1 INTRODUCTION

The description of many physical properties of condensed matter involves the theoretical treatment of an inhomogeneous electron gas in the potential of atomic nuclei. The ground-state structure, the vibrational and optical properties, and the magnetic properties of a solid are determined by the electrons and their interactions, quantum mechanically described by the (many-body) Schrödinger equation. Wave function–based approximations, like the Hartree–Fock method, have a long tradition of dealing with this complicated many-body problem. In the last 40 years, density-functional theory (DFT) has developed into a successful alternative to these methods and it seems to be currently one of the most widespread methods in computational solid-state theory (Argaman and Makov, 2000). It has applications in diverse fields like studying the properties of defects in solids, heterogeneous catalysis, organic and biomolecular reactions, and also magnetism.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

Magnetism in the solid state comprises a large variety of phenomena that can be characterized by quantities like the magnetic moment, the magnetic order, the ordering temperature, the magnetization direction, and so on. The physical concepts, used to describe these quantities on a theoretical basis, are again diverse and include relativistic quantum mechanics, statistical theories, and classical electrodynamics. The magnetic moment of a solid can be obtained, for example, by quantum-mechanical theories, while ordering temperatures can be accessed by statistical theories which use input parameters of quantum-mechanical calculations. Exchange interactions have to be described on a quantum-mechanical basis, but it is usually sufficient to describe dipole–dipole interactions classically.

Although there is no single theoretical approach to all magnetic phenomena, it can be stated that magnetism is a uniquely quantum-mechanical phenomenon and, in the solid state, DFT is the most widespread theoretical method used to determine the magnetic properties of matter. Vector-spin DFT allows – at least in principle – the access to the spin magnetic moment and the magnetic order of the ground state and it can serve to extract other quantities, like exchange interactions, that can serve as input for other theoretical approaches. Although DFT is designed as a ground-state method, that is, all results refer to a temperature of zero Kelvin, it can, nevertheless, be used to infer some finite-temperature properties of materials. This contribution starts with an outline of DFT and describes the successes and current limitations of the theory. Some methods to overcome these limitations, like self-interaction correction (SIC) or orbital polarization (OP), are discussed. Concepts to formulate spin dynamics based on DFT are presented and strategies to determine the magnetic ground state of a system are discussed. This involves also the mapping of DFT results on model Hamiltonians, which can be used to describe

other properties – like ordering temperatures – in a certain approximation. Orbital magnetism, which is particularly important in low-dimensional systems, is briefly discussed here and – in more detail – in later chapters.

Most examples given in this contribution are metallic systems, typically transition metals and their alloys and compounds. DFT has proved to be particularly valuable in the description of these materials, while other classes of magnetic systems – like magnetic insulators – have been traditionally approached with other methods. Modern magnetoelectronic and spintronic applications involving orbitally ordered systems, low-dimensional structures, and so on, may require theoretical approaches beyond those presented here. But for the majority of magnetic systems DFT presents a good starting point for a theoretical description.

2 DENSITY-FUNCTIONAL THEORY

In any realistic calculation, the straightforward quantum-mechanical treatment of a system of identical particles is limited to a very small number of particles. This is mainly due to the appearance of the many-body wave function, which contains a tremendous amount of information – but typically we are interested only in a limited number of physical observables. DFT starts directly from the density of the particles in question (in our case electrons) and, bypassing the troublesome many-body wave function, allows thereby the treatment of a large number of particles. In this section, only a short and certainly incomplete review of DFT can be given. For a more detailed account of this theory, the reader is referred to the review of Jones and Gunnarsson (1989) or to the books of Parr and Yang (1989) and Eschrig (2003).

2.1 The non-spin-polarized version of DFT

Hohenberg and Kohn (1964) worked out two central theorems that form the basis of DFT: For a system of N particles (e.g., electrons) moving in an external potential $v(\mathbf{r})$ (caused by, e.g., nuclei) in a nondegenerate ground state, (i) the many-body wave function Ψ and $v(\mathbf{r})$ are uniquely determined by the particle density distribution $n(\mathbf{r})$ and (ii) there exists an energy functional of this density, $E[n(\mathbf{r})]$, which is stationary with respect to variations of the ground-state density. These two theorems allow – at least in principle – the determination of the ground-state density and energy of an N-particle system. Extracting the classical Coulomb interaction energy, such a Hohenberg–Kohn energy functional takes the form

$$E[n(\mathbf{r})] = \int v(\mathbf{r})n(\mathbf{r})\mathrm{d}\mathbf{r} + \frac{1}{2}\int\int \frac{n(\mathbf{r})n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\mathrm{d}\mathbf{r}\mathrm{d}\mathbf{r}' + G[n(\mathbf{r})] \quad (1)$$

where the functional $G[n(\mathbf{r})]$ contains all other contributions.

If we succeed in finding the functional $G[n(\mathbf{r})]$ or a good approximation to it, the immediate advantage of DFT is that, instead of dealing with the full many-body wave function, $\Psi(\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N)$, we can work with the much more tractable density, $n(\mathbf{r})$. Although more information is directly accessible from the wave function than from the density,

$$n(\mathbf{r}) = \int \mathrm{d}\mathbf{r}_2 \ldots \int \mathrm{d}\mathbf{r}_N \Psi^*(\mathbf{r}, \mathbf{r}_2, \ldots, \mathbf{r}_N) \times \Psi(\mathbf{r}, \mathbf{r}_2, \ldots, \mathbf{r}_N) \quad (2)$$

in DFT many physical quantities, like the structural properties or bond strength, can be obtained for large systems, where a many-body wave function would be impossible to access. For example, calculations of the ground-state energies for different external potentials, as they result from a variation of the lattice parameters in a periodic solid, allow the determination of the equilibrium lattice constant, which is nowadays possible to within a few percents. Early attempts to use the density as a key parameter for calculations of periodic solids were made by Lenz (1932) based on the statistical method of Thomas (1927) and Fermi (1928). In this approach, $G[n(\mathbf{r})]$ was considered to contain the kinetic energy density (taken to be proportional to $[n(\mathbf{r})]^{(5/3)}$). In the Thomas–Fermi–Dirac method $G[n(\mathbf{r})]$ even contains an exchange energy density term proposed by Dirac (1930) (proportional to $[n(\mathbf{r})]^{(1/3)}$). Although the Thomas–Fermi theory still has its applications today, it never became useful as a theoretical method for the prediction of material properties (Slater and Krutter, 1934).

The key idea, that made DFT a success, was to extract from $G[n(\mathbf{r})]$ the kinetic energy T_0 of a noninteracting electron gas in its ground state which has the same density distribution, $n(\mathbf{r})$, as the interacting system. In this Kohn–Sham theory (Kohn and Sham, 1965), a new functional

$$E_{\mathrm{xc}}[n(\mathbf{r})] = G[n(\mathbf{r})] - T_0[n(\mathbf{r})] \quad (3)$$

appears, that remains to be determined. E_{xc} is a much smaller term than G and is called *exchange-correlation energy functional*, since – as we will see in the following text – without E_{xc} our energy functional E would yield just the energy in the Hartree approximation. If we take into account that particle conservation, that is, $N = \int n(\mathbf{r})\mathrm{d}\mathbf{r}$, has to be ensured,

we can formulate the stationarity of E in equation (1) with respect to variations of the ground-state density, n, as

$$\frac{\delta T_0}{\delta n(\mathbf{r})} + v(\mathbf{r}) + \int \frac{n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\mathrm{d}\mathbf{r}' + \frac{\delta E_{\mathrm{xc}}}{\delta n(\mathbf{r})} - \lambda = 0 \qquad (4)$$

where the Lagrange parameter λ ensures the particle conservation. Expressing the kinetic energy of the noninteracting particles via their wave functions, ϕ_i, we can recast equation (4) in the form of an effective single-particle Schrödinger equation, the Kohn–Sham equation:

$$\left[-\frac{\hbar^2}{2m}\nabla^2 + v(\mathbf{r}) + \int \frac{n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\mathrm{d}\mathbf{r}' + \frac{\delta E_{\mathrm{xc}}}{\delta n(\mathbf{r})}\right]\phi_i(\mathbf{r}) = \epsilon_i\phi_i(\mathbf{r}) \qquad (5)$$

which has to be solved self-consistently since $n(\mathbf{r}) = \sum_{i=1}^{N}|\phi_i(\mathbf{r})|^2$. We can see now that without E_{xc} equation (5) reduces to the Hartree equation. Therefore, this last term of the Hamiltonian is called the *exchange-correlation potential*.

Although λ was introduced as a Lagrange multiplier and the ϵ_i's also should be strictly interpreted in this way, it is usual to derive from the ϵ_i's band structures of a crystal and use the wave functions $\phi_i(\mathbf{r})$ as approximations to true quasiparticle wave functions. Some justification will be given below and comparison with experimental data often confirms this point of view, but there are also well-known examples, where this interpretation leads to significant 'errors', like in the comparison of the band gaps of semiconductors and insulators with band structures derived from these ϵ_i's.

2.2 The density and potential matrix

DFT allows us – at least in principle – to determine the correct ground-state charge density. For a magnetic system we are interested not only in $n(\mathbf{r})$ but also in accessing the magnetization density, $\mathbf{m}(\mathbf{r})$, directly. If $\psi_\alpha(\mathbf{r})$ is the field operator for a particle of spin α, the particle and the magnetization density can be formulated as

$$n(\mathbf{r}) = \sum_\alpha \langle\Psi|\psi_\alpha^+(\mathbf{r})\psi_\alpha(\mathbf{r})|\Psi\rangle;$$
$$\mathbf{m}(\mathbf{r}) = -\mu_{\mathrm{B}}\sum_{\alpha,\beta}\langle\Psi|\psi_\beta^+\boldsymbol{\sigma}_{\alpha\beta}\psi_\alpha(\mathbf{r})|\Psi\rangle \qquad (6)$$

where we introduced the Bohr magneton, $\mu_{\mathrm{B}} = (e\hbar/2mc)$, and the Pauli matrices (underlined symbols denote 2×2 matrices):

$$\underline{\sigma_x} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \underline{\sigma_y} = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \underline{\sigma_z} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \qquad (7)$$

Instead of $n(\mathbf{r})$ and $\mathbf{m}(\mathbf{r})$, we can now introduce a hermitian 2×2 spin-density matrix, $\underline{n}(\mathbf{r})$, with components defined as

$$n_{\alpha\beta}(\mathbf{r}) = \langle\Psi|\psi_\beta^+(\mathbf{r})\psi_\alpha(\mathbf{r})|\Psi\rangle \qquad (8)$$

The density matrix can then be decomposed into a scalar and a vectorial part, corresponding to the particle and spin density:

$$\underline{n}(\mathbf{r}) = \frac{1}{2}\left(n(\mathbf{r})\underline{\mathrm{I}} + \underline{\boldsymbol{\sigma}}\cdot\mathbf{s}(\mathbf{r})\right) = \frac{1}{2}\begin{pmatrix} n(\mathbf{r})+s_z(\mathbf{r}) & s_x(\mathbf{r})-is_y(\mathbf{r}) \\ s_x(\mathbf{r})+is_y(\mathbf{r}) & n(\mathbf{r})-s_z(\mathbf{r}) \end{pmatrix} \qquad (9)$$

where $\underline{\mathrm{I}}$ is a 2×2 unit matrix and $\mathbf{s}(\mathbf{r})$ is the spin density that differs from the magnetization density by a factor of $-\mu_{\mathrm{B}}$. Likewise, a potential matrix corresponding to this spin-density matrix is denoted as $\underline{v}(\mathbf{r})$ and can be written in terms of a scalar potential and magnetic field, $\mathbf{B}(\mathbf{r})$:

$$\underline{v}(\mathbf{r}) = v(\mathbf{r})\underline{\mathrm{I}} + \mu_{\mathrm{B}}\underline{\boldsymbol{\sigma}}\cdot\mathbf{B}(\mathbf{r}) \qquad (10)$$

In 1972, von Barth and Hedin used these matrices to extend the DFT concept to spin-polarized systems (von Barth and Hedin, 1972), replacing the scalar quantities by their 2×2 matrix counterparts. In this way, they were able to derive a spin-polarized version of the Kohn–Sham equations:

$$\left[\left(-\frac{\hbar^2}{2m}\nabla^2 + \sum_\alpha\int\frac{n_{\alpha\alpha}(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\mathrm{d}\mathbf{r}'\right)\underline{\mathrm{I}} + \underline{v}(\mathbf{r}) + \frac{\delta E_{\mathrm{xc}}}{\delta\underline{n}(\mathbf{r})}\right] \times \begin{pmatrix} \phi_i^{(+)}(\mathbf{r}) \\ \phi_i^{(-)}(\mathbf{r}) \end{pmatrix} = \epsilon_i\begin{pmatrix} \phi_i^{(+)}(\mathbf{r}) \\ \phi_i^{(-)}(\mathbf{r}) \end{pmatrix} \qquad (11)$$

In contrast to the original, non-spin-polarized, version of DFT, here the uniqueness of the potential is not guaranteed (Capelle and Vignale, 2001), but for most practical purposes this poses no problems. We can now write the exchange-correlation potential also as a 2×2 matrix:

$$\frac{\delta E_{\mathrm{xc}}}{\delta\underline{n}(\mathbf{r})} = \underline{v}_{\mathrm{xc}}(\mathbf{r}) = v_{\mathrm{xc}}(\mathbf{r})\underline{\mathrm{I}} + \mu_{\mathrm{B}}\underline{\boldsymbol{\sigma}}\cdot\mathbf{B}_{\mathrm{xc}}(\mathbf{r}) \qquad (12)$$

for which suitable approximations have to be found. A solution of equation (11) yields again Kohn–Sham wave functions, from which the density matrix can be determined:

$$n_{\alpha\beta}(\mathbf{r}) = \sum_{i=1}^{N}\phi_i^{*\alpha}(\mathbf{r})\phi_i^{\beta}(\mathbf{r}) \quad \text{where} \quad \alpha,\beta = (+),(-) \qquad (13)$$

As in the non-spin-polarized theory, a solution for equations (11) and (13) has to be obtained self-consistently.

If the density matrix turns out to be diagonal, at any point in space the magnetic moments are aligned along the same direction (z) and the magnetization is called *collinear*. Otherwise, we speak of noncollinear magnetic structures. Examples of collinear magnetization densities are displayed in Figure 1 for bcc and fcc Fe. Experimentally, fcc Fe can be stabilized as precipitate in Cu and was found to have a noncollinear magnetic structure (Tsunoda, 1989).

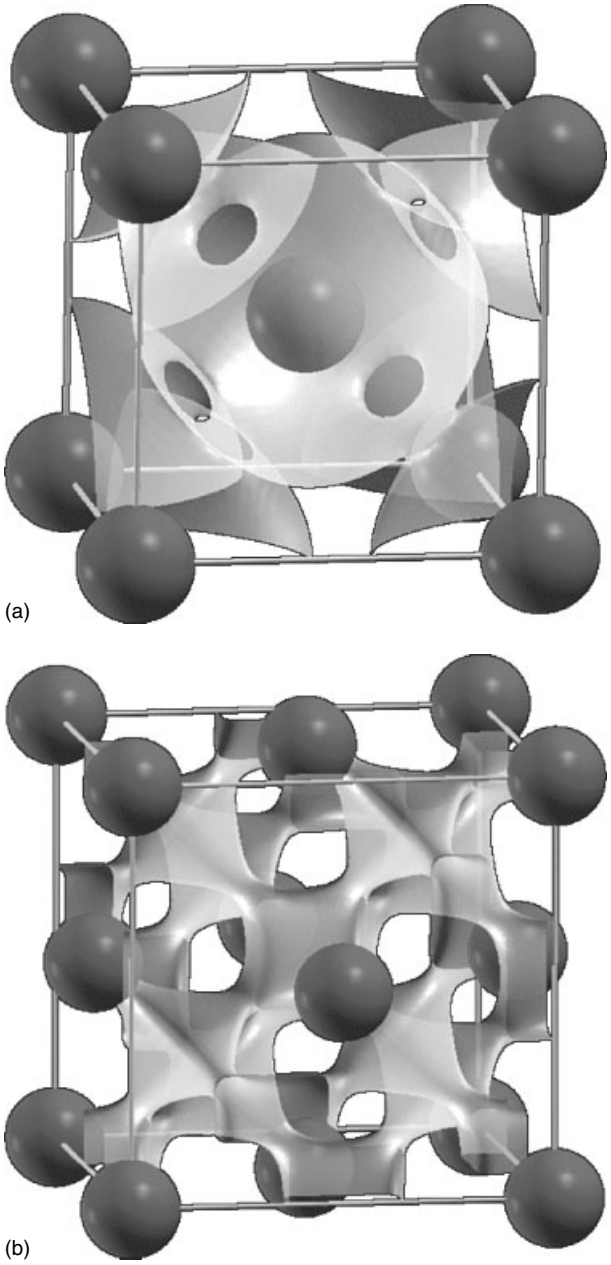

Figure 1. Isosurfaces of the magnetization density of ferromagnetic bcc Fe (a) and a (hypothetical) ferromagnetic fcc Fe with the lattice constant of bulk Cu (b). The isosurface in bcc Fe shows the boundary between regions of positive and negative magnetization density; in fcc Fe a small but negative magnetization density, m_z, is plotted. Plots were generated with a program of Kokalj (2003).

Numerically, equation (11) can be solved by expanding $\phi_i(\mathbf{r})$ in a linear combination of suitable basis functions $\chi_j(\mathbf{r})$. Then equation (11) transforms into a problem of linear algebra, that is, to find the eigenvalues and eigenvectors of a matrix. The eigenvectors, that have to be determined, give the linear combination coefficients, c_{ij}, of the expansion $\phi_i(\mathbf{r}) = \sum_j c_{ij}\chi_j(\mathbf{r})$. In such an eigenvalue problem, the computational effort scales in the most general case with the third power of the number of basis functions. Compared to the nonmagnetic problem, equation (5), this number is doubled in equation (11). Therefore, the computational effort for a general, noncollinear calculation is increased by a factor 8 as compared to the nonmagnetic calculation.

2.3 Collinear magnetic structures within DFT

Supposing that the potential matrices in equations (10) and (12) are diagonal (i.e., the magnetic and exchange fields point in z direction), equation (11) decouples into two equations of the type of equation (5):

$$\begin{aligned}
&\left(-\frac{\hbar^2}{2m}\nabla^2 + v_{\mathrm{Coul}}(\mathbf{r}) + v(\mathbf{r}) + B_z(\mathbf{r}) + v_{\mathrm{xc}}^{(+)}(\mathbf{r})\right)\\
&\quad\times \phi_i^{(+)}(\mathbf{r}) = \epsilon_i^{(+)}\phi_i^{(+)}(\mathbf{r})\\
&\left(-\frac{\hbar^2}{2m}\nabla^2 + v_{\mathrm{Coul}}(\mathbf{r}) + v(\mathbf{r}) - B_z(\mathbf{r}) + v_{\mathrm{xc}}^{(-)}(\mathbf{r})\right)\\
&\quad\times \phi_i^{(-)}(\mathbf{r}) = \epsilon_i^{(-)}\phi_i^{(-)}(\mathbf{r}) \qquad (14)
\end{aligned}$$

where v_{Coul} now denotes the classical Coulomb potential and $v_{\mathrm{xc}}^{(\pm)}$ the exchange-correlation potential that arises from the functional derivative of the exchange-correlation energy with respect to the spin-up (+) or spin-down (−) part of the diagonal density matrix.

The spin-up and spin-down part of the density can be calculated from the wave functions as

$$\begin{aligned}
n^{(+)}(\mathbf{r}) &= \sum_i w_i^{(+)}|\phi_i^{(+)}(\mathbf{r})|^2 \quad \text{and}\\
n^{(-)}(\mathbf{r}) &= \sum_i w_i^{(-)}|\phi_i^{(-)}(\mathbf{r})|^2 \qquad (15)
\end{aligned}$$

where the weight factors, w_i, are determined such that the density of states (DOS), $N(E)$, integrated up to the same

Fermi level, E_F, yields the correct number of particles:

$$N = \int^{E_F} [N^{(+)}(E) + N^{(-)}(E)]\mathrm{d}E \quad \text{where}$$
$$N^{(\pm)}(E) = \sum_i \delta(E - \epsilon_i^{(\pm)}) \tag{16}$$

In this way, the two equations (14) are coupled in the self-consistency cycle. Furthermore, a coupling occurs via the Coulomb potential and the exchange-correlation potential,

$$v_{xc}^{(\pm)} = v + B^{(\pm)} = \frac{\delta E_{xc}[n_{(+)}, n_{(-)}]}{\delta n_{(\pm)}(\vec{r})} \tag{17}$$

depending on the functional form of E_{xc}. A particularly simple form can be derived from the local approximation to Hartree–Fock theory and includes only the exchange part:

$$E_{xc} = E_x = -\frac{3}{2}\left(\frac{3}{4\pi}\right)^{\frac{1}{3}} \int \mathrm{d}\mathbf{r}\left[(n^{(+)}(\mathbf{r}))^{\frac{4}{3}} + (n^{(-)}(\mathbf{r}))^{\frac{4}{3}}\right] \tag{18}$$

Empirical modifications by a multiplicative factor have been used to compensate for the missing correlation energy, but modern functionals include reliable estimates for the correlation, so that no adjustable parameters are needed.

Systems that can be described by equation (14) are all kinds of magnetic materials that assume a collinear magnetic order, for example, ferromagnetic, antiferromagnetic, or ferrimagnetic states. Since the two equations (14) can be solved independently, the computational effort for a collinear calculation seems to be just twice the effort for a nonmagnetic calculation. However, most magnetic calculations are computationally considerably more demanding since the quantities in question (magnetic moments, energy differences between various magnetic configurations) require much higher accuracy than what is needed for nonmagnetic systems. To explore different magnetic orders in a system, unit cells much larger than the chemical unit cell are required, for example, antiferromagnetic body-centered cubic (bcc) chromium requires a calculation with at least two atoms in the unit cell (as compared to one, in a nonmagnetic calculation).

The ground-state density is a property that can – at least in principle – be obtained exactly in DFT. In the same way, the magnetization density is a property that can be obtained directly from spin-polarized DFT:

$$\mathbf{m}(\mathbf{r}) = -\mu_B \sum_{\alpha,\beta} \phi_\alpha^*(\mathbf{r})\boldsymbol{\sigma}_{\alpha\beta}\phi_\beta(\mathbf{r}) \tag{19}$$

The integral magnetic (spin) moment, M, for a collinear system is then (in units of μ_B) simply

$$M = |\int \mathbf{m}(\mathbf{r})\mathrm{d}\mathbf{r}| = \int (n^{(+)}(\mathbf{r}) - n^{(-)}(\mathbf{r}))\mathrm{d}\mathbf{r} \tag{20}$$

But what is essentially responsible for the formation of a magnetic moment in the DFT framework, that is, which term has to be included in the exchange-correlation potential to describe magnetic systems? For a qualitative understanding of this problem, it is instructive to develop a simple model for magnetism in the next subsection.

2.4 A Stoner-like model for magnetism

Consider a simple elemental magnet with a magnetic moment, M, per atom (again in units of μ_B). The exchange-correlation **B**-field, $v_{xc}^{(+)} - v_{xc}^{(-)}$, can be expanded in orders of M:

$$v_{xc}^{(+)} - v_{xc}^{(-)} = M v_{xc}^{(1)} + \mathcal{O}(M^2) \quad \text{where}$$
$$M = \int^{E_F} [N^{(+)}(E) - N^{(-)}(E)]\mathrm{d}E \tag{21}$$

This potential difference acts as a magnetic field that splits the eigenvalues, ϵ_i, according to

$$\Delta\epsilon_i = \epsilon_i^{(+)} - \epsilon_i^{(-)} \approx M\langle\phi_i|v_{xc}^{(1)}|\phi_i\rangle \tag{22}$$

that is, it introduces a shift of the eigenvalues of $\pm\frac{1}{2}MI(\epsilon_i)$. In the Stoner model (Stoner, 1939), it is assumed that all states are shifted by $\pm\frac{1}{2}MI$, where I is an energy-independent exchange integral, the Stoner parameter. Within DFT, a generalized Stoner parameter $I(\epsilon)$ can be introduced and calculated (Gunnarsson, 1976).

In the Stoner model, the magnetization that results from the splitting of the eigenvalues by $\pm\frac{1}{2}MI$ is given by

$$F(M) = \int^{E_F} \left[N\left(E + \frac{1}{2}IM\right) - N\left(E - \frac{1}{2}IM\right)\right]\mathrm{d}E \tag{23}$$

and this magnetization, $F(M)$, has to correspond to the magnetic moment M that induces the splitting. Since the DOS is always positive, $F(M)$ can only grow monotonously with M. Furthermore, we see from equation (23) that $F(M) = -F(-M)$ and in the limit $M \to \pm\infty$ it levels off to $\pm N$ (full spin polarization). From these conditions, we can derive that the equation $F(M) = M$ has the trivial solution $M = 0$ and two nontrivial solutions if $(\mathrm{d}F(M)/\mathrm{d}M)|_0 > 1$. This leads to the famous Stoner criterion

$$\frac{\mathrm{d}F(M)}{\mathrm{d}M}|_0 = IN(E_F) > 1 \tag{24}$$

Within DFT the Stoner parameter can be calculated from a given exchange-correlation potential and the wave functions. Typically, values around $0.4 - 0.5$ eV are obtained for transition metals and I turns out to be only weakly material dependent. Therefore, it is mainly the variation in the DOS at the Fermi level, $N(E_F)$, that determines whether a material is magnetic or not. DFT calculations of the (paramagnetic) DOS of a material already offer a first indication of whether (ferro)magnetism has to be expected or not. Assuming a parabolic DOS of the d-states, this explains why the magnetic moment is large in the middle of the 3d transition metals (Mn) and gets smaller for elements with almost filled or almost empty d-band. This behavior is similar to Hund's first rule, and can be observed well for thin magnetic films (See also **Magnetism of Low-dimensional Systems: Theory, Volume 1**).

Of course, the self-consistent calculation with spin-polarized DFT will give a much more accurate estimate of the magnetic moments than this model. But a comparison between the predictions of the Stoner-like model and the actual DFT calculation of the magnetic system (Figure 2) for bcc Fe shows that our simple Stoner-like model is not so far from a self-consistent, spin-polarized DFT solution.

An exchange-correlation potential that gives a reasonable estimate for the (generalized) Stoner parameter, I, can be expected to also give reasonable magnetizations. Therefore, even relatively simple exchange correlation energy functionals, like given in equation (18), describe magnetic trends in DFT qualitatively correct, provided the nonmagnetic DOS is also described correctly. Properties that are required for a (non)spin-polarized exchange correlation potential will be discussed in the next subsection.

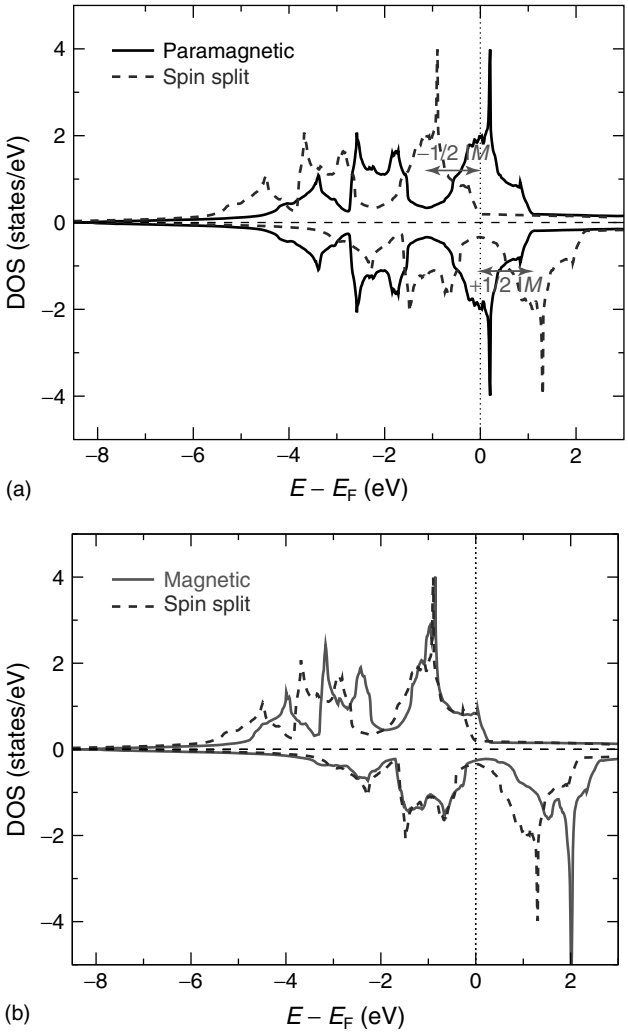

Figure 2. (a) Paramagnetic DOS of bcc Fe (black, full line) shifted by $\pm\frac{1}{2}IM$. The resulting DOS (dashed line) is compared (b) to the result of a spin-polarized DFT calculation (gray, full line). The spin-down DOS are plotted with negative values.

2.5 Exchange-correlation energy functionals

One of the first interpretations of the term, which emerged as the exchange-correlation potential in DFT, was given by Slater and Krutter (1934) in the context of the Thomas–Fermi method and later in connection with the Hartree–Fock method (Slater, 1951). Essentially, it describes the interaction of a particle with the 'hole' that is created by its own presence in the gas of the other particles. This means that the probability of finding an electron at a position $\mathbf{r}$ reduces the probability of finding another electron at a position $\mathbf{r}'$ nearby, depending of course also on the spin of the two particles (therefore, in the Hartree–Fock method this hole has been given the name 'exchange hole').

To derive some properties of the exchange-correlation energy functional, it is useful to write this 'hole' (exchange-correlation hole in DFT), n_{xc}, in terms of a two-particle correlation function, $g(\mathbf{r}, \mathbf{r}')$ (Kohn and Vashista, 1983):

$$n_{xc}(\mathbf{r}, \mathbf{r}') = n(\mathbf{r}') \int_0^1 d\lambda [g_n(\mathbf{r}, \mathbf{r}', \lambda) - 1]$$
$$\equiv n(\mathbf{r}') h(\mathbf{r}, \mathbf{r}') \qquad (25)$$

Here, $g_n(\mathbf{r}, \mathbf{r}', \lambda)$ is the correlation function of a system of charged particles where the Coulomb interaction is scaled by a factor λ and a λ-dependent potential has been added, so that the density, $n(\mathbf{r})$, is independent of λ. Additionally, the so-called hole function, $h(\mathbf{r}, \mathbf{r}')$, was introduced. The exchange-correlation energy can then be written as

$$E_{xc}[n(\mathbf{r})] = \frac{1}{2} \int d\mathbf{r} n(\mathbf{r}) \int d\mathbf{r}' \frac{1}{|\mathbf{r} - \mathbf{r}'|} n_{xc}(\mathbf{r}, \mathbf{r}') \qquad (26)$$

Although the exchange-correlation hole can be very complicated in shape, it was soon realized that only its radial dependence enters in the exchange-correlation energy (Gunnarsson, Jonson and Lundqvist, 1979). This means that, in practice, $E_{\rm xc}$ is rather insensitive to details of shape of $n_{\rm xc}$. Some properties of the exchange-correlation hole can be derived from the definition via the correlation function g, for example, there is a sum rule which states that $n_{\rm xc}$ corresponds exactly to one electron, that is, that

$$\int {\rm d}\mathbf{r}' n_{\rm xc}(\mathbf{r}, \mathbf{r}') = -1 \tag{27}$$

has to be fulfilled. Such relations can guide the construction of exchange-correlation functionals or help in judging the validity of existing approximations to $E_{\rm xc}$.

One of the big surprises in the early days of DFT was certainly the fact that even a simple exchange-correlation functional like the LDA leads to relatively convincing results. The LDA starts from the limit of the homogeneous electron gas, assuming $E_{\rm xc}$ rather as a function than as a functional of $n(\mathbf{r})$. Its success can now be explained by the fact that the exchange-correlation hole in the LDA is of the form

$$n_{\rm xc}^{\rm LDA}(\mathbf{r}, \mathbf{r}') = n(\mathbf{r}') h_0(|\mathbf{r} - \mathbf{r}'|; n(\mathbf{r}')) \tag{28}$$

where $h_0(|\mathbf{r} - \mathbf{r}'|; n)$ is the hole function of a uniform interacting electron gas of density n. For a uniform density, this exchange-correlation hole satisfies equation (27). For a nonuniform density, the sum rule should be at least approximately fulfilled and Gunnarsson and Lundqvist (1976) showed that in LDA this is, on average, the case. This, together with the fact that $E_{\rm xc}$ depends only on the spherical average of $n_{\rm xc}$, is mainly responsible for the success of the LDA.

Also modern, spin-dependent exchange-correlation functionals including gradient corrections are constructed in such a form that they fulfill certain conditions that are known exactly in different limits (like high or low density, constant or slowly varying density, etc.). In this way, exchange-correlation potentials are improved on a parameter-free basis. Alternatively, the functionals (or parts of the functionals, e.g. the correlation energy) can be fitted to numerical results from many-body calculations. Another strategy – often used in the chemical literature – is to adjust the functional to yield best results (like bond length, dissociation energies, etc.) for a given set of systems.

Although the exchange-correlation potential of spin-dependent DFT was first formulated in terms of 2×2 spin matrices, almost all practically used exchange-correlation functionals are restricted to the form

$$E_{\rm xc}[n^{(+)}(\mathbf{r}), n^{(-)}(\mathbf{r})] = \int {\rm d}\mathbf{r} n(\mathbf{r}) \varepsilon_{\rm xc}(n^{(+)}(\mathbf{r}), n^{(-)}(\mathbf{r})) \tag{29}$$

(local spin-density approximation, LSDA) and possibly also containing the gradients of $n^{(\pm)}(\mathbf{r})$ (GGA). There are also formulations including the kinetic energy density, $\tau^{(\pm)}(\mathbf{r})$, (meta-GGA) and other hybrid schemes (Tao, Perdew, Staroverov and Scuseria, 2003), which will not be discussed here since extensive tests on magnetic systems are not yet available. But all these schemes work basically with 'spin-up' and 'spin-down' quantities, and a study that went beyond this approximation (proposing a spin angular gradient approximation to DFT) indicated rather small effects on the calculated properties as compared to the collinear version of $E_{\rm xc}$ (Katsnelson and Antropov, 2003).

Early calculations of elemental ferromagnets demonstrated that LSDA is rather successful in the prediction of the (spin) magnetic moments. The increase of the magnetic moment with decreasing coordination (e.g., at surfaces or in thin films) is well described by DFT and chemical trends similar to Hund's first rule can be observed in lower dimensions. Some examples are presented in **Magnetism of Low-dimensional Systems: Theory, Volume 1**; some results for bulk systems are given in Table 1. It can be seen that spin polarization leads to a significant expansion of the lattice constant not only for Fe and Co but also for Mn and several magnetic alloys. This magnetovolume effect can be explained by the exchange splitting of the d-band, as observed in Figure 2 for Fe: It leads to an enhanced population of antibonding majority-spin states (at the top of the band) and a reduced population of bonding and nonbonding states (bottom and middle of the band) in the minority spin channel. The weaker bonding leads to an expansion of the lattice and also reduces the bulk modulus of these metals (Janak and Williams, 1976). While spin polarization improves the lattice constant as compared to non-spin-polarized LDA, for 3d metals LSDA still gives smaller values than observed experimentally. The use of gradient corrections and a correct treatment of the nonspherical charge distribution in the solid finally leads to reliable lattice constants for these transition metals (Asato *et al.*, 1999).

Here, one has to note that the LSDA results for the magnetic moments in Table 1 were obtained from calculations assuming the experimental lattice constants of the elements. Attempts to theoretically describe both the magnetic and structural properties of iron showed that LSDA predicts an fcc ground state with an almost vanishing magnetic moment (Wang, Klein and Krakauer, 1985). For this system, it turned out that only inclusion of gradient corrections can save the situation and GGA calculations finally correctly predicted a

Table 1. Magnetic moments (in μ_B per atom) and lattice constants (in Å) of ferromagnetic elements in the bulk. The experimentally determined total magnetization, M_{tot}, consists of spin and orbital moment contributions. The LDA (non-spin-polarized) and LSDA (spin-polarized) results for Fe, Co, and Ni are taken from Moruzzi, Janak and Williams (1978); the GGA values of the magnetic moments, from Shallcross, Kissavos, Meded and Ruban (2005) where experimental values are also quoted. The calculated Gd data is from Kurz, Bihlmayer and Blügel (2002) and the experimental one is from White *et al*. (1975). The GGA values of the lattice constants of Fe and Ni are from Asato *et al*. (1999) and the Co lattice constant is from Battocletti, Ebert and Akai (1996).

Property	Source	Fe (bcc)	Co (fcc)	Ni (fcc)	Gd (hcp)
M_{spin}	LSDA	2.15	1.56	0.59	7.63
M_{spin}	GGA	2.22	1.62	0.62	7.65

a_0	Experiment	2.86	3.53	3.53	3.63

bcc ground state structure with a magnetic moment that is slightly larger than the experimental one (Asada and Terakura, 1992).

As noted above, for 3d transition metals GGA improves the lattice constants and, thereby, in most cases also the magnetic moments. This success of the GGA is contrasted here with the case of Cr, where up to now no satisfactory agreement with experimental results was obtained: while LSDA calculations of antiferromagnetic Cr at the experimental lattice constant give a magnetic moment in good agreement with experimental data ($0.5 - 0.6\,\mu_B$), and also a slight stabilization of the experimentally observed incommensurate sinusoidal modulation of the antiferromagnetic structure was predicted (Hirai, 1998), calculations at the lattice constant determined with LSDA (which is 3% too small) yield a nonmagnetic ground state. GGA calculations, on the other hand, give a reasonable lattice constant but the magnetic moment is more than 60% too large (Singh and Ashkenazi, 1992). Furthermore, the unmodulated antiferromagnetic structure of Cr seems to be stabilized by GGA, whereas a modulated structure is observed experimentally (Hafner, Spišák, Lorenz and Hafner, 2002).

Despite these critical remarks on the success of DFT in describing Fe and Cr (and much more could be said on Mn (Hobbs and Hafner, 2003)), it should be emphasized that DFT is an excellent theory for the prediction of magnetic properties of materials – despite some limitations. As the vast amount of literature in this field shows, the area of applicability of this method is constantly expanding. Recent examples from the field of magnetism in low dimensions can be found in **Magnetism of Low-dimensional Systems: Theory, Volume 1**.

Up to now, we focused on the spin density and the resulting, in most cases collinear, magnetization. We should notice that the direction of this magnetization with respect to the lattice did not enter in the formalism and we relied on the assumption that the total energy is invariant with respect to a uniform rotation of the magnetization direction. This was implicitly assumed when we arbitrarily (or, better, for convenience) selected in equation (14) the z direction as global magnetization axis. Indeed, in the absence of an external **B**-field (or in its presence, as long as it is oriented in the z direction) this implies no loss in generality, if the interactions included in v_{xc} are isotropic in space. If we start from a Schrödinger–Pauli-like theory, there is indeed no term that could couple the spin space to the lattice. The dipole–dipole interaction, which can introduce a magnetic anisotropy, results from a relativistic two-particle term and is not contained in LSDA or GGA (but it can be added as a classical magnetostatic term 'by hand', if the magnetic moment is known). However, the presence of an orbital moment can introduce a coupling between spin and lattice by the spin-orbit coupling term, which follows from the single-particle Dirac equation. The formation of orbital moments in DFT will be discussed in the next subsection.

2.6 Orbital magnetism

The magnetization density and the magnetization, equation (19), are clearly a consequence of the imbalance of electrons with spin-up or spin-down and, therefore, the quantity defined in equation (20) is called *spin moment*. From atomic physics we know that the total magnetic moment is a sum of spin and orbital contributions, $M_{tot} = M_{spin} + M_{orb}$. The orbital moment results, in a classical picture, from the orbital motion of the electron

around the nucleus. Compared to the situation in a free atom, where M_{orb} can be even larger than M_{spin}, in a solid this motion is restricted by the crystal field that quenches the orbital moment. In bulk samples, small moments (typically 0.1–0.2 μ_{B}) can be found (compare Table 1).

DFT in the known LSDA or GGA formulations provides no term that could lead to the formation of an orbital moment in the presence of a crystal field. In an atomic LSDA calculation of scandium ($3d^1$ configuration), all d-levels of a given spin ($m_l = -2, -1, \ldots, 2$) are energetically degenerate if no external magnetic field is present. A small crystal field would immediately lead to the formation of linear combinations of these levels (e.g., d_{xy} or $d_{x^2-y^2}$) which carry no orbital moment. Current- and spin-density functional theory (Vignale and Rasolt, 1988) would provide a natural starting point for the description of orbital magnetism, but so far the success is limited.

As noted above, the Dirac equation provides a term that couples the spin to the orbital moment and, thereby, counteracts the influence of the crystal field and leads to the formation of an orbital moment. For a deep and fundamental discussion of relativistic effects in DFT, we refer the reader to a paper by Jansen (1988) and the review of Staunton (1994). Here, we take a simpler approach: interpreting the Kohn–Sham equation or its spin-polarized form, equation (11), like a single-particle Schrödinger equation, we can compare this equation with a two-component approximation to the Dirac equation from relativistic quantum mechanics (Bethe and Salpeter, 1977). This Pauli equation has the same form as the Schrödinger equation, but additionally several terms, like the Darwin or mass-velocity term, appear as a consequence of the relativistic treatment. If these terms are now included in the Kohn–Sham equation, we can hope to improve the description of heavier elements, without having to modify the exchange-correlation potential; for example, the scalar-relativistic approximation takes over from the Pauli equation these terms that are diagonal in spin and prove to be essential for the description of 5d elements.

Another term of the Pauli equation, the spin-orbit coupling term, couples up- and down-spin and also provides a mechanism that leads to orbital polarization, that is, the formation of an orbital moment. The electron, traveling on a classical trajectory around the nucleus, experiences the electric field (from the screened nucleus) as a magnetic field. This field couples to the magnetic (spin) moment of the electron and, thus, leads to a preferential orientation of the spin to the orbital motion. Using the orbital moment operator $\mathbf{L} = \mathbf{r} \times \mathbf{v}$, we can write the spin-orbit coupling term in the vicinity of a nucleus with a radial potential $v(r)$ as

$$H_{\mathrm{so}} = \frac{1}{r}\frac{\mathrm{d}v(r)}{\mathrm{d}r}(\boldsymbol{\sigma} \cdot \mathbf{L}) \tag{30}$$

Adding this term to equation (11) will destroy the decoupling of spin-up and -down equations like in equation (14). It also invalidates the aforementioned assumption that the total energy is not affected by a uniform rotation of the spin directions: the crystal field in a solid acts on the orbital motion of the electron so that there is a preferential plane for this orbital motion. Therefore, a total energy difference arises when the solid is magnetized in two different directions (Stöhr, 1999). This difference, the magnetocrystalline anisotropy energy (MCA) energy, is small for bulk systems with high symmetry, for example, cubic crystals like Fe or Ni. It is larger for crystals with a unique crystallographic axis, like hexagonal Co. But for lower-dimensional systems, thin films, or atomic wires, the MCA will essentially determine the magnetic properties, especially at finite temperatures (Bihlmayer, 2005). Examples of calculations of the MCA within DFT can be found in Wu and Freeman (1999). The MCA energy is also discussed in **Theory of Magnetocrystalline Anisotropy and Magnetoelasticity in Transition-metal Systems, Volume 1**.

The orbital magnetization can be defined in analogy to the spin magnetization, equation (19), now expressed in single-particle wave functions ϕ_i:

$$\mathbf{m}^{\mathrm{orb}}(\mathbf{r}) = -\mu_{\mathrm{B}} \sum_i \langle \phi_i | \mathbf{r} \times \mathbf{v} | \phi_i \rangle \tag{31}$$

At a certain atom ν, the orbital moment $\mathbf{M}_\nu^{\mathrm{orb}}$ can then be obtained by an integration (denoted $\langle\rangle_\nu$) in a sphere centered around this atom:

$$\mathbf{M}_\nu^{\mathrm{orb}} = -\mu_{\mathrm{B}} \sum_i \langle \phi_i | \mathbf{L} | \phi_i \rangle_\nu \tag{32}$$

Although this definition of the orbital moment poses no difficulties in periodic solids, we note here that the evaluation of the total orbital moment of a periodic crystal is more involved (Thonhauser, Ceresoli, Vanderbilt and Resta, 2005). As will be shown in later chapters, relativistic DFT calculations successfully predict the chemical trends (similar to Hund's second and third rules), the changes of the orbital moment with the coordination of the atom or the dimensionality of the system, and the variation of the orbital moment with the magnetization direction. It should be noted that in most cases the atomic orbital moments and also the MCA energies, obtained in DFT calculations, are too small compared to experiment; for example, the calculated orbital moments of Fe, Co, and Ni in LSDA are 0.05, 0.08, and 0.05 μ_{B}, respectively (Beiden *et al.*, 1998). Compared to the experimental values (Table 1, difference between total and spin moment) the values of Fe and Co are about 50% too small, for Ni the value is surprisingly

good. Orbital polarization can be incorporated in DFT to compensate for this deficiency at least partially (Solovyev, 2005). Similar approaches to correct the magnetic anisotropy energy have also been discussed in the literature (Yang, Savrasov and Kotliar, 2001). Some account of these methods will be presented in the next section. Finally, we should notice that the orbital moment, as expressed in equation (32), is not a quantity that can be directly accessed in DFT. In this equation, single-particle wave functions have been used that describe a noninteracting electronic system in an effective potential, and they yield the correct ground-state density but do not necessarily lead to the correct orbital moments.

The computational effort for calculations that include the spin-orbit coupling term, equation (30), in a straightforward way is comparable to a noncollinear calculation, even if collinear systems are considered. This effort can be reduced if this term is considered as a small perturbation to the nonrelativistic Schrödinger-Pauli Hamiltonian. Furthermore, the so-called magnetic force theorem (Weinert, Watson and Davenport, 1985) can be used to evaluate quantities like the MCA. But even these calculations require considerable computational resources, since the energy differences to be determined are very small and – compared to normal calculations – drastically increased numerical cutoffs can be necessary. Systems in which spin-orbit coupling is strong require a self-consistent treatment including equation (30) in the Hamiltonian. In these systems, of course, the relativistic effects are stronger so that moderate numerical cutoffs can be used, but the computational complexity brought by the spin-orbit coupling term and the loss of symmetry leads to an increased computational effort.

3 EXTENSIONS TO 'STANDARD DFT' APPROACHES

While the 'standard DFT' approaches, like LSDA or GGA, are quite successful for many metals, semiconductors, and most insulators, it was realized that there are certain classes of materials that require an extension to the usual exchange-correlation terms (van der Marel and Sawatzky, 1988); for example, many transition metal oxides, like FeO or CoO, turn out to be metallic in LSDA, while they are actually wide band gap insulating. Problems also occur with 4f metals, where the treatment of the localized f-electrons with LDA or GGA is often insufficient. Some strategies to overcome these problems are presented in this section. A more detailed account of some of these methods will follow in later chapters of this book.

3.1 Self-interaction correction

Let us consider DFT in the LDA for a single particle in a potential $v(\mathbf{r})$. Our equation,

$$E^{\mathrm{SP}}[n(\mathbf{r})] = T_0 + \int v(\mathbf{r})n(\mathbf{r})\mathrm{d}\mathbf{r} + \frac{1}{2}\int\int \frac{n(\mathbf{r})n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\mathrm{d}\mathbf{r}\mathrm{d}\mathbf{r}' + \int n(\mathbf{r})\varepsilon_{\mathrm{xc}}(n(\mathbf{r}))\mathrm{d}\mathbf{r} \tag{33}$$

would be correct, that is, its functional derivative with respect to the density would lead to the ordinary Schrödinger equation, if in the last term $\varepsilon_{\mathrm{xc}}$ would compensate for the spurious Coulomb interaction of the single electron interacting with itself,

$$U^{\mathrm{SP}}[n(\mathbf{r})] = +\frac{1}{2}\int\int \frac{n(\mathbf{r})n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\mathrm{d}\mathbf{r}\mathrm{d}\mathbf{r}' \tag{34}$$

This means that the exact 'exchange-correlation energy density for a single particle' (which certainly does not deserve this name) would have the form

$$\varepsilon_{\mathrm{xc}}^{\mathrm{SP}}(n(\mathbf{r})) = -\frac{1}{2}\int \frac{n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\mathrm{d}\mathbf{r}' \tag{35}$$

More properly, this last term should be named a *self-interaction correction* (*SIC*). While the situation is simple for one particle, in DFT normally many particles are described. To eliminate the self-interaction for a many-particle system is naturally more complicated than the case studied above.

Since the exact DFT energy functional has to be self-interaction-free, E_{xc} has to account in some way for a correction. Although in the limit of very low densities SIC can be seen to give only a small contribution, for very localized electrons this correction can be important. One of the first attempts to include SIC in DFT was made by Perdew and Zunger (1981). Their idea was to introduce an orbital-wise removal of the self-interaction on top of a given approximation to the exchange-correlation potential. If the density of single, fully occupied orbital of spin α is $n_{i,\alpha} = |\phi_{i,\alpha}|^2$, then the self-interaction-corrected version of an exchange-correlation energy (e.g., in LSDA) would be

$$E_{\mathrm{xc}}^{\mathrm{SIC}} = E_{\mathrm{xc}}^{\mathrm{LSDA}}[n^{(+)}(\mathbf{r}), n^{(-)}(\mathbf{r})] - \sum_{i,\alpha}\left(U[n_{i,\alpha}(\mathbf{r})] - E_{\mathrm{xc}}^{\mathrm{LSDA}}[n_{i,\alpha}(\mathbf{r}), 0]\right) \tag{36}$$

If we use for an estimate of this correction the inequality (Gadre, Bartolotti and Handy, 1980)

$$U[n(\mathbf{r})] \leq 1.092N^{\frac{2}{3}}\int [n(\mathbf{r})]^{\frac{4}{3}}\mathrm{d}\mathbf{r} \quad \text{where} \quad N = \int n(\mathbf{r})\mathrm{d}\mathbf{r} \tag{37}$$

and compare this to equation (18), we see that for an orbital i, α the correction $\delta_{i,\alpha}$ is bounded by

$$\delta_{i,\alpha} \leq 0.16 \int [n_{i,\alpha}(\mathbf{r})]^{\frac{4}{3}} \mathrm{d}\mathbf{r} \quad \text{and} \quad E_{\mathrm{xc}}^{\mathrm{SIC}} = E_{\mathrm{xc}}^{\mathrm{LSDA}} - \sum_{i,\alpha} \delta_{i,\alpha} \tag{38}$$

Here, the correction amounts to about 17% of the $E_{\mathrm{x}}^{\mathrm{HF}}$ evaluated for a single orbital. In any case, the SIC introduces a significant complication of the Kohn–Sham equations, since the exchange-correlation potential that follows from (36) is now orbital dependent. This leads to the SIC equations (Svane, 1996):

$$(H^{\mathrm{LSDA}} + V_{i,\alpha}^{\mathrm{SIC}})\phi_{i,\alpha} = \epsilon_{i,\alpha}\phi_{i,\alpha} + \sum_{\{i,\alpha\}'}^{occ'} \lambda_{\{i,\alpha\},\{i,\alpha\}'}\phi_{\{i,\alpha\}'} \tag{39}$$

where the Lagrange multipliers $\lambda_{\{i,\alpha\},\{i,\alpha\}'}$ ensure orthogonality of the wave functions. The SIC potential, $V_{i,\alpha}^{\mathrm{SIC}}$ is the functional derivative of $E_{\mathrm{xc}}^{\mathrm{SIC}}$ as defined in equation (36) with respect to the density of the state $\{i, \alpha\}$. Methods exist to solve these equations at different levels of approximations; for a review see Temmerman *et al*. (2000).

As a typical system where SIC helps improve the DFT results we consider NiO here. In LDA a small gap of 0.2–0.5 eV is found, while experimentally it is more than 4.0 eV. Of course we should be careful when comparing Kohn–Sham band structures with real spectra, but in this case the error is exceptionally large. Also, the band ordering turns out to be wrong and – most disturbingly – the magnetic moment is only $1.0\,\mu_{\mathrm{B}}$ as compared to the experimental value of $1.7\,\mu_{\mathrm{B}}$ (Anisimov, Zaanen and Andersen, 1991). If the strongly localized d-electrons of Ni in NiO are the sources of the error here, we can suspect that SIC can help improve the situation. Indeed, an inclusion of SICs not only increases the magnetic moment to $1.6\,\mu_{\mathrm{B}}$ but also opens up the band gap to more than 3.0 eV and considerably improves the calculated spectra (Dudarev *et al*., 1998). Other examples, like the 4f metal Ce, can be found in Temmerman *et al*. (2000).

3.2 The LDA+U method

Dealing with f and some d transition metals and their compounds, it was realized that, while the s, p and some d electrons can successfully be described in standard DFT methods, for the strongly localized electrons an atomic-like description is appropriate (van der Marel and Sawatzky, 1988). Taking into account the different atomic potentials and the stronger screening in the metal, an atomic theory (Slater, 1929) for these localized states can describe the situation quite satisfactorily. Following this approach, Anisimov, Zaanen and Andersen (1991) merged this atomic picture with band theory (i.e. standard DFT), to get a 'band approach' to Hubbard-type models: for the localized d and f states, the Coulomb interaction of the electrons is formulated in the spirit of the Anderson model:

$$E_{\mathrm{ee}} = \frac{1}{2} U \sum_{i \neq j} n_i n_j \tag{40}$$

where the n's are the d-orbital occupation numbers here and U is the famous Hubbard parameter, describing the on-site Coulomb interaction. In the LDA to this model, the energy of the d–d interaction is (Anisimov, Aryasetiawan and Lichtenstein, 1997)

$$E_{\mathrm{ee}}^{\mathrm{LDA}} = \frac{1}{2} U N(N-1) \quad \text{where} \quad N = \sum_i n_i \tag{41}$$

If we add E_{ee} from equation (40) to the LDA energy functional, $E_{\mathrm{ee}}^{\mathrm{LDA}}$ should be subtracted, so that

$$E^{\mathrm{LDA}+U} = E^{\mathrm{LDA}} + \frac{1}{2} U \sum_{i \neq j} n_i n_j - \frac{1}{2} U N(N-1) \tag{42}$$

This is a simple version of the LDA+U method. Such a modification of the LDA results in a shift of the LDA eigenvalues:

$$\epsilon_i = \frac{\mathrm{d}E}{\mathrm{d}n_i} = \epsilon_i^{\mathrm{LDA}} + U\left(\frac{1}{2} - n_i\right) \tag{43}$$

that is, more-than-half-filled bands are shifted down in energy, while less-than-half-filled bands are shifted up. Despite the formal similarity with the Stoner model of section 2.4, it should be noted that the physical background of this model is quite different (Anisimov, Zaanen and Andersen, 1991). A simple example is given in Figure 3, where the LDA+U method was used to correct the positions of the $4f$ states in ferromagnetic bcc Eu. It is easy to see that the correction has almost no effect on the s and p states, but shifts down the occupied $4f$ states (an enhanced localization of these states can be seen by the narrowing of the band) and pushes the unoccupied 4f levels to higher energies. How large this shift is depends of course on the chosen U. Before we turn to the question of how to obtain a reasonable estimate for U, we have to refine the model to see how we can apply the LDA+U method on a certain set of states (e.g., 4f) at a given atom.

To separate the localized orbitals from the itinerant states, for which the LDA already provides a good description, one chooses a site-centered, $\{l, m\}$-dependent orbital basis,

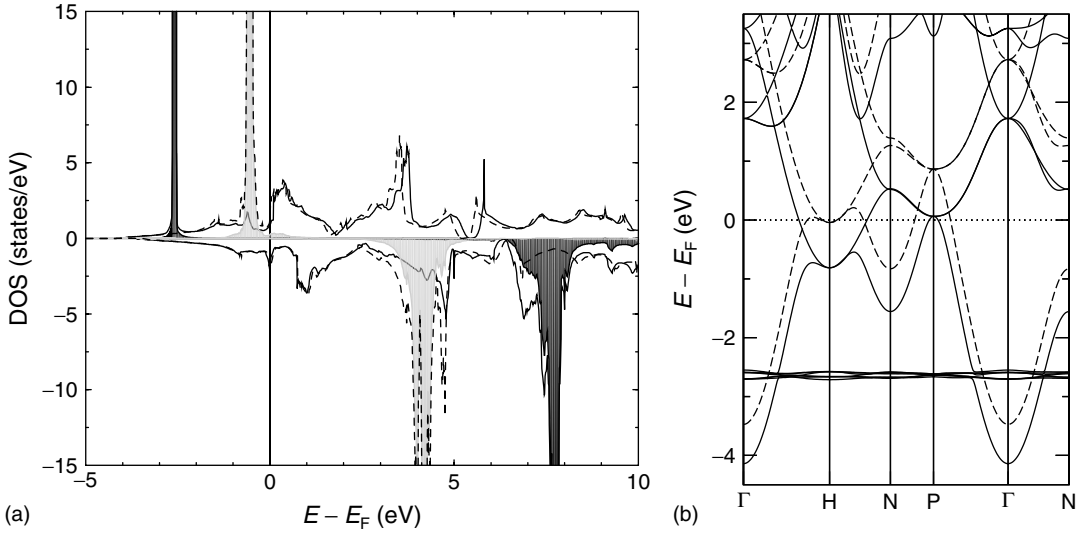

Figure 3. (a) Density of states of bcc Eu calculated with standard LDA (dashed line) and the LDA+U (full line) method. A Hubbard U of about 6 eV was used to correct the positions of the $4f$ states. The local partial 4f DOS as obtained in LDA is shown as gray shaded area, the LDA+U result in black. (b) Eu band structure obtained in the LDA+U method: majority-spin states (full lines) and minority-spin states (broken lines).

$|\nu, l, m\rangle$, where ν is the site index of the selected atom and l and m are the angular and azimuthal quantum numbers, respectively. If the density is given by Kohn–Sham orbitals like in equation (15), we can define a density matrix for spin α in m, m'-space:

$$n^{\alpha\nu}_{mm'} = \sum_i w_i^\alpha \langle \nu, l, m|\phi_i^\alpha\rangle\langle\phi_i^\alpha|\nu, l, m'\rangle \tag{44}$$

If we want to apply the LDA+U method on $4f$ states, we need for each spin a 7×7 density matrix, where the diagonal elements give the occupancy of the $l = 3, m = -3, -2, \ldots, 3$ orbitals of the selected atom. Using this density matrix, the electron–electron interaction energy can be formulated as (Liechtenstein, Anisimov and Zaanen, 1995)

$$E_{ee} = \frac{1}{2}\sum_\nu \sum_{mm'pq}^{\alpha,\beta} n^{\alpha\nu}_{mm'}\Big[\langle m, p|V_{ee}|m', q\rangle - \langle m, p|V_{ee}|q, m'\rangle\delta_{\alpha\beta}\Big]n^{\beta\nu}_{pq} \tag{45}$$

and used instead of the simpler version, equation (40). Here, the electron–electron interaction can be expressed in terms of an angular part, contained in a_k, and the radial part that is given by the effective Slater integrals (Slater, 1929), F_k:

$$\langle m, p|V_{ee}|m', q\rangle = \sum_k a_k(m, p, m', q)F_k; \quad 0 \le k \le 2l \tag{46}$$

In terms of the screened Coulomb and exchange parameters, U and J, the Slater integrals can be approximated, for example, for $l = 2$, as

$$U = F_0; \quad J = \frac{F_2 + F_4}{14} \quad \text{and} \quad \frac{F_4}{F_2} = \frac{5}{8} \tag{47}$$

and the a_k are sums of integrals of the angular part of the wave function with spherical harmonics. Then, we can define an orbital selective potential,

$$V^{\alpha\nu}_{mm'} = \sum_{pq\beta}\big[\langle m, p|V_{ee}|m', q\rangle - \langle m, p|V_{ee}|q, m'\rangle\delta_{\alpha\beta}\big]n^{\beta\nu}_{pq} - \left[U\left(n^\nu - \frac{1}{2}\right) - J\left(n^{\alpha\nu} - \frac{1}{2}\right)\right]\delta_{mm'} \tag{48}$$

where $n^{\alpha\nu} = \sum_m n^{\alpha\nu}_{mm}$ and $n^\nu = \sum_\alpha n^{\alpha\nu}$. This spin-, site- and l, m-dependent potential now enters the Kohn–Sham equation via

$$\big[-\nabla^2 + V^\alpha_{LDA}(\vec{r})\big]\phi_i^\alpha + \sum_\nu\sum_{mm'} V^{\alpha\nu}_{mm'}\frac{\delta n^{\alpha\nu}_{mm'}}{\delta\phi_i^\alpha} = \epsilon_i^\alpha\phi_i^\alpha \tag{49}$$

Thus, we have introduced a Hartree–Fock-like potential term that acts on a certain subset of the orbitals, leaving the others (in a first approximation) unchanged. Equation (49) has to be solved self-consistently, until both the density and the density matrix are converged. If the Kohn–Sham equations are solved by expanding the wave function into some basis set, for different types of basis sets also a different

orbital basis, $|\nu, l, m\rangle$, will be convenient. It is clear that the result of the LDA+U calculation will also depend, to some extent, on the choice of the orbital basis, but in practice for the same parameters U and J also qualitatively the same answers are reached.

When applied to 4f metals like Eu or Gd, one can use the LDA+U method to shift the position of the 4f as a function of U. A comparison to the position where they are spectroscopically measured can be used to determine a value for U, although other methods are described below. One of the problems of LSDA, the prediction of an antiferromagnetic ground state for hcp Gd, is resolved when the LDA+U method is applied in this way (Kurz, Bihlmayer and Blügel, 2002). Another success of the LDA+U approach can be seen in the case of Eu, where LDA would predict a much too small lattice constant, while LDA+U removes this overbinding caused by the $4f$ states (Turek *et al.*, 2003). Also the problems in NiO, mentioned in the last section in connection with the SIC, can be resolved in this way (Dudarev *et al.*, 1998).

Although the LDA+U method is rather simple and quite successful, it faces the problem that it introduces an external parameter and thus destroys the *ab initio* character of the conventional LDA approach. Therefore, concepts to calculate U within constrained DFT (Solovyev, Dederichs and Anisimov, 1994) (see also subsection 4.2) and with the GW method (Solovyev and Imada, 2005) (cf. subsection 3.4) have been developed. Fortunately, in many cases the results do not depend too sensitively on the exact values of U and J. But there are also systems, like $YMnO_3$, where depending on the value of U different magnetic ground states can be stabilized (Picozzi, Yamauchi, Bihlmayer and Blügel, 2006). A collection of applications of the LDA+U method can be found in Anisimov, Aryasetiawan and Lichtenstein (1997).

3.3 Orbital polarization

As we noted in subsection 2.6, one of the deficiencies of standard DFT approaches is to underestimate the orbital moments in solids, especially in lower dimensions (thin films, chains, adatoms). To get a better description of the total moments of bulk actinides, Brooks (1985) proposed a correction term inspired by Hartree–Fock theory, which induces a splitting of the eigenvalues of states with positive and negative azimuthal quantum number m, proportional to the difference in population of states with positive and negative m:

$$\epsilon(m^{(+)}) - \epsilon(m^{(-)}) = -I^{\mathrm{OP}}\left(N(m^{(+)}) - N(m^{(-)})\right) \qquad (50)$$

where I^{OP} can be estimated from a Slater-type atomic theory. The structure of this correction looks similar to the simple LDA+U approach of equation (43). Later Eriksson, Brooks and Johansson (1990) refined this idea, again based on the atomic theory of the orbital moments. They followed an analogy of the mean-field-like approach (MFA) to the interaction between spin moments **s**:

$$-\sum_{\nu\nu'} \mathbf{s}_\nu \mathbf{s}_{\nu'} \xrightarrow{\mathrm{MFA}} -\left(\sum_\nu s_\nu^z\right)\left(\sum_{\nu'} s_{\nu'}^z\right) = -S_z^2 \qquad (51)$$

which leads to a spin-polarization energy of $-I S_z^2$ where I is the Stoner parameter (subsection 2.4). The same approach for the orbital moment **l**,

$$-\sum_{\nu\nu'} \mathbf{l}_\nu \mathbf{l}_{\nu'} \xrightarrow{\mathrm{MFA}} -\left(\sum_\nu l_\nu^z\right)\left(\sum_{\nu'} l_{\nu'}^z\right) = -L_z^2 \quad \text{leads to}$$

$$E^{\mathrm{OP}} = -\frac{1}{2} I^{\mathrm{OP}} L_z^2 \qquad (52)$$

so that an orbital-dependent potential for a state with the quantum number m_l was proposed:

$$\Delta V_{m_l} = -\frac{1}{2} I^{\mathrm{OP}} L_z \hat{m}_l \quad \text{where} \quad L_z = \sum_i w_i \langle \phi_i | \hat{m}_l | \phi_i \rangle \qquad (53)$$

and $\hat{m}_l$ is the z-component of the angular momentum operator (again the magnetization is assumed to be oriented along z). For d electrons I^{OP} is the Racah parameter, B, and can be obtained from the Slater integrals similar to U and J. For f-electrons this term is denoted as $E^{(3)}$. This OP was used successfully for bulk metals (Rodriguez *et al.*, 2001) and systems of different dimensionality (Ederer, Komelj and Fähnle, 2003), although sometimes a rescaling of the Racah parameter obtained from the Slater integrals of the local atomic wave functions is necessary (Gambardella *et al.*, 2003). Like in the LDA+U approach, this then introduces an external parameter in the DFT and destroys the *ab initio* character of the method.

Although the proposed OP provides an intuitive and often successful approach to include OP in DFT, its physical interpretation remains somewhat unclear. Solovyev, Liechtenstein and Terakura (1998) derived an OP term in the framework of open-shell Hartree–Fock theory as a limiting case, which is generally more complicated than the OP suggested in equation (53). This simple form can be recovered when $U \approx 1.5J$ (for d electrons). For this choice of U and J, the LDA+U method is close to the OP scheme derived above. It is clear that the LDA+U method can also be used to include OP in DFT and successes in this direction have been reported by Shick and Mryasov (2003). A comparison can be found in Table 2.

Table 2. Orbital moments of Fe and Co with the magnetization oriented along the direction $\hat{M}$. The LDA and OP (1) results are from Rodriguez *et al*. (2001), OP (2) is from Trygg, Johansson, Eriksson and Wills (1995), while the LDA+U calculations were performed by Shick and Mryasov (2003). The experimental values are quoted in these references.

	$\hat{M}$	$M^{\mathrm{orb}}(\mu_{\mathrm{B}})$				
		LDA	OP (1)	OP (2)	LDA+U	Experimental
Fe (bcc)	[001]	0.048	0.086	0.078	0.085	0.08
Co (hcp)	[0001]	0.079	0.13	0.123	0.153	0.14

3.4 Methods using DFT output: *GW* and LDA+DMFT

In many cases, it is also desirable to go beyond DFT because one is interested in properties that cannot be accessed directly in conventional DFT, for example, band gaps or finite-temperature properties. To describe spectral properties or lifetimes of quasiparticle states, it is therefore more natural to start from many-body theory, where the quasiparticle equation (Hedin, 1965) can be studied. It has a similar structure as the Kohn–Sham equation, but the nonlocal, energy-dependent, self-energy $\Sigma(\mathbf{r}, \mathbf{r}', \epsilon)$ takes the role of the exchange-correlation potential here. The wave functions describe now quasiparticles and the eigenvalues are energies that are required to remove or add an electron. In principle, the solution of such an equation gives just the quantities lacking in conventional DFT schemes, but in practice these equations are too complicated to solve except for some special cases. Therefore, they are often used to provide a 'correction' to the Kohn–Sham eigenvalues. One of these schemes is the many-body perturbation theory in the GW approximation (Aryasetiawan and Gunnarsson, 1998), where the self-energy is approximated by the product of a Green function G and the screened Coulomb interaction W, both obtained from the output quantities of a DFT calculation. Of course there are DFT-based methods, like time-dependent density-functional theory (TDDFT), which provide a way to calculate spectra and there are also temperature-dependent nonlocal exchange-correlation potentials. It is too early to say whether these methods will become more popular than other well-established methods like the GW method, but some, like TDDFT, are active research fields today (Onida, Reining and Rubio, 2002).

In the last three subsections we discussed different extensions of the conventional DFT schemes that are designed to circumvent some of the problems of the common LSDA or GGA functionals. In general they consist of an orbital-dependent potential, that is added to the Kohn–Sham equation, which is solved self-consistently. In this way, 'many-body effects' are incorporated in an approximate form, for example, static correlations that are underestimated by LDA are included by the LDA+U method. But these are mean-field-type approximations that cannot describe dynamical correlation effects that go beyond Hartree–Fock-like methods. If dynamical correlations are important for the description of a certain property of a specific material, then it is necessary to go beyond these approaches. To study such many-body effects, one has to start from an explicit many-body problem which normally can only be solved for model Hamiltonians under special conditions. To account for the realistic material properties, DFT results are then incorporated in these many-body theories, hoping that this synthesis provides a realistic description both of the many-body effects and of the material properties.

As an example for a method that is used to study magnetism in the solid state, we mention here the dynamical mean field theory (DMFT) which, in conjunction with LDA or GGA band structures, is a popular approach to describe dynamical correlations in realistic materials. Correlations can determine order parameters in transition-metal oxides (Tokura and Nagaosa, 2000) or phase transitions in low-dimensional systems (Sachedev, 2000) which are outside a mean-field description. Since lattice Hamiltonians, like the Hubbard Hamiltonian, give at least the right qualitative behavior of many quantities of interest, one starts from a multiband Hubbard model:

$$H = -\sum_{\nu\nu'}\sum_{mm'}^{\alpha} t_{mm'}^{\alpha\nu\nu'}(c_m^{\alpha\nu})^{\dagger}c_{m'}^{\alpha\nu'} + \frac{1}{2}\sum_{\nu} \times \left(\sum_{mm'}^{\alpha\neq\beta} U_{mm'}^{\nu} n_m^{\alpha\nu} n_{m'}^{\beta\nu} + \sum_{m\neq m'}^{\alpha} (U_{mm'}^{\nu} - J_{mm'}^{\nu}) n_m^{\alpha\nu} n_{m'}^{\alpha\nu}\right) \quad (54)$$

This can be interpreted as hopping terms between an orbital m on site ν and an orbital m' on site ν' plus an electron–electron interaction term as encountered in the LDA+U method, equation (40), but keeping only the diagonal of the density matrix. If the hopping parameters t are taken from a DFT calculation, a Hartree–Fock-like solution of this model is similar to the first iteration in the LDA+U method. The DMFT goes beyond Hartree–Fock, but at the expense of other simplifications, like the use of a local

self-energy instead of a nonlocal or momentum-dependent one (Liechtenstein and Katsnelson, 2001). A description of this method and its extensions is given in **Dynamical Mean-field Theory of Itinerant Electron Magnetism, Volume 1**. Here, it should be sufficient to say that this LDA+DMFT approach was successfully applied to the description of many transition-metal oxides, orbitally ordered systems, and actinides. For a review, see Held *et al*. (2002).

4 THE MAGNETIC GROUND STATE AND BEYOND

In the first section, we dealt with the problem of finding the magnetic ground state in DFT without worrying about possible metastable solutions or local minima on the total energy surface. Indeed, non-spin-polarized DFT calculations for a given external potential (i.e., a selected arrangement of the atomic nuclei) normally lead to a single solution. In spin-polarized calculations it is possible to start the calculations from different initial magnetizations and to stabilize different magnetic solutions, say a ferromagnetic and an antiferromagnetic one, and obtain total energies for both magnetic states. In this section, we will discuss methods to find the magnetic state of lowest energy, the ground state.

To determine the magnetic ground state it is possible to follow several directions: similar to molecular-dynamics calculations, spin dynamics allows the study of the magnetic degrees of freedom by exploring the ground state configuration. Another possibility is to determine the magnetic interactions between the atoms by DFT calculations which are then mapped onto a model (in the simplest case a classical Heisenberg model). This model is then solved, either analytically or numerically. In both cases we introduce a discretization of the (vector) magnetization density: In spin dynamics, the evolution of discrete spins, that is, vectors attached to certain (atomic) positions can be monitored. Also mapping the *ab initio* results to a model Hamiltonian which contains interactions between spins requires that it is possible to assign a definite spin to an atom, so that it should be possible to write in the vicinity of an atom ν, for example, within some sphere centered at the nucleus, the magnetization density, $\mathbf{m}(\mathbf{r})$, as

$$\mathbf{m}(\mathbf{r}) = |\langle \mathbf{m}(\mathbf{r}) \rangle_\nu | \hat{\mathbf{e}}_\nu = M_\nu \hat{\mathbf{e}}_\nu \tag{55}$$

where M_ν is the magnetization and $\hat{\mathbf{e}}_\nu$ is the magnetization direction. Vector-spin DFT calculations allow the estimation of whether equation (55) is a good approximation or not (cf. Figure 4).

If the magnetization density in the vicinity of some atom ν is expressible by equation (55), then the total energy of a magnetic system as a function of its magnetic structure can be described as a functional $E[\{\hat{\mathbf{e}}_\nu\}]$ of the directions of the magnetic moments at the atoms ν in the magnetic unit cell. In this context, collinear states ($\hat{\mathbf{e}}_\nu$ is parallel for all atoms) are special solutions where $E[\{\hat{\mathbf{e}}_\nu\}]$ has a local or global extremum. Therefore, they constitute an important class of magnetic configurations that are often realized in magnetic materials in the ground state. But to describe magnetic materials at elevated temperatures even in this case more general, noncollinear, magnetic configurations have to be calculated. Some techniques will be presented in this

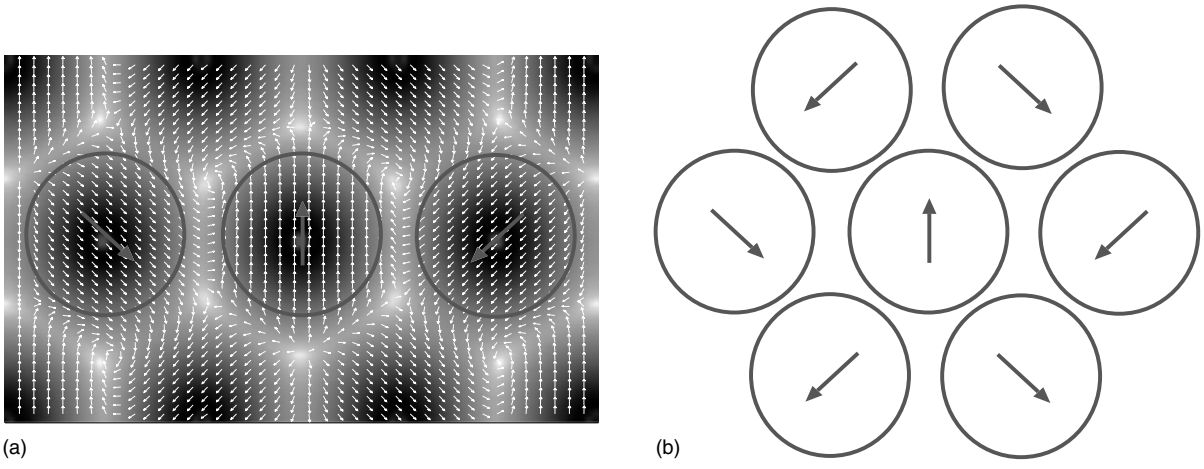

Figure 4. (a) Ground-state magnetization density of a hexagonal Cr monolayer with the Cu(111) in-plane lattice constant; the absolute value of the magnetization is shown in grayscale and the local directions are marked by small arrows. The average magnetization direction around an atom is indicated as gray arrow. (b) Schematic picture of the magnetic structure (Néel state) of the hexagonal Cr monolayer. (Reprinted figures from Kurz, P., Bihlmayer, G., Hirai, K. and Blügel, S. Three-Dimensional Spin Structure on a Two-Dimensional Lattice: Mn/Cu(111), *Phys. Rev. Lett* **86**, 1106–1109. Copyright 2004 by the American Physical Society.)

section. A more detailed presentation can be found in the book of Kübler (2000).

4.1 Spin dynamics, magnetic torque

If one is interested in the magnetic ground state of a system of given chemical composition and atomic positions, the final goal is to minimize the functional $E[\{\hat{\mathbf{e}}_\nu\}]$. The dimensionality of this problem will, of course, depend on the size of the chosen unit cell (some multiple of the chemical unit cell) and this minimization will involve the tricky task of determining the absolute minimum on a high-dimensional total energy surface. In analogy to molecular dynamics, that is, the problem of minimizing the energy as a function of the atomic positions, we introduce here a spin dynamics, where the magnetic orientations, $\hat{\mathbf{e}}_\nu$, take the role of the variables.

Any vector-spin DFT calculation has to start with a reasonably chosen spin configuration in a prescribed unit cell. On a simple level, one can 'relax' the directions of the magnetization at the atoms by allowing the directions $\hat{\mathbf{e}}_\nu$ to change during the self-consistency cycle. The magnetization directions will then change to minimize the total energy (cf. Figure 5), but the final magnetic state that will be reached will, in general, depend on the starting point of the calculation. Therefore, a more elaborate technique will be needed to avoid being trapped in some local minimum of $E[\{\hat{\mathbf{e}}_\nu\}]$.

To this end, we have to develop an equation of motion for the magnetization of an atom. To keep things simple, we will focus on the case where the magnetization stays collinear within the vicinity of the atom. Let us start from the Hamiltonian of equation (11) and assume that the external potential matrix, $\underline{v}(\mathbf{r})$, has been chosen to be diagonal and the exchange-correlation potential is separated into diagonal and off-diagonal parts. Following Antropov, Katsnelson, van Schilfgaarde and Harmon (1995) and Antropov *et al*. (1996) we set up a time-dependent analogon of equation (11):

$$i\frac{\mathrm{d}\Phi}{\mathrm{d}t} = \left[H_\mathrm{d} - \underline{\boldsymbol{\sigma}}\cdot\mathbf{B}(\mathbf{r},t)\right]\Phi \text{ where } \Phi = \begin{pmatrix}\phi^{(+)}\\ \phi^{(-)}\end{pmatrix} \quad (56)$$

and H_d is the Hamiltonian that now contains only diagonal parts.

In the spirit of the Born–Oppenheimer approximation, we can separate the evolution of the magnetization into fast (value of the magnetization) and slow (direction of the magnetization) degrees of freedom. The former part will be described quantum mechanically, while the latter is treated on a semiclassical level. At a given time, t, the time-independent version of equation (56) can be solved for a given magnetization characterized by $\{\hat{\mathbf{e}}_\nu\}$. Now we have to determine an equation of motion for the magnetization $\mathbf{m}(\mathbf{r},t)$.

This equation of motion can be obtained by multiplying equation (56) from the left with $\Phi^*\underline{\boldsymbol{\sigma}}$ and adding the complex conjugate equation. Comparing with the time derivative of equation (19) and using the relation $\underline{\boldsymbol{\sigma}}(\underline{\boldsymbol{\sigma}}\cdot\mathbf{B}) = \mathbf{B} - i\underline{\boldsymbol{\sigma}}\times\mathbf{B}$,

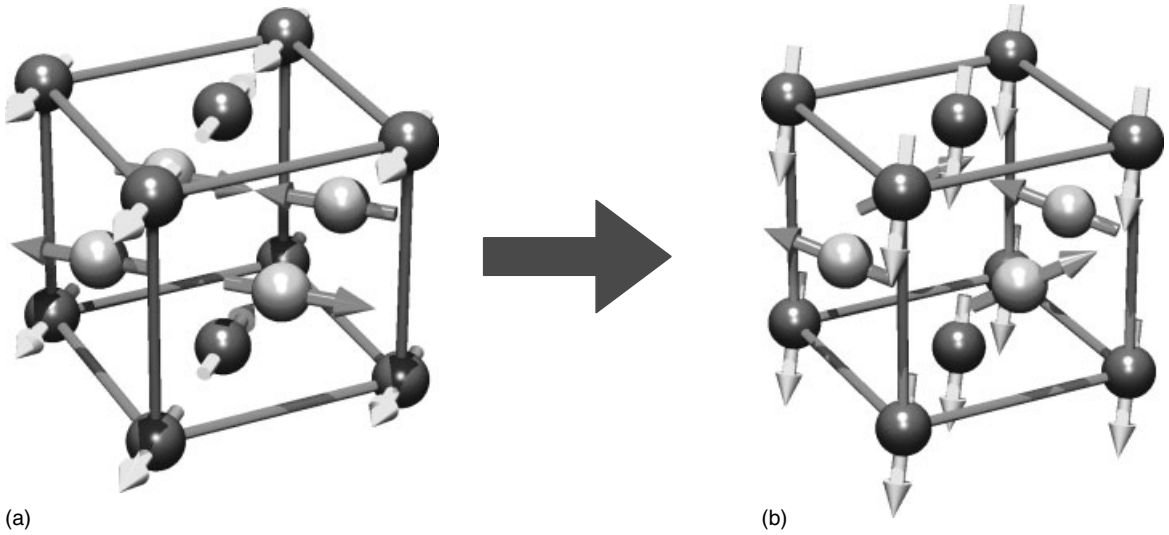

Figure 5. Determination of the magnetic ground state of ordered FeMn. Experimentally, FeMn is a disordered alloy and the 2**q**-state is the magnetic ground state. This is the initial magnetic configuration for a simulated ordered alloy (a). A more complex magnetic arrangement is obtained (b) when the local spin directions are allowed to change in the simulation. The Fe moments are shown by lighter arrows, the Mn moments by darker arrows.

we get in units of μ_B

$$\frac{d\mathbf{m}(\mathbf{r},t)}{dt} = 2\mathbf{m}\times\mathbf{B} + \frac{i}{2}\nabla(\Phi^*\underline{\boldsymbol{\sigma}}\cdot\nabla\Phi - c.c.) \qquad (57)$$

The second term on the right side is complicated and describes longitudinal changes of the magnetization, which we will not consider at this level. Omitting this term, equation (57) describes the precession of the magnetization direction at an atom under the influence of the magnetic field generated by the atom itself and other atoms of the crystal.

Returning once more to equation (55), we can simplify equation (57) and write for the evolution of the magnetization direction in atom ν

$$\frac{d\hat{\mathbf{e}}_\nu}{dt} = -\frac{2}{\mu_B}\hat{\mathbf{e}}_\nu\times\mathbf{I}_\nu \qquad (58)$$

where $\mathbf{I}_\nu = \mu_B\mathbf{B}$. If we explicitly also want to take into account the effect of other fields acting onto a magnetization direction, for example, stemming from the spin-orbit interaction (magnetic anisotropy) or dipole–dipole interaction, these fields can be added to equation (58) into $\mathbf{I} = \mathbf{I}_\nu + \mathbf{I}_{SO} + \mathbf{I}_{d\text{–}d}$. More general expressions of equation (58), suitable for spin dynamics with finite temperatures included, can be found in the paper of Antropov *et al*. (1996).

The next question, that has to be answered, is how to determine the fields $\mathbf{I}_\nu$, that is, given a certain set of magnetization directions $\{\hat{\mathbf{e}}_\nu\}$ what is the torque on a selected magnetic moment (Stocks *et al*., 1998)? This problem can be solved in constrained vector-spin DFT, as introduced in the next section.

4.2 Constrained DFT

In general, an arbitrary magnetic configuration given by a set of local (atomic) magnetization directions $\{\hat{\mathbf{e}}_\nu\}$ is not an extremum or a stationary solution of the total energy functional $E\left[\underline{n}(\mathbf{r})\right]$. Exceptions are high-symmetry states, like collinear magnetic states, a certain class of spin-spiral states (see Section 4.3) and particular linear superpositions of several spin-spiral states. The constrained DFT developed by Dederichs, Blügel, Zeller and Akai (1984) provides the necessary generalization to deal with arbitrary magnetic configurations, that is, configurations where the orientations of the local moments are constrained to nonequilibrium directions. We define a generalized energy functional $\tilde{E}\left[\underline{n}(\mathbf{r})|\{\hat{\mathbf{e}}_\nu\}\right]$, where we ensure that the average magnetization in an atom, $\langle\mathbf{m}\rangle_\nu$, points in the direction $\hat{\mathbf{e}}_\nu$. This condition, $\hat{\mathbf{e}}_\nu\times\langle\mathbf{m}\rangle_\nu = 0$, is introduced by a Lagrange multiplier, $\boldsymbol{\lambda}$, so that (Kurz *et al*., 2004)

$$\begin{aligned}\tilde{E}\left[\underline{n}(\mathbf{r})|\{\hat{\mathbf{e}}_\nu\}\right] &= E\left[\underline{n}(\mathbf{r})\right] + \sum_\nu \boldsymbol{\lambda}^\nu\cdot(\hat{\mathbf{e}}_\nu\times\langle\mathbf{m}\rangle_\nu)\\ &= E\left[\underline{n}(\mathbf{r})\right] + \mu_B\sum_\nu \mathbf{B}_c^\nu\cdot\langle\mathbf{m}\rangle_\nu \qquad (59)\end{aligned}$$

Here, we recast the Lagrange multiplier in the form of a magnetic field, $\mathbf{B}_c^\nu$, which is the constraining field in atom ν that keeps the local (integrated) magnetic moment, that is, the magnetization density averaged over the sphere where equation (55) holds,

$$\langle\mathbf{m}(r)\rangle_\nu = \mathbf{M}^\nu = \int_{MT^\nu}\mathbf{m}(\mathbf{r})\,d^3r \qquad (60)$$

parallel to the prescribed direction $\hat{\mathbf{e}}_\nu$.

In an actual constrained local moment (CLM) calculation, $\underline{n}(\mathbf{r})$ and $\mathbf{B}_c^\nu$ have to be determined self-consistently. The density matrix is calculated in the usual self-consistency cycle. At the same time, the local constraint fields $\mathbf{B}_c^\nu$ have to be adjusted, until the constraint conditions, $\hat{\mathbf{e}}_\nu\times\langle\mathbf{m}\rangle_\nu = 0$, are fulfilled (cf. Figure 6). At the end of such a calculation, we obtain the self-consistent densities and a set of local constraint $\mathbf{B}$ fields. The total energy of the system is given by the constrained energy functional, equation (59).

According to the Hellmann–Feynman theorem we find that the change of the energy due to a change in magnetization direction, $d\hat{\mathbf{e}}_\nu$, is given by $dE = -\mu_B\mathbf{M}^\nu\cdot(\mathbf{B}_c^\nu\times d\hat{\mathbf{e}}_\nu)$. Therefore, the constraint field can be interpreted as a torque acting on the magnetic moment, in the spirit of the spin dynamics, formulated in the previous section. Combined with techniques known from molecular dynamics, like simulated annealing, this provides a formalism that allows the finding – at least in principle – of the magnetic ground state of a system (Újfalussy *et al*., 1999). The chapter **Dissipative Magnetization Dynamics Close to the Adiabatic Regime, Volume 1** gives a more complete account of adiabatic spin dynamics and its applications.

CLM calculations can also be used in a different way. In the next section, we describe how they can be used to determine the exchange interactions in a system and utilize these results in models, such as the classical Heisenberg model, to obtain information about the ground state, but also about excited states of a magnetic system. Of course, constrained DFT can also be used to fix the value of the magnetic moment (Dederichs, Blügel, Zeller and Akai, 1984) (in this case, the constraining field is a longitudinal magnetic field, in contrast to the transverse field discussed above) or to vary the occupation numbers of a certain band (e.g., the *d* band) for an estimate of the Hubbard parameter U (Solovyev, Dederichs and Anisimov, 1994).

4.3 Mapping on model Hamiltonians

From the classical Heisenberg model, we can derive a Hamiltonian that describes the interaction between two spins **S** at sites ν and ν' in the form

$$H = -\sum_{\nu\nu'} J_{\nu\nu'} \mathbf{S}_\nu \cdot \mathbf{S}_{\nu'} \tag{61}$$

where $J_{\nu\nu'}$ is the exchange coupling constant between the two spins. The sign of $J_{\nu\nu'}$ determines whether a parallel (ferromagnetic) or antiparallel (antiferromagnetic) alignment of $\mathbf{S}_\nu$ and $\mathbf{S}_{\nu'}$ is preferred. This can be used as a phenomenological starting point in the investigation of the magnetic interaction in a crystal. Although the Heisenberg model was originally introduced for magnetic insulators with localized moments (Anderson, 1963), we can also apply equation (61) to metallic systems, as shown in Figure 7. In these hexagonal unsupported monolayers the behavior of the total energy as a function of the relative angle between the atoms can be described as cosinelike function, the exchange coupling constant being negative for Cr and Mn (preferring antiferromagnetic coupling) and positive for Fe (leading to a ferromagnetic ground state). The total energy has been calculated by a constrained DFT calculation as described above. We further see that the magnetic moment does not change significantly as the spins are rotated, an important requirement for the application of the classical Heisenberg model. For spin systems which do not fulfill this requirement, a spin-cluster expansion has been developed to map energetics obtained by DFT calculations on a more general model that has been inspired by alloy theory (Drautz and Fähnle, 2004).

From the right part of Figure 7 we can see that rotating the local magnetic moment direction of one atom in the two-atom unit cell of the hexagonal lattice will change the relative orientation of that atom to four nearest neighbors, but does not affect two of the nearest-neighbor (NN) atoms. Likewise, only four of the six second-NN atoms will change the relative orientation to the original atom. This leads to an expression for the total energy in the classical Heisenberg model up to second-NN:

$$E = -S^2(J_1 + J_2)(2 + 4\cos\theta) \tag{62}$$

if **S** is now the total spin moment treated as a classical vector. This means, from a CLM calculation we can at least estimate the size of $(J_1 + J_2)$. It is not difficult to find other unit cells and rotations that allow the determination of other linear combinations of J_1 and J_2, thereby separating the individual

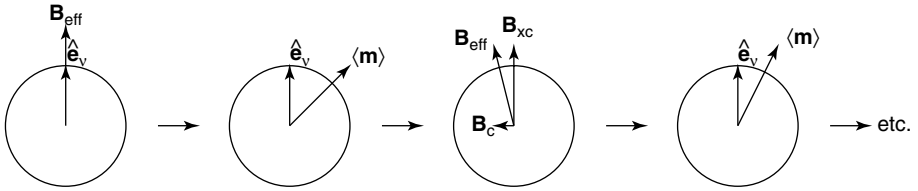

Figure 6. Determination of the constraint field: Initially, the effective **B** field is parallel to the prescribed direction $\hat{\mathbf{e}}^\nu$ (left). The resulting magnetization, $\langle \mathbf{m} \rangle$, is generally not parallel to this direction. Therefore, a constraint field $\mathbf{B}_c$ is introduced that points in a direction opposite to the component of the magnetization that is perpendicular to $\hat{\mathbf{e}}^\nu$. Using this $\mathbf{B}_{\text{eff}}$, the direction of the magnetization is then adjusted toward $\hat{\mathbf{e}}^\nu$ (right).

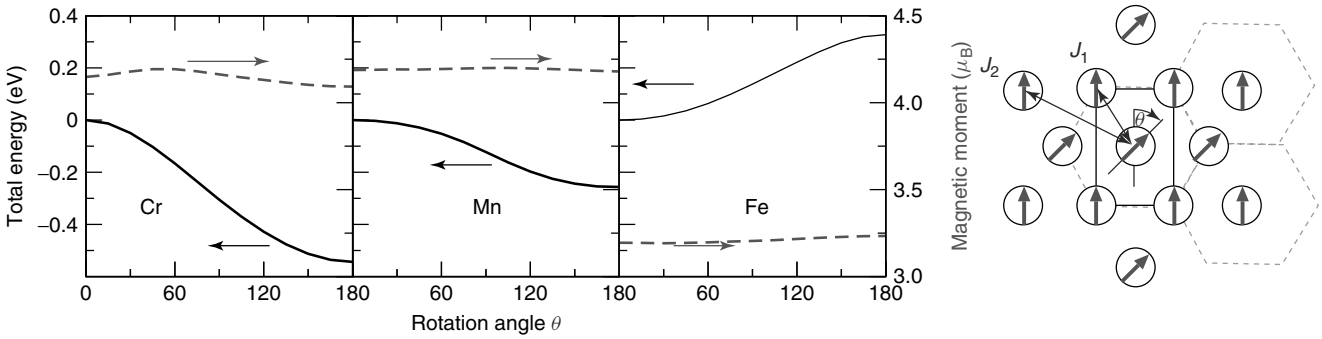

Figure 7. Total energy (full black line) and magnetic moment (dashed gray line) of hexagonal monolayers of Cr, Mn, and Fe as a function of the angle of the magnetization in a two-atom unit cell (right). $\theta = 0^\circ$ corresponds to a ferromagnetic state, $\theta = 180^\circ$ is a row-wise antiferromagnetic state. As lattice constant we chose the parameters of the Ag(111) surface. In the schematic picture of the hexagonal monolayer (right), the coupling to nearest neighbors (J_1) and next-nearest neighbors (J_2) is indicated.

exchange coupling constants (Kurz, Bihlmayer, Hirai and Blügel, 2001).

Of course, the energies obtained from the CLM calculation contain contributions of all J_ν and also from interactions that are not described by the Heisenberg model. Examples such as the biquadratic interaction or the four-spin interaction result from processes that have to be described by an Hamiltonian which includes a product of four spin operators. Taking spin-orbit interaction into account gives rise to a third-order process, the so-called Dzyaloshinsky–Moriya interaction (Yosida, 1996). All these different interaction terms can be extracted from a set of suitable *ab initio* calculations (possibly including spin-orbit interaction) and can be used to determine the magnetic ground state within the chosen model.

4.4 Low temperatures: magnons and spin waves

In a periodic crystal, it is convenient to replace the quantities in equation (61) by their Fourier-transformed equivalents:

$$\mathbf{S}(\mathbf{q}) = \frac{1}{N}\sum_\nu \mathbf{S}_\nu \mathrm{e}^{-i\mathbf{q}R_\nu} \quad \text{and} \quad J(\mathbf{q}) = \sum_\nu J_{0\nu}\mathrm{e}^{-i\mathbf{q}R_\nu} \tag{63}$$

Exploiting the translational invariance of the lattice, we can then rewrite equation (61) as

$$H = -N\sum_{\mathbf{q}} J(\mathbf{q})\mathbf{S}(\mathbf{q})\cdot\mathbf{S}(-\mathbf{q}) \tag{64}$$

where we have to ensure that the length of all spins $\mathbf{S}_\nu^2 = S^2$ is conserved on all sites ν. This condition is fulfilled by solutions of the type (Yosida, 1996)

$$\mathbf{S}_\nu = S\left(\hat{\mathbf{e}}_x\cos(\mathbf{q}\cdot\mathbf{R}_\nu) + \hat{\mathbf{e}}_y\sin(\mathbf{q}\cdot\mathbf{R}_\nu)\right) \tag{65}$$

where the unit vectors $\hat{\mathbf{e}}_x$ and $\hat{\mathbf{e}}_y$ just have to be perpendicular to each other, otherwise their directions are arbitrary. Equation (65) describes an spiral spin density wave (SSDW)

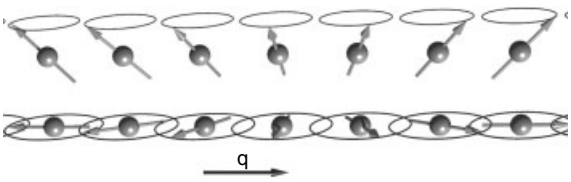

Figure 8. Spiral spin-density wave (SSDW) or spin spiral propagating along the with a wave vector $\mathbf{q}$. The opening angle is 45° in the upper and 90° in the lower example. (Reprinted figures from Kurz, P., Bihlmayer, G., Hirai, K. and Blügel, S. Three-Dimensional Spin Structure on a Two-Dimensional Lattice: Mn/Cu(111), *Phys. Rev. Lett* **86**, 1106–1109. Copyright 2004 by the American Physical Society.)

as shown in the lower half of Figure 8. A more general form of SSDWs can be obtained, when the magnetization precesses on a cone with an opening angle ϑ:

$$\mathbf{S}_\nu = S\left(\hat{\mathbf{e}}_x\cos(\mathbf{q}\cdot\mathbf{R}_\nu)\sin\vartheta + \hat{\mathbf{e}}_y\sin(\mathbf{q}\cdot\mathbf{R}_\nu)\sin\vartheta + \hat{\mathbf{e}}_z\cos\vartheta\right) \tag{66}$$

as shown in the upper half of Figure 8.

All solutions of the classical Heisenberg model can be described as SSDWs or, if there are several degenerate solutions, as linear combination of SSDWs. From equation (64), we can conclude that the SSDW with the lowest total energy will be the one with the propagation vector $\mathbf{Q}$ which maximizes $J(\mathbf{q})$. If $\mathbf{Q} = 0$ maximizes $J(\mathbf{q})$, the solution corresponds to the ferromagnetic state; if $\mathbf{Q} = \hat{\mathbf{e}}_z\frac{\pi}{a_z}$ and a_z is the lattice constant in z-direction, then the structure is layered antiferromagnetic in z-direction. Three examples for bcc crystals are illustrated in Figure 9: Cr is a typical antiferromagnet, where no stable ferromagnetic solution can be found and magnetic moments form only for large $\mathbf{q}$-vectors. In Mn both a ferro- and an antiferromagnetic phase can be formed, the former with a smaller and the latter with a larger magnetic moment. From the energy $E(\mathbf{q})$ it can be seen that bcc Mn is antiferromagnetic, while bcc Fe is ferromagnetic. In Fe, the magnetic moment changes continuously from the ferromagnetic solution ($2.2\,\mu_\mathrm{B}$) to the antiferromagnetic one ($1.5\,\mu_\mathrm{B}$).

SSDWs are sometimes also called *frozen magnons*, since a spin-spiral looks like a 'snapshot' of a single magnon at a fixed time. Spin-spiral calculations can therefore be used to simulate the effect of temperature on a magnetic system in the adiabatic approximation, in particular at very low temperatures, when magnons with long wavelengths dominate. But also at $T = 0$ many compounds and even elements show SSDW ground states. Some examples are shown in Figure 10.

At low, but finite temperatures, collective spin-wave excitations or magnons are excited in the ferromagnetic crystal. These magnons can again be characterized by their wave vector $\mathbf{q}$. In the long wavelength limit, that is, around $\mathbf{q} = 0$, the spin-wave dispersion behaves almost quadratically and can be described as $E(\mathbf{q}) = Dq^2$. The spin stiffness, D, characterizes the magnetic properties of a ferromagnet at low temperatures and can be calculated from the exchange coupling constants in real space (Pajda *et al*., 2001). Since

$$E(\mathbf{q}) = E(\mathbf{0}) + 2S\sum_{\nu\neq 0} J_{0\nu}\left(1 - \mathrm{e}^{i\mathbf{q}R_\nu}\right) \tag{67}$$

by differentiation D is obtained as

$$D = \frac{M}{6\mu_\mathrm{B}}\sum_\nu J_{0\nu}R_\nu^2 \tag{68}$$

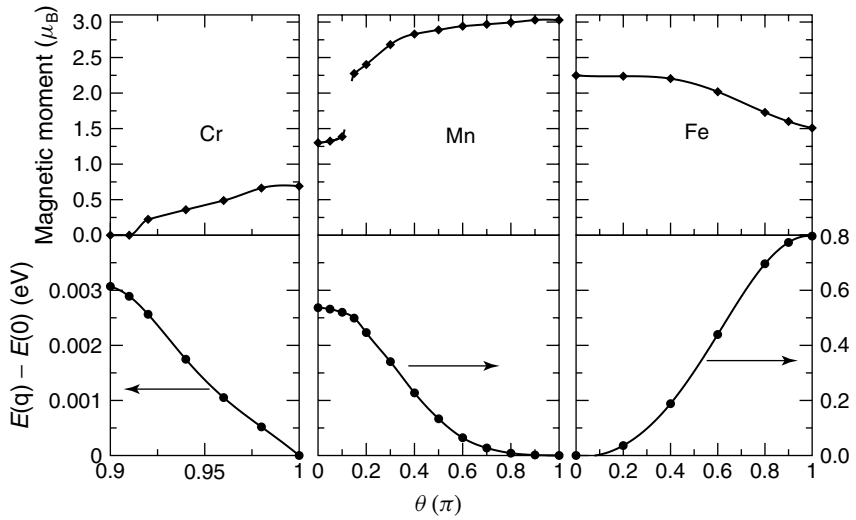

Figure 9. Change of the energy, $E(\mathbf{q})$, and the local magnetic moments, M, in bcc Cr, Mn, and Fe in a spin-spiral state as a function of the turning angle θ between the magnetization axes of two consecutive (001) planes. Magnetic moments are aligned ferromagnetically within each (001) plane. Results are calculated for the experimental lattice constants. ($\theta = \pi$) $\theta = 0$ corresponds to the (anti)ferromagnetic state. Note the different energy and θ scale for bcc Cr.

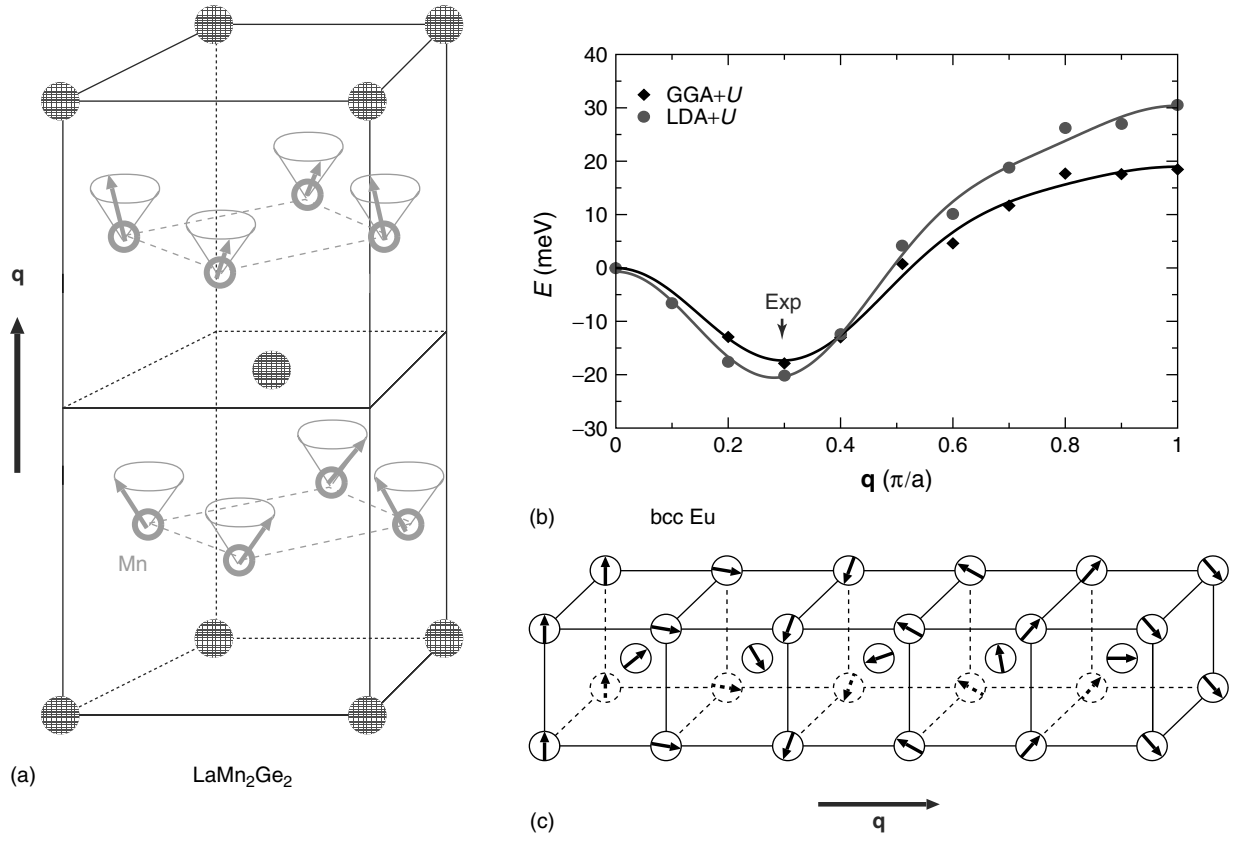

Figure 10. Examples of noncollinear ground states: (a) in $LaMn_2Ge_2$ the spins on the Mn sublattice can be described by a conical spin spiral, that is, the magnetization precesses on a cone with a semi-cone angle of 58° from layer to layer in z direction. The turning angle per layer is 128°. The magnetic structure is in good agreement with first-principles calculations (di Napoli *et al.*, 2004). Bulk bcc europium has a flat spiral in [001] direction as ground state (c), the length of the **q**-vector, describing this precession, is correctly reproduced in DFT calculations (Turek *et al.*, 2003) (b).

Here, $M = 2\,\mu_B S$ is the magnetic moment of the ferromagnetic state. Some results of *ab initio* calculations are given in Table 3. For Fe and Co, agreement with experimental data is reasonable, but for Ni most methods fail to reproduce the experimental spin stiffness. More about spin waves can be found in **Spin Waves: History and a Summary of Recent Developments, Volume 1** and in the review of Staunton (1994).

Owing to the long-range nature of the exchange interactions in itinerant magnets, the so-called Rudermann–Kittel–Kasuya–Yoshida (RKKY) interaction, the evaluation of equation (68) is problematic (Pajda *et al.*, 2001). Therefore, it is more natural to evaluate $E(\mathbf{q})$ directly in reciprocal space. This can be efficiently done, using the generalized Bloch theorem introduced in the next subsection.

4.5 Spin spirals and the generalized Bloch theorem

A very elegant treatment of spin spirals by first-principles calculations is possible when the generalized Bloch theorem (Herring, 1966; Sandratskii, 1986) is applied. However, this theorem can only be proved when spin-orbit coupling is neglected. For this reason, the spin-rotation axis will always be considered parallel to the z axis of the spin coordinate frame. Thus, only the m_x and m_y components are rotated, while m_z does not change. Following Sandratskii (1986) we can define a generalized translation, $\mathcal{T}_\nu$, that combines a lattice translation, $\mathbf{R}_\nu$, and a spin rotation $\mathbf{U}$ that commutes with the Hamiltonian H. Applying such a generalized translation to $H\Phi$ yields

$$\begin{aligned}\mathcal{T}_\nu H(\mathbf{r})\Phi(\mathbf{r}) &= \mathbf{U}(-\mathbf{q}\mathbf{R}_\nu)H(\mathbf{r}+\mathbf{R}_\nu)\mathbf{U}^\dagger(-\mathbf{q}\mathbf{R}_\nu)\mathbf{U}(-\mathbf{q}\mathbf{R}_\nu)\\ &\times \Phi(\mathbf{r}+\mathbf{R}_\nu) = H(\mathbf{r})\mathbf{U}(-\mathbf{q}\mathbf{R}_\nu)\Phi(\mathbf{r}+\mathbf{R}_\nu) \qquad (69)\end{aligned}$$

where $\mathbf{U}(\mathbf{q}\mathbf{R}_\nu)$ is the spin 1/2 rotation matrix

$$\mathbf{U}(\mathbf{q}\mathbf{R}_\nu) = \begin{pmatrix} \mathrm{e}^{-i\varphi/2} & 0 \\ 0 & \mathrm{e}^{i\varphi/2} \end{pmatrix}, \quad \varphi = \mathbf{q}\cdot\mathbf{R}_\nu \qquad (70)$$

In analogy with the proof of Bloch's theorem (Ashcroft and Mermin, 1976), it follows that the eigenstates can be chosen such that

$$\mathcal{T}_\nu\Phi(\mathbf{k},\mathbf{r}) = \mathbf{U}(-\mathbf{q}\mathbf{R}_\nu)\Phi(\mathbf{k},\mathbf{r}+\mathbf{R}_\nu) = \mathrm{e}^{i\mathbf{k}\cdot\mathbf{R}_\nu}\Phi(\mathbf{k},\mathbf{r}) \quad (71)$$

Since these eigenstates are labeled with the same Bloch vector $\mathbf{k}$ as the eigenstates of the translation operator without the spin rotation, the lattice periodic part of these states follows the chemical lattice, $\mathbf{R}_\nu$, that is, we can calculate the spin-spiral state in the chemical unit cell. In a reciprocal-space method, that is, when all quantities like potential or wave functions are expressed as Fourier transforms, the computational effort scales with the volume of the unit cell. Without the application of the generalized Bloch theorem the investigation of spin-spiral states requires very large unit cells, and a description of SSDWs that are incommensurate with the lattice would be not possible. Within this formalism, incommensurate magnetic structures can also be described in the framework on DFT. Two recent examples, $LaMn_2Ge_2$ and bcc Eu (Turek *et al.*, 2003), are shown in Figure 10.

Since the spin spiral is the exact solution of the classical Heisenberg model at $T = 0$, it is believed that it covers a large and important part of the phase space of possible spin states. Thus, among all possible magnetic states, spin spirals are the next relevant class of spin states besides the high-symmetry magnetic states, that is, the ferromagnetic, antiferromagnetic, or ferrimagnetic configurations.

A further computational simplification can be reached when the SSDW is considered just as a small perturbation to the parent (most often ferromagnetic) structure. This may be justified in the limit of small $\mathbf{q}$-vectors or small opening angles ϑ (cf. equation (66)). The limit of $\vartheta \to 0$ is particularly important in the study of finite temperature effects, since it describes elementary perturbations of the collinear ground state. In this limit, the magnetic force theorem (Weinert, Watson and Davenport, 1985) can be applied again, thus reducing the computational efforts significantly (Ležaić, 2005).

In real-space methods the calculation of $J(\mathbf{q})$ is most conveniently done via the right of equation (63), that is, the evaluation of $J_{0\nu}$. In this case the direction of the magnetization at a reference atom, 0, is perturbed and the response on the other atoms, ν, calculated. Also in this case, a kind of magnetic force theorem can be used (Turek *et al.*, 2003).

4.6 High temperatures: T_C and T_N

Let us now see how higher temperatures influence the magnetic order in a ferromagnetic solid. Staying within the Heisenberg model, we will assume that the magnitude of the magnetic moments at the atoms will – in first approximation – not be changed, and discuss just their mutual orientation. At $T = 0$, the spin at a selected atom will be fixed in parallel direction to the spins at all other atoms by an effective field that will be proportional to $S\sum_{\nu\neq 0} J_{0\nu} = SJ_0$. At a finite temperature T, this field, that acts on the spin at site 0, is reduced owing to the thermal fluctuation on the sites ν. The thermal average of the projection of the spin at site ν on the spin at site 0 is denoted as $\langle S(\mathbf{R}_\nu)\rangle$. In the 'mean-field approximation' (MFA), it is assumed

Table 3. Calculated and experimental spin-wave stiffness (D) for Fe, Co, and Ni. The theoretical data was obtained in different approximations as described by Rosengaard and Johansson (1997) (theoretical (1)), Kübler (2000) (theoretical (2)), Shallcross, Kissavos, Meded and Ruban (2005) (theoretical (3)), and Pajda *et al*. (2001) (theoretical (4)); the experimental data was taken as cited in these references.

	D (meV Å^2)				
	Theoretical (1)	Theoretical (2)	Theoretical (3)	Theoretical (4)	Experimental
Fe (bcc)	247	355	322, 313	250	280, 314, 330
Co (fcc)	502	510	480, 520	663	510, 580
Ni (fcc)	739	790	541, 1796	756	422, 550, 555

that the effective field at finite temperatures that acts on spin 0 is

$$B_{\text{eff}} = \sum_{\nu} J_{0\nu} \langle S(\mathbf{R}_\nu) \rangle \tag{72}$$

In this model it is possible to calculate the temperature dependence of the average magnetization of the solid and, specifically, the temperature where the average magnetization vanishes, the critical temperature. For a ferromagnet this temperature is called *Curie temperature* and in the MFA it is given by

$$T_{\text{C}} = \frac{2S(S+1)}{3k_{\text{B}}} J_0 \tag{73}$$

It has to be mentioned that in most cases the MFA severely overestimates T_{C} (in bulk crystals by about 20 to 50%, depending on the lattice; in lower dimensions MFA is even qualitatively wrong). Nevertheless, it gives a simple estimate of the ordering temperature in bulk systems, where the approximations of the Heisenberg model are reasonable. On the other hand, some properties, like the – material independent – critical exponents, are in any case not usefully reproduced by the MFA.

On a more sophisticated level, the 'random phase approximation' (RPA) can give quite reliable results. In contrast to the MFA, where the thermal averaging was done over the sites ν that determine B_{eff}, here the Hamiltonian is first transformed into reciprocal space (equation (64)), and then the averaging is done over one of the Fourier components:

$$H = -N \sum_{\mathbf{q}} J(\mathbf{q}) \mathbf{S}(\mathbf{q}) \cdot \langle \mathbf{S}(-\mathbf{q}) \rangle \tag{74}$$

If the term $S(S+1)$ (in a classical model S^2) is included in the exchange coupling constants (as it is usually done, when the J's are determined from first-principles calculations), then the Curie temperature in the MFA and RPA can be expressed as

$$k_{\text{B}} T_{\text{C}}^{\text{MFA}} = \frac{2}{3} J_0 = \frac{2}{3} \sum_{\nu} J_{0\nu} = \frac{M}{6\mu_{\text{B}}} \frac{1}{N} \sum_{\mathbf{q}} E(\mathbf{q}) \tag{75}$$

$$k_{\text{B}} T_{\text{C}}^{\text{RPA}} = \frac{2}{3} N \left(\sum_{\mathbf{q}} \frac{1}{J(\mathbf{0}) - J(\mathbf{q})} \right)^{-1} = \frac{M}{6\mu_{\text{B}}} N \left(\sum_{\mathbf{q}} \frac{1}{E(\mathbf{q})} \right)^{-1} \tag{76}$$

where N is the number of $\mathbf{q}$-vectors included in the sum. If the exchange coupling constants are calculated in reciprocal space ($J(\mathbf{q})$) by using the generalized Bloch theorem, the calculation of T_{C} requires a dense $\mathbf{q}$-point sampling in both approximations. From equations (75) and (76) it can be seen that MFA gives more weight to the interaction with near neighbors, while in RPA the exchange interaction with distant neighbors is emphasized. Therefore, the Curie temperature in RPA is smaller than in MFA and usually also in better agreement with experimental values.

Also for antiferromagnets (or generally spin-spiral states characterized by a vector $\mathbf{Q}$) expressions for the ordering temperature, the Néel temperature T_{N}, can be derived. In the MFA with $S(S+1)$ again included in J, this is given simply by

$$k_{\text{B}} T_{\text{N}}^{\text{MFA}} = \frac{2}{3} J(\mathbf{Q}) \tag{77}$$

while a slightly more involved expression can be derived in the random phase approximation (Turek *et al*., 2003). Comparison of these results with experimental values gave reasonable results, for example, for bcc europium, Néel temperatures of 147 K and 110 K were obtained in MFA and RPA, respectively (Turek *et al*., 2003). These values have to be compared with the experimental T_{N} of 90.5 ± 0.5 K.

Although there exist several additional methods to calculate critical temperatures from DFT results, we outline just one further possibility here, which seems to be rather flexible and appropriate for many systems with different

Table 4. Calculated and experimental Curie temperature T_C for some ferromagnetic materials. MFA and RPA data for Fe, Co, and Ni taken from Pajda *et al*. (2001), MFA2 results and experimental values as quoted by Shallcross, Kissavos, Meded and Ruban (2005), while the MC results were obtained by Rosengaard and Johansson (1997). Spin dynamics (SD) calculations have been performed by Antropov (2005). Data for Gd can be found in the papers of Kurz, Bihlmayer and Blügel (2002) and Turek, Kudrnovský, Bihlmayer and Blügel (2003).

	T_C (K)					
	MFA	MFA2	RPA	MC	SD	Experimental
Fe (bcc)	1414	550, 1190	950	1060	1070	1044–1045
Co (fcc)	1645	1120, 1350	1311	1080		1388–1390
Ni (fcc)	397	320, 820	350	510	470	624–631
Gd (hcp)	334					293

magnetic ground states: the Monte Carlo technique (MC) allows the study of finite-temperature magnetic properties by implementation of a Heisenberg Hamiltonian (equation (61), possible with extensions like biquadratic terms or a uniaxial anisotropy (see following text)), into a Metropolis algorithm (Metropolis *et al*., 1953). Unit cells of different size are then studied so that finite-size effects can be eliminated. In these unit cells, the evolution of the magnetic property in question (in our case the average magnetization) as a function of temperature can then be monitored.

Results of *ab initio* calculations of the Curie temperature of Fe, Co, and Ni are presented in Table 4. From this table one can easily see that, compared to RPA, the MFA typically overestimates T_C by 25–50%. For Fe and Co, RPA gives quite good estimates of the Curie temperature, while for Ni, T_C is underestimated in both approximations. MC simulations work better for Ni and Fe, but give too low a T_C for Co. Finally, the results of spin dynamics calculations, performed along the line sketched in subsection 4.1, give results comparable to MC calculations for Fe and Ni, but have the advantage that they do not rely on a model Hamiltonian (Antropov, 2005). More information on finite-temperature effects and their calculation can be found in **Electron Theory of Finite Temperature Magnetism, Volume 1**.

While we quoted here results for 'simple' metals, it is nowadays possible to investigate in the same manner the temperature-dependent properties of complex multicomponent systems, for example, half-metallic Heusler alloys (Şaşıoğlu, Sandratskii and Bruno, 2005) or dilute magnetic semiconductors (Sato, Dederichs and Katayama-Yoshida, 2005). In this way, materials for modern spintronic applications can be studied at physically relevant temperatures and their detailed magnetic properties can be predicted on the basis of quantum mechanics. The combination of advanced numerical techniques and massively parallel supercomputers makes computational material science based on DFT one of the most rapidly growing fields of physics with relevance for basic and applied science. It covers many aspects of magnetism and some of them have been outlined in this chapter. A more complete and more detailed presentation will be given in the following chapters.

Multiband Hubbard Models and the Transition Metals

Gernot Stollhoff
Max-Planck-Institut für Festkörperforschung, Stuttgart, Germany

1 INTRODUCTION

A breakthrough in the understanding of the itinerant ferromagnetism of the 3d transition metals occurred when density-functional (DF) calculations, performed in the local density approximation (LDA) (Hohenberg and Kohn, 1964; Kohn and Sham, 1965) or rather its spin generalized variant, local spin-density approximation (LSDA) (Gunnarsson and Lundqvist, 1976), obtained seemingly perfect values for the magnetic moments of the metals. Good results were also obtained for other ground-state properties: binding energies, equilibrium volumes, bulk moduli, and Fermi surfaces, to name a few (Poulson, Kollar and Anderson, 1976; Janak and Williams, 1976; Callaway, 1981).

A crucial aspect in this context is the behavior of the 3d electrons. The 3d atomic orbitals are largely localized in space around the nuclei, and form rather narrow tight-binding bands with a width of roughly 5 eV. This localization is considerably stronger for the 3d than for the heavier 4d or 5d transition metals. In the following work, the consequences of this localization are investigated for the 3d transition metals.

While there have been many speculations about a full localization of the 3d electrons and about a representation of their degrees of freedom by spin Hamiltonians, the delocalization is a feature that is strongly supported by experiment. Already before the success of LSDA, the experimental binding energies were unambiguously connected to delocalized 3d electrons (Friedel, 1969). In LSDA, the explicit part of the kinetic energy is obtained from a maximally delocalized single-determinant reference state while correlation corrections are contained in a functional. Consequently the former part represents the limit of maximal delocalization of the 3d electrons. On the other hand, there is evidence that the LSDA results overemphasize binding by up to 20% (Moruzzi, Janak and Williams, 1978), possibly owing to a mishandling of correlation corrections. This deviation in turn sets an upper limit to possible correlation corrections. In particular, strong correlations or electronic degrees of freedom that can be described in terms of atomic moments are ruled out.

With the 3d electrons basically delocalized in tight-binding bands, magnetism must result from the electronic interactions. As already mentioned, these cannot be so strong that localized atomic moments arise. Even more, it needs to

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

be understood why the LSDA is apparently able to handle these interactions that are definitely connected to the spatially strongly localized atomic orbital representation of the 3d electrons. It is hard to imagine how a homogeneous electron-gas exchange-correlation potential can adequately deal with such inhomogeneous atomic features. In fact it cannot.

Bare local Coulomb-interaction matrix elements between electrons in these atomic orbitals are of the order of 20 eV, far larger than the kinetic energy gained from delocalization into bands. Therefore, a second problem is to understand how these bare interactions are reduced into the required smaller interactions.

The optimal way to deal with these questions would be a full *ab initio* correlation calculation. The only method available for such a treatment is the local ansatz (LA) (Stollhoff and Fulde, 1980; Stollhoff, 1996). It starts from Hartree–Fock (HF) *ab initio* calculations for solids and adds correlations in a variational way like quantum chemistry (QC) methods do. However, it differs from these methods by using specifically constructed subsets of correlation operators with a well-defined local meaning instead of trying to cover the whole correlation space in an orthogonal representation. This results in a loss of typically one to a few percent of the correlation energy in a given basis, but it leads to a large gain in efficiency, and it enables the LA to treat metals. First *ab initio* calculations for metals (Heilingbrunner and Stollhoff, 1993) and for a metallic transition metal compound (Stollhoff, 1998) have already been performed, and calculations for nonmagnetic transition metals are under way (Stollhoff, unpublished), but a complete coverage of the magnetic problem has not yet been obtained. Therefore, the problems mentioned above could so far only be addressed using correlation calculations for models.

The minimal level of complexity for such models is well defined: a tight-binding Hamiltonian for the 3d electrons, that is, a five-band (per spin) Hamiltonian. The hope is that the 4s and 4p orbitals of the transition metals do not need to be explicitly included for the basic understanding of magnetism, since they contribute little to the electronic density of states in the relevant energy range around the Fermi energy. This omission certainly causes defects, for example, of the Fermi surface. For the interactions, a first choice is the inclusion of only local (atomic) interactions of the 3d electrons. It is known that these can be condensed into three Slater parameters. We will, in the following, rearrange those terms and call the resulting interactions Hubbard (U) interaction, Hund's rule exchange terms (J), and anisotropy terms (ΔJ) (Kleinmann and Mednick, 1981). The underlying assumption is that longer-range contributions of the Coulomb interaction are almost perfectly screened for these metals.

Such models have for long been the basis of attempts to understand the itinerant ferromagnetism. However, these attempts were mostly restricted to simplified single-band models and/or to the approximate treatment of the interaction in HF approximation, or when the treatment was extended to finite temperatures within a functional integral formulation, in an equivalent static approximation. For an early overview, refer to Moriya (1981).

Here, the LA led to a sizable improvement. Since it can be applied to models as well as to *ab initio* calculations, we were able to perform satisfactory correlation calculations for the model described above, and we have computed the nonmagnetic (Stollhoff and Thalmeier, 1981) as well as the magnetic (Oleś and Stollhoff, 1984) cases. The tool to understand the magnetic phase transition for the case of delocalized electrons is the Stoner–Wohlfarth theory (Stoner, 1938; Wohlfarth, 1949). Such an analysis had been earlier performed in the case of LSDA computations (Gunnarsson, 1976). We also analyzed our results in the same way (Oleś and Stollhoff, 1988; Stollhoff, Oleś and Heine, 1990), and managed to work out why the LSDA calculations had been so successful for the transition metals but had failed for a set of transition-metal compounds (Stollhoff, Oleś and Heine, 1990, 1996). We abstained from any attempts to generalize the treatment of the order parameter beyond a mean-field (or Stoner–Wohlfarth) approximation. It should be noted that for the simplified handling of the interaction in HF or static approximation, a generalized spin fluctuation theory is available (Moriya, 1985).

It turned out from our analysis that the fivefold degeneracy of the model bands is very relevant. Single-band or two-band models are not able to catch the essence of the 3d magnetism at all. Many of the degeneracy features also are lost when restricting to a HF or static approximation. As will be shown in the subsequent text, a reduction of the degeneracy would require also larger and larger interactions and would incorrectly push the treatment into a strong-correlation direction which is inadequate for the 3d transition metals.

Five-band models have been rarely treated by other methods beyond HF approximation. A first attempt was made in the context of an insufficient second-order perturbation computation (Kajzar and Friedel, 1978; Treglia, Ducastelle and Spanjaard, 1980). Quasiparticle calculations followed using the Kanamori t-matrix approach (Kanamori, 1963) for almost filled degenerate band systems such as Ni (Liebsch, 1979, 1981; Penn, 1979; Davis and Feldkamp, 1980). Recently, calculations have been performed for nine-band models starting from an $R = 0$ approximation that had also been used by the LA but employing a full configuration interaction (CI) calculation instead of the weak-correlation expansion or of a two-particle excitation CI calculation both within the LA (Bünemann, Weber and Gebhard, 1998; Bünemann *et al*., 2003). Finally, the dynamical mean-field theory (DMFT) has been used for such a model (Lichtenstein, Katsnelson and

Kotliar, 2001). The latter is the appropriate generalization of the functional integral schemes just mentioned, and goes beyond the static approximation.

We will in the following introduce the five-band model plus its interactions, and describe in detail the LA treatment and the different approximations made. We will also establish connections to the other computational schemes.

In a next step, results of the calculations for the nonmagnetic case will be presented, and the different approximations will be tested. A further step is to compute and analyze the magnetic results for Fe, Co, and Ni. Based on them, conclusions on the comparability to experiment and on specific deficiencies of the LSDA and its results will be made.

Finally, connections between the model and first *ab initio* correlation results will be made, and the limits of the Hubbard-model scenario will be revealed.

2 MODEL HAMILTONIAN AND SINGLE-PARTICLE GROUND STATE

The aim of the qualitative treatment is to understand the delocalization and interaction of the 3d electrons which is the expected key for the understanding of magnetism in the 3d-elemental solids. There are five 3d electrons per spin and site (atom). A compact description of their delocalization is in the form of canonical d bands (Andersen and Jepsen, 1977). This is essentially a tight-binding description and has the additional advantage of containing only a single open parameter, namely, the 3d bandwidth W. The single-particle part of the model Hamiltonian (H_0) is given in terms of these orbitals in eigenvalue representation. In the computations, these bands are constructed for the two relevant lattices, bcc and fcc.

For these electrons we further assume that they only interact when they are on the same atom l. These interactions can be given in terms of three Slater interactions; here we choose a slightly different but equivalent notation. The full Hamiltonian H reads as

$$H = H_0 + H_1 \tag{1}$$

$$H_0 = \sum_{\nu\sigma\mathbf{k}} e_\nu(\mathbf{k}) n_{\nu\sigma}(\mathbf{k}) \tag{2}$$

$$H_1 = \sum_{\mathbf{l}} H_1(\mathbf{l}) \tag{3}$$

$$\begin{aligned} H_1(\mathbf{l}) = {} & \frac{1}{2}\sum_{ij\sigma\sigma} U_{ij} a^\dagger_{i\sigma}(l) a^\dagger_{j\sigma'}(l) a_{j\sigma'}(l) a_{i\sigma}(l) \\ & + \frac{1}{2}\sum_{ij\sigma\sigma} J_{ij} \Big[a^\dagger_{i\sigma}(l) a^\dagger_{j\sigma'}(l) a_{i\sigma'}(l) a_{j\sigma}(l) \\ & + a^\dagger_{i\sigma}(l) a^\dagger_{i\sigma'}(l) a_{j\sigma'}(l) a_{j\sigma}(l) \Big] \end{aligned} \tag{4}$$

The $e_\nu(\mathbf{k})$ represent the five ($\nu = 1.5$) canonical bands, and the $n_{\nu\sigma}(\mathbf{k})$ the corresponding number operators of the Bloch eigenstates, whose creation and annihilation operators are $c^\dagger_{\nu\sigma}(\mathbf{k}), c_{\nu\sigma}(\mathbf{k})$. The U_{ij} and J_{ij} are the local (atomic) interaction matrices and are related by

$$U_{ij} = U + 2J - 2J_{ij} \tag{5}$$

where U and J are the average Coulomb and exchange interaction constants. The matrix J_{ij} contains the third interaction parameter ΔJ that is a measure of the difference between the e_g and t_{2g} interactions. For details of this matrix, we refer to Kleinmann and Mednick (1981) and Oleś and Stollhoff (1984). For $\Delta J = 0$, it holds that $J_{ij} = J$. The interactions are expressed in terms of the five local 3d orbitals i on atomic positions l whose creation and annihilation operators are given as $a^\dagger_{i\sigma}(l), a_{i\sigma}(l)$.

The size of these parameters will be fixed later. Typically, it holds that the bandwidth W that scales the single-particle part H_0 is roughly 5 eV. The interactions are reduced to a single free parameter by setting $J \simeq 0.2U$ and $\Delta J \simeq 0.2J$. For U it holds that typically $U \simeq 0.5W$.

Starting point of the following correlation treatment is the solution to the single-particle Hamiltonian H_0, called Ψ_0. This is written as

$$|\Psi_0(n_d, 0)\rangle = \prod_{\substack{\mathbf{k}\nu\sigma \\ e_{\mathbf{k}\nu} \le e_\mathrm{F}(n_d)}} c^\dagger_{\nu\sigma}(\mathbf{k})|0\rangle \tag{6}$$

This solution differs slightly from the self-consistent field (SCF) solution of the full model Hamiltonian H. The latter generates additional self-consistently obtained crystal-field terms that may lead to charge redistributions between the e_g and t_{2g} orbitals. However, since the interactions are not too large, and the original site occupations are almost degenerate, these redistributions can be almost neglected. An exception that will be discussed later is the case of ferromagnetic Ni where the second requirement does not hold. Such a solution is found for all fillings n_d per atom of the five-band system, with n_d ranging from 0 to 10. $e_\mathrm{F}(n_d)$ is the occupation-dependent Fermi energy.

In addition to this nonmagnetic solution, magnetic solutions with a moment m are constructed by generating states

$$|\Psi_0(n_d, m)\rangle = \prod_{\substack{\mathbf{k}\nu \\ e_{\mathbf{k}\nu} \le e_\mathrm{F}(n_d+m)}} \prod_{\substack{\mathbf{k}'\nu \\ e_{\mathbf{k}'\nu} \le e_\mathrm{F}(n_d-m)}} c^\dagger_{\nu\uparrow}(\mathbf{k}) c^\dagger_{\nu\downarrow}(\mathbf{k}')|0\rangle \tag{7}$$

Here, the majority band with spin up is occupied with $(n_d + m)/2$ electrons, and the minority band with spin down with $(n_d - m)/2$. This ansatz is a rigid band approach. Again, a self-consistent solution might lead to small charge

redistributions in the minority and majority bands if these are not empty or filled, respectively.

The Fermi energy for the individual cases like Fe, Co, Ni is chosen so that the maximal magnetic moment agrees with the same one of the LSDA calculations. This implies an occupation of 7.4, 8.4, 9.4 for Fe, Co, and Ni, respectively. It is known from more careful charge analyzes that the true atomic 3d occupations are somewhat smaller. For Fe for example they amount to 6.5. Consequently, the d orbitals of this model Hamiltonian are not maximally localized 3d tight-binding orbitals but their tails have small 4s, 4p contributions.

3 CORRELATED GROUND STATE

3.1 Deficiencies of the single-particle ground state

The single-particle ground state Ψ_0 is an eigenstate for the single-particle part of the Hamiltonian but results in a poor coverage of the interaction part. Being represented by eigenfunctions in momentum space, this state has maximal local charge fluctuations that are uncorrelated for the different bands. A measure of these charge fluctuations is the atomic quantity Δn^2 for a given wave function. It is given as

$$\Delta n^2 = \langle\Psi|n^2(l)|\Psi\rangle - \langle\Psi|n(l)|\Psi\rangle^2 \tag{8}$$

$$n(l) = \sum_{i\sigma} n_{i\sigma}(l) \tag{9}$$

where $n_{i\sigma}(l)$ is the density operator for an electron with spin σ in orbital i on site l.

For the single-particle ground state, it holds that

$$\Delta n^2(\Psi_0(n_d, 0)) = \sum_{i\sigma} n_{i\sigma}(1 - n_{i\sigma}) \tag{10}$$

$$n_{i\sigma} = \langle\Psi_0|n_{i\sigma}(l)|\Psi_0\rangle \tag{11}$$

These fluctuations increase linearly with the number of bands. For the half-filled five-band case with degenerate occupation we find that $\Delta n^2 = 2.5$. Correspondingly, the interaction energy costs per atom of this state in comparison to the disordered atomic limit amount to $1.25\left(U - \frac{2}{9}J\right)$. This needs to be compared to a kinetic energy gain, which for a roughly constant density of states equals $-1.25W$. This indicates that half the delocalization energy is lost in this approximation for a ratio $U \simeq 0.5W$. However, the electrons on the individual atoms order by Hund's rule and can gain an energy of $-\frac{70}{9}J$ at half-filling. Consequently even for this relatively modest screened interaction, the solid is no longer bound in single-particle approximation, and a better treatment is required, that is, the correlated ground state needs to be computed. Without including correlations explicitly, any broken symmetry, even disordered local moments would be favorable.

3.2 The local ansatz

For a three-dimensional model with five degenerate bands, the correlation treatment cannot be done exactly but only approximately. Since the parameter choice let us expect that the electrons are not too strongly correlated, the natural approach is to start from the single-particle ground state and add correlations as corrections.

This is how the LA is set up. Here, the following variational ansatz is made for the correlated ground state:

$$|\Psi_{\text{corr}}\rangle = e^{-S}|\Psi_0\rangle \tag{12}$$

$$S = \sum_{\nu} \eta_\nu O_\nu \tag{13}$$

$$O_\nu = \begin{cases} n_{i\uparrow}(l)n_{i\downarrow}(l) \\ n_i(l)n_j(l') \\ \vec{s}_i(l)\cdot\vec{s}_j(l') \end{cases} \tag{14}$$

The $n_{i\sigma}(l)$ and $\vec{s}_i(l)$ are density and spin operators for an electron in the local orbital i on site l. The operators have a transparent meaning. For example, the first operator $n_{i\uparrow}(l)n_{i\downarrow}(l)$, when applied to $|\Psi_0\rangle$, picks out all configurations with two electrons in orbital i. When applied with a variational parameter η_ν, as in equation (12), it partially suppresses those configurations. For a single-band Hubbard model such an ansatz was first made by Gutzwiller (1965). Similarly, the operators $n_i(l)n_j(l')$ introduce density correlations between electrons in local orbitals i, j either on the same site or on different sites l, l'. The wave function generated by these two sets of operators, when applied to the homogeneous electron gas problem, is the Jastrow function (Jastrow, 1955). The operators $\vec{s}_i \cdot \vec{s}_j$ generate spin correlations. On the same site, they introduce Hund's rule correlations, while when applied for different sites they result in magnetic correlations.

For the same sites, all these operators are directly connected to H_1. They allow to correct exactly those features that are addressed by the interaction terms.

In the following, we will no longer use the full operators but only their two-particle excitation contributions. The standard approximation to derive the energy and to obtain the variational parameters is an expansion in powers of η, up to second order,

$$E_{\text{G}} = E_{\text{SCF}} + E_{\text{corr}} \tag{15}$$

$$E_{\text{corr}} = -2\sum_{\nu} \eta_\nu \langle O_\nu^\dagger H\rangle + \sum_{\mu\nu} \eta_\nu\eta_\mu \langle O_\nu^\dagger H O_\mu\rangle_{\text{c}} \tag{16}$$

When optimizing this energy, the following equations arise that determine the energy and the variational parameters.

$$E_{\mathrm{corr}} = -\sum_{\nu} \eta_\nu \langle O_\nu^\dagger H \rangle \tag{17}$$

$$0 = -\langle O_\nu^\dagger H \rangle + \sum_{\mu} \eta_\mu \langle O_\nu^\dagger H O_\mu \rangle_{\mathrm{c}} \tag{18}$$

Here, $\langle A \rangle$ is the expectation value of the operator A within $|\Psi_0\rangle$, and $\langle\rangle_{\mathrm{c}}$ indicates that only connected contributions are included. It holds that $E_{\mathrm{SCF}} = \langle H \rangle$ These equations can also be identified as a linearized coupled-cluster expansion with singles and doubles (LCCSD), restricted to particular two-particle (double) and one-particle (single) excitations. The concept of coupled-cluster (CC) equations was introduced into many-body physics and into QC a long time ago (Coester, 1958; Coester and Kümmel, 1960; Cizek, 1966, 1969). In the presented calculations on models, single-particle excitations were, in contrast to the *ab initio* calculations, not included in the correlation treatment itself, but were covered by direct modifications in the trial single-particle wave functions.

The full treatment of these equations poses no problems, in particular, when the operators are restricted to on-site terms. Then, without consideration of intrinsic symmetries, one has 5 Gutzwiller-like operators and 10 density and spin operators each. The most expensive step is the solution of a set of linear equations with dimension 25.

3.3 The $R = 0$ approximation and alternatives to the local ansatz

The correlation calculations can be performed in a further approximation in which one may go beyond the LCCSD equations. This approximation applies only when restricting to on-site operators. In this case, one can approximately set all those terms in the matrices $\langle OH \rangle$ and $\langle OHO \rangle$ equal to zero where the operators in the O or in H_1 are not on the same site. In this approximation, the full correlation treatment separates into independent contributions covering a single site each in a noncorrelated and noninteracting environment. This approximation is called *single-site* or $R = 0$ *approximation*. It was introduced for the first time in a second-order perturbation treatment of a five-band Hamiltonian that is very similar to the one used here. There, however, no restriction to a particular choice of correlation operators was made but the full two-particle operator space was covered (Treglia, Ducastelle and Spanjaard, 1980). In the single-site approximation of the LA, all required terms are simply obtained from two sets of single-particle elements, the individual occupations $n_{i\sigma}$ and the average energies on these sites, $e_{i\sigma}$, are given as

$$e_{i\sigma} = \int_{-\infty}^{e_{\mathrm{F}}} e n_{i\sigma}(e)\, \mathrm{d}e \tag{19}$$

where $n_{i\sigma}(e)$ is the local partial density of states for orbital i with spin σ. More details can be found in Stollhoff and Thalmeier (1981) and Oleś and Stollhoff (1984). All terms that are left out in the single-site approximation contain nondiagonal density matrix elements of the form $P_{ij}(l, l') = \langle a_i^\dagger(l) a_j(l') \rangle$ with $R = l - l' \neq 0$, explaining the name. With rising number of nearest neighbors, these contributions shrink in weight and disappear for the limit of infinitely many neighbors (or equivalently dimensions d). The approximation was therefore more recently called $d = \infty$ approximation (Vollhardt *et al.*, 1999).

In a way, this approximation represents the correlation generalization of an approximate coherent potential approximation (CPA) where a single-site mean-field calculation with broken symmetry is performed which leads to disordered local moments. With on-site correlations properly included, a broken symmetry result no longer arises, at least not prior to a Mott–Hubbard transition. Or, in other words, disordered local moments are a poor man's approach to correlations.

This single-site approximation allows a more general treatment than the LCCSD approximation. One possibility is to perform a CI calculation for this single site. The exact energy of the variational state with two-particle excitations included is obtained. It represents a lower limit to the exact result, while the LCCSD approximation usually overshoots the latter. The correlated wave function for the single site l is defined as

$$|\Psi_{\mathrm{corr}}(l)\rangle = \left(1 - \sum_{\nu \in l} O_\nu\right) |\Psi_0\rangle \tag{20}$$

Its exact energy is

$$E_{\mathrm{G}}(l) = E_{\mathrm{SCF}} + E_{\mathrm{corr}}(l) \tag{21}$$

$$E_{\mathrm{corr}}(l) = \frac{-2 \sum_{\nu}{}' \eta_\nu \langle O_\nu^\dagger H' \rangle + \sum_{\mu\nu}{}' \eta_\nu \eta_\mu \langle O_\nu^\dagger H' O_\mu \rangle_{\mathrm{c}}}{1 + \sum_{\mu\nu}{}' \eta_\nu \eta_\mu \langle O_\nu^\dagger O_\mu \rangle_{\mathrm{c}}} \tag{22}$$

Here the $\sum'$ indicates a restriction of the summation to operators on site l, and $H' = H_0 + H_1(l)$. When optimizing this energy, the resulting equations that determine the energy and the variational parameters can be written in close

similarity to the LCCSD equations (17) and (18).

$$E_{\mathrm{corr}}(l) = -\sum_{\nu}{}' \eta_\nu \langle O_\nu^\dagger H' \rangle \tag{23}$$

$$0 = -\langle O_\nu^\dagger H' \rangle + \sum_{\mu}{}' \eta_\mu \langle O_\nu^\dagger H' O_\mu \rangle_{\mathrm{c}} + \sum_{\mu}{}' \eta_\mu \langle O_\nu^\dagger O_\mu \rangle_{\mathrm{c}} \sum_{\mu'}{}' \eta_{\mu'} \langle H' O_{\mu'} \rangle_{\mathrm{c}} \tag{24}$$

The newly added terms in equation (24) are responsible for the difference. One may generalize in this approximation and perform a full CI calculation not restricted to two-particle operators. The system of equations (20), (22)–(24) stays the same but the operators O_ν are not restricted to two-particle excitations. The available operator space explodes exponentially with degeneracy, and the numerical demands rise sharply, but recently even nine-band models could be addressed this way (i.e., the 3d plus the 4s and 4p orbitals were included) (Bünemann, Weber and Gebhard, 1998; Bünemann *et al*., 2003).

An even more extended approach is to perform an exact calculation for the single-site problem, based on dynamically fluctuating disordered local moments, called DMFT (for an introduction of its origins, see Vollhardt *et al*., 1999). This computation is based on a Green's function formalism, and is by far the most expensive method. Formally, the operator space is extended beyond strictly local operators. Not all electrons are covered equally but their treatment is influenced by their individual energies. Applications for a nine-band model were done for Fe and Ni (Lichtenstein, Katsnelson and Kotliar, 2001) by this method. A further advantage of this scheme is that quasiparticle results can be obtained and a transition to thermodynamic quantities is possible since the computations are performed on a Green's function level.

Let's return to the most simple scheme, the LA. In contrast to the other methods, it cannot be applied to the Mott–Hubbard transition. However, it is the only scheme that can be extended beyond $R = 0$ and can treat finite dimension corrections. Furthermore, it can deal with long-range interactions, and even manage *ab initio* calculations with the full interaction.

There is actually a rather simple extension of the LA that makes it more tolerant of stronger correlations. This is the application of the full coupled-cluster expansion with singles and doubles (CCSD) equations. They arise from a full equation of motion of the original ansatz for the wave function, and not from a weak coupling approximation. The resulting equations read as follows:

$$E_{\mathrm{corr}} = -\sum_{\nu} \eta_\nu \langle O_\nu^\dagger H \rangle \tag{25}$$

$$0 = -\langle O_\nu^\dagger H \rangle + \sum_{\mu} \eta_\mu \langle O_\nu^\dagger H O_\mu \rangle_{\mathrm{c}} - \frac{1}{2} \sum_{\mu\mu'} \eta_\mu \eta_{\mu'} \langle O_\nu^\dagger H O_\mu O_{\mu'} \rangle_{\mathrm{c}} \tag{26}$$

This generalization would improve the results for larger ratios of U/W. When applied to a single-band Hamiltonian in $R = 0$ approximation, the result should, with single-particle operators properly added, reproduce the Gutzwiller approximation (Stollhoff and Heilingbrunner, 1991).

3.4 Error estimates of the different approximations in the local ansatz

In the present treatment of the LA, three approximations are made that need to be controlled.

The first is the weak-correlation approximation. It may be tested by a comparison of the LCCSD and the CI result in the $R = 0$ approximation.

The second is the $R = 0$ approximation itself. It can be tested only in the weak-correlation approximation.

The last is the restriction in correlation operator space. Again, this will be tested in the weak-correlation expansion.

The last restriction is best tested for the one-dimensional single-band Hubbard model. Here, the exact energy is known, and also its weak-correlation limit. The corresponding Gutzwiller ansatz, which contains only single-site operators yields 92% of the exact correlation energy in this limit for the half-filled case. A large fraction of the missing energy can be obtained by longer-range density and spin correlations.

The situation is worse for almost empty bands. Here, additional correlation operators of the form $[H_0, O_\nu]$ are required for a satisfactory result. Such operators do not open new correlation channels but allow us to take into account the band energies of the electrons involved in the correlation process. Such operators are included in the *ab initio* scheme and have turned out to be important in a different context (Stollhoff, 1996). We had found for the nonmagnetic five-band calculations (Stollhoff and Thalmeier, 1981; Stollhoff, 1986) that these operators do not lead to noticeable changes. Although being of nonlocal nature, such operators contribute in $R = 0$ approximation, and bridge the difference between a correlation calculation restricted to local correlation operators and a DMFT calculation.

For the five-band model, we had also included nearest-neighbor operators in the nonmagnetic calculations (Stollhoff and Thalmeier, 1981). The energy gain due to these terms was only a few percent; thus we can trust the results of calculations restricted to on-site correlations for the five-band Hamiltonian.

The $R = 0$ approximation depends on the number of neighbors. For a two-site problem with a single orbital each, the $R = 0$ result is only half the correct result. For the one-dimensional Hubbard model, the $R = 0$ result needs to be enhanced by 33% to obtain the final LA result with on-site operators for half-filling, but already nearest neighbor or $R = 1$ corrections reduce the deficiency to 1%. For the five-band problems treated here, the $R = 1$ corrections turned out to be 2–3% for fcc or bcc, respectively (Stollhoff and Thalmeier, 1981). Most of our calculations and all calculations for the magnetic state were therefore restricted to the $R = 0$ approximation. On the other hand, these results indicate that an $R = 0$ or d_∞ approximation should not be applied to systems with less than six neighbors.

Let's finally turn to the validity of the weak-correlation approximation. It will definitely fail around half-filling for ratios $(U/W) > 1$. In Figure 1, correlation energies in the $R = 0$ approximation are given for a ratio of $U = 0.5W$. The dashed curve gives the HF-energy costs $\Delta E_{\mathrm{SCF}} = E_{\mathrm{SCF}} - \langle H_0 \rangle$. The topmost curve gives the result of a correlation calculation performed in second-order perturbation (MP2) expansion (the LCCSD equation can be reduced to MP2 by replacing $\langle OHO \rangle$ by $\langle OH_0O \rangle$). This result overshoots the HF term and is definitely wrong. The second solid curve gives the final result in LCCSD, and the dotted curve below it gives the CI result. The maximal relative difference around half-filling amounts to 25%. When considering that the CI result is a true lower limit, the LCCSD result should not overshoot the correct result by more than 5%. The lowest curves display the energies that are lost when spin correlations are omitted. Here, the relative differences between CI and LCCSD are considerably larger but again the true result is expected to be close to the LCCSD result.

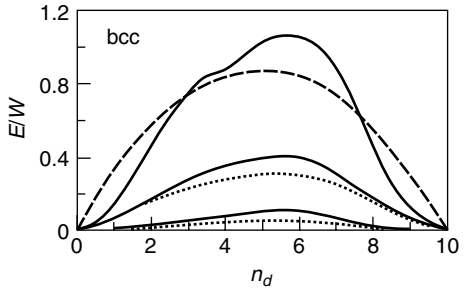

Figure 1. Several energies in units of W as a function of band filling n_d. The interaction energy costs in SCF approximation are given by the dashed line. The top full line gives the MP2 correlation result, the second full line the LCCSD result, and the dotted line just below it the CI result. The lowest full line and the dotted line below give the amount of correlation energy that is lost when the spin correlation operators are omitted from the LCCSD or CI calculations, respectively. All correlation calculations were performed for the bcc case and in the $R = 0$ approximation. (Reproduced from G. Stollhoff and P. Thalmeier: 'Variational Treatment of Electronic Correlations in d-Band Metals', *Z. Physik B* **43**, 13 (1981) with permission from Springer Science and Business Media.)

These particular features are closely connected to the degeneracy. As mentioned before, fluctuation costs arise in five channels i in the HF approximation. The correlation ansatz however makes 15 density correlation channels i, j available. Thus, treating these channels independently as is done in perturbation theory very soon overscreens the fluctuations. The term H_1 in $\langle OHO \rangle$ by which the LCCSD equations differ from MP2 guarantees that the different channels take note of each other and act coherently. This distribution of correlation corrections among many different states also makes it plausible why the CI and LCCSD results are so close to each other although five degenerate orbitals need to be treated.

For the spin correlations, the situation is different. Here each pair i, j can gain an interaction energy J independent of each other. This is reproduced in the LCCSD equations, while it is a particular feature of the CI calculations restricted to two-particle excitations that at each moment one has either the one or the other electron pair corrected. Thus, the different contributions, also the spin and density contributions actually impede each other, and a considerably smaller energy is obtained. This explains why the largest part of the difference between the two schemes in the full calculation arises from the addition of the spin correlations. On a CI level, this deficiency might only be corrected by including in the variational ansatz for the CI wave function not only 2-particle excitations but also their products, and finally up to 10-particle excitations.

The failure of MP2 found here is related to the failure of this approximation when the screening of the long-range Coulomb interactions in metals is concerned. There fluctuations are also diagonal, that is, connected to the local sites l. The correlation space, however, offers l, l' density correlations that are independent in MP2 and cause the well-known divergence of the correlation energy. The LCCSD scheme used here does not result in a divergence but it is not perfect either for the homogeneous electron gas. It generates only half of the screening of the long-range charge fluctuations (Stollhoff and Heilingbrunner, 1991).

The weak-correlation expansion used here, looks very simple, but this is not at all the case when evaluated in a diagrammatic representation. In the linear equations (17) and (18) the interaction is included in both sets of terms. In a

diagram representation, this means that infinite orders of diagrams are summed up. The LCCSD approximation includes the Tamm–Dancoff approximation plus all related exchange diagram corrections, and also contains the Kanamori limit. It does not yet contain the random phase approximation (RPA) limit (plus all exchange corrections). The RPA limit is covered by the full CCSD equations in (25) and (26).

These findings also explain why reliable Green's function results for the transition metals are rare. The only area well accessible was the almost empty or filled band case, the Kanamori limit (Liebsch, 1979, 1981; Penn, 1979; Davis and Feldkamp, 1980). For the case of Fe, one was restricted to MP2 calculations that are more or less empirically renormalized (Unger, Igarashi and Fulde, 1994; Katsnelson and Lichtenstein, 1999). Only the DMFT has made a significant progress by the use of large scale Monte Carlo computations (Lichtenstein, Katsnelson and Kotliar, 2001).

4 RESULTS FOR THE NONMAGNETIC GROUND STATE

4.1 Ground-state energies

In the last section, some specific total energy contributions have been analyzed. Here, we discuss them in more detail. The results discussed represent the bcc case, and the ratio $(U/W) = (1/2)$ is used. Also ΔJ is disregarded in the qualitative discussion for simplicity.

All total energies are related to an average interaction energy of electrons with the same occupation with localized electrons and without Hund's rule ordering:

$$E_0(n_d) = \left(U - \frac{2}{9}J\right) n_d(n_d - 1) \tag{27}$$

The Hund's rule energy gain for the ordered atoms is then

$$E_{\text{atom}}(n_d) = -\frac{7}{18} J \tilde{n}_d(\tilde{n}_d - 1) \quad \text{where} \tag{28}$$

$$\tilde{n}_d = \begin{cases} n_d \text{ for } n_d \leq 5 \\ (10 - n_d) \text{ for } n_d \geq 5 \end{cases} \tag{29}$$

The occupation dependence of this energy is shown in Figure 2 (upper full line). It is strongly peaked at $n_d = 5$. It is compared to the ground-state energy for H_0 that is contained in the figure as the lowest solid line. This figure indicates the binding due to the 3d electron delocalization. Disregarding slight shifts, the difference between these two extremal curves is a good representation of the LDA binding energy contributions of the 3d electrons. This can be seen when comparing Figure 2 with the LDA binding energy Figure 1.1 in Moruzzi, Janak and Williams (1978). Two corrections should be made. The first one is that the real atoms have occupations differing from the solids (Fe atom, $n_d = 6$ vs $n_d = 7.4$ in the model), and the second one is that the bands are narrower for the heavier elements. By setting $W = 5\,\text{eV}$, a typical binding of 2.5 eV arises.

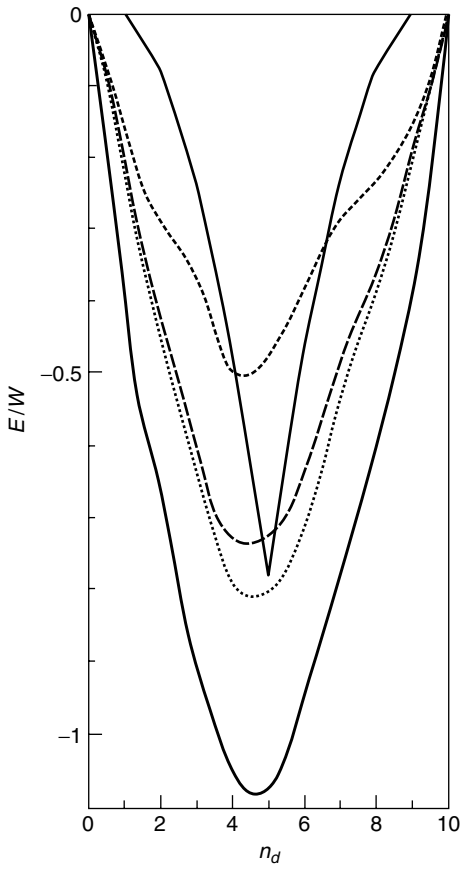

Figure 2. Energies for various approximations of the ground state in powers of W as a function of band filling n_d for the bcc case. The upper solid line represents the atomic energy, the lowest solid line the kinetic energy. The upper broken line represents the HF energy, the lower broken line, the result with density correlations included, and the dotted line, the final LA result.

The upper broken curve in Figure 2 represents the HF energy. As already mentioned, half of the band energy gain is lost. Even worse, the uncorrelated ground state is no longer binding in the occupation range from 4 to 7. The situation is corrected when the full correlation treatment is performed (dotted curve). The correlated ground state is always bound, although marginally at half-filling. This is in rough agreement with experiment, where the d-orbital contributions to the binding in Mn are not larger than 1 eV. Actually, the difference between the noninteracting and the fully correlated result matches roughly the difference between the LSDA and experimental binding energies for these cases (see again

Figure 1.1 in Moruzzi, Janak and Williams, 1978), and might well explain it as will be discussed later. The figure also contains the energy when spin correlations are omitted (lower broken curve). As can be seen, the contributions of the spin correlations to the total energy are not large but important.

4.2 Correlation functions

From our calculations, local correlation functions for the transition metals were obtained for the first time. The effects of the correlations are large, and should be basically experimentally accessible wasn't it for the yet lacking spatial resolution of X-rays, and for the too small energies of the neutrons. But it is still valuable to discuss a few theoretical results. The first correlation function is the atomic charge fluctuation Δn^2. The reduction of this quantity due to correlations is shown in Figure 3. As can be seen, it is sizable, although the electrons are not strongly correlated. This is due to the many available correlation channels. When turning to the spin correlation function S^2, one has to be aware that the autocorrelation of the electrons leads to a finite value even in the uncorrelated state. This is given as the lower broken line in Figure 3(b). Of importance is also the fully localized limit whose values of S^2 are given as the dotted line in this figure. The correlation result is given as the full line. As can be seen, spin correlations are strong, but significantly smaller than in the localized limit. They are almost halfway in between, the relative change being 0.45, almost independent of band filling. This also indicates that the proximity of the energy to the atomic limit at half-filling (see Figure 2) does not yet cause a resonance-like correlation enhancement.

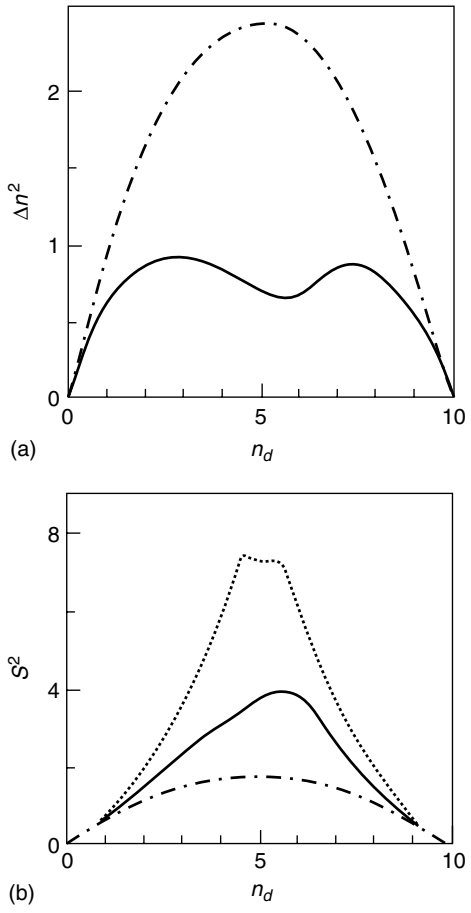

Figure 3. (a) Charge fluctuations as function of d-band filling n_d (bcc). Upper curve without correlations, lower curve with correlations included. (b) Local spin correlations S^2 as function of d-band filling n_d (bcc). Upper curve: Atomic limit, lower curve: SCF result. Full line: LA result. (Reproduced from G. Stollhoff and P. Thalmeier: 'Variational Treatment of Electronic Correlations in d-Band Metals', *Z. Physik B* **43**, 13 (1981) with permission from Springer Science and Business Media.)

This presence of relatively strong spin correlations poses the question whether these can be treated in a good approximation as quasilocal moments, whether they for example, already require a different timescale, or whether these correlations decay as fast as the electrons move, and only form a polarization cloud around the moving electrons.

The answer cannot be directly obtained from ground-state calculations. There is, however, an indirect way to address this question, where one includes short-range magnetic correlations into the LA calculation. There is no direct neighbor interaction in the Hamiltonian. Thus a strong magnetic neighbor correlation would indicate the formation of local moments, at least in cases when the nonmagnetic ground state is only metastable, and a ferromagnetic ground state exists. The calculation can be easily done by adding neighbor spin operators to the correlation treatment. This rules out an $R=0$ approximation. In the required computation, all matrix elements $P_{ij}(0,l)$ with l nearest neighbors are included, and all nearest-neighbor correlations are added up (Stollhoff, 1986).

The discussion of the obtained quantities requires some care because the nonmagnetic ground state is a singlet. This implies that the positive magnetic correlation function on the same site must be compensated by short-range antiferromagnetic correlations in order to obtain $S^2_{\rm tot}|\Psi_i\rangle = 0$, no matter whether the single particle ($i=0$) or correlated ($i=$ corr) ground state is concerned. Neighbor antiferromagnetic correlations have therefore no relevance as such, but only their eventual changes due to added degrees of freedom are of importance. Consequently, we compare for every filling every change in correlation with the maximal possible change, namely, the local moment formation. We discuss therefore the quantity

$$\Delta S^2_\delta = \frac{C(\delta) - C_0(\delta)}{S^2_{\rm loc} - S^2_0} \tag{30}$$

Here, it holds that

$$C(\delta) = \langle \Psi_{\text{corr}} | S(l) S(l+\delta) | \Psi_{\text{corr}} \rangle \tag{31}$$

$$C_0(\delta) = \langle \Psi_0 | S(l) S(l+\delta) | \Psi_0 \rangle \tag{32}$$

Figure 4 displays these relative changes. In the upper part, the relative change of the on-site spin correlation is given, in the lower part the one of the neighbor functions. The solid line displays the result without neighbor correlations that had just been discussed. The upper curve indicates on an average 45% of the maximal correlation, and the lower curve indicates the required antiferromagnetic reordering due to the on-site correlations in the neighbor function. This calculation was performed for the bcc case. As can be seen, the ratio is a slightly lesser than 1/4. Therefore additional longer-range compensation effects are expected. The most interesting result is the changes due to added neighbor correlations. The resulting curves are given in Figure 4 as dotted lines. These changes are very small. However, it is interesting that they recover the expected trends correctly. They indicate a tendency toward antiferromagnetism only around half-filling (from occupations of $3.5 < n_d < 6.5$). Apparently, the magnetic susceptibilities are slightly enhanced for the proper magnetic ordering. However, the moments themselves do not change at all, except around half-filling. Here, the stability of the nonmagnetic state is smallest, as discussed above. It should be noted that for this choice of parameters, the stable ground state is ferromagnetic for band fillings of $n_d > 7.0$.

To conclude, on-site correlations on neighbor atoms do not support each other. Barely, noticeable neighbor correlations form. These results strongly contradict a local moment assumption. The energy gain due to the added operators

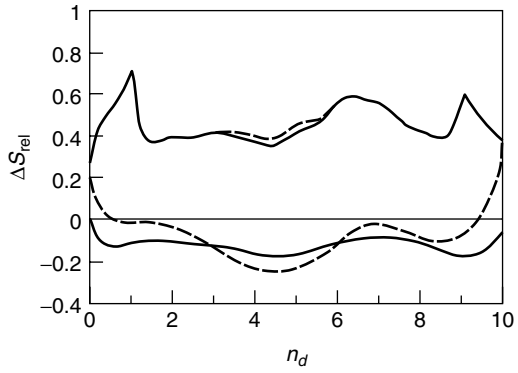

Figure 4. Relative change of the spin correlation function as function of band filling. Upper curves: change of on-site correlations, lower curves: change of neighbor correlations. Full lines without neighbor correlations, broken curves with neighbor correlations added. (Reproduced from G. Stollhoff: 'Magnetic correlations in the paramagnetic state of 3d-transition metals', *J. Magn. Magn. Mat.* 1043 (1986), copyright © 1986, with permission from Elsevier.)

is small – it amounts to less than 100 K per atom for Fe. Consequently, the strong on-site correlations cannot be interpreted as quasi static local moments. Magnetic ordering restricted to nearest neighbors does not exist in these compounds. If magnetic order exists – and it must exist – then it is only for domains considerably larger than a single atom and its neighbors. This demonstrates again that the electrons in the transition metals are delocalized, and that spin fluctuations can only exist for small moments q, as experiments demonstrate (the stiffness constant of Fe, for example, allows magnetic excitations with energies smaller than T_c only for moments q smaller than one fifth of the Brillouin zone). If there is really a need to address the strong magnetic scattering above T_c for Ni, (Brown, Deportes, Givord and Ziebeck, 1982), by methods extending beyond a critical Stoner enhancement that was computed in Steiner, Albers and Sham (1992), then this can only be done by long-range spin or order parameter fluctuation theories (Korenman, Murray and Prange, 1977; Capellmann, 1974, 1979).

4.3 Compton scattering

While experiments have not yet been able to provide information about correlation functions, they have succeeded for another quantity that displays correlation effects: the density distribution in momentum space, $n(\mathbf{k})$. The scattering intensity $I(\mathbf{q})$ measured in Compton scattering is given by the integral over all densities $n(\mathbf{k})$ with $\mathbf{kq} = \mathbf{q}^2$. The variation in $I(\mathbf{q})$ with direction $\mathbf{q}$ provides a direct measure of the anisotropy of the Fermi surface (Bauer and Schneider, 1985). These experimental results are in good qualitative agreement with Fermi surfaces obtained in LSDA for Cu (Bauer and Schneider, 1985), Va (Rollason, Cooper and Holt, 1983; Wakoh and Matsumoto, 1990), Cr (Wakoh and Matsumoto, 1990), and Ni (Anastassopoulos *et al.*, 1991) with exception of a constant scaling factor. For Fe (Rollason, Holt and Cooper, 1983; Sundararajan, Kanhere and Singru, 1991), the agreement is less good.

This constant scaling factor provides a measure of the correlation correction. In the single-particle approximation, all states with energies smaller than the Fermi energy are filled and the others are empty. This implies a maximal step at $n(\mathbf{k_F})$. This result is changed by correlations. The changes are qualitatively depicted in Figure 5(a). For simplicity let us assume that correlations cause a constant shift α in occupations for the occupied and unoccupied parts of the partially filled bands. Then this correction α can be directly extracted from the scaling factor by which experiments (correlations included) and single-particle calculations (no correlations included) differ.

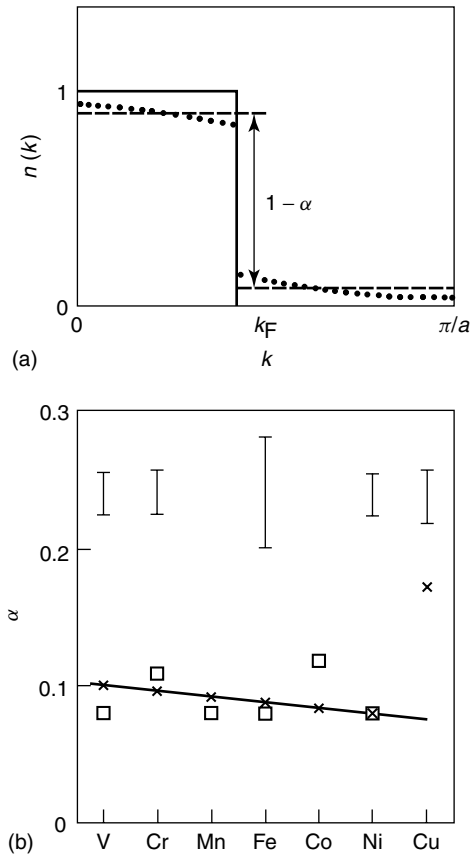

Figure 5. (a) Qualitative picture of changes in occupation around the Fermi energy owing to correlations. Dots represent the real behavior, and the dotted line the average change. (b) Values of the quantity α in the left figure for different transition metals. The bars represent the values deduced from experiment in comparison to LSDA results. Crosses give a homogeneous electron gas estimate α_{hom}, and squares give the contributions α_{LA} due to the atomic correlations of the screened d electrons alone to this value. (From Stollhoff, 1995a.)

Figure 5(b) contains the values for α for the mentioned transition metals and for Cu as deduced from experiment. As can be seen, this reduction amounts to 20–25% in all cases.

This reduction α can be compared to its counterpart α_{hom} obtained for a homogeneous system with the same average density. For its derivation, we refer to Bauer and Schneider (1985) and Stollhoff (1995a). When taking for Cu a single valence electron only (i.e., considering the d electrons as part of the core), the experimental value is regained. This indicates that as far as this property is concerned, the 4s (and 4p) electrons correlate as a homogeneous system of the same average density. For the transition metals, on the other hand, the d electrons need to be incorporated into the estimate. The resulting r_s value is much smaller than in the case of Cu which implies – within the theory of the homogeneous electron gas – a smaller reduction of the occupation. The latter amounts to less than half of the correlation effects determined experimentally.

Within our scheme, the reduction α_{LA} is obtained from the change of the expectation value of H_0, the so-called kinetic or band energy, with correlations. For the uncorrelated ground state, it holds that

$$E(\text{band})_0 = \langle \Psi_o | H_0 | \Psi_0 \rangle = \sum_{\nu\sigma} \int_{e_\nu(\mathbf{k}) \le e_F(\sigma)} d^3\mathbf{k} e_\nu(\mathbf{k}) \quad (33)$$

while the band energy of the correlated ground state is

$$E(\text{band}) = \langle \Psi_{\text{corr}} | H_0 | \Psi_{\text{corr}} \rangle = (1 - \alpha_{\text{LA}}) E(\text{band})_0 \quad (34)$$

because the model Hamiltonian is constructed such that $\text{Tr}(H_0) = 0$. Thus, the quantity α_{LA} also represents the relative change of the band or kinetic energy of the model by correlations. For the magnetic cases, the values for the magnetic ground state are selected. The interaction parameters are chosen so that they correspond to the actual transition metals. The values found indicate again that the electrons are weakly correlated. Only 10% of the kinetic energy is lost due to atomic correlations.

The restriction to this model implies that only a part of the correlation corrections α can be obtained, namely, the one that arises from the atomic correlations due to the strongly screened atomic d-electron interactions. The contributions of the screening itself to the momentum density, for example, are not included in this estimate. As can be seen from Figure 5, the particular atomic correlation contributions α_{LA} alone as derived from the model computations are as large as the total homogeneous electron gas values α_{hom}. Therefore, they must to a large extent be neglected in a homogeneous electron gas approximation as was explained before. They amount to almost half the experimental value α and can therefore explain the largest part of the deficit of a homogeneous electron gas treatment.

Correlations are included in a homogeneous electron gas approximation when LSDA calculations are performed. Such calculations must therefore lack a satisfactory description of these atomic correlations for the case of the transition metals.

5 RESULTS FOR THE MAGNETIC GROUND STATE

5.1 Parameterization of the Hubbard Hamiltonian

Of main interest in the case of the magnetic transition metals is the magnetic moment itself. So far, for Hubbard models the interaction parameters were always chosen such

Table 1. Parameters for our model (energies in electron volts). (From Oleś and Stollhoff, 1984.)

	Fe	Co	Ni
n	7.4	8.4	9.4
m	2.1	1.6	0.6
W	5.4	4.8	4.3
U	2.4	3.1	3.3

that the experimental magnetic moment was obtained. It is an indication for the accuracy of the different discussed correlation treatments that these parameters are now closely related. Global differences for the most typical value $U + 2J$ are not larger than 10% and are connected with band structure differences between five-band and nine-band models. This holds true as long as the interaction is restricted. When interactions on and between the 4s, 4p orbitals are also included, the 3d interaction also needs to be enhanced and the screening of the latter interaction by the 4s, 4p electrons is explicitly covered.

The values for W and U for our model are given in Table 1 together with the moment used. In all cases, the ratio $J = 0.2 * U$ was kept. Only for the case of Fe was U unambiguously determined from the magnetic moment. In the other cases, we had only lower limits which were 2.6 and 3.1 eV for Co and Ni, respectively. We will, in the subsequent text, make comparison between the values of U, obtained here, and the ones obtained from other sources.

5.2 Dependence of magnetism on degeneracy

The degeneracy of the energy bands of the transition metals is of vital importance for magnetism itself, and also imposes strict boundary conditions on the possible treatments. To explain this, the magnetic energy gain and its magnetic moment dependence are analyzed as a function of the represented method i for the actual moment m_0.

$$\Delta E_i(m_0) = E_i(m_0) - E_i(0) \tag{35}$$

This energy gain as a function of magnetization is rewritten in the following form:

$$\Delta E_i(m_0) = \frac{1}{4}\int_0^{m_0^2} D(m)\mathrm{d}m^2 - \frac{1}{4}\int_0^{m_0^2} I_i(m)\mathrm{d}m^2 \tag{36}$$

Here, the first term describes the loss in (noninteracting) band or kinetic energy. It holds that

$$D(0) = \frac{1}{n(E_\mathrm{F})} \tag{37}$$

is the inverse total density of states per spin at the Fermi energy. Its generalization for finite m is simple and can be found in Stollhoff, Oleś and Heine (1990). The second part describes the interaction energy gain and is defined by this function. It is a generalized Stoner parameter. The optimal magnetic moment in approximation i is defined by the condition

$$D(m_0) = I_i(m_0) \tag{38}$$

For $m_0 = 0$, this is the standard Stoner criterion, and the Stoner parameter I_i is the limiting $I_i(O)$. For a system with orbital degeneracy N and a Hubbard interaction in the form of equation (4), it holds in HF approximation

$$I_\mathrm{SCF}(m_0) = \frac{1}{N}(U + J(N+1)) \tag{39}$$

If we assume a structureless density of states with a bandwidth W, then $D(0) = W/N$, and for the single-band model the Stoner criterion in SCF approximation reads $U + 2J = W$. In a single-band Hamiltonian, the interaction terms are usually condensed into a single U, but for the degeneracy treatment we will stay in our notation. Ferromagnetism in a single-band system can therefore only be expected for a strong interaction with $U \geq W$ where correlations are important. Correlations however, strongly diminish I from I_SCF, and shift the onset of magnetism to an even larger interaction. Thus, if spurious magnetism due to peaks in the density of states is disregarded, itinerant magnetism with large moments and weak correlations can arise only for highly degenerate systems. This is why we could obtain magnetism for five-band systems with rather weak interactions of $U/W \geq 0.5$. The atomic exchange interaction J is the relevant quantity in this respect, and it requires an adequate treatment. Note that for the case with the smallest interaction, Fe, magnetism is strongly supported by a peak in the density of states, and that Fe does not become fully magnetic.

We had already mentioned that the treatment of degenerate band systems puts strong additional demands on the many-body methods used. This also is the case for magnetic properties. Figure 6 contains for the bcc Fe case the correlated Stoner parameter $I(0)$ as a function of interaction U, renormalized by the SCF Stoner parameter (roughly $(U + 6J)$) to $\overline{I}$. For $U = 0$, $\overline{I}(0)$ is therefore equal to 1, and it decreases due to correlation corrections. As can be seen, there is first a fast decrease, but then, at $U/W = 0.1$ a rigorous slowing down of the screening occurs. From the logarithmic derivative, it can be seen that the exponent changes from 2 to 1/2. This is the point where a second-order perturbation treatment is no longer sufficient, and a better approach is necessary.

Owing to these experiences we decided to include in this review neither contributions that used false degeneracies nor

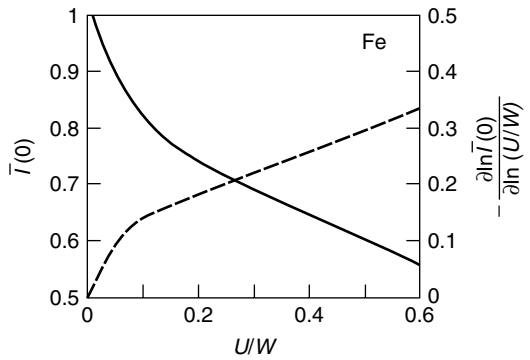

Figure 6. $I(0)$ as depending on the ratio (U/W) for Fe. In addition, the logarithmic deviation is given. (Reproduced with permission from fig. 5 in G. Stollhoff, A. M. Oles, and V. Heine: 'Stoner exchange interaction in transition metals', *Phys. Rev. B* **41**, 7028 (1990), copyright © 1990 by the American Physical Society.)

contributions that are unable to treat degenerate systems well. Therefore, we did not cover work that is based on MP2 or lowest-order diagram techniques. Besides the LA only the full CI method given in Bünemann, Weber and Gebhard (1998) and Bünemann *et al*. (2003); Kanamori t-matrix applications, and the first full application of the DMFT to the transition metals (Lichtenstein, Katsnelson and Kotliar, 2001) remained.

5.3 Magnetic energy gains, Stoner parameter, and T_c

Besides the moment that was taken from experiment, the most basic ground-state quantity connected with the broken symmetry is the magnetization energy gain ΔE.

The values of the energy gain are given in Table 2 for our calculations in the single-particle approximation, for the full treatment of correlations, and for LSDA calculations (Gunnarsson, 1976). A comparison of ΔE_{HF} and ΔE_{corr} shows how correlations reduce the magnetization energy gains. Be aware that the interactions employed are already strongly reduced screened interactions. When comparing the model and LSDA magnetic energy gains, the LSDA quantities come out twice as large for Fe and Ni. Without caring for any specific dependences on details of the density of states, this would imply a corresponding reduction in the Stoner T_c. An exception is the case of Co but here we had possibly chosen a model interaction that was too large for reasons explained in the subsequent text.

Table 2. Magnetic energy gain in HF approximation and for the correlated ground state (Oleś and Stollhoff, 1984) and from LSDA calculations (Gunnarsson, 1976). Stoner-transition temperatures from LSDA calculations (Gunnarsson, 1976), DMFT (Lichtenstein, Katsnelson and Kotliar, 2001), and experiment.

	Fe	Co	Ni
ΔE_{HF} (eV)	0.56	0.43	0.12
ΔE_{corr}	0.15	0.13	0.03
ΔE_{LSDA}	0.28	0.10	0.08
T_c(LSDA)(K)	4400	3300	2900
T_c(DMFT)	2000		700
T_c(exp)	1040	1400	631

The differences between the LA and the LSDA results can be understood by a discussion of the Stoner parameter $I(m)$. In the SCF-approximation, it holds for the degenerate band case

$$I_{\mathrm{SCF}}(m) = \frac{1}{5}(U + 6J) \tag{40}$$

(the terms ΔJ are disregarded). I_{SCF} is independent of magnetization. The function ΔE_{LSDA} contains the same expression for the kinetic energy as the quantities defined in the preceding text because in this approximation the uncorrelated kinetic energy of the reference wave function is used, and also I_{LSDA} turns out to be independent of magnetic moment. Even more important, I_{LSDA} is also essentially independent of the kind of transition-metal atom and its environment. It holds (within 10% variation) $I_{\mathrm{LSDA}} = 0.9\,\mathrm{eV}$ (Gunnarsson, 1976).

While in LSDA, the uncorrelated kinetic energy is used, and the losses in band energy due to magnetism are large, correlations reduce these losses for Fe by 30% (Stollhoff, Oleś and Heine, 1990). These corrections are included in $I(m)$. In particular, if $D(m)$ changes with m, then a partial, compensating change must occur in this function. This holds true for Fe, where it is well known that $D(m)$ strongly rises with m and cuts off the magnetic moment before the maximum. It holds that $D(m_0) = 1.6 \times D(0)$ (Stollhoff, Oleś and Heine, 1990). Correspondingly, $I_{\mathrm{corr}}(m)$ must contain a correcting change. Since $I_{\mathrm{corr}}(m_0) = D(m_0)$, it holds that $I_{\mathrm{corr}}(m_0) = 1.2 I_{\mathrm{corr}}(0)$ due to this effect alone.

There is a further interesting correction that can be seen immediately for Co where the density of states is constant and causes no m dependences in $I(m)$. Figure 7 displays the function $I_{\mathrm{corr}}(m)$, (called $I(m)$ in the figure) in comparison to $D(m)$. As can be seen, it increases sizably with m. The origin is due to spin correlations. When these are turned off in the correlation calculation, the resulting quantity $I_2(m)$ no longer displays m dependencies. Spin correlations are most relevant in the nonmagnetic state and die out in the full magnetic limit. Also contained in the figure is the quantity $I_3(m)$ which is obtained when all interaction contributions originating from J are treated in the HF approximation.

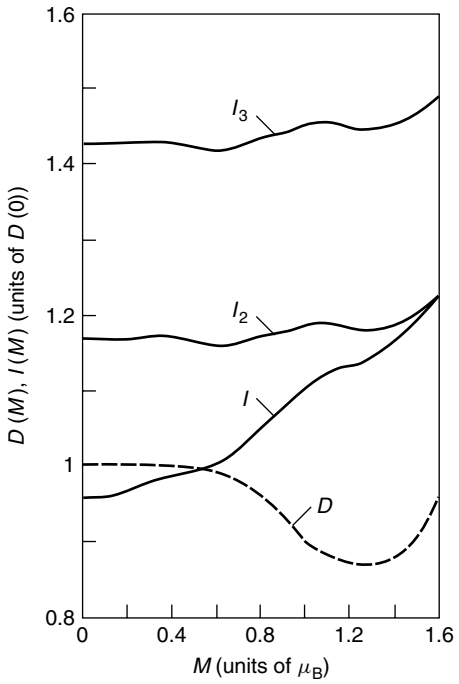

Figure 7. Kinetic energy loss function $D(M)$ in comparison to the Stoner parameter $I(M)$, obtained correctly (I), without inclusions of spin correlations I_2, and without any correlation corrections for the J contributions, I_3. (Reproduced with permission from fig. 3 in G. Stollhoff, A. M. Oles, and V. Heine: 'Stoner exchange interaction in transition metals', *Phys. Rev. B* **41**, 7028 (1990), copyright © 1990 by the American Physical Society.)

This proper treatment of Hund's rule effects which corrects the Stoner parameter, strongly contrasts to fictitious disordered local moments that result from a locally symmetry broken HF treatment of the exchange interaction. If such local moments existed in reality, then they would from the beginning prefer to order and to enhance the kinetic energy of the electrons.

The effect seen here is a quasi 'antidisordered' local moment effect. It definitely squeezes Co into a first-order magnetic phase transition. The nonmagnetic ground state for Co is even metastable at $T = 0$. It requires a polarization beyond a critical size to destabilize it toward the ground state. Consequently, we would expect that the LSDA value for the transition temperature is not only overestimated due to a missing correlation correction of the kinetic energy loss, but that the true first-order transition is considerably below that corrected quantity. We have not performed thermodynamic estimates but it looks as if the experimental T_c for Co might be reached this way. Our original choice of U for Co (Oleś and Stollhoff, 1984) had been motivated by the wish to bring Co close to a second-order phase transition.

Where Ni is concerned, our results indicate a strong reduction of the magnetic energy in comparison to LSDA. For this case, a proper thermodynamic treatment has been made in DMFT (Lichtenstein, Katsnelson and Kotliar, 2001). The Hamiltonian was very close to the one that we used, and here also a local mean field or Stoner theory was applied. The outcome was a T_c slightly above the experimental value. Also the critical spin fluctuations due to Stoner enhancement just above T_c were in good qualitative agreement with experiment. Corrections by spin-wave fluctuations that were disregarded in the DMFT calculations are definitely of relevance but have apparently little effect. One should remember, though, that the values of the interaction U are not unambiguously fixed for the Ni-model calculations. The agreement of the DMFT calculations and experiment might originate in part from a value for U that is slightly too small. On the other hand, there is again the trend that $I(m_0)$ is 20% larger than $I(m)$ (Stollhoff, Oleś and Heine, 1990), in part due to the spin correlations, and in part due to a small reduction of the change in $D(m)$. Since these two corrections are missing in LSDA calculations, one would expect that the true Stoner T_c is considerably smaller than the LSDA T_c.

For Fe, relative changes in the partial n_{e_g} and $n_{t_{2g}}$ occupations with magnetization arise as artifacts of the five-band model. These cause an enhancement of $I_{SCF}(m)$ for small m. Being only partly screened by correlations, this partially compensates the above mentioned corrections for small m. Nevertheless, a reduction of the magnetic energy by half was still found (Stollhoff, Oleś and Heine, 1990). However, this should, due to the pathology of the Fe density of states, only lead to a reduction of T_c by less than half (Gunnarsson, 1976). The DMFT calculation for a nine-band Hamiltonian for Fe produced a T_c of 2000 K (Lichtenstein, Katsnelson and Kotliar, 2001), which is unsatisfactory. Here, the interactions were unambiguously fixed, and the deficiencies of the five-band model should not occur.

Thus Fe is the only case that still poses a major problem. There are two possible scenarios for its solution: either the phase transition in Fe is not at all correctly described by a Stoner-like picture but rather by spin-wave fluctuation theories (for the earliest ones, see Korenman, Murray and Prange, 1977; Capellmann, 1974, 1979), or alternatively the starting point, the rigid band system derived from LSDA together with local Hubbard interactions is insufficient. Very recently, we obtained evidence (Stollhoff, unpublished) that the latter case holds true. Its discussion is necessary for an understanding of the limits of a Hubbard-model treatment but goes beyond the original scope of this contribution. It will therefore be shortly addressed at the end.

5.4 Anisotropic exchange splitting for Ni

For ferromagnetic Ni, an interesting anisotropy occurs. The majority bands are completely filled. The charge in

the minority bands is not equally distributed among the different 3d orbitals, but charge is missing almost exclusively from the t_{2g} orbitals which form the most antibonding band states. This anisotropic charge distribution is to a smaller amount already present for the nonmagnetic state without interaction (occupations of 0.98 or 0.92 for the e_g and t_{2g} orbitals, respectively). In the SCF approximation, already for the nonmagnetic state, an anisotropic crystal field exists. Even more interesting, for the ferromagnetic state, an anisotropic exchange splitting builds up. With exchange splitting, we refer to the difference between majority and minority crystal-field terms. In the SCF approximation, it holds for the splitting $\Delta_{\mathrm{SCF}}(i)$ (with terms in the Hamiltonian ΔJ disregarded)

$$\Delta_{\mathrm{SCF}}(i) = (U + J)(n_{i\uparrow} - n_{i\downarrow}) + Js_z \tag{41}$$

where

$$s_z = \sum_i (n_{i\uparrow} - n_{i\downarrow}) \tag{42}$$

While the second term is isotropic and amounts to 0.4 eV for Ni, the first one contributes a splitting of 0.7 eV only for the t_{2g} orbitals.

With correlations, the interaction effects are partially screened. Also, a single-particle potential is no longer unambiguously defined. We obtained approximate values from our ground-state calculations by keeping the correlation operators restricted to two-particle excitations, and by energy optimizing correlated states starting from different single-determinant trial states that were each generated with particular exchange splittings. The optimal trial state determined the ground-state exchange splitting. We obtained for Ni exchange splittings of $\Delta_{\mathrm{corr}}(e_g) = 0.15\,\mathrm{eV}$ and $\Delta_{\mathrm{corr}}(t_{2g}) = 0.57\,\mathrm{eV}$ (Oleś and Stollhoff, 1984). Actually, here interaction terms ΔJ contributed. Without them, the splittings would be 0.27 and 0.50 eV, respectively. These changes indicate a screening of the J contributions by almost half, and of the U contributions by more than half. Exchange splittings from LSDA come out isotropic and amount to 0.6 eV.

These anisotropies were measured in angle-resolved photoemission experiments (Eastman, Himpsel and Knapp, 1978; Eberhardt and Plummer, 1980) and came out as 0.1 or 0.4 eV, respectively. The agreement with our values is good particularly, if one takes into account that we computed our splitting for non-renormalized bands while in photoemission experiments the 15–20% mass renormalization due to many-body effects is included (Eastman, Himpsel and Knapp, 1980; Cooke, Lynn and Davis, 1980).

Many-body calculations for quasiparticle properties had actually been done before for a five-band Hamiltonian with very similar interactions (lacking the ΔJ contributions). This calculation was based on the Kanamori t-matrix approximation and had obtained splittings of 0.21 and 0.37 eV, with which our results agreed well. That computation had not only obtained the anisotropic splitting but also reasonable band renormalizations of 15% and even the experimentally seen shake-up peak (Liebsch, 1979, 1981). Very recently, ground-state calculations for a Hamiltonian similar to ours were performed, this time again within the $R = 0$ approximation but for a nine-band model Hamiltonian, and by a full CI calculation. The agreement for the exchange splitting was again very good (0.16 and 0.38 eV), but this time also relativistic contributions were included, and the experimental Fermi surface was reproduced with high quality (Bünemann *et al.*, 2003). Here, the anisotropic exchange splitting plays a big role, and the Fermi surface of the LSDA is false.

In the computations, such anisotropies in the exchange splitting did not show up for Co, but we found them for Fe. In Fe, the e_g orbitals carry a larger moment because the majority states are completely filled, but the minority bands are less populated than the t_{2g} analogs. We had found splittings of $\Delta(e_g) = 1.74\,\mathrm{eV}$ and $\Delta(t_{2g}) = 1.30\,\mathrm{eV}$. LSDA calculations obtain an isotropic splitting of 1.55 eV, and experiments obtain 1.45 eV (Eastman, Himpsel and Knapp, 1980) but cannot resolve an anisotropy.

6 INTERACTION PARAMETERS U

It is of interest to compare the interaction parameters U obtained for Fe to Ni to parameters obtained by other means, and to try to gain a more global understanding. Figure 8 contains these parameters as functions of the band filling.

Spectroscopy experiments for transition-metal impurities in noble metals were interpreted with the help of atomic interactions (van der Marel and Sawatzky, 1988). The values of the resulting quantity, U (or F_0, as it is called in van der Marel and Sawatzky, 1988), are given in Figure 8, too. They are in very good agreement with the values of U obtained by the LA, in particular, if one considers the different environments. This indicates that the screening patterns must be similar, and must also originate from the 4s, 4p orbitals on the one hand, or from the 5s, 5p orbitals on the other. In the impurity case, results exist for a whole range of transition metal impurities. The maximal reduction is obtained for the half-filled case (Cr) with $U = 0.9\,\mathrm{eV}$ taken from spectroscopy results, while for less then half-filling, the interaction increases again (van der Marel and Sawatzky, 1988).

The occupation dependence of U can be understood with the help of a residual neighbor electron interaction V.

It has been worked out before for a single-band model (Stollhoff, 1995b), how a Hamiltonian with on-site and

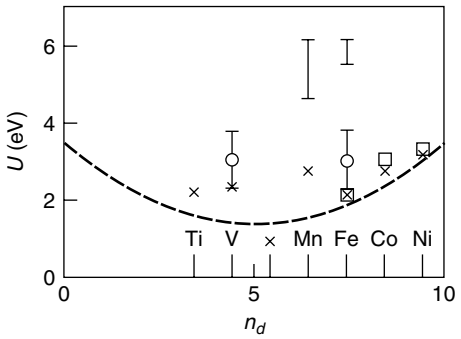

Figure 8. Values of the interaction U, obtained for different transition metals as a function of band filling. The values obtained by the LA are given as squares, the ones obtained from core spectroscopy (van der Marel and Sawatzky, 1988) are given by crosses. The full curve indicates the occupation dependence when a residual neighbor interaction V is included. Bars with circles indicate estimates of U, obtained from *ab initio* LA calculations (Stollhoff, unpublished), bars without circles estimates from frozen charge approximation computations (Anisimov and Gunnarsson, 1991; Drchal, Gunnarsson and Jepsen, 1991).

neighbor interactions,

$$H_{\text{int}} = U_0 \sum_i n_\uparrow(i) n_\downarrow(i) + \frac{V}{2} \sum_{(i,j)} a^\dagger_\sigma(i) a^\dagger_{\sigma'}(j) a_{\sigma'}(j) a_\sigma(i) \tag{43}$$

can be mapped into the Hubbard interaction $H_{\text{int}} = U \sum_i n_\uparrow(i) n_\downarrow(i)$. The sum over (i, j) runs over the z nearest neighbors j for each atom i. Here, it is implicitly assumed that all longer-range interactions are equal to zero. For the Hamiltonian with only on-site interactions, the only meaningful response to the interaction can be condensed into the expectation value $\langle n_\uparrow(i) n_\downarrow(i) H_{\text{int}} \rangle$. It is therefore plausible to choose U so that it yields the same response as the pair U_0, V. Assuming for Ψ_0 the following relations for the single-particle density matrix, $P(0) = \langle |n_\sigma(0)| \rangle = n$, $P(0, l) = \langle |a^\dagger_\sigma(0) a_\sigma(l)| \rangle \simeq p$ for (l) nearest neighbors, and zero elsewhere, one obtains

$$\langle |\overline{n_{i\uparrow} n_{i\downarrow}} H_{\text{int}}| \rangle = U_0((n(1-n))^2 + zp^4) - 2Vzn(1-n)p^2 \tag{44}$$

and

$$U = U_0 - \frac{2Vzn(1-n)p^2}{(n(1-n))^2 + zp^4} = U_0 - \alpha V \tag{45}$$

The parameter U depends therefore on band filling as well as on the number of nearest neighbors. For almost empty bands, it holds that $p \simeq n$ since $k_{\text{F}} \ll 1/(|\vec{R}_i - \vec{R}_j|)$ and consequently $U \simeq U_0$. At half-filling, it holds from $P^2 = P$, that $n \simeq n^2 + zp^2$ and therefore $\alpha = 2z/(z+1)$. For almost completely filled bands it holds that $\alpha \sim \delta n$, where δn represents the number of holes. The curve drawn into Figure 8 is based on an $U_0 = 3.5\,\text{eV}$ and a $V = 1.2\,\text{eV}$. It is deliberately put 0.5–1.0 eV below the data points. Apparently, a pair of interactions $U = 4.2\,\text{eV}$, $V = 1.2\,\text{eV}$ can replace the so far independent terms for the specific elements.

Accepting such a residual interaction V for the transition metals resolves a further problem. The LDA bandwidth for transition metals is known to roughly agree with experiment for Fe but to be too large for Co and Ni (Cooke, Lynn and Davis, 1980; Eastman, Himpsel and Knapp, 1980). The latter deficiency has been understood to arise from correlations caused by the on-site interactions (Liebsch, 1979). From model calculations with the LA (Oleś and Stollhoff, 1984; Stollhoff, Oleś and Heine, 1990), it can be deduced that the reduction of the bandwidth δW due to U is similar in all three (!) cases. The apparent discrepancy for the case of Fe can be resolved when a neighbor interaction $V = 1.2\,\text{eV}$ is included. The exchange broadening δW due to V increases the bandwidth of Fe by 10% which partly compensates the correlation correction due to U. The exchange corrections for Co and Ni are smaller since it holds again that $\delta W \sim V \delta n$.

Effective local interactions U were computed from LDA frozen charge calculations for the transition metal Fe and for Mn impurities in Ag (Anisimov and Gunnarsson, 1991; Drchal, Gunnarsson and Jepsen, 1991). They are plotted in Figure 8 as well. Apparently, these results do not depend on band filling. They are of the same size as for the case of Cu with a completely filled 3d band (Anisimov and Gunnarsson, 1991). There, they match experiment. These frozen charge calculations actually computed the interaction costs to bring two electrons together from infinite distance but not the change in interaction from a neighbor site to the same site which is the relevant quantity in a half-filled band system. It is thus not astonishing that frozen charge LDA calculations are unable to treat band filling effects on effective local interactions.

The convolution of a longer-range interaction into an on-site term alone is not sufficient to determine a model U. A model always lacks degrees of freedom that are present in the *ab initio* calculation. If degrees of freedom were removed, then there is an alternative procedure to obtain a residual local interaction U. It is to require that particular correlation properties of the model are identical to the same *ab initio* quantities. Owing to the restriction of the model interaction to atomic terms, the relevant properties are atomic correlations. For the cases discussed here, the proper representative is the change of the atomic charge fluctuations Δn^2. For the model, this quantity was discussed in Section 4.2. Exactly the same quantity can be calculated from *ab initio* calculations. There, atomic orbitals are unambiguously defined, the same operators are included into the correlation calculations, and the same correlation function is available. U is then chosen

so that the model correlation function matches the *ab initio* result. First applications have been presented in Stollhoff, 1995b. From first *ab initio* calculations, correlation functions for V and Fe are available (Stollhoff, unpublished). They lead to values of U that are also included in Figure 8. The big error bars originate from a mismatch of the five-band Hamiltonian to the correct atomic orbitals. We did not want to enter poorly described 3d orbitals with 4s and 4p tails into the *ab initio* calculations. On the other hand, lacking a general tight-binding program, we could not improve the model. Also, in our *ab initio* calculation, we did not treat the very short-range part of the correlation hole well. Thus, our *ab initio* results rather represent an upper limit to the U.

Even for these error bars, the results show that an unambiguous convolution and condensation of the full Coulomb interaction into meaningful model interactions is possible. So far, model interactions were always chosen to fit a model to experiment. We had done so for the transition metals, and had obtained good agreement, but we had encountered other cases where a particular physical effect was incorrectly connected solely to an on-site interaction, and the resulting fit led to a wrong U. The case we have in mind is polyacetylene whose bond alternations also depends on interactions but not solely on a local term U (König and Stollhoff, 1990; Stollhoff, 1995b).

Of interest is also the case of the high-T_c superconducting compounds where we had performed such an analysis (Stollhoff, 1998, 2002).

7 RELATION OF THE HUBBARD-MODEL RESULTS TO THE LSDA

In the previous sections, we had shown how difficult an adequate treatment even of model interactions is. This makes it even more astonishing that LSDA calculations managed to get sizable parts of magnetism correct, in particular, the magnetic moments of the transition metals. To a certain degree this results from the fact that the 3d electrons are not too strongly correlated, and that for the delocalized electrons extended-Hückel features prevail, which the LSDA describes well. This may explain the cases of Co and Ni, where the magnetic moment is maximal, provided the 3d-band occupation is correct.

But as our evaluations have made clear, the correct magnitude of the magnetic moment of Fe required an accuracy that the LSDA cannot possess. Consequently, the correct result can only arise due to a chance compensation of a set of errors. As was shown, the magnetic moment is determined by the Stoner parameter I, which depends equally on the local interactions U and J for fivefold degenerate systems.

Let us first sum up all contributions where U alone is relevant, and connect these to LSDA deficiencies. U dominates the strength of correlations. Owing to it, electrons lose considerably more kinetic or band energy than would be expected for a homogeneous electron gas approximation. This can be seen in the Compton scattering. From the latter, one gets the impression that a treatment based on homogeneous electron gas ideas must miss most of U.

The next topics are binding energies, equilibrium distances, and magnetovolume effect. All transition metals have LSDA binding energies that are too large – actually almost exactly by the amount which is removed by the residual U. Also the equilibrium distances are too short. The LSDA magnetovolume effect is always too large – in part, it can be corrected by effects of the residual U (Stollhoff, Oleś and Heine, 1990; Kaiser, Oleś and Stollhoff, 1988).

Finally, the interaction U causes sensitivities to charge anisotropies. This is relevant for the anisotropic exchange splitting of Ni. Owing to its effect on the Fermi surface, it is basically a ground-state property. LSDA lacks this splitting.

Consequently one may safely conclude that LSDA misses all U contributions, or more cautiously expressed, it reduces U to J (this would avoid attractive interactions). This finding, however, raises a problem. U is very important for the Stoner parameter and for the magnetic moment. Roughly half of the weight in the latter comes from U. Consequently, a second error in connection with J must occur.

J leaves a direct imprint only on a single feature, namely, the m dependence of $I(m)$. Owing to the inclusion of spin correlations, $I(0)$ is typically reduced by 10–20% in comparison to $I(m)$. Sadly, other contributions (in particular, correlation effects due to U cause a magnetic moment dependence too. There is a single exception, Co. LSDA shows no feature like this, but on the other hand, there is not yet experimental evidence for this effect.

It is worthwhile to investigate in more detail how I_{LSDA} is obtained from LSDA calculations. As mentioned before, whenever an LSDA calculation is made, even for atoms, I_{LSDA} has the same value. In the atomic case, LSDA is assumed to describe the Hund's rule ground state, and LDA is usually assumed to describe an average over all possible atomic states. Consequently, I_{LSDA} must describe just the atomic exchange J, and it must do so in a mean-field approximation – no moment without broken symmetry. In this respect, it must behave exactly like a HF theory, or like the incorrect SCF approximation of our model Hamiltonian.

Only if LSDA behaves this way can one understand why it obtains the correct moment for Fe (Stollhoff, Oleś and Heine, 1990, 1996). I depends roughly to equal parts on U and J. Correlations reduce the effects of these terms by 40% from the SCF limit. As a consequence, the error involved in skipping U (or in reducing it to J) is almost

exactly compensated by the error in not correlating J. For magnetism in general, this compensation works only for fivefold degeneracy. The error on the U side is considerably larger than the error on the J side for a single-band system. Consequently the LDA must and usually does underestimate magnetism in general.

This latter deficiency is actually known, as the popularity of more recent 'LDA plus U' approximations demonstrates. Here, a local interaction is added and treated in mean-field approximation to boost magnetism. However, all attempts to generate a kind of compensation within the DF framework to upkeep the correct magnetic moment of Fe have failed. They had to fail because the second error, the one for J is of a different origin and thus independent. Even worse, these two are not the only LDA errors in the transition-metal context as will be demonstrated in the next section.

These findings also call a particular field of LSDA applications into question, namely, all so-called *ab initio* disordered local moment calculations with which one has attempted to correct the false LSDA Stoner theory results. As just derived, these LSDA disordered local moments are nothing but the false and inadequate model disordered local moment approximations for the Hubbard model. The local degrees of freedom generated by either method are artifacts of the approximation and have no connection to reality.

The only meaningful extensions of LDA schemes are like the ones we had made for the first time a quarter century ago (Stollhoff and Thalmeier, 1981; Oleś and Stollhoff, 1984) and like those that are now made in connection with DMFT applications (Lichtenstein, Katsnelson and Kotliar, 2001): to condense the LDA results into a tight-binding Hamiltonian, to connect it to a local model interaction and to perform a careful correlation treatment of the latter.

A problem arises with the charge distributions in the ground state of these models. It is often but not always a good choice to freeze the charge distribution of this state to the one of the LDA input. Counterexamples are the changes in the Fermi surface of Ni that would not show up this way, or the inverse magnetovolume effect of Ni that arises from anisotropic exchange contributions that cause a charge transfer from the 4s, 4p to the 3d orbitals. There are also systems like the high-T_c superconductors where the LDA-charge distribution is wrong (Stollhoff, 1998, 2002). As shown next, the case of Fe is another example where it does not pay off to stay close to LSDA results even for the charge distribution.

8 *AB INITIO* CORRELATION CALCULATIONS FOR Fe

As mentioned before, the model calculations using the LA are only a special application of the original *ab initio* scheme. Here, first results of an *ab initio* calculation for nonmagnetic Fe will be presented in order to contribute to the resolution of the open problem of T_c. We address nonmagnetic Fe because we assume that the ferromagnetic state is rather well reproduced in LSDA. The moment is correct, and also the Fermi surface seems to be in agreement with experiment. The deficiencies in the description of the magnetic phase transition might instead be connected to the nonmagnetic ground state.

Like the nonmagnetic HF ground state and the LDA ground state, the correlated nonmagnetic ground state is theoretically well defined. The only possible problem in the latter case might be that the added correlations allow long-range ferromagnetic patterns, and that in the approximation used the calculations turn instable. We proceeded only up to second nearest-neighbor corrections for the case of Fe, and found no instability up to this range.

The details of the calculation will be given elsewhere (Stollhoff, unpublished). It should just be mentioned that for the HF calculation and the parallel LDA calculation the program Crystal was used (Saunders *et al*., 1998). The basis set quality was of double-ζ quality, and better for the 3d electrons, and the computation was performed at the experimental lattice constant. A first correlation calculation starting from the LDA ground state single determinant worked fine. Although the calculation was performed with the full and unscreened interaction, the electrons in the nine valence orbitals screened each other perfectly. Correlations were as weak as for the model calculation with screened interaction. Note that this time for the 9 fluctuating channels, 45 correlation channels were available.

From the 3d-correlation patterns we could also obtain an estimate on the effective local interactions, as mentioned before. This turned out to be 3 ± 1 eV and was in reasonable agreement with the interaction needed for the Hubbard-model treatment.

The LDA-charge distribution was analyzed using the LA. Within this scheme, precise atomic orbitals are required for correlation purposes. A method had been developed to unambiguously obtain these from the single-particle density matrix $P_{ij}(l, l')$ (Pardon, Gräfenstein and Stollhoff, 1995). For a similar application, see Stollhoff (1998, 2002). The two right columns of Table 3 contain our charge analysis in comparison to a standard tight-binding fit (Papaconstantopoulos, 1968). There is good agreement, except a small charge transfer from the 4p orbitals into the 3d orbitals in the case of the fit. We assume that this occurs because for the fit, the completely empty 4p bands needed to be included which probably hybridize with the 4d bands. This apparently has an effect on the resulting charge distribution. In our numerical determination, only the occupied part of the bands was of relevance. The occupation anisotropy $\Delta = n_{t_{2g}} - n_{e_g}$ which is most relevant comes out the same.

Table 3. Charge distributions for bcc nonmagnetic Fe. Given are values for the HF, LA, and LDA calculations. Also values of a LDA tight-binding fit (Papaconstantopoulos, 1968) are included.

Orbital	HF	LA	LDA	LDA(tbf)
4s	0.272	0.273	0.288	0.29
4p	0.203	0.173	0.163	0.06
3d(t_{2g})	0.966	0.715	0.678	0.73
3d(e_g)	0.100	0.542	0.611	0.66
Δ	0.866	0.173	0.067	0.07

While performing the HF calculation, a very different charge distribution was obtained. The 4s- and 4p-orbital occupations did not change but a complete charge rearrangement occurred for the 3d orbitals. The t_{2g} orbitals were almost completely filled, and the e_g orbitals almost empty. This charge distribution is definitely incorrect. It would never deliver the required sizable binding energy contributions of the 3d bands. The values for the true ground state are also given. In particular Δ is considerably closer to the LDA value.

This charge transfer represented by Δ is originally not connected to on-site interactions. Neither did our correlation calculation based on the LDA ground state show instabilities toward a charge transfer, nor had the earlier model calculations given any hint for such a behavior.

Rather, this charge transfer is due to a quantity that has been almost completely disregarded in the past: the nonlocal exchange. The long-range exchange contributions per site are formally of the form

$$\Delta E_{\text{exch}} = -\sum_{ijl} V(i,0;\,j,l)\,P_{ij}(0,l)^2 \tag{46}$$

Here, V is the Coulomb-interaction term between orbital i on site 0 and orbital j on site l, and $P_{ij}(0,l)$ the corresponding density matrix that was introduced above. For the density matrix of a single-determinant state, the following sum rule applies

$$\sum_{jl} P_{ij}(0,l)^2 = n_i \tag{47}$$

As a consequence, delocalization pushes weight from neighbor terms into longer-range terms and costs considerable exchange energy. The amount is related to the size of long-range fluctuations and depends strongly on the density of states $n(E_{\text{F}})$. The latter, and even more the peak structure around it, is very large for nonmagnetic Fe and is extremely costly in exchange energy. The peak structure is formed by antibinding e_g and t_{2g} orbitals. For the only nonlocal contribution to the LDA calculation, the kinetic energy, this peak is apparently irrelevant, but adding only a small part of the nonlocal exchange immediately starts to separate the different contributions. The e_g orbitals are pushed up, and the t_{2g} orbitals are pushed down. When computed using the LDA, then the big charge transfer toward the LA ground state costs less than 0.1 eV per atom in energy. This is negligibly small in comparison to the binding energy and still smaller than the magnetization energy. However, 1.5 eV are gained from the full exchange, and 0.3 eV remain when the latter is screened. The ground-state charge distribution is then further influenced by the strong spin correlations between the e_g electrons forming when these reach half-filling.

The most relevant quantity in our context is the resulting density of states. The LDA total density of states (summed over spins) and the one of the LA ground state are given in Figure 9. As can be seen, the LDA peak close to the Fermi energy splits and is shifted to both sides of it. $n(e_{\text{F}})$ is reduced from 3.2 to 1.1 eV^{-1}. It becomes so small that the Stoner criterion is no longer fulfilled. Consequently, there is a true metastable nonmagnetic bcc ground state for Fe, and the magnetic phase transition is of first order. Thus it is no wonder that there has been no chance to obtain a reasonable transition temperature starting from the unphysical nonmagnetic ground state of the LDA. The instability of the LDA state is such that already an admixture of only 5% of nonlocal exchange is sufficient to reduce the density of state at the Fermi energy by half.

These nonlocal exchange effects create a general trend toward weak localization. In Fe, they can act without symmetry breaking, but for single-band systems they would enter mostly via a symmetry lowering charge-density wave instability.

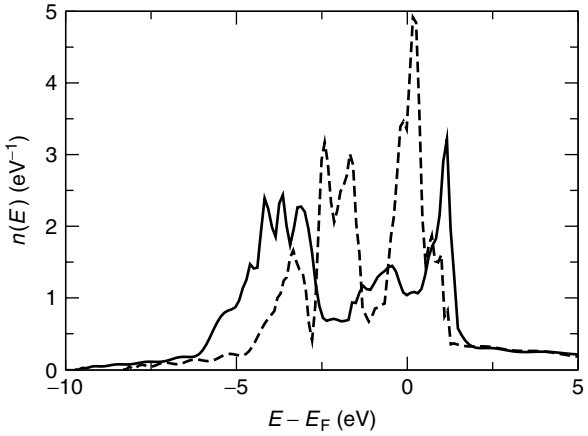

Figure 9. Total density of states $n(E)$ for bcc nonmagnetic Fe, obtained in LDA (dotted line) and by the LA (full line). E_{F} is set to zero for both cases.

The LA density of states indicates a widening of the 3d bands by 1.0 eV. It has been obtained from a single-particle calculation with such a fraction of the nonlocal exchange added that the correct charge distribution was reproduced. Neither this density of states nor the original LDA density of states contain any mass enhancements due to further many-body contributions. The latter should amount to 15–20% and shrink the bandwidths accordingly.

Sadly, no experimental information about the density of states above the magnetic transition temperature is available. They might immediately verify our results since these differ strongly from LDA, and also from the ferromagnetic results obtained either experimentally or in LSDA. There is no strong peak just below the Fermi energy either, as it originates from the majority states in the ferromagnetic case.

There is an experiment, though, that can be explained by these new results: the measurements of the unoccupied Fe energy bands (Kirschner, Gloebl, Dose and Scheidt, 1984).

For this purpose, the energy bands of the LDA and of the LA ground state are presented in Figure 10.

The full lines represent the LA case, and the dotted lines the LDA case. This time, the LA bands have been renormalized so that the occupied width matches the LDA case, in order to facilitate comparison. The renormalization factor is 0.8, and may be deduced from Figure 9. As can be seen, nonlocal exchange has pushed the bands with e_g-character around E_F roughly 1 eV above E_F, while bands with t_{2g} character are a little lowered (around the H and N points). This explains the changes in the density of states.

It is of interest to compare the energy bands of the true nonmagnetic state with the ones of the ferromagnetic ground state. The latter can be derived from the LDA bands by either an upward shift by 1 eV for the minority bands or a downward shift by the same amount for the majority bands. As a consequence, the unoccupied minority bands are almost exactly where the corresponding nonmagnetic bands are. An exception is the H point where minority and majority bands enclose the nonmagnetic band asymmetrically.

With temperature increasing toward T_c, the unoccupied minority bands are therefore expected to stay in place while the bands around the H points are shifted. This is exactly what has been measured. The unoccupied minority and majority bands around the H point are shifted towards a center position, the former slightly more. The minority bands measured in the vicinity of the P point and in between N and P points did not shift at all, however (Kirschner, Gloebl, Dose and Scheidt, 1984). These experiments fully confirm our results for the nonmagnetic ground state.

So far, the experimental results have been interpreted differently. It has been speculated that parts of the magnetic order do not break down when T_c is reached, and that certain directions in momentum space might keep a magnetic memory for some unknown reasons. It would be worthwhile to reanalyze the experimental data and also to extract how the majority bands become unfilled and jump towards the true nonmagnetic bands.

The proper computation of the first order phase transition remains a topic to be adressed in the future. On the model level, this would imply the inclusion of at least neighbor interactions,

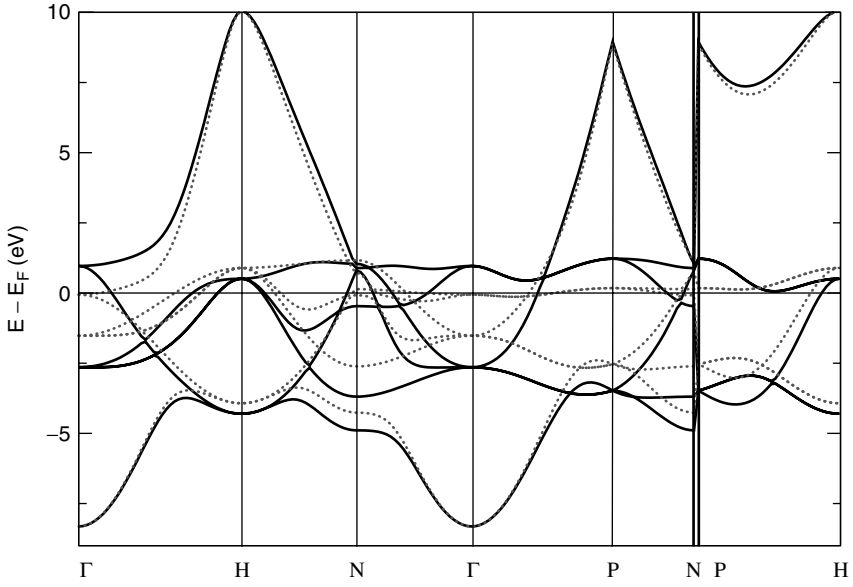

Figure 10. Energy bands of nonmagnetic bcc Fe from the LDA calculation (dots) and from the LA calculation (full lines). The occupied bandwidth of the latter bands is renormalized to the one of the LDA bands.

and is definitely out of the range for the present DMFT. Further speculations on giant spin fluctuation theories should be put on hold, however, because it is very probable that they will never be needed for Fe, either.

We do not expect that nonlocal exchange contributions play a role for the ferromagnetic ground state of Fe, except for a certain band widening as discussed above (this is also why we have rescaled the LA bands to the LDA bands in Figure 10). $n(E_F)$ is already rather low for the ferromagnetic case. The role of nonlocal exchange contributions shrinks further when dealing with more strongly occupied bands as for Co and Ni. Also, there is no peak in the density of states at the Fermi energy in these systems that might be removed.

On the other hand, we expect that these nonlocal exchange contributions play a significant role for the Fe compounds. It is known that the LSDA usually does not treat these correctly, but it does so without an apparent systematic trend. The Fe–O compounds come out more magnetic in reality than using the LSDA while for the Fe–Al compounds the inverse holds true. In all these cases, there is a sizable crystal field that Fe itself lacks. This would make these compounds even more susceptible to a charge redistribution and accompanying weak localization than Fe itself.

There is not only a competition between nonmagnetic and magnetic states for the transition metals, but also one between more or less weakly localized states. While the interactions behind the former competition are U and J, the ones behind the latter are V.

9 CONCLUSION

The aim of this work has been to present theoretical achievements in the computation of multiband Hubbard models for transition metals. Luckily, this application turned out to be sufficiently remote from any kind of Mott–Hubbard transition so that currently well-controlled weak-correlation expansions could be used. As a consequence, we can be certain that a model and not a deficiency in the treatment is responsible if we do not match experiment. We could exclude a strong correlation scenario for a set of experimental findings, but the strongest argument against this scenario is the not fully magnetized ground state of Fe.

This weak-correlation scenario also made it possible to connect with LSDA calculations, and to analyze and explain a set of errors, even failures of the latter method.

Our findings indicate the seeming success of LSDA for the magnetism of the transition metals is basically due to a chance compensation of two big errors, an overscreening of U on the one hand, and a mishandling of the atomic exchange interaction J in a mean-field approximation on the other.

We have shown that these model interactions are of very similar size when obtained from fits to different experiments, and that it is even possible to understand the trend among these values for different transition metals. This indicates that these model interactions are more meaningful quantities than just fitting parameters. We have also given an indication of how these parameters will, in the future, be directly computed from *ab initio* correlation calculations using the LA.

On the model level, a set of different properties could be understood. Also with the help of more extensive CI calculations (Bünemann *et al*., 2003), and in particular, thanks to quasiparticle calculations using the DMFT (Lichtenstein, Katsnelson and Kotliar, 2001), a basic understanding has finally been reached of the problems that had been raised half a century ago (Stoner, 1938; van Vleck, 1945; Wohlfarth, 1949; Gutzwiller, 1965; Herring, 1966), and that had been mostly put aside in the last 40 years as far as the DF approach was concerned.

We now know that the magnetic phase transition of the transition metals can basically be described following the ideas of Stoner and Wohlfarth, and that the electrons stay almost completely delocalized. We also know that orbital degeneracy plays the most important role in this context, and that the atomic exchange interaction is of great importance.

A very surprising twist is that for the magnetism of Fe, also residual nonlocal interactions seem to be relevant. There has been earlier evidence that they are present in Fe, originating from trends in the dependence of U on the individual atoms, and from matches and mismatches of theoretical and experimental photoemission results. These nonlocal interaction contributions lead to big changes of the LDA results for the nonmagnetic ground state, although those latter results were and still are the basis of a satisfying description of the ferromagnetic ground state.

All these findings demonstrate how important it is to understand and to treat the interactions of the electrons directly. It is an advantage of the LA that the correlation treatment does not disappear within the black box of a numerical program but that all different correlation details can be obtained directly and understood. One aim of this contribution was to present, with the help of the LA, a lucid and understandable decomposition of the complex many-body world.

Dynamical Mean-field Theory of Itinerant Electron Magnetism

Alexander I. Lichtenstein[1] and Mikhail I. Katsnelson[2]

[1] *Universität Hamburg, Hamburg, Germany*
[2] *Radboud University Nijmegen, Nijmegen, The Netherlands*

1 INTRODUCTION

The theory of electronic structure and magnetism of solids has historically been split into two distinct parts, namely, the model investigations of many-body effects and the calculations of the energy spectra and properties of specific compounds in the framework of density functional theory (DFT) (Hohenberg and Kohn, 1964; Kohn and Sham, 1965; Jones and Gunnarsson, 1989). Recently, within the dynamical mean-field theory (DMFT, for a review see Georges, Kotliar, Krauth and Rozenberg, 1996) correlation effects have been incorporated into realistic electronic structure calculations (Anisimov *et al*., 1997; Lichtenstein and Katsnelson, 1997, 1998; Katsnelson and Lichtenstein, 1999, 2000; Chitra and Kotliar, 2000; Held *et al*., 2001b; Lichtenstein and Katsnelson, 2001; Lichtenstein, Katsnelson and Kotliar, 2002; Savrasov and Kotliar, 2004; Kotliar and Vollhardt, 2004). This method has been successfully applied to a number of classical problems of solid state physics such as the finite-temperature magnetism of iron group metals (Lichtenstein, Katsnelson and Kotliar, 2001), $\alpha - \delta$ transition in plutonium (Savrasov, Kotliar and Abrahams, 2001), and electronic structure of doped Mott insulators (Held *et al*., 2001a). In contrast with the standard DFT scheme, in this new approach known as *local density approximation* (LDA)+DMFT (Anisimov *et al*., 1997; Lichtenstein and Katsnelson, 1997, 1998), the total energy of the system (or, more accurately, thermodynamic potential Ω) is considered as a functional of the local Green function instead of the density matrix (Katsnelson and Lichtenstein, 2000; Chitra and Kotliar, 2000; Lichtenstein and Katsnelson, 2001; Lichtenstein, Katsnelson and Kotliar, 2002; Savrasov and Kotliar, 2004). To stress this new feature more explicitly, we will use the term *spectral density functional* (SDF). The analytical properties of the Green function guarantee that the knowledge of the spectral density is equivalent to the knowledge of the time-dependent Green function whereas, the density matrix is just the static value of the latter (Abrikosov, Gorkov and Dzyaloshinski, 1975). Here we will describe the basic ideas of the SDF method, both in the framework of standard DMFT and from a more general point of view, and consider the applications of SDF to the correlation effects and

magnetism in transition metals and other itinerant-electron magnets.

2 REALISTIC DESCRIPTION OF MAGNETIC CRYSTALS USING DYNAMICAL MEAN-FIELD THEORY

2.1 LDA+DMFT: general considerations

In order to calculate the electronic structure of strongly correlated systems, we have to solve a complicated many-body problem for a crystal corresponding to the inhomogeneous gas of interacting electrons in an external periodic potential. To this aim, the original problem is split into effective *one-particle* problem for the crystal (in DFT approach this is the Kohn–Sham equation, Hohenberg and Kohn, 1964; Kohn and Sham, 1965; Jones and Gunnarsson, 1989) and a many-body problem for some appropriate auxiliary system (for LDA to DFT this is a homogeneous electron gas). Since intra-atomic electron correlations are the strongest and the most important for local-moment formations in metals, we will use DMFT approach as a best local approximation. The DMFT scheme (Georges, Kotliar, Krauth and Rozenberg, 1996) maps the interaction lattice models into *quantum impurity* models (see Figure 1) subject to a self-consistency condition. This quantum impurity is an atom in a self-consistent effective medium. In this sense, the DMFT approach is complementary to the LDA stressing from the beginning atomic-like features in the electronic structure. The resulting many-body multi-orbital impurity problem can be solved by various rigorous approaches (Quantum Monte Carlo (QMC), exact diagonalization, etc.) or by approximate schemes such as iterated perturbation theory (IPT), local fluctuating exchange (FLEX) approximation, or noncrossing approximation (NCA) (Georges, Kotliar, Krauth and Rozenberg, 1996; Lichtenstein and Katsnelson, 1997, 1998; Held *et al*., 2001b; Lichtenstein and Katsnelson, 2001; Lichtenstein, Katsnelson and Kotliar, 2002).

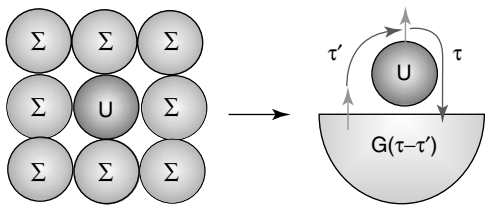

Figure 1. Mapping of the lattice model to the quantum impurity model in the dynamical mean-field theory: the local self-energy one can be obtained from the solution of one correlated site in effective time-dependent fermionic bath $\mathcal{G}(\tau - \tau')$.

In this section, we describe LDA+DMFT approach for the electronic structure calculations. The method was first applied in a simplified one-band approximation to $La_{1-x}Sr_xTiO_3$ (Anisimov *et al*., 1997) which is a classical example of a strongly correlated metal. A general formulation of LDA+DMFT, including the justification of the effective impurity formulation in multiband case has been proposed in Lichtenstein and Katsnelson (1997, 1998) and applied to iron in Katsnelson and Lichtenstein (1999, 2000).

The simplest way to develop the LDA+DMFT scheme is to start with the band-structure approach where an explicit tight-binding Hamiltonian exist, such as a first-principle linear muffin-tin orbital (LMTO) tight-binding method (Andersen, 1975; Andersen and Jepsen, 1984):

$$H_0 = \sum_{ilm,jl'm',\sigma} (\epsilon_{il}\, n_{ilm\sigma}\delta_{ilm,jl'm'} + t_{ilm,jl'm'}\, c^{\dagger}_{ilm\sigma}\, c_{jl'm'\sigma}) \tag{1}$$

where i is site index, lm are orbital indices and σ is spin index, c^+, c are the Fermi creation and annihilation operators ($n = c^+c$); ϵ_{il} are orbital energies and $t_{ilm,jl'm'}$ are hopping matrix elements. Note that the DMFT approach was also implemented in the full-potential LMTO method (Savrasov and Kotliar, 2004) and in multiple-scattering methods such as exact muffin-tin orbital (EMTO) (Chioncel *et al*., 2003b) or Korringa–Kohn–Rostoker (KKR) (Minár *et al*., 2005) schemes.

The LDA one-electron potential (Kohn–Sham potential) is orbital independent and the Coulomb interaction between d-electrons is taken into account in this scheme in an averaged way. In the LDA+DMFT method, as well as in the static limit, which corresponds to LDA+U (Anisimov, Aryasetiawan and Lichtenstein, 1997), this Hamiltonian is generalized for the explicit local Coulomb correlations with the additional interaction term for correlated il shell:

$$H_{int} = \frac{1}{2}\sum_{ilmm'\sigma} U^{il}_{mm'} n_{im\sigma} n_{im'-\sigma} + \frac{1}{2}\sum_{ilm\neq m'\sigma} (U^{il}_{mm'} - J^{il}_{mm'}) n_{im\sigma} n_{im'\sigma} \tag{2}$$

where i is the site index and m is the orbital quantum numbers; $\sigma = \uparrow, \downarrow$ is the spin projection; ϵ and t in equation (1) are effective one-electron energies and hopping parameters obtained from the LDA in the orthogonal LMTO basis set. To avoid double counting of electron–electron interactions one must subtract the averaged Coulomb interaction energy term, which is present in the LDA. In the spirit of LDA+U, we introduce new ϵ^0_d where the d–d Coulomb interaction is excluded. There are few possibilities to subtract the double-counting term coming from average interactions already

taking into account in the LDA: the so-called *fully localized limit* (Anisimov *et al*., 1993; Anisimov, Aryasetiawan and Lichtenstein, 1997) which is suitable for strongly correlated materials and the so-called *around mean field* (Anisimov, Zaanen and Andersen, 1991; Czyzyk and Sawatzky, 1994) which is appropriate for more delocalized systems. We used the first scheme, which corresponds to the following form of subtraction of average atomic Coulomb (U) and exchange (J) interactions

$$\epsilon^0_{d\sigma} = \epsilon_{d\sigma} - U\left(n_d - \frac{1}{2}\right) + \frac{1}{2}J\left(n^\sigma_d - \frac{1}{2}\right) \tag{3}$$

where U and J are the average values of $U_{mm'}$ and $J_{mm'}$ matrices and n_d is the average number of d-electrons.

The screened Coulomb and exchange vertex for the d-electrons are defined as

$$\begin{aligned} U_{mm'} &= <mm'|V_{ee}(\mathbf{r}-\mathbf{r}')|mm'>, \\ J_{mm'} &= <mm'|V_{ee}(\mathbf{r}-\mathbf{r}')|m'm> \end{aligned} \tag{4}$$

Then, the new Hamiltonian will have the following form:

$$\begin{aligned} H &= H_0 + H_{int} \\ H^0 &= \sum_{ilm,jl'm,'\sigma} (\epsilon^0_{il} n_{ilm\sigma}\delta_{ilm,jl'm'} + t_{ilm,jl'm'} c^\dagger_{ilm\sigma} c_{jl'm'\sigma}) \end{aligned} \tag{5}$$

In reciprocal space the matrix elements of the operator H^0 are

$$\begin{aligned} H^0_{qlm,q'l'm'}(\mathbf{k}) = H^{LDA}_{qlm,q'l'm'}(\mathbf{k}) - \delta_{qlm,q'l'm'}\delta_{ql,i_dl_d} \\ \times\left[U\left(n_d - \frac{1}{2}\right) - \frac{1}{2}J\left(n^\sigma_d - \frac{1}{2}\right)\right] \end{aligned} \tag{6}$$

(q is an index of the atom in the elementary unit cell). It is worthwhile to note that the method can also be formulated with a complete rotationally invariant LDA+U Hamiltonian where the interaction is described by complete *four* orbital indices (Lichtenstein and Katsnelson, 1997, 1998; Katsnelson and Lichtenstein, 1999).

One of the main difficulties of standard DFT approach in describing the finite-temperature magnetism is related with the problem of unknown temperature dependence of exchange-correlation potential. In practice, it is not difficult to take into account the Stoner-like temperature effects into the electronic structure calculations via the Fermi distribution function. However, it is well known, that the Bose degrees of freedom such as spin fluctuations are the dominant temperature dependent effects. At the same time both Fermi and Bose excitations can be easily treated in the framework of the SDF using standard many-body Green function approach. For describing the correlations effects in magnets we will use the finite-temperature Matsubara formalism (Abrikosov, Gorkov and Dzyaloshinski, 1975). In the local, frequency dependent, dynamical mean-field theory, the effect of Coulomb correlation is described by the self-energy matrix $\Sigma(i\omega_n)$ in the basis of correlated atomic orbitals. Our main goal within the finite-temperature formalism is to obtain the one-electron Green functions $G_{m,m'}(\tau - \tau') = -\langle T_\tau c^\dagger_m c_{m'}\rangle$ which describe all single particle dynamics of many-body systems (Abrikosov, Gorkov and Dzyaloshinski, 1975). The inverse Green function matrix is defined as

$$\begin{aligned} G^{-1}_{qlm,q'l'm'}(\mathbf{k}, i\omega_n) = (i\omega_n + \mu)\delta_{qlm,q'l'm'} - H^0_{qlm,q'l'm'}(\mathbf{k}) \\ -\delta_{ql,q'l'}\delta_{ql,i_dl_d}\Sigma_{m,m'}(i\omega_n) \end{aligned} \tag{7}$$

where μ is chemical potential, $\omega_n = (2n+1)\pi T$ are the Matsubara frequencies for temperature $T \equiv \beta^{-1}$ ($n = 0, \pm 1, \ldots$) and the local Green function obtained via integration over a Brillouin zone:

$$G_{qlm,q'l'm'}(i\omega_n) = \frac{1}{V_B}\int \mathrm{d}\mathbf{k} G_{qlm,q'l'm'}(\mathbf{k}, i\omega_n) \tag{8}$$

(V_B is the volume of the Brillouin zone).

A so-called *bath Green function* which defines a hybridization with the surrounding crystal in the effective Anderson model and preserves the double-counting of the local self-energy is obtained by a solution of the effective impurity problem (Georges, Kotliar, Krauth and Rozenberg, 1996):

$$\mathcal{G}^{-1}_{m,m'}(i\omega_n) = G^{-1}_{m,m'}(i\omega_n) + \Sigma_{m,m'}(i\omega_n) \tag{9}$$

In the simplest case of massive downfolding to the d-orbital problem, we could incorporate the double counted correction in the chemical potential μ obtained self-consistently from the total number of d-electrons

$$\frac{1}{\beta}\sum_{i\omega_n} e^{i\omega_n 0^+} G(i\omega_n) = N_d \tag{10}$$

Further, one has to find the self-energy $\Sigma_{m,m'}(i\omega_n)$ in terms of the bath Green function $\mathcal{G}_{m,m'}(i\omega_n)$ and use it in the self-consistent LDA+DMFT loop (equations 8 and 9) schematically presented in Figure 2.

2.2 The quantum Monte Carlo solution of the impurity problem

Here we describe the most rigorous way to solve an effective impurity problem using the multiband QMC method

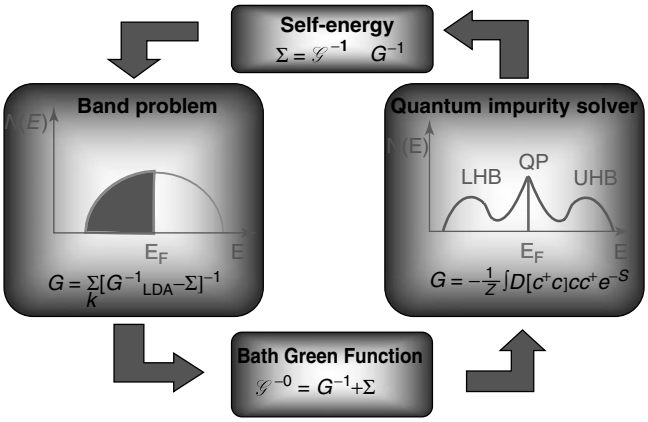

Figure 2. The schematic view of the LDA+DMFT cycle: one can start from a guess for the self-energy, find the local Green function in the electronic structure program, then obtain the effective bath Green function and solve quantum-impurity problem, and then obtain the new self-energy till a self-consistent solution is reached.

(Takegahara, 1993; Rozenberg, 1997). In the framework of the LDA+DMFT, this approach was used first in Katsnelson and Lichtenstein (2000) for the case of ferromagnetic iron. We use the path integral formalism and describe the discrete Hubbard–Stratonovich transformations for calculations of partition functions:

$$Z = \int D[c^{+}(\tau), c(\tau)]e^{-S} \tag{11}$$

and corresponding Green function. In this method, the local Green function is calculated for the imaginary time interval $[0, \beta]$ with the mesh $\tau_l = l\Delta\tau$, $l = 0, \ldots, L-1$, where $\Delta\tau = \beta/L$ ($\beta = \frac{1}{T}$ is the inverse temperature) using the path integral formalism (Georges, Kotliar, Krauth and Rozenberg, 1996). The multi-orbital DMFT problem can be reduced to the general impurity action (see Figure 1):

$$\begin{aligned} S = &- \int_0^\beta \mathrm{d}\tau \int_0^\beta \mathrm{d}\tau' \sum_{i,j} c_i^{+}(\tau)\mathcal{G}_{ij}^{-1}(\tau - \tau')c_j(\tau') \\ &+ \frac{1}{2}\int_0^\beta \mathrm{d}\tau \sum_{i,j} n_i(\tau)U_{ij}n_j(\tau) \end{aligned} \tag{12}$$

where $i = \{m, \sigma\}$ labels both orbital and spin indices (we should remind the reader that we have no site indices since we are now solving the one-site effective impurity problem). Without spin-orbital coupling we have $\mathcal{G}_{ij} = \mathcal{G}^{\sigma}_{m,m'}\delta_{\sigma\sigma'}$.

In the auxiliary fields Green function QMC scheme, one used the discrete Hubbard–Stratonovich transformation introduced by Hirsch and Fye (1986)

$$\begin{aligned} &\exp\left[-\Delta\tau U_{ij}\left(n_i n_j - \frac{1}{2}(n_i + n_j)\right)\right] \\ &= \frac{1}{2}\sum_{s_{ij}=\pm 1} \exp\left[\lambda_{ij}s_{ij}(n_i - n_j)\right] \end{aligned} \tag{13}$$

where $s_{ij}(\tau)$ are the auxiliary Ising fields for each pair of spins, orbitals, and time slices with the strength:

$$\lambda_{ij} = \operatorname{arccosh}\left[\exp\left(\frac{\Delta\tau}{2}U_{ij}\right)\right] \tag{14}$$

Using Hirsch's transformation we can transform the nonlinear action to a normal Gaussian one and exactly integrated out fermionic fields in the path integral (equation 11). Then the resulting partition function and Green function matrix have the following form (Georges, Kotliar, Krauth and Rozenberg, 1996)

$$\begin{aligned} Z &= \frac{1}{2^{N_f L}}\sum_{s_{ij}(\tau)} \det[\widehat{G}^{-1}(s_{ij})] \\ \widehat{G} &= \frac{1}{Z}\frac{1}{2^{N_f L}}\sum_{s_{ij}(\tau)} \widehat{G}(s_{ij}) \det[\widehat{G}^{-1}(s_{ij})] \end{aligned} \tag{15}$$

where N_f is the number of Ising fields, L is the number of time slices, and $\widehat{G}(s_{ij})$ is the Green function of *noninteracting* fermions for a given configuration of the external Ising fields:

$$\begin{aligned} G_{ij}^{-1}(s) &= \mathcal{G}_{ij}^{-1} + \Delta_i\delta_{ij}\delta_{\tau\tau'} \\ \Delta_i &= (e^{V_i} - 1) \\ V_i(\tau) &= \sum_{j(\neq i)} \lambda_{ij}s_{ij}(\tau)\sigma_{ij} \end{aligned} \tag{16}$$

here, we introduce the generalized Pauli matrix:

$$\sigma_{ij} = \begin{cases} +1, i < j \\ -1, i > j \end{cases}$$

For efficient calculation of the Green function $G_{ij}(s)$ for arbitrary configuration of Ising fields one can use the following Dyson equation (Hirsch and Fye, 1986):

$$G' = [1 + (1 - G)(e^{V'-V} - 1)]^{-1}G \tag{17}$$

where V and G are potential and Green function before the Ising spin flip and V' and G' are those after the flip. The QMC important sampling scheme allowed us to integrate over the Ising fields with the modulus of $(\det[\widehat{G}^{-1}(s_{ij})])$

as a stochastic weight (Hirsch and Fye, 1986; Georges, Kotliar, Krauth and Rozenberg, 1996). Using the output local Green function from QMC and input bath Green functions, the new self-energy is obtained via equation (9) and the self-consistent loop can be closed through equation (8) (see Figure 2). The main problem of the multiband QMC formalism is the large number of the auxiliary fields $S^l_{mm'}$. For each time slice l, it is equal to $M(2M-1)$ where M is the total number of the orbitals which gives 45 Ising fields for the d-states case and 91 fields for the f-states. Analytical continuations of the QMC Green functions from the imaginary time to the real energy axis can be done within the maximum entropy method (Jarrell and Gubernatis, 1996).

It is important to emphasize that for the diagonal Green function $G_{ij} = G_i\delta_{ij}$, the determinant ratio is always positive. This means that the sign problem, which is the main obstacle for the application of the QMC method to fermionic problems (von der Linden, 1992), does not arise for this case. Real computational experience shows that even for generic multiband case, the sign problem for the effective impurity calculations is not serious. This means that the QMC solution in the context of DMFT can be considered as a practically exact scheme.

3 SPECTRAL DENSITY VERSUS DENSITY FUNCTIONALS

In the standard DFT approach, the thermodynamic potential Ω^c for noncorrelated conduction – 'c' electrons is represented as a functional of the electron density $\rho(\mathbf{r})$ which is, generally speaking, a matrix in spin indices. Formally it can be represented as a thermodynamic potential of the Kohn–Sham quasiparticles (QPs) (Hohenberg and Kohn, 1964; Kohn and Sham, 1965), Ω_{sp}, minus the contribution of the so-called *double counted* terms, Ω_{dc}:

$$\begin{aligned}
\Omega^c &= \Omega^c_{sp} - \Omega^c_{dc} \\
\Omega^c_{sp} &= -Tr\log[i\omega + \nabla^2/2 - V_{KS}] \\
\Omega^c_{dc} &= \int V_{KS}(\mathbf{r})\rho(\mathbf{r})\,\mathrm{d}\mathbf{r} - \int V_{ext}(\mathbf{r})\rho(\mathbf{r})\,\mathrm{d}\mathbf{r} \\
&\quad -\frac{1}{2}\int \frac{\rho(\mathbf{r})\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\mathrm{d}\mathbf{r}\mathrm{d}\mathbf{r}' - E_{xc}[\rho]
\end{aligned} \tag{18}$$

where $Tr = Tr_{\omega qL\sigma}$, Tr_ω is the sum over Matsubara frequencies $Tr_\omega \ldots = T\sum_\omega e^{i\omega 0^+}\ldots$, $\omega = \pi T\,(2n+1)$, $n = 0, \pm 1, \ldots$, T is the temperature, and $qL\sigma$ are site numbers (q), orbital quantum numbers ($L = l, m$), and spin projections σ, correspondingly, $V_{ext}(\mathbf{r})$ is the external potential, $E_{xc}[\rho]$ is the exchange-correlation energy, and the Kohn–Sham effective potential is defined as

$$V_{KS}(\mathbf{r}) = V_{ext}(\mathbf{r}) + \int \frac{\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\mathrm{d}\mathbf{r}' + \frac{\delta E_{xc}[\rho]}{\delta\rho(\mathbf{r})} \tag{19}$$

In contrast to the standard DFT, the SDF approach deals with the real dynamical QPs for correlated 'd-electrons' defined via the local Green functions rather than with Kohn–Sham 'QPs' which are, strictly speaking, only auxiliary states used to calculate the total energy. Therefore, instead of working with the thermodynamic potential Ω as a *density* functional we start from its general expression in terms of an exact Green function (Luttinger and Ward, 1960; Carneiro and Pethick, 1975; Chitra and Kotliar, 2001; Georges, 2004)

$$\begin{aligned}
\Omega^d &= \Omega^d_{sp} - \Omega^d_{dc} \\
\Omega^d_{sp} &= -Tr\left\{\ln\left[\Sigma - G_0^{-1}\right]\right\} \\
\Omega^d_{dc} &= Tr\,\Sigma G - \Phi
\end{aligned} \tag{20}$$

where G, G_0, and Σ are the exact Green function, its bare value, and self-energy, respectively. Φ is the Luttinger-Ward generating functional (sum of the all connected skeleton diagrams without free lines), correspondingly. A complete SDF thermodynamic potential is equal to $\Omega = \Omega^c + \Omega^d$. We have to also keep in mind the Dyson equation

$$G^{-1} = G_0^{-1} - \Sigma \tag{21}$$

and the variational identity

$$\Sigma = \frac{\delta\Phi}{\delta G} \tag{22}$$

When neglecting the QP damping, Ω_{sp} will be nothing but the thermodynamic potential of 'free' fermions but with exact QP energies. Formal analogy between equations (18) and (20), (19) and (22) are obvious: the self-energy plays the role of the Kohn–Sham potential (without the external potential) and the Green function plays the role of the density matrix. As an example of this correspondence one can prove (Katsnelson and Lichtenstein, 2000), in the framework of the SDF, a useful identity known as the *local force theorem* basically in the same way as it has been done in DFT scheme (Mackintosh and Andersen, 1980; Liechtenstein, Katsnelson, Antropov and Gubanov, 1987). We will use this property in the next section to derive the expressions for exchange parameters in LDA+DMFT (Katsnelson and Lichtenstein, 2000).

4 EFFECTIVE EXCHANGE INTERACTIONS

Let us discuss the problem of calculation of effective exchange interactions (J_{ij}) in correlated systems. In principle, the J_{ij} parameters are not well-defined for arbitrary magnetic systems, and the traditional way to study spin excitations is related to the calculation of nonlocal frequency dependent spin susceptibility (Georges, Kotliar, Krauth and Rozenberg, 1996; Aryasetiawan and Karlsson, 1999; Katsnelson and Lichtenstein, 2004). In this case, the auxiliary space–time dependent magnetic field is added to the Hamiltonian: $\boldsymbol{\sigma}\mathbf{h}(\mathbf{r}, \tau)$ and the second derivative of free-energy with respect to magnetic field gives the interacting spin susceptibility: $\chi^{-1} = \chi_0^{-1} - \Gamma$, where χ_0 is an empty-loop susceptibility and Γ is the vertex corrections (Georges, Kotliar, Krauth and Rozenberg, 1996; Aryasetiawan and Karlsson, 1999). Here we consider a simple approximation of 'rigid spin rotation' of spectral density for a small angle:

$$\delta\mathbf{e}_i = \delta\boldsymbol{\varphi}_i \times \mathbf{e}_i, \tag{23}$$

where $\mathbf{e}_i$ is a unit vector determining general direction of constrained effective spin-dependent potential on site i and $\delta\boldsymbol{\varphi}_i$ is an infinithesimal rotation vector. In this case it is useful to write explicitly the spinor structure of the self-energy and Green functions:

$$\begin{aligned} \Sigma_i &= \Sigma_i^c + \boldsymbol{\Sigma}_i^s\boldsymbol{\sigma} \\ G_{ij} &= G_{ij}^c + \mathbf{G}_{ij}^s\boldsymbol{\sigma} \end{aligned} \tag{24}$$

where $\Sigma_i^{(c,s)} = \frac{1}{2}\left(\Sigma_i^{\uparrow} \pm \Sigma_i^{\downarrow}\right)$, $\boldsymbol{\Sigma}_i^s = \Sigma_i^s\mathbf{e}_i$, $\boldsymbol{\sigma} = (\sigma_x, \sigma_y, \sigma_z)$ are Pauli matrices, $G_{ij}^c = \frac{1}{2}Tr_\sigma(G_{ij})$ and $\mathbf{G}_{ij}^s = \frac{1}{2}Tr_\sigma(G_{ij}\boldsymbol{\sigma})$.

We suppose that the bare Green function G^0 does not depend on spin directions and all the spin-dependent terms including the Hartree–Fock terms are incorporated in the self energy. In the rigid spin approximation we assume that the unit vector $\mathbf{e}_i$ does not depend on the energy, orbital indices and represents the direction of the average local magnetic moment on the site i. Note, that the thermodynamic potential Ω should be considered as a constrained SDF which depends on $\mathbf{e}_i$ as external parameter (cf. Stocks *et al.*, 1998). Then the variation of the thermodynamic potential with respect to small-spin rotation can be written as

$$\delta\Omega = \delta^*\Omega_{sp} + \delta_1\Omega_{sp} - \delta\Omega_{dc} \tag{25}$$

where δ^* is the variation without taking into account the change of the 'self-consistent potential' (i.e., self-energy) and δ_1 is the variation due to this change of Σ. Taking into account equation (22) it can be easily shown (cf. Luttinger and Ward, 1960; Carneiro and Pethick, 1975) that

$$\delta_1\Omega_{sp} = \delta\Omega_{dc} = TrG\delta\Sigma \tag{26}$$

and hence

$$\delta\Omega = \delta^*\Omega_{sp} = -\delta^*\ Tr\ln\left[\Sigma - G_0^{-1}\right] \tag{27}$$

which is an analog of the magnetic 'local force theorem' in the DFT (Liechtenstein, Katsnelson, Antropov and Gubanov, 1987).

In the case of rigid spin rotation the corresponding variation of the thermodynamic potential can be written as

$$\delta\Omega = \mathbf{V}_i\delta\boldsymbol{\varphi}_i \tag{28}$$

where the torque $\mathbf{V}_i$ is equal to

$$\mathbf{V}_i = 2Tr_{\omega L}\left[\boldsymbol{\Sigma}_i^s \times \mathbf{G}_{ii}^s\right] \tag{29}$$

On the basis of the expansion of this expression (29) in a sum of pairwise contributions one can obtain a useful formula for the effective magnetic interactions (Katsnelson and Lichtenstein, 2000):

$$J_{ij} = -Tr_{\omega L}\left(\Sigma_i^s G_{ij}^{\uparrow}\Sigma_j^s G_{ji}^{\downarrow}\right) \tag{30}$$

and, correspondingly, for the stiffness tensor of a ferromagnet:

$$D_{\alpha\beta} = -\frac{2}{M}Tr_{\omega L}\sum_{\mathbf{k}}\left(\Sigma^s\frac{\partial G^{\uparrow}(\mathbf{k})}{\partial k_\alpha}\Sigma^s\frac{\partial G^{\downarrow}(\mathbf{k})}{\partial k_\beta}\right) \tag{31}$$

where M is the magnetic moment per unit cell. These results generalize the LDA expressions of Liechtenstein, Katsnelson, Antropov and Gubanov (1987) to the case of correlated systems. Note that the crucial step from equation (29) to equation (30) is not rigorous, since the exchange parameters are connected with the second variations of the Ω-potential and use of the local force theorem cannot be justified. Relations between the local force theorem and more accurate approach based on the magnetic susceptibility is discussed in Katsnelson and Lichtenstein (2004); Bruno (2003) and Antropov (2003). An alternative approach to the exchange parameters in the context of the LDA+DMFT based on the diagrammatic perturbation theory in the rotation angle (Katsnelson and Lichtenstein, 2002) proves that equation (30) corresponds to the 'empty-loop' approximation neglecting the vertex corrections. At the same time, for the stiffness constant the latter are absent and equation (31) appears to be exact provided that the self-energy and three-point vertex are local (as in the DMFT) (Lichtenstein and Katsnelson, 2001).

5 ELECTRON CORRELATIONS AND FINITE-TEMPERATURE MAGNETISM IN IRON AND NICKEL

We now describe the applications of the SDF approach to the classical problem of finite-temperature magnetism of the iron group transition metals (Lichtenstein, Katsnelson and Kotliar, 2001). Despite a lot of attempts starting from the seminal works by Heisenberg and Frenkel (for review of early theories see e.g., Herring, 1966; Vonsovsky, 1974; Moriya, 1985), we have no complete quantitative theory describing their magnetic and spectral properties. In order to describe the magnetic properties of Fe, Co, and Ni, one has to solve the problem of moderately strong electronic correlations for systems where approaches developed both for weakly correlated systems such as normal group metals and to highly correlated systems such as Mott insulators are not reliable. There were a lot of attempts to introduce correlation effects in the real electronic structure of these metals (Liebsch, 1981; Treglia, Ducastelle and Spanjaard, 1982; Manghi, Bellini and Arcangelli, 1997; Manghi *et al*., 1997; Nolting, Rex and Mathi Jaya, 1987; Steiner, Albers and Sham, 1992). But the question of applicability of specific approximations, such as the lowest order perturbation theory (Treglia, Ducastelle and Spanjaard, 1982; Steiner, Albers and Sham, 1992), moment method (Nolting, Rex and Mathi Jaya, 1987), or three-body Faddeev equations (Manghi, Bellini and Arcangelli, 1997; Manghi *et al*., 1997) is still not clear. On other hand, it has been demonstrated in Lichtenstein, Katsnelson and Kotliar (2001) that the *ab initio* dynamical mean-field theory does give a very successful description of both correlation effects in the electron energy spectra and the finite-temperature magnetic properties of Fe and especially, Ni. Here we present the corresponding results.

We start with the LDA Hamiltonian in the tight-binding orthogonal LMTO representation $H^{LDA}_{mm'}(\mathbf{k})$ (1), where m describes the orbital basis set containing $3d$-, $4s$-, and $4p$-states. The interactions are parameterized by the matrix of the screened local Coulomb interactions and a matrix of exchange constants $J_{mm'}$ (2), which are expressed in terms of two screened Hubbard parameters U and J describing the average Coulomb repulsion and the interatomic ferromagnetic exchange respectively. We use the values $U =$ 2.3 (3.0) eV for Fe (Ni) and the same value of the interatomic exchange, $J = 0.9$ eV for both Fe and Ni, a result of constrained LDA calculations (Bandyopadhyay and Sarma, 1989) and the static limit of GW calculations (Aryasetiawan *et al*., 2004). These parameters, which are consistent with those of many other studies result in a very good description of the physical properties of Fe and Ni.

We used the impurity QMC scheme described in the preceding text for the solution of the multiband DMFT equations. In order to sample efficiently all the spin configurations in the multiband QMC scheme, it is important to use 'global' spin-flips: $[s^{\sigma\sigma'}_{mm'}] \rightarrow [-s^{-\sigma-\sigma'}_{mm'}]$, in addition to the local moves of the auxiliary fields (Lichtenstein, Katsnelson and Kotliar, 2001). The number of QMC sweeps was of the order of 10^5. A parallel version of the DMFT program was used to sample the 45 Ising fields for $3d$-orbitals. We used 256 **k**-points in the irreducible part of the Brillouin zone for the **k** integration. Ten to 20 DMFT iterations were sufficient to achieve convergence far from the Curie point. Owing to the cubic symmetry of the bcc (Fe) and fcc (Ni) lattices, the local Green function is diagonal in the basis of real spherical harmonics. The spectral functions for real frequencies were obtained from the QMC data by applying the maximum entropy method.

Our results for the local spectral function for iron and nickel are shown in Figures 3 and 4, respectively. The SDF approach describes well all the qualitative features of the density of states (DOS), which are especially nontrivial for nickel. Our QMC results reproduce well the three main correlation effects of the one-particle spectra below T_C (Iwan, Himpsel and Eastman, 1979; Eberhardt and Plummer, 1980; Altmann *et al*., 2000): the presence of the famous 6 eV satellite; the 30% narrowing of the occupied part of d-band; and the 50% decrease of exchange splitting compared to the LDA results. Note that the satellite in Ni has substantially more spin-up contributions in agreement with photoemission spectra (Altmann *et al*., 2000). The exchange splitting of the d-band depends very weakly on temperature from $T = 0.6T_C$

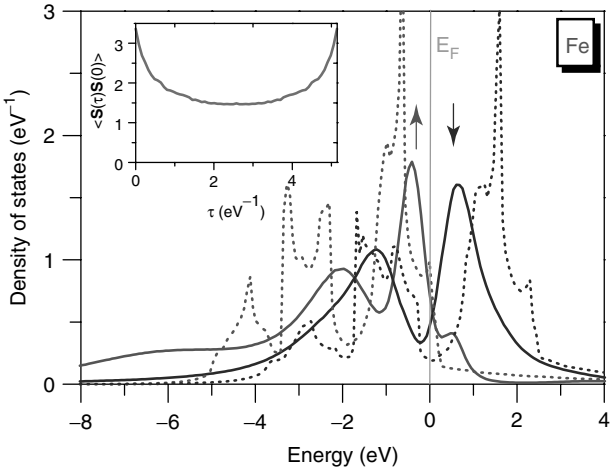

Figure 3. LDA+DMFT results for ferromagnetic iron ($T = 0.8T_C$). The partial densities of d-states (full lines) is compared with the corresponding LSDA results at zero temperature (dashed lines) for the spin-up (arrow up) and spin-down (arrow down) states. The insert shows the spin–spin autocorrelation function for $T = 1.2T_C$.

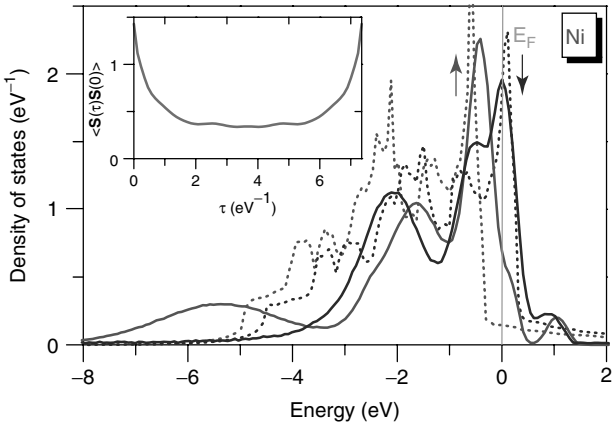

Figure 4. Same quantities as in Figure 3 for ferromagnetic nickel ($T = 0.9T_C$). The insert shows the spin–spin autocorrelation function for $T = 1.8T_C$.

to $T = 0.9T_C$. Correlation effects in Fe are less pronounced than in Ni, due to its large spin splitting and the characteristic bcc structural dip in the DOS for spin-down states near Fermi level, which reduces the DOS for particle hole excitations.

Now we discuss the applications of the SDF approach to the description of finite-temperature magnetic properties of iron and nickel. Although DFT can, in principle, provide a rigorous description of the thermodynamic properties, at present there is no accurate practical implementation available. As a result the finite-temperature properties of magnetic materials are estimated following a simple suggestion (Liechtenstein, Katsnelson, Antropov and Gubanov, 1987), whereby constrained DFT at $T = 0$ is used to extract exchange constants for a *classical* Heisenberg model, which in turn is solved using approximation methods (e.g., random phase approximation (RPA), mean field) from classical statistical mechanics of spin systems (Liechtenstein, Katsnelson, Antropov and Gubanov, 1987; Rosengaard and Johansson, 1997; Halilov, Eschrig, Perlov and Oppeneer, 1998; Antropov *et al*., 1996). The most recent implementation of this approach gives good values for the transition temperature of iron but not of nickel (Pajda *et al*., 2001). Although these localized spin models give, by construction, at high temperatures a Curie–Weiss-like magnetic susceptibility, as observed experimentally in Fe and Ni, they encountered difficulties in predicting the correct values of the Curie constants (Staunton and Gyorffy, 1992).

The uniform spin susceptibility in the paramagnetic state: $\chi_{q=0} = \mathrm{d}M/\mathrm{d}H$ was extracted from the QMC simulations by measuring the induced magnetic moment in a small external magnetic field. It includes the polarization of the impurity Weiss field by the external field (Georges, Kotliar, Krauth and Rozenberg, 1996). The dynamical mean field results account for the Curie–Weiss law which is observed experimentally in Fe and Ni. As the temperature increases above T_C, the atomic character of the system is partially restored resulting in an atomic-like susceptibility with an effective moment:

$$\chi_{q=0} = \frac{\mu_{eff}^2}{3(T - T_C)} \tag{32}$$

The temperature dependence of the ordered magnetic moment below the Curie temperature and the inverse of the uniform susceptibility above the Curie point are plotted in Figure 5 together with the corresponding experimental data for iron and nickel (Wolfarth, 1986). The LDA+DMFT calculations describe the magnetization curve and the slope of the high-temperature Curie–Weiss susceptibility remarkably well. The calculated values of high-temperature magnetic moments extracted from the uniform spin susceptibility are $\mu_{eff} = 3.09\,(1.50)\,\mu_B$ for Fe (Ni), in good agreement with the experimental data $\mu_{eff} = 3.13\,(1.62)\,\mu_B$ for Fe (Ni) (Wolfarth, 1986).

We have estimated the values of the Curie temperatures of Fe and Ni from the disappearance of spin polarization in the self-consistent solution of DMFT problem and from the Curie–Weiss law in equation (32). Our estimates $T_C = 1900\,(700)\,K$ are in reasonable agreement with experimental values of 1043 (631) K for Fe (Ni) respectively (Wolfarth, 1986), considering the single-site nature of the DMFT approach, which is not able to capture the reduction of T_C due to long wavelength spin waves. These effects are governed by the spin-wave stiffness. Since the ratio of the spin-wave stiffness (D) to T_C, $T_C a^2/D$ is nearly a factor of 3 larger for Fe than for Ni (Wolfarth, 1986) (a is the lattice distance), we expect the DMFT T_C to be much higher than the observed Curie temperature in Fe than in Ni. Note that this is a consequence of the long-range oscillating character

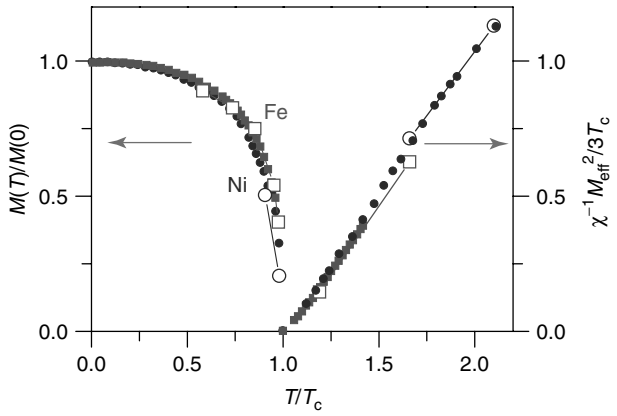

Figure 5. Temperature dependence of ordered moment and the inverse ferromagnetic susceptibility for Fe (open square) and Ni (open circle) compared with experimental results for Fe (square) and Ni (circle).

of exchange interactions in iron compared to short-range ferromagnetic exchange interactions in nickel (Pajda *et al*., 2001). The deeper reason for this difference is the almost half-metallic character of the electron energy spectrum for nickel (with almost complete majority-spin d-band), whereas for well-pronounced Friedel oscillations of the exchange parameters the spectrum should be metallic for both spin projections.

Within DMFT one can also compute the local spin susceptibility defined by

$$\chi_{loc} = \frac{g_s^2}{3} \int_0^\beta \mathrm{d}\tau \, \langle \mathbf{S}(\tau) \, \mathbf{S}(0) \rangle \tag{33}$$

where $g_s = 2$ is the gyromagnetic ratio and $\mathbf{S} = \frac{1}{2} \sum_{m,\sigma,\sigma'} c^\dagger_{m\sigma} \boldsymbol{\sigma}_{\sigma\sigma'} c_{m\sigma'}$ is single-site spin operator. It differs from the $q = 0$ susceptibility, by the absence of spin polarization in the Weiss field of the impurity model. Equation (33) cannot be probed directly in experiments but it is easily computed in DMFT-QMC. Its behavior as a function of temperature, gives a very intuitive picture of the degree of correlations in the system. In a weakly correlated system we expect expression (33) to be nearly temperature independent, whereas in a strongly correlated system we expect a leading Curie–Weiss behavior at high temperatures $\chi_{local} = \mu^2_{loc}/(3T + const)$ where μ_{loc} is an effective local magnetic moment. In the Heisenberg model with spin S, $\mu^2_{loc} = S(S+1)g_s^2$ and well-defined local magnetic moments (e.g., for rare earth magnets), this quantity should be temperature independent. For the itinerant-electron magnets μ_{loc} is temperature dependent due to a variety of competing many-body effects such as Kondo screening, the induction of local magnetic moment by temperature (Moriya, 1985), and thermal fluctuations which disorders the moments (Irkhin and Katsnelson, 1994). All these effects are included in the DMFT calculations. The τ-dependence of the correlation function $\langle \mathbf{S}(\tau) \, \mathbf{S}(0) \rangle$ results in the temperature dependence of μ_{loc} and is displayed in the inserts in the Figures 3 and 4. Iron can be considered as a magnet with very well-defined local moments above T_C (the τ-dependence of the correlation function is relatively weak), whereas nickel is a more itinerant-electron magnet (stronger τ-dependence of the local spin–spin autocorrelation function).

The comparison of the values of the local and the $q = 0$ susceptibility gives a crude measure of the degree of short-range order which is present above T_C. As expected, the moments extracted from the local susceptibility equation (33) are a bit smaller ($2.8\,\mu_B$ for iron and $1.3\,\mu_B$ for nickel) than those extracted from the uniform magnetic susceptibility. This reflects the small degree of the short-range correlations which remain well above T_C (Mook and Lynn, 1985). The high-temperature LDA+DMFT clearly show the presence of a local moment above T_C. This moment is correlated with the presence of high-energy features (of the order of the Coulomb energies) in the photoemission. This is also true below T_C, where the spin dependence of the spectra is more pronounced for the satellite region in nickel than that of the QP bands near the Fermi level (see Figure 4). This can explain the apparent discrepancies between different experimental determinations of the high-temperature magnetic splittings (Kisker, Schröder, Campagna and Gudat, 1984; Sinkovic *et al*., 1997; Kreutz, Greber, Aebi and Osterwalder, 1998) as being the result of probing different energy regions. The resonant photoemission experiments (Sinkovic *et al*., 1997) reflects the presence of local-moment polarization in the high-energy spectrum above Curie temperature in nickel, whereas the low-energy angle-resolved photoemission (ARPES) investigations (Kreutz, Greber, Aebi and Osterwalder, 1998) result in nonmagnetic bands near the Fermi level. This is exactly the DMFT view on the electronic structure of transition metals above T_C. Fluctuating moments and atomic-like configurations are large at short times, which result in correlation effects in the high-energy spectra such as spin-multiplet splitting. The moment is reduced at longer timescales, corresponding to a more band-like, less correlated electronic structure near the Fermi level.

Angle-resolved photoemission spectra of iron, as well as spin-polarized thermoemission data for cesiated iron were discussed in the context of LDA+DMFT in Katsnelson and Lichtenstein (1999), a perturbative FLEX-based solver of the effective impurity problem being used instead of QMC. For both types of spectra, an agreement between theory and experiment is drastically improved in comparison with standard LDA calculations. The QP damping in iron can be as large as 30% of the binding energy for the states in the region of majority-spin DOS peak.

Using the self-consistent values for $\Sigma(i\omega)$ computed by QMC technique, we calculate the exchange interactions (equation 30) and spin-wave spectrum for Fe (Katsnelson and Lichtenstein, 2000) and Ni (Katsnelson and Lichtenstein, 2002). The spin-wave spectrum for ferromagnetic iron is presented in Figure 6 in comparison with the results of LSDA-exchange calculations (Liechtenstein, Katsnelson, Antropov and Gubanov, 1987) and with different experimental data (Lynn, 1975; Mook and Nicklow, 1973; Perring *et al*., 1991). This room-temperature neutron scattering experiments has a sample dependence (Fe-12%Si in Lynn (1975); Perring *et al*. (1991) and Fe-4%Si in Mook and Nicklow (1973)) due to problems with the bcc-Fe crystal growth. Note that for high-energy spin waves the experimental data (Perring *et al*., 1991) has large error-bars due to Stoner damping (we show one experimental point with the uncertainties in the **q** space). On the other hand, the expression of magnon frequency in terms of exchange parameters itself becomes problematic in

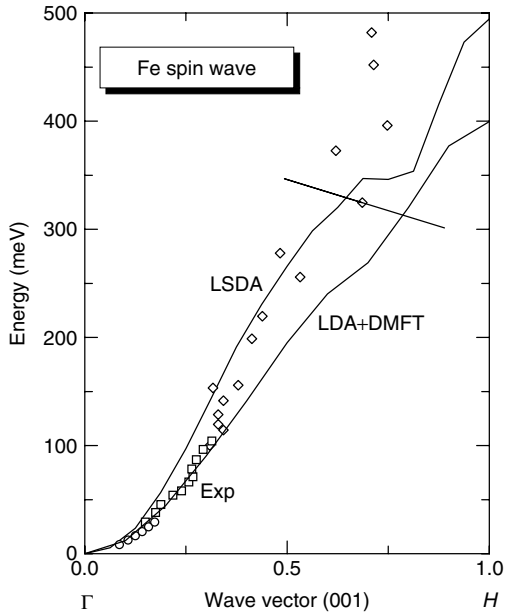

Figure 6. The spin-wave spectrum for ferromagnetic iron in the LSDA and LDA+DMFT approximations compared with different experiments (circles Lynn, 1975, squares Mook and Nicklow, 1973, and diamonds Perring, Boothroyd, Paul, *et al*., 1991).

that region due to the breakdown of adiabatic approximation, as discussed in the preceding text.

Therefore, we think that comparison of theoretical results with experimental spin-wave spectrum for the large energy needs additional investigation of Stoner excitation and requires calculations of dynamical susceptibility in the LDA+DMFT approach (Georges, Kotliar, Krauth and Rozenberg, 1996). Our LSDA spin-wave spectrum agrees well with the results of frozen magnon calculations (Sandratskii and Kübler, 1992; Halilov, Eschrig, Perlov and Oppeneer, 1998). At the lower energy, where the present adiabatic theory is reliable, the LDA+DMFT spin-wave spectrum agrees better with the experiments than the result of the LSDA calculations. Experimental value of the spin-wave stiffness $D = 280\,\text{meV}\,\text{Å}^{-2}$ (Mook and Nicklow, 1973) agrees well with the theoretical LDA+DMFT estimations of $260\,\text{meV}\,\text{Å}^{-2}$ (Katsnelson and Lichtenstein, 2000). We have shown that correlation effects in magnon spectra are less important than in the electron spectra but, in general, an agreement between theory and experiment is also better for the LDA+DMFT approach.

6 CORRELATION EFFECTS IN ARPES: THE CASE OF fcc-Mn

Electronic spectra of transition metals have been probed intensively by angle-resolved photoemission, a technique that allows for the determination of the dispersion law that describes the dependence of the QP energy on quasimomentum. Copper was the first metal to be investigated thoroughly by this technique and the results were in excellent agreement with band structure calculations (Thirty *et al*., 1979; Knapp and Himpsel, 1979). The same technique, however, showed substantial deviations when applied to Ni and provided evidence for many-body behavior, such as the famous 6 eV satellite discussed in the previous section. Correlation effects are indeed important for metals with partially filled 3d bands and should be taken into account for an adequate description of ARPES spectra. Nevertheless, the main part of the spectral density in Fe is related to usual QPs, and the spectral weight of the satellite in Ni amounts to only 20% (Altmann *et al*., 2000). Surprisingly strong correlation effects have been found both experimentally and theoretically for the case of fcc-(γ) phase of manganese (Biermann *et al*., 2004).

Normally the geometrical frustrations in crystals (such as in the fcc lattice) further enhance electronic correlations (Georges, Kotliar, Krauth and Rozenberg, 1996) so that one of the best candidates among the transition metals for the search of strong correlation effects is the fcc-(γ) phase of manganese. It is an example of a very strongly frustrated magnetic system; according to band-structure calculations, (Moruzzi, Marcus and Kübler, 1989) the antiferromagnetic ground state of γ-Mn lies extremely close to the boundary of the nonmagnetic phase. Moreover, an anomalously low value of the bulk modulus (Guillermet and Grimvall, 1989) might be considered as a first experimental hint of strong electronic correlations (Zein, 1995).

The physical properties of bulk γ-Mn are hardly accessible in the experiment, since the γ-phase is only stable at temperatures between 1368 K and 1406 K, where it shows paramagnetic behavior. In Biermann *et al*. (2004) thin films of γ-Mn grown on $Cu_3Au(100)$ substrate have been experimentally investigated by ARPES. The spectra were characterized by two striking features. These are a weakly dispersive QP band near the Fermi level E_F and a broad and almost **k**-independent maximum at approximately 2.7 eV below E_F. This data cannot be understood in the framework of a standard QP picture, since calculations of the first principles of the band structure for different magnetic phases of γ-Mn show an energy dispersion of more than 1.5 eV (Crockford, Bird and Long, 1991). Instead, the overall shape of the experimental spectra is very close to that of the Hubbard model on the metallic side of the Mott transition with a QP band near the Fermi level and a broad Hubbard band (HB) below E_F (Georges, Kotliar, Krauth and Rozenberg, 1996).

To test this hypothesis, LDA+DMFT calculations have been done with the QMC solution of the effective impurity problem within the same approximations as described in the preceding text for Fe and Ni. Carrying out between 10 and 15 DMFT iterations with about 10^5 Quantum Monte

Carlo sweeps allowed us to obtain not only the local Green function $G(\tau)$ but also highly accurate self-energies which can then be used for the computation of the **k**-resolved local Green function. Inversion of the spectral representations of the local Green's function and the dd-block of the **k**-resolved one by means of a Maximum Entropy scheme (Jarrell and Gubernatis, 1996) yields the DOS $\rho(\omega)$ and the spectral function $A(\mathbf{k}, \omega)$.

The results for the **k**-resolved spectral functions $A(\mathbf{k}, i\omega)$ are shown in Figure 7, for **k** points in the Γ-L directions (Biermann, Lichtenstein and Katsnelson, 2001). In the negative energy part (i.e., for the occupied states) of all spectra two main peaks carry – for a given **k**−point – the main part of the spectral weight: a narrow QP feature near the Fermi level and a very broad HB (at about −2.4 eV). These features are shared between the experimental and theoretical curves. Given the facts that (i) the experiments are done at a somewhat lower temperature than the calculations, (ii) we did not take into account matrix elements for interpreting the photoemission data and (iii) using the Maximum Entropy scheme for determining the spectral function introduces a further approximation, the theoretical spectra agree reasonably well with the experimental data. The absence of LDA bands in the energy region near E_F carrying most of the spectral weight around the Γ-point is striking and underlines the necessity of a proper many-body treatment as done in LDA+DMFT. Note that assuming antiferromagnetic order (of the type detailed in the subsequent text) would slightly shift the LDA bands. However, the antiferromagnetic LDA band structure displays a dispersion of more than 2 eV and thus, could not explain the nondispersive photoemission feature.

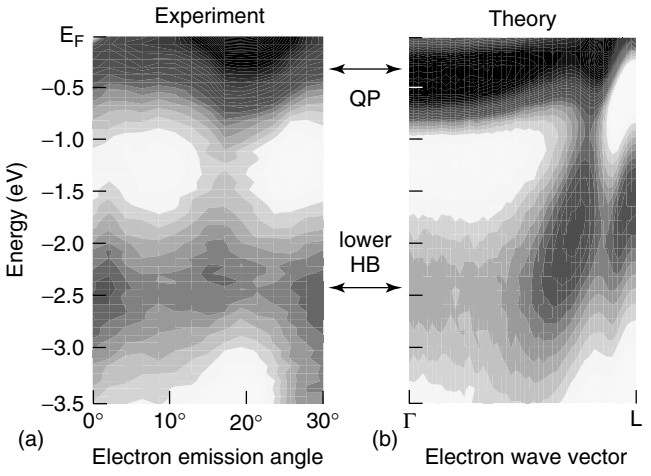

Figure 7. Spectral function for fcc-Mn from ARPES data and calculated within the LDA+DMFT approach, with $U = 3$ eV and $J = 0.9$ eV.

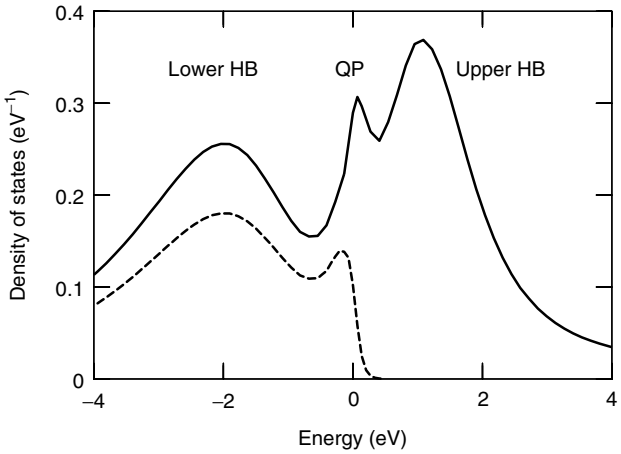

Figure 8. Local DOS for fcc-Mn from LDA+DMFT calculations. The 'three-peak structure' with the two broad HBs and a narrow QP resonance at the Fermi level is typical of strongly correlated systems. The dashed line is the calculated photoemission spectrum.

The calculated (**k**-integrated and **k**-resolved) DOS curves (see Figure 8) demonstrate a characteristic 'three-peak structure', with two broad HBS and a narrow QP Kondo resonance at the Fermi level which is typical of strongly correlated electron systems (Georges, Kotliar, Krauth and Rozenberg, 1996).

The energy scale associated with the correlation effects that lead to the formation of the HBs ($\sim U$) is much larger than that of the magnetic interactions. Therefore, the effects under discussion are not very sensitive to long-range magnetic order. We have carried out the electronic structure calculations for both the paramagnetic and the antiferromagnetic structure with wave vector $\mathrm{Q} = (\pi, 0, 0)$, which is typical of γ-Mn-based alloys (Fishman and Liu, 1999). The magnetic ordering changes the electron spectrum less in comparison with the nonmagnetic case. However, in comparison with the results of standard band theory (Moruzzi, Marcus and Kübler, 1989), the correlation effects stabilize the antiferromagnetic structure leading to a magnetic moment of about $2.9\,\mu_{\mathrm{B}}$.

According to these results, γ-Mn can be considered a unique case of a strongly correlated transition metal. An even larger correlation would transform the system to a Mott insulator where every atomic multiplet forms its own narrow but dispersive HB (Mott, 1974). On the other hand, in most metals correlations are small enough for the QPs to be well-defined in the whole energy region, and usual band theory gives a reasonable description of the energy dispersion. Note that the correlation strength and bandwidth have almost the same magnitude for all 3*d* metals. γ-Mn is probably an exceptional case among the transition elements due to the half-filled d-band and geometric frustrations in the fcc structure.

The ARPES data for the γ-phase of manganese and their theoretical analysis by means of LDA+DMFT, an approach that accounts not only for band-structure effects on the LDA level but also allows for a full description of local effects of strong Coulomb correlations, provide evidence for the formation of HBs in metallic manganese. This is a qualitatively new aspect in the physics of magnetic transition metals.

7 CORRELATION EFFECTS IN HALF-METALLIC FERROMAGNETS

Half-metallic ferromagnets (HMFs) (de Groot, Mueller, van Engen and Buschow, 1983; Irkhin and Katsnelson, 1994; Pickett and Moodera, 2001) recently attracted a great scientific and industrial attention due to their importance for spin-dependent electronics or 'spintronics' Prinz, 1998. The HMFs have metallic electronic structure for one-spin projection (majority- or minority-spin states), but for the opposite spin direction the Fermi level lies in the energy gap (de Groot, Mueller, van Engen and Buschow, 1983). Therefore, the spin-up and spin-down contributions to electronic transport properties have different orders of magnitude, which can result in a huge magnetoresistance for heterostructures containing the HMFs (Irkhin and Katsnelson, 1994).

At the same time, the HMFs are very interesting conceptually as a class of materials which may be suitable for investigation of the essentially many-body physics 'beyond standard band theory'. In most cases, many-body effects lead only to renormalization of the QP parameters in the sense of Landau's Fermi-liquid theory, the electronic *liquid* being *qualitatively* similar to the electron *gas* (see, e.g., Nozieres, 1964; Pines and Nozieres, 1966; Vonsovsky and Katsnelson, 1989a, 1989b). On the other hand, due to specific band structure of the HMF, an important role belongs to incoherent (nonquasiparticle (NQP)) states which occur near the Fermi level because of correlation effects (Irkhin and Katsnelson, 1994). The appearance of NQP states in the energy gap near the Fermi level is one of the most interesting correlation effects typical for the HMFs. The origin of these states is connected with 'spin-polaron' processes: the spin-down low-energy electron excitations, which are forbidden for the HMFs in standard one-particle scheme, turn out to be possible as superpositions of spin-up electron excitations and virtual magnons. The density of these NQP states vanishes at the Fermi level, but increases drastically at the energy scale of the order of a characteristic magnon frequency $\overline{\omega}$. The NQP states were first considered theoretically by (Edwards and Hertz, 1973) in the framework of a broadband Hubbard model for itinerant-electron ferromagnets. Later it was demonstrated (Irkhin and Katsnelson, 1983, 1985) that for a *narrow-band* (infinite-U) Hubbard model, the *whole* spectral weight for one-spin projection belongs to the NQP states which is of crucial importance for the problem of stability of Nagaoka's ferromagnetism (Nagaoka, 1966) and for adequate description of the corresponding excitation spectrum. The NQP states in the $s-d$ exchange model of magnetic semiconductors have been considered in Auslender and Irkhin (1985). It was shown that depending on the sign of the $s-d$ exchange integral, the NQP states can form either only below the Fermi energy E_F or above it. Later it was realized that the HMFs are natural substances for theoretical and experimental investigating of the NQP effects (Irkhin and Katsnelson, 1990). A variety of these effects in the electronic and magnetic properties has been considered (for review of the earlier works see Irkhin and Katsnelson (1994)). As an example of highly unusual properties of the NQP states, we note that they can contribute to the T-linear term in the electron heat capacity (Irkhin and Katsnelson, 1990; Irkhin, Katsnelson and Trefilov, 1989, 1994), despite their density at E_F vanishing at temperature $T = 0$. Existence of the NQP states at the HMFs surface has been predicted in Katsnelson and Edwards (1992) and may be important for their detection by surface-sensitive methods such as the ARPES or by spin-polarized scanning tunneling microscopy. NQP states are also essential for the transport properties of tunneling junctions between HMFs (Irkhin and Katsnelson, 2002; McCann and Fal'ko, 2003), and for the temperature dependence of nuclear magnetic relaxation rate in HMFs (Irkhin and Katsnelson, 2001); they also contribute to their core-level spectra (Irkhin and Katsnelson, 2005). Recently, the density of NQP states has been calculated from first principles for a prototype HMF, NiMnSb (Chioncel, Katsnelson, de Groot and Lichtenstein, 2003a).

Before considering the real HMF case, it is worthwhile to check the applicability of DMFT scheme for quantitative description of the NQP states. Let us start from the DMFT calculations for the one-band Hubbard Hamiltonian

$$H = -\sum_{i,j,\sigma} t_{ij}(c^{\dagger}_{i\sigma}c_{j\sigma} + c^{\dagger}_{j\sigma}c_{i\sigma}) + U\sum_{i} n_{i\uparrow}n_{i\downarrow} \qquad (34)$$

on the Bethe lattice with coordination $z \to \infty$ and nearest-neighbor hoping $t_{ij} = t/\sqrt{z}$ (in this limit the DMFT is formally exact (Georges, Kotliar, Krauth and Rozenberg, 1996). In this case, the DOS have a semicircular form:

$$N(\epsilon) = \frac{1}{2\pi t^2}\sqrt{4t^2 - \epsilon^2} \qquad (35)$$

In order to stabilize the HMF state in our toy model, we have added an external magnetic spin splitting Δ, which mimics the local Hund polarization from other electrons in

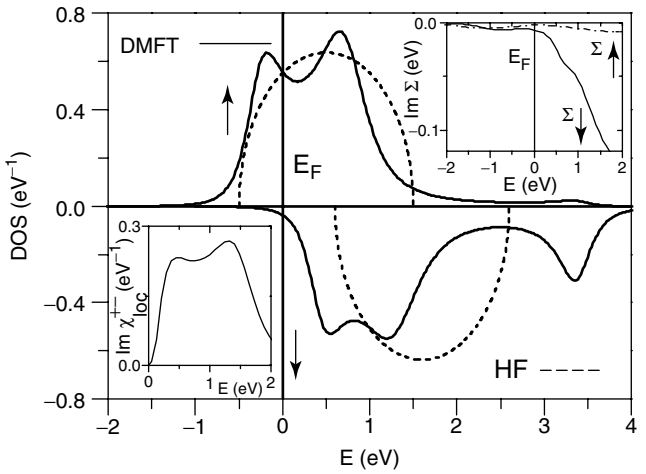

Figure 9. Density of states for HMFs in the Hartree–Fock (HF) approximation (dashed line) and the QMC solution of DMFT problem for semicircular model (solid line) with the bandwidth $W = 2\,\text{eV}$, Coulomb interaction $U = 2\,\text{eV}$, spin splitting $\Delta = 0.5\,\text{eV}$, chemical potential $\mu = -1.5\,\text{eV}$, and temperature $T = 0.25\,\text{eV}$. Insets: imaginary part of the local spin-flip susceptibility (left) and the spin-resolved self-energy (right).

the real NiMnSb compound. This HMF state corresponds to a mean-filed (Hartree–Fock) solution with a LSDA-like DOS (see Figure 9).

We can study an average magnon spectrum in this model through the two-particle correlation function. The local spin-flip susceptibility represents the response function required and can be calculated using the numerically exact enumeration QMC scheme (Georges, Kotliar, Krauth and Rozenberg, 1996). The model DMFT results are presented in Figure 9. In comparison with a simple Hartree–Fock solution (dashed line), one can see an additional well-pronounced states appearing in the spin-down gap region, just above the Fermi level. This new many-body feature corresponds to the NQP states. In addition to these states visible in both spin channels of the DOS around 0.5 eV, a many-body satellite appears at the energy of 3.5 eV.

The left inset in Figure 9 represents the imaginary part of local spin-flip susceptibility. One can see a well pronounced shoulder (around 0.5 eV), which is connected with an average magnon DOS. In addition there is a broad maximum (at 1 eV) corresponding to the Stoner excitation energy. The right inset in Figure 9 represents the imaginary part of self-energy calculated from our 'toy model'. The spin-up channel can be described by a Fermi-liquid type behavior with a parabolic energy dependence $-\text{Im}\Sigma^{\uparrow} \propto (E - E_F)^2$, whereas in the spin-down channel the imaginary part $-\text{Im}\Sigma^{\downarrow}$ shows the 0.5 eV NQP shoulder. Owing to the relatively high temperature of our QMC calculation (an exact enumeration technique with the number of time slices equal to $L = 24$), the NQP tail goes a bit below the Fermi level; at temperature $T = 0$ the NQP tail should end exactly at the Fermi level.

Let us consider now the calculations for real HMF material–NiMnSb. The details of the computational scheme have been described in Chioncel, Katsnelson, de Groot and Lichtenstein (2003a), and only the key points will be mentioned here. In order to integrate the DMFT approach into the band structure calculation, the so-called exact muffin-tin orbital method (EMTO) was used; the implementation of the DMFT scheme in the EMTO method is described in detail in the Chioncel *et al*. (2003b). One should note that in addition to the usual self-consistency of the many-body problem (self-consistency of the self-energy), a charge self-consistency has been achieved.

For the interaction Hamiltonian, a most general rotationally invariant form of the generalized Hubbard Hamiltonian with four-index interaction matrix has been used (Lichtenstein and Katsnelson, 1997, 1998; Katsnelson and Lichtenstein, 1999). The effective many-body impurity problem was solved using the spin polarized T-matrix plus fluctuation-exchange approximation (SPTF) scheme proposed in the Katsnelson and Lichtenstein (2002). It is important that this perturbative scheme includes off-diagonal in spin indices (spin-flip) effective interaction which is responsible for spin-platonic effects.

The results for DOS using LSDA and LDA+DMFT (with $U = 3\,\text{eV}$ and $J = 0.9\,\text{eV}$) approaches are presented in the Figure 10. For the spin-up states we have a normal Fermi-liquid behavior $-\text{Im}\Sigma_d^{\uparrow}(E) \propto (E - E_F)^2$ with a typical

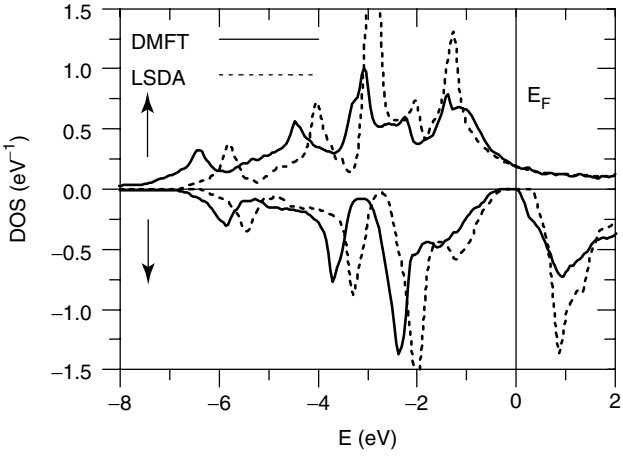

Figure 10. Density of states for HMF NiMnSb in LSDA scheme (dashed line) and in LDA+DMFT scheme (solid line) with effective Coulomb interaction $U = 3\,\text{eV}$, exchange parameter $J = 0.9\,\text{eV}$ and temperature $T = 300\,\text{K}$. The NQP state is evidenced just above the Fermi level for spin-down band.

energy scale of the order of several eV. The spin-down self-energy behaves in a similar way below the Fermi energy, with a slightly smaller energy scale (which is still larger than 1 eV). At the same time, a significant increase in $\mathrm{Im}\Sigma_d^{\downarrow}(E)$ with a much smaller energy scale (few tenths of eV) occurs just above the Fermi level, which is more pronounced for t_{2g} states. The similar behavior of the imaginary part of electronic self-energy and the DOS just above Fermi level is a signature of the NQP states and is also noticed in the model calculation (see Figure 9).

8 CONCLUSIONS

SDF approach in the LDA+DMFT approximation allows the study of correlation effects in solids based on the realistic electronic structure calculations. Among all possible applications we have chosen the magnetism of transition metals and other itinerant-electron magnets. From these examples, one can see all the main advantages of the new approach in comparison with the standard density functional theory. First, we can describe the spectral density transfer phenomena (e.g., the formation of 6 eV satellite in Ni), the QP damping and other effects connected with the frequency dependence of the self-energy, including the formation of NQP states of spin-polaronic origin; all these phenomena are absent completely not only in the DFT approach but also in the Hartree–Fock, LDA+U, or self-interaction corrections approximation. Second, we can adequately describe the contribution of the Bose degrees of freedom (e.g., spin fluctuations) to the electronic structure and thermodynamic properties. In the DFT-based calculations the temperature is taken into account only via the thermal expansion and the Fermi distribution function (Jarlborg, 1997). It was the main reason for which the standard band theory failed to describe the finite-temperature effects in magnetic metals. We show that the LDA+DMFT approach gives satisfactory solution of this complicated problem of itinerant-electron magnetism.

ACKNOWLEDGMENTS

We are grateful to G. Kotliar, A. Georges, L. Chioncel, and S. Biermann for helpful discussions.

1 INTRODUCTION

The comparison of experimental measurements on quantum magnets to microscopic models requires the ability to accurately calculate magnetic and other thermodynamic properties of these models. Like for most many-body problems, exact solutions are not available except for certain models, such as the two-dimensional classical Ising model or some one-dimensional quantum spin models. While mean-field theories can give reliable results in high-dimensional systems deep inside ordered phases, they are unreliable when fluctuations are strong. These can be either classical thermal fluctuations close to finite-temperature phase transitions or strong quantum fluctuations in low-dimensional systems.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

Unbiased numerical methods are required to obtain reliable results for classical and quantum lattice models of magnetic systems, especially in the vicinity of phase transitions, in frustrated models, and in systems where quantum effects are important. For classical magnets, the Monte Carlo method is the method of choice since it can treat large systems. Using modern sampling algorithms, such as cluster updates, extended ensemble methods, or parallel tempering strategies, most classical magnets can be efficiently simulated with the computational effort scaling, with a low power of the system size, and are usually linear in system size. The notable exceptions are spin glasses, known to be nondeterministic-polynomially (NP) hard (Barahona, 1982) and where, most likely, no polynomial-time algorithm can exist (Cook, 1971).

For quantum magnets, quantum Monte Carlo (QMC) methods are also the methods of choice whenever they are applicable. Over the last decade, the efficient algorithms for classical Monte Carlo simulations have been generalized to quantum systems, and systems with millions of quantum spins have been simulated (Kim and Troyer, 1998).

Unfortunately, in contrast to classical magnets, QMC methods are efficient only for nonfrustrated magnets. Frustration in quantum systems usually leads to the 'negative sign problem', when the weights of some configurations become negative (Troyer and Wiese, 2005). These negative weights cannot be directly interpreted as probabilities in the Monte Carlo process and lead to cancellation effects in the sampling. As a consequence, the statistical errors grow exponentially with inverse temperature and system size, and the QMC methods are restricted to small systems and not too low temperatures. For quasi-one-dimensional quantum systems such as spin chains and spin ladders, the density matrix renormalization group (DMRG) method can be an alternative (White, 1992,1993; Schollwöck, 2005). The problem of simulating

strongly frustrated quantum magnets in more than one dimension and at low temperatures is, however, still an unsolved problem.

In this article, we will review the QMC method for nonfrustrated or weakly frustrated quantum magnets where efficient algorithms are available. We will start in section 2 with an introduction to the general theory of Markov chain Monte Carlo sampling, followed in section 3 by an overview of classical Monte Carlo methods, and how the problem of critical slowing down at phase transition can be solved by using cluster update algorithms or generalized ensembles. Section 4 will provide a review of world-line QMC algorithms for purely magnetic models such as the quantum Heisenberg model and variants thereof. The final section 5 will introduce determinental QMC algorithms for the more microscopic fermionic models of quantum magnets, such as the Hubbard model.

2 THE MONTE CARLO METHOD

In this chapter, we outline the Monte Carlo method for calculating general integrals of the form

$$\langle O \rangle = \int_{\Omega} \mathrm{d}x\, P(x) O(x) \tag{1}$$

Here Ω denotes a discrete or continuous configuration space with elements x and $P(x)$ is a probability distribution on this space, where

$$\int_{\Omega} \mathrm{d}x\, P(x) = 1 \quad \text{and} \quad P(x) \geq 0 \; \forall \; x \in \Omega. \tag{2}$$

O is an observable (or random variable) on the configuration space Ω. In later chapters, we will show how this general method can be applied to quantum magnets.

Stochastic processes are based on the idea that it suffices to sample configurations x according to their importance, $P(x)$. For a given chain of configurations, $x_1, \cdots, x_N$, sampled according to their importance, we can then approximate our observable $\langle O \rangle$ with

$$\langle O \rangle_N \simeq \frac{1}{N} \sum_{i=1}^{N} O(x_i) \tag{3}$$

Clearly the value of $\langle O \rangle_N$ depends on the specific realization of the chain of configurations. However, under the assumptions that $O(x_i)$ are statistically independent and that N is large enough, the central limit theorem tells us that, $\langle O \rangle_N$ follows a Gaussian distribution of width

$$\sigma = \sqrt{\frac{1}{N-1}\left(\frac{1}{N}\sum_{i=1}^{N} O(x_i)^2 - \left(\frac{1}{N}\sum_{i=1}^{N} O(x_i)\right)^2\right)} \tag{4}$$

σ corresponds to the error. Hence, the accuracy of the Monte Carlo approach scales as the inverse square root of the computational time, N, irrespective of the dimensionality of the configuration space. It is this feature which makes the Monte Carlo approach attractive in the limit of large dimensions.

Our task is now to generate a chain of configurations $x_1, \cdots, x_N$, sampled according to $P(x)$. For simplicity let us consider a discrete configurations space Ω. We introduce a Monte Carlo time t and a time-dependent probability distribution $P_t(x)$ which evolves according to a Markov process, that is, the future $(t+1)$ depends only on the present (t). To define the Markov process, we introduce a matrix $T_{y,x}$ which corresponds to the transition probability from state x to state y. The time evolution of $P_t(x)$ is given by:

$$P_{t+1}(y) = \sum_{x} T_{y,x} P_t(x) \tag{5}$$

T has to satisfy the following properties.

$$\sum_{y} T_{y,x} = 1, \quad T_{y,x} \geq 0 \tag{6}$$

Hence, if $P_t(x)$ is a probability distribution then $P_{t+1}(x)$ is equally a probability distribution.
T has to be ergodic:

$$\forall x, \; y \in \Omega \; \exists \, s | \left(T^s\right)_{y,x} > 0 \tag{7}$$

Thus, we are assured of sampling the whole phase space provided the above equation is satisfied. Finally, the requirement of stationarity:

$$\sum_{x} T_{y,x} P(x) = P(y) \tag{8}$$

Once we have reached the desired distribution, $P(x)$, we wish to stay there. Stationarity is automatically satisfied if

$$T_{y,x} P(x) = T_{x,y} P(y) \tag{9}$$

as may be seen by summing on both sides over x. This relation is referred to as detailed balance or microreversibility. However, one has to keep in mind that stationarity and not detailed balance is essential.

As given in the preceding text, in the Monte Carlo simulation we will generate the Markov Chain,

$$x_1, x_2, \cdots, x_N \tag{10}$$

where the conditional probability of sampling the state x_{t+1} given the state x_t reads:

$$P(x_{t+1}|x_t) = T_{x_{t+1},x_t} \tag{11}$$

One can show that as $n \to \infty$ the fraction of the time one can expect the Markov process to be in state x reads $P(x)$ independently of the initial state x_1. More precisely, since the probability of being in state x at time t in the Markov process reads $\left[T^t\right]_{x,x_1}$, one can show that

$$\lim_{n\to\infty} \frac{1}{n} \sum_{t=1}^{n} \left[T^t\right]_{x,x_1} = P(x) \tag{12}$$

irrespective of the starting point x_1. For a demonstration of the above, the reader is referred to (Kemeny and Snell, 1960).

Having defined T, we now have to construct it explicitly. Let $T^0_{y,x}$ be the probability of proposing a transition from x to y and $a_{y,x}$ be the probability of accepting it. $1 - a_{y,x}$ corresponds to the probability of rejecting the move. T^0 is required to satisfy equation (6). Since, in general, we want to propose moves which change the initial configuration, $T^0_{x,x} = 0$. With $a_{y,x}$ and $T^0_{y,x}$ we build $T_{y,x}$ with:

$$T_{y,x} = \begin{cases} T^0_{y,x} a_{y,x} & \text{if} \quad y \neq x \\ \sum_{\substack{z \\ z\neq x}} T^0_{z,x} \left(1 - a_{z,x}\right) & \text{if} \quad y = x \end{cases} \tag{13}$$

Clearly $T_{y,x}$ satisfies equation (6). To satisfy the stationarity, we impose the detailed balance condition to obtain the equality:

$$T^0_{y,x} a_{y,x} P_x = T^0_{x,y} a_{x,y} P_y \tag{14}$$

Let us set:

$$a_{y,x} = \mathcal{F}\left(\frac{T^0_{x,y} P_y}{T^0_{y,x} P_x}\right) \tag{15}$$

with $\mathcal{F}:]0:\infty[\to [0,1]$. Since

$$a_{x,y} = \mathcal{F}\left(\frac{T^0_{y,x} P_x}{T^0_{x,y} P_y}\right) = \mathcal{F}\left(\frac{1}{\frac{T^0_{x,y} P_y}{T^0_{y,x} P_x}}\right) \tag{16}$$

the detailed balance condition reduces to:

$$\frac{\mathcal{F}(Z)}{\mathcal{F}(1/Z)} = Z \quad \text{where} \quad Z = \frac{T^0_{x,y} P_y}{T^0_{y,x} P_x} \tag{17}$$

There are many possible choices. The Metropolis algorithm (Metropolis *et al.*, 1953) is based on the choice:

$$\mathcal{F}(Z) = \min(Z, 1) \tag{18}$$

Thus, one proposes a transition from x to y and accepts it with probability $Z = \frac{T^0_{x,y} P_y}{T^0_{y,x} P_x}$. In the practical implementation, one picks a random number r in the interval $[0, 1]$. If $r < Z (r > Z)$ one accepts (rejects) the move. Alternative choices of $\mathcal{F}(Z)$ are for example:

$$\mathcal{F}(Z) = \frac{Z}{1+Z} \tag{19}$$

which is referred to as the heat bath method.

Whether the so constructed T matrix is ergodic depends upon the choice of T^0. In many cases, one will wish to combine different types of moves to achieve ergodicity. For a specific move i, we construct $T^{(i)}$ as shown above so that $T^{(i)}$ satisfies conditions (6) and (9). The moves may be combined in two ways:

$$T = \sum_i \lambda_i T^{(i)}, \quad \sum_i \lambda_i = 1 \tag{20}$$

which is referred to as random updating since one picks with probability λ_i the move $T^{(i)}$. Clearly, T equally satisfies (6), (9) and if the moves have to be chosen appropriately to satisfy the ergodicity condition. Another choice is sequential updating. A deterministic ordering of the moves is chosen to obtain:

$$T = \prod_i T^{(i)} \tag{21}$$

This choice does not satisfy detailed balance condition, but does satisfy stationarity (8) as well as (6). Again ergodicity has to be *checked* on a case-to-case basis.

The observable O may now be estimated with:

$$\langle O \rangle_P \approx \frac{1}{N} \sum_{t=1}^{N} O(x_t) \tag{22}$$

The required value of N depends on the autocorrelation time of the observable O:

$$C_O(t) = \frac{\frac{1}{N}\sum_{s=1}^{N} O(x_s) O(x_{s+t}) - \left(\frac{1}{N}\sum_{s=1}^{N} O(x_s)\right)^2}{\frac{1}{N}\sum_{s=1}^{N} O(x_s)^2 - \left(\frac{1}{N}\sum_{s=1}^{N} O(x_s)\right)^2} \tag{23}$$

One expects $C_O(t) \sim e^{-t/\tau_O}$ where τ_O corresponds to the autocorrelation time. The autocorrelation time corresponds to

the time scale on which memory of the initial value of the observable is lost. To obtain meaningful results as well as a reliable estimate of the error, $N \gg \tau_O$ is needed.

3 CLASSICAL MONTE CARLO METHODS AND CRITICAL SLOWING DOWN

3.1 The local update algorithm for the Ising model

Before discussing quantum magnets in the following chapters, we first apply the Monte Carlo method to classical lattice models to illustrate the important issues, algorithms, and sampling strategies on simple classical models. We will start with the Ising ferromagnet with Hamilton function

$$H = -J \sum_{\langle i,j \rangle} \sigma_i \sigma_j - g\mu_B h \sum_{i=1}^{N} \sigma_i \tag{24}$$

where J is the exchange constant, h the magnetic field, g the Landee g-factor, μ_B the Bohr magneton, and N the total number of spins. The sum runs over all pairs of nearest neighbors i and j and $\sigma_i = \pm 1$ is the value of the Ising spin at site i.

To calculate the value of an observable, such as the mean magnetization at an inverse temperature $\beta = 1/k_B T$ with T being the temperature and k_B the Boltzmann constant, we need to evaluate

$$\langle m \rangle = \sum_c m(c) \exp(-\beta E(c))/Z \tag{25}$$

where,

$$m(c) = \frac{1}{N} \sum_{i=1}^{N} \sigma_i \tag{26}$$

is the magnetization of the configuration c, $E(c)$ the energy of the configuration and

$$Z = \sum_c \exp(-\beta E(c)) \tag{27}$$

the partition function. Comparing to equation (1) in the previous chapter we identify the space Ω with the space of configurations $\{c\}$, the observable $O(x)$ with the magnetization $m(c)$ and the weight $P(x)$ with the Boltzmann weight $\exp(-\beta E(c))/Z$.

As discussed above, Monte Carlo sampling can be performed using the Metropolis or heat bath methods, which, in their simplest form, are local updates of single spins:

1. Pick a random site i.
2. Calculate the energy cost ΔE for flipping the spin at site i: $\sigma_i \to -\sigma_i$.
3. Flip the spin either with the Metropolis probability $\min[1, \exp(-\beta \Delta E)]$ or the heat bath probability $\exp(-\beta \Delta E)/(1 + \exp(-\beta \Delta E))$. If rejected, keep the original spin value.
4. Perform a measurement independent of whether the spin-flip was accepted or rejected.

The same local update algorithm can be applied to systems with longer-range interactions and with coupling constants that vary from bond to bond. For more complex classical models, such as Heisenberg models, local updates will no longer consist of simple spin flips, but of arbitrary rotations of the local spin vectors.

3.2 Critical slowing down and cluster update algorithms

Local update algorithms are easy to implement and work well away from phase transitions. Problems arise in the vicinity of continuous (second order) phase transitions, when these algorithms suffer from 'critical slowing down' (Swendsen and Wang, 1987). As the correlation length ξ diverges upon approaching the phase transition, the autocorrelation times τ_O also diverge as

$$\tau_O \propto \min(L, \xi)^z \tag{28}$$

with a dynamical critical exponent of $z \approx 2$. L is the linear extent of the system. The origin of critical slowing down is the fact that close to the critical temperature large ordered domains of linear extent ξ are formed and the single-spin updates are not effective in changing these large domains. The value $z \approx 2$ can be understood considering that the time for a domain wall to move a distance ξ by a random walk scales as ξ^2.

The solutions to critical slowing down are cluster updates, flipping carefully selected clusters of spins instead of single spins. Cluster update algorithms were originally invented by Swendsen and Wang for the Ising model (Swendsen and Wang, 1987) and soon generalized to $O(N)$ models, such as the Heisenberg model (Wolff, 1989). These cluster update algorithms are discussed in textbooks on classical Monte Carlo simulations and in computational physics textbooks. While most cluster algorithms require spin-inversion invariance and thus do not allow for external magnetic fields, extensions to spin models in magnetic fields have been proposed (Redner, Machta and Chayes, 1998; Evertz, Erkinger and von der Linden, 2002).

An open-source implementation of local and cluster updates for Ising, Potts, *XY* and Heisenberg models is available through the ALPS (Applications and Libraries for Physics Simulations) project (Alet *et al*., 2005) at the web page http://alps.comp-phys.org/.

3.3 First order phase transitions and the multicanonical ensemble

While cluster updates can solve critical slowing down at second order phase transitions, they are usually inefficient at first order phase transitions and in frustrated systems. Let us consider a first order phase transition, such as in a two-dimensional q-state Potts model with Hamilton function

$$H = -J \sum_{\langle i,j \rangle} \delta_{\sigma_i \sigma_j} \tag{29}$$

where the spins σ_i can now take the integer values $1, \ldots, q$. For $q > 4$ this model exhibits a first order phase transition, accompanied by exponential slowing down of local single-spin updates. The exponential slowdown is caused by the free energy barrier between the two coexisting metastable states at the first order phase transition.

This barrier can be quantified by considering the energy histogram

$$H_{\text{canonical}}[E] = g(E) P_{\text{Boltzmann}}(E) \propto g(E) \exp(-\beta E) \tag{30}$$

which is the probability of encountering a configuration with energy E during the Monte Carlo simulation. Here

$$g(E) = \sum_c \delta_{E,E(c)} \tag{31}$$

is the density of states. Away from first order phase transitions, $H_{\text{canonical}}[E]$ has approximately Gaussian shape, centered around the mean energy. At first order phase transitions where the energy jumps discontinuously, the histogram $H_{\text{canonical}}[E]$ develops a double-peak structure. The minimum of $H_{\text{canonical}}[E]$ between these two peaks, which the simulation has to cross in order to go from one phase to the other, becomes exponentially small upon increasing the system size. This leads to exponentially large autocorrelation times.

A solution to this tunneling problem are extended ensembles, such as the multicanonical ensemble (Berg and Neuhaus, 1991, 1992), where the weight of a configuration c is given by $P_{\text{multicanonical}}(c) \propto 1/g(E(c))$ instead of the Boltzmann weight $\exp(-\beta E(c))$. The multicanonical ensemble leads to a flat histogram in energy space

$$\begin{aligned} H_{\text{multicanonical}}[E] &= g(E) P_{\text{multicanonical}}(E) \propto g(E) \frac{1}{g(E)} \\ &= \text{constant} \end{aligned} \tag{32}$$

removing the exponentially small minimum. After performing a simulation, measurements in the multicanonical ensemble are reweighted by a factor $P_{\text{Boltzmann}}(E)/P_{\text{multicanonical}}(E)$ to obtain averages in the canonical ensemble.

Since the density of states $g(E)$ and thus the multicanonical weights $P_{\text{multicanonical}}$ are not known initially, a scalable algorithm to estimate these quantities is needed. The Wang-Landau algorithm (Wang and Landau, 2001a, b) is a simple iterative method to obtain the density of states $g(E)$ and the multicanonical weights $P_{\text{multicanonical}}(E) \propto 1/g(E)$.

Recent investigations have shown that a flat histogram, as obtained by the multicanonical ensemble, is not optimal but still shows signs of critical slowing down (Dayal *et al*., 2004). Optimized ensembles, assigning larger weights to configurations in the critical region, can be found and lead to further improvements in the efficiency of algorithms by several orders of magnitude (Trebst, Huse and Troyer, 2004).

3.4 Frustrated systems and parallel tempering

The simulation of frustrated systems suffers from a similar tunneling problem as the simulation of first order phase transitions: local minima in energy space are separated by barriers that grow with system size. While the multicanonical or optimized ensembles do not help with the NP-hard problems faced by spin glasses, they are efficient in speeding up simulations of frustrated magnets without disorder.

An alternative to these extended ensembles for the simulation of frustrated magnets is the 'parallel tempering' or 'exchange' Monte Carlo method (Hukushima and Nemoto, 1996). Instead of performing a single simulation at a fixed temperature, simulations are performed for M replicas at a set of inverse temperatures $\beta_1, \ldots, \beta_M$. In addition to standard Monte Carlo updates at a fixed temperature, exchange moves are proposed to swap two replicas between adjacent temperatures. These swaps are accepted with a probability $\min[1, \exp(-\Delta\beta \Delta E)]$, where $\Delta\beta$ is the difference in inverse temperatures and ΔE the difference in energy between the two replicas.

The effect of these exchange moves is that a replica can drift from a local free energy minimum at low temperatures to higher temperatures, where it is easier to cross energy barriers. Upon cooling (by another sequence of exchanges), it can end up in a different local minimum in time that is

much shorter than for a single simulation at a fixed low temperature.

4 QUANTUM MONTE CARLO WORLD-LINE ALGORITHMS

4.1 The $S = 1/2$ quantum XXZ model

In this chapter, we will generalize the Monte Carlo methods described in chapter 3 for classical spin systems to quantum spin systems. As examples we will use the spin-1/2 quantum Heisenberg or XXZ models with Hamiltonian

$$\begin{aligned} H &= \sum_{\langle i,j\rangle}\left[J_z S_i^z S_j^z + J_{xy}\left(S_i^x S_j^x + S_i^y S_j^y\right)\right] - g\mu_B h\sum_{i=1}^{N} S_i^z \\ &= \sum_{\langle i,j\rangle}\left[J_z S_i^z S_j^z + \frac{J_{xy}}{2}\left(S_i^+ S_j^- + S_i^- S_j^+\right)\right] - g\mu_B h\sum_{i=1}^{N} S_i^z \end{aligned} \tag{33}$$

where S_i^α are spin $S = 1/2$ operators fulfilling the standard commutation relations and in the second line, we have replaced S_i^x and S_i^y by the spin raising and lowering operators S_i^+ and S_i^-.

The case $J_{xy} = 0$ corresponds to the classical Ising model (24) up to a change in sign: while in classical Monte Carlo simulations (where there is no difference in the thermodynamics of the ferromagnet and the antiferromagnet) a positive exchange constant J denotes the ferromagnet, the convention for quantum systems is usually opposite with a positive exchange constant denoting the antiferromagnet. The other limit $J_z = 0$ corresponds to the quantum XY-model, while $J_z = J_{xy}$ is the Heisenberg model.

4.2 Representations

The basic problem for Monte Carlo simulations of quantum systems is that the partition function is no longer a simple sum over classical configurations as in equation (27) but an operator expression

$$Z = \mathrm{Tr}\exp(-\beta H) \tag{34}$$

where H is the Hamilton operator and the trace Tr goes over all states in the Hilbert space. Similarly the expression for an observable, like the magnetization, is an operator expression:

$$\langle m\rangle = \frac{1}{Z}\mathrm{Tr}\left[m\exp(-\beta H)\right] \tag{35}$$

and the Monte Carlo method cannot directly be applied except in the classical case where the Hamilton operator H is diagonal and the trace reduces to a sum over all basis states. The first step of any QMC algorithm is thus the mapping of the quantum system to an equivalent classical system

$$\langle m\rangle = \frac{1}{Z}\mathrm{Tr}\left[m\exp(-\beta H)\right] = \sum_c m(c)P(c) \tag{36}$$

where the sum goes over configurations c in an artificial classical system (e.g., a system of world lines), $m(c)$ will be the value of the magnetization or another observable as measured in this classical system and $P(c)$ the weight of the classical configuration. We will now present two different but related methods for this mapping: the path-integral representation and the SSE representation.

4.2.1 The path-integral representation

The path-integral formulation of a quantum system goes back to (Feynman, 1953), and forms the basis of most QMC algorithms. Instead of following the historical route and discussing the Trotter-Suzuki (checkerboard) decomposition (Trotter, 1959; Suzuki, 1976) for path integrals with discrete time steps $\Delta\tau$ we will directly describe the continuous-time formulation used in modern codes.

The starting point is a time-dependent perturbation expansion in imaginary time to evaluate the density matrix operator $\exp(-\beta H)$. Using a basis in which the S^z operators are diagonal, we follow (Prokofev, Svistunov and Tupitsyn, 1998) and split the Hamiltonian $H = H_0 + V$ into a diagonal term H_0, containing the S^z term and an off-diagonal perturbation V, containing the exchange terms $(J_{xy}/2)(S_i^+ S_j^- + S_i^- S_j^+)$. In the interaction representation, the time-dependent perturbation is $V(\tau) = \exp(\tau H_0)V\exp(-\tau H_0)$ and the partition function can be represented as:

$$\begin{aligned} Z &= \mathrm{Tr}\exp(-\beta H) = \mathrm{Tr}\left[\exp(-\beta H_0)\mathcal{T}\exp\int_0^\beta d\tau V(\tau)\right] \\ &= \mathrm{Tr}\left[\exp(-\beta H_0)\left(1 - \int_0^\beta d\tau_1 V(\tau_1) + \frac{1}{2}\int_0^\beta d\tau_1\right.\right. \\ &\quad \left.\left.\times\int_{\tau_1}^\beta d\tau_2 V(\tau_1)V(\tau_2) + \ldots\right)\right] \\ &= \sum_i \langle i|\left[\exp(-\beta H_0)\left(1 - \int_0^\beta d\tau_1 V(\tau_1) + \frac{1}{2}\int_0^\beta d\tau_1\right.\right. \\ &\quad \left.\left.\times\int_{\tau_1}^\beta d\tau_2 V(\tau_1)V(\tau_2) + \ldots\right)\right]|i\rangle \end{aligned} \tag{37}$$

where the symbol $\mathcal{T}$ denotes time-ordering of the exponential and in the last line, we have replaced the trace by a sum over

a complete set of basis states $|i\rangle$, that are eigenstates of the local S^z operators. Note that, in contrast to a real-time path integral, the imaginary-time path integral always converges on finite systems of N spins at finite temperatures β, and the expansion can be truncated at orders $n \gg \beta J_{xy} N$.

Equation (37) is now just a classical sum of integrals and can be evaluated by Monte Carlo sampling in the initial states $|i\rangle$, the order of the perturbation n and the times $\tau_i (i = 1, \ldots, n)$. This is best done by considering a graphical world-line representation of the partition function (37) shown in Figure 1. The zeroth order terms in the sum $\sum_i \langle i| \exp(-\beta H_0)|i\rangle$ are given by straight world lines shown in Figure 1(a). First order terms do not appear since the matrix elements $\langle i|V|i\rangle$ are zero for the *XXZ* model. The first nontrivial terms are appear in second order with two exchanges, as shown in Figure 1(b). A general configuration of higher order is depicted in Figure 2(a).

Since the *XXZ* Hamiltonian commutes with the z-component of total spin $\sum_i S_i^z$, the total magnetization is conserved and all valid configurations are represented by closed world lines as shown in Figures 1 and 2. Models that break this conservation of magnetization, such as general *XYZ* models with different couplings in all directions, models with transverse fields coupling to S_i^x or higher spin models with single ion anisotropies $(S_i^x)^2$ or $(S_i^y)^2$ will in addition contain configurations with broken world-line segments.

4.2.2 The stochastic series expansion representation

An alternative representation is the stochastic series expansion (SSE) (Sandvik and Kurkijärvi, 1991), a generalization of Handscomb's algorithm (Handscomb, 1962) for the Heisenberg model. It starts from a Taylor expansion of the

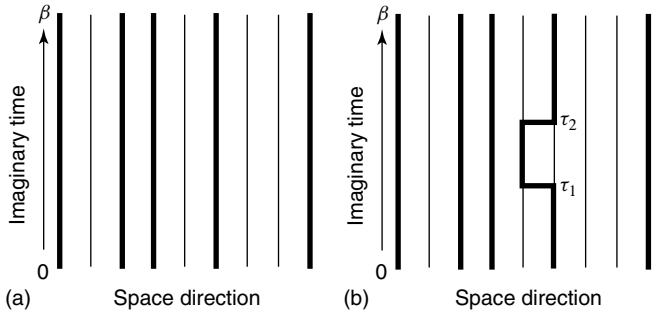

Figure 1. Examples of simple world-line configurations in imaginary time for a quantum spin model. Up-spins are shown by bold lines and down spins by thin lines. (a) a configuration in zeroth order perturbation theory where the spins evolve according to the diagonal term $\exp(-\beta H_0)$ and the weight is given by the classical Boltzmann weight of H_0. (b) a configuration in second order perturbation theory with two exchanges at times τ_1 and τ_2. Its weight is given by the matrix elements of the exchange processes and the classical Boltzmann weight of H_0 of the spins.

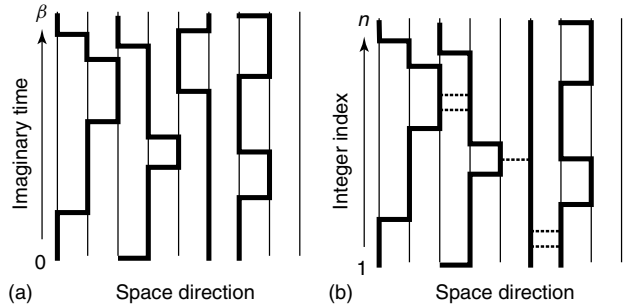

Figure 2. Examples of world-line configurations in (a) a path-integral representation where the time direction is continuous and (b) the stochastic series expansion (SSE) representation where the 'time' direction is discrete. Since the SSE representation perturbs not only in off-diagonal terms but also in diagonal terms, additional diagonal terms are present in the representation, indicated by dashed lines.

partition function in orders of β:

$$\begin{aligned} Z = \mathrm{Tr}\exp(-\beta H) &= \sum_{n=0}^{\infty} \frac{\beta^n}{n!} \mathrm{Tr}(-H)^n \\ &= \sum_{n=0}^{\infty} \frac{\beta^n}{n!} \sum_{\{i_1,\ldots,i_n\}} \sum_{\{b_1,\ldots,b_n\}} \langle i_1| - H_{b_1}|i_2\rangle \\ &\quad \times \langle i_2| - H_{b_2}|i_3\rangle \cdots \langle i_n| - H_{b_n}|i_1\rangle \end{aligned} \tag{38}$$

where, in the second line, we decomposed the Hamiltonian H into a sum of single-bond terms $H = \sum_b H_b$, and again inserted complete sets of basis states. We end up with a similar representation as equation (37) and a related world-line picture shown in Figure 2(b).

The key difference is that the SSE representation is a perturbation expansion in all terms of the Hamiltonian, while the path-integral representation perturbs only in the off-diagonal terms. Although the SSE method thus needs higher expansion orders for a given system, this disadvantage is compensated by a simplification in the algorithms: only integer indices of the operators need to be stored instead of continuous-time variables τ_i. Except in strong magnetic fields or for dissipative quantum spin systems (Sachdev, Werner and Troyer, 2004; Werner, Völker, Troyer and Chakravarty, 2005) the SSE representation is thus the preferred representation for the simulation of quantum magnets.

4.2.3 The negative sign problem

While the mapping from the quantum average to a classical average in equation (36) can be performed for any quantum system, it can happen in frustrated quantum magnets, that some of the weights $P(c)$ in the quantum system are negative, as is shown in Figure 3.

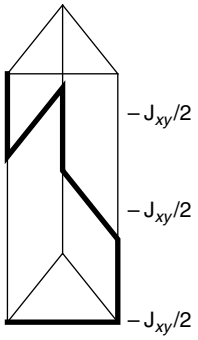

Figure 3. Example of a frustrated world-line configuration in a Heisenberg quantum antiferromagnet on a triangle. The closed world-line configuration contains three exchange processes, each contributing a weight proportional to $-J_{xy}/2$. The overall is proportional to $(-J_{xy}/2)^3$ and is negative, causing a negative sign problem for the antiferromagnet with $J_{xy} > 0$.

Since Monte Carlo sampling requires positive weights $P(c) > 0$, the standard way of dealing with the negative weights of the frustrated quantum magnets is to sample with respect to the unfrustrated system by using the absolute values of the weights $|P(c)|$ and to assign the sign, $s(c) \equiv \text{sign}\, P(c)$ to the quantity being sampled:

$$\langle m \rangle = \frac{\sum_c m(c) P(c)}{\sum_c P(c)} = \frac{\sum_c m(c) s(c) |P(c)| \Big/ \sum_c |P(c)|}{\sum_c s(c) |P(c)| \Big/ \sum_c |P(c)|} \equiv \frac{\langle ms \rangle'}{\langle s \rangle'} \tag{39}$$

While this allows Monte Carlo simulations to be performed, the errors increase exponentially with the particle number N and the inverse temperature β. To see this, consider the mean value of the sign $\langle s \rangle = Z/Z'$, which is just the ratio of the partition functions of the frustrated system $Z = \sum_c p(c)$ with weights $p(c)$ and the unfrustrated system used for sampling with $Z' = \sum_c |p(c)|$. As the partition functions are exponentials of the corresponding free energies, this ratio is an exponential of the differences Δf in the free energy densities:$\langle s \rangle = Z/Z' = \exp(-\beta N \Delta f)$. As a consequence, the relative error $\Delta s / \langle s \rangle$ increases exponentially with increasing particle number and inverse temperature:

$$\frac{\Delta s}{\langle s \rangle} = \frac{\sqrt{\left(\langle s^2 \rangle - \langle s \rangle^2\right)/M}}{\langle s \rangle} = \frac{\sqrt{1 - \langle s \rangle^2}}{\sqrt{M}\langle s \rangle} \sim \frac{\exp(\beta N \Delta f)}{\sqrt{M}} \tag{40}$$

Here M is the number of uncorrelated Monte Carlo samples. Similarly the error for the numerator increases exponentially and the time needed to achieve a given relative error scales exponentially in N and β.

It was recently shown that the negative sign problem is NP-hard, implying that almost certainly no solution for this exponential scaling problem exists (Troyer and Wiese, 2005). Given this exponential scaling of QMC simulations for frustrated quantum magnets, the QMC method is best suited for nonfrustrated magnets and we will restrict ourselves to these sign problem free cases in the following.

4.2.4 Measurements

Physical observables that can be measured in both the path-integral representation and the SSE representation include, next to the energy and the specific heat, any expectation value or correlation function that is diagonal in the basis set $\{|i\rangle\}$. This includes the uniform or staggered magnetization in the z direction, the equal time correlation functions and structure factor of the z-spin components and the z-component uniform and momentum-dependent susceptibilities.

Off-diagonal operators, such as the magnetization in the x- or y-direction, or the corresponding correlation functions, structure factors, and susceptibilities require an extension of the sampling to include configurations with broken world-line segments. These are hard to measure in local update schemes (described in section 4.3) unless open world-line segments are already present when the Hamiltonian does not conserve magnetization, but are easily measured when nonlocal updates are used (see section 4.4 and 4.5).

The spin stiffness ρ_s can be obtained from fluctuations of the winding numbers of the world lines (Pollock and Ceperley, 1987), a measurement which obviously requires nonlocal moves that can change these winding numbers.

Dynamical quantities are harder to obtain, since the QMC representations only give access to imaginary-time correlation function. With the exception of measurements of spin gaps, which can be obtained from an exponential decay of the spin-spin correlation function in imaginary time, the measurement of real-time or real-frequency correlation functions requires an ill-posed analytical continuation of noisy Monte Carlo data, for example using the Maximum Entropy Method (Jarrell and Gubernatis, 1996; von der Linden, 1995; Beach, 2004).

Thermodynamic quantities that cannot be expressed as the expectation value of an operator, such as the free energy or entropy cannot be directly measured but require an extended ensemble simulation, discussed in section 4.6.

4.3 Local updates

To perform a QMC simulation on the world-line representation, update moves that are ergodic and fulfill detailed balance are required. The simplest types of moves are again

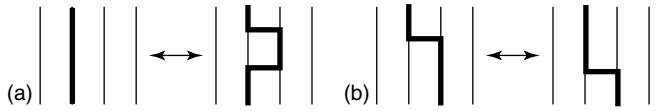

Figure 4. Examples of local updates of world lines. (a) a pair of exchange processes can be inserted or removed; (b) an exchange process is moved in imaginary time.

local updates. Since magnetization conservation prohibits the breaking of world lines, the local updates need to move world lines instead of just changing local states as in a classical model.

A set of local moves for a one-dimensional spin-1/2 model is shown in Figure 4 (Suzuki, Miyashita and Kuroda, 1977; Prokofev, Svistunov and Tupitsyn, 1996). The two required moves are the insertion and removal of a pair of exchange processes (Figure 4a) and the shift in time of an exchange process (Figure 4b). Slightly more complicated local moves are needed for higher-dimensional models, for example, to allow world lines to wind around elementary squares in a square lattice (Makivić and Ding, 1991). Since these local updates cannot change global properties, such as the number of world lines (the magnetization) or their spatial winding, they need to be complemented with global updates (Makivić and Ding, 1991).

While the local update world-line and SSE algorithms enable the simulation of quantum systems they suffer from critical slowing down at second order phase transitions. Even worse, changing the spatial and temporal winding numbers usually has an exponentially small acceptance rate. While the restriction to zero spatial winding can be viewed as a boundary effect, changing the temporal winding number and thus the magnetization is essential for simulations at fixed magnetic fields.

4.4 Cluster updates and the loop algorithm

The ergodicity problems of purely local updates and the critical slowing down observed also in quantum systems require the use of cluster updates. The loop algorithm (Evertz, Lana and Marcu, 1993) and its continuous-time version (Beard and Wiese, 1996), are generalizations of the classical cluster algorithms (Swendsen and Wang, 1987; Wolff, 1989) to quantum systems. They not only solve the problem of critical slowing down, but can also change the magnetization and winding numbers efficiently, avoiding the ergodicity problem of local updates. While the loop algorithm was initially developed for the path-integral representation, it can also be applied to simulations in the SSE representation.

Since there exist extensive recent reviews of the loop algorithm (Evertz, 2003; Kawashima and Harada, 2004), we will only outline the loop algorithm here. It constructs clusters of spins, similar to the Swendsen and Wang (1987) clusters of the classical Ising model (section 3.2). Upon applying the cluster algorithms to world lines in QMC we have to take into account that – in systems with conserved magnetization – the world lines may not be broken. This implies that a single spin cannot be flipped by itself, but, as shown in Figure 5, connected world-line segments of spins must be flipped together. These world-line segments form a closed loop, hence the name 'loop algorithm'.

While the loop algorithm was originally developed only for spin-1/2 models it has been generalized to higher spin models (Kawashima and Gubernatis (1994, 1995); Harada, Troyer and Kawashima, 1998; Todo and Kato, 2001) and anisotropic spin models (Kawashima, 1996). Since an efficient open-source implementation of the loop algorithm is available (see section 4.7) we will not discuss further algorithmic details but refer interested readers to the reviews (Evertz, 2003; Kawashima and Harada, 2004).

4.5 Worm and directed-loop updates

4.5.1 The loop algorithm in a magnetic field

As successful as the loop algorithm is, it is restricted – as most classical cluster algorithms – to models with spin-inversion symmetry. Terms in the Hamiltonian, which break this spin-inversion symmetry, such as a magnetic field, are not taken into account during loop construction. Instead, they enter through the acceptance rate of the loop flip, which can be exponentially small at low temperatures.

As an example consider two $S = 1/2$ quantum spins in a magnetic field:

$$H = J\mathbf{S}_1\mathbf{S}_2 - g\mu_B h(S_1^z + S_2^z) \tag{41}$$

In a field $g\mu_B h = J$, the singlet state $1/\sqrt{2}(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle)$ with energy $-3/4J$ is degenerate with the triplet state $|\uparrow\uparrow\rangle$ with energy $1/4J - h = -3/4J$. As illustrated in Figure 6(a), we start from the triplet state $|\uparrow\uparrow\rangle$ and propose

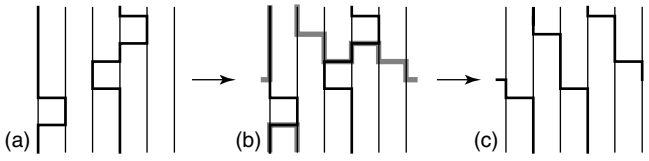

Figure 5. A loop cluster update. (a) world-line configuration before the update, where the world line of an up-spin is drawn as a thick line and that of a down-spin as a thin line; (b) world-line configuration and a loop cluster (grey line); (c) the world-line configurations after all spins along the loop have been flipped.

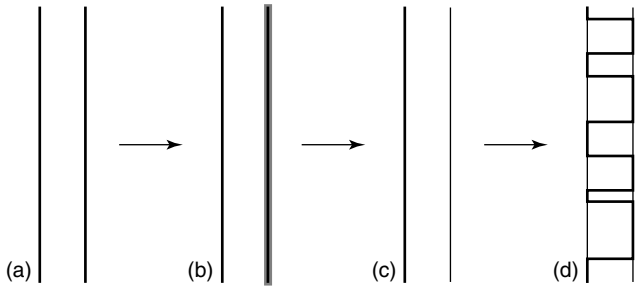

Figure 6. A loop update for two antiferromagnetically coupled spins in a magnetic field with $J = g\mu_B h$. (a) Starting from the triplet configuration $|\uparrow\uparrow\rangle$, (b) a loop is constructed, proposing to go to (c), the intermediate configuration $|\uparrow\downarrow\rangle$, which has an exponentially small acceptance rate, and finally into configurations like (d) which represent the singlet state $1/\sqrt{2}(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle)$. As in the previous figure, a thick line denotes an up-spin and a thin line a down-spin.

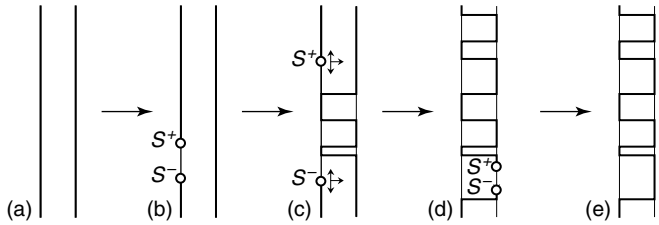

Figure 7. A worm update for two antiferromagnetically coupled spins in a magnetic field with $J = g\mu_B h$. (a) starting from the triplet configuration $|\uparrow\uparrow\rangle$ a worm is constructed in (b) by inserting a pair of S^+ and S^- operators. (c) these 'worm end' operators are then moved by local updates until (d) they meet again, when a move to remove them is proposed, which leads to the closed world-line configuration (e). As in the two previous figures a thick line denotes an up-spin and a thin line a down-spin.

a loop shown in Figure 6(b). The loop construction rules, which ignore the magnetic field, propose to flip one of the spins and go to the intermediate configuration $|\uparrow\downarrow\rangle$ with energy $-1/4J$ shown in Figure 6(c). This move costs potential energy $J/2$ and thus has an *exponentially small acceptance rate* $\exp(-\beta J/2)$. Once we accept this move, immediately many small loops are built, exchanging the spins on the two sites, and gaining exchange energy $J/2$ by going to the spin singlet state. A typical world-line configuration for the singlet is shown in Figure 6d). The reverse move has the same exponentially small probability, since the probability to reach a world-line configuration without any exchange term (Figure 6c) from a spin singlet configuration (Figure 6d) is exponentially small.

This example clearly illustrates the reason for the exponential slowdown: in the first step, we *lose all potential energy*, before *gaining it back in exchange energy*. A faster algorithm could thus be built if, instead of doing the trade in one big step, we could trade potential with exchange energy in small pieces, which is exactly what the worm algorithm does.

4.5.2 The worm algorithm

The worm algorithm (Prokofev, Svistunov and Tupitsyn, 1998) works in an extended configuration space, where in addition to closed world-line configurations one open world-line fragment (the 'worm') is allowed. Formally, this is done by adding a source term to the Hamiltonian, which for a spin model is

$$H_{\text{worm}} = H - \eta \sum_i (S_i^+ + S_i^-) \tag{42}$$

This source term allows world lines to be broken with a matrix element proportional to η. The worm algorithm now proceeds as follows: a worm (i.e., a world-line fragment) is created by inserting a pair (S_i^+, S_i^-) of operators at nearby times, as shown in Figure 7(a) and (b). The ends of this worm are then moved randomly in space and time (Figure 7c), using local Metropolis or heat bath updates until the two ends of the worm meet again as in Figure 7(d). Then an update which removes the worm is proposed, and if accepted we are back in a configuration with closed world lines only, as shown in Figure 7(e).

This algorithm is straightforward, consisting just of local updates of the worm ends in the extended configuration space but it can perform nonlocal changes. A worm end can wind around the lattice in the temporal or spatial direction and in this way change the magnetization and winding number.

In contrast to the loop algorithm in a magnetic field, where the trade between potential and exchange energy is done by first losing all of the potential energy, before gaining back the exchange energy, the worm algorithm performs this trade in small pieces, never suffering from an exponentially small acceptance probability.

While it is not as efficient as the loop algorithm in zero magnetic field (the worm movement follows a random walk while the loop algorithm can be interpreted as a self-avoiding random walk), the big advantage of the worm algorithm is that it remains efficient in the presence of a magnetic field.

4.5.3 The directed-loop algorithm

Algorithms with a similar basic idea as the worm algorithm in the path-integral representations are the operator-loop update (Sandvik, 1999; Dorneich and Troyer, 2001) and the directed-loop algorithms (Syljuasen and Sandvik, 2002) which can be formulated in both an SSE and a world-line representation. Like the worm algorithm, these algorithms create two world-line discontinuities, and move them around by local updates. The main difference compared to the worm algorithm is that

here these movements do not follow an unbiased random walk but have a preferred direction – always trying to move away from the last change, which further speeds up the simulations.

4.6 Extended ensemble methods and parallel tempering

Extended ensemble methods, such as the multicanonical ensemble, Wang-Landau sampling or parallel tempering can also be generalized to quantum systems (Troyer, Wessel and Alet, 2003, 2004). Similar to classical systems, they accelerate the tunneling through free energy barriers and thus speed up simulations at first order phase transitions. Note, however, that frustrated quantum spin systems generally suffer from the negative sign problem. Since the negative sign problem is a property of the representation and not the ensemble or the updates, the scaling will remain exponential even when using improved sampling algorithms, in contrast to classical simulations where extended ensemble algorithms and parallel tempering could speed up the simulations.

The main advantage of generalized ensemble simulations in quantum systems is thus, next to speeding up simulations of first order phase transitions, the ability to directly calculate the density of states and from this to calculate thermodynamic properties such as the entropy or the free energy that are not directly accessible in canonical ensemble simulations.

4.7 Open-source implementations: the ALPS project

The loop, worm, and directed-loop algorithms can be used for the simulation of a wide class of quantum magnets. They are of interest not only to theoretical physicists, but also to experimentalists who want to fit experimental measurements to theoretical models. The wide applicability of these methods has led to the publication of open-source versions of these algorithms as part of the ALPS project (Algorithms and Libraries for Physics Simulations) (Alet *et al*., 2005) on the web page http://alps.comp-phys.org/.

5 DETERMINENTAL ALGORITHMS

In this chapter, we review the basic concepts involved in the formulation of various forms of auxiliary field – or determinental – QMC algorithms. Auxiliary field methods are based on a Hubbard-Stratonovich (HS) decomposition of the two-body interaction term thereby yielding a functional integral expression for the partition function.

$$\mathrm{Tr}\left[e^{-\beta(H-\mu N)}\right] \propto \int \mathrm{d}\Phi(i,\tau) e^{-S[\phi(i,\tau)]} \tag{43}$$

Here, i runs over all lattice sites and τ from 0 to β. For a fixed HS field, $\Phi(i,\tau)$, one has to compute the action, $S[\Phi(i,\tau)]$, corresponding to a problem of noninteracting electrons in an external space and imaginary time-dependent field. The required computational effort depends on the formulation of the algorithm. In the Blankenbecler Scalapino Sugar (BSS) (Blankenbecler, Scalapino and Sugar, 1981) approach, appropriate for lattice models such as the Hubbard Hamiltonian, it scales as βN^3. In the Hirsch-Fye approach (Hirsch and Fye, 1986), appropriate for impurity problems, it scales as $\beta^3 N_{imp}^3$ where N_{imp} corresponds to the number of impurity or correlated sites. Having solved for a fixed HS field, we have to sum over all possible fields. This is done stochastically with the Monte Carlo method.

In comparison to loop algorithms, auxiliary field methods are slow. However, the attractive point of the approach lies in the fact that the sign problem is absent in many nontrivial cases where the loop algorithm fails. Here, we review different formulations appropriate for lattice and impurity problems.

5.1 Lattice methods

To describe the algorithm, we concentrate on the Hubbard model

$$\begin{aligned} H &= H_t + H_U \quad \text{with} \\ H_t &= -t \sum_{\langle \vec{i},\vec{j}\rangle,\sigma} c^\dagger_{\vec{i},\sigma} c_{\vec{j},\sigma} \quad \text{and} \\ H_U &= U \sum_{\vec{i}} \left(n_{\vec{i},\uparrow} - 1/2\right)\left(n_{\vec{i},\downarrow} - 1/2\right) \end{aligned} \tag{44}$$

and show how to compute

$$\langle O\rangle = \frac{\mathrm{Tr}\left[e^{-\beta(H-\mu N)} O\right]}{\mathrm{Tr}\left[e^{-\beta(H-\mu N)}\right]} \tag{45}$$

for an arbitrary observable O.

5.1.1 Formulation of the partition function

We first use the Trotter decomposition to separate the single body Hamiltonian H_t from the two-body interaction term in

the imaginary-time propagation.

$$Z = \mathrm{Tr}\left[e^{-\beta(H-\mu N)}\right] = \mathrm{Tr}\left[\left(e^{-\Delta\tau H_U} e^{-\Delta\tau H_t}\right)^m\right] + \mathcal{O}\left(\Delta\tau^2\right) \tag{46}$$

Here, we have included the chemical potential in a redefinition of H_t, and $m\Delta\tau = \beta$. The systematic error of order $\Delta\tau^2$ will be omitted in the following. There are many possible ways of decoupling the Hubbard interaction and the efficiency as well as the severity of the sign problem will depend upon this choice. The standard procedure is to use a discrete HS transformation introduced by Hirsch in which the field takes two values (Ising spin) and couples to the z-component of the magnetization.

$$e^{-\Delta\tau U\sum_{\vec{i}}\left(n_{\vec{i},\uparrow}-1/2\right)\left(n_{\vec{i},\downarrow}-1/2\right)} = C\sum_{s_1,\ldots,s_N=\pm 1} e^{\alpha\sum_{\vec{i}} s_{\vec{i}}\left(n_{\vec{i},\uparrow}-n_{\vec{i},\downarrow}\right)} \tag{47}$$

where $\cosh(\alpha) = \exp(\Delta\tau U/2)$ and on an N-site lattice, the constant $C = \exp(\Delta\tau U N/4)/2^N$. This equation is readily verified for a single site where the Hilbert space is spanned by the four states: $|\uparrow\rangle$, $|\downarrow\rangle$, $|\uparrow\downarrow\rangle$, and $|0\rangle$.

To simplify the notation we introduce the index $x = (\vec{i}, \sigma)$ to define:

$$H_t = \sum_{x,y} c_x^\dagger T_{x,y} c_y \equiv \vec{c}^\dagger T \vec{c} \quad \text{and}$$

$$\alpha\sum_{\vec{i}} s_{\vec{i}}\left(n_{\vec{i},\uparrow}-n_{\vec{i},\downarrow}\right) = \sum_{x,y} c_x^\dagger V(\vec{s})_{x,y} c_y \equiv \vec{c}^\dagger V(\vec{s})\vec{c} \tag{48}$$

We furthermore define the imaginary-time propagators:

$$U_{\vec{s}}(\tau_2,\tau_1) = \prod_{n=n_1+1}^{n_2} e^{\vec{c}^\dagger V(\vec{s}_n)\vec{c}} e^{-\Delta\tau\vec{c}^\dagger T\vec{c}} \quad \text{and}$$

$$B_{\vec{s}}(\tau_2,\tau_1) = \prod_{n=n_1+1}^{n_2} e^{V(\vec{s}_n)} e^{-\Delta\tau T} \tag{49}$$

where, $n_1\Delta\tau = \tau_1$ and $n_2\Delta\tau = \tau_2$

For a given HS configuration of Ising spins we can now integrate out the fermionic degrees of freedom to obtain:

$$\begin{aligned} Z &= C^m \sum_{\vec{s}_1,\cdots,\vec{s}_m} \mathrm{Tr}\left[U_{\vec{s}}(\beta,0)\right] \\ &= C^m \sum_{\vec{s}_1,\cdots,\vec{s}_m} \det\left[1 + B_{\vec{s}}(\beta,0)\right] \end{aligned} \tag{50}$$

5.1.2 The single particle Green function

One of the big advantages of the auxiliary field approach is its ability of measuring arbitrary observables. This is based on the fact that for a given HS field we have to solve a problem of noninteracting fermions in the external field. Hence Wick's theorem holds for a single HS configuration. Here, we concentrate on equal time observables, show how to compute Green functions, and finally demonstrate the validity of Wick's theorem within the present formulation.

In general, we have to evaluate:

$$\frac{\mathrm{Tr}\left[e^{-\beta H} O\right]}{\mathrm{Tr}\left[e^{-\beta H}\right]} = \sum_{\vec{s}} \mathrm{P}_{\vec{s}} \langle O\rangle_{\vec{s}} \tag{51}$$

where

$$\begin{aligned} \mathrm{P}_{\vec{s}} &= \frac{\det\left(1 + B_{\vec{s}}(\beta,0)\right)}{\sum_{\vec{s}}\det\left(1 + B_{\vec{s}}(\beta,0)\right)}, \\ \langle O\rangle_{\vec{s}} &= \frac{\mathrm{Tr}\left[U_{\vec{s}}(\beta,\tau) O U_{\vec{s}}(\tau,0)\right]}{\mathrm{Tr}\left[U_{\vec{s}}(\beta,0)\right]} \end{aligned}$$

Here, we measure the observable at time τ. Single body observables, $O = \vec{c}^\dagger A \vec{c}$ are given by:

$$\begin{aligned} \langle O\rangle_{\vec{s}} &= \left.\frac{\partial \ln \mathrm{Tr}\left[U_{\vec{s}}(\beta,\tau) e^{\eta O} U_{\vec{s}}(\tau,0)\right]}{\partial\eta}\right|_{\eta=0} \\ &= \left.\frac{\partial \ln \det\left[1 + B_{\vec{s}}(\beta,\tau) e^{\eta A} B_{\vec{s}}(\tau,0)\right]}{\partial\eta}\right|_{\eta=0} \\ &= \left.\frac{\partial \mathrm{Tr} \ln\left[1 + B_{\vec{s}}(\beta,\tau) e^{\eta A} B_{\vec{s}}(\tau,0)\right]}{\partial\eta}\right|_{\eta=0} \\ &= \mathrm{Tr}\left[B_{\vec{s}}(\tau,0)(1 + B_{\vec{s}}(\beta,0))^{-1} B_{\vec{s}}(\beta,\tau) A\right] \\ &= \mathrm{Tr}\left[\left(1 - (1 + B_{\vec{s}}(\tau,0) B_{\vec{s}}(\beta,\tau))^{-1}\right) A\right] \end{aligned} \tag{52}$$

In particular the Green function reads:

$$G_{x,y}(\tau,\tau) = \langle c_x c_y^\dagger\rangle_{\vec{s}} = (1 + B_{\vec{s}}(\tau,0) B_{\vec{s}}(\beta,\tau))^{-1}_{x,y} \tag{53}$$

5.1.3 Wick's theorem

We now show that any multipoint correlation function decouples into a sum of products of the above defined Green functions. First, we define the cumulants:

$$\begin{aligned} &\langle\langle O_n \cdots O_1\rangle\rangle_{\vec{s}} \\ &\quad = \left.\frac{\partial^n \ln \mathrm{Tr}\left[U_{\vec{s}}(\beta,\tau) e^{\eta_n O_n} \cdots e^{\eta_1 O_1} U_{\vec{s}}(\tau,0)\right]}{\partial\eta_n \cdots \partial\eta_1}\right|_{\eta_1\cdots\eta_n=0} \\ &\quad \text{with} \quad O_i = \vec{c}^\dagger A^{(i)} \vec{c} \end{aligned} \tag{54}$$

The following rule, which may be proven by induction (Tsvelik, 1995), emerges:

$$\begin{aligned}\langle O_n \cdots O_1 \rangle_{\vec{s}} = &\langle\langle O_n \cdots O_1 \rangle\rangle_{\vec{s}} \\ &+ \sum_{j=1}^{n} \langle\langle O_n \cdots \widehat{O_j} \cdots O_1 \rangle\rangle_{\vec{s}} \langle\langle O_j \rangle\rangle_{\vec{s}} \\ &+ \sum_{j>i} \langle\langle O_n \cdots \widehat{O_j} \cdots \widehat{O_i} \cdots O_1 \rangle\rangle_{\vec{s}} \langle\langle O_j O_i \rangle\rangle_{\vec{s}} \\ &+ \cdots + \langle\langle O_n \rangle\rangle_{\vec{s}} \cdots \langle\langle O_1 \rangle\rangle_{\vec{s}} \end{aligned} \tag{55}$$

where $\widehat{O_j}$ means that the operator O_j has been omitted from the product.

We can compute the cumulants order by order to see that they depend only on the single particle Green function. For instance, it is easy to show that

$$\begin{aligned}\langle\langle O_2 O_1 \rangle\rangle_{\vec{s}} &= \mathrm{Tr}\left(\overline{G_{\vec{s}}(\tau,\tau)} A^{(2)} G_{\vec{s}}(\tau,\tau) A^{(1)} \right) \\ \text{with} \quad \overline{G} &= 1 - G \end{aligned} \tag{56}$$

or that

$$\begin{aligned}&\langle\langle O_3 O_2 O_1 \rangle\rangle_{\vec{s}} \\ &\quad = \mathrm{Tr}\left(\overline{G_{\vec{s}}(\tau,\tau)} A^{(3)} G_{\vec{s}}(\tau,\tau) A^{(2)} G_{\vec{s}}(\tau,\tau) A^{(1)} \right) \\ &\quad\quad - \mathrm{Tr}\left(\overline{G_{\vec{s}}(\tau,\tau)} A^{(3)} G_{\vec{s}}(\tau,\tau) A^{(1)} \overline{G_{\vec{s}}(\tau,\tau)} A^{(2)} \right) \end{aligned} \tag{57}$$

Hence, with equation (55) we have shown that any n-point correlation function may be calculated from the knowledge of the Green function.

5.1.4 Imaginary-time-displaced Green functions.

Imaginary-time-displaced correlation yield important information. On one hand they may be used to obtain spin and charge gaps (Assaad and Imada, 1996b; Assaad, 1999), as well quasiparticle weights (Brunner, Assaad and Muramatsu, 2000). On the other hand, with the use of the Maximum Entropy method (Jarrell and Gubernatis, 1996; von der Linden, 1995) dynamical properties such as spin and charge dynamical structure factors, optical conductivity, and single particle spectral functions may be computed. Those quantities offer the possibility of direct comparison with experiments, such as photoemission, neutron scattering, and optical measurements.

Since there is again a Wick's theorem for time displaced correlation functions, it suffices to compute the single particle Green function for a given HS configuration. For a given HS field, we evaluate:

$$\begin{aligned} G_{\vec{s}}(\tau_1,\tau_2)_{x,y} &= \langle T c_x(\tau_1) c_y^\dagger(\tau_2) \rangle_{\vec{s}} \\ &= \begin{cases} \langle c_x(\tau_1) c_y^\dagger(\tau_2) \rangle_{\vec{s}} & \text{if} \quad \tau_1 \geq \tau_2 \\ -\langle c_y^\dagger(\tau_2) c_x(\tau_1) \rangle_{\vec{s}} & \text{if} \quad \tau_1 < \tau_2 \end{cases} \end{aligned} \tag{58}$$

where T corresponds to the time ordering. Thus for $\tau_1 > \tau_2 G_{\vec{s}}(\tau_1,\tau_2)_{x,y}$ reduces to

$$\begin{aligned}&\langle c_x(\tau_1) c_y^\dagger(\tau_2) \rangle_{\vec{s}} \\ &\quad = \frac{\mathrm{Tr}\left[U_{\vec{s}}(\beta,\tau_1) c_x U_{\vec{s}}(\tau_1,\tau_2) c_y^\dagger U_{\vec{s}}(\tau_2,0) \right]}{\mathrm{Tr}\left[U_{\vec{s}}(\beta,0) \right]} \\ &\quad = \frac{\mathrm{Tr}\left[U_{\vec{s}}(\beta,\tau_2) U_{\vec{s}}^{-1}(\tau_1,\tau_2) c_x U_{\vec{s}}(\tau_1,\tau_2) c_y^\dagger U_{\vec{s}}(\tau_2,0) \right]}{\mathrm{Tr}\left[U_{\vec{s}}(\beta,0) \right]} \end{aligned} \tag{59}$$

Evaluating $U^{-1}(\tau_1,\tau_2) c_x U_{\vec{s}}(\tau_1,\tau_2)$ boils down to the calculation of

$$c_x(\tau) = e^{\tau \vec{c}^\dagger A \vec{c}} c_x e^{-\tau \vec{c}^\dagger A \vec{c}} \equiv \left(e^{-A} \vec{c} \right)_x$$

We can use the above equation successively to obtain:

$$U_{\vec{s}}^{-1}(\tau_1,\tau_2) c_x U_{\vec{s}}(\tau_1,\tau_2) = (B_{\vec{s}}(\tau_1,\tau_2)\vec{c})_x \tag{60}$$

We can pull out B from the trace in equation (59) to obtain:

$$\begin{aligned} G_{\vec{s}}(\tau_1,\tau_2)_{x,y} &= \langle c_x(\tau_1) c_y^\dagger(\tau_2) \rangle_{\vec{s}} \\ &= [B_{\vec{s}}(\tau_1,\tau_2) G_{\vec{s}}(\tau_2,\tau_2)]_{x,y} \quad \tau_1 > \tau_2 \end{aligned} \tag{61}$$

where $G_{\vec{s}}(\tau_2,\tau_2)$ is the equal time Green function computed previously. A similar calculation will yield for $\tau_2 > \tau_1$

$$\begin{aligned} G_{\vec{s}}(\tau_1,\tau_2)_{x,y} &= -\langle c_y^\dagger(\tau_2) c_x(\tau_1) \rangle_{\vec{s}} \\ &= -\left[(1 - G_{\vec{s}}(\tau_1,\tau_1))\, B_{\vec{s}}^{-1}(\tau_2,\tau_1) \right]_{x,y} \end{aligned} \tag{62}$$

5.1.5 Local updates

Since an exact enumeration of all HS field configuration is out of reach on large lattice sizes, we sample the most relevant ones with the Monte Carlo method. The problem at hand is very similar in nature to the Ising model, presented in section 3. The important difference, however, is that the action is nonlocal. Under a single spin-flip we will have to compute the ratio

$$R = \frac{\mathrm{P}_{\vec{s}'}}{\mathrm{P}_{\vec{s}}} = \frac{\det\left[1 + B_{\vec{s}'}(\beta,0)\right]}{\det\left[1 + B_{\vec{s}}(\beta,0)\right]} \tag{63}$$

to decide if we accept the proposed update or not. Here $\vec{s}$ and $\vec{s}'$ differ only at one point in space and imaginary time, $\vec{i}, n$.

$$s'_{\vec{i}',n'} = \begin{cases} s_{\vec{i}',n'} & \text{if} \quad \vec{i}' \neq \vec{i} \quad \text{and} \quad n' \neq n \\ -s_{\vec{i},n} & \text{if} \quad \vec{i}' = \vec{i} \quad \text{and} \quad n' = n \end{cases} \tag{64}$$

The calculation of R boils down to computing the ratio of two determinants. For the Hubbard interaction with HS transformation of equation (47) only the matrix $V(\vec{s}_n)$ will be affected by the move. Hence, with

$$e^{V(\vec{s}'_n)} = \left[1 + \underbrace{\left(e^{V(\vec{s}'_n)} e^{-V(\vec{s}_n)} - 1 \right)}_{\Delta} \right] e^{V(\vec{s}_n)} \tag{65}$$

we have:

$$B_{\vec{s}'}(\beta, 0) = B_{\vec{s}}(\beta, \tau)\,(1 + \Delta)\,B_{\vec{s}}(\tau, 0) \tag{66}$$

The ratio is then given by:

$$\begin{aligned} R &= \frac{\det\left[1 + B_{\vec{s}}(\beta,\tau)(1+\Delta)B_{\vec{s}}(\tau,0)\right]}{\det\left[1 + B_{\vec{s}}(\beta,0)\right]} \\ &= \det\left[1 + \Delta B_{\vec{s}}(\tau,0)\,(1 + B_{\vec{s}}(\beta,0))^{-1}\,B_{\vec{s}}(\beta,\tau)\right] \\ &= \det\left[1 + \Delta\left(1 - (1 + B_{\vec{s}}(\tau,0)B_{\vec{s}}(\beta,\tau))^{-1}\right)\right] \\ &= \det\left[1 + \Delta\overline{G}_{\vec{s}}(\tau,\tau)\right] \end{aligned} \tag{67}$$

Here we have used the fact that $\det[1 + AB] = \det[1 + BA]$ for arbitrary rectangular matrices. Hence, the Green function determines the Monte Carlo dynamics.

Having calculated the ratio R for a single spin-flip one may now decide stochastically within, for example, a Metropolis scheme if the move is accepted or not. In case of acceptance, we have to update the Green function since this quantity is required at the next step.

Since in general the matrix Δ has only a few non-zero entries, it is convenient to use the Sherman-Morrison formulas (Press, Teukolsky, Vetterling and Flannery, 1992) to update the Green function. This formula states that:

$$(A + \vec{u} \otimes \vec{v})^{-1} = A^{-1} - \frac{\left(A^{-1}\vec{u}\right) \otimes \left(\vec{v}A^{-1}\right)}{1 + \vec{v} \bullet A^{-1}\vec{u}} \tag{68}$$

where A is a $N \times N$ matrix, $\vec{u}$, $\vec{v}$ N-dimensional vectors with tensor product defined as $(\vec{u} \otimes \vec{v})_{x,y} = \vec{u}_x \vec{v}_y$.

To show how to use the above formula for the updating of the Green function, let us first assume that matrix Δ has only one nonvanishing entry: $\Delta_{x,y} = \delta_{x,z}\delta_{y,z'}\eta^{(z,z')}$.

$$\begin{aligned} &G_{\vec{s}'}(\tau) \\ &\quad = [1 + (1 + \Delta)B_{\vec{s}}(\tau,0)B_{\vec{s}}(\beta,\tau)]^{-1} \\ &\quad = B_{\vec{s}}^{-1}(\beta,\tau)\,[1 + B_{\vec{s}}(\beta,\tau)(1+\Delta)B_{\vec{s}}(\tau,0)]^{-1}\,B_{\vec{s}}(\beta,\tau) \\ &\quad = B_{\vec{s}}^{-1}(\beta,\tau)\left[1 + B_{\vec{s}}(\beta,\tau)B_{\vec{s}}(\tau,0) + \vec{u} \otimes \vec{v}\right]^{-1} B_{\vec{s}}(\beta,\tau) \end{aligned} \tag{69}$$

where

$$\vec{u}_x = [B_{\vec{s}}(\beta,\tau)]_{x,z}\,\eta^{(z,z')} \quad \text{and} \quad \vec{v}_x = [B_{\vec{s}}(\tau,0)]_{z',x} \tag{70}$$

Using the Sherman-Morrison formula for inverting $1 + B_{\vec{s}}(\beta,\tau)B_{\vec{s}}(\tau,0) + \vec{u} \otimes \vec{v}$ yields

$$\begin{aligned} &[G_{\vec{s}'}(\tau,\tau)]_{x,y} \\ &\quad = [G_{\vec{s}}(\tau,\tau)]_{x,y} \\ &\qquad - \frac{[G_{\vec{s}}(\tau,\tau)]_{x,z}\,\eta^{(z,z')}\,[1 - G_{\vec{s}}(\tau,\tau)]_{z',y}}{1 + \eta^{(z,z')}\,[1 - G_{\vec{s}}(\tau,\tau)]_{z',z}} \end{aligned} \tag{71}$$

In the above, we have assumed that the matrix Δ has only a single non-zero entry. In general, it is convenient to work on a basis where Δ is diagonal with n nonvanishing eigenvalues. One will then iterate the above procedure n-times to update the Green function.

In principle, we now have all the elements required to carry out a QMC simulation. The space we have to sample is that of Nm Ising spins. Here N is the number of lattice sites and m is the number of imaginary-time slices. It is convenient to adopt a sequential updating scheme so as to sweep from time slice $\tau = 0$ to $\tau = \beta$. After initially computing the Green function on time at $\tau = 0$, we iteratively repeat the following steps:

1. Given the Green function on time slice τ, we sequentially go through all the spins on this time slice. For each Ising spin we compute R and flip the spin with probability $\min[1, R]$ or the heat bath probability $R/(1 + R)$. If accepted we update the Green function, and if rejected we keep the old Green function and old Ising spin configuration.
2. Perform measurements.
3. Propagate the Green function from time slice τ to times slice $\tau + 1$ using the equation

$$G_{\vec{s}}(\tau + 1, \tau + 1) = B_{\vec{s}}(\tau + 1, \tau)G_{\vec{s}}(\tau,\tau)B_{\vec{s}}^{-1}(\tau + 1, \tau) \tag{72}$$

4. Iterate the procedure.

It is to be noted that the implementation of the above algorithm suffers from numerical instabilities at low temperatures. One can, however, stabilize the code by avoiding the

mixing of different scales. An account of those numerical stabilization techniques can be found in (Assaad, 2002b; Loh and Gubernatis, 1992).

5.2 The sign problem

One of the big advantages of the auxiliary field method is that, one can use symmetries to show explicitly that the sign problem does not occur. In the case of the half-filled Hubbard model on a bipartite lattice, particle-hole symmetry ensures that the statistical weight is always positive. The usual proof is based on the factorization of the determinant. Consider the HS transformation of equation (47), then:

$$\det\left(1+B(\beta,0)\right)=\det\left(1+B^{\uparrow}(\beta,0)\right)\det\left(1+B^{\downarrow}(\beta,0)\right) \tag{73}$$

With the particle-hole transformation for a two-dimensional lattice

$$\mathcal{P}^{-1}c_{\vec{i}}^{\dagger}\mathcal{P}=(-1)^{i_x+i_y}c_{\vec{i}} \tag{74}$$

for spinless fermions and $h_t=\sum_{\vec{i},\vec{j}}c_{\vec{i}}^{\dagger}T_{\vec{i},\vec{j}}c_{\vec{j}}$ we have:

$$\begin{aligned}\det\left(1+B^{\uparrow}(\beta,0)\right)&=\mathrm{Tr}\left[\prod_n e^{\alpha\sum_{\vec{i}}s_{\vec{i},n}n_{\vec{i}}}e^{-\Delta\tau h_t}\right]\\&=\mathrm{Tr}\left[\prod_n e^{\alpha\sum_{\vec{i}}s_{\vec{i},n}\mathcal{P}n_{\vec{i}}\mathcal{P}}e^{-\Delta\tau\mathcal{P}^{-1}h_t\mathcal{P}}\right] \qquad (75)\\&=\mathrm{Tr}\left[\prod_n e^{\alpha\sum_{\vec{i}}s_{\vec{i},n}(1-n_{\vec{i}})}e^{-\Delta\tau h_t}\right]\\&=e^{\alpha\sum_{\vec{i},n}s_{\vec{i},n}}\det\left(1+B^{\downarrow}(\beta,0)\right) \qquad (76)\end{aligned}$$

Here, we assumed that $\mathcal{P}^{-1}h_t\mathcal{P}=h_t$ which restricts us to half-filling. Thus the symmetry locks together the sign of both determinants so that no sign problem occurs.

There are more general ways of showing the absence of the sign problem (Wu and Zhang, 2005) which are independent on the factorization of the determinant. If there exists an antiunitary transformation $\mathcal{T}$ such that:

$$\begin{aligned}&\mathcal{T}^{-1}H_t\mathcal{T}=H_t\ \mathcal{T}^{-1}\vec{c}^{\dagger}V(\vec{s}_n)\vec{c}\mathcal{T}=\vec{c}^{\dagger}V(\vec{s}_n)\vec{c}\quad\text{and}\\&\mathcal{T}^2=-1\end{aligned} \tag{77}$$

the eigenvalues of the matrix $1+B(\beta,0)$ always occur in complex conjugate pairs such that:

$$\det\left(1+B(\beta,0)\right)=\prod_i|\lambda_i|^2 \tag{78}$$

Hence, no sign problem occurs.

5.3 The Hirsch-Fye impurity algorithm

This algorithm is used to solve impurity problems such as the Kondo and Anderson models. The strong point of the algorithm is that the CPU time is independent of the volume of the system thus allowing one to carry out simulations directly in the *thermodynamic* limit. The price, however, is a β^3 scaling of the CPU time where β is the inverse temperature. The Hirsch-Fye algorithm is extensively used in the framework of dynamical mean-field theories (DMFT) which become exact in the limit of infinite dimensions. In this limit, the Hubbard model maps onto the single impurity Anderson model (SIAM) supplemented with a self-consistency loop. At each iteration step, an Anderson model has to be solved and this is carried out with the Hirsch-Fye algorithm (Jarrell, 1992; Georges, Kotliar, Krauth and Rozenberg, 1996). In this chapter, we will concentrate on the Anderson model defined as:

$$\begin{aligned}H-\mu N&=H_0+H_U\quad\text{with}\\H_0&=\sum_{\vec{k},\sigma}\left(\epsilon(\vec{k})-\mu\right)c_{\vec{k},\sigma}^{\dagger}c_{\vec{k},\sigma}\\&\quad+\frac{V}{\sqrt{N}}\sum_{\vec{k},\sigma}c_{\vec{k},\sigma}^{\dagger}f_{\sigma}+f_{\sigma}^{\dagger}c_{\vec{k},\sigma}+\epsilon_f\sum_{\sigma}f_{\sigma}^{\dagger}f_{\sigma},\\H_U&=U\left(f_{\uparrow}^{\dagger}f_{\uparrow}-1/2\right)\left(f_{\downarrow}^{\dagger}f_{\downarrow}-1/2\right)\end{aligned} \tag{79}$$

We have shown (see equation (50)) that the grand canonical partition function may be written as:

$$\begin{aligned}Z&\equiv\mathrm{Tr}\left[e^{-\beta(H-\mu N)}\right]\\&=\sum_{\vec{s}}\left[\prod_{\sigma}\det\left[1+B_m^{\sigma}B_{m-1}^{\sigma}\cdots B_1^{\sigma}\right]\right]\end{aligned} \tag{80}$$

with $m\Delta\tau=\beta$.

To define the matrices B_n^{σ}, we will label all the orbitals (conduction and impurity) with the index $\vec{i}$ and use the convention that $\vec{i}=0$ denotes the f-orbital and $\vec{i}=1\cdots N$ the conduction orbitals. We will furthermore define the fermionic operators:

$$a_{\vec{i},\sigma}^{\dagger}=\begin{cases}f_{\sigma}^{\dagger} & \text{if}\quad\vec{i}=0\\ c_{\vec{i},\sigma}^{\dagger} & \text{otherwise}\end{cases} \tag{81}$$

such that the noninteracting term of the Anderson model takes the form:

$$H_0=\sum_{\sigma}H_0^{\sigma},\quad H_0^{\sigma}=\sum_{\vec{i},\vec{j}}a_{\vec{i},\sigma}^{\dagger}(h_0)_{\vec{i},\vec{j}}a_{\vec{j},\sigma} \tag{82}$$

Using the HS transformation of equation (47), the B matrices read:

$$B_n^\sigma = e^{V_n^\sigma} e^{-\Delta\tau h_0}$$
$$(V_n^\sigma)_{\vec{i},\vec{j}} = \delta_{\vec{i},\vec{j}}\delta_{\vec{i},0}\alpha\sigma s_n, \quad \cosh(\alpha) = e^{\Delta\tau U/2} \tag{83}$$

The determinant in a given spin sector may be written as

$$\det\left[1 + B_m^\sigma B_{m-1}^\sigma \cdots B_1^\sigma\right] = \det O^\sigma \quad \text{with} \tag{84}$$

$$O^\sigma = \begin{pmatrix} 1 & 0 & . & . & 0 & B_1^\sigma \\ -B_2^\sigma & 1 & 0 & . & . & 0 \\ 0 & -B_3^\sigma & 1 & . & . & 0 \\ . & 0 & -B_4^\sigma & . & . & . \\ . & . & 0 & . & . & . \\ . & . & . & . & . & . \\ 0 & . & . & 0 & -B_m^\sigma & 1 \end{pmatrix} \tag{85}$$

One can verify that:

$$(O^\sigma)^{-1} \equiv g^\sigma = \begin{pmatrix} G^\sigma(1,1) & G^\sigma(1,2) & . & . & G^\sigma(1,m) \\ G^\sigma(2,1) & G^\sigma(2,2) & . & . & G^\sigma(2,m) \\ . & . & . & . & . \\ G^\sigma(m,1) & G^\sigma(m,2) & . & . & G^\sigma(m,m) \end{pmatrix} \tag{86}$$

where $G^\sigma(n_1, n_2)$ are the time displaced Green functions: defined in Equation (61) and (62). Given a HS configuration $\vec{s}$ and $\vec{s}'$ and associated matrices

$$V^\sigma = \begin{pmatrix} V_1^\sigma & 0 & . & . & . & 0 \\ 0 & V_2^\sigma & 0 & . & . & 0 \\ 0 & 0 & V_3^\sigma & 0 & . & 0 \\ . & . & . & . & . & . \\ 0 & . & . & . & 0 & V_m^\sigma \end{pmatrix} \tag{87}$$

and V'^σ the Green functions g^σ and g'^σ satisfy the following Dyson equation:

$$g^\sigma = g'^\sigma + g'^\sigma\Delta(1 - g^\sigma) \quad \text{with} \quad \Delta^\sigma = (e^{V'^\sigma} e^{-V^\sigma} - 1) \tag{88}$$

To demonstrate the above, we consider

$$\tilde{O}^\sigma = e^{-V^\sigma} O^\sigma = \begin{pmatrix} e^{-V_1^\sigma} & 0 & . & . & 0 & e^{-\Delta\tau h_0} \\ -e^{-\Delta\tau h_0} & e^{-V_2^\sigma} & 0 & . & . & 0 \\ 0 & -e^{-\Delta\tau h_0} & e^{-V_3^\sigma} & . & . & 0 \\ . & 0 & -e^{-\Delta\tau h_0} & . & . & . \\ . & . & 0 & . & . & . \\ . & . & . & . & . & . \\ 0 & . & . & 0 & -e^{-\Delta\tau h_0} & e^{-V_m^\sigma} \end{pmatrix} \tag{89}$$

so that (omitting the spin index σ)

$$\tilde{g} \equiv \tilde{O}^{-1} = [\tilde{O}' + \underbrace{\tilde{O} - \tilde{O}'}_{\equiv e^{-V} - e^{-V'}}]^{-1} = \tilde{g}' - \tilde{g}'\left(e^{-V} - e^{-V'}\right)\tilde{g} \tag{90}$$

The above equation follows from the identity: $\frac{1}{A+B} = \frac{1}{A} - \frac{1}{A}B\frac{1}{A+B}$. Substitution, $\tilde{g} = ge^V$, leads to the Dyson equation (88).

The above Dyson equation is the central identity in the Hirsch-Fye algorithm: all quantities required for the algorithm may be derived directly from this equality. An implementation of the algorithm involves two steps.

5.3.1 Calculation of the impurity Green function for a given HS configuration

The starting point of the algorithm is to compute the green function for a random HS configuration of Ising spins $\vec{s}'$. We will only need the Green function for the impurity f-site. Let $x = (\tau_x, \vec{i}_x)$ with Trotter index τ_x and orbital $\vec{i}_x$. Since

$$(e^{V'}e^{-V} - 1)_{x,y} = (e^{V'}e^{-V} - 1)_{x,x}\delta_{x,y}\delta_{\vec{i}_x,0} \tag{91}$$

we can use the Dyson equation only for the impurity Green function:

$$\left(g^\sigma_{f,f'} = g'^\sigma_{f,f'} + \sum_{f''} g'^\sigma_{f,f''}\Delta^\sigma_{f'',f''}(1 - g^\sigma)_{f'',f'}\right) \tag{92}$$

with indices $f \equiv (\tau, 0)$ running from $1 \cdots m$. Hence, the $m \times m$ impurity Green function matrix,

$$g^{I,\sigma}_{f,f'} = g^\sigma_{f,f'} \tag{93}$$

satisfies the Dyson equation:

$$g^{I,\sigma} = g'^{I,\sigma} + g'^{I,\sigma}\Delta^{I,\sigma}(1 - g^{I,\sigma}) \quad \text{with}$$
$$\Delta^{I,\sigma}_{f,f'} = \Delta^\sigma_{f,f'} \tag{94}$$

For $V = 0$, g^I is nothing but the impurity Green function of the noninteracting Anderson model which may readily be computed. Thus using the Dyson equation, we can compute the Green function g'^I for an arbitrary HS configuration $\vec{s}'$ at the cost of a $m \times m$ matrix inversion. This involves a CPU cost scaling as m^3 or equivalently β^3.

5.3.2 Updating

At this point we have computed the impurity Green function for a given HS configuration $\vec{s}$. Adopting a single-spin flip algorithm we will propose the configuration $\vec{s}'$ which stems from configuration $\vec{s}$ with one flipped spin at time f_1.

We accept this change with probability

$$R = \prod_{\sigma} R^{\sigma} \quad \text{with} \quad R^{\sigma} = \frac{\det\left[1 + B'^{\sigma}_{m} B'^{\sigma}_{m-1} \cdots B'^{\sigma}_{1}\right]}{\det\left[1 + B^{\sigma}_{m} B^{\sigma} m - 1 \cdots B^{\sigma}_{1}\right]}$$
$$= \det\left[g^{\sigma}(g'^{\sigma})^{-1}\right] = \det\left[1 + \Delta^{\sigma}\left(1 - g^{\sigma}\right)\right] \tag{95}$$

The last identity follows from the Dyson equation to express g^{σ} as $g^{\sigma} = g'^{\sigma}\left[1 + \Delta^{\sigma}\left(1 - g^{\sigma}\right)\right]$. Since $\vec{s}$ and $\vec{s}'$ differ only by one entry the matrix Δ^{σ} has one nonzero matrix element: $\Delta^{\sigma}_{f_1,f_1}$. Hence, $R^{\sigma} = 1 + \Delta^{\sigma}_{f_1,f_1}\left(1 - g^{\sigma}_{f_1,f_1}\right)$. Since the impurity Green function $g^{I,\sigma}$ is at hand, we can readily compute R.

If the move (spin-flip) is accepted, we will have to recalculate (update) the impurity Green function. From the Dyson equation (94), we have:

$$g'^{I,\sigma} = g^{I,\sigma}\left[1 + \Delta^{I,\sigma}\left(1 - g^{I,\sigma}\right)\right]^{-1} \tag{96}$$

To compute $\left[1 + \Delta^{I,\sigma}\left(1 - g^{I,\sigma}\right)\right]^{-1}$ we can use the Sherman-Morrison formulas (68) to obtain:

$$g'^{I,\sigma}_{f,f'} = g^{I,\sigma}_{f,f'} + \frac{g^{I,\sigma}_{f,f_1}\Delta^{\sigma}_{f_1,f_1}(g^{I,\sigma} - 1)_{f_1,f'}}{1 + (1 - g^{I,\sigma})_{f_1,f_1}\Delta^{\sigma}_{f_1,f_1}} \tag{97}$$

Thus, the updating of the Green function under a single spin-flip is an operation which scales as m^2. Since for a single sweep we have to visit all spins, the computational cost of a single sweep scales as m^3.

By construction, the Hirsch-Fye algorithm is free from numerical stabilization problems. Furthermore, the absence of the sign problem has recently been proven for the single impurity Anderson model (Yoo *et al.*, 2004). Clearly the attractive feature of the Hirsch-Fye impurity algorithm is that the algorithm may be formulated directly in the thermodynamic limit. This is not possible within the lattice formulation of the auxiliary field QMC method. Within this approach the dimension of the matrices scale as the total number of orbitals, N, and the CPU time for a single sweep as $N^3\beta$. The Hirsch-Fye algorithm is not limited to impurity models. However, when applied to lattice models, such as the Hubbard model, it is not efficient since the CPU time will scale as $(\beta N)^3$.

5.4 Projective methods

Each of the above finite-temperature methods has a projective counterpart to access ground state properties. We can start from a trial wave function $|\Psi_T\rangle$ in which we can embed prior knowledge of the ground state, $|\Psi_0\rangle$ such as symmetries or overlaps. Assuming that the trial wave is nonorthogonal to the ground state,

$$\frac{\langle\Psi_0|O|\Psi_0\rangle}{\langle\Psi_0|\Psi_0\rangle} = \lim_{\beta\to\infty}\frac{\langle\Psi_T|e^{-\beta H}Oe^{-\beta H}|\Psi_T\rangle}{\langle\Psi_T|e^{-2\beta H}|\Psi_T\rangle} \tag{98}$$

The extrapolation to infinite values of the projection parameter, β, is done numerically. A comparison of both algorithms for a SIAM is shown in Figure 8. We note that recently more efficient continuous time algorithms have been developed (Rubtsov, Savkin and Lichtenstein, 2005; Werner *et al.*, 2006; Werner and Millis, 2006) and refer the interested reader to these publications for details.

6 APPLICATIONS

We will finally present typical applications of the above algorithms by reviewing a small and necessarily biased selection.

6.1 Applications of the loop algorithm

The loop algorithm has been applied to a wide range of problems, ranging from purely theoretical questions to experimental data fitting. In the subsequent text, we list a small selection of applications that provide an overview of the possibilities

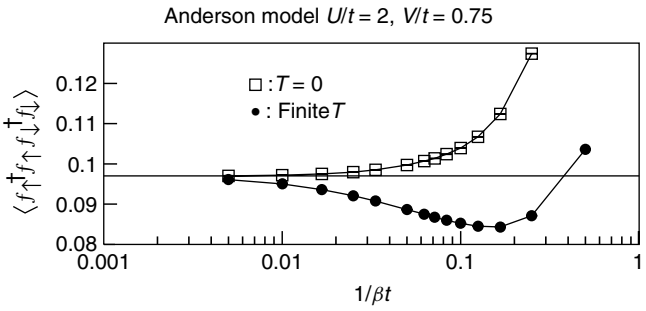

Figure 8. Comparison between the zero temperature (open squares) and finite-temperature Hirsch-Fye (bullets) algorithms for the symmetric Anderson model, with a one-dimensional half-filled density of states. For those parameters, the Kondo temperature is of the order of $0.02t$. In the limit $\beta t \to \infty$ both algorithms yield the same result for the double occupancy. Ground state results are, however, more efficiently obtained within the projective method. Furthermore, the projective approach is extremely efficient when used as an impurity solver in the framework of DMFT of the Hubbard model (Feldbacher, Assaad and Held, 2004).

of the loop algorithm. The first simulation using the loop algorithm was an accurate determination of the ground state properties (staggered magnetization, spin stiffness, and spin wave velocity) of the square-lattice spin-1/2 quantum Heisenberg antiferromagnet (Wiese and Ying, 1992). In a similar spirit the uniform susceptibility, correlation length, and spin gap of spin ladder models (Frischmuth, Ammon and Troyer, 1996; Greven, Birgeneau and Wiese, 1996) and integer spin chains (Todo and Kato, 2001) was calculated, confirming the presence of a spin gapped ground state in even-leg spin ladders and integer spin chains.

As the loop algorithm is efficient also at critical points, it has been used in the first high accuracy simulations of the critical properties of quantum phase transitions by studying the Néel to quantum paramagnet transition in two-dimensional quantum spin systems (Troyer, Imada and Ueda, 1997), for a determination of the low-temperature asymptotic scaling of two-dimensional quantum Heisenberg antiferromagnets (Kim and Troyer, 1998; Beard, Birgeneau, Greven and Wiese, 1998; Harada, Troyer and Kawashima, 1998), and for accurate calculations of the Néel temperature of anisotropic quasi-one- and quasi-two-dimensional antiferromagnets (Yasuda *et al*., 2005).

The loop algorithm is not only restricted to toy models, but can be applied to realistic models of quantum magnets. Comparisons to experimental measurements are done by fitting simulation data to experimental measurements, as for alternating chain compounds (Johnston *et al*., 2000b), spin ladder materials (Johnston, *et al*., 2000a) or frustrated square-lattice antiferromagnets (Melzi *et al*., 1999). In the latter material, the sign problem due to frustration limits the accuracy. As an example, we show in Figure 9 the good quality of a fit of QMC data to experimental measurements on the spin ladder compound $SrCu_2O_3$.

Another interesting application is to simulate realistic models for quantum magnets, using exchange constants calculated by *ab initio* methods. Comparing these *ab initio* QMC data to experimental measurements, as done for a series of vanadates (Korotin *et al*., 1998) and for ladder compounds (Johnston, *et al*., 2000a) allows to quantitatively check the *ab initio* calculations.

6.2 Applications of the worm and directed-loop algorithms

The worm and directed-loop algorithms are applied when magnetic fields are present. Typical examples include the calculation of magnetization curves of quantum magnets (Woodward *et al*., 2002), the determination of the first order nature of the spin flop transition in two dimensions (Schmid, Todo, Troyer and Dorneich, 2002) and the calculation of phase diagrams of dimerized quantum magnets in a magnetic field (Nohadani, Wessel, Normand and Haas, 2004).

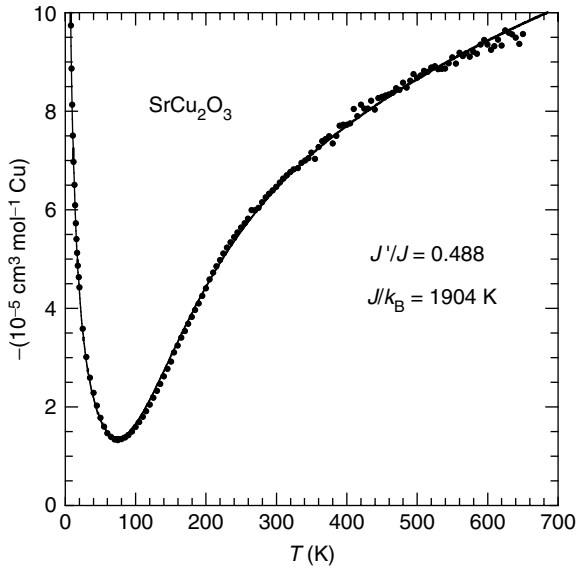

Figure 9. Fits of experimental measurements of the uniform susceptibility of $SrCu_2O_3$. (Azuma *et al*., 1994) to the results of QMC simulations, determining a coupling $J \approx 1904\ K$ along the chains of the ladder and a ratio $J'/J \approx 0.488$ for the rung to chain coupling.

6.3 Applications of the determinental algorithms

The applications of the auxiliary field algorithms to correlated electron systems are numerous. Here, we will only mention a few, starting with the attractive Hubbard model. This model essentially describes the electron–phonon problem in terms of the Holstein model which in the antiadiabatic limit maps onto the attractive Hubbard model (Hirsch and Fradkin, 1983). Both models are free of a sign problem in arbitrary dimensions and on arbitrary lattice topologies. The salient features of those models have been investigated in detail. For instance, the crossover from long coherence length (BCS) to short coherence length superconductors. In the short coherence length limit, a liquid of preformed pairs with non-Fermi liquid character is apparent above the transition temperature (Randeria, Trivedi, Moreo and Scalettar, 1992; Trivedi and Randeria, 1995). Furthermore, the disorder driven superfluid to insulator transition has been studied in the framework of the attractive Hubbard model (Randeria, Trivedi, Moreo and Scalettar, 1996).

Recently, a new class of models of correlated electron models showing no sign problem has been investigated (Assaad *et al*., 2003; Wu, Hu and Zhang, 2003; Capponi, Wu and Zhang, 2004; Wu and Zhang, 2005). Those models

have exotic ground states including phases with circulating currents (Capponi, Wu and Zhang, 2004; Assaad, 2005) striped phases (Assaad *et al*., 2003), as well as possible realizations of gapless spin liquid phases (Assaad, 2005).

A lot of work using the BSS algorithm is centered around the repulsive Hubbard model in two dimensions, as well as the three-band Hubbard model of the CuO_2 planes in the cuprates. On the basis of Monte Carlo simulations, it is now accepted that at half-band filling those models are Mott (charge transfer for the three-band model) insulators with long-range antiferromagnetic order (Hirsch and Tang, 1989; White *et al*., 1989; Dopf, Muramatsu and Hanke, 1992a). In the case of the three-band Hubbard model, a minimal set of parameters were found so as to reproduce experimental findings (Dopf, Muramatsu and Hanke, 1992b). The issue of superconductivity at low doping away from half-filling is still open. General concepts – independent of the symmetry of the pair wave function and including possible retardation effects – such as flux quantization and superfluid density have been used to attempt to answer the above question (Assaad, Hanke and Scalapino, 1994; Scalapino, White and Zhang, 1993). Within the algorithmic limitations, no convincing sign of superconductivity has been found to date.

The nature of the doping induced metal–insulator transition in the two-dimensional Hubbard model has attracted considerable interest (Furukawa and Imada, 1993; Assaad and Imada, 1995, 1996a). In particular, it has been argued the the transition is driven by the divergence of the effective mass rather than by the vanishing of the number of charge carriers. The origin of such a metal–insulator transition is to be found in a very flat dispersion relation around the $(\pi, 0)$ and $(0, \pi)$ points in the Brillouin zone (Dopf *et al*., 1992c; Gröber, Eder and Hanke, 2000). An extensive review of this topic as well as a consistent interpretation of the numerical data in terms of hyperscaling Ansatz may be found in (Imada, Fujimori and Tokura, 1998).

Aspects of the physics of heavy fermion systems have been investigated in the framework of the two-dimensional periodic Anderson model (PAM) (Vekic *et al*., 1995) and of the Kondo lattice model (KLM) (Capponi and Assaad, 2001). It is only recently that a sign free formulation of the KLM for particle-hole symmetric conduction bands has been put forward (Assaad, 1999). Extensive calculations both at $T = 0$ and at finite T allow to investigate the magnetic order–disorder transition triggered by the competition between the RKKY interaction and the Kondo effect (Capponi and Assaad, 2001). Across this quantum phase transition, single hole dynamics as well as spin excitations were investigated in detail. One can show numerically that the quasiparticle residue in the vicinity of $\vec{k} = (\pi, \pi)$ tracks the the Kondo scale of the corresponding single impurity problem. This statement is valid both in the magnetically ordered and disordered phases (Assaad, 2004). This suggests that the coherence temperature tracks the Kondo scale. Furthermore, the effect of a magnetic field on the Kondo insulating state was investigated. For the particle-hole symmetric conduction band, results show a transition from the Kondo insulator to a canted antiferromagnet (Milat, Assaad and Sigrist, 2004; Beach, Lee and Monthoux, 2004). Finally, models with regular depletion of localized spins can be investigated (Assaad, 2002a). Within the framework of those models, the typical form of the resistivity versus temperature can be reproduced.

The most common application of the Hirsch-Fye algorithm is in the framework of dynamical mean-field theories (Georges, Kotliar, Krauth and Rozenberg, 1996) which map the Hubbard model onto an Anderson impurity problem supplemented by a self-consistency loop. At each iteration, the Hirsch-Fye algorithm is used to solve the impurity problem at finite temperature (Jarrell, 1992) or at $T = 0$ (Feldbacher, Assaad and Held, 2004). For this particular problem, many competing methods such as DMRG (Nishimoto, Gebhard and Jeckelmann, 2004) and NRG (Bulla, 1999) are available. In the dynamical mean-field approximation, spatial fluctuations are frozen out. To reintroduce them, one has to generalize to cluster methods such as the dynamical cluster approximation (DCA) (Hettler, Jarrell and Krishnamurthy, 2000) or cellular-DMFT (CDMFT) (Kotliar, Savrasov, Pálsson and Biroli1, 2001). Within these approaches, the complexity of the problem to solve at each iteration is that of an N-impurity Anderson model (N corresponds to the cluster size). Generalizations of DMRG and NRG to solve this problem are difficult. On the other hand, as a function of cluster size the sign problem in the Hirsch-Fye approach becomes more and more severe but is, in many instances, still tractable. It, however, proves to be one of the limiting factors in achieving large cluster sizes.

7 CONCLUSION

To conclude, we discuss which algorithm is preferred for which models. For fermionic models, such as the Hubbard, the determinental quantum Monte Carlo (QMC) algorithm should be employed in more than one dimension because of the reduced sign problem in this formulation. For pure spin models the world-line algorithms are better because of their almost linear scaling with system size, in contrast to the cubic scaling of the determinental algorithms.

Among the world-line algorithms, the loop algorithm is the method of choice for problems with spin-inversion symmetry, that is, in the absence of magnetic fields, whereas

the worm or directed-loop algorithms should be used when magnetic fields are present. Implementations of these world-line QMC algorithms are available through the open-source ALPS project.

A negative sign problem occurs even for pure spin models, in the presence of frustration in the x- and y-components of the exchange couplings. This sign problem restricts simulations to temperatures not lower than the magnitude of the frustrating coupling. As a solution to this sign problem is unlikely (Troyer and Wiese, 2005), alternative methods, such as the density matrix renormalization group method (White, 1992, 1993; Schollwöck, 2005) should be considered for low-dimensional strongly frustrated quantum magnets at low temperatures.

Heavy Fermions: Electrons at the Edge of Magnetism

Piers Coleman
Rutgers University, Piscataway, NJ, USA

1 INTRODUCTION: 'ASYMPTOTIC FREEDOM' IN A CRYOSTAT

The term *heavy fermion* was coined by Steglich *et al*. (1976) in the late 1970s to describe the electronic excitations in a new class of intermetallic compound with an electronic density of states as much as 1000 times larger than copper. Since the original discovery of heavy-fermion behavior in $CeAl_3$ by Andres, Graebner and Ott (1975), a diversity of heavy-fermion compounds, including superconductors, antiferromagnets (AFMs), and insulators have been discovered. In the last 10 years, these materials have become the focus of intense interest with the discovery that intermetallic AFMs can be tuned through a quantum phase transition into a heavy-fermion state by pressure, magnetic fields, or chemical doping (von Löhneysen *et al*., 1994; von Löhneysen, 1996; Mathur *et al*., 1998). The 'quantum critical point' (QCP) that separates the heavy-electron ground state from the AFM represents a kind of singularity in the material phase diagram that profoundly modifies the metallic properties, giving them a a predisposition toward superconductivity and other novel states of matter.

One of the goals of modern condensed matter research is to couple magnetic and electronic properties to develop new classes of material behavior, such as high-temperature superconductivity or colossal magnetoresistance materials, spintronics, and the newly discovered multiferroic materials. Heavy-electron materials lie at the very brink of magnetic instability, in a regime where quantum fluctuations of the magnetic and electronic degrees are strongly coupled. As such, they are an important test bed for the development of our understanding about the interaction between magnetic and electronic quantum fluctuations.

Heavy-fermion materials contain rare-earth or actinide ions, forming a matrix of localized magnetic moments. The active physics of these materials results from the immersion of these magnetic moments in a quantum sea of mobile conduction electrons. In most rare-earth metals and insulators, local moments tend to order antiferromagnetically, but, in heavy-electron metals, the quantum-mechanical jiggling of the local moments induced by delocalized electrons is fierce enough to melt the magnetic order.

The mechanism by which this takes place involves a remarkable piece of quantum physics called the *Kondo effect* (Kondo, 1962, 1964; Jones, 2007). The Kondo effect describes the process by which a free magnetic ion, with a Curie magnetic susceptibility at high temperatures, becomes screened by the spins of the conduction sea, to ultimately form a spinless scatering center at low temperatures and low magnetic fields (Figure 1a). In the Kondo effect, this screening process is continuous, and takes place once the

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

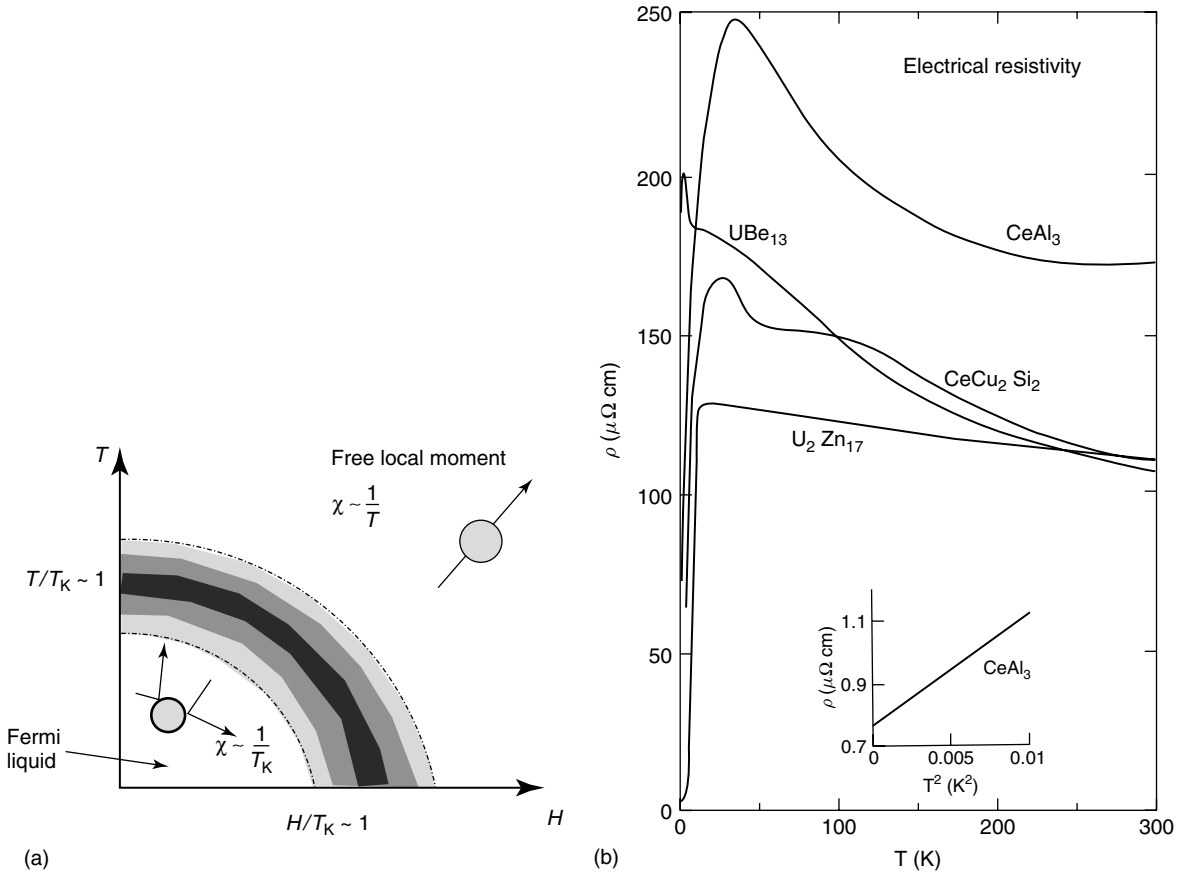

Figure 1. (a) In the Kondo effect, local moments are free at high temperatures and high fields, but become 'screened' at temperatures and magnetic fields that are small compared with the 'Kondo temperature' T_K, forming resonant scattering centers for the electron fluid. The magnetic susceptibility χ changes from a Curie-law $\chi \sim \frac{1}{T}$ at high temperature, but saturates at a constant paramagnetic value $\chi \sim \frac{1}{T_K}$ at low temperatures and fields. (b) The resistivity drops dramatically at low temperatures in heavy fermion materials, indicating the development of phase coherence between the scatering of the lattice of screened magnetic ions. (Reproduced from J.L. Smith and P.S. Riseborough, *J. Mag. Mat.* 47–48, 1985, copyright © 1985, with permission from Elsevier.)

magnetic field, or the temperature drops below a characteristic energy scale called the *Kondo temperature* T_K. Such 'quenched' magnetic moments act as strong elastic scattering potentials for electrons, which gives rise to an increase in resistivity produced by isolated magnetic ions. When the same process takes place inside a heavy-electron material, it leads to a spin quenching at every site in the lattice, but now, the strong scattering at each site develops coherence, leading to a sudden drop in the resistivity at low temperatures (Figure 1b).

Heavy-electron materials involve the dense lattice analog of the single-ion Kondo effect and are often called *Kondo lattice* compounds (Doniach, 1977). In the lattice, the Kondo effect may be alternatively visualized as the dissolution of localized and neutral magnetic f spins into the quantum conduction sea, where they become mobile excitations. Once mobile, these free spins acquire charge and form electrons with a radically enhanced effective mass (Figure 2). The net effect of this process is an increase in the volume of the electronic Fermi surface, accompanied by a profound transformation in the electronic masses and interactions.

A classic example of such behavior is provided by the intermetallic crystal $CeCu_6$. Superficially, this material is copper, alloyed with 14% Cerium. The Cerium Ce^{3+} ions in this material are Ce^{3+} ions in a $4f^1$ configuration with a localized magnetic moment with $J = 5/2$. Yet, at low temperatures, they lose their spin, behaving as if they were Ce^{4+} ions with delocalized f electrons. The heavy electrons that develop in this material are a thousand times 'heavier' than those in metallic copper, and move with a group velocity that is slower than sound. Unlike copper, which has Fermi temperature of the order 10 000 K, that of $CeCu_6$ is of the order 10 K, and above this temperature, the heavy electrons disintegrate to reveal the underlying magnetic moments of the Cerium ions, which manifest themselves as a Curie-law susceptibility $\chi \sim \frac{1}{T}$. There are many hundreds of different

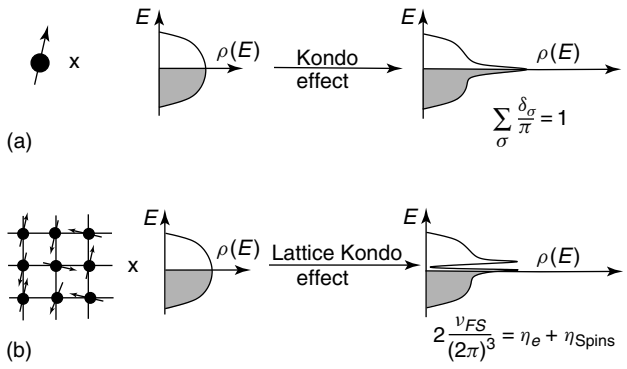

Figure 2. (a) Single-impurity Kondo effect builds a single fermionic level into the conduction sea, which gives rise to a resonance in the conduction electron density of states. (b) Lattice Kondo effect builds a fermionic resonance into the conduction sea in each unit cell. The elastic scattering of this lattice of resonances leads to the formation of a heavy-electron band, of width T_K.

varieties of heavy-electron material, many developing new and exotic phases at low temperatures.

This chapter is intended as a perspective on the the current theoretical and experimental understanding of heavy-electron materials. There are important links between the material in this chapter and the proceeding chapter on the Kondo effect by Jones (2007), the chapter on quantum criticality by Sachdev (2007), and the perspective on spin fluctuation theories of high-temperature superconductivity by Norman (2007). For completeness, I have included references to an extensive list of review articles spanning 30 years of discovery, including books on the Kondo effect and heavy fermions (Hewson, 1993; Cox and Zawadowski, 1999), general reviews on heavy-fermion physics (Stewart, 1984; Lee *et al*., 1986; Ott, 1987; Fulde, Keller and Zwicknagl, 1988; Grewe and Steglich, 1991), early views of Kondo and mixed valence physics (Gruner and Zawadowski, 1974; Varma, 1976), the solution of the Kondo impurity model by renormalization group and the strong coupling expansion (Wilson, 1976; Nozières and Blandin, 1980), the Bethe Ansatz method (Andrei, Furuya and Lowenstein, 1983; Tsvelik and Wiegman, 1983), heavy-fermion superconductivity (Sigrist and Ueda, 1991a; Cox and Maple, 1995), Kondo insulators (Aeppli and Fisk, 1992; Tsunetsugu, Sigrist and Ueda, 1997; Riseborough, 2000), X-ray spectroscopy (Allen *et al*., 1986), optical response in heavy fermions (Degiorgi, 1999), and the latest reviews on non-Fermi liquid behavior and quantum criticality (Stewart, 2001; Coleman, Pépin, Si and Ramazashvili, 2001; Varma, Nussinov and van Saarlos, 2002; von Löhneysen, Rosch, Vojta and Wolfe, 2007; Miranda and Dobrosavljevic, 2005; Flouquet, 2005). There are inevitable apologies, for this chapter is highly selective and, partly owing to lack of space, it neither covers dynamical mean-field theory (DMFT) approaches to heavy-fermion physics (Georges, Kotliar, Krauth and Rozenberg, 1996; Cox and Grewe, 1988; Jarrell, 1995; Vidhyadhiraja, Smith, Logan and Krishnamurthy, 2003) nor the extensive literature on the order-parameter phenomenology of heavy-fermion superconductors (HFSCs) reviewed in Sigrist and Ueda (1991a).

1.1 Brief history

Heavy-electron materials represent a frontier in a journey of discovery in electronic and magnetic materials that spans more than 70 years. During this time, the concepts and understanding have undergone frequent and often dramatic revision.

In the early 1930s, de Haas, de Boer and van der Berg (1933) in Leiden, discovered a 'resistance minimum' that develops in the resistivity of copper, gold, silver, and many other metals at low temperatures (Figure 3). It took a further 30 years before the purity of metals and alloys improved to a point where the resistance minimum could be linked to the presence of magnetic impurities (Clogston *et al*., 1962; Sarachik, Corenzwit and Longinotti, 1964). Clogston, Mathias, and collaborators at Bell Labs (Clogston *et al*., 1962) found they could tune the conditions under which iron impurities in Niobium were magnetic, by alloying with molybdenum. Beyond a certain concentration of molybdenum, the iron impurities become magnetic and a resistance minimum was observed to develop.

In 1961, Anderson formulated the first microscopic model for the formation of magnetic moments in metals. Earlier work by Blandin and Friedel (1958) had observed that localized d states form resonances in the electron sea. Anderson extended this idea and added a new ingredient: the Coulomb interaction between the d-electrons, which he modeled by term

$$H_I = U n_\uparrow n_\downarrow \tag{1}$$

Anderson showed that local moments formed once the Coulomb interaction U became large. One of the unexpected consequences of this theory is that local moments develop an antiferromagnetic coupling with the spin density of the surrounding electron fluid, described by the interaction (Anderson, 1961; Kondo, 1962, 1964; Schrieffer and Wolff, 1966; Coqblin and Schrieffer, 1969)

$$H_I = J\vec{\sigma}(0)\cdot\vec{S} \tag{2}$$

where $\vec{S}$ is the spin of the local moment and $\vec{\sigma}(0)$ is the spin density of the electron fluid. In Japan, Kondo (1962) set out to examine the consequences of this result. He found that when he calculated the scattering rate $\frac{1}{\tau}$ of

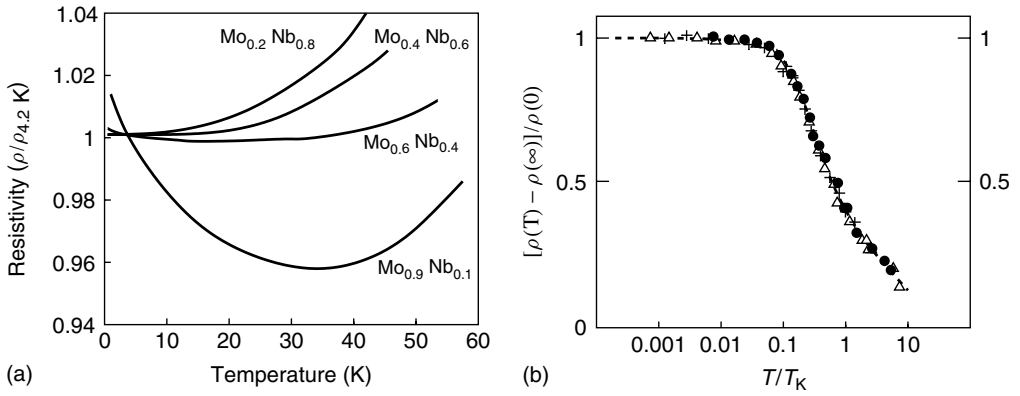

Figure 3. (a) Resistance minimum in Mo_xNb_{1-x}. (Reproduced from M. Sarachik, E. Corenzwit, and L.D. Longinotti, *Phys. Rev.* **135**, 1964, A1041, copyright © by the American Physical Society, with permission of the APS.) (b) Temperature dependence of excess resistivity produced by scattering off a magnetic ion, showing, universal dependence on a single scale, the Kondo temperature. Original data from White and Geballe (1979).

electrons of a magnetic moment to one order higher than Born approximation,

$$\frac{1}{\tau} \propto \left[J\rho + 2(J\rho)^2 \ln \frac{D}{T} \right]^2 \tag{3}$$

where ρ is the density of state of electrons in the conduction sea and D is the width of the electron band. As the temperature is lowered, the logarithmic term grows, and the scattering rate and resistivity ultimately rises, connecting the resistance minimum with the antiferromagnetic interaction between spins and their surroundings.

A deeper understanding of the logarithmic term in this scattering rate required the renormalization group concept (Anderson and Yuval, 1969, 1970, 1971; Fowler and Zawadowskii, 1971; Wilson, 1976; Nozières, 1976; Nozières and Blandin, 1980). The key idea here is that the physics of a spin inside a metal depends on the energy scale at which it is probed. The 'Kondo' effect is a manifestation of the phenomenon of 'asymptotic freedom' that also governs quark physics. Like the quark, at high energies, the local moments inside metals are asymptotically free, but at temperatures and energies below a characteristic scale the Kondo temperature,

$$T_K \sim D e^{-1/(2J\rho)} \tag{4}$$

where ρ is the density of electronic states; they interact so strongly with the surrounding electrons that they become screened into a singlet state, or 'confined' at low energies, ultimately forming a Landau–Fermi liquid (Nozières, 1976; Nozières and Blandin, 1980).

Throughout the 1960s and 1970s, conventional wisdom had it that magnetism and superconductivity are mutually exclusive. Tiny concentrations of magnetic impurities produce a lethal suppression of superconductivity in conventional metals. Early work on the interplay of the Kondo effect and superconductivity by Maple *et al*. (1972) did suggest that the Kondo screening suppresses the pair-breaking effects of magnetic moments, but the implication of these results was only slowly digested. Unfortunately, the belief in the mutual exclusion of local moments and superconductivity was so deeply ingrained that the first observation of superconductivity in the 'local moment' metal UBe_{13} (Bucher *et al*., 1975) was dismissed by its discoverers as an artifact produced by stray filaments of uranium. Heavy-electron metals were discovered by Andres, Graebner and Ott (1975), who observed that the intermetallic $CeAl_3$ forms a metal in which the Pauli susceptibility and linear specific heat capacity are about 1000 times larger than in conventional metals. Few believed their speculation that this might be a lattice version of the Kondo effect, giving rise to a narrow band of 'heavy' f electrons in the lattice. The discovery of superconductivity in $CeCu_2Si_2$ in a similar f-electron fluid, a year later by Steglich *et al*. (1976), was met with widespread disbelief. All the measurements of the crystal structure of this material pointed to the fact that the Ce ions were in a Ce^{3+} or $4f^1$ configuration. Yet, this meant one local moment per unit cell – which required an explanation of how these local moments do not destroy superconductivity, but, rather, are part of its formation.

Doniach (1977), made the visionary proposal that a heavy-electron metal is a dense Kondo lattice (Kasuya, 1956), in which every single local moment in the lattice undergoes the Kondo effect (Figure 2). In this theory, each spin is magnetically screened by the conduction sea. One of the great concerns of the time, raised by Nozières (1985), was whether there could ever be sufficient conduction electrons in a dense Kondo lattice to screen each local moment.

Theoretical work on this problem was initially stalled for want of any controlled way to compute properties of the Kondo lattice. In the early 1980s, Anderson (1981) proposed a way out of this log-jam. Taking a cue from the success of the $1/S$ expansion in spin-wave theory, and the $1/N$ expansion in statistical mechanics and particle physics, he noted that the large magnetic spin degeneracy $N = 2j + 1$ of f moments could be used to generate an expansion in the small parameter $1/N$ about the limit where $N \to \infty$. Anderson's idea prompted a renaissance of theoretical development (Ramakrishnan, 1981; Gunnarsson and Schönhammer, 1983; Read and Newns, 1983a,b; Coleman, 1983, 1987a; Auerbach and Levin, 1986), making it possible to compute the X-ray absorption spectra of these materials and, for the first time, examine how heavy f bands form within the Kondo lattice. By the mid-1980s, the first de Haas van Alphen experiments (Reinders *et al*., 1986; Taillefer and Lonzarich, 1988) had detected cyclotron orbits of heavy electrons in $CeCu_6$ and UPt_3. With these developments, the heavy-fermion concept was cemented.

On a separate experimental front, in Ott, Rudigier, Fisk and Smith (1983), and Ott *et al*. (1984) returned to the material UBe_{13}, and, by measuring a large discontinuity in the bulk specific heat at the resistive superconducting transition, confirmed it as a bulk heavy-electron superconductor. This provided a vital independent confirmation of Steglich's discovery of heavy electron superconductivity, assuaging the old doubts and igniting a huge new interest in heavy-electron physics. The number of heavy-electron metals and superconductors grew rapidly in the mid-1980s (Sigrist and Ueda, 1991b). It became clear from specific heat, NMR, and ultrasound experiments on HFSCs that the gap is anisotropic, with lines of nodes strongly suggesting an electronic, rather than a phonon mechanism of pairing. These discoveries prompted theorists to return to earlier spin-fluctuation-mediated models of anisotropic pairing. In the early summer of 1986, three new theoretical papers were received by *Physical Review*, the first by Monod, Bourbonnais and Emery (1986) working in Orsay, France, followed closely (6 weeks later) by papers from Scalapino, Loh and Hirsch (1986) at UC Santa Barbara, California, and Miyake, Rink and Varma (1986) at Bell Labs, New Jersey. These papers contrasted heavy-electron superconductivity with superfluid He-3. Whereas He-3 is dominated by ferromagnetic interactions, which generate triplet pairing, these works showed that, in heavy-electron systems, soft antiferromagnetic spin fluctuations resulting from the vicinity to an antiferromagnetic instability would drive anisotropic d-wave pairing (Figure 4). The almost coincident discovery of high-temperature superconductivity the very same year, 1986, meant that these early works on heavy-electron superconductivity were destined to exert huge influence on the evolution of ideas about high-temperature

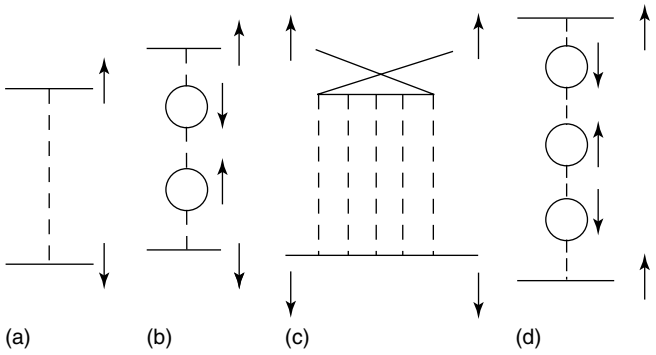

Figure 4. Figure from Monod, Bourbonnais and Emery (1986), one of three path-breaking papers in 1986 to link d-wave pairing to antiferromagnetism. (a) The bare interaction, (b), (c), and (d), the paramagnon-mediated interaction between antiparallel or parallel spins. (Reproduced from M.T.B. Monod, C. Bourbonnais, and V. Emery, *Phys. Rev. B.* **34**, 1986, 7716, copyright © 1986 by the American Physical Society, with permission of the APS.)

superconductivity. Both the resonating valence bond (RVB) and the spin-fluctuation theory of d-wave pairing in the cuprates are, in my opinion, close cousins, if not direct descendents of these early 1986 papers on heavy-electron superconductivity.

After a brief hiatus, interest in heavy-electron physics reignited in the mid-1990s with the discovery of QCPs in these materials. High-temperature superconductivity introduced many important new ideas into our conception of electron fluids, including

- Non-Fermi liquid behavior: the emergence of metallic states that cannot be described as fluids of renormalized quasiparticles.
- Quantum phase transitions and the notion that zero temperature QCPs might profoundly modify finite temperature properties of metal.

Both of these effects are seen in a wide variety of heavy-electron materials, providing an vital alternative venue for research on these still unsolved aspects of interlinked, magnetic, and electronic behavior.

In 1994 Hilbert von Löhneysen and collaborators discovered that by alloying small amounts of gold into $CeCu_6$, one can tune $CeCu_{6-x}Au_x$ through an antiferromagnetic QCP, and then reverse the process by the application of pressure (von Löhneysen, 1996; von Löhneysen *et al*., 1994). These experiments showed that a heavy-electron metal develops 'non-Fermi liquid' properties at a QCP, including a linear temperature dependence of the resistivity and a logarithmic dependence of the specific heat coefficient on temperature. Shortly thereafter, Mathur *et al*. (1998), at Cambridge showed that when pressure is used to drive the AFM $CeIn_3$

through a quantum phase transition, heavy-electron superconductivity develops in the vicinity of the quantum phase transition. Many new examples of heavy-electron system have come to light in the last few years which follow the same pattern. In one fascinating development, (Monthoux and Lonzarich, 1999) suggested that if quasi-two-dimensional versions of the existing materials could be developed, then the superconducting pairing would be less frustrated, leading to a higher transition temperature. This led experimental groups to explore the effect of introducing layers into the material $CeIn_3$, leading to the discovery of the so-called $1-1-5$ compounds, in which an XIn_2 layer has been introduced into the original cubic compound. (Petrovic *et al*., 2001; Sidorov *et al*., 2002). Two notable members of this group are $CeCoIn_5$ and, most recently, $PuCoGa_5$ (Sarrao *et al*., 2002). The transition temperature rose from 0.5 to 2.5 K in moving from $CeIn_3$ to $CeCoIn_5$. Most remarkably, the transition temperature rises to above 18 K in the $PuCoGa_5$ material. This amazing rise in T_c, and its close connection with quantum criticality, are very active areas of research, and may hold important clues (Curro *et al*., 2005) to the ongoing quest to discover room-temperature superconductivity.

1.2 Key elements of heavy-fermion metals

Before examining the theory of heavy-electron materials, we make a brief tour of their key properties. Table 1 shows a selective list of heavy fermion compounds

1.2.1 Spin entropy: a driving force for new physics

The properties of heavy-fermion compounds derive from the partially filled f orbitals of rare-earth or actinide ions (Stewart, 1984; Lee *et al*., 1986; Ott, 1987; Fulde, Keller and Zwicknagl, 1988; Grewe and Steglich, 1991). The large nuclear charge in these ions causes their f orbitals to collapse inside the inert gas core of the ion, turning them into localized magnetic moments.

Moreover, the large spin-orbit coupling in f orbitals combines the spin and angular momentum of the f states into a

Table 1. Selected heavy-fermion compounds.

Type	Material	T^* (K)	$T_c,\ x_c,\ B_c$	Properties	ρ	m J mol^{-1}K^{-2} γ_n	References
Metal	$CeCu_6$	10	–	Simple HF metal	T^2	1600	Stewart, Fisk and Wire (1984a) and Onuki and Komatsubara (1987)
Superconductors	$CeCu_2Si_2$	20	$T_c = 0.17$ K	First HFSC	T^2	800–1250	Steglich *et al*. (1976) and Geibel *et al*. (1991a,b)
	UBe_{13}	2.5	$T_c = 0.86$ K	Incoherent metal→HFSC	$\rho_c \sim 150\,\mu\Omega$ cm	800	Ott, Rudigier, Fisk and Smith (1983, 1984)
	$CeCoIn_5$	38	$T_c = 2.3$	Quasi 2D HFSC	T	750	Petrovic *et al*. (2001) and Sidorov *et al*. (2002)
Kondo insulators	$Ce_3Pt_4Bi_3$	$T_\chi \sim 80$	–	Fully gapped KI	$\sim e^{\Delta/T}$	–	Hundley *et al*. (1990) and Bucher, Schlessinger, Canfield and Fisk (1994)
	CeNiSn	$T_\chi \sim 20$	–	Nodal KI	Poor metal	–	Takabatake *et al*. (1990, 1992) and Izawa *et al*. (1999)
Quantum critical	$CeCu_{6-x}Au_x$	$T_0 \sim 10$	$x_c = 0.1$	Chemically tuned QCP	T	$\sim\frac{1}{T_0}\ln\left(\frac{T_0}{T}\right)$	von Löhneysen *et al*. (1994) and von Löhneysen (1996)
	$YbRh_2Si_2$	$T_0 \sim 24$	$B_\perp = 0.06$ T $B_\parallel = 0.66$ T	Field-tuned QCP	T	$\sim\frac{1}{T_0}\ln\left(\frac{T_0}{T}\right)$	Trovarelli *et al*. (2000), Paschen *et al*. (2004), Custers *et al*. (2003) and Gegenwart *et al*. (2005)
SC + other order	UPd_2Al_3	110	$T_{AF} = 14$ K, $T_{sc} = 2$ K	AFM + HFSC	T^2	210	Geibel *et al*. (1991a), Sato *et al*. (2001) and Tou *et al*. (1995)
	URu_2Si_2	75	$T_1 = 17.5$ K, $T_{sc} = 1.3$ K	Hidden order and HFSC	T^2	120/65	Palstra *et al*. (1985) and Kim *et al*. (2003)

Unless otherwise stated, T^* denotes the temperature of the maximum in resistivity. T_c, x_c, and B_c denote critical temperature, doping, and field. ρ denotes the temperature dependence in the normal state. $\gamma_n = C_V/T$ is the specific heat coefficient in the normal state.

state of definite J, and it is these large quantum spin degrees of freedom that lie at the heart of heavy-fermion physics.

Heavy-fermion materials display properties which change qualitatively, depending on the temperature, so much so, that the room-temperature and low-temperature behavior almost resembles two different materials. At room temperature, high magnetic fields, and high frequencies, they behave as local moment systems, with a Curie-law susceptibility

$$\chi = \frac{M^2}{3T} \qquad M^2 = (g_J \mu_B)^2 J(J+1) \tag{5}$$

where M is the magnetic moment of an f state with total angular momentum J and the gyromagnetic ratio g_J. However, at temperatures beneath a characteristic scale, we call T^* (to distinguish it from the single-ion Kondo temperature T_K), the localized spin degrees of freedom melt into the conduction sea, releasing their spins as mobile, conducting f electrons.

A Curie susceptibility is the hallmark of the decoupled, rotational dynamics of the f moments, associated with an unquenched entropy of $\mathcal{S} = k_B \ln N$ per spin, where $N = 2J + 1$ is the spin degeneracy of an isolated magnetic moment of angular momentum J. For example, in a Cerium-heavy electron material, the $4f^1$ ($L = 3$) configuration of the Ce^{3+} ion is spin-orbit coupled into a state of definite $J = L - S = 5/2$ with $N = 6$. Inside the crystal, the full rotational symmetry of each magnetic f ion is often reduced by crystal fields to a quartet ($N = 4$) or a Kramer's doublet $N = 2$. At the characteristic temperature T^*, as the Kondo effect develops, the spin entropy is rapidly lost from the material, and large quantities of heat are lost from the material. Since the area under the specific heat curve determines the entropy,

$$S(T) = \int_0^T \frac{C_V}{T'} \mathrm{d}T' \tag{6}$$

a rapid loss of spin entropy at low temperatures forces a sudden rise in the specific heat capacity. Figure 5 illustrates this phenomenon with the specific heat capacity of UBe_{13}. Notice how the specific heat coefficient C_V/T rises to a value of order 1 J mol^{-1}K^2, and starts to saturate at about 1 K, indicating the formation of a Fermi liquid with a linear specific heat coefficient. Remarkably, just as the linear specific heat starts to develop, UBe_{13} becomes superconducting, as indicated by the large specific heat anomaly.

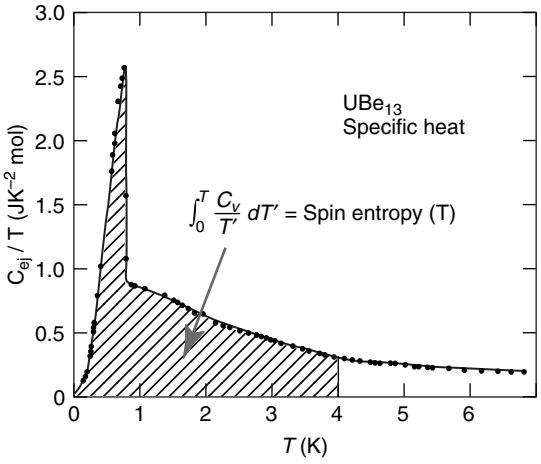

Figure 5. Showing the specific heat coefficient of UBe_{13} after (Ott, Rudigier, Fisk and Smith, 1985). The area under the C_V/T curve up to a temperature T provides a measure of the amount of unquenched spin entropy at that temperature. The condensation entropy of HFSCs is derived from the spin-rotational degrees of freedom of the local moments, and the large scale of the condensation entropy indicates that spins partake in the formation of the order parameter. Buyers (ed.): *Proceedings of the NATO Advanced Study Institute on Moment Formation in Solids, Vancouver Island*, August 1983, Valence Fluctuations in Solids (Plenum, 1985), p. 309. with permission of Springer Science and Business Media.)

1.2.2 'Local' Fermi liquids with a single scale

The standard theoretical framework for describing metals is Landau–Fermi liquid theory (Landau, 1957), according to which the excitation spectrum of a metal can be adiabatically connected to those of a noninteracting electron fluid. Heavy-fermion metals are extreme examples of Landau–Fermi liquids which push the idea of adiabaticity into an regime where the bare electron interactions, on the scale of electron volts, are hundreds, even thousands of times larger than the millivolt Fermi energy scale of the heavy-electron quasiparticles. The Landau–Fermi liquid that develops in these materials shares much in common with the Fermi liquid that develops around an isolated magnetic impurity (Nozières, 1976; Nozières and Blandin, 1980), once it is quenched by the conduction sea as part of the Kondo effect. There are three key features of this Fermi liquid:

- *Single scale:* T^* The quasiparticle density of states $\rho^* \sim 1/T^*$ and scattering amplitudes $A_{\mathbf{k}\sigma,\mathbf{k}'\sigma'} \sim T^*$ scale approximately with a single scale T^*.
- *Almost incompressible:* Heavy-electron fluids are 'almost incompressible', in the sense that the charge susceptibility $\chi_c = \mathrm{d}N_e/\mathrm{d}\mu \ll \rho^*$ is unrenormalized and typically more than an order of magnitude smaller than the quasiparticle density of states ρ^*. This is because the lattice of spins severely modifies the quasiparticle density of states, but leaves the charge density of the fluid $n_e(\mu)$, and its dependence on the chemical potential μ unchanged.

- *Local:* Quasiparticles scatter when in the vicinity of a local moment, giving rise to a small momentum dependence to the Landau scattering amplitudes (Yamada, 1975; Yoshida and Yamada, 1975; Engelbrecht and Bedell, 1995).

Landau–Fermi liquid theory relates the properties of a Fermi liquid to the density of states of the quasiparticles and a small number of interaction parameters (Baym and Pethick, 1992). If $E_{\mathbf{k}\sigma}$ is the energy of an isolated quasiparticle, then the quasiparticle density of states $\rho^* = \sum_{\mathbf{k}\sigma} \delta(E_{\mathbf{k}\sigma} - \mu)$ determines the linear specific heat coefficient

$$\gamma = \mathrm{Lim}_{T\to 0}\left(\frac{C_V}{T}\right) = \frac{\pi^2 k_\mathrm{B}^2}{3}\rho^* \tag{7}$$

In conventional metals, the linear specific heat coefficient is of the order 1–10 mJ mol^{-1} K^{-2}. In a system with quadratic dispersion, $E_\mathbf{k} = \frac{\hbar^2 k^2}{2m^*}$, the quasiparticle density of states and effective mass m^* are directly proportional

$$\rho^* = \left(\frac{k_F}{\pi^2\hbar^2}\right) m^* \tag{8}$$

where k_F is the Fermi momentum. In heavy-fermion compounds, the scale of ρ^* varies widely, and specific heat coefficients in the range 100–1600 mJ mol^{-1} K^{-2} have been observed. From this simplified perspective, the quasiparticle effective masses in heavy-electron materials are two or three orders of magnitude 'heavier' than in conventional metals.

In Landau–Fermi liquid theory, a change $\delta n_{\mathbf{k}'\sigma'}$ in the quasiparticle occupancies causes a shift in the quasiparticle energies given by

$$\delta E_{\mathbf{k}\sigma} = \sum_{\mathbf{k}'\sigma'} \mathrm{f}_{\mathbf{k}\sigma,\mathbf{k}\sigma'}\delta n_{\mathbf{k}'\sigma'} \tag{9}$$

In a simplified model with a spherical Fermi surface, the Landau interaction parameters only depend on the relative angle $\theta_{\mathbf{k},\mathbf{k}'}$ between the quasiparticle momenta, and are expanded in terms of Legendre Polynomials as

$$\mathrm{f}_{\mathbf{k}\sigma,\mathbf{k}\sigma'} = \frac{1}{\rho^*}\sum_l (2l+1)P_l(\theta_{\mathbf{k},\mathbf{k}'})[F_l^s + \sigma\sigma' F_l^a] \tag{10}$$

The dimensionless 'Landau parameters' $F_l^{s,a}$ parameterize the detailed quasiparticle interactions. The s-wave ($l = 0$) Landau parameters that determine the magnetic and charge susceptibility of a Landau–Fermi liquid are given by Landau (1957), and Baym and Pethick (1992)

$$\chi_s = \mu_\mathrm{B}^2 \frac{\rho^*}{1+F_0^a} = \mu_\mathrm{B}^2\rho^*\left[1 - A_0^a\right]$$

$$\chi_c = \mathrm{e}^2\frac{\rho^*}{1+F_0^s} = \mathrm{e}^2\rho^*\left[1 - A_0^s\right] \tag{11}$$

where the quantities

$$A_0^{s,a} = \frac{F_0^{s,a}}{1+F_0^{s,a}} \tag{12}$$

are the s-wave Landau scattering amplitudes in the charge (s) and spin (a) channels, respectively (Baym and Pethick, 1992).

The assumption of local scattering and incompressibility in heavy electron fluids simplifies the situation, for, in this case, only the $l = 0$ components of the interaction remain and the quasiparticle scattering amplitudes become

$$A_{\mathbf{k}\sigma,\mathbf{k}'\sigma'} = \frac{1}{\rho^*}\left(A_0^s + \sigma\sigma' A_0^a\right) \tag{13}$$

Moreover, in local scattering, the Pauli principle dictates that quasiparticles scattering at the same point can only scatter when in opposite spin states, so that

$$A_{\uparrow\uparrow}^{(0)} = A_0^s + A_0^a = 0 \tag{14}$$

and hence $A_0^s = -A_0^a$. The additional assumption of incompressibility forces $\chi_c/(e^2\rho^*) \ll 1$, so that now $A_0^s = -A_0^a \approx 1$ and all that remains is a single parameter ρ^*.

This line of reasoning, first developed for the single impurity Kondo model by Nozières and Blandin (1980) and, Nozières (1976) and later extended to a bulk Fermi liquid by Engelbrecht and Bedell (1995), enables us to understand two important scaling trends amongst heavy-electron systems. The first consequence, deduced from equation (11), is that the dimensionless Sommerfeld ratio, or 'Wilson ratio' $W = \left(\frac{\pi^2 k_\mathrm{B}^2}{\mu_\mathrm{B}^2}\right)\frac{\chi_s}{\gamma} \approx 2$. Wilson (1976) found that this ratio is almost exactly equal to 2 in the numerical renormalization group treatment of the impurity Kondo model. The connection between this ratio and the local Fermi liquid theory was first identified by Nozières (1976), and Nozières and Blandin (1980). In real heavy-electron systems, the effect of spin-orbit coupling slightly modifies the precise numerical form for this ratio, nevertheless, the observation that $W \sim 1$ over a wide range of materials in which the density of states vary by more than a factor of 100 is an indication of the incompressible and local character of heavy Fermi liquids (Figure 6).

A second consequence of locality appears in the transport properties. In a Landau–Fermi liquid, inelastic electron–electron scattering produces a quadratic temperature dependence in the resistivity

$$\rho(T) = \rho_0 + AT^2 \tag{15}$$

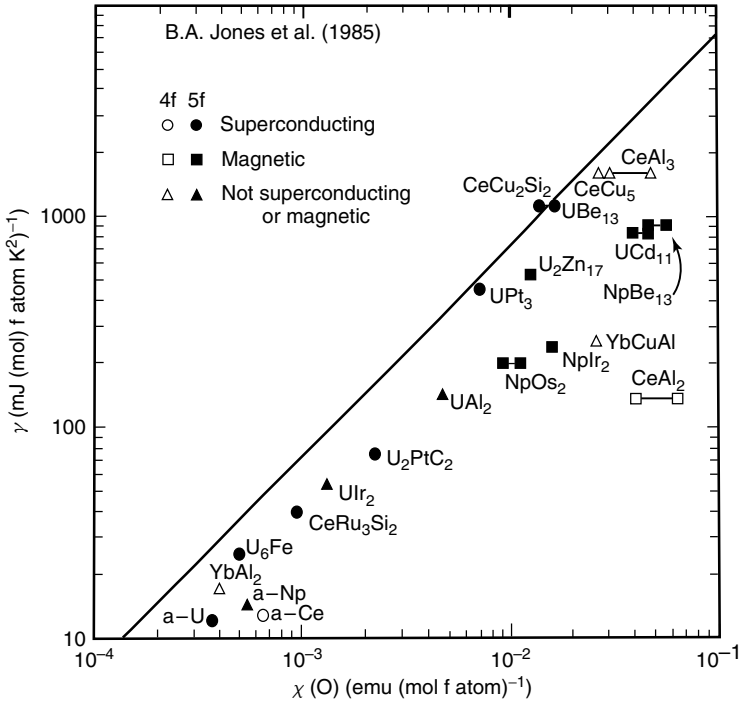

Figure 6. Plot of linear specific heat coefficient versus Pauli susceptibility to show approximate constancy of the Wilson ratio. (Reproduced from P.A. Lee, T.M. Rice, J.W. Serene, L.J. Sham, and J.W. Wilkins, *Comments Condens. Matt. Phys.* 9212, (1986) 99, with permission from Taylaor & Francis Ltd, www.informaworld.com.)

In conventional metals, resistivity is dominated by electron–phonon scattering, and the 'A' coefficient is generally too small for the electron–electron contribution to the resistivity to be observed. In strongly interacting metals, the A coefficient becomes large, and, in a beautiful piece of phenomenology, Kadowaki and Woods (1986), observed that the ratio of A to the square of the specific heat coefficient γ^2

$$\alpha_{\rm KW} = \frac{A}{\gamma^2} \approx (1 \times 10^{-5})\mu\Omega{\rm cm(mol\ K^2 mJ^{-1})} \qquad (16)$$

is approximately constant, over a range of A spanning four orders of magnitude. This can also be simply understood from the local Fermi-liquid theory, where the local scattering amplitudes give rise to an electron mean-free path given by

$$\frac{1}{k_{\rm F} l^*} \sim {\rm constant} + \frac{T^2}{(T^*)^2} \qquad (17)$$

The 'A' coefficient in the electron resistivity that results from the second term satisfies $A \propto \frac{1}{(T^*)^2} \propto \tilde{\gamma}^2$. A more detailed calculation is able to account for the magnitude of the Kadowaki–Woods constant, and its weak residual dependence on the spin degeneracy $N = 2J + 1$ of the magnetic ions (see Figure 7).

The approximate validity of the scaling relations

$$\frac{\chi}{\gamma} \approx {\rm cons}, \qquad \frac{A}{\gamma^2} \approx {\rm cons} \qquad (18)$$

for a wide range of heavy-electron compounds constitutes excellent support for the Fermi-liquid picture of heavy electrons.

A classic signature of heavy-fermion behavior is the dramatic change in transport properties that accompanies the development of a coherent heavy-fermion band structure (Figure 6). At high temperatures, heavy-fermion compounds exhibit a large saturated resistivity, induced by incoherent spin-flip scattering of the conduction electrons of the local f moments. This scattering *grows* as the temperature is lowered, but, at the same time, it becomes increasingly elastic at low temperatures. This leads to the development of phase coherence. the f-electron spins. In the case of heavy-fermion metals, the development of coherence is marked by a rapid reduction in the resistivity, but in a remarkable class of heavy fermion or 'Kondo insulators', the development of coherence leads to a filled band with a tiny insulating gap of the order $T_{\rm K}$. In this case, coherence is marked by a sudden exponential rise in the resistivity and Hall constant.

The classic example of coherence is provided by metallic $CeCu_6$, which develops 'coherence' and a maximum in

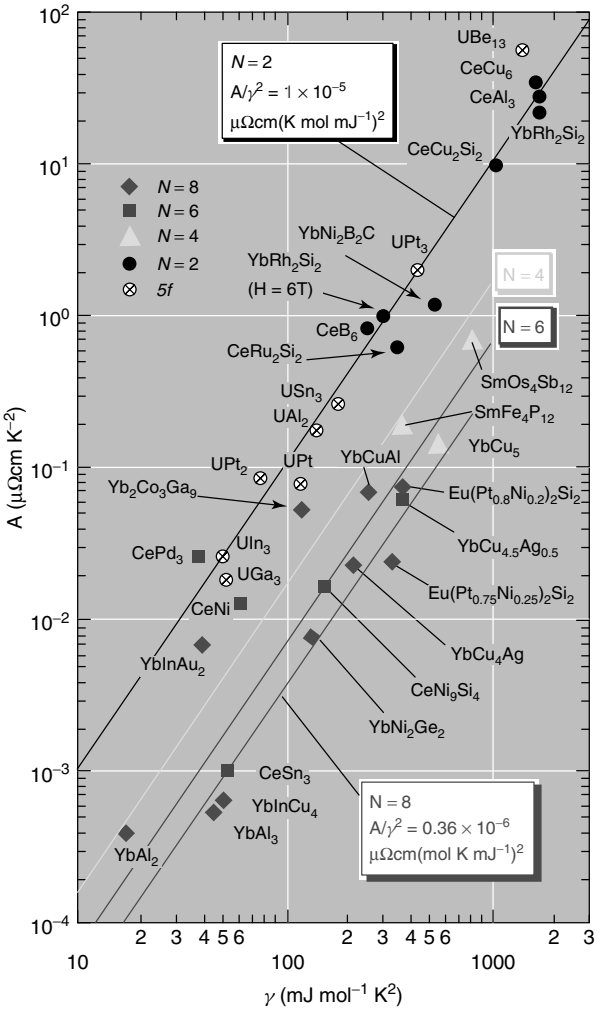

Figure 7. Approximate constancy of the Kadowaki–Woods ratio, for a wide range of heavy electrons. (After Tsujji, Kontani and Yoshimora, 2005.) When spin-orbit effects are taken into account, the Kadowaki–Woods ratio depends on the effective degeneracy $N = 2J + 1$ of the magnetic ion, which when taken into account leads to a far more precise collapse of the data onto a single curve. (Reproduced from H. Tsujji, H. Kontani, and K. Yoshimora, *Phys. Rev. Lett* 94, 2005, copyright © 2005 by the American Physical Sdociety, with permisison of the APS.057201.)

its resistivity around $T = 10\,\mathrm{K}$. Coherent heavy-electron propagation is readily destroyed by substitutional impurities. In $CeCu_6$, Ce^{3+} ions can be continuously substituted with nonmagnetic La^{3+} ions, producing a continuous crossover from coherent Kondo lattice to single impurity behavior (Figure 8).

One of the important principles of the Landau–Fermi liquid is the Fermi surface counting rule, or Luttinger's theorem (Luttinger, 1960). In noninteracting electron band theory, the volume of the Fermi surface counts the number of conduction electrons. For interacting systems, this rule survives (Martin, 1982; Oshikawa, 2000), with the unexpected corollary that

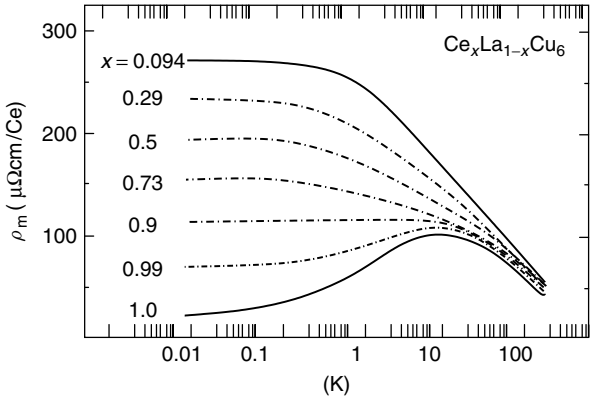

Figure 8. Development of coherence in $Ce_{1-x}La_xCu_6$. (Reproduced from Y. Onuki and T. Komatsubara, *J. Mag. Mat.* 63–64, 1987, 281, copyright © 1987, with permission of Elsevier.)

the spins of the screened local moments are also included in the sum

$$\frac{2V_{\mathrm{FS}}}{(2\pi)^3} = [n_e + n_{\mathrm{spins}}] \tag{19}$$

Remarkably, even though f electrons are localized as magnetic moments at high temperatures, in the heavy Fermi liquid, they contribute to the Fermi surface volume.

The most direct evidence for the large heavy f-Fermi surfaces derives from de Haas van Alphen and Shubnikov de Haas experiments that measure the oscillatory diamagnetism or and resistivity produced by coherent quasiparticle orbits (Figure 9). These experiments provide a direct measure of the heavy-electron mass, the Fermi surface geometry, and volume. Since the pioneering measurements on $CeCu_6$ and UPt_3 by Reinders and Springford, Taillefer, and Lonzarich in the mid-1980s (Reinders *et al*., 1986; Taillefer and Lonzarich, 1988; Taillefer *et al*., 1987), an extensive number of such measurements have been carried out (Onuki and Komatsubara, 1987; Julian, Teunissen and Wiegers, 1992; Kimura *et al*., 1998; McCollam *et al*., 2005). Two key features are observed:

- A Fermi surface volume which counts the f electrons as itinerant quasiparticles.
- Effective masses often in excess of 100 free electron masses. Higher mass quasiparticle orbits, though inferred from thermodynamics, cannot be observed with current measurement techniques.
- Often, but not always, the Fermi surface geometry is in accord with band theory, despite the huge renormalizations of the electron mass.

Additional confirmation of the itinerant nature of the f quasiparticles comes from the observation of a Drude peak in

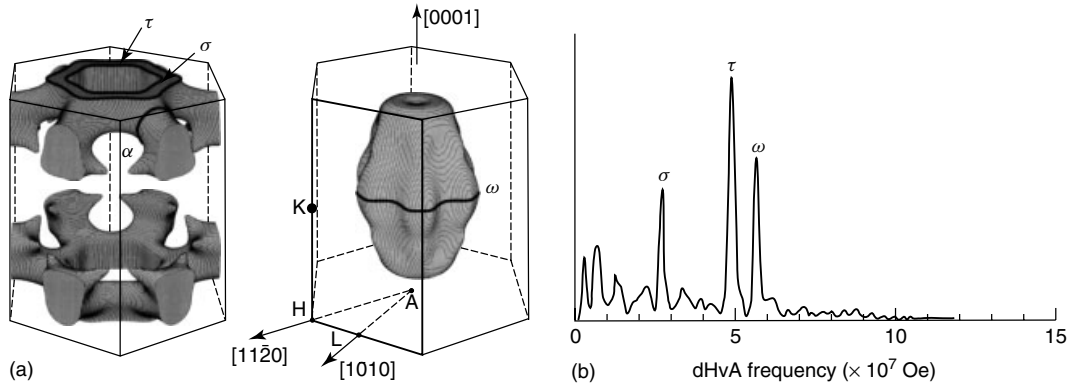

Figure 9. (a) Fermi surface of UPt_3 calculated from band theory assuming itinerant 5f electrons (Oguchi and Freeman, 1985; Wang *et al*., 1987; Norman, Oguchi and Freeman, 1988), showing three orbits (σ, ω and τ) that are identified by dHvA measurements. (After Kimura *et al*., 1998.) (b) Fourier transform of dHvA oscillations identifying σ, ω, and τ orbits shown in (a). (Kimura *et al*., 1998.)

the optical conductivity. At low temperatures, in the coherent regime, an extremely narrow Drude peak can be observed in the optical conductivity of heavy-fermion metals. The weight under the Drude peak is a measure of the plasma frequency: the diamagnetic response of the heavy-fermion metal. This is found to be extremely small, depressed by the large mass enhancement of the quasiparticles (Millis and Lee, 1987a; Degiorgi, 1999).

$$\int_{|\omega| \leq T_K} \frac{d\omega}{\pi} \sigma_{qp}(\omega) = \frac{ne^2}{m^*} \tag{20}$$

Both the optical and dHvA experiments indicate that the presence of f spins depresses both the spin and diamagnetic response of the electron gas down to low temperatures.

2 LOCAL MOMENTS AND THE KONDO LATTICE

2.1 Local moment formation

2.1.1 The Anderson model

We begin with a discussion of how magnetic moments form at high temperatures, and how they are screened again at low temperatures to form a Fermi liquid. The basic model for local moment formation is the Anderson model (Anderson, 1961)

$$H = \overbrace{\sum_{k,\sigma} \epsilon_k n_{k\sigma} + \sum_{k,\sigma} V(k)\left[c^\dagger_{k\sigma} f_\sigma + f^\dagger_\sigma c_{k\sigma}\right]}^{H_{\text{resonance}}} + \underbrace{E_f n_f + U n_{f\uparrow} n_{f\downarrow}}_{H_{\text{atomic}}} \tag{21}$$

where H_{atomic} describes the atomic limit of an isolated magnetic ion and $H_{\text{resonance}}$ describes the hybridization of the localized f electrons in the ion with the Bloch waves of the conduction sea. For pedagogical reasons, our discussion initially focuses on the case where the f state is a Kramer's doublet.

There are two key elements to the Anderson model:

- *Atomic limit:* The atomic physics of an isolated ion with a single f state, described by the model

$$H_{\text{atomic}} = E_f n_f + U n_{f\uparrow} n_{f\downarrow} \tag{22}$$

Here E_f is the energy of the f state and U is the Coulomb energy associated with two electrons in the same orbital. The atomic physics contains the basic mechanism for local moment formation, valid for f electrons, but also seen in a variety of other contexts, such as transition-metal atoms and quantum dots.
The four quantum states of the atomic model are

$$\left.\begin{array}{ll} |f^2\rangle & E(f^2) = 2E_f + U \\ |f^0\rangle & E(f^0) = 0 \end{array}\right\}\text{nonmagnetic}$$
$$|f^1\uparrow\rangle\ |f^1\downarrow\rangle\ \ E(f^1) = E_f \qquad \text{magnetic} \tag{23}$$

In a magnetic ground state, the cost of inducing a 'valence fluctuation' by removing or adding an electron to the f^1 state is positive, that is,

$$\text{removing:} \quad E(f^0) - E(f^1) = -E_f > 0 \Rightarrow \frac{U}{2} > E_f + \frac{U}{2} \tag{24}$$

$$\text{adding:} \quad E(f^2) - E(f^1) = E_f + U > 0 \Rightarrow E_f + \frac{U}{2} > -\frac{U}{2} \tag{25}$$

or (Figure 10).

$$\frac{U}{2} > E_f + \frac{U}{2} > -\frac{U}{2} \tag{26}$$

Under these conditions, a local moment is well defined, provided the temperature is lower than the valence fluctuation scale $T_{\rm VF} = \max(E_{\rm f} + U, -E_{\rm f})$. At lower temperatures, the atom behaves exclusively as a quantum top.

- *Virtual bound-state formation.* When the magnetic ion is immersed in a sea of electrons, the f electrons within the core of the atom hybridize with the Bloch states of surrounding electron sea (Blandin and Friedel, 1958) to form a resonance described by

$$H_{\rm resonance} = \sum_{k,\sigma} \epsilon_k n_{k\sigma} + \sum_{k,\sigma} \left[V(\mathbf{k}) c^\dagger_{k\sigma} f_\sigma + V(\mathbf{k})^* f^\dagger_\sigma c_{k\sigma} \right] \tag{27}$$

where the hybridization matrix element $V(\mathbf{k}) = \langle \mathbf{k} | V_{\rm atomic} | f \rangle$ is the overlap of the atomic potential between a localized f state and a Bloch wave. In the absence of any interactions, the hybridization broadens the localized f state, producing a resonance of width

$$\Delta = \pi \sum_{\mathbf{k}} |V(\mathbf{k})|^2 \delta(\epsilon_{\mathbf{k}} - \mu) = \pi V^2 \rho \tag{28}$$

where V^2 is the average of the hybridization around the Fermi surface.

There are two complementary ways to approach the physics of the Anderson model:

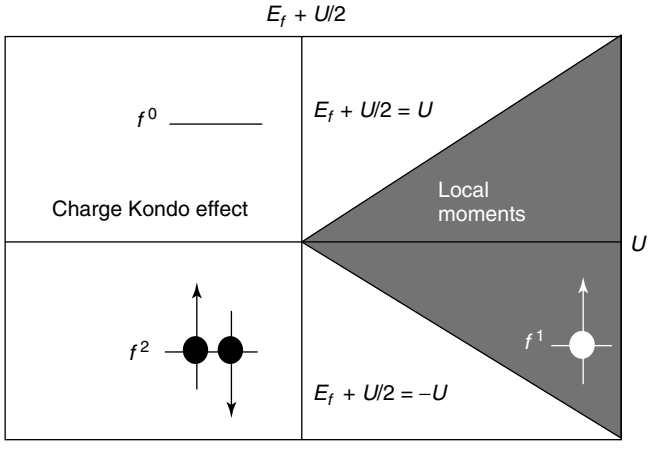

Figure 10. Phase diagram for Anderson impurity model in the atomic limit.

- The 'atomic picture', which starts with the interacting, but isolated atom ($V(k) = 0$), and considers the effect of immersing it in an electron sea by slowly dialing up the hybridization.
- The 'adiabatic picture', which starts with the noninteracting resonant ground state ($U = 0$), and then considers the effect of dialing up the interaction term U.

These approaches paint a contrasting and, at first sight, contradictory picture of a local moment in a Fermi sea. From the adiabatic perspective, the ground state is always a Fermi liquid (see 1.2.2), but from atomic perspective, provided the hybridization is smaller than U, one expects a local magnetic moment, whose low-lying degrees of freedom are purely rotational. How do we resolve this paradox?

Anderson's original work provided a mean-field treatment of the interaction. He found that at interactions larger than $U_c \sim \pi\Delta$ local moments develop with a finite magnetization $M = \langle n_\uparrow \rangle - \langle n_\downarrow \rangle$. The mean-field theory provides an approximate guide to the conditions required for moment formation, but it does not account for the restoration of the singlet symmetry of the ground state at low temperatures. The resolution of the adiabatic and the atomic picture derives from quantum spin fluctuations, which cause the local moment to 'tunnel' on a slow timescale τ_{sf} between the two degenerate 'up' and 'down' configurations.

$$e^-_\downarrow + f^1_\uparrow \rightleftharpoons e^-_\uparrow + f^1_\downarrow \tag{29}$$

These fluctuations are the origin of the Kondo effect. From the energy uncertainty principle, below a temperature $T_{\rm K}$, at which the thermal excitation energy $k_{\rm B}T$ is of the order of the characteristic tunneling rate $\frac{\hbar}{\tau_{sf}}$, a paramagnetic state with a Fermi-liquid resonance forms. The characteristic width of the resonance is then determined by the Kondo energy $k_{\rm B}T_{\rm K} \sim \frac{\hbar}{\tau_{sf}}$. The existence of this resonance was first deduced by Abrikosov (1965), and Suhl (1965), but it is more frequently called the *Kondo resonance*. From perturbative renormalization group reasoning (Haldane, 1978) and the Bethe Ansatz solution of the Anderson model (Wiegmann, 1980; Okiji and Kawakami, 1983), we know that, for large $U \gg \Delta$, the Kondo scale depends exponentially on U. In the symmetric Anderson model, where $E_f = -U/2$,

$$T_K = \sqrt{\frac{2U\Delta}{\pi^2}} \exp\left(-\frac{\pi U}{8\Delta}\right) \tag{30}$$

The temperature $T_{\rm K}$ marks the crossover from a a high-temperature Curie-law $\chi \sim \frac{1}{T}$ susceptibility to a low-temperature paramagnetic susceptibility $\chi \sim 1/T_{\rm K}$.

2.1.2 Adiabaticity and the Kondo resonance

A central quantity in the physics of f-electron systems is the f-spectral function,

$$A_f(\omega) = \frac{1}{\pi}\mathrm{Im}G_f(\omega - i\delta) \tag{31}$$

where $G_f(\omega) = -i\int_{-\infty}^{\infty} \mathrm{d}t\,\langle \mathrm{T} f_\sigma(t) f_\sigma^\dagger(0)\rangle \mathrm{e}^{i\omega t}$ is the Fourier transform of the time-ordered f-Green's function. When an f electron is added, or removed from the f state, the final state has a distribution of energies described by the f-spectral function. From a spectral decomposition of the f-Green's function, the positive energy part of the f-spectral function determines the energy distribution for electron addition, while the negative energy part measures the energy distribution of electron removal:

$$A_f(\omega) = \begin{cases} \overbrace{\sum_\lambda \left|\langle\lambda|f_\sigma^\dagger|\phi_0\rangle\right|^2 \delta(\omega - [E_\lambda - E_0])}^{\text{Energy distribution of state formed by adding one f electron}}, & (\omega > 0) \\ \underbrace{\sum_\lambda \left|\langle\lambda|f_\sigma|\phi_0\rangle\right|^2 \delta(\omega - [E_0 - E_\lambda])}_{\text{Energy distribution of state formed by removing an f electron}}, & (\omega < 0) \end{cases} \tag{32}$$

where E_0 is the energy of the ground state, and E_λ is the energy of an excited state λ, formed by adding or removing an f electron. For negative energies, this spectrum can be measured by measuring the energy distribution of photoelectrons produced by X-ray photoemission, while for positive energies, the spectral function can be measured from inverse X-ray photoemission (Allen *et al.*, 1986; Allen, Oh, Maple and Torikachvili, 1983). The weight beneath the Fermi energy peak determines the f charge of the ion

$$\langle n_f\rangle = 2\int_{-\infty}^{0} \mathrm{d}\omega A_f(\omega) \tag{33}$$

In a magnetic ion, such as a Cerium atom in a $4f^1$ state, this quantity is just a little below unity.

Figure 11 illustrates the effect of the interaction on the f-spectral function. In the noninteracting limit ($U = 0$), the f-spectral function is a Lorentzian of width Δ. If we turn on the interaction U, being careful to shifting the f-level position beneath the Fermi energy to maintain a constant occupancy, the resonance splits into three peaks, two at energies $\omega = E_f$ and $\omega = E_f + U$ corresponding to the energies for a valence fluctuation, plus an additional central 'Kondo resonance' associated with the spin fluctuations of the local moment.

At first sight, once the interaction is much larger than the hybridization width Δ, one might expect there to be no spectral weight left at low energies. But this violates the idea of adiabaticity. In fact, there are always certain adiabatic

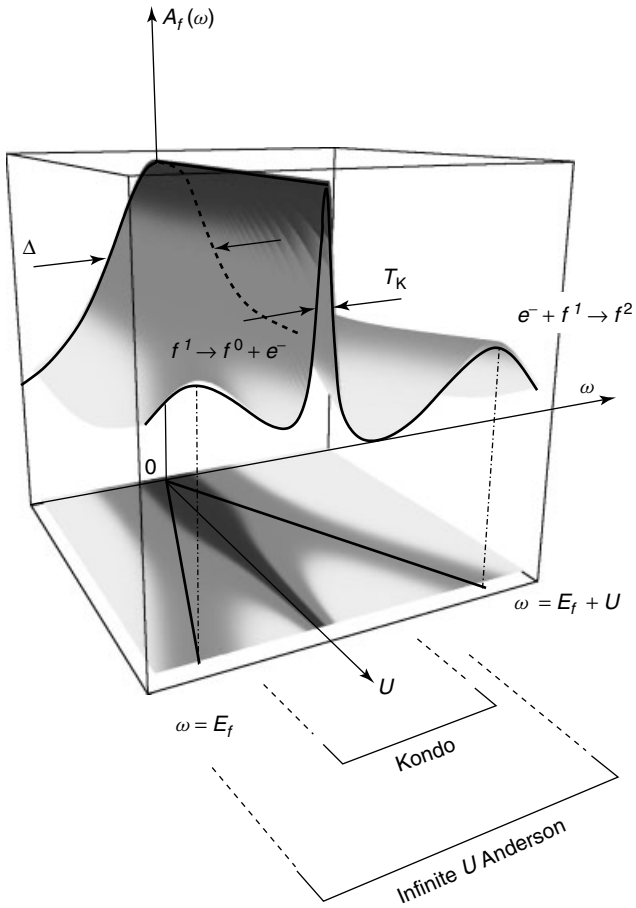

Figure 11. Schematic illustration of the evaluation of the f-spectral function $A_f(\omega)$ as interaction strength U is turned on continuously, maintaining a constant f occupancy by shifting the bare f-level position beneath the Fermi energy. The lower part of diagram is the density plot of f-spectral function, showing how the noninteracting resonance at $U = 0$ splits into an upper and lower atomic peak at $\omega = E_f$ and $\omega = E_f + U$.

invariants that do not change, despite the interaction. One such quantity is the phase shift δ_f associated with the scattering of conduction electrons of the ion; another is the height of the f-spectral function at zero energy, and it turns out that these two quantities are related. A rigorous result owing to (Langreth, 1966) tells us that the spectral function at $\omega = 0$ is directly determined by the f-phase shift, so that its noninteracting value

$$A_f(\omega = 0) = \frac{\sin^2\delta_f}{\pi\Delta} \tag{34}$$

is preserved by adiabaticity. Langreth's result can be heuristically derived by noting that δ_f is the phase of the f-Green's function at the Fermi energy, so that $G_f(0 - i\epsilon)^{-1} = |G_f^{-1}(0)|e^{-i\delta_f}$. Now, in a Fermi liquid, the scattering at the Fermi energy is purely elastic, and this implies

that $ImG_f^{-1}(0 - i\epsilon) = \Delta$, the bare hybridization width. From this, it follows that $ImG_f^{-1}(0) = |G_f^{-1}(0)| \sin\delta_f = \Delta$, so that $G_f(0) = e^{i\delta_f}/(\Delta \sin\delta_f)$, and the preceding result follows.

The phase shift δ_f is set via the Friedel sum rule, according to which the sum of the up-and-down scattering phase shifts, gives the total number of f-bound electrons, or

$$\sum_\sigma \frac{\delta_{f\sigma}}{\pi} = 2\frac{\delta_f}{\pi} = n_f \tag{35}$$

for a twofold degenerate f state. At large distances, the wave function of scattered electrons $\psi_f(r) \sim \sin(k_F r + \delta_f)/r$ is 'shifted inwards' by a distance $\delta_l/k_F = (\lambda_F/2) \times (\delta_l/\pi)$. This sum rule is sometimes called a *node counting* rule because, if you think about a large sphere enclosing the impurity, then each time the phase shift passes through π, a node crosses the spherical boundary and one more electron per channel is bound beneath the Fermi sea. Friedel's sum rule holds for interacting electrons, provided the ground state is adiabatically accessible from the noninteracting system (Langer and Ambegaokar, 1961; Langreth, 1966). Since $n_f = 1$ in an f^1 state, the Friedel sum rule tells us that the phase shift is $\pi/2$ for a twofold degenerate f state. In other words, adiabaticity tell us that the electron is *resonantly scattered* by the quenched local moment.

Photoemission studies do reveal the three-peaked structure characteristic of the Anderson model in many Ce systems, such as $CeIr_2$ and $CeRu_2$ (Allen, Oh, Maple and Torikachvili, 1983) (see Figure 12). Materials in which the Kondo resonance is wide enough to be resolved are more 'mixed valent' materials in which the f valence departs significantly from unity. Three-peaked structures have also been observed in certain U 5f materials such as UPt_3 and UAl_2 (Allen *et al*., 1985) materials, but it has not yet been resolved in UBe_{13}. A three-peaked structure has recently been observed in 4f Yb materials, such as $YbPd_3$, where the $4f^{13}$ configuration contains a single f hole, so that the positions of the three peaks are reversed relative to Ce (Liu *et al*., 1992).

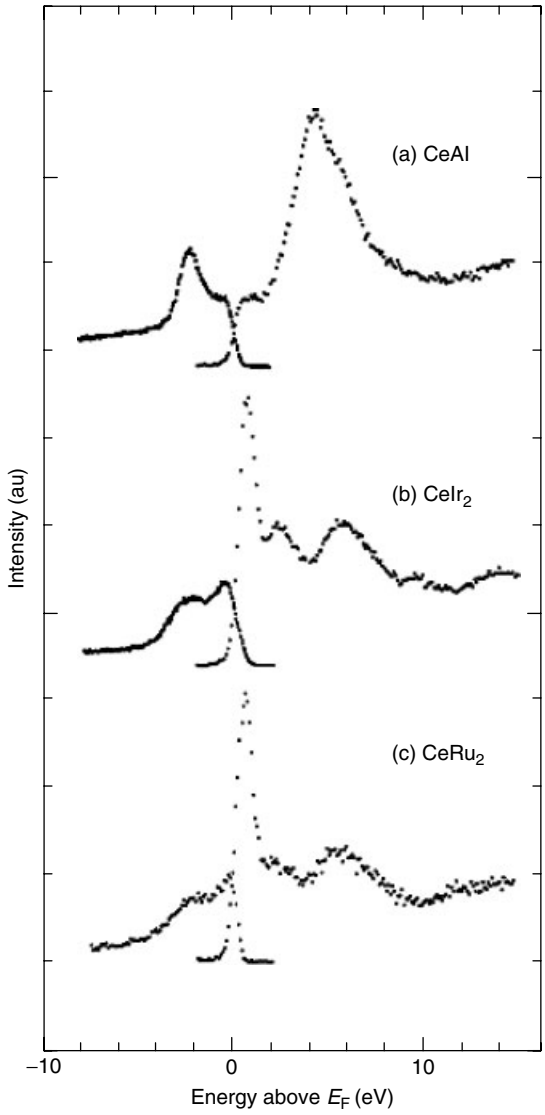

Figure 12. Showing spectral functions for three different Cerium f-electron materials, measured using X-ray photoemission (below the Fermi energy) and inverse X-ray photoemission (above the Fermi energy). CeAl is an AFM and does not display a Kondo resonance. (Reproduced from J.W. Allen, S.J. Oh, M.B. Maple and M.S. Torikachvili: *Phys. Rev.* **28**, 1983, 5347, copyright © 1983 by the American Physical Society, with permission of the APS.)

2.2 Hierarchies of energy scales

2.2.1 Renormalization concept

To understand how a Fermi liquid emerges when a local moment is immersed in a quantum sea of electrons, theorists had to connect physics on several widely spaced energy scales. Photoemission shows that the characteristic energy to produce a valence fluctuation is of the order of volts, or tens of thousands of Kelvin, yet the characteristic physics we are interested in occurs at scales hundreds or thousands of times smaller. How can we distill the essential effects of the atomic physics at electron volt scales on the low-energy physics at millivolt scales?

The essential tool for this task is the 'renormalization group' (Anderson and Yuval, 1969, 1970, 1971; Anderson, 1970, 1973; Wilson, 1976; Nozières and Blandin, 1980; Nozières, 1976), based on the idea that the physics at low-energy scales only depends on a small subset of 'relevant' variables from the original microscopic Hamiltonian. The extraction of these relevant variables is accomplished by

'renormalizing' the Hamiltonian by systematically eliminating the high-energy virtual excitations and adjusting the low-energy Hamiltonian to take care of the interactions that these virtual excitations induce in the low energy Hilbert space. This leads to a family of Hamiltonian's $H(\Lambda)$, each with a different high-energy cutoff Λ, which share the same low-energy physics.

The systematic passage from a Hamiltonian $H(\Lambda)$ to a renormalized Hamiltonian $H(\Lambda')$ with a smaller cutoff $\Lambda' = \Lambda/b$ is accomplished by dividing the eigenstates of H into a a low-energy subspace {L} and a high-energy subspace {H}, with energies $|\epsilon| < \Lambda' = \Lambda/b$ and a $|\epsilon| \in [\Lambda', \Lambda]$ respectively. The Hamiltonian is then broken up into terms that are block-diagonal in these subspaces,

$$H = \left[\begin{array}{c|c} H_{\rm L} & V^\dagger \\ \hline V & H_{\rm H} \end{array}\right] \tag{36}$$

where V and $V^\dagger$ provide the matrix elements between {L} and {H}. The effects of the V are then taken into account by carrying out a unitary (canonical) transformation that block-diagonalizes the Hamiltonian,

$$H(\Lambda) \to UH(\Lambda)U^\dagger = \left[\begin{array}{c|c} \tilde{H}_{\rm L} & 0 \\ \hline 0 & \tilde{H}_{\rm H} \end{array}\right] \tag{37}$$

The renormalized Hamiltonian is then given by $H(\Lambda') = \tilde{H}_{\rm L} = H_{\rm L} + \delta H$. The flow of key parameters in the Hamiltonian resulting from this process is called a *renormalization group flow*.

At certain important crossover energy scales, large tracts of the Hilbert space associated with the Hamiltonian are projected out by the renormalization process, and the character of the Hamiltonian changes qualitatively. In the Anderson model, there are three such important energy scales, (Figure 13)

- $\Lambda_I = E_f + U$, where valence fluctuations $e^- + f^1 \rightleftharpoons f^2$ into the doubly occupied f^2 state are eliminated. For $\Lambda \ll \Lambda_I$, the physics is described by the infinite U Anderson model

$$H = \sum_{k,\sigma} \epsilon_k n_{k\sigma} + \sum_{k,\sigma} V(k)\left[c^\dagger_{k\sigma} X_{0\sigma} + X_{\sigma 0} c_{k\sigma}\right] + E_f \sum_\sigma X_{\sigma\sigma}, \tag{38}$$

  where $X_{\sigma\sigma} = |f^1:\sigma\rangle\langle f^1:\sigma|$, $X_{0\sigma} = |f^0\rangle\langle f^1\sigma|$ and $X_{\sigma 0} = |f^1:\sigma\rangle\langle f^0|$ are 'Hubbard operators' that connect the states in the projected Hilbert space with no double occupancy.
- $\Lambda_{II} \sim |E_f| = -E_f$, where valence fluctuations into the empty state $f^1 \rightleftharpoons f^0 + e^-$ are eliminated to form a local moment. Physics below this scale is described by the Kondo model.
- $\Lambda = T_{\rm K}$, the Kondo temperature below which the local moment is screened to form a resonantly scattering local Fermi liquid.

In the symmetric Anderson model, $\Lambda_I = \Lambda_{II}$, and the transition to local moment behavior occurs in a one-step crossover process.

2.2.2 *Schrieffer–Wolff transformation*

The unitary or canonical transformation that eliminates the charge fluctuations at scales Λ_I and Λ_{II} was first

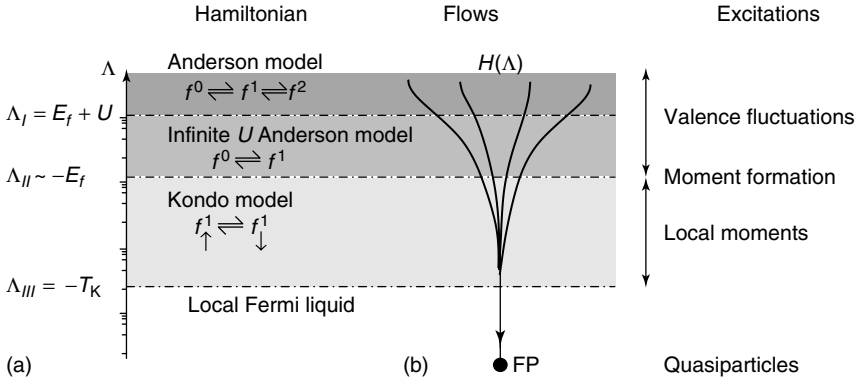

Figure 13. (a) Crossover energy scales for the Anderson model. At scales below Λ_I, valence fluctuations into the doubly occupied state are suppressed. All lower energy physics is described by the infinite U Anderson model. Below Λ_{II}, all valence fluctuations are suppressed, and the physics involves purely the spin degrees of freedom of the ion, coupled to the conduction sea via the Kondo interaction. The Kondo scale renormalizes to strong coupling below Λ_{III}, and the local moment becomes screened to form a local Fermi liquid. (b) Illustrating the idea of renormalization group flows toward a Fermi liquid fixed point.

carried out by Schrieffer and Wolff (1966), and Coqblin and Schrieffer (1969), who showed how this model gives rise to a residual antiferromagnetic interaction between the local moment and conduction electrons. The emergence of this antiferromagnetic interaction is associated with a process called *superexchange*: the virtual process in which an electron or hole briefly migrates off the ion, to be immediately replaced by another with a different spin. When these processes are removed by the canonical transformation, they induce an antiferromagnetic interaction between the local moment and the conduction electrons. This can be seen by considering the two possible spin-exchange processes

$$\begin{aligned} e^-_\uparrow + f^1_\downarrow &\leftrightarrow f^2 \leftrightarrow e^-_\downarrow + f^1_\uparrow \qquad \Delta E_I \sim U + E_f \\ h^+_\uparrow + f^1_\downarrow &\leftrightarrow f^0 \leftrightarrow h^+_\downarrow + f^1_\uparrow \qquad \Delta E_{II} \sim -E_f \end{aligned} \tag{39}$$

Both processes require that the f electron and incoming particle are in a spin-singlet. From second-order perturbation theory, the energy of the singlet is lowered by an amount $-2J$, where

$$J = V^2 \left[\frac{1}{\Delta E_1} + \frac{1}{\Delta E_2} \right] \tag{40}$$

and the factor of two derives from the two ways a singlet can emit an electron or hole into the continuum [1] and $V \sim V(k_{\rm F})$ is the hybridization matrix element near the Fermi surface. For the symmetric Anderson model, where $\Delta E_1 = \Delta E_{II} = U/2$, $J = 4V^2/U$.

If we introduce the electron spin-density operator $\vec{\sigma}(0) = \frac{1}{\mathcal{N}} \sum_{k,k'} c^\dagger_{k\alpha} \vec{\sigma}_{\alpha\beta} c_{k'\beta}$, where $\mathcal{N}$ is the number of sites in the lattice, then the effective interaction has the form

$$H_{\rm K} = -2J P_{S=0} \tag{41}$$

where $P_{S=0} = \left[\frac{1}{4} - \frac{1}{2} \vec{\sigma}(0) \cdot \vec{S}_f \right]$ is the singlet projection operator. If we drop the constant term, then the effective interaction induced by the virtual charge fluctuations must have the form

$$H_{\rm K} = J \vec{\sigma}(0) \cdot \vec{S}_f \tag{42}$$

where $\vec{S}_f$ is the spin of the localized moment. The complete 'Kondo Model', $H = H_c + H_{\rm K}$ describing the conduction electrons and their interaction with the local moment is

$$H = \sum_{\mathbf{k}\sigma} \epsilon_{\mathbf{k}} c^\dagger_{\vec{k}\sigma} c_{\vec{k}\sigma} + J \vec{\sigma}(0) \cdot \vec{S}_f \tag{43}$$

2.2.3 The Kondo effect

The antiferromagnetic sign of the superexchange interaction J in the Kondo Hamiltonian is the origin of the spin-screening physics of the Kondo effect. The bare interaction is weak, but the spin fluctuations it induces have the effect of *antiscreening* the interaction at low energies, renormalizing it to larger and larger values. To see this, we follow an Anderson's 'Poor Man's' scaling procedure (Anderson, 1973, 1970), which takes advantage of the observation that at small J the renormalization in the Hamiltonian associated with the block-diagonalization process $\delta H = \tilde{H}_{\rm L} - H_{\rm L}$ is given by second-order perturbation theory:

$$\delta H_{ab} = \langle a | \delta H | b \rangle = \frac{1}{2} \left[T_{ab}(E_a) + T_{ab}(E_b) \right] \tag{44}$$

where

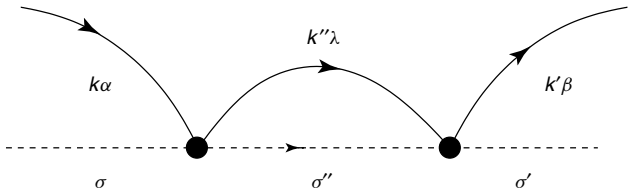
$$T_{ab}(\omega) = \sum_{|\Lambda\rangle \in \{H\}} \left[\frac{V^\dagger_{a\Lambda} V_{\Lambda b}}{\omega - E_\Lambda} \right] \tag{45}$$

is the many-body 't-matrix' associated with virtual transitions into the high-energy subspace $\{H\}$. For the Kondo model,

$$V = \mathcal{P}_{\rm H} J \vec{S}(0) \cdot \vec{S}_d \mathcal{P}_{\rm L} \tag{46}$$

where $\mathcal{P}_{\rm H}$ projects the intermediate state into the high-energy subspace, while $\mathcal{P}_{\rm L}$ projects the initial state into the low-energy subspace. There are two virtual scattering processes that contribute to the antiscreening effect, involving a high-energy electron (I) or a high-energy hole (II).

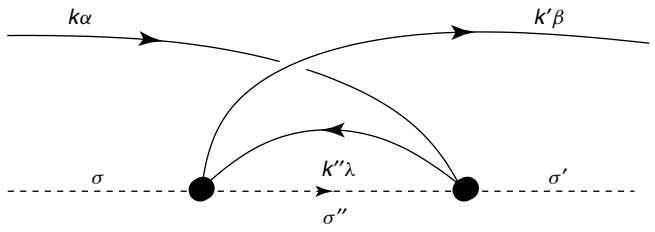
Process I is denoted by the diagram



and starts in state $|b\rangle = |k\alpha, \sigma\rangle$, passes through a virtual state $|\Lambda\rangle = |c^\dagger_{k''} \alpha \sigma''\rangle$ where $\epsilon_{k''}$ lies at high energies in the range $\epsilon_{k''} \in [\Lambda/b, \Lambda]$ and ends in state $|a\rangle = |k'\beta, \sigma'\rangle$. The resulting renormalization

$$\begin{aligned} &\langle k'\beta, \sigma' | T^I(E) | k\alpha, \sigma \rangle \\ &\quad = \sum_{\epsilon_{k''} \in [\Lambda - \delta\Lambda, \Lambda]} \left[\frac{1}{E - \epsilon_{k''}} \right] J^2 \times (\sigma^a_{\beta\lambda} \sigma^b_{\lambda\alpha})(S^a_{\sigma'\sigma''} S^b_{\sigma''\sigma}) \\ &\quad \approx J^2 \rho \delta\Lambda \left[\frac{1}{E - \Lambda} \right] (\sigma^a \sigma^b)_{\beta\alpha} (S^a S^b)_{\sigma'\sigma} \end{aligned} \tag{47}$$

In *Process II*, denoted by



the formation of a virtual hole excitation $|\Lambda\rangle = c_{k''\lambda}|\sigma''\rangle$ introduces an electron line that crosses itself, introducing a negative sign into the scattering amplitude. The spin operators of the conduction sea and AFM reverse their relative order in process II, which introduces a relative minus sign into the T-matrix for scattering into a high-energy hole-state,

$$\begin{aligned}
&\langle k'\beta\sigma'|T^{(II)}(E)|k\alpha\sigma\rangle \\
&\quad = -\sum_{\epsilon_{k''}\in[-\Lambda,-\Lambda+\delta\Lambda]}\left[\frac{1}{E-(\epsilon_k+\epsilon_{k'}-\epsilon_{k''})}\right] \\
&\qquad \times J^2(\sigma^b\sigma^a)_{\beta\alpha}(S^aS^b)_{\sigma'\sigma} \\
&\quad = -J^2\rho\delta\Lambda\left[\frac{1}{E-\Lambda}\right](\sigma^a\sigma^b)_{\beta\alpha}(S^aS^b)_{\sigma'\sigma} \qquad (48)
\end{aligned}$$

where we have assumed that the energies ϵ_k and $\epsilon_{k'}$ are negligible compared with Λ.

Adding equations (47 and 48) gives

$$\begin{aligned}
\delta H^{int}_{k'\beta\sigma';k\alpha\sigma} &= \hat{T}^I + T^{II} = -\frac{J^2\rho\delta\Lambda}{\Lambda}[\sigma^a,\sigma^b]_{\beta\alpha}S^aS^b \\
&= 2\frac{J^2\rho\delta\Lambda}{\Lambda}\vec{\sigma}_{\beta\alpha}\cdot\vec{S}_{\sigma'\sigma} \qquad (49)
\end{aligned}$$

so the high-energy virtual spin fluctuations enhance or 'antiscreen' the Kondo coupling constant

$$J(\Lambda') = J(\Lambda) + 2J^2\rho\frac{\delta\Lambda}{\Lambda} \qquad (50)$$

If we introduce the coupling constant $g = \rho J$, recognizing that $d\ln\Lambda = -\frac{\delta\Lambda}{\Lambda}$, we see that it satisfies

$$\frac{\partial g}{\partial\ln\Lambda} = \beta(g) = -2g^2 + O(g^3) \qquad (51)$$

This is an example of a **negative** β function: a signature of an interaction that grows with the renormalization process. At high energies, the weakly coupled local moment is said to be **asymptotically free**. The solution to the scaling equation is

$$g(\Lambda') = \frac{g_o}{1-2g_o\ln(\Lambda/\Lambda')} \qquad (52)$$

and if we introduce the 'Kondo temperature'

$$T_K = D\exp\left[-\frac{1}{2g_o}\right] \qquad (53)$$

we see that this can be written

$$2g(\Lambda') = \frac{1}{\ln(\Lambda/T_K)} \qquad (54)$$

so that once $\Lambda' \sim T_K$, the coupling constant becomes of the order one – at lower energies, one reaches 'strong coupling' where the Kondo coupling can no longer be treated as a weak perturbation. One of the fascinating things about this flow to strong coupling is that, in the limit $T_K \ll D$, all explicit dependence on the bandwidth D disappears and the Kondo temperature T_K is the only intrinsic energy scale in the physics. Any physical quantity must depend in a universal way on ratios of energy to T_K, thus the universal part of the free energy must have the form

$$F(T) = T_K\Phi\frac{T}{T_K} \qquad (55)$$

where $\Phi(x)$ is universal. We can also understand the resistance created by spin-flip scattering of a magnetic impurity in the same way. The resistivity is given by $\rho_i = \frac{ne^2}{m}\tau(T,H)$, where the scattering rate must also have a scaling form

$$\tau(T,H) = \frac{n_i}{\rho}\Phi_2\left(\frac{T}{T_K},\frac{H}{T_K}\right) \qquad (56)$$

where ρ is the density of states (per spin) of electrons and n_i is the concentration of magnetic impurities and the function $\Phi_2(t,h)$ is universal. To leading order in the Born approximation, the scattering rate is given by $\tau = 2\pi\rho J^2S(S+1) = \frac{2\pi S(S+1)}{\rho}(g_0)^2$ where $g_0 = g(\Lambda_0)$ is the bare coupling at the energy scale that moments form. We can obtain the behavior at a finite temperature by replacing $g_0 \to g(\Lambda = 2\pi T)$, where upon

$$\tau(T) = \frac{2\pi S(S+1)}{\rho}\frac{1}{4\ln^2(2\pi T/T_K)} \qquad (57)$$

gives the leading high-temperature growth of the resistance associated with the Kondo effect.

The kind of perturbative analysis we have gone through here takes us down to the Kondo temperature. The physics at lower energies corresponds to the strong coupling limit of the Kondo model. Qualitatively, once $J\rho \gg 1$, the local moment is bound into a spin-singlet with a conduction electron. The number of bound electrons is $n_f = 1$, so that by the Friedel sum rule (equation (35)) in a paramagnet the phase shift $\delta_\uparrow = \delta_\downarrow = \pi/2$, the unitary limit of scattering. For more

details about the local Fermi liquid that forms, we refer the reader to the accompanying chapter on the Kondo effect by Jones (2007).

2.2.4 *Doniach's Kondo lattice concept*

The discovery of heavy-electron metals prompted Doniach (1977) to make the radical proposal that heavy-electron materials derive from a dense lattice version of the Kondo effect, described by the **Kondo Lattice model** (Kasuya, 1956)

$$H = \sum_{\mathbf{k}\sigma} \epsilon_{\mathbf{k}} c^{\dagger}_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma} + J \sum_j \vec{S}_j \cdot c^{\dagger}_{\mathbf{k}\alpha} \vec{\sigma}_{\alpha\beta} c_{\mathbf{k}'\beta} \mathrm{e}^{i(\mathbf{k}'-\mathbf{k})\cdot\mathbf{R}_j} \tag{58}$$

In effect, Doniach was implicitly proposing that the key physics of heavy-electron materials resides in the interaction of neutral local moments with a charged conduction electron sea.

Most local moment systems develop an antiferromagnetic order at low temperatures. A magnetic moment at location $\mathbf{x}_0$ induces a wave of 'Friedel' oscillations in the electron spin density (Figure 14)

$$\langle \vec{\sigma}(\mathbf{x}) \rangle = -J\chi(\mathbf{x}-\mathbf{x}_0)\langle \vec{S}(\mathbf{x}_0) \rangle \tag{59}$$

where

$$\chi(\mathbf{x}) = 2\sum_{\mathbf{k},\mathbf{k}'} \left(\frac{f(\epsilon_{\mathbf{k}}) - f(\epsilon_{\mathbf{k}'})}{\epsilon_{\mathbf{k}'} - \epsilon_{\mathbf{k}}} \right) e^{i(\mathbf{k}-\mathbf{k}')\cdot\mathbf{x}} \tag{60}$$

is the nonlocal susceptibility of the metal. The sharp discontinuity in the occupancies $f(\epsilon_k)$ at the Fermi surface is responsible for Friedel oscillations in induced spin density that decay with a power law

$$\langle \vec{\sigma}(r) \rangle \sim -J\rho \frac{\cos 2k_{\mathrm{F}} r}{|k_{\mathrm{F}} r|^3} \tag{61}$$

where ρ is the conduction electron density of states and r is the distance from the impurity. If a second local moment is introduced at location $\mathbf{x}$, it couples to this Friedel oscillation with energy $J\langle \vec{S}(\mathbf{x}) \cdot \vec{\sigma}(x) \rangle$, giving rise to the 'RKKY' (Ruderman and Kittel, 1954; Kasuya, 1956; Yosida, 1957) magnetic interaction,

$$H_{\mathrm{RKKY}} = \overbrace{-J^2\chi(\mathbf{x}-\mathbf{x}')}^{J_{\mathrm{RKKY}}(\mathbf{x}-\mathbf{x}')} \vec{S}(\mathbf{x}) \cdot \vec{S}(\mathbf{x}') \tag{62}$$

where

$$J_{\mathrm{RKKY}}(r) \sim -J^2\rho \frac{\cos 2k_{\mathrm{F}} r}{k_{\mathrm{F}} r} \tag{63}$$

In alloys containing a dilute concentration of magnetic transition-metal ions, the oscillatory RKKY interaction gives rise to a frustrated, glassy magnetic state known as a *spin glass*. In dense systems, the RKKY interaction typically gives rise to an ordered antiferromagnetic state with a Néel temperature T_{N} of the order $J^2\rho$. Heavy-electron metals narrowly escape this fate.

Doniach argued that there are two scales in the Kondo lattice, the single-ion Kondo temperature T_{K} and T_{RKKY}, given by

$$\begin{aligned} T_{\mathrm{K}} &= D\mathrm{e}^{-1/(2J\rho)} \\ T_{\mathrm{RKKY}} &= J^2\rho \end{aligned} \tag{64}$$

When $J\rho$ is small, then T_{RKKY} is the largest scale and an antiferromagnetic state is formed, but, when the $J\rho$ is large, the Kondo temperature is the largest scale so a dense Kondo lattice ground state becomes stable. In this paramagnetic state, each site resonantly scatters electrons with a phase shift $\sim\pi/2$. Bloch's theorem then insures that the resonant elastic scattering at each site acts coherently, forming a renormalized band of width $\sim T_{\mathrm{K}}$ (Figure 15).

As in the impurity model, one can identify the Kondo lattice ground state with the large U limit of the Anderson lattice model. By appealing to adiabaticity, one can then link the excitations to the small U Anderson lattice model. According to this line of argument, the quasiparticle Fermi surface volume must count the number of conduction and f electrons (Martin, 1982), even in the large U limit, where it corresponds to the number of electrons *plus* the number of spins

$$2\frac{\mathcal{V}_{\mathrm{FS}}}{(2\pi)^3} = n_e + n_{\mathrm{spins}} \tag{65}$$

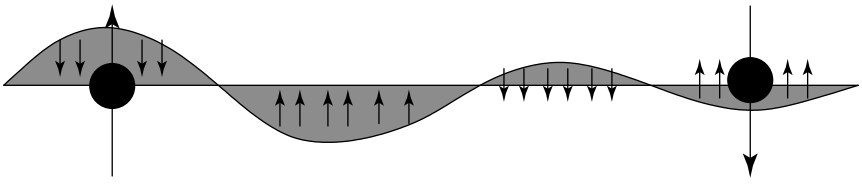


Figure 14. Spin polarization around magnetic impurity contains Friedel oscillations and induces an RKKY interaction between the spins.

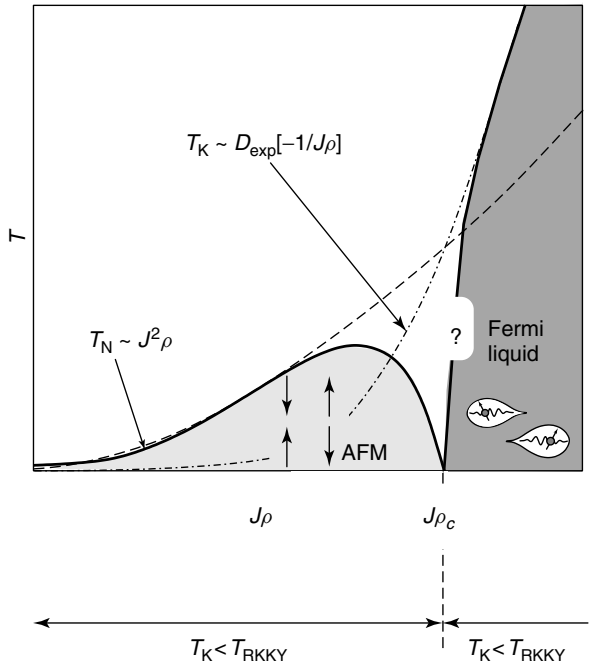

Figure 15. Doniach diagram, illustrating the antiferromagnetic regime, where $T_K < T_{RKKY}$ and the heavy-fermion regime, where $T_K > T_{RKKY}$. Experiment has told us in recent times that the transition between these two regimes is a quantum critical point. The effective Fermi temperature of the heavy Fermi liquid is indicated as a solid line. Circumstantial experimental evidence suggests that this scale drops to zero at the antiferromagnetic quantum critical point, but this is still a matter of controversy.

Using topology, and certain basic assumptions about the response of a Fermi liquid to a flux, Oshikawa (2000) was able to short circuit this tortuous path of reasoning, proving that the Luttinger relationship holds for the Kondo lattice model without reference to its finite U origins.

There are, however, aspects to the Doniach argument that leave cause for concern:

- It is purely a comparison of energy scales and does not provide a detailed mechanism connecting the heavy-fermion phase to the local moment AFM.
- Simple estimates of the value of $J\rho$ required for heavy-electron behavior give an artificially large value of the coupling constant $J\rho \sim 1$. This issue was later resolved by the observation that large spin degeneracy $2j+1$ of the spin-orbit coupled moments, which can be as large as $N = 8$ in Yb materials, enhances the rate of scaling to strong coupling, leading to a Kondo temperature (Coleman, 1983)

$$T_K = D(NJ\rho)^{\frac{1}{N}} \exp\left[-\frac{1}{NJ\rho}\right] \qquad (66)$$

Since the scaling enhancement effect stretches out across decades of energy, it is largely robust against crystal fields (Mekata *et al.*, 1986).

- Nozières' exhaustion paradox (Nozières, 1985). If one considers each local moment to be magnetically screened by a cloud of low-energy electrons within an energy T_K of the Fermi energy, one arrives at an 'exhaustion paradox'. In this interpretation, the number of electrons available to screen each local moment is of the order $T_K/D \ll 1$ per unit cell. Once the concentration of magnetic impurities exceeds $\frac{T_K}{D} \sim 0.1\%$ for ($T_K = 10\,\mathrm{K}$, $D = 10^4\,\mathrm{K}$), the supply of screening electrons would be exhausted, logically excluding any sort of dense Kondo effect. Experimentally, features of single-ion Kondo behavior persist to much higher densities. The resolution to the exhaustion paradox lies in the more modern perception that spin screening of local moments extends *up* in energy, from the Kondo scale T_K out to the bandwidth. In this respect, Kondo screening is reminiscent of Cooper pair formation, which involves electron states that extend upward from the gap energy to the Debye cutoff. From this perspective, the Kondo length scale $\xi \sim v_F/T_K$ is analogous to the coherence length of a superconductor (Burdin, Georges and Grempel, 2000), defining the length scale over which the conduction spin and local moment magnetization are coherent without setting any limit on the degree to which the correlation clouds can overlap (Figure 16).

2.3 The large N Kondo lattice

2.3.1 Gauge theories, large N, and strong correlation

The 'standard model' for metals is built upon the expansion to high orders in the strength of the interaction. This approach, pioneered by Landau, and later formulated in the language of finite temperature perturbation theory by Landau (1957), Pitaevskii (1960), Luttinger and Ward (1960), and Nozières and Luttinger (1962), provides the foundation for our understanding of metallic behavior in most conventional metals.

The development of a parallel formalism and approach for strongly correlated electron systems is still in its infancy, and there is no universally accepted approach. At the heart of the problem are the large interactions, which effectively remove large tracts of Hilbert space and impose strong constraints on the low-energy electronic dynamics. One way to describe these highly constrained Hilbert spaces is through the use of gauge theories. When written as a field theory, local constraints manifest themselves as locally conserved quantities. General principles link these conserved quantities

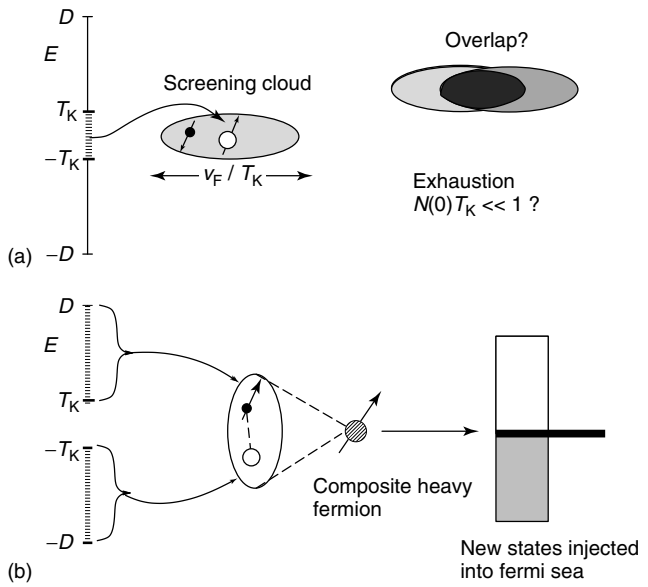

Figure 16. Contrasting (a) the 'screening cloud' picture of the Kondo effect with (b) the composite fermion picture. In (a), low-energy electrons form the Kondo singlet, leading to the exhaustion problem. In (b), the composite heavy electron is a highly localized bound-state between local moments and high-energy electrons, which injects new electronic states into the conduction sea at the chemical potential. Hybridization of these states with conduction electrons produces a singlet ground state, forming a Kondo resonance in the single impurity, and a coherent heavy electron band in the Kondo lattice.

with a set of gauge symmetries. For example, in the Kondo lattice, if a spin $S = 1/2$ operator is represented by fermions,

$$\vec{S}_j = f^\dagger_{j\alpha} \left(\frac{\vec{\sigma}}{2}\right)_{\alpha\beta} f_{j\beta} \tag{67}$$

then the representation must be supplemented by the constraint $n_f(j) = 1$ on the conserved f number at each site. This constraint means one can change the phase of each f fermion at each site arbitrarily

$$f_j \to \mathrm{e}^{i\phi_j} f_j \tag{68}$$

without changing the spin operator $\vec{S}_j$ or the Hamiltonian. This is the local gauge symmetry.

Similar issues also arise in the infinite U Anderson or Hubbard models where the 'no double occupancy' constraint can be established by using a slave boson representation (Barnes, 1976; Coleman, 1984) of Hubbard operators:

$$X_{\sigma 0}(j) = f^\dagger_{j\sigma} b_j, \qquad X_{0\sigma}(j) = b^\dagger_j f_{j\sigma} \tag{69}$$

where $f^\dagger_{j\sigma}$ creates a singly occupied f state, $f^\dagger_{j\sigma}|0\rangle \equiv |f^1, j\sigma\rangle$, while $b^\dagger$ creates an empty f^0 state, $b^\dagger_j|0\rangle = |f^0, j\rangle$. In the slave boson, the gauge charges

$$Q_j = \sum_\sigma f^\dagger_{j\sigma} f_{j\sigma} + b^\dagger_j b_j \tag{70}$$

are conserved and the physical Hilbert space corresponds to $Q_j = 1$ at each site. The gauge symmetry is now $f_{j\sigma} \to e^{i\theta_j} f_{j\sigma}$, $b_j \to e^{i\theta_j} b_j$. These two examples illustrate the link between strong correlation and gauge theories.

$$\begin{aligned} \text{Strong correlation} &\leftrightarrow \text{Constrained Hilbert space} \\ &\leftrightarrow \text{Gauge theories} \end{aligned} \tag{71}$$

A key feature of these gauge theories is the appearance of 'fractionalized fields', which carry either spin or charge, but not both. How, then, can a Landau–Fermi liquid emerge within a Gauge theory with fractional excitations?

Some have suggested that Fermi liquids cannot reconstitute themselves in such strongly constrained gauge theories. Others have advocated against gauge theories, arguing that the only reliable way forward is to return to 'real-world' models with a full fermionic Hilbert space and a finite interaction strength. A third possibility is that the gauge theory approach is valid, but that heavy quasiparticles emerge as bound-states of gauge particles. Quite independently of one's position on the importance of gauge theory approaches, the Kondo lattice poses a severe computational challenge, in no small part, because of the absence of any small parameter for resumed perturbation theory. Perturbation theory in the Kondo coupling constant J always fails below the Kondo temperature. How, then, can one develop a controlled computational tool to explore the transition from local moment magnetism to the heavy Fermi liquid?

One route forward is to seek a family of models that interpolates between the models of physical interest, and a limit where the physics can be solved exactly. One approach, as we shall discuss later, is to consider Kondo lattices in variable dimensions d, and expand in powers of $1/d$ about the limit of infinite dimensionality (Georges, Kotliar, Krauth and Rozenberg, 1996; Jarrell, 1995). In this limit, electron self-energies become momentum independent, the basis of the DMFT. Another approach, with the advantage that it can be married with gauge theory, is the use of large N expansions. The idea here is to generalize the problem to a family of models in which the f-spin degeneracy $N = 2j + 1$ is artificially driven to infinity. In this extreme limit, the key physics is captured as a mean-field theory, and finite N properties are obtained through an expansion in the small parameter $1/N$. Such large N expansions have played an important role in the context of the spherical model of statistical mechanics (Berlin and Kac, 1952) and in field theory (Witten, 1978). The next section discusses how the

gauge theory of the Kondo lattice model can be treated in a large N expansion.

2.3.2 *Mean-field theory of the Kondo lattice*

Quantum large N expansions are a kind of semiclassical limit, where $1/N \sim \hbar$ plays the role of a synthetic Planck's constant. In a Feynman path integral

$$\langle x_f(t)|x_i, 0\rangle = \int \mathcal{D}[x] \exp\left[\frac{i}{\hbar} S[x, \dot{x}]\right] \tag{72}$$

where S is the classical action and the quantum action $A = \frac{1}{\hbar}S$ is 'extensive' in the variable $\frac{1}{\hbar}$. When $\frac{1}{\hbar} \to \infty$, fluctuations around the classical trajectory vanish and the transition amplitude is entirely determined by the classical action to go from i to f. A large N expansion for the partition function Z of a quantum system involves a path integral in imaginary time over the fields ϕ

$$Z = \int \mathcal{D}[\phi] \mathrm{e}^{-NS[\phi,\dot{\phi}]} \tag{73}$$

where NS is the action (or free energy) associated with the field configuration in space and time. By comparison, we see that the large N limit of quantum systems corresponds to an alternative classical mechanics, where $1/N \sim \hbar$ emulates Planck's constant and new types of collective behavior not pertinent to strongly interacting electron systems start to appear.

Our model for a Kondo lattice of spins localized at sites j is

$$H = \sum_{\mathbf{k}\sigma} \epsilon_{\mathbf{k}} c^\dagger_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma} + \sum_j H_I(j) \tag{74}$$

where

$$H_I(j) = \frac{J}{N} S_{\alpha\beta}(j) c^\dagger_{j\beta} c_{j\alpha} \tag{75}$$

is the Coqblin Schrieffer form of the Kondo interaction Hamiltonian (Coqblin and Schrieffer, 1969) between an f spin with $N = 2j + 1$ spin components and the conduction sea. The spin of the local moment at site j is represented as a bilinear of Abrikosov pseudofermions

$$S_{\alpha\beta}(j) = f^\dagger_{j\alpha} f_{j\beta} - \frac{n_f}{N}\delta_{\alpha\beta} \tag{76}$$

and

$$c^\dagger_{j\sigma} = \frac{1}{\sqrt{\mathcal{N}}} \sum_{\mathbf{k}} c^\dagger_{\mathbf{k}\sigma} \mathrm{e}^{-i\mathbf{k}\cdot\vec{R}_j} \tag{77}$$

creates an electron localized at site j, where $\mathcal{N}$ is the number of sites.

Although this is a theorists' idealization – a 'spherical cow approximation', it nevertheless captures key aspects of the physics. This model ascribes a spin degeneracy of $N = 2j + 1$ to both the f electrons *and* the conduction electrons. While this is justified for a single impurity, a more realistic lattice model requires the introduction of Clebsch–Gordon coefficients to link the spin-1/2 conduction electrons with the spin-j conduction electrons.

To obtain a mean-field theory, each term in the Hamiltonian must scale as N. Since the interaction contains two sums over the spin variables, this criterion is met by rescaling the coupling constant replacing $J \to \frac{\tilde{J}}{N}$. Another important aspect to this model is the constraint on charge fluctuations, which in the Kondo limit imposes the constraint $n_f = 1$. Such a constraint can be imposed in a path integral with a Lagrange multiplier term $\lambda(n_f - 1)$. However, with $n_f = 1$, this is not extensive in N, and cannot be treated using a mean-field value for λ. The resolution is to generalize the constraint to $n_f = Q$, where Q is an integer chosen so that as N grows, $q = Q/N$ remains fixed. Thus, for instance, if we are interested in $N = 2$, this corresponds to $q = n_f/N = \frac{1}{2}$. In the large N limit, it is then sufficient to apply the constraint on the average $\langle n_f\rangle = Q$ through a static Lagrange multiplier coupled to the difference $(n_f - Q)$.

The next step is to carry out a 'Hubbard–Stratonovich' transformation on the interaction

$$H_I(j) = -\frac{J}{N}\left(c^\dagger_{j\beta} f_{j\beta}\right)\left(f^\dagger_{j\alpha} c_{j\alpha}\right) \tag{78}$$

Here, we have absorbed the term $-\frac{J}{N} n_f c^\dagger_{j\alpha} c_{j\alpha}$ derived from the spin-diagonal part of (equation (76)) by a shift $\mu \to \mu - \frac{Jn_f}{N^2}$ in the chemical potential. This interaction has the form $-gA^\dagger A$, with $g = \frac{J}{N}$ and $A = f^\dagger_{j\alpha} c_{j\alpha}$, which we factorize using a Hubbard–Stratonovich transformation,

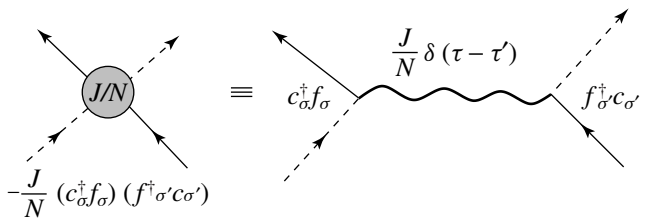
$$-gA^\dagger A \to A^\dagger V + \overline{V} A + \frac{\overline{V} V}{g} \tag{79}$$

so that (Lacroix and Cyrot, 1979; Read and Newns, 1983a)

$$H_I(j) \to H_I[V, j] = \overline{V}_j \left(c^\dagger_{j\sigma} f_{j\sigma}\right) + \left(f^\dagger_{j\sigma} c_{j\sigma}\right) V_j + N\frac{\overline{V}_j V_j}{J} \tag{80}$$

This is an exact transformation, provided the $V_j(\tau)$ are treated as fluctuating variables inside a path integral. The V_j can be regarded as a spinless exchange boson for the Kondo effect. In the parallel treatment of the infinite Anderson model (Coleman, 1987a), $V_j = Vb_j$ is the 'slave boson' field associated with valence fluctuations.

In diagrams:



(81)

The path integral for the Kondo lattice is then

$$Z = \int \mathcal{D}[V,\lambda] \overbrace{\int \mathcal{D}[c,f] \exp\left[-\int_0^\beta \left(\sum_{k\sigma} c^\dagger_{\mathbf{k}\sigma}\partial_\tau c_{\mathbf{k}\sigma} + \sum_{j\sigma} f^\dagger_{j\sigma}\partial_\tau f_{j\sigma} + H[V,\lambda]\right)\right]}^{=\mathrm{Tr}\left[T exp\left(-\int_0^\beta H[V,\lambda]d\tau\right)\right]} \tag{82}$$

where

$$H[V,\lambda] = \sum_{\mathbf{k}\sigma} \epsilon_{\mathbf{k}} c^\dagger_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma} + \sum_j \left(H_I[V_j, j] + \lambda_j[n_f(j) - Q]\right) \tag{83}$$

This is the 'Read–Newns' path integral formulation (Read and Newns, 1983a; Auerbach and Levin, 1986) of the Kondo lattice model. The path integral contains an outer integral $\int \mathcal{D}[V,\lambda]$ over the gauge fields V_j and $\lambda_j(\tau)$, and an inner integral $\int \mathcal{D}[c,f]$ over the fermion fields moving in the environment of the gauge fields. The inner path integral is equal to a trace over the time-ordered exponential of $H[V,\lambda]$.

Since the action in this path integral grows extensively with N, the large N limit is saturated by the saddle point configurations of V and λ, eliminating the the outer integral in equation (83). We seek a translationally invariant, static, saddle point, where $\lambda_j(\tau) = \lambda$ and $V_j(\tau) = V$. Since the Hamiltonian is static, the interior path integral can be written as the trace over the Hamiltonian evaluated at the saddle point,

$$Z = \mathrm{Tr} e^{-\beta H_{\mathrm{MFT}}} \qquad (N \to \infty) \tag{84}$$

where

$$H_{\mathrm{MFT}} = H[V,\lambda] = \sum_{\mathbf{k}\sigma} \epsilon_{\mathbf{k}} c^\dagger_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma} + \sum_{j,\sigma}\left(\overline{V} c^\dagger_{j\sigma} f_{j\sigma} + V f^\dagger_{j\sigma} c_{j\sigma} + \lambda f^\dagger_{j\sigma} f_{j\sigma}\right) + Nn\left(\frac{\overline{V}V}{J} - \lambda_o q\right) \tag{85}$$

The saddle point is determined by the condition that the Free energy $F = -T\ln Z$ is stationary with respect to variations in V and λ. To impose this condition, we need to diagonalize H_{MFT} and compute the Free energy. First we rewrite the mean-field Hamiltonian in momentum space,

$$H_{\mathrm{MFT}} = \sum_{\mathbf{k}\sigma} \left(c^\dagger_{\mathbf{k}\sigma}, f^\dagger_{\mathbf{k}\sigma}\right) \begin{bmatrix} \epsilon_{\mathbf{k}} & \overline{V} \\ V & \lambda \end{bmatrix} \begin{pmatrix} c_{\mathbf{k}\sigma} \\ f_{\mathbf{k}\sigma} \end{pmatrix} + Nn\left(\frac{\overline{V}V}{J} - \lambda q\right) \tag{86}$$

where

$$f^\dagger_{\vec{k}\sigma} = \frac{1}{\sqrt{\mathcal{N}}} \sum_j f^\dagger_{j\sigma} e^{i\vec{k}\cdot\vec{R}_j} \tag{87}$$

is the Fourier transform of the f-electron field. This Hamiltonian can then be diagonalized in the form

$$H_{\mathrm{MFT}} = \sum_{\mathbf{k}\sigma} \left(a^\dagger_{\mathbf{k}\sigma}, b^\dagger_{\mathbf{k}\sigma}\right) \begin{bmatrix} E_{\mathbf{k}+} & 0 \\ 0 & E_{\mathbf{k}-} \end{bmatrix} \begin{pmatrix} a_{\mathbf{k}\sigma} \\ b_{\mathbf{k}\sigma} \end{pmatrix} + N\mathcal{N}_s\left(\frac{|V|^2}{J} - \lambda q\right) \tag{88}$$

where $a^\dagger_{\mathbf{k}\sigma}$ and $b^\dagger_{\mathbf{k}\sigma}$ are linear combinations of $c^\dagger_{\mathbf{k}\sigma}$ and $f^\dagger_{\vec{k}\sigma}$, which describe the quasiparticles of the theory. The momentum state eigenvalues $E = E_{\vec{k}\pm}$ are the roots of the equation

$$\mathrm{Det}\left[E\underline{1} - \begin{pmatrix} \epsilon_{\mathbf{k}} & \overline{V} \\ V & \lambda \end{pmatrix}\right] = (E-\epsilon_{\mathbf{k}})(E-\lambda) - |V|^2 = 0 \tag{89}$$

so

$$E_{\mathbf{k}\pm} = \frac{\epsilon_{\mathbf{k}} + \lambda}{2} \pm \left[\left(\frac{\epsilon_{\mathbf{k}} - \lambda}{2}\right)^2 + |V|^2\right]^{\frac{1}{2}} \tag{90}$$

are the energies of the upper and lower bands. The dispersion described by these energies is shown in Figure 17. Notice that:

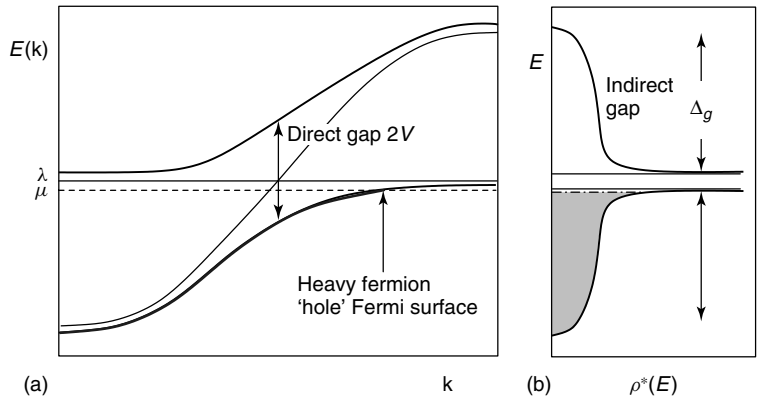


Figure 17. (a) Dispersion produced by the injection of a composite fermion into the conduction sea. (b) Renormalized density of states, showing 'hybridization gap' (Δ_g).

- hybridization between the f-electron states and the conduction electrons builds an upper and lower Fermi band, separated by an indirect 'hybridization gap' of width $\Delta_g = E_g(+) - E_g(-) \sim T_{\rm K}$, where

$$E_g(\pm) = \lambda \pm \frac{V^2}{D_\mp} \tag{91}$$

  and $\pm D_\pm$ are the top and bottom of the conduction band. The 'direct' gap between the upper and lower bands is $2|V|$.
- From (89), the relationship between the energy of the heavy electrons (E) and the energy of the conduction electrons (ϵ) is given by $\epsilon = E - |V|^2/(E-\lambda)$, so that the density of heavy-electron states $\rho^*(E) = \sum_{\mathbf{k},\pm}\delta(E - E^{(\pm)}_{\mathbf{k}})$ is related to the conduction electron density of states $\rho(\epsilon)$ by

$$\rho^*(E) = \rho\frac{{\rm d}\epsilon}{{\rm d}E} = \rho(\epsilon)\left(1 + \frac{|V|^2}{(E-\lambda)^2}\right) \sim \begin{cases} \rho\left(1+\frac{|V|^2}{(E-\lambda)^2}\right) & \text{outside hybridization gap,} \\ 0 & \text{inside hybridization gap,} \end{cases} \tag{92}$$

  so the 'hybridization gap' is flanked by two sharp peaks of approximate width $T_{\rm K}$.
- The Fermi surface volume **expands** in response to the injection of heavy electrons into the conduction sea,

$$Na^D\frac{V_{\rm FS}}{(2\pi)^3} = \left\langle \frac{1}{\mathcal{N}_s}\sum_{\mathbf{k}\sigma} n_{\mathbf{k}\sigma}\right\rangle = Q + n_c \tag{93}$$

  where a^D is the unit cell volume, $n_{\mathbf{k}\sigma} = a^\dagger_{\mathbf{k}\sigma}a_{\mathbf{k}\sigma} + b^\dagger_{\mathbf{k}\sigma}b_{\mathbf{k}\sigma}$ is the quasiparticle number operator and n_c is the number of conduction electrons per unit cell. More instructively, if $n_e = n_c/a^D$ is the electron density,

$$\overbrace{n_e}^{e^-\text{ density}} = \overbrace{N\frac{V_{\rm FS}}{(2\pi)^3}}^{\text{quasi particle density}} - \underbrace{\frac{Q}{a^D}}_{\text{positive background}} \tag{94}$$

  so the electron density n_c divides into a contribution carried by the enlarged Fermi sea, whose enlargement is compensated by the development of a positively charged background. Loosely speaking, each neutral spin in the Kondo lattice has 'ionized' to produce Q negatively charged heavy fermions, leaving behind a Kondo singlet of charge $+Qe$ (Figure 18).

To obtain V and λ, we must compute the free energy

$$\frac{F}{N} = -T\sum_{\mathbf{k},\pm}\ln\left[1 + {\rm e}^{-\beta E_{\mathbf{k}\pm}}\right] + \mathcal{N}_s\left(\frac{|V|^2}{J} - \lambda q\right) \tag{95}$$

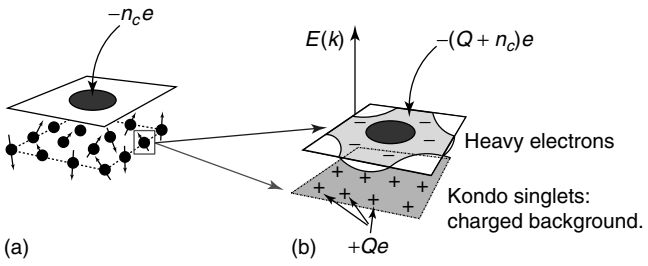

Figure 18. Schematic diagram from Coleman, Paul and Rech (2005a). (a) High-temperature state: small Fermi surface with a background of spins; (b) Low-temperature state, where large Fermi surface develops against a background of positive charge. Each spin 'ionizes' into Q heavy electrons, leaving behind a a Kondo singlet with charge $+Qe$. (Reproduced from P. Coleman, I. Paul, and J. Rech, *Phys. Rev. B* **72**, 2005, 094430, copyright © 2005 by the American Physical Society, with permission of the APS.)

At $T = 0$, the free energy converges the ground-state energy E_0, given by

$$\frac{E_0}{N\mathcal{N}_s} = \int_{-\infty}^{0} \rho^*(E)E + \left(\frac{|V|^2}{J} - \lambda q\right) \tag{96}$$

Using equation (92), the total energy is

$$\begin{aligned}\frac{E_o}{N\mathcal{N}_s} &= \int_{-D}^{0} \mathrm{d}\epsilon \rho E \mathrm{d}E + \int_{-D}^{0} \mathrm{d}E \rho |V|^2 \frac{E}{(E-\lambda)^2} \\ &\quad + \left(\frac{|V|^2}{J} - \lambda q\right) \\ &= \overbrace{-\frac{D^2\rho}{2}}^{E_c/(N\mathcal{N}_s)} + \overbrace{\frac{\Delta}{\pi}\ln\left(\frac{\lambda e}{T_{\mathrm{K}}}\right) - \lambda q}^{E_{\mathrm{K}}/(N\mathcal{N}_s)}\end{aligned} \tag{97}$$

where we have assumed that the upper band is empty and the lower band is partially filled. $T_{\mathrm{K}} = De^{-\frac{1}{J\rho}}$ as before. The first term in (97) is the conduction electron contribution to the energy E_c/Nn_s, while the second term is the lattice 'Kondo' energy $E_{\mathrm{K}}/N_{\mathcal{N}_s}$. If now we impose the constraint $\frac{\partial E_o}{\partial \lambda} = \langle n_f \rangle - Q = 0$ then $\lambda = \frac{\Delta}{\pi q}$ so that the ground-state energy can be written

$$\frac{E_{\mathrm{K}}}{N\mathcal{N}_s} = \frac{\Delta}{\pi}\ln\left(\frac{\Delta e}{\pi q T_{\mathrm{K}}}\right) \tag{98}$$

This energy functional has a 'Mexican Hat' form, with a minimum at

$$\Delta = \frac{\pi q}{e^2} T_{\mathrm{K}} \tag{99}$$

confirming that $\Delta \sim T_{\mathrm{K}}$. If we now return to the quasiparticle density of states ρ^*, we find it has the value

$$\rho^*(0) = \rho + \frac{q}{T_{\mathrm{K}}} \tag{100}$$

at the Fermi energy so the mass enhancement of the heavy electrons is then

$$\frac{m^*}{m} = 1 + \frac{q}{\rho T_{\mathrm{K}}} \sim \frac{qD}{T_{\mathrm{K}}} \tag{101}$$

2.3.3 The charge of the f electron

How does the f electron acquire its charge? We have emphasized from the beginning that the charge degrees of freedom of the original f electrons are irrelevant, indeed, absent from the physics of the Kondo lattice. So how are charged f electrons constructed out of the states of the Kondo lattice, and how do they end up coupling to the electromagnetic field?

The large N theory provides an intriguing answer. The passage from the original Hamiltonian equation (75) to the mean-field Hamiltonian equation (85) is equivalent to the substitution

$$\frac{J}{N} S_{\alpha\beta}(j) c^\dagger_{j\beta} c_{j\alpha} \longrightarrow \overline{V} f^\dagger_{j\alpha} c_{j\alpha} + V c^\dagger_{j\alpha} \mathrm{f}_{j\alpha} \tag{102}$$

In other words, the composite combination of spin and conduction electron are contracted into a single Fermi field

$$\frac{J}{N} \overbrace{S_{\alpha\beta}(j) c_{j\beta}}^{\dagger} = \left(\frac{J}{N} f^\dagger_{j\alpha} \overbrace{f_{j\beta} c_{j\beta}}^{\dagger}\right) \to V f^\dagger_{j\alpha} \tag{103}$$

The amplitude $V = \frac{J}{N} \overbrace{f_{j\beta} c_{j\beta}}^{\dagger} = -\frac{J}{N}\langle c^\dagger_{j\beta} f_{j\beta}\rangle$ involves electron states that extend over decades of energy out to the band edges. In this way, the f electron emerges as a composite bound-state of a spin and an electron. More precisely, in the long-time correlation functions,

$$\begin{aligned}&\langle \left[S_{\gamma\alpha}(i) c_{i\gamma}\right](t) \ \ \left[S_{\alpha\beta}(j) c^\dagger_{j\beta}\right](t')\rangle \\ &\xrightarrow{|t-t'| \gg \hbar/T_K} \frac{N|V^2|}{J^2} \langle f_{i\alpha}(t) f^\dagger_{j\alpha}(t')\rangle\end{aligned} \tag{104}$$

Such 'clustering' of composite operators into a single entity is well-known statistical mechanics as part of the operator product expansion (Cardy, 1996). In many-body physics, we are used to the clustering of fermions pairs into a composite boson, as in the BCS model of superconductivity, $-g\overbrace{\psi_\uparrow(x)\psi_\downarrow(x')} \to \Delta(x - x')$. The unfamiliar aspect of the Kondo effect is the appearance of a composite fermion.

The formation of these composite objects profoundly modifies the conductivity and plasma oscillations of the electron fluid. The Read–Newns path integral has two $U(1)$ gauge invariances – an external electromagnetic gauge invariance associated with the conservation of charge and an internal gauge invariance associated with the local constraints. The f electron couples to the internal gauge fields rather than the external electromagnetic fields, so why is it charged?

The answer lies in the broken symmetry associated with the development of the amplitude V. The phase of V transforms under both internal and external gauge groups. When V develops an amplitude, its phase does not actually order, but it does develop a stiffness which is sufficient to lock the internal and external gauge fields together so that, at low frequencies, they become synonymous. Written in a schematic long-wavelength form, the gauge-sensitive part of

the Kondo lattice Lagrangian is

$$\mathcal{L} = \sum_{\sigma} \int \mathrm{d}^D x \Big[c^{\dagger}_{\sigma}(x)(-i\partial_t + e\Phi(x) + \epsilon_{\mathbf{p}-e\vec{A}})c_{\sigma}(x) + f^{\dagger}_{\sigma}(x)(-i\partial_t + \lambda(x))f_{\sigma}(x) + \Big(\overline{V}(x)c^{\dagger}_{\sigma}(x)f_{\sigma}(x) + \text{ H.c}\Big)\Big] \tag{105}$$

where $\mathbf{p} = -i\vec{\nabla}$. Suppose $V(x) = |V(x)|e^{i\phi(x)}$. There are two independent gauge transformations that increase the phase ϕ of the hybridization. In the external, electromagnetic gauge transformation, the change in phase is absorbed onto the conduction electron and electromagnetic field, so if $V \to Ve^{i\alpha}$,

$$\begin{aligned} &\phi \to \phi + \alpha, \qquad c(x) \to c(x)e^{-i\alpha(x)}, \\ &e\Phi(x) \to e\Phi(x) + \dot{\alpha}(x), \quad e\vec{A} \to e\vec{A} - \vec{\nabla}\alpha(x) \end{aligned} \tag{106}$$

where $(\Phi, \vec{A})$ denotes the electromagnetic scalar and vector potential at site j and $\dot{\alpha} = \partial_t \alpha \equiv -i\partial_\tau \alpha$ denotes the derivative with respect to real time t. By contrast, in the internal gauge transformation, the phase change of V is absorbed onto the f fermion and the internal gauge field (Read and Newns, 1983a), so if $V \to Ve^{i\beta}$,

$$\begin{aligned} &\phi \to \phi + \beta, \qquad f(x) \to f(x)e^{i\beta(x)}, \\ &\lambda(x) \to \lambda(x) - \dot{\beta}(x) \end{aligned} \tag{107}$$

If we expand the mean-field free energy to quadratic order in small, slowly varying changes in $\lambda(x)$, then the change in the action is given by

$$\delta S = -\frac{\chi_Q}{2} \int \mathrm{d}^D x \mathrm{d}\tau \delta\lambda(x)^2 \tag{108}$$

where $\chi_Q = -\delta^2 F/\delta\lambda^2$ is the f-electron susceptibility evaluated in the mean-field theory. However, $\delta\lambda(x)$ is not gauge invariant, so there must be additional terms. To guarantee gauge invariance under both the internal and external transformation, we must replace $\delta\lambda$ by the covariant combination $\delta\lambda + \dot{\phi} - e\Phi$. The first two terms are required for invariance under the internal gauge group, while the last two terms are required for gauge invariance under the external gauge group. The expansion of the action to quadratic order in the gauge fields must therefore have the form

$$S \sim -\frac{\chi_Q}{2} \int \mathrm{d}\tau \sum_j (\dot{\phi} + \delta\lambda(x) - e\Phi(x))^2 \tag{109}$$

so the phase ϕ acquires a rigidity in time that generates a 'mass' or energy cost associated with *difference* of the external and internal potentials. The minimum energy static configuration is when

$$\delta\lambda(\mathbf{x}) + \dot{\phi}(\mathbf{x}) = e\Phi(\mathbf{x}) \tag{110}$$

so when the external potential changes slowly, the internal potential tracks it. It is this effect that keeps the Kondo resonance pinned at the Fermi surface. We can always choose the gauge where the phase velocity $\dot{\phi}$ is absorbed into the local gauge field λ. Recent work by Coleman, Marston and Schofield (2005b) has extended this kind of reasoning to the case where RKKY couplings generate a dispersion $j_{\mathbf{p}-\mathcal{A}}$ for the spinons, where $\mathcal{A}$ is an internal vector potential, which suppresses currents of the gauge charge n_f. In this case, the long-wavelength action has the form

$$S = \frac{1}{2} \int \mathrm{d}^3 x \mathrm{d}\tau \Big[\rho_s \left(e\vec{A} + \vec{\nabla}\phi - \vec{\mathcal{A}}\right)^2 - \chi_Q (e\Phi - \dot{\phi} - \delta\lambda)^2 \Big] \tag{111}$$

In this general form, heavy-electron physics can be seen to involve a kind of 'Meissner effect' that excludes the difference field $e\vec{A} - \vec{\mathcal{A}}$ from within the metal, locking the internal field to the external electromagnetic field, so that the f electrons, which couple to it, now become charged (Figure 19).

2.3.4 *Optical conductivity of the heavy-electron fluid*

One of the interesting consequences of the heavy-electron charge is a complete renormalization of the electronic plasma frequency (Millis, Lavagna and Lee, 1987b). The electronic

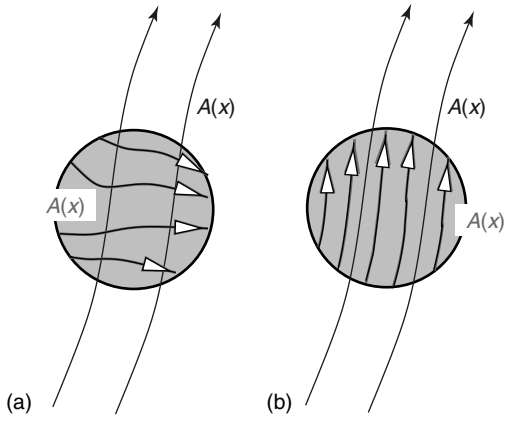

Figure 19. (a) Spin liquid, or local moment phase, internal field $\mathcal{A}$ decoupled from electromagnetic field. (b) Heavy-electron phase, internal gauge field 'locked' together with electromagnetic field. Heavy electrons are now charged and difference field $[e\vec{A}(x) - \mathcal{A}(x)]$ is excluded from the material.

plasma frequency is related via a f-sum rule to the integrated optical conductivity

$$\int_0^\infty \frac{\mathrm{d}\omega}{\pi}\sigma(\omega) = f_1 = \frac{\pi}{2}\left(\frac{n_c e^2}{m}\right) \tag{112}$$

where n_e is the density of electrons [2]. In the absence of local moments, this is the total spectral weight inside the Drude peak of the optical conductivity.

When the heavy-electron fluid forms, we need to consider the plasma oscillations of the enlarged Fermi surface. If the original conduction sea was less than half filled, then the renormalized heavy-electron band is more than half filled, forming a partially filled hole band. The density of electrons in a filled band is N/a^D, so the effective density of hole carriers is then

$$n_{\mathrm{HF}} = (N - Q - \mathcal{N}_c)/a^D = (N - Q)/a^D - n_c \tag{113}$$

The mass of the excitations is also renormalized, $m \to m^*$. The two effects produce a low-frequency 'quasiparticle' Drude peak in the conductivity, with a small total weight

$$\int_0^{\sim V} \mathrm{d}\omega\sigma(\omega) = f_2 = \frac{\pi}{2}\frac{n_{\mathrm{HF}}e^2}{m^*} \sim f_1 \times \frac{m}{m^*}\left(\frac{n_{\mathrm{HF}}}{n_c}\right) \ll f_1 \tag{114}$$

Optical conductivity probes the plasma excitations of the electron fluid at low momenta. The direct gap between the upper and lower bands of the Kondo lattice are separated by a direct hybridization gap of the order $2V \sim \sqrt{DT_{\mathrm{K}}}$. This scale is substantially larger than the Kondo temperature, and it defines the separation between the thin Drude peak of the heavy electrons and the high-frequency contribution from the conduction sea.

In other words, the total spectral weight is divided up into a small 'heavy fermion' Drude peak, of total weight f_2, where

$$\sigma(\omega) = \frac{n_{\mathrm{HF}}e^2}{m^*}\frac{1}{(\tau^*)^{-1} - i\omega} \tag{115}$$

separated off by an energy of the order $V \sim \sqrt{T_{\mathrm{K}}D}$ from an 'interband' component associated with excitations between the lower and upper Kondo bands (Millis and Lee, 1987a; Degiorgi, Anders, Gruner and Society, 2001). This second term carries the bulk $\sim f_1$ of the spectral weight (Figure 20).

Simple calculations, based on the Kubo formula, confirm this basic expectation, (Millis and Lee, 1987a; Degiorgi, Anders, Gruner and Society, 2001) showing that the relationship between the original relaxation rate of the conduction sea and the heavy-electron relaxation rate τ^* is

$$(\tau^*)^{-1} = \frac{m}{m^*}(\tau)^{-1} \tag{116}$$

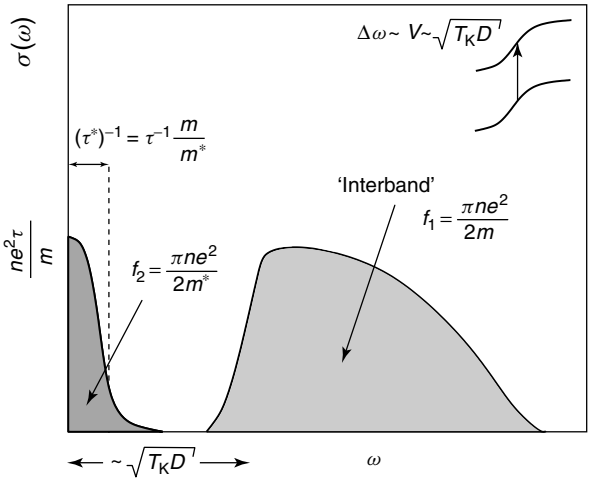

Figure 20. Separation of the optical sum rule in a heavy-fermion system into a high-energy 'interband' component of weight $f_2 \sim ne^2/m$ and a low-energy Drude peak of weight $f_1 \sim ne^2/m^*$.

Notice that this means that the residual resistivity

$$\rho_o = \frac{m^*}{ne^2\tau^*} = \frac{m}{ne^2\tau} \tag{117}$$

is unaffected by the effects of mass renormalization. This can be understood by observing that the heavy-electron Fermi velocity is also renormalized by the effective mass, $v_{\mathrm{F}}^* = \frac{m}{m^*}$, so that the mean-free path of the heavy-electron quasiparticles is unaffected by the Kondo effect.

$$l^* = v_{\mathrm{F}}^*\tau^* = v_{\mathrm{F}}\tau \tag{118}$$

The formation of a narrow Drude peak, and the presence of a direct hybridization gap, have been seen in optical measurements on heavy-electron systems (Schlessinger, Fisk, Zhang and Maple, 1997; Beyerman, Gruner, Dlicheouch and Maple, 1988; Dordevic *et al*., 2001). One of the interesting features about the hybridization gap of size $2V$ is that the mean-field theory predicts that the ratio of the direct to the indirect hybridization gap is given by $\frac{2V}{T_{\mathrm{K}}} \sim \frac{1}{\sqrt{\rho T_{\mathrm{K}}}} \sim \sqrt{\frac{m^*}{m_e}}$, so that the effective mass of the heavy electrons should scale as square of the ratio between the hybridization gap and the characteristic scale T^* of the heavy Fermi liquid

$$\frac{m^*}{m_e} \propto \left(\frac{2V}{T_{\mathrm{K}}}\right)^2 \tag{119}$$

In practical experiments, T_{K} is replaced by the 'coherence temperature' T^*, where the resistivity reaches a maximum. This scaling law is broadly followed (see Figure 21) in measured optical data (Dordevic *et al*., 2001), and provides further confirmation of the correctness of the Kondo lattice picture.

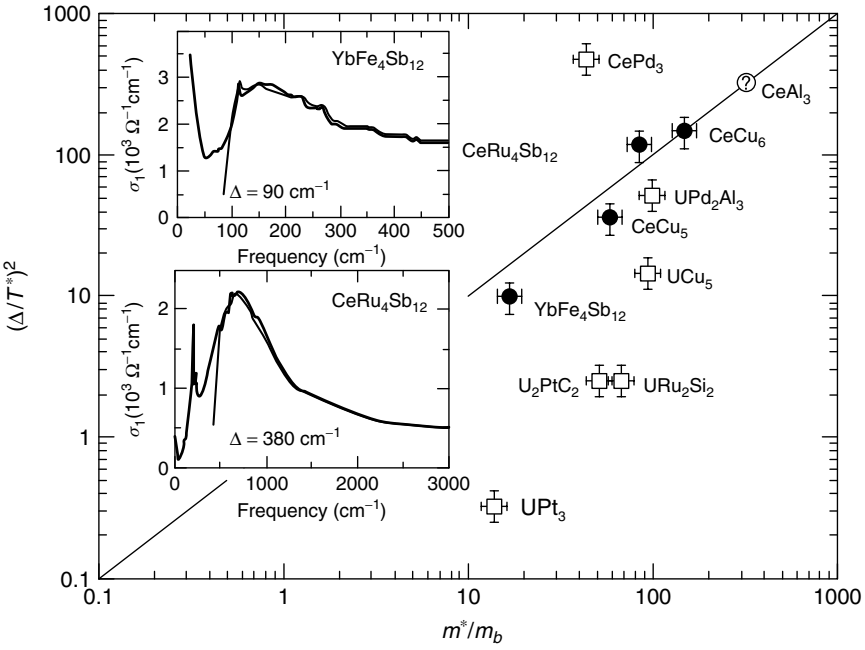

Figure 21. Scaling of the effective mass of heavy electrons with the square of the optical hybridization gap. (Reproduced from S.V. Dordevic, D.N. Basov, N.R. Dilley, E.D. Bauer, and M.B. Maple, *Phys. Rev. Lett.* **86**, 2001, 684, copyright © by the American Physical Society, with permission from the APS.)

2.4 Dynamical mean-field theory

The fermionic large N approach to the Kondo lattice provides an invaluable description of heavy-fermion physics, one that can be improved upon beyond the mean-field level. For example, the fluctuations around the mean-field theory can be used to compute the interactions, the dynamical correlation functions, and the optical conductivity (Coleman, 1987b; Millis and Lee, 1987a). However, the method does face a number of serious outstanding drawbacks:

- False phase transition: In the large N limit, the crossover between the heavy Fermi liquid and the local moment physics sharpens into a phase transition where the $1/N$ expansion becomes singular. There is no known way of eliminating this feature in the $1/N$ expansion.
- Absence of magnetism and superconductivity: The large N approach, based on the $SU(N)$ group, cannot form a two-particle singlet for $N > 2$. The $SU(N)$ group is fine for particle physics, where baryons are bound-states of N quarks, but, for condensed matter physics, we sacrifice the possibility of forming two-particle or two-spin singlets, such as Cooper pairs and spin-singlets. Antiferromagnetism and superconductivity are consequently absent from the mean-field theory.

Amongst the various alternative approaches currently under consideration, one of particular note is the DMFT. The idea of DMFT is to reduce the lattice problem to the physics of a single magnetic ion embedded within a self-consistently determined effective medium (Georges, Kotliar, Krauth and Rozenberg, 1996; Kotliar *et al*., 2006). The effective medium is determined self-consistently from the self-energies of the electrons that scatter off the single impurity. In its more advanced form, the single impurity is replaced by a cluster of magnetic ions.

Early versions of the DMFT were considered by Kuramoto and Watanabe (1987), and Cox and Grewe (1988), and others, who used diagrammatic means to extract the physics of a single impurity. The modern conceptual framework for DMFT was developed by Metzner and Vollhardt (1989), and Georges and Kotliar (1992). The basic idea behind DMFT is linked to early work of Luttinger and Ward (1960), and Kotliar *et al*. (2006), who found a way of writing the free energy as a variational functional of the full electronic Green's function

$$\mathcal{G}_{ij} = -\langle T\psi_i(\tau)\psi_j^\dagger(0)\rangle \tag{120}$$

Luttinger and Ward showed that the free energy is a variational functional of $F[\mathcal{G}]$ from which Dyson's equation relating the $\mathcal{G}$ to the bare Green's function $\mathcal{G}_0$

$$[\mathcal{G}_0^{-1} - \mathcal{G}^{-1}]_{ij} = \Sigma_{ij}[\mathcal{G}] \tag{121}$$

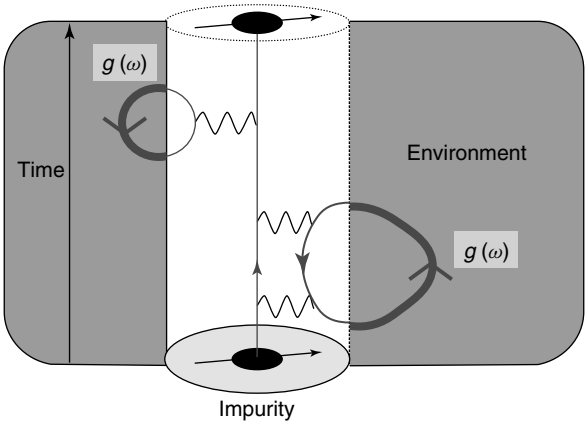

Figure 22. In the dynamical mean-field theory, the many-body physics of the lattice is approximated by a single impurity in a self-consistently determined environment. Each time the electron makes a sortie from the impurity, its propagation through the environment is described by a self-consistently determined local propagator $\mathcal{G}(\omega)$, represented by the thick gray line.

The quantity $\Sigma[\mathcal{G}]$ is a functional, a machine which takes the full propagator of the electron and outputs the self-energy of the electron. Formally, this functional is the sum of the one-particle irreducible Feynman diagrams for the self-energy: while its output depends on the input Greens function, the actual the machinery of the functional is determined solely by the interactions. The only problem is that we do not know how to calculate it.

DMFT solves this problem by approximating this functional by that of a single impurity or a cluster of magnetic impurities (Figure 22). This is an ideal approximation for a local Fermi liquid, where the physics is highly retarded in time, but local in space. The local approximation is also asymptotically exact in the limit of infinite dimensions (Metzner and Vollhardt, 1989). If one approximates the input Green function to Σ by its on-site component $\mathcal{G}_{ij} \approx \mathcal{G}\delta_{ij}$, then the functional becomes the local self-energy functional of a single magnetic impurity,

$$\Sigma_{ij}[\mathcal{G}_{ls}] \approx \Sigma_{ij}[\mathcal{G}\delta_{ls}] \equiv \Sigma_{\text{impurity}}[\mathcal{G}]\delta_{ij} \tag{122}$$

DMFT extracts the local self-energy by solving an Anderson impurity model embedded in an arbitrary electronic environment. The physics of such a model is described by a path integral with the action

$$S = -\int_0^\beta \mathrm{d}\tau \mathrm{d}\tau' f_\sigma^\dagger(\tau)\mathcal{G}_0^{-1}(\tau-\tau')f_\sigma(\tau') + U\int_0^\beta \mathrm{d}\tau n_\uparrow(\tau)n_\downarrow(\tau) \tag{123}$$

where $G_0(\tau)$ describes the bare Green's function of the f electron, hybridized with its dynamic environment. This quantity is self-consistently updated by the DMFT. There are, by now, a large number of superb numerical methods to solve an Anderson model for an arbitrary environment, including the use of exact diagonalization, diagrammatic techniques, and the use of Wilson's renormalization group (Bulla, 2006). Each of these methods is able to take an input 'environment' Green's function providing as output the impurity self-energy $\Sigma[\mathcal{G}_0] = \Sigma(i\omega_n)$.

Briefly, this is how the DMFT computational cycle works. One starts with an estimate for the environment Green's function $\mathcal{G}_0$ and uses this as input to the 'impurity solver' to compute the first estimate $\Sigma(i\omega_n)$ of the local self-energy. The interaction strength is set within the impurity solver. This local self-energy is used to compute the Green's functions of the electrons in the environment. In an Anderson lattice, the Green's function becomes

$$G(\mathbf{k},\omega) = \left[\omega - E_f - \frac{V^2}{\omega-\epsilon_{\mathbf{k}}} - \Sigma(\omega)\right]^{-1} \tag{124}$$

where V is the hybridization and $\epsilon_{\mathbf{k}}$ the dispersion of the conduction electrons. It is through this relationship that the physics of the lattice is fed into the problem. From $G(\mathbf{k},\omega)$, the local propagator is computed

$$\mathcal{G}(\omega) = \sum_{\mathbf{k}}\left[\omega - E_f - \frac{V^2}{\omega-\epsilon_{\mathbf{k}}} - \Sigma(\omega)\right]^{-1} \tag{125}$$

Finally, the new estimate for the bare environment Green's function $\mathcal{G}_0$ is then obtained by inverting the equation $\mathcal{G}^{-1} = \mathcal{G}_0^{-1} - \Sigma$, so that

$$\mathcal{G}_0(\omega) = \left[G^{-1}(\omega) + \Sigma(\omega)\right] \tag{126}$$

This quantity is then reused as the input to an 'impurity solver' to compute the next estimate of $\Sigma(\omega)$. The whole procedure is then reiterated to self-consistency. For the Anderson lattice, Cyzcholl (Schweitzer and Czycholl, 1991) has shown that remarkably good results are obtained using a perturbative expansion for Σ to the order of U^2 (Figure 23). Although this approach is not sufficient to capture the limiting Kondo behavior much, the qualitative physics of the Kondo lattice, including the development of coherence at low temperatures, is already captured by this approach. However, to go to the strongly correlated regime, where the ratio of the interaction to the impurity hybridization width $U/(\pi\Delta)$ is much larger than unity, one requires a more sophisticated solver.

There are many ongoing developments under way using this powerful new computational tool, including the incorporation of realistic descriptions of complex atoms, and the extension to 'cluster DMFT' involving clusters of magnetic moments embedded in a self-consistent environment. Let me

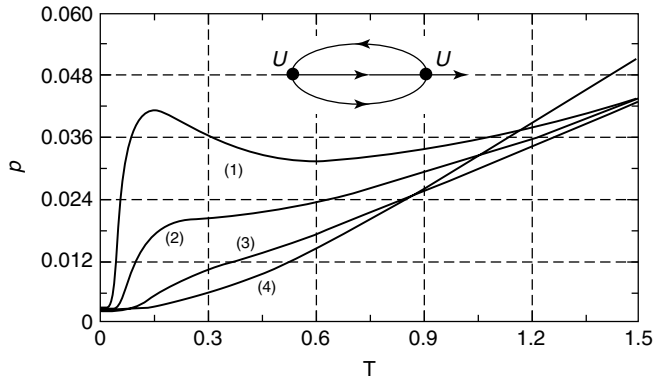

Figure 23. Resistivity for the Anderson lattice, calculated using the DMFT, computing the self-energy to order U^2. (1), (2), (3), and (4) correspond to a sequence of decreasing electron density corresponding to $n_{\mathrm{TOT}} = (0.8, 0.6, 0.4, 0.2)$ respectively. (Reproduced from H. Schweitzer and G. Czycholl, *Phys. Rev. Lett.* **67**, 1991, 3724 copyright © by the American Physical Society, with permission of the APS.)

end this brief summary with a list of a few unsolved issues with this technique

- There is, at present, no way to relate the thermodynamics of the bulk to the impurity thermodynamics.
- At present, there is no natural extension of these methods to the infinite U Anderson or Kondo models that incorporates the Green's functions of the *localized* f-electron degrees of freedom as an integral part of the DMFT.
- The method is largely a numerical black box, making it difficult to compute microscopic quantities beyond the electron-spectral functions. At the human level, it is difficult for students and researchers to separate themselves from the ardors of coding the impurity solvers, and make time to develop new conceptual and qualitative understanding of the physics.

3 KONDO INSULATORS

3.1 Renormalized silicon

The ability of a dense lattice of local moments to transform a metal into an insulator, a 'Kondo insulator' is one of the remarkable and striking consequences of the dense Kondo effect (Aeppli and Fisk, 1992; Tsunetsugu, Sigrist and Ueda, 1997; Riseborough, 2000). Kondo insulators are heavy-electron systems in which the the liberation of mobile charge through the Kondo effect gives rise to a filled heavy-electron band in which the chemical potential lies in the middle of the hybridization gap. From a quasiparticle perspective,

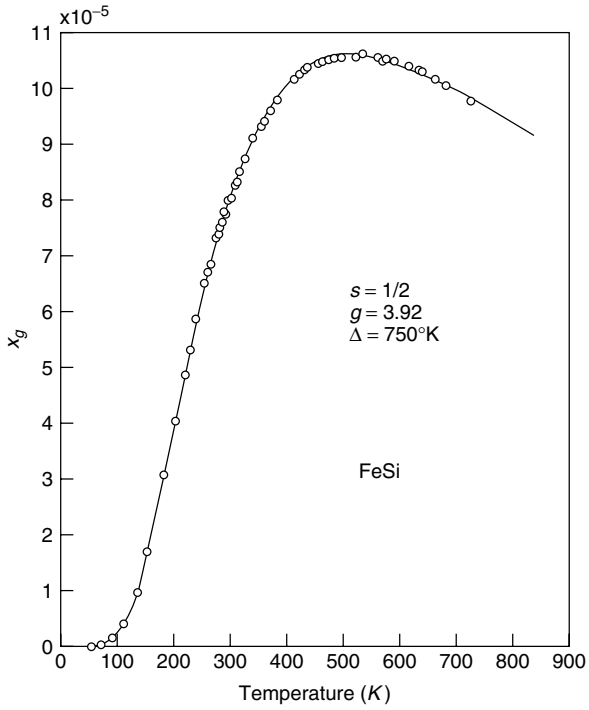

Figure 24. Schematic band picture of Kondo insulator, illustrating how a magnetic field drives a metal-insulator transition. Modified from Aeppli and Fisk (1992). (Reproduced from V. Jaccarino, G.K. Wertheim, J.H. Wernick, C.R. Walker and S. Arajs, *Phys. Rev.* **160**, 1967, 476 copyright © 1967 by the American Physical Society, with permission of the APS.)

Kondo insulators are highly renormalized 'band insulators' (Figure 24). The d-electron Kondo insulator FeSi has been referred to as *renormalized silicon*. However, like Mott–Hubbard insulators, the gap in their spectrum is driven by interaction effects, and they display optical and magnetic properties that cannot be understood with band theory.

There are about a dozen known Kondo insulators, including the rare-earth systems SmB_6 (Menth, Buehler and Geballe, 1969), YB_{12} (Iga, Kasaya and Kasuya, 1988), $CeFe_4P_{12}$ (Meisner *et al.*, 1985), $Ce_3Bi_4Pt_3$ (Hundley *et al.*, 1990), CeNiSn (Takabatake *et al.*, 1992, 1990; Izawa *et al.*, 1999) and CeRhSb (Takabatake *et al.*, 1994), and the d-electron Kondo insulator FeSi. At high temperatures, Kondo insulators are local moment metals, with classic Curie susceptibilities, but, at low temperatures, as the Kondo effect develops coherence, the conductivity and the magnetic susceptibility drop toward zero. Perfect insulating behavior is, however, rarely observed due to difficulty in eliminating impurity band formation in ultranarrow gap systems. One of the cleanest examples of Kondo-insulating behavior occurs in the d-electron system FeSi (Jaccarino *et al.*, 1967; DiTusa *et al.*, 1997). This 'flyweight' heavy-electron system provides a rather clean realization of the phenomena seen in other

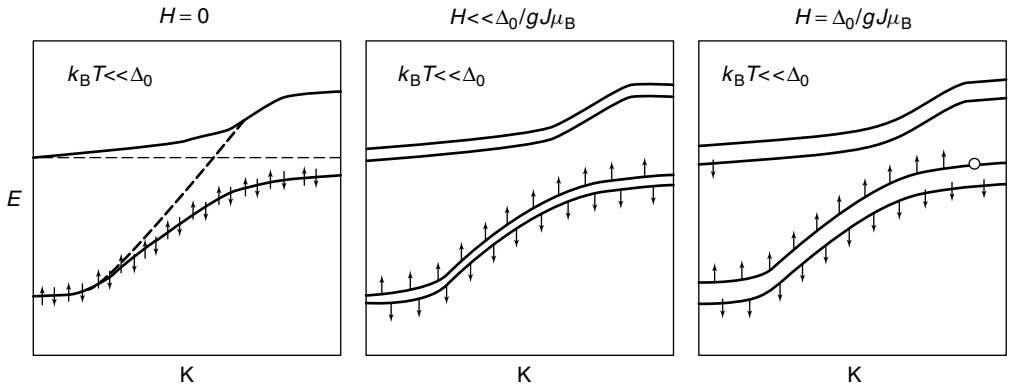

Figure 25. Temperature-dependent susceptibility in FeSi (after Jaccarino *et al*., 1967), fitted to the activated Curie form $\chi(T) = (C/T)e^{-\Delta/(k_B T)}$, with $C = (g\mu_B)^2 j(j+1)$, and $g = 3.92$, $\Delta = 750\,\mathrm{K}$. The Curie tail has been subtracted. (Reproduced from G. Aeppli and Z. Fisk, *Comm. Condens. Matter Phys.* **16** (1992) 155, with permission from Taylor & Franics Ltd, www/.nformaworld.com.)

Kondo insulators, with a spin and charge gap of about 750 K (Schlessinger, Fisk, Zhang and Maple, 1997). Unlike its rare-earth counterparts, the small spin-orbit coupling in this materials eliminates the Van Vleck contribution to the susceptibility at $T = 0$, giving rise to a susceptibility which almost completely vanishes at low temperatures (Jaccarino *et al*., 1967) (Figure 25).

Kondo insulators can be understood as 'half-filled' Kondo lattices in which each quenched moment liberates a negatively charged heavy electron, endowing each magnetic ion an extra unit of positive charge. There are three good pieces of support for this theoretical picture:

- Each Kondo insulator has its fully itinerant semiconducting analog. For example, CeNiSn is isostructural and isoelectronic with the semiconductor TiNiSi containing Ti^{4+} ions, even though the former contains Ce^{3+} ions with localized f moments. Similarly, $Ce_3Bi_4Pt_3$, with a tiny gap of the order 10 meV is isolectronic with semiconducting $Th_3Sb_4Ni_3$, with a 70 meV gap, in which the 5f-electrons of the Th^{4+} ion are entirely delocalized.
- Replacing the magnetic site with isoelectronic nonmagnetic ions is equivalent to doping, thus in $Ce_{1-x}La_xBi_4Pt_3$, each La^{3+} ion behaves as an electron donor in a lattice of effective Ce^{4+} ions. $Ce_{3-x}La_xPt_4Bi_3$ is, in fact, very similar to $CePd_3$, which contains a pseudogap in its optical conductivity, with a tiny Drude peak (Bucher *et al*., 1995).
- The magnetoresistance of Kondo insulators is large and negative, and the 'insulating gap' can be closed by the action of physically accessible fields. Thus, in $Ce_3Bi_4Pt_3$, a 30 T field is sufficient to close the indirect hybridization gap.

These equivalences support the picture of the Kondo effect liberating a composite fermion.

Figure 26(a) shows the sharp rise in the resistivity of $Ce_3Bi_4Pt_3$ as the Kondo-insulating gap forms. In Kondo insulators, the complete elimination of carriers at low temperatures is also manifested in the optical conductivity. Figure 26(b) shows the temperature dependence of the optical conductivity in $Ce_3Bi_4Pt_3$, showing the emergence of a gap in the low-frequency optical response and the loss of carriers at low energies.

The optical conductivity of the Kondo insulators is of particular interest. Like the heavy-electron metals, the development of coherence is marked by the formation of a direct hybridization gap in the optical conductivity. As this forms, a pseudogap develops in the optical conductivity. In a noninteracting band gap, the lost f-sum weight inside the pseudogap would be deposited above the gap. In heavy-fermion metals, a small fraction of this weight is deposited in the Drude peak – however, most of the weight is sent off to energies comparable with the bandwidth of the conduction band. This is one of the most direct pieces of evidence that the formation of Kondo singlets involves electron energies that spread out to the bandwidth. Another fascinating feature of the heavy-electron 'pseudogap' is that it forms at a temperature that is significantly lower than the pseudogap. This is because the pseudogap has a larger width given by the geometric mean of the coherence temperature and the bandwidth $2V \sim \sqrt{T_K D}$. The extreme upward transfer of spectral weight in Kondo insulators has not yet been duplicated in detailed theoretical models. For example, while calculations of the optical conductivity within the DMFT do show spectral weight transfer, it is not yet possible to reduce the indirect band gap to the point where it is radically smaller than the interaction scale U (Rozenberg, Kotliar and Kajueter, 1996). It may be that these discrepancies will disappear in future calculations based on the more extreme physics of the Kondo model, but these calculations have yet to be carried out.

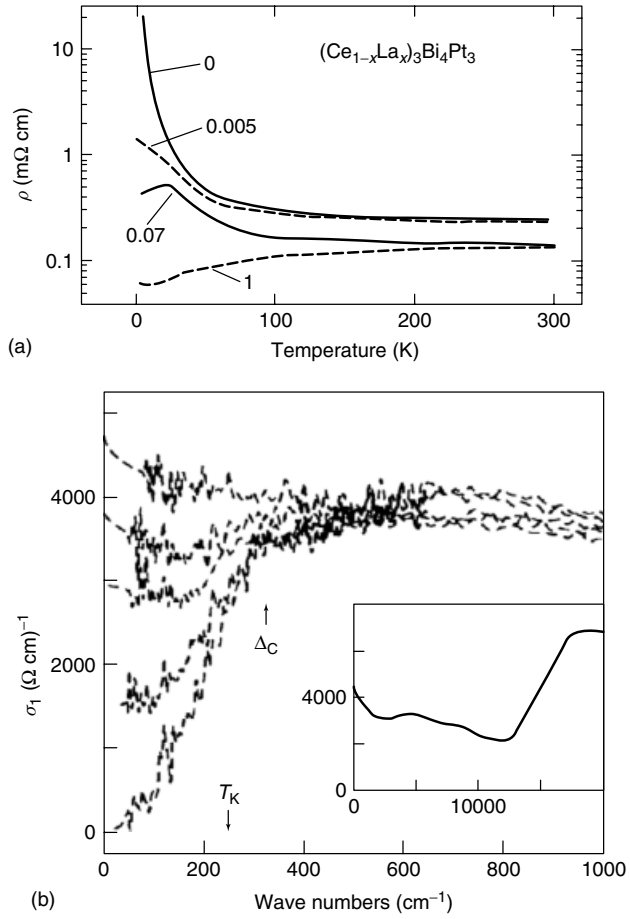

Figure 26. (a) Temperature-dependent resistivity of $Ce_3Pt_4Bi_3$ showing the sharp rise in resistivity at low temperatures. (Reproduced from M.F. Hundley, P.C. Canfield, J.D. Thompson, Z. Fisk, and J.M. Lawrence, *Phys. Rev. B.* **42**, 1990, 6842, copyright © 1990 by the American Physical Society, with permission of the APS.) Replacement of local moments with spinless *La* ions acts like a dopant. (b) Real part of optical conductivity $\sigma_1(\omega)$ for Kondo insulator $Ce_3Pt_4Bi_3$. (Reproduced from B. Bucher, Z. Schlessinger, P.C. Canfield, and Z. Fisk 03/04/2007 *Phys. Rev. Lett* **72**, 1994, 522, copyright © 1994 by the American Physical Society, with permission of the APS.) The formation of the pseudogap associated with the direct hybridization gap leads to the transfer of f-sum spectral weight to high energies of order the bandwidth. The pseudogap forms at temperatures that are much smaller than its width (see text). Insert shows $\sigma_1(\omega)$ in the optical range.

There are, however, a number of aspects of Kondo insulators that are poorly understood from the the simple hybridization picture, in particular,

- The apparent disappearance of RKKY magnetic interactions at low temperatures.
- The nodal character of the hybridization gap that develops in the narrowest gap Kondo insulators CeNiSn and CeRhSb.
- The nature of the metal-insulator transition induced by doping.

3.2 Vanishing of RKKY interactions

There are a number of experimental indications that the low-energy magnetic interactions vanish at low frequencies in a Kondo lattice. The low-temperature product of the susceptibility and temperature χT reported (Aeppli and Fisk, 1992) to scale with the inverse Hall constant $1/R_H$, representing the exponentially suppressed density of carriers, so that

$$\chi \sim \frac{1}{R_{\mathrm{H}} T} \sim \frac{\mathrm{e}^{-\Delta/T}}{T} \tag{127}$$

The important point here is that the activated part of the susceptibility has a vanishing Curie–Weiss temperature. A similar conclusion is reached from inelastic neutron scattering measurements of the magnetic susceptibility $\chi'(q,\omega) \sim$ in CeNiSn and FeSi, which appears to lose all of its momentum dependence at low temperatures and frequencies. There is, to date, no theory that can account for these vanishing interactions.

3.3 Nodal Kondo insulators

The narrowest gap Kondo insulators, CeNiSn and CeRhSb, are effectively semimetals, for although they do display tiny pseudogaps in their spin and charge spectra, the purest samples of these materials develop metallic behavior (Izawa *et al.*, 1999). What is particularly peculiar (Figure 27) about these two materials is that the NMR relaxation rate $1/(T_1)$ shows a T^3 temperature dependence from about 10 to 1 K, followed by a linear Korringa behavior at lower temperatures. The usual rule of thumb is that the NMR relaxation rate is proportional to a product of the temperature and the thermal average of the electronic density of states $N^*(\omega)$

$$\frac{1}{T_1} \sim T\overline{N(\omega)^2} \sim T[N(\omega \sim T)]^2 \tag{128}$$

where $\overline{N(\omega)^2} = \int \mathrm{d}\epsilon \left(-\frac{\partial f(\omega)}{\partial \omega}\right) N(\omega)^2$ is the thermally smeared average of the squared density of states. This suggests that the electronic density of states in these materials has a 'V' shaped form, with a finite value at $\omega = 0$. Ikeda and Miyake (1996) have proposed that the Kondo-insulating state in these materials develops in a crystal-field state with an axially symmetric hybridization vanishing along a single crystal axis. In such a picture, the finite density of states does not derive from a Fermi surface, but from the angular average of the coherence peaks in the density of states. The

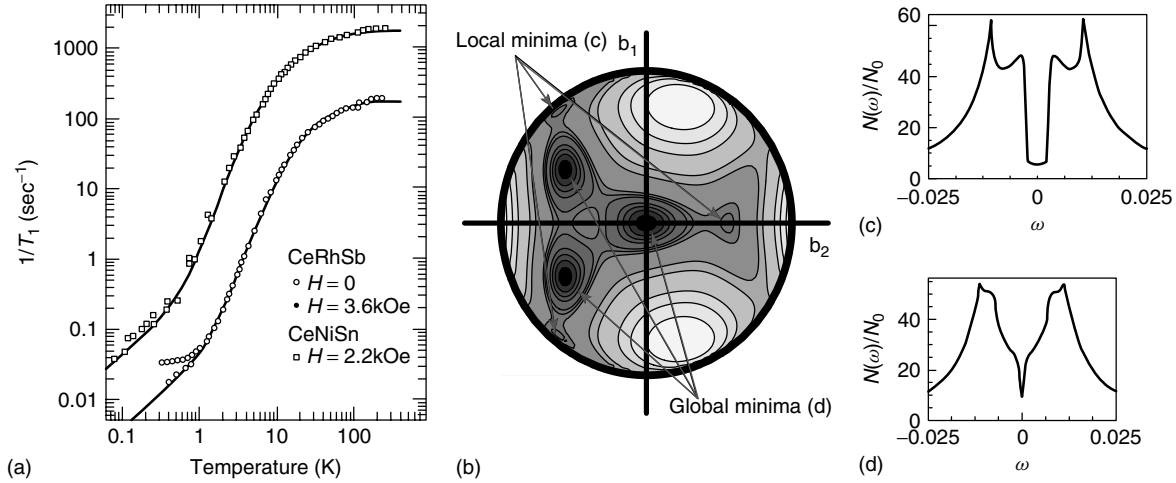

Figure 27. (a) NMR relaxation rate $1/T_1$ in CeRhSb and CeNiSn, showing a T^3 relaxation rate sandwiched between a low- and a high-temperature T-linear Korringa relaxation rate, suggesting a V-shaped density of states. (Reproduced from K. Nakamura, Y. Kitaoka, K. Asayama, T. Takabatake, H. Tanaka, and H. Fujii, *J. Phys. Soc Japan* **63**, 1994, 33, with permission of the Physical Society of Japan.) (b) Contour plot of the ground-state energy in mean-field theory for the narrow gap Kondo insulators, as a function of the two first components of the unit vector $\hat{b}$ (the third one is taken as positive). The darkest regions correspond to lowest values of the free energy. Arrows point to the three global and three local minima that correspond to nodal Kondo insulators. (Reproduced from J. Moreno and P. Coleman, *Phys. Rev. Lett.* **84**, 2000, 342, copyright © 2000 by the American Physical Society, with permission of the APS.) (c) Density of states of Ikeda and Miyake (1996) state that appears as the global minimum of the Kinetic energy. (Reproduced from H. Ikeda, and K. Miyake *J. Phys. Soc. Jpn.* **65**, 1996, 1769, with permission of the Physical Society of Japan.) (d) Density of states of the MC state (Moreno and Coleman, 2000) that appears as a local minimum of the Kinetic energy, with more pronounced 'V'-shaped density of states.

odd thing about this proposal is that CeNiSn and CeRhSb are monoclinic structures, and the low-lying Kramers doublet of the f state can be any combination of the $|\pm\frac{1}{2}\rangle$, $|\pm\frac{3}{2}\rangle$, or $|\pm\frac{5}{2}\rangle$ states:

$$|\pm = b_1|\pm 1/2\rangle + b_2|\pm 5/2\rangle + b_3|\mp 3/2\rangle \qquad (129)$$

where $\hat{b} = (b_1, b_2, b_3)$ could, in principle, point anywhere on the unit sphere, depending on details of the monoclinic crystal field. The Ikeda Miyake model corresponds to three symmetry-related points in the space of crystal-field ground states,

$$\hat{b} = \begin{cases} (\mp\frac{\sqrt{2}}{4}, -\frac{\sqrt{5}}{4}, \frac{3}{4}) \\ (0, 0, 1) \end{cases} \qquad (130)$$

where a node develops along the x, y, or z axis, respectively. But the nodal crystal-field states are isolated 'points' amidst a continuum of fully gapped crystal-field states. Equally strangely, neutron scattering results show no crystal-field satellites in the dynamical spin susceptibility of CeNiSn, suggesting that the crystal electric fields are quenched (Alekseev *et al*., 1994), and that the nodal physics is a many-body effect (Kagan, Kikoin and Prokof'ev, 1993; Moreno and Coleman, 2000). One idea is that Hund's interactions provide the driving force for this selection mechanism. Zwicknagl, Yaresko and Fulde (2002) have suggested that Hund's couplings select the orbitals in multi f electron heavy-electron metals such as UPt_3. Moreno and Coleman (2000) propose a similar idea in which virtual valence fluctuations into the f^2 state generate a many-body or a Weiss effective field that couples to the orbital degrees of freedom, producing an effective *crystal* field that adjusts itself in order to minimize the kinetic energy of the f electrons. This hypothesis is consistent with the observation that the Ikeda Miyake state corresponds to the Kondo-insulating state with the lowest kinetic energy, providing a rational for the selection of the nodal configurations. Moreno and Coleman also found another nodal state with a more marked V-shaped density of states that may fit the observed properties more precisely. This state is also a local minimum of the electron Kinetic energy. These ideas are still in their infancy, and more work needs to be done to examine the controversial idea of a Weiss crystal field, both in the insulators and in the metals.

4 HEAVY-FERMION SUPERCONDUCTIVITY

4.1 A quick tour

Since the discovery (Steglich *et al*., 1976) of superconductivity in $CeCu_2Si_2$, the list of known HFSCs has grown to

include more than a dozen (Sigrist and Ueda, 1991b) materials with a great diversity of properties (Sigrist and Ueda, 1991a; Cox and Maple, 1995). In each of these materials, the jump in the specific heat capacity at the superconducting phase transition is comparable with the normal state specific heat

$$\frac{(C_v^s - C_v^n)}{C_V} \sim 1 - 2 \tag{131}$$

and the integrated entropy beneath the C_v/T curve of the superconductor matches well with the corresponding area for the normal phase obtained when superconductivity is suppressed by disorder or fields

$$\int_0^{T_c} \mathrm{d}T \frac{(C_v^s - C_v^n)}{T} = 0 \tag{132}$$

Since the normal state entropy is derived from the f moments, it follows that these same degrees of freedom are involved in the development of the superconucting state. With the exception of a few anomalous cases, (UBe_{13}, $PuCoGa_5$, and $CeCoIn_5$), heavy-fermion superconductivity develops out of the coherent, paramagnetic heavy Fermi liquid, so heavy fermion superconductivity can be said to involve the pairing of heavy f electrons.

Independent confirmation of the 'heavy' nature of the pairing electrons comes from observed size of the London penetration depth λ_{L} and superconducting coherence length ξ in these systems, both of which reflect the enhanced effective mass. The large mass renormalization enhances the penetration depth, whilst severely contracting the coherence length, making these extreme type-II superconductors. The London penetration depth of HFSCs agree well with the value expected on the assumption that only spectral weight in the quasiparticle Drude peak condenses to form a superconductor by

$$\frac{1}{\mu_o \lambda_{\mathrm{L}}^2} = \frac{ne^2}{m^*} = \int_{\omega \in \mathrm{D.}P} \frac{\mathrm{d}\omega}{\pi} \sigma(\omega) \ll \frac{ne^2}{m} \tag{133}$$

London penetration depths in these compounds are a factor of 20–30 times *longer* (Broholm *et al*., 1990) than in superconductors, reflecting the large enhancement in effective mass. By contrast, the coherence lengths $\xi \sim v_{\mathrm{F}}/\Delta \sim hk_{\mathrm{F}}/(m^*\Delta)$ are severely contracted in a HFSC. The orbitally limited upper critical field is determined by the condition that an area ξ^2 contains a flux quantum $\xi^2 B_c \sim \frac{h}{2e}$. In UBe_{13}, a superconductor with 0.9 K transition temperature, the upper critical field is about 11 T, a value about 20 times larger than a conventional superconductor of the same transition temperature.

Table 2 shows a selected list of HFSCs. 'Canonical' HFSCs, such as $CeCu_2Si_2$ and UPt_3, develop superconductivity out of a paramagnetic Landau–Fermi liquid. 'Preordered' superconductors, such as UPt_2Al_3 (Geibel *et al*., 1991a,b), $CePt_3Si$, and URu_2Si_2, develop another kind of order before going superconducting at a lower temperature. In the case of URu_2Si_2, the nature of the upper ordering transition is still unidentified, but, in the other examples, the upper transition involves the development of antiferromagnetism. 'Quantum critical' superconductors, including $CeIn_3$ and $CeCu_2(Si_{1-x}Ge_x)_2$, develop superconductivity when pressure is tuned close to a QCP. $CeIn_3$ develops superconductivity at the pressure-tuned antiferromagnetic quantum critical point at 2.5 GPa (25 kbar). $CeCu_2$ $(Si,Ge)_2$ has two islands, one associated with antiferromagnetism at low pressure and a second at still higher pressure, thought to be associated with critical valence fluctuations (Yuan *et al*., 2006).

'Strange' superconductors, which include UBe_{13}, the 115 material $CeCoIn_5$, and $PuCoGa_5$, condense into the superconducting state out of an incoherent or strange metallic state. UBe_{13} has a resistance of the order 150 μΩcm at its transition temperature. $CeCoIn_5$ bears superficial resemblance to a high-temperature superconductor, with a linear temperature resistance in its normal state, while its cousin, $PuCoGa_5$ transitions directly from a Curie paramagnet of unquenched f spins into an anisotropically paired, singlet superconductor. These particular materials severely challenge our theoretical understanding, for the heavy-electron quasiparticles appear to form as part of the condensation process, and we are forced to address how the f-spin degrees of freedom incorporate into the superconducting parameter.

4.2 Phenomenology

The main body of theoretical work on heavy-electron systems is driven by experiment, and focuses directly on the phenomenology of the superconducting state. For these purposes, it is generally sufficient to assume a Fermi liquid of preformed mobile heavy electrons, an electronic analog of superfluid Helium-3, in which the quasiparticles interact through a phenomenological BCS model. For most purposes, the Landau–Ginzburg theory is sufficient. I regret that, in this short review, I do not have time to properly represent and discuss the great wealth of fascinating phenomenology, the wealth of multiple phases, and the detailed models that have been developed to describe them. I refer the interested reader to reviews on this subject. (Sigrist and Ueda, 1991a).

On theoretical grounds, the strong Coulomb interactions of the f electrons that lead to moment formation in heavy-fermion compounds are expected to heavily suppress the formation of conventional s-wave pairs in these systems. A large body of evidence favors the idea that the gap function and the anomalous Green function between paired heavy electrons $F_{\alpha\beta}(x) = \langle c_\alpha^\dagger(x) c_\beta^\dagger(0) \rangle$ is spatially

Table 2. Selected HFSCs.

Type	Material	T_c (K)	Knight shift (singlet)	Remarks	Gap symmetry	References
Canonical	$CeCu_2Si_2$	0.7	Singlet	First HFSC	Line nodes	Steglich *et al*. (1976)
	UPt_3	0.48	?	Double transition to T-violating state	Line and point nodes	Stewart, Fisk, Willis and Smith (1984b)
Preordered	UPd_2Al_3	2	Singlet	Néel AFM $T_N = 14\,K$	Line nodes $\Delta \sim \cos 2\chi$	Geibel *et al*. (1991a), Sato *et al*. (2001) and Tou *et al*. (1995)
	URu_2Si_2	1.3	Singlet	Hidden order at $T_0 = 17.5\,K$	Line nodes	Palstra *et al*. (1985) and Kim *et al*. (2003)
	$CePt_3Si$	0.8	Singlet and Triplet	Parity-violating crystal. $T_N = 3.7\,K$	Line nodes	Bauer *et al*. (2004)
Quantum critical	$CeIn_3$	0.2 (2.5 GPa)	Singlet	First quantum critical HFSC	Line nodes	Mathur *et al*. (1998)
	$CeCu_2\ (Si_{1-x}Ge_x)_2$	0.4 (P = 0) 0.95 (5.4 GPa)	Singlet	Two islands of SC as function of pressure	Line nodes	Yuan *et al*. (2006)
Quadrupolar	$PrOs_4Sb_{12}$	1.85	Singlet	Quadrupolar fluctuations	Point nodes	Isawa *et al*. (2003)
Strange	$CeCoIn_5$	2.3	Singlet	Quasi-2D $\rho_n \sim T$	Line nodes $d_{x^2-y^2}$	Petrovic *et al*. (2001)
	UBe_{13}	0.86	?	Incoherent metal at T_c	Line nodes	Andres, Graebner and Ott (1975)
	$PuCoGa_5$	18.5	Singlet	Direct transition Curie metal → HFSC	Line nodes	Sarrao *et al*. (2002)

anisotropic, forming either p-wave triplet or d-wave singlet pairs.

In BCS theory, the superconducting quasiparticle excitations are determined by a one-particle Hamiltonian of the form

$$H = \sum_{\mathbf{k},\sigma} \epsilon_{\mathbf{k}} f^{\dagger}_{\mathbf{k}\alpha} f_{\mathbf{k}\alpha} + \sum_{\mathbf{k}} [f^{\dagger}_{\mathbf{k}\alpha} \Delta_{\alpha\beta}(\mathbf{k}) f^{\dagger}_{-\mathbf{k}\beta} + f_{-\mathbf{k}\beta} \overline{\Delta}_{\beta\alpha}(\mathbf{k}) f_{\mathbf{k}\alpha}] \tag{134}$$

where

$$\Delta_{\alpha\beta}(\mathbf{k}) = \begin{cases} \Delta(\mathbf{k})(i\sigma_2)_{\alpha\beta} & \text{(singlet)} \\ \vec{d}(\mathbf{k}) \cdot (i\sigma_2 \vec{\sigma})_{\alpha\beta} & \text{(triplet)} \end{cases} \tag{135}$$

For singlet pairing, $\Delta(\mathbf{k})$ is an even parity function of $\mathbf{k}$, while for triplet pairing, $\vec{d}(\mathbf{k})$ is a an odd-parity function of $\mathbf{k}$ with three components.

The excitation spectrum of an anisotropically paired singlet superconductor is given by

$$E_{\mathbf{k}} = \sqrt{\epsilon^2_{\mathbf{k}} + |\Delta_{\mathbf{k}}|^2} \tag{136}$$

This expression can also be used for a triplet superconductor that does not break the time-reversal symmetry by making the replacement $|\Delta_{\mathbf{k}}|^2 \equiv \vec{d}^{\dagger}(\mathbf{k}) \cdot \vec{d}(\mathbf{k})$.

Heavy-electron superconductors are anisotropic superconductors, in which the gap function vanishes at points, or, more typically, along lines on the Fermi surface. Unlike s-wave superconductors, magnetic and nonmagnetic impurities are equally effective at pair breaking and suppressing T_c in these materials. A node in the gap is the result of sign changes in the underlying gap function. If the gap function vanishes along surfaces in momentum space, the intersection of these surfaces with the Fermi surface produces 'line nodes' of gapless quasiparticle excitations. As an example, consider UPt_3, where, according to one set of models (Blount, Varma and Aeppli, 1990; Joynt, 1988; Puttika and Joynt, 1988; Hess, Tokuyasu and Sauls, 1990; Machida and Ozaki, 1989), pairing involves a complex d-wave gap

$$\Delta_{\mathbf{k}} \propto k_z(\hat{k}_x \pm i k_y), \qquad |\Delta_{\mathbf{k}}|^2 \propto k_z^2(k_x^2 + k_y^2) \tag{137}$$

Here $\Delta_{\mathbf{k}}$ vanishes along the basal plane $k_z = 0$, producing a line of nodes around the equator of the Fermi surface, and along the z axis, producing a point node at the poles of the Fermi surface.

One of the defining properties of line nodes on the Fermi surface is a quasiparticle density of states that vanishes linearly with energy

$$N^*(E) = 2\sum_{\mathbf{k}} \delta(E - E_{\mathbf{k}}) \propto E \tag{138}$$

The quasiparticles surrounding the line node have a 'relativistic' energy spectrum. In a plane perpendicular to the node, $E_{\mathbf{k}} \sim \sqrt{(v_F k_1)^2 + (\alpha k_2)^2}$, where $\alpha = \mathrm{d}\Delta/\mathrm{d}k_2$ is the gradient of the gap function and k_1 and k_2 the momentum measured in the plane perpendicular to the line node. For a two-dimensional relativistic particle with dispersion $E = ck$, the density of states is given by $N(E) = \frac{|E|}{4\pi c^2}$. For the anisotropic case, we need to replace c by the geometric mean of v_F and α, so $c^2 \to v_F\alpha$. This result must then be doubled to take account of the spin degeneracy and averaged over each line node:

$$N(E) = 2\sum_{\text{nodes}} \int \frac{\mathrm{d}k_\parallel}{2\pi} \frac{|E|}{4\pi v_F \alpha} = |E| \times \sum_{\text{nodes}} \left(\int \frac{\mathrm{d}k_\parallel}{4\pi^2 v_F \alpha} \right) \tag{139}$$

In the presence of pair-breaking impurities and in a vortex state, the quasiparticle nodes are smeared, adding a small constant component to the density of states at low energies.

This linear density of states is manifested in a variety of power laws in the temperature dependence of experimental properties, most notably

- Quadratic temperature dependence of specific heat $C_V \propto T^2$, since the specific heat coefficient is proportional to the thermal average of the density of states

$$\frac{C_V}{T} \propto \overbrace{\overline{N(E)}}^{\propto T} \sim T \tag{140}$$

  where $\overline{N(E)}$ denotes the thermal average of $N(E)$.
- A ubiquitous T^3 temperature dependence in the nuclear magnetic relaxation (NMR) and nuclear quadrupole relaxation (NQR) rates $1/T_1$. The nuclear relaxation rate is proportional to the thermal average of the squared density of states, so, for a superconductor with line nodes,

$$\frac{1}{T_1} \propto T \overbrace{\overline{N(E)^2}}^{\propto T^2} \sim T^3 \tag{141}$$

  Figure 28 shows the T^3 NMR relaxation rate of the Aluminum nucleus in UPd_2Al_3.

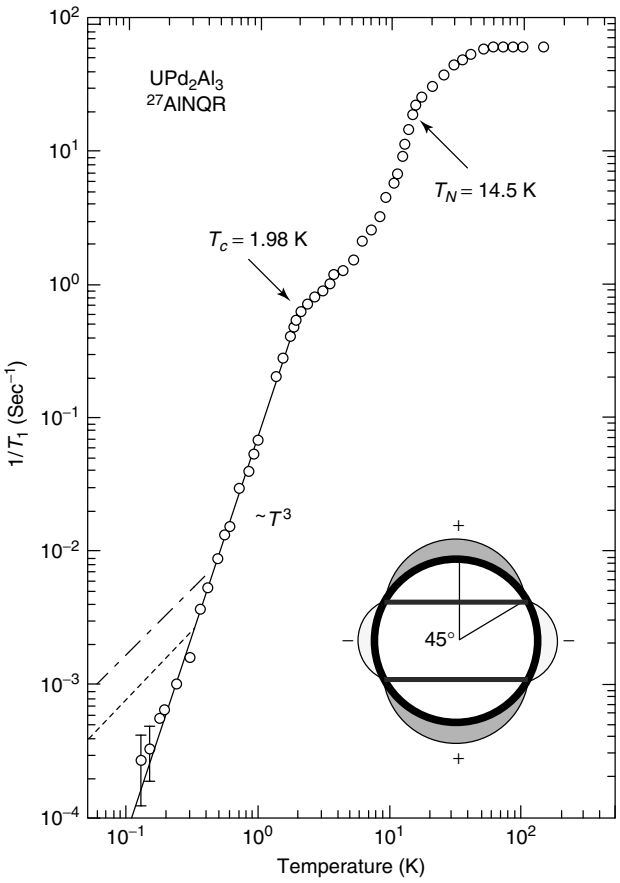

Figure 28. Temperature dependence of the ^{27}Al NQR relaxation rate $1/T_1$ for UPd_2Al_3 (after Tou *et al*., 1995) showing T^3 dependence associated with lines of nodes. Inset showing nodal structure $\Delta \propto \cos(2\theta)$ proposed from analysis of anisotropy of thermal conductivity in Won *et al*. (2004). (Reproduced from H. Tou, Y. Kitaoka, K. Asayama, C. Geibel, C. Schank, and F. Steglich, 1995, *J. Phys. Soc. Japan* **64**, 1995 725, with permission of the Physical Society of Japan.)

Although power laws can distinguish line and point nodes, they do not provide any detailed information about the triplet or singlet character of the order parameter or the location of the nodes. The observation of upper critical fields that are 'Pauli limited' (set by the spin coupling, rather than the diamagnetism), and the observation of a Knight shift in most HFSCs, indicates that they are anisotropically singlet paired. Three notable exceptions to this rule are UPt_3, UBe_{13}, and UNi_2Al_3, which do not display either a Knight shift or a Pauli-limited upper critical field, and are the best candidates for odd-parity triplet pairing. In the special case of $CePt_3Sn$, the crystal structure lacks a center of symmetry and the resulting parity violation must give a mixture of triplet and singlet pairs.

Until comparatively recently, very little was known about the positions of the line nodes in heavy-electron

superconductors. In one exception, experiments carried out almost 20 years ago on UPt_3 observed marked anisotropies in the ultrasound attenuation length and the penetration depth (Bishop *et al*., 1984; Broholm *et al*., 1990) that appear to support a line of nodes in the basal plane. The ultrasonic attenuation $\alpha_s(T)/\alpha_n$ in single crystals of UPt_3 has a T linear dependence when the polarization lies in the basal plane of the gap nodes, but a T^3 dependence when the polarization is along the c axis.

An interesting advance in the experimental analysis of nodal gap structure has recently occurred, owing to new insights into the behavior of the nodal excitation spectrum in the flux phase of HFSCs. In the 1990s, Volovik (1993) observed that the energy of heavy-electron quasiparticles in a flux lattice is 'Doppler shifted' by the superflow around the vortices, giving rise to a finite density of quasiparticle states around the gap nodes. The Doppler shift in the quasiparticle energy resulting from superflow is given by

$$E_{\mathbf{k}} \rightarrow E_{\mathbf{k}} + \vec{p} \cdot \vec{v}_s = E_{\mathbf{k}} + \vec{v}_F \cdot \frac{\hbar}{2}\vec{\nabla}\phi \tag{142}$$

where $\vec{v}_s$ is the superfluid velocity and ϕ the superfluid phase. This has the effect of shifting quasiparticle states by an energy of the order $\Delta E \sim \hbar\frac{v_F}{2R}$, where R is the average distance between vortices in the flux lattice. Writing $\pi H R^2 \sim \Phi_0$, and $\pi H_{c2}\xi^2 \sim \Phi_0$ where $\Phi_0 = \frac{h}{2e}$ is the flux quantum, H_{c2} is the upper critical field, and ξ is the coherence length, it follows that $\frac{1}{R} \sim \frac{1}{\xi}\sqrt{\frac{H}{H_{c2}}}$. Putting $\xi \sim v_F/\Delta$, where Δ is the typical size of the gap, the typical shift in the energy of nodal quasiparticles is of the order $E_H \sim \Delta\sqrt{\frac{H}{H_{c2}}}$. Now since the density of states is of the order $N(E) = \frac{|E|}{\Delta}N(0)$, where $N(0)$ is the density of states in the normal phase, it follows that the smearing of the nodal quasiparticle energies will produce a density of states of the order

$$N^*(H) \sim N(0)\sqrt{\frac{H}{H_{c2}}} \tag{143}$$

This effect, the 'Volovik effect', produces a linear component to the specific heat $C_V/T \propto \sqrt{\frac{H}{H_{c2}}}$. This enhancement of the density of states is largest when the group velocity $\vec{V}_F$ at the node is perpendicular to the applied field $\vec{H}$, and when the field is parallel to $\vec{v}_F$ at a particular node, the node is unaffected by the vortex lattice (Figure 29). This

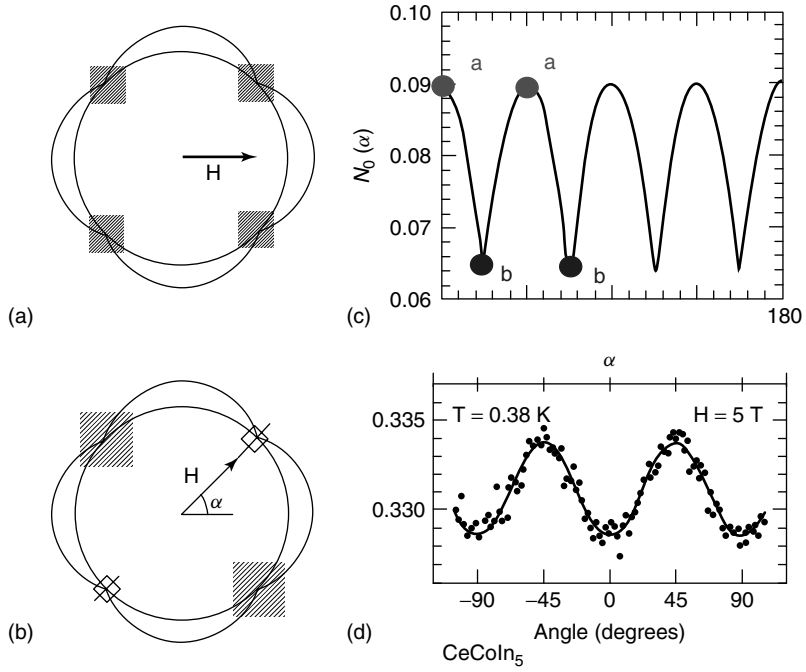

Figure 29. Schematic showing how the nodal quasiparticle density of states depends on field orientation (after Vekhter, Hirschfield, Carbotte and Nicol, 1999). (a) Four nodes are activated when the field points toward an antinode, creating a maximum in density of states. (b) Two nodes activated when the field points toward a node, creating a minimum in the density of states. (c) Theoretical dependence of density of states on angle. (After Vekhter, Hirschfield, Carbotte and Nicol, 1999.) (d) Measured angular dependence of C_v/T (after Aoki *et al*., 2004) is 45° out of phase with prediction. This discrepancy is believed to be due to vortex scattering, and is expected to vanish at lower fields. (Reproduced from I. Vekhter, P. Hirschfield, J.P. Carbotte, and E.J. Nicol, *Phys. Rev. B* **59**, 1998, R9023, copyright © 1998 by the American Physical Society, with permission of the APS.)

gives rise to an angular dependence in the specific heat coefficient and thermodynamics that can be used to measure the gap anisotropy. In practice, the situation is complicated at higher fields where the Andreev scattering of quasiparticles by vortices becomes important. The case of $CeCoIn_5$ is of particular current interest. Analyses of the field-anisotropy of the thermal conductivity in this material was interpreted early on in terms of a gap structure with $d_{x^2-y^2}$, while the anisotropy in the specific heat appears to suggest a d_{xy} symmetry. Recent theoretical work by Vorontsov and Vekhter (2006) suggests that the discrepancy between the two interpretations can be resolved by taking into account the effects of the vortex quasiparticle scattering that were ignored in the specific heat interpretation. They predict that, at lower fields, where vortex scattering effects are weaker, the sign of the anisotropic term in the specific heat reverses, accounting for the discrepancy

It is clear that, despite the teething problems in the interpretation of field-anisotropies in transport and thermodynamics, this is an important emerging tool for the analysis of gap anisotropy, and, to date, it has been used to give tentative assignments to the gap anisotropy of UPd_2Al_3, $CeCoIn_5$, and $PrOs_4Sb_{12}$.

4.3 Microscopic models

4.3.1 Antiferromagnetic fluctuations as a pairing force

The classic theoretical models for heavy-fermion superconductivity treat the heavy-electron fluids as a Fermi liquid with antiferromagnetic interactions amongst their quasiparticles (Monod, Bourbonnais and Emery, 1986; Scalapino, Loh and Hirsch, 1986; Monthoux and Lonzarich, 1999). UPt_3 provided the experimental inspiration for early theories of heavy-fermion superconductivity, for its superconducting state forms from within a well-developed Fermi liquid. Neutron scattering on this material shows signs of antiferromagnetic spin fluctuations (Aeppli *et al*., 1987), making it natural to presuppose that these might be the driving force for heavy-electron pairing.

Since the early 1970s, theoretical models had predicted that strong ferromagnetic spin fluctuations, often called *paramagnons*, could induce p-wave pairing, and this mechanism was widely held to be the driving force for pairing in superfluid He–3. An early proposal that antiferromagnetic interactions could provide the driving force for anisotropic singlet pairing was made by Hirsch (1985). Shortly thereafter, three seminal papers, by Monod, Bourbonnais and Emery (1986) (BBE), Scalapino, Loh and Hirsch (1986) (SLH) and by Miyake, Miyake, Rink and Varma (1986) (MSV), solidified this idea with a concrete demonstration that antiferromagnetic interactions drive an attractive BCS interaction in the d-wave pairing channel. It is a fascinating thought that at the same time that this set of authors was forging the foundations of our current thoughts on the link between antiferromagnetism and d-wave superconductivity, Bednorz and Mueller were in the process of discovering high-temperature superconductivity.

The BBE and SLH papers develop a paramagnon theory for d-wave pairing in a Hubbard model with a contact interaction I, having in mind a system, which in the modern context, would be said to be close to an antiferromagnetic QCP. The MSV paper starts with a model with a preexisting antiferromagnetic interaction, which, in the modern context, would be associated with the 't–J' model. It is this approach that I sketch here. The MSV model is written

$$H = \sum \epsilon_{\mathbf{k}} a^{\dagger}_{\mathbf{k}\sigma} a_{\mathbf{k}\sigma} + H_{\rm int} \tag{144}$$

where

$$H_{\rm int} = \frac{1}{2} \sum_{\mathbf{k},\mathbf{k}'} \sum_{\mathbf{q}} J(\mathbf{k}-\mathbf{k}') \vec{\sigma}_{\alpha\beta} \cdot \vec{\sigma}_{\gamma\delta} \times \left(a^{\dagger}_{\mathbf{k}+\mathbf{q}/2\alpha} a^{\dagger}_{-\mathbf{k}+\mathbf{q}/2\gamma} \right) \left(a_{-\mathbf{k}'+\mathbf{q}/2\delta} a_{\mathbf{k}'+\mathbf{q}/2\beta} \right) \tag{145}$$

describes the antiferromagnetic interactions. There are a number of interesting points to be made here:

- The authors have in mind a strong coupled model, such as the Hubbard model at large U, where the interaction cannot be simply derived from paramagnon theory. In a weak-coupled Hubbard model, a contact interaction I and bare susceptibility $\chi_0(q)$, the induced magnetic interaction can be calculated in a random phase approximation (RPA) (Miyake, Rink and Varma, 1986) as

$$J(q) = -\frac{I}{2[1 + I\chi_0(q)]} \tag{146}$$

  MSV make the point that the detailed mechanism that links the low-energy antiferromagnetic interactions to the microscopic interactions is poorly described by a weak-coupling theory, and is quite likely to involve other processes, such as the RKKY interaction, and the Kondo effect that lie outside this treatment.
- Unlike phonons, magnetic interactions in heavy-fermion systems cannot generally be regarded as retarded interactions, for they extend up to an energy scale ω_0 that is comparable with the heavy-electron bandwidth T^*. In a classic BCS treatment, the electron energy is restricted to lie within a Debye energy of the Fermi energy. But

here, $\omega_0 \sim T^*$, so all momenta are involved in magnetic interactions, and the interaction can transformed to real space as

$$H = \sum \epsilon_{\mathbf{k}} a^\dagger_{\mathbf{k}\sigma} a_{\mathbf{k}\sigma} + \frac{1}{2}\sum_{i,j} J(\mathbf{R}_i - \mathbf{R}_j)\vec{\sigma}_i \cdot \vec{\sigma}_j \quad (147)$$

where $J(\mathbf{R}) = \sum_{\mathbf{q}} e^{i\mathbf{q}\cdot\mathbf{R}} J(\mathbf{q})$ is the Fourier transform of the interaction and $\vec{\sigma}_i = a^\dagger_{i\alpha}\vec{\sigma}_{\alpha\beta}a_{i\beta}$ is the spin density at site i. Written in real space, the MSV model is seen to be an early predecessor of the t–J model used extensively in the context of high-temperature superconductivity.

To see that antiferromagnetic interactions favor d-wave pairing, one can use the 'let us decouple the interaction' in real space in terms of triplet and singlet pairs. Inserting the identity [3]

$$\vec{\sigma}_{\alpha\beta} \cdot \vec{\sigma}_{\gamma\delta} = -\frac{3}{2}(\sigma_2)_{\alpha\gamma}(\sigma_2)_{\beta\delta} + \frac{1}{2}(\vec{\sigma}\sigma_2)_{\alpha\gamma} \cdot (\sigma_2\vec{\sigma})_{\beta\delta} \quad (148)$$

into equation (147) gives

$$H_{\rm int} = -\frac{1}{4}\sum_{i,j} J_{ij}\left[3\Psi^\dagger_{ij}\Psi_{ij} - \vec{\Psi}^\dagger_{ij}\cdot\vec{\Psi}_{ij}\right] \quad (149)$$

where

$$\begin{aligned}\Psi^\dagger_{ij} &= \left(a^\dagger_{i\alpha}(-i\sigma)_{\alpha\gamma}\ a^\dagger_{j\gamma}\right)\\ \vec{\Psi}^\dagger_{ij} &= \left(a^\dagger_{i\alpha}(-i\vec{\sigma}\sigma_2)_{\alpha\gamma}\ a^\dagger_{j\gamma}\right)\end{aligned} \quad (150)$$

create singlet and triplet pairs with electrons located at sites i and j respectively. In real space, it is thus quite clear that an antiferromagnetic interaction $J_{ij} > 0$ induces attraction in the singlet channel, and repulsion in the triplet channel. Returning to momentum space, substitution of equation (148) into (145) gives

$$H_{\rm int} = -\sum_{\mathbf{k},\mathbf{k}',\mathbf{q}} J(\mathbf{k}-\mathbf{k}')\left[3\Psi^\dagger_{\mathbf{k},\ \mathbf{q}}\Psi_{\mathbf{k}',\ \mathbf{q}} - \vec{\Psi}^\dagger_{\mathbf{k},\ \mathbf{q}}\cdot\vec{\Psi}_{\mathbf{k}',\ \mathbf{q}}\right] \quad (151)$$

where $\Psi^\dagger_{\mathbf{k},\mathbf{q}} = \frac{1}{2}\left(a^\dagger_{\mathbf{k}+\mathbf{q}/2\ \alpha}(-i\sigma_2)_{\alpha\gamma}\ a^\dagger_{-\mathbf{k}-\mathbf{q}/2\ \gamma}\right)$ and $\vec{\Psi}^\dagger_{\mathbf{k},\mathbf{q}} = \frac{1}{2}\left(a^\dagger_{\mathbf{k}+\mathbf{q}/2\ \alpha}(-i\vec{\sigma}\sigma_2)_{\alpha\gamma}\ a^\dagger_{-\mathbf{k}-\mathbf{q}/2\ \gamma}\right)$ create singlet and triplet pairs at momentum $\mathbf{q}$ respectively. Pair condensation is described by the zero momentum component of this interaction, which gives

$$H_{\rm int} = \sum_{\mathbf{k},\mathbf{k}'}\left[V^{(s)}_{\mathbf{k},\mathbf{k}'}\Psi^\dagger_{\mathbf{k}}\Psi_{\mathbf{k}'} + V^{(t)}_{\mathbf{k},\mathbf{k}'}\vec{\Psi}^\dagger_{\mathbf{k}}\cdot\vec{\Psi}_{\mathbf{k}'}\right] \quad (152)$$

where $\Psi^\dagger_{\mathbf{k}} = \frac{1}{2}\left(a^\dagger_{\mathbf{k}\alpha}(-i\sigma_2)_{\alpha\beta}\ a^\dagger_{-\mathbf{k}\beta}\right)$ and $\vec{\Psi}^\dagger_{\mathbf{k},\mathbf{q}} = \frac{1}{2}\left(a^\dagger_{\mathbf{k}\alpha}(-i\vec{\sigma}\sigma_2)_{\alpha\beta}\ a^\dagger_{-\mathbf{k}\beta}\right)$ create Cooper pairs and

$$\begin{aligned}V^{(s)}_{\mathbf{k},\mathbf{k}'} &= -3[J(\mathbf{k}-\mathbf{k}') + J(\mathbf{k}+\mathbf{k}')]/2\\ V^{(t)}_{\mathbf{k},\mathbf{k}'} &= \ [J(\mathbf{k}-\mathbf{k}') - J(\mathbf{k}+\mathbf{k}')]/2\end{aligned} \quad (153)$$

are the BCS pairing potentials in the singlet and triplet channel, respectively. (Notice how the even/odd-parity symmetry of the triplet pairs pulls out the corresponding symmetrization of $J(\mathbf{k}-\mathbf{k}')$.)

For a given choice of $J(\mathbf{q})$, it now becomes possible to decouple the interaction in singlet and triplet channels. For example, on a cubic lattice of side length, if the magnetic interaction has the form

$$J(\mathbf{q}) = 2J(\cos(q_x a) + \cos(q_y a) + \cos(q_z a)) \quad (154)$$

which generates soft antiferromagnetic fluctuations at the staggered $\mathbf{Q}$ vector $\mathbf{Q} = (\pi/a, \pi/a, \pi/a)$, then the pairing interaction can be decoupled into singlet and triplet components,

$$\begin{aligned}V^s_{\mathbf{k},\mathbf{k}'} &= -\frac{3J}{2}\big[s(\mathbf{k})s(\mathbf{k}') + \mathrm{d}_{x^2-y^2}(\mathbf{k})\mathrm{d}_{x^2-y^2}(\mathbf{k}')\\ &\qquad + \mathrm{d}_{2z^2-r^2}(\mathbf{k})\mathrm{d}_{2z^2-r^2}(\mathbf{k}')\big]\\ V^t_{\mathbf{k},\mathbf{k}'} &= \frac{J}{2}\sum_{i=x,y,z} p_i(\mathbf{k})\,p_i(\mathbf{k}')\end{aligned} \quad (155)$$

where

$$\begin{aligned}s(\mathbf{k}) &= \sqrt{\tfrac{2}{3}}(\cos(k_x a)\\ &\quad + \cos(k_y a) + \cos(k_z a)) \qquad \text{(extended s-wave)}\\ \left.\begin{aligned}\mathrm{d}_{x^2-y^2}(\mathbf{k}) &= (\cos(k_x a) - \cos(k_y a)\\ \mathrm{d}_{2z^2-r^2}(\mathbf{k}) &= \tfrac{1}{\sqrt{3}}(\cos(k_x a)\\ &\quad + \cos(k_y a) - 2\cos(k_z a))\end{aligned}\right\} &\text{(d-wave)}\end{aligned} \quad (156)$$

are the gap functions for singlet pairing and

$$p_i(\mathbf{q}) = \sqrt{2}\sin(q_i a), \quad (i = x, y, z), \quad \text{(p-wave)} \quad (157)$$

describe three triplet gap functions. For $J > 0$, this particular BCS model then gives rise to extended s- and d-wave superconductivity with approximately the same transition temperatures, given by the gap equation

$$\sum_{\mathbf{k}} \tanh\left(\frac{\epsilon_{\mathbf{k}}}{2T_c}\right)\frac{1}{\epsilon_{\mathbf{k}}}\begin{Bmatrix} s(\mathbf{k})^2 \\ \mathrm{d}_{x^2-y^2}(\mathbf{k})^2 \end{Bmatrix} = \frac{2}{3J} \quad (158)$$

4.3.2 Toward a unified theory of HFSC

Although the spin-fluctuation approach described provides a good starting point for the phenomenology of heavy-fermion superconductivity (HFSC), it leaves open a wide range of questions that suggest this problem is only partially solved:

- How can we reconcile heavy-fermion superconductivity with the local moment origins of the heavy-electron quasiparticles?
- How can the incompressibility of the heavy-electron fluid be incorporated into the theory? In particular, extended s-wave solutions are expected to produce a large singlet f-pairing amplitude, giving rise to a large Coulomb energy. Interactions are expected to significantly depress, if not totally eliminate such extended s-wave solutions.
- Is there a controlled limit where a model of heavy-electron superconductivity can be solved?
- What about the 'strange' HFSCs UBe_{13}, $CeCoIn_5$, and $PuCoGa_5$, where T_c is comparable with the Kondo temperature? In this case, the superconducting order parameter must involve the f spin as a kind of 'composite' order parameter. What is the nature of this order parameter, and what physics drives T_c so high that the Fermi liquid forms at much the same time as the superconductivity develops?

One idea that may help understand the heavy-fermion pairing mechanism is Anderson's RVB theory (Anderson, 1987) of high-temperature superconductivity. Anderson proposed (Anderson, 1987; Baskaran, Zou and Anderson, 1987; Kotliar, 1988) that the parent state of the high-temperature superconductors is a two-dimensional spin liquid of RVBs between spins, which becomes superconducting upon doping with holes. In the early 1990s, Coleman and Andrei (1989) adapted this theory to a Kondo lattice. Although an RVB spin liquid is unstable with respect to the antiferromagnetic order in three dimensions, in situations close to a magnetic instability, where the energy of the antiferromagnetic state is comparable with the Kondo temperature, $E_{\rm AFM} \sim T_{\rm K}$, conduction electrons partially spin-compensate the spin liquid, stabilizing it against magnetism (Figure 30a). In the Kondo-stabilized spin liquid, the Kondo effect induces some RVBs in the f-spin liquid to escape into the conduction fluid where they pair charged electrons to form a heavy-electron superconductor.

A key observation of the RVB theory is that, when charge fluctuations are removed to form a spin fluid, there is no distinction between particle and hole (Affleck, Zou, Hsu and Anderson, 1988). The mathematical consequence of this is that the the spin-1/2 operator

$$\vec{S}_f = f^\dagger_{i\alpha}\left(\frac{\vec{\sigma}}{2}\right)_{\alpha\beta} f^\dagger_\alpha, \qquad n_f = 1 \tag{159}$$

is not only invariant under a change of phase $f_\sigma \to e^{i\phi} f_\sigma$, but it also possesses a continuous particle-hole symmetry

$$f^\dagger_\sigma \to \cos\theta\, f^\dagger_\sigma + \mathrm{sgn}\sigma \sin\theta\, f_{-\sigma} \tag{160}$$

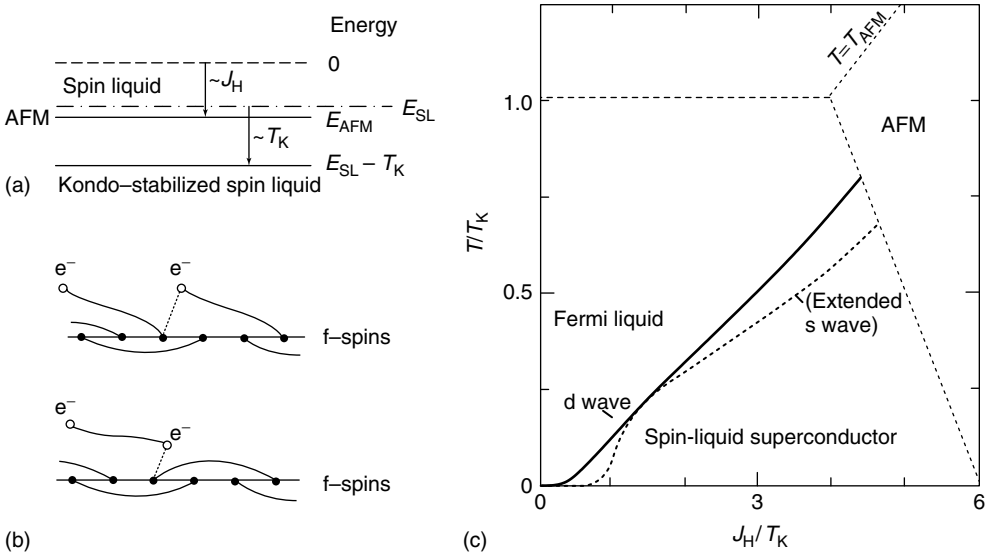

Figure 30. Kondo-stabilized spin liquid, diagram from Coleman and Andrei (1989). (a) Spin liquid stabilized by Kondo effect, (b) Kondo effect causes singlet bonds to form between spin liquid and conduction sea. Escape of these bonds into the conduction sea induces superconductivity. (c) Phase diagram computed using $SU(2)$ mean-field theory of Kondo Heisenberg model. (Reproduced from P. Coleman and N. Andrei, 1989, *J. Phys. Cond. Matt. C* **1** (1989) 4057, with permission of IOP Publishing Ltd.)

These two symmetries combine to create a *local* $SU(2)$ *gauge symmetry*. One of the implications is that the constraint $n_f = 1$ associated with the spin operator is actually part of a triplet of Gutzwiller constraints

$$f^\dagger_{i\uparrow} f_{i\uparrow} - f_{i\downarrow} f^\dagger_{i\downarrow} = 0, \quad f^\dagger_{i\uparrow} f^\dagger_{i\downarrow} = 0, \quad f_{i\downarrow} f_{i\uparrow} = 0 \tag{161}$$

If we introduce the Nambu spinors

$$\tilde{f}_i \equiv \begin{pmatrix} f_{i\uparrow} \\ f^\dagger_{i\downarrow} \end{pmatrix}, \qquad \tilde{f}^\dagger_i = (f^\dagger_{i\uparrow}, f_{i\downarrow}) \tag{162}$$

then this means that all three components of the 'isospin' of the f electrons vanish,

$$\tilde{f}^\dagger_i \vec{\tau} \tilde{f}_i = (f^\dagger_{i\uparrow}, f_{i\downarrow}) \left[\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \right] \times \begin{pmatrix} f_{i\uparrow} \\ f^\dagger_{i\downarrow} \end{pmatrix} = 0 \tag{163}$$

where $\vec{\tau}$ is a triplet of Pauli spin operators that act on the f-Nambu spinors. In other words, in the incompressible f fluid, there can be no *s-wave* singlet pairing.

This symmetry is preserved in spin-1/2 Kondo models. When applied to the Heisenberg Kondo model

$$H = \sum_{\mathbf{k}\sigma} \epsilon_{\mathbf{k}} c^\dagger_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma} + J_H \sum_{(i,j)} \mathbf{S}_i \cdot \mathbf{S}_j + J_K \sum_j c^\dagger_{j\sigma} \vec{\sigma}_{\sigma\sigma'} c_{j\sigma'} \cdot \mathbf{S}_j \tag{164}$$

where $\mathbf{S}_i = f^\dagger_{i\alpha} \left(\frac{\vec{\sigma}}{2}\right)_{\alpha\beta} f_{i\beta}$ represents an f spin at site i, it leads to an $SU(2)$ gauge theory for the Kondo lattice with Hamiltonian

$$H = \sum_{\mathbf{k}} \epsilon_{\mathbf{k}} \tilde{c}^\dagger_{\mathbf{k}} \tau_3 \tilde{c}_{\mathbf{k}} + \sum \vec{\lambda}_j \tilde{f}^\dagger_j \vec{\tau} \tilde{f}_j + \sum_{(i,j)} [\tilde{f}^\dagger_i U_{ij} \tilde{f}_j + \text{H.c}] + \frac{1}{J_\text{H}} \text{Tr}[U^\dagger_{ij} U_{ij}] + \sum_i [\tilde{f}^\dagger_i V_i \tilde{c}_i + \text{H.c}] + \frac{1}{J_\text{K}} \text{Tr}[V^\dagger_i V_i] \tag{165}$$

where λ_j is the Lagrange multiplier that imposes the Gutzwiller constraint $\vec{\tau} = 0$ at each site, $\tilde{c}_k = \begin{pmatrix} c_{k\uparrow} \\ c^\dagger_{-k\downarrow} \end{pmatrix}$ and $\tilde{c}_j = \begin{pmatrix} c_{j\uparrow} \\ c^\dagger_{j\downarrow} \end{pmatrix}$ are Nambu conduction electron spinors in the momentum and position basis, respectively, while

$$U_{ij} = \begin{pmatrix} h_{ij} & \Delta_{ij} \\ \overline{\Delta}_{ij} & -\overline{h}_{ij} \end{pmatrix} \qquad V_i = \begin{pmatrix} V_i & \overline{\alpha}_i \\ \alpha_i & -\overline{V}_i \end{pmatrix} \tag{166}$$

are matrix order parameters associated with the Heisenberg and Kondo decoupling, respectively. This model has the local gauge invariance $\tilde{f}_j \to g_j \tilde{f}_j$, $V_j \to g_j V_j$ $U_{ij} \to g_i U_{ij} g^\dagger_j$, where g_j is an $SU(2)$ matrix. In this kind of model, one can 'gauge fix' the model so that the Kondo effect occurs in the particle-hole channel ($\alpha_i = 0$). When one does so, however, the spin-liquid instability takes place preferentially in an anisotropically paired Cooper channel. Moreover, the constraint on the f electrons not only suppresses singlet s-wave pairing, it also suppresses extended s-wave pairing (Figure 30).

One of the initial difficulties with both the RVB and the Kondo-stabilized spin liquid approaches is that, in its original formulation, it could not be integrated into a large N approach. Recent work indicates that both the fermionic RVB and the Kondo-stabilized spin-liquid picture can be formulated as a controlled $SU(2)$ gauge theory by carrying out a large N expansion using the group $SP(N)$ (Read and Sachdev, 1991), originally introduced by Read and Sachdev for problems in frustrated magnetism, in place of the group $SU(N)$. The local particle-hole symmetry associated with the spin operators in $SU(2)$ is intimately related to the symplectic property of Pauli spin operators

$$\sigma_2 \vec{\sigma}^T \sigma_2 = -\vec{\sigma} \tag{167}$$

where $\vec{\sigma}^T$ is the transpose of the spin operator. This relation, which represents the sign reversal of spin operators under time-reversal, is only satisfied by a subset of the $SU(N)$ spins for $N > 2$. This subset defines the generators of the symplectic subgroup of $SU(N)$, called $SP(N)$.

Concluding this section, I want to briefly mention the challenge posed by the highest T_c superconductor, $PuCoGa_5$ (Sarrao *et al.*, 2002; Curro *et al.*, 2005). This material, discovered some 4 years ago at Los Alamos, undergoes a direct transition from a Curie paramagnet into a heavy-electron superconductor at around $T_c = 19\,\text{K}$ (Figure 31). The Curie paramagnetism is also seen in the Knight shift, which scales with the bulk susceptibility (Curro *et al.*, 2005). The remarkable feature of this material is that the specific heat anomaly has the large size ($110\,\text{mJ}\,\text{mol}^{-1}\,\text{K}^2$ (Sarrao *et al.*, 2002)) characteristic of heavy-fermion superconductivity, yet there are no signs of saturation in the susceptibility as a precursor to superconductivity, suggesting that the heavy quasiparticles do not develop from local moments until the transition. This aspect of the physics cannot be explained by the spin-fluctuation theory (Bang, Balatsky, Wastin and Thompson, 2004), and suggests that the Kondo effect takes place simultaneously with the pairing mechanism. One interesting possibility here is that the development of coherence between the Kondo effect in two different channels created by the different symmetries of the valence fluctuations into the f^6 and f^4 states might be the driver of this intriguing new superconductor (Jarrell, Pang and Cox, 1997; Coleman, Tsvelik, Andrei and Kee, 1999).

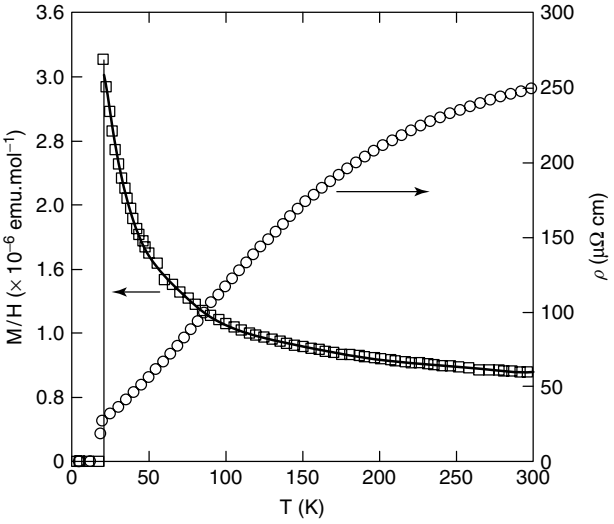

Figure 31. Temperature dependence of the magnetic susceptibility of $PuCoGa_5$. (After Sarrao *et al.*, 2002.) The susceptibility shows a direct transition from Curie–Weiss paramagnet into HFSC, without any intermediate spin quenching. (Reproduced from Sarrao, J.L., L.A. Morales, J.D. Thompson, B.L. Scott, G.R. Stewart, F. Wastlin, J. Rebizant, P. Boulet, E. Colineau, and G.H. Lander, 2002, with permission from Nature Publishing. © 2002.)

5 QUANTUM CRITICALITY

5.1 Singularity in the phase diagram

Many heavy electron systems can be tuned, with pressure, chemical doping, or applied magnetic field, to a point where their antiferromagnetic ordering temperature is driven continuously to zero to produce a 'QCP' (Stewart, 2001, 2006; Coleman, Pépin, Si and Ramazashvili, 2001; Varma, Nussinov and van Saarlos, 2002; von Löhneysen, Rosch, Vojta and Wolfe, 2007; Miranda and Dobrosavljevic, 2005). The remarkable transformation in metallic properties, often referred to as 'non-Fermi liquid behavior', which is induced over a wide range of temperatures above the QCP, together with the marked tendency to develop superconductivity in the vicinity of such 'quantum critical points' has given rise to a resurgence of interest in heavy-fermion materials.

The experimental realization of quantum criticality returns us to central questions left unanswered since the first discovery of heavy-fermion compounds. In particular:

- What is the fate of the Landau quasiparticle when interactions become so large that the ground state is no longer adiabatically connected to a noninteracting system?
- What is the mechanism by which the AFM transforms into the heavy-electron state? Is there a breakdown of the Kondo effect, revealing local moments at the quantum phase transition, or is the transition better regarded as a spin-density wave transition?

Figure 32 illustrates quantum criticality in $YbRh_2Si_2$ (Custers *et al.*, 2003), a material with a 90 mK magnetic transition that can be tuned continuously to zero by a modest magnetic

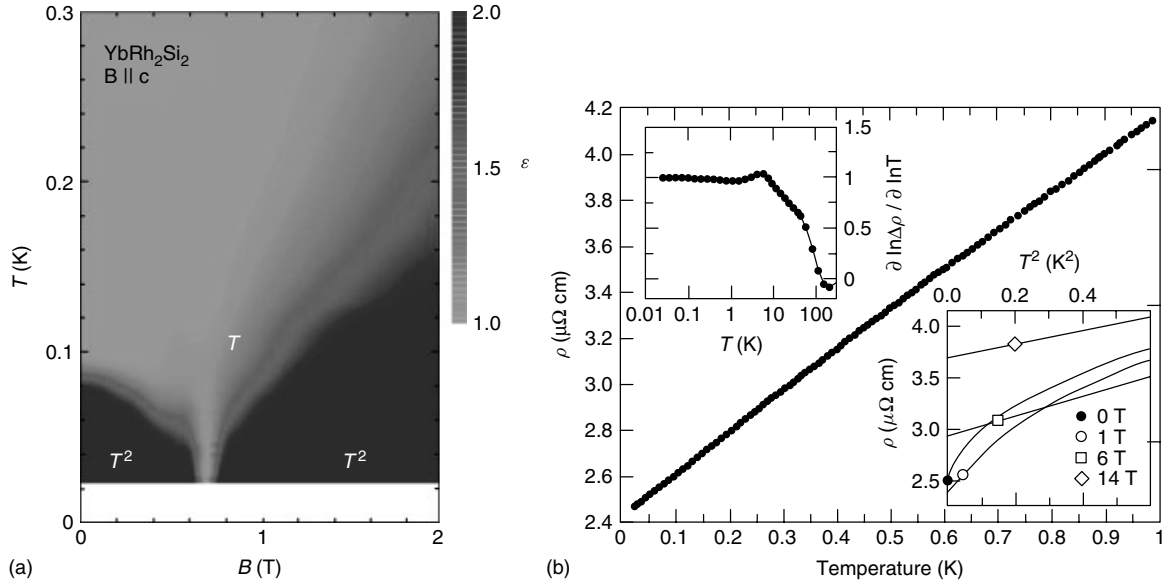

Figure 32. (a) Grayscale plot of the logarithmic derivative of resistivity $d\ln\rho/d\ln T$. (Reproduced from Custers *et al.*, 2003, with permission from Nature Publishing. © 2003.) (b) Resistivity of $YbRh_2Si_2$ in zero magnetic field. Inset shows logarithmic derivative of resistivity. (Reproduced from O. Trovarelli, C. Geibel, S. Mederle, C. Langhammer, F. Grosche, P. Gegenwart, M. Lang, G. Sparn, and F. Steglich, *Phys. Rev. Lett.* **85**, 2000, 626, copyright © 2000 by the American Physical Society, with permission of the APS.)

field. In wedge-shaped regions, either side of the transition, the resistivity displays the T^2 dependence $\rho(T) = \rho_0 + AT^2$ (black) that is the hallmark of Fermi-liquid behavior. Yet, in a tornado shaped region that stretches far above the QCP to about 20 K, the resistivity follows a *linear* dependence over more than three decades. The QCP thus represents a kind of 'singularity' in the material phase diagram.

Experimentally, quantum critical heavy-electron materials fall between two extreme limits that I shall call 'hard' and 'soft' quantum criticality. 'Soft' quantum critical systems are moderately well described in terms quasiparticles interacting with the soft quantum spin fluctuations created by a spin-density wave instability. Theory predicts (Moriya and Kawabata, 1973) that, in a three-dimensional metal, the quantum spin-density wave fluctuations give rise to a weak $\sqrt{T}$ singularity in the low-temperature behavior of the specific heat coefficient

$$\frac{C_V}{T} = \gamma_0 - \gamma_1\sqrt{T} \tag{168}$$

Examples of such behavior include $CeNi_2Ge_2$ (Grosche *et al*., 2000; Küchler *et al*., 2003) chemically doped $Ce_{2-x}La_xRu_2Si_2$ and 'A'-type antiferromagnetic phases of $CeCu_2Si_2$ at a pressure-tuned QCP.

At the other extreme, in 'hard' quantum critical heavy materials, many aspects of the physics appear consistent with a breakdown of the Kondo effect associated with a relocalization of the f electrons into ordered, ordered local moments beyond the QCP. Some of the most heavily studied examples of this behavior occur in the chemically tuned QCP in $CeCu_{6-x}Au_x$ (von Löhneysen *et al*., 1994; von Löhneysen, 1996; Schroeder *et al*., 1998, 2000). and $YbRh_2Si_{2-x}Ge_x$ (Custers *et al*., 2003; Gegenwart *et al*., 2005) and the field-tuned QCP of $YbRh_2Si_2$ (Trovarelli *et al*., 2000) and YbAgGe (Bud'ko, Morosan and Canfield, 2004, 2005; Fak *et al*., 2005; Niklowitz *et al*., 2006). Hallmarks of hard quantum criticality include a logarithmically diverging specific heat coefficient at the QCP,

$$\frac{C_v}{T} \sim \frac{1}{T_0}\ln\left(\frac{T_0}{T}\right) \tag{169}$$

and a quasilinear resistivity

$$\rho(T) \sim T^{1+\eta} \tag{170}$$

where η is in the range 0–0.2. The most impressive results to date have been observed at field-tuned QCPs in $YbRh_2Si_2$ and $CeCoIn_5$, where linear resistivity has been seen to extend over more than two decades of temperature at the field-tuned QCP (Steglich *et al*., 1976; Paglione *et al*., 2003, 2006; Ronning *et al*., 2006). Over the range where linear, where the ratio between the change in the size of the resistivity $\Delta\rho$ to the zero temperature (impurity driven) resistivity ρ_0

$$\Delta\rho/\rho_0 \gg 1 \tag{171}$$

$CeCoIn_5$ is particularly interesting, for, in this case, this resistance ratio exceeds 10^2 for current flow along the c axis (Tanatar, Paglione, Petrovic and Taillefer, 2007). This observation excludes any explanation which attributes the unusual resistivity to an interplay between spin-fluctuation scattering and impurity scattering (Rosch, 1999). Mysteriously, $CeCoIn_5$ also exhibits a $T^{3/2}$ resistivity for resistivity for current flow in the basal plane below about 2 K (Tanatar, Paglione, Petrovic and Taillefer, 2007). Nakasuji, Pines and Fisk (2004) have proposed that this kind of behavior may derive from a *two fluid* character to the underlying conduction fluid.

In quantum critical $YbRh_2Si_{2-x}Ge_x$, the specific heat coefficient develops a $1/T^{1/3}$ divergence at the very lowest temperature. In the approach to a QCP, Fermi liquid behavior is confined to an ever-narrowing range of temperature. Moreover, both the linear coefficient of the specific heat and the the quadratic coefficient A of the resistivity appear to diverge (Estrela *et al*., 2002; Trovarelli *et al*., 2000). Taken together, these results suggests that the Fermi temperature renormalizes to zero and the quasiparticle effective masses diverge

$$T_F^* \to 0 \qquad \frac{m^*}{m} \to \infty \tag{172}$$

at the QCP of these three-dimensional materials. A central property of the Landau quasiparticle is the existence of a finite overlap 'Z', or 'wave function renormalization' between a single quasiparticle state, denoted by $|\mathrm{qp}^-\rangle$ and a bare electron state denoted by $|e^-\rangle = c^\dagger_{\mathbf{k}\sigma}|0\rangle$,

$$Z = |\langle e^-|\mathrm{qp}^-\rangle|^2 \sim \frac{m}{m^*} \tag{173}$$

If the quasiparticle mass diverges, the overlap between the quasiparticle and the electron state from which it is derived is driven to zero, signaling a complete breakdown in the quasiparticle concept at a 'hard' QCP (Varma, Nussinov and van Saarlos, 2002).

Table 3 shows a tabulation of selected quantum critical materials. One interesting variable that exhibits singular behavior at both hard and soft QCPs is the Grüneisen ratio. This quantity, defined as the ratio

$$\Gamma = \frac{\alpha}{C} = -\frac{1}{V}\left.\frac{\partial \ln T}{\partial P}\right|_S \propto \frac{1}{T^\epsilon} \tag{174}$$

Table 3. Selected heavy-fermion compounds with quantum critical points.

	Compound	x_c/H_c	$\frac{C_v}{T}$	$\rho \sim T^a$	$\Gamma(T) = \frac{\alpha}{C_P}$	Other	References
	$CeCu_{6-x}Au_x$	$x_c = 0.1$	$\frac{1}{T_0}\ln\left(\frac{T_0}{T}\right)$	$T + c$	–	$\chi''_{\mathbf{Q}_0}(\omega, T) = \frac{1}{T^{0.7}}F\left[\frac{\omega}{T}\right]$	von Löhneysen *et al*. (1994), von Löhneysen (1996) and Schroeder *et al*. (1998, 2000)

	$CeNi_2Ge_2$	$P_c = 0$	$\gamma_0 - \gamma_1\sqrt{T}$	$T^{1.2-1.5}$	T^{-1}	–	Grosche *et al*. (2000) and Küchler *et al*. (2003)

of the thermal expansion coefficient $\alpha = \frac{1}{V}\frac{\mathrm{d}V}{\mathrm{d}T}$ to the specific heat C, diverges at a QCP. The Grüneisen ratio is a sensitive measure of the rapid acquisition of entropy on warming away from QCP. Theory predicts that $\epsilon = 1$ at a 3D spin density wave critical point, as seen in $CeNi_2Ge_2$. In the 'hard' quantum critical material $YbRh_2Si_{2-x}Ge_x$, $\epsilon = 0.7$ indicates a serious departure from a 3D spin-density wave instability (Küchler *et al*., 2003).

5.2 Quantum versus classical criticality

Figure 33 illustrates some key distinctions between classical and quantum criticality (Sachdev, 2007). Passage through a classical second-order phase transition is achieved by tuning the temperature. Near the transition, the imminent arrival of order is signaled by the growth of droplets of nascent order whose typical size ξ diverges at the critical point. Inside each droplet, fluctuations of the order parameter exhibit a universal power-law dependence on distance

$$\langle \psi(x)\psi(0)\rangle \sim \frac{1}{x^{d-2+\eta}}, \qquad (x \ll \xi) \tag{175}$$

Critical matter 'forgets' about its microscopic origins: Its thermodynamics, scaling laws, and correlation exponents associated with critical matter are so robust and universal that they recur in such diverse contexts as the Curie point of iron or the critical point of water. At a conventional

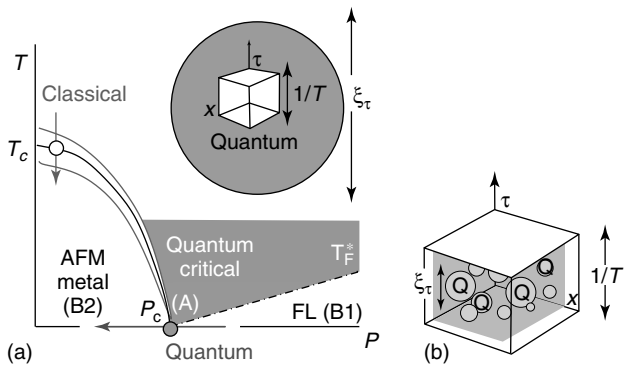

Figure 33. Contrasting classical and quantum criticality in heavy-electron systems. At a QCP, an external parameter P, such as pressure or magnetic field, replaces temperature as the 'tuning parameter'. Temperature assumes the new role of a finite size cutoff $l_\tau \propto 1/T$ on the temporal extent of quantum fluctuations. (a) Quantum critical regime, where $l_\tau < \xi_{\mathrm{tau}}$ probes the interior of the quantum critical matter. (b) Fermi-liquid regime, where $l_\tau > \xi_\tau$, where like soda, bubbles of quantum critical matter fleetingly form within a Fermi liquid that is paramagnetic (B1), or antiferromagnetically ordered (B2).

critical point, order-parameter fluctuations are 'classical', for the characteristic energy of the critical modes $\hbar\omega(q_0)$, evaluated at a wave vector $q_0 \sim \xi^{-1}$, inevitably drops below the thermal energy $\hbar\omega(q_0) \ll k_B T_c$ as $\xi \to \infty$.

In the 1970s, various authors, notably Young (1975) and Hertz (1976), recognized that, if the transition temperature of a continuous phase transition can be depressed to zero, the

critical modes become quantum-mechanical in nature. The partition function for a quantum phase transition is described by a Feynman integral over order-parameter configurations $\{\psi(x,\tau)\}$ in both space *and* imaginary time (Sachdev, 2007; Hertz, 1976)

$$Z_{\text{quantum}} = \sum_{\text{space–time configurations}} \mathrm{e}^{-S[\psi]} \tag{176}$$

where the action

$$S[\psi] = \int_0^{\frac{\hbar}{k_B T}} \mathrm{d}\tau \int_{-\infty}^{\infty} \mathrm{d}^d x L[\psi(x,\tau)] \tag{177}$$

contains an integral of the Lagrangian L over an infinite range in space, but a *finite* time interval

$$l_\tau \equiv \frac{\hbar}{k_{\mathrm{B}} T} \tag{178}$$

Near a QCP, bubbles of quantum critical matter form within a metal, with finite size ξ_x and duration ξ_τ (Figure 33). These two quantities diverge as the quantum critical point is approached, but the rates of divergence are related by a dynamical critical exponent (Hertz, 1976),

$$\xi_\tau \sim (\xi_x)^z \tag{179}$$

One of the consequences of this scaling behavior is that time counts as z spatial dimensions, $[\tau] = [L^z]$ in general.

At a classical critical point, temperature is a tuning parameter that takes one through the transition. The role of temperature is fundamentally different at a quantum critical point: it sets the scale $l_\tau \sim 1/T$ in the time direction, introducing a *finite size correction* to the QCP. When the temperature is raised, l_τ reduces and the quantum fluctuations are probed on shorter and shorter timescales. There are then two regimes to the phase diagram,

$$\text{(a)} \qquad \text{Quantum critical:} \qquad l_\tau \ll \xi_\tau \tag{180}$$

where the physics probes the 'interior' of the quantum critical bubbles, and

$$\text{(b)} \qquad \text{Fermi liquid/AFM} \qquad l_\tau \gg \xi_\tau \tag{181}$$

where the physics probes the quantum fluid 'outside' the quantum critical bubbles. The quantum fluid that forms in this region is a sort of 'quantum soda', containing short-lived bubbles of quantum critical matter surrounded by a paramagnetic (B1) or antiferromagnetically ordered (B2) Landau–Fermi liquid. Unlike a classical phase transition, in which the critical fluctuations are confined to a narrow region either side of the transition, in a quantum critical region (a), fluctuations persist up to temperatures where l_τ becomes comparable the with the microscopic short-time cutoff in the problem (Kopp and Chakravarty, 2005) (which for heavy-electron systems is most likely, the single-ion Kondo temperature $l_\tau \sim \hbar/T_{\mathrm{K}}$).

5.3 Signs of a new universality

The discovery of quantum criticality in heavy-electron systems raises an alluring possibility of *quantum critical matter*, a universal state of matter that, like its classical counterpart, forgets its microscopic, chemical, and electronic origins. There are three pieces of evidence that are particularly fascinating in this respect:

1. Scale invariance, as characterized by E/T scaling in the quantum-critical inelastic spin fluctuations observed in $CeCu_{1-x}Au_x$ (Schroeder *et al.*, 1998, 2000). ($x = x_c = 0.016$),

$$\chi''_{\mathbf{Q}_0}(E,T) = \frac{1}{T^a} F(E/T) \tag{182}$$

   where $a \approx 0.75$ and $F[x] \propto (1 - ix)^{-a}$. Similar behavior has also been seen in powder samples of $UCu_{5-x}Pd_x$ (Aronson *et al.*, 1995).
2. A jump in the Hall constant of $YbRh_2Si_2$ when field tuned through its QCP (Paschen *et al.*, 2004). (see Figure 34a).
3. A sudden change in the area of the extremal Fermi surface orbits observed by de Haas van Alphen at a pressure-tuned QCP in $CeRhin_5$ (Shishido, Settai, Harima and Onuki, 2005). (see Figure 34b).

Features 2 and 3 suggest that the Fermi surface jumps from a 'small' to 'large' Fermi surface as the magnetic order is lost, as if the phase shift associated with the Kondo effect collapses to zero at the critical point, as if the f component of the electron fluid Mott-localizes at the transition. To reconcile a sudden change in the Fermi surface with a second-order phase transition, we are actually forced to infer that the quasiparticle weights vanish at the QCP.

These features are quite incompatible with a spin-density wave QCP. In a spin-density wave scenario, the Fermi surface and Hall constant are expected to evolve continuously through a QCP. Moreover, in an SDW description, the dynamical critical exponent is $z = 2$ so time counts as $z = 2$ dimensions in the scaling theory, and the effective dimensionality $D_{\text{eff}} = d + 2 > 4$ lies above the upper critical dimension, where mean-field theory is applicable and scale-invariant behavior is no longer expected.

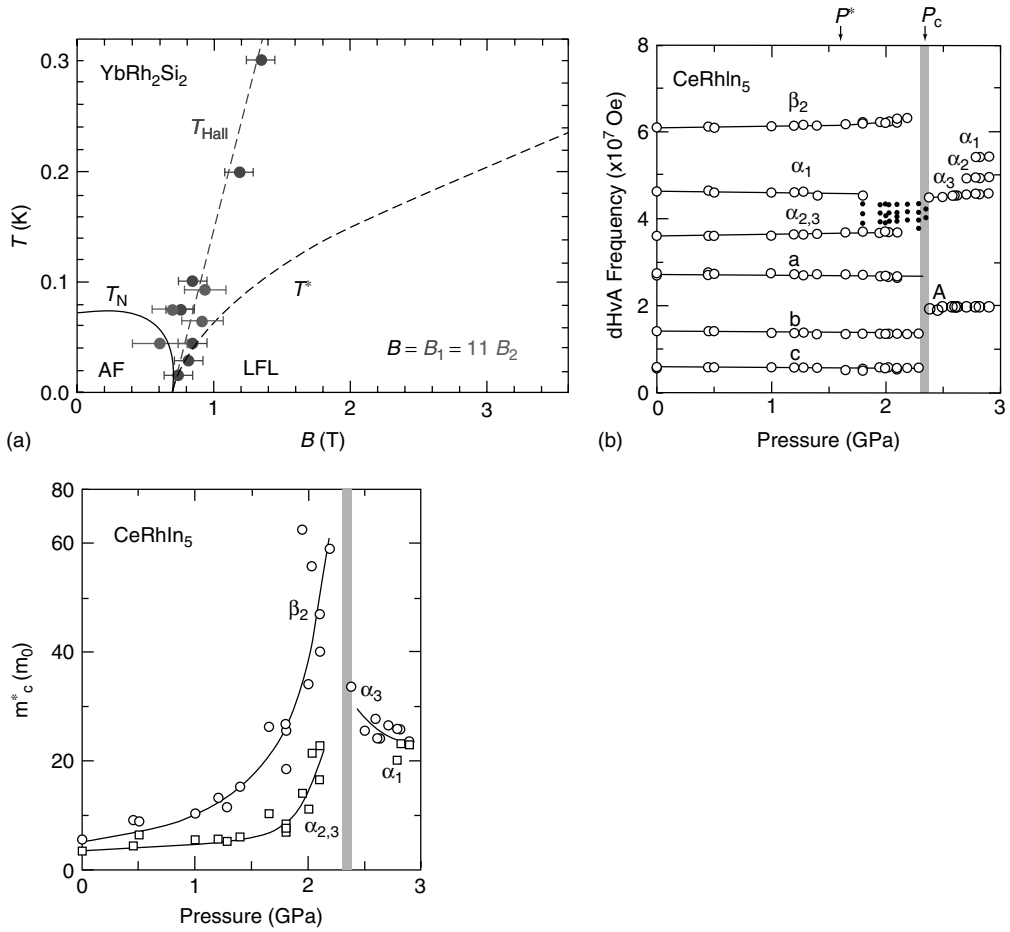

Figure 34. (a) Hall crossover line for sudden evolution of Hall constant in $YbRh_2Si_2$. (Reproduced from Paschen, S., T. Lühmann, S. Wirth, P. Gegenwart, O. Trovarelli, C. Geibel, F. Steglich, P. Coleman, and Q. Si, 2004, *Nature* **432**, 881.) (b) Sudden change in dHvA frequencies and divergence of quasiparticle effective masses at pressure-tuned, finite field QCP in $CeRhIn_5$. (Reproduced from H. Shishido, R. Settai, H. Harima, and Y. Onuki, *Journal of the Physical Society of Japan* **74**, 2005, 1103 weith permission of the Physical Society of Japan.)

These observations have ignited a ferment of theoretical interest in the nature of heavy-fermion criticality. We conclude with a brief discussion of some of the competing ideas currently under consideration.

5.3.1 Local quantum criticality

One of the intriguing observations (Schroeder *et al*., 1998) in $CeCu_{6-x}Au_x$ is that the uniform magnetic susceptibility, $\chi^{-1} \sim T^a + C$, $a = 0.75$ displays the same power-law dependence on temperature observed in the inelastic neutron scattering at the critical wave vector $\mathbf{Q}_0$. A more detailed set of measurements by Schroeder *et al*. (2000) revealed that the scale-invariant component of the dynamical spin susceptibility appears to be momentum independent,

$$\chi^{-1}(\mathbf{q}, E) = T^a[\Phi(E/T)] + \chi_0^{-1}(\mathbf{q}) \tag{183}$$

This behavior suggests that the critical behavior associated with the heavy-fermion QCP contains some kind of *local* critical excitation (Schroeder *et al*., 1998; Coleman, 1999).

One possibility is that this local critical excitation is the spin itself, so that (Coleman, 1999; Sachdev and Ye, 1993; Sengupta, 2000)

$$\langle S(\tau)S(\tau')\rangle = \frac{1}{(\tau - \tau')^{2-\epsilon}} \tag{184}$$

is a power law, but where $\epsilon \neq 0$ signals non-Fermi liquid behavior. This is the basis of the 'local quantum criticality' theory developed by Smith and Si (2000) and Si, Rabello, Ingersent and Smith (2001, 2003). This theory requires that the local spin susceptibility $\chi_{\rm loc} = \sum_{\mathbf{q}} \chi(\mathbf{q}, \omega)_{\omega=0}$ diverges at a heavy-fermion QCP. Using an extension of the methods of DMFT (Georges, Kotliar, Krauth and Rozenberg, 1996; Kotliar *et al*., 2006) Si *et al*. find that it is possible to account

for the local scaling form of the dynamical susceptibility, obtaining exponents that are consistent with the observed properties of $CeCu_{6-x}Au_x$ (Grempel and Si, 2003).

However, there are some significant difficulties with this theory. First, as a local theory, the quantum critical fixed point of this model is expected to possess a finite zero-point entropy per spin, a feature that is, to date, inconsistent with thermodynamic measurements (Custers *et al*., 2003). Second, the requirement of a divergence in the local spin susceptibility imposes the requirement that the surrounding spin fluid behaves as layers of decoupled two-dimensional spin fluids. By expanding $\chi_0^{-1}(\mathbf{q})$ (183) about the critical wave vector $\mathbf{Q}$, one finds that the singular temperature dependence in the local susceptibility is given by

$$\chi_{\rm loc}(T) \sim \int \mathrm{d}^d q \frac{1}{(\mathbf{q}-\mathbf{Q})^2 + T^\alpha} \sim T^{(d-2)\alpha/2} \qquad (185)$$

requiring that $d \leq 2$.

In my judgement, the validity of the original scaling by Schroeder *et al* still stands and that these difficulties stem from a misidentification of the critical local modes driving the scaling seen by neutrons. One possibility, for example, is that the right soft variables are not spin *per se*, but the fluctuations of the phase shift associated with the Kondo effect. This might open up the way to an alternative formulation of local criticality.

5.3.2 *Quasiparticle fractionalization and deconfined criticality*

One of the competing sets of ideas under consideration at present is the idea that, in the process of localizing into an ordered magnetic moment, the composite heavy electron breaks up into constituent spin and charge components. In general,

$$e_\sigma^- \rightleftharpoons s_\sigma + h^- \qquad (186)$$

where s_σ represents a neutral spin-1/2 excitation or 'spinon'. This has led to proposals (Coleman, Pépin, Si and Ramazashvili, 2001; Senthil, Vojta, Sachdev and Vojta, 2003; Pépin, 2005) that gapless spinons develop at the QCP. This idea is faced with a conundrum, for, even if free neutral spin-1/2 excitations can exist at the QCP, they must surely be confined as one tunes away from this point, back into the Fermi liquid. According to the model of 'deconfined criticality' proposed by Senthil *et al*. (2004), the spinon confinement scale ξ_2 introduces a second diverging length scale to the phase transition, where ξ_2 diverges more rapidly to infinity than ξ_1. One possible realization of this proposal is the quantum melting of two-dimensional $S = 1/2$ Heisenberg AFM, where the smaller correlation length ξ_1 is associated with the transition from AFM to spin liquid, and the second correlation length ξ_2 is associated with the confinement of spinons to form a valence bond solid (Figure 35).

It is not yet clear how this scenario will play out for heavy electron systems. Senthil, Sachdev and Vojta (2005) have proposed that, in a heavy-electron system, the intermediate spin liquid state may involve a Fermi surface of neutral (fermionic) spinons coexisting with a small Fermi surface of conduction electrons, which they call an FL* state. In this scenario, the QCP involves an instability of the heavy-electron fluid to the FL* state, which is subsequently unstable to antiferromagnetism. Recent work suggests that the Hall constant can indeed jump at such a transition (Coleman, Marston and Schofield, 2005b).

5.3.3 *Schwinger bosons*

A final approach to quantum criticality, currently under development, attempts to forge a kind of 'spherical model' for the antiferromagnetic QCP through the use of a large N expansion in which the spin is described by Schwinger bosons, rather than fermions (Arovas and Auerbach, 1988; Parcollet and Georges, 1997),

$$S_{ab} = b_a^\dagger b_b - \delta_{ab}\frac{n_b}{N} \qquad (187)$$

where the spin S of the moment is determined by the constraint $n_b = 2S$ on the total number of bosons per site. Schwinger bosons are well suited to describe low-dimensional magnetism (Arovas and Auerbach, 1988). However, unlike fermions, only one boson can enter a Kondo

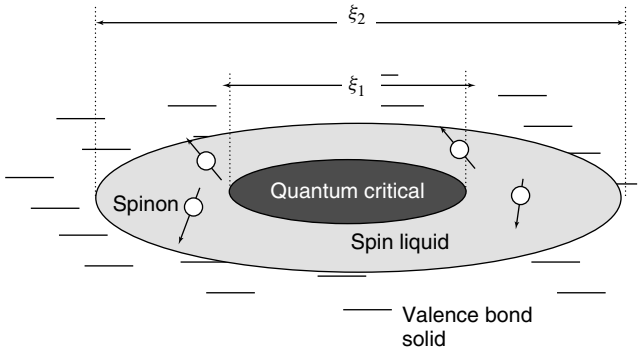

Figure 35. 'Deconfined criticality' (Senthil *et al*., 2004). The quantum critical droplet is defined by two divergent length scales - ξ_1 governing the spin correlation length, ξ_2 on which the spinons confine, in the case of the Heisenberg model, to form a valence bond solid. (Adapted using data from T. Senthil, A. Vishwanath, L. Balents, S. Sachdev and M.P.A. Fisher, *Science* **303** (2004) 1490.)

singlet. To obtain an energy that grows with N, Parcollet and Georges proposed a new class of large N expansion based around the multichannel Kondo model with K channels (Cox and Ruckenstein, 1993; Parcollet and Georges, 1997), where $k = K/N$ is kept fixed. The Kondo interaction takes the form

$$H_{\rm int} = \frac{J_K}{N} \sum_{\nu=1,K,\alpha,\beta} S_{\alpha\beta} c^\dagger_{\nu\beta\mu} c_{\nu\alpha} \qquad (188)$$

where the channel index ν runs from one to K. When written in terms of Schwinger bosons, this interaction can be factorized in terms of a charged, but spinless exchange fermion χ_ν ('holon') as follows:

$$H_{\rm int} \to \sum_{\nu\alpha} \frac{1}{\sqrt{N}} \left[(c^\dagger_{\nu\alpha} b_\alpha) \chi^\dagger_\nu + {\rm H.c} \right] + \sum_\nu \frac{\chi^\dagger_\nu \chi_\nu}{J_K} \qquad (189)$$

Parcollet and Georges originally used this method to study the overscreened Kondo model (Parcollet and Georges, 1997), where $K > 2S$.

Recently, it has proved possible to find the Fermi liquid large N solutions to the fully screened Kondo impurity model, where the number of channels is commensurate with the number of bosons ($K = 2S$) (Rech, Coleman, Parcollet and Zarand, 2006; Lebanon and Coleman, 2007). One of the intriguing features of these solutions is the presence of a gap for spinon excitations, roughly comparable with the Kondo temperature. Once antiferromagnetic interactions are introduced, the spinons pair-condense, forming a state with a *large* Fermi surface, but one that coexists with gapped spinon (and holon) excitations (Coleman, Paul and Rech, 2005a).

The gauge symmetry associated with these particles guarantees that, if the gap for the spinon goes to zero continuously, then the gap for the holon must also go to zero. This raises the possibility that gapless charge degrees of freedom may develop at the very same time as magnetism (Figure 36). In the two impurity model, Rech *et al.* have recently shown that the large N solution contains a 'Jones–Varma' QCP where a static valence bond forms

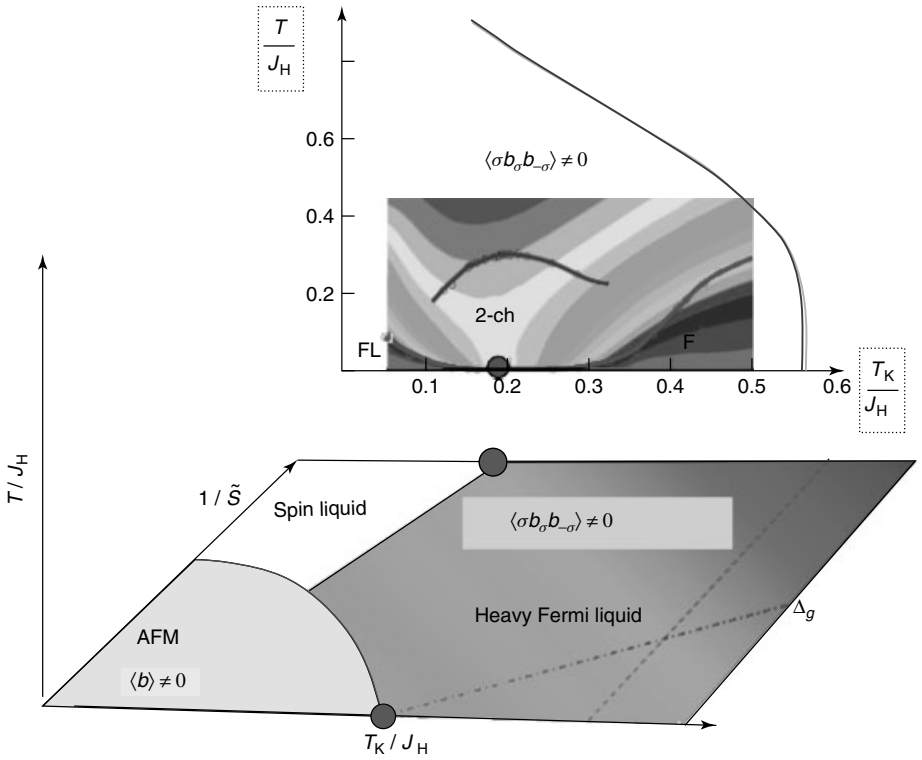

Figure 36. Proposed phase diagram for the large N limit of the two impurity and Kondo lattice models. Background – the two impurity model, showing contours of constant entropy as a function of temperature and the ratio of the Kondo temperature to Heisenberg coupling constant. (Reproduced from Rech, J., P. Coleman, O. Parcollet, and G. Zarand, 2006, *Phys. Rev. Lett* **96**, 016601.) Foreground – proposed phase diagram of the fully screened, multichannel Kondo lattice, where $\tilde{S}$ is the spin of the impurity. At small $\tilde{S}$, there is a phase transition between a spin liquid and heavy-electron phase. At large $\tilde{S}$, a phase transition between the AFM and heavy-electron phase. If this phase transition is continuous in the large N limit, then both the spinon and holon gap are likely to close at the QCP. (Reproduced from Lebanon, E., and P. Coleman, 2007, Fermi liquid identities for the Infinite U Anderson Model, *Phys. Rev. B* (submitted), URL http://arxiv.org/abs/cond-mat/0610027.)

between the Kondo impurities. At this point, the holon and spinon excitations become gapless. On the basis of this result, Lebanon, Rech, Coleman and Parcollet (2006) have recently proposed that the holon spectrum may become gapless at the magnetic QCP (Figure 36) in three dimensions.

6 CONCLUSIONS AND OPEN QUESTIONS

I shall end this chapter with a brief list of open questions in the theory of heavy fermions.

1. To what extent does the mass enhancement in heavy-electron materials owe its size to the vicinity to a nearby quantum phase transitions?
2. What is the microscopic origin of heavy-fermion superconductivity and in theextreme cases UBe_{13} and $PuCoGa_5$ how does the pairing relate to both spin quenching and the Kondo effect?
3. What is the origin of the linear resistivity and the logarithmic divergence of the specific heat at a 'hard' heavy-electron QCP?
4. What happens to magnetic interactions in a Kondo insulator, and why do they appear to vanish?
5. In what new ways can the physics of heavy-electron systems be interfaced with the tremendous current developments in mesoscopics? The Kondo effect is by now a well-established feature of Coulomb blockaded quantum dots (Kouwenhoven and Glazman, 2001), but there may be many other ways in which we can learn about local moment physics from mesoscopic experiments. Is it possible, for example, to observe voltage-driven quantum phase transitions in a mesoscopic heavy-electron wire? This is an area grown with potential.

It should be evident that I believe there is tremendous prospect for concrete progress on many of these issues in the near future. I hope that, in some ways, I have whet your appetite enough to encourage you also to try your hand at their future solution.

NOTES

[1] To calculate the matrix elements associated with valence fluctuations, take

$$|f^1c^1\rangle = \frac{1}{\sqrt{2}}(f^\dagger_\uparrow c^\dagger_\downarrow - c^\dagger_\uparrow f^\dagger_\downarrow)|0\rangle,$$
$$|f^2\rangle = f^\dagger_\uparrow f^\dagger_\downarrow|0\rangle \qquad \text{and} \qquad |c^2\rangle = c^\dagger_\uparrow c^\dagger_\downarrow|0\rangle$$

then $\langle c^2|\sum_\sigma V c^\dagger_\sigma f_\sigma|f^1c^1\rangle = \sqrt{2}V$ and $\langle f^2|\sum_\sigma V f^\dagger_\sigma c_\sigma |f^1c^1\rangle = \sqrt{2}V$

[2] The f-sum rule is a statement about the instantaneous, or short-time diamagnetic response of the metal. At short times $\mathrm{d}j/\mathrm{d}t = (n_c e^2/m)E$, so the high-frequency limit of the conductivity is $\sigma(\omega) = \frac{ne^2}{m}\frac{1}{\delta - i\omega}$. But using the Kramer's Krönig relation

$$\sigma(\omega) = \int \frac{\mathrm{d}x}{i\pi}\frac{\sigma(x)}{x - \omega - i\delta}$$

at large frequencies,

$$\omega(\omega) = \frac{1}{\delta - i\omega}\int \frac{\mathrm{d}x}{\pi}\sigma(x)$$

so that the short-time diamagnetic response implies the f-sum rule.

[3] To prove this identity, first note that any two-dimensional matrix, M, can be expanded as $M = m_0\sigma_2 + \vec{m}\cdot\sigma_2\vec{\sigma}$, $(b = (1, 3))$ where $m_0 = \frac{1}{2}\mathrm{Tr}[M\sigma_2]$ and $\vec{m} = \frac{1}{2}\mathrm{Tr}[M\vec{\sigma}\sigma_2]$, so that in index notation

$$M_{\alpha\gamma} = \frac{1}{2}\mathrm{Tr}[M\sigma_2](\sigma_2)_{\alpha\gamma} + \frac{1}{2}\mathrm{Tr}[M\vec{\sigma}\sigma_2]\cdot(\sigma_2\vec{\sigma})_{\alpha\gamma}$$

Now, if we apply this relationship to the $\alpha\gamma$ components of $\vec{\sigma}_{\alpha\beta}\cdot\vec{\sigma}_{\gamma\delta}$, we obtain

$$\vec{\sigma}_{\alpha\beta}\cdot\vec{\sigma}_{\gamma\delta} = \frac{1}{2}\left(\vec{\sigma}^T\sigma_2\vec{\sigma}\right)_{\delta\beta}(\sigma_2)_{\alpha\gamma} + \frac{1}{2}\sum_{b=1,3}\left(\vec{\sigma}^T\sigma_2\sigma_b\,\vec{\sigma}\right)_{\delta\beta}(\sigma_2\sigma_b)_{\alpha\gamma}$$

If we now use the relation $\vec{\sigma}^T\sigma_2 = -\sigma_2\vec{\sigma}$, together with $\vec{\sigma}\cdot\vec{\sigma} = 3$ and $\vec{\sigma}\sigma_b\vec{\sigma} = -\sigma_b$, we obtain

$$\vec{\sigma}_{\alpha\beta}\cdot\vec{\sigma}_{\gamma\delta} = -\frac{3}{2}(\sigma_2)_{\alpha\gamma}(\sigma_2)_{\delta\beta} + \frac{1}{2}(\vec{\sigma}\sigma_2)_{\alpha\gamma}\cdot(\sigma_2\vec{\sigma})_{\delta\beta}$$

ACKNOWLEDGMENTS

This research was supported by the National Science Foundation grant DMR-0312495. I would like to thank E. Lebanon and T. Senthil for discussions related to this work. I would also like to thank the Aspen Center for Physics, where part of the work for this chapter was carried out.

The Kondo Effect

Barbara A. Jones
IBM Almaden Research Center, San José, CA, USA

1 INTRODUCTION

The Kondo effect is interesting on a number of fronts, not the least that it is a fully many-body quantum-mechanical effect which can be seen at temperatures as high as room temperature or above, although typical Kondo temperatures are more in the tens, rather than hundreds, of kelvin. Moreover, it is a large effect, causing significant changes to transport and thermodynamics. Originally believed to reside mainly in systems of dilute magnetic impurities in a three-dimensional, metallic, host, Kondo effects are now seen on surfaces, in dense periodic structures such as heavy fermions (see also **Heavy Fermions: Electrons at the Edge of Magnetism, Volume 1**), and even in Kondo insulators (Aeppli and Fisk, 1992), in quantum dots (see also **The Kondo Effect in Mesoscopic Quantum Dots, Volume 5**), and in atomic-scale structures created on surfaces by scanning tunneling microscopes (STM).

The Kondo effect was suspected for some time before it was identified as such. In 1930 Meissner and Voight noted a rise in the resistivity of 'pure gold' below 10 K, in contrast to ordinary metals whose resistivity tends toward zero at low temperatures (owing to a decrease in vibrations). In reality the gold had traces of Fe impurities from the manufacturing process, and these were acting as the Kondo impurities. The effect was first definitively identified by Jun Kondo (1964) as arising from interactions in a system of dilute magnetic impurities in a metal. Later experimentalists would see characteristic peaks in the linear coefficient of specific heat, as well as a flattening in the magnetic susceptibility (see Figure 1). Further experimental signatures also appear in the magnetoresistance, thermopower, and excess entropy extracted from the specific heat.

The essence of the Kondo effect is the exchange interaction between a local magnetic moment and the spin of conduction electrons at the impurity site. As the temperature is lowered, a resonance develops in the interaction, and below a critical, Kondo, temperature, the spin of the local moment is screened. Pauli exclusion effects lead to a resulting increase of scattering at the impurity site. This scattering manifests itself as a resonance in the density of states at the Fermi level with width T_K, where $T_K \sim (\rho J)^{1/2} \exp(-1/\rho J)$; ρ is the density of states. There is evidence that such a resonance can be seen in X-ray photoemission spectroscopy (XPS) and/or bremsstrahlung-isochromat spectroscopy (BIS) experiments (Lee *et al*., 1986). A general review of the Kondo problem for single impurities leading up to heavy fermions is found in Hewson (1993).

The remainder of this review will proceed as follows. In Section 2, we review the now well-understood spin-1/2 single-impurity Kondo model, giving some historical development of the solution, and focusing on the numerical renormalization group (NRG) technique and solution. We next describe the Coqblin–Schrieffer model and the Nozières

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

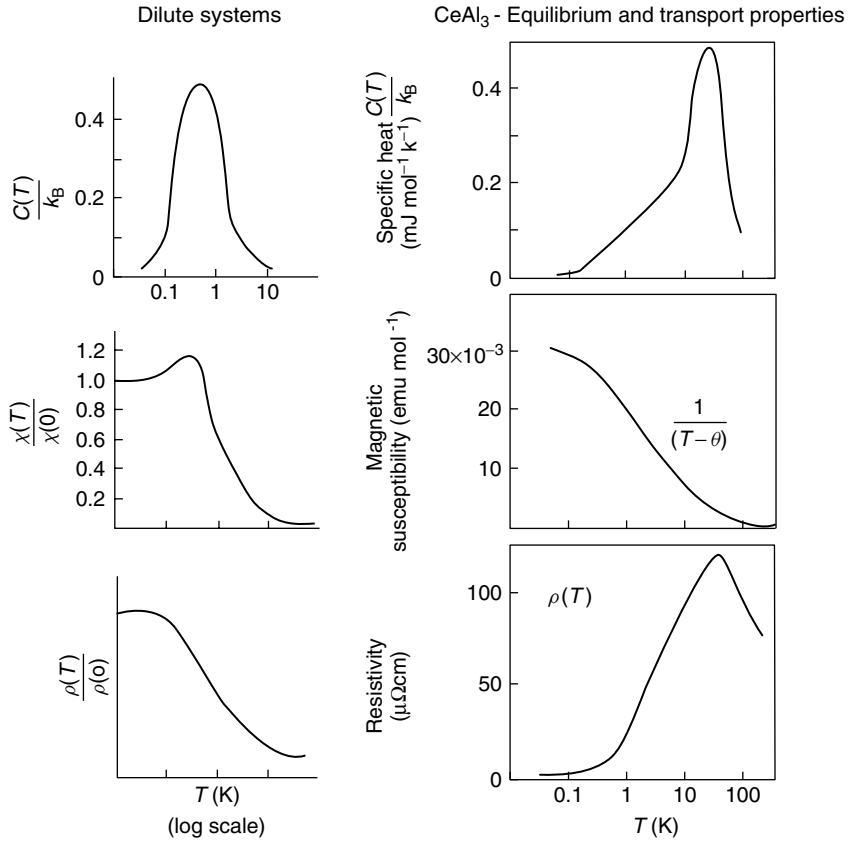

Figure 1. Universal functional forms for the spin-1/2 Kondo systems: specific heat, showing peak with extra ln2 entropy; magnetic susceptibility (note rollover to Pauli paramagnetism at low temperatures); and resistivity, clearly showing rise of scattering at low temperatures. Also for comparison are the same properties for a typical Kondo lattice system. Schematic drawings composed by the author for this article from typical experimental results.

and Blandin phenomenology of Kondo models with multiple channels and spins. An important example of a multichannel model is the two-channel Kondo model, which is described in some detail. We will focus primarily in this review on exact results, but refer to a few key perturbative calculations. In Section 3, we describe the challenges of two-impurity Kondo problems, and the unusual non-Fermi liquid (NFL) fixed point, which can occur for high symmetry. We also describe the effects on the NFL fixed point of the two-channel problem, when a second impurity is added. Section 4 covers the Anderson model, describing how the physics is different from the Kondo model, but related as a more general version of it. This section also covers in more detail the $1/N$ expansion method, reviewing key prior results and discussing its application to the two-impurity infinite-U Anderson model, which maps onto the two-impurity Kondo problem. We also provide a brief review of Kondo lattice physics, but refer the reader to **Heavy Fermions: Electrons at the Edge of Magnetism, Volume 1** for more detail, since the overlap with that subject is considerable. Finally in Section 5 we cover modern experimental developments with few-impurity Kondo systems. The work on quantum dots we refer to **The Kondo Effect in Mesoscopic Quantum Dots, Volume 5**, but cover in detail the experiments with STM in imaging Kondo effects, including interesting physics found outside that predicted by the Hamiltonian calculations of the previous sections. We end with a look at future opportunities in the area of physics of the Kondo effect.

2 SINGLE-IMPURITY KONDO PROBLEMS

The single-impurity Kondo problem is at this point considered completely understood – one of the few many-body quantum models of which this can be said.

The Kondo Hamiltonian for a single impurity is expressed, in second-quantized notation as,

$$H = \sum_{\mathbf{k}\mu} \varepsilon_k c^+_{\mathbf{k}\mu} c_{\mathbf{k}\mu} + J \sum_{\mathbf{k}\mathbf{k}'} \sum_{\mu\mu'} c^+_{\mathbf{k}\mu} \tfrac{1}{2}\boldsymbol{\sigma}_{\mu\mu'} c_{\mathbf{k}'\mu} \cdot \mathbf{S}_0 \quad (1)$$

Here the first term represents the kinetic energy of the sea of conduction electrons and the second term is the exchange interaction between the spin of the conduction electrons at the origin, taken to be the impurity site, and the local moment.

The exchange coupling J can in the abstract be of either sign. However, when derived from a Hamiltonian expressing the hybridization between local and itinerant wave functions (the Anderson model, see subsequently) it is antiferromagnetic, as it is when observed experimentally in many systems.

How such a deceptively simple Hamiltonian can give the dramatic thermodynamic and transport properties is a story that incorporates many of the advanced theoretical developments of the last half-century.

The simplest approach could be to take J to be a small parameter and do a perturbation expansion. However, as was found by Kondo (1964), logarithmic divergences appear at higher order and further expansion becomes invalid. This increase of the expansion parameter does give an indication that growth of the effective J (and of the scattering amplitude at low temperature) is an important part of the physics of the problem.

2.1 'Poor man's' scaling

An early approach was Anderson's poor man's scaling. (Anderson and Yuval, 1969; Anderson, Yuval and Hamann, 1970). Using perturbation theory, scattering processes are successively eliminated at lower and lower energies. Details can be found in the publications and in Anderson's book *Basic Notions of Condensed Matter Physics* (Anderson, 1984). This scaling results in an equation for the coupling $J\tau$ as a function of cutoff energy. (Here τ is the cutoff time, the time for an electron to pass the local spin.) As the cutoff energy is lowered, $J\tau$ increases if the exchange was antiferromagnetic and decreases for ferromagnetic. Thus the ferromagnetic Kondo problem is essentially trivial: the exchange scales to zero as temperature is lowered; the local moment remains essentially free, with no buildup of scattering or increase in resistivity.

For the more usual antiferromagnetic coupling, the exchange scales ever larger, with a cutoff imposed in realistic systems by other scales. If a Kondo temperature is defined by $J\tau = 1$, then an expression for T_K is obtained, $T_K \approx E_C(J\tau)^{1/2}e^{-1/(J\tau)}$, which is remarkably similar to the expression produced by the essentially exact NRG methods obtained by Wilson in the mid-1970s, with the 'cutoff time' replaced by the density of states at the Fermi energy. The physical picture produced by poor man's scaling, of logarithmic contributions to scattering and to the increase of J as temperature is lowered, has been established as correct. What remained as needed was an exact solution which carried all the way from small J, past T_K, down to $T = 0$, and which showed how the low- and high-temperature regimes are connected. For this came Wilson's method of NRG.

2.1.1 Numerical renormalization group

Wilson's method of NRG (Wilson, 1975) comprises several theoretical developments in all. First, it is a unique and insightful way of dividing real and energy space, to focus on behavior at the Fermi energy, and at lower and lower temperatures, and in recasting the Hamiltonian in this form. This aspect is analytical in nature. Second, it is an iterative, computational method for solving a many-body Hamiltonian. And thirdly, it incorporates the concepts of Fermi-liquid theory to extract the exact zero temperature thermodynamic properties, using the numerical results as input to set parameters in analytical expressions.

Wilson's own paper on the solution of the Kondo problem using the NRG is lengthy, and readers are referred to it, and to the exceptionally clear papers by Krishnamurthy, Wilkins, and Wilson (1980a,b) for details of NRG implementation. We will give a summary here.

The first steps are to discretize energy and real space. To prepare, the Hamiltonian is recast from sums over **k** states to integrals over energy. The Fermi surface is assumed to be a single, isotropic conduction band extending from $-D$ to D. New second-quantized operators are defined, which are a set of spherical waves about the impurity site. For a single impurity, only the s-wave states couple. Higher-angular-momentum states come in only in the kinetic energy and do not couple to the impurity; hence they are discarded.

The resulting simplified Hamiltonian is

$$H = \int_{-D}^{D} \mathrm{d}\varepsilon\, \varepsilon a^{+}_{\varepsilon\mu} a_{\varepsilon\mu} + J \iint_{-D}^{D} \mathrm{d}\varepsilon \mathrm{d}\varepsilon' \rho(\varepsilon) a^{+}_{\varepsilon\mu} \tfrac{1}{2}\boldsymbol{\sigma}_{\mu\mu'} a_{\varepsilon'\mu'} \cdot \mathbf{S}_0 \tag{2}$$

Taking $\rho(\varepsilon)$ to be a constant evaluated at the Fermi energy gives the dimensionless parameter ρJ.

Next is the logarithmic discretization of energy and space. A parameter Λ is defined, typically taken to be 2.5 or 3, and energy intervals defined by $\Lambda^{-(n+1)} < \pm\varepsilon < \Lambda^{-n}$. A set of complete orthonormal functions spanning energy space is defined by a Fourier series in each interval, and operators are expanded in this basis. Integrals over energy are now replaced by sums over intervals n. Finally, define new operators so that the first one, f_o, is localized nearest the impurity. Wilson has derived a set of orthonormal operators f_n that couple at most n to $n \pm 1$ in the kinetic energy. The result is an effective Hamiltonian for each energy scale, indexed by N. The zeroth level connects just with the impurity. A recursion relation connects Hamiltonians at level N to those at $N + 1$.

The next step is computational. The iterative procedure is carried out, diagonalizing Ho first, and then using the eigenstates, combined with the next $N = 1$ degree of freedom, to make basis states for the $N = 1$ iteration. At each stage, the Hamiltonian is diagonalized and the lowest energy levels, labeled by spin, are observed. During the first iterations, the energy levels typically change quite rapidly with iteration number. However, after a number of iterations, the eigenstates start to level out, and eventually the levels become exponentially less sensitive to iteration (with an added even-odd iteration differentiation). At this point the iterations are at an eigenstate of the Hamiltonian, and the relative values of the energy levels become meaningful.

Two technical points of the computational part of NRG: First, the rate at which the levels converge is determined by the parameter Λ. The larger Λ, the faster the convergence. The less-fine discretization of energy space results from larger Λ, however, and so the choice of Λ is a tradeoff between these two considerations. A typical range used is 2–3. (Oliveira *et al*. have pioneered the use of a much larger Λ to extract spectral functions and other detail not obtainable with smaller Λ (Campo and Oliveira, 2005; Silva *et al*., 1996), and references therein).) The second point is the imposition at each iteration of an energy cutoff, beyond which states are thrown away. Since every iteration $N \rightarrow N + 1$ introduces a new set of operators, the basis set would quickly grow to unmanageable size if this were not done. However, care must be taken so that the discarded states do not contribute to key energy levels, otherwise this step can be a source of error.

With the eigenstates identified, the final analytic stage of calculating properties can begin. In Fermi-liquid theory, especially as discussed by Nozières (1974), an effective Hamiltonian is formulated for each fixed point, with a certain number of parameters which reflect the low-energy degrees of freedom. In NRG, there is a systematic way to derive these terms, and then the coefficients are derived from the numerical eigenstates. Various thermodynamic properties can then be calculated analytically, using the approach of the energy levels to their fixed point values (i.e., small deviations in energy as a function of iteration number).

For the single-impurity Kondo problem there are two fixed points. The first is the $\rho J = 0$ point, which is free electrons with a free local moment, the so-called weak-coupling fixed point. The second fixed point is $\rho J \rightarrow \infty$. This effectively has the local moment removed from the low-temperature properties, to be replaced by scattering at the unitarity limit, that is, in both up and down spin channels the phase shift is $\pi/2$. By Friedel's sum rule (White, 1983) this means that effectively one electron has been removed from the problem, acting to screen the local moment. (A reminder here that the Kondo effect is not an actual bound state of a conduction electron with the local moment, but rather a resonance–the energy is at the Fermi energy, above the top of the potential 'well', which is the impurity level.) This is known as the *strong coupling fixed point*.

With the only relevant operator ρJ effectively removed from the problem, what remains at low temperatures are the leading irrelevant operators. For the single-impurity problem there are two: a hopping integral, and a local repulsive Coulomb-type interaction $U(n_1 - 1)^2$, involving the nearest-neighbor orbitals. This effective Hamiltonian around the $T = 0$ point enables the calculation of specific heat and susceptibility in the $T = 0$ limit. Wilson formulated a ratio (the Summerfeld–Wilson ratio) of susceptibility to linear coefficient of specific heat γ:

$$R \equiv (4\pi^2/3)(k_B{}^2/g\mu_B)^2 \chi/\gamma \tag{3}$$

This ratio takes the independent, universal value of 2 in the Kondo problem. For free electrons, the value is 1, indicating the enhanced role of spin interactions in the Kondo case.

A notable aspect of Kondo physics is the universal nature of the results. That is, there is only a single parameter, T_K, which governs the energy scale. While the value of the Kondo temperature varies with impurity and host, once the Kondo temperature is determined for a specific system, each physical property has a specific universal shape such that when the experiments are scaled by T_K, the curves all fall on top of one another. For example, as the temperature is lowered, the susceptibility changes near T_K from a Curie law to that of Pauli paramagnetism, indication that the moment has been quenched. The resistivity rises logarithmically and reaches a maximum at zero temperature. Figure 1 illustrates these universal curves.

2.1.2 *Summary of single-impurity spin-1/2 Kondo physics*

At this point we provide a summary of single-impurity Kondo physics. There are, for antiferromagnetic exchange coupling, two fixed points. The $\rho J = 0$ weak-coupling fixed point is unstable, and ρJ effectively scales to infinity as temperature is lowered to zero. The $\rho J = \infty$ fixed point at $T = 0$ is the true Kondo ground state, and it is characterized by scattering at the unitarity limit, $\delta_{\uparrow,\downarrow} = \pi/2$. The spin of the local moment has been screened and disappears from the problem. From an NRG point of view, one conduction electron has been removed from the system to do this screening. The Kondo ground state has universal scaling with the Kondo temperature T_K, and the Wilson ratio takes the universal value 2. In a magnetic field of order T_K, the Kondo effect's many-body spin-symmetric screening is broken, and no Kondo effect is obtained. Finally, the ferromagnetic

Kondo problem has ρJ scaling to 0, and the local moment stays free.

There are other methods which have notably been used for the Kondo problem. One of these is the exact solution by Bethe Ansatz (Andrei, 1980; Andrei and Lowenstein, 1981; Rajan, Lowenstein and Andrei, 1982; Wiegmann, 1980, 1981), obtained in the early 1980s. This solution is very complex, and although it enables the calculation of properties, the primary physical insight is in the nature of the symmetries at the ground state. Another solution method which is not exact, but with far more utility in fitting to a range of experiments, is the $1/N$ expansion (Read and Newns, 1983a,b; Coleman, 1984; Gunnarsson and Schonhammer, 1983; Bickers, Cox and Wilkins, 1987a). This method is remarkably precise in matching a wide range of experimental properties for an extensive range of materials which display single-impurity Kondo behavior. (It should be noted in contrast that for two Kondo impurities, although ferromagnetic interimpurity coupling is reproduced well, the antiferromagnetic regime is less well. More details in the subsequent text.) The $1/N$ expansion is actually implemented on a broader version of the Kondo Hamiltonian, the Anderson model, and will be described in that section.

2.1.3 Coqblin–Schrieffer model

Before moving on to the Anderson model, there are several important variants of the Kondo model. The first variant is to allow the spin to have more than s-wave behavior, and in fact to be larger than spin-1/2. Such a model, with orbital degrees of freedom is the Coqblin–Schrieffer model (Coqblin and Schrieffer, 1969),

$$H = \sum_{\mathbf{k},\alpha} \varepsilon_k \mathrm{c}^{+}_{\mathbf{k}\alpha}\mathrm{c}_{\mathbf{k}\alpha} + J \sum_{\mathbf{k}\mathbf{k}'} \sum_{\alpha\alpha'} \mathrm{c}^{+}_{\mathbf{k}\alpha}\mathrm{c}_{\mathbf{k}'\alpha'}\mathrm{f}^{+}_{\alpha'}\mathrm{f}_{\alpha} \qquad (4)$$

where $\mathrm{c}^{+}_{\mathbf{k}\alpha}$ are creation operators of the conduction electrons' partial harmonics with angular momentum $m = j + 1 - \alpha$, and $\alpha = 1, 2, \ldots 2j + 1$. Here j is the size of the spin. The f^{+}_{α} describe the impurity spin, with degrees of freedom α. Bethe Ansatz methods have been successfully used on this model (Bazhanov, Lukyanov and Tsvelik, 2003). Magnetic fields have a large effect on the Kondo temperature; if small fields, the Kondo temperature is the full value, which may be quite large, hundreds if not thousands of degrees for rare-earth impurities. If larger than T_{K}, magnetic fields can break the full spin symmetry and drive the system to lower-symmetry states with Kondo temperatures of just a few degrees. In general the behavior of this model is more complex than the spin-1/2 model, but tractable by modern methods (i.e., $1/N$, Bethe ansatz, NRG, some forms of scaling).

2.1.4 'M-N-ology'

In general one can consider a Kondo problem of N impurities (spins) and M channels. Multiple scattering channels in a Kondo problem can be obtained, for example, in crystal-electric fields (Cox, 1987) in which orthogonal sets of electrons, interacting with the impurity, can be considered as different 'flavors' of electrons. Using an analysis of channels, spins, and impurities, Nozières and Blandin (1980) have presented a picture which stands the test of time well. It is as follows. For systems in which the number of spin-1/2 impurities equals the number of scattering channels of conduction electrons, a Kondo effect will occur and the ground state will be a Fermi-liquid singlet. If the number of channels is less than the number of spin-1/2 impurities, then a partial Kondo effect will occur, the ground state will be a Fermi liquid, but with a net spin (underscreened case). But if the number of channels is greater than the number of spin-1/2 impurities (overscreened case), then the ground state is predicted to be an NFL unusual state.

We see from sample models how well this holds. For a single-impurity Kondo model, with one impurity and one channel, the ground state is indeed a Fermi liquid. A spin-1 single-impurity, single-channel system has a spin-1/2 Fermi-liquid ground state (Cragg and Lloyd, 1979; Jones and Varma, 1987). We will see below that two spin-1/2 impurities separated by a finite distance have two channels: spin and parity. The ground state is indeed a Fermi-liquid singlet at all parts of its phase space but one. And not all versions of the Fermi-liquid singlet in this case have a full Kondo effect. For the case of a single spin-1/2 with two channels, the so-called multichannel Kondo problem, unusual behavior is predicted – and indeed occurs.

2.1.5 The multichannel Kondo model

The multichannel Kondo Hamiltonian (Nozières and Blandin, 1980) has the form:

$$H = \sum_{\mathbf{k}\mu,\mathrm{n=a,b}} \varepsilon_k \mathrm{c}^{+}_{\mathbf{k}\mu\mathrm{n}}\mathrm{c}_{\mathbf{k}\mu\mathrm{n}} + \sum_{kk'} \sum_{\mu\mu',\mathrm{n=a,b}} J_{\mathrm{n}}\mathrm{c}^{+}_{\mathbf{k}\mu\mathrm{n}}\tfrac{1}{2}\boldsymbol{\sigma}_{\mu\mu'}\mathrm{c}_{\mathbf{k}'\mu'\mathrm{n}} \cdot \mathbf{S}_0 \quad (5)$$

The sources for the two channels can be multiple: crystal-electric field effects in certain heavy fermions (Cox, 1987, 1988; Cox and Jarrell, 1996; Cox and Zawadowski, 1999); electron-assisted tunneling in metallic glasses; and quantum dot systems with multiple explicit channels of conduction electron contacts (see also **The Kondo Effect in Mesoscopic Quantum Dots, Volume 5**).

When $J_{\mathrm{a}} \neq J_{\mathrm{b}}$, the system flows to scaling and a Kondo effect in whichever coupling constant is larger. However, when $J_{\mathrm{a}} = J_{\mathrm{b}}$, the system flows to a stable nontrivial critical point at $T = 0$ which displays NFL behavior such

as logarithmically diverging specific heat coefficient C/T and susceptibility. The residual entropy is $\frac{1}{2}\ln 2$ (that is, $2^{1/2}$ degrees of freedom in the ground state, compared to ln2 as the entropy removed by the regular Kondo effect). This Hamiltonian has been treated by Bethe ansatz (Andrei and Destri, 1984), NRG (Pang and Cox, 1991), and $1/N$ expansion (several authors, e.g., Cox and Ruckenstein, 1993). Of continued interest theoretically is the exact nature of the NFL point, and the relationship of the various solutions to one another. A naïve picture would have the local moment alternatively screened by the spin-up of both a and b channels, then by spin-down of both channels, in concentric rings around the impurity, in each case never obtaining a singlet ground state, extending all the way to infinity. This would have a net spin of 1/2. Some versions of the Bethe ansatz solution are spin symmetric. What then, are the $2^{1/2}$ degrees of freedom? Such can be the nonintuitive aspects of NFL states. Potential multichannel Kondo systems have long been observed in bulk materials, especially those with NFL properties (see also **Heavy Fermions: Electrons at the Edge of Magnetism, Volume 1**), but recently experimental evidence has been given for observing the effect in quantum dots, which should provide a cleaner system for study.

An important theoretical technique adapted from high-energy theory to study condensed matter systems is conformal field theory (CFT), pioneered in Kondo systems by Affleck and Ludwig (Affleck, Ludwig, Pang and Cox, 1992; Affleck and Ludwig, 1993). This is an exact solution, which emphasizes the role of symmetries and extracts the conformal operators for the various fixed points. Although it can identify fixed points independently, it is optimally used in conjunction with the NRG to utilize the energy levels to fix the values of the parameters. CFT was used on the multichannel problem, revealing anomalous critical properties of the NFL state, and was also used to obtain insight into the two-impurity Kondo problem (see subsequent text).

3 TWO-IMPURITY PROBLEMS

The next level of complexity is to introduce a second impurity. This is the simplest level of Hamiltonian to include interimpurity interactions, leading toward models for a lattice. The two-impurity Kondo problem has the form:

$$H = \sum_{\mathbf{k}\mu} \varepsilon_k \mathrm{c}^{+}_{\mathbf{k}\mu}\mathrm{c}_{\mathbf{k}\mu} + J[\mathbf{s_c}(\mathbf{r}_1)\cdot\mathbf{S}_1 + \mathbf{s_c}(\mathbf{r}_2)\cdot\mathbf{S}_2] \qquad (6)$$

where

$$\mathbf{s_c}(\mathrm{r}_i) = \sum_{\mathbf{k}\mathbf{k}'}\sum_{\mu\mu'} \mathrm{e}^{\mathrm{i}(\mathbf{k}'-\mathbf{k})\cdot\mathrm{r}_i}\mathrm{c}^{+}_{\mathbf{k}\mu}\tfrac{1}{2}\boldsymbol{\sigma}_{\mu\mu'}\mathrm{c}_{\mathbf{k}'\mu} \qquad (7)$$

Now the impurities can interact with each other as well as with the conduction electrons. The form of the interimpurity exchange is the Ruderman–Kittel–Kasuya–Yosida (RKKY) interaction (Ruderman and Kittel, 1954). In this interaction, the local moments spin polarize the conduction electron sea around them. There are not enough k vectors to make a delta function of spin at each impurity site, since filling the conduction electron states stops at the Fermi level (and a delta function would need Fourier components all the way to infinity). This sharp cutoff in energy occupation gives an oscillation to the spin polarization. One can calculate this by treating the interaction terms of the Hamiltonian as a perturbation on the kinetic energy, which gives a change in energy of the form $|\rho J|^2 F(R)\mathbf{S}_1\cdot\mathbf{S}_2$, where $F(R)$ is an oscillating function of impurity separation which decays as $\cos(k_\mathrm{F}R)/(k_\mathrm{F}R)^3$ for $R \to \infty$.

For ferromagnetic interactions the moments will just create a larger attraction for the Kondo effect. But for separations for which the interaction is antiferromagnetic, do the moments create their own spin singlet, which will preclude having a Kondo effect? Likewise, if a Kondo effect occurs will this preclude an RKKY interaction, since the moments are screened? How do ferromagnetic and antiferromagnetic sides of the phase diagram connect?

Prior to the exact solution, the thinking was that as soon as there was any antiferromagnetic interaction, the moments would quench each other. Thermodynamic scaling analysis (Jayaprakash, Krishnamurthy and Wilkins, 1981), for example, found an effective Hamiltonian with two parameters, the Kondo and RKKY couplings. For ferromagnetic RKKY, they found a two-stage Kondo effect. This is much in agreement with later NRG calculations. For antiferromagnetic interactions, however, the analysis indicated an either/or scenario: RKKY precluded Kondo and vice versa. Analysis by Doniach of his more complex Kondo necklace model (Doniach, 1977) indicated a similar dichotomy between states. Quantum Monte Carlo (Hirsch and Fye, 1986; Fye, Hirsch and Scalapino, 1987) was also tried on this model, with results which likewise have some comparison with the exact solutions.

The exact solution was obtained by NRG in the late 1980s (Jones and Varma, 1987; Jones, Varma and Wilkins, 1988). Whereas the single-impurity Kondo problem(s) proved eventually amenable to a variety of techniques (poor man's scaling, $1/N$ expansion, Bethe ansatz, NRG, conformal field theories, etc.), all of which gave consistent and correct results in the regimes in which they operated, the two-impurity problem, only one impurity more, and still far to go toward a lattice, produced subtle and unexpected results only completely seen by NRG and CFT (a Bethe ansatz solution for the two-impurity problem remains still problematic at this writing).

What was found by NRG was the following. Because of mirror symmetry about the center of the two impurities, parity is a conserved quantity. All states can be classified as being of either even or odd parity, in addition to having quantum numbers of spin and charge (actually axial charge, a symmetry of Kondo Hamiltonians discovered by the author (Jones, Varma and Wilkins, 1988; Jones, 1990), and later found in other strongly correlated Hamiltonians such as the Hubbard model). Interaction in the Hamiltonian can involve interactions between even parity alone, or odd parity, or a mix of even and odd (and spin-0 and spin-1 states of the impurities). The Hamiltonian in the particle–hole symmetric limit is as follows:

$$H/D = \int \mathrm{d}\varepsilon\, \varepsilon \left[a^{+}_{\varepsilon \mathrm{e}\mu} a_{\varepsilon \mathrm{e}\mu} + a^{+}_{\varepsilon \mathrm{o}\mu} a_{\varepsilon \mathrm{o}\mu}\right] + \rho J_{\mathrm{e}} \mathbf{s}_{\mathrm{e}} \cdot (\mathbf{S}_1 + \mathbf{S}_2) + \rho J_{\mathrm{o}} \mathbf{s}_{\mathrm{o}} \cdot (\mathbf{S}_1 + \mathbf{S}_2) + \rho J_{\mathrm{m}} (\mathbf{s}_{\mathrm{eo}} + \mathbf{s}_{\mathrm{oe}}) \cdot (\mathbf{S}_1 - \mathbf{S}_2),$$

$$\text{where } \mathbf{s}_{\mathrm{pp}'} = \iint \mathrm{d}\varepsilon \mathrm{d}\varepsilon' a^{+}_{\varepsilon \mathrm{p}\mu} \tfrac{1}{2} \boldsymbol{\sigma}_{\mu\mu'} a_{\varepsilon' \mathrm{p}'\mu'} \tag{8}$$

Here the integrals extend from -1 to 1 since the bandwidth has been scaled out. States are labeled by parity as e or o. Only one parity subscript on a spin term represents a repeated value of that parity. (In the most general, particle–hole asymmetric form, there are energy- and distance-dependent form factors within each integral, making it very challenging to implement the Wilson procedure of projection onto Fourier states in each logarithmic energy interval. The approximation represented here thus explores only a portion of phase space.)

Because there are in addition two spin scattering channels, the two-impurity Kondo problem has four channels of conduction electrons. The NRG analysis revealed three low-temperature fixed points, or ground states of the system.

1. For the case of particle–hole symmetry, there is a Kondo effect for all values of RKKY from moderately antiferromagnetic (RKKY/T_{K} near -2.2), through zero RKKY (two independent moments) to all values of ferromagnetic RKKY. For the larger values of ferromagnetic RKKY/T_{K}, there is a two-stage Kondo effect as previously predicted, with the Kondo effect happening separately in the even and the odd channels, with the larger coupling constant having the higher of the two Kondo temperatures. The ground state is a singlet with a $\pi/2$ phase shift in every scattering channel.
2. For larger antiferromagnetic RKKY, with RKKY/T_{K} more negative than -2.2, the moments form a singlet, and no Kondo effect occurs.
3. At a value of RKKY/T_{K} near -2.2, there is an unexpected unstable NFL fixed point. At this point there is a second-order quantum critical point as a function of the parameter RKKY/T_{K}, at $T = 0$. At this point the linear coefficient of specific heat and the magnetic susceptibility diverge. The staggered susceptibility (related to S1−S2) remains finite, with a possible finite discontinuity. These thermodynamics are shown in Figure 2.

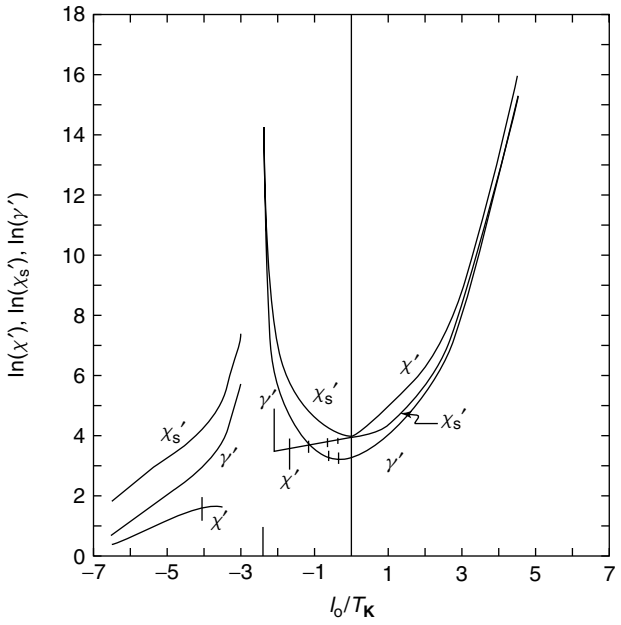

Figure 2. Thermodynamic properties for the two-impurity Kondo Hamiltonian (symmetric case), obtained by NRG. The magnetic susceptibility, the staggered susceptibility (susceptibility under an opposite magnetic field on the two sites), and the linear coefficient of specific heat, all at zero temperature, are plotted as a function of the ratio of the RKKY coupling to the Kondo temperature. Antiferromagnetic RKKY is on the left side of the figure. Note the divergence of staggered susceptibility and linear coefficient of specific heat at the non-Fermi-liquid fixed point, near an antiferromagnetic RKKY/T_{K} ratio of near 2.2. The uniform susceptibility remains finite, if with a possible discontinuity. The system is in a Kondo singlet to the right of the critical point, and in an antiferromagnetic singlet to the left with no Kondo effect. (Reproduced from Jones *et al*., 1988, with permission from the American Physical Society. © 1988.)

Further understanding of the phases of this system is obtained with the calculation of the bare spin−spin correlation function, shown in Figure 3. Notice that the spin−spin correlation function is smooth and continuous throughout the range of parameters, and only becomes ferromagnetic or antiferromagnetic at the extreme range of RKKY. How is this consistent with three separate ground states, one of which is an antiferromagnetic state for a finite range of RKKY? The answer is that the ground state phases are many-body states, involving not only the local moments, but a large percentage of the conduction electrons. The local moments take on intermediate values as the RKKY varies, but the conduction

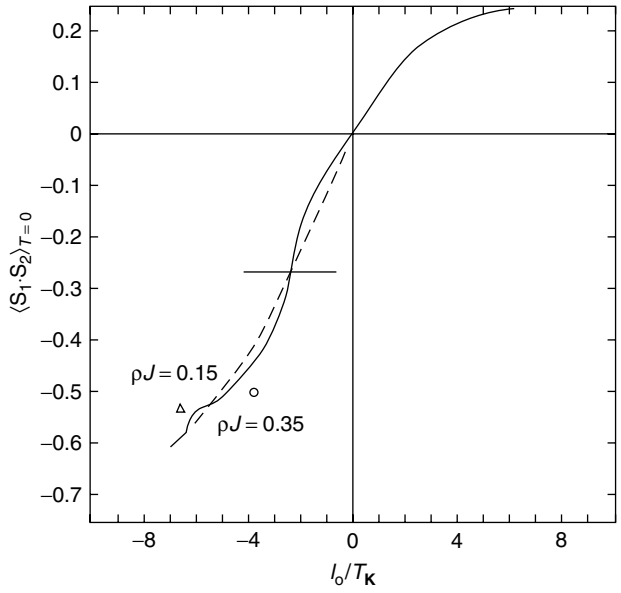

Figure 3. Spin–spin correlation function for the two-impurity Kondo Hamiltonian (symmetric case), obtained by NRG. (Same horizontal axis as Figure 2.) This is the correlation function between the bare local moments; the fixed point represents the moments as dressed by the electrons. Note that exchange coupling exists between the two impurities, even when they are in a Kondo state, and that a pure singlet state only exists at the limit of very large RKKY. Kondo does not preclude RKKY, nor vice versa. The spin–spin correlation function at the critical point takes the value $-1/4$. (Reprinted from Jones B.A. Ph.D. thesis, Cornell University, copyright 1988 by Barbara A. Jones.)

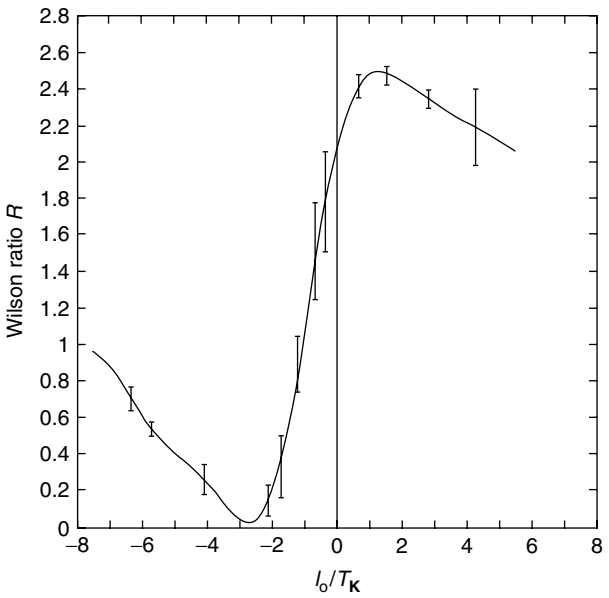

Figure 4. Wilson ratio, proportional to the ratio of the magnetic susceptibility to the linear coefficient of specific heat. The non-constant value shows the nonuniversal nature of the two-impurity system (no single-parameter scaling). Free electrons have value 1, a Kondo effect gives a value 2, and the critical point has a value near if not at 0, showing a suppression of magnetic interactions (or an enhancement of electronic ones). (Reproduced from Jones *et al*., 1988, with permission from the American Physical Society. © 1988.)

electrons have a noncontinuous reaction to this state, deciding that there is enough of a moment to make a Kondo effect for RKKY ratio greater than 2.2, and conversely helping the local moments to form a spin singlet without Kondo effect for larger antiferromagnetic RKKY.

What, then, are the conduction electrons aiding when the local moment spin–spin correlation function is $-1/4$, exactly half way between antiferromagnetic $-3/4$ and ferromagnetic 1/4? This is the location of the unstable NFL point. It seems that the unstable point is the point at which, coming down from more ferromagnetic RKKY, the moment is just barely too small to generate a Kondo effect. The electrons try to form a many-body resonance, but the cloud extends to infinity, and there is no finite-size screening cloud for electrons coming from infinite to scatter off of, and thus define a Fermi liquid (Jones, 1991).

The Wilson ratio has also been calculated and is shown in Figure 4. One can see the Wilson ratio going to the Kondo value of 2 and above for the ferromagnetic side. For the antiferromagnetic side, the Wilson ratio is always less than 2, and in fact goes to 0 at the value of the unstable fixed point. For large antiferromagnetic coupling, the Wilson ratio goes to the free-electron value of 1. One of the central findings of the two-impurity Kondo Hamiltonian is that the results are strongly nonuniversal. There is no one scaling parameter, as there is for the single-impurity case. The variation of R on the ferromagnetic side is less, with perhaps rough scaling possible there, but on the antiferromagnetic side it is clearly ruled out.

It should be noted that for much of the phase diagram, there is simultaneous Kondo effect and RKKY interactions, both ferromagnetic and antiferromagnetic. The RKKY is not stopped by the Kondo effect, nor do antiferromagnetic RKKY interactions necessarily preclude a Kondo effect. In fact, it is proposed that simultaneous antiferromagnetic RKKY and Kondo effect may be what is occurring in the Kondo lattice compounds, where there is a famous conundrum posed by P.W. Anderson, of where the electrons are coming from to form a Kondo singlet with every moment in the dense lattice, if only electrons within T_K of the Fermi energy can participate. In a lattice, there are not nearly enough electrons in that energy range to form a 'sea' for every moment. However, if the moments partially compensate each other, then far fewer compensating electrons are needed.

3.1 Removal of particle–hole symmetry

When the requirement of particle–hole symmetry is lifted (with for example the addition of potential scattering terms to the Hamiltonian above), for most values, the divergences in susceptibility and specific heat coefficient are rounded to peaks, and the quantum phase transition goes away (Jones, 1991). There is no unstable NFL point. All ground states are a Fermi liquid. The phase shifts in this case vary continuously from $\pi/2$ on the ferromagnetic side down to eventually 0 for very large antiferromagnetic RKKY. Thus the ground states for every value of antiferromagnetic RKKY are 'partial Kondo effect', with the moments doing part of the compensating and the electrons doing the rest. The Wilson ratio still varies, however, and the solution is still nonuniversal. Lest one conclude that the critical parameter is purely particle–hole symmetry, however, it should be noted that when potential scattering is added which has parity-symmetric form, although particle–hole symmetry is broken, these Hamiltonians still give a line of NFL fixed points. The symmetry breaking is somewhat subtle, and only has an effect when there is not a reflection symmetry between odd and even.

The exact nature of the critical operators was obtained later by conformal field theoretical analysis (Affleck and Ludwig, 1992; Affleck, Ludwig and Jones, 1995) and an SO(7) complex symmetry identified at the critical point. They calculated the staggered susceptibility at the critical point to depend logarithmically on temperature and frequency.

As a final conclusion, the single-particle result, the Kondo effect, is strongly modified by two-spin results, and hence pair interaction terms must be included in any theories for the lattice. RKKY and Kondo effects are not mutually exclusive, either for ferromagnetic or for antiferromagnetic coupling.

3.1.1 Two-impurity, two-channel Kondo

When adding a second impurity to the two-channel problem, the question naturally arises whether the NFL state for $J_a = J_b$ still remains. This problem has been looked at by NRG, and the solution is as follows (Ingersent, Jones and Wilkins, 1992). The phase diagram is shown in Figure 5. This is the calculation for $J_a = J_b$, and particle–hole symmetry. The previous, single-impurity NFL point is shown in the center of the figure at RKKY $I/T_K = 0$. This fixed point proves to be unstable to any RKKY interactions, ferromagnetic or antiferromagnetic. For antiferromagnetic RKKY, the previous fixed point flows to a line of fixed points, at a critical value of RKKY/T_K. Thus the physics of a bulk two-channel Kondo system should be governed more by the properties of the marginal line of NFL

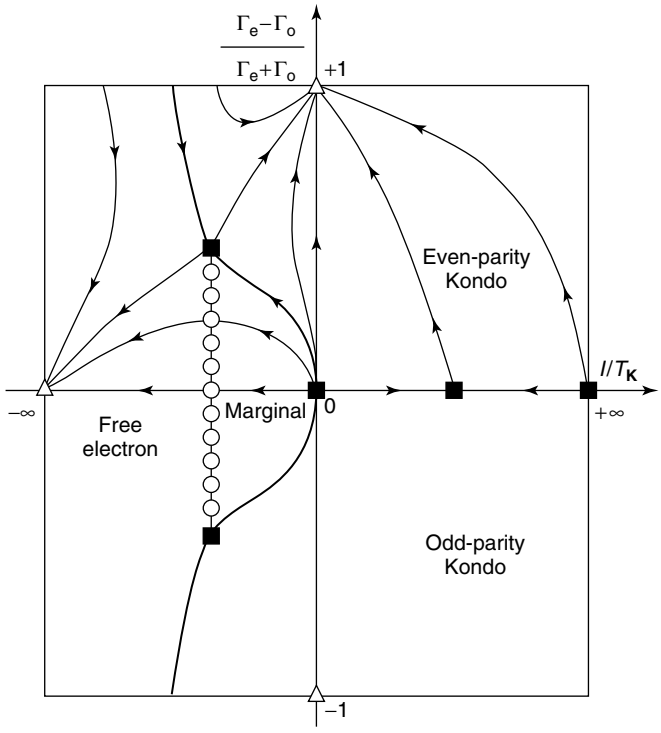

Figure 5. Phase diagram for the two-impurity, two-channel Kondo Hamiltonian in the symmetric case, obtained by NRG. The horizontal axis is the ratio of RKKY to Kondo temperature, as in figures 2–4. The non-Fermi-liquid fixed point for the one impurity case is at the center of the figure at the origin. Note that it is unstable in all directions, either to flow to a Fermi liquid, or to a line of non-Fermi-liquid fixed points at intermediate coupling. Even if the non-Fermi-liquid fixed points were to be changed to crossovers in the presence of particle–hole symmetry breaking, the point at the origin would still be unstable to the Fermi liquid around it. (Reproduced from Ingersent *et al*., 1992, with permission from the American Physical Society. © 1992.)

points, not by the single-impurity point! Similarly to the two-impurity, single-channel problem, for large enough antiferromagnetic RKKY, the moments form their own singlet and no Kondo effect occurs. This is a Fermi-liquid ground state.

For ferromagnetic RKKY, the single-impurity NFL point is again unstable. If there is any even-odd parity asymmetry, the RG flows are to a Kondo effect in either parity channel, with Fermi-liquid ground state. Only in the case of equal even- and odd–parity coupling (isolated points in the phase space of RKKY coupling) does the single-impurity NFL point flow to a new stable ferromagnetic NFL point at intermediate coupling.

In summary, the phase diagram for adding a second impurity to the two-channel problem is surprisingly complex. Unexpectedly, the single-impurity NFL result is unstable to any amount of RKKY coupling. If ferromagnetic, the most

likely result is a Fermi-liquid Kondo ground state with no NFL behavior. If antiferromagnetic coupling, the flow is to a line of new marginal NFL fixed points, with properties different from that of a noninteracting impurity. Two main questions are raised, the first being whether additional impurities add yet more complexity and yet different fixed points, so that it becomes difficult to predict the main interactions for a multichannel lattice. The second challenge is to treat a more general band structure, to see whether particle–hole symmetry has created some nonuniversal effects.

These questions have been looked at with the addition of potential scattering, and it appears that for general values of even- and odd-parity scattering, all the intermediate-RKKY NFL fixed points may be destabilized. A reminder that even though it remains, the NFL point at RKKY = 0, for two independent impurities, is unstable to any RKKY, and will flow to strong coupling fixed points. It appears that a Fermi liquid is the preferred general ground state. For the multichannel Kondo problem, except in special cases, the addition of a second impurity reduces complexity and flows are to stable Fermi-liquid fixed points. Since this Hamiltonian was the hope of modeling NFL in many systems, it raises the final question of where the microscopic Hamiltonian basis of NFL behavior may come from in a lattice model. Certainly at finite temperatures, even low ones, the system could flow near interesting phases in these models, since what is important are the crossover exponents.

4 THE ANDERSON MODEL

So far we have been discussing the Kondo model, in which the local moment occupation is kept fixed, a result of large, tending to infinite Coulomb repulsion. For many systems, however, there is a finite Coulomb repulsion on the impurity site, and fluctuations to double or no occupancy can occur. The more general model for these systems is the Anderson model (Anderson, 1961) with a Hamiltonian as follows:

$$H = \sum_{\mathbf{k}\mu} \varepsilon_k c^+_{\mathbf{k}\mu} c_{\mathbf{k}\mu} + \varepsilon_d c^+_{d\mu} c_{d\mu} + \sum_{\mathbf{k}\mu} (V_{k,d} c^+_{\mathbf{k}\mu} c_{d\mu} + V^*_{k,d} c^+_{d\mu} c_{\mathbf{k}\mu}) + U(c^+_{d\uparrow} c_{\mathbf{k}\uparrow})(c^+_{d\downarrow} c_{\mathbf{k}\downarrow}) \tag{9}$$

Here the first term is the kinetic energy of the conduction electrons; ε_d is the energy of the local level (be it d or f electrons), with operators $c^+_{\mathbf{d}\mu}$; $V_{k,d}$ is the hybridization between the local level and the conduction electrons; and U is the Coulomb repulsion at the local level site.

The Anderson model has some very interesting physics of its own, but first we wish to show how the Anderson and Kondo models are related. This is done by means of a Schrieffer–Wolff transformation (Schrieffer and Wolff, 1966). Assume that U is much larger than V. Then by choosing a generator matrix S, such that

$\tilde{H} = \exp(S)\ H\ \exp(-S)$ and $(I - P)\tilde{H}P = 0$, with P the projector onto the singly-occupied ground state, eliminate V to first order. The resulting Hamiltonian $\tilde{H}$ has a term of the Kondo form, with a coefficient, the effective J, depending on k and k'. Evaluating J at the Fermi energy gives a relation to the parameters of the Anderson model: $J = 2|V_{kf}|^2 U/(\varepsilon_d(\varepsilon_d + U))$. Often the symmetric case is considered, in which $\varepsilon_d = -U/2$, giving $J = -8|V_{kf}|^2/U$. One can see that for large U, J is usually fairly small. However, as we have seen from the single-impurity Kondo results, even small values of J scale to large as temperature is lowered. The Anderson model contains thus a larger subset of physics than the Kondo model, since the Kondo interactions are contained as a limiting case.

We now look at the Anderson model itself. The primary new behavior introduced by such a model is so-called mixed valent physics. That is, it allows the local moment to have an occupancy, which is a mix between two definite values. Such physics is seen in some rare-earth compounds (e.g., α-Ce), and the subject of mixed valent physics has been a very active one both experimentally and theoretically in the past. Unfortunately we do not have room here to review this literature, and will focus on the physics emerging from solutions of the Anderson Hamiltonian above.

The definitive NRG study of this Hamiltonian was done by Krishnamurthy, Wilkins and Wilson (1980a), who studied both the symmetric and asymmetric cases. The results are reviewed here. NRG finds that the local moment behavior described above as the Kondo effect occurs as a fairly large part of phase space. As long as U is roughly greater than the hybridization V, for fairly low temperatures, the system maps onto the spin-1/2 Kondo model with coupling given as per the Schrieffer–Wolff transformation, even up to very large values of ρJ. For U not particularly large, the impurity orbital remains essentially free at high temperatures, and then develops a moment when T drops below U. Finally, for small Coulomb repulsion U, the free impurity orbital flows straight to strong coupling at low temperature. (see Figure 6).

For the asymmetric case, the valence-fluctuating regime is the primary characteristic. This is reached for $-\varepsilon_d \ll T \ll U$. Here the $n_d = 0$ and $n_d = 1$ configurations are equally populated, and the effective impurity level energy becomes temperature dependent, and a function of the hybridization and U as well. Although properties are universal for the symmetric model, the asymmetric model shows evidence of nonuniversal behavior. Several varieties of Bethe ansatz solutions for the Anderson model have also been obtained, such as Schlottmann (1983).

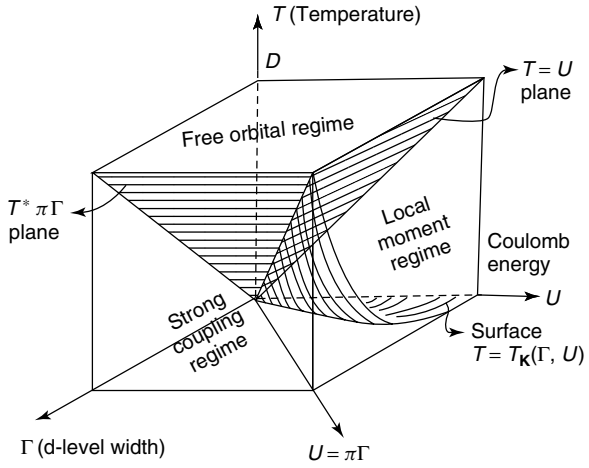

Figure 6. Phase diagram of the symmetric single-impurity Anderson model, with axes as labeled. At low temperature, the system scales to strong coupling for all values of hybridization and Coulomb energy U, even for very small values of U, unless U is identically zero. 4.1 $1/N$ calculations

Besides the NRG, another very successful technique for the single-impurity Anderson model has been the large-N expansion. Here N corresponds to the size of the impurity spin. While in archetypal Kondo systems the spin is 1/2, corresponding to $N = 2$, hardly a large number, in many alloy systems the magnetic moments have a reasonably large angular momentum. The $1/N$ method is in two parts, a mean field approximation, plus corrections, based on Gaussian approximation, to get the fluctuations from the mean field. The fluctuations enable the calculation of thermodynamics. The key benefits of the $1/N$ expansion have been its ability to obtain a unified approach to both the static and dynamic properties of magnetic alloys, and in particular the excitation spectrum. Dynamics are difficult for many techniques, and a good calculation provides insight into many key experiments. Also, unlike many perturbation methods, $1/N$ obtains a singlet ground state for Anderson and Kondo problems, which may be a clue to its success even for $N = 2$, spin-1/2 systems.

Pioneering work was done by Read and Newns, who developed the functional integral approach to $1/N$ calculations for the symmetric Anderson model (Read and Newns, 1983a; Newns and Read, 1987) (using formalism, in particular the slave-boson technique, laid by (Coleman, 1983, 1984, 1987). Over the following years, they and others calculated much of the transport coefficients, finding universal behavior especially in the Kondo regime. For a good review of the groundwork of $1/N$ techniques, see Bickers, (1987b). A major body of work for spectral functions for valence-fluctuating compounds was done using a $1/N$ technique by Gunnarsson and Schonhammer (1983). High-energy spectroscopy data and static susceptibility were calculated and fit to a wide range of materials using a single set of model parameters.

4.2 The two-impurity infinite-U Anderson model

Another advantage of the $1/N$ technique is that it can be straightforwardly extended to multiple impurities and even the lattice. For two impurities, it is the antiferromagnetic side, which poses the greatest challenges, and interest, to many alternative theoretical techniques. An example is the $1/N$ expansion done for the two-impurity problem, explicitly adding an RKKY term in order to span the full range of inter-impurity interactions (Jones, Kotliar and Millis, 1989; Millis, Kotliar and Jones, 1990).

In order to calculate for the Coulomb $U \to \infty$ limit, an auxiliary boson is added in the standard technique, giving a Hamiltonian:

$$\begin{aligned} H = & \sum_{\mathbf{k}\mathrm{m}} \varepsilon_{\mathrm{k}} \mathrm{c}^{+}_{\mathbf{k}\mathrm{m}} \mathrm{c}_{\mathbf{k}\mathrm{m}} + \sum_{\mathrm{m},\alpha=1,2} E_0 f^{+}_{\alpha\mathrm{m}} f_{\alpha\mathrm{m}} \\ & + V N^{1/2} \sum_{\mathbf{k}\mathrm{m},\alpha=1,2} (b^{+}_{\alpha} \mathrm{e}^{i\mathbf{k}\cdot\mathbf{r}\alpha} \mathrm{c}^{+}_{\mathbf{k}\mathrm{m}} f_{\alpha\mathrm{m}} + \mathrm{H.c.}) \\ & + \mathrm{I}/N \sum_{\mathrm{m}'\mathrm{m}} f^{+}_{1\mathrm{m}} f_{2\mathrm{m}} f^{+}_{2\mathrm{m}'} f_{1\mathrm{m}'} \end{aligned} \tag{10}$$

Here α labels spin sites 1 and 2, and the constraint is enforced $n_{\mathrm{f}\alpha} + n_{\mathrm{b}\alpha} = N/2$. In this constraint, $n_{\mathrm{f}\alpha}$ and $n_{\mathrm{b}\alpha}$ are the numbers of f electrons and auxiliary bosons at site α. N is the size of the spin, with the model valid in an $N \to \infty$ limit. I is the RKKY interaction, taken to be antiferromagnetic. Details of the subsequent analysis appear in Jones, Kotliar and Millis (1989).

The $1/N$ approach does find a phase transition for the case of particle-hole symmetry, and at about the right ratio of $T_{\mathrm{K}}/I \approx 0.5$, but (to leading order in $1/N$) it is primarily of first order rather than second. Since the order of the phase transition determines behavior of the thermodynamic properties in the entire region of the critical point, it is the thermodynamics of $1/N$, which differ the most, never diverging or strongly peaking at the critical point, as in the NRG solution. Nevertheless, the $1/N$ calculation does identify a critical parameter associated with particle–hole symmetry breaking, and indicates that breaking particle–hole symmetry can give rise to a gradual crossover rather than a transition, details which were confirmed by NRG calculations.

4.2.1 Multiple impurities and the Kondo lattice

Finally we touch on calculations for the lattice. It is here we overlap most with the chapter on heavy fermions, so this will be kept brief. Interestingly, many $1/N$ calculations for the Kondo lattice model show that Kondo effect occurs, but there is little interaction between local moments in the Kondo state. The ground state is a Fermi liquid. Other effects toward heavy-fermion behavior were shown by the early $1/N$ calculation for the lattice by Coleman (1983). There has been a large body of theoretical work on the Kondo lattice, using a variety of theoretical methods. Fairly recently a two-fluid model for the lattice was put forward (Nakatsuji, Pines and Fisk, 2004) composed of Kondo impurities and heavy electron Fermi liquids. Modern techniques for strongly correlated lattices developed within the last decade and a half include dynamical mean-field theory (Georges *et al*., 1996), a nonperturbative technique which effectively solves the problem at infinite number of dimensions. Also promising is density matrix renormalization group (DMRG) (White, 1992), a real-space renormalization, is an improvement on NRG, which optimizes the set of functions kept for basis states, to enable correct interactions with other sites, as well as on-site terms.

It is interesting to speculate, with all the exotic NFL states, which populate the few-impurity Kondo impurity systems, how much of this is likely to carry to the lattice. With the addition of degrees of freedom, will there be ever more unusual fixed points? A clue to this may be found from the two-impurity work in the most general cases, without particle–hole symmetry. In these, many of the NFL ground states are not reached, and the ground state is a Fermi liquid. It is likely that the most exotic fixed points are a result of a strong amount of local symmetry. In the lattice, there is a new symmetry, the periodicity of the material, which might lead to new types of interesting states, besides the heavy-fermion correlations, which have already been found. At this point a full solution of the Kondo or Anderson lattice is still pending. New experimental approaches such as construction of magnetic nanostructures using STM techniques also open possibilities for future interesting Kondo and Anderson model physics.

5 EXPERIMENTAL IMAGING USING STM TECHNIQUES

Experimentally, among the most promising for realizations of Kondo Hamiltonian systems have been two systems: quantum dots, for which the reader is referred to that chapter of this volume, and systems created by atomic manipulation and imaged by STM. We briefly review here the work on imaging Kondo systems at the atomic scale by STM. The single-impurity Kondo effect was first observed in 1998 for Co atoms on a Au(111) surface and for Ce atoms on a Ag(111) surface (Madhavan *et al*., 1998; Li, Schneider, Berndt and Delley, 1998). They observed a sharp Fano resonance (Újsághy, Kroha, Szunyogh and Zawadowski, 2000; Plihal and Gadzuk, 2001), characteristic of tunneling both into the impurity and also into the conduction states of the surface. The Crommie group subsequently measured the temperature-dependent electronic structure and observed the characteristic broadening of the Kondo resonance as temperature was increased (Nagaoka, Jamneala, Grobis and Crommie, 2002). A Kondo effect of the orbital moments can also occur (Kolesnychenko *et al*., 2002). In 2000 a remarkable feature was observed: the so-called quantum mirage effect (Manoharan, Lutz and Eigler, 2000). An ellipse was built of Co atoms, and one Co atom placed at just one focus of the ellipse. When the STM was placed over the Co atom, a Kondo resonance was observed. However, when imaging over the empty focus site, surprisingly the STM picked up a Kondo resonance as well, although with reduced amplitude: the mirage effect. If the foci were close together, this effect would be expected to include many-body correlations between the two sites. However, experimentally the foci were tens of angstroms apart, and the STM images were fit well by single-particle scattering calculations from a model Kondo phase shift (Fiete *et al*., 2001).

Kondo effects have also been observed in clusters of magnetic atoms. Clusters of Co on metallic single-walled carbon nanotubes give an effectively one-dimensional host for the observed Kondo effect (Odom, Huang, Cheung and Lieber, 2000). An antiferromagnetic trimer of Cr atoms also gives a Kondo effect (Jamneala, Madhavan and Crommie, 2001). Theoretical models indicate that for ferromagnetic clusters, the Kondo coupling is inversely proportional to the total spin of the cluster, and thus the Kondo temperature drops rapidly as the cluster size increases (Fiete, Zarand, Halperin and Oreg, 2002). Clusters can also have mesoscopic fluctuations of charge and magnetization, leading to asymmetric voltage dependence of the spectroscopic features.

The addition of surface layers of adsorbates between the magnetic impurity and the rest of the surface can change the Kondo features (Hirjibehedin, Lutz and Heinrich, 2006; Schneider *et al*., 2005a), leading to questions of whether the surface Kondo effect primarily concerns just the electrons of the surface states, and to what extent the bulk electrons are involved. Experiments show that the surface/bulk contribution ratio varies to some degree based on the combination of magnetic impurity and surface adsorbate layer, but that primarily the Kondo effect is a bulk effect (Knorr, Schneider and Diekhöner, 2002; Schneider *et al*., 2005b). This has been shown theoretically as well,

using properties of the electronic states of both surface and bulk (Lin, Castro Neto and Jones, 2005).

It seems clear that as theorists explore Kondo Hamiltonians of various symmetries, number of impurities, and channels, interesting NFL fixed points, and intriguing phase diagrams in general, will continue to be found. Likewise atomic manipulation on the STM, structures made with quantum dots, and spins in other low-dimensional systems provide a promising experimental ground for exploring Kondo physics, and even tuning the systems to achieve these special critical points predicted by theory which often need high symmetry. Finally, progress on understanding the phase diagram of the Kondo lattice will proceed on (at least) three fronts: with new theoretical techniques and insightful models, with new materials discoveries with bulk Kondo lattice materials, and with increased sophistication and imaging techniques, both real space and spectroscopy, from the STM, which will someday be able to build and measure a purpose built Kondo lattice.

Orbital Physics in Transition-metal Oxides: Magnetism and Optics

Peter Horsch
Max-Planck-Institut für Festkörperforschung, Stuttgart, Germany

1 INTRODUCTION

Strong correlations in transition-metal oxides (TMO) generate spins and orbitals as low-energy degrees of freedom. Their interplay with both real-charge motion and virtual-charge excitations lead to a fascinating richness of spin–charge–orbital-ordered phases, to striking phenomena like the colossal magnetoresistance (CMR), the switching of charge-ordered phases into metallic phases by applied magnetic fields, and many other fascinating effects (Tokura and Nagaosa, 2000; Tokura, 2003; Imada, Fujimori and Tokura, 1998). The focus of this article is on recent developments while discussions of known concepts are kept short. As compensation the article has a large bibliography.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

In undoped compounds, magnetism is determined via Heisenberg–Anderson superexchange (SE) interactions between spins (Anderson, 1959), which result from virtual-charge excitations. In orbital-degenerate systems, magnetism is controlled by spin-orbital models. These models contain apart from the Heisenberg-like spin dynamics also the quantum dynamics of the orbitals themselves as well as coupled spin-orbital interactions; that is, in addition to the relativistic spin-orbit interaction. In simple terms: Orbitals determine the interactions among spins, while spins determine the interaction between orbitals. In certain cases, the exchange interaction between spins may even fluctuate between ferromagnetic (FM) and antiferromagnetic (AF) if orbitals are dominated by quantum fluctuations. However, this subtle interplay may be controlled or quenched via an interaction with the lattice, like the Jahn–Teller (JT) interaction in $LaMnO_3$ which favors alternating orbitals and thereby selects ferromagnetism in the (a, b) plane and antiferromagnetism along c direction. In fact this is the typical case, that is, magnetism controlled by the Goodenough–Kanamori (GK) rules, where fixed, occupied orbitals determine the magnetic structure. Yet there are other systems which show evidence of the more complex interplay of spin and orbital quantum fluctuations. Candidates discussed here are t_{2g} systems like the cubic titanates and vanadates, and the orbital-Peierls effect in YVO_3.

The study of one-dimensional spin-orbital models has been an active field, stimulated by specific analytic and numerical tools. This has given some important deeper insights into the features of spin-orbital models. Some

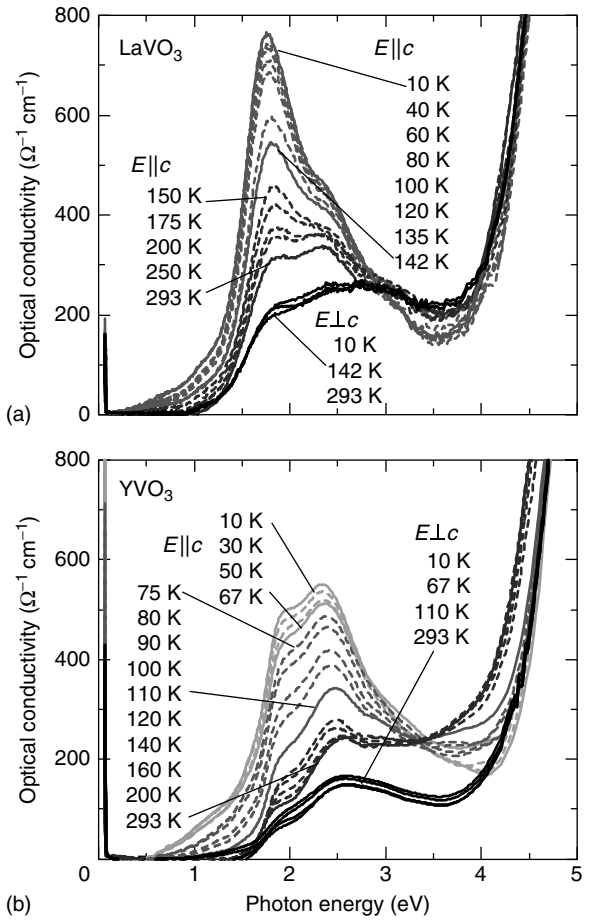

Figure 1. Temperature dependence and anisotropy of optical conductivity of cubic vanadate compounds $LaVO_3$ and YVO_3 reflects the interrelation of spectral weight transfers and magnetic structure (Data reproduced from Miyasaka, Okimoto and Tokura, 2002.) The strong increase of spectral weight for c polarization in the range of the high-spin multiplet transition ($1.5 < \omega < 2.5$ eV) with decreasing temperature reflects the evolution of ferromagnetism along c direction. The strong anisotropy of the basically cubic crystal structure is due to the magnetic anisotropy, that is, the so-called C-type magnetic order with antiferromagnetic correlations in the (ab) plane and ferromagnetism along c.

instructive aspects are described, such as the interplay of orbital and spin correlations in SU(4) and other spin-orbital models, spin-orbital entanglement, and the role of composite spin-orbital fluctuations.

Virtual-charge excitations which determine SE interactions, and thereby magnetism, correspond, on the other hand, to real optical transitions (see Figure 1). This fact provides an important link between the SE energy and the partial sum rules for the different optical multiplet transitions. Thus, the temperature dependence of the optical spectral weights and spectral weight transfers, particularly at phase transitions, are determined by the low-energy spin-orbital model. This leads to the unification of optics and magnetism, that is, in the sense that it allows to combine the interpretation of data obtained by optical spectroscopy and magnetic neutron scattering. Thus it yields important guidance for the further exploration of the electronic structure of TMO.

Finally, key features of the interplay of spin-, charge-, and orbital degrees of freedom in doped TMO are addressed. As examples, some of the complex-ordered phases and the CMR of manganites are discussed. Starting from a generalized orbital-degenerate Kondo-lattice model (KLM) we discuss the double-exchange (DE) interaction and the evidence for the orbital degree of freedom in the intrinsic CMR. Besides, the orbital liquid phase and the complexity of spin-/orbital-ordered phases is touched with a brief discussion of the charge-ordered phases in half-doped manganites.

There is another aspect of general importance and of conceptual novelty. In doped Mott insulators with degenerate or nearly degenerate orbitals charge carriers will move as composite polarons, where the doped holes are not only accompanied (or dressed) by lattice distortions but also by orbital excitations and spin clouds. A particular remarkable example is the orbital polaron in manganites which in combination with spin disorder in the paramagnetic phase offers an explanation for an intrinsic mechanism of CMR.

This field has already a history of about half a century. Its origin is usually connected with the seminal experimental work by Jonker and van Santen (1950) on the magnetotransport of manganites. Subsequently Zener (1951) proposed the DE mechanism and was thereby able to explain the appearance of ferromagnetism and metallicity at moderate doping. The upcoming thermal neutron scattering technique provided deep insight into the magnetic structure. The data obtained in the pioneering neutron work by Wollan and Koehler (1955) was subsequently interpreted by Goodenough, Kanamori, and others (Goodenough, 1955, 1963; Kanamori, 1959). The important insights achieved in those early years, revealed the interplay of magnetic structure and orbital occupation (Pauli principle and Hunds' rule). The insights up to the year 1963 has been summed up by Anderson in an article in 'Magnetism' by Rado and Suhl (Anderson, 1963).

Formally this physics is described by spin-orbital models, which may be interpreted as generalized Heisenberg models, where the magnetic exchange integrals are themselves operators which are controlled by the orbital degrees of freedom. SE models for transition-metal perovskites with partly filled degenerate orbitals have a more complex structure than for nondegenerate orbitals and have been discussed in a seminal review by Kugel and Khomskii (1982a). Such models allow for both AF and FM SE (Kugel and Khomskii, 1982a; Cyrot and Lyon-Caen, 1975; Inagaki, 1975; Castellani, Natoli and Ranninger, 1978). The different contributions to SE results

from the multiplet structure of excited transition metal ions which depends on the Hund's exchange J_H and generates a competition between high-spin and low-spin excitations. The exchange interactions are then intrinsically frustrated *even on a cubic lattice*, which enhances quantum effects both for e_g, (Khaliullin and Oudovenko, 1997; Feiner, Oleś and Zaanen, 1998; Khaliullin and Kilian, 1999; Oleś, Feiner and Zaanen, 2000) and for t_{2g} systems. (Khaliullin and Maekawa, 2000; Khaliullin, 2001; Khaliullin, Horsch and Oleś, 2001). This frustration is partly removed in anisotropic AF phases, which break the cubic symmetry and may lead to dimensionality changes, such as in A-type AF phase realized in $LaMnO_3$, or in C-type AF phase in $LaVO_3$.

The renaissance of orbital physics in the 90th was triggered by the discovery of CMR in the manganites (von Helmolt *et al*., 1993; Jin *et al*., 1994). The experimental and theoretical work on metal–insulator transitions in TMO has been subsequently reviewed by (Imada, Fujimori and Tokura, 1998). CMR has been reviewed by Kaplan and Mahanti (1998) and Tokura (2006) and orbital specific aspects have been addressed by Oleś, Cuoco and Perkins (2000), and Rückamp *et al*. (2005) and Khaliullin (2005). Moreover a number of valuable textbooks have already appeared (Dagotto, 2003; Maekawa *et al*., 2004; Fazekas, 1999).

This chapter describes CMR as an intrinsic phenomenon where the orbital degree of freedom plays a key role. The orbital liquid phase and various spin-, charge-, and orbital-ordered phases are discussed in the framework of theoretical models, such as the orbital degenerated KLM and the orbital $t-J$ model. Although advanced many-body treatment of the quantum physics characteristic for spin-orbital models is required in general, we want to present here simple principles which help to understand the heart of the problem and give some guidelines for interpreting experiments.

This text focuses on the generalization of spin models into spin-orbital models in the case of orbital degeneracy, thereby likewise important developments in the field are not touched. Most importantly the large progress in the field of *ab initio* band-structure methods is not covered. This field has made a significant leap forward through a merger with dynamical mean-field theory (DMFT) (Metzner and Vollhardt, 1989; Georges, Kotliar, Krauth and Rozenberg, 1996; Kotliar and Vollhardt, 2004), which allows to describe the Mott transition, that was out of reach of the traditional density-functional approaches. Still these approaches are not fully *ab initio*, as intermediate multiband Hubbard models need to be defined and then analyzed by help DMFT (Held). Often the more pragmatic LDA + U approach (Anisimov, Zaanen and Andersen, 1991) or the Hartree–Fock method (Solovyev, 2006) are used to compensate for the deficiency of LDA to describe Mott gaps.

2 ORBITAL-DEGENERATE MOTT INSULATORS AND SPIN-ORBITAL MODELS

2.1 Multiband Hubbard model and strong correlations

TMO with integer valence electron number are frequently insulators, that is Mott insulators because of the strong intra-atomic Coulomb interaction, and not because of a gap in the single-particle band structure. Typically this happens when the bandwidth W is smaller than the intraorbital Coulomb matrixelement U. At small hopping t the Mott-insulating state is formed by one single ionic configuration, for example, Mn^{3+} in $LaMnO_3$. All other ionization states are separated by large gaps. Such a state is very distinct from an uncorrelated or Hartree–Fock state where the local charge fluctuates strongly and involves all possible ionization states. In a Mott insulator the neighboring valency, for example, Mn^{2+} in $LaMnO_3$, is suppressed in the wave function by the factor t/U, and Mn^{1+} by $(t/U)^2$. It is this suppression of charge fluctuations and the emergence of the ionic structure which forms the basis of SE, that is, of spin models like the Heisenberg model or in the case of degenerate orbitals the spin-orbital models.

The effective spin-orbital models of TMO with partly filled degenerate orbitals depend in a characteristic way upon those aspects of the electronic structure which decide whether a given strongly correlated system can be classified as a Mott insulator or as a charge transfer (CT) insulator. As suggested in the original classification of Zaanen, Sawatzky and Allen (1985), the energy of the d–p CT excitation Δ has to be compared with the Coulomb interaction U – if $U < \Delta$, the first excitation is at a transition-metal ion and the system is a Mott insulator, otherwise it is a CT insulator. Yet both are strongly correlated insulators, in one limit the dominant virtual excitations are of d–d type, whereas in the other limit they are of p–d type. One may consider this issue more precisely by analyzing the full multiplet structure, and comparing the lowest excitation energy (to a high-spin configuration) *at a transition-metal ion*, $\varepsilon_{HS} = U - 3J_H$, with that of the lowest CT excitation (of energy Δ) *between a transition-metal ion and a ligand ion*. (We note, however, that frequently the average energy of a CT type excitation $\overline{\Delta}$ is considered instead and compared with U.) One can regard a given perovskite as a *charge transfer insulator* if $\varepsilon_{HS} > \Delta$, and as a *Mott–Hubbard insulator* if $\varepsilon_{HS} < \Delta$. By analyzing these parameters it follows that the late TMO may be classified as CT insulators (Imada, Fujimori and Tokura, 1998). In this case, important new contributions to the SE arise (Goodenough, 1963; Zaanen and Oleś, 1988; Eskes

and Jefferson, 1993; Mostovoy and Khomskii, 2004) called *charge transfer terms*. We shall avoid this discussion here, and refer to Oleś, Khaliullin, Horsch and Feiner (2005) for a detailed discussion of CT excitations in $KCuF_3$ and the $LaMnO_3$.

The spin-orbital SE model is an effective low-energy Hamiltonian which allows to discuss excitations on the energy scale $J \sim t^2/U$, such as spin waves and orbital excitations but also polaron formation and transport properties in the doped case. A convenient starting point for the derivation of SE is the multiband Hubbard model for the d-electron bands. First we consider the effective single-particle Hamiltonian operator H_0 for the transition-metal ion states, where the ligand states are integrated out. Hence only the magnetic ions appear explicitly in this formulation:

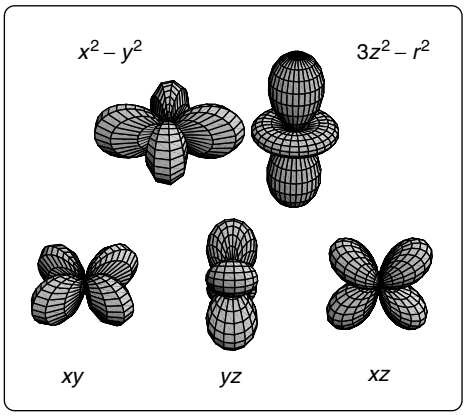
$$H_0 = \sum_{i\alpha\sigma} \varepsilon_{i\alpha} n_{i\alpha\sigma} + \sum_{ij,\alpha,\beta,\sigma} t_{i,j}^{\alpha,\beta} a_{i\alpha\sigma}^{\dagger} a_{j\beta\sigma} \qquad (1)$$

Here $\varepsilon_{i\alpha}$ is the single-particle energy of an electron in orbital α at site i, $n_{i\alpha\sigma}$ is the number operator that determines the number of electrons with spin σ in orbital α at site i. The second term describes the kinetic energy, that is, the hopping of electrons from site j to site i in terms of annihilation and creation operators $a_{j\beta\sigma}$ and $a_{i\alpha\sigma}^{\dagger}$, respectively. $t_{i,j}^{\alpha,\beta}$ are effective hopping elements via ligand orbitals – they depend on the type of considered orbitals, t_{2g} or e_g (Figure 2), as discussed in Andersen, Klose and Nohl (1978) and Zaanen and Oleś (1993), and are proportional to t_{pd}^2/Δ. The energy scale for the hopping is set by the largest hopping element t: the (ddσ) element in case of e_g systems, and the (ddπ) element when only π bonds are considered in systems with degenerate and partly filled t_{2g} orbitals. Whereas the hopping between t_{2g} orbitals is diagonal along the cubic axis, the e_g electrons do have off-diagonal matrix elements. The orientation of the e_g basis orbitals $\{|x\rangle, |z\rangle\} = \{x^2 - y^2, 3z^2 - r^2\}$ is reflected in the transfer matrices that describe the hopping in the (a, b) plane and along the c axis, respectively.

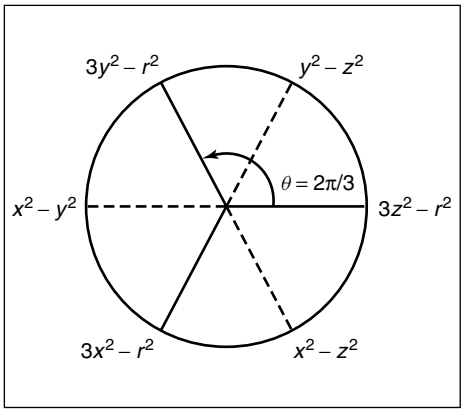
$$t_{ij||a(b)}^{\alpha,\beta} = \frac{t}{4}\begin{pmatrix} 3 & \mp\sqrt{3} \\ \mp\sqrt{3} & 1 \end{pmatrix}, t_{ij||c}^{\alpha,\beta} = t\begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \qquad (2)$$

Here $\mp$ distinguish hopping along the a and b cubic axis. The flexibility to choose the occupied orbital as some linear combination of the two basis orbitals is the underlying reason for the large flexibility of e_g systems to form complex orbital and spin-ordered patterns. The orbital state at site i:

$$|\theta\rangle = \cos\left(\frac{\theta}{2}\right)|z\rangle + \sin\left(\frac{\theta}{2}\right)|x\rangle \qquad (3)$$



(a)



(b)

Figure 2. (a) In a cubic crystal field the degeneracy of d orbitals is lifted. The energy of the e_g orbitals ($x^2 - y^2$ and $3z^2 - r^2$) is higher than the t_{2g} subgroup (xy, yx, zy) because the lobes of e_g orbitals at the transition metal A point toward the negative O ions in the AO_6 octahedra, whereas the t_{2g} orbitals point in between. (b) Schematic representation of states that can be obtained from the two e_g basis states by linear combination (rotation by angle θ, see equation (3)).

is here parameterized by an angle θ which defines the amplitudes of the orbital states

$$|z\rangle \equiv (3z^2 - r^2)/\sqrt{6}, \quad |x\rangle \equiv (x^2 - y^2)/\sqrt{2} \qquad (4)$$

being a local e_g orbital basis at each site. This remarkable flexibility offers the possibility to lower the dimensionality and to optimize thereby the SE energy, or in doped systems the kinetic energy.

For noninteracting electrons the Hamiltonian H_0 would lead to tight-binding bands, but in a Mott insulator the large Coulomb interaction U suppresses charge excitations in the regime of $U \gg t$. Thus for integer electron number per transition-metal ion the hopping elements can

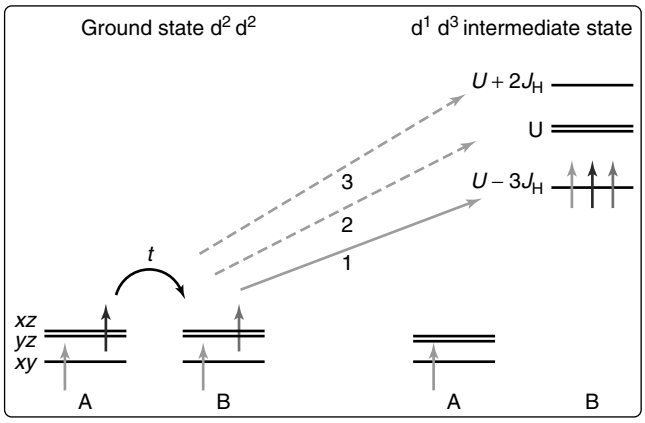


Figure 3. Sketch of superexchange (charge) excitations $\mathrm{d}_i^2\mathrm{d}_j^2 \rightarrow \mathrm{d}_i^3\mathrm{d}_j^1$ between two $S = 1$ V^{2+} ions. Because of Hund's rule the high-spin multiplet state (of the d^3 ion) is the lowest intermediate state ($U - 3J_\mathrm{H}$). Along c direction only xz and yz orbital have finite hopping matrix elements. With one electron in xy due to crystal-field splitting, the remaining electron of ion A is either in xz or yz and can form an orbital singlet with its neighbor B, while spins align ferromagnetically, and thereby profit from the virtual transition into the high-spin state at $U - 3J_\mathrm{H}$.

only contribute via virtual excitations, leading to the SE (Figure 3).

The SE in the 3d *cubic* systems with orbital degeneracy is described by spin-orbital models, which arise from virtual-charge excitations between two neighboring transition-metal ions, $\mathrm{d}_i^m\mathrm{d}_j^m \rightleftharpoons \mathrm{d}_i^{m+1}\mathrm{d}_j^{m-1}$, which involve an increase of energy owing to the Coulomb interactions. Such transitions are mediated by the ligand orbitals between the two ions and have the same roots as the SE in a Mott insulator with nondegenerate orbitals (Anderson, 1959). Their multiplet structure depends on the involved ionic configurations and the strength of the Hund coupling J_H. The relevant multiplet energies have to be determined by analyzing the eigenstates of the local Coulomb interactions H_int, where $H = H_0 + H_\mathrm{int}$ is the multiband Hubbard Hamiltonian:

$$\begin{aligned} H_\mathrm{int} = {} & U\sum_{i\alpha} n_{i\alpha\uparrow}n_{i\alpha\downarrow} \\ & + \sum_{i,\alpha<\beta}\Big(U_{\alpha\beta} - \frac{1}{2}J_{\alpha\beta}\Big)n_{i\alpha}n_{i\beta} - 2\sum_{i,\alpha<\beta} J_{\alpha\beta}\mathbf{S}_{i\alpha}\cdot\mathbf{S}_{i\beta} \\ & + \sum_{i,\alpha<\beta} J_{\alpha\beta}\Big(\mathrm{d}^\dagger_{i\alpha\uparrow}\mathrm{d}^\dagger_{i\alpha\downarrow}\mathrm{d}_{i\beta\downarrow}\mathrm{d}_{i\beta\uparrow} + \mathrm{d}^\dagger_{i\beta\uparrow}\mathrm{d}^\dagger_{i\beta\downarrow}\mathrm{d}_{i\alpha\downarrow}\mathrm{d}_{i\alpha\uparrow}\Big) \end{aligned} \quad (5)$$

with $\overline{\sigma} = -\sigma$. The multiplet structure depends in the general case on three Racah parameters A, B, and C (Griffith, 1971). In solids these parameters are screened and therefore smaller than the tabulated atomic values (Griffith, 1971). Whereas the intraorbital Coulomb element

$$U = A + 4B + 3C \quad (6)$$

is identical for all 3d orbitals, the interorbital Coulomb and exchange elements, $U_{\alpha\beta}$ and $J_{\alpha\beta}$, are anisotropic and depend on the involved pair of orbitals; the values of $J_{\alpha\beta}$ are given in Table 1. The Coulomb and exchange elements are related to the intraorbital element U by a relation which guarantees the invariance of interactions under rotation in the orbital space,

$$U = U_{\alpha\beta} + 2J_{\alpha\beta} \quad (7)$$

In cases where only the orbitals of one type ($\mathrm{e_g}$ or $\mathrm{t_{2g}}$) are partly filled, as, for example, in the titanates, vanadates, or copper fluorides, all relevant exchange elements $J_{\alpha\beta}$ are the same (see Table 1) and one may use a simplified form of on-site interactions (Oleś, 1983)

$$\begin{aligned} H_\mathrm{int}^{(0)} = {} & U\sum_{i\alpha} n_{i\alpha\uparrow}n_{i\alpha\downarrow} + \Big(U - \frac{5}{2}J_\mathrm{H}\Big)\sum_{i,\alpha<\beta} n_{i\alpha}n_{i\beta} \\ & + J_\mathrm{H}\sum_{i,\alpha<\beta}\Big(\mathrm{d}^\dagger_{i\alpha\uparrow}\mathrm{d}^\dagger_{i\alpha\downarrow}\mathrm{d}_{i\beta\downarrow}\mathrm{d}_{i\beta\uparrow} + \mathrm{d}^\dagger_{i\beta\uparrow}\mathrm{d}^\dagger_{i\beta\downarrow}\mathrm{d}_{i\alpha\downarrow}\mathrm{d}_{i\alpha\uparrow}\Big) \\ & - 2J_\mathrm{H}\sum_{i,\alpha<\beta}\mathbf{S}_{i\alpha}\cdot\mathbf{S}_{i\beta} \end{aligned} \quad (8)$$

with only two parameters: the intraorbital Coulomb (or Hubbard) interaction parameter U (6) and the Hund's coupling J_H, being $4B + C$ for $\mathrm{e_g}$ and $3B + C$ for $\mathrm{t_{2g}}$ systems, respectively. However, when both types of orbitals are partly filled (as in the manganites) and therefore both participate in charge excitations, the Hamiltonian (8) is only approximate, and the full excitation spectra of the transition-metal ions (Griffith, 1971) which follow from equation (5) have to be used instead. A few examples of spectra for $\mathrm{d}_i^m\mathrm{d}_j^m \rightleftharpoons \mathrm{d}_i^{m+1}\mathrm{d}_j^{m-1}$ charge excitations at transition-metal ions are shown in Figure 4. As a universal feature, the high-spin excitation is found at energy $U - 3J_H$ in all cases, provided that

Table 1. On-site interorbital exchange elements $J_{\alpha\beta}$ for 3d orbitals as functions of the Racah parameters B and C (for more details see Griffith, 1971).

Orbital	xy	yz	zx	x^2-y^2	$3z^2-r^2$
xy	0	$3B+C$	$3B+C$	C	$4B+C$
yz	$3B+C$	0	$3B+C$	$3B+C$	$B+C$
zx	$3B+C$	$3B+C$	0	$3B+C$	$B+C$
x^2-y^2	C	$3B+C$	$3B+C$	0	$4B+C$
$3z^2-r^2$	$4B+C$	$B+C$	$B+C$	$4B+C$	0

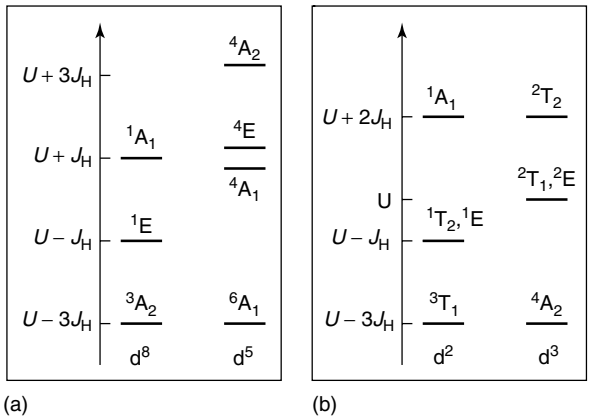

Figure 4. Energies of $d_i^m d_j^m \rightarrow d_i^{m+1} d_j^{m-1}$ charge excitations in selected cubic transition-metal oxides, as obtained from equation (8) for: (a) e_g excitations of Cu^{3+} (d^8) and Mn^{2+} (d^5) ions (in the d^5 case the spectrum was obtained from equation (5)); (b) t_{2g} excitations of Ti^{2+} (d^2) and V^{2+} (d^3) ions. The splittings between different states are due to Hund's exchange element J_H which refers to a pair of e_g electrons in (a), and to a pair of t_{2g} electrons in (b), respectively. (Reproduced from Oles *et al*., 2005, with permission from the American Physical Society. © 2005.)

J_H is understood as Hund's exchange for that partly filled manifold (e_g or t_{2g}) of degenerate d orbitals which participate in charge excitations. The structure of the excited states depends on the partly occupied orbitals (Fractional contributions due to exchange terms $\propto J_H$ shown in the spectrum for the d^5 case (see Figure 4a) follow from the differences between the exchange elements $J_{\alpha\beta}$ in Hamiltonian $H_{\rm int}$ (5) (see Table 1), and were obtained using the relation $C \simeq 4B$ satisfied approximately by the experimental values for Mn^{2+} ions (Zaanen and Sawatzky, 1990) and on the actual valence m – the distance between the high-spin and low-spin excitations increases with the number of electrons for $m \leq 5$ (holes for $m > 5$).

2.2 Superexchange at orbital degeneracy

At orbital degeneracy the SE which connects ions at sites i and j along the bond $\langle ij \rangle$ involves orbital operators which depend on the bond direction. Therefore, it is useful to introduce the index $\gamma = a, b, c$ to label the three *a priori* equivalent directions in a cubic crystal. In order to analyze the consequences of each individual charge excitation n that contributes to the SE in a given transition-metal compound with degenerate d orbitals, we shall use below a general way of writing the effective low-energy Hamiltonian as a superposition of such individual terms on each bond $\langle ij \rangle$,

$$\mathcal{H}_U = \sum_n \sum_{\langle ij \rangle \| \gamma} H_n^{(\gamma)}(ij) \tag{9}$$

with the energy unit (absorbed in individual $H_n^{(\gamma)}(ij)$ terms) given by the SE constant,

$$J = \frac{4t^2}{U} \tag{10}$$

It follows from d−d charge excitations with an effective hopping element t between transition-metal ions, and is the same as that obtained in a Mott insulator with nondegenerate orbitals in the regime of $U \gg t$ (Anderson, 1959).

In the SE Hamiltonian equation (9) the contributions which originate from all possible virtual excitations $d_i^m d_j^m \rightleftharpoons d_i^{m+1} d_j^{m-1}$ just add up to the total SE interaction, in which the individual terms cannot be distinguished. Yet each of these excitations involves a different state in the multiplet structure of at least one of the transition-metal ions, that is, either in the d^{m+1} or in the d^{m-1} configuration or in both, depending on the actual process and on the value of m. The same multiplet transitions also appear in the optical spectra. As pointed out in Khaliullin, Horsch and Oleś (2004), this fact can be used to calculate from the low-energy spin-orbital model the spectral weights of the individual transitions that occur at energies of several electron volts.

The generic structure of each individual SE contribution is for a bond $\langle ij \rangle$ given by

$$\begin{aligned} H_n^{(\gamma)}(ij) &= (a_n + b_n \mathbf{S}_i \cdot \mathbf{S}_j) Q_n^{(\gamma)}(\boldsymbol{\tau}_i, \boldsymbol{\tau}_j) \\ &= a_n Q_n^{(\gamma)}(\boldsymbol{\tau}_i, \boldsymbol{\tau}_j) + b_n Q_n^{(\gamma)}(\boldsymbol{\tau}_i, \boldsymbol{\tau}_j) \mathbf{S}_i \cdot \mathbf{S}_j \end{aligned} \tag{11}$$

where the orbital dependence of the SE is described by means of orbital projection operators $Q_n^{(\gamma)}$ which in the cases discussed here can be expressed in terms of components of orbital pseudospin $T = 1/2$ operators $\boldsymbol{\tau}_i, \boldsymbol{\tau}_j$ at sites i and j. The coefficients a_n and b_n, which measure the strength of the pure orbital part and of the spin and orbital part of the SE, respectively, follow from second-order perturbation theory involving the charge excitation n. In the case of perovskites, where the bond between two transition-metal ions through the ligand ion (F or O) connecting them is close to linear (180°), the coefficients a_n and b_n are of similar magnitude (in contrast to the situation in layered compounds like $LiNiO_2$ with 90° bonds where the pure orbital interaction is stronger by an order of magnitude than the spin and orbital interaction (Mostovoy and Khomskii, 2002; Reitsma, Feiner and Oleś, 2005).

Spin-orbital models have been derived for a number of TMOs, and we refer for the details of such derivations and further reference to the original literature: $KCuF_3$, La_2CuO_4 (Oleś, Feiner and Zaanen, 2000; Oleś, 2003, 2005), $LaTiO_3$ (Khaliullin and Maekawa, 2000; Khaliullin, 2001; Aharony *et al*., 2005), $LaVO_3$ (Khaliullin, Horsch and Oleś, 2001), $LiVO_2$ (Pen, van den Brink, Khomskii and Sawatzky,

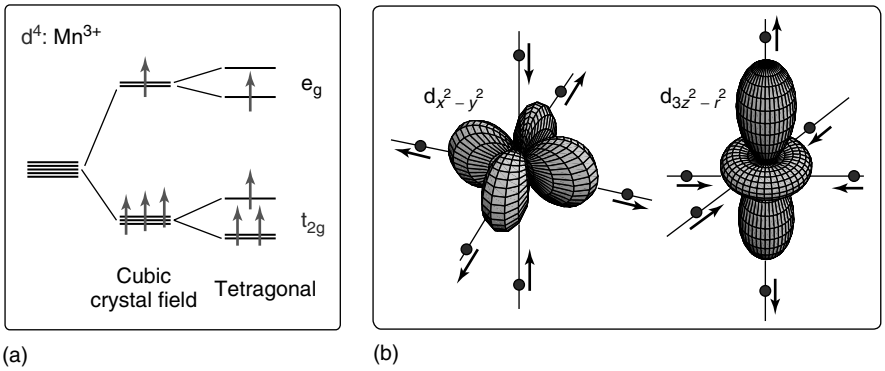

Figure 5. (a) Splitting of d-orbitals in a cubic crystal field ($\Delta E = 10Dq$) and the further splitting of e_g and t_{2g} orbitals in a tetragonal field. The parallel alignment of spins in the $d^4(S = 2)$ configuration of Mn^{3+} is dictated by the strong Hund coupling J_H. (b) Tetragonal symmetry where the oxygen octahedron is elongated (squeezed) along c direction favors the $d_{3z^2-r^2}$ ($d_{x^2-y^2}$) orbital, respectively.

1997), NaV_2O_5 (Mostovoy and Khomskii, 2000; Cuoco, Horsch and Mack, 1999), V_2O_3 (Shiina, Mila, Zhang and Rice, 2001; Di Matteo, Jackeli, Lacroix and Perkins, 2004; Di Matteo, Jackeli and Perkins, 2005), $LaMnO_3$ (Ishihara, Inoue and Maekawa, 1997; Shiina, Nishitani and Shiba, 1997; Feiner and Oleś, 1999), $LiNiO_2$ (Mostovoy and Khomskii, 2002; Reitsma, Feiner and Oleś, 2005; Vernay, Penc, Fazekas and Mila, 2004), the isoelectronic ruthenate alloy $Ca_{2-x}Sr_xRuO_4$ (Sigrist and Troyer, 2004), and the layered cobalt oxides Na_xCoO_2 (Khaliullin, Koshibae and Maekawa, 2004; Khaliullin, 2005).

2.3 Effective spin model and spin waves

Here, we consider systems having cubic symmetry at high temperature. Yet often already at rather high temperature this symmetry is spontaneously broken – usually driven by the joint effect of (i) the orbital part of the SE interaction, and (ii) the JT coupling of the same degenerate (and therefore JT active) 3d orbitals to lattice modes. The result is a simultaneous onset of a macroscopic lattice distortion and of orbital order (OO), that is, a cooperative JT effect. At temperatures well below the transition temperature T_s of this combined structural and orbital ordering phase transition the OO is effectively frozen, and the SE interactions between the spins may then be obtained by replacing the orbital projection operators in equation (9) by their expectation values,

$$Q_n^{(\gamma)}(\boldsymbol{\tau}_i, \boldsymbol{\tau}_j) \longrightarrow \langle Q_n^{(\gamma)}(\boldsymbol{\tau}_i, \boldsymbol{\tau}_j)\rangle = Q_n^{(\gamma)}(\langle\boldsymbol{\tau}_i\rangle, \langle\boldsymbol{\tau}_j\rangle) \quad (12)$$

Obviously, this leads to anisotropic magnetic interactions,

$$H_s = J \sum_n \sum_{\langle ij\rangle\|\gamma} b_n \langle Q_n^{(\gamma)}\rangle \, \mathbf{S}_i \cdot \mathbf{S}_j \quad (13)$$

which will in general induce a further magnetic phase transition at lower temperature. It is noteworthy that in this situation the spin degrees of freedom get decoupled from the orbital degrees of freedom, although the pure orbital (a_n) and spin and orbital (b_n) SE terms are of similar strength. Responsible for this behavior is the JT contribution to the structural phase transition, which enhances T_s above the value it would have if the transition were driven by orbital SE alone. A typical case is $LaMnO_3$ which shows OO below a structural transition at $T_s \sim 780$ K (Murakami *et al.*, 1998).

Thus starting from the microscopic spin-orbital SE model we arrive at low temperature, that is, in the orbital-ordered state, at an effective Heisenberg spin model. Rewritten from equation (13), its generic form is:

$$H_s = J_c \sum_{\langle ij\rangle_c} \mathbf{S}_i \cdot \mathbf{S}_j + J_{ab} \sum_{\langle ij\rangle_{ab}} \mathbf{S}_i \cdot \mathbf{S}_j \quad (14)$$

with two different effective magnetic exchange interactions: J_c along the c axis, and J_{ab} within the ab planes. The latter J_{ab} interactions could in principle still take two different values in case of inequivalent lattice distortions (caused, e.g., by octahedra tilting or pressure effects) making the a and b axes inequivalent. Here, we shall limit the discussion to idealized structures with these two axes being equivalent. The resulting spin–spin correlations along the c axis and within the ab planes,

$$s_c = \langle \mathbf{S}_i \cdot \mathbf{S}_j\rangle_c, \quad s_{ab} = \langle \mathbf{S}_i \cdot \mathbf{S}_j\rangle_{ab} \quad (15)$$

play, as we shall see below, an important role for the interpretation of the optical conductivity data, its anisotropy and its temperature dependence.

2.4 Spin-orbital models: two examples

2.4.1 t_{2g} systems $LaVO_3$ and YVO_3

The orientation of ferromagnetically aligned magnetic moments can be reversed in a sufficiently large magnetic field pointing in the opposite direction. This property is the basis of magnetic recording and storage devices. The cubic vanadate YVO_3 compound shows a very peculiar temperature induced magnetization reversal as reported by Ren *et al.* (1998). Actually there are two reversals in this compound, one at 77 K connected with a first-order structural phase transition. Upon heating the value of the magnetization decreases linearly and leads to another sign change at about ∼95 K. In these compounds, the net magnetic moment results from a tilting of the antiferromagnetically aligned moments of the $(S = 1)$ V^{3+} ions.

The SE in cubic vanadates originates from virtual-charge excitations, $d_i^2 d_j^2 \to d_i^3 d_j^1$, by the hopping t which couples pairs of identical orbitals. As shown in Figure 4 there are three multiplet levels $n = 1, 2, 3$ arising from the transitions to: (i) a high-spin state $^4A_2$ at energy $U - 3J_H$, (ii). two degenerate low-spin states $^2T_1$ and ^2E at U, and (iii) $^2T_2$ low-spin state at $U + 2J_H$. When all processes are analyzed and collected on individual bonds $\langle ij \rangle \parallel \gamma$ along each cubic axis $\gamma = a, b, c$, one finds the spin-orbital Hamiltonian for $S = 1$ spins $(J = 4t^2/U)$ (Khaliullin, Horsch and Oleś, 2001),

$$\mathcal{H} = J \sum_{\gamma} \sum_{\langle ij \rangle \parallel \gamma} \left[\frac{1}{2} (\mathbf{S}_i \cdot \mathbf{S}_j + 1) \hat{J}_{ij}^{(\gamma)} + \hat{K}_{ij}^{(\gamma)} \right] + H' \quad (16)$$

where the orbital operators $\hat{J}_{ij}^{(\gamma)}$ and $\hat{K}_{ij}^{(\gamma)}$ depend on the pseudospin $\tau = 1/2$ operators $\boldsymbol{\tau}_i = \{\tau_i^x, \tau_i^y, \tau_i^z\}$, given by two orbital flavors active along a given direction γ. For instance, yz and zx orbitals are active along c axis, and we label them as a and b, as they lie in the planes orthogonal to these axes. The c (xy) orbitals, on the other hand, have no finite hopping matrixelements $t_{i,j}^{\alpha,\beta}$ along c direction and are therefore inactive on such bonds. H' stands for other relevant (non-SE) interactions, to be discussed later. The general form of the SE (11) was discussed before, and has cubic symmetry in the orbital sector.

There is structural evidence that c (xy) orbitals are shifted to lower energies at the structural transition T_s (Mahajan, Johnston, Torgeson and Borsa, 1992; Noguchi *et al.*, 2000; Ren *et al.*, 2000; Blake *et al.*, 2001, 2002). In YVO_3 the latter occurs at ∼200 K; the subsequent magnetic transitions into the magnetic C (G phase) are at 114(77) K, respectively (Figure 6). $LaVO_3$ has only a C phase with $T_N = 140$ K. Hence, the cubic symmetry is broken and it is assumed that the xy orbitals are occupied $(n_{ic} = 1)$. Actually, this is also concluded from electronic structure calculations (Sawada, Hamada, Terakura and Asada, 1996). The electron densities in a and b orbitals satisfy the local constraint $n_{ia} + n_{ib} = 1$ and therefore can fluctuate along the c direction. Whereas along $a(b)$ direction orbital fluctuations are inhibited because of the occupied xy orbitals. This leads to a dramatic anisotropy of magnetic properties, which are always AF along $a(b)$ directions but can be strongly FM along c, due to orbital-singlet fluctuations.

The exchange constants are now operators depending on the orbital degrees of freedom (which are expressed in the present case by spin-1/2 pseudospin operators controlling the two active orbitals along each Cartesian direction). The interactions along the c axis are expressed as:

$$\hat{J}_{ij}^{(c)} = (1 + 2R)\left(\boldsymbol{\tau}_i \cdot \boldsymbol{\tau}_j + \frac{1}{4}\right) - r\left(\boldsymbol{\tau}_i \otimes \boldsymbol{\tau}_j + \frac{1}{4}\right) - R \quad (17)$$

$$\hat{K}_{ij}^{(c)} = R\left(\boldsymbol{\tau}_i \cdot \boldsymbol{\tau}_j + \frac{1}{4}\right) + r\left(\boldsymbol{\tau}_i \otimes \boldsymbol{\tau}_j + \frac{1}{4}\right) \quad (18)$$

they involve the fluctuations of a and b orbitals $\propto \boldsymbol{\tau}_i \cdot \boldsymbol{\tau}_j$, and $\boldsymbol{\tau}_i \otimes \boldsymbol{\tau}_j = \tau_i^x \tau_j^x - \tau_i^y \tau_j^y + \tau_i^z \tau_j^z$. The interactions along the $\gamma = a(b)$ axis depend on the static correlations $\propto n_{ib} n_{jb}$ $(n_{ia} n_{ja})$ only; for instance:

$$\hat{J}_{ij}^{(a)} = \frac{1}{2}\Big[(1 - r)(1 + n_{ib} n_{jb}) - R(n_{ib} - n_{jb})^2\Big] \quad (19)$$

$$\hat{K}_{ij}^{(a)} = \frac{1}{2}(R + r)(1 + n_{ib} n_{jb}). \quad (20)$$

The Hund's exchange $\eta = J_H/U$ determines the multiplet structure of d^3 excited states which enters via the coefficients: $R = \eta/(1 - 3\eta)$ and $r = \eta/(1 + 2\eta)$. The pseudospin operators in equations (17–18) may be represented by Schwinger bosons: $\tau_i^x = \frac{1}{2}(a_i^\dagger b_i + b_i^\dagger a_i)$, $\tau_i^y = \frac{1}{2} i (a_i^\dagger b_i - b_i^\dagger a_i)$, $\tau_i^z = \frac{1}{2}(n_{ia} - n_{ib})$.

To develop some deeper insight, we consider the limit of vanishing Hund coupling $J_H \to 0$. In this case, the d^3-multiplet splitting shrinks to zero and the SE expression becomes SU(2) symmetric also in the orbital sector:

$$\mathcal{H}_0 = \frac{1}{2} J \sum_{\langle ij \rangle \parallel c} (\mathbf{S}_i \cdot \mathbf{S}_j + 1) \left(\boldsymbol{\tau}_i \cdot \boldsymbol{\tau}_j + \frac{1}{4} n_i n_j\right)^{(c)} \quad (21)$$

where a constant energy of $-2J$ per V^{3+} ion is neglected, and also the coupling in the (a, b) plane is dropped for the moment.

To understand why orbital fluctuations along c direction support FM order it is instructive to consider $\mathcal{H}_0$ with all spins ferromagnetically aligned. The remaining orbital model is a spin-1/2 Heisenberg chain with the known Bethe

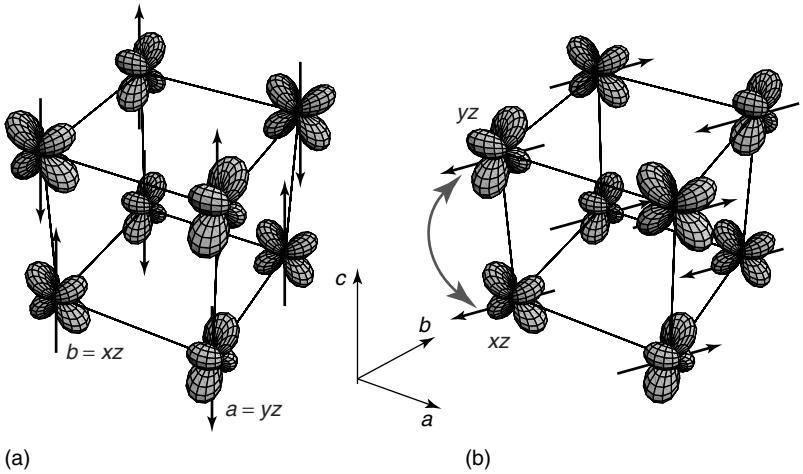

Figure 6. Orientation of occupied t_{2g} orbitals in: (a) the magnetic G type and orbital C type low-temperature structure of YVO_3 and (b) the magnetic C (orbital G) type low-temperature structure of $LaVO_3$. ($S = 1$ spins are indicated by black arrows.) For the C phase a double-side arrow indicates the fluctuating orbital occupation between $a = yz$ and $b = xz$ orbitals along the c direction. A second vanadium t_{2g} electron occupies the xy orbital ($n_c = 1$) at each vanadium ion and is not shown. The occupied xy orbital suppresses orbital fluctuations in the (a, b) plane.

ansatz result $\langle \boldsymbol{\tau_i} \cdot \boldsymbol{\tau_{i+1}} \rangle = -0.443$, that is, for the nearest-neighbor correlation function in the singlet ground state. Owing to the orbital quantum fluctuations this yields a very low energy per bond $E = -0.193J$. It should be noted that for a classical alternating orbital state $\langle \boldsymbol{\tau_i} \cdot \boldsymbol{\tau_{i+1}} \rangle = -1/4$, thus $J_{i,j}^{(c)} = 0$! That is, quantum fluctuations are essential for the ferromagnetism.

Yet surprisingly, the ground state of $\mathcal{H}_0$ is an orbital dimer state or orbital valence bond (OVB) state with energy $E_0 = -0.25J$ per bond. In the OVB state orbital singlets appear together with spin pairs coupled into a $S = 2$ state, the AF arrangement leads to basically decoupled pairs (see Figure 7). Therefore, the system can profit from the orbital dimer energy $\langle \boldsymbol{\tau_i} \cdot \boldsymbol{\tau_{i+1}} \rangle = -3/4$ on each second bond. That is, in the $\eta = 0$ case, the local dimers win over the global singlet. It requires finite Hund coupling J_H to stabilize the C phase (Horsch, Khaliullin and Oleś, 2003) (see Figure 7).

Next we consider the reasons for the stability of the G phase in YVO_3. Unlike $LaVO_3$ with almost equal V–V bonds, this compound crystallizes in the distorted structure (Goodenough, 1955; Kawano, Yoshizawa and Ueda, 1994), indicating that the JT effect plays a significant role. It was suggested that energy may be gained due to C-type orbital ordering, with a and b orbitals staggered in (a, b) planes and repeated along c axis, while $n_{ic} = 1$ (Ren *et al.*, 2000; Mizokawa, Khomskii and Sawatzky, 1999; Sawada and Terakura, 1998). Such ordering can be promoted by Khaliullin, Horsch and Oleś (2001)

$$H_{\rm JT} = -2V \sum_{\langle ij \rangle \| c} \tau_i^z \tau_j^z + V \sum_{\langle ij \rangle \| (a,b)} \tau_i^z \tau_j^z \qquad (22)$$

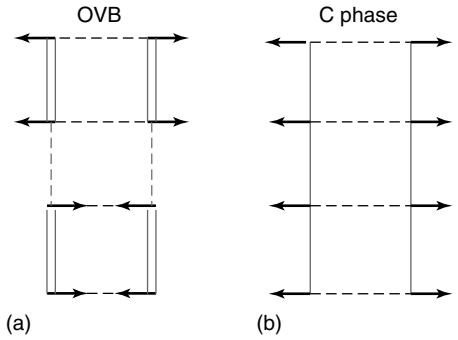

Figure 7. (a) Orbital valence bond (OVB) ground state of $\mathcal{H}_0$, equation (21), consists of orbital singlets (double line). The resulting FM coupling leads to a coupling of pairs of spin 1 into $S = 2$ spin pairs. These are only marginally coupled because of weak AF correlations between dimers. (b) FM aligned $S = 1$ spins lead to a global orbital-singlet state (solid line). Weak AF coupling between different chains along c is indicated by dashed lines.

and competes with the orbital disorder. This behavior is remarkably different from the e_g systems, where the JT effect and SE support each other, inducing orbital ordering (Kugel and Khomskii, 1982a,b; Tokura and Nagaosa, 2000; Oleś, Feiner and Zaanen, 2000). Although $V > 0$ causes orbital splitting by $4V$ and thus lowers the energy of the G phase (E_G), it has little effect on the energy of the C phase.

2.4.2 *e_g system $LaMnO_3$*

Although e_g and t_{2g} electrons behave quite differently in $LaMnO_3$ and are frequently treated as two subsystems, (Dagotto, Hotta and Moreo, 2001; Dagotto, 2003, 2005)

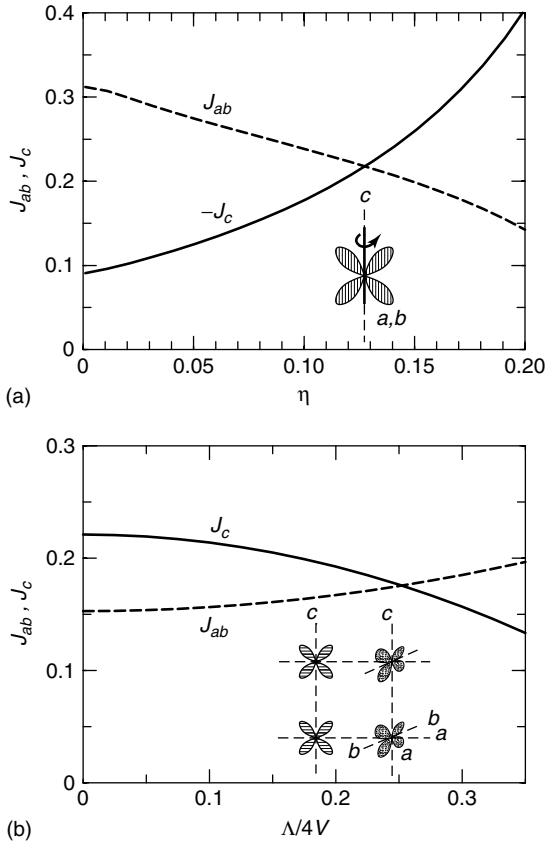

Figure 8. Magnetic exchange couplings J_c and J_{ab} (in units of J): (a) as function of Hund-coupling strength η in the C phase of $LaVO_3$ and YVO_3 with large ferromagnetic J_c due to strong orbital fluctuations along c direction. The inset indicates the fluctuation of $a(b)$ orbital occupancy. (b) Exchange constants in the G-antiferromagnetic low-temperature phase of YVO_3 versus relativistic spin-orbit coupling Λ/V. Inset shows the corresponding C-orbital structure. (Reproduced from Klhallili *et al*., 2001, with permission from the American Physical Society. © 2001.)

the neutron experiments (Hirota, Kaneko, Nishizawa and Endoh, 1996; Moussa, Hennion and Rodríguez-Carvajal, 1996; Biotteau *et al*., 2001) which measure the spin waves in the A−AF phase below T_N leave no doubt that an adequate description of the magnetic properties requires a magnetic Hamiltonian of the form given by equation (14), describing SE between total $S = 2$ spins of the Mn^{3+} ions. The high-spin ^5E ground state at each Mn^{3+} ion is stabilized by the large Hund's exchange J_H. The situation is more complex than in the vanadate system discussed before. The SE terms between Mn^{3+} ions originate from various $d_i^4 d_j^4 \rightleftharpoons d_i^5 d_j^3$ charge excitations, which can originate from transitions of both e_g or t_{2g} electrons. This leads to different excited states in the intermediate d^5 configuration on a $Mn^{2+}(d_i^5)$ ion. Such processes determine the U term $\mathcal{H}_U(d^4)$ defined by equation (9), and were analyzed in detail in (Feiner and Oleś, 1999), and lead to the structure of $\mathcal{H}_U(d^4)$ given below. However, the CT processes, $\mathcal{H}_\Delta(d^4)$, contribute as well and the complete model for $LaMnO_3$ reads

$$\mathcal{H}(d^4) = \mathcal{H}_U(d^4) + \mathcal{H}_\Delta(d^4) \tag{23}$$

The SE constant J is here defined again by equation (10), using an average hopping element along an effective $(dd\sigma)$ bond, $t = t_{pd}^2/\overline{\Delta}$, where $\overline{\Delta}$ is an average CT excitation energy.

We consider here only the more important U terms, $\mathcal{H}_U(d^4)$, due to excitations of e_g electrons (see Figure 4), and refer to Oleś, Khaliullin, Horsch and Feiner (2005) for a discussion of the CT contributions for $LaMnO_3$. The energies of the five possible excited states: Griffith (1971) (i) the high-spin $^6A_1$ state ($S = 5/2$), and (ii–v) the low-spin ($S = 3/2$) states: $^4A_1$, ^4E ($^4E_\epsilon$, $^4E_\theta$), and $^4A_2$, will be parameterized again by the intraorbital Coulomb element U (6), and by Hund's exchange J_H between a pair of e_g electrons. The energies of the excited states are given in terms of the Racah parameters in Griffith (1971); in order to parameterize this spectrum by J_H we apply an approximate relation $4B \simeq C$ which holds for the spectroscopic values of the Racah parameters for a Mn^{2+} (d^5) ion: (Zaanen and Sawatzky, 1990; Bocquet *et al*., 1992) $B = 0.107\,\text{eV}$ and $C = 0.477\,\text{eV}$. One finds then the excitation spectrum: $U - 3J_H$, $U + 3J_H/4$, $U + 5J_H/4$, $U + 5J_H/4$, and $U + 13J_H/4$ (Figure 4a). Unlike J_H, the value of U is known with less accuracy – hence one may use it as a parameter which can be deduced *a posteriori* from the SE J which is able to explain the experimental values for two exchange constants responsible for the A−AF phase observed in $LaMnO_3$ well below the structural transition (here again $T_N \ll T_s$).

Using the spin algebra (Clebsch–Gordon coefficients), and making a rotation of the terms derived for a bond $\langle ij \rangle \parallel c$ to the other two cubic axes a and b, one finds five contributions to $\mathcal{H}_U(d^4)$ due to different $(t_{2g}^3 e_g^1)_i (t_{2g}^3 e_g^1)_j \rightleftharpoons (t_{2g}^3 e_g^2)_i (t_{2g}^3)_j$ excitations by e_g electrons (Feiner and Oleś, 1999). In the following we shall drop the index U and denote the individual multiplet contributions $H_n^{(\gamma)}$:

$$H_1^{(\gamma)} = -\frac{J}{20} r_1 \left(\mathbf{S}_i \cdot \mathbf{S}_j + 6\right)\left(\frac{1}{4} - \tau_i^{(\gamma)} \tau_j^{(\gamma)}\right) \tag{24}$$

$$H_2^{(\gamma)} = \frac{3J}{160} r_2 \left(\mathbf{S}_i \cdot \mathbf{S}_j - 4\right)\left(\frac{1}{4} - \tau_i^{(\gamma)} \tau_j^{(\gamma)}\right) \tag{25}$$

$$H_3^{(\gamma)} = \frac{J}{32} r_3 \left(\mathbf{S}_i \cdot \mathbf{S}_j - 4\right)\left(\frac{1}{4} - \tau_i^{(\gamma)} \tau_j^{(\gamma)}\right) \tag{26}$$

$$H_4^{(\gamma)} = \frac{J}{32} r_4 \left(\mathbf{S}_i \cdot \mathbf{S}_j - 4\right)\left(\frac{1}{2} - \tau_i^{(\gamma)}\right)\left(\frac{1}{2} - \tau_j^{(\gamma)}\right) \tag{27}$$

$$H_5^{(\gamma)} = \frac{J}{32} r_5 \left(\mathbf{S}_i \cdot \mathbf{S}_j - 4\right)\left(\frac{1}{2} - \tau_i^{(\gamma)}\right)\left(\frac{1}{2} - \tau_j^{(\gamma)}\right) \tag{28}$$

The orbital operators $\tau_i^{(\gamma)}$ depend on the direction of a considered bond $\langle ij \rangle$, and are given by

$$\tau_i^{(ab)} = -\frac{1}{4}\left(\sigma_i^z \mp \sqrt{3}\sigma_i^x\right), \tau_i^{(c)} = \frac{1}{2}\sigma_i^z \qquad (29)$$

where σ_i^z and σ_i^x are Pauli matrices acting on the orbital pseudospins and the signs $\pm$ in $\tau_i^{(ab)}$ correspond to a and b axis, respectively. The coefficients

$$r_1 = \frac{1}{1-3\eta}, \quad r_2 = \frac{1}{1+3\eta/4},$$
$$r_3 = r_4 = \frac{1}{1+5\eta/4}, \quad r_5 = \frac{1}{1+13\eta/4} \qquad (30)$$

follow from the above multiplet structure of Mn^{2+} (d^5) ions, and $\eta = J_H/U$ is the Hund-coupling parameter. The meaning of the various terms is straightforward: the first term $H_1^{(\gamma)}$ describes the high-spin excitations to the $^6A_1$ state while the remaining ones, $H_n^{(\gamma)}$ with $n = 2, \ldots, 5$, arise due to the low-spin excited states $^4A_1$, $^4E_\theta$, $^4E_\epsilon$, and $^4A_2$, respectively.

The SE leads in the (a, b) plane to $(|x\rangle \pm |z\rangle)/\sqrt{2}$ OO in combination with ferromagnetism; this is driven by the r_1 term. Similarly OO in $LaMnO_3$ is favored by collective JT distortions (Kanamori, 1959; Goodenough, 1963), which may lead to a further rotation of alternating orbitals toward $d_{3x^2-r^2}$ and $d_{3x^2-r^2}$, respectively. This OO implies as consequence of SE FM spin order in the (a,b) plane, but AF order between planes, and is called *A-type order*. A powerful technique to determine the OO is the resonant X-ray scattering (RXS) technique (for a theoretical discussion, see Ishihara's account in Maekawa *et al*., 2004). The OO of $LaMnO_3$ has been determined by (Murakami *et al*., 1998) using RXS. They have shown that the OO in this compound sets in at $T_O = 780\,K$, while the AF ordering occurs at much lower Neél temperature $T_N = 140\,K$.

2.5 Goodenough–Kanamori rules and spin-orbital order

The magnetism of Mott-insulating TMO is traditionally interpreted by means of the GK rules (Goodenough, 1963; Kanamori, 1959). These rules state that the pattern of occupied orbitals determines the spin structure. In the case of 180° bonds, as shown in Figure 9 for a Mn^{3+}–O–Mn^{3+} bond, there are two key rules (Anderson, 1963):

1. If there is large overlap between partly occupied orbitals at two magnetic ions, the SE interaction between them is strongly AF, because the fluctuating electron meets another electron in the same orbital, thus Pauli principle requires antiparallel spins.
2. Large overlap between partly occupied and unoccupied orbitals on neighboring sites yields weak FM interaction due to Hund's exchange.

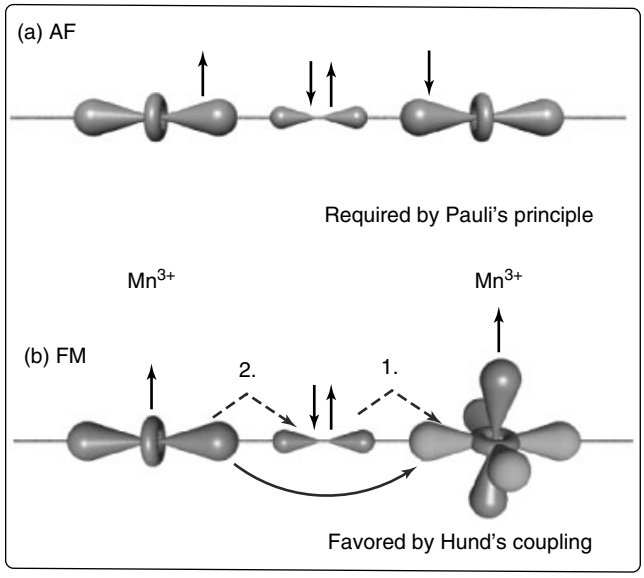

Figure 9. Sketch of Goodenough–Kanamori rules in case of Mn^{3+} with one e_g orbital occupied. (a) Large overlap of occupied orbitals favors antiferromagnetism because of Pauli's principle; In case (b) there is a large overlap between an occupied orbital at the left ion with an unoccupied orbital on the right ion, while in this case AF and FM orientation is possible, Hund's rule on the right ion will favor ferromagnetic alignment. For completeness the intermediate oxygen p orbitals which are active in the superexchange process are shown as well.

Whereas the AF–SE interaction (i) is proportional to t^2/U, the FM interaction (ii) is a weaker interaction $\sim t^2 J_H/U^2$, as it arises from a total balance of AF and FM SE processes, where the FM process wins by a factor J_H/U (see e.g., Figure 3). In the archetypical case of 180° bonds through a single ligand ion, this translates into a complementary interdependence between spin order and OO (Imada, Fujimori and Tokura, 1998): ferro-orbital (FO) order supports strong AF spin order, while alternating orbital (AO) order supports weak FM spin order. The canonical examples for this behavior are $LaMnO_3$ and $KCuF_3$. In $LaMnO_3$ the alternating OO in the (a, b) plane favors ferromagnetism. In $KCuF_3$ weak FM (positive) spin correlations in the ab planes and strong AF (negative) correlations along the c axis are accompanied by alternating OO in the ab planes and FO order along the c axis.

As the bond angle controls the hopping matrix elements it is obvious that the GK rules depend sensitively on the bond angle. Angles close to 90° deserve particular care.

In this case, AF–SE interaction may become small and the total interaction on a bond may become ferromagnetic as other SE channels become relevant (Mizuno *et al*., 1998; Tornow, Entin-Wohlman and Aharony, 1999). Also some compounds have more complex SE channels (Feldkemper and Weber, 1998; Daré, Hayn and Richard, 2003).

2.5.1 Crystal fields and Jahn–Teller distortions

The GK rules have been successful in explaining the magnetic structure in a wide range of materials. This may seem surprising because they presuppose that the orbital occupation is static, whereas it has become clear that if partly filled orbitals are degenerate, both spin and orbital degrees of freedom should be considered as dynamic quantum variables and be described by spin-orbital models as, for example, in equation (16):

$$\mathcal{H} = J \sum_{\gamma} \sum_{\langle ij \rangle \| \gamma} \left[\left(\mathbf{S}_i \cdot \mathbf{S}_j + S^2 \right) \hat{J}_{ij}^{(\gamma)} + \hat{K}_{ij}^{(\gamma)} \right] + \mathcal{H}_{\rm orb} \quad (31)$$

In fact, there are other interactions $\mathcal{H}_{\rm orb}$ between orbitals and the lattice, which can be stronger than the SE interactions and quench the orbital fluctuations. The GK rules work that well because in many compounds a structural phase transition, driven by the JT coupling of degenerate orbitals to the lattice, lifts the degeneracy and fixes the orbital occupation well above the magnetic transition. This happens typically for electrons in e_g orbitals where large cooperative JT distortions favor OO (Millis, 1996; Ahn and Millis, 2000). A good example is $LaMnO_3$ where the alternating OO, Figure 10, and the JT distortion occur simultaneously at $T_{\rm OO} \sim 780\,{\rm K}$ (Imada, Fujimori and Tokura, 1998). For t_{2g} orbitals, however, the JT coupling is rather weak. More significant in cubic vanadates RVO_3 and titanates $RTiO_3$ is the $GdFeO_3$ distortion which controls the t_{2g} level splitting (Mochizuki and Imada, 2003, 2004; Cwik *et al*., 2003; Solovyev, 2004; Pavarini, Yamasaki, Nuss and Andersen, 2005; Pavarini *et al*., 2004). Here, the dominant contribution to the crystal-field stems from the R ions and not from the O neighbors (Pavarini, Yamasaki, Nuss and Andersen, 2005), which reflects the fact that the O octahedra are rotated but only weakly distorted. This leads to a significant variation of orbital ordering transition temperatures in the cubic vanadate systems RVO_3 as function of the cation size which controls the $GdFeO_3$ distortion (Miyasaka, Okimoto, Iwama and Tokura, 2003), Figure 12. In layered ruthenates, the $GdFeO_3$ distortion even induces a metal–insulator transition (see following subsection). Recent experiments in pseudocubic perovskite titanates (Keimer *et al*., 2000) and vanadates (Ulrich *et al*., 2003), however, indicate that the relevant t_{2g} orbital occupations fluctuate and the conditions for applying the GK rules may not be not satisfied.

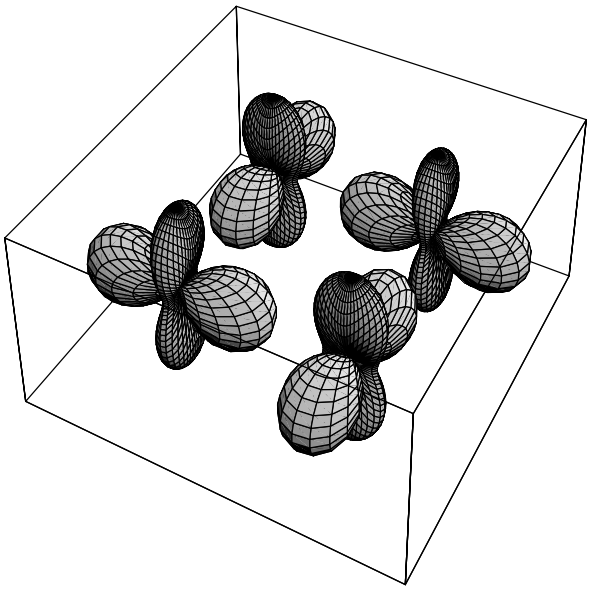

Figure 10. Alternating $(|x\rangle \pm |z\rangle)/\sqrt{2}$ in the ferromagnetic *ab* plane of $LaMnO_3$ as obtained from superexchange. The alternating orbital order is further stabilized by a cooperative Jahn–Teller distortion of the involved MnO_6 octahedra.

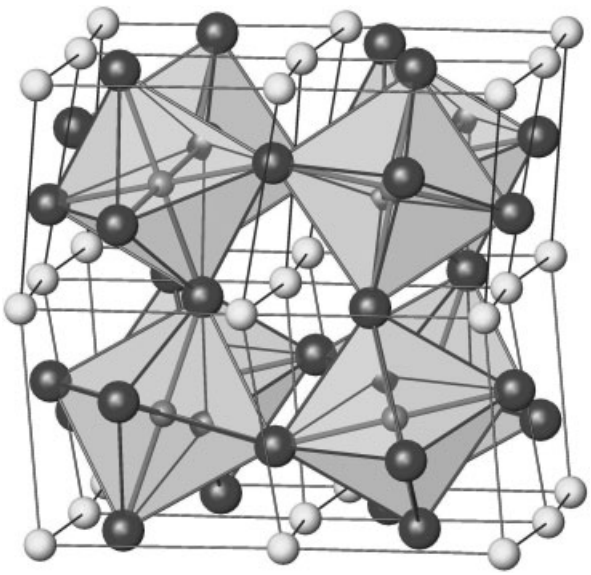

Figure 11. Crystal structure of the $GdFeO_3$ distorted perovskite vanadates RVO_3 and titanates $RTiO_3$ for small R ions. The corner-sharing octahedra are tilted around the *b* axis in alternating directions and subsequently rotated around the *c* axis. (Reproduced from E. Pavarini, Y. Yamasaki, J. Nuss, and O.K. Andersen, *New J. Phys.* **7**, 2005, 188, with permisison from Elsevier.)

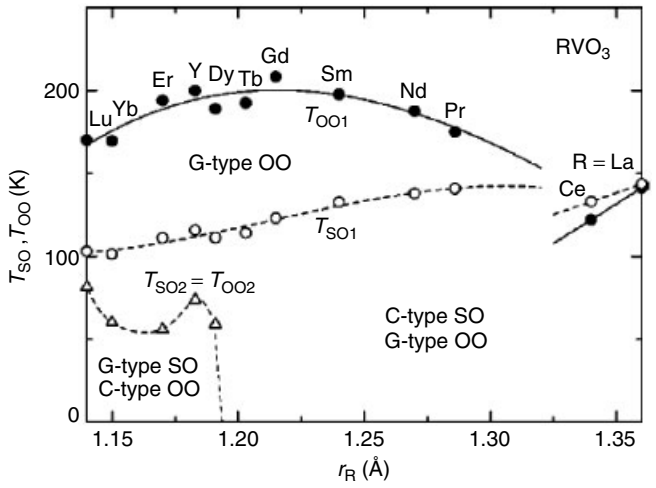

Figure 12. Spin-orbital phase diagram of RVO_3 (R = Lu–La) as function of the cation size r_R. Closed and open circles indicate G-type orbital ordering temperature T_{OO1} and C-type spin ordering T_{SO1}, respectively. Triangles indicate G-type spin (C-type orbital) ordering temperature $T_{SO2} = T_{OO2}$. (Reproduced from Miyasaki *et al*., 2003, with permission from the American Physical Society. © 2003.)

2.5.2 *Orbital-selective Mott transition in layered ruthenates*

The discovery of unconventional superconductivity in Sr_2RuO_4 (Maeno *et al*., 1994) has attracted considerable interest in the electronic properties of layered perovskite ruthenates. With a highest $T_c \sim 1.5\,K$ they are the only superconductors isostructural with the high-temperature superconducting cuprates. In contrast to singlet pairing in high-T_c superconductors, here triplet pairing with p-wave symmetry of the superconducting order parameter is the most probabe scenario. Spin-triplet pairing is favored by strong FM fluctuations that are believed to dominate the pair-formation in Sr_2RuO_4. These aspects have been reviewed in depth by Mackenzie and Maeno (2003).

Surprising insights were obtained when replacing the Sr ion in this compound. For example, the substitution of the smaller Ca^{2+} ions for Sr^{2+} ions does not lead to a more metallic state, as one might naively expect, but to an AF Mott insulator with a staggered moment of $S = 1$ as expected for a localized Ru^{4+} ion which has four electrons in the t_{2g} subshell.

The insulating behavior of Ca_2RuO_4 is triggered by the typical $GdFeO_3$ distortions that appear when small cations are inserted into the perovskite structure (Fang and Terakura, 2001; Anisimov *et al*., 2002; Friedt *et al*., 2001): (i) With the replacement of Sr^{2+} ions by Ca^{2+} ions the RuO_6 octahedra change from *c*-axis elongation to compression. This implies that the xy orbital is shifted below the degenerate xz and yz orbitals, that is, the systems

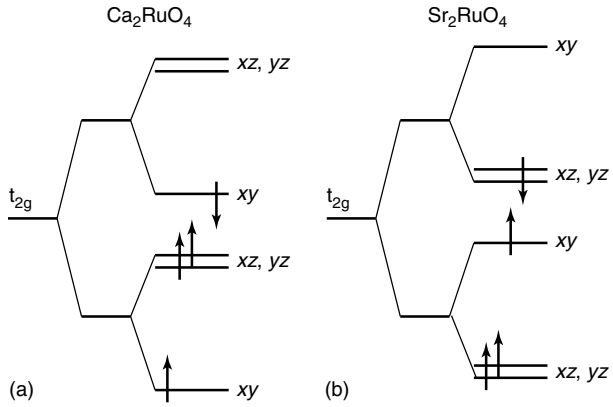

Figure 13. Local electronic structure of the end compounds of the isoelectronic alloy $Ca_{2-x}Sr_xRuO_4$ triggered by the GdFeO lattice distortion connected with the cation size. In Ca_2RuO_4 the down-spin electron occupies the xy-orbital in Ca_2RuO_4 (a), whereas in Sr_2RuO_4 (b) this electron occupies a level with xz/yz orbital degeneracy. (Reproduced from V.I. Anisimov, I.A. Nekrasov, D.E. Kondakov, T.M. Rice, and M. Sigrist, *Eur. Phys. J B* **25**, 2002, 191, with permisison of EDP Sciences.)

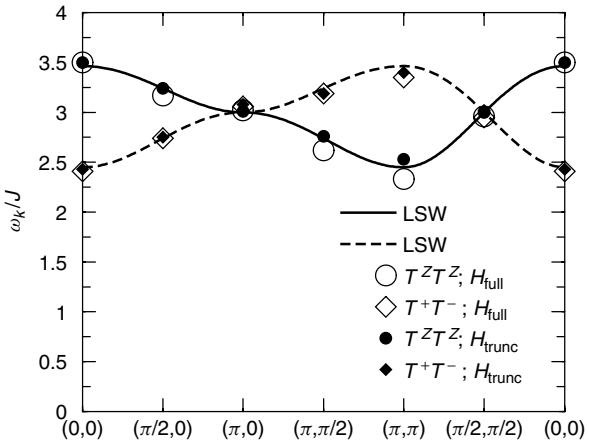

Figure 14. Orbital waves calculated for the alternating orbital order $((|x\rangle \pm |z\rangle)/\sqrt{2})$ of the 2D orbital model that represents the ferromagnetic *ab* plane of $LaMnO_3$. The solid (dashed) lines represent results for the two orbiton modes obtained by the linear spin-wave theory. The symbols indicate the orbital excitation energies obtained by exact diagonalization. (Reproduced from Van den Brink *et al*., 1999, with permission from the American Physical Society. © 1999.)

changes from an orbital-degenerate state into an insulating nondegenerate state in the case of Ca_2RuO_4. (ii) Moreover, the tilt of octahedra associated with the $GdFeO_3$ distortion reduces the resonance integrals. That is, the resulting smaller bandwidth implies stronger correlations. Thus, in combination with the Hund coupling this explains the Mott-insulating behavior of Ca_2RuO_4, as three of the four Ru^{4+} electrons fill the up-spin t_{2g} orbitals while the remaining electron fills the nondegenerate down-spin state with xy

symmetry. It should be seen that these arguments imply that the system is in the strong correlation regime, and the bandwidth is small compared to the relevant level splittings. This also suggests that Sr_2RuO_4 is a correlated metal. Recent high-precision angular resolved photoemission spectroscopy (ARPES) experiments measurements have indeed confirmed that Sr_2RuO_4 represents a Fermi liquid with a relatively strong renormalization of the Fermi velocity due to electron–electron interactions (Ingle *et al*., 2005).

The metal–insulator transition in the isoelectronic alloy $Ca_{2-x}Sr_xRuO_4$ has been dubbed *orbital-selective Mott transition* (Anisimov *et al*., 2002). In this context, degenerate two-band Hubbard models (with diagonal hopping) but with different bandwidth have been explored with different techniques. It was found that for different Coulomb interactions there are separate Mott transitions, that is, allowing for the coexistence of itinerant and localized electrons in the intermediate regime (Koga, Kawakami, Rice and Sigrist, 2004, 2005; Sigrist and Troyer, 2004; Knecht, Blümer and van Dongen, 2005; Liebsch, 2005). The detailed phase diagram of $Ca_{2-x}Sr_xRuO_4$ is discussed in Nakatsuji and Maeno (2000a,b), Friedt *et al*. (2001), and Anisimov *et al*. (2002). Resonant X-ray diffraction experiments indicate the appearance of OO in Ca_2RuO_4 at about 260 K, that is, well above the AF phase transition at $T_N = 110$ K (Zegkinoglou *et al*., 2005).

2.6 Orbital excitations and collective orbital waves

In the presence of OO we expect collective orbital excitations, that is, like phonons in a crystalline lattice. Such orbiton excitations may be visualized as a local orbital excitation that propagates through the orbital-ordered lattice. While a local crystal-field excitation also qualifies as orbiton, we have here in mind moving excitations with pronounced momentum dependence. We begin by considering a simple case, namely, a two-dimensional model for the alternating OO which is relevant for the A phase of $LaMnO_3$ (Figure 10). As the planes are basically saturated ferromagnets at zero temperature, it suffices to consider the orbital degree freedom. Introducing orbital operators $T_i^\alpha = \frac{1}{2}\sigma_i^\alpha$ we obtain from equation (24) the orbital Hamiltonian for the plane (van der Brink, Horsch, Mack and Oleś, 1999; Ishihara, Inoue and Maekawa, 1997; Shiina, Nishitani and Shiba, 1997)

$$H_J = \frac{1}{2}J \sum_{\langle ij\rangle||} \times \left[T_i^z T_j^z + 3T_i^x T_j^x \mp \sqrt{3}(T_i^x T_j^z + T_i^z T_j^x)\right] \qquad (32)$$

where $J = t^2/(U - 3J_H)$ as the high-spin transition is relevant. We will show here that in many cases linear spin-wave (or orbital-wave) theory is the convenient tool to study orbital excitations. One starts by introducing Holstein–Primakoff bosons

$$T_i^+ = \overline{a}_i^\dagger (1 - \overline{a}_i^\dagger \overline{a}_i)^{1/2},$$
$$T_i^- = (1 - \overline{a}_i^\dagger \overline{a}_i)^{1/2} \overline{a}_i,\ T_i^z = \overline{a}_i^\dagger \overline{a}_i - \frac{1}{2} \qquad (33)$$

The linearized Hamiltonian simplifies after Fourier transformation

$$H_{\mathrm{LSW}} = J \sum_k \left[A_k a_k^\dagger a_k + \frac{1}{2} B_k (a_k^\dagger a_{-k}^\dagger + a_k a_{-k})\right] \qquad (34)$$

leading finally to the dispersion

$$\omega_k^\pm = 3J\sqrt{1 \pm \frac{1}{3}\gamma_\parallel(k)},$$
$$\gamma_\parallel(k) = \frac{1}{2}(\cos k_x + \cos k_y) \qquad (35)$$

which consists of two branches, that is, analogous to the case of spin waves in an antiferromagnet.

Different from SU(2) symmetric spin models, the orbital correlation functions sensitively depend on the basis with respect to which the orbital correlation functions are defined. In Figure 15 the two correlation functions $\langle T_q^z T_{-q}^z\rangle$ and $\langle T_q^+ T_{-q}^-\rangle$ are defined with respect to the initial global $|z\rangle$, $|x\rangle$ basis equation (4). In this case the two orbiton branches in Figure 15 are displayed separately. The results obtained by linear spin (orbital) wave theory using the truncated Hamiltonian, where $T^z T^x$ terms have been dropped, coincide with the exact diagonalization results for that model. The numerical spectra for the full Hamiltonian equation (32) are more complex, but still the first moment is well captured by orbital-wave theory.

The alternating orbital order melts for the model defined by equation (32) at $T_O \sim J$ (Horsch, Jaklic and Mack, 1999; Mack and Horsch, 1999). Figure 16 shows the evolution of orbital excitations with temperature. At low temperature, in the (alternating) orbital-orderered phase, the spectra are characterized by a Bragg peak at $q = (\pi, \pi)$ and a well-defined orbital-wave branch. When the OO melts the orbitons disappear and pronounced quasielasic scattering is seen over the whole Brillouin zone and still there is a continuum of spectral weight up to the orbiton energy. That is, there are liquid like excitations up to the bare interaction scale $\sim 3J$.

A calculation of orbitons in $LaMnO_3$ with degenerate e_g orbitals was performed in (Ishihara, Inoue and Maekawa, 1997; Shiina, Nishitani and Shiba, 1997; van der Brink,

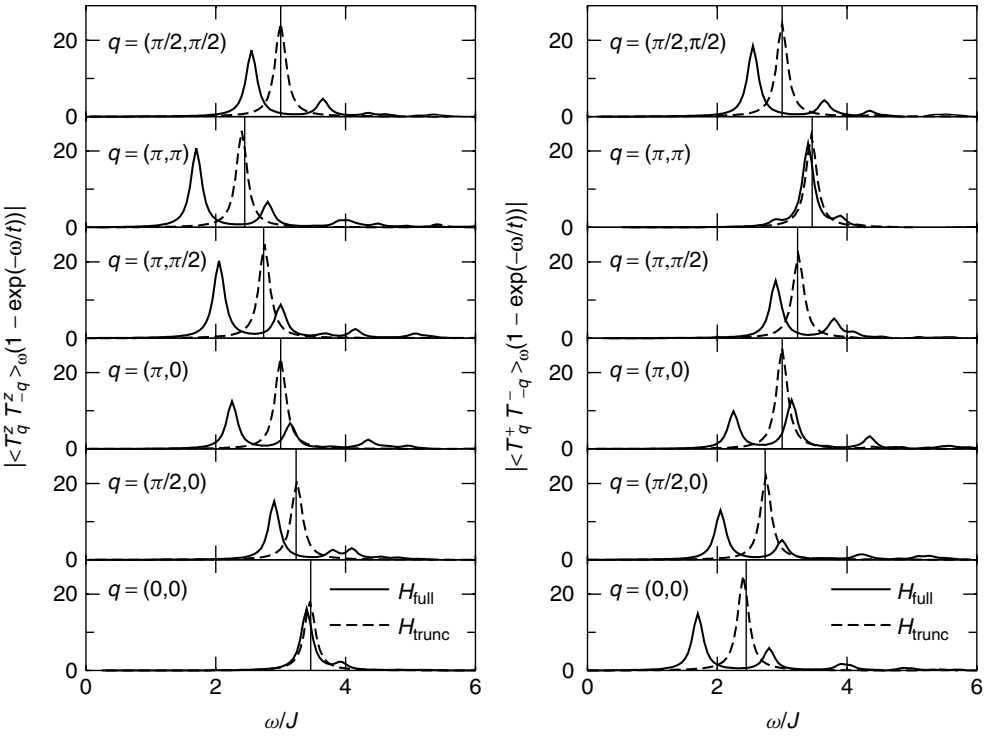

Figure 15. Orbital excitations and spectral functions of the 2D orbital model describing the alternating orbital order $(|x\rangle \pm |z\rangle)/\sqrt{2}$ of the ferromagnetic *ab* plane of $LaMnO_3$: Comparison of spectra $\langle T_q^z T_{-q}^z\rangle$ and $\langle T_q^+ T_{-q}^-\rangle$ obtained by exact diagonalization for (i) the full Hamiltonian (solid lines) and (ii) the truncated Hamiltonian (dashed lines), and the result (iii) from linear spin-wave theory obtained for case (ii) (vertical lines). (Reproduced from Van den Brink *et al*., 1999, with permission from the American Physical Society. © 1999.)

Horsch, Mack and Oleś, 1999). The effect of strong crystal-field splitting which is relevant to the $LaMnO_3$ case because of the strong compression of octahedra has also been considered (van der Brink, Horsch, Mack and Oleś, 1999). More recently Ishihara (Ishihara, 2004; Ishihara *et al*., 2005) has studied orbital waves in the orbital-ordered vanadate compounds $LaVO_3$ and YVO_3 as well as for the titanate $YTiO_3$. The direct observation of orbital waves has proven to be rather difficult, however. Insights concerning the status of experiment may be found in Rückamp *et al*. (2005) and Ishihara *et al*. (2005). Although $LaMnO_3$ appears at first glance an ideal candidate for the observation of orbitons, the evidence of orbitons in Raman scattering (Saitoh *et al*., 2001) has been discussed controversially (Grüninger *et al*., 2002; Saitoh *et al*., 2002). In real materials, the coupling of orbital excitations to lattice distortions (e.g., JT and breathing phonons) may modify the orbital excitation spectra considerably. Theoretical work in this direction has been undertaken in Perebeinos and Allen (2000), van den Brink (2001), Weisse and Fehske (2004), and Schmidt, Grüninger and Uhrig.

Strongly frustrated systems like the titanates may remain in an orbital liquid state or develop only weak OO in a strongly fluctuating orbital system as proposed by Khaliullin and Maekawa (2000) and Khaliullin and Okamoto (2002, 2003). In that case, the orbital excitation spectrum would resemble a (possibly gapped) continuum rather than collective modes. The orbital liquid picture relies on the expectation that crystal fields are sufficiently weak in compounds like $LaTiO_3$ so that the intrinsic frustration of the spin-orbital model leads to strong fluctuations. Recent Raman experiments of $LaTiO_3$ and $YTiO_3$ (Ulrich *et al*., 2006) and NMR data (Kiyama *et al*., 2005) have been indeed interpreted in terms of strongly fluctuating orbitals. However, there are experiments which are interpreted as evidence for strong crystal fields as well (Cwik *et al*., 2003).

While the origin of orbital liquid behavior in undoped systems is the inherent frustration of the spin-orbital SE interaction, that is, not all bonds can be optimized simultaneously, the lowering of symmetry does not help either. In that respect, the $S = 1/2$ cubic titanates are strikingly different from the $S = 1$ vanadate compounds. We shall encounter later in doped manganites another orbital liquid state, namely, the FM metallic phase where orbital liquid behavior is due the hole motion.

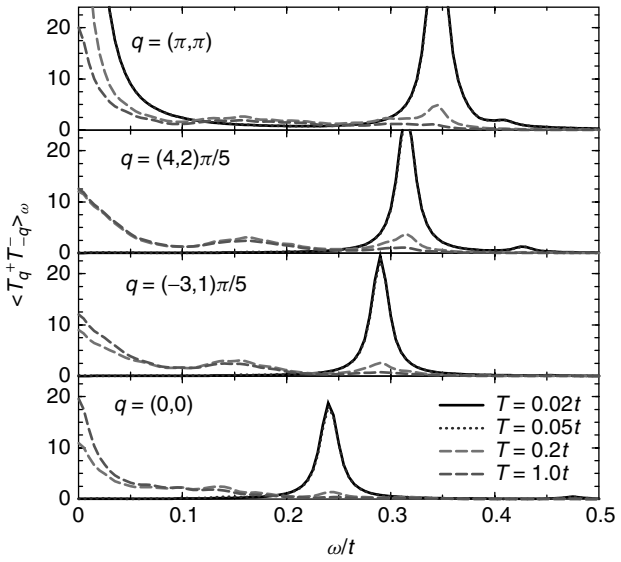

Figure 16. Temperature dependence of orbital excitations calculated for the orbital model (32). Results are obtained by the finite temperature Lanczos method for a 10 site cluster and $J/t = 0.1$. The alternating orbital order melts at about $T_O \sim J$. As the OO melts the orbitons disappear, and the excitation spectrum changes into that of an orbital liquid. (Horsch and Mack, unpublished.)

2.7 Composite spin-orbital phenomena

2.7.1 Spin-orbit coupling

The intrinsic quartic terms of the form $S_i S_j T_i T_j$ in the generic spin-orbital model can lead to entanglement of spin and orbital degrees of freedom. While such terms are not difficult to handle in some cases, as we shall discuss later, they lead in other cases to strong spin-orbital fluctuations and a complete breakdown of any mean-field (MF) theory. We postpone this discussion to Section 3.

Here, we shall address instead the additional coupling between orbital and spin resulting from the relativistic spin-orbit coupling H_λ.

$$H_\lambda = \Lambda \sum_i \mathbf{L}_i \cdot \mathbf{S}_j \tag{36}$$

where we introduce $\lambda = \Lambda/J$ as parameter. This interaction is quenched in the case of real OO, whereas when orbitals fluctuate like in $LaVO_3$ and YVO_3 this interaction can induce orbital moments (OMs) and decide over the alignment of spins (Ulrich *et al.*, 2002; Horsch, Khaliullin and Oleś, 2003). Hence in the t_{2g} systems where orbital fluctuations are strong it is important to include spin-orbit interaction as well. Here we add H_λ simply to the spin-orbital model $\mathcal{H}$, equation (16), for vanadates. An alternative approach would start from the multiband Hubbard model and a derivation of SE with H_λ included from the outset, as in Schmitz *et al.* (2005) for the titanates.

Owing to the $GdFeO_3$ distortion the individual VO_6 octahedra are tilted by the angle $\phi_i = \pm\phi$, which alternate along the c axis (Blake *et al.*, 2001, 2002). As the xy orbital is inactive, two components of the OM $\mathbf{L}_i$ are quenched, while the third one, $L_i^z = 2\tau_i^y$ parallel to the local axis of a VO_6 octahedron, couples to the spin projection. Because of AF correlations of τ_i^y moments, spin-orbit coupling induces a staggered spin component. As the spin interactions are FM, weak spin-orbit coupling would give no energy gain, if the spins were oriented along the c axis. Thus, finite Λ breaks the SU(2) symmetry and favors easy magnetization axis within the (a, b) plane. As quantization axis for $\mathbf{L}_i$ ($\mathbf{S}_i$) we use the octahedral axis. Thus the spin-orbit term is (Horsch, Khaliullin and Oleś, 2003):

$$H_\lambda = 2\Lambda \sum_i \left(S_i^x \cos\phi_i + S_i^z \sin\phi_i\right) \tau_i^y. \tag{37}$$

In Schwinger boson representation $\tau_i^y = \frac{1}{2} i (a_i^+ b_i - b_i^+ a_i)$, that is, this operator leads to local fluctuations of a and b orbital occupancy, whereas SE leads to similar fluctuations by exchanging a and b electrons between neighbor sites along the c axis.

Spin-orbit coupling H_λ competes with Hund's exchange (η terms), which favors real OO, and triggers a novel phase (see Figure 17), where the ordering of the t_{2g} orbital moments is stabilized by the tilting of the VO_6 octahedra. This explains qualitatively spin canting and the reduction of magnetization observed in YVO_3 (Ulrich *et al.*, 2002; Horsch, Khaliullin and Oleś, 2003). Moreover H_λ implies a substantial reduction of spin-wave energies.

2.7.2 Orbital-Peierls distortion in YVO_3

In a neutron scattering study, (Ulrich *et al.*, 2002) found evidence for a dimerization of the finite temperature C phase in YVO_3 (Figure 12) by the observation of a splitting finite temperature magnetic C phase. This was subsequently interpreted as evidence for orbital-Peierls distortion, as no significant lattice dimerization was observed. That is, the proposed mechanism is a modulation of spin exchange constants $J_{c,1}$ and $J_{c,2}$, that is, controlled by orbital dimer formation (Ulrich *et al.*, 2002; Horsch, Khaliullin and Oleś, 2003; Sirker and Khaliullin, 2003).

Thus the underlying idea is, that the system can profit from orbital dimer formation as in the OVB state. However, one also recognizes that the C−AF phase cannot dimerize at $T = 0$ because the FM (along c) state is inert, and does not allow for any modulation in the orbital sector. Orbital singlets need the decoupling via the magnetic sector. That is,

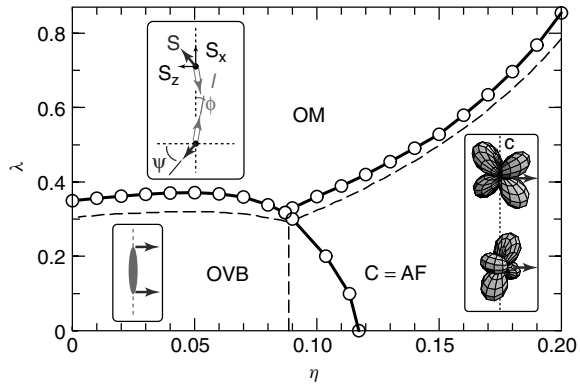

Figure 17. Phase diagram at zero temperature obtained from the spin-orbital model for cubic vanadates. The phase diagram shows the competition of different phases as function of the Hund-coupling constant $\eta = J_{\rm H}/U$ and the relativistic spin-orbit coupling λ. Near the origin the orbital valence bond (OVB) state is the stable solution, large λ favors orbital moment (OM) formation, while large η yields the C-type antiferromagnetic (C-AF) state, with ferromagnetic spin alignment and alternating orbital order along c direction. Solid lines and circles denote results from exact diagonalization, while dashed lines indicate results obtained by mean-field theory. Typical parameters for the vanadates are $\lambda \sim 0.3 - 0.4$ and $\eta \simeq 0.12$. (Reproduced from Horsch *et al*., 2003, with permission from the American Physical Society. © 2003.)

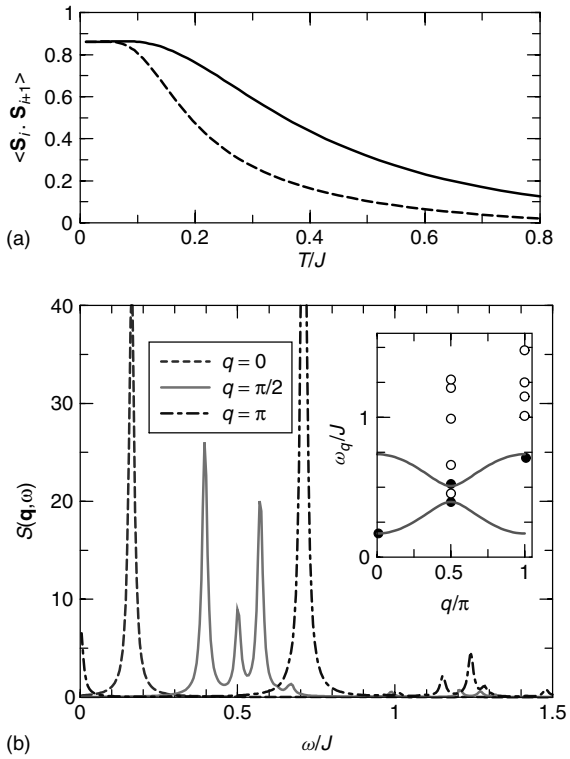

Figure 18. Calculated dimerization and spin-excitation spectra in the C-AF phase at $T > 0$: (a) temperature dependence of spin−spin correlations $\langle \mathbf{S}_i \cdot \mathbf{S}_{i+1} \rangle$ on strong and weak FM bonds (solid and dashed line); (b) spin response $S(\mathbf{q}, \omega)$ in the dimerized C-AF phase for $\mathbf{q} = (0, 0, q)$ with $q = 0, \frac{\pi}{2}, \pi$. Inset: filled (open) circles indicate strong (weak) features in $S(\mathbf{q}, \omega)$; lines show the fitted spin-wave dispersion for: $\eta = 0.12$, $\lambda = 0.4$. (Reproduced from Horsch *et al*., 2003, with permission from the American Physical Society. © 2003.)

the spin correlations $\langle \mathbf{S_i} \cdot \mathbf{S_j} \rangle$ on the adjacent bonds must be weakened by spin deviations, which may occur via thermal fluctuations at higher temperature.

Results obtained by finite temperature diagonalization (Horsch, Khaliullin and Oleś, 2003) show that the chain dimerizes at finite temperatures due to the intrinsic instability toward alternating orbital singlets (Sirker and Khaliullin, 2003). Except at low temperature, the spin correlations $\langle \mathbf{S}_i \cdot \mathbf{S}_{i+1} \rangle$ (Figure 18a), alternate between strong and weak FM bonds due to the orbital-Peierls dimerization, $2\delta_\tau = |\langle \boldsymbol{\tau}_i \cdot \boldsymbol{\tau}_{i+1} \rangle - \langle \boldsymbol{\tau}_i \cdot \boldsymbol{\tau}_{i-1} \rangle|$, which has a distinct maximum at $T \simeq 0.24J$ for $\eta = 0.12$. Consistent with the discussion in the preceding text, the modulation of $\langle \mathbf{S}_i \cdot \mathbf{S}_{i+1} \rangle$ vanishes in the C phase at low T.

Figure 18(b) shows the dynamical spin structure factor $S(\mathbf{q}, \omega)$ obtained by exact diagonalization of a cluster with periodic boundary conditions at $T = 0$, assuming the same orbital dimerization, $\langle \boldsymbol{\tau}_i \cdot \boldsymbol{\tau}_{i+1} \rangle$, as found in the preceding text for $T/J = 0.25$. At $\mathbf{q} = (0, 0, \frac{\pi}{2})$ one finds a splitting of the spin wave similar to experiment. The finite energy of the $\mathbf{q} = (0, 0, 0)$ mode results from the Λ-term in equation (37) and the MF coupling to neighbor chains. Additional features seen in $S(\mathbf{q}, \omega)$, for example, for $q = (0, 0, \pi)$ at $\omega \sim 1.25J$, can be attributed to the coupling to orbital excitations. The spin-wave energies can be fitted by a simple Heisenberg model with two FM coupling constants: $J_{c1} = 5.7$, $J_{c2} = 3.3$ meV, and a small anisotropy term, as shown in the inset (solid lines). A measure for the dimerization strength is the ratio $J_{c1}/J_{c2} \sim 1.73$ consistent with an experimental value 1.82 (Ulrich *et al*., 2002).

Subsequently, the quasi one-dimensional ($S = 1/2$) titanium pyroxene compound $NaTiSi_2O_6$ was proposed to reveal orbital dimerization, and is considered as second system showing the high-temperature orbital-Peierls phase (Konstantinović *et al*., 2004).

3 ONE-DIMENSIONAL SPIN-ORBITAL MODELS

The study of one-dimensional spin-orbital models has been an active field, stimulated by specific analytic and numerical tools. Particularly widely studied are models where it is assumed that also the orbital sector has the full rotational SU(2) symmetry. This has given some important deeper insights into the features of spin-orbital models and the

variety of phases of such models. Some instructive cases are described, such as the interplay of orbital and spin correlations in SU(4) and other spin-orbital models, spin-orbital entanglement and the role of composite spin-orbital fluctuations. One-dimensional spin-orbital models may also represent spin models on two-leg ladders with quartic interactions (Nerseyan and Tsvelik, 1997; Koleshuk and Mikeska, 1998; Mikeska and Koleshuk, 2004).

3.1 Spin-1/2 models

As the most prominent example, among others, the one-dimensional spin-orbital model with SU(4) symmetry, which describes a spin-1/2 system with twofold orbital degeneracy, has been widely investigated (Affleck, 1986; Sutherland, 1975; Itakura and Kawakami, 1995; Yamashita, Shibata and Ueda, 1998; Frischmuth, Mila and Troyer, 1999). A slightly extended 1D spin-orbital model with SU(2)⊗SU(2) symmetry and free constants A and B (Pati, Singh and Khomskii, 1998; Azaria, Gogolin, Lecheminant and Nersesyan, 1999; Azaria, Boulat and Lecheminant, 2000; Yamashita, Shibata and Ueda, 2000; Tsukamoto, Kawakami, Yamashita and Ueda, 2000; Itoi, Qin and Affleck, 2000)

$$\mathcal{H} = J \sum_i \left(\mathbf{S}_i \cdot \mathbf{S}_{i+1} + \frac{A}{4} \right) \left(\mathbf{T}_i \cdot \mathbf{T}_{i+1} + \frac{B}{4} \right) \qquad (38)$$

has been studied in detail. Here $\mathbf{S}_i$ is an $S = 1/2$ spin operator at the ith site and $\mathbf{T}_i$ is a $T = 1/2$ pseudospin operator acting on the doubly degenerate orbital degrees of freedom. In particular, the ground-state phase diagram has been established (Figure 19), which consists of a variety of phases including gapful/gapless spin and orbital phases (Pati, Singh and Khomskii, 1998; Azaria, Gogolin, Lecheminant and Nersesyan, 1999; Azaria, Boulat and Lecheminant, 2000; Yamashita, Shibata and Ueda, 2000; Tsukamoto, Kawakami, Yamashita and Ueda, 2000; Itoi, Qin and Affleck, 2000). At $(A, B) = (1, 1)$ on the I−V phase boundary the model has SU(4) symmetry and is Bethe ansatz integrable (Affleck, 1986; Sutherland, 1975; Itakura and Kawakami, 1995; Yamashita, Shibata and Ueda, 1998; Frischmuth, Mila and Troyer, 1999). The SU(4) symmetry results from the fact that the Hamiltonian in this case consists simply of permutation operators $\left(2\mathbf{S}_i \cdot \mathbf{S}_{i+1} + \frac{1}{2}\right)$, which interchange states on neighbor sites, and also includes the interchange of orbital and spin sector. The low-energy theory is a $SU(4)_1$ Wess–Zumino–Witten model with central charge $c = 3$. One can imagine the ground state formed by spin-singlet (orbital-triplet) pairs fluctuating into orbital-singlet (spin-triplet) pairs and back. A particularly striking result in the SU(4) case is the equality of the spin-, orbital-, and composite correlation

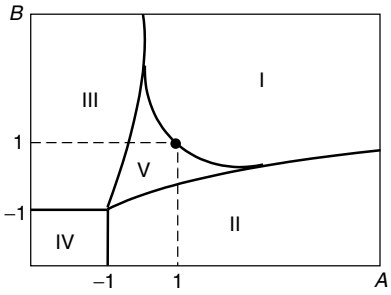

Figure 19. Phase diagram of the $S = 1/2$ spin-orbital model. Phase I is a gapful phase with doubly degenerate ground states which form alternating spin and orbital singlets. In the phase II, the spin degrees of freedom are in the fully polarized ferromagnetic state while the orbitals are in the antiferromagnetic ground state and vice versa in the phase III. Both spin and orbital degrees of freedom are in the fully polarized ferromagnetic states in the phase IV. The phase V is a gapless phase including an integrable SU(4) point ($A = B = 1$). (Reproduced from S. Miyashita and N. Kawakami, *J. Phys. Soc. Jpn.* **74**, 758 (2005), with permission from the Physical Society of Japan.)

functions (Li, Ma, Shi and Zhang, 1998; Frischmuth, Mila and Troyer, 1999):

$$\langle S_i^\alpha S_j^\alpha \rangle = \langle T_i^\alpha T_j^\alpha \rangle = 4 \langle S_i^\alpha S_j^\alpha T_i^\beta T_j^\beta \rangle = w_{i-j} \qquad (39)$$

independent of the indices $\alpha, \beta = x, y, z$. Remarkably the nearest-neighbor correlation functions (CFs) are all negative! For the infinite chain $w_1 = -0.07168(1)$ (Frischmuth, Mila and Troyer, 1999). That is, our usual imagination of MF factorization, that is, $\langle S_i^\alpha S_j^\alpha \rangle \langle T_i^\alpha T_j^\alpha \rangle$, which suggests that, if the individual CFs are negative, the composite CF should be positive, fails here dramatically.

3.2 Spin-1 models

Next we consider the $S = 1$ extension of the 1D spin-orbital model with uniaxial single-ion anisotropy D, which is characterized by two coupling constants A and B related to the spin and orbital degrees of freedom (Miyashita, Kawaguchi, Kawakami and Khaliullin, 2004; Miyashita and Kawakami, 2005). The Hamiltonian reads

$$\mathcal{H} = J \sum_i \left[(\mathbf{S}_i \cdot \mathbf{S}_{i+1} + A) \left(\mathbf{T}_i \cdot \mathbf{T}_{i+1} + \frac{B}{4} \right) \right] + D \sum_i \left(S_i^z \right)^2 \qquad (40)$$

where $\mathbf{S}_i$ is an $S = 1$ spin operator at the ith site and $\mathbf{T}_i$ is a $T = 1/2$ pseudospin operator acting on the doubly degenerate orbital degrees of freedom. J controls the magnitude of the exchange couplings, which will be taken as the energy

unit in the following discussions. The D term represents uniaxial single-ion anisotropy, which has been discussed in detail so far in the Haldane spin chain systems.

The model (40) is regarded as a natural extension of the 1D $S = 1/2$ spin-orbital model with SU(2)⊗SU(2) symmetry, for which the D term is absent, and $A \to A/4$ for the spin ($S = 1/2$) part. As spin $S = 1$ is more classical than $S = 1/2$ the comparison of these two models may allow to clarify the role of spin fluctuations.

At the special point ($A = B = 1$ and $D = 0$), the symmetry is enhanced to SU(2)⊗SU(2). It is known that the ground state in this case is the orbital liquid with a small spin gap, which is called the *orbital valence bond* (OVB) phase (Shen, Xie and Zhang, 2002; Horsch, Khaliullin and Oleś, 2003; Sirker and Khaliullin, 2003; Miyashita, Kawaguchi, Kawakami and Khaliullin, 2004). The spin-orbital model studied by Khaliullin *et al* for the cubic vanadates $LaVO_3$ and YVO_3 (Khaliullin, Horsch and Oleś, 2001; Sirker and Khaliullin, 2003; Horsch, Khaliullin and Oleś, 2003) includes the above special case in the limit of vanishing Hund coupling.

The asymmetry between the spin and orbital sector in the $S = 1$ model is particularly manifest in the OVB state I in Figure 20. Orbital singlets appear together with spin pairs coupled into a $S = 2$ state, the AF arrangement leads to basically decoupled pairs. Instead in phase II all spins are aligned ferromagnetically, while the pseudospins describing the orbitals form a $T = 1/2$ Heisenberg chain. It is quite surprising, that the total energy of phase I which stems from each second bond only can be lower than that of phase II which has a large contribution of the 1D Heisenberg chain on each bond. The OVB state has a small spin gap and a large orbital gap. The phase diagram of the $S = 1$ and the $S = 1/2$ model are quite similar, except that the phase V is missing. Negative uniaxial single-ion anisotropy D leads to further phases (Miyashita and Kawakami, 2005).

3.3 Spin-orbital entanglement and violation of GK rules

Composite spin-orbital excitations and the breakdown of mean-field (MF) theory has been studied by Oleś, Horsch, Feiner and Khaliullin (2006) for several 1D spin-orbital models. Spins and orbitals get entangled due to composite spin-orbital quantum fluctuations and the familiar static GK rules are violated to the extent that even the signs of the magnetic interactions may fluctuate in time. To demonstrate this general feature in the most transparent way, three different spin-orbital models are considered: Correlated insulators with 180° perovskite bonds between d^1, d^2, and d^9 ionic configurations, respectively, where the GK rules (Section 2.5) definitely predict complementary signs of spin and orbital intersite correlations. The first two models are derived for t_{2g} electrons as in $LaTiO_3$ (d^1) and $LaVO_3$ (d^2), and it is demonstrated that the GK rules are violated at small Hund coupling. The third model is for e_g holes as in $KCuF_3$ (d^9), in which the GK rules are perfectly obeyed. The qualitative difference results from the quantum nature of t_{2g} orbitals which may form singlets, while e_g orbitals behave more Ising-like and orbital singlets cannot form. The SE

$$\mathcal{H} = J \sum_{\langle ij \rangle \| c} \left[\left(\mathbf{S}_i \cdot \mathbf{S}_j + S^2 \right) \hat{J}_{ij}^{(c)} + \hat{K}_{ij}^{(c)} \right] + \mathcal{H}_{\rm orb} \qquad (41)$$

contains interactions like $(S_i^+ T_i^-)(S_j^- T_j^+) + (S_i^- T_i^+)(S_j^+ T_j^-)$, which generate *simultaneous* fluctuations of spins and orbitals described by the composite operators $Q_i^+ \equiv S_i^+ T_i^-$, and so on. At finite Hund coupling $\eta = H_{\rm H}/U$ both $\hat{J}_{ij}^{(c)}(d^1)$ and $\hat{J}_{ij}^{(c)}(d^2)$ (see Section 2.4.1) also contain

$$\mathbf{T}_i \otimes \mathbf{T}_j = \tfrac{1}{2}\left(T_i^+ T_j^+ + T_i^- T_j^- \right) + T_i^z T_j^z \qquad (42)$$

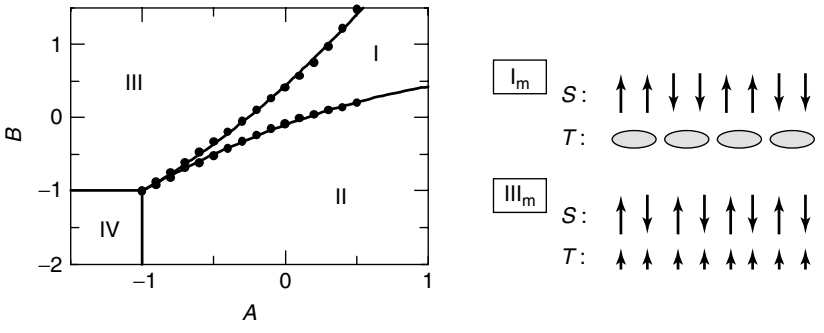

Figure 20. Phase diagram of the 1D $S = 1$ spin-orbital model in the $A - B$ plane without uniaxial single-ion anisotropy. The phase I is the OVB phase (see text). In the phase II, the spin part is in the fully polarized state while the orbital part forms the gapless antiferromagnetic $T = 1/2$ Heisenberg chain. On the other hand, in the phase III, the orbital sector is in the ferromagnetic phase while the spin sector is in the $S = 1$ Haldane phase. Spins and pseudospins are in the fully polarized ferromagnetic states in the phase IV. All the transitions are of first order. (Reproduced from S. Miyashita and N. Kawakami, *J. Phys. Soc. Jpn.* **74**, 758 (2005), with permission from the Physical Society.)

This operator appears because double occupancy of either active (yz or zx) orbital is not an eigenstate of the on-site Coulomb interaction. Consequently, the total T and T^z quantum numbers are not conserved and orbital fluctuations are amplified. Finally, $GdFeO_3$-type distortions induce nearest-neighbor orbital interactions $\mathcal{H}_{\rm orb} = -V \sum_{\langle ij \rangle} T_i^z T_j^z$ favoring FO order along the c axis (Mizokawa, Khomskii and Sawatzky, 1999).

It has been shown that a clear measure of entanglement is provided by the comparison of the intersite spin-, orbital-, and composite spin-orbital correlations. These have been calculated for the above spin-orbital models. To make the results comparable in all cases, the following definitions were chosen:

$$S_{ij} = \langle \mathbf{S}_i \cdot \mathbf{S}_j \rangle / (2S)^2 \tag{43}$$

for the spin correlations. The orbital and spin-orbital correlations are defined for the t_{2g} (d^1 and d^2) models as

$$T_{ij}^{(t)} = \langle \mathbf{T}_i \cdot \mathbf{T}_j \rangle, \tag{44}$$

$$C_{ij}^{(t)} = \left[\langle (\mathbf{S}_i \cdot \mathbf{S}_j)(\mathbf{T}_i \cdot \mathbf{T}_j) \rangle - \langle \mathbf{S}_i \cdot \mathbf{S}_j \rangle \langle \mathbf{T}_i \cdot \mathbf{T}_j \rangle \right] / (2S)^2 \tag{45}$$

If the composite correlation function $C_{ij}^{(t)} = 0$, orbitals and spins are disentangled and the two sectors can be factorized. Alternative measures of spin-orbital entanglement are possible, for example, (Chen, Wang, Li and Zhang, 2006) have used a reduced von Neumann entropy to explore the phase diagram of a spin-orbital chain with $SU(2) \otimes SU(2)$ symmetry. For the e_g (d^9) model the conventions are analogous, for details see Oleś, Horsch, Feiner and Khaliullin (2006). In Figure 21(a) relevant for the d^1 titanates one finds at $\eta = 0$ the SO (4) point where all correlation functions are negative. This exotic phase stops at $\eta S = 0.1$ where the spin correlation get FM and the correlation function C_{ij} that measures the entanglement becomes exactly zero. The anomalous behavior of CF's exists also in Figure 21(b) relevant for the $S = 1$ vanadates. If FM OO is enforced by the $GdFeO_3$-type distortion as in Figure 21(d) the entangled regime is reduced to intermediate values for ηS.

Particularly remarkable is a comparison of spin correlations in Figure 21 and the magnetic exchange constants $J_{ij} = \langle \hat{J}_{ij}^{(c)} \rangle$ (Figure 22) determined via a MF factorization of orbital and spin sector. In Figure 22 the shaded regions in case of t_{2g} models show negative (FM) exchange constant, whereas the actual spin correlations are AF!

Summarizing, in correlated insulators with partly filled t_{2g} shells, orbitals, and spins are entangled, and average spin and orbital correlations are typically in conflict with the (static) GK rules. The key difference between e_g and t_{2g} electrons is that the latter can form orbital singlets. Thus the dynamical spin and orbital correlations are complementary to each other, and fluctuate between orbital-singlet/spin-triplet and orbital-triplet/spin-singlet configurations. This implies the fluctuation of the sign of the spin exchange constants J_{ij}, as can be seen from equation (17).

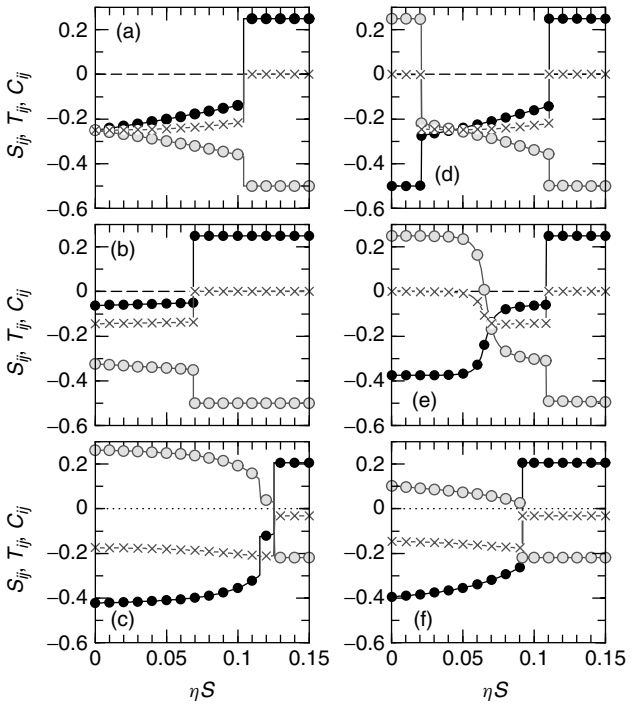

Figure 21. Intersite spin S_{ij} (filled circles), orbital $T_{ij}^{(t,e)}$ (empty circles), and composite spin-orbital $C_{ij}^{(t,e)}$ (crosses) correlations as functions of Hund's exchange ηS, for $V = 0$ (left) and for $V = J$ (right) for: (a,d) d^1 (titanate) model, (b,e) d^2 (vanadate) model, and (c,f) d^9 (cuprate) model. 4 SUPEREXCHANGE, MAGNETISM, AND OPTICS

Although this field is already quite mature, it has been realized only recently that the *magnetic* and the *optical* properties of correlated insulators with partly filled d orbitals are intimately related to each other, being just different experimental manifestations of the same underlying spin-orbital physics (Oleś, Khaliullin, Horsch and Feiner, 2005; Khaliullin, Horsch and Oleś, 2004; Lee, Kim and Noh, 2005). On the other hand, it has been well known that the often dramatic temperature dependence of optical spectra is connected to magnetic structure (Miyasaka, Okimoto and Tokura, 2002) and that the variation of spectral weights is controlled by

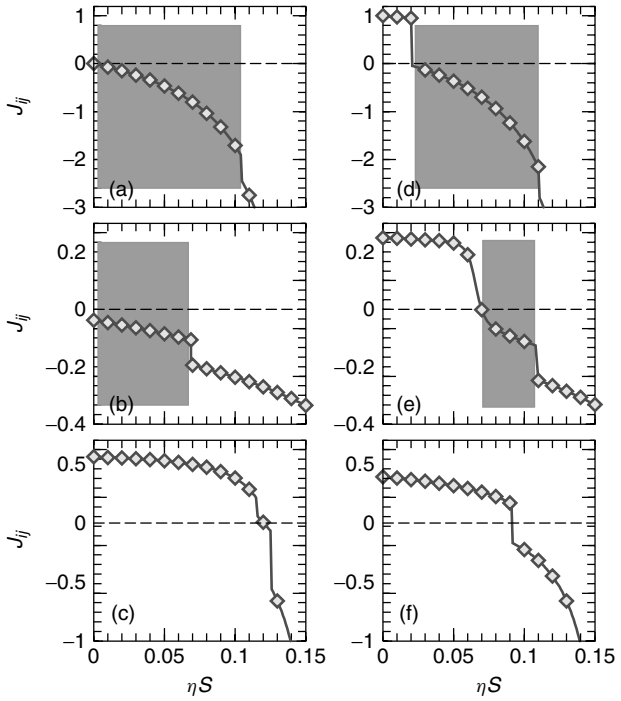

Figure 22. Spin exchange constants $J_{ij} = \langle \hat{J}_{ij}^{(c)} \rangle$ at $V = 0$ (left) and at $V = J$ (right) as functions of Hund's exchange ηS for (a), (d) d^1 model; (b), (e) d^2 model; (c), (f) d^9 model. In the shaded regions in (a), (b), (d), (e), J_{ij} is negative (FM) and yet the spin correlations are AF, $S_{ij} < 0$ (see Figure 21). (Reproduced from Oles *et al*., 2006, with permission from the American Physical Society. © 2006.)

the temperature dependence of the nearest-neighbor spin-correlation functions $\langle \mathbf{S}_i \cdot \mathbf{S}_j \rangle$, that is, by SE energy (Aichhorn, Horsch, von der Linden and Cuoco, 2002). Although it is clear that the *low-energy* effective SE Hamiltonian decides about the magnetic interactions, it is not immediately obvious that the *high-energy* optical excitations and their partial sum rules have the same roots and may be described by the SE as well.

The new concept of partial spectral weights makes it necessary to reanalyze the spin-orbital SE models to obtain the partial optical sum rules. In a further subsection, the three-dimensional spin-orbital model for the cubic vanadate compound $LaVO_3$ is solved approximately to illustrate the interdependence of spin and orbital correlations as well as the emergence of highly anisotropic optical spectral weights.

4.1 Partial optical sum rules and magnetism

The d-d charge excitations that are seen in optics reflect the rich multiplet structure of transition-metal ions determined by Hund's exchange coupling $J_{\rm H}$. The same multiplet transitions that reflect the spin and orbital degrees of freedom determine the SE interactions (Kugel and Khomskii, 1982a; Kugel and Khomskii, 1982b). When spin and orbital correlations change, for example, as function of temperature or magnetic field, the individual components of the optical multiplet reflect characteristic *spectral weight transfer*. Moreover, the cubic symmetry may be broken by orbital and spin order, and thus one expects *anisotropic optical absorption*. Indeed, pronounced anisotropy was reported for $LaMnO_3$ (Tobe, Kimura, Ohimoto and Tokura, 2001), both for the A-type AF phase (A-type (C-type) AF phase consists of ferromagnetic planes (chains) with AF order between them) as well as for the orbital-ordered phase above the Néel temperature $T_{\rm N}$. Recently, the anisotropy in optical absorption and its strong temperature dependence near the magnetic transitions were found for cubic vanadates (Miyasaka, Okimoto and Tokura, 2002; Tsvetkov *et al*., 2004; Motome, Seo, Fang and Nagaosa, 2003). This latter example is even more puzzling as the magnetic properties are anomalous (Mahajan, Johnston, Torgeson and Borsa, 1992; Noguchi *et al*., 2000). Neutron scattering (Ulrich *et al*., 2003) and Raman experiments (Miyasaka *et al*.,) have revealed nontrivial quasi one-dimensional (1D) correlations of spin and orbital degrees of freedom that are surprising for crystals with nearly cubic crystal structure. Indeed, a theory of spin and orbital states in cubic vanadates predicted that quasi-1D orbital fluctuations lead to a spontaneous breaking of the cubic symmetry in the SE model (Khaliullin, Horsch and Oleś, 2001).

The SE interaction in a cubic Mott insulator with orbital degrees of freedom has the generic form,

$$\mathcal{H}_J = H_s + H_\tau + H_{s\tau} = \sum_n \sum_{\langle ij \rangle \| \gamma} H_n^{(\gamma)}(ij) \qquad (46)$$

and consists of separate spin (H_s) and orbital (H_τ) interactions, and of a dynamical coupling between them ($H_{s\tau}$). This complex form of $\mathcal{H}_{\rm J}$, given by equation (46), follows from the terms $H_n^{(\gamma)}(ij)$ for each bond $\langle ij \rangle$ along a given cubic axis $\gamma = a, b, c$, that arise from the transitions to various upper Hubbard bands labeled by n. The *partial optical sum rules* for the different multiplet transitions n and photon polarization γ are determined by the respective terms of the SE energy (Khaliullin, Horsch and Oleś, 2004):

$$\frac{a_0 \hbar^2}{e^2} \int_0^\infty \sigma_n^{(\gamma)}(\omega) {\rm d}\omega = -\frac{\pi}{2} K_n^{(\gamma)} = -\pi \left\langle H_n^{(\gamma)}(ij) \right\rangle \qquad (47)$$

Here the tight-binding model is implied and a_0 is the distance between magnetic ions. $\left\langle H_n^{(\gamma)}(ij) \right\rangle$ is the SE energy for a bond $\langle ij \rangle$ along axis γ and multiplet transition n. The first equality in equation (47) follows from the optical sum rule for a given transition n, and relates the kinetic energy $K_n^{(\gamma)}$ to the optical conductivity $\sigma_n^{(\gamma)}(\omega)$ for this band, while the

second equality relates the associated kinetic energy to the SE energy via the *Hellman–Feynman theorem* (Baeriswyl, Carmelo and Luther, 1986).

Experimental data is often presented in terms of an effective carrier number (see, e.g., equation (2) of (Miyasaka, Okimoto and Tokura, 2002)), $N_{\mathrm{eff},n}^{(\gamma)} = (2m_0 v_0/\pi e^2)\int_0^\infty \sigma_n^{(\gamma)}(\omega)\mathrm{d}\omega$, where m_0 is the free electron mass, and $v_0 = a_0^3$ is the volume per magnetic ion. This gives the *partial optical sum rules* in the following form (Khaliullin, Horsch and Oleś, 2004):

$$N_{\mathrm{eff},n}^{(\gamma)} = -\frac{m_0 a_0^2}{\hbar^2}\, K_n^{(\gamma)} = -\frac{m_0 a_0^2}{\hbar^2}\left\langle 2H_n^{(\gamma)}(ij)\right\rangle \tag{48}$$

Each level n of the multiplet represents an upper Hubbard band with its own spin and orbital quantum numbers. The key point is that while the full kinetic energy and the corresponding total intensity may show only moderate T dependence and weak anisotropy, the behavior of the individual transitions is much richer. In particular, spectral weight transfers between different multiplet transitions directly reflect the change of spin and orbital correlations.

To conclude this section, we note that strong spin-orbital fluctuations imply large virtual kinetic energy, which is measured by the partial spectral weights. Hence by careful quantitative study of optical spectra, their anisotropy and temperature dependence it should be possible to decide whether orbitals fluctuate strongly or whether they are quenched by crystal fields or JT distortions.

4.2 Optical anisotropy and partial sum rules in cubic vanadates

In Mott insulators with orbital degeneracy the orbital occupation and correlation functions determine the interaction between spins, while the resulting spin correlations influence the interaction between orbitals. We have seen that in some cases quantum fluctuations decide about the resulting order, the lowering of dimensionality, and so forth. In the following, this interrelation and the implications for the partial optical spectral weights will be described for one case in more detail. In Section 2.4, we have already discussed the spin-orbital Hamiltonain, equation (16), for $LaVO_3$. Our main task here is to separate this expression into the individual contributions arising from the different multiplet transitions. These individual terms contain precisely the required information for the partial spectral weights of the different optical excitations (see Figure 3). In case of vanadates, one has three optical bands $n = 1, 2, 3$ arising from the transitions to: (i) a high-spin state $^4\mathrm{A}_2$ at energy $U - 3J_\mathrm{H}$, (ii) two degenerate low-spin states $^2\mathrm{T}_1$ and $^2\mathrm{E}$ at U, and (iii) $^2\mathrm{T}_2$ low-spin state at $U + 2J_\mathrm{H}$ (Khaliullin, Horsch and Oleś, 2001). Using $\eta = J_\mathrm{H}/U$, the multiplet structure is parameterized by: $R = 1/(1-3\eta)$ and $r = 1/(1+2\eta)$. In $LaVO_3$ xy orbitals are singly occupied (Mahajan, Johnston, Torgeson and Borsa, 1992; Noguchi *et al.*, 2000). Hence the cubic symmetry is broken and one obtains a high-spin contribution for bonds $\langle ij\rangle$ along c axis:

$$H_1^{(c)} = -\frac{1}{3}JR\sum_{\langle ij\rangle}\Big(\mathbf{S}_i\cdot\mathbf{S}_j + 2\Big)\Big(\frac{1}{4} - \boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j\Big) \tag{49}$$

while $H_1^{(ab)} = -\frac{1}{6}JR\sum_{\langle ij\rangle}(\mathbf{S}_i\cdot\mathbf{S}_j+2)(\frac{1}{4} - \tau_i^z\tau_j^z)$ for (a,b) planes. In equation (49) pseudospin operators $\boldsymbol{\tau}_i$ describe low-energy dynamics of (initially degenerate) xz and yz orbital doublet at site i; this dynamics is quenched in $H_1^{(ab)}$. The operator $\frac{1}{3}(\mathbf{S}_i\cdot\mathbf{S}_j+2)$ is the projection operator on the *high-spin* state for $S = 1$ spins.

The terms $H_n^{(c)}(ij)$ for *low-spin* excitations ($n = 2, 3$) contain instead the spin operator $(1 - \mathbf{S}_i\cdot\mathbf{S}_j)$ (which guarantees that these terms vanish for fully polarized spins on a considered bond, $\langle \mathbf{S}_i\cdot\mathbf{S}_j\rangle = 1$):

$$\begin{aligned} H_2^{(c)} &= -\frac{1}{12}J\Big(1 - \mathbf{S}_i\cdot\mathbf{S}_j\Big)\Big(\frac{7}{4} - \tau_i^z\tau_j^z - \tau_i^x\tau_j^x + 5\tau_i^y\tau_j^y\Big) \\ H_3^{(c)} &= -\frac{1}{4}Jr\Big(1 - \mathbf{S}_i\cdot\mathbf{S}_j\Big) \\ &\quad\times\Big(\frac{1}{4} + \tau_i^z\tau_j^z + \tau_i^x\tau_j^x - \tau_i^y\tau_j^y\Big) \end{aligned} \tag{50}$$

For the application of the partial sum rules, equation (48), we need to know the temperature dependence of the different spin and orbital correlation functions. One approach is a Bethe–Peierls MF approximation for the spin and orbital bond correlations which are determined self-consistently after decoupling them from each other in $\mathcal{H}_\mathrm{J}$ (46). Within such a MF treatment composite spin-orbital (quartic) interaction terms can be included perturbatively (Khaliullin, Horsch and Oleś, 2004). Spin correlations follow by solution of the effective spin Hamiltonian:

$$H_s = J_{ab}^s\sum_{\langle ij\rangle_{ab}}\mathbf{S}_i\cdot\mathbf{S}_j - J_c^s\sum_{\langle ij\rangle_c}\mathbf{S}_i\cdot\mathbf{S}_j \tag{51}$$

where the exchange integrals along c and $a(b)$ directions:

$$\begin{aligned} J_c^s &= \frac{1}{2}J\Big[\eta R - (R - \eta R - \eta r)\Big(\frac{1}{4} + \langle\boldsymbol{\tau}_i\cdot\boldsymbol{\tau}_j\rangle\Big) \\ &\quad - 2\eta r\langle\tau_i^y\tau_j^y\rangle\Big] \\ J_{ab}^s &= \frac{1}{4}J\Big[1 - \eta R - \eta r + (R - \eta R - \eta r) \\ &\quad\times\Big(\frac{1}{4} + \langle\tau_i^z\tau_j^z\rangle\Big)\Big] \end{aligned} \tag{52}$$

are determined by the corresponding nearest-neighbor orbital correlation functions! Note that J_c^s turns out FM because of singlet fluctuations in the orbital sector (a minus sign in front of J_c^s has been included in equation (51)).

The orbital correlation functions are determined by the orbital Hamiltonian which is given as:

$$H_\tau = \sum_{\langle ij\rangle_c} \left[J_c^\tau \boldsymbol{\tau}_i \cdot \boldsymbol{\tau}_j - J(1-s_c)\eta r \tau_i^y \tau_j^y \right] + J_{ab}^\tau \sum_{\langle ij\rangle_{ab}} \tau_i^z \tau_j^z \qquad (53)$$

with exchange integrals:

$$J_c^\tau = \frac{1}{2} J \Big[(1+s_c)R + (1-s_c)\eta(R+r) \Big]$$
$$J_{ab}^\tau = \frac{1}{4} J \Big[(1-s_{ab})R + (1+s_{ab})\eta(R+r) \Big] \qquad (54)$$

depending on spin correlations: $s_c = \langle \mathbf{S}_i \cdot \mathbf{S}_j \rangle_c$ and $s_{ab} = -\langle \mathbf{S}_i \cdot \mathbf{S}_j \rangle_{ab}$.

In addition to spin-orbital SE $\mathcal{H}_J$ (46), orbitally degenerate systems are sensitive to lattice distortions which may lift orbital degeneracy, like, for example, in the case of the JT effect. In the present vanadate case, the effect of such couplings on the degenerate a and b orbitals can be expressed by the following term (Khaliullin, Horsch and Oleś, 2001):

$$\mathcal{H}_V = V_{ab} \sum_{\langle ij\rangle_{ab}} \tau_i^z \tau_j^z - V_c \sum_{\langle ij\rangle_c} \tau_i^z \tau_j^z \qquad (55)$$

where the interactions $V_{ab} > 0$ originate from the coupling of nearest-neighbor t_{2g} orbitals in (a, b) planes to the bond stretching oxygen vibrations in corner-shared perovskite structure. They generate antidistortive oxygen displacements and staggered OO (supporting SE), whereas the $V_c > 0$ term due to the $GdFeO_3$-type distortion (Mizokawa, Khomskii and Sawatzky, 1999) favors *FO* alignment along c axis, and thus *competes* with SE. The complete model $\mathcal{H} = \mathcal{H}_J + \mathcal{H}_V$ represents a nontrivial many-body problem. Interactions are highly frustrated, leading to strong competition between different spin and orbital states.

It is evident that the calculations need to be done self-consistently. Figure 23 shows the high anisotropy in the orbital sector in the magnetic C phase of $LaVO_3$, that is, below $T_N/J = 0.4$. The quasi-1D behavior documented by the large exchange constant J_c^τ implies strong orbital-singlet fluctuations along the c direction supported by the FM correlations along c in the spin sector. Note that the magnetic structure is 3D, yet highly anisotropic. In particular, the FM J_c^s and the AF J_{ab}^s are of comparable size. The large value of the FM exchange coupling is due to the orbital-singlet

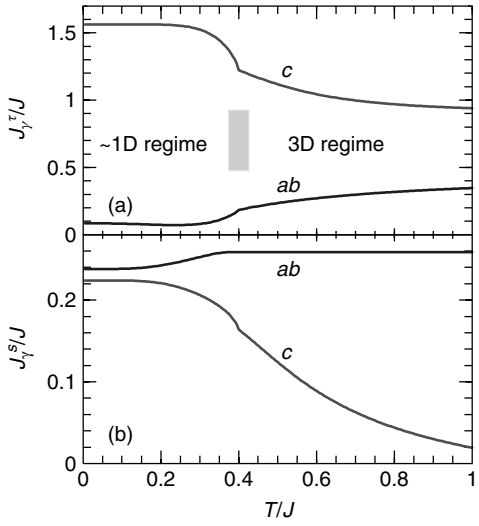

Figure 23. Exchange constants as functions of T along c (a/b) axis: (a) orbital J_γ^τ (54), and (b) spin J_γ^s (52). Parameters: $\eta = 0.12$, $V_c = 0.9J$, $V_{ab} = 0.2J$, $T_N = 0.4J$. (Reproduced from Khaliullin *et al.*, 2004, with permission from the American Physical Society. © 2004.)

fluctuations along c direction. Although the GK rules would also predict FM interaction along c in this case, the large value of the FM coupling J_c^s is unexpected.

Figure 24 shows the temperature dependence of the partial sum rules for the individual multiplet transitions. Because of the FM spin correlations along c in the C phase of $LaVO_3$ basically all weight is in the high-spin transition $n = 1$ below the Neél temperature T_N, whereas above T_N weight is transferred to the low-spin transitions $n = 2, 3$ reflecting the onset of paramagnetic behavior, consistent with experimental data. Because of antiferromagnetism in the ab plane the trends for $a(b)$ polarizations are reversed. At low temperature the main weight is in the low-spin channels, while there is almost no weight in the high-spin channel. This leads to the extreme anisotropy seen in the experimental data (see Figure 1).

Thus the basic experimental findings in the optical spectra of $LaVO_3$, (Miyasaka, Okimoto and Tokura, 2002) such as: (i) pronounced temperature dependence of c axis intensity (changing by a factor of 2 below 300 K), (ii) large anisotropy between the optical spectral weights along c and a/b axis (both below and above T_N), are qualitatively reproduced by this theory (see Figure 24). This strongly supports the picture of quantum orbital chains in the C-AF phase of vanadates.

The basic requirement for the study of partial spectral weights is the subdivision of the spin-orbital SE Hamiltonian into its multiplet contributions. Apart from the cubic vanadates (Khaliullin, Horsch and Oleś, 2004), this has been done in Oleś, Khaliullin, Horsch and Feiner (2005) for $KCuF_3$, $LaMnO_3$, and the cubic titanates. Ellipsometry data

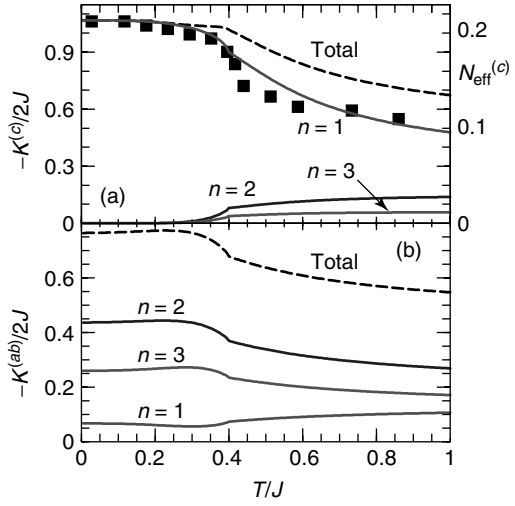

Figure 24. Partial kinetic energies $K_n^{(\gamma)}/2J$ (solid lines) and total kinetic energy (dashed lines) calculated for $LaVO_3$: (a) c axis and (b) ab-plane polarization. Parameters as in Figure 23. Experimental data (squares) for high-spin transition taken from Miyasaka, Okimoto and Tokura (2002). of $LaMnO_3$ was analyzed by (Kovaleva *et al*., 2004) using partial sum rules.

5 DOPED MANGANITES: INTERPLAY OF ORBITAL, SPIN, AND CHARGE

5.1 Phase diagram of manganites and double-exchange mechanism

The early history of transport properties of doped manganites starts with the pioneering work of Jonker and van Santen (1950). They observed that the manganite compounds $La_{1-x}A_xMnO_3$ (A = Sr, Ca, Ba) become around $x = 0.3$ FM and good metallic conductors, while they are antiferromagnets and insulators at low doping. The origin of the appearance of ferromagnetism upon doping holes was the central question in the early 1950s. It was answered by Zener (1951) who proposed the so-called double-exchange mechanism. Because of a large Hund coupling J_H the e_g electron spin of Mn^{3+} prefers the high-spin state, that is, to be aligned with the $S = 3/2$ spin of the t_{2g} core electrons (see Figure 25). In the case of doping the e_g electron of a Mn^{3+} ion can move on a Mn^{4+} site. However, to reach again the low-energy (high-spin) state, the t_{2g} spin on the neighbor site should be parallel, whereas for antiparallel alignment hopping is suppressed. Zener did not consider the e_g orbital degeneracy at the Mn^{3+} ion. The name DE stems from the fact that the hopping t between Mn^{3+} to Mn^{4+} involves two

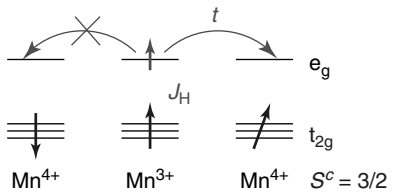

Figure 25. The large Hund coupling J_H forces the e_g electron spin parallel to the core spin $S^c = 3/2$ formed by the three t_{2g} electrons. The kinetic energy of itinerant e_g electrons favors parallel alignment of spins. This so-called double-exchange mechanism is the source of the ferromagnetic metallic phase in manganites at intermediate doping and low temperature.

scattering processes, namely, the creation of a hole in the occupied p orbital of the intermediate oxygen ligand ion and its subsequent annihilation. Thereby the Mn^{3+} and Mn^{4+} ions are interchanged.

The quantum treatment of DE usually starts from the FM KLM (Kubo and Ohata, 1972):

$$H = -t \sum_{\langle i,j\rangle\sigma} \mathrm{d}^\dagger_{i\sigma}\mathrm{d}_{j\sigma} - J_H \sum_{i\sigma\sigma'} \mathbf{S}_i^c \cdot \mathrm{d}^\dagger_{i\sigma}\boldsymbol{\sigma}_{\sigma\sigma'}\mathrm{d}_{i\sigma'} + J_{AF} \sum_{\langle i,j\rangle} \mathbf{S}_i^c \mathbf{S}_j^c \tag{56}$$

The model consists of the kinetic energy and the FM Hund coupling. To reflect the tendency toward antiferromagnetism in the undoped case here an AF interaction between core spins is included. The interplay of global AF interactions (on all bonds) and local FM alignment induced by the motion of an e_g electron via the DE mechanism is a subtle problem. In the high-temperature phase magnetism is controlled by FM polarons which move in the paramagnetic background (Varma, 1996; Horsch, Jaklic and Mack, 1999; Koller, Prüll, Evertz and von der Linden, 2003). The magnetic moment and size of the FM polarons increases with decreasing temperature until the system undergoes the phase transition into the FM phase.

In the paramagnetic phase charge carriers polarize the t_{2g} spins in their neighborhood to optimize their kinetic energy. The total spin of the polaron and its temperature dependence can be estimated using a *FM* spin-polaron picture (Varma, 1996; Horsch, Jaklic and Mack, 1999). The spin polaron is determined by the number P of ferromagnetically aligned spins around the hole which allows the particle to improve its kinetic energy in the paramagnetic system. The gain of kinetic energy is counterbalanced by the loss of spin entropy due to the coupling of P spins S_2, which can no longer rotate independently. An estimate for the change of free energy is $\delta F(P) = at/P^\eta + Pk_BT \ln(2S_2 + 1)$. The kinetic energy exponent $\eta = 2/3, 1, 2$ in

three, two, and one dimensions, respectively, and $S_2 = 2$ for Mn^{3+}. Minimization with respect to P gives the size of the spin polaron and its temperature dependence (Horsch, Jaklic and Mack, 1999):

$$P(T) = \left(\frac{\eta a t}{B k_B T}\right)^{1/(1+\eta)} \tag{57}$$

with $B = \ln(2S_2 + 1)$. The number $P(T)$ of aligned S_2 spins that form the FM polaron depends in a nonlinear fashion on the inverse temperature. This can be used further to calculate the temperature dependence of the susceptibility in the paramagnetic phase – in good agreement with numerical simulations (Horsch, Jaklic and Mack, 1999; Yi, Hur and Yu, 2000).

Thus at sufficiently low temperature the motion of charge carriers overcomes the spin entropy and leads to a full alignment of spins, that is to a paramagnetic to FM transition, where the Curie temperature T_C is expected to scale with doping. This scaling of T_C can be seen in the phase diagrams for $La_{1-x}A_xMnO_3$ (A = Sr, Ca) and $Nd_{1-x}Sr_xMnO_3$ shown in Figure 26. One unsatisfactory aspect of the (orbital nondegenerate) KLM is the high symmetry of the phase diagram with respect to doping, that is, $T_C \sim x(1-x)$ for $J_{AF} = 0$ (Horsch, Jaklic and Mack, 1999).

Often the t_{2g} spins are treated as classical spins, then the effective hopping of e_g electrons can be expressed in terms of the angles Θ_i of the core spins and a phase Φ_i (Müller-Hartmann and Dagotto, 1996):

$$t_{ij}/t = \cos\left(\frac{\Theta_i}{2}\right)\cos\left(\frac{\Theta_j}{2}\right) + \sin\left(\frac{\Theta_i}{2}\right)\sin\left(\frac{\Theta_j}{2}\right)\exp\left[i(\Phi_i - \Phi_j)\right] \tag{58}$$

The phase variable is of quantum-mechanical origin and may have important consequences. Nevertheless, frequently the absolute value $t_{ij} = t\cos(\Theta_{ij}/2)$ of the above expression is used. This model is usually called the *double-exchange model* and depends only on the relative angle Θ_{ij} between the t_{2g} spins (Anderson and Hasegawa, 1955). Recently it has been shown that Zener's model of ferromagnetism is also at work in dilute FM semiconductors like $Ga_{1-x}Mn_xAs$ and $Zn_{1-x}Mn_xTe$, and even allows to estimate relatively reliable values for the Curie temperature T_C (Dietl *et al.*, 2000). Ferromagnetism in dilute magnetic semiconductors depends on the existence of delocalized carriers or shallow impurity states that couple to the spins at the transition-metal site. Systems derived from wide-gap compounds like ZnO are considered particularly promising as candidates for spin-optoelectronic devices (Xu *et al.*, 2006).

5.2 Colossal magnetoresistance and optics

The observation of large magnetoresistance (von Helmolt *et al.*, 1993; Jin *et al.*, 1994) $\Delta R/R = (R_h - R_0)/R_h$ (R_h is the resistance in a magnetic field) in a number of manganite compounds stimulated research in orbital degenerate systems greatly. The name colossal magnetoresistance was proposed by Jin *et al.* (1994) who investigated thin films of $La_{1-x}Ca_xMnO_3$. The data by Tomioka, Asamitsu and Tokura (2000) displayed in Figure 27 shows the dramatic drop of the resistivity $\rho(T)$ in $La_{0.7}Ca_{0.3}MnO_3$ by 2 orders of magnitude. The gradual onset of magnetization at higher temperatures in finite magnetic fields leads to pronounced changes of $\rho(T)$.

An important characteristic feature of CMR is the activated behavior of $\rho(T)$ above the Curie temperature T_C, that is, in the paramagnetic phase. In the phase diagram, Figure 26, this regime is denoted as paramagnetic insulating (PI) phase in contrast to the paramagnetic metallic (PM) phase. CMR is intrinsically connected with the appearance of the PI phase.

The activated behavior of $\rho(T)$ in the PI phase has proven as central theoretical challenge. A short list of possible theoretical explanations includes: (i) Localization due to spin disorder in paramagnetic phase (Varma, 1996), (ii) small lattice polaron formation due to strong JT coupling (but neglect of correlations) (Millis, Littlewood and Shraiman, 1995), (iii) polaron-bipolaron mechanism (Alexandrov and Bratkovsky, 1999), (iv) localization due to charge disorder (Allub and Alascio, 1997), (v) nanoscale phase separation in metallic and insulating domains (Mayr *et al.*, 2001; Burgy, Dagotto and Mayr, 2003), (vi) spin disorder and orbital-polaron formation (Kilian and Khaliullin, 1999).

The localization due to spin disorder alone can be ruled out as mechanism for the strong activated behavior of $\rho(T)$. Calculations of the LKM using quantum spins do not give evidence of significant activated behavior. Nevertheless, spin disorder is crucial as it reduces the kinetic energy in the paramagnetic phase and thereby supports polaron formation and the tendency toward localization in combination with other mechanisms as in (ii), (iii), and (vi). Important further experimental constraints follow from the behavior of the optical conductivity as we shall see next.

The variation of the optical conductivity $\sigma(\omega)$ in manganites as function of doping and temperature is rather complex and is only partially understood. Here, we confine the discussion on the remarkable behavior of $\sigma(\omega)$ in the FM metallic phase and the PI phase, that is the doping range relevant for CMR. Naively one would expect that the FM polarized phase shows simple Drude behavior as spin disorder and fluctuations are frozen out, and only scattering from defects and phonons remain in a homogeneous system. Yet, the optical experiments show a completely different behavior, which was first reported by Okimoto *et al.* (1995, 1997)

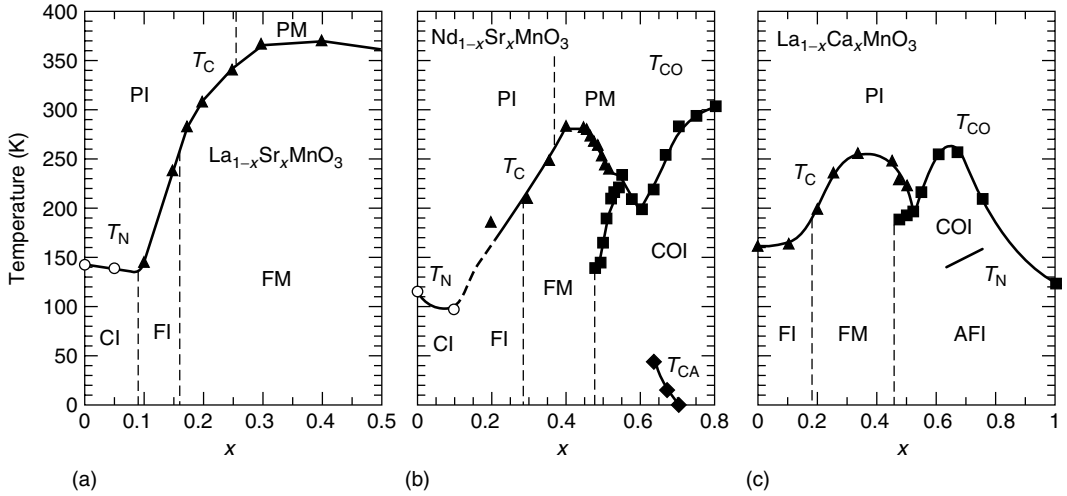

Figure 26. Electronic phase diagrams as function of doping concentration x and temperature T for the perovskite compounds: (a) $La_{1-x}Sr_xMnO_3$, (b) $Nd_{1-x}Sr_xMnO_3$, and (c) $La_{1-x}Ca_xMnO_3$. States are denoted as: PI: paramagnetic insulating; PM: paramagnetic metallic; CI: spin-canted insulating; COI: charge-ordered insulating; AFI: antiferromagnetic insulating, while T_N, T_C, T_{co} denote the Neèl, Curie, and charge-ordering temperature, respectively. (Reproduced from Imada *et al.*, 1998, with permission from the American Physical Society. © 1998.)

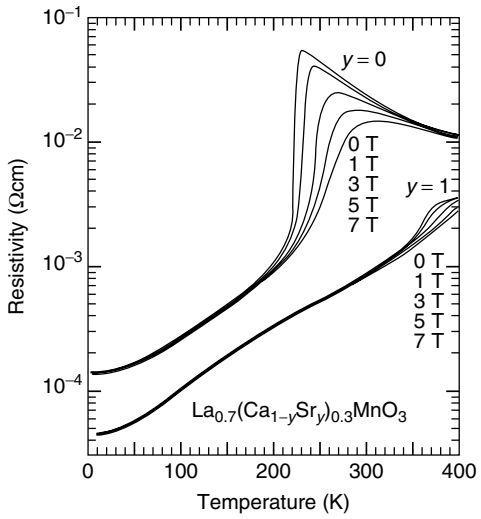

Figure 27. Temperature dependence of resistivity in various magnetic fields for $y = 0$ ($La_{0.7}Ca_{0.3}MnO_3$) and $y = 1$ ($La_{0.7}Sr_{0.3}MnO_3$) as an example of a bandwidth-controlled system. The $y = 0$ compound shows the typical CMR behavior, that is, low resistivity in the ferromagnetic phase and high resistivity together with activated behavior in the paramagnetic insulating (PI) phase. The anomalously large MR or CMR at $y = 0$ changes into a weaker MR behavior at $y = 1$. (Reproduced from Tonioko *et al.*, 2000, with permission from the American Physical Society. © 2000.)

and Saitoh, Asamitsu, Okimoto and Tokura (2000) for the $La_{1-x}Sr_xMnO_3$ compound.

Figure 28 shows the typical temperature dependence of the optical conductivity $\sigma(\omega)$ in the CMR doping regime. We note here four key features: (i) The gradual increase of absorption $\sigma(\omega)$ in the range $\omega < 0.5 - 1.0\,\text{eV}$ with decreasing temperature! That is, in the FM polarized phase this anomalous absorption is particularly large; (ii) this continuum appears to be gapless; (iii) evolution of a narrow Drude peak at low temperatures with strongly suppressed spectral weight (width $\sim 20 - 30\,\text{meV}$, see inset of Figure 28b); (iv) At high temperature, that is, in the PI phase, the optical conductivity develops a pseudogap $\sigma(\omega) \sim \omega$ up to about 1 eV.

This behavior clearly demonstrates, that the change of transport properties is connected with changes of the excitation spectra on the 1-eV scale, for example, distinct from quasielastic impurity scattering. In particular, the activated behavior of $\rho(T)$ in the PI phase is connected with pseudogap formation (iv).

5.3 Orbital $t-J$ model and orbital liquid

The peculiar behavior of the optical conductivity in the uniform FM phase at low temperature, namely, the simultaneous observation of a very narrow Drude absorption and a broad incoherent background of $\sim$1 eV width, finds a natural explanation in the orbital degree of freedom.

Orbital fluctuations in the FM state and their effect on the optical conductivity were studied first by Ishihara, Yamanaka and Nagaosa (1997) who arrived at the conclusion that the quasi-2D nature of orbital fluctuations leads to an orbital liquid in 3D cubic systems. Orbital disorder was treated in a static approximation. Because of this assumption there is no Drude component in the theoretical description of Ishihara, Yamanaka and Nagaosa (1997). Subsequently within a zero

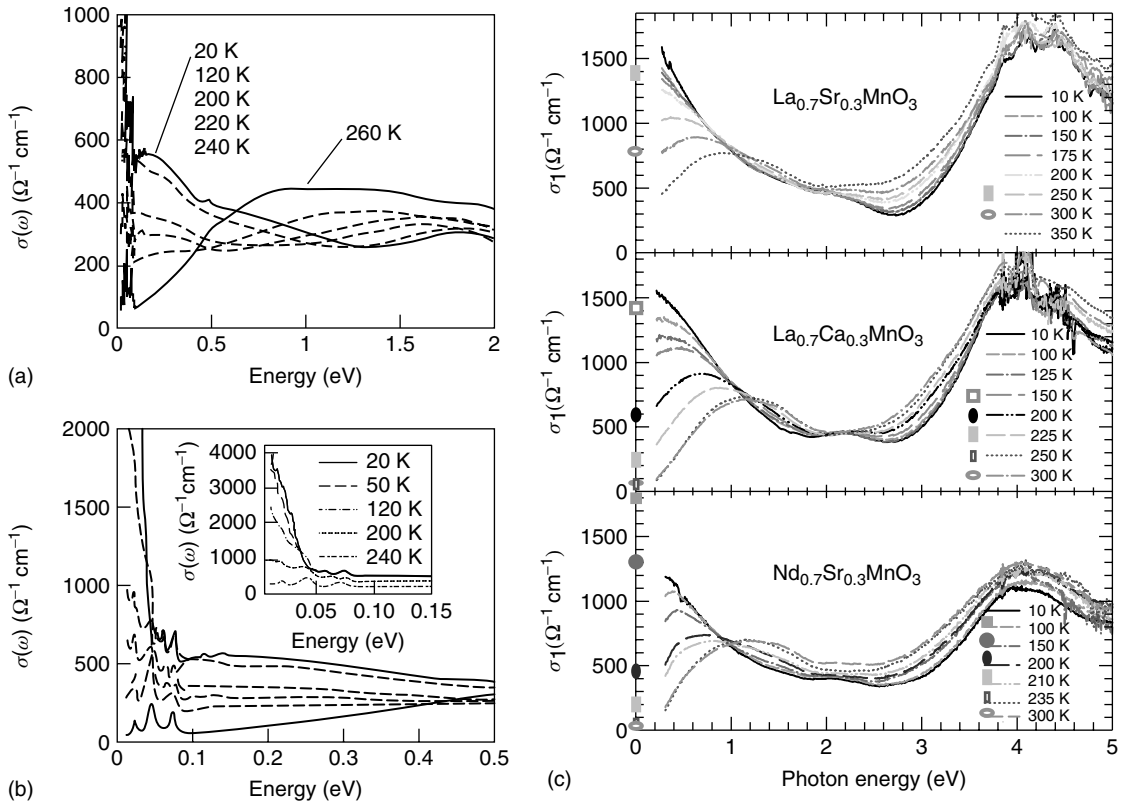

Figure 28. Temperature dependence of optical conductivity $\sigma(\omega)$ in the CMR regime of various compounds: Data of (Kim, Jung and Noh, 1998) for $La_{0.7}Ca_{0.3}MnO_3$ shows the typical behavior of $\sigma(\omega)$ in the CMR regime. (a) There is a strong spectral weight transfer on the 1-eV scale from high energy to low energy as function of decreasing temperature. This implies a continuous increase of the absorption $\sigma(\omega)$ (below 0.5 eV) as temperature decreases and indicates that this scattering has different origin than spin! Inset of (b): Surprisingly, despite of the anomalous low-energy scattering, there is a very narrow Drude peak (width ∼20–30 meV) that develops at low temperature. (c) Data of Quijada *et al*. (1998) for $La_{0.7}Sr_{0.3}MnO_3$, $La_{0.7}Ca_{0.3}MnO_3$ and $Nd_{0.7}Sr_{0.3}MnO_3$ amplifies that this behavior is universal. Notice that here the DC data implies the existence of a narrow Drude peak. Moreover all compounds show a characteristic pseudogap behavior in $\sigma(\omega) \sim \omega$ right above the Curie temperature over a wide energy range (0.5–1 eV)!

temperature slave boson approach Kilian and Khaliullin (1998) could show that there are both features (i) the highly incoherent spectrum due to the scattering of charge carriers from orbital fluctuations and (ii) a Drude peak with strongly reduced spectral weight.

The relevant (and most simple) model for the fully spin-polarized state is the orbital $t-J$ model, which consists of the SE interaction between orbitals and the kinetic energy of holes $H_{\rm kin}$. Actually it turns out that for typical values for the exchange interaction at moderate doping ($xt >> J$) the kinetic energy and the constraint dominate the behavior. The orbital $t-J$ model is defined as:

$$H_{otJ} = -\sum_{\langle ij\rangle_\gamma} \left(t_{ij}^{\alpha\beta} \tilde{d}_{i\alpha}^{\dagger} \tilde{d}_{j\beta} + \text{H.c.} \right) + J \sum_{\langle ij\rangle_\gamma} \left(\tau_i^\gamma \tau_j^\gamma - \frac{1}{4} n_i n_j \right) \tag{59}$$

with the constraint that each site can only be occupied by at most one (e_g) electron, that is, $\tilde{\rm d}_{i\alpha}^{\dagger} = {\rm d}_{i\alpha}^{\dagger}(1 - n_{i\overline{\alpha}})$, $\overline{\alpha}$ denotes the orthogonal e_g orbital with respect to α, and $\gamma = x, y, z$. The orbital SE is defined by pseudospin operators $\tau_i^{x/y} = -\frac{1}{4}(\sigma^z \pm \sqrt{3}\sigma^x)$, $\tau_i^z = \frac{1}{2}\sigma^z$, with Pauli matrices $\sigma_i^{x/z}$ acting on the orbital subspace. The orientation of the basis orbitals $\{|x\rangle, |z\rangle\} = \{x^2 - y^2, 3z^2 - r^2\}$ is reflected in the transfer matrices that describe the hopping in the (*a, b*) plane and along the *c* axis, respectively.

$$t_{ij\|a(b)}^{\alpha\beta} = \frac{t}{4} \begin{pmatrix} 3 & \mp\sqrt{3} \\ \mp\sqrt{3} & 1 \end{pmatrix} \quad t_{ij\|c}^{\alpha\beta} = t \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \tag{60}$$

Here $\mp$ distinguish hopping along *a* and *b* directions.

This model resembles the $t-J$ model which gives the description of hole motion in quantum antiferromagnets, that is one of the standard models for the high-T_C cuprates. Here the orbital index replaces the spin index in the $t-J$ model, and importantly the hopping has off-diagonal elements.

The $o-t-J$ and the $t-J$ model have in common the large incoherent absorption (with energy scale given by the free bandwidth) and the coherent motion of dressed charge carriers leading to a Drude absorption. A crucial difference of the two models is observed in 2D where the doped $t-J$ model is in a spin-liquid state, whereas due to the off-diagonal hopping elements the o–t–J model selects a long-range ordered state with x^2-y^2 OO that maximizes the kinetic energy in the 2D xy plane. The difference lies in the cubic and SU(2) symmetry of orbitals and spins, respectively. In the 3D cubic orbital t–J model, however, orbitals prefer a liquid state as x^2-y^2, x^2-z^2, and y^2-z^2 orbital correlations are equally possible, and the system is highly frustrated. Yet also the broken symmetry state with x^2-y^2 order appears in the manganite phase diagram as poor metallic highly doped A phase (Mack and Horsch, 1999).

The temperature dependence of the optical conductivity in the orbital $t-J$ model has been studied using finite temperature Lanczos method (Horsch, Jaklic and Mack, 1999). The frequency dependent conductivity $\sigma_0(\omega)$ consists of two parts:

$$\sigma_0(\omega) = 2\pi e^2 D_c \delta(\omega) + \sigma(\omega) \tag{61}$$

namely, the regular finite frequency absorption $\sigma(\omega)$ and a δ-function contribution which is proportional to the charge stiffness D_c (Kohn, 1964; Shastry and Sutherland, 1990). The latter vanishes in insulators. This contribution is broadened into a usual Drude peak in the presence of other scattering processes like impurities which are not contained in the present model. The finite frequency absorption (or regular part) $\sigma(\omega)$ is determined by the current–current correlation function using the Kubo formula

$$\sigma(\omega) = \frac{1-\mathrm{e}^{-\omega/T}}{N\omega}\mathrm{Re}\int_0^\infty \mathrm{d}t\mathrm{e}^{i\omega t}\langle j_x(t)\, j_x\rangle \tag{62}$$

where the x component of the current operator is proportional to the electron charge e and the x component of the hopping vector $\mathbf{u}$

$$j_x = -ie\sum_{j,\mathbf{u},ab} t^{ab}_{j+\mathbf{u}j} u_x \tilde{\mathrm{d}}^\dagger_{j+\mathbf{u}a}\tilde{\mathrm{d}}_{jb} \tag{63}$$

The increase of the anomalous absorption with decreasing temperature is quite natural as it reflects the increase kinetic energy of the orbital t–J model with decreasing T (Horsch, Jaklic and Mack, 1999), and is dictated by the optical sum rule (Baeriswyl, Carmelo and Luther, 1986). (This form of the sum rule applies for nn-hopping, for a more general case (see Aichhorn, Horsch, von der Linden and Cuoco, 2002):

$$\int_{-\infty}^{\infty}\sigma_0(\omega)\mathrm{d}\omega = -\frac{\pi e^2}{N}\langle H^{xx}_{kin}\rangle \tag{64}$$

here xx indicates that only hopping processes along x contribute. It is important to notice that the dominant coupling between charge and orbital degrees of freedom is the kinetic energy H_{kin}, therefore the half-width $\omega_{1/2}\sim 3t$ is related to the bandwidth (Figure 29). For a cubic lattice $\rho_0 = \hbar a/e^2$. If we consider $La_{1-x}Sr_xMnO_3$ with lattice constant $a = 5.5\,\text{Å}$ and $\hbar/e^2 = 4.11\,\mathrm{K\Omega}$ we obtain $\rho_0 = 0.23\cdot 10^{-3}\,\Omega$cm. Interestingly in combination with the sum rule the kinetic energy determines the maximal size of the incoherent absorption (given the energy scale of the continuum) and is consistent with typical experimental data (Horsch, Jaklic and Mack, 1999). The only unknown quantity is the broadening Γ of the δ function. In the inset of Figure 29 a value $\Gamma\sim 20\,\mathrm{meV}$ taken from experiment (Okimoto *et al.*, 1995) was used, and in combination with the calculated charge stiffness D_c this leads to consistent values for the DC conductivity. The scattering processes that determine Γ (and the DC conductivity) are extrinsic with respect to the electronic model (59). That is, Γ is due to impurities, grain boundaries, and at high temperatures also due to scattering with phonons.

Thus, the very peculiar features of the optical conductivity in the uniform FM regime can be naturally explained by orbital degeneracy. On the other hand, typical lattice polaron models require large electron phonon coupling g and large polaron binding energy to generate incoherent absorption up to $\sim$1 eV (Hartinger *et al.*, 2004; Puchkov *et al.*, 1995). However, in such a strong coupling regime no narrow Drude absorption does exist simultaneously (Reik and Heese, 1967).

5.4 Orbital-degenerate Kondo lattice model

For the study of the interplay of charge, orbital, and spin degree freedom in doped manganites a natural starting point is the orbital-degenerate KLM (Horsch, Jaklic and Mack, 1999; Mack and Horsch, 1999). As in the nondegenerate KLM, equation (56), the Mn e_g electrons are coupled ferromagnetically to the t_{2g} core spins via the Hund coupling J_{H}:

$$H_{\mathrm{KLM}} = -\sum_{\langle ij\rangle\alpha\beta,\sigma}\left(t^{\alpha\beta}_{ij}\tilde{\mathrm{d}}^\dagger_{i\alpha\sigma}\tilde{\mathrm{d}}_{j\beta\sigma} + \mathrm{H.c.}\right) - J_{\mathrm{H}}\sum_{\langle ij\rangle\alpha\sigma\sigma'}\mathbf{S}_i\cdot\tilde{\mathrm{d}}^\dagger_{\mathbf{i}\alpha\sigma}\boldsymbol{\sigma}_{\sigma\sigma'}\tilde{\mathrm{d}}_{i\alpha\sigma'} \tag{65}$$

where the kinetic energy matrix is defined as in equation (60) and the creation operators respect the constraint that

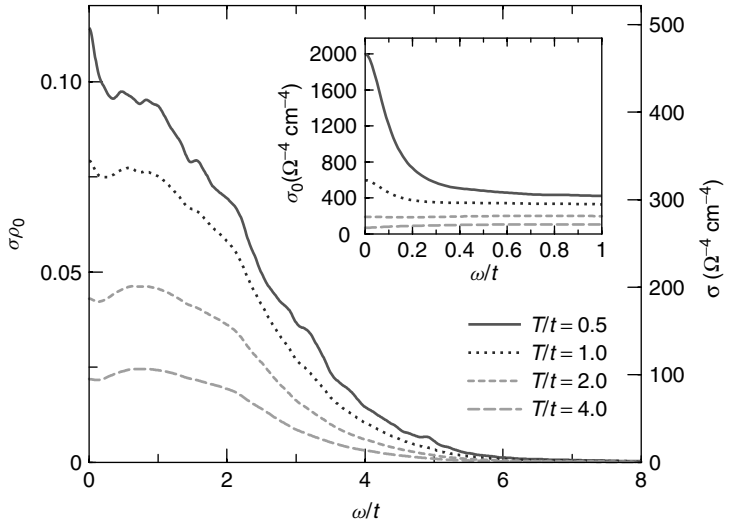

Figure 29. Temperature dependence of optical absorption $\sigma(\omega)$ in the orbital liquid phase. The results obtained for the orbital $t-J$ model at 20% doping show the characteristic increase of absorption with decreasing temperature and the gapless nature of the spectrum. Inset shows the appearance of a narrow Drude peak in $\sigma_0(\omega)$ at low temperature. Typical value for energy scale $t \sim 0.3\,\mathrm{eV}$. (Reproduced from Horsch *et al*., 1999, with permission from the American Physical Society. © 1999.)

allows only Mn^{4+} and Mn^{3+} configurations, that is, $\tilde{d}^{\dagger}_{i\alpha\sigma} = d^{\dagger}_{i\alpha\sigma}(1-n_{i\alpha\bar{\sigma}})\prod_{\sigma'}(1-n_{i\bar{\alpha}\sigma'})$, and all other alternative e_g states are projected out. The total Hamiltonian

$$H = H_{\mathrm{KLM}} + H' \tag{66}$$

usually contains additional relevant interactions that are summarized in H' and whose importance on the electronic properties may depend on the doping regime. Examples are the AF interaction between core spins, Coulomb interaction supporting charge ordering near quarter filling, or effective orbital interactions that simulate cooperative JT interactions.

For example, the tendency toward alternating charge order as in (a,b) plane of undoped or weakly doped $LaMnO_3$ may be expressed by a nearest-neighbor orbital interaction H_{OO}. There are two different mechanisms contributing to the OO interaction: (i) the cooperative JT effect (Feiner and Oleś, 1999) and (ii) SE interactions (Horsch, Jaklic and Mack, 1999; van der Brink, Horsch, Mack and Oleś, 1999). Neglecting more complex spin-orbital terms (Ishihara, Inoue and Maekawa, 1997; Shiina, Nishitani and Shiba, 1997; Feiner and Oleś, 1999) both effects can be described by van der Brink, Horsch, Mack and Oleś (1999)

$$H_{\mathrm{OO}} = 2\kappa \sum_{\langle ij\rangle} T_{ij} \tag{67}$$

where the two-site orbital operator, T_{ij}, between nearest-neighbor Mn sites in the $\{|x\rangle, |z\rangle\}$ basis has the form,

$$T_{ij} = T_i^z T_j^z + 3T_i^x T_j^x \mp \sqrt{3}(T_i^x T_j^z + T_i^z T_j^x) \tag{68}$$

T_i^z and T_i^x are described in terms of pseudospin operators: $T_i^+ = \sum_\sigma \tilde{d}^{\dagger}_{ix\sigma}\tilde{d}_{iz\sigma}$, and $T_i^- = \sum_\sigma \tilde{d}^{\dagger}_{iz\sigma}\tilde{d}_{ix\sigma}$. The sign of the mixed term $\propto \sqrt{3}$ depends on orbital phases and is negative in the a direction and positive in the b direction.

As in the orbital nondegenerate case further simplification can be achieved by introducing classical t_{2g} spins. This allows for the combination of (finite temperature) Monte Carlo simulation of the classical t_{2g} spins with exact diagonalization of the orbital many-body problem (Dagotto, 2003; Daghofer, Oleś, Neuber and von der Linden, 2006).

5.5 Orbital polarons and colossal magnetoresistance

A very important mechanism, that actually can trigger the CMR behavior as well as the appearance of the ferromagnetic insulating (FI) phase, is the orbital polarization around the charge carrier (hole) as proposed by Kilian and Khaliullin (1999),

$$H_{\Delta}^{\mathrm{3D}} = -\frac{1}{2}\Delta \sum_{\gamma} \sum_{\langle ij\rangle \| \gamma} (1-n_i)\tau_j^{\gamma} \tag{69}$$

where $\gamma = a,\ b,\ c$ refers to different lattice directions and the pseudospin operators in the $\{|x\rangle, |z\rangle\}$ orbital basis are defined as:

$$\tau_j^{a(b)} = -\frac{1}{2}\left(T_j^z \mp \sqrt{3}T_j^x\right), \quad \tau_j^c = T_j^z \tag{70}$$

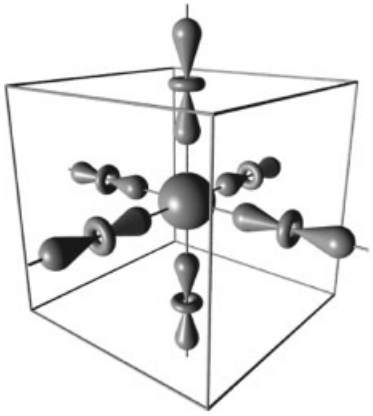

Figure 30. Orbital polaron in the strong coupling limit, where six e_g orbitals point toward the doped hole. This mechanism leads to heavy quasiparticles and eventually to localization. (Reproduced from Kilian & Khaliullin, 1999, with permission from the American Physical Society. © 1999.)

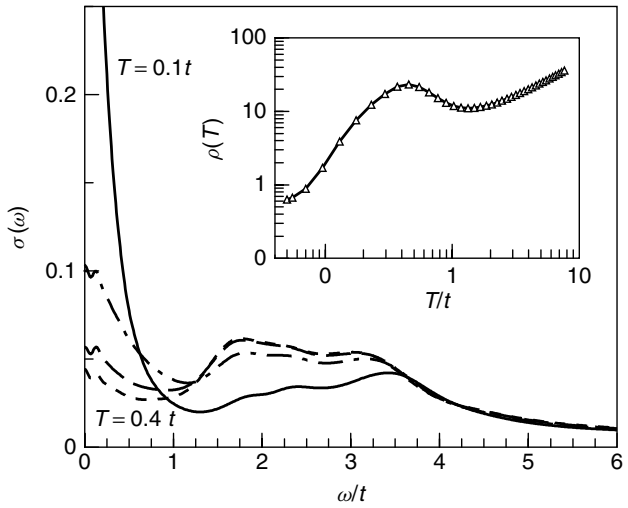

Figure 31. Optical conductivity $\sigma(\omega)$ calculated for a two-dimensional orbital-degenerate Kondo-lattice model at doping $x = 0.25$ for different temperatures $T = 0.1, 0.2, 0.3,$ and $0.4t$. The kinetic energy scale is $t \sim 0.2\,\mathrm{eV}$, the orbital-polaron coupling $\Delta = 2t$ and $\kappa = \Delta/5$. Inset: Resistivity $\rho(T)$ shows activated behavior in the paramagnetic range which is typical for CMR. Note the logarithmic scales. Both ρ and σ are given in dimensionless form. Comparison with experiment can be achieved by identifying the units with $\rho_0 = e^2/\hbar d \sim 0.2 \times 10^{-3}$ (Ωcm) and ρ_0^{-1}, respectively.

The interaction (69) splits locally the e_g states giving preference for the directional orbitals pointing toward an empty neighboring site as shown in Figure 30. Two main mechanisms for this level splitting were proposed: (i) the displacements of oxygen ions around an empty site; (ii) the Coulomb attraction between a hole and electrons on neighboring sites.

Various aspects of orbital polarons have been already investigated (Kilian and Khaliullin, 1999), here we briefly address the effects on optical conductivity and resistivity.The characteristic activated behavior of resisitivity $\rho(T)$ in the paramagnetic phase, and its dramatic decrease in the FM phase, follows in a natural way as a combined effect of orbital-polaron formation and spin disorder. Figure 31 shows results for $\sigma(\omega)$ and the resistivity obtained by the finite temperature Lanzcos method. The activated behavior of $\rho(T)$ is reflected by the evolution of a pseudogap in $\sigma(\omega)$.

We note, that the orbital polaron also describes the transition from the FM metallic into FI phase at low doping (see Figure 26). This is not immediately obvious as insulating implies that carriers do not move, whereas ferromagnetism via DE requires carrier motion! The resolution of this puzzle is straightforward (Kilian and Khaliullin, 1999), the coherent mass of the orbital polaron increases with reduced doping, such that the polaron can get bound by impurities or even form an orbital polaron lattice (at 1/8 filling) (Mizokawa, Khomskii and Sawatzky, 2000). Yet the internal motion of the hole inside the orbital polaron persists, that is the DE mechanism is still active and supports ferromagnetism.

Orbital polarization and its coupling to the lattice exists in the FM and the paramagnetic phase, but its effect is increased due to spin disorder in the paramagnetic regime. Thus leading to the activated behavior in the PI phase.The interplay of orbital-polaron dynamics and phonons is seen, for example, in the neutron scattering data of (Argyriou *et al.*, 2002) for the double layer compound $La_{2-2x}Sr_{1+2x}Mn_2O_7$, ($x = 0.38$), which shows a strongly coupled transverse optical phonon below the Curie temperature T_C but not above.

The properties of composite polarons are subtle as different mechanisms and energy scales are involved in renormalization of the charge carriers which may support or compete with each other. Other examples are the spin-lattice polarons (Ramšak, Horsch and Fulde, 1992; Mishenko and Nagaosa, 2004; Rösch *et al.*, 2005; Prelovšek, Zeyher and Horsch, 2006) in high-T_C compounds and spin-orbital polarons in layered cobaltates (Daghofer, Horsch and Khaliullin, 2006).

5.6 Spin waves in the double-exchange regime

In the uniform FM phase the spin-wave stiffness is determined by the kinetic energy, that is, in contrast to magnons in undoped compounds that are controlled by SE. One of the successes of DE theory was the derivation of the FM magnon dispersion ω_q from the (single orbital) KLM (Kubo and Ohata, 1972; Furukawa, 1996). The resulting dispersion corresponds to an isotropic, nearest-neighbor Heisenberg model. This prediction is well satisfied for manganites with large Curie temperature T_C like, for example, $La_{0.7}Pb_{0.3}MnO_3$

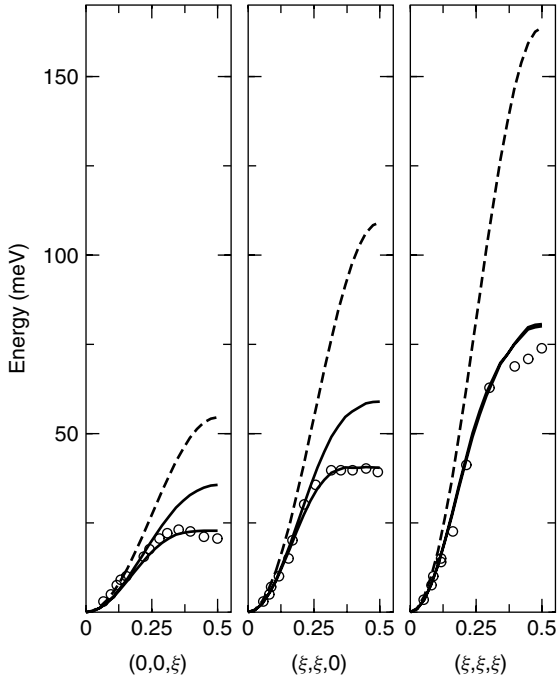

Figure 32. (a) Magnon dispersion of $Pr_{0.63}Sr_{0.37}MnO_3$ along three principal directions (circles) (Hwang *et al.*, 1998); $\xi = 0.5$ corresponds to the cubic Brillouin zone boundary; (b) mean-field dispersion corresponding to nearest-neighbor Heisenberg form (dashed lines); (c) Solid lines, theoretical results including charge, orbital, and lattices effects. (Reproduced from Khalliliun & Kilian, 2000, with permission from the American Physical Society. © 2000.)

(Furukawa, 1996). Yet in compounds with small T_C strong deviations from n.n. Heisenberg behavior were observed at large momentum transfer (see Figure 32).

We focus next on the role of the orbital fluctuations by considering the kinetic energy of the orbital-degenerate model (Khaliullin and Kilian, 2000; Oleś and Feiner, 2002). At small magnon numbers, that is, at low temperatures $T \ll T_C$, the kinetic energy operator in equation (65) can be mapped onto the following expression (Khaliullin and Kilian, 2000):

$$H_t = -\sum_{\langle ij\rangle_\gamma}\sum_{\alpha\beta} t_\gamma^{\alpha\beta}\hat{c}_{i\alpha}^\dagger \hat{c}_{j\beta} \times \left[\frac{3}{4} + \frac{1}{4S^2}\left(S_i^z S_j^z + S_i^- S_j^+\right)\right] + \text{H.c.} \qquad (71)$$

Equation (71) highlights an important point: The strength of DE bonds is a fluctuating complex quantity. Only when treating the orbital and charge sectors on average, that is, when replacing the bond operators $\hat{c}_{i\alpha}^\dagger \hat{c}_{i\beta}$ by their MF value $\langle \hat{c}_{i\alpha}^\dagger \hat{c}_{i\beta}\rangle$, an effective Heisenberg model as in a conventional MF treatment of DE is obtained: $H = J_{\text{DE}} \sum_{\langle ij\rangle} \mathbf{S}_i \mathbf{S}_j$ with the exchange constant dependent on the orbital and charge degrees of freedom:

$$J_{\text{DE}} = \frac{1}{2S^2}\sum_{\alpha\beta} t_\gamma^{\alpha\beta}\langle \hat{c}_{i\alpha}^\dagger \hat{c}_{j\beta}\rangle \qquad (72)$$

This determines the magnon energies $\omega_q = 2zSJ_{\text{DE}}\nu_q$, with $\nu_q = (2 - \cos q_x - \cos q_y)/4$ in 2D, or $\nu_q = (3 - \cos q_x - \cos q_y - \cos q_z)/6$ in 3D. Note that the isotropy of the spin Hamiltonian results from the orbital liquid state, where no direction is preferred.

Next we discuss the modification of the MF picture due to the fluctuations in the bond amplitude. The exchange J_{DE} is actually not a 'constant' but is varying with time. The FM interaction is connected with the hopping process of an e_g electron along a bond. In the case of orbital degeneracy such hopping processes are controlled by the orbital dynamics, that is, by the actual orientation of orbitals that fluctuate in time. As long as the energy scale of orbital fluctuations is large compared to the magnon scale J_{DE}, the magnon spectrum is basically unchanged, and given by time averages which restore the cubic symmetry. On the other hand, if orbitals fluctuate slower than spins or on the same timescale, the anisotropy and the damping of spin waves emerges. Figure 32 shows data from calculations of (Khaliullin and Kilian, 2000). In these calculations, in addition to charge and orbital fluctuations also the presence of JT phonons is considered.

5.7 Ordered and insulating phases prevail

The electronic properties of manganites $R_{1-x}A_xMn\ O_3$ are gradually changing from the wide band materials like (R = La, A = Sr) to the narrow band systems (La, Ca) and (Pr, Ca) as documented in Figure 33. The bandwidth is controlled by the ionic size of the cations R and A, respectively. Small cations lead to large $GdFeO_3$ type distortion (tilt of MnO_6 octahedra) with a large deviation of the Mn–O–Mn angle from 180°, which reduces the effective hopping between the Mn ions (Imada, Fujimori and Tokura, 1998). In the narrow band case the metallic (uniform FM) regime is confined to a narrow doping range, and new insulating phases emerge like the CE phase at and near $x = 0.5$ doping. The name of this phase is due to Goodenough (1955). It is remarkable that in the Orbital-degenerate manganites basically all phases are insulating, with the exception of the uniform FM phase. The A phase near $x = 0.5$ is a poor 2D metallic conductor. This is in striking contrast to the high-T_C cuprates where e_g orbital degeneracy is lifted by ∼1 eV and basically only at low doping insulating behavior is found.

The large variation of physical properties of manganites as function of doping or temperature originates from a complex interplay of spin, orbital, and charge degrees of freedom, as

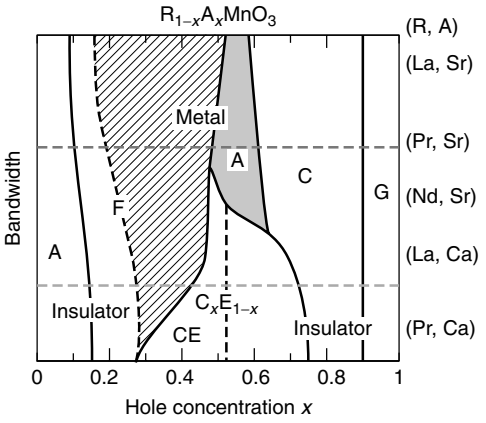

Figure 33. Schematic ground-state phase diagram of $R_{1-x}A_xMnO_3$ perovskites displaying the strong dependence on the bandwidth, that is, bandwidth increases from bottom to top. Here F denotes the FM state, while A, CE, C, and G denote antiferromagnetic states of A type, CE type, and G type, respectively. C_xE_{1-x} represents an incommensurate charge-/orbital-ordered state. (Reproduced from Kajimoto *et al*., 2002, with permission from the American Physical Society. © 2002.)

well as the interaction with the lattice (Tokura and Nagaosa, 2000; Tokura, 2003). An important example for the control of magnetic order due to the orbital degree of freedom is the checkerboard charge-ordered CE phase at quarter filling which we address here briefly. In the CE-phase FM zigzag chains are staggered antiferromagnetically and the occupied e_g orbitals at the Mn^{3+} sites are oriented along the FM bonds in the (a, b) planes (Goodenough, 1955) (Figure 34a,b). The CE structure reflects the cooperative action of AF SE and FM DE. Because of the AF correlations between FM chains, the carrier motion is basically confined to the FM chains. This consideration has stimulated the study of one-dimensional models for the CE phase (van den Brink, Khaliullin and Khomskii, 1999).

Yet it has been argued that these interactions alone do not guarantee the stability of the CE phase (Khomskii and Kugel, 2003; Calderon, Millis and Ahn, 2003; Bała, Horsch and Mack, 2004) and longer distant elastic strain and/or JT interactions are essential for the stability of the CE-OO. This claim is actually supported by the fact that CE-type orbital correlations have also been observed in the absence of antiferromagnetism, namely, in the FM metallic phase of $Nd_{1/2}Sr_{1/2}MnO_3$ (Geck *et al*., 2002). The JT distortion of the O ions and the resulting shift of the position of the Mn^{4+} ions shown in Figure 34(c) leads to a further neighbor JT coupling which supports CE-OO (Bała, Horsch and Mack, 2004; Bala and Horsch, 2005). The AF-CE phase was observed in cubic $(Nd,Pr)_{1/2}(Sr,Ca)_{1/2}MnO_3$ (Tokura and Nagaosa, 2000) and in layered $La_{1/2}Sr_{3/2}MnO_4$ (Sternlieb *et al*., 1996; Murakami *et al*., 1998), $LaSr_2Mn_2O_7$ (Kubota *et al*., 1999) manganites. An alternative proposal for the

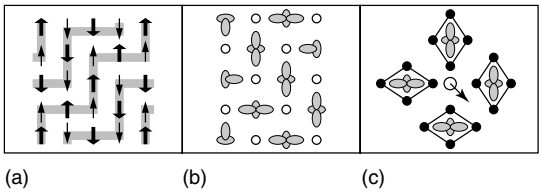

Figure 34. Spin-, orbital-, and charge structure of CE phase. (a) Shows the spin and charge order, where small (large) arrows indicate spin $S = 3/2(2)$ of Mn^{4+} (Mn^{3+}), respectively. (b) Orbital order consistent with the ferromagnetic zigzag chains. (c) Jahn–Teller distortion of the Mn^{3+} octahedra. (Reproduced from Bala & Horsch, 2005, with permission from the American Physical Society. © 2005.)

$x = 0.5$ structure, the Zener polaron picture, where the e_g electrons are centered on bonds (Daoud-Aladine *et al*., 1955; Efremov, van den Brink and Khomskii, 2004) rather than cite centered as in the CE structure, was not confirmed by experiment (Senff *et al*., 2006). An important feature of the CE phase is a large optical gap and a broad absorption maximum at 1–2 eV shifting toward lower frequencies with increasing temperature (Ishikawa, Ookera and Tokura, 1999; Jung *et al*., 2000; Kim *et al*., 2002). Remarkably a similar spectral shift is observed in photoexcitation experiments, which reveal ultrafast response times of such Mott-insulating structures (Tokura, 2003; Ogasawara *et al*., 2002).

It is evident that a real understanding of this or other phases is only achieved if not only the calculated magnetic and orbital structure is right but also the calculated excitation spectra are consistent with experiment. This statement is particularly important when several degrees of freedom act together like in the manganites and complex phase diagrams appear. For example insulating systems with CE structures like $Pr_{1/2}Ca_{1/2}MnO_3$ or $Nd_{1/2}Ca_{1/2}MnO_3$ show an insulator to metal transition connected with the collapse of the electronic gap of $\sim$1 eV in high magnetic fields (Tokura and Nagaosa, 2000). Similar transitions occur in the related Sr compounds at smaller magnetic fields of about 5 T. This suggests that by varying the spin structure the orbital and charge order collapses.

Figure 35 shows the calculated optical conductivity for the CE phase as function of temperature. The calculation was performed by finite temperature diagonalization starting from the KLM $H_{\rm KLM}$ with degenerate orbitals and residual interactions H' which include (i) the AF interaction between core spins, (ii) a nearest-neighbor Coulomb repulsion V which favors checkerboard charge order at quarter filling, and (iii) a second neighbor JT interaction κ' (Bala and Horsch, 2005).

There are still many open questions, for example, concerning the charge modulation of phases beyond $x = 0.5$. Even concerning the strength of charge modulations, that is, weak or strong, there is frequently disagreement among different theoretical approaches and also between different

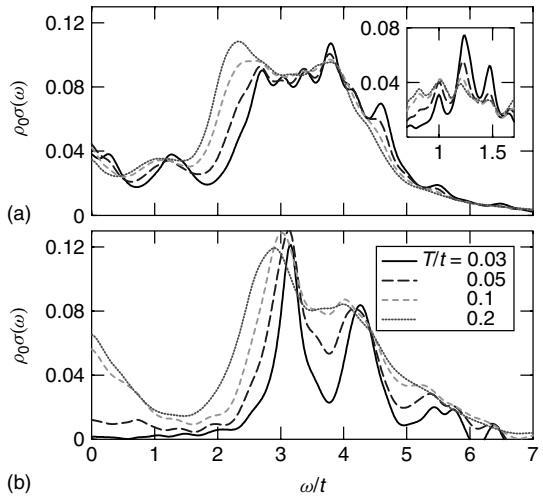

Figure 35. Temperature dependence of the optical conductivity $\sigma(\omega)$ obtained for two cases: (a) AF-CE order in the ground state, and (b) a FM-CE ground state for $J_{\mathrm{AF}} = 0.04t$. Partial melting of electron charge order leads to a reduction of the optical gap. Other parameters: (a) $V = 0.2t$, $\kappa' = 0.15t$; (b) $V = t$, $\kappa' = 0.05t$. The spectra are generated using a Lorentzian broadening $\Gamma = 0.2t$. Inset: Midgap absorption. (Reproduced from Bala & Horsch, 2005, with permission from the American Physical Society. © 2005.)

experimental techniques. Although the definition of the effective charge on an atom or ion is not that well defined, it is worrying that such seemingly simple questions cannot be better resolved. Electron diffraction studies of $La_{1-x}Ca_xMn O_3$ at doping concentrations $x = 0.52, 0.58, 0.67$ are compatible with a weak charge density wave modulation rather than strong charge order with discommensurations (Loudon *et al*., 2005). Thus these investigations suggest weak charge lattice coupling. Weak implies here, that modulations are not to be understood as stripes, that is, soliton-like discommensurations.

6 SUMMARY AND OUTLOOK

Through orbital, spin, and charge degrees of freedom strongly correlated electrons acquire an immense flexibility toward pattern formation. This is reflected in the complex phase diagrams of TMO families. Spin-orbital models that are derived from SE interactions describe the subtle interplay between spin and orbitals in TMO have been presented as useful theoretical approach. Spin-orbital models have only few parameters, the exchange constant J, the Hund-coupling parameter $\eta = J_{\mathrm{H}}/U$, the spin-orbit coupling λ and the JT coupling, for example. In any case a small number compared to multiband Hubbard models. Spin-orbital models allow to calculate orbital and spin ordering, spin excitations – that can be compared with data obtained by neutron scattering or other experiments. Surprisingly, these models also allow to calculate the absolute value of optical spectral weights of multiplet transitions in the electron volt regime. The temperature dependence of the optical weights closely reflects the variation of orbital and magnetic structure. Thus this provides a useful link between magnetic and optical experiments.

The complex electronic properties of TMO can be tuned by various means, for example, by magnetic field, by pressure, by internal pressure, that is chemically via the cation sizes. Charge-ordered states with large energy gap can by switched into conducting states by applying moderate magnetic fields. A new playing ground is opened by nanoscale multilayer interfaces of correlated materials (Okamoto and Millis, 2004). Careful control of orbital structure at interfaces between two materials can generate novel physical phenomena and functionalities, that are not a property of the constituent materials themselves. Examples are bilayers of Mott and band-insulating materials yielding a metallic interface (Ohmoto and Hwang, 2004). Other possibilities are combination of CMR manganite and high- T_{C} superconducting materials (Soltan, Albrecht and Habermeier, 2004; Chakhalian *et al*., 2006).

There are a number of developments that could not be covered here either because of limited space or because they have been discussed recently elsewhere in detail. This list includes, for example, magnetic field and photo-induced phase transitions in charge- and orbital-ordered systems (Tokura and Nagaosa, 2000), colossal electroresistance in perovskite oxides (Beck *et al*., 2000; Liu, Wu and Ignatiev, 2000), multiferroic behavior (Kimura *et al*., 2003; Efremov, van den Brink and Khomskii, 2004; Khomskii, 2006), the magnetoelectric effect (Fiebig, 2005; Katsura, Nagaosa and Balatsky, 2005; Arima *et al*., 2006).

The steady experimental progress in this field will continue to represent a strong stimulation to theory. The full theoretical problem, namely, the description of the interplay of spin, orbital, charge, and lattice degrees of freedom remains a challenge for improved and new simulation techniques. Analytical techniques dealing with these strongly correlated systems need to be developed further in the future and tested against numerical simulation. Last but not least, even the spin-orbital models describing the undoped systems represent a great challenge for theorists. One example is the orbital-Peierls dimerization. Spin-orbital models show more subtle behavior than the Heisenberg and Ising models that have been invented about 80 years ago, and have been explored ever since.

ACKNOWLEDGMENTS

I am grateful to G. Khaliullin and A.M. Oleś for many years of stimulating collaborations on this subject.

Magnetic Spectroscopy

H. Ebert
Universität München, München, Germany

1 INTRODUCTION

In the middle of the 19th century, it was found that linearly polarized light gets elliptically polarized when it is transmitted through a magnetized sample (Faraday, 1846). This was obviously the first clear demonstration that the spectroscopic properties of a solid depend on its magnetic properties. Later on, several other magneto-optical effects have been discovered, such as the Kerr, Zeeman, Voigt, or Cotton–Moutton effect (Reim and Schoenes, 1990), that can be exploited to monitor the magnetic state of a sample. This applies in particular to the magneto-optical Kerr effect (MOKE), which is extensively used for the recording of magnetic hysteresis loops, imaging of magnetic domains (Hubert and Schäfer, 1998), or in sensor and storage technology (Mansuripur, 1995). The various magneto-optical effects were originally observed in the energy regime of conventional optics. However, the availability of tunable synchrotron radiation of high intensity and well-defined polarization allowed the exploration of magneto-optical effects in the X-ray regime also (Beaurepaire, Scheurer, Krill and Kappler, 2001). Apart from the mentioned effects (Mertins *et al*., 2000), the most prominent phenomena are the magnetic linear dichroism in X-ray absorption (XMLD) (van der Laan *et al*., 1986) and magnetic circular dichroism in X-ray absorption (XMCD) (Schütz *et al*., 1987; Wende, 2004), the magnetic dichroism in X-ray fluorescence (Strange, Durham and Györffy, 1991), and the nonresonant and resonant magnetic scattering (Namikawa, Ando, Nakajima and Kawata, 1985; Gibbs *et al*., 1988; Lovesey, 1993). In addition, one has to mention the various dichroic effects in core-level (Baumgarten *et al*., 1990; Roth, Hillebrecht, Rose and Kisker, 1993) and valence-band (Kuch and Schneider, 2001) photoemission. Similar to the MOKE, dichroic effects in the X-ray regime can also be used to probe the magnetization of a sample. Because X-ray absorption and core-level photoemission imply the excitation of tightly bound core electrons, these spectroscopies supply the basis for element-specific hysteresis loop recording (Chen *et al*., 1993) and magneto-microscopy (Schneider *et al*., 1993; Eimüller *et al*., 2001).

Magneto-optical and dichroic effects in spectroscopy not only allow one to image the magnetization of a sample or to follow its variation with time (Ghiringhelli *et al*., 2001) but also supply a very important probe for their electronic structure. For the MOKE, it was shown around 1930 that it is caused by an interplay of magnetization and spin-orbit coupling (Hulme, 1932). This would later on be confirmed by detailed calculations based on an *ab initio* description of the electronic structure (Wang and Callaway, 1974; Oppeneer, Maurer, Sticht and Kübler, 1992). The mechanism leading to the MOKE was expected to give rise also to the XMCD (Erskine and Stern, 1975). Again, this would be confirmed by calculations that accounted for magnetism and spin-orbit coupling at the same time (Ebert, Strange and Györffy, 1988). In addition, it would be shown that XMCD spectra

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

essentially reflect the spin and orbital polarization (OP) of the electronic states above the Fermi level. This finding led to the sum rules that supply a formal basis for deducing from XMCD spectra an estimate for the spin and orbital magnetic moment of the absorbing atoms (Thole, Carra, Sette and van der Laan, 1992; Carra, Thole, Altarelli and Wang, 1993). Accordingly, recording the anisotropy of the XMCD signal gives information on the anisotropy of the orbital magnetic moment. Because of the interrelation of the latter and the magnetic anisotropy energy, ΔE_{aniso} (Bruno, 1989), one gets a spectroscopic access to ΔE_{aniso} (Stöhr, 1999). Owing to these outstanding features, the XMCD became a valuable tool to study the properties of a great variety of magnetic solids.

Angle-resolved valence-band photoemission spectroscopy allows one to probe the electronic structure of a solid in a most detailed way (Kevan, 1992). Spin-resolved experiments on magnetic solids, in addition, give access to the dispersion relation $E(\vec{k})$ of the two spin subsystems separately, that can be studied for example, as a function of temperature (Kisker, Schröder, Campagna and Gudat, 1984). The observation of various forms of dichroism, however, showed that such a decomposition is not strictly possible. Corresponding experimental and theoretical investigations demonstrated that spin- and angle-resolved valence-band photoemission spectroscopies – in contrast to all other spectroscopies – allow probing of the hybridization of states with different spin character in a rather direct and detailed way (Feder and Henk, 1996).

Among the various spectroscopies mentioned in the preceding text, the MOKE, the magnetic dichroism in X-ray absorption, and valence-band photoemission will be dealt with in this contribution as important and representative examples. For all three cases, the theoretical basis for a calculation and discussion of the corresponding spectra will be presented together with some examples. In the next section, it will be demonstrated by some simple arguments that the various magneto-optical and dichroic phenomena to be discussed are caused by an interplay of exchange splitting and spin-orbit coupling. For this reason, a brief overview on the techniques used to perform corresponding electronic structure calculations to supply an adequate basis for a quantitative study of the various phenomena is given in addition.

2 THEORETICAL FRAMEWORK

2.1 The importance of spin-orbit coupling for spectroscopy

Many spectroscopic properties of solids can be discussed on the basis of their optical conductivity tensor $\boldsymbol{\sigma}(\omega)$, whose shape reflects the symmetry of its crystal structure (Kleiner, 1966). In the case of a magnetic solid, the magnetic ordering reduces its symmetry compared to the nonmagnetic state, because any symmetry operation not only has to be conform with the crystal structure but also has to leave the magnetization $\vec{M}$ unchanged. For cubic systems for example, the effective symmetry is tetragonal, trigonal, or orthorhombic, respectively, depending on whether the magnetization is aligned along the [001], the [111], or the [110] axis (Cracknell, 1969). As a consequence, there are less restrictions for the shape of $\boldsymbol{\sigma}(\omega)$ leading for example, for the first and last cases to:

$$\boldsymbol{\sigma}^{[001]} = \begin{pmatrix} \sigma_{xx} & \sigma_{xy} & 0 \\ -\sigma_{xy} & \sigma_{xx} & 0 \\ 0 & 0 & \sigma_{zz} \end{pmatrix} \quad \text{and}$$

$$\boldsymbol{\sigma}^{[110]} = \begin{pmatrix} \sigma_{xx} & \sigma_{xy} & \sigma_{xz} \\ \sigma_{xy} & \sigma_{xx} & -\sigma_{xz} \\ -\sigma_{xz} & \sigma_{xz} & \sigma_{zz} \end{pmatrix} \qquad (1)$$

instead of the diagonal degenerate form in the case of a nonmagnetic cubic solid.

It is important to note that the reduction in symmetry due to the magnetization that is reflected by the preceding equations occurs only if spin-orbit coupling is present. If one could switch off spin-orbit coupling for a spin-polarized system, its properties would not depend on the orientation of the magnetization anymore, and, for this reason, its symmetry would be that of the corresponding nonmagnetic state. Thus, it is the magnetization together with spin-orbit coupling that leads to a symmetry reduction as compared to the nonmagnetic case. Accordingly, many important magneto-optical phenomena occur only because of the simultaneous presence of magnetic ordering and spin-orbit coupling. For a shape of the optical conductivity tensor $\boldsymbol{\sigma}(\omega)$ according to the upper part of of equation (1) for example, one can trace back the magneto-optical Faraday and Kerr effect in the optical regime to the occurrence of the off-diagonal element σ_{xy}. Expressing the X-ray absorption coefficient in terms of the absorptive parts of the elements of $\boldsymbol{\sigma}(\omega)$, one finds that magnetic circular dichroism, that is, the difference in absorption for left- and right-circularly polarized light, is again due to σ_{xy}. Magnetic linear dichroism (MLD), on the other hand, is caused by the difference in σ_{xx} and σ_{zz}. Similar symmetry considerations have to be made when dealing with photoemission experiments also. To achieve a full understanding of all observed phenomena, not only the spin-orbit coupling but also the influence of the surface on the symmetry of the system has to be accounted for (Feder and Henk, 1996).

The importance of spin-orbit coupling for the spectroscopy of magnetic solids can also be demonstrated in an alternative way by the excitation scheme shown in Figure 1. Here initial

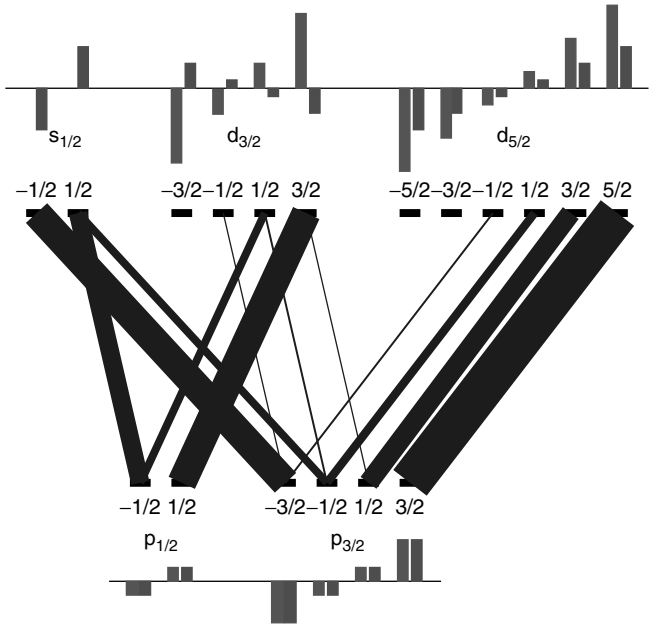

Figure 1. Absorption cross section for left-circularly polarized light represented by the line thickness, for transitions within a system with initial p and final s and d states. The various magnetic sublevels are indexed by the corresponding magnetic quantum number μ. The light and dark bars above and below the excitation scheme represent the expectation values $\langle \chi_\Lambda | \sigma_z | \chi_{\Lambda'} \rangle$ and $\langle \chi_\Lambda | l_z | \chi_{\Lambda'} \rangle$, that is, they are a measure for the spin and orbital magnetic moments, μ_{spin} and μ_{orb}, respectively, of these sublevels.

p and final s and d states that are split owing to the spin-orbit coupling into $j = l \pm 1/2$ levels and resolved according to the magnetic quantum number μ with $\mu = -j, \ldots, +j$ are considered. Using the angular matrix elements for the absorption of left-circularly polarized light (see following text), one arrives at an absorption cross section that strongly depends on the involved initial and final states. In the case of GaAs, one can identify the initial p states with the top of the valence band, while the final s states correspond to the bottom of the conduction band. Because of spin-orbit coupling of the p states, one has only $p_{3/2} \rightarrow s_{1/2}$ transitions at the absorption threshold. Owing to the μ dependence of the absorption cross section, the s states with $\mu = -1/2$ are dominantly populated leading to a spin polarization of the photoelectron current with $P = -50\%$. As long as the energy of the various levels does not depend on the sign of μ, the polarization is just reversed when the helicity of the light is reversed. This observation of spin-polarized photoelectrons from a nonmagnetic sample owing to the use of circularly polarized light is called *Fano effect* (Fano, 1969).

Interchanging the role of initial and final states in Figure 1 and identifying the s states with the 1s core shell and the final states with unoccupied p-like band states of a solid correspond to K-edge X-ray absorption. In this case, one finds that a finite orbital angular momentum is obtained for the final states occupied by absorption of circularly polarized light. Again the sign of the orbital angular momentum is reversed if the helicity is reversed. Shifting the various spin-orbit split levels in Figure 1, one has the excitation scheme for $L_{2,3}$-edge X-ray absorption spectra. Here one finds that the final states carry a spin and an orbital angular momentum that also change their sign upon reversing the helicity of the light. However, if the magnetic ordering destroys the remaining degeneracy with respect to μ, this symmetry disappears. In particular, one finds a magnetic circular dichroism (MCD) that reflects – depending on the involved transitions – the spin and OP of the final states.

These qualitative considerations show that spin-orbit coupling not only influences the spectroscopic properties of solids by its impact on the energy levels but also gives rise to new phenomena. Particularly for magnetic solids, this is the basis for many spectroscopies that allow one to monitor and probe their magnetic properties.

2.2 Electronic structure calculations

From the preceding considerations it is obvious that a full understanding of the spectroscopic properties of magnetic solids on a microscopic level can be achieved only by a description of the underlying electronic structure that accounts for magnetic ordering and spin-orbit coupling at the same time. For this purpose, either a localized or an itinerant point of view is taken depending on which is more appropriate for the system considered.

In the latter case one may assume, in addition, that spin magnetism dominates, implying that spin density functional theory (SDFT) or, in practice, the local spin density approximation (LSDA) supplies a satisfying framework for corresponding electronic structure calculations. To account for relativistic effects, it is quite common to incorporate, as a first step, only the appropriate scalar-relativistic corrections into the radial Kohn–Sham equations (Koelling and Harmon, 1977). These modifications, which represent the Darwin and mass–velocity terms, obviously do not involve the electronic spin. For that reason, they do not affect the symmetry of the system, allowing each subspin system to be treated separately. The spin-orbit coupling term (Rose, 1961):

$$\mathcal{H}_{\text{SOC}} = \frac{\hbar}{4m^2c^2} \frac{1}{r} \frac{\mathrm{d}V}{\mathrm{d}r} \frac{1}{2} \vec{\sigma} \cdot \vec{l} \qquad (2)$$

on the other hand, mixes the two subsystems leading to pronounced changes in the electronic structure.

As a direct consequence, one finds that spin is no more a good quantum number; that is, the expectation value $\langle \psi_{j\vec{k}} | \sigma_z | \psi_{j\vec{k}} \rangle$ for σ_z, with $|\psi_{j\vec{k}}\rangle$ being a Bloch state, is

not restricted to ± 1 but may take any value in between. In particular, the spin character may change continuously from majority to minority or vice versa when going along an electron band $E_{j\vec{k}}$. (An example for this can be found in Figure 8.) Another consequence of spin-orbit coupling is that the orbital angular momentum is no more quenched; that is, the finite expectation value $\langle \psi_{j\vec{k}} | l_z | \psi_{j\vec{k}} \rangle$ leads to a spin-orbit-induced orbital magnetic moment. Finally, it should be noted that the electronic band structure $E_{j\vec{k}}$ depends on the orientation of the magnetization $\vec{M}$ reflecting the magneto-crystalline anisotropy.

Using a conventional band structure scheme that is based on the variational principle, the corresponding basis functions are, in general, calculated on a scalar-relativistic level. Spin-orbit coupling is then accounted for within the variational step; that is, the spin-orbit coupling matrix evaluated using equation (2) and the basis functions are added to the LSDA-based Hamiltonian (Callaway and Wang, 1973). Alternatively, one first solves the LSDA-based band structure problem and then includes the effect of spin-orbit coupling in a second variational step for those states one is interested in (Singh, 1994). Using the Korringa-Kohn-Rostoker (KKR) or multiple-scattering approach instead of a variational method, spin-orbit coupling has to be included when calculating the basis functions (Koelling and Harmon, 1977; MacLaren and Victora, 1994).

All approaches mentioned so far have the common feature that they account for relativistic effects by appropriate corrections to an electronic system dealt on the basis of nonrelativistic SDFT. Accordingly, the underlying two-component basis functions and, with this, all derived electronic properties are classified by the conventional quantum numbers l, m_l and m_s. On the other hand, a scheme that treats spin magnetism and all relativistic effects on the same footing is achieved by starting from the Dirac equation set up within the framework of relativistic SDFT (Rajagopal and Callaway, 1973; MacDonald and Vosko, 1979):

$$\left[\frac{c}{i}\vec{\alpha}\cdot\vec{\nabla} + \frac{c^2}{2}(\beta - I) + V_{\mathrm{H}}(\vec{r}) + \overline{V}_{\mathrm{xc}}(\vec{r}) + \beta\vec{\sigma}\cdot\vec{B}(\vec{r})\right]\phi_i(\vec{r}, E) = E\,\phi_i(\vec{r}, E) \qquad (3)$$

with α_i and β being the standard Dirac matrices and $V_{\mathrm{H}}(\vec{r})$, the Hartree potential. The exchange correlation potential consists of a spin-averaged ($\overline{V}_{\mathrm{xc}}$) and a spin-dependent ($\vec{B}$) part.

Because of the spin-dependent part $\vec{B}$ of the potential, the four-component solutions to equation (3) for an isolated potential well have no unique spin-angular character, but have to be constructed as a superposition (Feder, Rosicky and Ackermann, 1983; Strange, Staunton and Györffy, 1984):

$$\phi_i(\vec{r}, E) = \sum_{\Lambda} \begin{pmatrix} g_{\Lambda i}(r, E)\,\chi_{\Lambda}(\hat{r}) \\ i f_{\Lambda i}(r, E)\,\chi_{-\Lambda}(\hat{r}) \end{pmatrix} \qquad (4)$$

Here $g_\Lambda(r, E)$ and $f_\Lambda(r, E)$ are the major as below and minor radial wave functions, respectively, and $\chi_\Lambda(\hat{r})$ are the spin-angular functions of the relativistic spin-orbit and magnetic quantum numbers κ and μ, respectively, ($\Lambda = (\kappa, \mu)$; $-\Lambda = (-\kappa, \mu)$) (Rose, 1961). Equation (4) implies that the degeneracy of the radial wave functions with respect to the quantum number μ is removed. In addition, for each linearly independent solution i to equation (3) not only a set of radial equations for $g_\Lambda(r, E)$ and $f_\Lambda(r, E)$ has to be solved but instead one also has to deal with an extended set of coupled radial equations depending on the quantum numbers and the geometrical shape of the potential (Huhne *et al.*, 1998). The technical problems caused by basis functions with the form given by equation (4) can be avoided by calculating in a first step the basis functions from equation (3) without the spin-dependent potential $V_{\mathrm{spin}}(\vec{r})$. Using a conventional band structure method this term can then be included in the variational step (Ebert, 1988). As an alternative to this, replacing equations (3–4) by an approximate interpolation scheme, a simpler form of the basis functions could be retained (Ankudinov and Rehr, 1997). In spite of the mentioned technical problems, several band structure schemes have been extended on the basis of equations (3–4) that indeed treat spin magnetism and all relativistic effects on the same level. This applies to several linear methods based on the variational principle (Ebert, 1988; Solovyev *et al.*, 1989; Krutzen and Springelkamp, 1989). For example for the linear muffin-tin orbital (LMTO) method, the Bloch wave functions $\psi_{j\vec{k}}$ can still be written in the standard way:

$$\psi_{j\vec{k}}(\vec{r}, E_{j\vec{k}}) = \sum_i A_i^{j\vec{k}}\phi_{i\nu}(\vec{r}) + B_i^{j\vec{k}}\dot{\phi}_{i\nu}(\vec{r}) \qquad (5)$$

with $\phi_{i\nu}$ and $\dot{\phi}_{i\nu}$ basis functions having the form given by equation (4). The expansion coefficients $A_i^{j\vec{k}}$ and $B_i^{j\vec{k}}$ are determined by the appropriate potential parameters, relativistic LMTO structure constants, and the eigenvectors. In addition, a corresponding extension to the KKR or multiple-scattering approach has been worked out. Again, the electronic Green's function $G(\vec{r}_n, \vec{r}_m, E)$ can be written in the usual way (Ebert, 2000):

$$G(\vec{r}_n, \vec{r}_m, E) = \sum_{\Lambda\Lambda'} Z_\Lambda(\vec{r}_n, E)\tau^{nm}_{\Lambda\Lambda'}(E)Z^{\times}_{\Lambda'}(\vec{r}_m, E) - \sum_{\Lambda} Z_\Lambda(\vec{r}_<, E)J^{\times}_{\Lambda}(\vec{r}_>, E)\delta_{nm} \qquad (6)$$

with $Z_\Lambda(\vec{r}_n, E)$ and $J_\Lambda(\vec{r}_n, E)$ being the solutions to the single-site Dirac equation (3) for site n with their form given by equation (4). The scattering path operator $\tau^{nm}_{\Lambda\Lambda'}(E)$ describes all multiple-scattering events in the system in a self-consistent way.

Compared with variational schemes, the KKR method has a number of appealing features. The calculation of the scattering path operator, that is, solving the band structure problem, can be done in principle for any geometry as, for example, finite, two-dimensional layered or three-dimensional bulk systems. The use of the Dyson equation allows one to deal with complex geometries starting from a simpler reference system as, for example, in the case of clusters deposited on a substrate. Representing the electronic structure in terms of the Green's function also enables the treatment of disordered systems by combining the KKR with the coherent potential approximation (CPA) alloy theory. Finally, the availability of the Green's function makes the KKR method a suitable platform, when dealing with spectroscopic properties.

For many core-level spectroscopies an adequate description of the involved core states that treat exchange splitting and spin-orbit coupling on the same level is indispensable (Mertins *et al*., 2001). This can also be achieved on the basis of the Dirac equation (3) (Ebert, 1989).

Using one of the schemes described in the preceding text to calculate properties that are connected to spin-orbit-induced orbital magnetism, the results are in general too low when compared to experimental data. In addition, one finds that correlation effects are often insufficiently described on the basis of plain LSDA. These problems can in most cases be reduced or removed by applying appropriate corrections to the Hamilton matrix or directly to the Dirac equation (3). This can be done for example, using Brooks' OP scheme (Brooks, 1985) or the LSDA + U method (Anisimov, Aryasetiawan and Lichtenstein, 1997). While the latter approach represents only static correlations, a more accurate treatment of correlation effects is achieved by a combination of LSDA and the dynamical mean field theory (DMFT) (Georges, Kotliar, Krauth and Rozenberg, 1996).

For strongly correlated systems, the various extensions to the LSDA seem to be insufficient and an approach putting strong emphasis on many-body effects is more appropriate. To describe, for example, the pronounced multiplet structure reflected by corresponding core-level spectra of rare earth systems, it is sometimes sufficient to deal with an isolated atom on a Hartree–Fock level (Vogel *et al*., 1991). A simple way to account for the influence of the surrounding on the electronic structure is to include a crystal field having a corresponding symmetry. As an alternative to this configuration interaction (CI), cluster model calculations are done that account for hybridization as well as for electron correlation effects.

2.3 Matrix elements

The various spectroscopies dealt with in the following text have in common that they hinge upon the interaction of electrons and photons. Treating the photon field in a classical way the electron–photon interaction operator is given by

$$X_{\vec{q}\lambda}(\vec{r}) = -\frac{1}{c}\vec{j}_{el} \cdot \hat{a}_\lambda A e^{i\vec{q}\vec{r}} \tag{7}$$

Here the vector potential $\vec{A}_{\vec{q}\lambda}(\vec{r}) = \hat{a}_\lambda A e^{i\vec{q}\vec{r}}$ represents radiation with amplitude A, wave vector $\vec{q}$, and polarization λ, with $\hat{a}_\lambda$ representing the corresponding polarization vector. Adopting a relativistic formulation, the electronic current density operator $\vec{j}_{el} = -ec\vec{\alpha}$ is expressed in terms of the Dirac α matrices.

Investigating electronic transitions on the basis of the description of the electronic structure described in the preceding text, one is led to transition matrix elements of the form

$$M^{\vec{q}\lambda}_{\mathrm{fi}} = \langle \Phi_\mathrm{f} | X_{\vec{q}\lambda} | \Phi_\mathrm{i} \rangle \tag{8}$$

where the initial and final wave functions $\Phi_{\mathrm{i(f)}}$ may stand for itinerant band states or tightly bound core states. Adopting the dipole approximation, the matrix elements connecting states ϕ_Λ with spin-angular character Λ are given by:

$$\begin{aligned} M^{\vec{q}\lambda}_{\Lambda\Lambda'} &= \langle \phi_\Lambda | \vec{\alpha} \cdot \hat{a}_\lambda | \phi_{\Lambda'} \rangle \\ &= i \left[R^1_{\Lambda\Lambda'} A^\lambda_{\Lambda-\Lambda'} - R^2_{\Lambda\Lambda'} A^\lambda_{-\Lambda\Lambda'} \right] \end{aligned} \tag{9}$$

in terms of the radial and angular matrix elements $R^{1(2)}_{\Lambda\Lambda'}$ and $A^\lambda_{\Lambda\Lambda'}$, respectively, with:

$$R^1_{\Lambda\Lambda'} = \int r^2 \, \mathrm{d}r g_\Lambda(r, E) f_{\Lambda'}(r, E') \tag{10}$$

$$R^2_{\Lambda\Lambda'} = \int r^2 \, \mathrm{d}r f_\Lambda(r, E) g_{\Lambda'}(r, E') \tag{11}$$

$$A^\lambda_{\Lambda\Lambda'} = \langle \chi_\Lambda | \vec{\alpha} \cdot \hat{a}_\lambda | \chi_{\Lambda'} \rangle \tag{12}$$

The angular matrix element $A^\lambda_{\Lambda\Lambda'}$ gives rise to the selection rules according to the polarization of the radiation (see Figure 1). The radial matrix elements $R^{1(2)}_{\Lambda\Lambda'}$, on the other hand, depend on the energy owing to the energy dependence of the radial wave functions. In general, the elements $R^{1(2)}_{\Lambda\Lambda'}$ strongly favor transitions with $l \to l' = l + 1$ as compared to those with $l \to l' = l - 1$ (Ebert *et al*., 1996). This, however, does not hold if a Cooper minimum occurs at a certain energy for one of these transitions (Durham, 1984).

Applications using the KKR Green's function method properly account for the energy dependence of the radial matrix elements, as the underlying wave functions $\phi_{\Lambda'}(\vec{r}, E)$ (corresponding to $Z_{\Lambda}(\vec{r}, E)$ and $J_{\Lambda}(\vec{r}, E)$ in equation (6)) are calculated for each energy E. Instead, using a linear band structure method as, for example, the LMTO, the energy dependence is accounted for in an approximate way by using $\phi_{i\nu}(\vec{r})$ and its energy derivative $\dot{\phi}_{i\nu}(\vec{r})$ evaluated at a fixed energy E_ν (see equation (5)). As E_ν can be chosen freely, this is not a severe numerical restriction in practice. However, using the TB formalism, the energy dependence of the radial matrix elements is completely ignored.

3 MAGNETO-OPTICAL PROPERTIES IN THE OPTICAL REGIME

3.1 The optical conductivity tensor and the magneto-optical effects

For many situations, it is adequate to neglect surface effects and to assume that magneto-optical properties reflect the electronic structure of a bulk material. The bridge between both sides is supplied by the dielectric tensor $\boldsymbol{\epsilon}(\omega)$ or, equivalently, the optical conductivity tensor $\boldsymbol{\sigma}(\omega)$, which are linked by the relation $\boldsymbol{\epsilon}(\omega) = 1 + \frac{4\pi i}{\omega}\boldsymbol{\sigma}(\omega)$. An expression for the optical conductivity tensor $\boldsymbol{\sigma}(\omega)$ was derived within the framework of Kubo's linear response formalism (Callaway, 1974):

$$\sigma_{\lambda\lambda'}(\omega) = \frac{ie^2}{m^2\hbar V} \sum_{\substack{j\vec{k}\,\text{occ.} \\ j\vec{k}\,\text{unocc.}}} \frac{1}{\omega_{jj'}} \left[\frac{\Pi^{\lambda}_{j'j}\Pi^{\lambda'}_{jj'}}{\omega - \omega_{jj'} + i/\tau} + \frac{(\Pi^{\lambda}_{j'j}\Pi^{\lambda'}_{jj'})^*}{\omega + \omega_{jj'} + i/\tau} \right] \tag{13}$$

with $\omega_{jj'} = (E_{j\vec{k}} - E_{j'\vec{k}})/\hbar$ and the matrix elements $\Pi^{\lambda}_{jj'} = \langle \Psi_{j\vec{k}} | p_\lambda | \Psi_{j'\vec{k}} \rangle$ of the electronic momentum operator. Here the argument $\vec{k}$ of $\omega_{jj'}$ and $\Pi^{\lambda}_{jj'}$ has been suppressed and $\lambda = \text{x, y, or z}$ denotes one of the Cartesian components. The quantity τ is the relaxation time parameter.

Although equation (13) can be used directly in connection with a nonrelativistic as well as a fully relativistic band structure calculation (Oppeneer and Antonov, 1996), it is advantageous to calculate in a first step only the absorptive parts of the tensor element (Wang and Callaway, 1974). The dispersive parts can then be obtained in a second step by making use of Kramers–Kronig relations (Ebert, 1996b).

The matrix elements $\Pi^{\lambda}_{jj'}$ in equation (13) imply a spatial integration over the whole crystallographic unit cell. Because the square of $\Pi^{\lambda}_{jj'}$ enters the expression for the optical conductivity tensor $\boldsymbol{\sigma}(\omega)$, however, it is not possible to decompose $\boldsymbol{\sigma}(\omega)$ unambiguously into site or component contributions in the case of compounds or multilayer systems. A corresponding decomposition gives rise to cross-term contributions that might be negative or even surpass the site-diagonal contributions (Koenig and Knab, 1990). For multilayer systems, such a decomposition turned out to be very helpful to analyze the rather complex spectra. For this purpose, a so-called layer-resolved optical conductivity tensor $\boldsymbol{\sigma}^{IJ}(\omega)$ was introduced (Perlov and Ebert, 2000) on the basis of equation (13), with I and J numbering the atomic layers within a multilayer. For the absorptive part of the corresponding diagonal tensor element $\sigma^{1\,IJ}_{\lambda\lambda}(\omega)$ one gets, for example, the expression

$$\sigma^{1\,IJ}_{\lambda\lambda}(\omega) = \frac{\pi e^2}{\hbar\omega m^2 V_I} \sum_{\substack{j\vec{k}\,\text{occ.} \\ j\vec{k}\,\text{unocc.}}} \Pi^{I\,\lambda}_{jj'}\,\Pi^{J\,\lambda}_{j'j}\,\delta(\omega - \omega_{jj'}) \tag{14}$$

with the evaluation of the matrix elements $\Pi^{I\,\lambda}_{jj'}$ restricted to layer I with volume V_I. Ignoring the variation of the electric field from layer to layer, a simplification that is in general inherently made when dealing with the optical properties of solids, allows one to introduce the layer-projected optical conductivity:

$$\sigma^{1,I}(\omega) = \sum_{J} \sigma^{1,IJ}(\omega) \tag{15}$$

which can be calculated by making use of Bloch's theorem. This leads to:

$$\sigma^{1\,I}_{\lambda\lambda}(\omega) = \frac{\pi e^2}{\hbar\omega m^2 V_I} \sum_{\substack{j\vec{k}\,\text{occ.} \\ j\vec{k}\,\text{unocc.}}} \Pi^{I\,\lambda}_{jj'}\,\Pi^{\lambda}_{j'j}\,\delta(\omega - \omega_{jj'}) \tag{16}$$

with the conventional matrix elements $\Pi^{\lambda}_{jj'} = \sum_{J\in\text{uc}} \Pi^{J\,\lambda}_{jj'}$ connected with the full unit cell; that is, the summation runs over all sites J within the unit cell. For the special case of a multilayer system, the unit cell is a column of atomic cells representing the stacking sequence of atomic layers. For that reason, the site specific matrix elements $\Pi^{J\,\lambda}_{jj'}$ are representative for the various types of atomic layers.

If the influence of the sample surface has to be accounted for, as for example, in the case of surface layer systems, the preceding expressions for the optical conductivity tensor are of limited use. However, reformulating equation (13) by representing the electronic structure in terms of the Green's function $G(E)$, a very general expression for the spatially resolved optical conductivity $\boldsymbol{\sigma}(\vec{r}, \vec{r}\,', \omega)$ is obtained. For a two-dimensional periodic layered system, the corresponding layer-resolved optical conductivity $\boldsymbol{\sigma}^{IJ}(\omega)$ is given by

(Huhne and Ebert, 1999b):

$$\begin{aligned}
&\sigma^{IJ}_{\lambda\lambda'}(\omega) \\
&\quad = \frac{i\hbar}{\pi^2 A_{WS}\,\mathrm{d}^I}\int_{-\infty}^{E_F}\mathrm{d}E\int_{E_F}^{\infty}\mathrm{d}E'\int_{A^I_{WS}}\mathrm{d}^2r\int_{\text{layer }I}\mathrm{d}r \\
&\qquad \times\int_{\text{layer }J}\mathrm{d}^3r'\frac{\mathrm{Trace}\left\{j_\lambda(\vec{r})\,\Im\,G^+(E')\,j_{\lambda'}(\vec{r}\,')\,\Im\,G^+(E)\right\}}{(E'-E-i\frac{\hbar}{\tau})(\hbar\omega+E-E'+i\frac{\hbar}{\tau})} \\
&\qquad +\frac{\mathrm{Trace}\left\{j_{\lambda'}(\vec{r}\,')\,\Im\,G^+(E')\,j_\lambda(\vec{r})\,\Im\,G^+(E)\right\}}{(E'-E+i\frac{\hbar}{\tau})(\hbar\omega+E'-E+i\frac{\hbar}{\tau})}
\end{aligned} \tag{17}$$

with d^I the thickness of layer I, A^I_{WS} the cross-section area of the corresponding unit cell and $j_{\lambda'}(\vec{r})$ the electronic current density operator.

When discussing magneto-optical phenomena, in general, two special geometric situations are of primary interest. For the Voigt or Cotton–Mouton configuration, the magnetization is aligned perpendicular to the wave vector $\vec{q}$ of the light, while for the Faraday or polar configuration it is parallel or antiparallel to the wave vector. In the case of the later configuration, a linearly polarized light beam that impinges on a magnetized sample will get elliptically polarized upon transmission or reflection. No matter whether the magnetization is present spontaneously or induced by an external magnetic field, these phenomena are called *Faraday* and *Kerr* effect, respectively. In both cases, the polarization ellipsis of the transmitted or reflected, respectively, light is characterized by its ellipticity ϵ and its rotation by the angle θ with respect to the original polarization vector (Reim and Schoenes, 1990). In the case of the Faraday effect, the rotation is a magnetic circular birefringence while the accompanying ellipticity is caused by magnetic circular dichroism. Making use of the connection of the dielectric tensor $\boldsymbol{\epsilon}(\omega)$ and the complex index of refraction $n_{\vec{q}\lambda}(\omega)$, one can express the ellipticity ϵ and rotation angle θ for the Faraday and Kerr effect in terms of the elements of the optical conductivity tensor $\boldsymbol{\sigma}(\omega)$ (Reim and Schoenes, 1990). For the complex Faraday rotation angle $\phi_\mathrm{F} = \theta_\mathrm{F} + i\epsilon_\mathrm{F}$, which combines both quantities, one finds:

$$\phi_\mathrm{F} \simeq \frac{2\pi i d}{c}\,\frac{\sigma_{\mathrm{xy}}}{\sqrt{1-\frac{4\pi i}{\omega}\sigma_{\mathrm{xx}}}} \tag{18}$$

with d the thickness of the sample. Accordingly, one has for the complex Kerr rotation angle $\phi_\mathrm{K} = \theta_\mathrm{K} + i\epsilon_\mathrm{K}$:

$$\phi_\mathrm{K} \simeq \frac{\sigma_{\mathrm{xy}}}{\sigma_{\mathrm{xx}}\sqrt{1-\frac{4\pi i}{\omega}\sigma_{\mathrm{xx}}}} \tag{19}$$

The expressions given in the preceding text for the Faraday and Kerr rotations ϕ_F and ϕ_K, respectively, are sufficiently accurate for angles up to several degrees. For the large rotation angles encountered sometimes in actinide compounds or the giant rotation angles up to 90 °C found for some Ce compounds (Yaresko *et al.*, 1996), one has to use the corresponding exact expressions. Another restriction for the use of equations (18 and 19) is connected with the symmetry of the investigated system. In deriving these equations, a shape of the optical conductivity tensor $\boldsymbol{\sigma}(\omega)$ has been assumed that corresponds to a system with its magnetization aligned to, at least, a threefold rotation axis that in turn is parallel to the light beam. This holds, for example, for cubic systems with the magnetization along one of the cubic axes or the [111] direction, as well as for a tetragonal or hexagonal system with the magnetization along the c axis. For systems with lower symmetry, the expressions for the Faraday and Kerr rotation can still be derived straightforwardly by solving the corresponding Fresnel equation for an anisotropic material. In this case, one will have a superposition of magneto-optical effects and natural birefringence.

Equations (18) and (19) have been derived for a homogeneous magneto-optical medium. An extension to inhomogeneous, that is, for example layered, media is straightforward if the layer thicknesses are relatively large. For thin magnetic surface films, however, the spatial variation of the optical conductivity has to be accounted for. The layer-resolved optical conductivity mentioned in the preceding text allows one to set up and solve the corresponding Maxwell equations for an inhomogeneous system (Huhne and Ebert, 2002). Various techniques to solve these equations have been developed and described in the literature (Huhne and Ebert, 2002; Vernes, Szunyogh and Weinberger, 2002).

Finally, it should be pointed out that equations (18) and (19) reflect the fact that (for the geometries considered in the preceding text) the Kerr effect occurs only for a nonvanishing off-diagonal element $\sigma_{xy}(\omega)$ of the conductivity tensor $\boldsymbol{\sigma}(\omega)$. Expressing $\boldsymbol{\sigma}(\omega)$ with respect to left (+) and right (−) circular and z-linear polarization of the light, one has the relationship $\sigma_\pm(\omega) = \sigma_{xx}(\omega) \mp i\sigma_{xy}(\omega)$. As demonstrated by several authors, $\sigma_+(\omega)$ and $\sigma_-(\omega)$ differ only if spin-orbit coupling and exchange splitting are simultaneously present (Erskine and Stern, 1973; Reim and Schoenes, 1990). This situation is therefore the source for the Kerr effect normally observed in the regime of conventional optics and also for the circular magnetic dichroism in X-ray absorption considered in the following text.

3.2 Magneto-optical properties of bulk materials

The formalism sketched in the preceding text was applied successfully for the first time at the beginning of the 1990s for a calculation of magneto-optical spectra (Oppeneer, Sticht

and Herman, 1991; Oppeneer, Maurer, Sticht and Kübler, 1992). By performing model calculations, with the strength of the spin-orbit coupling ξ and the exchange splitting ΔE_{xc} manipulated, one could demonstrate that the Kerr rotation is nearly proportional to ξ and varies monotonously with ΔE_{xc} (Oppeneer, Maurer, Sticht and Kübler, 1992; Ebert, Freyer, Vernes and Guo, 1996). In particular, for compounds like $CoPt_3$ it could be shown that a normally nonmagnetic component can have a large impact on the Kerr rotation if it possess a large spin-orbit coupling (Weller *et al.*, 1992).

In spite of the connection of the Kerr effect with the spin-orbit coupling and the exchange splitting demonstrated by these model calculations as well as analytical considerations (Erskine and Stern, 1973; Reim and Schoenes, 1990), there is no simple relationship between the Kerr rotation and ellipticity or, equivalently, the $\sigma_{xy}(\omega)$ spectra and the spin and orbital magnetic moments of the investigated solid. However, in analogy to the *f*-sum rule (Wallis and Balkanski, 1986), which relates the total number of electrons in the volume to the integral of the absorptive part of the diagonal optical conductivity $\sigma_{xx}(\omega)$ with respect to the frequency ω, a corresponding sum rule for the off-diagonal element $\sigma_{xy}(\omega)$ could be derived (Kunes and Oppeneer, 2000). Integrating the imaginary part of $\sigma_{xy}(\omega)$ with respect to the frequency ω leads to the total orbital magnetic moment in the volume and an additional term. In contrast to this, the sum rules dealing with the magnetic circular dichroism in X-ray absorption (see following text) imply the restriction to a specific absorption edge and, for that reason, give access to the spin and orbital magnetic moments in an angular momentum- and element-resolved way.

The aforementioned study on pure 3d ferromagnets was followed by a large number of theoretical investigations on a wide range of compounds (Ebert, 1996b; Antonov, Yaresko, Perlov and Nemoshkalenko, 1999). A comparison of theoretical spectra based on different approaches shows that inclusion of the spin-orbit coupling as a perturbation within a scalar-relativistic calculation is well justified in most cases.

When compared to the experimental spectra, a satisfying agreement is found in general for transition metal systems. Figure 2 shows as an example the Kerr rotation and ellipticity spectra for the Heusler alloys NiMnSb, PdMnSb, and PtMnSb, which have the C_{1b} structure. Previous band structure calculations revealed their half-metallic behavior, which was made responsible for the extraordinary Kerr rotation of PtMnSb (de Groot, Mueller, van Engen and Buschow, 1983). Other authors ascribed the high Kerr angle to a low plasma frequency (Feil and Haas, 1987) or to scalar-relativistic effects (Wijngaard, Haas and de Groot, 1989). However, the calculation of the spectra shown in Figure 2 demonstrated that a combination of various favorable properties of the band structure of PtMnSb – in particular the mentioned

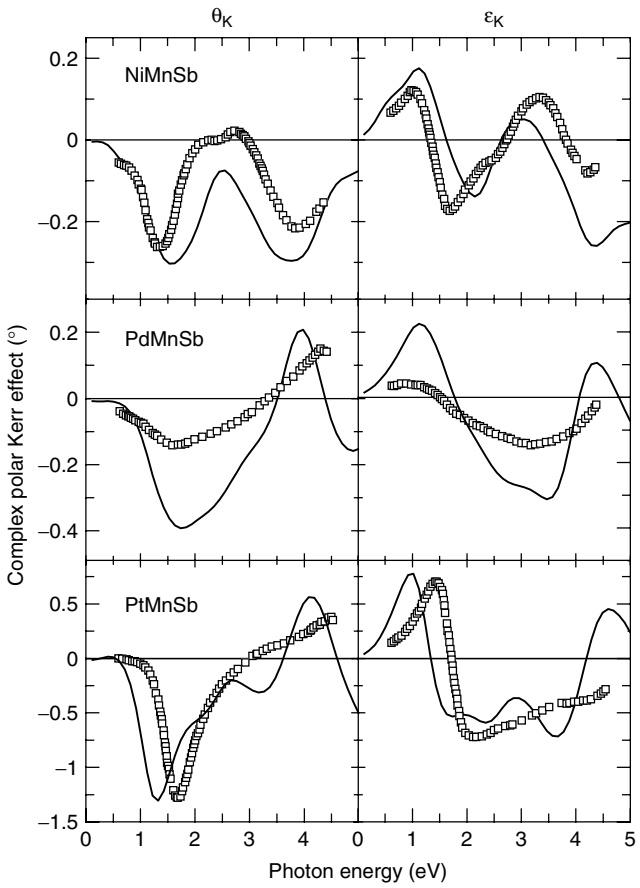

Figure 2. Experimental Kerr rotation and ellipticity spectra of NiMnSb, PdMnSb, and PtMnSb (van Engen, 1983) together with the corresponding theoretical spectra obtained using the relativistic LMTO method (Oppeneer and Antonov, 1996). (Reproduced from Oppeneer, P., *et al.*, 1996, with permission from Springer-Verlag GmbH. © 1996.)

half-metallic behavior and the low plasma frequency – is responsible for its large Kerr rotation.

The examples shown in Figure 2 demonstrate that calculated Kerr spectra may deviate in some cases in a significant way from corresponding experimental data. This is often caused by problems with the sample preparation, as could be convincingly demonstrated, for example for the compounds FeCo and FePt (Weller, 1996). On the other hand, one might ascribe deviations to the neglect of so-called local-field effects when using equation (13) directly. These effects stem from the fact that the actual electric field that acts on an electron differs from the external electric field associated with the light owing to induced charge fluctuations that, in principle, can be accounted for by a self-consistent field scheme (Wallis and Balkanski, 1986). For transition metals, these effects are generally assumed to be negligible. Correlation effects, that are not accounted for within plain SDFT seem to be more important. In fact, the use of Brooks' OP formalism or of

the local density approximation (LDA) + U led in the case of actinide systems to a much better agreement with experiment (Antonov *et al*., 1999). This also applies to calculations for transition metal systems based on the LSDA + DMFT scheme (Perlov, Chadov and Ebert, 2003).

3.3 Magneto-optical properties of layered systems

Most of the experimental as well as theoretical studies on the magneto-optical properties of transition metal systems were motivated by their application in sensor and storage technology (Kryder, 1985). This applies in particular for the investigations on multilayers. These systems allow to some extent the optimization of Kerr rotation spectra with regard to the position and height of prominent peaks by a suitable combination of atomic layers and choice of their thickness. This is demonstrated in Figure 3, which shows Kerr rotation and ellipticity spectra for the multilayer system 6Co/*m*Cu with the thickness *m* of the Co layers varied between 3 and 9 atomic layers (Uba *et al*., 1997). As mentioned in the preceding text, one notes that the peak positions in the theoretical spectra are somewhat shifted as compared to the experimental ones because the local-field and correlation effects are neglected. The various features of the Kerr rotation and ellipticity spectra and their variation with the thickness of the Cu layers, however, are well described by the calculations. This implies, in particular, that imperfections at the Co/Cu interface have only a minor influence on the experimental spectra.

Extensive studies have also been made on the multilayer systems *n*Co/*m*Pd and *n*Co/*m*Pt (Uba *et al*., 1995; Zeper, 1991; Bertero and Sinclair, 1995; Daalderop, 1991) because here the ferromagnetic component Co is combined with an element having a stronger spin-orbit coupling. In addition, Pd and Pt show a pronounced polarizability leading to an induced spin magnetic moment in the order of 0.2 μ_B at the interface (Schütz *et al*., 1993). Furthermore, the high spin-orbit coupling of Pd and Pt is one of the main reasons for the pronounced out-of-plane magnetic anisotropy of these Co-based multilayer systems.

Figure 3 suggests that the calculation of the magneto-optical spectra of multilayer systems should lead, in general, to rather reliable results. On the other hand, it is obviously quite hard or impossible to explain the various spectral features and their variation with the multilayer composition on the basis of such calculations. This severe problem could be reduced to some extent by the introduction of the layer-resolved optical conductivity (Huhne and Ebert, 1999a). The first application of this concept to bcc Fe demonstrated that the contribution of the neighboring atomic layers J to the optical response of an atomic layer I drops off very rapidly with the distance $|I - J|$ between the layers. In particular, it was found that the diagonal tensor element $\sigma_{xx}^{IJ}(\omega)$ is by far dominated by the layer-diagonal term ($I = J$), while for the off-diagonal tensor element $\sigma_{xy}^{IJ}(\omega)$ the contribution from neighboring layers ($|I - J| = 1$) is of the same order of magnitude as the layer-diagonal term ($I = J$). As a consequence, it turned out that it is, in general, sufficient to consider contributions from neighboring layers with $|I - J| = 3$–4 when constructing

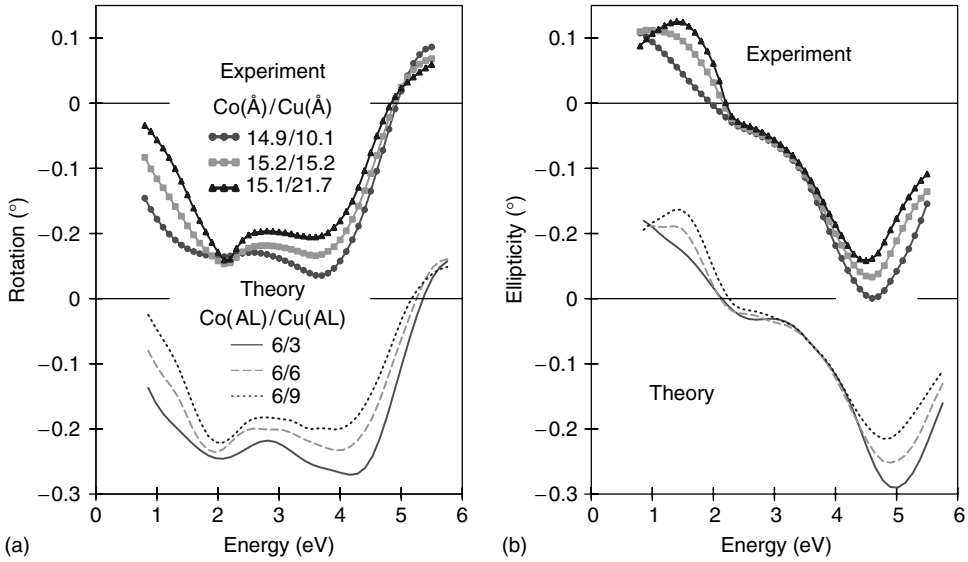

Figure 3. Experimental polar Kerr rotation (a) and ellipticity (b) spectra of Co/Cu multilayer systems. Co and Cu sublayer thicknesses are given in the key in units of Å and atomic layers (AL), respectively. (Reproduced from S. Uba *et al*., 1997, with permission from IOP Publishing Ltd. © 1997.)

the layer-projected optical conductivities $\sigma^I_{xx}(\omega)$ and $\sigma^I_{xy}(\omega)$ for layer I. Corresponding results for the absorptive part of the off-diagonal tensor element $\sigma^I_{xy}(\omega)$ of the multilayer system Co_9/Pd_9 are shown in Figure 4 for the inequivalent layers $I = 1$–10. For the innermost ($I = 1$) of the nine Co layers, one finds that $\sigma^{2,I}_{xy}(\omega)$ is nearly identical to that of pure fcc Co. This reflects the rapid decay of $\sigma^{IJ}_{xy}(\omega)$ with the layer distance $|I - J|$ and implies that the inner Co layers behave essentially like bulk Co concerning their magneto-optical response. Apparently, approaching the Co/Pd interface, $\sigma^{2,I}_{xy}(\omega)$ is more and more modified leading to an appreciable distortion for the spectrum of the Co interface layer ($I = 5$). As mentioned in the preceding text, there is an appreciable moment induced for the Pd layers next to the interface (see the numbers following the layer indices in Figure 4) that rapidly drops with the distance from the interface. The induced moments are reflected by an appreciable nonzero layer-projected off-diagonal tensor element $\sigma^{2,I}_{xy}$ that is most pronounced for the Pd layers close to the interface ($I = 6, 7$) and then decreases very rapidly. For the innermost Pd layer ($I = 10$) $\sigma^{2,I}_{xy}(\omega)$ is close to zero; that is, again one has nearly the magneto-optical behavior of nonmagnetic bulk Pd.

The results shown in Figure 4 imply that for most multilayer systems with relatively large thicknesses of the subsystems one may expect a pronounced variation of the local magneto-optical response only within 3–4 layers next to the interfaces, while the inner regimes should show a bulklike behavior. This property has been exploited with success to construct the magneto-optical response of multilayer systems with large subsystem thicknesses from the layer-projected optical conductivity tensor $\boldsymbol{\sigma}^I(\omega)$ calculated for a multilayer system with the same composition but smaller subsystem thicknesses (Baukasten or modular principle) (Perlov and Ebert, 2000).

The results in Figure 4 also imply that for increasing subsystem thicknesses the influence of the interface regime on the magneto-optical response of the whole layer system will diminish rapidly. As a consequence, representing the subsystems by the optical conductivity of the corresponding bulk material together with a treatment of the whole system by means of classical optics is well justified (Heavens, 1991). This approach has also been used when dealing with magnetic surface layers with a thickness of 20 Å or more on top of a nonmagnetic substrate. For this peculiar situation, one may write for the complex Kerr rotation

$$\phi_K = i\frac{4\pi d}{\lambda}\frac{\sigma_{xy}}{\sigma^{sub}_{xx}} \tag{20}$$

where λ is the wavelength of the radiation and σ^{sub}_{xx} is the diagonal optical conductivity of the substrate (Katayama *et al*., 1988; Reim and Weller, 1989). Equation (20) implies that one can get a resonance-like enhancement of ϕ_K if a suitable substrate is chosen. This holds, for example for Fe films deposited on top of a Cu, Ag, or Au substrate (Katayama *et al*., 1988; Suzuki *et al*., 1992; Suzuki *et al*., 1993) for which σ^{sub}_{xx} is rather small in the vicinity of the plasma edge of the noble metal. In fact, a very satisfying description of available experimental data has been achieved on the basis of equation (20). For thin magnetic films, however, this equation is no more applicable due to the occurrence of quantum confinement effects (Suzuki *et al*., 1992; Bennett, Schwarzacher and Egelhoff, 1990; Carl and Weller, 1995). In particular, it does not describe the oscillations of the Kerr rotation found as a function of the thickness of the magnetic film (Geerts *et al*., 1994) or of a capping nonmagnetic film (Suzuki *et al*., 1998). An explanation for the oscillations observed for the system Au(001)/*n*Fe/*m*Au could be given by a treatment of quantum confinement effects in

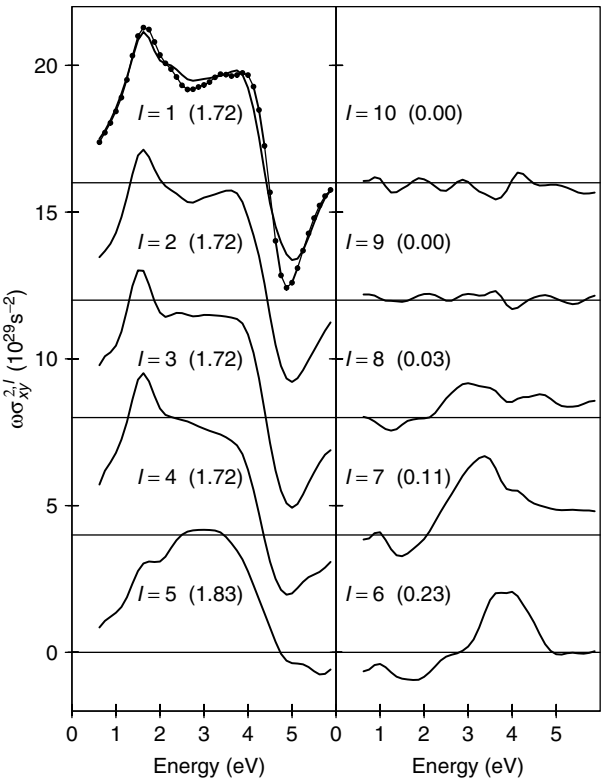

Figure 4. Absorptive part of the off-diagonal layer-projected optical conductivity tensor elements $\sigma^{2,I}_{xy}(\omega)$ for the 10 nonequivalent atomic layers in the multilayer system 9Co/9Pd. The layer index $I = 1$ denotes the innermost Co layer, while $I = 5$ labels the Co layer at the Co/Pd interface. Accordingly $I = 6$ and 10 are the interface and central Pd layers. The numbers accompanying the layer index give the corresponding spin magnetic moments per atom in Bohr magnetons μ_B. The results of bulk calculations for fcc Co are shown by a marked line (Perlov and Ebert, 2000). (Reproduced from Perlov *et al*., 2000, with permission from EDP Sciences. © 2000.)

analogy to the approach used when dealing with the interlayer exchange coupling. This way, the wavelengths of the oscillations were traced back to the bulk electronic structure of the magnetic (Fe) and capping (Au) film material. Calculations of the layer-resolved optical conductivity $\sigma^{IJ}(\omega)$ of Au(001)/nFe/mAu supplied the basis to set up and solve the corresponding inhomogeneous Maxwell equations (Huhne and Ebert, 2002). This approach allowed not only the calculation of the Kerr rotation spectra as a function of the layer thickness n and m, but also the investigation of the distribution of the current density induced by the electromagnetic radiation in the region near the surface. Similar investigations have also been made for the system Pt(111)/nCo (Vernes, Szunyogh and Weinberger, 2002).

4 X-RAY ABSORPTION SPECTROSCOPY

4.1 Absorption coefficient, magnetic dichroism, and sum rules

The absorption coefficient $\mu^{\vec{q}\lambda}(\omega)$ of a sample for radiation of energy $\hbar\omega$, wave vector $\vec{q}$, and polarization λ is determined by its complex index of refraction $n_{\vec{q}\lambda}$. Expressing $n_{\vec{q}\lambda}$ by means of the dielectric function $\epsilon_{\vec{q}\lambda}$ and making use of the relation $\boldsymbol{\epsilon}(\omega) = 1 + \frac{4\pi i}{\omega}\boldsymbol{\sigma}(\omega)$, one can express $\mu^{\vec{q}\lambda}(\omega)$ for the X-ray regime in terms of the absorptive part of the corresponding scalar optical conductivity $\sigma_{\vec{q}\lambda}(\omega)$:

$$\mu^{\vec{q}\lambda}(\omega) = \frac{4\pi}{c}\sigma^{1}_{\vec{q}\lambda}(\omega) \tag{21}$$

Accordingly, using either equation (13) or Fermi's golden rule, $\mu^{\vec{q}\lambda}(\omega)$ can be obtained from:

$$\mu^{\vec{q}\lambda}(\omega) = \frac{\pi c^2}{\hbar\omega m V A^2} \sum_{i\ \mathrm{occ.}} \sum_{f\ \mathrm{unocc.}} |\langle\Psi_f|X_{\vec{q}\lambda}|\Phi_i\rangle|^2 \times\delta(\hbar\omega - E_f + E_i) \tag{22}$$

where A specifies the amplitude of the radiation field according to equation (7).

When studying a specific absorption edge, the summation over the initial states $|\Phi_i\rangle$ can be restricted to the corresponding core shell. On the other hand, the final states $|\Psi_f\rangle$ can be represented by Bloch wave functions $\Psi_{j\vec{k}}$ when dealing with an ordered solid. A more general expression is obtained by representing the final states in terms of the Green's function $G(E)$ to get the form (Shaich, 1984):

$$\mu^{\vec{q}\lambda}(\omega) \propto \sum_{i\ \mathrm{occ.}} \langle\Phi_i|X^{\times}_{\vec{q}\lambda}\,\Im G(E_i + \hbar\omega)\,X_{\vec{q}\lambda}|\Phi_i\rangle \times\theta(E_i + \hbar\omega - E_{\mathrm{F}}) \tag{23}$$

This expression can be evaluated by making use of multiple-scattering theory to determine $G(E)$ (see equation (6)). Accordingly, equation (23) can be applied to arbitrary systems and is the basis for dealing not only with near-edge spectra but also with conventional (Rehr and Albers, 2000) as well as magnetic (Ebert, Popescu and Ahlers, 1999) extended X-ray absorption fine structure (EXAFS). In addition, it supplies an appropriate basis for including many-body effects (Schwitalla and Ebert, 1998).

In the case of rare earth systems, the preceding approach is often inadequate because of the formation of a ground-state electronic configuration according to Hund's rule. Restricting to a free-atom description one gets the corresponding absorption coefficient by considering all transitions from a single ground-state level $|J\,M_J^k\rangle$ to all final states $|J'\,M_J^k + q\rangle$ by absorption of light with polarization λ (Goedkoop *et al.*, 1988):

$$\mu_J^{\lambda k}(\omega) = \sum_{J'} \mu_{JJ'}^{\lambda k}(\omega) = \sum_k \left| \begin{pmatrix} J' & 1 & J \\ -(M_J^k + \lambda) & \lambda & M_J^k \end{pmatrix} \right|^2 \mu_k(\omega) \tag{24}$$

Here $(\ldots)$ is a Wigner 3j symbol and the μ_k are the partial absorption coefficients for the three possible values of $k = \Delta J = -1, 0, +1$.

For a nonmagnetic system, it can be shown that the absorption coefficient $\mu^{\vec{q}\lambda}$ evaluated on the basis of equation (22) or (23) can be written as a sum over partial angular momentum–resolved density of states (DOS) functions $n_\kappa(E)$ weighted by the corresponding absorption cross section $W_{n'\kappa'\to n\kappa}(E)$ (Mattheiss and Dietz, 1980). If an exchange splitting is present in addition to spin-orbit coupling, the degeneracy of the magnetic sublevels is removed (see Figure 1) and magnetic dichroism occurs. Alternatively, this can be demonstrated by considering an exchange-split system with spin-orbit coupling treated as a perturbation. Ignoring the energy and spin dependence of the cross section, the absorption coefficient for the K edge for left- (or right-) circularly polarized light is given by $W_{1s\to np}\sum_{m_s} n_{l=1,m_l,m_s}(E)$ with $m_l = +1(-1)$, where $n_{lm_lm_s}$ is the (l, m_l, m_s)-resolved DOS for p states. The corresponding magnetic dichroic signal $\Delta\mu_{\mathrm{K}} = \mu_{\mathrm{K}}^{+} - \mu_{\mathrm{K}}^{-}$ is therefore given by $W_{1s\to np}\sum_{m_s}(n_{1,+1,m_s}(E) - n_{1,-1,m_s}(E))$. From this expression, it is obvious that $\Delta\mu_{\mathrm{K}}$ vanishes if there is no exchange splitting or if there is no spin-orbit coupling. In addition, one can identify $\Delta\mu_{\mathrm{K}}$ – apart from the cross section – with the orbital polarization $\sum_{m_l}\sum_{m_s} m_l n_{lm_lm_s}(E)$ of the p states. Integrating the dichroic signal over the unoccupied regime of the np shell, one therefore gets a measure for the orbital magnetic moment connected with the p holes, or – by reversing the sign – of

the p electrons. This simple interpretation of the dichroic signal for initial states with s character (e.g., K or L_1 edges) can be expressed by the sum rule (Igarashi and Hirai, 1994):

$$\frac{\int \Delta\mu_{\mathrm{K}} / E \, \mathrm{d}E}{\int \overline{\mu}_{\mathrm{K}} / E \, \mathrm{d}E} = \frac{3}{N_{\mathrm{hp}}} \langle l_{\mathrm{z\,p}} \rangle \tag{25}$$

Here N_{hp} is the number of p holes and $\langle l_z \rangle_{\mathrm{p}}$ is the orbital angular momentum for the p electrons. The integration of the polarization-averaged absorption and dichroic spectra $\overline{\mu}_{\mathrm{K}}(E)$ and $\Delta\mu_{\mathrm{K}}(E)$, respectively, has to be extended from the absorption edge over all unoccupied states of the np shell.

Considerations similar to those presented in the preceding text for the K edge were first made for the $M_{2,3}$ edge of Ni (Erskine and Stern, 1975). Accounting for spin-orbit coupling only for the initial 3p core states and for exchange splitting only for the final 3d states, a relative intensity of the white line peaks at the M_2 and M_3 edges (branching ratio) of 1:2 is expected. For the corresponding circular dichroic signal $\Delta\mu_{\mathrm{M}_{2,3}}$ a ratio of $+1{:}-1$ should occur, with $\Delta\mu_{\mathrm{M}_{2,3}}$ reflecting the spin polarization of the 3d states. Extending the model by accounting, additionally, for the spin-orbit coupling for the final d-like states (Smith, Chen, Sette and Mattheis, 1991; Stöhr, 1999), these ratios deviate from the ideal values. In particular, $\Delta\mu_{\mathrm{M}_{2,3}}$ is now determined by the spin and orbital polarization and by an additional term connected with the magnetic dipole operator $T_{\mathrm{z}} = \frac{1}{2}\big(\vec{\sigma} - 3\hat{\vec{r}}(\hat{\vec{r}} \cdot \vec{\sigma})\big)_{\mathrm{z}}$. The corresponding sum rules for initial states with p character (e.g., $L_{2,3}$ or $M_{2,3}$ edges) are given by (Thole, Carra, Sette and van der Laan, 1992; Carra, Thole, Altarelli and Wang, 1993):

$$\int \left(\Delta\mu_{\mathrm{L}_3} - 2\Delta\mu_{\mathrm{L}_2}\right) \mathrm{d}E = \frac{N}{3N_{\mathrm{hd}}} \left(\langle\sigma_{\mathrm{z}}\rangle + 7\langle T_{\mathrm{z}}\rangle\right) \tag{26}$$

$$\int \left(\Delta\mu_{\mathrm{L}_3} + \Delta\mu_{\mathrm{L}_2}\right) \mathrm{d}E = \frac{N}{2N_{\mathrm{hd}}} \langle l_{\mathrm{z}}\rangle \tag{27}$$

where

$$N = \int \sum_{\lambda=\pm\mathrm{z}} (\mu^{\lambda}_{\mathrm{L}_2} + \mu^{\lambda}_{\mathrm{L}_3}) \, \mathrm{d}E \tag{28}$$

is the polarization-averaged absorption spectrum and N_{hd} is the number of d holes.

The various sum rules obviously supply a formal basis to deduce the spin and orbital magnetic moments from experimental spectra in an element specific way. For transition metal systems for example, the $L_{2,3}$-edge spectra give direct information on the d electrons, which are of central importance for their magnetic properties. Unfortunately, there are a number of problems when applying the sum rules to experimental data. The most obvious are that the number of holes N_{hd} is in general not known, the absorption spectra $\mu^{+(-)}$ have to be separated from the background, and the upper limit for the energy integration has to be fixed.

Originally, the sum rules have been derived on the basis of a localized description for the electronic structure. However, it could be shown that it is also possible to derive them adopting an itinerant description (Ankudinov and Rehr, 1995; Benoist, Carra and Andersen, 2000). Nevertheless, one has to keep in mind that a number of assumptions were made for their derivation. Corresponding test calculations demonstrated that these assumptions are reasonably well justified for many situations (Wu, Wang and Freeman, 1993; Ebert, 1996b). These calculations, in particular, showed that the sum rules also hold in their differential or energy-resolved form that is obtained by dropping the energy integration for the dichroic spectrum $\Delta\mu$ and replacing the expectation values by the corresponding polarization function, that is, replacing, for example, the spin moment $\langle\sigma_z\rangle$ by the spin polarization $\frac{\mathrm{d}}{\mathrm{d}E}\langle\sigma_z\rangle$ that corresponds to the difference of the DOS curves for spin up and down. Finally, it has to be noted that the applicability of the sum rules does not depend on whether the magnetic moment of the absorbing atom is spontaneously formed or whether it is induced via hybridization by neighboring magnetic atoms. This also applies for a magnetic moment that is induced by an external magnetic field. In this case, the sum rules give access to the component-projected spin and orbital magnetic susceptibilities (Ebert and Mankovsky, 2003).

While the sum rules allow one to determine the orbital magnetic moment separately, this is obviously not true for the spin magnetic moment that is connected with the term $\langle T_z\rangle$. The latter term, which has a counterpart in the hyperfine field and the magnetic form factor used when dealing with neutron scattering, can be seen as a measure for the angular variation of the spin magnetization. It is nonzero only for systems having a symmetry that is lower than cubic. For systems with a cubic lattice, $\langle T_z\rangle$ is therefore only nonzero due to the presence of spin-orbit coupling. Accordingly, it should be quite small in that case unless one is dealing with elements with a large atomic number. However, for low-dimensional magnetic systems such as multilayers (Guo, Ebert, Temmerman and Durham, 1994), films, wires (Komelj, Ederer, Davenport and Fähnle, 2002), or clusters (Gambardella *et al.*, 2003) $\langle T_z\rangle$ may be quite large and nonnegligible as compared to $\langle\sigma_z\rangle$.

4.2 Magnetic circular dichroism in X-ray absorption

Owing to technical reasons, the first successful experimental investigations on the XMCD have been made in the hard

X-ray regime. The measurements at the K edge of bcc Fe (Schütz *et al*., 1987) were soon followed by experiments at the $L_{2,3}$ edges of 5d transition metals dissolved substitutionally in bcc Fe (Wienke, Schütz and Ebert, 1991). Owing to the dipole selection rules and the l dependence of the X-ray absorption cross section, the corresponding spectra are dominated by p–d transitions. The strong spin-orbit splitting of the involved initial states, together with the appreciable exchange splitting of the final states – induced by the ferromagnetic host – leads to a relative XMCD signal of up to 20%. These spectra could be reproduced in a very satisfying way by corresponding calculations done on the basis of relativistic multiple-scattering theory (Ebert, 1996b). Use of the sum rules (26) to (27) allowed one to deduce from the experimental XMCD spectra $\Delta\mu_{L_{2,3}}$ the spin and orbital magnetic moments that are induced on the impurity atoms. As the XMCD probes the expectation value of the magnetic moment of the absorbing atom, $\langle\mu\rangle$, not only the magnitude of the induced magnetic moments but also their relative orientation with respect to that of the Fe host could be determined. Obviously, the results given in Figure 5 are in reasonable agreement with corresponding theoretical work (Kornherr, 1997), which allows a more detailed discussion of the data. In particular, theory allows one to ascribe the variation of the spin magnetic moment with the atomic number Z of the impurity atom to the relative position of its d level with respect to the exchange-split d levels of the host. The variation of the orbital magnetic moment, on the other hand, can be explained by treating spin-orbit coupling as a perturbation leading to a direct interrelation with the partial spin-resolved DOS of the impurity atom at the Fermi level (Popescu, Ebert, Nonas and Dederichs, 2001). The magnetic moments deduced from the XMCD spectra are obviously also in reasonable accordance with results of neutron-scattering experiments that, however, do not allow a simple decomposition of the moment into spin and orbital parts. Such a decomposition was possible in the past only by simulations of magnetic neutron-scattering form factors or indirectly on the basis of NMR data (Kawakami, Enokiya and Okamoto, 1985).

Figure 5 demonstrates that the XMCD supplies element-specific information because of the local nature of the involved initial core states. This outstanding feature that has been exploited in many subsequent investigations allowed the probing of the induced magnetic moment of an otherwise nonmagnetic impurity atom. Similar work has also been done on compounds, disordered alloys, and multilayer systems.

Measurements at the $L_{2,3}$ edges of 3d transition metals (Chen, Sette, Ma and Modesti, 1990) opened the way to study the magnetic properties of these important elements in a rather direct and detailed way. The large XMCD signal found normally in experiment can in general be described fairly well on the basis of an itinerant description of the underlying electronic structure. Nevertheless, there are often features in the experimental spectra that cannot be accounted for on the basis of plain LSDA and therefore require extensions to this.

Use of time dependent local density approximation (TDLDA) for example, allowed one to account for dynamical screening effects leading to an improved agreement of theory and experiment concerning the so-called $L_{2,3}$-edge branching ratio in the case of 3d transition metals (Schwitalla and Ebert, 1998; Ankudinov, Nesvizhskii and

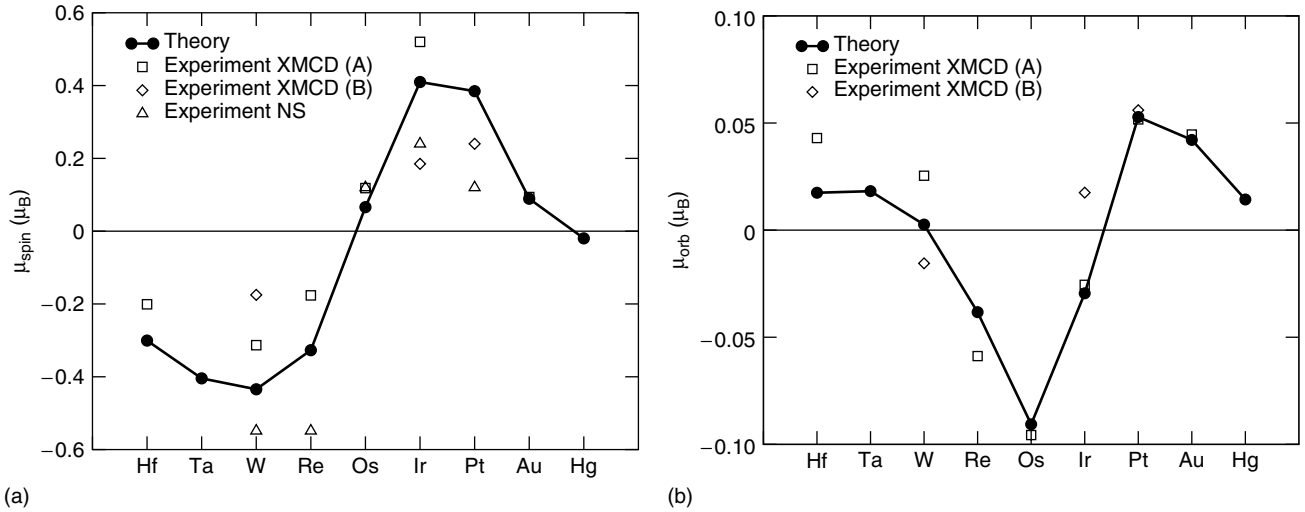

Figure 5. Induced spin (a) and orbital (b) magnetic moment, μ_{spin} and μ_{orb}, respectively, of 5d-transition metal impurities in Fe as deduced from experimental XMCD spectra at the $L_{2,3}$ edges (A: (Wienke, Schütz and Ebert, 1991; Schütz, Knülle and Ebert, 1993), B: (Wilhelm *et al*., 2001)) and neutron-scattering measurements (NS) (Campbell, 1966) and obtained from SPR-KKR band structure calculations (Kornherr, 1997).

Rehr, 2003). This approach led to corresponding changes for the XMCD spectra (Schwitalla, 1997) also. Using plain LSDA to calculate spin-orbit-induced ground-state properties as for example, orbital magnetic moments often gives results that are too small when compared with experiment. An improved description of correlation effects based on Brooks' OP scheme reduces or removes this problem in many cases. Using this approach while calculating XMCD spectra leads to changes with respect to plain-LSDA results that are in full accordance with the corresponding change in the orbital magnetic moment and the sum rules (Ebert, 1996a; Guo, 1997).

Application of the LSDA + U scheme also led in many cases to appreciable improvements compared to work based on plain LSDA. An interesting example for this is a study of the XMCD spectra of Fe in Fe_3O_4 (Antonov, Harmon and Yaresko, 2003) that is ferrimagnetically ordered below ≈850 K. The tetrahedral lattice sites (A) in the inverse spinel structure are occupied by Fe^{3+} ions, whereas the octahedral lattice sites (B) are occupied alternately by equal numbers of Fe^{2+} and Fe^{3+} ions. In contrast to this experimental finding, LSDA-based calculations lead to a half-metallic ferrimagnet, with the Fermi level crossed only by the majority spin bands and equivalent Fe ions on all B sites. The corresponding XMCD spectra for the $L_{2,3}$ edges of the inequivalent A and B sites are shown in Figure 6(a). Obviously, the ferrimagnetic order of the system is reflected by the different sign of the XMCD spectra for the two sites. The resulting total XMCD

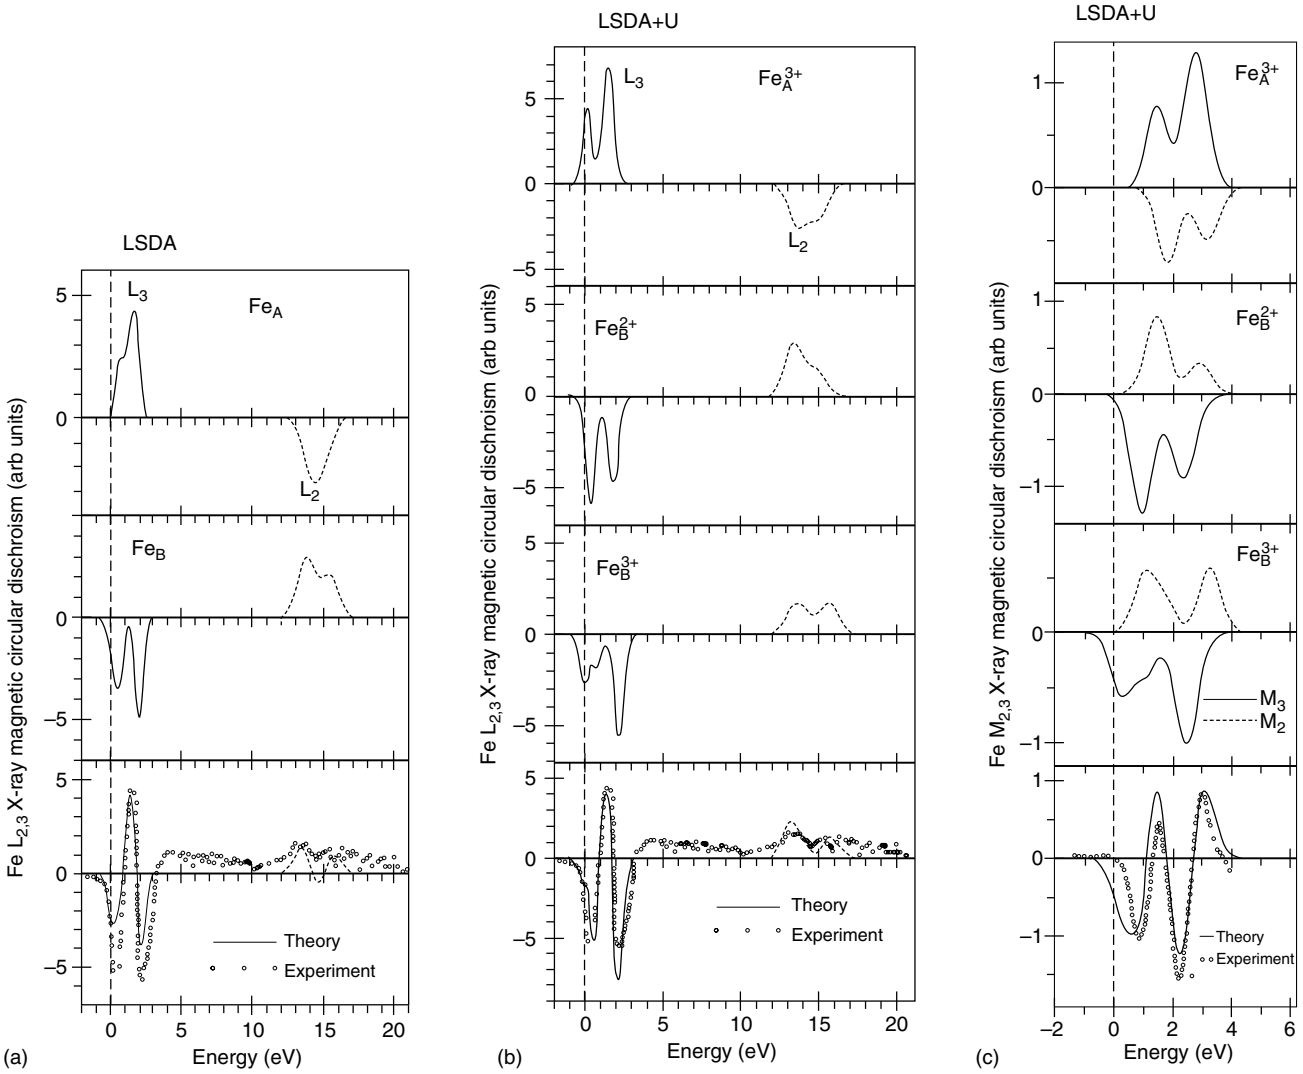

Figure 6. (a) and (b) show results for the total and site-resolved XMCD spectra at the $L_{2,3}$ edges of Fe in Fe_3O_4 obtained on the basis of the LSDA and LSDA + U, respectively, (Antonov, Harmon and Yaresko, 2003) in comparison with experiment (Kuiper *et al*., 1997). (c) shows the corresponding spectra for the $M_{2,3}$ edges of Fe in Fe_3O_4 in comparison with experiment. (Reproduced from Koide *et al*., 1996, with permission from Elsevier. © 1996.)

spectrum is in qualitative agreement with experiment that does not allow one to distinguish the various lattice site contributions. In contrast to LSDA, the use of the LSDA + U leads, in line with experiment, to a charge-ordered insulator with two inequivalent B sites. This qualitative change in the electronic structure is reflected by the various site-resolved XMCD spectra shown in Figure 6(b). As one notes, the resulting total XMCD spectrum is now in much better agreement with experiment. This also holds for $M_{2,3}$ edges for which the LSDA + U-based results are shown in Figure 6(c). Here obviously a strong overlap of the M_2 and M_3 spectra occurs because the spin-orbit splitting of the initial 3p core states is much smaller than that of the 2p core states involved in the $L_{2,3}$ spectra. As a result of this overlap, the total $M_{2,3}$-XMCD spectrum is strongly reduced in amplitude compared to the $L_{2,3}$ spectrum.

While the LSDA + U-based calculations reproduce the experimental $L_{2,3}$ and $M_{2,3}$ spectra very well, they are, nevertheless, not able to describe the small positive shoulder seen at the high-energy side of the main peaks of the L_3 spectrum. Similar problems occurred for other systems also. For example, a satellite at 6 eV above the L_3 absorption edge is found in the experimental XMCD spectrum of Ni, which obviously cannot be described by band structure calculations. On the other hand, adopting a CI viewpoint on the basis of the Anderson impurity model for the Ni d states, this satellite has been ascribed to a superposition of d^8, d^9, and d^{10} configurations for the ground state (Jo and Sawatzky, 1991).

4.3 Magnetic linear dichroism in x-ray absorption

The first successful experimental demonstration of the magnetic dichroism in X-ray absorption was done for the linear dichroism (XMLD) observed at the $M_{4,5}$ edge of Tb in Tb-Fe-garnet (van der Laan *et al*., 1986). These investigations were accompanied by simulations based on atomic Hartree–Fock calculations (Cowan, 1981) for transitions from the $4f^n(J)$ Hund's rule ground state to the manifold of $3d^9 4f^{n+1}(J')$ final states, which allowed the interpretation of the recorded spectra in detail. Results of similar investigations on the M_5 edge of Tb in amorphous Tb_xFe_{1-x} films (Vogel *et al*., 1991) are shown in Figure 7. Here the angular and temperature dependence of the absorption has been analyzed assuming a magnetic interaction that splits the $^7F_6$ ground state of Tb into 13 Zeeman levels. This allowed the estimation of the magnetic parameters in this alloy system as a function of the concentration, leading for example, for the saturation moment normal to the film surface to $5.5\,\mu_B$ and to an effective exchange field of about 14 T.

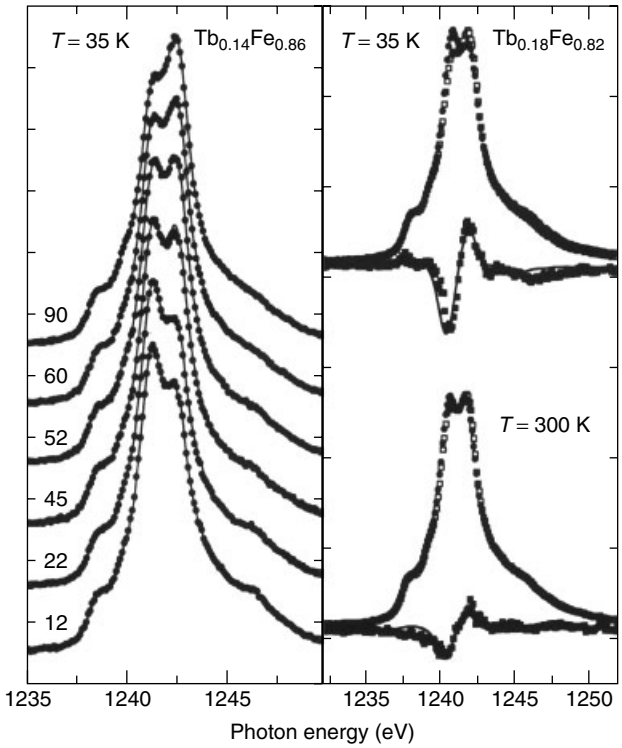

Figure 7. XMLD at the M_5 edge of Tb in amorphous Tb_xFe_{1-x} films as a function of angle (left) and temperature (right). Experimental data are represented by symbols. Theoretical results are given by lines. (Reproduced from Vogel *et al*., 1991, with permission from Elsevier. © 1991.)

Similar to the situation for the magneto-optical effects in the low-energy regime, where most experimental investigations were done for the polar geometry, the XMCD is in general much more pronounced than the XMLD. Nevertheless, the XMLD (Schwickert *et al*., 1998) and related phenomena (Mertins *et al*., 2001) observed in transition metal systems can be described fairly well on the basis of the formalism sketched in the preceding text. In addition, the anisotropy of the XMLD was investigated and found to be quite appreciable (Kunes and Oppeneer, 2003). As was pointed out already in the first XMLD studies on the XMLD (van der Laan *et al*., 1986), the effect measures the expectation value of the square of the magnetic moment of the absorbing atom, $\langle \mu^2 \rangle$. Accordingly, in contrast to the XMCD, the XMLD can also be observed in antiferromagnetic systems. This feature has been exploited, for example, to study the surface magnetism of a NiO(100) film grown on MgO(100) as a function of the temperature (Stöhr *et al*., 1999). Furthermore, the XMLD has been suggested to be used as a probe for the magnetocrystalline anisotropy (van der Laan, 1999). This approach in particular, avoids the determination of the orbital magnetic moment and its anisotropy on the basis of Bruno's model making use of the XMCD (van der Laan, 2001).

5 VALENCE-BAND PHOTOEMISSION

5.1 One-step model of photoemission

The traditional way to discuss valence-band photoemission spectroscopy (VB-PES) of solids is to use the so-called three-step model (Berglund and Spicer, 1964) that divides the photoemission process into excitation, transport to the surface, and escape to the vacuum. This scheme gives some justification for the reconstruction of the bulk dispersion relation $E(\vec{k})$ from experimental angle-resolved ultraviolet photoemission spectroscopy (ARUPS) data. For this procedure, however, a free electron–like dispersion has to be assumed in addition for the final state. More detailed information on the electronic structure of the investigated system is obtained by performing an ARUPS experiment using linearly and/or circularly polarized light together with a spin analysis of the photocurrent. On the basis of the underlying selection rules, information on the spin character and hybridization is gained for the probed electronic states that in principle allows one to map the spin and orbital magnetic moments along the electronic bands in a $\vec{k}$-resolved way (Braun, 1996). As for a magnetic solid, these properties depend strongly on the complex interplay of spin-orbit coupling and exchange splitting, corresponding experimental investigations have to be supported by appropriate accompanying theoretical work.

The most general basis to discuss photoemission experiments is supplied by the one-step model (Feibelman and Eastman, 1974) that describes all steps in a coherent way. Adopting the one-electron approximation and starting from Fermi's golden rule, the photoemission current emitted from a single crystal surface in an angle-resolved experiment is given by:

$$I^{\vec{q}\lambda} = -\frac{1}{\pi}\mathrm{Im}\int \mathrm{d}^3r \int \mathrm{d}^3r' \psi_{\mathrm{f}}^{*}(\vec{r},\vec{k},E_{\mathrm{f}}) X_{\vec{q}\lambda}(\vec{r}) G(\vec{r},\vec{r}\,',E_{\mathrm{i}}) \times X_{\vec{q}\lambda}^{\dagger}(\vec{r}\,')\psi_{\mathrm{f}}(\vec{r}\,',\vec{k},E_{\mathrm{f}}) \tag{29}$$

Here, excitation by light with wave vector $\vec{q}$, frequency ω, and polarization λ is considered with $X_{\vec{q}\lambda}(\vec{r})$ the corresponding electron–photon interaction operator. The manifold possible initial states at energy E_{i} are represented by the Green's function $G(\vec{r},\vec{r}\,',E_{\mathrm{i}})$, while the final states $\psi_{\mathrm{f}}(\vec{r},\vec{k},E_{\mathrm{f}})$ with wave vector $\vec{k}$, and energy $E_{\mathrm{f}} = E_{\mathrm{i}} + \hbar\omega$ are given by a time-reversed low energy electron diffraction (LEED) state (Feibelman and Eastman, 1974). If equation (29) is applied within a nonrelativistic calculation separately to the spin-up ($\uparrow$) and spin-down ($\downarrow$) states of a ferromagnet, one obtains corresponding spin-resolved partial intensities $I^{\uparrow(\downarrow)}$. Reversing the magnetization $\vec{M}$ while keeping all other parameters fixed, just interchanges $I^{\uparrow}$ and $I^{\downarrow}$. As a consequence, the spin polarization $\vec{P} = (I^{\uparrow} - I^{\downarrow})/(I^{\uparrow} + I^{\downarrow})\ \vec{M}/|\vec{M}|$, that is parallel to $\vec{M}$ reverses sign, while the total intensity $I = I^{\uparrow} + I^{\downarrow}$ remains unchanged. This situation, however, changes if the spin-orbit coupling is accounted for in addition to the exchange splitting. Symmetry and analytical considerations allow in this case to predict in detail under which conditions an asymmetry in the spin-averaged photocurrent upon reversal of magnetization, that is, a magnetic dichroism, can be observed (Feder and Henk, 1996; Henk, Scheunemann, Halilov and Feder, 1996).

For this purpose, it is most convenient to introduce the 2×2 spin density matrix (Ginatempo, Durham, Györffy and Temmerman, 1985; Feder and Henk, 1996):

$$\rho_{\sigma\sigma'}^{\vec{q}\lambda} = \frac{1}{2i}\left(I_{\sigma\sigma'}^{\vec{q}\lambda} - I_{\sigma\sigma'}^{\vec{q}\lambda *}\right) \tag{30}$$

with the partial intensity functions

$$I_{\sigma\sigma'}^{\vec{q}\lambda} = -\frac{1}{\pi}\mathrm{Im}\int \mathrm{d}^3r \int \mathrm{d}^3r' \psi_{\mathrm{f}\sigma}^{*}(\vec{r},\vec{k},E_{\mathrm{f}}) X_{\vec{q}\lambda}(\vec{r}) G(\vec{r},\vec{r}\,',E_{\mathrm{i}}) \times X_{\vec{q}\lambda}^{\dagger}(\vec{r}\,')\psi_{\mathrm{f}\sigma'}(\vec{r}\,',\vec{k},E_{\mathrm{f}}) \tag{31}$$

where the final state $\psi_{\mathrm{f}\sigma}(\vec{r},\vec{k},E_{\mathrm{f}})$ is restricted to have the spin character σ with respect to some chosen direction. This way, one has for the total intensity and spin polarization

$$I = \mathrm{Trace}\ \rho \quad \text{and} \quad \vec{P} = \mathrm{Trace}\ \vec{\sigma}\rho/I \tag{32}$$

with $\vec{\sigma}$ the vector of Pauli matrices.

The central condition for the occurrence of magnetic dichroism is that spin-orbit coupling gives rise to a component of the spin polarization $\vec{P}$ along the magnetization $\vec{M}$ if a corresponding nonmagnetic system is considered.

Assuming a sample is magnetized either perpendicular or in-plane with respect to the surface and normal emission induced by light impinging along the surface normal, this condition is met only for certain combinations of the symmetry of the system and polarization of the light. As Table 1 shows, MCD is observed for any system if the magnetization is oriented perpendicular but not if it is oriented in-plane. MLD, on the other hand, may occur for both orientations of the magnetization, depending on the symmetry and the relative orientation of the magnetization and the polarization vector of the light.

Symmetry and analytical considerations allow one to examine in detail the interplay of spin-orbit coupling and exchange splitting, which gives rise to magnetic dichroism in photoemission. A corresponding quantitative description is achieved by evaluating equations (30)–(32) within the framework of the relativistic multiple-scattering or KKR formalism of magnetic solids, which treats spin-orbit coupling and exchange splitting on the same footing. For the partial

Table 1. Magnetic dichroic effects and photoelectron spin-polarization components P_i for perpendicular ($\vec{M}||\hat{\vec{e}}_z$) and in-plane ($\vec{M}||\hat{\vec{e}}_y$) magnetization $\vec{M}$ of surfaces with twofold, threefold, or fourfold rotational axes. *s*, *p*, and *c* stand for s-, p-, and normally incident circularly polarized light. The signs indicate whether the respective component P_i occurs (+ sign) or not (− sign) and whether only spin-orbit coupling (first sign), only exchange splitting (second sign), or both (third sign) are present. MLD (L) and MCD (C) occur if a spin-polarization component parallel to $\vec{M}$ is produced by spin-orbit coupling in the nonmagnetic case, that is, if there is a combination (+, +, +) (Feder and Henk, 1996). intensity functions, one is led to the following expression:

$$
\begin{aligned}
&I_{m_s m_s'}(E, \vec{k}; \omega, \vec{q}, \lambda) \\
&\quad = \mathrm{C} \sum_{\Lambda\,\Lambda''} i^{l-l''} C_{\Lambda}^{-m_s} C_{\Lambda''}^{-m_s'} Y_l^{\mu+m_s *}(-\hat{k}) \\
&\qquad \times Y_{l''}^{\mu''+m_s'}(-\hat{k}) \sum_{m\,m'} e^{i\vec{k}(\vec{R}_m - \vec{R}_{m'})} \\
&\qquad \times \sum_{n\,n'} e^{i\vec{q}(\vec{R}_n - \vec{R}_{n'})} \sum_{\Lambda'\,\Lambda'''} \tau_{\Lambda'\Lambda}^{nm}(E') \tau_{\Lambda'''\Lambda''}^{n'm'*}(E') \qquad (33) \\
&\qquad \left[\sum_{\Lambda_1\,\Lambda_2} M_{\Lambda'\Lambda_1}^{\vec{q}\lambda} \tau_{\Lambda_1\Lambda_2}^{nn'}(E) \overline{M}_{\Lambda_2\Lambda'''}^{\vec{q}\lambda} - \delta_{n\,n'} \sum_{\Lambda_1} I_{\Lambda'\Lambda_1\Lambda'''}^{\vec{q}\lambda} \right]
\end{aligned}
$$

Here $M_{\Lambda\Lambda'}^{\vec{q}\lambda}$ and $\overline{M}_{\Lambda\Lambda'}^{\vec{q}\lambda}$ are matrix elements that are usually evaluated making use of the dipole approximation. The additional single-site term $I_{\Lambda\Lambda'\Lambda''}^{\vec{q}\lambda}$ stems from the irregular solution of the Dirac equation and contributes only if one uses a complex energy or self-energy Σ to account for finite lifetime or many-particle effects. Equation (33) involves several summations over lattice sites (n, n', m, m'). This can be evaluated in direct space when a restriction to a finite cluster is made (Woods, Ernst, Strange and Temmerman, 2001). In general, however, a half-infinite crystal is assumed that shows a two-dimensional periodicity for the atomic plane parallel to the surface. In this case the scattering within the planes can be treated by a two-dimensional Fourier transformation. The scattering between the planes is dealt with in a subsequent step either by introducing transmission and reflectivity matrices (Hopkinson, Pendry and Titterington, 1980) or by summing directly in real space (Lüders *et al*., 2001).

For high photon energies, multiple scattering can safely be neglected for the final states (single-scatterer approximation). This assumption seems to be well justified not only for the XPS regime but also down to several tens of eV (Lüders *et al*., 2001; Ostanin and Ebert, 1998). Using this single-scatterer approximation and taking the average with respect to the wave vector $\vec{k}$ of the emitted electrons, one ends up with a simple expression for the angle-integrated photoemission spectrum (PES). In the case of a paramagnetic system, one finds that angle-integrated PES for unpolarized light maps the sum over angular momentum–projected DOS curves that are weighted by a corresponding photoemission cross section (Marksteiner *et al*., 1986). Using circularly polarized light for the excitation, a spin polarization in the photoelectron current is induced; that is, the Fano effect can be observed (Minár *et al*., 2001). Reversing the helicity of the light just reverses the polarization of the photoelectron current. This symmetry is broken for a ferromagnet in the case of a polar geometry, giving rise also to magnetic circular dichroism for an angular-integrated spectrum (Ebert and Schwitalla, 1997).

5.2 Angle-resolved photoemission of transition metals

The formalism sketched in the preceding text allows one to investigate in a very detailed and quantitative way the various

dichroic phenomena observed in core-level (Venus, 1993) as well as valence-band (Kuch and Schneider, 2001) photoemission spectroscopy. As an example for the latter case, Figure 8 summarizes the results of an investigation on the spin- and angle-resolved normal photoemission from Ni(001) (Feder and Henk, 1996). Figure 8(a) of this figure shows the dispersion relation $E(\vec{k})$ for the magnetization $\vec{M}$ perpendicular to the surface. Owing to the inclusion of the spin-orbit coupling, the electronic states have no pure spin character but show only either dominantly spin-up or dominantly spin-down character, indicated by full and dotted lines, respectively. The dash-dotted line represents the relevant allowed final states that have negligible exchange splitting and can be reached with a photon energy of 21.22 eV. As they have been shifted downwards by that energy, the band intersections labeled $a-f$ indicate possible vertical transitions. Because of the symmetry of the system, the spin polarization $\vec{P}$ of the resulting photocurrent has to be aligned along the surface normal; that is, parallel or antiparallel to the magnetization. The corresponding partial and spin-projected intensities $I^{\uparrow}$ and $I^{\downarrow}$, respectively, obtained in a spin-resolved experiment with un- or s-polarized light are shown in panel (d). Obviously, these curves primarily reflect the exchange splitting of the material. As Table 1 suggests, use of circularly polarized radiation will lead to MCD. This is confirmed by the data shown in panel (c), where, instead of spectra for the two opposite orientations of $\vec{M}$, spectra for fixed $\vec{M}$ but opposite circular helicity of the light are presented. The origin of the observed asymmetry in intensity $I(\vec{M},\sigma_+) - I(\vec{M},\sigma_-)$ can be traced back in detail by studying the partial projected intensities $I^{\uparrow(\downarrow)}_{+(-)}$ shown in panel (b) of Figure 8. For the peak labeled b, an admixture of the spin-up character is found owing to spin-orbit coupling. Because of the symmetry-determined selection rules, only the final state with spin-up character can be reached, provided the excitation is done with light that has polarization σ_+. The right-hand side of Figure 8

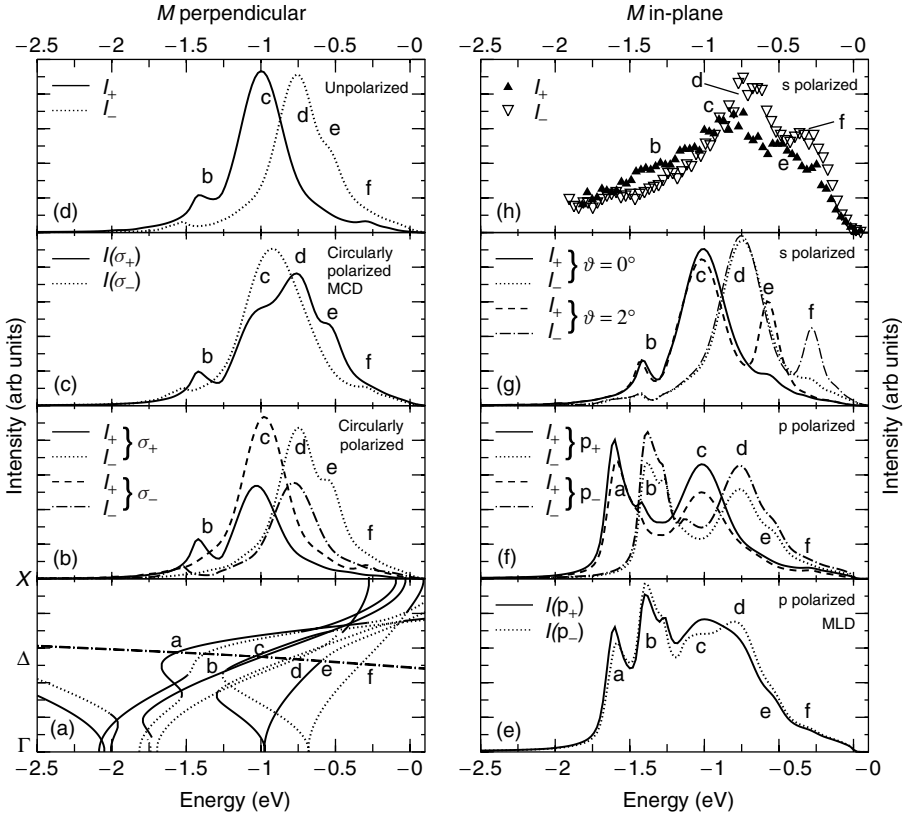

Figure 8. Normal photoemission from Ni(001) for normally incident light with 21.22 eV energy. Left: $\vec{M} \parallel [001]$ perpendicular to the surface: (a) $E(\vec{k})$ along $\Gamma-\Delta-X$. Solid (dashed) lines: states with positive (negative) spin expectation. The final-state bands (dash dotted) are shifted downwards by 21.2 eV. (b) Spin-resolved intensities $I_{\pm}$ for right-(σ_+) and left-(σ_-) circularly polarized light. (c) Spin-averaged spectra obtained from those of (b). (d) Spin-resolved intensities for unpolarized light. Right: $\vec{M} \parallel [110]$ in the surface plane: (e) Spin-averaged intensities for p-polarized light incident off-normally at $\varphi = \pi$ (solid) and $\varphi = 0$ (dotted). (f) Spin-resolved intensities corresponding to those in (a). (g) Spin-resolved intensities for s-polarized light together with off-normal emission spectra ($\vartheta = 2^{\circ}$C). (h) Experimental spin-resolved spectra (Clauberg, Hopster and Raue, 1984) corresponding to (c) (Feder and Henk, 1996). (Reproduced from Feder *et al*., 1996, with permission from Springer-Verlag GmbH. © 1996.)

shows results for the magnetization in-plane along [110]. The two upper panels showing theoretical (g) and experimental (h) spectra for s-polarized light demonstrate that a rather satisfactory agreement between both can be achieved, allowing for an unambiguous interpretation of the experimental spectra. Again, as suggested by Table 1 a linear magnetic dichroism can be expected for p-polarized light. This is confirmed by the results shown in panel (e), which have been obtained for the light incident at polar angle $\theta = 45\,^{\circ}$C in the plane normal to $\vec{M}$ with an azimuthal angle of $0\,^{\circ}$C (p_+) and $180\,^{\circ}$C (p_-). As for the MCD, a detailed analysis is achieved on the basis of the corresponding spin-projected spectra shown in panel (f).

Another example for the occurrence of the MLD in angle-resolved valence-band photoemission is given in Figure 9, which shows the corresponding spectra for normal emission from a seven monolayer Co film with hcp(0001) structure grown on a (110)-oriented W substrate. Within the experiment, the magnetization was aligned along the easy axis that coincides with the $[1\bar{1}0]$ direction of the W substrate. For an orientation of the plane of incidence of the p-polarized light perpendicular to the magnetization, the reversal of the magnetization changes the intensity of the photocurrent in line with the expectations based on Table 1.

When comparing experimental photoemission spectra with corresponding theoretical results based on plain LSDA, a qualitative agreement is found in general. Similar to the case of optical properties, however, the prominent spectral features are usually shifted against one another owing to the influence of many-body effects (Liebsch, 1979). For that reason, a shift of 2 eV in the photon energy has been applied for the theoretical spectra shown in Figure 9. The rather good agreement with experiment obtained this way justifies a detailed analysis of the experimental data on the basis of the theoretical results. As found very often in photoemission experiments on thin films (Henk and Johansson, 1999), the thickness of the Co film already gives rise to a dispersion relation corresponding to that of bulk hcp Co. Accordingly, the main peak seen in the photoemission spectra at around 0.7 eV binding energy, whose position depends only slightly on the photon energy, reflects a rather flat band of the Co band structure. The onset of the peak close to the Fermi level that is observed for the photon energy around 24 eV, on the other hand, is ascribed to a state at the Γ point.

The calculations of the photoemission spectra shown in Figure 9 have been done in a fully relativistic way. For that reason, they are able to reproduce the magnitude and the energy dependence of the observed MLD. From the calculations, it was suggested that the MLD is caused by a strong mixing of the initial-state spin subsystems owing to spin-orbit coupling together with a nonvanishing exchange splitting for the final states. In particular, it could be shown that the observed MLD is nearly exclusively connected with d–f transitions.

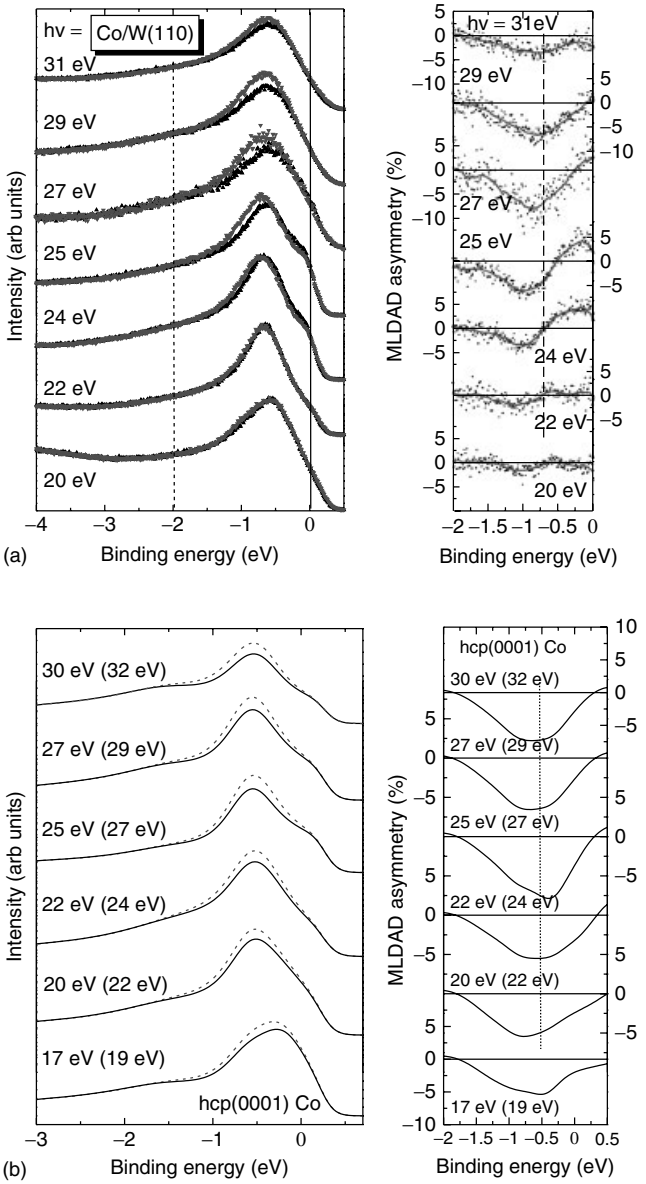

Figure 9. Left: Valence-band photoemission spectra from a seven ML thick hcp(0001) Co film on W substrate, taken with linearly polarized radiation for opposite magnetization directions. 1 INTRODUCTION

The importance of observations made by interpreting the scattering of radiation cannot be overstated. Indeed, many of the most important developments in science during the past century have come from scattering experiments. These developments include Rutherford's discovery of the atomic nucleus, atomic and nuclear structure, nuclear fission, antiferromagnetism, and additions to a classification within the elementary-particle zoo. Today, scattering experiments continually provide vital information in biology, physics, chemistry, and materials science that cannot be obtained by any other experimental technique.

The information derived about a material by shooting radiation at it depends on the nature of the radiation and its interaction with the constituents of the material, namely, electrons and nuclei. Beams of photons, leptons (electrons and muons), and baryons have proved to be the most useful for studies of condensed matter. Here, we discuss the scattering of neutrons and X rays by magnetic materials.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

Neutrons interact strongly with nuclei and, also, the magnetization from unpaired electrons, while the absence of a charge makes them a delicate probe of matter. X rays interact strongly with electrons, and the observations about their magnetization made by interpreting the scattering of X rays nicely complements that derived by interpreting the scattering of neutrons. While the latter is a well-established technique, some of the potential from X-ray scattering to the study of electron magnetism has been realized relatively recently with growth in the availability of bright, energy-tuneable, and polarized beams of X rays from synchrotron sources.

Scattering by a regular array of ions, in a crystal or fabricated structure, contains Bragg reflections that arise only when strict geometric conditions are satisfied. The experimental techniques of neutron and X-ray Bragg diffraction are cornerstones of crystallography. Atomic resonances can significantly influence X-ray scattering, and resonant X-ray Bragg diffraction has received much attention because it yields unique and valuable information in favorable cases. A fundamental limitation on resonant X-ray Bragg diffraction is that the contribution to scattering by the electrons of interest is not precisely factored. X-ray scattering off resonance and most applications of neutron scattering possess a precise factoring of the probe radiation from the electrons.

Bragg diffraction is a purely elastic scattering event, because in the kinematics of the event, the relevant mass is the mass of the sample. It is also purely coherent scattering because any form of disorder (static or dynamic) violates the strict geometric conditions to be satisfied in Bragg reflections. The amplitude for Bragg diffraction is always the mean value of the scattering amplitude, as this amplitude describes a perfect crystal. The Bragg amplitude is to be derived by

averaging the scattering amplitude over all forms of static and dynamic disorders, which may arise from both classical and quantum processes.

Inelastic neutron scattering is an immensely valuable technique, and it provides direct and extensive information on lattice vibrations and their magnetic counterparts called *spin waves* or *magnons*. Inelastic X-ray scattering provides a more limited coverage of lattice vibrations, but the information might be singularly valuable because it is inaccessible with neutron scattering by virtue of kinetic and intensity restrictions in the neutron scattering event. The relative balance in the strengths and weaknesses of neutron versus X-ray scattering techniques changes as the quality of instruments and radiation sources evolve. Certainly, some X-ray experiments recently performed were simply impossible to perform without the development of instruments supplied by synchrotron sources in the preceding decade.

The extreme inelastic X-ray scattering called *Compton scattering* is also incoherent scattering. The information it provides about electron magnetization is confined to spin magnetization. A separation of spin and orbital magnetization can be achieved with X-ray diffraction, whereas neutron diffraction is made by the total magnetization in the sample.

In the following sections, we survey salient features of the theory of neutron and X-ray scattering by magnetic materials. Observations are interpreted with a scattering amplitude (more correctly referred to as a *scattering length* because of its dimension) for each type of radiation. The distribution in space and energy of the radiation deflected by a material is related to a cross section that has the dimension of area divided by energy. The cross section in question is proportional to the square of the modulus of the scattering length and weighted by a δ-function that expresses the conservation of energy. Note that absorption of radiation by a material is related to the imaginary part of the scattering length evaluated for zero deflection. Thus, scattering and absorption of a radiation by a sample are two sides of one coin.

By and large, in this survey of magnetic scattering theory, we adopt the notation and conventions used by Lovesey (1987), Lovesey and Collins (1996) and Lovesey *et al.* (2005). The reader is referred to these articles for much of the background material, such as formal aspects of scattering theory, the description of states of partial polarization, and the Stokes parameters for a beam of X rays. Our survey is skewed toward magnetic X-ray scattering because it is less well established than magnetic neutron scattering which has been thoroughly reviewed in several places. We do not describe sources of radiation, diffraction instruments, or data analysis.

2 X-RAY SCATTERING

A beam of X rays illuminating a sample is principally deflected by the charge, spin, and orbital degree of freedom of the electrons in the sample. The nuclei in the sample also contribute, of course, but, in most cases, their contribution to scattering can be safely neglected because the ratio of the nuclear and electron scattering lengths is of the order of the inverse of the ratio of their masses which is $\approx 1/1836$.

2.1 Thomson scattering by a material with translational order

A translationally ordered material is represented by the regular repetition of a unit cell. The lattice that generates the regular repetition possesses a conjugate lattice defined by reciprocal lattice vectors, which we denote by $\boldsymbol{\tau}$. Bragg reflection can occur when the change in the wave vector of the radiation (X rays), upon scattering, matches a reciprocal lattice vector. Strong Bragg reflections in a diffraction pattern arise from equivalent electron charge densities in the unit cells that are related by translational symmetry. In an atomic model, the densities are attached to sites occupied by ions in the unit cell.

A relatively few electrons in the valence states of a material that possess angular anisotropy and, possibly, a magnetic moment, can cause weak reflections in a diffraction pattern. The importance of observations made by analyzing the weak reflections can hardly be exaggerated, for the valence electrons in question participate in many of the material's properties, including both structural and transport properties.

It is customary to develop the X-ray scattering length in powers of $E/m_e c^2$ where E is the primary energy and the rest mass energy of an electron $m_e c^2 = 0.511$ MeV. The first term in the development is proportional to the spatial Fourier transform of the electron charge density and it is responsible for the Thomson scattering of X rays. (The development referred to is summarized in equation (8.17) in Lovesey and Collins (1996).)

Let $\mathbf{k}$ denote the difference between the primary $\mathbf{q}$ and secondary $\mathbf{q}'$ wave vectors with $\mathbf{k} = \mathbf{q} - \mathbf{q}'$. The corresponding polarization vectors are $\boldsymbol{\varepsilon}$ and $\boldsymbol{\varepsilon}'$ and they satisfy $\mathbf{q}\cdot\boldsymbol{\varepsilon} = \mathbf{q}'\cdot\boldsymbol{\varepsilon}' = 0$. Writing $r_e = \alpha^2 a_0 = 0.282 \times 10^{-12}$ cm for the classical radius of the electron, the Thomson contribution to the X-ray scattering length per unit cell is $-r_e(\boldsymbol{\varepsilon}'\cdot\boldsymbol{\varepsilon})F_c(\mathbf{k})$ where $F_c(\mathbf{k})$ is the appropriate unit cell structure factor. Here, we attach a subscript c to denote the charge density.

In an atomic model of the electron density in the sample, $F_c(\mathbf{k})$ is a sum over every ion in the unit cell that contributes

to scattering. A site in the unit cell is labeled by its position $\mathbf{d}$. We then have

$$F_{\rm c}(\mathbf{k}) = \sum_{\mathbf{d}} {\rm e}^{i\mathbf{k}\cdot\mathbf{d}} \left\langle \sum_j {\rm e}^{i\mathbf{k}\cdot\mathbf{R}_j} \right\rangle_{\mathbf{d}} \tag{1}$$

where angular brackets denote the expectation value, or time-average, of the enclosed quantity and the j sum is over the positions $\mathbf{R}_j$ of the electrons associated with the site $\mathbf{d}$. The quantity $\left\langle \sum_j {\rm e}^{i\mathbf{k}\cdot\mathbf{R}_j} \right\rangle$ is often called an *atomic form factor* and it is equal to the number of electrons when $\mathbf{k} = 0$. If there is translational symmetry between the sites in the cell, $F_{\rm c}(\mathbf{k})$ is simply proportional to the sum of the spatial phase factors ${\rm e}^{i\mathbf{k}\cdot\mathbf{d}}$, and the sum is different from zero for $\mathbf{k} = \boldsymbol{\tau}(hkl)$, where the Miller indices hkl label a space group allowed reflection.

To describe the contribution made by valence electrons to $F_{\rm c}(\mathbf{k})$, we introduce an atomic tensor $\left\langle T_Q^K \right\rangle_{\rm c}$ for each ion. Here the positive integer K is the rank of the spherical tensor and the projection Q can take $(2K+1)$ integer values that satisfy $-K \le Q \le K$. An atomic tensor is also called a *multipole moment* and they are named by the Greek word for the number 2^K. For completeness, Table 1 contains the names of multipoles for $K = 1$ to $K = 6$.

An actual definition of $\left\langle T_Q^K \right\rangle_{\rm c}$ follows by separating the angular dependence of $\mathbf{k}$ and $\mathbf{R}_j$ in ${\rm e}^{i\mathbf{k}\cdot\mathbf{R}_j}$ which is accomplished with the identity,

$${\rm e}^{i\mathbf{k}\cdot\mathbf{R}_j} = 4\pi \sum_{KQ} i^K j_K\left(kR_j\right) \left\{ Y_Q^K(\hat{\mathbf{k}}) \right\}^* Y_Q^K(\hat{\mathbf{R}}_j) \tag{2}$$

Here, $\hat{\mathbf{k}} = \mathbf{k}/k$ and $\hat{\mathbf{R}}_j = \mathbf{R}_j/R_j$ are unit vectors, $j_K(kR_j)$ is a spherical Bessel function, and $Y_Q^K(\hat{\mathbf{k}}) = (-1)^Q \left\{ Y_{-Q}^K(\hat{\mathbf{k}}) \right\}^*$ is a spherical harmonic. Using (2), we write the expectation value of ${\rm e}^{i\mathbf{k}\cdot\mathbf{R}_j}$, which is required in the structure factor as

Table 1. Parity-even multipoles. Even-rank multipoles are time-even. Odd-rank multipoles are time-odd and they vanish in the absence of magnetic order.

Rank K	Name $= 2^K$
$K = 1$	Dipole
$K = 2$	Quadrupole
$K = 3$	Octupole
$K = 4$	Hexadecapole
$K = 5$	Triakontadipole
$K = 6$	Hexacontatetrapole

$$\left\langle \sum_j {\rm e}^{i\mathbf{k}\cdot\mathbf{R}_j} \right\rangle = (4\pi)^{\frac{1}{2}} \sum_{KQ} i^K \left\langle j_K \right\rangle (-1)^Q Y_{-Q}^K(\hat{\mathbf{k}}) \left\langle T_Q^K \right\rangle_{\rm c} \tag{3}$$

with

$$\left\langle T_Q^K \right\rangle_{\rm c} = (4\pi)^{\frac{1}{2}} \sum_j \left\langle Y_Q^K(\hat{\mathbf{R}}_j) \right\rangle \tag{4}$$

We note three properties of the Thomson atomic tensor. First, its Hermitian conjugate $\left(T_Q^K\right)^\dagger = (-1)^Q T_{-Q}^K$ and, secondly, Hermitian conjugation is identical to the reversal of time. Thirdly, under inversion of the electron coordinates $T_Q^K \to (-1)^K T_Q^K$. In equation (3), $\langle j_K(k) \rangle$ is the integral of a spherical Bessel function of order K weighted by the radial density of the valence wave function and $\langle j_k(0) \rangle = 0$ for $K > 0$. The atomic tensor $\left\langle T_Q^K \right\rangle_{\rm c}$ evaluated for $K = Q = 0$ is equal to the number of valence electrons. Weak Bragg reflections arise from tensors with rank $K > 0$.

We have written the right-hand side of (3) as a scalar product of two tensors of equal rank; if $\mathbf{A}$ and $\mathbf{B}$ are vector quantities (tensors of rank 1), their scalar product $\mathbf{A}\cdot\mathbf{B} = A_x B_x + A_y B_y + A_z B_z$ written in terms of spherical components, $A_{+1} = -(A_x + iA_y)/\sqrt{2}$, $A_0 = A_z$, and $A_{-1} = (A_x - iA_y)/\sqrt{2}$ and similar expressions for B_Q, is $\mathbf{A}\cdot\mathbf{B} = \sum_Q (-1)^Q A_{-Q} B_Q$.

After inserting (3) in (1), the Thomson structure factor may be written as

$$F_{\rm c}(\mathbf{k}) = (4\pi)^{\frac{1}{2}} \sum_{KQ} i^K \left\langle j_K \right\rangle (-1)^Q Y_{-Q}^K(\hat{\mathbf{k}}) \Psi_Q^K \tag{5}$$

where

$$\Psi_Q^K = \sum_{\mathbf{d}} {\rm e}^{i\mathbf{k}\cdot\mathbf{d}} \left\langle T_Q^K \right\rangle_{c,\mathbf{d}} \tag{6}$$

We assume that $\langle j_K \rangle$ is the same for each ion that contributes to the weak Bragg reflection in question, for which $\Psi_0^0 = 0$. Note that $F_{\rm c}(\mathbf{k})$ is a scalar product of a tensor $Y_Q^K(\hat{\mathbf{k}})$ associated with the X rays and a tensor Ψ_Q^K associated with the electrons. This feature of the structure factor will appear again and again in scattering processes, including resonant X-ray diffraction.

2.2 Thomson scattering by DyB_2C_2

By way of an example, let us consider diffraction by a crystal of dysprosium borocarbide (DyB_2C_2). On lowering the temperature to $T = 24.7$ K, the material undergoes a continuous structural phase transition in which there is a buckling of B and C rings of ions normal to the crystal c axis.

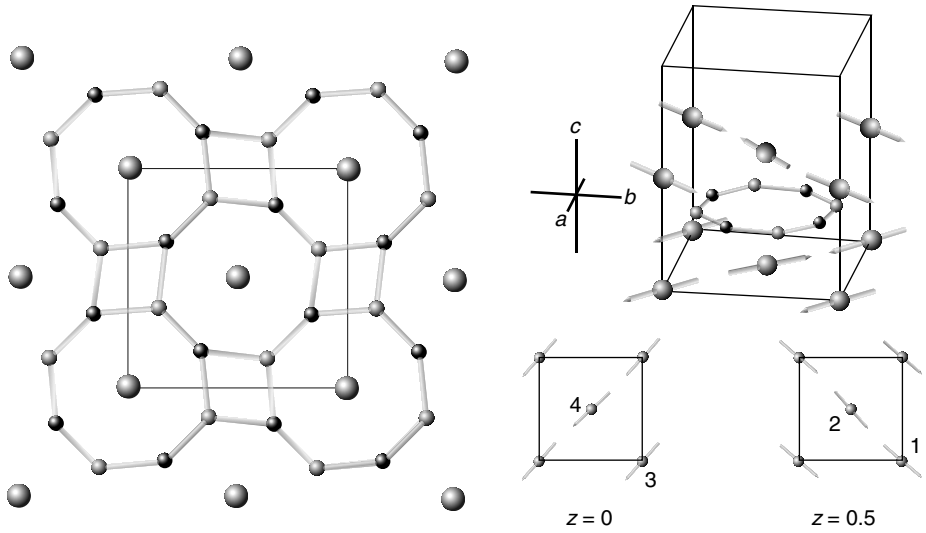

Figure 1. Low-temperature structure of DyB_2C_2 (Tanaka *et al*., 1999). In the left-hand panel, the c axis is normal to the plane of the diagram which contains the Dy ions represented by large shaded circles. The right-hand panel illustrates the configuration of Dy magnetic moments. (Reproduced from Y Tanaka *et al*: *J Phys: Condens. Matter* **11**, 1999, with permission from IOP Publishing Ltd.)

The transition reduces the crystal symmetry to $P4_2/mnm$, down from the crystal symmetry $P4/mbm$ (Tanaka *et al*., 1999). The change in symmetry is accompanied by doubling the unit cell along the c axis, and a reduction in symmetry of the sites occupied by Dy ions to $2/m$ (C_{2h}) from $4/m$ (C_{4h}). Various aspects of the crystal structure are illustrated in Figure 1.

When it comes to calculating Ψ_Q^K, we apply to $\left\langle T_Q^K \right\rangle_{c,\mathbf{d}}$ the symmetry operators that relate the four Dy sites in the unit cell of $P4_2/mnm$. One finds (Lovesey and Knight, 2001)

$$\Psi_Q^K = \left\langle T_Q^K \right\rangle_{c,1} \left\{1 + \nu_Q \mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}_3}\right\} + (-1)^K \nu_Q \left\langle T_{-Q}^K \right\rangle_{c,1} \times \left\{\mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}_2} + \nu_Q \mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}_4}\right\} \tag{7}$$

where $\nu_Q = \mathrm{e}^{iQ\pi/2}$. We consider two classes of space-group forbidden reflections hkl which we label (a) and (b). The corresponding spatial phase factors are as follows:

(a) $h + k$ odd and $l = (2n + 1)/2$,

$$\mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}_2} = \mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}_3} = -1, \ \mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}_4} = +1$$

(b) $h + k$ even and $l = (2n + 1)/2$,

$$\mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}_2} = +1, \ \mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}_3} = \mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}_4} = -1$$

We find

$$\Psi_Q^K(\mathrm{a}) = (1 - \nu_Q) \left\{\left\langle T_Q^K \right\rangle_{c,1} - (-1)^K \nu_Q \left\langle T_{-Q}^K \right\rangle_{c,1}\right\} \tag{8}$$

and

$$\Psi_Q^K(\mathrm{b}) = (1 - \nu_Q) \left\{\left\langle T_Q^K \right\rangle_{c,1} + (-1)^K \nu_Q \left\langle T_{-Q}^K \right\rangle_{c,1}\right\} \tag{9}$$

and the common prefactor guarantees $\Psi_0^K(\mathrm{a}) = \Psi_0^K(\mathrm{b}) = 0$, a result that is a signature of space-group forbidden reflections.

There are more selection rules on K and Q that are derived from Ψ_Q^K. First, for Thomson scattering, K is an even integer, as we mentioned, and the maximum $K = 2l$ when l is the angular momentum of the valence shell occupied by the equivalent electrons. In our example, the valence shell is expected to be formed by the Dy 4f state and $l = 3$. Thus, the possible Ψ_Q^K are Ψ_Q^2, Ψ_Q^4, Ψ_Q^6 which, respectively, are linear combinations of quadrupoles, hexadecapoles, and hexacontatetrapoles of the Dy 4f valence state. The contributions they make to $F_\mathrm{c}(\mathbf{k})$ are weighted by $\langle j_2\rangle$, $\langle j_4\rangle$, and $\langle j_6\rangle$, which vanish as $k = |\mathbf{k}|$ goes to zero, and the magnitude of $\langle j_2\rangle$ is typically much larger than the magnitudes of both $\langle j_4\rangle$ and $\langle j_6\rangle$. Secondly, the diad parallel to the c axis requires that $\left\langle T_Q^K \right\rangle_{c,1}$ be unchanged by a rotation by π about the c axis, that is, $\left\langle T_Q^K \right\rangle_{c,1} = \mathrm{e}^{iQ\pi} \left\langle T_Q^K \right\rangle_{c,1}$. The nontrivial condition is that Q be an even integer $Q = \pm 2, \pm 4, \ldots$. However, a necessary condition for scattering is $\nu_Q = \mathrm{e}^{iQ\pi/2} = -1$, and hence the allowed $Q = \pm 2, \pm 6, \ldots$. Notice that, in the room-temperature structure $P4/mbm$, there is no Thomson scattering because dysprosium ions occupy sites with a tetrad parallel to the c axis, and this rotation symmetry restricts Q to values $0, \pm 4, \pm 8, \ldots$ for which $\Psi_Q^K = 0$.

Below the structural phase transition, at $T = 24.7\,\mathrm{K}$, the structure factor for Thomson scattering is derived from

$$\Psi_Q^K(a) = 2\left\{\langle T_Q^K\rangle_{c,1} + \langle T_{-Q}^K\rangle_{c,1}\right\} = \Psi_{-Q}^K(a) = 4\mathrm{Re}\,\langle T_Q^K\rangle_{c,1} \tag{10}$$

and

$$\begin{aligned}\Psi_Q^K(b) &= 2\left\{\langle T_Q^K\rangle_{c,1} - \langle T_{-Q}^K\rangle_{c,1}\right\} = -\Psi_{-Q}^K(b)\\ &= 4i\,\mathrm{Im}\,\langle T_Q^K\rangle_{c,1}\end{aligned} \tag{11}$$

To express Ψ_Q^K in terms of the real or imaginary parts of $\left\langle T_Q^K\right\rangle_{c,1}$, we have used a result for $\left\langle T_{-Q}^K\right\rangle$ that is valid in the general case, namely, $\left\langle T_{-Q}^K\right\rangle = (-1)^Q\left\langle T_Q^K\right\rangle^*$, together with the fact that Q is an even integer.

The Thomson structure factors are (Tanaka *et al*., 2004)

$$\begin{aligned}F_\mathrm{c}(\mathbf{k}) &= (4\pi)^{\frac{1}{2}}\sum_{K=2,4,6} i^K \sum_{Q=2,6}\left[Y_{-Q}^K(\hat{\mathbf{k}}) + Y_Q^K(\hat{\mathbf{k}})\right]\\ &\quad\times\langle j_K\rangle\,\Psi_Q^K(a)\\ &= -4\sqrt{\frac{15}{2}}\,\langle j_2\rangle\left(\hat{k}_a^2 - \hat{k}_b^2\right)\mathrm{Re}\,\langle T_2^2\rangle_{c,1} + \cdots\end{aligned} \tag{12}$$

and

$$\begin{aligned}F_\mathrm{c}(\mathbf{k}) &= (4\pi)^{\frac{1}{2}}\sum_{K=2,4,6} i^K \sum_{Q=2,6}\left[Y_{-Q}^K(\hat{\mathbf{k}}) - Y_Q^K(\hat{\mathbf{k}})\right]\\ &\quad\times\langle j_K\rangle\,\Psi_Q^K(b)\\ &= -4\sqrt{30}\,\langle j_2\rangle\,\hat{k}_a\,\hat{k}_b\,\mathrm{Im}\,\langle T_2^2\rangle_{c,1} + \cdots\end{aligned} \tag{13}$$

Dots in these expressions denote terms with tensors of rank 4 and rank 6, and $\hat{k}_a$ and $\hat{k}_b$ are proportional to the Miller indices h and k, respectively. Our findings, (12) and (13), are in complete agreement with experimental data reported by Adachi *et al*. (2002), which we display in Figure 2.

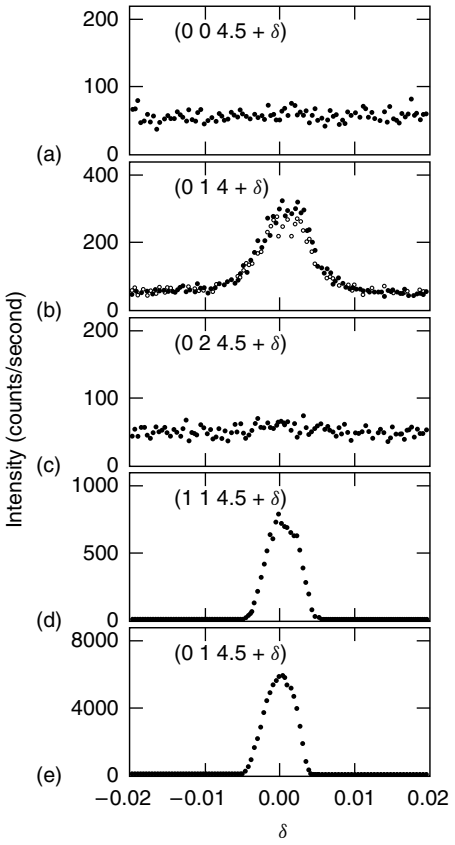

Figure 2. Thomson scattering by DyB_2C_2. Raw data of the l-scan measurements are displayed for various types of reflections. The crystal was held at a temperature of 18 K except for data gathered in scans about (014). Intensities reported in panel (b) were taken at 18 K (solid circles) and 30 K (open circles) and they are attributed to multiple scattering. 2.3 Magnetic X-ray scattering

The first correction, in an expansion of E/m_ec^2, to the Thomson contribution of the X-ray scattering length includes magnetic terms. These magnetic terms also appear in the amplitudes for the magnetic scattering of neutrons. In the neutron case, the spin (**S**) and orbital (**L**) magnetic moments of the unpaired electrons in the crystal are linked together and the amplitude is proportional to the total magnetic moment $\mathbf{L} + 2\mathbf{S}$, to a good approximation. By contrast, the magnetic X-ray amplitude is such that the spin and orbital moments can be separately measured (de Bergevin and Brunel, 1981; Brunel and de Bergevin, 1981).

Let us introduce a vector structure factor for spin moments and a vector structure factor for orbital moments, in analogy with the Thomson structure factor $F_\mathrm{c}(\mathbf{k})$. To a first approximation, that is often perfectly adequate for the analysis of observations, our new structure factors are

$$\mathbf{F}_\mathrm{S} \simeq \sum_{\mathbf{d}} f_\mathrm{S}(\mathbf{k};\mathbf{d})\langle\mathbf{S}\rangle_{\mathbf{d}}\mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}} \tag{14}$$

and

$$\mathbf{F}_\mathrm{L} \simeq \frac{1}{2}\sum_{\mathbf{d}} f_\mathrm{L}(\mathbf{k};\mathbf{d})\langle\mathbf{L}\rangle_{\mathbf{d}}\mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}} \tag{15}$$

Here, $f_\mathrm{S}(\mathbf{k};\mathbf{d})$ and $f_\mathrm{L}(\mathbf{k};\mathbf{d})$ are atomic form factors for the spin and orbital moment distributions, respectively, and $f_\mathrm{S}(0;\mathbf{d}) = f_\mathrm{L}(0;\mathbf{d}) = 1$. The general expressions for the

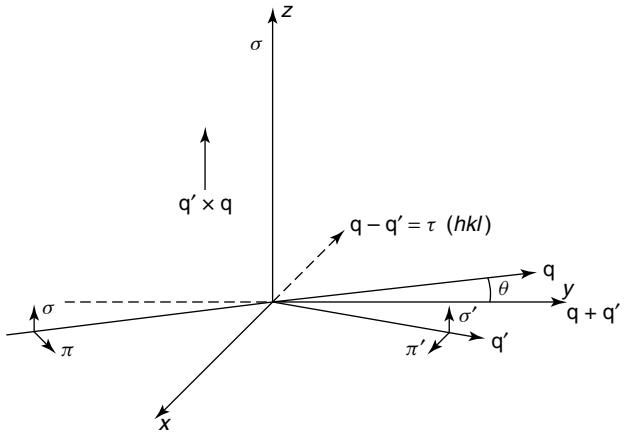

Figure 3. The diagram illustrates the Cartesian coordinate system (xyz) adopted for Bragg diffraction and the relation to the states of polarization, σ and π, in the primary and secondary beams of X rays.

magnetic structure factors can include octupole and higher-order multipole moments.

The magnetic X-ray scattering length has a nontrivial dependence on the polarization in the primary and secondary beams. It is normal practice to label by σ, polarization perpendicular to the plane of scattering, which is defined by $\mathbf{q}$ and $\mathbf{q}'$. Polarization in the plane is labeled by π. Our choice of Cartesian axes (xyz) for the geometry of the experiment is illustrated in Figure 3, where σ and z axis are parallel and $\mathbf{k} = \boldsymbol{\tau}(hkl)$ is directed along $-x$. The X-ray scattering length is expressed as $-r_e\mathrm{G}$, where G is a 2×2 matrix with components $G_{\sigma'\sigma}$, $G_{\pi'\pi}$, $G_{\sigma'\pi}$, and $G_{\pi'\sigma}$. The Thomson structure factor appears in channels where the polarization in the primary beam is not rotated on deflection by the crystal, namely, $G_{\sigma'\sigma}$ and $G_{\pi'\pi}$. These two channels may also contain magnetic components, $F_S^z(\mathbf{k})$ and $F_L^z(\mathbf{k})$, normal to the plane of scattering. The rotated channels, with amplitudes $G_{\sigma'\pi}$ and $G_{\pi'\sigma}$ are purely magnetic, and components of $\mathbf{F}_S(\mathbf{k})$ and $\mathbf{F}_L(\mathbf{k})$ lie in the plane.

It is convenient to express the components of $\mathbf{G}$ in terms of four other quantities specified in the following text:

$$\beta = -\frac{1}{2}(1+\cos 2\theta)\,F_c(\mathbf{k}) - i\delta\sin(2\theta)\left\{F_S^z(\mathbf{k}) + (1-\cos 2\theta)\,F_L^z(\mathbf{k})\right\} \tag{16}$$

$$\alpha_3 = -\frac{1}{2}(1-\cos 2\theta)\,F_c(\mathbf{k}) + i\delta(1-\cos 2\theta) \times \sin(2\theta)F_L^z(\mathbf{k}) \tag{17}$$

$$\alpha_2 = \delta\cos\theta\,(1-\cos 2\theta)\left\{2F_L^y(\mathbf{k}) + F_S^y(\mathbf{k})\right\} \tag{18}$$

$$\alpha_1 = -i\delta\sin\theta\,(1-\cos 2\theta)\,F_S^x(\mathbf{k}) \tag{19}$$

In these expressions, $\delta = E/m_ec^2 = \hbar q/m_ec$, and θ is the Bragg angle illustrated in Figure 3. The virtue in using (16–19), instead of $\mathbf{G}$, lies in the ease of handling polarization. If $\mathbf{P} = (P_1, P_2, P_3)$ is the Stokes vector, the X-ray cross section is simply

$$\frac{d\sigma}{d\Omega} = r_e^2\left\{\boldsymbol{\alpha}^*\cdot\boldsymbol{\alpha} + |\beta|^2 + \beta^*(\mathbf{P}\cdot\boldsymbol{\alpha}) + \left(\mathbf{P}\cdot\boldsymbol{\alpha}^*\right)\beta + i\mathbf{P}\cdot\left(\boldsymbol{\alpha}^*\times\boldsymbol{\alpha}\right)\right\} \tag{20}$$

By way of illustration of (20), let us consider pure charge scattering, that is, set $\mathbf{F}_S(\mathbf{k}) = \mathbf{F}_L(\mathbf{k}) = 0$ in (17–19). The equation (20) then reduces to

$$\frac{d\sigma}{d\Omega} = \frac{1}{2}r_e^2\,|F_c(\mathbf{k})|^2\left\{1+\cos^2(2\theta) + P_3\sin^2(2\theta)\right\} \tag{21}$$

The cross section for X rays polarized perpendicular to the plane $P_3 = +1$ (σ polarization) is larger than the cross section for X rays polarized in the plane $P_3 = -1$ (π polarization).

When the polarization is nearly perfect, the components of $\mathbf{G}$ provide the corresponding cross sections. For example, with pure σ polarization, the unrotated cross section is $r_e|G_{\sigma'\sigma}|^2$. The four components of $\mathbf{G}$ are,

$$\begin{aligned} G_{\sigma'\sigma} &= \beta + \alpha_3 = -F_c(\mathbf{k}) - i\delta\sin(2\theta)F_S^z(\mathbf{k}) \\ G_{\pi'\pi} &= \beta - \alpha_3 \\ G_{\sigma'\pi} &= \alpha_1 - i\alpha_2 \\ G_{\pi'\sigma} &= \alpha_1 + i\alpha_2 \end{aligned} \tag{22}$$

The component $G_{\sigma'\sigma}$ is written out in full to emphasize that it depends on the spin and not on the orbital magnetization.

The spin moment is the dominant magnetic contribution in the limit of small Bragg angles achieved with very hard X rays, and the appropriate cross section has a very simple form. For Bragg diffraction from planes of reflection separated by a distance d and X rays with a wavelength $\lambda \ll d$, the Bragg angle is of the order of (λ/d) and the cross section is

$$\frac{d\sigma}{d\Omega} = r_e^2\left|F_c(\mathbf{k}) + i\left(\frac{\lambda_0}{d}\right)F_S^z(\mathbf{k})\right|^2 \tag{23}$$

Here, $\lambda_0 = (2\pi\alpha a_0) = (2\pi r_e/\alpha) \simeq 0.0243$ Å is the Compton wavelength.

Let us now consider the calculation of $\mathbf{F}_S(\mathbf{k})$ and $\mathbf{F}_L(\mathbf{k})$. Results (14) and (15) are not adequate if the wave vector is large enough for $\langle j_2(k)\rangle$ to be larger than $\langle j_0(k)\rangle$, where $\langle j_K(k)\rangle$ is the Bessel function transform of order K of the radial component of the valence wave function introduced in

Section 2.1. In fact, (14) and (15) become exact in the limit $k \to 0$ at which the atomic form factors are unity.

The definition of $\mathbf{F}_{\mathrm{S}}(\mathbf{k})$ is similar to the definition of the Thomson (charge) structure factor (1), except that $\mathbf{F}_{\mathrm{S}}(\mathbf{k})$ is related to the spatial Fourier transform of the spin density and it is a vector quantity. We have

$$\mathbf{F}_{\mathrm{S}}(\mathbf{k}) = \sum_{\mathbf{d}} \mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}} \left\langle \sum_{j} \mathrm{e}^{i\mathbf{k}\cdot\mathbf{R}_j} \mathbf{s}_j \right\rangle_{\mathbf{d}} \tag{24}$$

where $\mathbf{R}_j$ and $\mathbf{s}_j$ are the position and spin operators of the jth electron associated with the site $\mathbf{d}$ in the unit cell. The orbital structure factor $\mathbf{F}_{\mathrm{L}}(\mathbf{K})$ is constructed from an operator built from $\mathrm{e}^{i\mathbf{k}\cdot\mathbf{R}_j}$ and the linear momentum $\mathbf{p}_j$. One finds

$$\mathbf{F}_{\mathrm{L}}(\mathbf{k}) = \sum_{\mathbf{d}} \mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}} \left\langle \left(\frac{1}{ik^2}\right) \sum_{j} \mathrm{e}^{i\mathbf{k}\cdot\mathbf{R}_j} \left(\mathbf{k} \times \mathbf{p}_j\right) \right\rangle_{\mathbf{d}} \tag{25}$$

In evaluating matrix elements of the operator in (25), one can usefully take advantage of the fact that $\mathbf{F}_{\mathrm{L}}(\mathbf{k})$ appears in $\mathbf{G}$ in a scalar product with vectors that are perpendicular to $\mathbf{k}$, namely, $\mathbf{q} + \mathbf{q}'$ and $\mathbf{q} \times \mathbf{q}'$

Spherical components of structure factors for the magnetic scattering of X rays by spin and orbital moments are

$$\left(\mathbf{F}_{\mathrm{S}}(\mathbf{k})\right)_p = \sum_{KQ} \sum_{K'Q'} (4\pi)^{\frac{1}{2}}\, Y_Q^K(\hat{\mathbf{k}}) \Psi_{Q'}^{K'}(S) \left(KQK'Q'|1p\right) \tag{26}$$

and

$$\left(\mathbf{F}_{\mathrm{L}}(\mathbf{k})\right)_p = \sum_{Q} \sum_{K'Q'} (4\pi)^{\frac{1}{2}}\, Y_Q^{K'-1}(\hat{\mathbf{k}}) \Psi_{Q'}^{K'}(L) \times \left(K'-1QK'Q'|1p\right) \tag{27}$$

In these expressions, $(KQK'Q'|jm)$ is a Clebsch–Gordan coefficient and,

$$\Psi_{Q'}^{K'}(S) = \sum_{\mathbf{d}} \mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}} \left\langle T_{Q'}^{K'} \right\rangle_{S,\mathbf{d}} \tag{28}$$

$$\Psi_{Q'}^{K'}(L) = \sum_{\mathbf{d}} \mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}} \left\langle T_{Q'}^{K'} \right\rangle_{L,\mathbf{d}} \tag{29}$$

Notice that $\mathbf{F}_{\mathrm{S}}$ is essentially a product of two spherical tensors, Y_Q^K and $\Psi_Q^{K'}$, that form a spherical tensor of rank 1 (a vector). The same is true of $\mathbf{F}_{\mathrm{L}}$ and we have in this case added the two contributions $K = K' \pm 1$.

The spherical tensors for spin and orbital magnetization in (28) and (29) are constructed for equivalent electrons in a valence shell with angular momentum quantum number l. For example, in the case of the ion Dy^{+3}, there are nine electrons in the 4f shell ($l = 3$). The spherical tensors are called *Hermitian tensors* for they satisfy (results (30–32) apply to the spin and orbital tensors, and we omit subscripts S and L)

$$\left(T_{Q'}^{K'}\right)^{\dagger} = (-1)^{Q'} T_{-Q'}^{K'} \tag{30}$$

Behavior with respect to time reversal is of paramount importance, and under this transformation

$$T_{Q'}^{K'} \longrightarrow (-1)^{K'+Q'} T_{-Q'}^{K'} \tag{31}$$

The results (30) and (31) tell us how the expectation value $\left\langle T_{Q'}^{K'} \right\rangle$ behaves with respect to reversal of the polarity of a magnetic field acting on the spin. The field, $\mathbf{H}$, can be an applied field or the direction of the spontaneous moment developed by the ion. The requested result is

$$\left\langle T_{Q'}^{K'} \right\rangle_{\mathbf{H}} = (-1)^{K'} \left\langle T_{Q'}^{K'} \right\rangle_{-\mathbf{H}} \tag{32}$$

from which we conclude that multipoles with odd K' are absent in a material with no long-range magnetic order. Tensors with odd (even) K' are said to be time-odd (time-even) on the basis of their behavior with respect to the polarity of $\mathbf{H}$. Under an inversion of the coordinates of the electrons ($\mathbf{R}_j \to -\mathbf{R}_j$ and $\mathbf{s}_j \to \mathbf{s}_j$), the spherical tensors do not change. Tensors with this property are called *parity-even tensors* and they are either true (or polar) tensors that have even K', or pseudotensors (or axial tensors) that have odd K'.

The integer K in (26) is even with $K = 0, 2, 4, \ldots, 2l$. The corresponding integer $K' = K$ and $K' = K \pm 1$. Thus, the spin structure factor can contain both even-rank (polar) tensors and odd-rank (axial) tensors even though the electrons are equivalent and occupy one atomic shell. However, even-rank tensors are often forbidden by a selection rule. One possibility is that $\Psi_{Q'}^{K'}(S)$ vanishes for even K' as a direct result of the motif of magnetic moments. A second possibility is that the reduced matrix element of $T_{Q'}^{K'}$ vanishes for even K'. This is the case when all electrons occupy a single manifold, labeled by quantum numbers S, L, and J. Turning to (27), for the orbital structure factor, the integer K is also even. However, K' is an odd integer and $K' = 1, 3, \ldots, (2l-1)$. In (27), we have exploited a result which relates the two contributions with $K = K' \pm 1$ and a given K'.

Expectation values of the spin and orbital spherical tensors can be calculated, given an appropriate wave function for the valence shell. An individual matrix element in the

expectation value is of the form

$$\left\langle SLJM \left| T^{K'}_{Q'} \right| S'L'J'M' \right\rangle = (-1)^{J-M} \begin{pmatrix} J & K' & J' \\ -M & Q' & M' \end{pmatrix} \times \left(SLJ||T^{K'}||S'L'J' \right) \quad (33)$$

and now we set out expressions for the reduced matrix elements $\left(SLJ||T^{K'}||S'L'J' \right)$. We choose to express the spin and orbital reduced matrix elements in terms of quantities $C(K, K')$ and $A(K, K')$, which are extensively tabulated for 3d and 4f valence shells (Balcar and Lovesey (1989, 2002)). Reduced matrix elements required in (26) and (27) can be derived from the tables in conjunction with the defining relations (Lovesey, 1987)

$$\left(SLJ|| \left(T^{K'} \right)_S ||S'L'J' \right) = i^K (-1)^{J'-J+K'} \times \left\{ \frac{1}{3}(2J+1)(2K'+1) \right\}^{\frac{1}{2}} C(K, K') \quad (34)$$

and

$$\left(SLJ|| \left(T^{K'} \right)_L ||S'L'J' \right) = (-1)^{J'-J+K'} (2J+1)^{\frac{1}{2}} \times \frac{2K'+1}{K'+1} A(K'-1, K') \quad (35)$$

The somewhat awkward form of these relations is a quirk of the historical development of magnetic neutron diffraction in which $C(K, K')$ and $A(K, K')$ were first used. Note that $C(K, K')$ and $A(K, K')$ depend on the full range of quantum numbers required to specify the valence shell of an ion.

We recall that the Thomson atomic tensors introduced in Section 2.1 satisfy (30), while under the time-reversal transform $T^K_Q \to (-1)^Q T^K_{-Q}$ in place of (31). These two properties give $\left\langle T^K_Q \right\rangle_{\mathrm{c},\mathbf{H}} = \left\langle T^K_Q \right\rangle_{\mathrm{c},-\mathbf{H}}$ in place of (32), which confirms that the Thomson atomic tensor is a time-even tensor. It is also a polar tensor.

2.4 Resonant X-ray Bragg diffraction

Figure 4 shows data collected in X-ray Bragg diffraction by V_2O_3 with the sample held at a temperature below its Néel temperature, at which it becomes a fully compensating antiferromagnet Paolasini *et al*. (1999, 2001). The crystal structure is a body-centered cell and all the data in Figure 4 are collected at space-group forbidden reflections, for which the sum of the Miller indices is an odd integer. The panels on the left-hand side of Figure 4 show the intensity as a function of X-ray energy collected near the vanadium K edge, and in the unrotated ($\sigma'\sigma$) and rotated ($\pi'\sigma$) channels of scattering. There is a strong resonance enhancement of the Bragg intensities, and the same phenomenon has been observed with many different resonant ions and many crystal structures. In the case of V_2O_3, the diffraction is due to magnetic multipoles that disorder above the Néel temperature and the Bragg intensities disappear. The strong feature in panel (a) of Figure 4 that sits around 5.475 keV is due to an El event from the vanadium K edge, at which an electron in the 1s core is photoejected in a process that changes orbital angular momentum by one unit. In panel (a), there is a second, weaker feature at an energy of 5.465 eV that is due to an E2 event at the vanadium K edge. With this process, the photoejected electron visits a 3d valence state, which is the state occupied by the unpaired electrons that form the vanadium magnetic moment. Looking at panel (c) in Figure 4, the El event is absent. This observation is one consequence of a selection rule that, for odd h and even $k+l$, forbids resonance events caused by vectorlike interactions, that is, tensors with rank $K = 1$.

Panels (b) and (d) in Figure 4 show Bragg intensities as a function of rotation of the V_2O_3 domain about the Bragg wave vector. If the scattering was from electronic states with no angular anisotropy, the intensity in such scans would be constant. As it is, Bragg intensities depend strongly on the angle of rotation and, also, states of polarization in the diffracted beam.

The data in Figure 4, collected on V_2O_3, nicely illustrates the wealth of information in X-ray resonance-enhanced Bragg diffraction. In this section, we outline a framework for the interpretation of the observations. Applied to V_2O_3, it shows that the observations reported in Figure 4 are in complete accord with the established chemical and magnetic structures. Parity-odd contributions to scattering, which are allowed because the resonant vanadium ions occupy sites that are not centers of inversion symmetry, are not visible in available diffraction data. In particular, data collected in reflections with odd h and even $k+l$ are a direct observation of the vanadium octupole moment created by orbital magnetization in the vanadium 3d valence shell.

Resonance-enhanced Bragg diffraction has most to offer when the intermediate state, visited by the photoejected core electron, is the valence state of the resonant ion occupied by unpaired electrons, namely, 3d, 4f, and 5f states of 3d transition, lanthanide, and actinide ions. In these experiments, the observations are directly related to states that participate in magnetic, magneto-electronic, and charge-ordering effects. Observations on other states of a resonant ion, for example, an El event at the K edge of a 3d transition-metal ion, can provide insight into the valence state of interest but it is less credible because there are more assumptions in the interpretation.

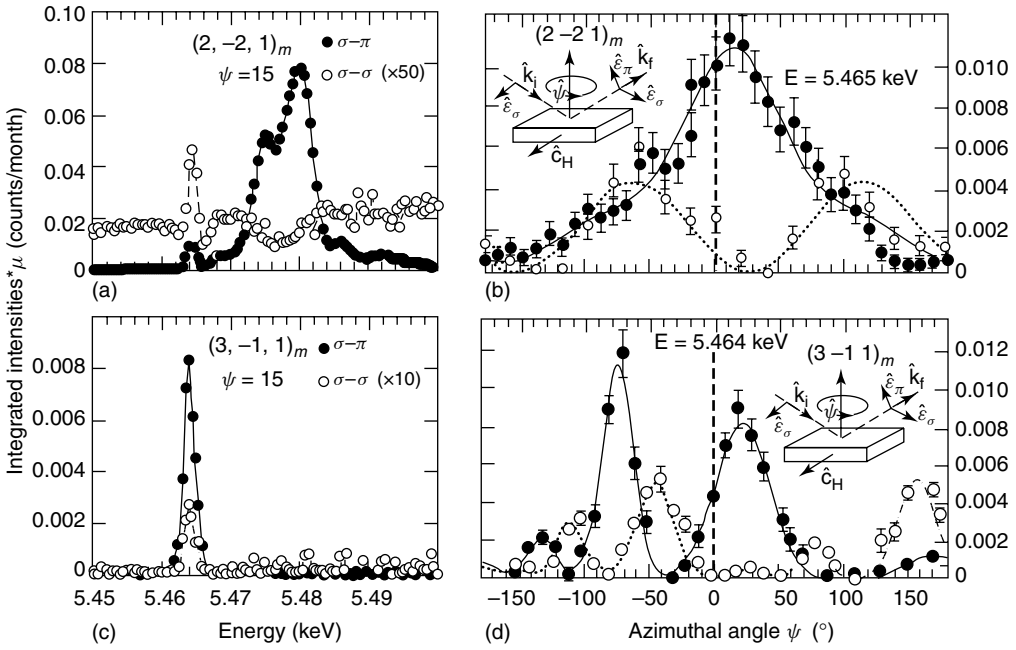

Figure 4. Energy profiles (panels a and c) and azimuthal-angle scans (panels b and d) for resonant Bragg diffraction by a domain within antiferromagnetic V_2O_3. The observations are at space-group forbidden reflections and in channels with unrotated and rotated polarization. (Information taken from Paolasini *et al*., 2001, with permission from Elsevier, and Paolasini *et al*., 1999, with permission from the American Physical Society. © 1999.)

The X-ray scattering length expanded to the first order in E/m_ec^2 has two contributions with denominators that depend explicitly on the X-ray energy. These terms arise in the scattering length from inclusion at the second level of application of the radiation–matter interaction that is linear in the vector potential. To be more specific, the two energy-dependent terms are second order in the current operator, $\mathbf{J}(\mathbf{q}) = \sum(\mathbf{p}_j + i\mathbf{s}_j \times \mathbf{q})e^{i\mathbf{q}\cdot\mathbf{R}_j}$, where $\mathbf{p}_j$, $\mathbf{R}_j$, and $\mathbf{s}_j$ are, respectively, the electron linear momentum, position, and spin operators. We have already encountered these two terms in the limit of large E where they are the source of the contribution to scattering by orbital angular momentum $\mathbf{l} = \mathbf{R} \times \mathbf{p}$. Taken together with the Thomson contribution to the scattering length and the limit of small E, the terms in question produce the Rayleigh limit of the cross section, while the one term that admits an energy resonance gives, in this condition, the Kramers–Heisenberg dispersion formula. Here, we are interested in the energy resonance and its influence on Bragg diffraction, which is a strictly elastic scattering process.

Let us label the virtual intermediate states by the quantum number η. Unlike the initial and final states of the crystal, intermediate states are not from the equilibrium configuration of the crystal and they decay on a timescale $\sim\hbar/\Gamma$, where Γ is the total width of the resonance. The resonant contribution to the scattering length for Bragg diffraction is

$$f = -\left(\frac{r_e}{m_e}\right)\sum_{\eta(\Delta)}\frac{\langle\{\boldsymbol{\varepsilon}'\cdot\mathbf{J}(-\mathbf{q}')|\eta\rangle\langle\eta|\boldsymbol{\varepsilon}\cdot\mathbf{J}(\mathbf{q})\}\rangle}{E-\Delta+i\Gamma/2} \tag{36}$$

where the sum of intermediate states is limited to those that contribute at the resonance energy Δ. Of course, Δ and Γ have a dependence on the intermediate states but this dependence is weak in some cases and the energy profile is observed to be that expected for a single oscillator like (36). Notice that one requires the expectation value of the operators in the numerator of f to describe Bragg diffraction.

Let us examine matrix elements of $\mathbf{J}(\mathbf{q})$. After expanding $\mathbf{J}(\mathbf{q})$ to the first order in $\mathbf{q}$,

$$\langle\eta|\boldsymbol{\varepsilon}\cdot\mathbf{J}(\mathbf{q})|\mu\rangle = (im_e\Delta)\sum_j\left\langle\eta|\boldsymbol{\varepsilon}\cdot\mathbf{R}_j\left(1+\frac{i}{2}\mathbf{q}\cdot\mathbf{R}_j\right)|\mu\right\rangle + \left(\frac{i}{2}\right)\langle\eta|\,(\mathbf{q}\times\boldsymbol{\varepsilon})\cdot(\mathbf{L}+2\mathbf{S})\,|\mu\rangle \tag{37}$$

where $\Delta = E_\eta - E_\mu$ is the energy of the resonance. The first contribution on the right-hand side is the sum of the El and E2 processes, and the second contribution is magnetic and includes a matrix element of the magnetic moment $\mathbf{L} + 2\mathbf{S}$. The relative magnitudes of the magnetic and El contributions is of the order (magnetic dipole/electric dipole) $\sim\mu_B/ea_0$, where μ_B and a_0 are the Bohr magneton and the Bohr radius, and the ratio $\mu_B/ea_0 = \alpha/2$ which leads us to expect that

the El process is the dominant one. On the other hand, the magnitudes of E2 and magnetic processes can be similar at very low energies although evidence in the X-ray region is that the E2 process is the most significant. Similarly, in the X-ray region, E1–E2 interference is more significant than the E1-magnetic interference process. Our calculation of resonant X-ray Bragg diffraction will therefore be based on the El and E2 processes in (37), parity-even events that are pure El or pure E2. Resonant Bragg diffraction in the E1–E2 interference channel, and associated dichroic signals, is discussed by Lovesey *et al*. (2005).

An additional assumption is to neglect in the numerator of (36), its dependence on the projection $\overline{M}$ of the angular momentum of the core state, $\overline{J}$. The assumption is valid in the absence of an interaction between the core state and the photoejected electron, and the absence of a significant exchange coupling of the core and valence states. An energy profile that is very different from a single Lorentzian shape, which is expected for a single oscillator, would suggest that the assumed degeneracy with respect to $\overline{M}$ is not good. The assumption that we make is equivalent to the fast-collision approximation used by Hannon *et al*. (1988, 1989) and Luo *et al*. (1993); See also Carra and Thole (1994).

For an E1 event, we write the resonant X-ray scattering length as

$$f = -\left(\frac{2\pi e}{\lambda}\right)^2 \frac{Z(\mathrm{E1})}{E - \Delta_1 + i\Gamma_1/2} \tag{38}$$

with

$$Z(\mathrm{E1}) = \sum_{\mathbf{d}} \mathrm{e}^{i\mathrm{k}\cdot\mathrm{d}} \sum_{\eta(\Delta)} \left\langle \sum_{j(\mathbf{d})} \{\boldsymbol{\varepsilon}'\cdot\mathbf{R}_j|\eta\rangle\langle\eta|\boldsymbol{\varepsilon}\cdot\mathbf{R}_j\} \right\rangle \tag{39}$$

The prefactor in (38) is obtained by equating Δ with the X-ray energy $E = \hbar cq = 2\pi\hbar c/\lambda$. Since $Z(\mathrm{E1})$ is a scalar quantity, the right-hand side of (39) can be written as a scalar product of a spherical tensor

$$X^K_Q = \sum_{qq'} \varepsilon'_q \varepsilon_{q'} \left(1q\,1q'|K\,Q\right) \tag{40}$$

and an atomic tensor $\left\langle T^K_Q \right\rangle_{\mathrm{E1}}$. The structure factor is

$$F(\mathrm{E1}) = \sum_{K\,Q} (-1)^Q X^K_{-Q} \Psi^K_Q \tag{41}$$

where, as in previous cases,

$$\Psi^K_Q = \sum_{\mathbf{d}} \mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}} \left\langle T^K_Q \right\rangle_{\mathrm{E1},\mathbf{d}} \tag{42}$$

and the sum on **d** is over all resonant ions in the unit cell. Because X^K_Q is constructed from two vector quantities, the triangular condition gives $K = 0$, 1, and 2.

A pure E2 event might be visible in the energy profile at an energy Δ_2 that is usually less than Δ_1. At this juncture, the reader can usefully visit Figure 4. With the assumption that we make, the contribution to the scattering length has the form shown in (38) with a resonance energy and total width Δ_2 and Γ_2, respectively. The numerator $Z(\mathrm{E2})$ is proportional to a structure factor which is a scalar product of H^K_Q that describes the polarization and directions of the primary and secondary X-ray beams, and Ψ^K_Q modeled on (42) but with an atomic tensor $\left\langle T^K_Q \right\rangle_{\mathrm{E2}}$. We find,

$$F(\mathrm{E2}) = \sum_{K\,Q} (-1)^{K+Q} H^K_{-Q} \Psi^K_Q \tag{43}$$

$$\Psi^K_Q = \sum_{\mathbf{d}} \mathrm{e}^{i\mathbf{k}\cdot\mathbf{d}} \left\langle T^K_Q \right\rangle_{\mathrm{E2},\mathbf{d}} \tag{44}$$

The definition of H^K_Q is found in Lovesey *et al*. (2005).

The atomic tensors in (42) and (44) satisfy (30–32). A time-odd contribution to an E1 event can appear in the rotated channel of scattering. This selection rule does not apply to an E2 event.

We see in Figure 4 that the Bragg intensity can vary as the crystal is rotated about the Bragg wave vector $\boldsymbol{\tau}(hkl)$ in an azimuthal-angle scan. The variation is directly related to the angular anisotropy in the valence shell that accommodates the photoejected electron, provided the X-ray beam illuminates a single domain within the crystal. Observations, like the ones reported in Figure 4, thus provide valuable insight into the ordering of the charge and orbital degrees of freedom in the valence shell. In the next section, we examine the observations made on DyB_2C_2.

2.5 Resonant Bragg diffraction by DyB_2C_2

Figure 5 shows the energy spectra of the (0 0 3/2), (0 0 5/2), (1 0 1/2), and (0 0 2) reflections observed for DyB_2C_2 at a temperature below the quadrupole order temperature $T_{\mathrm{Q}} = 24.7\,\mathrm{K}$. The azimuthal angle ψ is defined by the angle between the a axis and the scattering plane. The resonant enhancement at Dy L_{III} absorption edge is successfully interpreted in terms of the coherent sum of two oscillators for E1 and E2 transitions. Here, the E1 transition is from the 2p state to the 5d vacant state, and the E2 is from the 2p state to the 4f vacant state, respectively. Each oscillator is defined by a resonance energy Δ and a width Γ, and the

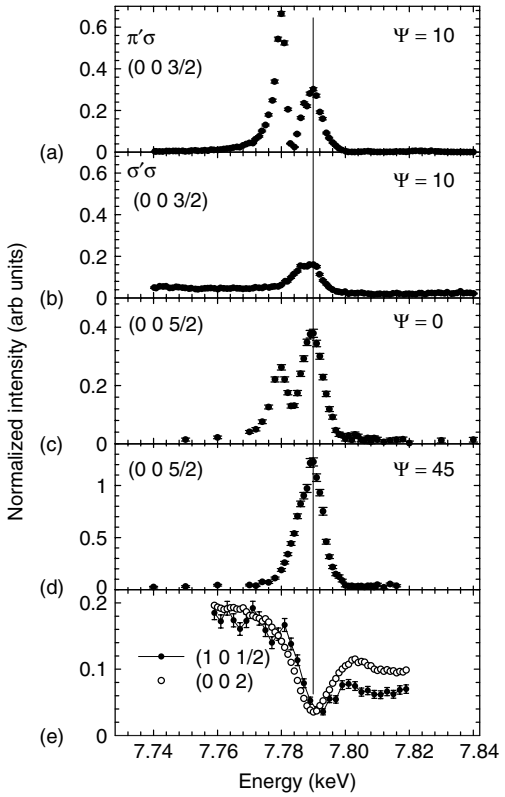

Figure 5. Energy dependence of the intensity of the (0 0 3/2) reflection at $\psi = 10^\circ$ (a) for the $\pi' - \sigma$ channel, (b) that for the $\sigma' - \sigma$ channel; the integrated intensity in ω scans of the (0 0 5/2) (c) at $\psi = 0$ and (d) that at $\psi = 45^\circ$; and (e) intensity of the (1 0 1/2) together with that of the (0 0 2) Bragg reflection. (Reproduced from Tanaka *et al*., 2004, with permission from the American Physical Society. © 2004.)

corresponding scattering length is

$$f_{\mu\nu} = \frac{F_{\mu\nu}^{(E1)}(hkl)}{E - \Delta_1 + \frac{i}{2}\Gamma_1} + r\frac{F_{\mu\nu}^{(E2)}(hkl)}{E - \Delta_2 + \frac{i}{2}\Gamma_2} \tag{45}$$

In this expression μ and ν label the secondary and primary polarizations, respectively, r is an unknown mixing parameter that could depend on μ, ν, and $F_{\mu\nu}^{(E1)}(hkl)$ and $F_{\mu\nu}^{(E2)}(hkl)$ are structure factors for E1 and E2 enhanced diffraction, expressed in terms of mean values of atomic tensors denoted by $\left\langle T_q^{(K)} \right\rangle$.

Scattering enhanced by an E1 event at $(0\,0\,l)$ reflections contain only $\left\langle T_q^{(2)} \right\rangle$. One finds

$$F_{\sigma'\sigma}^{(E1)}(0\,0\,l) = 4\sin(2\psi)\ \mathrm{Im}\left\langle T_{+2}^{(2)} \right\rangle_d \tag{46}$$

$$F_{\pi'\sigma}^{(E1)}(0\,0\,l) = -4\sin\theta\cos(2\psi)\ \mathrm{Im}\left\langle T_{+2}^{(2)} \right\rangle_d \tag{47}$$

In these expressions, we have added a subscript d to atomic tensors to indicate that absorption at the 2p edge and an E1 event lead to a sensitivity to d-like, presumably strongly 5d, valence states. The dependences of E1 structure factors on the azimuthal angle ψ and the Bragg angle θ are consistent with results reported by Tanaka *et al*. (2004).

Structure factors for an E2 event are

$$F_{\sigma'\sigma}^{(E2)}(0\,0\,l) = \sin^2\theta\sin(2\psi)\ \mathrm{Im}\left[3\sqrt{2}\left\langle T_{+2}^{(2)} \right\rangle - \sqrt{11}\left\langle T_{+2}^{(4)} \right\rangle\right] \tag{48}$$

$$F_{\pi'\sigma}^{(E2)}(0\,0\,l) = -\sin\theta\cos(2\psi)\ \mathrm{Im}\left[3\sqrt{2}\left\langle T_{+2}^{(2)} \right\rangle \times(3 - 4\sin^2\theta) + \frac{1}{2}\sqrt{11}\left\langle T_{+2}^{(4)} \right\rangle(1 + \sin^2\theta)\right] \tag{49}$$

The structure factors are linear combinations of the imaginary parts of $\left\langle T_{+2}^{(2)} \right\rangle$ and $\left\langle T_{+2}^{(4)} \right\rangle$, and these atomic tensors describe properties of the Dy 4f valence shell. We note that

$$\left\langle T_{+2}^{(2)} \right\rangle = \frac{1}{\sqrt{6}}\left\langle T_{xx}^{(2)} - T_{yy}^{(2)} + 2iT_{xy}^{(2)} \right\rangle \propto \langle Q_{aa} - Q_{bb} + 2iQ_{ab} \rangle \tag{50}$$

where the Cartesian tensors $\left\langle T_{\alpha\beta}^{(2)} \right\rangle$ are purely real. $F_{\mu\nu}^{(2)}(0\,0\,l)$ contains a component of the quadrupole moment $\left\langle T_{xy}^{(2)} \right\rangle \propto \langle Q_{xy} \rangle$ and that of the hexadecapole $\mathrm{Im}\left\langle T_{+2}^{(4)} \right\rangle$, and all contributions transform according to the representation A_g of $2/m$.

The data shown in panels from (a) to (d) in Figure 5 are interpreted by the coherent sum of two oscillators E1 and E2 transitions as shown in equation 45. The E1 and E2 transitions are located at 7.790 and 7.780 keV, respectively. Note that the E1 event width is so wide that the interference of two oscillators cannot be neglected at $E = \Delta_2$.

Figure 6 shows the azimuthal-angle scans for (0 0 1/2), (0 0 3/2), and (0 0 5/2) reflections, measured at $E = \Delta_1$ and $E = \Delta_2$. The fourfold periodicity and the antiphase signals for the $\sigma' - \sigma$ channel and $\pi' - \sigma$ channel are interpreted by equations from (46) to (49). The mixing parameter, r, in (45) is found to be independent of the states of polarization and independent of the Bragg angle, to a very good approximation. These findings provide confidence in the use of (45) to model the energy profiles.

2.6 Compton scattering

Magnetic Compton scattering is reviewed by Lovesey and Collins (1996) and Cooper *et al*. (2004), where it is argued

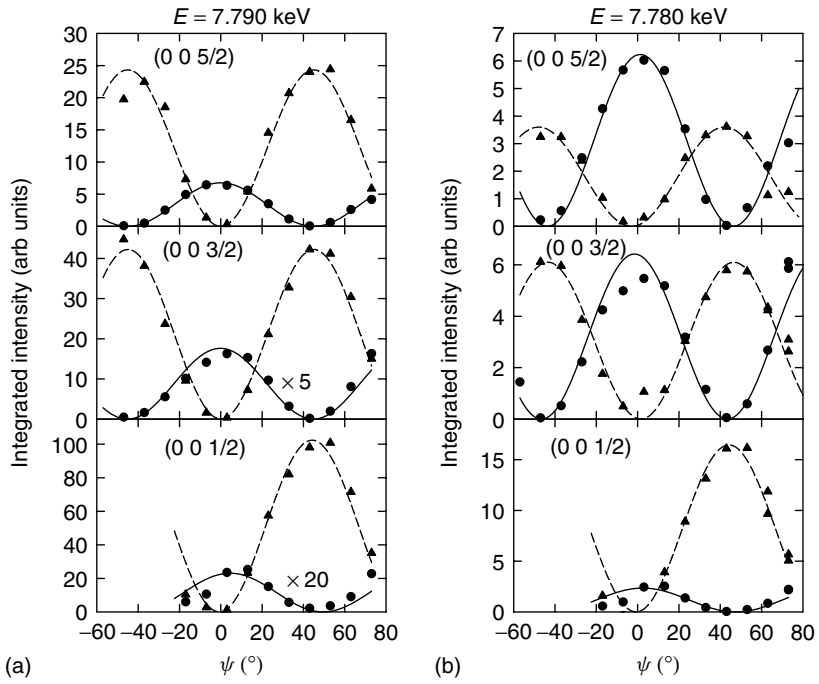

Figure 6. Change of the integrated intensities with the rotation of sample around the reflection vectors, (0 0 1/2), (0 0 3/2), and (0 0 5/2) at (a) 7.790 keV and at (b) 7.780 keV. Azimuthal angle ψ is defined by the angle between the a axis and the scattering plane. Circles (triangles) represent the signal through the $\pi' - \sigma$ ($\sigma' - \sigma$) channel. The full curves and broken curves are squared sinusoidal functions which are fit to each of the data. (Reproduced from Tanaka *et al*., 2004, with permission from the American Physical Society. © 2004.)

that it is a probe of the spin magnetization. Figure 7 shows the Compton profiles observed in extensive experiments on an iron crystal, together with the reconstructed spin density and the corresponding quantity calculated by a band-structure method. Dimunition in density at zero momentum transfer is believed to be a result of negative spin polarization of the s,p-like band electrons, while the surrounding ridge of density is due to d-like electrons in wave functions localized on sites occupied by Fe atoms.

The Compton limit of scattering is achieved with hard X rays. In the energy region $E \sim 40$–60 keV, the parameter $\delta = E/m_e c^2$ is small enough to be a good expansion parameter in which to develop the scattering length, as we indicated in Section 2.3. Experiments performed at much higher energies require, for their interpretation, a theory not based on a simple expansion in powers of δ (Bell, Felsteiner and Pitaevskii, 1996).

Using the scattering length already employed in Section 2.3, and developing the cross section for scattering at the first level of approximation in δ, we find a cross section that is the sum of the standard Compton limit plus an interference between charge and spin amplitudes induced by circular polarization in the primary X-ray beam. The origin of the interference term can be seen in (20). Taking $\mathbf{P} = (0, P_2, 0)$ the polarization dependent terms are of the form $\beta + \alpha_2$ and $\alpha_3 + \alpha_1$. Inspection of (16–19) shows that both $\beta + \alpha_2$ and $\alpha_3 + \alpha_1$ contain contributions of order δ. Only the charge–spin interference contribution to scattering survives in the Compton limit of these two terms.

Let us denote by $\rho(\mathbf{Q})$, the momentum distribution function of the bound electrons in the ground state of the material, namely,

$$\rho(\mathbf{Q}) = \langle \delta(\mathbf{Q} - \mathbf{p}) \rangle \tag{51}$$

where $\mathbf{p}$ in the argument of the δ-function is the operator for the linear momentum of an electron $\hbar = 1$. In the Compton limit of scattering, the conservation of energy is the same as that for scattering by a single, free electron with a wave vector $\mathbf{Q}$, and this is

$$\omega = E_R + \mathbf{k}\cdot\mathbf{Q}/m_e \tag{52}$$

where the recoil energy $E_R = k^2/2m_e$ and ω is the change in energy of the X rays. By setting $Q_0 = m_e(\omega - E_R)/k$ and choosing $\mathbf{k}$ parallel to the z axis, we find

$$\omega - E_R - \mathbf{k}\cdot\mathbf{Q}/m_e = (k/m_e)(Q_0 - Q_z) \tag{53}$$

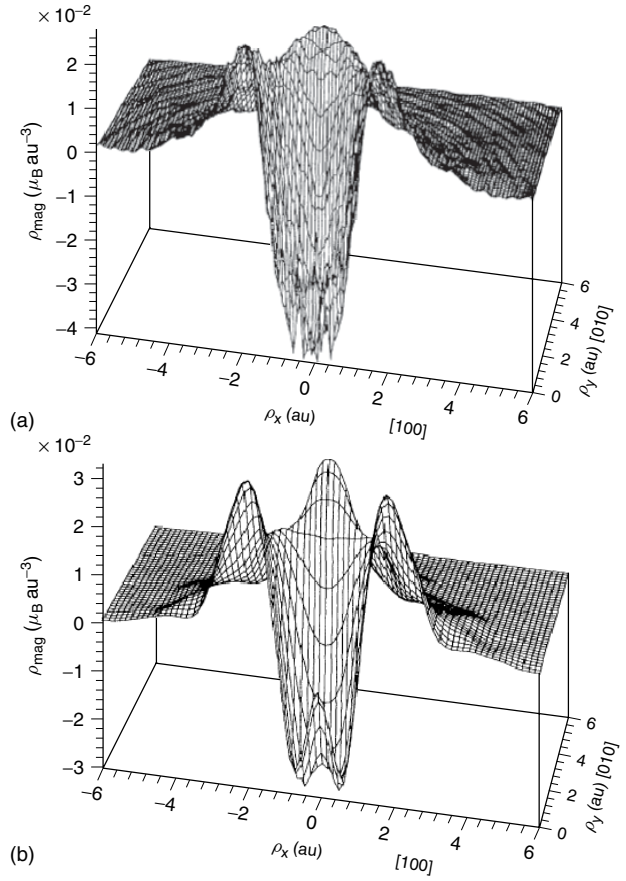

Figure 7. (a) A cross section of the experimental ρ_{mag} in the (001) plane including the Γ point. (b) A cross section of the theoretical ρ_{mag} in the (001) plane including the Γ point. The density is convoluted with the experimental resolution expressed by a Gaussian of full width at half-maximum (FWHM) 0.76 a.u. (Reproduced from Tanaka *et al*., 1993, with permission from the American Physical Society. © 1993.)

With these definitions, the standard Compton limit of scattering is described by a cross section

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega \mathrm{d}E'} = \frac{1}{2}(q'/q)r_{\mathrm{e}}^2\left(1+\cos^2 2\theta\right) \times \int \mathrm{d}\mathbf{Q}\rho(\mathbf{Q})\delta(\omega - E_{\mathrm{R}} - \mathbf{k}\cdot\mathbf{Q}/m_{\mathrm{e}}) \quad (54)$$

Here, $E' = E - \omega$ is the final X-ray energy, $\mathrm{d}\Omega$ is the element of solid angle subtended by the X-ray detector, and the X-ray beam is deflected through an angle 2θ. The so-called Compton profile $J(Q)$ is defined by

$$(m_{\mathrm{e}}/k)J(Q_0) = \int \mathrm{d}\mathbf{Q}\rho(\mathbf{Q})\delta(\omega - E_{\mathrm{R}} - \mathbf{k}\cdot\mathbf{Q}/m_{\mathrm{e}}) = (m_{\mathrm{e}}/k)\int \mathrm{d}Q_x \int \mathrm{d}Q_y \rho(Q_x, Q_y, Q_0) \quad (55)$$

We define a spin-weighted Compton profile, $J_S^{\alpha}(Q)$, where α is a Cartesian component, by an expression similar to (55). Let

$$(Nm_{\mathrm{e}}/k)J_S^{\alpha}(Q_0) = \int \mathrm{d}\mathbf{Q}\sum_j \left\langle \delta(\mathbf{Q} - \mathbf{p}_j)s_j^{\alpha}\right\rangle \times \delta(\omega - E_{\mathrm{R}} - \mathbf{k}\cdot\mathbf{Q}/m_{\mathrm{e}}) \quad (56)$$

The integral of $J(Q_0)$ over all Q_0 is unity, whereas the same integral of $\mathbf{J}_S(Q_0)$ is proportional to the spin magnetization.

Adding to (54) the charge–spin interference scattering, we arrive at a cross section

$$\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\,\mathrm{d}E'} = (Nr_{\mathrm{e}}^2 m_{\mathrm{e}}/k)\left\{\frac{1}{2}\left(1+\cos^2 2\theta\right)J(Q_0) - \delta P_2(1-\cos 2\theta)(\hat{\mathbf{q}}\cos 2\theta + \hat{\mathbf{q}}')\times \mathbf{J}_S(Q_0)\right\} \quad (57)$$

In this expression, P_2 is the helicity of the primary beam of X rays, and $\hat{\mathbf{q}}$ and $\hat{\mathbf{q}}'$ are unit vectors with $\hat{\mathbf{q}}\cdot\hat{\mathbf{q}}' = \cos 2\theta$. The charge–spin interference contribution to (57) can be separated from the standard Compton contribution, which is essentially Thomson scattering, by reversing either the magnetizing field applied to the sample or the handedness of primary helicity, P_2. The cross section (57) is the basis of the interpretation of data gathered on iron and displayed in Figure 7.

3 MAGNETIC NEUTRON SCATTERING

Neutrons are scattered by the magnetization in a material that is created by the spin and orbital moments of unpaired electrons (Lovesey, 1987). The orbital interaction is identical to the one encountered in the magnetic scattering of X rays, and the actual operator is displayed in (25). The spin interaction for neutron scattering is also very similar to the spin interaction in X-ray scattering. The one difference between the two cases is that in neutron scattering the spin of an electron is linked to the deflection of the beam in a double vector product $\mathbf{k}\times(\mathbf{s}_j\times\mathbf{k})/k^2$. We denote by $\mathbf{Q}_{\perp}$ the sum of the spin and orbital interactions

$$\mathbf{Q}_{\perp} = \sum_j \mathrm{e}^{i\mathbf{k}\cdot\mathbf{R}_j}\left(\frac{1}{k^2}\right)\left\{\mathbf{k}\times(\mathbf{s}_j\times\mathbf{k}) - i(\mathbf{k}\times\mathbf{p}_j)\right\} \quad (58)$$

A neutron with spin $\mathbf{s}_n$ has a scattering length $\gamma r_{\mathrm{e}}\mathbf{s}_n\cdot\mathbf{Q}_{\perp}$, where $\gamma = -1.9130$ is the gyromagnetic ratio.

The total neutron scattering length is the sum of the nuclear scattering and the magnetic scattering lengths. On borrowing the language adopted in Section 2.3, nuclear

scattering contributes to both β and $\boldsymbol{\alpha}$ while magnetic scattering contributes only to $\boldsymbol{\alpha}$. The cross section for neutron scattering can be derived from (20) where $\mathbf{P}$ is the mean value of $2\mathbf{s}_n$. Purely magnetic contributions to the cross section follow by the identifications $\boldsymbol{\alpha} = \gamma r_e \mathbf{Q}_\perp$ and $\beta = 0$.

3.1 Bragg diffraction

It is often convenient to employ an interaction operator $\mathbf{Q}$ which is related to $\mathbf{Q}_\perp$ through

$$\mathbf{Q}_\perp = \left\{\mathbf{k} \times (\mathbf{Q} \times \mathbf{k})/k^2\right\} \tag{59}$$

In neutron diffraction, we can use $\mathbf{F}_L(\mathbf{k}) + \mathbf{F}_S(\mathbf{k})$ for the expectation value $\langle \mathbf{Q} \rangle$, where the two structure factors are defined by (24) and (25).

For small scattering wave vectors, $\langle \mathbf{Q} \rangle$ is related to magnetic moments. With $\mu = \langle \mathbf{L} + 2\mathbf{S} \rangle$, one has $\mu = g\langle \mathbf{J} \rangle$ for a lanthanide ion, where g is the Landé splitting factor. For a 3d transition-metal ion, $\mu = g\langle \mathbf{S} \rangle$, and the gyromagnetic factor g is close to the value 2 that is correct when the orbital magnetic moment $\langle \mathbf{L} \rangle = (g-2)\langle \mathbf{S} \rangle$ is fully quenched. The small-k limit of $\langle \mathbf{Q} \rangle$ is,

$$\begin{aligned} \langle \mathbf{Q} \rangle &= \mathbf{F}_S(\mathbf{k}) + \mathbf{F}_L(k) \\ &\approx \frac{1}{2} \sum_{\mathbf{d}} e^{i\mathbf{k}\cdot\mathbf{d}} \boldsymbol{\mu}_d \end{aligned} \tag{60}$$

In the more general case, when the scattering wave vector is not particularly small, one needs to use (26) and (27) for the spin and orbital structure factors appearing in (60).

3.2 Inelastic scattering

When both the wave vector and the energy of the radiation change in a scattering event, the cross section is best described in terms of a correlation function. The correlation function in purely magnetic neutron scattering is $\left\langle \mathbf{Q}_\perp^\dagger \cdot \mathbf{Q}_\perp(t) \right\rangle$, where $\mathbf{Q}_\perp(t)$ is the Heisenberg operator created from (58), and $\mathbf{Q}_\perp = \mathbf{Q}_\perp(0)$. The conventional form of the cross section is

$$\frac{d^2\sigma}{d\Omega\, dE'} = (\gamma r_e)^2 (q'/q) S(\mathbf{k}, \omega) \tag{61}$$

where $\mathbf{k} = \mathbf{q} - \mathbf{q}'$ and $\omega = E - E'$ are the changes in the wave vector and the energy ($\hbar = 1$), respectively. $S(\mathbf{k}, \omega)$ in (61) is the Van Hove response function,

$$\begin{aligned} S(\mathbf{k}, \omega) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} dt e^{-i\omega t} \left\langle \mathbf{Q}_\perp^\dagger \cdot \mathbf{Q}_\perp(t) \right\rangle \\ &= \sum_{\alpha\beta} \left(\delta_{\alpha\beta} - \hat{k}_\alpha \hat{k}_\beta\right) \frac{1}{2\pi} \int_{-\infty}^{\infty} dt e^{-i\omega t} \left\langle Q_\alpha Q_\beta(t) \right\rangle \end{aligned} \tag{62}$$

Purely elastic scattering, such as Bragg diffraction, is described by the cross section obtained from (62) with $\left\langle \mathbf{Q}_\perp^\dagger \cdot \mathbf{Q}_\perp(t = \infty) \right\rangle = |\langle \mathbf{Q}_\perp \rangle|^2$.

The most general form of the cross section is derived from (20) treating $\boldsymbol{\alpha}$ and β as operators. Usually, the largest contributions to β and $\boldsymbol{\alpha}$ are the nuclear and magnetic interactions. In the general use of (20), it creates a partial differential cross section, like (61), and each of the five terms on the right-hand side is a response function similar to (62). For example, the third term $\beta^*(\mathbf{P}\cdot\boldsymbol{\alpha})$ in (20) is interpreted as the response function

$$\frac{1}{2\pi} \int_{-\infty}^{\infty} dt e^{-i\omega t} \left\langle \beta^\dagger \mathbf{P}\cdot\boldsymbol{\alpha}(t) \right\rangle \tag{63}$$

Analytic properties of the cross section are discussed by Lovesey and Watson (1998). The cross sections discussed in this section are the basis for the interpretation of data that provides the dispersion of spin waves and critical magnetic fluctuations in magnetic salts and metallic magnets.

Spin Waves: History and a Summary of Recent Developments

D.L. Mills
University of California, Irvine, CA, USA

1 INTRODUCTION

In diverse forms of condensed matter, both the thermodynamic properties and the linear response of materials to external probes are controlled by the nature of the collective excitations in the system of interest. In the case of macroscopic crystals, we have the well-known phonon modes, which are wave like excitations of atomic motions, which propagate through the crystal. Each phonon mode is described by a wave vector $\vec{k}$ which resides in the appropriate Brillouin zone. When $|\vec{k}|a_0 \ll 1$, with a_0 the lattice constant, the dispersion relation of these modes may be described by a continuum theory, the classical theory of elasticity. We must turn to fully microscopic theories when the wavelength and the lattice constant are comparable.

In ordered magnets of all forms (ferromagnets, antiferromagnets, ferrimagnets, . . .) we encounter the spin analog of the phonon modes just described. These are wave like excitations that propagate through the lattice of ordered spins; if we focus on the given spin in the lattice when such a mode is excited, the spin is tipped slightly away from its equilibrium direction and engages in circular or elliptical precession. As one progresses down the lattice of spins in a direction parallel to the wave vector, the phase angle $\varphi(\vec{l})$ associated with the motion of the spin on lattice site $\vec{l}$ varies as $\vec{k} \cdot \vec{l}$, once again with $\vec{k}$ a wave vector in the appropriate Brillouin zone. Introductory descriptions of these excitations may be found in textbooks. For example, see the discussion by Kittel (1976). As in the case of phonons, the energy of spin waves is quantized in units of $\hbar\omega(\vec{k})$, with $\omega(\vec{k})$ the frequency of the spin wave mode with wave vector $\vec{k}$. The relationship between frequency and wave vector is referred to as the *spin-wave dispersion relation*. When one wishes to emphasize the quantum-mechanical character of these collective excitations, one refers to them as *magnons*. For the purposes of this chapter, the term *spin wave* and *magnon* are regarded as interchangeable.

Spin-wave quanta or magnons are thermally excited, and at temperatures well below the magnetic ordering temperature (Curie temperature, Neel temperature) one may develop descriptions of the contribution of the magnetic degrees of freedom to the thermodynamic properties of magnets by combining the dispersion relation with the fact that spin waves are bosons (Kittel, 1963a). We have as an example the celebrated Bloch $T^{3/2}$ law which describes the initial falloff with increasing temperature of the magnetization in ferromagnets (Kittel, 1963a). It is the case as well that spin waves couple to external probes, thus allowing their study by experimental methods such as inelastic neutron scattering (Kittel, 1963b). In addition, they control the response of

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

magnetic materials to external probes, so long as one is in the linear response regime. If one wishes to describe a ferromagnetic resonance (FMR) experiment, for example, the physical origin of the resonant absorption is excitation of a long wavelength spin wave by the microwave field which illuminates the sample.

At the time of this writing, the theory of spin waves, along with their interaction with each other and with external probes is a mature, well-developed field. It is the case as well that experimental studies of spin waves and their influence on materials is also very well developed. Owing to this, it is impossible to review the field in any meaningful sense in a brief chapter such as this. We refer the reader to the classic Rado–Suhl volumes (Rado and Suhl, 1963a, 1963b, 1965, 1966), within which the reader will find an excellent collection of articles that describe basic aspects of spin waves and their interactions. These volumes, though published many years ago, still stand as excellent reference material on fundamental aspects of this topic. We shall focus here on recent developments. Our discussion will be focused on the theory and experimental study of the spin wave excitations in the ultrathin ferromagnets, which play such a central role in contemporary nanoscale magnetic devices. We shall also discuss the nature of spin waves in the bulk 3d ferromagnets and the means of studying them experimentally, since this will acquaint us with physics we need to understand spin dynamics in ultrathin metallic magnets. It should be remarked that in our discussion, we not only focus on very recent developments but also cover a considerable amount of material which has appeared after the Rado–Suhl volumes were published but nonetheless some years ago. This is required, in the mind of the author, to set down the conceptual basis for the work of more recent years.

Before we turn to this topic, some additional general remarks are in order. The ultrathin films of current interest are fabricated largely from the 3d ferromagnetic elements or their alloys. Certainly magnetism in bulk forms of the 3d ferromagnets along with that in thick (micron range) films has been studied in great detail for many decades. However, surprisingly our knowledge of the spin waves in these materials is not so complete. FMR studies and Brillouin light scattering (BLS) have provided us with detailed information on spin-wave modes in the regime where the wavelengths are long compared to the lattice constant. FMR probes modes in these metals whose wavelength is comparable to the microwave skin depth, the order of a micron. BLS, a spectroscopy confined to the near surface because of the optical skin depth ($\sim$150–200 Å), allows one to probe modes which propagate parallel to the surface with wavelengths of the order of that of visible light, approximately one-half micron. As we shall see, spin-wave modes of such long wavelengths may be described by a phenomenology similar in spirit to the theory of elasticity when it is applied to the description of phonons.

To obtain truly microscopic information on the physics of the response of the spin system, one needs to study modes whose wavelength is comparable to the underlying lattice constant. The method used standardly in the study of short wavelength collective excitations in condensed matter physics, the inelastic scattering of thermal neutrons, in these materials can probe only the near vicinity of the center of the Brillouin zone, perhaps wave vectors smaller than $10^7\,\mathrm{cm}^{-1}$. The reason for this is that the spin system is very 'stiff' in the 3d ferromagnets, with the consequence that the excitation energy of short wavelength spin waves ($|\vec{k}| \sim 10^8\,\mathrm{cm}^{-1}$) is in the range of 250–300 meV. Such large excitation energies are beyond the reach of thermal neutrons. Spallation sources must then be used, and it is also the case that the neutron excitation cross section is very small at large wave vectors. Experimental studies of short wavelength neutrons in the 3d ferromagnets are thus a challenge, with the consequence that only few studies are found in the literature.

Theoretical description of spin waves in these materials is also a challenge. The materials are itinerant ferromagnets, wherein the magnetic moment carrying electrons reside in the broad 3d energy bands, whose width is the order of 4 eV. (For an introduction to the fundamental physics of itinerant magnets, see the lengthy discussion by Herring, 1966.) Thus, one must begin with a full electronic structure calculation of the ferromagnetic ground state, and then generate a description of the spin waves through use of a methodology such as time dependent density-functional theory. Such an undertaking has been possible for a number of years now for bulk materials, but since data on the short wavelength spin waves is sparse, theoretical efforts which explore the entire Brillouin zone (as opposed to the spin-wave exchange stiffness which controls the long wavelength form of the dispersion relation) are not so large in number. It is curious and surprising that at the time of this writing, our knowledge of short wavelength spin waves in these most common of ferromagnets is less complete than those in very complex materials.

We shall see that a recently developed experimental method, spin polarized electron energy loss spectroscopy (SPEELS), now allows us to examine short wavelength spin waves in ultrathin films out to the boundary of the surface Brillouin zone. The method overcomes the difficulty associated with neutron probes through use of beam electrons with kinetic energy of several electron volts. It is the case as well that one realizes an appreciable cross section for exciting modes of short wavelength with this method.

The outline of this chapter is as follows. In Section 2, we discuss experimental methods of exciting and probing spin waves in the 3d transition-metal ferromagnets, with emphasis

on recent studies of ultrathin films. In Section 3, we discuss theoretical methods for describing these excitations. We remark that in this chapter our aim is to acquaint the reader with basic concepts, and we direct the reader to representative papers in the literature. This is not an exhaustive review, in which all papers in the subarea covered are cited and discussed. Relevant references are found in the papers we cite.

2 EXPERIMENTAL PROBES OF SPIN WAVES IN THE 3D FERROMAGNETS

In this section, we shall survey the principal experimental methods for exciting spin waves in bulk ferromagnetic metals, and also in the ferromagnetic ultrathin films. Two of the methods, FMR and BLS, probe modes whose wavelength is very long compared to the lattice constant. The second two we discuss, inelastic neutron scattering and SPEELS, endow us with the ability to look at modes whose wavelength is comparable to the underlying lattice constant, though neutron scattering has the limitations noted in the preceding text. We begin with some introductory remarks.

If our interest is in spin-wave modes with wavelength long compared to the lattice constant, then a description of the modes may be obtained from a phenomenology based on the Landau–Lifschitz–Gilbert (LLG) equation. This describes the motion of the magnetization per unit volume $\vec{M}(\vec{r}, t)$; the notion is that we may consider a volume whose linear dimensions are small compared to the wavelength of the mode of interest, and within this volume we have a large number of spins coupled together tightly by the strong exchange interactions responsible for the ferromagnetism. The magnetization per unit volume is then a vector of fixed length, which precesses in response to various effective magnetic fields, which exert a torque on it. For our purposes here, we write the LLG equation in the form

$$\frac{\mathrm{d}\vec{M}(\vec{r}, t)}{\mathrm{d}t} = -\gamma[\vec{H}_{\mathrm{eff}}(\vec{r}, t) \times \vec{M}(\vec{r}, t)] - \frac{G}{\gamma M_{\mathrm{S}}^2}\left[\vec{M}(\vec{r}, t) \times \frac{\mathrm{d}\vec{M}(\vec{r}, t)}{\mathrm{d}t}\right] \quad (1)$$

Here γ is the magnitude of the gyromagnetic ratio, and $\vec{H}_{\mathrm{eff}}(\vec{r}, t)$ is the effective magnetic field which drives the spin precession. The second term is a phenomenological damping term. We will have much to say about the appropriateness of this term in our discussion of FMR linewidths in ultrathin films.

The effective magnetic field has several contributions. First, there will be an externally applied Zeeman field, which gives rise to an internal field that one may assume to be constant in magnitude and direction for many simple sample geometries. Anisotropy contributes to the effective field along with macroscopic dipolar fields generated by virtue of motions of the spins. Also exchange interactions between the spins provide a restoring torque, which resists spatial gradients. This leads to a contribution to the effective field of the form $(D/M_{\mathrm{S}})\nabla^2\vec{M}(\vec{r}, t)$, where M_{S} is the saturation magnetization, and D is a parameter called the exchange stiffness, a magnetic analog to the elastic constants of elasticity theory. We shall present a more detailed discussion of this long wavelength phenomenology in Section 3.

The LLG equation is a nonlinear differential equation when written out in full, and allows a discussion of large amplitude motions of the spin system within the framework of its phenomenological basis. Spin waves are the magnetic normal modes, which describe small amplitude deviations of the spins from the ferromagnetic equilibrium orientation. Thus, in the infinitely extended crystal, one obtains a description of spin waves by linearizing the LLG equation and then seeking plane wave solutions where the small deviations have the dependence on space and time given by $\exp[i(\vec{k} \cdot \vec{r} - \omega(\vec{k})t)]$. From this procedure one can generate a dispersion relation for the spin waves. We shall quote the result for a simple case. We consider an infinitely extended ferromagnet with magnetization directed along an easy axis, and external Zeeman field applied parallel to the easy axis. The dispersion relation is then given by (Kittel, 1963a)

$$\omega(\vec{k}) = \gamma[(H + Dk^2)(H + 4\pi M_{\mathrm{S}} \sin^2\theta_{\vec{k}} + Dk^2)]^{1/2} \quad (2)$$

In this expression, $H = H_0 + H_{\mathrm{a}}$ is the sum of the external Zeeman field H_0 and the effective anisotropy field H_{a}, which acts parallel to the easy axis. The angle $\theta_{\vec{k}}$ is the angle between the wave vector $\vec{k}$ and the easy axis.

With the dispersion relation in equation (2) in hand, we can now discuss aspects of FMR and BLS in the metallic ferromagnets. We begin first with bulk materials or thick (several micron) films, and then we turn our attention to ultrathin ferromagnets.

2.1 Ferromagnetic resonance studies of the 3d ferromagnets

2.1.1 Bulk materials

In a FMR study, microwaves illuminate the sample, and one realizes resonant absorption of the microwaves when their frequency matches that of the long wavelength spin waves. In the usual geometry, the magnetization is parallel to the sample surface. The wave vector of the microwaves is normal

to the surface, and hence the wave vectors of the spin waves excited in the experiment are normal to the magnetization and also to the surface. Thus, in this geometry the dispersion relation of the spin waves is given by equation (2), for the case where the angle $\theta_{\vec{k}}$ is 90°.

The wavelength of the microwaves is so long that one might suppose one could also set the wave vector $\vec{k}$ to zero in equation (2). However, in the metallic 3d ferromagnets, the microwave field does not penetrate into the sample in a uniform manner, but is limited to the skin depth δ_0. As one approaches the ferromagnetic resonance frequency of the system, excitation of the spins in the ferromagnet causes the spin depth to contract. The skin depth is given by $\delta(\omega) = \delta_0/\sqrt{\mu_{\text{eff}}(\omega)}$, where $\mu_{\text{eff}}(\omega)$ is an effective susceptibility that peaks strongly on resonance. (For a recent discussion of the influence of the frequency variation of the skin depth on microwave devices, we refer the reader to a paper by Camley and Mills, 1997.) On resonance, the effective skin depth can contract to only a few hundred angstroms. Suppose, under these circumstances, one makes a spatial Fourier decomposition of the microwave field inside the sample. The resulting spectrum will contain a range of wave vectors from zero up to values as large as $10^6\,\text{cm}^{-1}$. Under these circumstances, the microwave field may excite finite wave vector spin waves, with wave vectors extending over this entire range. Thus, the frequency shifts contained in the exchange term Dk^2 must be incorporated into any analysis of data. We may use the value of the exchange stiffness of Fe to set the scale of such effects. In Fe, $D \sim 2.5 \times 10^{-9}\,\text{G-cm}^2$. Thus, in magnetic field units, a spin wave with wave vector of $10^6\,\text{cm}^{-1}$ is shifted away from the nominal FMR frequency $[H(H + 4\pi M_S)]^{1/2}$ by some 250 G.

Under the conditions just described, even in the absence of damping of the spin motions, the FMR spectrum will consist of a rather broad line, with line shape controlled by the spatial Fourier spectrum of the microwave field, which penetrates into the sample. In such experiments, one scans applied field and measures microwave absorption at fixed frequency; one realizes absorption of energy by spin waves over a rather wide range of fields.

It then follows that in such studies, one cannot determine the damping constant G which appears in the LLG equation simply from the observed width of the feature seen in the FMR spectrum. One must fit the spectrum carefully by a description of the absorption provided by an analysis based on application of the Maxwell equations in combination with the LLG equation. The theory of FMR absorption in the ferromagnetic metals was developed many years ago (Amendt and Rado, 1955). We refer the reader to a classic experimental study of ferromagnetic resonance in these materials, where detailed comparisons between theory and experiment were presented (Bhagat and Lubitz, 1974). These authors conclude that the damping term, which appears in the LLG equation accounts very well for their data, and they extract values for the (temperature dependent) damping constant G over a wide range of temperatures. Data is presented for Fe, Ni, and hcp-Co.

2.1.2 *Ultrathin films*

FMR has been used actively in the study of ultrathin ferromagnnets for well over a decade, at the time of this writing. It has proved a powerful means of exploring aspects of magnetism unique to these materials, along with damping or relaxation mechanisms not operative in the bulk ferromagnetic metals. Before we begin our discussion, we remark that the term ultrathin ferromagnet refers to a film consisting of a small number of atomic layers, from two or three layers to perhaps twenty or so. The thickness of these films thus ranges from a few angstroms to perhaps 50 Å.

First, we comment on the spin-wave spectrum of such materials. As noted above in a FMR measurement, one excites spin-wave modes whose wave vector parallel to the surface is very close to zero. In the case of FMR studies of thick, bulk crystals of the 3d ferromagnetic metals, we saw that in such measurements, a continuum of modes are excited; the wave vector perpendicular to the surface can take on any desired value, so long as it lies within the appropriate two-dimensional Brillouin zone. The range of wave vectors excited depends on the spatial profile of the microwave field inside the sample. In films of finite thickness, the perpendicular component of the wave vector is quantized, and assumes values of $\approx n\pi/d$ where d is the film thickness, and n an integer. The lowest mode with $n = 0$ is the uniform mode, wherein all spins in the film precess in phase. Consider the first standing wave mode, with $n = 1$. When we examine the structure of equation (2) in the preceding text, we see that the term $D(\pi/d)^2$ upshifts the mode in frequency in very much the same manner as a larger applied magnetic field. Suppose we consider the magnitude of this shift in a film whose thickness is in the range of 30 Å. We recall from our example in the preceding text that in Fe, we have $D \sim 2.5 \times 10^{-9}\,\text{G-cm}^2$. The exchange induced frequency shift of the first standing wave spin-wave mode for a 30-Å Fe film is thus equivalent to that provided by an effective field in the range of 2.5×10^5 G! The frequency of such a mode is in the 100 GHz range, well outside the regime accessible to conventional FMR spectrometers. Hence, in the ultrathin films under discussion here, the microwaves excite a single mode of the film, the uniform mode wherein all spins precess coherently.

The frequency of the uniform mode provides one with access to key properties of the ultrathin film, such as the anisotropy and also the value of the magnetization M_S.

Of central interest in the study of these materials is the nature of the anisotropy, which can be dramatically different than that found in bulk materials. It is beyond the scope of the present chapter to provide the reader with an understanding of the origin of anisotropy in ferromagnets, but we can provide a brief sketch. There are two forms of anisotropy, each with a very different origin. One, referred to as *shape anisotropy*, has its origin in the fact that ferromagnetic alignment of atomic moments creates a macroscopic dipolar field. If a thin film is magnetized in the z direction normal to its surfaces, one sees easily that magnetic poles on the film surface lead to an internal field of strength $-4\pi M_S \hat{z}$ perpendicular to the film surfaces, and antiparallel to the magnetization. Conversely, if the film is magnetized parallel to its surface, there is no such internal field. A consequence is that shape anisotropy forces the magnetization in ferromagnetic films to lie in plane, under circumstances where it is dominant. The second form of anisotropy has its origin in spin-orbit coupling, and the interaction of the moment bearing ions in the material with crystalline fields from the neighboring ions. This provides the magnetic moments with the means of sensing the local site symmetry. For a magnetic ion which sits in a site of cubic symmetry, the spin orbit induced anisotropy is quite weak, whereas in sites with uniaxial symmetry it can be up to 2 orders of magnitude stronger than for cubic sites. Elsewhere, in an article directed toward ultrathin ferromagnets, the present author has set forth a simple physical picture which allows one to appreciate why this is so (Mills, 1994).

In an ultrathin film, a very large fraction of the magnetic ions sit in either surface or interface sites, whose symmetry is necessarily very low. In a five-layer film, for instance, 40% of the ions sit in such sites. As a consequence, in an ultrathin film of Fe or Ni, the spin-orbit anisotropy can be enormously larger than realized in the bulk. It can overwhelm the shape anisotropy in magnitude and for many film/substrate combinations one can realize films where the easy axis is in fact normal to the surface. An additional source of spin orbit induced anisotropy arises from the mismatch between the lattice constants of the material in the film and the substrate. This results in films whose interior sites have tetragonal rather than cubic symmetry, and once again the easy axis associated with this source can be either normal to or in the plane perpendicular to the film surfaces. Clearly, one can control both the strength and character of the very strong anisotropy realized in ultrathin ferromagnets by varying the growth conditions, the substrate, and also the composition of any capping layer that may be present. This allows one to create materials with desired hysteresis loops or microwave response by design. One may refer to spin engineering in these materials, a magnetic analogue of the band gap engineering so important in semiconductor device design.

FMR proves to be a most powerful means of deducing the nature of the anisotropy present in any sample of interest. The key measurement is the variation of the FMR resonance field with angle relative to the various symmetry axes of the system. Such data can be interpreted in impressive quantitative detail, to provide one with a remarkably detailed picture of all aspects of anisotropy. We refer the reader to excellent articles where such experiments are reviewed, and the analysis required to interpret the data is discussed (Prinz, 1994; Heinrich, 1994).

An issue discussed very actively in the recent literature is the nature of the damping of the spin motions in ultrathin ferromagnets. Is the physics which underlies the damping in these systems the same as in the bulk 3d ferromagnets, or does one have new mechanisms unique to the ultrathin film environment, not present in the bulk? Indeed, one may also inquire if the damping term in the simple LLG equation is applicable to the thin-film environment; perhaps a more complex form is appropriate. These questions are very important from the point of view of contemporary device technology. Devices which contain ultrathin ferromagnets depend on either small amplitude motions of the magnetization, or perhaps its complete reversal as the basis for their operation. The speed of the device is clearly then controlled by damping rates realized on the nanoscale. By now it is very clear that in ultrathin films, new damping mechanisms not present in bulk materials are operative, and these can often be the dominant source damping. It is now well established that in commonly encountered structures, the damping term provided by the LLG phenomenology is qualitatively incorrect. We conclude this section with comments on this issue.

Two mechanisms unique to ultrathin ferromagnets have been invoked in discussions in the literature. One is intrinsic, and operative for ultrathin films on metallic substrates and the second is extrinsic and relies on growth defects to be activated.

The intrinsic mechanism is referred to in the literature as the spin pumping contribution to the damping rate. In physical terms, it is best visualized within the picture where we have local moments of spin $\vec{S}$ localized on each lattice sites. Each such local moment is coupled to conduction electrons by an exchange interaction $-J\vec{S}\cdot\vec{\sigma}$ with $\vec{\sigma}$ the conduction electron spin. While this is surely an oversimplified description of the 3d ferromagnets, which are fully itinerant in character, nonetheless this model has been used frequently in the literature, particularly in the early papers on spin pumping. When the FMR spin wave is excited, the local moments on the lattice engage in coherent precession. Through the exchange interaction just described, they transfer angular momentum to the conduction electrons. This results in a spin current normal to the interface between the film

and the substrate (assumed metallic), and there is thus a loss of spin angular momentum within the system of precessing local moments. This is then a damping mechanism, which relaxes the excited spins by returning them to their equilibrium orientation. This mechanism was first proposed as a relaxation mechanism by Berger (1996) and Slonczewski (1999). FMR studies in which this mechanism was found to play a key role were reported by Urban, Woltersdorf and Heinrich (2001). It should be remarked that this mechanism is fully compatible with the phenomenological damping term in the LLG equation. For instance, it provides a contribution to the FMR linewidth, which scales linearly with frequency, very much as provided by the phenomenology. In the recent literature, theoretical treatments have appeared which recognize the fully itinerant character of the magnetism in the 3d transition-metal films studied in these experiments. We shall discuss these in more detail in Section 3. Thus, we have a new mechanism operative for ultrathin films, and it may be incorporated into LLG phenomenology.

As noted above, a second mechanism found to contribute to the FMR linewidth and to spin damping in ultrathin ferromagnets is extrinsic in origin. This is referred to in the literature as two-magnon damping, a term introduced decades ago in the literature on FMR linewidths in macroscopic garnet samples. Thus, some brief historical remarks will prove useful.

Early experimental studies of FMR linewidths in the garnets encountered lines very much wider than expected from theory applied to the ideal Heisenberg ferromagnet, with localized spins coupled by exchange and dipolar interactions. In a key experimental paper, it was found that the FMR linewidth depended sensitively on the size of grit used to polish the sample surfaces (LeCraw, Spencer and Porter, 1958). In a seminal theoretical paper, Kittel and coworkers developed a theory based on what they called *two-magnon scattering* which provided an excellent account of the observations (Sparks, Loudon and Kittel, 1961). These authors noted that the frequency ω_{FMR} of the FMR modes in the garnet spheres used in the experiments is degenerate in frequency with finite wave vector spin waves, whose dispersion relation is given in equation (2) above for the limit where the wavelength of the spin wave is small compared to the radius of the sphere. Now for an absolutely perfect spherical sample, all of the spin wave modes are independent normal modes of the system, so energy cannot be transferred directly from the uniform precession FMR mode to the degenerate short wavelength spin waves. However, if defects are present in the sample, energy may be scattered from the FMR mode to the degenerate short wavelength spin waves through a matrix element provided by the defect. In the case of the garnet spheres, surface pits produced in the polishing process proved to be the source of the scattering. In the language of resonance physics, the two-magnon contribution to the linewidth is a dephasing mechanism. A process that scatters a spin wave quantum of the FMR mode to a short wavelength spin wave scrambles the phases of the spins all of which initially precess in phase.

It is the case that in ultrathin ferromagnetic films magnetized in plane, there are also finite wave vector spin waves degenerate with the uniform FMR mode. This occurs because of a peculiar aspect of the magnetic dipolar interaction between spins in the two-dimensional environment. If one has a film of thickness d, and considers the influence of dipolar interactions on spin waves whose wave vector satisfies $kd \ll 1$, then the dipolar interaction contributes a term to the dispersion relation *linear* in wave vector. For an in plane magnetized film and for range of propagation angles, the coefficient of this term is negative, so the spin-wave frequency decreases with increasing wave vector. The presence of exchange stiffness provides the contribution Dk^2, very much as in equation (2), so there is a minimum in the dispersion relation at a wave vector k_m which is in the range of $10^5\,\mathrm{cm}^{-1}$ for typical films. (A detailed theory of the contribution of two-magnon scattering in ultrathin films has been presented by Arias and Mills, 1999). Experimental confirmation of key predictions of the theory is found in the studies of Azevedo, Olivera, de Aguiar and Rezende (2000) and in earlier work of the NIST group, who suggested the importance of this mechanism in ultrathin ferromagnets grown on exchange biasing substrates (McMichael, Stiles, Chen and Egelhoff, 1998). It is now clear that this mechanism contributes to the FMR linewidth importantly in diverse ultrathin ferromagnets; it is the case that for films on exchange biased substrates, it is strong and usually dominant. For films on exchange biased substrates, we refer the reader to the theory and fascinating data presented by the Recife group (Rezende, Azevedo, Lucena and Augiar, 2001). We also refer the reader to a review article which discusses early experiments, and the theory (Mills and Rezende, 2003).

A key prediction of the LLG equation is that the FMR linewidth should scale linearly with ω_{FMR}, the frequency of the FMR mode. The theoretical prediction in the paper of Arias and Mills is that when the two-magnon mechanism is dominant, the linewidth should increase much more slowly with frequency than linearly. These authors argued that the observation of apparent linear frequency dependence in early studies (Celinski and Henrich, 1991) is a consequence of sampling a narrow range of FMR frequencies (10, 24, and 36 GHz). It was argued as well that the zero field linewidth inferred indirectly from such data could be an artifact (Arias and Mills, 1999). This discussion stimulated a remarkable series of new measurements of FMR linewidths in ultrathin Fe films, with data from 1 to 80 GHz (Lindner *et al.*, 2003). The data is fitted well by the sublinear dependence predicted

for the two-magnon mechanism, supplemented with a linear term such as that provided by the LLG phenomenology. A possible 'zero field linewidth' was included in the fitting process, but this parameter came out to be vanishingly small. There is also a very large in-plane anisotropy of the linewidth, compatible with the theory if the defects have a symmetry character proposed by Arias and Mills (1999). In the earlier work by the Recife group, it was also established experimentally that one realizes a very strong wave vector dependence in the measured linewidths; an extension of the original theory shows that a fully quantitative account of these observations follows from the two-magnon mechanism (Rezende, Azevedo, Lucena and Augiar, 2001). The LLG phenomenology is a theory of local damping, and there is thus no intrinsic wave vector dependence contained in this picture, in clear disagreement with the data.

Despite the fact the experiments cited in the preceding paragraph shows that the LLG phenomenology commonly provides a qualitatively incorrect description of both the wave vector and the frequency dependence of the linewidths observed in ultrathin ferromagnets, authors still often utilize the predictions of this well-known equation. If one measures the FMR linewidth at rather low frequencies, in the 10 GHz range, and wishes to asses the response characteristics at much higher frequencies, an extrapolation based on an assumed linear frequency dependence can be in serious error. Similarly, as magnetic devices are made smaller and smaller, one will have large spatial gradients in the dynamic magnetization, with the consequence that the strong wave vector dependence absent from LLG phenomenology will be of importance. The reader should keep in mind that for a permalloy film grown on an exchange biased substrate, the linewidth measure in BLS, where the spin-wave vector is in the range of $10^5\ \mathrm{cm}^{-1}$ is over five times larger than that found in FMR on the same sample (Rezende, Azevedo, Lucena and Augiar, 2001). The wave vector dependence can be dramatic, a clear contradiction with the prediction provided by the LLG equation.

Hence unless the origin of the damping mechanism in any given ultrathin film structure is understood, extrapolation of linewidths measured in FMR to higher or lower frequencies must be treated with caution. It is also the case that similar extrapolations to the damping of spin motions with an appreciable spatial gradient can lead to misleading conclusions regarding the damping rate of spin motions.

2.2 Brillouin light scattering studies of spin waves in 3d ferromagnets

We begin with introductory comments. In the BLS experiment, a laser photon is incident on the sample; the photons typically have frequencies in the visible range. The photon may interact with thermal fluctuations in the magnetization within the optical skin depth, typically 100–200 Å for the 3d ferromagnetic metals. Thus, for bulk samples or for films whose thickness is large compared to the optical skin depth, one learns about the nature of spin fluctuations near the surface, whereas in ultrathin films the incident laser fields are uniform throughout the film, to excellent approximation.

In the BLS scattering event, the laser photon can either emit ('Stokes scattering') or absorb ('anti-Stokes scattering') a thermal spin-wave quantum. The frequency ω_S of the scattered photon then follows from energy conservation, $\hbar\omega_S = \hbar\omega_I \pm \hbar\omega_{SW}$, where ω_I is the frequency of the incident photon, and ω_{SW} that of the spin wave involved in the scattering event. If the surfaces are smooth and flat, then the presence of translational symmetry in the plane parallel to the surfaces of the sample (we consider here only bulk, semi-infinite crystals, along with films or multilayers on substrates) requires that wave vector components of the interacting quanta parallel to the surfaces be conserved. Thus, the direction of the outgoing scattered photon is controlled by the conservation condition $\vec{k}_{S\parallel} = \vec{k}_{I\parallel} \pm \vec{k}_{SW\parallel}$. The direction of the outgoing photon is controlled by the wave vector $\vec{k}_{SW\parallel}$, since spin-wave frequencies are orders of magnitude smaller than the photon frequencies. In these statements, $\vec{k}_{\parallel}$ is the projection of $\vec{k}$ onto a plane parallel to the surface. Thus, for a particular scattering geometry, one obtains information regarding the frequencies of the spin waves in the sample whose wave vector projection onto the plane parallel to the surface is $\vec{k}_{SW\parallel}$. In the discussion below, we shall provide examples of BLS spectra taken on thick crystals, in films whose thickness is large compared to the optical skin and also for ultrathin films. Note that the wave vector of the spins probed in such measurements is in the range of that of optical frequency photons, so $|\vec{k}_{SW\parallel}| \sim 10^5\ \mathrm{cm}^{-1}$. Thus, the method reaches out into the Brillouin zone, in contrast to FMR which, as we have seen, samples spin waves for which $\vec{k}_{SW\parallel} \approx 0$. It remains the case, however, that BLS samples spin waves whose wavelength is very long compared to a lattice constant. They are thus well described by the macroscopic phenomenology employed to derive the bulk spin-wave dispersion relation displayed in equation (2), so no truly microscopic information is contained in the data. For this, we require a probe whose wavelength is comparable to a lattice constant. The BLS technique is complementary to FMR. A virtue of BLS is that when the sample is in a fixed external magnetic field, one may scan the frequency response of system in a continuous manner. In contrast, FMR experiment employs a resonant microwave cavity with a single resonance frequency. In FMR, one drives the frequency the spin wave of through the cavity resonance by varying the external magnetic field. In essence, one samples the response

of the system at one single frequency. To scan a broad range of frequencies, one must use several cavities, each with its own resonance frequency. However, the resolution of FMR is far greater than BLS, so FMR allows study linewidths. The BLS method can resolve linewidths only if the modes studies are rather broad.

2.2.1 Spin waves in the BLS spectra of bulk crystals

In this section, we review the information on spin waves one obtains from BLS spectra, which have been taken on thick crystals of the 3d ferromagnets. We should mention that the first BLS study of spin waves in magnetically ordered materials was reported by Grunberg and Metawe, who studied the semiconducting ferromagnet material EuO (Grunberg and Metawe, 1977). A theoretical account of these spectra was given shortly afterward by Camley and the present author (Camley and Mills, 1978a). Very soon after these very beautiful experiments, Sandercock and Wettling reported BLS spectra for thick samples of Fe and Ni. (Sandercock and Wettling, 1978, 1979). Camley and the present author developed the detailed theory of the nature of spin fluctuations near ferromagnetic surfaces, with BLS spectra of the metallic ferromagnets in mind, along with a quantitative theory of the final spectra (Camley and Mills, 1978b). With the emphasis of this chapter in mind, we shall focus our attention on the BLS spectra of the ferromagnetic metals. Before we turn to the nature of the actual spectra we need to comment on the nature of spin wave excitations on the surface of ferromagnetic materials, in the regime where the wavelength is long compared to the underlying lattice constant.

The spin-wave modes of a ferromagnetic film in the usual configuration, magnetized parallel to its surface, were studied in a classic paper by Damon and Eshbach (1960). They employed the magnetostatic approximation, in which the exchange stiffness parameter D is set to zero. By taking the limit as the film thickness becomes infinite and focusing on the near vicinity of the surface, one obtains the spin-wave frequencies and eigenvectors appropriate to the semi-infinite ferromagnet. One has bulk spin waves, whose dispersion relation is described by equation (2) with exchange stiffness set to zero, which can propagate up to and reflect the surface. These have frequencies, which range from γH_0 for propagation parallel to both the surface and the magnetization, to $\gamma[H_0(H_0 + 4\pi M_S)]^{1/2}$ for propagation in plane perpendicular to it. A most striking surface spin wave appears in this theory. Its frequency, $\gamma[H_0 + 2\pi M_S]$ lies *above* the frequency band appropriate to the bulk spin waves. It has the most peculiar feature that it is a 'unidirectional' wave: it will propagate from left to right across the magnetization, but not from right to left. Surface waves with asymmetric left/right propagation characteristics are referred to as having nonreciprocal propagation characteristics. We have here the most dramatic form of nonreciprocal propagation, where one realizes 'one way' propagation only. In a very thick film, with thickness large compared to the penetration depth of the Damon–Eshbach surface wave, on the lower surface of the film, one has a wave which propagates from left to right. The penetration depth of the mode is in fact just $|\vec{k}_{SW\|}|^{-1}$. If the film thickness d is decreased, the eigenvector extends over the entire film when $|\vec{k}_{SW\|}|d \sim 1$, with larger amplitude on the upper surface for right to left propagation, and larger amplitude on the lower surface for left to right propagation. In the thin film limit $|\vec{k}_{SW\|}|d \ll 1$, the eigenvector is uniform across the film and the frequency of the mode drops to the FMR frequency $\gamma[H_0(H_0 + 4\pi M_S)]^{1/2}$. As we shall see shortly, the Damon–Eshbach surface spin wave is a prominent feature in the BLS spectra of thick ferromagnetic crystals. We remark that this mode exists only when the magnetization is parallel to the surface, and there is no analogue of it when the magnetization is normal to the surface. For a discussion of the effects on Damon–Eshbach surface spin waves of tipping the magnetization out of plane, see the discussion presented by Rahman and the present author (Rahman and Mills, 1982).

The discussion in the previous paragraph describes magnetostatic spin waves, that is, modes whose wavelength is sufficiently long that exchange may be ignored in their description. As we see again from equation (2), as wave vector increases, exchange as manifested in the Dk^2 term in this equation, upshifts the frequency of short wavelength bulk spin waves above the upper bound $\gamma[H_0(H_0 + 4\pi M_S)]^{1/2}$ appropriate to the long wavelength magnetostatic waves. Thus, we have short wavelength bulk spin waves, upshifted by exchange, degenerate with the Damon–Eshbach wave. Camley and the present author have carried out detailed theoretical studies which show that even for a perfectly flat surface in the semi-infinite crystal, finite wave vector, Damon–Eshbach surface waves acquire a finite lifetime by decaying onto degenerate bulk spin waves. The lifetime associated with this process decreases with increasing wave vector, and vanishes at zero wave vector (Camley and Mills, 1978b).

The points discussed above are illustrated in Figure 1, where we reproduce a comparison between theory and experiment, for a BLS spectrum taken on bulk crystalline Fe magnetized parallel to its surface. The scattering geometry is arranged so the wave vector transfer is perpendicular to the magnetization. On the Stokes side, we see the strong, sharp peak associated with Brilluoin scattering from the Damon–Eshbach surface spin wave. The absence of such a feature on the anti-Stokes side of the spectrum is an elegant demonstration of the 'one way' character of these modes, as discussed above. If the magnetization is reversed,

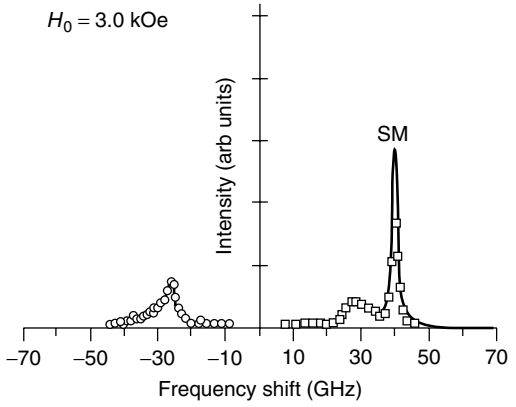

Figure 1. A comparison between theory (solid line) and experiment (open dots), for a Brilluoin light scattering spectrum taken on a single crystal of ferromagnetic Fe. The feature labeled SM is a Stokes feature associated with scattering from the Damon–Eshbach surface spin wave, and the broad bands are scatterings from bulk spin waves. (The data is that of Sandercock and Wettling, 1979, and the figure is taken from the paper by Camley, Rahman and Mills, 1981.)

this feature will appear on the anti-Stokes side, if the scattering geometry is held fixed. The broad asymmetric bands are features produced by scattering from bulk spin waves, which propagate up to and reflect off the surface. These have wavelengths sufficiently short that they are influenced importantly by exchange, so we see that the bulk spin-wave feature extends to frequencies well above that of the Damon–Eshbach wave. This figure shows clearly that the Damon–Eshbach wave sits on top of a manifold of bulk spin waves, and its linewidth in the BLS spectrum shown is influenced substantially by the decay process summarized in the preceeding paragraph. It should be remarked that no adjustable parameters are involved in the theoretically calculated spectrum. All parameters which control the shape of the spectrum are well known.

Very interesting BLS studies of spin waves in Ni/Mo superlattices have been reported by Keuny and collaborators (Kueny, Khan, Schuller and Grimsditch, 1984). There is an interesting issue in regard to such structures. When one considers their dynamic response, does one think of an array of uncoupled ferromagnetic films, or is it that the superlattice structure has its own spectrum of collective excitations, and thus its own unique response characteristics? In essence, have we created a new material?

The question just posed was explored within the theory of magnetostatic spin waves by Camley, Rahman, and Mills (1983). It is the case that magnetic superlattices have a unique collective excitation spectrum, even when the nonmagnetic spacer layer is sufficiently thick that exchange coupling between adjacent ferromagnetic films is negligible. A Damon–Eshbach surface spin wave on a given film generates a dynamic dipole field outside the film, which provides a means of interfilm coupling. One thus realizes collective excitations of the superlattice, where the new collective modes are appropriate linear combinations of single film eigenstates. There is a striking prediction of the theory. Suppose the ferromagnetic constituents have thickness d_1 while the nonmagnetic spacer layers have thickness d_2. If $d_1 > d_2$, the semi-infinite superlattice supports collective Damon–Eshbach wave with frequency identical to that of a semi-infinite whose magnetization is the same as that in the films. As one decreases d_1 for fixed nonmagnetic spacer layer thickness, when d_1 approaches d_2 the high-frequency side of the collective bulk spin-wave modes rises, until the Damon–Eshbach wave is merged into the bulk spin waves. The very extensive BLS studies of NiMo superlattices reported by Kueny *et al*. are in excellent accord with the predictions of Camley, Rahman, and Mills, except for superlattices with nonmagnetic spacer layers so thin that interfilm exchange influences the response characteristics of the sample. These experimental studies are remarkable, it should be said, since the magnetic properties of a very large number of samples were studied. In this work, superlattices whose constituents had thicknesses from 50 to 5000 Å were explored, with the ratio for d_1/d_2 assuming the values 1/3, 1, and 3.

2.2.2 BLS studies of ferromagnetic films

As one moves from very thick crystalline samples to thin ferromagnetic films, the Damon–Eshbach spin wave remains a prominent feature in the spectrum. With exchange neglected, in a film magnetized in plane with finite thickness, its frequency is given by Damon and Eshbach (1960)

$$\omega_{\mathrm{DE}}(k) = \gamma[(H_0 + 2\pi M_{\mathrm{S}})^2 - 4\pi^2 M_{\mathrm{S}}^2 \exp(-2kd)]^{1/2} \quad (3)$$

for the standardly studied case where the mode propagates perpendicular to the magnetization. At fixed wave vector, as the film thickness is decreased, the frequency of the mode decreases from the value appropriate to the semi-infinite crystal, $\gamma[H_0 + 2\pi M_{\mathrm{S}}]$ down to $\gamma[H_0(H_0 + 4\pi M_{\mathrm{S}})]^{1/2}$, which is the FMR frequency of the film, as we have commented earlier.

The bulk spin waves have wave vector component normal to the surface quantized, so the normal component of wave vector becomes $k_\perp = k_\perp^{(n)} \approx n\pi/d$. Thus, the bulk spin-wave continuum evident in the data on very thick crystals as illustrated by Figure 1 breaks up into a series of lines, each associated with a particular standing wave resonance of the film, as we have noted above.

We illustrate this in Figure 2(a) for a film of the amorphous ferromagnetic $Fe_{80}B_{20}$. The data is that of Grimsditch and his collaborators (1979). The thickness of the film used in this

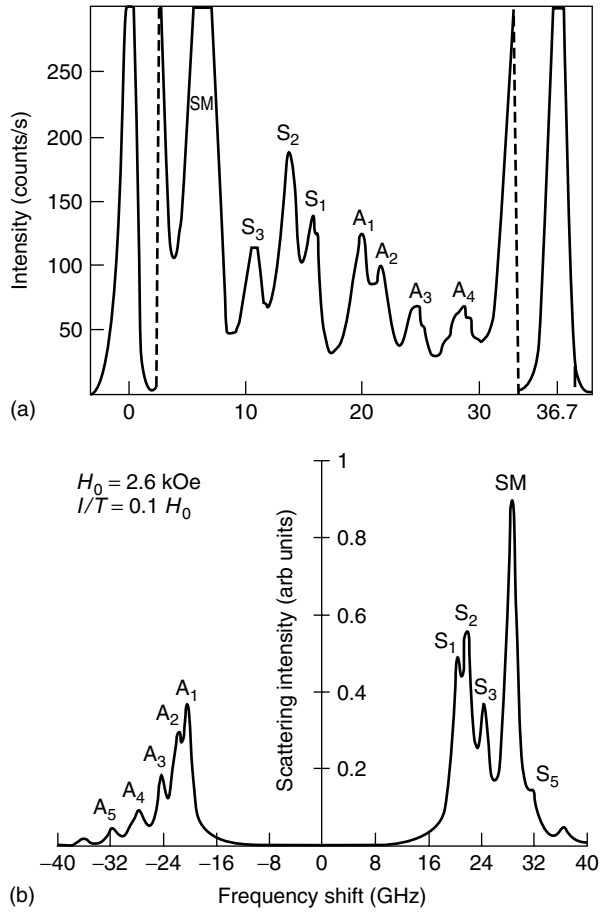

Figure 2. In (a), we show an experimental BLS spectrum taken from an $Fe_{80}B_{20}$ ferromagnetic film whose thickness is 106 nm. The frequency scale is in GHz, and a magnetic field of strength 2.6 kOe is applied in plane. (The data are from the paper by Grimsditch and collaborators, 1979.) In (b) we show theoretical spectra as calculated by Camley and coworkers (1981).)

experiment is 106 nm, and it is magnetized in plane with an external magnetic field of strength 2.6 kOe applied in plane. In order to understand this spectrum, some comments on the nature of the BLS measurement are useful. In these studies, the spectral composition of the scattered light is analyzed through use of a Fabry–Perot interferometer. Let light with only the laser frequency be introduced into this device. One then sees a sequence of interference features associated with the standing wave resonances of the interferometer. In Figure 2(a) two of these structures are evident, at the far left and the far right of the figure. In this particular detector, they are separated by 36.7 GHz, which is referred to as the spectral range of the device. The detector, it should be noted, is placed at an angle removed from that associated with specularly reflected light. Roughness on the surface leads to a bit of elastically scattered light off the specular direction and hence one sees 'markers' at the laser frequency as the spectrum is scanned. The spin-wave signal then consists of peaks, which fall between two such laser structures. The peaks labeled A_i in Figure 2(a) are anti-Stokes scatterings from bulk spin waves associated with the leftmost laser feature, and the peaks labeled S_i are bulk spin wave losses associated with the rightmost laser feature. The strong line labeled SM is the Damon–Eshbach surface magnon, which appears in the Stokes spectrum for this scattering configuration. We clearly see that the bulk spin-wave continuum evident in Figure 1 now consists of individual standing spin-wave modes. From the separation of these modes in frequency, one may infer the value of the exchange stiffness parameter which enters equation (2) in the preceding text.

In Figure 2(b), we reproduce a theoretical spectrum from the paper by Camley and collaborators (1981). One sees that the theory provides a remarkably quantitative account of the data. There is one parameter in the theory. At the film surfaces, the magnetic moments can encounter strong anisotropy fields with origin in the low symmetry of the surface environment, as we have discussed in the section on the FMR spectrum of films. Such anisotropy fields, if sufficiently strong, can 'pin' or suppress the spin motion at the surface. As illustrated in the paper just cited, the presence of surface anisotropy affects the relative intensity of the modes in the bulk spin-wave spectrum. For the particular sample explored in Figure 2(a), the data is accounted for very well assuming that surface anisotropy is absent.

As noted in the preceding text, the data in Figure 2(a) was taken on a rather thick film, with thickness of 106 nm. As the film is made thinner, the standing wave bulk modes shift upward in frequency, through action of the Dk^2 term in equation (2). We have seen one estimating this effect by replacing the k by its quantized value $k_\perp^{(n)} \approx n\pi/d$. In the ultrathin limit, the standing wave modes are shifted well above the spectral range accessible to the BLS technique, very much as in FMR. One is left with the signature of only the Damon–Eshbach mode, whose frequency is now very close to the FMR mode, as one sees from equation (3) with $kd \ll 1$. The eigenvector of this mode is now rather uniform across the film.

In the discussion we have given above, we have remarked that in thick samples, the Damon–Eshbach surface spin wave appears on only one side of the laser line in BLS studies, either the Stokes or the anti-Stokes side, depending on the details of the scattering geometry. In the very thin-film limit where $kd \ll 1$, one finds that the eigenvector of both the mode localized on the upper layer of the film and that localized on its lower surface become uniform across the film. Furthermore, in the ultrathin film limit, the optical skin depth is comparable to or perhaps even larger than the film thickness. In this limit, one should expect to see

the Damon–Eshbach mode on both the Stokes and the anti-Stokes side of the laser line with very close to equal intensity, since the incident light 'sees' both modes in a roughly equal manner. However, early experimental studies of films with thickness in the 10 nm range, where one should be well into the limit just described, a large Stokes/anti-Stokes asymmetry persists (Camley, Grunberg and Mayr, 1982). These authors set forth an elegant theoretical explanation of the data, based on an interesting interference effect in the matrix element for excitation of the Stokes and the anti-Stokes Damon–Eshbach mode.

The discussion in the preceding text sets forth the principal concepts, which control our understanding of BLS in ferromagnetic films. We now turn our attention to the information one may obtain by applying this method to ultrathin ferromagnets and bilayers or superlattices formed from ultrathin ferromagnetic films. There is by now a very extensive literature on this topic. Thus, a complete review of this literature is beyond the scope of the present chapter. In the discussion below, we shall select examples of what may be learned from this technique, which is complementary to FMR. We direct the reader to the excellent article by Cochran, which discusses key concepts and presents a complete list of the earlier seminal papers in this area (Cochran, 1994). Our focus will also be on earlier selected studies, since these set out the principal concepts illustrated by data on important systems.

A first question is whether the BLS technique has the sensitivity to study true ultrathin ferromagnets. In all the examples discussed in the preceding text, recall that the optical skin depth is in the range of 10–20 nm. Thus, the spectra are produced through coupling of the laser light to perhaps 50 or 100 atomic layers of spins. To illustrate spectra that can be measured from truly ultrathin films, in Figure 3, we reproduce data taken on a three monolayer film of Fe grown on the Cu(100) substrate (Dutcher *et al*., 1988). The signal-to-noise ratio in this data is most impressive indeed. Thus, it is clear that the BLS method may be used to probe spin waves down to the single monolayer level, if desired.

As remarked above, the BLS method has been employed to obtain quantitative information on the magnetic properties and response characteristics on diverse ultrathin films and magnetic multilayers. In an interesting early study, Grunberg and his collaborators explored the BLS spectra of ultrathin Fe, Ni, and Permalloy films (Grunberg, Mayr, Vach and Grimsditch, 1982). From the spectra, they extracted all the key magnetic properties of these films. All these materials had been studied earlier by FMR, and they compared the results obtained by BLS and FMR. The agreement is very good.

As we have mentioned in the preceding text in our discussion of FMR, in ultrathin films the strength of the effective anisotropy can be very much larger than in bulk materials with the same atomic constituents, because a large fraction

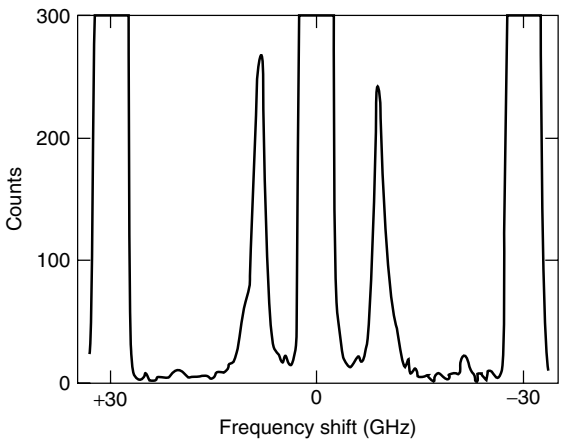

Figure 3. A Brillouin light scattering spectrum of three monolayers of Fe, grown on a Cu(100) substrate. (Reproduced from Dutcher, J.R. ,Heinrich, B., Cochran, J.F., Steigerwald, D.A., and Egelhoff Jr., W.F., (1988), "Magnetic Properties of Sandwiches and Superlattices of FCC Fe(100) Grown on Cu(100) Substrates", *J. Appl. Phys.* **63**, copyright © 1988 American Institute of Physics, with permission from the AIP.)

of atoms reside at surface or interface sites of low symmetry. In a very thin film, the spins are locked together tightly by the very strong exchange interactions as they engage in precession after a long wavelength spin wave is excited. Thus, one measures an effective anisotropy energy averaged over all layers, in both FMR and BLS studies of ultrathin films. Strong surface or interface anisotropy then contributes a term to the average anisotropy, which scales inversely with the film thickness. In BLS data, Hillebrands and coworkers observe very strong surface anisotropy, in BLS studies of ultrathin films of Fe grown on W(110) (Hillebrands, Baumgart and Guntherodt, 1987). The Fe films ranged in thickness from 15 nm down to a few monolayers; below 6 nm in thickness, the spin-wave frequency is found to increase strongly with decreasing thickness until it is larger than that appropriate to the thick films by a factor of 3. This is an illustration of the dramatic effect that the surface anisotropy can have on the dynamic response characteristics of ultrathin ferromagnets.

In the studies cited in the preceding text and many others, BLS is used to determine the fundamental parameters, which control the frequency spectrum of the dynamic response of ultrathin films. Examples are the nature of the anisotropy, the magnetization itself, and the exchange stiffness parameter. Another crucial feature of the response of such systems is the magnitude and nature of the damping of the spin motions. In general, FMR has far higher frequency resolution than BLS, and thus is more frequently used to explore the nature of damping. We presented a discussion of this topic above, in the section on FMR of ultrathin films. However, there are circumstances where BLS can also measure the intrinsic linewidth of spin-wave excitations

under circumstances where the damping is appreciable. It is the case that when films are grown on exchange biasing substrates, the two-magnon mechanism discussed in the preceding text can be very strong. Under such circumstances, the linewidths of the spin-wave modes can be substantial, and accessible to the BLS technique. Earlier we noted the paper by of Rezende *et al*. where large linewidths could be measured directly by the BLS method. These authors measured the linewidth in FMR and also in BLS, for the same samples of exchange biased Permalloy films. The BLS linewidth is five times larger than that found in FMR on the same film. The FMR linewidth is also large, and these authors applied the theory of two-magnon damping (Arias and Mills, 1999) to extract the magnitude of the matrix element which controls this process from the FMR linewidth, under the assumption that two-magnon scattering is dominant. They argue that this source of damping is wave vector dependent, and extended the theory of Arias and Mills to take this feature into account. They show that this is so by comparing theory with the BLS data; through use of exactly the same matrix element extracted from the FMR spectra, they were able to obtain a fully quantitative account of the larger linewidths found in BLS. As noted in our section on FMR in ultrathin films, their conclusion that the linewidth of long wavelength spin waves in ultrathin films is strongly wave vector dependent, combined with the dramatic deviations from the linear law in the dependence of the FMR linewidth in ultrathin films (Lindner *et al*., 2003) show that in materials where the two-magnon mechanism is operative the widely used LLG equation breaks down qualitatively.

In magnetic multilayer or superlattice structures, there will be interactions between adjacent films in the structure, with the consequence that the spin-wave modes are collective excitations of the structure as a whole. We have already encountered an example of such collective modes in our discussion above of the BLS studies of NiMo superlattices (for data see Kueny *et al*., 1984, and for theory related to these experiments, see Camley, Rahman and Mills, 1983). In these samples, the Ni and Mo films were quite thick, and the interfilm coupling responsible for the collective character of the modes studied had their origin in long-ranged dipolar interactions between the ferromagnetic constituents. As the spins in a given ferromagnetic film precess upon excitation of a spin wave within the film, a dynamic, time dependent dipolar field is generated outside the film by the spin motions. This field has strength and range given roughly by $4\pi M_S kd \exp(-kz)$ with d the film thickness, k the wave vector of the spin wave, and z the distance from the film, measured along the normal. Such dynamic fields couple the various films together, to produce collective modes of the structure as a whole as we have discussed.

If we consider a multilayer or superlattice wherein the ferromagnetic films are separated by nonmagnetic metallic spacers as in the example of the NiMo structure, when the spacer layers become very thin there is a direct exchange coupling between adjacent ferromagnetic films with origin in the spin polarization of the conduction electrons in the nonmagnetic spacer layer. The effective exchange coupling necessarily oscillates with the thickness of the spacer layer, as proved theoretically over four decades ago (Bardasis *et al*., 1965). Thus, the interfilm coupling may be antiferromagnetic or ferromagnetic in character, depending on the thickness of the spacer layer. (A recent review of this topic is provided by Stiles 2006.)

Exchange coupled ferromagnetic bilayers, wherein the magnetization of one of the two ferromagnets is pinned by strong anisotropy field provided by the exchange bias mechanism (Berkowitz and Kodama, 2006) are referred to as *spin valves*. These structures play a vital role in current computer technology, as we see from the new generation of read heads, which incorporate spin valves as essential elements. Very high sensitivity in the read head results from the phenomenon of giant magnetoresistance. (Fert, Barthelemy and Petroff, 2006). Thus, there is great interest in the study of the influence of interfilm exchange coupling on the dynamic response of magnetic nanostructures such as spin valves.

The BLS technique offers a means of directly measuring the strength of the exchange between adjacent ferromagnetic films separated by a nonmagnetic spacer. Consider two such films in the form of a ferromagnetic film grown on a substrate, a nonmagnetic spacer is then deposited on this film, and then a second film is deposited on top of the spacer. The system will exhibit collective spin-wave modes, with an in-phase acoustic mode and an out-of-phase 'optical' mode split in frequency by the exchange coupling and/or dipolar interactions between the films. Experimental studies of such modes along with the related theory have been reported by Grunberg and his collaborators, for Fe/Au/Fe and Fe/Cr/Fe structures (Grunberg *et al*., 1986). Subsequent measurements have provided direct access to the oscillatory exchange coupling in the important Co/Ru system. In these measurements, the value of the coupling between neighboring Co films as a function of Ru thicknesswas measured and the period of the oscillation was found to be 1.15 nm (Fassbender *et al*., 1992).

It is possible to grow bilayers or multilayers from ultrathin films in which both constituents are ferromagnets. An example is the Fe/Ni system, whose spin-wave modes have been studied by Heinrich and his colleagues (1988). Here one realizes strong interfilm exchange coupling across the interface between the two constituents. These authors also provided a theoretical analysis of the spin waves in ferromagnetic bilayers, including both the role of the exchange stiffness D discussed above, and also the influence

of dynamic dipole fields generated by the spin motions in the ferromagnets. There is an important comment one must make regarding this analysis and others found in the literature on similar systems. A boundary condition linking the dynamic magnetizations and their derivatives across the interface between the two ferromagnetic films is required, before one can solve the differential equations, which form the basis of the theory. Quite commonly a boundary condition is employed in such calculations (Hoffman, 1970). However, it is the case that the boundary condition found in Hoffman's paper leads to unphysical conclusions, as discussed by the present author (Mills, 1993). An energy conservation law is violated, since the energy transported across the interface is not conserved when the Hoffman boundary connects spin motions on both sides of the interface. Also, in the mathematical limit that the two ferromagnets become identical, the reflectivity can be nonzero. Thus, the Hoffman boundary condition is in fact unphysical. In the paper just cited by the present author, a boundary condition compatible with both of these constraints has been formulated and stated. Clearly for valid quantitative conclusions to be deduced from the data, one must use a boundary condition free of the difficulties found in the Hoffman boundary condition.

In this section on BLS studies of spin waves in ferromagnets, our attention has been directed toward bulk materials, films, ultrathin films, and magnetic multilayers composed of ultrathin films. In the recent literature, the method has been employed to explore patterned media of diverse sorts. This constitutes a most powerful extension of the method. For instance, BLS has been used to study spin dynamics in the vortex state of a circular magnetic dot (Novosad *et al*., 2002). A theoretical study of such spin excitations has been given by Giovanni and his colleagues (2004). An extension of theory and experiment to the study of dots of elliptical shape is given by Gubbiotti *et al*. (2005). A series of BLS studies of the spin-wave excitations of arrays of ferromagnetic ribbons has been carried out by Demokritov and his colleagues. A recent article discusses this work, and also covers the use of spatially resolved BLS to explore nonlinear spin-wave phenomena in systems driven beyond the linear response regime (Demokritov, Hillebrands and Slavin, 2001). We note that Arias and the present author have presented an exact theory of magnetostatic spin waves in ferromagnetic ribbons of arbitrary cross section, and compared the results of theory to the high aspect ratio ribbons studied by Demokritov and his colleagues (Arias and Mills, 2005).

2.3 Some general comments

The last two sections have reviewed both FMR and BLS studies of spin waves in the metallic ferromagnets, again in bulk crystalline form, in films, in ultrathin films, and in magnetic multilayers. We see that both of these important methods provide us with information on the basic magnetic parameters of materials in these diverse forms. Also, they are complementary in that each of these methods can probe different aspects of the response, as we have seen. However, they have one common feature. This is that both probe modes whose wavelength is very long compared to the lattice constant of the underlying material. Thus theoretical descriptions of the modes can be obtained from macroscopic theory constructed through use of phenomenological parameters. We shall review the structure of such theories in Section 3. The parameters generated by such analyses may, of course, be compared with the results of *ab initio* theories, wherein one begins with a density functional description of the ferromagnetic state, and then calculates from this point the relevant parameters deduced from the application of macroscopic theory. The current state of the art is such that we now may obtain reliable and quantitative accounts of these parameters from *ab initio* density functional based theory.

If we set damping parameters aside, by the means just discussed one may extract information from the data on anisotropies, magnetization of various constituents, the exchange stiffness, and in the case of ultrathin multilayer structures the spacer mediated exchange between ferromagnetic constituents, as we have noted in the preceding text. Although one requires a truly dynamical theory to describe the damping of spin motions, these parameters are all ground state parameters, which may be calculated by adiabatic methods from the description of the ground state. One might think that the exchange stiffness D is a dynamical parameter, but in fact in the phenomenology it describes the change in ground state energy with respect to long wavelength static distortions of the spin system. Thus this may be generated from information on the ground state. A recent discussion of this point has been given by Muniz and the present author, for ultrathin ferromagnetic films (Muniz and Mills, 2002).

To obtain truly microscopic information on the nature of spin excitations in any magnetically ordered material, one must study short wavelength spin excitations, with wave vectors of a considerable fraction of the distance from the center of the appropriate Brillouin zone to the zone boundary. The remainder of the present section will be devoted to experiments, which can probe this regime. At least for classical, well-studied materials like the bulk 3d ferromagnets Fe, Co, and Ni and their various alloys, one would think this to be well trodden ground. However, this is not the case. As we shall see, there is still much to learn about these basic and fundamental materials, whose ferromagnetism has been known for centuries.

2.4 Neutron scattering studies of the ferromagnetic transition metals

For many decades now, the technique of inelastic neutron scattering has been one of the most important means of studying diverse elementary excitations in materials. The experiment is conceptually similar to the BLS studies, which have just occupied our attention, except the probe beam now consists of monoenergetic neutrons rather than photons. The loss spectrum is measured as a function of scattering angle, and from the data one may then construct the dispersion curves of phonons, spin waves, and other elementary excitations as well. As we shall see, in contrast to BLS, neutron spectroscopy can reach throughout the entire Brilluoin zone. The kinematics of the excitation process may be described in exactly the same language we have just employed. Let $\vec{k}_{\mathrm{I}}$ be the wave vector of a neutron incident on a crystal, and suppose it creates or absorbs a quantum of an elementary excitation whose wave vector is $\vec{k}$. Then the wave vector of the scattered neutron will be $\vec{k}_{\mathrm{S}} = \vec{k}_{\mathrm{I}} \pm \vec{k}$, with the plus sign chosen for the case where the quantum is absorbed, and the minus sign if it is emitted. Energy conservation then reads $E(\vec{k}_{\mathrm{S}}) = E(\vec{k}_{\mathrm{I}}) \pm \hbar\omega(\vec{k})$. Here, $E(\vec{k}) = \hbar^2 k^2 / 2m_{\mathrm{N}}$ is the energy of a neutron of wave vector $\vec{k}$. Thus, a measurement of the loss spectrum of the neutron as a scattering angle allows one to construct the dispersion curves of elementary excitations of interest. There is by now a very large literature on neutron scattering from spin waves in diverse magnetic crystals, along with other 'magnetically active' excitations. We refer the reader to the excellent text by Lovesey for a detailed exposition of the theory of neutron scattering from spin excitations in magnetic materials (Lovesey, 1984).

Thermal neutrons are commonly used in such experiments, since very high neutron fluxes are generated by nuclear reactors designed for neutron spectroscopy. Thus, the neutrons in the beam have kinetic energies on the order of $k_{\mathrm{B}}T$, where the temperature is roughly room temperature. Thus, typical beam kinetic energies are in the range of 50 meV or somewhat less. The wave vector of such a neutron is approximately $5 \times 10^8\,\mathrm{cm}^{-1}$, so we can appreciate that in contrast to light scattering spectroscopy, we have here a means of reaching out to the boundary of the Brillouin zone. In regard to spin waves, for materials which may be described by a Heisenberg–Hamiltonian, a rule of thumb is that modes at the zone boundary have excitation energies in the range of $k_{\mathrm{B}}T_0$, with T_0 the ordering temperature (the Curie temperature for ferromagnets, or the Neel temperature for antiferromagnets). Almost all insulating magnetic materials have ordering temperatures in the vicinity of room temperature or below, so inelastic neutron scattering is a most powerful probe for the experimental study of spin waves in a very wide class of magnetic materials.

The ferromagnetic transition metals, which are the primary focus of this review have spin waves of a character qualitatively different than discussed in the previous paragraph. First, of course, almost all of these materials have Curie temperatures well above room temperature, in the vicinity of 1000 K. Second, the spin waves in these materials are very 'stiff', and the frequency of short wavelength spins waves can be much higher than $k_{\mathrm{B}}T_{\mathrm{C}}$. Consider, for instance, ferromagnetic Fe. The frequency of a spin wave of wave vector $\vec{k}$ may be approximated by Dk^2, for excitation energies sufficiently large that Zeeman, dipolar, and anisotropy energies may be set aside. For Fe, the low temperature value of the exchange stiffness D is approximately 300 meV Å^2. If we just extrapolate this quadratic form out to the Brillouin zone boundary, we see that spin-wave excitations energies will be in the range of 300 meV, or in temperature units we have 3000 K, far above the range accessible to thermal neutrons. The breakdown of the relationship between spin-wave energy at the zone boundary and $k_{\mathrm{B}}T_{\mathrm{C}}$ has its origin in the fact that these materials are itinerant electron ferromagnets, and a Heisenberg model with short ranged exchange interactions fails very badly for this important class of ferromagnets.

The remarks in the previous paragraph lead to the conclusion that thermal neutrons can explore only spin waves of rather small wave vector, in the 3d ferromagnets. To reach the zone boundary, one requires high-energy neutron beams, from a spallation source. It is the case that the neutron cross section is small at large wave vectors, so such experiments are a major challenge. A consequence is that there is little data in hand, even at this mature state of the field, on the nature of short wave length spin waves in the ferromagnetic transition metals. This situation is remarkable in the view of the present writer. The ferromagnetism of these metals has been known well since antiquity, and historically they have played a central role in electromagnetic technology since the nineteenth century. Indeed, they occupy center stage today, as we see from their role in the remarkable giant magnetoresistance (GMR) read heads, and in magnetic random access memories (MRAMs). Despite the very long history of study of these materials, and their central role in past and current technology, we have less information regarding the nature of their spin excitations than we do of very exotic materials.

2.4.1 Neutron scattering studies of spin waves in the bulk 3d ferromagnets

Early studies of spin waves in Fe, Co, and Ni were carried out by the Brookhaven group. We refer the reader to a review of this data (Shirane, Minkiewicz and Nathans, 1968). The data explored spin waves with excitation energy below

50 meV, and wave vector transfers in the range 0.5 A^{-1} and below. In this regime, the dominant contribution to the spin wave excitation energy is the classical Dk^2 term discussed in the preceding text. The data was fitted with the form $Dk^2(1 - \beta k^2)$, and values of the exchange stiffness D and the parameter β are found in this paper. For hcp-Co, the data explores spin waves, which propagate along the c direction. For the case of fcc-Co, Sinclair and Brockhouse have measured the exchange stiffness, through measurement of the spin-wave dispersion near the center of the Brillouin zone (Sinclair and Brockhouse, 1960). It should be remarked that in some of the measurements just cited, it was not possible to obtain pure single crystals large enough for detectable neutron signals. In the case of Fe and also fcc-Co, it was necessary to add several percent of Si for the purpose of stabilizing large crystals. Thus, the measured spin-wave dispersion in such studies may differ somewhat from that appropriate to the pure single crystal.

Mook and collaborators have extended the measurements to higher spin-wave excitation energies, to approximately 120 meV, and to wave vectors as large as 0.8 A^{-1}. In the case of Ni, they found a dramatic falloff in intensity, for spin waves above 100 meV in energy (Mook, Nicklow, Thompson and Wilkinson, 1969). They attributed this to damping by coupling of the spin wave to Stoner excitations, a process unique to itinerant ferromagnets. We shall discuss this damping process in detail in Section 3, when we turn our attention to theoretical descriptions of spin waves in these materials. Briefly stated, the damping process arises from the following. Imagine one sets up a spin wave in the material at time zero. The precession of the spins take place in a metallic environment, where all electrons reside in spin-polarized energy bands. The electronic system has a continuous energy spectrum of spin triplet particle hole pairs, formed by taking an electron from an occupied state in a majority spin band, thus creating a hole, and placing it in an unfilled state in the minority spin band. The continuum of such particle hole pairs is referred to as the Stoner excitation spectrum. The spin wave may then decay by creating such particle hole pairs. If the spin wave is destroyed by this process, as we know from elementary discussions of the properties of spin waves (Kittel, 1963a), destruction of a spin wave increases the spin angular momentum of the substrate by $\hbar$. Angular momentum conservation requires that the excitation to which its energy is transferred must have angular momentum $-\hbar$. Hence there must be a spin flip in the gas of conduction electrons in the process, which transfers the energy of the spin wave to the band electrons. We shall see that the decay process just described is of central importance when we discuss spin waves in ultrathin metallic ferromagnets. In the case of the neutron scattering studies of Ni, the sudden falloff in intensity found by Mook and coworkers was interpreted in terms of crossing a wave vector threshold for creating Stoner excitations. Mook and Nicklow shortly thereafter reported neutron scattering studies of spin waves in Fe, where similar behavior was found (Mook and Nicklow, 1973).

We shall discuss the theory of itinerant spin waves in the 3d ferromagnetic metals in Section 3. In the present section, we wish to make a comment on a theoretical prediction that has stimulated much discussion. Cooke and his collaborators presented the first theoretical description of spin waves in Ni and Fe, within the framework of the itinerant electron picture of ferromagnetism, combined with use of a realistic electronic band structure (Cooke, Lynn and Davis, 1980). One striking and unexpected feature found in this study was a curious hybridization gap in the spin-wave dispersion relation for Ni and Fe, along the [100] direction. One has an upper branch above this gap which is called an *optical spin wave* by Cooke and his collaborators. These materials are, of course, monatomic crystals with one atom per unit cell, so the appearance of such structures are both surprising, and of course very interesting. We shall discuss this topic in detail in Section 3. It is the view of present writer and his colleagues, based on our studies of spin waves in ultrathin films, that such features are in fact artifacts of poor convergence in the sums over wave vector in the Brillouin zone in constructing the kernal of the integral equation which must be solved to extract information on the spin wave excitations. In our own calculations of the spin-wave spectrum of Fe (Tang, Plihal and Mills, 1998) and Ni (Hong and Mills, 2000) we have not encountered such features. We did find hybridization gaps qualitatively similar to those in the paper of Cooke and his collaborators in our study of spin waves in the Fe monolayer on W(110) (Muniz and Mills, 2002). As we discussed in this paper, upon improving the convergence in our k space sums this feature disappeared.

Evidence for an apparent gap in the spin-wave dispersion relation in Ni along the [100] direction has been provided by Mook and Paul (1985). In the theory to which the data is compared, the hybridization feature is considerably more than that found in the data as one sees from the solid line in Figure 3 of the by Mook and Paul. There are no actual loss spectra displayed, in the wave regime where the hybridization gap is found. Evidently an optical spin-wave feature was not seen directly, but rather structure in the acoustical spin-wave loss peak was assumed to be evidence for the optical mode (Mook, private communication). Studies of high-frequency spin excitations in Fe also suggest that an optical spin-wave feature may have been observed (Perring *et al.*, 1991). Our calculations, however, suggest that this may be structure in the low-lying sector of the Stoner excitations. We refer the reader to Figure 5 of the paper by Tang, Plihal, and the present author, and the associated discussion (Tang, Plihal and Mills, 1998). We thus regard the question of the existence

of hybridization gaps in the spin-wave spectrum of the simple 3d transition-metal ferromagnets to be an open question, from both the experimental and the theoretical point of view.

2.4.2 Neutron scattering from ultrathin films and magnetic multilayers

Quite clearly it is not possible to detect inelastic neutron scattering from a single ultrathin film, simply because the signals will be orders of magnitude smaller than can be detected. The studies of spin waves in bulk materials described in the previous section were carried out on large single crystal samples. As we mentioned, to obtain such large, perfect crystals it was often necessary to allow Fe or Co with Si. Thus, even for the study of bulk spin waves, considerable effort must be expended in sample preparation and sometimes this requires a compromise. As we see, many of the experiments just discussed are carried out on alloys rather than perfect, elemental single crystals.

It is possible to detect magnetic neutron scattering from magnetic multilayers, which incorporate ultrathin films as elements. At the time of this writing, there is a considerable experimental literature devoted to studies of static spin arrangements in magnetic multilayers. A beautiful study of the evolution of the surface spin flop state in finite Fe/Cr superlattices provides one with an illustration of the power and sophistication of such experiments (Te Velthuis, Jiang, Bader and Felcher, 2002). We also refer the reader to a discussion of the application of neutrons to such studies; this paper also contains very impressive data, including preliminary data on inelastic neutron scattering from spin waves in Dy/Y superlattices (Schreyer *et al*., 2000). We are unaware of further studies of spin waves in magnetic multilayers by inelastic neutron scattering at the time of this writing.

2.5 Studies of spin waves by spin polarized electron energy loss spectroscopy (SPEELS)

Because of the limitations of neutron scattering when applied to the study of spin waves in the 3d ferromagnets, most particularly when they are in the form of ultrathin films, until very recently we have had in hand no experimental information on the nature of large wave vector, or short wavelength spin waves in such films. Indeed, as we have just seen, the number of experiments which explore the entire Brillouin zone, is remarkably limited for the bulk materials, even at this very mature point in the field. There is compelling reason to learn about the nature of large wave vector spin waves in ultrathin structures. In the current era, devices based on ultrathin film magnetic structures have had a massive impact on information technology, as we see from the remarkable GMR based read heads. MRAM is just coming on line in early form at the time of this writing. As such devices are made smaller and smaller, we require quantitative information on the nature of spin motions with large spatial gradients, in the materials that are the focus of the present chapter. Much in this area can be learned through the study of large wave vector spin waves in ultrathin films.

For a considerable number of years, there have been discussions in the electron energy loss spectroscopy (EELS) community regarding the possibility of utilizing electrons, spin polarized if possible, as a means of studying spin waves in ultrathin films or on magnetic surfaces. Indeed, the present author proposed this possibility many years ago (Mills, 1967), and explored issues in the area through model calculations of the spin wave contribution to the loss cross section of electrons scattered from the surface of a Heisenberg ferromagnet. An attempt to detect spin waves on a Ni(100) surface in 1983 was unsuccessful (Ibach, private communication), for reasons we now understand (Hong and Mills, 2000). We shall discuss this point in the following text, in the present section.

The use of electrons rather than neutrons to study large wave vector spin waves in ultrathin films overcomes two principal difficulties with neutron scattering. First, typical electron energies utilized in loss studies range from a few electron volts, to a few tens of electron volts. Thus, the incident particle has more than enough kinetic energy to excite spin waves in the 3d ferromagnets, in contrast to thermal neutrons. Furthermore, the mean free path of electrons in the 3d ferromagnets is very short, even for electrons with kinetic energy very close to the vacuum level (Abraham and Hopster, 1987). Thus, beam electrons backscattered from these surfaces sample magnetic moments in the outer surface layer primarily. The short penetration depth thus makes electrons ideal for the study of ultrathin film magnetism. All the electrons, which are detected, carry information primarily about the outer layer of atoms.

It should be remarked that for many years now, EELS has been utilized for the study of phonons on crystal surfaces. With this technique, one may measure dispersion curves of surface phonons out to the Brillouin zone boundary, and probe the influence of bulk phonons on surface vibrations as well. For a discussion of such a study, and a comparison between theory and experiment, we refer the reader to the discussion by Hall and Mills and the references cited therein (Hall and Mills, 1986). As one envisions using this method for the study of spin waves, it is highly desirable to be able to discriminate between losses produced by phonons or other ‘magnetically inactive’ excitations, and spin waves. The use of a highly spin-polarized electron beam allows one to identify spin-wave features in a unique manner.

In elementary text book discussions of spin waves, one sees that when a spin wave is excited in a ferromagnet, the spin angular momentum of the substrate decreases by exactly $\hbar$ (Kittel, 1963a). Suppose such a spin wave is excited by an electron whose spin is antiparallel to the ferromagnetically aligned spins in the sample. Then angular momentum will be conserved in the scattering process if beam electron flips its spin from antiparallel to parallel to the aligned spins in the substrate. If, however, the beam electron has its spin aligned parallel to those in the sample, it cannot excite the spin wave and conserve angular momentum in the scattering event. Hence, if the experiment were to be carried out with an ideal beam that is 100% polarized, one would see spin-wave losses when the spin polarization is antiparallel to the substrate spins, and the spin-wave feature would disappear when the beam polarization (or sample magnetization) is reversed.

Some years ago, there were SPEELS study of the magnetic excitations in both Fe (Venus and Kirschner, 1988) and Ni (Abraham and Hopster, 1989). In both of these experiments, termed *complete experiments*, the incident beam was spin polarized and the spin of the scattered electron was detected as well, a most challenging experimental undertaking. This allowed separation of losses into the two nonspin flip loss channels (both beam and scattered electron parallel or antiparallel to substrate majority spins), and the spin flip processes. The spin flip scattering events provide us with information on the nature of the continuum of Stoner excitations, and as we have seen earlier with sufficient resolution one should also be able to see spin waves. In both of these experiments, only the Stoner regime was studied. In Fe, the peak of this broad continuum is in the 2 eV range, well above the spin-wave loss regime. It is the case that the spectrometer utilized had insufficient energy resolution to explore the low-energy regime where one may expect to find spin waves. Much more interesting, from the perspective of our present discussion, is the data on Ni. In Ni, the exchange splitting in the d bands is roughly 300 meV, and thus the Stoner spectrum lies very close to the spin-wave regime. The data reported by Abraham and Hopster goes down to 100 meV, and the resolution of the instrument, 17 meV, was remarkably high. It is puzzling that under these conditions, no evidence of a spin-wave signal was found. This reminds one of Ibach's early failed attempt to detect spin waves in EELS, also on Ni(100).

The present author and his colleagues have been engaged in the studies of large wave vector spin waves in ultrathin films, and also of the theory of spin-polarized electrons loss spectra. We wish to comment on conclusions reached in these studies, before we introduce the reader to recent SPEELS data in which large wave vector spin waves were studied in very beautiful recent experiments.

A central question that was addressed in our studies was the following. As we have just seen, the spectrum of Stoner excitations had been detected in SPEELS studies of both Fe and Ni quite some time ago. So an important question is the relative intensity of the spin-wave loss feature to that of the Stoner spectrum. Is there enough integrated strength in the spin-wave loss structure at large wave vectors for it to stand out as a clear structure on the background of Stoner excitations? Through use of a microscopic description of the Coulomb exchange matrix element appropriate to SPEELS and a quantitative description of the spin-wave/Stoner excitation spectrum of Fe, it was predicted that in Fe, the spin-wave loss structure should be a prominent feature in the SPEELS spectrum (Plihal and Mills, 1998). The first spin-wave signature SPEELS was reported shortly thereafter, in a study of an ultrathin Fe film on W(110) (Plihal, Mills and Kirschner, 1999). Further study showed that the feature observed failed to disperse with wave vector transfer. Evidently, the Fe film had a substantial concentration of dislocations, with origin of the lattice mismatch between the Fe film and the underlying W(110) substrate. This could cause a breakdown of wave vector conservation in the spin-wave excitation process, thus producing a broad loss feature reminiscent of spectra associated with diffuse neutron scattering from phonons in disordered crystals. In such circumstances, the breakdown of $\vec{k}$ conservation produces a broad structure, which does not disperse with wave vector. It is clear, however, that the feature reported by Plihal *et al*. was a spin-wave structure.

At this point, one must inquire why spin waves were not detected in scattering from Ni(100); two experiments evidently failed to see such structures. We should remark that Ibach's 1983 attempt to observe spin waves was known widely in the electron loss community, and this discouraged attempts to see spin-wave features in the electron loss spectrum. We also know, of course, as discussed in the preceding text that large wave vector spin waves in bulk Ni have been studied by inelastic neutron scattering (Mook and Paul, 1985). Thus, the absence of these features in SPEELS is puzzling.

We have set forth an explanation for the above annoying situation (Hong and Mills, 2000). One must appreciate that the neutron and electron beams create spin waves through different mechanisms. Neutrons interact with electron spins in magnetic materials through the magnetic dipole interaction, which is a long-ranged interaction. Thus, the neutron senses the total magnetic moment in each unit cell, but is not sensitive to its shape or the details of its electronic structure. The theory of inelastic neutron scattering from magnetic materials show that the loss spectrum is controlled by a response function referred to by theorists as the wave vector and frequency dependent susceptibility, written as $\chi_{+,-}(\vec{k}, \omega)$. Here $\vec{k}$ is the wave vector transfer in the

scattering process, and $\hbar\omega$ is the energy loss of the neutron. This response is precisely the same response function which, in linear response theory, provides the magnitude of the transverse magnetic moment induced by a time and spatially dependent applied magnetic field, where the space and time dependence is given by $\cos(\vec{k}\cdot\vec{r}-\omega t)$. We shall have more to say on this topic in Section 3.

In contrast, the excitation of spin waves by electrons involves a Coulomb exchange scattering process, as mentioned earlier. In physical terms, one may picture this as follows. The d electrons inside an Fe or Ni atom reside in 3d orbitals of either e_g or t_g character, if we allow ourselves to think in terms of a localized atom picture for a moment. The incoming electron penetrates into the atom and in the process of creating a spin excitation may transfer a particular electron from one orbital to a distinctly different orbital. The shape of the moment cloud in real space has thus been altered in the excitation process. When the theoretical analysis is completed (Plihal and Mills, 1998), one finds that the SPEELS spectrum is described not by $\chi_{+,-}(\vec{k},\omega)$ but rather by a distinctly different response function we may refer to as $\chi_{\mathrm{SPEELS}}(\vec{k},\omega)$. When we calculate each of these two response functions, we find that the loss spectra described by them are dramatically different. In both bulk crystals and in ultrathin films, our extensive series of calculations show that the Stoner spectrum is virtually absent in $\chi_{+,-}(\vec{k},\omega)$. One sees only spin-wave loss features in this response function, and in our numerical calculations even at large wave vectors, the Stoner region is very weak. We first found this behavior in our studies of spin waves in bulk Fe, and in ultrathin Fe(100) films (Tang, Plihal and Mills, 1998). On the other hand, in both Fe and Ni, in $\chi_{\mathrm{SPEELS}}(\vec{k},\omega)$ the Stoner spectrum is a strong feature, very much as found in the early SPEELS studies of these materials. In Fe, as noted above, we also found a visible, clear spin wave in the low-energy wing of the Stoner loss spectrum, which as mentioned earlier peaks near 2 eV. However, in Ni, the SPEELS response function shows no sign of loss structures from spin waves, save very close to the center of the Brillouin zone. The Stoner spectrum lies very low in energy, in the vicinity of 300 meV as mentioned earlier, and this is all one sees in $\chi_{\mathrm{SPEELS}}(\vec{k},\omega)$. However, when we calculate $\chi_{+,-}(\vec{k},\omega)$ through use of precisely the same description of the electronic structure, we see clear spin-wave loss structures for Ni very much as in the neutron studies (Hong and Mills, 2000).

The remarks in the previous paragraph show that one can then understand the differences between the SPEELS spectra in Fe and Ni; in Fe, one sees clear spin-wave loss features, as predicted by theory Plihal and Mills (1998), while in Ni, so far as we know at present, one sees only the low-lying broad Stoner excitations. Quite in contrast to this, inelastic neutron scattering sees spin waves in both materials, and in the case of Ni the low-lying Stoner excitations are absent. This striking difference between loss spectra taken by the two methods, which seem so similar from the superficial point of view, have their origin in the fact that the neutrons and electrons interact with the magnetic moments in the material in a qualitatively different manner, with the consequence that the loss spectra are described by different response functions. This suggests that to observe spin waves in an itinerant ferromagnet with the SPEELS technique, one may be limited to materials with exchange splittings in the d bands that are large compared to spin-wave excitation energies.

After the observation of the spin-wave loss feature in Fe, a new spectrometer was designed and constructed in Julich, and then rendered operational in the Max Planck Institute in Halle. We now have very beautiful experimental studies in hand of spin wave dispersion and damping in an ultrathin film of Co on Cu(100) (Vollmer *et al*., 2003). As we shall see shortly, the data are in qualitative and quantitative agreement with the picture that has emerged from our theoretical studies. Subsequent studies of other ultrathin films have been completed by the Halle group. We shall not review these experiments in detail here, since an excellent and careful review of this body of data and the related theoretical literature is found elsewhere in this series (Etzkorn, Anil Kumar, and Kirschner, 2007). However, we wish to comment on some general features, and also on the new aspects of short wavelength spin excitations in ultrathin films predicted by theory, and illustrated by the data.

Earlier, we pointed out that by virtue of angular momentum conservation in the excitation process, spin-wave excitation is forbidden if the beam polarization is parallel to the majority spins in the substrate, and allowed only if the beam polarization is antiparallel to the majority spins. This is illustrated well in Figure 4, taken from the paper by Vollmer and collaborators (2003). The curve labeled $I_\downarrow$ is the loss spectrum taken for the case where the beam polarization is antiparallel to the spins of the majority electrons in the sample. We see a very clear loss feature. The curve labeled $I_\uparrow$ is for the case where the beam polarization is parallel to the substrate majority spins. The loss feature is absent, except for a small feature with origin in the fact that the beam is not perfectly polarized. This data serves as a lovely experimental verification of a fundamental conservation law, which follows from the fact that the excitation matrix element has its origin in the spin independent Coulomb interaction. We see clearly from this example that through use of polarized electron beams, one may unambiguously identify loss features as spin waves.

Figure 5, again reproduced from the paper of Vollmer *et al*., shows a series of loss spectra taken for a sequence of wave vector transfer directed along the [11] direction

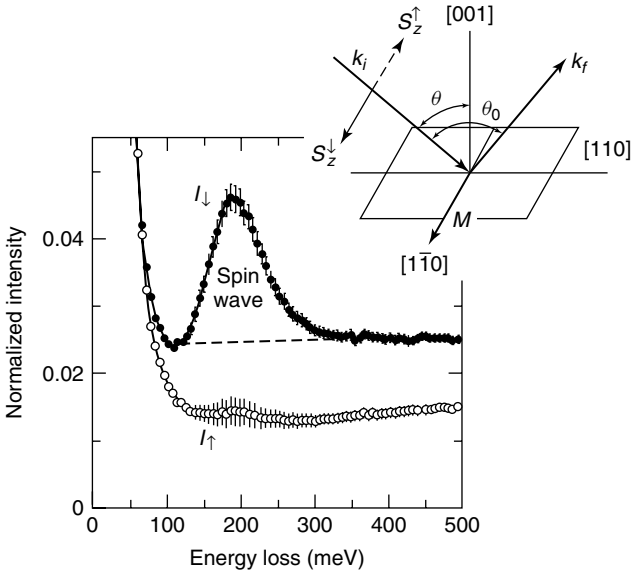

Figure 4. An example of the spin-wave loss feature in the SPEELS spectrum of an ultrathin Co film on Cu(001). The scattering geometry is illustrated in the inset. The curve labeled $I_\downarrow$ is a loss spectrum taken with beam polarization antiparallel to that of the majority spins in the substrate, whereas the curve labeled $I_\uparrow$ is taken with beam polarization parallel to the majority spins in the substrate. (Reproduced from Vollmer *et al*., 2003, with permission from the American Physical Society. © 2003.)

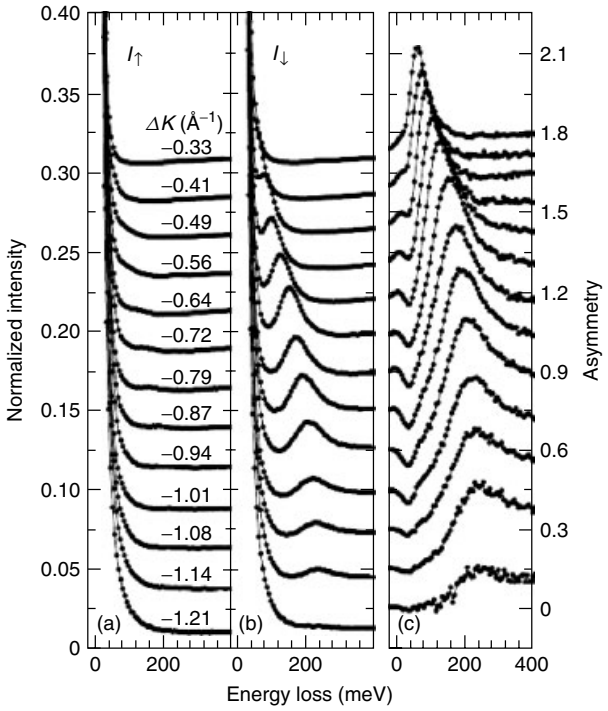

Figure 5. A series of loss spectra illustrating the spin-wave loss feature, taken for various wave vector transfers along the [11] direction of the surface Brillouin zone, for an ultrathin Co film on Cu(001). In (a), the loss spectra are for the case where the beam polarization is parallel to the majority spins in the sample, in (b) the beam polarization is antiparallel to the majority spins in the substrate, and (c) is the asymmetry A, defined as $(I_\downarrow - I_\uparrow)/(I_\downarrow + I_\uparrow)$. (Reproduced from Vollmer *et al*., 2003, with permission from the American Physical Society. © 2003.)

of the two-dimensional Brillouin zone. In (a), we have loss spectra taken with beam polarization parallel to the substrate majority spins, in (b) we have spectra taken for the antiparallel configuration, and in (c) we have the asymmetry A defined as $A = (I_\downarrow - I_\uparrow)/(I_\downarrow + I_\uparrow)$. One sees two key features in these data (i) there is a *single* loss feature, which shows dispersion with wave vector similar to that expected for a spin wave, and (ii) the linewidth increases with wave vector, to become very large at the largest wave vectors explored in the experiment. The spectrometer has resolution to resolve the linewidth in all the loss spectra shown. Thus, as we move out in the Brillouin zone, we have a very heavily damped excitation with a short lifetime.

The spectra just described are striking. To see this, we discuss what is expected on the basis of the commonly used model of spin excitations in ferromagnets, the Heisenberg model. Here one envisions localized magnetic moments on the lattice sites, described by the Hamiltonian $H = -\sum_{i,j} J_{i,j} \vec{S}_i \cdot \vec{S}_j$. If one applies this Hamiltonian to a ferromagnetic film with N layers, the following picture of the spin excitations emerges (Mills, 1970, 1984). First of all, by virtue of translational symmetry in the two directions of the surface all spin-wave modes are characterized by a two-dimensional wave vector $\vec{k}$, which resides in the appropriate two-dimensional Brillouin zone. Then for an N layer film, for each choice of $\vec{k}$, there are precisely N distinct spin-wave frequencies. Each mode, of course shows dispersion as the wave vector is varied. Very importantly, in the Heisenberg model, each of these N modes is an exact excited state of the Hamiltonian and has infinite lifetime. Of course at finite temperatures, there will be a finite linewidth for each mode, but well below the Curie temperature the linewidth calculated from the Heisenberg model is small.

So the spectra reported by Vollmer and coworkers differ qualitatively from the description in the previous paragraph. They are in full agreement with the predictions of our earlier calculations, carried out within the framework of an itinerant description of the metallic ferromagnetic film/substrate combination (Muniz and Mills, 2002; Costa, Muniz and Mills, 2003a,b). While these studies were carried out for Fe films on the W(110) surface rather than Co on Cu(100), as later work shows the qualitative nature of the theoretical spectra seems robust and very similar for these two different systems. The theory shows that near center of the Brillouin zone, one has an acoustical spin-wave mode where the spins

in the various layers precess in phase. This mode is rather weakly damped for small wave vectors. Near the center of the Brillouin zone, one finds higher energy standing spin-wave modes, with wave vector perpendicular to the film given to good approximation by $q_\perp \sim n\pi/d$, with d the film thickness. The Heisenberg model leads one to expect standing wave modes with n ranging from 1 to $N-1$ which, when combined with the acoustic mode provides us with N modes. The theory for these itinerant systems shows that even the mode with $n = 1$ is very heavily damped, and when the spin fluctuation spectrum of the film is calculated this mode has a linewidth larger than that of the acoustic mode by roughly 2 orders of magnitude. The higher order standing wave modes with $n > 1$ are so heavily damped that they are barely perceptible as structures in the spectrum of spin fluctuations. As one proceeds into the Brillouin zone toward the zone boundary, one sees two or three low-lying modes, which become progressively more heavily damped until they merge into a single broad feature. This single broad feature shows dispersion characteristic of a spin very much as we see in the spectra illustrated in Figure 5. The damping mechanism is unique to the metallic state of these ultrathin ferromagnets.

The physical picture of the origin of the damping is as follows. If one imagines setting up a coherent spin wave in the array of atomic moments at time $t = 0$, then the moments are precessing in a gas of conducting electrons. The spin motions are damped through what one might call a kind of friction created by stirring up the conduction electrons. To be more precise, the spin-wave frequency in these systems is embedded within the continuum of Stoner excitations, and thus the spin wave can decay to this manifold of excited states. This mechanism also enters in the metallic ferromagnets as we have seen and as discussed many years ago (Cooke, Lynn and Davis, 1980). However, the calculations for the ultrathin films show this damping to be much more severe than in the bulk materials. It is clear that the metallic nature of the substrate plays a role for the thinnest films. The damping is much less severe for free-standing films, in the theory, than for films adsorbed on metallic substrates. Also, in the bulk materials spin waves are characterized by a three-dimensional wave vector, and there is conservation of wave vector in the damping process. The combined wave vector of the particle and the hole in the final state Stoner excitation is constrained to sum up to that of the spin wave. In the film, the absence of translational symmetry in the system in the direction normal to the surface relaxes of perpendicular wave vector, thus opening up new decay channels.

In Figure 6, we show a comparison between theory and experiment, for data on the eight layer Co film on Cu(001) reported by Vollmer and his collaborators (Vollmer *et al*., 2003) In (a), the data and theory are compared

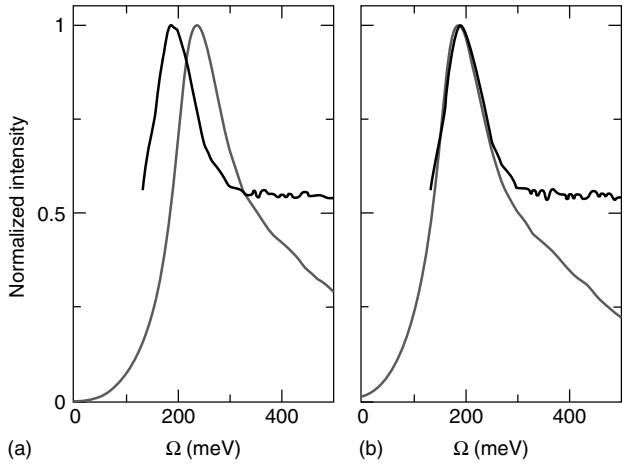

Figure 6. A comparison between theory and experiment, for the case of a spin-wave loss feature for the eight layer Co film on Cu(001). In (a) we have a direct comparison, and in the theory the spin wave is a bit higher in frequency than found in the experiment. In (b) the theoretical curve has been shifted down a bit so the width of the theoretical and experimental feature may be compared directly. (Reproduced from Costa *et al*., 2004, with permission from the American Physical Society. © 2004.)

directly. In the theory, which contains no free parameters, the calculated spin-wave frequency is a bit higher than found in the experiment. In (b), the theoretical curve has been shifted so the calculated linewidth and lineshapes may be compared with experiment. The agreement between theory and experiment is excellent. We note that, as discussed by Costa *et al*., the calculated spin-wave frequencies are found to be quite sensitive to the strength of the intra-atomic Coulomb repulsion between electrons within the 3d shell of the Co atoms (Costa, Muniz and Mills, 2004). A small shift in this parameter, taken from an empirical analysis of exchange splittings within d shells measured by photoemission, can bring the calculated frequencies in line with the data. In the data, we see the spin wave loss structure followed by an upturn in the loss spectrum. The upturn is the low frequency wing of the Stoner spectrum. This is from the theory, since the calculations explore not χ_{SPEELS} but rather $\chi_{+,-}$. The latter can be computed much more easily than the former, particularly for ultrathin films on substrates. A full calculation of χ_{SPEELS} for a multilayer ferromagnetic film on a substrate remains a computational challenge, so we must do with $\chi_{+,-}$ at present.

Thus, we see that the spin-wave features in the SPEELS loss spectra differ qualitatively from the expectations of the Heisenberg model. However, the general features of the observed spectrum are in accord with predictions, and in fact subsequent theory provides an excellent account of the observations. The metallic character of both the ultrathin ferromagnet and the substrate are responsible for the behavior

found. We shall have much more to say about this issue in the following section on theoretical descriptions of spin excitations in the 3d ferromagnets.

At the time of this writing, the experimental study of spin waves by the SPEELS technique is in its early stages. As new and improved spectrometers come on line, we may expect this method to emerge as a powerful tool for the study of spin excitations in diverse magnetic materials.

3 THEORETICAL DESCRIPTIONS OF SPIN WAVES IN THE 3D FERROMAGNETIC METALS

In Section 2, in our discussion of experimental studies of spin waves in the 3d ferromagnetic metals, we cited and discussed numerous theoretical papers which provide a conceptual base for understanding the measurements, and for interpretation of the data. However, we said very little about the theoretical techniques employed in these studies. In this section, we will describe how one goes about generating theoretical descriptions of the spin waves probed in the experiments described in the preceding text. We shall divide the discussion into three parts. First, we have seen that both FMR and BLS studies explore spin waves whose wavelength is long compared to the lattice constant of the material. As we have seen, such long wavelength modes may be described by phenomenology for which ferromagnetism is the analog to the theory of elasticity for the treatment of long wavelength acoustical phonons. We then discuss microscopic theories of spin waves in the bulk 3d ferromagnets, and finally we turn to theoretical descriptions of the ultrathin film systems

3.1 Phenomenological theory of long wavelength spin waves in bulk ferromagnets and in magnetic nanostructures

In remarks above, we outlined very briefly the principal concepts that enter the phenomenology of long wave spin waves in ferromagnets. Here, we discuss the topic in more detail.

The description proceeds by introducing the magnetization per unit volume $\vec{M}(\vec{r}, t)$. We consider a microscopic volume ΔV sufficiently large that many spins are contained within it. The spins within ΔV are tightly coupled by very strong exchange interactions so they always remain parallel and fully ferromagnetically aligned. As we move through the material and sample, the magnetization over length scales very large compared to the linear dimensions of ΔV, this quantity may vary slowly in space and time. As the magnetization precesses in response to an external probe, or engages in thermal fluctuations, this vector remains fixed in length everywhere. Thus, the phenomenology is confined to disturbances in the magnetization whose length scale is sufficiently long that a volume ΔV such as that just defined can be introduced.

To proceed with the discussion of the dynamics of the magnetization, we must construct an underlying Hamiltonian and then we must develop the means of generating an equation of motion from this Hamiltonian. For the purposes of this section, we limit our attention to the case for which the magnetization in its quiescent state is spatially uniform. We then write the magnetization as $\hat{z}M_S$, where M_S is referred to as the *saturation magnetization*. The assumption that the magnetization is uniform in space is adequate for many of the sample configurations encountered in practice. If we consider samples of selected shapes, application of a modest external magnetic field will suffice to remove domains, and produce a state wherein the magnetization is uniform over the sample. This is the case for films, which may be viewed as infinite in extent, for cylinders, for spheres, and more generally for samples of elliptical shape. Films, cylinders, and spheres are all special limits of an ellipsoid of revolution. In samples of more complex shape, such as a rectangular prism, in sufficiently high applied field the magnetization may be regarded as spatially uniform to good approximation, though one must proceed with caution in such situations, since the static internal demagnetizing fields generated by surface magnetic charges can be quite nonuniform in space. A measure of the strength of such fields can generally be taken to be $4\pi M_S$ as a rough guide, and the magnetization will be spatially uniform to good approximation only if the applied external field is large compared to this quantity.

We may construct a phenomenological Hamiltonian as follows. First, we have the Zeeman interaction of the magnetization with the externally applied field. This may be written

$$H_Z = -H_{\text{int}} \int_V M_z(\vec{r})\, \mathrm{d}^3 r \tag{4}$$

We prefer to discuss the phenomenology in the language of the quantum theory, since there are physical situations where we need to describe the quantum nature of the spin-wave excitations. An example is BLS, where single quanta are created or adsorbed in the scattering process. Thus, in equation (4), $M_z(\vec{r})$ is the operator, in the Schrodinger representation of quantum mechanics, corresponding to the z component of magnetization density. We shall have more to say about the structure of this operator shortly. In equation (4), H_{int} is the internal magnetic field, which is parallel to magnetization density for samples of the special

shapes outlined above. Thus, for a sphere, we have $H_{\rm int} = H_0 - 4\pi M_{\rm S}/3$, for a film magnetized parallel to its surface, $H_{\rm int} = H_0$ and for a film magnetized perpendicular to its surface, $H_{\rm int} = H_0 - 4\pi M_{\rm S}$. In the latter case, in the absence of surface anisotropy the perpendicular state is stable only if $H_0 > 4\pi M_{\rm S}$. Here H_0 is the externally applied field.

When the magnetization is set in motion, it generates a dipolar field we may call $\vec{h}_{\rm d}(\vec{r})$. We thus have a second term, the interaction of the magnetization with this dipolar field. This has the form

$$H_{\rm d} = -\frac{1}{2}\int_V \vec{h}^{(\rm d)}(\vec{r}) \cdot \vec{M}(\vec{r})\, {\rm d}^3 r \tag{5}$$

The factor of 1/2 enters equation (5) because, as we see next, the dipolar field is linearly proportional to the spatially varying magnetization itself, so we have here a self energy term in the Hamiltonian.

To excellent approximation, the dipolar field may be calculated from magnetostatics. Thus we may write $\vec{h}^{(\rm d)}(\vec{r}) = -\vec{\nabla}\Phi_{\rm M}(\vec{r})$, where the magnetic potential is found from the condition $\vec{\nabla} \cdot \vec{b} = 0$, with $\vec{b} = \vec{h}^{(\rm d)} + 4\pi\vec{M}$. Thus, we find the magnetic potential from Poisson's equation

$$\nabla^2 \Phi_{\rm M}(\vec{r}) = 4\pi \nabla \cdot \vec{M}(\vec{r}) \tag{6}$$

It is an elementary matter to write down the formal solution to equation (6). When this is used to calculate the dipolar field $\vec{h}^{(\rm d)}(\vec{r})$ and the result inserted into equation (5), one can express $H_{\rm d}$ as a quadratic form in the magnetization density $\vec{M}(\vec{r})$.

Spatial variations in the magnetization are resisted by the strong exchange interactions between the spins, which are responsible for the ferromagnetism in the material. This gives rise to a contribution to the energy density of the material, which is quadratic in the spatial derivatives $\partial M_\alpha/\partial x_\beta$. The coefficients are the analogue of the elastic constants of the theory of elasticity. For this exposition, we confine our attention to the case where the material is cubic in form. Then symmetry reduces the structure to one in which we have a single parameter D, the spin-wave exchange stiffness. We refer to this term as the exchange contribution to the Hamiltonian, and write it as (for the cubic case)

$$H_{\rm ex} = \frac{D}{2M_{\rm S}} \sum_\alpha \int_V \left|\vec{\nabla} M_\alpha(\vec{r})\right|^2 \tag{7}$$

When this formalism is applied to ultrathin films, care must be taken to structure an exchange term compatible with the symmetry of the system considered. For example, films grown on the W(110) surface have a rectangular unit cell. Explicit calculations of the exchange stiffness for an Fe monolayer on W(110) show that there is a very large in-plane exchange anisotropy for this case (Muniz and Mills, 2002). If a film is grown on a substrate where the two-dimensional unit cell is a square, such as the Cu(100) surface, then the lattice mismatch may lead to a unit cell in the film tetragonal in character. Thus, once again we have symmetry much lower than assumed in the commonly used form in equation (7). The in-plane exchange stiffness is necessarily the same in the two principal directions, but may differ substantially from that perpendicular to the plane in the example just cited. An example of a system where such a tetragonal distortion is large and exerts an influence on various magnetic properties has been discussed by Baberschke and his coworkers Schultz and Baberschke (1994). We shall remain here with the simple form in equation (7).

A partial integration on equation (7) yields a more useful form for the exchange energy:

$$\begin{aligned} H_{\rm ex} = &-\frac{D}{2M_{\rm S}} \sum_\alpha \int_V M_\alpha(\vec{r}) \nabla^2 M_\alpha(\vec{r})\, {\rm d}^3 r \\ &+\frac{D}{2M_{\rm S}} \sum_\alpha \int_S M_\alpha(\vec{r}) \hat{n} \cdot \vec{\nabla} M_\alpha(\vec{r})\, {\rm d}S \end{aligned} \tag{8}$$

The second term is an integral over the surface of the sample, with $\hat{n}$ an outward pointing unit normal to the surface.

In our earlier discussion of anisotropy, it was mentioned that there were two sources of anisotropy, the shape anisotropy and a local anisotropy of spin-orbit origin whose form is controlled by the local site symmetries in the material. Shape anisotropy, whose origin is in the long-ranged dipolar fields generated by the magnetization, is included fully by the above structure through $H_{\rm int}$. Anisotropy of spin-orbit origin must be introduced through additional terms in the Hamiltonian. These take the form

$$\begin{aligned} H_{\rm a} = &\sum_{\alpha\beta} \frac{K^{(2)}_{\alpha\beta}}{M_{\rm S}^2} \int_V {\rm d}^3 r\, M_\alpha(\vec{r}) M_\beta(\vec{r})\, {\rm d}^3 r \\ &+ \sum_{\alpha,\ldots\delta} \frac{K^{(4)}_{\alpha\beta\gamma\delta}}{M_{\rm S}^4} \int_V {\rm d}^3 r\, M_\alpha(\vec{r}) M_\beta(\vec{r}) M_\gamma(\vec{r}) M_\delta(\vec{r}) \end{aligned} \tag{9}$$

Time reversal symmetry allows only even powers of the magnetization to appear on the right hand side of equation (9). Symmetry controls which coefficients in equation (9) are nonzero. For the commonly encountered but special case of cubic symmetry, one has $K_{\alpha\beta} = K\delta_{\alpha\beta}$, so the first term is then proportional to $M_x^2 + M_y^2 + M_z^2 = M_{\rm S}^2$. Thus the first term is silent for such materials, and their anisotropy is controlled by the quartic term. We could include higher powers of the magnetization in equation (9), but they will be small

in magnitude because equation (9) can be understood to be a perturbation expansion in powers of the strength of the spin-orbit coupling, which is weak for the 3d ferromagnets. If λ measures the strength of the spin-orbit coupling, and W is the bandwidth of the itinerant 3d electrons which carry the magnetism in the materials of interest, then equation (9), formally, is an expansion in powers of (λ/W) (Mills, 1994).

We have one more term to discuss. This is the surface or interface anisotropy, which we have seen in the preceding text plays a critical role in ultrathin films and more generally in nanoscale magnetic structures. The site symmetry on surfaces and interfaces is uniaxial, and usually the leading term in an expansion such as that in equation (9) is dominant. We may then write the surface anisotropy in the form

$$H_{\mathrm{a}}^{(\mathrm{S})} = \int_{\mathrm{S}} \frac{K_{\mathrm{S}}(\hat{n})}{M_{\mathrm{S}}^2}[\hat{n}\cdot\vec{M}(\vec{r},t)]^2\,\mathrm{d}S \tag{10}$$

When $K_{\mathrm{S}}(\hat{n})$ is positive, the local region on the surface is a hard axis, and when it is negative, we have an easy axis. Here $\hat{n}$ is an outward directed unit vector normal to the surface.

The next step is to generate an equation of motion for the magnetization components. Within our quantum theoretic formulation, we may write down equations of motion for the operators $M_\alpha(\vec{r},t)$ in the Heisenberg representation. These have the well-known form

$$i\hbar\frac{\partial M_\alpha(\vec{r},t)}{\partial t} = [M_\alpha(\vec{r},t), H] \tag{11}$$

To proceed with the construction of the right hand side of equation (11), we require commutation relations between the various components of the magnetization. These have been derived by Kittel (1963a) and take the form

$$[M_x(\vec{r},t), M_y(\vec{r}',t)] = i\mu_0 M_z(\vec{r},t)\delta(\vec{r}-\vec{r}') \tag{12}$$

plus forms generated by permuting x, y, and z. We also have $[M_\alpha(\vec{r},t), M_\alpha(\vec{r}',t)] = 0$. In these expressions, μ_0 is the magnetic moment in each unit cell of the material.

The discussion just given allows one to derive equations of motion that describe not only the small amplitude spin motions of interest to spin-wave theory but also the full nonlinear equations which can be applied to large amplitude spin motions as well. One may show that the right hand side of equation (11) can be written in the form of the first torque term in equation (1), where the effective field $\vec{H}_{\mathrm{eff}}(\vec{r},t)$is given by $\hat{z}H_{\mathrm{int}} + \vec{h}_{\mathrm{d}}(\vec{r},t)$ plus terms from the exchange and anisotropy contributions to the Hamiltonian. We shall not quote the general form of this structure; the interested reader can derive its form for any particular model of interest. The relaxation term at the right hand side of equation (1) does not emerge from the formalism set up so far. This must either be added as a phenomenological structure such as that shown in equation (1) or derived from a suitable microscopic theory, though this cannot be done in general. As we have seen from our discussion of the two-magnon damping mechanism in the section on FMR in ultrathin films, in real materials the simple phenomenological form in equation (1) can prove inadequate.

If our desire is to discuss small amplitude motions of the magnetization appropriate to the description of spin waves, then one proceeds as follows. One writes

$$\vec{M}(\vec{r},t) = M_z(\vec{r},t)\hat{z} + m_x(\vec{r},t)\hat{x} + m_y(\vec{r},t)\hat{y} \tag{13}$$

where $m_{x,y}(\vec{r},t)$ are regarded as small. Then in the limit of small amplitude motions, from the constraint $m_x^2 + m_y^2 + M_z^2 = M_{\mathrm{S}}^2$, we have

$$M_z \cong M_{\mathrm{S}} - \frac{1}{2M_{\mathrm{S}}}(m_x(\vec{r},t)^2 + m_y(\vec{r},t)^2) \tag{14}$$

Through use of equations (13) and (14), the Hamiltonian may be reduced to a quadratic form in the small amplitudes $m_x(\vec{r},t)$ and $m_y(\vec{r},t)$. The relevant commutation relation for use in generating equations of motion for $m_x(\vec{r},t)$ and $m_y(\vec{r},t)$ becomes

$$[m_x(\vec{r},t), m_y(\vec{r},t)] = i\mu_0 M_{\mathrm{S}}\delta(\vec{r}-\vec{r}') \tag{15}$$

Suppose we apply the above formalism to a simple but commonly encountered geometry. This is a film of thickness d magnetized parallel to its surfaces, with surface anisotropy present. We take the z axis parallel to the magnetization, and the y axis normal to the film surfaces, which are then parallel to the xz plane. We have the ultrathin film limit in mind, and we suppose that surface anisotropy is dominant. The Hamiltonian can then be written

$$H = H_{\mathrm{V}} + H_{\mathrm{S}}^{>} + H_{\mathrm{S}}^{<} \tag{16}$$

where

$$\begin{aligned} H_{\mathrm{V}} = {} & \frac{H_0}{2M_{\mathrm{S}}}\int_V \left[m_x(\vec{r})^2 + m_y(\vec{r})^2\right]\mathrm{d}^3r \\ & -\frac{1}{2}\int_V \left[h_x^{(\mathrm{d})}(\vec{r})m_x(\vec{r}) + h_y^{(\mathrm{d})}m_y(\vec{r})\right]\mathrm{d}^3r \\ & -\frac{D}{2M_{\mathrm{S}}}\int_V \left[m_x(\vec{r})\nabla^2 m_x(\vec{r}) + m_y(\vec{r})\nabla^2 m_y(\vec{r})\right]\mathrm{d}^3r \end{aligned} \tag{17}$$

$$H_{\rm S}^{>} = +\frac{D}{2M_{\rm S}} \int\limits_{y=+d/2} \left[m_x(\vec{r}) \frac{\partial m_x(\vec{r})}{\partial y} + m_y \frac{\partial m_y(\vec{r})}{\partial y} \right] {\rm d}x{\rm d}z + \frac{K_{>}^{\rm S}}{M_{\rm S}^2} \int\limits_{y=+d/2} m_y(\vec{r})^2 {\rm d}x{\rm d}z \tag{18}$$

and

$$H_{\rm S}^{<} = -\frac{D}{2M_{\rm S}} \int\limits_{y=-d/2} \left[m_x(\vec{r}) \frac{\partial m_x(\vec{r})}{\partial y} + m_y(\vec{r}) \frac{\partial m_y(\vec{r})}{\partial y} \right] {\rm d}x{\rm d}z + \frac{K_{<}^{\rm S}}{M_{\rm S}^2} \int\limits_{y=-d/2} m_y(\vec{r})^2 \, {\rm d}x{\rm d}z \tag{19}$$

This Hamiltonian structure leads to equations of motion in the bulk of the film, in the regime $-(d/2) < y < +(d/2)$, of the form

$$\frac{\partial m_x}{\partial t} = -\gamma(H_0 - D\nabla^2)m_y + \gamma h_y^{(\rm d)} \tag{20a}$$

$$\frac{\partial m_y}{\partial t} = \gamma(H_0 - D\nabla^2)m_x - \gamma h_x^{(\rm d)} \tag{20b}$$

where once again we have $\vec{h}^{(\rm d)} = -\nabla\Phi_{\rm M}$ and for the film

$$\nabla^2\Phi_{\rm M} = 4\pi \left[\frac{\partial m_x}{\partial x} + \frac{\partial m_y}{\partial y} \right] \tag{20c}$$

We have boundary conditions at each surface of the film, which must be imposed, in order to obtain a solution to these equations. The first two may be called the *electrodynamic boundary conditions*. We must conserve the two tangential components of the dipolar field $\vec{h}^{(\rm d)}$across both surfaces; as we know from textbook discussions of magnetostatics, this is insured if the magnetic potential $\Phi_{\rm M}$ is conserved. Then we must also conserve the normal (y) component of $\vec{b} = \vec{h}^{(\rm d)} + 4\pi\vec{m}$. One must recognize that in general, the spin motion creates time dependent fields of dipolar origin outside the body of the film. One may describe these by introducing a magnetic potential $\Phi_{\rm M}^{(\rm ext)}$ the region outside the film, which satisfies LaPlace's equation.

There are then boundary conditions imposed by the surface terms contained in equations (18) and (19). Formally these introduce terms into the equations of motion for the variables m_x and m_y which are proportional to $\delta(y \pm d/2)$. The boundary conditions follow by requiring equation (19) to be satisfied everywhere in the film including $y = \pm d/2$, and then one must set the coefficients of the two delta functions to zero if this is to be the case. At the upper surface $y = +d/2$ one then has the two conditions,

$$D\frac{\partial m_y}{\partial y} + \frac{2K_{\rm S}^{>}}{M_{\rm S}} m_y \bigg|_{y=+d/2} = D\frac{\partial m_x}{\partial y}\bigg|_{y=+d/2} = 0 \tag{21a}$$

whereas on the lower surface $y = -d/2$ we have

$$D\frac{\partial m_y}{\partial y} - \frac{2K_{\rm S}^{<}}{M_{\rm S}} m_y \bigg|_{y=-d/2} = D\frac{\partial m_x}{\partial y}\bigg|_{y=-d/2} = 0 \tag{21b}$$

We have traced through this particular example to illustrate how the presence surface anisotropy enters the description of spin dynamics in ultrathin films. For this case, and for diverse magnetic nanostructures for which the continuum theory described above is appropriate, the surface anisotropy manifests itself in the boundary conditions applied to the dynamic magnetization at the surface of the sample.

In the exposition in the preceding text, we have phrased the discussion in terms of the quantum theory of magnetization motions, since there are circumstances one encounters where truly quantum phenomena are encountered in ultrathin films and also in other nanostructures. Thus, it is useful to have the full quantum-mechanical formalism in hand. We direct the reader to an excellent discussion by Heinrich and Cochran (Heinrich and Cochran, 1993). These authors frame the discussion entirely in the language of the classical physics. The equations of motion generated by the quantum theory are in fact identical to those generated by the classical approach. The fact that this is so is insured by the correspondence principle of quantum theory, and the fact that the magnetization density as defined here is a macroscopic variable. However, even though this is so, there are circumstances where a quantum theoretic formulation of the problem is essential. This is the case any time we wish to discuss phenomena in which a single spin-wave quantum is created or destroyed; as remarked above, BLS is an example of such a physical process.

Both the classical theory and the quantum theory necessarily produce identical eigenvectors for the spin-wave modes of a sample, since each emerges from the same equation of motion. However, in the discussion of quantum-dominated phenomena, including the calculation of the temperature dependent magnetization at low temperatures, one must phrase the discussion in terms of spin-wave annihilation and creation operators, which destroy or create spin waves described by properly normalized eigenstates. There is no way one can arrive at a normalization criterion through use of the classical approach. To do this properly, a quantum theory is required. Interestingly, for finite samples of general shape, the question of how to properly normalize the eigenfunction has been discussed only very recently, by the present author (Mills, 2006). It should also be remarked that the present author finds it much more straightforward to derive equations of motion in the quantum rather than the classical method, though this clearly is a matter of taste.

We conclude this section by referring once again to the review paper by Heinrich and Cochran cited in the preceding

text (Heinrich and Cochran, 1993). Here one finds application of the theory to the analysis of data on ultrathin films for diverse systems.

3.2 Microscopic theories of spin waves in the bulk 3d ferromagnets

In the previous section, we have seen that long wavelength spin waves in bulk crystals, films, and more generally magnetic nanostructures may be described by a simple phenomenology which involves a small number of parameters which may be fitted to data.

If our interest is in short wavelength spin waves whose wave vector is well out into the Brillouin zone, then we must resort to a microscopic model. For ferromagnets and other forms of magnetically ordered crystals, the standard approach is based on the use of the Heisenberg model, which utilizes a scheme based on the notion that in each unit cell of the material we have a spatially localized magnetic moment. One then envisions that these moments are coupled together by exchange interactions of the classical Heisenberg form; so two neighboring spins interact via the classical exchange interaction, which may be written as $-J_{12}\vec{S}_1\cdot\vec{S}_2$. Such interactions in many materials may extend to next nearest neighbors and beyond.

Although it is not uncommon to see such a picture applied to the 3d ferromagnets, in fact it is clear that the physics of spin excitations in these materials is very different than what follows from the Heisenberg model. We have discussed some of these issues above, and we will address them in more detail here.

The Heisenberg model is appropriate to insulating materials where the 'magnetically active' electrons are very tightly bound within the ions, which sit on the various lattice sites. Overlap between wave functions of the spin-aligned electons on neighboring lattice sites is very small, and the partially filled magnetic shell has wave functions which differ only slightly from those in the free atom. In the language of band theory, these electrons reside in bands of zero width. Such a picture applies very well to transition-metal ions in insulating crystals, and to the rare-earth magnets where the 4f electrons are very tightly bound indeed. A signature of the fact that the magnetic electrons are highly localized is that the magnetic moment associated with the various ions in the crystal lattice is very close to that expected for an isolated atom, influenced by crystal fields. One then finds the magnetic moment per ion to be very close to an integral number of Bohr magnetons. The first clue that this picture fails badly in the 3d ferromagnets is the fact that the moment per ion is a nonintegral number of Bohr magnetons. For example, in Fe, the moment per ion is $2.2\,\mu_B$, in Co $1.7\,\mu_B$, and in Ni one has $0.6\,\mu_B$, with μ_B the Bohr magneton.

At this point, the electronic band structure of the 3d ferromagnets is very well understood. The electrons of interest reside in a series of nine energy bands (per spin direction) formed from the 4p, 4s, and 3d states of the free atom. The Fermi energy intersects this band structure where the 3d admixture into the Bloch functions is very large; the width of this region is roughly 4 eV for the 3d metals, whereas the width of the 4sp complex is in the range of 10 eV. The Bloch functions of general wave vector are admixtures of s, p, and d character as a consequence of hybridization between these states.

Ferromagnetism occurs when the Coulomb interaction between electrons becomes sufficiently strong. A rather simple argument allows one to appreciate why this is so. Suppose we consider electrons in energy bands with a paramagnetic ground state, so for each wave vector $\vec{k}$ below the Fermi energy we have one electron with spin up, and one with spin down. We then have $E_\uparrow(\vec{k}) = E_\downarrow(\vec{k})$, where the subscript refers to spin direction, and also we have $N_\uparrow = N_\downarrow$ in this state.

Now suppose that we create a spin-polarized state by taking all down spin electrons within the energy ΔE of the Fermi level, increase the energy of each electron by ΔE, flip its spin and place in an empty state in the up spin band, just above the Fermi energy E_F. We suppose that $\Delta E \ll E_F$. The change in kinetic energy of the electrons is $\Delta T = \Delta E \Delta N = (\Delta N)^2/N(E_F)$, where ΔN is the number of electrons transferred. Thus, this operation has increased the kinetic energy of the electrons in the energy bands. It costs kinetic energy to create a spin-polarized state.

Now consider the influence of the Coulomb interaction between electrons. If we consider the 'magnetically active' 3d electrons in the transition metals, there is a strong Coulomb interaction between electrons which reside in the 3d shell on a given lattice site. The dominant Coulomb interaction is between antiparallel spins on each site; the Pauli principle does not allow two parallel spins to occupy the same point in space (the many-body wave function vanishes in this circumstance) and by continuity the probability that two parallel spin electrons come close together is small. There is no such restriction on electrons of opposite spin, so to first approximation we may write the Coulomb interaction as $UN_\uparrow N_\downarrow$. After we create the spin-polarized state, we have $N_\uparrow = N + \Delta N$ and $N_\downarrow = N - \Delta N$. Hence the change in Coulomb energy is $\Delta V_C = -U(\Delta N)^2$.

The above argument shows that by creating a net spin polarization in an initially paramagnetic metal, if the Coulomb interaction between antiparallel spins is sufficiently strong that the product $UN(E_F) > 1$, the paramagnetic state is unstable with respect to formation of ferromagnetism.

This is known as the *Stoner criterion*. The criterion, derived above from a crude argument, survives within the framework of contemporary density-functional theory, and in fact the theory provides one with an *ab initio* value for the parameter U (Marcus and Moruzzi, 1988).

We pause to remark that the Stoner criterion allows one to understand the occurrence of ferromagnetism in the 3d metals. As one moves from left to right in a given row of the transition-metal series, the nuclear charge increases and causes the d wave functions to contract. Hence U increases as we move from left to right, since it scales inversely with the radius of the d orbital. This also causes the d bands to narrow, since overlap between neighboring d orbitals decreases. This increases $N(E_F)$, so the Stoner product $UN(E_F)$ increases. The ferromagnetic metals Fe, Co, and Ni lie on the right side of the 3d row. As one moves vertically downward in a given column, the 4d orbitals are spatially more extended than the 3ds, and the 5d orbitals more so than the 4d wave functions. Hence as we go down a column from the 3d row to the 5d row, the Stoner product decreases. The consequence is that ferromagnetism is found only on the right end of the 3d series.

The first step in generating a microscopic description of spin waves in the itinerant 3d ferromagnets is then to complete an electronic structure calculation, wherein the ferromagnetism is driven by the presence of Coulomb interactions between the electrons. It is a nontrivial step to proceed from the electronic band structure calculation to a description of spin waves in the itinerant magnets.

The analysis proceeds by calculating the quantity referred to as the wave vector and frequency dependent susceptibility, denoted usually by $\chi_{+,-}(\vec{k}, \omega)$, and exploring its structure as a function of frequency for fixed wave vector. The physical meaning of this function is as follows. Suppose we take our ferromagnet with magnetization parallel to the z axis, and apply a circularly polarized magnetic field in the xy plane, which oscillates with frequency ω and has a spatial dependence characterized by the wave vector $\vec{k}$. The field is thus $\vec{h}(\vec{r}, t) = h_{\vec{k},\omega}[\hat{x}\cos(\vec{k}\cdot\vec{r} - \omega t) + \hat{y}\sin(\vec{k}\cdot\vec{r} - \omega t)]$. This applied field will excite the spins, and introduce a spatially varying disturbance, which may be written as $\langle S_+(\vec{r}, t)\rangle = \langle S_+\rangle_{\vec{k},\omega}[\hat{x}\cos(\vec{k}\cdot\vec{r} - \omega t) + \hat{y}\sin(\vec{k}\cdot\vec{r} - \omega t)]$. Linear response theory then provides one with a link between the amplitude of the exciting field and the response of the system. One writes

$$\langle S_+\rangle_{\vec{k},\omega} = \chi_{+,-}(\vec{k}, \omega) h_{\vec{k},\omega} \tag{22}$$

Thus, the wave vector and frequency dependent transverse susceptibility is the proportionality constant between the applied transverse field and the amplitude of the transverse spin density induced by the field.

One proceeds to study spin waves by devising a means of calculating the transverse susceptibility just described. For fixed wave vector, if frequency is scanned, there will be a pole of this function at the frequency $\omega(\vec{k})$ of the spin wave with wave vector $\vec{k}$. If the spin wave is damped by some intrinsic process, instead of a pole one will find a resonant peak with finite width; the lifetime of the spin wave is the inverse of this width. In results to be presented below, we shall show calculations of the quantity $\mathrm{Im}[\chi_{+,-}(\vec{k}, \omega)]$. The spin wave appears as a resonant peak in this quantity, centered around the spin-wave frequency $\omega(\vec{k})$.

The calculation of the transverse susceptibility takes one into the realm of many-body theory. One is led to an integral equation, which must be solved numerically for all but the most schematic descriptions of the electron band structure. An introduction to such analyses for the very simple one band Hubbard model, where the analysis is elementary and can be carried out analytically is given by White (1970).

Two methods have been used in the study of spin-wave excitations in the bulk 3d metals. The first, introduced by Cooke and collaborators (1980) utilizes an empirical tight binding description of the electron energy bands. One begins with *ab initio* energy bands for the paramagnetic state of the material of interest, and generates a tight binding description of the 3d/4sp complex by choosing intersite hopping integrals and 3d/4sp hybridization parameters to reproduce the band structure. Ferromagnetism is driven by empirically described Coulomb interactions between electrons, which reside within the 3d shell of an ion on a specific lattice site. Depending on the scheme used, there can be from one to three parameters for this purpose. The Coulomb parameters are adjusted empirically to fit certain ground state properties such as the total magnetic moment, the fraction of the moment of 3d character, which has e_g symmetry, and the fraction which has t_g symmetry. We may refer to such schemes as multiband generalizations of the well-known Hubbard model of magnetism in itinerant systems. One may find descriptions of such analyses in various papers (Cooke, Lynn and Davis, 1980; Tang, Plihal and Mills, 1998). We note that it is essential for the empirical term which describes the Coulomb interaction to be form invariant under spin rotations. The initial studies of Cooke and coworkers used a form that did not have this property (Cooke, Lynn and Davis, 1980), though in subsequent work we see this matter corrected (Blackman *et al.*, 1985).

The scheme just described is based on a realistic underlying electronic band structure, though this is described by the empirical method just discussed. The transverse susceptibility $\chi_{+,-}(\vec{k}, \omega)$ is calculated through use of a many-body scheme known as the *random phase approximation* (RPA). The method leads to a certain integral equation one must solve numerically. The virtue of the empirical tight binding

method is that once the kernal of the integral equation is generated by numerical methods, the actual solution of the integral equation is achieved through simple inversion of a small matrix. For this reason, at present the empirical tight method is the only means of addressing spin-wave excitations in adsorbed ultrathin films, which we discuss in the next section. A full *ab initio* treatment such as that discussed in the next paragraph is still beyond the computational power available at present.

A much more satisfactory means of generating theoretical descriptions of spin waves is through *ab initio* theory, where the spin-polarized version of density-functional theory is used to generate the ground state, without resort to the simple empirical description of the Coulomb interaction employed in the empirical tight binding scheme. The transverse susceptibility is then generated through application of time dependent density-functional theory. In this fully *ab initio* scheme there are no adjustable parameters, of course. Full density-functional calculations of spin waves in bulk Ni and Fe have been reported by Savrasov, and also by Karlsson and Aryasetiawan (Savrasov, 1998; Karlsson and Aryasetiawan, 2000a,b).

While as just stated, full *ab initio* calculations of spin-wave spectra are surely more satisfactory than those based on the empirical tight binding approach, from the perspective of the physics incorporated in the two methods, there are similarities. For instance, both methods utilize a simple self-consistent mean-field description of the ground state. In density-functional theory, the influence of electron correlation beyond that in, say, Hartree–Fock theory is embedded within the exchange correlation potential, which contains no adjustable parameters. In the empirical tight binding methods, correlation effects are surely incorporated into the effective Coulomb matrix elements, but as discussed in the preceding text these are adjusted to fit data on the ground state. If one describes the content of time dependent density-functional theory by Feynman diagrams, the diagrams summed are in fact the same as those, which enter the RPA. Both methods have the feature that once the ground state is described, no further parameters are introduced to generate the description of spin waves.

As one can see from the discussions above, there are important differences in the nature of the spin waves in the itinerant ferromagnets, and those insulating solids for which application of the Heisenberg model is appropriate. In the Heisenberg model, the spin waves are *exact* eigenstates of the Hamiltonian, as excitations from the ground state. This is not the case in the itinerant materials. Here one has, for each wave vector $\vec{k}$, a continuum of spin triplet particle hole excitations formed by taking an electron from a majority spin band, and then placing it in a state in the minority spin band complex after flipping its spin and translating its wave vector by the amount $\vec{k}$. These bands of particle hole excitations are called the *Stoner continuum* as noted in our discussion of neutron scattering from spin waves. As discussed there, spin waves in the itinerant ferromagnets thus have a finite lifetime by virtue of the fact that they can decay into the Stoner continuum. These features appear in the calculations cited in the preceding text, and the onset of strong damping with increasing wave vector is evident in the neutron data we have discussed in Section 2. We shall see in our discussion of spin waves in ultrathin films adsorbed on metal substrates that in such systems, the damping is very severe indeed, to the point where the spin wave 'lives' for only two or three periods, when its wave vector is large.

We wish to conclude this section with comments on an issue that has been discussed since the early work of Cooke and his colleagues (Cooke, Lynn and Davis, 1980). We also mentioned this matter earlier, and here we wish to explore it in more detail. These authors found apparent gaps in the spin-wave dispersion relation in both Fe and Ni, along high symmetry directions and roughly in the middle of the Brillouin zone. The physical reason why such gaps should occur is puzzling, at least to the present author. The piece of dispersion curve on the high-frequency side of the gap was called an *optical spin wave* by Cooke *et al*., though clearly these materials are monatomic in nature. As remarked earlier, in our studies of spin-wave dispersion in both Fe and Ni through use of the empirical tight binding method, we have failed to find such features. We find smooth dispersion curves throughout the Brillouin zone (Tang, Plihal and Mills, 1998; Hong and Mills, 2000).

However, other authors have also found apparent gaps in spin-wave dispersion relations for Fe and Ni. We note that a survey of the literature shows that there is no consensus regarding the direction in the Brilluoin zone or the point at which the apparent gaps occur. For instance, Cooke and coworkers report a doublet in the spectral density of Fe along [100] (Cooke, Lynn and Davis, 1980) while Savrasov finds a smooth featureless dispersion curve in Fe along this same direction, in clear conflict with the earlier paper (Savrasov, 1998). Karlsson and Aryasetiawan find a gap in the spin-wave dispersion along the [111] direction in Ni (Karlsson and Aryasetiawan, 2000a), but Cooke and collaborators find their structures along the [100] direction in Ni. Furthermore the nature of their structures differs qualitatively from the gap reported by Savrasov along Ni [100] (Savrasov, 1998; Cooke, Blackman and Morgan, 1985).

Thus, while various authors have found gaps and unusual structures in the effective spin-wave dispersion relations of both Fe and Ni, no two theoretical papers agree on their nature, or even which symmetry direction in the zone the features are found. With this in mind, we wish to discuss our

own experience in which we encountered such a structure. In our study of the spin waves in an Fe monolayer adsorbed on the W(110) surface, we initially found a dispersion relation with a clear gap when the wave vector was directed along the ΓX direction in the two-dimensional Brillouin zone. The gap in our case was an artifact caused by poor convergence in the k space sums required to construct the kernal of the integral equation one must solve in the RPA description of the transverse susceptibility. The convergence issue involved is quite curious, and we illustrate this in Figure 7, reproduced from our paper on the Fe monolayer on W(110) (Muniz and Mills, 2002). The three panels show

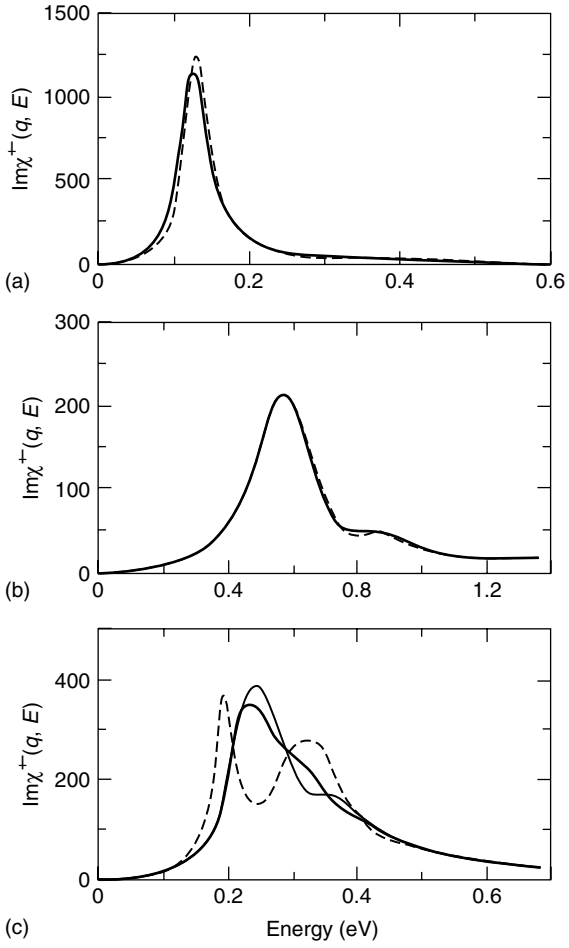

Figure 7. We illustrate convergence issues encountered in our calculation of the spin-wave dispersion relation for the Fe monolayer on W(110). We plot the imaginary part of the transverse susceptibility $\chi_{+,-}$ for selected wave vectors in the two-dimensional Brillouin zone, along the ΓX direction. In (a) the reduced wave vector is 0.25, in (b) it is 0.50, and in (c) it is 0.35. The dashed curve is a calculation based on 262 special points in the irreducible Brillouin zone for the kernal which appears in the RPA integral equation, the light solid curve is for 1036 special points, and the heavy solid curve is for 4120 points. (Reproduced from Muniz & Mills 2002, with permission from the American Physical Society. © 2002.)

the spin-wave resonance in $\mathrm{Im}(\chi_{+,-})$ for three selected reduced wave vectors along the ΓX direction. In (a), we show the calculation for a reduced wave vector of 0.25, in (b) we show the result for 0.50, and in (c) we show the result for 0.35. Let us first look at the results in (a) and in (b). In these figures, the dashed line results from a calculation where the computation of the kernal in the RPA integral equation utilized 262 special points in the irreducible Briilouin zone, and the thin solid line is a calculation, which employed 1036 such points. The dashed curve and the thin solid line nearly lie on top of each other, so it is reasonable to assume that for all wave vectors, adequate convergence can be achieved with use of 262 points. If we proceed to do this, then for a reduced wave vector of 0.35 we generate the double peaked structure evident in part (c) of the figure. If we were to stop here, and plot an effective dispersion for spin waves along the ΓX direction, we would find a gap near the reduced wave vector of 0.35. The dispersion curve and its gap have an appearance qualitatively similar to those found by Savrasov along Ni(100), and that found by Karlsson and Aryasetiawan along the (111) direction in Ni.

However, in our case the apparent gap and the doublet in Figure 7(c) are an artifact produced by poor convergence around the particular wave vector in the figure. When we use 1036 points, the doublet has disappeared (thin solid line), and we are left with a single peak. The calculation has now settled down, since use of 4120 points yields virtually the same structure.

This example, along with the contradictions found in the theoretical literature on spin waves in Fe and Ni suggests that further study of the apparent gaps and optical spin wave features should be undertaken before their existence is viewed as firmly established.

3.3 Theoretical studies of spin waves in ferromagnetic ultrathin films

It was remarked in the previous section that a full density-functional analysis of the spin-wave spectra of ultrathin ferromagnets adsorbed on substrates is beyond our capability at present. It is the case that through use of density-functional methods, one may calculate effective Heisenberg exchange interactions between nearby spins in a ferromagnetic lattice (Frota Pessoa, Muniz and Kudrnovsky, 2000; Grother, Ederer and Fahnle, 2001; Bruno, 2003). Such methods can be applied to ultrathin films to generate spin-wave spectra calculated within the adiabatic approximation (Padja *et al*., 2000; Udvardi, Szunyodh, Palotos and Weinberger, 2003). Such exchange couplings may be inserted into a Heisenberg–Hamiltonian and one may then generate a spin-wave

spectrum for the ultrathin film. In our discussion of the SPEELS data on spin waves in ultrathin films in Section 2, we have seen that a procedure such as this produces a misleading picture of the nature of short wavelength spin waves in ultrathin films. The author and his colleagues have formulated a means by which spin excitations in ultrathin structures on substrates of infinite extent may be described within a fully dynamical theory similar to the RPA descriptions discussed in the previous section of spin waves in the bulk 3d ferromagnets (Tang, Plihal and Mills, 1998; Muniz and Mills, 2002; Costa Muniz and Mills, 2003a). In the discussion presented in the subsequent text, we shall make explicit comparisons between results of full dynamical calculations and those generated from a Heisenberg–Hamiltonian applied to the ultrathin film. The dramatic failure of the latter approach will be evident. We first comment on aspects of the calculation.

A detailed discussion of our method is given in our first paper on adsorbed films (Muniz and Mills, 2002). We employ the empirical tight binding method to the adsorbed film/substrate combination. Thus, the one-electron states extend throughout the system, in general. To generate a description of the ground state of the structure, we require the one-electron Green's function. This can be built up for the film/substrate combination by an iteration method, applied numerically. As in the bulk ferromagnets, we use a mean-field description of the ferromagnetic ground state, but the magnetic moments in the ferromagnetic film are allowed to vary in a layer-by-layer fashion. There are some technical issues that must be addressed here. For instance, the multiband Hubbard model with on-site Coulomb interactions within the 3d shell does not properly incorporate the long-ranged feature of the full Coulomb interaction employed in *ab initio*, density functional based theories. Thus, one finds that the surface layer of the ultrathin film is highly charged, if one works within the multiband Hubbard model. The ground state so generated is thus rather unphysical. One must then adjust the energies of the one-electron orbitals in the surface so the orbital occupancies are brought in line with those generated from *ab initio* studies of the film. A detailed discussion of this issue, and comparisons between the empirical tight binding description of ultrathin films is presented in the paper by Tang and coworkers (1998).

Once a description of the ground state is found, one must set up an appropriate wave vector and frequency dependent susceptibility for the film by extending the concept described in the above for the bulk. This new object is defined as follows. We suppose we subject the film/substrate combination to a circularly polarized transverse magnetic field of frequency ω once again. This field has a wave vector $\vec{k}_\parallel$ in the plane parallel to the film surface, but may vary in the direction normal to the surface in an arbitrary manner. If we use l to label the atomic planes in the structure, then the externally applied field has the form

$$\vec{h}(\vec{r}_\parallel, l; t) = h_{\vec{k}_\parallel,\omega_\parallel}(l)[\hat{x}\cos(\vec{k}_\parallel \cdot \vec{r}_\parallel - \omega t) + \hat{y}\ \sin(\vec{k}_\parallel \cdot r_\parallel - \omega t)] \tag{23}$$

Such an external field induces a transverse moment $\langle S_+(\vec{r}_\parallel, l; t)\rangle$ of the form

$$\langle S_+(\vec{r}_\parallel, l; t)\rangle = \langle S_+(l)\rangle_{\vec{k}_\parallel,\omega_\parallel}(l)[\hat{x}\cos(\vec{k}_\parallel\cdot\vec{r}_\parallel - \omega t) + \hat{y}\sin(\vec{k}_\parallel\cdot r_\parallel - \omega t)] \tag{24}$$

From linear response theory, one finds that one can write

$$\langle S_+(l))\rangle_{\vec{k}_\parallel\omega} = \sum_{l'} \chi_{+,-}(l, l'; \vec{k}_\parallel, \omega)h(l')_{\vec{k}_\parallel,\omega} \tag{25}$$

One may formulate a means of calculating the response function introduced in equation (25) through use of the RPA. There is a kernal, referred to in the literature as the irreducible particle hole propagator, that must be generated from a convolution of two single particle Green's functions, which one knows once the description of the ground state of the system is completed. This object is a matrix structure with elements labeled by plane and orbital indices. A very considerable amount of computational effort is involved in generating the large number of elements to sufficient accuracy to insure converged results. Once this is done, however, for each wave vector and frequency the response function can be generated by means of a straightforward matrix inversion. This step is rendered simple by the fact that the Coulomb interaction between electrons is local in space, confined to the electrons within the 3d shell of a single ion. The computational labor required to carry through a full time dependent density-functional analysis of the large structures we have explored would be some orders of magnitude larger than that expended in our calculations.

A feeling for the physical content of the response function defined in equation (25) may be obtained by displaying its form if we do describe the spin-wave excitations in the film through use of the Heisenberg model. As we have seen, for a film with N layers, for each choice of the wave vector $\vec{k}_\parallel$ we have N spin-wave frequencies we may refer to as $\omega_\alpha(\vec{k}_\parallel)$, where α ranges from 1 to N. Associated with each mode is an eigenvector $e_\alpha(\vec{k}_\parallel; l)$, with l the layer index. The eigenvector tells us the amplitude of mode α on layer l. Then for suitably normalized eigenvectors, one finds

$$\chi_{+,-}(l, l'; \vec{k}_\parallel, \omega) = \sum_{\alpha=1}^{N} \frac{e_\alpha(\vec{k}_\parallel, l)e_\alpha(\vec{k}_\parallel l')}{\omega_\alpha(\vec{k}_\parallel) - \omega - i\eta} \tag{26}$$

Where η is infinitesimal. To illustrate the results generated from our full dynamical calculations we shall display the quantity $S(l;\vec{k}_\parallel,\omega) = (1/\pi)\mathrm{Im}\{\chi_{+,-}(l,l;\vec{k}_\parallel,\omega)\}$. We refer to this quantity as the spectral density of spin fluctuations on layer l of the film. For the Heisenberg model, one has

$$S(l;\vec{k}_\parallel,\omega) = \sum_{\alpha=1}^{N} e_\alpha(\vec{k}_\parallel,l)^2\delta(\omega-\omega_\alpha(\vec{k}_\parallel)) \qquad (27)$$

The spectral density function associated with layer l thus consists of, in the Heisenberg model, a series of delta functions at the spin-wave frequencies associated with the wave vector selected, and the integrated strength of each of the delta functions is the square of the amplitude of the eigenvector of each mode on layer l. When we calculate this function for the itinerant ferromagnetic film adsorbed on the substrate, the damping of each mode provided by its decay to the continuum of Stoner excitations will produce resonances of finite width. The lifetime of the damped spin wave is given by the inverse of this width. The integrated strength of the broadened feature can be taken to be an indication of the square of the amplitude of each of the modes, which appear in the spectrum.

We now turn to a discussion of our results for the layer dependent spectral densities for a five-layer film of bcc-Fe on W(110). These results illustrate the behavior of the spin-wave spectra we have calculated for several ultrathin film/substrate combinations.

In Figure 8(a), we show the layer dependent spectral densities for a reduced wave vector of 0.05 along the [10] direction of the two-dimensional Brillouin zone. The dashed lines are for a free-standing film, whereas the solid lines are for the film adsorbed on the substrate. For the adsorbed film, the low frequency feature is the acoustical spin-wave mode. This mode, extrapolated back to zero wave vector, is the mode one would observe in FMR. The linewidth is very narrow. We shall comment further on intrinsic linewidths in FMR later. Then the second mode is the first standing

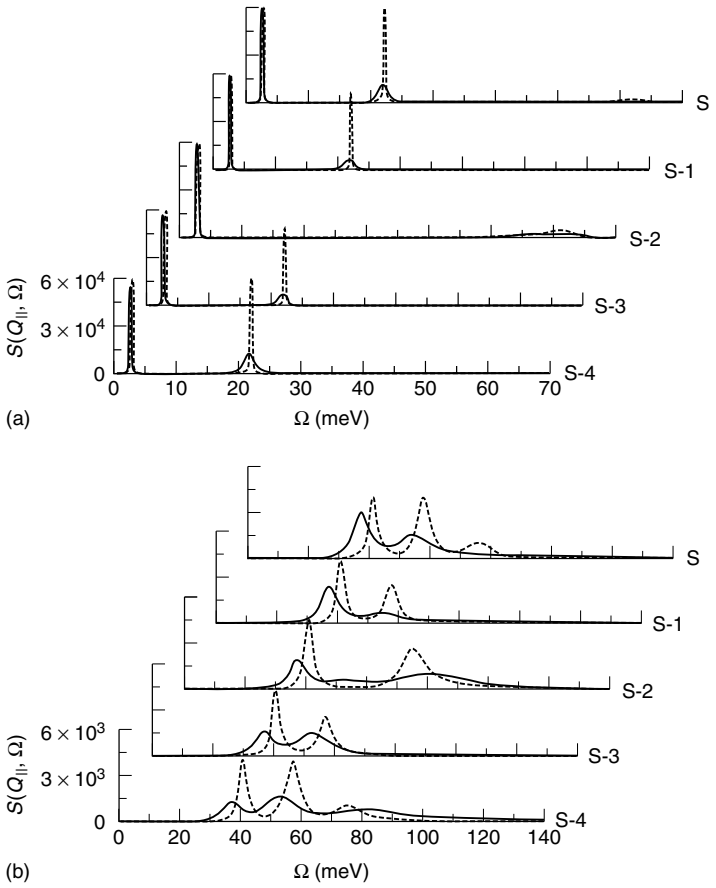

Figure 8. We show spectral densities calculated for a five-layer Fe film on W(110), for selected wave vectors along the [10] direction in the two-dimensional Brillouin zone. These are the layer dependent spectral densities defined in the text. The layer labeled S is the outer layer of the film, and layer 1 is at the interface between the film and substrate. In (a), we have results for the case where the reduced wave vector is 0.05, and in (b) the reduced wave vector is 0.2. (Reproduced from Costa *et al*., 2003, with permission from the American Physical Society. © 2003.)

spin-wave mode, whose eigenvector clearly has the cosine squared form expected through use of equation (27) as a means of representing the layer dependent spectral densities. It is, however, broadened enormously in comparison to the acoustic spin wave. Comparison of this mode with that for the free-standing film (dashed curves in Figure 8(a)) shows that the substrate plays a strong role in providing damping. This mode decays to the continuum of Stoner excitations, which carry off the spin angular momentum stored in the spin wave into the substrate by virtue of hybridization of the Fe film electron wave functions with those of the substrate. The third standing spin-wave mode is broadened so much that it is barely perceptible as a feature in the spectral density. There is a very small, broad feature evident in the middle layer of the film for this mode. Recall that if we apply the Heisenberg model to the film we would expect from equation (27) to see five modes, each with infinite lifetime. Clearly, such a picture is qualitatively wrong for systems such as these.

In Figure 8(b), we show the same information, but now for a reduced wave vector of 0.2. We see three modes, all heavily damped and they are beginning to merge into a single broad structure. Notice the difference in vertical scale between Figure 8(a) and (b). As we see from Figure 9, which shows the spectra for the reduced wave vector of 0.6, in the outer layer of the film probed by the electrons in SPEELS, we see a single broad feature. If one follows the position of this peak as a function of wave vector, one will obtain a spin wave like dispersion curve, as one sees from the example in Figure 2 of Costa Muniz and Mills (2004).

Finally in Figure 10, we show a comparison between spectral densities calculated within the full dynamical theory, and for a Heisenberg model with exchange interactions generated

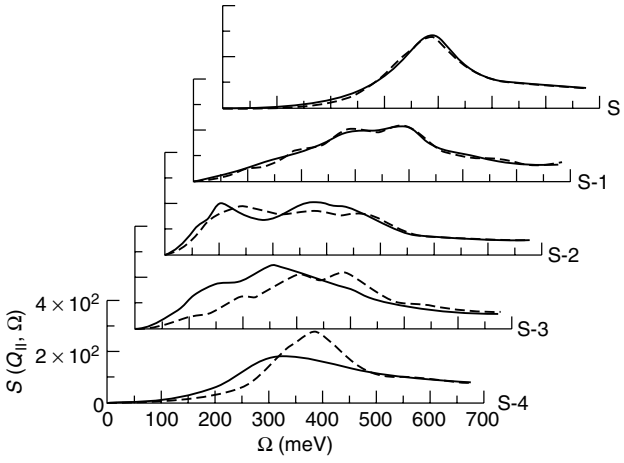

Figure 9. Same as Figure 8, except the reduced wave vector is 0.6. (Reproduced from Costa *et al*., 2003, with permission from the American Physical Society. © 2003.)

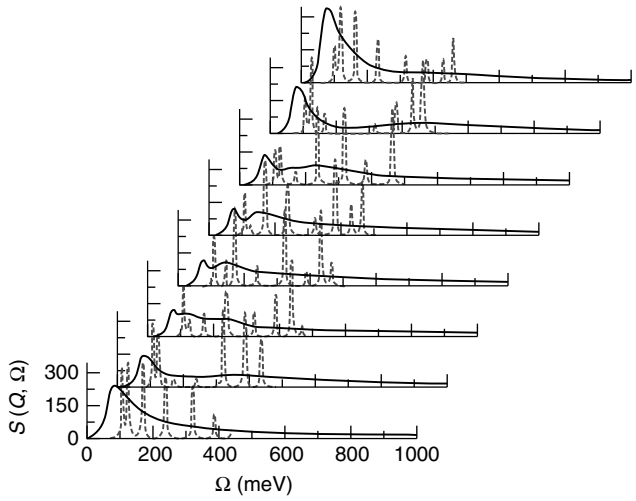

Figure 10. For an eight layer Co film on Cu(100), we show a comparison of the layer-by-layer spectral densities calculated within the full dynamical theory with those for a Heisenberg model of the film whose exchange integrals have been generated from adiabatic theory applied to the same electronic structure utilized in the full dynamical theory. The reduced wave vector is 0.3 along the [11] direction in the surface Brillouin zone. (Reproduced from Costa *et al*., 2004, with permission from the American Physical Society. © 2004.)

by adiabatic theory for the same electronic structure used in the full dynamical calculations. The calculations are for an eight layer fcc-Co film adsorbed on Cu(100), and for a reduced wave vector of 0.3 directed along the [11] direction of the surface Brillouin zone. We remind the reader that this is the system explored in the SPEELS experiments of Vollmer and collaborators (Vollmer *et al*., 2003).

We should comment on the reason for the breakdown of the Heisenberg model, when applied to the itinerant ultrathin ferromagnets. The basis for the Heisenberg model is the assumption that the adiabatic approximation is valid for a description of the spin excitations of the system. If one accepts this assumption, then one proceeds by calculating the exchange interactions between a selected pair of moments from the energy change associated with a static reorientation of the moments. If one tips a selected moment from the direction of the magnetization, torques are felt by neighboring moments, and one may deduce the value of the exchange interactions from the magnitude of the calculated torques. The infinitely long lived spin waves of the Heisenberg model follow by supposing the spin motions are sufficiently slow that adiabatic theory describes their dynamics. The calculations we have shown in Figures 8–10 show that for spin waves in the ultrathin, itinerant ferromagnets, we have a qualitative breakdown of adiabatic theory. The RPA is indeed a approximate many-body technique, but it is a fully dynamical scheme that does not invoke the adiabatic approximation.

We see from Figure 6, discussed above, that the results which emerge from this scheme applied to the empirical tight binding model appear to agree very well with the data.

In calculations of phonon spectra of metals, including that of adsorbate overlayers, the adiabatic approximation is standardly employed and the method works splendidly (Heid and Bohnen, 2003). One is tempted to argue that since the frequency of spin waves in the itinerant magnets is perhaps an order of magnitude larger than that of phonons in these same systems, this offers a basis for the breakdown of adiabatic theory for spin waves. This does not seem correct, however, because the damping rate of both phonons and spin waves scales linearly with frequency to good approximation. The damping of both phonons and spin waves in metals has its origin in decay to particle hole pairs, and if the frequency of both is low to the Fermi energy or any other characteristic energy of the electron band structure, then the damping term in the relevant dynamical response function must vary linearly with frequency. Thus, if there were no other difference, one would expect the 'Q factor' (the number of oscillations in one lifetime) of both spin waves and phonons to be roughly the same.

The breakdown of the adiabatic approximation for spin waves cannot thus be related to the much higher frequency of spin waves. Instead the breakdown has its origin in the fact that the coupling constant of the spin waves to the Stoner continuum is very much larger than the dimensionless electron–phonon coupling constant. In essence, for itinerant ferromagnets the dimensionless coupling constant is the Stoner factor, $UN(E_F)$ encountered in our simple discussion of the instability of the paramagnetic state of electrons with respect to the ferromagnetic state. This is of order unity for the 3d transition-metal ferromagnets, whereas the dimensionless electron–phonon coupling constant is small compared to unity.

We conclude this section with a discussion of one final topic, the intrinsic FMR linewidth in the ultrathin films. As discussed in the section on FMR, in the bulk form of 3d ferromagnets, the linewidth is a spin orbit based mechanism, whereas in the ultrathin films a new intrinsic mechanism is present and can be substantial in magnitude. This is the 'spin pumping' contribution to the linewidth, present when an ultrathin metallic ferromagnet is deposited on a metallic substrate. The picture set forth in the early theoretical papers which predicted the phenomenon (Berger 1996; Slonczewski, 1998) was discussed above. When the spins in the ultrathin ferromagnet are set in motion, angular momentum is transferred to the conduction electrons in these metallic films, and in the process a spin current normal to the interface is created. Thus, spin angular momentum is transported into the substrate where it is ultimately dissipated. These early calculations were based on a rather primitive model of localized spins exchange coupled to conduction electrons, viewed as free electrons. A theory of spin pumping based on one-electron theory has been set forth by Tserkovnyak, Brataas and Bauer (2002a,b) and subsequent calculations based on this formalism applied to a realistic electronic structure account well for data on spin pumping (Zwierzycki *et al*., 2005).

The spin pumping mechanism just described is clearly very much the same mechanism responsible for damping the large wave vector spin waves observed in SPEELS. To explore that this is so, we have applied our response function analyses to the issue of the linewidth in FMR. We may do this by calculating the spectral density functions at the center of the two-dimensional Brillouin zone, and then comparing the calculated linewidths to data. In our method, unfortunately, it is not possible to carry out calculations of the linewidth of the very low frequency modes actually studied in FMR. We must then apply an artificially large Zeeman and exploit the fact that the linewidth varies linearly with frequency. The method provides an excellent account of the data, as we see from Figure 11, where a comparison is made with the original observations of Urban, Woltersdorf and Heinrich (2001). We have applied our methodology also to trilayers (ferromagnetic film/nonmagnetic spacer/ferromagnetic film) adsorbed on metallic substrates, to find very excellent descriptions of the variation of linewidth of the acoustical and optical spin-wave mode of the trilayer with spacer thickness (Costa, Muniz and Mills, 2006).

It thus appears that we now have in hand theoretical descriptions of spin waves and their damping in the ultrathin ferromagnets from the zone center out to large wave vectors,

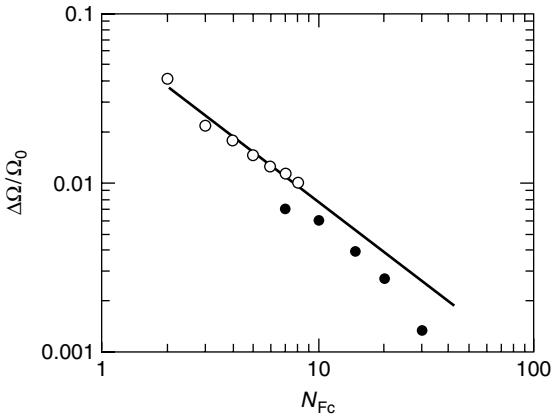

Figure 11. We show a comparison between theory (open circles) and experiment (solid dots) for the spin pumping linewidth, for Fe films on Au(100). For both theory and experiment, we show the linewidth divided by the FMR frequency, as a function of Fe film thickness. (Reproduced from Costa *et al*., 2006, with permission from the American Physical Society. © 2006. The data in the plot has been reported by Urban and coworkers, 2001.)

and the theory provides an excellent account of the data. A most important step remains. This is be the appearance of theoretical studies not based on the empirical tight binding method supplemented by the RPA but on the analyses, which employ full time dependent density-functional theory. It would be of very great interest to see such studies even for relatively small systems such as few layer free-standing films, so the results of full *ab initio* theory can be compared alongside those generated by the empirical approach. It is the view of this writer that we may see studies of small systems in the near future, but we are unfortunately far from the time where full *ab initio* calculations may be applied to the very large systems that have been studied by the empirical tight binding method. In density functional based theories of only the ground state, it is still necessary to approximate a semi-infinite substrate by a small number of layers. It is unlikely that use of such a scheme will provide adequate accounts on the damping of the spin-wave modes in ultrathin films adsorbed on metallic substrates though surely the ground state is well described with only a few substrate layers present.

Dissipative Magnetization Dynamics Close to the Adiabatic Regime

Manfred Fähnle and Daniel Steiauf
Max-Planck-Institut für Metallforschung, Stuttgart, Germany

1 INTRODUCTION

In the last few years, there has been extensive research activity to achieve a basic understanding of ultrafast magnetization processes in magnetically ordered materials. From the viewpoint of fundamental research, this issue is very interesting because the coupling of the electronic system to the lattice has to be taken into account for dissipative spin dynamics, and this is often achieved by a combination of methods of electron theory with methods of irreversible thermodynamics. From the viewpoint of magnet technology, a strong impetus came from the promising and possible applications of magnetization dynamics in micro- and nanosized magnets for advanced information storage and data processing devices in which the binary information is stored in two magnetization states, either *up* and *down*, or *up* and *zero* (i.e., demagnetized). Thereby, three different modes are currently discussed for changing the magnetic state (*switching*) – the application of an antiparallel or perpendicular (*precessional switching*) field pulse (Back and Pescia, 2004; Hillebrands and Fassbender, 2002); switching by use of a spin-polarized current (Stiles and Miltat, 2006); or switching by heating up a spot of the sample with an intensive laser pulse followed by demagnetization of the spin systems via thermalization of the highly excited electrons and excitation of phonons (Koopmans, 2003). The ultimate objective is to achieve switching times as short as possible.

The timescale of the magnetization processes is most essential for the physics and for the type of theories that are used to describe them. For near-adiabatic processes, the timescales are longer than typically several picoseconds, and then the electronic system is always close to its ground state with respect to the momentary magnetization configuration (see Section 4). Examples include the dynamics of domain walls (Thiaville, Nakatani, Miltat and Suzuki, 2005), the field- or current-induced magnetization dynamics in nanostructures (Back and Pescia, 2004; Hillebrands and Fassbender, 2002; Stiles and Miltat, 2006), and the propagation of spin waves of long wavelengths (Grotheer, Ederer and Fähnle, 2001). To describe spin waves with shorter wavelength (Costa, Muniz and Mills, 2003) or the relaxation processes on the sub-picosecond timescale after intense laser

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

pulses (Koopmans, 2003), strong electronic excitations from these ground states have to be taken into account (see also the contribution of D.L. Mills in volume I). In the present review, we confine ourselves mainly to processes close to the adiabatic limit. The main objective is to figure out the appropriate equation of motion (EOM) for magnetization dynamics, thereby including dissipative processes due to the coupling of magnetic degrees of freedom to the lattice degrees of freedom, which leads to damping. On a phenomenological level ((Kronmüller and Fähnle, 2003), see also the corresponding articles of volume II), magnetization dynamics is often described by the Gilbert equation (Gilbert, 1956) for magnetization $\mathbf{M}(\mathbf{r}, t)$,

$$\frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} = -\gamma(\mathbf{M} \times \mathbf{H}_{\mathrm{eff}}) + \frac{1}{M}\,\mathbf{M} \times \alpha \frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} \tag{1}$$

Here, γ is the gyromagnetic ratio; $\mathbf{H}_{\mathrm{eff}}$ is the effective field composed of the external field as well as the exchange, anisotropy, and dipolar fields; and α is a phenomenological damping parameter. We will see that this equation is strictly valid only under very restricted circumstances, and we will discuss appropriate modifications.

In earlier times, the dissipative magnetization dynamics driven by external fields has been discussed. In 1996, two pioneering papers (Slonczewski, 1996; Berger, 1996) initiated an overwhelming activity on magnetization dynamics induced by transport currents mainly in magnetic multilayers with very small layer thickness. In the present review, we concentrate mainly on processes driven by external fields and transport currents in single-phase systems (whereas (Stiles and Miltat (2006) and Heinrich (2005) give excellent overviews on the multilayer systems), and we just make comments on how the physical processes in non-multilayer and multilayer systems are interrelated. Furthermore, we concentrate on the spin dynamics in metals and do not consider insulators or magnetic semiconductors. We also neglect the effect of thermal fluctuations on EOM (for corresponding papers, see, e.g., Safonov and Bertram (2005) and Rebei and Parker (2003)).

A discussion of all the relevant papers on dissipative magnetization dynamics would go far beyond the scope of the present review. Instead, we illustrate the basic physical mechanisms by two intuitive and, in some respect, complementary models – the s–d model and the breathing Fermi surface model. The outline of our review is as follows. In Section 2, we define the dynamical magnetic variables used for various experimental situations, and damping is introduced in Section 3. In Section 4 we discuss two situations without (direct) damping, the case of vanishing and that of infinite scattering time of electrons. The scattering processes leading to direct damping mechanisms are discussed qualitatively in Section 5. In Section 6, we treat using two examples (s–d model and breathing Fermi surface model), how theory can describe damping by including the coupling of magnetization to other degrees of freedom in a phenomenological manner via relaxation times. In Section 7, the present status of spin dynamics simulations by the *ab initio* electron theory is described, and in Section 8, concluding remarks are given.

2 DYNAMICAL MAGNETIC VARIABLES

The starting point of any theory of magnetic dynamics is the definition of appropriate dynamical variables. The choice of these variables depends on the experimental setup that will be used to study magnetization dynamics. Because magnetization arises from spin and orbital degrees of freedom, the most general dynamical variable is the density of spin and orbital magnetic moment, $\mathbf{m}(\mathbf{r}, t) = \mathbf{m}_{\mathrm{s}}(\mathbf{r}, t) + \mathbf{m}_{\mathrm{l}}(\mathbf{r}, t)$, where $\mathbf{m}_{\mathrm{s}}$ and $\mathbf{m}_{\mathrm{l}}$ denote the spin and orbital contributions, respectively, which are defined as the quantum-mechanical expectation values of the corresponding Schrödinger operators,

$$\hat{\mathbf{m}}_{\mathrm{s}}(\mathbf{r}) = -\frac{g\mu_{\mathrm{B}}}{2} \sum_{s,s'} \hat{\psi}_s^{\dagger}(\mathbf{r})\ \hat{\boldsymbol{\sigma}}_{s,s'}\ \hat{\psi}_{s'}(\mathbf{r}) \tag{2}$$

$$\hat{\mathbf{m}}_{\mathrm{l}}(\mathbf{r}) = -\mu_{\mathrm{B}} \sum_{s} \hat{\psi}_s^{\dagger}(\mathbf{r})\ \hat{\mathbf{L}}\ \hat{\psi}_s(\mathbf{r}) \tag{3}$$

In these equations, μ_{B} is Bohr's magneton, $-g\mu_{\mathrm{B}}/2$ is the magnetic moment of the free electron, $\hat{\psi}_s$ is the s component of the spinor field operator, $\hat{\boldsymbol{\sigma}}$ is the vector of Pauli matrices, and $\hat{\mathbf{L}}$ is the angular momentum operator. The time dependencies of $\mathbf{m}(\mathbf{r}, t) = \langle \hat{\mathbf{m}}(\mathbf{r}) \rangle$ and the like arise because the expectation values have to be formed with the many-body Schrödinger wave function $|\psi(t)\rangle$ which is a solution of the time-dependent wave equation,

$$\hat{H}\,|\psi\rangle = \mathrm{i}\hbar\,|\dot{\psi}\rangle \tag{4}$$

where the Hamiltonian in general acts on the positional and spin degrees of freedom of all electrons and nuclei. (In the following, we neglect all effects resulting from dipolar interactions between magnetic moments; to take them into account would require the inclusion of a coupling term between current and vector potential in $\hat{H}$.)

Presently, there is no experimental technique to monitor $\mathbf{m}(\mathbf{r}, t)$ on all scales in space – including the subatomic scale – and on all timescales down to the shortest possible timescale (corresponding to the fast degrees of freedom) which is the electronic intersite hopping time $h/W \approx 10^{-15}$ s (h is Planck's quantum and W is the width of the electronic

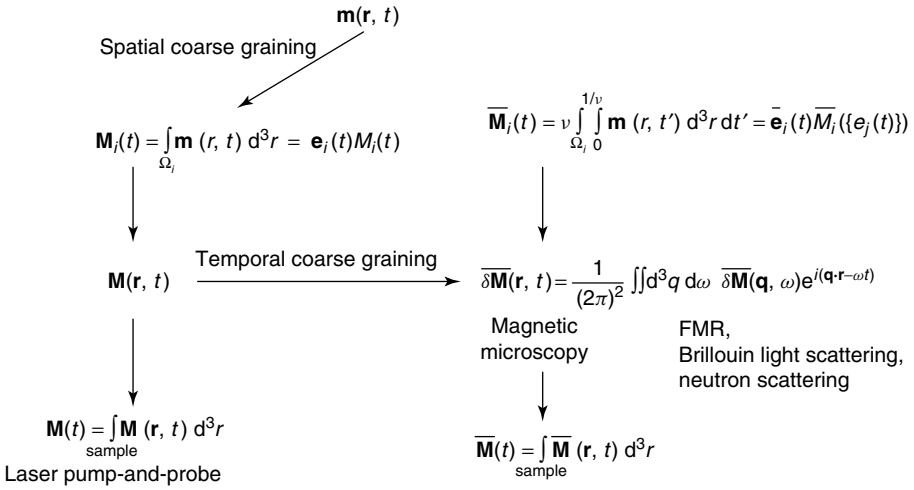

Figure 1. Schematic representation (see text) of the spatial and temporal coarse graining of $\mathbf{m}(\mathbf{r}, t)$ to define the appropriate dynamical variables for various experiments.

energy band in the solid). Therefore $\mathbf{m}(\mathbf{r}, t)$ is not an appropriate dynamical variable, it has to be coarse-grained step by step both in space and in time (see Figure 1). Concerning the coarse graining in space, we first eliminate the information at the subatomic level. To do this, we subdivide the system into disjunct space-filling parts around the atoms at sites i with volumes Ω_i, and we define atomic magnetic moments

$$\mathbf{M}_i(t) = \mathbf{e}_i(t)\, M_i(t) = \langle \hat{\mathbf{M}}_i \rangle \tag{5}$$

as expectation values for the site-moment operators

$$\hat{\mathbf{M}}_i = \int_{\Omega_i} \hat{\mathbf{m}}(\mathbf{r})\, \mathrm{d}^3 r \tag{6}$$

The atomic moments $\mathbf{M}_i(t)$ in equation (5) are characterized by their momentary directions $\mathbf{e}_i(t)$ that represent the transversal degrees of freedom and the magnitudes $M_i(t)$ that represent the longitudinal degrees of freedom. The operators $\hat{\mathbf{M}}_i$ fulfill certain commutation relations, for example, the spin part $\hat{\mathbf{M}}_{\mathrm{s},i}$ obeys

$$[\hat{M}_{\mathrm{s},i\alpha}, \hat{M}_{\mathrm{s},j\beta}] = -\mathrm{i}g\mu_{\mathrm{B}}\ \delta_{ij}\ \varepsilon_{\alpha\beta\gamma}\ \hat{M}_{\mathrm{s},i\gamma} \tag{7}$$

where α, β, and γ refer to the Cartesian indices, and where $\varepsilon_{\alpha\beta\gamma}$ are the components of the antisymmetric tensor of the fundamental three form. In the second step of spatial coarse graining, we get rid of the atomic scale information and keep only the information on the mesoscopic scale via a continuation of the atomic magnetization $\mathbf{M}_i/\Omega_i$, yielding the magnetization field $\mathbf{M}(\mathbf{r}, t)$,

$$\mathbf{M}(\mathbf{r}, t) = \sum_{i \in \Omega(\mathbf{r})} \frac{\mathbf{M}_i(t)}{\Omega_i} \tag{8}$$

where $\Omega(\mathbf{r})$ is the volume of a mesoscopic part of the sample around $\mathbf{r}$. Finally, we can define the magnetic moment $\mathbf{M}(t)$ of the whole sample via

$$\mathbf{M}(t) = \sum_i \mathbf{M}_i(t) = \int_{\mathrm{sample}} \mathbf{M}(\mathbf{r}, t)\, \mathrm{d}^3 r \tag{9}$$

In a typical laser pump-and-probe experiment (Koopmans, 2003), it is often the moment averaged over a more or less macroscopic regime which is monitored on the femtosecond timescale, so that $\mathbf{M}(t)$ as given by equation (9) is the appropriate dynamical variable. Many other experiments, however, explore only the slow magnetic degrees of freedom defined in the following way. Due to the mutual Coulomb and exchange interactions, the electronic intersite hopping is not random but the electrons arrive at an atom and leave the atom in a highly correlated way. As a result, a finite value remains for the time-averaged quantity

$$\overline{\mathbf{M}}_i(t) = \nu \int_0^{t+1/\nu} \mathbf{M}_i(t')\, \mathrm{d}t' \tag{10}$$

where $\nu \approx 10^{13}\,\mathrm{s}^{-1}$ is the frequency of a typical long-wavelength spin wave. On timescales larger than $1/\nu$, the orientations $\bar{\mathbf{e}}_i(t)$ of $\overline{\mathbf{M}}_i$ change in time and represent the independent transversal fluctuations. In contrast, the magnitudes $\overline{M}_i(t)$ are totally determined (see Section 4) by

the orientations $\overline{\mathbf{e}}_j(t)$ at all sites j, that is, the longitudinal fluctuation modes are 'slaved' by the independent transversal modes, and thus we can write

$$\overline{\mathbf{M}}_i(t) = \overline{\mathbf{e}}_i(t)\ \overline{M}_i(\{\overline{\mathbf{e}}_j(t)\}) \tag{11}$$

In analogy to equations (8 and 9), the quantities $\overline{\mathbf{M}}_i(t)$ may be further coarse grained in space, yielding $\overline{\mathbf{M}}(\mathbf{r}, t)$ and $\overline{\mathbf{M}}(t)$. In the following sections, only such situations are discussed, and therefore we omit the 'bar' denoting time average for simplicity, that is, with $\mathbf{M}_i(t)$ or $\mathbf{M}(\mathbf{r}, t)$ we address those slow degrees of freedom. As an example, for the magnetic microscopy on the nanosecond and subnanosecond timescale (e.g., by using (Stoll *et al*., 2004) the X-ray magnetic circular dichroism (XMCD)), the so-defined magnetization field $\mathbf{M}(\mathbf{r}, t)$ is the appropriate dynamical variable. Furthermore, we define the deviation, $\delta\mathbf{M} = \mathbf{M}(\mathbf{r}, t) - \mathbf{M}_{\mathrm{ref}}(\mathbf{r})$, from an appropriately chosen reference state with

$$\delta\mathbf{M}(\mathbf{r}, t) = \frac{1}{(2\pi)^2} \iint \mathrm{d}^3q\ \mathrm{d}\omega\ \ \delta\mathbf{M}(\mathbf{q}, \omega)\ \mathrm{e}^{\mathrm{i}(\mathbf{q}\cdot\mathbf{r} - \omega t)} \tag{12}$$

The limited spatial resolution thereby defines the upper limit for the $\mathbf{q}$ integration in equation (12), that is, the dynamical variable $\mathbf{M}(\mathbf{r}, t)$ also depends on the experimental details. Finally, there are other experiments on the slow timescale that investigate only single Fourier components of the deviation $\delta\mathbf{M}$ from a saturated ferromagnetic reference state. Examples are the ferromagnetic resonance (FMR) experiments (Lindner *et al*., 2003) for the uniform mode $\mathbf{q} = 0$, the Brillouin scattering experiments (Demokritov and Hillebrands, 2002) for spin waves with small $\mathbf{q}$, and the neutron scattering experiments (Mook and Paul, 1985) for spin waves with arbitrary $\mathbf{q}$. In these cases, the considered spin-wave mode $\delta\mathbf{M}(\mathbf{q}, \omega)$ is the appropriate dynamical variable.

Finally, we comment on the spin and orbital contributions to magnetization. When a sample is investigated by a magnetometer (mainly used for static situations), then the experimental signal is directly related to the total magnetic moment including both contributions. However, in most experiments with temporal and spatial resolution, things are more complicated. For instance, the signals from the XMCD microscopy (Stoll *et al*., 2004) at fixed X-ray energy are not proportional to the sum of spin and orbital contributions, but to a more complicated combination of these two contributions plus additional contributions (Ankudinov and Rehr, 1995). The resolution of spin and orbital contributions would require magneto-spectromicroscopy. Fortunately, in many metallic bulk magnets, the contribution of orbital magnetism is small for slow dynamics, and therefore in many papers (including the following sections of the present review), the term *magnetization* is used synonymously with the term *spin magnetization*. For the pump-and-probe experiments on the femtosecond timescale, however, it is important to investigate the transfer of magnetic moment between spin and orbital degrees of freedom. Such an analysis is rendered even more difficult because there is no simple relation (Koopmans, 2003) between the Kerr effect probe signal after the laser pulse and the magnetic moments.

3 DISSIPATION

When we include in the wave equation (4) the couplings between all positional and spin degrees of freedom of all electrons and nuclei, and solve it for $|\psi(t)\rangle$ for a given initial state $|\psi(t = 0)\rangle$, we obtain a quantum-mechanically coherent dynamics for $\mathbf{m}(\mathbf{r}, t)$ which contains far too much information than is required for an interpretation of most experiments. (The coherent part of the dynamics is of relevance only for the femtosecond dynamics after an intense laser pulse (Hübner and Zhang, 1998)). Furthermore, all equations would be local in time and the notion of damping would not appear in such a theory.

However, it is not the objective to investigate the dynamics of $\mathbf{m}(\mathbf{r}, t)$ obtained in this way, but to study the behavior of the dynamical variables that are appropriate for the experiment under consideration, and to write down an EOM that explicitly contains only these variables, for example, by integrating out all the other degrees of freedom. The outcome of this process is that in general the EOM contains terms which depend on the entire history (Suhl, 1998; Capelle and Gyorffy, 2003), and this is the signature for damping processes which describe the transfer of energy and angular momentum (and concomitant magnetic moment) from the considered dynamical variable to the eliminated degrees of freedom. As an example, the damping term in the Gilbert equation (1) may be conceived as the first term of the evaluation of a general damping term that is nonlocal in time, and the dissipated power R due to this term is given by Brown (1963)

$$R = \int \frac{1}{2}\frac{\alpha}{\gamma M}\left(\frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t}\right)^2 \mathrm{d}t \tag{13}$$

When all the eliminated degrees of freedom are nonmagnetic, then damping is denoted as *direct damping*, whereas relaxation processes describing the transfer from the considered dynamical variable to other magnetic degrees of freedom are called *indirect damping* (Suhl, 1998). Direct damping may be subdivided further (Heinrich, 2005) into intrinsic damping (related to 'unavoidable' phonons) and extrinsic damping (related to defects or complex geometrical features of the

sample). An example for indirect damping is the transfer from adiabatic magnetic variables to fast magnetic degrees of freedom (Costa, Muniz and Mills, 2003; Capelle and Gyorffy, 2003). Another example is the transfer from a special $\delta\mathbf{M}(\mathbf{q}, \omega)$ to other modes of the spectrum, for example, from the uniform ferromagnetic mode of an FMR experiment to spin-wave modes of finite wavelengths.

In spite of this well-defined definition of damping in theory, it is in general a delicate problem to analyze damping quantitatively, and to separate direct and indirect damping experimentally. A relatively simple situation arises if a special mode is investigated by external excitations, for example, the uniform mode in an FMR experiment or spin-wave modes in neutron or Brillouin light scattering experiments, because the excitation linewidth is a measure for damping. Furthermore, in FMR experiments on ultrathin ferromagnetic layers, the direct and indirect contributions can be separated by measuring the frequency dependence of the linewidth (Lindner *et al*., 2003). In more general situations, however, a simple procedure would exist only if there were experimentally accessible observables that are constants of motion for the case without damping. The magnetic energy E_{magn} is a constant of motion if there is no direct damping, but it is not a directly accessible observable. Another possible constant of motion is the total angular momentum of the system,

$$\mathbf{J} = \mathbf{L}_{\text{e}} + \mathbf{S}_{\text{e}} + \mathbf{L}_{\text{phonon}} \tag{14}$$

where $\mathbf{L}_{\text{e}}$ and $\mathbf{S}_{\text{e}}$ are the total orbital and total spin moment of the electrons, and $\mathbf{L}_{\text{phonon}}$ is the total lattice (phonon) contribution. (For simplicity, we have omitted the momentum of the electromagnetic field due to radiation at the moment.) If there is no direct damping, the electronic angular momentum $\mathbf{L}_{\text{e}} + \mathbf{S}_{\text{e}}$ is a constant of motion for isotropic systems. This, however, does not mean that the total magnetic moment, derived from equation (9) using equations (2 and 3),

$$\mathbf{M} = -\mu_{\text{B}}(\mathbf{L}_{\text{e}} + g\mathbf{S}_{\text{e}}) \tag{15}$$

is also a constant of motion. Only in bulk metallic systems where the orbital moment $-\mu_{\text{B}}\mathbf{L}_{\text{e}}$ is much smaller than the spin moment $-\mu_{\text{B}}g\mathbf{S}_{\text{e}}$ can we assume that the magnetic moment is approximately a constant of motion for macroscopically isotropic systems. Because the systems are not isotropic in most experiments, the investigation of $\mathbf{M}(t)$ often does not help the analysis of damping. Therefore, for a general situation the procedure to analyze damping is rather complicated. First, we have to determine $\mathbf{M}(\mathbf{r}, t)$ by some kind of magnetic microscopy (Back and Pescia, 2004; Hillebrands and Fassbender, 2002; Stoll *et al*., 2004), with the given resolution, in space and time, of the instrument. Then we compare the measured $\mathbf{M}(\mathbf{r}, t)$ with data from simulations based on an EOM including damping, for example, the Gilbert equation (1) hoping that this EOM describes the situation adequately. The comparison yields the damping constant α that can be compared with theoretical predictions in order to figure out which physical damping mechanism is operative. To check for consistency, we can calculate the magnetic energy E_{magn} from an energy functional $E_{\text{magn}}[\mathbf{M}(\mathbf{r}, t)]$ that is consistent with the nondamped part of the EOM, for example, the micromagnetic energy functional (Kronmüller and Fähnle, 2003) for the slow magnetic degrees of freedom, and E_{magn} should decrease in time if there is direct damping.

From the above discussion, it becomes obvious that damping is intimately related to the choice of the dynamical variable. Therefore it is not guaranteed that the parameters which describe damping for one choice are of much relevance for damping with respect to another choice. For instance, for the dynamics of the adiabatic variables, only electrons close to the Fermi surface are relevant (see Section 6.2), whereas for experiments on the femtosecond timescale after an intense laser pulse, 'hot' electrons are involved. Another example comes from the near-adiabatic regime. Due to the limited spatial resolution of a magnetic microscope, the adiabatic modes with wavelengths shorter than the scale of resolution are already 'integrated out' by the instrument. Therefore, instruments with different spatial resolutions in general yield at least slightly different damping parameters (Miltat, Albuquerque and Thiaville, 2002), and erroneous conclusions arise if this difference is tentatively related to different direct relaxation mechanisms.

The reader might have become disappointed after having heard about all these problems that render an accurate analysis of the data, in terms of damping mechanisms, difficult. Indeed, as is always the case for a complicated physical situation, many different experiments on many different materials will be required to arrive at a description that is at least to some extent consistent. Fortunately, a very detailed analysis is not always required to solve the big question on the ultimate timescales that can be achieved for the switching of the magnetic information in data processing devices. To do this, often the existing order of magnitude estimates are sufficient, and the large variety of experimental and theoretical investigations should be able to clarify this point.

For the rest of the paper, we consider as dynamical variables, mainly, the slow degrees of freedom; then, damping arises from any transfer of energy and angular momentum to other magnetic and nonmagnetic degrees of freedom. Examples of the involvement of the fast magnetic degrees of freedom are considered by Costa, Muniz and Mills (2003) and Capelle and Gyorffy (2003). In the following we discuss only the direct damping mechanisms related to the nonmagnetic degrees of freedom.

4 SITUATIONS WITHOUT DIRECT DAMPING – ZERO AND INFINITE ELECTRONIC SCATTERING TIMES

In the following we describe the system by an effective single-electron representation (e.g., the density-functional electron theory), and we discuss the effect of phonons or lattice defects by a scattering approach via a scattering time τ. Interestingly enough, there are two situations without damping, corresponding to $\tau \to \infty$ and $\tau \to 0$. The first case is intuitively clear because it describes the situation for which there is no coupling of the electronic system to the lattice, and hence no damping. Damping will be related to noninfinite scattering times, and for finite but still large τ we expect an increase of damping with decreasing τ. The second case corresponds to the strictly adiabatic limit ($\tau \to 0$), which will be discussed in the following. We will see that zero scattering time also rules out damping.

For the dynamics of the atomic magnetic moments $\mathbf{M}_i(t)$, we distinguish between transversal degrees of freedom, given by the orientations $\mathbf{e}_i$ of $\mathbf{M}_i = \mathbf{e}_i(t)M_i(t)$, and longitudinal degrees of freedom, given by $M_i(t)$. In the model of a strictly adiabatic situation (Gyorffy *et al.*, 1985), it is assumed that for the timescale of the slow magnetization fluctuations (see Section 2), the primary fluctuation modes of $\mathbf{M}_i(t)$ are the directional fluctuations $\mathbf{e}_i(t)$, whereas the longitudinal fluctuations are 'slaved' by the transversal fluctuations, that is, they are completely determined by the momentary orientational configurations $\{\mathbf{e}_j\}$ of the orientations $\mathbf{e}_j$ at all sites j, $M_i(t) = M_i[\{\mathbf{e}_j(t)\}]$. This means that the electronic system is assumed to be at any instant in its ground state with respect to the momentary configuration $\{\mathbf{e}_j(t)\}$. The operators $\hat{\mathbf{M}}_i$ given by equation (6) may then be represented in the form $\hat{\mathbf{M}}_i = M_i\hat{\mathbf{e}}_i$ where $\hat{\mathbf{e}}_i$ are the operators related to the dynamical variables $\mathbf{e}_i$ and M_i are just numbers at any instant. The idea is similar to the one of the Born–Oppenheimer approximation (Born and Oppenheimer, 1927), which separates the timescales for the dynamics of electrons and nuclei. Nevertheless, the magnetic situation is more complicated because it separates slow and fast degrees of freedom for the same 'species', that is, for the inhomogeneous spin-polarized electron liquid. Therefore, the derivation of an EOM for the slow degrees of freedom, that is, for $\mathbf{e}_i(t)$, is less straightforward. As a result, there are various approaches in the literature (Antropov, Katsnelson, van Schilfgaarde and Harmon, 1995; Antropov *et al.*, 1996; Halilov, Eschrig, Perlov and Oppeneer, 1998; Niu and Kleinman, 1998; Gebauer and Baroni, 2000; Grotheer, 2002) which are formally different but are all based on the same central idea. We present a derivation similar to the one given by Grotheer (2002) which is a variant of the approach of Niu and Kleinman (1998) and Gebauer and Baroni (2000).

We introduce an adiabatic state $|\psi(\{\mathbf{e}_j(t)\})\rangle$ that depends on the whole momentary configuration $\{\mathbf{e}_j(t)\}$ given by the momentary orientations $\mathbf{e}_j(t)$ at all sites j, with the following properties:

1.
$$\langle\psi(\{\mathbf{e}_j(t)\})|\,\hat{\mathbf{e}}_i\,|\psi(\{\mathbf{e}_j(t)\})\rangle = \mathbf{e}_i(t) \tag{16}$$

2. Among all the states compatible with equation (16), we select the one that corresponds to a minimal energy,
$$E(\{\mathbf{e}_j\}) = \langle\psi(\{\mathbf{e}_j(t)\})|\,\hat{H}\,|\psi(\{\mathbf{e}_j(t)\})\rangle = \min \tag{17}$$

From 1 and 2, it follows that $|\psi(\{\mathbf{e}_j(t)\})\rangle$ may be constructed as the ground state of a modified Hamiltonian,

$$\hat{H}' = \hat{H} - \sum_k \boldsymbol{\lambda}_k\hat{\mathbf{e}}_k \tag{18}$$

according to the lowest-energy solution of

$$\hat{H}'|\psi(\{\mathbf{e}_j(t)\})\rangle = E'(\{\mathbf{e}_j\})|\psi(\{\mathbf{e}_j(t)\})\rangle \tag{19}$$

with

$$E'(\{\mathbf{e}_j\}) = E(\{\mathbf{e}_j\}) - \sum_k \boldsymbol{\lambda}_k\mathbf{e}_k \tag{20}$$

Thereby the Lagrangian parameters $\boldsymbol{\lambda}_k = \boldsymbol{\lambda}_k(\{\mathbf{e}_j\})$ were introduced to guarantee that equation (16) is fulfilled. Please note that the state depends parametrically (via the $\mathbf{e}_j(t)$) on the time, but at any instant the state $|\psi(\{\mathbf{e}_j(t)\})\rangle$ is the ground state of the time-independent equation (19).

In the adiabatic approximation, we demand that the development in time of the state $|\psi(t)\rangle$ in Hilbert space is forced to be the one of the adiabatic states $|\psi(\{\mathbf{e}_j(t)\})\rangle$. In reality, however, when we solve the time-dependent wave equation with the initial state $|\psi(t=0)\rangle = |\psi(\{\mathbf{e}_j(t=0)\})\rangle$, the state $|\psi(t)\rangle$ deviates from the adiabatic state $|\psi(\{\mathbf{e}_j(t)\})\rangle$ very quickly if we neglect electronic scattering processes. The only way to realize a strictly adiabatic situation is to assume that the scattering processes instantaneously lead $|\psi(t)\rangle$ back to $|\psi(\{\mathbf{e}_j(t)\})\rangle$, that is, the adiabatic approximation corresponds to $\tau \to 0$. Using Ehrenfest's theorem, we then obtain the following EOM for $\mathbf{e}_k$,

$$\dot{\mathbf{e}}_k = \frac{1}{\mathrm{i}\hbar}\langle\psi(\{\mathbf{e}_j(t)\})|\,[\hat{\mathbf{e}}_k, \hat{H}]\,|\psi(\{\mathbf{e}_j(t)\})\rangle \tag{21}$$

Using equations (18–20) to reexpress $\hat{H}|\psi\rangle$, inserting equations (5–7), and making use of the relation

$$\boldsymbol{\lambda}_k = \frac{\delta E}{\delta \mathbf{e}_k} \tag{22}$$

which may be obtained from equation (19), we finally find the EOM in adiabatic approximation,

$$\dot{\mathbf{e}}_k = -\frac{2\mu_\mathrm{B}}{\hbar} \frac{\partial E}{\partial \mathbf{e}_k} \times \mathbf{e}_k \tag{23}$$

For instance, if the $\mathbf{e}_k$ deviate only slightly from a preferred direction, we can evaluate $E(\{\mathbf{e}_j\})$ into a Taylor series truncated after the second-order term and linearize equation (23) to obtain the well-known adiabatic EOM for spin waves (Grotheer, Ederer and Fähnle, 2001; Halilov, Eschrig, Perlov and Oppeneer, 1998). Of course, equation (23) already has the form of the Gilbert equation (1) without damping, that is, by the assumption $\tau \to 0$ underlying the strictly adiabatic limit, the damping of magnetization dynamics is eliminated. This will become clearer in Sections 6.1 (s–d model) and 6.2 (breathing Fermi surface model). The dissipated power density for magnetization dynamics described by the Gilbert equation (1) is $\frac{1}{2}\frac{\alpha}{\gamma M}(\dot{\mathbf{M}})^2$. Obviously, in the strict adiabatic limit, that is, for $\tau \to 0$ for which there is only a precession term but no damping term in the EOM, there is no energy dissipation. The situation is similar for the Drude model of electrical conductivity for which the dissipated power density is σE^2 with the electric field E and conductivity σ that is proportional to τ, that is, it vanishes for zero scattering time.

According to the above discussed limits of zero damping for $\tau \to 0$ and $\tau \to \infty$, we expect with increasing τ an increase of damping for small τ and a decrease of damping for large τ; see also Sections 5 and 6.

5 QUALITATIVE DISCUSSION OF VARIOUS DIRECT DAMPING MECHANISMS

In the following, the change of magnetic energy via electromagnetic radiation of the time-dependent magnetization field as well as relaxations due to dipolar interactions are neglected. Then a direct damping of spin magnetism is possible only in a system with spin-orbit coupling; otherwise, the Hamiltonian commutes with the operator of the total spin momentum, and the total magnetic spin moment is a constant of motion.

The various theories of direct damping of the slow magnetic degrees of freedom may be subdivided as follows:

1. Theories for the transfer of angular momentum directly from the slow magnetic degrees of freedom to the lattice;
2. Theories that treat this transfer at the electron level.

In class 1 theories, the spin-orbit coupling is taken into account implicitly on a phenomenological level via the magnetoelastic coupling between the magnetization field $\mathbf{M}(\mathbf{r}, t)$ and the lattice strain field $\underline{\underline{\varepsilon}}(\mathbf{r}, t)$ arising from a lattice defect or from a phonon distortion. Most theories determine the time for the scattering of one or more magnons at one or more phonons (Haas and Callen, 1963) or at lattice defects (e.g., Kloss and Kronmüller, 1971). In contrast, in Suhl (1998) the dynamics of a general magnetization field $\mathbf{M}(\mathbf{r}, t)$ is considered by solving the coupled system of EOMs for $\mathbf{M}(\mathbf{r}, t)$ and $\underline{\underline{\varepsilon}}(\mathbf{r}, t)$ which are derived from a general magnetoelastic energy functional. When including a shear viscosity term in the elastic part of this functional, the resulting EOM for $\mathbf{M}(\mathbf{r}, t)$ contains various other damping terms in addition to the Gilbert damping term of equation (1). Physically, damping arises because the magnetoelastic rearrangement of the atoms induced by a change of $\mathbf{M}(\mathbf{r}, t)$ requires a repopulation of phonon modes via phonon scattering ('phonon dragging') and hence requires time.

The theories of class 2 may be subdivided according to the physical mechanisms which transfer energy and magnetic moment from the atomic magnetic moments (describing the slow degree of freedom) to the single electrons, that is, Coulomb interactions or spin-current interactions. An example for the latter case is the eddy-current damping (Kittel, 1958), where the motion of the atomic moments $\mathbf{M}_i(t)$ induces electrical fields that couple to the conduction electrons in a metallic system. This leads to eddy currents which then experience Ohmic damping.

For the final transfer of energy and angular momentum from the electrons of type 2 theories to the lattice, a scattering at impurities or lattice vibrations is required. The eigenstates $\psi_k(\mathbf{r})$ of the band electrons with wave vector $\mathbf{k}$ may be written as

$$\psi_\mathbf{k}(\mathbf{r}) = a_\mathbf{k}(\mathbf{r})|\uparrow\rangle + b_\mathbf{k}(\mathbf{r})|\downarrow\rangle \tag{24}$$

where $|\uparrow\rangle$ and $|\downarrow\rangle$ are the spinor states with spin $\hbar/2$ and $-\hbar/2$, respectively. The two spinor states are in any case mixed by spin-orbit coupling (an additional source for this mixing is a noncollinearity of the magnetic configuration). For the small mixing via spin-orbit coupling the variety of states $\psi_\mathbf{k}$ can be subdivided into those that have predominantly spin-up character ($a_\mathbf{k}(\mathbf{r}) \gg b_\mathbf{k}(\mathbf{r})$, denoted by $\psi_\mathbf{k}^\uparrow(\mathbf{r})$) and those that have predominantly spin-down character ($b_\mathbf{k}(\mathbf{r}) \gg a_\mathbf{k}(\mathbf{r})$, denoted by $\psi_\mathbf{k}^\downarrow(\mathbf{r})$). Deviations from the translationary invariance of the system due to phonons

or lattice defects provide scattering potentials (Yafet, 1965) which mediate transitions between the various $\psi^{\sigma}_{\mathbf{k}}(\mathbf{r})$ which contribute to damping. We can therefore consider ordinary scattering processes (Yafet, 1965; Kamberský, 1970) among $\psi^{\uparrow}_{\mathbf{k}}$ and $\psi^{\uparrow}_{\mathbf{k}'}$ states or among $\psi^{\downarrow}_{\mathbf{k}}$ and $\psi^{\downarrow}_{\mathbf{k}'}$ states. Because states with various $\mathbf{k}$ correspond to different mixtures of $|\uparrow\rangle$ and $|\downarrow\rangle$, such processes will change the probability of finding the considered electron in one of the two spin states, that is, angular momentum will be transferred to the lattice. On the other hand, there are spin-flip processes (Yafet, 1965; Kamberský, 1970) that involve $\psi^{\uparrow}_{\mathbf{k}}$ and $\psi^{\downarrow}_{\mathbf{k}'}$ states, respectively. Finally, there are intraband scattering processes of electrons within the same energy band of the solid (for which the wave functions for different $\mathbf{k}$ often exhibit approximately the same orbital character) as well as interband scattering (for which the orbital character is often different). In Heinrich (2005) and Kamberský (1976, 1984) it is assumed that damping is proportional to the scattering time τ if the energy differences between the scattering states are small compared to $\hbar/\tau$, which is likely for intraband scattering and small τ, whereas it is proportional to τ^{-1} if the energy differences are larger than $\hbar/\tau$, which is likely for interband scattering and large τ. Because for near-adiabatic processes any deviations of the wave functions from the adiabatic wave functions are eliminated almost instantly by scattering, these scattering processes involve only slight changes in electronic single-particle energies, that is, they correspond to intraband scattering.

It is certainly a highly nontrivial problem to figure out which relaxation mechanisms are relevant for damping in a considered magnet. To get information on that, it is important to start with measurements on high-purity bulk crystals to separate the effect of intrinsic damping; then damping can be modified by doping with impurities and by bringing the material to a complex geometrical shape to study extrinsic damping. Systematic studies in this way are still lacking. For high-purity single-crystalline Ni, it was found (Heinrich, Meredith and Cochran, 1979) that the temperature dependence of damping below room temperature is well described by two terms which are equal in strength and proportional to the conductivity σ (ascribed to intraband scattering) and the resistivity ρ (ascribed to interband scattering). The effect of doping of Permalloy with Tb impurities was studied in Russek, McMichael, Donahue and Kaka (2003). A modest concentration of 2% of Tb resulted in a 10-fold increase of damping as measured by FMR (for an interpretation see also (Heinrich, 2005)). Extrinsic damping due to the geometry of an ultrathin film is discussed in Mills and Rezende (2003), and effects of interfaces between magnetic and nonmagnetic metallic layers are studied in Tserkovnyak, Brataas and Bauer (2002) and Berger (2001).

6 TWO QUANTITATIVE MODELS FOR DISSIPATIVE SPIN DYNAMICS

In the present section, we discuss two quantitative models for dissipative spin dynamics, the s–d model (Section 6.1) that covers both the cases of small and large scattering times, and the breathing Fermi surface model (Section 6.2) for small scattering times (Kamberský, 1970). In the s–d model, the electrons are subdivided into two types, itinerant electrons of which those that are close to the Fermi level E_{F} are responsible for spin-dependent transport and are denoted as *s electrons* (although conduction electrons with p character may of course also contribute); and localized electrons far below the Fermi level which form the magnetic moments (inducing in turn a spin polarization of the itinerant electrons) and which are denoted as *d electrons*. While the s–d model may be applied to metallic systems with 4f impurities (the 'd electrons' then represent the 4f electrons) or to sp metal hosts with 3d impurities, its application to 3d impurities in transition-metal hosts (Beuerle, Hummler, Elsässer and Fähnle, 1994) or to concentrated magnetic transition metals and alloys should be considered with much caution. The reason is that in these systems there is considerable weight of the d density of electronic states at the Fermi level so that a subdivision into itinerant and localized magnetic electrons is no longer possible. Because of its conceptual simplicity, the s–d model is used, nevertheless, also for magnetic transition metals. The breathing Fermi surface model does not require the subdivision into itinerant and localized electrons and may be applied to any magnetic system, but it is conceptually more difficult.

6.1 The s–d model

In the literature, there are several variants of the s–d model; our discussion will be based on the paper of Zhang and Li (2004).

In the following, we consider only the magnetization $\mathbf{M}(\mathbf{r}, t)$ related to electronic spin and neglect the orbital contribution. As outlined in the preceding text, in the s–d model, $\mathbf{M}(\mathbf{r}, t)$ is composed of a d contribution $\mathbf{M}_{\mathrm{d}}(\mathbf{r}, t)$ with fixed length M_{d}, and a contribution of the conduction electrons, $\mathbf{m}(\mathbf{r}, t)$

$$\mathbf{M}(\mathbf{r}, t) = \mathbf{M}_{\mathrm{d}}(\mathbf{r}, t) + \mathbf{m}(\mathbf{r}, t) \tag{25}$$

The basic physics of the s–d model is most easily discussed by looking at the homogeneous ferromagnetic precession mode. If there was no spin-flip scattering for the conduction electrons ($\tau_{\mathrm{sf}} \to \infty$), then the d magnetization and the conduction electron magnetization that are coupled

via the s–d exchange interaction would be in parallel alignment and would precess in phase. A finite scattering time τ_{sf} generates a part $\delta\mathbf{m}(\mathbf{r}, t)$ transversal to $\mathbf{M}_d$, as well as a torque acting on $\delta\mathbf{m}$, with a component which leads to a precession of $\delta\mathbf{m}$ around $\mathbf{M}_d$, and a component which turns $\delta\mathbf{m}$ toward $\mathbf{M}_d$. For large τ_{sf}, the latter component, which contributes to damping will increase with increasing scattering rate, that is, decreasing τ_{sf}. For small τ_{sf}, however, the magnitude of $\delta\mathbf{m}$ is reduced because the angular momentum related to $\delta\mathbf{m}$ is very quickly transferred to the lattice, that is, damping will decrease with increasing scattering rate, and finally we end up with the strictly adiabatic situation where the conduction electron magnetization exhibits at any instant its equilibrium value with respect to the momentary configuration $\mathbf{M}_d$. As outlined in Section 4, noninfinite scattering times are required for damping, but zero scattering times rule out damping.

For a quantitative formulation, Zhang and Li (2004) assumed that the dynamics of d magnetization is described by a Gilbert type EOM (see equation (1)) with an additional term $\mathbf{T}(\mathbf{r}, t)$,

$$\frac{\partial \mathbf{M}_d(\mathbf{r}, t)}{\partial t} = -\gamma(\mathbf{M}_d \times \mathbf{H}_{eff,d}) + \frac{1}{M_d}\,\mathbf{M}_d \times \alpha \frac{\partial \mathbf{M}_d}{\partial t} + \mathbf{T}(\mathbf{r}, t) \tag{26}$$

In equation (26), $\mathbf{H}_{eff,d}$ and α are the effective field experienced by the d magnetization and the damping constant that would describe damping of the d magnetization when switching off the conduction electron magnetization, that is, which is due to direct relaxation processes of the d electrons, respectively. The additional term $\mathbf{T}(\mathbf{r}, t)$ describes the torque density exerted on $\mathbf{M}_d(\mathbf{r}, t)$ by $\mathbf{m}(\mathbf{r}, t)$ when these two magnetization fields are not collinear. The two remaining problems are to calculate $\mathbf{T}(\mathbf{r}, t)$ from the two magnetization fields and to determine $\mathbf{m}(\mathbf{r}, t)$.

The first problem is solved by assuming a classical Heisenberg interaction,

$$E_{sd} = -J_{ex}\ \mathbf{s}(\mathbf{r}, t)\cdot\mathbf{S}(\mathbf{r}, t) \tag{27}$$

with the exchange coupling constant J_{ex}, yielding

$$\mathbf{T} = -\frac{1}{\tau_{ex} M_d}\,\mathbf{M}_d \times \mathbf{m} \tag{28}$$

with

$$\tau_{ex} = \frac{\hbar}{S J_{ex}} \tag{29}$$

For the solution of the second problem, the generalized continuity equation for the conduction electron spin density $\mathbf{m}(\mathbf{r}, t)$ is used, which may be written in the form

$$\frac{\partial \mathbf{m}(\mathbf{r}, t)}{\partial t} = \mathbf{T}_m \tag{30}$$

where

$$\mathbf{T}_m = -\nabla\cdot\mathcal{J} - \mathbf{T} - \Gamma_{re} \tag{31}$$

is the total torque density acting on the conducting electron spin density. Thereby $\mathcal{J}$ is the expectation value of the spin-current density tensor operator $\hat{\mathcal{J}}$,

$$\hat{\mathcal{J}} = \mathrm{Re}\sum_{s,s'} \hat{\psi}_s^{\dagger}(\mathbf{r})\ \hat{\boldsymbol{\sigma}}_{ss'} \otimes \hat{\mathbf{v}}\ \hat{\psi}_{s'}(\mathbf{r}) \tag{32}$$

which involves the outer product between $\hat{\boldsymbol{\sigma}}$ and the velocity operator $\hat{\mathbf{v}}$, and Γ_{re} represents the spin relaxation (Section 5) due to spin-flip scattering of the conduction electrons. Equations (30 and 31) tell that the torque on the conduction electron spin density in a volume element of volume $\mathrm{d}V$ arises from the net flux of spin current through the surface $\mathrm{d}\mathbf{S}$ bounding $\mathrm{d}V$, from the torque exerted by the d magnetization which would like to induce a precession of $\mathbf{m}$ around $\mathbf{M}_d$ with frequency τ_{ex}^{-1}, and from the spin-flip relaxation.

To solve equation (30), phenomenological ansatzes are made for the quantities $\mathbf{m}(\mathbf{r}, t)$, $\mathcal{J}(\mathbf{r}, t)$, and Γ_{re}. The conduction electron spin density is separated into two parts,

$$\mathbf{m}(\mathbf{r}, t) = \mathbf{m}_0(\mathbf{r}, t) + \delta\mathbf{m}(\mathbf{r}, t) \tag{33}$$

where $\mathbf{m}_0$ represents the *adiabatic* spin density that would arise if the conduction electron magnetization followed the d magnetization $\mathbf{M}_d(\mathbf{r}, t)$ instantaneously, and $\delta\mathbf{m}(\mathbf{r}, t)$ is the nonadiabatic contribution. In the paper of Zhang and Li (2004) it is assumed that $\mathbf{m}_0(\mathbf{r}, t)$ is parallel to $\mathbf{M}_d(\mathbf{r}, t)$,

$$\mathbf{m}_0(\mathbf{r}, t) = m_0\ \frac{\mathbf{M}_d(\mathbf{r}, t)}{M_d} \tag{34}$$

While equation (34) certainly holds for a spatially homogeneous d magnetization, the situation in general is much more complicated for an inhomogeneous $\mathbf{M}_d(\mathbf{r}, t)$ where the directions of the s and p contributions to the magnetic moments may deviate strongly from the directions of the d contributions (Fähnle, Singer, Steiauf and Antropov, 2006). For strong cantings of the magnetic moments on an atomic scale, for example, in the center of a vortex or in an extremely narrow domain wall, this complication may change the results both qualitatively and quantitatively. For the sake of simplicity we adopt equation (34), and this should be justified for systems with slow spatial variations of $\mathbf{M}_d(\mathbf{r}, t)$.

The spin-current density $\mathcal{J}(\mathbf{r}, t)$ is nonzero even in a situation where there is no transport current. Then $\nabla\cdot\mathcal{J}$

describes the dependence of the kinetic energy on the relative orientations of the magnetic moments, and it has been emphasized repeatedly (see, e.g., Antropov, Harmon and Smirnov, 1999; Grotheer, Ederer and Fähnle, 2001; Stiles and Miltat, 2006) that this kinetic exchange term is very essential. In the paper of Zhang and Li (2004), the kinetic exchange for conduction electrons is neglected (which again may be justified approximately for systems with slow spatial variations of $\mathbf{M}_\mathrm{d}(\mathbf{r}, t)$) and only the contribution of a possible transport spin current is taken into account. In analogy to equation (33), the spin-current density is then subdivided into an adiabatic part $\mathcal{J}_0(\mathbf{r}, t)$ and a nonadiabatic part $\delta\mathcal{J}(\mathbf{r}, t)$,

$$\mathcal{J}(\mathbf{r}, t) = \mathcal{J}_0(\mathbf{r}, t) + \delta\mathcal{J}(\mathbf{r}, t) \tag{35}$$

The adiabatic part $\mathcal{J}_0(\mathbf{r}, t)$ is written in a form that holds for one-dimensional problems (Stiles and Miltat, 2006), that is, as an outer product of the charge current density $\mathbf{j}_\mathrm{e}$ and the spin direction $\mathbf{e}$ of the transport electrons,

$$\mathcal{J}_0(\mathbf{r}, t) = -\frac{\mu_\mathrm{B} P}{e_0}\, \mathbf{j}_\mathrm{e} \otimes \mathbf{e} \tag{36}$$

Here e_0 is the elementary charge, and the quantity P is the modulus of the spin-current polarization in the ferromagnet which is the up spin current minus the down spin current, all divided by the total current. In the paper of Zhang and Li (2004), it is assumed that P is a constant throughout the material, that is, the transport current has a spin polarization of constant magnitude but varying direction, which is certainly an approximation. Furthermore, it is assumed that for the adiabatic part of $\mathcal{J}$, the spin direction $\mathbf{e}$ of the transport electrons is parallel to $\mathbf{M}_\mathrm{d}(\mathbf{r}, t)$ everywhere, that is,

$$\mathbf{e}(\mathbf{r}, t) = \frac{\mathbf{M}_\mathrm{d}(\mathbf{r}, t)}{M_\mathrm{d}} \tag{37}$$

Let us pause to elucidate the physics behind equation (37). The assumption underlying this equation is equivalent to Slonczewski's assumption (Slonczewski, 1996) of complete spin filtering of an ideal, homogeneously magnetized ferromagnetic layer, which is assumed to completely remove that component of the spin polarization of an incident spin-polarized current perpendicular to the layer magnetization. To explain the spin filter effect see, e.g., Stiles and Miltat, 2006, the spinor field of an incident electron with given spin direction is written as a coherent superposition of spinor states with spin up and spin down relative to the direction of the layer magnetization. Because the conduction electrons in the ferromagnet experience an exchange interaction which produces a spin-dependent effective potential, the transmission probability will be larger for spin up than for spin down, that is, the perpendicular component of the spin of an electron entering the ferromagnet is reduced (*spin filtering*) but it is not yet zero. Furthermore, in the ferromagnet the two components of the spinor field with different spin belong to different wave vectors $\mathbf{k}_1$ and $\mathbf{k}_2$ because of the different effective potentials. Therefore the phase between the spin-up and the spin-down part of the spinor field in the ferromagnet, $\exp[\mathrm{i}(k\uparrow - k\downarrow)x]$, changes as the electron penetrates into the magnet, describing the precession of the electron with nonzero perpendicular spin around magnetization. Because electrons on different parts of the Fermi surface precess at different rates, there is a dephasing of different electrons. As a result of this dephasing, the remaining transverse spin current entering the ferromagnet decays with a characteristic decay length which is smaller, the more dissimilar the Fermi surfaces for spin-up and spin-down electrons. When scattering is included, that is, when the assumption of ballistic transport underlying the above reasoning is abandoned and a diffusive transport is considered, then the transverse component of spin polarization (called *spin accumulation*) decays exponentially on a short length scale and then its elimination takes place very close to the interface. (The influence of the small residual transverse spin accumulation which creates an effective field for the precession of the ferromagnetic magnetization is discussed, in Heide, Zilberman and Elliott, 2001; Heide, 2001, 2002). Equation (37) represents a generalization of all these considerations to the case of a continuously varying magnetization configuration. In general, this equation will be valid only if the length that characterizes the magnetization inhomogeneity is much larger than the characteristic decay length for the transverse component of the spin polarization, and this often will require strong scattering. However, in the special case of a domain wall, the conduction electron spin polarization will stay close to the magnetization of the domain wall even in the ballistic limit, because of the special properties of the precession of the conduction electrons in a domain wall (Waintal and Viret, 2004).

In the paper of Zhang and Li (2004) the quantities P and $\mathbf{j}_\mathrm{e}$ appearing in equation (36) are fixed, that is, it is assumed that the transport current $\mathbf{j}_\mathrm{e}$ is constant and has a spin polarization of constant magnitude but varying direction (always parallel to $\mathbf{M}_\mathrm{d}$), which is certainly an approximation. In contrast, for a theoretical description of a multilayer with abrupt changes of magnetization, these quantities are not prescribed but determined by classical or semiclassical transport theories for which the results of the calculations for spin filtering at the interfaces enter as boundary conditions (for a review, see Stiles and Miltat, 2006).

The nonadiabatic contribution $\delta\mathcal{J}$ is related to the nonadiabatic $\delta\mathbf{m}$ via a diffusion equation with diffusion constant D_0,

$$\delta\mathcal{J} = -D_0\ \nabla \otimes \delta\mathbf{m} \tag{38}$$

in very much the same way as the current density is related to the concentration gradient in a nonequilibrium situation. In the following we consider situations where magnetization varies on a length scale much larger than the spin diffusion transport length; then the term $\nabla \otimes \delta\mathbf{m}$ is neglected (Zhang and Li, 2004) in equations (30 and 31) (of course this approximation does not apply for the layer systems with abrupt changes of magnetization).

Finally, for the relaxation term a simple relaxation time approximation is used,

$$\Gamma_{\mathrm{rel}} = \frac{\delta\mathbf{m}(\mathbf{r}, t)}{\tau_{\mathrm{sf}}} \tag{39}$$

with a relaxation time τ_{sf} for the spin-flip scattering of the conduction electrons.

As outlined in Section 5, it is customary to subdivide the scattering processes into ordinary scattering between states with the same spin index ($\uparrow$ or $\downarrow$) and spin-flip scattering between states with different spin index. However, it should be recalled that due to spin-orbit coupling, the up and down states are not pure spin states but states with small spin mixing, so that even ordinary scattering processes change the probability to find the considered electron in one of the spin states $|\uparrow\rangle$ or $|\downarrow\rangle$. The quantity τ_{sf} then encompasses both spin-flip scattering and ordinary scattering.

Solving equations (30, 31, 33–37, and 39) with $\delta\mathcal{J} = 0$, thereby neglecting the higher-order term $\partial\delta\mathbf{m}/\partial t$, yields four contributions to the torque $\mathbf{T}$ on the d magnetization according to equation (28),

$$\mathbf{T} = \sum_{i=1}^{4} \mathbf{T}_i \tag{40}$$

$$\mathbf{T}_1 = \frac{\xi m_0}{(1+\xi^2)M_{\mathrm{d}}^2}\ \mathbf{M}_{\mathrm{d}} \times \frac{\partial \mathbf{M}_{\mathrm{d}}}{\partial t} \tag{41}$$

$$\mathbf{T}_2 = -\frac{m_0}{(1+\xi^2)M_{\mathrm{d}}} \frac{\partial \mathbf{M}_{\mathrm{d}}}{\partial t} \tag{42}$$

$$\mathbf{T}_3 = -\frac{\mu_{\mathrm{B}} P}{(1+\xi^2)e_0 M_{\mathrm{d}}^3}\ \mathbf{M}_{\mathrm{d}} \times [\mathbf{M}_{\mathrm{d}} \times (\mathbf{j}_{\mathrm{e}} \cdot \nabla)\mathbf{M}_{\mathrm{d}}] \tag{43}$$

$$\mathbf{T}_4 = -\frac{\mu_{\mathrm{B}} P \xi}{(1+\xi^2)e_0 M_{\mathrm{d}}^2}\ \mathbf{M}_{\mathrm{d}} \times (\mathbf{j}_{\mathrm{e}} \cdot \nabla)\mathbf{M}_{\mathrm{d}} \tag{44}$$

$$\xi = \frac{\tau_{\mathrm{ex}}}{\tau_{\mathrm{sf}}} \tag{45}$$

While $\mathbf{T}_3$ and $\mathbf{T}_4$ are related to the transport current $\mathbf{j}_{\mathrm{e}}$, the terms $\mathbf{T}_1$ and $\mathbf{T}_2$ do not depend on $\mathbf{j}_{\mathrm{e}}$ but arise as a consequence of the dynamical evolution of the d magnetization, that is, they exist for $\partial\mathbf{M}_{\mathrm{d}}/\partial t \neq 0$. For very strong spin-flip scattering, that is, $\tau_{\mathrm{sf}} \to 0$ and $\xi \to \infty$, the nonadiabatic contribution $\delta\mathbf{m}$ vanishes; that is, $\mathbf{m}$ follows $\mathbf{M}_{\mathrm{d}}$ adiabatically and all contributions $\mathbf{T}_i$ to $\mathbf{T}$ are zero.

First we consider the case without transport current $\mathbf{j}_{\mathrm{e}}$, that is, $\mathbf{T}_3 = \mathbf{T}_4 = 0$. For small τ_{sf} (i.e., large ξ), the torque $\mathbf{T}_1$ results primarily from the relaxation term Γ_{rel} of equations (30 and 31), whereas for large τ_{sf} (small ξ), $\mathbf{T}_2$ is primarily related to the s–d exchange torque $\mathbf{T}$ in these equations that leads to a precession of $\mathbf{m}$ around $\mathbf{M}_{\mathrm{d}}$. The equations (26 and 40–42) yield an EOM of Gilbert form, equation (1), with γ and α replaced by

$$\gamma' = \frac{\gamma}{1+\eta} \tag{46}$$

$$\alpha' = \frac{\alpha + \xi\eta}{1+\eta} \tag{47}$$

$$\eta = \frac{m_0}{(1+\xi^2)M_{\mathrm{d}}} \tag{48}$$

The torque $\mathbf{T}_1$ thereby gives a new contribution,

$$\Delta\alpha = \xi\eta \tag{49}$$

for the damping constant, while $\mathbf{T}_2$ renormalizes γ and $(\alpha + \Delta\alpha)$ by the factor $1/(1+\eta)$.

We note that $\Delta\alpha$ is proportional to τ_{sf}^{-1} for the case of low spin-flip rate, $\tau_{\mathrm{ex}} \ll \tau_{\mathrm{sf}}$, $\xi \ll 1$. As outlined in the introduction of Section 6.1, deviations $\delta\mathbf{m}$ are produced by spin-flip scattering processes and hence damping increases for decreasing τ_{sf} at large values of τ_{sf}. In Tserkovnyak, Fiete and Halperin (2004) it is pointed out that the physics of this low-spin-flip-rate regime is similar to the *spin-pumping* damping (Tserkovnyak, Brataas and Bauer, 2002; Zwierzycki *et al.*, 2005) of a thin ferromagnetic film on a nonmagnetic conductor. The moving magnetization in the film 'pumps' spins into the conduction electron system. For a low spin-flip scattering rate, the spin polarization of these conduction electrons is conserved for a long time and relaxes only far inside the nonmagnetic conductor, leading to a nonlocal damping of magnetization dynamics in the film. The only difference is that in the present section the spins are pumped into the own delocalized states of the magnet rather than in the delocalized states outside the magnet. For the case of high spin-flip rate, $\tau_{\mathrm{ex}} \gg \tau_{\mathrm{sf}}$, $\xi \gg 1$, $\Delta\alpha$ is proportional to τ_{sf}. This corresponds to the situation outlined in the introduction of Section 6.1 that for a high spin-flip rate the magnitude of $\delta\mathbf{m}$ is strongly reduced because the related angular momentum is transferred very quickly to the lattice.

Insofar, the s–d model yields two contributions to damping, the first proportional to τ_{sf}^{-1} and the second one proportional to τ_{sf}. It is tempting to relate these two contributions to the two contributions found experimentally for pure Ni (Heinrich, Meredith and Cochran, 1979) that are proportional to the conductivity $\sigma \sim \tau$ at low temperatures and to the resistivity $\rho \sim \tau^{-1}$ at higher temperatures. However, there are two important differences. First, we have to distinguish between the relaxation time τ_{sf} for spin-flip scattering and the Drude relaxation time τ appearing in the theory of electrical conduction which involves both spin channels. Second, in the experiments the term proportional to τ dominates at large τ (resp. low temperature), whereas in the s–d model the term proportional to τ_{sf} dominates for small τ. See also the next paragraph for the relevance of the s–d damping $\Delta\alpha$.

Estimates for J_{ex} and τ_{sf} are given in Zhang and Li (2004) ($J_{ex} \approx 1.6 \times 10^{-12}$ erg, $\tau_{sf} \approx 10^{-12}$ s) and in Waintal and Viret (2004) ($J_{ex} \approx 10^{-13}$ erg, $\tau_{sf} \approx 5 \times 10^{-14}$ s), yielding the values $\xi \approx 4 \times 10^{-4}$ and $\xi = 10^{-1}$ for $S = 2$. A typical value of $\eta \approx m_0/M_d$ is 1/20. This yields $\Delta\alpha = 2 \times 10^{-5}$ and 0.5×10^{-2}; typical experimental values for the damping constant are in the range of multiples of 10^{-2} to multiples of 10^{-1}. In Zhang and Li (2004), it was therefore concluded that the damping of magnetization dynamics in metals is not dominated by spin-flip scattering of s and p electrons. Probably the factor $\eta \approx m_0/M_d$ which describes the smallness of the conduction electron magnetization as compared to the d magnetization is responsible for this (see also the footnote 5 of Kamberský, 1970). Obviously, a theory of damping in metallic magnets has to include the scattering of the d electrons (as will be the case in the d band models of Kamberský (1976, 1984) and in the breathing Fermi surface model (Kamberský, 1970), see Section 6.2).

We now discuss the influence of a transport current $\mathbf{j}_e$. Equations (43 and 44) show that $\mathbf{j}_e$ is effective only for an inhomogeneous situation, that is, when the direction of $\mathbf{M}_d(\mathbf{r}, t)$ varies in space. The current $\mathbf{j}_e$ enters the EOM (30) for $\mathbf{m}(\mathbf{r}, t)$ via the term $\nabla\cdot\mathcal{J}_0$ (see equation (31)). Because the spin polarization of the conduction electrons is parallel to $\mathbf{M}_d(\mathbf{r}, t)$ everywhere for $\mathcal{J}_0$, the angular momentum of the spin current has to change in space: When the spin-polarized conduction electrons flow into the volume element d^3r around $\mathbf{r}$, that part of the spin polarization which is originally transverse to $\mathbf{M}_d(\mathbf{r}, t)$ will be totally transferred to the surroundings in d^3r. The result is the torque $-\nabla\cdot\mathcal{J}_0$ exerted on the magnetization $\mathbf{m}(\mathbf{r}, t)$, generating a component $\delta\mathbf{m}(\mathbf{r}, t)$ that is not parallel to $\mathbf{M}_d(\mathbf{r}, t)$, that will experience a precession around $\mathbf{M}_d$ via the s–d exchange torque $\mathbf{T}$ in equation (30), and a relaxation via the term Γ_{rel}. It becomes obvious from equation (43) that the term $\mathbf{T}_3$ (denoted (Zhang and Li, 2004) as *adiabatic spin torque*) results primarily (apart from the factor $(1 + \xi^2)$ in the denominator) from the s–d exchange term $\mathbf{T}$ in combination with $\nabla\cdot\mathcal{J}_0$, whereas $\mathbf{T}_4$ (denoted (Zhang and Li, 2004) as *nonadiabatic spin torque*) is primarily related to the relaxation term Γ_{rel} in combination with $\nabla\cdot\mathcal{J}_0$. The term $\mathbf{T}_3$ may be considered (Li and Zhang, 2004) as a generalization to the case of a continuously nonuniform magnetization of the spin-transfer torque due to complete spin filtering introduced by Slonczewski (1996) for multilayers where magnetization changes abruptly at the interface. Formally, the mathematical structure of the term $\mathbf{T}_4$ looks like a corresponding generalization of an additional multilayer torque arising from an effective field generated by the residual transverse spin accumulation (Zhang, Levy and Fert, 2002; Shpiro, Levy and Zhang, 2003). Thiaville, Nakatani, Miltat and Suzuki (2005) have introduced in a phenomenological manner a term of the form $\mathbf{T}_4$ in addition to the torque $\mathbf{T}_3$ to describe the current-driven domain-wall motion.

Zhang and Li (2004) have applied their theory to investigate the effects a spin-polarized transport current on the form and the dynamics of a Néel wall in a nanowire. The adiabatic $\mathbf{T}_3$ term causes a domain-wall distortion and is responsible for the initial velocity of the wall, whereas the terminal velocity of the wall is controlled by the nonadiabatic $\mathbf{T}_4$ term (although it is much smaller in size than $\mathbf{T}_3$). It should be noted that, while in the above discussed paper of Zhang and Li (2004) the diffusive conduction electron flow is considered, Waintal and Viret (2004) determine the torque exerted on the domain wall by the ballistic motion of conduction electrons, yielding other torques that are explicitly related to the precession of the electron spins around the magnetization in the domain wall.

Finally, we note that Xiao, Zangwill and Stiles (2006) argue that the phenomenological form of Γ_{rel} as given by equation (39) should not be used for systems with an inhomogeneous situation, and therefore doubt the existence of the nonadiabatic spin torque. Furthermore, they commented critically on the torque reported by Waintal and Viret (2004).

6.2 Breathing Fermi surface model

As outlined in Section 6.1, a theory of damping in ferromagnetic metals has to take into account the scattering of d electrons, like the breathing Fermi surface model originally introduced by Kamberský (1970) and further developed in Kuneš and Kamberský (2002, 2003) and Steiauf and Fähnle (2005). In the following, we discuss extensively the basic physical assumptions of this phenomenological model and the results of a calculation that determines the quantities entering this model by the *ab initio* density-functional electron theory.

For a complete quantum-mechanical description of the angular momentum and energy transfer from the electrons to the lattice, one had to start from the time-dependent wave equation for electrons and nuclei, involving spin-orbit coupling. Instead, we want to describe the situation approximately by an effective single-particle theory that involves only electrons and that describes the transfer empirically via relaxation times. In such a theory, the expectation values of the observables are determined by the matrix elements of the respective operators formed with the single-particle spinor wave functions $\psi_{j\mathbf{k}}(\mathbf{r}, t)$ – where j and $\mathbf{k}$ denote the band index and the wave vector – and by the occupation numbers $n_{j\mathbf{k}}(t)$ describing the occupation of these states at time t. For instance, the spin magnetization density is given by

$$\mathbf{m}_{\mathrm{s}}(\mathbf{r}, t) = -\frac{g\mu_{\mathrm{B}}}{2} \sum_{\substack{j,\mathbf{k} \\ s,s'}} n_{j\mathbf{k}}(t)\ \psi^{*}_{j\mathbf{k}s}(\mathbf{r}, t)\, \hat{\boldsymbol{\sigma}}_{ss'}\, \psi_{j\mathbf{k}s'}(\mathbf{r}, t) \tag{50}$$

where $\psi_{j\mathbf{k}s}$ is the s component of the spinor $\psi_{j\mathbf{k}}$, and the band-structure energy is

$$\begin{aligned} E_{\mathrm{band}}(t) &= \sum_{j\mathbf{k}} n_{j\mathbf{k}}(t)\ \left\langle \psi_{j\mathbf{k}}(t) \middle| \hat{H} \middle| \psi_{j\mathbf{k}}(t) \right\rangle \\ &= \sum_{j\mathbf{k}} n_{j\mathbf{k}}(t)\ \epsilon_{j\mathbf{k}}(t) \end{aligned} \tag{51}$$

where $\hat{H}$ is the effective single-particle Hamiltonian of the density-functional electron theory.

In principle, the $\psi_{j\mathbf{k}}(\mathbf{r}, t)$ should be determined from the time-dependent single-electron wave equation. In a strictly adiabatic situation, however, the $\psi_{j\mathbf{k}}(\mathbf{r}, t)$ are given by solutions of the time-independent wave equation for the effective potential related to the momentary directions $\{\mathbf{e}_i(t)\}$ of the atomic moments, $\psi_{j\mathbf{k}}(\mathbf{r}, t) = \psi_{j\mathbf{k}}(\mathbf{r}, \{\mathbf{e}_i(t)\})$. Correspondingly, we have $\epsilon_{j\mathbf{k}}(t) = \epsilon_{j\mathbf{k}}[\{\mathbf{e}_i(t)\}]$ and $n_{j\mathbf{k}}(t) = f(\epsilon_{j\mathbf{k}}[\{\mathbf{e}_i(t)\}]) = f_{j\mathbf{k}}$, where the $f_{j\mathbf{k}}$ are the Fermi–Dirac equilibrium occupation numbers, with a Fermi energy $\varepsilon_{\mathrm{F}}[\{\mathbf{e}_i(t)\}]$ and a corresponding Fermi surface. For a noncollinear magnetization configuration, the $\psi_{j\mathbf{k}}$ and $\epsilon_{j\mathbf{k}}$ depend on the orientations $\{\mathbf{e}_i(t)\}$ mainly because the orientations determine the kinetic exchange part of $\hat{H}$. For a homogeneous magnetization, the dependence of the $\epsilon_{j\mathbf{k}}$ on the $\{\mathbf{e}_i\}$ arises from the spin-orbit coupling. When changing $\{\mathbf{e}_i\}$ in time, the adiabatic $\psi_{j\mathbf{k}}$, $\epsilon_{j\mathbf{k}}$, and ε_{F} also change in time and the Fermi surface will continuously attain a slightly different form (*breathing Fermi surface*).

There are two basic assumptions of the breathing Fermi surface model. The first one is that even in a slightly nonadiabatic situation we can insert into equations (50 and 51) the adiabatic wave functions and the adiabatic single-electron energies corresponding to the momentary directions $\{\mathbf{e}_i(t)\}$. The deviation from the adiabatic situation is taken into account only by nonadiabatic occupation numbers $n_{j\mathbf{k}}(t)$ which lag behind the adiabatic occupation numbers $f(\epsilon_{j\mathbf{k}}[\{\mathbf{e}_i(t)\}])$. The reason is that the redistribution of the occupation numbers, which is necessary to adjust to the steadily changing Fermi surface requires scattering processes between various electronic states $j\mathbf{k}$ around the Fermi surface, and hence requires time. For quasistatic changes, the characteristic timescale $\tau_{\mathbf{e}}$ for the changes of the momentary directions $\mathbf{e}_i$ is much larger than the characteristic timescale τ_{s} for the scattering process, $\tau_{\mathbf{e}} \gg \tau_{\mathrm{s}}$, and then $n_{j\mathbf{k}}(t) = f_{j\mathbf{k}}(t)$ at any instant. In the general case, however, $n_{j\mathbf{k}}$ never catches up with $f_{j\mathbf{k}}$, and the deviation between $n_{j\mathbf{k}}$ and the fictitious $f_{j\mathbf{k}}$ generates the dynamical evolution of $n_{j\mathbf{k}}$. In Kamberský's theory, this process is described by a relaxation ansatz (Kamberský, 1970)

$$\frac{\mathrm{d}n_{j\mathbf{k}}(t)}{\mathrm{d}t} = -\frac{1}{\tau_{j\mathbf{k}}} \left[n_{j\mathbf{k}}(t) - f_{j\mathbf{k}}(t) \right] \tag{52}$$

with the relaxation times $\tau_{j\mathbf{k}}$, which in general will depend on the respective electronic state $j\mathbf{k}$. It becomes obvious that the breathing Fermi surface model describes a situation close to the adiabatic limit, that is, for very small relaxation times $\tau_{j\mathbf{k}}$.

The exact solution of equation (52) is

$$n_{j\mathbf{k}}(t) = \int_{t_0}^{t} \frac{1}{\tau_{j\mathbf{k}}} f_{j\mathbf{k}}(t')\ \mathrm{e}^{-(t-t')/\tau_{j\mathbf{k}}}\ \mathrm{d}t' + n_{j\mathbf{k}}(t_0)\ \mathrm{e}^{-(t-t_0)/\tau_{j\mathbf{k}}} \tag{53}$$

Neglecting the second term in equation (53) for $t_0 \to -\infty$ and evaluating $f_{j\mathbf{k}}(t')$ around $t' = t$ into a Taylor series, we find for $n_{j\mathbf{k}}(t)$ a power series in $\tau_{j\mathbf{k}}$,

$$n_{j\mathbf{k}}(t) = f_{j\mathbf{k}}(t) - \tau_{j\mathbf{k}}\, \frac{\mathrm{d}f_{j\mathbf{k}}(t)}{\mathrm{d}t} + \ldots \tag{54}$$

which converges for $\tau_{j\mathbf{k}} \ll \tau_{\mathbf{e}}$. In the case of a large timescale $\tau_{\mathbf{e}}$ for changes of the moment directions the deformation of the Fermi surface is very gradual and requires only scattering processes between electronic states that are close in energy, that is, those belonging to the same energy band j and – in the case of small spin mixing due to spin-orbit coupling – to the subband with the same spin index. Therefore the use of equation (54) implies that we make a theory of damping due to ordinary intraband scattering with small relaxation times.

In the following, we consider a homogeneous situation where $\mathbf{M}_i = \mathbf{M} = M\mathbf{e}$ for all sites i and where the absolute value M depends only slightly on $\mathbf{e}$ so that we take it as a constant. For the strictly adiabatic situation the EOM (23)

then reads

$$\dot{\mathbf{M}}_i = -\gamma(\mathbf{M}_i \times \mathbf{H}_{\mathrm{eff},i}) \tag{55}$$

with the adiabatic effective field

$$\mathbf{H}_{\mathrm{eff},i} = -\frac{1}{M}\frac{\delta E}{\delta \mathbf{e}_i} \tag{56}$$

The second basic assumption of the breathing Fermi surface model is that for the slightly nonadiabatic situation the form of the EOM (55) is retained, with $\mathbf{H}_{\mathrm{eff},i}$ replaced by a nonadiabatic effective field,

$$\tilde{\mathbf{H}}_{\mathrm{eff},i} = -\frac{1}{M}\frac{\delta F_{\mathrm{diss}}}{\delta \mathbf{e}_i} \tag{57}$$

Here the effect of damping is included in a dissipative free-energy functional F_{diss} of the magnetization configuration. For instance, a simple phenomenological F_{diss} has been written down by Brown (1963) by including a Rayleigh dissipation function in the free energy (see equation (13)).

For $T = 0\,\mathrm{K}$, we construct the dissipative free-energy functional for the breathing Fermi surface model from a phenomenological extension of the total energy expression of the density-functional theory,

$$E[n, \{\mathbf{e}_i(t)\}] = \sum_{j\mathbf{k}} n_{j\mathbf{k}}\epsilon_{j\mathbf{k}} + E_{\mathrm{dc}}[n] \tag{58}$$

where $n = [\rho(\mathbf{r}, \{\mathbf{e}_i(t)\}); \mathbf{m}(\mathbf{r}, \{\mathbf{e}_i(t)\})]$ with the electron density ρ. The first (second) term is the band-structure energy (double-counting term), and the phenomenological extension consists of inserting the nonadiabatic occupation numbers $n_{j\mathbf{k}}(t)$, equation (54), rather than the $f_{j\mathbf{k}}(t)$. Using the variational property of $E[n]$, and assuming that changes of the $n_{j\mathbf{k}}$ due to a change of $\{\mathbf{e}_i(t)\}$ occur exclusively for states close to ε_{F} with relaxation times $\tau_{j\mathbf{k}}$ that do not depend on the state $j\mathbf{k}$, that is, $\tau_{j\mathbf{k}} = \tau$, we find

$$\tilde{\mathbf{H}}_{\mathrm{eff}} = -\frac{1}{M}\sum_{j\mathbf{k}} n_{j\mathbf{k}}(\mathbf{e}(t))\,\frac{\partial \epsilon_{j\mathbf{k}}(\mathbf{e}(t))}{\partial \mathbf{e}} \tag{59}$$

Inserting (54) into (59) yields

$$\tilde{\mathbf{H}}_{\mathrm{eff}} = \mathbf{H}_{\mathrm{aniso}} + \mathbf{H}_{\mathrm{damp}} \tag{60}$$

with the anisotropy field

$$\mathbf{H}_{\mathrm{aniso}} = -\frac{1}{M}\sum_{j\mathbf{k}} f_{j\mathbf{k}}\,\frac{\partial \epsilon_{j\mathbf{k}}(\mathbf{e})}{\partial \mathbf{e}} \tag{61}$$

and the damping field

$$\mathbf{H}_{\mathrm{damp}} = -\frac{1}{\gamma M}\,\underline{\underline{\alpha}} \cdot \frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} \tag{62}$$

with the damping matrix

$$\frac{\alpha_{lm}}{\tau} = -\frac{\gamma}{M}\sum_{j\mathbf{k}} \frac{\partial f_{j\mathbf{k}}}{\partial \epsilon_{j\mathbf{k}}}\,\frac{\partial \epsilon_{j\mathbf{k}}}{\partial e_l}\bigg|_{\mathbf{M}}\,\frac{\partial \epsilon_{j\mathbf{k}}}{\partial e_m}\bigg|_{\mathbf{M}} \tag{63}$$

We note the similarity of equation (63) with the Drude equation for the conductivity tensor $\underline{\underline{\sigma}}$ in semiclassical approximation,

$$\frac{\sigma_{lm}}{\tau} = -e_0^2\sum_{j\mathbf{k}} \frac{\partial f_{j\mathbf{k}}}{\partial \epsilon_{j\mathbf{k}}}\,\frac{\partial \epsilon_{j\mathbf{k}}}{\partial k_l}\,\frac{\partial \epsilon_{j\mathbf{k}}}{\partial k_m} \tag{64}$$

Please note that in equations (63 and 64), the quantity τ describes the Drude relaxation time and not the spin-flip scattering time τ_{sf} that appeared in the s–d model.

Inserting equations (60–62) into equation (55) yields the EOM

$$\dot{\mathbf{M}} = -\gamma\mathbf{M} \times \mathbf{H}_{\mathrm{aniso}} + \frac{1}{M}\mathbf{M} \times \left(\underline{\underline{\alpha}} \cdot \frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t}\right) \tag{65}$$

which looks very much like the original Gilbert equation (1), with the only but very important difference that the damping scalar of equation (1) is replaced by a damping matrix $\underline{\underline{\alpha}}$ of the form (Steiauf and Fähnle, 2005)

$$\begin{bmatrix} a^2 & ab & 0 \\ ab & b^2 & 0 \\ 0 & 0 & 0 \end{bmatrix} \tag{66}$$

so that in general $\mathbf{H}_{\mathrm{damp}}$ is not parallel to $\mathrm{d}\mathbf{M}/\mathrm{d}t$. A Gilbert equation is obtained only for the special case that $\mathrm{d}\mathbf{M}/\mathrm{d}t$ corresponds to one of the two eigenvectors of $\underline{\underline{\alpha}}(\mathbf{M})$, which are orthogonal to the momentary $\mathbf{M}$ and orthogonal to each other (and then the respective momentary damping constant is given by one of the eigenvalues $\tilde{\alpha}_p$, $p = 1, 2$), or if $\mathbf{M}$ is momentarily aligned to a threefold of fourfold symmetry axis of the system. For a general $\mathrm{d}\mathbf{M}/\mathrm{d}t$, it is always possible to write down (Steiauf and Fähnle, 2005) a 'momentary' Gilbert equation with a 'momentary' gyromagnetic ratio $\tilde{\gamma}(\dot{\mathbf{M}}, \mathbf{M})$ and a 'momentary' damping scalar $\tilde{\alpha}(\dot{\mathbf{M}}, \mathbf{M})$ that is between $\tilde{\alpha}_1$ and $\tilde{\alpha}_2$.

Altogether, the breathing Fermi surface model yields an EOM which, to lowest order, in the Taylor expansion (54), that is, for situations very close to the adiabatic limit, is an extension of the Gilbert EOM to the case of a damping matrix. Higher-order terms in equation (54) would contribute

further terms to the EOM. The theory predicts a damping matrix which is proportional to the relaxation time τ as the conductivity σ. It does not yield the contribution proportional to the resistivity $\rho \sim 1/\tau$ found experimentally for high-purity Ni (Heinrich, Meredith and Cochran, 1979; see Section 5). The reason is (see the preceding text) that the theory implies $\tau \ll \tau_{\mathbf{e}}$, and hence it corresponds to the regime with high relaxation rates for which α vanishes for $\tau \to 0$ like σ. Experimentally, the contribution proportional to σ has been found for pure single crystals of Ni (Heinrich, Meredith and Cochran, 1979) and Co (Bhagat and Lubitz, 1974), but not for Fe (Bhagat, Anderson and Hirst, 1966; Bhagat, Anderson and Ning, 1967).

The quantity $\underline{\underline{\alpha}}/\tau$ according to equation (64) has been calculated by the *ab initio* density-functional electron theory for bulk materials (Kuneš and Kamberský, 2002, 2003; Steiauf and Fähnle, 2005), as well as for hexagonal monolayers and for monatomic wires (Steiauf and Fähnle, 2005) of Fe, Co, and Ni, yielding the following results:

(1) For reasonable assumptions about τ, the calculated value of α for bulk Ni is in reasonable agreement with the experimental data at low temperatures (Kuneš and Kamberský, 2002).

(2) The dependence of the two eigenvalues $\tilde{\alpha}_p$ on the orientation of magnetization is already substantial in bulk materials (e.g., variations up to a factor of 4 in hexagonal Co, see Figure 2), and it is very strong for systems with reduced dimensionality like monatomic layers and monatomic wires. In these systems there are orientations of **M** for which damping is identically zero for any $\mathrm{d}\mathbf{M}/\mathrm{d}t$. For the layer, these orientations are perpendicular, in-plane orientations parallel to the most densely packed rows of the layer, and in-plane orientations perpendicular to these rows. For the wire, these are the orientations perpendicular to the wire or in its direction, see Figure 3. Altogether, the dependence of damping on the orientation of **M** represents an additional option to optimize a magnetization reversal process in a nanostructured system by choosing a magnetization trajectory that is most appropriate from the viewpoint of damping. So far the magnetization dynamics in nanostructures has been optimized in micromagnetic simulations only with respect to the shape of the sample, the form of the switching field and the magnitude of the damping scalar are assumed to be independent of the orientation of **M**.

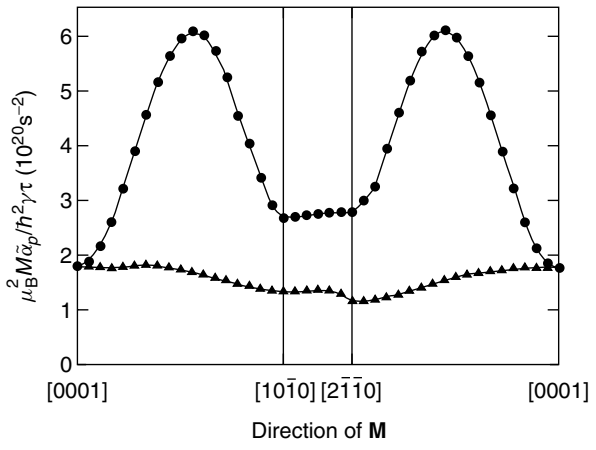

Figure 2. The two eigenvalues $\tilde{\alpha}_p$ (symbols ● and ▲) of $\underline{\underline{\alpha}}$ for different orientations of **M** in bulk hcp Co. (Reprinted figure from Steiauf, D. and Fähnle, M. (2005), *Physical Review B*, **72**, 064450-1–13. With permisson from APS. © 2005.)

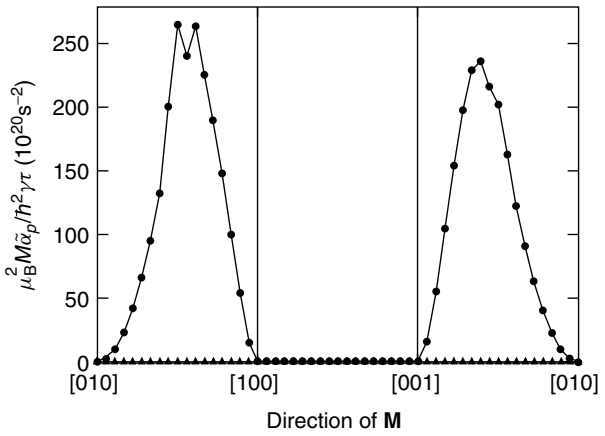

Figure 3. The two eigenvalues $\tilde{\alpha}_p$ of $\underline{\underline{\alpha}}$ for different orientations of **M** in a monatomic wire of Ni. The wire is along [010]. Note that both eigenvalues are zero for **M** perpendicular to the wire or in wire direction, that is, there is no damping for any arbitrary $\mathrm{d}\mathbf{M}/\mathrm{d}t$ out of this direction. In addition, for an arbitrary orientation, the eigenvalue corresponding to a rotation of the magnetization around the wire axis (symbol ▲) is also zero (because this rotation is equivalent to a reverse rotation of the coordinate system which does not change anything), whereas the second eigenvalue (symbol ●) is large. (Reprinted figure from Steiauf, D. and Fähnle, M. (2005), *Physical Review B*, **72**, 064450-1–13. With permisson from APS. © 2005.)

(3) It is often assumed that the larger the damping, the larger the magnetic anisotropy. From the inspection of equations (61 and 64), it becomes clear that this is not at all guaranteed: The anisotropy field contains the derivatives $\partial\epsilon_{j\mathbf{k}}/\partial\mathbf{e}$ linearly. These derivatives may exhibit positive and negative values, which may compensate to a large extent when performing the summation in equation (61). In contrast, the derivatives enter quadratically when calculating α_{ll} from equation (64). In fact, Table 1 shows that there is no simple relation between damping and magnetic anisotropy. For instance, for bulk Co the magnetic anisotropy is 2 orders of magnitude

Table 1. The maximum eigenvalues $\mu_B^2 M\tilde{\alpha}_p/\hbar^2\gamma\tau$ and the maximum anisotropy energies ΔE_{magn} for Co and Ni bulk, monolayer, and wire. The magnetic anisotropies of bulk Co and Ni have not been calculated. The experimental room-temperature anisotropy constants for bulk Fe, Co, and Ni are $K_1 = 4.6 \times 10^5$, 4.1×10^6, -5×10^4 erg cm^{-3} and $K_2 = 1.5 \times 10^5$, 1×10^6, -3×10^4 erg cm^{-3}.

	Bulk	Monolayer	Wire
Co			
$\mu_B^2 M\tilde{\alpha}_p/\hbar^2\gamma\tau$ (10^{20} s^{-2})	6	230	6500
ΔE_{magn}/atom (mRy)	–	6	8
Ni			
$\mu_B^2 M\tilde{\alpha}_p/\hbar^2\gamma\tau$ (10^{20} s^{-2})	15.5	95	250
ΔE_{magn}/atom (mRy)	–	0.1	9

larger than for bulk Ni, but damping of Ni is a factor of 2 larger than the one of Co (when we insert the same τ). For the monolayer, the magnetic anisotropy is a factor of 60 larger in Co than in Ni, but damping is only a factor of about 2.5 larger. Finally, for the wire the magnetic anisotropy is about the same for Co and Ni but damping is a factor of about 30 larger for Co.

In future the theory has to be extended to account for noncollinear magnetization configurations (Fähnle, Singer, Steiauf and Antropov, 2006). For strong noncollinearities on an atomic scale, like in the center of a vortex or in narrow domain walls in nanowires, the electronic eigenvalues $\epsilon_{j\mathbf{k}}$ change strongly when changing the magnetic configuration, and this might result in very strong damping because the Fermi surface shows large deformations in time, which have to be realized by strong redistributions of the occupation numbers via scattering processes. It will be interesting to see whether damping for a strongly noncollinear situation indeed differs from the one of a homogeneous situation.

7 *AB INITIO* SPIN DYNAMICS

The theoretical investigations of magnetization dynamics in the literature may be subdivided essentially in those based on micromagnetic simulations (e.g., see Stiles and Miltat, 2006; Kronmüller and Fähnle, 2003; Thiaville, Nakatani, Miltat and Suzuki, 2005; Thiaville *et al.*, 2003; Leineweber and Kronmüller, 1999; Hertel, 2002; Berkov, 2002; Van Wayenberge, 2006) and those based on the classical nearest-neighbor Heisenberg model (see, e.g., Nowak and Hinzke, 2001). The micromagnetic simulations are designed to resolve magnetization inhomogeneities on a mesoscopic scale, and use mainly the Gilbert equation (1) with the phenomenological micromagnetic effective field $\mathbf{H}_{\text{eff}}(\mathbf{r}, t)$ (Kronmüller and Fähnle, 2003). Forming the scalar product of equation (1) with $\mathbf{M}$ yields

$$\mathbf{M} \cdot \frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} = \frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\mathbf{M}^2 = \mathbf{M} \cdot \left(-\gamma \mathbf{M} \times \mathbf{H}_{\text{eff}} + \frac{1}{M}\,\mathbf{M} \times \alpha \frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t}\right) = 0 \tag{67}$$

because the vector in the bracket of equation (67) is perpendicular to $\mathbf{M}$. This means that the magnitude $\mathbf{M}(\mathbf{r}, t)$ is conserved at any position $\mathbf{r}$. In the Heisenberg model the magnitudes $\mathbf{M}_i(t)$ of the atomic moments at sites $\mathbf{r}$ are also taken as constants. Therefore both approaches are unable to describe configurations with strong cantings of the magnetic moments on an atomic scale for which the $\mathbf{M}_i(t)$ depend strongly on the orientations of the surrounding magnetic moments (Heine, Lichtenstein and Mryasov, 1990; Turzhevskii, Likhtenshtein and Katsnel'son, 1990; Singer, Fähnle and Bihlmayer, 2005). As an example, Figure 4 shows the magnitude M_0 of a Ni moment $\mathbf{M}_0$ at site $i = 0$, which is surrounded by ferromagnetic Ni bulk and for which the orientation of $\mathbf{M}_0$ is fixed via constraining fields (Singer, Fähnle and Bihlmayer, 2005) with an angle θ_0 between $\mathbf{M}_0$ and the surrounding moments. The magnitude M_0 strongly decreases with increasing θ_0 and collapses to zero for $\theta_0 = 90^\circ$. A similar strong dependence is found for Co albeit the magnitude M_0 never vanishes totally, whereas for Fe the moments are much more stable (Singer, Fähnle and Bihlmayer, 2005). It is thus clear that configurations with atomic scale cantings can be described neither by micromagnetic simulations nor by the Heisenberg model. Finally, the conventional Heisenberg model neglects the influence of multispin interactions (Müller-Hartmann,

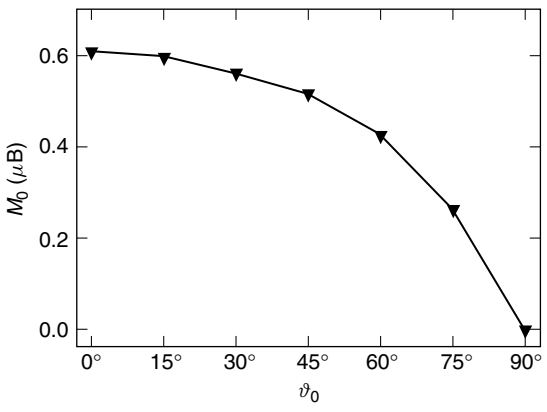

Figure 4. The magnitude M_0 of the magnetic moment $\mathbf{M}_0$ of a Ni atom at site 0 which is rotated by an angle ϑ_0 out of the ferromagnetic alignment of the surrounding fcc Ni bulk. (Reprinted figure from Singer, R., Fähnle, M. and Bihlmayer, G. (2005), *Physical Review B*, **71**, 214435-1–6. With permission from APS. © 2005)

Köbler and Smardz, 1997; Drautz and Fähnle, 2004, 2005), which may also become important for strongly canted configurations. Such configurations often appear in nanoscale materials that may have high-technological relevance in the future, examples are domain walls on the atomic scale in quasi-one-dimensional Fe nanostripes (Pratzer *et al*., 2001), vortex structures in platelets (Miltat and Thiaville, 2002) with a radius of the vortex core of 4–5 nm, and Bloch-point-mediated processes for vortices (Thiaville *et al*., 2003). All the above problems are avoided in microscopic simulations based on the *ab initio* spin density-functional electron theory.

Starting point of the existing *ab initio* spin dynamics simulations is the EOM, equation (23), for the orientations $\mathbf{e}_k$ of the atomic moments at sites k in the strictly adiabatic situation,

$$\dot{\mathbf{e}}_k = -\frac{2\mu_\mathrm{B}}{\hbar}\frac{\partial E(\{\mathbf{e}_i\})}{\partial \mathbf{e}_k} \times \mathbf{e}_k \tag{68}$$

Suggestions on how to take into account the damping of spin systems as well as stochastic fluctuation fields that model finite temperature effects are given in Antropov *et al*. (1996) and Fähnle *et al*. (2005), and a method for simultaneous molecular and spin dynamics is discussed in Antropov *et al*. (1996). In this latter reference, it is also shown that equation (68) holds not only for orientations of the total magnetic moments $\mathbf{M}_k$ composed of different orbital states ν (ν = s, p, d, . . .) but, approximately, also for the separate orbital contributions $\mathbf{M}_{\nu,k}$ with corresponding effective fields $\partial E/\partial \mathbf{e}_{\nu,k}$ for the various orbitals ν.

In principle, simulations based on equation (68) proceed in the following line. First, the initial orientation configuration $\{\mathbf{e}_i(t = t_0)\}$ at the initial time t_0 is generated, in the most strict way by use of constraining fields (Stocks *et al*., 1998; Singer, Fähnle and Bihlmayer, 2005), and the 'slaved' magnitudes $M_k(\{\mathbf{e}_i(t = t_0)\})$ are calculated by the *ab initio* density-functional electron theory, yielding the initial magnetic configuration $\{\mathbf{M}_i(t_0) = M_i(t_0)\,\mathbf{e}(t_0)\}$. Furthermore, the 'effective fields' $\partial E(\{\mathbf{e}_i\})/\partial \mathbf{e}_k$ are calculated by appropriate methods of the *ab initio* electron theory (Stocks *et al*., 1998; Singer, Fähnle and Bihlmayer, 2005). Then the orientational configuration for the time $t_0 + \mathrm{d}t$ is calculated from equation (68), the new magnitudes $M_k(\{\mathbf{e}_i(t_0 + \mathrm{d}t)\})$ and the new effective fields $\partial E/\partial \mathbf{e}_k$ are determined *ab initio*, and so on. By far, the most time-consuming step in this procedure is the *ab initio* calculation of the quantities M_k and $\partial E(\{\mathbf{e}_i\})/\partial \mathbf{e}_k$, which makes the present *ab initio* spin dynamics simulations extremely costly. Therefore, there are so far only extremely few *ab initio* studies of the magnetization dynamics. In Section 7.1 an alternative method is described that circumvents the use of the *ab initio* electron theory for each time step of the solution of equation (68), while still providing near-*ab initio* accuracy. A code based on this new method will probably be very much faster than the existing *ab initio* spin dynamics simulation codes.

7.1 The spin-cluster expansion

The basic idea to facilitate the use of equation (68) for *ab initio* spin dynamics simulations is to construct analytical parameterizations for the functionals $M_k(\{\mathbf{e}_i\})$ and $E(\{\mathbf{e}_i\})$ from which the required quantities M_k and $\partial E/\partial \mathbf{e}_k$ can be calculated analytically so that their *ab initio* determination in each time step can be avoided. In order to obtain near-*ab initio* accuracy, the parameterizations have to be obtained by the use of the *ab initio* electron theory, which will be the most costly part of the method. However, this parameterization has to be done just once before starting the simulation, and the simulation itself will then be very easy.

To obtain the desired parameterization, the recently developed (Drautz and Fähnle, 2004) spin-cluster expansion (SCE) technique, which is an extension of the conventional cluster expansion method in alloy theory (Sanchez, Ducastelle and Gratias, 1984), can be used. In the SCE, it is shown that every quantity $O(\{\mathbf{e}_i\})$ may be written as a sum of contributions of all conceivable spin clusters, α (pairs, triplets, quartets, etc.), in the system,

$$O(\{\mathbf{e}_i\}) = O_0 + \sum_\alpha \sum_\nu O_{\alpha\nu}\Phi_{\alpha\nu}(\{\mathbf{e}_i\}) \tag{69}$$

$$\Phi_{\alpha\nu}(\{\mathbf{e}_i\}) = Y_{\nu_1}(\mathbf{e}_{i_1})Y_{\nu_2}(\mathbf{e}_{i_2})\ldots Y_{\nu_k}(\mathbf{e}_{i_k}) \tag{70}$$

Here $\alpha = (i_1, i_2, \ldots, i_k)$ labels the sites included in the cluster α; $\nu = (\nu_1, \nu_2, \ldots, \nu_k)$ gives the quantum numbers (l, m) characterizing the spherical harmonics Y_{lm}; and $O_{\alpha\nu}$ are expansion coefficients. In a practical calculation, the SCE has to be terminated at a maximum cluster α_max and by a maximum quantum number l_max. The expansion coefficients can then be obtained by fitting the terminated SCE to the observables calculated for a relatively small number of appropriately chosen reference spin configurations $\{\mathbf{e}_i\}_\mathrm{ref}$ by the *ab initio* electron theory for noncollinear spin systems (see, e.g., Grotheer, Ederer and Fähnle, 2001; Antropov *et al*., 1996; Halilov, Eschrig, Perlov and Oppeneer, 1998; Stocks *et al*., 1998; Grotheer, 2002; Singer, Fähnle and Bihlmayer, 2005), prescribing the directions $\mathbf{e}_i$ by local transverse constraining fields (Stocks *et al*., 1998; Singer, Fähnle and Bihlmayer, 2005). When we thereby take into account the spin-orbit coupling, $E(\{\mathbf{e}_i\})$ encompasses the magnetic anisotropy in addition to the exchange energy, and in Drautz and Fähnle (2004), it is shown how the dipolar energy and the Zeeman energy can be incorporated in the SCE. On the basis of the experience gained for conventional

cluster expansions in the alloy theory, we expect that SCEs for $E(\{\mathbf{e}_i\})$ and $M_k(\{\mathbf{e}_i\})$ which exhibit *ab initio* or near *ab initio* accuracy, can be obtained by including relatively few clusters. Finally, it should be noted that $O(\{\mathbf{e}_i\})$ has to fulfill symmetry demands, for example, it must be invariant with respect to the operations of the symmetry group of the magnetic systems. In Singer and Fähnle (2006), it is shown how this can be achieved for the case of magnetically isotropic systems by constructing from the basis functions $\Phi_{\alpha\nu}$ of equation (70), appropriate rotationally invariant basis functions.

8 CONCLUDING REMARKS

From the discussion of the preceding sections, it can be concluded that the basic physics that determines magnetization dynamics in metallic magnets close to the adiabatic limit is known. First, it should be recalled that direct damping is a consequence of the spin-orbit coupling in the system. Second, because of the itineracy of magnetism in 3d transition metals, any theory for these systems should start from the delocalized electronic states. Thereby, the s–d model has shown that damping in metallic bulk magnets results mainly from the scattering of d electrons, and that s and p electrons play only a minor role in situations without transport currents. The breathing Fermi surface model is an intuitive physical model to deal with the scattering of s, p, and d electrons on equal footing in the limit of high scattering rates (i.e., impure crystals and/or high temperatures), and it is able to incorporate in a reliable manner the specific electronic properties of a given material when it is combined with the state-of-the-art *ab initio* density-functional electron theory. It has been shown in Section 6.2 that this is highly important for systems with reduced dimensionality, which are promising candidates for future technological applications. So far this model has been worked out quantitatively only for homogeneous magnetization. For this simple situation, the theory yields an EOM of Gilbert form with the only but very important difference that the damping scalar of the Gilbert equation is replaced by a damping matrix $\underline{\underline{\alpha}}(\mathbf{M})$ which depends on the momentary orientation of $\mathbf{M}$. This dependence can be very large for systems with reduced dimensionality, offering a further option to optimize magnetization dynamics especially in nanostructured materials. The damping matrix is proportional to the electronic relaxation time τ as the conductivity σ, and this results from the fact that the model is designed to describe a near-adiabatic situation with high scattering rates. Damping that is proportional to $1/\tau$ as the resistivity (found in experiments on pure samples) probably arises mainly for small scattering rates, and it is not included in the breathing Fermi surface model. Inserting reasonable values for τ obtained from conductivity measurements yields damping comparable in magnitude to experimentally observed damping. It remains to generalize the model to the case of strongly noncollinear magnetization configurations for which strong damping is expected.

Altogether the breathing Fermi surface model is a powerful model to describe dissipative spin dynamics in metallic magnets in the limit of high scattering rates, for example, in highly doped materials. It is a big challenge to explore the limitations of the near-adiabatic approach. Because the model is designed for a near-adiabatic situation, it probably does not make sense to try to extend it to the regime of small scattering rates. There are other theories including this regime (Kamberský, 1976, 1984; Korenman and Prange, 1972) which, however, are rather formal and do not exhibit the physical intuition of the breathing Fermi surface model.

In our opinion, it is rather difficult to figure out which physical mechanisms (electronic scattering at phonons or various types of lattice defects) determine the damping of a specific material under consideration. In order to investigate the intrinsic damping due to phonons, high-purity crystals have to be used. Research on high-purity crystalline Ni samples has shown convincingly (Heinrich, 2005) that intrinsic damping in Ni is indeed caused by the delocalized nature of the electrons in combination with spin-orbit scattering. Damping may be considerably increased by introducing defects, for example, rare-earth impurities, giving the chance to engineer the desired damping properties for technological applications. Finally, it should be noted that it is possibly questionable whether much information on the damping mechanism can be extracted from the comparison of experiments for the near-adiabatic timescale and for the subpicosecond timescale of laser pump-and-probe experiments because electronic states at different energies are involved in these two situations.

The s–d model – albeit unable to describe damping in metallic bulk magnets – is a good starting point to describe the effect of a transport current on magnetization dynamics, both in bulk materials with continuous inhomogeneous magnetization configurations like domain walls as well as in layered systems with discontinuous changes of magnetization. (In Section 6.1 the interrelations between the torque arising for these two situations are discussed.) Quantitatively there are certainly many open questions for bulk materials already. (For problems in the treatment of layered structures, see Stiles and Miltat, 2006). For instance, the role of noncollinearity between the s, p, and d contributions for situations with strong cantings of magnetic moments has to be figured out. Furthermore, it is an open question as to how the ballistic (Waintal and Viret, 2004) and the diffusive (Zhang and Li, 2004) approach to describe the influence of transport currents on domain walls should be reconciled.

In the last few years, it became possible to treat the adiabatic spin dynamics by means of the *ab initio* density-functional electron theory, albeit the respective computer codes are very time consuming. This latter problem may by overcome by use of the SCE method, as described in Section 7. The remaining challenge is to incorporate into the *ab initio* spin dynamics the effect of damping. One way would be to construct a SCE with expansion coefficients that depend parametrically on the positions of the atoms, thereby including the spin-orbit coupling in the calculation of the magnetic energy of the respective reference configurations. A simultaneous treatment of spin dynamics and atomic dynamics (with *ab initio* determined force constants) would then represent an *ab initio* theory for the spin dynamics including intrinsic damping via phonons.

ACKNOWLEDGMENTS

Phase Transitions and Finite Temperature Magnetism: Experiment and Analysis

Sharika Nandan Kaul
University of Hyderabad, Hyderabad, India

1 INTRODUCTION

In magnetic insulator compounds (e.g., transition metal oxides) and the majority of rare earth metals, atomic magnetic moments are localized at lattice sites and have integral magnitudes (amplitudes) that are temperature independent. While superexchange interactions (usually antiferromagnetic in nature) couple magnetic moments in the former type of materials, indirect exchange interaction mediated by conduction electrons performs this function in rare earth metals. Within the framework of the Heisenberg model, the magnetic ground state of the system is determined by the sign of the interatomic exchange interaction constant, J, and the range of exchange interactions. For instance, in the ground state, spins on all the lattice sites are ferromagnetically (antiferromagnetically or ferrimagnetically) coupled in a three-dimensional Heisenberg system with short-range exchange interactions when $J > 0$ ($J < 0$). The Heisenberg (localized-spin) model and the generalizations thereof that make allowance for magnetic anisotropies (of either dipolar or spin-orbit plus crystal-field origin) adequately describe the ground state as well as finite temperature properties of the localized moment systems. In this model, the only form of collective excitations is the thermally excited propagating transverse spin fluctuations (spin waves) which have a small energy dispersion and fill the entire Brillouin zone.

By contrast, the electrons responsible for magnetism in transition metals, alloys, and intermetallic compounds are itinerant and have delocalized wave functions that are phase coherent over large distances at very low temperatures. At every atomic site, the magnetic moment originates from a spin splitting of the d-electron bands owing to the intra-atomic exchange interaction. The typical time, t_q, for a 3d electron to hop from one lattice site to the other is of the order of $t_q \approx h/W \approx 10^{-15}$s, where W is the bandwidth. As a result of the electron hopping, even in the ground state the magnetic moment has very fast quantum fluctuations and hence does not have a constant magnitude. An experiment with a 'time window' larger than t_q will average over the quantum fluctuations and measure the average magnetic moment per atom (or equivalently, 'atomic moment') which is necessarily nonintegral in magnitude. At low temperatures, the spin-flip excitation spectrum consists of single-particle excitations and collective excitations. Spin-up holes and spin-down electrons, created by intra-atomic spin-flip transitions of electrons from a spin-up band to a spin-down band (as sketched in Figure 1(a) and (b) for weak and strong itinerant-electron ferromagnets) and moving independent of one another in a common mean (exchange) field, constitute the single-particle excitations.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

Such excitations form the Stoner continuum, which, at finite momentum transfer q, extends from $E_q = 0$ in Figure 1(a) ($E_q = \Delta' = E_F$(Fermi energy) $- E_\uparrow^{top}$ in Figure 1b) to high energies, as schematically depicted in Figure 2(a) and (b) for weak (strong) itinerant-electron ferromagnets. Single-particle excitations with zero momentum transfer ($q = 0$) cost an energy equal to the exchange splitting Δ (Figure 2). The transfer of an electron–hole pair excitation, which results from a spin flip on an atom, from atom to atom gives rise to spin-wave excitations (Figure 3). The typical spin-wave energy is nearly 2 orders of magnitude smaller than the bandwidth and hence the timescale associated with this energy is $t_{sw} \approx 10^{-13}$s. In itinerant-electron ferromagnets, spin waves exist as well-defined collective excitations only in the small q and small $E_q = \hbar\omega_q$ region in the Brillouin zone (Figure 2), where the Stoner single-particle excitations require high energies of the order of intra-atomic exchange splitting $\Delta = I(n_\uparrow - n_\downarrow)$; I is the intra-atomic exchange interaction and $n_\uparrow(n_\downarrow)$ is the population of the spin-up (spin-down) band (Figures 1 and 3). As the momentum transfer q increases from zero, the energy gap between the Stoner continuum and spin-wave spectrum reduces rapidly such that beyond a certain threshold value of $q = q_{SB}$, the spin-wave dispersion curve enters the Stoner continuum. For $q > q_{SB}$, the spin

waves get damped with the result that the collective magnetic excitations in the Stoner continuum are the overdamped (nonpropagating) modes of exchange-enhanced longitudinal and transverse spin-density fluctuations (Figure 2). For spin fluctuations of given q, in the longitudinal mode, the magnetic moments point in the same direction but their amplitude fluctuates from one lattice site to the other, whereas in the transverse mode, amplitude of the magnetic moments remains nearly constant while their direction varies from site to site. Since spin-wave modes of larger and larger q are excited as the temperature is raised from $T = 0$, the transition at $q = q_{SB}$ from well-defined spin waves to nonpropagating exchange-enhanced transverse spin fluctuations should be observed at a certain finite value of temperature. By contrast, the thermally excited nonpropagating exchange-enhanced longitudinal spin-density fluctuations persist down to $q = 0$ and coexist with, but are swamped by, spin waves for $q \leq q_{SB}$. A detailed description of the nature of magnetic excitations in different systems and their experimental determination is furnished in Section 2.

A phase transition from a magnetically ordered state to a magnetically disordered (paramagnetic) state occurs at a well-defined temperature when critical fluctuations of the order parameter (spontaneous magnetization) get correlated over distances of the order of the system size. At the critical point, spin waves in localized-spin systems and nonpropagating longitudinal as well as transverse spin-density fluctuations in weak itinerant-electron systems destroy long-range magnetic order. The rudiments of thermally driven phase transitions and critical phenomena as well as the intricacies in the data analyses are dealt with at length in Section 3.

For a detailed theoretical background to the nature of magnetic excitations and phase transitions in Heisenberg (localized-spin) and band (itinerant-electron) magnets, the reader is referred to Gautier (1982), Moriya (1985), Capellmann (1987), Barbara, Gignoux and Vettier (1988), Callaway (1991), Yosida (1996), and Mohn (2003), see also

2 MAGNETIC EXCITATIONS

As the temperature of the spin system is raised from very low temperatures, different types of magnetic excitations become important, in the following sequence, in different temperature regimes till the critical point is reached at which the long-range magnetic order is completely destroyed and a phase transition to the magnetically disordered (paramagnetic) state occurs.

2.1 Propagating transverse spin fluctuations (spin waves)

In a wide variety of spin systems regardless of whether they are crystalline or amorphous, insulating (localized-electron) or metallic (itinerant-electron), ferromagnetic or antiferromagnetic, or even ferrimagnetic, spin waves exist as well-defined low-lying (in energy) collective magnetic excitations from the ground state. Spin-wave excitations, involving energy transfers typically of the order of 100 meV, are amenable to direct detection in the inelastic neutron-scattering (INS) experiments on bulk samples.

If z axis is chosen as the spin quantization direction, the partial differential cross-section for the inelastic (*inel*) scattering of unpolarized thermal neutrons due to the magnetic interaction between neutron spin and the spins of unpaired electrons, localized at the lattice sites of a system of N atoms, is given by Squires (1978), Lovesey (1987), and Stirling and McEwen (1987)

$$\left(\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega \mathrm{d}E}\right)_{\text{inel}} = \left(\frac{\gamma e^2}{m_e c^2}\right)^2 \frac{k'}{k}\left\{\frac{1}{2}\, g\, F(\mathbf{Q})\right\}^2 \times e^{-2W(\mathbf{Q})}\, \frac{N}{\pi (g\mu_B)^2}\, [1 + n(\omega)] \times \Big[(1 - \hat{\mathbf{Q}}_z^2)\, \mathrm{Im}\chi_{||}(\mathbf{Q}, \omega) + (1 + \hat{\mathbf{Q}}_z^2)\, \mathrm{Im}\chi_{\perp}(\mathbf{Q}, \omega)\Big] \quad (1)$$

In this equation, $\mathbf{k}$ and $\mathbf{k}'$ are the wave vectors of the incident and scattered neutrons, $\mathbf{Q} = \mathbf{k} - \mathbf{k}'$, $\hat{\mathbf{Q}}_z$ is the z component of the unit vector $\hat{\mathbf{Q}} = \mathbf{Q}/|\mathbf{Q}|$, $F(\mathbf{Q})$ and $e^{-2W(\mathbf{Q})}$ are the form factor and the Debye–Waller factor, respectively, for the magnetic lattice, $E = \hbar\omega = (\hbar^2/2m_n)(k^2 - k'^2)$ is the energy transfer, $n(\omega) = [\exp(\hbar\omega/k_B T) - 1]^{-1}$ is the Bose function, $\mathrm{Im}\chi_{||}(\mathbf{Q}, \omega)$ and $\mathrm{Im}\chi_{\perp}(\mathbf{Q}, \omega)$ are the imaginary parts of the longitudinal (i.e., along the direction of magnetization (z axis)) and transverse (i.e., perpendicular to z axis) wave-vector- and frequency-dependent magnetic susceptibilities and the remaining symbols have their usual meaning. In equation (1), the inelastic scattering cross-section is the sum of longitudinal and transverse contributions. At low temperatures, where the linear spin-wave approximation holds and the spin-wave linewidths are negligible, the longitudinal part of the cross section leads (Squires, 1978; Lovesey, 1987) only to elastic scattering, whereas the transverse part takes the form (Squires, 1978; Lovesey, 1987; Stirling and McEwen, 1987):

$$\left(\frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega \mathrm{d}E}\right)^{\perp}_{\text{inel}} = \left(\frac{\gamma e^2}{m_e c^2}\right)^2 \frac{k'}{k}\left\{\frac{1}{2}\, g\, F(\mathbf{Q})\right\}^2 \times e^{-2W(\mathbf{Q})}\, (1 + \hat{\mathbf{Q}}_z^2)\, \frac{S}{2}\, \frac{(2\pi)^3}{v_0} \times \sum_{\mathbf{q},\boldsymbol{\tau}} \Big\{(n_{\mathbf{q}} + 1)\, \delta(E_{\mathbf{q}} - E)\, \delta(\mathbf{Q} - \mathbf{q} - \boldsymbol{\tau}) + n_{\mathbf{q}}\, \delta(E_{\mathbf{q}} + E)\, \delta(\mathbf{Q} + \mathbf{q} - \boldsymbol{\tau})\Big\} \quad (2)$$

where $n_{\mathbf{q}} = [\exp(\hbar\omega_{\mathbf{q}}/k_B T) - 1]^{-1}$ is the (Boson) occupation factor for the magnons (spin waves) of wave vector $\mathbf{q}$ and energy $E_{\mathbf{q}} = \hbar\omega_{\mathbf{q}}$, $(2\pi)^3/v_0$ is the volume of a unit cell in the reciprocal lattice and $\boldsymbol{\tau}$ is the reciprocal-lattice vector. The first (second) term in the inelastic scattering cross-section corresponds to the creation (annihilation) of an infinite-lifetime magnon and the consequent neutron energy loss (gain). Note that the expression for the transverse inelastic cross section for the scattering of neutrons by spin waves in an itinerant-electron ferromagnet bears a striking similarity (Lovesey, 1987) with equation (2), which is valid for a Heisenberg ferromagnet. Since both momentum- and energy-conservation conditions govern the creation or annihilation of a magnon, the INS experiments provide a direct means of determining the whole spin-wave spectrum (dispersion). Obviously, creation of magnons is favored over annihilation at low temperatures ($k_B T \ll \hbar\omega$). At higher temperatures, dynamic magnon–magnon interactions become important and broaden the spin-wave peaks. In order to fit the constant-q INS scans, the spectral weight function $F_{\perp}(\mathbf{Q}, \omega)$ in the expression $\mathrm{Im}\chi_{\perp}(\mathbf{Q}, \omega) = \pi\omega\, \chi_{\perp}(\mathbf{Q})\, F_{\perp}(\mathbf{Q}, \omega)$ (where $\chi_{\perp}(\mathbf{Q})$ is the static wave vector–dependent susceptibility), and hence in equation (2) via equation (1), is often approximated by either a double Lorentzian (DL)

$$F_{\perp}^{\mathrm{DL}}(\mathbf{q}, E) = \frac{1}{2\pi}\left[\frac{\Gamma_{\mathbf{q}}}{(E - E_{\mathbf{q}})^2 + \Gamma_{\mathbf{q}}^2} + \frac{\Gamma_{\mathbf{q}}}{(E + E_{\mathbf{q}})^2 + \Gamma_{\mathbf{q}}^2}\right] \quad (3)$$

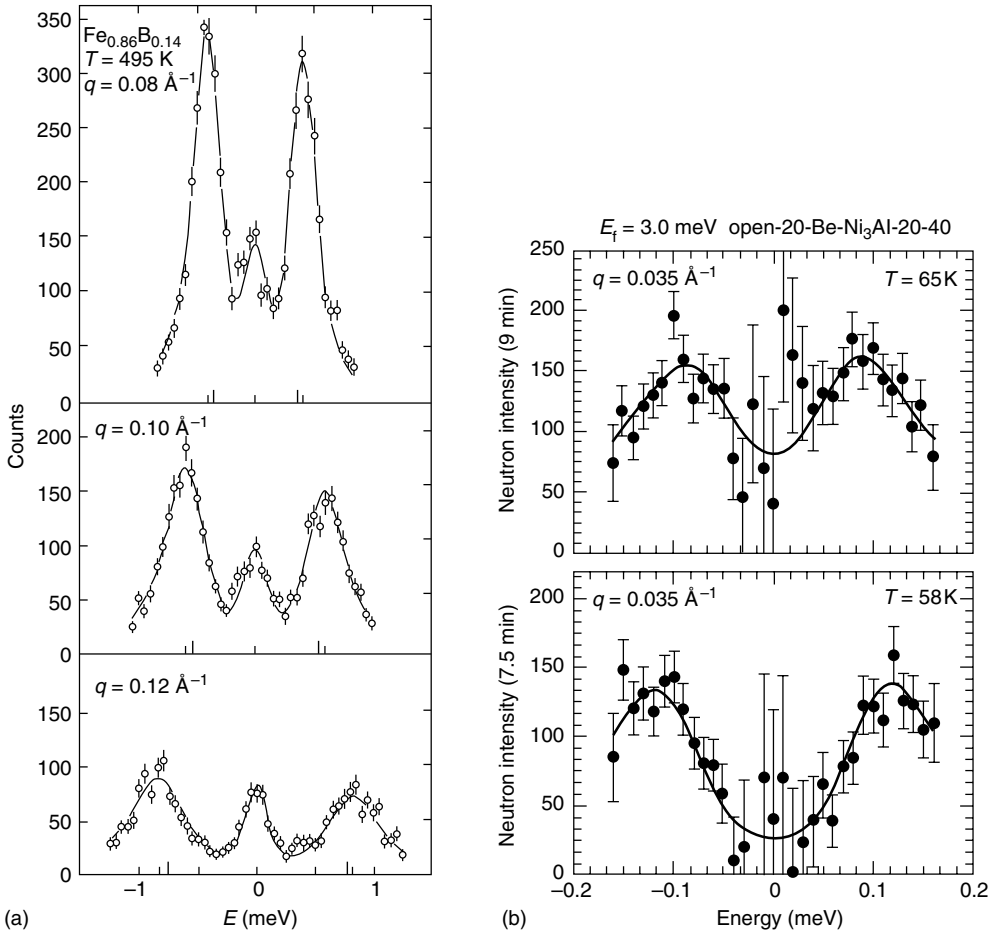

Figure 4. Constant-q scans for (a) amorphous $Fe_{86}B_{14}$ at $q = 0.08$, 0.10, and $0.12\,\text{Å}^{-1}$ and $T = 495\,\text{K}$ and (b) the weak itinerant-electron ferromagnet Ni_3Al at $q = 0.035\,\text{Å}^{-1}$ and $T = 58\,\text{K}$ ($0.8T_C$), 65 K ($0.9T_C$). The solid curves denote the least-squares fits based on equation (3).

or a damped-harmonic-oscillator (DHO) form

$$F_{\perp}^{\text{DHO}}(\mathbf{q}, E) = \frac{1}{\pi} \frac{\Gamma_{\mathbf{q}}(E_{\mathbf{q}}^2 + \Gamma_{\mathbf{q}}^2)}{[(E - E_{\mathbf{q}})^2 + \Gamma_{\mathbf{q}}^2][(E + E_{\mathbf{q}})^2 + \Gamma_{\mathbf{q}}^2]} \quad (4)$$

where $\Gamma_{\mathbf{q}}$ is the $\mathbf{q}$-dependent half-width at half-maximum (HWHM) of the spin-wave peak. Figure 4(a) (taken from Fernandez-Baca, Lynn, Rhyne and Fish, 1987) and 4(b) (taken from Semadeni *et al*., 2000), pertaining, respectively, to the amorphous Invar alloy $Fe_{86}B_{14}$ (which behaves as a Heisenberg ferromagnet but the canonical examples of such a ferromagnet are EuO and EuS) and the well-known weak itinerant-electron ferromagnet Ni_3Al, serve to illustrate as to how the magnon dispersion for a ferromagnet is measured in an INS experiment. In Figure 4, (i) the spin-wave excitations manifest themselves as inelastic peaks centered at $\pm E_{\mathbf{q}}$ (on either side of the elastic peak centered at $E = 0$) in the neutron-scattering intensity versus the energy transfer E isotherm taken at a fixed value of q, (ii) the continuous curves in Figure 4 are the theoretical fits obtained by assuming that the spectral weight function in the transverse (longitudinal) part of the cross section in equation (1) can be approximated by equation (3) (a δ function centered at $E = 0$ in Figure 4a) and treating $E_{\mathbf{q}}$ and $\Gamma_{\mathbf{q}}$ as free parameters, (iii) $E_{\mathbf{q}}$ and $\Gamma_{\mathbf{q}}$ corresponding to different values of q are thus directly obtained from the constant-q scans taken at a given temperature while their temperature variations, $E_{\mathbf{q}}(T)$ and $\Gamma_{\mathbf{q}}(T)$, are determined from the constant-q scans taken at different temperatures. Details about the INS determination of the spin-wave spectrum in a wide variety of magnetic systems are given in Stirling and McEwen (1987), Tomiyoshi *et al*. (1987), Mook (1988), Lynn and Rhyne (1988), Shapiro (1988), and Fernandez-Baca *et al*. (1990); see also **X-ray and Neutron Scattering by Magnetic Materials, Volume 1** and **Spin Structures and Spin Wave Excitations, Volume 3**.

Regardless of the nature (localized or itinerant) of magnetic electrons, the spin-wave dispersion relation has the form

$$E_{\mathbf{q}}(T) = \hbar\omega_{\mathbf{q}}(T) = \Delta_{\mathrm{SW}} + D(T)q^2(1 - \beta q^2) \qquad (5)$$

where Δ_{SW} is an effective energy gap in the spin-wave spectrum originating from dipole–dipole interactions, magnetic anisotropy, and external magnetic field (if present) and the spin-wave stiffness, D, renormalizes with temperature according to the relation

$$D(T) = D(0)(1 - D_2\,T^2 - D_{5/2}\,T^{5/2}) \qquad (6)$$

for both localized-electron (Izuyama and Kubo, 1964; Keffer, 1966) and itinerant-electron (Izuyama and Kubo, 1964; Mathon and Wohlfarth, 1968) models. Within the framework of the Heisenberg model, the T^2 term is appreciable only when the localized spins interact with one another via the spin of conduction electrons and this term is normally several orders of magnitude smaller than the $T^{5/2}$ term, which arises from the magnon–magnon interactions. By contrast, the T^2 term in the band model results from the interaction between spin waves and single-particle excitations and dominates over the $T^{5/2}$ term, which originates from the magnon–magnon interactions, as in the localized-electron case. Thus, the expressions $D(T) = D(0)(1 - D_2\,T^2)$ and $D(T) = D(0)(1 - D_{5/2}\,T^{5/2})$ essentially denote the variation of the spin-wave stiffness with temperature for the itinerant- and localized-electron models, respectively. These models also make specific predictions about the functional dependence of $\Gamma_{\mathbf{q}}$ on q. In the long-wavelength ($q \to 0$) limit, equation (5) reduces to $E_{\mathbf{q}}(T) = D(T)\,q^2$ for an isotropic ferromagnet in the absence of external magnetic field. In the limit as $q \to 0$, $E_{\mathbf{q}}(T) \propto q^2$ ($E_{\mathbf{q}}(T) \propto q$) for a ferrimagnet (antiferromagnet).

By virtue of the fact that the INS experiments directly determine $E_{\mathbf{q}}(q, T)$ (and hence $D(T)$) and $\Gamma_{\mathbf{q}}(q, T)$, the INS technique is the most powerful experimental tool for clearly distinguishing between the localized and band models (and thereby reveal the exact nature of magnetic electrons) by unambiguously verifying their predictions concerning the thermal renormalization of spin-wave stiffness, $D(T)$, and the variations of spin-wave linewidth with q and temperature, $\Gamma_{\mathbf{q}}(q, T)$. This is particularly true when spin waves fill the entire Brillouin zone and the spin-wave dispersion falls within the energy transfer range covered in the INS experiments (as is the case for Heisenberg ferromagnets). However, the INS technique suffers from a number of drawbacks. First, owing to very weak interaction of neutrons with matter, this method has the required sensitivity only for bulk samples or large multilayer systems. Second, it fails to detect other excitations accompanying spin waves. For instance, in those amorphous ferromagnets or Invar systems that have a noncollinear ground-state arrangement of local magnetic moments (caused by a strong competition between the ferromagnetic and antiferromagnetic interactions), the diffusive modes ('diffusons') associated with the longitudinal spin fluctuations contribute to the $T^{3/2}$ decrease of magnetization as significantly as the propagating transverse spin fluctuations (spin waves) do (Continentino and Rivier, 1979; Valiev and Menshikov, 1995; Kaul, 1999). Unlike spin waves, the diffusons show up as the central (elastic) peak (which already contains contributions from small-angle and incoherent scattering from the sample and its environment) in the constant-q INS scans. It is, therefore, not possible to resolve this component from the nuclear scattering. Further complication arises when the coupling between the longitudinal spin fluctuations and the spin-wave modes gives rise to inelastic peaks that are centered at the spin-wave energies (Vaks, Larkin and Pikin, 1968), besides a much smaller central peak corresponding to spin diffusion. Third, the limited range of energy transfer accessible to the INS experiments does not permit a simultaneous detection of spin waves and (high energy) Stoner single-particle excitations, which are present in itinerant-electron ferromagnets. The first and third limitations of the INS method have been overcome in a relatively new experimental technique called the *spin-polarized electron-energy-loss spectroscopy* (SPEELS). In this experiment, the spin-polarized incident electron beam of fixed energy gets scattered from the surface of an itinerant-electron ferromagnet and spin polarization of the scattered beam is measured as a function of the energy loss suffered by the electrons during the scattering process. Recognizing that the energy loss is mainly due to the exchange scattering from electron–hole pair excitations, this technique directly probes the Stoner single-particle (spin-flip or non-spin-flip) excitations (Venus and Kirschner, 1988; Penn and Apell, 1988; Abraham and Hopster, 1989). SPEELS, with considerably improved energy resolution, has recently enabled observation of large wave vector ($\cong 1\,\text{Å}^{-1}$) and large energy ($\cong 250\,\text{meV}$) spin waves in ultrathin Fe or Co films (Plihal, Mills and Kirschner, 1999; Vollmer *et al*., 2003, 2004; see also **High-energy Surface Spin Waves Studied by Spin-polarized Electron Energy Loss Spectroscopy, Volume 3**). Like SPEELS, the ferromagnetic resonance and Brillouin light scattering techniques are extremely powerful surface-sensitive experimental tools but they can detect spin waves of small wave vector ($\leq 0.01\,\text{Å}^{-1}$) only. As far as the second limitation is concerned, a comparison of the value of spin-wave stiffness at 0 K, directly determined from the INS experiments, $D_n(0)$, with that, $D_m(0)$, deduced from the magnetization measurements, reveals the existence or absence of the concomitant excitations and gives important clues about the nature of such excitations (Kaul, 1984a). This calls for high-resolution magnetization measurements and an elaborate data analysis, as elucidated in the following text.

The decline in magnetization, $M(T, H)$, due to the thermally excited long-wavelength spin-wave excitations at temperature, T, and external magnetic field, H, for Heisenberg (Keffer, 1966) as well as band (Kaul, 1999, 2005) ferromagnets is given by

$$M(T, H) = M(0, H) - g\mu_B \int_0^\infty \frac{n_{SW}(\omega)\, d\omega}{e^{(\hbar\omega + g\mu_B H_{eff})/k_B T} - 1} \tag{7}$$

In equation (7), the magnon density of states, $n_{SW}(\omega)$, and the effective field, H_{eff}, have the forms

$$n_{SW}(\omega) = \frac{1}{4\pi^2}\left(\frac{\hbar}{D(T)}\right)^{3/2} \omega^{1/2} \tag{8}$$

and $H_{eff} = H - H_D + H_L + H_A$ with H_D, H_L, and H_A representing the demagnetizing, Lorentz, and anisotropy fields, respectively, while the magnon (Bose) occupation factor makes use of the spin-wave dispersion relation, equation (5), but with $\beta = 0$ (i.e., $\hbar\omega(T) = D(T)\, q^2$) and $\Delta_{SW} = g\mu_B H_{eff}$. In a more general case, where the Bose factor in equation (7) is replaced by $[\exp\{\hbar\omega_{\mathbf{q}}(T)/k_B T\} - 1]^{-1}$ (with $\hbar\omega_{\mathbf{q}}(T)$ given by equation (5)) and $n_{SW}(\omega)$ by $n_{SW}(\omega_{\mathbf{q}})$, and both spin-wave (SW) and Stoner single-particle (SP) excitations contribute to the fractional decrease in magnetization, defined as $\Delta m(T, H) \equiv [M(0, H) - M(T, H)]/M(0, H)$, $\Delta m(T, H)$ has the functional form (Thompson, Wohlfarth and Bryan, 1964; Keffer, 1966)

$$\Delta m(T, H) = \Delta m_{SW}(T, H) + \Delta m_{SP}(T, H) \tag{9}$$

$$\Delta m_{SW}(T, H) = \frac{g\mu_B}{M(0, H)}\left[Z(3/2, t_H)\left(\frac{k_B T}{4\pi D(T)}\right)^{3/2} + 15\pi\beta\, Z(5/2, t_H)\left(\frac{k_B T}{4\pi D(T)}\right)^{5/2}\right] \tag{10}$$

$$\Delta m_{SP}(T, H) = A'(H) T^{3/2} \exp(-\Delta_{SP}/k_B T)$$

for a strong itinerant-electron ferromagnet

$$= A(H) T^2$$

for a weak itinerant-electron ferromagnet

(11)

In equation (10), the Bose–Einstein integral functions $Z(s, t_H) = \sum_{n=1}^{\infty} n^{-s} \exp(-nt_H)$ and $t_H = g\mu_B H_{eff}/k_B T$ allow for the extra energy gap $g\mu_B H_{eff} (= \Delta_{SW} = k_B T_g)$ in the spin-wave spectrum arising from the effective field that the spins experience within the sample, and the $T^{3/2}$ ($T^{5/2}$) term has its origin in the q^2 (q^4) term in the spin-wave dispersion relation, equation (5). Taking cognizance of the theoretical prediction that $D(T)$ in equation (10) varies as T^2 or $T^{5/2}$ for band or Heisenberg ferromagnets, it is obvious from the expressions (10) and (11) that magnetization is expected to be a smoothly varying function of temperature that may include $T^{3/2}$, T^2, $T^{5/2}$, $T^{7/2}$, and exponential terms. An unambiguous determination of the spin-wave and single-particle contributions is, therefore, not possible unless the magnetization is measured with extremely high precision and an elaborate data analysis is carried out. This strategy has been successfully implemented, and has yielded several interesting results, in a number of systems that include Fe and Ni (Ododo and Anyakoha, 1983), crystalline (Nakai, 1983, 1990; Nakai, Ono and Yamada, 1983; Nakai and Maruyama, 1992), and amorphous (Kaul, 1983; Yamada *et al.*, 1986; Nakai *et al.*, 1987; Kaul and Babu, 1994a, 1998; Semwal and Kaul, 1999, 2004) Invar alloys. For instance, from a reanalysis of the already published magnetization data on Fe and Ni, Ododo and Anyakoha (1983) concluded that (i) at low temperatures ($T \leq 0.4T_C$), besides the dominant spin-wave contribution, Stoner non-spin-flip single-particle excitations rather than their spin-flip counterpart significantly contribute to thermal demagnetization in both Fe and Ni, and (ii) a gap between the 'acoustic' and 'optical' branches in the spin-wave dispersion spectrum of Ni occurs at the wave vector $q_{co} = 0.47 \pm 0.01$ Å^{-1} and energy $E_{co} = 120 \pm 6$ meV, and predicted a similar gap between the 'acoustic' and 'optical' magnon branches at $q_{co} = 0.74 \pm 0.02$ Å^{-1} and $E_{co} = 166 \pm 10$ meV in Fe. While the SPEELS (Venus and Kirschner, 1988; Penn and Apell, 1988; Abraham and Hopster, 1989) experiments on Fe and Ni, and INS experiments (Mook and Paul, 1985) on Ni, later confirmed the findings (i) and (ii), the prediction of a gap in the spin-wave spectrum of Fe has found firm support in the recent many-body calculations (Karlsson and Aryasetiawan, 2000). Similarly, in conformity with the results of the magnetoresistance (Kaul and Rosenberg, 1983), spin-polarized photoemission (Hopster *et al.*, 1985), Compton scattering (Anderjczuk *et al.*, 1992), and spin-polarized INS (Lynn, Rosov and Fish, 1993) measurements, an extensive analysis of high-resolution magnetization data (Kaul and Babu, 1994a) reveals that all the compositions in the amorphous $(Fe_pNi_{1-p})_{80}$ $(B,Si)_{20}$ alloy series behave as weak itinerant-electron ferromagnets, while a transition from weak to strong itinerant ferromagnetism occurs at $p \cong 0.75$ in the amorphous $(Fe_pNi_{1-p})_{80}P_{14}B_6$ alloys and that propagating longitudinal spin fluctuations make as significant a contribution to the $T^{3/2}$ decrease of magnetization as their transverse counterpart (spin waves) does for the compositions $p > 0.75$ in both the alloy series. An example (Semwal and Kaul, 1999, 2004), shown in Figure 5, serves to illustrate (see the deviation plots in the lower panel) that at temperatures $T \leq 0.24T_C$ (where T_C is the Curie temperature) spin waves (manifesting themselves as $M(T) \sim T^{3/2}$) swamp the contributions to magnetization arising from both Stoner single-particle ($M(T) \sim T^2$) and nonpropagating collective electron–hole pair ($M^2(T) \sim T^2$; for details,

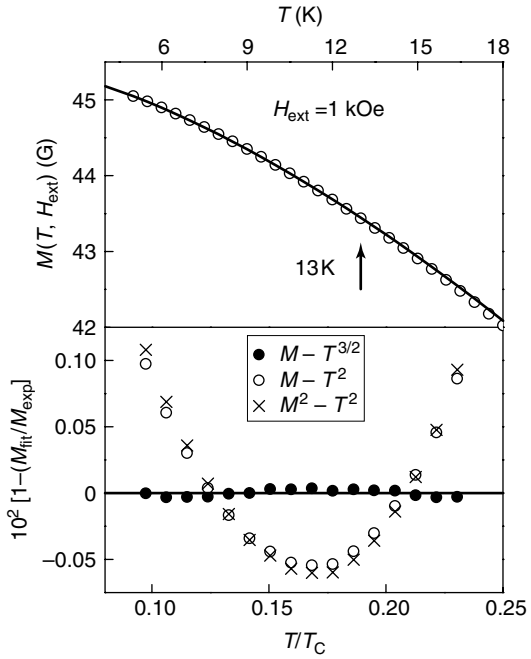

Figure 5. The upper panel depicts the temperature variation of magnetization measured at an external magnetic field of $H_{ext} = 1$ kOe for the weak itinerant-electron ferromagnet Ni_3Al at low temperatures and the continuous curve is the least-squares fit based on equation (10). The lower panel displays the percentage deviation of the data from the least-squares fits based on equations (10) and (11). Notice that the functional form given by equation (10) yields minimum deviations.

see Section 2.3) excitations in the weak itinerant-electron ferromagnet Ni_3Al. Furthermore, the observation (Semwal and Kaul, 1999) that $D_n(0) = D_m(0)$, within the uncertainty limits, permits the conclusion that no diffusons are present in this material.

2.2 Magnon-fracton crossover

Understanding the nature of quantized excitations in fractal networks, the crossover between extended (phonon, magnon) and strongly localized (fracton) excitations, and the effect of this crossover on thermodynamic and transport properties of random physical systems, continues to be a fascinating subject (Nakayama, Yakubo and Orbach, 1994). Alexander and Orbach (1982) determined the density of states and the dispersion relation for vibrational excitations of D_f-dimensional fractal network. They termed such excitations as fractons and conjectured that the *fracton dimensionality* $\tilde{d}_f = 4/3$ for percolation networks with Euclidean dimension $d \geq 2$. One of the well-known realizations of a self-similar (fractal) network is a quenched random site–diluted Heisenberg magnet with the concentration of magnetic atoms (p) near the percolation threshold (p_c). At $p = p_c$, an infinite magnetic cluster first appears (i.e., for $p < p_c$, only finite magnetic clusters are present and no long-range magnetic order exists even for temperatures as low as $T \approx 0$ K), and the percolation correlation length at $T = 0$ K, $\xi_0(p)$, diverges in accordance with the relation (Stauffer and Aharony, 1992)

$$\xi_0(p) = \xi_p (p - p_c)^{-\nu_p} \tag{12}$$

The divergence in $\xi_0(p) \equiv \xi(T = 0, p)$ induces a crossover in the dynamics of Heisenberg spins from hydrodynamic (magnon) behavior for $q\xi < 1$ to critical (fracton) behavior for $q\xi > 1$, where q is the inverse wavelength of spin waves in the hydrodynamic regime and the inverse characteristic length of the localized fracton modes in the critical regime. Change from Euclidean dimension, d, to *fractal dimension*, D_f, causes a crossover in the dispersion relation and the density of states from their long-wavelength (low-frequency, $\omega \ll \omega_{co}$) magnon forms to short length scale (high-frequency, $\omega \gg \omega_{co}$) magnetic fracton forms at a characteristic frequency ω_{co}. Such a crossover has a profound effect on those static thermal properties that are directly related to the excitation of spin waves such as magnetization and specific heat. The dilution-induced hydrodynamic-to-critical crossover in the dynamics of Heisenberg spins on a percolation network and the consequent crossover in the thermal behavior of magnetization for concentrations just above the percolation threshold, has been theoretically studied by Stinchcombe and Pimentel (1988). This crossover is, however, distinctly different from the usual thermal-to-percolation crossover (Stauffer and Aharony, 1992) which occurs when the thermal fluctuations of the order parameter become critical at a concentration-dependent temperature $T_C(p)$, as the percolation critical point $Q(p = p_c, T = 0)$ is approached by reducing the temperature to zero at fixed values of p with $p \to p_c$ in the $T - p$ diagram (Figure 6). For a given concentration, p, of the magnetic atoms, $T_C(p)$ is the temperature at which a transition from a magnetically disordered (paramagnetic) state to a magnetically ordered (ferromagnetic, antiferromagnetic, or ferrimagnetic) state occurs when the temperature is lowered from high temperatures.

In its most general scaling form, the density of vibrational states of a percolating network for $p > p_c$ is given by (Aharony, Alexander, Entin-Wohlman and Orbach, 1985; Aharony, Entin-Wohlman, Alexander and Orbach, 1987)

$$N(\omega) = A\,\omega^{x-1} f(\omega/\omega_{co}) \tag{13}$$

where x is the *fracton* dimensionality whose explicit expression depends on the particular fractal model chosen, ω_{co} is the frequency at which a crossover from hydrodynamic (phonon or magnon) regime to the critical (fracton) regime occurs,

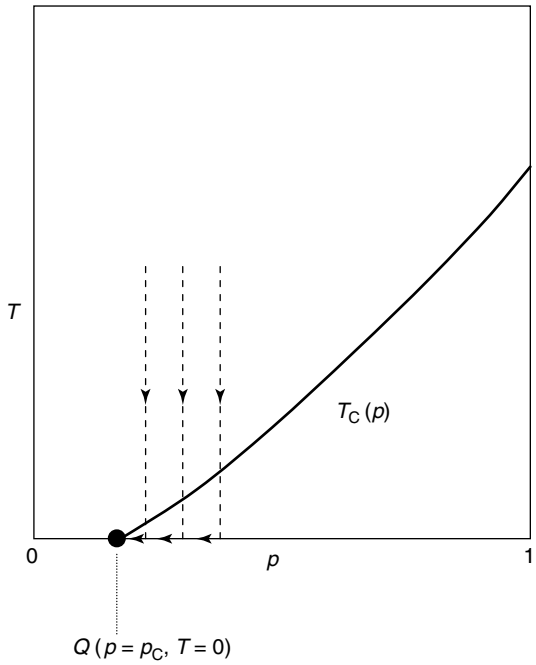

Figure 6. Schematic $T - p$ phase diagram in which the arrows depict the path through which the percolation critical point $Q(p = p_C, T = 0)$ is approached by reducing temperature to zero at fixed values of the concentration, p, of the magnetic atoms for p just above the percolation threshold, p_C. This diagram also roughly sketches a typical thermal-to-percolation crossover line, $T_C(p)$.

and A is a constant independent of ω_{co}. The scaling function in equation (13) has the asymptotic limits $f(z) \to 1$ as $z \to \infty$ and $f(z) \to z^{d'-x}$ as $z \to 0$ so that (Aharony, Alexander, Entin-Wohlman and Orbach, 1985; Aharony, Entin-Wohlman, Alexander and Orbach, 1987)

$$N_{hy}(\omega) = A\,\omega_{co}^{x-d'}\,\omega^{d'-1} \tag{14}$$

in the hydrodynamic ($\omega \ll \omega_{co}$) limit and

$$N_{cr}(\omega) = A\,\omega^{x-1} \tag{15}$$

in the critical ($\omega \gg \omega_{co}$) limit. In the case of magnon–fracton crossover, the fracton dimensionality x and the dimension d' are $x = \tilde{d}_f/2$ and $d' = d/2$. Salamon and Yeshurun (1987) suggested an expression for the effective density of states, $n_{eff}(\omega)$, in $d = 3$ percolating ferromagnetic networks that is supposed to be valid not only in the magnon and fracton regimes but also in the entire crossover region. Early attempts (Salamon and Yeshurun, 1987; Yeshurun and Salamon, 1987; Zadro, 1996) to experimentally determine the fracton contribution to $M(T)$ in site-diluted amorphous ferromagnets with $p \geq p_c$, based on this form of $n_{eff}(\omega)$, however, yielded widely different values for $\tilde{d}_f$. Subsequently, this discrepancy in the values of $\tilde{d}_f$ was traced to a number of major flaws (Kaul and Srinath, 2001) in both the form of the effective density of states and the data analysis used by Salamon and Yeshurun (1987) and Zadro (1996). The extensive investigations of ferromagnetic fractons in quenched random site–diluted ferromagnets (Kaul and Srinath, 2001; Kaul and Semwal, 2004) have completely got rid of these flaws by carrying out a thorough data analysis and by using the density of states of the form

$$n_{eff}(\omega) = \left(\frac{1}{4\pi^2}\right)\left[\frac{\hbar}{D(p)}\right]^{d/2}(p - p_c)^{\nu_p(D_f - d)} \times \omega^{(d/2)-1}\left(1 + \frac{\omega}{\omega_{co}}\right)^{(\tilde{d}_f - d)/2} \tag{16}$$

proposed by Kaul and Srinath (2001). Unlike the earlier (Salamon and Yeshurun, 1987) form of the density of states, equation (16) (i) yields the correct asymptotic forms (Aharony, Alexander, Entin-Wohlman and Orbach, 1985; Aharony, Entin-Wohlman, Alexander and Orbach, 1987; Stauffer and Aharony, 1992)

$$n_{SW}(\omega) = A'\,\omega_{co}^{(\tilde{d}_f - d)/2}\,\omega^{(d/2)-1} \tag{17}$$

and

$$n_{fr}(\omega) = A'\,\omega^{(\tilde{d}_f/2)-1} \tag{18}$$

with $A' = (1/4\pi^2)\{\hbar\omega_p^{[1-(\tilde{d}_f/d)]}/d_p\}^{d/2}$, in the magnon ($\omega \ll \omega_{co}$) (cf. equations (14) and (17)) and fracton ($\omega \gg \omega_{co}$) (cf. equations (15) and (18)) regimes, (ii) ensures a smooth crossover between the two regimes at $\omega = \omega_{co}$, and (iii) consistent with the theoretical predictions (Aharony, Alexander, Entin-Wohlman and Orbach, 1985; Aharony, Entin-Wohlman, Alexander and Orbach, 1987; Stauffer and Aharony, 1992) yields the ratio $n_{fr}(\omega_{co})/n_{SW}(\omega_{co})$, which is a constant independent of ω_{co} (i.e., the ratio is noncritical). In arriving at the equations (17) and (18), use has been made of the following relations (Nakayama, Yakubo and Orbach, 1994)

$$D(p) = d_p\,(p - p_c)^{2\nu_p[(D_f/\tilde{d}_f)-1]} \tag{19}$$

and

$$\omega_{co}(p) = \omega_p\,(p - p_c)^{2\nu_p D_f/\tilde{d}_f} \tag{20}$$

Note that for $d = 3$ equation (17) has the same form as equation (8). For computing magnetization at finite fields and temperatures with greater ease, an alternative form of

equation (16), given below, is preferred (Kaul and Srinath, 2001)

$$n_{\rm eff}(\omega) = \left(\frac{1}{4\pi^2}\right)\left[\frac{\hbar}{D(p)}\right]^{d/2}\left(\frac{m_p^*}{M_0(p)}\right) \times \omega^{(d/2)-1}\left(1+\frac{\omega}{\omega_{\rm co}}\right)^{(\tilde{d}_{\rm f}-d)/2} \quad (21)$$

This expression is obtained from equation (16) by using the relations (Stauffer and Aharony, 1992; Nakayama, Yakubo and Orbach, 1994)

$$D_{\rm f} = d - (\beta_{\rm p}/\nu_{\rm p}) \quad (22)$$

and

$$M_0(p) = m_{\rm p}^*\,(p-p_{\rm c})^{\beta_{\rm p}} = m_{\rm p}\,(p-p_{\rm c})^{\beta_{\rm p}} \times [1 + a\,(p-p_{\rm c})^{\Delta}] \quad (23)$$

The main steps involved in the data analysis are as follows. At first, employing the usual extrapolation (to $H = 0$) method, spontaneous magnetization at 0 K for each composition, $M_0(p) \equiv M(T = 0, p)$, is determined from the $M - H$ isotherm taken at the lowest possible temperature ($T_0 \cong 1$ K). The percolation critical exponent (amplitude), $\beta_{\rm p}\,(m_{\rm p})$, the 'correction-to-scaling' amplitude, a, and the percolation threshold, $p_{\rm c}$, (and hence the quantity $m_{\rm p}^*$) are determined from the best theoretical fit to the $M_0(p)$ data, based on equation (23), in which the 'correction-to-scaling' exponent Δ is fixed at its theoretically predicted value $\Delta = 1$ (Stauffer and Aharony, 1992) while $m_{\rm p}$, $p_{\rm c}$, $\beta_{\rm p}$, and a, are treated as free fitting parameters. Next, the magnetization $M(T, H)$ is calculated from equation (7) by replacing the magnon density of states, $n_{\rm SW}(\omega)$, with the effective density of states, $n_{\rm eff}(\omega)$, given by equation (21), and performing the integration over ω numerically. At any given field strength, the agreement between the observed and calculated values of M at different temperatures $T \le T_{\rm C}$ is optimized, at first, by keeping $\tilde{d}_{\rm f}$ fixed at values differing by 0.01 in the range $1.0 \le \tilde{d}_{\rm f} \le 2.0$ (which embraces the theoretically expected (Alexander and Orbach, 1982) value of $\tilde{d}_{\rm f} = 4/3$ for percolation networks with Euclidean dimension $d \ge 2$) and varying $M(0, H)$, D, and $\omega_{\rm co}$. A cross-check for a correct estimation of these parameters is provided by the stringent conditions that the above optimization process should yield the result $M(0, H) = M(T_0, H)$ (the value of magnetization corresponding to a given field measured at $T = T_0$) and $\tilde{d}_{\rm f}$ independent of both H and p. The values of $M(0, H)$ and $\tilde{d}_{\rm f}$, so obtained, are kept constant in the subsequent fits that involve only two parameters, D and $\omega_{\rm co}$. This procedure not only unravels the true functional form of the thermal renormalization of spin-wave stiffness, $D(T)$, and of the magnetic field dependence of magnon-to-fracton crossover frequency, $\omega_{\rm co}(H)$, but also yields accurate values for $D_0(p) \equiv D(T = 0, p)$, $\omega_{\rm co}(p) \equiv \omega_{\rm co}(p, 0) \equiv \omega_{\rm co}(p, H = 0)$, (and their corresponding percolation critical exponents) and $\tilde{d}_{\rm f}$ for $d = 3$ percolating ferromagnetic networks with the concentration of magnetic atoms, p, just above the percolation threshold, $p_{\rm c}$ (Kaul and Babu, 1994b; Kaul and Srinath, 2001; Kaul and Semwal, 2004).

$\omega_{\rm co}(p)$ permits determination of the temperature $T_{\rm co}^*(p) = \hbar\omega_{\rm co}(p)/k_{\rm B}$ at which the crossover from hydrodynamic regime to critical regime occurs. The locus of $T_{\rm co}^*$ values for different compositions in a given quenched random site-diluted ferromagnetic alloy series is the crossover line that divides the ferromagnetic (FM) phase into two regions (1) and (2) in the magnetic phase diagrams, as illustrated by the dashed curve shown in Figure 7 for the amorphous $(Fe_pNi_{1-p})_{80}B_{16}Si_4$ and $(Co_{p'}Ni_{1-p'})_{80}B_{16}Si_4$ alloys (Kaul and Srinath, 2001). In region (2), thermal demagnetization is solely due to hydrodynamic spin waves, whereas in region (1) both hydrodynamic and critical magnons (i.e.,

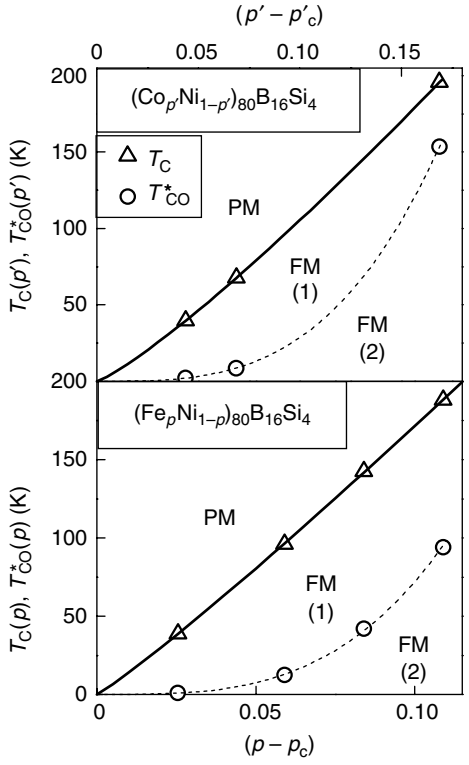

Figure 7. Magnetic phase diagrams for the amorphous alloy series $(Fe_pNi_{1-p})_{80}B_{16}Si_4$ and $(Co_{p'}Ni_{1-p'})_{80}B_{16}Si_4$ that display the two crossover lines: the thermal-to-percolation crossover line, $T_{\rm C}(p)$, (solid curves) and the magnon-to-fracton crossover line, $T_{\rm co}^*(p)$, (dashed curves) within the ferromagnetic (FM) phase.

ferromagnetic fractons) are responsible for the decline of spontaneous magnetization with increasing temperature. The magnon-to-fracton crossover line appears at lower temperatures in addition to the thermal-to-percolation crossover line (continuous curve), that is, the phase boundary between the magnetically *disordered* (paramagnetic, PM) phase and *ordered* (ferromagnetic, FM) phase. The magnetic phase diagram predicted by the theory (Stinchcombe and Pimentel, 1988) for a quenched random site–diluted Heisenberg ferromagnet conforms well to the phase diagrams shown in Figure 7. Note that in the amorphous $(Fe_pNi_{1-p})_{80}M_{20}$ and $(Co_{p'}Ni_{1-p'})_{80}M_{20}$ (M = P,B,Si) alloys Ni atoms (substituting for Fe and Co atoms at random) carry very small magnetic moments (Kaul, 1981; Liebs and Fähnle, 1996) and hence these systems are the experimental realizations of quenched random site–diluted Heisenberg ferromagnets.

Extensive investigations on amorphous (Kaul and Babu, 1994b; Kaul and Srinath, 2001) and crystalline (Kaul and Semwal, 2004) systems (i) enable an accurate determination of the hydrodynamic-to-critical spin-wave crossover line in the magnetic phase diagram, the percolation-to-thermal crossover exponent, the fractal and fracton dimensionalities, the percolation critical exponents for magnetization, and the spin-wave stiffness, (ii) vindicate the Alexander–Orbach conjecture (Alexander and Orbach, 1982) by demonstrating that $\tilde{d}_f \cong 4/3$ for $d = 3$ percolating network, and (iii) conclusively prove that quenched randomness does not alter the critical behavior of percolation on a regular $d = 3$ lattice. A direct experimental evidence for antiferromagnetic fracton excitations in a $d = 3$ site-diluted Heisenberg antiferromagnet with the concentration of the magnetic atoms near the percolation threshold, $RbMn_{0.39}Mg_{0.61}F_3$, has recently been provided by INS experiments (Ikeda *et al*., 1994).

2.3 Nonpropagating exchange-enhanced spin-density fluctuations

Weak itinerant-electron ferromagnets, as opposed to their strong counterparts, facilitate the study of the interaction of collective spin-wave modes with the Stoner single-particle excitations since the relatively small spin splitting of the d band ensures that spin-wave dispersion curve intersects the boundary of Stoner continuum (henceforth referred to as the *Stoner boundary*, SB) tangentially at much lower values of energy, $E_{\mathbf{q}}$, and momentum, $\mathbf{q}$ (Moriya, 1985). Within the $(E_{\mathbf{q}}, \mathbf{q})$ space covered by the Stoner continuum, spin waves are degenerate in energy with single-particle excitations and hence have a short lifetime. The lifetime depends on the density of states of Stoner excitations; the higher the density of states, the shorter the spin-wave lifetime and broader the spin-wave peaks in the INS cross-section. Thus, the spin-wave linewidth increases abruptly at the SB, whereas the integrated intensity (of the spin-wave peaks) starts decreasing before the spin-wave dispersion curve enters the Stoner continuum at a threshold value $q = q_{SB}$ (Figure 2) and falls to very low values above q_{SB}, indicating thereby that the spin waves are severely damped upon crossing the SB. An abrupt increase in the linewidth and a steep drop in the intensity of spin-wave peaks in the inelastic scattering cross-section of unpolarized (spin-polarized) neutrons at the SB has been observed by Ishikawa, Shirane, Tarvin and Kohgi (1977) and Semadeni *et al*. (1999) in the weak itinerant-electron ferromagnet MnSi at the energy transfer $E_{SB} \cong 2.5\,\text{meV}$ ($E_{SB} \cong 3.0\,\text{meV}$) and momentum transfer $q_{SB} \cong 0.25\,\text{Å}^{-1}$ ($q_{SB} \cong 0.36\,\text{Å}^{-1}$), and by Mook, Nicklow, Thompson, and Wilkinson (1969) and Mook and Nicklow (1973) in the early INS experiments on itinerant-electron ferromagnets Fe and Ni at the energies $E_{SB} \cong 80\,\text{meV}$ and $E_{SB} \cong 110\,\text{meV}$, respectively. A drop in the magnon intensity as the SB is approached in an itinerant-electron ferromagnet sharply contrasts with the q-independent spin-wave intensity in the case of localized-spin ferromagnets. An experimental determination of the dependence of magnon intensity on q by INS thus provides a decisive means (Ishikawa, 1978) of ascertaining whether the spins in a given system are localized or itinerant. For $q > q_{SB}$, the collective magnetic excitations in an itinerant-electron ferromagnet are the overdamped (nonpropagating) modes of exchange-enhanced longitudinal and transverse spin-density fluctuations (henceforth simply termed as *spin fluctuations*) that give rise to the elastic peak centered at zero energy transfer, $E = 0$, in the partial differential INS cross-section, $d^2\sigma/d\Omega dE$, versus E plot at a fixed value of q (i.e., in the constant-q scan). At very low temperatures ($T \ll T_C$), spin-wave modes and nonpropagating longitudinal spin fluctuations of q in the range $0 \leq q \leq q^{up}$ (say) are thermally excited. Note that propagating transverse and nonpropagating longitudinal spin fluctuation modes of larger and larger q get thermally excited as the temperature is raised from $T = 0\,\text{K}$ and hence q^{up} increases with temperature. As the temperature is progressively raised, a temperature $T = T_{SB}$ is reached when $q^{up} = q_{SB}$. Consequently, at temperatures $T \leq T_{SB}$, spin waves and longitudinal spin fluctuations of wave vectors $0 \leq q \leq q_{SB}$ coexist, whereas for $T_{SB} < T \leq T_C$, spin-wave modes of $0 \leq q \leq q_{SB}$ accompany longitudinal spin fluctuations of $0 \leq q \leq q^{up}$ as well as transverse spin fluctuations of $q_{SB} < q \leq q^{up}$. Thus, in the constant-q scans taken at temperatures $T \leq T_C$, the inelastic spin-wave peaks centered at $E = \pm E_{\mathbf{q}}$ occur in association with the elastic peak centered at $E = 0$ arising from longitudinal spin fluctuations (both longitudinal and transverse spin fluctuations) for $T \leq T_{SB}$ ($T_{SB} < T \leq T_C$). Occurrence of inelastic peaks alongside an elastic peak, however, limits the energy transfer resolution of the elastic spin-fluctuation

peak. Since spin waves cease to exist at temperatures above the Curie point, spin fluctuations are amenable to an accurate experimental scrutiny only in the paramagnetic state where the spin system is completely isotropic with the result that $\mathrm{Im}\chi(\mathbf{Q},\omega) \equiv \mathrm{Im}\chi_{||}(\mathbf{Q},\omega) \cong \mathrm{Im}\chi_{\perp}(\mathbf{Q},\omega)$ in the partial differential neutron-scattering cross section, given by equation (1). The energy- and momentum-resolved neutron-scattering experiments, employing the time-of-flight technique, on canonical weak itinerant-electron ferromagnets such as Ni_3Al (Bernhoeft, Lonzarich, Paul, and Mitchell, 1986), $ZrZn_2$ (Bernhoeft, Lonzarich, Paul, and Mitchell, 1986; Bernhoeft, Law, Lonzarich and Paul, 1988), and MnSi (Ishikawa *et al*., 1985; Ishikawa, 1986) at temperatures $T > T_C$ as well as on the exchange-enhanced paramagnet Ni_3Ga (Bernhoeft *et al*., 1989) have revealed that the scattering of neutrons from thermally excited nonpropagating spin fluctuations in these materials is characterized by a simple Lorentzian frequency spectrum, that is, by the imaginary part of the dynamic wave vector–dependent susceptibility, $\mathrm{Im}\chi(\mathbf{Q},\omega)$, of the form

$$\mathrm{Im}\chi(\mathbf{Q},\omega) = \omega\,\chi(\mathbf{q})\,\frac{\Gamma(\mathbf{q})}{\omega^2+\Gamma^2(\mathbf{q})} \tag{24}$$

in equation (1), where the momentum transfer $\mathbf{q}$ is measured from a reciprocal-lattice point. In accordance with the predictions of the random phase approximation (RPA) for an electron gas in the low q limit (Moriya, 1985; Lonzarich and Taillefer, 1985), the wave vector-dependent susceptibility, $\chi(\mathbf{q})$, and the relaxation frequency, $\Gamma(\mathbf{q})$, of spin fluctuations, in the above expression, are given by

$$\chi(\mathbf{q}) = \chi(\mathbf{q},\omega=0) = \chi(0)\,\frac{\kappa^2}{\kappa^2+q^2} \tag{25}$$

$$\Gamma(\mathbf{q}) = \gamma q \chi^{-1}(\mathbf{q}) = \gamma\, q\, c\,(\kappa^2+q^2) \tag{26}$$

In equations (25) and (26), $\chi(0) = \chi(\mathbf{q}=0) = (c\kappa^2)^{-1}$ is the bulk static susceptibility, κ is the inverse spin fluctuation–spin fluctuation correlation length, c is a constant which can be identified with the coefficient of the gradient squared term in the Ginzburg–Landau free energy expansion, and γ characterizes the relaxation transport of spin carriers (Lonzarich and Taillefer, 1985); the quantities c and γ depend on the details of the band structure near the Fermi level (Lonzarich and Taillefer, 1985). The neutron-scattering intensity, $I(\mathbf{Q},\omega)$, is calculated from the partial differential scattering cross-section by evaluating the integral

$$I(\mathbf{Q},\omega) = \int \frac{\mathrm{d}^2\sigma}{\mathrm{d}\Omega\mathrm{d}(\hbar\omega)}(\mathbf{Q}',\omega')\,R(\mathbf{Q}-\mathbf{Q}',\omega-\omega')\,\mathrm{d}\omega'\,\mathrm{d}\mathbf{Q}' \tag{27}$$

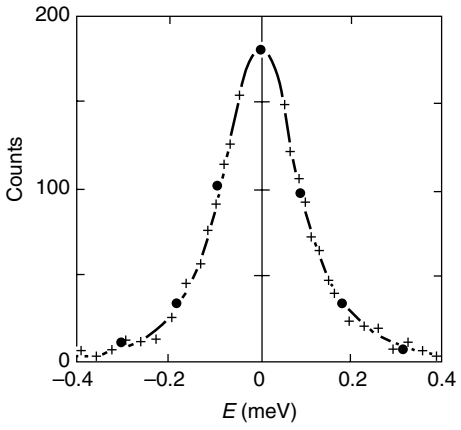

Figure 8. Energy dependence of the neutron-scattering intensity (+) in Ni_3Al at 45 K ($T > T_C$) relative to the 5 K background, measured by the time-of-flight technique for an elastic scattering wave vector $q = 0.063\,\text{Å}^{-1}$ and incident neutron wavelength $\lambda \cong 8\,\text{Å}$. The solid circles represent the scattering intensity calculated from equations (1) and (24–27) using $c = 1.5 \times 10^5\,\text{Å}^2$ and $\hbar\gamma = 3.3\,\mu\text{eV Å}$.

where $R(\mathbf{Q}-\mathbf{Q}',\omega-\omega')$ is the resolution function of the spectrometer. As an illustrative example, Figure 8 (taken from Bernhoeft, Lonzarich, Paul, and Mitchell, 1986) compares the energy transfer dependence of the neutron-scattering intensity observed in Ni_3Al at a temperature $T > T_C$ (plus symbols) with that calculated (solid circles) from the equations (1) and (24–27) by treating the quantities c and γ as free fitting parameters while optimizing agreement between theory and experiment. Note that the band parameter c can also be independently determined from the relation (Moriya, 1985; Lonzarich and Taillefer, 1985) $D(T) = g\,\mu_B\,M(T)\,c$ between the spin-wave stiffness, D, and spontaneous magnetization, M, and once c is known, κ can be calculated from the observed bulk susceptibility, $\chi(0)$, using the relation $\kappa = (c\chi(0))^{-1/2}$. The band parameters c and γ, in turn, permit a quantitative analysis of the thermodynamic properties of weakly or nearly ferromagnetic or antiferromagnetic metals.

Besides complementing the information about the underlying band structure deduced from the neutron-scattering experiments, the bulk magnetization measurements enable a thorough investigation of spin fluctuations at intermediate temperatures and for temperatures close to T_C (the temperature range normally inaccessible to the neutron-scattering experiments so far as an accurate determination of the band parameters c and γ is concerned) because in this temperature range, the contribution due to spin fluctuations to the thermal demagnetization dominates over the spin-wave contribution. For a better understanding of what can be learnt about spin fluctuations from bulk magnetization studies, a brief account of the theoretical developments in this field, given in the

following text, is required. One of the earliest theories that self-consistently renormalizes the mutually coupled modes of exchange-enhanced spin fluctuations (*localized* in the reciprocal (q) space), the so-called self-consistent renormalization theory (Moriya and Kawabata, 1973), yielded the temperature dependence of spontaneous magnetization for weakly ferromagnetic metals as $M^2(0,0) - M^2(T,0) = aT^2$ at low temperatures and $M^2(T,0) = a'(T_C^{4/3} - T^{4/3})$ over a wide temperature range below T_C by taking into account only the transverse modes of thermally excited spin fluctuations. Takeuchi and Masuda (1979) extended this theory to include the effect of external magnetic field on magnetization by using the electron gas model to calculate the magnetic field – and temperature-dependent static susceptibility that is consistent with the magnetic equation of state (MES). A good quantitative agreement between the theoretically predicted and experimentally observed variations of magnetization with temperature and magnetic field in the weak itinerant-electron ferromagnet Sc_3In was achieved (Takeuchi and Masuda, 1979) by using a number of adjustable parameters. Recognizing the importance of longitudinal spin fluctuations and the fact that the electron gas model forms an oversimplified description of the band structure of real weak itinerant-electron magnetic systems, Lonzarich and Taillefer (1985) calculated the MES of nearly or weakly ferromagnetic metals, which includes corrections to the conventional Stoner theory arising from both longitudinal and transverse spin fluctuations, by making use of the band parameters obtained from neutron-scattering experiments rather than the unrealistic electron gas model. The effect of including longitudinal spin fluctuations (in addition to the transverse spin fluctuations) is to (Lonzarich and Taillefer, 1985) widen the temperature range (which now includes intermediate temperatures as well) over which the squared spontaneous magnetization varies with temperature as $M^2(T,0) \sim T^2$ and narrow down the temperature range (so as to restrict it to temperatures not too far from T_C) where $M^2(T,0) \sim T^{4/3}$. The above-mentioned spin-fluctuation models considered only the thermally-excited spin fluctuations but completely ignored the contribution to magnetization due to zero-point (quantum) spin fluctuations whose significance was realized only later (Takahashi, 1986, 2001; Solontsov and Wagner, 1994, 1995; Kaul, 1999; Kaul and Semwal, 1999). Among the theoretical approaches that take into account both thermally excited and zero-point spin fluctuations (Takahashi, 1986, 2001; Kaul, 1999; Kaul and Semwal, 1999), the treatment proposed by Kaul (1999) clearly brings out the roles of zero-point and thermally excited spin fluctuations in the thermal demagnetization of weak itinerant-electron ferromagnets and the extent to which these excitations get suppressed by the external magnetic field. The results of the bulk magnetization studies on amorphous (Kaul and Babu, 1998) and crystalline (Kaul and Semwal, 1999; Semwal and Kaul, 1999, 2004) weakly ferromagnetic metallic alloys validate this theoretical approach (Kaul, 1999), as illustrated in the following text.

The thermal variances of the local magnetization parallel (||), $\langle m_{||}^2 \rangle$, and perpendicular ($\perp$), $\langle m_{\perp}^2 \rangle$, to the average magnetization, **M**, are related to the imaginary part of the dynamical wave-vector-dependent susceptibility, $\mathrm{Im}\chi_\nu(\mathbf{q},\omega)$, where $\nu(= ||, \perp)$ is the polarization index, through the well-known fluctuation-dissipation relation (Moriya, 1985; Lonzarich and Taillefer, 1985; Takahashi, 1986)

$$\langle m_\nu^2 \rangle = 4\hbar \int \frac{\mathrm{d}^3\mathbf{q}}{(2\pi)^3} \int \frac{\mathrm{d}\omega}{2\pi} \left(n(\omega) + \frac{1}{2} \right) \mathrm{Im}\chi_\nu(\mathbf{q},\omega) \quad (28)$$

where the thermally-excited spin fluctuations and zero-point spin fluctuations are represented by the Bose function, $n(\omega)$, and the factor $1/2$, respectively. Calculating the longitudinal, $\langle m_{||}^2 \rangle$, and transverse, $\langle m_{\perp}^2 \rangle$, spin-fluctuation contributions to magnetization (in the ferromagnetic state) from equation (28) by combining the equations (24–26) and (28), and substituting the result in the MES (Lonzarich and Taillefer, 1985; Kaul, 1999)

$$\left[\frac{M(T,H)}{M(0,0)} \right]^2 = 1 - \frac{3\langle m_{||}^2 \rangle + 2\langle m_{\perp}^2 \rangle}{M^2(0,0)} + 2\chi(0,0)\frac{H}{M(T,H)} \quad (29)$$

finally yields the expressions for magnetization (Kaul, 1999)

$$M(T,H) = M(0,H)[1 - (T/T_0)^2 - (T/T_1)^{4/3}]^{1/2} \quad (30)$$

and

$$M(T,H) = M(0,H)[1 - A(H)\,T^{4/3}]^{1/2} \quad (31)$$

at intermediate temperatures and for temperatures close to T_C but outside the critical region, respectively. The expressions (30) and (31) are valid for both zero and finite magnetic fields. The T^2 term in equation (30) originates from thermally-excited spin fluctuations alone and its coefficient T_0^{-2} depends on H through the field dependence of the static susceptibility, $\chi_\nu(0)$. By contrast, the $T^{4/3}$ term in equation (30) is a net outcome of the competing claims made by the thermally-excited and zero-point components of spin fluctuations (the contribution due to thermally-excited spin fluctuations decreases with T as $T^{4/3}$ and is dominated by the one arising from zero-point spin fluctuations, which increases with T as $T^{4/3}$) and its coefficient $T_1^{-4/3}$ is essentially independent of field. Owing to this competition, the $T^{4/3}$ term in equation (30) is very small compared to the T^2 term. In equation (31), the $T^{4/3}$ term for

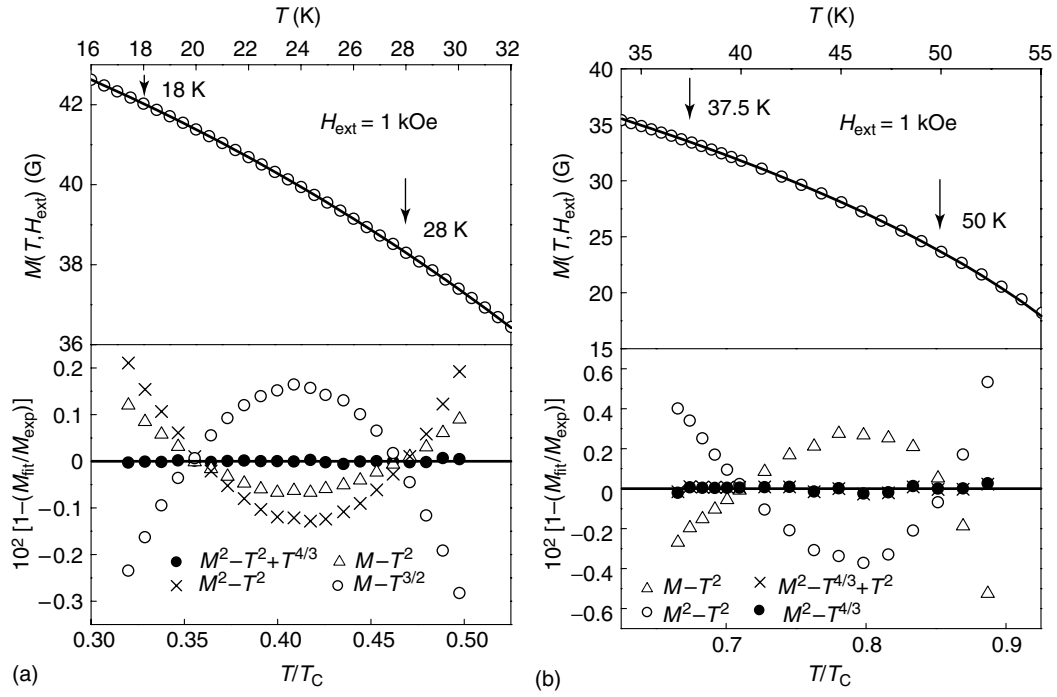

Figure 9. The upper panels depict the temperature variation of magnetization measured at an external magnetic field of $H_{\rm ext} = 1$ kOe for the weak itinerant-electron ferromagnet Ni_3Al at (a) intermediate temperatures and (b) temperatures close to the Curie temperature, and the continuous curves are the least-squares fits based on (a) equation (30) and (b) equation (31). The lower panel displays the percentage deviation of the data from the least-squares fits based on equations (10), (11), (30), and (31). Notice that the functional forms given by equations (30) and (31) yield minimum deviations in the cases (a) and (b), respectively.

$H = 0$ has its origin in both zero-point and thermally excited spin fluctuations (SF) in that their contributions to the coefficient, $A(H = 0) = (T_C^{\rm SF})^{-4/3}$, of this term are additive; however, for $H \neq 0$, the thermally excited spin fluctuations alone are responsible for the coefficient $A(H) = A(H = 0)[1 - \eta\sqrt{H}]$, of the $T^{4/3}$ term. The results of extensive magnetization measurements performed on amorphous weakly ferromagnetic metallic alloys (Kaul and Babu, 1998) and crystalline weak itinerant-electron ferromagnet Ni_3Al with (Semwal and Kaul, 2004) and without site disorder (Kaul and Semwal, 1999; Semwal and Kaul, 1999) corroborate the above theoretical predictions (Kaul, 1999) concerning the relative magnitudes of the zero-point and thermally excited spin-fluctuation contributions to thermal demagnetization and the functional forms of their dependence on temperature and magnetic field in different temperature ranges. Treating the well-known weak itinerant-electron ferromagnet Ni_3Al as an example, Figure 9 (taken from Semwal and Kaul, 1999) and Figure 10 (taken from Semwal and Kaul, 2004), respectively, serve to demonstrate the validity of the theoretical expressions (30), (31), and $A(H) = A(H = 0)[1 - \eta\sqrt{H}]$ (i.e., magnetic field suppresses thermally excited spin fluctuations according to the theoretically predicted $\sqrt{H}$ power law). Nuclear spin-lattice relaxation

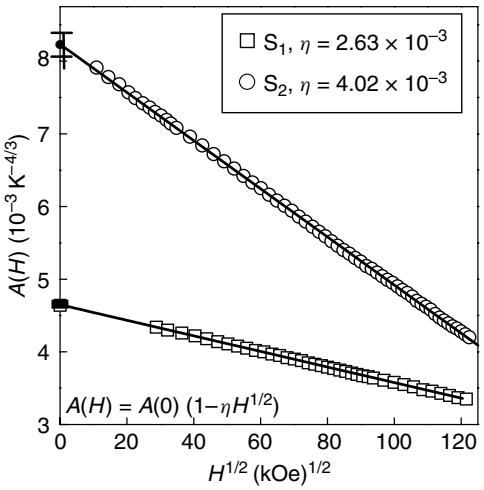

Figure 10. $\sqrt{H}$ variation of the coefficient A of the $T^{4/3}$ term in equation (31) for the annealed (S_1) and quenched (S_2) samples of the weak itinerant-electron ferromagnet Ni_3Al.

provides yet another powerful experimental technique to study spin fluctuations. The relevant details about the theoretical and experimental aspects of this technique are given by Moriya (1985).

3 THERMALLY-DRIVEN MAGNETIC PHASE TRANSITIONS

In the critical region (whose extent depends on the type of material and is typically of the order of $|\varepsilon| = |(T - T_C)/T_C| \leq 0.01$, where T_C is the critical temperature) as the critical temperature is approached, the thermally-excited critical fluctuations of the local spin-density (order parameter) rapidly pick up in amplitude and get correlated in space over larger and larger distances with the result that they destroy the long-range magnetic order at T_C, where the spin-density-fluctuation–spin-density-fluctuation correlation length, $\xi(T = T_C)$, (henceforth referred to as *spin–spin correlation length*, for brevity) diverges and the magnetic order–disorder phase transition occurs. Note that the thermally-driven 'classical' phase transitions are distinctly different from the quantum phase transitions which occur only at the temperature of absolute zero where the quantum (zero-point) fluctuations, demanded by the Heisenberg uncertainty principle, destroy cooperative ordering in the system (the reader is referred to **Quantum Phase Transitions, Volume 1** for a detailed discussion of quantum phase transitions). Experimental investigations in the critical region near a thermally-driven phase transition provide a unique and direct means of probing the type of interactions present and the interplay between them, which finally decides the nature of magnetic order prevailing in the systems under study for temperatures below the transition temperature. This is so because the critical behavior of a system is solely governed by the nature of the underlying interactions. For instance, an interplay between interactions, such as crystal-field (leading to uniaxial anisotropy), isotropic short-range (ISR) Heisenberg, and long-range dipole–dipole interactions, in a localized-spin system gives rise to a series of crossovers from uniaxial dipolar (UD) critical regime (where both uniaxial anisotropy and dipolar interactions dominate) to isotropic dipolar critical regime (where anisotropy is negligibly small and isotropic dipolar interactions take over) to isotropic Heisenberg critical regime (where short-range isotropic Heisenberg interactions become prominent), and so on, as the temperature is raised above T_C in the critical region. To facilitate understanding of the magnetic phase transitions, the prerequisites such as the definition of the asymptotic critical exponents and amplitudes, which quantify the static critical behavior near a magnetic order–disorder phase transition, and the physical concepts relating to the critical phenomena such as the scaling hypothesis, universality, renormalization group (RG) approach, and crossover between different critical regimes, are covered in the following subsections.

3.1 Static critical exponents and amplitudes

In the asymptotic critical region, the behavior of a magnetic system is characterized by a set of critical exponents and amplitudes (Stanley, 1971; Kaul, 1985). Critical exponents are the exponents in the power laws that define the deviations of various thermodynamic quantities from their values at the critical point T_C and the corresponding amplitudes are the forefactors in these power laws. The asymptotic critical exponents and amplitudes for the second-order ferromagnetic (FM) to paramagnetic (PM) phase transition are defined as follows.

3.1.1 Spontaneous magnetization

In the asymptotic critical region, spontaneous magnetization, M_S, the order parameter for the FM–PM phase transition, varies with the reduced temperature $\varepsilon = (T - T_C)/T_C$ as

$$M_S(T) = \lim_{H \to 0} M(T, H) = B\,(-\varepsilon)^{\beta} \qquad \varepsilon < 0 \tag{32}$$

3.1.2 Initial susceptibility

Initial susceptibility, defined as $\chi_0 = \lim_{H \to 0}[\partial M/\partial H]_T$, diverges at T_C as

$$\chi_0(T) = \Gamma^{-}\,(-\varepsilon)^{-\gamma^{-}} \qquad \varepsilon < 0 \tag{33}$$

$$\chi_0(T) = \Gamma^{+}\,\varepsilon^{-\gamma^{+}} \qquad \varepsilon > 0 \tag{34}$$

3.1.3 Critical isotherm

At $T = T_C$, magnetization M varies with field H as

$$M(T_C, H) = A_0\,H^{1/\delta} \qquad \text{or}$$

$$H = D\,M^{\delta} \qquad \varepsilon = 0 \tag{35}$$

3.1.4 Specific heat

Zero-field ($H = 0$) specific heat diverges at T_C as

$$C_{H=0}(T) = \frac{A^{-}}{\alpha^{-}}[(-\varepsilon)^{-\alpha^{-}} - 1] + B^{-} \qquad \varepsilon < 0 \tag{36}$$

$$C_{H=0}(T) = \frac{A^{+}}{\alpha^{+}}[\varepsilon^{-\alpha^{+}} - 1] + B^{+} \qquad \varepsilon > 0 \tag{37}$$

Specific heat exhibits a cusp at T_C when $\alpha < 0$, whereas for $\alpha = 0$ the singularity is logarithmic. B^{-} and B^{+} represent the nonsingular background for $\varepsilon < 0$ and $\varepsilon > 0$, respectively, in the asymptotic critical region.

3.1.5 Spin–spin correlation function

At T_C, the correlation function for the spin fluctuations at the points **0** and **r** in space, $G(\mathbf{r}) \equiv \langle[\mathbf{S}(\mathbf{r}) - \langle\mathbf{S}\rangle][\mathbf{S}(\mathbf{0}) - \langle\mathbf{S}\rangle]\rangle$, decays with distance, r, as

$$G(|\mathbf{r}|) = N\,|\mathbf{r}|^{-(d-2+\eta)} \qquad [\text{large}|\mathbf{r}|, \varepsilon = H = 0] \tag{38}$$

where d is the dimensionality of the lattice and η is a measure of the deviation from the mean-field behavior.

3.1.6 Spin–spin correlation length

Correlation length, ξ, is the distance over which the order parameter fluctuations are correlated and is defined through the relation $G(|\mathbf{r}|) = e^{-|\mathbf{r}|/\xi(T)}/|\mathbf{r}|$, where $|\mathbf{r}| \to \infty$. In the critical region, ξ depends on temperature as

$$\xi(T) = \xi_0^-\,(-\varepsilon)^{-\nu^-} \qquad \varepsilon < 0, H = 0 \tag{39}$$

$$\xi(T) = \xi_0^+\,\varepsilon^{-\nu^+} \qquad \varepsilon > 0, H = 0 \tag{40}$$

In equations (32–40), $\beta, \gamma^-, \gamma^+, \delta, \alpha^-, \alpha^+, \eta, \nu^-$, and ν^+ are the asymptotic critical exponents and $B, \Gamma^-, \Gamma^+, A_0$, or D, A^-, A^+, N, ξ_0^-, and ξ_0^+ are the corresponding asymptotic critical amplitudes. There are nine critical exponents in total but only two of them are independent (Stanley, 1971). This is a consequence of the scaling relations between them, for example, $\alpha^+ = \alpha^-$, $\gamma^+ = \gamma^-$, $\nu^+ = \nu^-$, $\beta\delta = \beta + \gamma$ (Widom equality), $\alpha + 2\beta + \gamma = 2$ (Rushbrooke equality), $\alpha + \beta(\delta + 1) = 2$ (Griffiths equality), $(2 - \eta)\nu = \gamma$ (Fisher equality), and $d\nu = 2 - \alpha$ (Josephson equality), to name a few.

The single power laws are strictly valid only at $T = T_C$. In practice, however, the power laws are fitted to the experimental data over a finite temperature range. Consequently, such an approach yields only average exponent values since, in general, the amplitudes as well as the exponents are temperature-dependent and they assume temperature-independent values only in the asymptotic critical region (Kaul, 1985). In order to tackle this problem effectively, the concept of effective critical exponent was introduced by Riedel and Wegner (1974). The effective critical exponents provide a local measure for the degree of singularity of physical quantities in the critical region. The effective critical exponent, $\lambda_{\text{eff}}(\mu)$, of a function $f(\mu)$ is defined by the logarithmic derivative $\lambda_{\text{eff}}(\mu) = \mathrm{d}\ln f(\mu)/\mathrm{d}\ln\mu$. In the limit $\mu \to 0$, $\lambda_{\text{eff}}(\mu)$ coincides with the asymptotic critical exponent λ.

3.2 Scaling and universality

Historically, the observation that a huge body of experimental data on a variety of systems could be represented in the form of a scaled equation of state led to the scaling hypothesis, which asserts that in the asymptotic critical region the singular part of the Gibbs free energy, $G_s(\varepsilon, H)$, is a generalized homogeneous function (Stanley, 1971) of its arguments ε and H. Scaling hypothesis or, equivalently, the homogeneity postulate makes two specific predictions: (i) it relates various critical exponents through the scaling equalities, and (ii) makes specific predictions concerning the form of the equation of state. For magnetic systems, the scaling hypothesis predicts that all the magnetization, $M(\varepsilon, H)$, curves (either magnetization isotherms at different temperatures or $M(\varepsilon)$ at different fields) taken in the critical region collapse onto two universal curves, one for $\varepsilon < 0$ and the other for $\varepsilon > 0$, if scaled magnetization, $M/|\varepsilon|^\beta$, is plotted against scaled field, $H/|\varepsilon|^\Delta$, where $\Delta = \beta\delta$ is the gap exponent. Both the above-mentioned scaling predictions have been vindicated by experiments on widely different magnetic systems (Stanley, 1971; Kaul, 1985; Kellner, Fähnle, Kronmüller and Kaul, 1987; Fähnle, Kellner and Kronmüller, 1987; Kaul and Sambasiva Rao, 1991, 1994; Sambasiva Rao and Kaul, 1995; Seeger, Kaul, Kronmüller and Reisser, 1995; Babu and Kaul, 1997; Fischer, Kaul and Kronmüller, 2002). The RG approach (Section 3.3) makes use of the homogeneity postulate to relate critical exponents to the eigenvalues of the RG operator and thereby permits quantitative determination of the critical exponents.

A related concept is the universality, which basically amounts to cataloging, under a single category (class), all types of systems that possess the same values for critical exponents and critical amplitude ratios and for which the equation of state and the correlation functions become identical near criticality, provided the order parameter, the ordering field, and the correlation length (time) are scaled properly by material-dependent factors. Thus, the critical exponents and the ratios between critical amplitudes (but not the amplitudes themselves) are universal (Kaul, 1985; Privman, Hohenberg and Aharony, 1991; Kaul and Sambasiva Rao, 1994; Seeger, Kaul, Kronmüller and Reisser, 1995; Babu and Kaul; 1997; Fischer, Kaul and Kronmüller, 2002) in the sense that they possess exactly the same numerical values for a number of widely different systems belonging to the same universality class. The universality class, in turn, is decided by (i) the space dimensionality 'd', (ii) the number of order parameter components, or equivalently, the order parameter dimensionality 'n', (iii) the symmetry of the Hamiltonian, and (iv) the range of interactions. For $d = 3, n = 1$ corresponds to a three-dimensional Ising system in which the spins on a three-dimensional lattice are constrained to point either in the $+z$ (up) or $-z$ (down) directions. In this example, the range of interactions is too short compared to the spin–spin correlation length and the symmetry of the Hamiltonian is reflected through the extremely large uniaxial anisotropy which constrains the spins to point up or down.

3.3 Renormalization group and crossover phenomena

Wilson's RG treatment has provided a powerful theoretical method to accurately calculate not only the asymptotic critical exponents and asymptotic critical amplitude ratios but also the 'correction-to-scaling' critical exponents and critical amplitudes. The RG approach has, therefore, become the subject of many books and reviews, the recent ones being Goldenfeld (1994), Cardy (1996), Domb (1996), and Fisher (1998). The main essence of one of the variants of RG (Ma, 1976) and its practical implications are given in the following text. Starting with an effective cell-Hamiltonian (Ma, 1976) (i.e., the Hamiltonian of a unit cell of spins), the RG transformation proceeds in two steps. First, the cell size in each direction is increased by a factor b and the bigger cell-Hamiltonian is constructed out of the smaller cell-Hamiltonian using the well-known Kadanoff transformation. Second, a scale transformation, in which the length scale changes by a factor $b = \mathrm{e}^{l}$ in all linear dimensions, is performed such that the bigger-cell volume shrinks back to the original smaller-cell volume, that is, $V(l) = \mathrm{e}^{-dl} V(0)$. As a consequence, free energy is left unaltered but the free energy density transforms according to $g_{l=0} = \mathrm{e}^{-dl} g_l$, while the Hamiltonian $\mathcal{H}_0 = \mathcal{H}\{\mu_i\}$ transforms into $\mathcal{H}_l = \mathcal{H}\{\mu_i \mathrm{e}^{y_i l}\}$, where μ_i are the scaling fields and y_i are the scaling exponents. RG transformation thus requires that (Wegner, 1972; Fisher, 1974; Kaul, 1994)

$$g\{\mu_i\} = g(\mu_0) - \mathrm{e}^{-dl}\, g_{\sin g}\{\mu_i\, \mathrm{e}^{y_i l}\} \tag{41}$$

The scaling fields μ_i can be identified with the relevant fields $\mu_\varepsilon = |\varepsilon|$ and $\mu_h = H = h$. Since the parameter l is arbitrary, it can be chosen such that $|\varepsilon|\, \mathrm{e}^{y_\varepsilon l} = 1$ or $\mathrm{e}^{-y_\varepsilon l} = |\varepsilon|$. Thus,

$$\mathrm{e}^{-dl} = (\mathrm{e}^{-y_\varepsilon l})^{d/y_\varepsilon} = |\varepsilon|^{d/y_\varepsilon} = |\varepsilon|^{2-\alpha} \tag{42}$$

and

$$\mathrm{e}^{y_h l} = (\mathrm{e}^{-y_\varepsilon l})^{-y_h/y_\varepsilon} = |\varepsilon|^{-\Delta} \tag{43}$$

where $2 - \alpha = d/y_\varepsilon$ and $\Delta = y_h/y_\varepsilon$. Combining equations (41–43) yields (Kaul, 1994)

$$g(T, H) = g_0(T) - |\varepsilon|^{2-\alpha}\, Y_{\pm}(\pm 1, h/|\varepsilon|^{\Delta}) \tag{44}$$

For the sake of convenience, the microscopic volume of the system is set equal to unity ($V = 1$). Thus, the first- and second-order derivatives of g with respect to H yield magnetization $M(T, H)$ and 'in-field' susceptibility $\chi(T, H)$, respectively, whereas the second-order derivative of g with respect to temperature yields the specific heat, $C(T, H)$. Therefore (Aharony and Fisher, 1983; Kaul, 1994),

$$\begin{aligned} M(T, H) &= -\left(\frac{\partial g(T, H)}{\partial H}\right)_T \\ &= |\varepsilon|^{2-\alpha-\Delta}\left(\frac{\partial Y_{\pm}(\pm 1, h/|\varepsilon|^{\Delta})}{\partial h}\right)_T \quad \text{or} \\ M(\varepsilon, h) &= |\varepsilon|^{\beta} f_{\pm}(h/|\varepsilon|^{\Delta}) \end{aligned} \tag{45}$$

$$\begin{aligned} \chi(T, H) &= \left(\frac{\partial M(T, H)}{\partial H}\right)_T \\ &= |\varepsilon|^{2-\alpha-2\Delta}\left(\frac{\partial f_{\pm}(h/|\varepsilon|^{\Delta})}{\partial h}\right)_T \quad \text{or} \\ \chi(\varepsilon, h) &= |\varepsilon|^{-\gamma}\left(\frac{\partial f_{\pm}(h/|\varepsilon|^{\Delta})}{\partial h}\right)_T \end{aligned} \tag{46}$$

$$\begin{aligned} C(T, 0) &= -T\left(\frac{\partial^2 g}{\partial T^2}\right)_{H=0} = C(\varepsilon, 0) \\ &= (1-\alpha)(2-\alpha) T_{\mathrm{C}}^{-1} Y_{\pm}(0)\, |\varepsilon|^{-\alpha}(1+\varepsilon) \end{aligned} \tag{47}$$

In equations (44–47), $Y_{\pm}(\pm 1, h/|\varepsilon|^{\Delta})$, $f_{\pm}(h/|\varepsilon|^{\Delta})$, $(\partial f_{\pm}(h/|\varepsilon|^{\Delta})/\partial h)_T$ and $Y_{\pm}(0)$ are the scaling functions, which, in the asymptotic limit, assume constant values and $+$ and $-$ signs denote $\varepsilon > 0$ and $\varepsilon < 0$, respectively. A comparison of (45–47) with the definitions (32–34), (36), and (37) reveals that these constant limiting values are nothing but the asymptotic critical amplitudes and that $\beta = 2 - \alpha - \Delta$ and $\gamma = -2 + \alpha + 2\Delta$. From these relations, it immediately follows that $\beta + \gamma = \Delta$ and $\alpha + 2\beta + \gamma = 2$ (which is the Rushbrooke scaling equality). Furthermore, equation (45) is the MES or just the scaling equation of state (SES). As $\varepsilon \to 0$, $|\varepsilon|^{\Delta}/h \to 0$ and the MES can be cast into an alternate form (Aharony and Fisher, 1983; Kaul, 1994)

$$M(\varepsilon, h) = |h|^{\beta/\Delta} f_0\left(\frac{|\varepsilon|}{|h|^{1/\Delta}}\right) \tag{48}$$

In the limit $|\varepsilon|/|h|^{1/\Delta} \ll 1$, the function $f_0(z)$ can be expanded in a Taylor series around $z = 0$ with the result $M(\varepsilon, h) = |h|^{\beta/\Delta}[f_0(0) + (|\varepsilon|/|h|^{1/\Delta}) f_0'(0) + \ldots]$. At $|\varepsilon| = 0$, $M(0, h) = f_0(0)\, |h|^{\beta/\Delta}$ or equivalently,

$$M(0, H) = f_0(0)\, H^{1/\delta} \tag{49}$$

Comparing (49) with (35) gives $\beta/\Delta = 1/\delta$ or $\beta\delta = \Delta$. Now that $\beta + \gamma = \Delta$ (as shown in the preceding text), $\beta + \gamma = \beta\delta$, which is the Widom scaling equality. The foregoing calculations serve to illustrate how the RG approach relates asymptotic critical amplitudes with the scaling functions and provides a theoretical basis for the scaling equalities between asymptotic critical exponents.

Having defined renormalization group, the RG transformation is iterated through the repeated application of the RG operator, $\mathbf{R}$, that is, $\mathcal{H}' = \mathbf{R}[\mathcal{H}], \mathcal{H}'' = \mathbf{R}[\mathcal{H}'], \ldots$, till the fixed point of RG transformation, that is, the critical point, is reached where the Hamiltonian maps onto itself under the RG transformation and such a Hamiltonian is called a *fixed point Hamiltonian*, $\mathcal{H}^*$. The fixed point Hamiltonian is defined by its invariance under RG transformation, that is, $\mathbf{R}[\mathcal{H}^*] = \mathcal{H}^*$. A visualization of the approach to criticality is facilitated when the RG operator is linearized about $\mathcal{H}^*$, for example, (Fisher, 1974)

$$\mathcal{H}' = \mathbf{R}[\mathcal{H}] = \mathbf{R}[\mathcal{H}^* + \mu\mathbf{Q}] = \mathcal{H}^* + \mu\mathbf{L}\mathbf{Q} + \vartheta(\mu^2) \quad (50)$$

where $\mathbf{L}$ is a linear operator defined by the eigenvalue equation

$$\mathbf{L}\,\mathbf{Q}_i = \mathrm{e}^{y_i l}\,\mathbf{Q}_i \quad (51)$$

This equation also defines eigenoperators (or eigenperturbations) $\mathbf{Q}_i$, eigenvalues $\mathrm{e}^{y_i l}$, and scaling exponents y_i. Assuming that the eigenoperators form a complete set of operators, any Hamiltonian $\mathcal{H}_0$ can be expanded in terms of this complete set, that is, $\mathcal{H}_0 = \mathcal{H}^* + \sum_i \mu_i \mathbf{Q}_i$. In this expression, the Hamiltonian is parameterized by the scaling fields μ_i. Thus,

$$\mathcal{H}_l = \mathbf{R}[\mathcal{H}_0] = \mathcal{H}^* + \sum_i \mu_i\,\mathrm{e}^{y_i l}\,\mathbf{Q}_i \quad (52)$$

For instance, we saw earlier that when $\mathcal{H}_0 = \mathcal{H}^* + \mu_\varepsilon\mathbf{Q}_\varepsilon + \mu_h\mathbf{Q}_h$ with $\mu_\varepsilon = |\varepsilon|$ and $\mu_h = h$, the singular part of the free energy density is given by $g_{\sin g}(\varepsilon, h) = |\varepsilon|^{2-\alpha}\,Y_\pm(\pm 1, h/|\varepsilon|^\Delta)$. If one starts with the Hamiltonian $\mathcal{H}_0 = \mathcal{H}^* + \mu_\varepsilon\mathbf{Q}_\varepsilon + \mu_h\mathbf{Q}_h + \mu_i\mathbf{Q}_i$, generalization of this procedure yields, within the linear approximation, the Hamiltonian

$$\mathcal{H}_l = \mathcal{H}^* + \mu_\varepsilon\,\mathrm{e}^{y_\varepsilon l}\,\mathbf{Q}_\varepsilon + \mu_h\,\mathrm{e}^{y_h l}\,\mathbf{Q}_h + \mu_i\,\mathrm{e}^{y_i l}\,\mathbf{Q}_i \quad (53)$$

and the singular part of the free energy density (Wegner, 1972)

$$g_{\sin g}(\varepsilon, h, \mu_i) = |\varepsilon|^{2-\alpha}\,Y_\pm\left(\pm 1, \frac{h}{|\varepsilon|^\Delta}, \frac{\mu_i}{|\varepsilon|^{\phi_i}}\right) \quad (54)$$

Depending upon the sign of the exponent ϕ_i, three different cases arise.

1. $\phi_i < 0$. As the critical point is approached, ($|\varepsilon| \to 0$), the reduced fields $\overline{\mu_i} = \mu_i/|\varepsilon|^{\phi_i}$ tend to zero. The leading singularity in the asymptotic behavior is the same as if all the scaling fields μ_i were zero. Hence the operators $\mathbf{Q}_i$ are irrelevant and μ_i are called *irrelevant scaling fields*. However, a Taylor expansion of the scaling function $Y_\pm(x)$ about $x = 0$ corrects the dominant singular terms by additive terms (called the *correction-to-scaling* terms) proportional to $|\varepsilon|^{2-\alpha+|\phi_i|}$.
2. $\phi_i > 0$. As $|\varepsilon| \to 0$, three distinct temperature regions can be identified, $|\varepsilon|^{\phi_i} \gg \mu_i$, $|\varepsilon|^{\phi_i} \approx \mu_i$, and $|\varepsilon|^{\phi_i} \ll \mu_i$. In the first region, far from the critical point, $\overline{\mu_i}$ are extremely small and the behavior is as if μ_i are zero. In the second region, centered at the crossover temperature $|\varepsilon^*| \approx \mu_i^{1/\phi_i}$, the perturbation begins to make its presence felt. Finally in the third region, closest to the critical point, the reduced fields $\overline{\mu_i}$ become very large and grow rapidly as $|\varepsilon| \to 0$ with the result that the perturbative treatment breaks down. Either there is no critical behavior at all, as, for instance, in the presence of a magnetic field, which suppresses the transition ($\Delta = \beta\delta$ is always positive and hence can be thought of as a crossover exponent ϕ_i), or else the actual critical behavior is quite different from that corresponding to $\mu_i = 0$ and depends on the nature of the operators $\mathbf{Q}_i$ (i.e., the perturbation). Such crossover phenomena from one kind of critical behavior to another reflect competition between two critical regimes; the $\mu_i = 0$ critical behavior yields progressively to the $\mu_i \neq 0$ critical behavior as the critical point is approached such that the latter critical behavior takes over at $\varepsilon = 0$. This also implies that the presence of the relevant operator $\mathbf{Q}_i$ and relevant scaling fields μ_i leads to a crossover from one critical regime to the other and causes a shift in the critical temperature from $T_C(\mu_i = 0)$ to $T_C(\mu_i \neq 0)$. In sharp contrast with a crossover between different critical regimes brought about by the linear relevant scaling fields, the nonlinear relevant (irrelevant) scaling fields give rise to analytic (nonanalytic) 'correction-to-scaling' terms (Aharony and Fisher, 1983; Kaul, 1994) that become important for temperatures far away from the critical point (in the asymptotic critical region).
3. $\phi_i = 0$. In this case, the operators $\mathbf{Q}_i$ and scaling fields μ_i are marginal and they can have various consequences, such as multiplicative logarithmic corrections (MLCs) to the power laws, or critical exponents varying continuously with the strength of the scaling fields μ_i. The subsequent subsections deal with the experimental realizations of the cases (1–3).

3.4 Static critical phenomena

From the foregoing text, it is clear that the critical behavior of a spin system near the magnetic order–disorder phase

transition depends on the nature of the perturbing interactions, that is, whether they are irrelevant, relevant, or marginal in the RG sense, and the physical phenomena in the critical region (i.e., the critical-point phenomena or simply the critical phenomena) are characterized by the asymptotic critical exponents and asymptotic critical amplitude ratios. A vast body of literature exists on the determination of critical exponents for a very large number of magnetic systems using a variety of experimental techniques. Among static critical exponents, the exponents α, β, γ, and δ for 'zero-field' specific heat, spontaneous magnetization, initial magnetic susceptibility, and the magnetization versus magnetic field isotherm at $T = T_C$ have been more frequently determined. In most cases, either the asymptotic analysis (AA) or the SES analysis (for details, see Kaul, 1985) is used to deduce above critical exponents from specific heat or electrical resistivity, magnetization and ac susceptibility data. It is customary to fit the data to single power laws (i.e., equations (32–37)) in AA or to the different forms of the SES in the SES analysis over temperature ranges that lie either completely or partly outside the asymptotic critical region. Now that the single power laws, or equivalently, the scaling, are strictly valid only in the asymptotic critical region, this exercise invariably yields the effective critical exponents (e.g., α_{eff}, β_{eff}, and γ_{eff}) that depend on the temperature range chosen for a given analysis. The effective critical exponents, so obtained, can be quite different (Kellner, Fähnle, Kronmüller and Kaul, 1987; Fähnle, Kellner and Kronmüller, 1987; Kaul, 1988; Kaul and Sambasiva Rao, 1991, 1994; Sambasiva Rao and Kaul, 1995; Babu and Kaul, 1997) from the asymptotic critical exponents. Thus, a quantitative comparison between the values of effective critical exponents and those of the asymptotic critical exponents, yielded by the theory, is rendered meaningless in that no definite conclusions about the nature and origin of the leading singularity at T_C can be drawn. This situation is remedied by the following approach which permits an accurate determination of asymptotic critical exponents and amplitudes.

3.4.1 *Irrelevant scaling fields: additive 'correction-to-scaling' terms*

The RG calculations (Lubensky, 1975; Grinstein and Luther, 1976), based on the random-exchange model (which combines within itself both quenched random site- and bond-diluted spin models), reveal that the asymptotic critical behavior of a quenched random spin system is the same as that of an ordered counterpart if the specific heat critical exponent, α_p, of the ordered system is negative (better known as *Harris criterion*) since in this case the quenched randomness acts as an irrelevant scaling field in the RG sense. Thus, according to these RG calculations, spontaneous magnetization, $M_S(\varepsilon)$, initial susceptibility, $\chi_0(\varepsilon)$, and specific heat or equivalently (Kaul, 1985), the temperature derivative of electrical resistivity normalized to the resistivity value at T_C, $r(\varepsilon) \equiv (\mathrm{d}\rho(T)/\mathrm{d}T)/\rho(T_C)$, of a quenched random Heisenberg system with space dimensionality $d = 3$ and spin dimensionality $n = 3$ are not described by the simple power laws (32–34), (36), and (37) in the asymptotic critical region but by the expressions

$$M_S(\varepsilon) = m_0(-\varepsilon)^{\beta}[1 + a_{M_1}^{-}(-\varepsilon)^{\Delta_1} + a_{M_2}^{-}(-\varepsilon)^{\Delta_2}] \qquad \varepsilon < 0 \tag{55}$$

$$\chi_0(\varepsilon) = \Gamma\varepsilon^{-\gamma}[1 + a_{\chi_1}^{+}\,\varepsilon^{\Delta_1} + a_{\chi_2}^{+}\,\varepsilon^{\Delta_2}] \qquad \varepsilon > 0 \tag{56}$$

$$r(\varepsilon) = (A^{\pm}/\alpha^{\pm})\,(\pm\varepsilon)^{-\alpha^{\pm}}\left[1 + a_{c_1}^{\pm}\,\alpha^{\pm}\,(\pm\varepsilon)^{\Delta_1} + a_{c_2}^{\pm}\,\alpha^{\pm}\,(\pm\varepsilon)^{\Delta_2}\right] - (A^{\pm}/\alpha^{\pm}) + B^{\pm} \tag{57}$$

In equations (55–57), plus and minus signs denote temperatures above and below T_C; m_0, $\Gamma \equiv (m_0/h_0)$, $A^{\pm}(a_{M_1}^{-}, a_{M_2}^{-}; a_{\chi_1}^{+}, a_{\chi_2}^{+}; a_{c_1}^{\pm}, a_{c_2}^{\pm})$ and β, γ, $\alpha^{\pm}$ (Δ_1, Δ_2) are the asymptotic (leading 'correction-to-scaling') critical amplitudes and critical exponents, respectively. It immediately follows that equations (55–57) reduce to the simple power laws (32–34), (36), and (37) only in the limit $\varepsilon \to 0$. Note that, like asymptotic critical exponents and amplitude ratios, the 'correction-to-scaling' critical exponents and amplitude ratios are universal (i.e., they possess unique values for systems falling within a given universality class). However, in practice, simple power laws are fitted to the data taken in a finite temperature range around T_C with the result that both the amplitudes and exponents in these power laws now depend on temperature. In other words, in such a temperature range, the simple power laws assume the modified forms

$$M_S(\varepsilon) = m_0^{\text{eff}}(\varepsilon)\,(-\varepsilon)^{\beta_{\text{eff}}(\varepsilon)} \qquad \varepsilon < 0 \tag{58}$$

$$\chi_0(\varepsilon) = \Gamma_{\text{eff}}(\varepsilon)\,\varepsilon^{-\gamma_{\text{eff}}(\varepsilon)} \qquad \varepsilon > 0 \tag{59}$$

$$r(\varepsilon) = [A_{\text{eff}}^{\pm}(\varepsilon)/\alpha_{\text{eff}}^{\pm}(\varepsilon)]\,[(\pm\varepsilon)^{-\alpha_{\text{eff}}^{\pm}(\varepsilon)} - 1] + B_{\text{eff}}^{\pm}(\varepsilon) \tag{60}$$

The most direct way of determining the asymptotic critical exponents and amplitudes is to fit the expressions (55–57) to the experimental data in the asymptotic critical region and optimize agreement between theory and experiment by treating T_C, asymptotic and 'correction-to-scaling' critical amplitudes and critical exponents as free parameters (Kaul, 1988; Kaul and Sambasiva Rao, 1991, 1994; Sambasiva Rao and Kaul, 1995; Babu and Kaul, 1997). An alternative method of determining these quantities makes use of the relations between the effective and asymptotic critical exponents and amplitudes, as explained in the following text for $M_S(\varepsilon)$ and $\chi_0(\varepsilon)$. Having calculated $M_S(T)$ $[\chi_0^{-1}(T)]$ from the intercepts on the ordinate

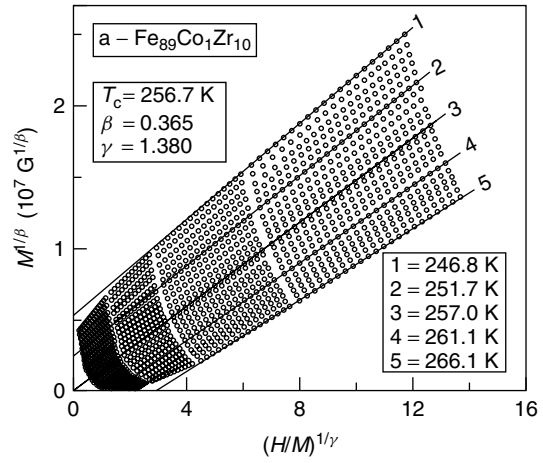

Figure 11. A typical modified Arrott ($M^{1/\beta}$ vs $(H/M)^{1/\gamma}$) plot in the critical region.

(abscissa) at $T < T_C\,[T > T_C]$ obtained by linearly extrapolating the modified Arrott plot (i.e., $[M(T, H)]^{1/\beta}$ versus $[H/M(T, H)]^{1/\gamma}$ plot) isotherms taken in the asymptotic critical region to $H = 0$ (as shown in Figure 11, taken from Babu and Kaul, 1997), the quantities $Y(T)$ and $X(T)$, defined as

$$Y(T) \equiv M_S(T)[dM_S(T)/dT]^{-1} = (T - T_C)/\beta_{eff}(\varepsilon) = [T_C/\beta_{eff}(\varepsilon)]\varepsilon \quad (61)$$

$$X(T) \equiv \chi_0^{-1}(T)[d\chi_0^{-1}(T)/dT]^{-1} = (T - T_C)/\gamma_{eff}(\varepsilon) = [T_C/\gamma_{eff}(\varepsilon)]\varepsilon \quad (62)$$

are computed from the $M_S(T)$ and $\chi_0^{-1}(T)$ data. The right-hand sides of equations (61) and (62) follow from equations (58) and (59). Since β_{eff} and γ_{eff} approach their asymptotic values β and γ only in the limit $T \to T_C$, $Y(T)$ and $X(T)$ plots tend to be linear in the immediate vicinity of T_C so that the $Y(T)$ and $X(T)$ straight lines yield the inverse slopes as β_{eff} and γ_{eff} (which are very close to β and γ) and intercepts on the T axis as T_C^- and T_C^+, respectively. Closer the T_C is approached in a given experiment, closer are the values of β_{eff} and γ_{eff} to β and γ, and more rigorously is the equality $T_C^- = T_C^+$ satisfied. This procedure fixes the value of T_C very accurately. With T_C fixed at the value so obtained, the effective critical exponents β_{eff} and γ_{eff} as functions of temperature are deduced from the $Y(T)$ and $X(T)$ data using equations (61) and (62), that is, the relations $\beta_{eff}(\varepsilon) = T_C\,\varepsilon/Y(T)$ and $\gamma_{eff}(\varepsilon) = T_C\,\varepsilon/X(T)$. In the asymptotic critical region, the effective critical exponents β_{eff} and γ_{eff} are related to the asymptotic critical exponents β and γ through the relations (Kaul, 1988; Kaul and Sambasiva Rao, 1994; Sambasiva Rao and Kaul, 1995; Babu and Kaul, 1997).

$$\beta_{eff}(\varepsilon) = \frac{d[\ln M_S(\varepsilon)]}{d\ln\varepsilon} = \beta + a_{M_1}^-\Delta_1(-\varepsilon)^{\Delta_1} + a_{M_2}^-\Delta_2(-\varepsilon)^{\Delta_2} \quad (63)$$

$$\gamma_{eff}(\varepsilon) = \frac{d[\ln \chi_0^{-1}(\varepsilon)]}{d\ln\varepsilon} = \gamma - a_{\chi_1}^+\Delta_1\varepsilon^{\Delta_1} - a_{\chi_2}^+\Delta_2\varepsilon^{\Delta_2} \quad (64)$$

The corresponding relations between the effective and asymptotic critical amplitudes are (Kaul, 1988; Kaul and Sambasiva Rao, 1994)

$$m_0^{eff}(\varepsilon) = m_0\left[1 + a_{M_1}^-(-\varepsilon)^{\Delta_1} + a_{M_2}^-(-\varepsilon)^{\Delta_2}\right](-\varepsilon)^{-[a_{m_1}^-\Delta_1(-\varepsilon)^{\Delta_1} + a_{M_2}^-\Delta_2(-\varepsilon)^{\Delta_2}]} \quad (65)$$

$$\Gamma_{eff}(\varepsilon) = \Gamma(1 + a_{\chi_1}^+\varepsilon^{\Delta_1} + a_{\chi_2}^+\varepsilon^{\Delta_2})\varepsilon^{-(a_{\chi_1}^+\Delta_1\varepsilon^{\Delta_1} + a_{\chi_2}^+\Delta_2\varepsilon^{\Delta_2})} \quad (66)$$

It is evident from equations (63) and (64) that over a finite temperature range around T_C, where the 'correction-to-scaling' confluent singularity terms are significant, the effective critical exponents can appreciably differ from the asymptotic ones and that $\beta_{eff}(\varepsilon)$ and $\gamma_{eff}(\varepsilon)$ coincide with β and γ only in the limit $|\varepsilon| \to 0$. The $\beta_{eff}(\varepsilon)$ and $\gamma_{eff}(\varepsilon)$ data, typical of amorphous ferromagnets, presented in Figure 12 (taken from Babu and Kaul, 1997) not only testify to the validity of this statement but also depict the optimum theoretical fits (continuous curves), based on equations (63) and (64), obtained by treating β, $a_{M_1}^-$, and $a_{M_2}^-$, and γ, $a_{\chi_1}^+$, and $a_{\chi_2}^+$ as free fitting parameters and fixing Δ_1 and Δ_2 at their theoretically predicted values. The values of β, $a_{M_1}^-$, and $a_{M_2}^-$, and γ, $a_{\chi_1}^+$, and $a_{\chi_2}^+$, so determined, are then used in equations (65) and (66) to compute the values of the asymptotic critical amplitudes m_0 and Γ. This method thus enables an accurate determination of the universal critical exponents $\alpha^{\pm}$, β, γ, critical amplitude ratios A^+/A^-, Dm_0^{δ}/h_0, 'correction-to-scaling' critical exponents Δ_1, Δ_2 (in some cases, Kaul, 1988; Kaul and Sambasiva Rao, 1994) and amplitude ratios $a_{M_1}^-/a_{\chi_1}^+$, $a_{M_2}^-/a_{\chi_2}^+$, $a_{c_1}^+/a_{c_1}^-$, $a_{c_2}^+/a_{c_2}^-$, $a_{c_1}^+/a_{\chi_1}^+$, $a_{c_2}^+/a_{\chi_2}^+$, and thereby allows a complete characterization of the leading singularity at T_C. True asymptotic critical behavior of a large number of ferromagnets with quenched random-exchange disorder (Kaul, 1988; Kaul and Sambasiva Rao, 1991, 1994; Sambasiva Rao and Kaul, 1995; Babu and Kaul, 1997; Peruma *et al*., 2001; Perumal, Srinivas, Rao and Dunlap, 2003) and site-disordered magnetic spinel semiconductors (Tsurkan *et al*., 1999) has been determined by following the above method of analysis. Other important points to note are as follows: (i) ac susceptibility data, taken at a driving ac field of very small root-mean-square amplitude (typically

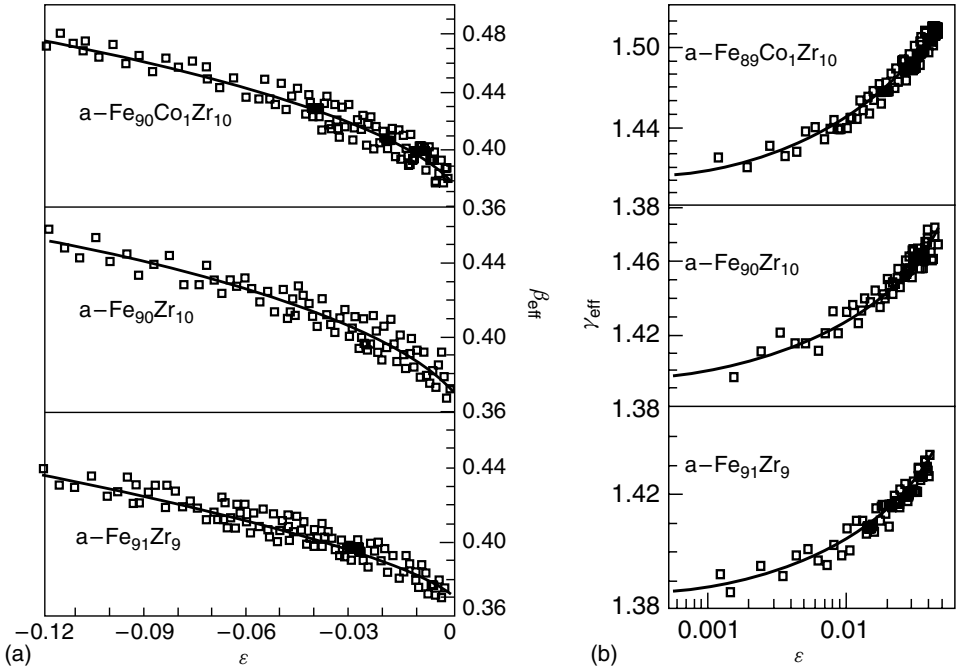

Figure 12. The effective critical exponents (a) for spontaneous magnetization, β_{eff}, and (b) susceptibility, γ_{eff}, as functions of the reduced temperature $\varepsilon = (T - T_{\text{C}})/T_{\text{C}}$ in the asymptotic critical region. The solid curves represent the least-squares fits based on (a) equation (63) and (b) equation (64).

1×10^{-7} or 10^{-6} T) after compensating for the earth's magnetic field, get rid of the errors, if any, introduced by the extrapolation of the modified Arrott plots. The results of the above-mentioned analysis of the ac susceptibility data thus serve as a cross-check (Kaul, 1988; Kaul and Sambasiva Rao, 1994) for those extracted from the extrapolated susceptibility data. (ii) Loss of accuracy suffered in constructing the temperature derivative of resistivity, $\mathrm{d}\rho(T)/\mathrm{d}T$, from $\rho(T)$ data can be avoided by directly measuring $\mathrm{d}\rho(T)/\mathrm{d}T$ employing the heat-pulse method. Recently, the direct relations between the magnetic contributions to sound velocity and 'zero-field' specific heat, and between the magnetic contribution to Young's modulus and inverse magnetic susceptibility have been exploited to accurately determine (Balakrishnan and Kaul, 2002) the specific heat and susceptibility asymptotic and 'correction-to-scaling' critical exponents and amplitudes for amorphous weak itinerant-electron ferromagnets.

3.4.2 Relevant scaling fields: isotropic Heisenberg to isotropic dipolar crossover

In insulating magnetic systems, localized magnetic moments interact with one another not only through Heisenberg exchange interactions but also via relatively weak dipole–dipole interactions. Compared to ISR (Heisenberg) exchange interactions, magnetic dipole–dipole interactions have both a long range and a reduced symmetry. The RG calculations (Aharony and Fisher, 1973; Wilson and Kogut, 1974; Bruce and Aharony, 1974; Bruce, Kosterlitz and Nelson, 1976; Bruce, 1977; Frey and Schwabl, 1991) on ferromagnets with both short-range Heisenberg exchange and long-range dipolar interactions revealed the following. (i) Dipolar perturbations, being relevant scaling fields, make the ISR (nearest-neighbor) Heisenberg fixed point of RG unstable and give rise to a new stable 'dipolar' fixed point, whose nature depends on the type (cubic, XY, Ising) of anisotropy present. (ii) In an isotropic $d = 3, n = 3$ spin system, isotropic dipolar fixed point is characterized by critical exponents whose values differ only slightly from those associated with $d = 3$ pure isotropic Heisenberg ferromagnet. (iii) Even though the asymptotic critical behavior of an isotropic dipolar ferromagnet is practically indistinguishable from that of a $d = 3$ ferromagnet with ISR Heisenberg exchange interactions only, such ferromagnets exhibit a deep minimum (a dip) in the effective critical exponent for susceptibility, γ_{eff}, versus reduced temperature, $\varepsilon = (T - T_{\text{C}})/T_{\text{C}}$, ($T_{\text{C}}$ is the Curie temperature of isotropic dipolar ferromagnet), curve in the crossover region for $\varepsilon > 0$. Such a dip in $\gamma_{\text{eff}}(\varepsilon)$ turns out to be a universal feature of $d = 3$ ferromagnets with weak isotropic dipolar interactions.

The scaling approach (Bruce, Kosterlitz and Nelson, 1976; Bruce, 1977), when applied to the crossover phenomena in a $d = 3$ ISR Heisenberg ferromagnet with weak isotropic dipolar interactions of normalized strength $g_{\rm D}$, yields 'zero-field' susceptibility for temperatures close to criticality as

$$\chi(\varepsilon_H, g_{\rm D}) = \Gamma\, \varepsilon_H^{-\gamma_H}\, X(y) \tag{67}$$

where $\varepsilon_H = [T - T_{\rm C}(0)]/T_{\rm C}(0)$ and Γ is a nonuniversal constant; $T_{\rm C}(0) \equiv T_{\rm C}(g_{\rm D} = 0)$ and γ_H, respectively, are the transition temperature and susceptibility critical exponent of pure ($g_{\rm D} = 0$) ISR Heisenberg ($d = 3, n = 3$) spin system, $y = x/x_g, x \equiv g_{\rm D}/\varepsilon_H^{\phi}, x_g \equiv g_{\rm D}/\varepsilon_g^{\phi}, \varepsilon_g = [T_{\rm C}(g_{\rm D}) - T_{\rm C}(0)]/T_{\rm C}(0)$ is the shift in the transition temperature caused by long-range dipolar interactions, ϕ is the crossover exponent which equals γ_H, and $X(y)$ is the crossover scaling function. As the true transition temperature $T_{\rm C} \equiv T_{\rm C}(g_{\rm D})$, is approached, dipolar interactions dominate and give rise to a singularity in $X(y)$ at $y = 1$ (or equivalently, at $\varepsilon = [(T - T_{\rm C})/T_{\rm C}] = 0$) with the result

$$X(y \approx 1) \sim (1 - y)^{-\gamma_{\rm D}} \tag{68}$$

where $T_{\rm C}$ and $\gamma_{\rm D}$ are the transition temperature and the susceptibility critical exponent of the isotropic dipolar ferromagnet. According to equations (67) and (68), dipolar interactions make their presence felt when a crossover temperature $\varepsilon_{\rm co} \equiv g_{\rm D}^{1/\phi}$ is reached by lowering the temperature from high temperatures ($T \gg T_{\rm C}$) such that for $\varepsilon \gg \varepsilon_{\rm co}$ the spin system behaves as a pure $d = 3, n = 3$ system with only ISR exchange interactions, whereas for $\varepsilon \ll \varepsilon_{\rm co}$ the asymptotic critical behavior is that of a $d = 3$ isotropic dipolar ferromagnet. A detailed RG calculation (Bruce, Kosterlitz and Nelson, 1976; Bruce, 1977) of the crossover scaling function yields the explicit forms of the susceptibility and its effective critical exponent (defined as $\gamma_{\rm eff}(\varepsilon) = {\rm d}[\ln \chi^{-1}(\varepsilon)]/{\rm d}(\ln \varepsilon)$) as

$$\chi(y) = \tilde{\Gamma}\, y^{\gamma_H/\phi}\, (1 - y)^{-\gamma_{\rm D}}\, p(y) \tag{69}$$

and

$$\gamma_{\rm eff}(y) = (1 - y^{1/\phi}) \left[\gamma_H + \phi\, \gamma_{\rm D} \left(\frac{y}{1 - y} \right) + \phi \left(\frac{y\, p'(y)}{p(y)} \right) \right] \tag{70}$$

in terms of the 'correction-to-scaling' function, $p(y)$. The reduced temperature, ε, is related to y as $y^{-1/\phi} - 1 = \hat{\varepsilon} = [(1 + \varepsilon_g)/\varepsilon_g]\, \varepsilon$. The expression (70), like (69), is valid across the entire crossover region and yields the limiting values $\gamma_{\rm D} = \gamma_{\rm eff}(y \to 1)$ and $\gamma_H = \gamma_{\rm eff}(y \ll 1)$ that characterize the critical behavior of susceptibility in the isotropic long-range dipolar (ILD) and ISR Heisenberg regimes, respectively. According to equation (70), $\gamma_{\rm eff}$ as a function of y goes through a minimum at a certain value of $\hat{\varepsilon}$ in the crossover region. Moreover, in the asymptotic critical regime ($0 < \varepsilon \ll \varepsilon_{\rm co}$) $y \cong 1$, the function $p(y)$ in equations (69) and (70) can be expanded to obtain (Kogon and Bruce, 1982) the expressions

$$\chi(\varepsilon) = A_\chi\, \varepsilon^{-\gamma_{\rm D}}\, (1 + a_\chi\, \varepsilon^{\Delta_{\rm D}}) \tag{71}$$

$$\gamma_{\rm eff}(\varepsilon) = \gamma_{\rm D} - a_\chi\, \Delta_{\rm D}\, \varepsilon^{\Delta_{\rm D}} \tag{72}$$

$$a_\chi \cong 0.099\, \varepsilon_g^{-\Delta_{\rm D}} \tag{73}$$

$$\varepsilon_g \cong 0.349\, \dot{\varepsilon} \tag{74}$$

where a_χ and $\Delta_{\rm D}$ are the leading 'correction-to-scaling' amplitude and exponent, respectively, and $\dot{\varepsilon}$ is the reduced temperature ε at which the inverse initial (intrinsic) susceptibility $\chi^{-1} = 4\pi$.

Despite intense efforts (Menyuk, Dwight and Reed, 1971; Høg and Johansson, 1973; Huang, Pindak and Ho, 1974; Berkner, 1975; Kornblit and Ahlers, 1975; Als-Nielsen, Dietrich and Passell, 1976; Kornblit, Ahlers and Buehler, 1978) to unravel the exact nature of the leading singularity in the asymptotic critical region of well-known $d = 3$ dipolar ferromagnets EuO and EuS in the past, the above theoretical predictions had to wait for experimental confirmation till recently when their validity was demonstrated by the results of extensive ac ('zero-field') susceptibility measurements (Srinath, Kaul and Sostarich, 2000; Srinath and Kaul, 2000) on amorphous $(Fe_pNi_{1-p})_{80}B_{16}Si_4$ and $(Co_{p'}Ni_{1-p'})_{80}B_{16}Si_4$ alloys with p and p' just above the respective critical concentrations for the onset of long-range ferromagnetic order, that is, $p_{\rm C} = 0.0285(5)$ and $p'_{\rm C} = 0.0688(5)$. The effective critical exponent for susceptibility as a function of reduced temperature, $\gamma_{\rm eff}(\varepsilon)$, is obtained from the measured ac susceptibility after correcting it for demagnetization by following the procedure described in detail in the previous subsection. $\gamma_{\rm eff}(\varepsilon)$ exhibits a pronounced dip at $\varepsilon_{\rm min}$ and attains the ILD and ISR Heisenberg values $\gamma_{\rm D}$ and γ_H in the limits $\varepsilon \to 0$ and $\varepsilon \to \varepsilon^{**}$ for the alloys with the Fe or Co concentration p or p' just above $p_{\rm C}$ or $p'_{\rm C}$ in which dipolar interactions are comparable in strength to ISR Heisenberg exchange interactions. A detailed quantitative comparison between theory (equations (67–74)) and experiment is depicted in Figure 13 (taken from Srinath, Kaul and Sostarich, 2000). Another important physical implication of the above experimental study (Srinath, Kaul and Sostarich, 2000; Srinath and Kaul, 2000) on amorphous ferromagnets, which either do or do not exhibit reentrant behavior at low temperatures, is that it clearly brings out the importance of isotropic dipolar interactions in establishing long-range ferromagnetic order in reentrant amorphous ferromagnets. For different types of crossover phenomena, the reader is referred to Kaul (2002).

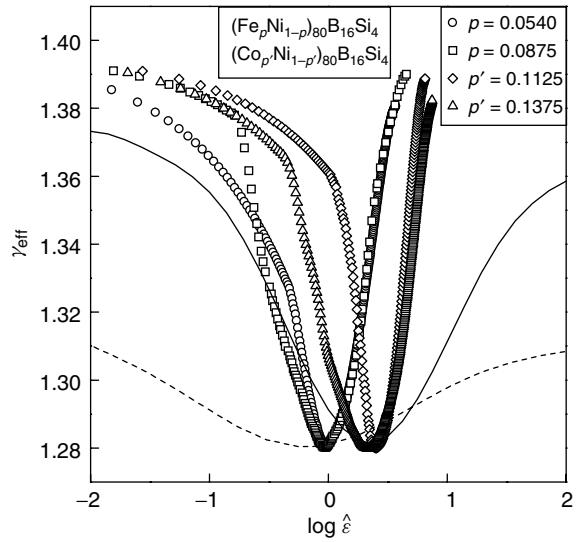

Figure 13. Comparison between the theoretically predicted and experimentally observed temperature variation of the susceptibility effective critical exponent, γ_{eff}, for the amorphous $(Fe_pNi_{1-p})_{80}B_{16}Si_4$ and $(Co_{p'}Ni_{1-p'})_{80}B_{16}Si_4$ alloys with the concentration of magnetic Fe or Co atoms just above the percolation threshold for long-range ferromagnetic order. This figure serves to highlight the dip in $\gamma_{\text{eff}}(\varepsilon)$ that is characteristic of the isotropic long-range dipolar to isotropic short-range Heisenberg crossover.

3.4.3 Marginal scaling fields: multiplicative logarithmic corrections to the power laws

The crossover scenario as well as the asymptotic critical behavior gets more complicated when, in addition to the dipolar interaction, magnetic anisotropy is present in an otherwise ISR $(d = 3, n = 3)$ Heisenberg spin system. In the presence of magneto-crystalline anisotropy, dipolar interactions act as marginal scaling fields and hence modify the critical behavior of the $d = 3, n = 1$ system (i.e., three-dimensional spin system with infinite uniaxial anisotropy) so much so that, instead of behaving as a three-dimensional Ising ferromagnet in the asymptotic critical region, it exhibits mean-field behavior with logarithmic multiplicative corrections (Wegner and Riedel, 1973; Brézin and Zinn-Justin, 1976; Frey and Schwabl, 1990; Ried, Millev, Fähnle and Kronmüller, 1995) in this regime. Elaborate RG study (Frey and Schwabl, 1990; Ried, Millev, Fähnle and Kronmüller, 1995) of the second-order phase transition in a Heisenberg ferromagnet in which, in addition to the dominant short-range exchange interactions, dipole–dipole interactions and uniaxial anisotropy are present, reveals that, due to a competition between the three types of interactions that differ in symmetry and range, the critical region embraces a series of crossovers between four nontrivial fixed points: Gaussian → ISR Heisenberg → isotropic dipolar → uniaxial dipolar, as the critical point is approached from high temperatures. In this case, 'zero-field' susceptibility takes the scaling form

$$\chi(\varepsilon_H, g_{\text{D}}, g_{\text{A}}) \propto \varepsilon_H^{-\gamma_H} X\left(\frac{g_{\text{D}}}{\varepsilon_H^{\phi_{\text{D}}}}, \frac{g_{\text{A}}}{\varepsilon_H^{\phi_A}}\right) \tag{75}$$

where $\varepsilon_H = [T - T_{\text{C}}(0)]/T_{\text{C}}(0), T_{\text{C}}(0) = T_{\text{C}}(g_{\text{D}} = g_{\text{A}} = 0)$ and γ_H, respectively, are the reduced temperature, transition temperature, and susceptibility critical exponent of pure $(g_{\text{D}} = g_{\text{A}} = 0)$ ISR Heisenberg $(d = 3, n = 3)$ spin system. The crossover exponents ϕ_{D} and ϕ_{A} are positive while $g_{\text{D}}\,(g_{\text{A}})$ is the dimensionless ratio of dipolar energy (anisotropy energy) and ISR exchange energy. Alternatively, g_{D} and g_{A} are a direct measure of the dipolar and anisotropy (relevant) perturbations. For sufficiently high temperatures, that is, $\varepsilon_H \gg g_{\text{D}}^{1/\phi_{\text{D}}}, g_{\text{A}}^{1/\phi_{\text{A}}}$, the critical behavior is that of an isotropic Heisenberg ferromagnet. As the temperature is lowered toward the critical point, a series of crossovers occur depending on the initial values of g_{A} and g_{D} and their relative strengths. In the temperature ranges $g_{\text{D}}^{1/\phi_{\text{D}}} \ll \varepsilon_H \ll g_{\text{A}}^{1/\phi_{\text{A}}}$ and $g_{\text{A}}^{1/\phi_{\text{A}}} \ll \varepsilon_H \ll g_{\text{D}}^{1/\phi_{\text{D}}}$, the spin system exhibits anisotropic short-range (e.g., $d = 3, n = 1$) and isotropic dipolar critical behavior, respectively. The behavior of the system in the asymptotic critical region, that is, at temperatures $\varepsilon_H \ll g_{\text{D}}^{1/\phi_{\text{D}}}, g_{\text{A}}^{1/\phi_{\text{A}}}$ or equivalently, in the limit $\varepsilon \to 0$, is determined by both anisotropy and dipolar interactions; the reduced temperature ε measures the temperature deviation from the critical temperature $T_{\text{C}}(g_{\text{D}} \neq 0, g_{\text{A}} \neq 0)$ of the anisotropic dipolar fixed point. The RG calculations (Frey and Schwabl, 1990; Ried, Millev, Fähnle and Kronmüller, 1995) have addressed three distinctly different cases. On the basis of the calculated temperature dependence of the effective critical exponent for susceptibility, $\gamma_{\text{eff}}(\varepsilon) = \mathrm{d}\ln\chi^{-1}(\varepsilon)\mathrm{d}\ln\varepsilon$, at temperatures spanning the asymptotic critical region and crossover regimes, these RG theories predict the following sequences of crossovers as the temperature is lowered from high temperatures to the critical point, T_{C}. Case I: when both g_{D} and uniaxial anisotropy (g_{U}) are extremely large (Frey and Schwabl, 1990), Gaussian regime → short-range Ising (I) → uniaxial dipolar (UD) fixed point (characterized by mean-field power laws with MLCs (Wegner and Riedel, 1973; Brézin and Zinn-Justin, 1976; Frey and Schwabl, 1990; Ried, Millev, Fähnle and Kronmüller, 1995)). Case II: when $g_{\text{U}} \gg g_{\text{D}}$ (Ried, Millev, Fähnle and Kronmüller, 1995), Gaussian → isotropic short-range Heisenberg (IH) → I → UD. Case III: when $g_{\text{U}} \ll g_{\text{D}}$ (Ried, Millev, Fähnle and Kronmüller, 1995), Gaussian → IH → isotropic long-range dipolar (ID) → UD.

The existence of MLCs to the mean-field power laws, characteristic of the UD fixed point, in uniaxial ferromagnets $GdCl_3$, $LiTbF_4$, and $LiHoF_4$ (Kötzler and Scheithe, 1973; Frowein and Kötzler, 1982; Griffin, Huster and Folweiler, 1980; Frowein, Kötzler, Schaub and Schuster, 1982) as well

as a crossover from Ising to asymptotic UD critical behavior in $LiTbF_4$ (Frey and Schwabl, 1990) was confirmed experimentally by Frowein, Kötzler, Schaub and Schuster (1982). Even though early electrical resistivity (Geldart, De'Bell, Cook and Laubitz, 1987) and specific heat (Bednarz, Geldart and White, 1993) data strongly indicated that the asymptotic critical behavior of Gd could be that of a UD ferromagnet, it was only recently that an elaborate analysis of extensive high-resolution ac susceptibility (Srinath, Kaul and Kronmüller, 1999) and bulk magnetization (Srinath and Kaul, 1999) data taken along the c axis (easy direction of magnetization) of a high-purity Gd single crystal over four decades in the reduced temperature $\varepsilon = (T - T_C)/T_C$ provided a conclusive experimental evidence for (i) a UD asymptotic critical behavior, (ii) a sequence of crossovers: UD $\rightarrow$ isotropic dipolar (ID) $\rightarrow$ Gaussian (the latter crossover proceeds without the intervening ID $\rightarrow$ isotropic short-range Heisenberg (IH) crossover, predicted theoretically by Frey and Schwabl (1990) and by Ried, Millev, Fähnle and Kronmüller (1995) for temperatures above T_C (critical temperature corresponding to the UD fixed point) as $T \rightarrow T_C^+$, and (iii) the UD $\rightarrow$ IH crossover as the temperature is lowered below T_C^-. The UD $\rightarrow$ IH crossover is accompanied by a transition from linear (uniaxial dipolar/Ising) domain wall to Bloch (Heisenberg) domain wall and no theoretical predictions exist for this crossover (details given in Srinath and Kaul, 1999). The effective critical exponents $\beta_{\rm eff}(\varepsilon)$ and $\gamma_{\rm eff}(\varepsilon)$ for spontaneous magnetization and 'zero-field' susceptibility (obtained by employing the method of data analysis already described in Section 3.4.1) displayed in Figure 14 (taken from Srinath and Kaul, 1999) highlights the crossovers UD $\rightarrow$ IH for $T < T_C^-$ and UD $\rightarrow$ ID for $T > T_C^+$. A detailed analysis (Srinath and Kaul, 1999) of the spontaneous magnetization, $M(\varepsilon, 0)$, (inverse 'zero-field' susceptibility, $\chi^{-1}(\varepsilon)$) data in the asymptotic critical region, that is, $|\varepsilon| \leq |\varepsilon_{\rm co}^{\rm UD\rightarrow IH}|$ [$|\varepsilon| \leq |\varepsilon_{\rm co}^{\rm UD\rightarrow ID}|$], and the critical $M - H$ isotherm reveals that, in conformity with the RG predictions (Wegner and Riedel, 1973; Brézin and Zinn-Justin, 1976; Frey and Schwabl, 1990; Ried, Millev, Fähnle and Kronmüller, 1995) for a $d = 3$ UD ferromagnet, the asymptotic critical behavior of these quantities is accurately described by the expressions

$$M(\varepsilon, 0) = \hat{B}\,(-\varepsilon)^{\beta}\,|\ln|\varepsilon||^{x^-} \qquad \varepsilon < 0 \qquad (76)$$

$$\chi^{-1}(\varepsilon) = \hat{\Gamma}^{-1}\varepsilon^{\gamma}\,|\ln\varepsilon|^{-x^+} \qquad \varepsilon > 0 \qquad (77)$$

$$H = \hat{D}\,M^{\delta}\,|\ln|M||^{-3x^-} \qquad \varepsilon = 0 \qquad (78)$$

with the asymptotic critical exponents $\beta = 0.5002(6)$, $\gamma = 1.0003(3)$, $\delta = 3.005(5)$, and logarithmic correction exponents $x^- = 0.330(2)$, $x^+ = 0.329(1)$. These experimental values match quite well with the theoretical values $\beta = 0.5$, $\gamma = 1$, $\delta = 3$, and $x^- = 3/(n+8)$, $x^+ = (n+2)/(n+8)$ with $n = 1$. Such a close agreement is also true for the universal amplitude ratio $R_\chi = \hat{D}\hat{B}^{\delta-1}\hat{\Gamma}$ and hence these results unambiguously establish that the asymptotic critical behavior of Gd is that of a $d = 3$ UD ferromagnet.

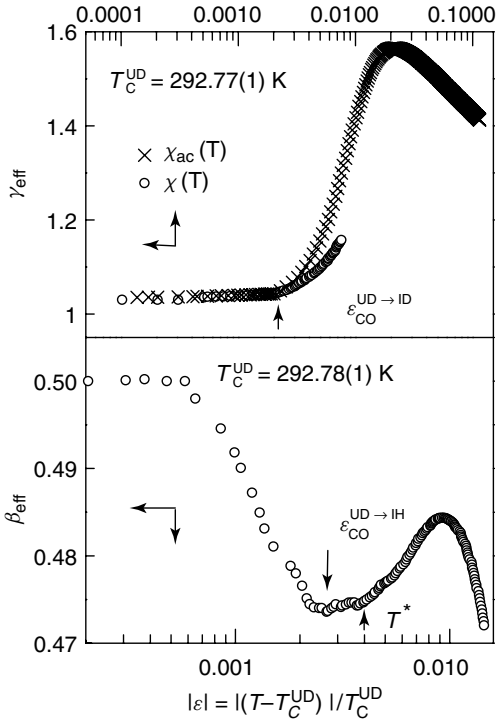

Figure 14. Temperature variations of the effective critical exponents $\beta_{\rm eff}$ (bottom panel) and $\gamma_{\rm eff}$ (top panel) for gadolinium metal. The onset temperatures of the uniaxial dipolar (UD)-to-isotropic Heisenberg (IH) and uniaxial dipolar (UD)-to-isotropic dipolar (ID) crossovers as well as the peak in $\beta_{\rm eff}(\varepsilon)$, where a transition from the linear domain wall to Bloch domain wall occurs, are marked by the arrows.

Another example of marginal scaling fields is provided by the long-range exchange interactions of the specific form $J(r) \sim r^{-(d+\sigma)}$ with $\sigma = d/2$ (Fisher, Ma and Nickel, 1972) that couple spins in an isotropic d-dimensional spin system with n-component order parameter. Such interactions thus give rise to logarithmic corrections (Fisher, Ma and Nickel, 1972) to the mean-field critical behavior. MLCs to the mean-field power laws in the asymptotic critical region (henceforth referred to as the MLC fixed point) of the type given by equations (76–78) and a gradual crossover to the Gaussian fixed point at temperatures outside the critical regime have been unambiguously detected in recent bulk magnetization and ac susceptibility experiments on various polycrystalline samples of $d = 3, n = 3$ weak itinerant-electron ferromagnet $Ni_{75}Al_{25}$ 'prepared' in different states of site disorder (Semwal and Kaul, 2001, 2002). In these samples, crossover to the Gaussian fixed point is followed at

higher temperatures ($T > T_C$) by a crossover from Gaussian (G) to mean-field (MF) regime. Site disorder (or equivalently, quenched random-exchange disorder) turns out to be irrelevant (Semwal and Kaul, 2002) in the RG sense in $Ni_{75}Al_{25}$. The MLC fixed point is distinctly different from the UD fixed point in that the universal amplitude ratio $R_\chi = \hat{D}\hat{B}^{\delta-1}\hat{\Gamma}$ and the logarithmic correction exponents have widely different values (Semwal and Kaul, 2002) in the two cases.

4 CONCLUDING REMARKS

In this brief review of the vast field of finite temperature magnetism and magnetic phase transitions (from the experimental point of view), more emphasis has been deliberately laid on itinerant-electron (band or metallic) magnetism than on localized-spin (Heisenberg) magnetism, for the following reasons. First, itinerant systems form the bulk of real magnetic materials. Second, magnetic excitations and magnetic phase transitions are more varied in nature in metallic systems than in localized systems. Inability of the early INS experiments (due to the limited range of energy transfer accessible to them) to simultaneously detect spin waves and Stoner single-particle excitations, together with nonpropagating longitudinal and transverse spin fluctuations, in strong or weak itinerant-electron systems not only gave birth to SPEELS (a relatively new experimental technique) but also led to significant improvements in the traditional neutron-scattering techniques; one such improvised technique is the spin-polarized neutron scattering with spin-polarized detection. Third, weak itinerant magnets act as model systems for understanding strongly correlated systems, which have gained considerable attention in the scientific community recently because of the discovery of high-temperature superconductivity and magnetically mediated superconductivity, on the one hand, and renewed interest in the metal-insulator transition particularly in the colossal magnetoresistance materials (doped $LaMnO_3$ compounds), on the other.

Phase transitions in spin systems with quenched random-exchange disorder attracted considerable attention in the late 1970s and early 1980s because certain features of the critical behavior, inherent to these systems, were distinctly different from those witnessed earlier in crystalline systems. One such feature is the nonmonotonic temperature dependence of the effective exponent, γ_{eff}, for susceptibility in amorphous ferromagnets (Kaul, 1984b, 1985) over an extremely wide temperature range above the Curie point, T_C (i.e., with temperature increasing above T_C, γ_{eff} increases from a value close to that ($\gamma = 1.386$) for a $d = 3$ Heisenberg ferromagnet in the asymptotic critical region to a broad maximum before decreasing at a very slow rate toward the mean-field value of $\gamma = 1.0$ at $T \gg T_C$). This nonmonotonic behavior of $\gamma_{\text{eff}}(\varepsilon)$ arises from the interplay between the thermal spin–spin correlation length, $\xi(T)$, (of the spins in the ferromagnetic 'backbone'/network) and the length scale characteristic of random structural disorder (temperature-dependent length scale determined by the caliper dimension of the finite spin clusters at $T > T_C$) in the correlated molecular-field theory proposed by Fähnle and Herzer (1984) (in the infinite-ferromagnetic-network plus finite-spin-clusters model due to Kaul (1984b, 1985)). The Monte Carlo simulations of the phase transitions in bond- and site-disordered ferromagnets (Fähnle, 1984, 1985, 1987) revealed that the nonmonotonic temperature dependence of γ_{eff} was mainly due to site disorder.

The experimental techniques and the methods of data analysis used in the literature to study static critical phenomena in magnetic systems were extensively reviewed by Kaul (1985) with particular emphasis on ferromagnets with quenched random-exchange disorder. By contrast, Section 3 of the present article deals exclusively with refinements in the data analyses and recent advances in the experimental detection of the asymptotic (static) critical behavior and crossover between different critical regimes in ISR exchange ferromagnets with or without long-range interactions (e.g., dipole–dipole interactions) and magnetic anisotropy. However, due to space restrictions, this description of the static critical phenomena has in a sense preempted the dynamical aspects of such phenomena, which are equally interesting and sometimes yield more decisive information about the nature of underlying interactions in a given system. One of the most glaring examples where this is indeed the case is the following. The static critical behavior of $d = 3$ ISR Heisenberg ferromagnet is practically indistinguishable from that of $d = 3$ ILD ferromagnet since the values of the static critical exponents for such ferromagnets differ only slightly (by less than 0.5%). By contrast, the dynamical critical exponent z (which characterizes the dynamics of the critical spin fluctuations) has widely different values $z \cong 2$ and $z \cong 2.5$ for the ILD and ISR Heisenberg fixed points and hence permits a clear-cut distinction between them. A 'feel' for the dynamical critical phenomena is essentially conveyed by the observation of a cooperative growth of the short-range magnetic order (or equivalently, spin patches or clusters), characterized by a correlation length, ξ, and a correlation time, τ, both of which diverge at T_C, as the critical point is approached from temperatures above T_C. This is the well-known 'critical slowing down' phenomenon. To account for this dynamical aspect of critical phenomena, the (equal time) correlation function, given earlier by equation (38), should be generalized to include time, that is, $G(\mathbf{r}, \tau) = [\langle \mathbf{S_0}(0) \cdot \mathbf{S_r}(\tau)\rangle - \langle \mathbf{S_0}\rangle\langle \mathbf{S_r}\rangle]$. As a consequence of this generalization, the lifetime of the

spin fluctuations of wave vector q is governed by a temperature dependence $|\varepsilon|^{-z\nu}$ (where z and ν are the dynamical and correlation length critical exponents, respectively), with a characteristic divergence as $T \rightarrow T_C$. Excellent reviews of the subject of dynamical critical phenomena are available in the literature both from theoretical (Hohenberg and Halperin, 1977; Frey and Schwabl, 1994; Henneberger *et al*., 1999) and experimental (Hohenemser, Rosov and Kleinhammes, 1989; Collins, 1989) standpoints.

ACKNOWLEDGMENTS

The author has greatly benefited from discussions or correspondence with A. Aharony, A. S. Arrott, M. Fähnle, D. J. W. Geldart, C. Hohenemser, J. Kötzler, H. Kronmüller and W. Nolting. Thanks are also due to the members of the research groups at the University of Hyderabad, India, and at the Max Planck Institute for Metal Research, Stuttgart, whose contributions have been extensively used in this article. These researchers include P. D. Babu, S. F. Fischer, W.-U. Kellner, Ch. V. Mohan, R. Reisser, M. Sambasiva Rao, M. Seeger, Anita Semwal, V. Siruguri and S. Srinath. The author thanks Sanjeev Kumar for his assistance in preparing the diagrams for this article.

Electron Theory of Finite Temperature Magnetism

Jürgen Kübler
Technische Universität Darmstadt, Darmstadt, Germany

1 INTRODUCTION

Wohlfarth, in an important review (1980), stated that the three ferromagnetic transition metals are of importance to the whole subject of metallic magnetism and their properties should be thoroughly understood before attempting to understand those of the transition-metal alloys. In fact, we repeat only one of Wohlfarth's tables in Table 1 and can now state, clearly, how far our understanding goes and where the challenge lies.

The saturation magnetization appearing in the first two lines of Table 1 can be calculated to very good precision *ab initio* using the density-functional theory in the local spin-density functional approximation (LSDA), an approximation that is well documented and is widely used for calculating ground-state properties. In the next section, some of the salient facts of the LSDA are collected. So, depending somewhat on one's point of view, one can say that these data are well understood.

The Curie temperatures listed in the third line of Table 1 and the fourth line are not so well understood, but progress has been made in the recent past as we have documented here.

Historically, the important question was whether the magnetic carriers were localized or itinerant and each of these two viewpoints had eminent proponents. Although, of course, colloquially, the terms *localized* or *itinerant* seem clear, a physical definition is more helpful. A simple one was given more than 40 years ago by Rhodes and Wohlfarth (1963). This is how they might have argued.

The susceptibility in the paramagnetic state of a local moment ferromagnet is given by the Curie–Weiss law:

$$\chi = \frac{C}{T - T_c} \tag{1}$$

The Curie constant, C can be written as

$$C = \frac{1}{3} q_c (q_c + 2) \mu_B^2 / k_B \tag{2}$$

where q_c is called the *number of magnetic carriers*, which is obtained from the experimental Curie–Weiss susceptibility. In Table 1, the values of q_c are collected and the ratio q_c/q_s is also listed, where q_s is the moment at zero temperature. A local moment system is characterized by the ratio $q_c/q_s = 1$. We see from Table 1 how the elemental ferromagnets Fe, Co, and Ni progressively deviate from locality.

Rhodes and Wohlfarth obtained the ratios of q_c/q_s for a large number of ferromagnetic metallic compounds and alloys from experimental data and plotted them as a function of the measured Curie temperatures. The result is now called the Rhodes-Wohlfarth plot, as shown in Figure 1.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

Table 1. Fundamental magnetic properties of bcc Fe, Co, and fcc Ni (Co is hcp at low and fcc at high temperatures). (Reproduced from E.P. Wohlfarth, 1980, with permission of Elsevier.)

	Fe	Co	Ni
Saturation magnetization [emu g^{-1}]	221.71 ± 0.08	162.55	58.57 ± 0.03
Saturation magnetization (q_s) [μ_B per atom]	2.216	1.715	0.616
Curie temperature (T_c) (K)	1044 ± 2	1388 ± 2	627.4 ± 0.3
kT_c [meV]	90.0	119.6	54.1
Number of magnetic carriers from Curie–Weiss law (q_c)	2.29	2.29	0.90
q_c/q_s	1.03	1.34	1.46

This phenomenological curve gives intuitive insight into the different kinds of magnetism. For, considering a system with localized moments, we do not expect the magnitude of the moment to change much when it is measured below and above T_c, giving ratios q_c/q_s of order unity. Thus, we find systems with localized moments on the line $q_c/q_s = 1$. We attribute the rather systematic deviation of q_c/q_s from unity to magnetic moments due to itinerant, that is, essentially delocalized, magnetic moments. Of course, the saturation moments become small in general for decreasing T_c, but the increase in q_c/q_s is mainly due to increasing effective magnetic carriers at high temperatures. The challenge is that we do not deal with two disjunct cases, localized or itinerant, but with a distribution, which requires a unified treatment that interpolates between the two limits.

The theory of itinerant-electron magnetism has traditionally been pursued along two different directions, until recently by two separate communities. One uses model Hamiltonians, most prominently the Hubbard (1979) model, in conjunction with many-body techniques, the other density-functional theory and its LSDA. In contrast to the former, the latter is an *ab initio* approach that does not require empirical parameters as input. It appears, however, that the two main streams are about to merge into one; of the many examples, only the work of Lichtenstein, Katsnelson and Kotliar (2001) should be mentioned here because of its relevance for the finite-temperature properties of Fe and Ni. Since, otherwise, the model Hamiltonian approach will receive much attention in this volume (see for instance **Density-functional Theory of Magnetism, Volume 1** and **Dynamical Mean-field Theory of Itinerant Electron Magnetism, Volume 1**), we can pass over this important topic here and turn to the density-functional approach, which will carry us a long way.

A readable and clear introduction to the history of magnetism and various ways to the treatment of localized and itinerant-electron magnets can be found in the book by Mohn (2003). In the book by Kübler (2000), much of the methodology is described, which makes the spin-density-functional theory amenable to numerical solutions.

Returning now to the need of a unified treatment of itinerant-electron magnetism, we emphasize the work of Moriya and his students (Moriya and Takahashi, 1978a,b; Moriya, 1985,1987), which supplies such a unified concept and spells out the key approximations, as for instance the *adiabatic approximation* to be dealt with later on. Although

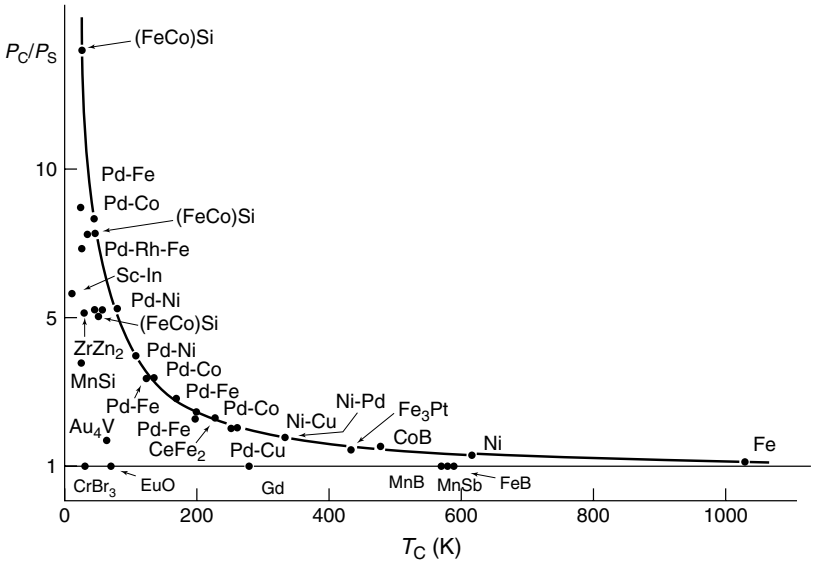

Figure 1. Rhodes–Wohlfarth plot: ratio P_c/P_s, where P_c is obtained from the experimental Curie constant, and P_s is the saturation magnetization versus the Curie temperature. Note that the notation is changed in this historical plot, the letter P replacing q used in the text. (Reproduced from P. Rhodes and E.P. Wohlfarth: *Proceedings of the Royal Society* **A273**, 1963, p 247, with permission from The Royal Society.)

the theory in its entirety is not easily amenable to *ab initio* calculations, which are at the heart of this chapter, we will make an attempt to follow the physical insight it supplies as far as possible without too many formal derivations. It emerges that starting from the elemental metals is not advantageous. It is the limit of the weak ferromagnets with very large values of q_c/q_s that provides initially more insight into the physics of the itinerant-electron magnets.

2 SPIN-DENSITY-FUNCTIONAL THEORY

We begin with a brief excursion into density-functional theory. It is of some didactic advantage to do this using the version by Mermin (1965), which is formulated for finite temperatures. We give an outline of this theory even though we presently do not know a physically meaningful approximation to the finite-temperature exchange-correlation potential. The discussion given in this section, therefore, serves on the one hand to restate, in the modern form, the Stoner–Wohlfarth theory (and why it fails) and, on the other hand, to define our limits of understanding. It should be noted that the formulation that follows – differing from Mermin's – is based on two-component spinor functions this way accounting for the spin of the electron in a sufficiently detailed, yet simple way.

We consider a many-electron system in an external potential giving first the connection of the external potential with the density matrix:

$$V[\tilde{\rho}] = \sum_{\alpha\beta} \int v^{\text{ext}}_{\alpha\beta}(\mathbf{r})\tilde{\rho}_{\beta\alpha}(\mathbf{r})\mathrm{d}\mathbf{r} \tag{3}$$

where $\alpha, \beta = 1, 2$ are spin indices and $\tilde{\rho}_{\beta\alpha}(\mathbf{r})$ are the elements of the density matrix, $\tilde{\rho}$, which define the particle density through the trace

$$\rho(\mathbf{r}) = \text{Tr } \tilde{\rho}(\mathbf{r}) \tag{4}$$

and the vector of the magnetization by

$$\mathbf{m}(\mathbf{r}) = \text{Tr } \boldsymbol{\sigma}\tilde{\rho}(\mathbf{r}) \tag{5}$$

where $\boldsymbol{\sigma}$ is given by the Pauli spin matrices.

Mermin (1965) laid the formal foundations for the proof that in the grand canonical ensemble at a given temperature T and chemical potential μ the equilibrium density matrix $\tilde{\rho}(\mathbf{r})$, that is, the equilibrium particle density $\rho(\mathbf{r})$ and the equilibrium magnetization $\mathbf{m}(\mathbf{r})$ are determined by the external potential and magnetic field that make up $v^{\text{ext}}_{\alpha\beta}(\mathbf{r})$. It must be added, however, that Mermin did not discuss magnetic systems and based his theory on the density, not the density matrix. Allowing for this generalization without any formal proofs, we state that the correct $\rho(\mathbf{r})$ and $\mathbf{m}(\mathbf{r})$ minimize the Gibbs grand potential Ω:

$$\Omega[\tilde{\rho}] = \sum_{\alpha\beta} \int v^{\text{ext}}_{\alpha\beta}(\mathbf{r})\tilde{\rho}_{\beta\alpha}(\mathbf{r})\mathrm{d}\mathbf{r} + \iint \mathrm{d}\mathbf{r}\,\mathrm{d}\mathbf{r}' \frac{\rho(\mathbf{r})\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} - \mu \int \mathrm{d}\mathbf{r}\rho(\mathbf{r}) + G[\tilde{\rho}] \tag{6}$$

where G is a unique functional of charge and magnetization at a given temperature T and chemical potential μ. The reader interested in more details is referred to Mermin's original paper or to reviews like that by Ramana and Rajagopal (1983), Kohn and Vashishta (1983), and Eschrig (1996). The quantity $G[\tilde{\rho}]$ in equation (6) is written as the sum of three terms, that is,

$$G[\tilde{\rho}] = T_0[\tilde{\rho}] - TS_0[\tilde{\rho}] + \Omega_{xc}[\tilde{\rho}] \tag{7}$$

with T_0, S_0 being, respectively, the kinetic energy and entropy of a system of noninteracting electrons with density matrix $\tilde{\rho}$ at a temperature T. The quantity Ω_{xc} is the exchange and correlation contribution to the Gibbs grand potential.

We now construct the minimum of the grand potential using a system of noninteracting electrons moving in an effective potential. We thus assume we can determine single-particle functions $\{\psi_{i\alpha}(\mathbf{r})\}$ that permit us to write the elements of the density matrix as

$$\tilde{\rho}_{\beta\alpha}(\mathbf{r}) = \sum_{i=1}^{\infty} \psi_{i\beta}(\mathbf{r})\psi^*_{i\alpha}(\mathbf{r}) f(\varepsilon_i) \tag{8}$$

where α and β, due to the electron spin, take on the values 1 and 2 and $f(\varepsilon) = \left[1 + \exp\beta(\varepsilon - \mu)\right]^{-1}$ is the Fermi–Dirac distribution function ($\beta = 1/k_B T$). We obtain the single-particle spinor functions by solving the Schrödinger equation

$$\sum_{\beta} [-\delta_{\alpha\beta}\nabla^2 + v'_{\alpha\beta}(\mathbf{r}) - \varepsilon_i\delta_{\alpha\beta}]\psi_{i\beta}(\mathbf{r}) = 0 \tag{9}$$

and attempt to determine the potential, v', by minimizing the grand potential, thus obtaining the effective potential as

$$v'_{\alpha\beta}(\mathbf{r}) \equiv v^{\text{eff}}_{\alpha\beta}(\mathbf{r}) = v^{\text{ext}}_{\alpha\beta}(\mathbf{r}) + 2\delta_{\alpha\beta}\int \frac{\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\mathrm{d}\mathbf{r}' + v^{xc}_{\alpha\beta}(\mathbf{r}) \tag{10}$$

where

$$v^{xc}_{\alpha\beta}(\mathbf{r}) = \frac{\delta}{\delta\tilde{\rho}_{\beta\alpha}(\mathbf{r})}\Omega_{xc}[\tilde{\rho}] \tag{11}$$

With the result for the effective potential, we may finally rewrite the grand potential as

$$\Omega[\tilde{\rho}] = -\beta^{-1}\sum_{i=1}^{\infty}\ln[1+\exp\beta(\mu-\varepsilon_i)] - \iint \mathrm{d}\mathbf{r}\mathrm{d}\mathbf{r}'\frac{\rho(\mathbf{r})\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} - \sum_{\alpha\beta}\int \mathrm{d}\mathbf{r} v^{xc}_{\alpha\beta}(\mathbf{r})\tilde{\rho}_{\beta\alpha}(\mathbf{r}) + \Omega_{xc}[\tilde{\rho}] \qquad (12)$$

Formally, the problem now appears to be solved: the potential in the Schrödinger equation, equation (9), is given by the equations (10) and (11) in which the density matrix is given by equation (8). For a ferromagnet at zero temperature, we know that the basic Schrödinger equation, in the local-density-functional approximation, is diagonal in spin space and hence easily solved. But, at finite temperatures, the formal expression for the exchange-correlation potential, $v^{xc}_{\alpha\beta}(\mathbf{r})$, equation (11), gives no clue regarding its general properties. If we assume it remains diagonal in spin space and use the zero-temperature exchange-correlation potential, we may again solve the Schrödinger equation, temperature in this case entering only through the Fermi–Dirac distribution in equation (8). This is not a hard calculation and one obtains for the temperature where the magnetization vanishes, values that, compared with the experimental Curie temperatures, are unacceptably large.

This disagreement is part of what is normally called the *failure of Stoner–Wohlfarth theory*. Another well-known defect is the magnetic susceptibility for which one calculates for the temperature range of interest Pauli-like (i.e., temperature independent) behavior. This is in stark contradiction to the well-known, experimentally observed Curie–Weiss law, which receives a lot of attention in Section 3.

We have chosen here to discuss the problem using a version of Mermin's finite-temperature density-functional theory and see that our basic assumption of a diagonal effective potential is most likely the weak part of this treatment. Restricting the effective potential to diagonal form implies that the magnetization decreases as the temperature increases because of excitations that are of the order of the exchange splitting, that is, of rather high energies, since the exchange splitting is large on the scale of the Curie temperatures. We are thus led to look for low-energy excitations to explain the magnetic phase transition.

Awareness of low-energy excitations arose in the 1970s predominantly through the pioneering work of Korenman Murray and Prange (1977), Hubbard (1979), Hasegawa (1979), Edwards (1982), Heine and Samson (1983), Moriya (1985), and Gyorffy *et al*. (1985), and others, the review of Staunton (1994) constituting a clear summary. The broad consensus reached was that *orientational fluctuations of the local magnetization* represent the essential ingredients of a thermodynamic theory. This cannot be incorporated in a straightforward way into the Stoner–Mermin theory.

To proceed with the density-functional theory, one ignores the difficulties connected with the exchange-correlation grand potential and assumes in its place the exchange-correlation total energy at zero temperature making, at the same time, the LSDA. One may use here any of the established schemes like those of von Barth and Hedin (1972) or Perdew and Wang (1992). The next step then is a formulation of the LSDA that allows for general, that is, *noncollinear configurations* of the magnetic moments in a magnetic crystal. To accomplish this, one may proceed as follows.

In its most simple version, one partitions the space in the crystal into atomic spheres over which one integrates the density matrix defined in equation (8), that is, one determines the quantity

$$\rho_{\alpha\beta} = \int_S \tilde{\rho}_{\alpha\beta}(\mathbf{r})\mathrm{d}\mathbf{r} \qquad (13)$$

for the atomic sphere S. Having chosen a quantization axis, usually the z axis, the integrated (or *atomic*) density matrix $\rho_{\alpha\beta}$ will naturally be diagonal for a ferromagnet in the ground state. For other kinds of magnetic systems, it may not be so; in this case, one can diagonalize the magnetic moment by means of the spin-1/2 rotation matrix, $U(\theta,\varphi)$, by performing the operation $U\rho U^{\dagger}$. The spherical polar coordinates, θ and φ then define the orientation of the magnetic moment of the atom in sphere S with respect to the z axis (Kübler, Höck, Sticht and Williams, 1988; Sticht, Höck and Kübler, 1989). We note that the integration in equation (13) to obtain the atomic density matrix is not a necessary step as one can deal directly with the full space dependence of $\tilde{\rho}_{\alpha\beta}(\mathbf{r})$ and calculate polar angles for each point in space as was done by Knöpfle, Sandratskii and Kübler (2000) for the noncollinear ground state of γ-Fe; this topic, however, is not pursued here any further. A relation connecting the diagonal with the nondiagonal atomic density matrix can easily be obtained as

$$\frac{\delta\rho_i}{\delta\rho_{\alpha\beta}} = U_{i\alpha}U^{\dagger}_{\beta i} \qquad (14)$$

Hence, the exchange-correlation potential in equation (11) can be written as

$$v^{xc}_{\alpha\beta}(\mathbf{r}) = \sum_{i=1}^{2} U^{\dagger}_{\alpha i}\left(\frac{\delta\Omega_{xc}}{\delta\rho_i}\right)U_{i\beta} \qquad (15)$$

This allows the determination of the nondiagonal elements of the exchange-correlation potential from the usual functional derivative of the Gibbs potential (total energy).

The next step now is to model the effects of nonzero temperatures by 'freezing in' deviations from the ground-state spin orientation by a meaningful choice of noncollinear moment arrangement. The most appealing approach is that by Herring (1966), which was later independently rediscovered by Sandratskii (1986a,b); they showed that spiral magnetic structures have ideal mathematical properties for this purpose. These are described in reciprocal space. Another approach exists, which, starting with real space, has great virtues when translational symmetry is broken or partially broken. We will deal with this after the reciprocal-space approach.

2.1 Magnetic interactions from a reciprocal-space approach

A spiral magnetic structure is defined by giving the Cartesian coordinates of the magnetization vector, $\mathbf{M}_n$, as

$$\mathbf{M}_n = M\left[\cos(\mathbf{q}\cdot\mathbf{R}_n)\sin\theta, \sin(\mathbf{q}\cdot\mathbf{R}_n)\sin\theta, \cos\theta\right] \quad (16)$$

Here, M is the magnitude of the magnetic moment at site $\mathbf{R}_n$, and $(\mathbf{q}\cdot\mathbf{R}_n)$ as well as θ are polar angles. On first sight, it appears that the periodicity is lost with respect to lattice translations nonorthogonal to $\mathbf{q}$. One should notice, however, that all atoms of the spiral structure separated by a translation $\mathbf{R}_n$ are equivalent, possessing magnetic moments of equal magnitude. This equivalence leads to the useful property for the single-particle spinor functions, which is embodied in a generalized Bloch theorem:

$$\{\mathbf{q}\cdot\mathbf{R}_n|\epsilon|\mathbf{R}_n\}\psi_{\mathbf{k}}(\mathbf{r}) = \mathrm{e}^{i\mathbf{k}\cdot\mathbf{R}_n}\psi_{\mathbf{k}}(\mathbf{r}) \quad (17)$$

where the $\psi_{\mathbf{k}}(\mathbf{r})$ are eigenspinors. The operator $\{\mathbf{q}\cdot\mathbf{R}_n|\epsilon|\mathbf{R}_n\}$ combines a lattice translation $\mathbf{R}_n$ and the identity space rotation, denoted by the identity symbol ϵ, with a spin rotation about the z axis by an angle $\mathbf{q}\cdot\mathbf{R}_n$. The vectors $\mathbf{k}$ lie in the first Brillouin zone, which is defined in the usual way. The spin spiral defined in equation (16) does not break the translational symmetry of the lattice, although, in general, the point-group symmetry is reduced. This statement is independent of the choice of $\mathbf{q}$, which, therefore, need not be commensurate with the lattice. A practical consequence is that no supercell is needed to solve the Schrödinger equation in the presence of spin spirals. From a representation of the generalized translation operator, which is easily obtained from the spin-1/2 rotation matrix as

$$\{\mathbf{q}\cdot\mathbf{R}_n|\epsilon|\mathbf{R}_n\}\psi(\mathbf{r}) = \begin{pmatrix}\exp(\mathrm{i}\mathbf{q}\cdot\mathbf{R}_n/2) & 0\\ 0 & \exp(-\mathrm{i}\mathbf{q}\cdot\mathbf{R}_n/2)\end{pmatrix}\psi(\mathbf{r}-\mathbf{R}_n) \quad (18)$$

one can see that for elemental metals the spiral wave vector $\mathbf{q}$ is chosen from inside the first Brillouin zone; $\mathbf{q}$ vectors outside give nothing new. The details of the underlying analysis can be found in the original literature or the review paper by Sandratskii (1998).

Finally, if the Schrödinger equation (9) is written in the usual form as $\mathcal{H}_{\mathbf{q}}\psi = \varepsilon\psi$, then by means of equation (15), the Hamiltonian, $\mathcal{H}_{\mathbf{q}}$, can be specified in the following form

$$\mathcal{H}_{\mathbf{q}} = -\mathbf{1}\nabla^2 + \sum_n \Theta(|\mathbf{r}_n|)U^{+}(\theta,\varphi,\mathbf{q}) \times \begin{pmatrix} v_{+}^{\mathrm{eff}}(|\mathbf{r}_n|) & 0\\ 0 & v_{-}^{\mathrm{eff}}(|\mathbf{r}_n|)\end{pmatrix} U(\theta,\varphi,\mathbf{q}) \quad (19)$$

where $|\mathbf{r}_n| = |\mathbf{r}-\mathbf{R}_n|$, $\Theta(|\mathbf{r}_n|)$ is the unit step function that vanishes outside the atomic sphere centered at $|\mathbf{R}_n|$ and the indices $+$ and $-$ label the spin-up and spin-down effective potential in the local diagonal frame of reference.

An important observation is that the Hamiltonian in the preceding text, $\mathcal{H}_{\mathbf{q}}$, depends on a parameter $\mathbf{q}$, the wave vector characterizing the spin spiral. Niu and Kleinman (1998) realized that, just like the adiabatic approximation for decoupling the electronic from the ionic motion in solids, this parameter leads to a Berry phase (Berry, 1984). In fact, they, and later Niu *et al*. (1999), showed that the Berry curvatures involved in the equation of motion describe how the total spin component along the symmetry axis changes due to spin deviations from the ground-state configuration. So, if the total energy is calculated by constraining the magnetic moment to the ground-state value M for a small value of θ, then the spin wave energy for an itinerant-electron ferromagnet is (in atomic units) given by

$$\omega(\mathbf{q}) = \lim_{\theta\to 0}\frac{4}{M}\frac{E(\mathbf{q},\theta)}{\sin^2\theta} \quad (20)$$

where the total energy $E(\mathbf{q},\theta)$ is counted from the ground-state value. Since the total energy is very nearly proportional to $\sin^2\theta$, the choice of θ is not very critical. This formula not only establishes the spiral energy as a physical quantity but has also been shown to lead to very good agreement with measured magnon energies for Fe, Co, and Ni (Halilov, Eschrig, Perlov and Oppeneer, 1998; Brown, Nicholson, Wang and Schulthess, 1999; Gebauer and Baroni, 2000).

To summarize, it is the total energy and its changes with some parameters that are at the center of interest. To manage

these calculations, one solves the single-particle equations, equation (9), self-consistently. This means, in particular, a solution of the Schrödinger equation $\mathcal{H}_{\mathbf{q}}\psi = \varepsilon\psi$, where $\mathcal{H}_{\mathbf{q}}$ is given by equation (19); the Bloch function ψ and the energy eigenvalues ε depend on the parameter $\mathbf{q}$, and on the angles θ and φ. To proceed, one commonly expands the Bloch function in terms of suitable basis sets and then uses the variational principle. The result is the total energy, $E(\mathbf{q}, \theta, \varphi)$.

In practical applications, one must bear in mind that, for a general value of θ, that is, $\theta \neq 0$ and $\theta \neq 90^{\circ}$, the magnetic moment experiences a torque; the resulting precession leads to convergence problems and inaccurate values of the total energy change. This problem can be solved by means of constraints that are formulated with appropriate Lagrange multipliers in the Schrödinger equation. An elegant method has been proposed and successfully applied by Grotheer, Ederer and Fähnle (2001).

An alternative way is to employ Green's functions to solve the single-particle Schrödinger equation. The great virtue is their applicability when translational symmetry is broken. Clearly, surfaces and nanostructures call for such a method. But, even if one considers twisting slightly the magnetic moment of one atom in an otherwise ferromagnet environment, one encounters a problem of broken symmetry. Therefore, before we embark on the main topic of this chapter, we now digress and describe the Green's function or real-space approach.

2.2 Magnetic interactions from a real-space approach

The Green's function approach can be expressed as the solution of the multiple scattering problem. Thus, if G describes free particle propagation from any individual scattering event to the next, for which the single-site scattering matrix is denoted by t, we may describe multiple scattering by means of the sum

$$\tau = t + tGt + tGtGt + \cdots = t + tG(t + tGt + tGtGt + \cdots) = t + tG\tau \tag{21}$$

or

$$\tau = (1 - tG)^{-1}t = (t^{-1} - G)^{-1} \tag{22}$$

where τ is called the *scattering path operator* or the *scattering path matrix*.

Next, the total energy change to be effected is written in a simple way by using the so-called *force theorem*. This concept, originally due to Heine (1980) as well as Mackintosh and Andersen (1980) – later extended to magnetic systems by Oswald, Zeller, Braspenning and Dederichs (1985) – allows the total energy change in first order to be written as the change in the sum on the single-particle energies, provided the potential is kept as its unperturbed value. It is brought about by a subtle cancellation of terms. So, looking in particular at equation (12) – for simplicity evaluated at $T = 0$ – a first-order change of the grand potential is the sum of changes in the first term on the right-hand side and the other three terms, the so-called *double-counting terms*; the latter cancel the change in the former. For mathematical details and limitations, see Methfessel and Kübler (1982).

The force theorem was applied by Liechtenstein, Katsnelson and Gubanov (1984) Liechtenstein, Katsnelson, Antropov and Gubanov (1987) to obtain the magnetic interactions as follows.

A total energy change, brought about by a change of the magnetic structure, which changes the density of states (DOS) by $\delta n(\varepsilon)$, is given by

$$\delta E = \int^{E_{\mathrm{F}}} \varepsilon \delta n(\varepsilon)\, \mathrm{d}\varepsilon \tag{23}$$

After integration by parts, one obtains

$$\delta E = -\int^{E_{\mathrm{F}}} \delta N(\varepsilon)\, \mathrm{d}\varepsilon \tag{24}$$

where $N(\varepsilon)$ is the integrated DOS, or $n(\varepsilon) = \mathrm{d}N/\mathrm{d}\varepsilon$. Now, let the magnetic structure be described by the Heisenberg Hamiltonian

$$\mathcal{H} = -\sum_{ij}{}' J_{ij}\mathbf{e}_i \cdot \mathbf{e}_j \tag{25}$$

where J_{ij} are the exchange parameters (including the magnetic moment squared) and $\mathbf{e}_i$ is the unit vector in the direction of the magnetization. Then, the twisting of one magnetic moment at site 0 by the angle θ causes the energy to change by

$$\delta E = 2\sum_j J_{0j}(1 - \cos\theta) \simeq J_0\theta^2 \tag{26}$$

where we defined $J_0 = \sum_j J_{0j}$. Next, one uses the fact that the integrated DOS is connected with the scattering path operator by means of Lloyd's formula (Lloyd and Smith, 1972), that is,

$$N(\varepsilon) = N_0 + \frac{1}{\pi}\mathrm{Im\ tr} \ln \tau(\varepsilon) \tag{27}$$

Thus, equating (26) with equation (24) and using equation (27), one obtains

$$J_0\theta^2 = \frac{1}{\pi}\int^{E_F} \text{Im tr ln}[1 + \delta t^{-1}\tau(\varepsilon)]\,\mathrm{d}\varepsilon \tag{28}$$

Liechtenstein, Katsnelson, Antropov and Gubanov (1987) next specify the form of the t-matrix change at site i as

$$t_i = \frac{1}{2}(t_{i\uparrow} + t_{i\downarrow}) + \frac{1}{2}(t_{i\uparrow} - t_{i\downarrow}) \times (\mathbf{e}_i \cdot \boldsymbol{\sigma}) \tag{29}$$

where the components of the vector $\boldsymbol{\sigma}$ are the Pauli matrices. This implies

$$\delta t_i^{-1} = \frac{1}{2}(t_{i\uparrow}^{-1} - t_{i\downarrow}^{-1}) \times (\delta\mathbf{e}_i \cdot \boldsymbol{\sigma}) \tag{30}$$

which gives with the chosen spin rotation, $\delta\mathbf{e}_0 = (\sin\theta, 0, \cos\theta - 1)$

$$\delta t_i^{-1} = \frac{1}{2}\delta_{i,0}(t_{i\uparrow}^{-1} - t_{i\downarrow}^{-1}) \times \begin{pmatrix} \cos\theta - 1 & \sin\theta \\ \sin\theta & 1 - \cos\theta \end{pmatrix} \tag{31}$$

The trace of the logarithm in spinor-space is now evaluated using the relation tr ln T = ln det T. One obtains from equation (28)

$$J_0 = -\frac{1}{4\pi}\int^{E_F} \text{Im tr}_L[\Delta_0(\tau_\uparrow^{00} - \tau_\downarrow^{00}) + \Delta_0\tau_\uparrow^{00}\Delta_0\tau_\downarrow^{00}] \tag{32}$$

where $\Delta_0 = (t_{i\uparrow}^{-1} - t_{i\downarrow}^{-1})$.

The pair interaction parameter J_{ij} is obtained by rotating two spin moments at the sites i and j by opposite angles $\pm\theta/2$. Taking care of double counting, one obtains the desired parameter from

$$\delta E_{ij} - \delta E_i - \delta E_j \simeq \frac{1}{2}J_{ij}\theta^2 \tag{33}$$

and, after some manipulations, for which the reader can find the details in the paper by Liechtenstein, Katsnelson, Antropov and Gubanov (1987), one finally derives the result

$$J_{ij} = \frac{1}{4\pi}\int^{E_F} \text{Im tr}_L[\Delta_i\tau_\uparrow^{ij}\Delta_j\tau_\downarrow^{ji}] \tag{34}$$

A collection of formulas of the preceding type valid for more general perturbations can be found in the paper by Antropov, Harmon and Smirnov (1999). A brief review of the theory appeared in the book by Gubanov, Liechtenstein and Postnikov (1992), and early numerical applications of the formalism are quite encouraging.

When the formalism is applied to the determination of spin-wave spectra, the parameter θ is no longer small, but is of the order of $\mathbf{q}\cdot\mathbf{R}$, $\mathbf{q}$ being the magnon wave vector. This limits the applicability of the theory to the limit of small $|\mathbf{q}|$. To overcome this limit, Bruno (2003) developed a theory for renormalized magnetic interactions, or a *renormalized magnetic force theorem*.

It is also of interest to point out that the multiple scattering theory sketched in the preceding text is the key to a formulation of the disordered local moment (DLM) picture in the coherent-potential approximation (Gyorffy *et al*., 1985). We will briefly return to this theory in Sections 3.3.3 and 4.3, but continuing here in detail would carry us too far afield.

Finally, a method to calculate the effective exchange interaction parameters for correlated magnetic crystals, for which the LSDA is no longer applicable, has been formulated by Katsnelson and Lichtenstein (2000) very much along the lines of the approach in the preceding text.

3 THERMODYNAMICS

3.1 Weakly ferromagnetic metals: formulation

We begin the thermodynamics with the weakly ferromagnetic metals and later take up the other cases. In Chapter 4 of his book, Moriya (1985) obtained the energies of various spin configurations in metals by using the Hartree–Fock approximation (HFA) and random phase approximation (RPA), whereas here the energies are based on those of spin spirals. It is thus assumed that the frozen-magnon energies represent the relevant excited states sufficiently well. One can put this differently by saying that the adiabatic approximation is invoked, which is loosely justified by observing that the motion of the electrons is much faster than that of the magnetic moments, since the latter possess energies of the order of milli-electron volts, whereas the former move in bands of widths of the order of electron volts. However, it is not *a priori* clear how well this approximation is justified in general.

The space-varying spin density $\mathbf{M}(\mathbf{R})$ is now regarded as a classical field and the free energy F is formally obtained by the following functional integral:

$$F = -k_B T\ \ln\int \delta\mathbf{M}(\mathbf{R})\ \exp\{-\Psi[\mathbf{M}(\mathbf{R})]/k_B T\} \tag{35}$$

where $\Psi[\mathbf{M}(\mathbf{R})]$ is the energy functional of the spin configuration. The latter is written as

$$\mathbf{M}(\mathbf{R}) = M\mathbf{e}_z + \mathbf{m}(\mathbf{R}) = M\mathbf{e}_z + \sum_{j,\mathbf{q}} m_{j\mathbf{q}}\exp(\mathrm{i}\mathbf{q}\cdot\mathbf{R})\mathbf{e}_j \tag{36}$$

Here, M is the magnetization along some direction, say the z-direction, and $\mathbf{m}(\mathbf{R})$ is a local deviation of the magnetization, which is expanded in a Fourier series. Since it is real, the Fourier coefficients obey $m_{j-\mathbf{q}} = m^*_{j\mathbf{q}}$. The quantities $\mathbf{e}_j (j = 1, 2, 3)$ are Cartesian unit vectors.

For weakly ferromagnetic metals, the local amplitude of spin fluctuations, $m_{j\mathbf{q}}$, is expected to be relatively small. Therefore, the energy functional can be expanded in powers of the magnetization. In this step, one follows the work of Murata and Doniach (1972), who, however, took a scalar field for the spin density, whereas here a vector field is employed. The work of Lonzarich and Taillefer (1985) constitutes one of the key papers in the field of weak itinerant ferromagnets, and a lucid introduction to the physics of spin fluctuations can be found in the book by Mohn (2003).

The mode–mode coupling functional proposed is written in two parts

$$\Psi = \Psi_1 + \Psi_2 \tag{37}$$

where

$$\Psi_1 = \frac{1}{2}\alpha \frac{1}{N} \sum_n \mathbf{M}(\mathbf{R}_n)^2 + \frac{1}{4}\beta \frac{1}{N} \sum_n \mathbf{M}(\mathbf{R}_n)^4 \tag{38}$$

and

$$\Psi_2 = \frac{1}{N} \sum_{n,m} J\,(\mathbf{R}_n - \mathbf{R}_m)\, \mathbf{M}(\mathbf{R}_n) \cdot \mathbf{M}(\mathbf{R}_m) \tag{39}$$

where N denotes the number of particles in the system and the coefficients α and β can be viewed as Landau coefficients controlling changes of the size of the magnetization. They here are assumed to be independent of the temperature. The quantity $J(\mathbf{R})$ describes the exchange interaction between sites separated by $\mathbf{R}$. In the weakly ferromagnetic limit, only the fourth-order term in equation (38) is needed, which simplifies the analysis considerably, but carrying the expansion to a higher order poses no real difficulties.

To obtain the free energy, a variational principle is used by employing a Gaussian functional in this subsection

$$\Phi = \sum_{j,\mathbf{q}} a_{j\mathbf{q}} |m_{j\mathbf{q}}|^2 \tag{40}$$

$a_{j\mathbf{q}}$ being variational parameters. Using the convexity properties of exponentials (also called the *Bogoliubov–Peierls* inequality), one writes

$$F < -k_\mathrm{B}T \ \ln \int \delta\mathbf{M} \ \exp\left(\frac{-\Phi}{k_\mathrm{B}T}\right) + \langle \Psi - \Phi \rangle_0 \doteq \tilde{F} \tag{41}$$

The average $< \ldots >_0$ is defined through the Gaussian distribution, equation (40). By substituting equation (36) and Fourier transforming, one obtains after some algebra

$$\begin{aligned} \tilde{F} = &-\frac{1}{2} k_\mathrm{B} T \sum_{j,\mathbf{q}} \ln\left(\pi \left\langle |m_{j\mathbf{q}}|^2 \right\rangle_0\right) + \frac{1}{2}\alpha \left(M^2 + 2m_\perp^2 + m_\parallel^2\right) \\ &+ \frac{1}{4}\beta \Big[M^4 + 2M^2 \left(2m_\perp^2 + 3m_\parallel^2\right) + 8m_\perp^4 + 4m_\perp^2 m_\parallel^2 \\ &+ 3m_\parallel^4 \Big] + 2 \sum_{\mathbf{q}} j(\mathbf{q}) \left\langle |m_{\perp\mathbf{q}}|^2 \right\rangle_0 + \sum_{\mathbf{q}} j(\mathbf{q}) \left\langle |m_{\parallel\mathbf{q}}|^2 \right\rangle_0 \end{aligned} \tag{42}$$

where $j = \perp$ and $j = \parallel$ distinguish the fluctuations perpendicular and parallel to the macroscopic magnetization. Furthermore,

$$m_j^2 = \sum_{\mathbf{q}} \left\langle |m_{j\mathbf{q}}|^2 \right\rangle_0 \tag{43}$$

for $j = \perp$ and $j = \parallel$. The quantity $j(\mathbf{q})$ is defined by the Fourier transform

$$j(\mathbf{q}) = \sum_n J(\mathbf{R}_n) \exp(i\mathbf{q} \cdot \mathbf{R}_n) \tag{44}$$

and describes the exchange interaction in reciprocal space.

The minimization of $\tilde{F}$ with respect to the variational parameter $a_{j\mathbf{q}}$ is equivalent to minimization with respect to the fluctuations because equation (40) implies $\left\langle |m_{j\mathbf{q}}|^2 \right\rangle_0 = k_B T/(2a_{j\mathbf{q}})$. The result of the minimization is most compactly written as

$$m_j^2 = \frac{k_\mathrm{B} T}{N} \sum_{\mathbf{q}} \chi_j(\mathbf{q}) \tag{45}$$

where, one finds for the longitudinal case, $j = \parallel$,

$$\chi_\parallel^{-1}(\mathbf{q}) = \alpha + \beta(3M^2 + 2m_\perp^2 + 3m_\parallel^2) + 2j(\mathbf{q}) \tag{46}$$

and for the perpendicular case, $j = \perp$,

$$\chi_\perp^{-1}(\mathbf{q}) = \alpha + \beta(M^2 + 4m_\perp^2 + m_\parallel^2) + 2j(\mathbf{q}) \tag{47}$$

Equation (45) is the static (or high-temperature) limit of an exact relation, which states that in linear response theory the average fluctuations squared are connected with the frequency-dependent, nonuniform susceptibility $\chi_{nj}(\mathbf{q}, \omega)$ in the form

$$\left\langle |m_{j\mathbf{q}}|^2 \right\rangle = \frac{2}{\pi N} \int_0^\infty \mathrm{d}\omega \ \mathrm{Im}\left\{\chi_j(\mathbf{q}, \omega)\right\} N(\omega) \tag{48}$$

where, $N(\omega)$, omitting zero-point fluctuations, denotes the Planck distribution function. This is the famous *fluctuation-dissipation theorem* (Callen and Welton, 1951; Becker and Sauter, 1968; Jones and March, 1973; White, 1983).

The connection between equation (48) and the equations (43) and (45) is made in the limit of high temperatures and by using the Kramers–Kronig relations.

The partial derivative of the free energy with respect to the magnetization gives the magnetic field. Requiring this to be zero, one obtains

$$\frac{M^2}{M_0^2} = 1 - \frac{(2m_\perp^2 + 3m_\parallel^2)}{M_0^2} \tag{49}$$

known also as the *Moriya relation*. Here, the relation $\alpha = -\beta M_0^2$ was used, which is the minimum condition for the free energy in the absence of all fluctuations, that is, at zero temperature, $T = 0$, at which the magnetization is M_0.

For a vanishing magnetization, that is, above the ordering temperature, the longitudinal and perpendicular fluctuations and susceptibilities become equal. Thus, writing $m_\perp^2 = m_\parallel^2 = m_\mathrm{p}^2$, one determines the paramagnetic fluctuations using

$$m_\mathrm{p}^2 = \sum_{\mathbf{q}} \left\langle |m_{\mathbf{pq}}|^2 \right\rangle_0 = \frac{k_\mathrm{B}T}{N} \sum_{\mathbf{q}} \left[\alpha + 5\beta m_\mathrm{p}^2 + 2j(\mathbf{q}) \right]^{-1} \tag{50}$$

The inverse susceptibility is then given by

$$\chi^{-1} = \alpha(1 - 5m_\mathrm{p}^2/M_0^2) \tag{51}$$

It was initially thought (Uhl and Kübler, 1996; Kübler, 2000, Ch.5) that self-consistent solutions of the basic equations (45)–(47) together with equations (49) and (51) describe the phase transition below and above the Curie temperature for the elemental ferromagnets. We will see that this, unfortunately, is not true. In fact, numerical values for the two Landau coefficients, α and β were obtained by constraining the magnetic moment, M, such that the total energy counted from the nonmagnetic state $E(M)$ is expressed as a function of M. This is achieved by a Langrange multiplier in the total energy calculations (Dederichs, Blügel, Zeller and Akai, 1984). The function $E(M)$ thus obtained can then be identified with equation (38) in the absence of all fluctuations, which is written in this case as $\Psi_1(0)$, a simple fit subsequently giving

$$\Psi_1(0) = \frac{1}{2}\alpha M^2 + \frac{1}{4}\beta M^4 \tag{52}$$

This is very similar to the approach taken by Luchini, Heine and McMullan (1991) to describe the magnetic fluctuations of iron. The other parameter appearing in the basic equations is the exchange function $j(\mathbf{q})$, which was calculated by assuming the noncollinear moment arrangement of the form given in equation (16). The total energy change ensuing, $\Delta E(\mathbf{q})$, gives $j(\mathbf{q})$ through

$$\Delta E(\mathbf{q}) = M_0^2 j(\mathbf{q}) \sin^2\theta \tag{53}$$

choosing $\theta = 90^\circ$ and constraining the magnetic moment to its ground-state value, M_0. This choice of θ leads to a small error, which can be removed by better constraints, as was shown by Grotheer, Ederer and Fähnle (2001) and Singer, Fähnle and Bihlmayer (2005). But, for the sake of simplicity, we stick to this simple choice. No cutoff parameter is needed for the summations (integrations) in reciprocal space since, because of equation (44), the function $j(\mathbf{q})$ is periodic. Finally, if the phase transition calculated is of second order, one obtains from the basic equations the following formula for the Curie temperature:

$$k_\mathrm{B}T_\mathrm{c}^{SF} = \frac{2M_0^2}{5} \left[\frac{1}{N} \sum_{\mathbf{q}} \frac{1}{j(\mathbf{q})} \right]^{-1} \tag{54}$$

which carries the label SF, for spin fluctuation, in order to distinguish it from other expressions that are given in the subsequent text.

Before the partial success and the shortcomings of this approach are discussed, it is worthwhile to improve the approximations by going beyond the static approximation. The essential step here is the replacement of equation (45) by equation (48); the resulting theory is commonly called the *dynamic approximation*. The importance of this step has been stressed repeatedly by Moriya (1985).

One may conveniently start by writing the free energy in the form

$$F(M,T) = \frac{1}{2}\alpha M^2 + \frac{1}{4}\beta M^4 + F_1(M,T) \tag{55}$$

and employ a formula for the free energy part $F_1(M,T)$ that is due to Dzyaloshinski and Kondratenko (1976). This is

$$F_1(M,T) = F_0(T) + \frac{1}{2N} \sum_{j,\mathbf{q}} \int_{-\infty}^{\infty} \frac{\mathrm{d}\omega}{2\pi} \times \mathrm{Im} \left\{ \ln \chi_j^{-1}(\mathbf{q},\omega) \right\} \coth\left(\frac{\omega}{2k_\mathrm{B}T} \right) \tag{56}$$

Here, $F_0(T)$ does not depend on the magnetization and is, therefore, at this point, of no concern. The inverse dynamic susceptibilities are approximated by

$$\chi_j^{-1}(\mathbf{q},\omega) = \chi_j^{-1}(\mathbf{q}) - \frac{i\omega}{\Gamma q} \tag{57}$$

where the real part, $\chi_j^{-1}(\mathbf{q})$, is assumed to be given by the results of the static approximation, equation (46) for $j = \parallel$ and equation (47) for $j = \perp$.

The complex part of the inverse, dynamic susceptibility is a widely used approximation for the weakly ferromagnetic metals, where long wavelength fluctuations of small frequencies predominate. It rests on a broad experimental and theoretical basis (Moriya, 1985; Lonzarich and Taillefer, 1985). The latter has most concisely been summarized by Lonzarich and Taillefer, who give the small ω and small q expansion of the dynamic Lindhard susceptibility as equation (57), valid for a single tight-binding band and omitting matrix elements. In this approximation, one can express the dissipation constant Γ in terms of band-structure quantities as

$$\Gamma = (4/\pi V)\mu_B^2 N_F E_F / k_F \tag{58}$$

where V is the volume of the primitive unit cell, N_F is the DOS at the effective Fermi energy E_F, k_F is the Fermi wave vector, and the magnetization is assumed to be small.

By taking next the second derivative of the free energy, equations (55) and (56) with respect to M (but neglecting derivatives of the fluctuations), one verifies that the uniform, static, longitudinal susceptibility is given by $\chi_\parallel(\mathbf{q} = 0)$, equation (46), provided the fluctuations are connected with the susceptibility through the fluctuation-dissipation theorem, equation (48). The transverse susceptibility, however, is slightly different from $\chi_\perp(\mathbf{q} = 0)$, equation (47). It is believed, though, that this is still a good approximation since numerically the two susceptibilities come out very nearly the same.

The remaining calculation is the evaluation of the fluctuation equation (48). With the preceding approximation for the dynamic susceptibility, the frequency integration can be carried out analytically, as was done by Lonzarich and Taillefer (1985), who refer to a paper by Ramakrishnan (1974), obtaining $\langle |m_{j\mathbf{q}}|^2 \rangle = k_B T \chi_j(\mathbf{q}) g(z)/N$ where $g(z) = 2z\,(\ln z - 1/2z - \psi(z))$, $\psi(z)$ is Euler's psi function and $z = \Gamma|\mathbf{q}|\chi_j^{-1}(\mathbf{q})/2\pi k_B T$. To a very good approximation, one can write $g(z) \simeq 1/(1 + 5.63602z)$, which finally gives

$$\sum_{\mathbf{q}} \langle |m_{j\mathbf{q}}|^2 \rangle = \frac{k_B T}{N} \sum_{\mathbf{q}} \chi_j(\mathbf{q}) - \frac{\xi\Gamma}{N} \sum_{\mathbf{q}} |\mathbf{q}| \times \left[1 + \frac{\xi\Gamma|\mathbf{q}|}{k_B T} \chi_j^{-1}(\mathbf{q}) \right]^{-1} \tag{59}$$

The constant appearing is $\xi = 0.897$. Note that, for $\Gamma = 0$, the results of the static approximation are obtained.

One could now argue that all important quantities are determined by the total energy and the band structure. However, the assumptions underlying equation (58) are heavily idealized, and so this relation can only be expected to give an order of magnitude estimate of the dissipation constant Γ, as we will see. In principle, the dynamic susceptibility can be easily formulated, but, in the appropriate integral equation, a kernel remains unknown (Antropov, Harmon and Smirnov, 1999). A desirable approach would be that of Savrasov (1998), who calculated the dynamical susceptibility *ab initio* but did not direct his attention to the problems addressed here. Similarly, the *ab initio* theory of Staunton *et al*. (2000) should be applied to ferromagnets.

Furthermore, even more serious, as it turns out, is a conceptual error made in the determination of the Landau coefficients α and β from the total energy. This point is exposed in detail in the following examples.

The determination of the exchange function $j(\mathbf{q})$, however, is seen to be quite reliable, thus turning out to be one of the strong points of the theory.

3.2 Weakly ferromagnetic metals: examples

3.2.1 An exploratory calculation for nickel

Although Ni is not understood to be a weakly ferromagnetic metal, we start with this case since the calculations are quickly performed, allowing the formalism to be exposed together with its strengths and weaknesses.

In Table 2, we collect some of the relevant data for nickel. The lattice constant used for the calculations is seen to be somewhat smaller than the experimental value, which is due to the well-known overbinding property of the LSDA. The calculated value of the magnetic moment, M_0, is also listed. Its being smaller than the experimental value is due to the missing orbital and spin-orbit coupling (SOC) contributions. By means of total energy calculations, the input coefficients α, $\beta = -\alpha/M_0^2$, and $j(\mathbf{q})$ are easily obtained and the basic equations (45)–(47) together with equation (49) as well as equations (50) and (51) are solved numerically, first in the static approximation. The Curie temperature given in equation (54) is evaluated and given in Table 2. With the knowledge of the exchange function $j(\mathbf{q})$, other approximations for the Curie temperature can be

Table 2. Calculated and experimental values for Ni: lattice constant, a, calculated spin fluctuation, T_c^{SF}, spherical model, T_c^{SP}, and mean field, T_c^{MF} Curie temperatures, and magnetic moment, M_0.

	a (Å)	T_c^{SF} (K)	T_c^{SP} (K)	T_c^{MF} (K)	M_0 (μ_B)
Calculated	3.468	322	537	643	0.598
Experimental	3.525		627		0.616

obtained. These are

$$k_B T_c^{SP} = \frac{2M_0^2}{3}\left[\frac{1}{N}\sum_{\mathbf{q}}\frac{1}{j(\mathbf{q})}\right]^{-1} \tag{60}$$

which are derived in Section 3.3.1 in the *spherical approximation*. This equation is also known as the *RPA expression*. The well-known *mean-field approximation* gives for the Curie temperature

$$k_B T_c^{MF} = \frac{2M_0^2}{3N}\sum_{\mathbf{q}} j(\mathbf{q}) \tag{61}$$

This is a convenient formula to express the average value of the exchange function $j(\mathbf{q})$. Results obtained in the spherical and mean-field approximations are also listed in Table 2 and are seen to approximate the measured Curie temperature much better than the spin-fluctuation value.

When, however, the basic equations are solved with the value of α obtained from the total energy, the phase transition to the paramagnetic state is found to be weakly of first order, giving a Curie temperature of about 370 K. Although the inverse susceptibility above the Curie point is calculated to be a Curie–Weiss law, its slope is much too large, giving a value for the number of carriers, q_c smaller than q_s, the saturation value at zero temperature.

In an attempt to analyze the situation, one first finds a condition for the transition to be of second order. This is $\alpha M_0^2/J_0 < 1$, where J_0 is the average of $j(\mathbf{q})$ defined by the sum in equation (61). This condition is not satisfied for the value of α used in the preceding text. Next one expresses the coefficient α by the total energy gained in the ferromagnetic state, which in Figure 2(a) is denoted by E_B; this is trivially from equation (52) $\alpha = -4E_B/M_0^2$. To continue, it is convenient to turn to the *dynamic approximation*, choosing a dissipation constant Γ such that the experimental Curie temperature is obtained, assuring, however, that the transition is of second order by using smaller values of α than required by the total energy value E_B. Thus, Figure 2(b) illustrates that the inverse susceptibility shows, indeed, Curie–Weiss behavior; however, its value agrees with the experimental data (also given in the figure) only for a vastly reduced E_B (or α). Can one justify this reduction?

The simple relation $\alpha = -4E_B/M_0^2$ shows that the coefficient α is defined with respect to the nonmagnetic ground state, since this is the offset for E_B. For Ni – or any other ferromagnet – the nonmagnetic ground state, however, is a computational *fiction*. Another reference state should be used, one that is magnetic with no long-range order. In Chapter 7 of his book, Moriya (1985) identified the reference state qualitatively by means of the Anderson condition,

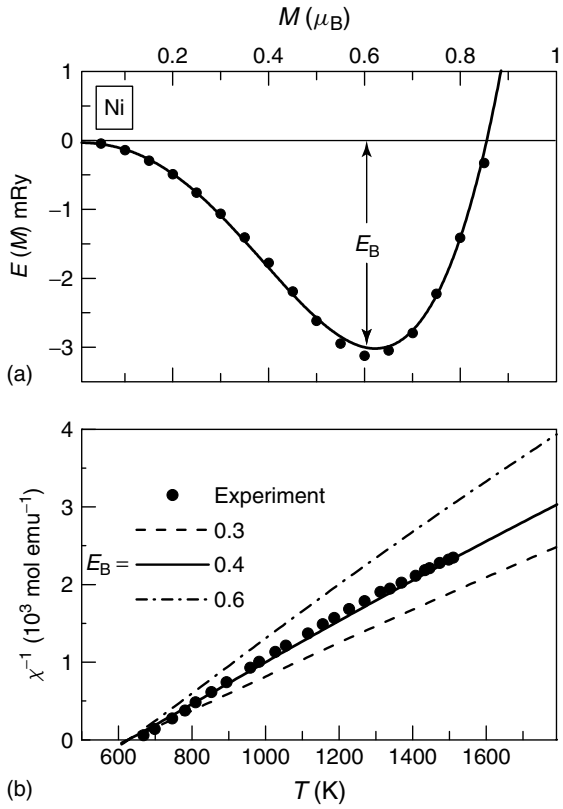

Figure 2. (a) Total energy of Ni as a function of the magnetic moment, M, obtained by a constrained-moment calculation (dots), counted from the nonmagnetic state. Solid line is the fit, equation (52). Label E_B is used as parameter in part (b) of this figure. Inverse susceptibility for Ni above the Curie point. Experimental data (circles) from Shimizu (1981); data calculated in the dynamic approximation are shown for different values of the parameter E_B in mRy.

which marks the appearance of randomly oriented local moments in metals. We will come back to this problem in Section 3.3.

It is clear now that the Landau coefficients must be renormalized. One is tempted therefore to abandon the LSDA in favor of a many-body treatment since there is no formal answer within the theory presented. It is still worthwhile to continue anyway by observing that the appearance (or disappearance) of local moments can clearly be seen in the enhancement of the *nonuniform* susceptibility, $\chi(\mathbf{q})$. The susceptibility enhancement was discussed, for instance, by Sandratskii and Kübler (1992) (see also Kübler, 2000, Ch.4), who obtained $\chi(\mathbf{q})$ by using spiral-moment arrangements in LSDA calculations and demonstrated that it peaks strongly at values of $\mathbf{q}$, where the magnetic moment becomes small. The calculations have been repeated here for Ni with high precision and the results are shown in Figure 3 for $\mathbf{q}$ along the (1,0,0)-direction. Since, locally, in reciprocal space, the

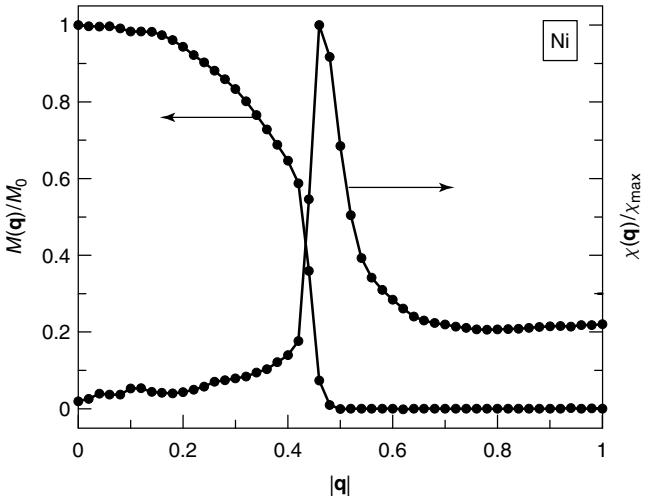

Figure 3. Relative magnetic moment of Ni, $M(\mathbf{q})/M_0$ and relative nonuniform susceptibility $\chi(\mathbf{q})/\chi_{\max}$, both as a function of the wave vector $\mathbf{q} = (q, 0, 0)$ in units of $2\pi/a$. A value of $\chi_{\max} = 149\mu_B^2/Ry = 0.35 \cdot 10^{-3}$emu mol^{-1} is obtained along this direction in the Brillouin zone.

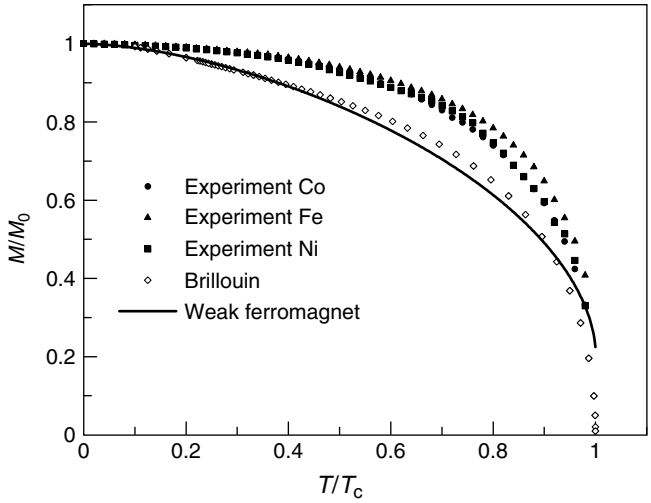

Figure 4. Temperature dependence of the magnetization of Ni in reduced units from theory of weak ferromagnetism.

total energy can be expanded as

$$E(\mathbf{q}, M) = E(\mathbf{q}, M_0(\mathbf{q})) + \frac{(M - M_0(\mathbf{q}))^2}{2\chi(\mathbf{q})} \qquad (62)$$

one sees that the total energy is very flat as a function of M in those regions of the Brillouin zone where the susceptibility becomes large. Proceeding empirically, we assume that it is this value of the total energy that determines the coefficient α and consequently E_B. We are thus led to using $\alpha = -(2\chi_{\max})^{-1}$, which gives $E_B = 0.4$ mRy. Figure 2(b) shows that this leads to very good agreement with the experimental Curie–Weiss susceptibility. We take this agreement as an indication for a useful procedure to apply to all weakly ferromagnetic materials, which are described in the sequel of the chapter.

In Figure 4, we show the magnetization as a function of the temperature for Ni in reduced units. For comparison, the experimental data for Fe, Co, and Ni are also shown together with the well-known Brillouin function valid in the mean-field approximation. One can see that especially at low temperatures the calculated curve does not agree with the experimental values. This is due to an improper treatment of the magnon excitations. As will be explained later, for the case of iron, the low-temperature phase transition is better described by a local moment approximation.

We complete this subsection by giving the value of the dissipation constant that leads to the experimental Curie temperature shown in Figure 2(b); this is $\Gamma = 0.641\,\mu\text{eV}\text{Å}^2$. Although, differing from equation (57), the experimental wave-vector dependence proportional to q^2 was used in the calculations, we cannot expect agreement with the measured value of Γ, which is 3 orders of magnitude larger (Steinsvoll, Majkrzak, Shirane and Wicksted, 1984). This should not be surprising in view of the simplifications made in the modeling of the imaginary part of the susceptibility.

3.2.2 The weakly ferromagnetic compound $ZrZn_2$

$ZrZn_2$, like the compounds Ni_3Al, MnSi, and Sc_3In, belongs to the class of weakly ferromagnetic materials with small magnetic moments (of the order of a tenth of a μ_B) and small Curie temperatures (of the order of 5–40 K). Because of its large effective moment in the paramagnetic phase, it is found on the far left in Figure 1. It was discovered by Matthias and Bozort (1958) to be ferromagnetic. The unit cell of the cubic C15 Laves phase of $ZrZn_2$ contains six atoms, the two Zr atoms occupying a diamond lattice and the four Zn atoms forming tetrahedra in the interstices. A number of generalizations need be done to apply the theory given in Section 3.1 to a crystal structure possessing a basis, as $ZrZn_2$ does. Thus, equation (36) is changed to

$$\mathbf{M}_\tau(\mathbf{R}) = M_\tau \mathbf{e}_z + \sum_{n,j,\mathbf{q}} m_{nj\mathbf{q}} C_{n\tau} \exp(i\mathbf{q}\cdot\mathbf{R})\mathbf{e}_j \qquad (63)$$

where τ labels the basis and the coefficient $C_{n\tau}$ allows one to treat normal modes, which are numbered by n. All other symbols are defined as in equation (36).

Beginning with the *static approximation*, the Curie temperature, the magnetic order parameter, and the high-temperature susceptibility are calculated by evaluating the basic equations (45)–(47) together with equation (49) as

well as equations (50) and (51) as a function of the pressure (volume) (Kübler, 2004). The two equivalent magnetic Zr atoms lead to two normal modes and two exchange functions $j_{11}(\mathbf{q})$ and $j_{12}(\mathbf{q})$, which require a number of simple modifications in the basic equations. Thus, the total energy change, equation (53), is replaced by

$$\Delta E = 2M_0^2 j_{11}(\mathbf{q}) + 2M_0^2 j_{12}(\mathbf{q}) \cos(\mathbf{q} \cdot \boldsymbol{\tau}) \qquad (64)$$

where $\boldsymbol{\tau} = (\frac{1}{4}, \frac{1}{4}, \frac{1}{4})$ in units of the lattice constant is the basis vector for the second magnetic atom in $ZrZn_2$, assuming the first at the origin. The quantity M_0 is the Zr moment in the ground state. Since, by virtue of equation (44), the exchange functions are periodic with the periodicity of the reciprocal lattice, but $\cos(\mathbf{k} \cdot \tau)$ is not, we may determine $j_{11}(\mathbf{q})$ and $j_{12}(\mathbf{q})$ from equation (64) with a choice of a reciprocal lattice vector, $\mathbf{K} = (0, 0, 2)\ 2\pi/a$, where a is the lattice constant. Thus, replacing $\mathbf{q}$ by $\mathbf{q} + \mathbf{K}$, we get an equation to solve for $j_{11}(\mathbf{q})$, finally eliminating the cosine by choosing all phases to be zero to obtain $j_{12}(\mathbf{q})$.

The variation described in Section 3.1 now leads via a standard normal-mode analysis to two inverse static susceptibilities, $\chi^{-1}_{\parallel,\pm}(\mathbf{q})$ and $\chi^{-1}_{\perp,\pm}(\mathbf{q})$, which replace the equations (46)–(47) by changing the single exchange functions there to $j_{11}(\mathbf{q}) \pm j_{12}(\mathbf{q})$. The Curie temperature is then

$$k_B T_c = \frac{4}{5} M_0^2 \cdot \left(\frac{1}{N} \sum_{\mathbf{q}} \frac{1}{j_{11}(\mathbf{q}) + j_{12}(\mathbf{q})} + \frac{1}{N} \sum_{\mathbf{q}} \frac{1}{j_{11}(\mathbf{q}) - j_{12}(\mathbf{q})} \right)^{-1} \qquad (65)$$

instead of equation (60), provided the phase transition is of second order.

The total energy calculations to obtain the exchange functions should be done by constraining the magnetic moments to the ground-state values. Much more efficient, however, is to use the force theorem, that is, by calculating the total energy differences from the band energies, as described and justified in Section 2.2. This was done here, even though an error is to be expected, as pointed out by Bruno (2003). By a somewhat lengthy numerical computation, the error was estimated and found to amount to roughly a factor of 1.7.

Some pertinent experimental and theoretical data for $ZrZn_2$ are collected in Table 3. As in the case of Ni, the coefficient α is to be obtained from the maximum value of the enhanced, nonuniform susceptibility, $\alpha = -\chi^{-1}_{\mathrm{Max}}/2$. We stress that this renormalization is not derived theoretically, but is motivated empirically through the appearance of the magnetic moment in the metal (see also Section 3.2.1). Figure 5 shows that the appearance (or disappearance) of the moment is accompanied by a large enhancement of the susceptibility, which is shown for two different volumes. With this choice of α, the phase transition is calculated to be of second order. The results for the Curie temperature are graphed in Figure 6, where the full pressure range used for the calculations is shown. The measured value of T_c at ambient pressure is 28.1 K where in the calculations – due to the well-known LSDA-overbinding – the pressure is found to be negative. Here, the calculated value of T_c is $T_c = 30$ K. Although it agrees well with the experimental value, we discard it in favor of the calculation at the theoretical equilibrium at $P = 0$: $T_c = 8$ K obtained using the force theorem; this value is underestimated and could be as large as 14 K in a constrained total energy calculation of the type suggested by Grotheer, Ederer and Fähnle (2001) and Singer, Fähnle and Bihlmayer (2005). In the spherical approximation, the Curie temperature

Table 3. Calculated and experimental values for $ZrZn_2$: lattice constant, a, calculated spin fluctuation, T_c^{SF}, spherical model, T_c^{SP} Curie temperatures, magnetic moment, M_0, and Curie–Weiss law ratio q_c/q_s. Values in parentheses are estimates derived from constrained-moment total energy calculations.

Calculated	7.284	8.0 (14)	13.3 (23)	0.20	2.8
Experimental	7.393	28.1		0.17	4.1

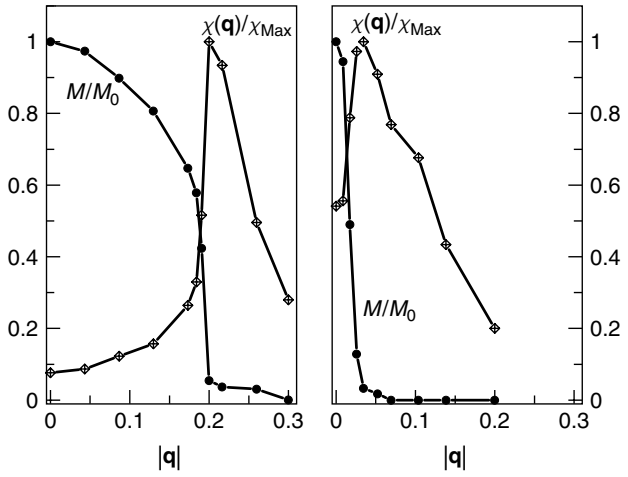

Figure 5. Reduced magnetic moment, M/M_0, and reduced susceptibility, $\chi(\mathbf{q})/\chi_{\mathrm{Max}}$, as a function of the wave vector, $\mathbf{q}$, along the (1,1,1)-direction. Left panel calculated at the experimental lattice constant, $a = 7.393$ Å, right panel calculated for $a = 7.217$ Å, corresponding to the last nonvanishing magnetization before the transition. The values of M_0 and χ_{Max} are $M_0 = 0.36\ \mu_B$ per formula unit and $\chi_{\mathrm{Max}} = 3.111 \cdot 10^{-3}$ emu mol^{-1} on the left; on the right they are $M_0 = 0.079\ \mu_B$ per formula unit and $\chi_{\mathrm{Max}} = 1.652 \cdot 10^{-3}$ emu mol^{-1}.

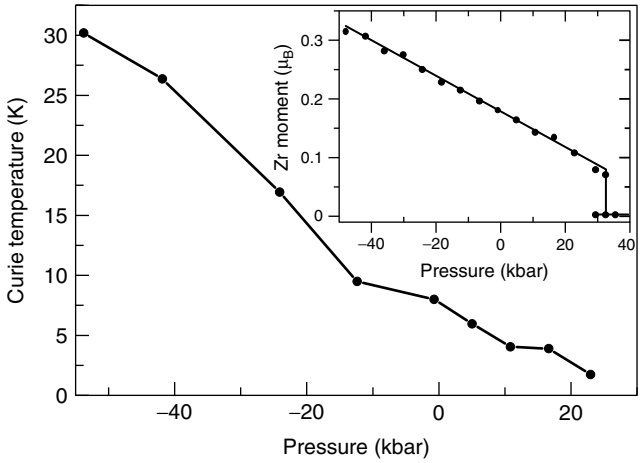

Figure 6. Curie temperature of $ZrZn_2$ as function of the pressure calculated with equation (65) using the force theorem to calculate the exchange functions $j_{11}(\mathbf{q})$ and $j_{12}(\mathbf{q})$. Inset: Magnetic moment of Zr as function of the pressure.

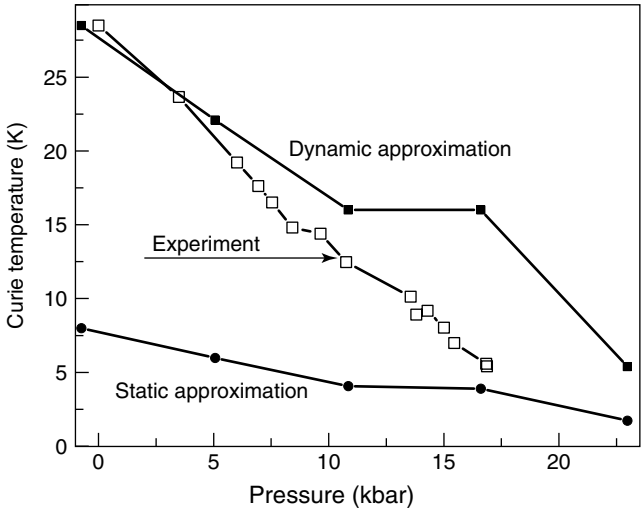

Figure 7. Curie temperature of $ZrZn_2$ as function of the pressure calculated with equation (65) (static approximation with the force theorem) and using finite dissipation constant (see text on dynamic approximation). The experimental data shown are from Pfleiderer *et al*. (2001).

is calculated to be of the order of 13.3–23 K. The estimated values are given in parentheses in Table 3.

Turning now to the *dynamic approximation*, we start the calculation with an experimental value for the dissipation constant, Γ, which was obtained by Bernhoeft, Law, Lonzarich and Paul (1988) by neutron-scattering studies. Above the Curie temperature, this value is given as $\Gamma = 1.8\,\mu\text{eV\AA}$. Inserting this value into our equations, however, we overestimate the Curie temperature by a factor of 2. In fact, the experimental value of the Curie temperature at ambient pressure is obtained by using a value of $\Gamma = 0.44\,\mu\text{eV\AA}$.

We may relate these values to the simple approximation given in equation (58). Taking the calculated value for the density of states at the Fermi energy to be about 40 states per Ry and k_F of the order of $2\pi/a$ (Kübler, 2004), the experimental value of Γ suggests a value of the Fermi energy of about 1.6 eV, whereas the theoretical value would require 0.4 eV, both values being within range of the band structure of $ZrZn_2$. But, a rigorous value of Γ cannot be extracted from equation (58).

In an attempt to use the value of $\Gamma = 0.44\,\mu\text{eV\AA}$ for higher pressures revealed that it must be reduced further for very low temperatures, thus obtaining the pressure dependence shown in Figure 7 (labelled dynamic approximation). The results of the static approximation and the experimental results of Pfleiderer *et al*. (2001) are also shown.

In Figure 8(a), the calculated relative magnetization as a function of the temperature is shown, which is compared with experimental data from Uhlarz, Pfleiderer and Hayden (2004). The agreement is very good. It depends sensitively on the value of the dissipation constant Γ, concerning not only the Curie temperature but also the curvature of the magnetization; smaller values of Γ, in particular the static approximation ($\Gamma = 0$), lead to a much flatter $M(T)$. It should be noticed that the disagreement seen in the calculated magnetization for Ni at low temperatures is not present in this case.

The calculated susceptibility in the paramagnetic temperature range is shown in Figure 8(b). Being very nearly linear, this shows a nice Curie–Weiss law. Its slope depends only very weakly on the dissipation constant, but is largely determined by the value of the coefficient α. The empirical renormalization leads to the value of q_c/q_s given in Table 3, where it is also compared with an experimental estimate of Uhlarz, Pfleiderer and Hayden (2004).

In this context, it is of interest to point out the work of Takahashi (1986), who formulated a theory for the Rhodes–Wohlfarth plot. His theory, however, relies on the zero-point spin fluctuations, which we ignored, and the assumption of a conserved local spin-fluctuation amplitude. Although zero-point spin fluctuations may play a certain role, we cannot make definite *ab initio* estimates because a cutoff frequency is needed.

3.2.3 The weakly ferromagnetic compound Ni_3Al

Another, thoroughly studied itinerant-electron weak ferromagnet is Ni_3Al. Early experimental work is that by De Boer, Schinkel, Biesterbos and Proost (1969), followed by Kortekaas and Franse (1976), Buis, Franse and Brommer (1981), and others. Bernhoeft, Lonzarich, Mitchell and

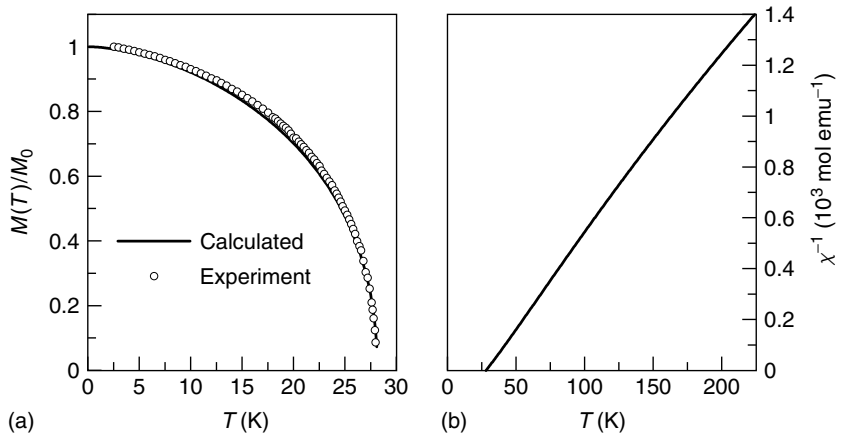

Figure 8. (a) Reduced magnetic moment, M/M_0, as a function of T for $ZrZn_2$. The experimental data (circles) were kindly supplied by Ch. Pfleiderer (Uhlarz, Pfleiderer and Hayden, 2004) (b) Calculated Curie–Weiss law.

Paul (1983) did neutron-scattering studies. In the theoretical work of Lonzarich and Taillefer (1985) and Lonzarich (1986), Ni_3Al was used as the prime example.

Ni_3Al is simple-cubic and has the Cu_3Au structure, which possesses a basis of three atoms. Thus, three normal modes are taken into account in equation (63), of which two are found to be degenerate. One obtains the three inverse static susceptibilities from $\chi^{-1}_{\parallel,\pm}(\mathbf{q})$ and $\chi^{-1}_{\perp,\pm}(\mathbf{q})$ by using that labelled with the minus sign twice. This is defined by changing the single exchange functions in the equations (46)–(47) by the combination $j_{11}(\mathbf{q}) - j_{12}(\mathbf{q})$, whereas the susceptibility labeled with the plus sign is defined by the combination $j_{11}(\mathbf{q}) + 2j_{12}(\mathbf{q})$. The Curie temperature is then given by

$$k_B T_c = \frac{6}{5} M_0^2 \cdot \left(\frac{1}{N} \sum_{\mathbf{q}} \frac{2}{j_{11}(\mathbf{q}) - j_{12}(\mathbf{q})} + \frac{1}{N} \sum_{\mathbf{q}} \frac{1}{j_{11}(\mathbf{q}) + 2j_{12}(\mathbf{q})} \right)^{-1} \tag{66}$$

provided the transition is of second order.

The exchange functions are obtained from the total energy of a spin spiral given in the case of Ni_3Al by

$$\Delta E = M_0^2 [3j_{11}(\mathbf{q}) + 2j_{12}(\mathbf{q}) \sum_{i=1}^{3} \cos(\mathbf{q} \cdot \boldsymbol{\tau}_i)] \tag{67}$$

The quantity M_0 is the Ni moment in the ground state and $\boldsymbol{\tau}_i$ are the basis vectors. Since the exchange functions are periodic with the periodicity of the reciprocal lattice, they are obtained from equation (67) with a choice of three reciprocal lattice vectors, $\mathbf{K}_1 = (1, 0, 0)$, $\mathbf{K}_2 = (0, 1, 0)$, and $\mathbf{K}_3 = (0, 0, 1)$ in units of $2\pi/a$, where a is the lattice constant. Thus, replacing $\mathbf{q}$ by $\mathbf{q} + \mathbf{K}_j$ $j = 1, 2, 3$, we get equations to solve for $j_{11}(\mathbf{q})$, finally eliminating the cosine by choosing all phases to be zero to determine $j_{12}(\mathbf{q})$.

The static approximation gives a second-order phase transition if the coefficient α is obtained from the maximum of the nonuniform susceptibility as described before. Its $\mathbf{q}$-dependence is very similar to that shown for $ZrZn_2$ in Figure 5; its maximum value of $\chi_{\mathrm{Max}} \simeq 0.88 \cdot 10^{-3}\,\mathrm{emu\,mol^{-1}}$ is smaller, however, and occurs at $\mathbf{q} \simeq (0.1, 0, 0)2\pi/a$.

The total energy differences needed to evaluate the exchange functions are obtained by both the force theorem and constrained-moment calculations. Together with other pertinent experimental and theoretical data, the result of the latter is given in Table 4, where it is denoted by T_c^{SF}. As expected, it is larger than the estimate from the force theorem, which leads to $T_c = 12.7$ K.

To obtain the experimental Curie temperature in the *dynamic approximation*, the dissipation constant is chosen as $\Gamma = 0.15\,\mu\mathrm{eV\AA}$. The calculated temperature dependence of the magnetization is shown in Figure 9(a) and is seen to agree nearly perfectly with the experimental data measured by De Boer, Schinkel, Biesterbos and Proost (1969). The value of Γ is, however, considerably smaller than the neutron-scattering value of $\Gamma = 3.3\,\mu\mathrm{eV\AA}$ measured by Bernhoeft, Lonzarich,

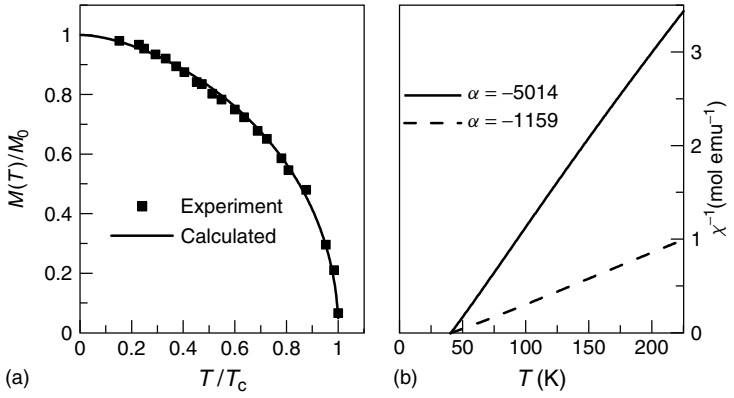

Figure 9. (a) Reduced magnetic moment, $M(T)/M_0$, as a function of the reduced temperature, T/T_c of Ni_3Al. The experimental data (circles) were taken from the paper by Lonzarich (1986) who used data by De Boer, Schinkel, Biesterbos and Proost (1969). (b) Calculated Curie–Weiss law using $\alpha = -5014$ determined with susceptibility maximum, $\chi_{\text{Max}} = 0.88 \cdot 10^{-3}$ emu mol^{-1}, and $\alpha = -1159$. (Reproduced from G.G. Lonzarich and L. Taillefer: 'Effect of spin fluctuations on the magnetic equation of state of ferromagnetic or nearly ferromagnetic metals', *Journal of Physics C: Solid State Physics B* **18** (1985), 4339.)

Mitchell and Paul (1983). Finally, the calculated inverse Curie–Weiss susceptibility shown in Figure 9(b) (solid line with $\alpha = -5014$ in Gaussian units) gives an effective magnetic moment at $T > T_c$ larger than in the ground state, as it should, but the calculated ratio of q_c/q_s given in Table 4 is too small. Possible reasons for this discrepancy may be our empirical renormalization scheme and (or) Stoner excitations, which could decrease the coefficient α considerably. To illustrate the dependence on α, we include in Figure 9(b) (dashed line) the results for a value of $\alpha = -1159$, which was found by Lonzarich and Taillefer (1985) to describe the experimental data. This value gives for the ratio q_c/q_s the value $q_c/q_s = 5$.

3.2.4 The weakly ferromagnetic compound MnSi

As the final example, we discuss the compound MnSi. It is considered to be a weak itinerant-electron ferromagnet (Moriya, 1985; Lonzarich and Taillefer, 1985), although in zero magnetic field it possesses a helical ground state with a very long period (170 Å) (Ishikawa, Tajima, Bloch and Roth, 1976). In recent experimental work (Pfleiderer, McMullan, Julian and Lonzarich, 1997; Pfleiderer *et al.*, 2004), MnSi was studied under hydrostatic pressure, P. At $P = 14.6$ kbar, a phase transition to a state identified as a non-Fermi liquid was found. The neutron diffraction studies of Pfleiderer *et al.* (2004) reveal that long-range magnetic order is suppressed at $P_c = 14.6$ kbar, but sizable quasistatic magnetic moments survive far into the non-Fermi liquid state. It is the helical modulation along a $\mathbf{Q}$ vector in the (111)-direction that is crucial for the experiments, since the corresponding Bragg scattering at $|\mathbf{Q}| = 0.037$ Å^{-1} is easily tracked as a function of the pressure. The findings are a challenge for the theory presented in this chapter.

MnSi is simple-cubic in the B-20 crystal structure possessing four Mn and four Si atoms in the unit cell at the positions (u, u, u), $(\frac{1}{2} + u, \frac{1}{2} - u, -u)$, $(-u, \frac{1}{2} + u, \frac{1}{2} - u)$, and $(\frac{1}{2} - u, -u, \frac{1}{2} + u)$, where for Mn $u = 0.137$ and for Si $u = 0.845$. This structural information is important because the symmetry of the crystal structure and the type of magnetic order are intimately connected (Sandratskii, 1998). The reasoning is as follows.

Beginning an electronic structure calculation with the Hamiltonian given in equation (19) for a spin spiral of a given $\mathbf{q}$, we find for MnSi the total-energy minimum at $\mathbf{q} = 0$. Indeed, from the work of Bak and Jensen (1980), Nakanishi, Yanase, Hasegawa and Kataoka (1980), and Kataoka, Nakanishi, Yanase and Kanamori (1984), it is known that the helical ground state of MnSi has its origin in the SOC, which is neglected in the scalar relativistic Hamiltonian. It is not difficult to add an appropriate SOC Hamiltonian to equation (19) (Sandratskii, 1998) but, since SOC does not commute with the generalized translations introduced in Section 2, a spin spiral or helical structure is unstable. We will immediately come back to this apparent contradiction, but first discuss SOC in MnSi in the *absence* of a helical state. In this case, self-consistent calculations lead to a ferromagnet with slightly canted moments. This type of magnetic order is a consequence of the symmetry of the lattice in combination with the SOC. The latter requires the application of a spin–space group (Sandratskii, 1998), which in this case is D_2. The elements of this group permute the Mn atoms together with their magnetic moments. The canting angles calculated are rather small, being at the theoretical equilibrium lattice constant $\theta_1 \simeq 0.3^\circ$ and $\phi_1 \simeq 120^\circ$ (θ_j and ϕ_j for $j = 1 \ldots 4$ such that a regular rectangle is formed). Under pressure, the canting increases slightly. The calculations reveal, furthermore, a second state with a small

Table 5. Calculated and experimental values for MnSi: lattice constant, a, calculated spin-fluctuation Curie temperature, T_c^{SF}, magnetic moment, M_0, and compressibility, κ.

	a (Å)	T_c^{SF} (K)	M_0 (μ_B)	κ (10^{-4} kbar^{-1})
Calculated	4.483	42	0.55	4.7
Experimental	4.56	30	0.4	6

magnetic moment and slightly higher total energy (fractions of a mRy per unit cell), which possesses canting angles with $\theta_1 \simeq 1.0^\circ$ and $\phi_1 \simeq 143^\circ$.

Some pertinent calculated and experimental data for MnSi are collected in Table 5. The calculated lattice constant is as usual smaller than the experimental one, but is larger than that determined by Yamada and Terao (1999), presumably because they ignored SOC. The calculated magnetic moment is somewhat larger than the experimental one, but is of the same order as that determined by Yamada and Terao at our lattice constant; the compressibility is in moderate agreement with the experiment.

Before we comment on the calculated value of the Curie temperature, we return to the apparent contradiction posed by the observed helical spin structure.

The physics of the observed helical structure is different from that discussed in Section 2. In fact, it was shown (Bak and Jensen, 1980; Nakanishi, Yanase, Hasegawa and Kataoka, 1980; Kataoka, Nakanishi, Yanase and Kanamori, 1984) to come about through the Dzyaloshinski–Moriya exchange interaction (DMI) (Dzyaloshinsky, 1958; Moriya, 1960), which is a consequence of the SOC. It is of the form $\mathbf{D}(\mathbf{S_1} \times \mathbf{S_2})$ and is finite if the crystal lacks an inversion center, as in the case of MnSi. The simultaneous rotation of all magnetic moments about the direction of the 'exchange vector' $\mathbf{D}$ does not change the energy of the system. This property of the DMI allows the symmetry, with respect to the generalized translations, to be maintained, which is a necessary condition for the stability of helical structures (Sandratskii and Lander, 2001). The work of Bak and Jensen (1980), Nakanishi, Yanase, Hasegawa and Kataoka (1980), and Kataoka, Nakanishi, Yanase and Kanamori (1984) reveals that the DMI breaks the symmetry of the wave-vector-dependent susceptibility with respect to the reversal of $\mathbf{q}$, as a consequence of which the total energy $E(\mathbf{q})$ is no longer invariant under a reversal of $\mathbf{q}$, leading to a small shift of the minimum of the total energy to an incommensurate $\mathbf{Q}$. Presently, this cannot be simulated with an *ab initio* total energy calculation.

It should be clear now that, strictly speaking, one cannot use spin spirals to determine the exchange function of MnSi and whence the Curie temperature. However, assuming that SOC has only a small effect on the electronic structure, leaving aside its subtle influence on the magnetic order, we may use the converged potentials to calculate the band structure without SOC and subsequently determine the total energy for spin spirals by employing the force theorem. To do this, one notes that the four magnetic atoms in MnSi require four normal modes in equation (63) and the total energy difference of a spin spiral becomes

$$\Delta E = M_0^2[4j_{11}(\mathbf{q}) + 2j_{12}(\mathbf{q}) \sum_{i=1}^{6} \cos(\mathbf{q} \cdot \boldsymbol{\tau}_i)] \tag{68}$$

where M_0 is the Mn moment in the ground state and $\boldsymbol{\tau}_i$ are the six basis vector differences describing the regular tetrahedron characteristic for the crystal structure of MnSi. To obtain the two exchange functions, one calculates the set of reciprocal lattice vectors, $\{\mathbf{K}_\kappa\}$ for which

$$\sum_{\kappa=1}^{8} \sum_{i=1}^{6} \cos[(\mathbf{q} + \mathbf{K}_\kappa) \cdot \boldsymbol{\tau}_i] = 0 \tag{69}$$

The Curie temperature in the static approximation is then given by

$$k_B T_c = \frac{12}{5} M_0^2 \cdot \left(\frac{1}{N} \sum_{\mathbf{q}} \frac{3}{j_{11}(\mathbf{q}) - j_{12}(\mathbf{q})} + \frac{1}{N} \sum_{\mathbf{q}} \frac{1}{j_{11}(\mathbf{q}) + 3j_{12}(\mathbf{q})} \right)^{-1} \tag{70}$$

where we used the appropriate combinations of the exchange functions that describe the normal modes.

The result of the numerical calculations is given in Table 5 as T_c^{SF}. In contrast to $ZrZn_2$ and Ni_3Al, it is larger than the experimental value and the overestimate increases if the dynamic approximation is applied. Furthermore, it is found that the pressure dependence of the calculated T_c^{SF} is much too weak being near ambient pressure $dT_c/dP \simeq -0.3\,\mathrm{K\,kbar^{-1}}$, which is to be compared with the experimental value of $dT_c/dP \simeq -1.6\,\mathrm{K\,kbar^{-1}}$ (Pfleiderer *et al.*, 2004). Since the calculated compressibility is in fair agreement with the measured value of Pfleiderer *et al.* (2004) (see Table 5), we conclude that the subtle properties of the magnetic structure are ill-described by the naive application of the spin spiral configurations.

3.3 Toward a unified theory

It is desirable to have a theory that covers the whole range of cases, from weak ferromagnets to the local moment limit, ideally all the cases displayed by the Rhodes–Wohlfarth

plot, Figure 1. Such a theory was proposed by Moriya and Takahashi (1978a,b) (Moriya, 1985, Chapters 7–8) who used the Stratonovich–Hubbard functional integral method. One can construct a simple form for the functional that does not contain the original model parameters, thus representing all the spin configurations including intermediate cases in an approximate way. In a notation somewhat different from that of Moriya and Takahashi, the formalism may be described as follows.

A functional $\Psi = \Psi(M, M_{\mathrm{L}}, \mathbf{M_q})$ is constructed that depends on the magnetization, M, the length of the moments, M_{L}, and the fluctuation vector $\mathbf{M_q} = (m_{x\mathbf{q}}, m_{y\mathbf{q}}, m_{z\mathbf{q}})$. The functional integral to be evaluated is then

$$\exp(-F/k_{\mathrm{B}}T) \propto \int \mathrm{d}M_{\mathrm{L}}^2 \int \prod_{\mathbf{q}} \mathrm{d}\mathbf{M_q} \times \exp[-\Psi(M, M_{\mathrm{L}}, \mathbf{M_q})/k_{\mathrm{B}}T] \tag{71}$$

which supplies the free energy, F. An important approximation is now to use Lagrange multipliers, λ_α, to enforce all lengths of the magnetic moments to be near a most probable length, thus writing for the functional

$$\Psi = \sum_{\mathbf{q}} j(M_{\mathrm{L}}^2, \mathbf{q})|\mathbf{M_q}|^2 + E(M, M_{\mathrm{L}}^2) - \sum_{\alpha} \lambda_\alpha \left(M_{\alpha\mathrm{L}}^2 + M^2 - \sum_{\mathbf{q}} |m_{\alpha\mathbf{q}}|^2 \right) \tag{72}$$

Here $j(M_{\mathrm{L}}^2, \mathbf{q})$ is the exchange interaction that may be determined with the methods described in Section 2 and is defined such that $j(M_{\mathrm{L}}^2, \mathbf{q} = 0) = 0$. $E(M, M_{\mathrm{L}}^2)$ is the energy of the configuration having the magnetization M and the local magnetic moment M_{L}. The integral over $\mathbf{M_q}$ can now be carried out easily. But, we single out the $\mathbf{q} = 0$ component $\mathbf{M_{q=0}} = (0, 0, m_{z0}) = (0, 0, M)$, which is identified as the macroscopic magnetization. The result is

$$\exp(-F/k_{\mathrm{B}}T) \propto \int \mathrm{d}M_{\mathrm{L}}^2 \int \mathrm{d}M \times \exp\left\{ -\frac{[E(M, M_{\mathrm{L}}^2) - \sum_\alpha \lambda_\alpha M_{\alpha\mathrm{L}}^2]}{k_{\mathrm{B}}T} - \frac{1}{2} \sum_{\alpha,\mathbf{q}} \ln \frac{\lambda_\alpha + j(M_{\mathrm{L}}^2, \mathbf{q})}{\pi k_{\mathrm{B}}T} \right\} \tag{73}$$

Next, differentiating with respect to λ_α, we get for the length, $M_{\mathrm{L}}^2 = \sum_{\alpha=1}^{3} M_{\alpha\mathrm{L}}^2$,

$$M_{\mathrm{L}}^2 = \frac{k_{\mathrm{B}}T}{N} \sum_{\alpha} \sum_{\mathbf{q}} \chi_\alpha(\mathbf{q}) \tag{74}$$

where

$$\chi_\alpha(\mathbf{q}) = \frac{1}{[2\lambda_\alpha + 2j(M_{\mathrm{L}}^2, \mathbf{q})]} \tag{75}$$

The saddle-point condition for $M_{\alpha\mathrm{L}}^2$ gives another equation by taking the derivative with respect to $M_{\alpha\mathrm{L}}^2$. This gives

$$\lambda_\alpha = \frac{\partial E(M, M_{\mathrm{L}}^2)}{\partial M_{\alpha\mathrm{L}}^2} + \frac{k_{\mathrm{B}}T}{N} \sum_{\mathbf{q}} \chi_\alpha(\mathbf{q}) \frac{\partial j(M_{\mathrm{L}}^2, \mathbf{q})}{\partial M_{\alpha\mathrm{L}}^2} \tag{76}$$

Here the inverse susceptibility is identified with the fluctuation-dissipation theorem in the static approximation. If the magnetization is finite, that is, below the Curie temperature, the integration over M indicated in equation (73) must be carried out. Treating this also with a saddle-point integration, we obtain the condition

$$\frac{\partial E(M, M_{\mathrm{L}}^2)}{\partial M} + \frac{k_{\mathrm{B}}T}{N} \sum_{\alpha} \sum_{\mathbf{q}} \chi_\alpha(\mathbf{q}) \frac{\partial j(M_{\mathrm{L}}^2, \mathbf{q})}{\partial M} = 0 \tag{77}$$

To determine the local magnetic moment, the magnetization and the susceptibility, and thus the Curie temperature, the four equations (74)–(77) must be solved simultaneously.

Unfortunately, this formalism does not provide a new method to determine the energy functional $E(M, M_{\mathrm{L}}^2)$. In the work referred to by Moriya (1985), an approximation to the grand potential defined in equation (12) is employed. Indeed, one can extract the appropriate terms for $E(M, M_{\mathrm{L}}^2)$ from equation (42) and find that the preceding formalism leads exactly to the theory described in Section 3.1 in the *static approximation*, provided the derivatives $\partial j(M_{\mathrm{L}}^2, \mathbf{q})/\partial M_{\alpha\mathrm{L}}^2$ and $\partial j(M_{\mathrm{L}}^2, \mathbf{q})/\partial M$ are neglected in equations (76) and (77). This again implies the need to renormalize the coefficients in equation (42) if one attempts to calculate them in the LSDA. One can construct expansions of order higher than that given in equation (42), which involve the magnetization and the fluctuations, the latter – it must be emphasized – appearing as Gaussian averages. An example of this can be found in the seminal review article by Shimizu (1981), who gives an expansion up to eighth order in M. Actual numerical experiments with expansions of varying order show, however, that only very little is gained in accuracy by high-order expansions compared to the simpler low-order cases. In Chapter 8 of his book, Moriya (1985), correctly points out that the preceding equations are more general than any expansions. They are also useful for explaining physical trends; it must be emphasized, however, that powerful *ab initio* algorithms still have to be developed. For this, a promising approach using a spin-cluster expansion appears to be that recently proposed by Drautz and Fähnle (2004).

The unified approach sketched in the preceding text can still be profitably used for a simple demonstration

of a formula for the Curie temperature in the spherical approximation. Usually, the resulting formula is known as the *RPA formula*, which is derived for localized-moment systems by Green's function methods (see Tahir-Keli and ter Haar, 1962a,b; Tahir-Keli and Jarrett, 1964; Tyablikov, 1969; Wagner, 1972). Furthermore, the unified approach sheds light on bcc Fe above the Curie temperature and provides means to interpolate between the intermediate cases in the Rhodes–Wohlfarth plot. While the interpolation is quite empirical and is not pursued here any further (see Moriya, 1985, Chapter 7), it is worthwhile to use the unified approach for the 'nearly localized' case of bcc Fe at and above the Curie temperature.

3.3.1 The spherical approximation and bcc iron

In the paramagnetic region, that is, above the Curie temperature, $T > T_c$, the equations (74)–(76) simplify because of isotropy and become

$$M_L^2 = \frac{3k_B T}{N} \sum_{\mathbf{q}} \chi(\mathbf{q}) \tag{78}$$

as well as

$$\chi_0^{-1} = 2\frac{\partial E(M_L^2)}{\partial M_L^2} + \frac{6k_B T}{N} \sum_{\mathbf{q}} \chi(\mathbf{q}) \frac{\partial j(M_L^2, \mathbf{q})}{\partial M_L^2} \tag{79}$$

where

$$\chi(\mathbf{q}) = 1/[\chi_0^{-1} + 2j(M_L^2, \mathbf{q})] \tag{80}$$

M_L^2 is the magnetic moment squared at high temperatures, which for a local moment system is equal to the saturation moment squared, $M_L^2 = M_0^2$. Since at the Curie temperature $\chi_0^{-1} = 0$, equations (78) and (80) imply

$$k_B T_c^{SP} = \frac{2}{3} M_0^2 \left[\frac{1}{N} \sum_{\mathbf{q}} \frac{1}{j(M_0^2, \mathbf{q})} \right]^{-1} \tag{81}$$

which gives the Curie temperature in the spherical approximation, or, as was pointed out in the preceding text, in the RPA. Note that equation (79) was ignored in this step. Continuing to ignore this equation, one can discuss a Curie–Weiss law that is obtained by requiring $M_L^2 = M_0^2$ at all temperatures above T_c but calculating χ_0^{-1} by using equation (80) in equation (78). This problem is easily solved numerically and the inverse susceptibility that results is shown as the dashed curve in Figure 10; it can, obviously, not explain the experimental susceptibility. A collection of data pertinent for bcc Fe is given in Table 6.

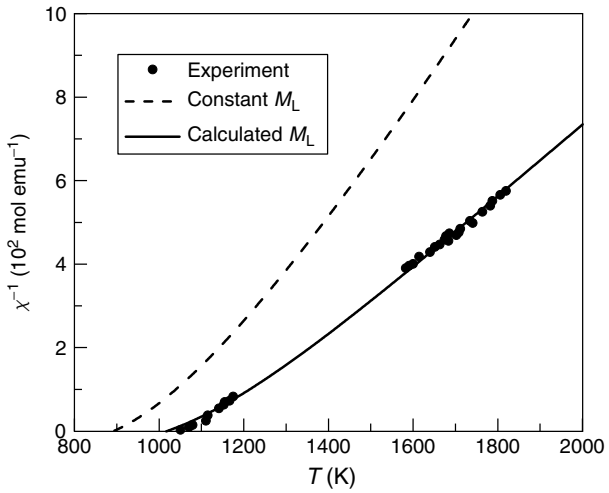

Figure 10. Calculated inverse susceptibility of bcc Fe (for the definition of M_L, see the text). Dashed curve is the spherical approximation inverse susceptibility, solid curve is obtained from solving equations (78)–(80) self-consistently. Experimental data from Shimizu (1981). [a]This calculation at theoretical lattice constant.
[b]This calculation at experimental lattice constant.
[c]Moran, Ederer and Fähnle (2003).
[d]Moran, Ederer and Fähnle (2003).

The exchange function $j(\mathbf{q})$ was in the cases discussed here obtained by total energy calculations using equation (53) for $\theta = 90^\circ$ constraining the magnetic moment in the atom or local frame of reference to the desired self-consistent ground-state value. Results are given for two lattice constants, the first line in Table 6 applying to the theoretical equilibrium and the second line to the experimental atomic volume. Values for the calculated spherical approximation Curie temperature and the mean-field value from equation (61) for the appropriate atomic volumes are also listed in Table 6. Before discussing these numbers any further, we show that a semiempirical explanation of the Curie–Weiss law is possible by considering equation (79) together with equations (78) and (80).

If one assumes that for the case of a nearly localized ferromagnet an expansion of the energy function $E(M_L^2)$ about the value of $M_L^2/M_0^2 = 1$ is meaningful, then the derivative of the exchange function with respect to M_L^2 in equation (79) might be estimated from $\partial j(M_0^2, \mathbf{q})/\partial M_0^2$, that is, replacing M_L by M_0. The latter derivative can be obtained numerically by finite differences using constrained total energy calculations to values of the magnetic moment, $M_0 \pm \Delta M$.

The derivative calculated for bcc Fe may be characterized by the number

$$\frac{1}{N}\sum_{\mathbf{q}} \frac{\partial \log j(M_0^2, \mathbf{q})}{\partial M_0^2} \simeq -0.129 \tag{82}$$

and an evaluation of the self-consistency equations (78)–(80) gives, using the expansion

$$E(M_L^2) = \frac{1}{4}\chi_{\text{eff}}^{-1}(M_L^2/M_0^2 - 1) \tag{83}$$

the result shown in Figure 10 as solid line. The value used here for the expansion coefficient is $\chi_{\text{eff}} \simeq 0.67 \cdot 10^{-4}$ emu mol^{-1}. The Curie temperature is obtained as $T_c = 1018$ K and is also given in Table 6. The value of the magnetic moment at the calculated Curie temperature is $M_L \simeq 1.07 M_0$. It should be stressed that the only input parameter is χ_{eff}, which together with the *ab initio* exchange function $j(M_0^2, \mathbf{q})$ explains both the slope and the Curie temperature. The expansion coefficient χ_{eff} should be obtained from a renormalized theory, which is beyond the scope of our approach. But it is interesting to observe that it is of the order of magnitude of a Brillouin zone average of the nonuniform susceptibility $\chi(\mathbf{q})$. The agreement with the experimental data is surprising, but perhaps fortuitous.

For completeness, we report results for the magnetization of bcc Fe below the Curie temperature. An application of an expansion of the energy function $E(M, M_L^2)$ in equations (76) and (77) of rather high order cannot explain the magnetization properly. But since the magnon-spectrum can be calculated by means of spiral total energies, using for instance a formula like equation (20), one can resort to established theories for local moment systems. Antropov, Harmon and Smirnov (1999) used an interpolation formula given by Tyablikov (1969) and calculated magnon energies to obtain the magnetization shown in Figure 11, which explains the experimental results to an amazing accuracy. It should be added, however, that the visual agreement is enhanced by using reduced units, which was not done in the original publication by Antropov, Harmon and Smirnov (1999).

We complete the discussion by commenting on the remaining numbers in Table 6. Moran, Ederer and Fähnle (2003)

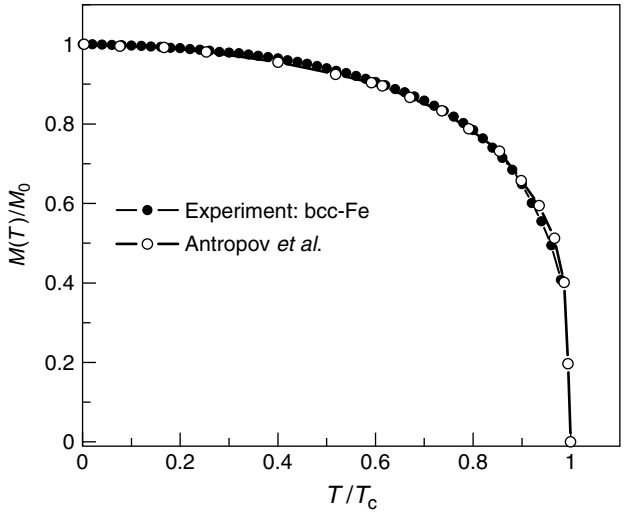

Figure 11. Temperature dependence of the magnetization of bcc Fe in reduced units. The data for the curve labelled Antropov *et al.* were extracted from Figure 13 of the paper of Antropov, Harmon and Smirnov (1999) and are based on the Tyablikov formalism.

calculated the Curie temperature as a function of the volume and found that its value increases as the volume is decreased. Two of their values are included in Table 6 together with two values calculated here. The latter support the calculations of Moran *et al.*, although our rate of change is somewhat smaller, being $\partial T_c^{SP}/\partial P \simeq 0.58$ K kbar^{-1} compared with their value of $\partial T_c^{RPA}/\partial P \simeq 1.8$ K kbar^{-1}. It is not the difference in these numbers that is of importance (our estimate perhaps being less precise because of our simplified constraining scheme, see Grotheer, Ederer and Fähnle, 2001 and Singer, Fähnle and Bihlmayer (2005)), it is the sign that is quite counterintuitive. Indeed, it violates the Bethe–Slater curve, according to which the nearest-neighbor exchange constant for iron should decrease with decreasing interatomic distance (Sommerfeld and Bethe, 1933; see also Kouvel and Wilson, 1961 as well as Jiles, 1998). Moran *et al*. point out that one has to go far beyond the nearest and next-nearest exchange constants to see the origin of the behavior in the rate of change. Since the experimental data give $\partial T_c/\partial P \simeq 0$ (Leger, Loriers-Susse and Vodar, 1972), they conclude that the pressure effect cannot be correctly described by the Heisenberg model. (Note that the quantities T_c^{SP} or T_c^{RPA} or T_c^{MF} depend only on the exchange function $j(\mathbf{q})$). Thus, we have to look at the role of pressure in the energy function $E(M_L^2)$, for which, unfortunately, an *ab initio* expression is lacking.

3.3.2 Other work on elementary magnets

We begin this subsection by referring back to the grand potential given in equation (12) and consider the

paramagnetic state as consisting of local moments that are disordered like atoms in a disordered alloy. To evaluate the grand potential for this situation, one needs a method to solve the single-particle equations in the presence of disorder. A powerful scheme to treat the disorder is the coherent-potential approximation (CPA) (Ehrenreich and Schwartz, 1976), which can be combined with Green's function methods implied in Section 2.2, where the real-space method for obtaining the exchange interactions was sketched. The initial steps of the CPA theory are easily explained.

If we are given a situation where the concentration of A atoms is x, then, in a binary alloy, that of the B atoms is $(1 - x)$ and the average of the scattering path matrix defined in equation (22) is

$$\langle \tau \rangle = x\tau^A + (1 - x)\tau^B \doteq \tau_{\mathrm{C}} \tag{84}$$

where a scattering path operator, τ_{C}, of a coherent medium is defined. Physically, a random crystal potential is replaced by an effective medium that is described with a single scattering path matrix τ_{C}. Starting from here, a single-site t-matrix is defined in correspondence with equation (22). There are a number of different ways to proceed, all are, however, beyond the scope of this chapter. A good discussion can be found in the paper by Gyorffy *et al*. (1985). We stress that the CPA is ideally suited for obtaining the exchange constants from the real-space approach.

The paramagnetic state of a magnet is now modeled as a random distribution of an equal amount of up- and down-spin atoms and the grand potential is determined variationally dropping all double-counting terms. Using this approach, which leads to the so-called *disordered local moment picture* (*DLM*), Staunton, Gyorffy, Stocks and Wadsworth (1986) have derived an expression for the temperature-dependent, paramagnetic spin susceptibility. This approach has been very successful in explaining the magnetic correlations in the paramagnetic state of several magnetic metals and alloys as well as determining the Curie temperatures (Staunton and Gyorffy, 1992).

We begin our comparison of a number of noteworthy, *ab initio* calculations for the Curie temperatures for Fe, Co, and Ni with the results of Staunton and Gyorffy (1992), which appear in the first column of Table 7. This prominent paper also contains a demonstration of the Curie–Weiss law and its relation to experimental data. It should be noted that this theory does not require a mapping onto an effective Heisenberg model.

The remaining entries of Table 7 are calculated with methods more in line with the present review. Thus, the second column summarizes the results of Halilov, Eschrig, Perlov and Oppeneer (1998), who, in an important and very detailed paper, obtained the exchange interaction in the reciprocal-space approach. They also, besides detailed magnon spectra, calculated and showed the magnetization as a function of the temperature for Fe, Co, and Ni, giving the Curie temperatures in the mean-field approximation.

The results obtained by Uhl and Kübler (1996) (Reference[c] in Table 7) were based on the spin-fluctuation theory using, besides the exchange function $j(\mathbf{q})$, the calculated values for the expansion coefficients α and β. This, as was pointed out in the preceding text, unfortunately leads to inaccurate Curie constants.

The results by Rosengaard and Johansson (1997) in the column marked Reference[d] are described in a very inspiring paper, in which the real-space and reciprocal-space approaches for obtaining the exchange interaction are compared. The actual calculations were carried out with exchange constants obtained in the reciprocal space approach using spin spirals. The magnetization as a function of the temperature was determined using the Monte Carlo method, which, in principle, is exact, given exact exchange constants and a sufficiently large sampling volume. Unfortunately, this method cannot be dealt with here, so a reference must suffice (Landau and Binder, 2000). (See also **Quantum Monte**

Table 7. Collection of calculated Curie temperatures and experimental values (from Table 1) in Kelvin of bcc Fe, fcc Co, and fcc Ni.

[f]This work, mean-field and spherical approximation given.
[g]Experimental results, see Table 1.

Carlo Methods, Volume 1). The Curie constants are also obtained and found to be smaller than the experimental values.

Finally, we emphasize that Pajda *et al*. (2001) determine the exchange constants using the real-space approach obtaining the spin-wave stiffness constants, and Curie temperatures of Fe, Co, and Ni in the RPA and mean-field approximation. Their results are shown in Table 7 in the column marked Reference[e]. They are seen to basically agree with ours, given in the column marked Reference[f], although they are not identical.

We close this subsection by briefly remarking on the antiferromagnetic metals fcc Fe and fcc Mn. Their electronic and magnetic structure is unusual, showing for a certain range in the atomic volume noncollinear order, see for instance Chapter 4 in Kübler (2000), and for more recent results Knöpfle, Sandratskii and Kübler (2000) and references therein. The case of fcc Fe is of particular interest because of the possibility of epitaxially growth, which is further discussed in Section 4.3.

Zhou, Wang and Kawazoe (1999) determined for both fcc Fe and fcc Mn 11 pair exchange constants by means of total energy calculations for magnetic supercells of considerable size. By means of the Monte Carlo method, they then computed the Néel temperatures obtaining for fcc Mn a value of $T_N = 383\,\mathrm{K}$, which should be compared with a spin-fluctuation value by Uhl and Kübler (1997) of $T_N = 446\,\mathrm{K}$ and an experimental estimate from Mn alloys of $T_N = 490\,\mathrm{K}$ (Endoh and Ishikawa, 1971). For fcc Fe, their results were $T_N = 156\,\mathrm{K}$. A comparison with an experimental value is not straight forward: neutron diffraction measurements by Onodera *et al*. (1994) on coherent fcc Fe precipitates in Cu yielded a value of $T_N = 67 \pm 2\,\mathrm{K}$, whereas films epitaxially grown on Cu(100) by Qian *et al*. (2001) indicated a Néel temperature of about 275 K.

4 APPLICATIONS FOR MAGNETS DESIGN

In this section, essentially, two formulas are retained, that is, equations (60) and (61), the spherical approximation (or RPA) and the mean-field approximation to predict the Curie temperature of magnetic systems that might be of interest for technological applications. We stress that all these theories require a mapping to an effective Heisenberg model.

Without an attempt at completeness, a number of recent papers concerned with, broadly speaking, spin-electronics (or *spintronics*) are reviewed first, followed by some selected studies on magnet films and multilayers. (See also **Heusler Alloys, Volume 4**).

4.1 Half-metallic ferromagnets

Half-metallic ferromagnets possess the unusual property that in one spin channel the electrons are metallic, in the other they are insulating with a sizable energy gap, provided SOC can be neglected. Thus, at least at the absolute zero, the electrons are 100% spin polarized at the Fermi edge. In the presence of SOC, the degree of polarization is still nearly perfect. An early review is contained in the book by this author (Kübler, 2000, Ch.4). A recent review article containing a large number of original references is that by Shirai (2004); thus, half-metallic ferromagnets may be used as potential materials for spintronic device applications, for example, as an electrode of a magnetic tunnel junction, a source of spin injection into semiconductors, and newly proposed transistors.

4.1.1 Heusler alloys

Examples of half-metallic ferromagnets are the 'classical' $C1_b$-type Heusler alloys NiMnSb, PtMnsb, and so on, magnetite, rutile-type CrO_2, the $L2_1$-type Heusler alloys, perovskite manganites, double perovskites, the diluted magnetic semiconductors, and the recently discovered zinc-blend half-metals, for references see Shirai (2004). For any of these compounds to be of technical use, the Curie point must be above room temperature. Modern simulations thus not only concentrate on the electronic and magnetic properties but also on predictions of the Curie temperature.

To begin with, one needs to know if the techniques described here are sufficiently accurate for meaningful predictions. Calculations by Enkovaara *et al*. (2003) on the $L2_1$-type Heusler alloys Ni_2MnGa and Ni_2MnAl as well as by Sasioglu, Sandratskii and Bruno (2004) on Ni_2MnX (X = Ga,In,Sn,Sb) serve this purpose quite well. Although these compounds are not half-metallic, their finite-temperature properties are quite revealing. Improving considerably earlier work by Kübler, Williams and Sommers (1983), Enkovaara *et al*. and Sasioglu *et al*. used modern calculational method and the LSDA including the generalized gradient approximation (GGA) (Perdew and Wang, 1992) to determine the exchange parameters in the reciprocal-space approach. The Curie temperature is obtained in the mean-field approximation modified by considering more than one magnetic sublattice. The latter improvement is similar to the diagonalization employed for the treatment of the multi-sublattice case in Section 3.2, except for the fact that Sasioglu, Sandratskii and Bruno (2004) use it for the mean-field approximation.

The results of these calculations are extremely satisfying. The experimental Curie temperatures of Ni_2MnX (X = Ga,In,Sn,Sb) are known and found in the range from 315 K to 380 K, the theoretical values deviating in the worst

case by only 9% of the experimental value for the case of Ni_2MnIn, where $T_c^{exp} = 315\,K$ compared with $T_c^{calc} = 343\,K$ (Sasioglu, Sandratskii and Bruno, 2004).

Sasioglu, Sandratskii and Bruno (2005) in another paper considered two further $L2_1$-type Heusler alloys, Mn_2VAl and Mn_2VGe, the former of which was found by Weht and Pickett (1999) to be a half-metallic ferrimagnet with a magnetic moment of 2 μ_B/f.u. The Curie temperature for Mn_2VAl calculated in the same way as in the previous paper (Sasioglu, Sandratskii and Bruno, 2004) comes out to be $T_c^{MF} = 638\,K$, underestimating the experimental value of $T_c = 760\,K$ somewhat. For Mn_2VGe, they predict a Curie point of $T_c^{MF} = 413\,K$. For more recent results see Kübler (2006).

Clearly, it is of interest to calculate the Curie temperatures of the 'classical' $C1_b$-type Heusler alloys first discovered by de Groot, Mueller, van Engen, Buschow and Jongebreur (1983). This was done here using the augmented spherical wave (ASW) method (Williams, Kübler and Gelatt, 1979) in the LSDA, employing the reciprocal-space method and the force theorem to obtain the exchange parameters. The results for Curie temperatures in the spherical and mean-field approximation are collected in Table 8.

For NiMnSb, the lattice constant was optimized; the results are given in footnote a. At the smaller theoretical lattice constant, NiMnSb remains half-metallic but the calculated Curie temperature increases. We draw the attention to the drop in the measured and calculated Curie temperatures for PtMnSn, which is not half-metallic. Furthermore, although overestimates by the mean-filed approximation are not uncommon, it is startling to see the consistent overestimates in the calculated T_cs by the spherical approximation, except for the case of PtMnSn. Unpublished results by this author indicate that the same discrepancy is found in the half-metallic ferromagnet CrO_2. One could argue that estimates of T_c using the static approximation to the spin-fluctuation theory, which are lower by a factor of 0.6 compared with the spherical approximation (compare equation (54) with equation (60)), are more appropriate here. This can be ruled out for the following reasons.

Table 8. Calculated and experimental (van Engen, Buschow and Jongebreur, 1983) values for the 'classical' half-metallic ferromagnets: lattice constant, a, experimental magnetic moments, M_0, calculated magnetic moments, M_0^{calc}, both in μ_B/f.u., experimental Curie temperatures, T_c, calculated Curie temperatures: spherical approximation (RPA) T_c^{SP} and mean-field approximation, T_c^{MF}.

	a (Å)	M_0	M_0^{calc}	T_c (K)	T_c^{SP} (K)	T_c^{MF} (K)
PtMnSb	6.210	3.97	4.02	582	741	991
PdMnSb	6.285	3.95	4.09	500	744	927
NiMnSb[a]	5.920	3.85	4.00	730	1002	1305
PtMnSn[b]	6.264	3.42	3.84	330	188	354

[a]Calculated lattice constant is $a = 5.725$ Å with $T_c^{SP} = 1141\,K$.
[b]Not half-metallic.

Capelle and Vignale (2001) as well as Eschrig and Pickett (2001) in two recent papers drew attention to a nonuniqueness problem in spin-density-functional theory. Eschrig and Pickett start out with the observation that the spin-only magnetic susceptibility is zero for a half-metallic ferromagnet (which it manifestly is), although the conductivity is that of a metal. Zero susceptibility, however, implies that the ground-state spin density does not change when an external magnetic field is changed. They prove that *two magnetic fields whose difference is constant in magnitude, but possibly is nonunidirectional, may give rise to the same ground state.* Both papers arrive at the same conclusions finding that the exchange-correlation energy is not always a differentiable function of the spin density and *the ground state does not contain all information about excited states in the presence of a magnetic field.* As a consequence, applications of the spin-density functional approximation must be critically reexamined.

It is thus not surprising, for instance, that calculations for the ground-state energy, where the magnetic moment is constrained to a given value (the constraint is achieved by a magnetic field (Dederichs, Blügel, Zeller and Akai, 1984)), result in a kink at the ground-state magnetization. The kink implies that a power series expansion of the total energy in terms of the magnetization fails precluding an expansion of the form of equation (38). Since the kink, however, pins the value of the magnetic moment near the ground-state value in the wave-vector-dependent energy changes, the spherical approximation still seems applicable. Furthermore, calculations employing the force theorem are carried out without any constraining magnetic fields, so the information gained in this case seems justified too. The apparent discrepancy remains and could be due to the LSDA. Indications exist that the GGA provides the necessary corrections.

4.1.2 Zinc-blende compounds

In the search for new materials suitable for spintronics applications Akinaga, Manago and Shirai (2000) predicted by LSDA calculations and subsequently grew zinc-blende CrAs (zb-CrAs) on GaAs by molecular-beam epitaxy. It was found to be ferromagnetic at room temperature and the calculations revealed zb-CrAs to be half-metallic.

In fact, a large number of recent electronic structure calculations concentrated on zinc-blende compounds of transition elements, in some cases comparing the electronic properties in the unstable zinc-blende phase with that of the stable NiAs crystal structure (Sanvito and Hill, 2000; Xu, Liu and Pettifor, 2002; Sakuma, 2002). A systematic study of zinc-blende

compounds involving transition-metal elements with N, P, As, Sb, S, Se, and Te is that by Galanakis and Mavropoulos (2003), who also examined the half-metallic behavior of the transition-element-terminated surfaces. Subsequently, there appeared calculations of the Curie temperatures, T_c, of some of the compounds that might be of technological importance. In addition, the calculated trends in T_c were interpreted and related with salient features of the electronic structure (Kübler, 2003; Sanyal, Bergqvist and Eriksson. 2003).

The calculations by this author (Kübler, 2003) were based on spin-fluctuation theory in the LSDA, which is not justified because of the nonuniqueness problem addressed in the preceding text. However, the Landau parameter α plays no prominent role here, therefore the results for the Curie temperatures can easily be scaled up to the spherical approximation (compare equation (54) with equation (60)) and are given in Table 9, which also contains results obtained by Sanyal, Bergqvist and Eriksson (2003), who used the GGA for the determination of the underlying exchange constants.

The calculations were carried out for two lattice constants, namely, those of GaAs (5.65 Å) and InAs (6.06 Å). For both cases, the compounds VAs and CrAs are half-metallic ferromagnets, with magnetic moments of 2 μ_B/f.u. and 3 μ_B/f.u., respectively. The compound MnAs, however, is only half-metallic with a moment of 4 μ_B/f.u. for the larger lattice constant of InAs; for that of GaAs, the Fermi edge, E_F, moves into the conduction band (see for instance Figure 1 of Kübler (2003)) and the magnetic moment drops to 3.65 μ_B/f.u. Connected with this shift of E_F is a large decrease of the calculated Curie temperature, which is seen in the last row of Table 9.

There is only rough agreement between the two sets of numbers appearing in Table 9, the more precise values of Sanyal *et al*. (second and third row) are lower throughout. The differences in the mean-field results indicate different exchange constants, presumably because in one case the GGA was employed. The Monte Carlo results are in principle exact, given exact exchange constants.

Both sets of numbers indicate same orders of magnitude and, in the cases of VAs and CrAs, an increase in the calculated Curie temperatures when the lattice constant is decreased. The same trend is observed in the half-metallic ferromagnet NiMnSb, for which estimates of the Curie temperature are given in Table 8.

This subsection is closed with the remark that experimental observations confirm the theoretical results in that zb-CrAs grown on GaAs possesses a Curie temperature above 400 K (Akinaga, Manago and Shirai, 2000), while that of zb-MnAs is below room temperature (Ono *et al*., 2002).

Table 9. Calculated Curie temperatures for three zinc-blende materials at two different lattice constants, a, which are those of GaAs (5.65 Å) and InAs (6.06 Å). The second and third row are calculations by Sanyal, Bergqvist and Eriksson (2003) using the GGA, the fourth and fifth row are our own results obtained by the LSDA. Mean-field, T_c^{MF}-, Monte Carlo T_c^{MC}-, and spherical approximation T_c^{SP}-results are given in K.

	VAs	VAs	CrAs	CrAs	MnAs	MnAs
a (Å)	5.65	6.06	5.65	6.06	5.65	6.06
T_c^{MF} [a]	990	610	1320	1100		640
T_c^{MC} [a]	830	490	980	790		530
T_c^{MF} [b]		1175		1367	569	1363
T_c^{SP} [b]		882		820	301	953

4.2 Diluted magnetic semiconductors

Diluted magnetic semiconductors (DMSs), like the prototypical Mn-doped GaAs, (Ga,Mn)As, and others to be discussed in the subsequent text, are intended to be technologically applied in devices that combine functions of semiconductors and magnetic devices. Here, methods need to be developed to manipulate and propagate the spin polarization in order to control the spin degree of freedom of electrons in semiconductors. These semiconductors are envisioned to be ferromagnetic possessing Curie points above room temperature, in order to realize, for instance, a spin-polarized transistor, integrated spin-logic in a nonvolatile spin memory, and phase-coherence in a quantum computer – just to name some of the presently much talked about key projects.

Because of the great wealth of experimental and theoretical work on DMSs, our treatment here is necessarily incomplete. An earlier review paper on the theoretical side is that by König, Schliemann, Jungwirth and MacDonald (2003) and the experimental situation was covered by Ohno (1999).

Perhaps one of the key materials fabricated is the DMS with the formula $(Ga_{0.947}Mn_{0.053})As$ having a Curie temperature of $T_c = 110$ K (Ku *et al*., 2003). However, fabrication of DMS materials possessing higher Curie temperatures (characterized with unambiguous experimental methods like magnetic circular dichroism) met with difficulties so far, with perhaps one exception discussed in the subsequent text. Numerous theoretical efforts thus concentrated on identifying and understanding those physical mechanisms, which could guide experimental efforts to result in optimized materials. A small selection of these papers are reviewed here.

At present, the DMS materials discussed are (Ga,Mn)As, (In,Mn)As, and (Ga,Mn)N of the III-V type, (Zn,Cr)Te of the II-VI type, and $Ge_{1-x}Mn_x$ of group-IV type. The question to be clarified theoretically concerns mainly the physical mechanism that determines the exchange interactions over

rather large distances. Here, one finds theories that rely on model Hamiltonians, particularly noteworthy being that by Dietl, Ohno and Matsukura (2001). Another approach uses *ab initio* methods, like that by Akai (1998) who extracts concepts for the exchange mechanism from his calculations.

Since we opt for describing results of *ab initio* methods, we should stress that the various exchange mechanisms appear in the calculational results in mixed form. This is in contrast to the model Hamiltonian approach where different perturbational treatments give different exchange interactions, depending on the relative magnitude of the relevant physical properties. Still, it is common to treat the magnetism of a DMS in terms of the competition between the antiferromagnetic superexchange and the ferromagnetic double exchange through charge carriers (Andersen, 1963). In the work, we want to start with (Sandratskii and Bruno, 2002, 2003a,b) the term *double exchange* is replaced by kinetic exchange, since, it is argued that the term *double exchange* occurs in the interpretation of mixed valence systems, which are important in another context. The physics, however, considered in the original definition of double exchange (de Gennes, 1960) is the same as that considered here under the label kinetic exchange (Sandratskii and Bruno, 2003a). This is shown by these authors, who use a simple two-band tight-binding model and varying band occupations.

The supercell calculations have the virtue of great simplicity, but they ignore the role of disorder, thus representing simplifications that could be questioned. Still, the insight gained by the work of Sandratskii and Bruno (2002, 2003a,b) is quite enormous. Furthermore, refined calculations that do consider the role of disorder *ab initio* support the supercell calculations to a large extend, as shown by us in the following text.

Sandratskii and Bruno deal with the DMSs consisting of (Ga,Cr)As, (Ga,Mn)As, (Ga,Fe)As, and (Zn,Cr)Te containing various concentrations of the magnetic ions. For simplicity, we here select results for (Ga,Mn)As and (Zn,Cr)Te and show in Figure 12 the calculated DOS for (Ga,Mn)As for the two Mn concentrations of (i) 25% and (ii) 12.5%. In Figure 12(c), we show the DOS of (Zn,Cr)Te with 25% Cr. They are easily reproduced with the help of a notebook computer using, just as Sandratskii and Bruno, the ASW-method (Williams, Kübler and Gelatt, 1979) in the LSDA. In the original work, to which we refer for all details, one also finds the concentrations 6.25% and 3.125%, obtained in the case of (Ga,Mn)As for the lattice constant of GaAs. We here use a slightly larger lattice constant ($a = 5.87$ Å instead of $a = 5.65$ Å) so that the DMSs are half-metallic for all concentrations. That these DMSs are, indeed, half-metallic, at least in supercell calculations, is one of the first results to be noticed.

In somewhat more detail, the calculations show (Figure 12 and those of Sandratskii and Bruno (2002, 2003a,b)) that the

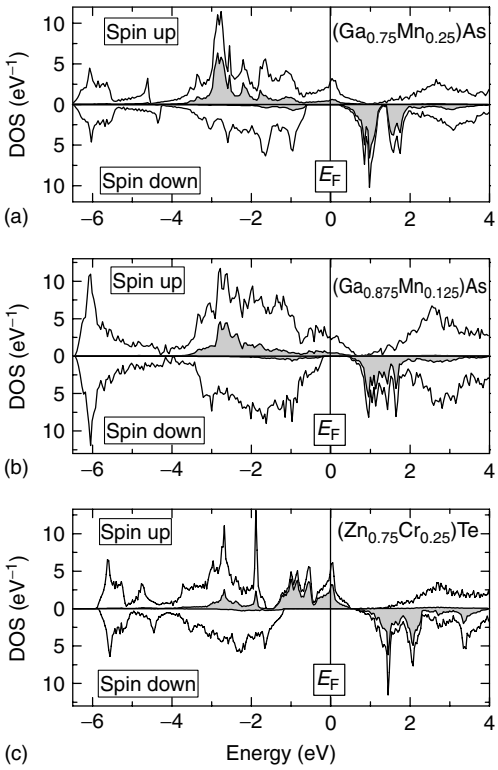

Figure 12. Total and partial density of states (DOS) of (a) $(Ga_{0.75}Mn_{0.25})As$, (b) $(Ga_{0.875}Mn_{0.125})As$, and (c) $(Zn_{0.75}Cr_{0.25})Te$ obtained by supercell calculations. Curves bordering shaded areas depict d-states of Mn or Cr, respectively.

replacement of one Ga atom in the supercell of GaAs by a Mn atom does not change the number of spin-down states in the valence band. In the spin-up states, however, five new hybridized energy bands related to the 3d states of Mn are created. The situation is analogous for the case of ZnTe with Cr. The atomic configurations of Ga being $4s^2 4p^1$ and that of Mn $4s^2 3d^5$ implies that four electrons occupy the five states, leaving one state unoccupied at the top of the valence band, which is interpreted as a hole state. The same hole state appears for ZnTe doped with Cr.

The important issue to be clarified by the calculations is the role of the charge carriers in mediating the exchange interaction. The experimental studies (Ohno, 1999) show that the concentration of holes is lower than the concentration of the Mn atoms. One of the factors leading to the low concentration is the presence of As antisites, that is, a small fraction of As occupies Ga sites. Sandratskii and Bruno now succeed in demonstrating the importance of the hole states by changing their occupation. This is done in a rigid-band approximation for different numbers of electrons, n, changing the charge state of Mn, each time calculating the Curie temperature by both equations (60) and (61), the spherical (or RPA), and the mean-field

approximation, respectively, as a function of n self-consistently. The reciprocal-space approach is used for the determination of the Curie temperatures.

For $n = 0$, that is, the nominal number of carriers, the calculated Curie temperatures are given in Table 10 and compared with experimental values. The DMS (Zn,Cr)Te was grown with a concentration of 20% having an exceptionally large Curie temperature of 300 K (Saito, Zayets, Yamagata and Ando, 2003). It was studied by Sato and Katayama-Yoshida (2001) theoretically and simulated with a supercell containing 25% Cr by Sandratskii and Bruno (2003b), which seems close enough to the experimental value.

For both DMS materials, a decrease in the number of holes ($n > 0$) decreases the exchange interactions and thus both estimates of the Curie temperature. For a small number of holes, when the valence band is nearly filled, the exchange interaction becomes antiferromagnetic, that is, the superexchange mechanism begins to dominate over the kinetic exchange. For an increased number of holes ($n < 0$), the exchange interaction and correspondingly the Curie temperature initially increases. The calculations reported by Sandratskii and Bruno (2002, 2003a,b) cover the range $-2 \leq n \leq 2$ and show oscillatory behavior. The experimental Curie temperatures are found to be in good agreement with the calculations obtained for $n = 0.6$, indicating a hole concentration lower than the concentration of Mn atoms, also agreeing with the experimental observation of Ohno (1999). In the case of $(Zn_{0.75}Cr_{0.25})$Te, the differences between the two calculations cited in Table 10 is somewhat startling and might be due to different precisions in sampling the exchange function $j(\mathbf{q})$.

The next step in theoretical refinements consists in incorporating disorder in the *ab initio* calculations. This is done by employing the CPA, introduced briefly in Section 3.3.3.

In a short paper, Bouzerar, Kudrnovsky, Bergqvist and Bruno (2003) focus their attention on the effects of randomness and the compensating effects by As antisites in the DMSs described by the formula $(Ga_{0.95-y}As_yMn_{0.05})$As. The CPA is used obtaining the exchange constants from the real-space approach. Furthermore, the approximations for the Curie temperature are examined by using the Monte Carlo method (Landau and Binder, 2000) (See also **Quantum Monte Carlo Methods, Volume 1**). As a result, the general picture obtained by the supercell simulations is not changed, although the various approximations for the Curie temperature lead to somewhat higher values, including the Monte Carlo estimate, which is larger by about 30 K compared with the mean-field value given in Table 10. However, a finite concentration of As antisites in both the supercell- and the CPA-approximation leads to decreasing calculated values resulting for $y = 0.01$ in the Monte Carlo approximation in $T_c^{MC} = 117\,\mathrm{K}$.

Table 10. Experimental Curie temperatures for $(Ga_{0.95}Mn_{0.05})$As and $(Zn_{0.8}Cr_{0.2})$Te and results of supercell calculations in the spherical (RPA), T_c^{SP}, and mean-field, T_c^{MF}, approximation.

	$(Ga_{0.95}Mn_{0.05})$As	$(Zn_{0.8}Cr_{0.2})$Te
T_c^{MF} (K)	225[a]	346[c] 429[d]
T_c^{SP} (K)	175[a]	369[d]
T_c^{exp} (K)	110[b]	300[e]

[a]Calculated by Sandratskii and Bruno (2002, 2003a).
[b]Experimental value (Ohno *et al*., 1996).
[c]Calculated by Sandratskii and Bruno (2003b) for $(Zn_{0.75}Cr_{0.25})$Te.
[d]Own calculation for $(Zn_{0.75}Cr_{0.25})$Te.
[e]Experimental value (Saito, Zayets, Yamagata and Ando, 2003).

Sato, Dederichs, Katayama-Yoshida and Kudrnovsky (2004) also employ the CPA to investigate the exchange mechanism and the Curie temperature for the diluted magnetic semiconductors (Ga,Mn)N, (Ga,Mn)P, (Ga,Mn)As, and (Ga,Mn)Sb. A concentration range up to 15% Mn is assumed, for which the Curie temperature is obtained in the mean-field approximation. The exchange constants are determined using the total energy difference between the ferromagnetic state and the 'DLM' state (see Section 3.3.3.), which can be described with the formula $(Ga_{(1-c)}Mn^{\uparrow}_{c/2}Mn^{\downarrow}_{c/2})$X, whereas the ferromagnetic state is denoted by $(Ga_{(1-c)}Mn^{\uparrow}_{c})$X. This means that in the latter state the Mn impurities with concentration c having parallel aligned magnetic moments are randomly distributed at Ga sites, whereas in the former three components, $Mn^{\uparrow}$, $Mn^{\downarrow}$, and Ga are considered on the Ga site.

The calculations by Sato, Dederichs, Katayama-Yoshida and Kudrnovsky (2004) show that the compounds remain half-metallic except for (GaMn)Sb. To compare with the supercell calculations a Curie temperature of $T_c^{MF} \simeq 250\,\mathrm{K}$ for 5% Mn in GaAs can be read from their Figure 1, which is in acceptable agreement with the value given in Table 10. The important thing about this paper is that the exchange mechanism is analyzed in great detail. The concentration dependence of the Curie temperature for small c is found to be $\propto \sqrt{c}$, which is convincingly interpreted to be the signature of kinetic exchange, called *double exchange* by these authors. In contrast to this is the case of (Ga,Mn)Sb, for which the concentration dependence is surprisingly different, being nearly linear in c. Sato *et al*. argue that in this case the magnetic moments are to be considered as localized so that the p-d exchange model seems more suitable here. In fact, this model was employed successfully by Jungwirth, Atkinson, Lee and MacDonald (1999) and by Dietl, Ohno and Matsukura (2001). The p-d-model (in other contexts called the s-f-model) is the basis of the well-known RKKY interaction, but the value of the p-d-exchange integral is a disposable parameter. The transition to localized states seems

to be a possibility here, but more experimental data are needed to establish this firmly.

There are two further notable papers: Kudrnovsky *et al*. (2004a) on (Ga,Mn)As as well as (Ge,Mn) and Kudrnovsky *et al*. (2004b) on the same DMSs and (Zn,Cr)Te. They supply important details and enlarge the scope of the paper by Bouzerar, Kudrnovsky, Bergqvist and Bruno (2003), supporting in all respects the exchange mechanisms exposed in the preceding text and the role of anitsite atoms. They, furthermore, find that due to disorder and the half-metallic character of the systems, the pair exchange interactions are exponentially damped with increasing distance of the Mn atoms. They are also reduced with increasing concentrations of the Mn atoms and the As antisites.

Eriksson *et al*. (2004), finally, are concerned with the stability of the magnetic moment as a function of the As antisite concentration. They argue that agreement between theory and experiment is obtained only when the magnetic atoms are randomly positioned on the Ga or Zn sites. They suggest that the ordering of the DMS materials is heavily influenced by magnetic percolation and that the measured Curie temperatures should be very sensitive to details in the sample preparation, which, indeed, they are.

4.3 Reduced-dimensional magnets

The importance of the magnetism of ultrathin films and multilayers need not really be stressed since their applications in the magnetic storage technology are numerous, as, for instance, the giant magnetoresistance of the multilayer systems employed in present-day read-heads. Equally (or even more) important is the fundamental point of view on epitaxial thin-film materials, which offer opportunities for exploring the relationship between structure and magnetism because new phases of matter can be stabilized on suitable growth templates. It is only natural that the thermal properties of these new phases, in particular, the Curie temperatures of ferromagnets, are of great importance here. Examples are the DMSs in Section 4.2. But the topic of this subsection are other systems, to which we now turn.

A recent experimental study by Vollmer, van Dijken, Schleberger and Kirschner (2000) has shown that the Curie temperature of fcc(001)-Fe ultrathin films on a Cu(001) substrate is modified upon coverage by a Cu-cap layer, varying in a nonmonotonous manner as a function of the Cu-cap layer thickness. Qian *et al*. (2001) noted that the close correlation between magnetism and structure makes this system quite unique. An oscillatory behavior of the Curie temperature as a function of the spacer thickness was also found by Ney *et al*. (1999) in fcc(001)-Co/Cu/Ni trilayers. As Pajda *et al*. (2000) point out, the understanding of these systems in the framework of itinerant-electron magnetism is a very serious challenge. One of the problems is as follows.

In an important paper, Mermin and Wagner (1966) proved rigorously that *the one- and two-dimensional isotropic Heisenberg models with interactions of finite range can be neither ferromagnetic nor antiferromagnetic at nonzero temperature*. This implies that the Heisenberg model, as specified in the preceding text, cannot explain the finite-temperature ferromagnetism observed in ultrathin films. There seem to be (at present) two ways out.

We recall that many of the theories (but not all) require a mapping onto an effective Heisenberg model, which is postulated *ad hoc* in the cases where this applies. Thus, one can either map onto a *modified* effective Heisenberg model or avoid the mapping all together. The first possibility is quite plausible because of SOC, which is a relativistic effect, not included in the Heisenberg model implied by Mermin and Wagner, and known to be more important in thin films than in bulk materials. This line of thought is pursued by Pajda *et al*. (2000), who modify the mapping by using a Heisenberg model with the inclusion of SOC. This manifestly renders the Mermin–Wagner theorem inoperative.

The other possibility is to abandon the Heisenberg model for the description of itinerant-electron magnetism. Thus, one might revisit Moriya's unified approach (Section 3.3), or revert to the DLM picture, which was briefly explained in Section 3.3.3. To the best of the author's knowledge, the unified approach has not yet been used for two-dimensional magnets, but the DLM picture has in papers by Razee, Staunton, Szunyogh and Gyorffy (2002a,b).

We begin with the paper by Pajda *et al*. (2000) on fcc(001)-Fe (or -Co) ultrathin films on Cu(001) covered by a Cu-cap layer of varying thickness. In the first step, they obtain the exchange constants, J_{ij}, for i and j in the Fe- or Co-film by the real-space method, subsequently doing a two-dimensional Fourier transform, which results in the exchange function $j(\mathbf{q}_{||})$, where $\mathbf{q}_{||}$ lies in the fcc(001) surface Brillouin zone.

If one now rewrites equation (60) suitably adopted to the two-dimensional case in terms of the spin-wave spectrum obtainable from $j(\mathbf{q}_{||})$, observing that the latter has a quadratic dispersion, one finds the Curie temperature to be zero, just as required by the Mermin–Wagner theorem. In the presence of SOC, however, the spin-wave spectrum develops a gap at the zone center. Thus, one can write in the RPA or spherical approximation

$$k_{\mathrm{B}}T_{\mathrm{c}}^{RPA} = \frac{2M_0^2}{3}\left[\frac{1}{N_{||}}\sum_{\mathbf{q}_{||}}\frac{1}{[j(\mathbf{q}_{||})+\Delta]}\right]^{-1} \tag{85}$$

where $N_{||}$ is the number of sites per layer, M_0 is the film's magnetic moment, and the sum extends over the fcc(001) surface Brillouin zone. The quantity Δ, except for a constant, is the spin-wave gap, which was estimated roughly.

The calculated Curie temperatures are too large compared with the experimental values, but qualitatively they show the oscillatory behavior seen in the experimental data as a function of the cap thickness, which is interpreted by Pajda *et al*. (2000) as evidence of the oscillatory RKKY character of exchange interactions in itinerant ferromagnets.

In contrast to the work by Pajda *et al*., the theory by Razee, Staunton, Szunyogh and Gyorffy (2002a,b) for the Curie temperature in reduced dimensions does not map onto an effective Heisenberg model. It uses the concept of DLMs above the Curie temperature in the same way as the DLM theory for bulk systems by Gyorffy *et al*. (1985), Staunton, Gyorffy, Stocks and Wadsworth (1986), as well as Staunton and Gyorffy (1992), which was briefly described in Section 3.3.3. Thus, the layer-dependent paramagnetic spin susceptibility of films and multilayers above the Curie temperature is calculated for various geometries and the instability of the paramagnetic state is interpreted as the Curie temperature. Unfortunately, the formal development of the theory is too space consuming to be included here. It is of importance, however, to notice that relativistic effects are not incorporated. Since DLM employ the Bogoliobov–Peierls variational principle and a rather simple trial grand potential, just like the spin-fluctuation theory in Section 3.1 (equations (40) and (41)), this is a mean-field theory, a point which could invite criticism. Yet, even though a rigorous proof for the validity of the DLM theory in lower-dimensional systems is apparently lacking, it does not seem to be justified to treat the DML mean field on the same footing as the Heisenberg mean field, which erroneously gives a nonzero Curie temperature in two (and even in one) dimensions.

Razee, Staunton, Szunyogh and Gyorffy (2002a,b) consider in detail thin films of Fe and Co (1–8 layers) on and embedded in nonmagnetic substrates, specifically bcc Fe/W(100), fcc Fe/Cu(100), and fcc Co/Cu(100). In uncapped Fe/W(100), they find intralayer ferromagnetic correlations in all thicknesses of the iron film except in the layer nearest the W substrate; the interlayer couplings are ferromagnetic and short ranged. There are also ferromagnetic intra- and interlayer couplings throughout the Co films in fcc Co/Cu(100). In the Fe/Cu(100) system, the top two layers are coupled ferromagnetically and the rest antiferromagnetically. Cu capping is found to have a profound effect upon the magnetic coupling in both Fe/Cu(100) and Co/Cu(100) with the Curie temperature showing an oscillatory behavior as a function of the cap layer thickness. As an example, we show in Figure 13 their results for the fcc Fe/Cu(100) system. The oscillations are clearly seen; also seen is that the

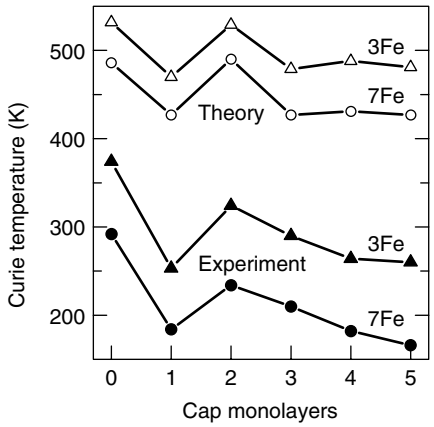

Figure 13. The Curie temperature for 3 and 7 layers of Fe on and embedded in Cu(100) as a function of the number of cap monolayers. The experimental data were extracted by Razee, Staunton, Szunyogh and Gyorffy (2002a) from Kerr data measured by Vollmer, van Dijken, Schleberger and Kirschner (2000). This figure was redrawn using Figure 1 of Razee, Staunton, Szunyogh and Gyorffy (2002a) with permission of the authors.

calculated values overestimate the measured ones, although they are much smaller than mean-field values on the basis of an effective Heisenberg model (Pajda *et al*., 2000).

It is quite certain that much more work will be done on these challenging problems in the future.

5 SUMMARY

The theory of finite-temperature magnetism of metals is formulated within the LSDA, the salient features of which are described briefly. However, calculational details are largely left to the specialized literature. The essential ingredients to the thermodynamic theory are orientational fluctuations of the local magnetization for which an adiabatic principle is postulated. The excitation energies of the fluctuations are determined from frozen magnons or more general frozen configurations, which are modeled by constrained total energy changes or, in justified approximations, from band-energy changes due to noncollinear spin orientations. As a result, exchange constants are defined and determined *ab initio* either in a real- or in a reciprocal-space approach.

The range to be covered to describe the magnetism of itinerant electron metals is a wide one extending from localized or nearly localized systems to the weakly ferromagnetic metallic compounds and alloys. A guide line for this review is Moriya's work that supplies a general framework, even though it does not yet give detailed algorithms for all cases.

The limit of weakly ferromagnetic metals is formulated with special emphasis on dissipation effects, which are incorporated in the nonuniform, dynamical susceptibility, the latter

being treated in a widely used approximation. The resulting static and dynamic approximations to the spin-fluctuation theory are applied to and discussed for the cases of $ZrZn_2$, Ni_3Al, MnSi, and tentatively for nickel. It is pointed out that an *ab initio* theory for the dissipation constant is lacking, although in some cases its order of magnitude can be estimated from the band structure. Furthermore, it becomes apparent that the energy governing the length changes of the magnetic moment, usually formulated in terms of a Landau-type expansion, needs special attention and can only be obtained from the total energy by rescaling (renormalizing) the latter if it is determined from constrained-moment calculation.

Moriya's unified theory is then used to derive the spherical approximation or RPA, which supplies a useful formula also for those cases where a mapping onto an effective Heisenberg model is a necessary approximation. The unified theory is discussed further in view of the static approximation for both the weak ferromagnetism and the opposite limit of the ferromagnetism of iron.

The Curie temperatures of the ferromagnetic metals, Fe, Co, and Ni have been determined by a great number of methods; there is the DLM picture by Staunton and Gyorffy, which is briefly introduced, and there are others that use a mapping onto an effective Heisenberg model obtaining estimates by the mean-field approximation, the RPA, and the Monte Carlo technique. These results for the Curie temperatures, as well as results for Néel temperatures of fcc Fe and fcc Mn, are collected and discussed.

Some selected applications for magnets design, in particular, for the novel field of spintronics, are then introduced. This includes a collection of theoretical and experimental Curie temperatures of half-metallic ferromagnets like Heusler alloys and Zinc-blende compounds, and the diluted magnetic semiconductors. Here, a catalogue of exchange mechanisms and their interpretations play an important role, which are particularly emphasized.

Finally, the finite-temperature properties of epitaxial thin-film materials and multilayers are addressed. The role played by the theorem of Mermin and Wagner is stressed and two different techniques to determine the Curie temperatures of low-dimensional systems are compared. One is a relativistic extension of the mapping onto an effective Heisenberg model and the other is the DLM picture as applied to thin magnetic films on and embedded in Cu substrates.

Theory of Magnetic Phase Transitions

David P. Landau
The University of Georgia, Athens, GA, USA

1 INTRODUCTION

The study of phase transitions has played a central role in many subfields of physics and related disciplines, and research in magnetism has been crucial to progress in the understanding of diverse types of phase transitions. This is, in part, because simple magnetic models have time-reversal symmetry that results in symmetries in phase diagrams that are absent in other models in statistical mechanics. In part, it also results from the rich diversity of experimental measurements of magnetic systems that allows comparison between theory and physical reality. Although simple approaches, such as Landau theory (mean-field theory), provide an intuitive picture of magnetic phase transitions, we now know that such approaches are generally inadequate for the provision of a truly quantitative description. More sophisticated methods of investigation have been developed and a mature framework is now in place for the understanding and classification of phase transitions based on a combination of theoretical and numerical approaches.

In general terms, the distinguishing feature of magnetic phase transitions is the appearance of a nonzero value of an 'order parameter' in the ordered phase, below some transition temperature, T_c, which is zero in the disordered phase above T_c. In a ferromagnet, the order parameter is simply the normalized spontaneous magnetization

$$m = \frac{1}{N}\sum_i S_i \tag{1}$$

where S_i is the spin at site i and the sum is over all N sites in the lattice. Of course, in general the spin may have many components; but for simplicity, here we will consider the one-component (scalar) case. In an antiferromagnet, the order parameter is the 'staggered magnetization'

$$m^+ = \frac{1}{N}\sum_i S_i e^{i\vec{k}\cdot\vec{r}} \tag{2}$$

where $\vec{r}$ gives the position of the spin and $\vec{k}$ is the wave vector that characterizes the ordered antiferromagnetic structure for the lattice under consideration.

Other thermodynamic properties will also show discontinuities or singularities at T_c, and these may be measured by a variety of experimental methods. However, even in the disordered state, a system will have microscopic regions in which the local properties of the material are correlated and these can be described quantitatively by a two-point correlation function

$$G(r) = \langle m(0)m(r)\rangle - \langle m\rangle^2 \tag{3}$$

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

where r is the spatial distance at which the correlation is being measured and m is the quantity of interest. (The correlations may be both space dependent and time dependent, but for static properties, the equal-time correlations, that is, time-independent correlations, are adequate.) The correlations will decay as a function of distance (although not always monotonically); and the order parameter will be zero at any temperature for which the reduced correlation, that is, the first term in equation (3), decays to zero as the distance goes to infinity.

At a phase transition, the thermodynamic properties may show dramatic changes of different kinds. If the first derivatives of the free energy are discontinuous, the transition is termed first order. The size of the discontinuity is unimportant in terms of the classification of the phase transition, but there are diverse systems with either very large or rather small 'jumps'. In contrast, for second-order phase transitions the first derivatives are continuous, and transitions (critical points) at some temperature T_c (critical temperature) and 'field' H (critical field) are characterized by singularities in the second derivatives of the free energy. Properties of different systems can then be related by considering not the absolute temperature but instead the *reduced distance* from the transition $\varepsilon = |1 - T/T_c|$. (We note that the notation in the literature has varied over time. Initially the symbol ε was used to represent the 'distance' from the critical point, but as expansion methods in renormalization group (RG) theory were developed, the symbol ε took on the meaning of the difference between the spatial dimension of the system and the 'upper critical dimension' at which the transition became mean-field-like. The symbol t was then introduced in the place of ε. Then, however, the increased performance of computers and algorithms made computer simulations more important in the study of magnetic models. In simulations, the symbol t generally represented 'time', so it again became common to use ε to denote the *reduced distance* from the transition. The reader must be careful to determine what convention is being used in a given publication.) At a first-order phase transition, the free-energy curves for ordered and disordered states cross with a finite difference in slope, and both stable and metastable states may exist for some region of temperature beyond the transition. In contrast, at a second-order transition the two free-energy curves meet tangentially and no metastability is seen (in the usual sense). In the following discussion we will consider a portion of the diversity of magnetic phase transitions that may exist and provide estimates for important 'characteristic' quantities. Since first-order phase transitions do not have the same underlying, unifying characteristics that second-order transitions have, very little can be theoretically predicted about them without specific knowledge of the nature and interaction constants for a particular system. Consequently, second-order transitions will prove to be far more interesting and, thus, will consume a greater part of the presentation in the remainder of this article, and the reader is referred elsewhere (Binder, 1987) for a more detailed discussion of first-order transitions.

The wealth of information provided about magnetic phase transitions via numerous careful, high-quality experiments has been important in helping to guide the development of ideas about phase transitions. Nevertheless, substantial difficulties remain for experiments: Sample quality is always a problem, for example, grain boundaries, impurities, and so on, so that the approach to the critical temperature is limited by 'rounding'. Since the asymptotic critical region is often restricted to very small distances from the critical point, experiment may not always explore the asymptotic behavior near T_c. Consequently, computer simulations sometimes provide the best 'experimental' information. On the other hand, a magnetic system may be so complex that appropriate models cannot be solved analytically. In this case, computer simulations provide 'theoretical' information for comparison with experiment. In this article we shall thus include results from a variety of analytical and computational approaches under the general rubric of 'theory', although a more accurate view of approaches to the study of magnetic phase transitions can be depicted schematically by Figure 1.

We wish to emphasize that the theory of magnetic phase transitions is an extremely rich topic (see Fisher, 1967; Landau, 1996 for earlier reviews), and it is impossible to cover all relevant aspects in a limited amount of space. Some (subjective) selection of topics must be made, and the author apologizes at the outset to those researchers whose high-quality work is not mentioned.

In the following section we will review some background and general concepts that are essential for understanding the theory of magnetic phase transitions. In Section 3 we will

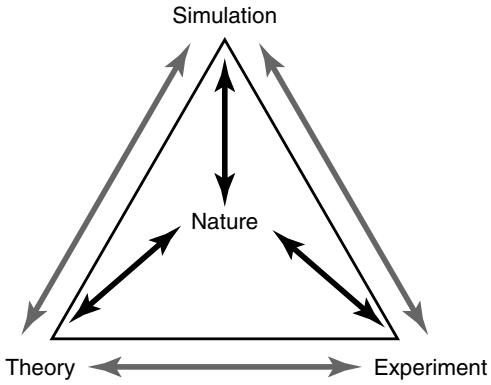

Figure 1. Schematic view of possible approaches that have been applied to the study of magnetic phase transitions.

describe specific theoretical and computational approaches that are applicable to the study of phase transitions. Some detail will be provided about these techniques to help the reader understand the advantages and limitations of each method. In Section 4 we will present some numerical results for several different models and consider the general state of our knowledge. A few final conclusions will be drawn in the final section.

2 BACKGROUND AND GENERAL CONCEPTS

2.1 Static critical behavior and critical exponents

As mentioned in Section 1, the behavior of thermodynamic properties near second-order phase transitions can be described using a formalism in which the fundamental quantity is the reduced distance from the critical temperature. Extensive experimental research has long provided a testing ground for developing theories (Kadanoff *et al*., 1967), and more recently computer simulations have been playing an increasingly important role. Of course, experiments are limited not only by instrumental resolution but also by unavoidable sample imperfections; consequently, the beautiful specific-heat peak for $RbMnF_3$, shown in Figure 2, is quite difficult to characterize for $\varepsilon \leq 10^{-4}$. Data from multiple experiments as well as analytic and numerical results for a number of exactly soluble models show that the thermodynamic properties can be described by a set of simple power laws in the vicinity of the critical point T_c, for example, for a magnetic system, the order parameter m, the specific heat C, the susceptibility χ, and the correlation length ξ vary as (Stanley, 1971; Fisher, 1974)

$$m = m_o \varepsilon^{\beta} \tag{4a}$$

$$\chi = \chi_o \varepsilon^{-\gamma} \tag{4b}$$

$$C = C_o \varepsilon^{-\alpha} \tag{4c}$$

$$\xi = \xi_o \varepsilon^{-v} \tag{4d}$$

where $\varepsilon = |1 - T/T_c|$ and the powers (Greek characters) are termed 'critical exponents'. Note that equations (4a–d) represent asymptotic expressions, which are valid only in the limit as $\varepsilon \to 0$, and more complete forms would include additional 'corrections to scaling' terms, which describe the deviations from the asymptotic behavior. Consequently, the behavior of the susceptibility χ near a critical point is better described by

$$\chi = \chi_o \varepsilon^{-\gamma}(1 + a_\theta \varepsilon^{\theta} + \cdots) \tag{5}$$

where only the first correction term, characterized by the exponent θ, is shown. (Similar corrections are present for other quantities.) The extraction of estimates for this new exponent, however, is notoriously difficult to accomplish.

Although the critical exponents for each thermodynamic quantity are believed to be identical when T_c is approached from above or below (but the singularity in the order parameter occurs only below T_c), the prefactors, or 'critical amplitudes', are usually different, and the estimation of various amplitude ratios has been of extensive interest (Privman, Hohenberg and Aharony, 1991). Lastly, along the critical isotherm, that is, at $T = T_c$, we can define another critical exponent using an expression which for a ferromagnet in a uniform applied field H is

$$m = DH^{1/\delta} \tag{6}$$

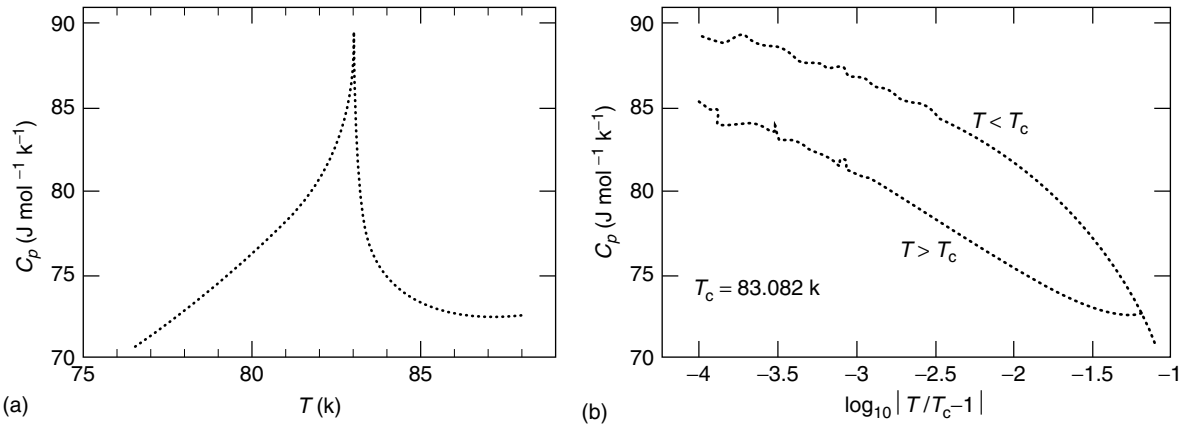

Figure 2. (a) Experimental data and (b) analysis of the critical behavior of the specific heat of the Heisenberg-like antiferromagnet $RbMnF_3$. The critical temperature is T_c. (Reproduced from Kornblit, A. and Ahlers, G. (1973), with permission from the American Physical Society. © 1973.)

(Note that an analogous expression would apply for a liquid–gas system at the critical temperature as a function of the deviation from the critical pressure.) For a system in d dimensions the two-body correlation function defined in equation (3), $G(r)$, should decay with distance well above the critical temperature with the Ornstein–Zernike form

$$G(r) \propto r^{-(d-1)/2} \exp(-r/\xi), \quad r \to \infty \tag{7}$$

Instead, at T_c the decay of the correlation function is given by a power law

$$G(r) = G_o r^{-(d-2+\eta)}, \quad r \to \infty \tag{8}$$

where η is another characteristic critical exponent. Systems that have the same set of critical exponents are said to belong to the same 'universality class'.

2.2 Some systems of special interest

2.2.1 The Ising model

The critical exponents defined in the previous section are known exactly for only a small number of magnetic models, most notably the two-dimensional Ising square lattice (Onsager, 1944), whose exact solution shows a logarithmic divergence of the specific heat. The simple Ising model (Ising, 1925; Brush, 1967), with Hamiltonian

$$\mathcal{H} = -J \sum_{\text{nn}} \sigma_i \sigma_j \tag{9}$$

where $\sigma_i = \pm 1$ has played a special 'fruit fly' role in the development of our understanding of phase transitions. This is, in part, because of its simplicity and, in part, because the model on a square lattice is one of the few cases that can be solved exactly. Onsager's solution yields a critical point at $k_B T_c/J = 2.26159\ldots$ (where k_B is Boltzmann's constant), and the critical exponents for this model are $\alpha = 0$, $\beta = 1/8$, $\gamma = 7/4$, $\nu = 1$, and $\eta = 1/4$. (In three dimensions, however, an exact solution is lacking even after many decades of attempts to find one.) A simple, nearest-neighbor (nn) Ising antiferromagnet on a bipartite lattice in a uniform magnetic field has the same critical exponents for all field values below H_c, the $T = 0$ critical field. This remarkable behavior will become clearer when we consider the problem in the context of RG theory.

2.2.2 The Heisenberg model

Many magnetic systems, however, cannot be described by an Ising model. As an example, we show in Figure 2 that the experimental data for the specific heat of $RbMnF_3$ increases even more slowly than a logarithm as $\varepsilon \to 0$ implying that $\alpha < 0$, that is, the specific heat is nondivergent. In fact, a suitable theoretical model for $RbMnF_3$ is not the Ising model but a 3-dim Heisenberg model with classical spins of unit length and nn interactions

$$\mathcal{H} = -J \sum_{\text{nn}} (S_{ix} S_{jx} + S_{iy} S_{jy} + S_{iz} S_{jz}), \quad |\vec{S}_i| = 1 \tag{10}$$

which has slightly different critical exponents than the Ising model. (The Mn^{2+} ions have spin $S = 5/2$ and can thus be well described by classical spins.) Although no exact solutions are available for Heisenberg models, as we shall see later, quite precise values of the exponents are available from field theoretic RG (Le Guillou and Zinn-Justin, 1980) and extensive Monte Carlo simulations, at least for classical spin version (Chen, Ferrenberg and Landau, 1993). There are even better known magnetic systems, like body centered cubic (bcc) iron, whose behavior also appears to be well described by a classical Heisenberg model. Of course, many real magnetic systems cannot be described by a classical version of the Heisenberg model and, particularly at low temperatures, the quantum effects can become important. Extensive series expansions indicate, however, that near a finite temperature phase transition the critical exponents are independent of spin value, although the critical amplitudes are not. For this reason, we can expect that the essential character of phase transitions in most physical Heisenberg spin systems can be described by classical spin models.

2.2.3 2-dim XY model

The preceding picture is still incomplete because there are special cases that do not fit into that general scheme at all. Most notable are 2-dimensional XY models with Hamiltonian

$$\mathcal{H} = -J \sum_{\text{nn}} (S_{ix} S_{jx} + S_{iy} S_{jy}) \tag{11}$$

where $\vec{S}_i$ is a unit vector that may have either two components (plane-rotator model) or three components (XY model). The Mermin–Wagner theorem has shown that in 2-dim (two spatial dimensions), at any nonzero temperature, classical spin models are unstable against the spontaneous formation of spin waves that destroy the long-range order. Because of this, the 2-dim Heisenberg model shows no phase transition at any $T > 0$. Although the 2-dim XY model also develops no long-range order below any nonzero transition temperature, it does nonetheless possess topological excitations termed vortices and antivortices; and below some transition temperature, T_{KT}, vortex–antivortex pairs become

bound together (Kosterlitz and Thouless, 1973). Both the correlation length and magnetic susceptibility for this model are predicted to diverge exponentially fast as T_{KT} is approached from above, that is,

$$\xi \propto \exp(a\varepsilon^{-\nu}) \tag{12}$$

and every temperature below T_{KT} is a critical point. Furthermore, the value of ν is predicted to be 1/2 for both quantities. At T_{KT} the correlation function should decay with distance, r, as $r^{-\eta}$ with $\eta = 1/4$. For all lower temperatures, the decay should still be a power law, but with a power that becomes smaller with decreasing temperature. Another characteristic of this phase transition is that the helicity modulus Υ drops discontinuously from $\Upsilon = 0.636508\ldots$ to zero at the transition. (The helicity modulus gives the reaction of the system to a twist.) In summary, there are a number of explicit predictions about the character of this unusual transition.

2.2.4 *Blume–Capel model*

As mentioned earlier, not all magnetic phase transitions are of second order. One classic example of a real system is UO_2 which was shown, half a century ago, to possess a first-order transition at about 30 K from a high-temperature paramagnetic state to a low-temperature antiferromagnetic state. Blume (1966) proposed a simple model in which a singlet electronic ground state was separated from a higher-lying triplet at an energy Δ above the ground state. Furthermore, this triplet would be split by near-neighbor exchange couplings, and Blume showed, using mean-field (Landau) theory, that if Δ is sufficiently small, one of the triplet components would lie below the singlet. Hence, an ordered ground state will result. If, however, Δ is sufficiently large, the transition will become first order. Lastly, if Δ exceeds a certain value, the ground state is always a singlet and no magnetic ground state results. A similar scenario was investigated by Capel (1966), who considered a similar Hamiltonian, but with a high-lying doublet instead of a triplet. This latter model has become known as the Blume–Capel model, that is,

$$\mathcal{H} = -J \sum_{\text{nn}} \sigma_i \sigma_j + D \sum_i \sigma_i^2, \quad \sigma_i = 1, 0, -1 \tag{13}$$

The Blume–Capel model has played an important role in the development of our understanding of some multicritical phenomena, which will be outlined in the next section.

2.2.5 *Other interesting models with unusual behavior*

Simple extensions of the 2-dim Ising model, for example, with three-body couplings instead of two-body interactions, known as the Baxter–Wu model (Baxter and Wu, 1973), or with enhanced next-nearest-neighbor (nnn) couplings may have critical behavior that is distinctly different from the simple Ising model. Another 'classic' model is the q-state Potts model (Potts, 1952; Wu, 1982) for which the Hamiltonian is

$$\mathcal{H} = -J \sum_{\text{nn}} \delta_{\sigma_i \sigma_j}, \quad \sigma_i = 1, 2, \ldots q \tag{14}$$

This model may show either first-order or second-order transitions, depending upon the number of states q. There are many other classical spin models with suitable competing interactions or lattice structures that may also show 'unusual' transitions (Landau, 1993), which, in some cases, include different behavior of multiple order parameters at T_c. These models are generally best studied by computer simulation, but to a large extent will not be considered here because of space limitations.

The preceding discussion was limited to static aspects of phase transitions and critical phenomena. The entire question of dynamic behavior will be treated in a later subsection using extensions of the current formulation.

2.3 Scaling and universality

Homogeneity arguments provide a way of simplifying mathematical expressions that contain thermodynamic singularities. As an example, consider a simple Ising ferromagnet in a small uniform magnetic field H at a temperature T that is near T_c. A 'scaling' form can be used to express the singular portion of the free energy $F(T, H)$ as

$$F_s = \varepsilon^{2-\alpha} \Im^{\pm}(H/\varepsilon^{\Delta}) \tag{15}$$

where Δ is termed the 'gap exponent' and is equal to $1/2(2 - \alpha + \gamma)$. $\Im^{\pm}$ is a function of the 'scaled' variable (H/ε^{Δ}) and does not depend upon H and ε independently. This formula has the consequence that the expressions for various thermodynamic quantities, for example, specific heat, susceptibility, and so on, can also be written in scaling forms. Even the correlation function can be expressed in terms of a scaling function but requires an extra variable, that is,

$$G(r, \xi, \varepsilon) = r^{-(d-2+\eta)} \wp(r/\xi, H/\varepsilon^{\Delta}) \tag{16}$$

where $\wp(x, y)$ is now a scaling function of two variables.

With a bit more mathematical development, one can show that not all of the critical exponents defined in the preceding text are independent. Thermodynamic arguments can be used to derive a series of exponent relations called 'scaling laws', which show that only two exponents are generally unrelated.

For example, taking the derivative of the free energy, as expressed in a scaling form, we find that the singular part near a phase transition behaves as

$$-\frac{\partial F_{\sin g}}{\partial H} = M = \varepsilon^{2-\alpha-\Delta}\Im'(H/\varepsilon^{\Delta}) \tag{17}$$

where $\Im'$ is the derivative of the function $\Im$. This equation can be compared directly with the formula for the temperature dependence of the order parameter to show that $\beta = 2 - \alpha - \Delta$. Similarly, by integrating a scaling expression for the magnetic susceptibility

$$\chi = \varepsilon^{-\gamma}\tilde{\chi}(H/\varepsilon^{\Delta}) \tag{18}$$

we find

$$m \propto \varepsilon^{\Delta-\gamma} \tag{19}$$

The combination of these relations yields the 'Rushbrooke equality'

$$\alpha + 2\beta + \gamma = 2 \tag{20}$$

and this relationship should hold regardless of what the individual exponent values are. Another important relationship that exists between critical exponents and the lattice dimensionality d of a system is termed the 'hyperscaling' expression:

$$\mathrm{d}\upsilon = 2 - \alpha \tag{21}$$

The physical justification of the homogeneity assumption given in equation (15) is discussed elsewhere, for example, Yeomans (1992); however, these scaling relations are a prerequisite for the understanding of finite size scaling, which is a basic tool in the analysis of simulational data near phase transitions. Hyperscaling may sometimes be violated, for example, the upper critical (spatial) dimension for the Ising model is $d = 4$ beyond which mean-field (Landau theory) exponents apply and hyperscaling fails. Integration of the spin–spin correlation function over all spatial separation yields the magnetic susceptibility

$$\chi = \varepsilon^{-\upsilon(2-\eta)} \tag{22}$$

and by comparing with the 'definition', cf. equation (4b), of the critical behavior of the susceptibility we easily see that

$$\gamma = \upsilon(2 - \eta) \tag{23}$$

Those systems that have the same set of critical exponents are said to belong to the same 'universality class' (Fisher, 1974), although, some of the critical exponents in different universality classes may be similar. Relevant properties that determine the universality class include spatial dimensionality, spin dimensionality, symmetry of the ordered state, the presence of symmetry-breaking fields, and the range of interaction. Thus, nn Ising ferromagnets on different lattices of the same dimensionality should have identical critical exponents and belong to the same universality class, but square-lattice and sc Ising models would be expected to have different critical behavior.

Some models have simple symmetries that can be easily broken. For example, an isotropic ferromagnet changes from the Heisenberg universality class to the Ising class when exchange anisotropy is introduced:

$$\mathcal{H} = -J\sum_{i,j}[(1-\lambda)(S_{ix}S_{jx} + S_{iy}S_{jy}) + S_{iz}S_{jz}] \tag{24}$$

with $\lambda > 0$. The variation of the critical temperature is then given by

$$T_{\mathrm{c}}(\lambda) - T_{\mathrm{c}}(\lambda = 0) \propto \lambda^{1/\phi} \tag{25}$$

where ϕ is termed the 'crossover exponent' (Riedel and Wegner, 1972). If $\lambda < 0$, however, the model becomes an easy-axis magnet and should have XY-model critical behavior instead.

Before leaving the topic of scaling, we will introduce an important, related approach to the understanding of the behavior of finite system size. At a second-order phase transition, the critical behavior of a system in the thermodynamic limit can be extracted from the size dependence of the singular part of the free energy using finite size scaling theory (Fisher, 1971; Landau, 1976; Privman, 1990; Binder, 1992). If we adopt a scaling ansatz similar to the scaling of the free energy with thermodynamic variables T, H and infinite lattice critical exponents α and υ, we can write the free energy for a system of linear dimension L as

$$F(L, T) = L^{(2-\alpha)/\upsilon}\Im(\varepsilon L^{1/\upsilon}) \tag{26}$$

where $\varepsilon = (T - T_{\mathrm{c}})/T_{\mathrm{c}}$. The choice of the scaling variable $x = \varepsilon L^{1/\nu}$ is motivated by the observation that the correlation length ξ attempts to diverge as $\varepsilon^{-\nu}$ when the transition is approached but is limited by the lattice size L. Thermodynamic properties then also have corresponding scaling forms, for example,

$$m = L^{-\beta/\upsilon}\mathcal{M}^{\mathrm{o}}(\varepsilon L^{1/\upsilon}) \tag{27a}$$

$$\chi = L^{\gamma/\upsilon}\chi^{\mathrm{o}}(\varepsilon L^{1/\upsilon}) \tag{27b}$$

$$C = L^{\alpha/\upsilon}\mathcal{C}^{\mathrm{o}}(\varepsilon L^{1/\upsilon}) \tag{27c}$$

where $\mathcal{M}^{\rm o}$(x), $\chi^{\rm o}$(x), and $\mathcal{C}^{\rm o}$(x) are finite size scaling functions. These expressions are valuable for interpreting data for finite systems obtained by a variety of numerical methods as well as for understanding the relationship between experimental data on small systems and in the corresponding thermodynamic limit. Corrections to scaling and finite size scaling must be taken into account for yet smaller systems and temperatures away from $T_{\rm c}$. Because of the complexity of the origins of these corrections, we direct the reader elsewhere (Liu and Fisher, 1990; Ferrenberg and Landau, 1991) for a detailed discussion of these corrections and techniques for including them in the analysis of MC data.

An alternative form for finite size scaling was proposed (Kim, 1994) in terms of the variable $x = \xi_{\rm L}/L$ where $\xi_{\rm L}$ is the correlation length in a system of linear dimension L. Kim, de Souza and Landau (1996) demonstrated that this approach was surprisingly effective for the Ising model even though the data used in the analysis were taken rather far from the critical temperature.

Finite size scaling has revealed important 'new' information about the nature of critical phenomena. In a classic paper, Binder (1981) examined the distribution functions for the order parameter in finite size systems and in subblocks of such systems. In particular, he showed that in addition to the first two moments of the distribution, that is, the order parameter and the susceptibility, the fourth-order cumulant also provided important information. For a system with time-reversal symmetry, the fourth-order cumulant is defined by

$$U_L = 1 - \frac{\langle m^4 \rangle}{3\langle m^2 \rangle^2} \tag{28}$$

although, in the general case, the full cumulant must be used (included odd moments, which do not then vanish). However, the 'reduced' form (also known as the *Binder parameter*) has become a valuable tool for the determination of the universality class of a model from simulational data.

As mentioned earlier, critical behavior depends upon the dimensionality of the system. An interesting question then arises: how can we understand how the critical behavior changes as the system changes from 2-dim to 3-dim. This too can be predicted using a slight adaptation of finite size scaling. For a system of n layers, the order parameter is given by

$$m = n^{-\beta_3/\nu_3} \mathcal{M}^{\rm o}(\varepsilon n^{1/\nu_3}) \tag{29}$$

where ν_3 describes the divergence of the correlation length in the 3-dim system. For small values of $(z - z_c)$, where $z = (\varepsilon n^{1/\nu_3})$ and z_c is the value obtained using $T_{\rm c}(n)$, the scaling function $\mathcal{M}^{\rm o}(z) \to (z - z_c)^{\beta_2}$. Thus, crossover from 3-dim to 2-dim behavior occurs, and it shows up in the 'critical amplitude' (Binder, 2003). However, as $n \to \infty$, $\mathcal{M}^{\rm o}(x) \to x^{\beta_3}$ so that 3-dim critical behavior is recovered. One consequence is that the shift in critical temperature is expected to be

$$\frac{T_{\rm c}(\infty) - T_{\rm c}(n)}{T(\infty)} \propto n^{-\phi} \tag{30}$$

where ϕ is the 'shift exponent'. Normally, $\phi = 1/\nu_3$, that is, hyperscaling holds.

For first-order transitions, the size dependence is governed by the system volume, that is, L^d, and the underlying theoretical formulations for both temperature-driven phase transitions (Challa, Landau and Binder, 1986) and field-driven phase transitions (Binder and Landau, 1984) have been examined via Monte Carlo simulations.

2.4 Phase diagrams and multicritical behavior

For some magnets, for example, antiferromagnets, phase boundaries will be traced out in a multidimensional thermodynamic parameter when some thermodynamic field, for example, uniform magnetic field, is varied. Perhaps the classic example of a thermodynamic phase diagram is that of water, in which lines of first-order transitions separate ice–water, water–steam, and ice–steam. The three first-order transitions join at a 'triple point', and the water–steam phase line ends at a 'critical point' where a second-order phase transition occurs. A much simpler phase diagram than that for water occurs for the Ising ferromagnet in a magnetic field

$$\mathcal{H} = -J \sum_{\rm nn} \sigma_i \sigma_j - H \sum_i \sigma_i \tag{31}$$

where $\sigma_i = \pm 1$ represents a 'spin' at lattice site i that interacts with nearest neighbors on the lattice with interaction constant $J > 0$. At low temperatures a first-order transition occurs as H is swept through zero, and the phase boundary terminates at the critical temperature $T_{\rm c}$. Time-reversal symmetry requires that the phase boundary must occur at magnetic field $H = 0$ so that the only remaining 'interesting' question is the location of the critical point. For $J < 0$, the antiferromagnetic phase remains stable in nonzero field, although the critical temperature is depressed. The phase boundary for the Ising antiferromagnet has defied analytic solution although there are several rather precise numerical determinations of its shape. As in the case of the ferromagnet, the phase diagram is symmetric about $H = 0$.

Under certain circumstances, the order of a phase transition changes as some thermodynamic parameter is modified. At first glance such behavior appears to violate the principles of universality, but examination of the system in a larger thermodynamic space makes the change easy to understand.

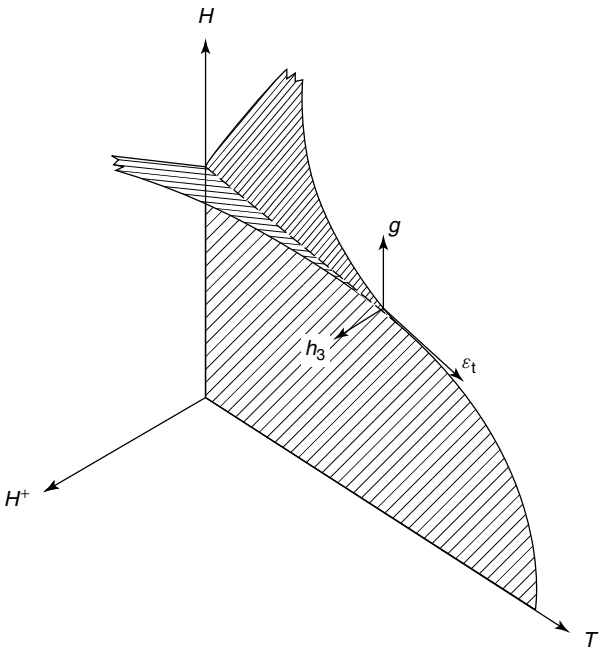

Figure 3. Phase diagram for an Ising antiferromagnet with a tricritical point in the three-dimensional thermodynamic field space, which includes both ordering (H^+) and nonordering (H) fields. Tricritical scaling axes are labeled ε_t, g, and h_3.

The intersection point of multiple curves of second-order phase transitions is known as a multicritical point. Examples include the intersection of three such curves, known as a tricritical point (Griffiths, 1970; Stryjewski and Giordano, 1977; Lawrie and Sarbach, 1984), which occurs in strongly anisotropic ferromagnets. The intersection of two second-order phase boundaries, or a bicritical point (Fisher and Nelson, 1974; Nelson, Kosterlitz and Fisher, 1974), appears on the phase boundary of a moderately anisotropic Heisenberg antiferromagnet in a uniform magnetic field. In this latter system, at low temperature a low-field antiferromagnetic state is separated from a 'spin-flop' state by a line of first-order transitions. This line ends at a bicritical point at which the second-order phase boundaries to the ordered high-field and low-field states meet. The characteristic phase diagram for a tricritical point is shown in Figure 3 in which three first-order surfaces intersect along a line of first-order transitions and the three second-order boundaries to the first-order surfaces of phase transitions meet at the tricritical point. This is one of the simplest cases of a more general set of transitions that are known as multicritical points. One of the well-known models that exhibits such behavior is the Ising antiferromagnet with nn and nnn coupling

$$\mathcal{H} = J_{\mathrm{nn}} \sum_{\mathrm{nn}} \sigma_i \sigma_j - J_{\mathrm{nnn}} \sum_{\mathrm{nnn}} \sigma_i \sigma_j - H \sum_i \sigma_i - H^+ \sum_i \sigma_i \tag{32}$$

where $\sigma_i = \pm 1$, H is the uniform magnetic field, which couples to the uniform magnetization, and H^+ is the staggered magnetic field, which couples to the order parameter (staggered magnetization). The presence of a tricritical point introduces a new 'relevant' field g, which as shown in Figure 3 makes a nonzero angle with the phase boundary, and a second scaling field ε_t, which is tangential to the phase boundary at the tricritical point. Near the tricritical point a 'crossover' scaling expression is valid

$$F(\varepsilon, H^+, g) = |g|^{2-\alpha_\varepsilon} \Im(H^+ |g|^{-\Delta_\varepsilon}, \varepsilon |g|^{-\phi_\varepsilon}) \tag{33}$$

where α_ε is the specific-heat exponent appropriate for a tricritical point, Δ_ε is the corresponding 'gap exponent', and ϕ_ε is a new 'crossover' exponent that describes the separation between the critical region near the second-order line and the tricritical region near the tricritical point. In addition, there are power law relations that describe the vanishing of discontinuities as the tricritical point is approached from below, for example, the jump in the magnetization from M^- to M^+ as the first-order phase boundary is crossed for $T < T_t$ decreases as

$$\Delta M = M^+ - M^- \propto |1 - T/T_{\mathrm{t}}|^{\beta_u} \tag{34}$$

The 'u-subscripted' exponents are related to the 'ε-subscripted' ones by a crossover exponent,

$$\beta_u = (1 - \alpha_\varepsilon)/\phi_\varepsilon \tag{35}$$

as will be discussed subsequently, the mean-field values of the tricritical exponents are $\alpha_\varepsilon = 1/2$, $\Delta_\varepsilon = 5/2$, $\phi_\varepsilon = 1/2$, and hence $\beta_u = 1$. Tricritical points have been explored using both computer simulations of model systems and by experimental investigation of physical systems, and their theoretical aspects have been studied in detail (Lawrie and Sarbach, 1984).

Mean-field theory predicts that for sufficiently strong coupling between spins in the same sublattice, the tricritical point may decompose into a critical endpoint and a double critical point with the topology shown in Figure 4. Qualitatively, the possible occurrence of the phase diagram in Figure 4 rather than of Figure 3 can be understood from mean-field theory, although the quantitative predictions for the conditions for which this should happen turn out to be incorrect.

Another kind of multicritical behavior occurs in an anisotropic Heisenberg antiferromagnet with a uniform magnetic field included. The Hamiltonian is

$$\mathcal{H} = -J \sum_{\mathrm{nn}} [(1 - \lambda) S_{ix} S_{jx} + S_{iy} S_{jy} + S_{iz} S_{jz}] - H \sum_i S_{iz} \tag{36}$$

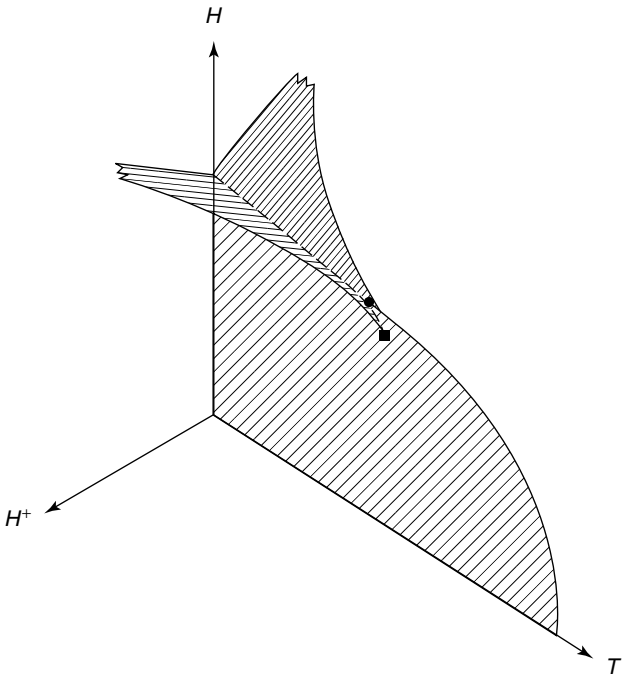

Figure 4. Schematic view of phase diagram for which the tricritical point has decomposed into a critical endpoint (filled circle) and a double critical point (filled square).

For small magnetic fields, there is an ordered antiferromagnetic state at low temperatures and as the temperature is increased an Ising-like transition occurs to the paramagnetic state. If instead, the field is increased, a first-order transition to a 'spin-flop' state takes place. In this state the z components of the spins are aligned along the field but the x and y components are antiferromagnetically aligned. At fields above the spin-flop field, with increasing temperature, there is an XY transition involving the perpendicular spin components. At the confluence of the two phase boundaries, that is, at the end of the spin-flop phase boundary, there is a single bicritical point with Heisenberg behavior. As the phase boundaries approach the bicritical point, they form an umbilicus that is completely missing in mean-field theory. Scaling axes for the bicritical point are predicted to be skew and have the following form

$$g = \Delta(H^2) - p\varepsilon_b \tag{37a}$$

$$\tilde{\varepsilon} = \varepsilon_b + q\Delta(H^2) \tag{37b}$$

where $\Delta(H^2) = H^2 - H_b^2$ and $\varepsilon_b = |1 - T/T_b|$. The shapes of the upper and lower phase boundaries near the bicritical point are predicted to be determined by the crossover scaling form

$$g/\tilde{\varepsilon}^{\phi} = +w_{\perp}, -w_{||} \tag{38}$$

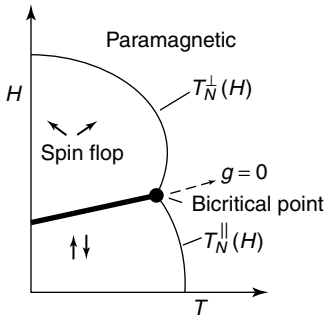

Figure 5. Schematic phase diagram predicted for an anisotropic Heisenberg antiferromagnet. The heavy solid line is a first-order transition and the lighter solid lines are second-order transitions. For fields below the bicritical point, the order parameter is the staggered magnetization component that is parallel to the applied field; above the bicritical point, the perpendicular staggered magnetization is critical.

where $w_{\perp}, w_{||}$ are model dependent and may also differ above and below the bicritical point. This behavior for an anisotropic Heisenberg antiferromagnet is shown schematically in Figure 5. We conclude this section with a comment about analysis of critical exponents when the appropriate scaling fields are not parallel to the 'applied' thermodynamic fields. In such cases, 'field mixing' can complicate the analysis, and we refer the reader elsewhere (Wilding and Bruce, 1992; Wilding, 1995) for a more detailed discussion.

2.5 Surface critical behavior

Although it had long been common to only consider phase transitions in systems of infinite extent, several authors realized that critical behavior that is explicitly associated with surfaces of magnetic systems was itself of interest (for a detailed description of surface transitions, see Binder, 1983). Binder and Hohenberg (1972, 1974) realized that a new set of surface critical exponents could be defined that were not necessarily related to the exponents of the corresponding bulk. For example, if the free energy is separated into a bulk term f_b and a surface term f_s in analogy with the bulk magnetization, defined using a bulk field H,

$$m_{\mathrm{b}} = -\left(\frac{\partial f_{\mathrm{b}}}{\partial H}\right) \tag{39}$$

we can define a surface layer magnetization

$$m_1 = -\left(\frac{\partial f_{\mathrm{s}}}{\partial H_1}\right) \tag{40}$$

where H_1 is a magnetic field that acts only on the surface layer. There are also new thermodynamic response functions,

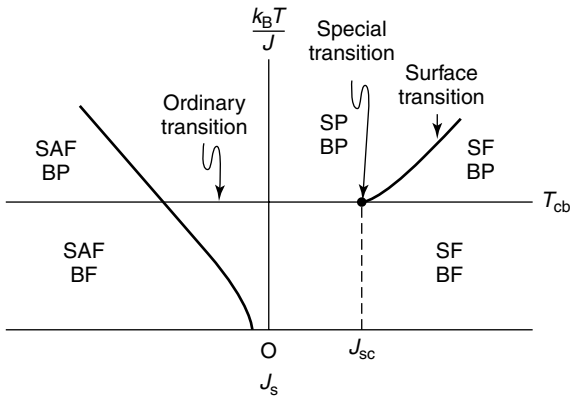

Figure 6. Schematic view of phase transition behavior occurring at the surface of a semi-infinite magnetic system. Each phase is labeled according to whether it is bulk (B) or surface (S) and ferromagnetic (F) or antiferromagnetic (AF). J_{sc} denotes the coupling for the surface–bulk multicritical point. (Reproduced from K. Binder: 'Critical Behavior at Surface' in C. Domb and J.L. Lebowitz (eds): *Phase Transitions and Critical Phenomena*, vol. 8 (Academic Press, 1983), with permission from Elsevier.)

such as the magnetic susceptibility, that appear in addition to the bulk ones, that is,

$$\chi_b = -\left(\frac{\partial^2 f_b}{\partial H^2}\right) \tag{41a}$$

$$\chi_1 = -\left(\frac{\partial^2 f_s}{\partial H \partial H_1}\right) \tag{41b}$$

$$\chi_{1,1} = -\left(\frac{\partial^2 f_s}{\partial H_1^2}\right) \tag{41c}$$

Binder and Hohenberg also worked out a schematic (mean field) phase diagram, shown in Figure 6, that shows the general features for a phase diagram for a simple model with an exchange parameter J in the bulk and a surface interaction constant J_s, as the temperature is varied. The 'special transition' is a multicritical point at which bulk and surface fluctuations become simultaneously critical at temperature $T_{cs} \equiv T_{cb}$. Separate sets of surface critical exponents should describe the different kinds of transitions, for example,

$$m_1 \propto (1 - T/T_{cs})^{\beta_1} \tag{42}$$

The mean-field values of the surface exponents often differ at the ordinary transition, the special transition, and the surface transition and may also differ from the bulk exponents:

$$\beta_b = 1/2; \quad \beta_{ord} = 1; \quad \beta_{sp} = 1/2; \quad \beta_{surf} = 1/2;$$
$$\gamma_b = 1; \quad \gamma_{1,ord} = 1/2; \quad \gamma_{1,sp} = 1; \quad \gamma_{1,surf} = 1;$$
$$\gamma_{11,ord} = -1/2; \quad \gamma_{11,sp} = 1/2; \quad \gamma_{11,surf} = 1$$

There are additional thermodynamic properties that have distinct surface behavior, but we will not discuss this topic further. For more details see Binder (1983).

2.6 Systems with disorder

Systems with extreme disorder that produces frustration develop spin glass order, but this behavior is beyond the scope of this article. In this section we will only be concerned with the introduction of modest amounts of quenched (i.e., nonmobile) site or bond disorder that does not change the nature of the ordered state. When the concentration of impurities exceeds a critical level, the magnetic bonds can no longer percolate, and no long-range order can occur. The seminal paper on the effects of nonmagnetic impurities by Harris (1974) predicted that if random, quenched, nonmagnetic impurities are added to a magnetic system, new critical exponents will be produced only if $\alpha > 0$ in the pure system. Of course, there are other possible types of disorder and these will be discussed briefly later in Section 4.

2.7 Dynamic critical behavior

The framework for understanding the static behavior of magnetic systems near phase transitions has been rather thoroughly developed, in part because of the ability to make high-resolution experiments and in part because of the development of sophisticated numerical techniques. Understanding of the time-dependent behavior of magnetic properties of systems near phase transitions has proved more difficult.

As a critical point T_c is approached, the large spatial correlations that develop have long temporal correlations associated with them as well. At T_c the characteristic time scales diverge in a manner that is determined, in part, by the nature of the conservation laws. This 'critical slowing down' has been observed in multiple physical systems by light-scattering experiments (critical opalescence) as well as by neutron scattering. In a classic work, Hohenberg and Halperin (1977) laid the foundation for understanding dynamic critical behavior by proposing the existence of a number of dynamic universality classes on the basis of the number of degrees of freedom of the order parameter and the lattice and spin dimensionalities as well as any applicable conservation laws. The characteristic feature of the framework of dynamic critical behavior was the introduction of a new, dynamic critical exponent z that was distinct from, and in many cases unrelated to, the static critical exponents. One important conclusion was that multiple classes could exist for models with the same Hamiltonian but different conservation laws.

Two classes were identified as having only stochastic, or 'relaxational', behavior:

Model A – Ising model with neither magnetization nor energy conserved.
Model B – Ising model with conserved magnetization.

The conventional theory of critical slowing down (Van Hove, 1954) predicts that $z = 2 - \eta = 1.75$ for model A Ising critical relaxation, where η is the exponent describing the decay of the static, two-point correlation function at the critical point (equation 8). Model B should describe the growth of magnetic domains in a system with fixed magnetization and, according to Lifshitz–Slyozov theory (Lifshitz and Slyozov, 1961), the characteristic length scale $L(t)$ of the domains should grow as $t^{1/3}$.

Several other classes, however, have true dynamics, that is, deterministic behavior governed by equations of motion, derived from the Hamiltonian:

Model E – Planar spin model, $H_z = 0$
Model F – Planar spin model, $H_z > 0$
Model G – Antiferromagnetic Heisenberg model
Model J – Ferromagnetic Heisenberg model.

One consequence of this classification scheme is that there may be models that are in the same static universality class but in different dynamic classes. For example, an Ising model with 'spin-flip' kinetics and the same Ising model with 'spin-exchange' kinetics may be in different universality classes. Similarly, the Heisenberg model treated by Monte Carlo (stochastic) simulations and the same model solved by integrating coupled equations of motion may also be in different dynamic universality classes.

For relaxational models, such as the stochastic Ising model, the time-dependent behavior is described by a master equation

$$\partial P_n(t)/\partial t = -\sum_{n \neq m} [P_n(t) W_{n \to m} - P_m(t) W_{m \to n}] \qquad (43)$$

where $P_n(t)$ is the probability of the system being in state 'n' at time t, and $W_{n \to m}$ is the transition rate for $n \to m$. The solution to the master equation is a sequence of states developing in time, but the 'time' is a stochastic quantity that is not equivalent to true time. A quantitative measure of time correlations *within* equilibrium is obtained by first defining a relaxation function $\varphi(t)$, for example, for the magnetization M

$$\varphi_{MM}(t) = \frac{\langle M(0)M(t)\rangle - \langle M\rangle^2}{\langle M^2\rangle - \langle M\rangle^2} \qquad (44)$$

and a similar relaxation function can be defined for the internal energy. When normalized as in equation (44), the relaxation function is equal to unity at $t = 0$ and decays to zero as $t \to \infty$. The asymptotic, long-time decay of the relaxation function is exponential, that is,

$$\varphi(t) \to e^{-t/\tau} \qquad (45)$$

and the correlation time τ diverges as T_c is approached. This dynamic (relaxational) critical behavior can be expressed in terms of a power law as well

$$\tau \propto \xi^z \propto \varepsilon^{-\nu z} \qquad (46)$$

where ξ is the (divergent) correlation length, $\varepsilon = |1 - T/T_c|$, and z is the dynamic critical exponent. Estimates for z have been obtained for Ising models by ε-expansion RG theory (Bausch, Dohm, Janssen and Zia, 1981) but numerical estimates (Landau, Tang and Wansleben, 1988; Wansleben and Landau, 1991; Ito, 1993) have been inconsistent and have only recently come to reasonably consistent values.

The approach to equilibrium can be used to define another, nonlinear relaxation function

$$\varphi_M(t) = \frac{\langle M(t) - M(\infty)\rangle}{\langle M(0)\rangle - \langle M(\infty)\rangle} \qquad (47)$$

which also has an exponential decay at long times. According to Fisher and Rácz (1976), however, there is only a single, independent dynamic exponent and

$$z = z_{nl}^M + \beta/\nu \qquad (48)$$

or, in terms of the time dependence for the internal energy, then

$$z = z_{nl}^E + (1 - \alpha)/\nu \qquad (49)$$

At T_c the nonlinear relaxation is expected to decay at long times as a power law

$$m(t) \sim t^{-\beta/z\nu} \qquad (50)$$

and a 'local exponent', λ_m, extracted from Monte Carlo data,

$$\lambda_m = -\frac{\mathrm{d}\log m(t)}{\mathrm{d}\log t} \qquad (51)$$

should extrapolate to $\beta/z\nu$. The critical temperature can be determined by locating the temperature at which the nonlinear (nonequilibrium) relaxation obeys equation (50) and with use of the static critical exponents the dynamic exponent z can be estimated. Somewhat surprisingly, short time dynamics can also be used to extract information about critical dynamics and short time dynamic scaling has been

well established (Janssen, Schaub and Schmittmann, 1989; Zheng, 2006).

There are other systems, such as spin glasses and models with impurities, where the decay of the relaxation function is more complex, for example, a 'stretched exponential'

$$\varphi(t) \propto \exp[-(t/\tau)^n], \quad n < 1 \tag{52}$$

and the correct behavior of τ may not be simple. (In such cases, quite long observation times may be needed to measure the asymptotic behavior of the relaxation function.) Such systems are beyond the scope of this article and will not be considered further.

For continuous-spin systems with true dynamics, the time-dependent properties are determined by the dynamic structure factor

$$S(\vec{q}, \omega) = \frac{1}{2\pi} \sum_{\vec{r},\vec{r}'} e^{i\vec{q}\cdot(\vec{r}-\vec{r}')} \int_{-\infty}^{\infty} e^{i\omega t} C(\vec{r} - \vec{r}', t)\, \mathrm{d}t \tag{53}$$

The dynamic structure factor depends upon the static correlation length ξ and thus shows characteristic behavior as the critical temperature is approached. Near the critical temperature a dynamic scaling hypothesis can be formulated in terms of the behavior of the characteristic frequency ω_m in terms of the wave vector q and the correlation length ξ

$$\omega_m \propto \xi^{-z} \Omega(q\xi) \tag{54}$$

and the dynamic structure factor can also be written in a suitable scaling form

$$S(q, \omega) = \frac{2\pi}{\omega_m} S(q) F\left(\frac{\omega}{\omega_m}, q\xi\right) \tag{55}$$

The functional form for Ω in equation (54) will vary with the details of the model, but the dynamic critical exponent z should be invariant within a given dynamic universality class. The 'conventional theory' of critical dynamics (Van Hove, 1954) predicts that the behavior of the characteristic frequency is

$$\omega \propto \xi^{-z} (q\xi)^2 \tag{56}$$

with $z = 4 - \eta$. Mode-coupling theory and the RG were then used to make predictions about the values of the dynamic critical exponent z, and these generally differed from the predictions of the conventional theory. Within the context of the ε-expansion RG, the prediction for model A is $z = 2 + c\eta$ where $c = [6ln(4/3) - 1]$. The planar magnet is predicted to have exponent $z = d/2 + \alpha'/2\nu$ where $\alpha' = \max(\alpha, 0)$. For the isotropic Heisenberg antiferromagnet, RG theory predicts $z = d/2$, whereas for the isotropic ferromagnet the prediction is $z = (d + 2 - \eta)/2$. For a review of the theory and applicability to real materials see Frey and Schwabl (1994).

3 THEORETICAL APPROACHES

3.1 Landau theory

One of the fundamental approaches used to describe magnetic phase transitions is Landau theory, which begins with the assumption that near the transition the free energy of a system can be expanded in terms of the order parameter. For a d-dimensional system the free energy, in terms of a simple one-component order parameter $m(x)$, is given by

$$F = F_o + \int d^d x \left\{ \frac{1}{2} r m^2(x) + \frac{1}{4} u m^4(x) + \frac{1}{6} v m^6(x) - \frac{H}{k_B T} m(x) + \frac{1}{2d} [R \nabla m(x)]^2 + \ldots \right\} \tag{57}$$

In this equation, a factor of $(k_B T)^{-1}$ has been absorbed so the coefficients r, u, and v are dimensionless. (Time-reversal symmetry has also been used to eliminate all odd order terms for $H = 0$.) For more complex systems, additional terms, for example, cubic products of components of a multicomponent order parameter, might appear; but such considerations are beyond the scope of our present discussion. For a simple, homogeneous system with a spatially uniform order parameter the free energy becomes (V being the volume)

$$F = F_o + V \left(\frac{1}{2} r m^2 + \frac{1}{4} u m^4 + \frac{1}{6} v m^6 - \frac{mH}{k_B T} + \ldots \right) \tag{58}$$

In equilibrium, the free energy must be a minimum, and if $u > 0$ the preceding equation can be truncated and the minimization criterion $\partial F / \partial m = 0$ can be applied to find three possible solutions:

$$m_1 = 0 \tag{59a}$$

$$m_{2,3} = \pm\sqrt{-r/u} \tag{59b}$$

The first solution describes the disordered (i.e., $T > T_c$) state. Expanding r in the vicinity of T_c so that $r = r'(T - T_c)$, we find then for $r < 0$ (i.e., $T < T_c$),

$$m_{2,3} = \pm (r' T_c / u)^{1/2} (1 - T/T_c)^{1/2} \tag{60}$$

Solutions $m_{2,3}$ correspond to behavior below T_c where the order parameter approaches zero with a characteristic

power law (see equation 4a) with critical exponent $\beta = 1/2$. Similarly, an analysis of the susceptibility yields $\gamma = 1$ for the susceptibility and $\delta = 3$ for the order parameter along the critical isotherm. Unfortunately, Landau theory does not correctly describe the behavior of most physical systems that generally have values of $\beta \approx 1/3$ (Kadanoff *et al.*, 1967) instead of the Landau value of $\beta = 1/2$. Lastly, the 'fixed-point' (see the next section) value of the reduced fourth-order cumulant for the Landau (mean field) model with a one-component order parameter is $U^* \sim 0.2705$ (Brézin and Zinn-Justin, 1985).

The appearance of tricritical points can be easily understood within the context of Landau theory by retaining the sixth-order term in equation (58). If the term in m^4 is less than 0, the solutions are as follows:

$$m_1 = 0 \tag{61a}$$

$$m_{2,3} = \pm[\tfrac{1}{2v}(-u + \sqrt{u^2 - 4rv})]^{1/2} \tag{61b}$$

$$m_{4,5} = \pm[\tfrac{1}{2v}(-u - \sqrt{u^2 - 4rv})]^{1/2} \tag{61c}$$

The first solution again describes the disordered state. For positive values of v, there are multiple solutions showing long-range order and the phase transition is first order. A tricritical point appears when $r = u = 0$, and the tricritical exponents that result from this analysis are

$$\alpha_t = 1/2 \tag{62a}$$

$$\beta_t = 1/4 \tag{62b}$$

$$\gamma_t = 1 \tag{62c}$$

$$\delta_t = 5 \tag{62d}$$

Note that most of these tricritical exponents are quite different than those predicted for the critical point. The crossover exponent describing the behavior of the second-order phase boundary in the vicinity of the tricritical point is predicted by Landau theory to be $\phi = 1/2$.

As mentioned earlier, the thermodynamic properties of a system are not constant in time but fluctuate as the system explores different regions of phase space. The relative fluctuations of extensive thermodynamic variables scale inversely with the number of sites N, so that global fluctuations vanish in the thermodynamic limit. Nevertheless, local fluctuations can have dramatic effects and require a separate discussion. As long as fluctuations do not play a significant role, the predictions of Landau theory should be correct. This can be expressed mathematically for the fluctuations in $m(x)$ for a d-dimensional system over the 'correlation volume' ξ^d. If the mean value of the order parameter is m_o, fluctuations can be ignored if

$$\frac{\langle [m(x) - m_o]^2 \rangle}{m_o^2} \ll 1 \tag{63}$$

This inequality, termed the Ginsburg criterion, leads to the expression

$$\xi^d m_o^2 \chi^1 \gg \text{const} \tag{64}$$

Once the appropriate power laws for critical behavior are inserted into equation (64) the inequality becomes

$$\varepsilon^{-\nu d + 2\beta + \gamma} \gg \text{const} \tag{65}$$

This implies that Landau exponents will be valid if

$$\varepsilon^{(d-4)/2} \ll \text{const} \tag{66}$$

that is, the lattice dimensionality must be greater than or equal to an upper critical dimension $d_u = 4$. Below some lower critical dimensionality, d_l, fluctuations completely dominate and no transition will occur. Fluctuations at tricritical points can be examined if the next order term $\sim v m^6$ in the Landau free energy is retained. Mean-field theory (i.e., Landau theory) is also valid for tricritical behavior above some upper critical dimension for the Ising model with competing interactions $d_u = 3$. However, for $d = 3$ there are also logarithmic corrections (Wegner and Riedel, 1973), which complicate the verification of these predictions by numerical means.

Improvements on Landau, that is, mean field, theory are nontrivial to implement, particularly for systems with inhomogeneous interactions, for example, amorphous magnets. However, a correlated mean-field theory (Fähnle, Herzer, Egami and Kronmüller, 1982; Kronmüller and Fähnle, 2003) is able to describe the experimentally observed upward curvature in the inverse susceptibility for random exchange ferromagnets.

3.2 Renormalization group theory

The concepts of scaling and universality can be given a firm foundation through the use of RG theory. The fundamental physical ideas underlying RG theory were introduced by Kadanoff (1971) using a simple coarse-graining approach, and a mathematical basis was provided by Wilson (1971a,b). Instructional overviews of RG theory can be found in Domb and Green (1976) and Fisher (1974). Kadanoff subdivided a system into cells of characteristic size b (in terms of the nn spacing a) and $b < \xi$, where ξ is the correlation length of the system. The starting point is the expression of the singular

part of the free energy in terms of cell variables instead of the original site variables, that is,

$$F_{\text{cell}}(\tilde{\varepsilon}, \tilde{H}) = b^d F_{\text{site}}(\varepsilon, H) \tag{67}$$

where $\varepsilon = |1 - T/T_c|$, $\tilde{\varepsilon}$ and $\tilde{H}$ are cell variables, and d is the spatial dimensionality. Homogeneity of the free energy then implies that

$$F(\lambda^{a_T}\varepsilon, \lambda^{a_H} H) = \lambda F(\varepsilon, H) \tag{68}$$

where a_T and a_H are new exponents that can be related to those already defined. Using formal RG theory, the initial Hamiltonian is transformed, or *renormalized*, to produce a new Hamiltonian. With successive repetitions, the resultant Hamiltonians, enumerated using index n to describe the number of times the transformation has been applied, are related by

$$\mathcal{H}^{(n+1)} = \boldsymbol{R}_b \mathcal{H}^{(n)} \tag{69}$$

Each application of the RG operator $\boldsymbol{R}_b$ reduces the number of degrees of freedom by b^d. New interaction terms that were not present in the original Hamiltonian may appear in the renormalized Hamiltonian, but the partition function Z must not change since it is only being expressed in terms of new variables. Eventually the renormalized Hamiltonian reaches a stable, or 'fixed point', form $\mathcal{H}^*$ and no longer changes with further repetition, that is,

$$\mathcal{H}^* = \boldsymbol{R}_b \mathcal{H}^* \tag{70}$$

Thus, the Hamiltonian of a system at its critical point 'flows' towards the fixed-point Hamiltonian upon successive application of the RG transformation until it no longer changes. For points in Hamiltonian parameter space for which the system is not initially at a critical point, the Hamiltonian instead 'flows' away from the fixed point (Figure 7). For an Ising-type Hamiltonian above T_c there is also a trivial fixed point corresponding to the ideal paramagnet at $T \to \infty$ that is eventually reached. (After a few rescalings, the block size b^n exceeds ξ and the different blocks are then uncorrelated.) For $T < T_c$, the flow is to a different, zero-temperature fixed point. The Hamiltonian is written in the same general framework at each application of the transformation, for example, an Ising-type Hamiltonian

$$\mathcal{H}/k_B T = K_1 \sum_i \sigma_i + K_2 \sum_{\langle i,j \rangle} \sigma_i \sigma_j + K_3 \sum_{\langle i,j,k \rangle} \sigma_i \sigma_j \sigma_k + K_4 \sum_{\langle i,j,k,\ell \rangle} \sigma_i \sigma_j \sigma_k \sigma_{ell} + \cdots \tag{71}$$

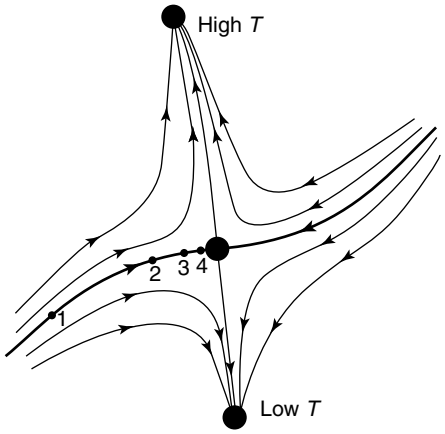

Figure 7. Schematic RG flow diagram in a two-dimensional parameter space. The heavy curve represents the critical hypersurface. Point 1 is the critical value for the initial Hamiltonian and the other points labeled show the flow toward the fixed point (heavy filled circle).

where the set of coupling constants $\{K_1, K_2, \ldots\}$ forms the space in which the flow is considered.

As additional couplings are included in the Hamiltonian, an entire hypersurface of critical points is produced. Whenever the Hamiltonian begins on the critical hypersurface, it should 'flow' towards the fixed point. If, instead, the system is at a multicritical point, the Hamiltonian should flow towards a new 'fixed point' and not towards the critical fixed point. Close to the multicritical point, however, there should be complex 'crossover' behavior: the system may first appear to flow towards a critical fixed point but upon further iteration of the RG transformation begin to flow towards the 'new' fixed point. RG theory provides insight into the principle of universality of critical phenomena because each type of criticality is controlled by a different 'fixed point' of the RG transformation.

Near the fixed point, the problem can be linearized so that the Hamiltonian $\mathcal{H}'$ is related to the fixed point by

$$\mathcal{H}' = \boldsymbol{R}_b[\mathcal{H}^*] + h\boldsymbol{L}\boldsymbol{Q} = \mathcal{H}^* + h\boldsymbol{L}\boldsymbol{Q} + \ldots \tag{72}$$

The linear operator $\boldsymbol{L}$ has the eigenvalue equation

$$\boldsymbol{L}Q_j = \lambda_j Q_j \tag{73}$$

where λ_j is the eigenvalue and Q_j the eigenvector. In terms of the spatial rescaling factor b the eigenvalue is

$$\lambda_j = b^{y_j} \tag{74}$$

where y_j is an 'exponent eigenvalue', which can be related to the usual critical exponents. In terms of these λ_j, the

transformed Hamiltonian can be expressed as

$$\mathcal{H}' = \mathcal{H}^* + \sum h_j \lambda_j Q_j + \ldots \tag{75}$$

and eigenvalues may be extracted from recursion relations ($h_j^{(k+1)} \approx \lambda_j h_j^{(k)}$). The free energy in terms of the original and renormalized variables is again unchanged:

$$f(h_1, h_2, h_3, \ldots) \approx b^{-d} f(b^{\lambda_1} h_1, b^{\lambda_2} h_2, \ldots) \tag{76}$$

where $h_1 = k_1 \varepsilon$, $h_2 = k_2 H$, and so on. Choosing b so that $b^{\lambda_1} \varepsilon = 1$, we can rewrite this equation with k_1, k_2 constants

$$F(\varepsilon, H, h_3) \approx \varepsilon^{d/\lambda_1} f(k_1, k_2 H/\varepsilon^{\lambda_1/\lambda_2}, \ldots) \tag{77}$$

Scaling has then been 'derived' if we identify $d/\lambda_1 = 2 - \alpha$ and $\lambda_2/\lambda_1 = \Delta$.

Alternatively, one may develop a momentum space approach to RG theory in which the coarse-graining and rescaling is defined in k space (momentum space) so that

$$\mathcal{H}(m) = 1/2 \int \mathrm{d}k (k^2 + r_\mathrm{o}) |m(k)|^2 + \ldots \tag{78}$$

A cutoff momentum Λ is introduced, and the k values that lie between Λ and Λ/b are integrated out so the variable of integration is rescaled by $k' = bk$. The order parameter is then renormalized and steps are repeated. A perturbation expansion leads to recursion relations for the effective interaction parameters and their solution gives the 'fixed points'. Perturbation parameters may include the deviation from the upper critical dimension, d_u, or the inverse of the number of components of the order parameter n. For simple magnetic systems with isotropic, short-range couplings, the upper critical dimension is $d_u = 4$ and the leading order estimates (Wilson and Fisher, 1972) for critical exponents from the ε expansion are (note that the parameter ε in the following equation has a special meaning and does *not* refer to the reduced distance from the critical temperature) as follows:

$$\alpha = \frac{4 - n}{2(n + 8)} \varepsilon + \cdots \quad \text{where} \quad \varepsilon = 4 - d \tag{79a}$$

$$\beta = \frac{1}{2} - \frac{3}{2(n + 8)} \varepsilon + \cdots \tag{79b}$$

$$\gamma = 1 + \frac{(n + 2)}{2(n + 8)} \varepsilon + \cdots \tag{79c}$$

Of course, for some simple models higher-order expressions have been derived; and although these expressions do not always vary simply with ε, rather accurate estimates for critical exponents have been extracted, see for example, Brézin, Le Guillou, Zinn-Justin and Nickel (1973) and Le Guillou and Zinn-Justin (1980). A reliable analysis of the expansions generally requires substantial sophistication. RG theory was also applied to tricritical points by Wegner and Riedel (1973), who showed that Landau theory correctly predicted tricritical exponents in 3-dim but that the critical behavior is modified by the presence of logarithmic corrections. Further, an RG analysis of bicritical and related tetracritical points has been carried out by Nelson, Kosterlitz and Fisher (1974). While the momentum space RG has yielded fairly accurate results for the critical exponents of the n-vector model, the accuracy for other problems is far more modest, for example, universal scaling functions describing the equation of state, or describing the crossover from one universality class to another, are typically available only in low-order ε expansion. The momentum space RG, in principle, also yields information about universal properties but not for the critical coupling constants (T_c, etc.) or critical amplitudes. Real space RG, described below, can yield this information. Momentum space RG has been particularly valuable in the examination of systems with dipolar coupling (Fisher and Aharony, 1973), an addition which, of course, has important implications for many real, physical systems. This treatment showed that Ising models with dipolar interactions have mean-field exponents (Larkin and Khmel'nitskii, 1969; Aharony, 1973; Brézin and Zinn-Justin, 1976). Ried, Millev, Fähnle and Kronmüller (1995) extended the momentum space RG to Heisenberg models with uniaxial anisotropy and dipolar coupling. The crossover transitions between four nontrivial fixed points (Heisenberg, Ising, uniaxial dipolar, and isotropic dipolar) were described in terms of an effective exponent. Their results were later confirmed by experiments on Gadolinium (Srinath and Kaul, 1999). Of course, RG theory has been discussed extensively, and the reader is directed elsewhere for a more detailed description (e.g., Domb and Green, 1976).

Several simple RG transformations have been used with generally good success. For these, the space of allowed coupling constants is low-dimensional: This is an uncontrolled approximation but allows rapid calculations that are needed for the actual renormalization transformation. As an example, the 'block-spin' transformation replaces a $b \times b$ block of spins by a 'super spin', whose state is determined by the state of the majority of spins in the block. (When the number of spins in a block is even, one site in each block is chosen as a 'tiebreaker'.) In an nn antiferromagnet, a (2×2) block spin would give zero for all block spins if the system were in the ground state. Instead 'block spins' are best composed of more complex structures where each block resides on a single sublattice. (A $\sqrt{5} \times \sqrt{5}$ transformation rotates the lattice through an angle $\varphi = \pi/4$ so if a second transformation then rotates the lattice through angle $-\varphi$, the original orientation is recovered.) With continued

application of the rescaling transformation, the number of couplings $\{K_i\}$ in the Hamiltonian increases; however, in practice, as the rescaling is iterated, the space of coupling constants has to be truncated. In an analytic approach, other uncontrolled approximations may be necessary to relate the new and old couplings, but with the Monte Carlo renormalization group (MCRG) methods described subsequently such problems can be avoided.

The large-cell MCRG transformation was used to study the 2-dim Ising model with nn coupling (Friedman and Felsteiner, 1977). A system of size $L \times 2L$ was considered and two block spins σ'_1 and σ'_2 were created from application of the majority rule to 'large' cells of size $L \times L$. The block spins interact with Hamiltonian

$$\mathcal{H} = K'\sigma'_1\sigma'_2 \tag{80}$$

where the magnitude of the new effective coupling constant K' is determined from

$$\langle\sigma'_1\sigma'_2\rangle = \tanh(2dK') \tag{81}$$

where d is the spatial dimensionality. Note that this corresponds to a transformation with scale factor $b = L$. The thermal eigenvalue y_T is then determined from the expression

$$\frac{\mathrm{d}K'}{\mathrm{d}K} = L^{y_\mathrm{T}} \tag{82}$$

where the derivative can be calculated via Monte Carlo simulation from averages, that is,

$$\frac{\mathrm{d}K'}{\mathrm{d}K} = \langle\sigma'_1\sigma'_2 S\rangle - \langle\sigma'_1\sigma'_2\rangle\langle S\rangle \tag{83}$$

where $S = \sum \sigma_i\sigma_j$. If L is increased with the system held at the critical coupling the estimates for y_T should converge to the correct value of $1/\nu$.

Methods that require calculation of the renormalized Hamiltonian do not work well. A very different approach that avoids calculation of renormalized couplings is usually more effective. For simplicity, we express the Hamiltonian in the form

$$\mathcal{H} = \sum_\alpha K_\alpha S_\alpha \tag{84}$$

where the various S_α are sums of different products of spin operators and the K_α are the corresponding dimensionless coupling constants. Examples of S_α are as follows:

$$S_1 = \sum \sigma_i \tag{85a}$$

$$S_2 = \sum \sigma_i\sigma_j \tag{85b}$$

$$S_3 = \sum \sigma_i\sigma_j\sigma_k \tag{85c}$$

Near the fixed-point Hamiltonian $\mathcal{H}^*(K^*)$ the linearized transformation takes the form

$$K_\alpha^{(n+1)} - K_\alpha^* = \sum_\beta T^*_{\alpha\beta}(K_\beta^{(n)} - K_\beta^*) \tag{86}$$

where the sum is over all possible couplings. The eigenvalues λ_i of $T^*_{\alpha\beta}$ are related to eigenvalue exponents by

$$\lambda = b^y \tag{87}$$

where the y are related to the usual critical exponents, for example, $y_\mathrm{T} = \nu^{-1}$. The equations are valid for all real space RG methods, and the common challenge becomes the determination of matrix elements $T^*_{\alpha\beta}$ at the fixed point. Perhaps the most successful implementation of real space RG methods has been through the use of MCRG simulations (see Swendsen, 1982). In this approach, the elements of the linearized transformation matrix are written in terms of expectation values of correlation functions at different levels of renormalization. Thus,

$$T_{\alpha\beta} = \frac{\partial K_\alpha^{(n+1)}}{\partial K_\beta^{(n)}} \tag{88}$$

where the elements can be extracted from solution of the chain rule equation

$$\frac{\partial\langle S_\gamma^{(n+1)}\rangle}{\partial K_\beta^{(n)}} = \sum \left\{\frac{\partial K_\alpha^{(n+1)}}{\partial K_\beta^{(n)}}\right\}\left\{\frac{\partial\langle S_\gamma^{(n+1)}\rangle}{\partial K_\alpha^{(n+1)}}\right\} \tag{89}$$

The derivatives can be obtained from correlation functions, which can be evaluated by Monte Carlo simulation, that is,

$$\frac{\partial\langle S_\gamma^{(n+1)}\rangle}{\partial K_\beta^{(n)}} = \langle S_\gamma^{(n+1)} S_\beta{}^{(n)}\rangle - \langle S_\gamma^{(n+1)}\rangle\langle S_\beta^{(n)}\rangle \tag{90}$$

and

$$\frac{\partial\langle S_\gamma^{(n)}\rangle}{\partial K_\alpha^{(n)}} = \langle S_\gamma^{(n)} S_\alpha^{(n)}\rangle - \langle S_\gamma^{(n)}\rangle\langle S_\alpha^{(n)}\rangle \tag{91}$$

In practice, the $T_{\alpha\beta}$ matrix is truncated and the number of renormalizations is also limited. The estimates for eigenvalues need to be examined as a function of the number of

couplings N_c used in the analysis as well as the number of iterations N_r. Exact results are obtained only for $N_r \to \infty$ and $N_c \to \infty$, but convergence is often rapid. Comparisons for different size lattices indicate whether finite lattice effects are biasing the answers.

MCRG may be used to locate critical points by matching correlation functions for transformed and untransformed systems. However, finite size effects can be subtle, so, two different lattices that differ in size by scale factor b are needed. Near a critical point, a linear approximation relates the difference between the original and renormalized correlation functions to the distance to the critical point, that is,

$$\langle S_\alpha^{(n)}\rangle_L - \langle S_\alpha^{(n-1)}\rangle_S = \sum_\beta \left[\frac{\partial \langle S_\alpha^{(n)}\rangle_L}{\partial K_\beta^{(0)}} - \frac{\partial \langle S_\alpha^{(n-1)}\rangle_S}{\partial K_\beta^{(0)}} \right] \delta K_\beta^{(0)} \tag{92}$$

The predicted 'distance' from the critical coupling $\delta K_\beta^{(0)}$ can be extracted by inverting equation (92) for different values of n. Thus, an initial estimate for the critical coupling is chosen, the above process is carried out, and the procedure is iterated.

The methods that have just been described can also be used to investigate multicritical behavior. This usually requires a search in a two-dimensional parameter space; moreover there are usually additional critical eigenvalue exponents due to the presence of additional scaling fields.

Investigations of critical dynamics may also be performed using RG theory and matching, time-dependent correlation functions. A sequence of states that have been blocked at difference levels is generated, and the correlation functions are 'matched' at different blocking levels at different times. The relationship between the blocking level and the time at which they match gives the dynamic exponent z:

$$C(N, m, T_2, t) = C(Nb^d, m+1, T_1, b^z t) \tag{93}$$

where the critical temperature is $T_1 = T_2 = T_c$. Two different size lattices must be used so that there are an identical number of spins in the large lattice after blocking as in the smaller lattice with one less blocking. Of course, the matching can be carried out successfully only for sufficiently large m for which the effect of irrelevant variables is small. This approach was first implemented by Tobochnik, Sarker and Cordery (1981) for simple 1- and 2-dim Ising models. Multiple lattice sizes should be used so that finite size effects can be determined, and the procedure should be repeated for different times to insure that the asymptotic, long-time behavior is being probed.

3.3 Series expansions

The method of series expansions is a well-tested approach that has found great utility in the examination of magnetic phase transitions for over half a decade. The challenges of performing calculations with the series-expansion technique can be subdivided into two types: generation of the series and analysis of the series. Each aspect has its own subtleties and difficulties.

The basic idea of series expansions is rather simple, but the practical implementation of this method demands considerable sophistication. The partition function contains all relevant information about the static properties of a magnetic system:

$$Z = \sum_i e^{-\mathcal{H}/k_B T} \tag{94}$$

where the sum is over all states of the system. At high temperatures, the exponential can be expanded in a power series in T^{-1}or in $\tanh(J/k_B T)$, and at low temperatures an expansion in $\exp\left(-\frac{J}{k_B T}\right)$is possible. The individual terms can generally be computed in terms of the permutations of bonds to form different graphs, and computer algorithms have been devised that allow the precise creation of quite long expansions for simple models. (For more details on how to develop series expansions for magnetic systems, see Domb and Green (1974).)

A series-expansion approach can also be used for critical dynamics. Using the master equation given in equation (43) we can define a time evolution operator

$$\mathcal{L} = \sum_k W_k(S_k)(1 - P_k) \tag{95}$$

where W_k is the spin-flip transition rate and P_k is the spin-flip operator. The long-time behavior is described by

$$\tau \sim \sum_{i,j} \langle s_i \mathcal{L}^{-1} s_j \rangle \tag{96}$$

and τ is estimated by expanding $\mathcal{L}^{-1}$ in a series.

Quite sophisticated methods of analysis have been derived and each approach has its own strengths and weaknesses. (For a more detailed review, see Guttmann (1989) and Adler (1995).) Ratio methods and Padé approximants have long been favorites. The radius of convergence of a series

$$F(z) = \sum_n a_i z^n \tag{97}$$

is determined by a singularity in the complex z plane (not to be confused with the dynamic critical exponent z), and

the strongest singularity on the positive real axis will be identified as the critical point. Of course, there may be other singularities in the complex z plane, so analysis of the series may be nontrivial. In the ratio method, the critical point z_c is estimated by examining ratios of successive prefactors and extrapolating to $n \to \infty$, for example, for the magnetic susceptibility

$$\frac{a_n}{a_{n-1}} = \frac{1}{z_n} = \frac{1}{z_c}\left[1 - \frac{\gamma}{n} + \cdots\right] \tag{98}$$

The ratio method works poorly however, when the coefficients in the series are irregular in sign and/or magnitude. An alternative approach that has great value is that of Padé approximants in which $F(z)$ is approximated by the ratio of two polynomials, that is, the $[L, M]$ approximant is

$$F(z) = \frac{p_0 + p_1 z + \ldots + p_L z^L}{q_0 + q_1 z + \ldots + q_M z^M} \tag{99}$$

The poles and residues of the diagonal approximants are then used to determine the critical points and exponents. If the function $F(z)$ has an algebraic branch cut at $z = z_c$, a new function $G(z)$ can be defined

$$G(z) = F(z)(z_c - z)^{\gamma} z_c^{-\gamma} \tag{100}$$

and the logarithmic derivative

$$D(z) = \frac{\mathrm{d}}{\mathrm{d}z} F(z) = \frac{-\gamma}{z - z_c} + \frac{\mathrm{d}}{\mathrm{d}z} G(z) \tag{101}$$

has a simple pole at $z = z_c$ and the approximant should converge faster for $D(z)$ than for $F(z)$.

Differential approximants have been used to analyze series in terms of singularities with nonanalytic corrections but these have not always been effective. One promising approach has been the Roskies transform in which a change of variables is performed

$$y = 1 - (1 - T/T_c)^{\theta} \tag{102}$$

so that the nonanalytic term in $(T - T_c)$ becomes analytic in $(1 - y)$. The new series only has weaker nonanalytic corrections involving a second irrelevant exponent θ_2.

As the preceding discussion shows, the extraction of critical behavior from series expansions can be subtle, and series that are too short and unreliable analyses have led to controversies in the past literature. Quite long series now exist for a few, simple magnetic models on regular lattices, and we believe that the estimates derived from these series expansions that we shall review later are reliable.

3.4 Monte Carlo simulations

A rich diversity of importance sampling Monte Carlo methods has been used to study magnetic phase transitions (Landau and Binder, 2005). In the classic Metropolis method (Metropolis *et al*., 1953), configurations are generated from a previous state using a transition probability that depends on the energy difference between the initial and final state. The sequence of states produced follow a time-ordered path, but the time in this case is really only a nondeterministic 'Monte Carlo time'. (From a theoretical perspective, the commutator of the Hamiltonian and a spin gives the time dependence of that spin. For the Ising model, this is zero and there is no deterministic behavior.) Instead, for relaxational models, such as the (stochastic) Ising model (Kawasaki, 1972), the time-dependent behavior is described by a master equation (equation (43) for the probability $P_n(t)$ that the system is in state n at time t, and $W_{n\to m}$ is the transition rate for $n \to m$. If the system is in equilibrium, $\partial P_n(t)/\partial t = 0$ and the two terms on the right-hand side of equation (43) must be equal! The resultant expression is known as 'detailed balance':

$$P_n(t) W_{n\to m} = P_m(t) W_{m\to n} \tag{103}$$

The probability of the nth state occurring in a classical system is given by

$$P_n(t) = e^{-E_n/k_B T}/Z \tag{104}$$

where Z is the partition function. This probability is usually not exactly known because of the denominator; however, by generating a Markov chain of states we can avoid the need to determine it. If we generate the nth state from the mth state, the relative probability is the ratio of the individual probabilities and the denominator in equation (104) cancels out. This means that only the difference in energy between the two states is needed, for example,

$$\Delta E = E_n - E_m \tag{105}$$

Any transition rate that satisfies detailed balance is acceptable. The choice of rate initially used in simulations of magnetic systems was the single spin-flip Metropolis form

$$W_{m\to n} = \tau_o^{-1} \exp(-\Delta E/k_B T), \quad \Delta E > 0 \tag{106a}$$

$$= \tau_o^{-1}, \quad \Delta E < 0 \tag{106b}$$

where τ_o is the time required to attempt a spin flip. (Often τ_o is set equal to unity and thus not explicitly shown in the equations.) A spin flip is accepted if a random number r, chosen *uniformly* in the interval [0,1], is less than the flipping probability. (Of course, the random number stream must have

a long period, and successive random numbers should be uncorrelated. Some simulations in the literature have suffered from poor-quality random numbers.) The 'standard' unit of Monte Carlo time is the Monte Carlo step/site (MCS/site), which corresponds to the consideration of every spin in the system once. With this algorithm, states are generated with the correct probability once the initial transients are past. Then, the desired averages $\langle A \rangle = \sum_n P_n A_n$ of a variable A become arithmetic averages over the entire sample of states. Note that if an attempted spin flip is rejected, the old state is counted again in the average.

For early times, the system relaxes towards equilibrium, but the internal energy and magnetization may have different characteristic time scales. At later times, the system is in equilibrium and the properties exhibit thermodynamic fluctuations; and at yet longer times global spin reversal might occur, that is, between states of equal energy and oppositely directed spontaneous magnetization. If sites are selected randomly in a system with N sites, one MCS/site corresponds to the consideration of N randomly chosen sites. Note that, some spins will probably be chosen more than once and some not at all during one MCS/site. The time development of the system will be similar to that for sites being visited in order, but the explicit variation and time scales will differ. Random site selection should be used if dynamic correlation functions of the corresponding stochastic model are to be measured and not just static equilibrium properties.

The Metropolis flipping probability is not a unique solution to the master equation. An alternative method, commonly referred to as 'Glauber dynamics' (Glauber, 1963) uses the single spin-flip transition rate

$$W_{n\to m} = \tau_{\mathrm{o}}^{-1}[1 + \sigma_i \tanh(E_i/k_{\mathrm{B}}T)] \qquad (107)$$

where $\sigma_i E_i$ is the energy of the ith spin in state n. Unlike the Metropolis method, the Glauber rate is antisymmetric about 0.5 for $E_i \to -E_i$. Müller-Krumbhaar and Binder (1973) showed that both Glauber and Metropolis algorithms are just special cases of a more general transition rate form. Note that at very high temperatures, the Metropolis algorithm will flip a spin on *every* attempt because the transition probability approaches 1 for $\Delta E > 0$; the system is then nonergodic and merely oscillates between the two states. With the Glauber algorithm, however, the transition probability approaches 1/2 and the process remains ergodic.

Algorithmic simplifications are possible for the Ising model and these may modify the 'time dependence'. For example, for each spin there are only a small number of different environments that are possible, for example, for a square lattice with nn interactions, there are only five different energy changes associated with a successful spin flip and each flipping probability can be computed and stored in a table. Spins are chosen randomly to be flipped and the time that elapses between flips is determined with another random number. Averages are thus over lifetimes of each state. This 'event-driven' simulation does not give the same sequence of states as the 'time-step-driven' algorithms, for example, the Metropolis method, so the 'dynamic' properties will be different.

The Ising model as originally formulated and discussed in the preceding text may be viewed as a spin-S model with $S = 1/2$, but the definition can be extended to the case of higher spin without difficulty. For example, for $S = 1$ there are three possible states, 1, 0, and -1, at each site. An nn pair can, therefore, have *three* possible states with different energies and the total space of possible lattice configurations is similarly enlarged. A spin-S Ising model can be simulated using the method just described except that the 'new' state to which a given spin attempts to flip must be chosen from among multiple choices using another random number.

Of course, other Monte Carlo algorithms have been developed to overcome the limitations of the Metropolis technique. Cluster algorithms (Swendsen and Wang, 1987; Wolff, 1989), based on the Fortuin–Kasteleyn theorem, have been developed to overcome critical slowing down near phase transitions. Such methods create clusters by randomly adding bonds to a starting site with a characteristic probability, and then entire clusters of spins are flipped. These algorithms greatly reduce the characteristic relaxation times of the sampling. Although the 'dynamic' critical behavior is thus modified, that is, the dynamic exponent z is reduced, the static properties remain unchanged.

A different approach was taken by Berg and Neuhaus (1992) who proposed a new, multicanonical method. They used a sampling probability that differed from the canonical probability in order to increase the sampling of intermediate states between configurations of high probability that were separated by a region of quite low probability. This is the situation at first-order phase transitions and leads to loss of ergodicity. More recently, Wang and Landau (2001a,b) described a quite different approach to Monte Carlo simulations that directly estimated the density of states, that is, rewriting the partition function as

$$Z = \sum_i e^{-E_i/k_{\mathrm{B}}T} \equiv \sum_E g(E) e^{-E/k_{\mathrm{B}}T} \qquad (108)$$

The technique uses a simple 'recipe' to construct $g(E)$ in an iterative fashion. A random walk is performed in energy space using a modified probability that does not depend upon temperature

$$p(E_1 \to E_2) = \min\left(\frac{g(E_1)}{g(E_2)}, 1\right) \qquad (109)$$

Once $g(E)$ has been estimated, the canonical probability, and hence all thermodynamic properties, may be determined for all temperatures, from a single simulation.

The principle of ergodicity requires that all possible configurations of the system should be reachable. Below a phase transition, multiple different-ordered states that are well separated in phase space may appear. If the phase transition from the disordered phase to the ordered phase is associated with 'symmetry breaking', the different-ordered states are related by a symmetry operation (e.g., a reversal of the sign of the order parameter for an Ising ferromagnet). Within the context of dynamical behavior of such systems, symmetry breaking usually means ergodicity breaking, that is, the system stays in one separate region in phase space. For example, in the simulation of an Ising system that may have all spins up or all spins down, we may wish to keep the system from exploring all of phase space so that only positive magnetization values are observed. For a fully ergodic simulation algorithm, both positive and negative values of magnetization will be sampled and the average will be zero.

3.5 Spin dynamics simulations

We have previously mentioned that the Monte Carlo method is fundamentally stochastic in nature, so that there is, in general, no correlation between 'Monte Carlo time' and 'real time', although the static averages are the same. An approach to the investigation of true time-dependent properties is to generate initial states, drawn from a canonical ensemble using Monte Carlo methods and to use these as starting points for the integration of the coupled equations of motion. This approach, referred to as 'spin dynamics', has been quite successful (Landau and Krech, 1999). In the general case, we have a system of N spins, which interact with the general Hamiltonian

$$\mathcal{H} = -J \sum_{\langle i,j \rangle} (S_{ix} S_{jx} + S_{iy} S_{jy} + \lambda S_{iz} S_{jz}) + D \sum_i S_{iz}^2 + H \sum_i S_{iz} \tag{110}$$

where the first sum is over all nn pairs, λ represents exchange anisotropy, D is the single ion anisotropy, and H is the external magnetic field. There are a number of real magnet systems that are well approximated by such Hamiltonians, although one or more of the parameters may vanish in particular cases. For $\lambda = 1$ and $D = 0$, the Hamiltonian describes the isotropic Heisenberg ferromagnet for $J > 0$ or for $J < 0$ the Heisenberg antiferromagnet.

For models with continuous spins, equations of motion can be derived from the quantum mechanical commutator,

$$\frac{\partial \mathbf{S}_i}{\partial t} = -\frac{i}{\hbar}[\mathbf{S}_i, \mathcal{H}] \tag{111}$$

by allowing the spin value to go to infinity and normalizing the length to unity to yield

$$\frac{\mathrm{d}\vec{S}_i}{\mathrm{d}t} = \frac{\partial \mathcal{H}}{\partial \vec{S}_i} \times \vec{S}_i = -\vec{S}_i \times \vec{H}_{\mathrm{eff}} \tag{112}$$

where $\vec{H}_{\mathrm{eff}}$ is an 'effective' interaction field. For the isotropic Heisenberg ferromagnet, $\vec{H}_{\mathrm{eff}} = -J \sum_{\mathrm{nn}} \vec{S}_j$. Through these coupled equations of motion, a spin can be described as precessing about an 'effective interaction field', which itself changes as the other spins move. The time dependence of each spin $S_i(t)$ can be determined by numerical integration of these coupled equations of motion.

The simplest approach is to simply expand about the current spin value using a small-time-step Δ as the expansion variable in a Taylor expansion. The resulting estimate depends upon how many terms are retained in the series. Typical values of Δ that deliver reliable results to a reasonable maximum integration time $t_{\max}$ are $\sim\Delta = 0.005$. A very simple improvement can be made by implementing a 'leapfrog' procedure (Gerling and Landau, 1983)

$$S_i^\alpha(t+\Delta) = S_i^\alpha(t-\Delta) + 2\Delta \dot{S}_i^\alpha(t) + \frac{2}{3!}\Delta^3 \dddot{S}_i^\alpha(t) + \cdots \tag{113}$$

The local error in this integration is $O(\Delta^5)$ and allows larger values of Δ to be used, hence extending the maximum possible integration time, $t_{\max}$. Several standard numerical methods can also be applied, for example, fourth-order predictor–corrector methods have proved quite effective for spin dynamics simulations (local truncation error of $\sim\Delta^5$). Note, however, that the conservation laws discussed below will only be observed within the accuracy set by the truncation error of the method. In practice, this limits the time-step to $\sim\Delta = 0.01/J$ in $d = 3$ (Chen and Landau, 1994) for the isotropic model ($D = 0$), where $t_{\max} \leq 200/J$.

For a typical spin dynamics study, most of the CPU time is consumed by the numerical time integration, so a large time step is most desirable. However, 'standard' methods impose a severe restriction on the size of Δ for which the conservation laws of dynamics are obeyed. Symmetries of the Hamiltonian impose additional conservation laws, so, for the isotropic Heisenberg model, the magnetization $\vec{m}$ is conserved. For an anisotropic Heisenberg model, that is, $\lambda \neq 1$ or $D \neq 0$, only the z component m_z of the magnetization

is conserved. Conservation of spin length and energy is particularly crucial, and it would therefore also be desirable to devise an algorithm that conserves these two quantities exactly. In this spirit, a new, large-time-step integration procedure, which is based on Trotter–Suzuki decompositions of exponential operators and conserves both spin length and energy *exactly* for $D = 0$, has been devised (Krech, Bunker and Landau, 1998). For high order decompositions, time steps as large as $\Delta = 0.2/J$ can be used so that $t_{\max}$ may be greatly extended to $1000/J$ or more. Variants of this method for more general models also allow the use of very large time steps but do not necessarily conserve all quantities exactly.

4 NUMERICAL RESULTS: CURRENT STATUS

4.1 Ising model

The simplest and most-studied magnetic system is surely the Ising model. This model consists of spins $\sigma_i = \pm 1$ placed at lattice sites i, and near neighbors interact. In the simplest case, the coupling is only between nearest neighbors, but the addition of nnn interactions and a magnetic field can lead to a tricritical point. Although the 1-dim model in zero field, solved in Ising's classic paper (Ising, 1925), exhibited no phase transition, Onsager's '*tour de force*' analytic solution of the 2-dim zero-field model showed that there was only a weak divergence of the specific heat with $\alpha = 0$ (a logarithmic divergence); moreover, the spontaneous magnetization goes to zero at T_c with exponent $\beta = 1/8$. These exponent values are quite different from those predicted by Landau theory and are a result of the large fluctuations that exist in two dimensions. Since not all properties of the 2-dim Ising model are known exactly, Monte Carlo simulations are nonetheless of substantial value. For example, Nicolaides and Bruce (1988) have shown that the 'fixed-point' value of the reduced fourth-order cumulant (Binder parameter) for the Ising square lattice is $U^* \sim 0.61562(90)$.

The spin configurations that are generated by Monte Carlo simulations provide substantial insight into the nature of the critical behavior. A 'snapshot' of the 2-dim Ising model at the critical temperature (Figure 8) shows quite clearly that the critical clusters that form are *not* compact but rather quite ramified. At the critical temperature, clusters of all sizes are present, but the slow 'dynamics' result from the slow changes in the largest or 'infinite' cluster.

MCRG simulations have been used to study the proximity of the nn Ising square lattice Hamiltonian to the fixed-point value. The thermal eigenvalue exponent estimates for $L \times L$ square lattices converge quickly to the asymptotic value y_T equals to 1.0 (Swendsen, 1982). As the number of iterations increases, the exponent rapidly approaches the exact value, but this is true only as long as at least one additional coupling is generated. Even for only one iteration and a single nn coupling $y_T = 0.912(2)$, and after three iterations with only two couplings $y_T = 0.998(2)$. Finite size effects also begin to appear slowly and become increasingly important as the iteration number increases. Nonetheless, the conclusion that may be drawn is that the original Hamiltonian is rather close to the fixed point.

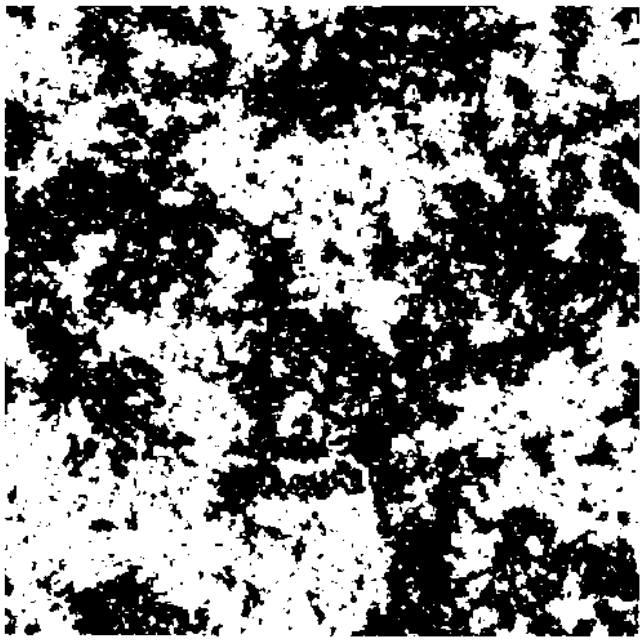

Figure 8. Snapshot generated by a Monte Carlo simulation of a 2-dim Ising model at T_c for a 256×256 lattice with periodic boundary conditions. Dark and light squares represent oppositely directed spins.

Experience with other models, and with the Ising model in higher dimension, has shown that, in general, the convergence of MCRG with iteration is not as rapid as for the 2-dim Ising model, and great care must be used to insure that a sufficient number of couplings and renormalizations have been used. This also means that the lattices must be large enough to avoid finite size effects in the renormalized systems.

Although the 2-dim Ising model has been solved analytically, the 3-dim model has defied exact solution and may not even be solvable. Extensive numerical studies of Ising models on different lattices have given a fairly detailed view of the transition. Several high-quality MCRG studies attempted to deduce the critical behavior for the simple cubic (sc) lattice. In the latest of these studies, Baillie, Gupta, Hawick and Pawley (1992) used lattices as large as 128^3 with 53 even operators and 46 odd operators. They

concluded that $K_c = 0.221652(3)$ and $\nu = 0.624(2)$. Large scale Monte Carlo simulations of the Ising sc model with results analyzed using finite size scaling have given quite precise estimates for both the critical temperature and critical exponents. Using lattices as large as $96 \times 96 \times 96$, Ferrenberg and Landau (1991) estimated $K_c = 0.2216595(26)$ and $\nu = 0.6289(2)$. A reanalysis of the data including corrections to scaling found $\nu = 0.6294(2)$, and by fixing ν, the authors found $K_c = 0.2216574(18)$. Blöte, Luijten and Heringa (1995) made very high statistics runs on many smaller systems, but used more detailed corrections to finite size scaling using correction exponents from RG theory and found $K_c = 0.2216546(10)$. The estimate for the fixed-point value of the fourth-order cumulant was $U^* \sim 0.47$, a value that is far below that of the 2-dim Ising model. Critical behavior has also been estimated from the nonequilibrium time behavior. Ito, Hukushima, Ogawa and Ozeki (2000) used substantial Monte Carlo simulations to study the nonlinear relaxation of the magnetization for large $(405 \times 405 \times 406)$ sc Ising lattices and found $K_c = 0.2216595(15)$ and $\nu = 0.635(5)$. Deng and Blöte (2003) performed extensive Monte Carlo simulations on a number of models that are believed to be in the same universality class. By requiring consistency in the estimates of universal quantities, they concluded that for the sc lattice $K_c = 0.22165455(3)$. This latter value together with the earlier MCRG result and the latest series expansion would seem to exclude the 'exact conjecture' by Rosengren (1986), that is, $\tanh K_c = (\sqrt{5} - 2)\cos(\pi/8)$ or $K_c = 0.22165863$. A good summary of results obtained from different methods for several simple Hamiltonians, including the Ising Hamiltonian, can be found in Pelissetto and Vicari (2002).

The crossover from 2-dim to 3-dim critical behavior in the Ising model was probed by Binder (1974) using Monte Carlo simulations. The observed shift in the critical temperature (due to crossover) is well described by equation (30) with $\phi = 1/\nu_3$ (Figure 9). Of course, the asymptotic behavior is not reached until the number of layers has reached a sufficiently large value. A similar situation in terms of the appropriate variables occurs for other crossover phenomena.

Surface critical behavior in 3-dim Ising models has also been studied using extensive Monte Carlo simulations. Although the qualitative picture presented by mean-field theory seems to be correct, the location of the special transition as well as all of the surface critical exponents are not quantitatively correct. Monte Carlo simulations (Landau and Binder, 1990) first suggested that $J_{sc}/J = 1.52$, but later simulations (Ruge, Dunkelmann, Wagner and Wulf, 1993) suggested that the value was slightly smaller. Instead of the mean-field value $\beta_1 = 1$ at the ordinary transition, Monte Carlo estimates were about 0.78 or 0.80. Field theoretic RG theory predictions (Diehl and Dietrich, 1981; Diehl and Shpot, 1998) were 0.816 and later 0.796. Critical exponents for the special transition have also been estimated by different numerical methods. Instead of the mean-field value $\phi = 1/2$, RG theory first predicted $\phi = 0.68$ and an improved estimate was $\phi = 0.539$. Monte Carlo simulations yielded $\phi = 0.56$, and more recent simulations found smaller values, 0.45 and 0.46 (Deng, Blöte and Nightingale, 2005).

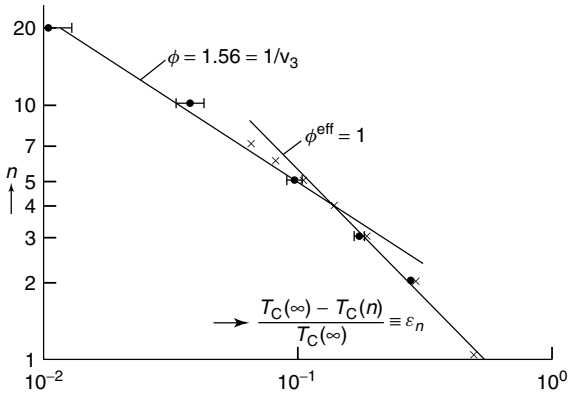

Figure 9. Shift of the critical temperature for Ising films of thickness n. Crosses (x) are series expansions results and the solid points (•) are results from Monte Carlo simulations. (Reproduced from K. Binder: 'Monte Carlo study of thin magnetic Ising films', *Thin Solid Films* **20**, 1974, pp 367–381, copyright © 1974, with permission from Elsevier.)

The determination of 'dynamic' critical exponents for Ising (model A) systems has been an arduous task. For several decades, the estimates for the dynamic exponent in 2-dim varied from study to study and showed little tendency to converge towards 'accepted' values. Finally, a careful series-expansion analysis (Dammann and Reger, 1993, 1995) for the 2-dim Ising model yielded the estimate $z = 2.183(5)$, although a reanalysis of the series by Adler (1996) gave $z = 2.165(15)$. Using extremely large lattices ($L = 496{,}640$), Stauffer (1997) examined the decay of the magnetization at T_c (see equation 50) and concluded that $z = 2.18$. Then, a high precision Monte Carlo study (Wang and Gan, 1998) yielded $z = 2.169(3)$ and a variance-reducing Monte Carlo simulation of the stochastic matrix (Nightingale and Blöte, 1998) gave $z = 2.1665(12)$. It thus appears as though the model A dynamic exponent is now well known for the 2-dim Ising model. For the 3-dim Ising model, rather good estimates were obtained from finite size scaling of the linear correlation time at T_c, $z = 2.04(3)$ (Wansleben and Landau, 1991); and from the 'statistical dependence time', $z = 2.030(4)$ (Kikuchi and Ito, 1993); and from the nonlinear relaxation Ito, Hukushima, Ogawa and Ozeki (2000) estimated $z = 2.055(10)$. Therefore, it appears as though the model A Ising dynamic exponent is smaller in 3-dim than in 2-dim but is still larger than 2.

Rather recently, very high quality series-expansion determinations of critical exponents for general spin Ising models on the sc and bcc lattices have confirmed expectations that the spin value was unimportant in the determination of the static universality class (Butera and Comi, 2002). Using high-temperature series with a large number of terms, through T^{-23} and T^{-25} (for different quantities), they found that $\gamma = 1.2371(1)$, $\nu = 0.6299(2)$, and the leading correction to scaling exponent is $\theta = 0.50$ for spin values between 1/2 and ∞.

4.2 3-dim Heisenberg model

Rather long high-temperature series expansions (Butera and Comi, 1996) have also been used to obtain rather precise values of critical exponents for both the sc and bcc lattices. Including corrections to scaling, they found $K_c = 0.69305(4)$, $\nu = 0.712(10)$, $\gamma = 1.40(1)$ for the sc lattice, and $K_c = 0.486820(4)$, $\nu = 0.714(2)$, $\gamma = 1.402(3)$ for the bcc lattice. These may be compared with results of high-resolution Monte Carlo simulations (Chen, Ferrenberg and Landau, 1993). These produced critical temperature estimates $K_c = 0.693035(37)$, $\nu = 0.7036(23)$, $\gamma = 1.3896(70)$ for the sc lattice and $K_c = 0.486798(12)$, $\nu = 0.7059(37)$, $\gamma = 1.385(10)$ for the bcc lattice. Holm and Janke (1993) obtained similar answers but with larger error bars. Another Monte Carlo study (Ballesteros, Fernandez, Martín-Mayor and Muñoz Sudupe, 1996) compared data from two different size lattices and used finite size scaling to extract the values $K_c = 0.693002(12)$, $\nu = 0.7128(14)$, $\gamma = 1.396(3)$. They also provided the estimate $U^* = 0.6217(8)$. ε-expansion RG calculations have also been performed for the 3-dim Heisenberg model. The estimate (Le Guillou and Zinn-Justin, 1980) $\nu = 0.710(7)$ has been improved by a newer study (Guida and Zinn-Justin, 1998) with smaller errors that predicts $\nu = 0.7096(8)$. Thus, although small differences between different numerical estimates remain, it must be concluded that both critical temperatures and static critical exponents are rather well known.

The 'dynamic' critical behavior of the Heisenberg model is more complex than the static behavior. For the Heisenberg ferromagnet a finite size scaling analysis of spin dynamics simulations data (Chen and Landau, 1994) yielded an estimate for the dynamic exponent $z = 2.478(27)$. This value was in excellent agreement with the dynamic scaling prediction (identical to ε-expansion RG theory) of $z = (d + 2 - \eta)/2 = 2.478(28)$. For the Heisenberg antiferromagnet there was a controversy about the shape of the dynamic structure factor. Although mode-coupling theory predicted that at T_c there would only be a spin wave peak, both inelastic neutron-scattering experiments and spin dynamics simulations found a central peak at T_c, that is, a maximum for $\omega = 0$, in addition to a spin wave peak. In addition, although for the Heisenberg antiferromagnet the theoretical prediction that $z = 1.5$ was not initially confirmed by either experiment or by spin dynamics simulation, a more detailed finite size scaling analysis (Tsai and Landau, 2003) showed that $z = 1.5$ was correct for sufficiently small values of q. If, instead, the time-dependent behavior (critical kinetics) of the Heisenberg model is studied via Monte Carlo simulations, that is, treating the Heisenberg model stochastically as in model A, the dynamic exponent is $z = 1.96(6)$ (Peczak and Landau, 1993). Thus, although there is a single set of static critical exponents for the classical Heisenberg model, there are three different 'dynamic' exponents.

4.3 2-dim *XY* model

Various forms of the 2-dim *XY* model have been extensively studied using Monte Carlo simulations. In most cases, the plane rotator (two-component spins) has been used, but different studies have yielded different, and sometimes contradictory, results. The general feature of the predictions at the transition, that is, the unbinding of vortex pairs has been confirmed by early Monte Carlo simulations (see Figure 10). The vortex-pair density goes up with increasing temperature, and at $T_{KT} \sim 0.9\, J/k_B$ the pairs begin to unbind. Although the systems used in this simulation were relatively small and the numerical values of transition temperature and critical exponents were not terribly precise, this study clearly provided insight into the underlying correctness of the Kosterlitz–Thouless picture. The subsequent estimation of the numerical values for the transition temperature and critical exponents proved quite difficult as various studies yielded different results. The difficulties were, at least in part, due to a slow approach to the asymptotic critical region and corrections to finite size scaling. The most recent and highest-resolution study (Hasenbusch, 2005) has clarified a somewhat murky situation. Hasenbusch simulated plane-rotator models on $L \times L$ square lattices at two different temperatures, $K = 1.1199$ and $K = 1.12091$, which had been estimated as being T_{KT} by two different groups. A single-cluster update algorithm was used with lattices as large as $L = 2048$ and a minimum of 2.5×10^6 MCSs were taken for each temperature and lattice size. An analysis of the second moment correlation length and the helicity modulus confirm $K_c = 1.1199$ as the transition temperature. An analysis of the magnetic susceptibility showed that for sufficiently large L it followed the form

$$\chi \propto L^{2-\eta}(\ln L + C)^{-2r} \tag{114}$$

with the theoretically predicted values of $\eta = 1/2$ and $r = -1/16$.

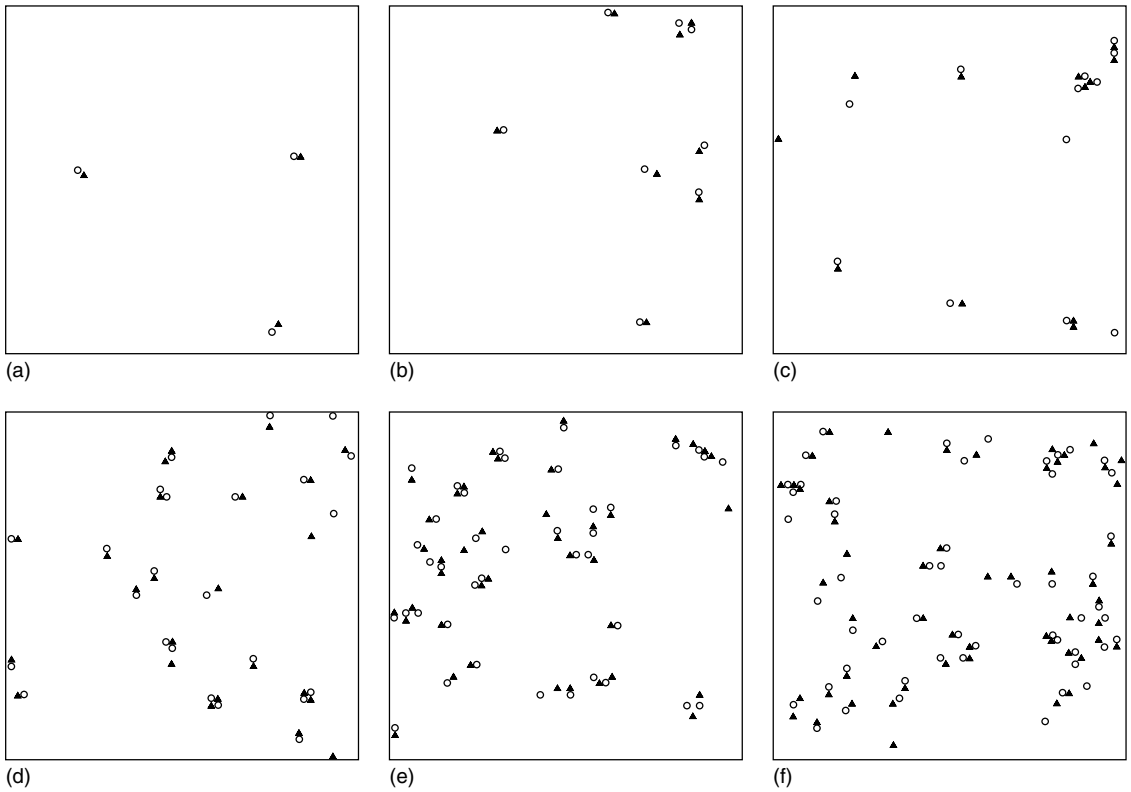

Figure 10. Vortex-pair unbinding in the 2-dim *XY* model. Open circles are vortices and triangles are antivortices: (a) $T = 0.80$; (b) $T = 0.85$; (c) $T = 0.90$; (d) $T = 0.95$; (e) $T = 1.00$; (f) $T = 1.05$, where $J/k_{\mathrm{B}} = 1$. 4.4 Blume–Capel model: a window on tricritical behavior

The Blume–Capel model on a face centered cubic (fcc) lattice was studied by Saul, Wortis and Stauffer (1974) using both low-temperature and high-temperature series expansions. They traced out the phase diagram and found a tricritical point at $k_B T_t/J = 3.138(84)$ with a tricritical coupling ratio (see equation 13) of $D_t/J = 5.659(12)$. The tricritical exponents were consistent with the predicted mean-field (Landau) values (or equivalently the Riedel–Wegner Gaussian fixed point). Using Monte Carlo simulations, Jain and Landau (1980) found $k_B T_t/J = 3.072(24)$ with a tricritical coupling ratio of $D_t/J = 5.652(48)$. A finite size scaling analysis also yielded tricritical exponents that were consistent with Gaussian fixed-point predictions, including logarithmic corrections for the order parameter.

The examination of tricritical behavior in 2-dim was perhaps more interesting and more challenging. MCRG methods (Landau and Swendsen, 1986) were used to study the 2-dim Blume–Capel ferromagnet as well as for the 2-dim Ising antiferromagnet with nnn interactions in a magnetic field. The MCRG study showed that for quite a wide range of couplings below the predicted (mean field) critical value, there was only an ordinary tricritical point with no indication of the predicted decomposition into a critical endpoint and double critical point. The numerical estimates obtained for both the dominant and subdominant eigenvalue exponents were also unchanged with modifications in the couplings and agreed well with the predicted values for an ordinary tricritical point. Kimel, Black, Carter and Wang (1987) performed a Monte Carlo study of the antiferromagnetic Blume–Capel model in two dimensions and found similar results, that is, no decomposition of the tricritical point with tricritical exponents that agreed with values extracted for the Blume–Capel ferromagnet. Thus, fluctuations in the 2-dim model completely destroy mean-field behavior and also maintain simple tricritical behavior.

4.5 Bicritical behavior in the anisotropic Heisenberg model

Monte Carlo simulations were carried out for the anisotropic Heisenberg model in 3-dim by Landau and Binder (1978). They found a low-field Ising-like ordered, antiferromagnetic

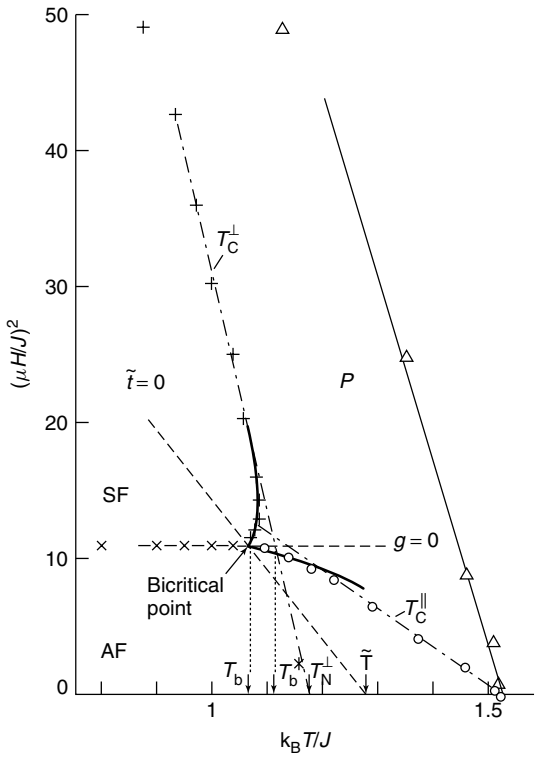

Figure 11. Phase diagram of the anisotropic Heisenberg antiferromagnet in the $H_{||} - T$ plane. The symbols are the results of Monte Carlo simulations, the mean-field lines (·····) and bicritical temperature T_b^* are shown for comparison. The heavy solid curves represent the asymptotic phase boundaries resulting from a fit to equation (38). The dashed lines are theoretical scaling axes. The triangles show the critical field data in the $H_{\perp} - T$ plane. (Reproduced from Landau, D.P. and Binder, K. (1978), with permission from the American Physical Society. © 1978.)

state and as the field was increased, the system underwent a first-order transition to a spin-flop state (Figure 11). The data showed Ising-like critical behavior of the z component of the staggered magnetization for low fields and XY-like critical behavior of the perpendicular component of the staggered magnetization at high fields. They found the predicted bicritical umbilicus and showed that the behavior of the phase boundary in the vicinity of the bicritical point could indeed be described by the predicted nonlinear scaling axes. The indention of the bicritical point was substantially greater than the mean-field prediction. The phase boundary for a perpendicular field, also shown in Figure 11, follows a simple, quadratic dependence upon the field.

4.6 Competing interactions: surprises and unanswered questions

The classical Heisenberg ferromagnet discussed in previous sections has a second-order transition with critical behavior that is now well characterized. The addition of anisotropy can make significant modifications to the phase transition. Mouritsen, Knak Jensen and Bak (1977) used Monte Carlo simulations to examine variation of the Heisenberg model in which fluctuations in the order parameter make a discontinuous transition (first order) energetically favorable. Next-nearest-neighbor couplings as well as fourth-order anisotropy were added to the Hamiltonian. As a consequence, the fourth-order invariants of the six components of the order parameter of this model are the same as for UO_2 or $NdSn_3$ and all three cases should have the same kind of phase transition. Indeed, Monte Carlo calculations by Mouritsen, Knak Jensen and Bak (1977) showed clear hysteresis in both the order parameter and the internal energy (shown in Figure 12) that was indicative of a first-order transition. In contrast, mean-field theory predicts a second-order transition.

The model just described is not the only case in which competition can lead to first-order transitions. The simple Ising model on an fcc lattice with antiferromagnetic nn coupling shows geometric frustration because it is impossible to produce a ground state in which all nn bonds are satisfied. When a magnetic field is added, the system shows 'order out of disorder' in which long-range order is observed. If the fcc lattice is subdivided into four interpenetrating sc sublattices,

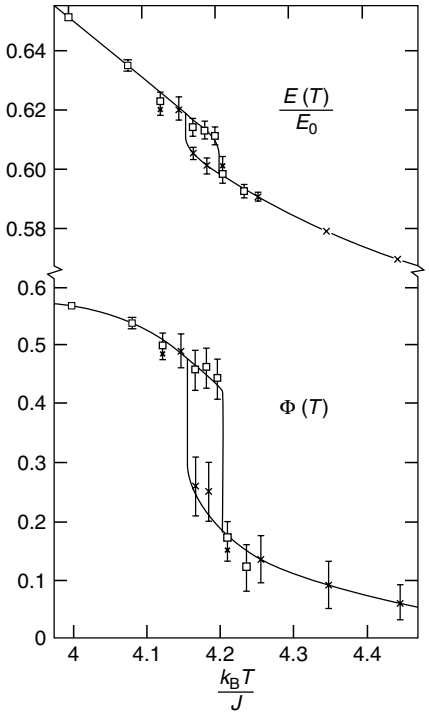

Figure 12. Temperature dependence of the order parameter and internal energy of a competing interaction Heisenberg model with fourth-order anisotropy. (Reproduced from Mouritsen, O.G., Knak Jensen, S.J., and Bak, P. (1977), with permission from the American Physical Society. © 1977.)

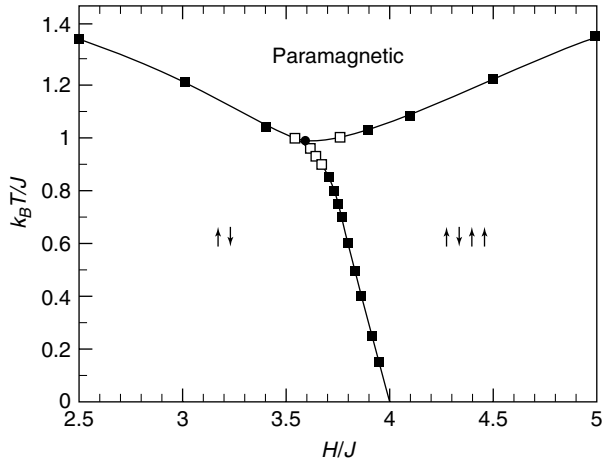

Figure 13. Phase diagram for the fcc lattice with antiferromagnetic nn interactions. The lines connecting the points are guides to the eye and indicate first-order phase boundaries. The intersection of all three boundaries (solid dot) is either a multicritical point or a triple point. (Reproduced from Kämmerer, S., Dünweg, B., K. Binder, and d'Onorio de Meo, M. (1996), with permission from the American Physical Society. © 1996.)

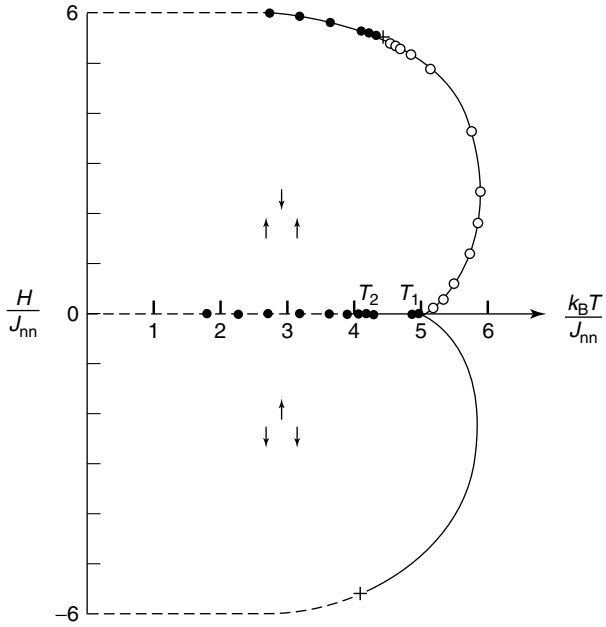

Figure 14. Phase diagram for a triangular Ising antiferromagnet with nnn interactions. The solid curves indicate second-order transitions and the dashed lines indicate first-order transitions. The region between T_1 and T_2 shows Kosterlitz–Thouless behavior. The (+) are tricritical points. (Reproduced from Landau, D.P. (1983), with permission from the American Physical Society. © 1983.)

for low fields a multiply degenerate antiferromagnet is produced in which two of the sublattices are up and two are down, and at higher fields, a ferromagnetic state appears in which three of the four sublattices are up. Although early Monte Carlo simulations were somewhat contradictory, more recent simulations have shown that all phase boundaries are then first order as shown in Figure 13. However, the 'jumps' along the first-order line tend to zero, so it is unclear if the confluence of the three first-order phase boundaries is a triple point or a multicritical point (Kämmerer, Dünweg, Binder and d'Onorio de Meo, 1996).

Another kind of unexpected, and rather complex, behavior occurs in the triangular Ising antiferromagnet with the addition of ferromagnetic nnn interactions (Landau, 1983). With only nn interactions, there is no phase transition in zero magnetic field; however, when a uniform magnetic field is added, a ferrimagnetic phase becomes stable with positive net magnetization for positive field and negative net magnetization for negative field. Each ferrimagnetic state is separated from the paramagnetic state by a three-state Potts-like line of second-order transitions, but the lines only intersect for $T = 0$. When ferromagnetic nnn interactions are included, the unusual phase diagram, depicted in Figure 14 results. At high temperature in zero magnetic field, the system is paramagnetic. Then, as the temperature is lowered to T_1, in zero magnetic field, a Kosterlitz–Thouless-like transition is encountered (even though the model is an Ising model!). At a still lower temperature, T_2, the transition becomes first order. Thus, below T_2, the field-driven transition separating the two ferrimagnetic states is discontinuous. For small magnetic fields, the transition is second order (for both positive and negative fields) and in the three-state Potts universality class, and as the field increases, a three-state Potts-like tricritical point appears on the boundaries. Thus this simple Ising model shows *no* Ising behavior.

4.7 Systems with disorder

The Ising model with site impurities has been studied by Monte Carlo simulations with contradictory results. The relevant issues are reviewed by Selke (1993). Holey and Fähnle (1990) carried out an MCRG study of the sc Ising model with nonmagnetic impurities and concluded that for 20% impurities, the critical behavior was modified with respect to the pure system. (However, for smaller impurity concentrations the asymptotic critical behavior could not be observed.) The estimate $\nu = 0.688(13)$ was only about 8% higher than the pure Ising value, but the error bars clearly excluded the pure Ising estimate. Using Monte Carlo simulations and an analysis that included corrections to scaling, Ballesteros *et al.* (1998) were able to show rather convincingly that the line of phase transitions that results when different amounts of nonmagnetic site impurities are added is controlled by a single impurity fixed point. Their exponent estimates, for example, $\nu = 0.6837(29)$ agreed

with the earlier MCRG values. An important contributory factor to the precision of their analysis was the inclusion of corrections to scaling in their extrapolation to infinite lattice size. Estimates of critical exponents for the dilute Ising model from four-loop field theoretic RG expansions had also indicated a change in exponents but the numerical values were slightly different than those obtained from the high-quality Monte Carlo simulations mentioned in the preceding text.

Matthews-Morgan, Landau and Swendsen (1984) used MCRG to study the isotropic Baxter model (Baxter, 1972) with nonmagnetic site impurities. In the pure system, the critical behavior is nonuniversal and depends upon the ratio of the four-spin and two-spin couplings. In the site dilute case, the MCRG results suggest that the critical exponents can be described by the pure Baxter fixed line for negative four-spin coupling (slightly renormalized in interaction ratio) terminating at an Ising fixed point. These results substantiate the validity of the Harris criterion within the context of a single model with wide-ranging critical exponents.

Another intriguing aspect of critical behavior in systems with 'simple' disorder (Hui and Berker, 1989) was the prediction that any amount of randomness in a system with a first-order transition should lead to a vanishing of the latent heat, that is, the transition should become first order. This was tested for the first-order transition in the eight-state, ferromagnetic Potts model where the magnitude of the ferromagnetic coupling was modified for some of the bonds. Using MCRG simulations, Chen, Ferrenberg and Landau (1992) confirmed the prediction and found exponents that were consistent with Ising values. Cardy and Jesperson (1997) later reexamined this problem for the q-state Potts model using finite size scaling and conformal invariance. They found evidence for exponents that vary with the number of states q, and a value of $\nu \approx 1$ that varies weakly with q. For spatial dimensionality greater than 2, they also predict that a tricritical point should appear.

Clearly, then the effects of disorder can be surprising and rich, and numerical techniques have only just begun to probe these phenomena.

5 SUMMARY AND PERSPECTIVE

The theory of magnetic phase transitions is now a mature endeavor. Although few models can be solved exactly, Landau theory provides some qualitative insight into phase transition behavior, and a variety of computational approaches allow the precise determination of transition temperatures and critical exponents for many models. Quite long series expansions, however, are difficult to produce for all but the simplest models, and RG theory is also difficult to apply for more complex systems. Nevertheless, both methods have led to substantial understanding of many aspects of phase transitions. Computer simulations are quite flexible and can often be applied to more complicated systems. Finite size scaling allows the extrapolation of simulational data to the thermodynamic limit, and simulations are also rapidly approaching the point at which they can predict the behavior for magnetic nanoparticles of sizes that can be studied in the laboratory. Differences remain between various numerical estimates, and it is not unusual to find that as newer studies are performed using improved methods and computers small, systematic differences are found with respect to older work. Nonetheless, the power of numerical methods is now manifest and when used in concert with analytical theory, such techniques can now provide quite precise results for comparison with experiment.

1 INTRODUCTION

Why should we study magnetic systems with disorder? Since perfect crystals are rare in nature we clearly need to understand how disorder changes the behavior of crystals in order to explain experiments on real materials. More importantly, we now realize that disordered systems exhibit *new phenomena* which are not present in perfect crystals, and so are *of interest in their own right*.

The simplest case of disorder is substitutional disorder, in which a ferromagnetic crystal for example, is randomly diluted with nonmagnetic atoms, (see Figure 1 and Stinchcombe, 1973). If the concentration of nonmagnetic atoms is small enough, a percolating 'network' of spins connected by (e.g., nearest neighbor) exchange interactions is still present in the crystal, and so long-range magnetic order is maintained at low enough temperatures. This is the case assumed in Figure 1 since there is a 'cluster' of spins spanning the lattice from the bottom to the top. Figure 1 shows of a simple Ising model, described by the Hamiltonian (Stanley, 1971)

$$\mathcal{H}_{\text{Ising}} = -\sum_{\langle i,j\rangle} J_{ij} S_i S_j - \sum_i H_i S_i, \quad (S_i = \pm 1) \tag{1}$$

where H_i is a magnetic field acting on site i ($H_i = H$ for a uniform field) and J_{ij} are the exchange constants (which depend only on the relative distance between lattice sites i and j in an ideal crystal). Assuming that $J_{ij} = J$ is nonzero only if i, j are nearest neighbors and that the concentration variable x_i is equal to 1 if site i is occupied by a magnetic atom and zero otherwise, we have

$$J_{ij} = \begin{cases} x_i x_j J, & \text{if } i, j \text{are nearest neighbors} \\ 0, & \text{otherwise} \end{cases}$$
$$H_i = x_i H \tag{2}$$

in the case of Figure 1. An alternative to this 'site disorder' is the case of (nearest-neighbor) 'bond disorder' in which exchange constants take values J_1 with probability p and J_2 with probability $1 - p$. In other words, the probability distribution $P(J_{ij})$ has the form

$$P(J_{ij}) = p\delta(J_{ij} - J_1) + (1 - p)\delta(J_{ij} - J_2) \tag{3}$$

Bond dilution (for which $J_1 = J$, $J_2 = 0$) and the $\pm J$ Ising spin glass model (Binder and Young, 1986) (for which $J_1 = J, J_2 = -J$) are special cases of such disorder (which can only be physically realized in the case of indirect exchange between magnetic ions).

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

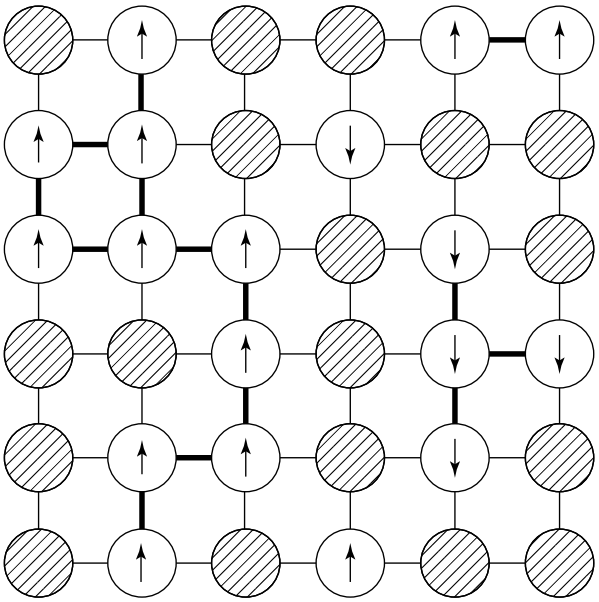

Figure 1. Diluted ferromagnetic Ising model on the square lattice. In the Ising model, spins can point only up or down, as indicated by arrows. Nonmagnetic atoms are shaded. Nearest-neighbor exchange interactions are indicated by thick lines.

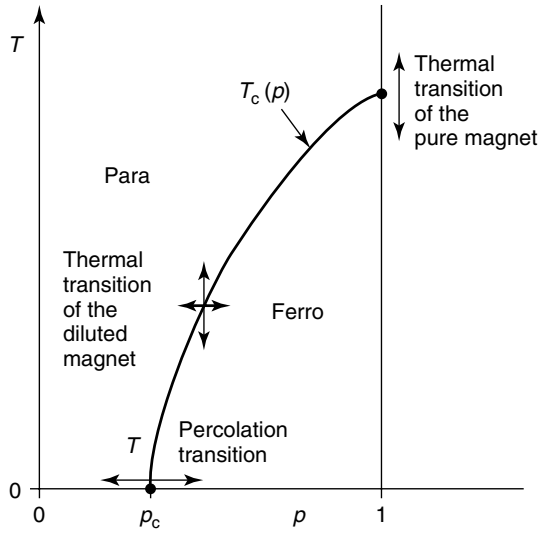

Figure 2. Schematic phase diagram of a bond-diluted nearest-neighbor ferromagnet, using temperature T and the concentration of ferromagnetic bonds as variables. A line of critical points $T_c(p)$ separates the disordered paramagnetic phase (para) from the phase with ferromagnetic long-range order (ferro). This line begins at the critical point of the pure system $\{T_c(p = 1)\}$ and ends at the percolation threshold $\{T_c(p = p_c) = 0\}$. Crossing the line $T_c(p)$ at $T > 0$ one observes a thermal transition, with critical exponents that are believed to be universal along the whole line $T_c(p)$ as long as $p_c < p < 1$ (i.e., excluding the endpoints of this critical line), for three-dimensional Ising systems. With respect to its critical exponents the diluted Ising ferromagnet belongs to a different 'universality class' than the pure model. Still different exponents apply for the percolation transition, which is observed by varying p at $T = 0$. The various phase transitions are indicated by double arrows.

Note that in this article we choose units such that the magnetic moment per spin is incorporated in the magnetic field in equations (1) and (2), so both exchange constants J_{ij} and fields H_i have a dimension of energy. In the limit of a noninteracting Ising paramagnet, the zero-field susceptibility per spin takes the simple form $\chi_0 = (k_B T)^{-1}$, that is, it has the dimension of inverse energy, while the magnetization per spin (M) is dimensionless.

We shall return to the case of spin glasses below; here we focus on the simplest case: the phase diagram of the bond-diluted nearest-neighbor Ising ferromagnet (Figure 2). Disorder has only two effects: (i) a depression of the critical temperature $T_c(p)$ for $p_c < p < 1$ relative to its pure value $T_c(1)$ and (ii) a change of the critical behavior (in the case of Ising ferromagnets in three dimensions). More details on the behavior of diluted ferromagnets will be given in the next section. Particularly interesting is the case $p = p_c$ where $T_c(p) = 0$. This is the concentration below which there is no longer a 'spanning infinite cluster' of spins connected by nearest-neighbor bonds extending throughout the system. At p_c, this infinite cluster (Stauffer and Aharony, 1992) is a 'fractal' (see Section 3 and Meakin, 1998). For $p < p_c$, only finite clusters of spins connected by nearest-neighbor bonds exist, and consequently at low temperature the system behaves as a 'superparamagnet'.

Of course, the assumption that the magnetic interactions extend only to nearest neighbors is inappropriate for many magnetic materials, and the effect of the longer range of the exchange needs to be considered. If the sign of the exchange $J(r)$ is uniformly positive, then, irrespective of the distance r between magnetic atoms, all that happens is that the percolation threshold is shifted to a smaller concentration. However, if ferromagnetic and antiferromagnetic exchange constants (bonds) compete, the magnetic ordering does not energetically satisfy all the bonds. This 'frustration' of some of the bonds combined with the disorder leads to very interesting effects, such as the occurrence of a 'spin glass' phase (Section 4).

Figure 3 qualitatively illustrates the behavior in the case of nearest-neighbor ferromagnetic ($J_{nn} > 0$), and next-nearest-neighbor antiferromagnetic ($J_{nnn} < 0$) exchange interactions in one lattice plane of a simple cubic lattice. In the absence of disorder, if $R \equiv J_{nnn}/J_{nn}$ is greater than some critical value R_m the ground state is still ferromagnetic, while for $R < R_m$ an antiferromagnetic type of order takes over. However, in the case of quenched disorder, there are statistical fluctuations in the concentration of ferromagnetic bonds and as a result, for sufficiently strong dilution and low enough temperature,

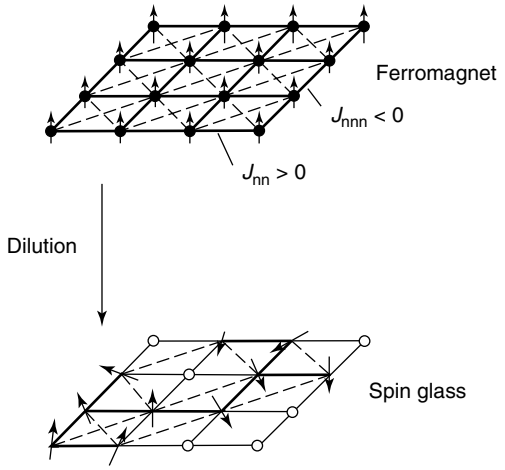

Figure 3. Schematic picture of the spin ordering in one lattice plane of a ferromagnet with nearest-neighbor ferromagnetic exchange J_{nn} (full bonds) and next-nearest-neighbor antiferromagnetic exchange J_{nnn} (broken bonds), upper part. Sufficiently strong dilution (lower part) destroys the conventional magnetic long range of the spins and may lead to a spin glass phase. Nonmagnetic atoms are shown as open circles.

long-range order of either ferromagnetic or antiferromagnetic type is not the equilibrium magnetic structure, but rather the spins 'freeze' into a random-looking state called a *spin glass*. In Figure 3, we have assumed site disorder, since a similar model applies to the face-centered cubic Heisenberg ferromagnet EuS diluted with nonmagnetic Sr (Maletta and Zinn, 1989).

Figure 4 illustrates in a rather speculative way how the phase diagram for a diluted Ising ferromagnet on the simple cubic lattice might look. In particular, there is a 'multicritical point' at $x = x_m$ where paramagnetic, ferromagnetic, and spin glass phases meet. Note that this phase diagram contains several unproven assumptions. Firstly, it is assumed that, for $R_m < R < 0$, the phase boundary of the ferromagnetic phase in the $(T, 1 - x)$ plane is 'reentrant', that is, for $x_c'' < x < x_m$ one observes a transition from paramagnet to ferromagnet *and then to a spin glass*, when the temperature is lowered. This assumption is motivated by experimental observations for some real spin glass systems but has been difficult to reproduce theoretically. Secondly, it is assumed that the zero temperature phase boundary between the spin glass state and the (super)paramagnet does not simply coincide with the next-nearest-neighbor percolation threshold (shown as a broken straight line in Figure 4). This assumption is motivated by some numerical evidence for bond-diluted spin glasses (Aharony and Binder, 1980). The resulting phase at $T = 0$ for $x_p^{nnn} < x < x_c'$ is thought to not exhibit long-range spin correlations of any kind, and this is termed a *cooperative paramagnet* (Binder, Kinzel and Stauffer, 1979) in Figure 4.

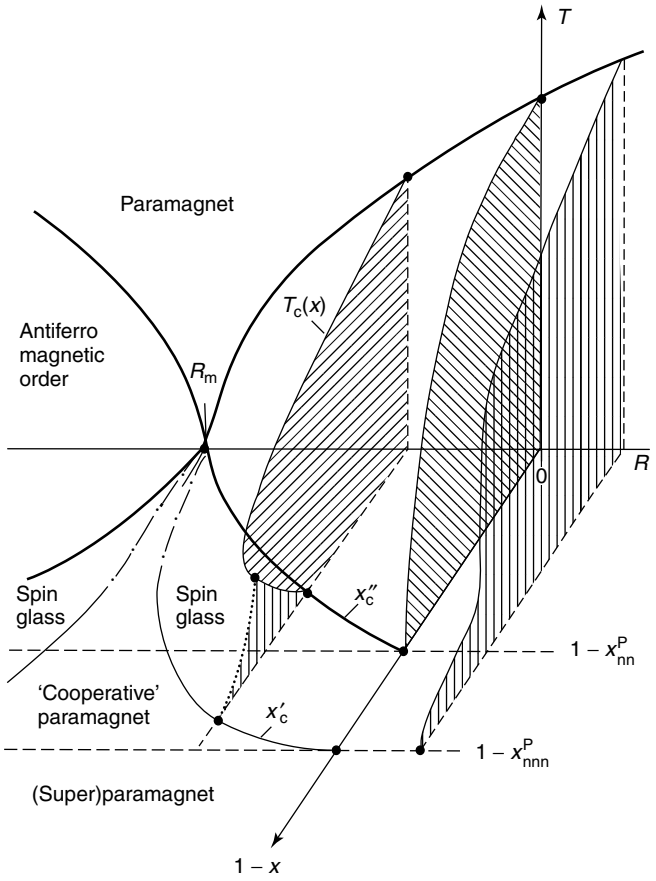

Figure 4. Schematic phase diagram of an Ising model with nearest (J_{nn}) and next-nearest (J_{nnn}) exchange as a function of temperature T, concentration of nonmagnetic ions $1 - x$, and the ratio $R = J_{nnn}/J_{nn}$. Thick curves highlight phase boundaries in the planes $x = 0$ and $T = 0$, respectively. Three phase diagrams are shown (shaded) – for fixed R (for $R_m < R < 0$ a spin glass phase occurs, for $R = 0$ one has the same type of phase diagram as in the case of bond disorder (Figure 2), and for $0 < R - 1 \ll 1$ at low T the stability of the ferromagnetic order extends up to the next-nearest-neighbor site percolation threshold x_{nnn}^p.) For further explanations see text.

Actually, the most commonly studied spin glasses are not diluted magnetic insulators with short-range exchange, modeled as in Figure 3, but rather nonmagnetic noble metals, such as Au, Ag, Cu, or Pt, with a small concentration, of the order of a few percent, of transition-metal magnetic impurities such as Fe or Mn. These magnetic atoms then interact with the indirect exchange mediated by the scattering of conduction ions, the so-called RKKY interaction, $J_{ij}(R) \propto \cos(2k_F R + \varphi_0)/R^3$, in which k_F is the Fermi wave number and φ_0 is a constant. In a dilute system (Figure 5), the distances R between the spins at lattice sites i, j are random, and so some pairs of spins will experience a ferromagnetic and others an antiferromagnetic exchange in a random way. Owing to the long range of this RKKY interaction we expect

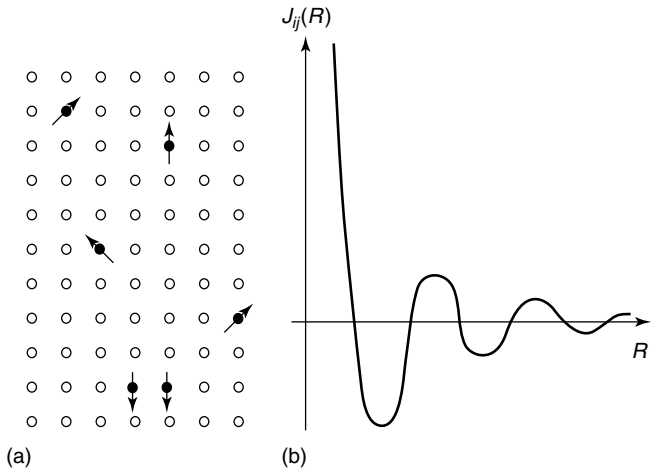

Figure 5. Schematic sketch of magnetic moments (dots with arrows) in a nonmagnetic metallic matrix (open circles, a) and the resulting RKKY exchange plotted as a function of distance R (b).

a random distribution of exchange constants $P(J_{ij})$ strongly peaked at $J_{ij} = 0$.

Disregarding this detailed atomistic structure underlying the problem, Edwards and Anderson (1975) suggested a coarse-grained model, now termed the *Edwards–Anderson model* or *EA model*, which contains what are generally believed to be the two essential ingredients of a spin glass: *disorder* and *frustration*. The Hamiltonian of the EA model is still given by equation (1) but the interactions J_{ij} are chosen to be independent random variables with mean $\overline{J}$ and standard deviation J. Two common choices are the '$\pm J$' model for which

$$P(J_{ij}) = \frac{1}{2}\left[\delta(J_{ij} - J) + \delta(J_{ij} + J)\right] \tag{4}$$

and the Gaussian distribution where

$$P(J_{ij}) = (\sqrt{2\pi}\,J)^{-1} \exp\left[-(J_{ij} - \overline{J})^2/(2J^2)\right] \tag{5}$$

Use of the EA model replaces the original site-disorder problem of Figure 5 by a bond-disorder problem, since the latter is easier to treat by theoretical methods. Many chemically different spin glass systems show qualitatively similar properties, and this supports the view that microscopic details are unimportant and a simple model, such as the EA model, that has disorder and frustration should capture the basic physics of spin glasses. The simplest case, and the one usually taken, is zero mean, $\overline{J} = 0$, since this has no bias toward ferromagnetism or antiferromagnetism.

The EA model, which is described by equation (1) plus the specification of the bond distribution, is generally considered in one of two versions: the short range version where $J_{ij} \neq 0$ only if i, j are nearest-neighbor sites of the lattice, and the long-range version where every spin i in the system interacts with every other spin j with the same (Gaussian) distribution equation (5). However, in the latter case, to ensure a sensible thermodynamic behavior when the number of spins $N \to \infty$, one assumes a scaling $\overline{J} \equiv J_0/N$, $J \equiv \tilde{J}/\sqrt{N}$ with J_0 and $\tilde{J}$ being finite. This Sherrington–Kirkpatrick (SK) model (Sherrington and Kirkpatrick, 1975) has been considered extensively with the motivation that mean-field theory should become exact for infinite-range interactions. However, as briefly discussed further in Section 4, developing a mean-field theory of spin glasses has been a major *tour de force*.

Disorder as shown in Figures 3 and 5 not only prevents the occurrence of conventional magnetic long-range order but it is also rather plausible that the spin arrangement that minimizes the (free) energy of the system is not unique. Consequently, the 'energy landscape' (i.e., the energy of the system as a function of 'phase space coordinates', see Figure 6) contains many (more or less equivalent) 'valleys', separated by large (free) energy barriers. This picture provides a qualitative interpretation of why a very slow relaxation is observed in spin glass systems when one approaches the transition to the spin glass phase from the paramagnetic side. In fact, in the spin glass phase below the transition, the spectrum of relaxation times extends from microscopic times (10^{-12} s or so) up to times considerably longer than that of the experiment. Hence a spin glass at low temperatures is not in equilibrium. Nonequilibrium effects have been conveniently characterized in 'aging' experiments (Nordblad and Svedlindh, 1998), and give rise to surprising and rather poorly understood phenomena such as 'memory' and 'rejuvenation' (Jonason *et al.*, 1998; Bert *et al.*, 2004; Picco, Ricci-Tersenghi and Ritort, 2001).

These slow dynamical aspects of spin glass behavior are qualitatively reminiscent of the behavior of structural glasses,

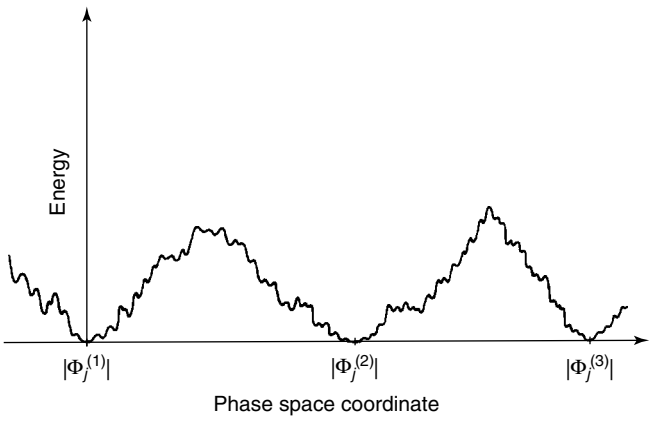

Figure 6. Schematic plot of the coarse-grained free energy of a spin glass plotted versus a phase space coordinate which measures the projection of the considered state to a particular ordered state.

and this is the reason why this kind of disordered magnetic system is called a *spin glass*. However, in the opinion of the authors, there is a significant difference between structural glasses and spin glasses. As we shall see, spin glasses in zero field have an equilibrium transition at finite temperature where there is a divergent correlation length. To our knowledge, no divergent *equilibrium* length scale has been seen in structural glasses.

It should be noted that a complicated energy landscape with many degenerated ground states can be obtained as a result of only frustration without any disorder. The classic example is the nearest-neighbor Ising antiferromagnet on the triangular lattice, which stays disordered at all nonzero temperatures (while on the square lattice the Ising antiferromagnet orders at the same temperature as the Ising ferromagnet). Figure 7 illustrates this concept of frustration for an isolated triangle of spins connected by antiferromagnetic bonds of the same strength, showing that it is not possible to find a spin configuration that is energetically optimal for all three bonds. In the ground state there is always one bond which is 'dissatisfied', that is, 'frustrated'. However, this can be any of the three bonds, and hence there is an enhanced ground-state degeneracy: while a ferromagnetic triangle has a twofold degenerate ground state (all spins up or all spins down) the ground state of the corresponding antiferromagnet is sixfold degenerate, see Figure 7. An infinite triangular lattice with antiferromagnetic bonds between the Ising spins has a nonzero entropy per spin.

Similar frustration effects are also possible on other lattices, for example, the square lattice, when we have both ferro–and antiferromagnetic bonds. Consider, for example, an elementary square with three ferromagnetic and one antiferromagnetic bonds. One finds that this 'plaquette' is frustrated because again no spin configuration can be found that is favorable for all the bonds, and the ground state is now eightfold degenerate. Obviously, any closed loop of bonds on

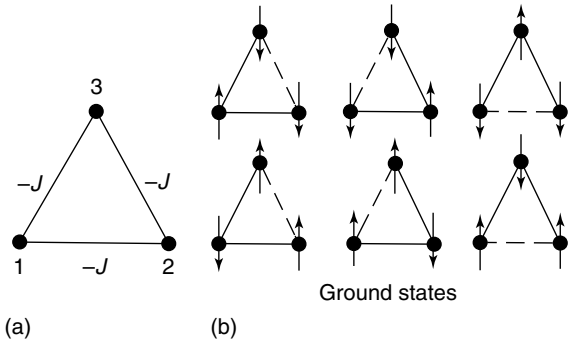

Figure 7. Frustrated triangle of Ising spins (a) and its six ground states (b) where the 'dissatisfied' bonds are shown as broken straight lines.

the lattice is frustrated if the variable $\phi_{\mathrm{p}} \equiv \mathrm{sign}(\prod_{\mathrm{bonds}} J_{ij})$ is equal to -1. One can therefore construct square and simple cubic lattices with a periodic arrangement of frustrated plaquettes, which have very interesting magnetic properties. In particular, for XY spins, that is, a model where magnetic anisotropy constrains the spins to orient isotropically in a particular plane (Stanley, 1971), or for Heisenberg spins (a fully isotropic magnet), noncollinear spin alignments occur. We shall briefly return to such frustrated spin systems without disorder in Section 5.

A still different type of disorder can be obtained when the field H_i in equation (1) is a random variable such that it is zero on average. Again, two common choices are the Gaussian distribution

$$P(H_i) = (2\pi h^2)^{-1/2} \exp\left[-H_i^2/(2h^2)\right] \tag{6}$$

and a two δ function distribution,

$$P(H_i) = \frac{1}{2}\left[\delta(H_i - h) + \delta(H_i + h)\right] \tag{7}$$

In both cases averages over the quenched disorder, indicated by $[\cdots]_{\mathrm{av}}$, have the property

$$[H_i]_{\mathrm{av}} = 0, \quad [H_i^2]_{\mathrm{av}} = h^2 \tag{8}$$

Since such a random field couples linearly to the (local) order parameter (the magnetization of the ferromagnet), even very weak random fields can have drastic effects (Imry and Ma, 1975; Nattermann, 1998). While physical realizations of random fields in ferromagnets are not known, this type of disorder is found in diluted antiferromagnets exposed to a uniform magnetic field (Fishman and Aharony, 1979), since in this way one indirectly creates a random 'staggered field', which couples linearly to the 'staggered magnetization', which is the order parameter of an antiferromagnet. Consequently it has been possible to perform beautiful experiments (Belanger, 1998) testing the theoretical concepts on random fields. We shall briefly return to this problem in Section 6.

2 WEAKLY DILUTED FERRO- AND ANTIFERROMAGNETS

In this section, we discuss the phase transition of ferromagnets (or antiferromagnets in zero magnetic field) which contain quenched disorder due to random dilution with nonmagnetic species (see Figure 2). We restrict attention to short-range exchange forces, disregard long-range correlations in the positions of the impurities, and assume that the

phase transition of the 'pure' system (i.e., an ideal crystal with no impurities) is a second-order transition (Stanley, 1971). In other words, the order parameter ψ, associated susceptibility χ, specific heat C, and correlation length ξ have critical behavior characterized by the following power laws when the temperature is close to the critical temperature $T_c = T_c(p = 1)$:

$$\psi \sim (1 - T/T_c)^{\beta}, \quad \chi \sim |1 - T/T_c|^{-\gamma}$$
$$C \sim |1 - T/T_c\,|^{-\alpha}, \quad \xi \sim |1 - T/T_c|^{-\nu} \tag{9}$$

The many critical exponents $\alpha, \beta, \gamma, \nu$, and so on, are not independent but are related via scaling laws (Stanley, 1971; Fisher, 1974) (see also **Theory of Magnetic Phase Transitions, Volume 1**) such as

$$2\beta + \gamma = 2 - \alpha = d\nu \tag{10}$$

The last of these relations, involving the dimensionality d of the system, is an example of a 'hyperscaling relation'. Critical exponents are 'universal', that is, they do not depend on irrelevant details (such as ratios of exchange constants between nearest and more distant neighbors, lattice symmetry, etc.), but only on the space dimensionality d and the 'spin dimensionality' n, where $n = 1$ is the Ising model, $n = 2$ is the XY model, and $n = 3$ is the Heisenberg model. Thus, critical exponents are the same for all materials in a given 'universality class', and a question of primary interest is how they are affected when quenched disorder occurs.

A rather strong statement on this problem is the 'Harris criterion' (Harris, 1974), which suggests that for $p_c < p < 1$ the critical exponents remain unchanged, that is, they are the same as that of the pure system if the specific-heat exponent of the pure system, α, is negative. This is the case for XY and Heisenberg magnets in $d = 3$, and hence for these systems quenched disorder should be irrelevant. This means that sufficiently close to $T_c(p)$ one should observe the critical exponents of the pure system. Conversely, if $\alpha > 0$, the random system will have new critical exponents $\alpha_r, \beta_r, \gamma_r, \nu_r$. Renormalization group arguments (Stinchcombe, 1973) imply that these new exponents are again universal, and, in particular, should not depend on p (though the temperature range $|T - T_c(p)|$ where they can be observed depends on p and is often very small). Much effort, both experimentally and theoretically, with numerical methods (Monte Carlo simulations, extrapolation of systematic series expansions; see Stinchcombe, 1973) has been devoted to this problem. The asymptotic critical region is so narrow that it is practically inaccessible, and hence in practice one observes 'effective' critical exponents that depend on p. However the data is consistent with the asymptotic behavior being independent of p.

The Harris criterion is inconclusive for the special case $\alpha = 0$, which occurs, for example, for the $d = 2$ Ising model where the specific heat of the pure system has a logarithmic singularity, $C \sim \ln|1 - T/T_c(p)|$. By various theoretical methods, evidence has been accumulated (Selke, 1991) that in this case the critical behavior is altered into an even more subtle logarithmic form, $C \sim \ln|\ln|1 - T/T_c(p)||$.

Finally, we mention that in the diluted system some (exponentially weak) singularities already set in at $T_c(p = 1)$, the critical temperature of the pure system. These 'Griffiths singularities' (Griffiths, 1969) come from statistical fluctuations in the occupancy of the sites in a randomly diluted system. There is always a nonzero probability to find an arbitrarily large region with no dilution sites (though this probability decreases exponentially with the volume of such a region), and these regions already order at T_c. While the effect of these anomalies occurring for $T_c(p) < T < T_c(p = 1)$ on *static* properties is hardly noticeable, they have a bigger effect on *dynamics*, causing a slow stretched exponential relaxation which is not expected in the pure case. Related 'Griffiths–McCoy' singularities have more pronounced effects in quantum spin glasses (Bhatt, 1998), see Section 4.

3 PERCOLATION

Here we continue the discussion of the phase diagram in Figure 2, but now consider the concentration, p_c, where the critical temperature vanishes, $T_c(p = p_c) = 0$. This endpoint of the line $T_c(p)$ is a special multicritical point since a different type of critical behavior is observed when p is varied at $T = 0$ than when the critical line is crossed at finite T. For simplicity we restrict our attention to nearest-neighbor ferromagnetic exchange.

For $p < p_c$, all spins are in finite clusters, where a cluster is defined by the criterion that each spin of the cluster must have at least one bond to another spin in the same cluster. As an example, the 6×6 lattice of Figure 1 contains clusters with $s = 2, 4$, and 10 spins. On a lattice with N sites, it is useful to define a *cluster concentration* $n_s(p) = N_s(p)/N$, where $N_s(p)$ is the number of clusters with s spins. Note that all spins inside a cluster at $T = 0$ are aligned parallel with respect to each other but different clusters can orient independently (Figure 1). Since each spin must belong to some cluster, we have the sum rule

$$\sum_{s=1}^{\infty} s n_s(p) = p, \quad (p < p_c) \tag{11}$$

The restriction $p < p_c$ is because, for $p \geq p_c$, an infinite 'percolating' cluster occurs in an infinite lattice, and this

needs to be considered separately. The probability that a given spin is part of the percolating cluster is called the *percolation probability* $P_\infty(p)$ and is related to the cluster concentrations n_s via

$$P_\infty(p) = 1 - (1/p) \sum_{s=1}^{\infty}{}' s n_s(p), \quad (p > p_c) \tag{12}$$

since spins which do not belong to the infinite cluster must belong to finite clusters. The prime in the sum in equation (12) indicates that the infinite cluster is not included.

The spontaneous magnetization m is obtained by taking the limit of an infinitesimally small field. Finite clusters can point equally in both directions as the field tends to zero and so contribute nothing to m. However, the infinite cluster must point in the direction of the field as long as the field is not strictly zero, and so $P_\infty(p)$ is the spontaneous magnetization per lattice site as $T \to 0$. When $p \to p_c^+$, there occurs a power law analogous to equation (9), $P_\infty(p) \propto (p - p_c)^{\beta_p}$, but the critical exponent β_p differs from β and β_r.

For $p < p_c$ the spontaneous magnetization of the lattice is zero, but we obtain a magnetization applying a magnetic field H

$$M(T, h) = (1/p) \sum_{s=1}^{\infty} n_s s \tanh(s\mu H / k_B T), \quad (T \to 0) \tag{13}$$

μ being the magnetic moment per spin. This is equivalent to the equilibrium magnetization of superparamagnetic particles containing s spins and having a particle size distribution n_s. From equation (13) the zero-field susceptibility is given by

$$\chi_p = (\chi_0/p) \sum_{s=1}^{\infty} n_s s^2 \quad (p < p_c) \tag{14}$$

where χ_0 is the susceptibility of a single spin. An analogous formula holds for $p > p_c$, if the infinite cluster is omitted from the sum. For $p \to p_c$ one finds a power law $\chi_p \propto |p - p_c|^{-\gamma_p}$. The free energy of the superparamagnet in the limit of a vanishingly small field comes from the entropy $(\ln 2)$ of each of the finite clusters. Hence

$$F(T, 0) = -k_B T \ln 2 \sum_{s=1}^{\infty} n_s(p) \tag{15}$$

which has a singular part that can be written as $F_{sing} \propto |p - p_c|^{2-\alpha_p}$ for $p \to p_c$.

Note that the spin–spin correlation function now has the meaning of a 'pair-connectedness function' $G(r)$, see Stauffer and Aharony (1992) for more details, and one can introduce a correlation length ξ_p describing the exponential decay of $G(r)$ with distance r, $G(r) \propto \exp(-r/\xi_p)$. Again a power law holds, $\xi_p \propto |p - p_c|^{-\nu_p}$, and the exponents $\alpha_p, \beta_p, \gamma_p, \nu_p$ satisfy the same type of scaling relations as in equation (9).

Exactly at the percolation concentration p_c, $G(r)$ decays with a power law, $G(r) \propto r^{-(d-2+\eta_p)}$. (There is an analogous relation for the spin correlation function at a thermally driven second-order phase transition.) For the percolation transition, the geometric interpretation of this power law is particularly interesting. Let us consider the number n of sites within a (hyper)sphere of radius R around a site of the (incipient) percolating cluster precisely at $p = p_c$:

$$n = \int \mathrm{d}r [G(r)/P_R] \propto P_R^{-1} \int_0^R G(r) r^{d-1}\, \mathrm{d}r \tag{16}$$

Here $P_R \propto R^{-\beta_p/\nu_p}$ is the probability that an occupied site within the hypersphere belongs to the largest cluster (and not to any of the many smaller clusters that are also present and counted in $G(r)$). Using the power law for $G(r)$ at $p = p_c$ then yields

$$n \propto R^{2-\eta_p+\beta_p/\nu_p} = R^{d_f}, \quad \text{where}$$
$$d_f = 2 - \eta_p + \frac{\beta_p}{\nu_p} = \frac{1}{2}(d + 2 - \eta_p) \tag{17}$$

To get the last relation, we have used another hyperscaling relation. For a compact object of radius R the number of lattice sites in the object, n, is clearly proportional to R^d, so the exponent d_f in equation (17) can be interpreted as a 'fractal dimension' characterizing the geometrical self-similar structure of a noncompact object. It is intuitively clear that $d_f < d$, and this follows because $d - 2 + \eta_p > 0$ since correlations must decrease (rather than increase) with distance at criticality. It turns out that the structure of the spin correlations at the critical point at thermally driven magnetic phase transitions can also be similarly interpreted in terms of the geometric concepts about 'fractals'.

We also mention briefly the nature of long-wavelength magnetic excitations (magnons) in strongly disordered Heisenberg magnets near the percolation threshold. One can show that for wave number $q \to 0$ and near the percolation threshold, the dispersion relation of the characteristic frequency $\omega_c(q)$, has a 'dynamic scaling' structure (Hohenberg and Halperin, 1977)

$$\omega_c(q) \propto q^2 (p - p_c)^{\mu - \beta_p} \tilde{\omega}_p \left(q(p - p_c)^{-\nu_p}\right) \quad (p \geq p_c) \tag{18}$$

where μ is a new exponent and $\tilde{\omega}_p$ a scaling function. The relation $\omega_c \propto q^2$ is just the standard dispersion law

for ferromagnetic spin waves, but the factor $(p - p_c)^{\mu-\beta_p}$ implies that for $p \to p_c$ the spin-wave frequencies vanish, that is, the spin waves become 'soft modes'. Keeping q small but fixed and taking $p \to p_c^+$, the scaling function $\tilde{\omega}_p(\xi)$ must behave as $\tilde{\omega}_p(\xi) \propto \xi^{(\mu-\beta_p)/\nu_p}$ in order to have a well-defined limit for $p \to p_c$, and hence the characteristic frequency $\omega_c(q)$ scales as $\omega_c(q) \propto q^z$, where z, the dynamical exponent is given by $z = 2 + (\mu - \beta_p)/\nu_p$. One sometimes expresses this result in terms of a 'spectral dimension' d_s where $d_s = 2d_f/z$ and d_s is related to the density of energy excitations between w and $\omega + d\omega$ by $g(\omega) \propto \omega^{ds/2-1}$. Unfortunately, the precise estimate of the dynamic exponent z (or equivalently the exponent d_s) is difficult, and also the nature of magnetic excitations in disordered magnets outside the scaling regime near the percolation threshold is a complicated problem (Kovalenko, Krasny and Krey, 2001).

Fractals have many applications outside of magnetic systems also, such as conductivity of disordered materials containing random mixtures of conducting and nonconducting regions, flow of water or oil through porous rocks, diffusion-limited aggregation, and other random growth phenomena (Meakin, 1998). However these are beyond the scope of this article.

4 SPIN GLASSES

Spin glasses are magnetic systems with competing interactions and quenched disorder that is strong enough that no conventional ferro- and antiferromagnetic order can occur, but rather the spins are frozen in random directions. As mentioned in Section 1, there exists a great variety of physical systems that show this behavior. A common feature is a rather sharp cusp in the (frequency-dependent) magnetic susceptibility, but there is no corresponding anomaly in the specific heat. The position of the cusp is weakly dependent on frequency ω but seems to converge toward a static transition temperature T_c, below which hysteresis effects set in. In particular, for $T < T_c$, the zero-field-cooled and field-cooled susceptibilities differ (see Figure 8 and for example, Nagata, Keesom and Harrison, 1979) and aging phenomena are observed (Nordblad and Svedlindh, 1998) as well.

It soon became clear that the observed behavior does not simply come from a gradual slowing down of the dynamics to timescales beyond those of experiments, but is due to an underlying *equilibrium* phase transition. To illustrate how this can lead to a cusp in the susceptibility, consider, for simplicity, a symmetric distribution of bonds, $P(J_{ij}) = P(-J_{ij})$, that is, $\overline{J} = 0$ in equation (5). For this case one can easily show that, on average, magnetic two-spin

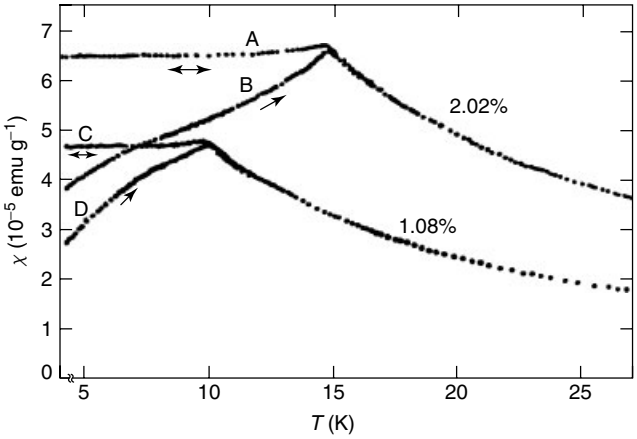

Figure 8. Static susceptibilities of CuMn versus temperature for 1.08 and 2.02 at% Mn. After zero-field cooling ($H < 0.05$ Oe), initial susceptibilities (B) and (D) were taken for increasing temperature in a field of $H = 5.9$ Oe. The susceptibilities (A) and (C) were obtained in the field $H = 5.9$ Oe, which was applied above T_c before cooling the samples. (Reprinted figure with permission from Shoichi Nagata, P.H. Keesom and H.R. Harrison, *Phys. Rev. B.* Vol. 19, 1633–1638 (1979) Copyright 1979 by the American Physical Society.)

correlations are trivial, $[\langle \vec{S}_i \cdot \vec{S}_j \rangle]_{\rm av} = \delta_{ij}$. (Here we have allowed for a vector character of the spins). Using the fluctuation–dissipation relation, which expresses the susceptibility in terms of spin pair correlations, we have, in the limit of vanishingly small field,

$$k_B T \chi = N^{-1} \sum_{i,j} \left[\langle S_i \cdot S_j \rangle_T - \langle S_i \rangle_T \cdot \langle \vec{S}_j \rangle_T \right]_{\rm av}$$
$$= 1 - q \tag{19}$$

where the spin glass order parameter q is defined by $q = [\langle S_i \rangle_T^2]_{\rm av}$. q becomes nonzero for $T < T_c$, $q \propto (1 - T/T_c)^\beta$, which gives a cusp in the zero-field susceptibility.

Actually, as for other critical phenomena, one can identify correlations that become long ranged as one approaches the freezing transition from above, however this correlation is not the standard spin pair correlation but is of a higher order, $g_{\rm SG}(r) = [\langle S_i \cdot S_j \rangle_T^2]_{\rm av}$. The square is needed because the spin–spin correlations can have either sign at random. It is useful to sum $g_{\rm SG}(r)$ over all space to get the spin glass susceptibility, $\chi_{\rm SG} = \sum_r g_{\rm SG}(r)$, since this diverges at the spin glass transition, $\chi_{\rm SG}(T) \propto (T/T_c - 1)^{-\gamma}$. Although $\chi_{\rm SG}$ is not directly measurable it is very closely related to the nonlinear susceptibility, $\chi_{\rm nl}$, defined by

$$M = \chi_0 H - \chi_{\rm nl} H^3 + \cdots \tag{20}$$

where M is the magnetization and H the magnetic field. In fact, for an EA Ising spin glass with a symmetric distribution

of interactions, the relation is

$$(k_{\mathrm{B}}T)^3\chi_{\mathrm{nl}} = \chi_{\mathrm{SG}} - \frac{2}{3} \tag{21}$$

Remember our choice of units, for which the magnetic field has a dimension of energy, magnetization is dimensionless, and hence the (linear) susceptibility has a dimension of inverse energy, the nonlinear susceptibility has a dimension of inverse energy to the minus third power, while the spin glass susceptibility was defined as a dimensionless quantity.

For the case of a nonsymmetric bond distribution, this relation is no longer true but, nonetheless, χ_{nl} and χ_{SG} still diverge in the same way. Experiments, for example, Omari, Préjean and Souletie (1983), suggest that a critical divergence of χ_{nl} does occur ($\gamma \approx 3.25$ in Omari, Préjean and Souletie (1983)). Furthermore, one finds a scaling of the nonlinear part of the magnetization,

$$1 - M/(\chi_0 H) = (1 - T/T_{\mathrm{c}})^{\beta}\widetilde{M}\left\{(H/T)^2(1-T/T_{\mathrm{c}})^{-(\gamma+\beta)}\right\} \tag{22}$$

with $\beta \approx 0.75 - 0.95$ (Omari, Préjean and Souletie, 1983). Note, however, that the critical behavior of the correlation length ξ_{SG} describing the decay of $g_{\mathrm{SG}}(r)$ with distance, $\xi_{\mathrm{SG}} \propto (|T/T_{\mathrm{c}} - 1|^{-\nu})$, cannot be measured directly, and thus can only be inferred indirectly from experimental determinations of β and γ combined with the scaling relation (equation (10)).

Analyzing the dynamic susceptibility near T_{c}, the dramatic increase of the relaxation time τ can be attributed to standard critical slowing down (Hohenberg and Halperin, 1977), $\tau_{\mathrm{SG}} \propto \xi_{\mathrm{SG}}^{z} \propto (T/T_{\mathrm{c}} - 1)^{-\nu z}$, but with an anomalously large dynamic exponent z, giving $z\nu \approx 7.2 \pm 0.5$ (Bontemps, Rajchenbach, Chamberlin and Orbach, 1984). However, when one compares analyses of different groups, one finds a rather large spread in the values of the suggested critical exponents, irrespective of whether these groups analyze the same spin glass systems or different ones (see, e.g., Table 1 of Maletta and Zinn, 1989). Thus, it is fair to say that there is qualitative evidence from experiment that a static phase transition in spin glasses does exist, but the associated critical exponents are not yet accurately known.

Turning to the theoretical work on spin glasses, the first problem to consider is how one can carry out the averaging $[\cdots]_{\mathrm{av}}$ over the random bond distribution. To calculate the average free energy, $[F]_{\mathrm{av}} = -k_{\mathrm{B}}T[\ln Z\{J_{ij}\}]_{\mathrm{av}}$, and its derivatives a common approach is to use the 'replica trick' (Edwards and Anderson, 1975)

$$[\ln Z\{J_{ij}\}]_{\mathrm{av}} = \lim_{n\to 0}\frac{1}{n}\left(\left[Z^n(J_{ij})\right]_{\mathrm{av}} - 1\right) = \lim_{n\to 0}\frac{\partial}{\partial n}\left[Z^n(J_{ij})\right]_{\mathrm{av}} \tag{23}$$

The problem of averaging $\ln Z$ is thus reduced to the problem of averaging Z^n, and, at least for positive integer n, this is a simpler problem since one can interpret Z^n as a product of n identical replicas of the system. At the end of the calculation one takes the limit $n \to 0$.

For nearest-neighbor interactions with the Gaussian distribution in equation (5), it is easy to 'complete the square' and show that $Z_n \equiv [Z^n\{J_{ij}\}]_{\mathrm{av}} = Tr_{\{S_i^\alpha\}}\exp[-\mathcal{H}_n^{\mathrm{eff}}(S_i^\alpha)/k_{\mathrm{B}}T]$, where

$$\mathcal{H}_n^{\mathrm{eff}}\{S_i^\alpha\} = \frac{\overline{J}}{k_{\mathrm{B}}T}\sum_{i\neq j}\sum_{\alpha=1}^{n} S_i^\alpha S_j^\alpha + \frac{1}{2}\left(\frac{J}{k_{\mathrm{B}}T}\right)^2\sum_{i\neq j}\sum_{\alpha,\beta} S_i^\alpha S_j^\alpha S_i^\beta S_j^\beta \tag{24}$$

The initial problem with the Hamiltonian $\mathcal{H}\{J_{i,j}\}$, which lacks translational invariance, has now been replaced by an equivalent problem that *is* translationally invariant (equation (24)). The price of this simplification is that the degrees of freedom S_i^α now carry an additional index α, $1 \leq \alpha \leq n$, the 'replica index', and, owing to disorder, the various replicas of the system get coupled to each other.

In the mean-field approximation, one replaces $S_i^\alpha S_j^\alpha$ by $S_i^\alpha\langle S_j^\alpha\rangle$, and $S_i^\alpha S_i^\beta S_j^\alpha S_j^\beta$ by $S_i^\alpha S_i^\beta\langle S_j^\alpha S_j^\beta\rangle$ and determines self-consistently the 'order parameters' $m_\alpha \equiv \langle S_\alpha^j\rangle$, $q_{\alpha\beta} = \langle S_j^\alpha S_j^\beta\rangle$ ($\alpha \neq \beta$). More precisely, noting from equation (23) that we need to let $n \to 0$ and that no index α should be singled out, one obtains for the magnetization M and the EA order parameter q

$$M = \lim_{n\to 0}\frac{1}{n}\sum_{\alpha=1}^{n}\langle S_i^\alpha\rangle,\quad q = \lim_{n\to 0}\frac{1}{n(n-1)}\sum_{\alpha\neq\beta}\langle S_i^\alpha S_i^\beta\rangle \tag{25}$$

For the infinite-range case, mean-field theory can be obtained rigorously in terms of a saddle point approximation, as worked out by Sherrington and Kirkpatrick (1975) for the 'replica-symmetric' case in which $m_\alpha = M$ and $q_{\alpha\beta} = q$ independent of the replica indices. One finds

$$M = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{+\infty} \mathrm{d}z\mathrm{e}^{-z^2/2}\tanh\left(\frac{1}{k_{\mathrm{B}}T}\left[\tilde{J}\sqrt{q}z + J_0 M + H\right]\right) \tag{26}$$

and

$$q = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{+\infty} \mathrm{d}z\mathrm{e}^{-z^2/2}\tanh^2\left(\frac{1}{k_{\mathrm{B}}T}[\tilde{J}\sqrt{q}z + J_0 M + H]\right) \tag{27}$$

which generalizes the well-known result for the Ising ferromagnet, $M = \tanh([J_0 M + H]/k_{\mathrm{B}}T)$. For $H = J_0 = 0$,

equation (27) allows a nonzero solution for q for $T < T_c = \tilde{J}/k_B$, namely, $q = 1 - T/T_c + (1 - T/T_c)^2/3 + \cdots$, so $\beta = 1$ in mean-field theory. The magnetic equation of state for $T > T_c$ becomes

$$M = \frac{H}{k_B T}\left\{1 - \frac{1}{3}\left(\frac{H}{k_B T}\right)^2 \frac{T^2 + 2T_c^2}{T^2 - T_c^2} + \cdots\right\} \qquad (28)$$

which shows that the nonlinear susceptibility does indeed diverge (as stated in Section 1), with the mean-field exponent $\gamma = 1$.

However, a closer look on the SK solution given by equations (26) and (27) shows that it is not acceptable, since at low temperatures the entropy becomes negative, and χ_{SG} for $T \leq T_c$ turns out to be negative as well (de Almeida and Thouless, 1978). The problem lies in the assumption of replica symmetry. However, the means for breaking the symmetry of the matrix $q_{\alpha\beta}$ in the limit $n \to 0$ was not entirely clear. Eventually, in a brilliant piece of work, Parisi (1979) made an ansatz (which appears to be exact for the infinite-range SK model) in which the matrix is reduced to an order parameter function $q(x)$. For $H = J_0 = 0$ and T close to T_c, Parisi finds

$$q(x) = x/2, \ (0 < x \leq x_1),$$
$$q(x) = x_1/2, \ (x_1 \leq x \leq 1) \qquad (29)$$

This order parameter function arises because, for $T < T_c$, the phase space is split into many 'valleys' (compare Figure 6) separated by infinitely high barriers. These valleys or 'ergodic components' are not orthogonal to each other however, but the spin configurations in different valleys have an overlap q. It turns out (Parisi, 1983) that the derivative of the inverse function of $q(x)$, namely, $\mathrm{d}x/\mathrm{d}q$, is the probability, $P(q)$, that there is an overlap q between two states. Note that replica calculations use statistical mechanics, in which there is a nonzero probability of the system being in any of the valleys. By contrast, if one followed the dynamical evolution of the system, the system would be trapped in a single valley, so time averages differ from ensemble averages.

The multivalley structure of an Ising spin glass in the mean-field limit not only exists at zero field, but over a range of fields up to the so-called AT line (de Almeida and Thouless, 1978), which near T_c is given by

$$T_c - T_{AT}(H) \propto H^{2/3} \qquad (30)$$

Of course, experience from standard phase transitions is that mean-field theory is, at best, only qualitatively correct for real systems with short-range forces (Fisher, 1974). Only if the spatial dimensionality d of the system exceeds the 'upper critical dimension', d_u (with $d_u = 4$ for ferromagnets), do the critical exponents of mean-field theory apply to real systems. However, for $d_l < d < d_u$, where d_l is the 'lower critical dimension', the exponents take nontrivial values and depend on d and also on the spin dimensionality. For $d < d_l$, statistical fluctuations (that are neglected by mean-field theory) destroy the phase transition altogether so $T_c = 0$. For ferromagnets, $d_l = 1$ for Ising systems and $d_l = 2$ for isotropic vector models (e.g., XY or Heisenberg).

For spin glasses, however, it turns out that $d_u = 6$, and hence the physical dimensionality $d = 3$ is much less than d_u; so drastic discrepancies between mean-field theory and experiments should be expected. These discrepancies would be even more dramatic if d_l were greater than 3, because then the transition predicted in mean-field theory would not occur at all. However, at least for Ising spin glasses, it is now well established that there *is* a finite-temperature spin glass transition in three dimensions (Ballesteros *et al*., 2002), though not in $d = 2$ (see, for example, Hartmann *et al*., 2002), so d_l lies between 2 and 3.

For XY and Heisenberg ferromagnets, however, the situation has been more controversial. It is known that for the pure case, topological excitations may be important since unbinding of vortex–antivortex pairs controls the phase transition of the XY model (Kosterlitz and Thouless, 1973) in two dimensions. For the pure case, vortices only occur through thermal fluctuations since the ground state is collinear. However, in a model with frustration the ground state is noncollinear, and so one has vortices quenched in even at $T = 0$. It is therefore important to understand the role of vortices (often called chiralities) in XY spin glasses (and the analogous chiralities in Heisenberg spin glasses). While for a long time it was believed that $d_l = 4$, so there would be no order in isotropic spin glass systems in $d = 3$, it was later (Kawamura and Tanumura, 1991) suggested that chiral glass ordering in isotropic vector spin glasses occurs without accompanying spin glass ordering. However, this was not universally accepted, and, in particular, recent, careful Monte Carlo simulations (Lee and Young, 2003) have shown that isotropic spin glasses *d*o have a nonzero *spin glass* transition temperature in $d = 3$, and that chiral and spin glass ordering set in at the same temperature. Thus one can explain the observed finite T_c in spin glasses such as CuMn and $Eu_xSr_{1-x}S$, which are isotropic to a good approximation, without invoking the small anisotropy that these systems must possess.

Even though a spin glass is not in thermal equilibrium below T_c, it is still of theoretical interest to understand the equilibrium state that the system is trying to reach. Two main phenomenological descriptions have been proposed. The first is the 'replica symmetry breaking' (RSB) approach in which

it is supposed that the spin glass state in real systems is similar to the multivalley structure found (Parisi, 1979) in the SK model. This has (i) a nontrivial order parameter function $P(q)$ and (ii) a phase transition (AT line) in a magnetic field. The other approach is the 'droplet picture' developed by Fisher and Huse (1986) (see also Bray and Moore, 1986; McMillan, 1984). In this picture spin glasses have just a single 'pure state' (apart from states related by global symmetry such as spin inversion). Consequently $P(q)$ is trivial (just a delta function at the single order parameter q), and there is no AT line (a field wipes out the transition as it does in a ferromagnet). According to numerics, there does not appear to be an AT line (Katzgraber and Young, 2004), which favors the droplet model, although $P(q)$ appears to be nontrivial (Marinari, Parisi and Ruiz-Lorenzo, 1998; Katzgraber, Palassini and Young, 2001), which favors RSB. Hence an intermediate scenario (Krzakala and Martin, 2000; Palassini and Young, 2000) called *TNT* for *trivial–nontrivial*, fits the data best. However, numerics can only be done on small systems, so it is not clear whether TNT describes the asymptotic behavior on large length scales.

Since a spin glass is not in full equilibrium below T_c, the eventual goal of spin glass theory must be to explain nonequilibrium effects, such as aging (Nordblad and Svedlindh, 1998) and memory and rejuvenation (Jonason *et al.*, 1998; Bert *et al.*, 2004; Picco, Ricci-Tersenghi and Ritort, 2001), referred to in Section 1. There has also been considerable interest in the nature of violations of the fluctuation–dissipation theorem (Bouchaud, Cugliandolo, Kurchan and Mézard, 1998; Crisanti and Ritort, 2003). Unfortunately we do not have space to discuss these fascinating topics here.

In addition, generalizations of the spin glass problem such as the p-spin interaction models and p-state Potts spin glass models have received a lot of attention, because these models are possibly related to the problem of the glass transition of undercooled fluids (Binder, 2004).

Another very interesting extension concerns spin glass models in which quantum fluctuations rather than classical fluctuations play a key role (Bhatt, 1998). An example is the Ising spin glass in a transverse magnetic field at zero temperature, where one can study a quantum phase transition by varying the strength of this field. The diluted dipolar Ising magnet $LiHo_xY_{1-x}F_4$ provides an experimental example (Wu, Bitko, Rosenbaum and Aeppli, 1993). It is interesting to note that quantum spin glasses do have a 'quantum phase transition' (i.e., a transition at $T = 0$) even in $d = 2$ dimensions, and that rare fluctuations of the random distribution can cause a divergence of the nonlinear susceptibility already in the paramagnetic phase of the spin glass (Bhatt, 1998).

5 PERIODIC FRUSTRATED SYSTEMS

Following the pioneering work of Villain (1977), there has been interest in understanding the behavior of models with frustration but without disorder. In addition to theoretical interest, further motivation for studying these models comes from the existence of related experimental systems with which one can compare theoretical predictions (Diep, 1994).

The effect of periodically distributed frustrated 'plaquettes', that is, elementary polygons (triangles on the triangular or face-centered cubic lattices, squares on the square or simple cubic lattices) depends crucially on whether one considers Ising or continuous spins (e.g., XY and Heisenberg models). As already discussed (see Figure 7), the ground state degeneracy in frustrated systems is enhanced relative to that of unfrustrated systems.

Ising models in $d = 2$, such as the triangular antiferromagnet or the 'fully frustrated' square lattice do not order at any temperature. In $d = 3$, the face-centered cubic antiferromagnet in zero field has a first-order transition to the paramagnetic state, that has been carefully studied by Monte Carlo methods. However, the phase diagram of the fcc Ising antiferromagnet in a magnetic field is still not fully understood (Kämmerer, Dünweg, Binder and D'Onorio De Meo, 1996). Ising models on frustrated simple cubic lattices and stacked triangular lattices presumably exhibit second-order phase transitions, which have been studied by Monte Carlo simulations and renormalization group methods (Plumer and Mailhot, 1995).

Ising-like systems on the pyrochlore lattice, such as holmium and dysprosium titanate, have aroused a lot of recent interest (Siddharthan, Shastry and Ramirez, 2001; Melko, den Hertog and Gingras, 2001). This lattice comprises corner-sharing tetrahedra and on each tetrahedron, energetics requires two of the four spins to be 'in' and two 'out', similar to the Bernal–Fowler rules for the hydrogen bonds in ice. In fact, there is a strong similarity between these magnetic systems and ice, even down to the residual entropy at $T = 0$ first calculated for ice by Pauling, so the name *spin ice* has been given to them. The advantage of the magnetic system over ice is that it couples to a continuously variable parameter, the magnetic field, and so complicated phase boundaries can be mapped out. This has been done in detail for a related Heisenberg system (Ramirez *et al.*, 2002).

The behavior of frustrated XY antiferromagnets is also of interest because the spin ordering around a frustrated plaquette is noncollinear, and so chiralities may play a role, as also proposed for XY spin glasses discussed in Section 4. For the frustrated triangular XY antiferromagnet, spins around an elementary triangle are rotated by 120°, and

one has left-handed and right-handed chiral states. Therefore, the symmetry of the order parameter space is $Z_2 \times$ SO(2) instead of the continuous rotational invariance. Similarly, there are chiral as well as spin degrees of freedom in the fully frustrated XY model on the square lattice. The main issue is whether spin and chiralities order at the same temperature, or whether the chiralities order at a higher temperature. There is some evidence (see, e.g., Lee, Lee and Kosterlitz, 1997) for two separate transitions but the difference in transition temperatures is very small so it is difficult to know whether this effect is real or an artifact due to systematic corrections to finite size scaling.

If one stacks triangular lattices to make a three-dimensional lattice, one can have ordering at finite temperature, and Kawamura (1988) pointed out that the transition belongs to a new universality class, assuming it is second order. There has been controversy, which does not seem to be settled, as to whether the transition is really second order, in which case the exponents are close to those expected at a tricritical point ($\beta = 1/4, \gamma = 1, \nu = 1/2$), or whether the transition is weakly first order (see, e.g., Delamotte, Mouhanna and Tissier, 2004). Unfortunately, the wide variety of experimental systems (e.g., $CsMnBr_3$) does not give a clear picture of the critical behavior of these systems (Plumer and Mailhot, 1995).

A variety of complex phase diagrams and multicritical phenomena is expected when one considers frustrated XY and Heisenberg antiferromagnets exposed to magnetic fields. This still is an active area of research (Diep, 1994).

6 RANDOM MAGNETIC FIELDS

In this section we focus on systems where the quenched disorder leads to a local 'field' coupling linearly to the order parameter, and examine how the phase transition, for example, to a ferromagnetic phase, is affected. The simplest model is an n-component ferromagnet with nearest-neighbor exchange J exposed to a random field H_i that acts on every lattice site i and is completely uncorrelated with zero mean and variance h^2:

$$\mathcal{H} = -J \sum_{\langle i,j \rangle} S_i \cdot S_j - \sum_i H_i \cdot S_i,$$
$$[H_i]_{av} = 0, \; [H_i \cdot H_j]_{\text{av}} = h^2 \delta_{ij} \tag{31}$$

A basic question is how to determine the value of the lower critical dimension d_l, below which arbitrarily weak random fields are able to destroy uniform long-range order by breaking the system up into domains (Imry and Ma, 1975). In a domain of linear size L in d dimensions there will be an excess of random fields of either sign of order $L^{d/2}$, due to statistical fluctuations. Thus, overturning the magnetization in this domain causes an energy gain of the order of $hL^{d/2}$. However, for $T < T_c$, creating a domain wall costs an energy of the order of JL^{d-1} in the Ising case and JL^{d-2} in the case of XY and Heisenberg. Balancing these energies, one finds that a uniform magnetization is unstable against domain formation in arbitrarily weak random fields for $d < 2$ in the Ising case and for $d < 4$ in the XY and Heisenberg cases. Thus, a phase transition is still expected to occur for the $d = 3$ Ising model, but not for the $d = 3$ XY and Heisenberg model where arbitrary weak random fields should lead to a rounding of the transition. The transition is also rounded for the $d = 2$ Ising model, for which a more refined analysis shows (Binder, 1983; Moore, Stinchcombe and de Queiroz, 1996) that the domain size scales exponentially with h/J.

Understanding the phase transition of the $d = 3$ random field Ising model has been controversial for a long time, partly because random field systems, like spin glasses, have very slow dynamics around and below T_c. Assuming a second-order transition, one finds that the hyperscaling relation equation (10), needs to be modified as (Nattermann, 1998)

$$2\beta + \gamma = 2 - \alpha = (d - \theta)\nu \tag{32}$$

A heuristic argument to understand equation (32) assumes that the singular part of the free energy of a correlated region of volume ξ^d scales as the energy that is necessary to flip the region. At a thermal transition this is $k_B T$, and hence $k_B T \sim \xi^d \xi^{-(2-\alpha)/\nu}$, which gives equation (10). However, in the present case, thermal fluctuations are irrelevant in comparison with the random fields, and the energy is assumed to be $h\xi^\theta$ rather than $k_B T$, with a new exponent θ, and then equation (32) readily follows. While equation (32) appears to have three independent exponents, there are strong arguments (Nattermann, 1998) that there are actually only two, since there should exist an additional scaling relation $\theta = 2 - \eta$. Evidence from series expansions (Gofman *et al.*, 1996) is compatible with this relation.

Experiments (Belanger, 1998) on random field Ising systems have given beautiful evidence for the destruction of the transition in $d = 2$ and have obtained estimates for critical exponents in $d = 3$. These exponent values are in reasonable agreement with the best numerical study (Middleton and Fisher, 2002), though there is a puzzle concerning the specific heat (Hartmann and Young, 2001). Simulations also find that the order parameter exponent β is very close to $\beta = 0$. A different value is found in experiments (Ye *et al.*, 2002) but the discrepancy is probably because the experiment is done below T_c (the order parameter is only nonzero there),

where the system is not fully in equilibrium (D. P. Belanger, private communication).

Also of interest is the dynamics of domain growth (which is probably logarithmic in time) and the suggestion that the critical dynamics may be of a thermally activated type (Nattermann, 1998).

7 CONCLUSIONS

Disordered and frustrated spin systems are model materials which illuminate the interplay between nonthermal random fluctuations (due to quenched disorder) and thermal fluctuations on ordering phenomena in condensed matter. New types of phase transitions and unconventional types of order, such as the spin glass, are found in these systems, and important concepts of critical phenomena and the statistical mechanics of solids can be exemplified and tested. Many of the new concepts developed first for these magnetic systems have later been carried over to different systems, such as the problem of the glass transition of undercooled fluids, and orientational glass behavior found in diluted dielectric materials and randomly mixed molecular crystals. Random field effects in magnetic systems find counterparts in the behavior of binary fluids in porous media, and in the mesophase formation of binary polymer networks or mixed 'polymer brushes', and even in phase separation phenomena in biological membranes.

Just as magnetic ordering in ideal crystals has played a key role in developing the theory of phase transitions and critical phenomena, disordered magnets are critical for understanding the effects of quenched disorder in condensed matter. Furthermore, theoretical techniques for understanding ground states of spin glasses and random field systems have allowed important spin offs in fields outside of physics, such as neural networks, pattern recognition, optimization problems in computer science, and economics. Despite much effort, there are still many interesting open questions, so we expect that the field will stay an active area of research in the future.

Quantum Phase Transitions

Subir Sachdev
Harvard University, Cambridge, MA, USA

1 INTRODUCTION

The study of quantum phase transitions has been a major focus of theoretical and experimental work in systems of correlated electrons and in correlated ultracold atoms in recent years. However, some of the best-characterized and understood examples of quantum phase transitions are found in magnetic materials. These, therefore, serve as a valuable laboratory for testing our understanding of real systems in the vicinity of quantum critical points. We will review some of the simplest model systems in the subsequent text, along with their experimental realizations. This will be followed by a discussion of recent theoretical advances on some novel quantum critical points displayed by quantum magnets that have no direct analog in the theory of classical phase transitions at finite temperature (T). Portions of this article have been adapted from another recent review by the author (Sachdev, 2005).

In all the magnetic systems considered in the subsequent text, there is at least one ground state in which the symmetry of spin rotations is broken. So in this phase we have

$$\langle \hat{S}_j^\alpha \rangle \neq 0 \tag{1}$$

at $T = 0$. Here $\hat{S}$ is the electron spin operator on site j and $\alpha = x, y, z$ are the spin components. In all cases that are considered here, the Hamiltonian has at least a symmetry of spin inversion, and this symmetry is broken by (1). We are quite familiar with such magnetic systems, as all antiferromagnets, ferromagnets, or even spin glasses obey (1) at sufficiently low temperatures.

Let us now try to access a *paramagnetic* phase where

$$\langle \hat{S}_j^\alpha \rangle = 0 \tag{2}$$

Normally, we do this by raising the temperature. The resulting phase transition between phases characterized by (1) and (2) is well understood and described by the well-developed theory of classical phase transitions. This shall *not* be our interest here. Rather, we are interested in moving from a magnetic system obeying (1) to a *quantum paramagnet* obeying (2), by varying a system parameter at $T = 0$. There are many experimental and theoretical examples of such transitions: at the critical point, there is a qualitative change in the nature of the quantum wave function of the ground state.

One crucial feature of quantum phase transitions is that (2) is usually *not* sufficient to characterize the paramagnetic phase. In the Landau–Ginzburg–Wilson (LGW) approach to classical phase transitions, one focuses on the broken symmetry associated with (1) and defines a corresponding order parameter. A field theory of the thermal fluctuations of this order parameter is then sufficient to describe the transition to the paramagnetic phase and also to completely characterize the paramagnet. As we will discuss in

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 1: *Fundamentals and Theory*. ISBN: 978-0-470-02217-7.

Section 4, this procedure is not sufficient in some of the most interesting and physically important quantum phase transitions. The paramagnetic phase is not completely characterized by (2) and typically breaks some other symmetry of the Hamiltonian or has a more subtle 'topological' order. Furthermore, this additional 'order' of the paramagnet plays an important role in the theory of the quantum critical point.

We will begin Section 2 by introducing some simple lattice models and their experimental realizations, which exhibit quantum phase transitions. The theory of the critical point in these models is based on a natural extension of the LGW method, and this will be presented in Section 3. This section will also describe the consequences of a zero-temperature critical point on the nonzero-temperature properties. Section 4 will consider more complex models in which quantum interference effects play a more subtle role and which cannot be described in the LGW framework: such quantum critical points are likely to play a central role in the understanding of many of the correlated electron systems of current interest.

2 SIMPLE MODELS

2.1 Ising ferromagnet in a transverse field

This quantum phase transition is realized (Bitko, Rosenbaum and Aeppli, 1996) in the insulator $LiHoF_4$. The Ho ion has an $S = 1/2$ Ising spin that prefers to orient itself either parallel or antiparallel to a particular crystalline axis (say z). These Ising spins interact via the magnetic dipolar coupling and normally form a ferromagnetic ground state that obeys (1) for $\alpha = z$. As described in the subsequent text, upon application of a (transverse) magnetic field in the plane perpendicular to the z axis, quantum fluctuations of the Ising spin are enhanced, and there is eventually a quantum phase transition to a paramagnetic state obeying (2) for $\alpha = z$.

Rather than explore the full complexity of the experimentally relevant model, we will restrict our attention to a simple one-dimensional model with nearest-neighbor couplings that displays much of the same physics. The dynamics of this quantum Ising spin chain is described by the simple Hamiltonian

$$H_I = -J \sum_{j=1}^{N-1} \hat{\sigma}_j^z \hat{\sigma}_{j+1}^z - gJ \sum_{j=1}^{N} \hat{\sigma}_j^x \tag{3}$$

where $\hat{\sigma}_j^\alpha$ are the Pauli matrices, which act on the Ising spin degrees of freedom ($\hat{S}_j^\alpha \propto \hat{\sigma}_j^\alpha$), $J > 0$ is the ferromagnetic coupling between nearest-neighbor spins, and $g \geq 0$ is a dimensionless coupling constant, which determines the strength of the transverse field. In the thermodynamic limit ($N \to \infty$), the ground state of H_I exhibits a second-order quantum phase transition as g is tuned across a critical value $g = g_c$ (for the specific case of H_I it is known that $g_c = 1$), as we will now illustrate.

First, consider the ground state of H_I for $g \ll 1$. At $g = 0$, there are two degenerate *ferromagnetically ordered* ground states

$$|\Uparrow\rangle = \prod_{j=1}^{N} |\uparrow\rangle_j \quad ; \quad |\Downarrow\rangle = \prod_{j=1}^{N} |\downarrow\rangle_j \tag{4}$$

Each of these states breaks a discrete 'Ising' symmetry of the Hamiltonian – rotations of all spins by 180 °C about the x axis. These states are more succinctly characterized by defining the ferromagnetic moment N_0 by

$$N_0 = \langle \Uparrow | \hat{\sigma}_j^z | \Uparrow \rangle = - \langle \Downarrow | \hat{\sigma}_j^z | \Downarrow \rangle \tag{5}$$

At $g = 0$, we clearly have $N_0 = 1$. A key point is that in the thermodynamic limit this simple picture of the ground state survives for a finite range of small g (indeed, for all $g < g_c$), but with $0 < N_0 < 1$. The quantum tunneling between the two ferromagnetic ground states is exponentially small in N (and, so, can be neglected in the thermodynamic limit), and so the ground state remains twofold degenerate, and the discrete Ising symmetry remains broken. The change in the wave functions of these states from equation (4) can be easily determined by perturbation theory in g: these small g quantum fluctuations reduce the value of N_0 from unity but do not cause the ferromagnetism to disappear.

Now consider the ground state of H_I for $g \gg 1$. At $g = \infty$ there is a single *nondegenerate* ground state, which fully preserves all symmetries of H_I:

$$|\Rightarrow\rangle = 2^{-N/2} \prod_{j=1}^{N} \left(|\uparrow\rangle_j + |\downarrow\rangle_j \right) \tag{6}$$

It is easy to verify that this state has no ferromagnetic moment $N_0 = \langle \Rightarrow | \hat{\sigma}_j^z | \Rightarrow \rangle = 0$. Further, perturbation theory in $1/g$ shows that these features of the ground state are preserved for a finite range of large g values (indeed, for all $g > g_c$). One can visualize this ground state as one in which strong quantum fluctuations have destroyed the ferromagnetism, with the local magnetic moments quantum tunneling between 'up' and 'down' on a timescale of the order $\hbar/J$.

Given the very distinct signatures of the small g and large g ground states, it is clear that the ground state cannot evolve smoothly as a function of g. There must be at least one point of nonanalyticity as a function of g: For H_I it is known

that there is only a single nonanalytic point, and this is at the location of a second-order quantum phase transition at $g = g_c = 1$.

The character of the excitations above the ground state also undergoes a qualitative change across the quantum critical point. In both the $g < g_c$ and $g > g_c$ phases, these excitations can be described in the Landau *quasiparticle* scheme, that is, as superpositions of nearly independent particle-like excitations; a single, well-isolated quasiparticle has an infinite lifetime at low excitation energies. However, the physical nature of the quasiparticles is very different in the two phases. In the ferromagnetic phase, with $g < g_c$, the quasiparticles are domain walls between regions of opposite magnetization:

$$|j, j+1\rangle = \prod_{k=1}^{j} |\uparrow\rangle_k \prod_{\ell=j+1}^{N} |\downarrow\rangle_\ell \tag{7}$$

This is the exact wave function of a stationary quasiparticle excitation between sites j and $j+1$ at $g = 0$; for small nonzero g, the quasiparticle acquires a 'cloud' of further spin flips and also becomes mobile. However, its qualitative interpretation as a domain wall between the two degenerate ground states remains valid for all $g < g_c$. In contrast, for $g > g_c$, there is no ferromagnetism, and the nondegenerate paramagnetic state has a distinct quasiparticle excitation:

$$|j\rangle = 2^{-N/2} \left(|\uparrow\rangle_j - |\downarrow\rangle_j\right) \prod_{k \neq j} \left(|\uparrow\rangle_k + |\downarrow\rangle_k\right) \tag{8}$$

This is a stationary 'flipped-spin' quasiparticle at site j, with its wave function exactly at $g = \infty$. Again, this quasiparticle is mobile and applicable for all $g > g_c$, but there is no smooth connection between equations (8) and (7).

2.2 Coupled dimer antiferromagnet

Now we consider a model of $S = 1/2$ spins that interact via an antiferromagnetic exchange, and the Hamiltonian has full SU(2) spin rotation invariance. Physically, the cuprates are by far the most important realization of Hamiltonians in this class. However, rather than facing the daunting complexity of those compounds, it is useful to study simpler insulators in which a quantum phase transition from an antiferromagnet to a paramagnet can be explored. One experimentally and theoretically well-studied system (Tanaka *et al.*, 2001; Oosawa *et al.*, 2003; Rüegg *et al.*, 2003; Matsumoto, Normand, Rice and Sigrist, 2002, 2004) is $TlCuCl_3$. Here the $S = 1/2$ spins reside on the Cu^+ ions, which reside in a rather complicated spatial arrangement. As in Section 2.1, we will not explore the full complexity of the experimental magnet, but be satisfied with a caricature that captures the essential physics. The most important feature of the crystal structure of $TlCuCl_3$ (as will become clear in Section 4) is that it is naturally *dimerized*, that is, there is a pairing between Cu spins that respects all symmetries of the crystal structure. So we will consider the simplest dimer antiferromagnet of $S = 1/2$ spins that exhibits a quantum phase transition essentially equivalent to that found in $TlCuCl_3$.

The Hamiltonian of the dimer antiferromagnet is illustrated in Figure 1 and is given by

$$H_d = J \sum_{\langle jk \rangle \in A} \left(\hat{\sigma}_j^x \hat{\sigma}_k^x + \hat{\sigma}_j^y \hat{\sigma}_k^y + \hat{\sigma}_j^z \hat{\sigma}_k^z\right) + \frac{J}{g} \sum_{\langle jk \rangle \in B} \left(\hat{\sigma}_j^x \hat{\sigma}_k^x + \hat{\sigma}_j^y \hat{\sigma}_k^y + \hat{\sigma}_j^z \hat{\sigma}_k^z\right) \tag{9}$$

where $J > 0$ is the antiferromagnetic exchange constant, $g \geq 1$ is the dimensionless coupling, and the set of nearest-neighbor links $\mathcal{A}$ and $\mathcal{B}$ are defined in Figure 1. An important property of H_d is that it is now invariant under the full SU(2) group of spin rotations under which the $\hat{\sigma}^\alpha$ transform as ordinary vectors (in contrast to the Z_2 symmetry group of H_I). In analogy with H_I, we will find that H_d undergoes a quantum phase transition from a paramagnetic phase that preserves all symmetries of the Hamiltonian at large g to an *antiferromagnetic* phase that breaks the SU(2) symmetry at small g. This transition occurs at a critical value $g = g_c$, and the best current numerical estimate is (Matsumoto, Yasuda, Todo and Takayama, 2002) $1/g_c = 0.52337(3)$.

As in the previous subsection, we can establish the existence of such a quantum phase transition by contrasting the disparate physical properties at large g with those at $g \approx 1$. At $g = \infty$ the exact ground state of H_d is

$$|\text{spin gap}\rangle = \prod_{\langle jk \rangle \in A} \frac{1}{\sqrt{2}} \left(|\uparrow\rangle_j |\downarrow\rangle_k - |\downarrow\rangle_j |\uparrow\rangle_k\right) \tag{10}$$

and is illustrated in Figure 2. This state is nondegenerate and invariant under spin rotations and, so, is a paramagnet: the qubits are paired into spin-singlet valence bonds across

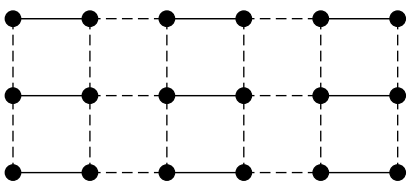

Figure 1. The coupled dimer antiferromagnet. Qubits (i.e., $S = 1/2$ spins) are placed on the sites, the $\mathcal{A}$ links are shown as full lines, and the $\mathcal{B}$ links as dashed lines.

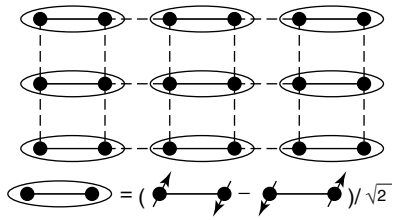

Figure 2. The paramagnetic state of H_d for $g > g_c$. The state illustrated is the exact ground state for $g = \infty$, and it is adiabatically connected to the ground state for all $g > g_c$.

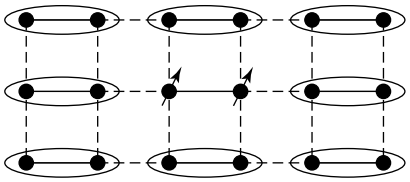

Figure 3. The triplon excitation of the $g > g_c$ paramagnet. The stationary triplon is an eigenstate only for $g = \infty$ but it becomes mobile for finite g.

all the $\mathcal{A}$ links. The excitations above the ground state are created by breaking a valence bond, so that the pair of spins form a spin triplet with total spin $S = 1$ – this is illustrated in Figure 3. It costs a large energy to create this excitation, and at finite g the triplet can hop from link to link, creating a gapped *triplon* quasiparticle excitation. This is similar to the large g paramagnet for H_I, with the important difference that each quasiparticle is now threefold degenerate.

At $g = 1$, the ground state of H_d is not known exactly. However, at this point, H_d becomes equivalent to the nearest-neighbor square-lattice antiferromagnet, and this is known to have antiferromagnetic order in the ground state, as illustrated in Figure 4. This state is similar to the ferromagnetic ground state of H_I, with the difference that the magnetic moment now acquires a staggered pattern on the two sublattices, rather than the uniform moment of the ferromagnet. Thus, in this ground state,

$$\langle \mathrm{AF}| \hat{\sigma}_j^{\alpha} |\mathrm{AF}\rangle = N_0 \eta_j n_{\alpha} \tag{11}$$

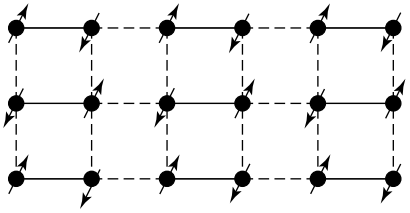

Figure 4. Schematic of the ground state with antiferromagnetic order with $g < g_c$.

where $0 < N_0 < 1$ is the antiferromagnetic (or Néel) moment, $\eta_j = \pm 1$ identifies the two sublattices in Figure 4, and n_{α} is an arbitrary unit vector specifying the orientation of the spontaneous magnetic moment that breaks the O (3) spin rotation invariance of H_d. The excitations of the antiferromagnet are also distinct from those of the paramagnet: they are a *doublet* of spin waves consisting of a spatial variation in the local orientation n_{α} of the antiferromagnetic order; the energy of this excitation vanishes in the limit of long wavelengths, in contrast to the finite energy gap of the triplon excitation of the paramagnet.

As with H_I, we can conclude from the distinct characters of the ground states and excitations for $g \gg 1$ and $g \approx 1$ that there must be a quantum critical point at some intermediate $g = g_c$.

3 QUANTUM CRITICALITY

The simple considerations of Section 2 have given a rather complete description (based on the quasiparticle picture) of the physics for $g \ll g_c$ and $g \gg g_c$. We turn, finally, to the region $g \approx g_c$. For the specific models discussed in Section 2, a useful description is obtained by a method that is a generalization of the LGW method developed earlier for thermal phase transitions. However, some aspects of the critical behavior (e.g., the general forms of equations (14–16)) will apply to the quantum critical point of Section 4 also.

Following the canonical LGW strategy, we need to identify a collective order parameter that distinguishes the two phases. This is clearly given by the ferromagnetic moment in equation (5) for the quantum Ising chain and the antiferromagnetic moment in equation (11) for the coupled dimer antiferromagnet. We coarse-grain these moments over some finite averaging region, and at long wavelengths this yields a real-order parameter field ϕ_{α}, with the index $\alpha = 1 \ldots n$. For the Ising case, we have $n = 1$ and ϕ_{α} is a measure of the local average of N_0 as defined in equation (5). For the antiferromagnet, a extends over the three values x, y, z (so $n = 3$), and the three components of ϕ_{α} specify the magnitude and orientation of the local antiferromagnetic order in equation (11); note that the average orientation of a specific spin at site j is η_j times the local value of ϕ_{α}.

The second step in the LGW approach is to write down a general field theory for the order parameter that is consistent with all symmetries of the underlying model. As we are dealing with a quantum transition, the field theory has to extend over *space–time*, with the temporal fluctuations representing the sum over histories in the Feynman path integral approach. With this reasoning, the proposed partition function for the vicinity of the critical point takes the

following form:

$$\mathcal{Z}_\phi = \int \mathcal{D}\phi_\alpha(x,\tau)\exp\Bigg[-\int \mathrm{d}^d x\,\mathrm{d}\tau\left(\frac{1}{2}\big((\partial_\tau\phi_\alpha)^2 + c^2(\nabla_x\phi_\alpha)^2 + s\phi_\alpha^2\big) + \frac{u}{4!}\left(\phi_\alpha^2\right)^2\right)\Bigg] \tag{12}$$

Here τ is imaginary time, there is an implied summation over the n values of the index a, c is a velocity, and s and $u > 0$ are coupling constants. This is a field theory in $d+1$ space–time dimensions, in which the Ising chain corresponds to $d = 1$ and the dimer antiferromagnet to $d = 2$. The quantum phase transition is accessed by tuning the 'mass' s: There is a quantum critical point at $s = s_c$, and the $s < s_c$ ($s > s_c$) regions correspond to the $g < g_c$ ($g > g_c$) regions of the lattice models. The $s < s_c$ phase has $\langle\phi_\alpha\rangle \neq 0$, and this corresponds to the spontaneous breaking of spin rotation symmetry noted in equations (5) and (11) for the lattice models. The $s > s_c$ phase is the paramagnet with $\langle\phi_\alpha\rangle = 0$. The excitations in this phase can be understood as small harmonic oscillations of ϕ_α about the point (in field space) $\phi_\alpha = 0$. A glance at equation (12) shows that there are n such oscillators for each wave vector. These oscillators clearly constitute the $g > g_c$ quasiparticles found earlier in equation (8) for the Ising chain (with $n = 1$) and the triplon quasiparticle (with $n = 3$, illustrated in Figure 3) for the dimer antiferromagnet.

We have now seen that there is a perfect correspondence between the phases of the quantum field theory $\mathcal{Z}_\phi$ and those of the lattice models H_I and H_d. The power of the representation in equation (12) is that it also allows us to get a simple description of the quantum critical point. In particular, readers may already have noticed that if we interpret the temporal direction τ in equation (12) as another spatial direction, then $\mathcal{Z}_\phi$ is simply the classical partition function for a thermal phase transition in a ferromagnet in $d+1$ dimensions: this is the canonical model for which the LGW theory was originally developed. We can now take over standard results for this classical critical point and obtain some useful predictions for the quantum critical point of $\mathcal{Z}_\phi$. It is useful to express these in terms of the dynamic susceptibility defined by

$$\chi(k,\omega) = \frac{i}{\hbar}\int \mathrm{d}^d x \int_0^\infty \mathrm{d}t\,\left\langle\left[\hat{\phi}(x,t),\hat{\phi}(0,0)\right]\right\rangle_T e^{-ikx+i\omega t} \tag{13}$$

Here $\hat{\phi}$ is the Heisenberg field operator corresponding to the path integral in equation (12), the square brackets represent a commutator, and the angular brackets an average over the partition function at a temperature T. The structure of χ can be deduced from the knowledge that the quantum correlators of $\mathcal{Z}_\phi$ are related by analytic continuation in time to the corresponding correlators of the classical statistical mechanics problem in $d+1$ dimensions. The latter are known to diverge at the critical point as $\sim 1/p^{2-\eta}$ where p is the $(d+1)$-dimensional momentum, η is the anomalous dimension of the order parameter ($\eta = 1/4$ for the quantum Ising chain). Knowing this, we can deduce the form of the quantum correlator in equation (13) at the zero-temperature quantum critical point
