Wiesendanger
Universität Hamburg, Hamburg, Germany

1 INTRODUCTION

Soon after the invention of scanning tunneling microscopy (STM) by Binnig and Rohrer in 1982 numerous derived scanning probe methods have been developed (Binnig and Rohrer, 1982, 1987). These methods, often named SXM, where X either stands for the measured quantity or for the utilized interaction, allow the imaging of a wide variety of surface properties in real space and with high spatial resolution. Besides STM, the most frequently used SXM technique is atomic force microscopy (AFM). Whereas STM detects the quantum-mechanical tunneling current across a vacuum gap between two closely spaced conductive electrodes, that is, a sharp tip and sample surface, AFM senses the electromagnetic force between a surface and a tip, which is located at the free end of a cantilever, and is therefore not limited to conductive systems. Since magnetic properties of surfaces and small particles are of great technical relevance for the development of magnetic data storage devices it was soon considered to extend the scanning probe methods to this direction. In principle, two approaches were chosen: the detection of the rather long-range magnetostatic tip–sample force by magnetic force microscopy (MFM) (Martin and Wickramasinghe, 1987; Sáenz *et al*., 1987) or by making use of the spin-dependent conductivity between a magnetic STM tip and a magnetic sample, the so-called spin-polarized scanning tunneling microscopy (SP-STM) (Wiesendanger *et al*., 1990b).

In the following two sections we survey the basic concepts, experimental conditions, modes of operation, tip preparation, and the contrast mechanisms of MFM and SP-STM. Several examples for both methods are presented to demonstrate their capabilities. Whereas MFM requires minimum sample preparation, is easy to adopt, and can be applied to nonconducting samples as well, SP-STM is able to achieve spin sensitivity with atomic resolution. The different contrast mechanisms and the resulting resolution are particularly evident on magnetic vortices which can be observed in small magnetic structures, as discussed in Sections 2.10 and 3.4.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

2 MAGNETIC FORCE MICROSCOPY

2.1 Basic concept of MFM and modes of operation

MFM detects the magnetostatic interaction between a force sensor, that is, a tip located at the free end of a cantilever, and the stray field emanating from a specimen. This technique allows the imaging of domain patterns of ferromagnetic (and ferrimagnetic) specimen with high spatial resolution down to about 10 nm (Wiesendanger and Güntherodt, 2002). In principle, MFM experiments are possible with any AFM setup. However, obviously the force sensor has to be ferromagnetic and the data acquisition has to be slightly modified. One important advantage of MFM compared to

other magnetic imaging techniques, for example, magneto-optical imaging, is the possibility to acquire high-resolution topography data simultaneously. SP-STM has the same advantage and certainly a much better spatial resolution down to the atomic scale. However, MFM is not restricted to conductive samples and, since it detects the magnetostatic interaction far above the specimen, it is quite insensitive to surface contaminations. The latter enables experiments in ambient conditions and without special surface preparation.

MFM is a noncontact technique, where the tip apex never touches the surface neither in the static nor in any dynamic mode of operation. Typical tip–sample separations range from 10 to 100 nm. Therefore, the rather long-range magnetostatic interaction can be separated from the short-range interactions, which are used in AFM to image the topography. At this point, it has to be mentioned that electrostatic forces have the same range and might still be present, thereby hampering data interpretation. Therefore, it is helpful to minimize the influence of electrostatic forces by balancing the contact potential difference with a corresponding bias voltage between tip and sample (Schönenberger, Alvarado, Lambert and Sanders, 1990; Yu, Ahner and Weller, 2004). In contrast to AFM, no z-feedback control is employed for imaging. Instead, the MFM signal is directly recorded in a constant height above the sample using either the lift mode, where the tip follows the prerecorded topography (Wadas, Moreland, Rice and Katti, 1994) or the plane-subtraction mode (Dreyer, Löhndorf, Wadas and Wiesendanger, 1998), where only the tilt between tip and sample is compensated. The former method is widely used but has one big disadvantage. While prerecording the topography, the tip is very close to the surface and the magnetostatic interaction is much stronger than during MFM data acquisition. As a result, the magnetic structure of the sample (or the tip) might be modified. In principle, the plane-subtraction mode requires only two scan lines, one in x and one in y direction, to define a plane parallel to the surface. They can be even recorded far away from the region of interest. Therefore, it should be certainly used for relatively flat samples. However, results as good as in the lift mode can be obtained on samples with large topographical features, although it is not a constant height mode in a strict sense then.

Unfortunately, the nomenclature regarding the different modes of operation of AFM, and therefore also of MFM, emerged in the context of instrumental developments and is often inconsistent and hard to understand. In general, one can distinguish between static and dynamic modes on one side and between contact, cyclic contact, and pure noncontact modes on the other side. As mentioned in the preceding text, MFM is always operated in the pure noncontact mode, that is, the tip never enters the strongly attractive or repulsive regime of short-range interactions, which are used for topography imaging. In the static mode (also known as *dc mode*), the cantilever deflection Δz due to the tip–sample interaction is monitored and can be directly converted into the tip–sample force F_z via Hook's law, that is,

$$F_z = c_z \cdot \Delta z \tag{1}$$

where c_z is the spring constant of the cantilever. In the various dynamic modes the cantilever oscillates with amplitude A, either self-excited or externally driven, at or near the resonance frequency $\omega_0 = 2\pi f_0 = \sqrt{c_z/m}$, where m_{eff} is the effective mass of the cantilever, which reflects the mass distribution along the cantilever. Two main detection schemes exist, that is, frequency modulation (FM) and amplitude modulation (AM), respectively. The former mode is used in vacuum for *true* atomic-resolution imaging and is in this context also known as *noncontact AFM* (Morita, Wiesendanger and Meyer, 2002). The cantilever is self-excited and either cantilever amplitude or excitation amplitude is kept constant (CA or CE mode, respectively). The AM mode is also named ac mode or tapping mode (TM), because of the cyclic contact during topography scans with the surface at the lower turnaround point of the oscillation. This technique is used in ambient conditions or liquids. In all dynamic modes, the MFM signal is related to the force gradient F_z' provided that A (typically between 5 and 50 nm) is much smaller than the range of the magnetostatic interaction. Owing to the stronger distance dependence, the dynamic modes are superior to the static mode, wherefore they are nowadays nearly exclusively used.

To calculate F' one can assume the spring constant of the cantilever to be effectively softened or hardened by an attractive or repulsive long-range interaction, respectively, that is, $c_{\text{eff}} = c_z - F_z'$. Thereby, the actual oscillation frequency ω deviates from the frequency of the free cantilever ω_0 by $\Delta\omega = \omega - \omega_0$. Assuming $F_z' << c_z$, the frequency shift for FM-MFM data is directly proportional to the force gradient, that is, $F_z' = -2c_z \cdot \frac{\Delta\omega}{\omega_0}$. AM-MFM uses the variation of phase ϕ or amplitude A as signal instead. Both quantities change together with frequency. This can be understood if one writes down the steady state solutions for an externally excited damped harmonic oscillator, that is,

$$A = A_0 \cdot \frac{\omega_0^2}{\sqrt{(\omega^2 - \omega_0^2)^2 + 4\gamma^2\omega^2}} \tag{2}$$

and

$$\phi = \arctan\frac{2\gamma\omega}{\omega^2 - \omega_0^2} \tag{3}$$

respectively, where γ is the damping factor, which is related to the quality factor Q of the oscillator by $Q = m_{\text{eff}}\omega_0/2\gamma$.

The resulting force gradient due to the amplitude change ΔA or phase shift $\Delta\phi$ can be calculated by $F_z' = -\Delta A \times 3^{1.5} \times c_z/2 \times Q \times A_0$ or $F_z' = -\Delta\phi \times c_z/Q$, respectively.

Like for every scanning probe method, the lateral resolution of MFM is limited by the tip–sample separation and the effective tip size. For flat samples, the separation can be below 20 nm. For rough samples, much larger distances (up to 100 nm) are necessary. The effective tip size for MFM is determined by the spreading of the emanating stray field of the tip and not by its physical size. However, the latter influences the confinement of the stray field via the shape anisotropy (cf. Section 2.3). The minimal detectable force or force gradient is limited by all sorts of external noise sources and by the sensitivity of the deflection sensor. For example, if the minimal detectable deflection is 10 pm as routinely obtained with interferometers (Rugar, Mamin and Guethner, 1989), the minimal detectable force is 1 pN for a soft cantilever with $c_z = 0.1$ typically used in the static mode. However, from a fundamental point of view the sensitivity is thermomechanically limited. In analogy with the well-known Johnson noise in a resistor a mechanical resistance Γ can be introduced. Then the minimal detectable force $F_{\min}$ for a given temperature T and measurement bandwidth B is

$$F_{\min} = \sqrt{\Gamma k_B T B} \tag{4}$$

where k_B is Boltzmann's constant. For a rectangular cantilever of length l, width w, and thickness t, Γ is given by

$$\Gamma = \frac{wt^2}{lQ}\sqrt{E\rho} \tag{5}$$

where Q, ρ, and E are the quality factor, density, and elastic modulus, respectively (Stowe *et al*., 1997). For typical soft ($c_z \approx 0.1\,\mathrm{N\,m^{-1}}$) rectangular silicon cantilevers ($E = 1.79 \times 10^{11}\,\mathrm{N\,m^{-1}}$, $\rho = 2.33\,\mathrm{kg\,m^{-3}}$, $l = 200\,\mu\mathrm{m}$, $w = 30\,\mu\mathrm{m}$, $t = 1\,\mu\mathrm{m}$) in ambient conditions ($Q = 300$) at room temperature ($T = 300\,\mathrm{K}$), the thermomechanical limit is about 0.1 pN in a bandwidth of 1 kHz. At low temperatures and in vacuum, where Q values are 1000 times larger, much higher force sensitivities are possible. With specially designed ultrasoft cantilevers, sub-attonewton force sensitivity has been achieved (Stowe *et al*., 1997; Mamin and Rugar, 2001). For the dynamic modes, the force gradient sensitivity can be formulated similarly (Albrecht, Grütter, Horne and Rugar, 1991), that is,

$$\frac{\partial F_{\min}}{\partial z} = \sqrt{\frac{4c_z k_B T B}{\omega_0 Q \langle A^2\rangle}} \tag{6}$$

where $\langle A^2\rangle$ is the mean-square amplitude of the cantilever oscillation. For typical cantilevers and parameter in ambient condition ($Q = 300$) at room temperature ($T = 300\,\mathrm{K}$) used in dynamic modes ($f_0 = 100\,\mathrm{kHz}$, $c_z = 1\,\mathrm{N\,m^{-1}}$, $A = 10\,\mathrm{nm}$), the minimal detectable force gradient is about $3 \times 10^{-5}\,\mathrm{N\,m^{-1}}$ in a bandwidth of 1 kHz. Equation (6) is valid for the FM mode. However, for the AM mode the factor 4 in the nominator has to be replaced by 2. Note that the factor $\sqrt{k_B T/Q}$ is present in equations (4) and (6), respectively. Therefore, the sensitivity can be enhanced in vacuum (higher Q values) and low temperatures (Hug *et al*., 1993; Volodin, Temst, van Haesendonck and Bruynseraede, 2000; Liebmann, Schwarz, Langkat and Wiesendanger, 2002).

2.2 Tip preparation

At the beginning of MFM, bent wires from ferromagnetic materials like iron or nickel, with electrochemically etched tips were used until de Boef (den Boef, 1990) suggested to galvanize nonmagnetic tungsten wires with a ferromagnetic material. Nowadays, standard microfabricated silicon or silicon nitride force sensors with a ferromagnetic thin film are usually employed, because their magnetic properties can be adjusted by choosing a suitable ferromagnetic material (Fe, Ni, Co, permalloy, CoCr, etc.) with an appropriate film thickness (Grütter *et al*., 1990). Coated force sensors are commercially available, but only with a limited choice. Much better results can be obtained by using a normal tip and optimizing the coating for a specific specimen. As a general rule, material and thickness should be chosen to get the largest possible MFM signal without disturbing the magnetic structure of the sample and vice versa. Another important point is the lateral resolution. In case of MFM the effective size is mainly determined by the localization of magnetic stray field emanating from the tip. The appropriate strategy is to use sharp tips with high aspect ratios.

It is possible to increase the aspect ratio of standard tips oneself, but it requires a focused ion beam instrument to tailor an existing tip (Liu, Dan, Jinjun and Wu, 2002) or a scanning electron microscope to grow a tip by electron-beam deposition (Rührig, Porthun and Lodder, 1994). Recently, carbon nanotubes have been attached to standard tips and subsequently coated with cobalt (Deng *et al*., 2004). A very convenient and effective way to reduce the spreading of the tip magnetic stray field is to coat only one side face of the pyramidal tip. The triangular shape of the side face automatically induces an easy axis toward the tip apex. Moreover, since for geometrical reasons the cantilever beam is usually not parallel to the surface, but tilted by about 15°, it is possible to prepare tips that are nearly exclusively sensitive to the z component of the sample stray field, by choosing the side face that points nearly perpendicular toward the surface (Liebmann *et al*., 2005). With such tips data interpretation is much easier, cf., equations (10) and (11) in

Section 2.3. Note that it is impossible to avoid disturbing additional in-plane sensitivities, if all side faces of a tilted pyramid are coated.

2.3 Contrast formation and image interpretation

From a physical point of view the magnetostatic tip–sample interaction energy E_{TS} can be described in two equivalent ways, that is,

$$E_{\mathrm{TS}} = -\int \vec{J}_{\mathrm{T}}\vec{H}_{\mathrm{S}}\mathrm{d}V = -\int \vec{J}_{\mathrm{S}}\vec{H}_{\mathrm{T}}\mathrm{d}V \tag{7}$$

Either the sample magnetic stray field $\vec{H}_{\mathrm{S}}$ above the surface is probed with the tip magnetic polarization $\vec{J}_{\mathrm{T}}$ or the sample magnetic polarization $\vec{J}_{\mathrm{S}}$ is probed with the magnetic stray field $\vec{H}_{\mathrm{T}}$ emanating from the tip. Since different distributions of the magnetic polarization in the sample result in the same stray field above the sample, it is generally impossible to unambiguously deduce the magnetic polarization in the sample from an MFM image. To evaluate MFM data qualitatively, it is often helpful to use a different representation of equation (7), obtained after partial integration, that is,

$$E_{\mathrm{TS}} = -\int \rho_{\mathrm{S}}\Phi_{\mathrm{T}}\mathrm{d}V - \int \sigma_{\mathrm{S}}\Phi_{\mathrm{T}}\mathrm{d}S \tag{8}$$

Here, ρ_{S} and σ_{S} are the volume and surface magnetic pole densities, respectively, and Φ_{T} is the scalar potential of the tip stray field. Both quantities are related via $\vec{H}_{\mathrm{T}} = -\vec{\nabla}\Phi_{\mathrm{T}}$. If no magnetic poles are present in the volume, that is, $\rho_{\mathrm{S}} = 0$, MFM images basically reflect the surface charge density smoothed by the finite size of the tip stray field given by the degree of localization of Φ_{T}. This simplified interpretation is valid for thin films with out-of-plane polarized magnetic domains.

As mentioned above, MFM detects either the force (static mode) or the force gradient (dynamic mode). Expressions for both quantities can be derived from equation (7). If we approximate the magnetic polarization of the tip as a simple dipole $\vec{m}$, then the force is given by

$$\vec{F} = \vec{\nabla}E_{\mathrm{TS}} = \mu_0\vec{\nabla}(\vec{m}_{\mathrm{T}}\vec{H}_{\mathrm{S}}) \tag{9}$$

Since only the vertical z component is detected, equation (9) simplifies to

$$F_z = \mu_0\frac{\partial}{\partial z}(\vec{m}_{\mathrm{T}}\vec{H}_{\mathrm{S}}) = \mu_0(m_x\frac{\partial H_x}{\partial z} + m_y\frac{\partial H_y}{\partial z} + m_z\frac{\partial H_z}{\partial z}) \tag{10}$$

Further partial differentiation leads to the force gradient,

$$\frac{\partial}{\partial z}F_z = \mu_0(m_x\frac{\partial^2 H_x}{\partial z^2} + m_y\frac{\partial^2 H_y}{\partial z^2} + m_z\frac{\partial^2 H_z}{\partial z^2}) \tag{11}$$

Note that for tips solely polarized along the z direction, that is, $m_x = m_y = 0$, force and force gradient depend only on the first or second derivative of the stray field's z component respectively.

A very helpful and successful method of interpreting MFM images qualitatively are micromagnetic simulations. The specimen is subdivided into cells, which are described by a single magnetic polarization vector. Typical cell sizes are a few cubic nanometers, so that each vector represents a large number of atomic spins. The time dependence of the magnetic polarization $\vec{J}(t)$ under the influence of an effective magnetic field $\vec{H}_{\mathrm{eff}}$ (including the external as well as the anisotropy fields) is solved for each cell until the spin orientations in all cells remain stable. This is done by means of the Landau–Lifshitz–Gilbert equation

$$\frac{\mathrm{d}\vec{J}}{\mathrm{d}t} = -\gamma\vec{J}\times\vec{H}_{\mathrm{eff}} + \frac{\alpha}{|\vec{J}|}\vec{J}\times\frac{\mathrm{d}\vec{J}}{\mathrm{d}t} \tag{12}$$

where γ is the gyromagnetic ratio and α is the damping constant of the precessing magnetic polarization vector. The calculated distribution of magnetic polarizations can be used to obtain the stray field components and its derivatives above the surface. According to equation (10) and (11) the result qualitatively corresponds to the MFM signal, if the tip is reasonably well represented by a point dipole.

Several proposals have been made to calculate magnetic properties quantitatively from MFM images by some kind of calibration procedure (Göddenhenrich *et al*., 1990; Lohau, Carl, Kirsch and Wassermann, 2001; Hug *et al*., 1998; Zhu, Lin, Shi and Luo, 1998). However, because of the principle restrictions set by equation (7), all approaches are only of limited validity. Therefore, MFM is not a well-suited tool to determine the magnitude of magnetic polarization, but to visualize magnetic structures and their correlation with topographic features with high spatial resolution and minimal sample preparation. In the following text, several examples are shown, which demonstrate the capabilities of MFM.

2.4 Magnetic data storage

From the very beginning, MFM has been applied to investigate components involved in magnetic data storage. In fact, MFM was first demonstrated on a magnetic recording head (Martin and Wickramasinghe, 1987). The quick increase of the areal density in magnetic storage devices like hard disks and tapes demanded (and still demands)

high spatial resolution techniques. From the invention of MFM in 1987 until the year 2000, the areal density on hard disks increased from about 10 Mb in.$^{-2}$ (Thompson and Best, 2000) to about 10 Gb in.$^{-2}$ with a track width of 0.9 µm and a bit length of 70 nm. Recently, more than 100 Gb in.$^{-2}$ have been reported in laboratory runs of hard disks.

The MFM image in Figure 1 shows an example of a digital tape with a longitudinal bit structure, that is, the magnetic polarization along the track direction is in plane. No specific preparation was performed for the measurement in ambient conditions. Neighboring tracks are slightly tilted against each other. Track width and bit length are about 10 and 1 µm, respectively. The areal density is considerably smaller than that on hard disks, because the magnetic coating on a tape is supported by a flexible substrate and suffers from more external disturbances than a well protected rigid disk in its stable case. However, the volume density is much higher, wherefore tapes are still used as inexpensive mass storage devices, for example, in backup applications. Whereas a read head only detects zeros and ones while reading, MFM allows to study much more details of the bit pattern. For example, the magnification in the inset shows the transition region between two tracks. This region is of particular importance, because the magnetic signals of bits in neighboring tracks interfere, whereby the readback signal is diminished. Since MFM detects basically the same quantity as the read head, that is, the magnetic stray field above the surface, it can clarify how the implementation of different materials or any other change of the design, for example, tilt angle between tracks, influence the signal quality.

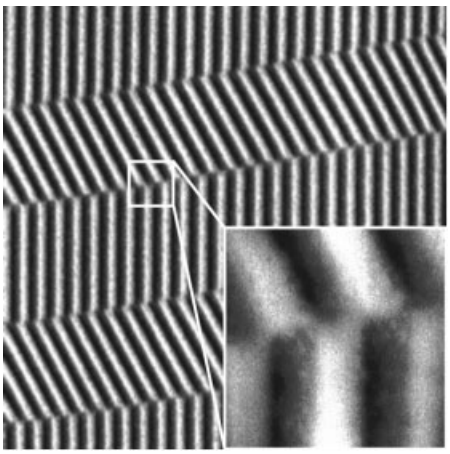

Figure 1. Lift-mode AM-MFM image ($50 \times 50\,\mu m^2$) of the bit structure of a magnetic tape for mass storage. The inset shows a magnification ($5 \times 5\,\mu m^2$) of the transition region, where two tracks meet.

2.5 Magnetization reversal

MFM can also be used in high magnetic fields, because the magnetic tip is effectively a dipole, wherefore the net force exerted on the tip is basically zero. Since the tip is typically just about 10 µm high, this is even true for quite inhomogeneous fields. In the example presented here the domain pattern evolution of an 80-nm-thick $La_{0.7}Sr_{0.3}MnO_3$ film with out-of-plane polarized domains has been recorded along its major hysteresis loop while ramping an external magnetic field $\mu_0 H = B$ from 0 mT (remanence) to 600 mT (saturation) and back again to 0 mT (Schwarz *et al*., 2004). The data have been recorded with a low-temperature force microscope (Liebmann, Schwarz, Langkat and Wiesendanger, 2002) in ultrahigh vacuum at 5.1 K. From such an image series, it was possible to reconstruct the major hysteresis loop (Liebmann *et al*., 2005). Figure 2(a) and (b) show two consecutively recorded images on the decreasing branch from saturation toward remanence. The difference image (c) = (a) − (b) reveals the individual reversal events (Barkhausen jumps) between (a) and (b). By merging (c) into the original domain pattern (a) as displayed in (d), growth events (regions, which touch an already existing domain like the event marked with G) can be distinguished from nucleation events (isolated regions like the event marked with N). By analyzing all images in this way the size distribution for nucleation (e) and growth events (f) can be studied. The Gaussian distribution for nucleation radii can be explained by the critical droplet theory. Since the energy cost for a domain wall creation scales with its surface area, and the energy gain and cost for the stray field energy and the Zeeman energy, respectively, scale with the volume, stable nucleation is only possible above a certain critical radius. Its value depends on parameters like exchange stiffness and magnetocrystalline anisotropy energy, which can vary locally and thereby result in a Gaussian distribution of radii around the mean value. The growth events are much smaller than the nucleation events (the smallest have diameters below 10 nm) and they exhibit a very different size distribution, that is, a power law with an exponential cutoff. It can be related either to self-organized criticality (Bak, Tang and Wiesenfeld, 1987), where externally driven (magnetic field) systems organize themselves in barely stable (critical) state by avalanches (Barkhausen jumps), or to domain wall propagation through a disordered medium (Alessandro, Beatrice, Bertotti and Montorsi, 1990). A similar analysis can be performed for the increasing branch (from remanence to saturation). Additionally, the correlation between domain patterns and, in particular, the position of nucleation events and with respect to topographical features, for example, due to the granular structure of the specimen, can be investigated (Liebmann, Schwarz, Langkat and Wiesendanger, 2002).

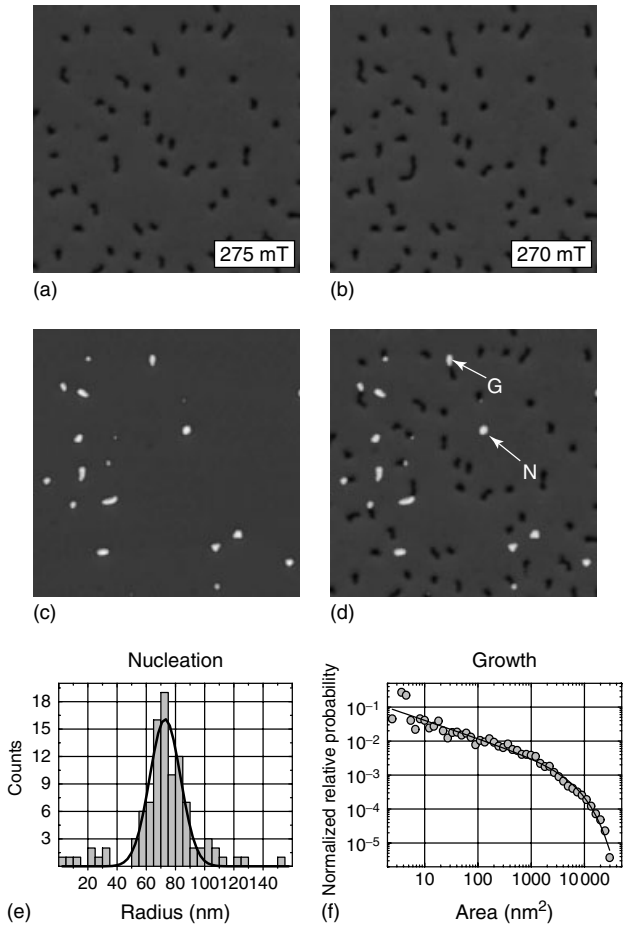

Figure 2. Real space observation of individual magnetization reversal processes in a $La_{0.7}Sr_{0.3}MnO_3$ film with out-of-plane uniaxial anisotropy. (a), (b) Two plane-subtraction mode FM-MFM images ($4 \times 4\,\mu m^2$) from a series recorded along the major hysteresis loop. They have been recorded consecutively in a slightly different external magnetic field. (c) Difference image (a) − (b). Only the magnetization reversal events, that is, the Barkhausen jumps, remain visible. After merging (c) into the original MFM image (a), nucleation (N), and growth (G) events can be distinguished in (d). (e) Gaussian distribution of nucleation radii after evaluation of the whole image series. (f) Size distribution of the growth areas. The solid line corresponds to a power law with exponential cutoff.

2.6 Reorientation transition

The energy of a ferromagnetic material is given by the magnetic anisotropy energy and the stray field energies. The former is related to the spin-orbit coupling. Symmetry changes at surfaces or those due to stress within the material can alter the bulk magnetic anisotropy significantly. The stray field energy strongly depends on the shape of the specimen. Thin films, for example, tend to be polarized in plane, whereby the density of free poles at the surface can be reduced compared to an out-of-plane polarized film. However, for very thin films (a few atomic layers), the surface anisotropy can become dominating and might force the spins in an out-of-plane direction. Consequently, a thickness-dependent reorientation transition can be observed, for example, by the magneto-optical Kerr effect (Qiu, Pearson and Bader, 1993; Baudelet *et al*., 1995), scanning electron microscopy with spin analysis (Speckmann, Oepen and Ibach, 1995) and MFM (Wadas, Dreyer, Kleiber and Wiesendanger, 1998). Figure 3 displays two images from a whole series (Dreyer, Kleiber, Wadas and Wiesendanger, 1999), where the Co thickness on a Au(111) substrate has been increased stepwise up to 7.0 monolayers (ML). The data were recorded in ultra-high vacuum with a magnetic tip that was polarized along the tip axis, which is oriented perpendicular to the surface. Below 2.0 ML no MFM signal could be verified. From 2.0 to 3.8 ML the MFM images exhibit a clear out-of-plane domain contrast, as visible in Figure 3(a). For higher thicknesses, a domain wall contrast is observed as shown for 6 ML in Figure 3(b). Since the same perpendicularly polarized tip was used, an in-plane domain structure can be inferred, indicating a thickness-dependent reorientation transition. On the same material, it was observed that the surface anisotropy energy can be strongly affected by contaminations (Dreyer, Kleiber, Wadas and Wiesendanger, 1999). For a thickness of 4.3 ML the in-plane polarization switched back to an out-of-plane polarization by adsorption of carbon onto the cobalt film from the residual gas in the vacuum chamber. Another important parameter is the temperature, which can also induce a reorientation transition due to the temperature dependence of the magnetic anisotropy energy.

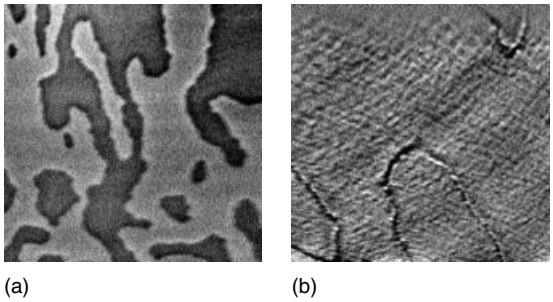

Figure 3. Thickness-dependent reorientation transition of Co on Au(111). The plane-subtraction mode FM-MFM images (a) and (b), both recorded in zero field and in an area of $5 \times 5\,\mu m^2$, have been recorded with the same out-of-plane polarized tip, but with different nominal Co thicknesses, that is, 2.0 ML and 6.0 ML, respectively. In (a) domains are visible, while (b) exhibits a domain wall contrast.

2.7 Domain wall structure

Apart from domain imaging MFM also allows the investigation of domain walls (Proksch, Foss, Dahlberg and Prinz,

1994; Schneider, Müller-Pfeiffer and Zinn, 1996; Löhndorf, Wadas, van den Berg and Wiesendanger, 1996). There are two principle ways for the magnetic polarization in neighboring antiparallel in-plane polarized magnetic domains in a film geometry to rotate by 180°. The polarization vector either rotates fully out-of-plane or remains in-plane all the time. The former case is called Bloch wall and the latter Néel wall, respectively. As a general rule, Bloch walls are observed in rather thick films, where the magnetostatic energy density due to the interaction between the free poles in the Bloch walls on opposite surfaces is negligible. For thinner films this energy contribution becomes dominant and Néel walls, where no free poles are generated at the surfaces, are energetically favorable. However, the thickness-dependent transition from a Bloch to a Néel wall is not abrupt. In an intermediate thickness range a mixture of both types is present – a so-called cross-tie wall. Figure 4 shows an MFM image of such a wall in a 50-nm-thick polycrystalline Co film on a SiO_2 substrate imaged with an out-of-plane polarized tip (Löhndorf, Wadas, van den Berg and Wiesendanger, 1996). Bright and dark areas correspond to the complex distribution of free poles at the surface (cf. equation (8)) within the domain wall as indicated in the inset. The Bloch lines in the middle of the rhombi, where the magnetic polarization points normal to the surface, exhibit the strongest contrast. Even far away from the domain wall the MFM contrast is not uniform. The textured MFM signal indicates that the magnetic polarization is not exactly in-plane everywhere, but tilts slightly out-of-plane locally (Löhndorf, Wadas and Wiesendanger, 1997). This effect results in the well-known magnetic ripple structure, which is often observed in thin films.

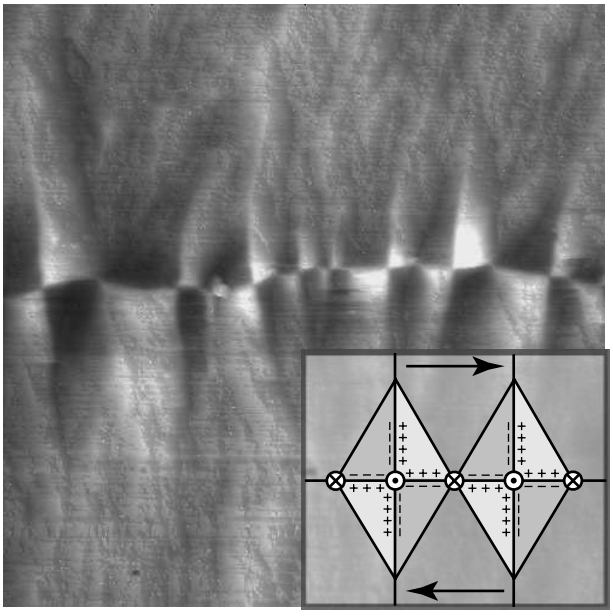

Figure 4. Static mode MFM image ($20 \times 20\,\mu m^2$) recorded in the lift mode of a cross-tie wall acquired with an out-of-plane polarized tip. Sign and distribution of magnetic poles, which are responsible for the contrast formation, are displayed in the inset.

2.8 Multidomain particles

From a technical point of view domain patterns of laterally structured thin film elements become increasingly important owing to the development of micro- and nanoscale magnetoelectronic devices. In hybrid ferromagnetic-semiconductor spintronic systems, such elements act as source for spin-polarized electrons, which is obviously influenced by local variations of the spin orientation due to the presence of differently oriented domains and domain walls between them. Since the relative portion of edges becomes larger for smaller lateral dimensions, the existence of closure domains, where the direction of the magnetic polarization runs parallel to the edges, is the most obvious feature in finite size elements. Figure 5 shows a lithographically prepared rectangular $4.0 \times 2.0\,\mu m^2$ large element. In (a) and (b) the film thicknesses are 100 nm and 70 nm, respectively (Barthelmess, Pels, Thieme and Meier, 2004). The in-plane polarized closure domain pattern remains unchanged, but the type of domain wall between the two main domains is different. In (a) a simple Bloch wall facilitates the 180° rotation, while the thinner structure in (b) exhibits a cross-tie wall, as described in the previous section (cf. Figure 4). Image (c) displays a micromagnetic simulation of (b). All features visible in the

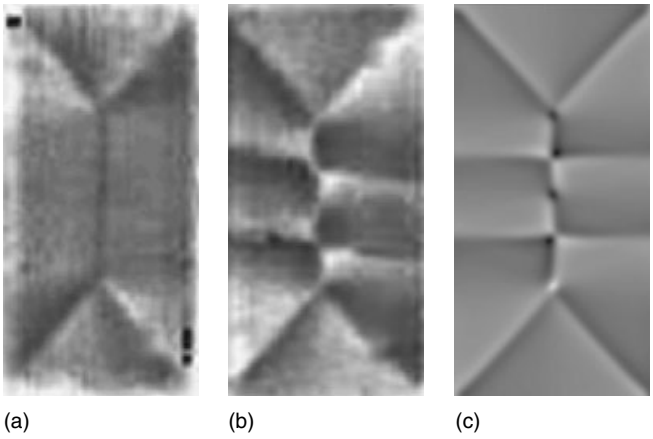

Figure 5. Lift-mode AM-MFM images of polycrystalline $Ni_{83}Fe_{15}$ (permalloy) multidomain particle ($4.0 \times 2.0\,\mu m^2$) with (a) 100 nm and (b) 70 nm thickness. The two central domains in the thicker film (a) are separated by a simple Bloch wall, while the more complex cross-tie wall evolves in the thinner film (b). In (c) a micromagnetic simulation of the experimental situation in (b) is shown, which reproduces the MFM contrast well. (Courtesy of G. Meier (Barthelmess, Pels, Thieme and Meier, 2004).)

MFM image, that is, domain pattern as well as the cross-tie wall, are very well reproduced. Note that the simulation appears sharper than the MFM image, because the real tip is not a point dipole. Furthermore, in experimental data domain walls are often somewhat distorted if the tip modifies the spin orientation locally.

2.9 Single domain particles

If the size of ferromagnetic particles is shrunk below a certain value, the energy cost by inserting a domain wall to minimize the stray field energy is too high. Since the stray field energy scales with R^3, but the domain wall energy only with R^2, a critical particle radius exists, below which the stable configuration even in remanence is the single domain state with two discrete directions of the magnetic polarization (Kittel, 1946; Frei, Shtrikman and Treves, 1957). Note that only ellipsoidal bodies can exhibit a truly uniform remanent magnetic polarization in which the magnetic polarization is parallel at all places within the particle.

Assuming a rotational ellipsoid, a critical diameter D_c can be determined by comparing the energy difference between a single- and a two-domain state (Kronmüller, Goll, Hertel and Schütz, 2004)

$$D_c = \frac{3\mu_0\gamma_{DW}}{N(1-\beta)J_S^2} \tag{13}$$

Here, γ_{DW} is the wall energy, for example, $4\sqrt{AK}$ for a Bloch wall, N is the shape-dependent demagnetization factor, and β is the factor by which the stray field energy is reduced in the two-domain configuration compared to the single domain configuration. Using typical parameters for cobalt, that is, $A_{ex} \approx 3 \times 10^{-11}\,\mathrm{Jm}^{-1}$, $K \approx 4.5 \times 10^5\,\mathrm{Jm}^{-3}$ and $J_S \approx 1.8\,\mathrm{T}$, single domain behavior can be observed for magnetic particles with diameters below $D_c \approx 34\,\mathrm{nm} \cdot (N(1-\beta))^{-1}$. Note that N, $\beta < 1$, and therefore $(N(1-\beta))^{-1} > 1$), that is, the single domain state for Co particles is observed on length scales often much larger than 34 nm.

Figure 6 shows two MFM images of a quadratic array of disks shaped particles with a periodicity of 500 nm (Kleiber *et al.*, 1998). The 17-nm-thick Co disks with a diameter of 200 nm have been produced lithographically on a GaAs substrate with 3-nm Cr adhesion layer as spacer. Owing to their shape, the easy axis of magnetic polarization is in plane. The in-plane demagnetization factor for this diameter to thickness ratio is about $N \approx 0.1$, whereby the critical length scale for the single domain state is larger than 300 nm, which is larger than the disk diameter.

Image (a) has been recorded with a standard out-of-plane polarized tip, while the tip in image (b) was polarized in plane. The inset in the lower right corner displays a simulation of the MFM contrast. In (a) the bright and dark contrast reflects the north and south pole of the magnetic dot, where the direction of the stray field is out of plane and oriented either parallel (bright) or antiparallel (dark) with the magnetic polarization of the tip. Note that the area occupied by the dark and bright contrast is somewhat larger than the particle size. For an in-plane tip the orientation of its magnetic polarization and stray field outside of the particle coincides at three positions above the particle: above the center and at two ends, where the field lines leave and reenter the particle. At the two ends the direction of the magnetic field lines are opposite to the direction of the field lines above the particle center. Therefore, image (b) exhibits a stripelike contrast. Since the sample was magnetized in plane before the measurements, all magnetic polarization vectors are in the same direction. Without magnetization they are randomly distributed as long as the interparticle distance is large enough. Otherwise, dipolar coupling results in local ordering. It is also possible to study the switching between the two states of a single domain particle by using the stray field from the tip plus an external field (Kleiber *et al.*, 1998). Specific orientations of the easy axis within the plane can be induced by preparing elliptical particles (Kleiber *et al.*, 1998).

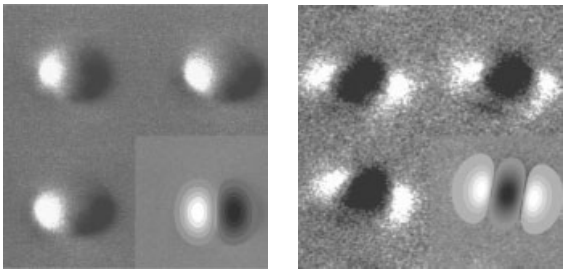

Figure 6. Two Lift-mode AM-MFM images ($1.1 \times 1.1\,\mu\mathrm{m}^2$) of the same single domain particle sample scanned with differently polarized ferromagnetic tips. The disks with a diameter of 200 nm are 17 nm thick with an in-plane easy axis and have been aligned in an external in-plane field of $\mu_0 H_{||} = B_{||} = 0.3\,\mathrm{T}$. The inset in the lower right corner shows simulations of the contrast assuming a purely out-of-plane (a) and in-plane (b) polarized tip, respectively.

The properties and behavior of single domain particles, for example, their magnetization reversal, are of particular interest for magnetic data storage. Granular thin films with typical grain diameters of about 12 nm are used in cobalt based recording media (Thompson and Best, 2000). Today, only a few hundred grains constitute one bit. One source of noise in the readback signal is the presence of domain walls. If only one bit is stored in just one grain, this problem can be overcome. However, one problem is to increase the packing

density of well-defined particle arrays. Another important issue is the so-called superparamagnetic limit. When the size is reduced even more, the direction of the magnetic polarization rotates freely due to thermal excitation and in some respects the particle behaves like a paramagnet and therefore is useless for data storage.

2.10 Magnetic vortices

In small thin square-shaped elements certain magnetic configurations exist, where the magnetic polarization is not uniform, but no real domain walls exist, for example, the so-called C-, S-, and Flower states (Goll, Schütz and Kronmüller, 2003). If the lateral dimensions of the square are large enough, the Landau flux-closure pattern develops, where the magnetic polarization is oriented parallel to the edges. Along the diagonals 90° domain walls are formed. In the center of the square, spin frustration leads to a full out-of-plane rotation of the magnetic polarization. Something similar can occur in disks. For a given disk diameter and a thickness above the critical thickness, below which the single domain state is stable, a vortex state can develop. The magnetic polarization follows the disk curvature and rotates out of plane toward the center, where it finally orients perpendicular to the disk plane. Such a vortex state can be seen in Figure 7 (Shinjo *et al*., 2000). Each permalloy ($Ni_{80}Fe_{20}$) disk is 50 nm thick. The tip was polarized along its axis. Bright and dark dots in their centers mark the positions of the vortices, where the magnetic stray field of the sample and the magnetic polarization of the tip are parallel or antiparallel, respectively. In (a) all disk diameters are 1 µm, while they vary from 100 nm to 1 µm in (b). Unlike in (a) all central dots are dark in (b), because the specimen has been magnetized prior to the MFM measurement. The resolution of MFM does not allow to investigate the fine structure of the vortex core. However, this has been achieved by SP-STM (see Section 3.4). At this point, it should be mentioned that another vortex type has been observed with MFM. Superconducting vortices (flux lines) occur in type II superconductors and consist of a normal conducting core, which is screened by circular currents from the superconducting phase. Each vortex carries one quantum flux, which can be detected by MFM via its stray field. In particular, the arrangements of vortices, for example, the glass state (Moser *et al*., 1995) or the regular Abrikosov lattice (Volodin, Temst, van Haesendonck and Bruynseraede, 1998) and the influence of defects (Pi *et al*., 2004) have been studied. Since the physics behind superconductivity is somewhat different from the magnetism treated here, it will be not discussed further.

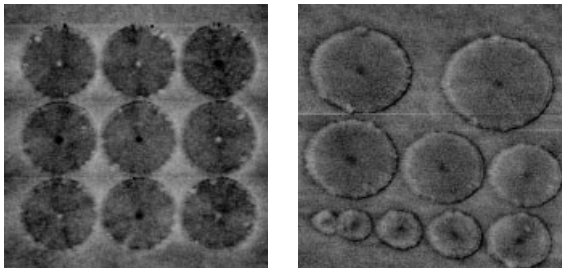

Figure 7. Lift-mode AM-MFM images ($3.6 \times 3.6\,\mu m^2$) of permalloy ($Ni_{80}Fe_{20}$) disks with a thickness of 50 nm. In (a) all disks have a diameter of 1 µm. The spot in the center indicates a vortex, where the magnetization is forced out of plane due to spin frustration. It is bright, if vortex polarity and tip magnetic polarization are parallel, or dark if vortex polarity and tip magnetic polarization are antiparallel. The diameters in (b) range from 100 nm to 1 µm. All vortices exhibit the same polarity, because they were aligned in an external magnetic field of $\mu_0 H_\perp = B_\perp = 1.5\,T$ normal to the sample surface. (Courtesy T. Shinjo (Shinjo *et al*., 2000).)

2.11 The future of MFM

MFM detects only the long-range magnetostatic tip–sample interaction. However, magnetic ordering exists due to the exchange interaction between the electron spins of neighboring atoms in a solid. Several theoretical calculations predicted the feasibility to detect the exchange force between an individual spin of a magnetically ordered sample and the spin of the foremost atom of a magnetic tip at sufficiently small tip–sample distances (Wiesendanger *et al*., 1990a; Mukasa *et al*., 1994; Foster and Shluger, 2001; Momida and Oguchi, 2005). AFM in the dynamic mode using the FM technique in vacuum has proven its capability of achieving *true* atomic resolution (FM-AFM, also known as NC-AFM, cf. Section 2.1). However, the experimental realization of *magnetic exchange force microscopy* (MExFM) is very difficult, because the exchange force is much weaker than the chemical interactions that are responsible for the atomic-scale contrast. Experiments with ferromagnetic tips have been performed on the antiferromagnetic NiO(001) surface at room temperature (Hosoi, Sueoka, Hayakawa and Mukasa, 2000) and with a considerably better signal-to-noise ratio at low temperatures (Allers, Langkat and Wiesendanger, 2001; Hoffmann *et al*., 2003). Although it was possible to achieve atomic resolution, a periodic contrast that could be attributed to the antiferromagnetically ordered spins of the nickel atoms could not be observed in those experiments. However, very recently MExFM has been successfully established by operating a low-temperature AFM in a strong external field, whereby the magnetic polarization of the tip was aligned in a favourable direction. Under these conditions the arrangement of the magnetic moments at the NiO(001) surface could clearly be resolved (Kaiser, Schwarz and Wiesendanger, 2006).

3 SPIN-POLARIZED SCANNING TUNNELING MICROSCOPY

A magnetically sensitive imaging technique which offers an even higher lateral resolution than MFM is spin-polarized scanning tunneling microscopy and spectroscopy (SP-STM/STS). It combines the atomic-resolution capability of conventional, that is, spin-averaged, STM with spin sensitivity. This is achieved by making use of the tunneling magnetoresistance effect between two magnetic electrodes which – in planar geometries and with oxidic barriers – is well studied and routinely utilized for data storage applications. Similar to conventional, that is, spin-averaged STM an atomically sharp tip is scanned at close distance ($\approx$1 nm) across the sample surface. As a bias voltage, typically in the range of several millivolts to a few volts, is applied between tip and sample; a tunneling current flows. Since this tunneling current is strongly distance dependent with a decay constant in the range of $10^{-10}\,\mathrm{m}^{-1}$ it can effectively be used for sampling contours of constant local electronic density of states (LDOS) (Tersoff and Hamann, 1983) which – in the case that the sample's LDOS does not vary too strongly – closely resembles the sample's topography. The tunneling magnetoresistance effect used in SP-STM is based on the principle that, in general, the spin of an electron is conserved during tunneling across a vacuum barrier. Since magnetic materials exhibit an intrinsic imbalance between the spin-majority and spin-minority electronic DOS this leads to a junction transmittance which depends on the relative magnetization directions of the two electrodes involved (Wiesendanger *et al*., 1990b). This review will describe three different operational modes, each with specific amenities and limitations, which allow the measurement of the sample's local magnetization direction.

3.1 Modes of operation

A simple yet powerful theoretical description of these methods was developed by Wortmann and coworkers (2001). They decomposed the tunneling current I measured at tip position $\vec{r}_\mathrm{T}$ and bias voltage U into spin-averaged and spin-dependent contributions, I_0 and I_SP, respectively:

$$I(\vec{r}_\mathrm{T}, U, \theta) = I_0(\vec{r}_\mathrm{T}, U) + I_\mathrm{SP}(\vec{r}_\mathrm{T}, U, \theta) \tag{14}$$

θ is the angle between the magnetization vectors of tip and sample, $\vec{m}_\mathrm{T}$ and $\vec{m}_\mathrm{S}$. By employing Bardeen's description of tunneling Wortmann and coworkers got

$$I(\vec{r}_\mathrm{T}, U, \theta) = \frac{4\pi^3 C^2 \hbar^3 e}{\kappa^2 m^2}\left[n_\mathrm{T}\widetilde{n}_\mathrm{S}(\vec{r}_\mathrm{T}, U) + \vec{m}_\mathrm{T}\widetilde{\vec{m}}_\mathrm{S}(\vec{r}_\mathrm{T}, U)\right] \tag{15}$$

where n_T is the non-spin-polarized LDOS at the tip apex, $\widetilde{n}_\mathrm{S}$ is the energy-integrated LDOS of the sample, and $\vec{m}_\mathrm{T}$ and $\widetilde{\vec{m}}_\mathrm{S}$ are the corresponding vectors of the (energy-integrated) spin-polarized (or magnetic) LDOS:

$$\widetilde{\vec{m}}_\mathrm{S}(\vec{r}_\mathrm{T}, U) = \int_{E=E_\mathrm{F}}^{E=eU} \vec{m}_\mathrm{S}(\vec{r}_\mathrm{T}, E)\,\mathrm{d}E \tag{16}$$

with

$$\vec{m}_\mathrm{S} = \sum \delta(E_\mu - E)\boldsymbol{\Psi}_\mu^{S\dagger}(\vec{r}_\mathrm{T})\boldsymbol{\sigma}\boldsymbol{\Psi}_\mu^{S}(\vec{r}_\mathrm{T}) \tag{17}$$

$\boldsymbol{\Psi}_\mu^S$ denotes the spinor of the sample wave function

$$\psi_\mu^S = \begin{pmatrix} \psi_{\mu\uparrow}^S \\ \psi_{\mu\downarrow}^S \end{pmatrix} \tag{18}$$

and $\boldsymbol{\sigma}$ is Pauli's spin matrix.

According to equation (15) the tunneling current is expected to depend on the relative magnetic orientation between tip and sample since – similar to Slonczewski's model (Slonczewski, 1989) for planar junctions – I_SP scales with the projection of $\widetilde{\vec{m}}_\mathrm{S}$ onto $\vec{m}_\mathrm{T}$, or, in other words, with the cosine of the angle included between the magnetization directions of the two electrodes, $\cos\theta$. Usually, an STM is operated in the constant-current mode where a feedback circuit drives the z component of the piezoelectric actuator such that the tunneling current remains constant while scanning the tip over the sample surface. Since, however, the tunneling current scales exponentially with the tip–sample distance,

$$I \propto \exp(-\kappa z) \tag{19}$$

with κ on the order of $10^{-10}\,\mathrm{m}^{-1}$, even a rather substantial variation of the total tunneling current by several 10% leads to a variation of the tip height on the order of a few tens of picometers ($1\,\mathrm{pm} = 10^{-12}\,\mathrm{m}$) only (Wiesendanger *et al*., 1990b; Kleiber, Bode, Ravlić and Wiesendanger, 2000). Such tiny effects are difficult to detect and also hard to separate from height variations of purely structural or electronic origin. Therefore, as will be demonstrated in Section 3.7, the constant-current mode of SP-STM is primarily suitable for atomic resolution studies on atomically flat surfaces.

One possibility to overcome the difficulties of separating topographic, electronic, and magnetic information is the measurement of the local differential conductance $\mathrm{d}I/\mathrm{d}U$.

Hereby, a small modulation U_{mod} is superimposed to the bias voltage U and the resulting current modulation is detected by means of lock-in technique. Assuming a featureless electronic structure of the tip, the spin-averaged measurement of the differential conductivity, $\mathrm{d}I/\mathrm{d}U_0\,(\vec{r}_{\mathrm{T}}, U) \propto n_{\mathrm{S}}$, gives access to the sample's non-spin-polarized LDOS n_{S} (Selloni, Carnevali, Tosatti and Chen, 1985; Tersoff and Hamann, 1983). If we apply magnetic tips, however, spin-polarized components also contribute and, according to Wortmann *et al*. (2001), the differential conductance can be written as:

$$\begin{aligned}\frac{\mathrm{d}I}{\mathrm{d}U}(\vec{r}_{\mathrm{T}}, U) &= \frac{\mathrm{d}I}{\mathrm{d}U}(\vec{r}_{\mathrm{T}}, U)_0 + \frac{\mathrm{d}I}{\mathrm{d}U}(\vec{r}_{\mathrm{T}}, U)_{\mathrm{SP}} \\ &\propto n_{\mathrm{T}} n_{\mathrm{S}}(\vec{r}_{\mathrm{T}}, E_{\mathrm{F}} + eU) + \vec{m}_{\mathrm{T}}\vec{m}_{\mathrm{S}}(\vec{r}_{\mathrm{T}}, E_{\mathrm{F}} + eU)\end{aligned} \tag{20}$$

This so-called local differential conductance or $\mathrm{d}I/\mathrm{d}U$ mode is sensitive to the spin polarization within a narrow energy interval ΔE around $E_{\mathrm{F}} + eU$. Therefore, it can nicely be applied to spin-polarized surface states (Bode, Getzlaff and Wiesendanger, 1998; Kleiber, Bode, Ravlić and Wiesendanger, 2000) which often provide a large conductance and a high polarization. Even more important, the $\mathrm{d}I/\mathrm{d}U$ signal can be measured simultaneously with the topographic information, thereby allowing an efficient means of separating topographic from electronic and magnetic information. It is important to note, however, that the spin polarization of the magnetic LDOS $\vec{m}_{\mathrm{S}}$ not only changes in size but may also change its sign if different energy intervals ΔE are compared. For example, the surface (and also the tip) may exhibit a positive spin polarization in one energy interval but a negative spin polarization in another (Bode, Getzlaff and Wiesendanger, 1998; Wiesendanger, Bode and Getzlaff, 1999). Consequently, a high $\mathrm{d}I/\mathrm{d}U$ signal does not imply that the magnetization directions of both electrodes are parallel, but rather that the magnetic LDOS in both electrodes have the same sign.

As long as surfaces with homogeneous (spin-averaged) electronic properties are investigated, the differential conductance mode offers a convenient way of imaging magnetic domains at high spatial resolution. For surfaces with an inhomogeneous structure a separation of spin-averaged electronic from magnetic effects can be accomplished by first recording a $\mathrm{d}I/\mathrm{d}U$ image with a bias voltage for which the spin asymmetry defined by

$$A = \frac{\mathrm{d}I/\mathrm{d}U_{\uparrow\downarrow} - \mathrm{d}I/\mathrm{d}U_{\uparrow\uparrow}}{\mathrm{d}I/\mathrm{d}U_{\uparrow\downarrow} + \mathrm{d}I/\mathrm{d}U_{\uparrow\uparrow}} \tag{21}$$

becomes zero (electronic contrast image) and simultaneously recording a second $\mathrm{d}I/\mathrm{d}U$ image with a bias voltage for which the spin asymmetry is maximum (magnetic contrast image) (Pietzsch, Kubetzka, Bode and Wiesendanger, 2004). An alternative means of separating the magnetic contributions which is based an a similar approach by Johnson and Clarke (1990) was developed by Wulfhekel and Kirschner (1999). In analogy to experiments performed on planar tunnel junctions they used a tiny coil for periodically switching the tip magnetization $\vec{m}_{\mathrm{T}}$ back and forth. If the modulation frequency exceeds the cutoff frequency of the feedback loop the measured signal of this so-called local tunneling magnetoresistance mode becomes proportional to the local magnetization of the sample (Wortmann *et al*., 2001):

$$\frac{\mathrm{d}I}{\mathrm{d}\vec{m}_{\mathrm{T}}}(\vec{r}_{\mathrm{T}}) \propto \vec{m}_{\mathrm{S}}(U) \tag{22}$$

Although this mode of operation can effectively separate structural and spin-averaged electronic contributions from magnetic effects, it is important to note that the spin polarization of the magnetic LDOS $\widetilde{\vec{m}}_{\mathrm{S}}$ is not constant, but that its size and sign depends on the respective energy range under study. It may occur, for instance, that contributions with positive and negative spin polarization cancel each other. In this case, the spin polarization of the total tunneling current and thereby the $\mathrm{d}I/\mathrm{d}\vec{m}_{\mathrm{T}}$ signal vanishes in spite of the fact that a local magnetization exists. Another limitation of this technique is that ferromagnetic probe tips have to be used and that their stray field may affect the local magnetization distribution of the sample under investigation.

3.2 Tip preparation

The most delicate part when operating an SP-STM is the preparation of suitable probe tips. So far, two concepts were successfully used, that is, thin-film tips prepared by evaporation of magnetic material onto the tip apex for the constant-current mode and the differential conductance mode as well as amorphous bulk tips for the local magnetoresistance mode.

Thin-film tips are usually prepared by deposition of magnetic material onto an electrochemically etched W tip. Upon etching, the tip is introduced into the vacuum system via a load lock. Early experiments indicated that films evaporated onto untreated tips are mechanically unstable and can easily be lost when approaching toward the sample surface or while scanning. It was found that the film stability can be improved significantly by briefly heating the tip by electron bombardment prior to deposition to about 2200 K. Probably, this high-temperature flash melts the tip apex and removes contaminations which weaken the interfacial sticking. As evidenced by the scanning electron microscopy images shown in Figure 8, however, it also results in blunt tips with a typical diameter of about 1 µm (Bode, Pietzsch, Kubetzka and Wiesendanger, 2001). If such a tip

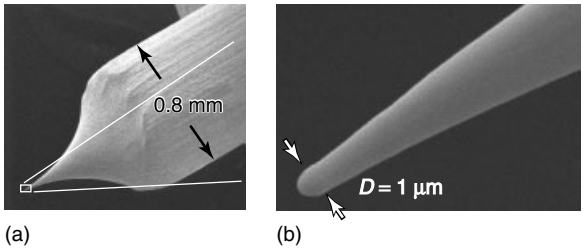

Figure 8. Scanning electron microscopy images of a flashed W tip at (a) medium and (b) higher magnification revealing a tip diameter of about 1 µm.

is coated with 5–10 AL Gd, a GdFe alloy, or a rather thin Cr film (50 AL), out-of-plane sensitivity is obtained. However, the easy magnetization axis of such tips is not always along the tip axis; for example, tips coated with 5–10 AL Fe or more than 100 AL Cr were found to be in-plane sensitive (Bode *et al.*, 2001). Obviously, material-specific surface and interface anisotropies seem to be more important than the shape anisotropy for determining the tip's magnetization direction.

The local magnetoresistance mode, where bulk magnetic material is periodically switched by an external coil, requires a careful choice of the tip material as the tip's magnetization reversal may mechanically couple into the tunnel junction by magnetoelastic coupling (Wulfhekel and Kirschner, 1999). Furthermore, the stray field may cause unwanted changes of the sample's domain structure. In order to minimize these problems, the amorphous ferromagnet CoFeSiB is a suitable material as it combines a low magnetoelastic coupling constant with a low saturation magnetization. By choosing appropriate tip geometries it was possible to tune the sensitivity between out of plane or in plane. As mentioned in the preceding text, the magnetic contrast scales with the angle between the magnetization directions of tip and sample. Out-of-plane sensitivity is easily achieved as a pointed object like an STM tip usually prefers a magnetization direction along the tip axis since this reduces its magnetostatic energy. Figure 9(a) schematically shows an out-of-plane sensitive tip together with the coil which drives the periodic magnetization reversal. Owing to the intrinsic geometry of the STM it is much more difficult to obtain in-plane magnetic contrast. This could be achieved by using tiny ring-shaped tips (Schlickum, Wulfhekel and Kirschner, 2003) as schematically illustrated in Figure 9(b).

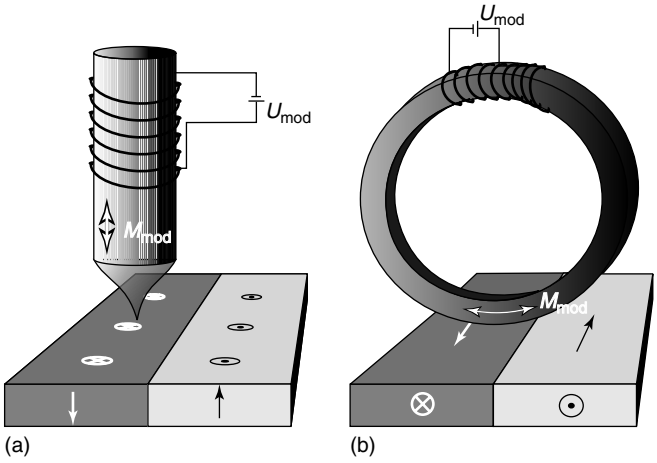

Figure 9. Schematic experimental setup for local magnetoresistance measurements with the STM using (a) an out-of-plane pointed tip and (b) an in-plane-sensitive ring-shaped probe.

3.3 Domain wall structure

In order to prove the high spatial resolution capability of SP-STM a suitable and well-defined test sample is required. The surface spin structure of in-plane magnetized Fe(001) whiskers has been intensively studied by scanning electron microscopy with polarization analysis (SEMPA) in the past (Scheinfein, Unguris, Celotta and Pierce, 1989; Oepen and Kirschner, 1989). In contrast to bulk domain walls, which exhibit a Bloch-like profile, a so-called Néel cap was found on the surface, that is, the magnetization rotates within the plane in order to reduce the magnetostatic energy.

Figure 10(a) and (b) show the topography and the simultaneously measured local magnetoresistance $\mathrm{d}I/\mathrm{d}\vec{m}$ of the

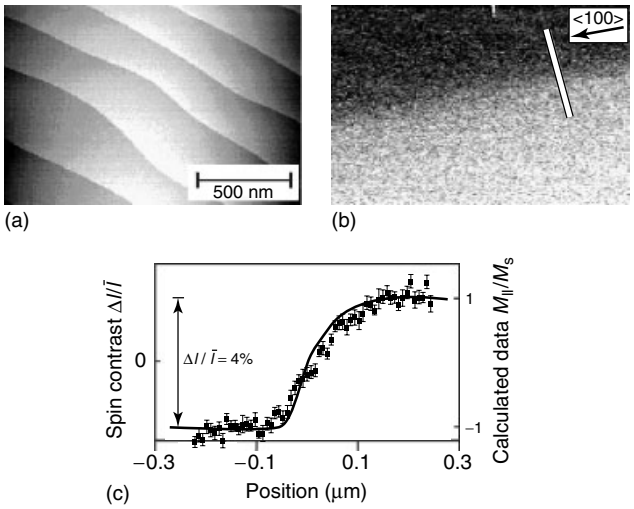

Figure 10. (a) Topography (left column) and (b) the simultaneously measured local tunneling magnetoresistance signal in the central region of an Fe(001) whisker. A domain wall running along a ⟨100⟩ direction can be recognized. A line profile measured along the line in (b) together with a simulated profile is plotted in (c). (Data with courtesy of W. Wulfhekel (Schlickum, Wulfhekel and Kirschner, 2003).)

central region of an Fe(001) whisker, respectively. The topography exhibits six monatomic step edges which separate atomically flat terraces. As visible in the $\mathrm{d}I/\mathrm{d}\vec{m}$ signal in Figure 10(b) a domain wall separates two domains being visible in the upper and the lower part of the magnetic image. The averaged line profile of Figure 10(c) which was taken along the line in (b) reveals a contrast $\Delta I/\overline{I}$ of 4% and a domain wall width of about 100 nm. Comparison with a simulated line profile (black line) shows fair agreement between experiment and micromagnetic calculations (Scheinfein *et al*., 1991).

Much more narrow domain walls were found in Fe nanowires on stepped W(110) (Kubetzka, Pietzsch, Bode and Wiesendanger, 2003). The upper left panel of Figure 11(a) shows a spin-resolved $\mathrm{d}I/\mathrm{d}U$ map of 1.8 AL Fe on W(110) as measured with an in-plane-sensitive tip at zero field (0 mT). Since the total coverage is below two atomic layers the second layer is not closed. Instead, it forms nanowires (DL) along the substrate's step edges which are separated by narrow regions of monolayer coverage. Within the DL nanowires white and black lines can be recognized. They originate from 180° walls which are parallel or antiparallel with respect to the tip magnetization direction, respectively. The wall width amounts to $w \approx 7$ nm. The intermediate $\mathrm{d}I/\mathrm{d}U$ signal (gray) corresponds to a perpendicular magnetization oriented either up or down, two cases which cannot be distinguished with a tip exhibiting pure in-plane sensitivity. The other panels of Figure 11(a) show the same sample area exposed to an increasing perpendicular magnetic field of up to 800 mT. Owing to the Zeeman energy, areas which are magnetized parallel to the field direction grow at the expense of antiparallel ones. Pairs of 180° walls which enclose an antiparallel domain (with respect to the external field) are forced together. Thereby, 360° domain walls are formed.

The internal structure of the 360° walls has been analyzed in detail by Kubetzka *et al*. (2003). Figure 11(b) shows experimental line sections (gray circles) of two adjacent domain walls. The wall profiles can be described by the sum of two 180° walls at the positions $\pm c$:

$$\varphi_{360}(x) = \sum_{+,-} \arcsin\left(\tanh\left(\frac{x \pm c}{w/2}\right)\right) \qquad (23)$$

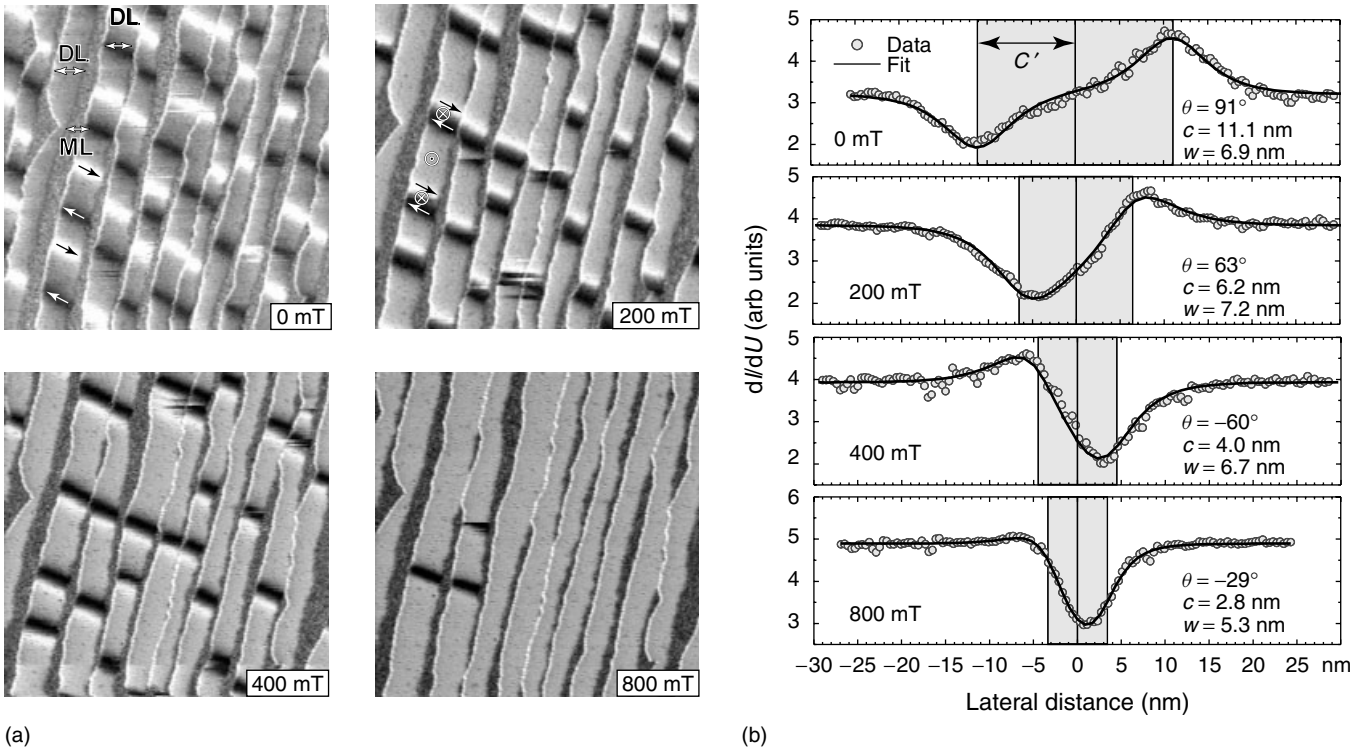

Figure 11. (a) Spin-resolved $\mathrm{d}I/\mathrm{d}U$ maps (scan range: $200 \times 200\,\mathrm{nm}^2$) of perpendicularly magnetized Fe double-layer (DL) nanowires separated by monolayer segments measured at different external fields. At zero field (upper left) black and white lines can be recognized which are approximately equidistant. These lines correspond to differently oriented domain walls (arrows) indicating that the tip is in-plane sensitive. As the external field is enhanced domain wall pairs are formed. Thereby, the domain which is antiparallel to the external field (⊗) is clamped between two domain walls. (b) Experimental line sections (○) of the spin-resolved $\mathrm{d}I/\mathrm{d}U$ signal taken across two domain walls and fits with two 180° domain wall profiles (black line).

The values of c and w can then be extracted from the data if the varying tip magnetization is taken into account. Using the function

$$y(x) = y_0 + a \cdot \cos(\varphi_{360}(x) + \theta) \tag{24}$$

one obtains the fitted curves which are shown as black lines in Figure 11(b). The resulting fit parameters θ, c, and w are displayed within the figure. Owing to the impact of the external field on the ferromagnetic tip θ decreases from 90° to about 30°. The extension of the inner 180° rotation between the two opposite in-plane orientations, which is approximately $2c$, has been marked by a shaded area.

3.4 Magnetic vortices

As described in the previous section (Section 2.10) the existence of perpendicularly magnetized magnetic vortex cores was proven by MFM (Raabe *et al*., 2000; Shinjo *et al*., 2000). However, MFM cannot elucidate the internal spin structure of vortex cores because: (i) the lateral resolution is typically limited to $\approx$20–50 nm, that is, larger than the vortex core, (ii) the magnetic stray field of the MFM tip easily interferes with the vortex, and (iii) the sensitivity is restricted to the out-of-plane component of the stray field gradient. All three problems are avoided by SP-STM using antiferromagnetic probe tips (Kubetzka, Bode, Pietzsch and Wiesendanger, 2002; Wachowiak *et al*., 2002).

Before focusing on the high spatial resolution capabilities of SP-STM we want to demonstrate that magnetic thin-film tips in the differential conductance mode can also be used to study the magnetic domain structure of soft magnetic particles on a nanometer scale. Micromagnetic calculations by Hertel (2002) showed that the lowest-energy domain configuration also depends on the thickness. With increasing thickness a transition from the so-called C-state via the Landau-type or vortex configuration into a diamond state (double-vortex) was found. This behavior is caused by the thickness-dependent contribution of the magnetostatic energy which has to be paid wherever the magnetization is perpendicular to the element's rim. At a certain critical thickness it is energetically favorable to avoid the stray field by magnetizing the element along the edges throughout the entire particle, leading to a so-called flux-closure arrangement.

This transition can be studied by SP-STM. The left column of Figure 12 shows the topography of Fe islands which were epitaxially grown on W(110). The mean island height h varies between 3.5 nm (Figure 12a) and 8.5 nm (Figure 12c). Note that the lateral dimensions of the islands – irrespective of their height – are almost equal, that is, about $250 \times 500\,\mathrm{nm}^2$ along the $[1\bar{1}0]$ and the [001] direction, respectively. In the right column of Figure 12 $\mathrm{d}I/\mathrm{d}U$ maps measured with in-plane-sensitive Cr-coated tips are shown. Since Cr is an antiferromagnetic material these tips possess no stray field and cannot interact with the sample's domain structure via magnetostatic interactions (Kubetzka, Bode, Pietzsch and Wiesendanger, 2002). Since the Fe islands exhibit either a low (dark) or a high (bright) $\mathrm{d}I/\mathrm{d}U$ signal without any significant variation on each particular island, we conclude that the Fe islands shown in Figure 12(a) are in the single domain state. Evidently, there exists a close correlation between the magnetization direction of individual Fe islands and the surrounding Fe ML: dark (bright) Fe islands are always surrounded by a dark (bright) ML. magnetized along $[1\bar{1}0]$. The island in Figure 12(b) exhibits a height $h = 7.5$ nm. The corresponding spin-resolved $\mathrm{d}I/\mathrm{d}U$ map shows the typical pattern of a single vortex state (Wachowiak *et al*., 2002). A diamond state is found on the even higher island shown in Figure 12(c) ($h = 8.5$ nm) (Bode *et al*., 2004).

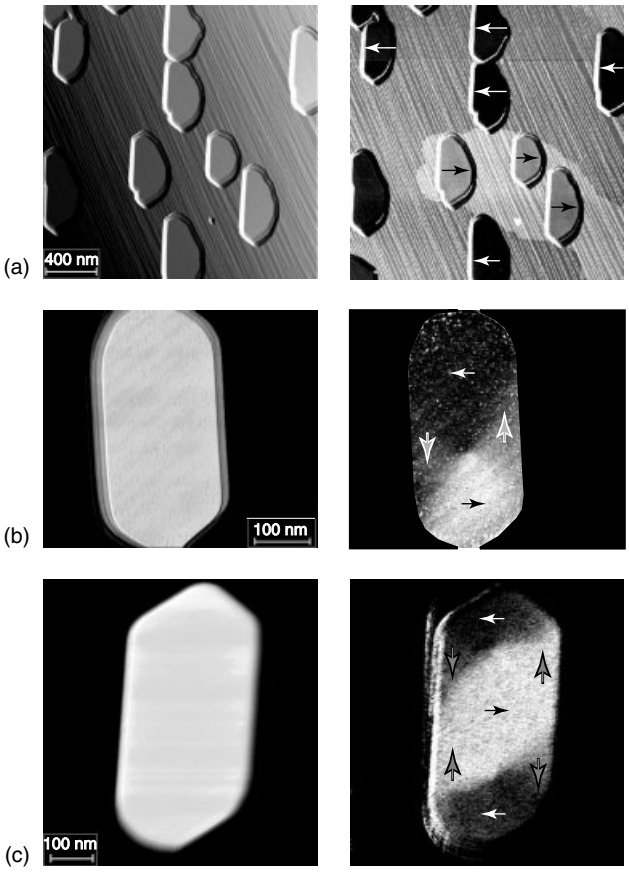

Figure 12. Topography (left column) and spin-resolved $\mathrm{d}I/\mathrm{d}U$ maps (right) of Fe islands on W(110). The mean island height is (a) 3.5 nm, (b) 7.5 nm, and (c) 8.5 nm. With increasing island thickness the magnetic ground state develops from single domain to the vortex configuration and finally to the diamond state.

According to equation (15), the magnetic contrast of SP-STM data scales with the projection of the vector representing the sample magnetization onto the tip magnetization. Consequently, we expect a cosine-like dependence of the magnetic signal if the sample magnetization rotates continuously. This condition is fulfilled in the vortex configuration as observed in Figure 12(b). Here, the magnetization tangentially curls around the particle's center, where a discontinuity of the magnetization is avoided by the formation of an out-of-plane magnetized vortex core, which – depending on the actual material used – is about 10–50 nm in diameter.

Figure 13(a) shows a schematic representation of the expected SP-STS contrast in the vicinity of a vortex core. The actual tip magnetization direction is indicated by an arrow at the left. If bias-dependent effects are not considered, we expect a high (low) signal, if tip and sample are magnetized (anti)parallel and an intermediate contrast, if they are perpendicular. This is indicated by different gray values in the background of Figure 13(a).

In order to illustrate the contrast mechanism of the differential conductance or $\mathrm{d}I/\mathrm{d}U$ mode in more detail, Figure 13(b) shows tunneling $\mathrm{d}I/\mathrm{d}U$ spectra which were measured with an in-plane-sensitive Cr-coated probe tip on top of an about 8 nm high island showing a vortex configuration (Wachowiak *et al.*, 2002). Although the spin-averaged electronic structure of the Fe(110) surface is homogeneous, the STS data reveal a strong spatial variation of the spectral intensity over a wide sample bias range. This variation is due to spin-polarized vacuum tunneling between the STM tip and the magnetic sample surface. With this particular tip only a small spin-dependent $\mathrm{d}I/\mathrm{d}U$ contrast is found at positive bias voltages $U > 0.5\,\mathrm{eV}$. At $U = +0.56\,\mathrm{V}$ all spectra cross and the corresponding spin-dependent $\mathrm{d}I/\mathrm{d}U$ map (inset) shows no systematic contrast. At $0.43\,\mathrm{V} < U < +0.56\,\mathrm{V}$ the spin-resolved $\mathrm{d}I/\mathrm{d}U$ signal in the lower right corner is higher than in the upper left corner of the $\mathrm{d}I/\mathrm{d}U$ map. The highest spin asymmetry of about 0.5 is obtained at $U = -0.18\,\mathrm{V}$. The $\mathrm{d}I/\mathrm{d}U$ peaks are probably caused by a spin-minority d-like surface resonance, which is well known from spin-resolved photoelectron emission experiments (Kim, Vescovo, Heinze and Blügel, 2001). At $U = -0.43\,\mathrm{V}$ the spin-dependent $\mathrm{d}I/\mathrm{d}U$ contrast vanishes and inverts at even lower bias voltage. At $U = 0.70\,\mathrm{V}$ the $\mathrm{d}I/\mathrm{d}U$ spectrum measured in the lower left corner of the spin-dependent $\mathrm{d}I/\mathrm{d}U$ map exhibits a local minimum, while the spectrum in the opposite corner exhibits a shoulder. This results in a very high spin asymmetry of about 70% (see bottom panel).

The data of Figure 13(b) nicely demonstrate that a high spin-resolved $\mathrm{d}I/\mathrm{d}U$ signal not necessarily implies that sample and tip are magnetized parallel. Without an external field available, the sample's magnetization direction can only be determined absolutely if the tip magnetization and the spin character (minority vs. majority) of the concerned electronic states are known. The spin-resolved $\mathrm{d}I/\mathrm{d}U$ spectra and maps of Figure 13(b) were acquired by measuring a full spectrum at every pixel which is very time consuming. If just the domain configuration has to be imaged it is sufficient to perform the measurement at one particular bias voltage with a large spin asymmetry.

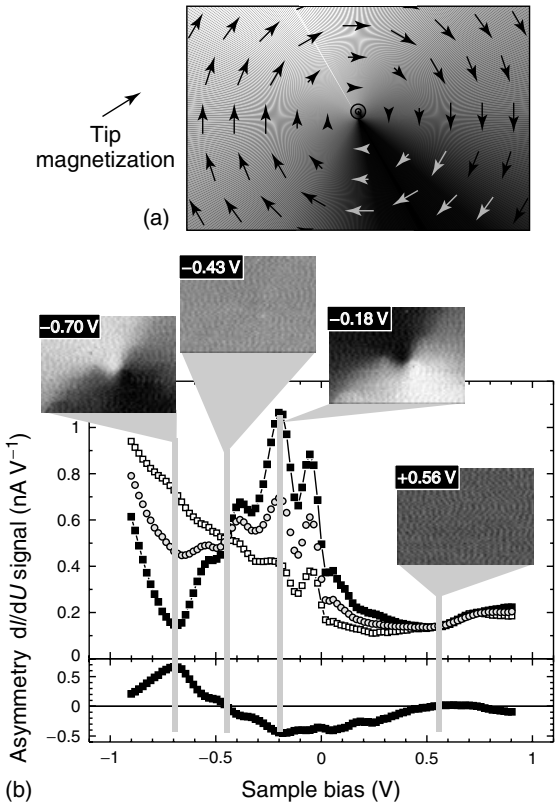

Figure 13. (a) Schematic arrow representation of the tip magnetization (left) and the magnetic structure in the vicinity of a vortex core (right). The contrast in SP-STS images, which is expected to scale with the cosine of the angle included by the tip and local sample magnetization, is shown in gray scale. White, black, and intermediate contrast represents high, low, and medium conductance due to parallel, antiparallel, and orthogonal tip and sample magnetization directions. (b) Tunneling spectra and corresponding spin-resolved $\mathrm{d}I/\mathrm{d}U$ maps (inset) measured with a magnetic tip in the vicinity of a vortex core. The lower panel shows the spin asymmetry between the $\mathrm{d}I/\mathrm{d}U$ spectra measured on the white and black domain.

We have zoomed into the central region of an Fe island where the rotation of the magnetization into the surface normal is expected. Figure 14 shows maps of the spin-resolved $\mathrm{d}I/\mathrm{d}U$ signal measured with Cr-coated tips that are sensitive to the in-plane and out-of-plane components of $\vec{M}_\mathrm{S}$ depending on the thickness of the Cr coating. While the in-plane-sensitive $\mathrm{d}I/\mathrm{d}U$ signal (left column) exhibits the

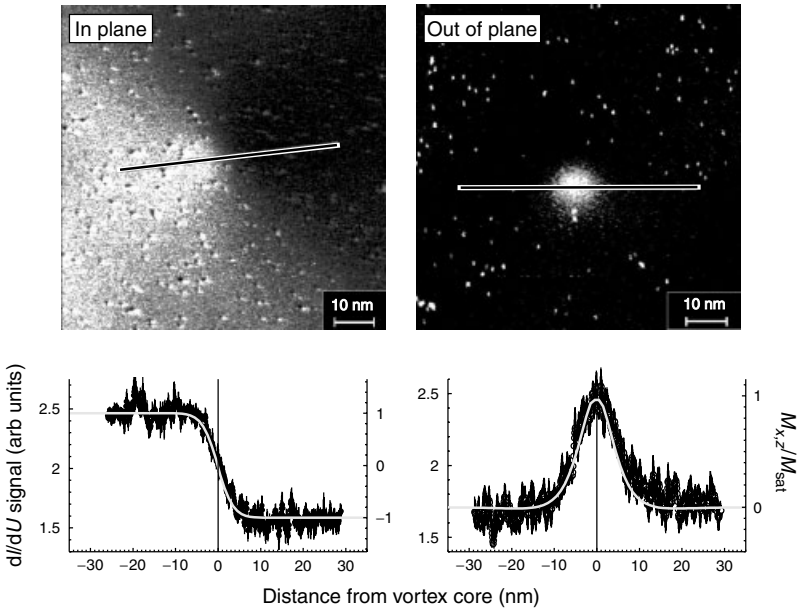

Figure 14. High-resolution spin-resolved $\mathrm{d}I/\mathrm{d}U$ maps taken with in-plane (left) and out-of-plane sensitive Cr-coated tips (right). Experimental line sections taken along the black lines are compared to micromagnetic simulations (gray lines) http://math.nist.gov/oommf/ in the lower panel.

typical Landau pattern the out-of-plane image (right column) shows a homogeneous $\mathrm{d}I/\mathrm{d}U$ signal for the entire island except for a small bright spot approximately located at the island center. This spot is caused by the perpendicular orientation of the magnetization in the vortex core. Line sections drawn along the indicated lines in the experimental $\mathrm{d}I/\mathrm{d}U$ maps (black lines) are plotted in the lower panel. It was predicted theoretically (Feldtkeller and Thomas, 1965; Hubert and Schäfer, 1998) that the shape of a vortex core is determined by the minimum of the total energy, which is dominated by the exchange and the magnetostatic or demagnetization energy. Compared to the latter the magnetocrystalline anisotropy energy, which is relevant for the width of bulk Bloch walls, and the surface anisotropy are negligible, as long as thin films made of soft magnetic materials like Fe are used. For the thin-film limit, that is, $D = 0$, it has been shown (Feldtkeller and Thomas, 1965; Hubert and Schäfer, 1998) that the vortex width as defined by the slope of the in-plane magnetization component in the vortex center is $w_{D=0} = 2\sqrt{A/K_\mathrm{d}} \approx 6.4\,\mathrm{nm}$, where A is the exchange stiffness and $K_\mathrm{d} = \mu_0 {M_\mathrm{sat}}^2/2$ is the magnetostatic energy density with M_sat being the saturation magnetization. This value is in reasonable agreement with the experimental result $w_\mathrm{exp} = 9 \pm 1\,\mathrm{nm}$. For comparison we have also performed micromagnetic calculations employing the widely used OOMMF software http://math.nist.gov/oommf/. In short, the islands were divided into cuboids with lateral dimensions of $1 \times 1\,\mathrm{nm}^2$ and a height of 8 nm. The simulation was started in a perfect vortex state, that is, without any perpendicular component even in the vortex core. Upon relaxation, the simulated profiles (gray lines) are in excellent agreement with the experimental data.

3.5 Exchange-coupled nanoparticles

The ultimate spatial resolution of SP-STM/STS makes it a unique technique for imaging single magnetic particles with dimensions on the single-digit nanometer scale, which can nicely be prepared by epitaxial growth on low-index surfaces of single crystals. For example, Figure 15 shows (a) the topography and (b) the magnetic $\mathrm{d}I/\mathrm{d}U$ signal of a 1.28 ML film as grown on a W(110) substrate held at room temperature. This preparation leads to a closed and thermodynamically stable monolayer of iron and double-layer (DL) iron islands, where the local coverage is $\theta_\mathrm{loc} = 2$ atomic layers (AL) (Gradmann, Liu, Elmers and Przybylski, 1990; Weber *et al*., 1997). As can be recognized in Figure 15(a) the Fe DL islands are about 10 nm wide and elongated along the [001] direction leading to a length of approximately 30 nm on average. This sample system has previously been investigated by Kerr effect measurements (Weber *et al*., 1997) which have been interpreted in terms of a thickness-dependent anisotropy: while the monolayer preferentially keeps the magnetization within the film plane, the DL islands exhibit a perpendicular anisotropy. Consequently, a Gd tip with out-of-plane magnetization is expected to image the domain structure of the DL islands. Indeed, as

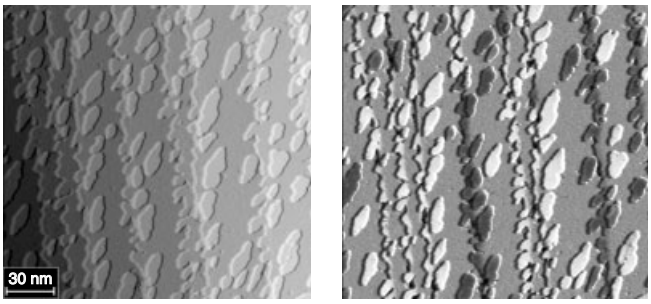

Figure 15. Overview images showing 1.3 AL Fe/W(110): (a) topography and (b) spin-resolved dI/dU map. The perpendicularly magnetized double-layer islands can reduce their magnetostatic energy by changing the magnetization direction of adjacent Fe islands between up and down.

can be recognized in Figure 15(b) two different values of the dI/dU signal are observed representing islands which are magnetized parallel or antiparallel with respect to the tip magnetization. Approximately an equal number of black and white DL islands can be found. By changing the magnetization direction of adjacent Fe islands between up and down on a nanometer scale, the stray field above the sample surface can be reduced. A similar behavior has also been found for narrow Fe DL nanowires where adjacent stripes couple antiparallel (Hauschild, Gradmann and Elmers, 1998; Elmers, Hauschild and Gradmann, 1999; Elmers, 1998; Pietzsch, Kubetzka, Bode and Wiesendanger, 2000).

Images with an even higher magnification (Figure 16) show, however, that the magnetic structure of the Fe DL islands is more complex than a simple demagnetized, noncontinuous out-of-plane medium. Instead, the topography and the corresponding magnetic dI/dU map of Figure 16(a) and (b), respectively, reveal that some islands exhibit an intermediate contrast level. While the dI/dU signal of island A and C is high and low, respectively, island B appears gray, that is, the dI/dU signal measured on this island has an intermediate value. This analysis is also supported by a histogram of the dI/dU signal strength measured above the three DL islands shown Figure 16(c). The experimental observation of Figure 16 can only be explained if island B is either nonmagnetic or in-plane ferromagnetic. As analytically described by a one-dimensional model by Kubetzka *et al.* (2001) – which is based on the model of spatially switching anisotropies introduced by Elmers (1998) – the magnetic behavior of the Fe double-layer islands is governed by the close proximity of regions with different anisotropies: while the closed ML exhibits an in-plane easy axis it is perpendicular for the DL. As long as the DL island is sufficiently large the

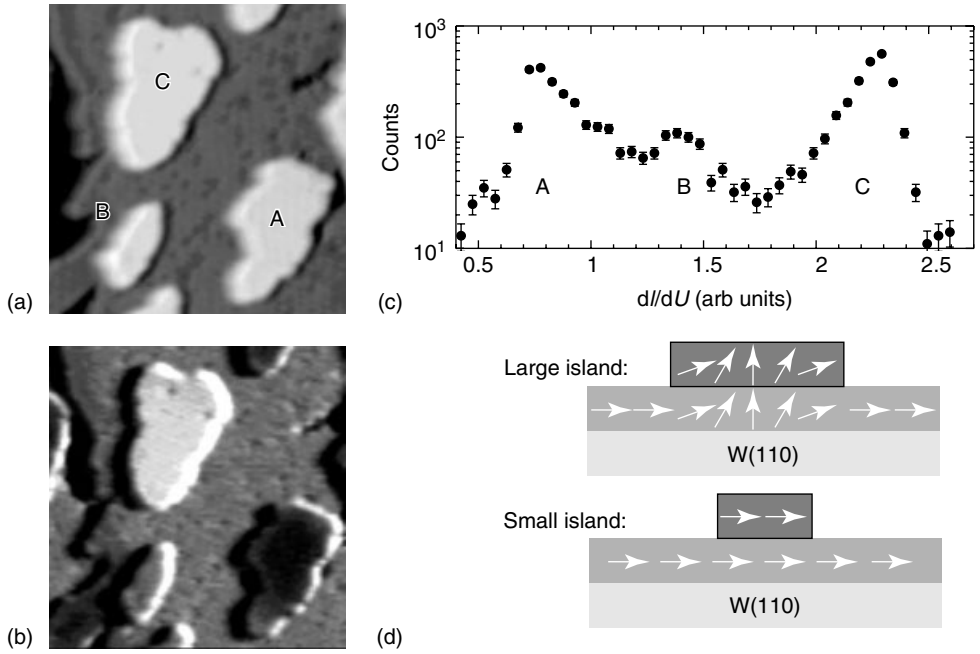

Figure 16. (a) Topography and (b) spin-resolved dI/dU map (scan range: $20 \times 22\,\mathrm{nm}^2$) showing three double-layer islands marked A–C. (c) Histogram of the spin-resolved dI/dU signal measured on the islands' surfaces. Obviously, island B exhibits an intermediate spin-resolved dI/dU signal. (d) In large Fe DL islands, the magnetization rotates out of the easy plane of the monolayer (ML) into the perpendicular easy axis of the double layer (DL) thereby forming a 90° domain wall. As the Fe DL islands become too small it is energetically favorable to keep the magnetization in plane as the domain wall costs too much energy. As a result of the exchange coupling between the DL islands and the in-plane magnetized ML the magnetization of small islands remains within the surface plane.

local magnetization rotates by 90° from in plane to out of plane at the boundary between the closed Fe ML and the DL islands. As the DL islands become smaller and smaller the energy which is gained by turning the magnetization into the easy magnetization direction of the DL decreases, until it is smaller than the energy that has to be paid for the 90° domain wall that surrounds the DL island. Then it is energetically favorable to keep the magnetization of the DL in plane, in spite of the fact that the local anisotropy suggests a perpendicular magnetization direction. This example shows that the high spatial resolution of spin-polarized STM leads to a better understanding of the magnetic properties, especially, if the material is inhomogeneous on the nanoscale.

3.6 Dynamic processes

Microscopy techniques, which acquire the data sequentially by scanning the sample point by point and line by line, offer usually a very limited time resolution which is restricted to the image sampling rate. This is also valid for STM and its spin-sensitive form, that is, SP-STM. Nevertheless, it is possible to observe dynamic processes like the thermal switching behavior of sufficiently small magnetic particles, if the switching time is sufficiently slow.

Epitaxial superparamagnetic particles can be prepared by the evaporation of about 0.1–0.3 AL Fe on Mo(110). For example, the topography of 0.25 AL Fe on Mo(110) is shown in Figure 17(a). Mo is nonmagnetic and therefore cannot couple adjacent islands by direct exchange. As can be seen in Figure 17(b) which was measured with an out-of-plane sensitive Cr tip at $T = 13 \pm 1$ K, most of the Fe islands are too large (area $a > 40\,\mathrm{nm}^2$) and therefore magnetically stable on the timescale of imaging, that is, several seconds. These islands exhibit either a high or a low spin-resolved $\mathrm{d}I/\mathrm{d}U$ signal representing islands being magnetized (anti)parallel with respect to the tip. The spin-dependent $\mathrm{d}I/\mathrm{d}U$ signal of some islands, however, is not constant but changes either between two subsequent lines within one particular image (black arrows in Figure 17(b) and (c)) or between subsequent images (white arrows) indicating that they are magnetically unstable.

As mentioned in the preceding text, the scanning process of SP-STM strongly limits the achievable time resolution. This restriction can be bypassed by giving up one or even both scanning directions and operating the STM in the so-called line or point mode, respectively. In this case, the time resolution is not limited by the image repetition rate but by the line frequency or by the increment between two successive points within one particular scan line. An example of a measurement performed in the line mode is presented in Figure 18. In the lower part of the topographic image of Figure 18(a) a line marks four islands, the section of which is shown in Figure 18(b). These islands are labeled A–D from left to right. By repeatedly scanning along the same line for about 40 min, thereby crossing islands A–D at a rate of 1 Hz, one obtains spin-resolved $\mathrm{d}I/\mathrm{d}U$ maps as shown in Figure 18(c). Since the position of the slow scanning direction is spatially fixed, this direction represents the time rather than a lateral scale. The spin-resolved $\mathrm{d}I/\mathrm{d}U$ maps of Figure 18(c) have been recorded at the same site of the sample at $T = 13$ K (bottom panel) and $T = 19$ K (top panel). At $T = 13$ K islands A and D exhibit a low and island C a high $\mathrm{d}I/\mathrm{d}U$ signal. Since these islands are rather large no switching processes were observed on the timescale of the experiment. Only island B, which is much smaller, switches about 50 times. As the temperature is raised to $T = 19$ K, however, larger islands become magnetically unstable, too. Now even the largest island, D, switched once.

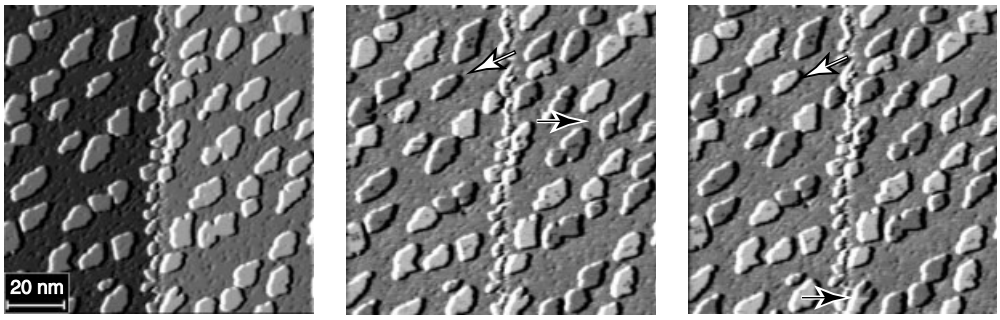

Figure 17. (a) Topography and (b) the simultaneously recorded spin-resolved $\mathrm{d}I/\mathrm{d}U$ map of 0.25 AL Fe/Mo(110). The islands are perpendicularly magnetized up or down. The use of an out-of-plane sensitive Cr-coated probe tip results in a spin-polarized contribution which appears as two distinct $\mathrm{d}I/\mathrm{d}U$ contrast levels. The black arrows indicate Fe islands which switch between two subsequent scan lines of the same image. Obviously, these islands are magnetically unstable at the measurement temperature $T = 13$ K. (c) Another island (white arrow) magnetically switches in the time interval of two successive $\mathrm{d}I/\mathrm{d}U$ maps.

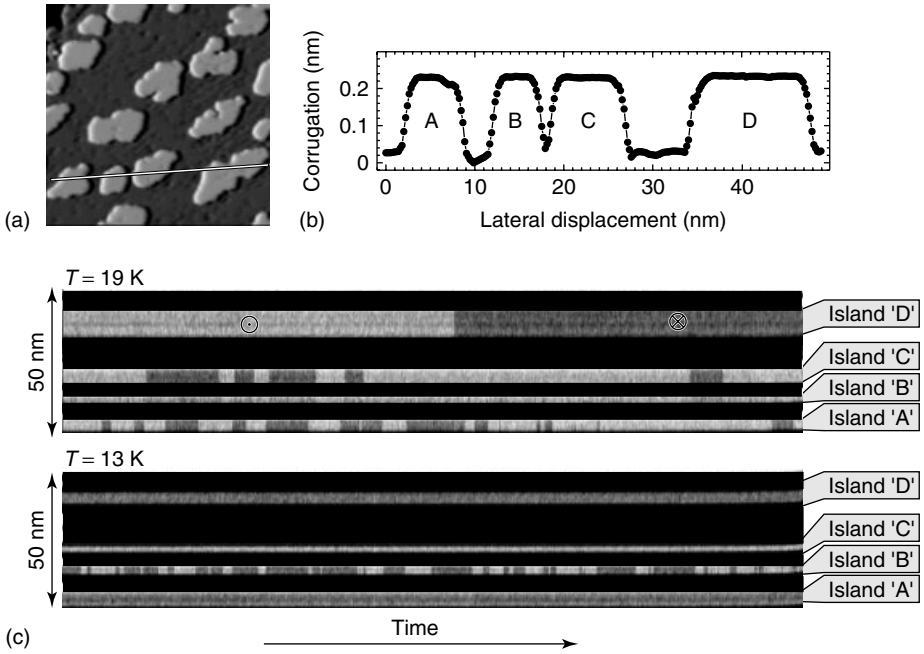

Figure 18. (a) Topography of Fe monolayer islands on Mo(110). The scan range amounts to $40 \times 40\,\mathrm{nm}^2$. (b) Line section showing the profile of four individual islands labeled A–D. (c) Spin-resolved $\mathrm{d}I/\mathrm{d}U$ maps of the islands A–D shown in (b) as measured in the line mode at $T = 13\,\mathrm{K}$ (bottom panel) and $T = 19\,\mathrm{K}$ (top panel).

3.7 Atomic resolution

The special strength of STM is its unique spatial resolution down to the atomic scale. After showing that the SP-STM can also be utilized to obtain information about magnetic properties like the surface domain structure or the spin-dependent LDOS, it is quite straightforward to ask whether atomic spin resolution can also be achieved. Obviously, this task requires an appropriate test sample. The smallest possible magnetic structure is a magnetically ordered surface where the magnetic moment alternates between adjacent atomic sites, that is, an antiferromagnet.

Many materials, which are known to be antiferromagnets in the bulk, are either alloys with a complex stoichiometry that cannot be stabilized at the surface or exhibit a surface magnetic ordering which differs from the bulk (Hänke *et al*., 2005). Therefore, we decided to search for a thin-film antiferromagnet, which can be grown epitaxially on a refractory metal. One potential candidate is the Fe monolayer on W(001). Early density-functional calculations (Wu and Freeman, 1992) surprisingly predicted an antiferromagnetic ground state that has been confirmed recently (Kubetzka *et al*., 2005). Figure 19(a) shows the topography of 1.1 AL Fe/W(001). Several double-layer islands with lateral dimensions of less than 10 nm can be recognized.

With an out-of-plane sensitive Cr-coated probe tip we have zoomed into the monolayer region approximately in the center of Figure 19(a) (see box). Figure 19(b) and (c) show the simultaneously measured spin-resolved constant-current image and $\mathrm{d}I/\mathrm{d}U$ map, respectively. Besides two adsorbates which appear as protrusions, the constant-current image shows a two-dimensional lattice which represents the antiferromagnetic (2×2) superlattice: owing to the spin-polarized contribution to the tunneling current the tip is retracted from (approached toward) the sample surface wherever the tip's magnetic LDOS is (anti)parallel with respect to the sample. As can be seen in the top panel of Figure 19(d) the corrugation amounts to 2 pm only with a periodicity of about 0.5 nm which is in good agreement with the expected 0.45 nm. In the spin-resolved $\mathrm{d}I/\mathrm{d}U$ map of Figure 19(c) the same superstructure is visible.

In order to unambiguously prove the magnetic origin of the superstructure, we have performed field-dependent experiments employing ferromagnetic tips. Since the exchange coupling within the Fe monolayer is much stronger than the Zeeman energy, the external field leaves the sample's magnetic structure unaffected but only changes the vertical component of the tip magnetization. Figure 20 shows images taken within the same $4 \times 4\,\mathrm{nm}^2$ large region around an adsorbate. Between the measurements we have changed the field direction from $+2.5\,\mathrm{T}$ to $-2.5\,\mathrm{T}$. This field strength is sufficient to force the magnetization of Fe-coated tips out of their native in-plane direction to out of plane. If the observed superstructure is indeed of magnetic origin the

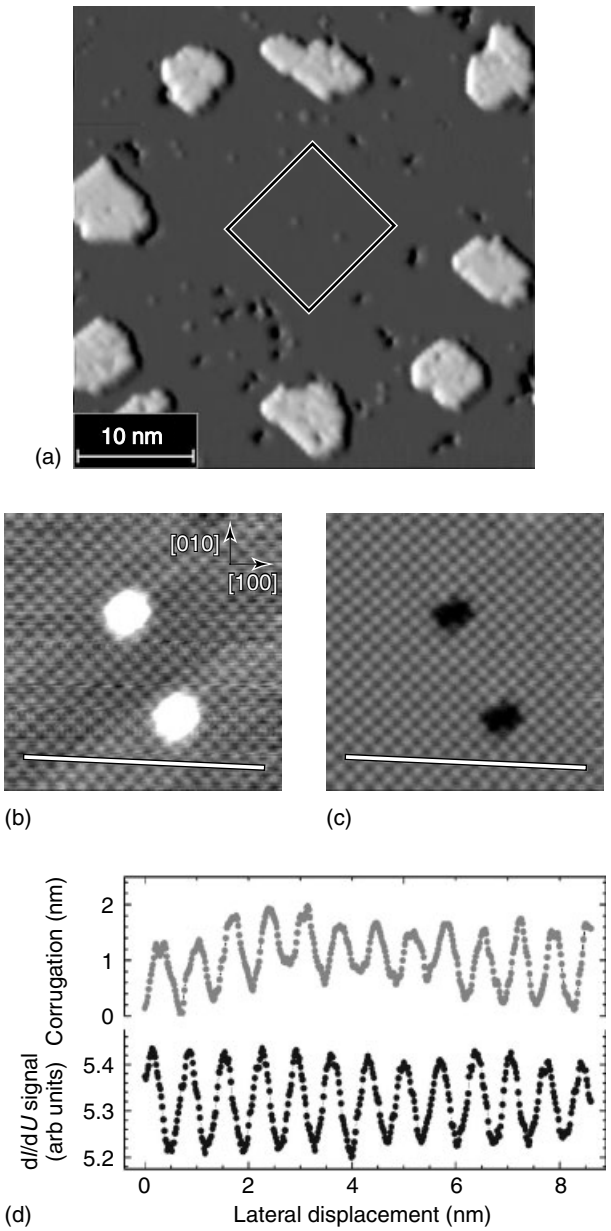

Figure 19. (a) Topography of 1.1 AL Fe on W(001). Within the region marked by the box we have simultaneously measured (b) a spin-resolved constant-current image and (c) a spin-resolved $\mathrm{d}I/\mathrm{d}U$ map. Note that the two adsorbates appear as protrusions in the topography but exhibit a lower $\mathrm{d}I/\mathrm{d}U$ signal strength. (d) Line sections taken along the lines in (b) and (c).

pattern must invert. In contrast, the superstructure would remain unchanged if it were caused by structural effects. The top and bottom images of Figure 20 display the sum and the difference of the two images, respectively. Indeed, the contrast vanishes in the sum and is enhanced in the difference image. Interestingly, the magnetic superstructure is visible even at the position of the adsorbate. This observation

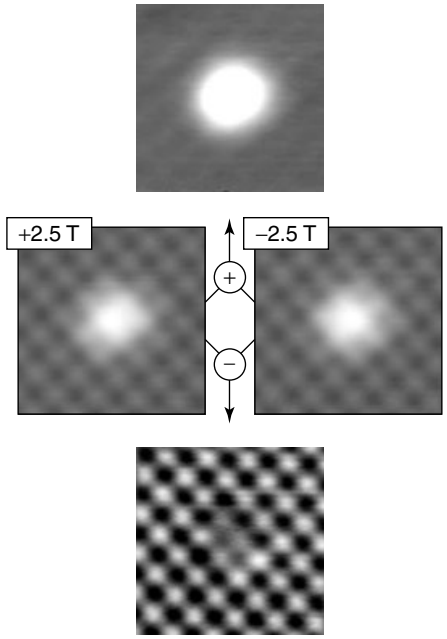

Figure 20. Constant-current images of a $4 \times 4\,\mathrm{nm}^2$ region of an Fe monolayer on W(001) around a native adsorbate measured with an Fe-coated tip at different external fields ($I = 30\,\mathrm{nA}$, $U = -40\,\mathrm{mV}$). Since the exchange coupling within the Fe monolayer is much stronger than the Zeeman energy, the external field leaves the sample's magnetic structure unaffected but only changes the vertical component of the tip magnetization. Thereby, any magnetic contrast is inverted but topographic and spin-averaged electronic contributions remain unchanged (middle row). Consequently, the sum (top row) and the difference (bottom row) of two images recorded with opposite tip magnetization directions allow the separation of nonmagnetic from magnetic contributions, respectively.

indicates that the Fe antiferromagnetic state is largely unaffected by the adsorbate.

SUMMARY

The results shown in this chapter demonstrate that both methods, MFM as well as SP-STM, have been developed into powerful tools for high-resolution studies of the domain structure of nanoscale samples. While MFM is easily applicable even under ambient conditions but offers a rather limited resolution of about 20 nm, SP-STM achieves atomic spin resolution with the drawback that it can only be applied under ultrahigh vacuum UHV conditions so far. Future developments may enable to overcome these limitations; for example, the spatial resolution of MFM can be improved by a further reduction of the tip–sample distance until the magnetic exchange force can be detected (Kaiser, Schwarz and Wiesendanger, 2006). In order to apply SP-STM under ambient conditions one may passivate the sample with an appropriate adsorbate layer (Berbil-Bautista *et al*., 2006).

Alternative Patterning Techniques: Magnetic Interactions in Nanomagnet Arrays

Jacques Ferré and Jean Pierre Jamet
UMR CNRS, Université Paris-Sud, Orsay, France

1 INTRODUCTION

There is presently an increasing challenge to prepare and study 2D assemblies of identical nanoparticles or magnetic nanoelements (nanomagnets) by sophisticated techniques. This approach is complementary to the investigation of isolated, well-characterized nanomagnets (see also **Magnetization Configurations and Reversal in Small Magnetic Elements, Volume 2** and **Superparamagnetic Particles, Volume 4**). In arrays, the interactions with the surrounding elements cannot be generally neglected. Many techniques (Martin *et al*., 2003; Carl and Wassermann, 2002) are used to prepare arrays of nanomagnets, based on bottom-up (see also **Chemical Synthesis of Monodisperse Magnetic Nanoparticles, Volume 3**, **Template-based Synthesis and Characterization of High-density Ferromagnetic Nanowire Arrays, Volume 4** and **Novel Nanoparticulate Magnetic Materials and Structures, Volume 4**) or top-down approaches (see also **Nanoimprint Technology for Patterned Magnetic Nanostructures, Volume 3**), these last methods being applied to ultrathin film structures.

A combination of lithography and ion milling processes is the most common top-down technique used for patterning ultrathin films to create arrays of magnetic nanoelements (see also **Nanoimprint Technology for Patterned Magnetic Nanostructures, Volume 3**). The ultimate resolution is presently obtained by electron-beam lithography, but this method is limited to the fabrication of small size arrays. In counterpart, optical lithography allows one to realize arrays of nanomagnets with a rather small period (80 nm) over large areas, but without perfect identicae shape. Thus, new nonconventional ways of top-down high-resolution patterning over relatively large areas are highly desirable, especially to design new types of discrete high-density magnetic recording media or arrays of memory cells.

While always focusing on the issues of Volume 3 of the Handbook, this chapter will begin in earnest in Section 2 by dealing with alternative top-down patterning methods used for designing arrays of magnetic clusters or ultrathin film nanoelements. This review will be concerned only with simple 2D-metallic patterned nanostructures. Note that only limited data are available so far on magnetic semiconductor (Heimbrodt and Klar, 2002) or insulating film nano structures. In this chapter, particular emphasis is devoted to patterning by ion irradiation, either through masks or by focused ion beam (FIB). Following a survey of magnetic properties in arrays of nanoelements in Section 3, the specific behavior

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

of selected nanostructures will be examined in Section 4. Periodic arrays of nanomagnets are good candidate to understand the role played by competitive interdot exchange and magnetostatic interactions. We will investigate the evolution of magnetic properties from isolated to strongly interacting and correlated nanoelements especially in the simple case of Pt/Co/Pt out-of-plane magnetized nanostructures.

All along the review, the applicability to ultrahigh density magnetic recording will be emphasized. Arrays of identical nanomagnets, also called *quantum magnetic dots* (Chou, Wei, Krauss and Fischer, 1994), are promising media for ultrahigh density recording (Ferré, 2001; Lodder, Haast and Abelmann, 2001; Lodder, 2004; Carl and Wassermann, 2002). In this spirit, nanodot arrays deposited by sputtering on preetched wafers will be examined. The case of electrodeposited magnetic wires deposited inside periodic holes in membranes or alumite templates will be treated in another contribution (see also **Template-based Synthesis and Characterization of High-density Ferromagnetic Nanowire Arrays, Volume 4**). The case of patterned nanodot arrays for magnetic recording fabricated by interference optical lithography (Lodder, 2004) will not be treated here.

2 FABRICATION METHODS

In this chapter, we will restrict ourselves to top-down fabrication techniques, excluding lithography as a single step process. Lithography techniques have been previously reviewed (Martin *et al*., 2003; Carl and Wassermann, 2002), but they do not address to new alternative techniques such as films deposited on preetched templates or patterned by ion irradiation patterning.

2.1 Deposition on prepatterned templates

2.1.1 Preetched substrates prepared by lithography

This method was first proposed by Gadetsky, Erwin, Mansuripur and Suzuki (1996) to prepare perpendicular magnetic recording media. Photolithography was used first to pattern square arrays of dots on glass or plastic substrates, on which a thin SiN (10 nm)/Tb-rich TbFeCo (25 nm) magnetic film structure was subsequently deposited. The etching depth, dot size, and periodicity were 10, 250, and 500 nm, respectively.

More recently, Landis, Rodmacq and Dieny (2000) have patterned Si wafer templates in the form of square nanopillars by conventional lithography and reactive etching techniques. The last step of the preparation consists of sputter depositing a Co/Pt multilayer at low Ar pressure onto the entire preetched substrate. The lateral size of the Si nanopillars was first reduced down to 80 nm, with spacing as small as 100 nm (Moritz *et al*., 2002) (Figure 1). But, by reactive ion etching and nanoimprinting, arrays of 30nm dots with 60nm periodicity were finally fabricated. A relatively weak surface roughness of 0.8 nm was measured on the top of 47 or 200-nm-high nanopillars. Large pattern sizes, up to 3 mm × 3 mm were realized. Sputtering of Co at normal incidence and of Pt at a small incidence angle allowed one to deposit a Pt-rich PtCo ultrathin film alloy (i.e., a nonmagnetic material) on one sidewall of the nanopillars and CoO on the opposite sidewall. As a result, ferromagnetic coupling between the CoPt nanodots deposited on the top of nanopillars and the PtCo layer located in between was eliminated.

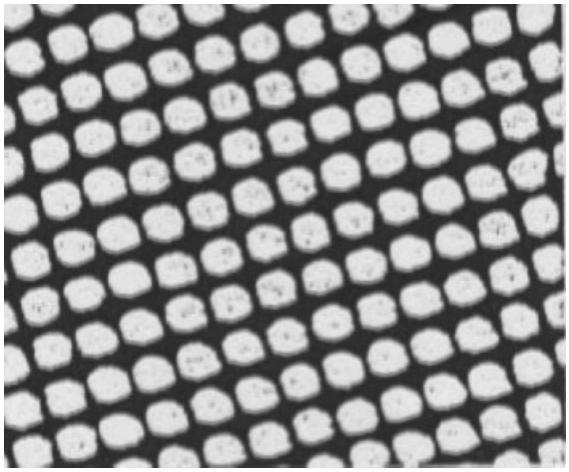

Figure 1. Atomic force microscopy (AFM) image of a square array of dots with a diameter of 80 nm, the edge to edge spacing being equal to 100 nm, prepared by ion sputtering on a preetched Si wafer. (Moritz *et al*., *IEEE Trans. Magn* **38**, 1731–36 (2002), (© 2002 IEEE).)

2.1.2 Functionalized templates prepared by focused ion beam (FIB)

A FIB or laser beam can locally modify the properties of the substrate before depositing nanostructures. The irradiated small regions serve as seeded sites that attract incident magnetic ions to form aggregates at preselected places. Square arrays of ferromagnetic CoPt aggregates were grown after functionalizing a convenient substrate at the apex of a square array of defects created by Ga FIB (Perez *et al*., 2002; Hannour *et al*., 2005). In spite of their small size, the shape of aggregates remains, up to now, highly ramified.

Another emergent technique to design periodic arrays of nanoparticles is to use a chemical FIB-assisted method (Kageyama and Suzuki, 2004). Co particles were produced at selected places on a template by decomposing its octacarbonyl precursor under a scanning FIB. This method has been

recently extended to produce periodic assemblies of FePt and CoPt magnetic particles (Xu, Kageyama and Suzuki, 2005).

2.2 Ion irradiation through a mask

Argon ions are currently used for milling material, for example, for designing patterns through a resist mask. The removal of a large amount of matter is then required and the surfacic ion dose must be rather high. In counterpart, it has been shown recently (Chappert *et al*., 1998; Vieu *et al*., 2002; Rettner *et al*., 2002a) that the magnetic properties of ultrathin film structures are often strongly modified by irradiation under low ion dose without etching and creating any additional surface roughness. Thus, before discussing ion beam patterning methods, a general survey on irradiation process in ultrathin film structures is proposed. Some aspects of this topic have been reviewed recently by Fassbender, Ravelosona and Samson (2004).

Nanopatterning can be realized by uniform ion irradiation through a contact mask deposited directly on the film, or through a removable stencil mask. All types of ions may be used. Another solution that avoids the preparation of a mask is to pattern directly the film by scanning a nanosize gallium FIB. The principles of these three techniques are schematically depicted on Figure 2.

2.2.1 Uniform ion irradiation at low dose

Before investigating the modifications of magnetic properties under irradiation, we will discuss the change of morphological, structural, and physicochemical properties of ultrathin film structures versus the type of ion, its energy, and dose.

Their radiation damage, etching depth, and intermixing of ions at interfaces under low irradiation dose can be estimated from the Transport of ions in matter (TRIM) calculations for various ion energies (Ziegler, 1992). The used ion energy ranges currently between 10 and 100 keV. For a given dose and ion energy, damage increases with the mass of the incident ions. At the same time, the mean implantation depth of incoming ions is reduced. An increase of the ion energy provides straighter trajectories, which allows one to minimize the lateral ion straggling inside the media. More damage is obviously created at higher energy, as when increasing the dose.

The structural modifications induced by irradiation depend much on the material. For example, in the Pd/FePd/Pd thin-film structure, chemical ordering can be reinforced under He irradiation since it favors the formation of the $L1_0$ stable phase (Bernas *et al*., 2003). This elegant procedure allowed significant increase of the anisotropy in this promising perpendicular recording media. In some other cases, a chemical disordering is induced under irradiation (Fassbender, Ravelosona and Samson, 2004). For the archetypal Co/Pt ultrathin layered structure, ion irradiation induces intermixing at interfaces that is found to reduce its perpendicular magnetic anisotropy (Chappert *et al*., 1998).

Now, let us focus on the widely studied case of irradiation effects by light He ions at 30 keV on a room-temperature sputter-grown Pt/Co/Pt ultrathin film structure. In that case, He ions do not themselves perturb the structure since they become deeply implanted far away from the film inside the substrate (>100 nm). But He ion irradiation produces a controlled *ion beam mixing* of the Co–Pt interfaces. This effect brings into play the purely ballistic collisional mixing and the chemical heat of mixing. At low dose, the mixing rate is linear with He dose. As a result of a large negative heat of mixing, a Co atom displaced from the interface into the Pt layer stabilizes in a collision-induced site without further relaxation. When reorganizing around a vacancy induced by irradiation, atoms have a high probability to find a higher thermodynamic configuration that minimizes energy. Since Co and Pt elements are miscible in any proportion, irradiation induce stable intermixing between Co and Pt around interfaces. One important point is that for irradiation with He ions at low dose, no etching of the film surface is observed, so that the initial sample roughness is conserved. A planar method for patterning magnetic recording media

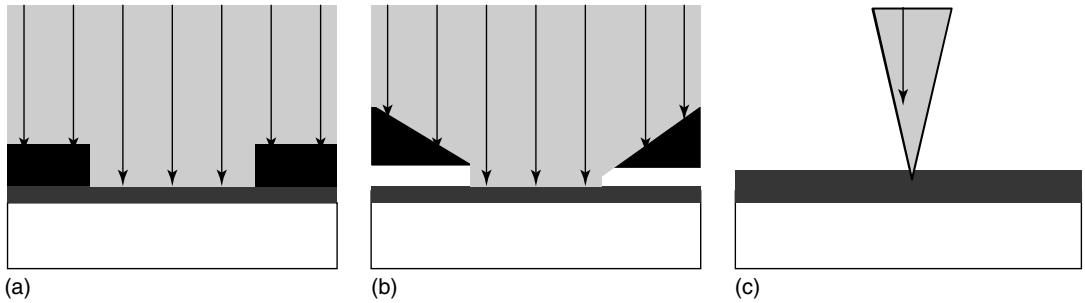

Figure 2. Local irradiation: (a) by He ions through a contact mask, (b) by irradiation through a removable stencil mask, and (c) by a focused Ga ion beam (FIB).

was proposed (Chappert *et al*., 1998); in magnetic recording, planarization ensures a higher stability of heads flying very close above the disk. It is also interesting to note that the optical indices of the Co/Pt structure are not significantly modified under irradiation by He light ions with a typical energy of 30 keV. All these features are conducive to magnetic investigations by near field techniques.

As-grown Pt/Co/Pt films are ferromagnetic at room temperature. For a Co thickness below 2 nm, the easy magnetization axis aligns perpendicular to the film plane as the result of a large positive interface anisotropy. Using a simple model, the observed magnetic changes can be related to the irradiation-induced intermixing (Bernas *et al*., 1999). This intermixing lowers the interfacial anisotropy, the coercive field, and the Curie temperature (Ferré *et al*., 1999). The magnetic properties of Co_{1-x} Pt_x alloys are well known (Sanchez, Moran-lopez, Leroux and Cadeville, 1988): for $x < 75\%$, the alloy becomes ferromagnetic at room temperature and the magnetic moment decreases monotonously from $1.7\,\mu_B$ for $x = 0$ to $0.75\,\mu_B$ for $x = 0.75$. The variation of the Co–Pt concentration within the ultrathin Co layer structure with the He dose can account for the observed Curie temperature decrease. At room temperature, the perpendicular coercive field decreases monotonously when increasing the He ion dose (Figure 3), and finally a transition to a paramagnetic state takes place for a $D = 2.5 \times 10^{16}$ ions/cm^2 dose. When changing the ion dose and temperature, paramagnetic and ferromagnetic phases with in-plane, oblique, and perpendicular anisotropy can be identified. The 'temperature versus He ion dose' phase diagram has been determined for a Pt/Co(0.5 nm)/Pt sample (Figure 4)

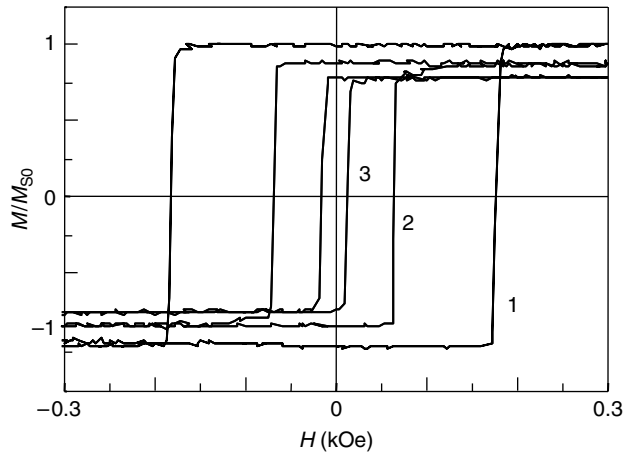

Figure 3. Polar MOKE (PMOKE) hysteresis loops of a Pt/Co(0.5 nm)/Pt film versus the He irradiation dose at 30 keV. (1) As-grown sample, (2) $D = 3 \times 10^{15}$ ions/cm^2, and (3) $D = 10^{16}$ ions/cm^2. Magnetization of all loops is normalized to the saturation magnetization M_{SO} of the as-grown sample. (Chappert, C. *et al*. (1998). *Science*, **280**, 1919.)

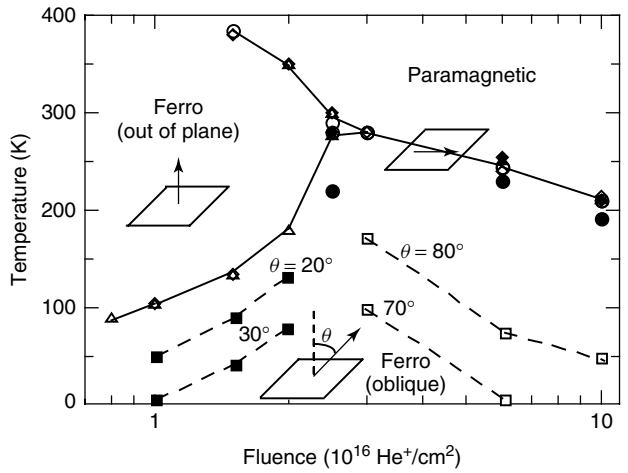

Figure 4. Temperature–dose magnetic phase diagram of an He-irradiated Pt/Co(0.5 nm)/Pt ultrathin film at 30 keV. Several isodeviation lines are indicated for the oblique phase. (J. Ferré *et al*., *J. Phys. D: Appl. Phys.* **36**, 3103 (2003).)

(Ferré *et al*., 2003). When the Co thickness exceeds 1.4 nm, another perpendicular-to-oblique reorientation transition is evidenced first when increasing the He ion dose at room temperature.

Helium irradiation effects are even more efficient in Co/Pt multilayers. Two transitions may be successively identified, first from a perpendicular to an in-plane magnetized state (Figure 5), and finally to a superparamagnetic phase (not shown in Figure 5). As proved from the pure critical behavior

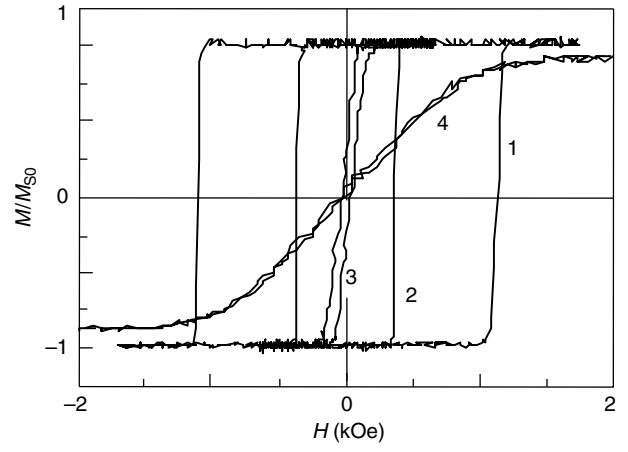

Figure 5. Room-temperature PMOKE hysteresis loop of an He-irradiated Pt/[Pt(1.4 nm)/Co(0.3 nm)]$_6$/Pt multilayer with He ions at 30 keV. (1) as-grown sample, (2) $D = 2 \times 10^{15}$ ions/cm^2, (3) $D = 6 \times 10^{15}$ ions/cm^2, and (4) $D = 10^{16}$ ions/cm^2. Magnetization, M, of all loops has been normalized to the saturation magnetization M_{SO} of the as-grown sample. (Chappert, C. *et al*. (1998). *Science*, **280**, 1919.)

of the magnetization in the vicinity of the Curie temperature, intermixing is highly uniform over the full sample area.

Since the ion intermixing at interfaces is induced by ballistic effects, the atomic displacement efficiency and damage are more significant when using ions which are heavier than He, like Ga. The Co–Pt in-depth intermixing profile produced by Ga ions inside the Pt/Co/Pt film structure has been calculated by TRIM simulations (Ziegler, 1992) (Figure 6). Qualitatively, similar magnetic changes are expected to occur in Pt/Co/Pt films irradiated either by Ga or He ions, but at a much lower dose for the heavier Ga ions (compare the dependence of the coercive field with the dose for He (Figure 3)

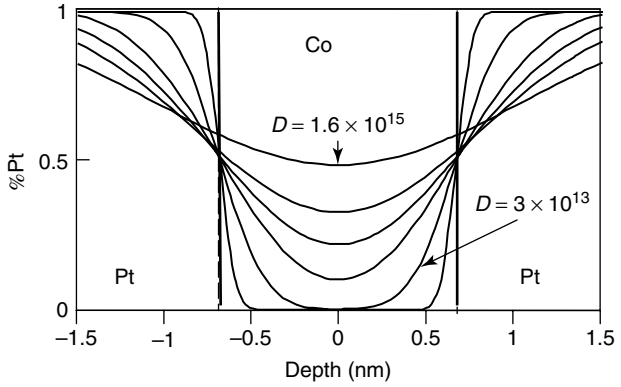

Figure 6. Co–Pt intermixing at the interfaces in a Pt/Co(1.4 nm)/Pt film calculated by TRIM simulations for different values of the Ga ion dose D increasing from 10^{13} ions/cm^2 to 1.6×10^{15} ions/cm^2. The origin of the depth is located at the center of the Co layer. (From Hyndman, unpublished.)

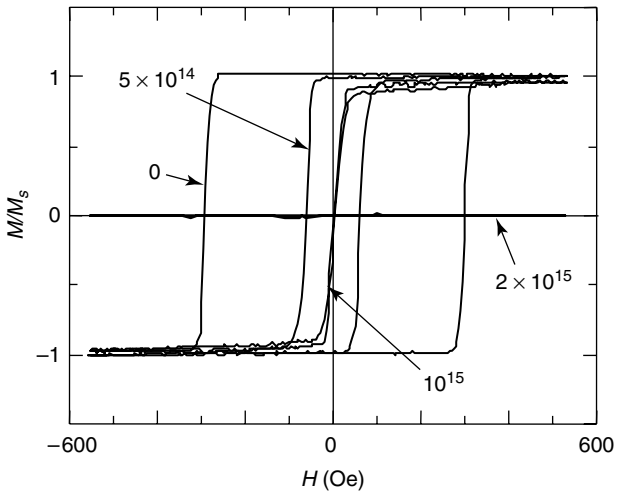

Figure 7. Normalized PMOKE hysteresis loops of the as-grown and irradiated Pt/Co(1.4 nm)/Pt film. The values of the dose D indicated in the figure are in Ga ions/cm^2 units. Note that the sample becomes paramagnetic for $D = 2 \times 10^{15}$ ions/cm^2. (Vieu *et al*., *Journal of Applied Physics.* **91**, 3103 (2002).)

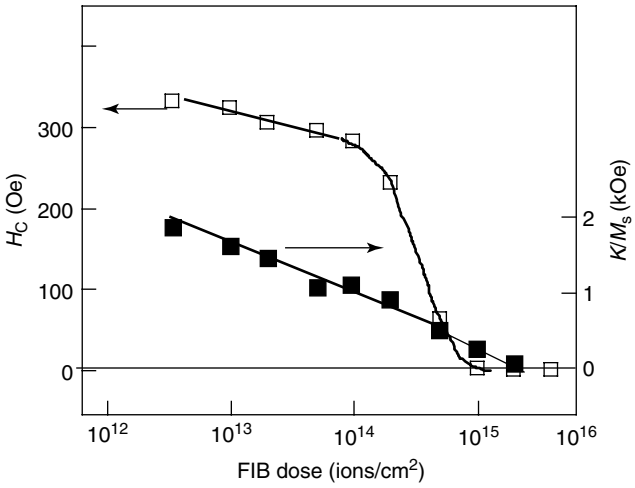

Figure 8. Semilogarithmic variation of the coercive field (open squares) and of the anisotropy (black squares) of the Pt/Co(1.4 nm)/Pt film with the Ga ion dose. (Vieu *et al*., *Journal of Applied Physics.* **91**, 3103 (2002).)

and Ga (Figures 7 and 8)). The irradiation efficiency on coercivity in a Co/Pt multilayer has been determined by Rettner *et al*. (2002a) for different types of ions with energy in the 20–30 keV range (Figure 9). Similar behavior has also been evidenced for ions with far higher energy, that is, in the megaelectron volt MeV range (Figure 9) (Rettner *et al*., 2002a; Kim *et al*., 2002). A main point is that lateral ion straggling inside the film and morphological and structural damages are relatively much more significant for heavier ions.

As an example, the results of TRIM calculations (Ziegler, 1992) in an ultrathin Pt(6.5 nm)/Co(1 nm)/Pt(3.4 nm) film,

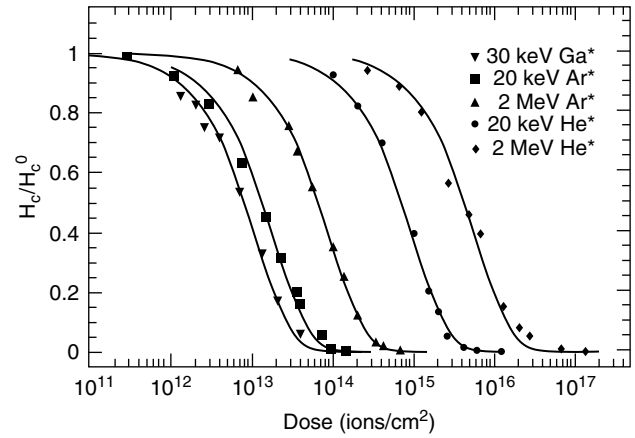

Figure 9. Semilogarithmic plot of the reduced coercive field as a function of the He, Ar, and Ga ion irradiation dose. He and Ar irradiations were performed at 20 keV, 30 keV, and 2 MeV energy. (Rettner *et al*., APL 80, 279–281 (2002).)

show the following trends:

- Sixty-five percent of the Ga ions are implanted in the Pt/Co/Pt film structure (vs no implantation with He).
- Multiple collisions for Ga (vs pure ballistic collisions for He) and creation of 80 lacuna per Ga ion (vs 0.5 for He).
- The sputtering efficiency is six atomic planes for Ga (vs 0.15 for He). The calculated etched depth has been experimentally confirmed on Co/Pt structures for different Ga ion doses (Hyndman *et al*., 2001a). Ga ions generate a rougher surface than He irradiation. Moreover, Ga irradiation favors expansion of the Pt crystallite sizes along the (111) direction.
- In terms of magnetization and magnetic anisotropy, 10^{16} He ion/cm^2 or 10^{15} Ga ion/cm^2 irradiation doses give comparable magnetic changes in this Pt/Co/Pt film.

The above trends confirm that light ions, such as He, produce far less structural and morphological damage than heavier ions, like Ar and Ga when restricting to doses that give comparable changes in magnetism.

Several authors investigated the irradiation-induced changes in the magnetic properties of permalloy films with in-plane easy anisotropy (Kaminsky *et al*., 2001). As expected, since magnetic interface effects are far less efficient in determining anisotropy in in-plane films than those with perpendicular anisotropy, rather large ion doses are necessary to modify their magnetism by implantation of Ga into the Co ferromagnetic layer. A transition from antiferromagnetic to ferromagnetic coupling between the two Fe layers in the Fe/Cr/Fe structure can be induced by Ga irradiation, allowing to design a new type of magnetic patterning (Blomeier *et al*., 2005). Magnetic micropatterning of FeNi/FeMn exchange bias layers by ion irradiation through a mask has also been demonstrated (Mougin *et al*., 2001). This method allows to modify and control the exchange bias field value locally.

2.2.2 *Patterning through a contact mask*

Starting again from a Pt/Co/Pt film structure, a thick enough resist or insulating layer (SiO_2, SiN) is deposited first on the film. Then, circular or square nanoholes are opened through the contact mask by electron lithography and ion etching. Finally, arrays of soft magnetic nanoelements in a harder medium may be designed by uniform He ion beam irradiation through this shadow mask. The contact mask may also be made of an array of nanopillars (Krauss, Fischer and Chou, 1994). In that case, by uniform ion irradiation, an array of ferromagnetic nanodots can be designed below these nanopillars, while the nonprotected irradiated surrounding area can become paramagnetic or weakly magnetized. Arrays of $Co_{25}Pt_{75}$ nanodots with perpendicular anisotropy surrounded by a weakly magnetic matrix have been fabricated through such a mask by He irradiation (Devolder *et al*., 2003).

For a first demonstration, arrays of parallel ferromagnetic stripes have been prepared by He irradiation through a resist mask (Figure 10) (Chappert *et al*., 1998). To design ultranarrow elements with highly contrasted borders, it is more appropriate to deposit first a silica mask (about 400 nm thick), which is subsequently patterned by electron lithography and reactive ion etching. Silica masks with parallel ultrathin 30-nm-wide walls have been also prepared successfully (Figure 11). Using a similar mask with 60-nm-wide walls, an array of ultranarrow ferromagnetic Pt/Co/Pt stripes, separated by micrometer wide irradiated paramagnetic regions, have been prepared (Figure 12) (Devolder *et al*., 1999, 2000).

The collisional lateral straggling inside the film, the collateral damage at mask borders, and the resolution of the mask patterning technology, limit the sharpness of magnetic nanostructures (Bernas *et al*., 1999). The lateral straggling, which characterizes He ion-stopping profile is only about

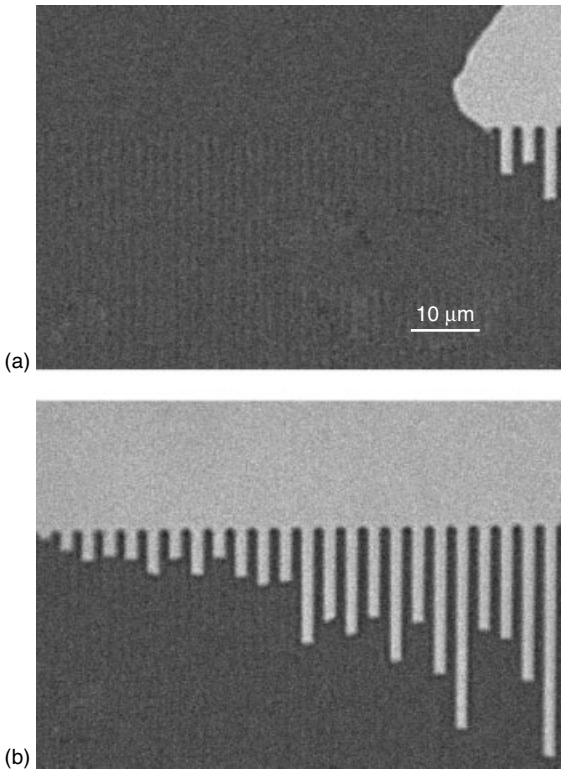

Figure 10. PMOKE images of an array of 1-μm-wide ferromagnetic stripes connected to a reservoir, separated by 1-μm-wide irradiated paramagnetic regions. Magnetic patterning, in the Pt/Co(0.5 nm)/Pt film, has been performed by He irradiation ($D = 10^{16}$ ions/cm^2, 30 keV) through a PMMA resist contact mask. Images (a) and (b) are both differences from a magnetically saturated image, and the reversed domains appear in gray. A magnetic field pulse of amplitude 82 Oe and duration 2 s was applied between snapshots A and B. (Chappert, C *et al*. (1998). *Science*, **280**, 1919.)

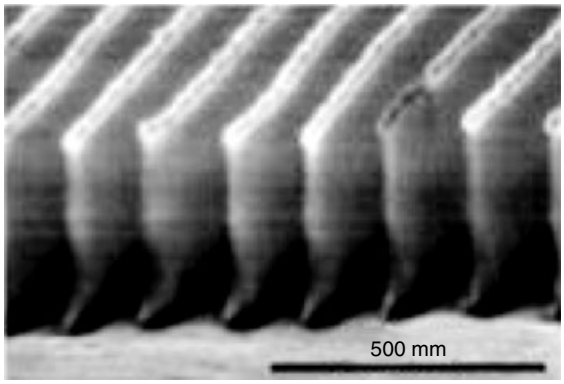

Figure 11. Scanning electron microscopy image of a SiO_2 mask. The walls are 450 nm high, 30 nm thick and are separated here by 150 nm. (Devolder *et al*., APL 74, 3383–3385 (1999).)

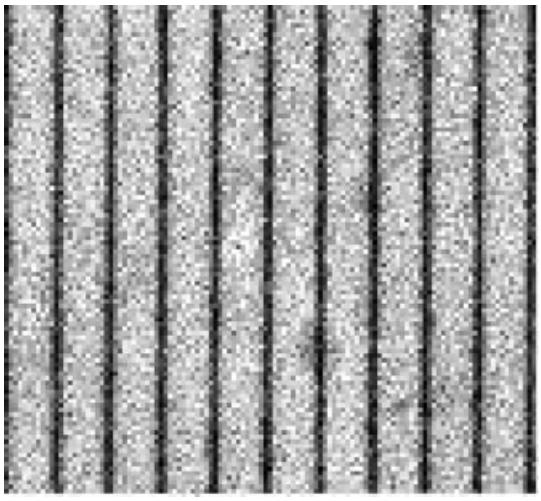

Figure 12. PMOKE image ($33 \times 29\,\mu m^2$) of the magnetic state of an array of 60-nm-wide Co/Pt tracks, separated by 2.5 µm, obtained after saturating the sample in a negative field (black) and applying a positive field of 348 Oe during 10 s. This field was large enough to reverse the magnetization in weakly ferromagnetic irradiated areas (gray) between tracks (black). (Devolder *et al*., APL 74, 3383–3385 (1999).)

2 nm in ultrathin layers. Therefore, the resolution is in fact limited by collateral damage due to ion beam divergence below the silica mask, estimated to be 14 nm in the present case (Devolder, Chappert and Bernas, 2002; Devolder *et al*., 2001). This effect limits the sharpness of the designed nanoelements. Moreover, imperfections of the mask's edges generate roughness at the border of the magnetic nanoelements. When combining state-of-the-art lithographic techniques, an ultimate nanometer-scale patterning of magnetic properties can be reached using He irradiation while preserving the smoothness of the surface, a required condition for ultrahigh density information storage technology.

2.2.3 Patterning through a stencil mask

Ion beam patterning can also be realized through a removable stencil mask placed just above the film (Figure 2). This method is also called *proximity ion beam lithography*. Wolfe *et al*. (1996) discussed about the limitations of this technique for realizing arrays of small (20–50 nm) nanostructures. Devolder, Chappert and Bernas (2002) reported on the ultimate resolution that can be reached by stencil masks using He irradiation. The pertinent parameters are the gap G separating the magnetic film from the mask, and the aspect ratio (AR), that is, the ratio between thickness and size of the mask openings. It appears that the gap must be chosen in the $0.1 \ll G \ll 25\,\mu m$ range, and the replication quality is the best if $AR > 3$. For a 200-nm-diameter hole, drilled into a 340-nm-thick SiC membrane, the collateral damage can extend over 50 nm for $G = 100$ nm. It is highly reduced (to about 10 nm) if a thicker 600-nm membrane is used.

Realistic mass production of discrete magnetic media requires removable masks that replicate a given large pattern many times. Stencil masks are potentially good candidates for such an application. They have been used to design periodically organized soft magnetic dots in Co/Pt and FePt chemically ordered superlattice films by ion irradiation (Terris *et al*., 2000). However, the quality of the stencil masks was not good enough at that time to reach the optimum resolution.

We will not discuss patterning using heavy ions at high energy since they produce too much damage that is difficult to control. Both etching and thermal effects have then to be considered (Xiao *et al*., 1994; Cai *et al*., 1997).

2.2.4 Ion projection lithography

Patterned magnetic media can be produced by highly stable ion projection lithography (Bruenger *et al*., 2002). A uniform ion beam passes through an array of nanoholes drilled into a stencil mask that is previously fabricated by lithography. An electronic lens gives a demagnified image of this hole array on the sample. Starting from a 3-µm-thick Si stencil mask with 500-nm-wide holes, separated by 2 µm, arrays of 60-nm-diameter magnetic dots have been realized using a uniform Ar beam irradiation and an eight times demagnification. This method does not require the use of a resist mask, so it can be applied to pattern recording media (Dietzel *et al*., 2002; Bruenger *et al*., 2002).

2.3 Direct writing techniques

2.3.1 Focused electron-beam writing

It has been demonstrated that magnetic properties of ultrathin magnetic film structures can also be affected by a focused

electron beam (Allenspach, Bischof, Düring and Grütter, 1998). To obtain a high electron-ion ballistic collisional efficiency, electrons must have very high energy. In most cases, the produced ion intermixing at interfaces is rather low, so only weak magnetic changes are observed. Electron-beam-assisted magnetic ion deposition can be more efficient for designing nanostructures, but nearly no example is reported so far in the literature.

2.3.2 Focused Ga ion beam (FIB) writing

This is certainly one of the most promising techniques to pattern thin films with an ultimate nanometer resolution. Since Ga ions are focused over a very small film area, damage can be controlled over an extended range of doses. At relatively high Ga doses ($D > 10^{16}$ ions/cm^2), FIB sputtering causes the film to be etched away to depths larger than 10 nm. At low doses ($D < 10^{14}$ ions/cm^2), the etching effect has a very low efficiency, but the magnetic properties of ultrathin film structures can still be locally modified. Ultrathin film FIB patterning is usually performed with a weak probe current ($\approx$10 pA) at 30 keV energy. Irradiated lines separating nanomagnetic regions are designed by scanning the FIB spot in fast successive steps with a great precision, over a distance typically equal to the FIB spot diameter in order to ascertain overlap of irradiated areas along a given direction. The ultimate FIB spatial resolution is presently 5 nm (Gierak *et al*., 2005), giving an irradiated linewidth in the film of about 10 nm at low dose. The dose deposited in lines is controlled by the exposure time of the spot varying from 0.1 to 100 ns. This allows the design of irradiated lines with an equivalent surfacic dose from 3×10^{12} to 3×10^{15} ions/cm^2. At low dose ($<10^{14}$ Ga ions/cm^2) (Figure 13a), irradiated lines become weakly ferromagnetic without creating new surface roughness on the virgin film. At mean dose (Figure 13b), the central part of irradiated lines is rendered paramagnetic, while their edges are weakly ferromagnetic. Thus, arrays of tracks or dots may be designed by scanning the FIB along one direction or two orthogonal directions, respectively (Aign *et al*., 1998; Hyndman *et al*., 2001b; Toporov, Langford and Petford-Long, 2000). Periodic arrays of drilled holes, called *antidots*, have also been fabricated (Toporov, Langford and Petford-Long, 2000). In order to realize complex structures or to isolate magnetically a single magnetic nanoelement, the FIB spot size can be adjusted between 10 and 50 nm, and even scanned over a large sample area to sputter material. This technique has been successfully used to fabricate single high-quality in-plane magnetized permalloy nanoelements (Xiong, Allwood, Cooke and Cowburn, 2001).

In most materials, the removal rate with 30 keV Ga ions is around 1–10 atoms per incident Ga ion. For each incident Ga ion on a Co/Pt film structure, approximately 500/Pt and 500 Co ion displacements are generated. This rapidly induces a large density of defects. For Pt/Co/Pt films, one estimates that 300 ion impacts over a 10mn FIB spot diameter (equivalent to $D = 4 \times 10^{14}$ ions/cm^2) give rise to a 1-nm-height surface film blister, which spreads over about 100 nm. This swelling is due not only to Ga implantation (Basnar *et al*., 2003) but also to a damage which modifies the crystal structure. Voids and interstitial atoms are created, leading to a volume enhancement associated to an amorphization process. When increasing the FIB spot dose, etching effects (drilled depth of 1.3 nm by 750 Ga ions per spot, i.e., for 10^{15} Ga ions/cm^2) tend to form a cross-section volcano-type profile. For 2250 ions, the depth of the drilled central hole is already 3 nm. This phenomenon can be evidenced from small local changes in light reflectivity, as already observed for an array of Ga ion irradiated lines in a Pt/Co(1.4 nm)/Pt film used for producing a square nanodot array (Figure 14). So, the FIB writing technique can be inappropriate for designing nanostructures in some cases, in particular, when it already modifies too much the surface topology at low dose.

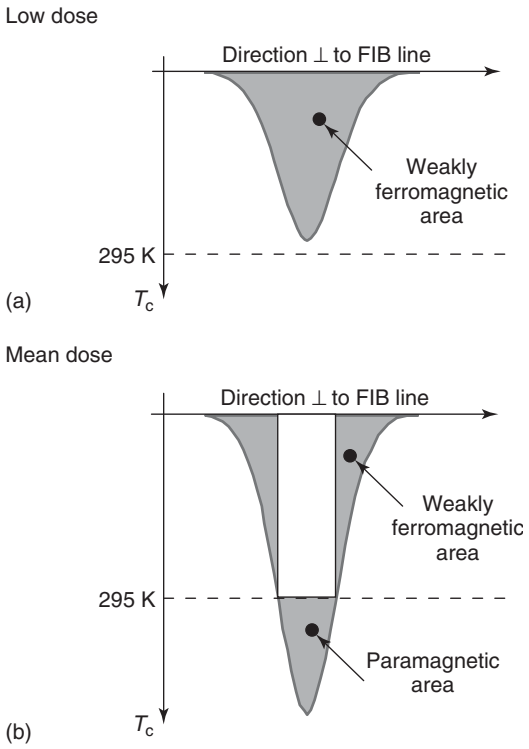

Figure 13. Schematic cross-section view of the lateral variation of the Curie temperature through a line irradiated by a scanned FIB having a Gaussian dose profile. (a) At low dose, the irradiated line is still weakly ferromagnetic at its center. (b) At higher dose, the central part of the line becomes paramagnetic while its edges are weakly ferromagnetic. This explains why nanodot borders act as a nucleation reservoir for further domain wall motion inside the dot.

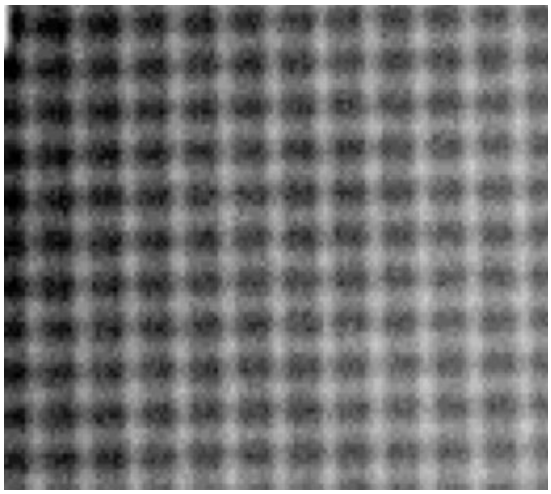

Figure 14. Optical image of a Pt/Co(1.4 nm)/Pt film patterned as a square ($1 \times 1\,\mu m^2$) nanodot array by two orthogonal sets of Ga irradiated lines, here revealed in light gray. The width of the irradiated lines is overestimated because of the convolution with the limited resolution (0.4 µm) of the optical microscope. The used lineic Ga dose was $3\,nC\,cm^{-1}$. (From Aign *et al*., 1998.)

2.4 Comparison between patterning techniques

At this stage, it is interesting to compare the performances of different top-down techniques for realizing arrays of magnetic nanoelements (Table 1).

Among the usual top-down patterning methods, only electron-beam lithography is competitive with FIB for creating so narrow nanostructures. FIB and electron lithography are both slow fabrication procedures, but FIB stands as a direct writing method while electron lithography needs first the mask fabrication and the use of a lift-off process. Another advantage of the FIB technique is that magnetic patterning in film structures can be often realized under a low dose that avoids material etching and reduces considerably the duration of the patterning process.

One possible drawback of the FIB patterning is due to the Gaussian profile of the beam, and straggling effects that lead to gradients in the magnetic properties at the edges of the patterned nanoelements. Note that the width of these regions can be limited, in the best cases, to only 10 nm. Since irradiation often reduces coercivity, a field-induced domain nucleation at dot edges can favor a better control of the magnetic switching behavior (Aign *et al*., 1998). FIB can be used to delimit the edges of a single track. Jamet *et al*. (2001a) have shown that domain walls move much more rapidly in such designed tracks than in wires patterned by engraving techniques. This can be interpreted as a magnetic wetting effect along the edges of the stripe. In other words, FIB can partly suppress pinning effects for wall motion by smoothing the track edges magnetically.

3 MAGNETISM IN NANOMAGNET ARRAYS

3.1 Definitions and characteristic lengths

Nanomagnet is used to name all types of nanometer size magnetic entities. When designed by a top-down patterning technique they will be called *magnetic nanoelements*. Nanoelements having a shape symmetry will be named *dots* when their thickness t does not exceed 50 nm, or *pillars* when t becomes comparable or thicker than their lateral size a (Krauss, Fischer and Chou, 1994). *Tracks* or *stripes* are long nanoelements with rectangular cross section (width: w, thickness: t). From this definition, they differ from wires that are generally grown by bottom-up methods in drilled templates (see also **Advanced Magnetic Microwires, Volume 4** and **Template-based Synthesis and Characterization of High-density Ferromagnetic Nanowire Arrays, Volume 4**). In the investigated periodic arrays, nanomagnets will be positioned at nodes of a square lattice with in-plane periodicity P. The separation $S = (P - a)$ represents the distance between the edges of two neighboring nanoelements.

As well known (see also **Magnetization Configurations and Reversal in Small Magnetic Elements, Volume 2**), several characteristic lengths control the magnetic behavior of magnetic nanoelements:

- The exchange length, $l_{ex} = \pi(2A/\mu_0 M_S)^{1/2}$, over which the spin orientations are highly correlated. Here A stands

[c]Conical shape of the nanoelement.

for the exchange stiffness, μ_0 the Bohr magneton, and M_S the magnetization at saturation. A typical value of l_{ex} for Fe or Co is 10 nm.

- The dipolar length, D_0 expressed as the ratio of the domain wall over the dipolar energy density, $D_0 = 2(AK)^{1/2}/\mu_0 M_S^2$. This quantity controls the stability condition for magnetic bubble formation, the vortex core size in circular magnetized nanoelements, and it allows to predict large domain size in ultrathin films with perpendicular anisotropy (Kaplan and Gehring, 1993).
- The domain wall width, $\Delta = \pi(A/K)^{1/2}$, where K is the magnetic anisotropy. Δ is about 3–10 nm for films with large out-of-plane anisotropy, and is much larger (30–100 nm) for usual films with in-plane anisotropy.

3.2 Noninteracting arrays of nanomagnets

One of the major challenges is to determine the statics and the dynamics of the magnetization reversal of well-defined magnetic nanoelements when their sizes become comparable or smaller than the characteristic exchange or dipolar length and domain wall width. For narrow tracks, the pertinent parameters are obviously the width w and thickness t. Then, the data must be compared to refined analytical calculations but more generally to micromagnetic simulations (Handbook of magnetism, Vol. 2). The size, shape, and magnetic anisotropy of these nanomagnets play a crucial role in the magnetization reversal process (Cowburn, 2000), and for determining equilibrium and field-induced metastable states. Obviously, the best solution is to select only one magnetically isolated nanoelement. Unfortunately, even sophisticated methods are, most of the time, not sensitive enough to measure such a weak magnetic moment. Up to now, only two techniques have succeeded to check the magnetic behavior of nanomagnets at a scale smaller than characteristic magnetic lengths: (i) Micro-SQUID magnetometry was used to investigate the magnetization reversal of a single Co particle as small as 3 nm in diameter (Jamet *et al*., 2001b), and therefore to test unambiguously the Néel's prediction of a coherent spin reversal process. (ii) Spin-polarized scanning tunneling microscopy (SP-STM) allowed measurements of the field-induced magnetization reversal in small nanocrystals (Bode, Pietzch, Kubetzka and Wiesendanger, 2004). Nevertheless, such sophisticated methods can only be used in a very limited number of cases. For nanoelements with sizes of a few tens of nanometers, transmission electron microscopy (TEM) in Lorentz mode or electron holography can yield useful local magnetic information (Hubert and Schäfer, 1998). However, no technique is presently able to investigate fast and ultrafast magnetization reversal dynamics on a single nanomagnet.

Consequently, it is highly desirable to deduce the magnetic behavior of individual nanoelements from that of dot assemblies. This can be only realized if nanoelements are structurally and magnetically identical, that is, with monodisperse properties and without interdot coupling. This last condition can be only fulfilled if the magnetostatic interaction can be neglected, that is, when the separation between nanoelements is at least five times larger than their thickness. This is a difficult challenge since most nanomagnet assemblies exhibit switching field distributions. Distributions are expected in many cases: of the size and shape of the nanoelements, of the magnitude and/or of the direction of their magnetic anisotropy, the statistics of nucleation, and so on. The most prejudicial effects for fundamental studies and applications come from nucleation field distributions. For example, in the case of Au/Co/Au films, with perpendicular magnetic anisotropy, an increase of the nanodot density gives rise to a huge enhancement of the mean coercive field, while the first dot is switching exactly at the field found for magnetization reversal in the virgin film (Jamet *et al*., 1998). This means that dot switching is related to the distribution of nucleation fields inside the virgin layer. All possible distributions obviously mask the predicted specific magnetization reversal process of single nanoelement. Unfortunately, the detail of distributions is generally unknown so that individual processes cannot be, *a priori*, rigorously evaluated. As discussed in the following text, these limitations can be overcome for FIB-patterned arrays of magnetic nanoelements. We will show how a very narrow distribution of magnetic dot properties can be obtained in that case.

3.3 Dipolar and exchange interactions in magnetic dot arrays

Only single spherical or elliptical nanoelements exhibit a uniform internal self-demagnetizing field. In counterpart, the self-demagnetizing field of nonspherical nano elements becomes inhomogeneous near the edges for both in-plane and out-of-plane magnetized samples. Inside ultrathin nanoelements, the demagnetizing field shape factor tends toward 0 or 2π for layers with in-plane or perpendicular magnetic anisotropy, respectively. For example, as checked by micromagnetic calculations, the self-demagnetizing field of out-of-plane magnetized nanoelements is non-homogeneous at their edges over a distance that can be up to five times the layer thickness. So, the reduction of the self-demagnetizing field favors field-induced nucleation and reversal of domains at nanoelement's edges. A clear consequence of self-demagnetizing effects is the generation of a large variety of domain configurations in thick nanodots with

perpendicular magnetic anisotropy (Hehn *et al*., 1996). When the separation S between nanoelements is smaller than their own thickness, the interelement magnetostatic interaction has to be considered.

In practice, nearly no array of nanoelements with in-plane anisotropy have been produced so far by the preparation techniques concerned in this review. Consequently, we will not report much on interelement magnetostatic effects in these in-plane magnetized nanodot arrays. They have been discussed by Fruchart *et al*. (1998). In that case, the dipole–dipole interaction between ultrathin nanoelements is short range, and decreases rapidly with their separation S. Contrarily to the 3D case, where dipole–dipole interactions are long range, a magnetic material confined in a 2D space shows a smaller associated magnetostatic energy.

The effect of interdot interaction on magnetization reversal in circular or square dot arrays with in-plane anisotropy have been studied theoretically by Guslienko *et al*. (2001). The magnetostatic interaction influences the nucleation and annihilation of magnetic vortices. This has been checked experimentally in permalloy dots by varying the dot separation (Novosad *et al*., 2003). The chirality of vortices is also controlled by magnetostatic interactions (Natali *et al*., 2002). Magnetostatic interactions in 1D-coupled dots have been investigated in simple systems with planar anisotropy. Novosad *et al*. (2003) have shown that the shape of the nanoelements influences the magnetization reversal process in chains. For in-plane magnetized nanomagnets arranged on a rectangular lattice, a transition from a magnetic disordered state to an ordered state, similar to a paramagnetic–ferromagnetic transition, has been evidenced when reducing the periodicity in one direction (Cowburn, 2000).

Let us now concentrate on dot arrays with out-of-plane magnetic anisotropy. The perpendicular (z) stray field component H^z_{dip}, created outside an ultrathin magnetic nanoelement decreases rapidly with the lateral distance x from its edge. An approached analytical expression of H^z_{dip} with x can be derived. If x is greater than the thickness t of the element, but smaller than the dot diameter, the nanomagnet can be considered as an electric wire, which surrounds the element, carrying a current $\mu_0 M_S t$. According to the Ampere's law, this current creates a dipolar stray field component H^z_{dip} proportional to $M_S t/x$. When x is larger than the element size, that is, in a macrospin approximation, H^z_{dip} vanishes more rapidly being proportional to $1/x^3$.

Now, let us try to estimate the dipolar stray field experienced by a central dot from the other dots positioned around it on a square lattice. An analytical expression has been deduced in the macrospin approximation, for nanoelements of volume V with perpendicular magnetic moments confined at nodes of a square lattice with period P. So, the dipolar stray field H^z_{dip} is written as (Haginoya *et al*., 1999):

$$H^z_{\mathrm{dip}} = [(0.716V)/P^3 + N](M_S/\mu_0) \qquad (1)$$

The self-demagnetizing field shape factor of a nanoelement, N, is supposed to be constant. The first term in the brackets represents the demagnetizing field factor due to all surrounding macrospins. As quoted by several authors (Haginoya *et al*., 1999; Haast *et al*., 1998), N is smaller for nanoelements than for the virgin continuous film, so that the equivalent demagnetizing field factor in the brackets of expression (1) is reduced as well. As a consequence, the remanent ratio, M_R/M_S, and hence the loop squareness, can be significantly improved, for example, from 0.2 for the virgin film to 1 for the patterned medium (Haginoya *et al*., 1999).

Numerical calculations are required if one wishes to account for the shape of the nanoelements. Nonhomogeneous stray fields are generated by a nanoelement on itself and by the surrounding nanoelements. For example, the case of an array of square ultrathin flat ($t \ll a$) magnetic nanoelements which are fully magnetized perpendicularly to their surface, has been treated. The mapping of the z component of the demagnetizing field in a central dot is depicted on Figure 15 (Jamet *et al*., 1999) for 1-μm wide ultrathin Co($t = 1.4$ nm) magnetic square dots separated by $S = 50$ nm. As expected, the dipolar stray field is highly non-homogeneous at dot edges and especially at corners. For arrays of thicker nanoelements, that is, pillars, stronger demagnetizing field effects are expected because of a higher magnetic moment per element.

When the magnetic ultrathin nanoelements come close to each other ($S \sim 1$–2 nm), interexchange interaction can also play a role through the nonmagnetic metal substrate

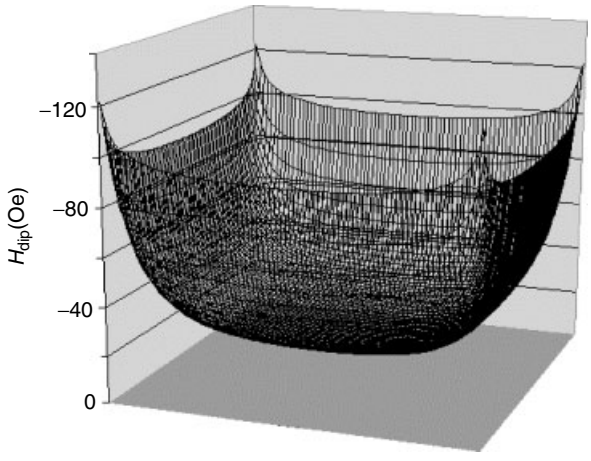

Figure 15. In-plane dipolar field mapping inside a ($1 \times 1\,\mu m^2$) Pt/Co(1.4 nm)/Pt square dot due to the field radiated by all other dots supposed to be in the same initial magnetic state. (J.P. Jamet *et al*., *J. Magn. Soc. Jpn.*, **23**, suppl No S1 (1999).)

or lateral insulating tunnel barriers (Kondratyev and Lutz, 1998). Magnetic ordering then occurs through an oscillating exchange coupling between the nanoelements that modifies the electronic state density. It results in either a net local ferromagnetic or antiferromagnetic interelement coupling depending upon the nature and size of the separation between nanoelements.

3.4 Experimental determination of interelements interactions

No direct method is able to determine the magnitude of interactions between magnetic nanoelements when the lattice period becomes smaller than the size of the magnetic probe. This happens when the distance between nanomagnets is typically shorter than 50 nm. As discussed in the preceding text, interactions can be intrinsic when they are due to the dipolar coupling or the exchange interaction mediated by the substrate, but sometimes nanoparticles can also touch each other as a consequence of an imperfect patterning process. To check magnetic interactions in dot arrays, the so-called ΔM method, related to the Henkel plot procedure, has been first proposed by Kelly, O'Grady, Mayo and Chantrell (1989). It is now widely used to probe the sign of magnetic interactions in several types of recording media, but also for studies of new chemically synthesized self-organized lattices of small quasi-monodisperse nanoparticles ($a \approx 6$ nm) which are separated by only a few nanometers (Sun *et al*., 2000). This ΔM method has been applied successfully to determine interactions in nanometer size particle assemblies designed for future magnetic recording media (Wu, van de Veerdonk, Chantrell and Weller, 2003; Zeng *et al*., 2002). It will be justified later in Section 4.3.2 for coupled Pt/Co/Pt dot arrays.

The ΔM method has been recently amended to introduce switching field distributions of nanoelements (Wu, van de Veerdonk, Chantrell and Weller, 2003). The variation of ΔM with the applied field, H, that is, the $\Delta M(H)$ curve can be extracted from the knowledge of the dc demagnetization (DCD) and of the isothermal remanent magnetization (IRM) curves. In DCD, the sample state is initially saturated in a negative field, while an ac-demagnetized initial state is considered for IRM. In both cases, the remanent magnetization $M_{\mathrm{DCD}}(H)$ or $M_{\mathrm{IRM}}(H)$ are measured for increasing H values after switching H to zero. From the $M_{\mathrm{DCD}}(H)$ and $M_{\mathrm{IRM}}(H)$ plots, the pertinent quantity, $\Delta M(H) = M_{\mathrm{DCD}}(H) - [1 - 2\ M_{\mathrm{IRM}}(H)]$ is deduced. $\Delta M(H)$ is related to deviations from the case of noninteracting elements. The integrated area between the $\Delta M(H)$ curve and the field axis is found to be positive for interparticle coupling dominated by exchange interaction, and positive when it is dipolar in origin.

3.5 Arrays of interacting nanomagnets

This topic was partly treated by Martin *et al*. (2003) in their review. In the case of a 2D array of single magnetic layer nanoelements, in-plane magnetic interactions play a major role on the magnetic switching behavior. However, for nanoelements built from a magnetic multilayer structure, interlayer interactions within a dot have also to be considered. The second case is of vivid interest for new generations of memories, such as magnetic random access memories (MRAMs). At first, we will limit ourselves to the simple case of single magnetic layer nanoelements.

Nanomagnets can be laterally coupled by exchange (Kondratyev and Lutz, 1998) or magnetostatic interactions. Exchange interactions through buffer or top layers are only efficient for very closely spaced ($S \sim 1$–2 nm) nanoelements. Only a few predictions on exchange-coupled particles or nanomagnets have been reported so far in the literature (Scheinfein, Schmidt, Heim and Hembree, 1996; Chen *et al*., 2002; Navarro *et al*., 2004). This is due to the intrinsic difficulty in designing regular assemblies of particles with controlled nanometer size separations. The study of the magnetism of model systems made up by assemblies of nanomagnets with competitive exchange and dipolar interactions is of fundamental interest since they can mimic real magnetic films for recording application (Zhu and Neal Bertram, 1989).

Most of the investigations have been limited to pure magnetostatic interactions. From the macroscopic side, a very instructive study of a lattice of in-plane dipolar-coupled compass needles has been reported by Olive and Molho (1998). They deduced the system's thermodynamic properties under a random applied field that is supposed to mimic thermal fluctuations. A phase transition between an ordered and a disordered state has been evidenced and successfully interpreted by numerical simulations.

As discussed in the preceding text for noninteracting nanomagnets in real systems (Section 3.2), we are also faced with unknown distributions of their magnetic properties. So, assuming an assembly of identical macrospins (single magnetic domain state nanoelements), simple theoretical models can only predict general trends. Nevertheless, in the best experimental cases, with nanomagnets showing quasi-monodisperse magnetic properties, several basic problems have already been solved:

1. The thermodynamics of simple 2D-Ising or XY-coupled systems, in particular, the transition between ordered and disordered macrospin states (0D (isolated element) to 1D (chains of elements), 1D to 2D (in-plane distributed elements), and 2D to 3D (elements in space) arrangements of nanomagnets (Cowburn, 2000)).

2. The switching field statistics of a nanomagnet interacting with neighbors, and their related consequences on the magnetization reversal of the array as a whole (Fruchart *et al*., 1998; Repain *et al*., 2004).
3. The dynamics of dipolar-coupled Ising nanomagnets distributed on a regular lattice and modeled using a macrospin approximation (Sampaio *et al*., 2001).

Many theoretical treatments have been proposed to evaluate magnetic properties of arrays of nanomagnets and the role of interactions including several types of distributions. A neural network approach, composed of a self-organized array of short- and long-range interacting magnetic dots, has also been proposed (Horvath, Gmitra and Vavra, 2001; Horvath and Gmitra, 2003; Gmitra and Horvath, 2003). Many theoretical treatments in statistical physics are devoted to dynamics, and some of them concern 2D interacting systems. However, most of the models predict slow dynamics only; for example, a logarithmic relaxation is expected in hierarchically constrained systems (Bray and Prados, 2001). A 2D lattice of interacting magnetic dipoles gives rise to quasilogarithmic or stretched exponential time decay (Sun and Weili, 1997; Lottis, White and Dahlberg, 1991). Experimental studies of magnetic relaxation (also called *magnetic aftereffect*) have been performed either on simple clusters of nanomagnets (Luis *et al*., 2002) or on a large array of quasi-identical nanoelements (Sampaio *et al*., 2001); the relaxation phenomenon always becomes slower when increasing the complexity of interactions and the size of the array.

With reference to applications, the performances of a so-called continuous magnetic recording medium are highly dependent on its nanoscale heterogeneity and on the magnetostatic and exchange interactions between crystallites. This is also true for discrete media made up of interacting single-domain nanomagnets. Experiments and modeling are essential to determine the stability, integrity, and compactness of data storage and processing devices.

In that context, we wish to first recall predictions or results in granular films formed by crystallites interacting through grain boundaries; some models include distributions of particle properties. The exchange coupling depends on the intercrystallite spacing, but long-range magnetostatic interactions are always efficient. Computer simulations in CoCr recording granular thin-film media with perpendicular anisotropy have been reported several years ago by Zhu and Neal Bertram (1989). They used a model consisting of a periodic nanocolumnar magnetic structure with both intergranular exchange and dipolar interactions between columns. Columns were supposed to be single crystalline with identical properties and uniformly magnetized (macrospin approximation) during magnetization reversal. In a more recent publication, also devoted to magnetic recording media with perpendicular anisotropy, Victora, Willoughby, MacLaren and Xue (2003) developped an electronic structure theory with a local spin density approximation and coupled it to micromagnetic simulations. Monte Carlo simulations with exchange and dipolar interactions between nanoparticles have also been proposed by El-Hilo, Chantrell and O'Grady (1998) to deduce the temperature and time dependence of magnetic properties. The magnetic behavior depends drastically on the strength and nature of the interactions. The main trends issued from these calculations are as follows:

- Magnetostatic effects give rounded hysteresis loops without modifying the coercivity much (Zhu and Neal Bertram, 1989). The remanent magnetization is modified accordingly.
- Domain patterns following an ac demagnetization are very sensitive to the intergranular exchange strength J (Figure 16).
- Spatial disorder or distribution of the interactions tend to round the hysteresis loop shape (Ribeiro, 1991; Victora, Willoughby, MacLaren and Xue, 2003).
- As shown on Figure 17, the value of the intergranular exchange coupling has direct consequences on the hysteresis loop squareness and coercivity.
- For a film with distributed small intergranular J values, the field-induced magnetic domain structure tends to mimic the discreteness of the film morphology (Victora, Willoughby, MacLaren and Xue, 2003; Zhu and Neal Bertram, 1989). For increasing J, the magnetization in neighboring crystallites tends more to align with each

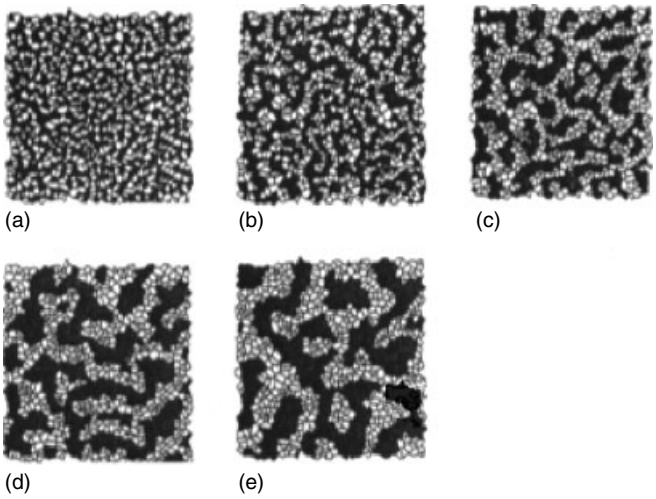

Figure 16. Simulated magnetic domain patterns for 2d ac-demagnetized granular films with perpendicular anisotropy for various intergranular exchange constants: (a) $J = 0$, (b) $J = 0.25$, (c) $J = 0.5$, (d) $J = 0.75$, and (e) $J = 1$. (Victora *et al*., *IEEE Trans. Magn.* **39**, 710–715 (2003) (© 2003 IEEE).)

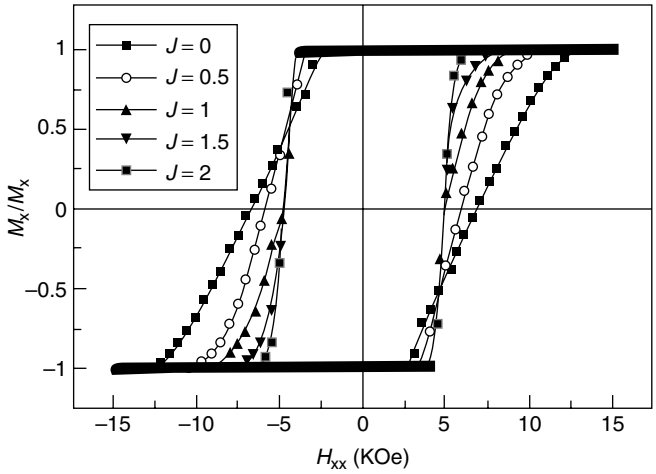

Figure 17. Hysteresis loops in a perpendicular granular medium simulated for different values of the exchange integral J, taking an anisotropy constant $K = 1.8 \times 10^6$ ergs cm^{-3}. (Victora *et al.*, *IEEE Trans. Magn.* **39**, 710–715 (2003) (© 2003 IEEE).)

other and the characteristic ac (Figure 16) or field-induced magnetic domain size grows significantly.

- As expected, the shape of the magnetic relaxation curves depend strongly on the exchange coupling, consistent with nucleation (large dipolar coupling)- or wall propagation (large exchange coupling)-dominated effects.

Kerr microscopy observations in a granular Co–Cr film (Schmidt and Hubert, 1986) allowed to verify some of the above predictions.

4 FROM MAGNETICALLY ISOLATED TO COUPLED DOT ARRAYS

4.1 Arrays of dots on prepatterned templates

In Section 2.1.1, we described the preparation method of magnetic nanodots deposited on the top of Si nanopillars (Landis, Rodmacq and Dieny, 2000). These nanodots are shown to be ferromagnetically decoupled. Owing to an easy wall motion, the final stable states in square nanodots are magnetically saturated. So, configurations with only up- or down-magnetized dots are observed in the remanent state. The distribution of switching fields depends on nucleation pinning energy at sidewalls; it is mainly related to the precise shape of the dots. Regular arrays of [Pt(20 nm)/Co(0.5 nm)/Pt(1.8 nm)]$_4$ magnetic nanodots ($a = 80$ nm, $P = 180$ nm) were deposited on 220-nm-high Si-etched pillars (Moritz *et al.*, 2002). The manipulation of the magnetization state in single nanodots can be done by local heating using an atomic force microscopy (AFM) tip (Figure 18), as well as using conventional write heads for disk drives. Good writing and reading performances have been established in Co/Pt multilayer (100×200 nm^2) nanoelement arrays (Moritz *et al.*, 2004). Compared with a continuous film, the value of the signal-to-noise ratio is high, due to a reduction of the bit transition noise. Using prepatterned Si templates, Baltz *et al.* (2005a) succeeded to prepare arrays of exchange bias ferromagnetic–antiferromagnetic nanoelements with a lateral size smaller than 100 nm.

4.2 Nanoelement arrays prepared by ion-induced magnetic patterning through masks

4.2.1 Magnetism in track arrays prepared by He ion irradiation through contact masks

High-resolution magnetic patterning by He ion irradiation through a contact mask was first demonstrated on Pt/Co(0.5 nm)/Pt films (Chappert *et al.*, 1998). The 850-nm-thick Polymethyl metacrylate (PMMA) resist layer mask was deposited directly on the film and patterned by electron-beam lithography. The irradiation dose was large enough to render the Co layer paramagnetic in nonprotected areas, as revealed by Polar magneto optical kerr microscopy (PMOKE) microscopy on a stripe array connected to a reservoir (Figure 10).

In order to check the ultimate resolution of patterning, arrays of ultranarrow tracks, with width as narrow as $w = 50$ nm, were designed in a [Pt(0.6 nm)/Co(0.3 nm)]$_6$ multilayer (Devolder *et al.*, 1999, 2001). For this purpose, a 450-nm-thick SiO_2 layer was deposited on the film, in order to stop 30 keV He ions, and patterned to form a high-resolution mask (30-nm-wide trenches) by electron-beam lithography and dry etching (Figure 11). Finally, the Co/Pt multilayer was irradiated under uniform He beam at low dose ($D = 2 \times 10^{15}$ He ions/cm^2). Under the mask-protected areas, an array of ultranarrow ferromagnetic tracks was preserved and the track magnetization state imaged by magneto-optical microscopy after the application of a small field (Figure 12), which was larger than the coercivity of the irradiated areas. The continuity of the structure and magnetism along the tracks, down to $w = 30$ nm, was then demonstrated. PMOKE microscopy is thus able to detect a large-enough magnetic contrast coming from spaced ultranarrow wires. This is possible in spite of the rather large value of the optical wavelength, $\lambda = 535$ nm, or of the optical resolution (400 nm), while the contrast is theoretically reduced by the $(w/\lambda)^2$ factor. The coercive field in tracks was found slightly lower (20%) than in the virgin film, evidencing ion straggling effects (Section 2.2.2).

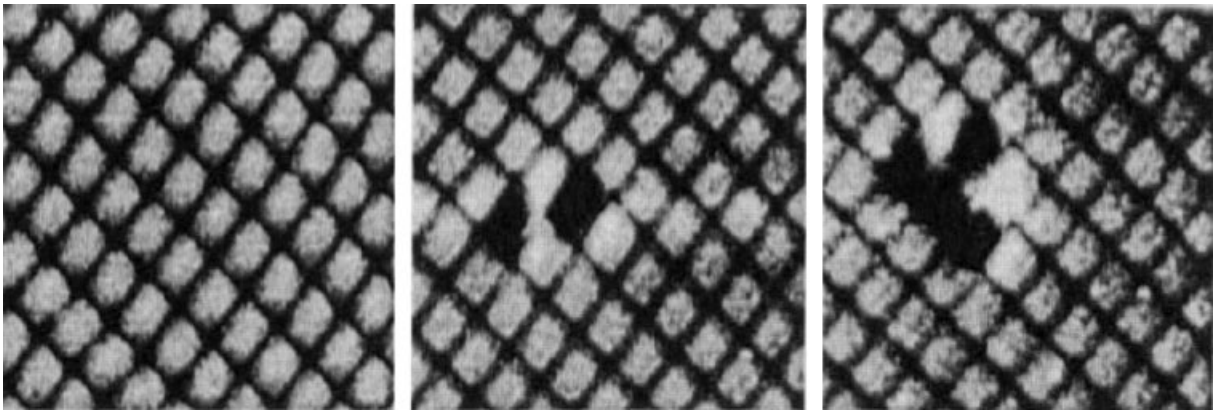

Figure 18. Magnetic force microscopy (MFM) image of an array of etched Si dots covered by a Pt(20 nm)/[Co(0.5 nm)/Pt(1.8 nm)]$_4$ multilayer before (left image) and after thermomagnetic switching of dots induced by an AFM tip. The dots have a lateral size of 400 nm, with an edge-to-edge spacing of 100 nm. The controlled thermomagnetic switching of individual dots has been achieved by flowing pulse of current from the metallic AFM tip to the dot and simultaneously applying a uniform field of about 200 Oe over the whole sample. (Moritz *et al*., *IEEE Trans. Magn* **38**, 1731–36 (2002), (© 2002 IEEE).)

Arrays of $Co_{25}Fe_{75}$ perpendicularly magnetized ferromagnetic dots have also been designed by He irradiation through a pillar-type mask (Devolder *et al*., 2003) (see Section 2.2.2). This structure is especially interesting for magnetic recording since magnetization reversal is nucleation free and proceeds by domain wall injection from the surrounding magnetically soft matrix. This guarantees a narrow coercivity dispersion.

4.2.2 Magnetism in track arrays prepared by He ion irradiation through a stencil mask

As described in Section 2.2.3, a noncontact stencil mask is fabricated by drilling holes in a membrane. This membrane is suspended above the film surface. Magnetic patterning of the film is realized by uniform ion irradiation through the stencil mask. Dense CoCrPt dot arrays with perpendicular anisotropy have been prepared using stencil masks (Terris *et al*., 2000).

More recently, Abes *et al*. (2005) demonstrated that irradiation by 40 keV He ions ($D = 6 \times 10^{16}$ ions/cm^2) transforms $L1_0$–$Co_{50}Pt_{50}$ magnetic hard films with perpendicular anisotropy into an in-plane soft magnetic alloy. So, through a stencil mask with $1 \times 1\,\mu m^2$ square apertures, they were able to pattern an array of soft in-plane magnetized dots inside a hard out-of-plane magnetized material.

4.2.3 Magnetism in nanoelement arrays with easy in-plane anisotropy fabricated by ion irradiation through a mask

Up to now there exists only a limited number of investigations devoted to estimate magnetic changes due to ion irradiation in in-plane magnetized films. Permalloy layers have been patterned under Ar ion irradiation (dose range: 10^{13}–10^{16} Ar ions/cm^2) at 200 keV, in the presence of an applied field (Woods *et al*., 2002). This field reorients the easy anisotropy axis in irradiated areas. So in-plane magnetic anisotropy patterning can be realized by irradiation through a mask. The same phenomenon has been evidenced in amorphous soft magnetic FeCoSiB films (McCord *et al*., 2005) but using He ions. Magnetic domain imaging allowed the authors to follow the rotation of the field-dependent anisotropy axis orientation. Anisotropy patterned structures have also been designed by irradiation through masks that were previously prepared by photolithography.

4.3 Magnetic nanoelement arrays prepared by focused Ga ion beam (FIB)

4.3.1 Arrays of magnetic nanodots patterned by Ga FIB

We will essentially limit ourselves to FIB patterning under low Ga ion dose for changing locally magnetic properties of ultrathin film structures at nanometer scale. Patterns are then produced by scanning a FIB over the film surface to magnetically separate the nanoelements by irradiated lines (Gierak *et al*., 2005). The first attempt to realize large ($50 \times 50\,\mu m^2$) arrays of quasi-identical ultrathin film magnetic square dots by using a FIB has been reported by Aign *et al*. (1998). In this first case, the dose was large enough to etch lines separating Pt/Co(1.4 nm)/Pt dots with a width estimated to be 50 nm.

So, under moderate Ga ion dose ($>3 \times 10^{15}$ ions/cm^2), arrays of discrete magnetic nanoelements can be efficiently

patterned (Rettner *et al*., 2002b; Aign *et al*., 1998). Fortunately, as for He ions, Ga ion irradiation at relatively low dose is able to act directly on the magnetism of Co/Pt ultrathin film structures without etching the sample too much (Sections 2.1.1 and 2.3.2). This was realized in Pt/Co/Pt films and Co/Pt multilayers with doses as low as 10^{12}–10^{14} Ga ions/cm^2 (Vieu *et al*., 2002; Hyndman *et al*., 2001a). Thus, by favoring intermixing at interfaces, irradiation strongly modifies both the interface anisotropy and the exchange interaction. For example, as seen in Section 2.1.1, a ferromagnetic Pt/Co(1.4 nm)/Pt film becomes paramagnetic at room temperature under irradiation for a dose of 2×10^{15} Ga ions/cm^2 (Ferré *et al*., 1999), while the perpendicular anisotropy orientation is maintained at smaller dose. The effect of irradiation is even more drastic in Co/Pt multilayers (Hyndman *et al*., 2001a); two successive transitions occur from a perpendicular to an in-plane anisotropy state for 10^{13} Ga ions/cm^2, and then to a paramagnetic state for 10^{15} Ga ions/cm^2. In spite of these strong changes in magnetism, the etching process is quite inefficient at low doses (1 ML for 1.5×10^{14} Ga ions/cm^2).

As we shall see later, when increasing the dose within the irradiated lines separating nanoelements, the exchange interaction is first reduced in a sharp zone (<10 nm) separating Pt/Co/Pt tracks or dots. These sharp lines become weakly ferromagnetic with either perpendicular or in-plane anisotropy (Figure 13a). Under a little higher dose, the central part of the lines becomes paramagnetic (Figure 13b). At higher doses, etching cuts the magnetic layer, and so separates physically the nanoelements.

4.3.2 *Pt/Co/Pt dot arrays with out-of-plane anisotropy: a model system for studying magnetization reversal in the presence of interdot exchange and dipolar interactions*

The magnetic properties of Ising-like Pt/Co(1.4 nm)/Pt(3.5 nm) square dot or track arrays, having perpendicular magnetic anisotropy and patterned by FIB, have been extensively studied (Aign *et al*., 1998; Jamet *et al*., 1999; Sampaio *et al*., 2001; Hyndman *et al*., 2002a,b; Repain *et al*., 2004; Gierak *et al*., 2005). Here, patterning is realized by scanning a sharp (5–30 nm diameter) FIB spot over the film (Figure 13). TRIM calculations (Ziegler, 1992) allow one to determine the density of collision events in irradiated lines (Figure 19). The interaction between Pt/Co(1.4 nm)/Pt tracks or dots can then be monitored by choosing the

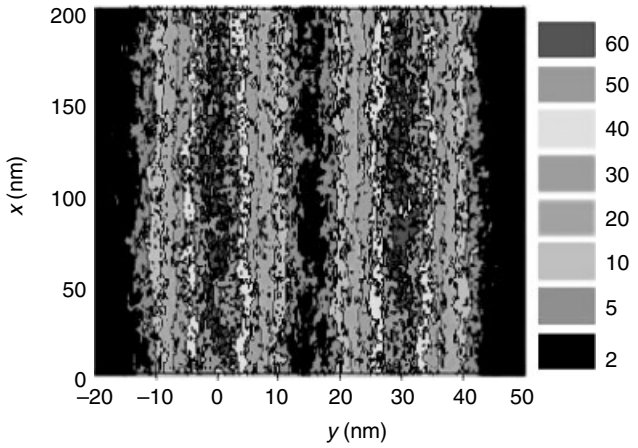

Figure 19. TRIM simulation of the density of collision events for two parallel FIB lines centered at $y = 0$ and 30 nm, and patterned on a Pt(3 nm)/Co(1.4 nm)/Pt(5.6 nm) film. The FIB spot diameter was set to 10 nm. Along x, the lines were built by a succession of overlapping FIB spot irradiations separated by 10 nm. The number of collision events is indicated on the right side of the image in 10^{16} ions/cm^2 units. (From Hyndman, unpublished.)

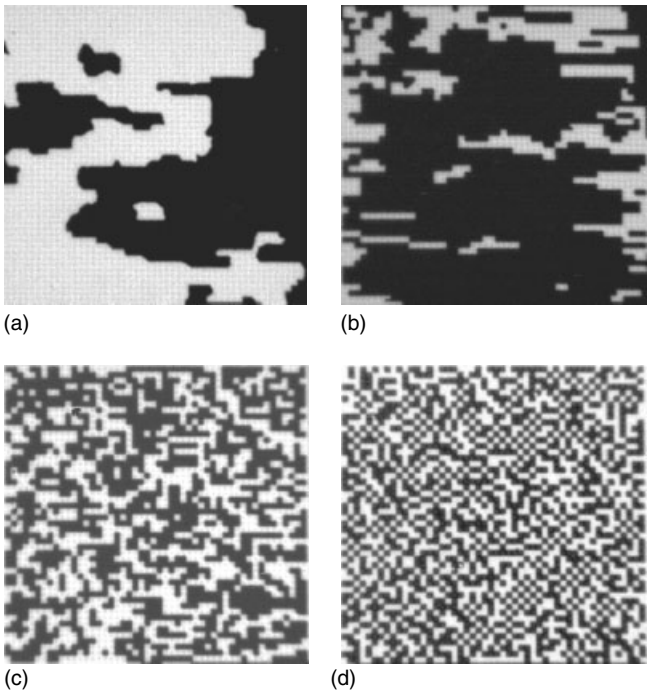

Figure 20. PMOKE images of ac-demagnetized states of ($1 \times 1\,\mu m^2$) Pt/Co(1.4 nm)/Pt dot arrays patterned with lineic Ga ion doses of: (a) 0.05 nC cm^{-1}, (b) 0.1 nC cm^{-1}, (c) 0.2 nC cm^{-1}, and (d) 0.5 nC cm^{-1}, and a spot diameter of 10 nm. (V. Repain *et al*., *Journal of Applied Physics.* **91**, 3103 (2002).)

irradiation dose (Hyndman *et al*., 2001b, 2002a; Repain *et al*., 2004) (Figure 20). At high Ga ion dose ($D > 4 \times 10^{15}$ Ga ions/cm^2), the Co layer is entirely etched away

so that the tracks and dots are surely exchange decoupled; in that case, only the interdot magnetostatic interaction remains efficient. Owing to the magnetostatic coupling in a thick-enough ferromagnetic layer, the ac-demagnetized state of a Pt/Co($t = 1.4$ nm)/Pt film shows a rather high degree of checkerboard arrangements of the magnetization in dot arrays (Figure 21e). In counterpart, no correlation is found between the magnetic state of thin enough Co dots, as for $t = 0.5$ nm (Figure 21d). At a lower dose (1.5×10^{14} Ga ions/cm^2 $< D < 3 \times 10^{15}$ Ga ions/cm^2), the Pt overlayer is partly etched, but not the Co layer. Nevertheless, the magnetism of the Co layer is affected by irradiation: the Co layer becomes paramagnetic at room temperature for a dose $D > 2 \times 10^{15}$ Ga ions/cm^2. It has been shown (Ferré *et al.*, 1999) that for a smaller dose the perpendicular anisotropy and the Curie temperature are reduced when increasing the dose. In other words, the exchange interaction between tracks or dots can be accurately modified and controlled over a short distance ($\approx$2–10 nm) on the central part of the irradiated lines. Thus, the magnetic behavior of arrays of tracks or dots can be subsequently investigated when changing the relative strength between exchange and dipolar couplings (Hyndman *et al.*, 2001a; Repain *et al.*, 2004) (Figure 20).

Let us first focus on the magnetic behavior of arrays of purely dipolar-coupled arrays of perpendicularly magnetized

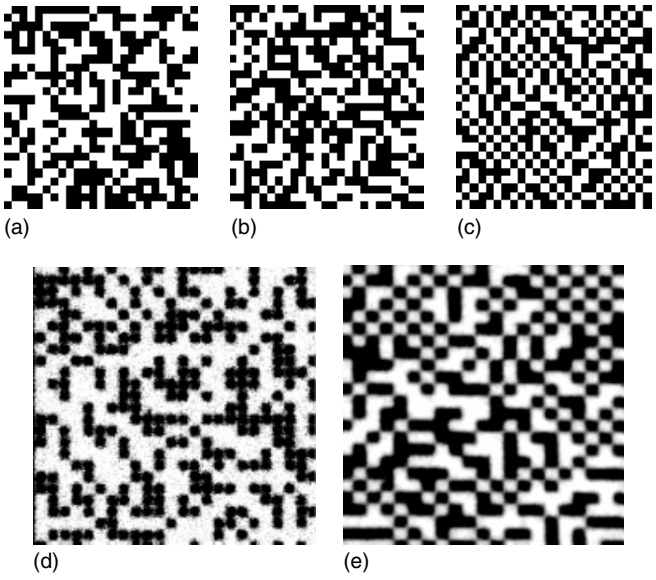

Figure 21. First row: results of the simulation of the demagnetized states of ($1 \times 1\,\mu$m^2) Pt/Co(1.4 nm)/Pt dot arrays for an increasing strength of the dipolar interaction: (a) $R = 0$, (b) $R = 0.44$, and (c) $R = 4.4$. Second row: PMOKE images of ac-demagnetized domain structures for ($1 \times 1\,\mu$m^2) dot arrays patterned on (d) Pt/Co(0.5 nm)/Pt, or (e) Pt/Co(1.4 nm)/Pt films. (Reprinted figure with permission from V. Aign *et al.*, PRL 81, 5656 (1998). Copyright 1998 by the American Physical Society.)

tracks or dots. It is not straightforward to predict the equilibrium state of a large assembly of elements coupled by long-range dipolar interactions. One way is to use Monte Carlo simulations assuming a well-defined switching field for each track or dot in the array; this treatment neglects self-magnetostatic interactions within the nanoelements. In order to model real systems, a distribution of nanoelement switching fields has to be introduced. Such calculations have been done to describe the demagnetized state of a 1.3-μm periodic array of square Pt(4.5 nm)/Co(1.4 nm)/Pt(3.5 nm) dots separated by nonmagnetic 60-nm-wide irradiated lines for several values of the parameter $R = (\Delta H_{SW}/H_{dip})$ (Figure 21a–c). R is the ratio between the width (ΔH_{SW}) of the switching field distribution and the interdot dipolar field (H_{dip}). When $H_{dip} > \Delta H_{SW}$, each dot tends to be surrounded by dots having opposite magnetization; a checkerboard configuration is then favored. However, since the magnetization reversal can be initiated by the switching of different dots at the same time, several checkerboards develop simultaneously around these centers and merge together by generating magnetically frustrated areas. Such demagnetized patterns were also found in arrays of long wires or pillars (Ross *et al.*, 2001). At a larger scale, this situation mimics a complex antiferromagnetic state with antiphase boundaries. Each antiferromagnetically coupled spin is replaced here by a dipolarly interacting macrospin. The observed magnetic pattern of a Pt/Co(1.4 nm)/Pt ac-demagnetized array (Figure 21e) is comparable to that calculated for $R = 4.4$ (c). This result agrees with independently determined experimental values of $\Delta H_{SW} \approx 20$ Oe and $H_{dip} = 81$ Oe (Aign *et al.*, 1998). FIB patterning is especially convenient to avoid distributions of switching fields in Co/Pt dots. In usual systems, a highly distributed nucleation mechanism determines local switching fields. Using a FIB patterning procedure with a Gaussian beam profile, dot borders are weakly irradiated (Figure 13); consequently, the edges become magnetically softer than the inside of the dots. Moreover, self- and interdot magnetostatic interactions also favor nucleation at dot edges. So, for these two reasons, the magnetization reverses first at dot edges in small field. This creates a reservoir of nucleation from which magnetization can subsequently switch by fast domain wall motion, as soon as H reaches H_{SW}. Thus, the distribution of switching fields here is nothing else than that of the propagation field, which is particularly narrow for high-quality films, as proved by the squareness of the hysteresis loop (Figure 3). Fast reversal has the direct consequence that all dots appear either in a single up- or down-magnetized state.

The mean dipolar field value can be calculated (Aign *et al.*, 1998; Repain *et al.*, 2004) or evaluated from the following local picture of the magnetization reversal. As expected, it was experimentally verified by PMOKE imaging that the reversal of a dot depends on the magnetic configuration of the

surrounding dots. Starting from a saturated magnetized state of the array, and applying a field in the opposite direction, the first and last dots are supposed to reverse at fields $H_S^{min} = H_{SW} - H_{dip}$ and $H_S^{max} = H_{SW} + H_{dip}$, respectively, neglecting the small H_{SW} distribution. From high-resolution PMOKE microscopy snapshots, the hysteresis loops of a single central dot have been deduced for magnetization reversal in the two extreme configurations (nearest-neighbor dots magnetized in the same direction or oppositely to the central dot) of the surrounding dots (Figure 22). This allowed the authors to estimate the strength of the dipolar field, $H_{dip} \approx (H_S^{max} - H_S^{min})/2$. In the central part of the dots, the magnetization has been found to switch abruptly, consistently with a fast wall motion-assisted reversal initiated from a low field nucleated state at dot edges.

The effects of magnetostatics on the magnetization reversal have been investigated on patterned dots, open tracks, and compared to those happening in the virgin film (Figure 23). The reversal process has been imaged for different field values, and the hysteresis loop reconstructed from the analysis of multiple snapshots similar to those presented in Figure 23. An abrupt magnetization reversal takes place in the virgin part as well as in the track array. Nevertheless, as a consequence of the dipolar interaction between tracks, intermediate states with alternate magnetized tracks are favored (Figure 23c). Some dots begin to switch before the onset of the reversal of the virgin film; this behavior is expected, as already shown when investigating the reversal of the first dot (Figure 22). As calculated, the tilted loop shape for the dot array is still a consequence of the interdot magnetostatic interaction (Figure 23).

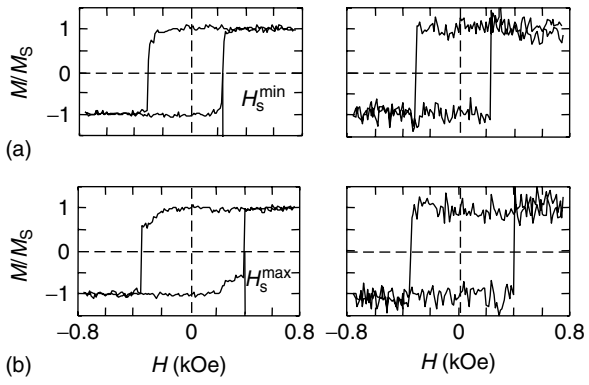

Figure 22. Magnetic hysteresis loops measured on a single Pt/Co(1.4 nm)/Pt $1 \times 1\,\mu m^2$ square dot in the FIB-patterned array. (a) Reversal of the first dot, initially surrounded by dots magnetically oriented in the same direction, (b) reversal of the last dot initially surrounded by dots magnetically oriented in the opposite direction. The loops at the left side are measured over the full area of a dot, while the loops at the right side are probing only the central part of the dot ($0.33 \times 0.45\,\mu m^2$). Figure 23. Pt/Co(1.4 nm)/Pt film (a–f) PMOKE snapshots of the field-induced magnetization reversal of several areas existing on the sample: (left part) virgin film, (middle part) dot array, and (right part) track array, connected to the virgin film at its right side. After saturating the film in a negative field (black state), a positive field is applied with successive values: (a) 160 Oe, (b) 211 Oe, (c) 219 Oe, (d) 230 Oe, (e) 257 Oe, and (f) 279 Oe. The patterning has been done by FIB ($D = 5 \times 10^{15}$ ions/cm^2). The image size is $30 \times 20\,\mu m^2$. (g) Remanent hysteresis loops in the virgin part of the sample, and in the dot and track patterned parts deduced from the analysis of snapshots recorded for many field values. Magnetostatic effects give an increase of coercivity in patterned areas. (Reprinted from *Journal of Magnetism and Magnetic Materials*, Vol 240, Hyndman *et al.*, Magnetization reversal in weakly coupled magnetic patterns, Pages 34–36, 2002, with permission from Elsevier.)

Starting from such a 2D-Ising model system, it is possible to investigate by PMOKE microscopy the magnetization reversal dynamics in a regular array of dipolar or exchange-coupled dots (Hyndman *et al.*, 2001b; Sampaio *et al.*, 2001). The magnetization reversal in this system exhibits slow dynamics because of the presence of many equivalent quasi-degenerate ground states. After saturating first the dot array in a positive field and reversing it to a value smaller than the coercivity, the observed slow relaxation of the magnetization M (magnetic aftereffect) can be fitted by a power law: $M = At^{-\alpha}$ (Sampaio *et al.*, 2001). The exponent α is shown to increase with the applied field. This time dependence is consistent with a many-body type of relaxation. Monte Carlo simulations also support this form for the expression of the relaxation law and the field dependence of α. A power law has also been determined by

Monte Carlo simulations for a 1D model of aligned small particles coupled by dipolar interactions (Ribas and Labarta, 1996).

For lines irradiated under a relatively large lineic dose ($0.5\,\mathrm{nC\,cm^{-1}}$), the discreteness of the magnetic dot array is clearly evidenced from the image of the ac-demagnetized state (Figure 20d). At low lineic irradiation dose ($D < 0.05\,\mathrm{nC\,cm^{-1}}$) (Figure 20a), the ac-demagnetized state is formed by large up- or down-magnetized domains whose walls are pinned on the reminiscent underlying FIB line pattern. In another case of large dipolar effects in granular Co–Cr films, the effect of textural discreteness has been already evidenced by magneto-optical microscopy (Schmidt and Hubert, 1986). When comparing granular and FIB-patterned films, crystallite boundaries and irradiated lines are supposed to play a similar role. In a narrow dose range, around $D \approx 0.2\,\mathrm{nC\,cm^{-1}}$ (Figure 20c), competitive interdot dipolar and exchange interactions take place; this mimics a kind of spin-glass state. The experimentally found demagnetized patterns, when increasing the dose in irradiated lines, can be well understood from simulations in random granular media. In that case, both magnetostatic interactions and reduction of the exchange interaction at grain boundaries are considered (Figure 16) (Victora, Willoughby, MacLaren and Xue, 2003). In the Pt/Co/Pt model system, the ratio between interdot exchange and dipolar energy can be precisely adjusted with the ion dose in irradiated lines. Thus, ideal granular media, that is, without distributions of grain sizes and interactions, can be compared to patterned Pt/Co/Pt dot arrays (Repain *et al.*, 2004) and modeled by simulations (Zhu and Neal Bertram, 1989).

As reported in the preceding text (Section 3.4), the ΔM method remains a powerful tool to characterize the sign of the resulting interdot interaction in discrete recording media. The trends of this method appeared quite empirical at first glance. With a 2D-Ising model system of quasi-identical interacting dots located at the nodes of a square lattice, it was possible to check the validity of this ΔM method (Repain *et al.*, 2004). The $\Delta M(H)$ curves have been deduced for Pt/Co(1.4 nm)/Pt dot arrays when varying the exchange to dipolar coupling ratio with the ion dose in FIB irradiated lines. Experimental data are in good qualitative agreement with predictions: ΔM is positive for exchange-dominated interdot interaction and negative for favored dipolar coupling (Figure 24). The origin of ΔM can be understood from the examination of PMOKE snapshots. Interactions can be better quantified by looking at the field dependence of the magnetic pattern at different scales. ΔM is clearly related to the two-macrospin correlation functions of neighboring dots (Figure 25).

What are the consequences of a reduction of periodicity P and lateral dot size a at nanometer scales, when preserving the irradiation dose in irradiated FIB lines? This was studied for etched lines using a 5×10^{15} Ga ions/cm^2 irradiation dose in a Pt(4.5 nm)/Co(1.4 nm)/Pt(3.5 nm) film (Hyndman *et al.*, 2002a). The width of the etched central part of the lines

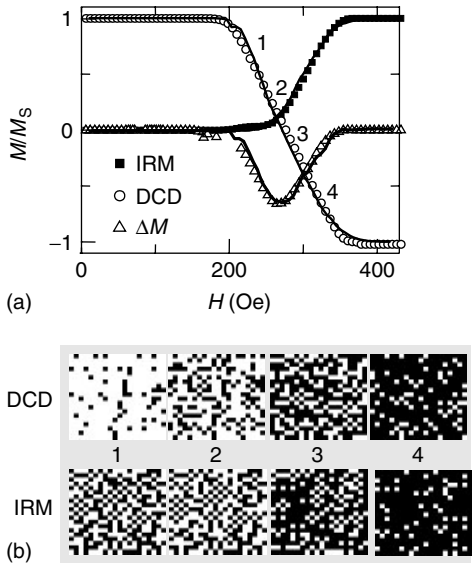

Figure 24. (a) Renormalized magnetization (DCD(H) or IRM(H)) and $\Delta M(H)$ curves for a Pt/Co(1.4 nm)/Pt dot array patterned with a lineic Ga ion dose of $0.5\,\mathrm{nC\,cm^{-1}}$. Data points are visualized on the graph by symbols. Continuous lines are simulation results considering a Gaussian switching field distribution centered at 272 Oe, with a small standard deviation of 15 Oe. (b) PMOKE snapshots of the DCD(H) and IRM(H) remanent magnetic states over the central part of the array for different values of the applied field H (indicated by 1–4 on the graph). The switched magnetic dots are in black. (V. Repain *et al.*, *Journal of Applied Physics.* **91**, 3103 (2002).)

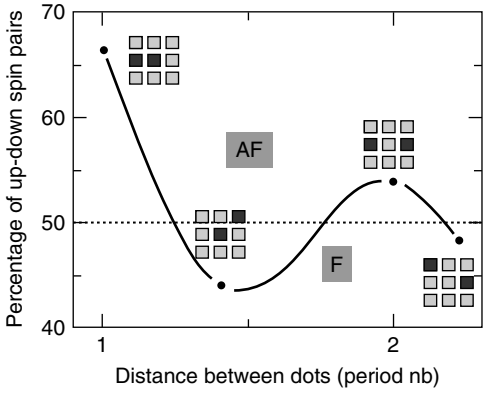

Figure 25. Macrospin pair correlation function versus the distance between Pt/Co(1.4 nm)/Pt dots in arrays patterned with a lineic Ga ion dose of $0.5\,\mathrm{nC\,cm^{-1}}$. Data points correspond to first-, second-, or third-neighbor dots, as shown in the figure. The line is a fit for the eyes. The observed oscillation does not exist and the macrospin correlation values are close to 50% for exchange-coupled dots, that is, for a dose $D = 0.2\,\mathrm{nC\,cm^{-1}}$. (From Repain *et al.*, 2004.)

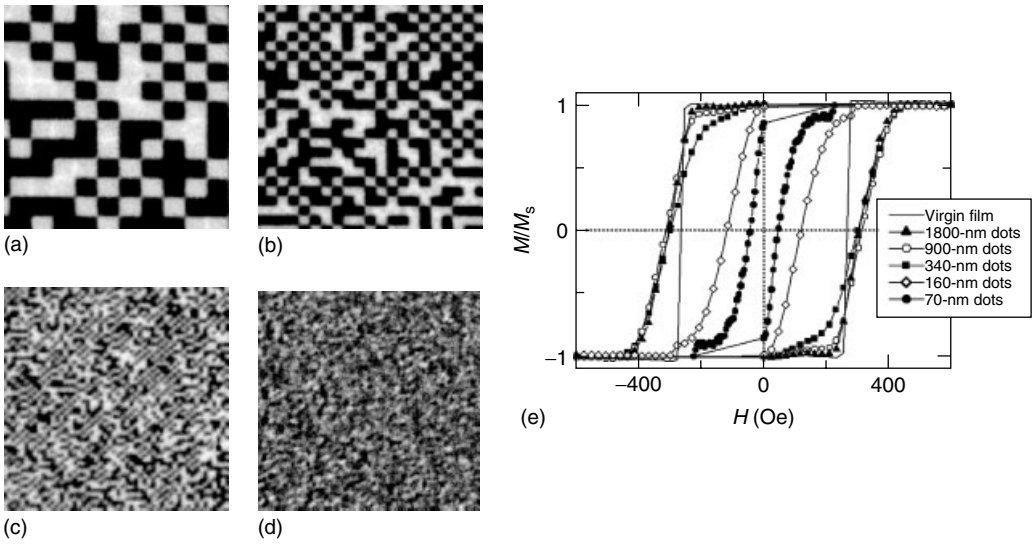

Figure 26. PMOKE images ($18 \times 18\,\mu m^2$) of the central part of each of four demagnetized dot arrays with dot sizes: (a) 1800 nm, (b) 900 nm, (c) 340 nm, and (d) 70 nm. Normalized remanent hysteresis loops are shown in (e). (R. Hyndman *et al*., *Trans. Magn. Soc. Jpn*, **2**, 175 (2002).)

was estimated to be about 20 nm in that case. PMOKE images of the demagnetized states of square dot arrays are shown in Figure 26(a–d) (four values of the lattice periodicity) ($1800 < P < 70$ nm). The limited resolution of the PMOKE microscope does not allow one to resolve separate magnetized dots when $P < 300$ nm (Figure 26d). As can be seen in Figure 26(e), the remanent magnetization and the coercive field are fortunately still finite at room temperature even for reduced dot sizes ($a = 50$ nm). This means that, in spite of a small reduction of the dot anisotropy by ion straggling effects at their edges, the superparamagnetic limit is not yet reached in that case. Starting from the usual criterium $KV = 40\,kT$ for the superparamagnetic limit, and since $V = 3500\,nm^3$, the anisotropy constant K must be higher than $0.5 \times 10^6\,erg\,cm^{-3}$ to keep ferromagnetism in these nanodots at room temperature. This is reasonable since the anisotropy constant is higher ($K = 1.4 \times 10^6\,erg\,cm^{-3}$) for the virgin 1.4 nm Co film and inside patterned dots.

As reported in the preceding text (Section 2.1.1), the change in magnetism by ion irradiation is much more efficient in Co/Pt multilayers than in Pt/Co/Pt films; the reason is that the main physical process is linked to the presence of interfaces. While a virgin Pt(6.5 nm)/[Co(0.3 nm)/Pt(0.6 nm)]$_6$/Pt(2.8 nm) multilayer exhibits perpendicular anisotropy it becomes in-plane magnetized after a uniform Ga irradiation with $D = 10^{14}$ Ga ions/cm^2 (Fig. 5). An array of 1-μm square dots has been patterned by FIB with this dose, and its magnetic state studied by PMOKE microscopy and Differential phase contrast Transmission electron microscopy (DPC-TEM) in Lorentz mode (Warin *et al*., 2001). The remanent state consists of opposite out-of-plane magnetized dots (Figure 27) separated by narrow (50 nm wide) in-plane magnetized FIB lines (Figure 28). Head-to-head domain walls were evidenced by TEM inside the irradiated lines. The direction of the magnetization may be reversed independently in the dots or in the irradiated lines under a magnetic field applied either out-of-plane or in plane. Thus, FIB appears here as a convenient technique here to produce patterning by anisotropy modulation.

Figure 27. PMOKE image ($45 \times 35\,\mu m^2$) of an ac-demagnetized state of the virgin [Pt(0.6 nm)/Co(0.3 nm)]$_6$ multilayer film (top part of the image), and of the FIB ($D = 10^{14}$ Ga ions/cm^2) patterned part (bottom of the image). (P. Warin *et al*., *Journal of Applied Physics*, **90**, 3850 (2001).)

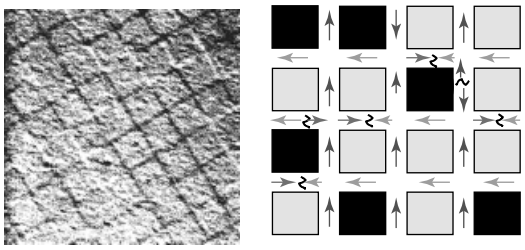

Figure 28. (a) DPC-TEM image ($7 \times 7\,\mu m^2$) of part of the ac-demagnetized multilayer array considered in Figure 27, for an untilted specimen. In this configuration in-plane magnetization is only probed. (b) Schematic view of the magnetization distribution within an area inserted in (a). Gray and black dots are oppositely perpendicularly magnetized. The arrows indicate the orientation of the magnetization inside the irradiated lines ($D = 10^{14}$ Ga ions/cm^2). (P. Warin *et al*., *Journal of Applied Physics*, **90**, 3850 (2001).)

4.3.3 Arrays of tracks with out-of-plane anisotropy

The dipolar interaction between tracks separated by non-magnetic irradiated narrow lines is clearly revealed by the magnetic configuration of the array. As expected, the PMOKE image of an ac-demagnetized periodic array of Pt/Co(1.4 nm)/Pt tracks shows that they are preferentially alternatively up and down magnetized (Figure 29) (Hyndman *et al*., 2002a). As expected, remanent magnetization remains finite for 70-nm-wide tracks. The same type of antiferromagnetic arrangement has also been found for dipolar-coupled in-plane magnetized single-domain rectangular nanoelements (Kirk, Chapman and Wilkinson, 1997) (Figure 30). Such type of configuration was also evidenced in the case of in-plane magnetized single-domain circular nanoelements which form chains and interact through dipolar fields (Cowburn, 2002). The alternate magnetized state can be interrupted after a few periods giving rise to ferromagnetically oriented nearest-neighbor nanoelements (Fig. 29b). Several equivalent demagnetized states with nearly the same probability of occurrence can be generated, depending upon slightly different initial conditions.

4.3.4 Magnetic dot arrays with out-of-plane anisotropy: Application to ultrahigh density perpendicular recording

The advantages of magnetic recording media with discrete nanodots, also called *quantum magnetic storage media*, especially with perpendicular anisotropy, have been often pointed out (Chou, Wei, Krauss and Fischer, 1994; Ferré, 2001; Lodder, Haast and Abelmann, 2001; Lodder, 2004; Khizroev and Litvinov, 2004). Importantly, the signal-to-noise ratio can be significantly improved in discrete media as compared to continuous ones. Just after the first demonstration that patterning of discrete dots could be realized efficiently by Ga FIB (Aign *et al*., 1998), IBM – Hitachi produced 140 Gbit in.$^{-2}$ CoCrPt dot arrays with perpendicular magnetic anisotropy (Rettner, Best and Terris, 2001). A that time, the quality of the patterning was not sufficiently high enough due to instabilities of the particular FIB machine when used at such a small scale. They improved the process rapidly and obtained promising ultrahigh density magnetic storage up to 200 Gbit in.$^{-2}$ using arrays of 20-nm-thick $Co_{70}Cr_{18}Pt_{12}$ square ($a = 67$ nm) dots overcoated by a 5-nm-thick C layer (Lohau *et al*., 2001; Albrecht *et al*., 2002; Albrecht *et al*., 2003) (Figure 31). The

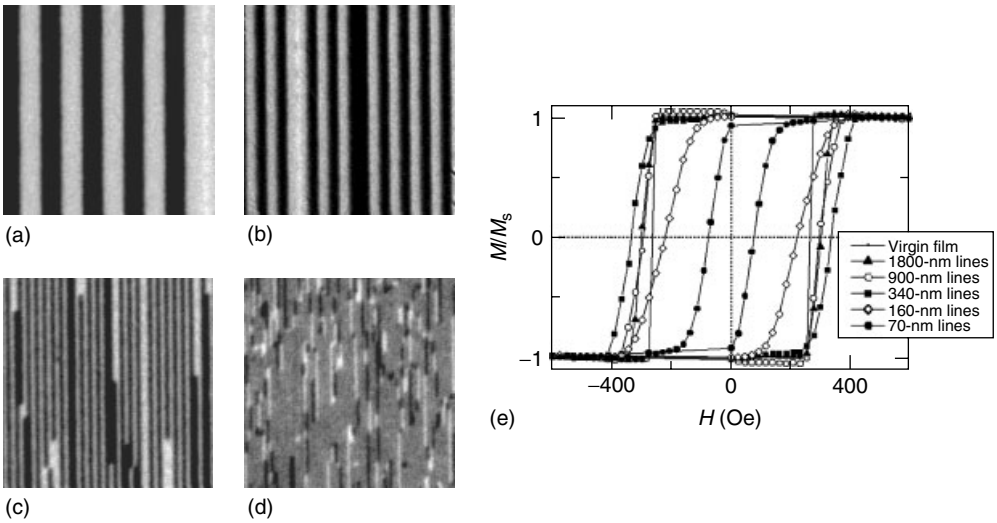

Figure 29. PMOKE images ($18 \times 18\,\mu m^2$) of the central part of four demagnetized stripe arrays. The width of the stripes are respectively: (a) 1800 nm, (b) 900 nm, (c) 340 nm, and (d) 160 nm. Together with data for 70-nm-wide stripes, normalized remanent PMOKE hysteresis loops are shown in (e). (R. Hyndman *et al*., *Trans. Magn. Soc. Jpn.*, **2**, 175 (2002).)

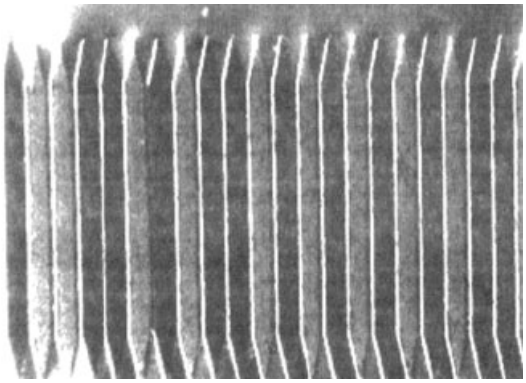

Figure 30. TEM Foucault image of NiFe elements with two pointed ends in an array with 250-nm center-to-center spacing. The component of the induction is mapped in the vertical direction. (Kirk *et al*., APL 71, 539–541 (1997).)

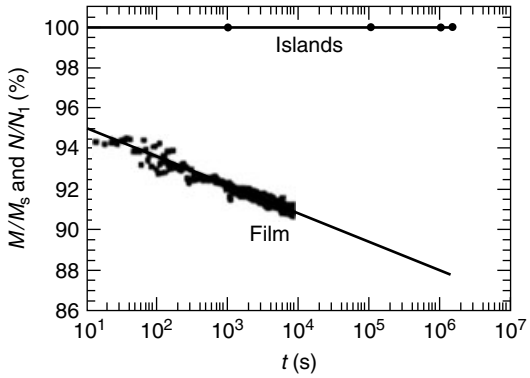

Figure 32. Thermal decay of single-domain 80-nm nanodots from MFM data and full decay as measured by Vibrating sample magnetometer VSM. The decay rates were measured at room temperature in the absence of an applied magnetic field. (Rettner *et al*., *IEEE Trans. Magn.* **38**, 1725–1730 (2002) (© 2002 IEEE).)

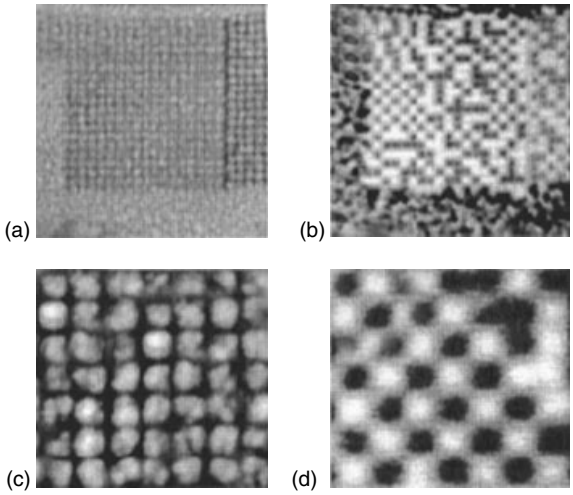

Figure 31. AFM and MFM images of a $2 \times 2\,\mu m^2$ patterned region in a CoCrPt film are shown in (a) and (b), respectively, along with higher magnification images of small regions in (c) and (d), respectively. The pattern period is ~100 nm. (Rettner *et al*., *IEEE Trans. Magn.* **38**, 1725–1730 (2002) (© 2002 IEEE).)

nonmagnetic separation of the dots by FIB trenches was estimated to be 30 nm. They found that 5-nm-deep trenches ($D = 0.04\,nC\,cm^{-1}$) were sufficient to isolate the nanodots magnetically. They suggested that the carbon overcoat was implanted into the trenches along with Ga. Thus, the magnetic isolation was achieved by a physicochemical mechanism involving a combination of Ga and C poisoning, and by damage of the Co ions, but not only from sputtering of $Co_{70}Cr_{18}Pt_{12}$. The irradiated region has certainly not a large enough anisotropy to support domain walls or remanent magnetization, so that magnetic domains could not extend beyond the nanodot edges.

As already found in other systems, due to the variation of the shape anisotropy, a transition from in-plane to out-of-plane magnetized nanodots occurs when decreasing their lateral size a (Fernandez *et al*., 1996). As proved by AFM, this reorientation transition also takes place for $Co_{70}Cr_{18}Pt_{12}$ nanodots when a <150 nm. As for Pt/Co/Pt, the magnetization at the dot edges reverses first. However, contrary to Pt/Co/Pt nanodots, a multidomain structure appears during magnetization reversal in $Co_{70}Cr_{18}Pt_{12}$ nanodots because of large self-demagnetizing effects.

An important point concerns the magnetic stability in nanodots. A very clear proof of the stabilization of the magnetization state in nanodot arrays as compared to virgin films has been demonstrated for $Co_{70}Cr_{18}Pt_{12}$ by Rettner *et al*. (2002b). Magnetic relaxation (or magnetic aftereffect) measurements show a larger decay rate for the virgin continuous film than for the nanodot array (Fig. 32). The stability is enhanced over that of the unpatterned film, even though the coercivity and anisotropy are reduced. The self-demagnetizing field is also reduced for nanodots (Section 3.3), which consequently slows down the relaxation.

As previously mentioned (Section 4.3.2), the dipolar coupling acting on single-domain nanodots gives rise to a checkerboard magnetized dot structure in an ac-demagnetized state (Figure 31). Nevertheless, Rettner *et al*. (2002b) claim that $Co_{70}Cr_{18}Pt_{12}$ dot arrays are favorable for recording since the interdot dipolar interaction does not exceed the coercivity. Moreover, these nanodots show a narrow switching field distribution and an enhanced thermal stability. Using a quasistatic write–read tester, feasibility of writing and reading information has been demonstrated at the competitive ultrahigh density of 200 Gbit in.$^{-2}$. Patterning has been shown to drastically reduce the jitter and to improve the

signal-to-noise ratio and the addressing performance. Perpendicular recording with bit widths of less than 65 nm has also been demonstrated independently by Seagate (Khizroev *et al*., 2002). Additionally, the FIB technique has also been tested satisfactorily for structuring 20-nm-thick Co longitudinal recording media (Albrecht *et al*., 2003).

The fabrication of arrays of nanosensors can be also realized by FIB (Fassbender, Ravelosona and Samson, 2004). Khizroev and Litvinov (2004) have proposed to design MRAMs and Microelectro mechanical systems (MEMS) by this FIB technique.

5 CONCLUSION

New patterning techniques for fabricating dense arrays of nanoelements with similar properties are still emerging. In the present contribution we have shown how the mastered technique of depositing films on prepatterned wafers allows one to prepare high-density recording media and MRAM cells. Multilevel recording on multiple storage layers was proposed recently (Albrecht *et al*., 2005; Baltz, Landis, Rodmacq and Dieny, 2005b).

Light He ion irradiation through a mask is a very promising planar technique to pattern ultrathin film media with an ultimate resolution. New developments are expected soon with this technique. Fassbender *et al*. (2002) have demonstrated that irradiation of NiFe/FeMn by He ions allows one to modify and control the magnitude of the exchange bias field on a submicron scale without affecting the surface roughness.
