perturbation techniques, magnetization dynamics in far-from-equilibrium conditions (Bertotti, Mayergoyz and Serpico, 2001a). In this respect, it is appropriate here to mention that in recent times there has been increasing interest in situations (e.g., precessional switching; Kaka and Russek, 2002 or spin-transfer-driven magnetization dynamics; Kiselev *et al*., 2003, and Rippard *et al*., 2004) where the magnetization of nanomagnetic elements is forced to execute large motions.

5.1.1 LLG equation in the rotating frame

We consider here a spheroidal particle with symmetry axis along the z axis. In this section, we do not assume that inequality (19) is necessarily valid. By subscript '$\perp$' we will denote components of vectors in the plane orthogonal to the z axis. The magnetostatic field $\mathbf{h}_S$ is given by

$$\mathbf{h}_S = -N_z m_z - N_\perp \mathbf{m}_\perp \tag{117}$$

where the $N_x = N_y = N_\perp$ $(N_z + 2N_\perp = 1)$. As we have done previously, we also assume that the crystal anisotropy is uniaxial, with the anisotropy axis along the z direction:

$$\mathbf{h}_K = \kappa m_z \mathbf{e}_z \tag{118}$$

The external field consists of the constant component $h_{az}\mathbf{e}_z$ directed along the symmetry axis and the circularly polarized rf component $\mathbf{h}_{a\perp}(t)$ in the perpendicular plane (see Figure 13), that is,

$$\mathbf{h}_a(t) = \mathbf{h}_{a\perp}(t) + h_{az}\mathbf{e}_z \tag{119}$$

where

$$\mathbf{h}_{a\perp}(t) = h_{a\perp}\left(\cos\omega t\,\mathbf{e}_x + \sin\omega t\,\mathbf{e}_y\right) \tag{120}$$

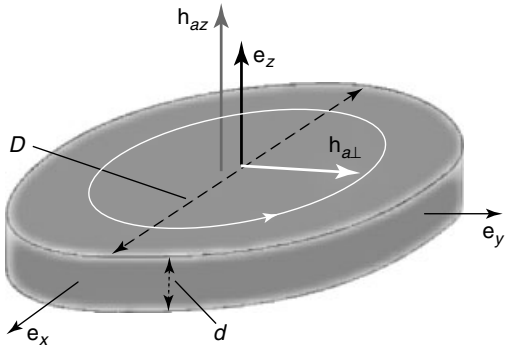

Figure 13. Sketch of uniaxial nanomagnet subject to circularly polarized microwave fields.

The free energy of the system is

$$g_L(\mathbf{m};\mathbf{h}_a) = \frac{1}{2}\left(N_z m_z^2 + N_\perp m_\perp^2\right) - \frac{1}{2}\kappa m_z^2 - \mathbf{h}_a\cdot\mathbf{m} \tag{121}$$

and the effective field can be written as

$$\mathbf{h}_{\text{eff}} = -\frac{\partial g_L}{\partial \mathbf{m}} = \mathbf{h}_{a\perp} + (h_{az} + \kappa_{\text{eff}} m_z)\,\mathbf{e}_z - N_\perp \mathbf{m} \tag{122}$$

where:

$$\kappa_{\text{eff}} = \kappa + N_\perp - N_z \tag{123}$$

Under these conditions, we want to study LLG equation, which is reported below for the reader's commodity:

$$\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} - \alpha\mathbf{m}\times\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = -\mathbf{m}\times\mathbf{h}_{\text{eff}} \tag{124}$$

The system under study is characterized by the parameters $(\alpha, \kappa_{\text{eff}})$, whereas the excitation conditions are described by the control parameters $(\omega, h_{az}, h_{a\perp})$.

The dynamical system on the unit sphere described by equation (124) is nonautonomous, because $\mathbf{h}_{\text{eff}}$ explicitly depends on time through the external field $\mathbf{h}_{a\perp}(t)$. However, the nontrivial complications usually encountered in the analysis of nonautonomous systems can be circumvented by taking advantage of the rotational symmetry of the problem. This becomes evident when one considers the form of equation (124) in the rotating frame of reference in which the external field is stationary. In this frame, which is rotated at the angular frequency ω around the $\mathbf{e}_z$ axis, the magnetization derivative is transformed as follows:

$$\left[\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t}\right]_{\text{lab frame}} = \left[\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t}\right]_{\text{rot frame}} - \omega\mathbf{m}\times\mathbf{e}_z \tag{125}$$

Therefore, in the rotating-frame equation (151) takes the form:

$$\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} - \alpha\mathbf{m}\times\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = -\mathbf{m}\times(\mathbf{h}_{\text{eff}} - \omega\mathbf{e}_z + \alpha\omega\mathbf{m}\times\mathbf{e}_z) \tag{126}$$

The field $\mathbf{h}_{\text{eff}}$ is still given by equation (122), but $\mathbf{h}_{a\perp}$ is now time independent by construction. On the other hand, no new time dependence appears as a result of the transformation to the rotating frame, as all the parameters of the problem are invariant with respect to rotations about the symmetry axis. Thus, no explicit time dependence is present anymore in the right-hand side of equation (126). In other words, the transformation to the rotating frame brings the dynamics to autonomous form.

In equation (126), the role of 'effective' energy is played in by the quantity:

$$\tilde{g}_{\mathrm{L}}\left(\mathbf{m};\mathbf{h}_{\mathrm{a}}\right)=g_{\mathrm{L}}\left(\mathbf{m};\mathbf{h}_{\mathrm{a}}\right)+\omega m_z \tag{127}$$

This can be shown by introducing the associated effective field

$$\tilde{\mathbf{h}}_{\mathrm{eff}}\equiv\frac{-\partial\tilde{g}_{\mathrm{L}}}{\partial\mathbf{m}}=\mathbf{h}_{\mathrm{eff}}-\omega\mathbf{e}_z \tag{128}$$

and by writing equation (126) in the form:

$$\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t}=-\mathbf{m}\times\tilde{\mathbf{h}}_{\mathrm{eff}}+\alpha\mathbf{m}\times\left(\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t}-\omega\mathbf{m}\times\mathbf{e}_z\right) \tag{129}$$

where all the contributions proportional to the damping parameter have been collected into a single term. Whenever damping is negligible one has that $\tilde{\mathbf{h}}_{\mathrm{eff}}\cdot\mathrm{d}\mathbf{m}/\mathrm{d}t=0$, that is, $\tilde{g}_{\mathrm{L}}$ is conserved.

When α is nonzero, the effective energy $\tilde{g}_{\mathrm{L}}$ is no longer constant along the magnetization trajectories. One obtains from equation (129) that $\tilde{g}_{\mathrm{L}}$ changes at the rate:

$$\frac{\mathrm{d}\tilde{g}_{\mathrm{L}}}{\mathrm{d}t}\equiv-\tilde{\mathbf{h}}_{\mathrm{eff}}\cdot\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t}=-\alpha\left(\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t}-\omega\mathbf{m}\times\mathbf{e}_z\right)\cdot\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} \tag{130}$$

The right-hand side of equation (189) can be negative and positive, depending on the orientation of $\mathbf{m}$. This means that the dynamics in the rotating frame is not a mere relaxation toward minima of the effective free energy, and one cannot exclude (as it was discussed in the case of constant applied field) that the presence of periodic steady states (limit cycles) in which the energy has a periodic variation in time (see Figure 14). This latter kind of steady state in the rotating frame corresponds to quasiperiodic solution in the lab frame.

Let us also underline that the term in equation (129) proportional to α can be often treated as a perturbation to the undamped dynamics controlled by the effective energy $\tilde{g}_{\mathrm{L}}$, owing to the fact that $\alpha\ll 1$ for all systems of physical interest. This perturbative approach is particularly useful in the study of limit cycles.

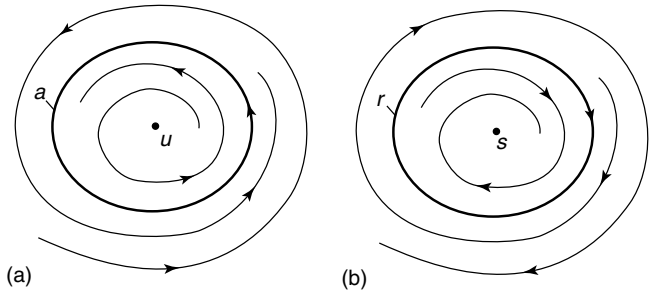

Figure 14. Schematic representation of limit cycles. (a) Stable limit cycle (a, i.e., attractive) surrounding unstable focus; (b) unstable limit cycle (r, i.e., repulsive) surrounding stable focus.

The study of LLG dynamics in the rotating frame of reference can be conveniently carried out by introducing the spherical-angle state variables (θ,ϕ), representing the angle of $\mathbf{m}$ with respect to $\mathbf{e}_z$ $(0\le\theta\le\pi)$ and the lag angle of $\mathbf{m}_\perp$ with respect to $\mathbf{h}_{\mathrm{a}\perp}$ $(-\pi\le\phi\le\pi)$, respectively. In other words, we express the magnetization as:

$$\begin{aligned}\mathbf{m}&=m_{a\perp}\mathbf{e}_a+m_{b\perp}\mathbf{e}_b+m_z\mathbf{e}_z\\&=\sin\theta\cos\phi\mathbf{e}_a-\sin\theta\sin\phi\mathbf{e}_b+\cos\theta\mathbf{e}_z\end{aligned} \tag{131}$$

where $(\mathbf{e}_a,\mathbf{e}_b,\mathbf{e}_z)$ is a right-handed Cartesian set of unit vectors for the rotating frame, of which $\mathbf{e}_a$ is directed along $\mathbf{h}_{\mathrm{a}\perp}$. The minus sign in the expression for $m_{b\perp}$ is due to the fact that ϕ represents the angle by which the magnetization *lags* the field. Equation (129) in spherical coordinates reads

$$\begin{aligned}\frac{\mathrm{d}\theta}{\mathrm{d}t}-\alpha\sin\theta\frac{\mathrm{d}\phi}{\mathrm{d}t}&=\frac{1}{\sin\theta}\frac{\partial\tilde{g}_{\mathrm{L}}}{\partial\phi}-\alpha\omega\sin\theta\\&=h_{a\perp}\sin\phi-\alpha\omega\sin\theta\end{aligned} \tag{132}$$

$$\begin{aligned}\alpha\frac{\mathrm{d}\theta}{\mathrm{d}t}+\sin\theta\frac{\mathrm{d}\phi}{\mathrm{d}t}&=\frac{\partial\tilde{g}_{\mathrm{L}}}{\partial\theta}=h_{a\perp}\cos\phi\cos\theta\\&\quad-\left(h_{az}-\omega+\kappa_{\mathrm{eff}}\cos\theta\right)\sin\theta\end{aligned} \tag{133}$$

where $\tilde{g_{\mathrm{L}}}(\theta,\phi)$ is the effective free energy expressed in spherical coordinates.

Spherical coordinates are quite a natural reference system to represent magnetization evolution on the sphere and they are very convenient to derive analytical formulas. However, the ensuing description of magnetization dynamics is not always completely transparent in the vicinity of the sphere poles where the angle ϕ is undefined. For this reason, especially in phase portraits where limit cycles are present, it is useful to introduce the stereographic projection of the unit sphere on the plane. The stereographic coordinates w_x and w_y are connected to the Cartesian coordinates by the following relations:

$$w_x=\frac{m_x}{1+m_z}\qquad w_y=\frac{m_y}{1+m_z} \tag{134}$$

where $\mathbf{w}=w_x\mathbf{e}_x+w_y\mathbf{e}_y$. The main properties of this transformation are the following: angles between intersecting lines are preserved (conformal transformation) Schwerdtfeger, 2001; $\mathbf{m}=+\mathbf{e}_z$ is projected into the origin of the plane; the north hemisphere ($m_z>0$) is projected inside the unit circle; the south hemisphere ($m_z<0$) is projected outside the unit circle; $\mathbf{m}=-\mathbf{e}_z$ is projected into infinity. In order to have a complete picture of the phase portrait, we also consider the stereographic projection which projects the

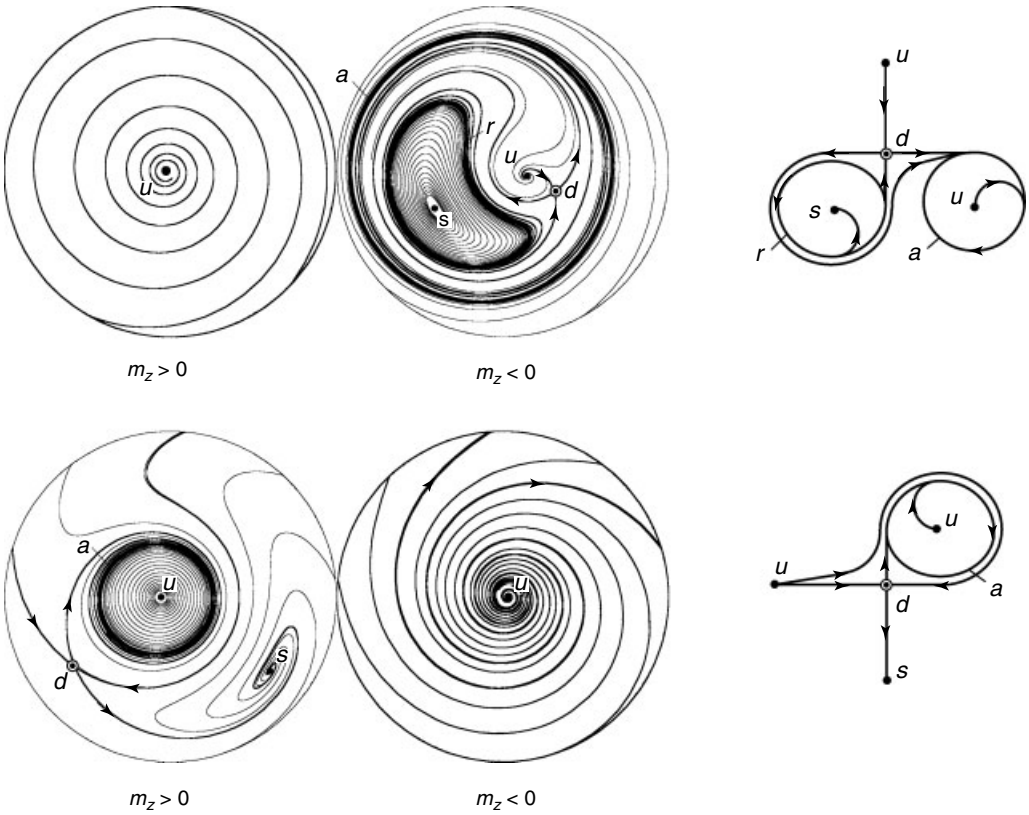

Figure 15. Examples of phase portraits of LLG dynamics in the rotating frame of reference. Each phase portrait is represented in terms of joint stereographic projections of $m_z > 0$ and $m_z < 0$ hemispheres onto the unit circle. The point of contact of the $m_z > 0$ and $m_z < 0$ circles corresponds to $m_{a\perp} = 1$, that is, magnetization fully aligned along the rf field $\mathbf{h}_{a\perp}$. s: stable node; u: unstable node; d: saddle; a: stable limit cycle; r: unstable limit cycle. System parameters: $\alpha = 0.1$, $\kappa_{\text{eff}} = -1$. Field frequency: $\omega = 0.5$. Upper portrait: $h_{az} = -0.2$, $h_{a\perp} = 0.08$. Lower portrait: $h_{az} = 0.8$, $h_{a\perp} = 0.08$. Simplified graphical representation of phase portraits is given on the right.

south hemisphere into the unit circle and the north hemisphere outside the unit circle. This is simply given by the transformation: $w_x = m_x/(1 - m_z)$ and $w_y = m_y/(1 - m_z)$. Two examples of phase portraits represented by means of stereographic projection are reported in Figure 15.

5.1.2 Topological aspects

Equation (126) (LLG equation in the rotating frame of reference) describes an autonomous dynamical system evolving on the surface of the unit sphere $|\mathbf{m}|^2 = 1$. For this reason the topological aspects discussed in Section 2.2.1. By using the rotating frame of reference and the consequent autonomous character of the dynamics permits one to study its properties in geometric terms, through the phase portrait (Wiggins, 1990; Hubbard and West, 1995; Perko, 1996; Hale and Kocak, 1991) of the equation (see Figure 15 for an example). In particular we can arrive to the following conclusions:

- *Existence of fixed points:* The phase portrait on the sphere must necessarily contain a nonzero number of fixed points for which $\mathrm{d}\mathbf{m}/\mathrm{d}t = 0$ (Perko, 1996). These fixed points occur in the rotating frame of reference. In the laboratory frame, each of them results in a magnetization mode in which the magnetization precesses about the symmetry axis in synchronism with the external field. These rotating modes will be termed **P** modes. Therefore, one reaches the remarkable conclusion that a certain number of **P** modes must necessarily exist *for any value* of the control parameters $\left(\omega, h_{a\parallel}, h_{a\perp}\right)$. Interestingly, in a **P** mode the system response to a time-harmonic excitation (see equation (120)) is itself time harmonic, with no generation of higher-order harmonics, despite the inherent strongly nonlinear character of the dynamics. These **P** modes can be also seen as magnetization modes that are frequency and phase locked to the external microwave field.
- *Number of fixed points:* By using the Poincaré index theorem (Perko, 1996) (see also Section 2.2.1). one can infer that the number of **P** modes is at least two and is even under all circumstances. Following this result, one can classify LLG phase portraits for rotationally

invariant systems according to the number and nature of their fixed points as follows:
- phase portraits with two fixed points: two nodes or foci;
- phase portraits with four fixed points: three nodes or foci + 1 saddle;
- ...

The nature of a fixed point (node, focus, or saddle) can be determined through the analysis of its stability. This aspect will be discussed in Section 5.2.2.

- *Presence of limit cycles:* The fact that the effective energy is not always decreasing as a function of time (see equation (189)) gives rise to the possibility of existence of periodic steady state (limit cycles, see Figure 14 for a sketch). Limit cycles in the rotating frame correspond to quasiperiodic solutions in the laboratory frame, named **Q** modes, which results from the combination of the frequency of the limit cycle (generated by the system itself) and the frequency of the external field. These **Q** modes can be also seen as magnetization modes that are *not* frequency or phase locked to the external microwave field.
- *Nonexistence of chaos:* Chaos is precluded, because the phase space is two dimensional (Wiggins, 1990). The onset of chaotic phenomena is not compatible with the simultaneous presence of rotational symmetry and uniform magnetization. Only when one or both of these requirements are relaxed, chaotic phenomena may appear (Wigen, 1994; Alvarez, Pla and Chubykalo, 2000).

5.2 P modes, Q modes, and ferromagnetic resonance

*5.2.1 Periodic modes (**P** modes)*

By setting $\mathrm{d}\theta/\mathrm{d}t = \mathrm{d}\phi/\mathrm{d}t = 0$ in equations (132) and (133) one obtains the equations for the fixed points of the dynamics in the rotating frame:

$$h_{a\perp} \sin\phi_0 = \alpha\omega \sin\theta_0 \tag{135}$$

$$h_{a\perp} \cos\phi_0 \cos\theta_0 = (h_{az} - \omega + \kappa_{\mathrm{eff}} \cos\theta_0) \sin\theta_0 \tag{136}$$

By taking the ratio of the corresponding sides of equations (135) and (136), one obtains:

$$\alpha\omega \cot\phi_0 = \frac{h_{az} - \omega}{\cos\theta_0} + \kappa_{\mathrm{eff}} \tag{137}$$

Then, by dividing both sides of equation (136) by $\cos\theta_0$ and summing the square of the two sides of the equation with the squares of the corresponding sides of (135), one obtains

$$\frac{h_{a\perp}^2}{\sin^2\theta_0} = \left(\frac{h_{az} - \omega}{\cos\theta_0} + \kappa_{\mathrm{eff}}\right)^2 + (\alpha\omega)^2 \tag{138}$$

For later use it is convenient to introduce the quantity:

$$\nu_0 = \alpha\omega \cot\phi_0 \tag{139}$$

By using ν_0 equations (137) and (138) can be rewritten as

$$\nu_0 = \frac{h_{az} - \omega}{\cos\theta_0} + \kappa_{\mathrm{eff}} \tag{140}$$

$$\nu_0^2 = \frac{h_{a\perp}^2}{\sin^2\theta_0} - \alpha^2\omega^2 \tag{141}$$

The convenience in using ν_0 comes from the following considerations. The angle ϕ_0 is in one-to-one correspondence with ν_0 because $0 \le \phi_0 \le \pi$ under all circumstances. In fact, equation (135) shows that $\sin\phi_0 \ge 0$ for all **P** modes, because $h_{a\perp}$, α, ω, and $\sin\theta_0$ are all positive quantities by definition. In other words, in a **P** mode the magnetization always lags the field. The plane $(\cos\theta_0, \nu_0)$ is the natural plane for the representation of **P** modes. A generic **P** mode will be located in the region $-1 \le \cos\theta_0 \le 1$, $-\infty < \nu_0 < \infty$, that is, $0 \le \theta_0 \le \pi$, $0 \le \phi_0 \le \pi$.

By solving equations (140) and (141), one obtains the values of $(\cos\theta_0, \nu_0)$ for the various **P** modes existing under given excitation conditions $(\omega, h_{az}, h_{a\perp})$. In practise this can be done by solving equation (138) which can be seen as the following fourth order equation in m_z:

$$\frac{h_{a\perp}^2}{1 - m_z^2} = \left(\frac{h_{az} - \omega}{m_z} + \kappa_{\mathrm{eff}}\right)^2 + (\alpha\omega)^2 \tag{142}$$

which, after simple manipulation can be written as

$$(1 + \Omega^2)m_z^4 + 2b_z m_z^3 + [b_\perp^2 + b_z^2 - (1 + \Omega^2)]m_z^2 - 2b_z m_z - b_z^2 = 0 \tag{143}$$

where

$$\Omega = \frac{\alpha\omega}{\kappa_{\mathrm{eff}}}, \quad b_z = \frac{h_{az} - \omega}{\kappa_{\mathrm{eff}}}, \quad b_\perp = \frac{h_{a\perp}}{\kappa_{\mathrm{eff}}} \tag{144}$$

Equation (143) will admit either two or four real roots which correspond to the coexistence of two or four periodic solution of original LLG equation. It is interesting to notice that equation (143) reduces to equation (35) obtained for the Stoner–Wohlfarth model, by considering the limit $\omega \to 0$, and replacing m_x with m_z. This is consistent with the view that the **P** mode theory is a special dynamical generalization

of the Stoner–Wohlfarth model (Magni, Bertotti, Serpico and Mayergoyz, 2001).

In order to find the excitation conditions corresponding to a given **P** mode $(\cos\theta_0, \nu_0)$ one can use the same equations (140) and (141), written in the form

$$h_{az} = (\nu_0 - \kappa_{\text{eff}})\cos\theta_0 + \omega \tag{145}$$

$$h_{a\perp} = \sqrt{\left(1 - \cos^2\theta_0\right)\left(\nu_0^2 + \alpha^2\omega^2\right)} \tag{146}$$

Given a particular **P** mode solution of equations (140) and (141), its rotating-frame components defined by equation (131) can be expressed in terms of $\cos\theta_0$ only, by using equations (135) and (136) to eliminate ϕ_0:

$$m_{a\perp} = \left(\frac{h_{az} - \omega}{\cos\theta_0} + \kappa_{\text{eff}}\right)\frac{\sin^2\theta_0}{h_{a\perp}} \tag{147}$$

$$m_{b\perp} = -\frac{\alpha\omega\sin^2\theta_0}{h_{a\perp}} \tag{148}$$

$$m_z = \cos\theta_0 \tag{149}$$

It important to stress that **P** mode solutions correspond to spatial uniform periodic solutions of the original LLG equation. If we denote a **P** mode in the lab frame with $\mathbf{m}_0(t)$, we immediately have that

$$\frac{\mathrm{d}\mathbf{m}_0}{\mathrm{d}t} = \omega\mathbf{e}_z \times \mathbf{m}_0(t) \tag{150}$$

which comes from the fact that $\mathbf{m}_0(t)$ is uniformly rotating unit vector around the z axis with angular frequency ω. If we substitute (150) into the original LLG equation:

$$\frac{\mathrm{d}\mathbf{m}_0}{\mathrm{d}t} - \alpha\mathbf{m}_0 \times \frac{\mathrm{d}\mathbf{m}_0}{\mathrm{d}t} = -\mathbf{m}_0 \times \mathbf{h}_{\text{eff}0} \tag{151}$$

we end up with the following condition

$$\mathbf{m}_0(t) \times (\mathbf{h}_{\text{eff}0}(t) - \omega\mathbf{e}_z + \alpha\omega\mathbf{m}_0(t) \times \mathbf{e}_z) = 0 \tag{152}$$

where $\mathbf{h}_{\text{eff}0}(t)$ is the effective field associated to $\mathbf{m}_0(t)$. Equation (152) implies that the following condition is verified at each time instant

$$\left[\mathbf{h}_{\text{eff}0}(t) - \omega\mathbf{e}_z + \alpha\omega\mathbf{m}_0(t) \times \mathbf{e}_z\right] = \lambda_0\mathbf{m}_0(t) \tag{153}$$

where λ_0 is a constant depending on $(\cos\theta_0, \nu_0)$. If we pass now to the rotating reference frame and express **m** through equations (147–149), one can prove that λ_0 has the following simple expression:

$$\lambda_0 = \nu_0 - N_\perp \tag{154}$$

Equation (153) is particularly useful in the discussion of stability of **P** mode.

5.2.2 *P mode stability*

The results obtained in the previous section do not say anything about the fact that a given **P** mode may or may not be physically realizable. Only the modes that are dynamically stable will survive for long times and will be experimentally observable. Dynamical stability can be studied by perturbing the **P** mode solution and by analyzing the ensuing time behavior of the perturbation. To be completely general, this analysis should be carried out for arbitrary space-time dependent perturbations compatible with the boundary conditions of the problem. In the present section, this analysis is limited to spatially uniform perturbations only. Physically this means that we are going to consider magnetic particles so small that exchange forces rule out the appearance of space nonuniformities, however, small. The problem of stability of **P** modes against spatially nonuniform perturbations is treated in details in Bertotti, Mayergoyz and Serpico (2001a, 2006b).

Under the assumption of space uniformity, a given **P** mode will be dynamically stable if the corresponding fixed point of the rotating-frame dynamics is stable. Stability is studied by standard methods (Hubbard and West, 1995; Kuznetsov, 1995), by linearizing equation (126) around the **P** mode fixed point. Nevertheless, it is instructive to start our analysis in the lab frame. Let us denote a **P** mode in the lab frame by $\mathbf{m}_0(t)$ (which is periodic with period $2\pi/\omega$). We want to study the dynamics of $\mathbf{m}(t)$ in the vicinity of the periodic solution $\mathbf{m}_0(t)$. In other terms, we consider magnetization states

$$\mathbf{m}(t) = \mathbf{m}_0(t) + \Delta\mathbf{m}(t) \tag{155}$$

with

$$|\Delta\mathbf{m}(\mathbf{r}, t)| \ll |\mathbf{m}_0(t)| = 1 \tag{156}$$

If we substitute equation (155) into LLG equation (124), and neglect all terms which are second or higher order in the components of the vector $\Delta\mathbf{m}$, we arrive to the following linearized LLG equation.

$$\frac{\partial}{\partial t}\Delta\mathbf{m} - \alpha\mathbf{m}_0 \times \frac{\partial}{\partial t}\Delta\mathbf{m} - \alpha\Delta\mathbf{m} \times \frac{\mathrm{d}}{\mathrm{d}t}\mathbf{m}_0 = -\Delta\mathbf{m} \times \mathbf{h}_{\text{eff}0} - \mathbf{m}_0 \times \Delta\mathbf{h}_{\text{eff}} \tag{157}$$

where

$$\Delta\mathbf{h}_{\text{eff}} = D_x\Delta m_x\mathbf{e}_x + D_y\Delta m_y\mathbf{e}_y + D_z\Delta m_z\mathbf{e}_z \tag{158}$$

Equation (157) can be put in the following simpler form:

$$\frac{\partial}{\partial t}\Delta\mathbf{m} - \alpha\mathbf{m}_0 \times \frac{\partial}{\partial t}\Delta\mathbf{m} = -\Delta\mathbf{m} \times \left(\mathbf{h}_{\text{eff}0} - \alpha\frac{\mathrm{d}}{\mathrm{d}t}\mathbf{m}_0\right) + \mathbf{m}_0 \times \Delta\mathbf{h}_{\text{eff}} \tag{159}$$

Now by using equations (150) and (152), we can write equation (159) as

$$\frac{\partial}{\partial t}\Delta\mathbf{m} - \alpha\mathbf{m}_0 \times \frac{\partial}{\partial t}\Delta\mathbf{m} = -\Delta\mathbf{m} \times (\lambda_0\mathbf{m}_0 + \omega\mathbf{e}_z) + \mathbf{m}_0 \times \Delta\mathbf{h}_{\text{eff}} \tag{160}$$

From this last equation and equation (150) one immediately derive that

$$\mathbf{m}_0(t)\cdot\frac{\partial}{\partial t}\Delta\mathbf{m} = +\Delta\mathbf{m}\cdot\mathbf{m}_0(t) \times \omega\mathbf{e}_z = -\Delta\mathbf{m}\cdot\frac{\mathrm{d}}{\mathrm{d}t}\mathbf{m}_0 \tag{161}$$

which implies that

$$\frac{\partial}{\partial t}\left[\Delta\mathbf{m}(t)\cdot\mathbf{m}_0(t)\right] = 0 \tag{162}$$

namely, that, at each instant of time the components of perturbation in the direction of $\mathbf{m}_0(t)$ are constant. This means that, as far as small perturbations around periodic solution are concerned, we can limit ourselves to the components of $\Delta\mathbf{m}(t)$ orthogonal to $\mathbf{m}_0(t)$. In this respect, it is convenient to introduce in the plane perpendicular to $\mathbf{m}_0$ the following uniformly rotating unit vectors:

$$\mathbf{e}_1 \propto (\mathbf{e}_z \times \mathbf{m}_0) \times \mathbf{m}_0 \tag{163}$$

$$\mathbf{e}_2 \propto \mathbf{e}_z \times \mathbf{m}_0 \tag{164}$$

where the symbol '$\propto$' has the meaning of 'being directed along'.

Let us express $\Delta\mathbf{m}$ as

$$\Delta\mathbf{m}(t) = \Delta m_1(t)\mathbf{e}_1(t) + \Delta m_2(t)\mathbf{e}_2(t) \tag{165}$$

We observe that studying magnetization dynamics in the reference frame ($\mathbf{m}_0$, $\mathbf{e}_1$, $\mathbf{e}_2$) is tantamount of studying the dynamics in the rotating reference frame previously introduced.

Let us now substitute equation (165) into (160), and take into account that

$$\frac{\mathrm{d}\mathbf{e}_1(t)}{\mathrm{d}t} = \omega\mathbf{e}_z \times \mathbf{e}_1(t), \qquad \frac{\mathrm{d}\mathbf{e}_2(t)}{\mathrm{d}t} = \omega\mathbf{e}_z \times \mathbf{e}_1(t) \tag{166}$$

after appropriate manipulation one arrives to the following equation

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix}\Delta m_1\\ \Delta m_2\end{pmatrix} + \begin{pmatrix}0 & \alpha\\ -\alpha & 0\end{pmatrix}\begin{pmatrix}\Delta m_1\\ \Delta m_2\end{pmatrix} = \begin{pmatrix}-\alpha\omega\cos\theta_0 & -(\nu_0 - N_\perp)\\ (\nu_0 - N_\perp) & -\alpha\omega\cos\theta_0\end{pmatrix}\begin{pmatrix}\Delta m_1\\ \Delta m_2\end{pmatrix} + \begin{pmatrix}0 & 1\\ -1 & 0\end{pmatrix}\begin{pmatrix}\Delta h_{\text{eff1}}\\ \Delta h_{\text{eff2}}\end{pmatrix} \tag{167}$$

where Δh_{eff1} and Δh_{eff2} are the projections of $\Delta\mathbf{h}_{\text{eff}}$ (see equation (158)) along the two directions $\mathbf{e}_1(t)$ and $\mathbf{e}_2(t)$. Let us now analyze the form of this two components. The anisotropy part of $\Delta\mathbf{h}_{\text{eff}}$, it is given by

$$\Delta\mathbf{h}_{\text{eff,AN}} = \mathbf{e}_1(t)(\mathbf{e}_1(t)\cdot\mathbf{e}_z)\kappa\Delta m_z \tag{168}$$

and by taking into account that

$$\mathbf{e}_1(t)\cdot\mathbf{e}_z = \sin\theta_0,\ \Delta m_z = \Delta m_1 \sin\theta_0 \tag{169}$$

one obtains that

$$(\Delta\mathbf{h}_{\text{eff,AN}})_{1,2} = \begin{pmatrix}\kappa\sin^2\theta_0 & 0\\ 0 & 0\end{pmatrix}\cdot\begin{pmatrix}\Delta m_1\\ \Delta m_2\end{pmatrix} \tag{170}$$

It is interesting to notice that, due to the symmetry and despite the time-varying nature of the basis ($\mathbf{e}_1$, $\mathbf{e}_2$), the part of $\Delta\mathbf{h}_{\text{eff}}$ related to anisotropy is time independent.

The magnetostatic part of $\Delta\mathbf{h}_{\text{eff}}$ is given by

$$\Delta\mathbf{h}_{\text{M}} = -N_\perp\Delta\mathbf{m}_\perp - N_z\Delta m_z\mathbf{e}_z = -N_\perp\Delta\mathbf{m} + (N_\perp - N_z)\,\Delta m_z\mathbf{e}_z \tag{171}$$

thus,

$$\Delta h_{\text{M1}} = -N_\perp\Delta m_1 + (N_\perp - N_z)\sin^2\theta_0\Delta m_1,$$
$$\Delta h_{\text{M2}} = -N_\perp\Delta m_2 \tag{172}$$

By using these results one finds that equation (174) is simply reduced to

$$\begin{pmatrix}1 & \alpha\\ -\alpha & 1\end{pmatrix}\frac{\partial}{\partial t}\begin{pmatrix}\Delta m_1\\ \Delta m_2\end{pmatrix} = \begin{pmatrix}-\alpha\omega\cos\theta_0 & -\nu_0\\ \nu_0 - \kappa_{\text{eff}}\sin^2\theta_0 & -\alpha\omega\cos\theta_0\end{pmatrix}\begin{pmatrix}\Delta m_1\\ \Delta m_2\end{pmatrix} \tag{173}$$

which coincides with the equation that would be obtained by linearizing LLG equation in the rotating reference frame in spherical coordinates (see equations (132 and 133)) around a given **P** mode and making the following correspondence $\Delta\theta = \Delta m_1$, $\sin\theta_0\Delta\phi = \Delta m_2$.

Equation (172) can be put in the following explicit form

$$\frac{\mathrm{d}}{\mathrm{d}t}\begin{pmatrix}\Delta m_1\\ \Delta m_2\end{pmatrix} = A_0\begin{pmatrix}\Delta m_1\\ \Delta m_2\end{pmatrix} \tag{174}$$

where:

$$A_0 = \frac{1}{1+\alpha^2}\begin{pmatrix}1 & -\alpha\\ \alpha & 1\end{pmatrix}\begin{pmatrix}-\alpha\omega\cos\theta_0 & -\nu_0\\ \nu_0 - \kappa_{\text{eff}}\sin^2\theta_0 & -\alpha\omega\cos\theta_0\end{pmatrix} \tag{175}$$

and the pair $(\cos\theta_0, \nu_0)$ identifies the particular **P** mode considered. Stability is controlled by the eigenvalues of the matrix A_0. More precisely, let us calculate the determinant of A_0:

$$\det A_0 = \frac{1}{1+\alpha^2}\left(\nu_0^2 - \kappa_{\text{eff}}\sin^2\theta_0\,\nu_0 + \alpha^2\omega^2\cos^2\theta_0\right) \quad (176)$$

its trace:

$$\text{tr}A_0 = -\frac{2\alpha}{1+\alpha^2}\left(\nu_0 - \frac{\kappa_{\text{eff}}\sin^2\theta_0}{2} + \omega\cos\theta_0\right) \quad (177)$$

and the characteristic frequency $\omega_0^2 = \det A_0 - (\text{tr}A_0)^2/4$:

$$\omega_0^2 = \frac{1}{\left(1+\alpha^2\right)^2}\left[\left(\nu_0 - \frac{\kappa_{\text{eff}}\sin^2\theta_0}{2} - \alpha^2\omega\cos\theta_0\right)^2 - \left(1+\alpha^2\right)\frac{\kappa_{\text{eff}}^2\sin^4\theta_0}{4}\right] \quad (178)$$

Then, **P** mode stability can be classified as follows (Hubbard and West, 1995).

- $\det A_0 < 0$. Saddle-type fixed point.
- $\det A_0 > 0$ and $\omega_0^2 < 0$. Node-type fixed point:
  - $\text{tr}A_0 < 0$: stable node;
  - $\text{tr}A_0 > 0$: unstable node.
- $\det A_0 > 0$ and $\omega_0^2 > 0$. Focus-type fixed point:
  - $\text{tr}A_0 < 0$: stable focus;
  - $\text{tr}A_0 > 0$: unstable focus.

The difference between a node and a focus is not relevant to the rest of our analysis: we will use the term node in a generic sense, to denote either of them. The symbols (s), (u), and (d) will be used to denote stable nodes, unstable nodes, and saddles, respectively. A given **P** mode represents a physically realizable mode only when it is of (s) type ($\det A_0 > 0$ and $\text{tr}A_0 < 0$).

Stability results acquire a transparent form in the $(\cos\theta_0, \nu_0)$ **P** mode plane. Stability is controlled by the equations $\det A_0 = 0$ and $(\text{tr}A_0 = 0, \det A_0 > 0)$, where $\det A_0$ and $\text{tr}A_0$ are given by equations (176) and (177), respectively. These equations can be solved in order to obtain ν_0 as a function of $\cos\theta_0$. The results are as follows.

- $\det A_0 = 0$:

$$\nu_0 = \frac{\kappa_{\text{eff}}\sin^2\theta_0}{2} \pm \sqrt{\frac{\kappa_{\text{eff}}^2\sin^4\theta_0}{4} - \alpha^2\omega^2\cos^2\theta_0} \quad (179)$$

The above two values are real in the interval:

$$\cos^2\theta_0 \le \left(\sqrt{1+\frac{\alpha^2\omega^2}{\kappa_{\text{eff}}^2}} - \left|\frac{\alpha\omega}{\kappa_{\text{eff}}}\right|\right)^2 \quad (180)$$

- $(\text{tr}A_0 = 0, \det A_0 > 0)$:

$$\nu_0 = \frac{\kappa_{\text{eff}}\sin^2\theta_0}{2} - \omega\cos\theta_0 \quad (181)$$

By inserting equation (181) into equation (176) one finds that $\det A_0 \ge 0$ for

$$\cos^2\theta_0 \ge \left(\sqrt{1+\frac{\omega^2\left(1+\alpha^2\right)}{\kappa_{\text{eff}}^2}} - \left|\frac{\omega\sqrt{1+\alpha^2}}{\kappa_{\text{eff}}}\right|\right)^2 \quad (182)$$

Figure 16 shows the lines $\det A_0 = 0$ and $(\text{tr}A_0 = 0, \det A_0 > 0)$ calculated from equations (179) and (181) for a thin film with negligible crystal anisotropy. These lines divide the **P** mode plane into three regions associated with stable nodes (**S**), unstable nodes (**U**), and saddles (**D**). Physically realizable modes are only those located in the region **S**.

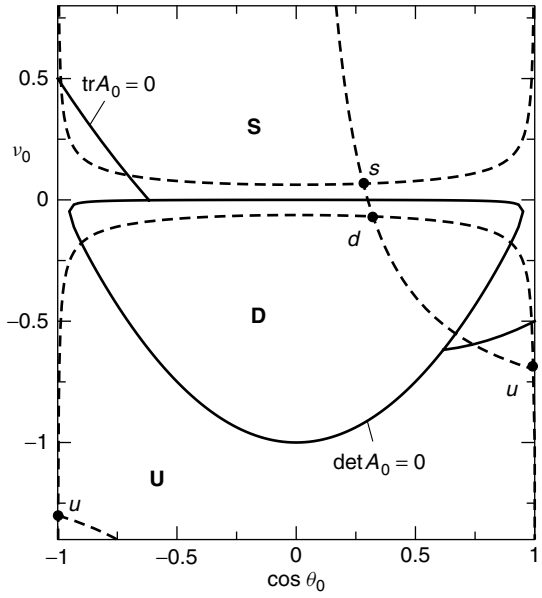

Figure 16. Representation of **P** modes in $(\cos\theta_0, \nu_0)$ plane. Continuous lines: $\det A_0 = 0$ and $(\text{tr}A_0 = 0, \det A_0 > 0)$. **P** modes lying inside region **D** are saddles of the rotating-frame dynamics, while those outside **D** are stable nodes (region **S**) or unstable nodes (region **U**). Broken lines: equation (140) for $h_{a\parallel} = 0.8$ and equation (141) for $h_{a\perp} = 0.08$. Solid points: intersection points representing the four **P** modes associated with $h_{a\parallel} = 0.8$, $h_{a\perp} = 0.08$ (see bottom phase portrait in Figure 15). System parameters: $\alpha = 0.1$, $\kappa_{\text{eff}} = -1$. Field frequency: $\omega = 0.5$.

These results take a more complex form in the field control plane $(h_{a\parallel}, h_{a\perp})$. Because there are two or four **P** modes associated with any given point of this plane, the functions $\det A_0$ and $\mathrm{tr}A_0$ will take the form of twofolded or fourfolded sheets when represented in this plane. According to Poincaré index theorem, when four **P** modes are present one of them is necessarily a saddle characterized by $\det A_0 < 0$. Therefore, the control plane region admitting four **P** modes coincides with the region where $\det A_0 < 0$ for one of the **P** modes. By substituting equation (179) into equations (145) and (146), one obtains a parametric representation of the boundary ($\det A_0 = 0$) between the two and four **P** mode regions, with $\cos\theta_0$ as the independent variable (see Figure 17). By similar considerations, one can determine the line ($\mathrm{tr}A_0 = 0, \det A_0 > 0$) (broken line in Figure 17) by substituting equation (181) into equations (145) and (146). The $\det A_0 < 0$ region can be construed as the dynamic generalization of Stoner–Wohlfarth asteroid region (Stoner and Wohlfarth, 1948; Bertotti, 1998). Indeed, it can be verified that this region coincides with the usual asteroid region in the limit $\omega \to 0$.

Equations (140) and (141) are invariant under the transformation: $\cos\theta_0 \to -\cos\theta_0$, $\nu_0 \to -\nu_0$, $\kappa_{\mathrm{eff}} \to -\kappa_{\mathrm{eff}}$. Given a **P** mode solution of the original equations, this transformation gives a corresponding **P** mode solution for the case where the effective anisotropy takes the opposite value. Equations (176) and (177) show that $\mathrm{tr}A_0 \to -\mathrm{tr}A_0$ and $\det A_0 \to \det A_0$ as a result of the above transformation. This means that when the sign of anisotropy is reversed stable **P** modes are changed into unstable ones and vice versa while the $\det A_0 = 0$ and $\mathrm{tr}A_0 = 0$ lines remain unaltered. These rules permit one to extend known results to systems with effective anisotropy of opposite sign. In addition, equation (176) shows that $\det A_0 > 0$ whenever ν_0 and κ_{eff} have opposite signs. Therefore the saddle point can exist only provided ν_0 and κ_{eff} have identical sign. This means that for the saddle points we have $0 \le \phi_0 < \pi/2$ when $\kappa_{\mathrm{eff}} > 0$ and $\pi/2 < \phi_0 \le \pi$ when $\kappa_{\mathrm{eff}} < 0$.

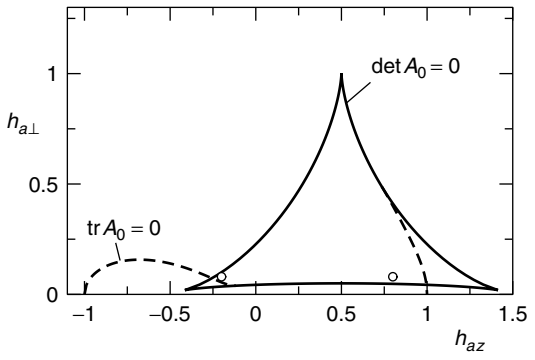

Figure 17. Representation of $\det A_0 = 0$ line and ($\mathrm{tr}A_0 = 0$, $\det A_0 > 0$) line in $(h_{a\parallel}, h_{a\perp})$ control plane. System parameters: $\alpha = 0.1$, $\kappa_{\mathrm{eff}} = -1$. Field frequency: $\omega = 0.5$. Small empty circles represent location of the two phase portraits shown in Figure 15.

It is worth remarking that the mentioned connection between fixed-point stability and anisotropy sign reflects a more general property of LLG dynamics (equations (132) and (133)), namely, the fact that reversing the sign of the effective anisotropy is essentially equivalent to reversing the direction of time. Indeed, equations (132) and (133) are invariant under the transformation: $\theta \to \pi - \theta$, $\phi \to \pi - \phi$, $\kappa_{\mathrm{eff}} \to -\kappa_{\mathrm{eff}}$, $t \to -t$, from which the **P** mode symmetries just discussed can be derived as a particular case.

5.2.3 *Quasiperiodic modes (**Q** modes)*

In order to be physically realizable, a **P** mode must be a stable node of the rotating-frame dynamics. When no **P** mode is stable, there will exist (at least) one attracting limit cycle in the dynamics (Poincaré-Bendixson theorem) (Perko, 1996). A limit cycle represents a periodic magnetization motion along a closed path on the unit sphere. This conclusion holds in the rotating reference frame. In the laboratory frame, the periodic motion along the limit cycle has to be combined with the rotation of the reference frame and this results in a quasiperiodic magnetization mode (**Q** mode) (see Figure 18). The quasiperiodicity arises because the external field and the limit-cycle periods are usually not commensurable.

The following argument proves that **Q** modes are necessarily present under appropriate conditions. Let us consider the case of small rotating field amplitudes, $h_{a\perp} \to 0$, where $\sin\theta_0 \to 0$ and $\cos\theta_0 \to \pm 1$. By making use of equations (140) and (141), one can write equations (176) and (177) in the approximate form:

$$\det A_0 \simeq \frac{1}{1+\alpha^2}\left(\nu_0^2 + \alpha^2\omega^2\right) \tag{183}$$

$$\mathrm{tr}A_0 \simeq -\frac{2\alpha}{1+\alpha^2}\left(\kappa_{\mathrm{eff}} \pm h_{a\parallel}\right) \tag{184}$$

Only two **P** modes are possible, because $\det A_0 > 0$. Furthermore, the sign of $\mathrm{tr}A_0$ is opposite to that of κ_{eff} for both modes in the interval $|h_{a\parallel}| < |\kappa_{\mathrm{eff}}|$. Therefore, in this interval both **P** modes are unstable for any system with negative effective anisotropy and a **Q** mode will necessarily appear.

This formal result has an intuitive physical interpretation. Let us assume that $\kappa_{\mathrm{eff}} < 0$ and that initially only the constant positive field $h_{a\parallel} < |\kappa_{\mathrm{eff}}|$ is applied, that is, $h_{a\perp} = 0$. In this case, no time-dependent driving field is present. In the laboratory frame, there exists a continuous set of static, marginally stable equilibrium states characterized by fixed

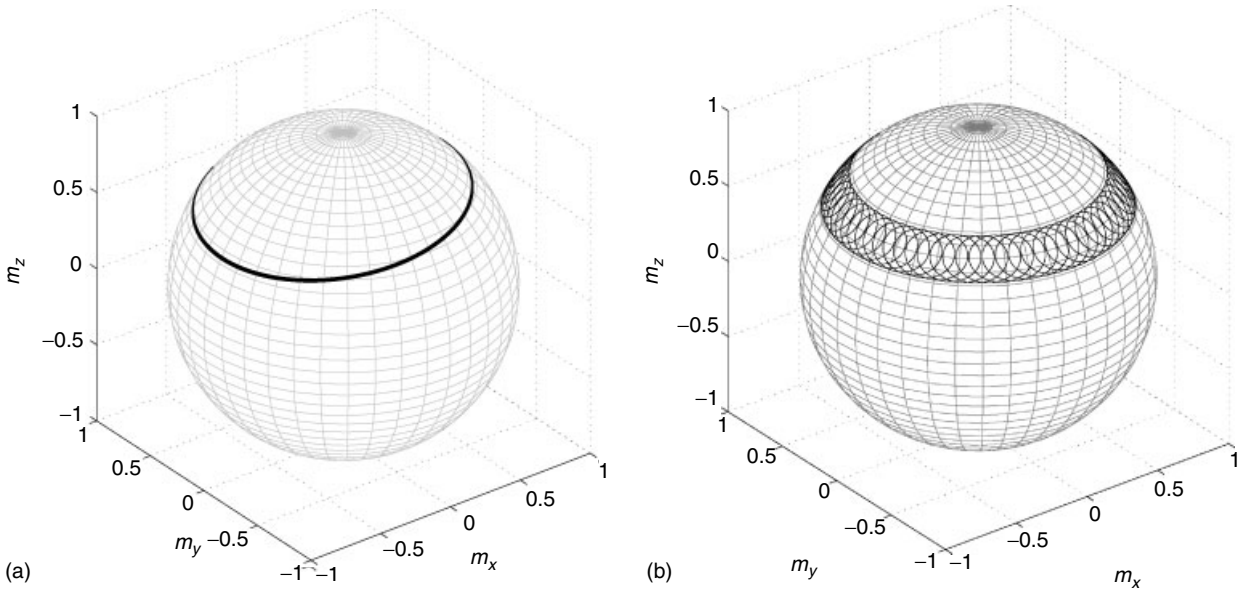

Figure 18. Representation on unit sphere of quasiperiodic motion (**Q** mode) in the rotating reference frame (a) and in the laboratory reference frame (b). In the rotating reference frame the **Q** mode appear as a limit cycle. System parameters: $\alpha = 0.1$, $\kappa_{\text{eff}} = -1$. Field frequency: $\omega = 0.5$. Field amplitude: $h_{a\parallel} = 0.8$, $h_{a\perp} = 0.08$.

$\cos\theta$ and arbitrary ϕ. In fact, by expressing the energy of the system (equation (121)) in terms of θ and ϕ one finds:

$$g_{\text{L}}\left(\theta, \phi; h_{a\parallel}, h_{a\perp}\right) = \frac{N_\perp}{2} - \frac{\kappa_{\text{eff}}}{2}\cos^2\theta - h_{a\parallel}\cos\theta - h_{a\perp}\sin\theta\cos\phi \tag{185}$$

When $\kappa_{\text{eff}} < 0$ and $h_{a\perp} = 0$ the energy is independent of ϕ and assumes its minimum value for $\cos\theta = h_{a\parallel}/|\kappa_{\text{eff}}|$. In the rotating frame, this continuous set of states results in a limit cycle of period $2\pi/\omega$. When the small rotating field $h_{a\perp}$ is applied, the set of equivalent static states is changed into a quasiperiodic motion. In fact, the rotating field is not strong enough to force the magnetization into synchronous rotation. The magnetization follows the field only for a small part of each rotation period and then periodically falls off synchronism. The result is a **Q** mode characterized by a slow average **m** precession around the symmetry axis, accompanied by a notation of frequency ω. Only when $h_{a\perp}$ exceeds a certain threshold, **m** gets locked to the field and the **Q** mode is destroyed in favor of a stable **P** mode.

In general, one expects that both stable (denoted by (a), i.e., attracting) and unstable (denoted by (r), i.e., repelling) limit cycles may be present in the dynamics (see Figure 15). The problem of theoretically predicting the number and the location of limit cycles for a given dynamical system is of extraordinary mathematical difficulty. However, when dissipation is small (that is, $\alpha \ll 1$ in equation (129)) some insight can be obtained (Serpico, d'Aquino, Bertotti and Mayergoyz, 2004) by a perturbative approach known as the Poincaré–Melnikov method for slightly dissipative systems (Perko, 1996; Guckenheimer and Holmes, 1997) (this method is discussed in detail in Bertotti, Mayergoyz and Serpico (2006a) where it is applied to spin-torque driven magnetization dynamics). Here, we simply present the key elements permitting one to apply the method to rotationally invariant LLG dynamics.

The starting point of our discussion is the equation for the undamped dynamics obtained by taking $\alpha = 0$ in equation (129):

$$\frac{\text{d}\mathbf{m}}{\text{d}t} = -\mathbf{m} \times \tilde{\mathbf{h}}_{\text{eff}} \tag{186}$$

This equation shows that the effective energy $\tilde{g}_{\text{L}}$ defined by equation (127) is an integral of motion for the undamped dynamics, because $\tilde{\mathbf{h}}_{\text{eff}} \cdot \text{d}\mathbf{m}/\text{d}t = 0$. Thus the magnetization trajectories coincide with the closed level curves of the $\tilde{g}_{\text{L}}$ function. From equations (121) and (127) one finds that $\tilde{g}_{\text{L}}(\mathbf{m}; \mathbf{h}_{\text{a}})$ can be expressed as:

$$\tilde{g}_{\text{L}}(\mathbf{m}; \mathbf{h}_{\text{a}}) = \frac{1}{2}N_\perp - \frac{1}{2}\kappa_{\text{eff}} m_z^2 - (h_{az} - \omega)m_z - h_{a\perp}m_{a\perp} \tag{187}$$

Therefore, the line $C(\tilde{g}_0)$ of constant energy $\tilde{g}_0$ is described by the equation:

$$\kappa_{\text{eff}} m_z^2 + 2(h_{az} - \omega)m_z + 2h_{a\perp}m_{a\perp} = N_\perp - 2\tilde{g}_0 \tag{188}$$

When α is nonzero, the effective energy $\tilde{g}_L$ is no longer constant along the magnetization trajectories. One obtains from equation (129) that $\tilde{g}_L$ changes at the rate:

$$\frac{\mathrm{d}\tilde{g}_{\mathrm{L}}}{\mathrm{d}t} \equiv -\tilde{\mathbf{h}}_{\mathrm{eff}} \cdot \frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = -\alpha \left(\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} - \omega \mathbf{m} \times \mathbf{e}_z \right) \cdot \frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} \quad (189)$$

Thus, whenever $\alpha \ll 1$ the energy $\tilde{g}_{\mathrm{L}}$ will be a slowly varying function of time and magnetization trajectories will be only slightly distorted with respect to the undamped ones. Let us now consider a limit cycle of the dissipative dynamics. According to the previous reasoning, the corresponding closed trajectory will be close to a certain trajectory $C(\tilde{g}_0)$ of the undamped dynamics. By definition, the limit cycle represents a periodic motion, so the energy of the system will also be periodic when calculated along the limit cycle. This means that the time integral of the right-hand side of equation (189) along the limit cycle will be zero. Since the limit cycle is very close to the undamped trajectory $C(\tilde{g}_0)$ we can calculate this integral along the undamped trajectory without making an appreciable error. By also taking into account that equation (186) holds for the undamped motion and that $\tilde{\mathbf{h}}_{\mathrm{eff}} = \mathbf{h}_{\mathrm{eff}} - \omega \mathbf{e}_z$, we conclude that the integral of the right-hand side of equation (189) along the limit cycle will be approximately equal to $-\alpha M(\tilde{g}_0)$, where:

$$M(\tilde{g}_0) = -\oint_{C(\tilde{g}_0)} (\mathbf{m} \times \mathbf{h}_{\mathrm{eff}}) \cdot \mathrm{d}\mathbf{m} \quad (190)$$

Therefore, it is expected that $M(\tilde{g}_0) \simeq 0$ for a limit cycle. This heuristic reasoning can be given a rigorous mathematical formulation by invoking Poincaré–Melnikov method (Perko, 1996; Guckenheimer and Holmes, 1997). In particular, one can prove that in the limit of small damping the equation $M(\tilde{g}_0) = 0$ represents the *necessary and sufficient condition* for the existence of a limit cycle. The limit cycle is stable or unstable depending on whether $\mathrm{d}M/\mathrm{d}\tilde{g}_0$ is respectively positive or negative at the point where $M(\tilde{g}_0) = 0$. Therefore, the knowledge of the undamped dynamics is sufficient to predict the number and location of limit cycles, provided the damping constant α is sufficiently small.

The Melnikov function $M(\tilde{g}_0)$ can be studied by analytical or numerical methods under quite general conditions because $\mathbf{h}_{\mathrm{eff}}$ (equation (122)) and $\tilde{g}_{\mathrm{L}}$ (equation (127)) are all known functions of $\mathbf{m}$. There is no need to determine the precise time dependence $\mathbf{m}(t)$ for the undamped magnetization motion in order to calculate the Melnikov function: it is enough to know the geometrical shape of the unperturbed trajectories, that is, the constant $\tilde{g}_{\mathrm{L}}$ lines given by equation (188). Figure 19 illustrates the example where this method is applied to the thin film with negligible crystal anisotropy considered in Figure 15. The Melnikov function is calculated from equations (122), (127), and (190) for all energies

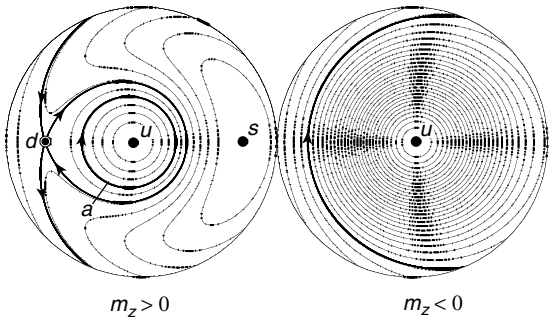

Figure 19. Phase portrait for nondissipative system. Trajectories are given by lines of constant effective energy $\tilde{g}_L(\mathbf{m}; \mathbf{h}_a) = \tilde{g}_0$ (see equations (121) and (127)). s: $\tilde{g}_{\mathrm{L}}$ minimum; u: $\tilde{g}_{\mathrm{L}}$ maxima; d: $\tilde{g}_{\mathrm{L}}$ saddle. System parameters: $\alpha = 0$, $\kappa_{\mathrm{eff}} = -1$. Field frequency: $\omega = 0.5$. Field amplitude: $h_{a\parallel} = 0.8$, $h_{a\perp} = 0.08$. Trajectory labeled by a is stable limit cycle present in dissipative dynamics in the limit of small damping α, as predicted by Melnikov theory (compare with bottom phase portrait in Figure 15).

in the interval $\tilde{g}_d \leq \tilde{g}_0 \leq \tilde{g}_u$, where $\tilde{g}_d$ and $\tilde{g}_u$ represent the energies of the d and u stationary points in the $m_z > 0$ hemisphere in Figure 19. One finds that: $M(\tilde{g}_d) < 0$; $M(\tilde{g}_u) = 0$ (indeed, the Melnikov function is zero by definition for every energy extremum); $\mathrm{d}M/\mathrm{d}\tilde{g}_0|_{\tilde{g}_0 = \tilde{g}_u} < 0$ (this means that the energy maximum is going to be an unstable focus of the dissipative dynamics). These boundary properties imply that there must exist at least one additional $M(\tilde{g}_0)$ zero inside the interval $\tilde{g}_d < \tilde{g}_0 < \tilde{g}_u$. In fact, one finds just one additional zero. The corresponding trajectory is labeled by a in Figure 19. This trajectory is going to be a stable limit cycle of the dissipative dynamics for sufficiently small α. The comparison with Figure 15 shows that this limit cycle is indeed present in the dynamics even when α is as large as 0.1.

5.2.4 Nonlinear ferromagnetic resonance

The field region close to the right-hand corner of the region $\det A_0 < 0$ in Figure 17 is where ferromagnetic resonance phenomena occur (Wigen, 1994; Gurevich and Melkov, 1996). In typical ferromagnetic resonance experiments, the large dc field $h_{az} > 0$ is initially applied to the system. The ensuing **P** mode coincides with the saturation state along the positive $\mathbf{e}_z$ axis. Then the microwave field of amplitude $h_{a\perp}$ and angular frequency ω is switched on. The resonance experiment is carried out by slowly decreasing the field h_{az} while keeping $h_{a\perp}$ and ω constant. Resonance occurs when the Larmor frequency associated with the effective field becomes equal to the rotating field frequency ω. In dimensionless notation, this means that $h_{az} + \kappa_{\mathrm{eff}} \simeq \omega$.

The resonance becomes manifest when one considers the power p absorbed by the **P** mode under fixed $h_{a\perp}$ and

variable h_{az}. By using equations (148) and (141) one obtains:

$$p \equiv \mathbf{h}_{a\perp} \cdot \frac{\mathrm{d}\mathbf{m}_\perp}{\mathrm{d}t} = \alpha\omega^2 \sin^2\theta_0 = \frac{\alpha\omega^2 h_{a\perp}^2}{\nu_0^2 + \alpha^2\omega^2} \qquad (191)$$

When the microwave field is small, the angle θ_0 is small as well and one can use equation (140) under the approximation $\cos\theta_0 \simeq 1$ to express ν_0 in terms of h_{az}. Under this approximation, equation (191) yields:

$$p = \frac{\alpha\omega^2 h_{a\perp}^2}{(h_{az} + \kappa_{\mathrm{eff}} - \omega)^2 + \alpha^2\omega^2} \qquad (192)$$

We obtain the lorentzian line shape typical of linear resonant behavior. The absorbed power is maximum for $h_{az} + \kappa_{\mathrm{eff}} = \omega$, as previously anticipated, and the linewidth is $\alpha\omega$. When progressively larger microwave field amplitudes are considered, large precessional motions set in and the approximation $\cos\theta_0 \simeq 1$ is no longer acceptable. To deal with this nonlinear regime, we can make use of equations (140)–(141) to express h_{az} as a function of $\cos\theta_0$ for the **P** mode under consideration. One finds:

$$h_{az} = \omega - \kappa_{\mathrm{eff}} \cos\theta_0 \pm \cos\theta_0 \sqrt{\frac{h_{a\perp}^2}{\sin^2\theta_0} - \alpha^2\omega^2} \qquad (193)$$

Equations (191) and (193) give the parametric representation of the absorbed power $p(h_{az})$ under nonlinear conditions, with $\cos\theta_0$ as the independent variable. An example is shown in Figure 20 for the case of a thin-film disk with negligible crystal anisotropy ($\kappa_{\mathrm{eff}} = -1$). The initial condition, where $\cos\theta_0 \simeq 1$ and h_{az} is very large, corresponds to choosing the branch with the positive sign in equation (193). This is the correct branch to consider when $\cos\theta_0$ is decreased from $\cos\theta_0 = 1$ down to $\sin^2\theta_0 = h_{a\perp}^2/\alpha^2\omega^2$, where the square root in equation (193) vanishes. This is where the absorbed power is maximum. From here, the branch with the negative sign in equation (193) must be considered for $\cos\theta_0$ increasing from the minimum resonance value back to $\cos\theta_0 = 1$. As shown in Figure 20, the absorbed power profile gets increasingly distorted under increasing rf field amplitude. According to equation (191), the state of maximum absorbed power always corresponds to $\nu_0 = 0$. From equations (140) and (141) one finds that this condition is described by the equation:

$$h_{a\perp} = \frac{\alpha\omega}{|\kappa_{\mathrm{eff}}|} \sqrt{\kappa_{\mathrm{eff}}^2 - (h_{az} - \omega)^2} \qquad (194)$$

which is the curved dashed line shown in Figure 20.

When κ_{eff} is negative and large enough, the distortion of the absorbed power profile can become so important that the system becomes unstable and hysteretic jumps appear in the absorbed power. This phenomenon has been observed indeed and is known in the literature as 'foldover' (Seagle, Charap and Artman, 1985; Fetisov, Patton and Sygonach, 1999). Foldover effects are properly understood by using the bifurcation analysis presented in Section 5.2.2. Let us consider the representation of **P** modes in the $(h_{az}, h_{a\perp})$ field control plane. During the resonance experiment, the **P** mode under study moves from right to left along a horizontal line in the control plane, as shown in Figure 20. If this line crosses the boundary of the $\det A_0 < 0$ region (point A in Figure 20), a saddle-node pair of additional **P** modes is created. The **P** mode motion executed by the system is destroyed at point B in Figure 20 by a second saddle-node bifurcation involving the saddle previously created at point A. Consequently, the system becomes unstable and jumps to a different **P** mode motion of definitely smaller amplitude. If the field h_{az} is now increased, the newly attained **P** mode evolves under the action of the field until it is destroyed by the saddle-node bifurcation at point A in Figure 20 where the system jumps back to the original **P** mode. It is clear from this analysis that the $h_{a\perp}$ threshold beyond which foldover

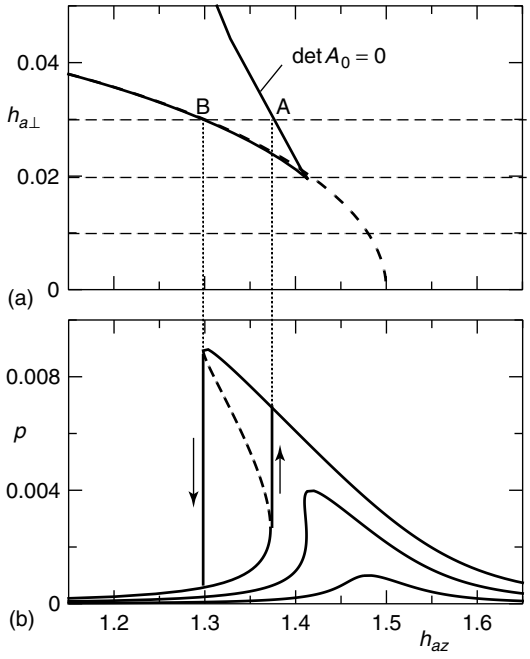

Figure 20. (a) Magnified view of right-hand corner of $\det A_0 < 0$ region for the thin-film disk shown in Figure 17. Horizontal dashed lines: field history for resonance experiments under rf field amplitudes $h_{a\perp} = 0.01, 0.02, 0.03$. Curved dashed line: $\nu_0 = 0$ nonlinear resonance condition (equation (194)). *A* and *B*: saddle-node bifurcation points where instability in system response may occur. (b) Absorbed power (equations (191) and (193)) for $h_{a\perp} = 0.01, 0.02, 0.03$ with representation of foldover jumps taking place for the highest rf field amplitude at points A and B. System parameters: $\alpha = 0.1$, $\kappa_{\mathrm{eff}} = -1$. Field frequency: $\omega = 0.5$.

becomes possible coincides with the ordinate of the lower right-hand tip of the $\det A_0 < 0$ region. That is the point where the two roots of the equation $\det A_0 = 0$ coincide. This means that $\kappa_{\text{eff}} \sin^2\theta_0 = 2\alpha\omega\cos\theta_0$ (see equation (176)), which yields:

$$\cos\theta_0 = \sqrt{1 + \frac{\alpha^2\omega^2}{\kappa_{\text{eff}}^2}} - \frac{\alpha\omega}{|\kappa_{\text{eff}}|}, \nu_0 = \alpha\omega\cos\theta_0 \quad (195)$$

Substitution of this result into equation (141) leads to the following expression for the threshold for foldover:

$$h_{a\perp}^2 = \frac{4\,(\alpha\omega)^3}{|\kappa_{\text{eff}}|} \frac{\sqrt{1 + \frac{\alpha^2\omega^2}{\kappa_{\text{eff}}^2}}}{\left(\frac{\alpha\omega}{|\kappa_{\text{eff}}|} + \sqrt{1 + \frac{\alpha^2\omega^2}{\kappa_{\text{eff}}^2}}\right)^2} \quad (196)$$

This exact result is the generalization of the estimate $h_{a\perp}^2 \simeq 3.08(\alpha\omega)^3/|\kappa_{\text{eff}}|$ obtained for the thin-film geometry by Anderson and Suhl (1955) through an approximate linear analysis.

Classical Spin Models

Ulrich Nowak
University of York, York, UK

1 INTRODUCTION

Classical spin models bridge the gap between a full electronic description of a magnetic material and conventional micromagnetism where magnetic properties are calculated on the basis of a continuum theory for the energy of a system. While quantum effects are obviously neglected, classical spin models take into account the discrete nature of matter, so that they allow for an investigation of magnetic particles in the nanometer regime where a continuum theory would fail. The fact that magnetic structures are described on an atomic level makes it possible to investigate ferromagnets (FMs) as well as antiferromagnets (AFMs) or even heterostructures composed of both of them. Methods exist for the calculation of thermal equilibrium properties and, to some extent, also for nonequilibrium properties. Classical spin models are thus particularly suited to the study of thermal effects. On the other hand, numerical calculations with an atomic resolution are restricted to system sizes of the order of 10^7 spins so that only systems sizes of the order of some 10 nm can be treated numerically (at the moment). However, magnetic materials are controllable down to the nanometer scale, leading to a fundamental interest in the understanding of the magnetism of small ferromagnetic particles or heterostructures (Schneider and Blügel, 2005). This interest is even amplified by the broad variety of industrial applications in pure magnetic as well as spin electronic devices. For theoretical investigations numerical methods are thus desirable, especially methods that are capable of treating realistic magnetic model systems including heterostructures and the effects of thermal activation.

This chapter focuses on classical spin models, physical principles as well as numerical methods. Section 2 deals with the basics of classical spin Hamiltonians, thermal averages, and the equation of motion – the Landau–Lifshitz–Gilbert (LLG) equation. In Section 3 the two most established numerical methods in this context are discussed, namely Monte Carlo methods (Binder and Heermann, 1997) and Langevin dynamics simulations (Lyberatos and Chantrell, 1993). Special emphasis is laid on the relation between these different methods, which leads to time-quantified Monte Carlo methods (Nowak, Chantrell and Kennedy, 2000). Sections 4 and 5 are an introduction to two topics which are typical for a modeling within the framework of classical spin models, namely thermally activated switching in nanoparticles (Nowak, 2001) and exchange bias (EB) (Nogués and Schuller, 1999), an effect arising in compound systems of ferro- and antiferromagnetic materials. Section 6 concludes this article.

2 THEORETICAL CONCEPTS

2.1 Classical spin models

A classical spin model is the classical limit of a quantum mechanical, localized spin model – the Heisenberg model (Heisenberg, 1928) (see Steevens, 1963; Anderson, 1963; Levy, 2000, for the theoretical background). The Hamiltonian of a classical spin model describing a magnetic system may contain contributions from exchange interactions, crystalline anisotropies, the external magnetic field, and dipole–dipole interactions. There might also be other contributions (e.g., a magnetovolume coupling) which, for the sake of simplicity, will not be considered in the following. An appropriate Hamiltonian may then be written in the form

$$\mathcal{H} = \mathcal{H}_{\text{exc}} + \mathcal{H}_{\text{anis}} + \mathcal{H}_{\text{field}} + \mathcal{H}_{\text{dipol}} \tag{1}$$

Within the framework of the classical Heisenberg model the exchange energy is expressed as

$$\mathcal{H}_{\text{exc}} = -\sum_{\langle ij \rangle} J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j \tag{2}$$

where the $\mathbf{S}_i = \boldsymbol{\mu}_i / \mu_s$ are three-dimensional magnetic moments reduced to unit length. This part represents the exchange of the magnetic moments and it is often (but not necessarily) restricted two nearest-neighbor interactions with a unique exchange coupling constant J. For $J > 0$ this part of the Hamiltonian leads to ferromagnetic order while for $J < 0$ it can lead to antiferromagnetic order if the lattice structure allows for antiferromagnetic order without frustration effects.

The simplest example for a crystalline anisotropy is

$$\mathcal{H}_{\text{anis}} = -d_z \sum_i S_{iz}^2 \tag{3}$$

which is a uniaxial anisotropy favoring the z axis as easy axis of the system for positive anisotropy constant d_z. Of course, other anisotropy terms describing any crystalline, stress, or surface anisotropies could also be considered.

The Zeeman energy is

$$\mathcal{H}_{\text{field}} = -\mathbf{b} \cdot \sum_i \mathbf{S}_i \tag{4}$$

describing the coupling of the moments to an external magnetic field with $\mathbf{b} = \mu_s \mathbf{B}$. Here, μ_s is the absolute value of the magnetic moment which for an atomic moment is of the order of a Bohr magneton.

The dipole–dipole coupling of the magnetic moments leads to an energy

$$\mathcal{H}_{\text{dipole}} = -w \sum_{i<j} \frac{3(\mathbf{S}_i \cdot \mathbf{e}_{ij})(\mathbf{e}_{ij} \cdot \mathbf{S}_j) - \mathbf{S}_i \cdot \mathbf{S}_j}{r_{ij}^3} \tag{5}$$

with $w = \mu_s^2 \mu_0 / 4\pi a^3$ when the spins are on a regular lattice with spacing a. The atomic magnetic moments are handled in a point dipole approximation. The r_{ij} are the normalized distances between moments i and j and the $\mathbf{e}_{ij}$ are unit vectors in the direction of $\mathbf{r}_{ij}$. Since the dipole–dipole interaction of two moments depends on their distance vector, the dipolar energy contribution will depend on the shape of the sample. Dipoles try to be aligned, minimizing free surface charges, which leads to shape anisotropy and to the fact that domain structures may minimize the energy of the system. Hence, dipole–dipole coupling is the microscopic origin of the magnetostatic stray field energy.

Classical spin models are in some sense 'between' a full quantum mechanical first-principles description and a micromagnetic continuum approach. But they can also be interpreted as the discretized version of a micromagnetic continuum model, where the charge distribution for a single cell of the discretized lattice is approximated by a point dipole (Berkov, Ramstöck and Hubert, 1993; Hubert and Schäfer, 1998). Also, for certain magnetic systems their description in terms of a lattice of magnetic moments is based on the mesoscopic structure of the material, especially when a particulate medium is described (Chantrell, Lyberatos and Wohlfarth, 1986; Nowak, Rüdiger, Fumagalli and Güntherodt, 1996; Nowak, 1997; Nowak, Heimel, Kleinefeld and Weller, 1997; Chantrell, Walmsley, Gore and Maylin, 2000; Verdes *et al*., 2002). In this case it is assumed that one grain or particle can be described by a single magnetic moment. Therefore, the size of the particles and the temperature must be small enough so that internal degrees of freedom are not relevant for the special problem under consideration.

When compared, the use of classical spin models for the description of magnetic materials has advantages as well as disadvantages. The main disadvantage is that owing to the atomic resolution the system size is clearly restricted to a nanoscale (at the moment to the order of, say, 10^7 spins, steadily increasing with computational power). But the advantages are (i) realistic lattice structures and interactions can be taken into account without assuming a continuous magnetization (Vedmedenko *et al*., 2004), (ii) finite temperatures can be taken into account without cutting the spin-wave spectra because of the discretization (Berkov, 2007), (iii) the form and the parameters of the Hamiltonian can be derived from first-principles calculations (see e.g., Mryasov, Nowak, Guslienko and Chantrell, 2005), and (iv) the modeling of

para-, ferri-, ferro- or antiferromagnets, and even heterostructures composed of several of these different materials is straightforward.

Hence typical magnetic systems for a description using classical spin models are nanostructures or systems with very narrow domain walls (Garanin, 1991; Kazantseva, Wieser and Nowak, 2005), especially when thermal excitations are relevant (Garanin, 1997; Nowak, 2001), and magnetic heterostructures including antiferromagnetic components (Malozemoff, 1987; Nowak *et al*., 2002b).

2.2 Thermodynamics and the equation of motion

In order to calculate thermodynamic equilibrium properties one has to calculate thermal averages for the properties of interest. For instance, in a canonical ensemble the temperature-dependent reduced magnetization becomes

$$\mathbf{m}(T) = \frac{1}{N}\left\langle \sum_i \mathbf{S}_i \right\rangle = \frac{1}{N}\mathrm{Tr}\,\frac{1}{Z} e^{-\mathcal{H}/k_\mathrm{B}T} \sum_i \mathbf{S}_i \qquad (6)$$

where $\langle \ldots \rangle$ denotes a thermal average and $Z = \mathrm{Tr}\, e^{-\mathcal{H}/k_\mathrm{B}T}$ is the canonical partition function (see, e.g., Reif, 1965). For N classical spins the calculation of the trace would involve an integral over phase space, that is, integrals over N unit spheres. This high-dimensional integral can usually not be calculated exactly for realistic magnetic systems. Instead either approximations have to be used, the most famous one being the mean-field approximation (Wagner, 1972; Levy, 2000) or numerical techniques like Monte Carlo methods.

Moreover, one often is interested in nonequilibrium properties. Then, the basic equation of motion for magnetic moments coupled to a heat bath is the LLG equation (Landau and Lifshitz, 1935; Gilbert, 1955; Brown, 1963a) with Langevin dynamics. For electronic magnetic moments it can be written in the form

$$\dot{\mathbf{S}}_i = -\frac{\gamma}{(1+\alpha^2)\mu_s}\mathbf{S}_i \times \left(\mathbf{H}_i(t) + \alpha\, \mathbf{S}_i \times \mathbf{H}_i(t)\right) \qquad (7)$$

where $\gamma = 1.76 \times 10^{11}(\mathrm{T\,s})^{-1}$ is the absolute value of the gyromagnetic ratio and $\mathbf{H}_i(t) = \boldsymbol{\zeta}_i(t) - \partial\mathcal{H}/\partial\mathbf{S}_i$. The thermal noise $\boldsymbol{\zeta}_i(t)$ obeys

$$\langle \boldsymbol{\zeta}_i(t) \rangle = 0 \qquad (8)$$

$$\langle \zeta_{i\eta}(t)\zeta_{j\theta}(t') \rangle = \delta_{i,j}\delta_{\eta,\theta}\delta(t-t')2\alpha k_\mathrm{B}T\mu_s/\gamma \qquad (9)$$

i and j denote once again the sites of the lattice and η and θ the Cartesian components. The first part of equation (7) describes the spin precession, which can be derived from Heisenberg's equation of motion in the classical limit, while the second part includes the relaxation of the moments. α is a dimensionless parameter describing phenomenologically the strength of the coupling to the heat bath. Note, that this microscopic coupling parameter is not necessarily identical with the usual macroscopic damping parameter (Chubykalo, Nowak, Chantrell and Garanin, 2006) but we will, nevertheless, refer to α as damping parameter in the following. As a consequence of the fluctuation dissipation theorem, α governs the relaxation aspect of the coupling to the heat bath as well as the fluctuations via the strength of the thermal noise (Lyberatos and Chantrell, 1993; Chubykalo *et al*., 2003b; Berkov, 2007). The assumption of uncorrelated noise on an atomic level is a simplification reflecting the lack of knowledge regarding the fundamental physical mechanisms involved in the coupling between spins and heat bath. The microscopic understanding of damping is an outstanding challenge for current research (Smith and Arnett, 2001; Safonov and Bertram, 2002; Rebei and Parker, 2003). However, the strength of the noise in equation (9) ensures correct thermal averages.

One can solve the LLG equation easily for an isolated spin coupled to an external field $\mathbf{B}$, neglecting the thermal fluctuations. Then the first term in equation (7) leads to a spin precession with the precession time $\tau_p = 2\pi(1+\alpha^2)/(\gamma B)$. The second part describes a relaxation of the spin from an initial state into local equilibrium on the relaxation timescale $\tau_r = \tau_p/\alpha$. In other words, α sets the relation between the timescales of precession and relaxation. In the high damping limit, which in the following will turn out to be important in connection with Monte Carlo simulations, mainly the second term of the LLG equation is relevant and the time can be rescaled by the factor $(1+\alpha^2)\mu_s/(\alpha\gamma)$. Hence, this factor should completely describe the α and γ dependence of any timescale in the high damping limit.

The LLG equation is a stochastic equation of motion. Starting repeatedly from identical initial conditions will lead to different trajectories in phase space because of the influence of noise. Hence, averages have to be taken in order to describe the system appropriately. The basis for the statistical description of an ensemble of systems where each one is described by a Langevin equation is the corresponding Fokker–Planck (FP) equation. This is a differential equation for the time evolution of the probability distribution in phase space (Coffey, 1996). In his pioneering work Brown (1963b) developed a formalism for the description of thermally activated magnetization reversal on the basis of the FP equation which led to a low-temperature asymptotic formula for the escape rates in simple magnetic systems (for an overview see Coffey, 1996). The solution of the FP equation will converge to equilibrium properties, that is to the same values defined by equation (6).

However, realistic calculations for systems with many degrees of freedom need computational approaches. The two basic methods for the simulation of classical spin systems are Langevin dynamics and Monte Carlo methods. The following section is devoted to these methods, especially to their relation which will lead to time-quantified Monte Carlo methods.

3 NUMERICAL METHODS

3.1 Langevin dynamics simulations

The basic numerical approach for the description of thermally activated spin dynamics is the direct numerical integration of equation (7). Instead of solving the corresponding FP equation, one calculates trajectories in phase space following the underlying equation of motion. In order to obtain results in the sense of a thermodynamic average one has to calculate many of these trajectories starting with the same initial conditions, taking an average over these trajectories for the quantities of interest. This method is referred to as *Langevin dynamics simulation* (Lyberatos and Chantrell, 1993).

The LLG equation with Langevin dynamics is a stochastic differential equation with multiplicative noise. For this kind of differential equation a problem arises which is called the *Itô–Stratonovich dilemma* (Greiner, Strittmatter and Honerkamp, 1988). As a consequence, different time discretization schemes may with decreasing time step converge to different results (see Wolf, 1998, for a discussion of the different discretization schemes from a physical point of view). As was pointed out by García-Palacios and Lázaro (1998) the multiplicative noise in the Langevin equation was treated in Brown's original work – and also in subsequent publications – by means of the Stratonovich interpretation. Hence, in order to obtain numerical results that are comparable to these approaches via the FP equation one has to use adequate methods. Note, that the simplest method for the integration of first-order differential equations, the Euler method, converges to an Itô interpretation of the Langevin equation. The simplest appropriate discretization scheme leading to a Stratonovich interpretation is the Heun method (Greiner, Strittmatter and Honerkamp, 1988; Wolf, 1998; García-Palacios and Lázaro, 1998; Nowak, 2001) which is described in the following [1].

For simplicity, the Heun discretization scheme is introduced here for a one-dimensional problem. We consider a first-order differential equation with multiplicative noise,

$$\dot{x}(t) = f\Big(x(t), t\Big) + g\Big(x(t), t\Big)\zeta(t) \tag{10}$$

where $\zeta(t)$ represents a noise with a distribution of moments $\langle\zeta(t)\rangle = 0$ and $\langle\zeta(t)\zeta(t')\rangle = D\delta(t-t')$. The time variable is discretized in intervals Δt so that $t_n = n\Delta t$ and $x_n = x(t_n)$. Then, owing to Heun's method equation (7) becomes

$$\begin{aligned} x_{n+1} = x_n &+ \frac{1}{2}\Big(f(x_n, t_n) + f(\overline{x}_{n+1}, t_{n+1})\Big)\Delta t \\ &+ \frac{1}{2}\Big(g(x_n, t_n) + g(\overline{x}_{n+1}, t_{n+1})\Big)\tilde{\zeta}_n \end{aligned} \tag{11}$$

This method is a predictor–corrector method where the predictor $\overline{x}_{n+1}$ is calculated from an Euler integration scheme,

$$\overline{x}_{n+1} = x_n + f(x_n, t_n)\Delta t + g(x_n, t_n)\tilde{\zeta}_n$$

$\tilde{\zeta}_n$ are random numbers with a distribution characterized by the two first moments $\langle\tilde{\zeta}_n\rangle = 0$ and $\langle\tilde{\zeta}_n\tilde{\zeta}_m\rangle = D\Delta t\delta_{n,m}$, which can be achieved by use of random numbers with a Gaussian distribution, $p(\zeta) \sim \exp(-\zeta^2/2\sigma)$, with width $\sigma = D\Delta t$. The generalization of the scheme in the preceding text to equation (7) is straightforward.

3.2 Monte Carlo methods

Monte Carlo methods are well established in the context of equilibrium thermodynamics, where mainly Ising-type models have been investigated because of the broad variety of applications of this class of models in statistical physics (Stauffer, Hehl, Winkelmann and Zabolitzky, 1993; Binder and Heermann, 1997). However, in the context of magnetic materials the use of Ising models is restricted to the modeling of materials with a very large uniaxial anisotropy (Kirby, Shen, Hardy and Sellmyer, 1994; Lyberatos, Earl and Chantrell, 1996; Nowak, Heimel, Kleinefeld and Weller, 1997), while more realistic models have to include finite anisotropies.

Within a Monte Carlo approach trajectories in phase space are calculated following a master equation (Reif, 1965) for the time development of the probability distribution $P_s(t)$ in phase space,

$$\frac{\mathrm{d}P_s}{\mathrm{d}t} = \sum_{s'}(P_{s'}w_{s'\to s} - P_s w_{s\to s'}) \tag{12}$$

Here, s and s' denote different states of the system and the w are the transition rates from one state to another one which have to fulfill the condition (Reif, 1965)

$$\frac{w_{s\to s'}}{w_{s'\to s}} = \exp\left(\frac{E(S) - E(S')}{k_\mathrm{B}T}\right) \tag{13}$$

The master equation describes exclusively the coupling of the system to the heat bath. Hence, only the irreversible part of the dynamics of the system is considered including the relaxation and the fluctuations, but not the energy conserving part of the equation of motion – the precession. Instead, only a random-walk-like motion due to the coupling to the heat bath can appear. We will discuss the connection to Langevin dynamics later and continue with a general description of Monte Carlo algorithms for vector spin models, as far as they are different from algorithms for Ising models due to their continuum degrees of freedom.

Even though for Ising systems (Swendsen and Wang, 1987) as well as for Heisenberg systems (Wolff, 1989) cluster algorithms exist, which – depending on the details of the problem – can equilibrate a system much faster, we restrict ourselves to the simple case of single-spin-flip dynamics since here, the connection to a realistic dynamical behavior of the system is more straightforward. For the Ising model there exists no equation of motion and the master equation in connection with a single-spin-flip dynamics governs the so-called Glauber dynamics (Glauber, 1963), which is thought to describe a qualitatively realistic dynamic behavior. For a system of classical magnetic moments the situation is different due to the existence of an equation of motion – the LLG equation.

A single-spin-flip algorithm is performed in the following way: at the beginning one single spin from the lattice is chosen either randomly or in some systematic order and a trial step of this selected spin is made (possible choices for trial steps will be described in detail in the subsequent text). Then the change of the energy of the system is computed according to equation (1). Finally the trial step is accepted, for instance with the heat bath probability,

$$w_{s\to s'} = \frac{w_0}{1+\exp\left(\frac{E(S')-E(S)}{k_{\mathrm{B}}T}\right)} \tag{14}$$

which is one possible choice among others satisfying the condition in equation (13) for any arbitrary constant w_0. Scanning the lattice and performing the procedure explained in the preceding text once per spin (on average) is called *one Monte Carlo step* (MCS). It defines a quasitime scale of the simulation. The connection to real time will be discussed later on.

The way the trial step is chosen is of importance for the validity and efficiency of the algorithm as well as for the physical interpretation of the dynamic behavior of the algorithm (Hinzke and Nowak, 1999). For an Ising system the trial step is naturally a spin flip. For a Heisenberg spin there are many choices. One possible trial step is a small deviation from the former state. For a spin this could be a random movement of the spin with uniform probability distribution within a given opening angle around the former spin direction. Here, each spin can only move by a limited step size and hence, in a model with a uniaxial anisotropy, it has to overcome the anisotropy energy barrier for a complete reversal. This might be a realistic choice for many model systems. But if one is, for instance, interested in the crossover from Heisenberg to Ising-like behavior with increasing anisotropy, one has to allow also for larger steps which are able to overcome a given anisotropy energy barrier. Otherwise the dynamics of the system would freeze and in a system with very large anisotropy (Ising limit) no spin flip would occur at all (Hinzke and Nowak, 1999).

Another possible trial step that circumvents this problem is a step with a uniform distribution in the entire phase space. Here, an arbitrary spin direction that does not depend on the initial direction of the spin is chosen at random. This step samples the whole phase space efficiently and a single spin is not forced to overcome the anisotropy energy barrier. Instead it is allowed to change from one direction to any other one instantaneously. Both of these trail steps are allowed choices in the sense that the corresponding algorithms lead to correct equilibrium properties since they fulfill two necessary conditions: they are ergodic and symmetric.

Ergodicity requires that the whole phase space can be sampled by an algorithm. An example for an nonergodic algorithm is one that performs only Ising-like trial steps, $S_z \to -S_z$, in a Heisenberg model. Here, starting from some initial direction the spin can only reach two positions out of the whole phase space which would be a unit sphere for a Heisenberg spin. Nevertheless, one is allowed to perform such reflection steps as long as one uses *also* other trial steps that guarantee ergodicity. These ideas lead to combinational algorithms which – depending on the problem – can be very efficient (Hucht, Moschel and Usadel, 1995; Hinzke and Nowak, 1999).

The second condition that has to be fulfilled by any algorithm is a symmetry condition: for the probability to do a certain trial step it must be $p_t(s \to s') = p_t(s' \to s)$. Otherwise equation (13) is not fulfilled since the probabilities to perform certain trial steps contribute to the transition rates. The symmetry condition would for instance be violated in a Heisenberg system if one chooses new trial spin directions by simply generating three random numbers as S_x, S_y, and S_z coordinates within a cube and normalizing the resultant vector to unit length. Then before normalization the random vectors are homogeneously distributed within the cube and after the normalization they have some nonuniform probability distribution on the unit sphere which is higher along the diagonal directions of the cube. Hence, trial steps from any other direction into the diagonal direction are more probable then vice versa and the algorithm yields wrong results. A description, how to choose unit vectors

with random directions and a constant probability distribution correctly can be found in the book of Vesely (1993).

3.3 Time-quantified Monte Carlo simulations

In general, Monte Carlo methods do not allow for an interpretation of the results in terms of a realistic dynamics. Only recently, a time-quantified Monte Carlo method was introduced (Nowak, Chantrell and Kennedy, 2000; Smirnov-Rueda *et al*., 2000; Chubykalo *et al*., 2003a; Cheng, Jalil, Lee and Okabe, 2006) and it was shown that at least the dynamics of a high damping scenario can indeed be simulated by a Monte Carlo simulation since here the exact knowledge of the precessive motion of the spins is not necessary. The main idea of time-quantified Monte Carlo methods is to compare the fluctuations that are established in the Monte Carlo simulation within one MCS with the fluctuations that are established within a given timescale associated with the linearized stochastic LLG equation (Ettelaie and Moore, 1984; Smirnov-Rueda *et al*., 1999).

Following the original work (Nowak, Chantrell and Kennedy, 2000), we start with a calculation of the magnetization fluctuations in the Langevin equation. Close to a local energy minimum one can expand the energy of a system given that first-order terms vanish as

$$E \approx E_0 + \frac{1}{2}\sum_{i,j} A_{ij} S_i S_j \tag{15}$$

where S_i are now variables representing small deviations from equilibrium. Let us consider a single spin only with a uniaxial anisotropy (anisotropy constant d_z, see equation (3)) and a field $\mathbf{b} = \pm b_z \hat{\mathbf{z}}$, which is also aligned with the easy axis (a more general calculation can be found in Chubykalo *et al*., 2003b). In this system, we find equilibrium along the z axis, leading to variables S_x and S_y describing small deviations from the equilibrium position $\mathbf{S} = \pm\hat{\mathbf{z}}$. The energy increase ΔE associated with fluctuation in S_x and S_y is then simply

$$\Delta E \approx \frac{1}{2}\left(A_{xx} S_x^2 + A_{yy} S_y^2\right) \tag{16}$$

with $A_{xx} = A_{yy} = 2d_z + b_z$. Rewriting the LLG equation in the linearized form without the thermal fluctuations,

$$\begin{aligned} \dot{S}_x &= L_{xx} S_x + L_{xy} S_y \\ \dot{S}_y &= L_{yx} S_x + L_{yy} S_y \end{aligned} \tag{17}$$

we can identify the matrix elements

$$\begin{aligned} L_{xx} = \ L_{yy} \ &= -\frac{\alpha\gamma}{(1+\alpha^2)\mu_s}(2d_z + b_z) \\ L_{xy} = -L_{yx} &= \frac{\gamma}{(1+\alpha^2)\mu_s}(2d_z + b_z) \end{aligned}$$

As shown in Lyberatos, Berkov and Chantrell (1993) the correlation function for the variables describing small deviations from equilibrium can be expressed in the form

$$\langle S_i(t) S_j(t')\rangle = \mu_{ij}\delta_{ij}\delta(t - t') \tag{18}$$

Here, i and j denote the Cartesian components and Dirac's δ function is an approximation for exponentially decaying correlations on timescales $t - t'$ that are larger than the timescale of the exponential decay τ_r. The covariance matrix μ_{ij} can be calculated from the system matrices A_{ij} and L_{ij} as (Lyberatos, Berkov and Chantrell, 1993)

$$\mu_{ij} = -k_\mathrm{B} T\left(L_{ik} A_{kj}^{-1} + L_{jk} A_{ki}^{-1}\right)$$

For our problem this yields

$$\begin{aligned} \mu_{xx} &= \mu_{yy} = 2k_\mathrm{B} T \frac{\alpha\gamma}{(1+\alpha^2)\mu_s} \\ \mu_{xy} &= \mu_{yx} = 0 \end{aligned} \tag{19}$$

Integrating the fluctuating quantities $S_x(t)$ and $S_y(t)$ over a finite time interval Δt, equations (18) and (19) yield

$$\langle \overline{S}_x^2\rangle = \langle \overline{S}_y^2\rangle = 2k_\mathrm{B} T \frac{\alpha\gamma}{(1+\alpha^2)\mu_s}\Delta t \tag{20}$$

representing the fluctuations of $S_x(t)$ and $S_y(t)$ respectively, averaged over a time interval Δt.

For comparison, we now calculate the fluctuations $\langle S_x^2\rangle$ which are established within one MCS of a Monte Carlo simulation (Nowak, Chantrell and Kennedy, 2000). We select an algorithm where the trial step of the Monte Carlo algorithm is a random deviation of the magnetic moment from its former direction up to a certain maximum opening angle. In order to achieve this efficiently one first constructs a random vector with constant probability distribution within a sphere of radius R by use of the rejection method (Vesely, 1993). This random vector is then added to the initial moment and subsequently the resulting vector is again normalized. Note that the probability distribution following from this trial step is nonuniform but isotropic, so that the symmetry condition mentioned in the previous subsection is guaranteed.

For this algorithm the probability distribution for trial steps of size $r = \sqrt{S_x^2 + S_y^2}$ is $p_t = 3\sqrt{R^2 - r^2}/(2\pi R^3)$ for $0 < r < R$. The acceptance probability using a heat bath

algorithm is $w(r) = 1/(1 + \exp(\Delta E(r^2)/k_\mathrm{B}T))$. Assuming that the spin is close to its (local) equilibrium position, as before, $\Delta E(r^2)$ for small r can be taken from equation (16). In order to calculate the fluctuations within one MCS we have to integrate over that part of the phase space that can be reached within one MCS,

$$\langle S_x^2 \rangle = \int_0^{2\pi} \mathrm{d}\varphi \int_0^R r\ \mathrm{d}r\ \frac{r^2}{2}\ w(r)\, p_t(r) = \frac{R^2}{10} - \mathcal{O}\left(\frac{(2d_z + b_z)R^4}{k_\mathrm{B}T}\right) \tag{21}$$

where the last line is an expansion for small R leading to the validity condition

$$R \ll \frac{k_\mathrm{B}T}{(2d_z + b_z)} \tag{22}$$

By equalizing the fluctuations within a time interval Δt of the LLG equation and one MCS we find the relation

$$R^2 = \frac{20 k_\mathrm{B} T \alpha \gamma}{(1 + \alpha^2)\mu_s} \Delta t \tag{23}$$

for the trial step width R (Nowak, Chantrell and Kennedy, 2000). Equation (23) now relates one MCS, performed using an algorithm as explained before, with a real time interval of the Langevin equation. In this equation $(\alpha\gamma/(1 + \alpha^2)\mu_s)\Delta t$ is simply the reduced time of the LLG equation, rescaled in the high damping limit where only the second part of equation (7) is relevant. The more interesting result of equation (23) is the temperature dependence since it turns out that there is no trivial assignment of one MCS to a fixed time interval. Instead, the larger the temperature, the larger the trial steps of the Monte Carlo algorithm in order to allow for the appropriate fluctuations.

In principle, equation (23) gives the possibility to choose the trial step width for a Monte Carlo simulation in such a way that one MCS corresponds to some microscopic time interval, but there are of course restrictions for possible values of the trial step width and also for the validity of the algorithm: R must be small enough so that the truncated expansion in equation (21) is a good approximation. On the other hand R should not be too small since otherwise the Monte Carlo algorithm needs too much computation time to sample the phase space. Therefore, either one chooses such a value for Δt so that R takes on reasonable values or one chooses a reasonable constant value for R and uses equation (23) to calculate Δt as the real time interval associated with one MCS. Furthermore, effects from spin precession are neglected so that in general only the high damping limit with a purely diffusive spin motion can be simulated. Also, since the derivation in the preceding text started from a linearized equation of motion (equation (17)) and since the energy expression (equation (15)) is an expansion, equation (23) can only be valid close to equilibrium.

For any numerical method, analytically solvable models are important as test tools for the evaluation of the numerical techniques. Originally, (Nowak, Chantrell and Kennedy, 2000) the goal was a comparison of characteristic timescales for the thermally activated reversal obtained numerically with those following from an analytical treatment of isolated Stoner–Wohlfarth particles with a uniaxial anisotropy and a field at an oblique angle to the easy axis (Coffey *et al.*, 1998c). The results are shown in Figure 1.

Here, an ensemble of isolated single-domain particles is considered where each particle is represented by a magnetic moment with energy

$$E(\mathbf{S}) = -d_z S_z^2 - \mu_s \mathbf{B}\cdot\mathbf{S} \tag{24}$$

The material parameters are those for a 20-nm Co particle. Both of the simulations, Monte Carlo as well as Langevin dynamics, start with the magnetic moments in positive z direction. The magnetic field which is well below the Stoner–Wohlfarth limit for athermal reversal has a negative z component so that the magnetization will reverse after some time. The time that is needed for the z component of the magnetization to change its sign averaged over a large number of runs ($N = 1000$) is the numerically obtained characteristic time τ. During a simulation for temperatures which are low as compared to the energy barrier, the system is in the metastable, initial state for a very long time, while the time needed for the magnetization reversal itself is

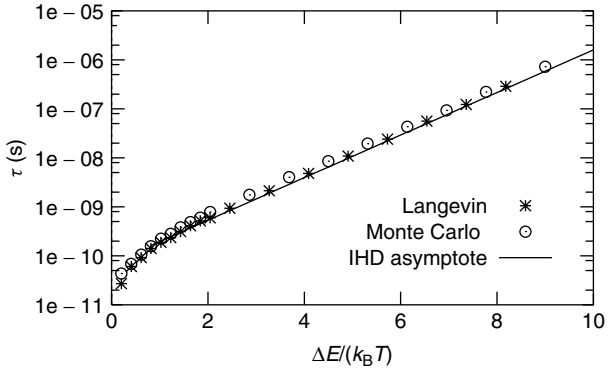

Figure 1. Characteristic times versus inverse temperature. Comparison of the intermediate to high damping asymptote with results from Langevin dynamics and Monte Carlo simulations with time quantification. (Reprinted figure with permission from *Physical Review Letters*, **84**, 1, 163, 2000. Copyright 2000 by the American Physical Society.)

rather short. In this case the characteristic time τ should be comparable to the escape time following from an analytical calculation via the FP equation.

The time-quantified Monte Carlo simulations in Figure 1 were done with an algorithm using a trial step according to equation (23) with $\Delta t \approx 6 \times 10^{-12}\,\mathrm{s}$ and $\alpha = 1$. The magnetic field is $|\mathbf{B}| = 0.2\,\mathrm{T}$ with an angle of 27° to the easy axis. The results for $\tau(T)$ are compared with results from Langevin dynamics simulations using the Heun method as described before and with analytical results obtained in the intermediate to high damping (IHD) limit (Coffey *et al*., 1998a,b,c). This asymptote has the general form of a thermal activation law, namely

$$\tau = \tau_0 e^{\Delta E / k_\mathrm{B} T} \tag{25}$$

The explicit expressions for τ_0 and ΔE were derived in Coffey *et al*. (1998a,b,c). The validity condition for the IHD formula is $\alpha \Delta E / k_\mathrm{B} T \gg 1$ which has been satisfied in the case presented here.

From Figure 1 it is clear that the Langevin dynamics data agree very well with the analytical asymptote in the preceding text. For higher temperatures, $k_\mathrm{B} T > \Delta E$, the asymptote is no longer appropriate. Here, the numerical data for τ tend to zero for $T \to \infty$ as one expects. The Monte Carlo data deviate slightly but the agreement is remarkable – especially taking into account the simple form of equation (23) underlying this algorithm and also considering the fact that there is no adjustable parameter in all our simulations and formulae.

Figure 2 shows how the time-quantified Monte Carlo methods converges in the high damping limit. The data were obtained for the same parameter values as before and $\Delta E / k_\mathrm{B} T = 3.3$. The figure shows that for increasing damping constant α the Monte Carlo data converge to the IHD formula and to the data from Langevin dynamics simulation for large α.

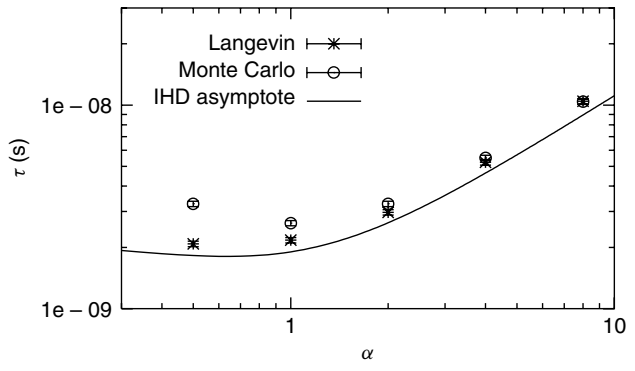

Figure 2. Characteristic time versus damping constant: comparison of the intermediate to high damping asymptote with Langevin dynamics and Monte Carlo simulations. (Reprinted figure with permission from *Physical Review Letters*, **84**, 1, 163, 2000. Copyright 2000 by the American Physical Society.)

Even though the Monte Carlo time step quantification by equation (23) was derived originally only for the simple system which we considered here (Nowak, Chantrell and Kennedy, 2000), it turned out to be successfully applicable to more complicated, interacting spin systems also (Hinzke and Nowak, 2000a,b; Chubykalo *et al*., 2003a,b; Cheng, Jalil, Lee and Okabe, 2006). However, one should note that the method rests on a comparison with Langevin dynamics. Here, the coupling to the heat bath is added phenomenologically to the equation of motion leading to a damping constant α, the microscopic evaluation of which is still missing.

4 THERMALLY ACTIVATED MAGNETIZATION REVERSAL

4.1 Introduction

The understanding of thermally activated spin dynamics is a major challenge for the knowledge of magnetic systems and devices. The pioneering work of Brown (1963b) represents the basis for the understanding of thermally activated dynamic processes in isolated single-domain particles. The basic idea is that the energy barrier ΔE separating two (meta)stable magnetic states of a nanoparticle can be overcome by thermal activation on a certain timescale which can be calculated within the framework of Langevin dynamics. In the limit of low temperatures the escape time τ follows a thermal activation law (see equation (25)), where the prefactor as well as the energy barrier depend on the mechanism of the reversal. As a solvable example, Brown considered an ensemble of isolated magnetic moments with a uniaxial anisotropy. Each single particle of the ensemble is described as one superspin of constant length. The superspin is thought to represent the magnetic moment of a whole particle since it was assumed that if the particle is sufficiently small it is always homogeneously magnetized and its microscopic, internal degrees of freedom can be neglected. After the original work of Brown, extensive calculations were performed in order to calculate the energy barrier as well as the prefactor asymptotically for various model systems (Aharoni, 1969; Braun, 1993; Coffey *et al*., 1998a; García-Palacios and Svedlindh, 2000; Chantrell, Walmsley, Gore and Maylin, 2000).

Experiments on isolated, magnetic particles have confirmed this approach. Wernsdorfer *et al*. measured the switching time of isolated nanometer-sized particles (Wernsdorfer

et al., 1996b, 1997b), and wires (Wernsdorfer *et al*., 1996a, 1997a). For sufficiently small particles (Wernsdorfer *et al*., 1997b) agreement was found with the theoretical predictions of Brown (1963b). For larger particles (Wernsdorfer *et al*., 1996b) and wires (Wernsdorfer *et al*., 1996a, 1997a) activation volumes were found which were much smaller than the corresponding particle and wire volumes. Obviously, different reversal mechanisms can dominate the thermally activated switching behavior of nanoparticles depending on their geometry and size, such as coherent rotation, nucleation, and curling.

These modes may appear in different limits of a cylindrical geometry. Coherent rotation and nucleation can be modeled in the one-dimensional limit by a simple spin chain – a model which is very useful since it was treated analytically and asymptotic results for the energy barriers as well as for the escape rates are available (Braun, 1993; 1994a,b). We will discuss this model in the following text. A three-dimensional model for an extended nanowire is discussed in the last subsection in connection with curling.

Let us start with a chain of magnetic moments of length L (number of spins) with periodical boundary conditions defined by the Hamiltonian

$$\mathcal{H} = \sum_i \Big[- J\mathbf{S}_i \cdot \mathbf{S}_{i+1} - d_z (S_i^z)^2 + d_x (S_i^x)^2 - \mu_s B S_i^z \Big] \tag{26}$$

This is a discretized version of the one-dimensional model for a magnetic nanowire considered by Braun (1993). For $d_z, d_x > 0$ the z axis is the easy axis and the x axis the hard axis of the system. These anisotropy terms may contain contributions from shape anisotropy as well as crystalline anisotropies (Braun, 1994a). In the interpretation as shape anisotropy, this single-ion anisotropy is assumed to imitate the influence of a dipolar interaction of strength $w = d_z/\pi$ (Braun, 1993). Nevertheless, an exact numerical treatment of the dipolar interactions is possible (Hinzke and Nowak, 2000b; Nowak, 2001; Nowak *et al*., 2005; Wieser, Usadel and Nowak, 2006).

4.2 Coherent rotation

In the case of small chain length the magnetic moments rotate coherently, minimizing the exchange energy while overcoming the energy barrier due to the anisotropy of the system. Owing to the hard-axis anisotropy the rotation is mainly in the yz plane. As long as all spins are mostly parallel, they can be described as one effective magnetic moment which behaves like the one-spin model described before. The corresponding energy barrier ΔE is the same as that of a Stoner–Wohlfarth particle since the additional hard axis does not change the energy of the optimal path in phase space from one minimum to the other. The escape time was calculated from the FP equation in the large damping limit (Braun, 1994b). The results is a thermal activation law (equation (25)) where the energy barrier is now proportional to the system size L,

$$\Delta E_{\mathrm{cr}} = L d_z (1-h)^2 \tag{27}$$

while the explicit form of the prefactor transformed into the units used here is

$$\tau_{\mathrm{cr}} = \frac{2\pi(1+\alpha^2)}{\alpha\gamma B_{\mathrm{c}}} \times \frac{\sqrt{d(1+h)/(1-h+d)}}{1-h^2-d+\sqrt{(1-h^2+d)^2+4d(1-h^2)/\alpha^2}} \tag{28}$$

We introduced the coercive field $B_{\mathrm{c}} = 2d_z/\mu_s$ and the reduced quantities $h = \mu_s B/(2d_z)$ and $d = d_x/d_z$. The first term in equation (28) is the microscopic relaxation time of one spin in the field B_{c} (see Section 2.1), while the second term includes corrections following from the details of the model. The equation in the preceding text should hold for low temperatures $k_{\mathrm{B}}T \ll \Delta E_{\mathrm{cr}}$ and obviously for $B < B_{\mathrm{c}}$ since otherwise the energy barrier is zero, leading to a spontaneous reversal without thermal activation. Note, however, that recently deviations were found for increasing system size, suggesting that even for a coherent rotation the internal degrees of freedom lead to longitudinal fluctuations which are not contained in a single-spin description (Hinzke and Nowak, 2000a; Nowak *et al*., 2005; Chubykalo, Nowak, Chantrell and Garanin, 2006).

4.3 Soliton–antisoliton nucleation

With increasing system size nucleation must become energetically favorable since here the energy barrier is a constant, while it is proportional to the system size in the case of coherent rotation. For the spin chain under consideration, switching by soliton–antisoliton nucleation was proposed (Braun, 1994a) for sufficiently large system size. Here, the nucleation process initiates a pair of domain walls which splits the system into domains with opposite directions of magnetization parallel to the easy axis (for graphical representations see Hinzke, Nowak and Usadel, 2000; Nowak, 2001). These two domain walls pass the system in the subsequent reversal process. Owing to the hard-axis anisotropy the spin rotation is once again mainly in the yz plane. Since these two domain walls necessarily have opposite helicities within this easy plane they were called a *soliton–antisoliton pair*.

The energy barrier ΔE_{nu} which has to be overcome during this nucleation process is

$$\Delta E_{\mathrm{nu}} = 4\sqrt{2Jd_z}\left(\tanh R - hR\right) \tag{29}$$

with $R = \operatorname{arccosh}(\sqrt{1/h})$ (Braun, 1994a). For vanishing magnetic field this energy barrier has the form $\Delta E_{\mathrm{nu}}(h = 0) = 4\sqrt{2Jd_z}$ which represents the well-known energy of two Bloch walls (Hubert and Schäfer, 1998). As usual, the corresponding escape time obeys a thermal activation law, where the prefactor has been calculated for various limits (Braun, 1994a). The prefactor obtained in the overdamped limit (equation (5.4) in Braun, 1994a) in our units is

$$\tau_{\mathrm{nu}} = \frac{2\pi(1+\alpha^2)}{\alpha\gamma B_{\mathrm{c}}} \frac{(\pi k_{\mathrm{B}}T)^{1/2}(2J)^{1/4}}{16L\, d_z^{3/4}|E_0(R)| \tanh R^{3/2} \sinh R} \tag{30}$$

As in equation (28) the left part is the microscopic relaxation time of a spin in the coercive field B_{c}. The eigenvalue $E_0(R)$ has been calculated numerically (Braun, 1994a). In the limit $h \to 1$ it is $|E_0(R)| \approx 3R^2$. The $1/L$ dependence of the prefactor reflects the size dependence of the probability of nucleation. The larger the system the more probable is the nucleation process and the smaller is the timescale of the relaxation. Furthermore, the prefactor has a remarkable $\sqrt{k_{\mathrm{B}}T}$ dependence.

We should note that all the results in the preceding text are for systems with periodic boundary conditions (or rings), which restricts the applicability to finite nanowires where nucleation processes may start at the ends of the sample. Therefore, the case of open boundaries was also considered, analytically (Braun, 1999, 2000) as well as numerically (Hinzke and Nowak, 2000b). Even though the prefactor of the thermal activation law could not be obtained up to now, it was shown (Braun, 1999) that the energy barrier is just halved in that case, due to the fact that in systems with open boundaries the nucleation can set in at only one end. Hence, solitons and antisolitons do not necessarily emerge pairwise. In the case of two solitons (or two antisolitons) nucleating simultaneously at both ends, these cannot annihilate easily in the later stage of the reversal process due to their identical helicity. Instead a 360° domain wall remains in the system.

Let us now investigate the intermediate temperature range. Owing to the larger thermal fluctuations as compared to the sole soliton–antisoliton nucleation several nuclei may grow simultaneously, also depending on system size. Obviously, depending on the nucleation probability many nuclei may arise during the time period of the reversal process (for graphical representations see again Hinzke, Nowak and Usadel, 2000; Nowak, 2001). This multiple nucleation process was investigated mainly in the context of Ising models where it is called *multidroplet nucleation* (a review is given by Rikvold and Gorman, 1994).

The characteristic time τ_{mn} for the multidroplet nucleation can be estimated with respect to the escape time for a single nucleation process with the aid of the classical nucleation theory (Becker and Döring, 1935). Here, the following scenario is assumed: in the first stage many nuclei of critical size arise within the same time interval. Later these nuclei expand with a certain domain wall velocity v and join each other. This leads to a change of magnetization

$$\Delta M(t) = \int_0^t \frac{(2vt')^D}{\tau_{\mathrm{nu}}}\,\mathrm{d}t' \tag{31}$$

after a time t in D dimensions. The characteristic time when half of the system ($L^D/2$) is reversed is then given by (Rikvold and Gorman, 1994; Hinzke and Nowak, 2000a)

$$\tau_{\mathrm{mn}} = \left(\frac{L}{2v}\right)^{\frac{D}{D+1}} \left((D+1)\tau_{\mathrm{nu}}^*\right)^{\frac{1}{D+1}} \exp\frac{\Delta E_{\mathrm{nu}}}{(D+1)k_{\mathrm{B}}T} \tag{32}$$

The domain-wall velocity in a spin chain following the LLG equation for small fields is (Wieser, Nowak and Usadel, 2004)

$$v = \frac{\gamma B}{\alpha} \tag{33}$$

Hence for the one-dimensional system under consideration the characteristic time is given by

$$\tau_{\mathrm{mn}} = \sqrt{\frac{\alpha L \tau_{\mathrm{nu}}}{\gamma B}} \exp\frac{\Delta E_{\mathrm{nu}}}{2k_{\mathrm{B}}T} \tag{34}$$

This means that the (effective) energy barrier for the multidroplet nucleation is reduced by a factor 1/2, and the characteristic time no longer depends on the system size since τ_{nu}^* for the soliton–antisoliton nucleation has a $1/L$ dependence (see equation (30)).

All the different reversal mechanisms mentioned in the previous sections can occur within the same model system – the spin chain – depending on the system size among other parameters. The crossover from coherent rotation to soliton–antisoliton nucleation was studied in Braun (2000) for a periodic system. Here, the value L_{c} of the chain length below which only uniform solutions of the Euler–Lagrange equations of the problem exist (coherent rotation) was calculated to be

$$L_{\mathrm{c}} = \pi\sqrt{\frac{2J}{d_z(1-h^2)}} \tag{35}$$

For vanishing magnetic field this crossover length scale is $L_c = \pi\sqrt{2J/d_z}$, a value that is clearly related to the Bloch wall width $\delta = \sqrt{J/2d}$ (Hubert and Schäfer, 1998), because of the fact that two domains walls have to fit into the system during the nucleation process. For a chain with open boundary conditions the crossover length scale is halved since here only one domain wall has to fit into the system (Braun, 2000). One can understand this result from a slightly different point of view also, namely by comparing the energy barrier of soliton–antisoliton nucleation (equation (29)) with that of coherent rotation (equation (27)). This results in a very similar condition for the crossover from coherent rotation to nucleation (Hinzke and Nowak, 2000a), which can also be generalized to higher dimensions (Hinzke and Nowak, 1998).

For even larger system size, multiple nucleation becomes probable. Comparing the escape time for soliton–antisoliton nucleation with the characteristic time for multiple nucleation, one gets for the intersection of these two times the crossover condition (Hinzke and Nowak, 2000a)

$$L_{\mathrm{sm}} = \sqrt{\frac{\gamma B \tau_{\mathrm{nu}} L_{\mathrm{sm}}}{\alpha}}\, \exp\frac{\Delta E_{\mathrm{nu}}}{2k_{\mathrm{B}}T} \tag{36}$$

The corresponding time L_{sm}/v is the time that a domain wall needs to cross the system. In other words, as long as the time needed for the nucleation event itself is large as compared to the time needed for the subsequent reversal by domain-wall motion, one single nucleus determines the characteristic time. In the opposite case many nuclei will appear during the time needed for the first soliton–antisoliton pair to cross the system, resulting in multidroplet nucleation. These considerations are comparable to calculations in Ising models (Rikvold, Tomita, Miyashita and Sides, 1994).

Figure 3 summarizes the system size dependence of the reduced characteristic time (Hinzke and Nowak, 2000a). Results from Monte Carlo simulations are shown as well as the appropriate asymptotes described in the preceding text for two different temperatures. For small system sizes the spins rotate coherently. Here the energy barrier (equation (27)) is proportional to the system size leading to an exponential increase of τ with system size. Following equation (28) the prefactor of the thermal activation law should not depend on L but, as already mentioned in the preceding text, numerically one finds slight deviations from the asymptotic expressions due to longitudinal magnetization fluctuations (Nowak *et al.*, 2005; Chubykalo, Nowak, Chantrell and Garanin, 2006). In the region of soliton–antisoliton nucleation the energy barrier does not depend on the system size but the prefactor varies as $1/L$ (see equations (29) and (30)). Interestingly, this leads to a decrease of the characteristic time with increasing system size. Therefore, there

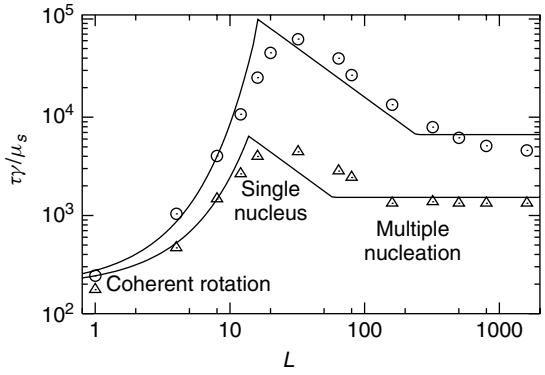

Figure 3. Reduced characteristic time versus system size for $k_{\mathrm{B}}T = 0.024J$ (triangles) and $k_{\mathrm{B}}T = 0.016J$ (circles). $h = 0.75$. Solid lines are piecewise the appropriate asymptotes and the data are from Monte Carlo simulations. (Reprinted from *Phys. Rev. B.*, Vol. 61, 6734, 2000. Copyright 2000 by the American Physical Society.)

is a maximal characteristic time – the maximum of the stability of the particle – close to that system size where the crossover from coherent rotation to nucleation occurs. This decrease ends where multidroplet nucleation sets in, following equation (36). For still larger systems the characteristic time has a constant value which is given by equation (34). Qualitatively the same behavior can be found in the particle size dependence of the dynamic coercivity which is the coercive field one observes during hysteresis on a given timescale τ: solving the equation describing the thermal activation in the three regimes explained in the preceding text for $h(L)$ at constant τ one finds an increase of the dynamic coercivity in the coherent rotation regime, a decrease in the nucleation regime, and at the end a constant value for multiple nucleation. These findings are qualitatively in agreement with measurements of the size dependence for the dynamic coercivity of barium ferrite recording particles (Chang, Zhu and Judy, 1993).

4.4 Curling

In the previous subsections we considered a model which even though it is one-dimensional shows properties that are far from being trivial since different switching mechanisms can occur. Many of the findings obtained from this model are relevant for real magnetic nanowires, as long as those are thin enough to be effectively one-dimensional. Nevertheless, for a realistic description of magnetic nanoparticles one needs three-dimensional models and one has to consider the dipole–dipole interaction. In the following we will discuss the degree to which the physics of the switching process changes when one considers a three-dimensional model

including dipole–dipole interaction. Only few numerical results exist so far, some of them we discuss in the following.

Considering the mathematical form of the dipole–dipole interaction in equation (5) one notes that dipoles tend to align, with that trying to build up closed loops or vortices. On the other hand, a loop has an enhanced exchange energy. Therefore to calculate the spin structure of an extended magnetic system is a complicated optimization problem. Even a sufficiently small magnetic nanostructure which, in equilibrium, is in a single-domain state, could reverse its magnetization by more complicated modes than coherent rotation or nucleation. A characteristic length scale below which it is energetically unfavorable for the system to break the long-range order and split into domains is the so-called *exchange length* δ_x (Hubert and Schäfer, 1998). Like the Bloch wall width $\delta = \sqrt{J/2d}$ mentioned earlier, it is a characteristic length scale for a given material. For a spin model it can be derived in the following way: a twist of the direction of the spins by an angle of π over a length scale l (number of spins) costs an exchange energy of

$$\begin{aligned}\Delta E_x &= -J \sum_{i=1}^{l} (1 - \mathbf{S}_i \cdot \mathbf{S}_{i+1}) \\ &\approx -J \sum_{i=1}^{l} \frac{(\theta_i - \theta_{i+1})^2}{2} \approx \frac{J\pi^2}{2l}\end{aligned} \tag{37}$$

assuming constant changes of the angle θ from one spin to the next one (which can also be shown to be the wall profile with the minimum energy by a solution of the corresponding Euler–Lagrange equations). The dipolar field energy of a chain of parallel-oriented dipoles can be expressed via Riemann's ζ function using

$$\zeta(3) = \sum_{i=1}^{\infty} \frac{1}{i^3} \approx 1.202 \tag{38}$$

Hence, the gain of dipolar energy of a chain of l spins can roughly be estimated to be at most $3wl\zeta(3)$, where $w = \mu_s^2 \mu_0 / 4\pi a^3$ is the strength of the dipole–dipole coupling (see equation (5) and also (Hucht, Moschel and Usadel, 1995) for a similar calculation in two dimensions). A comparison of the energies yields the exchange length (measured as number of atoms)

$$\delta_x = \pi \sqrt{\frac{J}{6\zeta(3)w}} \tag{39}$$

Note that in a continuum theory the dipolar energy is estimated from formulae for the magnetostatic energy of ellipsoids (Hubert and Schäfer, 1998). The results deviate slightly since the factor $3\zeta(3)$ is replaced by π. We prefer the expression in the preceding text derived directly for a spin model.

Let us now consider a nanowire, that is either a cylindrical system or an extremely elongated ellipsoid. As long as the thickness of the particle is smaller than the exchange length, the magnetization will be homogeneous in the planes perpendicular to the long axis so that the system behaves effectively one-dimensionally (Braun, 1999). For thicknesses larger than the exchange length, reversal modes may occur where the magnetization is nonuniform in the perpendicular planes, for example curling (Aharoni, 1996) (for graphical representations see Nowak, 2001).

The existence of the crossover from nucleation to curling was investigated by simulations of cylindrical systems (Hinzke and Nowak, 2000b; Nowak, 2001). Here, for the first time fast Fourier transformation (FFT) methods for the calculation of the dipolar fields were combined with Monte Carlo simulations with quantified time step. These methods allowed for a statistical investigation of particle sizes of up to 32 768 spins in three dimensions. A systematic numerical determination of the corresponding energy barriers and characteristic times is nevertheless still missing.

5 SIMULATION OF ANTIFERROMAGNETS: EXCHANGE BIAS

For compound materials consisting of an FM in contact with an AFM a shift of the hysteresis loop along the magnetic field axis can occur, which is called *exchange bias* (*EB*). Often, this shift is observed after cooling the entire system in an external magnetic field below the Néel temperature T_N of the AFM. For reviews on EB the reader is referred to the articles by Nogués and Schuller (1999) and Stamps (2000). Although EB has been well known since many years (Meiklejohn and Bean, 1956, 1957) its microscopic origin is still discussed controversially.

A detailed understanding of EB can only be achieved by an understanding of the antiferromagnetic spin structure so that classical spin models are the common starting point for microscopic models of EB. In an early approach by Malozemoff (1987, 1988a,b), EB is attributed to the formation of domain walls in the AFM, perpendicular to the FM/AFM interface due to interface roughness. These domain walls are supposed to occur during cooling in the presence of the magnetized FM and to carry a small net magnetization at the FM/AFM interface (see Figure 4a). This interface magnetization is furthermore supposed to be stable during the reversal of the FM, consequently shifting the hysteresis loop. However, the formation of domain walls in the AFM

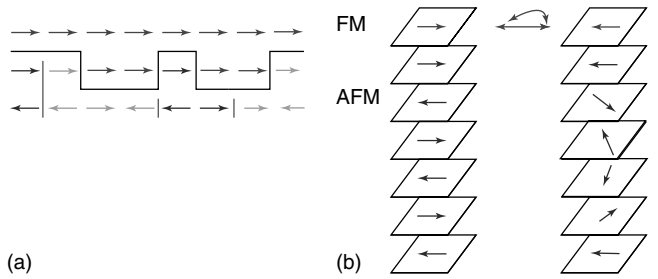

Figure 4. (a) Sketch of the model after Malozemoff (1987, 1988a,b) which shows the FM on top of the AFM in a domain configuration. (b) Sketch of the model Mauri, Siegmann, Bagus and Kay (1987). During reversal of the FM a spring is wound up in the AFM. (Reprinted from *Journal of Magnetism and Magnetic Materials*, Vol 240, 2002, Pages 243–247. Copyright 2002, with permission from Elsevier.)

only due to interface roughness is energetically unfavorable and its occurrence and stability have never been proved.

Alternative approaches have been developed. In a model introduced by Mauri, Siegmann, Bagus and Kay (1987) EB is obtained through a mechanism in which a domain-wall forms in the AFM parallel to the interface while the magnetization of the FM rotates (see Figure 4b). In contrast to experimental findings this mechanism works only for uncompensated interfaces where the interface layer of the AFM is such that is carries a net magnetization. Furthermore the interface is assumed to be perfectly flat since otherwise it would be effectively compensated by roughness. An extension by Koon (1998) for compensated interfaces where the model of Mauri was combined with a spin-flop coupling was later on proved to show no EB (Schulthess and Butler, 1998, 1999). To obtain EB Schulthess and Butler had to assume uncompensated AFM spins at the interface. However, their occurrence and stability during a magnetic hysteresis loop was not explained.

In a recent experiment Miltényi *et al*. (2000) showed that it is possible to strongly influence EB in Co/CoO bilayers by diluting the antiferromagnetic CoO layer, that is by inserting nonmagnetic substitutions ($Co_{1-x}Mg_xO$) or defects ($Co_{1-y}O$) not at the FM/AFM interface but rather throughout the volume part of the AFM. In the same letter in was shown that a corresponding theoretical model, the domain-state (DS) model, investigated by Monte Carlo simulations shows a behavior very similar to the experimental results. It was argued that EB has its origin in a DS in the AFM which triggers the spin arrangement and the FM/AFM exchange interaction at the interface. Later it was shown that a variety of experimental facts associated with EB can be explained within this DS model (Nowak, Misra and Usadel, 2001, 2002; Nowak *et al*., 2002b; Keller *et al*., 2002; Misra, Nowak and Usadel, 2003, 2004; Beckmann, Nowak and Usadel, 2003, 2006; Scholten, Usadel and Nowak, 2005; Spray and Nowak, 2006). The importance of defects for the EB effect was also confirmed by experiments on $Fe_xZn_{1-x}F_2$/Co bilayers (Shi, Lederman and Fullerton, 2002) and by experiments (Mewes *et al*., 2000; Mougin *et al*., 2001) where it was shown that it is possible to modify EB by means of irradiating an FeNi/FeMn system by He ions in presence of a magnetic field. Depending on the dose of the irradiation and the magnetic field present at the time of irradiation, it was possible to manipulate both the magnitude and even the direction of the EB field. Further support for the relevance of domains in EB systems is given by a direct spectroscopic observation of AFM domains (Nolting *et al*., 2000; Ohldag *et al*., 2001). In the following we focus on the DS model.

5.1 Domain-state model

The DS model for EB (Miltényi *et al*., 2000) consists of t_{FM} monolayers of FM and t_{AFM} monolayers of diluted AFM. The FM is exchange coupled to the topmost layer of the AFM. The geometry of the model is sketched in Figure 5.

The system is described by a classical Heisenberg model with nearest-neighbor exchange on a simple cubic lattice with exchange constants J_{FM} and J_{AFM} for the FM and the AFM respectively, while J_{INT} stands for the exchange constant between FM and AFM. For simplicity we assume that the values of the magnetic moments of FM and AFM are identical (included in the magnetic field energy B). The Hamiltonian of the system is then

$$\begin{aligned}\mathcal{H} = &-J_{\mathrm{FM}} \sum_{\langle i,j \rangle} \boldsymbol{S}_i \cdot \boldsymbol{S}_j - \sum_i \left(d_z S_{iz}^2 + d_x S_{ix}^2 + \boldsymbol{S}_i \cdot \boldsymbol{B} \right) \\ &-J_{\mathrm{AFM}} \sum_{\langle i,j \rangle} \epsilon_i \epsilon_j \boldsymbol{\sigma}_i \cdot \boldsymbol{\sigma}_j - \sum_i \epsilon_i \left(k_z \sigma_{iz}^2 + \boldsymbol{\sigma}_i \cdot \boldsymbol{B} \right) \\ &-J_{\mathrm{INT}} \sum_{\langle i,j \rangle} \epsilon_j \boldsymbol{S}_i \cdot \boldsymbol{\sigma}_j \end{aligned} \tag{40}$$

where $\mathbf{S}_i$ denote normalized spins at sites of the FM layer and $\boldsymbol{\sigma}_i$ denote normalized spins at sites of the AFM.

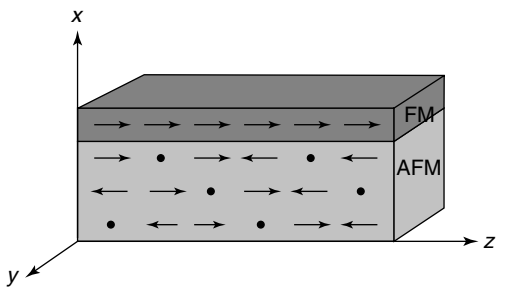

Figure 5. Sketch of the DS model with one FM layer and three diluted AFM layers. The dots mark defects. The easy axis of both FM and AFM is the z axis.

The first line of the Hamiltonian describes the energy of the FM with the z axis as its easy axis (anisotropy constant $d_z > 0$). The dipolar interaction is approximated in the model by an additional anisotropy term (anisotropy constant $d_x = -0.1 J_{\mathrm{FM}}$ in the present case) which includes the shape anisotropy, leading to a magnetization which is preferentially in the y–z plane. The second line is the contribution from the AFM also having its easy axis along z direction. The AFM is diluted, that is a fraction p of sites is left without a magnetic moment ($\epsilon_i = 0$) while the other sites carry a moment ($\epsilon_i = 1$). The last term describes the interaction of the FM with the interface AFM monolayer.

Equation (40) suggests a simple ground state argument for the strength of the bias field. Assuming that all spins in the FM remain parallel during field reversal and that some net magnetization of the interface layer of the AFM remains constant during the reversal of the FM a simple calculation gives the usual estimate for the bias field,

$$t_{\mathrm{FM}} B_{\mathrm{EB}} = J_{\mathrm{INT}} m_{\mathrm{INT}} \tag{41}$$

where m_{INT} is the stable part of the interface magnetization of the AFM (per spin) which is responsible for the EB. For an ideal uncompensated and totally stable interface one would expect $m_{\mathrm{INT}} = 1$. As is well known, this estimate leads to a much too high bias field, while for an ideal compensated interface, on the other hand, one would expect $m_{\mathrm{INT}} = 0$ and, hence, $B_{\mathrm{EB}} = 0$. Experimentally, however, often there is on the one hand no big difference between compensated and uncompensated interfaces and on the other hand, it is found that B_{EB} is much smaller than $J_{\mathrm{INT}}/t_{\mathrm{FM}}$, rather of the order of a few percent of it. The solution of this puzzle is that m_{INT} is neither constant during field reversal nor is it a simple known quantity (Keller *et al*., 2002; Nowak *et al*., 2002b) and we discuss this quantity in the following.

5.2 Results from Monte Carlo simulation

Apart from the mean-field work by Scholten, Usadel and Nowak (2005) mainly Monte Carlo methods were used to investigate the DS model. Some of them focused on the Ising limit for the AFM (Nowak, Misra and Usadel, 2001; Nowak *et al*., 2002b; Beckmann, Nowak and Usadel, 2003, 2006; Spray and Nowak, 2006) while others used the full Heisenberg Hamiltonian of the previous subsection (Nowak, Misra and Usadel, 2002; Misra, Nowak and Usadel, 2003). In the latter case a heat bath algorithm with single-spin-flip dynamics was used where the trial step of the spin update consisted of two steps: firstly a small variation within a cone around the former spin direction, followed, secondly, by a total spin flip. This twofold spin update is ergodic and symmetric and can take care of a broad range of anisotropies, from very soft spins up to the high anisotropy (Ising) limit. To observe the domain structure of the AFM one has to guarantee that typical length scales of the domain structure fit into the system and typical system sizes were a lateral extension of 128×128 and a thickness of $t_{\mathrm{FM}} = 1$ and t_{AFM} ranging from 3 to 9. Periodical boundary conditions were used within the film plane and open boundary conditions perpendicular to it.

The main quantities monitored were the thermal averages of the z component of the magnetic moment for each individual monolayer normalized to the magnetic moment of the saturated monolayer. In simulations the system is first cooled from above to below the ordering temperature of the AFM. During cooling the FM is initially magnetized along the easy z axis resulting in a nearly constant exchange field for the AFM monolayer at the interface. Also, the system is cooled in the presence of an external magnetic field, the cooling field. In addition to the exchange field from the ordered FM this field acts on the AFM also. When the desired final temperature is reached, a magnetic field along the easy axis is applied and reduced in small steps down to a certain minimum value and afterward raised again up to the initial value. This corresponds to one cycle of the hysteresis loop. A hysteresis loop obtained as described in the preceding text is depicted in Figure 6. Results for the magnetization of the

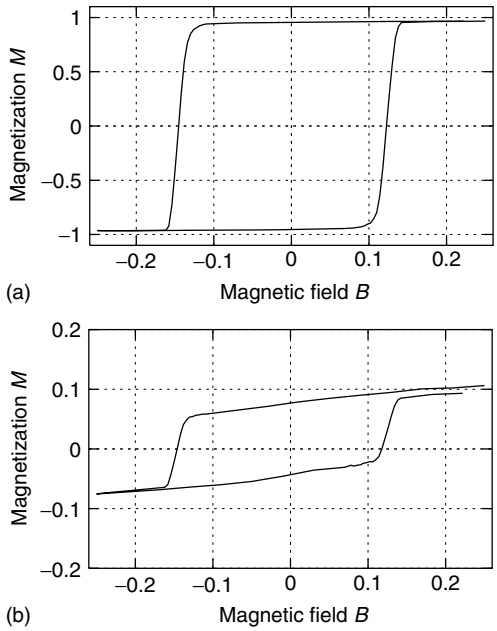

Figure 6. Simulated hysteresis loops of the DS model as explained in the text. Dilution $p = 0.4$, $k_{\mathrm{B}}T = 0.1 J_{\mathrm{FM}}$, positive interface coupling, $J_{\mathrm{INT}} = |J_{\mathrm{AFM}}|$. AFM anisotropy $k_z = J_{\mathrm{FM}}/2$. The cooling field was $B_{\mathrm{c}} = 0.25 J_{\mathrm{INT}}$. The magnetic moment of the FM (a) and the interface monolayer of the AFM (b) normalized to its saturation value is shown. (Reprinted from *Journal of Magnetism and Magnetic Materials*, Vol 240, 2002, Pages 243–247. Copyright 2002, with permission from Elsevier.)

FM (a) as well as that of the AFM interface monolayer (b) are shown. Exchange biasing is clearly observed.

An analysis of the magnetization curve of the interface layer gives an interesting insight into the nature of EB. After the field cooling procedure the AFM interface carries a magnetization. A part of this AFM interface magnetization is stable during hysteresis and leads to the fact that the magnetization curve of the interface layer of the AFM is shifted upward. This irreversible part of the interface magnetization of the AFM acts as an additional effective field on the FM, resulting in EB. Note that the interface magnetization of the AFM also displays hysteresis as a result of the exchange coupling to the FM. This means that the whole interface magnetization of the AFM consists of a reversible part leading to an enhanced coercivity and an irreversible part leading to EB.

In experiments, usually the magnetization of the whole FM/AFM bilayer is measured. The corresponding sample magnetization loop might not only be shifted horizontally but also vertically. The vertical shift contains contributions from the volume part of the AFM as well as from its interface. The volume magnetization of the AFM is induced by the cooling field and hence not shifted when the cooling field is zero and shifted upward when it is finite. The interface contribution depends on the sign of the interface coupling and may be positive, as in our calculation or even negative for negative interface coupling (Nogués, Leighton and Schuller, 2000; Keller *et al*., 2002; Nowak *et al*., 2002b).

With the following two sketches we wish to illustrate on a more microscopic basis where the interface magnetization of the AFM comes from, including its partitioning in reversible and irreversible parts. Figure 7(a) shows spin configurations in a small portion of the interface monolayer of the AFM after field cooling. The simulated system size is $64 \times 64 \times 10$ with only one FM monolayer. For simplicity, this simulation was performed in the Ising limit for the AFM ($k_z \to \infty$). The dilution p of the AFM is 50%, nevertheless the spins are much more connected than it appears from the sketch via the third dimension.

Obviously, the AFM is in a DS, where a domain is defined as a region of undisturbed antiferromagnetic order. The reason for the domain formation and, consequently, for the lack of long-range order is the interface magnetization which couples to the exchange field coming from the FM and the external field (both pointing up) lowering the energy of the system. The interface magnetization follows from two contributions. Examples for both are indicated via the circles. One contribution comes from parallel spin pairs in the domain walls (*domain-wall magnetization*), all pointing up in our example (Figure 7a), that is, into the direction of the exchange field of the FM and the external field. A second contribution comes from an imbalance of the number of defects of the two antiferromagnetic sublattices

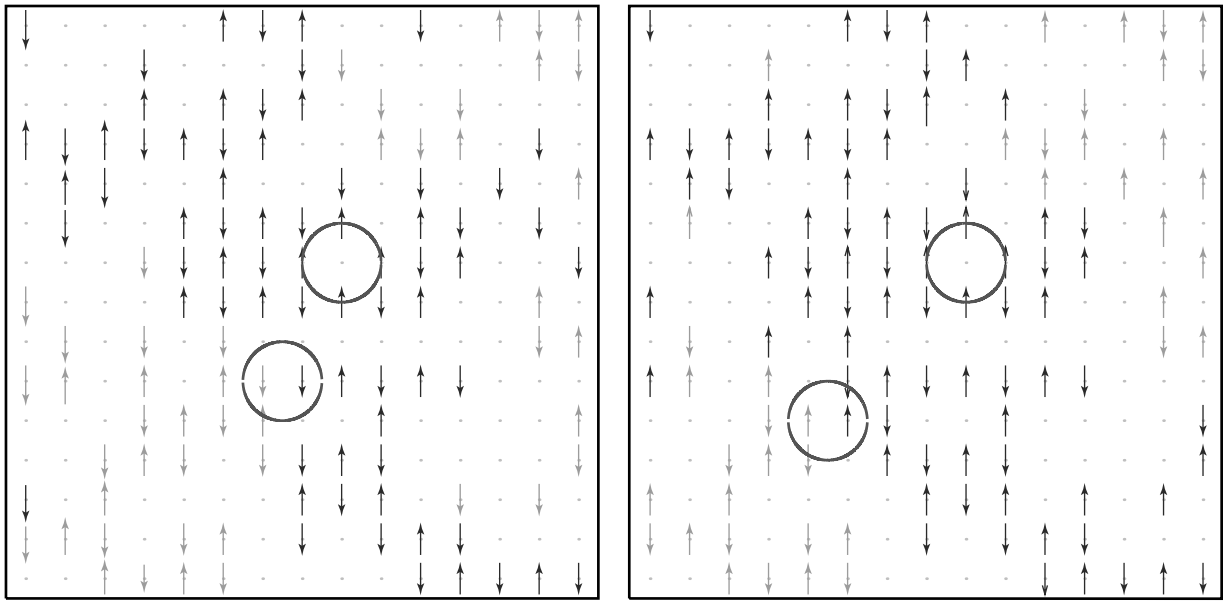

Figure 7. Snapshots of spin configurations in a small portion of the interface monolayer of the AFM after field cooling with the external field and the FM magnetization pointing upward (a) and after reversal of the FM (b). The interface coupling is assumed to be positive. The gray shading distinguishes different AFM domains. The circles mark sources of magnetization, wall magnetization as well as volume magnetization.

(*volume magnetization*). The imbalance of the number of defects of the two antiferromagnetic sublattices also leads to a net magnetization within a domain which couples to the exchange field of the FM and the external field. The reason for the imbalance is that the domain structure is not random. Rather, it is an optimized structure arising during the initial cooling procedure with as much magnetization as possible coupling to the exchange field of the FM and the external field, following the energy minimization principle.

However, an AFM interface magnetization alone cannot lead to EB. Only the irreversible part of it (during hysteresis) may lead to EB. Figure 7(b) shows, for comparison, spin configurations in the same portion of the interface monolayer of the AFM after reversal of the FM. Clearly, the major part of the domain structure did not change during reversal of the FM. However, there are rearrangements on smaller length scales, leading mainly to the fact that the domain-wall magnetization changes its sign. In Figure 7(b) all of the spin pairs within domain walls are pointing down following the reversed FM and the external field.

However, the volume magnetization coming from the defects remains frozen. The stability of the domain structure stems from the fact that the domain walls are pinned at defects sites as well as between pairs of spins which are aligned with the field. Hence, during a movement of the domain-wall energy barriers may have to be overcome by thermal activation. This explains why a large domain in general will stay in a metastable state on exponentially long timescales, while rearrangements on a shorter length scale are possible, of course depending on the temperature and the material parameters of the AFM.

Many of the essential properties of diluted AFMs, the occurrence of DSs, metastability, remnant magnetization, and slow relaxation, among others, have been investigated before, even though not in the context of EB (for reviews on diluted AFMs see Kleemann, 1993; Belanger, 1998, for a detailed discussion of the connection between diluted AFMs and EB systems see Nowak *et al*., 2002b).

Important features of EB systems found experimentally (Keller *et al*., 2002) have their counterpart in the simulations (Nowak *et al*., 2002b), such as the order of magnitude of EB fields, the shape of hysteresis curves, the dilution dependence of EB, its temperature dependence, the training effect, and the occurrence of positive EB. Other properties of EB systems, which were successfully investigated within the framework of the DS model are the dependence of EB on thickness of the AFM (Nowak, Misra and Usadel, 2001; Ali *et al*., 2003), the dependence on the anisotropy of the AFM in Nowak, Misra and Usadel (2002), the influence of ion irradiation (Misra, Nowak and Usadel, 2003) asymmetric reversal modes (Beckmann, Nowak and Usadel, 2003), properties of the AFM domain structures (Misra, Nowak and Usadel, 2004), the enhanced coercivity (Scholten, Usadel and Nowak, 2005), the cooling field dependence (Beckmann, Nowak and Usadel, 2003), and the influence of interface roughness (Spray and Nowak, 2006). However, finally one should note that most of the AFMs used in EB systems have a polycrystalline structure (Stiles and McMichael, 1999; Suess *et al*., 2003), which so far was not taken into account by the DS model. Work following these lines is still missing and would certainly contribute to the further understanding of EB.

6 CONCLUSIONS AND OUTLOOK

Within the framework of classical spin models it is possible to investigate magnetic properties of a variety of different materials, as for example, ferri-, ferro-, or antiferromagnets, and even heterostructures composed of several different materials. Simulation techniques for the investigation of thermal equilibrium properties exist and – to some extent – also for nonequilibrium situations.

However, classical spin models neglect quantum effects and, furthermore, one expects certain limits for the validity of the stochastic LLG equation regarding its short-time spin dynamics as well as the form of the damping which still suffers from a lack of microscopic understanding. A mathematical formulation of damping (Smith and Arnett, 2001; Safonov and Bertram, 2002; Rebei and Parker, 2003) as well as a systematic construction and parameterization of classical spin model Hamiltonians (Mryasov, Nowak, Guslienko and Chantrell, 2005) for certain given materials on the basis of first-principles calculation remain a challenge for current research.

NOTE

[1] The fact that the noise is multiplicative in the LLG equation has been questioned, since the parameter space is the unit sphere, so that the relevant random-field term (giving rise to a torque) and the magnetization derivative are restricted to the tangent plane. The use of a Heun scheme might thus not be mandatory.

Magnetization Configurations and Reversal in Small Magnetic Elements

Mathias Kläui[1] and Carlos António Fernandes Vaz[2]

[1] *Universität Konstanz, Konstanz, Germany*
[2] *University of Cambridge, Cambridge, UK*

1 INTRODUCTION

The recent surge of interest in the magnetism of small elements stems from a combination of three factors: firstly, the continuous development in the techniques for deposition of thin metal films and, in particular, molecular-beam epitaxy, which allows for the growth of metal structures virtually free of impurities and with controllable crystallinity; secondly, the development of electron beam lithography in the context of semiconductor technology, which has been subsequently co-opted for the structuring of metal elements, either by direct lithography or by metal deposition through a lithographically defined mask; and finally, the simultaneous development of magnetic characterization techniques, which have become ever more sensitive and are able to operate on shorter timescales and with greater spatial resolution. The happy confluence of these three trends has created the ideal conditions for a fruitful and rapid exploration of the magnetism of small magnetic structures, in particular, of their equilibrium and dynamic properties. A constant motivation throughout has been the potential for device applications that fit in with the current trend of miniaturization in magneto- and microelectronic technology.

It is in this context that we attempt here to review some of the aspects of the magnetism of small elements; this would seem a thankless task given the large body of work devoted to this subject, but we hope that, by focusing on the equilibrium static properties and quasiequilibrium dynamics of small elements, a broad picture of the recent achievements in this area may be uncovered, and also that a general understanding of the physics governing the magnetic properties of systems in the nano- and mesoscale, for which the shape of the element plays a critical role, may be exposed. With this purpose in mind, we propose to discuss the magnetism of small elements based on soft magnetic materials (*3d* transition ferromagnets and alloys), and we shall also limit ourselves largely to in-plane magnetized elements, that is, those for which the magnetic anisotropies are relatively small. The present chapter is organized as follows. In Section 2, we mention briefly some of the experimental techniques which have been used for the magnetic characterization of the magnetic structures mentioned in later sections. In Section 3, we consider the different magnetic energy terms which govern the magnetic behavior of materials on a macroscopic scale and which are implemented in micromagnetic simulators. In the next

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

sections, we introduce single domain systems (Section 4) and then move to the magnetism of mesoscopic elements (Section 5), characterized by magnetic states of nonuniform magnetization and which we distinguish from the multidomain states that one encounters in large elements (discussed briefly in Section 6). From the magnetostatics, we move to the magnetodynamics and discuss next the magnetization reversal of small elements (Section 7). In Section 8, we provide a brief summary of our overview.

2 CHARACTERIZATION TECHNIQUES

An impressive array of experimental techniques has been developed recently that aim at the detection and measurement of magnetic signals in small structures and thin films. This is particularly true of imaging techniques, whose increased spatial and time resolutions have made possible the study of both the detailed static spin configuration and the dynamic properties (down to the picosecond range) of small elements. Here, we only introduce the experimental techniques, which can give information about the magnetic configuration of small structures or thin films. While the available experimental techniques can be classified in many ways, we distinguish here between imaging and magnetometric techniques, which allow respectively a more direct or indirect access to the spin structure of magnetic systems.

Imaging techniques directly return information about the spatial magnetization distribution. These include, in order of increasing spatial resolution, scanning Kerr microscopy (SKM), based on the magneto-optic Kerr effect (MOKE), which has been used for the imaging of both continuous magnetic films and of small structures (Heidkamp and Erskine, 2000). Although the spatial resolution is limited to a few micrometers (in some cases extended to the submicrometer range (Stotz and Freeman, 1997)), when associated with stroboscopic techniques, it allows for time resolutions down to the sub-nanosecond (Ballentine, Hiebert, Stankiewicz and Freeman, 2000; Acremann *et al*., 2001; Hicken *et al*., 2002; Choi and Freeman, 2005). Scanning Hall effect microscopy (Bekaert *et al*., 2002) can achieve similar spatial resolutions, and is based on the Hall voltage generated by a miniaturized Hall probe that measures the stray field originating from the sample. Magnetic force microscopy (MFM) is based on the interaction of a magnetic tip with the stray field and magnetic charges issuing from the sample (Grütter, Mamin and Rugar, 1992; Hubert, Rave and Tomlinson, 1997). As such, it has the disadvantage that tip-sample interaction may disturb the magnetic pattern of soft magnetic materials (Memmert, Müller and Hartmann, 2000, 2001; García, Thiaville and Miltat, 2002), and, in some instances, it is even known to assist in the switching of the magnetization (Ohkubo, Kishigami, Yanagisawa and Kaneko, 1991; Manalis *et al*., 1995; Li *et al*., 2002). An additional complication is the fact that the stray field is not uniquely defined (Vellekoop, Abelmann, Porthun and Lodder, 1998). The spatial resolution of MFM is of the order of 50 nm, but it is a very slow technique (scanning times of the order of minutes). Better spatial resolution is provided by magnetic transmission X-ray microscopy (MTXM) (Fischer *et al*., 2001; Kang *et al*., 2005) and photoemission electron microscopy (PEEM) (Schneider *et al*., 1997; Schönhense, 1999; Locatelli *et al*., 2002; Scholl *et al*., 2002; Hopster and Oepen, 2005), with spatial resolution (currently) of $\sim$30 nm; its acquisition times are of the order of a few minutes, but ultrafast PEEM in conjunction with stroboscopic techniques have time resolutions in the sub-nanosecond range (Kuksov *et al*., 2004). Scanning electron microscopy with polarization analysis (Spin-SEM or SEMPA) (Scheinfein *et al*., 1989; Unguris, Scheinfein, Celotta and Pierce, 1990; Allenspach, 1994) has a spatial resolution of the order of 20 nm, and techniques with even higher spatial resolutions ($\leq$10 nm) include Lorentz microscopy (Chapman, 1984) and electron holography (Dunin-Borkowski *et al*., 2000). The ultimate imaging technique, as far as spatial resolution is concerned, is spin-polarized scanning tunneling microscopy (Wulfhekel and Kirschner, 1999; Bode, Pietzsch, Kubetzka and Wiesendanger, 2001), with subatomic resolution, but acquisition times tend to be long.

In magnetometric techniques, we include those techniques which give information about the magnetization structure, but which cannot determine unequivocally what such configuration may be. In order of increasing sensitivity, VSM (vibrating sample magnetometer), AGFM (alternating gradient magnetometer), and SQUID (superconducting quantum interference device), allow the measurement of *M-H* characteristics over arrays of small elements, but usually they are encumbered by the presence of the large diamagnetic contribution of the substrate. MOKE (Bader, 1991; Qiu and Bader, 1998) and its variants (Vavassori *et al*., 1999; Guedes *et al*., 2000) are surface-sensitive techniques (with probing depth of the order of the skin depth of the material under study, around 20 nm for most metals) and have been extensively used for the magnetic characterization of thin films and arrays of structures; it combines high sensitivities with fairly simple setups and typical spot sizes are of the order of 100 µm. Other techniques that require arrays of elements for sufficient signal-to-noise ratios include (polarized) neutron scattering (Fitzsimmons *et al*., 2004), ferromagnetic resonance (FMR) (Goglio *et al*., 1999; Giesen *et al*., 2005; Martyanov *et al*., 2005), and Brillouin light scattering (BLS) (Demokritov, Hillebrands and Slavin, 2001; Gubbiotti *et al*., 2002), the latter two probing directly the spin-wave spectra of the small structures. Recent developments include a microfocus BLS setup, with spatial

resolution of the order of 300 nm (Demidov *et al*., 2004). Hall effect magnetometry (Oral, Bending and Henini, 1996; Rahm *et al*., 2001; Schuh *et al*., 2001; Wunderlich *et al*., 2001; Steiner and Nitta, 2004) has also been employed, where individual microscopic elements are measured by placing them directly onto the Hall probe, allowing therefore a spatial discrimination of the order of or better than 1 μm; magnetoresistance (MR) is also a very powerful technique, which has the advantage that the signal does not decrease with decreasing size of the element and which is usually based on the anisotropic MR effect (Hong and Giordano, 1995; Aumentado and Chandrasekhar, 1999; Wegrowe *et al*., 1999); it has been used, for example, to probe the magnetization structure in nanometer-sized constrictions (Kläui *et al*., 2003b, 2004d) and also for studies of atomic contacts (García, Muñoz and Zhao, 1999; Gabureac, Viret, Ott and Fermon, 2004; Montero *et al*., 2004). Extraordinary Hall effect has been employed in perpendicularly magnetized structures as a very sensitive technique for the study of the magnetic configurations and magnetization dynamics in small structures, offering good time resolution but rather involved data analysis (Webb, 1990; Ravelosona *et al*., 2002; Belmeguenai, Devolder and Chappert, 2005). Micro-SQUID probes were developed by Mailly, Chapelier and Benoit (1993) and Wernsdorfer (2001) to probe the switching properties of nanometer-sized particles, and also rely on the placement of the nanoparticle onto the micro-SQUID junction; it combines high spatial discrimination with the extreme sensitivity of SQUID junctions. In general terms, these techniques allow the study of both static and dynamic properties, such as coercivities, magnetic anisotropies, magnetic moment, and spin-wave dynamics, and as such provide information that is critical for a complete characterization of the system. This is important because, for thin films and small structures, we may expect changes in the magnetic properties with respect to the bulk material, and also because the effect of interaction between elements or the effect of the physical shape of the element also strongly affects the magnetic properties of the system.

A more detailed description of these techniques can be found in volume 3 of this series.

3 MAGNETIC ENERGY TERMS IN MICROMAGNETISM

In small elements, as in bulk materials and thin films, the static and dynamic magnetic properties are determined by the relative contribution of the different magnetic energy terms to the free energy, namely, exchange, magnetostatic, magnetic anisotropy, and the Zeeman energy (if an external field is present). However, the sensitivity of the magnetic dipolar energy to the shape of the element changes dramatically the relative importance of the different energy terms in small structures, where boundaries constitute a significant portion of the whole system. In fact, while the magnetostatic energy term favors states of magnetic flux closure, and therefore multidomain states or states of nonuniform magnetization, such states come at a significant cost in exchange energy, since now regions of nonuniform magnetization (such as domain walls) occupy a large portion of the overall system. As the size of the element is reduced, the exchange energy becomes dominant, and, below a critical dimension, the single domain state is the lowest in energy. We can therefore speak of three magnetic regimes characterized by different types of equilibrium states (Vaz *et al*., 2006): the *multidomain* state regime, for elements with dimensions typically above $\sim$2 μm, which exhibit equilibrium states with magnetic domains of uniform magnetization; the *nonuniform* magnetic state regime, for sizes in the range $\sim$0.2–2 μm, where the states of lowest energy correspond to complicated magnetic configurations which are a result of a delicate balance between the different energy terms and which cannot be described by individual magnetic domains (Vaz *et al*., 2005); and the *quasiuniform* regime, for sizes below $\sim$200 nm, which is characterized by magnetic states that closely resemble the uniform state (Barbara, 2005). These boundaries are not rigid, however, and depend strongly on the strength of the magnetic anisotropy, among other factors, but our view is that they are qualitatively correct for most *3d* cubic and polycrystalline magnetic materials.

While the sensitivity of the magnetic energy to the shape of the element opens an endless range of possibilities for the study of small structures, in practice, we may expect that simple magnetic states may be more stable in highly symmetric structures, such as circles, squares, rings, ellipses, or wires. These structures have in fact received the bulk of the attention in this research area, partly because of their potential for technological applications, where simple and reproducible magnetic states with fast magnetic switching are key.

3.1 Exchange energy

This is the energy term which is at the origin of ferromagnetic order. Its microscopic origin is related to a combination of the Pauli exclusion principle and the Coulomb repulsive interaction between ions. Depending on the particular atomic arrangement, it may lead to several magnetic spin arrangements, such as ferromagnetism (Fe, Co, Ni, Gd, Dy, CrO_2, etc.), antiferromagnetism (Cr, FeO, CoO, NiO, FeMn, etc.), ferrimagnetism (γ-Fe_2O_3, Fe_3O_4, $Y_3Fe_5O_{12}$, etc.), helicoidal magnetism (Ho, Er), and so on. (Keffer, 1966; Gautier, 1982; Hurd, 1982; Pierre, 1982). Here we shall consider

only ferromagnetic materials, but ferrimagnets are susceptible to an identical analysis; the case of antiferromagnetism requires a special treatment, since these materials exhibit properties that are quite different from those of ferromagnets (Nagamiya, Yosida and Kubo, 1955; Fawcett, 1988; Fawcett *et al*., 1994; Aeppli, 2004).

The exchange energy is minimum when all spins are aligned parallel to each other, and, therefore, as far as this energy term is concerned, states of uniform magnetization are the lowest in energy. Although the strength of the exchange interaction is very high (of the order of $k_B T_c$, where T_c is the Curie temperature) it is, however, a short range interaction, such that, over large samples, other magnetic energy terms may be comparable or larger. This marks the transition from a state of uniform to a state of nonuniform magnetization; this transition has received particular attention over the years due to its practical implications for the manufacture of permanent magnets and particulate recording media. In fact, one could say that nanomagnetism is a field that dates from the early 1930s, when Frenkel and Dorfman (1930) first estimated the critical size for a single domain particle.

It is worth noting that, although the 3*d* transition metals are itinerant systems due to the high electron hopping frequency, the orbital bands responsible for the magnetic order (the 3*d* bands) are fairly localized such that the description of the exchange energy by the Heisenberg Hamiltonian is a good approximation. In fact, it has been suggested that the band structure of ferromagnets remains largely unaltered at temperatures above the Curie temperature, suggesting that the paramagnetic phase is not a result of the collapse of the band exchange spliting, but is rather due to spin disorder introduced by thermal agitations (Korenman, 1983). A unified description of localized and itinerant magnetism has been provided in the context of the generalized spin-fluctuation picture developed by Moriya (1985).

Although magnetic order arises ultimately from the electron spin (of the 3*d* bands in the case of the 3*d* transition metals and from the 4*f* orbitals in the case of the 4*f* transition metals), it is usually sufficient to consider a continuum approximation when the size of the magnetic system is much larger that the atomic dimensions; in this case, the Heisenberg Hamiltonian gives for the excess exchange energy for cubic or isotropic materials due to inhomogeneous spin configurations (Landau and Lifshitz, 1935; Carr, 1966; Kittel, 1987) (See also **General Micromagnetic Theory, Volume 2**):

$$E_{\text{ex}} = A \int_{\Omega} (\nabla \mathbf{m})^2 \, \mathrm{d}v \tag{1}$$

where A is the exchange constant, $\mathbf{m} = \mathbf{M}/M_s$ is the magnetization unit vector (M_s is the saturation magnetization) and Ω is the volume.

3.2 Magnetostatic self-energy

This is the classical interaction energy between magnetic dipoles. It is a long-range term and the source of most complications as far as magnetic configurations are concerned. There are several ways in which this term can be represented; perhaps the most common is to note that, in the absence of electric currents and in the static case, Maxwell's equations give $\nabla \times \mathbf{H} = 0$, that is, $\mathbf{H}$ is irrotational and therefore can be written as the gradient of a potential ϕ whose source is given by the fictitious magnetic charge distribution $\nabla^2 \phi = -\nabla \cdot \mathbf{H} = \nabla \cdot \mathbf{M}$ (Jackson, 1975; Brown, 1962). Although a solution for ϕ can be written explicitly, its calculation is often very difficult:

$$\phi(\mathbf{r}) = -\frac{1}{4\pi} \int_{\Omega} \frac{\nabla \cdot \mathbf{M}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} \, \mathrm{d}v + \frac{1}{4\pi} \int_{\partial\Omega} \frac{\mathbf{n} \cdot \mathbf{M}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} \, \mathrm{d}s \tag{2}$$

where $\mathbf{n}$ is the unit vector perpendicular to the volume surface $\partial\Omega$. The field $\mathbf{H}_d = -\nabla\phi$ is called the *magnetic dipolar field* and it tends to oppose the direction of magnetization (inside the magnetized body); the magnetostatic energy is given by

$$E_{\text{MS}} = \frac{\mu_0}{2} \int_{\Omega} \mathbf{H}_d \cdot \mathbf{M} \, \mathrm{d}v \tag{3}$$

This is the energy term that is responsible for the existence of magnetic domains: it favors states of closed flux magnetization and therefore competes directly with the exchange energy term. Only in simple cases it is possible to express the magnetostatic energy analytically: in single domain particles with very regular geometries, thin films, and infinite wires. Since it is a global term, it is the most difficult and lengthy energy term to calculate in micromagnetic simulations.

3.2.1 Demagnetizing factor

The calculation of the magnetostatic energy is significantly simplified in the case of uniform magnetized states, for which the first term of (2) is zero. It is often easier to calculate the magnetostatic energy than the dipolar field explicitly, and we call the ratio between this energy and the factor $\mu_0 M_s^2/2$ the *magnetometric demagnetizing factor*, or demagnetizing factor for short. The usefulness of these expressions is that we may compare the energy of the uniform state with that of other nonuniform configurations and determine the phase diagram separating the regions of stability for each of the magnetic states. This requires, however, that energy expressions for the other states are available and also a knowledge of what other magnetic states may be stable. Good guesses are based on the symmetry of the element, but more accurate knowledge can be obtained from the results

of micromagnetic simulations. While the demagnetizing factors for ellipsoids have been made available for a long time (Maxwell, 1891), a useful presentation of the results have been provided by Osborn (1945) and Stoner (1945) along the revolution axes and for a range of particular cases. The case of cylinders and disks has also been considered extensively (Joseph, 1966; Kaczér and Klem, 1976; Hegedus, Kadar and Torre, 1979; Aharoni, 1981; Chen, Brug and Goldfarb, 1991; Goode and Rowlands, 2003; Beleggia *et al*., 2005), including approximate expressions for the limiting cases of wires and disks (Joseph, 1966, 1976). The case of a flat square prism has also been considered by Joseph (1976), while the demagnetizing factor for rings have been studied by several authors (Kaczér and Klem, 1976; Hegedus, Kadar and Torre, 1979; Chen, Brug and Goldfarb, 1991; Vaz, Athanasiou, Bland and Rowlands, 2006).

3.3 Magnetic anisotropy

Magnetic anisotropy refers to variations in the magnetic energy with the spatial orientation of the magnetization. From a microscopic perspective, several terms can be distinguished, such as the intrinsic magnetocrystalline anisotropy, the magnetoelastic anisotropy, surface anisotropy, field-induced anisotropy (all of which originate microscopically from the spin-orbit coupling), growth-induced (morphology related) anisotropy, exchange anisotropy, and so forth. However, from a macroscopic perspective, we may collect all the energy contributions with a given symmetry into a single *effective anisotropy* when discussing its effect on the equilibrium or dynamic behavior of the magnetization configuration. This is useful on many counts. For example, one often deals with polycrystalline materials, which consist of small crystallites randomly oriented with respect to each other such that no anisotropy is present, that is, the material behaves as an isotropic material. In weakly anisotropic materials, this is a good description if the crystallite size is of the order of the exchange length of the material or smaller, but for larger crystallite sizes local deviations of the magnetization may occur; in the other extreme, for very small elements composed of a small number of crystallites, it may be possible that the magnetic anisotropy no longer averages to zero, and an effective magnetocrystalline anisotropy may remain, which needs to be taken into account (New, Pease and White, 1996; Ross *et al*., 2000; Spargo, Ridley, Roberts and Chantrell, 2002).

Phenomenologically, one can write the magnetic anisotropy energy in terms of the direction cosines of the magnetization consistent with the magnetic symmetry of the system. For a cubic system, the general expression is of the form:

$$E_{\text{cub}} = \int_{\Omega} \left(K_1 \sum_{i>j} \alpha_i^2 \alpha_j^2 + K_2 \alpha_1^2 \alpha_2^2 \alpha_3^2 + K_3 \sum_{i>j} (\alpha_i^2 \alpha_j^2)^2 + \ldots \right) \mathrm{d}v \tag{4}$$

where K_1, K_2, and so on are the effective anisotropy constants.

3.4 Zeeman energy

This energy term corresponds to the dipole interaction with an external magnetic field. For a uniform field, its effect is that of exerting a torque on the dipole moment when this is aligned along directions different from that of the external field. The expression for this energy term is given by

$$E_{\text{Zeeman}} = -\mu_0 \int_{\Omega} \mathbf{H}_0 \cdot \mathbf{M} \, \mathrm{d}v \tag{5}$$

3.5 Lengthscales in magnetism

The preceding expressions for the magnetic energy terms allows one, in principle, to calculate the equilibrium states that minimize the Landau free energy of the system, given by

$$G(\mathbf{H}, T) = U - TS - \mu_0 \int_{\Omega} \mathbf{H_0} \cdot \mathbf{M} \, \mathrm{d}v \tag{6}$$

where S is the entropy, T the temperature, and U the internal energy of the system (which includes the previously mentioned magnetic energy terms and is a functional of the magnetization configuration); the last term is the Zeeman energy term. Such a calculation is, in general, very complicated, and here we shall consider only the equilibrium state at zero temperature. This approximation is justified if the energy barriers that have to be overcome during switching are much higher than the thermal energy (i.e., temperature) of the system. In this case, it is possible to calculate numerically the magnetic equilibrium state as a function of applied fields in the continuum approximation (*micromagnetism* (Brown, 1963; Aharoni, 1996)); while in principle the equilibrium configurations can be calculated analytically from Brown's equation (Brown, 1963); in practice such calculations can only be carried out in some special cases. When the atomic structure of the system cannot be neglected, the spins have to be treated individually and quantum effects have to be taken into account (Hilzinger and Kronmüller, 1972, 1973;

Wernsdorfer, 2001). We consider here systems where micromagnetics should still hold (See also **General Micromagnetic Theory, Volume 2**), and we shall limit ourselves to quasistatic equilibrium processes, that is, we assume that the applied magnetic field changes slowly compared to the magnetization dynamics.

A case that can be solved analytically is that of a system that acts like a macrospin, that is, a system with uniformly aligned magnetization (single domain particle). As discussed in the preceding text, this state is favored by the exchange interaction but comes at a cost of magnetostatic energy. We can obtain an estimate of the dimensions of a magnetic particle below which it is a single domain by comparing the order of magnitude of the exchange energy ($\sim Al$) and magnetostatic energy ($\sim \mu_0 M_s^2 l^3/2$); this gives the characteristic *exchange length* $l_s = (2A/\mu_0 M_s^2)^{1/2}$, below which twisting of the magnetization is energetically unfavorable; this also follows from the scaling of the energy terms (Schabes and Bertram, 1988; Hertel, 2004). For larger particles, another characteristic lengthscale which is of importance is the *domain wall width*, $l_k = (A/K)^{1/2}$, which gives an indication of the strength of the anisotropy energy with respect to the exchange energy (and therefore determines the width of the domain wall separating magnetic domains in multidomain states). In this context, it is worth mentioning a third parameter corresponding to the ratio between the magnetic anisotropy constant and the magnetostatic energy, $Q = 2K/\mu_0 M_s^2$, called the *quality factor*. This is an important parameter in perpendicularly magnetized films (See also **Alternative Patterning Techniques: Magnetic Interactions in Nanomagnet Arrays, Volume 3**).

4 SINGLE DOMAIN SYSTEMS WITH UNIFORM MAGNETIZATION

When analyzing a magnetic system, we are firstly interested in the stable equilibrium magnetization configurations, that is, the directions of the spins in the system for a given set of external parameters. From this information, key properties, such as the switching fields, can be deduced. In general, due to the large number of degrees of freedom, such an analysis has to be carried out using numerical techniques. A more easily accessible case is a single domain system, where the magnetization configuration can be described by a single angle of a macrospin. We start with the description of such a system, where instructive analytical calculations are possible, to illustrate how the different energy terms discussed in the preceding text govern the magnetic behavior.

4.1 Theory of single domain systems: the Stoner–Wohlfarth model

If a system is in a single domain state in equilibrium and the spins rotate uniformly during reversal, then it can be described by a macrospin model. While single domain systems may reverse by inhomogeneous modes, such as curling (Aharoni, 1996; Frei, Shtrikman and Treves, 1957; Kronmüller and Fähnle, 2003) (see Section 7.3), we start here with a system with a uniform magnetization at all times.

The simplest classical model describing single domain systems with coherent rotation was developed by Stoner and Wohlfarth (1948), and Néel (1947) and is commonly referred to as the *Stoner–Wohlfarth model*. The aim of this model is to analytically calculate the equilibrium directions of the magnetization for a given anisotropy and a given applied field (and field history). Further, for a magnetic field applied along a given direction, one can calculate the field value at which the magnetization reverses.

Since spatial variations do not have to be taken into account in this model, the exchange energy does not play a role and the magnetic switching is governed by the interplay between the Zeeman energy and the effective anisotropy. In line with the original calculations (Stoner and Wohlfarth, 1948), we restrict ourselves here to the two-dimensional case, which is easier to understand intuitively (many experimental thin film systems can be described to a first approximation by the two-dimensional mode). The theory has, however, been extended to three dimensions by Thiaville (Thiaville, 1998, 2000) to deal with systems such as clusters (Jamet *et al.*, 2001).

Well below the Curie temperature, the magnetization vector can be assumed to be of constant length, so that the problem of finding the magnetization direction angle θ that minimizes the energy for a given applied field $\mathbf{H}$ with the direction ϕ can be mathematically formulated as follows:

$$E(\mathbf{h}) = \min[F(\mathbf{m}(\theta)) - 2\mathbf{h} \cdot \mathbf{m}(\theta)] \tag{7}$$

Here $\mathbf{m} = \mathbf{M}/M_s$ is the normalized magnetization direction vector, $F(\mathbf{m})$ is the anisotropy energy density divided by the anisotropy constant K and $\mathbf{h} = \mu_0 \mathbf{H} M_s/2K$ is the reduced applied field. In polar coordinates, $\mathbf{m} = (\cos\theta, \sin\theta)$ and the orthogonal vector is $\mathbf{e} = (-\sin\theta, \cos\theta)$. In equilibrium

$$\frac{\mathrm{d}E}{\mathrm{d}\theta} = \frac{\mathrm{d}F}{\mathrm{d}\theta} - 2\mathbf{h} \cdot \mathbf{e} = 0 \tag{8}$$

and whether the position is a stable minimum or not can be determined by the second derivative:

$$\frac{\mathrm{d}^2E}{\mathrm{d}\theta^2} = \frac{\mathrm{d}^2F}{\mathrm{d}\theta^2} + 2\mathbf{h} \cdot \mathbf{m} \tag{9}$$

This determines the equilibrium magnetization direction for a given field. Now, one is interested in the critical field where the solution becomes unstable, that is, when the second derivative is zero (saddle point). Using both equations to solve for the x and y components of the critical field $\mathbf{h_c}$ one obtains

$$\mathbf{h_c} = \frac{1}{2}\left(\frac{\mathrm{d}F}{\mathrm{d}\theta}\mathbf{e} - \frac{\mathrm{d}^2F}{\mathrm{d}\theta^2}\mathbf{m}\right) \tag{10}$$

For a twofold anisotropy $F = K_t \sin^2\theta$ this gives

$$h_{c,x}(\theta) = \cos^3\theta \tag{11}$$

$$h_{c,y}(\theta) = \sin^3\theta \tag{12}$$

For a given magnetization direction defined by θ, one obtains a critical field strength and field direction where the energy of the system has a saddle point. Hence, if a field larger than the critical field is applied, there is only one stable direction for the magnetization. If one considers, *M-H* hysteresis loop measurements, the magnetization exhibits an irreversible jump at the critical field. For the twofold anisotropy, a polar plot of $\mathbf{h_c}$ (Stoner–Wohlfarth asteroid) is shown in Figure 1. The aim, which was to express the critical field as a function of the applied field direction $\mathbf{h_c}(\phi)$, has not been reached yet as only $\mathbf{h_c}(\theta)$ has been determined. The relationship between the two angles is given by

$$\phi = \arctan(h_{c,y}(\theta)/h_{c,x}(\theta)) \tag{13}$$

In the case of twofold anisotropy, this can be solved follows: $\theta = \arctan(\tan^{1/3}\phi)$. $\theta(\phi)$ can then be introduced into equations (11) and (12) and the well-known formula for the dependence of the switching field on the angle of the applied field is obtained (Kronmüller and Fähnle, 2003):

$$h_c(\phi) = (\sin^{2/3}\phi + \cos^{2/3}\phi)^{-3/2} \tag{14}$$

While there is an explicit formula for the switching fields, the hysteresis loops in general have to be calculated numerically. For the case of twofold anisotropy, the result is shown in Figure 2. Further information and explanations can be found in Slonczewski (1956), Wernsdorfer (2001), Kronmüller and Fähnle (2003).

Now we consider the case of a fourfold anisotropy, where a general analytical expression for the switching field $\mathbf{h_c}$ as a function of the angle of the applied field cannot be calculated (even though analytical expressions for fields applied close to the hard and easy axes can be derived (Kläui, 2003)).

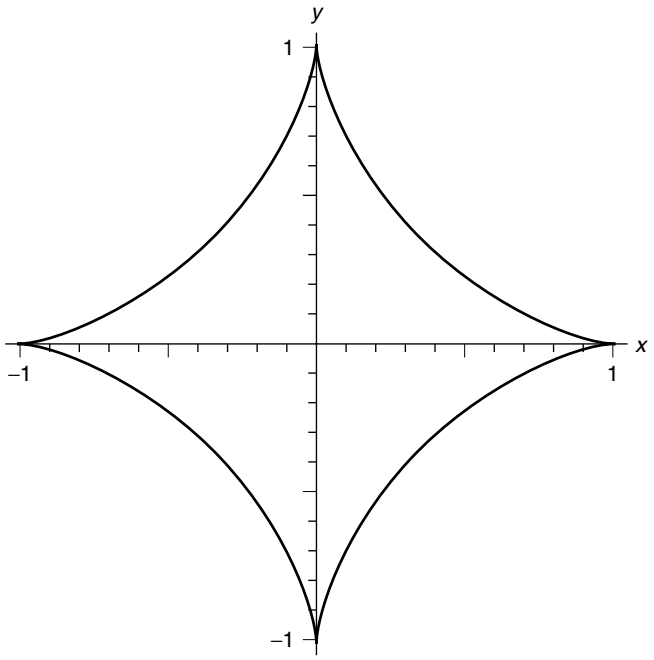

Figure 1. Plot of the critical fields (solid line) for a twofold anisotropy.

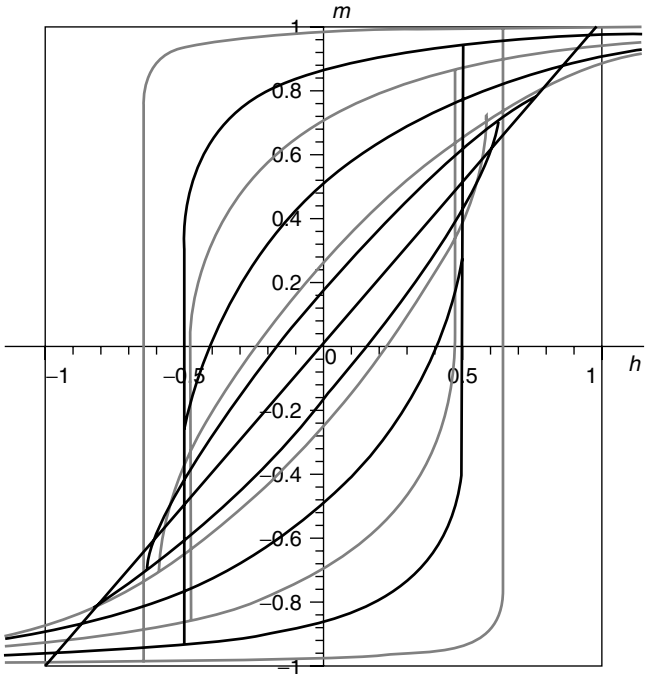

Figure 2. Longitudinal *M-H* hysteresis loops for 0 (innermost line through the origin, hard axis), 5, 10, 30, 45, 60, 85, and 90 (outermost square loop, easy axis) degrees away from the hard axis for the case of a twofold anisotropy.

In the case of the fourfold anisotropy, $F = K_1 \sin^2 2\theta$, and inserting this expression into equation (10), we obtain

$$h_{c,x}(\theta) = \frac{-5}{4}\cos 3\theta - \frac{3}{4}\cos 5\theta \tag{15}$$

$$h_{c,y}(\theta) = \frac{5}{4}\sin 3\theta - \frac{3}{4}\sin 5\theta \tag{16}$$

Again, *M-H* measurements along the easy or hard axis show jumps at the critical field. For other angles, more complicated multistep switching occurs corresponding to transitions between different local energy minima, which are due to the presence of two easy axes in the fourfold anisotropy case (Wernsdorfer, 2001). The angular dependence of the switching fields is presented in Figure 3.

Owing to the additional energy minima, the interpretation of these graphs is not as straightforward as in the case of a twofold anisotropy (an in-depth description on how to interpret them can be found in Thiaville (1998), and Wernsdorfer (2001)).

The preceding results provide a framework with which to interpret experimental data. Firstly, if a system exhibits a simple uniaxial (twofold) or cubic (effectively, a fourfold anisotropy in two dimensions) anisotropy and we know the saturation magnetization, we can deduce the anisotropy constants. In general, however, more than one anisotropy term is present in real systems and the anisotropy energy terms can be expanded in a power series of $m_x^a m_y^b m_z^c$ with $a + b + c = 2, 4, 6$ etc. Calculations of the switching fields for different anisotropies indicate, in fact, that there is not necessarily a simple map between the switching fields and the anisotropies, meaning that the switching fields can be calculated from the anisotropies, but not necessarily vice versa, which is usually the desired case.

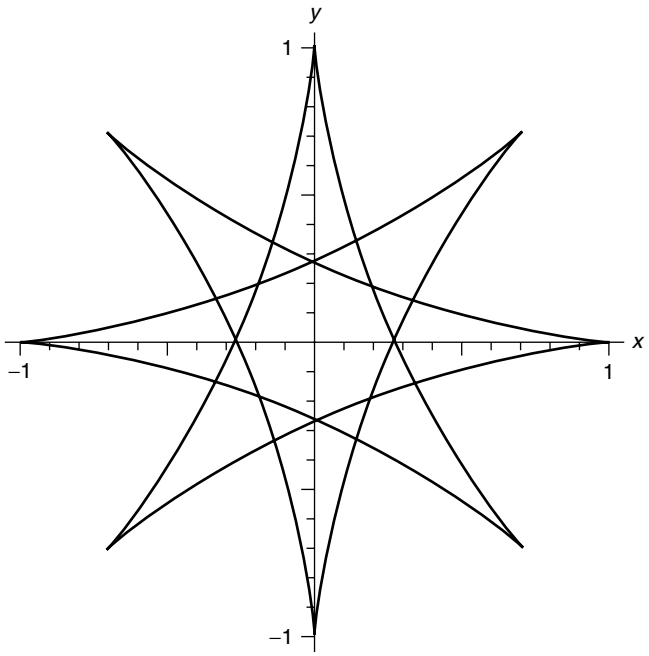

Figure 3. Plot of the critical fields (solid line) for a fourfold anisotropy.

4.2 Experimental observations of single domain systems

Structures which reverse via coherent rotation are promising for applications (Prinz, 1999, 1998) as this switching process can occur on very short timescales (Schumacher *et al*., 2003). Coherent rotation is predominantly found in small particles where the exchange energy dominates. For the fabrication of small magnetic elements, top-down and bottom-up approaches have been put forward (Martín *et al*., 2003; Terris and Thomson, 2005). Top-down patterning using standard lithographic methods allows us to fabricate structures easily down to lateral sizes of around 50 nm (Martín *et al*., 2003). For these sizes, one can simply engineer the shape anisotropy by varying the element geometry, but such top-down fabricated structures often do not exhibit the properties expected of single domain particles that reverse via coherent rotation. In particular, the angular dependence of the switching fields fits the Stoner–Wohlfarth behavior only for angles close to the hard axis, where the effects of defects, domain formation, and, in general, twisting of the spins away from the single domain configurations are not very significant (Wernsdorfer *et al*., 1995a,b). Even though some structures show an angular dependence of the switching fields, which is, for some directions, similar to the Stoner–Wohlfarth asteroids magnetic, relaxation experiments revealed a nucleation volume that is much smaller than the physical volume (Fruchart *et al*., 1999; Wernsdorfer *et al*., 1995a,b) and most of the larger elements display complicated domain structures (Section 6). The bottom-up technique has been shown to be more fruitful for the fabrication of single domain particles. In particular, clusters fabricated by laser ablation or in dedicated cluster sources have been shown to be uniform in size with up to some 1000 atoms and with diameters of a few nanometers (Jamet *et al*., 2001), and these exhibit well-defined anisotropies. Although small, these clusters are essentially three-dimensional in shape, whereas the thin film elements discussed earlier are flat.

It should be mentioned that measurements on such small structures are extremely challenging. In particular, since the anisotropies of these elements can be randomly oriented, individual structures need to be measured with extremely high magnetic sensitivity. A powerful technique that is well suited for such measurements is the μ-SQUID technique

pioneered by Mailly, Chapelier and Benoit (1993) and Wernsdorfer (2001), which is capable of determining the angular dependence of the switching fields for comparison with calculated Stoner–Wohlfarth asteroids.

The first systems for which clear coherent rotation was observed with this technique were BaFeO nanoparticles with a pronounced twofold anisotropy (Wernsdorfer *et al*., 1997a) and Co nanoparticles (Bonet *et al*., 1999; Jamet *et al*., 2001), which were fabricated in a matrix using a laser vaporization and inert gas condensation source. An example of the angular dependence of the switching field distribution of such a particle with twofold anisotropy is shown in Figure 4. The measured asteroid follows very closely the theoretical asteroid (Figure 1). While we do not discuss thermal effects here, it should be pointed out that they have been studied and lead to a reduction in the switching fields with increasing temperature (Wernsdorfer, 2001).

Alternatively, nanodisks have been fabricated by depositing magnetic material on top of prepatterned nanopillars (Kläui *et al*., 2002a). In this approach for the fabrication of small circular elements with diameters down to a few nanometers, Au colloids with diameters down to 5 nm are used as etch masks (Lewis and Ahmed, 1999). After patterning of the semiconductor substrate into nanopillars, the metal nanodisk layers are grown with molecular-beam epitaxy (Kläui *et al*., 2002a). A scanning electron microscopy (SEM) image and a scanning transmission electron microscopy (STEM) image of such fabricated structures are shown in Figure 5. In the STEM image, a clear contrast between the silicon pillar, the cobalt, and the gold-capping layer is visible.

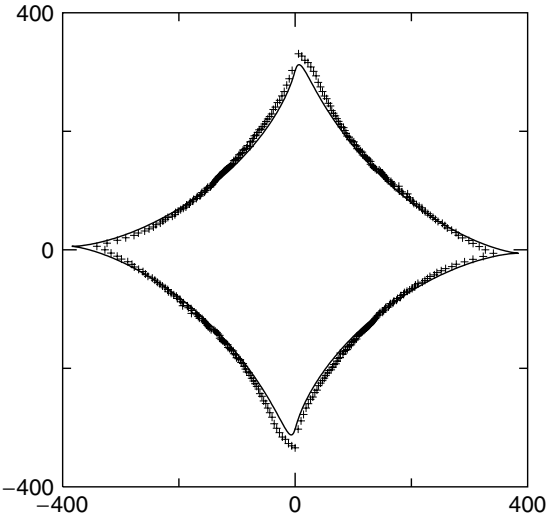

Figure 4. Stoner–Wohlfarth asteroid for a Co particle with a twofold anisotropy: comparison between experiment (crosses) and theory (solid line). Both scales are in mT ($1\,\mathrm{mT} \approx 800\,\mathrm{Am}^{-1}$). (Reprinted figure with permission from Bonet *et al*., *Phys. Rev. Lett.* **83**, 4188 (1999). Copyright 1999 by the American Physical Society.)

In Figure 6, three examples of measurements of the angular switching field dependence are shown (cold-mode measurement, for details see Wernsdorfer (2001)). These were taken on three individual 30-nm wide pillars with a 15-nm-thick Co nanodisk on top (Thirion *et al*., 2006). Figure 6 (a) shows an example of a dominant twofold anisotropy, which is very similar to the previously discussed case of a pure twofold anisotropy (see Figure 1).

The fit in Figure 6(a) (solid line) was obtained by rotating the twofold anisotropy term and invoking a three-dimensional model to account for a tilting between the μ-SQUID and the plane of the nanodisk. In (b), a particle with a dominant fourfold anisotropy is shown, which exhibits an asteroid that is very similar to that of a pure fourfold anisotropy (Figure 3). The particles are round, so no in-plane shape anisotropy is expected, and the magnetocrystalline anisotropy of fcc Co is cubic, so a perfect crystal should have a purely cubic anisotropy (in Jamet *et al*. (2001) high-resolution images revealed small Co elements in the fcc phase). For a thin film system, the anisotropy is then reduced to a fourfold anisotropy in the plane. In nanoclusters and other small particles, this cubic magnetocrystalline anisotropy had always been superseded by surface or defect-induced strong uniaxial (twofold) anisotropy terms (Wernsdorfer, 2001; Jamet *et al*., 2001). As seen in Figure 6(b), there are nanodisks that exhibit a nearly perfect fourfold anisotropy, meaning that, in some of these nanodisks, the anisotropy is governed by the magnetocrystalline anisotropy with an extracted anisotropy constant that is very similar to what has been measured on fcc Co films (Krams *et al*., 1992). Thus, in these structures, defects (in the magnetic film such as stacking faults, local oxidation etc., and shape deviations from a perfectly round disk) are less important. When defects are artificially introduced, for instance, by letting the sample oxidize in air, the twofold anisotropies start to dominate and all nanodisks exhibit asteroids such as the one in Figure 6(a). Thus, by measuring the anisotropies, the quality of the nanodisks can be judged and consequently the relation between fourfold magnetocrystalline and defect-induced twofold anisotropy can be used as a quality-gauge tool.

For the case of a mixed cubic and uniaxial anisotropy, as shown in Figure 6(c), the simulated asteroid does not reproduce the measured asteroid very well, which points to the already mentioned difficulty that there is no easy way to extract the anisotropy constants for an arbitrary measured asteroid. Since we have restricted ourselves to a combination of fourfold and twofold anisotropies, neglecting any other anisotropies and higher-order terms, the discrepancy is not surprising.

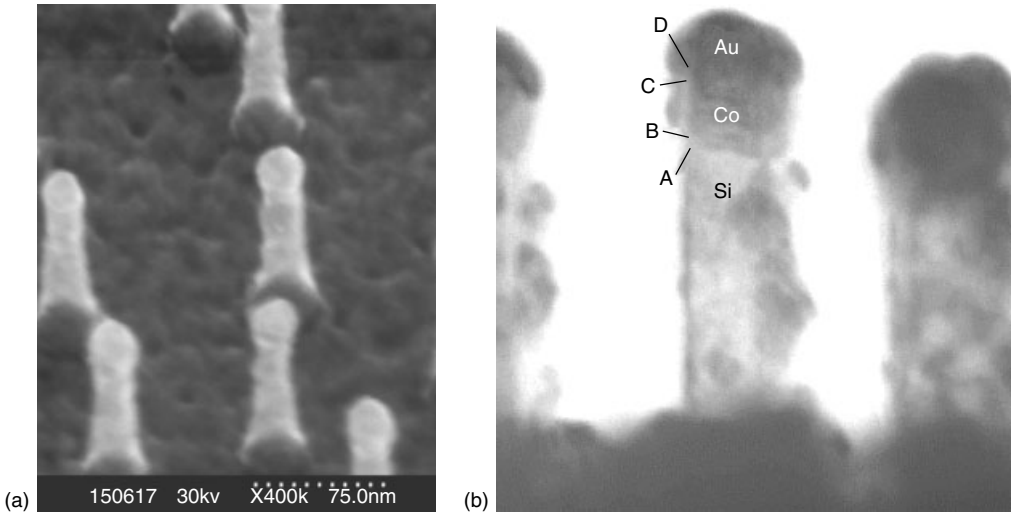

Figure 5. (a) SEM image of Si pillars after etching and removal of the 30-nm large gold colloids but before the metal deposition shows a nanopillar with a round top. (b) Bright field STEM image of a single 30-nm wide nanopillar with Au(6 nm)/Cu(2 nm)/Co(15 nm) deposited on top, showing a clear contrast between the different layers (the materials were identified using electron energy loss spectroscopy, EELS: A, silicon; B, C, cobalt, and D, gold). (Reprinted from Fabrication & Magnetic properties of patterned epitaxical nanodots. *Microelectron. Eng.*, **61**, 593. M. Kläui *et al*.)

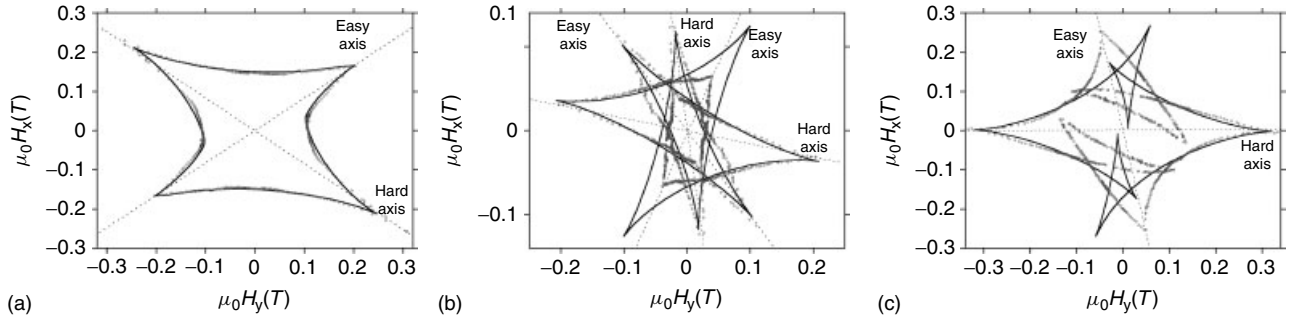

Figure 6. Stoner–Wohlfarth asteroids measured for different nanodisks of the same sample (30-nm-wide dots with 15-nm thick Co on Si pillars). (a) Measured (circles) and simulated (full line) asteroid with a dominant twofold anisotropy. (b) Measured and simulated asteroid with a dominating fourfold anisotropy. (c) Asteroid corresponding to a mixed fourfold and twofold anisotropy with different strengths and different easy and hard axis directions. (C. Thirion, W. Wernsdorfer, M. Klaui, C.A.F. Vaz, P. Lewis, H. Ahmed, J.A.C. Bland and D. Mailly in Nanotechnology 17, 1960–1963 (2006) IOP Publishing Ltd.)

Thus, we see that while the basics of the Stoner–Wohlfarth model are easy to grasp, the calculations even for the two simplest cases of a twofold and a fourfold anisotropy are already difficult and not always analytically solvable. Comparison to experimental observations shows good agreement for some systems, but the limitations of the model become already apparent for slightly more complicated systems.

5 NONUNIFORM STATES

For particle sizes above a critical dimension, one expects the uniform state to become energetically unfavorable due to the contribution of the magnetostatic energy term; magnetic configurations that lower the latter energy tend to be states that minimize magnetic flux leakage from the sample, while simultaneously conforming with the topology of the element (Tchernyshyov and Chern, 2005). Such states have been studied theoretically for many decades in the context of the critical size for single domain particles (Aharoni, 1996), but the recent development of imaging techniques has allowed the direct probing of the magnetic configuration of small elements, particularly those fabricated from thin films, since most techniques are only sensitive to the surface spin distribution. In this case, one often assumes that the magnetization does not vary with thickness (ultrathin film regime),

which in thin films is valid when the film thickness is smaller or comparable to the exchange length. In small elements, one expects this to be valid, but the presence of perpendicular interface anisotropies or large surface roughness, for instance, may lead to nonuniform distributions of the magnetization along the out-of-plane direction.

In this section, we are interested in describing the different magnetic states that occur in small elements in the size range from around 200 nm up to around 2 μm, where multidomain states have not yet set in. These states are characterized by relatively complicated spin configurations where the magnetization tends to vary over the whole element and does not lend to a simple analytical description, except in some cases. This complexity is a result of the fine balance between the different energy terms, exchange, magnetostatic, and anisotropy, and is intimately connected with the physical shape of the element (via the magnetostatic energy contribution). Often, several magnetic states are local minima of the total energy and in principle can be stabilized and observed if the energy barrier separating the different minima is higher than the thermal or other excitations.

Of the geometries that have been most studied, disks and cylinders, prisms, ellipses, and wires are among the most widespread. The advantage of such geometries is that they are simple enough to have cylindrical or Cartesian symmetry (and therefore one expects relatively simple equilibrium magnetic states) while still containing just enough complexity to make them ideal choices for the study of the magnetism of small elements. Next, we consider each of these geometries separately, with particular focus on the equilibrium properties. However, we shall also include some discussion of the steady-state magnetization dynamics, such as spin-wave modes (See also **Magnetic Modes in Circular Thin Film Elements, Experiment and Theory, Volume 2**, **Spin Waves: History and a Summary of Recent Developments, Volume 1**, **Spin Structures and Spin Wave Excitations, Volume 3**, and **Investigation of Spin Waves and Spin Dynamics by Optical Techniques, Volume 3** for a more detailed discussion).

5.1 Disks

The disk geometry is the simplest of the planar geometries described here, but this simplicity can be misleading. While to first order it can be approximated by a very flat ellipsoid, it turns out that such an approximation is not a very accurate one, as far as the magnetostatic energy density is concerned (it is underestimated) (Pardavi-Horvath, 1999). Topologically, the edges of the disk introduce singularities in the magnetic potential, and theoretically the ground state of such elements is not the uniform state (Usov, 1993), although for small enough structures the deviations from the uniform state are negligible (Brown, 1969; Aharoni, 1996). As the size of the disk increases, the magnetostatic energy density contribution also increases (linearly with thickness for in-plane magnetized elements) up to a point where the uniform state is no longer the lowest in energy. The theoretical determination of such nonuniform equilibrium states is not possible, since the Brown equation for such a general case is too difficult to be solved analytically; the states we know are the result of either good guesses (such as the vortex state), or the result of micromagnetic simulations and experimental observation.

Stable magnetic nonuniform states at remanence for in-plane magnetized disks with low anisotropy include the vortex state (Cowburn *et al*., 1999; Schneider, Hoffmann and Zweck, 2000; Zhu and Zheng, 2002; Vaz *et al*., 2003), the C-state (Guslienko *et al*., 2002; Ha, Hertel and Kirschner, 2003; Wei *et al*., 2003), the S-state (Guslienko *et al*., 2002; Ha, Hertel and Kirschner, 2003), the triangle state (Zhu and Zheng, 2002; Guslienko *et al*., 2002; Vaz *et al*., 2005), and the diamond state (Prejbeaunu *et al*., 2002; Zhu and Zheng, 2002; Vaz *et al*., 2005) (see Figure 7). The C, S, and triangle states have a relatively large remanence and can be seen as deviations from the uniform state in order to accommodate the larger contribution of the magnetostatic energy. The C and S states have been predicted to be stable for small diameters and are therefore difficult to resolve experimentally (and it is likely that the uniform state ascribed to high remanence states in disks may be in fact often either of these states); effectively, only for the C-state we are aware of experimental observation in submicrometer $Ni_{80}Fe_{20}$ circular elements (Heumann, Uhlig and Zweck, 2005; Acremann *et al*., 2006). At larger diameters (0.4–2 μm), the triangle state has been predicted from micromagnetic simulations (Zhu and Zheng, 2002; Guslienko *et al*., 2002) and observed experimentally in Co polycrystalline disks 2 μm in diameter (Vaz *et al*., 2005) (see Figure 7c). This is a metastable state which is stabilized by energy barriers separating it from states lower in energy (Vaz *et al*., 2005, 2006). It is characterized by a buckling of the magnetization, and, like the previous two states, by the presence of two 'edge vortices' where a strong stray field is present. The diamond and the vortex state are states of almost zero remanence; the vortex state consists of a circular distribution of the magnetization and is characterized by the presence of a vortex core in the middle of the disk. The diamond state consists of two vortices that resemble a seven-domain configuration in square elements (Figure 7b); however, the magnetization is not uniform in any region except in the inner part of the disk, which is, in any case, not bounded by sharp domain walls (this inner domain resembles a rhombus). Again, the diamond state is not that of lowest

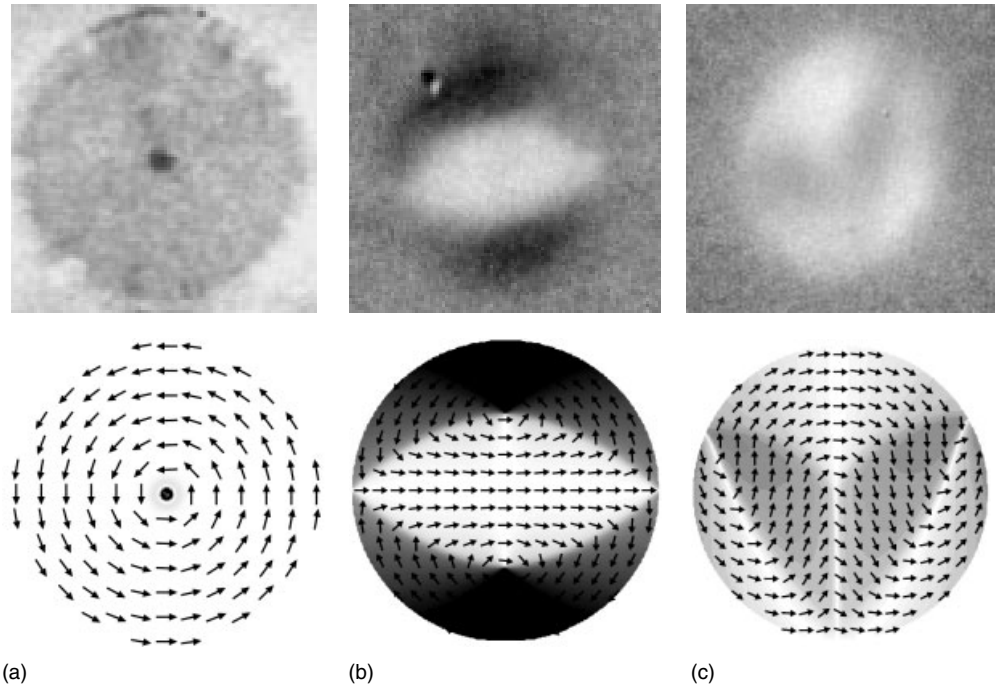

Figure 7. Experimental observation of magnetic states in disk elements and comparison with the results of micromagnetic simulations: (a) Vortex state, showing the out-of-plane magnetization component at the vortex core (MFM, $Ni_{80}Fe_{20}$, 1 μm diameter, 50 nm thick (Reprinted figure with permission from Science AAAS, T. Shinjo, *Science* **289**:930, 2000. Copyright 2000 AAAS.); (b) Diamond state (PEEM, fcc Co, 1.65 μm diameter, 29 nm thick (Vaz *et al*., 2005); (c) triangle state (PEEM, polycrystalline Co, 1.65 μm diameter, 19 nm thick (Vaz *et al*., 2005)). In (b) and (c), the magnetic contrast is along the horizontal direction.

energy, but may be stabilized by the presence of energy barriers separating it from the vortex state (Vaz *et al*., 2005, 2006), and may be nucleated in the process of the magnetization relaxation from the saturated state (Mattheis, Berkov and Gorn, 1999; Prejbeaunu *et al*., 2002).

The vortex state has attracted much attention since it is the ground state of disk elements over a wide range of diameters and thicknesses; the phase boundary for the ground state between the vortex and the uniform state has been well studied theoretically (Jubert and Allenspach, 2004; Vaz, Athanasiou, Bland and Rowlands, 2006) and experimental results also give an idea of the relative stability range (Cowburn *et al*., 1999; Prejbeaunu *et al*., 2002); also, schemes devised to control the circulation of the magnetization have been suggested (Schneider, Hoffmann and Zweck, 2001; Taniuchi, Oshima, Akinaga and Ono, 2005). An interesting aspect of the vortex state is the core at its center, where the large exchange energy cost due to the large twisting of the spins leads to a configuration where the magnetization points along the out-of-plane direction, at a cost of magnetostatic energy. The balance between these two contributions determines the size of the vortex core, which is of the order of the exchange length of the material (Feldtkeller and Thomas, 1965; Usov and Kurkina, 2002; Jubert and Allenspach, 2004; Vaz, Athanasiou, Bland and Rowlands, 2006). The very small out-of-plane component of the magnetization has been observed experimentally (Shinjo *et al*., 2000; Raabe *et al*., 2000; Wachowiak *et al*., 2002; Okuno *et al*., 2002) (see Figure 7a). This is indeed another striking example of the manifestation of the fine balance between these two energy contributions.

The magnetization dynamics of disk elements has also been addressed in the literature; here we mention the steady-state spin-wave dynamics, which has been probed by FMR (Buess *et al*., 2004; Raabe *et al*., 2005; Novosad *et al*., 2005) and BLS (Demokritov, Hillebrands and Slavin, 2001; Novosad *et al*., 2002; Gubbiotti *et al*., 2002; Gubbiotti *et al*., 2006). These experimental results give information about the spectral and spatial components of the spin wave modes and show the existence of both azimuthally and radially excited modes, which are determined largely by the topology of the element (Buess *et al*., 2004; Raabe *et al*., 2005). Other modes of excitation, which occur at much lower frequencies, correspond to the resonant displacement of the vortex core of the disk in the vortex state (Novosad *et al*., 2005), or the gyrotropic mode corresponding to a spiral motion of the magnetization at the vortex core as it approaches the equilibrium position (Park *et al*., 2003). Similar type of excitations

are observed by means of electric current driven excitations, such as the resonant excitation of a vortex wall in nanowires reported by Saitoh, Miyajima, Yamaoka and Tatara (2004).

It is also important to mention the effect of magnetocrystalline anisotropy on the magnetic configuration of disk elements. For in-plane magnetized elements, its effect for low values of the anisotropy is that of distorting the magnetic configuration that is observed in the isotropic case. For example, for fcc Co disk elements, the ground state consists of a hybrid between the vortex state and the quadrant, or Landau–Lifshitz, state: it resembles the vortex state close to the periphery of the disk (in order to minimize the stray field), while close to the center the magnetization becomes uniform along the four directions of easy magnetization, separated by sharp domain walls (Vaz *et al*., 2003, 2004b), again an instructive example of the balance between the three energy terms, anisotropy, exchange, and magnetostatic. This is also apparent when plotting the domain wall width as a function of the radial coordinate, which shows a plateau at small values (corresponding to a value close to the expected domain wall width) and reverts to the geometrical limit (as in the vortex state) for values close to the disk radius; this has been called a *geometrically constrained domain wall*, in analogy with identical geometrical constraints in other magnetic structures (Bruno, 1999; Jubert, Allenspach and Bischof, 2004; Kläui *et al*., 2003b, 2005a). An identical type of distortion on the vortex state due to the presence of a small uniaxial anisotropy has been studied numerically by (Jubert and Allenspach, 2004). It is worth pointing out that the presence of anisotropy tends to favor the uniform state over the vortex state (Jubert and Allenspach, 2004; Vaz, Athanasiou, Bland and Rowlands, 2006). Another state which is favored in disks with strong uniaxial anisotropy is the bidomain state, as observed in 34-nm Fe(110)/GaAs(110) epitaxial elements 1–4 μm in diameter (Pulwey, Zölfl, Bayreuther and Weiss, 2002) (in the same study, a Landau–Lifshitz state for Fe(100) disks with cubic anisotropy is reported, but the details of the domain wall cannot not be resolved from the MFM images obtained). Another situation occurs when a perpendicular magnetic anisotropy is present; in this case, the magnetization may no longer be confined to the plane of the element and other magnetic states may occur. The relative importance of the perpendicular magnetic anisotropy is measured by the *quality factor* Q (see Section 3.5). For quality factors close to or larger than one, perpendicular states of the magnetization are favored; this can be a simple uniform state, but other low-energy states are possible, such as the bubble state, bidomain states, or other more complex configurations (Hehn *et al*., 1997; Ohno, Miyajima, Shigeto and Shinjo, 1999; Eames and Dahlberg, 2002; Skidmore, Kunz, Campbell and Dan Dahlberg, 2004; Komineas, Vaz, Bland and Papanicolaou, 2005; Kageyama and Suzuki, 2006). A review covering perpendicularly magnetized elements is given in **Alternative Patterning Techniques: Magnetic Interactions in Nanomagnet Arrays, Volume 3**.

5.2 Rings

A geometry that has received much attention recently is the ring geometry. It differs from the disk geometry in that it has a lower energy vortex state due to the absence of the energetically costly vortex core (Zhu, Zheng and Prinz, 2000; Rothman *et al*., 2001); one consequence of this is that the vortex state is more stable compared to the uniform state (in addition, the presence of extra surfaces in the inner hole also results in an increase in the magnetostatic energy of the uniform state (Vaz, Athanasiou, Bland and Rowlands, 2006)). However, it was observed experimentally that such structures are able to attain a high remanence state, called the *onion state* (Rothman *et al*., 2001; Li *et al*., 2001; Kläui *et al*., 2003a), in which the magnetization in each half of the ring has an opposite sense of circulation. This is a metastable equilibrium state, made more stable by energy barriers introduced by defects and irregularities (such as edge roughness) and in fact the switching field from the onion to the vortex state can be quite high (Rothman *et al*., 2001). Such magnetic states have been observed experimentally with SEMPA and PEEM (Kläui, Vaz, Lopez-Diaz and Bland, 2003, Kläui *et al*., 2003a) (see Figure 8a). While the vortex state in these structures is quite simple, the details of the onion state are more subtle (Figures 8b and c). The region separating the two oppositely magnetized halves constitutes a domain wall, which is either a vortex or a transverse wall (Kläui *et al*., 2003a), in accordance with what is predicted for wires (McMichael and Donahue, 1997; Nakatani, Thiaville and Miltat, 2005). The presence of one or the other type of wall is determined by the interplay between the magnetostatic and exchange energy; for thick and wide rings, the magnetostatic energy dominates and vortex walls are favored (these lead to a nearly complete flux closure of the magnetization), while for thin and narrow rings the exchange energy dominates and transverse walls are favored (in such case, the energy gain in reducing the stray field would not compensate for the increase in exchange energy due to a large twisting of the spins in a narrow region). Phase diagrams separating the regions of stability for the domain wall type in the onion state have been reported for polycrystalline Co (Kläui *et al*., 2004b) and $Ni_{80}Fe_{20}$ (Laufenberg *et al*., 2006) ring elements. In the limit of very wide rings, we recover the disk geometry and magnetic configurations that are characteristic of disk elements (Kläui *et al*., 2006).

In some instances, the observation of 360° domain walls has been reported in rings with diameters from 360 to 520 nm

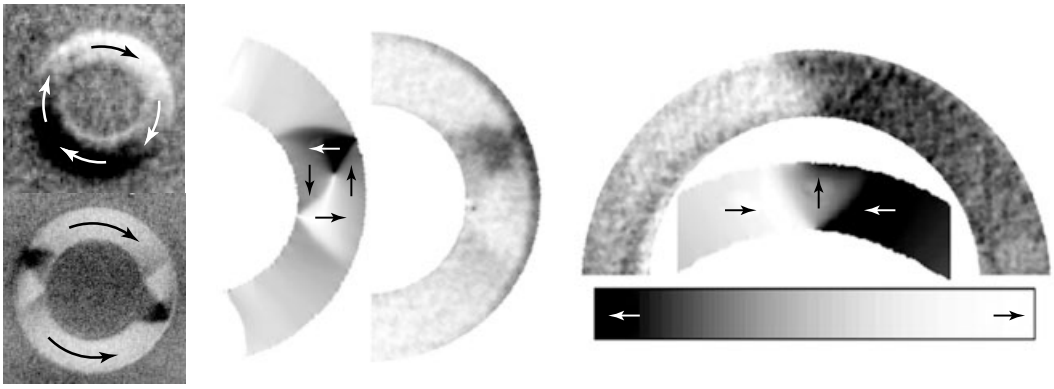

Figure 8. (a) PEEM images of rings in the vortex state (top) and in the onion state (bottom, exhibiting vortex walls). The rings are 30-nm-thick $Ni_{80}Fe_{20}$, 2.7 μm outer diameter, 530 nm wide, and the magnetic contrast is approximately along the vertical direction. (b) Detail of vortex wall in a polycrystalline Co ring (34 nm thick, 350 nm wide, 1.65 μm outer diameter) and (c) of a transverse wall (10 nm thick, 260 nm wide, 1.65 μm outer diameter) imaged by PEEM and compared with the results of micromagnetic simulations (Kläui *et al*., 2004b).

and widths from 30 to 200 nm, and such states have been termed *twisted states* (Zhu and Zhu, 2003; Castaño *et al*., 2003; Castaño *et al*., 2004). These occur at the transition from onion to vortex state when two transverse walls with opposite senses of rotation, although attracted to each other due to dipolar coupling, are prevented from annihilating by the exchange energy associated with the required large spin twisting involved in this proess. (Castaño *et al*., 2003); it turns out that such walls are fairly stable against a wide range of applied external fields (Castaño *et al*., 2004). In addition, other more complicated states were also observed in such ring structures, such as states consisting of two 360° domain walls (Castaño *et al*., 2003) and double-vortex walls in very thick rings (Park *et al*., 2006).

The effect of magnetic anisotropy on the properties of ring elements has been less studied; in part, this is because the magnetic behavior is dominated by the exchange and magnetostatic energies (shape), while other magnetic anisotropies are expected to introduce only small perturbations to the isotropic case. This happens to be the case for narrow rings and for small anisotropies; for instance, for 34-nm-thick fcc Co(001) rings with 1.7 μm outer diameter, it is observed that the magnetic state of 250-nm-wide rings is not affected by the magnetic anisotropy, while 400-nm-wide rings in the onion state show the presence of local domains pointing along directions of easy magnetization (Kläui *et al*., 2003a). From the magnetic switching behavior of fcc Co rings (16–29 nm thick, 1.65 μm outer diameter), it is observed that the magnetic easy axis of fcc Co becomes a direction of 'hard' magnetization for the ring structure; this is a consequence of the fact that in rings in the onion state the magnetization close to the end-wall point along the hard axis, making this magnetic direction easier to switch than when the onion state points along the hard axis direction (Vaz *et al*., 2004a); this behavior is in agreement with the results of micromagnetic simulations (Lopez-Diaz, Rothman, Kläui and Bland, 2001b).

The spin dynamics of ring elements have also been probed with FMR (Giesen *et al*., 2005; Neudecker *et al*., 2006), time-resolved MOKE (Neudecker *et al*., 2006), and BLS (Schultheiss *et al*., 2006). For the ring widths studied, azimuthal modes in the onion state are evident, along with other excitation modes that are associated with the head-to-head walls. Micro-BLS results (Schultheiss *et al*., 2006) suggest that, at the transverse wall of the onion state, the spin quantization is predominantly caused by the inhomogeneities of the local internal field, similar to what is observed in transversally magnetized stripes (Jorzick *et al*., 1999).

In addition to circular rings, other toroidal structures were also investigated, such as elliptical rings (Castaño, Ross and Eilez, 2003; Jung *et al*., 2004), and 'window-frame'-type structures (Vavassori *et al*., 2003; Zhu, Grütter, Metlushko and Ilic, 2003; Wei *et al*., 2004; Libál *et al*., 2005; Adeyeye, Singh and Goolaup, 2005). The motivation using elliptical rings is that of creating easy direction of magnetization (shape anisotropy) and therefore to constrain the onion state to point along one direction (Castaño, Ross and Eilez, 2003). It is found that, upon saturation along the long axis, twisted states are not easily formed, while, upon saturation along the short axis, such metastable states are often observed (Castaño, Ross and Eilez, 2003). In the case of 'window-frame'-type of structures, the magnetic states resemble those observed for ring structures, except for the presence of two additional states at remanence when the field is applied along the side of the square, one close to saturation (with two transverse walls at those sides perpendicular to the direction of the applied magnetic field) and a horseshoe type of state, with one head-to-head and one tail-to-tail wall on one side of

the square (Vavassori *et al*., 2003; Zhu, Grütter, Metlushko and Ilic, 2003).

Besides thin magnetic films, other types of structures, such as spin valves and pseudo-spin valves (the former have an antiferromagnetic pinning layer to set a unidirectional easy axis, while the latter do not) have been investigated with a view to using each element as a memory bit, which could be read by electrical means using the giant MR effect (Castaño, Morecroft, Jung and Ross, 2005; Morecroft, Castaño, Jung and Ross, 2006).

5.3 Square and rectangle (bar) elements

Again, the equilibrium magnetic states observed in these types of structures reflect the Cartesian symmetry of this geometry and are also determined by the size and particular aspect ratio of the element. For square elements, and bars with lengths comparable to the width, with dimensions below $\sim$100 nm, we expect equilibrium states such as the flower and the leaf states (magnetization parallel or diagonal to the edge direction, respectively), which correspond to small deviations from the uniform state (Usov and Peschany, 1994a; Cowburn and Welland, 1998; Goode and Rowlands, 2005); micromagnetic studies show that the flower state is expected to be the equilibrium state at larger thicknesses, while the leaf state is the equilibrium state at small thicknesses (Cowburn and Welland, 1998). For more elongated structures, the equilibrium state is expected to be a mixture of the flower and the leaf state, and resembles the S-state found in larger elements (Tartakovskaya, Tucker and Ivanov, 2001; Goode and Rowlands, 2005).

For larger elements, for which the magnetostatic energy term becomes dominant, we find, in addition to the high remanence S- and C-states, the flux closure quadrant (Landau–Lifshitz) or the seven-domain states (Kirk, Chapman and Wilkinson, 1997; Dunin-Borkowski, McCartney, Kardynal and Smith, 1998; Gomez *et al*., 1999a; Schneider *et al*., 2004) (see Figure 9). These zero remanence states are characterized by the presence of uniform magnetic domains separated by 90° Néel domain walls; as a consequence, such states could be classified as multidomain states, but given the critical role played by the shape of the element in small square and bar elements in determining the equilibrium state, we prefer to see it as another example of a nonuniform magnetic state, determined by the fine balance between the magnetostatic and exchange energy terms. We note that, besides the cost in exchange energy, there is also some magnetostatic energy associated with these Néel walls. The high remanence states such as the S- and the C-state have been studied numerically (Gadbois and Zhu, 1995; Zheng and Zhu, 1997; Fidler *et al*., 2004; Kronmüller, Goll, Hertel and Schütz, 2004) and experimentally (Chapman *et al*., 1998; Dunin-Borkowski, McCartney, Kardynal and Smith, 1998; Dunin-Borkowski *et al*., 2000; Kirk *et al*., 2001; García, Thiaville and Miltat, 2002; Shi, Li and Tehrani, 2002; Liu, Chapman, McVitie and Wilkinson, 2004a). These states are in fact quite similar and they correspond to a central uniform spin configuration, which is terminated by end domains, where the magnetization runs parallel to the edge; the C-state corresponds to the case when both edge domains point in different directions, while the S-state corresponds to the case when they point along the same direction (see Figure 9). Another type of edge domain, which is observed in elongated rectangles after saturation in an applied field, consists of a 'squeezed' vortex which sits toward one corner of the element with the largest domain pointing in the direction of the average magnetization (Kirk, Chapman and Wilkinson, 1997; Dunin-Borkowski, McCartney, Kardynal and Smith, 1998; Gomez *et al*., 1999a; Shi *et al*., 1999; Kirk *et al*., 2001); also, cross-tie domain walls are observed in thick $Ni_{80}Fe_{20}$ elements (Gomez *et al*., 1999a,b; Shigeto *et al*., 2002). For larger elements (typically above 5 μm), multidomain configurations set in (Seynaeve *et al*., 2001; Hirohata *et al*., 2002). These elongated elements have received much attention because they constitute an obvious choice for memory elements; the shape asymmetry introduces an effective (shape) magnetic anisotropy and therefore an increase in thermal stability; however, the presence of such edge domains has been shown to cause irreproducibilities in the magnetic switching (Zheng and Zhu, 1997), which is detrimental for applications; in fact, modifications in the edge structure, such as pointed ends, have been suggested in order to make the switching process more reproducible (Schrefl, Fidler, Kirk and Chapman, 1997; Yu *et al*., 1999; Herrmann, McVitie and Chapman, 2000; Liu, Chapman, McVitie and Wilkinson, 2004a).

The spin dynamics of square and rectangular elements have also been studied numerically (Fidler *et al*., 2004) and experimentally by BLS (Chérif, Dugautier, Hennequin and Moch, 1997; Gubbiotti *et al*., 2000; Chérif, Roussigné and Moch, 2002; Jorzick *et al*., 2002) and time-resolved MOKE (Park *et al*., 2003; Perzlmeier *et al*., 2005). The experimental BLS studies mentioned were performed under an applied magnetic field and show that the spin wave frequencies, determined mostly by the dipolar field, are sensitive to the lateral confinement imposed by the element (in a similar fashion as observed in wire structures); Jorzick *et al*. (2002), in particular, have shown that spatially localized spin waves arise in square elements as a consequence of the potential well created by the inhomogeneous internal magnetic field within the element. The numerical study of Fidler *et al*. (2004), on the other hand, has shown that the spin-wave spectrum for the S-state in square elements is distinct from

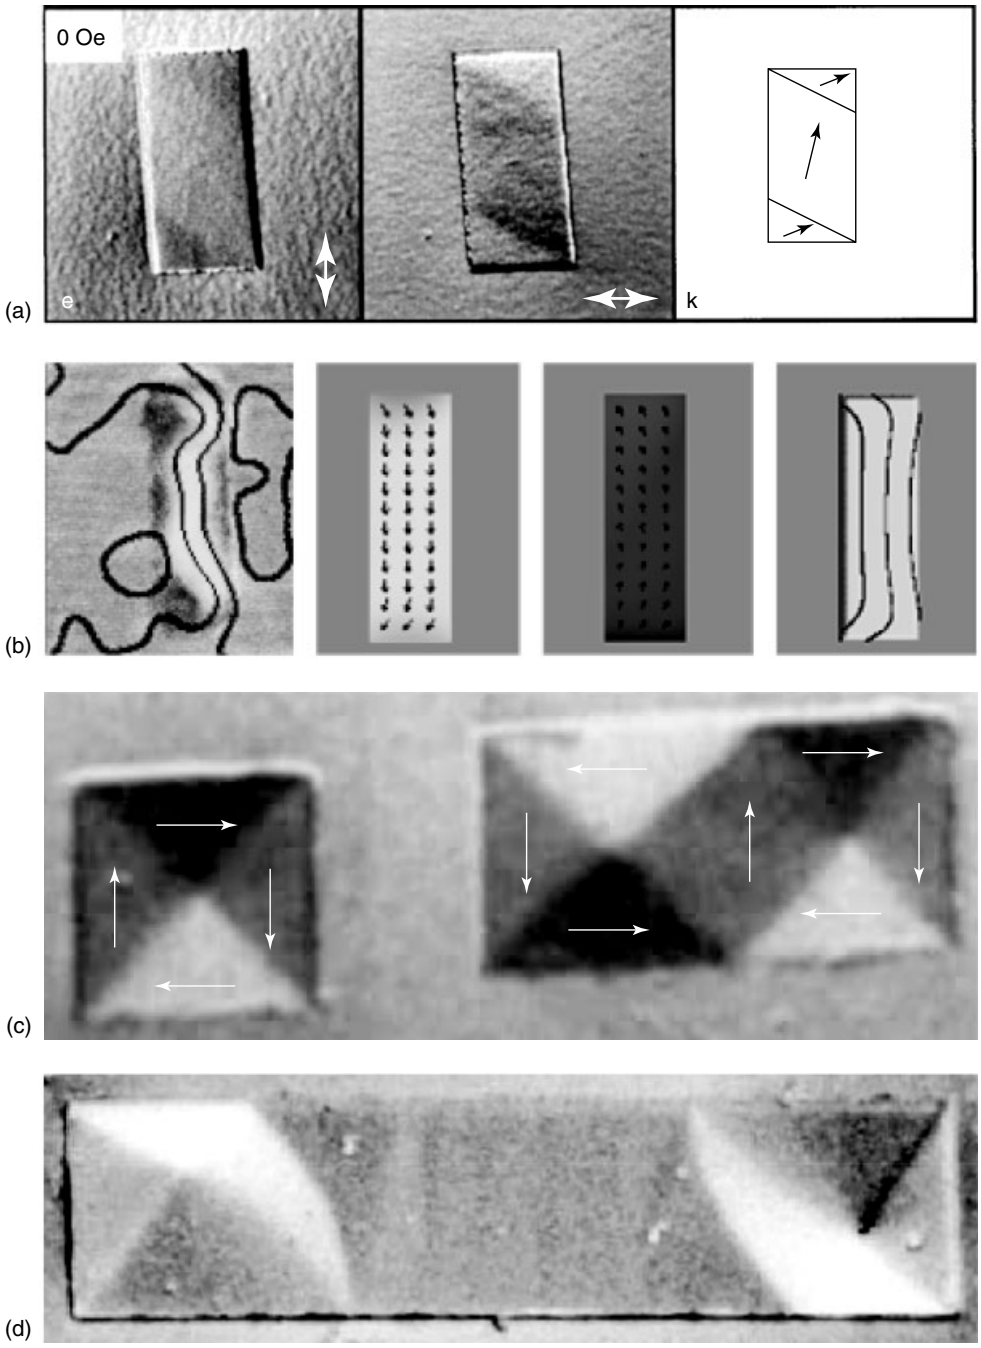

Figure 9. Magnetic images of remanent states of square and rectangular elements; (a) Lorentz image (Foucault mode) of a $2 \times 4\,\mu m^2$ NiFe(8 nm)/Cu(2.5 nm)/NiFe(6 nm) element in the S-state (Reprinted with permission from Institute of Physics, Direct Observation of Magnetization . . . , *Journal of Applied Physics*, **83**, 5321. that of the C-state: as a consequence of the larger effective fields present in the C-state, the eigenfrequencies for this state are shifted to higher frequencies. Park *et al*. (2003) have studied the spin dynamics of square elements in the quadrant (Landau–Lifshitz) state,which was found to exhibit two types of excitations, one corresponding to the precession of the magnetization about the local demagnetizing field in each quadrant and the other localized in the domain walls.

5.4 Ellipses

The motivation behind the study of elliptical elements lies in the introduction of magnetic (shape) anisotropy, while avoiding the formation of edge domains and their negative influence on the reproducibility of the magnetic switching (Liu, Chapman, McVitie and Wilkinson, 2004a). Hybrids between bars and ellipses, such as bars with tapered ends, have also been studied with the same goal in mind (see previous paragraph). Understandably, most studies on elliptical elements focus on ellipses with large aspect ratios, and the magnetic states found in micrometer and submicrometer size ellipses depend on the applied magnetic field direction: after saturation along the long axis, they tend to remain in the uniform state, while when the field is applied along the short axis, a larger variety of magnetic states are observed, including the vortex state, the diamond state, the triangle state, and the uniform state magnetized along the long axis (Bedrossian, Gibbons and Cerjan, 1997; Fernandez, Gibbons, Wall and Cerjan, 1998; Usov, Chang and Wei, 2001; Liu, Chapman, McVitie and Wilkinson, 2004a; Liu, Chapman, McVitie and Wilkinson, 2004b; Felton *et al*., 2004; Buchanan *et al*., 2005). The spin dynamics of the diamond state in elliptical NiFe dots has been studied recently by Buchanan *et al*. (2005) and by Gubbiotti *et al*. (2005) using BLS and it is observed that the frequency modes depend strongly on the dot eccentricity and direction of the magnetic field.

5.5 Wires

These consist of structures where the length is much larger than the width, and therefore the relevant geometrical parameters are the width and thickness. A large body of work has been devoted to the study of wire structures and a number of fabrication techniques have allowed the fabrication of magnetic wires with widths ranging from a few nanometers to several micrometers. Depending on the fabrication process, planar wires, or wires with circular cross section can be fabricated (namely, by electrodeposition using porous membranes as templates (Whitney, Jiang, Searson and Chien, 1993; Lederman, O'Barr and Schultz, 1995; Ferré *et al*., 1997)). Here we cite some studies as a way of illustrating the distinctive magnetic properties exhibited by wire structures (see also **Domain Wall Propagation in Magnetic Wires, Volume 2**).

The study of monolayer thick bcc Fe wires grown on W(110) has provided much insight into the magnetism of two-dimensional structures (Pratzer *et al*., 2001; Pratzer and Elmers, 2003; Kubetzka, Pietzsch, Bode and Wiesendanger, 2003). Such two-dimensional Fe wires have a very strong uniaxial anisotropy along the direction perpendicular to the wire axis (due to the Fe/W(110) lattice mismatch), and are observed to form magnetic domains along the direction orthogonal to the wire length (Pratzer *et al*., 2001; Pratzer and Elmers, 2003; Kubetzka, Pietzsch, Bode and Wiesendanger, 2003). Spin-polarized STM studies of such domains allowed the determination of the wall width down to the subatomic resolution; for a 1-ML Fe wire, 17 nm wide, the domain wall width was determined to be 0.6 ± 0.2 nm, while for a 2-ML Fe/W(110) stripe, 8.5 nm wide, it was found to be 3.8 ± 0.2 nm. Such sharp domain walls for the monolayer wire are energetically more favorable than extended domain walls since, for such thicknesses, the exchange and anisotropy energies dominate over the magnetostatic energy (Braun, 1994). In general, one expects that, in comparison to bulk materials, atomically thin narrow nanowires may present new and exciting properties, such as effects due to quantum confinement and strongly modified electronic properties (Himpsel, 1995).

Arrays of wider Ni wires, 70–130 nm wide, have been grown on grooved InP(001) substrates (Jorritsma and Mydosh, 1998) by deposition at non-normal angles; this method explores the etching anisotropy of InP(001) with respect to specific etchants (Jorritsma, Gijs, Kerkhof and Stienen, 1996). Jorritsma and Mydosh (1998) have found that the Ni wires thus fabricated change the magnetization easy axis from longitudinal to transverse to the wire direction with decreasing temperature, an effect they attribute to the stress due to thermal expansion mismatch between Ni and InP.

The term *nanowires* is virtually a synonym for electrodeposited structures; they can vary in width from tens to a few hundreds of nanometers (Whitney, Jiang, Searson and Chien, 1993; Lederman, O'Barr and Schultz, 1995; Ferré *et al*., 1997). A number of seminal experiments have measured individual nanowires using highly sensitive micro-SQUID junctions (Wernsdorfer *et al*., 1996a); they have also been used to study domain wall MR effects, an effect which seems to be particularly large in Co and Ni nanowires and attributed to the spin accumulation effect (Ebels *et al*., 2000).

More conventionally, arrays of wires have been fabricated by standard lithography techniques, with widths varying from $\sim$100 nm to tens of μm (Adeyeye *et al*., 1996, 1997a,b). The coercivity is found to decrease with increasing wire width (Adeyeye *et al*., 1996); this is explained by a buckling

of the magnetization perpendicular to the length of the wire, creating perpendicular domains that do not move and block the reverse domain from propagating during magnetization reversal (Kryder *et al*., 1980), an effect that becomes more pronounced with decreasing wire width (see also Sections 7.3 and 7.4). The effect of magnetic interaction between micrometer wide wires has also been addressed, and shows that magnetic interactions between wires become unimportant for distances above the wire width (Adeyeye *et al*., 1997a); this behavior is characteristic of small elements and a critical factor as far as the design of high density storage media is concerned (Kläui, Vaz, Bland and Heyderman, 2005). In this context, the small stray field provided by flux closure states is very advantageous.

The magnetic states sustained by wire elements do not consist only of the uniform state, with the magnetization along the wire axis (in the absence of strong transverse anisotropies). Effectively, either as a consequence of applied transverse magnetic fields, or of fields applied in the direction opposite to the wire magnetization, reverse domains can be sustained along the wire. This has been observed in Co nanowires (Ebels *et al*., 2000; García, Thiaville and Miltat, 2002). In flat wires, the region separating such opposite domains constitute 180° domain walls, and their character can be either transverse or vortex, as already mentioned (McMichael and Donahue, 1997; Nakatani, Thiaville and Miltat, 2005); experimental observation of such wall structures in straight wires has been reported in the literature (Yamaguchi *et al*., 2004; Kläui *et al*., 2005b). Under applied fields close to the 'hard axis' of the wire, edge domains consisting of Néel walls parallel to the wire were observed in $Ni_{80}Fe_{20}$ wires 2–10 μm wide and 10–30 nm thick, giving rise to hysteretic behavior in rotational hysteresis measurements (Mattheis, Ramstöck and McCord, 1997); this is a result of the stray field at the wire edges when the magnetization points away from the wire axis. For wires with strong transverse anisotropies, the ground state is either the transverse uniform state or an open-stripe domain structure, depending on the wire thickness and width (Prejbeaunu *et al*., 2001).

5.6 Pillars

By pillars, we refer to structures whose aspect ratio (thickness/lateral size) is of the order of unity. The magnetic states in these structures can be quite complex, since now the magnetization will vary along the three spatial directions; in the case of cylindrical elements, some states preserve the cylindrical symmetry but have a radial magnetization distribution that varies across the element thickness. We lose the simplicity characteristic of thin elements, but it may be possible that the additional complexity results in properties that can be harnessed for applications or other studies. Since three-dimensional imaging is not possible as yet (see however, (Hertel *et al*., 2005)), these magnetic states may be deduced either from their *M-H* characteristics or from their surface signature when imaged by the usual imaging techniques; these results can also be confirmed by the results of micromagnetic simulations. Equilibrium magnetic states depend on the element geometry, but they tend to form states such as the flower, vortex, uniform, bidomain, and bubble states (Rave, Fabian and Hubert, 1998; Maicas *et al*., 2002; Hertel and Kronmüller, 2002; Ross *et al*., 2002; Kronmüller, Goll, Hertel and Schütz, 2004; Usov and Peschany, 1994b; Komineas, Vaz, Bland and Papanicolaou, 2005; Moutafis *et al*., 2006). For example, the uniform and flower states are states of high magnetic moment, characterized by an almost uniform magnetization; in the flower state, local deviations of the magnetization are a result of the inhomogeneous dipolar field (the uniform state is likely to occur in systems with strong magnetic anisotropies or in systems with high aspect ratios (Huang *et al*., 2000)). The vortex, bidomain, and bubble states are states of small total magnetic moment, and in which the magnetization varies strongly along all directions in space; for example, the vortex state resembles the center of a vortex state of a disk, where the vortex core constitutes a large portion of the magnetic state, and therefore a sizeable remanence may be expected for this magnetic state. Bubble states are expected to occur in systems with a large quality factor and consist of two circular domains pointing in opposite directions and also, in this case, the magnetization varies along the out-of-plane direction (Komineas, Vaz, Bland and Papanicolaou, 2005; Moutafis *et al*., 2006) such states are stable under no applied magnetic field (as opposed to bubble states in continuous films) and have been observed experimentally in cylindrical Ni dots (Skidmore, Kunz, Campbell and Dan Dahlberg, 2004), Co dots (Hehn *et al*., 1997; Kageyama and Suzuki, 2006), and $Ni_{80}Fe_{20}$ dots (Eames and Dahlberg, 2002).

6 MULTIDOMAIN STATES

As usually defined, multidomain states are magnetic states characterized by the presence of more than one region where the magnetization is uniform. The driving force behind the splitting into domains is the long-range magnetic dipolar interaction, which acts to minimize magnetic 'pole charges' at the sample surface. Strictly speaking, in an ideal crystal one would expect, if not an absolute energy minimum, at least a small number of magnetic configurations with similar energies separated by intrinsic energy barriers such that the system may fall into one such state and remain there in the absence of disturbances. As the size of the system is reduced,

we would expect such energy degeneracy to be lifted, and the resulting energy differences to be sufficient to drive the system into the ground state, through energy gradients or thermal excitations. It is this distinction that has led us to consider magnetic states such as the quadrant state in small elements as a nonuniform state rather than a multidomain state; for larger elements, other multidomain states are stable other than the quadrant state. A large body of work has been built up over several decades specifically dedicated to the understanding of equilibrium magnetic domain structures in samples larger than those discussed in this chapter; the most extensive discussion of such work to date is that of Hubert and Schäfer (1998) and will not be discussed here (a shorter overview can be found in Kleman (1982)).

One major complication in studying magnetic configurations in real samples is the presence of imperfections that act as extrinsic pinning sites for the magnetization and that tend to stabilize nonequilibrium magnetic configurations (Kleman, 1982). If the energy barrier separating these states is much larger than that of external excitations, such states may be considered as metastable equilibrium states, otherwise they give rise to thermal relaxation effects; in particular, the stability of such states depends strongly on the temperature. Another effect of these pinning sites is to give rise to magnetic configurations that are much more complicated than those expected for perfect crystals due partly to the randomness associated with defects. Since the incorporation of pinning in micromagnetism is difficult, there are very few studies of extrinsic contributions to the magnetic configurations. We give a couple of examples to drive this point home. In Figure 10(a), we show an MFM image at remanence of an array of 25-nm-thick NiFe square elements obtained by Gubbiotti *et al*. (2000); we see that, while we expect the ground state to be the quadrant state, many elements exhibit more complicated domain structures that may be metastable (and vanish under small applied fields) but, nevertheless, are accessible after saturation or other field histories (Uhlig, Li, Han and Shi, 2002; Liou *et al*., 2001); this is an important consideration for practical applications that require well-defined domain configurations for reliable operation. Another example is shown in Figure 10(b) for 15-nm-thick bcc Fe(001) elements imaged by Lorentz microscopy (at remanence after saturation along the easy axis) by Gu *et al*. (1997); here, the puzzling behavior is the breaking into magnetic domains as the size of the element decreases, which at first sight seems counterintuitive. However, the size of the elements is fairly large, and, for the larger square, edge domains are observed, which presumably arise from edge imperfections, and these may help stabilize this large single domain.

In general, since the range of magnetic configurations increases with the size of the element, it follows that a vast number of complex spin arrangements is possible for larger systems (Hubert and Schäfer, 1998). One practical advantage of smaller elements is that the accessible magnetic states are much more limited.

7 SWITCHING

So far, we have discussed the stable equilibrium magnetization configurations that are found in small magnetic structures. The next step is the dynamic description of how such state a magnetic system approaches equilibrium. The equilibrium is given by a local energy minimum of the corresponding thermodynamic potential (e.g., the Landau Free Energy, equation (6) (Bertotti, 1998)). Here, We take the case where the equilibrium condition is changed by varying the applied field (Zeeman energy). But, changes of other energy terms can also occur, such as changes in the magnetic anisotropies when the temperature is varied.

We limit ourselves here to quasistatic reversal, which means that the field is ramped much more slowly than the dynamics of the magnetization. Depending on the materials and systems considered, the rates of change where the reversal can be described as quasistatic vary. For the materials considered here, this means slew rates of less than approximately $80\,\mathrm{kAm^{-1}\,s^{-1}}$. In the quasistatic case, the magnetic system is thus always in equilibrium as the external conditions change (e.g., the field is ramped). Dynamic switching, where the field changes are on a timescale that is comparable to the magnetization dynamics, is treated in **Magnetic Modes in Circular Thin Film Elements, Experiment and Theory, Volume 2**. We limit our discussion to magnetic field-induced switching, but other reversal schemes, such as those based on current-induced magnetic switching have been proposed (Katine *et al*., 2000; Grollier *et al*., 2002; Wegrowe *et al*., 2002; Kläui *et al*., 2005c) and are discussed in detail in **Theory of Spin-transfer Torque, Volume 2**, **Microwave Generation in Magnetic Multilayers and Nanostructures, Volume 2**, **Spin Angular Momentum Transfer in Magnetoresistive Nanojunctions, Volume 5**, and **Current Induced Domain-wall Motion in Magnetic Nanowires, Volume 2**.

7.1 Theoretical treatment of dynamical behavior

To determine the magnetization dynamics, we start with the quantum mechanical Heisenberg equation for the time evolution of the spin operator

$$i\hbar\frac{\mathrm{d}}{\mathrm{d}t}\langle\hat{\mathbf{S}}(t)\rangle = \langle[\hat{\mathbf{S}}(t), \hat{\mathcal{H}}(\hat{\mathbf{S}}(t))]\rangle \tag{17}$$

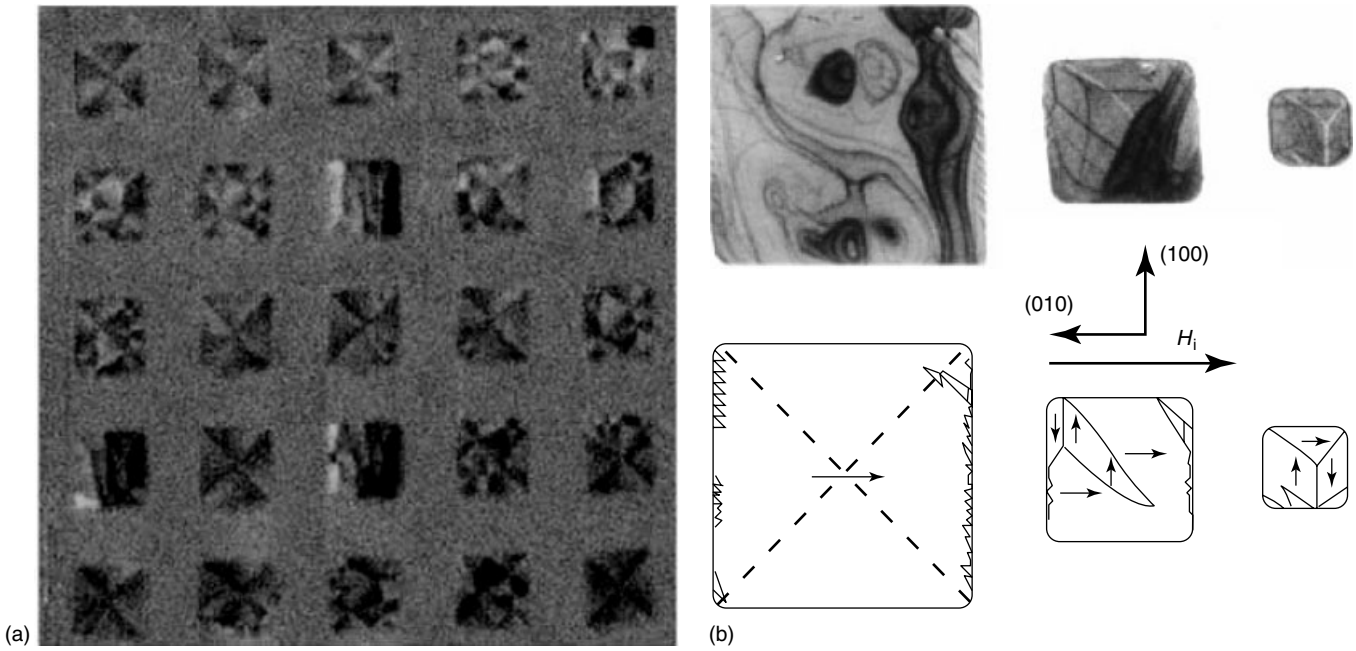

Figure 10. (a) MFM image of an array of 25-nm NiFe squares, 2 µm in size, at remanence. (Reprinted with permission from American Institute of Physics, Finite size effects in patterened magnetic permalloy films. *Journal of Applied Phys.* **87**, 5633. Copyright 2000, American Institute of Physics.) (b) Lorentz microscopy image (Fresnel mode) of 15-nm bcc Fe(001) squares (55, 30, 12 µm in size), at remanence. (Reprinted figure with permission from American Physical Society, *Phys Rev. Lett.* **78**, 1158 (1997) E. Gu *et al*. Copyright 1997 by the American Physical Society.)

with $\hat{\mathbf{S}}$ the spin operator and $\hat{\mathcal{H}}$ the Hamiltonian, which is here proportional to $\hat{\mathbf{S}} \cdot \hat{\mathbf{H}}_{\text{eff}}$ with $\hat{\mathbf{H}}_{\text{eff}}$ the effective magnetic field (Nalwa, 2002). Magnetic moments behave like angular momenta, since they observe the quantum mechanical bracket relations $[S_x, S_y] = i\hbar S_z$, etc. For an electron spin, the former is related to the latter by

$$\mathbf{m}_{\text{spin}} = \gamma\hbar\mathbf{S} = (\hbar q_e/m_e)\mathbf{S} \tag{18}$$

with q_e and m_e the electron mass. Evaluating equation (17) using the bracket relations and the Ehrenfest theorem to transform to the classical magnetization yields for the time evolution (Nalwa, 2002)

$$\frac{\partial \mathbf{m}}{\partial t} \equiv \dot{\mathbf{m}} = \gamma \mathbf{m} \times \mathbf{H}_{\text{eff}} \tag{19}$$

The change in angular momentum is given by the torque $\boldsymbol{\Gamma} = \mathbf{m} \times \mathbf{H}_{\text{eff}}$ exerted on it by the field $\mathbf{H}_{\text{eff}}$ and this describes the gyroscopic precession. From equation (5) with $\mathbf{H}_0$ now replace by $\mathbf{H}_{\text{eff}}$, it follows that $dE/dt = 0$, i.e., the energy is conserved. Hence, equation (19) cannot describe a system which is changing its energy such as a system approaching equilibrium. To introduce energy dissipation, Brown (1963) used the analogy to classical mechanics, where the force responsible for energy dissipation (friction) is proportional to the generalized velocities. In this case, the generalized coordinates are the Cartesian components of the magnetization $\mathbf{m}$ and the general forces are the components of $\mathbf{H}_{\text{eff}}$. Introducing this into equation (19) yields

$$\dot{\mathbf{m}} = \mathbf{m} \times (\gamma \mathbf{H}_{\text{eff}} - \alpha \dot{\mathbf{m}}) \tag{20}$$

where α is the phenomenological dimensionless proportionality factor for the damping. This equation is known as *Gilbert's equation*. Another formulation of this equation was given by *Landau* and *Lifshitz*:

$$\dot{\mathbf{m}} = \gamma_{\text{LL}} \mathbf{m} \times \mathbf{H}_{\text{eff}} - \alpha_{\text{LL}} \mathbf{m} \times (\mathbf{m} \times \mathbf{H}_{\text{eff}}) \tag{21}$$

It should be noted that γ_{LL} and γ from equation (20) are different (Bertotti, 1998; Heinrich, 2005). To a first approximation, all dissipation processes can be assumed to be included in the phenomenological damping factor α. In general, α is not very well known, and intensive research is being carried out to understand its microscopic origins (Buess, Haug, Scheinfein and Back, 2005; Heinrich, 2005).

7.2 Uniform reversal of single domain systems by coherent rotation

Equations (20) and (21) are directly applicable for single domain particles where the spins stay aligned during the reversal, which is called *reversal by coherent rotation* (Section 4.1). Here, we can simply evaluate these equations for a single (macro)spin. Analytical solutions have long been available (Gilette and Oshima, 1958; Kikuchi, 1956) and, more recently, numerical studies have been performed (Serpico, Mayergoyz and Bertotti, 2003; Fidler and Schrefl, 2000). These studies were also extended to include the response of single domain particles to short field pulses (Bauer, Fassbender, Hillebrands and Stamps, 2000). The results of two (macro)spin calculations are shown in Figure 11. In Figure 11(a), it can be seen that the magnetization direction starts to rotate toward the $-y$ direction, since the acting field component is in the $-z$ direction. It then turns toward $+z$ and continues to precess around the field direction and spirals due to the damping toward the field direction. Whereas in Figure 11(a) the damping constant is 0.2, it has a more realistic smaller value of 0.02 in Figure 11(b). This reduced damping leads to many more precessions of the magnetization around the field direction, before the magnetization has spiraled toward its equilibrium direction along the field direction. Experimentally, such switching trajectories have been observed for pulsed reversal (Schumacher *et al.*, 2003).

7.3 Nonuniform reversal of single domain systems

As pointed out before, there are geometries for which the remanent magnetization configuration is a single domain state, but where the reversal does not take place via coherent rotation, such as larger ellipsoidal elements with a constant demagnetization factor. In general, coherent rotation is only one possible reversal mode (Aharoni, 1996; Frei, Shtrikman and Treves, 1957; Kronmüller and Fähnle, 2003) and occurs only if the critical switching field for this mode is lower than for any other reversal mode. We consider now another possible reversal mode, which, for certain geometries, leads to a lower critical switching field than that attained by coherent rotation.

An example is a long cylinder, where the shape anisotropy favors the magnetization to lie along the cylinder axis to form a single domain state. If the radius of the cylinder is larger than the exchange length l_s, then a reversal via the so-called curling mode is favorable (Lederman, O'Barr and Schultz, 1995). The curling mode is strictly only applicable to ellipsoids of revolution (Aharoni, 1996; Kronmüller and Fähnle, 2003), but has been extended to describe approximately the reversal in other regularly shaped elements (Aharoni, 1999). In this mode, the magnetization reverses by forming a vortex structure where the magnetization lies parallel to the cylinder wall forming concentric circles around the cylinder axis. Analytically, the angular dependence of the switching

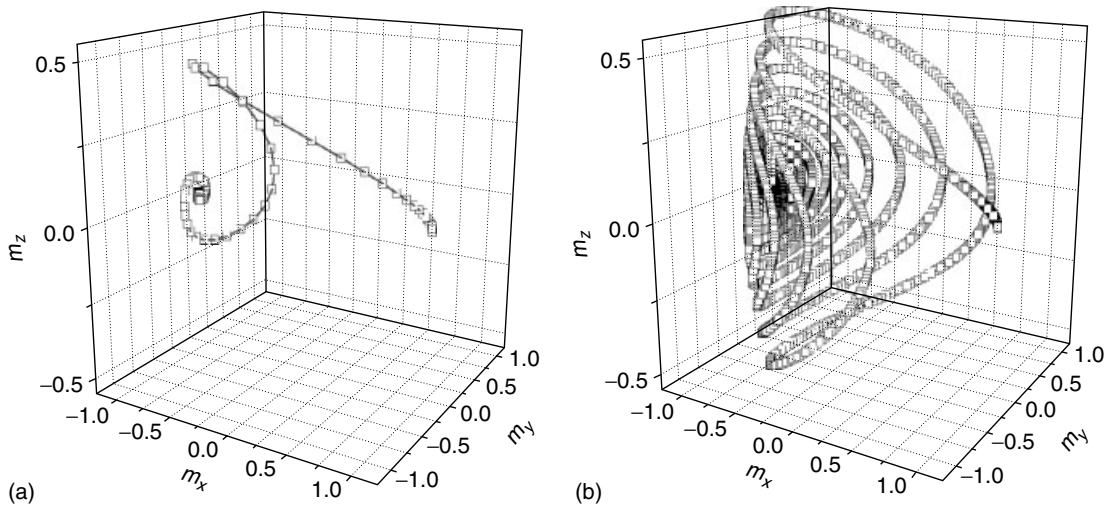

Figure 11. The trajectory (spin directions) of single domain permalloy ($Ni_{80}Fe_{20}$) systems are shown during the reversal from $m_x = 1$ (spin pointing along the positive x-direction) to the field direction (5° away the $-x$ direction toward $-z$ as visible in the final direction of the spin) for a damping of $\alpha = 0.2$ (a) and $\alpha = 0.02$ (b). The anisotropies are equivalent to those of a particle with aspect ratio 10:10:1 (x:y:z) and the field strength is x-component $-63.8\,\mathrm{kAm^{-1}}$; z-component $-5.6\,\mathrm{kAm^{-1}}$.

fields can be calculated for ellipsoids of revolution for a field applied along the direction of the long axis of the ellipsoid and is then given by Aharoni (1997):

$$H_{\text{curl}} = \frac{M_s}{2} \frac{a_x a_z}{\sqrt{a_z^2 \sin^2\theta + a_x^2 \cos^2\theta}} \tag{22}$$

with θ the angle between the applied field and the long axis of the ellipsoid, $a_{x,z} = 2N_{x,z} - k/S^2$, $N_{x,z}$ the demagnetization factors, $S = R/l_s$, and R the minor semiaxes of the ellipsoid. The parameter k is a monotonically decreasing function of the aspect ratio of the ellipsoid with values ranging from $k = 1.079$ for an infinite cylinder to $k = 1.379$ for a sphere (Aharoni, 1986). As an example, the switching fields for a long cylinder for various values of S are shown in Figure 12. For $S<1$ the switching field for coherent rotation reversal is lower and switching occurs by coherent rotation. It should be pointed out that, in contrast to the mode of coherent rotation, the curling mode is limited to these geometries and cannot be analytically extended to cope with any three-dimensional anisotropy functions, but approximate calculations have been proposed (Aharoni, 2000; Ishii, 1991).

In addition to reversal by the curling mode, some authors (Kronmüller and Fähnle, 2003) consider the buckling mode, while for others the existence of further modes is more contentious (Aharoni, 1996). The buckling mode is obtained by starting from the uniform mode and modulating the magnetization direction in sinusoidal fashion along the cylinder axis. The extra exchange energy is then compensated by the reduced stray field energy due to alternating surface charges. Only for a small geometry range can this mode have a lower critical switching field (Aharoni, 1996; Kronmüller and Fähnle, 2003). Such a reversal mode has also been reported to occur in wire structure (Adeyeye *et al*., 1996, Kryder *et al*., 1980) (see also Section 5.5).

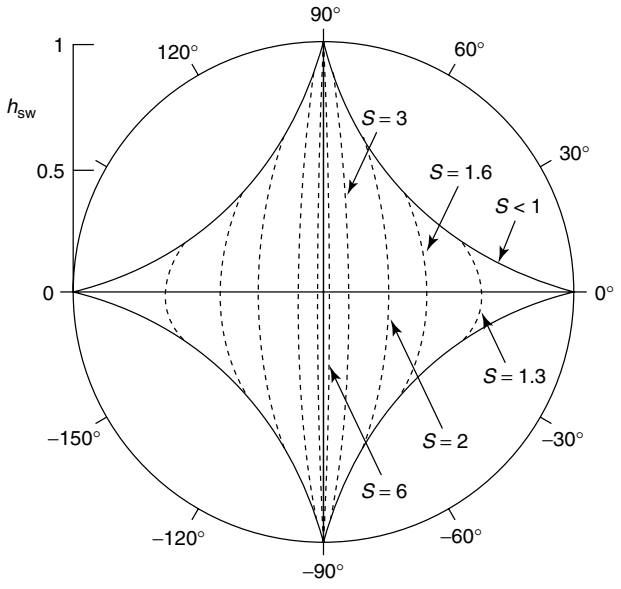

Figure 12. Angular dependence of the switching fields of the curling mode calculated according to equation (22) for an infinite cylinder. (Reproduced by permission of Wiley-Interscience from W. Wernsdorfer, (2001). Classical and quantum magnetization reversal studied in nanometer-sized particles and clusters. *Adv. Chem. Phys.*, **118**, 99.)

7.4 Experimental evidence for nonuniform reversal modes

As theoretically discussed in Sections 4 and 7.3, reversal via coherent rotation is reserved for a limited set of systems. Most magnetic structures exhibit more complicated reversal modes. One of these modes is reversal by curling as theoretically treated in the previous section. This reversal mode was predicted to prevail in long wire structures, where the wire radius is larger than the exchange length. The calculated dependence of the switching fields is compared with measured values for Ni wires with different radii in Figure 13.

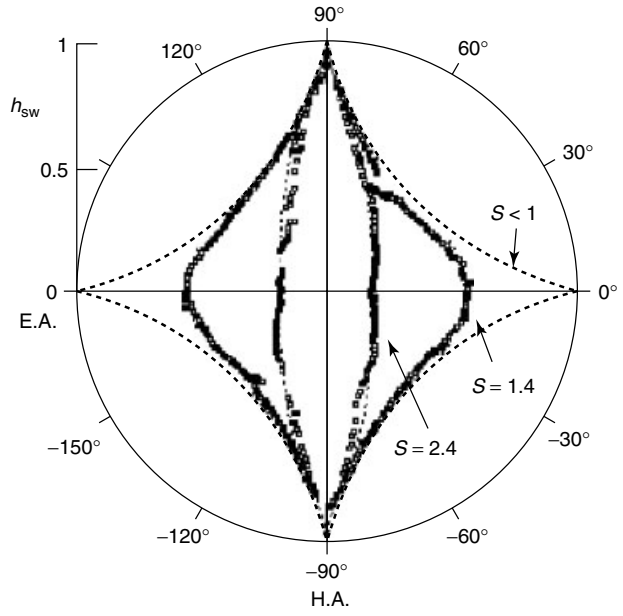

Figure 13. Angular dependence of the experimentally measured switching fields of two Ni wires with diameters of 45 and 92 nm corresponding to S = 1.4 and S = 2.4 (squares) and theoretical values (dotted line). The switching fields are normalized by 124 mT (99 kAm^{-1}) and 280 mT (224 kAm^{-1}) respectively. (Reproduced by permission of Wiley-Interscience from W. Wernsdorfer, (2001). Classical and quantum magnetization reversal studied in nanometer-sized particles and clusters. *Adv. Chem. Phys.*, **118**, 99.)

It should be pointed out that the curling mode as developed theoretically (Aharoni, 1996) does not describe the complete reversal. It rather describes points of instability where the reversal sets in, from which the angular dependence of the switching fields can be predicted, for example. Dynamic measurements on wires have often yielded a nucleation volume that is much smaller than the wire volume (Wernsdorfer *et al*., 1996a,b, 1997b). This points to a more inhomogeneous reversal that starts in part of the wire and then propagates along the wire to completely reverse it and not to a reversal taking place uniformly along the wire. This picture is also supported by theoretical calculations and micromagnetic simulations (Ferré *et al*., 1997; Braun, 1999). This already points to the limits of the applicability of the reversal modes discussed above.

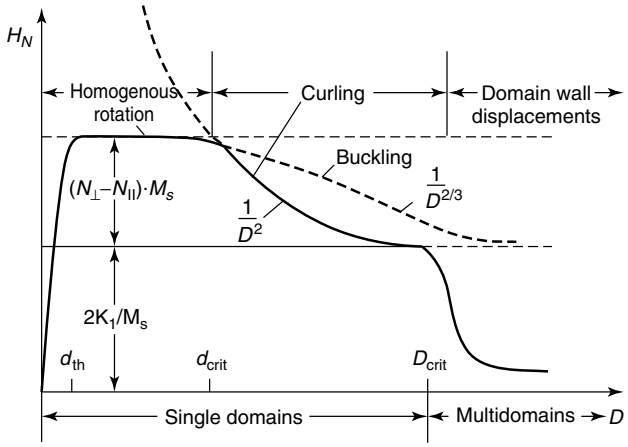

Figure 14. Schematic of switching fields of the different reversal modes as a function of particle diameter. The type of magnetic configuration is also shown in the bottom axis (single domain or multidomain, which includes nonuniform configurations here). (Helmut Kronmüller, Manfred Fähnle, Micromagnetism and the Microstructure of Ferromagnetic Solids, (2003), Figure 6.12. Cambridge University Press.)

7.5 Size range for magnetization reversal by coherent rotation, curling, and buckling

Now that the main different reversal modes in single domain systems have been discussed, a brief review of the applicability of the theory is appropriate (Schmidts, Martinek and Kronmüller, 1992).

An experimental example of a measurement where the limits of the applicability of the single domain theory becomes clear was already carried out by Kneller and Luborsky (1963) who measured the coercivity and remanence of Fe particles as a function of size. This result is shown schematically in Figure 14. A maximum switching field is observed for particle size between d_{th} and d_{crit}, while below d_{th} the coercivity is reduced due to thermal excitations (superparamagnetism (Aharoni, 1996; Bean, 1955; Bean and Livingstone, 1959)) (and we may also expect that the classical 0 K theory discussed here is not applicable for very small systems, where quantum effects play a significant role, as for example, in molecular magnets (Hilzinger and Kronmüller, 1972; Hilzinger and Kronmüller, 1973; Wernsdorfer, 2001)).

In the region where the coercivity is maximum, the switching fields usually agree with the theories of coherent rotation for single domain systems presented in Section 4.1 (Aharoni, 1986). The switching field for coherent (homogeneous) rotation of an ellipsoidal particle, $H_N = 2K_1/M_s + (N_\perp - N_\parallel)M_s$, is due to the superposition of the material anisotropy K_1 (e.g., magnetocrystalline) and the shape anisotropy, represented by the demagnetizing factors $N_\perp$ and $N_\parallel$ (Kronmüller and Fähnle, 2003).

At d_{crit}, the transition from reversal by coherent rotation to curling and buckling occurs (see Kronmüller and Fähnle (2003); Frei, Shtrikman and Treves (1957) for details). D_{crit} is the diameter above which domain formation sets in, which is of the order of l_k (Section 3.5). Such magnetization configurations then experience a very inhomogeneous reversal. Next, we will expand on such nonhomogeneous reversal modes including the reversal of structures that also exhibit nonhomogeneous magnetization configurations, such as those discussed in Sections 5 and 6.

7.6 Inhomogeneous reversal

For inhomogeneous magnetization configurations such as nonuniform and multidomain magnetization configurations, the reversal can be expected to be inhomogeneous. We discuss here transitions between some of the nonuniform magnetization configurations presented in Sections 5 and 6.

The details of the actual switching processes shown here were obtained from micromagnetic simulations (see also **Numerical Micromagnetics: Finite Difference Methods, Volume 2** and **Numerical Methods in Micromagnetics (Finite Element Method), Volume 2**), since they allow direct access to the magnetization configurations, which are more instructive than *M-H* curves for example. Furthermore, single shot nanometer and picosecond scale space- and time-resolved measurements are very difficult. While there are some measurements of the dynamical switching processes, these have been primarily measured for larger structures using fast-pulsed fields and not for the quasistatic reversal we treat here This is because most dynamic measurements are pump probe (Schumacher *et al*., 2003; Beach *et al*., 2005) which are more suited to repeatable dynamic reversal than

to quasistatic reversal that can contain stochastic features. Where both simulations and experiments have been carried out, micromagnetic simulations have been shown to give a good indication of the dynamics of the reversal process, and this is in particular true when the original and final magnetic state as well as the switching fields agree with the experimental results.

Since in larger elements the effective field is inhomogeneous, the magnetic states as well as the reversal are inhomogeneous. We have seen that we can categorize the magnetic states into two broad categories, nonuniform and multidomain states containing domain walls. Since the reversal depends on the initial and the final magnetization configuration, there are a large number of combinations that lead to a large number of different reversals. Thus, it is not possible here to discuss the details of all the different reversal modes for all geometries. But, similar to the categorization of the states, we can categorize the reversal according to the fundamental processes that occur most frequently: (i) rotation of spins (coherent or noncoherent), (ii) nucleation of domains and domain walls, (iii) propagation of domain walls, and (iv) annihilation of domain walls. We emphasize, however, that the boundaries between these categories are not strict.

We start with a case where the initial and final states are simple and do not deviate much from the single domain state, such as the S-state (see Figure 9) and for which we expect a rather simple reversal. When an opposite field is applied to this S-state, the magnetization switches to the opposite S-state at a critical switching field. For a certain geometry ($500 \times 125 \times 3\,\mathrm{nm}^3$ NiFe), this is the micromagnetic standard problem #4, which is a test case for micromagnetic calculations but also relevant for applications, where elements of this size are often considered. Solutions have been variously calculated (Kronmüller, Fischer, Hertel and Leineweber, 1997; Kronmüller and Hertel, 2000; Albuquerque, Miltat and Thiaville, 2001; McMichael, Donahue, Porter and Eicke, 2001; Tsiantos, Suess, Schrefl and Fidler, 2001) and can involve intermediate states that are more inhomogeneous than the initial and final S-state. The magnetization configurations during such a reversal are shown in Figure 15. We see that first the area at the edges of the bar reverses, since there the torque on the magnetization by a reverse field is largest. In the center, the magnetization is still pointing in the original direction. The area where the spins have reversed then expands to cover the whole sample and the opposite S-state is attained. Depending on the size of the element, this reversal can involve very inhomogeneous states in larger elements, but, as the size decreases, the reversal becomes more homogeneous until the coherent rotation process is obtained for single domain particles. In larger elements, such as the one discussed in the preceding text, intermediate states occur that resemble multidomain states, even though the domains are transient features where the size

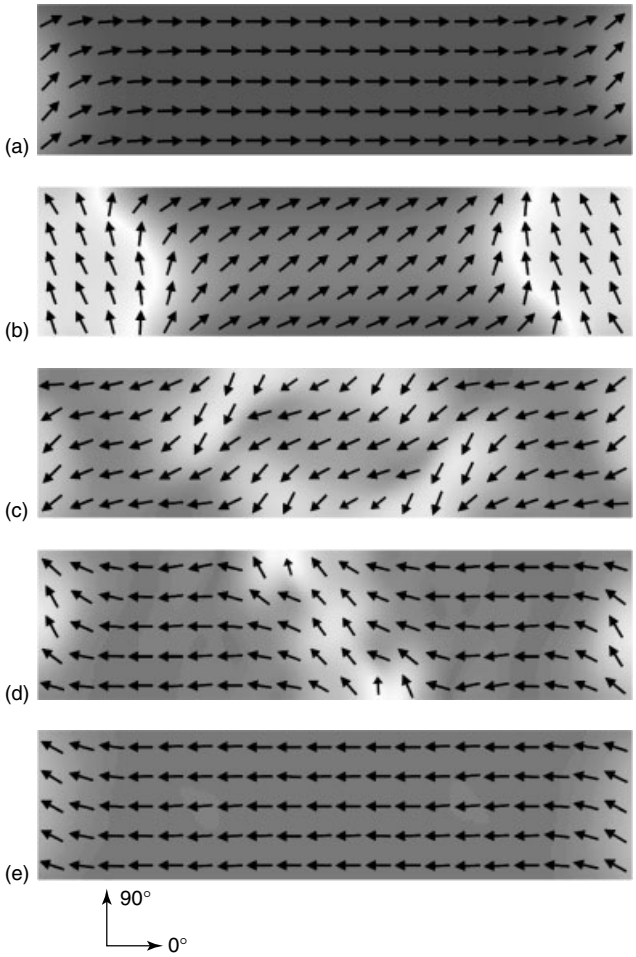

Figure 15. Magnetization configurations during the transition from the S-state to the opposite S-state in a $500 \times 125\,\mathrm{nm}^2$ NiFe element with 3 nm thickness. A field of 250 Oe ($\approx 20\,\mathrm{kA\,m^{-1}}$) is applied along 170°. (a) S-state at remanence; (b) after the field is applied, first the areas at the borders start to reverse; (c), (d) during the switching, different inhomogeneous states are attained; (e) the opposite S-state.

and the angle between them changes very quickly. These have also been observed experimentally (Choi *et al*., 2001; Hiebert, Lagae and De Boeck, 2003).

For the more complicated processes involving domain walls, we can concentrate on one geometry, which exhibits transitions involving all the processes mentioned above. A suitable choice is the ring geometry, since it exhibits well-defined and well-understood states with and without domain walls that have been discussed in Section 5.2. We recall briefly the magnetic states, observed in rings: (i) the flux closure vortex state, which does not contain domain walls; (ii) the onion state, characterized by the presence of a head-to-head and a tail-to-tail wall (see Figure 8). The *M-H* hysteresis loop of such a ring exhibits a double switching (open circles in Figure 16).

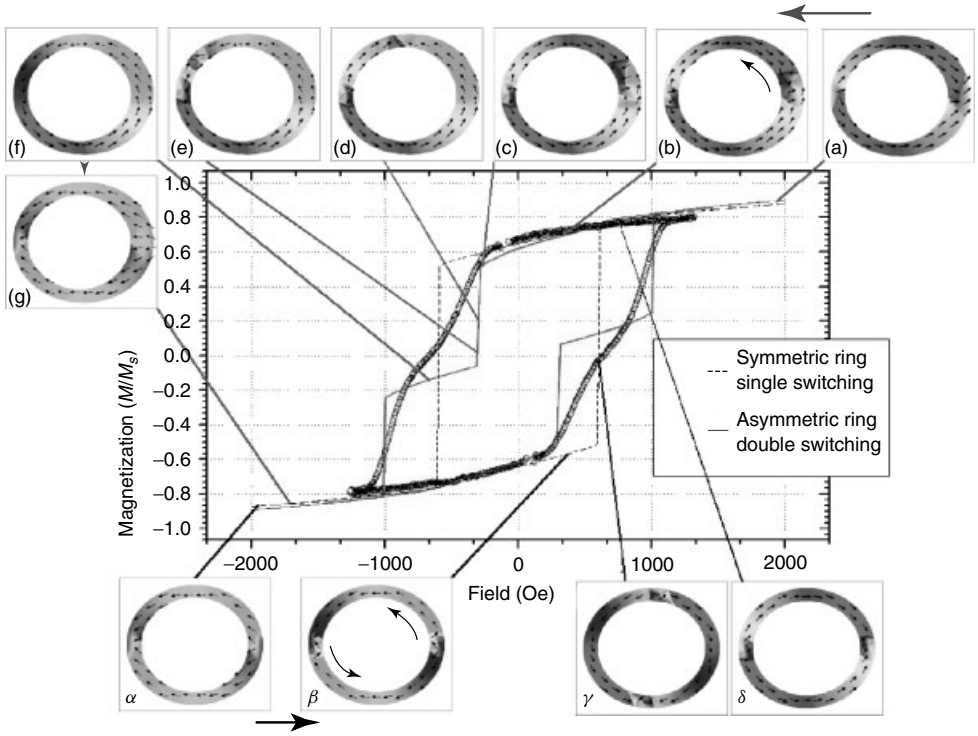

Figure 16. Dotted line with a single jump: Calculated hysteresis loops of a symmetric ring (outer diameter $D_{\text{ext}} = 1625\,\text{nm}$, width $W = 170\,\text{nm}$, thickness $t = 34\,\text{nm}$ fcc Co); Solid line with a double jump: Calculated hysteresis loops of an asymmetric ring (outer diameter $D_{\text{ext}} = 1625–1750\,\text{nm}$, width $W = 170–220\,\text{nm}$, thickness $t = 34\,\text{nm}$ fcc Co); open circles: Experimental data for an array of such rings (from Rothman *et al*., 2001). The calculated magnetization configurations for the onion-to-vortex transition are shown in insets (a)–(f) (color code as in Figure 17). (g) Shows the reverse onion state. It is found that the symmetric ring switches directly from the onion to the reverse onion configuration (insets $\alpha - \delta$). (Reprinted figure with permission from Rothman *et al*., *Phys. Rev. Lett.* **86**, 1098 (2001). Copyright 2001 by the American Physical Society.)

Here, we detail the physical processes occurring during the reversals. A double switching is observed in the experiment and, if asymmetries are present in the ring, as in all experiments, the simulations also yield a double switching (solid line) (Rothman *et al*., 2001). Let us concentrate on the first transition from a state containing domain walls to one without. After relaxing the field from positive saturation, the onion state is formed (first with a transverse domain wall Figure 16(a) and then, as the field is relaxed to zero, with a vortex domain wall (b), depending on the geometry (Kläui *et al*., 2004b, 2004d)). After reversing the field, both walls feel a force with a direction that depends on the wall position with respect to the field direction (Kläui *et al*., 2002c). Since one wall is, in general, more strongly pinned than the other, a transition into a vortex state takes place when the other wall has de-pinned (in the direction of the black arrow in Figure 16b) and has moved toward the pinned wall (Figure 16c–e), resulting in the annihilation of both walls (Figure 16f). The simulated switching field for the onion-to-vortex transition, $H_{C1} = 350$ Oe ($\approx 28\,\text{kA}\,\text{m}^{-1}$), falls well within the distribution of the experimental values (Rothman *et al*., 2001).

There is direct evidence for this reversal mechanism since in some rings the domain walls were pinned during their propagation somewhere around the perimeter of the ring and such states (similar to Figure 16d) have been observed (Welp *et al*., 2003; Zhu, 2002). Furthermore, by using a notch to selectively pin one of the domain walls, we have been able to make use of this switching process in order to control the domain wall propagation and thereby select the circulation direction of the resulting vortex state (Kläui *et al*., 2002c).

This transition from a state with domain walls (onion state) to one without (vortex state) exhibits the typical features of transitions characterized by the propagation and annihilation of domain walls. Here, two domain walls annihilate each other, while in other cases domain walls can also be annihilated by simply being pushed outside the magnetic element. Examples are the transition from a multidomain Landau state (Figure 9) to a quasiuniform S-state when a field is applied to a rectangular bar (García *et al*., 2002; Chapman *et al*., 1998), or transitions from more complicated multidomain states to quasiuniform states in rectangles and squares (Gomez *et al*., 1999a; Gu *et al*., 1998). In discs, the transition from the vortex to the S-state or C-state takes place via the displacement and the annihilation

of the vortex core, which is annihilated (expelled) at one of the edges. In wide rings, where the 'vortexcore' state (Kläui *et al*., 2003a) is present, the reversal from the vortexcore state to the onion state takes place by a similar expulsion of the vortex core (Kläui *et al*., 2004a; Kläui, Vaz, Lopez-Diaz and Bland, 2003).

In simulations, an asymmetry had to be introduced into the ring (variation of the ring width) to reproduce the onion-to-vortex transition. In the *M-H* loop of a perfectly symmetric ring (dotted line in Figure 16), only one transition is observed: the ring switches directly from one state containing domain walls (onion state) to the opposite onion state that contains the same number of domain walls, without falling into the vortex state. The switching mechanism in this case is surprisingly simple and close to domain wall motion. The two walls start to move simultaneously in the same rotational direction so that they chase each other around the perimeter of the ring as seen in the insets $\alpha - \delta$ of Figure 16. The onion state is completely switched when the walls have reached the opposite side. Even though this transition is not easily observed with a quasistatic field, it can be induced using pulsed fields (Lopez-Diaz, Kläui, Rothman and Bland, 2001a), varying size and geometry (Zhu *et al*., 2006) or by using fields that are not exactly applied opposite the wall positions (Uhlig and Zweck, 2004). This transition from a state containing domain walls (onion state) to another containing domain walls (reversed onion state) is one of the simplest cases of such a reversal containing domain wall propagation, since here no domain walls have to be nucleated or annihilated. Of course, in such transitions, the number of domain walls does not have to be constant and may in fact involve the nucleation and/or annihilation of domain walls in addition to domain wall motion.

The process we discuss next is that of domain wall nucleation. An example where this occurs is the second transition in Figure 16 (solid line), from the vortex state (Figure 16f) with no domain walls to the onion state (Figure 16g) that contains two domain walls (Kläui *et al*., 2002b). In Figure 17, the magnetization configurations during the reversal are shown as well as the configuration before and after the switching: Figure 17(a) shows the ring in the vortex state at zero field. As the applied field is increased, the spins rotate slightly but the ring remains in the vortex state as seen in Figure 17(b). At the critical field, a reverse domain is nucleated at the edge of the ring (indicated by the black arrow in Figure 17c). This domain then grows in size and the walls gradually propagate along the perimeter of the ring and outwards (Figures 17d–e) until the onion state is attained (Figure 17f). The calculated switching field H_{C2} at around 1000 Oe ($\approx 80\,\mathrm{kAm^{-1}}$) (solid line in Figure 16) again falls within the observed switching field distribution (open circles in Figure 16). Other reversals that contain such processes

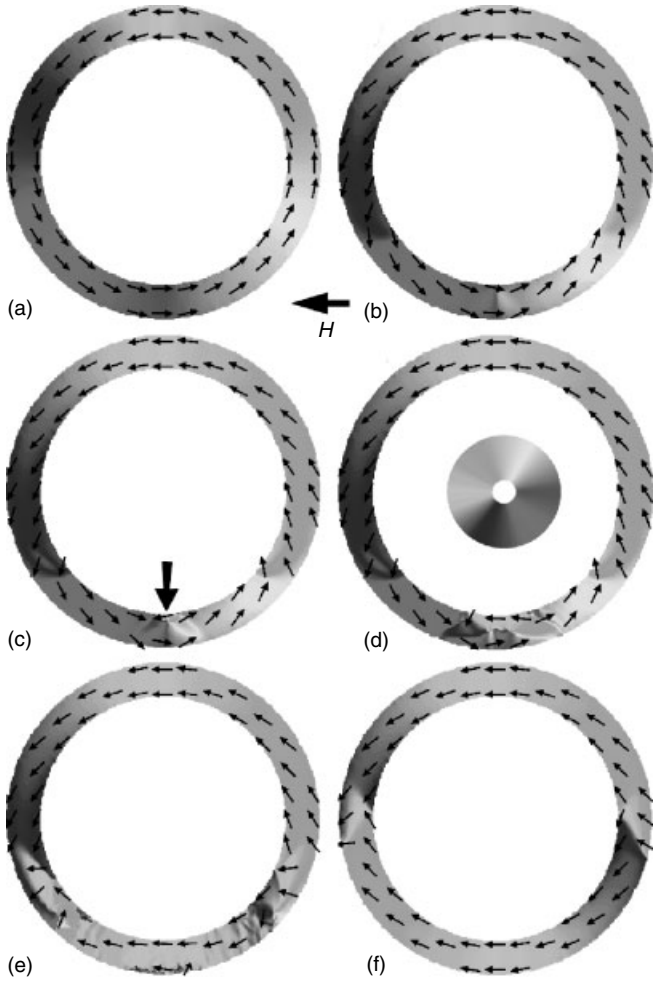

Figure 17. Magnetization configurations during the vortex-to-onion transition. (a) Vortex state at remanence; (b) just before switching; (c), (d), (e) during the switching; (f) onion state. Figures (a), (b), and (f) are equilibrium states, whereas (c), (d), and (e) are snapshots of the dynamics of the reversal. The direction of the applied field is indicated by arrows and the color code for the magnetization directions is presented.

are, for example, the formation of the Landau states and other multidomain states in rectangular bars: when an applied field is reduced from saturation, and an opposite field is applied, domain walls are nucleated at the edges (García *et al*., 2002; Gu *et al*., 1998). Such a nucleation also occurs in other transitions, such as the transition in a disc from the S-state to the vortex state, which occurs by the nucleation of a vortex core at the edge. The core then moves to the center and thereby reverses half of the disc to form the vortex state (Cowburn *et al*., 1999; Wernsdorfer, 2001; Fernandez, Gibbons, Wall and Cerjan, 1998).

A combination of domain wall nucleation, propagation, and annihilation can be found in wires with diameters above the range where reversal by coherent rotation or curling takes

place. The reversal then occurs by the nucleation of a domain wall at one end, the propagation of the domain wall along the wire, which thereby reverses the complete wire, and the final annihilation of the domain wall when it has reached the opposite end (Fidler *et al*., 2002; Ono *et al*., 2001). Wires are discussed in more detail in **Domain Wall Propagation in Magnetic Wires, Volume 2**.

It should be pointed out that, for example, in the case of strong wall pinning (where the field for domain wall propagation is higher than that for domain nucleation), the reversal can be dominated by the nucleation of a large number of reverse domains with only little wall propagation rather than by the nucleation and propagation of a single domain wall (Rosenbusch, Lee, Lauhoff and Bland, 1997). In general, the fields at which a certain process sets in governs the type of reversal.

In summary, the inhomogeneous reversal can be characterized by the interplay of different processes, which can be seen as the building blocks of the actual reversal: (i) rotation of spins, (ii) nucleation of domains, domain walls/vortices, (iii) propagation of domain walls/vortices, and (iv) annihilation of domain walls/vortices. One consequence of these different kinds of processes is that the different switching fields have different temperature dependences (Kläui *et al*., 2004c). For example, the nucleation field of a reverse domain is much less temperature dependent than the domain wall propagation field (Kläui *et al*., 2004c). Furthermore, the different processes also depend differently on defects, such as edge irregularities. This leads, for instance, to a larger switching field distribution for the domain wall depinning and propagation field than for the nucleation of a reverse domain field (Kläui *et al*., 2004c).

There are innumerable reversal routes for small magnetic elements, many of which can be very intricate. But the reversal is most often composed of the processes that we discussed, with each process being individually influenced by intrinsic as well as extrinsic factors.

8 CONCLUSIONS

We have attempted in this chapter to present the general types of magnetization configurations and the reversal processes in small magnetic elements. While it is not possible to give an exhaustive overview of such a vast and fast moving field, we hope that we have nonetheless discussed the most important aspects and provided instructive examples, from which an extrapolation to other systems may be possible.

Theoretically, the systems considered here can be modeled within the micromagnetics framework. This means that the magnetic properties can be described using a classical continuum approximation, which limits us to systems that are large enough so that quantum effects do not play a significant role and small enough so that computational cost is not prohibitive. This size regime between a few nanometers and a few micrometers is extremely relevant for applications. At the same time, such systems exhibit novel physical properties that are distinctly different from the bulk magnetic properties, due to their reduced dimensions (2-D films, 1-D wires, 0-D dots), and because an appreciable fraction of the atoms is located at surfaces or interfaces.

The different energy terms that are relevant in determining the magnetization configurations have been discussed:

(1) For very small systems, *the exchange energy* dominates, favoring single domain states, which can be described by a macrospin. Such systems are described theoretically by the analytical Stoner–Wohlfarth theory. At zero field, the equilibrium magnetization directions are governed by the *anisotropy energy* due to the electronic structure, strain, or other symmetry-breaking effects. Experimental examples of systems that exhibit a range of anisotropies and behave as single domain structures have been presented.

(2) For larger structures, the stray field becomes important and the *magnetostatic self-energy* governs the magnetization configurations. To minimize the stray field, the spins align themselves with the periphery of the element and thus the shape strongly influences the magnetic states. Elements tend to exhibit magnetization configurations that are commensurate with the geometry, such as the vortex state in a disc or a ring and Landau states in rectangular elements. Adding anisotropies yields states that are governed by the interplay between the three energy terms, such as the combination of the vortex and the quadrant state in a disc with a fourfold anisotropy.

(3) When external fields are applied, the *Zeeman energy* starts to play a role by trying to align the magnetization with the field direction. This leads to the concept of magnetic reversal, when elements change their magnetization configuration in response to the field. Theoretically, the reversal can be described within the micromagnetics theory by the Landau–Lifshitz–Gilbert equation, which describes the precession of the magnetization around the applied field direction and includes a phenomenological damping term that accounts for energy dissipation and which forces the magnetization to align with the applied field direction. For single domain systems, these two terms manifest themselves in a superposition of precession and damping that leads to a spiral motion of the spin direction toward the equilibrium position. For more complicated magnetization configurations, inhomogeneous reversal occurs. While the reversal routes can be intricate, they can be broken down into elementary processes for which we give a number of examples.

It is the intricate interplay between these different micromagnetic energy terms that leads to the rich magnetostatic and magnetodynamic behavior observed in small magnetic structures.

ACKNOWLEDGMENTS

We are indebted to a number of people for invaluable help. We would like to thank Professor H. Kronmüller for providing Figure 14. Dr W. Wernsdorfer has kindly helped us revise the section on single domain particles and provided Figures 4, 6, 12, and 13. Dr L. Lopez-Diaz has calculated the data for Figures 11 and 15, has provided valuable micromagnetics insights, and helped with proofreading. We are also very grateful to Professor T. Shinjo, Professor J. N. Chapman, Dr R. E. Dunin-Borkowski, Professor K. J. Kirk, and Dr G. Gubbiotti for kindly allowing us to reproduce here selected figures from their published work. We are also deeply grateful to Professor B. Hillebrands for allowing us to discuss unpublished results. Dr T. Moore has kindly proofread the chapter, for which we are very thankful. It is also a pleasure to acknowledge the contribution of our colleagues and collaborators, from whom we have learned and profited much during these formative years.

M. Kläui is greatly indebted to Professor U. Rüdiger and C. A. F. Vaz to Professor J. A. C. Bland for continuous support.

Magnetic Properties of Systems of Low Dimensions

Rolf Allenspach
IBM Research, Zurich Research Laboratory, Rüschlikon, Switzerland

1 INTRODUCTION

To a large extent, size and geometry govern magnetic domain patterns in large ferromagnetic specimens: it is the long-range magnetic dipolar interaction that is responsible for the occurrence of magnetic domains, and this interaction is determined by an integration over the entire volume of the sample. In this chapter, small objects rather than bulk ferromagnets will be discussed. The topic is closely related to the chapter by Kläui and Vaz (2007). Their chapter covers the range from very small nanometer-sized particles to micrometer-sized objects, with an extensive discussion of the underlying energy terms relevant for a micromagnetic understanding, with a description of the single-domain (SD) particle and its magnetization reversal, and a brief overview on multidomain (MD) states in larger geometries.

In this chapter, a different route is taken. The focus is on well-defined magnetic elements mainly of micrometer size, specifically on their domain structures and their domain walls. In particular, the effects that are related to the presence of boundaries, edges, and constrictions are described, and how they are influenced by geometry of the system is studied. An important aspect is the presence of anisotropy. So far most studies, both experimental and theoretical, have been done in systems in which anisotropy is essentially negligible. In this chapter, emphasis is given to a system in which anisotropy is a key factor in determining domain patterns. We are interested in the size-dependent properties of these domain patterns, and illustrate them in phase diagrams spanning a wide range of length scales and thicknesses. Even though magnetization reversal is closely linked to domain patterns, it is not discussed here – for the sake of brevity. The approach taken is the one of an experimentalist: we concentrate on experimental findings and use micromagnetic simulations to elucidate the physics underlying the observations.

Size effects not only determine domain patterns, but also affect domain walls. The finite, small size of a magnetic element confines the domain wall to a narrow environment, and thereby modifies domain-wall profiles and types in a controlled way. This geometrical tunability is a new aspect of domain walls that is starting to be exploited in alternative schemes to move domain walls, such as in spin-transfer torque devices, as described in the chapters by Ono (2007) and Thomas and Parkin (2007).

In both of these topics, 'low dimensional' is synonymous to 'small in size'. Magnetism in low-dimensional systems, however, has an additional important aspect that extends beyond a mere comparison of simulated micromagnetic patterns with their experimental counterparts. 'Low dimensional' has a specific thermodynamic meaning: effects that require a description in a three-dimensional framework are excluded. Typical properties in ferromagnets relating to this type of dimensionality are phase transitions. As cooperative

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

phenomena, they are described by order parameters and critical exponents. It is not intended to provide a comprehensive report of the physics of phase transitions in low-dimensional ferromagnets. Instead, phase transitions are approached from a microscopic viewpoint by classifying the phases and their transitions according to domain patterns and their origin. This specific topic thus embraces two seemingly disparate fields of condensed matter physics: micromagnetism and critical phenomena.

Even by limiting this chapter to these three topics, it would be a hopeless task to aim for an all-embracing review. The theme of low-dimensional ferromagnets is therefore presented by means of examples: Three specific systems illustrate low-dimensional phase transitions, domain patterns, and domain walls. Section 2 is devoted to ultrathin, perpendicularly magnetized Fe/Cu films. Their rich variety of stripe-domain phases provide new insight into the microscopic aspects of phase transitions in two dimensions. Small elements of a ferromagnet with in-plane magnetization and tunable anisotropy are discussed in Section 3. The Co/Cu system exhibits a wide range of different domain patterns that distinctly depend on the lateral size and thickness of the elements. Finally, in Section 4, geometric confinement is extended from domains to domain walls. Domain walls in small $Fe_{20}Ni_{80}$ elements exhibit complex spin arrangements that strongly deviate from the wall types commonly encountered in magnetic thin films, and they can be modified and tuned by changing the size of the element and by introducing constrictions.

2 PHASES AND PHASE TRANSITIONS

This section deals with dimensionality in a thermodynamic sense: effects in ferromagnets that are two-dimensional (2D) rather than three-dimensional (3D) are considered. Hence aspects in magnetic films that relate magnetic properties to cooperative phenomena and their phase transitions are discussed. Phase transitions are characterized by a specific set of parameters, such as order parameters and critical exponents. Note that by restricting ourselves to 2D effects, we do not necessarily limit the system size: the important quantity is the correlation length. For a system to be regarded as 2D, the only requirement is that the correlation length has to be bigger than one of the system extensions.

The prototypical system for the investigation of 2D phase transitions is a magnetic film. In fact, the development of many theories describing phase transitions was inspired by ferromagnetic model systems. The nature of the phase transition and many of its properties are determined by magnetic anisotropies. For vanishing anisotropy, the isotropic Heisenberg model describes reality best, whereas for large uniaxial anisotropy, it is the Ising model. Both these limiting cases (and also intermediate ones) have been investigated in detail in a variety of magnetic films. In almost all studies, the goal was to deduce the critical exponent that describes the approach of the magnetization to Curie temperature, T_C. Experimentally, the critical exponents vary widely, covering the entire range from the mean-field-approximation value to the exponent characteristic of the Ising model. A few model systems exist that seem to be magnetically simple enough to exhibit unequivocal behavior. A prominent one is an ultrathin Fe film, only one or two monolayers (MLs) thick, grown on W(110) (Elmers, Hauschild and Gradmann, 1996). This system, with its uniaxial in-plane anisotropy, essentially behaves as a 2D Ising system. Critical exponents are very close to those expected for the Ising system, and the universality hypothesis has been experimentally confirmed with high accuracy, even with a magnetic field applied (Back *et al*., 1995).

Although such studies test and confirm very fundamental assumptions in theories of cooperative phenomena, they do not provide insight into the microscopic aspects of phase transitions. Length scales, in particular, enter only through the scaling hypothesis, and the order parameter – magnetization – is a macroscopic quantity. The investigation of microscopic aspects of phase transitions is experimentally demanding. At T_C, the spontaneous magnetization vanishes, and temporal fluctuations may become relevant. On the theoretical side, the situation is of similar complexity. For instance, even for the simplest model – the 2D Ising system – no exact solution for the transition in an external field is known.

In the past few years, however, remarkable progress has been made in the understanding of the microscopic aspects of these phases and their transitions. Most of the progress comes from the investigation of Ising systems, realized in perpendicularly magnetized ferromagnetic films. These films exhibit two characteristics that make a microscopic investigation rewarding: the existence of a specific domain state, a regular array of stripe domains, and the occurrence of a spin-reorientation transition, in which the magnetization changes direction. Theoretically, the challenge comes from the fact that a strong short-range interaction – the exchange – competes with a weak long-range interaction, the dipole–dipole interaction. 2D systems with short-range attraction and long-range repulsion are widespread and include – besides the ferromagnets – for instance, polymers, gels, self-assembled MLs, and ferrofluidics. In the following text, some recent investigations of the microscopic properties of phases and phase transitions in perpendicularly magnetized ferromagnets are summarized; but the implications might eventually go beyond this class of materials. In these investigations micromagnetism is relevant, but equally

important is an understanding of the topology and critical phenomena.

2.1 Perpendicular magnetization and the spin-reorientation transition

Domain patterns in perpendicularly magnetized films have been investigated theoretically almost since the first realistic micromagnetic approaches appeared. Kittel (1946) considered the case in which the thickness of the ferromagnet is much larger than the domain size, so that the magnetostatic interaction of the two surfaces could be safely neglected. He concluded that the domain width in a regular array of stripe domains increases with the square root of the film thickness, provided that the relevant material constants, such as magnetization and anisotropy, remain the same. This result was extended to films for which the thickness is comparable with the domain width (Málek and Kamberský, 1958), and later on, the influence of an applied magnetic field was also considered (Kooy and Enz, 1960). All these approaches were essentially based on analytical micromagnetic models, complemented where necessary by partial solving of the problems numerically.

Garel and Doniach (1982) looked at the domain pattern from a different perspective. They realized that stripe domains and their transformation in a magnetic field could be described as a phase transition. A 2D Ginzburg–Landau model was applied, and a first-order transition to a hexagonal bubble phase was predicted, followed by a further transition to the uniform, saturated state. Close to the critical temperature, stripe or bubble melting was predicted to occur. Here, dimensionality embraced micromagnetism: it was explicitly mentioned that because of the long-range character of magnetic dipolar forces the dimensionality becomes relevant.

The formation of the stripe-domain phase results from a competition between a short-range interaction – the exchange that tends to align neighboring spins – and the long-range dipolar interaction favoring antiparallel alignment between distant spins. By application of a magnetic field, the stripe pattern can be transformed into various domain arrangements, such as bubbles, mazes, chevrons, or labyrinths (Molho *et al.*, 1987). The extrapolation of these thick films to the ultrathin limit is not straightforward, and the analogy to smectic liquid crystals was pointed out (Sornette, 1987). In their pioneering paper, Yafet and Gyorgy (1988) finally calculated that a stripe-domain configuration is also the ground state in zero magnetic field in the ultrathin limit, provided that the ratio of anisotropy and magnetostatic energy is close to 1. Numerical simulations (Kaplan and Gehring, 1993) confirmed that the stripe-domain phase is very close to but slightly lower in energy than the checkerboard configuration (Czech and Villain, 1989) and suggested that an irregular domain pattern as observed in ultrathin Co/Au(111) films (Allenspach, Stampanoni and Bischof, 1990) is consistent with this model. Whereas, originally, the magnetization in the walls between the stripes was assumed to vary like a cosine function (Yafet and Gyorgy, 1988), it was recently stated that this profile is modified by the long-range dipolar interaction, and hence the magnetization modulation depends on the stripe width (Kisielewski, Maziewski, Polyakova and Zablotskii, 2004).

Ultrathin film systems with stripe domains often exhibit an additional interesting characteristic: a spin-reorientation transition. In films with perpendicular magnetization, a reorientation of the spin is the natural consequence of the shape anisotropy winning over surface anisotropy at large thickness or at high temperature. The easy magnetization axis changes and the spins reorient, as shown in Figure 1. Only if the Curie temperature happens to be below the reorientation temperature, does the perpendicular magnetization exist up to the paramagnetic phase. Both cases exist and will be illustrated.

Figure 1 illustrates the microscopic features of a spin reorientation in a 5.3-ML fcc-Fe/Cu(001) film (1 ML = 0.18 nm) with increasing temperature (Allenspach and Bischof, 1992),

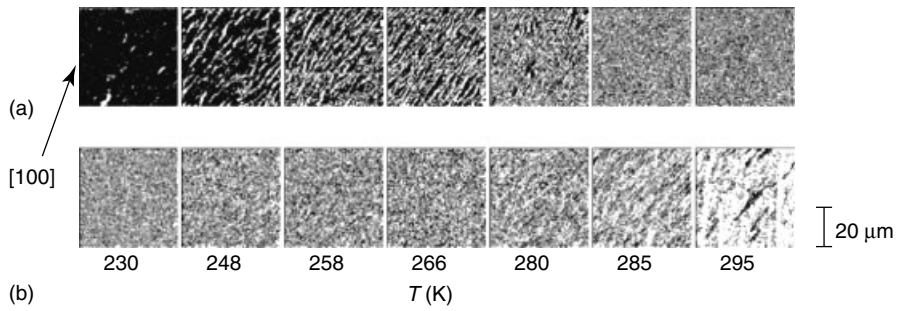

Figure 1. Evolution of the domain pattern in 5.3-ML fcc Fe on Cu(001) with temperature. (a) Out-of-plane magnetization component, (b) in-plane magnetization component. Stripe domains are formed and stripe narrowing occurs with increasing temperature before the magnetization reorients into the plane. (Reproduced from Allenspach and Bischof, 1992, with permission from the American Physical Society. © 1992.)

determined experimentally by spin-polarized scanning electron microscopy (spin-SEM) (Allenspach, 2000). Below $T = 230\,\mathrm{K}$, the film is perpendicularly magnetized and in an SD state. With increasing temperature, irregularly shaped, reversed domains nucleate, growing in number as the temperature increases further. These domains elongate and start to form a stripe-domain pattern, with stripes running along the crystallographic [100] direction. At even higher temperatures, the distance between stripes narrows. Finally, the magnetization reorients into the plane, and an irregular domain pattern forms.

The observation of a stripe pattern qualitatively confirmed the predictions by Yafet and Gyorgy (1988). The stripe period, however, remained unexplained: it should only be accessible to the experiment if the perpendicular anisotropy and the magnetostatic energy (or shape anisotropy) nearly cancel each other. Otherwise, the stripe period should grow beyond typical sample sizes and hence an SD state should be observed. Moreover, the observation of stripe narrowing with temperature contradicted theory (Seul and Wolfe, 1992). However, if finite-temperature spin fluctuations are taken into account (Kashuba and Pokrovsky, 1993; Abanov, Kalatsky, Pokrovsky and Saslow, 1995), the stripe phase is much more abundant and becomes the preferred ground state as long as exchange exceeds a certain value (MacIsaac, Whitehead, Robinson and De'Bell, 1995). Moreover, with increasing temperature, disorder should occur, and the phase transforms from a 2D smectic crystal phase to a nematic phase, and eventually to a fourfold symmetric phase called a tetragonal liquid (Abanov, Kalatsky, Pokrovsky and Saslow, 1995). This transition is a distinct feature of a 2D melting process and is absent in thick magnetic films (Vaterlaus *et al*., 2000). Monte Carlo simulations (Booth, MacIsaac, Whitehead and De'Bell, 1995) arrive at essentially the same conclusion. However, whether the intermediate nematic phase exists or a first-order phase transition occurs remains elusive.

A detailed experimental investigation of the evolution of the striped phase going beyond Allenspach and Bischof (1992) has been recently performed, again in the fcc-Fe/Cu(001) system (Portmann, Vaterlaus and Pescia, 2003). By choosing a smaller thickness of the ferromagnet, the Curie temperature T_C drops below the reorientation temperature and hence the stripe phase can be followed up to the paramagnetic phase (see Figure 2). Far below T_C, stripes are observed to be meandering around a preferential orientation and to exhibit specific defects. Experimentally, four different types of dislocations have been identified, which are in agreement with the topological defect classification (Abanov, Kalatsky, Pokrovsky and Saslow, 1995). At higher temperature, orientational melting occurs, and the domain phase transforms into a more symmetric labyrinth phase in which the stripes terminate preferentially in square corners, confirming the prediction of the tetragonal liquid phase. This fourfold symmetry is not unexpected as it reflects the crystalline symmetry of the Fe/Cu(001) system. It is still a matter of debate whether the transition from the stripe phase to the tetragonal phase is a continuous transition going through a nematic phase or a first-order phase transition. The most recent Monte Carlo simulations and analytical modeling favor a weak first-order transition, based on the calculated scaling of the specific heat (Cannas, Stariolo and Tamarit, 2004). Strikingly, at even higher temperature, the tetragonal order is lost again, and a lower symmetry phase reoccurs with reduced stripe width before the paramagnetic phase is reached (Portmann, Vaterlaus and Pescia, 2003).

The microscopic mechanisms of both the melting and the inverse melting process are quite intricate. In the melting process, the stripes emit fingers and branches orthogonal to the stripe direction, that is, a transverse instability (Molho *et al*., 1987) promotes the loss of orientational ordering. A similar evolution of disorder has been observed in thick garnet films (Seul and Wolfe, 1992). There, the stripe phase transformed through a sequence of highly regular patterns, such as undulations and chevrons, into a phase characterized by disclination defects. The labyrinthine phase in garnets, on the other hand, displays hexagonal

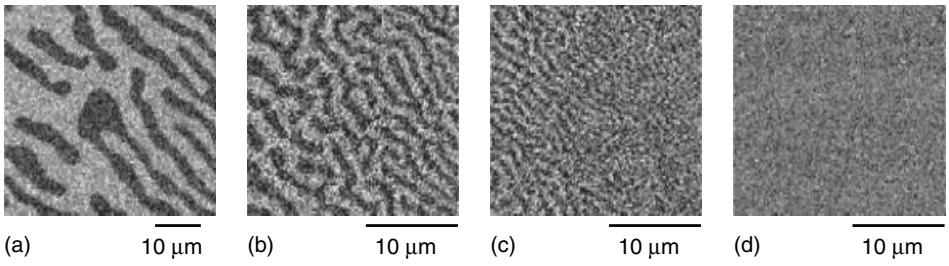

Figure 2. The four domain phases in perpendicularly magnetized ultrathin fcc-Fe/Cu(001) films upon approaching the paramagnetic phase, measured by spin-SEM. The film thickness is 1.89 ML. (a) Stripe phase at $T = 210\,\mathrm{K}$; (b) labyrinth tetragonal liquid phase at $T = 268\,\mathrm{K}$; (c) reentrant stripe phase at $T = 283\,\mathrm{K}$; (d) paramagnetic phase at $T = 313\,\mathrm{K}$. Note that the image size varies as indicated by the scale bars. (Reproduced from Portmann, Vaterlaus and Pescia, 2003, with permission from Nature Publishing Group.)

rather than tetragonal symmetry, controlled by the crystalline orientation, and is reached by a dynamic relaxation that is nonexponential and compatible with the expectations for a glassy state (Reimann, Richter and Rehberg, 2002). The inverse melting process in Fe/Cu(001) goes through repetitive steps of detaching short stripe-domain segments from knee-bend domains to arrive at smooth and straight stripe domains. Here – as in the transition from the stripe phase to the tetragonal liquid phase – the strength of the long-range dipolar interaction might play an important role. This interaction effectively leads to a transverse compressive force on the stripes and, depending on its strength, a crossover from defect-mediated stripe melting (or freezing) to spin disorder is predicted to occur (Stoycheva and Singer, 2000).

Very recently, it was shown that the approach to the paramagnetic phase contains a dynamic component (Portmann, Vaterlaus and Pescia, 2006): the stripe domains become mobile in a narrow temperature interval of a few Kelvin around T_C (see Figure 3). Stripe sections have been observed to displace on a timescale of seconds, locally keeping a high degree of orientational order. This stripe mobility exists upon both annealing and cooling through T_C. These observations are in marked contrast to the phase transition in an in-plane-magnetized thin-film system (Kerkmann, Pescia and Allenspach, 1992), and it has been argued that they are related to a dynamical singularity associated with the liquid-to-glass transition in stripes (Portmann, Vaterlaus and Pescia, 2006). First hints of the existence of a dynamic domainlike behavior near or even above the Curie temperature in perpendicularly magnetized ultrathin Fe/Ni(111) films were already drawn from susceptibility measurements in a detailed investigation of the spin-reorientation transition (Arnold, Pappas and Venus, 1999). The real-space observation of the dynamic aspects of this phase transition goes a step further: it provides new experimental insight into the microscopic nature of 2D phase transitions, against which theories and models can be tested.

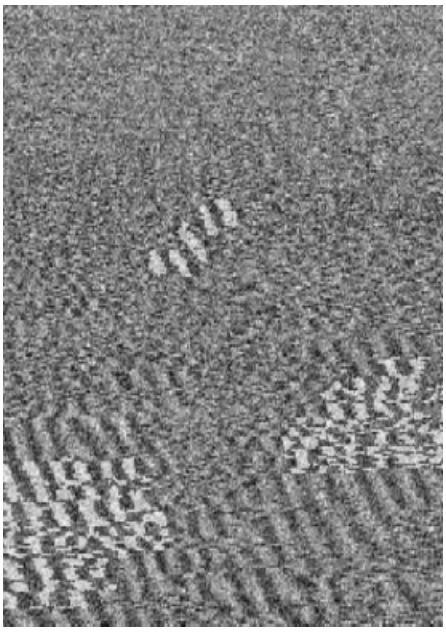

Figure 3. Transition from the paramagnetic to the stripe-domain phase observed by spin-SEM in a fcc-Fe/Cu(001) film of 1.96-ML thickness. The temperature is around room temperature and decreases by 3 K while successive line scans are taken from top to bottom. Image width: 18 µm. The contrast of some of the areas that indicate stripe mobility has been enhanced. (Reproduced from Portmann, Vaterlaus and Pescia, 2006, with permission from the American Physical Society. © 2006.)

2.2 The stripe-domain width

The geometrical and topological classification presented previously describes phase transitions in a rather qualitative manner. Phase transitions, however, are characterized by experimentally verifiable quantitative parameters, such as the scaling lengths and critical exponents. One important parameter of the stripe-domain phase is the average width D of the stripes. In the past decade, several experimental studies were performed to determine the domain width upon approaching the spin reorientation or the ferro- to paramagnetic phase transition. The first determination of the domain size during spin reorientation was done in Co/Au(111) films (Allenspach and Stampanoni, 1992), followed soon after by a systematic study of the evolution of the domain width with the film thickness on a wedge-type sample (Speckmann, Oepen and Kirschner, 1995). It was found that at constant temperature the domain size decreases exponentially upon approaching the spin-reorientation thickness (see Figure 4a). Close to the spin-reorientation thickness, this observation was in line with the prediction (Kaplan and Gehring, 1993) that the domain width D depends on film thickness t according to the functional dependence $D = 0.955\, t \exp(\sigma_w/(4\, M_s^2\, t))$, where σ_w is the domain-wall energy and M_s is the saturation magnetization.

In the Fe/Ni/Cu(001) system, both the thickness and the temperature dependence of D are experimentally accessible. In both cases, D exhibits an exponential dependence (Won *et al.*, 2005; see Figure 4b). The Fe/Ni system is particularly attractive because – for appropriate Fe and Ni thicknesses – anisotropies and demagnetization energies can be balanced in such a way that the spin-reorientation temperature, T_R, is below or above T_C (Zhao *et al.*, 2004). Interestingly, if $T_C < T_R$, the exponential dependence of the domain width on temperature is preserved up to an

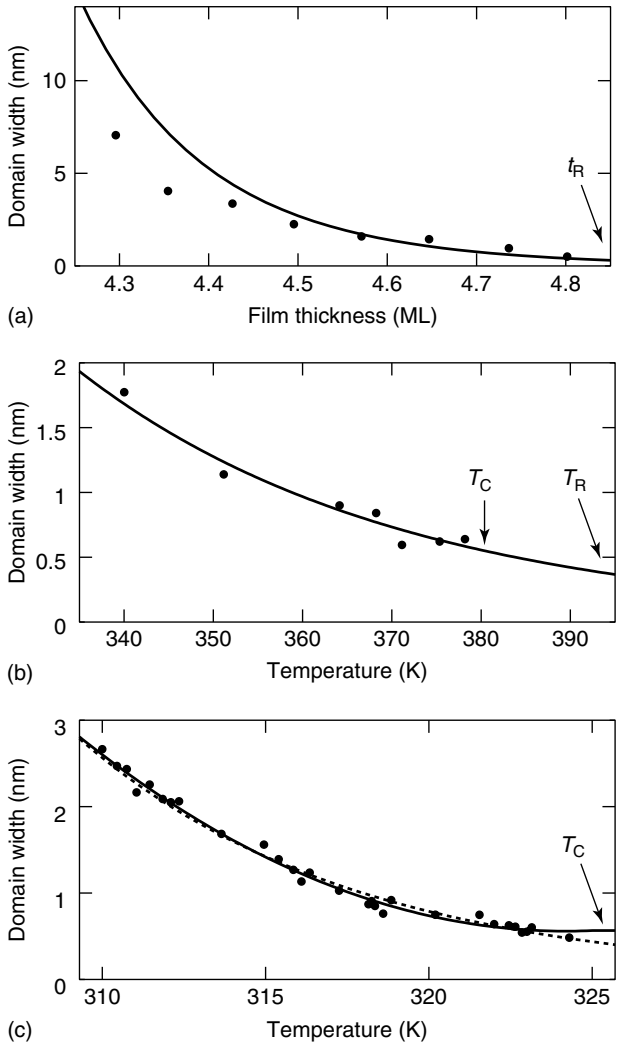

Figure 4. Domain width upon approaching the phase transition. (a) Width versus Co film thickness in the Co/Au(111) system. The reorientation transition takes place at $t_R \approx 4.9$ ML (1 ML = 0.2 nm). The exponential fit follows the model of Kaplan and Gehring (1993), with the only fit parameter being the interface anisotropy. From Speckmann, Oepen and Kirschner (1995). (b) Width versus temperature in the Fe/Ni/Cu(001) system, with 2.7 ML Fe and 5.4 ML Ni (1 ML = 0.18 nm). In this system, $T_C < T_R$, with $T_C \approx 380$ K and $T_R \approx 395$ K. The exponential fit extrapolates through T_C up to T_R. From Won *et al.* (2005). (c) Width versus temperature in Fe on Cu(001), with a Fe thickness of 1.95 ML (1 ML = 0.18 nm). At this thickness, no reorientation transition takes place. T_C is estimated to be 325.7 K. From Portmann, Vaterlaus and Pescia (2006). The solid line gives a quadratic power-law fit, the dashed line the best exponential fit for comparison.

extrapolated T_R, which means that the domain width at T_C remains finite. Similarly, an exponential behavior has also been found in exchange-coupled layers if the anisotropy and interlayer coupling are taken into account (Wu *et al.*, 2004). In the Fe/Cu(001) system, the stripe-domain width has been fitted by a power-law dependence upon approaching T_C, $D \sim D_C + (T_C - T)^2$, keeping a finite width D_C at the transition temperature (Portmann, Vaterlaus and Pescia, 2006; see Figure 4c). The differences to an exponential dependence, however, are minute, and future experiments will have to show whether this is significant. Conceptually, such a phase transition can always be described by a power-law series, and at zero temperature reality is accurately described by an exponential dependence. Hence both approaches tackle the problem from a different perspective: micromagnetics in the case of the exponential dependence and critical phenomena in the case of the power-law dependence.

In summary, the stripe-domain phase is a commonly observed domain pattern in perpendicularly magnetized ferromagnets, in the entire range from ultrathin to thick films. The prerequisite for their existence in micrometer-thick specimens is that the anisotropy is so large that closure domains are energetically avoided. From a purist's point of view, all these systems are strictly low dimensional: for an infinitely extended film, any finite width is sufficient to describe the system as being 2D. Many of the phenomena described occur in specimens of any thickness. It is the competition between attractive short-range and repulsive long-range interactions that leads to the stripe phase and to even more complex modulated phases and the formation of structures on mesoscopic length scales. Nevertheless, significant differences are observed between an ultrathin and a thick film. The reentrant behavior of the stripe phase and its mobility close to the Curie temperature have only been observed in ultrathin films of Fe/Cu(001). It remains a matter for future work to clarify, both theoretically and experimentally, whether these effects are specific to this system or a general feature of ultrathin ferromagnets. The most prominent difference between ultrathin and thick films is the width of the stripe domains. Only in ultrathin films, a strong dependence of the stripe width on the temperature – even far away from the phase-transition temperature – has been observed. This observation is not limited to the Fe/Cu(001) system and has also been theoretically described. In thick films, stripe narrowing is explicitly excluded (Seul and Wolfe, 1992) or considered to be negligible as long as the temperature is not too close to T_C (Molho *et al.*, 1987). Only very close to T_C is the stripe width not frozen and can adjust with temperature. In ultrathin films, fluctuations are much more prominent and extend the critical temperature range. In this respect, the situation is similar to in-plane-magnetized ultrathin films (Kerkmann, Pescia and Allenspach, 1992). The investigation of phase transitions using microscopic imaging has led to new insight into such very fundamental, truly low-dimensional magnetic properties.

3 SIZE DEPENDENCE OF DOMAIN PATTERNS

In this section, effects related to the geometrical dimensions of a ferromagnet are considered. In this respect, 'low dimensional' can be regarded as being synonymous to 'small in size'. Size aspects govern magnetic domain patterns. Hence magnetic domain patterns and their variations with changing size are discussed here. While the exchange interaction tends to keep all spins aligned and thus favors a uniform SD state, the long-range magnetostatic interaction tries to avoid stray fields emanating from the ferromagnetic element. The balance of these two energies is responsible for the existence of an inhomogeneous magnetization distribution: domains and domain walls, or – alternatively – rapidly varying magnetization distributions such as vortices. This balance depends on the size and the geometry. If the sample size becomes smaller than the width of a typical domain wall, this state is replaced by a more uniform magnetization distribution. The transition from a uniform to a nonuniform state is thus determined by the exchange and the magnetostatic energy. The magnetic patterns observed in the nonuniform state, however, are largely governed by magnetic anisotropy. Although this holds for systems with arbitrary anisotropy axis, we restrict ourselves here to systems with in-plane magnetization. The domain patterns in ferromagnets with perpendicular magnetization direction have been discussed in the preceding section, in the context of the stripe-domain phase.

A wealth of studies have been performed to investigate domain patterns in small in-plane-magnetized elements, with the vast majority of the work having been done in NiFe alloys with negligible magnetocrystalline anisotropy (Cowburn *et al*., 1999; Gomez *et al*., 1999; Hubert and Rührig, 1991; Barthelmess, Pels, Thieme and Meier, 2004). Of particular interest, is the transition from the nearly SD state to the nonuniform state with increasing thickness and lateral size of the element. In small disks, domain patterns with well-defined walls are absent because anisotropy is negligible. The nonuniform magnetization distribution corresponds to a circular magnetization arrangement with a centered, narrow core having perpendicular magnetization, the vortex state (Shinjo *et al*., 2000). If the shape of the element deviates from a disk, deviations from both SD and vortex states occur. For the SD state, the geometrical dependencies lead to an effective configurational anisotropy (Schabes and Bertram, 1988), which can stabilize alternative patterns such as leaf states (Cowburn and Welland, 1998a), flower states (Schabes and Bertram, 1988), or even more complex twisted flower states (Hertel and Kronmüller, 2002).

This section discusses domain patterns in a system with nonvanishing magnetocrystalline in-plane anisotropy. We restrict ourselves to one particular model system, namely, epitaxial fcc Co/Cu, rather than providing a comprehensive review of domain formation in such systems. We will vary the thickness t and lateral size L of the elements in a wide range to obtain a complete phase diagram of domain patterns in the (t, L) space. Some regions of this phase diagram have been investigated before, with a focus on small t (Stamm *et al*., 1998) and on the magnetization reversal after an SD state has been set (Oepen, Lutzke and Kirschner, 2002). Epitaxial Co on MgO was also studied, with the emphasis on domain states in elements having small L and large t (Kazakova, Hanson, Blomquist and Wäppling, 2001). Similar patterns are encountered in other epitaxial systems that exhibit nonnegligible magnetocrystalline anisotropy, such as bcc Fe/GaAs(001) (Pulwey, Zölfl, Bayreuther and Weiss, 2003).

Epitaxial Co films grown on stepped Cu(001) substrates exhibit a complex magnetocrystalline anisotropy: because the substrate is miscut from the (001) direction, a uniaxial step anisotropy is superimposed on the cubic anisotropy required by the fourfold symmetry of the Cu(001) substrate (Berger, Linke and Oepen, 1992). The ratio of uniaxial anisotropy K_u to fourfold cubic anisotropy K_1 can be adjusted by the film thickness or the miscut angle, which is equivalent to changing the average step distance. For typical miscut angles of a few degrees, K_u is not larger than a few percent of K_1. Nevertheless it can be accurately determined by analyzing the shape of the hysteresis loop (Weber, Allenspach and Bischof, 1997), and it is responsible for the occurrence of quantum size oscillations in magnetic anisotropy (Weber *et al*., 1996b). Here, we will consider Co/Cu elements miscut by 1° with respect to the (001) direction. The step-edge direction runs along $[1\bar{1}0]$, leading to a vicinal Co(1 1 81) system with an average step distance of 10 nm. The thickness dependence of K_u and K_1 has been determined on continuous films (Weber *et al*., 1996a). At small thickness, the easy magnetization axis is parallel to the step-edge direction. At a thickness of 3.1 nm, the uniaxial anisotropy changes sign. This leads to a switching of the easy magnetization direction by 90° from the $[1\bar{1}0]$ to the [110] direction. Correspondingly, the intermediate axis switches from [110] to $[1\bar{1}0]$. The evolution of the anisotropy constants K_u and K_1 as a function of thickness is shown at the top of Figure 5.

Patterning of the elements can be done in various ways. The approach taken most often is fabrication by lithographic means (either optical or electron beam), which requires the use of photoresists and lift-off techniques (For a review of techniques used to deposit magnetic materials, see Ross, 2001). In ultrathin films, that is, films of a few atomic layers, this technique is applicable only if the films are protected against the ambient atmosphere. Moreover, it is

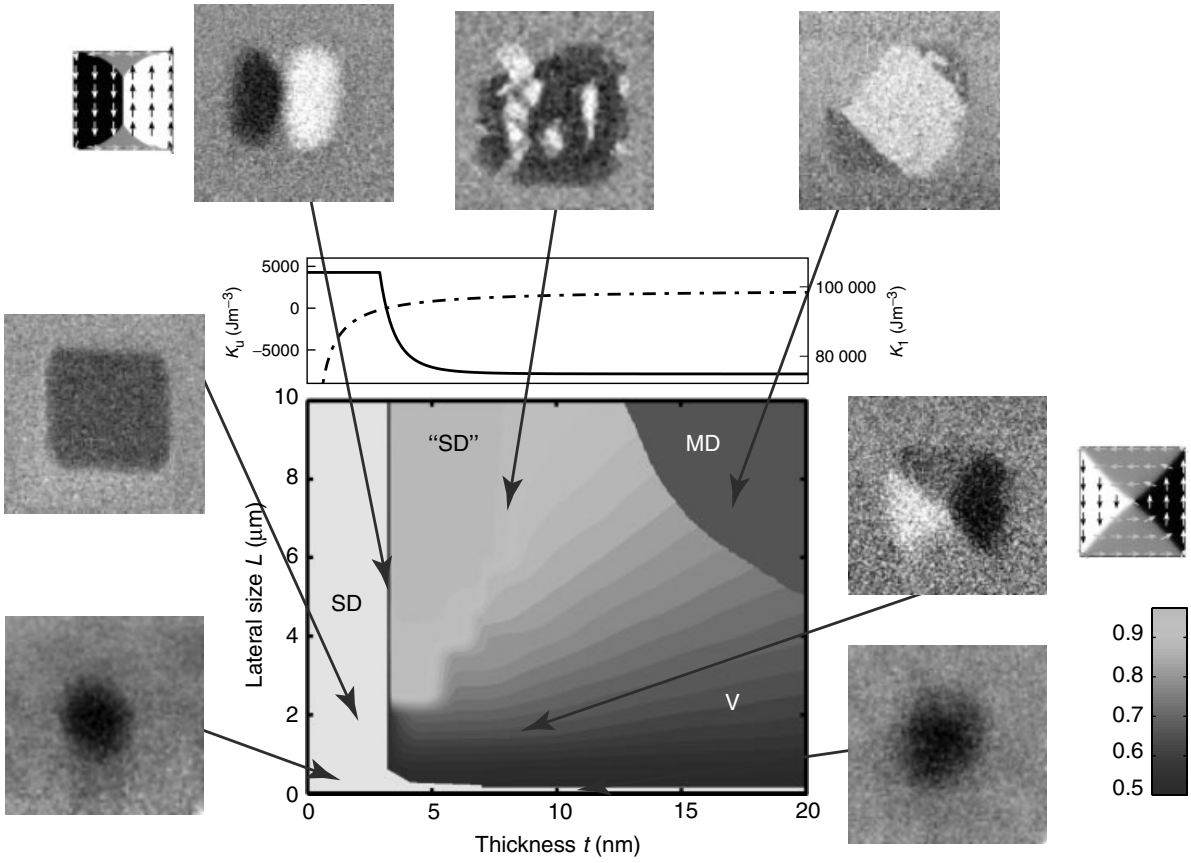

Figure 5. Phase diagram of the lowest-energy configurations in stepped Co/Cu(001) elements. At the top, the evolution of uniaxial (K_u, straight line) and cubic (K_1, dash-dotted line) anisotropy with thickness used in the micromagnetic simulations is shown. The experimental domain patterns were determined by spin-SEM; the arrows point to the thicknesses t and lengths L of the elements. The micromagnetic simulations have been performed on a narrow grid of (t, L) parameters. Two simulations are shown next to the experimental patterns with the same (t, L) parameters. The contour lines plot $\langle M_x^2 \rangle = \int (M_x/M_s)^2 \, dV$ as a measure of the deviations from the perfectly symmetric vortex state. States are classified as single-domain (SD), vortex (V), and multidomain (MD) states. A true, uniform SD state with $\langle M_x^2 \rangle = 0$ (for $t < 3.1$ nm) exists in the region labeled SD. The region labeled V exhibits $\langle M_x^2 \rangle$ values between 0.5 and 0.98 (see bar at the right). A gradual transition from a perfect V to an almost uniform state labeled "SD" (with $\langle M_x^2 \rangle$ close to 1) is observed for large L (>6 μm) near $t \approx 5$ nm.

often observed that the edges of lithographically produced elements exhibit altered magnetic properties. Hard pinning centers responsible for incomplete magnetization reversal are frequently ascribed to such material issues. To study the intrinsic magnetic properties of ultrathin uncovered structures, a different approach is used here: the patterns are produced by a nanostencil deposition technique in which the elements are fabricated by evaporation through thin Si-nitride shadow masks (Zahl, Bammerlin, Meyer and Schlittler, 2005), thus avoiding the use of lithographic steps during fabrication. Square elements, having variable edge lengths between 500 nm and 10 μm and thicknesses between 0.5 and 20 nm, were epitaxially grown using standard deposition parameters (Weber, Allenspach and Bischof, 1997) and in field-free environment. For smaller elements (250 to <500 nm), stencil masks produced by optical interference lithography have been employed, restricting the shape to circular or elliptical disks.

The experimental work is compared with micromagnetic simulations carried out with the OOMMF code (Donahue and Porter, 1999). A new module was added to the 3D solver package to take the complex anisotropy term relevant for stepped Co films into account. The material parameters used in the simulations were the literature values of fcc Co, with a saturation magnetization $M_s = 1424\,\mathrm{kAm^{-1}}$ and an exchange constant $A = 30 \times 10^{-12}\,\mathrm{Jm^{-1}}$. For each thickness, the anisotropy constants K_u and K_1 as given at the top of Figure 5 were used. A wide range of parameters for the thickness and lateral size was simulated to arrive at a full phase diagram of the minimum energy domain state versus the thickness and lateral size of the element. Different starting configurations for the simulations often resulted

in different converged final states. Therefore, for each set of parameters, a variety of domain states were calculated. Comparison of converged states always included the uniform SD state and the flux-closed vortex state as starting configurations. At small lateral sizes, flower, leaf, and buckle states were included, whereas at large sizes, diamond states were tested.

As with all micromagnetic simulations, it cannot be guaranteed that the global energy minimum has been reached. The same problem is faced in experiments: it is unclear to what extent the as-grown, the remanent, or the demagnetized state should be considered for such studies. All elements have been demagnetized by an alternating field of sufficient strength to overcome the anisotropy barriers. Although there is no proof for either the simulations or the experiment that the lowest-energy configuration has indeed been attained, we are confident that the trend is correctly reproduced.

Figure 5 shows a representative selection of magnetic configurations obtained experimentally. Different patterns are observed depending on the thickness and lateral size: an SD state, vortex (V) states gradually approaching a flux-closed Landau state, and MD states. To facilitate a comparison of this wide variety of states with the simulation results, each simulated pattern is characterized by the averaged square of the magnetization component along the easy magnetization axis for the ultrathin Co film (the $[1\bar{1}0]$ direction), $\langle M_x^2 \rangle = \int (M_x/M_s)^2 \, dV$. Accordingly, an SD state is described by $\langle M_x^2 \rangle = 0$ or $\langle M_x^2 \rangle = 1$ depending on the easy axis direction, whereas a perfect V state has $\langle M_x^2 \rangle = 0.5$. The details of the phase diagram are discussed next.

For elements with small lateral size L (typically below 500 nm), a transition from an SD to a V state is observed with increasing thickness. This SD-to-V transition is characterized by the balance of magnetostatic energy in the SD state with the sum of the exchange and anisotropy energy in the V state. The thinner the element, the smaller its demagnetizing energy, and, correspondingly, the transition is shifted to larger L. This SD-to-V transition has been investigated before in $Fe_{20}Ni_{80}$ with negligible anisotropy. Qualitatively the experimentally observed trend with size and thickness was reproduced by numerical simulations even though the simulations predict the transition to occur at smaller L than what was experimentally observed (Cowburn *et al.*, 1999). The authors remarked, however, that the calculation should be considered as a lower limit rather than an actual representation of the boundary. This discrepancy is not caused by numerical instabilities or inaccuracies of the finite-difference method used in the simulation, as proved by studies that compared the numerical simulations with an analytical description of the SD-to-V transition (Jubert and Allenspach, 2004; Vaz, Athanasiou, Bland and Rowlands, 2006). The analytical description and the simulations agreed, but the discrepancy with the experiment remained and could also not be attributed to a possible weak anisotropy. A likely explanation is that roughness at the element edges could be responsible for the discrepancy (Jubert and Allenspach, 2004). Including this roughness will indeed shift the SD-to-V transition, albeit not sufficiently (Vaz, Athanasiou, Bland and Rowlands, 2006).

For very small square elements, additional stable configurations exist, which are characterized by small deviations from the SD state (Cowburn and Welland, 1998b; Pulwey, Zölfl, Bayreuther and Weiss, 2003). They allow the demagnetization energy to be reduced significantly by letting the spins align themselves parallel to the element edges, without introducing a complete vortex with its prohibitively large exchange and anisotropy energy. In our stepped Co/Cu system, the buckle or C state is the lowest-energy state for a narrow band of parameters near the SD-to-V boundary for $L < 200$ nm. No leaf state (Cowburn and Welland, 1998b) exists because the configurational anisotropy is too small to keep a diagonal magnetization against K_u and K_1. Experimentally, this region is not accessible: the smallest elements investigated have a length $L = 250$ nm and a circular shape, which suppresses the occurrence of these states.

At very small thicknesses, the magnetostatic energy is small. Flux closure is not required and the SD state prevails irrespective of the lateral size (Stamm *et al.*, 1998). As K_u is large, deviations from the uniform state are virtually absent. A first phase transition occurs at $t \approx 3$ nm, at which the cost in demagnetization energy for the SD state becomes larger than the exchange and anisotropy energy for the V state. The observed configuration is strongly influenced by anisotropy. Although the pattern is still derived from a V configuration, it is more reminiscent of a two-domain state with triangular closure domains at the edges. Compared with a fully symmetric vortex, the two triangular domains in which the magnetization points along the intermediate axis are shrunk, and $\langle M_x^2 \rangle$ is increased from 0.5 for a perfect vortex to $\approx$0.8. This leads to an appreciable reduction of the anisotropy energy and overcompensates the energy cost of the newly formed 180° domain wall. Only at $t = 3.1$ nm, where K_u vanishes, a perfect fourfold symmetry of the vortex is regained, and hence $\langle M_x^2 \rangle = 0.5$. At larger thickness, K_u changes sign, interchanging the role of the easy and the intermediate magnetization axes. A second phase transformation back to a more uniform state occurs, rotated by 90° with respect to the direction at small thickness. As the magnetostatic energy of this SD state increases with increasing t, a distortion towards a V state occurs. The deviations from the fourfold symmetry are less pronounced than at small t. This argument is somewhat oversimplified, because in reality the demagnetization energy scales with t/L rather than with t. As a result, the demagnetization energy

of the SD configuration increases with decreasing L. Correspondingly, the SD state at $t \approx 4.5$ nm becomes increasingly less stable for smaller L and eventually disappears.

Squares with very large lateral size ($L \approx 10\,\mu$m) exhibit additional phase transitions with increasing thickness (see Figure 5): Starting from an SD state, a crossover to a V-type configuration takes place, which reverts to an almost uniform SD state before reaching – via some V component as characterized by a reduction in $\langle M_x^2 \rangle$ – a MD configuration. The cost of the additional domain-wall energy is compensated by the gain in magnetostatic energy, while anisotropy plays only a minor role at this transition. Correspondingly, the V-to-MD transition was also observed in low-anisotropy permalloy elements (Gomez *et al*., 1999). However, in various magnetic force microscopy studies, it remained a matter of debate whether the observed patterns have to be interpreted as signatures of MD or of V states (Fernandez, Gibbons, Wall and Cerjan, 1998; Van Bael, Temst, Moshchalkov and Bruynseraede, 1999; Kazakova, Hanson, Blomquist and Wäppling, 2001). In the Co elements considered here, the MD state is experimentally already attained for thicknesses well below those calculated. These irregularly shaped domain patterns are reminiscent of the irregular domains observed in extended in-plane films after demagnetization (Oepen *et al*., 1990). Only in thicker elements straight domain walls are observed, finally approaching the 3D world of micromagnetics. It is worth mentioning that at even larger L, a further transition has been reported in a system with fourfold anisotropy. In 15-nm-thick Fe(001) elements on GaAs, a transition from the MD state to an essentially SD state is observed upon increasing L to $\approx$50 μm (Gu *et al*., 1997). This transition was ascribed to the competition of in-plane dipolar and anisotropy energies, and in essence marks the transition to the uniformly magnetized infinitely extended film, containing a few irregular closure domains at the element edges.

In summary, a very rich phase diagram of domain states in stepped Co/Cu(001) elements exists: with varying lateral size and thickness of the element, distinct configurations are identified, in particular SD, V, and MD patterns. This complex behavior is caused by the complex anisotropy and its thickness dependence. It results from the competition between the uniaxial step-induced anisotropy, the cubic anisotropy, and the magnetostatic stray-field energy. Anisotropy favors a uniform magnetization pattern, whereas a reduction of magnetostatic energy requires a flux-closure pattern. Micromagnetic simulations and experimental observations largely agree. Simulations find marginal deviations from the perfectly uniform magnetization distribution in the region of the phase diagram labeled as SD. The SD-to-V boundary at small lateral size is, as in earlier studies, qualitatively reproduced by simulations or by an analytical approach, whereas the V-to-MD transition at large lateral size is shifted to reduced thicknesses. Apart from these minor discrepancies, Figure 5 proves that micromagnetic simulations have become an essential tool to calculate magnetization patterns in large elements, extending well into the micrometer length scale, thanks to the amazing increase in computing power in the past few years.

The Co/Cu model system shows that anisotropy is crucial for the type of domain patterns observed. As uniaxial anisotropy is determined by the miscut or the step distance of the substrate, these crystallographic aspects determine the domain pattern in an adjustable and tunable manner. The conclusion that the SD state prevails regardless of size, shape, and magnetic history (Stamm *et al*., 1998) is only valid in the narrow parameter space of the phase diagram in which the thickness vanishes. However, it is remarkable that thanks to the tunability of anisotropy stable SD configurations can be induced and V states avoided at much larger thicknesses, as is required for certain technological applications such as magnetic random-access memories.

This discussion completely ignores thermal effects. Ultrathin films, however, in general show a pronounced temperature dependence of their magnetic properties, as for instance, described in Section 2: fluctuations of domain patterns have been observed near the Curie temperature. Moreover, if SD particles become small enough, superparamagnetic behavior is observed (Bean and Livingston, 1959): the anisotropy energy is so small that thermal fluctuations can overcome this barrier and reverse the magnetization spontaneously. In Co/Cu(001) elements, we have observed ferromagnetic instabilities. The magnetization in 300-nm dots that are only a few ML thick begins to fluctuate on the timescale of the spin-SEM experiment (see Figure 6). Hence, even though ultrasmall elements are in an SD state at low temperature, this state is prone to time-dependent magnetization switching. This precludes an application of these dots as magnetic bits for 'nanorecording', as was suggested earlier (Stamm *et al*., 1998).

4 CONFINED DOMAIN WALLS

4.1 Domain walls in small elements

The concept of a magnetic domain wall is a direct consequence of the theory of magnetic domains proposed 100 years ago by Weiss (1907). On the typical length scale encountered in a ferromagnet, this transition is a continuous rotation from the magnetization direction in one domain to the direction in the adjacent one, because it extends over many lattice constants. Soon after Bloch (1932) realized this fact, Landau and Lifshitz (1935) introduced a variational approach to calculate the first domain-wall width and

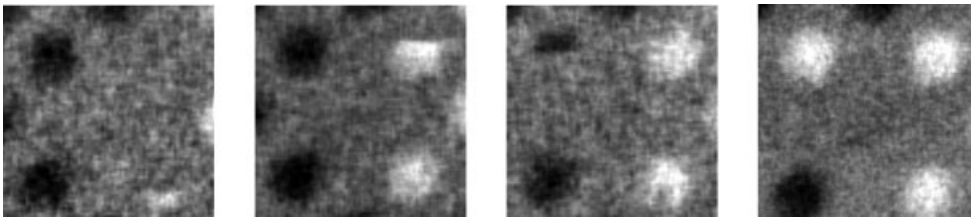

Figure 6. Magnetization fluctuations in 300-nm Co dots on slightly miscut Cu(001), measured by spin-SEM. The four images from left to right were taken consecutively. No magnetic field was applied. The in-plane magnetization component M_y along the page is shown, coded as white for magnetization along $+y$ and black along $-y$; magnetization along $\pm x$ appears gray. All dots except the one at the lower left corner switch within the timescale of the experiment (about 4 h). The top left dot, for instance, switched from $-y$ to $\pm x$ and to $+y$. The abrupt gray scale change along the x direction within a dot indicates a magnetization switching from one line scan to the next.

wall profile. Only two material parameters are involved, the exchange constant A and the anisotropy energy K. The magnetization then varies as $\tanh(x/w_0)$, with w_0 being a convenient definition of the wall width, $w_0 = \sqrt{(A/K)}$.

This prototypical one-dimensional (1D) Bloch wall is rarely observed because it requires an infinite sample or very large anisotropy energy, as otherwise the dipolar magnetic energy cannot be neglected. In a finite system, boundaries such as edges and surfaces are important, and dipolar contributions need to be taken into account. In a thin film with in-plane anisotropy, for instance, the magnetization within a Bloch wall would point out of plane, adding an appreciable amount of surface demagnetizing energy to the total wall energy. Néel (1955) proposed an alternative domain-wall type, for which the magnetization rotates entirely within the plane. This wall has an internal magnetostatic energy but no surface energy, and is energetically favored in thin films. A detailed analytical description of the Néel wall profile is complex. Its main features are a narrow core, in which the magnetization rotates rapidly, and a long tail of several micrometers in length, which is characterized by a gradual change of the magnetization direction. The core width depends on the uniaxial anisotropy and the shape anisotropy energy $1/2\,\mu_0\,M_s^2$, with $w_{\text{core}} = c\sqrt{(A/(K + 1/2\,\mu_0\,M_s^2))}$, where c is a proportionality constant of the order of 1 (Riedel and Seeger, 1971).

But even for this more complex case, the width of a domain wall is solely determined by intrinsic material parameters. Only very recently, it has become clear that the width of a wall could depend on the dimensions of the sample. In particular, very narrow domain walls could exist in nanoscopic elements. A first experimental observation of a wall width of a few nanometers was explained by a pronounced increase of the exchange or by the breakdown of the micromagnetic continuum approach on the atomic scale (Pratzer *et al.*, 2001). On the other hand, it was suggested that a domain wall can be much narrower than w_0 if the angle of rotation across the wall is small (Ding, Wulfhekel and Kirschner, 2002). However, the domain-wall width is reduced in small dimensions even if both these arguments are not applicable. An example of such a confined magnetic domain wall is shown in Figure 7 for an epitaxial Co element of 300-nm diameter and 10-nm thickness. On these length scales, continuum micromagnetics still perfectly describes the physics. The wall is a 180° Néel wall, that is, the magnetization rotates by a large angle. A line profile across the wall gives a wall width of about 50 nm. Compared with an extended film, this value is roughly a factor of 4 smaller than the width of the unconstrained wall (Berger and Oepen, 1992). Because the material parameters such as magnetization, anisotropy, and exchange are largely the same, the wall width is reduced for geometrical reasons: it decreases when the lateral size of the element shrinks. This reduction is caused by a modification of the magnetic dipolar energy contribution at the element edges, as discussed in the next paragraph in more detail.

A systematic study of the geometry dependence of the Néel wall width has been done in lithographically fabricated

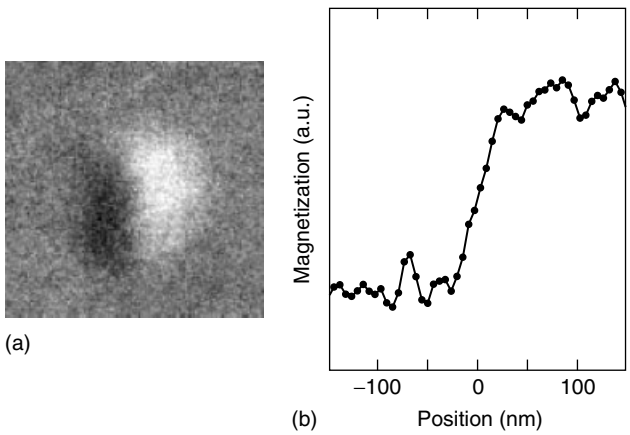

Figure 7. (a) In-plane magnetization image of an individual epitaxial 300-nm-diameter Co dot on Cu(001), with a thickness of 10 nm, fabricated using the nanostencil method (Zahl, Bammerlin, Meyer and Schlittler, 2005) and measured *in situ* by spin-SEM. The dot decays into a multidomain state containing two antiparallel regions with a 180° domain wall in between. (b) Line scan across the wall taken along the horizontal axis. The wall width is about 50 nm.

micrometer-sized structures. In 20-nm-thick $Fe_{20}Ni_{80}$ rectangular elements, a 180° Néel wall has been pinned at the center by a narrow notch. The width of the element has been systematically varied between 1 and 4 μm, and the domain-wall profile has been measured (Jubert, Allenspach and Bischof, 2004). Without notch, a well-defined two-domain state would not be the lowest-energy state of the element. The dimensions of the notch, however, can be chosen such that the wall width is not affected by the presence of the notch. Figure 8 shows that the finite width of the element leads to wall confinement. The domain-wall width decreases with shrinking element size, on length scales larger than a micrometer. The limiting value in the infinitely extended 10-nm-thick film could not be determined experimentally because it was not possible to stabilize a 180° Néel wall after demagnetization in an alternating field. In somewhat thicker films, long tails with an extension of several micrometers were reported (Suzuki, Wilts and Patton, 1968; Wong and Laughlin, 1996). In a small element, these tails are limited by the element width, leading to a modified profile and a reduced width of the Néel wall core. Micromagnetic simulations confirm the experimentally observed trend, but quantitative deviations remain. Similar discrepancies have been found in studies of small disks (Vaz *et al*., 2003). Their origin remains unclear. It has been proposed that exchange is underestimated in the simulations (Jubert, Allenspach and Bischof, 2004). The observed wall-width reduction originates in the tails of the wall: they are cut at the element edges. Hence, the magnetostatic charges that are present in the tails need to be redistributed within the entire Néel wall. This rearrangement of charges is rather intricate and not fully understood theoretically (Holz and Hubert, 1969). Such a wall-width reduction on a micrometer scale is only expected to occur in Néel walls. Bloch walls are uncharged: wall tails are absent, and hence no energy is gained by confining the wall on these length scales.

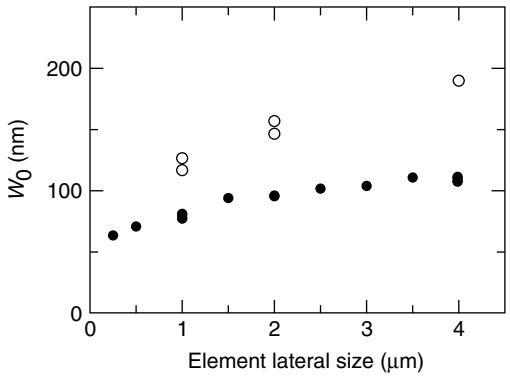

Figure 8. Domain-wall width versus element width for rectangular $Fe_{20}Ni_{80}$ elements with a thickness of 20 nm, for a 180° Néel wall. The experimental results (empty circles) are obtained from spin-SEM; the simulations (filled circles) are calculated with the OOMMF code. (Reproduced from Jubert, Allenspach and Bischof, 2004, with permission from the American Physical Society. © 2004.)

At length scales smaller than the exchange length, the continuum micromagnetic approximation is no longer appropriate. The discreteness of the atomic lattice and hence of the spin distribution becomes important. This was recognized a long time ago (Hilzinger and Kronmüller, 1973). For narrow domain walls, it was calculated that the coercive field should depend on the exact position of the wall with respect to the atomic positions in the crystal lattice, but the effect should be on the order of a few percent only. In a recent study, a drastic influence of the orientation of magnetic domain walls in Fe nanowires was observed (Vedmedenko *et al*., 2004). Regardless of the wire orientation, the domain walls are oriented along two crystallographic directions (see Figure 9). Most walls run along the $[1\bar{1}1]$ direction, and in some cases a $[3\bar{3}1]$ direction is observed. Neither orientation

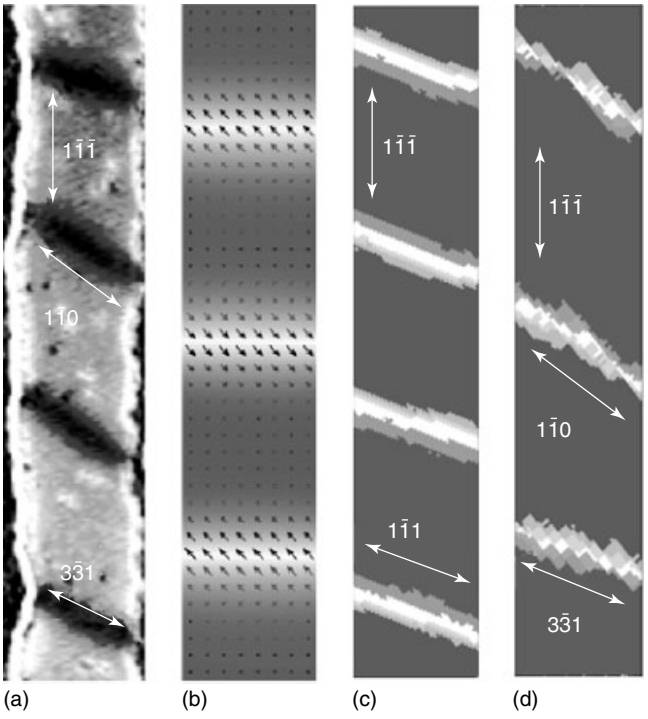

Figure 9. Domain walls in a Fe/W(110) nanowire section, with a thickness of 2 ML and a width of 20 nm. (a) Image taken by spin-polarized scanning tunneling microscopy; the domain walls appear dark, with orientations along the $[1\bar{1}0]$ and the $[3\bar{3}1]$ directions. (b) Micromagnetic continuum simulation with isotropic exchange. The domain walls (bright) run perpendicular to the nanowire direction to minimize the wall length. (c–d) Monte Carlo simulation on a discrete lattice; in (c) the exchange was taken to be identical along all nearest neighbors, while in (d), lattice relaxation was taken into account, with the largest exchange coupling taken along the $[1\bar{1}0]$ direction. (Reproduced from Vedmedenko, Kubetzka and Bergmann, 2004, with permission from the American Physical Society. © 2004.)

can be reconciled with a micromagnetic simulation in which a uniform exchange constant is assumed. Monte Carlo simulations on the discrete lattice, however, are able to reproduce the experimental result. The wall orientation is determined by the atomic lattice and the strength of the exchange constant between neighboring atoms along different directions. In contrast to what is expected in continuum micromagnetics, magnetic anisotropy and magnetostatic energy play only a minor role in the wall orientation.

4.2 Domain walls at constrictions

The examples shown in Figures 7 and 8 illustrate that scaling of the element size down to (sub)micrometer dimensions leads to appreciable effects on the domain-wall width. Micromagnetically, this is a straightforward extension of what happens when going from a bulk ferromagnet to a thin film. The existence of magnetic dipolar energy contributions at the surface favors the transition from a Bloch to a Néel wall, and, similarly, the existence of boundaries at which the tail of the Néel wall is cut off leads to a redistribution of magnetic charges across the entire domain wall. A further rearrangement is expected if additional geometrical changes are introduced, such as notches or protrusions. Interestingly, this more complex geometry recently gained more attention by theoreticians than the simpler case of a small element.

Using a 1D analytical approach, Bruno predicted that Bloch walls shrink in constrictions that are smaller in size than the width of the unconstrained wall (Bruno, 1999). He suggested that this geometrically constrained wall should be considered as a new wall type, different from both a Bloch and a Néel wall. This work was inspired by the intriguing result that the magnetoresistance in Ni nanocontacts reached values of 280%, and it was speculated that the domain-wall width depends on the contact size (García, Muñoz and Zhao, 1999). Shortly afterwards, world record magnetoresistance values have been announced (Chopra and Hua, 2002; Hua and Chopra, 2003), but a critical evaluation came to the conclusion that artifacts due to magnetostrictive, magnetostatic, and magnetomechanical effects can mimic ballistic magnetoresistance (Egelhoff *et al*., 2004).

In the limit of very small constrictions, Bruno calculated that the wall width is determined solely by geometry and not by the material parameters. The wall width can be as small as the constriction diameter. Such a narrow wall costs exchange energy density. The total wall energy, however, can yet be lowered with a larger energy density, because the wall is confined to a smaller volume. Dipolar effects are neglected in this model and it is assumed that the wall remains planar and of Bloch type even within the constriction. However, classical Monte Carlo simulations and micromagnetic modeling have shown that the Bloch wall is only stable at large constriction. When the constriction is made smaller, a crossover to a vortex wall takes place before finally a Néel configuration is energetically preferred at very small constrictions (Labaye, Berger and Coey, 2002). Micromagnetic modeling showed that the domain walls are not straight but rather 2D (Jubert and Allenspach, 2005) or even 3D (Molyneux, Osipov and Ponizovskaya, 2002) configurations which bend outside the constriction area. Thus, while the phenomenon of a geometrically constrained domain wall is well described by the analytical model, the restriction to 1D fails to predict the wall-width reduction quantitatively. A direct comparison of the analytical model to micromagnetic simulations is given in Figure 10. In contrast to the analytical model, the simulations do not show scaling: it is the constriction size and not the ratio of constriction to element size that matters (Jubert and Allenspach, 2005). The origin of this discrepancy stems from the assumption of the analytical model that the wall remains planar, thus having a length extending throughout the element if the wall is positioned outside the constriction.

Experimentally, Bloch walls with decreased width have been observed by spin-polarized scanning tunneling microscopy (STM) in epitaxial Fe stripes which self-organize on W(110) substrates: the unconstrained wall width is 6 nm, the wall pinned at the constriction of about 1 nm in size

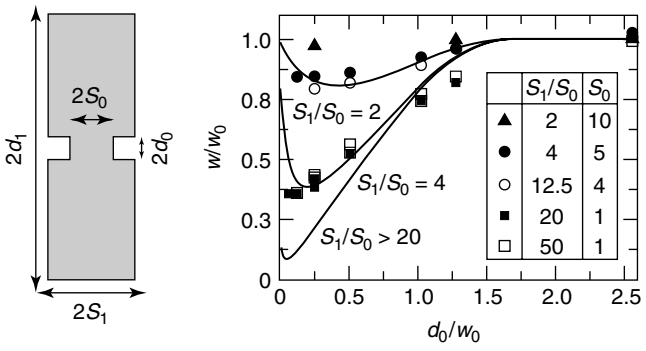

Figure 10. (a) Schematic description of a thin rectangular magnetic element with width $2d_1$ and length $2S_1$ containing a constriction characterized by its width $2d_0$ and its length $2S_0$. (b) Evolution of the domain-wall width versus constriction dimension d_0 for various values of S_0 and S_1 as given in the inset, calculated by micromagnetic simulations with the OOMMF code. Both axes are normalized with the unconstrained Bloch wall width, $w_0 = \sqrt{(A/K)}$. The lines give the wall-width variations calculated with Bruno's analytical model for three ratios of S_1/S_0. (Reproduced from Jubert and Allenspach, 2005 © 2005, with permission from Elsevier.)

is reduced to 2 nm (Pietzsch, Kubetzka, Bode and Wiesendanger, 2000). Pinning of an in-plane domain wall at a lithographically fabricated NiFe constriction has been observed by magnetic force microscopy in a search for increased magnetoresistance effects (Miyake *et al*., 2002). Even though the wall width was found to be reduced, no evidence of a substantial ballistic magnetoresistance was observed. Comparison with simulations is difficult in this case because the wall is a head-to-head domain wall. A systematic study to correlate the constriction geometry to the wall width has been performed on 180^o Néel walls (Jubert, Allenspach and Bischof, 2004). These walls were stabilized in thin $Ni_{80}Fe_{20}$ elements containing a constriction by employing a rectangular shape, which favors an antiparallel two-domain state. This configuration with a 180° Néel wall positioned in the constriction is obtained after demagnetization by an alternating magnetic field. Without constriction, an SD prevails. The 2D magnetization pattern (and hence the domain-wall profile) in the constriction was determined by spin-SEM and compared with micromagnetic simulations (see Figure 11).

The profile across the wall is shown in Figure 11(e). The agreement with the calculated profile is excellent. A symmetric Néel wall with its two distinct features can be identified: a core region with a rapid magnetization rotation, which can be approximated by a hyperbolic tangent function, and long tails extending over large distances.

The wall is somewhat more complex, though. A close-up of the constriction region illustrates that it is 2D and asymmetric (see Figure 12). The magnetization rotates by 180° at the constriction, but for topological reasons differently at the two constriction edges. Exchange forces the spins to remain as closely aligned as possible with each other, and hence the rotation occurs over a longer distance in the outer part of the turn. The small intermediate domain nucleated at one constriction edge results from the fact that low-angle Néel walls are energetically favored over large-angle walls, and thus energy can be gained by replacing a 180° domain wall by two 90° walls (Holz and Hubert, 1969). A micromagnetic simulation successfully reproduces all these features (see Figure 12). The same energy argument also applies to a Bloch wall. Hence, a Bloch wall is also, in general, a 2D object. However, it remains symmetric at the constriction edges because the magnetization rotates in planes perpendicular to the film surface (Jubert and Allenspach, 2005).

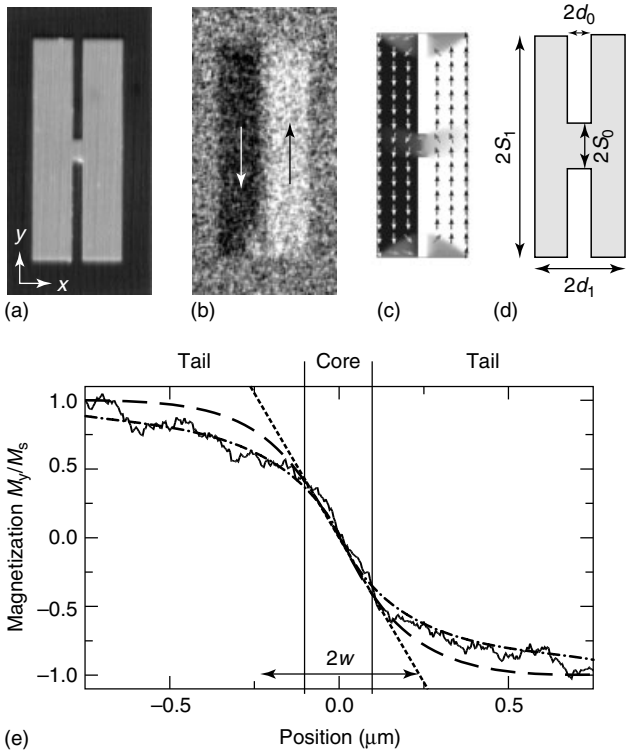

Figure 11. $Fe_{20}Ni_{80}$ rectangle 10 μm × 4 μm in size containing a constriction with $d_0 = 225$ nm and $S_0 = 500$ nm; thickness 7.5 nm. (a) Topographic image and (b) magnetization configuration after demagnetization as determined by spin-SEM. The arrows indicate the magnetization direction. (c) Micromagnetic simulation for an element having the same dimensions. (d) Schematic defining the element and constriction parameters. (e) Domain-wall profile across the constriction. The experimental profile is compared with the simulation (dash-dotted line) and a hyperbolic tangent function (dashed line). (Reproduced from Jubert, Allenspach and Bischof, 2004, with permission from the American Physical Society. © 2004.)

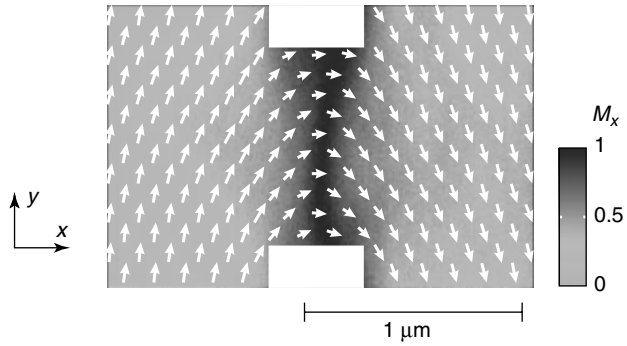

Figure 12. Magnetization configuration in a 7.5-nm-thick $Fe_{20}Ni_{80}$ rectangular element containing a constriction, measured by spin-SEM. Only the center part of the 10 μm × 4 μm rectangle is shown, exhibiting a two-domain state with magnetization along $+y$ (to the left of the constriction) and $-y$ (to the right). The gray scale represents the magnetization component M_x, the arrows give the in-plane magnetization direction as determined from the measured M_x and M_y components. The wall configuration is asymmetric with respect to the top and bottom edges, with a wider wall exhibiting a triangular domain with magnetization along $+x$ at the top constriction. The constriction dimensions are $d_0 = 225$ nm and $S_0 = 500$ nm, as defined in Figure 11(d). (Adapted from Allenspach and Jubert, 2006.)

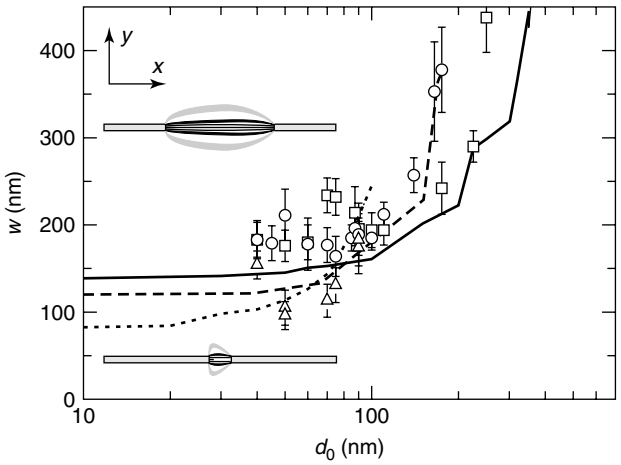

Figure 13. Domain-wall width w versus constriction dimension d_0 in $Fe_{20}Ni_{80}$ with $S_0 = 100\,\text{nm}$ (triangles, dotted line), 250 nm (circles, dashed line), and 500 nm (squares, solid line). Dots are experimental values and lines are micromagnetic simulations. The element is 7.5-nm thick, with a lateral size of $10\,\mu\text{m} \times 4\,\mu\text{m}$. Two simulated domain walls with fixed d_0 but varying S_0 show the outward bending of the wall. (Reproduced from Jubert, Allenspach and Bischof, 2004, with permission from the American Physical Society. © 2004.)

By varying the constriction dimensions, the wall width can be modified continuously over a wide range. Figure 13 presents the evolution of the wall width as a function of the constriction width d_0, with the constriction length S_0 as a parameter. For small d_0, the domain-wall width w is almost constant. As d_0 becomes larger than about 100 nm, w increases strongly with d_0. The minimum value of w attained at small d_0 depends on S_0, with w being smaller for smaller S_0. The increase of w for larger d_0 is steeper for smaller S_0. The domain-wall widths determined from the simulated micromagnetic patterns reproduce the experimental trend very well. The 2D nature of the patterns helped us understand the observed wall-width variations in a quantitative way.

Far from the constriction edges, the 180° Néel wall width is determined by the material parameters and the extension of the element, as discussed in Section 4.1. The width of this wall is defined to be w_0. If the wall is located in a constriction, however, it is affected by the constriction parameters. The magnetization is forced to lie parallel to the constriction edges, because the dipolar energy can be minimized in this way. Hence, the wall width locally corresponds to d_0. Such a small wall width cannot be maintained throughout the constriction if $2d_0 < w_0$ because the cost in exchange energy is too large. Hence, the wall deforms in the constriction, adopting a 2D shape with outward deformation (see lower inset in Figure 13). The situation is completely analogous to the case of the Bloch wall presented in Figure 10. For large S_0, the wall profile in the constriction center is unaffected as the deformation is restricted to the region near the edges. In this case, the measured wall width is almost constant, $w \approx w_0$ (see upper inset in Figure 13). For small S_0, on the other hand, the wall width at the center is reduced, $w < w_0$. Keeping it at a width w_0 would require a very rapid wall variation along the constriction and hence cost excessive exchange energy. Accordingly, a reduction of w is observed below a threshold value of $S_0 \approx 250\,\text{nm}$.

The opposite limit of $2d_0 > w_0$ can be understood along the same lines. Again, the wall attains a 2D shape, but bends inward instead of outwards. For small S_0, the wall at the center becomes wider rather than narrower, $w > w_0$. For large S_0, the confinement is again limited to the constriction edges, and correspondingly the increase of w is shifted to larger d_0. In the limit of d_0 approaching S_0, the domain-wall-type changes completely: the domain formed at the constriction edge visible in Figure 12 expands toward the center of the constriction, leading to a splitting of the 180° Néel wall into two 90° Néel walls, as was observed experimentally (Jubert, Allenspach and Bischof, 2004).

These experiments demonstrate that domain-wall dimensions and profiles can be tailored by constriction geometry. For the same material properties, the wall width can be varied in a wide range. It is strongly confined in small and narrow constrictions, but stretched for wide constrictions owing to significant dipolar energy contributions at the constriction edges. For specific constriction geometries, even the wall type can be changed. These observations are not limited to the prototypical 180° Néel walls considered here. 90° Néel walls in T-shaped junctions exhibit the same behavior: the wall width pinned at the contact region strongly depends on the contact dimensions (Haug *et al.*, 2005).

In conclusion, magnetic domain walls in small elements can be strongly affected by two geometrical approaches, by the lateral dimensions of the element, and by constrictions. Lateral confinement causes Néel walls to shrink because of a redistribution of demagnetization versus exchange energy, while Bloch walls are not affected. Constrictions influence both Néel and Bloch walls: wall profiles can be reduced or expanded in width and attain a complex 2D topology, and wall types can be modified. This geometrical tunability offers an additional handle on a domain wall. It is possible to tailor domain walls without resorting to changing the material parameters. This might become important for future applications in which logical bits are represented as individual domain walls (Allwood *et al.*, 2002; Parkin, 2004). In such concepts, geometrical effects are also successfully used to inject domain walls (Thomas *et al.*, 2005) or to favor a propagation direction, because the pinning and de-pinning of a domain wall depends on the geometry (Hirohata *et al.*, 2000; Allwood, Xiong and Cowburn, 2004; Himeno, Kasai

and Ono, 2005). The examples presented demonstrate that experiments, micromagnetic simulation and – where available – analytical models agree reasonably well. Some discrepancies remain and are not yet resolved, even on length scales at which continuum micromagnetics is still applicable. Theoretically, also the thermal effects are still largely unexplored. A recent study predicts an interesting change in wall profile because of thermal activation (Kazantseva, Wieser and Nowak, 2005).

ACKNOWLEDGMENTS

The unpublished experimental data on small epitaxial Co/Cu elements in Sections 3 and 4 have been acquired together with Samy Boukari and Andreas Bischof, the simulations were done in collaboration with Pierre-Olivier Jubert.

Domain Wall Propagation in Magnetic Wires

Teruo Ono
Kyoto University, Uji, Japan

1 DOMAIN WALL PROPAGATION BY AN EXTERNAL MAGNETIC FIELD

1.1 Detection of domain wall propagation using GMR effect

Recent developments in nanolithography techniques have made it possible to prepare well-defined dots and wires; magnetism in mesoscopic systems has become an updated topic from both the scientific and technological points of view. The process of magnetization reversal in a single-domain ferromagnetic structure is fundamental in magnetism, and it has been of considerable interest to theorists and experimentalists since the pioneering work of Néel. An understanding of this problem is of fundamental importance for the magnetization reversal in complex systems, such as assemblies of fine particles, thin films, and bulk materials. The process of magnetization reversal is also very important in practical applications such as hard disk drive (HDD) magnetoresistive random access memory (MRAM) and so on.

Nucleation and propagation of a magnetic domain wall are two important processes in magnetization reversal. These processes can be clearly seen in the magnetic wire with submicron width. As shown in Figure 1(a), in very narrow ferromagnetic wires, the magnetization is restricted to be directed parallel to the wire axis due to the magnetic shape anisotropy. When the external magnetic field is applied against the magnetization, a magnetic domain wall nucleates at the end of the wire and the magnetization reversal proceeds by the propagation of this domain wall through the wire (Figure 1b and 1c). However, it is very difficult to detect the propagation of the domain wall, because the change in magnetic moments in this process is very small due to the small volume of the magnetic wire.

Here, the principle of how to detect the domain wall propagation in magnetic wires using the magnetoresistance gaint magnetoresistance (GMR) effect is described. The GMR effect is the change in electrical resistance caused by the change of the magnetic structure in magnetic multilayers (Baibich *et al*., 1988). This means that the magnetic structure of the system can be detected by resistance measurements. Consider the GMR system shown in Figure 2, which is composed of magnetic, nonmagnetic, and magnetic layers. The resistance is largest for the antiparallel magnetization configuration (Figure 2a), and it is smallest for the parallel configuration (Figure 2d). During the magnetization reversal of one of the two magnetizations (Figure 2b and 2c), the total resistance of the system is given by the sum of the resistances of the parallel magnetization part and the antiparallel magnetization part. Thus, the resistance of this system, R, is given by

$$R = \frac{x}{L} R_{\uparrow\uparrow} + \frac{L - x}{L} R_{\uparrow\downarrow} \tag{1}$$

where x is the position of the domain wall, L is the length of the wire, $R_{\uparrow\uparrow}$ is the resistance for parallel configuration, and $R_{\uparrow\downarrow}$ is the resistance for antiparallel configuration. Therefore,

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

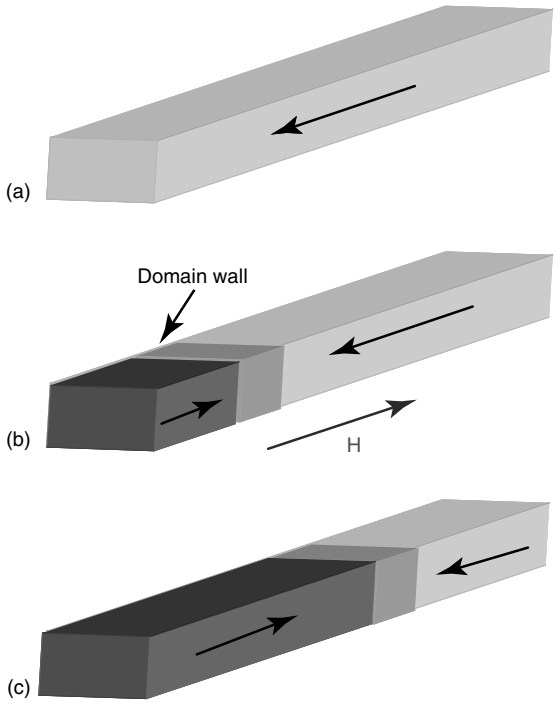

Figure 1. Schematic illustration of the magnetization reversal process in a magnetic wire.

the position of the domain wall can be determined by the resistance measurements.

The above idea has been demonstrated experimentally (Ono, Miyajima, Shigeto and Shinjo, 1998). The samples were prepared using lift-off techniques. $Ni_{81}Fe_{19}$(20 nm)/Cu(10 nm)/$Ni_{81}Fe_{19}$(5 nm) trilayer film was deposited on the patterned mask by electron-beam evaporation in a vacuum of 1×10^{-8} Torr. The wire with trilayered structure was obtained after the resist mask was removed. Owing to the large Cu-layer thickness, the interlayer exchange coupling between the thin and thick NiFe layers is negligible. The magnetoresistance measurements were performed at 300 K. The magnetic field was applied along the axis of the wires. Resistance was determined using a four-point dc technique. As seen in Figure 3, the samples have four current–voltage terminals where the voltage is probed over a distance of 20 μm. Furthermore, the samples have an artificial neck (0.35-μm width) introduced at one-third of the distance from one voltage probe in order to monitor the magnetic domain wall propagation.

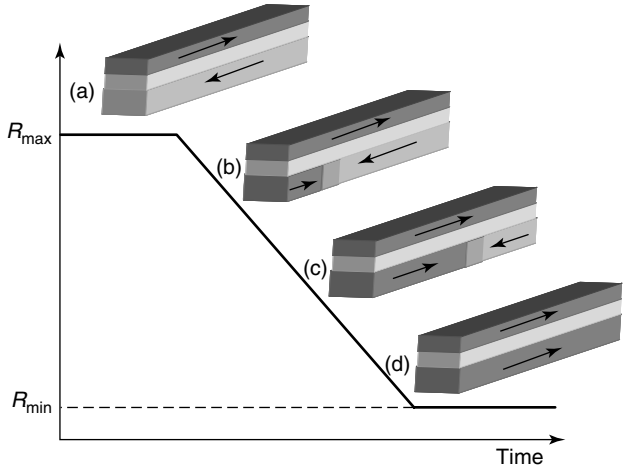

Figure 2. Schematic explanation for the detection of the domain wall propagation in magnetic wires using the magnetoresistance effect.

Figure 4 shows the resistance of the trilayer system as a function of the external magnetic field. Prior to the measurement, a magnetic field of 100 Oe was applied in order to achieve magnetization alignment in one direction. Then, the resistance was measured in steps of 1 Oe as the field was swept toward the counter direction. The result of the magnetoresistance measurement displays essentially four very sharp leaps. The first and second leaps correspond to the magnetization reversal of the thin NiFe layer, whereas the third and fourth leaps correspond to the magnetization reversal of the thick NiFe layer.

The magnetization reversal takes place in the sample as follows: As long as the counter field is smaller than the critical field, the magnetizations of both thin and thick NiFe layers align parallel, and the resistance shows the lowest value. As the applied magnetic field exceeds 5 Oe, the resistance abruptly jumps and maintains a constant value up to 10 Oe. Then, exceeding 10 Oe, the resistance abruptly jumps again and maintains the largest value up to 22 Oe. The result indicates

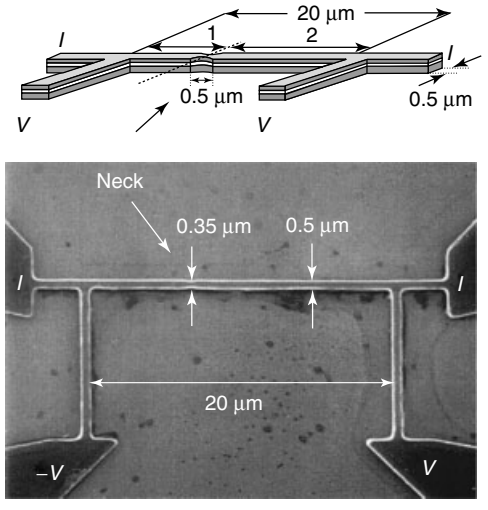

Figure 3. SEM image and schematic illustration of the sample. The sample consists of a $Ni_{81}Fe_{19}$(20 nm)/Cu(10 nm)/$Ni_{81}Fe_{19}$(5 nm). (Reproduced from Ono *et al.*, 1998, with permission from the American Physical Society. © 1998.)

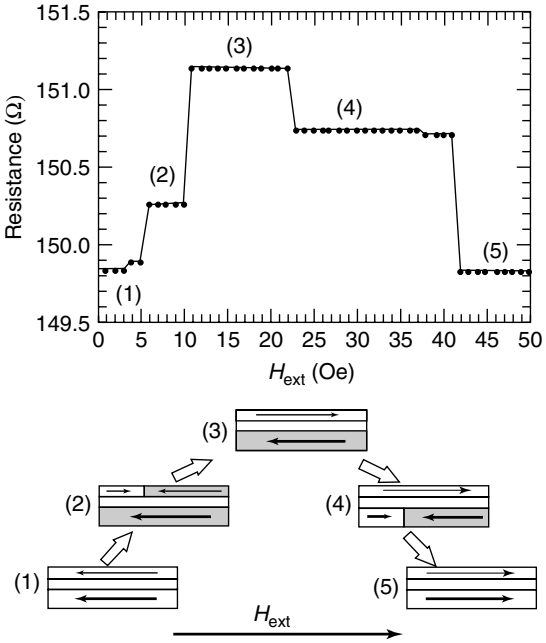

Figure 4. Resistance as a function of the external magnetic field at 300 K. The magnetic domain structures inferred from the resistance measurement and the direction of the external field are schematically shown. (Reproduced from Ono *et al.*, 1998, with permission from the American Physical Society. © 1998.)

that the antiparallel magnetization alignment is realized at an external field between 11 and 22 Oe, where the resistance shows the largest value. The ratio of the resistance changes at the first and second leaps is 1:2. This means that one-third of the total magnetization of the thin NiFe layer changes its direction at the first leap in Figure 4, since the GMR change is directly proportional to the switching layer magnetization. The ratio, 1:3, corresponds to the ratio of the length between one voltage probe and the neck to the overall length of the wire between the voltage probes. Therefore, in this case, a magnetic domain wall nucleates in the shorter part of the wire (left side of the scanning electron microscopy (SEM) image in Figure 3) and propagates to the neck, where it is pinned up to 10 Oe. The second leap, upon exceeding 10 Oe, corresponds either to de-pinning of the magnetic domain wall from the neck or to nucleation and propagation of another magnetic domain wall on the other side of the neck (right side of the SEM image in Figure 3). These two possibilities cannot be distinguished from the result shown in Figure 4. Since the ratio of the resistance changes at the third and fourth leaps is also 1:2, the magnetization reversal of the thick NiFe layer takes place in the same manner as in the thin NiFe layer described in the preceding text.

It was shown that a magnetic domain wall can be trapped by the artificial structure introduced into the wire. This is an example of the control of the magnetization reversal process by controlling the shape of mesoscopic magnets. Though the nucleation position of the domain wall could not be determined in the above experiments, it has been reported that one can inject a domain wall from one end of a wire by breaking its symmetry (Shigeto, Shinjo and Ono, 1999). It should be noted that the GMR method corresponds to a very highly sensitive magnetization measurement. For the sample investigated in the preceding text, the sensitivity is as high as 10^{-13} emu (10^7 spins). The method, in principle, can be applied to smaller samples as long as the resistance of the samples can be measured and the relative sensitivity increases with decreasing sample volume.

1.2 Domain wall velocity measurements

Sixtus and Tonks (1931) first measured the domain wall velocity in bulk magnetic wires. Figure 5 shows a schematic diagram of the circuit for velocity measurements. Under a homogeneous magnetic field, a magnetic domain wall is nucleated by adding a local magnetic field, which is produced by an adding coil. The domain wall traveling along the wire from left to right produces successive voltage surges in two search coils, which are placed around the wire at a known separation. The velocity of the domain wall can be calculated from the time interval of the voltage surges and the separation of the coils. The domain wall velocity, obtained experimentally, was discussed in terms of the dissipation of the magnetic energy by eddy currents.

The GMR detection method described in Section 1.1 has an advantage in dynamic measurements because of its simplicity. Here, velocity measurements of a single-domain wall propagating in a magnetic nanowire are presented (Ono *et al.*, 1999). Because the GMR detection method provides information on the domain wall position, as shown in equation (1),

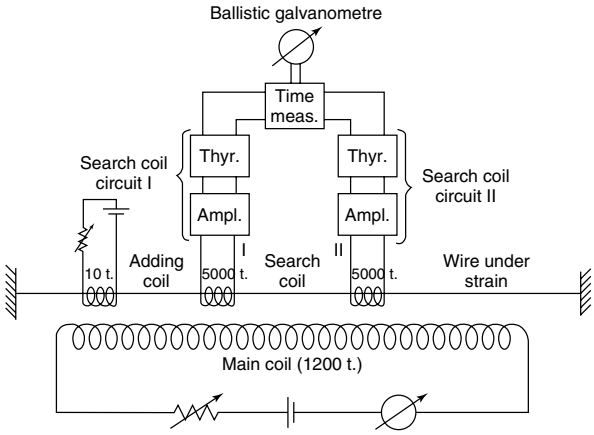

Figure 5. Schematic diagram of the circuit for velocity measurements by Sixtus and Tonks (1931). (Reproduced from Sixtus & Tonks 1931, with permission from the American Physical Society. © 1931.)

the domain wall velocity, $v = \mathrm{d}x/\mathrm{d}t$, can be determined by the time-domain measurements, and v is given by

$$v = \frac{\mathrm{d}x}{\mathrm{d}t} = \frac{L}{R_{\uparrow\downarrow} - R_{\uparrow\uparrow}} \frac{\mathrm{d}R}{\mathrm{d}t} \tag{2}$$

Thus, the GMR method can offer the time variation of velocity. This is an advantage over the experiments on bulk magnetic wires by Sixtus and Tonks, where only the average velocity of a domain wall can be obtained during the propagation in bulky scale (Sixtus and Tonks, 1931).

The samples for the domain wall velocity measurements have trilayer structures of $Ni_{81}Fe_{19}$(40 nm)/Cu(20 nm)/$Ni_{81}Fe_{19}$(5 nm). The width of the wire is 0.5 μm and the sample has four current–voltage terminals where the voltage is probed over a distance of 2 mm. The magnetic field was applied along the wire axis. The resistance was determined using a four-point dc technique. An electrical current flowing in a sample was supplied by a battery (1.5 V) to minimize the noise from a current source. The magnitude of the electrical current was adjusted by using a proper resistance in the circuit. The typical current was 100 μA. The voltage across two voltage probes was monitored by a differential preamplifier and a digital oscilloscope. The current passing through the electromagnet was also monitored by the digital oscilloscope, so as to obtain both resistance and applied magnetic field during the magnetization reversal, simultaneously.

Figure 6 shows the resistance change of the trilayer system at 77 K as a function of the applied magnetic field. Prior to the measurement, a magnetic field of 500 Oe was applied in order to align the magnetization in one direction. Then, the resistance was measured at 10 ms intervals with the sweeping field toward the counter direction at the sweeping rate of 20 Oe s^{-1}. Provided that the counter field is smaller than a critical field (70 Oe), both magnetizations in two NiFe layers are aligned in parallel, and the resistance takes the smallest value. When the applied magnetic field exceeds 70 Oe, the resistance increases and remains at the largest value until the field reaches 120 Oe, and then the resistance abruptly decreases to the smallest value. The result indicates that the antiparallel magnetization alignment is realized in the field range between 80 and 120 Oe, where the resistance shows the largest value. The change in resistance at 80 and 120 Oe is attributed to the magnetization reversals of the 5-nm-thick NiFe and 40-nm-thick NiFe layers, respectively. Since we did not find any measured point during the magnetization reversal of the 40-nm-thick NiFe in Figure 6, it is concluded that the magnetization reversal of the 40-nm-thick NiFe is completed within 10 ms. On the other hand, the magnetization reversal of the 5-nm-thick NiFe proceeds gradually with increasing applied magnetic field. This indicates that the magnetization reversal of the 5-nm-thick NiFe takes place by the pinning and de-pinning of the magnetic domain wall. Hereafter, we focus on the magnetization reversal of the 40-nm-thick NiFe.

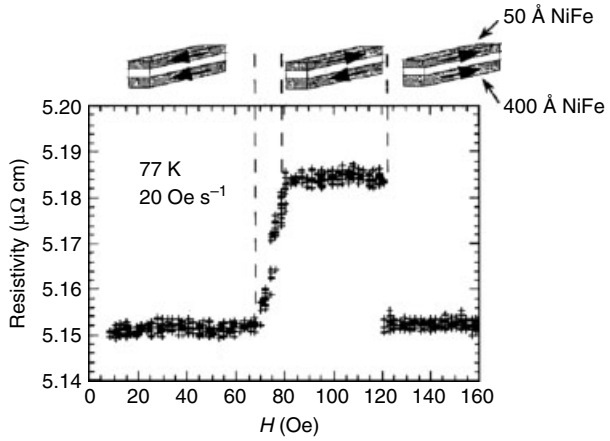

Figure 6. Resistance as a function of the external magnetic field at 77 K. The resistance was measured at 10 ms intervals while sweeping the field toward the counter direction at the sweeping rate of 20 Oe s^{-1}. The magnetic domain structures inferred from the resistance measurement are schematically shown. (Reproduced from T. Ono, H. Miyajima, K. Shigeto, K. Mibu, N. Hosoito, and T. Shinjo, *Science*, **284** (1999), with permission from AAAS.)

Figure 7 shows an experimental result on the time variation of the resistance during the magnetization reversal of the 40-nm-thick NiFe layer. The data were collected at 40-ns intervals. The linear variation of resistance with time

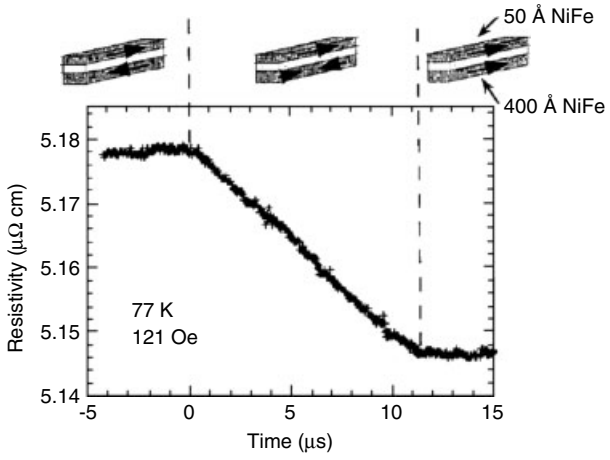

Figure 7. Time variation of the resistance during the magnetization reversal of the 40-nm-thick NiFe layer at 77 K, which was collected at 40 ns intervals. The applied magnetic field simultaneously monitored by digital oscilloscope was 121 Oe. As the sweeping rate of the applied magnetic field was 20 Oe s^{-1}, the variation of the applied magnetic field during magnetization reversal is less than 2×10^{-5} Oe, that is, the applied magnetic field is regarded as constant during the measurements. (Reproduced from T. Ono, H. Miyajima, K. Shigeto, K. Mibu, N. Hosoito, and T. Shinjo, *Science*, **284** (1999), with permission from AAAS.)

in Figure 7 indicates that the propagation velocity of the magnetic domain wall is constant during the magnetization reversal of the 40-nm-thick NiFe layer. The propagation velocity of the magnetic domain wall at the applied field of 121 Oe is estimated to be 182 m s^{-1}, which is calculated from the separation (2 mm) of the two voltage probes and the time (11 μs) the wall traveled across it. Since the sweeping rate of the applied magnetic field was 20 Oe s^{-1}, the variation of the applied magnetic field during magnetization reversal is less than 2×10^{-5} Oe, that is, the applied field is regarded as constant during the measurements.

Since the reversal field of the 40-nm-thick NiFe varied in every measurement, ranging from 90 to 140 Oe, the wall velocities at various magnetic fields were obtained by repeating the measurements. The result at 100 K is shown in Figure 8. The wall velocity depends linearly on the applied magnetic field, and it is described as $v = \mu(H - H_0)$, where v is the wall velocity, H the applied magnetic field, μ so-called wall mobility, and it was obtained that $\mu = 2.6$ (m s^{-1} Oe^{-1}) and $H_0 = 38$ (Oe). Here, we utilized the statistical nature of the magnetization reversal field to obtain the external magnetic field dependence of the domain wall velocity. A similar but more sophisticated experiment was performed by Himeno *et al*. (2004). They set two Cu wires to cross the magnetic wire at the ends of the wire, which produced a pulsed local magnetic field by a flow of pulsed electric current. This pulsed local magnetic field can nucleate a domain wall at the end of the magnetic wire under a given external magnetic field. This enables us to determine the domain wall velocity as a function of the external magnetic field in a controlled manner.

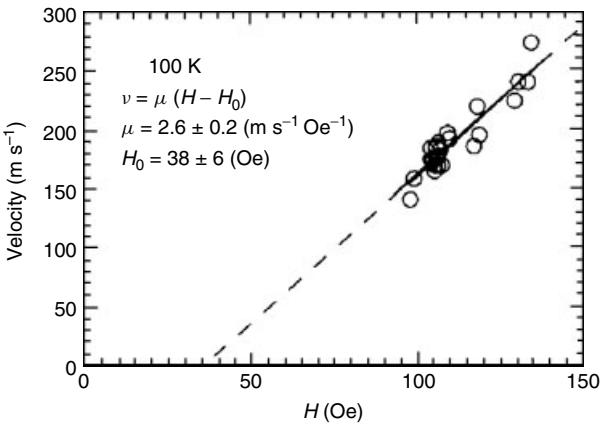

Figure 8. Dependence of domain wall velocity v on amplitude H of the applied magnetic field at 100 K. The wall velocity depends linearly on the applied magnetic field and is described as $v = \mu(H - H_0)$, where $\mu = 2.6$ (m s^{-1} Oe^{-1}) and $H_0 = 38$ (Oe). (Reproduced from T. Ono, H. Miyajima, K. Shigeto, K. Mibu, N. Hosoito, and T. Shinjo, *Science*, **284** (1999), with permission from AAAS.)

Magneto-optic Kerr effect magnetometer in micron-scale spatial resolution, together with the pulsed magnetic field, offers another approach to measure a domain wall velocity. It has been reported that very high domain wall velocity over 1000 m s^{-1} was realized for a single-layer 5-nm-thick $Ni_{80}Fe_{20}$ wire with 200 nm in width (Atkinson *et al*., 2003). The result has been reproduced well by the micromagnetics simulation by considering the corrugation of the magnetic wire (Nakatani, Thiaville and Miltat, 2003).

2 DOMAIN WALL PROPAGATION BY AN ELECTRIC CURRENT

Figure 9(a) illustrates a domain wall between two domains in a magnetic wire; the arrows show the direction of magnetic moments. The magnetic domain wall is a transition region of the magnetic moments between domains, and the direction of moments gradually changes in the domain wall. What will happen if an electric current flows through a domain wall? Suppose a conduction electron passes though the domain wall from left to right. During this travel, the spin of conduction electron follows the direction of local magnetic

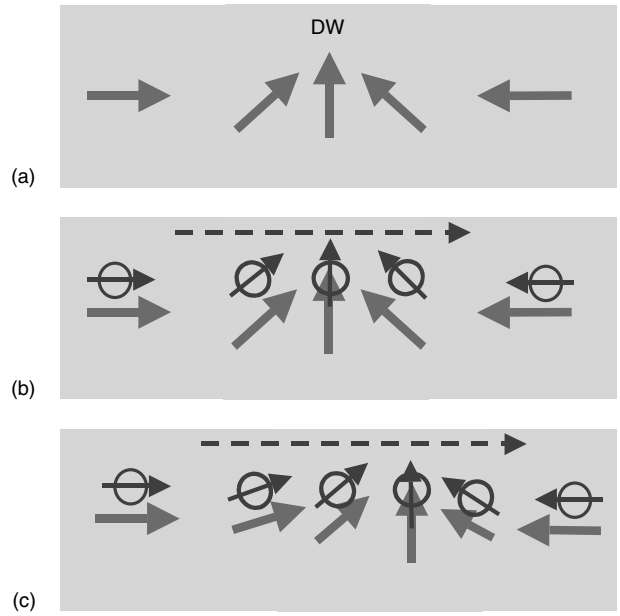

Figure 9. Schematic illustration of current-driven domain wall motion; (a) a domain wall between two domains in a magnetic wire. The arrows show the direction of magnetic moments. The magnetic domain wall is a transition region of the magnetic moments between domains, and the direction of moments gradually changes in the domain wall. (b) The spin of conduction electron follows the direction of local magnetic moments because of the s–d interaction. (c) As a reaction, the local magnetic moments rotate in the reverse direction, and in consequence, the electric current displaces the domain wall.

moments because of the s–d interaction (Figure 9b). As a reaction, the local magnetic moments rotate in the reverse direction (Figure 9c), and, in consequence, the electric current can displace the domain wall (Berger, 1984, 1992). This current-driven domain wall motion provides a new strategy to manipulate a magnetic configuration without the assistance of a magnetic field, and will improve drastically the performance and functions of recently proposed spintronic devices, whose operation is based on the motion of a magnetic domain wall (Allwood *et al*., 2002; Versluijs, Bari and Coey, 2001). Reports on this subject have been increasing in recent years from both theoretical (Tatara and Kohno, 2004; Li and Zhang, 2004; Zhang and Li, 2004; Waintal and Viret, 2004; Thiaville, Nakatani, Miltat and Vernie, 2004; Thiaville, Nakatani, Miltat and Suzuki, 2005) and experimental (Grollier *et al*., 2003; Tsoi, Fontana and Parkin, 2003; Klaui *et al*., 2003; Kimura, Otani, Tsukagoshi and Aoyagi, 2003; Yamaguchi *et al*., 2004; Lim *et al*., 2004; Vernier *et al*., 2004; Yamanouchi, Chiba, Matsukura and Ohno, 2004; Saitoh, Miyajima, Yamaoka and Tatara, 2004; Klaui *et al*., 2005) points of view because of its scientific and technological importance. However, many important results cannot be reviewed here owing to limitations of space. In this section, only the result of direct observation of the current-driven domain wall motion in a microfabricated magnetic wire is presented (Yamaguchi *et al*., 2004). Magnetic force microscopy (MFM) is used to show that a single-domain wall can be displaced back and forth by positive and negative pulsed currents.

An L-shaped magnetic wire with a round corner, as schematically illustrated in Figure 10, was prepared for the experiments. One end of the L-shaped magnetic wire is connected to a diamond-shaped pad, which acts as a domain wall injector (Shigeto, Shinjo and Ono, 1999), and the other end is sharply pointed to prevent a nucleation of a domain wall from this end (Schrefl, Fidler, Kirk and Chapman, 1997). L-shaped magnetic wires of 10-nm-thick $Ni_{81}Fe_{19}$ were fabricated onto thermally oxidized Si substrates by means of an e-beam lithography and a lift-off method. The width of the wire is 240 nm.

In order to introduce a domain wall positioned in the vicinity of the corner, the direction of the external magnetic field was tilted from the wire axis in the substrate plane as shown in Figure 10. In the initial stage, a magnetic field of +1 kOe was applied in order to align the magnetization in one direction along the wire. Then, a single-domain wall was introduced by applying a magnetic field of −175 Oe. After that, the MFM observations were carried out in the absence of a magnetic field. The existence of the single-domain wall in the vicinity of the corner was confirmed as shown in Figure 11(a). The domain wall is imaged as a bright contrast, which corresponds to the stray field from positive

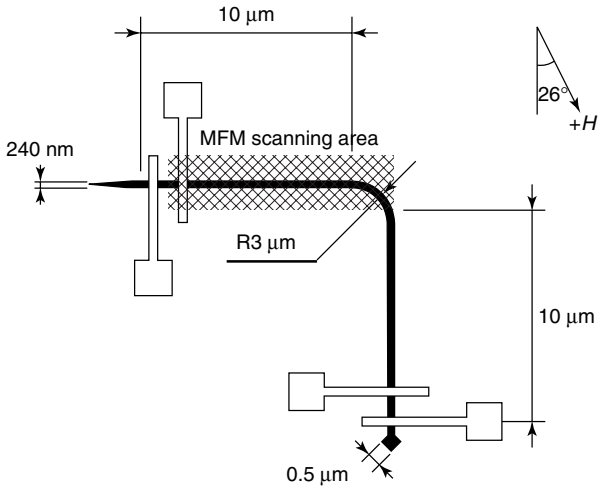

Figure 10. Schematic illustration of a top view of the sample. One end of the L-shaped wire is connected to a diamond-shaped pad, which acts as a domain wall injector, and the other end is sharply pointed to prevent a nucleation of a domain wall from this end. The wire has four electrodes made of Cu. MFM observations were performed for the hatched area at room temperature. (Reproduced from Yamaguchi *et al*., 2004, with permission from the American Physical Society. © 2004.)

magnetic charge. In this case, a head-to-head domain wall is realized as illustrated schematically in Figure 11(d). The position and the shape of the domain wall were unchanged after several MFM scans, indicating that the domain wall was pinned by a local structural defect, and that a stray field from the probe was too small to change the magnetic structure and position of the domain wall.

After the observation of Figure 11(a), a pulsed current was applied through the wire in the absence of a magnetic field. The current density and the pulse duration were $7.0 \times 10^{11}\,\mathrm{A\,m^{-2}}$ and 5 μs, respectively (The values of the current density here are different from those in Yamaguchi *et al*., (2004). In Yamaguchi *et al*., (2004), the current density has been calculated using the pulsed voltage applied to the sample with the sample resistance at room temperature. However, it was found in the following study that the sample resistance, when the current-driven domain wall motion occurred, was much higher than the sample resistance at room temperature. Thus, the values of the current density in Yamaguchi *et al*., (2004) were inaccurate. The current density presented here was calculated using the value of the pulsed current, which was directly measured). Figure 11(b) shows the MFM image after an application of the pulsed current from left to right. The domain wall, which had been in the vicinity of the corner (Figure 11a), was displaced from right to left by the application of the pulsed current. Thus, the direction of the domain wall motion is opposite to the current direction. Furthermore, the direction of the domain

wall motion can be reversed by switching the current polarity as shown in Figure 11(c). These results are consistent with the spin transfer mechanism (Berger, 1984, 1992).

The same experiments for a domain wall with different polarities, a tail-to-tail domain wall, were performed to examine the effect of a magnetic field generated by the current (Oersted field). The tail-to-tail domain wall was generated by the following procedure. A magnetic field of −1 kOe was applied in order to align the magnetization in the direction opposite to that in the previous experiment. Then, a tail-to-tail domain wall (DW) was introduced by applying a magnetic field of +175 Oe. The introduced DW is imaged as a dark contrast in Figure 12(a), which indicates that a tail-to-tail domain wall is formed as schematically illustrated in Figure 12(d). Figure 12(a–c) show that the direction of the tail-to-tail DW displacement is also opposite to the current direction. The fact that both head-to-head and tail-to-tail domain walls are displaced opposite to the current direction indicates clearly that the domain wall motion is not caused by the Oersted field.

Figure 13(a–k) are successive MFM images with one pulsed current applied between each consecutive image. The current density and the pulse duration were $7.0 \times 10^{11}\,\mathrm{A\,m^{-2}}$ and 0.5 μs, respectively. Each pulse displaced the domain wall opposite to the direction of the current. The difference in the displacement for each pulse is possibly due to the pinning by randomly located defects. The average displacement per pulse did not depend on the polarity of the pulsed current. The average domain wall displacement per pulse as a function of the pulse duration under the condition of constant current density of $7.0 \times 10^{11}\,\mathrm{A\,m^{-2}}$ is shown in Figure 14. The average domain wall displacement is proportional to the pulse duration, which indicates that the domain wall has a constant velocity of $3.0\,\mathrm{m\,s^{-1}}$. It was also confirmed that the domain wall velocity increases with the current density.

It was shown that the domain wall position in the wire can be controlled by tuning the intensity, the duration and the polarity of the pulsed current, and thus the current-driven domain wall motion has the potential for the spintronic device application. However, there are several issues posed to its practical applications. The most important of these issues is the reduction of the high current density required for the current-driven domain wall motion. Recent experiments indicated that, in some cases, the high current density results in the considerable Joule heating of the sample (Yamaguchi *et al*., 2005). Though the lower threshold current density of $10^{9}\,\mathrm{A\,m^{-2}}$ has been reported for ferromagnetic semiconductor (Ga, Mn)As, the Curie temperature of this

material is below room temperature (Yamanouchi, Chiba, Matsukura and Ohno, 2004). Thus, it is indispensable to explore a way to reduce the threshold current density for ferromagnetic metals from the viewpoint of practical applications.

Current Induced Domain-wall Motion in Magnetic Nanowires

Luc Thomas and Stuart Parkin
IBM Almaden Research Center, San José, CA, USA

1 INTRODUCTION

Over the past several years, there has been renewed interest in understanding the interaction between spin-polarized current and magnetic domain walls (DWs), a phenomenon that was first studied more than 20 years ago in macroscopic magnetic thin films. Although there are several possible ways in which current can interact with domain walls, perhaps the most interesting interaction is that in which spin angular momentum from spin-polarized current can result in motion of the domain wall. Current passing through almost any magnetic material readily becomes spin polarized through spin-dependent electron scattering processes. Since motion of a domain wall requires reversal of magnetic moments, and, since spin angular momentum is conserved, the transfer of spin angular momentum from the current to the magnetic system can result in domain-wall excitation or movement, both precessional and translational.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

Advances in lithographic techniques now allow the study of domain walls in confined magnetic nanostructures with lateral dimensions as small as a few tens of nanometers. Moreover, the magnetic configurations of such structures can be engineered by properly shaping them. Thus, whereas earlier studies involved complex patterns of several domain walls, it is now possible to study the current-induced motion of a single domain wall by injecting a wall into a nanopatterned magnetic device.

In this chapter, we review recent theoretical developments and experiments related to the current-driven motion of domain walls in magnetic nanowires. This is a challenging task, since this field of research is still in its infancy and yet the field is developing at a rapid pace. Note that several aspects of the current-induced motion of domain walls from spin momentum transfer are closely related to that of the current-induced excitation and switching of magnetization in spin-valve and magnetic tunnel junction structures. These latter phenomena are reviewed extensively elsewhere in this encyclopedia.

In the first part of this chapter, we briefly review the structure of DWs in magnetic nanowires. We then discuss theoretical models, which have been developed to describe the interaction of spin-polarized current with such DWs, and discuss some of the consequences and predictions of these models.

The second part of this chapter is devoted to firstly, a review of various experimental procedures and techniques, including the fabrication of magnetic nanodevices and useful DW detection techniques. Secondly, the manipulation of DWs using magnetic fields is discussed in some detail since this is very helpful in appreciating the significantly different consequences of their manipulation by current.

Finally, we review experiments on the current-driven motion of DWs.

In the final part of this chapter, we briefly discuss possible applications of the phenomena described in this chapter to potential magnetic memory and logic devices.

2 THEORY AND SIMULATIONS

2.1 Domain walls in nanowires

Magnetic DWs have been studied in bulk samples and thin films for nearly a century. DWs have structures which range from the simplest Bloch wall, which can be described analytically by a one-dimensional model, to complex two- and three-dimensional structures. There are several excellent reviews of this topic including, for example, Hubert and Schafer's comprehensive textbook (Hubert and Schäfer, 2000). In this section, we discuss the most common DW structures found in soft magnetic nanowires, the so-called head-to-head (or tail-to-tail) DWs. We also describe Bloch walls, which can be found in nanowires formed from materials with large perpendicular magnetic anisotropy.

2.1.1 Head-to-head domain walls in soft magnetic nanowires

Macroscopic magnetic structures will typically form flux-closed magnetic domain structures, which lower their energy. In sufficiently narrow nanowires made from soft magnetic materials, for example, submicron-wide permalloy ($Ni_{81}Fe_{19}$) wires, flux-closed domain structures are no longer energetically favored. Rather, owing to the nanowire's magnetic shape anisotropy, magnetic domains are aligned along the nanowire's length, with magnetizations pointing toward (or away) from each another. These domains are separated by head-to-head (or tail-to-tail) DWs.

The structure of head-to-head DWs was first studied using micromagnetic simulations by McMichael and Donahue (1997). They found two distinct DW structures: the transverse (T) wall and the vortex (V) wall. Simulated magnetization maps for these two wall structures are shown in Figure 1(g) and (h). Which of these two DWs has the lowest energy depends on the width w and thickness t of the wire: the (w, t) boundary between these two states was found numerically to be given by:

$$t \cdot w = C\delta^2$$

where the exchange length δ is given by $\delta^2 = \frac{A}{\mu_0 M_s^2}$ (1)

For permalloy ($M_s = 800\,\mathrm{emu\,cm^{-3}}$, $A = 1.3 \times 10^{-6}\,\mathrm{erg\,cm^{-1}}$), the exchange length is very short at about $\delta = 4\,\mathrm{nm}$ and the numerical constant C was determined to be 128. This phase diagram has been refined recently by Nakatani, Thiaville and Miltat (2005), who have identified an intermediate magnetic state between the T and V walls, as an asymmetric transverse wall.

Note that the relative stability of T and V walls was also studied by calculating the energy of the V wall as a function of the position of the vortex core with respect to the center of the nanowire (Youk *et al*., 2006). When the V wall is the lowest energy state, its energy is minimized when its core is at the center of the wire, whereas when the T wall has the lower energy, the V wall's energy is minimized when its core is at one edge of the nanowire. Interestingly, the authors also identified metastable configurations in which the vortex core is offset from the center of the wire.

The DW width is a critical parameter for both field and current-driven DW motion. However, this quantity is not well defined, since the magnetization of both T and V walls varies significantly across the width of a nanowire, as shown in Figure 1. In Nakatani, Thiaville and Miltat (2005), the DW width parameter Δ was estimated by fitting the DW magnetization profile with that derived for a 1D Bloch wall, namely:

$$\begin{aligned} \theta(x) &= 2\arctan[e^{x/\Delta}] \\ m_x &= \cos[\theta(x)] = \tanh\frac{x}{\Delta} \\ m_y &= \sin[\theta(x)] = \frac{1}{\cosh\frac{x}{\Delta}} \end{aligned} \quad (2)$$

where $m_{x,y}$ are the two in-plane components of the magnetization normalized to the saturation value, and θ is the angle between the local magnetization direction and the nanowire's long axis x (i.e., the easy magnetization direction). This profile describes the transverse wall form quite well, providing that Δ is allowed to vary across the nanowire's width (i.e., the direction y), as shown by the solid lines in Figure 1(a)–(c). By contrast, these expressions do not account for the V wall's profile. Nakatani, Thiaville and Miltat (2005) extracted a width for the V wall by fitting the profile of the longitudinal magnetization averaged across the width of the nanowire (Figure 1c and f). For both V and T walls, the DW width parameter Δ was found to depend only weakly on the wire thickness, but to scale with the wire width w, according to the approximate relations (Nakatani, Thiaville and Miltat, 2005):

$$\Delta_{TW} = \frac{w}{\pi} \quad \Delta_{VW} = \frac{3w}{4} \quad (3)$$

The V wall is significantly wider than the T wall. Note that the actual length scale over which most of the magnetization change occurs is $\pi\Delta$, which is much larger than that given by equation (3) (Malozemoff and Slonczewski, 1979).

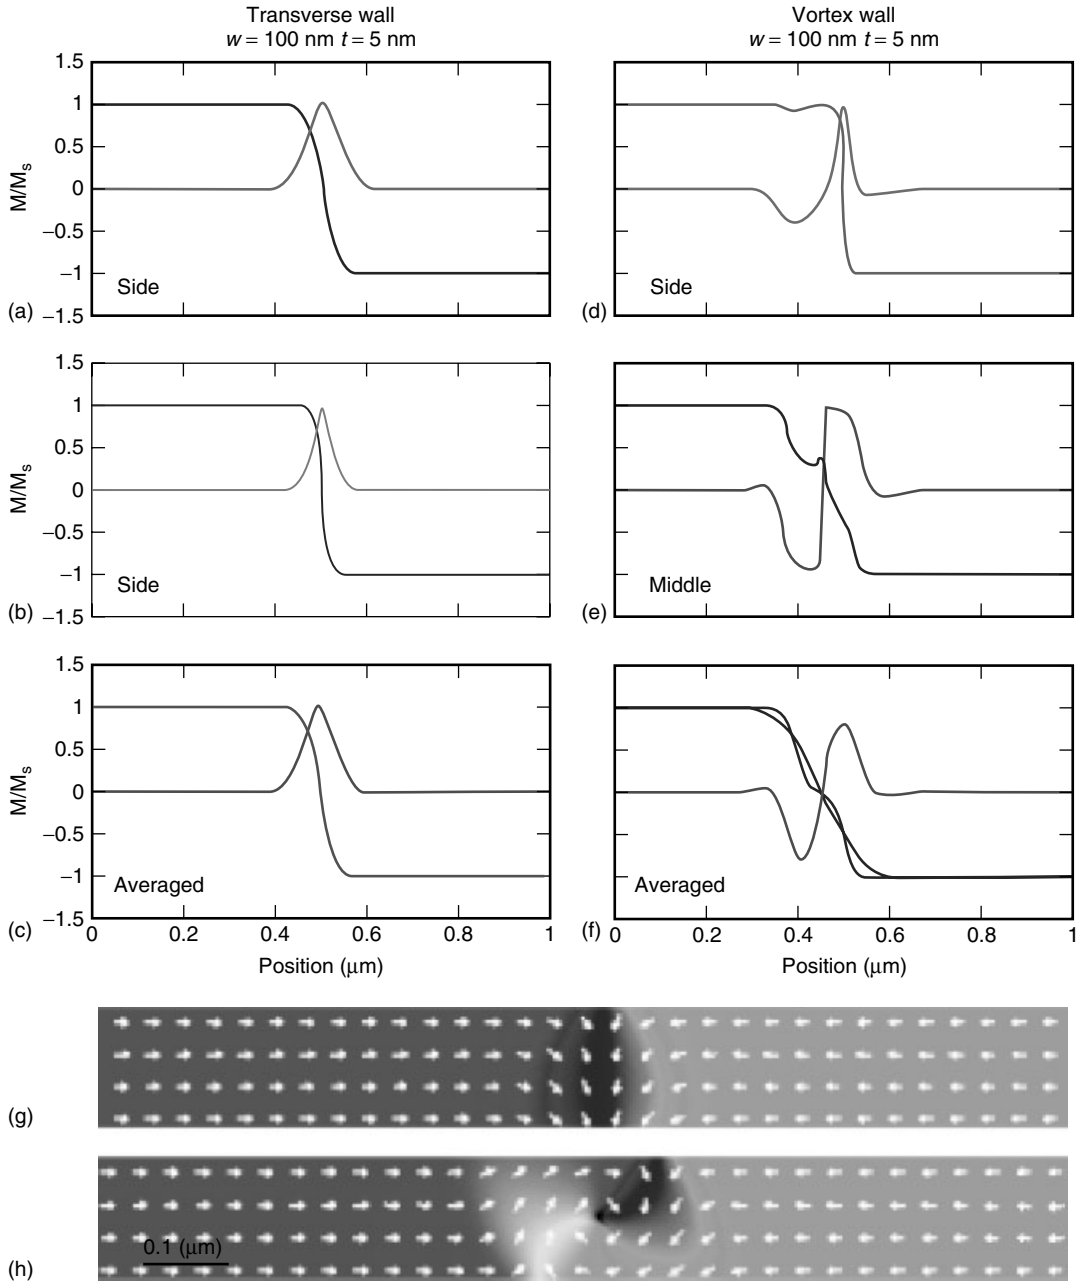

Figure 1. Calculated structures of transverse (T) and vortex (V) head-to-head DWs derived from micromagnetic simulations. Profiles of the longitudinal (dark gray) and transverse (medium gray) magnetizations along the nanowire's length are shown at different positions across the nanowire's width: T wall: top and bottom edges; V wall: topside and center. The profiles of the magnetization averaged over the width of the nanowire for both the T and V walls are also shown. Fits to the analytical 1D Bloch wall, equation (2), are shown in all cases for the T wall, but only for the averaged longitudinal magnetization for the V wall. For the T wall, the magnetization profile has roughly the same form across the width of the wire, although the DW width varies significantly. By contrast, the magnetization profiles are quite different for the V wall at the edges and at the center of the wire.

The DW width can be deduced in several other ways. For example, as discussed in Section 3.4.3, the DW velocity is proportional to Δ in small magnetic fields. The dynamical DW width derived in this way is in good agreement with that obtained from the 1D DW expression of equation (2) for the transverse wall, but this is not the case for the V wall. Indeed, since the V wall moves more slowly than the T wall, the dynamical DW width is actually smaller for the V than for the T wall. As shown by Nakatani, Thiaville and Miltat (2005), a better agreement with the dynamical DW width is

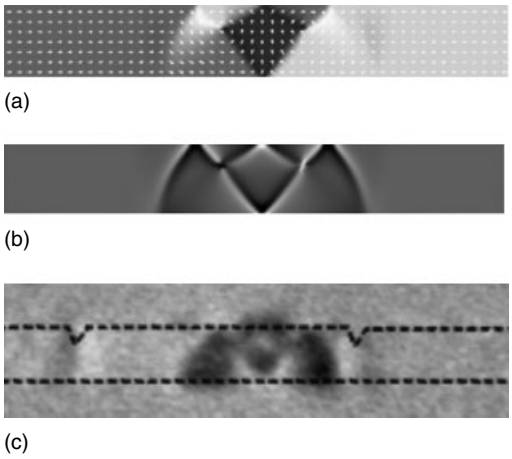

Figure 2. (a) Magnetization distribution of a two-vortex wall calculated from micromagnetic simulations of a permalloy nanowire (200 nm wide, 40 nm thick). The middle map (b) shows the divergence of the magnetization for comparison with the MFM image (c) of such a two-vortex wall measured in a 40-nm-thick, 300-nm-wide permalloy nanowire. The dotted lines show the edges of the nanowires as determined by AFM.

found by using a definition of the DW width proposed by Thiele (1973a), in which the inverse DW width is given by:

$$\Delta^{-1} = \frac{1}{2wtM_S^2}\int_V \left(\frac{\partial \vec{M}}{\partial x}\right)^2 \mathrm{d}V \qquad (4)$$

Another experimental method of estimating the DW width, which is relevant to many of the experimental results discussed in this chapter, is from the anisotropic magnetoresistance (AMR) of the DW (see Section 3.3.1).

More complex head-to-head DW structures than either the T or the V DW can also be found in magnetic nanowires, depending on their size and the aspect ratio of their cross section. Figure 2 shows an example of a DW found in sufficiently thick nanowires. Flux-closed domain structures, which can be seen in the figure at the upper edge of the nanowire, form so as to reduce the magnetostatic energy of the DW. Two-vortex DWs of opposite chirality can be seen in the figure. We have observed this wall structure using magnetic force microscopy (MFM) imaging in permalloy nanowires more than 20 nm thick. Florez, Krafft and Gomez (2005) have reported similar structures in permalloy wires, 40 nm thick.

In narrow wires with circular or square cross sections, a vortex wall can also appear, with the vortex core parallel to the long axis of the wire. This structure has been described by Thiaville and Nakatani as a Bloch-point wall (Thiaville and Nakatani, 2006).

An interesting methodology for categorizing these different DW structures was proposed recently by Youk *et al.* (2006), Tchernyshyov and Chern (2005), and Chern, Youk and Tchernyshyov (2006). They describe the DWs as composite objects built from a certain number of topological defects characterized by a winding number n. Vortices in the bulk of the wire have $n = 1$ and antivortices, $n = -1$, whereas edge defects present in the transverse wall have winding numbers $n = \pm 1/2$. The vortex DW wall is built from one bulk defect (the vortex itself) and two edge defects $n = -1/2$, and the transverse wall from two edge defects $n = \pm 1/2$. For any DW structure, the total topological charge, including both edge and bulk defects, must be zero. The authors propose that the DW dynamics can be described by the creation, propagation, and annihilation of these topological defects.

As an illustration, magnetic domain structures in U-shaped nanowires of various widths, formed from 10- and 20-nm-thick CoFe films are shown in Figure 3. These images are measured in zero magnetic field by photoemission electron microscopy (PEEM). The gray scale reflects the projection of the nanowire's in-plane magnetization along the vertical axis of the image (see Section 3.3 for more details). The nanowire's magnetization is first saturated along this direction with a large magnetic field (1 kOe). After this field is reduced to zero, the magnetization is aligned along the arms of the U-shaped structure so that a DW is nucleated in the curved portion of the U. In the narrowest wires (200 nm wide), the DWs have a T structure, clearly identified by the single black triangle-shaped region. For intermediate widths, the PEEM images clearly show an asymmetric transverse wall structure (see, e.g., the 400-nm-wide/20-nm-thick or the 600-nm-wide/10-nm-thick nanowires). When the wide width is increased, V walls can clearly be identified by the alternating black/white regions (e.g., the 600-nm-wide/20-nm-thick wire). Note that for the same 600 nm width, the 10-nm-thick wire still exhibits an asymmetric T wall structure, whereas the 20-nm-thick wire already shows the V structure, following the trend shown by the phase boundary of equation (1). The 800-nm-wide wires show more complex domain patterns, with ripples starting to appear along the arms of the wire.

Similar experiments have been reported by Klaui *et al.* (2004) who used PEEM microscopy to study the DW structure in cobalt rings, whose thicknesses were varied between 2 and 38 nm, and whose widths were varied from 100 to 730 nm. A clear phase boundary between T and V walls was observed as a function of the ring dimensions. However, this transition did not agree with that anticipated by equation (1). The T wall was observed for dimensions where the V wall should be more stable. This discrepancy is a consequence of the metastability of the two wall structures. Even though the V has lower energy, an energy barrier prevents the transformation of the T wall into the V wall.

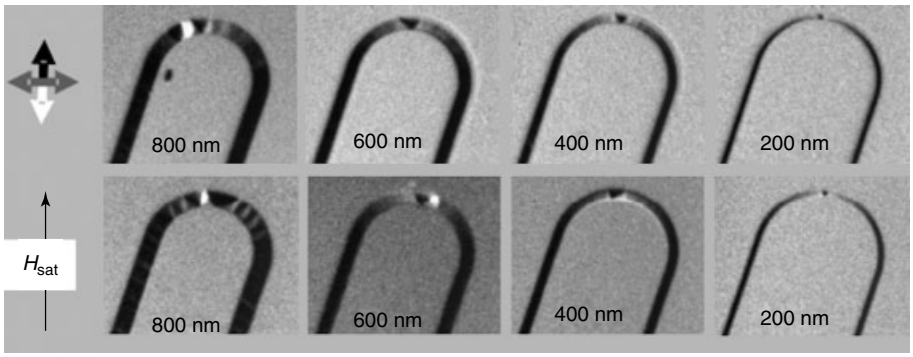

Figure 3. PEEM images of the magnetic domain structure of U-shaped CoFe nanowires with different widths and a thickness of 10 nm (upper) or 20 nm (lower). The samples were first saturated along the direction indicated by the arrow, and the images were taken in remanence.

It turns out that the T wall is favored by the DW injection process (using a large transverse field), so T walls are observed for a wide range of ring sizes.

2.1.2 Other types of walls

Head-to-head DWs are only stable in nanowires with strong shape anisotropy and/or uniaxial anisotropy along the nanowire's direction. In the presence of significant crystalline anisotropy in the in-plane transverse or out-of-plane directions, other domain patterns can be observed even for submicron wires. For example, Schrefl, Fidler, Kirk and Chapman (1997) have reported flux-closed domain patterns in NiFe elements as narrow as 200 nm in which the domains' magnetization is aligned transverse to the nanowire's direction. This was unexpected in nominally soft NiFe, but was explained by a strong stress-induced anisotropy. For materials such as Pt/Co/Pt trilayers with strong perpendicular anisotropy ($\sim 10^7\,\mathrm{erg\,cm^{-3}}$), the domains' magnetization is oriented along the out-of-plane anisotropy direction. In such nanowires, the DWs are nearly ideal Bloch walls (Wunderlich *et al*., 2001; Cayssol *et al*., 2004), with widths as small as 5 nm. In the case of (Ga,Mn)As epilayers, in-plane cubic anisotropy has been reported (Tang, Kawakami, Awschalom and Roukes, 2003), giving rise to 90° DWs (Holleitner *et al*., 2004; Honolka *et al*., 2005; Tang *et al*., 2004; Tang and Roukes, 2004) albeit in large structures (100 µm wide).

2.2 Theoretical models of current-driven domain-wall motion

2.2.1 Early work

The interplay between magnetization and charge carriers in metallic ferromagnets has been studied for several decades. The first reported interaction of current on DWs in such materials was due to eddy-current losses (Williams, Shockley and Kittel, 1950). The DW mobility in macroscopic samples at low fields was found to be almost two orders of magnitude smaller than that expected from calculations by Landau and Lifshitz, which took into account magnetic relaxation.

The influence of an electric current flowing within a ferromagnet, or in the vicinity of it, was first studied in the 1970s by Carr (1974a,b), Emtage (1974), and Charap (1974), and independently by Berger (1974), Partin, Karnezos, deMenezes and Berger (1974). These authors found that in materials for which the current flow is sensitive to the magnetization, for example, because of the Hall effect or magnetoresistance, the presence of a DW would, in turn, affect the current distribution. For example, in the case of a 180° DW, the reversal of the magnetization is associated with reversal of the Hall electric field. The nonuniform current distribution can be modeled by a uniform current on which an eddy-current loop concentric with the center of the DW is superimposed. This current loop thus creates a magnetic field, which exerts a net force on the DW in the direction of the drift velocity of the carriers and, thereby, can lead to DW motion. This mechanism was called *self-induced DW drag* or *hydromagnetic domain drag*. The force on the DW can be written, following Berger's notation, as:

$$F_x = 2M_s\mu_e^{-1}(R_1 J - v_w) \quad \mu_e = \frac{\pi^3 \rho}{8.4 t M_s} \tag{5}$$

where J is the current density perpendicular to the wall, R_1 is the anomalous Hall constant, v_w is the wall velocity, μ_e is the wall mobility, as limited by eddy currents, (which is different from the intrinsic wall mobility, which is related to damping), and t is the film thickness. Since the net force on the DW increases with the sample thickness it vanishes for very thin wires.

Because magnetic fields extend over fairly long distances, the DW drag mechanism can also occur if the current does not flow directly through the DW, but rather through a

neighboring over or underlayer, such as a semiconducting (Carr, 1974b; Charap, 1974) or a permalloy (Carr, 1974a; Emtage, 1974) layer. This is particularly applied to the motion of DWs in magnetic bubble materials, which were made of high-resistivity oxides, and which were the subject of much of this early work.

Note that all these theories describe 180° DWs, for which the current is perpendicular to the magnetization direction both in the domains and in the DW. In this case, the Hall electric field reverses across the DW, irrespective of the DW structure. This is not the case for head-to-head DWs, for which current and magnetization are parallel everywhere except within the DW.

This first mechanism derives solely from electromagnetic effects. The influence of the carrier spins was recognized a few years later by Berger (1978). He proposed that the s–d exchange interaction between the conduction electrons and the localized magnetic moments could influence the DW dynamics in two different ways. The first contribution, which Berger called *s–d exchange drag* (Berger, 1984), is a viscous force on the DW which is proportional to the current. This term arises from the difference between the spin-dependent reflection coefficients of the conduction electrons at the DW. The second contribution is an 'exchange torque' related to the transfer of spin angular momentum from the s conduction electrons to the localized magnetization (Berger, 1978, 1986). This mechanism is analogous to the spin-transfer torque proposed by Slonczewski in magnetic heterostructures in which magnetic layers are separated by thin metal or insulating layers (Slonczewski, 1996).

2.2.2 *Recent results: two types of torques*

In the past few years, new experimental results on the interaction between electric current and magnetic DWs have triggered a flurry of theoretical studies (Shibata, Tatara and Kohno, 2005; Bazaliy, Jones and Zhang, 1998; Tatara and Kohno, 2004; Tatara *et al*., 2006; Zhang and Li, 2004; Li and Zhang, 2004a,b; He, Li and Zhang, 2005; Barnes and Maekawa, 2005; Thiaville, Nakatani, Miltat and Vernier, 2004; Thiaville, Nakatani, Miltat and Suzuki, 2005; Waintal and Viret, 2004; Xiao, Zangwill and Stiles, 2006; Dugaev *et al*., 2006; Tserkovnyak, Skadsem, Brataas and Bauer, 2006; Tatara, Vernier and Ferre, 2005; Ohe and Kramer, 2006). In most cases, theorists follow a two-step approach. First, they calculate the current-induced torque on the magnetization from the spin-polarized s conduction electrons in the limit of static magnetic moments, since the magnetization dynamics are slow compared to those of the electrons. Second, the influence of the current-related torque on the DW dynamics is studied by solving the Landau–Lifshitz–Gilbert (LLG) equation of motion, usually by approximating the DW structure, so as to obtain analytical expressions.

The influence of the current on the magnetization dynamics is often treated by including two spin-torque terms proportional to the gradient of the magnetization in the LLG equation. In the case of homogeneous magnetic material, and assuming the current is flowing in the x direction, the LLG equation can be written as (Thiaville, Nakatani, Miltat and Suzuki, 2005):

$$\frac{\partial \vec{m}}{\partial t} = -\gamma\, \vec{m} \times \vec{H} + \alpha\, \vec{m} \times \frac{\partial \vec{m}}{\partial t} - u \frac{\partial \vec{m}}{\partial x} + \beta u\, \vec{m} \times \frac{\partial \vec{m}}{\partial x} \quad (6)$$

where m is the magnetization normalized to the saturation value, H is the micromagnetic effective field, γ is the gyromagnetic factor, and α is the Gilbert damping constant. For permalloy films, α is of the order of 0.01 (Nibarger, Lopusnik and Silva, 2003; Nibarger, Lopusnik, Celinski and Silva, 2003)

The first two terms on the right-hand side of equation (6) are the usual precessional and damping terms, respectively, and the last two terms describe the interaction with the current.

The first current contribution is derived in the adiabatic limit. In the adiabatic limit, which, *a priori*, is justified for sufficiently wide DWs, the conduction electrons spin orientation follows the local magnetization direction. The magnitude of the adiabatic spin torque, which can be derived directly from the conservation of spin angular momentum, is given by:

$$u = \frac{g \mu_B J P}{2 e M_s} \quad (7)$$

where g is the Lande factor ($\sim$2), J is the current density, P is the spin polarization of the current, $\mu_B = 0.927 \times 10^{-20}$ emu, the Bohr magnetron, and $e = 1.6 \times 10^{-19}$ C, the electron charge. For permalloy, for which $M_s = 800\,\mathrm{emu\,cm^{-3}}$, and assuming $P = 0.4$, $u = 1\,\mathrm{m\,s^{-1}}$ when $J = 3.5 \times 10^6\,\mathrm{A\,cm^{-2}}$. Note that the polarization is sometimes replaced by the Slonczewski function (Slonczewski, 1996) $g(P)$.

The second contribution of the current is often dubbed the *nonadiabatic spin-torque* or β *term*. As shown by equation (6), it behaves as a spatially varying magnetic field which is proportional to the gradient of the magnetization. The magnitude of the nonadiabatic term is given by the dimensionless constant β, which is of the order of the damping constant α. Both the origin and the magnitude of the 'β term' is under much debate.

Zhang and Li (2004) have proposed a model in which there is a slight mistracking between the electron spin and the local magnetization direction. This generates a nonequilibrium

spin accumulation across the DW, which relaxes by spin-flip scattering toward the magnetization direction. This model leads to both adiabatic and nonadiabatic spin-torque terms (there are also two small terms proportional to the time derivative of the magnetization, which slightly modify the gyromagnetic ratio and the damping constant). The magnitude of the nonadiabatic term is written as $\beta = \tau_{ex}/\tau_{sf}$, where τ_{ex} is the relaxation time associated with the s–d exchange energy $J_{ex}(\tau_{ex} = \hbar/SJ_{ex})$ and τ_{sf} is the spin-flip relaxation time. Numerical estimates are obtained by assuming that $J_{ex} \sim 1\,\text{eV}$, $S = 2$, and $\tau_{sf} \sim 1\,\text{ps}$, giving $\beta \sim 0.01$. Note that this model assumes the DW width to be much larger than the length scale of the transverse spin accumulation (only a few nanometers), such that the nonadiabatic contribution does not vanish even for very wide DWs.

Xiao, Zangwill and Stiles (2006) cast doubt on the existence of this nonadiabatic contribution. They find that although there is a transverse spin accumulation across the DW, the spin current follows the magnetization adiabatically unless the DW width is extremely small. In the narrow wall limit, the nonadiabatic spin torque is nonlocal and oscillatory in space.

Tatara and Kohno (2004) have also calculated the two current interaction terms shown in equation (2), in both the narrow and wide DW limits. In their model, the relevant length scale is the Fermi wavelength (a few angstrom). In the wide DW limit, they obtain a spin-transfer-torque term dubbed *spin transfer* with the same form as that shown in equations (6) and (7). In the narrow DW limit, they derive a forcelike term called *momentum transfer*, which plays the same role as the β term integrated over the DW. This momentum transfer is very similar to the s–d *exchange drag* proposed by Berger (1984) and is a function of the DW resistance R_{DW}. The momentum transfer per unit cross-sectional area of the DW is written as:

$$F_{el} = neR_{DW}J(tw) = \frac{R_{DW}}{R_0}J(tw) = \frac{\rho_{DW}}{R_0}J\Delta \qquad (8)$$

where J is the current density, t and w are the wire thickness and width, respectively, n is the electron density, R_0 is the ordinary Hall coefficient ($1/R_0 = ne$), and $\rho_{DW} = R_{DW}tw/\Delta$, is the DW resistivity, where Δ is the DW width.

The linak between the nonadiabatic spin torque and DW resistance is also mentioned by Zhang and Li (2004). Although they do not explicitly discuss this relationship, it is interesting to consider the relationship between the momentum transfer force (8) and the β term. It can be seen from the LLG equation (6) (and more obviously from the integrated form (13)) that the β term indeed plays the same role as the magnetic field force term. It follows that the β-term-related force (per unit cross-sectional area) can be written as:

$$F_\beta = \frac{2M_s}{\gamma\Delta}\beta u \qquad (9)$$

By equating this with equation (8), it follows that

$$\beta = \frac{\gamma\Delta^2 e}{g\mu_B P}\frac{\rho_{DW}}{R_0} \qquad (10)$$

Interestingly, if the DW resistivity decreases as $1/\Delta^2$, as predicted by the Levy–Zhang model on DW magnetoresistance (Levy and Zhang, 1997), β will be roughly constant, independent of the DW width. In order to obtain a numerical estimate, we consider the DW resonance experiments of Saitoh, Miyajima, Yamaoka and Tatara (2004), which will be discussed later in this chapter. The sample is a permalloy nanowire, with a thickness $t = 45\,\text{nm}$ and a width $w = 70\,\text{nm}$. The DW has a transverse structure such that the DW width can be estimated as $\Delta \sim 22\,\text{nm}$ (as discussed in Section 2.1). We assume a spin polarization $P \sim 0.5$, and a Hall resistance $R_0 \sim 1.3 \times 10^{-10}\,\text{C m}^{-3}$ for permalloy (as measured, e.g., by Freitas and Berger (1985)). The DW resistance is reported to be $R_{DW} = 0.26\,\text{m}\Omega$, such that the DW resistivity is about $3.7 \times 10^{-11}\,\Omega\text{m}$. From equation (10), this leads to $\beta \sim 0.4$.

In a recent paper, Berger has developed the relationship between nonadiabatic spin torque (exchange drag in his terminology) and DW resistance further so as to describe in a single scaling plot experimental results for DW velocity, DW resistance, and critical current for DW depinning (Berger, 2006).

In both Tatara and Kohno and Zhang and Li's models, in the absence of the β term, there is an intrinsic threshold current for irreversible DW motion, even in an ideal wire without any DW pinning sites. Below this threshold value, the DW only moves short distances while the current is applied, but moves back to its original position after the current is turned off (note that this is not the case if there is an irreversible deformation of the DW's structure or if DW pinning is taken into account). Barnes and Maekawa (2005) argue that this intrinsic pinning does not exist (Barnes, 2006; Tatara Takayama and Kohno, 2006). In their model, the ground state in the presence of current corresponds to the DW moving at a constant velocity u, without any tilt or distortion. This corresponds to massless motion and in the ideal case (no roughness), there is no threshold current for DW motion: the DW starts moving, albeit very slowly, as soon as the current is nonzero. The discrepancy arises from the means of introducing damping into the LLG equation. Whereas, both the Gilbert $\left(\alpha\vec{m} \times \frac{\partial\vec{m}}{\partial t}\right)$ and the Landau–Lifshitz $\left(\frac{\alpha\gamma}{1+\alpha^2}\vec{m} \times \vec{m} \times \vec{H}\right)$ formulations are

equivalent in the absence of current, this is no longer the case when the current interaction terms are included. When the adiabatic spin-torque term is added to the LLG equation in its Gilbert or Landau–Lifshitz forms, the resulting equation differs by a term $\alpha u\, \vec{m} \times \frac{\partial \vec{m}}{\partial x}$. In other words, in the second case, the adiabatic spin torque includes a β term, with $\beta = \alpha$.

In a recent extension of their work, Tatara *et al*. (2006) have made a distinction between the nonadiabatic spin torque (i.e., momentum transfer) defined by equation (8) and the β term. The implication of both the adiabatic and nonadiabatic spin torques on the DW dynamics will be discussed in more detail in Section 2.2.3, in the framework of the semianalytical one-dimensional model.

Several recent papers cast doubts about the previous description and find that the current-induced torques cannot be written as a simple function of the magnetization gradient. Xiao, Zangwill and Stiles (2006) find that in the very narrow DW limit, the nonadiabatic torque oscillates across the DW, and extends over a length scale much larger than the DW width. Other authors find that the nonadiabaticity of the conduction electrons lead to the precession of their spins (Waintal and Viret, 2004), in turn generating spin waves which influence the DW motion (Ohe and Kramer, 2006). A recent study focused on GaMnAs also shows that the spin-orbit coupling increases the reflection of the carriers (holes in this case) at the DW, leading to spin accumulation and the enhancement of the nonadiabatic spin torque (Nguyen, Skadsem and Brataas, 2007).

Although thermal effects are not included in most theories, a few authors have addressed thermally assisted processes. Tatara, Vernier and Ferre (2005) find that in a rigid wall approximation, thermally activated wall motion occurs below the zero-temperature threshold value, and the DW velocity varies exponentially with the spin current. They also find that the velocity exhibits a 'universal behavior' in the sense that it does not depend on the pinning potential or the material parameters. In their model, thermal fluctuations are simply introduced as the transition rate over an energy barrier, which is derived from the transverse anisotropy. Recently, Duine, Nunez and Mac Donald (2007) have developed a more complete description of thermally activated processes by deriving the Langevin equations of the nonzero temperature motion of a rigid DW. They find that at nonzero temperatures, the DW velocity varies linearly with current, even without a β term.

2.2.3 *Analytical descriptions: one-dimensional model and vortex model*

Although DWs are complex three-dimensional objects, it is very useful to develop models that allow for an analytical or semianalytical description of the DW dynamics. The most widely used approach is the so-called one-dimensional (1D) model, which was developed in the 1970s and has been described in detail by Malozemoff and Slonczewski in their comprehensive book about magnetic bubbles (Malozemoff and Slonczewski, 1979). The model assumes that the DW has the 1D profile given by equation (2), such that the magnetization varies only in the direction perpendicular to the DW (here the x direction). It is also assumed that the static profile is essentially preserved during the DW motion, although the DW width is allowed to change. The dynamical DW structure is described by (in spherical coordinates):

$$\theta(x,t) = \pm 2 \arctan\left(\mathrm{e}^{\frac{x-q(t)}{\Delta}}\right)$$
$$\psi(x,t) = \Psi(t) \tag{11}$$

where q is the position of the DW center, Ψ is the tilt angle of the DW magnetization away from its equilibrium position (see Figure 4), and Δ is the DW width parameter. The latter is written as:

$$\Delta_0 = \sqrt{\frac{A}{K_0}}\Delta = \frac{\Delta_0}{\sqrt{1 + \frac{K}{K_0}\sin^2(\Psi)}} \tag{12}$$

where A is the exchange constant (erg cm^{-1}). K_0 is the magnitude of the uniaxial anisotropy that defines the magnetization direction in the magnetic domains, and K is the magnitude of the uniaxial transverse anisotropy. In the head-to-head configuration, the transverse anisotropy is that within the plane perpendicular to the wire's long axis. The magnitude of the transverse anisotropy can also be written as an anisotropy field $H_k = 2K/M_s$, where M_s is the saturation magnetization of the material. This profile was originally derived for the 1D Bloch wall. It also gives a good description of the Néel wall and the head-to-head transverse wall, provided that the axes are properly defined (see Figure 4 for the T wall). Qualitative agreement with experiments is also obtained for more complex wall structures such as the head-to-head vortex wall (Thomas *et al*., 2006).

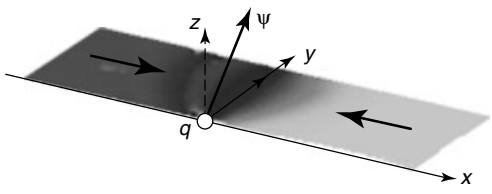

Figure 4. Transverse DW showing the definition of the variables of the 1D model: q (position of the center of mass of the DW) and Ψ (tilt angle of the DW's magnetization out of the plane of the nanowire).

In this model, the LLG equation (6) can be integrated over the static DW profile and the dynamics are described by two time-dependent variables q (DW position) and Ψ (domain distortion). The DW width Δ depends on Ψ such that it is also time dependent unless $K_0 \gg K$. For simplicity, we assume that Δ is not time dependent in the following discussion.

The LLG equation including the current-related terms can be rewritten as:

$$\begin{aligned}(1+\alpha^2)\dot{\Psi} &= -\frac{\gamma}{2M_s}\left(\frac{\partial\sigma}{\partial q}\right) - \frac{\gamma\alpha}{2}H_k \sin(2\Psi) + \frac{(\beta-\alpha)u}{\Delta} \\ (1+\alpha^2)\dot{q} &= -\frac{\alpha\gamma\Delta}{2M_s}\left(\frac{\partial\sigma}{\partial q}\right) + \frac{\gamma\Delta}{2}H_k \sin(2\Psi) + (1+\alpha\beta)u\end{aligned} \tag{13}$$

The DW potential energy $\sigma(q)$ includes the contributions from an external field and from position-dependent energy terms arising, for example, from defects in the nanowire. The field term is simply written as $\sigma(q) = -2M_s Hq$. The influence of roughness or pinning may be approximated by potential wells or barriers, which depend only on q.

It was pointed out long ago (Malozemoff and Slonczewski, 1979) that equation (13) resembles Hamilton's equations of motion for two canonical conjugate variables q and $2M_s\Psi/\gamma$, that is the position and its conjugate momentum. Following this analogy, the DW mass (Döring mass) can be defined as:

$$m_D = \frac{2M_s}{\gamma^2 \Delta H_k} S \tag{14}$$

S is the cross section of the nanowire. These equations can be solved analytically in many cases, yielding useful expressions for both the critical current and the DW velocity. As discussed earlier, the physics of the current-driven DW motion depend strongly upon the presence or absence of the β contribution. Without the β term and in zero magnetic field ($\partial\sigma/\partial q = 0$), there is an intrinsic critical current, below which the DW only moves transiently. This critical current is readily calculated by finding stationary solutions of equation (13). The stationary solution, such that $\dot{\Psi} = 0$ and $\dot{q} = v = 0$, only exists if u is smaller than a critical value, given by:

$$u_c = \frac{\gamma \Delta H_k}{2} \tag{15}$$

Note that u_c depends only on the magnetic material parameters, unless there is extremely large pinning (Tatara and Kohno, 2004). In permalloy nanowires (or other soft materials where crystalline anisotropy can be neglected), the transverse anisotropy field H_k is proportional to the shape anisotropy in the plane perpendicular to the long axis of the wire. Note that this anisotropy field is also the key parameter in models of field-driven DW motion. For example, the Walker breakdown field is directly proportional to H_k (Malozemoff and Slonczewski, 1979). If the current is smaller than this critical value, the velocity decreases rapidly (over a few nanoseconds) and the DW stops. However, when the current is reduced to zero (for example, at the end of a current pulse), the DW moves back to its initial position. On the contrary, for currents higher than this critical value, the wall can move irreversibly over long distances. In this regime, the instantaneous velocity oscillates strongly in time, in a way reminiscent of the field-driven DW motion above the Walker limit. The average velocity can be written as:

$$v = \frac{\sqrt{u^2 - u_c^2}}{1+\alpha^2} \tag{16}$$

The situation is very different when the β term is taken into account. Indeed, for an ideal wire without pinning, irreversible DW motion occurs as soon as the current is nonzero, and the terminal velocity is simply $v = \beta u/\alpha$. Therefore, in this case, the critical current becomes extrinsic, and is dependent on the magnitude of any pinning (i.e., will be related to roughness and defects).

The two key parameters of the model are the DW width Δ and the transverse anisotropy field H_k. It is essential to estimate realistic values in order to attempt a quantitative (or even qualitative) description of experiments or simulations. The DW width is readily defined for a head-to-head transverse wall, as described in Section 2.1.1. Its definition becomes slightly more ambiguous for a vortex wall, where the 'physical' DW width, largely dominated by the tails of the DW does not account for the field-driven DW dynamics. Much better agreement is obtained using the so-called dynamical DW width defined by Thiele (see Section 2.1.1), in which the (small) vortex core has larger 'weight' than the (large) tails of the DW. The transverse anisotropy H_k, which prevents the rotation of the DW's magnetization out of the plane of the wire, is somewhat more delicate. In permalloy nanowires with head-to-head transverse walls, the transverse anisotropy is directly related to the shape anisotropy of the cross section of the wire. For small values of Ψ (only small out-of-plane rotation of the wall's magnetization), calculating H_k from the shape anisotropy appears reasonable. However, for large values of Ψ, the DW's magnetization does not rotate coherently out of plane. Lower energy paths are possible, which involve deformations of the wall structure, for example, by nucleation of an antivortex. In such a case, the effective value of H_k is smaller than that calculated from the shape anisotropy. Thus, if the dynamics involves high Ψ values, the value of H_k obtained from the shape anisotropy does not provide a good quantitative description. For example, the Walker breakdown field, which is directly proportional to H_k

in the 1D model, is significantly overestimated. Another strategy is to find other methods to estimate H_k, for example, from the value of the Walker breakdown field found from micromagnetic simulations. However, *a contrario*, this value might not account for the low Ψ dynamics. The definition of H_k becomes even more problematic in the case of a vortex wall, for which the 1D approximation is certainly not correct. However, we have shown (Thomas *et al*., 2006) that the 1D model can still be useful in describing the DW dynamics, provided that H_k can be estimated from micromagnetic simulations.

Examples of DW trajectories obtained by numerical integration of equation (13) are shown in Figure 5. We chose values of the parameters to match the properties of the nanowire described in the following paragraph using micromagnetic simulations ($\Delta = 48$ nm, $H_k = 1600$ Oe). The damping constant is $\alpha = 0.01$. The first two panels show the time evolution of the variables q and Ψ for a constant current corresponding to $u = 100\,\mathrm{m\,s^{-1}}$, calculated for different values of the β term. Since u is smaller than the critical value $u_c = 675.8\,\mathrm{m\,s^{-1}}$ given by equation (15), the DW motion stops after a transient time for $\beta = 0$. Similarly, Ψ saturates to a constant value given by $\sin(2\Psi) = -2u/(\gamma\Delta H_k)$ (stationary solution of equation (13)). If $\beta \neq 0$, the DW moves at a constant velocity after a transient time, the terminal velocity is given by $\beta u/\alpha$ and Ψ saturates at a value

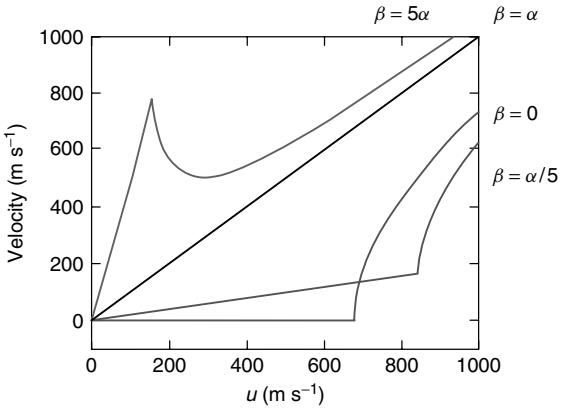

Figure 6. Averaged DW velocity calculated within the 1D model for the same set of parameters as in Figure 4, for different values of the ratio β/α.

$\sin(2\Psi) = -2u(1-\beta/\alpha)/(\gamma\Delta H_k)$. Figure 5 shows the time evolution of q and Ψ for $\beta = 0$ and different values of u. For values smaller than the critical current, the behavior is that described in the preceding text. Above the critical value (see curve for $u = 800\,\mathrm{m\,s^{-1}}$), the DW keeps moving continuously and its motion becomes precessional, in a fashion similar to the field-driven motion mechanism above the Walker breakdown field. The angle Ψ increases as the DW magnetization rotates continuously form one in-plane direction to the

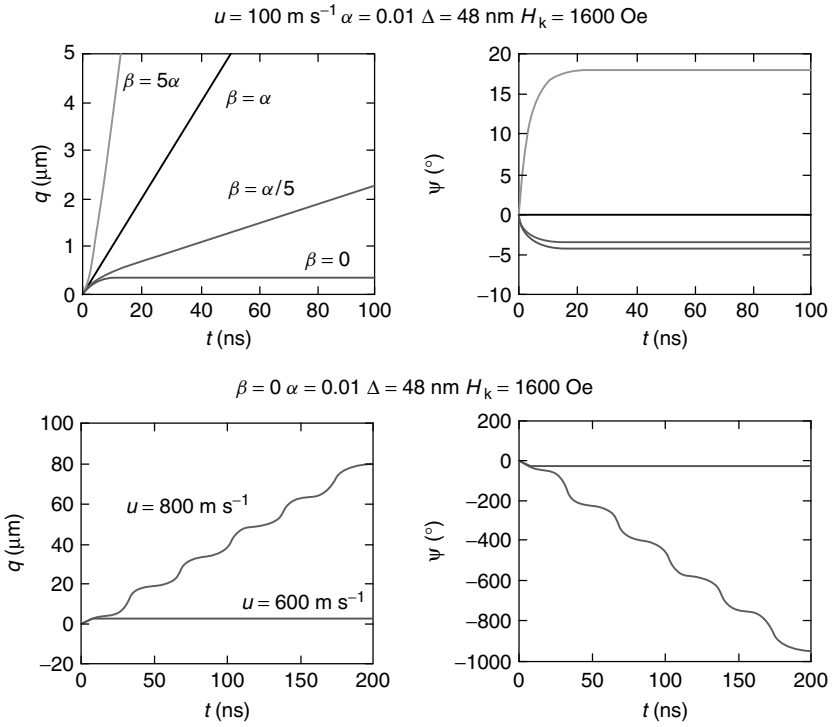

Figure 5. Time dependence of the DW position q and tilt angle Ψ calculated using equation (13) for the parameters indicated in the figure.

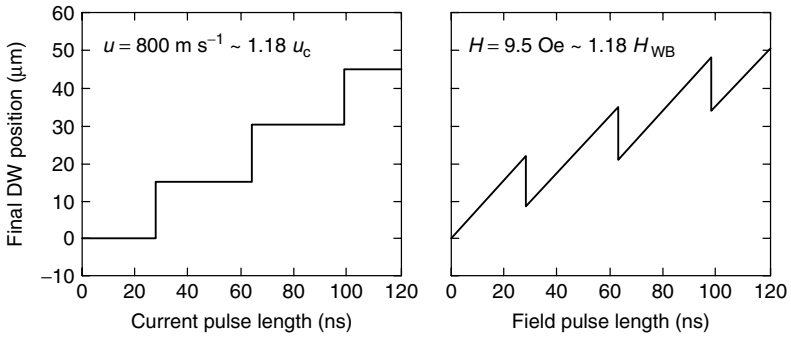

Figure 7. Final DW position after a current or field pulse, calculated using the same parameters as in Figure 4, for $\beta = 0$.

other, and the DW velocity oscillates accordingly. Note that the DW velocity is a maximum when the DW magnetization rotates across the out-of-plane direction ($\Psi = \pm\pi/2$), contrary to the field case, for which the velocity drops (and even reverses). Time-averaged terminal velocity curves are shown in Figure 6 as a function of u, for different ratios of β/α.

An interesting feature of the current-driven motion for zero-β is that for $u > u_c$, the DW displacement after current pulses appears to be quantized. The DW moves only by multiples of $\pi\Delta/\alpha$. This peculiar property follows from the DW's relaxation toward its equilibrium state, $\Psi = 0$, after the current is turned off. The same DW relaxation also occurs at the end of a field pulse, leading to a discontinuity of the DW position as a function of the pulse length rather than a quantized position. This can be understood from equation (13). Let us assume that the DW moves in the stationary regime with either field ($\dot{q} = v = \gamma\Delta H/\alpha$, $\sin(2\Psi) = 2H/(\alpha H_k)$) or current ($\dot{q} = v = 0$, $\sin(2\Psi) = -2u/(\gamma\Delta H_k)$). After the field and current are turned off, the equations of motion are the same. The DW velocity is simply proportional to $\sin(2\Psi)$. Therefore, in the field case, since Ψ is positive, the DW velocity remains positive and decreases to zero. On the contrary, in the current case, $\sin(2\Psi)$ is negative, such that the velocity become negative when the current is turned off, and the DW moves back to its original position. If u is larger than the critical current u_c, the relaxation after the pulse will be either backward (if $\Psi < \pi/2 \pmod{\pi}$) or forward (if $\Psi > \pi/2 \pmod{\pi}$). The DW's final position is shown in Figure 7 as a function of the length of a current or field pulse, for the same parameters used previously.

Note that because of this relaxation mechanism, the critical current given by equation (15) is only correct for dc currents. For current pulses, irreversible DW motion only occurs if the pulse is long enough for Ψ to exceed $\pi/2$. If not, the DW goes back to its original position even if $u > u_c$. As a result, the critical current varies as the inverse of the pulse length.

The addition of a magnetic field and/or pinning potential to equation (13) yields many interesting results. For example, the depinning from a potential well is very different depending on the depth of the pinning potential, the value of the β term and the external magnetic field. This leads to different expressions for the depinning current in different regimes, as described by Tatara *et al*. (2006).

Thiaville and Nakatani (2006) have studied in detail the comparison between the 1D model and micromagnetic simulations for the case of field-driven DW dynamics. To paraphrase their conclusions, 'it is very helpful for a qualitative understanding, and it becomes quantitative at really small sizes, a few exchange lengths.'

A different approach is clearly needed to describe complex wall structures such as the head-to-head vortex wall. A more general description of the steady state DW motion has been proposed by (Thiele, 1973a,b) and extended by Thiaville, Nakatani, Miltat and Suzuki (2005) to include both contributions from the current. Thiele's approach has been used successfully to describe quantitatively the dynamics of a vortex located in a small elliptical disk, driven either by magnetic field (see, e.g., the recent papers Novosad *et al*., 2005; Buchanan *et al*., 2005) or spin-polarized current (Shibata *et al*., 2006). However, a quantitative description of a moving DW using this framework is still lacking, although first attempts have been published recently (He, Li and Zhang, 2006a).

2.2.4 *Micromagnetic simulations*

Micromagnetic simulations are extremely useful to explore DW dynamics because realistic DW structures can be studied without limitations, and in particular, transformations of the DW structure can be described without approximation. Moreover, nonuniform fields (such as the Oersted field from the current) or nonuniform current distributions can be readily included. In addition, roughness and pinning can be easily introduced.

Several authors have published results of micromagnetic simulations of current-driven DW motion for both vortex and transverse DW structures (Thiaville, Nakatani, Miltat and Vernier, 2004; Thiaville, Nakatani, Miltat and Suzuki, 2005;

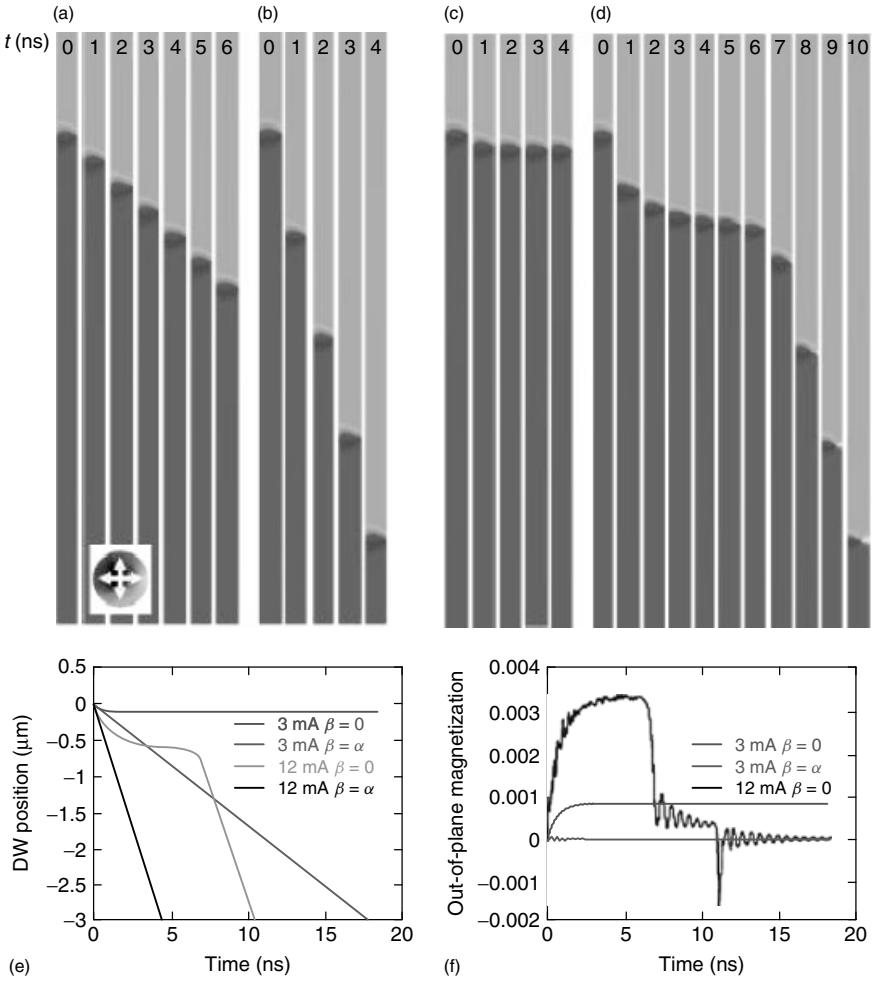

Figure 8. Micromagnetic simulations of the motion of a transverse DW in a permalloy nanowire, 150 nm wide, and 5 nm thick, for $I = 3$ and 12 mA. Top panels, from left to right: magnetization maps for $I = 3$ mA, $\beta = \alpha$ (a, left), $I = 12$ mA, $\beta = \alpha$ (b), $I = 3$ mA, $\beta = 0$ (c) and $I = 12$ mA, $\beta = 0$ (d, right). Bottom panels: Time dependence of the DW position (e) and the out of plane magnetization (f) in all four cases.

He, Li and Zhang, 2006a,b). There are also a few recent reports of the field-driven DW motion in similar structures (Thiaville and Nakatani, 2006; Nakatani, Hayashi, Ono and Miyajima, 2001; Nakatani, Thiaville and Miltat, 2003; Porter and Donahue, 2004).

Examples of micromagnetic simulations of the current-driven propagation of DWs for different nanowires (5 and 20 nm thick, 150 nm wide, 4 μm long) are shown in Figures 8 and 9. These calculations were performed using the LLG micromagnetic simulator code developed and commercialized by Mike Scheinfein. Standard parameters for permalloy are used, and the Gilbert damping constant is set at $\alpha = 0.01$. The cell size is $5 \times 5 \times 5$ and $5 \times 5 \times 10\,\text{nm}^3$ for 5- and 20-nm-thick wires, respectively. Fixed boundary conditions are applied at both ends of the nanowire to pin the magnetization along the wire axis. Note that the Oersted field is included in the simulations.

The first example (Figure 8) shows the time evolution of a transverse wall (the most stable structure for a nanowire of these dimensions), for two different current values (3 and 12 mA), and for the cases $\beta = 0$ (adiabatic torque only, b) and $\beta = \alpha$ (a). Note that the current is turned on instantaneously at time zero. In the latter case ($\beta = \alpha$), as discussed earlier in the framework of the 1D model, the DW propagates without distortion, at a constant velocity, directly proportional to the current.

On the contrary, when $\beta = 0$, there is an intrinsic threshold current (whose value is given by equation (15)). Below this value, at $I = 3$ mA, the DW only moves during the first nanosecond after the current is turned on. The DW velocity is a maximum at $t = 0$ and then drops progressively to zero as an out-of-plane magnetization component develops (proportional to Ψ in the one-dimensional model) as shown in the bottom panel of Figure 8. The DW displacement

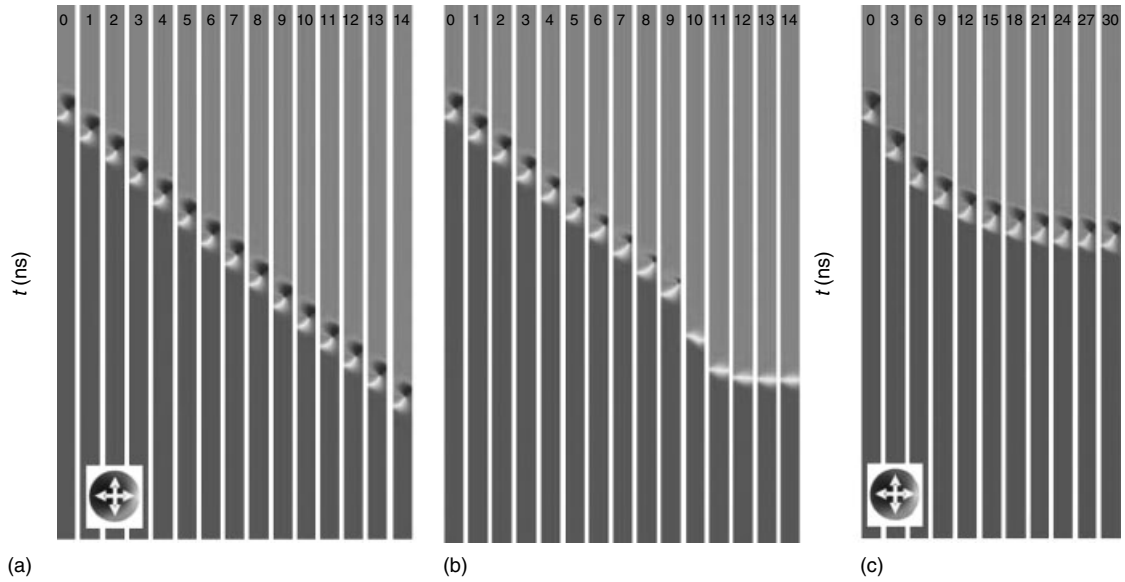

Figure 9. Micromagnetic simulations of the motion of a vortex DW in permalloy nanowires (a and b) width 150 nm, thickness 5 nm, current 3 mA, $\beta = \alpha$ and $\beta = 0$, respectively (c) width 150 nm, thickness 20 nm, current 9 mA, $\beta = 0$.

is completely reversible: if the current is turned off, the DW moves back to its initial position (not shown). On the contrary, for $I = 12$ mA (above the threshold current), the DW motion is irreversible. The first stage of the motion is qualitatively similar to the low-current case: the DW starts moving at its maximum velocity and then slows down. However, the displacement is much larger than in the low-current case. More importantly, the out-of-plane component is also larger, and the DW is not in dynamical equilibrium: an antivortex is nucleated at the right side of the wire, and its propagation across the width of the nanowire is associated with a strong increase of the DW velocity (note that just above the threshold current, the nucleation of the antivortex is extremely slow, on the order of tens of nanoseconds). Once the antivortex is expelled at the left side of the wire, the DW recovers the same structure as its initial state, except its magnetization has been rotated by 180°. If the current is maintained then the DW motion is periodic, and the DW structures oscillates between T walls with left- and right-handed orientations, and the DW velocity oscillates between high and low values as antivortices penetrate and are expelled from the nanowire. If the current is turned off, the DW will relax to an equilibrium state without current, namely an undistorted left or right-handed T wall, such that it can move either forward or backward after the current is turned off, depending upon its state at this time. Note that the current density needed to reach this regime is very high, on the order of 1.6×10^9 A cm^{-2}.

The second example (Figure 9) shows the case of a vortex wall for $I = 3$ mA, and for $\beta = \alpha$ (a) and $\beta = 0$ (b). Results are very similar to the T wall case. In the first case ($\beta = \alpha$), the DW moves at roughly constant velocity. Contrary to the field-driven motion, the DW velocity is not related to the DW structure, and the V and T walls move at the same velocity $v = \beta u/\alpha$. In the second case ($\beta = 0$), the DW structure is distorted as the vortex core is progressively pushed to the side and finally expelled from the nanowire. Note that for smaller currents, a dynamical equilibrium would be reached, in which the V wall would stop moving, as described below for the 20-nm-thick wire case. However, in the case shown here, the current is larger than the threshold for the V wall, but smaller than that for the T wall; therefore, the V wall is transformed into a T wall and then follows the same behavior as that described before. Since the V wall is very unstable for these dimensions (see equation (1)), this transformation can occur at very low current (<1 mA, about 1.3×10^8 A cm^{-2}). Similar results have been described by He *et al*. for a 128-nm-wide, 8-nm-thick nanowire (He, Li and Zhang, 2006a,b). They concluded that the V wall has a smaller critical current that the T wall.

For wire dimensions such that the V wall is the stable structure, the threshold current of the V wall increases, and may even exceed that of the T wall. As shown in Figure 9(c) for a 20-nm-thick wire (with $\beta = 0$), at 9 mA (current density of 3×10^8 A cm^{-2}) a dynamical equilibrium is reached and the DW stops moving. Larger current (∼15 mA) are required to overcome this dynamical equilibrium and achieve irreversible motion. Interestingly, if the initial state is a T wall, a current of 9 mA is sufficient to drive the T wall ∼2 μm, before it is transformed into a V wall and eventually stops (not shown). Note that the timescale is much slower for this larger structure.

Note that the details of the propagation mechanism above the threshold current depend on both the size of the structure and the magnitude of the current, in the same way as the DW propagation mechanism for fields larger than the Walker breakdown field. When the current (or similarly the magnetic the field) increases, higher energy routes become possible. In the example shown in Figure 8, an antivortex is nucleated. For larger structures, more complex scenarios can occur (reversal of the vortex core magnetization, nucleation, and annihilation of one or more vortices, etc.).

3 EXPERIMENTS

3.1 Device fabrication

3.1.1 Lithography techniques

Submicron-sized magnetic wires can be fabricated by various lithography techniques, such as focused ion beam (FIB), optical lithography, and electron-beam lithography. Other methods, which are not discussed here include nanoimprint and interference lithography.

FIB lithography is essentially a one-step process: the nanostructure is drawn from a plain film by milling the magnetic material locally with a high-energy ion beam (typically, Ga^+ ions accelerated at $\sim$30 keV). The ion current can be tuned to achieve high resolution (Xiong, Allwood, Cooke and Cowburn, 2001). Large currents (a few nanoamperes) are used to mill wide areas, whereas much smaller currents (a few picoamperes) are used to define finer features of the structure. This multistep approach ensures that critical cuts are made in as short a time as possible, thus reducing blurring due to stage drift. Resolutions down to about 20 nm can be achieved. Fairly complex structures can be fabricated, such as tracks for DW logic (Allwood *et al*., 2002b). However, it is not simple to make electric contacts to the nanostructure without adding an additional electron-beam lithography step. One method is to use the magnetic material itself as a contact, by leaving small bridges between the nanostructures themselves and a larger outer structure. In the example shown in Figure 10(a), a large area permalloy element ($10 \times 0.1\,mm^2$) was first fabricated by magnetron sputter deposition through a metal shadow mask. The nanowire was then patterned using a multistep FIB milling process. A 6.6 nA beam was used to cut two 5-μm-wide trenches perpendicular to the wire's long axis (see inset of Figure 10a). Much lower current beams (11 and 4 pA) were then used to precisely shape the nanowire. This method has a major disadvantage for studies of DW propagation. Since the nanowires are connected at both ends by magnetic material, it is difficult to control the nucleation and injection of a single DW. To solve this problem, the magnetic nanowire can be isolated completely form the outer structure during milling, both electrically and magnetically. The ends of the nanowires can be shaped to favor or suppress DW nucleation. Electrical connections can be restored by using the FIB to deposit a metal locally by reduction of an organometallic vapor (Thomas *et al*., 2005). In the example shown in Figure 10(b), small Pt contacts were deposited at both ends of the wire.

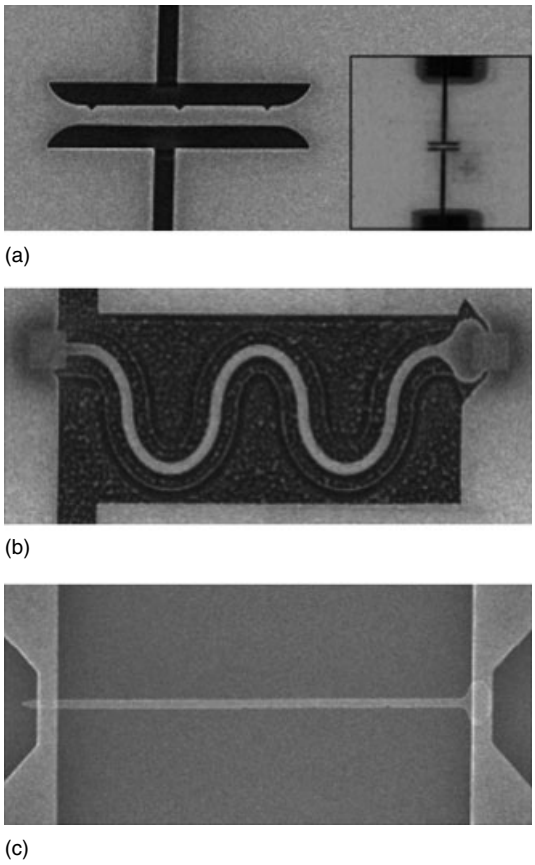

Figure 10. Examples of nanowires fabricated by FIB (a and b) and electron-beam lithography (c). (Courtesy of Charles Rettner.)

FIB lithography allows the fabrication of only one device at a time, and thus it is not practical for systematic studies of nanowires with different sizes and shapes. It is also worth noticing that FIB lithography is not suitable for all materials. For example, the giant magnetoresistance (GMR) of spin-valve structures patterned by FIB is strongly reduced, which is likely related to damage at the edges of the device (Katine, Ho, Ju and Rettner, 2003).

Conventional optical and electron-beam lithography techniques are more convenient to fabricate nanowires and their electric contacts in successive lithographic steps. Both liftoff and ion milling methods have been successfully used to fabricate magnetic nanowires. An example of a nanowire fabricated by electron-beam lithography and ion milling is

shown in Figure 10(c). The nanowire was first patterned from an extended film. Its ends were tapered to favor the nucleation and propagation of a DW from one end of the device. The nonmagnetic metallic contacts at either end were added in a second step.

These film-based methods usually produce 'flat' nanowires whose widths are much larger than their thicknesses. The layout in the sample plane can be changed easily, and complex structures have been fabricated. Nanowire shapes are most often designed to accommodate constraints such as the measurement technique (Hall crosses for Hall-effect detection), the control of the DW injection and pinning (L- or U-shaped structures, rings, etc.).

3.1.2 Nanoporous templates – electroplating

Electroplating is also a powerful (and inexpensive) technique to fabricate nanowires. In this approach, the first step is the fabrication of a template with pores of appropriate diameter. These templates can be track-etched polycarbonate membranes, anodized alumina films (Whitney, Jiang, Searson and Chien, 1993) or photoresist patterned by electron-beam lithography techniques (Duvail *et al*., 1998). The pores in the template are then filled by electrodeposition. This leads to an array of nanowires that can be studied in the template or after dissolution of the template. Several methods have been reported to make electric contacts to a single nanowire, either in the template or after dissolution. These methods include monitoring the resistance during the deposition so as to stop after only one nanowire becomes electrically connected (Wegrowe *et al*., 1998) and depositing contacts in a later step using electron-beam or optical lithography (Vila, Piraux, George and Faini, 2002).

Nanowires prepared by electrodeposition are usually cylinders, with a roughly circular cross section and potentially very high aspect ratios (length/diameter up to $\sim$1000). Bent nanowires have also been fabricated by centrifugation, after dissolution of the membrane and suspension in a liquid (Tanase, Silevitch, Chien and Reich, 2003).

Although nanowires fabricated by electrodeposition have been used to study DW magnetoresistance (Ebels *et al*., 2000) or magnetization reversal (Wernsdorfer *et al*., 1996), there are no reports as yet of current-driven DW motion in such samples. However, multilayered nanopillars made by electrodeposition have been used to study current-driven magnetization reversal (Wegrowe *et al*., 2004, 1999).

3.2 Materials

The list of materials used for current-driven DW motion studies is surprisingly short. The majority of experiments use permalloy ($Fe_{81}Ni_{19}$). There are also a few reports on other soft magnetic materials (CoFe and Ni), on hard magnetic materials with perpendicular magnetization (epitaxial Pt/Co/Pt multilayers), on diluted magnetic semiconductors (epitaxial GaMnAs) as well as one or two studies on nanowires formed from spin-valve structures.

There are several requirements for materials suitable for the study of current-driven DW motion in nanowires. First, their magnetic properties must be well behaved, so as to allow for well-defined DWs on the submicron scale. Soft magnetic materials are well suited, since long exchange lengths and large wall widths make them less sensitive to local structural defects. The crystalline quality becomes more important for harder materials. Second, the resistivity must be small to limit losses and Joule heating. Third, the spin polarization must be high so as to enhance spin-transfer efficiency. Fourth, in order to detect the DW motion by electrical means, materials with significant magnetoresistance (AMR, GMR, or anomalous Hall resistance) are most useful.

These constraints have so far precluded the exploration of very many materials. This means that the detailed influence of material parameters, such as the saturation magnetization and the magnetic anisotropy, have not yet been studied in detail.

3.3 Detection of domain walls in nanowires

In this section, we describe some of the experimental techniques that have been used to probe DWs in nanowires. General principles and technical details can be found elsewhere. Here we emphasize the main aspects of these different measurement techniques in the specific context of probing DWs in nanowires, and address some of their advantages and drawbacks. It is important to note that different techniques are useful for measuring different DW properties. For example, some measurement methods such as the magneto-optical Kerr effect (MOKE) and GMR (Parkin and Wessels, 1995) are sensitive to the magnetization of the magnetic domains, from which the presence of DWs and their location can be inferred. By contrast, other methods, such as the AMR probe the presence of the DW itself but lack sensitivity to its position. Therefore, depending on the characteristics and the sensitivity of the measurement technique, modifications of the DW structure or motion over small distances can be detected or be completely overlooked. This can result in significant ambiguities, for example, in the definition of the critical current for DW motion.

Another key aspect of the measurement method is the capability to acquire enough statistics to account for stochastic variations in the motion of the DW. For example, many microscopy techniques are slow. Thus, even though these

techniques have sufficient spatial resolution to access the static DW structure before and after its motion, the limited number of experiments which can be performed in a reasonable time may not allow for the measurement of all possible configurations. On the other hand, techniques such as time-resolved MOKE require a large number of repetitions of nominally the same DW motion to achieve adequate signal to noise, and so can lead to misleading results if fluctuations in this motion are important.

3.3.1 Electrical measurements

Magnetoresistance measurements are very convenient to detect DWs in nanowires. The AMR and GMR effects are most commonly used (Parkin and Wessels, 1995). There are also several experimental studies based on the ordinary and anomalous Hall effects (HE). These techniques, which are based on electrical measurements, are fast, allowing for extensive and systematic studies of current-driven DW motion.

Anisotropic magnetoresistance (AMR)

The resistivity of ferromagnetic metals typically exhibits AMR, whereby it depends on the angle θ between the magnetization and the electric current direction in the material, according to the relation:

$$\rho(\theta) = \rho_\perp + \delta\rho\cos^2(\theta) \quad \text{with} \quad \delta\rho = \rho_\parallel - \rho_\perp \tag{17}$$

The normalized AMR ratio is defined as $\delta\rho/\rho_{av} = \delta\rho/(\rho_\parallel/3 + 2\rho_\perp/3)$. This effect, which arises from spin-orbit coupling, can exceed 5% for some Ni–Fe and Co–Ni alloys at room temperature (and can be much larger at lower temperatures). The AMR values of many 3d transition-metal alloys are listed in the review paper of McGuire and Potter (1975).

The presence of a DW in a nanowire, which exhibits AMR, changes the nanowire's resistance because the magnetization within the DW deviates from the wire's long axis and thus from the current direction. In order to estimate the magnitude of the signal, consider the case of two head-to-head domains separated by a DW of width Δ with a magnetization profile following the 1D Bloch wall of equation (2). When no DW is present, and the magnetization lies parallel to the nanowire's long axis, the resistance is simply:

$$R_{\text{sat}} = \frac{\rho_\parallel L}{wt} \tag{18}$$

where L, w, and t are the length, width and thickness of the wire, respectively. When a DW is present within the nanowire, its resistance becomes:

$$R_{\text{DW}} = \int_{-L/2}^{L/2} \rho[\theta(x)]\frac{\mathrm{d}x}{wt} \tag{19}$$

Thus, the contribution of the DW to the nanowire's resistance, in the limit $L \gg \Delta$ is:

$$R_{\text{DW}} - R_{\text{sat}} = \frac{-\delta\rho 2\Delta}{wt} \tag{20}$$

The signal from the DW is directly proportional to the AMR ratio and the DW width. In permalloy, to a first approximation, the DW width scales with the nanowire's width $\Delta \propto w$ (see Section 2.1.1). Therefore, the DW contribution to the resistance is of the order of $\delta\rho/t$ and is independent of the wire width. Note that since the AMR signal arises from the DW itself, its relative contribution to the total nanowire resistance decreases as $1/L$, and can become quite small in long wires. It can also be easily washed out by drifts in the nanowire resistance over time (e.g., owing to small changes in temperature).

An important characteristic of the AMR signal is that it does not depend on the position of the DW (in uniform, homogeneous nanowires). Thus, the AMR signal detects the presence, or absence, of a DW between the electrical contacts used to probe the nanowire's resistance.

An example of the magnetoresistance (MR) hysteresis loop of a straight NiFe nanowire, 300 nm wide and 10 nm thick, is shown in Figure 11(a). The distance between the electrical contacts is 4 μm. One end of the nanowire has a tapered tip, to prevent DW nucleation, and the other end is attached to a large nucleation pad to assist DW injection (see Section 3.4.1). Note that these pads have very different shapes in Figure 11(a) and (b). A triangular notch is patterned on one side of the wire, which acts as a pinning center for the DW. A magnetic field H is applied parallel to the nanowire's long axis. When the magnetization is saturated along this axis, so that it is parallel to the current flow, the resistance is highest. When the field is decreased to $H = -25$ Oe a DW is injected into the nanowire and is trapped at the pinning site. This results in a sharp drop of resistance by $\sim$0.2 Ω. The resistance level decreases further by $\sim$30% as the field becomes more negative. This may be because the DW is moved further into the notch or because the DW becomes wider as it is stretched away from the notch. This will depend on the detailed structure of the DW (whether V or T and its chirality). When the field exceeds ~ -25 Oe, the DW is driven from the pinning site to the other end of the nanowire outside the region between the contacts and the resistance reverts back to the saturation value. Note that since the AMR is only sensitive to the presence of the DW between the contacts, no signal is detected in these quasistatic

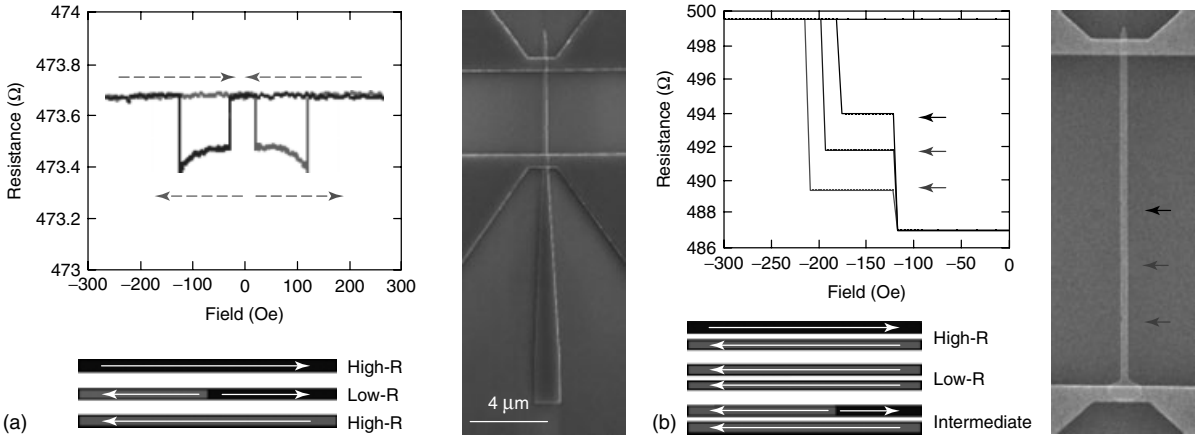

Figure 11. Examples of magnetoresistance curves obtained when the propagation of a DW along the nanowire is probed by AMR in a NiFe nanowire (a) or GMR in a spin-valve nanowire, which has the basic structure of NiFe/Cu/CoFe/Ru/CoFe/IrMn (b).

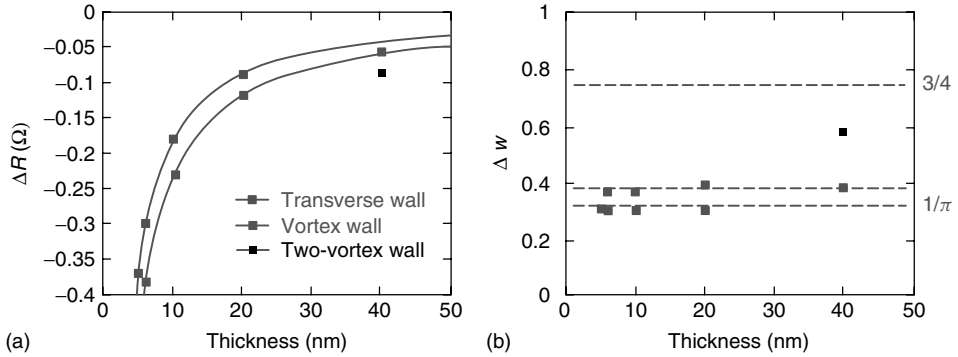

Figure 12. (a) DW resistance, for three different DW structures, in a permalloy nanowire of width 20 nm, as a function of the nanowire thickness t, calculated from micromagnetic simulations. (b) Ratio of the DW widths, obtained from equation (20), to the nanowire width (symbols), and comparison with values obtained from fits of the magnetization profile to the 1D Bloch wall model profile.

measurements if the DW is not trapped between the contacts after injection but rather propagates directly to the end of the wire.

Although the signal is rather small, the AMR is highly sensitive to details of the DW structure. For example, since the AMR signal depends on the DW width, V and T walls can be distinguished. The AMR signals calculated from micromagnetic simulations for three different DW structures in 100-nm-wide NiFe wires are shown in Figure 12, as a function of the wire thickness. Values of resistivity of 30 μΩcm and an AMR ratio of 1% are used. Interestingly, the V wall exhibits a signal about 30% larger than the T wall and the double-V wall shows an even larger signal. The calculated values vary inversely with nanowire thickness, as expected from equation (20). The DW widths can be estimated from this same equation (Figure 12b). Interestingly, the ratio of the DW width to the nanowire width (Δ/w) is nearly independent of thickness for the V and T walls. For the T wall, Δ/w is $\sim 1/\pi$, as proposed by Nakatani, Thiaville and Miltat (2005). However, for the V wall, Δ/w is ∼0.4, which is much smaller than that obtained by fitting the magnetization profile to the 1D Bloch wall profile, that is, 3/4.

Experimentally, we find that the AMR signal does not depend much on the wire width, in good agreement with equation (20). The comparison between nanowires with different thicknesses is less conclusive since both the nanowire resistivity and the AMR ratio vary with thickness. However, different wall structures can be well resolved (Hayashi *et al.*, 2006b). The AMR signatures of four different DWs trapped at a notch in a 300-nm-wide, 10-nm-thick permalloy nanowire are shown in Figure 13.

In summary, AMR is a powerful technique to probe the presence of DWs in magnetic nanowires. The main drawbacks of AMR measurements are the small output signal, the lack of sensitivity to DW displacement, and the limited choice of magnetic materials with large enough AMR ratios.

Note that AMR is not the only contribution to the resistance of the DW. Spin-dependent scattering across the DW can also contribute to its resistance (Levy and

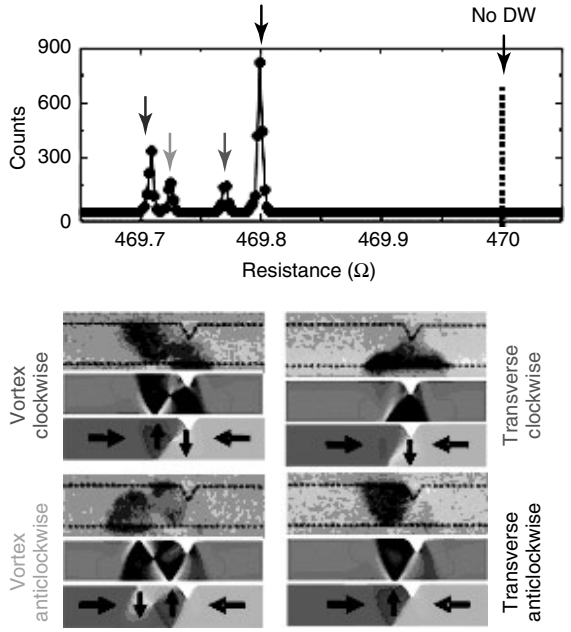

Figure 13. Histogram of measurements of the resistance of a permalloy nanowire (10 nm thick and 300 nm wide) after injection of a DW in a series of repeated experiments. The four peaks in the histogram correspond to four different DW structures. The DW structure, corresponding to each resistance value, was determined by MFM imaging and reproduced by micromagnetic simulations. For all four DW structures are shown the MFM image (top), the corresponding magnetization map from micromagnetic simulation (bottom) and the map of the divergence of the magnetization (middle). (Reproduced from Masamitsu Hayashi, Luc Thomas, Charles Rettner, Rai Moriya, Xin Jiang, and Stuart S.P. Parkin, *Phys. Rev. Lett.* **97**, 207205 (2006), copyright © by the American Physical Society, with permission from APS.)

Zhang, 1997). This latter effect is often termed the *intrinsic DW resistance*. Although the resistance of DWs has been extensively studied in the past decade (Marrows, 2005), the intrinsic contribution is usually smaller than the AMR in 3d transition-metal nanowires (∼0.1 to 1% of the resistivity). Indeed, in permalloy nanowires, we find that the AMR can largely account for the DW resistance in wires wider than ∼100 nm. Large intrinsic DW effects have been reported in nanoconstrictions in permalloy nanowires although it is difficult to rule out contributions from magnetoelastic effects. Intrinsic contributions to the DW resistance in GaMnAs wires have also been reported (Ruster *et al*., 2003).

Giant magnetoresistance

GMR is observed in multilayered structures in which two or more ferromagnetic layers are separated by thin nonmagnetic metallic spacer layers (Parkin and Wessels, 1995; Parkin, 1994). The current can flow either parallel or perpendicular to these layers. These geometries are often termed *current-in-plane* (*CIP*) and *current perpendicular to plane* (*CPP*), respectively. Few GMR measurements of DW motion have been reported although both the CIP (Ono, Miyajima, Shigeto and Shinjo, 1998; Ono *et al*., 1999a; Grollier *et al*., 2002, 2003, 2004; Lim *et al*., 2004.) and CPP (Zambano and Pratt, 2004) geometries have been used, typically with a spin-valve structure (Parkin and Wessels, 1995; Parkin *et al*., 2003). One magnetic layer, nominally in a single domain state, acts as a *reference* layer, and the DW motion is observed in a second magnetic layer, the *free* layer, where the two layers are separated by a thin Cu layer (Parkin, 1994). Although GMR values of more than 70% are found in Co/Cu multilayers at room temperature (Parkin, Li and Smith, 1991), typical GMR effects in spin-valve structures useful for DW studies are much smaller (∼1–5%). However, the GMR signals are much larger than the AMR signal from a DW in a permalloy nanowire, since the GMR arises from the magnetic domains and not from the DW alone. This also means that the GMR signal is sensitive to the precise position and thus the motion of a DW along a nanowire.

A typical example is illustrated in Figure 11(b), in which the resistance hysteresis loops of a 200-nm-wide spin-valve nanowire formed from a NiFe/Cu/CoFe/Ru/CoFe/IrMn structure are shown. In the field range shown, only the magnetization of the free layer (a 20-nm-thick NiFe layer) reverses. When the free layer's moment is completely switched from being parallel to antiparallel to the reference layer (an NiFe layer exchange biased by an antiferromagnetic IrMn layer) the resistance of the device changes by ∼12 Ω, which is nearly 100 times larger than the AMR signal (0.2 Ω) for a permalloy nanowire device with similar resistance. In the example shown in Figure 11(b) the nanowire was fabricated with three notches of different depths along one side of the nanowire (as shown in the scanning electron micrograph (SEM) in Figure 11b) so that the DW is trapped successively at these pinning sites. This accounts for the resistance plateaus in the figure.

While GMR appears well suited to the study of the motion of DWs in nanowires, the necessary use of additional magnetic and nonmagnetic layers causes severe problems. In particular, the shunting of current through the nonmagnetic spacer layer, which is typically much more conducting than the other layers in the stack, results in an inhomogeneous current distribution through the stack. This may lead to Oersted fields from the current within the magnetic layer in which the DWs move. A second, perhaps even more important problem, is the interaction of the fringing fields from the DWs with the reference layer moment through magnetic dipolar interactions (Gider, Runge, Marley and Parkin, 1998; Thomas, Samant and Parkin, 2000; Thomas *et al*., 2000). Moreover, any inhomogeneities in the reference layer (either magnetic or structural) will likely lead to pinning centers for the DWs in the free layer, again through dipolar fields. A

third significant problem is that the current densities needed to move DWs in transition-metal ferromagnetic materials are often so high that the device becomes significantly heated, so that the exchange bias is weakened (typical blocking temperatures are ∼500 K) and the reference layer moment is no longer magnetically stabilized. Notwithstanding these problems, GMR has a particular advantage in that, since the GMR effect derives largely from spin-dependent interface scattering (Parkin, 1992, 1993), many different free layer ferromagnetic materials can be studied by inserting ultrathin layers at the interface with the Cu spacer layer which give high GMR (Parkin, 1993).

Hall effect

The Hall effect is also a powerful technique to study DW motion. For materials with magnetization perpendicular to the sample plane, for example, CoPt alloys or multilayers and GaMnAs, the anomalous hall effect (AHE) provides a direct measurement of the DW position (Wunderlich *et al*., 2001; Yamanouchi, Chiba, Matsukura and Ohno, 2004). Indeed, just as for GMR, the AHE is proportional to the net magnetization (within the Hall cross), although the signal can be even larger. For example, in epitaxial GaMnAs nanowires, a change in resistance of more than 400 Ω has been reported (although at low temperatures) (Wunderlich *et al*., 2001). This large signal allows the detection of DWs moving over distances as short as 10 nm (Ravelosona *et al*., 2005).

The Hall effect is also observed for samples magnetized in plane when the magnetization is not exactly parallel to the current, as a consequence of the AMR. Although the effect is quite small in metallic samples (Berger, 1991a; Sato *et al*., 2000; Gopalaswamy and Berger, 1991), a giant planar Hall effect has been reported in GaMnAs films magnetized in plane (Tang, Kawakami, Awschalom and Roukes, 2003) and this effect has been used to detect a single DW (Honolka *et al*., 2005; Tang *et al*., 2004; Tang, Masmanidis and Kawakami, 2004). Hall-effect-based measurements require the device to be patterned in a Hall-cross geometry, thus limiting the flexibility of the device structure. Moreover, DWs can be strongly pinned at the cross, as shown by Wunderlich *et al*. (2001).

3.3.2 Optical measurements

The magneto-optical Kerr effect (MOKE) has been used to probe DW motion (Lee *et al*., 2000; Cowburn, Allwood, Xiong and Cooke, 2002; Allwood *et al*., 2002a; Atkinson *et al*., 2003; Vernier *et al*., 2004; Beach *et al*., 2005, 2006; Yamanouchi, Chiba, Matsukura and Ohno, 2004; Yamanouchi *et al*., 2006). However, using conventional optics, the spatial resolution of MOKE is limited by the wavelength of the light used, typically to about 0.5 μm. This makes it difficult to detect DWs directly. However, it is possible to detect the magnetization of magnetic domains, and thereby detect the presence and position of a DW in nanowires even as narrow as 120 nm (Vernier *et al*., 2004). Even though the size of the light source is diffraction limited, the motion of DWs can be detected over much shorter distances, that is, within the light spot, when the signal to noise ratio of the Kerr detection scheme is high enough, for example, by using pump-probe MOKE experiments. The main advantages of MOKE detection are its application to a wide range of magnetic materials and, perhaps most importantly, the fact that it does not perturb the magnetic structure.

3.3.3 Magnetic microscopy techniques

High-resolution magnetic microscopy is extremely useful to unambiguously measure a DW's structure. As discussed in paragraph 3.3.1, resistance measurements can be very sensitive to the DW structure, but can only be fully interpreted in conjunction with magnetic microscopy images. The Kerr effect can be used to image magnetic structures, either by scanning a beam of light across the sample or by using an optical microscope. The latter has been used to study injection and pinning of DWs in permalloy nanowires, as narrow as 500 nm wide (Yokoyama *et al*., 2000).

MFM is an elegant and simple technique, with a resolution of ∼25 nm, which is good enough to well resolve the structure of many DWs. However, it has very serious drawbacks. First, by contrast with the MOKE effect, MFM probes not the magnetization but rather the dipole fields generated by inhomogeneities in the magnetization. For samples magnetized in plane these fields are approximately proportional to the divergence of the magnetization. This means that it can be difficult to resolve the structure of complex DW structures from an MFM image without the aid of micromagnetic simulations. Second and more important is the interaction between the MFM magnetic tip and the sample, which is often large enough to perturb the magnetic structure of the sample. The field from the tip can both distort and cause transformations in the structure of DWs (Lacour *et al*., 2004) and can also drag DWs along a nanowire even if the DWs are trapped at pinning centers. Clearly, it is preferable to use MFM magnetic tips with the lowest possible magnetic moments, as discussed in several studies (Saitoh, Miyajima, Yamaoka and Tatara, 2004; Yamaguchi *et al*., 2004). Examples of MFM images of T and V DWs trapped at a notch are shown in Figure 13. Also shown are maps of the divergence of the magnetization computed for these DW structures using micromagnetic simulations, which are in good agreement with the experimental measurements. Another example is shown in Figure 2 in which the MFM image of a double-V structure is compared with the simulated

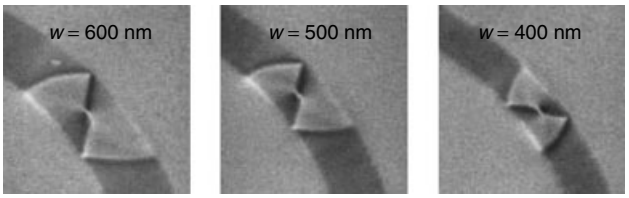

Figure 14. MFM images of a vortex DW in 40-nm-thick FeCoNi nanowires with widths of 400, 500, and 600 nm.

structure. Figure 14 shows MFM images of V walls located in curved nanowires with different widths. In these cases the nanowires are relatively thick (40 nm), so that the vortex core polarity can be resolved even though the core dimensions ($\sim$5 nm radius) are much smaller than the experimental resolution. Note that the core appears as the white signal in the middle of the V wall.

In homogeneous nanowires with smooth edges and surfaces DWs can be moved in fields of just a few oersteds so that even low moment MFM tips can destabilize such DWs. Even though a DW may appear stable in consecutive MFM images, the structure observed may have been modified by the proximity of the tip even before the first image was taken. Moreover, the signal measured with low moment MFM tips is quite small, particularly for thin magnetic layers ($<$10 nm). MFM provides the most useful results for strongly pinned DWs or DWs in nanowires with large propagation fields.

Scanning tunneling microscopy (STM) has atomic lateral resolution and does not perturb the magnetic structure. STM has been used successfully to image the vortex core in Fe islands (Wachowiak *et al*., 2002) and has potential for the study of DW motion.

Other magnetic imaging techniques include PEEM and various X-ray microscopy techniques, which are typically most useful when carried out at a synchrotron, which can provide energy resolved photon fluxes of high intensity. PEEM is sensitive to the projection of the magnetization in the X-ray incidence plane, and has a spatial resolution below 100 nm. Examples of PEEM images of magnetic domain structures are shown in Figures 3 and 15. V and T wall structures can readily be identified. A particular advantage of PEEM is its elemental selectivity, which can be used to detect the magnetization of individual layers in multilayered structures. Other advantages are that PEEM is nonperturbative, and it is suitable for time-resolved measurements of magnetization dynamics in submicron structures (Choe *et al*., 2004). PEEM can be used to study samples grown on any substrate, provided the capping layer is thin enough. However, PEEM is sensitive only to the surface of the sample ($\sim$10–20 Å), which can be both good and bad. For example, PEEM can measure very thin samples but, on the other hand, surface contamination can significantly affect the measurement. Since PEEM is an electron microscopy technique, imaging in the presence of magnetic fields is not possible. Moreover, large voltages (15 to 20 kV) are required which risks electrical discharges, which can damage the sample. This means that it is also difficult to apply electric currents to the samples *in situ*.

Transmission X-ray microscopy and scanning transmission X-ray microscopy (STXM) can also be used for imaging magnetic nanostructures both in the time and spatial domains (Puzic *et al*., 2005; Van Waeyenberge *et al*., 2006). The spatial resolution is higher than that of PEEM and it is much easier to apply magnetic fields and electric current to the sample. However, these techniques require special samples grown on thin transparent membranes. This can be an issue for current-driven DW motion studies, for which the dissipation of heat through the substrate from Joule heating of the wire may be important.

Electron microscopy techniques are also suitable for imaging DWs in nanowires with high spatial resolution. Transmission electron microscopy in the Lorentz mode has been used successfully to study magnetization processes in permalloy and Co nanowires with widths as small as 100 nm (Schrefl, Fidler, Kirk and Chapman, 1997). Spin-resolved scanning electron microscopy (spin-SEM, or SEMPA) is also nonperturbative and has very high lateral resolution ($\sim$20 nm). This technique has been used successfully to image the DW structure in nanoconstrictions (Jubert, Allenspach, and Bischof, 2004) and the DW displacement induced by current pulses in nanowires (Klaui *et al*., 2005b, Jubert *et al*., 2006). By combining high-resolution images of the two in-plane components of the magnetization, Klaui *et al*. (Klaui *et al*., 2005b) have shown the progressive distortion of a vortex wall and its eventual transformation into a transverse wall as a result of the injection of several current pulses. Note that spin-SEM has the same drawbacks as other electron microscopy based techniques such as PEEM, for example the surface sensitivity (such that capping layers cannot be used or need to be removed in-situ) and the difficulty of using magnetic fields while imaging. Recently, high-resolution electron holography was used to study the structure of DWs trapped in constrictions (Klaui *et al*., 2005a).

3.3.4 Time-resolved experiments

Time-resolved measurements are extremely useful to study the dynamics of DW propagation. Measurements using the Kerr effect (Atkinson *et al*., 2003; Beach *et al*., 2005), GMR (Ono *et al*., 1999a,b), and AMR (Hayashi *et al*., 2006a) have been reported. In all cases reported so far, reasonable signal to noise ratios could only be achieved by signal averaging over very many repeated measurements. However, with improved detection sensitivity all of these techniques have the potential for single-shot detection. Other techniques

offer the potential for time-resolved measurements of current-driven DW motion, for example, PEEM (Choe *et al*., 2004), STXM (Puzic *et al*., 2005), or inductive measurements (Silva, Lee, Crawford and Rogers, 1999). However, all these methods rely upon a pump-probe approach, which is rather inconvenient for the measurement of irreversible processes such as DW motion. Indeed, the sample must be reset to an identical initial state before each measurement, and the motion must be reasonably reproducible in order to obtain useful results. An important technical point is that the sample reset must be relatively fast to collect data in a reasonable amount of time. This can be difficult if even modest fields are required for this process.

3.4 Field-driven domain-wall motion in magnetic nanowires

Understanding and controlling the field-driven motion of DWs in nanowires is an important preliminary step to studying their current-driven dynamics.

The simplest way to create a DW in a magnetic nanowire is to first saturate its magnetization along its long axis and then in a second step to apply a smaller magnetic field in the opposite direction. The magnetization reversal process has been studied both experimentally (Schrefl, Fidler, Kirk and Chapman, 1997) and numerically (Nakatani, Hayashi, Ono and Miyajima, 2001) in nanowires with square ends. In these cases the magnetization reversal originates from closure domains at the ends of the nanowire, which expand as the magnetization rotates rotate toward the applied field. The field associated with the nucleation of the reversed domain can be large, since it must overcome the shape anisotropy of the wire. This field decreases as the inverse of the wire width and can reach several hundred oersteds in submicron-wide permalloy or Co nanowires (Shigeto *et al*., 2000).

Since the field required to nucleate a DW in a nanowire is generally much larger than the field needed to propagate a DW along the wire, once a DW is created it will be swept along the length of the wire. Different schemes can be used to circumvent this problem and generate a single DW in a nanowire whose field- and current-driven motion can subsequently be studied. All these schemes enable the independent control of the three critical steps of field-driven DW motion (i) DW nucleation, (ii) DW injection into the nanowire, and (iii) DW propagation along the nanowire. These will be discussed in the following paragraphs.

3.4.1 Nucleation and injection of domain walls

Three methods have been proposed to nucleate DWs in soft magnetic nanowires.

Nucleation pad

Shigeto, Shinjo and Ono (1999) first introduced the technique of using a nucleation pad attached to one end of a nanowire to generate a DW in the wire. The pad's lateral dimensions are much larger than the wire width, typically of the order of or larger than 1 μm. Various pad shapes have been used including squares, diamonds, and ellipses. Owing to the pad's size and shape, the field required to nucleate a DW inside the pad is smaller than that needed to nucleate a DW within the nanowire itself. If the shape of the pad favors a flux-closed structure, a DW may reside in the pad at remanence. Cowburn *et al*. (Cowburn, Allwood, Xiong and Cooke, 2002) studied a 1-μm-sized square pad attached to a 100-nm-wide, 5-nm-thick permalloy wire. DW propagation was probed by MOKE at different positions along the nanowire. The reversal field of the nanowire alone, when terminated with square ends, exhibits a reversal field of ∼180 Oe. When the nucleation pad is attached to the nanowire, the reversal field is reduced significantly to ∼40 Oe. The same principle means that by shaping the end of the nanowire, for example to a point, so as to increase the local shape anisotropy, the nucleation field for a DW can be significantly increased (Schrefl, Fidler, Kirk and Chapman, 1997).

The nucleation of a DW in the pad does not guarantee that it can be injected into the nanowire. The junction between the wire and the pad is a local energy minimum, and a magnetic field is required to move the DW into the wire. This injection field depends on the dimensions and shape of the nucleation pad and the nanowire. The injection field typically decreases for wider wires. However, it can be quite large for wire widths below 500 nm. For example, in experiments reported by Yokoyama *et al*. (2000), the injection field with a diamond-shaped nucleation pad is ∼60 Oe for a 500-nm-wide, 20-nm-thick permalloy wire. Without the nucleation pad, the injection field is slightly higher (about 85 Oe). For 2-μm-wide nanowires, these fields are reduced to ∼25 and ∼35 Oe, respectively.

The relatively high value of the injection field makes it difficult to inject a DW into a nanowire without the DW moving along the length of the nanowire. The DW will move along the nanowire when the field exceeds a critical propagation field, which is determined by any defects in the nanowire, such as edge or surface roughness. For smooth wires, the propagation field may be as small as a few oersteds, which is much smaller than the injection field in most cases. Therefore, nucleation pads do not solve the problem of the controlled injection of a DW into the nanowire, unless there is significant pinning along the nanowire. One way to solve this problem is to fabricate an artificial pinning center within the nanowire. The distinction between nucleation, injection, and propagation fields is illustrated in Figure 15, in which PEEM imaging was used to study field-driven DW injection in a

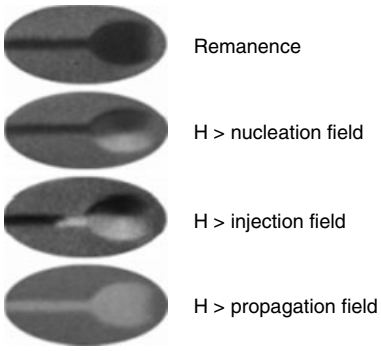

Figure 15. PEEM images of the domain structure of a 20-nm-thick, 250-nm-wide permalloy nanowire, measured at remanence after application of magnetic fields of various amplitudes (Thomas *et al*., 2005). The elliptical pad is ∼1.7 µm long, 1 µm wide. (Reproduced from L. Thomas, C. Rettner, M. Hayashi, M.G. Samant, S.S.P. Parkin, A. Doran, and A. Scholl: 'Observation of injection and pinning of domain walls in magnetic nanowires using photoemission electron microscopy', *Applied Physics Letters* **87**, (2005) copyright © 2006 American Institute of Physics, with permission from the AIOP.)

permalloy nanowire (Thomas *et al*., 2005). Note that DWs can also be injected from a nucleation pad into a nanowire without an artificial pinning site if sufficiently short field pulses are used, such that the DW does not have time to fully propagate along the nanowire (Beach *et al*., 2005). This is only possible if the applied field can be changed on a short timescale determined by the DW propagation speed.

Nonlinear nanowire shape

The second scheme for DW nucleation uses a shaped nanowire whose remanent state after saturation along a particular orientation of an external magnetic field exhibits one or several DWs. Numerous shapes are possible including U- or L-shaped wires (Thomas *et al*., 2006; Yamaguchi *et al*., 2004, 2006a), zig-zag wires (Klaui *et al*., 2005b; Taniyama, Nakatani, Namikawa and Yamazaki, 1999; Taniyama, Nakatani, Yakabe and Yamazaki, 2000), and rings (Rothman *et al*., 2001; Klaui *et al*., 2005b; Laufenberg *et al*., 2006b). An example of DW nucleation is shown in Figure 16 for an L-shaped wire. In this case a saturation field, high enough to overcome the nanowire's shape anisotropy, is applied at ∼45° to the two straight legs of the nanowire. The magnetization in both legs of the nanowire rotates toward the field to reach an angle defined by the ratio of the external field and the shape anisotropy field. When the field is reduced to zero, the magnetization rotates back toward the wire's axis (the easy direction of the shape anisotropy), so nucleating a DW near the bend. This method is attractive because it generates a DW highly reproducibly, even in smooth nanowires without any pinning centers. However, its main drawback is that it requires a large external field, big enough to overcome the wire's shape anisotropy.

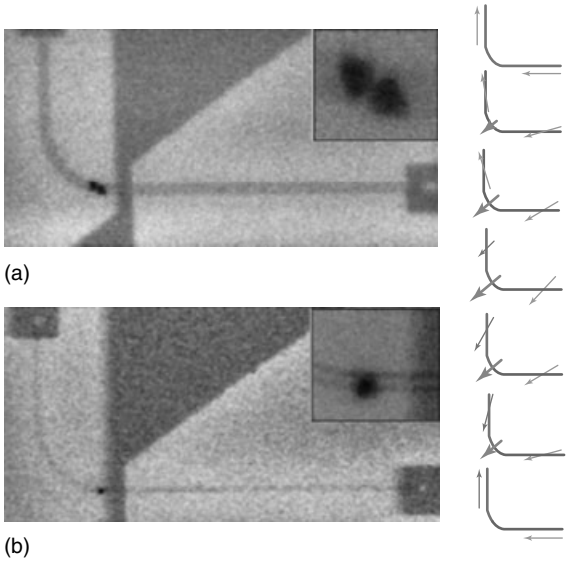

Figure 16. Schematic of the field-induced injection of a DW into the bend of a L-shaped nanowire by applying an external field at ∼45° to the two straight legs of the nanowire. MFM measurements at remanence after the injection of a DW into 20-nm-thick permalloy nanowires with widths of (a) 300 and (b) 100 nm, respectively. Magnified images of the DWs are shown in the inset.

Nucleation line

The third technique to nucleate a DW in nanowire uses a separate conducting wire situated above or below and approximately perpendicular to the magnetic nanowire (Hayashi *et al*., 2006a,b; Himeno, Kasai and Ono, 2005; Himeno *et al*., 2005). A current is passed through this wire, which generates a localized Oersted field which is used to reverse the magnetization of a section of the nanowire immediately adjacent to the conducting wire (see Figure 17). Thus two DWs are created. The Oersted field will cause the DWs to move along the nanowire away from the conducting wire a short distance till the Oersted field is decreased below the propagation field of the nanowire. This method is very attractive because it allows the local application of significant local fields of several hundred oersteds on the nanosecond timescale at a very high repetition rate compared to an external electromagnet. On the other hand the current needed to nucleate the DW may be quite high, particularly for thick nanowires with square aspect ratios, so that heating or electromigration may be an issue.

3.4.2 Domain-wall pinning and depinning from local pinning sites

Once a DW is nucleated and injected into a nanowire, it will move along the wire if an applied magnetic field exceeds the propagation field. The propagation field arises from local pinning centers associated, for example, with roughness or defects in the nanowire. For permalloy, it is strongly

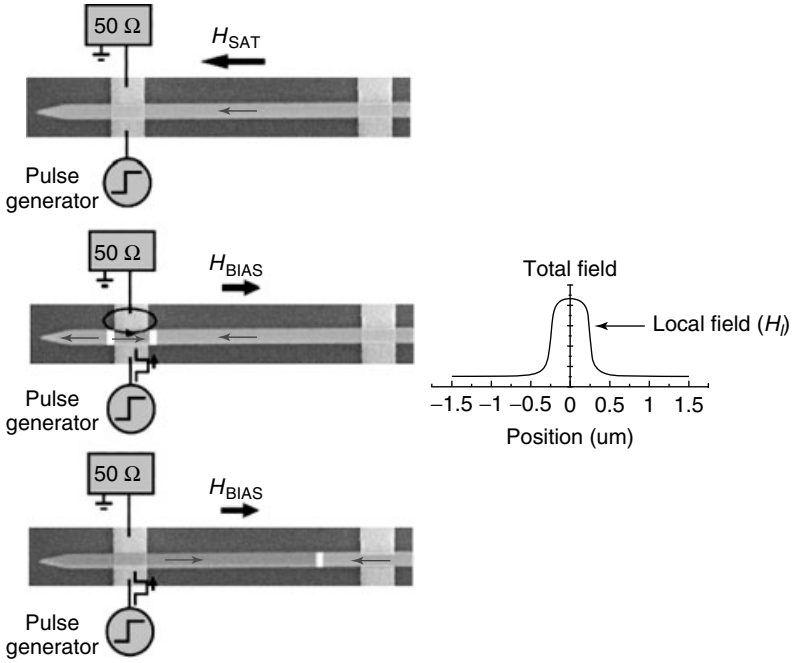

Figure 17. A schematic diagram showing DW injection using a local Oersted field generated in a nearby current lead. (Courtesy of Masamitsu Hayashi.)

dependent on the quality of the samples, and can take values from a few (Faulkner *et al*., 2004) to tens of oersteds (Yamaguchi *et al*., 2004). Note that the propagation field typically depends on the DW position along the nanowire. This means that the observed propagation field for motion of the DW over a given length will depend both on the initial DW position and this length.

Artificial pinning sites can be provided by fabricating appropriately shaped local modifications of the nanowire. In soft nanowires, quite a variety of designs can be used to successfully pin DWs. These include notches, humps, constrictions, or crosses, which lead to potential wells (attractive) or potential barriers (repulsive) of various widths and depths. Pinning centers can also be provided by creating local modifications of the nanowire using, for example, ion bombardment (Holleitner *et al*., 2004) or possibly localized oxidation, localized thermal annealing treatments or by using atomic force microscopes to physically or chemically modify the nanowire (Schumacher *et al*., 2001). It is also possible to use magnetic materials deposited under, on, or near the nanowire to change the magnetic properties of the nanowire in localized regions. One example is the use of magnetically hard CoSm pads on permalloy nanowires (Nagahama, Mibu and Shinjo, 2000). DW pinning has been carried out by varying the thickness of GaMnAs nanowires (Yamanouchi, Chiba, Matsukura and Ohno, 2004) and by using a Hall-cross geometry (Pt/Co/Pt layers by Wunderlich *et al*. 2001) for perpendicularly magnetized nanowires.

The depinning field from a symmetric V-shaped notch is roughly proportional to the notch depth (Yokoyama *et al*., 2000; Himeno *et al*., 2003; Faulkner *et al*., 2004; Klaui *et al*., 2005a). For permalloy wires, depinning fields can reach several hundred oersteds. Values as high as ∼1 kOe have been reported at low temperature in permalloy nanorings (Klaui *et al*., 2003a) and in CoFe nanowires at room temperature (Tsoi, Fontana and Parkin, 2003).

A very important point is that the depth of a pinning potential depends on details of the DW's structure and may, for example, be quite different for T and V walls and even for the same wall if it is of clockwise or counterclockwise chirality. Moreover, since the structure of a DW may evolve with time, for example, because of forces on the DW from current or field, the pinning potential itself may change with time and even during the transit time of a DW across the potential. This makes the notion of DW pinning very complex!

Another point is that the depinning field of a DW from a notch (or protuberance) may depend on the direction of motion of a DW. For example, the propagation field of DWs in nanowires with highly asymmetrically shaped protuberances (Himeno, Kasai and Ono, 2005; Allwood, Xiong and Cowburn, 2004) was found to differ by a factor of two depending on the direction of DW motion. However, even if the pinning site is symmetric, for example a V-shaped notch, the DW depinning fields to either side of the notch may be quite different. This can be because the DW may not

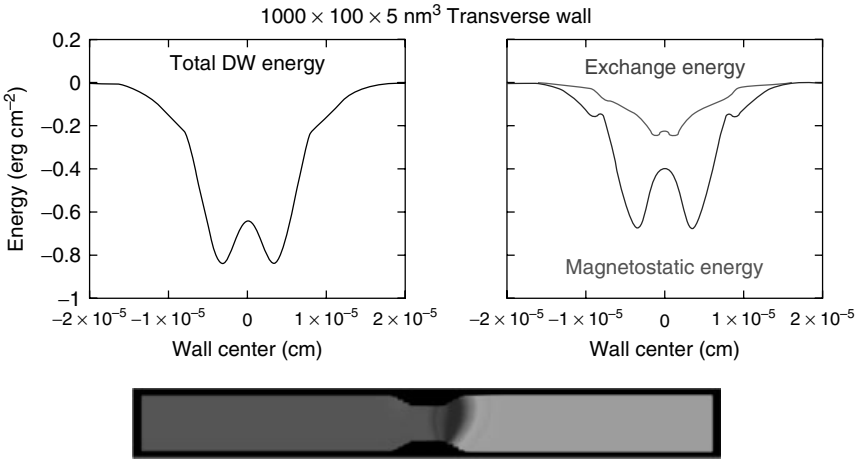

Figure 18. Micromagnetic simulations of the energy landscape of a DW pinned at a notch.

reside in the center of the notch but rather to one side, as discussed later in more detail.

Micromagnetic calculations are very helpful in understanding the pinning of DWs in pinning sites such as notches (see, e.g., a symmetric notch in Figure 18). The pinning potential is determined as follows. First, a stable DW structure is prepared at a specific location, either inside or outside the notch. This state is relaxed in zero field until equilibrium is reached. This equilibrium state is in general a metastable state. Second, a magnetic field is applied so that the DW moves along the nanowire, either away from or across the notch. The magnitude of the field is chosen to be large enough to overcome the pinning potential but is as small as possible so as to ensure that the DW follows the lowest energy trajectory. The latter is encouraged by using a large damping constant (e.g., $\alpha = 1$). The potential energy landscape for the DW is then obtained from the total energy of the system minus the Zeeman energy. The DW position is then calculated from the net longitudinal magnetization of the nanowire. In general, boundary conditions are used to fix the direction of the magnetization of the nanowire at either end along the long axis of the nanowire. Thus the DW energy will be modified when too close to the ends of the nanowire. For the example shown in Figure 18 the nanowire has a width and thickness of 100 and 5 nm, respectively, so that the stable state of the DW in the nanowire is a T wall. There are two minima in the pinning potential at either side of the notch. By considering the contributions of the exchange and magnetostatic energies to the total potential, it is clear that the DW pinning is associated with two main factors (i) the reduction of the DW volume within the notch (i.e., due to the reduced width of the nanowire) and (ii) the reduction of the DW energy when the nanowire's edges are not parallel to the nanowire's long axis. The exchange energy is minimized when the DW volume is reduced. However, the magnetostatic energy plays the more dominant role and, in particular, accounts for the energy minima when the DW sits within either of the two wedged portions of the nanowire, which define the edges of the notch. It should be emphasized that the magnetostatic energy is the dominant contribution to the energy for both V and T head-to-head DWs, accounting for ~80–90% of the wall's energy (McMichael and Donahue, 1997). Thus, the pinning potential is dominated by magnetostatic rather than volumetric effects in the head-to-head DW case, in contrast to the theoretical prediction for a Bloch wall trapped at a nanconstriction (Bruno, 1999).

The pinning potential becomes more complex for thicker wires, as illustrated in Figure 19. The nanowire width and notch shape are the same as before, except that the nanowire

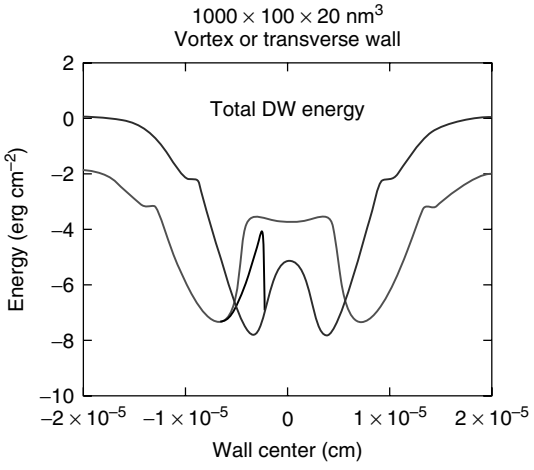

Figure 19. Micromagnetic calculations of the energies of a V (medium gray) and a T (dark gray) DW pinned at a notch of the same form as that shown in Figure 18. The black curve shows the energy of the DW when it transforms from a V to a T wall as it enters the notch.

thickness is increased from 5 to 20 nm. In this case, the stable state outside the notch is a V wall. In these simulations, the initial state was either a V or a T wall centered in the notch and the DW was moved away from the notch to the left or right with magnetic fields to calculate the potential. The pinning potential exhibits the same features as for the thinner wire, with two minima at either side of the notch, for both the V and T DWs. However, there is an additional shallow local minimum in the middle of the notch for the V wall. This example is interesting because the structure of the DW with the lower energy is different within (T wall) and outside the notch (V wall). This leads to a change of the wall structure when the V wall moves across the notch, as illustrated by the black curve in Figure 19. The energy barrier for this transformation is indeed smaller than that needed to move the vortex wall across the notch.

It is quite typical that there are significant variations in the DW pinning and depinning processes in repeated experiments, leading to, for example, variations in depinning fields. As discussed earlier, one reason is that there may be several metastable structures of a DW trapped at a notch, each with a different pinning potential (Hayashi *et al*., 2006b). A particularly interesting example is shown in Figure 20 for the case of a DW injected and trapped at an artificial pinning site in a permalloy nanowire, 10 nm thick and 300 nm wide. Four distinct DW states are found, whose structures, as determined from MFM images, correspond to two V walls and two T walls, one of each with a clockwise and the other with a counterclockwise chirality. Note that the DWs are pinned at the left side of the notch in the images because they were injected from the left side. Each of these DWs is a metastable state with a corresponding pinning potential and associated depinning fields, which can be well reproduced by micromagnetic calculations. Interestingly, even though the notch is symmetric, the pinning potential is quite asymmetric for one chirality of the T and V DW. Similar results have been reported by Miyake *et al*. (2005) for a nanocontact much narrower (∼15 nm) than the example shown in Figure 20.

3.4.3 Time-resolved experiments

Field-driven DW dynamics were studied in detail in the 1970s with regard to magnetic bubble memory applications, as extensively reviewed by Malozemoff and Slonczewski (1979). As mentioned in paragraph 2.2.3, a 1D theory of DW motion was developed to account for Bloch-like DWs. Many of the results of this theory, however, also apply to more complex DW structures.

In an ideal situation without pinning, the motion of a DW along a magnetic nanowire has distinct characteristics depending on the strength of the applied field. The motion

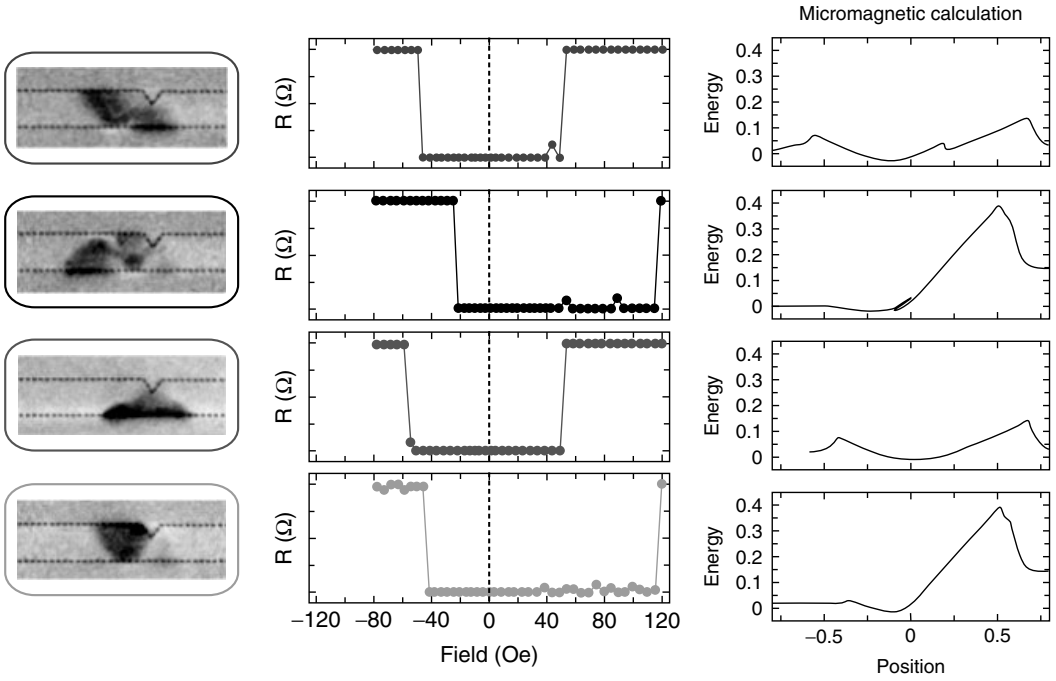

Figure 20. Measured depinning fields from a notch for DWs with metastable T and V structures, in a 10-nm-thick, 300-nm-wide permalloy nanowire. Also shown are the corresponding energy landscapes calculated from micromagnetic simulations. (Reproduced from Masamitsu Hayashi, Luc Thomas, Charles Rettner, Rai Moriya, Xin Jiang, and Stuart S.P. Parkin, *Phys. Rev. Lett.* **97**, 207205 (2006), copyright © by the American Physical Society, with permission from APS.)

can be described analytically within the 1D model. In a first regime, at low fields, the DW velocity increases at short times to attain a steady value. In this stationary regime, the velocity increases linearly with field, according to the relation:

$$v(H) = \frac{\gamma \Delta}{\alpha} H \tag{21}$$

When the field exceeds a certain threshold value, the so-called Walker breakdown field, the average DW velocity drops sharply. Above this field, the DW moves in a complex manner, and its velocity oscillates in time. When the field is increased further, the average velocity is again proportional to the field, although the wall mobility is strongly reduced compared to the low-field value. The velocity in this second regime depends on field according to the relation:

$$v(H) = \frac{\gamma \Delta}{\alpha + \alpha^{-1}} H \tag{22}$$

When pinning is included, the DW only moves along the nanowire when the field exceeds a critical value H_c. Depending on the nature of the potential (whether it is conservative or nonconservative), the DW velocity can be written (Malozemoff and Slonczewski, 1979; Baldwin and Culler, 1969), for $|H| > H_c$, as:

$$v(H) \propto \frac{(H^2 - H_c^2)}{H}$$
$$\text{or} \qquad v(H) \propto H - H_c \qquad \text{respectively} \tag{23}$$

Only a few experimental studies have explored the time-resolved motion of DWs in nanowires. Ono *et al*. (1999b) have used GMR measurements to probe the propagation of a DW in a trilayer structure NiFe (40 nm)/Cu (20 nm)/NiFe (5 nm). The nanowire was 500 nm wide and extremely long (2 mm). The DW motion in the 40-nm-thick layer was probed on the microsecond timescale, for magnetic fields between 100 and 150 Oe. The DW velocity was found to increase linearly with field above a threshold field ($\sim$35–40 Oe). The wall velocity v was between 150 and 250 m s^{-1}, corresponding to wall mobilities v/H of about 2.6 m s^{-1} Oe^{-1}. Atkinson *et al*. (2003) performed a similar study on a single layer permalloy nanowire (5 nm thick, 200 nm wide) using time-resolved MOKE experiments. The wire was much shorter (about 50 µm) than that used in the study of Ono *et al*. and the DW motion was probed on much shorter timescales (20–500 ns). These authors also found that the DW velocity increased linearly with field for fields above $\sim$25 Oe. However, the DW mobility was more than 10 times higher ($\sim$38 m s^{-1} Oe^{-1}). These two experiments were performed in relatively high fields, compared to the expected Walker breakdown fields. Moreover, in both cases the propagation fields were large. Nevertheless, these authors interpreted their data using the theory in the low-field regime, (equation (21)) in which the velocity is proportional to field. They deduced extraordinarily high values of the Gilbert damping constant, namely, $\alpha = 0.63$ (Ono *et al*., 1999b) and $\alpha = 0.053$ (Atkinson *et al*., 2003), in both cases much higher values than those found in thin permalloy films (0.01–0.02) (Nibarger, Lopusnik and Silva, 2003; Nibarger, Lopusnik, Celinski and Silva, 2003).

Recent experiments by Beach *et al*. (2005) and our work (Hayashi *et al*., 2006a) suggest that these surprisingly high damping constants (i.e., small DW mobilities) more likely indicate DW motion in the high-field regime above the Walker threshold field, in which equation (21) is not valid. Indeed, in the high-field regime, the velocity also increases linearly with field, but is lowered by a factor α^2 compared to the low-field regime (see equations (21) and (22)). Clear evidence of the Walker breakdown was observed in the work of both Beach *et al*. (2005) and Hayashi *et al*. (2006a), with a field dependence of the velocity following the textbook behavior (as shown, e.g., in Figure 22). The Walker breakdown field was found to be only a few oersteds, and the data are consistent with reasonable values of the Gilbert damping constant. Note that we have recently reported the experimental observation of periodic oscillations of the DW structure, as predicted above the Walker breakdown (Hayashi *et al*., 2007b).

The experiments discussed above address the ballistic (or viscous) regime for DW motion, for which the DW dynamics can be described by the Landau–Lifshitz–Gilbert equation at zero temperature. Thermally activated processes allow for DW motion below the critical field H_c. This has been observed in nanowires made with thin Pt/Co/Pt trilayers and two regimes have been identified. The thermally activated regime is characterized by a wall velocity written as (Wunderlich *et al*., 2001; Ravelosona *et al*., 2005):

$$v(H, T) = v_0 \exp\left(\frac{-2M_s V(H_c - H)}{k_B T}\right) \tag{24}$$

where k_B is the Boltzmann constant and T the temperature, H and H_c are the applied and propagation fields, respectively, and V is the activation volume. In the creep regime, the DW velocity is written as (Cayssol *et al*., 2004):

$$v(H, T) = v_0 \exp\left(\frac{-U_c (H_c/H)^{1/4}}{k_B T}\right) \tag{25}$$

with U_c and H_c are the scaling energy and the critical field, respectively. In this creep regime, the wall velocity was found to vary as the inverse of the wire width, and to decrease for larger wire roughness (Cayssol *et al*., 2004). Both regimes are characterized by very small DW velocities ($\ll$1 m s^{-1}).

3.5 Current-induced domain-wall motion

3.5.1 Experimental considerations

The first studies of current-driven DW motion were performed by Berger *et al*. in extended permalloy films. In these studies (and also in the more recent work of Gan *et al*. (2000)), the DWs have 180° Bloch, Néel, or cross-tie DW structures, the current flows in the direction perpendicular both to the wall and the magnetization within the domains, and there is no pinning besides the local defects responsible for the film's coercivity. Several DWs are probed at the same time, in contrast to recent experiments on magnetic nanowires, which probe single DWs. For nanowire samples with perpendicular anisotropy, the current is also perpendicular to both the wall and to the domain magnetization direction, as in extended films. However, for head-to-head DWs in nanowires, the current is perpendicular to the wall but parallel to the magnetization in the domains. These different geometries must be taken into account in experiments, which probe the current-induced motion of DWs since, for example, the role of the self-field (Oersted field) and the hydromagnetic domain drag are different.

Current-induced DW experimental studies can be separated into two broad categories, current-induced DW propagation and current-induced DW depinning. In the first category, the position of the DW in a nanowire is probed before and after the application of the current. Thus, the critical current for DW motion and the DW displacement direction and distance can be inferred. When current pulses are used, the DW velocity can also be determined. In the second category, the field to depin DW is measured as a function of the applied current.

3.5.2 Current-induced domain-wall motion in zero field

From an experimental viewpoint, current-induced DW motion occurs above a critical current density J_c. As mentioned earlier, this is an important parameter both for comparing experiment with theory and for potential technological applications. It is unfortunate that the magnitude of J_c is often ambiguous, making comparison between data and theory difficult.

1. Uncertainties with regard to the definition of the critical current
   (a) What is the experimental definition of the critical current?
   The experimental definition of the critical current depends on the type of measurement and the sensitivity of the experimental technique. Indeed, the critical current for DW motion over micron-sized distances can be quite different from that needed to change the DW structure within a notch or move a DW over very short distances between neighboring pinning sites. For example, in the early work by Salhi and Berger (1994), wall motion was detected by Kerr microscopy, such that 'the critical current density is determined by finding the smallest value for which a sequence of 600 pulses produces a detectable wall displacement'. Given the resolution of the setup, this corresponds to an overall displacement of about 12 μm (or 20 nm/pulse, assuming all pulses induce the same DW displacement, which is far from certain). By contrast, in a recent report by Ravelosona *et al*. (2005), DW motion over a few tens of nanometers can be detected directly in a Hall cross, owing to the high sensitivity of the AHE effect. In summary, the experimental definition of the critical current is as vague as 'the minimum current for some measurable change to take place'.
   (b) Joule heating
   The current densities used in most experiments are large (see Table 1) and Joule heating is significant. This temperature increase can play a significant role in current-induced DW dynamics, as discussed later. Here we only address experimental consequences of the heating of the nanowire. In particular, current pulse generators often deliver constant voltage pulses rather than constant current pulses so that the current delivered depends on the load resistance. While, for dc or long current pulses this is easily corrected by directly measuring the actual current delivered to the nanowire, this correction becomes more difficult for short current pulses. The temperature of a nanowire can increase by many hundreds of degrees on the nanosecond timescale depending on the amount of Joule heating. This is obviously more significant the larger the current and the higher the resistivity of the nanowire (and the electrical contacts to the nanowire). Thus, the resistivity of permalloy nanowires, for example, can easily increase by a factor of 2 or 3 in 1 or 2 ns, and similarly decrease on very short timescales so that these temperature changes cannot be detected by dc measurements after the current pulses are applied. Thus, it is very important to carry out time-resolved resistance measurements. The change in the nanowire resistance due to heating can lead to incorrect values of critical currents for DW motion, if it is not properly taken into account. For example, this effect accounts for a reduction of the critical current density by a factor of 2 between the values published by Yamaguchi *et al*. (2004, 2005).

Table 1. Compilation of values of the critical current density for DW motion in various nanowires. Note that some experiments are performed at low temperature.

P: DW propagation experiment; S: switching experiment; dc: dc current; rt: rise time of the current pulse for exponentially shaped pulses; c/nc: values corrected/ not corrected for resistance change induced by Joule heating.

There is another more subtle consequence of the resistance increase during the application of current pulses to a nanowire. Indeed, both the rate of change and the magnitude of the temperature rise from Joule heating depend strongly on the thermal conductivity of the nanowire to the substrate. The timescale of the resistance increase can vary by 1 or 2 orders of magnitude depending on the thermal conductivity of the seed layers on which the nanowire is prepared, the quality of the nanowire/seed layer interface and the substrate material. For short pulses compared to this thermal timescale, the current becomes time dependent. Therefore, the actual value of the critical current for DW motion can depend on the relative timescales of heating and that of the DW dynamics.

(c) Inhomogeneous current flow

For nanowires with varying width or for multilayered structures, such as spin valves, the definition of the current density is ambiguous. In the case of nanowires with notches, the current density reaches its maximum value in the narrowest part of the wire. However, in many cases, the DW is not trapped in the middle of the notch, but rather to one side of the notch, so that it is not clear which nanowire width should be used to calculate the critical current density. For the case of spin-valve stacks, a large fraction of the current flows in the nonmagnetic spacer. The structure studied by Grollier *et al*. is one example (Grollier *et al*., 2003). The spin-valve stack used was composed of CoO (3)/Co (7)/Cu (10)/NiFe (5)/Au (3), where the thicknesses are given in nanometers and DW motion was studied in the NiFe layer. If the current density is assumed to be uniform throughout all the layers then the critical current density reported by Grollier *et al*. in zero field was $\sim 8 \times 10^6\,A\,cm^{-2}$. On the other hand, if one assumes reasonable values of the conductivity of each layer, the critical current density in the NiFe layer is only $\sim 1.8 \times 10^6\,A\,cm^{-2}$,

which is nearly five times smaller! It is interesting to note that, in either case these critical current densities are surprisingly low compared to other studies of current-induced DW motion. Similarly, when a magnetic nanowire is prepared on a seed layer (e.g., for improved film quality) or with a cap layer (e.g., to prevent oxidation or to aid in the fabrication of nanowire devices), some of the current may flow through these layers and affect the determination of the critical current density in the magnetic layer itself.

(d) Parasitic magnetic fields and self-field
The field dependence of the critical current for DW motion will be discussed in more detail in Section 3.5.4. However, for weakly pinned DWs and nanowires with small propagation fields, parasitic magnetic fields such as the remanent field of an electromagnet, or the self-field from current passing through the electrical leads to the sample can easily influence critical current measurements. The self-field from the current passing through the magnetic nanowire itself can also play a significant role. For straight nanowires, its influence is often neglected because there is no net field along the nanowire direction, assuming uniform current flow. However, there will be strong highly nonuniform components of the currents self-field in directions transverse to the nanowire. Even though the average value should be zero in the ideal case, it is difficult to rule out 'wall streaming' effects, which were described by Berger in several publications (Salhi and Berger, 1994; Berger, 1992): the local inhomogeneous fields associated with a current pulse can shake the DW significantly and assist its motion by effectively reducing the local pinning. In any case, for inhomogeneous current flows, for example, in spin-valve stacks, as mentioned above, there will be a net nonzero contribution of the Oersted field in the direction transverse to the nanowire within the magnetic layer in which the DW is moved.

2. Critical current density in zero field
Values of the critical current density measured in zero fields for various magnetic nanowires are complied in Table 1. Most of these data were obtained for permalloy nanowires. Very few experimental results have been reported for other materials. It is interesting that much smaller current densities have been reported in nanowires formed from GaMnAs, Pt/Co/Pt and spin-valve-based structures than for permalloy nanowires, although all of these experiments are subject to detailed interpretation.
Results reported for permalloy nanowires by different groups vary significantly, perhaps not surprising considering the wide variety of techniques and geometries used in these studies and the uncertainty in the measurement of J_c. Some general conclusions can be drawn from these data, which are plotted in Figure 21 as a function of the sample thickness:

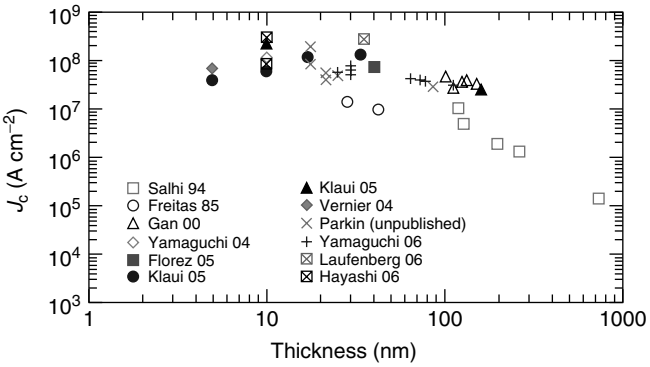

Figure 21. Critical current for DW motion in permalloy structures reported in the literature as listed in Table 1, plotted as a function of the sample thickness.

(a) Shorter current pulses allow the use of higher current densities before breakdown of the nanowire. The dependence of the critical current density on pulse length has been investigated by several groups. Pulse lengths between 50 and 300 ns were explored in Salhi and Berger (1994) and between 0.4 and 2 ns in Lim *et al.* (2004). In both cases, no significant variation in J_c was found.

(b) The wire width does not seem to play a significant role. In particular, 180° DWs in large structures and head-to-head walls in narrow wires exhibit very similar critical current densities. However, in all these experiments, the aspect ratio of the nanowire's cross section is about the same, the width always being much larger than the thickness.

(c) The wire thickness seems to play a more important role. For films thicker than about 50 nm, Salhi and Berger (1994) have observed that J_c decreases as $1/t^2$ (in the 120–740 nm range). This dependence is explained by current-induced distortions of the Bloch wall. For wires thinner than about 40 nm, J_c is between 5 and 30×10^7 A cm^{-2}, if the current is corrected for the resistance increase during the pulse. There is no clear dependence of J_c in this thickness range when considering all the available experimental data. However, Klaui *et al.* (2005c) have reported a significant increase, from 5.0×10^7 A cm^{-2} for 5-nm-thick to 1.3×10^8 A cm^{-2} for 35-nm-thick permalloy nanowires. Note that these experiments were performed at low temperature.

(d) There is no clear correlation between J_c and the wall structure. In particular, head-to-head DWs in narrow wires and 180° DWs in large structures exhibit very similar values.

(e) Surprisingly, the magnitude of the DW pinning does not appear to play any significant role on the critical current density. Data summarized in Figure 21 show results for both strongly pinned DWs (with depinning fields up to 200 Oe) and extended films, with propagation fields of a few oersteds. Different theories of DW motion arrive at different conclusions as to whether J_c is intrinsic or extrinsic. To date experimental results seem rather inconclusive. Indeed, there have been two apparently contradictory attempts to find a scaling rule for different magnetic nanowire samples. In the first case (Yamaguchi *et al*., 2006a), Ono's group plot J_c versus the transverse anisotropy times the DW width $H_k\Delta$ for permalloy nanowires. A roughly linear variation is observed, as given by equation (15) which describes an intrinsic critical current, in the presence of adiabatic spin torque, without a β term. By contrast, Berger presents a different scaling law (Berger, 2006), in which the DW mobility is plotted versus the aspect ratio of the wire (itself a function of the DW width) and includes different magnetic materials. His conclusion is that exchange drag (i.e., momentum transfer or nonadiabatic spin torque) can largely account for the various results, which means that the critical current is in fact extrinsic (i.e., only related to coercivity or pinning).

3. DW propagation direction and distance

Experimental results for samples made with 3d metals (NiFe, CoFe, Ni, Pt/Co/Pt) show consistently that DWs move along the electron flow (or opposite to the current direction) at zero or low fields, in agreement with the spin-torque model. The direction of DW motion is also opposite to the current direction for GaMnAs, even though the carriers in this system are holes (Yamanouchi, Chiba, Matsukura and Ohno, 2004). Two other important experimental findings agree with spin-torque models. First, the DW motion direction reverses with the current polarity. Second, head-to-head and tail-to-tail DWs move in the same direction with current, so that simple field-driven mechanisms can be ruled out.

Even though the overall propagation is along the electron flow, the propagation distance can vary significantly, both for a single wall over repeated experiments and for several walls during the same current excitation. This was first reported by Berger, who observed that only a subset of walls in the field of view of a Kerr microscope moved during a current pulse (Freitas and Berger, 1985). This behavior was explained by local variations of the coercivity and/or the presence of a parasitic field. Gan *et al*. (2000) also observed significant variations of wall motion in large structures (20 μm wide). The distribution of the DW propagation distance was significantly different, and in some cases, DWs moved backwards (opposite to the electron flow). Moreover, portions of the same wall sometimes moved in opposite directions.

Experiments on current-induced DW motion in nanowires exhibit similarly strong variations. For example, Yamaguchi *et al*. (2004) report that five identical current pulses applied to a V wall result in motion of the DW of 2.2, 0.9, 0, 1.9, and 1.1 μm, respectively. In our own experiments we have also observed wide variations in DW motion direction and distance in many cases. Occasionally, DWs are found to move opposite to the electron flow, particularly when DWs are depinned from a notch.

These fluctuations could be related to local variations of the DW pinning strength, as was invoked for larger structures. However, DWs can be moved repeatedly across exactly the same position in a nanowire and thus, it should be possible to correlate the DW displacement induced by a current pulse with position in the nanowire. There is no evidence of such an effect in Yamaguchi's paper. Another possibility is that the DW structure may evolve during motion, as was observed in experiments by (Klaui *et al*., 2005b; Jubert *et al*., 2006), who report a gradual decrease of the displacement of a V DW when consecutive pulses are injected across it. The DW eventually stops after a few pulses. High-resolution imaging with SEMPA revealed that the DW structure was modified by the current pulses, which caused the DW to evolve from a V to a T wall structure. Such a systematic variation of the DW displacement with successive pulses has not been observed in other studies (Yamaguchi *et al*., 2004; Gan *et al*., 2000).

Many other results are not fully understood. For example, Lim *et al*. (2004) have observed a reversal of the DW propagation direction when the current increases above some threshold value.

3.5.3 Domain-wall velocity

The first measurements of current-driven DW velocity were obtained by simply dividing the observed DW displacement after the current pulsed had been applied by the current pulse length, for microsecond long current pulses. However as discussed in the preceding text, the DW displacement often exhibits significant fluctuations over repeated experiments. It is unclear whether such estimates of the DW velocity are meaningful.

In several reports, it was shown that the DW displacement scales approximately with the pulse length (Yamaguchi *et al*., 2004; Klaui *et al*., 2005b; Jubert *et al*., 2006) giving a more reliable measurement of the wall velocity. In both studies, the current density was slightly higher than J_c and long pulses were used, between 0.3 and 1 µs in Yamaguchi *et al*. (2004), and 1 order of magnitude larger (10 µs) in Yamaguchi *et al*. (2004) and Klaui *et al*. (2005b). The measured velocities were very small, of the order of $3-5\,\mathrm{m\,s^{-1}}$ and $0.1-0.5\,\mathrm{m\,s^{-1}}$, respectively.

Interestingly, DW velocities estimated by dividing the DW displacement by the current pulse length are much higher when short pulses (nanoseconds long) are used. For example, Lim *et al*. (2004) reported switching a spin-valve nanowire in zero field with pulses as short as 0.4 ns and concluded that the DW moves >20 µm in less than 1 ns. The corresponding DW velocity of about $20\,\mathrm{km\,s^{-1}}$ seems much too high to be meaningful. It may suggest a more complex mechanism of DW motion, perhaps involving DW motion long after the end of the current pulse. Such overshooting and a DW inertia effect have been observed in the context of field-driven motion of magnetic bubbles (Malozemoff and Slonczewski, 1979). We have also performed experiments using pulse lengths between 0.5 and 100 ns. In some cases, we have observed DW displacements of ∼1 µm for current pulse lengths of 1 ns, with an associated 'velocity' of up to $1000\,\mathrm{m\,s^{-1}}$. Importantly, we do not observe any clear linear scaling of the DW displacement with the pulse length for these long pulses (note that the data vary widely). This also suggests that the mechanism of DW motion is more complex for short excitations.

Recently, the DW velocity in permalloy nanowires has been measured more accurately by time-resolved measurements, in the presence of a combination of field and current (Hayashi *et al*., 2006a; Beach *et al*., 2006) as well as current alone (Hayashi *et al*., 2007a). Both measurements were 'time-of-flight' experiments, in which the velocity is obtained by dividing a distance traveled by the DW by the time the DW takes to move between two points along the nanowire. In both cases, data were averaged over a large number of repetitions. The distance was between different positions of the laser spot in the Kerr measurements by Beach *et al*. (2006) and between two electrical contacts in the AMR studies by Hayashi *et al*. (2006a, 2007a).

In the presence of field and current, the DW velocity is affected differently depending on the relative magnitude of the field and current and the current polarity (Hayashi *et al*., 2006a) (see Figure 22). When the electron flow is along the direction of the field-driven motion, the DW velocity is enhanced by up to $\sim 100\,\mathrm{m\,s^{-1}}$. The Walker breakdown field is not significantly affected, at least not for the current densities investigated. By contrast, when the electron flow is opposite to the direction of field-driven motion, the DW velocity is reduced. The DW motion can even be stopped (or slowed below the experimental detection limit) – when the field is smaller than ∼25 Oe (2.5 times the Walker breakdown field). Note that in the case of a moving DW, there does not seem to be a critical current: the velocity varies continuously with the current density, and even small currents influence the DW velocity.

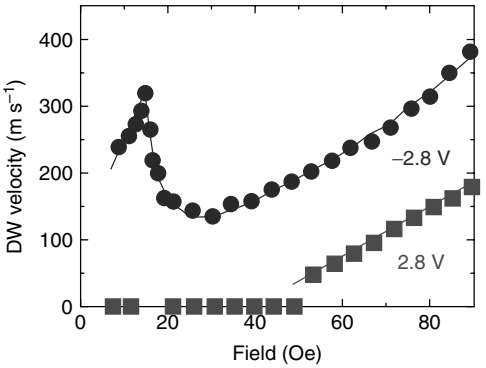

Figure 22. DW velocity determined by time-resolved AMR measurements in a 10-nm-thick, 200-nm-wide permalloy nanowire, in the presence of current flowing in both directions. The current density is $\sim 1.4 \times 10^8\,\mathrm{A\,cm^{-2}}$. (Reproduced from figure 2(c) in M. Hayashi, L. Thomas, C. Rettner, R. Moriya, and S.S.P. Parkin, 'Direct observation of the coherent precession of magnetic domain walls propagating along permalloy nanowires', *Nature Physics* **3**, 21 (2007).)

DW motion driven by current only was also reported. In this case, the DW motion was only detected for current densities higher than $\sim 7-10 \times 10^7\,\mathrm{A\,cm^{-2}}$. Motion was along the electron flow. The DW velocity increases with the current, from $\sim 80\,\mathrm{m\,s^{-1}}$ at the threshold current up to about $150\,\mathrm{m\,s^{-1}}$. Note that the DW velocity saturates for the highest current densities investigated, although the origin of this effect is not clear. Interestingly, such high velocities (more than 2 orders of magnitude larger than those reported by Yamaguchi and Klaui) approach and may even exceed the rate of spin angular momentum transfer given by the parameter u (equation (15)) (Hayashi *et al*., 2007b).

Finally, we briefly mention experiments performed on the current-induced motion of DWs in GaMnAs nanowire structures by Ohno's group (Yamanouchi, Chiba, Matsukura and Ohno, 2004; Yamanouchi *et al*., 2006) (similar data were also published recently by Tang, Kawakami, Awschalom and Roukes, 2006) but only in combination with a magnetic field). Ohno *et al*. report DW motion, driven by current only, with DW velocities spanning more than 5 orders of magnitude up to $22\,\mathrm{m\,s^{-1}}$. Two different regimes are observed: the DW velocity increases roughly linearly with the current density for currents above a threshold current (between 3.5 and $5.5 \times 10^5\,\mathrm{A\,cm^{-2}}$ depending upon the temperature). The data

are consistent with the spin-transfer efficiency expected from equation (15) (albeit slightly larger), once the temperature dependence of the magnetization and the spin polarization are taken into account. A second subthreshold regime is observed, in which the DW velocities are between 10^{-5} and $1\,\mathrm{m\,s^{-1}}$, which is interpreted as DW creep.

3.5.4 Field dependence of the critical current

The field dependence of the critical current has been studied by several groups. In most of these experiments, the DW is first pinned at either a defect (Thomas *et al*., 2006; Laufenberg *et al*., 2006b; Grollier *et al*., 2004; Lim *et al*., 2004), or a notch (Florez, Krafft and Gomez, 2005; Hayashi *et al*., 2006b; Klaui *et al*., 2005c) or at a cross (Ravelosona *et al*., 2005). In one report (Vernier *et al*., 2004), a quite different experimental method was used: the propagation field along a nanowire is measured while dc currents of both polarities are applied. All these studies show some consistent trends:

- The critical current for DW depinning decreases when the field is increased.
- DW motion occurs along the field direction, except for very small fields.
- The polarity dependence of the depinning current is weak. The strongest effect of the current is a reduction of the depinning field independent of the current polarity.
- Both linear and nonlinear field dependences of the critical current have been reported.

We have studied the field dependence of the critical current for depinning a DW from a notched pinning site, with widely varying pinning strengths, in NiFe wires with various different dimensions (see e.g., Hayashi *et al*., 2006b). Our results show very little dependence on the current polarity, in agreement with other studies. In most cases, the critical current exhibits a strongly nonlinear variation with field. We observe two distinct regimes. In a low-field regime, the critical current depends only weakly on the notch pinning strength (as measured by the depinning field) and the magnetic field. By contrast, in a high-field regime, the field dependence is much stronger. An illustration of these two regimes is shown in Figure 23, for permalloy nanowires with different notches. Note that for these experiments, two DWs were nucleated on either side of the wire. Current-driven depinning most likely causes annihilation of these two DWs.

3.5.5 Subcritical domain-wall transformations and metastability

The role of metastable DW states was first noted by Berger (1992). He pointed out that in some thickness range, Bloch and Neel walls are nearly degenerate. Thus, only a small torque is needed to rotate the wall's magnetization from one DW state to the other, resulting in a reduced critical current.

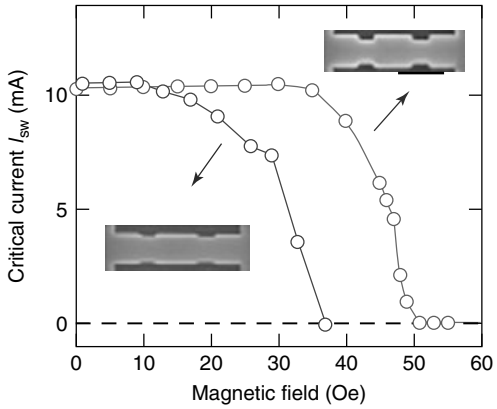

Figure 23. Field dependence of the critical dc current for depinning DWs in 18-nm-thick, 315-nm-wide, permalloy nanowires.

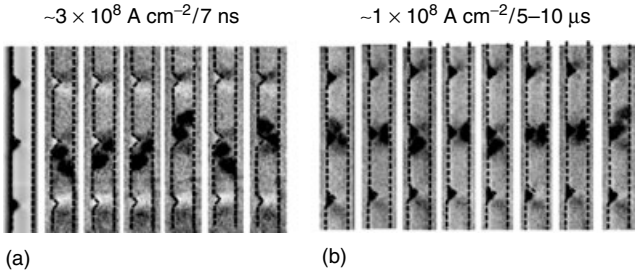

Figure 24. DW transformations measured by MFM in 20-nm-thick, 300-nm-wide permalloy nanowires upon successive application of current pulses.

Current-driven DW changes can take place below the critical value or depinning. For example, in the work of Florez, Krafft and Gomez (2005), it was observed that the wall structure was modified even though the DW was still trapped within the notched pinning site. We have also observed this behavior, both using MFM and AMR experiments. Examples of the modification of the DW structure upon application of current pulses are shown in Figure 24. The NiFe nanowire is 300 nm wide and 20 nm thick. In the first set of experiments (a), the DW retains its V structure, but the V chirality is reversed. In the second set of images (b), the original V DW is transformed into a T wall, which remains stable for a few pulses before transforming back to into a V wall (with a reversed chirality). The detailed mechanisms responsible for this behavior are not fully understood. However, these experiments suggest that the electric current allows the magnetic system to access metastable states, even if the energy barriers separating these states are often very high (for example, $\sim 6 \times 10^{-11}$ erg in the

example of Figure 19). Thermally activated transformations are also possible if the energy barrier is smaller. For example, transformation from a T to a V DW was observed at ∼550 K by Laufenberg *et al*. (2006a) in 7-nm-thick, 730-nm-wide permalloy nanorings. This corresponds to an energy barrier of $\sim 8.0 \times 10^{-14}$ erg.

Current-driven depinning also exhibits significant stochastic variations, particularly in low fields. In repeated experiments, the probability for DW depinning varies significantly. In other words, the critical current at a given field can vary widely. This can partly be related to the multiple metastable DW states at a notch.

3.5.6 Dynamical effects

Most experiments published so far have used dc currents or long pulses (microseconds). Little is known on possible dynamical effects driven by shorter pulses or alternating current. Until recently, there were only a few experimental reports on the influence of the pulse length for nanosecond-long current pulses. Salhi and Berger (1994) studied the influence of a series of square pulses with lengths between 50 and 300 ns on the critical current, and they did not observe any dependence. The same insensitivity to pulse length has been reported by Lim *et al*. (2004) for a spin-valve nanowire, for much shorter pulses (between 0.4 and 2 ns).

However, Berger has proposed several interesting dynamical effects related to current pulses or ac currents. For example, in the case of pulses with fast rise-times and slow fall-times, he proposed a 'wall streaming' mechanism in which the DW can escape a pinning potential on the trailing edge of the pulse (Salhi and Berger, 1994; Berger, 1992). He also proposed several other notions such as the existence of a 'Ferro–Josephson' effect (Berger, 1986) where the precession of the DW driven by the current generates a dc voltage across the DW, following a mechanism quite similar to the Josephson effect in superconducting junctions. In a further development, he showed that the combination of a hard-axis, high-frequency field and a dc current could lead to the locking of the DW precession frequency with the ac field. This would give rise to steps in the current dependence of this induced voltage, similar to Shapiro steps in Josephson junctions (Berger, 1991b). Finally, he also showed that ac currents could generate oscillations of a DW, with a resonance frequency of ∼10–100 MHz (Berger, 1996).

In a recent experiment, the influence of a small ac excitation has been studied by Saitoh *et al*. in a U-shaped permalloy nanowire (Saitoh, Miyajima, Yamaoka and Tatara, 2004). The authors observed a peak in the device resistance as a function of the frequency of the ac current in the MHz range. The peak frequency could be tuned between ∼5 and 25 MHz by varying the applied magnetic field. Interestingly, the peak was observed even though the excitation is extremely small (about two orders of magnitude smaller than the dc critical current). These data are understood in terms of a current-driven resonance of the DW in the parabolic potential created by the applied field. This interpretation is supported by a model by Tatara, Saitoh, Ichimura and Kohno (2005). The authors propose that this behavior results from momentum transfer (or nonadiabatic spin torque) rather than spin transfer. Even though the momentum transfer (proportional to the DW resistance in Tatara's model) is very small, it is amplified at resonance and becomes dominant. The authors also suggest that the amplitude of the DW displacement is very large (∼10 μm), although there is no direct evidence to support this claim.

We have reported recently that the current-driven motion from a local pinning potential is indeed very sensitive to the pulse length (Thomas *et al*., 2006). We have shown that the probability of depinning a DW from a local pinning site oscillates with the length of the current pulse, with a period of a few nanoseconds (see Figure 25). Importantly, both head-to-head and tail-to-tail DWs exhibited the same behavior. These oscillations of depinning probability lead to strong oscillations in the critical current. We have shown that this behavior is related to the current-induced precession of the DW trapped in a pinning potential. When the pulse length is close to a multiple of half the precession period, the amplitude of the DW oscillation is amplified after the end of the current pulse, in turn leading to DW depinning. Importantly, this is a subthreshold behavior, which occurs for currents smaller than the dc critical current. Moreover, in this depinning regime, we showed that the DW displacement is against the electron flow, opposite to the propagation direction above threshold. This behavior can be accounted for within the framework of the 1D model described in Section 2.2.3. Even though the DW in the experiment was a vortex wall, we were able to achieve a good qualitative description of the experimental results Yamanouchi *et al*., (2006).

3.5.7 Thermal effects: current-induced heating and nucleation of domain walls

As already emphasized, the high critical current density required to achieve current-induced DW motion in most samples induces significant Joule heating. The effect of temperature on the current/ DW interaction is not fully understood. One obvious effect is the decrease of magnetization and anisotropy of the magnetic material. According to equation (15), this should help to reduce the intrinsic critical current, since J_c is proportional to $M_s H_k$, and H_k is an anisotropy field which is itself proportional to M_s. However, the polarization of the current should also be reduced, which should compensate at least partially the gain from

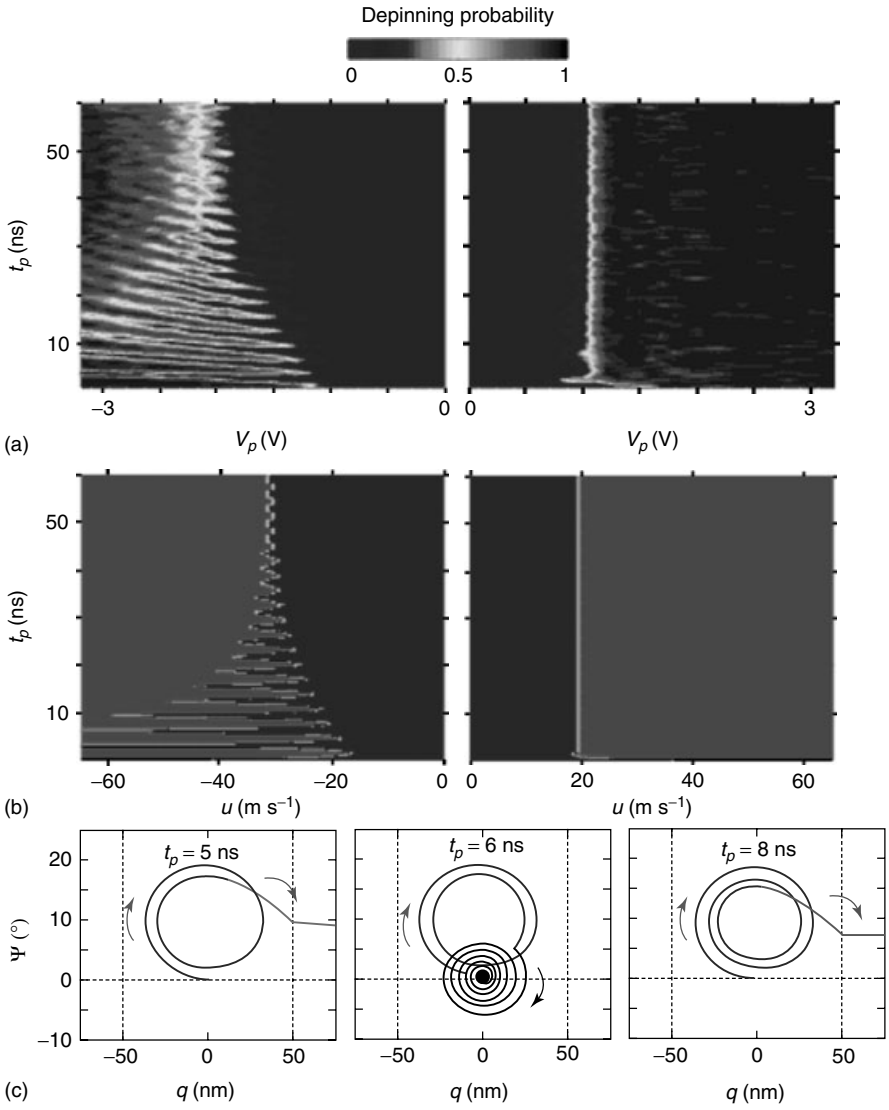

Figure 25. Oscillatory depinning of a DW as a function of the current pulse length. Experiments (a), calculations (b), and schematic explanation of the mechanism (c). (From Thomas *et al*. (2006).)

the reduction of M_s. Moreover, spin-wave excitations can be amplified by the spin torque and lead to chaotic behavior, thus preventing DW motion.

In a recent report on permalloy nanorings, Laufenberg *et al*. (2006b) observed a slight increase of the critical current with temperature between 4 and 300 K, from ∼2 to 2.8×10^8 A cm^{-2}. This variation is opposite to that of the DW depinning field, which decreases with temperature. The authors conclude that the spin-transfer efficiency decreases with temperature, although the origin of such a variation is not clear. In this temperature range, far below the Curie temperature for permalloy, the magnetic properties exhibit little variation. The authors propose to explain this decrease in efficiency by thermally excited spin waves, which couple with the current flow, effectively absorbing some spin angular momentum. Results are opposite for GaMnAs structures for which the critical current decreases by ∼50% when the temperature increases between 100 and 107 K, as the spin-torque efficiency increases owing to the temperature dependence of the magnetization and spin polarization (Yamanouchi *et al*., 2006).

Temperature effects were also addressed by Yamaguchi *et al*. (2005) in a much higher temperature range. It was shown that spontaneous DW nucleation occurs in permalloy nanowires when the current density exceeds 7.5×10^7 A cm^{-2}. The authors suggest that this phenomenon occurs because the temperature exceeds the Curie temperature for NiFe during the pulse, thus leading to the breakdown of the nanowire into a multidomain state. We have observed similar effects in many nanowires. Interestingly

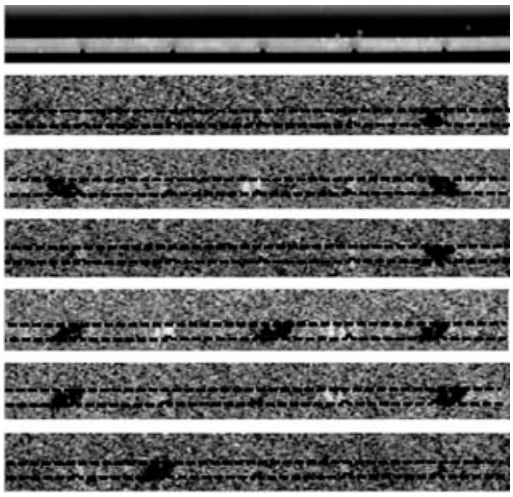

Figure 26. MFM images measured from a 10-nm-thick, 300-nm-wide permalloy nanowire, upon successive application of 3-ns-long current pulses, with a current density of $\sim 7 \times 10^8\,\mathrm{A\,cm^{-2}}$ (value not corrected for resistance increase due to heating).

in the example shown in Figure 26, DWs are nucleated, whereas preexisting DWs are essentially unaffected by the current pulse. This suggests that DW generation can occur below the Curie temperature, for example, because of the reversal of the magnetization in one or several portions of the nanowire, thereby generating pairs of DWs. In the many cases where we have observed this behavior, the ends of the nanowires are not reversed, and the DWs always appear in pairs, thus supporting this interpretation. Micromagnetic simulations that include thermal effects also suggest that the spin torque amplifies magnetization fluctuations and can thereby eventually lead to the complete reversal of parts a nanowire.

Interestingly, Shibata *et al*. find by theoretical calculations that, above a current threshold, the ground state of a ferromagnet becomes a multidomain state with several DWs (Shibata, Tatara and Kohno, 2005). The threshold for nucleation is given by (using the notation of Section 2.2.3):

$$u_{\mathrm{nuc}} = \gamma \Delta H_{\mathrm{k0}} \left(1 + \sqrt{\frac{H_{\mathrm{k}}}{H_{\mathrm{k0}}}}\right) \tag{26}$$

where H_{k0} and H_{k} are the longitudinal and transverse anisotropy fields, respectively. If $u_{\mathrm{nuc}} < u_{\mathrm{c}}$ (u_{c} the intrinsic critical current given by equation (13)), that is if $H_{\mathrm{k}} > 8H_{\mathrm{k0}}$, the multidomain state is stable, and this could appear as the spontaneous nucleation of multiple DWs in a nanowire, as observed experimentally. An estimate of the current density required to reach this nucleation regime is found to be $\sim 3 \times 10^9\,\mathrm{A\,cm^{-2}}$ for Co. For permalloy, this value could be lower, particularly since Joule heating would contribute to a reduction of the magnetization, since permalloy has a lower Curie temperature than Co.

4 OUTLOOK

The observation that current can induce motion in DWs has a long history dating back more than 25 years. Indeed, it was appreciated long ago that there are several ways in which current can interact with DWs, including the notion that the transfer of spin angular momentum from current to DWs can perturb a DW. However, there were few experiments on this important interaction perhaps because it is only dominant in magnetic structures on the nanoscale, and is thus is obscured by other effects in larger structures. As the capability to make ever smaller high quality structures has evolved over the past years it has become possible to fabricate structures in which single DWs can be controllably injected and whose motion can be probed following or even during the application of nanosecond-long current and field pulses. These experimental studies have clearly demonstrated that spin-polarized current does result in the motion of DWs along magnetic nanowires. Moreover, short current pulses, whose length is matched with the precessional frequency of a DW, can resonantly excite the precession of the DW. While there are a number of open questions, as discussed briefly at the end of the last section, the notion of moving DWs with current is not only of considerable scientific interest, but suggests a number of interesting technological applications.

More than a quarter of a century ago there was considerable interest in the possibility of building magnetic memory devices by storing information in the form of magnetic domains or bubbles in single-crystalline garnet thin films. In this original planar magnetic memory the bubbles were defined and moved by magnetic fields created on chip. Much creative and imaginative work was expended to develop ingenious structures to reliably manipulate magnetic domains in these materials, as discussed in several review articles and papers (see, e.g., Malozemoff and Slonczewski, 1979; de Leeuw, Van Den Doel and Enz, 1980; Bar'yakhtar, Ivanov and Chetkin, 1985; Schneider, 1975; Pugh, Critchlow, Henle and Russell, 1981; Eschenfelder, 1980). In this chapter we focused the discussion on the motion of head-to-head DWs in magnetic nanowires. One problem with manipulating such types of DWs by magnetic fields is that head-to-head and their counterpart tail-to-tail walls move in opposite direction in the presence of a magnetic field. This problem can be solved by using spin momentum transfer from current to move DWs since the current becomes repolarized over very short distances (e.g., the spin relaxation length can be as short as $\sim 5\,\mathrm{nm}$ in permalloy (Bass and Pratt, 2007)). Thus current moves head-to-head and tail-to-tail DWs in permalloy and other transition metals in the *same* direction. This distinctive feature of current-induced DW motion allows the possibility of interesting new device technologies not previously possible with field manipulation. One of the more interesting

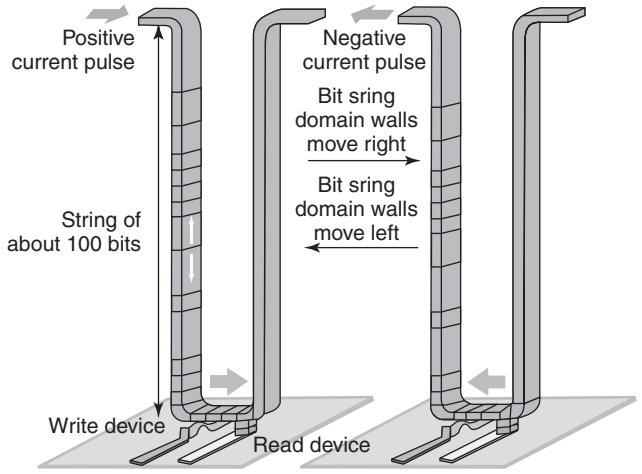

Figure 27. Schematic of the magnetic racetrack memory device.

of these devices is the magnetic racetrack memory (MRM) (Parkin, 2004).

The magnetic racetrack memory promises a nonvolatile solid-state data-storage device that combines the very low cost of conventional magnetic hard-disk drives with the high reliability and high performance of nonvolatile solid-state memory. The MRM concept is that of a magnetic shift register in which individual spintronic reading and writing elements, formed using conventional CMOS technology, are married to magnetic 'racetracks' in which 10 to 100 nanoscale bits are stored as magnetic domains (schematically shown in Figure 27). The racetracks are vertical columns of magnetic material, formed in the third dimension, perpendicular to a plane of CMOS logic elements and devices formed on a silicon substrate. Each of these columns is addressed by a single read and write element whereby the magnetic domains in the racetrack are moved, by nanosecond-long current pulses using current-induced motion of DWs, to the read and write devices. Since the racetracks are formed in the third dimension the footprint of each racetrack in the CMOS logic plane is very small and therefore the cost should be low. Indeed the goal of the MRM is to store $\sim$100 data bits in the same area of a silicon wafer that one data bit in conventional solid-state memories would occupy. Since the cost of a CMOS memory or logic device is largely determined by the area of the silicon wafer the proposed magnetic shift memory has the potential to be $\sim$100 times cheaper per bit than conventional solid-state memory and so comparable in cost to a HDD. At the same time the proposed solid-state memory will have the reliability and integrity of conventional solid-state memories. Thus, the proposed spintronic magnetic shift memory will have a previously unrealized combination of extremely low cost, high reliability, and excellent performance as compared to flash drives and HDDs.

The magnetic racetrack is just one example of a possible new technology which takes advantage of the new physics of current-driven DW motion, which has just begun to be fully appreciated and understood in the past few years. As discussed throughout this chapter, however, many aspects of current-driven DW motion remain unanswered. The most fundamental question is the detailed theoretical description of the current-magnetization interaction. Of particular interest is the understanding of the role of nonadiabatic contributions to the current–magnetization interaction. There is considerable debate over the existence and nature of this contribution, and, consequently whether there is an intrinsic threshold current for DW motion in uniform, homogeneous magnetic nanowires.

Another important question is the maximum possible speed of DWs driven by current alone. Many experimental studies, mostly in permalloy but also in GaMnAs, have indicated extremely low current-driven DW velocities. These velocities are so small that they are difficult to rationalize within today's theoretical models. Clearly, further experimental and theoretical studies are called for. Systematic studies of the relationship between the critical current needed to move a DW as well as the DW velocity and the intrinsic material parameters of the magnetic material (e.g., magnetization, anisotropy, and spin polarization of the current) will likely lead to a much improved understanding of the basic mechanisms involved in the current–DW interaction.

A particularly interesting question is the magnitude of the current required to sustain the motion of a DW along a nanowire and whether this is largely determined by the spin polarization of the current and the magnetization of the magnetic domains or whether other factors may play a significant role. The answer to this important question will determine how useful current-induced DW motion will be for technological applications. From both a technological and a scientific perspective, the understanding and control of the DW structure and the interaction between DWs is both challenging and interesting.

The renewed interest in DW dynamics in magnetic nanostructures has already revealed new physical phenomena and the considerable activity in this field promises exciting future discoveries.

ACKNOWLEDGMENTS

We would like to thank our colleagues at the Almaden Research Center for their contribution to this work: Masamitsu Hayashi, Rai Moriya, Charles Rettner, Xin Jiang, Yaroslaw Bazaliy, Bastiaan Bergman, Brian Hughes and Kevin Roche. We are also grateful to Pierre-Olivier Jubert and Michael Scheinfein for their helpful comments on the

manuscript. This work was partly supported by the Defense Microelectronics Activity.

The Motion of Domain Walls in Nanocircuits and its Application to Digital Logic

Russell P. Cowburn
Imperial College London, London, UK

1 INTRODUCTION

Spintronics describes the concept of attempting to use both the charge and the spin on the electron in microelectronic devices (Prinz, 1998; Wolf *et al*., 2001). One of the most highly sought after functionalities in microelectronics is non-volatility, that is, the ability to retain memory even when power is removed. This is particularly true as the popularity of mobile electronic communication and computing devices grows. In principle, ferromagnetic materials could provide this functionality because of the hysteresis, and hence memory, that accompanies most ferromagnets. Unfortunately, no suitable room-temperature ferromagnetic semiconductor material has yet been identified (Dietl *et al*., 2000); the most common ferromagnetic materials are metals. The aim of this research has been to see how far we can push the properties of basic ferromagnetic metallic alloys, which are usually considered to have relatively simple magnetic and electrical properties, toward highly functional devices that mimic and complement the digital logic functions of semiconductor microelectronics. Obtaining complex functionality from these simple materials will only be possible in nanoscale devices: in the bulk, the magnetic response of the alloy considered here would be purely linear. This work in many ways exemplifies the principle of nanotechnology: not simply a more miniature version of what we could already do, but rather making use of the unique behavior that develops when dimensions are reduced to the nanometer scale in order to make devices that have no larger-scale equivalent.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

2 DOMAIN-WALL PROPAGATION AND NUCLEATION

All of the devices described in this chapter are based upon magnetic nanowires made from the common ferromagnetic alloy permalloy ($Ni_{80}Fe_{20}$). Magnetic nanowires are nanometer-sized magnetic structures, which are artificially fabricated using laboratory-scale versions of the lithographic techniques commonly used in microchip manufacture. In particular, the work in this chapter uses either electron beam lithography (EBL) or focused ion beam (FIB) milling (Xiong, Allwood, Cooke and Cowburn, 2001). A typical process will involve the deposition of a thin magnetic film, either using thermal evaporation or sputter deposition, followed by the

exposure of a computer-generated pattern. The pattern is exposed by rastering either a focused electron beam or a focused gallium beam. A development and pattern-transfer step then transfers the exposed image onto the deposited magnetic metal. The ability to create high-definition shapes of precisely the designer's choosing is extremely important, since the underlying principle at work throughout this research is that magnetic properties may be artificially modified by changing the shape and size of the nanostructure. This principle is not commonly seen on the macroscopic scale: the coercivity and anisotropy of a bulk material are usually intrinsic properties, which do not depend strongly on the shape of the sample. On the nanometer scale, however, the local demagnetizing fields are of comparable strength to the exchange fields (the quantum mechanical interaction responsible for ferromagnetism). A rich interplay results, which leads to magnetic properties being strongly dependent on shape and size.

Magnetic properties throughout this chapter are measured using a high-sensitivity laser probe (Cowburn, Koltsov, Adeyeye and Welland, 1998) based on the magneto-optical Kerr effect (MOKE) (Hubert and Schaeffer, 1998). The Kerr effect causes the polarization state of light to be slightly modified when it is reflected from a magnetic surface by an amount that is proportional to the component of magnetization in a given direction. Although the polarization rotations are small (typically 1° if all of the light is focused onto magnetic material, and proportionately less if the nanostructure is smaller than the focused beam size), MOKE is an excellent highly localized magnetometry.

Figure 1 shows two typical nanowires used in this chapter (see Cowburn, Allwood, Xiong and Cooke, 2002 for experimental details and Ono *et al*., 1999 for further examples of domain-wall nucleation and propagation). Shown are localized hysteresis loop measurements made at different positions along the length of the wire. One sees a coercivity of around 200 Oe in the case of Figure 1(a) and a coercivity of around 40 Oe in the case of Figure 1(b). What is striking is that the only difference between these two cases is that in Figure 1(b) the end of the nanowire has been formed into a large island area, known as an *injection pad*. The reason that their coercivities differ by a factor of 5 is because the magnetization reversal mechanism is altered by the presence or absence of the injection pad. In the structure without a pad, magnetization reversal occurs by the nucleation of a new reverse domain, probably close to the end of the nanowire where the demagnetizing fields are strongest, followed by a rapid propagation of the domain wall associated with the newly nucleated domain along the length of the nanowire. The limiting step for this process is the nucleation of the reverse domain, a highly energetic process. The strength of the reversed magnetic field required to force this nucleation is therefore quite high (200 Oe). In the structure with a pad, however, the new domain can easily nucleate inside the large pad because its thickness-to-width ratio (which determines the shape anisotropy) is lower. Once the reverse domain has been nucleated, the associated domain wall is free to move from the pad into the nanowire and propagate along it, effecting reversal of the complete wire. Domain-wall propagation in such nanowires is a very low energy process and so can still occur even at the much lower field at which the nucleation process occurred.

We assign the name *nucleation field* (H_n) to the coercivity reported in Figure 1(a) (200 Oe), that is, the field that must be applied to induce magnetization reversal if no domain wall is introduced artificially from any other source. We also define the term *propagation field* (H_p), which is the field that must be applied to move an existing domain wall along a nanowire. We might be tempted to say from Figure 1(b) that H_p is 40 Oe for this nanowire. In fact, however, even Figure 1(b) is still nucleation limited, albeit at a lower value inside the large pad. Figure 2 shows a different means of accessing H_n and H_p in a nanowire. In this case, we apply a magnetic field which is oriented along the wire axis for most of its sweep, but which rotates to 45° toward the extrema of the loop. This guarantees the starting magnetization state in both arms of the L-shaped nanowire as the applied field sweeps back toward zero. We generate such an applied field sequence by controlling the current in two pairs of coils, which apply fields in the X (nanowire axis) and Y (transverse) directions. If we choose the relative signs of the X and Y fields such that the 45° pulse is tangential to the corner of the L-shaped nanowire, then no domain wall exists in the wire and so the coercivity corresponds to a nucleation-limited reversal. In this case we measure H_n as 205 Oe, virtually identical to the case of Figure 1. If we now reverse the sign of the Y field, the 45° pulse becomes perpendicular to the corner, resulting in a single domain wall being created there. The coercivity now corresponds to the propagation field, since reversal in the main length of the wire is achieved simply by pushing that already-created domain wall around the corner and along the wire. Remarkably, we find a value of just 3 Oe for H_p. The coercivity of the nanowire has been modified by a factor of 65 simply by the presence or absence of a single domain wall.

3 DOMAIN-WALL CONDUITS

When the ratio between H_p and H_n is substantial, we describe the magnetic nanowires as *domain-wall conduits*. This is because if one applies a magnetic field H in the range $H_p < H < H_n$, then the nanowire will accept any domain wall introduced to it and propagate it along the wire, but will not reverse if no domain wall is given. For the nanowires

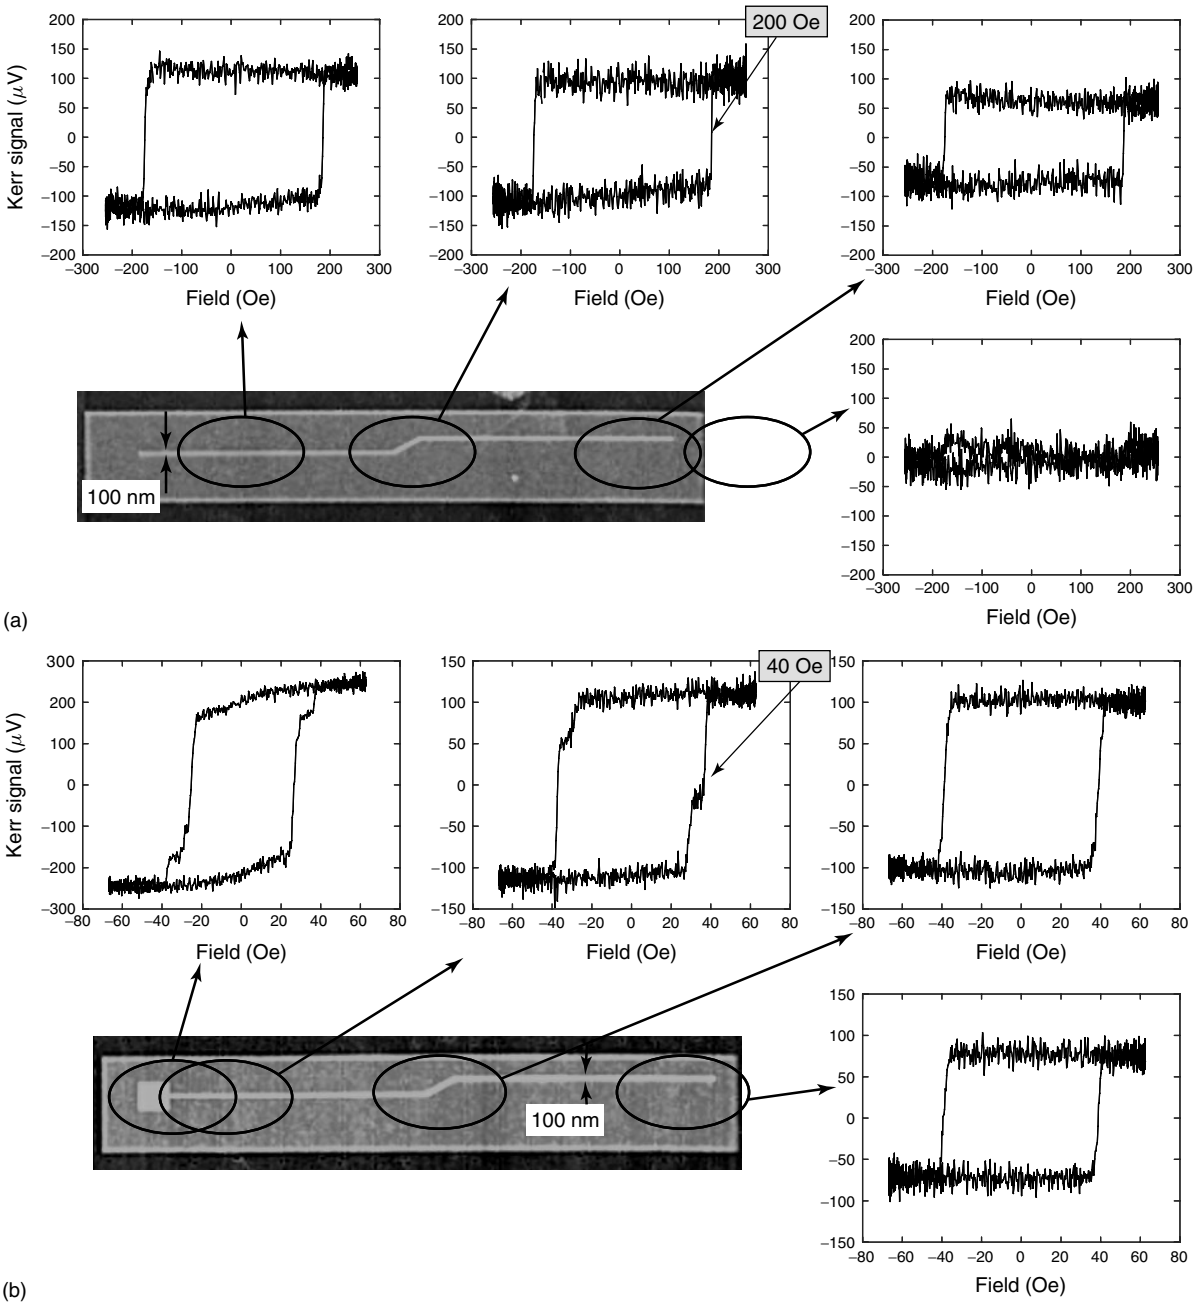

Figure 1. MOKE measurements of two 100-nm-wide 5-nm-thick permalloy nanowires. The ellipses shows approximately the averaging volume of the MOKE measurements. (Reused with permission from R.P. Cowburn, D.A. Allwood, G. Xiong and M.D. Cooke, *Applied Physics Letters*, **91**, 6949 (2002) © 2002, American Institute of Physics.)

shown here, this range is very large (any field between 3 and 205 Oe in the case of Figure 2 will result in domain-wall-conduit behavior). There is thus a parallel between electrical conductors and domain-wall conduits: an electrical conductor transports the electrical potential applied at one end to the other by a flow of electrons; a domain-wall conduit transports the magnetization direction applied at one end to the other by the flow of a single domain wall. Interestingly, electrical conduction results in losses due to the resistance of the conductor; the potential at the far end will always be slightly different from the potential at the near end. Although there are also losses in the transport of a domain wall through spin-wave emission by the wall as it moves, these energy losses are exactly compensated by the energy absorbed from the externally applied magnetic field H. The externally applied magnetic field therefore has a parallel to a power supply,

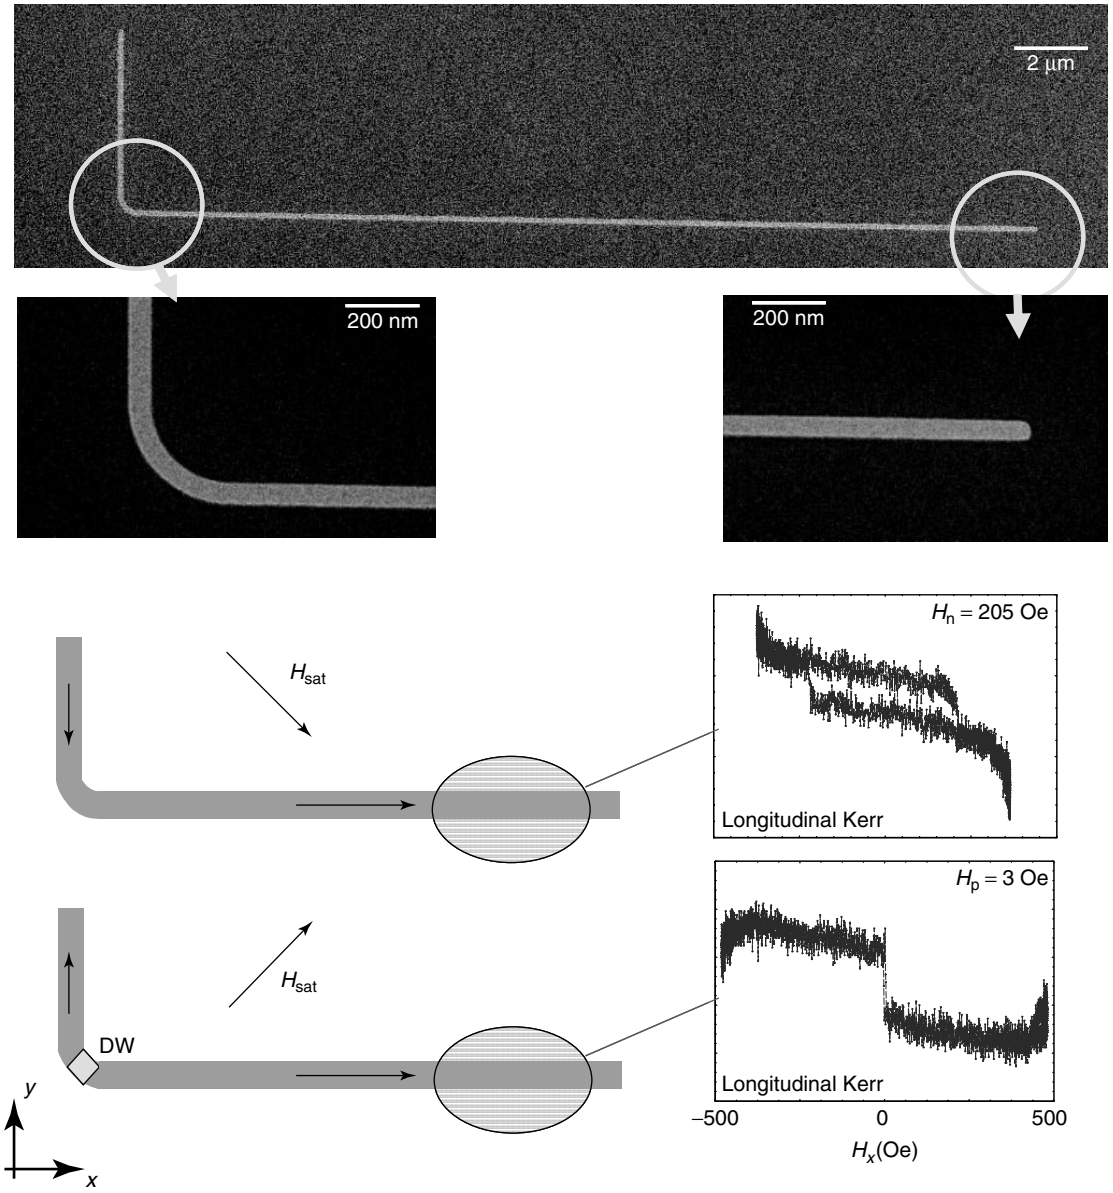

Figure 2. Domain nucleation and domain-wall propagation in a 120-nm-wide, 8-nm-thick permalloy nanowire.

and the domain-wall conduit should be considered as being an active component that can draw on that power supply, rather than the simpler, passive two-terminal component that is an electrical conductor. The propagation field is loosely analogous to a contact potential: it is the offset field that must be overcome before domain-wall conduction will occur. The nucleation field is loosely analogous to breakdown: it is the strength of field at which the magnetization state of the domain-wall conduit no longer relates to the input, but is overridden by the externally applied magnetic field or power supply.

Domain-wall conduits allow us to propagate magnetization states from one place to another, and so for spintronic applications it is natural to assign those magnetization states to Boolean states, allowing us to move information. We define a Boolean '1' as being when the magnetization direction is parallel to the direction in which information flows, and a Boolean '0' as being when the magnetization direction is antiparallel to the direction in which information flows. This may seem a little complex and the question may be asked: why not simply use 'right is 1, left is 0'. The answer is because of the possibility of using the nanowires in more complex geometries than simple straight lines. What will happen if we turn a corner, or, moreover, turn two 90° corners? The U-turn would have introduced a data inversion if we had used a simple fixed-space definition of

Boolean state. Clearly this would be undesirable. By using the direction of flow of information as the basis direction we can turn corners without affecting the data.

There is an additional complexity in propagating information through nanowire domain-wall conduits, caused by the vector nature of magnetization. Figure 3 demonstrates the problem. Suppose we wish to propagate a data sequence made up of 1s and 0s. Domain walls in nanowires carry a magnetic charge, due to the divergence of magnetization in the wall. Walls that lie between the two heads of the magnetization arrows are called *head-to-head* domain walls and carry a positive magnetic charge (since the magnetization has a positive divergence in the vicinity of the wall). Conversely, walls that lie between the two tails of the magnetization arrows are called *tail-to-tail* domain walls and carry a negative magnetic charge. When a magnetic field is applied to the domain wall, positive walls move in the direction of the field, but negative walls move against the direction of the field. Consequently, any data pattern that is more complex than simply all 1s will not propagate correctly, rather, the 1s will expand and annihilate the 0s.

A new approach to solving this problem is the use of spin-momentum transfer, in which a spin-polarized electrical current is used to drive the domain walls through the nanowire (Berger, 1984; Vernier *et al*., 2004; Lim *et al*., 2004; Yamaguchi *et al*., 2004). Spin-momentum transfer through a domain wall does not depend on the sign of the charge carried by the wall, and so all walls move in the same direction. However, this phenomenon is relatively weak and is not yet well understood. While it may provide an interesting solution in the future, at this stage we continue to use externally applied magnetic fields to propagate information.

The solution is to use a magnetic field that rotates in the plane of the nanowire and to impose a minimum spacing on the domain walls. If we require that positive and negative walls are always separated by at least two 90° corners, then although they will move in opposite directions for a given applied field, both of these directions will be the correct direction of information flow. Moreover, once separated by this degree, they will always remain so and will not catch up and annihilate. The only other constraint is that nanowires should only turn corners in one sense: the same as the sense of rotation of the applied magnetic field. So if the field is rotating in an anticlockwise direction, then all corners should turn left, as viewed from the direction of propagation of the domain walls. If the network requires a right-hand turn, then it is simply necessary to perform three left-hand turns instead. Once these constraints are obeyed, it is possible to build an arbitrary network of nanowires and to propagate information reliably through it. It is interesting to note that the combination of a fixed rotating field sense (or chirality) combined with having only a single sense of corner defines a propagation direction around the network. In electronic systems, it is usually necessary to have a semiconductor element such as a diode or transistor before inputs can be isolated from outputs. This result is the first indication that we are achieving a higher level of functionality from the magnetic nanowires than a simple metal would suggest was possible. It is also of enormous practical importance, since one of the frequent failures that one observes in new-concept nanoelectronic devices is the inability to achieve input–output isolation and hence to define an information flow direction through a network.

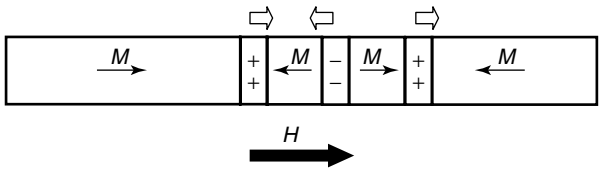

Figure 3. The problem of propagating a data pattern in a nanowire under an externally applied magnetic field, H. The white arrows show the direction of motion of the different domain walls.

A consequence of using a rotating field to propagate domain walls of both signs is that the domain-wall conduits become synchronous. Rising edges always propagate half a rotating field cycle before falling edges, and every 90° corner introduces a 90° phase shift into the signal. This presents both challenges and opportunities for the design of spintronic circuits based on domain-wall-carrying nanowires. The greatest challenge is that conventional microelectronic design tools assume that signals propagate through interconnect asynchronously and at a fraction of the speed of light. It will be difficult to use these tools in this new world where entire clock cycles of delay can be introduced simply by the choice of interconnect routing. On the positive side, the synchronous delay associated with each corner means that there is a large amount of embedded memory automatically distributed around the network. New architectural concepts will be required to exploit this memory, but it is noteworthy that one of the challenges facing microelectronics in the future is how to reduce the separation and resulting bottleneck between logic and memory. A further benefit, which will be expanded in more detail toward the end of this chapter, is that shift registers are extremely simple to realize in domain-wall logic – they are largely just lengths of interconnect.

4 LOGIC ELEMENTS

Now that we have interconnect for magnetic logic signals which can be used in near-arbitrary networks and hence move information to wherever we choose, the next step is to find ways of acting on that information in order to

perform computations. Any Boolean logic function can be realized once a two-input function (e.g., AND, OR) and an inverter (NOT) are available, simply by combinations of these basic functions. In addition, two architectural elements are required, namely, a fan-out structure, which creates two identical copies of a single signal without any loss in signal strength, and a crossover junction, which allows two perpendicular signal paths to cross without interference. In principle, once these four basic elements are available in domain-wall logic, any other circuit can be constructed.

4.1 The NOT gate

Figure 4 shows the design we have adopted for the NOT gate. See Allwood *et al*. (2002) for experimental detail. Since data are encoded by the direction of magnetization, the inverter function (which maps a 1 to a 0 and a 0 to a 1) is implemented by forcing a 180° rotation on the magnetization. The simplest way to achieve this is through a cusp structure. As the nanowire turns through the first quarter cycle of the cusp, the magnetization attempts to remain parallel to the nearest edge in order to minimize its potential energy. The magnetization therefore rotates with the cusp. During the second quarter cycle of the cusp, the magnetization continues rotating, with the result that the magnetization on the input side of the cusp is rotated 180° with respect to that on the output side. What makes this structure so useful is that it not only works statically, as described here, but also dynamically. That is to say that if a domain wall is incident upon the input side, corresponding to a transition edge in the data, the first half of the cusp looks like an anticlockwise corner and so the domain wall is carried into it by the external rotating magnetic field. Once in the central stub section, the domain wall finds that the second half of the cusp *also* looks like an anticlockwise corner and, so, is also pushed around it by the next quarter cycle of the rotating field, emerging on the other side of the cusp. It is a defining topological feature of a cusp that as one moves through it, both halves appear to have the same chirality.

The simplest way to test a NOT gate is by connecting its output to its input and thus forming a ring oscillator, as shown experimentally in Figure 4. While in microelectronics this would result in a high-frequency oscillation, the frequency of which would be determined by the propagation delay on the gate, the synchronous nature of domain-wall logic leads to a slightly different result. Figure 5 shows the equivalent electronic circuit. The half-cycle synchronous delay associated with propagating the domain wall through the cusp (or, put another way, because 1s and 0s propagate half a clock cycle apart in this architecture, the output of the NOT function must change half a cycle after its input) is shown as a $T/2$ delay, where T is the period of the rotating field. Additionally, there is a further delay of T due to the synchronous

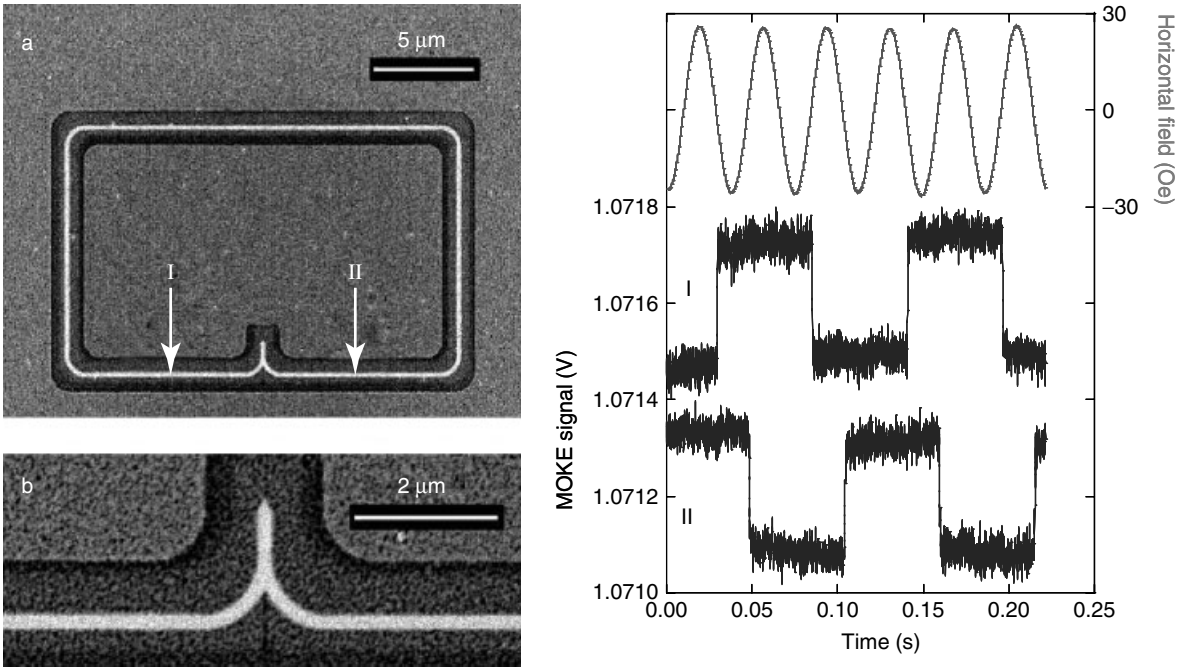

Figure 4. A NOT gate in a closed loop to form a synchronous ring oscillator. The bright white shade is 5-nm-thick permalloy. Signal measurements are made by MOKE at the two positions I and II. The device is bathed in an in-plane rotating magnetic field, one component of which is plotted.

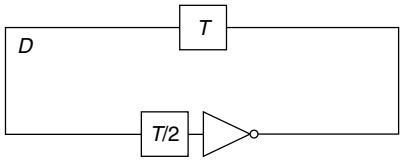

Figure 5. The equivalent electronic circuit for the synchronous ring oscillator shown in Figure 4. The square blocks are delay elements; T is the periodic time of the rotating magnetic field.

way in which the domain walls will move through the loop connecting the output to the input. The total loop time is therefore $3T/2$, which simple analysis shows will lead to a self-sustained oscillation with a periodicity of $3T$.

Figure 4 shows the result of measuring the magnetization on firstly the input arm I, and then the output arm II of the NOT gate while the entire chip is bathed in a rotating magnetic field. All of the expected features are visible. There is a half clock-cycle delay between the rising edge on the input of the gate and the corresponding falling edge on the output of the gate. The periodicity of the result is also seen to be three times the rotating field frequency, as expected. Although in this experiment we do not see the domain wall directly, the response periodicity of $3T$ is the sign that everything is functioning correctly. See Zhu *et al*. (2005) for direct magnetic force microscopy images of the domain wall moving around the loop and through the gate.

This simple circuit can be used to demonstrate how the chirality of the rotating field imposes an information propagation direction on the data. Figure 6 shows similar data to those shown in Figure 4, except that the applied field was stopped half way through the experiment and its sense of rotation reversed. It can be seen that when the applied field was rotating anticlockwise, the signal at the left-hand side of the NOT gate was leading the signal at the right-hand side by half a cycle, meaning that data were flowing from left to right through the NOT gate. Once the applied field was switched to clockwise rotation, the signal at the left-hand side of the NOT gate lagged that at the right-hand side by half a cycle, showing that data were flowing from right to left. The mirror symmetry of the cusp shape means that, in principle, either end can act as input, but a definite direction is, nevertheless, imposed by the sense of rotation of the applied field.

Once simple nanowires are formed into more complex shapes such as NOT gates, the ideality of the conduit begins to fail. For example, as the domain wall passes from the first quarter turn of the cusp to the second quarter turn, there is an instant when the wall cannot be considered to be in a well-defined conduit, and a complex micromagnetic pattern emerges. Consequently, the propagation field is augmented by the structural discontinuities in the logic gate. It is important to assess whether this increase in H_p is sufficiently large to reduce the available margin between H_p and H_n in which conduit behavior occurs. We do this by measuring the two-dimensional operating margin plot shown in Figure 7. The rotating field is expressed as an arbitrary ellipse with principle axes aligned along the X and Y directions, and measurements are made for different sizes and shapes of the

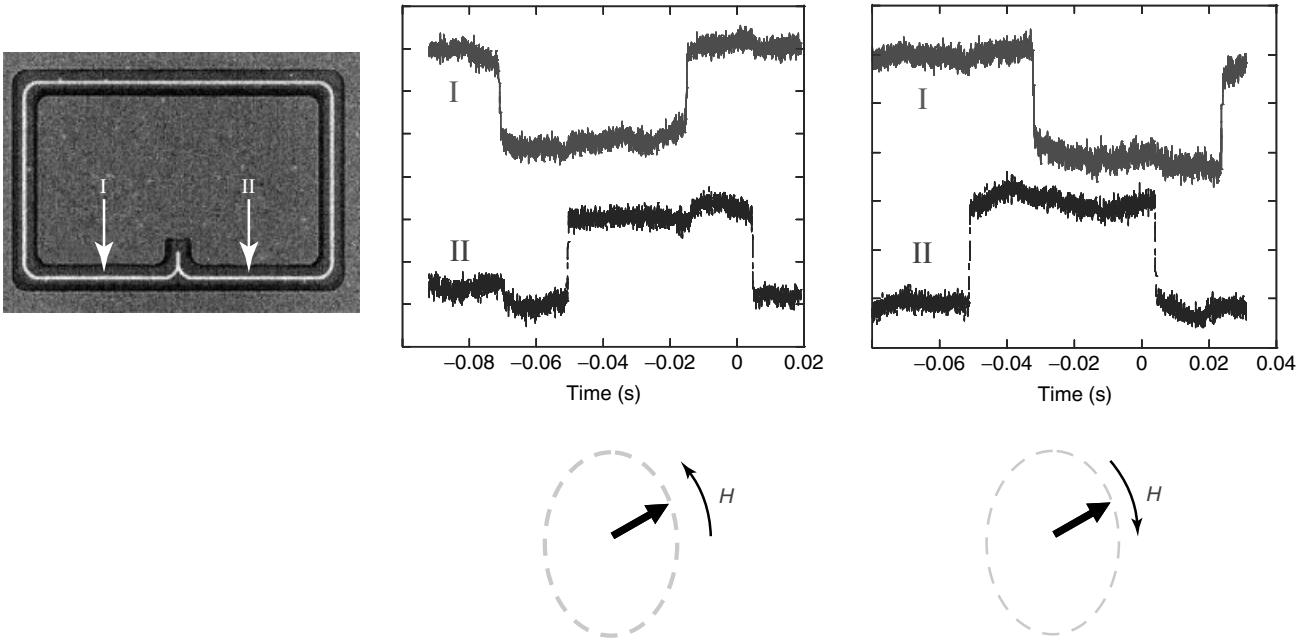

Figure 6. A NOT gate in a closed loop operated under two different senses of rotating field. The signal traces are made by MOKE at points I and II.

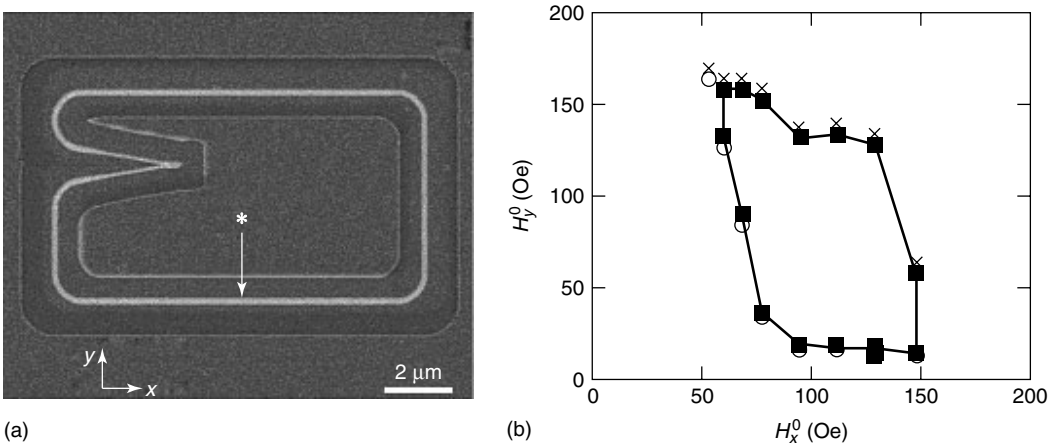

Figure 7. (a) An optimized NOT gate and (b) its operating margin phase diagram. The rotating magnetic field is described as an ellipse with major axis strengths $H^0{}_x$ and $H^0{}_y$. All field values inside the closed loop are found to operate the device correctly. (Reused with permission from D.A. Allwood, Gang Xiong, M.D. Cooke, C.C. Faulkner, D. Atkinson and R. Cowburn, *Journal of Applied Physics*, **95**, 8264 (2004). © 2004, American Institute of Physics.)

field locus as to whether the circuit functions or not. One sees in Figure 7 a well-defined enclosed operating area. Outside the top right of the operating area, the applied field is too strong and nucleation occurs in the NOT gate. This is observed experimentally by the periodicity of the response changing from $3T$ to T, as the gate begins switching in step with the applied field, regardless of the incoming data value. Outside the bottom left of the operating area, the applied field is too weak and domain walls are unable to propagate through the structural discontinuities of the cusp. Close to the boundary one sees occasional dephasing of the response, meaning that the device skipped a cycle as a domain wall became trapped; further away from the boundary (closer to the origin), there is no response at all, since domain walls are unable to move. See Allwood *et al*. (2004) for further discussion on NOT-gate operating margins and optimization of the shape of NOT gates.

The size of the operating margin (i.e., the area within the operating area) is important for two reasons. Firstly, it defines the fabricational fault tolerance of the gate, since small changes to the gate shape will most likely shift the operating area: we assume that the larger the margin was to start with, the more it can be shifted without device failure. Secondly, when we come to combine different types of gate, it is necessary to overlay their different operating areas and limit the applied field to areas that are common to all devices. This process is usually easier if the individual margins are large to start with.

4.2 The AND/OR gate

Figure 8 shows the structure used to perform either the AND or the OR function. See Faulkner *et al*. (2003) for further experimental details. Two nanowires are brought together through a shallow angle to a nodal point. A small amount of tapering is applied to the wire width immediately before the nodal point. The principle of operation is that for a domain wall to pass from one of the input arms to the output arm it must reverse a volume of spins in the node; if there is a domain wall coming down each arm at that instant, together they can reverse the center far more easily than a single wall could. Thus, there are two propagation fields for the device: H_{p1} that is the field required to propagate a single domain wall down an input arm and through to the output, and H_{p2} that is the field required to propagate a domain wall down both inputs arms and through to the output. We can set up these two conditions (plus a control experiment of no domain walls, which leads to the nucleation field for the gate being measured) by making different structures with different numbers of injection pads (Figure 8 shows one example where a single domain wall is injected). As in the case of the NOT gate, we measure the two-dimensional operating area phase diagram (see Figure 8). It is clear from this figure that $H_{\mathrm{p2}} < H_{\mathrm{p1}} < H_{\mathrm{n}}$. Just as there was a certain field range H such that $H_{\mathrm{p}} < H < H_{\mathrm{n}}$ in which a magnetic nanowire could be considered to be a domain-wall conduit, similarly there is a certain field range in which the two-input nanowire junction can be considered to be a logic gate. If we limit the applied field to the range $H_{\mathrm{p2}} < H < H_{\mathrm{p1}}$ then we describe the junction as being AND-like. This means that the applied field is strong enough to switch the output if each input supplies a domain wall, but not strong enough if only one input (or no inputs) supplies a domain wall. We use the term *AND* in the description of this gate because, like the true AND gate, it requires both inputs to act before the output will change. We say 'like', because this condition is

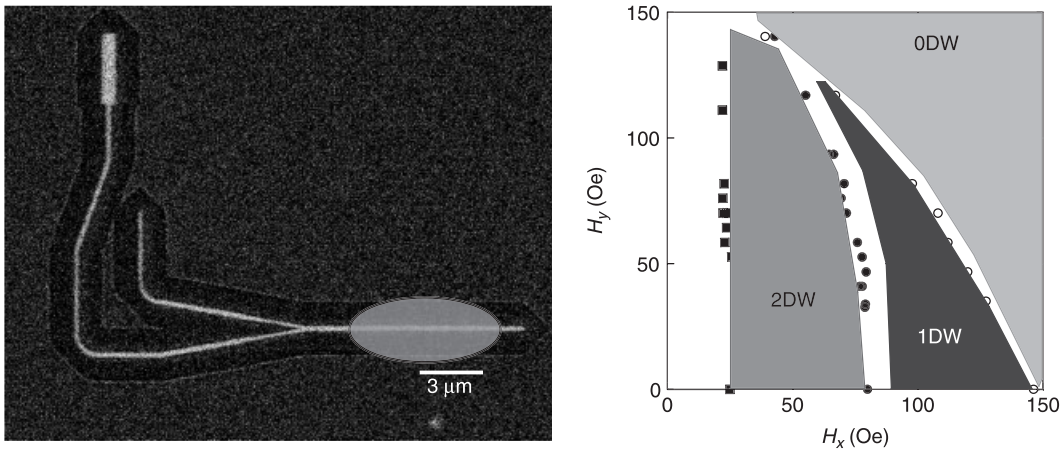

Figure 8. An AND gate and its operating margin phase diagram. Externally applied field strengths lying within the 2 DW region can only reverse the gate if two domain walls are injected into it. The 1 DW region can reverse if either one or two domain walls are injected. The 0 DW region can reverse even without artificial injection of domain walls (nucleation).

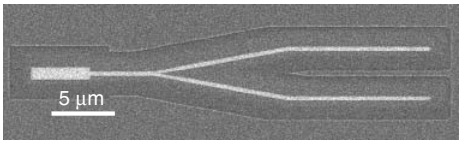
not enough to fully implement the Boolean AND function. Figure 9 shows the truth tables for the AND-like gate and compares it with the true AND function. The problem occurs for the case where the output is high and one of the inputs goes low. In a true AND gate, this would be enough to take the output low; in the AND-like gate, the output remains in its existing state. There is thus an undesirable hysteresis in the AND-like gate, although this may have some application in an alternative architecture which can take advantage of the memory associated with that hysteresis.

Similarly, if we limit the applied field to the range $H_{\mathrm{p2}} < H_{\mathrm{p1}} < H < H_{\mathrm{n}}$ then we describe the junction as being OR like. This means that the applied field is strong enough to switch the output if either (or both) input supplies a domain wall. As with the AND-like gate, this is close but not exactly the same as the true Boolean OR function. In this case, the failure occurs when one input is high and the other is low. A true OR gate would have a high output in this case; in the OR-like gate the output actually oscillates freely with the applied field (see Figure 9).

The OR-like and AND-like gates can be converted into a true Boolean function simply by adding a bias to the applied rotating field. Assuming the gates are oriented along the X direction, we simply shift the ellipse of the locus of the rotating field by $-\Delta H_x$. This means that the X component of the rotating field now sweeps between $H_x - \Delta H_x$ at its positive extreme and $-H_x - \Delta H_x$ at its negative extreme. We then arrange that $H_{\mathrm{p2}} < (H_x - \Delta H_x) < H_{\mathrm{p1}}$ and $H_{\mathrm{p1}} < (H_x + \Delta H_x) < H_{\mathrm{n}}$, that is, the gate is AND-like in positive fields and OR-like in negative fields. Together these conditions make a true AND gate. What is attractive about this scheme is that if the gate is simply reflected about its Y axis, the effective sign of ΔH_x is reversed, and the gate becomes OR-like in positive fields and AND-like in negative fields, which is the same as a true OR gate. Thus, by simply adding a single global bias to the rotating field, we can have both AND gates and OR gates in the same circuit, without having to localize the bias to the gate in question. AND gates result when the gate is oriented such that information flows in the opposite direction to the bias, and OR gates result when oriented such that information flows in the direction of the bias. A working experimental demonstration of the true AND gate will be given later in this chapter.

4.3 Fan-out gate

Figure 10 shows the structure used to perform the fan-out operation. It is essentially the AND/OR gate reversed such that domain walls flow into the single terminal and out through the two terminals. When the incoming domain wall meets the nodal junction it splits into two walls, each being half the original



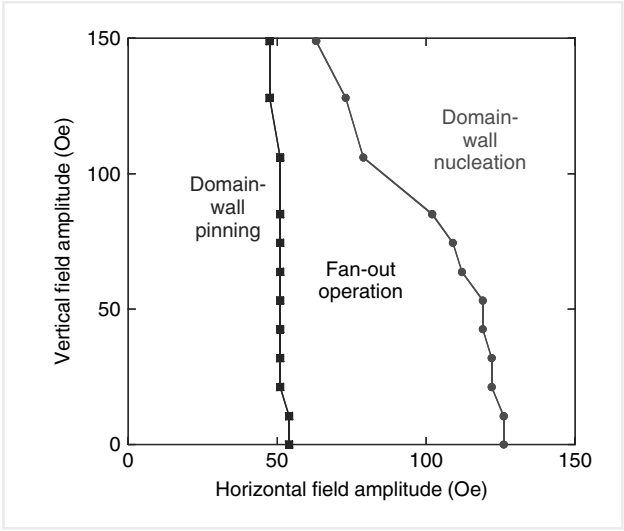


Figure 10. The fan-out gate with its operating margin phase diagram.

length. As these two walls pass along the tapered output arms, their length increases gradually until the full length has been restored. The energy of a domain wall is proportional to its length, and so work must be done to achieve this expansion. This energy is taken from the applied field and is manifested as a small increase in propagation field during the expansion. Figure 10 shows the operating margin diagram for the fan-out gate. It is a relatively robust gate, with large margins. Interestingly, the symmetry of the operating space follows the symmetry of the device: *Y*-axis fields have very little influence on its operation, since both the magnetization and the information flow directions are along the *X* axis.

That a fan-out gate is possible demonstrates the fact that domain walls are actually kink solitons (Bar'yakhter, Chetkin, Ivanov and Gadetskii, 1994). There is no equivalent to 'half-strength' domain walls and so there is no dilution of signal when it is split into two copies, as would be the case in a simple linear system. Rather, the extra energy that is needed is absorbed from the applied field and two full-strength signals emerge. From an electronic systems point of view, this shows that domain-wall logic possesses the equivalent of *gain*, since the domain-wall solitons are able to absorb from the applied field power supply whatever energy is required firstly to overcome losses and secondly to amplify the signal level through the fan-out gate. Gain is usually only associated with active semiconductor devices, once again demonstrating the high level of functionality present in the magnetic nanowire system.

4.4 Crossover gate

When two signal paths need to cross without interference in conventional microelectronics, a via is used to route one signal up to a higher level. A similar system could be envisaged in domain-wall logic, although the via would have to be a sloped ramp rather than a straight column to ensure that the domain wall could propagate under the action of an in-plane rotating field. It is possible, however, to cross two signal paths in domain-wall logic in the same plane, without any magnetic separation of the two, by using the crossover gate. If the via is analogous to a motorway flyover, then the crossover gate parallels a traffic-light-controlled crossroad. Figure 11 shows the structure used. A small taper is applied to each nanowire before contacting the central node to minimize the size of the central area where the domain-wall conduit is badly defined. The domain wall will experience a certain pinning force at this point due to its momentary loss of sidewalls; there will thus again be an operating area phase diagram for the device. There should never be a collision between two domain walls, providing the two signal paths approach each other at right angles, ensuring that domain walls in one arm always arrive one-quarter of a rotating field cycle before the other arm.

To date, the crossover gate is the structure with the smallest operating margin, largely due to the high propagation field created by the central node. It is hoped that in future developments the margin can be increased.

5 NANOCIRCUITS CONTAINING MULTIPLE GATES

As explained earlier in this chapter, the challenge in moving from single gates to different gates operating in the same nanocircuit is that there can only be one applied rotating

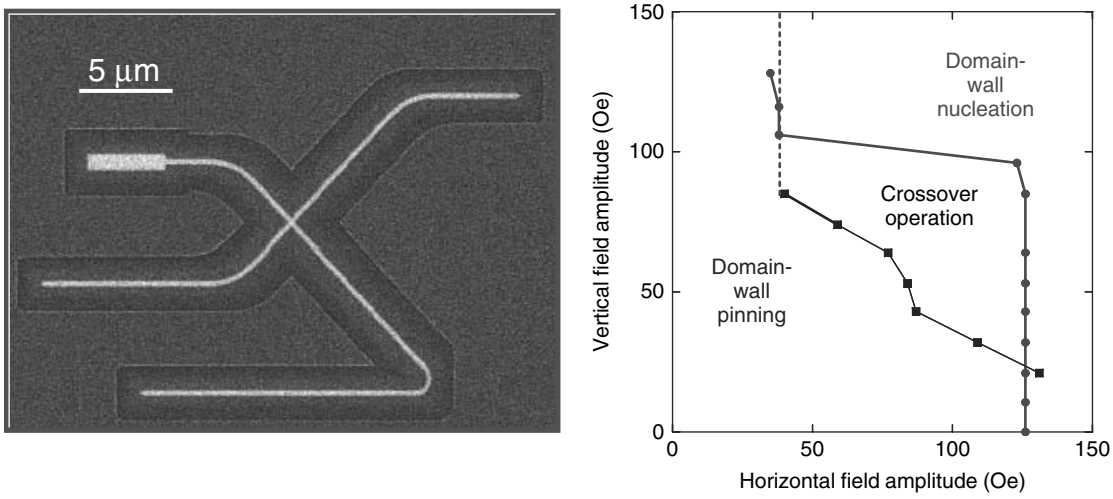

Figure 11. The crossover gate with its operating margin phase diagram.

field locus (since the field is applied globally to the entire chip) and this must lie within the operating margins of *all* the different types of gates in the circuit. At present, there is a common overlap area to the four types of gates, but it is very small. Future development will focus on increasing the size of the common overlap. Nevertheless, the overlap is currently large enough to allow a variety of combinations of gates to be demonstrated.

Figure 12 demonstrates the ability to concatenate multiple gates of the same function. Eleven NOT gates are formed into a loop (Allwood *et al.*, 2002). The measured circuit response shows a periodicity of $13T$ (T is the periodicity of the rotating field). This is exactly what would be expected: there is a loop delay time of $11/2T$ due to the $T/2$ delay introduced by each of the 11 NOT gates, and then there is an extra T delay for the closed loop, making a total loop delay of $13/2T$, and hence an oscillating periodicity of $13T$. It is noteworthy that in order to obtain a good signal-to-noise ratio from the MOKE measurements, we usually average many cycles (just like a cathode-ray oscilloscope). The response shown in Figure 12 was averaged approximately 100 000 times. This means that the single domain wall in the nanocircuit performed over 1 000 000 transits through a NOT gate. The fact that the transitions in the response remained sharp despite extensive signal averaging shows that there was no dephasing of the response at all during that time. In other words, it is highly probable that all 1 000 000 NOT operations were achieved successfully. Once again, we see the solitonic nature of the domain wall: unless the domain wall has a mechanism for compensating energy losses, it would not be possible for the same single wall to undergo this many logic operations.

Figure 13 shows the first combination of two different types of gate within the same circuit: a NOT gate is combined with a crossover gate by putting an extra twist into the feedback loop. The measured response is seen to be an

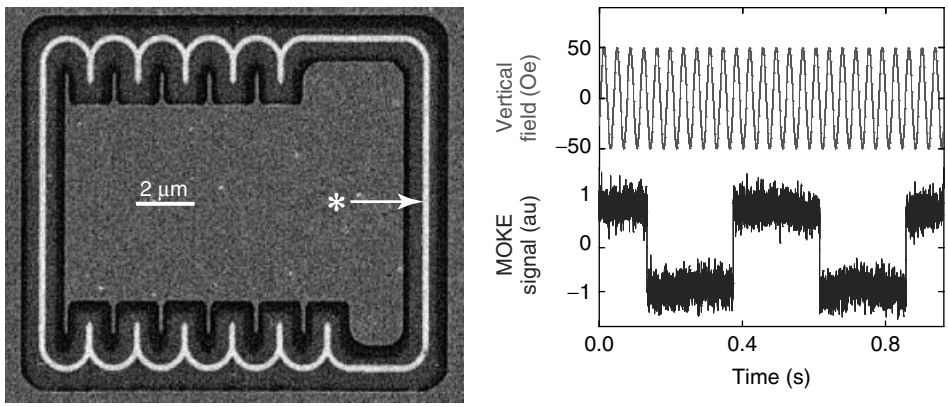

Figure 12. Eleven NOT gates connected to form a serial shift register. A MOKE measurement at the asterisked point shows a synchronous oscillation at 1/13th of the rotating field frequency (one component of which is plotted).

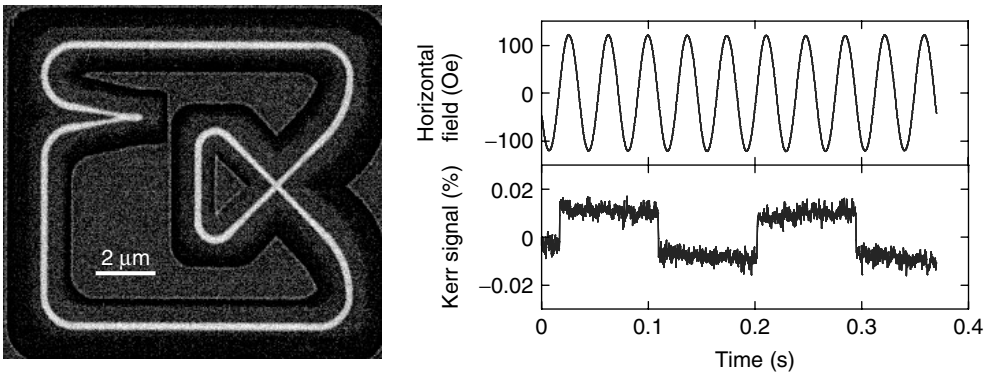

Figure 13. A NOT gate and a crossover gate combined in the same nanocircuit and operating under the same externally applied magnetic field. One component of the rotating magnetic field is shown, along with the signal response within the loop, as measured by MOKE.

oscillation with a periodicity of $5T$. Recall that in Figure 4, a single NOT gate in a closed loop usually gives a response periodicity of only $3T$. The change in periodicity is the sign that the domain wall is executing the crossover junction correctly, and is not taking a short cut at the crossover gate by turning right or left when it should be going straight on. By going straight on, it incurs an extra full minor loop on top of the existing major loop and hence the total delay due to the full closed loop increases from T to $2T$. When added to the $T/2$ delay due to the NOT gate itself, the loop delay time becomes $5/2T$, and hence the expected response periodicity is $5T$, as observed.

Figure 14 shows another combination of two different types of gate within the same circuit, except this time it is a NOT gate combined with several fan-out gates. A simple $3T$ ring oscillator is formed around the NOT gate, but a fan-out gate is inserted into the loop in order to extract a copy of the response. This signal is then split into two copies, and each of those is split again to make four copies of the original ring oscillator signal. MOKE measurements localized to each of the four outputs show that, indeed, the $3T$ signature can be seen on each. Multiple fan-out operations are one way of amplifying the total volume of magnetic material switching to make final detection easier, as well as being an integral part of any logic circuit.

There is an additional way to fan-out signals, and that is to use the central stub of the NOT gate, which carries a copy of the input signal. This signal is accessed simply by extending the length of the stub into a full nanowire. Figure 15 shows an example of a ring oscillator connected to a serial-in, parallel-out shift register formed from a chain of NOT gates with accessible stubs. The ring oscillator in this case is simply providing a convenient signal to trace through the shift register. The shift in the MOKE signal as we move the laser probe from one nanowire to the next shows the correct operation.

The twists on the end of the nanowires perform an important role by preventing domain walls from reflecting and reentering the system. Depending on the precise shape of the end of a nanowire, a domain wall may or may not

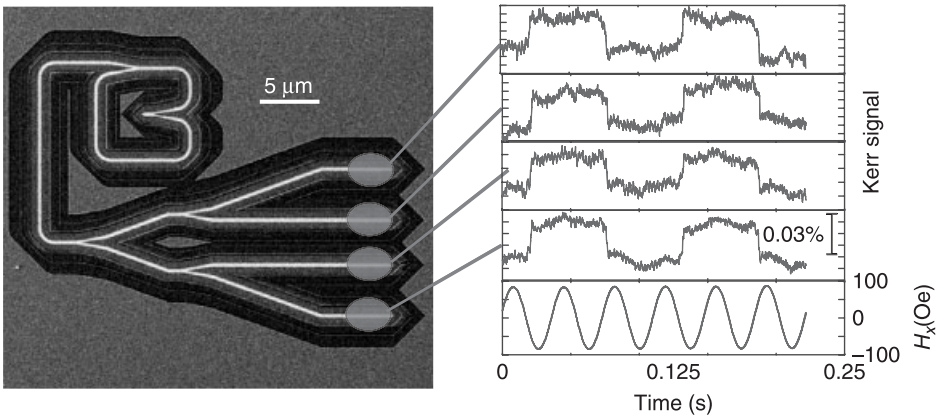

Figure 14. A NOT gate combined with four fan-out gates. MOKE measurements show four identical copies of the signal expected inside the NOT-gate ring oscillator.

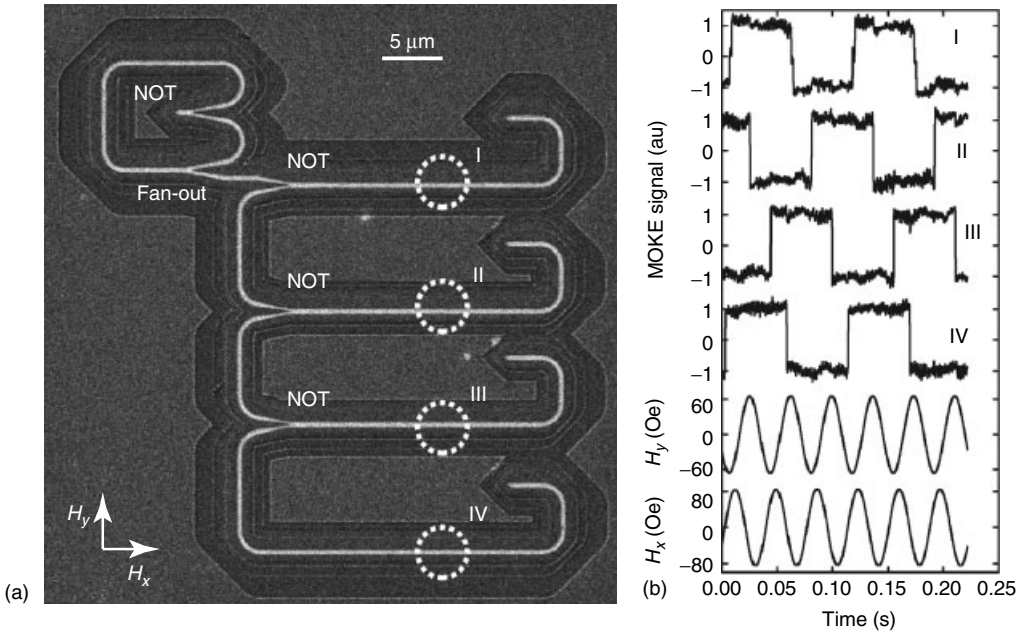

Figure 15. A nanocircuit which uses the central stub of the NOT gate to replicate the input signal. (Reused with permission from D.A. Allwood, *Applied Physics Letters*, **89**, 10254 (2006). © 2006. American Institute of Physics.)

annihilate. If it does not annihilate, it will be backpropagated half a clock cycle later and may interfere with the correct operation of the logic gates. If annihilation at the end of the conduit cannot be guaranteed, the conduit can be correctly terminated by ensuring that there are two 90° corners between its end and the final logic element. The 180° turn forms what we refer to as a *domain-wall black hole*: should a domain wall enter into it and not annihilate at the end, the rotating field will be unable to backpropagate it through the double corner, since these corners are of the wrong chirality. In the rotating field scheme, whatever goes into a black hole never reemerges.

We now move to the next level of integration and begin to combine three different types of gate within a single nanocircuit. Figure 16 shows the combination of NOT gates, fan-out gates, and a single AND gate. We know it is an AND gate and not an OR gate because of the sign of the bias that was applied to the rotating field. The bottom-left NOT gate forms a ring oscillator in order to generate a local signal, which can be traced through the circuit. A fan-out gate copies that signal out of the closed loop and then a second fan-out forms two identical copies. One of these copies is routed directly into the AND gate, while the second copy is inverted in a NOT gate. The primary function of this is to generate two dephased signals, which will cycle the AND gate through the four states of its truth table. We have sketched in Figure 16 the expected signals incident upon the AND gate. We then move the laser probe to the output of the AND gate and make an experimental measurement of its output. Figure 16 shows a $3T$ period signal, but with a nonsymmetrical mark–space ratio. This is exactly what would be expected from an AND gate being cycled through its truth table. Three of the four possible input states involve at least one 0, and so the output remains low for these three states. Only in the fourth state, when both inputs go to 1 would we expect to see the output go high. The three-element circuit thus functions correctly, and has also provided a useful test bed for cycling the AND gate through all of its states.

The final step is then to replace the second NOT gate in this circuit with a crossover gate, as shown in Figure 17, in order to form a nanocircuit that contains at least one example of each of the four basic gates. See Allwood *et al*. (2005) for experimental details. In this case we test the ring oscillator and the two fan-outs first by making a measurement in the bottom right-hand corner, work out what the signals should now be at the input to the AND gate, and then measure its output. The only difference in the operation of these circuits is that there is a longer phase delay between the two signals entering the AND gate: in Figure 16 the second NOT gate introduces a half clock–cycle delay, while in Figure 17 the minor loop with crossover introduces a one clock–cycle delay.

In principle, now that the four basic elements have all been demonstrated to work together in the same nanocircuit, domain-wall logic could be used to construct any digital logic circuit of arbitrary complexity. In practice, further work needs to be done to augment the size of the operating margin of the complete circuit in order to reintroduce the

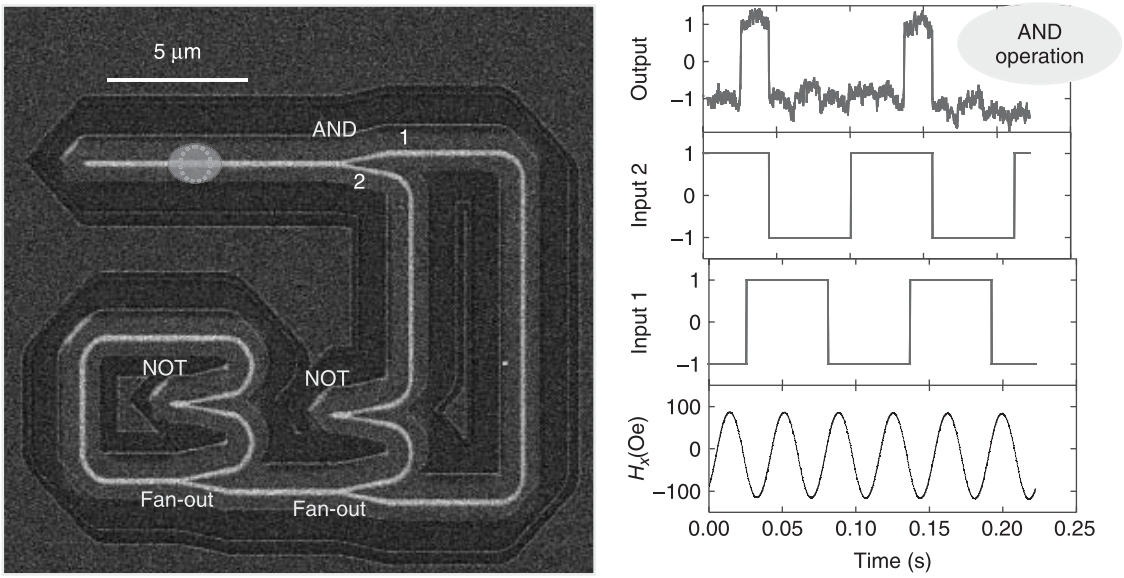

Figure 16. A nanocircuit containing three different types of gate: NOT gates, fan-out gates and an AND gate. The two signal incident upon the AND gate are shown schematically, along with an experimental measurement of the output of the AND gate as it is cycled through its four states.

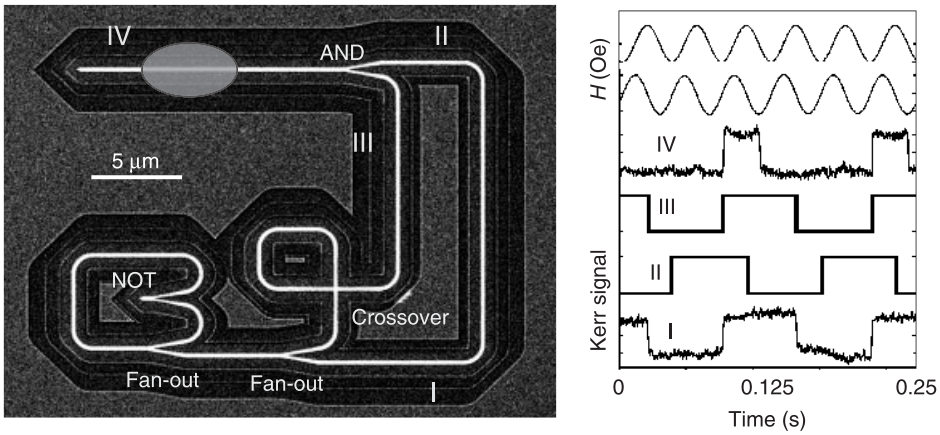

Figure 17. A nanocircuit containing the four basic gates: NOT, AND, crossover, and fan-out.

fabricational fault tolerance that is already present in the large margins of the individual gates. Further understanding is also required about the precise influence of synchronous interconnect on large circuits.

6 DATA INPUT–OUTPUT

The recently developed technology of magnetic random access memory (MRAM) (Engel *et al*., 2005) has already solved most of the engineering issues involved in interfacing between a soft ferromagnetic layer and an underlying CMOS system. Specifically, in MRAM, data writing is achieved by passing an electrical current through a conductor placed close to the magnetic element, allowing the magnetic field generated around the current to nucleate a reverse domain in the magnetic nanostructure. Data reading is achieved by the use of a magnetic tunnel junction (MTJ) (Moodera *et al*., 1995) in which the electrical resistance of two magnetic layers separated by a thin film of insulator is found to depend strongly on the relative magnetization directions. By fixing the magnetization direction of one layer, it becomes a reference against which the magnetization direction of the other layer may be measured. Signal levels large enough to interface directly with CMOS transistors are achieved by this method. We intend to piggyback off these developments for interfacing signals between the magnetic system and conventional electronics. Domain-wall logic can be considered as an

extension to MRAM. In MRAM, the data storing magnetic layer is very simple and is only used to store a single bit of information. The concepts developed in magnetic logic can be used to extend the functionality of that storage layer, allowing data to be processed as well as stored.

We have developed an alternative data input method, which may be important if three-dimensional structures are implemented in domain-wall logic. One of the major limitations to creating ultrahigh-density three-dimensional microelectronic circuits is the cost of making connections to the multiple layers. A useful strategy for realizing the ultrahigh data density of three-dimensional structures without increasing the cost is to attempt to find a way in which the input and output to the three-dimensional structure is maintained in two dimensions. Figure 18 shows a device we have developed which allows this to be done with domain-wall logic. See Allwood *et al*. (2005) for further experimental details. The figure shows a chain of eight NOT gates, where one gate has had its central stub enlarged. This reduces the shape anisotropy in that stub and hence reduces its nucleation field a little. Consequently, if the *globally applied* rotating magnetic field is modulated in amplitude slightly, it is possible to cause nucleation in the NOT gate with the elongated pad, thus forcing its data state to the direction of the global field. Importantly, the strength of modulation needed to achieve this is not so strong as to lie outside the operating margin of all the other gates in the chain, and so they continue to work normally. Thus, by modulating the global field, we can write data directly into the serial shift register and then shift that same data throughout the rest of the shift register. In this case, the globally applied rotating magnetic field is not only serving as a power supply and clock, as it does in all other domain-wall circuits, but it is also acting as a serial input data channel. Figure 18 shows a working demonstration of this experiment, where we have written the data sequence 11010 into the shift register by modulating the rotating field. This writing sequence is applied only once. An hour later, we then begin cycling the rotating field without modulation and use the MOKE laser probe to read the serial data circulating around the shift register. We see the sequence 11010 repeatedly, as it goes around the circular shift register. We have thus succeeded in injecting data into the nanoscale storage ring, although the source of field modulation was 1 cm away from the chip itself. As a control experiment, we show also in Figure 18 a straight trace, obtained during reading when the 11010 sequence had not been previously written. The reason that we do not see a 10T periodic signal as might be expected based on earlier results is that there is an even number of NOT gates in this loop, which prevents it from acting as a ring oscillator.

This result is significant because it demonstrates the ability to write data into nanoscale storage rings from a distance. This immediately opens up the possibility of a three-dimensional data storage cube, in which all magnetic field generation and sensing is performed on the bottom CMOS layer, but where data can be remotely targeted to specific parts of the three-dimensional volume simply according to where one places the NOT gate with the enlarged stub. Such a device would have the storage density of a three-dimensional device but the fabricational cost structure of a two-dimensional device. This idea is explored further later in this chapter.

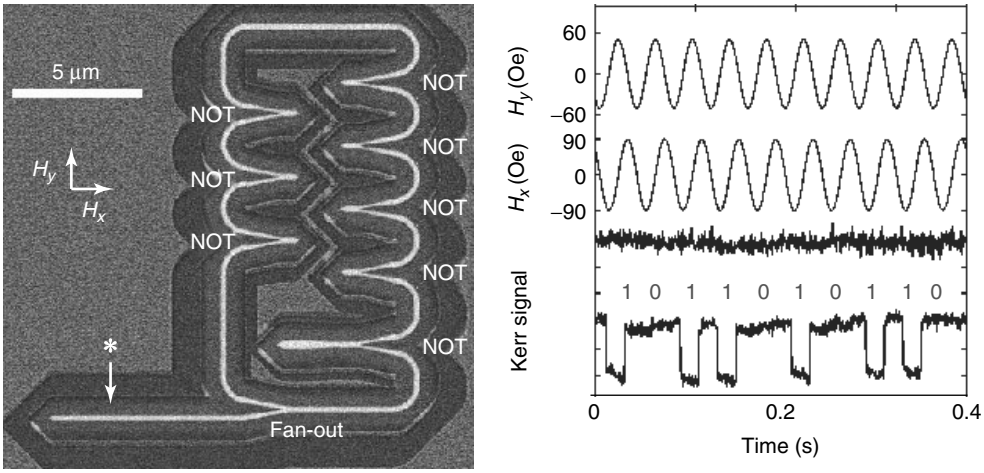

Figure 18. A serial shift register formed from eight NOT gates, with the central stub of one NOT gate enlarged to form a data input element. The data sequence 11010 is written into the shift register by modulating the rotating magnetic field. The signal traces show the recovered data sequence circulating around the shift register, as well as a flat trace showing the result when the writing sequence is not performed.

7 DOMAIN-WALL SPEED

Modern microprocessors run at clock frequencies in excess of 1 GHz and it is important to understand how domain logic compares against this target. All of the results presented so far in this chapter have been at very low frequencies. This is not a fundamental limit, but rather reflects the convenience of using a large iron-cored electromagnet during laboratory testing. There are two speed limitations inherent in domain-wall logic. Firstly, domain walls propagate by the precession of the spins in the center of the wall around the local effective magnetic field. The speed of propagation is thus ultimately limited by the gyromagnetic precession frequency. However, the speed will also depend upon the degree to which precession is damped through energy losses, which can be both material and geometry dependent. In particular, at the beginning of this work, it was not clear to what degree nanoscale confinement in the nanowire would increase damping. It is important that the domain-wall propagation speed should be fast enough to maintain the synchronous nature of the system: a domain wall must have had time to propagate as far as it needs to within a given quadrant of the rotating field phase.

The second limitation comes from how quickly the externally applied magnetic field can be rotated. If it were generated from a microwave strip line, then tens of gigahertz would be possible. However, this would require the line to terminate in a 50 Ω load, which would dissipate very large amounts of power, making the power dissipation from the chip uncompetitive. The alternative method for generating the rotating field is to use microfabricated coils. These can be highly efficient if made thick enough (the power dissipation could be as low as 1 W cm^{-2}, 100 times lower than the dissipation limit of silicon). However, the inductance of such coils limits their frequency. It would not be possible to generate rotating field frequencies much higher than 10 MHz across an extended area, although very high frequencies could be achieved if only covering a few square millimeters.

Thus, different constraints apply depending on the size of the chip. Small chips can operate quickly if the domain-wall propagation speed is high enough. Large chips will always be limited by the generation of the rotating field, and so domain-wall speed (unless very slow) is less important.

Figure 19 summarizes the experiments we have performed to measure the domain-wall propagation speed through a simple nanowire. See Atkinson *et al*. (2003) for further experimental details. The nanowires are fabricated directly onto the top of a microwave strip line, through which we can launch current pulses with sub-nanosecond rise times. These current pulses lead to a magnetic field pulse across the width of the strip line, which is used to accelerate a domain wall from one end of a nanowire of known length to the other. The domain wall is introduced to the starting end of the straight 'racetrack' by a perpendicular wire, and the MOKE laser probe is placed at the other end of the nanowire in order to detect the arrival of the domain wall. We assume that the domain wall has very little inertia and will stop propagating virtually as soon as the applied field pulse terminates. We continually test this assumption by repeating experiments with two pulses of half the original width to see if the results remain unchanged. In most magnetic systems this assumption is found to hold. Equally importantly, we also test that we are indeed measuring domain-wall propagation and are not nucleating a reversal by the pulsed field by changing the bias field applied to the injecting arm to prevent it from injecting a domain wall. When we do this, all switching in the racetrack is also seen to stop, proving that it was indeed the injected domain wall that was responsible for the reversal. We measure speed by applying different widths of pulse and finding the probability of switching at the far end of the nanowire as a function of pulse width. From the 50% probability point, we can determine the average time

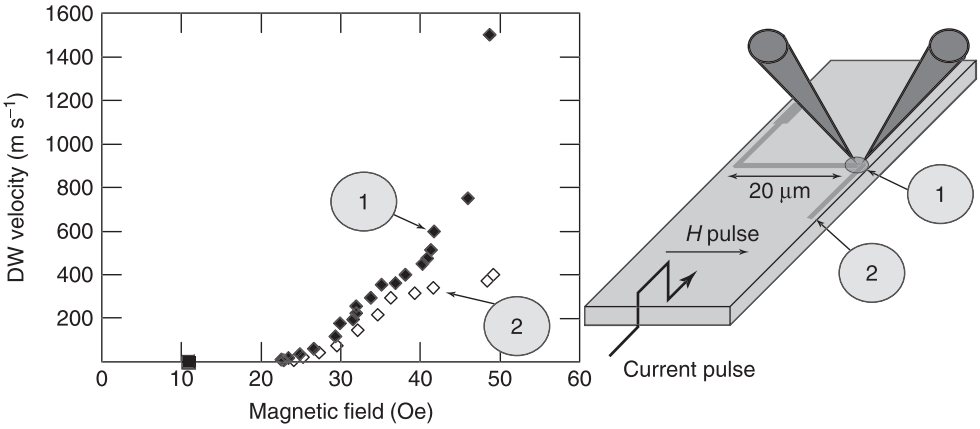

Figure 19. A measurement of the domain-wall propagation speed in a magnetic nanowire fabricated on the back of a microwave strip line.

required for the domain wall to cover the racetrack, and since we know its length, we can calculate its speed. We repeat this process for different amplitudes of pulsed field, and hence can measure the domain-wall speed as a function of the field strength (Figure 19). The domain wall is found to move with speeds of up to $1000\,\mathrm{m\,s^{-1}}$ for fields of the strength that would be applied in logic devices. Importantly, we note slight differences in result at the highest speeds, depending on whether we place the laser probe at the end of the race track or a little further down a perpendicular extension to the race track. This indicates that there is some dynamic 'bouncing' of the wall as it attempts to navigate the corner. One thousand meters per second is $1\,\mu\mathrm{m\,ns^{-1}}$ and most logic gates are $1\,\mu\mathrm{m}$ or less in length and so transit times of around 1 ns could be expected. This is reasonably competitive with microelectronic speeds, although not with the very fastest. Across-chip clock frequencies of up to 200 MHz could probably be made to work, which would not be fast enough for the very fastest applications, but would certainly be fast enough for some applications.

Alternative experimental methods for obtaining domain-wall velocities in nanowires have been described by Ono *et al*. (1999), in which a giant magneto resistance trilayer is formed from the nanowire under test and two other layers, allowing the resistance of the trilayered nanowire to serve as a probe of the fraction of the nanowire that has magnetically reversed and hence the position of the domain wall. (See also **Domain Wall Propagation in Magnetic Wires, Volume 2**.)

8 SCALABILITY

The successful uptake of any new microelectronic technology often depends upon its scaling properties. The capital costs of deploying new technologies are so high that a financial return can only be made if the technology continues to be used for several years. During that time, the definition of lithography will continue to improve and so the technology must be capable of continuing to operate as its dimensions are reduced. The way in which magnetic devices sometimes struggle with scaling is that thermal fluctuations usually depend upon the product KV, where K is the magnetic anisotropy and V is the volume of magnetic material corresponding to a single data bit. As lithographic feature sizes are reduced, V falls and so to restabilize the device it is necessary to increase K. This is usually possible, either by a change of magnetic material, or in the case of domain-wall device simply by changing the thickness-to-width ratio of the nanowires, leading to an increase in the shape anisotropy. However, the strength of magnetic field, which must be applied to operate the device usually scales with K, and so the result is a device which is stable but which requires a stronger magnetic field to operate it. In some technologies (e.g., hard disk drives and MRAM) it can be difficult to achieve those increased levels of magnetic field, either because of magnetic saturation or because of power dissipation.

We have analyzed the scaling limitations in domain-wall logic. We have addressed two specific questions, namely: (i) how should the thickness of the nanowire be scaled as the width is reduced; (ii) will the domain wall always be a small object, or will it become so extended in small nanowires that we can no longer make useful logic gates?

Regarding the first of these, we have identified two different scaling regimes. In the first instance, where structures are being scaled from the current 200-nm-width downwards, the thickness should be scaled with F as the width of the wire is also scaled with F (F is the minimum feature size of the lithography). This keeps the thickness-to-width ratio of the nanowires constant, and so the shape anisotropy field also remains constant. Consequently, the strength of applied rotating field required to operate the device should remain unchanged. During this first scaling regime, the power-delay product (see the next section for a definition) will reduce with F^3, since it is proportional only to the volume if the applied field amplitude remains constant. The limit of this scaling regime comes when the power-delay product becomes comparable to a few tens of $k_\mathrm{B}T$, where k_B is Boltzmann's constant and T is room temperature. At this point, thermal fluctuations begin to disrupt the data, and so it is necessary during further scaling to avoid any extra reduction in the power-delay product. We do this by switching to the second scaling regime in which the thickness of the nanowires is scaled with $F^{-1/2}$ while the width continues to scale with F, that is, the thickness rises as the width of the nanowire falls. The power-delay product should then remain roughly unchanged with this scaling law, while the strength of field needed to drive the device rises. Since the applied magnetic field does not have to be localized to a small volume, it is possible to generate relatively large fields without excessive current densities. Generating magnetic fields over extended areas is much more energy efficient than generating them in localized areas, since in the former case the thickness of the conductors can be increased almost arbitrarily without loss of contribution of the magnetic flux. We therefore do not anticipate a premature limit to scaling caused by this rise in driving field.

Regarding the domain-wall width (i.e., measured along the long axis of the nanowire), we have used micromagnetic simulations (Web: math.nist.gov/oommf/) to calculate the domain-wall profile in a nanowire as a function of the size of the nanowire. Figure 20 shows the result. At the current width of 200 nm, the plot shows that the domain wall should

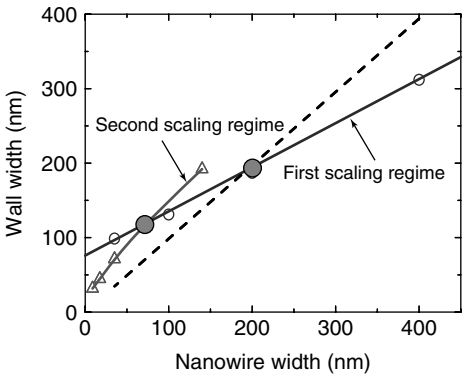

Figure 20. Domain-wall width (measured along the long axis of the nanowire) as a function of nanowire width for the two scaling regimes.

be approximately 200 nm wide, that is, it can be considered to be a square object. During the first scaling regime, the domain-wall width shrinks less rapidly than the width of the nanowire, and so the domain wall becomes slightly rectangular, but not excessively so: at the limit of the first scaling regime at (70-nm-wide nanowires), the domain wall is only 110 nm wide. During the second scaling regime, the increase in shape anisotropy causes the domain wall to become shorter again and the growth in elongation ceases. By the time the nanowire is 32 nm wide, the domain wall is 50 nm, meaning that it remains roughly a rectangle with an aspect ratio of 1.5 throughout the entire second scaling regime.

9 POTENTIAL APPLICATIONS OF DOMAIN-WALL LOGIC

Domain-wall logic is not a contender for a wholesale replacement of CMOS microelectronics. CMOS is a highly mature technology with many advantages, and still has many years of scaling available to it. However, a strong trend in microelectronics, which is expected to apply to the relationship between CMOS and many other areas of nanotechnology in the future, is to combine multiple technologies on a single platform: the system on chip (SoC). Mature economies usually break into a large number of specialists each doing what he or she does best. The same principle applies to complex microelectronic devices. In this context, domain-wall logic brings another item to the menu of available technologies. So what does domain-wall logic do well?

- It gives high level of functionality to relatively simple structures. To implement an AND gate in CMOS would take six transistors; domain-wall logic achieves it simply by bringing two nanowires together. Similarly, the other high-level properties that have been highlighted in this chapter, such as input–output isolation and signal/power gain are all intrinsic to the nanowire and do not have to be explicitly created.
- The power dissipation per logic gate is extremely low. Microelectronic engineers usually measure dissipation from a gate by the power-delay product, that is to say the product of how much power is dissipated multiplied by how long the gate takes to process a single function. The units of this quantity are energy, corresponding to the energy dissipated during the evaluation of the function performed by the gate. CMOS power-delay product depends on the size of the devices. To compare like with like, we therefore take the 200-nm minimum feature size CMOS value of 10^{-2} pJ (Waser, 2003). On very general magnetic grounds, we can say that an upper bound for the power-delay product for domain-wall logic is $2M_{\mathrm{s}}VH$, where M_{s} is the saturation magnetization of the magnetic material, V is the volume of magnetic material in a gate and H is the amplitude of the applied field. Applying the parameters for a typical 200-nm domain-wall logic gate gives 10^{-5} pJ, that is, 1000 times lower than the equivalent CMOS device. Because of the inefficiencies inherent in the generation of high-speed magnetic fields (see the preceding text), this does not necessarily mean that domain-wall logic chips will not consume much power. What it does mean, however, is that the waste heat will be generated from the global field generator and not from the logic devices themselves. This is of particular relevance if one comes to stack the devices into three-dimensional neural-like circuits. The two key technical difficulties to doing this in CMOS are (i) distributing the power and clock to everywhere inside the volume of network and (ii) extracting the waste heat from the center of the network so that the device does not melt. We believe that domain-wall logic is an excellent choice of primitive for three-dimensional architectures.
- Nonvolatility comes as standard. In a world of mobile computing and portable (or even wearable) devices, the concept of 'instant on' is becoming increasingly important. Users accept that devices cannot be expected to operate when there is no power. However, as soon as power becomes available, users want the device to be ready, and not have to undergo a long boot process, or to have forgotten what it was doing when the power last failed. Since there are currently very few nonvolatile memory technologies available which can be embedded directly into CMOS, a data transfer process is usually required between a high-speed, volatile memory register in the heart of the CMOS logic and an off-chip

low-speed, nonvolatile store where the state variables of the system are stored. With domain-wall logic, all of this becomes redundant. Providing that the rotating field is properly controlled so that it stops gracefully as power fails and does not apply intermediate levels of field leading to data corruption, the domain-wall logic circuit should simply stop and retain all of its state variables. As soon as the power returns, the logic continues from where it left off.

- Domain-wall logic can make use of redundant space on top of CMOS. Because no complex heterostructures are required, the logic elements can sit in a single layer fabricated as a back end of line process after the CMOS has been laid down. This can improve the efficiency of the underlying CMOS by farming out some space-consuming task to the domain-wall logic on top. Since this space was never accessible to CMOS itself anyway, it all counts as a gain.
- Being metals, the basic computational elements of domain-wall logic are automatically radiation hard, and so are suitable for use in space or in military applications.
- Domain-wall logic is very good at forming high-density shift registers. These could be used as nonvolatile serial memory. Serial memory is used for storing entire files, and so does not require high-speed random access. The hard disk drive and NAND flash devices (e.g., as used to store the photographs in a digital camera) are examples of nonvolatile serial memory. Both of these devices are currently two-dimensional in form. Shift registers made from domain-wall logic elements have the potential to be stacked into three dimensions without incurring extra wiring complexity, since data and power can be transmitted remotely through magnetic fields, as demonstrated earlier in this chapter. In a hard disk drive the data are stored as rows of magnetic domains, and this would remain the same in a domain-wall logic serial memory. What would differ is that in a hard disk the domains are mechanically rotated on their disk underneath a static sensor, while in domain-wall logic the domains themselves would move under the action of an externally applied magnetic field along static domain-wall conduits, potentially stacked into an ultrahigh-density three-dimensional array.

The weaknesses of domain-wall logic have already been described throughout this chapter, but are in summary (i) limited operational speed and (ii) unconventional synchronous interconnect. Whether the latter should be regarded as an advantage or a disadvantage is open to debate, since it is the same property that makes domain-wall logic so suitable for high-density serial memory. Nevertheless, interfacing with conventional design tools remains a challenge.

10 CONCLUSION

While bulk magnetic alloys usually exhibit very simple linear properties, structuring on the nanoscale introduces more complex, nonlinear behavior that can be used for a new generation of spintronic devices. In particular, the coercivity of the magnetic material, which is usually an intrinsic property in the bulk, becomes very dependent on whether the magnetization reversal mechanism is limited by domain nucleation or by domain-wall propagation. We have demonstrated modifications to the coercivity of as much as a factor of 65 simply by whether a domain wall is artificially injected or not. The huge ratio between the domain-wall propagation field and domain nucleation field that exists in magnetic nanowires has allowed us to introduce the concept of the domain-wall conduit, in which the nanowire can be considered to be a highly efficient conductor for domain walls. If information is encoded by the domains, then domain-wall conduits allow that information to be moved around an arbitrary network, and the possibility of building computational devices emerges. Furthermore, we have shown that by precisely modifying the shape of the nanowire, we can exert topological control over the information and hence implement Boolean NOT gates, AND gates, fan-out gates, and crossover gates. These four basic elements can then be interconnected to form fully functioning nanoscale logic circuits. We have demonstrated, among others, a functioning circuit that contains at least one example of each of these basic gates all operating together in the same circuit. From here, in principle, any digital logic circuit could now be implemented without transistors.

We have discussed the strengths and weaknesses of domain-wall logic as compared to other mainstream digital technologies and concluded that, like most nanoscale devices, domain-wall logic is not a one-stop replacement for all areas of digital logic, but rather should be used selectively to perform the functions that it does best. We have highlighted, in particular, the benefits of forming three-dimensional shift registers from domain-wall logic elements for the purpose of ultrahigh-density data storage.

Guided Spin Waves

Riccardo Hertel
Research Center Jülich, Jülich, Germany

1 INTRODUCTION

Considering the breathtaking progress in nanomagnetism over the last decades, it is remarkable that the role assigned to magnetic elements in technological applications has hardly evolved away from the mere storage of information. This also holds for modern magnetoelectronic devices such as the nonvolatile magnetic random access memory (MRAM) (Wolf *et al*., 2001). There, ferromagnetic patterned elements act as bistable systems to store a unit of information, that is, '1' or '0', depending on their magnetization state. Once the magnetically stored information is read (e.g., using the tunnel-magnetoresistance effect), it is elaborated by other means, like integrated electronic circuits. One of the purposes of this chapter is to present a concept that allows to read, transmit, and elaborate magnetically stored information in a purely ferromagnetic system. This could be achieved with spin waves propagating along wave guides and, in particular, by using the phase of the spin waves. In fact, it is demonstrated that the phase of propagating spin waves can be manipulated by introducing magnetic domain walls in the wave guides. If the presence or absence of a domain wall in a magnetic strip is used as an elementary unit to store information, the phase-shift effect induced by the domain walls gives the possibility of using propagating spin waves to read this information. By exploiting constructive and destructive interference effects, logical operations can be performed with spin waves. The concept of spin-wave logics proposed in this chapter could be the first step toward the development of a new generation of programmable logic devices that may be able to both store information and perform logical operations.

The chapter is structured as follows. First, in Section 2, the basics of the theory of micromagnetism and of the numerical method are presented. In Section 3, the possibility of splitting and merging spin waves is discussed. The effect of a domain wall on a propagating spin wave is described in Section 4. It is shown that the phase of a spin wave changes when it runs through a domain wall. In Section 5, how spin-wave-based logical devices could be realized by using the effects presented in the previous sections is discussed. Spin-wave guides can be combined in a simple way in order to obtain programmable devices that can perform basic logical operations such as AND, OR, NOT, NXOR. Finally, Section 6 briefly discusses Berry-phase effects of magnons in a ferromagnetic ring. Such Berry-phase effects have recently been related to the effect of the domain-wall-induced phase shift in propagating spin waves described in this chapter.

1.1 Magnetic ringing

The field-driven magnetization reversal of a magnetic thin-film element is connected with the release of energy.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

The Zeeman energy depends on the relative orientation of the sample's magnetization and the direction of the external field. In the simple case of a homogeneously magnetized nanostructure with volume V and saturation magnetization M_s, the energy difference between the magnetization state oriented antiparallel to an external magnetic field H and the one oriented parallel to the field, that is, between the initial and the final state, is $\Delta E = 2\mu_0 H M_s V$.

On its path from the initial, antiparallel state toward the final equilibrium state with homogeneous magnetization parallel to the external field, the magnetic system dissipates this energy difference.

Phenomenologically, the dissipation of energy occurring during the dynamic magnetization process is described by the damping constant α in the Landau–Lifshitz–Gilbert (LLG) equation. However, this intrinsic damping is generally not sufficient to dissipate the entire amount of energy within the typical time of a magnetization reversal process, which for submicron-sized thin-film elements is usually on the subnanosecond time scale. Therefore, immediately after the reversal, a magnetic thin-film element remains in an energetically excited state, which decays relatively slowly to its equilibrium state, typically within a few nanoseconds. In thin-film elements, the residual energy is converted into magnetostatic spin waves (Choi, Belov, Ballentine and Freeman, 2001). These spin waves are known as *magnetic ringing*. The magnetic ringing may persist for several nanoseconds after the magnetization reversal (Acremann *et al.*, 2001; Koch, Deak and Abraham, 1998). An example of such a dynamical magnetization reversal process and the magnetic ringing occurring after the magnetic switching is shown in Figure 1. Some snapshots of the simulated magnetic reversal process in a Permalloy thin-film element exposed to an external in-plane magnetic field are shown in Figure 1(a)–(d). As can be seen in Figure 1(e), the x component of the magnetization switches almost completely into the field direction after only 300 ps, but the y component displays pronounced oscillations that decay only after about 2 ns. The occurrence of spin waves can be seen in the out-of-plane magnetization component (cf. Figure 1(f)–(h)), which displays a noisy modulation of the magnetic structure. These spin waves contain a considerable amount of exchange energy and stray field energy. The specifications of this example are chosen according to the μMAG Standard Problem No. 4 (McMichael, 2000) and are described in the sketch in Figure 1. As far as the material properties are concerned, the saturation polarization is $J_s = \mu_0 M_s = 1\,\mathrm{T}$, the exchange constant is $A = 1.3 \cdot 10^{-11}\,\mathrm{Jm}^{-1}$, and the damping constant is $\alpha = 0.02$.

1.2 Using spin waves

Obviously, the magnetic ringing is undesirable from a technological point of view. The long-lasting perturbation of the

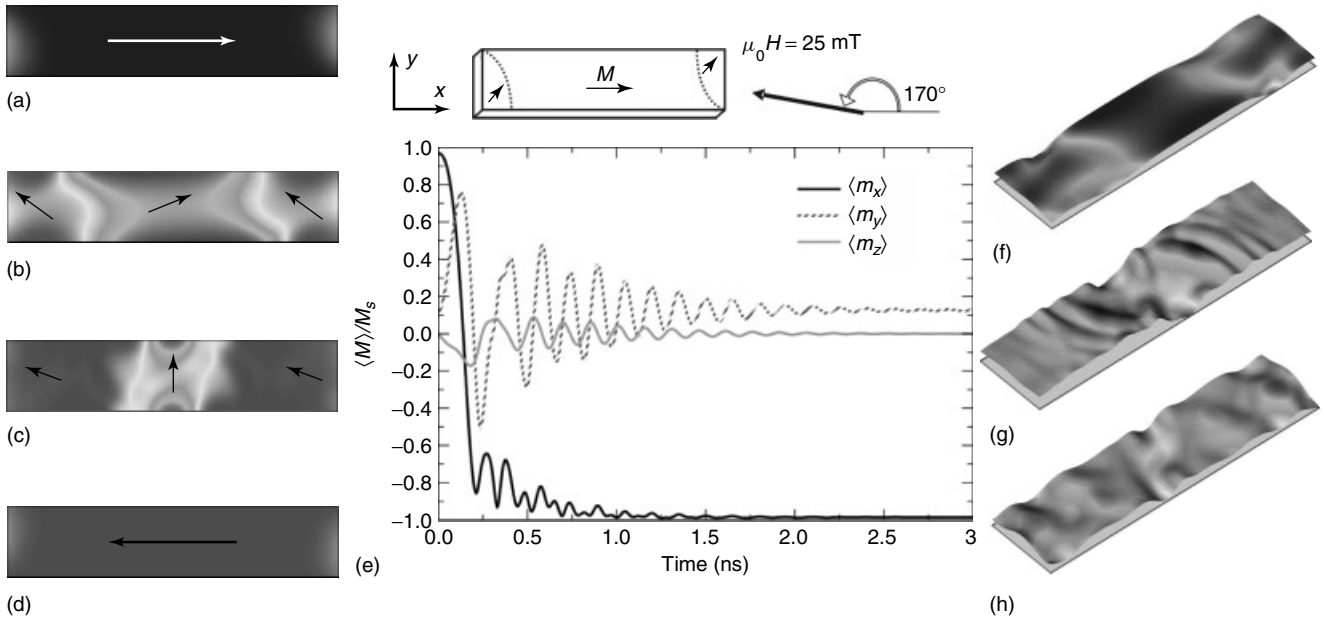

Figure 1. Simulated magnetization reversal in a thin-film element (Permalloy, 500 nm × 125 nm × 3 nm). (a)–(d) Snapshots of the reversal process at different times after applying the field; (a) 0 ps, (b) 145 ps, (c) 402 ps, and (d) 1170 ps. The gray scale represents the x component of the magnetization. (f)–(h) Out-of-plane component of the magnetization (magnified) at (f) 402 ps, (g) 1170 ps, (h) 1577 ps. (e) Volume-averaged components of the normalized magnetization as a function of time. The initial magnetization state and the applied external field are sketched on top of frame (e).

magnetization after the reversal represents a disturbing noise, which should be avoided if a magnetic thin-film element is to be used as a switch to store information. For application purposes, the ideal magnetic thin-film element should switch as quickly as possible from a '1' to a '0' without any noise and perturbation. In order to suppress the spin waves (i.e., the ringing), the intrinsic damping of the material can be increased (Bailey, Kabos, Mancoff and Russek, 2001), thereby dissipating the Zeeman energy difference directly into heat. However, a damping that is too large would lead to a slower, 'viscous' magnetization reversal (Kikuchi, 1956). Therefore, considerable effort has been made to find alternative ways to switch the magnetization, particularly with a technique known as *precessional switching* (Gerrits *et al*., 2002), with which a fast magnetization reversal and suppression of spin waves can be achieved. This precessional switching process is, however, difficult to realize. Magnetic field pulses have to be applied in the film plane perpendicular to the magnetization direction. The shape of these field pulses must be chosen carefully within small margins to ensure a well-defined reversal process. A detailed discussion of the precessional switching mechanism goes beyond the scope of this chapter. Rather than presenting advanced concepts of magnetization switching, the central question of the concept discussed in this chapter is the following: 'Can spin waves be used instead of considering them as a disturbing, collateral effect that occurs when a magnetic nanostructure switches'? An appealing aspect of this idea is that spin waves occur in a natural way in ferromagnetic thin films, as can obviously be recognized by the fact that it is difficult to suppress them. It has recently been suggested (Hertel, Wulfhekel and Kirschner, 2004) that spin waves may be used as carriers of information, and, in particular, that it should be possible to evaluate this information by exploiting the *phase* of spin waves.

This work is entirely based on micromagnetic computer simulations. Although the accuracy and the predictive power of modern micromagnetic algorithms has recently evolved to a point where such simulations can be regarded as reliable computer experiments, a real experimental verification of the new effects reported in this chapter would be desirable to confirm these predictions.

2 MICROMAGNETISM AND NUMERICAL METHOD

The theoretical, analytic study of spin waves in ferromagnetic materials is a vast subject of research (Hillebrands and Ounadjela, 2002; Akhiezer, Baryachtar and Peletminsky, 1968; Damon and Eshbach, 1961; Hurben and Patton, 1996). By using simplifying assumptions and by linearizing the dynamic equations, numerous modes have been studied analytically. In the nonlinear regime, the occurrence of solitons has been reported (Slavin, Demokritov and Hillebrands, 2002) and studied analytically.

Although the analytic theory of spin waves provides important information and helps in understanding the qualitative behavior of spin waves, it frequently suffers from serious limitations. These limitations are due to the simplifications required to make the problem analytically treatable, including, for example, the assumption of infinite extension of the material or other simplifying approximations, the validity of which is often doubtful. Particularly in the case of nanostructured materials, where finite-size effects are known to have a decisive impact on the magnetic properties, some of these approximations are questionable. In fact, even the calculation of realistic *static* magnetization structures in nanostructured ferromagnets – which certainly represent a simpler case compared to the treatment of the magnetization dynamics of spin waves – can generally only be obtained by means of numerical simulations.

Computational micromagnetism gives the possibility of investigating dynamic magnetization processes in nanostructured materials on time and length scales that are difficult to access experimentally. Micromagnetic simulations provide detailed information on the dynamics of the whole three-dimensional magnetization field in the sample. In the simulations, a patterned element of a given material, size, and shape can be exposed, for example, to an external field pulse and the response of the magnetization can be modeled by integrating the equation of motion. The correctness of such calculations has been firmly ensured in the last years by cross checking the results obtained with different codes and by directly comparing experimental observations with micromagnetic simulations. The fundamental equation that is used in micromagnetic simulations to describe the magnetization dynamics is the Landau–Lifshitz–Gilbert equation.

2.1 The Landau–Lifshitz–Gilbert equation

In the theory of micromagnetism, magnetization is represented as a continuous, directional field $\boldsymbol{M}(\boldsymbol{r}, t)$ with constant magnitude, $|\boldsymbol{M}| = M_s$. The task of dynamic micromagnetic simulation consists in the calculation of the spatiotemporal evolution of the magnetization field $\boldsymbol{M}(\boldsymbol{r}, t)$ in a ferromagnet. The Gilbert equation

$$\frac{\mathrm{d}\boldsymbol{M}}{\mathrm{d}t} = -\gamma\,(\boldsymbol{M} \times \boldsymbol{H}_{\mathrm{eff}}) + \frac{\alpha}{M_s}\left(\boldsymbol{M} \times \frac{\mathrm{d}\boldsymbol{M}}{\mathrm{d}t}\right) \qquad (1)$$

is the equation of motion of the magnetization $\boldsymbol{M}(\boldsymbol{r}, t)$, where $\boldsymbol{H}_{\text{eff}}$ is the effective field, γ is the gyromagnetic ratio, and α is a phenomenological damping constant. The effective field is generally a complicated function of the magnetization distribution of the sample. This is discussed in more detail in the next paragraphs. The Gilbert equation can be rewritten into an explicit form, which is known as the *Landau–Lifshitz–Gilbert (LLG) equation*

$$\frac{\mathrm{d}\boldsymbol{M}}{\mathrm{d}t} = -\frac{\gamma}{1+\alpha^2}(\boldsymbol{M} \times \boldsymbol{H}_{\text{eff}}) - \frac{\alpha\gamma}{M_s(1+\alpha^2)}[\boldsymbol{M} \times (\boldsymbol{M} \times \boldsymbol{H}_{\text{eff}})] \tag{2}$$

Analytic solutions of the Gilbert equation are usually only possible in the macro-spin approximation (Kikuchi, 1956), where the magnetic structure of the sample is assumed to be homogeneous throughout the reversal process. Usually, the macro-spin approximation is only valid for special cases or for very small magnetic particles of up to about 10 nm size (Wernsdorfer, Orozco and Hasselbach, 1997). The macro-spin approximation is, in any case, not suitable for describing magnetization waves. To calculate the dynamics of the inhomogeneous, three-dimensional vector field of the magnetization, numerical methods are required, with which the LLG equation is integrated in time.

2.2 Effective field terms

The energy of a ferromagnet depends on its magnetic structure (Brown, 1963). In a static equilibrium state, the magnetization field $\boldsymbol{M}(\boldsymbol{r})$ arranges in such a way as to minimize the total energy. This minimum can either be a local or a global one, depending on the magnetic history of the sample.

The most important contributions to the total energy are usually the ferromagnetic exchange energy, the dipolar or magnetostatic energy, the magnetocrystalline anisotropy energy and the Zeeman energy in an external magnetic field. These energy terms are briefly described in the next paragraphs. A more detailed discussion of the micromagnetic energy terms and of the LLG equation can be found in textbooks on micromagnetism (Brown, 1963; Hubert and Schäfer, 1998; Aharoni, 1996; Kronmüller and Fähnle, 2003).

The effective field $\boldsymbol{H}_{\text{eff}}$ is defined as the negative variational derivative of the micromagnetic energy density e with respect to the magnetization,

$$\mu_0 \boldsymbol{H}_{\text{eff}} = -\frac{\partial e}{\partial \boldsymbol{M}} \tag{3}$$

It is therefore sufficient to introduce the energy terms that contribute to the total micromagnetic energy density, from which the effective field can then be derived according to equation (3). In most cases, a discussion of the energy terms is also more instructive than a derivation of the various effective field terms.

2.2.1 Exchange energy

The characteristic property of ferromagnetic materials is their tendency to keep neighboring magnetic moments parallel to each other. The short-range exchange interaction prevents strong inhomogeneities of the magnetization on small length scales. In other words, any increase in inhomogeneity of the magnetization field increases the exchange energy. The simplest and, in most cases, perfectly sufficient representation of the exchange energy density is given by

$$e_{\text{exc}} = \sum_{i=x,y,z} A \cdot (\nabla m_i)^2 \tag{4}$$

where A is the exchange constant and $\boldsymbol{m} = \boldsymbol{M}/M_{\text{s}}$ is the reduced or normalized magnetization (Aharoni, 1996). This expression can also be derived from a Taylor expansion of the Heisenberg term assuming small-angle deviations between neighboring moments (Kronmüller and Fähnle, 2003).

2.2.2 Magnetostatic energy

Each magnetic moment in a ferromagnetic sample represents a magnetic dipole and therefore contributes to a total magnetic field $\boldsymbol{H}_{\text{s}}$ inside the sample. The energy connected with this field is known as the *stray field energy* or the *magnetostatic energy*. The local stray field energy density depends on the orientation of the magnetic moments with respect to this field,

$$e_{\text{st}} = -\frac{\mu_0}{2}\boldsymbol{H}_{\text{s}} \cdot \boldsymbol{M} \tag{5}$$

In the literature, different terms are used for the field $\boldsymbol{H}_{\text{s}}$. It is called the *magnetic stray field*, the *dipolar field*, the *demagnetizing field*, or the *magnetostatic field*. The factor $1/2$ in equation (5) is required for self-energy terms. This energy contribution arises from the long-range magnetostatic interaction between the magnetic moments in the sample. It can be shown that the total stray field energy, which results from a volume integration of equation (5), is always positive definite (Brown, 1962; Aharoni, 1996). The consideration of the stray field energy therefore always increases the total energy of the system, for any arrangement of the magnetization. In order to minimize the stray field energy of a ferromagnet, the sources of the field $\boldsymbol{H}_{\text{s}}$ have to be minimized. This is known as *Brown's pole avoidance principle* (Brown, 1962).

The stray field $\boldsymbol{H}_s(\boldsymbol{r})$ at one point $\boldsymbol{r}$ results, in principle, from a summation of the form

$$\boldsymbol{H}_s(\boldsymbol{r}) = \frac{1}{4\pi}\left(\sum_i \frac{\boldsymbol{\mu}_i}{|\boldsymbol{r}-\boldsymbol{r}_i|^3} - 3\cdot\frac{(\boldsymbol{\mu}_i\cdot\boldsymbol{r})\cdot\boldsymbol{r}}{|\boldsymbol{r}-\boldsymbol{r}_i|^5}\right) \tag{6}$$

which extends over all the magnetic moments inside the sample.

The magnetic dipole moments $\boldsymbol{\mu}_i$ can be assumed to be localized on an atomic length scale. It is not practicable to perform a calculation of the stray field in mesoscopic particles by means of the summation over these point dipoles. In the framework of micromagnetism, such dipolar sums are therefore not considered. A possible approximation consists in locating 'effective' dipoles at the (more or less arbitrarily chosen) sites of discretization points, and performing the summation only over these points. However, this approximation can be problematic because it implicitly assigns a physical meaning to a numerical entity, and this could result in large numerical errors. It has been shown that these errors can be reduced by using multipoles rather than dipoles at the discretization points (Blue and Scheinfein, 1991). However, these multipoles have to be extended to quite high orders to achieve accurate results, as was shown by applying the fast multipole method (FMM) to micromagnetic problems (Seberino and Bertram, 2001). The micromagnetic calculation of demagnetizing fields involves a transition from the discrete sum (equation (6)) to a continuum integration. By converting the sum (equation (6)) over the individual magnetic dipoles into an integral over the sample volume (Brown, 1963), the stray field can be obtained from

$$\begin{aligned}\boldsymbol{H}_s(\boldsymbol{r}) = &-\frac{1}{4\pi}\int \frac{(\boldsymbol{r}-\boldsymbol{r}')\rho(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|^3}\,\mathrm{d}V' \\ &+\frac{1}{4\pi}\oint \frac{(\boldsymbol{r}-\boldsymbol{r}')\sigma(\boldsymbol{r}')}{|\boldsymbol{r}-\boldsymbol{r}'|^3}\,\mathrm{d}S'\end{aligned} \tag{7}$$

where $\boldsymbol{n}$ is the surface normal vector. The magnetic charges $\rho = -\nabla\cdot\boldsymbol{M}$ and $\sigma = \boldsymbol{M}\cdot\boldsymbol{n}$ are the sources of the demagnetizing field.

2.2.3 Magnetocrystalline anisotropy

The magnetocrystalline anisotropy energy results from the crystalline structure of a ferromagnet. According to the crystal symmetry, the direction of the magnetization favors energetically an alignment toward certain axes. In the simplest case of a uniaxial magnetocrystalline anisotropy, the energy density connected with this term is to the first nonvanishing order given by

$$e_{an} = K_u\left[1-(\boldsymbol{m}\cdot\boldsymbol{k})^2\right] \tag{8}$$

where K_u is the uniaxial anisotropy constant and $\boldsymbol{k}$ is a unit vector parallel to the easy axis. The easy axis represents the preferential orientation of the magnetization in the crystal.

In the present study, only ideally soft-magnetic materials are considered, that is, ferromagnets with vanishing magnetocrystalline anisotropy.

2.2.4 Further energy terms

If a ferromagnet is exposed to an externally applied magnetic field $\boldsymbol{H}_{ext}$, its energy obviously depends on the orientation of the magnetization with respect to the field. The Zeeman energy of the system is simply

$$e_{ext} = -\mu_0\boldsymbol{H}_{ext}\cdot\boldsymbol{M} \tag{9}$$

Further energy terms that may be relevant in certain cases are the surface anisotropy and the energy connected with magnetoelastic effects. These energy terms are discussed in detail elsewhere (Brown, 1963; Hubert and Schäfer, 1998; Aharoni, 1996; Kronmüller and Fähnle, 2003). Magnetoelastic effects can be ignored in most practical cases. The consideration of the latter would require the solution of additional differential equations, thus remarkably complicating the overall calculation.

2.3 Finite-element micromagnetics

The numerical integration of the Landau–Lifshitz–Gilbert equation (2) requires the calculation of the effective field $\boldsymbol{H}_{eff}$. The effective field results from the local energy densities described in the preceding text. In this study, the numerical calculation of the effective fields and of the magnetic structure is performed with the finite-element method (FEM).

A relatively extended description of the finite-element formulation is given in the next few paragraphs. The readers who are not interested in these numerical details are invited to skip these paragraphs and proceed with Section 3, where propagating spin waves in thin magnetic strips are discussed.

Although the basic concepts required for the development of a micromagnetic finite-element algorithm have been published in a number of papers (Schrefl, 1999a,b; Yang and Fredkin, 1996, 1998; Chen, Fredkin and Koehler, 1993; Koehler and Fredkin, 1992; Hertel, 2001), it seems that they are generally not well known, unlike the better-known *finite difference (FD) method* (Berkov, Ramstöck and Hubert, 1993). Obviously, a complete description of the mathematics and the numerics of the FEM and the boundary element method (BEM) cannot be covered in a single article. Therefore, only the most essential ingredients of a micromagnetic FEM–BEM formulation are presented.

2.3.1 Discretization

An important property of the FEM is given by its spatial discretization scheme, which differs significantly from the simpler and more frequently used FD scheme. The latter uses a regular grid of cubic or prism-shaped discretization cells. In the FEM, the sample's volume is subdivided into tetrahedral elements of irregular size, shape, and orientation. This allows the approximation of the shape of magnetic elements of general geometry, for example, with curved boundaries, in a more precise way compared to FD schemes, where a staircase approximation (Garcia-Cervera, Gimbutas and Weinan, 2003) is required (cf. Figure 2). In this chapter, the propagation of spin waves in a ring-shaped magnetic thin-film element is discussed. For the modeling of ring shapes, the geometrical flexibility connected with the FEM is of major importance in order to rule out numerical errors and spurious effects as they may arise from a 'staircase' approximation.

The vertex points of the finite elements, that is, the nodes (cf. Figure 3), are the set of discretization points at which all the required values are calculated, like the effective fields, the magnetization, and the magnetic scalar potential. The discretization points are connected to each other by means of linear interpolation functions within each element.

The shape functions $\eta_i^{(n)}(\boldsymbol{r})$ are part of the FEM discretization scheme. They are linear functions of the form

$$\eta_i^{(n)}(\boldsymbol{r}) = a_i + b_i x + c_i y + d_i z \tag{10}$$

where the coefficients are defined for each node i of an element (n) so that

$$\eta_i^{(n)}(\boldsymbol{r}_j) = \delta_{ij} \tag{11}$$

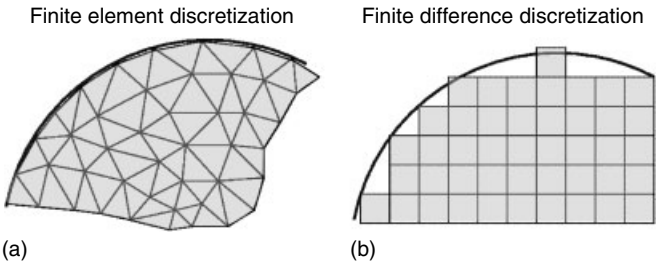

Figure 2. Schematic representation of the smoother approximation of the boundaries with finite elements (a) and a coarser staircase approximation with a regular grid (b). In practice, a finer grid of cubic cells would be used to reduce the errors resulting from the staircase approximation. However, even if the stair steps are infinitely small, the approximation with finite differences leads to a systematic error since the length of the boundary is not considered correctly.

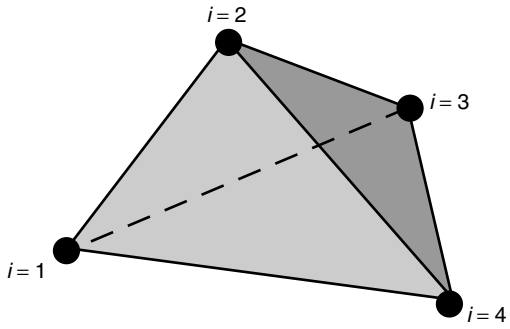

Figure 3. Tetrahedral finite elements are used as discretization cells. In these elements, the discretization points are located at the nodes, that is, the corner points of the elements. Linear shape functions $\eta_i^{(n)}(\boldsymbol{r})$ are defined for each node i of each element n.

The name 'shape functions' indicates that the values of the coefficients only depend on the shape of the finite element. In equation (11), $\boldsymbol{r}_j$ is the position of the node j of the element and δ_{ij} is the Kronecker symbol. If $\boldsymbol{r}$ is outside the element n, the shape functions $\eta_i^{(n)}(\boldsymbol{r})$ are zero. By using these shape functions, a piecewise linear representation of the discretized functions is achieved in the whole computational region. Inside the element n, which contains a point $\boldsymbol{x}$, a piecewise linear representation $\tilde{f}$ of a function f can be written as

$$f(\boldsymbol{x}) \simeq \tilde{f}(\boldsymbol{x}) = \sum_{i=1}^{4} \eta_i^{(n)}(\boldsymbol{x})\alpha_i \tag{12}$$

where $\alpha_i = f(\boldsymbol{x}_i)$ and $\boldsymbol{x}_i$ are the positions of the nodes of the vertices i.

2.3.2 Calculation of the demagnetizing field

While the numerical calculation of most of the contributions of the effective field is quite straightforward, a complicated task consists in solving the long-range magnetostatic interaction. Instead of evaluating the integral (7) for each discretization point in the sample in order to calculate $\boldsymbol{H}_\mathrm{s}(\boldsymbol{r})$, an equivalent way of calculating the stray field consists in introducing a scalar potential U that solves Poisson's equation $\Delta U = \nabla \cdot \boldsymbol{M}$. From this potential, the demagnetizing field (or stray field) is obtained as the gradient field $\boldsymbol{H}_\mathrm{s} = -\nabla U$. The stray field $\boldsymbol{H}_\mathrm{s}$ can usually be obtained much faster by solving Poisson's equation than by performing the integration according to equation (7). A combination of the FEM and the BEM is applied to calculate the potential U. This hybrid FEM–BEM scheme (Fredkin and Koehler, 1990) is an elegant and precise Greens function method.

In the first step, the potential U is split in two parts $U = U_1 + U_2$. Outside the sample, U_2 is zero. With ordinary

finite-element techniques (i.e., the Galerkin method), it is relatively easy to solve Poisson's equation

$$\Delta U_1 = -\rho \tag{13}$$

with the Neumann boundary condition

$$\left.\frac{\partial U_1}{\partial \boldsymbol{n}}\right|_{in} - \left.\frac{\partial U_1}{\partial \boldsymbol{n}}\right|_{out} = \sigma \tag{14}$$

However, the solution of this problem is not unique. Any potential U_3 with continuous derivatives at the boundary that satisfies Laplace's equation $\Delta U_3 = 0$ could be added to U_1 and the result would still represent a solution of the Poisson equation with Neumann boundary conditions. To obtain a unique solution for the potential $U = U_1 + U_2$, one has to solve the Laplace equation $\Delta U_2 = 0$ for U_2 with the correct Dirichlet boundary conditions. These Dirichlet boundary conditions for U_2 are unique once the values of U_1 are known at the boundary. Solving Laplace's equation for U_2 is numerically as unproblematic as solving Poisson's equation for U_1. The difficulty lies rather in finding the correct Dirichlet boundary conditions that make U_2 and finally U the unique solution. Assuming that a solution for U_1 with correct Neumann boundary conditions has been found, the next task consists in calculating the values of U_2 at the boundary of the sample.

Introducing the Greens function

$$G = \frac{1}{|\boldsymbol{r} - \boldsymbol{r'}|} \tag{15}$$

the scalar potential U for a given magnetization vector $\boldsymbol{M}$ fulfills the equation

$$U = \int \boldsymbol{M} \cdot (\nabla G)\, \mathrm{d}V \tag{16}$$

A further relationship that is required is

$$\Delta G = -4\pi\delta(\boldsymbol{r} - \boldsymbol{r'}) \tag{17}$$

where $\delta(\boldsymbol{r})$ is the Dirac δ-function. Integrating equation (13) and equation (17) over the sample volume V and applying Greens' theorem yields

$$-\oint U_1 \frac{\partial G}{\partial \boldsymbol{n}}\, \mathrm{d}S = 4\pi \int U_1 \delta(\boldsymbol{r})\, \mathrm{d}V - 4\pi \int \boldsymbol{M} \cdot (\nabla G)\, \mathrm{d}V \tag{18}$$

Here, the Neumann boundary condition (14) has been used. Insertion of equation (16) results in

$$-\oint U_1 \frac{\partial G}{\partial \boldsymbol{n}}\, \mathrm{d}S = 4\pi \int U_1 \delta(\boldsymbol{r})\, \mathrm{d}V - 4\pi (U_1 + U_2) \tag{19}$$

If $\boldsymbol{r}$ is inside the integration volume, the integral over the δ-function is, by definition,

$$\int U_1 \delta(\boldsymbol{r} - \boldsymbol{r'})\, \mathrm{d}V' = U_1(\boldsymbol{r}) \tag{20}$$

In the case that the point $\boldsymbol{r}$ is located at the boundary, the solid angle Ω subtended at that point is important. Outside the magnetic region, U_1 is equal to zero, while inside it has a finite value. Hence, if $\boldsymbol{r}$ is at the surface of the integration volume, the integration over the δ-function is weighted with a factor $\Omega/4\pi$.

$$\int U_1 \delta(\boldsymbol{r})\, \mathrm{d}V = \frac{\Omega}{4\pi} U_1 \tag{21}$$

For any point $\boldsymbol{r}$ located at the boundary, this finally yields

$$U_2(\boldsymbol{r}) = \frac{1}{4\pi} \oint U_1(\boldsymbol{r'}) \frac{\partial G}{\partial \boldsymbol{n}}\, \mathrm{d}S' + \left(\frac{\Omega}{4\pi} - 1\right) U_1(\boldsymbol{r}) \tag{22}$$

Hence, the values U_2 at the boundary can be calculated from the values U_1 at the boundary by integrating over the sample surface (Lindholm, 1984). Having obtained the Dirichlet boundary values of U_2 from the surface integration performed with the BEM, the Laplace equation $\Delta U_2 = 0$ can be solved with the FEM. This hybrid FEM–BEM scheme yields accurate solutions for $U = U_1 + U_2$, and hence for the stray field $\boldsymbol{H}_\mathrm{s} = -\nabla U$.

The somewhat lengthy equations of this section may create the impression that this method to calculate $\boldsymbol{H}_\mathrm{s}$ is complicated and time-consuming. But, in fact, the numerical calculation can be performed quickly and precisely. The numerical implementation of this hybrid FEM–BEM scheme is, on the other hand, quite an ambitious undertaking compared to the implementation of the fast Fourier transform method (FFT) used in FD schemes.

2.3.3 Calculation of the exchange field

Besides the calculation of the stray field $\boldsymbol{H}_\mathrm{s}$, determining the effective field of the ferromagnetic exchange $\boldsymbol{H}_\mathrm{exc}$ also represents a nontrivial task in finite-element micromagnetic simulations. The three Cartesian components H^x_exc of the exchange field can be calculated from

$$H^{(i)}_\mathrm{exc} = \frac{2A}{\mu_0 M_\mathrm{s}} \Delta m_i \tag{23}$$

where $i = x, y, z$. For the calculation of $H^{(i)}_\mathrm{exc}$, the Galerkin method is used to convert the Laplace operator on the right-hand side of equation (23) into a set of linear equations, as explained below. A very similar procedure is also applied for solving the Poisson equation for the potential U, but here the

situation is simpler, mainly because the BEM is not required for the calculation of the exchange field. Equation (23) has to be solved in the whole ferromagnet, that is, for every discretization point. The Galerkin method makes use of test functions w in the sense that the problem is reformulated as follows: If

$$\int w \cdot H_x \,\mathrm{d}V = \int w \cdot \frac{2A}{\mu_0 M_\mathrm{s}} \Delta \boldsymbol{m}_x \,\mathrm{d}V \tag{24}$$

holds for *any* test function w, then $H_\mathrm{exc}^{(i)}$ is a solution of equation (23). This is known as the *weak form* of equation (23). In equation (24), the x component has been chosen for i without loss of generality, and the subscript 'exc' has been dropped.

Integrating by parts yields

$$\begin{aligned}\int_\Omega w \cdot H_x \,\mathrm{d}V &= -\frac{2A}{\mu_0 M_\mathrm{s}} \int_\Omega \nabla w \cdot \nabla m_x \,\mathrm{d}V \\ &\quad + \frac{2A}{\mu_0 M_\mathrm{s}} \oint_{\partial\Omega} w \cdot \nabla m_x \,\mathrm{d}\boldsymbol{S} \qquad (25) \\ &= -\frac{2A}{\mu_0 M_\mathrm{s}} \int_\Omega \nabla w \cdot \nabla m_x \,\mathrm{d}V \qquad (26)\end{aligned}$$

where the Brown condition $\partial m_x / \partial \boldsymbol{n}|_{\partial\Omega} = \boldsymbol{0}$ for the derivatives of the magnetization at the particle boundary $\partial\Omega$ has been used (Brown, 1940), Ω is the particle volume and $\boldsymbol{n}$ is the surface normal vector. The integration over the volume Ω can be transformed into a sum of integrations over the N finite elements:

$$\sum_{n=1}^{N} \int_{\Omega_n} w \cdot H_x \,\mathrm{d}V = \sum_{n=1}^{N} -\frac{2A}{\mu_0 M_\mathrm{s}} \int_{\Omega_n} \nabla w \cdot \nabla m_x \,\mathrm{d}V \tag{27}$$

In each element n, the test functions w, the exchange field H_x and the magnetization components m_i can be represented using the set of aforementioned shape functions according to equation (12). Inserting this expansion into equation (24) leads to an enormous sum:

$$\begin{aligned}&\sum_{n=1}^{N} \sum_{k=1}^{4} \sum_{l=1}^{4} w_k h_x^l \int_{\Omega_n} \eta_k^{(n)} \eta_l^{(n)} \,\mathrm{d}V \\ &\quad = \sum_{n=1}^{N} \sum_{k=1}^{4} \sum_{j=1}^{4} -\frac{2A}{\mu_0 M_\mathrm{s}} w_k m_x^j \int_{\Omega_n} \nabla \eta_k^{(n)} \nabla \eta_j^{(n)} \,\mathrm{d}V \qquad (28)\end{aligned}$$

In this equation, $\{w_k\}$ are the values of the test functions at the nodes k, $\{h_x^l\}$ are the values of the x component of the exchange field at the nodes l, and $\{m_x^j\}$ are the x component of the normalized magnetization at the nodes j. Since equation (28) must be valid for any arbitrary test function w, a comparison of coefficients w_k can be performed. This transforms this huge sum into a large set of linear equations. The matrix $\underline{\underline{A}}$ of this set of linear equations is very sparse, meaning that by far most of the elements of this matrix are zero. By using special indexing methods (Press, Flannery, Teukolsky and Vetterling, 1986), it is possible to store only the nonvanishing elements of the matrix, thus saving a large amount of computer memory. The fact that the matrix of this set of linear equations is very sparse allows to efficiently solve the set of equations iteratively by using the conjugate gradient method. Note that for such large, sparse systems of linear equations, iterative solutions are always much faster and more accurate than any result that could be achieved by trying to calculate the inverse matrix $\underline{\underline{A}}^{-1}$. In fact, an inversion of $\underline{\underline{A}}$ is not possible in practical cases because the inverse matrix $\underline{\underline{A}}$ would generally not be a sparse matrix any more and could therefore not even be stored if the typical rank n is in the order of several tens of thousands. The integrals containing the shape functions η in equation (28) need to be performed only once at the beginning of the calculation.

Compared to the exchange field, the remaining contributions to the effective field, that is, the effective fields of the magnetocrystalline anisotropy and the Zeeman field are much simpler to calculate.

2.3.4 *Integration of the Landau–Lifshitz equation*

For the algorithm to be fast, it is imperative that the procedures to calculate the effective fields are programmed in an efficient way, since these calculations have to be performed several thousands of times during the simulation of a realistic dynamic magnetization process. In every time step, the contributions to the effective fields are calculated according to the current magnetization distribution $\boldsymbol{M}(\boldsymbol{r}, t)$, and the total effective field $\boldsymbol{H}_\mathrm{eff}$ is updated at each nodal point of the finite-element mesh. These values of $\boldsymbol{H}_\mathrm{eff}$ then enter the LLG equation, which is used to determine the next configuration of the magnetization $\boldsymbol{M}(\boldsymbol{r}, t)$. In the numerical form, the time derivative of the magnetization is replaced by a difference quotient,

$$\frac{\mathrm{d}\boldsymbol{M}}{\mathrm{d}t} \longrightarrow \frac{\Delta \boldsymbol{M}}{\Delta t} \tag{29}$$

so that the magnetization after a time step Δt reads

$$\begin{aligned}\boldsymbol{M}(t + \Delta t) &= \boldsymbol{M}(t) + \Delta \boldsymbol{M} \\ &= \boldsymbol{M}(t) - \Delta t \cdot \left[\frac{\gamma}{1+\alpha^2} \boldsymbol{M} \times \boldsymbol{H}_\mathrm{eff} \right. \\ &\quad \left. + \frac{\alpha\gamma}{M_\mathrm{s}(1+\alpha^2)} \boldsymbol{M} \times (\boldsymbol{M} \times \boldsymbol{H}_\mathrm{eff}) \right] \qquad (30)\end{aligned}$$

The numerical integration of equation (30) can be quite problematic. Purely explicit integration schemes that only use the previously calculated values at the time t to determine $\Delta \boldsymbol{M}$ show poor stability properties. To improve the stability of the integration of the differential equation, implicit schemes can be applied, which also use the values of the effective fields at the time $(t + \Delta t)$. However, these methods require the calculation of a large Jacobian matrix. For the code used in this study, the best results for the time integration have been obtained with a semi-implicit Adams backward difference (BDF) scheme (Hindmarsh, 1983). In this scheme, the size of the time steps is calculated adaptively and is typically in the subpicosecond range.

With this general purpose micromagnetic algorithm, the dynamics of the magnetization can be simulated for virtually arbitrary shapes. In the study reported in this chapter, the code has been applied to investigate the propagation of spin waves in submicron-sized ferromagnetic strips.

3 PROPAGATING SPIN WAVES

The first point that has to be addressed in order to study whether spin waves can be used to carry and to manipulate information consists in ensuring a controlled propagation of spin waves. The spin waves occurring after a magnetic switching process as shown in Figure 1 consist of a large number of spin-wave modes with different propagation direction, wave number, phase, and amplitude. These spin waves may be reflected several times at the boundary, thus leading to an incoherent noise.

The simplest idea for a controlled propagation of spin waves is to use a thin and narrow ferromagnetic strip as a waveguide (Slavin, Demokritov and Hillebrands, 2002). In this geometry, the spin waves enter on one side of the strip and propagate along the strip line until they reach the opposite end. The geometric confinement enforces a one-dimensional propagation of spin waves. Figure 4 illustrates such a simple case of a flat magnetic strip (Permalloy, 360 nm × 36 nm × 6 nm) that acts as a waveguide for spin waves. The equilibrium magnetic structure of this thin platelet at zero field is simple: in order to minimize the magnetostatic energy, the magnetization aligns along the strip axis, owing to the element's shape anisotropy. The sample is homogeneously magnetized, apart from some small deviations (known as *flower state*, Schabes and Bertram, 1988) at the particle's end (cf. Figure 4a), which are unimportant for the present study. To generate propagating spin waves in this strip, a percussional perturbation is applied at one end of the sample. In an experiment, such a sudden and localized perturbation of the equilibrium structure could be achieved, for example, by applying a short and strong electric current pulse in a small region, running perpendicularly through the strip. When an electric current flows through a ferromagnet, it is spin-polarized. Owing to the spin-transfer-torque effect (Berger, 1996; Slonczewski, 1996), a sufficiently strong spin-polarized electric current can exert a considerable torque on the magnetization, thus leading to the generation of spin waves. In these simulations, the procedure is simpler. By lifting the magnetization by 10° out of the plane in a small region at one end of the slab, the demagnetizing energy and the exchange energy is locally increased.

When the system is released, spin waves are emitted from the perturbed region. The spin waves propagate through the strip and reach the opposite end after some time. In our example, after about 100 ps. Contrary to the magnetic ringing in the previous case, these spin waves have a well-defined propagation direction along the film strip. Instead of a noisy perturbation resulting from the superposition of several spin waves, plane waves are now propagating along the strip. Although, as in the case of magnetization ringing, several spin-wave modes with frequencies in the range of several gigahertz are generated, the wave vector of these spin waves is now parallel to the magnetic strip and the spin waves have a well-defined phase. To detect the arrival of the spin waves at the opposite end of the strip, a 'seismographic' record can be plotted that displays the out-of-plane component of

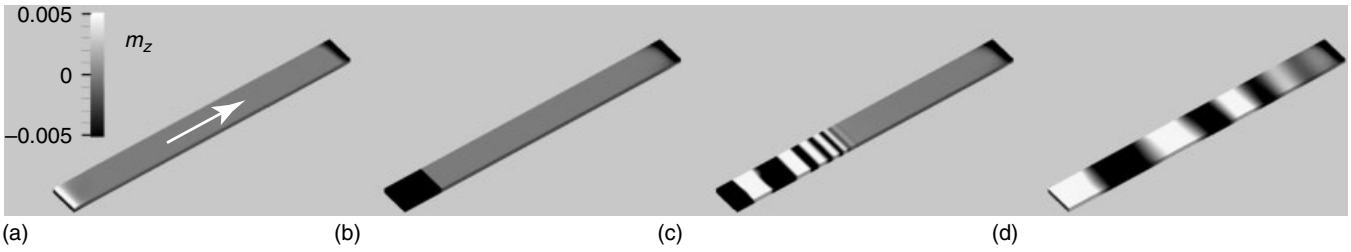

Figure 4. Wave propagation in a magnetic nano-strip. The gray scale displays the out-of-plane component. (a) Initial, zero field state. The arrow depicts the in-plane magnetization. (b) The initial state is perturbed by locally lifting the magnetization out of the film plane (black region on the left). (c) and (d) Snapshots of the spin-wave propagation in zero field at $t = 27$ ps (c) and $t = 298$ ps (d) after the system is released.

the magnetization as a function of time at a selected point on the strip (cf. Figure 5). Experimentally, the spin waves could be detected using the giant-magnetoresistance effect (Baibich *et al*., 1988; Binasch, Grünberg, Saurenbach and Zinn, 1989). The spectrum of spin waves that is generated immediately after the release of the system contains a broad range of frequencies. Owing to dispersion, the short-wavelength, high-frequency oscillations propagate faster than spin waves of lower frequencies. The first signal in the seismograph is a series of small spikes, indicating the onset of small, high-frequency oscillations. These spikes are followed by a stronger signal that displays an almost harmonic oscillation.

Besides transmitting spin waves in a controlled fashion with such waveguides, it is also possible to split the signal transported by a spin wave. The propagation of spin waves in a Y-shaped magnetic thin-film element is a simple example for this. At zero field, the magnetization in the magnetic 'nano-tuning fork' shown in Figure 6 is aligned parallel to the branches. When the system is perturbed at the broader end of the sample in the same way as was done before, spin waves are generated that propagate toward the junction, where they split symmetrically into the two branches. Similarly, spin waves arriving from two branches can be merged into one strip. This can lead to different interference effects, depending on the phase of the spin waves. In order to use spin waves for logical operations, such a splitting and merging of the signal is essential.

4 DOMAIN-WALL-INDUCED PHASE SHIFTS

The mere propagation of spin waves only allows to guide a signal along a magnetic strip. However, if the *phase* of a

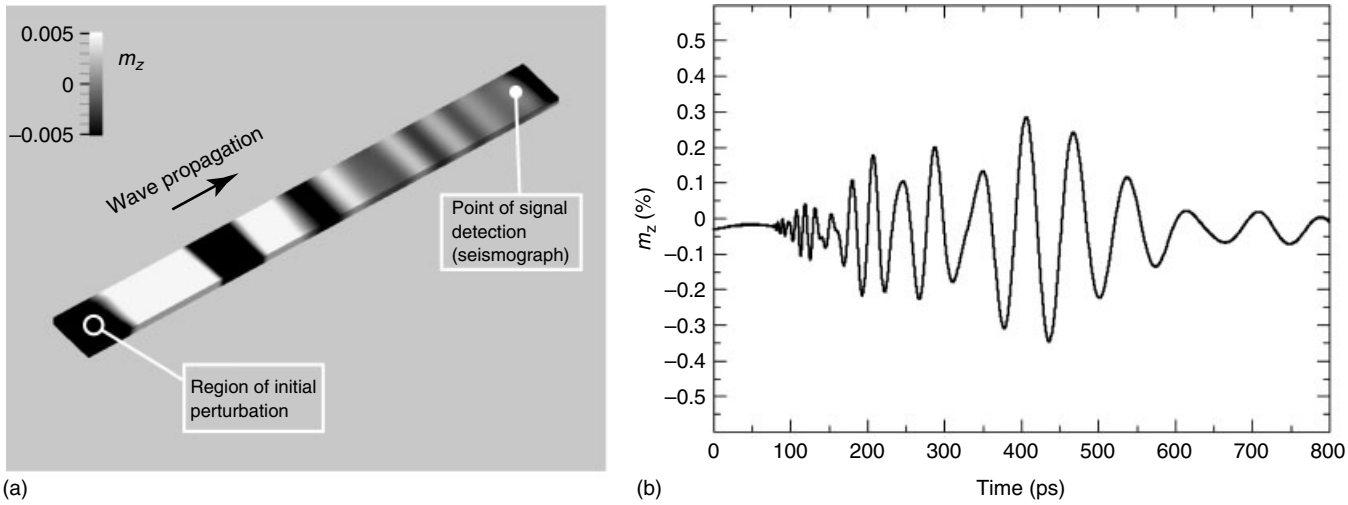

Figure 5. Spin waves generated at one end of a magnetic strip can be recorded with a magnetic 'seismograph' displaying the out-of-plane magnetization component as a function of time at one point on the opposite end.

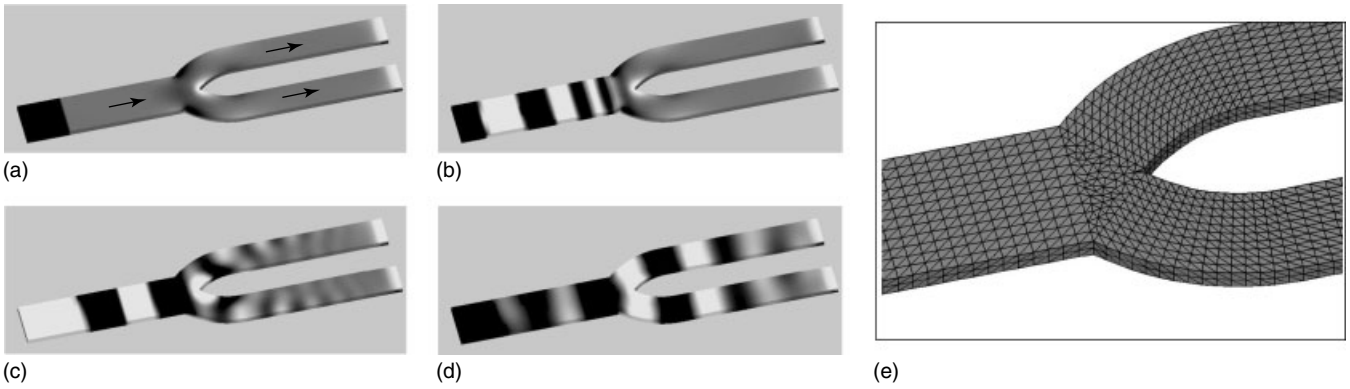

Figure 6. Four images of a Permalloy 'tuning fork' with propagating spin waves. The frames (a)–(d) are at 0, 40, 100, and 215 ps after the release, respectively. A part of the finite-element mesh is shown in frame (e) to illustrate the smooth approximation of the curved boundary. The length of the nanomagnetic tuning fork is 353 nm and its film thickness is 6 nm.

spin wave can be modified in a controlled way, it becomes feasible to perform logical operations with propagating spin waves. The principle of such logical devices is discussed in more detail in the next section. In the following text, it is shown that a spin wave changes its phase when it passes through a magnetic domain wall.

To study the influence of a domain wall on propagating spin waves, the numerical experiment on the propagation of spin waves in a magnetic strip shown in Figure 4 is repeated with different initial conditions. Instead of the homogeneously magnetized magnetic ground state, a bi-domain state with a 180° head-to-head wall in the middle is used as the static magnetic configuration in the nano-strip before generating the spin waves. In the case of a head-to-head domain configuration in magnetic strips, transverse domain walls occur if the sample is sufficiently narrow and thin (McMichael and Donahue, 1997; Kläui, Vaz *et al.*, 2004a). In larger strips, the transverse wall is replaced by a vortex-type domain wall (McMichael and Donahue, 1997). In the micromagnetic simulation, the transverse domain wall develops automatically if appropriate initial conditions are chosen. The position of the domain wall in the strip can be pinned by introducing small notches at the boundary, which attract the transverse domain walls (Kläui, Vaz and Wernsdorfer, 2004b). In the example shown in Figure 7(a), the strip does not contain such notches and the domain-wall position is not stable. In fact, the strip is a single-domain particle in the strict sense that the only stable magnetization state is the homogeneous one. Therefore, the 180° head-to-head domain wall eventually propagates toward one end of the sample and dissolves. The motion of the domain wall is very slow compared to the speed of the spin waves. In this example, it takes about 10 ns until the domain wall exits the sample. Hence, the magnetization state with a 180° domain wall can be regarded as stable on the timescale connected with the propagation of spin waves.

By lifting the magnetization slightly out of the plane at one end of the slab again and letting the system relax, spin waves are generated that run along the strip. When they meet the domain wall, no reflection is visible. Plane wave fronts are restored after the spin wave has run through the domain wall. The spin wave seems to pass unhindered through the domain wall (cf. Figure 7(c and d)).

As in the previous case, a 'seismograph' of the z component at a point at the opposite end of the slab can be recorded to display the arrival of the spin waves. The characteristics of the oscillation of the z component as a function of time are very similar to the case of a homogeneously magnetized slab. A comparison of the seismographs obtained in the two cases, however, reveals an interesting difference concerning the low-frequency oscillations. If the spin wave has run through the domain wall, the *phase* of these oscillations is shifted by about $\pi/2$ with respect to the case of homogeneous magnetization (Figure 8a). The main signal, that is, the envelope of the oscillation, arrives after the same time as in the homogeneous case and is therefore not slowed down by the domain wall. According to the simulations, the domain wall is transparent for spin waves, but the presence of a domain wall changes the phase of spin waves. This phase shift depends strongly on the wavelength. The short, high-frequency oscillations appear to be unaffected by the domain wall, while the low-frequency oscillations with larger

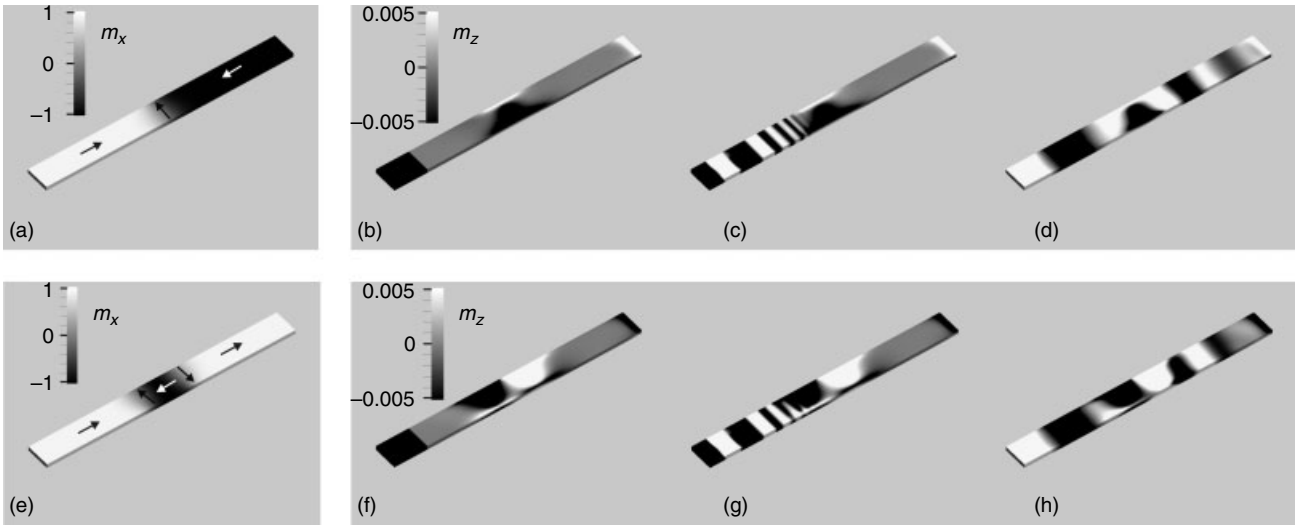

Figure 7. Wave propagation in a strip with a 180° domain wall (a–d) and with a 360° domain wall (e–h). The gray scale in frames (a) and (e) shows the in-plane magnetization along the strip, the other frames display the out-of-plane components like those in Figure 5. The snapshots are taken at $t = 0$ ps (b) and (f); 27 ps (c) and (g); and 298 ps (d) and (h).

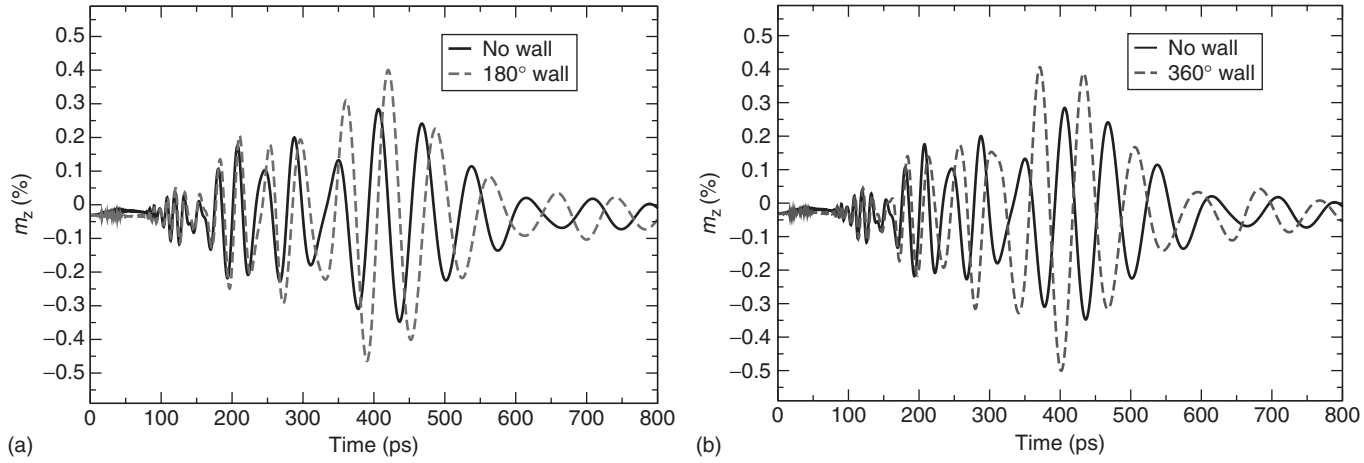

Figure 8. Magnetic seismographs recorded at the opposite end of the strip in the case of a 180° wall (a) and a 360° wall (b). The oscillations are compared with the signal obtained without domain wall, as shown in Figure 5(b).

wavelength that carry the main signal are phase shifted by $\Delta\Phi \simeq \pi/2$. In addition to the wavelength, simulations on other strip geometries show that the film thickness also has a strong influence on the value of the phase shift. This is probably related to the sensitive dependence of the domain-wall width on the film thickness. However, more detailed studies are required to systematically investigate the correlation between the phase shift and quantities like domain-wall width, magnetocrystalline anisotropy, film thickness, lateral width of the strip, and so on. Simulations with different values of the Gilbert damping parameter indicate that the phase shift effect is not sensitive to α.

The surprising phase-shift effect can also be probed with a 360° domain wall (cf. Figure 7(e–h)). This leads to a doubling of the phase shift and the main oscillations now shift by $\Delta\Phi \simeq \pi$ with respect to the homogeneous strip (cf. Figure 8b). While in the simulations a 360° domain wall can be prepared relatively easily by choosing suitable initial conditions for the calculation, such a magnetic structure is more difficult to obtain experimentally. Interestingly, 360° domain walls in thin magnetic nanorings have recently been observed by means of magnetic force microscopy, and it seems to be possible to generate and to remove 360° domain walls experimentally in a controlled way by means of an external magnetic field (Castano, Ross and Frandsen, 2003).

The phase shift induced by a magnetic domain wall in propagating spin waves has recently been calculated analytically for the case of a 180° Bloch wall (Bayer, Schultheiss, Hillebrands and Stamps, 2005). This study was stimulated by the micromagnetic simulations discussed in the preceding text, which predicted such an effect (Hertel, Wulfhekel and Kirschner, 2004). Similar to the present study, Bayer, Schultheiss, Hillebrands and Stamps (2005) find that a Bloch wall does not lead to the reflection or absorption of a spin wave and that a phase shift is obtained, depending on the wave vector of the spin wave. It can be assumed that the present case of a Néel wall is comparable to the situation with a Bloch wall studied by Bayer, Schultheiss, Hillebrands and Stamps (2005).

The possibility of manipulating the phase of spin waves, demonstrated here by means of magnetic domain walls, in combination with the ability to split and to merge spin waves propagating along thin magnetic strips, paves the way to interference experiments with spin waves. These interference effects could represent the working principle of programmable devices performing logical operations with spin waves, which is discussed in the next section.

5 SPIN-WAVE LOGICS

Phase differences of spin waves can be studied with magnetic ring structures, with which spin waves can be split into two branches. If the spin waves propagating in the branches acquire a phase difference with respect to each other, the phase shift should lead to characteristic interference effects when the waves are merged on the opposite side of the ring. The concept to split a wave on a ring and to use interference effects to probe the phase is similar to the Aharonov–Bohm effect (Aharonov and Bohm, 1959). A model for a spin-wave interferometer is an elongated ring with two small plates on opposite sides, as shown in Figure 9. One of the outer plates is used to excite spin waves and the other to measure the signal after the spin waves have traveled through the ring.

In a first example, the static magnetic structure in the ring is the so-called *onion state* (Rothman, Kläui and Lopez-Diaz, 2001). This is an almost homogeneous structure with the magnetization locally aligned parallel to the strip

and to the branches in order to reduce magnetic surface charges (cf. Figure 9(a and b)). In this configuration, the magnetization direction is essentially parallel to the direction of propagation of the spin waves.

If spin waves are generated on one of the outer platelets, the spin waves propagate toward the junction, where they are split symmetrically on the two branches and eventually merge on the opposite side. This process is shown in Figure 10(a)–(d). In this ring geometry, some high-frequency, edge-localized spin-wave modes are observed, which did not occur in the case of a straight bar. These modes, which are apparently connected with the curvature of the branches, dissipate very quickly so that they are almost completely attenuated before they reach the opposite side of the ring. Apart from these additional modes at the edge, the excitation spectrum consists of almost plane waves. When the branches meet again, the wave fronts merge with the same phase. The arrival of the spin waves at the opposite end can again be displayed with a 'seismograph'. The spectrum is similar to the previous case of a single strip.

To study the influence of a domain wall on the phase of the spin waves, a 360° domain wall is inserted in one of the branches, and the simulation is repeated with this structure. The result is shown in Figure 10(e)–(h). The spectrum of the signal that arrives on the opposite side is significantly different from the previous case with a homogeneously magnetized ring (cf. Figure 11a). While the fast excitations of short wavelength are essentially the same as before, the central low-frequency oscillation is much more strongly damped in the case with a 360° domain wall. This strong

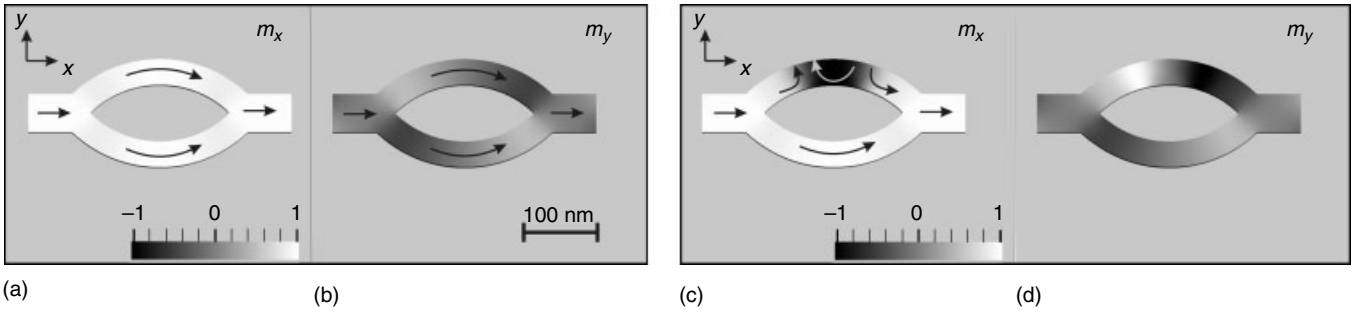

Figure 9. Two magnetization states in a flat, elongated ring structure. (a) and (b) Quasihomogeneous 'onion state'. The magnetization is oriented in the x-direction, with some small deviations in the ring branches. (c) and (d) Inhomogeneous state with a 360° wall in one branch of the ring.

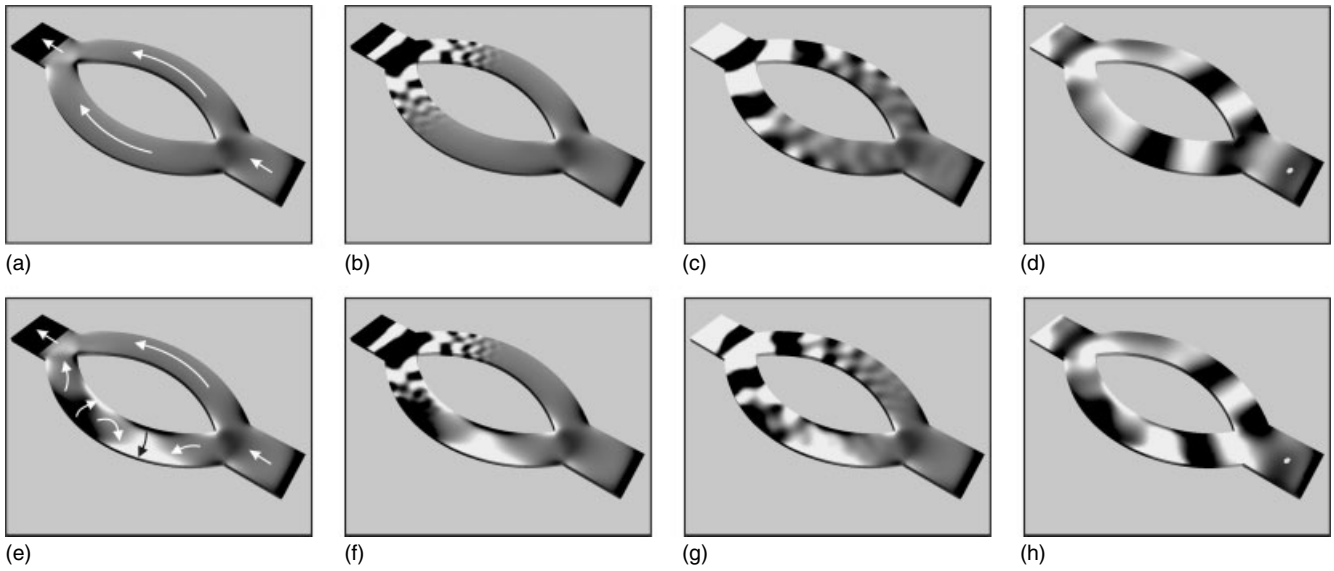

Figure 10. Propagating spin waves in a ring-shaped element. Top row, onion state; bottom row, ring with 360° wall. The gray scale shows the out-of-plane component, like in the previous examples. The arrows in frames (a) and (e) depict the in-plane magnetization structure. Snapshots of the dynamic relaxation process are taken at 0 ps (a) and (e); 27 ps (b) and (f); 67 ps (g); 90 ps (c); 298 ps (d) and (h). The white point in the frames (d) and (h) indicates the region where the seismograph of Figure 11(a) is recorded.

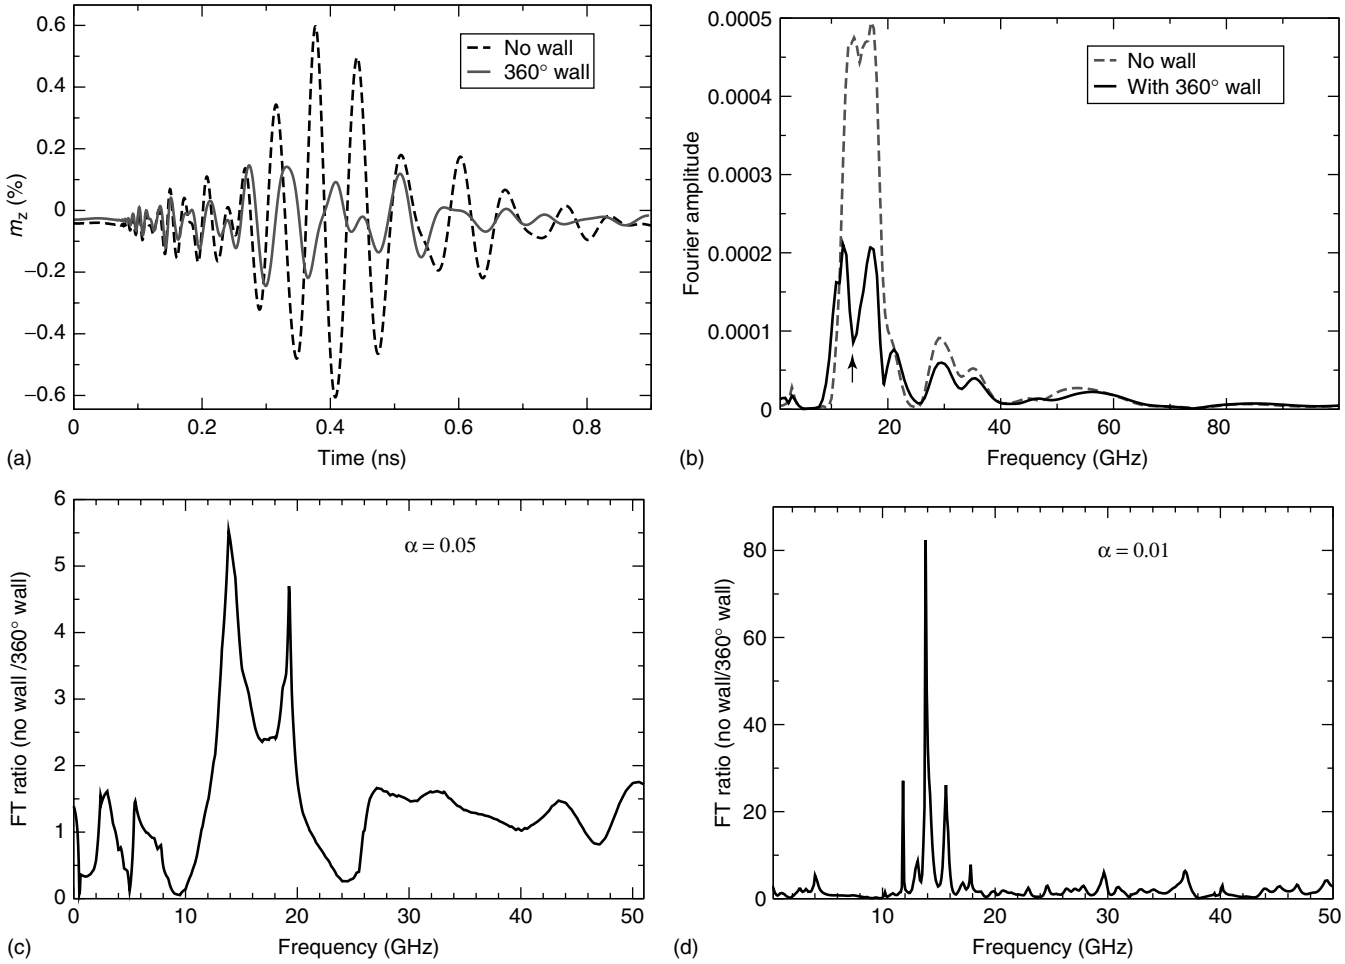

Figure 11. (a) Seismographs of the spin waves arriving at the opposite end of the ring in the case of the onion state and in the inhomogeneous state with a 360° wall. (b) Fourier transforms of the signals from frame (a). (c) Ratio of the Fourier amplitudes from frame (b). (d) Ratio of Fourier transforms as shown in frame (c) in the case of lower damping ($\alpha = 0.01$).

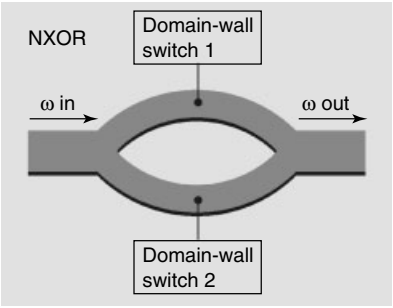
attenuation results from destructive interference when the spin waves merge (Figure 10h).

Since the phase shift depends on the frequency, there is a small range of frequencies in the spectrum of the excitations that matches the condition of opposite phase almost exactly. This can best be seen by analyzing the Fourier spectra of the magnetic seismographs for both cases. The arrow in Figure 11(b) points at the frequency that is most strongly damped by the presence of the domain wall. This results in a peak at about 14 GHz when the ratio of the Fourier components of these two cases is plotted, cf. Figure 11(c). This data refers to the case shown in the simulation, where a relatively large damping constant $\alpha = 0.05$ was used. A lower value of α (0.01) leads to a reduction of the line width of the Fourier components. In this case, the ratio of the Fourier components displays a much sharper peak at 14 GHz (Figure 11d). The spin waves with this frequency are almost completely filtered out by the ring with a 360° domain wall. Therefore, the spin interferometer can also be considered as a spin-wave filter for one characteristic frequency. If the signal is carried with this frequency, the ratio of the signal without a domain wall to the one with a 360° domain wall is very large, in our case of the order of 80.

If we assume that a 360° domain wall can be inserted and removed in the branches, this magnetic ring can be regarded as a spin-wave-based logical device that performs a disjunctive exclusive OR (NXOR) operation. This is illustrated in Figure 12. The input signal consists in placing domain walls acting as phase-shifting units into the branches, and the probing is obtained by letting a spin wave of suitable frequency run through the ring, which is either transmitted or blocked by the device.

This NXOR switch is the most simple type of a spin-wave-based logical device. Other logical operations can be achieved by combining such rings, as sketched in Figure 13. In the switches, phase shifters are inserted or removed,



Domain wall in branch 1	Domain wall in branch 2	Signal out
0	0	1
1	0	0
0	1	0
1	1	1

Figure 12. The property of the ring to block the propagation of spin waves of a certain frequency depending on the presence or absence of domain walls in the ring branches can – in principle – be used for logical operations. In this example, the ring acts like a disjunctive, exclusive OR switch (NXOR).

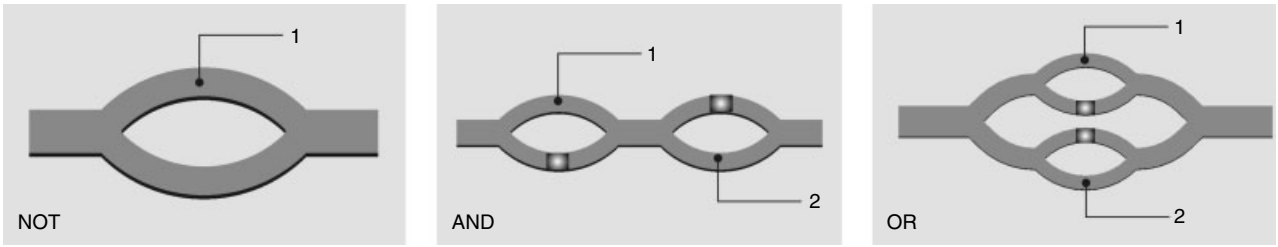


Figure 13. Other logical operations based on spin-wave propagation can be performed by combining rings. The switches 1 and 2 in these schematics are regions where a 360° wall is inserted or removed. The larger dots in the AND and in the OR sketch represent fixed phase-shifting units (360° walls).

according to the signal that is to be probed, in the same way as was done in the NXOR switch when a domain wall was inserted or removed in one branch.

6 BERRY-PHASE EFFECTS IN FERROMAGNETIC RINGS

Because of the similarity of the effects, it may be suspected that the domain-wall-induced phase shift in spin waves occurring in an elongated magnetic ring has a similar origin as the Berry phase (Berry, 1984, 1985) that an electron wave acquires due to the magnetic vector potential in the Aharonov–Bohm effect.

Effects connected with a Berry phase or a Hannay angle (Hannay, 1985) in propagating spin waves are related to the precessional motion of the magnetization around the effective field (Braun and Loss, 1996). This is illustrated in an example for a Berry-phase effect in a thin ferromagnetic ring with vortex magnetization in the plane (cf. Figure 14b). In this case, the dispersion relation of spin waves propagating along the ring does not depend on the sense of propagation being parallel $(\boldsymbol{k}_1, \omega_1)$ or antiparallel $(\boldsymbol{k}_2, \omega_2) = (-\boldsymbol{k}_1, \omega_1)$ to the local magnetization direction. Micromagnetic simulations confirm the occurrence of standing spin-wave patterns in such a case, which can be decomposed in sets of identical spin waves with opposite sense of propagation.

If the magnetization is lifted out of the plane by means of an external field applied perpendicular to the ring plane (cf. Figure 14c), the degeneracy is lifted (Ivanov and Zaspel, 2005). The quasistanding spin waves resulting in this case display a slow and constant motion of the nodal points of the oscillations; either clockwise or counterclockwise, depending on the sign of the external field. To understand this effect, it is important to note that – according to the LLG equation – the precession of the magnetization in an effective field always has the same sense of rotation (Figure 14a). If spin waves propagate parallel to the direction of the effective field, this precession is perpendicular to the propagation direction. By lifting the effective field out of the ring plane, the precessional motion of the magnetization obtains a component along the propagation direction, which is either in the same or in the opposite sense, thereby lifting the degeneracy of clockwise and counterclockwise propagation. A mechanical analogy for this is Foucault's pendulum: The oscillation of the pendulum can be decomposed in two circular components with opposite sense of rotation. During one day, the pendulum is adiabatically transported on a circular orbit due to the rotation of the earth. If the pendulum is at the equator, the rotation axis of the earth is perpendicular to the rotation axis. In this case, the clockwise and the counterclockwise oscillations are degenerate. This corresponds in our case to the effective field lying in the film plane. A chirality of the system is imposed in both cases:

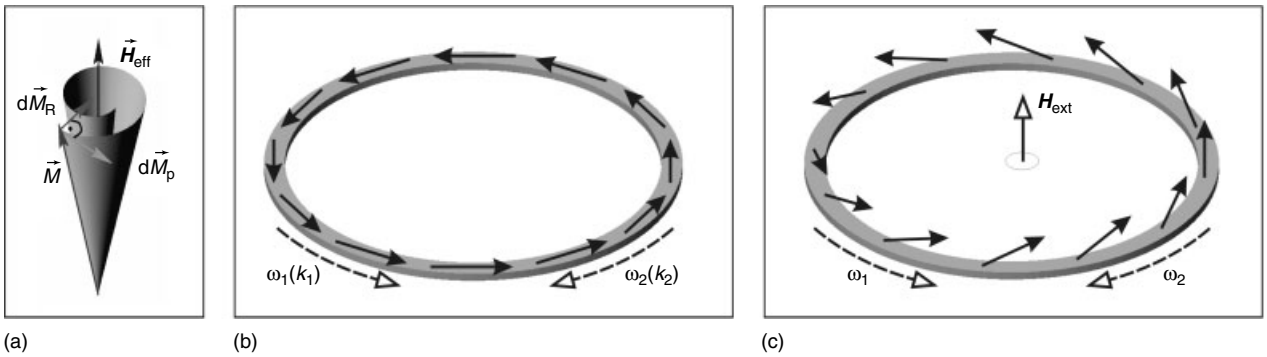

Figure 14. (a) Schematics of the magnetization dynamics described by the LLG equation. (b) Thin magnetic ring with vortex configuration. Spin waves propagating parallel ($\boldsymbol{k}_1$) or antiparallel ($\boldsymbol{k}_2$) to the magnetization direction are degenerate. (c) The degeneracy can be lifted by tilting the magnetization out of the ring plane with an external magnetic field.

the sense of rotation of the earth is constant, as is the sense of rotation of the magnetization in the precessional motion around the effective field. If Foucault's pendulum is located at a latitude away from the equator, the earth's slow rotation is superimposed on the circular components of the swinging pendulum, and the degeneracy of these oscillations is lifted. Hence, the plane of oscillation slowly rotates with respect to the surface. In the case of spin waves, this would correspond to the situation when the precession axis has a component perpendicular to the propagation direction, that is, when the average magnetization is lifted out of the ring plane.

Apart from this simple example, which only serves to present the basic idea of Berry phases in magnons, thorough analytical studies on this topic have been reported very recently by Bruno (2004) and Dugaev, Bruno, Canals and Lacroix (2005). These studies confirm the effect of a phase shift of a spin wave running through a domain wall, as predicted by the simulations. They provide an explanation for the phase shift in terms of a Berry-phase effect. The study of Berry phases in magnons is a new topic in magnetism, which has been elaborated analytically to a good extent. Further numerical and possibly experimental work is required to establish a more comprehensive picture of such effects in magnetism.

7 CONCLUSION

Thin ferromagnetic strips can serve as waveguides for propagating spin waves. Micromagnetic finite-element simulations show that such waveguides can be used to split and merge spin waves coherently. If a propagating spin wave meets a 180° head-to-head or a 360° domain wall, it runs through it without being scattered. However, the domain-wall changes the phase of the spin wave. By manipulating the phase of the spin waves, constructive and destructive interferences can be generated. This could be the working principle of a new type of programmable logical devices based on spin-wave propagation. Of course, the technical applicability of such devices is questionable, and it is doubtful whether this new concept for logical devices could ever compete with the advanced electronic technology that has been developed in the last decades. Compared to the recently proposed concept of magnetic logics based on domain-wall motion (Allwood *et al*., 2002), however, the spin-wave-based logics presented here would have the advantage of a nondestructive read-out process and a faster signal propagation. Probably more important than these technical issues is the fact that an interesting and fundamental effect in magnetism has been revealed by micromagnetic simulations, that is, the interaction of spin waves with domain walls. This has stimulated a number of interesting analytical studies, including Berry-phase effects in magnons, and will hopefully also trigger experimental investigations on this effect.

ACKNOWLEDGMENTS

I would like to thank Prof. A. S. Arrott for reading the manuscript and for several helpful suggestions.

Note: Since this chapter was written, a number of interesting developments have been reported in the literature. Remarkable examples for this are the recent works of Choi, Lee, and Kim (2006) and Choi, Lee, Guslienko and Kim (2007).

Micromagnetism–Microstructure Relations and the Hysteresis Loop

Dagmar Goll
Max-Planck-Institut für Metallforschung, Stuttgart, Germany

1 INTRODUCTION

Magnetic materials are widely used in many (modern) application fields ranging from electrical engineering, car industry, and energy technique to sensor systems, high-density recording, and applications in medicine and biology. For technological progress in these fields and for an application-oriented magnet design, the characteristic magnetic properties of the hysteresis loop are of great importance. Their steady improvement brings about, in particular, a continuous miniaturization of magnetic devices (hard magnetic materials) and a continuous reduction of energy losses during energy transmission (soft magnetic materials) leading to innovations in many new application fields and consequently to a rapid growth of the worldwide market.

Modern high-quality magnets are based on both optimized microstructures (including defect structures) and compounds with outstanding intrinsic material parameters, such as the spontaneous polarization $J_s = \mu_0 M_s$ (spontaneous magnetization M_s, vacuum permeability $\mu_0 = 4\pi \times 10^{-7}\,\mathrm{Vs\,Am^{-1}}$), the magnetocrystalline anisotropy constants K_1 and K_2, and the magnetostriction λ. Optimized microstructures are composed of amorphous regions and/or ensembles of small magnetic grains with length scales varying from nanometer to centimeter. These extrinsic magnetic properties can be controlled by the choice of the alloy composition from the phase diagram (including small amounts of additives) and by the processing route as, for example, sintering, rapid quenching, sputtering, or molecular beam epitaxy (including thermal and mechanical treatments). The detailed analysis of microstructure–magnetic property relationships by means of different high-resolution electron microscopy techniques and magnetic hysteresis loop measurements in combination with the theory of micromagnetism allows a quantitative interpretation of magnetization processes responsible for magnetic softening/hardening. This provides general rules for a successful specific tailoring of optimized characteristic magnetic properties of the hysteresis loop in the whole ferromagnetic (or ferrimagnetic) temperature range.

In the following text, the micromagnetism–microstructure correlation and its influence on the characteristic magnetic properties of the hysteresis loop is reviewed. The following three sections give a survey of the basic characteristics of the hysteresis loop (Section 2), microstructure (Section 3), and

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

micromagnetism and magnetization processes (Section 4). In Sections 5 and 6 the micromagnetism–microstructure relations are discussed for hard and soft magnetic materials. In Section 7, the micromagnetism–microstructure relations are investigated in the approach to saturation. In Section 8, it is demonstrated how the detailed knowledge of the micromagnetism–microstructure correlation can be used for a systematic design of high-performance magnets.

2 HYSTERESIS LOOP

The macroscopic magnetic properties of a ferromagnet are characterized by the hysteresis loop and determine the suitability of magnetic materials for a given application. The hysteresis loop is obtained by applying a magnetic field $\mu_0 H$ to the specimen and measuring the ensuing change of the magnetic polarization J in field direction. Starting from the initial demagnetized state ($J = \mu_0 H = 0$ T) the polarization increases with increasing field and finally reaches the saturation polarization ($J = J^{\mathrm{sat}}$). When the magnetizing field is reduced to zero from the saturated state the sample remains magnetized. This polarization at zero field is called remanence J_r. It can be returned to zero by applying a reverse magnetic field of strength $\mu_0 H_\mathrm{c}$ known as the coercive field which is, therefore, the measure for the magnet's resistance against demagnetizing fields. Further increase of the reversed applied field magnetizes the sample to saturation in the opposite direction ($J = -J^{\mathrm{sat}}$). A large spontaneous polarization J_s is a prerequisite for high J_r values, whereas a large magnetocrystalline anisotropy constant may result in large coercivities. In principle, ferromagnetic substances can be classified into soft and hard magnetic materials depending on how easily the material can be (de)magnetized as illustrated in Figure 1.

Hard magnets provide stable permanent magnetic fields (after exposure to a magnetic field) and create surface poles without continuous expenditure of electrical energy. They are characterized by high coercivity ($\mu_0 H_\mathrm{c} \approx 0.1$–$4$ T, $H_\mathrm{c} \approx 80$–$3200\,\mathrm{kA\,m^{-1}}$), high remanence, and a high maximum energy product ($(BH)_{\max} \approx 10$–$500\,\mathrm{kJ\,m^{-3}}$). The maximum energy product represents the magnetic energy per unit volume which can be maximally stored by a hard magnet, thereby specifying the performance or strength of a permanent magnet. $(BH)_{\max}$ is defined as the maximum rectangular area within the $B(H) = \mu_0 H + J$ hysteresis loop in the second quadrant. The theoretical upper limit of $(BH)_{\max}$ is given by $(BH)^{\mathrm{theo}}_{\max} \approx J_\mathrm{r}^2/(4\mu_0)$ as long as the condition $\mu_0 H_\mathrm{c} > 0.5 J_\mathrm{r}$ is fulfilled. Typical hard magnetic materials are based on RE-TM compounds, hard ferrites, AlNiCo, and CoPt/FePt.

Soft magnetic materials enable amplification of the flux produced by an electrical current considerably, therefore being important in any application involving a change in magnetic induction. They are characterized by low coercivity ($\mu_0 H_\mathrm{c} \approx 0.2\,\mu\mathrm{T}$–$1.25\,\mathrm{mT}$, $H_\mathrm{c} \approx 0.16$–$1000\,\mathrm{A\,m^{-1}}$), high (initial) permeability $\mu_\mathrm{i} = \mathrm{d}B/\mathrm{d}(\mu_0 H)$ or (initial) susceptibility $\chi_0 = \mathrm{d}M/\mathrm{d}H = \mu_\mathrm{i} - 1$ ($\mu_\mathrm{i} \approx \chi_0 \approx 10^5$–$10^6$ for $H \to 0$) which describe the response of magnetic materials to a small magnetic field, therefore indicating how much magnetic induction B is generated by the material in a given magnetic field strength H and low high-frequency losses. The characteristics usually go along with low conductivity and small magnetostriction which describes the change of the shape of a ferromagnetic specimen during the magnetization process. Soft magnets are based on Fe, Fe–Si, Fe–Ni (permalloy), Fe–Co ((su)permendur), soft ferrites, and metallic glasses.

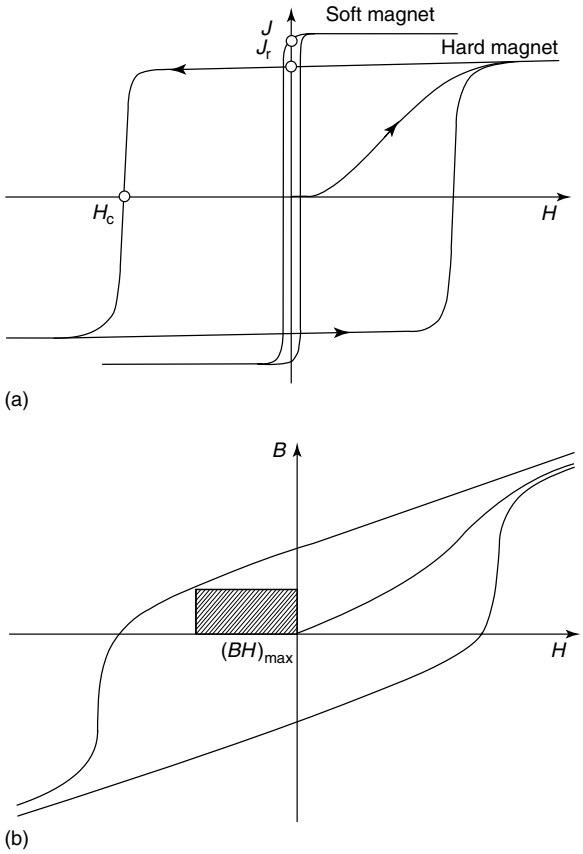

Figure 1. Characteristic magnetic properties: (a) $J(H)$ hysteresis loop with coercivity H_c and remanence J_r for typical soft and hard magnetic materials. (b) $B(H)$ hysteresis loop with the maximum energy product, that is, the maximum rectangular area within the loop in the second quadrant.

In addition to hard and soft magnetic materials, there exists a number of sophisticated magnetic materials with unusual properties like giant magnetostriction (see also **Magnetostrictive Materials and Magnetic Shape Memory Materials, Volume 4**), giant magnetoresistance, and giant magnetoimpedance.

3 MICROSTRUCTURE

Depending on whether the atoms of a magnet are arranged spatial periodically in crystal lattices or randomly, the magnetic material is crystalline or amorphous. Whereas in the former case, the distances between nearest neighbors are constant (short-range atomic order) and a base lattice is regularly repeated (long-range atomic order), in the latter case only short-range ordering occurs. Therefore, the interference pattern of crystalline magnets resulting from X-ray, electron, or neutron diffraction is sharp and reflects the symmetry of the crystal lattice. In contrast, only diffuse interference patterns are observed for amorphous magnets for small diffraction angles. In general, all solids are of a finite extension and show unavoidable disordering in the volume. These deviations from the ideal crystalline or amorphous structure (ideal microstructure) are called defect structures (real microstructure) and result in inhomogeneities of the intrinsic material parameters which influence the magnetic properties of the material decisively.

3.1 Crystalline magnets

A crystalline magnet whose crystal lattice shows perfect translational periodicity is called a single crystal. Correspondingly, a polycrystal consists of many single crystalline grains of different orientations. Depending on whether the grain size is on the micrometer or nanometer scale the polycrystalline magnets are microcrystalline or nanocrystalline, respectively. The defect structures in crystalline magnets are classified according to their geometrical extensions into point defects (zero dimensional), dislocations (one dimensional), planar defects (two dimensional), and volume defects (three dimensional). Single crystalline magnets contain only point defects and dislocations; in polycrystalline magnets planar defects may additionally occur. Volume defects such as pores or cracks are macroscopic defects and will not be taken into account in this article.

Point defects (Figure 2a) are atomic defects such as vacancies, self-interstitials, impurity interstitials, substitutional impurity atoms, or atomic disorder in ordered alloys resulting in lattice distortions.

Dislocations mostly appear as edge and screw dislocations or as a mixture of both. An edge dislocation (Figure 2b) is characterized by an additional net plane which ends within the bulk of the crystal. The line direction **l** of the inner edge of this half-plane is perpendicular to the Burgers vector **b** described by the distance between net planes. A screw dislocation (Figure 2c) corresponds to a shear deformation where one part of the crystal is displaced by a nearest neighbor distance with respect to the other part. The line direction **l** and the Burgers vector **b** are parallel to each other. The stress fields of dislocations are of long-range type and vary as $1/r$.

Planar defects may appear abruptly as it is the case for phase boundaries and twin boundaries or are of one or several atomic widths as it is the case for stacking faults, antiphase boundaries in intermetallics, and grain boundaries. At a phase boundary (Figure 3a) between two different phases the intrinsic material parameters change abruptly. When the lattices between the two phases match perfectly the phase boundary is called coherent, otherwise incoherent. Two phase boundaries may form precipitations as in $Sm_2(Co,Cu,Fe,Zr)_{17}$ permanent magnets (Figure 3c) where a three-phase precipitation nanostructure develops in a self-organized process during a complex annealing procedure and consists of Fe-rich cells, Cu-rich cell walls, and Zr-rich lamellae. At a twin boundary (Figure 3b) two grains are grown together at a common interface and the lattice periodicity is interrupted at the interface without displacement of the lattice atoms. Stacking faults (Figure 4a) occur when in close-packed lattices the stacking sequence is disturbed, for example, ABCACABC instead of ABCABCA. When the stacking fault is not extended over the whole grain

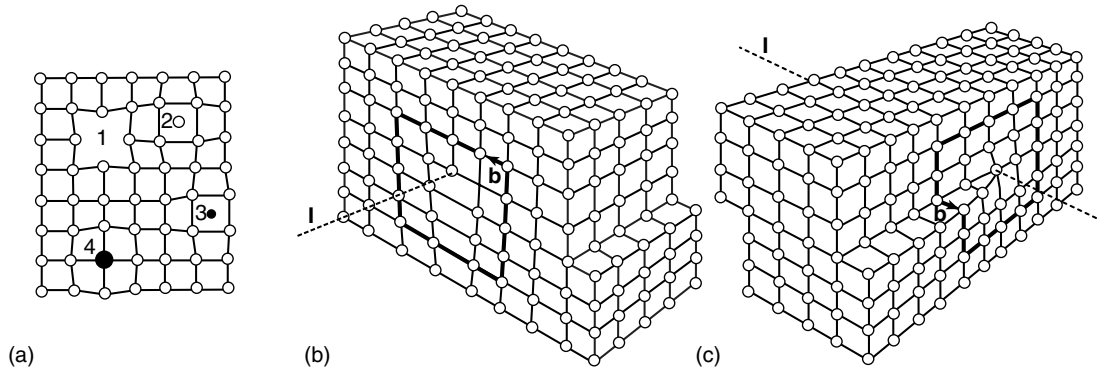

Figure 2. Schematic models of point defects and dislocations: (a) Point defects (1: vacancy, 2: self-interstitial, 3: impurity interstitial, 4: substitutional impurity atom), (b) edge dislocation (**l** $\perp$ **b**), and (c) screw dislocation (**l**$\|$**b**).

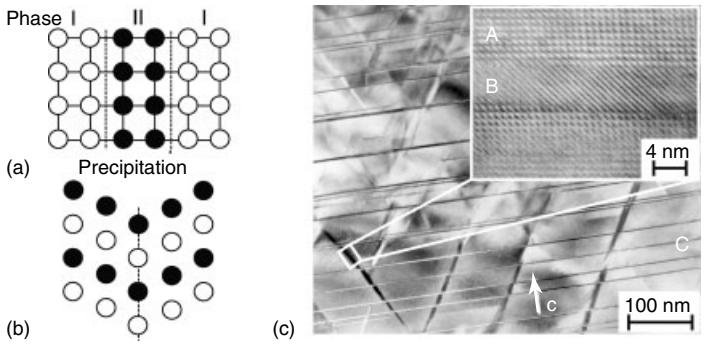

Figure 3. Abrupt planar defects: (a) Atomic configuration of a phase boundary. (b) Atomic configuration of a twin boundary. (c) Phase boundaries leading to precipitations in $Sm_2(Co,Cu,Fe,Zr)_{17}$ micrometer-scaled hard magnetic grains (A: Fe-rich 2:17 cells, B: Cu-rich 1:5 cell walls, C: Zr-rich lamellae). (Reproduced from D. Goll, H. Kronmüller, and H.H. Stadelmaier: Micromagnetism and the microstructure of high-temperature permanent magnets, *J Applied Physics*, **96** (2004), copyright © 2004 American Institute of Physics, with permission from the AIP.)

but ends along a line, the limiting line corresponds to an incomplete dislocation where the length of the Burgers vector is smaller than the distance between net planes. Antiphase boundaries (Figure 4b) are characterized by an abrupt change in the lattice of multiatomic alloys so that atoms of the same kind become neighbored.

For grain boundaries between single crystalline grains of different orientations there exists a variety of atomic structures. For a small twist angle θ between the orientations of two neighboring grains the interface is a low-angle grain boundary based on a regular dislocation structure. In the easiest case, a linear array of edge dislocations of distance d compensates the twist angle θ ($b/d = 2\sin\theta/2 \approx \theta$) as illustrated in Figure 5(a). An array of screw dislocations or mixed arrays result in more complex low-angle grain boundaries. For larger misorientation angles ($\theta > 15^\circ$), high-angle grain boundaries occur where the regular arrangement of dislocations is missing and the boundary region of about 2 nm in size is strongly disturbed. In the case of complete disorder the structure of the grain boundary becomes amorphous (Figure 5b). This intergranular film is independent of the orientation of the grains and can be regarded as a cement that holds the grains together. In the case of thermal equilibrium, high-angle grain boundaries may show some kind of periodicity in the strongly disturbed boundary region (Figure 5c). As an example for grain boundaries, in Figure 6 three different kinds of nanostructures are shown for $RE_2Fe_{14}B$ (RE = Nd, Pr) based permanent magnets where grain boundaries between grains of different orientations and different phases.

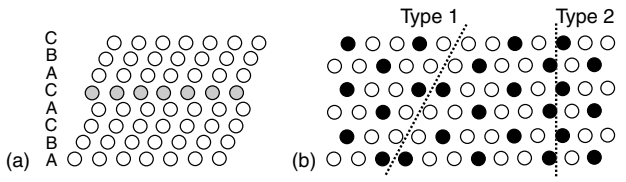

Figure 4. Extended planar defects: (a) Stacking fault (intrinsic, when one plane is missing; extrinsic, when one plane is added). (b) Two types of antiphase boundaries of hexagonal $SmCo_5$ showing the changes of nearest neighbor interactions.

3.2 Amorphous magnets

Amorphous magnets are also called glassy or noncrystalline magnets. The ideal amorphous state and also the liquid state of the melt are characterized by statistical intrinsic fluctuations of the mass density, known as free or antifree volumes (Cohen and Turnbull, 1959; Egami, Maeda and Vitek, 1980), and therefore by intrinsic fluctuations of the intrinsic material parameters, especially of the exchange energy and the local magnetic anisotropy. The free volumes result from vacant spaces between topologically disordered atoms. The intrinsic fluctuations lead to inhomogeneities in the orientation of the spontaneous polarization. All deviations from this are considered as defect structures in the amorphous material. The defect structures in amorphous magnets result from atomic rearrangements during the quenching process which lead to a chemical short-range order, to magnetic aftereffects, or to agglomerations of the free or antifree volumes providing internal stress sources therefore being restricted to magnetorestrictive amorphous materials. The quenched-in defect structures are the reason for the metastable character of the amorphous state. They can be classified into intrinsic defects which are stable below the crystallization temperature and extrinsic defects which recover during an annealing treatment below the crystallization temperature.

Especially the formation of chemical short-range order without loss of the topological amorphous state has its origin in magnetic annealing effects and the tendency for crystallization of the amorphous metastable state. Within small clusters of chemically ordered regions atomic metal–metal pairs of different metal atoms (e.g., Ni–Fe) may exist

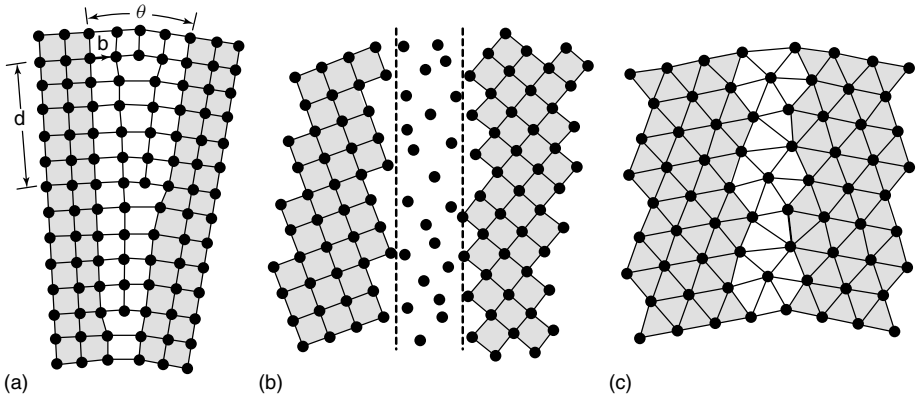

Figure 5. Grain boundaries: (a) Low-angle grain boundary of parallel edge dislocations with constant distances d compensating the twist angle θ between two grains misoriented relative to each other. (b) High-angle grain boundary (amorphous case). (c) High-angle grain boundary (thermal equilibrium).

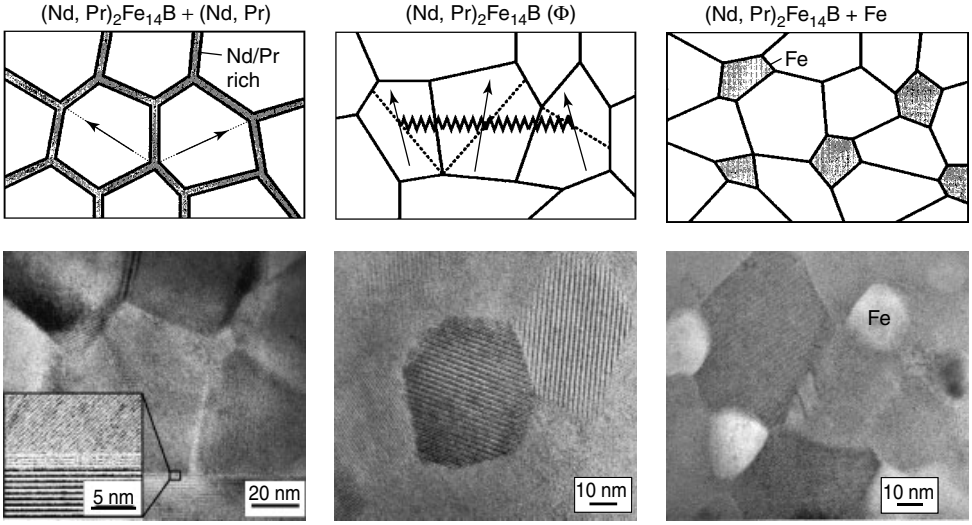

Figure 6. Grain boundaries between grains of different orientations and different phases exemplary for nanocrystalline $RE_2Fe_{14}B$ (RE = Nd,Pr) based permanent magnets. $RE_2Fe_{14}B$+(Nd,Pr) (high-coercivity magnet): Decoupled magnet where the hard magnetic $RE_2Fe_{14}B$ grains are magnetically isolated by the overstoichiometric RE which forms an amorphous paramagnetic interlayer that holds the grains together. $RE_2Fe_{14}B$ (high-coercivity, high-remanence magnet): Stoichiometric magnet where the hard magnetic $RE_2Fe_{14}B$ grains are in direct contact with each other. The exchange interaction in between induces a magnetic texture. $RE_2Fe_{14}B$+Fe (high-remanence magnet): Composite magnet with overstoichiometric Fe resulting in additional soft magnetic Fe grains which are exchange coupled to the hard magnetic $RE_2Fe_{14}B$ grains (exchange hardening) (Goll, Seeger and Kronmüller, 1998; Goll and Kronmüller, 2000).

which are aligned parallel to the spontaneous polarization, thus, giving rise to an induced magnetocrystalline anisotropy (Luborsky and Walter, 1977; Fujimori, Obi, Masumoto and Saito, 1976).

On the other hand, agglomerations of free or antifree volumes created during rapid quenching of the melt are rather stable with respect to annealing treatments and therefore cannot be removed completely from the material (Kronmüller, 1981b). They have their origin in the partial instability of the free volumes below the melting point. Relaxations of the dispersed free volumes by themselves result in quasi-point defects with short-range elastic stress fields varying as $1/r^3$ (Figure 7a). By a relaxation of the atomic network, the vacancy clusters may collapse locally and therefore generate planar defects which are equivalent to dislocation dipoles exerting short-range elastic stress fields varying as $1/r^2$ (Figure 7b). If the arrangement of the quasidislocation dipoles is correlated with a gradient in density along one direction, then uncompensated poles exist over large distances and also generate long-range elastic stress fields varying as $1/r$ (Figure 7c).

Local structural relaxation effects may result in magnetic aftereffects which are thermally activated processes. As shown in Figure 8(a), by a small displacement of the free

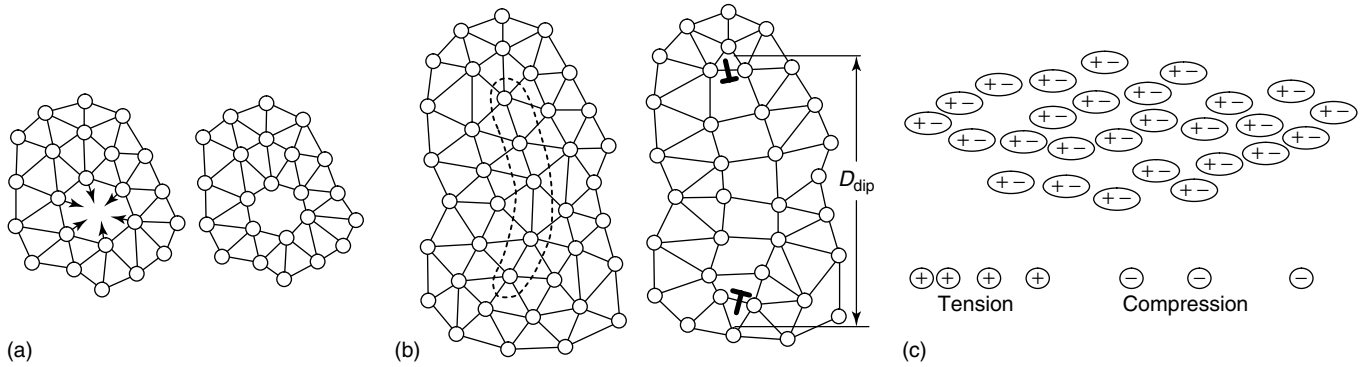

Figure 7. Agglomerations of free or antifree volumes: (a) Vacancy type defect in the unrelaxed and relaxed network model. (b) Two-dimensional model of a quasidislocation dipole formed by agglomerated free volumes. (c) Long-range stresses due to an inhomogeneous arrangement of dislocation dipoles.

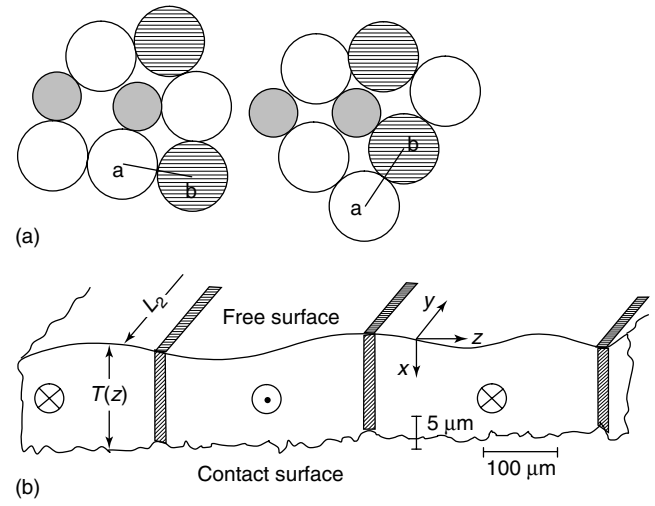

Figure 8. (a) Structural reorientation of the atom pair a–b by means of the free volume. (b) Amorphous ribbon with fluctuating thickness $T(y, z)$ showing a large surface roughness on the contact surface (wavelength $\lambda \approx 10\,\mu m$) and a weak surface roughness on the free surface (wavelength $\lambda \approx 100\,\mu m$).

volume the atom-pair axes are reoriented. Such reorientations lead to a decrease of the magnetic energy depending on the orientation of the spontaneous polarization and the atom-pair axes.

The surface irregularities due to the natural surface roughness of rapidly quenched amorphous magnets can be regarded as macroscopic defect structures. The thickness fluctuations of the ribbons are due to the uneven surface of the roller as well as inhomogeneous solidification processes on the free surface (Becker, 1981; Wang and Kronmüller, 1982). Whereas the contact surface between the ribbon and the roller according to Figure 8(b) reveals a large surface roughness, on the free surface only a weak surface roughness is observed.

4 MICROMAGNETISM AND MAGNETIZATION PROCESSES

The theory of micromagnetism (see also **General Micromagnetic Theory, Volume 2**) developed by Landau and Lifshitz (1935) and Brown (1940) is a rather effective tool for the description of magnetization processes (including magnetic domain patterns) (see also **Magnetization Configurations and Reversal in Small Magnetic Elements, Volume 2**) and characteristic properties of the hysteresis loop of ferromagnetic materials. The validity of this continuum theory ranges on a length scale which is large compared to typical atomic distances but small in comparison to macroscopic sample dimensions. With the theory of micromagnetism, the orientation of the spontaneous polarization J_s can be determined as a function of position r and external field H_{ext} by minimizing Gibbs total energy and solving the resulting micromagnetic equations.

4.1 Single-domain particles

Single-domain particles are homogeneously magnetized particles. The hysteresis loop of a single-domain particle corresponds to a rectangular loop (Figure 9a) when the magnetic field is applied parallel to the easy axis. For a certain opposite field, the nucleation field H_N, the magnetization of the particle switches spontaneous irreversibly into the opposite direction. The nucleation field depends on the type of nucleation mode that initiates the reversal of the magnetization. The three most important nucleation modes are coherent rotation, curling, and buckling. They are represented in Figure 9(c–e) for an infinite cylinder. The coherent rotation mode corresponds to homogeneous rotation of the magnetization and is characterized by vanishing exchange energy but magnetic stray field components. The curling mode corresponds to a

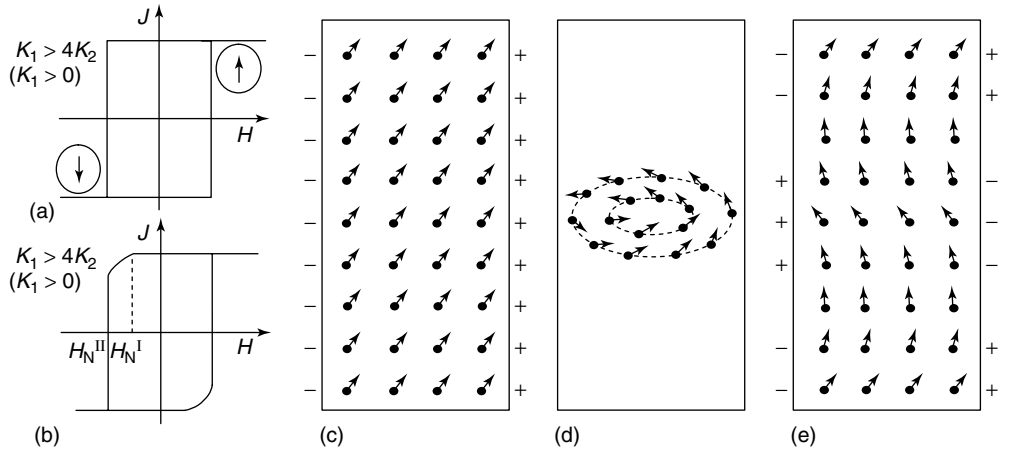

Figure 9. Hysteresis loop of a single-domain particle with easy axis parallel to the applied field: (a) $4|K_2| < |K_1|$ and (b) $4|K_2| > |K_1|$. Nucleation modes of an infinite cylinder (Frei, Shtrikman and Treves, 1957): (c) homogeneous rotation, (d) curling, and (e) buckling.

magnetization orientation perpendicular to the radial vector, that is, there exists no radial component of the magnetization anywhere in the particle, and is characterized by a vanishing stray field energy but nonvanishing exchange energy. The buckling mode corresponds approximately to homogeneous rotation for each cross section with sinusoidal variation of the amplitude along the cylinder axis where the alternating surface charges lead to an increase of the exchange energy which, however, is overcompensated by the gain in stray field energy.

The reversal process is governed by the nucleation mode with the smallest nucleation field. Therefore, the buckling mode is not important in practice.

For a single-domain particle of rotational-ellipsoidal shape and demagnetization factors $N_{||}$ and $N_\perp$ parallel and perpendicular to the easy axis the nucleation field H_N is obtained as eigenvalue of the linearized micromagnetic equations (with constant material parameters J_s, K_1, and A) (Aharoni and Shtrikman, 1958; Brown, 1963; Frei, Shtrikman and Treves, 1957):

$$H_N^{\text{coherent}} = \frac{2K_1}{J_s} - (N_{||} - N_\perp)\frac{J_s}{\mu_0}$$
$$H_N^{\text{curling}} = \frac{2K_1}{J_s} - N_{||}\frac{J_s}{\mu_0} + 2\pi k\frac{A}{R^2 J_s} \qquad (1)$$

with $k = 1.08$ for an infinite cylinder and $k = 1.38$ for a sphere. In other words, whereas the coherent rotation mode is independent of the particle size R, the nucleation field in the case of the curling mode decreases with increasing particle size. This means that for small single-domain particles, nucleation takes place by the coherent rotation process and for larger single-domain particles by the curling process. The critical particle diameter D_{crit} for which the nucleation field of both processes becomes equal is given by

$$D_{\text{crit}} = 2\sqrt{\pi k}\sqrt{\frac{2\mu_0 A}{N_\perp J_s^2}} \qquad (2)$$

A completely different reversal behavior occurs when the anisotropy constant K_2 gains in influence ($4|K_2| > |K_1|$) (Figure 9b). Then the magnetization rotates reversibly out of the easy axis at $H_N^{\text{I}} = H_N^{\text{coherent}}$ and the instability field for irreversible demagnetization is (Kronmüller, 1985; Herzer, Fernengel and Adler, 1986)

$$H_N^{\text{II}} = \frac{8K_2}{3\sqrt{3}J_s}\left(1 + \frac{K_1 + J_s^2(N_\perp - N_{||})/\mu_0}{2K_2}\right)^{3/2} \qquad (3)$$

4.2 Multidomain particles

A multidomain particle is subdivided into homogeneously magnetized domains, in which the magnetization is oriented along an easy axis. The transition region between two domains, which ranges over several lattice planes, is called domain wall. Domain formation reduces the stray field energy, whereby the gain in stray field energy is larger than the exchange energy and magnetocrystalline anisotropy energy needed for domain wall formation, because the magnetic moments in the walls are oriented neither parallel to each other nor along an easy axis. The resulting domain configuration always corresponds to a minimum total magnetic energy.

In the case of 180° domain walls separating two domains with magnetization direction oriented antiparallel to each other, two different types of domain walls may occur – Bloch walls producing surface charges and Néel walls producing volume charges (Figure 10a). The energy of the two wall

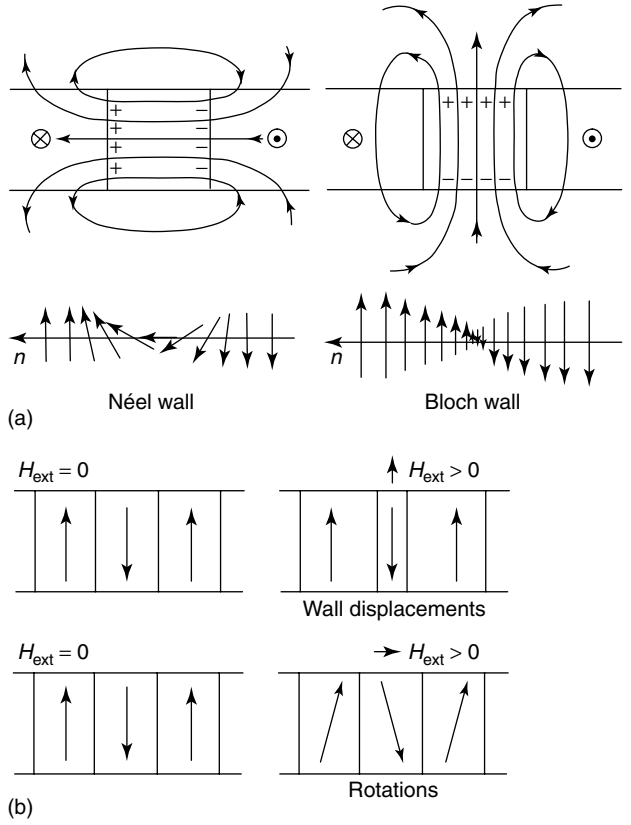

Figure 10. (a) Magnetization distribution in a Néel wall and a Bloch wall. (b) Two types of magnetization processes (wall displacements and rotations of the magnetization) due to the application of an external magnetic field.

types depend decisively on the particle dimensions. In the case of a macroscopic sample (sample dimension $\gg$ domain wall thickness), the Bloch wall is stray field free as its surface charges can be neglected. In the case of a thin film (sample dimension $\ll$ domain wall thickness), the Néel wall is stray field free as its volume charges can be neglected. According to the theory of micromagnetism the wall energy γ and the wall thickness δ are for the stray field free wall given by

$$\gamma = 4\sqrt{AK_1} \quad \text{and} \quad \delta = \pi\sqrt{A/K_1} \tag{4}$$

In general, the wall of the smallest stray field energy is energetically preferred. The critical particle dimension for which the Bloch and Néel wall become energetically equal is given by $D_{\text{crit}} = 0.14\sqrt{A/K_1}$ (Hubert, 1974) where the exchange length $l_{\text{K}} = \sqrt{A/K_1}$ is a measure for the distance over which a inhomogeneity in a homogeneous magnetization distribution is lowered to $1/e$.

By applying an external magnetic field a multidomain particle can be magnetized by two types of magnetization processes, wall displacements and rotations (Figure 10b). In the case of wall displacements, the applied field leads to a force on the domain wall so that domains which are oriented in field direction start growing at the expense of the other domains. In the case of rotations, the applied field leads to a torque $J_{\text{s}} \times H$ on the magnetization resulting in a magnetization rotation into field direction. When the magnetic field is applied perpendicular (parallel) to a lamellar domain structure, rotations (wall displacements) are dominating resulting in flat-type (more rectangular-shaped) hysteresis loops with small (large) $J_{\text{r}}/J_{\text{s}}$ ratios.

4.3 Critical particle sizes for single domain behavior

As long as the gain in stray field energy is smaller than the wall energy needed, domain formation does not occur and the single-domain state is energetically favored. This is the case for particle sizes smaller than a critical diameter D_{crit} (Kittel, 1946). For middle-hard and hard magnetic materials, the magnetic energies of the single-domain state (stray field energy) and the two-domain state (stray field energy and wall energy) become equal at $D^{\text{sd}}_{\text{crit}}$ so that the single-domain state becomes unstable and transforms into the two-domain state. For a particle of ellipsoidal shape, from the energy balance of the two states at $D^{\text{sd}}_{\text{crit}}$ (a, b: short, long axis of an ellipsoid)

$$\frac{1}{2\mu_0} N_{||} J_{\text{s}}^2 \frac{4\pi}{3} a^2 b = \pi a b \gamma_{\text{B}} + \alpha \frac{1}{2\mu_0} N_{||} J_{\text{s}}^2 \frac{4\pi}{3} a^2 b \tag{5}$$

the critical particle diameter follows as

$$D^{\text{sd}}_{\text{crit}} = 2a = \frac{3\gamma_{\text{B}}\mu_0}{N_{||}(1-\alpha)J_{\text{s}}^2} \tag{6}$$

The parameter α denotes a factor by which the stray field energy of the two-domain state is reduced compared to the single-domain state. For a spherical particle where $N_{||} = 1/3$ and $\alpha = 0.47 \approx 1/2$ (Goll, Berkowitz and Bertram, 2004) the critical particle diameter is given by $D^{\text{sd}}_{\text{crit}} = 18\gamma_{\text{B}}\mu_0/J_{\text{s}}^2$. For platelets with $N_{||} \approx 1$, D_{crit} turns out to be a factor of 3 smaller than for spherical particles. For needle-type particles with $N_{||} \ll 1$ the critical particle diameter becomes largest which makes them important for magnetic recording systems. For hollow spherical particles characterized by an inner and an outer particle diameter ($\varepsilon = D^{\text{i}}/D^{\text{o}}$) the critical particle diameter also increases for increasing ε ratios. For soft magnetic materials at D_{crit} the single-domain state transforms into a vortex state.

To guarantee thermal stability of single-domain particles for time intervals of decades the particle size must be larger than the critical diameter $D^{\text{theor}}_{\text{crit}}$. Otherwise, reversion of the polarization J_{s} is induced by the thermal fluctuation energy kT of the thermally excited spin system. According to

Néel (1950) the lifetime of a ferromagnetic particle of volume V follows an Arrhenius law $\tau = \tau_0 \exp(K_{\text{eff}} V/(kT))$ where $K_{\text{eff}} = K_1 + 1/(2\mu_0)(N_\perp - N_{||})J_s^2$ is the effective anisotropy constant of an ellipsoidal particle and τ_0 denotes the resonance relaxation time of the spin system which is approximately given by $\tau_0^{-1} = \gamma H_{\text{eff}}/(2\pi)$ (γ: gyromagnetic ratio, $H_{\text{eff}} = 2K_{\text{eff}}/J_s$). For a hard magnetic particle as FePt ($K_{\text{eff}} = 6.6 \times 10^6\,\text{J m}^{-3}$, $\tau_0 = 3.1 \times 10^{-12}\,\text{s}$) the lifetime amounts to $\tau = 0.1\,\text{s}$ for $D = 3\,\text{nm}$ and to $\tau = 10^{10}$ s for $D = 3.9\,\text{nm}$. For a soft magnetic particle as Fe ($K_{\text{eff}} = 4.6 \times 10^4\,\text{J m}^{-3}$, $\tau_0 = 6.7 \times 10^{-10}\,\text{s}$) the lifetime is given by $\tau = 0.1\,\text{s}$ for $D = 14.8\,\text{nm}$ and by $\tau = 10^{10}$ s for $D = 19.6\,\text{nm}$. In any case, there exists a very narrow range of diameters where the transition from a thermally unstable to a thermally stable state takes place.

5 HARD MAGNETIC MATERIALS: MICROMAGNETISM AND MICROSTRUCTURE

The RE-TM intermetallics (RE–Fe–B: $Nd_2Fe_{14}B$, $Pr_2Fe_{14}B$; Sm–Co: $SmCo_5$, $Sm_2(Co,Cu,Fe,Zr)_{17}$; Sm–Fe: $Sm_2Fe_{17}N_3$, $Sm_2Fe_{15}Ga_2C_2$) (see also **Rare-earth Nanocrystalline and Nanostructured Magnets, Volume 4**; **Dilute Magnetic Oxides and Nitrides, Volume 4**) are the most promising hard magnetic materials at present where the high spontaneous polarization J_s and Curie temperature T_C of the transition metals (TM = Fe, Co) are combined with high magnetocrystalline anisotropy K_1 of the rare-earth metals (RE = Nd, Pr, Sm) resulting in exceptional intrinsic magnetic properties ($J_s > 1.2$ T, $T_C > 250\,^\circ\text{C}$, $K_1 > 10^6\,\text{J m}^{-3}$). The highest $(BH)_{\max}$ values are currently supplied by the ternary intermetallics $RE_2Fe_{14}B$ (RE = Nd, Pr) ($(BH)_{\max} = 450\,\text{kJ m}^{-3}$) at room temperature and by the quinary intermetallic $Sm_2(Co,Cu,Fe,Zr)_{17}$ ($(BH)_{\max} = 100\,\text{kJ m}^{-3}$ at $400\,^\circ\text{C}$) at elevated temperatures. Hard ferrites of the type $(Ba/Sr)Fe_{12}O_{19}$ (Kojima, 1982) are considered as ceramic hard magnets with a low crystal symmetry which results in a high (uniaxial) magnetocrystalline anisotropy ($K_1 = 0.3\,\text{MJ m}^{-3}$, $J_s = 0.47$ T, $T_C = 450\,^\circ\text{C}$, $(BH)_{\max} = 23\,\text{kJ m}^{-3}$). AlNiCo magnets (Mc Currie, 1982) owe their hard magnetic properties to the shape anisotropy of small elongated ferromagnetic FeCo particles precipitated in a weakly magnetic AlNi matrix ($K_1 = 0.04\,\text{MJ m}^{-3}$, $J_s = 1.2$ T, $T_C = 860\,^\circ\text{C}$, $(BH)_{\max} = 45\,\text{kJ m}^{-3}$). FePt and CoPt based permanent magnets (Buschow, 1997) ($(BH)_{\max} = 200\,\text{kJ m}^{-3}$) reveal their high (uniaxial) magnetocrystalline anisotropies ($6.6\,\text{MJ m}^{-3}$ and $4.9\,\text{MJ m}^{-3}$, respectively) from an ordered face-centered tetragonal phase (L_{10} phase) which develops at lower temperatures from a disordered face-centered cubic phase.

Hard magnets are manufactured by two principle processing routes – sintering (see also **Rare-earth Transition-metal Magnets, Volume 4**) and melt spinning (see also **Rare-earth Nanocrystalline and Nanostructured Magnets, Volume 4**) (instead of spinning sometimes mechanical alloying or HDDR (hydrogenation, disproportionation, desorption, and recombination) are used). Sintering leads to anisotropic (textured) microcrystalline magnets with multidomain particles of size 1–20 μm whose easy axes are oriented along one direction. Sintered magnets have to be after-treated by sawing or grinding. Melt spinning results in isotropic nanocrystalline magnets with single-domain particles of size 10–200 nm whose easy axes are isotropically distributed. The nanocrystalline ribbons can be powderized and bonded with epoxy to form isotropic polymer bonded magnets of any final shape without expensive after-treatments. For nanocrystalline permanent magnets three different types of nanostructures can be distinguished: high-coercivity magnets where the grains are magnetically decoupled by a paramagnetic intergranular film; high-remanence–high-coercivity magnets where the hard magnetic grains are magnetically coupled by exchange interactions which induce a magnetic texture; and high-remanence magnets with a mixture of hard and soft magnetic grains where in addition to the effect of exchange coupling between the grains the large polarization of the soft magnetic grains also enhances the remanence by exchange hardening. All three types of nanostructures can be realized for $(Nd,Pr)_2Fe_{14}B$ based magnets by a suitable choice of the chemical composition from the phase diagram as shown in Figure 6 ($(Nd,Pr)_2Fe_{14}B$ + (Nd,Pr): decoupled magnets, $(Nd,Pr)_2Fe_{14}B$: stoichiometric magnets, $(Nd,Pr)_2Fe_{14}B$ + Fe: composite magnets). Another type of nanostructure develops in a self-organized process during a complex annealing procedure in $Sm_2(Co,Cu,Fe,Zr)_{17}$ which is illustrated in Figure 3(c) with the cell walls providing effective planar pinning sites for domain walls which may result in exceptional coercivity values up to elevated temperatures.

Owing to economic aspects, hard ferrites account for half the value of all permanent magnets worldwide. The other half of the market is mostly for RE magnets with their maximum energy products up to 15 times larger than for ferrites. Until now, sintering has been the commercially most important process. However, melt spinning combined with polymer bonding is gaining in importance, especially in the case of $RE_2Fe_{14}B$ (RE = Nd, Pr).

5.1 Coercivity

The large coercive fields of permanent magnets and, therefore, the magnetic hardening are alternatively accomplished by two basic mechanisms – reversal of the magnetization

by nucleation of reversed domains (nucleation mechanism) or reversal of the magnetization by displacement of pinned domain walls (pinning mechanism). For both hardening mechanisms the coercivity can be well described in the framework of the theory of micromagnetism by the universal relation (Kronmüller, 1987; Sagawa und Hirosawa, 1987; Kronmüller and Fähnle, 2003)

$$\mu_0 H_c = \mu_0 \alpha \frac{2K_1}{J_s} - N_{\text{eff}} J_s \tag{7}$$

where the parameters α and N_{eff} which may in turn depend on the intrinsic material parameters include the influence of the microstructure on the coercivity. The microstructure is the reason for Brown's paradox (Brown, 1945), that is, the experimentally realized coercivities as shown in Figure 11(a) in general amount a factor of $3-5$ smaller than the ideal nucleation field $\mu_0 H_N = 2K_1/J_s$ of a spherical single-domain particle whose magnetization is reversed by an irreversible homogeneous rotation process ($\alpha = 1$, $N_{\text{eff}} = 0$ in equation (7)).

Depending on the particle size the effect of the microstructure on the coercivity can be quite different (Figure 11b). Whereas in the case of nucleation hardening (single-domain range) crystal imperfections reduce the coercivity, in the case of pinning hardening (multidomain range) imperfections increase the coercivity due to the pinning effect of the domain walls. It is nowadays generally accepted that in $(Nd,Pr)_2Fe_{14}B$, $SmCo_5$ and conventional ferrite magnets the nucleation mechanism governs the coercivity, whereas in $Sm_2(Co,Cu,Fe,Zr)_{17}$ type magnets domain wall pinning processes are dominant.

For both hardening mechanisms, the demagnetization factor N_{eff} is due to the locally enhanced stray fields occurring at edges and corners of the grains which cannot be described by the demagnetizing factors $N_\perp$ and $N_{||}$ any more.

5.1.1 Nucleation

Nucleation is initiated in inhomogeneous boundary regions and occurs only for magnets consisting of single-domain nanoparticles or of micrometer-scaled multidomain particles with a small defect density. The latter particles behave (once saturated) like single-domain particles until reaching the coercivity as their nucleation field is much larger than the macroscopic demagnetizing field. In the case of nucleation hardening the microstructural parameter $\alpha = \alpha_K \alpha_\psi \alpha_{ex}$ can be subdivided into three parameters.

a Nucleation in magnetically inhomogeneous regions (parameter α_K): The crystal structure of the hard magnetic grains is not perfect throughout the grains. There exist surface

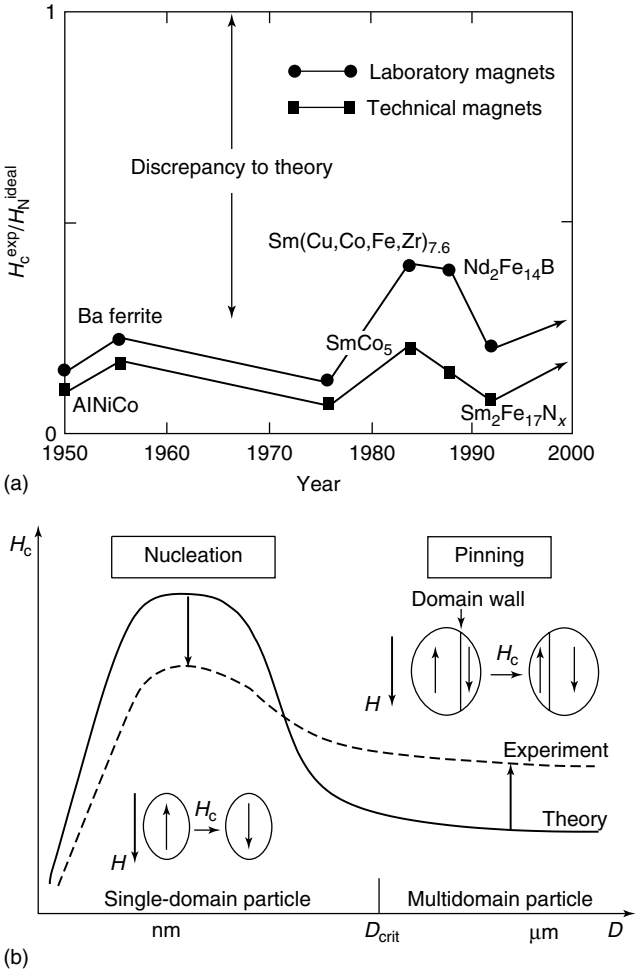

Figure 11. (a) Brown's paradox: The experimentally realized coercivities amount to a factor of $3-5$ smaller than the ideal nucleation field. (b) Schematic representation of the coercive field as a function of the particle size D (———ideal magnet with perfect particles, - - - - real magnet with imperfect particles).

regions where the atomic lattice is distorted by stresses and/or the stoichiometry has changed due to diffusion processes, especially when different phases are neighbored. As a consequence, the crystal anisotropy is locally reduced in the surface regions leading to a reduction of the nucleation field by a factor α_K (as the inhomogeneous regions influence K_1 much stronger than J_s or A, the two latter parameters can be regarded as constants). For the one-dimensional model potential

$$K_1(z) = K_1(\infty) - \frac{\Delta K}{\cosh^2(z/r_0)} \tag{8}$$

which is illustrated in Figure 12(a–b) for a planar grain boundary, the microstructural parameter α_K has been calculated analytically by Kronmüller (1987) from the

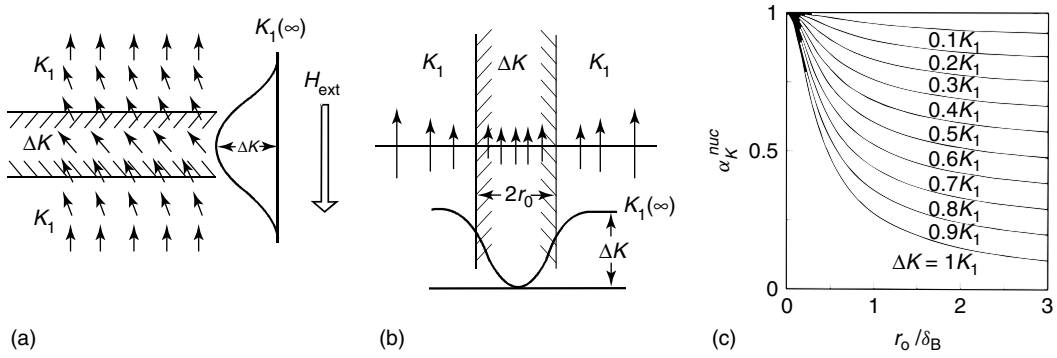

Figure 12. Nucleation of a reversed domain within a planar intergranular phase of reduced anisotropy of width $2r_0$: (a) Stripe perpendicular to the direction of the applied field. (b) Stripe parallel to the direction of the applied field. (c) Microstructural parameter α_K as a function of r_0/δ_B for different ΔK.

micromagnetic equations

$$\alpha_K = 1 - \frac{\delta_B^2}{4\pi^2 r_0^2}\left(1 - \sqrt{1 + \frac{4\pi^2 r_0^2}{\delta_B'^2}}\right)^2$$

$$= \begin{cases} 1 - \pi^2 \dfrac{\delta_B^2}{\delta_B'^4} r_0^2 & \text{for} \quad r_0 \ll \delta_B \\ \dfrac{1}{\pi}\dfrac{\delta_B^2}{\delta_B'}\dfrac{1}{r_0} + \dfrac{K_1 - \triangle K}{K_1} & \text{for} \quad 2\pi r_0 \geq \delta_B \\ \dfrac{K_1 - \triangle K}{K_1} & \text{for} \quad r_0 \gg \delta_B \end{cases} \qquad (9)$$

where $K_1 = K_1(\infty)$ is the anisotropy constant inside the grain, ΔK denotes the relative reduction at the grain surface, $2r_0$ describes the extension of the magnetic defect, $\delta_B = \pi\sqrt{A/K_1(\infty)}$ is the wall width of the perfect crystal and $\delta_B' = \pi\sqrt{A/\Delta K}$ corresponds to a fictitious wall width of a material with anisotropy ΔK. For $\Delta K \approx K_1$ the three limiting cases are given by $\alpha_K = 1 - \pi^2 r_0^2/\delta_B^2$, $\alpha_K = \delta_B/(\pi r_0)$, and $\alpha_K = 0$.

The nucleation field in the first limit corresponds approximately to the ideal nucleation field and in the third limit to the nucleation field of the inhomogeneous (soft magnetic region). For the second limit the nucleation field writes

$$H_N = \frac{2K_1}{J_s}\frac{\delta_B}{\pi r_0} - \frac{N_{eff} J_s}{\mu_0} = \frac{\gamma_B}{2J_s}\frac{1}{r_0} - \frac{1}{\mu_0} N_{eff} J_s \qquad (10)$$

where $\gamma_B = 4\sqrt{AK_1}$ describes the wall energy per unit area. In Figure 12(c), α_K is presented as a function of r_0/δ_B and for ΔK as a parameter.

b Nucleation field of misaligned grains (parameter α_ψ): If the magnetic field is applied under an angle ψ_0 with respect to the negative c axis of a uniaxial single-domain particle the nucleation field is reduced by a factor α_ψ. Owing to the misalignment the hysteresis loop shows deviations from the ideal rectangular shape as shown in Figure 13(a). The spontaneous polarization starts immediately to rotate reversibly until the rotation angle reaches the critical angle θ_N (Stoner and Wohlfarth, 1948; Kronmüller, Durst and Martinek, 1987)

$$\theta_N = \arctan\sqrt[3]{\tan\psi_0} + \frac{2}{3}\frac{K_2}{K_1 + (N_{||} - N_\perp)J_s^2/(2\mu_0)} \qquad (11)$$

where the spontaneous polarization rotates irreversibly into a direction near to the direction of the applied field. The microstructural parameter α_ψ has been determined by Stoner–Wohlfarth for $K_2 = 0$ (Stoner and Wohlfarth, 1948) and by Kronmüller for $|K_1| > 4|K_2|$ (Kronmüller, Durst and Martinek, 1987) and is given by

$$\alpha_\psi = \frac{H_N(\psi_0)}{H_N(0)} = \frac{1}{\left\{(\cos\psi_0)^{2/3} + (\sin\psi_0)^{2/3}\right\}^{3/2}} \times \left[1 + \frac{2K_2}{K_1 + (N_{||} - N_\perp)J_s^2/(2\mu_0)}\frac{(\tan\psi_0)^{2/3}}{1 + (\tan\psi_0)^{2/3}}\right] \qquad (12)$$

The condition $|K_1| > 4|K_2|$ is fulfilled for $Nd_2Fe_{14}B$, $SmCo_5$, and Sm_2Co_{17} for $T < T_C$. The angular dependence of the microstructural parameter α_ψ is shown in Figure 13(b) for a spherical $Nd_2Fe_{14}B$ particle at room temperature. Accordingly, the nucleation field shows a minimum for a misorientation angle $\psi_0 \approx 45^\circ$. This minimum nucleation field H_N^{min} has been derived explicitly by Martinek and Kronmüller (1990)

$$H_N^{min} = \frac{1}{2\sqrt{2}J_s}\left[K_1 + \frac{K_2}{4}\left(W - \frac{K_1}{K_2} + 3\right)\right] \times \sqrt{W\left(\frac{K_1}{K_2} + 1\right) - \left(\frac{K_1}{K_2}\right)^2 - \frac{2K_1}{K_2} + 3} \qquad (13)$$

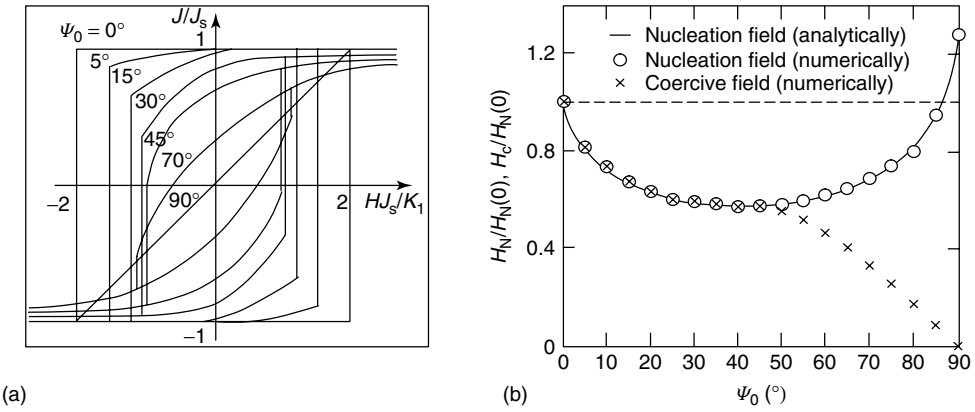

Figure 13. (a) Hysteresis loops of a single-domain particle as a function of the misorientation angle ψ_0 (after E.C. Stoner and E.P. Wohlfarth, Philosophical Transactions of the Royal Society of London, 1948, 240, pp 599–642, with permission from The Royal Society). For $\psi_0 = 90^\circ$ magnetization reversal takes place by reversible rotations ($H_c(90^\circ) = 0$). (b) Angular dependence of the nucleation field and the coercive field of a $Nd_2Fe_{14}B$ sphere in reduced units ($\alpha_\psi = H_N/H_N(0)$).

with

$$W = \pm\sqrt{\left(\frac{K_1}{K_2} + 1\right)^2 + 8} \tag{14}$$

where the + sign holds for $K_2 > 0$ and $K_1 > -2K_2$ and the − sign for $K_2 < 0$ and $K_1 > 0$. For small $|K_2|$ values ($|K_2| < 0.25\,|K_1|$) the minimum nucleation field of a spherical particle is approximately given by

$$H_N^{\min} \approx \frac{K_1 + K_2}{J_s} \tag{15}$$

Also presented in Figure 13(b) is the corresponding angular dependence of the coercive field $H_c/H_N(0)$ which coincides with the angular dependence of the nucleation field only for $\psi_0 < \pi/4$, but decreases for $\psi_0 > \pi/4$ according to $H_c = K_1/J_s \sin(2\psi_0)$ as then nucleation takes place in the third quadrant.

In the case of isotropic (decoupled) magnets with an isotropic distribution of easy axes, the average of all misalignment angles ψ_0 has to be taken for α_ψ. As $\langle\alpha_\psi\rangle$ is of the order of 0.53 in the range $30^\circ < \psi_0 < 60^\circ$ which corresponds approximately to the minimum value $\alpha_\psi^{\min} \approx 0.5$ at $\psi_0 = \pi/4$ in equation (7), α_ψ can be replaced by $\alpha_\psi^{\min} = (K_1 + K_2)/(2K_1) \approx 0.5$ or $\alpha_\psi(2K_1/J_s)$ by $H_N^{\min}$.

c Nucleation field of exchange-coupled grains (parameter α_{ex}): In the case of exchange coupling between the grains, the coercivity is further reduced as compared to exchange-decoupled grains. Possible sources contributing to this decrease of H_c are the random-anisotropy effect and strongly misaligned grains. The random-anisotropy effect (see Section 6.1) results in a reduction of the effective anisotropy constant. This effect becomes important if the grain size D is smaller than the domain wall width $\delta_B = \pi(A/K_1)^{1/2}$. However, as in the case of hard magnetic materials the condition $D < \delta_B$ is not fulfilled ($\delta_B < 5$ nm, $D \approx 10$–20 nm) so far, the random-anisotropy effect cannot become effective. In the case of strongly misaligned grains ($\pi/4 \le \psi_0 \le \pi/2$) the coercivity decreases to zero with increasing misalignment angle ψ_0 (Figure 13b) and magnetization reversal of those grains takes place mainly by reversible rotations. Due to the exchange coupling the strongly misaligned grains induce a rotation of the spontaneous polarization J_s within the neighboring grains so that the magnetization reversal is enhanced even in well-oriented grains since the critical angle θ_N is reached already for smaller fields. The reversal process in exchange-coupled grains, therefore, is a collective process where a cluster of grains becomes demagnetized by the grain of largest misalignment. As the average coercive field of strongly misaligned grains is of the order of $0.25(2K_1/J_s)$ the microstructural parameter α_{ex} is approximately given by 0.5.

d Micromagnetic analysis of nucleation processes: The micromagnetic analysis of nucleation processes and of the temperature dependence of the coercivity starts from equation (7). In general, the grains with the smallest H_c values, that is, the grains characterized by $\alpha_\psi^{\min}$, with $H_N^{\min} = \alpha_\psi^{\min} H_N$ equation (7) can be rewritten as

$$\mu_0 H_c = \alpha_K \alpha_{ex} \mu_0 H_N^{\min} - N_{eff} J_s \tag{16}$$

Consequently, if the dominant process for the magnetization reversal is the nucleation of reversed domains, plotting the temperature dependent $\mu_0 H_c(T)/J_s(T)$ values versus the temperature dependent $\mu_0 H_N^{\min}(T)/J_s(T)$ values yields a straight line. The slope and axis intersection of the straight

line correspond to the microstructural parameters $\alpha_K\alpha_{ex}$ and N_{eff}, respectively, in the case of temperature independent microstructural parameters. Hereby, $\mu_0 H_c(T)/J_s(T)$ results from hysteresis loop measurements at different temperatures in the ferromagnetic temperature range, whereas $\mu_0 H_N^{min}(T)/J_s(T)$ is determined by the intrinsic material parameters J_s, K_1, and K_2 well known from single crystals.

The validity of the nucleation model has been demonstrated for a large number of different permanent magnets. Figure 14 shows exemplarily the $\mu_0 H_c/J_s$ versus $\mu_0 H_N^{min}/J_s$ plots for sintered $SmCo_5$ and $BaFe_{12}Fe_{19}$ (Figure 14a–b) and for different types of nanocrystalline $Pr_2Fe_{14}B$ based magnets (Figure 14c) (Goll, Seeger and Kronmüller, 1998; Goll and Kronmüller, 2003; Kronmüller and Fähnle, 2003). In all cases a linear relationship is obtained. With the assumption $\alpha_{ex} = 1$ for sintered and decoupled magnets and $\alpha_{ex} \leq 1/2$ for exchange-coupled magnets, α_K values between 0.3 and 0.8 are received from the measured $\alpha_K\alpha_{ex}$ values which correspond to a width of the inhomogeneity region of $0.3\delta_B < 2r_0 < \delta_B$. For example, in the case of $SmCo_5$ with $\alpha_K = 0.33$ and $\alpha_{ex} = 1$, $2r_0$ approximately amounts to 1 nm. In the case of nanocrystalline $Pr_2Fe_{14}B$ based permanent magnets, there exists a large range of the values for $\alpha_K\alpha_{ex}$. For decoupled $Pr_2Fe_{14}B$ + Pr with overstoichiometric Pr for which $\alpha_{ex} = 1$ can be assumed, α_K values of 0.8 are obtained, whereas the exchange-coupled stoichiometric $Pr_2Fe_{14}B$ magnets and composite $Pr_2Fe_{14}B$+Fe magnets with overstoichiometric Fe show $\alpha_K\alpha_{ex}$ values between 0.06 and 0.32. The reduced values of $\alpha_K\alpha_{ex}$ reflect a reduction in coercivity and may be attributed to the small anisotropy constant of α-Fe and to the parameter α_{ex} which reduces the $\alpha_K\alpha_{ex}$ values by at least 50% due to exchange coupling between the grains inducing collective demagnetization processes of clusters of grains. Concerning the N_{eff} values large values of $N_{eff} \geq 1$ are obtained for sintered magnets, whereas the values of nanocrystalline permanent magnets range from 0 to 0.2 for exchange-coupled magnets up to 0.8 for decoupled magnets. The reasons for small N_{eff} values are both a more spherical grain shape and the fact that the locally enhanced stray fields are drastically reduced owing to the smoothing effect of the exchange interaction at the grain boundaries. It is noteworthy that for the bonded magnets nearly the same microstructural parameters are observed as for their fully dense counterpart. The validity of the nucleation model was also successfully tested for $Nd_2Fe_{14}B$, $Sm_2Fe_{17}N_x$ and $Sm_{2+\delta}Fe_{14}Ga_2C_2$-based permanent magnets (Bauer, Seeger, Zern and Kronmüller, 1996; Kronmüller and Fähnle, 2003).

5.1.2 Pinning

Pinning is connected with the existence of magnetic inhomogeneities inside the grains acting as pinning centers for domain wall motion. The pinning centers are most effective when the whole wall area is involved as is the case for planar defects or precipitations. Such defects are called repulsive (attractive) for domain walls when their wall energy is larger (smaller) than the wall energy of the surrounding matrix. In the case of pinning, hardening the microstructural parameter $\alpha = \alpha_{K,pin}\alpha_{\psi,pin}$ is a measure for the pinning strength and can be subdivided into two parameters. The parameter $\alpha_{\psi,pin}$ denotes the misorientation of the grains and is given by $\alpha_{\psi,pin} = 1/\cos\psi_0$ (Kronmüller, Durst and Sagawa, 1988) where ψ_0 is again the angle between the applied field and the negative c axis.

a Pinning by phase boundaries: At the phase boundary $z = z_0$, the intrinsic material parameters J_s, K_1, and A change abruptly from the parameters of the magnetic softer

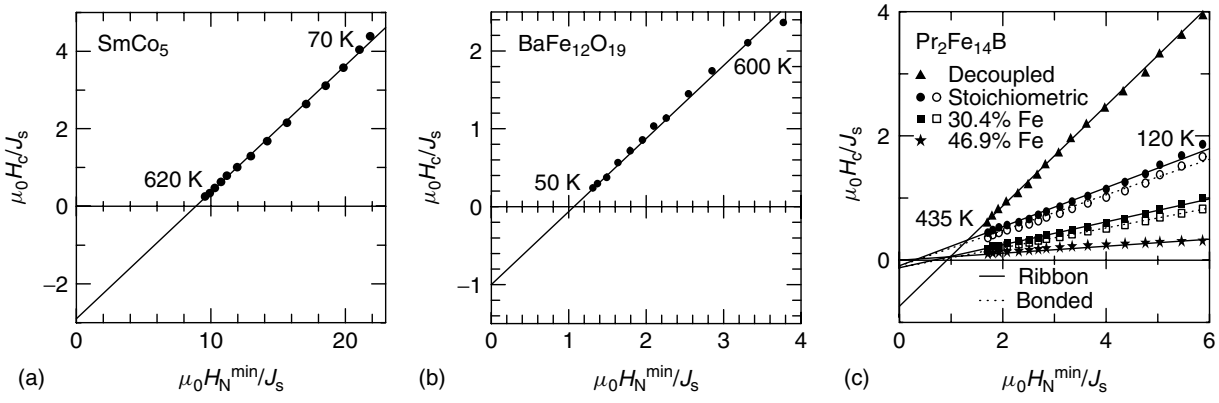

Figure 14. Plots of $\mu_0 H_c/J_s$ versus $\mu_0 H_N^{min}/J_s$ to determine the microstructural parameters $\alpha_K\alpha_{ex}$ and N_{eff}: (a) $SmCo_5$ sintered magnet ($\alpha_K = 0.33$, $N_{eff} = 2.9$), (b) Ba-ferrite sintered magnet ($\alpha_K = 0.94$, $N_{eff} = 1.0$), and (c) $Pr_2Fe_{14}B$ melt-spun magnets: decoupled ($\alpha_K = 0.8$, $N_{eff} = 0.74$), stoichiometric ($\alpha_K\alpha_{ex} = 0.32$, $N_{eff} = 0.09$), composite (30.4% Fe) ($\alpha_K\alpha_{ex} = 0.18$, $N_{eff} = 0.12$), composite (46.9% Fe) ($\alpha_K\alpha_{ex} = 0.06$, $N_{eff} = 0.0$).

phase I to the parameters of the magnetic harder phase II. A domain wall characterized by the azimuthal angle φ_0 of J_s at z_0 is pushed by an applied magnetic field against the phase boundary and moves spontaneously from phase I into phase II when the coercivity is reached (Figure 15). Minimizing the total energy of this domain wall configuration results in the coercivity (Kronmüller and Goll, 2002)

$$\mu_0 H_c = \mu_0 \frac{2K_1^{II}}{J_s^{II}} \frac{1 - \varepsilon_K \varepsilon_A}{(1 + \sqrt{\varepsilon_A \varepsilon_J})^2} \tag{17}$$

$$\cos \varphi_0^{crit} = \frac{\sqrt{\varepsilon_A \varepsilon_J} - 1}{\sqrt{\varepsilon_A \varepsilon_J} + 1} \tag{18}$$

with the ratios $\varepsilon_A = A^I/A^{II}$, $\varepsilon_K = K_1^I/K_1^{II}$, and $\varepsilon_J = J_s^I/J_s^{II}$. The coercive field vanishes for $\varepsilon_K \varepsilon_A = 1$ and particularly for $\varepsilon_A = \varepsilon_K = 1$, that is, if phase I and phase II are equivalent with respect to K_1 and A. For $\varepsilon_J \varepsilon_A = 1$ the critical angle becomes $\varphi_0^{crit} = \pi/2$, that is, equal parts of the 180° domain wall are located in phase I and phase II. If phase I corresponds to a soft magnetic phase ($\varepsilon_K = 0$), H_c is given by

$$\mu_0 H_c = \mu_0 \frac{2K_1^{II}}{J_s^{II}} \frac{1}{(1 + \sqrt{\varepsilon_A \varepsilon_J})^2} \tag{19}$$

In hard magnetic materials large spontaneous polarizations and Curie temperatures guarantee large energy products and excellent temperature stability. The suitable condition therefore is $\varepsilon_J = \varepsilon_A = 1$ for which the coercive field writes

$$\mu_0 H_c = \mu_0 \frac{2K_1^{II}}{J_s^{II}} (1 - \varepsilon_K) \tag{20}$$

and becomes maximum for $\varepsilon_K = 0$, then corresponding to one-quarter of the ideal nucleation field.

b Pinning by narrow planar defects: A narrow planar defect is composed of N individual crystal planes of distance d. Its extension $r_0 = N\,d$ is smaller than the domain wall width and each plane is characterized by a local anisotropy constant K_1^i and a local exchange constant $A_{i,i+1}$. For calculating the coercive field the domain wall is divided into three regions as illustrated in Figure 15(b). Then the unperturbed regions I and III (anisotropy constant K_1, exchange constant A) can be treated by the continuum theory of micromagnetism (Kronmüller, 1973; Friedberg and Paul, 1975), whereas in region II which contains the defect, the individual crystal planes are treated by the discrete Heisenberg model (Hilzinger and Kronmüller, 1975; Hilzinger, 1977). Minimizing the total energy of this planar configuration leads to the following coercivity

$$\mu_0 H_c = \mu_0 \frac{\pi}{3\sqrt{3}} \frac{2K_1}{J_s} \alpha_{\psi,pin} \frac{d}{\delta_B} \left| \sum_{i=1}^{N-1} \left(\frac{A}{A_{i,i+1}} - \frac{K_1^i}{K_1} \right) \right|$$

$$- N_{eff} J_s = \mu_0 \alpha_{\psi,pin} \alpha_{K,pin} \frac{2K_1}{J_s} - N_{eff} J_s \tag{21}$$

If the material parameters of all perturbed layers are identical ($K_1^i = K_1^*$, $A_{i,i+1} = A^*$) equation (21) results in

$$\mu_0 H_c = \mu_0 \frac{\pi}{3\sqrt{3}} \alpha_{\psi,pin} \frac{Nd}{\delta_B} \left| \frac{A}{A^*} - \frac{K_1^*}{K_1} \right| \frac{2K_1}{J_s} - N_{eff} J_s \tag{22}$$

and the parameter $\alpha_{K,pin}$ increases linearly with increasing r_0/δ_B (Figure 17).

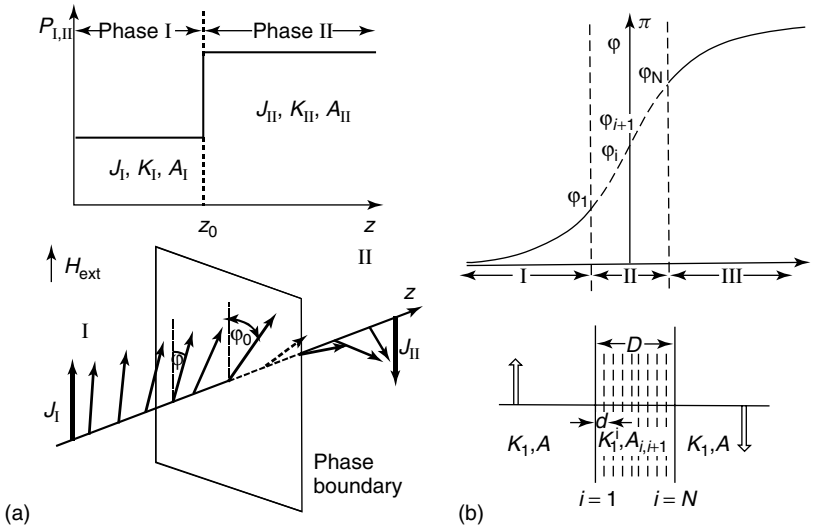

Figure 15. (a) Micromagnetic model of an ideal phase boundary with abrupt changes of the material constants and spin configuration of a domain wall pressed against the phase boundary. (b) Discrete model of a domain wall interacting with a narrow planar defect of N net planes.

c Pinning by extended planar defects: If the extension of the planar defect r_0 is larger than the domain wall width δ_B the coercive field is given by

$$\mu_0 H_c = \mu_0 \frac{1}{2J_s} \alpha_{\psi,\mathrm{pin}} \left. \frac{\mathrm{d}\gamma_B(z)}{\mathrm{d}z} \right|_{\max} - N_{\mathrm{eff}} J_s \qquad (23)$$

where $\left. \mathrm{d}\gamma_B(z)/\mathrm{d}z \right|_{\max}$ describes the maximum slope of the wall energy $\gamma_B(z) = 4\sqrt{AK_1(z)}$. For a linear change of $\gamma_B(z)$ between two phases I and II $\left. \mathrm{d}\gamma_B(z)/\mathrm{d}z \right|_{\max}$ is given by $\left|\gamma_{II} - \gamma_I\right| / r_0$. For the model potential of equation (8) the coercivity given by equation (23) results in

$$\begin{aligned} \mu_0 H_c &= \mu_0 \frac{2K_1(\infty)}{J_s} \frac{2\delta_B}{3\pi r_0} \alpha_{\psi,\mathrm{pin}} - N_{\mathrm{eff}} J_s \\ &= \mu_0 \frac{\gamma_B}{3J_s} \frac{1}{r_0} \alpha_{\psi,\mathrm{pin}} - N_{\mathrm{eff}} J_s \end{aligned} \qquad (24)$$

with $\alpha_{K,\mathrm{pin}} = 2\delta_B/(3\pi r_0)$, that is, with increasing r_0/δ_B, the parameter $\alpha_{K,\mathrm{pin}}$ decreases according to a $1/r_0$ law (Figure 17).

d Domain wall bowing: If a planar defect is interrupted, domain walls can bow and pass the inhomogeneity when the applied field reaches a critical value. According to Kronmüller and Hilzinger (1976) in the case of an interruption length d_{il} and one-dimensional bowing processes, the coercivity is given by

$$\mu_0 H_c = \mu_0 \frac{\pi}{\sqrt{2} J_s^{\mathrm{defect}}} \gamma^{\mathrm{matrix}} \frac{1}{d_{il}} \qquad (25)$$

e Micromagnetic analysis of pinning processes: In the case of high-temperature $Sm_2(Co,Cu,Fe,Zr)_{17}$ hard magnets, the temperature dependence of H_c is narrowly connected to the magnetic material parameters of the cell 2:17 and the cell wall 1:5 phases. Information about these material parameters is obtained from the analysis of the distribution of the five elements Co, Sm, Fe, Cu, Zr within the cells and the cell walls which has been performed by high-resolution energy dispersive X-ray (EDX) measurements (Goll, Kleinschroth, Sigle and Kronmüller, 2000; Goll, Kronmüller and Stadelmaier, 2004).

A quantitative description of $H_c(T)$ starts from equation (17). With the temperature dependencies of the intrinsic material parameters J_s, K_1, and A for the cell 2:17 (index I) and the cell wall 1:5 (index II)

$$\begin{aligned} J_s^{\mathrm{I,II}}(T) &= c_J^{\mathrm{I,II}}(1 - T/T_C^{\mathrm{I,II}})^{\beta}; \\ K_1^{\mathrm{I,II}}(T) &= c_K^{\mathrm{I,II}}(1 - T/T_C^{\mathrm{I,II}})^{3\beta}; \\ A^{\mathrm{I,II}}(T) &= c_A^{\mathrm{I,II}}(1 - T/T_C^{\mathrm{I,II}})^{2\beta} \end{aligned} \qquad (26)$$

where β denotes the critical exponent ($\beta = 0.5$: molecular field theory, $\beta = 0.365$: Heisenberg model) and $c_x^{\mathrm{I,II}}$ is

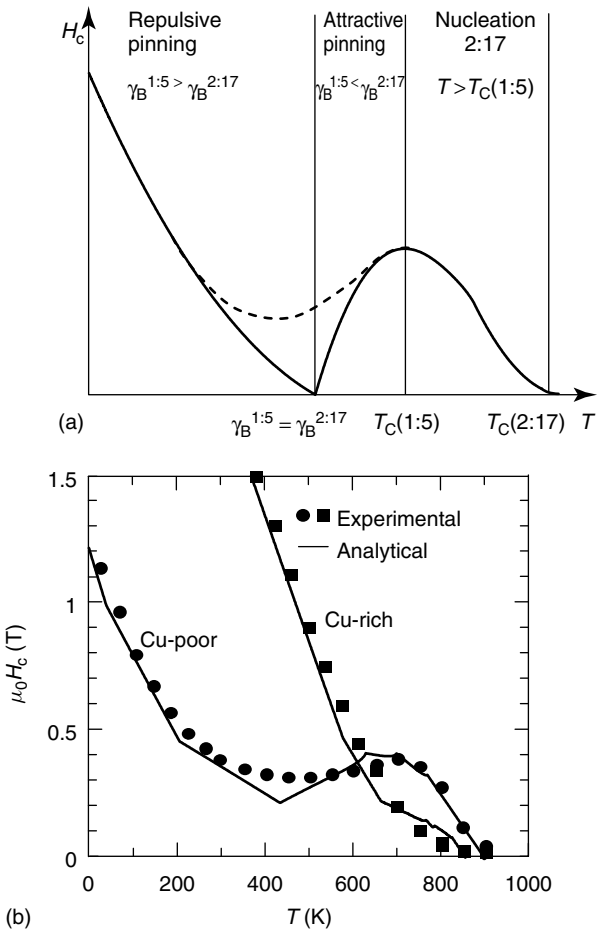

Figure 16. (a) Schematic temperature dependence $H_c(T)$ according to equation (27) showing the three ranges of repulsive and attractive pinning as well as the high-temperature nucleation range. (b) Conventional (Cu-rich cell walls) and anomalous (Cu-poor cell walls) $H_c(T)$ behavior of $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets.

related to the material constants at $T = 0$, the coercivity can be rewritten as (Kronmüller and Goll, 2003)

$$\begin{aligned} \mu_0 H_c(T) = \mu_0 \frac{2c_K^{\mathrm{II}}}{c_J^{\mathrm{II}}} \left(1 - \frac{T}{T_C^{\mathrm{II}}}\right)^{2\beta} \\ \times \frac{1 - \varepsilon_{KA} \left(\frac{1 - T/T_C^{\mathrm{I}}}{1 - T/T_C^{\mathrm{II}}}\right)^{5\beta}}{\left[1 + \left\{\varepsilon_{AJ} \left(\frac{1 - T/T_C^{\mathrm{I}}}{1 - T/T_C^{\mathrm{II}}}\right)^{3\beta}\right\}^{1/2}\right]^2} \end{aligned} \qquad (27)$$

with the parameters $\varepsilon_{KA} = c_K^{\mathrm{I}} c_A^{\mathrm{I}} / c_K^{\mathrm{II}} c_A^{\mathrm{II}}$ and $\varepsilon_{AJ} = c_A^{\mathrm{I}} c_J^{\mathrm{I}} / c_A^{\mathrm{II}} c_J^{\mathrm{II}}$. The expression allows a quantitative discussion of the temperature dependence of H_c (Figure 16a) As in general $\varepsilon_{KA} < 1$, $\varepsilon_{AJ} > 1$ and $T_C^{\mathrm{I}} > T_C^{\mathrm{II}}$ holds, two crossover temperatures exist. At low temperatures ($\varepsilon_A \varepsilon_K < 1$, $\varepsilon_A \varepsilon_J \approx 1$) H_c is determined by repulsive pinning at the cell walls leading

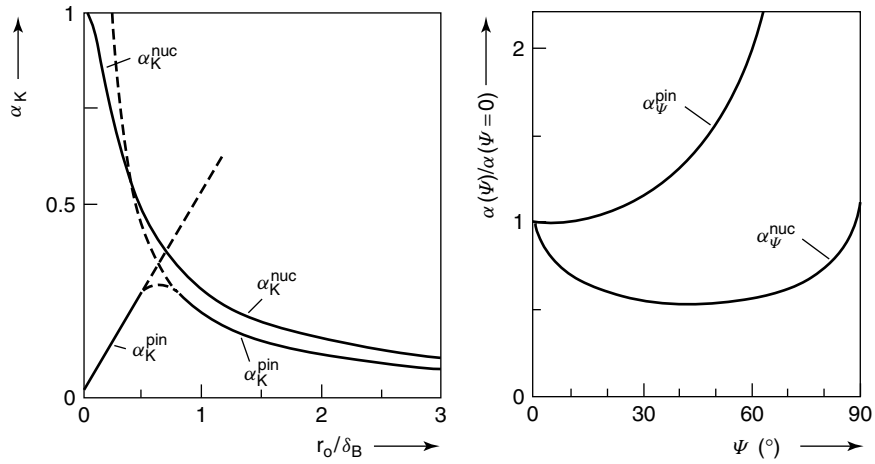

Figure 17. (a) Comparison of the α_K parameters for pinning and nucleation in planar defects of width r_0 as a function of r_0/δ_B (Kronmüller, Durst and Sagawa, 1988). (b) Comparison of the α_ψ parameters for pinning and nucleation as a function of the misorientation angle ψ_0. (Kronmüller *et al*., 1988/1987.)

to a monotonous decrease of H_c with increasing temperature. At intermediate temperatures repulsive pinning changes into attractive pinning in the cell walls at $\varepsilon_{KA} < 1$, $\varepsilon_{AJ} = 1$ with K_1^{II} becoming smaller than K_1^{I} because $T_C^{I} > T_C^{II}$ holds. In this temperature range, the indices I and II have to be exchanged in equations (26) and (27) and $H_c(T)$ may increase up to a maximum value at $T = T_C^{I}$. At the Curie temperature of the cell wall phase, the matrix pyramids become single-domain particles being magnetically isolated by thin paramagnetic cell walls. Accordingly, for higher temperatures the coercive field is determined by the nucleation field $(2K_1^{2:17}/J_s^{2:17})\alpha$ of the 2:17 cells and therefore decreases.

In Figure 16(b) by the superposition of the three $H_c(T)$ curves for varying parameters ε_{KA} and ε_{AJ} and average Curie temperatures the experimental result of a positive and a negative temperature gradient dH_c/dT could be nicely explained (Goll, Kronmüller and Stadelmaier, 2004).

5.1.3 Comparison of the hardening mechanisms

The type of hardening mechanism can be determined in principle from the temperature dependence of the coercivity. In Figure 17, the microstructural parameters α_K and α_ψ are compared with each other for the nucleation and pinning mechanism. Whereas for $\alpha_K > 0.3$ nucleation is the only reversal mechanism which may occur, for $\alpha_K < 0.3$ nucleation and pinning may take place. Consequently, the maximum coercivity of pinning-hardened magnets amounts to 30% of the ideal nucleation field. In the case of the microstructural parameter α_ψ, with increasing misorientation angle α_ψ increases for pinning-hardened magnets and shows a minimum at $\psi_0 = 45^\circ$ for nucleation hardened magnets. Another distinguishing feature is the initial magnetization curve. Whereas for pinning-hardened magnets the magnetization increases rather slowly for small applied fields due to the pinning of domain walls, the magnetization increases rapidly for nucleation hardened magnets consisting of multidomain particles in the thermally demagnetized state. As a consequence, in the latter case the saturation is achieved for smaller fields.

5.1.4 Others

In the phenomenological nucleus expansion model ('global model') (Givord and Rossignol, 1996) a preformed nucleus of reversed polarization expands due to thermal activation within the lifetime of the reversed nucleus which follows an Arrhenius equation $\tau = \tau_0 \exp(-\Delta E/kT)$ where τ_0 is of the order of 10^{-11} s and $\Delta E(t) = kT \ln(t/\tau_0) \approx 25\,kT$ ($t \approx 1$–10^3 s) corresponds to the activation enthalpy necessary for the spontaneous expansion of the nucleus by overcoming the magnetic enthalpy. If the nucleus is characterized by its surface area s, its volume v, and its domain wall energy γ_B', at the coercive field H_c the energy balance between ΔE and the magnetic enthalpy consisting of domain wall energy, magnetostatic energy of the external field at H_c and the demagnetization energy is given by

$$s\gamma_B' - J_s H_c v - \frac{1}{\mu_0} N_{eff} J_s^2 v = 25kT \qquad (28)$$

As the nucleus forms in perturbed regions the specific wall energy γ_B' of the nucleus can be related to the ideal wall energy γ_B of the perfect crystal by $\gamma_B' = \alpha_B \gamma_B = 4\sqrt{AK_1}\alpha_B$ with the microstructural parameter $\alpha_B < 1$. Similarly, the

nucleus surface can be related to the nucleus volume by $s = \alpha_s v^{2/3}$ where α_s corresponds to a geometrical factor given by $\alpha_s = (36\pi)^{1/3} = 4.84$ for a sphere and by $\alpha_s = (\pi \cot\theta)^{1/3}/\cos\theta$ for a cone with apex angle θ. With these substitutions the following expression can be derived from equation (28) for the coercivity

$$\mu_0 H_c = \mu_0 \frac{\alpha_s \alpha_B \gamma_B}{J_s v^{1/3}} - J_s N_{eff} - \mu_0 \frac{25kT}{v J_s} \qquad (29)$$

As the nucleus volume is related to the wall width $\delta_B = \pi\sqrt{AK_1}$ as $v = \alpha_v^3 \delta_B^3$ equation (29) can be rewritten as

$$\mu_0 H_c = \mu_0 \frac{\alpha_s \alpha_B}{\alpha_v} \frac{1}{J_s} \frac{\gamma_B}{\delta_B} - J_s N_{eff} - \mu_0 \frac{25kT}{v J_s}$$
$$= \mu_0 \frac{2K_1}{J_s} \frac{2\alpha_s \alpha_B}{\pi \alpha_v} - J_s N_{eff} - \mu_0 H_f \qquad (30)$$

with the thermal fluctuation field $\mu_0 H_f = \mu_0 25kT/(vJ_s)$ which corresponds to 5–10% of the coercive field. The microstructural parameters α_s and α_B can be obtained from plotting $\mu_0(H_c + H_f)/J_s$ versus $\mu_0 \gamma_B/(J_s^2 v^{1/3})$ where H_c, v, and H_f are received experimentally and J_s and γ_B are given by the intrinsic material parameters. In Figure 18(a) (Becher, Seeger and Bauer, 1998) the temperature dependence of the activation volume of different types of magnets is shown. Figure 18(b) (Becher, *et al.* 1998) shows the plots from which the microstructural parameters $\alpha_s\alpha_B$ and N_{eff} can be derived. From equation (30) it becomes obvious that the coercivity due to nucleus expansion is described by the same type of equation as in the case of nucleation. The only difference between the two models seems to be that the nucleation model is based on the micromagnetic equations, whereas the nucleus expansion model starts from an empirical energetic approach which corresponds just to the integrated micromagnetic equations. Although the parameters α_s, α_B, and α_v can be identified with the parameters α_K and α_{ex} as $4\alpha_s\alpha_B/\pi\alpha_B \equiv \alpha_K\alpha_{ex}$ it has to be noted that the nucleus expansion model turns out to be incompatible with the real microstructure. As the measured activation volumes v are of the order of $300\,\text{nm}^3$ the grain boundaries would extend over a width of $5\delta_B \approx 20\,\text{nm}$. In contrast, according to the nucleation model the reversal of the polarization starts in regions of width 0.5–2 nm which is in excellent agreement with the real microstructure. Furthermore, the microstructural parameters α_s, α_B, and α_v are less defined. In particular, their temperature dependence is unknown and can only be quantified by further assumptions on the nucleus shape (González *et al.*, 1994). Naturally, the thermal fluctuation field can also be introduced into the nucleation model as a further term which reduces the nucleation field. However, normally the thermal fluctuation field can be neglected as it corresponds only to 5–10% of the coercivity and the micromagnetic energy terms are dominating.

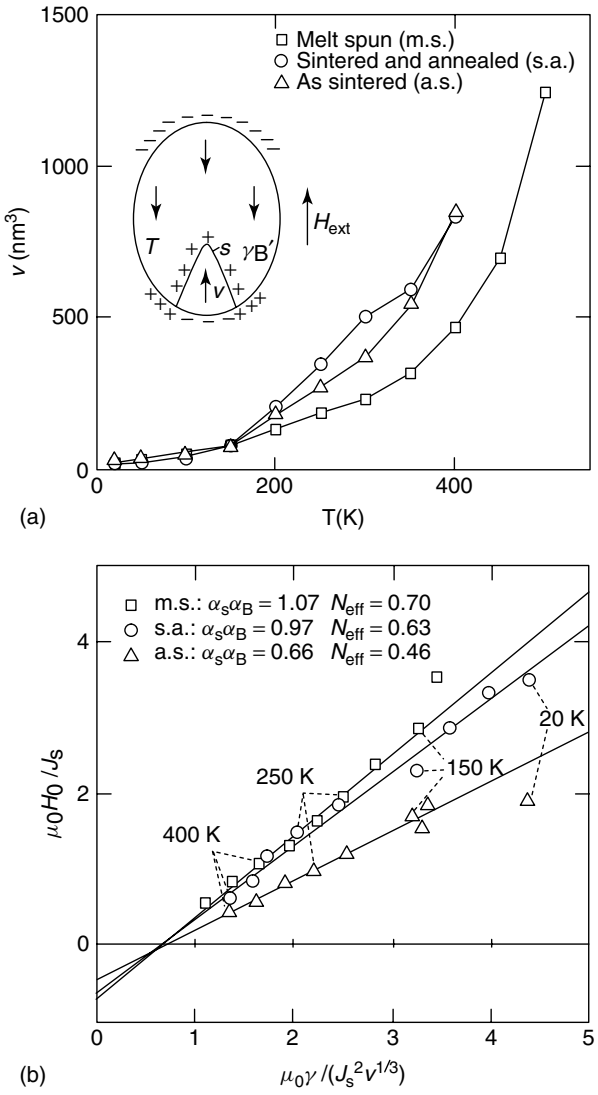

Figure 18. (a) Temperature dependence of the activation volume of three different types of $Nd_2Fe_{14}B$ based magnets. The inset illustrates the spike-type nucleus of volume v, surface area s, and wall energy γ'_B (Becher, Seeger and Bauer, 1998). (b) Corresponding plots to determine $\alpha_s\alpha_B$ and N_{eff} according to the global model (Becher, Seeger and Bauer, 1998).

5.2 Remanence and $(BH)_{max}$

Depending on the degree of the texture the remanence varies between $J_r \approx J_s$ in the case of a perfect orientation of the easy axes along one direction and $J_r = 0.5 J_s$ in the case of an isotropic orientation of the easy axes and magnetically decoupled grains. In the case of exchange-coupled grains, a magnetic texture is induced within a region

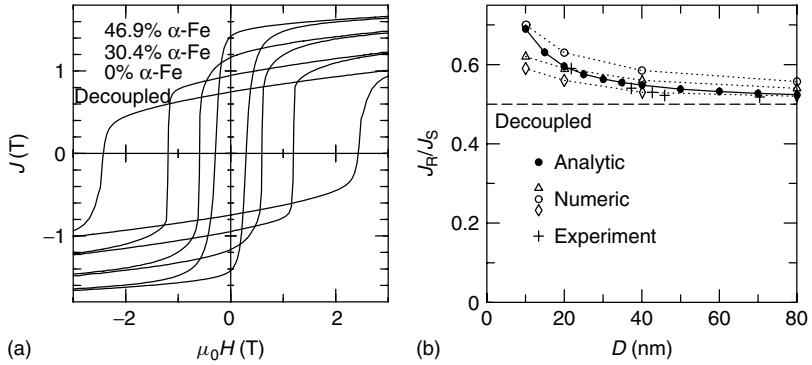

Figure 19. (a) Remanence enhancement in nanocrystalline stoichiometric and composite $Pr_2Fe_{14}B$ + α-Fe isotropic magnets compared to a nanocrystalline decoupled $Pr_2Fe_{14}B$ + Pr isotropic magnet (Goll, Seeger and Kronmüller, 1998). The corresponding nanostructures are shown in Figure 6. (b) Grain-size dependence of the reduced remanence of $Nd_2Fe_{14}B$ according to equation (31) in comparison with numerical (Δ, $\circ$: directly contacted grains; *diamond*: $A_{gb} = A/10$ (width of grain boundaries: 3 nm) and experimental results. (Reproduced from D. Goll: 'Micromagneticism and microstructure – tailoring of high performance magnets', *Z Metallkunde* **93**, (2002) 1009–1017, with permission of Carl Hanser Verlag.)

of $\delta_B = \pi(A/K_1)^{0.5} = \pi l_K$ at the grain boundaries with the texture axis parallel to the direction of the applied field involving a significant remanence enhancement compared to decoupled magnets (Figure 19a). The influence of the exchange coupling on the remanence can be expressed analytically by using a simple micromagnetic model which describes the exchange coupling between two neighboring grains in analogy to a Bloch wall. From minimizing the total magnetic Gibbs energy the remanence of stoichiometric magnets is obtained as

$$J_r \approx \frac{1}{2} J_s + 1.5 \frac{J_s}{D} l_K \tag{31}$$

Here, the first term (*Stoner–Wohlfarth* term) denotes the decoupled contribution to the remanence, whereas the second one describes the remanence enhancement effect due to exchange coupling at the grain boundaries. Accordingly, J_r of an exchange-coupled single-phase magnet is determined by the average grain size D and the intrinsic material parameters J_s, K_1, and A of the grains. For a given material, the remanence enhancement increases with decreasing grain sizes. In Figure 19(b) (Goll, 2002), the grain-size dependence of the reduced remanence according to equation (31) is compared for $Nd_2Fe_{14}B$ to that calculated numerically for a three-dimensional ensemble of hard magnetic exchange coupled grains as well as to the experimental data obtained by Manaf, Buckley, Davies and Leonowicz (1991). Consequently, for an efficient remanence (and therefore $(BH)_{max}$) enhancing effect, the grain size should be smaller than 20 nm. In composite magnets the remanence (and therefore $(BH)_{max}$) is further increased as the large spontaneous polarization of α-Fe ($J_s = 2.15$ T) significantly intensifies the magnetic texturing effect (Figure 19a). For a complete exchange hardening of the soft magnetic grains, it is imperative that the grain size of the soft magnetic grains is of the order of twice the Bloch wall width δ_B of the hard magnetic phase.

6 SOFT MAGNETIC MATERIALS: MICROMAGNETISM AND MICROSTRUCTURE

Crystalline soft magnetic materials (see also **Advanced Soft Magnetic Materials for Power Applications, Volume 4**) as permalloy, sendust, Fe–Si-transformer steel and MnZn ferrites are characterized by a low magnetocrystalline anisotropy and a low magnetostriction (at least for a certain temperature). In order to achieve large initial susceptibilities (or initial permeabilities) and small coercivities in these materials, defect structures should be reduced as much as possible. As some of these materials have a low critical shear stress, plastic deformations are serious sources for deteriorating the soft magnetic properties.

Amorphous soft magnetic materials (see also **Amorphous Alloys, Volume 4**; **Soft Magnetic Bulk Glassy and Bulk Nanocrystalline Alloys, Volume 4**) are mainly based on transition metal–metalloids with compositions near $(Fe, Co, Ni)_{80}(B, Si, C)_{20}$ and are commonly divided into two major groups: iron-based and Co-based alloys. The Fe-based amorphous alloys (e.g., $Fe_{67}Co_{18}B_{14}Si$) are based on inexpensive raw materials, have a high saturation polarization ($J_s =$ 1.1–1.8 T), but their magnetostriction ($\lambda_s \approx 30 \times 10^{-6}$) is large which limits their soft magnetic behavior. By adding Ni, for example, $Fe_{40}Ni_{40}P_{14}B_6$ or $Fe_{40}Ni_{40}B_{20}$, the saturation polarization and at the same time the magnetostriction become smaller. The Co-based amorphous alloys, for example, $Co_{71}Fe_1Mo_1Mn_4Si_{14}B_9$ reveal nearly zero magnetostriction ($\lambda_s < 3 \times 10^{-7}$), therefore offering a superior

soft magnetic behavior, but their saturation polarization is by a factor of 2 lower than that of the Fe-based materials. Amorphous alloys are produced mainly by rapid quenching ($\sim 10^6\,\mathrm{K\,s^{-1}}$) from the melt or by either sputtering or evaporation. They allow a wide range of property variation, for example, the initial permeability can be varied continuously from $\mu_i \approx 1000$ to $\mu_i \approx 300\,000$. Disadvantages of all amorphous alloys are their thermal instability and a low Curie temperature.

Nanocrystalline soft magnetic materials (see also **Soft Magnetic Materials – Nanocrystalline Alloys, Volume 4**) consist of ultrafine grains with an average size of ∼5–15 nm which are embedded in an amorphous matrix. They are prepared by crystallization of amorphous melt-spun ribbons (with the addition of Cu and Nb) during annealing. The volume ratio of the nanocrystalline phase can be controlled by the annealing temperature and ranges between 50 and 80%. The most widely investigated alloy is $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ (Yoshizawa, Oguma and Yamauchi, 1988; Herzer, 1996) which combines the highest achievable permeabilities ($\mu_i \approx 200\,000$) with the simultaneously highest saturation polarizations ($J_s \approx 1.2$–1.3 T) and which is also characterized by vanishing anisotropy (due to exchange softening) and a near zero magnetostriction ($\lambda_s < 1 \times 10^{-7}$). Nanocrystalline soft magnets are more stable above room temperature and have a larger remanence as compared to amorphous Co-based soft magnets, whereas the large electrical resistivity ($\rho = 100$–$130\,\mu\Omega$cm) and the low losses are of the same order. The only drawback of nanocrystalline soft magnets is the severe embrittlement upon crystallization.

In Figure 20(a) the typical initial permeabilities and saturation polarizations are presented for amorphous, nanocrystalline, and crystalline soft magnetic alloys with nonzero magnetostriction.

6.1 Coercivity and permeability

In soft magnetic materials the domain walls interact with a large number of (statistically distributed) defects, for example, for a dislocation density of $10^{10}\,\mathrm{cm^{-2}}$ there are 10^4 dislocations within a domain wall of cross section $10^{-6}\,\mathrm{cm^2}$, and the interaction force has to be determined by statistical methods. The quantities which have to be determined by statistics are coercive field H_c and the initial susceptibility χ_0 (or initial permeability μ_i) and the Rayleigh constant α_R of the Rayleigh (1887) law $J = \chi_0\mu_0 H + \alpha_R(\mu_0 H)^2$ which describes the reversible (first term) and the irreversible (second term) part of magnetization at small fields. Initial permeability and coercivity obey a reciprocal relationship so that materials with low coercivity necessarily have a high initial permeability and vice versa.

In soft magnetic materials the coercivity sensitivity depends on the grain size D. According to Figure 20(b), good soft magnetic properties are received for amorphous magnets for nanocrystalline magnets with grain sizes smaller than 20 nm and for (micro)crystalline magnets with very large grain sizes $D > 100\,\mu$m.

6.1.1 Models

The models of the statistical pinning potential (Kronmüller, 1970; Kronmüller and Fähnle, 2003) and of the random anisotropy (Alben, Becker and Chi, 1978; Herzer, 1990) are effective tools to describe the hysteresis loops of soft magnetic materials.

a Statistical pinning potential: The defects in soft magnetic materials cause a statistically fluctuating Bloch-wall potential or field of force as shown in Figure 21(a) which is the reason for irreversible domain wall movements and therefore for

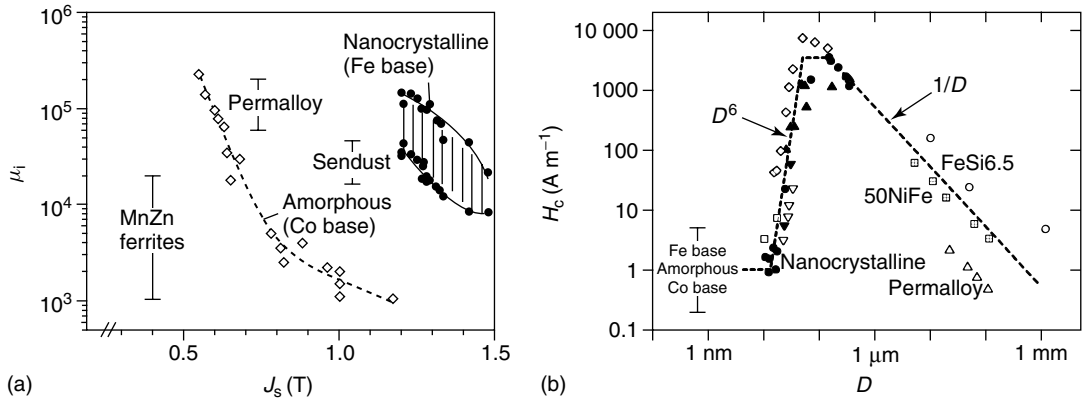

Figure 20. (a) Typical initial permeabilities μ_i and saturation polarizations J_s for a variety of soft magnetic materials (Petzold, 2002). (Reproduced from Petzold *et al*., 2002, with permission from Elsevier. © 2002.) (b) Dependence of the coercivity H_c on the grain size D for soft magnetic materials showing the amorphous, nanocrystalline, and microcrystalline regions (Herzer, 1995). Figure 21. (a) Characteristic parameters of the statistical field of force acting on a domain wall. The broken line indicates reversible and irreversible displacements of the domain wall. With increasing (decreasing) field, a domain wall moves from a to f (f to m). The inset shows schematically the corresponding hysteresis loop resulting from the reversible (χ_{rev}) and irreversible (χ_{irr}) magnetization processes. (b) Schematic magnetization curve with four characteristic regions of magnetization processes.

the hysteresis loop. By applying a magnetic field a domain wall is reversibly displaced in its potential valley and reaches a force maximum at a certain field value, then performing a spontaneous irreversible Barkhausen jump (Barkhausen, 1919) to the next higher force maximum, and so on. According to Figure 21(b), four characteristic regions of magnetization processes can be distinguished as a function of the applied magnetic field. In region I ($0 < H < H_{\mathrm{R}}$, $H_{\mathrm{R}} < 0.1H_{\mathrm{c}}$) magnetization occurs by displacements of domain walls which can be described by Rayleigh's law. In region II ($0.1H_{\mathrm{c}} < H < H_{\mathrm{c}}$) magnetization takes place by large irreversible Barkhausen jumps and the permeability reaches its maximum value. In region III ($H_{\mathrm{c}} < H < 2K_{\mathrm{eff}}/J_{\mathrm{s}}$) narrow domain regions as closure domains are magnetized parallel to the applied field by domain wall displacements and by rotational processes. In region IV ($H > 2K_{\mathrm{eff}}/J_{\mathrm{s}}$) magnetization approaches to saturation and occurs by microscopic reversible rotations in regions of inhomogeneous spin states around defect structures. Similarly, the coercivity can be regarded as the field strength for which demagnetization via large Bloch wall jumps over force maxima become possible.

In a quantitative description, the total force acting on a rigid domain wall is given by the sum extending over all defects

$$P(z) = \sum_j p(z - z_j) \tag{32}$$

where $p(z - z_j)$ describes the individual force of a defect at position z_j acting on a domain wall at position z and z is the coordinate parallel to the domain wall normal. According to Figure 21(a) the statistical field of force $P(z)$ is characterized by the averages of the wavelength $2L_0$ which is defined as twice the distance between neighboring zero positions of $P(z)$ and which is independent of the defect density, of the maximum $P_{\max}$ and of the reciprocal slopes $1/R = 1/(\mathrm{d}P/\mathrm{d}z)$ at $P(z) = 0$. When the total force $P(z)$ obeys a Gaussian distribution function f, the probability of finding an interaction force between P and $P + \mathrm{d}P$ or a slope $R = \mathrm{d}P/\mathrm{d}z$ between R and $R + \mathrm{d}R$ is given by

$$f(P) = \frac{1}{\sqrt{2\pi}\,B_0} \exp\left(-\frac{P^2}{2B_0}\right);$$
$$f(R) = \frac{1}{\sqrt{2\pi}\,B_1} \exp\left(-\frac{R^2}{2B_1}\right) \tag{33}$$

where B_0 and B_1 are the correlation functions which are related to the individual interaction forces as follows:

$$B_0 = \frac{F_{\mathrm{B}}N}{L_3} \int_{-L_3/2}^{L_3/2} \left[p^2(z) - \langle p(z)\rangle^2\right] \mathrm{d}z;$$
$$B_1 = \frac{F_{\mathrm{B}}N}{L_3} \int_{-L_3/2}^{L_3/2} \left\{\left[\frac{\mathrm{d}\,p(z)}{\mathrm{d}\,z}\right]^2 - \left\langle\frac{\mathrm{d}\,p(z)}{\mathrm{d}\,z}\right\rangle^2\right\} \mathrm{d}\,z \tag{34}$$

with F_{B} the domain wall area, L_3 the domain wall distance, and N the defect density. In this case, the characteristic parameters of the statistical potential are correlated with the

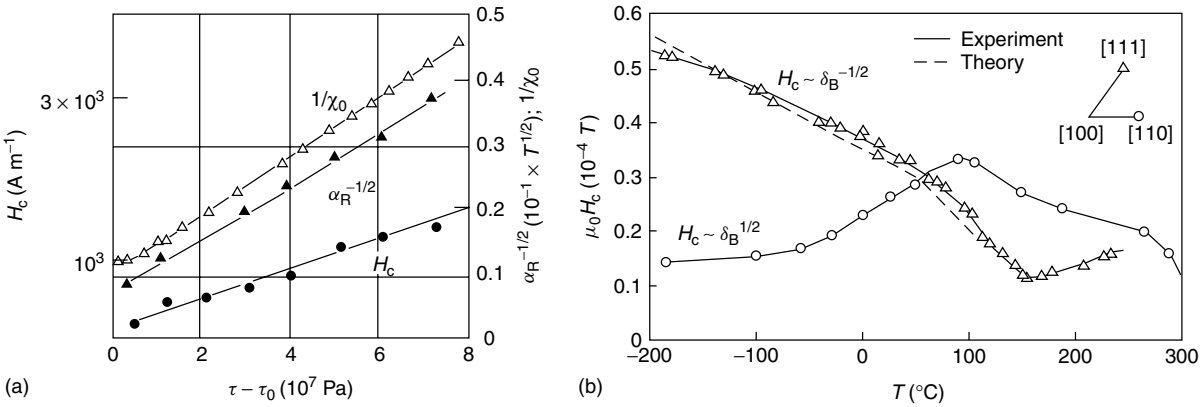

Figure 22. (a) Dependence of H_c, χ_0, and α_R on the dislocation density N of a plastically deformed Ni single crystal. N is related to the applied flow stress τ by $\tau-\tau_0=0.36\,Gb(Nl)^{1/2}$ (τ_0: initial flow stress, G: shear modulus, b: Burgers vector, l: dislocation line strength interacting with a domain wall) (Kronmüller, 1972). (Reproduced from H. Kronmüller: 'Magnetic techniques for the study of dislocations in ferromagnetic materials' in *Internat J Nondestr. Testing*, **3** (1972) 315–350, with permission from Taylor & Francis Ltd, www.informaworld.com.) (b) Temperature dependence of the coercive field of Ni single crystals owing to dislocations ($\propto \delta_B^{1/2}$) in the as-grown crystal and to dislocation dipoles ($\propto \delta_B^{-1/2}$) after heavy neutron irradiation. The broken line corresponds to the theoretical prediction for $H_c(T)$ of dislocation dipoles (Kronmüller, 1966). (Reproduced from H. Kronmüller: 'Magnetisierungskurve der Ferromagnetike' in A. Seeger (ed): *Moderne Probleme der Metallphysik*, vol. 2 (Springer, Berlin, 1966), with permission of Spruigner Science and Business Media.)

correlation functions in the following way:

$$\overline{2L_0}=2\pi\sqrt{\frac{B_0}{B_1}};\quad \overline{\frac{1}{R}}=\sqrt{\frac{\pi}{2B_1}};\quad \overline{P}_{\max}=\sqrt{\frac{B_0}{2\pi}} \tag{35}$$

and the relationship of the coercive field H_c as well as of the initial susceptibility χ_0 and the Rayleigh constant α_R to these parameters is obtained as

$$\mu_0 H_c=\frac{\mu_0\sqrt{\pi}}{J_s F_B\left|\cos\varphi_0\right|}\overline{P}_{\max}\sqrt{\frac{\ln L_3}{2L_0}};$$

$$\chi_0=\frac{(2J_s\cos\varphi_0)^2 F_B}{\mu_0 L_3}\overline{\frac{1}{R}};\quad \alpha_R=\frac{\left|2J_s\cos\varphi_0\right|^3 F_B^2}{(2\mu_0\pi)^2}\frac{L_0}{L_3}\frac{1}{(\overline{P}_{\max})^3} \tag{36}$$

where φ_0 is the angle between the applied field and J_s within the domains. The combination of equation (35) with equation (36) leads to the following relations between H_c, χ_0, and α_R

$$\frac{\chi_0 H_c}{J_s}=\frac{\sqrt{\pi}}{2\mu_0}\left|\cos\varphi_0\right|\frac{L_0}{L_3}\left(\ln\frac{L_3}{2L_0}\right)^{1/2};$$

$$\mu_0\frac{\alpha_R H_c}{\chi_0}=\frac{8}{3\sqrt{\pi}}\left(\ln\frac{L_3}{2L_0}\right)^{1/2};$$

$$\frac{\chi_0^2}{J_s\alpha_R}=\frac{3\pi}{16}\frac{L_0}{L_3}\left|\cos\varphi_0\right| \tag{37}$$

where the average wavelength is approximately given by $2L_0\approx 2\delta_B$. From equations (34, 35, 36) the dependence of H_c, χ_0, and α_R on the defect density is predicted as $H_c\propto N^{1/2}$, $\chi_0\propto 1/N^{1/2}$, and $\alpha_R\propto 1/N$ which has been tested successfully for plastically deformed Ni single crystals as shown in Figure 22(a) where the interaction force is proportional to the magnetoelastic stresses of the domain wall.

b Random anisotropy: In an ensemble of exchange-coupled grains (size D, volume fraction v) with a random distribution of the easy directions the polarization cannot abruptly follow the changes of the easy direction. Within a range of the exchange length $l_K=\sqrt{A/K_1}$ the polarization rotates into the direction of the easy axis. For $l_K>D$ the polarization is not able to follow the easy axes of the individual grains, but is increasingly forced to align parallel by exchange interaction. Consequently, for $l_K>D$ an averaging over the $N=v(l_K/D)^3$ grains lying within the volume $(l_K)^3$ takes place and the resulting effective anisotropy constant $\langle K\rangle$ and effective exchange length l_K^{eff} are given by

$$\langle K\rangle\approx v\frac{K_1}{\sqrt{N}}=\sqrt{v}K_1\left(\frac{D}{l_K^{\text{eff}}}\right)^{3/2}=v^2\frac{K_1^4}{A^3}D^6$$

$$=v^2K_1\left(\frac{D}{\delta_B}\right)^6\pi^6;\quad l_K^{\text{eff}}=\sqrt{\frac{A}{\langle K\rangle}} \tag{38}$$

For example, for grain sizes $D\approx l_K/3\approx 10$–15 nm the magnetocrystalline anisotropy K_1 is reduced by 3 orders of magnitude to a few joule per cubic meter and the effective exchange length l_K^{eff} becomes 2 orders of magnitude larger than the exchange length l_K. In nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B$ indeed wide domain widths of

approximately 2 µm could be observed by high-resolution Kerr effect studies (Schäfer, Hubert and Herzer, 1991). If additionally a significant macroscopic anisotropy K_u exists resulting from shape anisotropy, induced anisotropy, or magnetoelastic anisotropy the total averaged anisotropy can be written as (Herzer and Varga, 2000)

$$\langle K \rangle = K_u + \frac{1}{2} v \sqrt{K_u K_1} \left(\frac{D}{l_K^{eff}} \right)^3 \tag{39}$$

The expressions for the random anisotropy, which are valid for uniaxial and cubic crystals, can be used to determine χ_0 and H_c of nanocrystalline soft magnetic materials.

6.1.2 Application to (single-)crystalline materials

In (single-)crystalline soft magnetic materials dislocations, dislocation dipoles and point defects or impurity atoms act as pinning centers for domain walls. Dislocations have a magnetostrictive interaction with domain walls due to the elastic interaction energy of the magnetostrictive elastic stresses of the domain wall and the longer-range elastic stresses of the dislocations. In many cases, the dislocation structure of plastically deformed materials is composed of dislocation dipoles which may be formed by cyclic deformation or by agglomerations of vacancies or interstitial atoms.

For dislocations, dislocation dipoles, and point defects the temperature dependence of H_c and χ_0 is determined by the intrinsic material parameters J_s, K_1, A, and the magnetostriction λ_s. In the case of individual dislocations the temperature dependence of H_c and χ_0 is given by

$$H_c(T) \propto \frac{\lambda_s}{J_s} \left(\frac{A}{K_1} \right)^{1/4} \sqrt{N} \propto \delta_B^{1/2};$$
$$\chi_0(T) \propto \frac{J_s^2}{\lambda_s} \left(\frac{A}{K_1} \right)^{1/4} \frac{1}{\sqrt{N}} \propto \delta_B^{1/2} \tag{40}$$

with the same dependence of H_c and χ_0 on δ_B, that is, the pinning effect decreases with decreasing wall width δ_B. However, with increasing magnetostriction λ_s and dislocation density N, χ_0 decreases, whereas H_c increases. The Rayleigh constant α_R is independent of δ_B and its temperature dependence on the magnetic material parameters is given by $\alpha_R \propto J_s^3/(\lambda_s^2 N)$. As according to equation (36) α_R is inversely proportional to L_3, with increasing domain wall density α_R increases. In the case of dislocation dipoles (and point defects), the temperature dependence of H_c follows the law

$$H_c(T) \propto \frac{\lambda_s}{J_s} \left(\frac{K_1}{A} \right)^{1/4} \sqrt{N} \propto \delta_B^{-1/2} \tag{41}$$

and the interaction force increases with decreasing wall width δ_B. The initial susceptibility χ_0 decreases according to a $\delta_B^{3/2}$ law with decreasing wall width δ_B.

For Ni single crystals the $\delta_B^{1/2}$ and the $\delta_B^{-1/2}$ dependence of H_c has been measured as illustrated in Figure 22(b). The temperature dependence of H_c in as-grown single crystals is owing to dislocations as main pinning centers and to dislocation dipoles after heavy neutron irradiation. As K_1 increases with decreasing temperature, H_c decreases in the case of dislocations and increases in the case of dislocation dipoles with decreasing temperature.

6.1.3 Application to nanocrystalline materials

In nanocrystalline soft magnetic materials, the macroscopic magnetocrystalline anisotropy reveals very small or virtually zero due to the random-anisotropy effect. For grains with diameters smaller than the wall width, the hysteresis loops typically show an enhanced remanence ($J_r/J_s > 0.90$) and the coercivity H_c and the initial susceptibility χ_0 are closely related to $\langle K \rangle$ by

$$H_c = P_c \frac{\langle K \rangle}{J_s} \propto D^6; \quad \chi_0 = P_\chi \frac{J_s^2}{\mu_0 \langle K \rangle} \propto D^{-6} \tag{42}$$

with the parameters $P_c = 0.96$ and $P_\chi = 0.33$ for uniaxial grains and $P_c = 0.94$ and $P_\chi = 0.33$ for cubic grains and $K_1 > 0$. For the Rayleigh constant α_R a D^{-12} law holds due to equations (37). In Figure 23 the D^6, D^{-6} and D^{-12}-law for H_c, χ_0, and α_R have been tested for different nanocrystalline iron-based alloys (Herzer, 1997).

In nanocrystalline magnets, the magnetization process takes place by domain wall displacements for $D < l_K^{eff}$ and by rotational processes for $D > l_K^{eff}$: The selfconsistency conditions for domain wall displacements and rotational processes respectively are given by

$$\frac{\chi_0 H_c \mu_0}{J_s} = \frac{\sqrt{\pi}}{2} v \frac{\delta_B}{L_3} \left(\ln \frac{L_3}{2\delta_B} \right)^{1/2};$$
$$\frac{\chi_0 \mu_0 H_c}{J_s} = P_c P_\chi \approx 0.32 \tag{43}$$

where in the first relation v corresponds to the relative volume and the domain walls are oriented parallel to the applied field and the second relation holds for uniaxial and cubic symmetry. By plotting $\chi_0 H_c \mu_0 / J_s$ the type of magnetization processes can be analyzed as shown in

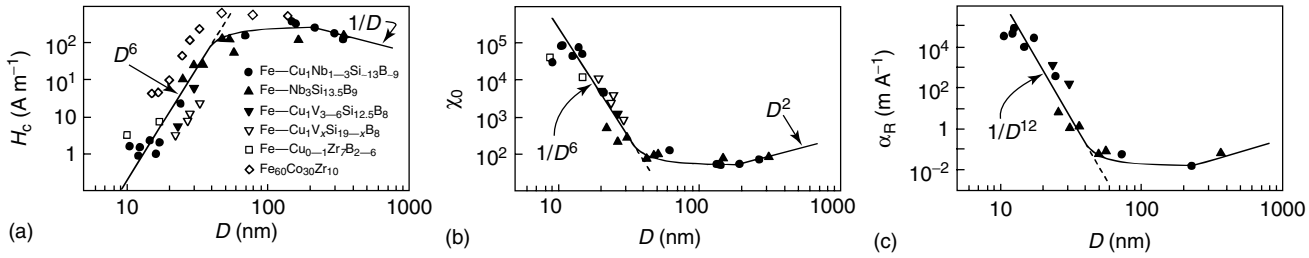

Figure 23. Coercivity H_c (a), initial susceptibility χ_0 (b), and Rayleigh constant α_R (c) of nanocrystalline iron-based alloys as a function of the grain size D showing the predicted D^6, D^{-6}, and D^{-12}-dependencies. (Reproduced from Herzer 1997, with permission from Elsevier. © 1997.)

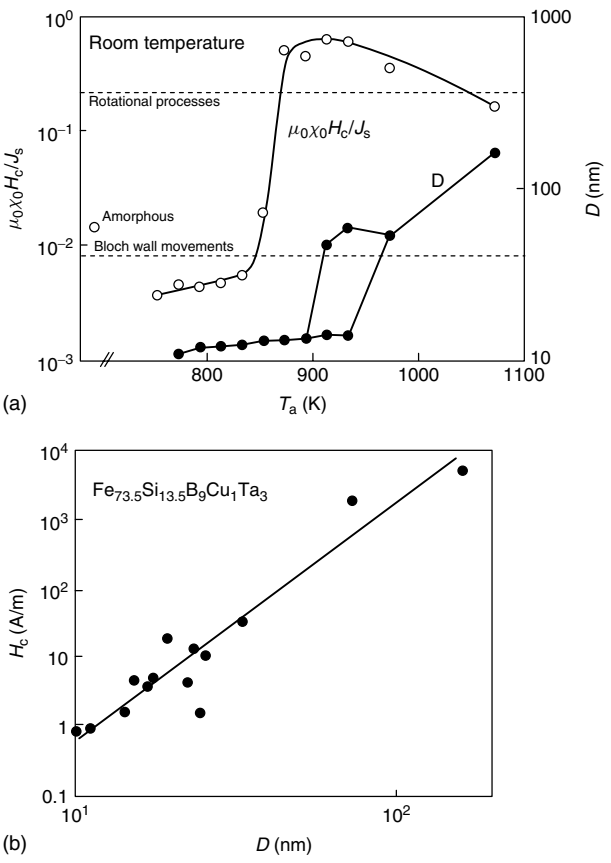

Figure 24. (a) $\mu_0\chi_0H_c/J_s$ as a function of the grain size controlled by the annealing temperature compared with predictions for domain wall displacements and rotational processes (Hofmann, Reininger and Kronmüller, 1992). (b) Dependence of the coercivity on the grain size D for $Fe_{73.5}Si_{13.5}Nb_3Cu_1B_9$ with uniaxial induced anisotropy ($H_c = 2.9 \times 10^{-4} d^{3.35}$ A m^{-1}). (Reproduced from Murillo & González 2000, with permission from Elsevier. © 2000.)

Figure 24(a) for nanocrystalline $Fe_{73.5}Si_{13.5}Nb_3Cu_1B_6$ (Hofmann, Reininger and Kronmüller, 1992). For annealing temperatures $T_A < 850$ K ($D < l_K^{eff}$) domain wall displacements occur, whereas for $T_a > 900$ K ($D > l_K^{eff}$) rotational processes take place.

For grains with diameters significantly larger than the wall width ($D \gg l_K^{eff}$, $D > 100$ nm) domains can be formed within the grains and H_c and χ_0 are given by Kronmüller and Hilzinger (1976)

$$H_c = \frac{2\gamma_B}{J_s \cos\varphi_0}\frac{1}{D}; \quad \chi_0 = \frac{2}{3}\frac{J_s^2 \cos\varphi_0 D^2}{4\pi\mu_0\gamma_B L_3} \qquad (44)$$

where φ_0 is the angle between the applied field and the polarization within the domains. Then the magnetization process takes place by the bowing of domain walls at grain boundaries. In Figure 23 for large D the $1/D$ and D^2 law for H_c and χ_0 have been obtained for different nanocrystalline iron-based alloys.

In the case of an appreciable macroscopic-induced anisotropy, according to equation (39), H_c obeys a D^3 law which has been experimentally confirmed by Murillo and González (2000) and by Suzuki, Herzer and Cadogan (1998) as shown in Figure 24(b).

6.1.4 Application to amorphous materials

In amorphous alloys at least five pinning effects for domain walls may contribute to the total coercivity (Kronmüller, 1981a; Kronmüller and Fähnle, 2003). These contributions are intrinsic fluctuations (H_c^i) which give rise to a lower limit of the coercivity, short-range-ordered effects (H_c^{cl}) and relaxation effects (H_c^{rel}) both of which may be minimized by a suitable annealing treatment, surface effects (H_c^{surf}) which can be minimized by extremely smooth surfaces and internal stress sources (H_c^{σ}) interacting with domain walls which can only be reduced significantly by using nonmagnetostrictive alloys. Within the framework of the statistical potential theory the contributions due to statistically distributed types of pinning centers add quadratically whereas the effect of relaxation processes has to be added linearly because each domain wall is submitted to a stabilization energy with wavelength $2L_0$. Thus, the total coercivity is given by

Kronmüller (1981a)

$$H_c^{\text{total}} = \left[(H_c^{\sigma})^2 + (H_c^{\text{surf}})^2 + (H_c^{\text{cl}})^2 + (H_c^{\text{i}})^2\right]^{1/2} + H_c^{\text{rel}} \tag{45}$$

In the special case where the contribution of the pinning due to surface irregularities is larger than all other contributions, the different terms add linearly as the wavelength of the surface pinning is much larger ($\approx$10 µm) than that of the intrinsic fluctuations (<0.5 µm). In the following text, the five contributions are ordered with increasing influence on H_c.

a Intrinsic fluctuations: The intrinsic fluctuations of exchange interactions and local anisotropies due to the non-periodic atomic arrangement may act as pinning centers for domain walls. In general, the statistical fluctuations of an intrinsic material parameter $P(\mathbf{r})$ is the sum of the volume average $\langle P(\mathbf{r})\rangle$ and the fluctuating part $\delta P(\mathbf{r})$ of the parameter

$$P(\mathbf{r}) = \langle P(\mathbf{r})\rangle + \delta P(\mathbf{r}) \tag{46}$$

If a domain wall is exposed to fluctuations of the local anisotropy energy $\delta K(r)$ and of the exchange energy $\delta A(r)$ the resulting intrinsic coercive field is given by Kronmüller (1981b)

$$\mu_0 H_c^{\text{i}} = \frac{\sqrt{\pi}}{M_s}\frac{\sqrt{\rho_M}\langle\Omega\rangle}{\sqrt{2F_B\delta_B}} \times \left(\frac{8}{15}\langle\delta K^2\rangle + \frac{11}{15}\langle\delta A^2\rangle\frac{\pi^4}{\delta_B^4}\right)^{1/2}\left(\ln\frac{L_3}{2L_0}\right)^{1/2} \tag{47}$$

where ρ_M corresponds to the density of magnetic ions and $\langle\Omega\rangle$ to the average atomic volume. For statistical independent fluctuations $\langle\delta K^2\rangle$ and $\langle\delta A^2\rangle$ may be replaced by $\langle K^2\rangle$ and $\langle A^2\rangle$. Depending on the material parameters $\mu_0 H_c^{\text{i}}$ of amorphous soft magnetic materials amounts to 10^{-7}–10^{-4} mT (e.g., Fe: $\mu_0 H_c^{\text{i}} = 3.2\times10^{-5}$ mT).

b Clusters of chemical short-range-ordered regions: The formation of chemical short-range-ordered clusters which are characterized by the number n_{cl} of atoms per cluster results in an enhancement of the intrinsic coercive field by a factor $\sqrt{n_{\text{cl}}}$ (Kronmüller, 1981a)

$$\mu_0 H_c^{\text{cl}} = \mu_0 H_c^{\text{i}}\sqrt{n_{cl}} \tag{48}$$

Depending on the material parameters $\mu_0 H_c^{\text{cl}}$ is smaller than 10^{-4} mT.

c Surface irregularities: The natural surface roughness of amorphous ribbons may also influence the coercivity. A planar domain wall of lateral extension L_2 in y direction (Figure 8b) moving through a ribbon of thickness $T(z)$ therefore changes its domain wall area as a function of position z. Its total energy and the force exerted on it may be written as

$$\phi_\gamma(z) = \gamma_B L_2\langle T(z)\rangle;$$
$$P^{\text{surf}}(z) = -\gamma_B L_2\frac{\mathrm{d}}{\mathrm{d}z}\langle T(z)\rangle \tag{49}$$

where $\langle T(z)\rangle$ corresponds to the statistical average of T in y direction and γ_B is the specific wall energy. For a sinusoidal z dependence $\langle T(z)\rangle = \langle T\rangle + \Delta T\sin(2\pi z/\lambda)$ (λ: wavelength of the surface irregularities, ΔT: amplitude of the surface irregularities) the surface coercive field is given by Kronmüller (1981a)

$$\mu_0 H_c^{\text{surf}} = \frac{\pi}{M_s}\frac{\Delta T}{\langle T\rangle}\gamma_B\sqrt{\rho_s}\sqrt{\frac{L_2}{2\lambda}\ln\left(\frac{L_3}{2L_0}\right)} \propto \frac{1}{\langle T\rangle} \tag{50}$$

where $\rho_s \leq \lambda^2$ denotes the number of surface pinning centers per unit area. The increase of H_c^{surf} with decreasing $\langle T\rangle$ after several surface pretreatments is shown in Figure 25(a). The increase is largest for grinding with glasspaper and smallest for electropolished samples. $\mu_0 H_c^{\text{surf}}$ normally amounts to 10^{-4}–10^{-3} mT.

d Relaxation effects: Domain wall mobility is furthermore affected by the magnetic aftereffects. As the relaxations are thermally activated, the mobility of the domain walls becomes time dependent. The reorientation of atom-pair axes within the domain wall into energetically more favorable orientations results in a stabilization of the domain wall. The additional field required to overcome this statistical force field is the time-dependent coercive field of relaxation (Kronmüller, 1981a)

$$\mu_0 H_c^{\text{rel}}(t) = \text{const}\frac{\varepsilon_p^2\rho_p}{kT}(1 - \mathrm{e}^{-t/\tau}) \tag{51}$$

where ρ_p is the atom-pair density reorienting with a relaxation time τ and ε_p is the interaction energy of atom pairs with the spontaneous polarization. If the displacement of domain walls can be described by the statistical potential theory H_c^{rel} can be derived from the fundamental relation

$$\chi_0(t)H_c(t) \approx \frac{J_s\delta_B}{L_3} \tag{52}$$

Accordingly, a relaxation $\Delta\chi$ of the initial susceptibility χ_0 is related to an increase ΔH_c of the coercive field as given by

$$H_c^{\text{rel}}(t) = \Delta H_c(t) = -\frac{\Delta\chi(t)}{\chi_0}H_c(0) \tag{53}$$

where $H_c(0)$ is the unrelaxed coercivity. As experimentally the relative relaxation $\Delta\chi/\chi_0$ was found to vary from 0.05 to

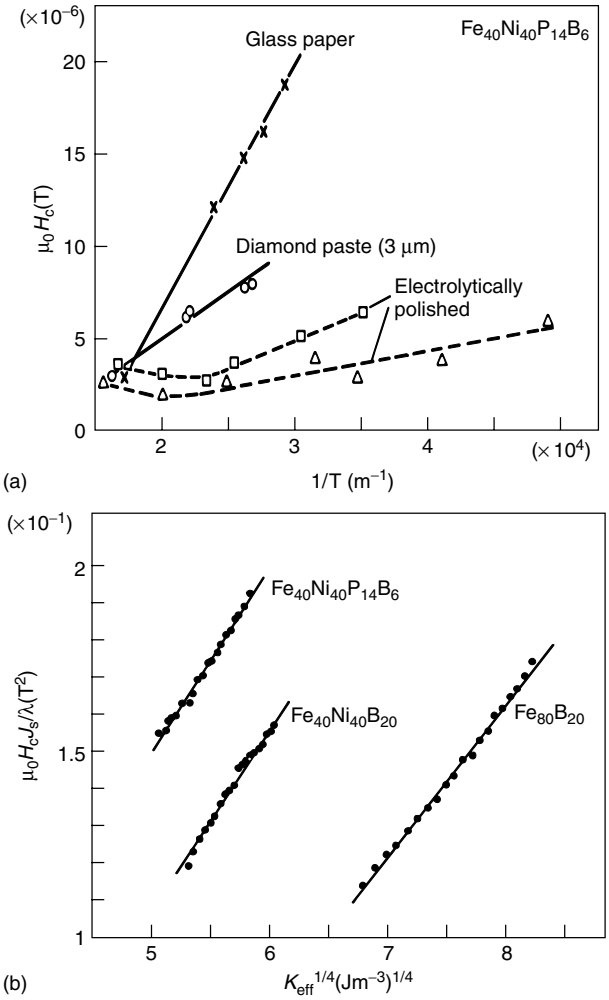

Figure 25. (a) Coercivity H_c of $Fe_{40}Ni_{40}P_{14}B_6$ as a function of the ribbon thickness T after different types of surface treatments. The slopes increase with increasing degree of roughness. (Reproduced from Kronmüller 1981, with permission from Elsevier. © 1981.) (b) Temperature dependence of H_c for magnetostrictive Fe–Ni-based alloys in the temperature range 100–310 K. (Reproduced from Gröger & Kronmüller 1981, with permission from Elsevier. © 1981.)

1.0 (Allia, Mazzetti and Vinai, 1980; Moser and Kronmüller, 1980) H_c^{rel} may contribute significantly to the total coercive field ($\mu_0 H_c^{rel} = 10^{-5}$–$10^{-3}$ mT).

e Internal stresses: In magnetostrictive materials elastic stress sources are the dominant pinning centers, therefore, governing the coercive field. With increasing magnetostriction λ_s the coercivity H_c increases and χ_0 decreases. For quasidislocation dipoles, which are the main sources of elastic stresses, the coercive field is given by

$$\mu_0 H_c^{\sigma} \propto \frac{\lambda_s}{J_s}\left(\frac{K_1}{A}\right)^{1/4} \tag{54}$$

This relation has been tested in Figure 25(b) for various nickel–iron based amorphous alloys showing the predicted temperature dependence of H_c (Gröger and Kronmüller, 1981). It has been shown (Kronmüller, Lenge and Habermeier, 1984) that elastic dipoles of extensions 1–10 nm are present in amorphous alloys with a high density of 10^{18} m^{-3}. Depending on the material parameters and the defect density $\mu_0 H_c^{\sigma}$ amounts to 10^{-3}–10^{-2} mT.

6.2 High-frequency behavior and losses

When a soft magnetic material is subjected to a time-varying magnetic field $H(t)$ various energy dissipation mechanisms occur so that part of the energy injected into the system by the external field is irrevocably transformed into heat. In a cyclic field of frequency f the loss per cycle, that is, the energy per unit volume converted into heat, is given by

$$W = \int H \frac{\mathrm{d}B}{\mathrm{d}t}\mathrm{d}t \tag{55}$$

The loss per unit time is called power loss $P = f \times W$ [W m^{-3}]. The total power loss P at frequency f is the sum of the (static) hysteresis loss P_h due to defect structures interacting with domain walls, the classical (eddy current) loss P_{cl} due to the specimen geometry and the excess (eddy current) loss P_{exc} (formerly called anomalous loss) due to the existence of magnetic domains. The frequency dependence of the three contributions to the total power loss per cycle are shown in Figure 26(a). When the material is (de)magnetized under sinusoidal induction rate, the total power loss P is given by Bertotti (1998) and Bertotti (2006)

$$P = P_h + P_{cl} + P_{exc}; \quad P_h = 4k_{hyst}B^{\beta}f;$$
$$P_{cl} = \frac{\pi^2\sigma d^2}{6}(Bf)^2; \quad P_{exc} = k_{exc}\sqrt{\sigma}(Bf)^{3/2} \tag{56}$$

where σ is the electrical conductivity of the material and B the amplitude of magnetic induction. k_{hyst} and β include the structural aspects which affect domain wall pinning and magnetization reversal, k_{exc} includes microstructural effects as grain-size fluctuations or wavelengths of stresses. The eddy current losses give rise to changes in the shapes of the hysteresis loops as shown in Figure 26(a).

The hysteresis loss is the power loss obtained when the field is cycled slowly under quasistatic conditions. It is (like the coercivity) directly related to structural disorder in the material which provides sources for domain wall pinning. The hysteresis loss is a consequence of the fact that magnetization proceeds through Barkhausen jumps of domain walls which are unpinned from defects by the pressure of the external field. Each wall jump results in an

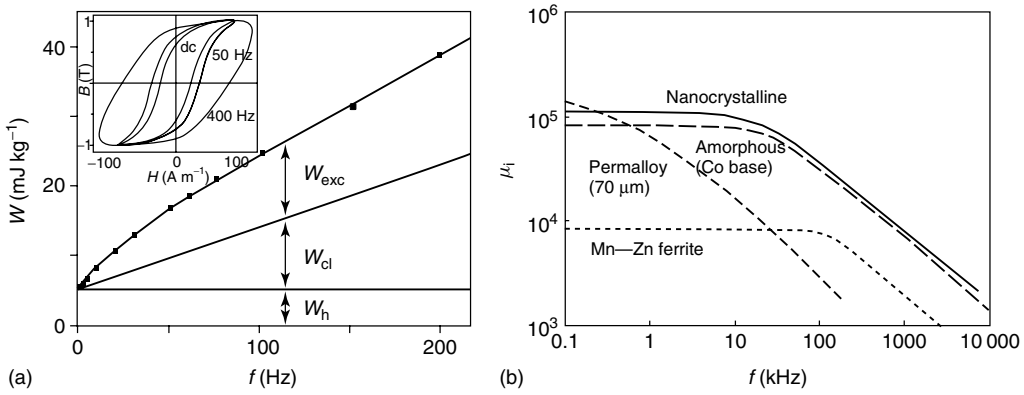

Figure 26. (a) Separation of the total power loss per cycle into its components (W_h: hysteresis loss, W_{cl}: classical loss, W_{ex}: excess loss) as a function of frequency f for grain-oriented Fe-3wt%Si (specimen thickness 0.3 mm). The inset shows typical dynamical hysteresis loops for nonoriented Fe-3wt%Si (specimen thickness 0.35 mm) (quasistatic (dc), 50 Hz, 400 Hz). (Reproduced from Bertotti 2006, with permission from Elsvier. © 2006.) (b) Magnetic initial permeability μ_i as a function of frequency f for different soft magnetic materials (Hilzinger and Tenbrink, 2001). (Reproduced from Hilzinger & Tenbrinck, 2006, with permission from Elsevier. © 2006.)

induction change which induces local eddy currents which in turn dissipate a finite amount of energy as heat. The sum over all jumps results in the hysteresis loss. The amount of energy which is dissipated during individual wall jumps is determined by the height of the energy barrier created by the pinning obstacle. As a general rule, the smaller the coercivity, the smaller is the hysteresis loss. According to equation (56) the hysteresis loss is independent of the electrical conductivity σ and of the sample thickness d when pinning effects are volume effects (however, when the surface of the sample acts as relevant pinning source, the hysteresis loss increases with decreasing thickness of the sample). The hysteresis loss per cycle ($W_h = P_h/f$), which is equivalent to the area enclosed by the quasistatic hysteresis loop, is furthermore independent of the frequency f.

The classical loss is always present in metallic soft magnetic materials. It is obtained from solving Maxwell's equations for a homogeneous conducting medium with no structural inhomogeneities and no magnetic domains (Bozorth, 1993). The boundary conditions which are given by the system geometry determine the distribution of eddy currents in the specimen and the ensuing heat dissipation. The classical loss can be minimized by reducing both the electrical conductivity σ and the specimen thickness d. Therefore, magnetic cores of devices are never made of bulk soft magnetic materials.

The excess loss results from the large-scale motion of domain walls in the specimen. Around the moving domain walls eddy currents tend to concentrate. The influence of excess losses significantly depends on the size and arrangement of magnetic domains. For a regular arrangement of longitudinal domains the expression for the excess loss in equation (56) simplifies to $P_{exc} = 1.63(2L/d)P_{cl}$ (d: specimen thickness, L: average domain width) (Bishop, 1976). The finer the domain structure, the smaller is the excess loss. The excess loss can be neglected when the domain width is much smaller than the specimen thickness or when magnetization changes homogeneously by rotation as is the case for flat-type hysteresis loops with small J_r/J_s ratios (for hysteresis loops with large J_r/J_s ratios where the magnetization process takes place by domain wall displacements excess eddy current losses do occur).

The initial permeability μ_i is independent of the frequency for low frequencies, whereas for high frequencies μ_i approaches unity (Figure 26b) The frequency at which μ_i starts to decrease depends on the magnetic material and has its origin in the occurence of resonance effects, for example, dimensional resonance due to the sample geometry, magnetic resonance due to the rotation of the magnetization against the action of the anisotropy field or due to the resonant oscillation of domain walls.

Especially amorphous and nanocrystalline alloys reveal low losses and a high permeability even at elevated frequencies which is essentially related to the facts that they are produced as thin ribbons and that their electrical resistivity is high, both reducing eddy current losses.

7 APPROACH TO SATURATION: MICROMAGNETISM AND MICROSTRUCTURE

The approach to saturation of a ferromagnetic hysteresis loop is known as the region of quasisaturation where the angle between the spontaneous polarization J_s and the applied field H is very small. In this region the hysteresis loop can be regarded as fully reversible and the field dependence of the

polarization can be generally written as (Kronmüller, 1959; Kronmüller and Fähnle, 2003)

$$J(H,T) = J_s - \sum_{i=1}^{6} \frac{a_{i/2}}{H^{i/2}} + \Delta J_{SW} + \chi_p \mu_0 H \qquad (57)$$

that is the approach to saturation is determined by intrinsic and extrinsic properties.

Intrinsic properties are magnetocrystalline anisotropies, spin waves, and the Pauli paramagnetic susceptibility χ_p. In (nano) crystalline magnets the magnetocrystalline anisotropy results in a a_2/H^2 term and a a_3/H^3 term. For uniaxial anisotropy, Danan (1958) derived for the coefficients $a_2 = 4K_1^2/(15J_s^2)$ and $a_3 = 16K_1^3/(105J_s^3)$. For cubic anisotropy, Akulov (1931), Gans (1932), and Becker and Döring (1939) found for the coefficients $a_2 = 8K_1^2/(105J_s^2)$ and $a_3 = 192K_1^3/(5005J_s^3)$. In amorphous magnets, local fluctuations of the magnetocrystalline anisotropy give rise to a $a_{1/2}/H^{1/2}$ term at small fields and a a_2/H^2 term at large fields. The spin-wave contribution ΔJ_{SW} for a quadratic dispersion law of the spin-wave energy spectrum can be derived according to Holstein and Primakoff (1940) as

$$\begin{aligned}\Delta J_{SW} &= -J_s \left(\frac{T}{T_0}\right)^{3/2} + \Delta J_{para} \\ &= -J_s \left(\frac{T}{T_0}\right)^{3/2} + C(T) f_{HP}\end{aligned} \qquad (58)$$

where the first term corresponds to the well-known Bloch's $T^{3/2}$ law and the second term takes care of the spin-wave paraeffect which results from the reduction of the number of magnons by an applied magnetic field. The characteristic temperature T_0 and the function $C(T)$ are related to the spin-wave stiffness constant D_{sp} of the magnon energy spectrum $\epsilon_k = D_{sp}k^2$ (k: spin-wave wave vector) and f_{HP} is the Holstein–Primakoff function

$$\begin{aligned} k_B T_0 &= D_{sp} \left(\frac{J_s(0)}{0.117\mu_B}\right)^{2/3}; \\ C(T) &= \left(\frac{\mu_B^{3/2} k_B}{2\pi}\right) \frac{\mu_0}{(2D_{sp})^{3/2}} T; \\ f_{HP} &= 3\sqrt{\mu_0 H} + \sqrt{J_s(0)} \frac{\mu_0 H + J_s(0)}{J_s(0)} \sin^{-1} \\ &\quad \times \left(\frac{J_s(0)}{\mu_0 H + J_s(0)}\right)^{1/2} \end{aligned} \qquad (59)$$

with k_B Boltzmann's constant and $J_s(0)$ the spontaneous polarization at $T \to 0$. The enhanced Pauli paramagnetism of the band structure gives rise to the linear term $\chi_p \mu_0 H$.

Extrinsic properties are due to magnetoelastic stress sources which produce inhomogeneous spin states. The corresponding deviations from saturation are determined by the geometry of the defect, the range of the spin inhomogeneity, and the interaction between defects. Typical spin distributions around point defects, dislocations, and dislocation dipoles are shown in Figure 27. Point defects with stress fields varying as $\sigma \propto 1/r^3$ give rise to a $a_{1/2}/H^{1/2}$ term. Straight dislocation dipoles with stress fields $\sigma \propto 1/r^2$ lead to a a_1/H term as long as the distance D between the two dislocations is smaller than the exchange length $l_H = \sqrt{2A/(J_s H)}$. Otherwise, the two dislocations act as two single straight (opposite) dislocations exhibiting a $\sigma \propto 1/r$ dependence of the stress field which gives rise to a a_2/H^2 term. Nonmagnetic spherical inclusions of radius r_0 result in a $a_{1/2}/H^{1/2}$ term for $r_0 < l_H$ and in a $a_{3/2}/H^{3/2}$ term for $r_0 > l_H$.

In general, in the high-field region the paraeffect becomes important whereas in the lower field region the microstructural effects are prevailing. For hard magnetic materials the influence of the microstructural effects can be neglected compared to the influence of the magnetocrystalline anisotropy.

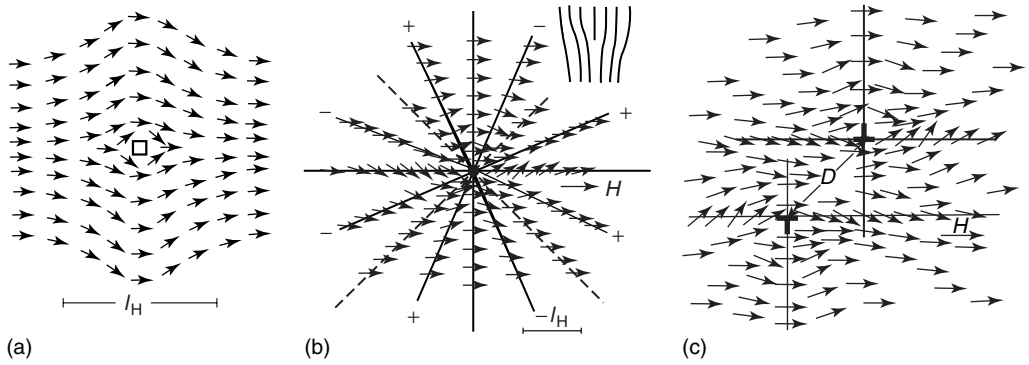

Figure 27. Spin distribution around (a) a vacancy type defect, (b) an isolated quasidislocation, and (c) a quasidislocation dipole.

The law of approach to saturation can be used to analyze the defect structures in (nano)crystalline magnets and especially in amorphous magnets where conventional techniques as X-ray or neutron diffraction or transmission electron microscopy fail due to the nonperiodic structure. The analysis of the field dependence also opens the possibility to determine the temperature dependence of the spontaneous polarization $J_s(T, 0) = J_s[1 - (T/T_0)^{3/2}]$ at zero magnetic field after separation of the microstructural effects and the paraeffect.

In order to determine the microstructural terms, $J(T, H)$ has to be plotted as a function of $1/H^{n/2}$. Figure 28 shows the result of such plots for amorphous $Fe_{40}Ni_{40}P_{14}B_6$ and $Fe_{40}Ni_{40}B_{20}$. In the case of $Fe_{40}Ni_{40}P_{14}B_6$ the approach to saturation is described by a a_1/H term for $\mu_0 H < 0.2\,\mathrm{T}$. In contrast, $Fe_{40}Ni_{40}B_{20}$ follows a a_1/H law in the field range $0.01 \leq \mu_0 H \leq 0.03\,\mathrm{T}$ and obeys a a_2/H^2 law for $0.03\,\mathrm{T} \leq \mu_0 H \leq 0.2\,\mathrm{T}$. The steep increase in the $J(H, T)$ versus $1/H^{n/2}$ diagrams for $\mu_0 H > 0.2\,\mathrm{T}$ for both materials is due to the spin-wave term. For an analysis of this region the spin-wave contribution to $J(H, T)$ can be eliminated by extrapolating the microstructural effects to higher fields ($1/H_n \to 0$). In Figure 29(a) the paraeffect ΔJ_{para} is represented as a function of the Holstein–Primakoff function f_{HP} for $Fe_{40}Ni_{40}P_{14}B_6$. It follows from this that the paraeffect depends linearly on f_{HP}. From the slopes of the straight lines the functions $C(T)$ given in equation (59) are obtained. The magnetoelastic origin of the inhomogeneity terms becomes obvious in Figure 29(b) where in rapidly quenched or plastically deformed materials the $1/H$ term is predominant proving the presence of quasidislocation dipoles, whereas in nearly nonmagnetostrictive alloys as $Co_{58}Ni_{10}Fe_5Si_{11}B_{16}$ the $1/H$ term is rather small.

It should be noted that perfect single crystals can be saturated completely when the magnetic field is applied parallel to an easy or heavy direction of the crystal. In the case of orientation parallel to an easy axis the field strength necessary to reach ferromagnetic saturation is rather small as the movement of the domain walls is not impeded. In the case of orientation parallel to a heavy axis ferromagnetic saturation is reached for $\mu_0 H = 2\mu_0 K_1/J_s$ by reversible rotations.

8 TAILOR-MADE HIGH-PERFORMANCE MAGNETS

According to Sections 5 and 6, both hard and soft magnetic materials are strongly dependent not only on intrinsic material parameters but also on the special types of microstructures. Actually the deviations from the ideal lattice in many cases are responsible for certain outstanding properties. The

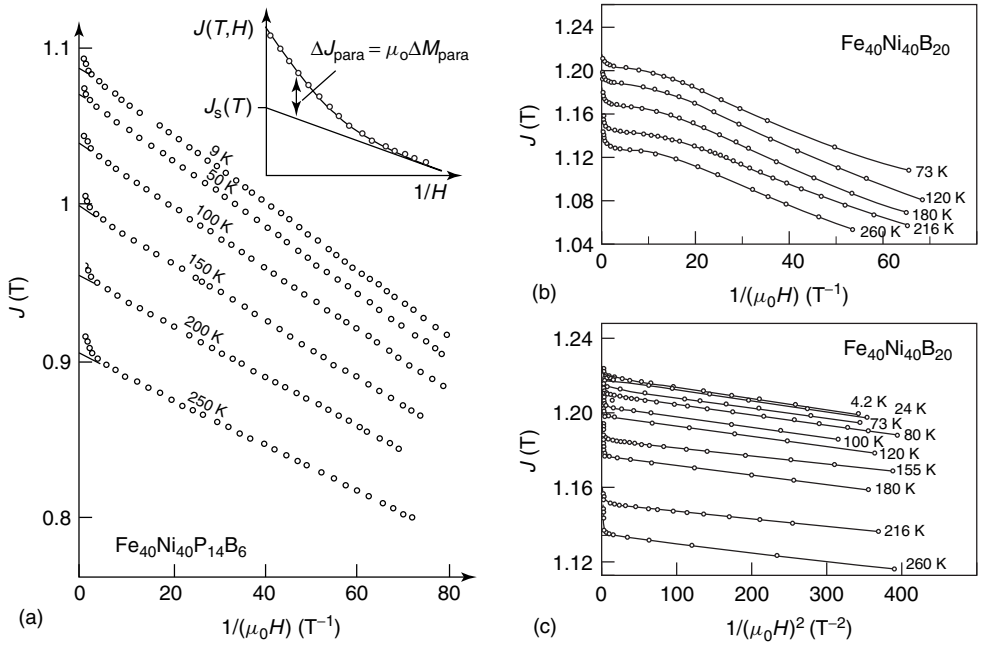

Figure 28. Field dependence of the polarization $J(T, H)$ at different temperatures of (a) amorphous $Fe_{40}Ni_{40}P_{14}B_6$ as a function of $1/(\mu_0 H)$ (Kronmüller and Grimm, 1977), (Reproduced from Kronmüller & Grimm 1977, with permission from Elsevier. © 1977.) detailed knowledge of the micromagnetism–microstructure correlation can be used for a systematic design of high-performance magnets. In particular, nanocrystalline and nanostructured magnets allow a wide variation of microstructures and therefore offer a new opportunity for tailoring extremely hard and extremely soft magnetic materials. Using suitable additives the grain sizes as well as the magnetic properties and the chemical composition of the grain boundaries can be tailored on an atomic scale.

8.1 Optimization of hard and soft magnets

With nanocrystalline hard magnets based on $RE_2Fe_{14}B$, magnets with definite properties of the hysteresis loop can be designed due to the fact that small deviations from the stoichiometry and small amounts of certain additives may lead to drastic changes in the magnetic properties. In Figure 30(a) it is illustrated how the room temperature magnetic properties change with increasing Fe content for melt-spun $Pr_2Fe_{14}B$ magnets. The increasing Fe content not only results in an enhancement of the remanence but also in a decrease of the coercivity. However, as long as the condition $\mu_0 H_c > 0.5 J_r$ is fulfilled, $(BH)_{max}$ increases. Otherwise, $(BH)_{max}$ is limited by irreversible demagnetization processes.

With nanocrystalline soft magnets based on $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ the magnetic properties of the hysteresis loop can be controlled only in part by the grain-size effect. If the grain size is small enough, the composition and the volume fraction of the individual phases take over the control of the soft magnetic properties. Soft magnetic applications require not only highest permeability but also lowest coercivity. A well defined shape of the hysteresis loop with a well defined level of permeability adjusted to the particular application is equally important. A wide spectrum of properties can be tailored by magnetic field annealing which induces a uniaxial anisotropy with easy axis parallel to the direction of the magnetic field applied during the heat treatment. As an example, Figure 30(b) shows the hysteresis loops after different heat treatments with and without magnetic field. Accordingly, almost perfect rectangular (flat shaped) hysteresis loops are obtained for magnetic fields along (tranverse) to the magnetic path in the application, whereas a more round shaped hysteresis loop is obtained by conventional annealing without a magnetic field. Field induced anisotropies K_u are due to atomic pair ordering which minimizes the spin-orbit coupling energy. K_u directly controls the soft magnetic properties, for example, after tranverse field annealing the permeability is constant up to saturation and is given by $\mu = J_s^2/(2\mu_0 K_u)$ and after longitudinal field annealing low induced anisotropies facilitate domain refinement resulting in reduced excess losses.

A further important aspect many applications look for is a small temperature coefficient of the magnetic properties over a large temperature range. Especially, for nanostructured $Sm_2(Co,Cu,Fe,Zr)_{17}$ hard magnets depending on the compostion and on the annealing parameters the temperature dependence of the coercivity H_c can be easily changed according to Section 5.1.2 from the conventional monotonic to the recently developed nonmonotonic behavior showing coercivities up to 1 T even at 400 °C. For nanocrstalline soft magnets a very temperature stable behavior of the permeability is guaranteed as the averaging out of the magnetocrystalline anisotropy by exchange interaction is effective over a large temperature range.

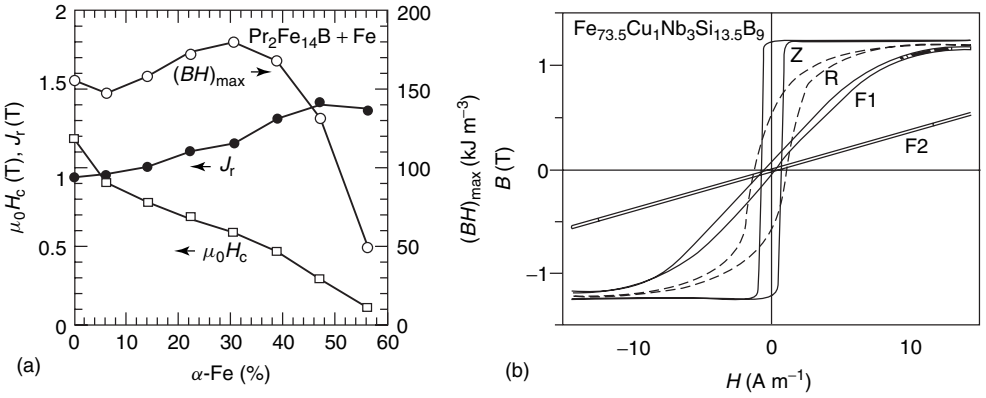

Figure 30. (a) Magnetic properties of nanocrystalline composite $Pr_2Fe_{14}B$ permanent magnets as a function of excess α-Fe. For an iron excess of 30.4 vol%, J_r amounts to 1.17 T, that is, an increase of 51% as compared to the decoupled value of 0.78 T and $(BH)_{max}$ is measured to be 180.7 kJ m^{-3}. (Reproduced from Goll *et al*., 1998, with permission from Elsevier. © 1998.) (b) Hysteresis loops of nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ soft magnets annealed without (R) and with a magnetic field applied parallel (Z) and tranverse (F2) ($K_u \approx 20\,\mathrm{J\,m^{-3}}$, $\mu \approx 30 \times 10^3$) to the magnetic path. Sample F1 ($K_u \approx 6\,\mathrm{J\,m^{-3}}$, $\mu \approx 100 \times 10^3$) was first crystallized and then annealed in a transverse field. (Reproduced from Herzer, 1996, with permission from Elsevier. © 1996.)

8.2 Computational micromagnetism

A rather successful tool for a quantitative and also predictive treatment of the complex microstructure–property relationship are numerical micromagnetic finite-element simulations (see also **Numerical Methods in Micromagnetics (Finite Element Method), Volume 2**) which may provide general rules for the design of optimized magnets. Simulations of magnetization processes of ensembles of grains are obtained from a minimization of the magnetic free enthalpy G with respect to the orientation of the spontaneous polarization J_s:

$$\delta G = \delta \int (\phi_A + \phi_K + \phi_S + \phi_H)\,\mathrm{d}V = 0 \qquad (60)$$

where G is composed of four contributions: exchange energy $\phi_A = A(\nabla\varphi)^2$, crystal anisotropy $\phi_K = K_1 \sin^2\varphi + K_2 \sin^4\varphi$, stray field energy $\phi_S = -1/2 H_s J_s$ and magnetostatic energy $\phi_H = -H_{ext} J_s$ (φ: angle between easy axis and J_s, H_s: stray field which follows from a scalar potential U by $H_s = -\nabla U$ and U obeys Poisson's equation $\Delta U = (1/\mu_0)\,\mathrm{div} J_s$). The minimization is usually performed by using the finite-element technique (FEM). For three-dimensional numerical simulations a cubic model particle composed of polyhedral regular or irregular grains is taken into consideration. In the model particle, the average grain size and the magnetic material parameters of the grains and grain boundaries can be modified which enables a systematic study of the main influences on the characteristic properties of the hysteresis loop.

As an example, Figure 31 shows the orientation of the spontaneous polarization J_s of the remanent state for a model composite permanent magnet composed of 35 irregular grains with an average grain diameter of 10 nm and with easy axes distributed isotropically. Fifty-one percent of the grains are soft magnetic α-Fe grains which are embedded in 49% hard magnetic grains of $Nd_2Fe_{14}B$ (Fischer, Schrefl, Kronmüller and Fidler, 1995). At the grain boundaries the orientation of J_s changes smoothly within a region of width δ_B from one easy direction to another one. Under the assumption of a perfect exchange coupling between the grains, Figure 32(a) illustrates the dependence of J_r and $\mu_0 H_c$ on the grain size D. Both quantities decrease with increasing grain size and J_r and H_c can be fitted empirically by the following logarithmic laws (Fischer, Schrefl, Kronmüller and Fidler, 1996)

$$J_r = J_{sat}\left(0.84 - 0.085 \ln \frac{D}{\delta_B^{hard}}\right);$$
$$H_c = H_N^{(0)}\left(0.22 - 0.041 \ln \frac{D}{\delta_B^{hard}}\right) \qquad (61)$$

with $H_N^{(0)} = 2K_1^{hard}/J_s$ and $J_{sat} = J_s^{hard} v^{hard} + J_s^{soft} v^{soft}$ where the upper indices refer to the saturation polarizations and volume fractions of the hard and soft magnetic phases. It turns out that for grain sizes of 20 nm ($5\delta_B^{hard}$) the coercivity amounts to $H_c \approx 0.15 H_N^{(0)}$ and the remanence is considerably larger than the isotropic value of $0.5 J_s$. Figure 32(b) shows the numerical results for J_r, H_c, and $(BH)_{max}$ as a function of the α-Fe content in comparison with experimental data. Whereas for J_r a fairly well agreement is obtained, the theoretical predictions for H_c and $(BH)_{max}$ are appreciably larger than the experimental values. In the case of $(BH)_{max}$ this is due to the fact that for the experimental results the condition $\mu_0 H_c > 0.5 J_r$ is only valid for α-Fe concentrations smaller

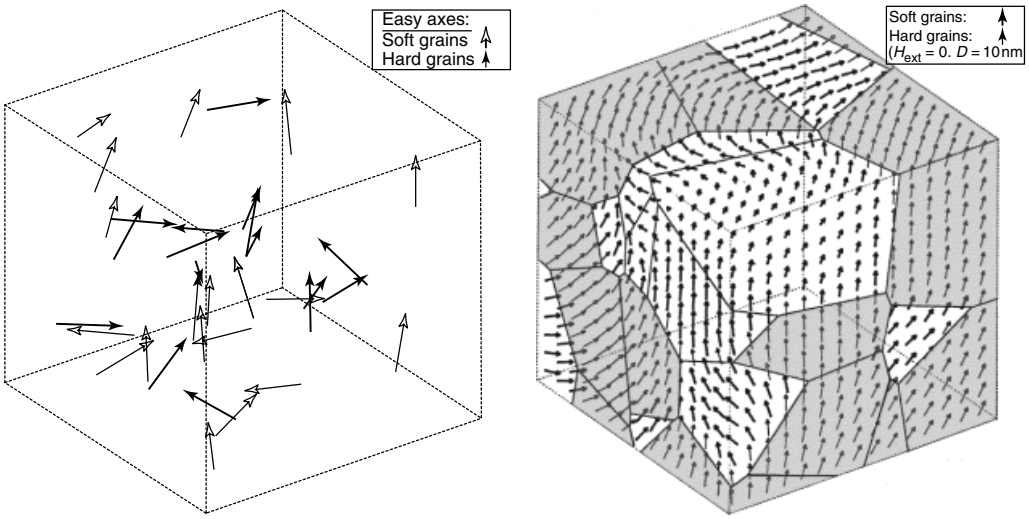

Figure 31. Configurations of the easy axes and of the remanent polarization of 35 irregular grains of average diameter 10 nm within a cube with a volume fraction of 51% α-Fe (*dark*) and 49% $Nd_2Fe_{14}B$ (*light*). (Reproduced from Fischer *et al*., 1995, with permission from Elsevier. © 1995.)

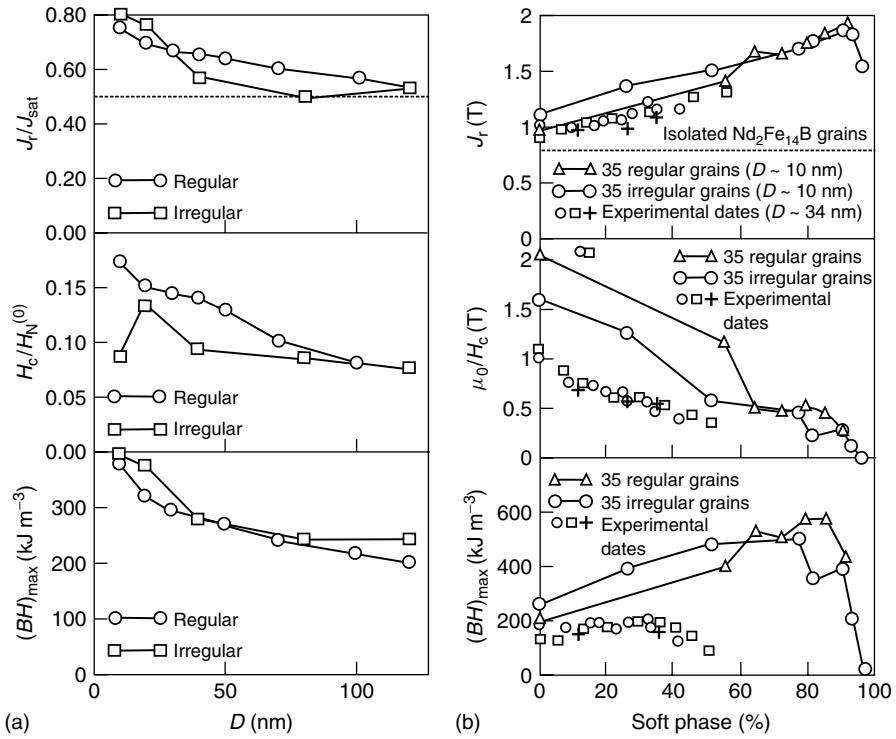

Figure 32. (a) J_r, $\mu_0 H_c$ and $(BH)_{max}$ for the irregular configuration of Figure 31 and a regular dodecahedral grain structure as a function of mean grain size D (Fischer, Schrefl, Kronmüller and Fidler, 1996). (b) Numerical results for J_r, $\mu_0 H_c$ and $(BH)_{max}$ as a function of the α-Fe content in comparison with experimental results. (Reproduced from Fischer *et al*., 1996, with permission from Elsevier. © 1996.)

than 30%, whereas the numerical results fulfill this condition up to 50%. The observed discrepancy between numerical and experimental results can be explained by modifying the intrinsic material parameters within the grain boundaries. Owing to the atomic disorder within grain boundaries it can be assumed that especially A and K_1 have reduced values within the grain boundaries. Figure 33(a) shows the influence of the reduction of these two parameters on the demagnetization curve for a cube of 64 grains of average diameter 20 nm (Fischer and Kronmüller, 1998). For the simulation

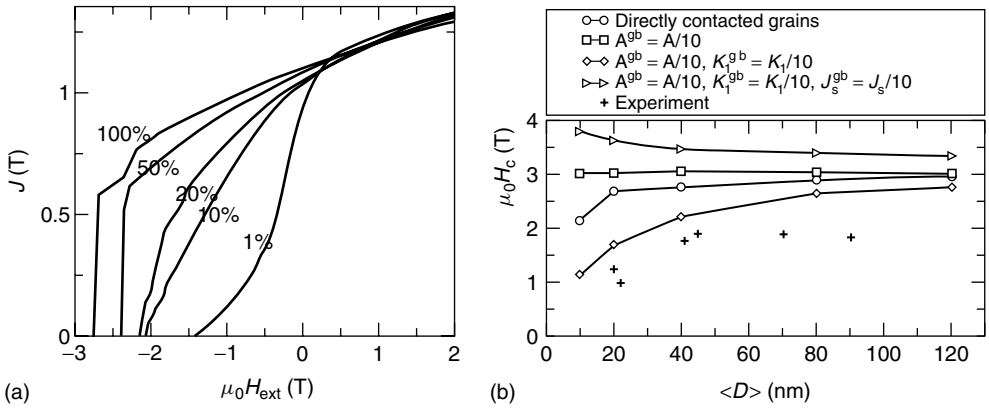

Figure 33. (a) Demagnetization curves for an assembly of 64 $Nd_2Fe_{14}B$ grains (average grain diameter 20 nm) and an intergranular phase of reduced anisotropy and exchange constant (thickness 3 nm). (Reproduced from Fischer & Kronmüller 1998, with permission from Elsevier. © 1998.) (b) Coercive field as a function of the mean grain diameter $\langle D \rangle$ and grain boundaries of width 3 nm and reduced material parameters in comparison with experimental results (Fischer and Kronmüller, 1998).

3 nm grain boundaries are assumed where A and K_1 suffer a steplike reduction. With decreasing A and K_1 within the grain boundaries $\mu_0 H_c$ and J_r also decrease. If the parameter $f = A^{gb}/A = K_1^{gb}/K_1$ (gb: grain boundary) is introduced, $\mu_0 H_c$ and J_r obey the following relations

$$\frac{H_c}{H_N^{(0)}} = 0.304 + 0.098 f; \frac{J_r}{J_{sat}} = 0.646 + 0.036 f \qquad (62)$$

A further interesting property is the dependence of the coercive field on the average grain diameter $\langle D \rangle$ (Figure 33b). Here it turns out that the experimental results obtained by Manaf, Buckley, Davies and Leonowicz (1991) for nanocrystalline $Nd_{13.2}Fe_{79.6}B_6Si_{1.2}$ can only be received in numerical simulations by modifying A and K_1 within the grain boundaries. Figure 34 shows the corresponding magnetization reversal process for an individual grain separated from neighboring grains by grain boundaries with reduced values of A and K_1 (Fischer and Kronmüller, 1998). Obviously, magnetization reversal primarily nucleates within the grain boundaries, whereas in the grain the polarization starts to rotate reversibly into the direction of the applied field.

8.3 Future visions and limits

Further progress in the fields of extremely hard and extremely soft magnetic materials is possible if one succeeds to develop materials with optimal property spectra where magnetic, electrical, mechanical, corrosive, and thermal properties are optimized simultaneously. The development of outstanding multiproperty materials requires interdisciplinary research activities where the development of intrinsic properties as well as investigations of the microstructure and of local chemical compositions are carried out.

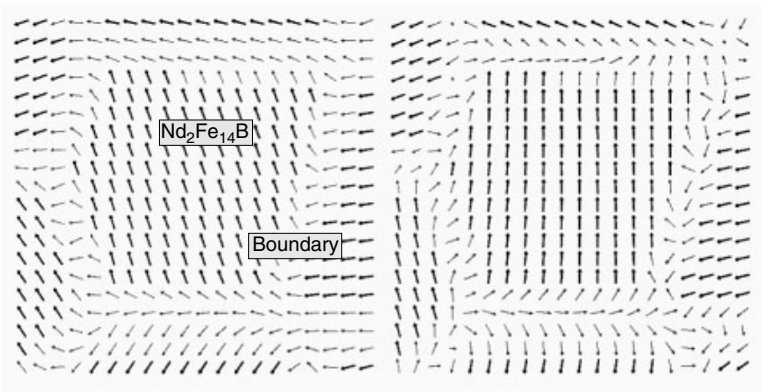

Figure 34. Magnetization distribution at the remanent state and at the overcritical state (field to the right, $\mu_0 H = 0.6$ T) just before magnetization reversal. The strong arrows indicate the magnetic moments within the bulk of the grains. (Reproduced from Fisher & Kronmüller 1998, with permission from Elsevier. © 1998.)

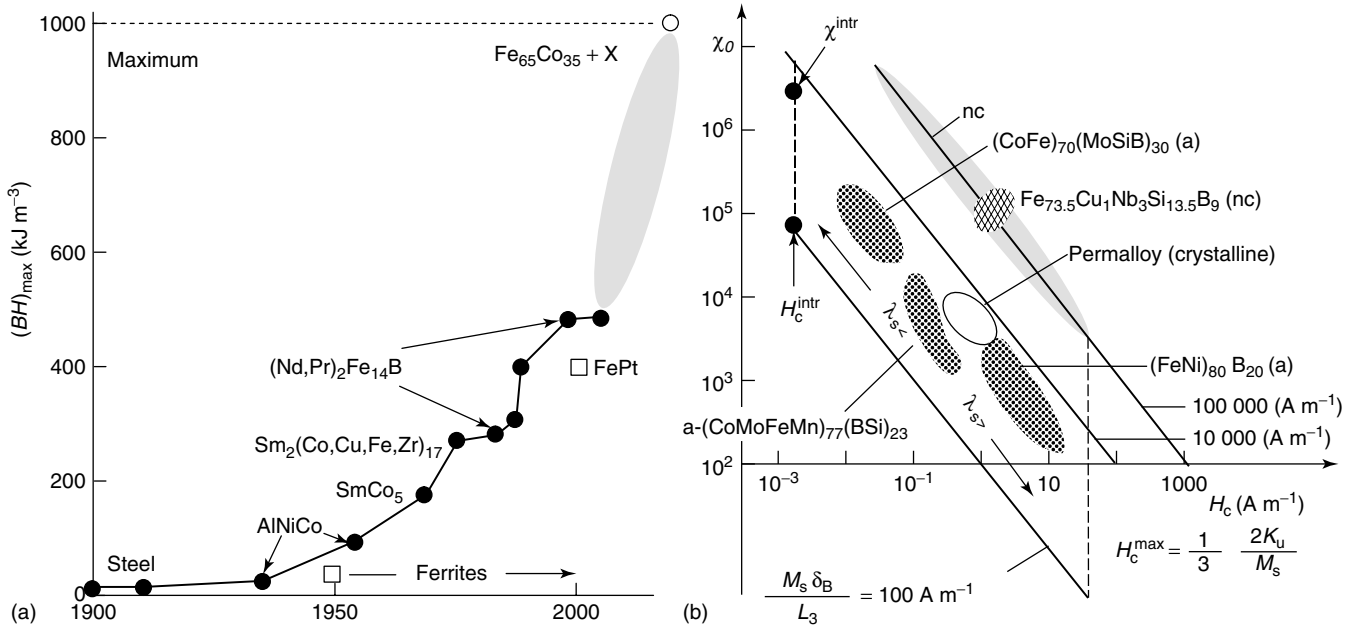

Figure 35. (a) Progress in improving $(BH)_{max}$ of hard magnetic materials over the last century. The shaded region covers hypothetical FeCo-based alloys which are magnetically hardened by additives X. (b) Upper and lower bounds for χ_0 and H_c of soft magnetic materials based on the fundamental relation $\chi_0 H_c = M_s \delta_B / L_3$.

High-coercivity materials are currently based on the intermetallic compounds $Nd_2Fe_{14}B$, $SmCo_5$, and Sm_2Co_{17}. Deficiencies of these compounds are the low Curie temperature of $Nd_2Fe_{14}B$ ($T_C = 312\,^\circ$C) and the low spontaneous polarization of $SmCo_5$ (1.05 T) and Sm_2Co_{17} (1.25 T). This allows applications only up to 100 °C for the $Nd_2Fe_{14}B$ systems and the maximum energy products of the SmCo systems are a factor of 2–3 smaller at room temperature than that of $Nd_2Fe_{14}B$. To achieve Curie temperatures of the order of 450 °C far more additives have to be investigated in the $Nd_2Fe_{14}B$ system. Figure 35(a) presents the development of the maximum energy product $(BH)_{max}$ during the last century. The shaded region shows the progress, which could be still achieved if a FeCo-based magnet with a large spontaneous polarization of 2.45 T could be realized by introducing strong planar pinning centers.

High-permeability materials require large spontaneous polarization, vanishing magnetocrystalline anisotropy, and vanishing magnetostriction. A further breakthrough for these materials could be achieved if nanocrystalline alloys with a larger spontaneous polarization; however, still a low magnetostriction could be found. The spontaneous polarization of the presently used Finemet of 1.25 T could be raised to 1.5 T by using a FeZrB alloy. Also the Curie temperature would be improved and could be further raised by adding Co. The upper and lower bounds for χ_0 and H_c of soft magnetic materials can be derived from the self-consistence relationship of equation (37) which can be approximately written as $\chi_0 \approx M_s \delta_B / (H_c L_3)$ as the square root of the logarithm $\sqrt{\ln(L_3/2L_0)}$ does not depend sensitively on $L_3/(2L_0)$ and is of the order of 2 ($L_3 \approx 100\delta_B - 1000\delta_B$). For ratios δ_B/L_3 varying between 10^{-3} and 10^{-1} and $M_s = 10^5$ A m^{-1} the bounds are given by $100\,\mathrm{A\,m^{-1}} < M_s\delta_B/L_3 < 10^4\,\mathrm{A\,m^{-1}}$. According to Figure 35(b) the CoFe- and NiFe-based amorphous and crystalline alloys lie between these two limits, whereas nanocrystalline FeSiNbCuB alloys are located at $M_s\delta_B/L_3 = 100\,\mathrm{kA\,m^{-1}}$ due to the random-anisotropy effect resulting in domain wall widths of a factor of 5–10 larger than in amorphous alloys. The fine shaded region shows the future possible improvement by using optimized nanocrystalline soft magnets. The absolute lower and upper limits of H_c and χ_0, respectively, are expected for ideal amorphous materials with $K_1 \to 0$ and $\lambda_s \to 0$.

Modeling of Nonlinear Behavior and Hysteresis in Magnetic Materials

David C. Jiles and Yevgen Melikhov
Cardiff University, Cardiff, UK

1 INTRODUCTION

Material properties, including magnetic properties, depend on a number of factors operating on different length scales so that often the situation is beyond a description based on simple theories with one or two equations. Even though progress is still being made to make computer-aided design simulators for materials more realistic, much more is still needed before a material with the desired performance can be designed from first principles. Reliable accurate theoretical models are needed which can provide enough predictive accuracy. For magnetic materials, a model accurately describing hysteresis loops should be the foundation of such computer-aided design tools. Many magnetic properties such as coercivity, remanence, susceptibility, and energy loss can then be determined from the modeled hysteresis loop.

There were many attempts in the past to develop analytical models that accurately describe actual experimental magnetization data. Models have been suggested to describe the magnetization of ferromagnetic materials. However, only some of these have had prolonged success. These include the Preisach model (Preisach, 1935), the Stoner–Wohlfarth model (Stoner and Wohlfarth, 1948, 1991), the Globus model (Globus, 1962, 1975), and the Jiles–Atherton model (Jiles and Atherton, 1986). A detailed review on these models has been given by Liorzou, Phelps and Atherton (2000). Before these models can be used in a meaningful way, one has to be aware of the strengths and weaknesses of each model, since none of these is capable of giving a truly comprehensive description of the many magnetic processes that take place in a magnetic material.

2 DEVELOPMENT OF HYSTERESIS THEORIES AND CONCEPTS

The phenomenon of hysteresis arises most often as a result of cooperative behavior of a large number of identical interacting elements (Vicsek, 2001). The most familiar examples occur in ferromagnetism, but similar behavior occurs in ferroelectrics (Chen and Montgomery, 1980), ferroelastics (Tuszynski, Mroz, Kiefte and Clouter, 1988), and mechanics,

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

particularly fatigue. For a long time, theory and modeling of hysteresis in magnetic materials was a subject for the specialist investigator. However, in recent years, the widespread accessibility and increasing capability of computers has made modeling available to a much wider range of investigators, so that this area of study has become of much broader interest.

In order to improve materials on a systematic basis, it is necessary to have an understanding of the underlying physics of the magnetization process and, in particular, the relationship between structure and properties of magnetic materials. This understanding can then be used to direct research along directions that are likely to be successful in identifying materials with the desired properties. Another reason for modeling the magnetic properties is in the design of devices, using computer-aided design methods, whereby the performance of materials with different properties can be assessed and compared. These techniques can be used to identify suitable materials properties for particular applications and can show how devices are likely to perform. This approach means that much of the expense in designing and constructing devices could be eliminated through the use of computer-aided modeling techniques so that design changes and optimization are performed on a computer and the final construction is then based on the ideal design including an accurate description of the magnetic properties.

The magnetic modeling methods that are in use today are quite diverse and the choice of model depends crucially on the length scale of interest. Ultimately these models depend on the presence of magnetization (magnetic moment per unit volume) in certain localized volumes of materials. This magnetic moment per unit volume can be represented in terms of a net magnetic moment per atom, although in many cases, the magnetic moment is not actually localized on the atomic/ionic cores, but instead, is caused by itinerant electrons. The models that we will consider here range from first principles calculations at the level of discrete magnetic moments, such as those of Landau, Lifshitz, and Gilbert, to methods that can be used to model whole magnetic components of devices on the macroscopic scale such as the Preisach model.

3 MODELING OF NONLINEAR MAGNETISM AT THE DISCRETE LEVEL

From the time of ampere and oersted, it was known that on the macroscopic scale, a magnetic dipole moment of fixed magnitude m would rotate under a magnetic field H with torque Λ according to the equation

$$\Lambda = \mu_0 m \times H \tag{1}$$

This same concept, the general torque equation, can be applied at the atomistic scale, or at the level of discrete magnetic moments of fixed magnitude, but variable orientation. This approach can be used to describe the behavior of an individual magnetic moment. The behavior of the entire material can then be determined by integrating the same process over the entire solid. The rate of change of magnetization M with time depends on the torque

$$\frac{\partial M}{\partial t} = -\gamma \Lambda \tag{2}$$

where γ is the gyromagnetic ratio. In the absence of damping a magnetic moment that is not initially aligned with the total field will precess around the field direction with a resonance frequency ω_0, which depends on the strength of the field and the magnitude of the moment

$$\omega_0 = \gamma \, \mu_0 \, H \tag{3}$$

In the complete absence of damping, this precession will continue for infinite time as shown in Figure 1(a). In practice, there is always some damping in solids and therefore for light damping (long time constant) there will be some precessional motion, and some rotational motion toward the field direction as shown in Figure 1(b). The time taken to do this will depend on the damping coefficient. At high levels of damping (short time constant), the precessional component of the motion is suppressed because the moment reaches its final equilibrium orientation before precession has taken place, as shown in Figure 1(c).

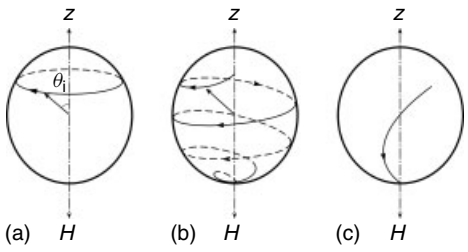

Figure 1. The motion of magnetic moment under the action of a magnetic field depends crucially on the level of damping. (a) No damping results in precession, (b) light damping results in a spiraling motion of the magnetic moment into the field direction, and (c) heavy damping results in a rotation of the moment into the field direction with no precession.

3.1 The Landau–Lifschitz–Gilbert model

The preceding equations describe the behavior of magnetic moments in isolation. In a magnetic material, there are interactions between the moments, so that magnetism in solids is a cooperative process. Therefore, the preceding equation must be modified when dealing with moments in a solid to take into account these interactions. Landau and Lifshitz (1935) and Landau (1967) suggested the following modification

$$\frac{\partial M}{\partial t} = -\gamma \Lambda - \frac{4\pi \lambda_{\mathrm{d}}}{M^2}(M \times M \times H) \tag{4}$$

where λ_{d} is the damping coefficient and the second term on the right-hand side of the equation is the damping term which restrains, effectively slows down, the rotation of the moments under the action of a field. There is no direct experimental verification of the damping term, but the existence of such a term in bulk materials is reasonable from a theoretical standpoint.

A crucial question arises over the exact form of the magnetic field H that should be used in this equation. For an isolated magnetic moment in free space, this will be just the classical magnetic field obtained from Maxwell's equations. However, in view of the magnetic interactions that exist within a material, this total field must also include any other interactions that give rise to a turning force on a dipole. An obvious and well-known example of this is the exchange interaction, which is not included in the classical description of the magnetic field under Maxwell's equations.

The damping coefficient in the model equation is treated as an adjustable parameter, since there appears to be no obvious way to determine this from first principles. A value is used that is consistent with experimental data and this is then used to determine the behavior of an array consisting of a large number of individual magnetic moments under the action of an applied field. The model does not explicitly include temperature in the calculations, although one can argue that the damping coefficient is temperature dependent. However, this provides only one rather arbitrary way of including temperature effects in the model.

Subsequently Gilbert considered the problem from a continuum perspective, and developed a modified form of the equation (Gilbert, 1955, 2004). The Gilbert form of the equation, as shown in the following text, is now used more often than the Landau–Lifshitz form of the equation:

$$\frac{\partial M}{\partial t} = -\gamma \mu_0 M \times H + \frac{\alpha}{M}\left(M \times \frac{\partial M}{\partial t}\right) \tag{5}$$

where α is damping parameter.

In principle, the Landau–Lifshitz–Gilbert (LLG) model can be used either at the atomistic scale or at the 'micromagnetic' continuum scale with the unit cells being much smaller than a single domain. The model is really directed toward volumes smaller than a single domain. Practical applications of the model are made at length scales much greater than the atomistic. Individual 'moments' are defined for the purposes of the model at the level of typically 50 nm and each of these moments is treated as an indivisible unit. This can be justified if there is coherent rotation of the atomic moments occurring over the volume occupied by these moments. The model is suitable for time-dependent calculations of the reorientation of magnetic moments under the action of a field. It has the advantage over other models of not requiring the moments within a domain to be parallel, in fact as shown in Figure 2 it calculates the optimum orientations of moments, which in general are not necessarily parallel.

The results of calculations based on the LLG model can be averaged to provide hysteresis curves of materials as shown in Figure 3. The model can be extended beyond the range of the single domain into simulations of multidomain specimens through the use of finite element methods. This approach, known as *computational micromagnetics*, enables both micro- and macroscale calculations to be incorporated into a single model simulation (Kronmuller, Fischer, Hertel and Leineweber, 1997; Fidler and Schrefl, 2000). This allows microstructure of a material to be included in the simulation and in this way it is possible to combine the advantage of exact theoretical equations developed for a small number of interacting magnetic moments with applications to practical materials.

4 MODELING OF NONLINEAR MAGNETISM BY DOMAIN ROTATION

Some aspects of hysteresis can be described in terms of a model of the rotation of magnetization. This takes no account of the details of the individual moments below the single domain in scale and therefore unlike the LLG model, it does not try to account for the differences in orientations of individual magnetic moments within the domain.

Within domains, the model considers the competing effects of anisotropy and magnetic field on the orientation of moments as shown in Figure 4. The domains themselves can have random alignments or they can be textured (meaning preferred orientation) or they can be even completely aligned in certain directions, although this would be a relatively trivial case requiring nothing more than a calculation of moment orientations within one single-domain particle.

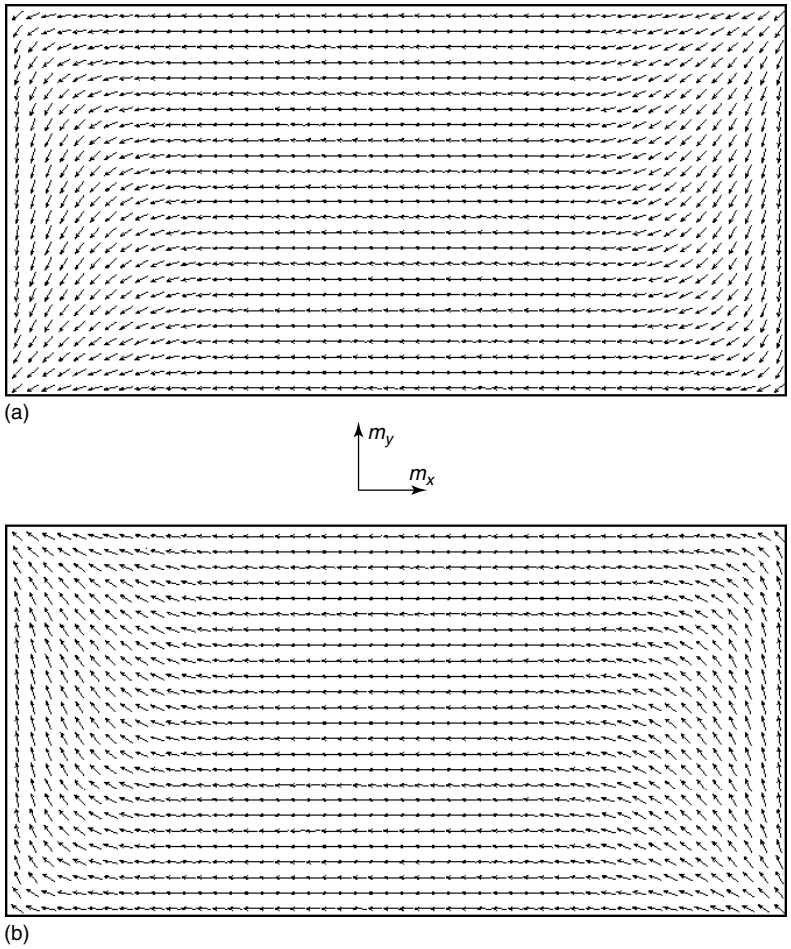

Figure 2. Solution of the Landau–Lifshitz–Gilbert equation for an array of magnetic moments representing a thin film of permalloy of dimensions 2 μm by 0.5 μm. (After R.D. McMichael, http://www.ctcms.nist.gov/~rdm/mumag.org.html.) For the purposes of calculation, each individual magnetic moment occupies an area of 0.05 μm ×0.05 μm. The solution shows the remanent state after the magnetization had been saturated along the long axis (a) and after the magnetization had been saturated along the short axis (b). (With special thanks to Dr Robert D McMichael.)

4.1 The Stoner–Wohlfarth model

The Stoner–Wohlfarth model takes as its basis an array of single-domain particles that can reorient their magnetization by coherent rotation of all moments within the domain. The model considers a dispersion of single-domain magnetic particles in some other unspecified matrix material. The model in its original formulation assumed that there were no magnetic interactions between the particles. In other words, the distribution of the particles was so dilute that each particle was effectively isolated and could not be influenced by the orientation of any other particles. This assumption can be changed, and in fact, it has been changed by others, although including such interactions adds greatly to the computational complexity of the model. The model in its original formulation also assumed axial anisotropy. This is the simplest type of anisotropic calculation to make. Other forms of anisotropy such as cubic can be included (Lee and Bishop, 1966).

The basic idea of the model is to consider the reorientation of a magnetic moment within a single-domain particle in which the applied field is at some arbitrary angle to the anisotropic easy axis. In the case of the uniaxial easy axis along the field direction (Figure 5), this results in a bimodal switching behavior with resultant coercive fields in the forward and reverse directions. In the other extreme case, where the magnetic field is applied along the anisotropic hard axis, this results in a magnetization curve with no coercivity (Figure 6). In general, the domains will be oriented at an arbitrary angle relative to the field and such domains will have properties that lie between these two extremes (Figure 7). A material may be considered to consist of an assembly of domains, each at different angles to the field direction (Figure 8). The overall magnetization of the multidomain

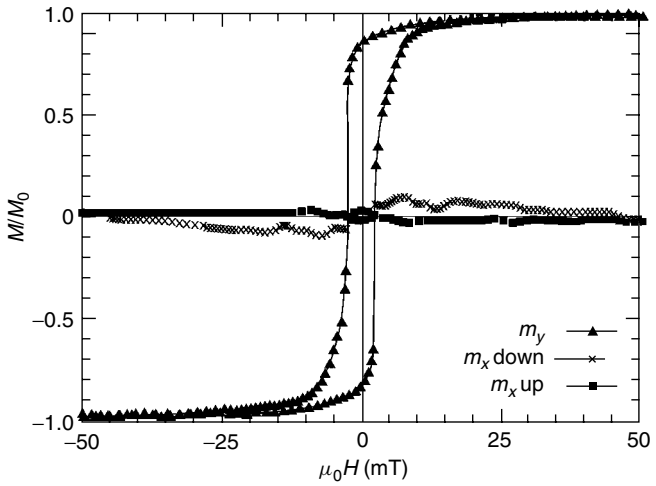

Figure 3. Calculated magnetization curve for the 2 mm $\times$0.5 mm permalloy film shown in Figure 2. 'm_y' shows the component of magnetization along the long axis.

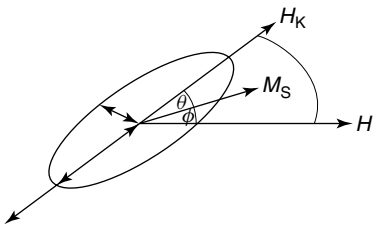

Figure 4. Rotation of magnetization M_S of an isolated single domain under the competing effects of magnetic field H and anisotropy H_K.

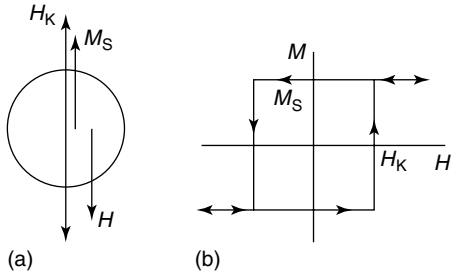

Figure 5. (a) Rotation of the direction of magnetization M_S of a single-domain particle with uniaxial anisotropy, oriented with its easy axis H_K along the direction of the applied field H, and (b) its corresponding magnetization curve.

sample is then the vector sum of all of the magnetic moments of the domains divided by the total volume as shown in Figure 9.

The turning force on a magnetic moment due to the applied field depends on the vector product of magnetic moment with magnetic field. The turning force on the magnetic

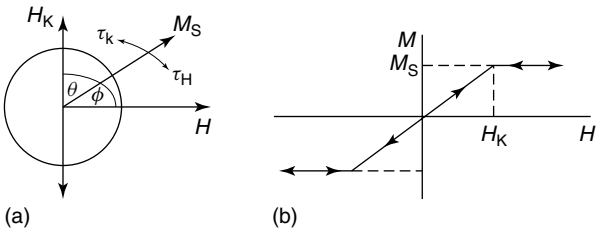

Figure 6. (a) Rotation of the direction of magnetization M_S of a single domain particle with uniaxial anisotropy, oriented with its easy axis H_K perpendicular to the direction of the applied field H, and (b) its corresponding magnetization curve (note absence of hysteresis).

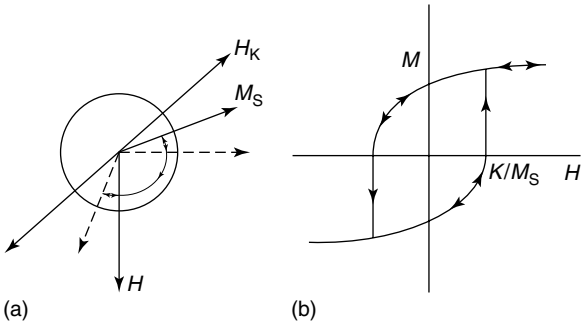

Figure 7. (a) Rotation of the direction of magnetization M_S of a single domain particle with uniaxial anisotropy, oriented with its easy axis H_K at an arbitrary angle to the direction of the applied field H, and (b) its corresponding magnetization curve.

moment due to anisotropy is the derivative of the energy with respect to angle. The Stoner–Wohlfath model determines the equilibrium orientation of magnetization by equating these terms. For a particle with uniaxial anisotropy, the equilibrium orientation is given by

$$\mu_0 H M_S \sin\phi - 2K_1 \sin\theta\cos\theta - 4K_2 \sin^3\theta\cos\theta = 0 \quad (6)$$

where ϕ is the angle of the magnetization M_S relative to the field H, K_1 and K_2 are the first and second anisotropy coefficients, respectively, and θ is the angle of the magnetization relative to the magnetic easy axis. From the Stoner–Wohlfarth model, it is possible to calculate the saturation field H_S needed to rotate the magnetization of the most difficult domain oriented at 90° to the field direction,

$$H_S = \frac{2K_1 + 4K_2}{\mu_0 M_S} \quad (7)$$

It is also possible to calculate the coercivity of the domains based on the switching field needed to reorient the domain aligned antiparallel to the field,

$$H_C = \frac{2K_1}{\mu_0 M_S} \quad (8)$$

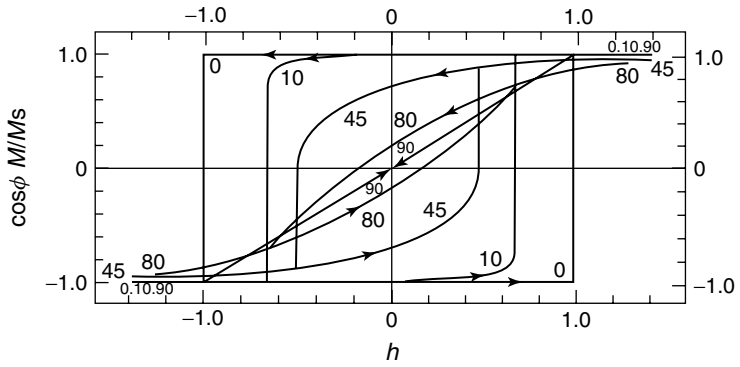

Figure 8. Magnetization curves obtained using the Stoner–Wohlfarth model for domains with uniaxial anisotropy oriented with different directions of the easy axis relative to the applied field. The field axis is shown in units of 'reduced field' h, whereby $h = 1$ corresponds to a field strength of $K/(\mu_0 M_S)$, where K is the anisotropy coefficient and M_S is saturation magnetization. The magnetization axis shows the component of magnetization along the field direction, normalized relative to the saturation magnetization M_S.

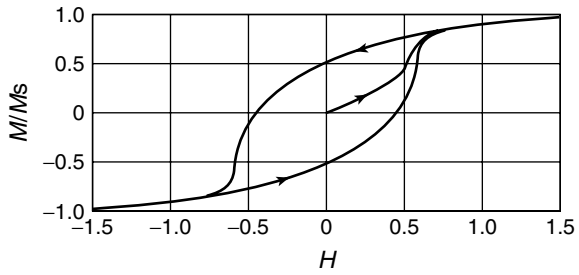

Figure 9. A composite hysteresis curve obtained by summing the elementary magnetization curves for a randomly distributed orientation of easy axes.

The model has been widely used for describing the dependence of magnetic properties of materials on anisotropy and texture. In addition, many of the original ideas behind the model have been developed and extended and have found applications in fine particle systems (Spratt, Bissell, Chantrell and Wohlfarth, 1988; Chantrell, 1997).

5 MODELING OF NONLINEAR MAGNETISM BY DOMAIN BOUNDARY MOVEMENT

In multidomain samples, much of the magnetization change occurs in the domain boundary regions and therefore it is of great interest to know and understand what changes are occurring at the boundary in order to describe and predict the properties of such materials. The importance of domain boundary motion has been recognized by many investigators including (Becker, 1932; Kersten, 1943, 1956; Neel, 1944, 1959; Globus, 1962, 1975; Globus and Duplex, 1966, 1969; Globus, Duplex and Guyot, 1971; Globus and Guyot, 1972; Guyot and Globus, 1973; Escobar, Valenzuela and Magana, 1983; Escobar, Magana and Valenzuela, 1985) and more recently by Bertotti (1988). The main idea in the treatment of domain boundary motion is to separate the motion into two components: reversible and irreversible. In most respects, this separation is somewhat artificial, since both processes take place together in multidomain materials. However, the physics of the situation can be more easily analyzed if these processes are separated. Irreversible processes necessarily cause energy dissipation and lead to coercivity and hysteresis while reversible processes do not.

The motion of domain walls can further be divided into two types: flexible wall motion and rigid wall motion. The higher the surface energy of the domain walls, the greater the tendency to move in planar fashion, particularly if the pinning sites that restrain the domain wall are weaker. On the other hand, domain walls with lower surface energy will tend to bend first, particularly if the pinning sites are stronger. In practice, components of both types of movement occur together.

5.1 The Becker–Doring model

In the case of planar wall motion, much of the early modeling was developed by Becker, who was particularly concerned with the movement of domain walls interacting with regions of inhomogeneous strain, such as dislocations. Simplifying assumptions need to be made in order that an analytical solution can be obtained. Assuming a simplified periodically varying internal potential through which the domain walls move, an expression for the initial susceptibility χ_{in} for a material of a volume V composed of 180° domain walls of thickness δ can be derived in terms of the amplitude and

wavelength of the periodic potential,

$$\chi_{\text{in}} = \frac{2\ A\ l^2\ \mu_0\ M_S^2\ \cos^2\theta}{3\pi^2\ \lambda_S\ \sigma_0\ V\ \delta} \tag{9}$$

where θ is the angle of the domain magnetization relative to the applied magnetic field, A is the cross-sectional area of the wall, l is the periodicity of the internal potential with amplitude $E_{\max} = 3\ \lambda_S\ \sigma_0/2$ due to periodically varying stress of amplitude σ_0 in a material of magnetostriction λ_S. The critical field, or local coercivity, occurs when the domain wall moves over one of the local maxima in the slope of the potential and is therefore given by

$$H_C = \frac{\pi\ E_{\max}\ \delta}{l\ \mu_0\ M_S\ \cos\theta} \tag{10}$$

5.2 The Kersten–Néel model

Models have been developed by Néel and Kersten in the case of domain wall bending as shown in Figure 10. Kersten, in particular, was concerned with the movement of domain walls that were pinned by 'inclusions', which meant simply inhomogeneous volumes within the material. In this case, equations can be derived for the initial susceptibility for small deformations of the domain wall

$$\chi_{\text{in}} = \frac{\mu_0 M_S^2\ l^3 h(\cos\theta_1 - \cos\theta_2)^2}{3\gamma_\pi V} = \frac{\mu_0 M_S^2\ l^2 h(\cos\theta_1 - \cos\theta_2)^2}{3\gamma_\pi L} \tag{11}$$

where l is the spacing between the pinning sites, L is the length of the domain, γ_π is the domain wall energy per unit area, V is a volume of a material, and h is the length of the section of domain wall as shown. For the local coercivity

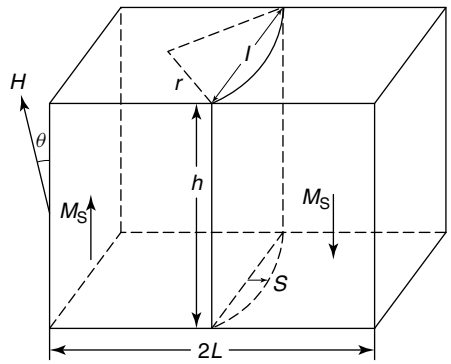

Figure 10. Deformation of a domain wall under the action of an applied magnetic field.

or critical field H_C above which the domain wall will break away from the pining site

$$H_C = \frac{\gamma_\pi\ \cos\phi_{\text{crit}}}{\mu_0\ M_S\ l\ (\cos\theta_1 - \cos\theta_2)} \tag{12}$$

where θ_1 and θ_2 are the angles of the magnetization relative to the magnetic field on either side of the domain wall.

5.3 The Globus–Guyot model

In the case of ferrites in which the defects are mostly confined to grain boundaries, the domain walls will be pinned principally at the grain boundaries and therefore the behavior can be modeled assuming that the domain walls move simply by bending like an elastic membrane as described by Globus (1962). The Globus model depends on equations for deformation of the domain walls similar to those of Kersten. For the purposes of modeling, an approximation is made in which the grains are assumed to be spherical. Most applications of ferrites are for higher frequency magnetic field and therefore the domain walls can be considered to vibrate under the action of a time-dependent field.

Under the action of a 'weak' applied magnetic field, the domain walls deform but remain fixed on the grain boundaries. From this it was predicted that the permeability depended linearly on the grain diameter. Comparison with experiment yielded good agreement (Globus and Duplex, 1966). Further studies showed that wall motion components dominate in ferrites, while rotational processes, which are dependent on anisotropy but not grain size, are of secondary importance in these materials (Globus and Duplex, 1969). The equation governing the deformation of the magnetic domain walls are described by Globus, Duplex, and Guyot (1971). Although the model was developed originally to describe the properties of ferrites, it was later shown to be valid for spinels and garnets. Dissipative processes resulting from translation of the domain walls at higher field strengths were added to the model subsequently by Guyot (Globus and Guyot, 1972; Guyot and Globus, 1973).

The most comprehensive treatment of the underlying theory of this model, including most of the equations, has been given by Escobar, Valenzuela and Magana (1983) and Escobar, Magana and Valenzuela (1985). Accordingly, the initial susceptibility due to domain wall bending is

$$\chi_{\text{in}} = \frac{\mu_0\ M_S^2\ D}{\gamma_\pi} \tag{13}$$

where M_S is saturation magnetization, γ_π is the domain wall surface energy, and D is the grain diameter. The value of the

critical field for the unpinning of domain walls is

$$H_C = \frac{2\ f}{\mu_0\ M_S\ D} \tag{14}$$

where f is the pinning force per unit length on the domain wall along the grain boundary, which is assumed to be independent of the applied field.

5.4 The statistical pinning theory model

If the force $f(z - z_J)$ between a defect at position z_J in a ferromagnetic material and a domain wall at position z moving perpendicular to z is introduced, the total force $F(z) = \sum_{J=1}^{N} f(z - z_J)$ of all defects N interacting with the domain wall could be taken into account using statistical methods. Such model was elaborated by Kronmuller and others (Kronmuller, 1992), and allowed computing the properties of the initial magnetization curve and the parameters of the hysteresis loop in the Rayleigh region $M = \chi_{in}\, H + \alpha_R\, \mu_0\, H^2$:

$$\begin{aligned} H_C &= \frac{1}{\mu_0 M_S A|\cos\phi|}\left(\frac{B_0}{2}\right)^{1/2}\left(\ln\frac{L_3}{2L_0}\right)^{1/2} \\ \chi_{in} &= \frac{\mu_0 A(2M_S\cos\phi)^2}{L_3}\left(\frac{\pi}{2B_1}\right)^{1/2} \\ \alpha_R &= \frac{\mu_0 A^2|2M_S\cos\phi|^3}{2\pi}\frac{L_0}{L_3}\frac{1}{B_0} \end{aligned} \tag{15}$$

where L_0 is the distance between two adjacent defects, L_3 and A are the domain wall length and area, respectively, ϕ is the angle between the applied field and magnetization. B_0 and B_1 are correlation functions, which are directly proportional to the number of defects N and are related to the individual interaction force $f(z - z_J)$ of a defect.

5.5 The stochastic process model

Domain wall modeling concepts can be through the use of domain wall eddy current dissipation (Bertotti, 1988) and stochastic process models, in which the domain wall moves through a randomly fluctuating potential (Alessandro, Beatrice, Bertotti and Montorsi, 1990; Bertotti, Mayergoyz, Basso and Magni, 1999). The randomness of the potential seen by the domain walls can be quantified using two independent parameters, which represent mathematically the physical properties of the potential in terms of an average amplitude and an average fluctuation wavelength.

If H_C is a randomly fluctuating function of position, then it will also be a randomly fluctuating function of the flux Φ. Local maxima in H_C represent pinning sites in the material, and for large displacements of domain walls, there will be a correlation length ζ which represents the range of interaction of domain walls with pinning sites. These effects can be described if it is assumed that the local coercivity H_C obeys a Langevin equation of the form

$$\frac{dH_C}{d\Phi} + \frac{H_C - \langle H_C\rangle}{\zeta} = \frac{dW}{d\Phi} \tag{16}$$

where now the 'flux' Φ is the measure of displacement of domain walls, instead of the position, $W(\Phi)$ is a randomly fluctuating ('white noise') function whose average value will be zero, and ζ is the interaction length, or correlation length, for domain walls with pinning sites. Eventually with some additional limiting assumptions the equation reduces to

$$\frac{d\dot{\Phi}}{dt} + \frac{1}{\tau}(\dot{\Phi} - \mu_0\, A\ \dot{M}) = -\frac{1}{\sigma\ G}\frac{dH_C}{dt} \tag{17}$$

where A is cross-sectional area of the domain wall, G is a dimensionless parameter, τ is a characteristic relaxation time, and σ is the electrical conductivity.

The motion of domain walls through the internal randomly fluctuating potential, leads to discontinuous changes in magnetization. These discontinuous processes are manifested as Barkhausen noise (Schlesinger, 2001), which is closely connected with the existence of hysteresis. Hysteresis is found to be a direct result of discontinuous, dissipative processes occurring over small volumes which when summed together produce the familiar hysteresis over larger volumes. The Barkhausen emissions are fractal in nature, which means that the structure of the Barkhausen emissions is independent of the scale. A review of the theory behind domain wall dynamics and the Barkhausen effect has been given by Jiles (2000).

The domain boundary models are best applied to multidomain materials in which the movement of magnetic domain boundaries is the principal magnetization mechanism. This means mostly bulk soft magnetic materials with low anisotropy and with large density of inhomogeneities either in the form of strains (dislocations) or inclusions (particles of a second phase).

6 MODELING OF NONLINEAR MAGNETISM BY SWITCHING MECHANISMS

A model for description of hysteresis based on switching mechanisms such as the Barkhausen effect was proposed by Preisach (1935). This assumes that a material is composed of an assembly of elemental volumes that each have

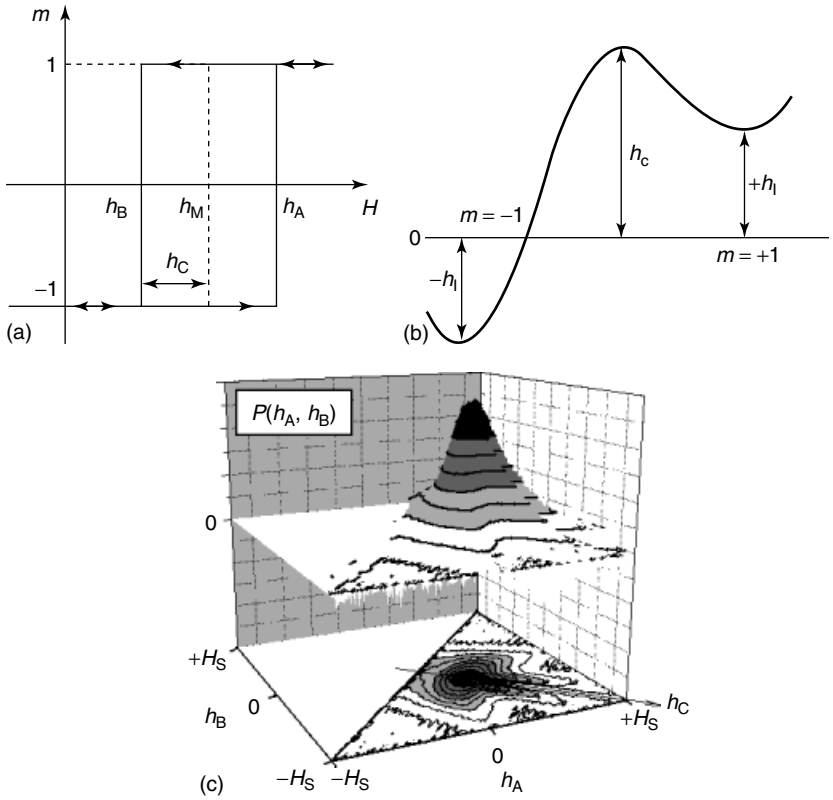

Figure 11. (a) Magnetization curve for an elementary hysteresis loop and (b) its energetic representation as an elementary metastable two-level subsystem, where the two states $m = \pm 1$ (represented by local minima) are divided by a barrier. Differences between extrema and energy level 0 are shown in units of magnetic field. (c) An example of a 3D plot of a Preisach function $P(h_A, h_B)$ and its corresponding contour plot.

a characteristic pair of switching fields (forward and reverse coercivities) from which the local magnetization curve of the elemental volume can be represented by a rectangular hysteresis loop. The following possibilities are allowed: (i) the width of the elementary loops have a certain distribution function, whereby loops with zero width can occur; (ii) the elementary local hysteresis loops can have their midpoints offset from zero field, which is known as a *bias field*. It is evident that the magnetic state of such local regions will be field-history dependent. All of the above considerations will therefore result in magnetic hysteresis.

6.1 The classical Preisach model

The classical Preisach model (CPM), (Preisach, 1935; Mayergoyz, 1986, 1991) is based on the assumption that a ferromagnetic material consists of a large number of elemental switching volumes. Each fragment is described by an elementary rectangular hysteresis loop, which has two field parameters, the critical or the coercive field of the free fragment h_C, and the bias field, or offset field, h_I. It is useful and convenient to introduce the switching field parameters h_A and h_B (Figure 11(a)):

$$h_A = h_I + h_C, h_B = h_I - h_C \tag{18}$$

The meaning of the switching fields is the following: if the external magnetic field is increased to H_1, all elemental switching volumes whose switching field h_A was lower or equal to the external field $h_A \leq H_1$ would switch their magnetization up; if the magnetic field is decreased to H_2, all elemental switching volumes whose switching field h_B was higher or equal to the external field $h_B \geq H_2$ would be switched down. The magnetization of all other elemental switching volumes will depend on previous history of changes of the external magnetic field.

Introducing the plane defined by the switching fields h_A, h_B. Each elemental switching volume has its own point on that plane and that point is unique for each volume. It is possible to assume, from the physical point of view, that h_C may be nonnegative only $h_C \geq 0$, that is, the half of the plane, $h_A \geq h_B$, will be meaningful only. A probability distribution function of the elemental switching volumes with

the switching fields h_A, h_B or Preisach function $P(h_A, h_B)$ may be defined in the plane of the Preisach variables h_A, h_B. It is necessary to stress that by definition and from the physical meaning of the probability distribution function, the values of the Preisach function $P(h_A, h_B)$ are nonnegative on the whole plane $h_A \geq h_B$ (Figure 11(c)):

$$P(h_A, h_B) \geq 0 \tag{19}$$

It is possible to show (Mayergoyz, 1991) that the half of the plane $h_A \geq h_B$ is always divided into two parts, $S^{(+)}$ and $S^{(-)}$, by a staircase line $L(t)$ (where t is time), which represents the history of the changes of the external magnetic field (Figure 12). All elemental switching volumes in the part $S^{(+)}$ are switched up and have the magnetization '+1', all elemental switching volumes in the part $S^{(-)}$ have the magnetization '−1'.

Introducing a simple hysteresis operator $\gamma(h_A, h_B)$ defined on the plane h_A, h_B:

$$\gamma(h_A, h_B)H(t) = Q(h_A, h_B) = \begin{cases} +1, & \text{if} \quad (h_A, h_B) \in S^{(+)} \\ -1, & \text{if} \quad (h_A, h_B) \in S^{(-)} \end{cases} \tag{20}$$

According to the CPM, the total magnetization of the system with hysteresis can be written in the form:

$$\begin{aligned} M(t) &= M_S \iint_{h_A \geq h_B} P(h_A, h_B)\gamma(h_A, h_B)H(t)\, \mathrm{d}h_A\, \mathrm{d}h_B \\ &= M_S \iint_{h_A \geq h_B} P(h_A, h_B)\, Q(h_A, h_B)\, \mathrm{d}h_A\, \mathrm{d}h_B \\ &= M_S \iint_{S^{(+)}} P(h_A, h_B)\, \mathrm{d}h_A\, \mathrm{d}h_B - M_S \\ &\quad \times \iint_{S^{(-)}} P(h_A, h_B)\, \mathrm{d}h_A\, \mathrm{d}h_B \end{aligned} \tag{21}$$

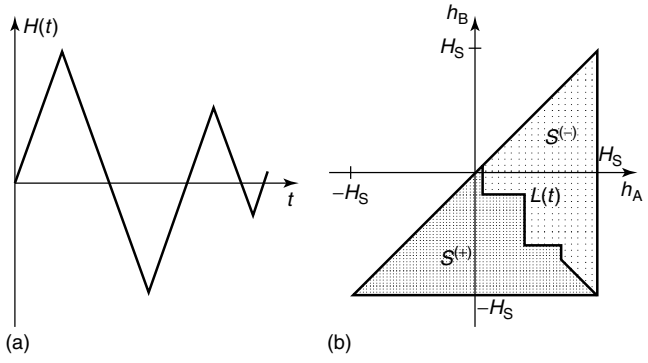

Figure 12. (a) A history of changes of the external magnetic field and (b) its representation by a staircase line $L(t)$ in the plane of the switching fields h_A, h_B. The staircase line $L(t)$ divides the Preisach plain into two areas $S^{(+)}$ and $S^{(-)}$. H_S is magnetic field at which magnetic saturation of sample is achieved.

where M_S represents saturation magnetization of the specimen.

The magnetization always reaches a saturation point, which means that any increase of the external magnetic field H after some field H_S will not influence the total magnetization of the system any further. This means, taking into account equations (19) and (21), that in such regions where $h_A \geq H_S$ or $h_B \leq -H_S$, the Preisach function is strictly equal to zero $P(h_A, h_B) = 0$. For the geometric interpretation of the CPM, it is possible to look only at the Preisach triangle which is defined by these inequalities: $-H_S \leq h_A \leq H_S, -H_S \leq h_B \leq H_S, h_A \geq h_B$.

Starting from the demagnetized state, which assumes equality of numbers of the switched up and switched down elemental volumes, together with the symmetry of the $P(h_A, h_B)$ function along the $h_A = -h_B$ line, the Preisach triangle will be divided as shown in Figure 13(a).

Increase of the external magnetic field now results in the initial magnetization curve or virgin curve (Figure 13(b)). After the saturation field H_S is achieved, all elemental volumes will be switched up and the system will be saturated. Next gradual decrease of the external magnetic field to the negative value of the saturation magnetic field $-H_S$ gives first the remanent magnetization M_R (Figure 13(c)), then the coercive field H_C, and finally a negative saturation state.

The basic properties of the CPM and the fundamental representation theorem will be mentioned here briefly. A detailed description of the properties and the proof of the theorem may be found in Mayergoyz (1986, 1991).

Staircase line $L(t)$, the prehistory of the material: The interface $L(t)$ between the regions $S^{(+)}$ and $S^{(-)}$ has a staircase shape. Moreover, past extreme values of the external magnetic field may be found on this line as h_A, h_B coordinates of the vertices of each 'step'.

W*iping-out property*: Each local input maximum wipes out the vertices of $L(t)$ whose h_A coordinates are below this maximum, and each local minimum wipes out the vertices whose h_B coordinates are above this minimum. It is worth noting that the wiping-out property is usually fulfilled in real magnetic materials.

Congruency property: All minor hysteresis loops corresponding to back-and-forth variations of the external magnetic field between the same two consecutive extreme values are congruent. Unlike the wiping-out property, the congruency property is not fulfilled very often for real magnetic materials.

Symmetry of the CPM: The symmetry property may be written as

$$P(h_A, h_B) = P(-h_B, -h_A) \tag{22}$$

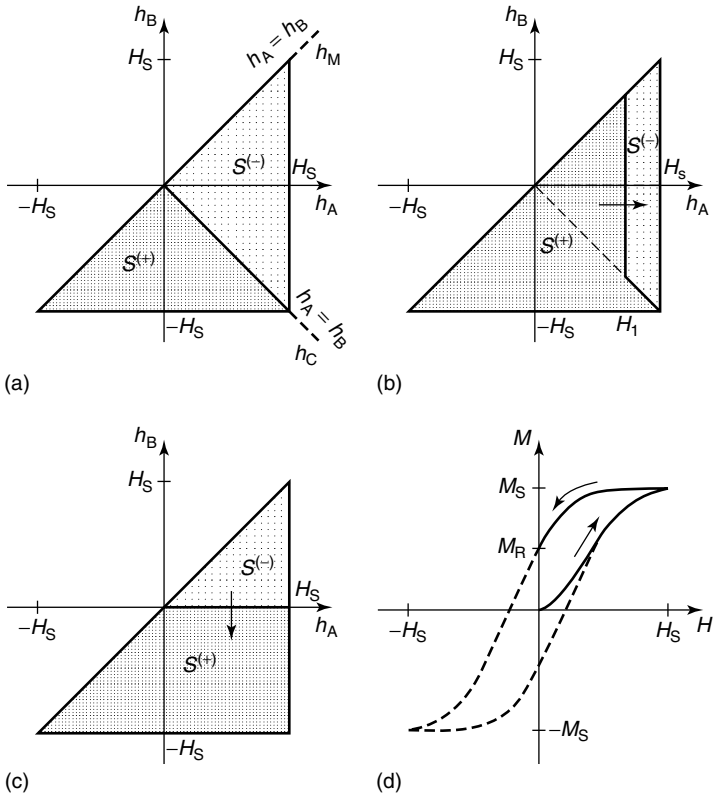

Figure 13. The Preisach triangle in the plane of the switching fields (a) at the demagnetized state, (b) for the initial curve, and (c) at the remanent magnetization. (d) Hysteresis curve corresponding to the (a)–(c) paths.

Representation theorem: The wiping-out property and the congruency property constitute the necessary and sufficient conditions for a hysteresis nonlinearity to be represented by the CPM on a set of monotonically increasing field amplitudes.

To use the CPM one needs first to check the wiping-out and congruency properties and then to define the Preisach function $P(h_A, h_B)$. It is difficult to determine the analytical form of the $P(h_A, h_B)$ even in cases where it is possible to describe the system by the CPM. However, the numerical form, in a matrix formulation, of $P(h_A, h_B)$ may be found without any difficulties. For this purpose, the discretization of the external magnetic field is employed in which, the coordinates h_A and h_B describe a mesh over the Preisach triangle. Assuming that the Preisach function is a constant over any single cell (meaning the average value for the cell) and finding the variation of the magnetization connected with this cell, one may find the average value of $P(h_A, h_B)$ for the cell. Such changes in magnetization can be determined if a set of symmetric minor loops or a set of first-order transition (reversal) curves is used.

Starting from the demagnetized state, the two nearest symmetric minor loops were measured (Figure 14); the loop

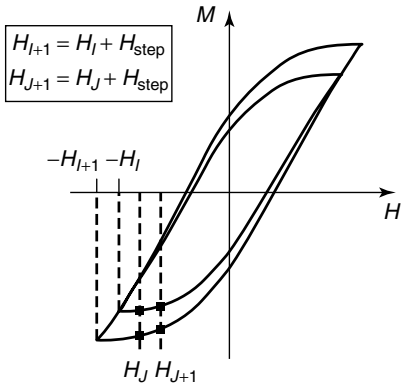

Figure 14. Two neighboring measured symmetrical minor loops used for experimental identification of the Preisach function.

with the larger amplitude of the external magnetic field is measured after the loop with the smaller amplitude. Let us consider the ascending branches of both loops. The maximum fields H_I and $H_{I+1} = H_I + H_{step}$ are the h_B coordinates for the loops; during the measurement of each loop, the h_A coordinate is varied only.

The integrated or local coercive field distribution function $P(h_C)$ (Basso, Bertotti, Infortuna and Pasquale, 1995) may

be constructed from the Preisach function $P(h_A, h_B)$:

$$P(h_C) = \int_0^{H_S} P(h_C, h_I)\, dh_I \tag{23}$$

This function gives the probability of finding all elemental volumes whose coercive field is equal to h_C.

Knowing the probability distribution function $P(h_A, h_B)$, it is possible to follow magnetization M as a function of the external magnetic field H by using equation (21) if the system is describable by the CPM. This procedure is known as *backward transformation*.

6.2 Variations of the Preisach model

The *moving Preisach model*, presented by Della Torre (1966), is the extension of the CPM when the Preisach function is modified to have magnetization dependence:

$$M(t) = M_S \iint_{h_A \geq h_B} P(h_A + \alpha M, h_B + \alpha M) \times \gamma(h_A, h_B) H(t)\, dh_A\, dh_B \tag{24}$$

where α is a mean field parameter that is material dependent. The moving model obeys congruency and wiping-out properties; however, congruency in this case is substituted by skew-congruency, where loops are congruent if they are bounded by the two skewed lines with $H + \alpha M = \text{const}$. The identification procedure for the moving Preisach model requires detection of α first and then finding the Preisach function in a standard way (Della Torre, 1991). The *complete moving hysteresis model* is a further extension of the moving Preisach model where, instead of a single square elementary magnetic hysteresis loop for each elemental volume, a more complicated elementary magnetic hysteresis loop with a parameter squareness S was introduced and this elementary loop was divided into fully irreversible and fully reversible components. This allowed both the locally reversible and irreversible components of the magnetization to be computed even for asymmetrical magnetizing processes (Vajda, Della Torre and Pardavi-Horvath, 1992; Vajda and Della Torre, 1993).

Another modification of the CPM with the Preisach function having magnetization dependence is called the *product model* (Kadar, 1987), which can be presented in the form:

$$\frac{dM}{dH} = R(M)\left[\beta + \int Q(h_A, h_B) dh_A\right] \tag{25}$$

where β represents a reversible component (reversible susceptibility when $M = 0$), $Q(h_A, h_B)$ is the residual Preisach function with the symmetrical properties of the classical Preisach function, and $R(M)$ is a noncongruency function,

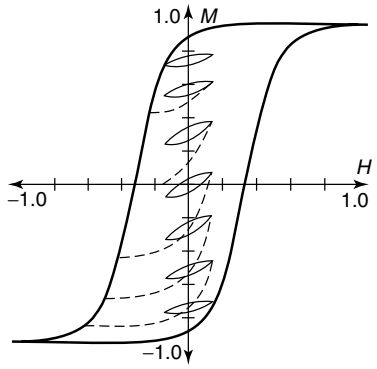

Figure 15. Nonlinear congruency property for the product model. In the classical Preisach model, the 'heights' of the minor loops ΔM, which are bounded by two vertical lines $H = \text{const}$, are equal. In case of product model, these 'heights' follow a nonlinear function. (Reproduced from from G. Kadar and E. Della Torre: 'Hysteresis modelling: I. Noncongruency', *IEEE Transactions on Magnetics* **23** (1987), © IEEE 1987, with permission from the IEEE.)

which has to be an even function of M, should have a maximum at $M = 0$ and should approach zero as M approaches saturation $\pm M_S$, such as $R(M) = 1 - (M M_S)^2$. The product model obeys wiping-out property (see Figure 15); however, congruency becomes nonlinear such that the 'height' of the minor loops ΔM which are bounded by two vertical lines $H = \text{const}$ is a nonlinear function (Kadar and Della Torre, 1987).

The wiping-out property is equivalent to the immediate formation of a stable hysteresis loop after only one cycle of field variation back and forth (see Figure 16). But in reality, accommodation occurs often in ferromagnetic materials. Accommodation, which is a gradual drifting of the minor hysteresis loop toward an equilibrium loop when the magnetic field is cycled between two limiting values, can be described by the modified Preisach models as was shown by Kadar and Della Torre (Della Torre and Kadar, 1987; Della Torre, 1994). In a *Preisach model for accommodation*, it is

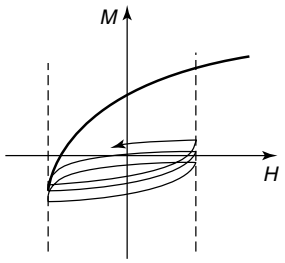

Figure 16. Accommodation, a gradual drifting of the minor hysteresis loop, which is cycled between two fields toward an equilibrium loop, as described by the *Preisach model for accommodation*. (Reproduced from E. Della Torre: 'A Preisach model for accommodation', *IEEE Transactions on Magnetics* **30** (1994), © IEEE 1994, with permission from the IEEE.)

assumed that the interaction field h_I of a hysteron can be changed, or equivalently that the elementary hysteresis loops can be 'moved'. It is also assumed that when a hysteron moves, its magnetization may either remain the same as it was or it may reverse into the opposite state. If it remains in the same magnetized state, it dilutes the neighboring hysterons. This situation is modeled by assuming that $Q(h_A, h_B)$ from equation (20) can be a constant value different from ± 1. Introducing the replacement factor $\xi, 0 \leq \xi < 1$, it is possible to take into account the accommodation of the minor loop.

6.3 The time-dependent Preisach model

In order to describe the dynamic hysteresis loops by the Preisach model, an elementary hysteresis loop $Q(h_A, h_B)$ from equation (20) was modified to include time $Q(h_A, h_B; t)$, so its time rate of change is proportional to the difference between the actual external field and the switching fields according to

$$\frac{\partial Q(h_A, h_B; t)}{\partial t} = \begin{cases} k\,[H(t) - h_A], & \text{when} \quad H(t) > h_A \\ k\,[H(t) - h_B], & \text{when} \quad H(t) < h_B \end{cases} \tag{26}$$

where k is an additional model parameter (Bertotti, 1992a; Bertotti and Pasquale, 1992b). This *rate-dependent Preisach model* allowed computing dynamic hysteresis loops and successfully interpreting dynamic losses per cycle per unit mass as a function of magnetizing frequency for soft magnetic materials, such as, for example, nonoriented SiFe steel. The similar idea of modifying an elementary hysteresis loop was also realized in Lu *et al*. (2003). For faster computations, keeping in mind engineering applications, another rate-dependent model, called the *external dynamic Preisach model*, was proposed in Fuzi (1999), where magnetization was computed by the CPM with modified input field, delayed with respect to the actual field strength. An example of the dynamic hysteresis loop computed by the external dynamic Preisach model is presented in Figure 17.

Krasnoselskii and Pokrovskii (1983) separated the basis of the model from its physical meaning and developed a general mathematical tool for description of hysteresis, be it magnetic, electric, mechanical, or any other general type of hysteretic phenomenon. Since then, a number of extensions of this model have been tried and applied for different purposes, but all of these are still derivatives of the original classical Preisach magnetic model.

6.4 The temperature-dependent Preisach model

Static energetic representation of a hysteron in which two minima and a barrier between them exist (see Figure 11(b)),

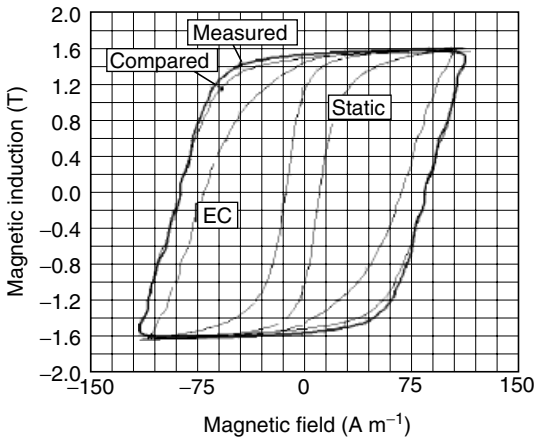

Figure 17. Static, eddy current and dynamic magnetizing loops computed by the external dynamic Preisach model and compared with the measured dynamic loop for the grain-oriented silicon iron steel sheet magnetized in rolling direction under field-control condition with frequency 250 Hz. (Reproduced from Janos Fuzi: 'Computationally efficient rate dependent hysteresis model', *COMPEL* **18**:3 (1999), with permission from Emerald Group Publishing.)

can be expanded if temperature T and time t are introduced (Mitchler, Dan Dahlberg, Wesseling and Roshko, 1996).

Without temperature if a hysteron is in a local minimum, the energy barrier will prevent the magnetization switching into the state with a global minimum energy. With finite temperature, jump into the global minimum can occur spontaneously by thermal activation, with the characteristic time

$$\tau = \tau_0 \exp\left(\frac{W}{k_B T}\right) \tag{27}$$

where τ_0^{-1} is a microscopic attempt frequency and W represents the height of the barrier, which will lead to the evolution of $Q(h_A, h_B)$, from equation (20) with time and to the appearance of the superparamagnetic state. As an example, a graphical representation of field cooling (FC) magnetic measurement is shown in Figure 18(a) and zero field cooling (ZFC) in Figure 18(b) (Song and Roshko, 2000).

Successful application of the proposed model, that is, the construction of the FC and ZFC curves, isothermal-remanent moment (IRM), thermo-remanent moment (TRM), and hysteresis loops at various temperatures, was done for ferromagnetic perovskites, such as $La_{0.95}Mg_{0.05}MnO_3$ and $La_{0.5}Sr_{0.5}CoO_3$ (Zhao *et al*., 2001) and $SrRuO_3$ (Roshko and Huo, 2001), for ferromagnetic nanoparticles embedded in a nonmagnetic matrix, such as Fe nanoparticles in alumina (Roshko, Viddal, Ge and Gao, 2004), and in others. In these studies, the Preisach function for particulate ferromagnetic materials can be decomposed into two distributions of the h_C and h_I fields, such as, for example, in

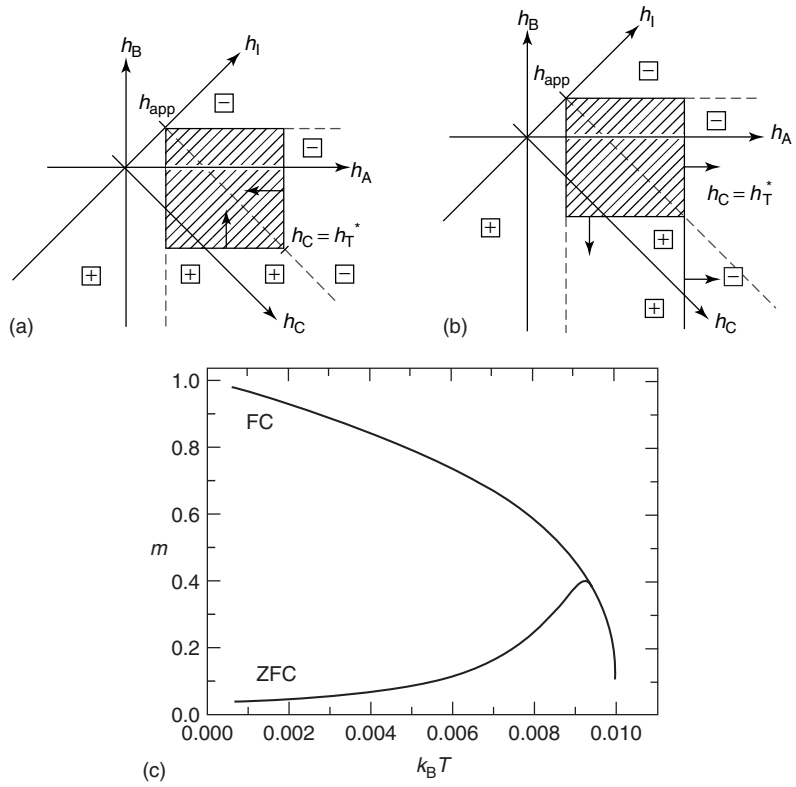

Figure 18. (a) Subsystem states at temperature T after cooling in an applied field h_{app} (FC). (b) Subsystem states at temperature T in an applied field h_{app} after cooling in zero field (ZFC). (The shaded region is superparamagnetic and arrows show boundary evolution of this region with time). (c) Temperature dependence of the field-cooled (FC) and zero field-cooled (ZFC) moment. (Reproduced from T. Song and R.M. Roshko: 'A Preisach model for systems with magnetic order', *Physica B*, **275** (2000), copyright © Elsevier 2000, with permission of Elsevier.)

Zhao *et al*. (2001):

$$P(h_C, h_I) = \frac{1}{2\pi\sigma_C\sigma_I h_C} \exp\left[-\frac{(\log(h_C/h_{CM}))^2}{2\sigma_C^2} - \frac{h_I^2}{2\sigma_I^2}\right] \tag{28}$$

All parameters in this Preisach function are functions of temperature and are proportional to $(1 - T/T_C)^\Gamma$ with Curie temperature T_C and critical exponent Γ.

7 MODELING OF NONLINEAR MAGNETISM BY ENERGY DISSIPATION

Theoretical description of bulk magnetic properties such as coercivity, remanence, permeability, and hysteresis loss, encounters other problems that make it difficult, if not impossible, to simply scale up the predictions of models that are based on consideration of one or two domains. Therefore, a more general approach is needed in order to develop equations that represent the average behavior of the materials. These models necessarily use statistical thermodynamic principles to describe the resulting magnetization behavior of a very large number of magnetic domains. The earliest thermodynamic approaches were developed for the simplest systems, specifically paramagnets. Paramagnets have the simplicity of being magnetically homogeneous, unlike ferromagnets. Later models were developed for ferromagnets without including hysteresis, and finally hysteresis models were developed. The classical model for magnetism on this scale is the Langevin–Weiss model which considers an array of magnetic moments in thermal equilibrium at a particular temperature.

7.1 The Jiles–Atherton model

The Langevin–Weiss approach was used as the basis for developing a model of hysteresis (Jiles and Atherton, 1986). The model of hysteresis that was developed in this way depends on statistical mechanics and is most relevant on the mesoscopic scale. It works well for materials with low

anisotropy for which the main mechanism is domain boundary movement. It can be used for simple anisotropies such as axial and planar anisotropies with minor modifications. For highly anisotropic materials it can still be used with the understanding that a simple analytic anhysteretic equation cannot in general be developed for anisotropic materials and therefore the mathematical approximations become less realistic, the greater the anisotropy and the larger the number of magnetic easy directions.

The orientations of the magnetic moments are distributed statistically and integrating the distribution of moments over all possible orientations leads to an equation for the bulk magnetization. The form of this equation depends on the restrictions imposed by anisotropy, so, for example, different solutions are obtained depending on whether the magnetic moments experience axial anisotropy, planar anisotropy, or are in a completely isotropic environment (Jiles, Lee, Kenkel and Metlov, 2000).

The extension of the Langevin–Weiss theory used to describe ferromagnetic materials incorporates a coupling among magnetic moments acting as a strong magnetic field to align the magnetic moments in a domain parallel to each other. To quantify this coupling, a mean field is invoked, which is proportional to the bulk magnetization M, so that the effective field is $\tilde{H} = H + \alpha M$. This mean field approach to describing the interactions needs to be applied with some caution, but recent work by Chamberlin (2000) has shown that the mean field approach is viable for clusters of spins on the nanoscopic scale.

7.2 Description of the anhysteretic magnetization

In the absence of energy dissipation, all energy supplied to the material is equal to the change in magnetostatic energy in the material. This is the anhysteretic magnetization. Instead of considering details of the coupling between each individual magnetic moment, a mean field approximation is used to represent the interdomain coupling. By replacing the classical magnetic field H with the effective magnetic field $H + \alpha M$, which includes coupling to the magnetization, an equation for the anhysteretic magnetization of a ferromagnetic material can be obtained as follows:

$$M = M_{\mathrm{S}} L\left(\frac{\mu_0\, m\, (H + \alpha M)}{k_{\mathrm{B}} T}\right) \tag{29}$$

where $L(x)$ is the anhysteretic function, $x = \frac{\mu_0\, m\, \tilde{H}}{k_{\mathrm{B}}\, T}$, and $\tilde{H} = H + \alpha M$ is the effective field which includes both the applied field and the self-coupling field. The exact form of the function $L(x)$ depends on the anisotropy of the material: for isotropic materials the anhysteretic function is the Langevin function:

$$M = M_{\mathrm{S}} \{\coth(x) - 1/x\} \tag{30}$$

for materials exhibiting axial anisotropy the anhysteretic function is a hyperbolic tangent,

$$M = M_{\mathrm{S}} \tanh(x) \tag{31}$$

and for materials exhibiting planar anisotropy

$$M = \frac{k_{\mathrm{B}}\, T}{\mu_0} \frac{\mathrm{d}}{\mathrm{d}\tilde{H}} \log Z = M_{\mathrm{S}} \frac{I_0'(x)}{I_0(x)} \tag{32}$$

where Z is the statistical partition function and

$$I_0(x) = \sum_{s=0}^{\infty} \frac{1}{(s!)^2} \left(\frac{x}{2}\right)^{2s} \tag{33}$$

and

$$I_0'(x) = \sum_{s=1}^{\infty} \frac{s}{(s!)^2} \left(\frac{x}{2}\right)^{2s-1} \tag{34}$$

An extension to cover other more complicated anisotropies was made (Ramesh, Jiles and Roderick, 1996), in which the energy of a magnetic moment with anisotropic perturbation was calculated in three dimensions and therefore different kinds of anisotropic materials could be described. This allows an increasing range of magnetic materials in which anisotropy and texture play a significant role to be modeled, for example, hard magnetic materials.

Following the development of the generalized anhysteretic function (Jiles, Ramesh, Shi and Fang, 1997; Fang *et al.*, 1998a,b)

$$M_{\mathrm{aniso}} = M_{\mathrm{S}} \frac{\sum\limits_{\text{all moments}} \mathrm{e}^{-E/k_{\mathrm{B}}T} \cos\theta}{\sum\limits_{\text{all moments}} \mathrm{e}^{-E/k_{\mathrm{B}}T}} \tag{35}$$

where θ is the angle between the direction of the magnetization M and the direction of the applied field, and E is the energy of the magnetic moment m

$$E = \mu_0 \langle m \rangle (H + \alpha M) + E_{\mathrm{aniso}} \tag{36}$$

where E_{aniso} is the anisotropic component of energy which depends on the structure of the material. For example, in the case of cubic anisotropy,

$$E_{\mathrm{aniso}} = K_1 \sum_{i \neq j}^{3} \cos^2\theta_i \cos^2\theta_j \tag{37}$$

with the normal convention on symbols. In this description, only the first anisotropy coefficient K_1 was used since this approximation in most cases provides a sufficiently accurate description of the different magnetization curves along different directions. A texture coefficient f_{text}, which is a statistical evaluation of the volume fraction of the textured portion of a material, was also introduced. The anhysteretic magnetization M_{an} can then be given as

$$M_{\text{an}} = f_{\text{text}}\, M_{\text{aniso}} + (1 - f_{\text{text}})\, M_{\text{iso}} \tag{38}$$

where M_{aniso} is the anisotropic anhysteretic magnetization contribution, and M_{iso} is the isotropic anhysteretic magnetization contribution. For more complicated textured materials, there may be several different texture orientations such that each particular direction has a proportion of the grains oriented along it. The anisotropic contribution of each part must be calculated separately and the net anisotropic portion of the anhysteretic magnetization is the weighted sum of the components of magnetization of these orientations along the direction of the applied field.

From this description of the thermodynamic anhysteretic magnetization, it is possible to develop a description of hysteresis through consideration of energy dissipation mechanisms. The irreversible and reversible components of magnetization can be described separately in the mathematical formulation, although physically they are not separate. The two components of magnetization can then be combined to give an equation for the total magnetization.

7.3 Extension to hysteresis

In the case of hysteresis, the energy supplied to the material appears either as magnetostatic energy or hysteresis loss. The magnetostatic energy in the material is the energy difference between input energy and the energy loss due to processes such as domain wall pinning. One of the assumptions of the model is that the energy loss is proportional to the change in magnetization. Although this was derived from the domain wall motion under the action of a magnetic field, it is not limited to magnetization by domain wall motion and therefore the model applies to any situation in which the energy loss is proportional to the change in magnetization as could occur also under domain rotation.

An equation for the irreversible change in magnetization is obtained,

$$\frac{\mathrm{d}M_{\text{irr}}}{\mathrm{d}H} = \frac{M_{\text{an}} - M_{\text{irr}}}{\delta\, k - \alpha(M_{\text{an}} - M_{\text{irr}})} \tag{39}$$

where the directional parameter δ takes $+1$ when H increases in the positive direction ($\mathrm{d}H/\mathrm{d}t > 0$), and -1 when H increases in the negative direction ($\mathrm{d}H/\mathrm{d}t < 0$), ensuring that the pinning always opposes the change in magnetization.

During magnetization, there is also a reversible component of magnetization that can result from reversible domain wall bowing, reversible translation of domain walls, or reversible domain rotation. For the purposes of modeling, the reversible component M_{rev} of magnetization was assumed to be proportional to the difference between the anhysteretic magnetization M_{an} and irreversible magnetization M_{irr}, with a constant of proportionality, the reversibility coefficient c, which represents the fraction of magnetization change that is reversible. Hence, the total magnetization M is the sum of reversible magnetization and irreversible magnetization:

$$M = M_{\text{irr}} + M_{\text{rev}} = (1 - c)\, M_{\text{irr}} + c\, M_{\text{an}} \tag{40}$$

where the constant coefficient c ranges from 0 (completely irreversible magnetization) to 1 (completely reversible magnetization). The model equation for the total magnetization, which includes both irreversible and reversible magnetization, is then

$$\frac{\mathrm{d}M}{\mathrm{d}H} = (1 - c)\frac{(M_{\text{an}} - M)}{\delta k - \alpha(M_{\text{an}} - M)} + c\frac{\mathrm{d}M_{\text{an}}}{\mathrm{d}H} \tag{41}$$

Solutions of this equation with a suitable anhysteretic function give a typical sigmoid-shaped hysteresis loop as shown in Figure 19. By changing the values of the hysteresis parameters, this model is able to predict the magnetization of both soft and hard magnetic materials.

The anhysteretic and hysteresis equations represent the component of magnetization along the field direction. Therefore, the calculated resultant magnetization M is the component of magnetization parallel to the direction of the applied field. As a result, although the model equation for hysteresis remains basically the same, there is a significant difference in the modeled magnetic properties along different field directions due to the differences in the anhysteretic magnetization along different directions.

7.4 Extension to describe the effects of stress

The effects of stress on magnetization of materials can also produce very significant changes. The incorporation of these effects into a more general model, which includes magnetic field and temperature, has been achieved. The key to this is to provide a description under which both magnetic field and stress can be treated as similar. An equation for the stress equivalent field has been identified (Sablik, Kwun, Burkhardt

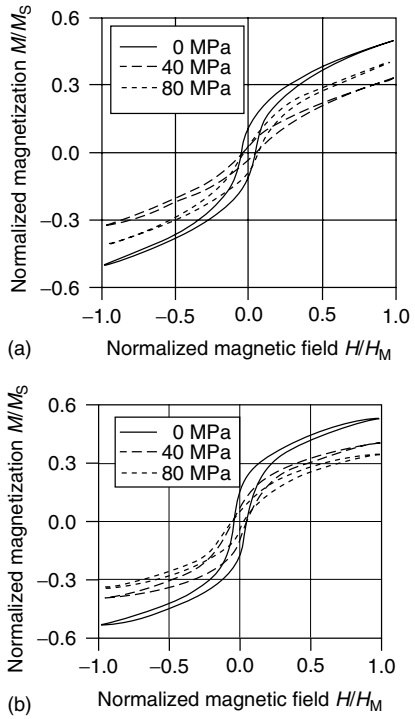

Figure 19. (a) Hysteresis measurements and (b) Jiles–Atherton model simulations of an amorphous $Co_{77}B_{23}$ ribbon, at different levels of applied tensile stress. (Hauser *et al*., 2005.) (Reproduced from H. Hauser, D.C. Jiles, Y. Melikhov, L. Li, and R. Grossinger: 'An approach to modeling the dependence of magnetization on magnetic field in the high field regime', *Journal of Magnetism and Magnetic Materials*, 2005, copyright © Elsevier 2005, with permission from Elsevier.)

and Jiles, 1987; Sablik and Jiles, 1988),

$$H_\sigma = \frac{3}{2}\frac{\sigma}{\mu_0}\left(\frac{\partial\lambda}{\partial M}\right)_T \tag{42}$$

$$H_\sigma(\theta) = \frac{3}{2}\frac{\sigma}{\mu_0}(\cos^2\theta - \nu\sin^2\theta)\left(\frac{\partial\lambda}{\partial M}\right)_T \tag{43}$$

where λ is magnetostriction, ν is Poisson ratio, and θ is angle between stress and measured magnetic field.

Variable stress also has effects that go beyond those that are described by the above equation. In fact, the application of stress causes unpinning of domain walls, and this effect can be described by a law of approach to the anhysteretic (Jiles, 1995; Jiles and Devine, 1995). This is given by the following equation for the change in irreversible component of magnetization $M_{\rm irr}$ with elastic energy W

$$\frac{{\rm d}M_{\rm irr}}{{\rm d}W} = \frac{1}{\xi}(M_{\rm an} - M_{\rm irr}) \tag{44}$$

where ξ is a coefficient with dimensions of energy per unit volume, and adding on the reversible component gives the

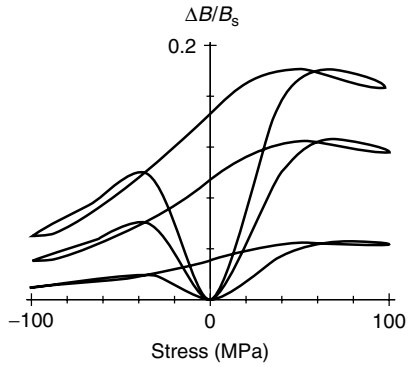

Figure 20. The calculated variation of magnetic induction with stress at fields of 26, 80, and $132\,{\rm A\,m^{-1}}$. The specimen was demagnetized and then subjected to an applied stress of up to 100 MPa, either in tension of compression. (After D. Jiles: Theory of the Magnetomechanical effect, *Journal of Physics D: Applied Physics* **28**, 1995, with permission from IOP Publishing Ltd.)

change in the total magnetization,

$$\frac{{\rm d}M}{{\rm d}W} = \frac{1}{\xi}(M_{\rm an} - M) + c\frac{{\rm d}M_{\rm an}}{{\rm d}W} \tag{45}$$

The anhysteretic is itself stress dependent because of the contribution of H_σ to the effective field, so the law of approach really contains two components: a reversible component that represents the change in the anhysteretic with stress, and an irreversible component which represents the change in the displacement of the magnetization from the prevailing stress dependent anhysteretic as shown in Figure 20.

7.5 Extension to describe time dependence

The effects of the frequency of the magnetic field on magnetization can also be included in this model (Jiles, 1994). In this case, the effects of eddy currents add to the dissipation and so result in higher coercivity and hysteresis loss.

$$\begin{aligned}&\left(\frac{\mu_0{\rm d}^2}{2\rho\beta}\frac{{\rm d}H}{{\rm d}t}\right)\left(\frac{{\rm d}M}{{\rm d}H}\right)^2 \\ &+\left(\frac{G{\rm d}w\mu_0 H_0}{\rho}\right)^{1/2}\left(\frac{{\rm d}H}{{\rm d}t}\right)^{1/2}\left(\frac{{\rm d}M}{{\rm d}H}\right)^{3/2} \\ &+\left[k\delta - \alpha\left(M_{\rm an}(H) - M(H) + k\delta c\frac{{\rm d}M_{\rm an}}{{\rm d}H_{\rm e}}\right)\right]\left(\frac{{\rm d}M}{{\rm d}H}\right) \\ &-\left[M_{\rm an}(H) - M(H) + k\delta c\frac{{\rm d}M_{\rm an}}{{\rm d}H_{\rm e}}\right] = 0\end{aligned} \tag{46}$$

Other approaches to the frequency dependence of magnetization are needed for insulating materials, in which eddy currents do not play a major role. This has been described previously for the case of high-frequency ferrites

(Jiles, 1993). The differential equation governing the magnetization in this case is

$$\frac{\mathrm{d}^2}{\mathrm{d}t^2}M(t) + 2\eta\frac{\mathrm{d}}{\mathrm{d}t}M(t) + \omega_\mathrm{n}^2 M(t) = \omega_\mathrm{n}^2 M_\infty(H) \qquad (47)$$

The extension to the basic model as given in the above equations, describes magnetic properties in terms of a multidomain structure that makes it widely applicable. The physical basis of this model is adjustable to cover the case of anisotropic and textured structures. This eliminates the need for the isotropic approximation and expands the applicability of this model to more complicated situations.

The differential magnetic susceptibility depends on the displacement of the prevailing magnetization from the anhysteretic magnetization. The anhysteretic magnetization is a function of the energy of the moments within a domain. To include anisotropic effects into the model, the anisotropy energy must be incorporated into the total energy of the moments.

The general equation for hysteresis can be solved with the incorporation of the appropriate anisotropic, textured, or stress-dependent anhysteretic magnetization, M_an. This gives the magnetization curves along particular directions. An advantage of this model is that the basic hysteresis equation remains the same, as do the hysteresis coefficients, so that the only change has been the incorporation of different forms of anisotropy into the equation for the anhysteretic.

8 SUMMARY

This paper has described the underlying basis for hysteresis models that can be used to describe the magnetic properties of materials. These provide a diverse range of modeling capabilities that span length scales from the discrete atomistic scale through nanoscopic and continuum/microscopic up to the macroscopic everyday scale of devices and components. Effects of anisotropy, stress, frequency of excitation, compacting processing, chemical composition, and heat treatment have been incorporated in these models. Experimental results and simulation data have shown that these effects have an impact on the magnetic properties and that these effects can be described and understood through the various hysteresis models.

LIST OF SYMBOLS

A	Cross-sectional area
a	Domain density parameter – Jiles–Atherton model
B_0, B_1	Correlation functions
c	Reversibility coefficient – Jiles–Atherton model
D	Diameter of grains/crystallites – Globus model
d	Dimensional parameter (diameter) – eddy current model
E	Energy
E_aniso	Anisotropy energy
E_max	Amplitude of internal potential
$F(z)$	Total force of all defects interacting with a domain wall
f	Pinning force per unit length – Globus model
f_text	Texture parameter – Jiles–Atherton model
$f(z - z_J)$	Individual interaction force of a defect
G	Dimensionless eddy current parameter – Bertotti model
H	Magnetic field
$\tilde{H}$	Effective magnetic field
H_0	Internal effective field due to potential
H_C	Coercive field
H_K	Anisotropy field
H_S	Saturating field
H_σ	Stress equivalent field
h	Length along domain wall perpendicular to direction of bending
h_A	Switching field – Preisach model
h_B	Switching field – Preisach model
h_C	Critical or the coercive field of the free fragment – Preisach model
h_I	Offset field, or bias field, for elemental switching volumes in Preisach model
$I(x)$	Bessel function series
K, K_1, K_2	Anisotropy coefficient
k	Pinning parameter (or dissipation parameter) – Jiles–Atherton model
k	Rate proportionality parameter – Preisach model
k_B	Boltzmann's constant
L	Length
L_0	Distance between two adjacent defects
L_3	Domain wall length
$L(x)$	anhysteretic function with $x = \frac{\mu_0 m\tilde{H}}{k_\mathrm{B}T}$ and $\tilde{H} = H + \alpha M$ – Jiles–Atherton model
$L(t)$	Staircase line which divides areas $S^{(+)}$ and $S^{(-)}$ – Preisach model
l	Length between domain wall pinning sites
M	Magnetization
M_R	Remanent magnetization
M_S	Saturation magnetization

M_{an}	Anhysteretic magnetization
M_{aniso}	Anisotropic anhysteretic magnetization – Jiles–Atherton model
M_{irr}	Irreversible component of magnetization
M_{iso}	Isotropic anhysteretic magnetization – Jiles–Atherton model
M_{rev}	Reversible component of magnetization
M_{∞}	Quasi static or equilibrium magnetization
m	Magnetic moment
N	Number of defects
$P(h_A, h_B)$	Preisach distribution function – Preisach model
$P(h_C, h_I)$	Preisach distribution function – Preisach model
$P(h_C)$	Integrated or local coercive field distribution function – Preisach model
$Q(h_A, h_B)$	Elementary hysteresis loop – Preisach model
$Q(h_A, h_B; t)$	Modified elementary hysteresis loop – Preisach model
$R(M)$	Noncongruency function – Preisach model
S	Squareness of the hysteresis loop
$S^{(+)}$ and $S^{(-)}$	Areas in the Preisach plain – Preisach model
T	Temperature
T_C	Curie temperature
t	Time
V	Volume
$W(\Phi)$	White noise function
W	Dimensional parameter (width) – eddy current model
W	Energetic barrier value – Preisach model
W	Elastic energy – Jiles–Atherton model
Z	Thermodynamic partition function
α	Damping parameter – Landau–Lifshitz–Gilbert model
α	Mean field coupling coefficient
α_R	Rayleigh constant
β	Shape parameter
β	Reversible component – Preisach model
χ	Susceptibility
χ_{in}	Initial susceptibility
δ	Domain wall thickness
δ	Directional parameter (± 1)
Φ	Magnetic flux
ϕ	Angle
Γ	Critical power
γ	Gyromagnetic ratio
γ_π	Domain wall energy per unit area
$\gamma(h_A, h_B)$	Hysteresis operator – Preisach model
η	Damping coefficient for harmonic motion
Λ	Torque
λ	Magnetostriction
λ_S	Saturation magnetostriction
λ_d	Damping coefficient – Landau–Lifshitz–Gilbert model
μ_0	Permeability of free space
ν	Poisson's ratio
θ	Angle
ρ	Resistivity
σ	Stress
σ_0	Stress amplitude
σ_C	Standard deviation of coercive field distribution – Preisach model
σ_I	Standard deviation of interaction field distribution – Preisach model
ζ	Correlation (or interaction) length – Bertotti model
τ	Time constant
ω_0	Resonance frequency
ω_n	Natural resonance frequency for harmonic motion
ξ	Decay coefficient – Law of approach
ξ	Replacement factor – Preisach model
ξ	Magnetization-elastic stress coefficient – Jiles–Atherton model

Magnetization Dynamics: Thermal-driven Noise in Magnetoresistive Sensors

Jian-Gang Zhu
Carnegie Mellon University, Pittsburgh, PA, USA

1 INTRODUCTION

Since the discovery of giant magnetoresistance (GMR) effect in Fe/Cr multilayers (Baibich *et al*., 1988), various magnetoresistive flux sensor-based thin-film multilayer structures have rapidly been developed into a variety of commercial applications. One of the most significant applications is the read heads for hard disk drives (HDDs), which has directly enabled the rapid growth of disk drive capacities over the last 10 years (Zhu, 2003). The large magnetoresistance in either the metallic magnetoresistive multilayer structures or the magnetic tunnel junctions can provide a high read back signal level, quickly replacing conventional anisotropic magnetoresistive (AMR) read heads, which had replaced inductive read heads earlier. The large magnetoresistive ratio has substantially enhanced the signal-to-electronic noise ratio of the read head, enabled the use of very low magnetic moment media in the longitudinal recording configuration, and facilitated the rapid area-density increase for HDDs in the past decade.

In all the magnetoresistive field sensors, magnetization rotation in the multilayer sensing stack driven by the magnetic flux produces a change in the resistance of the stack via magnetoresistive effect. In HDDs, the lateral dimension of the read sensor in a head has been rapidly decreasing and is below 100 nm at present. Thermally excited fluctuation of magnetization rotation in the sensor stack gives rise to voltage noise via the same magnetoresistive effect. If the head noise is dominated by this thermal magnetic noise, known as *mag-noise*, increasing the magnetoresistive effect will not enhance the signal-to-noise ratio (SNR) of the head. Therefore, understanding the mag-noise becomes critical since it could be the ultimate limit of the SNR in magnetoresistive sensors (Zhu, 2003).

In this chapter, we shall discuss a mechanism that results in stochastic oscillation of the magnetization orientation in magnetoresistive sensors, especially in magnetoresistive read heads used in HDD applications.

2 MAGNETORESISTIVE HEADS

Figure 1 shows a typical, magnetoresistive head design currently used in a HDD for data retrieval. The sensor stack is either a spin valve sensing current flowing in the plane (CIP) or a magnetic tunnel junction sensing current flowing perpendicular to the plane (CPP). In the CIP spin valve head, the sensing stack is a magnetic multilayer structure that consists of a free layer, an interlayer of normal metal

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

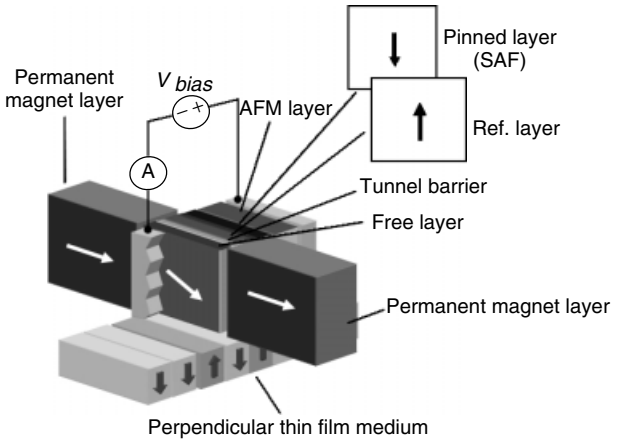

Figure 1. Schematic drawing of a typical tunneling magnetoresistive head with abutted permanent magnets for domain stabilization.

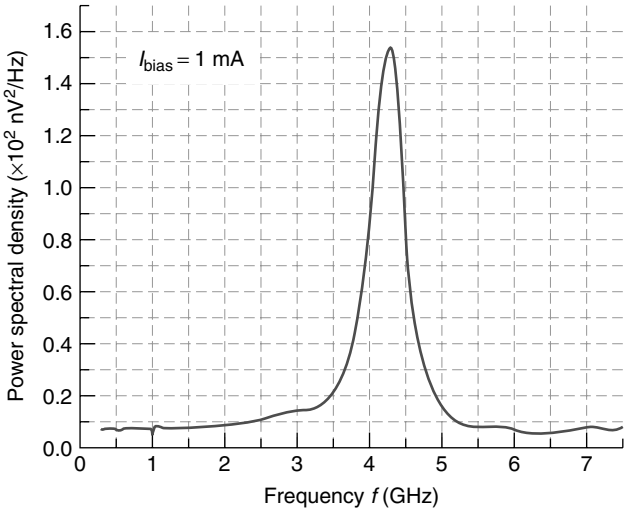

Figure 2. Measured power spectral density of a tunneling magnetoresistive head with a nominal resistance of 48 Ω. The physical track width of the head is 120 nm, with similar stripe height. The measurement was performed at 1-mA sensing current and no external magnetic field was applied. The electronic noise power spectral density, obtained by saturating the magnetic free layer with a large magnetic field along the magnetization direction of the permanent magnet, has been subtracted.

(Cu is always used), a synthetic antiferromagnetic trilayer, and an antiferromagnetic layer. The magnetic moment in the free layer rotates in response to the magnetic field arising from the recorded transitions in a disk medium, performing the function of sensing. The synthetic antiferromagnetic trilayer is a pair of ferromagnetic layers sandwiching a thin metallic layer, usually $Co_{90}Fe_{10}$/Ru/$Co_{90}Fe_{10}$. The magnetic moments of the two $Co_{90}Fe_{10}$ layers are coupled by a strong antiparallel, interlayer exchange coupling and are forced to orient perpendicular to the air-bearing surface (ABS) by the exchange bias field arising from the interface with the antiferromagnetic layer. The free layer, the normal metal interlayer, and the adjacent $Co_{90}Fe_{10}$ layer form a giant magnetoresistive trilayer, whose resistance depends on the relative orientation of the magnetic moments of the layers. In a magnetic tunnel junction head, often referred to as a *tunneling magnetoresistive* (*TMR*) *head*, the normal metal interlayer is replaced by an insulative tunnel barrier that is so thin that spin-dependent electron tunneling occurs. A pair of thin-film permanent magnets is abutted to the sensor stack in the horizontal direction to ensure a single domain configuration in the free layer. The width of the spin valve sensor stack is about 100 nm in present HDDs with similar dimension in height. The free layer is usually a $Co_{90}Fe_{10}$/$Ni_{81}Fe_{19}$ composite layer with a typical thickness of 1/3 nm, respectively.

3 MAG-NOISE AND ITS POWER SPECTRAL DENSITY

Owing to the small volumetric dimension of the free layer, its magnetization rotation can be excited by thermal energy. Figure 2 shows an experimentally measured voltage noise power spectral density (NPSD) of a typical TMR head in its quiescent state (the state with no external field present). This phenomenon was first reported by Smith and Arnett by measuring the noise power of a CIP spin valve head and they referred to this type of noise as *mag-noise* (Smith and Arnett, 2001, 2002; Smith *et al*., 2003).

The NPSD shown in Figure 2 arises from the dynamics of the magnetization in the free layer, excited by thermal fluctuations (Bertram, Jin and Safonov, 2002; Zhu, 2002; Zhou, Roesler and Zhu, 2002; Zhang and Lederman, 2002; Brown, 1978). In the absence of both an external magnetic field and thermal excitation, the magnetization is locally aligned with the effective magnetic field. Thermal excitation causes the magnetization to deviate away from the local equilibrium direction. When the deviation occurs, magnetization gyrates around the local equilibrium direction while the deviation angle decreases, a motion referred to as *damping*. Both gyromotions can be described by the Landau-Lifshitz-Gilbert equation (Bertram and Zhu, 1992; Gilbert, 1956):

$$\frac{\mathrm{d}\hat{m}}{\mathrm{d}t} = -\gamma \hat{m} \times \vec{h} + \alpha \frac{\mathrm{d}\hat{m}}{\mathrm{d}t} \times \hat{m} \tag{1}$$

where $\hat{m}$ is magnetization unit vector, $\vec{h}$ is total effective magnetic field, and γ is the gyromagnetic ratio. The first term in the equation describes the gyromotion of the magnetization vector, and the second term the damping motion. This particular vector form of the damping

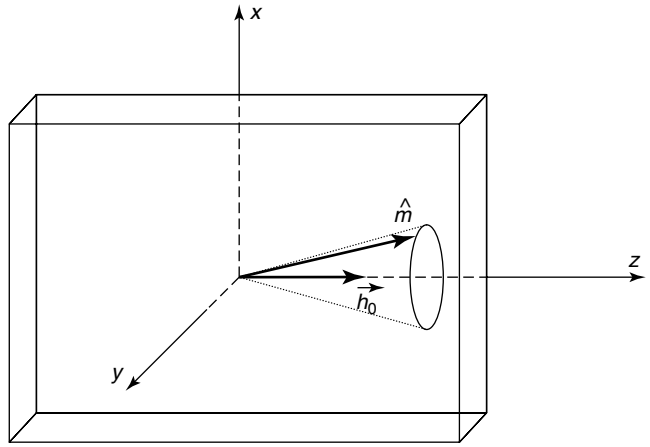

Figure 3. Magnetization gyromotion around its equilibrium direction, z axis, with $\vec{h}_0$ representing the stabilization field provided by the permanent-magnet layers abutted at the side edges of the free layer.

motion was first proposed by Gilbert (1956) and α is known as the *Gilbert damping constant*. In the following discussion, we shall basically follow the derivation given by Smith (2001), though, in a much more simplified manner.

Assuming that the magnetization in the free layer is uniform and that the thermally excited magnetization deviation from the equilibrium direction is small, the magnetization unit vector can be written as below following the coordinates given by Figure 3.

$$\begin{aligned}\hat{m} &= m_x\hat{e}_x + m_y\hat{e}_y + m_z\hat{e}_z \\ &\approx m_x\hat{e}_x + m_y\hat{e}_y + 1\cdot\hat{e}_z\end{aligned} \tag{2}$$

and the field can be written as

$$\begin{aligned}\vec{h} &= h_x\hat{e}_x + h_y\hat{e}_y + h_z\hat{e}_z \\ &= \left(h_{T,x} - D_x m_x\right)\hat{e}_x + \left(h_{T,y} - D_y m_y\right)\hat{e}_y + h_0\hat{e}_z\end{aligned} \tag{3}$$

where $h_{\mathrm{T},x}$ and $h_{\mathrm{T},y}$ are the effective random thermal fields along x and y directions, respectively; D_x and D_y are the effective demagnetizing factors along x and y directions, respectively; and h_0 is the stabilization field. Thus, equation (1) becomes

$$\begin{aligned}&\begin{bmatrix}1 & \alpha\\ -\alpha & 1\end{bmatrix}\begin{bmatrix}\dot{m}_x\\ \dot{m}_y\end{bmatrix} \\ &\quad= \begin{bmatrix}0 & -\gamma\left(h_0 + D_y\right)\\ \gamma\left(h_0 + D_x\right) & 0\end{bmatrix}\begin{bmatrix}m_x\\ m_y\end{bmatrix} + \gamma\begin{bmatrix}h_{T,y}\\ -h_{T,x}\end{bmatrix}\end{aligned} \tag{4}$$

Assume that the reference layer magnetization is 'fixed' along the x axis, through the strong interlayer exchange coupling between the pinned and the reference layers and the strong exchange bias field provided by the antiferromagnetic layer. The magnetoresistance is, then, only a function of m_x; eliminating m_x and $\dot{m}_y$ in the above equations, we have

$$\begin{aligned}&\ddot{m}_x + \eta\dot{m}_x + \omega_0^2 m_x \\ &\quad= \frac{\gamma}{1+\alpha^2}\left(\sqrt{1+\alpha^2}\,\omega_y h_{\mathrm{T},x} + \alpha\dot{h}_{\mathrm{T},x} + \dot{h}_{\mathrm{T},y}\right)\end{aligned} \tag{5}$$

where the resonance frequency is

$$\omega_0 = \sqrt{\omega_x\omega_y} \tag{6}$$

and

$$\omega_x = \frac{\gamma\left(h_0 + D_x\right)}{\sqrt{1+\alpha^2}} \tag{7}$$

$$\omega_y = \frac{\gamma\left(h_0 + D_y\right)}{\sqrt{1+\alpha^2}} \tag{8}$$

and

$$\eta = \frac{\alpha\left(\omega_x + \omega_y\right)}{\sqrt{1+\alpha^2}} \tag{9}$$

Equation (5) has the form of a damped harmonic oscillator. The following statistic properties of the random thermal fields on the right-hand side can be derived using the fluctuation-dissipation theorem (Brown, 1963; Kubo, 1966; Smith, 2002; Zheng, Bertram and Dakroub, 2002):

$$\lim_{\tau_0\to\infty}\frac{1}{2\tau_0}\int_{-\tau_0}^{\tau_0} h_{\mathrm{T},x}(\tau)h_{\mathrm{T},x}(\tau - t)\,\mathrm{d}\tau = \frac{2k_{\mathrm{B}}T\alpha}{M_{\mathrm{s}}V\gamma}\delta(t) \tag{10}$$

$$\lim_{\tau_0\to\infty}\frac{1}{2\tau_0}\int_{-\tau_0}^{\tau_0} h_{\mathrm{T},y}(\tau)h_{\mathrm{T},y}(\tau - t)\,\mathrm{d}\tau = \frac{2k_{\mathrm{B}}T\alpha}{M_{\mathrm{s}}V\gamma}\delta(t) \tag{11}$$

and

$$\lim_{\tau_0\to\infty}\frac{1}{2\tau_0}\int_{-\tau_0}^{\tau_0} h_{\mathrm{T},x}(\tau)h_{\mathrm{T},y}(\tau - t)\,\mathrm{d}\tau = 0 \tag{12}$$

where k_{B} is the Boltzmann constant, T is the absolute temperature, and V and M_s are the volume and the saturation magnetization of the free layer, respectively. Since the power spectral density (PSD) for m_x is defined as

$$\begin{aligned}&PSD_{m_x}(\omega) \\ &\quad= \int_{-\infty}^{+\infty}\left(\lim_{\tau_0\to\infty}\frac{1}{2\tau_0}\int_{-\tau_0}^{\tau_0} m_x(\tau)m_x(\tau - t)\,\mathrm{d}\tau\right)e^{-j\omega t}\,\mathrm{d}t\end{aligned} \tag{13}$$

one obtains

$$PSD_{m_x}(\omega) = \frac{2k_B T\alpha\gamma}{M_s V\left(1+\alpha^2\right)}\left(\frac{\omega_y^2+\omega^2}{\left(\omega_0^2-\omega^2\right)^2+\eta^2\,\omega^2}\right) \quad (14)$$

The above expression can also be rewritten as follows:

$$PSD_{m_x}(\omega) \approx PSD_{m_x}(0)\cdot\left(\frac{\omega_0^4}{\left(\omega_0^2-\omega^2\right)^2+\frac{PSD_{m_x}(0)}{PSD_{m_x}(\omega_0)}\omega_0^2\,\omega^2}\right) \quad (15)$$

where $\omega_y \gg \omega_0$, true for all magnetoresistive read heads, has been assumed. The measured PSD is then:

$$PSD_{V_x}(\omega) = PSD_{m_{x_x}}(\omega) \times I_{\text{bias}}^2 \Delta R^2 \quad (16)$$

where ΔR is the full amplitude of the magnetoresistance change of the read sensor stack.

Figure 4 shows a voltage spectral comparison between an experimentally measured NPSD of a CIP spin valve read head and the analytical expression given by equations (14) and (16) assuming $\alpha = 0.0185$. Such agreement has been found for a variety of spin valve and TMR heads without any exception, and the assumed values of α are all in the vicinity of $\alpha = 0.019$. This fact validates that the Gilbert damping form in equation (1) does indeed give a correct description of the dynamic damping motion of the magnetization vector, at least in metallic magnetic thin films.

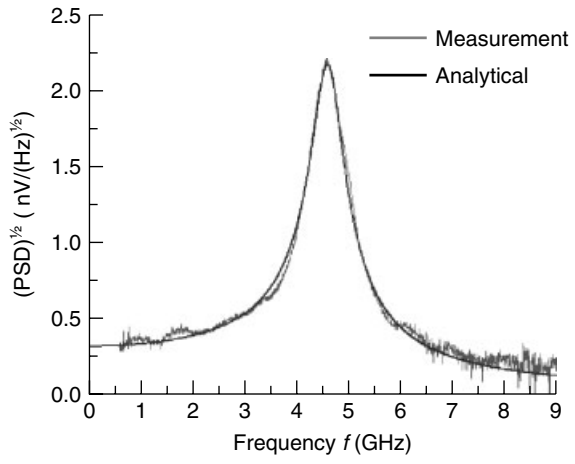

Figure 4. Comparison between an experimentally measured voltage spectral density of a CIP spin valve head (black) and the analytical expression of equations (14) and (16) (gray), assuming the Gilbert damping constant $\alpha = 0.0185$. The excellent agreement indicates the validity of the Gilbert damping form in metallic magnetic thin films.

4 MICROMAGNETIC MODELING AND SIMULATION ANALYSIS

Micromagnetic models have been developed to simulate the thermally activated magnetization processes in small-dimension magnetic devices, including the spin valve read heads (Zhu, 2002; Zheng, Bertram and Dakroub, 2002; Heinonen and Cho, 2004; Akimoto *et al*., 2005). Here, a rather comprehensive method developed for modeling spin valve read heads is described. Although the model is for specific spin valve sensors, it is quite representative for all types of applications involving small thin-film magnetic devices.

In this model, each of the three magnetic layers in the sensor stack is discretized into a layer of square mesh cells as shown in Figure 5. Within each mesh cell, the magnetization is assumed to be uniform. The volumetric energy density of each mesh cell, E, is calculated by summing up the following energy contributions: the local magnetic anisotropy energy, E_a, including magnetocrystalline anisotropy energy and anisotropy induced because of deposition in a magnetic field; the ferromagnetic exchange energy within the layer, E_{ex}; the magnetostatic energy, E_m, including interlayer interactions; the interlayer exchange energy, $E_{\text{int-ex}}$; the interfacial exchange pinning energy between the pinned layer and the antiferromagnetic layer, E_{pin}; and the Zeeman energy due to the field external to the sensor stack, E_Z. The effective magnetic field within each mesh cell, $\vec{H}$, is then calculated by taking a negative gradient of the energy density with respect to the local magnetization, $\vec{M}$ (Brown, 1978; Bertram and Zhu, 1992).

$$\vec{H} = -\frac{\partial E}{\partial \vec{M}} = -\left(\frac{\partial E}{\partial M_x}\hat{e}_x + \frac{\partial E}{\partial M_y}\hat{e}_y + \frac{\partial E}{\partial M_z}\hat{e}_z\right) \quad (17)$$

where

$$E = E_a + E_{ex} + E_m + E_{\text{int-ex}} + E_{pin} + E_Z \quad (18)$$

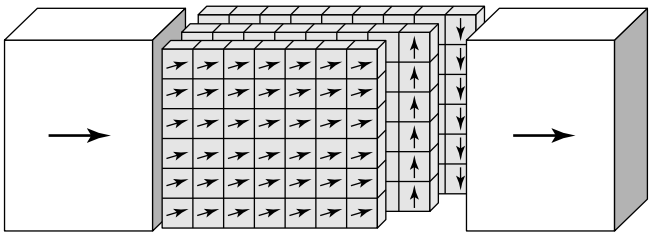

Figure 5. Schematic drawing of the modeling mesh of a magnetoresistive read head structure. Each of the three magnetic layers is discretized into a two-dimensional mesh of cells. The magnetization within each cell is assumed to be uniform and its orientation at any instant follows the Landau-Lifshitz-Gilbert equation (equation (1)).

The orientation of the magnetization in each mesh cell is assumed to follow the Landau-Lifshitz-Gilbert equation, equation (1) (Brown, 1978; Bertram and Zhu, 1992). If N is the total number of mesh cells in the stack, there are $3N$ coupled, nonlinear first-order differential equations. The thermal excitation is modeled by adding a random thermal field, $\vec{h}_{\mathrm{T}}$, to the effective field $\vec{H}$, for each mesh cell. The thermal field is completely random in orientation from cell to cell. The magnitude of the random thermal fields follows a Gaussian distribution with the variance determined by the fluctuation-dissipation theorem (Brown, 1979; Lyberatos, Berkov and Chantrell, 1993; Koch, Woods, Kirtley and Sun, 2001).

$$\overline{h_{\mathrm{T}}^2} = \frac{2k_{\mathrm{B}}T\alpha}{\gamma M_{\mathrm{s}}\Delta V\Delta t} \tag{19}$$

where ΔV is the volume of each mesh cell and Δt is the time duration over which the chosen random fields are kept unchanged. A different set of random fields is chosen every Δt period. The value of Δt is chosen to be in the range of 20–100 ps. The simulation results are insensitive to any value chosen within this region for modeling metallic magnetic thin films. The simulation time step for integrating the coupled differential equations needs to be significantly smaller than the random field duration, Δt.

Figures 6(a–c) show a set of simulation results for a CIP spin valve head. Figure 6(a) shows a snap shot of the thermally excited gyromagnetic motion of the magnetization in the free layer (the angle has been amplified by a factor of 10). Figure 6(b) shows the time domain waveform of the voltage signal and Figure 6(c) shows the corresponding noise voltage spectral density. The spatially nonuniform magnetization gyromotion in the free layer due to the nonuniform magnet fields, including both the magnetic field from the side-abutted permanent magnets and the demagnetization field from the edges, gives rise to multiple peaks, which have also been observed experimentally. In other words, the smaller peak at a higher frequency in the calculated spectrum is due to a nonzero, higher-order magnetostatic mode in the thermally excited spin wave (usually, ferromagnetic resonance only refers to the uniform rotation mode).

Micromagnetic modeling of thermal-driven noise in magnetoresistive sensors can also provide very useful insights on various characteristics of magnetoresistive heads. Here is one example. Figure 7 shows a calculated magnetization configuration at the quiescent state for both the free layer and the abutted permanent magnetic layer via micromagnetic simulation. The permanent-magnet film, consisting of closely packed CoPt magnetic grains, is also modeled. In the permanent-magnet layer, each magnetic grain has a relatively strong uniaxial magnetocrystalline anisotropy, with a single easy axis, the c axis of the hcp crystalline structure, lying in the film plane. However, the easy axes are oriented randomly from grain to grain, resulting in a rippling magnetization configuration, often referred to as

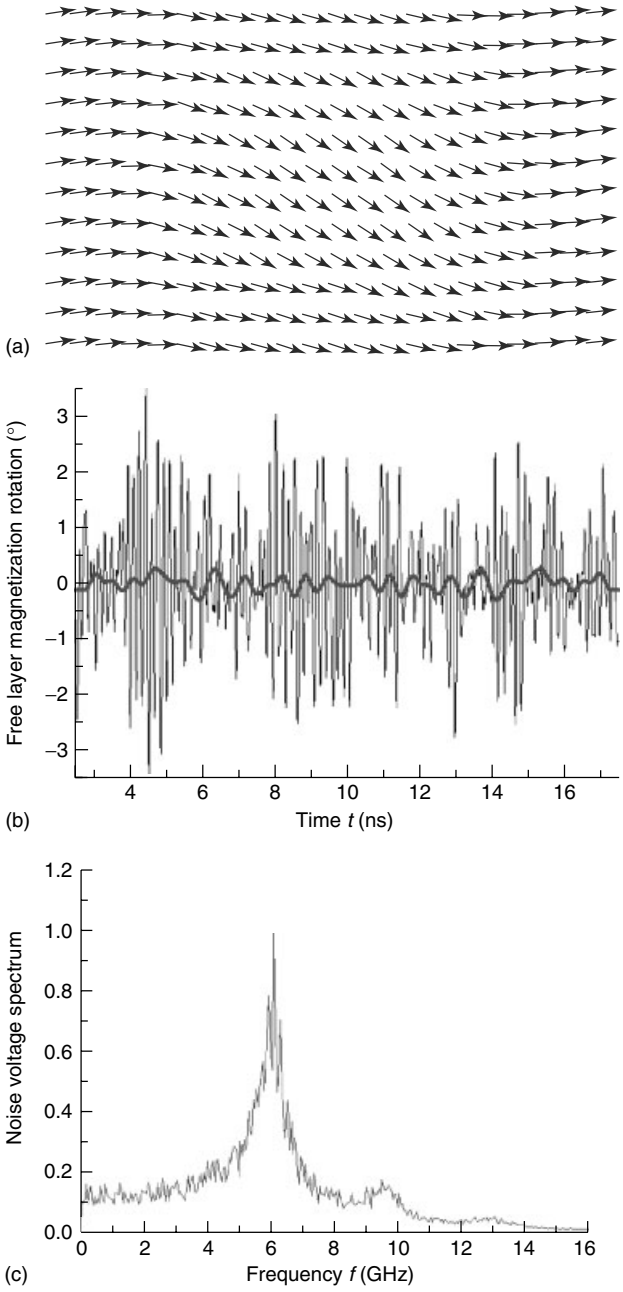

Figure 6. (a) A snap shot of magnetization rotation by thermal excitation in the free layer. The magnetization angles are exaggerated by a factor of 10 in this plot for visualization. The temperature in the free layer is assumed to be 60°C. (b) The angle of magnetization rotation, averaged over the entire free layer, is plotted as a function of time. The thicker curve in the center is the result of passing through a 2-GHz bandwidth low-pass filter. (c) The corresponding voltage spectral density of the modeled spin valve head.

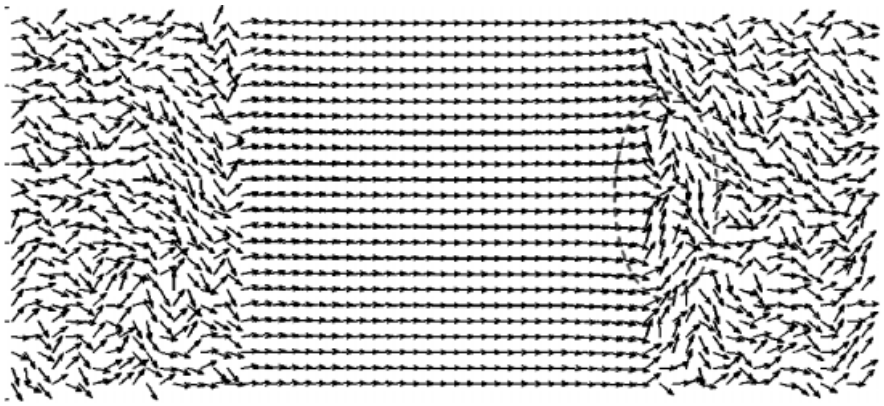

Figure 7. Calculated microscopic magnetization configurations in the free layer and abutted permanent-magnet (PM) layer for a CIP spin valve head. A CoPt film with a thickness of 30 nm has been assumed for the PM layer with a grain size of 10 nm. The physical track width of the free layer is assumed to be $w = 300$ nm and stripe height $h = 240$ nm.

magnetization ripples, as shown in the figure. The magnetization ripple results in microscale variations of the magnetic field provided by the permanent-magnet layer at the abutted junctions. This microscale bias field variation could be responsible for the often-observed head-to-head variation of various performance characteristics, such as read-track width variation, even for heads produced from the same wafer. The microscale variation of the field can also yield spatial variation of thermally excited magnetization oscillation in the free layer. Figure 8 shows the simulated magnetization oscillations at three different locations using the permanent-magnet magnetization configuration shown in Figure 7 and the color scale shows the rms value of the vertical magnetization component in the spatial map of the free layer. A locally weak field from the permanent magnetic layer at the right edge results in a significantly larger oscillation amplitude in the nearby region than elsewhere in the free layer. The calculated PSDs in the three corresponding locations show that the resonance frequency corresponding to the weak biased region at the right edge is significantly lower than that

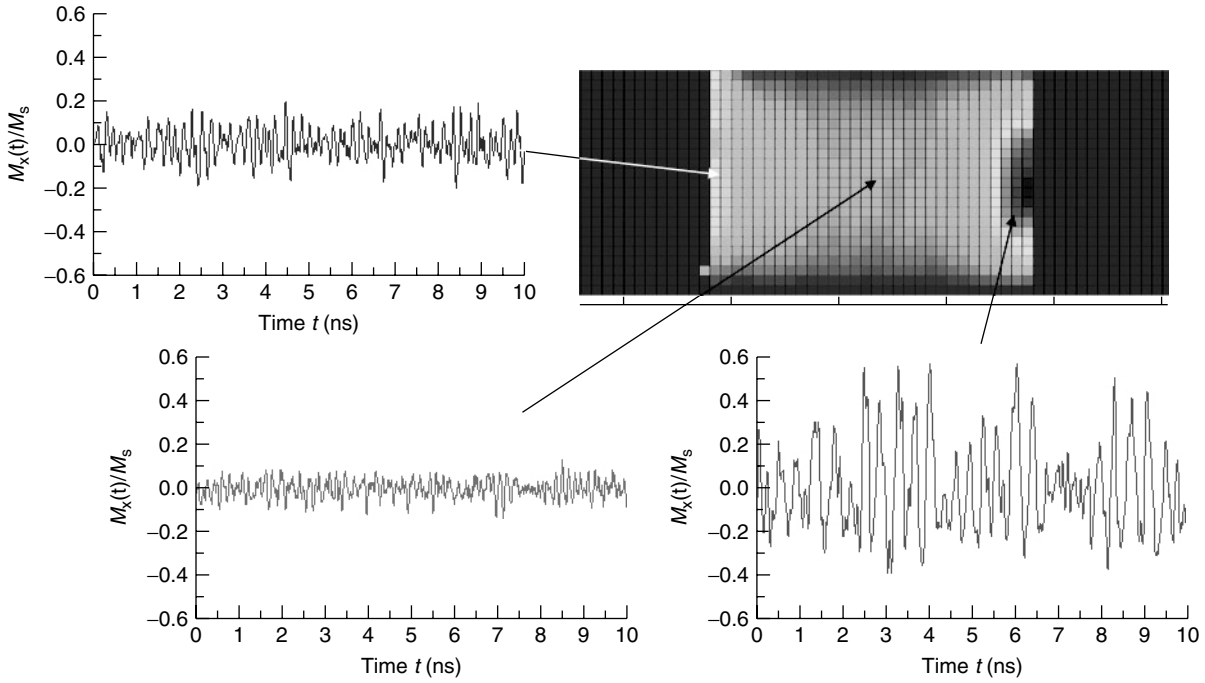

Figure 8. Simulated thermally excited magnetization oscillations at three different locations of the free layer with the permanent-magnet layer magnetization configuration shown in Figure 7. The color scale in the spatial color map (upper right) shows the rms amplitude of the oscillation.

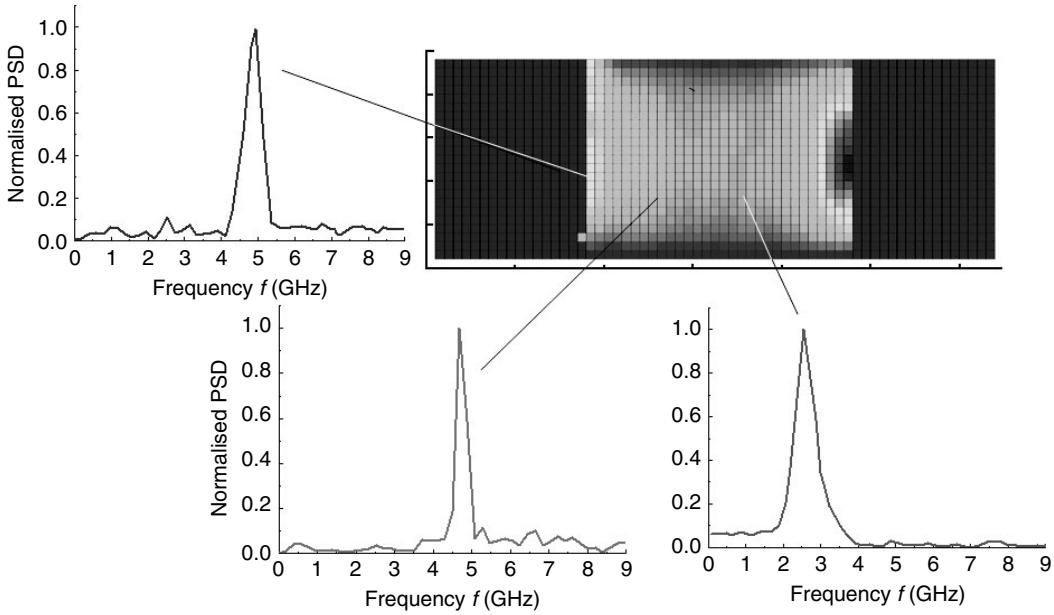

Figure 9. Calculated power spectral density of the magnetization oscillation at the three locations indicated in Figure 8. The weak biased region at the right edge of the free layer results in a significantly lower resonance frequency than the single resonance frequency elsewhere.

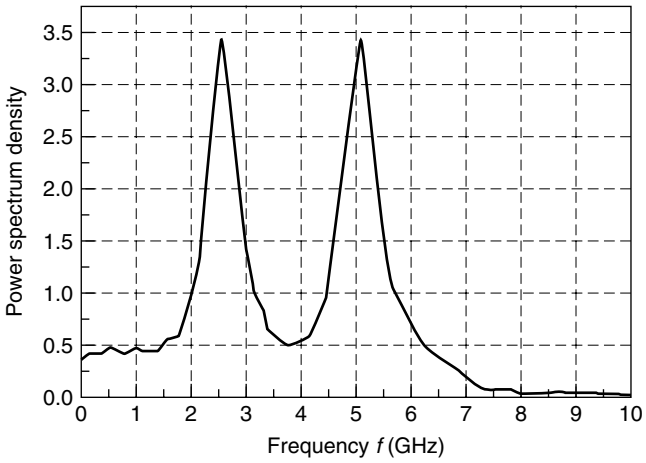

Figure 10. Calculated output voltage spectral density (au) from the micromagnetic simulation of the spin valve head presented in Figures 6–8.

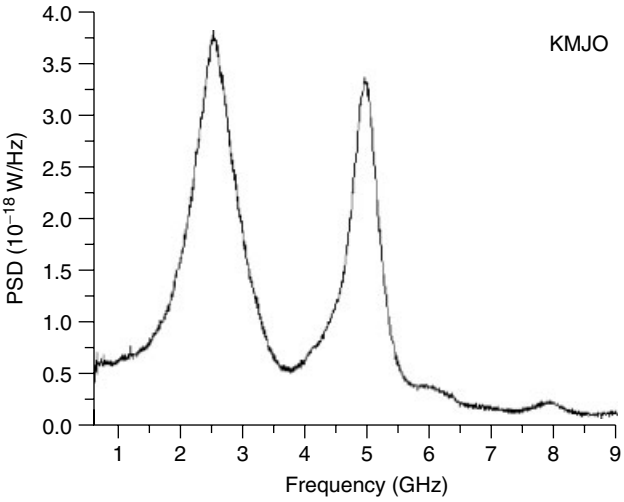

Figure 11. Experimentally measured power spectral density of a CIP spin valve head with abutted permanent-magnet stabilization. The higher peak at the lower frequency yields a high mag-noise level below 1 GHz.

elsewhere in the free layer, as shown in Figure 9. The head output voltage PSD is shown in Figure 10, clearly showing two distinctive resonance peaks. The lower-frequency peak results in a relatively high noise level in the frequency region below 1 GHz.

The predicted phenomenon has actually been often observed for spin valve heads, especially the ones with relatively large stripe heights. Figure 11 shows the measured NPSD of a spin valve head that exhibits the same features as the calculated one shown in Figure 10. The two heads have the same track width, stripe height, and magnetic layers.

5 THERMAL EXCITATION OF REFERENCE LAYER

The excellent predictability of micromagnetic simulation has provided many insights on the mag-noise characteristics of various types of magnetoresistive read heads (Zhou, Zhu and Kim, 2003), including the effect of thermally excited magnetization rotation in the reference/pinned synthetic

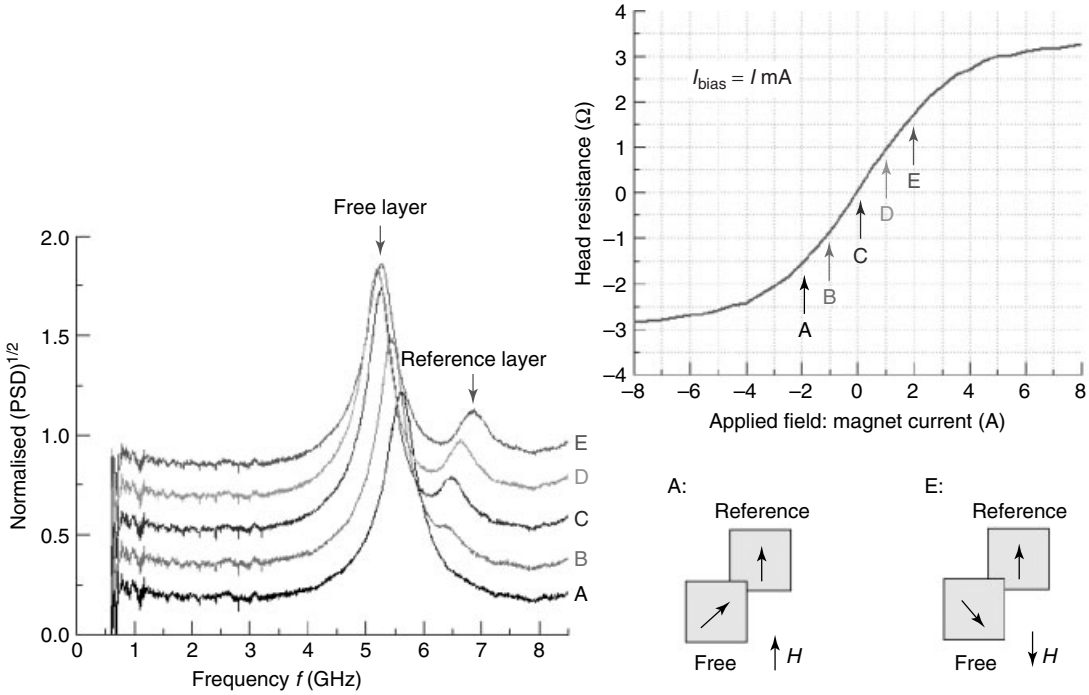

Figure 12. Experimentally measured power spectral densities of a magnetic tunnel junction head with abutted permanent-magnet stabilization at various fields applied perpendicular to the air-bearing surface, as indicated by the accompanying transfer curve. The baselines of the spectra were shifted vertically for visualization. The slight rising of the spectra below 2 GHz is magnetic in nature and is likely due to the acoustic mode of the ferromagnetic resonance of the synthetic antiferromagnet reference layer structure (Morrish, 2001).

antiferromagnet structure at insufficient exchange pinning fields (Heinonen and Cho, 2004; Akimoto, Mukouyama, Kanai and Uehara, 2006). Since the magnetization in the reference layer is usually at a 90° angle with respect to that in the free layer, the magnetoresistive output voltage can be written as

$$V \approx I_{\text{bias}} \cdot \Delta R \cdot \left(m_{x,\text{free}} + m_{z,\text{ref}}\right) \tag{20}$$

where $m_{x,\text{free}}$ and $m_{z,\text{ref}}$ are essentially the magnetization rotation angles away from equilibrium orientation in the free and reference layers, respectively. Assuming negligible coupling between the free and reference layers and small fluctuation angles, the variance of the output voltage can be written as

$$\begin{aligned}\overline{V^2} &\approx I_{\text{bias}}^2 \cdot \Delta R^2 \cdot \left(\overline{m_{x,\text{free}}^2} + \overline{m_{z,\text{ref}}^2} + 2 \cdot \overline{m_{x,\text{free}} \cdot m_{z,\text{ref}}}\right) \\ &= I_{\text{bias}}^2 \cdot \Delta R^2 \cdot \left(\overline{m_{x,\text{free}}^2} + \overline{m_{z,\text{ref}}^2}\right)\end{aligned} \tag{21}$$

Thus, the PSD of the output voltage can be written as the following:

$$PSD_V(\omega) = I_{\text{bias}}^2 \cdot \Delta R^2 \cdot \left(PSD_{m_x,\text{free}}(\omega) + PSD_{m_z,\text{ref}}(\omega)\right) \tag{22}$$

where $PSD_{mx,\text{free}}(\omega)$ and $PSD_{mz,\text{ref}}(\omega)$ are the PSDs of magnetization components in the free and reference layers, respectively.

Figure 12 shows a series of measured PSD curves for a magnetic tunnel junction head at a series of magnetic field values as indicated by the accompanied transfer curve. The field is applied perpendicular to the ABS of the head. As shown in the figure, the satellite peak to the right of the main peak in the voltage spectral densities shifts toward higher frequencies while increasing its magnitude when the applied field changes from the same direction as the reference layer magnetization to the opposite direction. The reference layer is a part of the exchange-biased synthetic antiferromagnet trilayer. The fact that the opposite frequency shifts for the two resonant peaks under the applied field indicates that the two peaks arise from separate magnetic layers. The satellite peak off the main resonance peak is, therefore, likely due to the thermally excited ferromagnetic resonance of the reference trilayer structure.

6 SUMMARY

Thermally excited magnetization precession results in magnetization oscillation in the magnetic layer(s) of magnetoresistive read heads in HDDs. The magnetization oscillation

behaves like a random-force-driven damped oscillator. Experimentally measured PSDs show excellent agreement with the formulation derived from the gyromagnetic equation with the Gilbert damping. The measured damping constant has been found to be around $\alpha = 0.019$ for the $Ni_{81}Fe_{19}/Co_{90}Fe_{10}$ composite free layer in all measured CIP spin valve heads. Micromagnetic modeling has become an excellent tool in the study of various noise spectral characteristics in spin valve heads. Combining micromagnetic modeling with spectral measurements of the read heads, many microscale "defects" in the heads could be diagnosed and understood.

ACKNOWLEDGMENTS

The author would like to thank Dr Yuchen Zhou, Ms Nayoung Kim, and Ms Veronica J. Yusz for the experimental measurements presented in this article. The author would also like to thank Professor H. Neal Bertram for many enlightening discussions on the subject and Mr H. Akimoto for insightful communication on the thermal excitation of the reference layer structure in spin valve heads. The research results presented and the writing of this article were made possible by the ABB endowed chair fund and the support from the Data Storage Systems Center at Carnegie Mellon University.

Magnetic Modes in Circular Thin Film Elements, Experiment and Theory

Christian H. Back and Matthias Buess
Universität Regensburg, Regensburg, Germany

1 INTRODUCTION

In the last several years high-frequency-confined spin-wave eigenmodes of micrometer-sized magnetic elements have been systematically studied for the straightforward case of elements possessing an almost mono domain state (Hiebert *et al*., 1997; Demokritov and Hillebrands, 2002; Jorzick *et al*., 1999; Wu *et al*., 2002; Gubbiotti *et al*., 2003; Novosad *et al*., 2002). Only in recent years, the experimental analysis of modes confined to inhomogeneous magnetized ferromagnetic elements has been tackled. The excitations exhibit added complexity when the ground-state magnetization configuration is the flux-closed magnetic vortex whose inner core supports perpendicular magnetization components on a nanometer length scale (Shinjo *et al*., 2000; Raabe *et al*., 2000; Wachowiak *et al*., 2002).

Let us consider applying a short magnetic field pulse to a magnetic element. At the positions where the field is not aligned with the ground-state magnetization direction, there will be a torque and $\boldsymbol{M}$ will start a precessional motion, according to the Landau–Lifshitz–Gilbert (LLG) equation. However, dynamics are strongly affected by the finite size of the element and the existence of boundaries. This results in various eigenmodes whose spatial distribution and frequency depend on the shape and size of the element. A connection to acoustic eigenmodes of macroscopic plates can be drawn and the similarities and differences will be discussed.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

2 EXPERIMENTAL TECHNIQUE

Time-resolved Kerr microscopy is a frequently used method to study the spin dynamics of thin-film systems in the time domain. It combines high temporal resolution of 150 fs with a spatial resolution of 300 nm for the setup used in the experiments described in the following text. To observe the precessional response of a spin system in the time domain, the magnetization has to be tipped off the equilibrium position. This has been done by laser-induced unpinning in ferromagnetic/antiferromagnetic system (Ganping *et al*., 1999), by using the temperature dependence of the anisotropy (van Kampen *et al*., 2002) or by optical current generation at a Schottky barrier (Acremann *et al*., 2001). We use the magnetic field generated in a lithographically produced microcoil. A Ti-sapphire laser operating at a repetition rate of 80 MHz triggers the current pulse by an optical switch (Hiebert *et al*., 1997). The excitation of the motion is monitored by a probe pulse aimed at measuring the perpendicular component of the magnetization $\boldsymbol{M}$. The probe pulse is frequency doubled to enhance the optical resolution and focused onto the sample. The detector analyzes the polarization of the reflected laser spot. A Wollaston prism splits the beam into two orthogonal linear polarization

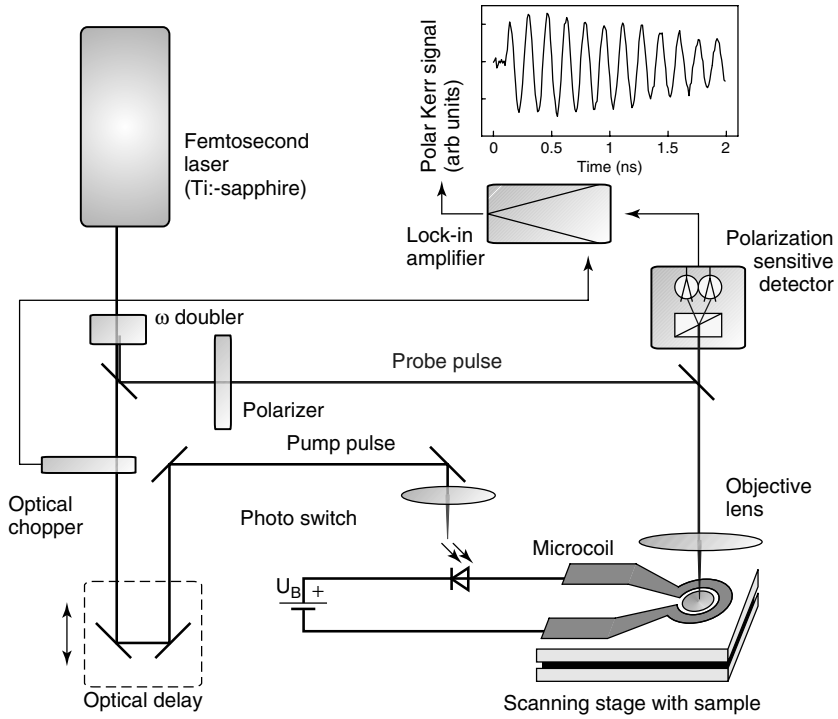

Figure 1. Diagram of the experimental setup using a microcoil. The probe pulse triggers an electric pulse by a photo switch that produces a magnetic field pulse in the microcoil, where the sample is located. The sample can be scanned under the lens of the microscopy by a piezo stage.

components whose intensity is detected in photodiodes. The polar magneto-optic Kerr effect induces a rotation of the plane of polarized light due to the perpendicular magnetization component. The time position is defined by the delay time between the field pulse and the measurement pulse. This is achieved by an optical delay line that changes the length of the pump beam path. The pump beam is mechanically chopped at kilohertz frequency and lock-in technique is used for detection of the small Kerr rotation. A piezo scanning stage moves the sample with respect to the microscope laterally and the vertical positioning is used to control and adjust the working distance (focus) of the lens. Figure 1 shows a diagram of the setup.

3 RADIAL EXCITATION FOR A CIRCULAR VORTEX-STATE PLATELET

The idealized magnetic element is a thin circular platelet with small aspect ratio d/R. Its ground state is the closed flux vortex state which can be best described in circular coordinates: $M_0(r, \varphi, z) = M_s \cdot (0, 1, 0)$

We consider the Landau–Lifshitz equation of motion

$$\frac{\partial \boldsymbol{M}}{\partial t} = \gamma \boldsymbol{M} \times \frac{\delta \mathcal{E}[\boldsymbol{M}]}{\delta \boldsymbol{M}(\boldsymbol{r})} \tag{1}$$

where the negative derivative of the energy functional $\mathcal{E}[\boldsymbol{M}]$ represents the effective field acting onto $\boldsymbol{M}$. In a 'back of the envelope' model we consider exclusively the external pulse field and the dipolar interaction inside the sample. For the circularly symmetric sample, no anisotropies are introduced. Generally, exchange interaction tends to align neighboring spins and establishes long-range ferromagnetic order. Here, the circulating flux configuration is the ground state for the sample and can be explained by dipolar interaction alone. In addition, micromagnetic simulations have been conducted to explore this limit and show that the exchange interaction will become relevant for smaller samples and higher modes. In the size regime we examined, no deviations of the modal frequencies from the dipolar dominated model are observed. Therefore, exchange interaction can be neglected [1] for the size range of our platelets, which is much bigger than the exchange length and the optical resolution of the experiment. As a consequence, the central region with the vortex core pointing out of plane will not be modeled. More detailed theories have been established using more general boundary conditions and a description of the core region ((Ivanov and Zaspel, 2005; Zivieri and Nizzoli, 2005) and references therein) but are not needed here to explain our experimental data.

The dipolar energy is expressed by the magnetic charge density.

$$\mathcal{E}_\mathrm{d} = \frac{\mu_0}{8\pi} \iint \frac{\rho_\mathrm{M}(\boldsymbol{r})\, \rho_\mathrm{M}(\boldsymbol{r}')}{|\boldsymbol{r} - \boldsymbol{r}'|} \mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{r}' \tag{2}$$

We estimate the deviation from the ground-state configuration to be smaller than 5%, so that the component of $\boldsymbol{M}$ along φ is assumed to remain equal to the ground-state value $M_{0\varphi} = M_\mathrm{s}$ for all times and the derivatives in φ direction are neglected to lowest order. The energy functional describing the total dipolar energy now reads

$$\begin{aligned}\mathcal{E}_\mathrm{d}[\boldsymbol{M}] = {} & \frac{\mu_0}{8\pi} \iint \frac{\partial_z^\mathrm{r} M_\mathrm{z}(\boldsymbol{r}) \partial_z^{\mathrm{r}'} M_\mathrm{z}(\boldsymbol{r}')}{|\boldsymbol{r} - \boldsymbol{r}'|} \mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{r}' \\ & + \frac{\mu_0}{8\pi} \iint \frac{\nabla_\parallel^\mathrm{r} \cdot \boldsymbol{M}_\parallel(\boldsymbol{r}) \nabla_\parallel^{\mathrm{r}'} \cdot \boldsymbol{M}_\parallel(\boldsymbol{r}')}{|\boldsymbol{r} - \boldsymbol{r}'|} \mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{r}' \end{aligned} \tag{3}$$

where $\parallel$ indicates the vector components parallel to the plane and z is the coordinate perpendicular to it. We use the identity

$$\left(\partial_z^\mathrm{r}\, \partial_z^{\mathrm{r}'} + \nabla_\parallel^\mathrm{r} \cdot \nabla_\parallel^{\mathrm{r}'}\right) \frac{1}{|\boldsymbol{r} - \boldsymbol{r}'|} = 4\pi\, \delta(\boldsymbol{r} - \boldsymbol{r}') \tag{4}$$

and homogeneous $\boldsymbol{M}$ along the z-direction to write

$$\begin{aligned}\mathcal{E}_\mathrm{d}[\boldsymbol{M}] = {} & \frac{\mu_0\, d}{2} \int_\mathrm{disk} M_\mathrm{z}^2(r)\, \mathrm{d}\boldsymbol{r} \\ & + \frac{\mu_0\, d^2}{8\pi} \int_\mathrm{disk} \int_\mathrm{disk} \frac{\nabla_\mathrm{r} \boldsymbol{M}_\mathrm{r}(r) \nabla_\mathrm{r} \boldsymbol{M}_\mathrm{r}(r')}{|\boldsymbol{r} - \boldsymbol{r}'|} \mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{r}' \end{aligned} \tag{5}$$

where $\nabla_\mathrm{r} \boldsymbol{M}_\mathrm{r} = \frac{1}{r} \frac{\partial}{\partial r}(r M_\mathrm{r}(r))$. Equation (5) contains only integrals over the disk area and is a perturbative expression. The first term is the energy arising from M_z appearing during the motion. It is of order $d\, R^2$ and contributes an effective field of the order $d\, R^2/(d\, R^2) \approx 1$. The next term in M_z would contribute a field of the order d/R and is neglected because, as $d \ll R$, it would only provide a minor correction. Thus, the field acting on $\boldsymbol{M}$ by virtue of the lowest-order term in M_z amounts to the standard demagnetizing field $-M_\mathrm{z}$ pointing in the direction opposite to M_z. This is the field of a perpendicularly magnetized plate with infinite radius. The finite radius introduces corrections of the order d/R which are neglected here. The second term is due to a radial component appearing during the motion. Its functional derivative is the radial field $H_\mathrm{r}[M_\mathrm{r}]$

$$H_\mathrm{r}[M_\mathrm{r}] = \frac{d}{4\pi} \frac{\partial}{\partial r} \int_\mathrm{disk} \frac{1}{|\boldsymbol{r} - \boldsymbol{r}'|} \frac{1}{r'} \frac{\partial}{\partial r'} (r' M_{\mathrm{r}'})\, \mathrm{d}r' \tag{6}$$

which is a linear functional of M_r. Notice that it is of the order d/R. However, if neglected, no precessional motion develops, in contrast to the experiment. Thus, within this perturbative approach, it makes sense to neglect the contribution of order d/R of the effective field along z, but it makes no sense to neglect the contribution of the same order d/R to the radial field. With all relevant fields specified, we obtain the system of coupled linear equations

$$\frac{\partial M_\mathrm{r}}{\partial t} = -\gamma_0 M_\mathrm{s} (H_\mathrm{ext} - M_\mathrm{z}) \tag{7}$$

$$\frac{\partial M_\varphi}{\partial t} = 0 \tag{8}$$

$$\frac{\partial M_\mathrm{z}}{\partial t} = +\gamma_0 M_\mathrm{s} H_\mathrm{r}[M_\mathrm{r}] \tag{9}$$

Generally, the Landau–Lifshitz (LL) equations couple different components. By taking the second derivative of 7 and inserting into 9, the LL equations can be decoupled to

$$\frac{\partial^2 M_\mathrm{r}}{\partial t^2} = -\gamma_0 M_\mathrm{s} \frac{\partial H_\mathrm{ext}}{\partial t} + (\gamma_0 M_\mathrm{s})^2 H_\mathrm{r}[M_\mathrm{r}] \tag{10}$$

$$M_\mathrm{z}(r, t) = \frac{1}{\gamma_0 M_\mathrm{s}} \sum_i \dot{c}_i(t) M_\mathrm{r}^i(r) + H_\mathrm{ext}(\boldsymbol{r}, t) \tag{11}$$

Equation (10) shows explicitly that the problem cannot be reduced to a standard wave equation. Equation (11) allows M_z to be straightforwardly calculated once M_r is known. We seek a solution of equation (10) with the separation ansatz $M_\mathrm{r}(r, t) = \sum_i c_i(t) M_\mathrm{r}^i(r)$. The radial functions $M_\mathrm{r}^i(r)$ are the solutions of the eigenvalue equation

$$H_\mathrm{r}[M_\mathrm{r}^i] = -N_\mathrm{r}^i M_\mathrm{r}^i \tag{12}$$

Inserting the separation ansatz in equation (10) leads to a set of decoupled ordinary differential equations for the coefficients c_i

$$\ddot{c}_i + \omega_i^2 c_i = -\gamma_0 M_\mathrm{s} \left(H_\mathrm{ext}(r),\, M_\mathrm{r}^i(r)\right) \dot{H}_\mathrm{ext}(t) \tag{13}$$

where the eigenfrequencies ω_i are related to the sought for eigenvalues N_r^i by the relation

$$N_\mathrm{r}^i = \frac{\omega_i^2}{\gamma_0^2 M_\mathrm{s}^2} \tag{14}$$

We use the scalar product $(a, b) = \int_0^R a(r) b(r) 2\pi r\, \mathrm{d}r$ and the external field pulse is written as $H_\mathrm{ext}(t) H_\mathrm{ext}(\boldsymbol{r})$. As equation (13) is the equation of motion of a classical undamped forced harmonic oscillator, it can be solved exactly, provided eigenmodes and eigenvalues are known, so that the coefficients c_i and thus $M_\mathrm{z}(r, t)$ can be calculated

analytically:

$$c_i = -\gamma_0 M_s \Big(H_{ext}(r), M_r^i(r) \Big) \int_{-\infty}^{\infty} H_{ext}(\tau)\, G(t,\tau)\, d\tau \quad (15)$$

with the Greens function $G(t,\tau) = \frac{1}{\omega_i} \sin(\omega_i (t-\tau))$. The ideal case of $H_{ext}(t) \propto \delta(t)$ can be solved at a glance and produces a solution equivalent to imposing a finite value to M_r at $t = 0$. The key elements of this problem are the eigenmodes $M_r^i(r)$. To determine them, we first notice that the integral in equation (6) diverges for $r = 0$ unless $M_r|_{r=0}$ is zero. This establishes the first boundary condition: the radial component of the magnetization must vanish in the center of the disk. Next, we notice that the exact solution of the eigenvalue equation for a disk with infinite radius is (see (Buess *et al.*, 2005))

$$N_r = \frac{1}{2}\, dk_r \quad (16)$$

and $M_r \propto J_1(k_r r)$, J_1 being the first-order Bessel function and k_r being the in-plane radial wave vector labeling the low energy excitations with frequency $\omega \propto \sqrt{k_r}$. When the disk has a finite radius, $H_r[M_r]$ contains a contribution arising from the magnetic charge ρ_M building up at $r = R$ in virtue of abrupt change of M_r from $M_r(R)$ to zero. This contribution diverges the unless $M_r|_{R=0} = 0$. This establishes the second boundary condition [2]. Thus, within our two dimensional model, the appearance, during the motion, of a finite radial component M_r at the center of the disk or at the boundary $r = R$ is associated with an infinite magnetostatic energy, so that pinning $M_r|_{0,R} = 0$ must be introduced to avoid this divergence. By virtue of the vanishing of M_r at $r = R$, the operator $H_r[M_r]$ defined on a disk with finite radius becomes a hermitic one. In the spirit of the Ritz variational principle, $J_1(k_r)$ are 'good' eigenfunctions for finite R as well, provided k_r is chosen to fulfill the boundary condition $J_1(k_r)|_{r=R} = 0$. This produces a discrete set of eigenvalues N_r^i and a complete orthonormal basis set M_r^i on the disk. In this approximation, the frequencies ω_i of the eigenmodes can be calculated as

$$\omega_i^2 = \frac{1}{2}\gamma_0^2 M_s^2 dk_r = \frac{1}{2}\gamma_0^2 M_s^2 \frac{d}{R}\, x_{1i} \quad (17)$$

where x_{1i} is the i-th zero of the J_1 Bessel function. In the next section, this relation is put to the test by comparing with the experimental data.

4 FOURIER TRANSFORM IMAGING OF THE EIGENMODES

In this section, the multimode excitation spectrum measured by time-resolved Kerr microscopy is analyzed.

The samples are single 15-nm thick ferromagnetic permalloy disks with diameters of 3 µm, 4 µm, and 6 µm and are produced by e-beam evaporation. The details are described in (Buess *et al.*, 2004). A Cu microcoil was prepared that surrounds the sample with an inner diameter of 8 µm and an outer diameter of 12 µm. In the ground state the magnetic elements exhibit a flux-closure vortex configuration (Raabe *et al.*, 2000). This state is perturbed by a short magnetic field pulse perpendicular to the sample plane, that is used to tip $\boldsymbol{M}$ off the equilibrium direction. This magnetic field pulse exerts a torque onto the local magnetization vector that launches the precessional motion of the magnetization.

4.1 Time-domain measurement

A current pulse of about 100 ps rise time launched into the microcoil provides the perpendicularly oriented magnetic tipping field pulse exciting the spin precessional motion (Hiebert *et al.*, 1997; Acremann *et al.*, 2000; Buess *et al.*, 2003) of the ferromagnetic microstructures under examination. The magnetic response of the individual disks is examined by recording a time-resolved movie with a high spatial resolution of 300 nm. The maximum strength of the field pulse is less than $\approx$4000 A m^{-1} (50 Oe) and is estimated by the current through the microcoil. This leads to a small deviation from the ground state. Figure 2 shows a stroboscopic sequence of polar Kerr microscopy images obtained during and after the application of the field pulse for a disk with 3 µm radius. The time interval between each image is 30 ps. The image contrast is produced by the z-component of the magnetization vector undergoing a spatially nonuniform motion. Notice that our experiment measures changes of M_z with respect to the ground state configuration. Therefore, the image of the initial state (the first image) shows no contrast. Despite the complexity of the sequence, one recognizes an overall periodicity of the motion with maxima (bright) and minima (dark) of M_z recurring after a characteristic time of the order of 350 ps. The modal structure of the motion is not immediately apparent from Figure 2 but will emerge from the Fourier transformation (FT) analysis. Note that in this regime of small deviations from the ground state, the in-plane tangential component of the magnetization vector is, to first order, unaffected by the motion. The radial component M_r (not measured in the present experiment) is connected to $M_z(t)$ by the relation $\dot{M}_r \propto M_z$ and has a phase difference of $\pi/2$, so that the magnetization vector performs an elliptical precessional path as shown in (Acremann *et al.*, 2000). Thus, in this linear limit, it is sufficient to consider only one component in order to have the full knowledge of the modal structure. We have measured here only the component that

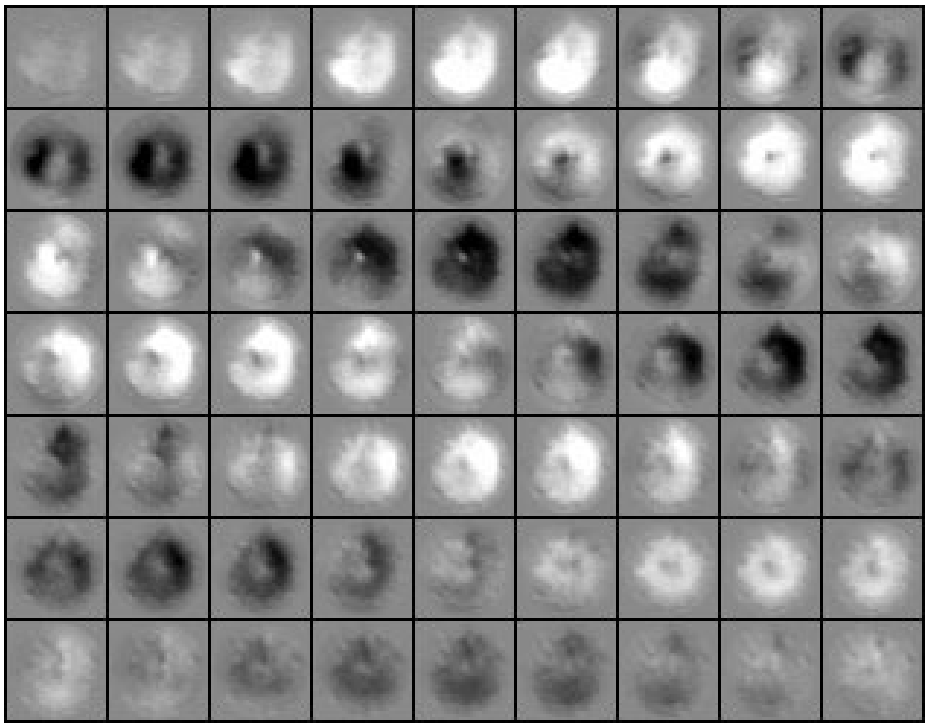

Figure 2. Temporal evolution of the precessional motion. $M_z(t) - M_z(t = 0)$ – that is, the difference between the value of the z-component of the magnetization vector before application of the pulse and after application of the pulse – is imaged as a function of the time elapsed after the magnetic field pulse. Notice that some images show a central spot, which is clearly distinguishable from the surroundings. This feature will be discussed in connection with Figure 10. From such a sequence one may extract an overall periodicity corresponding to the strongest excited mode. The spin motion, however, is not uniform, but is the superposition of a number of modes. (Reprinted with permission from M. Buess *et al*., *Phys. Rev. Lett.*, **93**, 077207 (2004).)

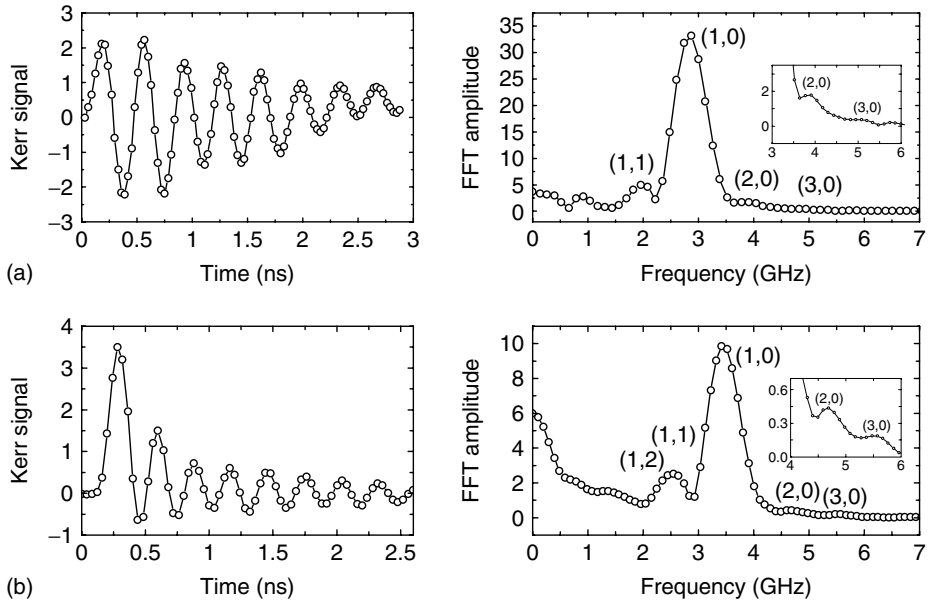

Figure 3. Spatially averaged signal (left) and Fourier transform amplitude (on the right). The insets show the same frequency domain data enlarged, to depict the small peaks at higher frequency more clearly. (a) Data from 6-μm disk (b) from 4-μm disk. The labeling of the maxima is explained later in Section 4.6.

could be detected with the greatest precision, namely, the one perpendicular to the disk (M_z).

4.2 Spatially averaged signal

The information of the spatio-temporal data presented in the last section cannot be understood at first view. In the first approach, we spatially average the signal over each frame in the data of Figure 3 and plot it as a function of delay time. This is the same result that we would get by using a laser spot of the size of the element. The oscillating signal of the 6 µm-diameter disk is shown in Figure 3(a) (left) with its FT amplitude (on the right). The dominant peak at 2.9 GHz is easily identified in the FT amplitude and recognized as the (almost uniform) precessional motion of the magnetization. No clear indication of other modes can be seen. For a different sample, a 4-µm-diameter disk, the averaged signal is shown in Figure 3(b) in the time domain (on the left) and the frequency domain (on the right). The principal peak for this smaller disk is found at a higher frequency of 3.4 GHz in agreement with Section 3 where the frequency is found to be proportional to the square root of the wave vector. A smaller peak at 2.5 GHz is also prominent.

4.3 Mode images by local Fourier transform

One of the difficulties in identifying the dynamical eigenmodes is that the excitation by, for example, a short magnetic field pulse results in a complicated spin motion where several modes are superposed in an intricate way. This difficulty is circumvented by using a phase-sensitive FT technique. Frequency domain analysis of the time sequenced images reveals resonances corresponding to the eigenmodes defined by the lithographically produced elements.

A detailed view of the various eigenmodes driving the spin motion in Figure 2 is obtained by Fourier transforming the time-domain signal recorded at each location into the frequency domain. This is referred to as the local FT. Of each FT, not only the amplitude – as in Ref. (Park *et al*., 2003; Hicken *et al*., 2003) – is retained but also the phase. The location of the maximum of these resonances can be determined with an accuracy of 0.2 GHz (corresponding to the separation of data points in the FT). The typical width of the resonance curves is 0.5–1.0 GHz. The values of the resonance frequencies have been accurately reproduced by an analytical calculation based on Ref. (Buess *et al*., 2003) and by a micromagnetic simulation (see Section 5, (LLG)).

Images of the amplitude (top) and the phase (bottom) at resonance of various eigenmodes are displayed in Figure 4. One recognizes two types of modes: some are organized into concentric rings with circular nodes having the spectral weight and phase distribution Figure 4(a–c) obeying the axial symmetry of the ground state as $M_s = 860\,\mathrm{kA\,m^{-1}}$. The modes in Figure 4(d) and (e) instead, have one and two diametric nodes, respectively, and break the axial symmetry. The various nodal lines are easily identified because at their spatial location the spectral weight is small and the phase jumps by π.

4.4 Axially symmetric (radial) modes

Fourier amplitude (left) and -phase (right) images of the three low-lying axially symmetric modes are displayed in Figure 4(a–c). The left-hand side of each image shows the result of the micromagnetic calculation, the right hand side is amplitude (or phase) of the FT of the experimental time-domain images. The modes can be classified according to the number of nodes: the fundamental and highest-amplitude mode has a node only in the center of the disk and at its border ($n = 1$: 4a). The phase is uniform over the disk. The next mode has a node at approximately half distance between the core and the boundary ($n = 2$: 4b). Going across the node the temporal phase changes by π, just as in any standing wave. Finally, we observe a third mode with two nodes within the disk ($n = 3$: 4c) and with π phase jump across each node. This modal structure is well described by the first-order Bessel function $J_1(k_n r)$, where k_n assumes discrete values determined by the boundary conditions and r is the radius. Such modes are natural basis functions in a circular membrane (Sparks, 1970). The frequencies can be calculated by an analytical model described in Sections 3 and 4.9.

4.5 Nonaxially symmetric (azimuthal) modes

Only axially symmetric modes are expected if the tipping pulse is uniform over the disk and all geometries are perfectly axially symmetric. Symmetry breaking modes, instead, require a nonuniform tipping pulse or a deviation of the sample from a perfect cylindrical shape. Our computation of the field configuration arising from the single turn coil reveals that the tipping pulse has a sizable gradient in the plane of the vortex, owing to the coil opening toward the leads. The maximum difference in tipping field amplitude reaches 30%. As revealed by our micromagnetic simulation (LLG), this asymmetry is capable of exciting nonaxially symmetric modes. Figure 4(d) shows Fourier amplitude (top) and Fourier phase (bottom) of a single-node, nonaxially symmetric mode at 2.08 GHz. The lowest lying nonaxially symmetric mode is imaged in Figure 4(e) (top: amplitude, bottom:

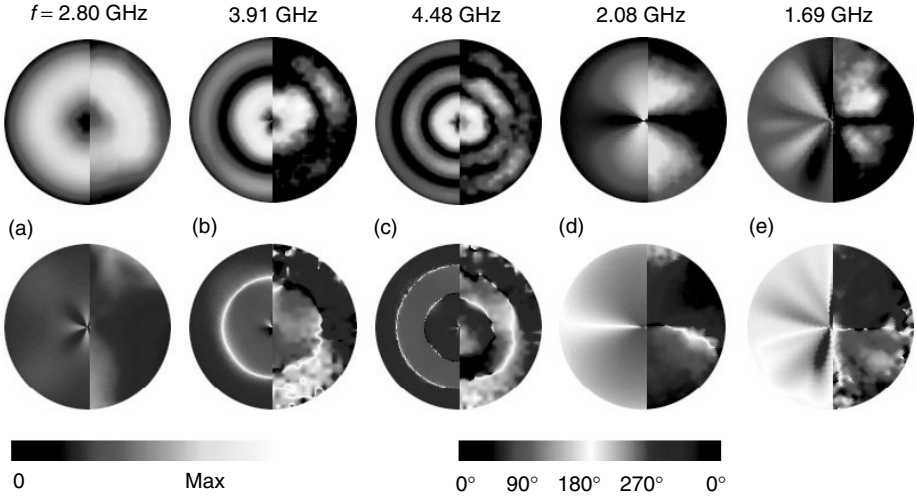

Figure 4. Images of the eigenmodes for a disk with radius $R = 3\,\mu$m. FT of Figure 2 at each location results in a spectrum with five resonances. The top row shows the absolute value of the Fourier amplitude at resonance and the bottom row shows the phase. The modal maps are composed from two half-images: the left from the micromagnetic simulation, the right from the experiment. (a–c) Axially symmetric modes showing concentric nodes ($n = 1, 2, 3$, $m = 0$). Mode (a) has the largest spectral weight, that is, it is dominating the motion and is responsible for the overall periodicity apparent from Figure 2(b) and (c) are higher modes with regions exhibiting different phases. (d–e) These modes have nodal lines going across the image. (d) exhibits one azimuthal node (1,1) and (e) two azimuthal nodes (1,2). This mode consists of four regions, oscillating in pairs in phase. Note that across the nodal lines the phase changes by 180°. A Hamming cutoff window was used to obtain the fast Fourier transform (FFT) data from the 3.33 ns long scans. The half-images from the time-domain micromagnetic simulation data (see Section 5) were obtained using the same procedure. (Reprinted with permission from M. Buess *et al.*, *Phys. Rev. B*, **71**, 104415 (2005).)

phase). This mode has two mutually orthogonal radial nodal lines (top). While passing through each node, the phase changes by π (bottom). We observe, for the single-node nonaxial mode, a systematic striking behavior, illustrated in Figure 5 for a 6 µm (top) and 3 µm-diameter disk (bottom). The Fourier amplitude is shown on the left of Figure 5(a) and (c), the Fourier phase on the right, and the reconstructed time sequences in Figure 5(b) and (d). The phase changes in both cases – in particular in Figure 5(c) – almost continuously along a circular path surrounding the center are in contrast to Figure 5(a). Correspondingly, the time-domain sequences in Figure 5(b) and (d) reveal that this mode is traveling along a circular trajectory surrounding the core. We explain this motion by noticing that the symmetry of this problem allows the existence of *two* mutually orthogonal degenerate single-node modes which can be simultaneously excited, their relative weight depending on the actual geometry of the tipping pulse. Superposition of such modes can produce the observed 'circularly polarized' eigenmode – just as, by analogy, linearly polarized light can be superposed to yield circular polarization. In this specific sample, the optical micrographs reveal that the 3 µm disk is rather displaced from the coil center whereas the 6 µm-disk is not: this explains why the 'circularly polarized' mode is more pronounced in Figure 5(c) and (d) than in Figure 5(a) and (b).

4.6 Wave vectors and boundary conditions

We first relate the nodal structure of the modes to a $\boldsymbol{k}$-vector and construct experimental dispersion relations. The modal structure observed in Figure 4 requires the introduction of polar coordinates r, φ in the plane of the disk. We define the wave vector $\boldsymbol{k} = (k_\mathrm{r}, k_\varphi)$ of a spin excitation by introducing an orthogonal set of basis functions suitable for the two-dimensional vortexlike spin configuration. $m_\mathrm{r}(r, \varphi) \sim \mathrm{J}_1(k_\mathrm{r} r)\exp(ik_\varphi \varphi)$. It can be shown that the radial part is an exact solution for infinite radius (Buess *et al.*, 2005). These functions are the analog for circular geometries of plane waves in Cartesian geometries. The 2π periodicity in φ requires $k_\varphi^m = 0, \pm 1, \pm 2, \ldots$, with the index $m = 0, \pm 1, \pm 2, \ldots$ counting the number of diametric nodes.

The boundary conditions at $r = 0$ and at $r = R$ (Kakazei *et al.*, 2004; Buess *et al.*, 2003) establish a set of possible values for k_r: $k_\mathrm{r}^n = \frac{x_n}{R}$, x_n indicating the zeroes of the Bessel functions J_1; $n \in \mathcal{N}$ counts the number of circular antinodes. $n = 1$ corresponds to the state with nodes at $r = R$ and $r = 0$. From Figure 4 – counting the nodes and their location – one can read out the mode numbers (n, m) of the measured modes. We can now construct the experimental dispersion relations f versus $(n, m = 0)$ (radial modes, Figure 6a) and f versus $(n = 1, m)$ (azimuthal modes, Figure 6b). We observe a positive dispersion (monotonically increasing) for

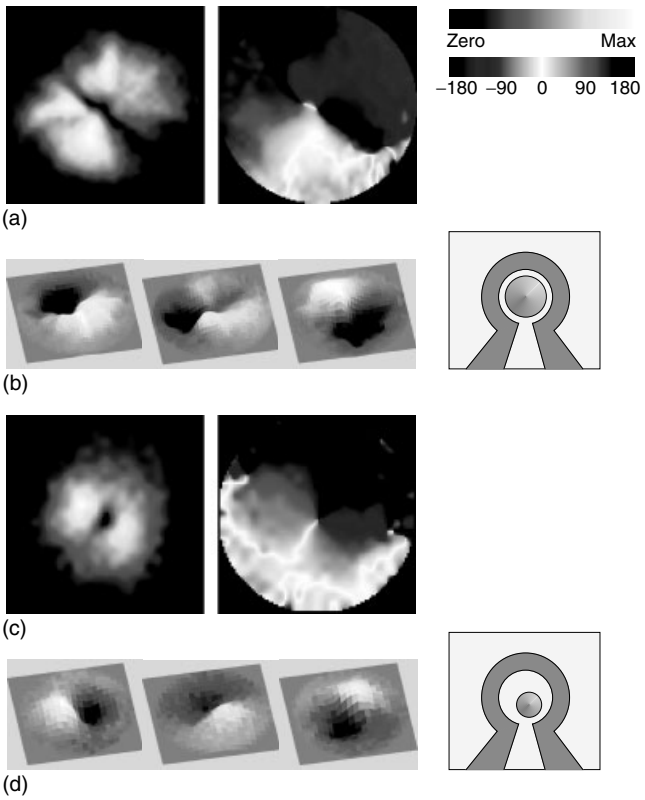

Figure 5. Single-node symmetric mode ($n = 1, m = 1$). (a) On the left the amplitude and on the right the phase of the mode from the 6 µm-diameter disk at 1.9 GHz are displayed. This corresponds to the sample show in the rightmost illustration. The mode consists of two regions divided by a node and oscillating with equal Fourier amplitude, but roughly opposite phase. Three images of the temporal evolution of this mode by back transformation are given in (b). Time interval between the middle (right) image and the left image: 120 (270) ps. (c) The single-node nonaxially symmetric mode in a 3 µm disk occurs at 2.8 GHz. The node is barely visible (left) and the phase (right) changes gradually along a trajectory surrounding the core center. Correspondingly, the temporal sequence obtained by back transformation – given in (d) after a time interval of 125 and 250 ps consists of a bright dark doublet rotating around the disk center. The respective illustration on the right indicates that the magnetic sample (bright) is off centered, which may explain the difference in the excitation of the two samples.

the axially symmetric modes $m = 0$ and negative dispersion (monotonically decreasing) for the modes with $m \neq 0$.

4.7 Negative dispersion

For the time being, we notice that the classification has revealed the surprising result of negative dispersion for the azimuthal quantization direction. The frequency of the two-node eigenmode (1,2) is lower than the one of the single-node eigenmode (1,1) which in turn is lower than the fundamental (1,0) mode. The energy and the frequency decrease as the number of nodes increase. Micromagnetic simulations (LLG; OOMMF) reproduce both values and sequence very accurately. In a simple view, one might consider the dynamic magnetostatic stray field produced by the precessing magnetization. When increasing the node number along the azimuthal direction this stray field and thus the total effective field is reduced, leading to decreasing frequency with increasing node number. This explanation works until the exchange interaction dominates and the frequency starts to increase again. Thus, the observed modes are analogous to magnetostatic backward volume modes which can show negative dispersion, albeit in a circular structure. A more detailed theory is presented in Section 4.9.

An important result is the existence of two distinct types of dynamical modes, one with positive dispersion and one with negative dispersion. Negative dispersion – the lowering of the frequency with increasing wave vector – is occasionally measured in light optics for negative index media (Pendry and Smith, 2004; Pendry and Smith, 2003), special photonics crystals (Parimi *et al*., 2004; Kosaka *et al*., 1998), and media with inverted population (Chiao, 1993). The references (Damon and Eshbach, 1960; Fletscher and Kittel, 1960; Sparks, 1970; Dillon, 1960; Gubbiotti *et al*., 2003; Park *et al*., 2002; Bayer *et al*., 2004; Demokritov *et al*., 2001; Kakazei *et al*., 2004; Perzlmaier *et al*., 2005) quoted here (the list is by no means exhaustive) indicate that this should be a quite general phenomenon, not limited to the geometry and size investigated in the present chapter, when the excitation spectrum is dominated by magnetostatic modes. As suggested by Fletcher and Kittel more than 40 years ago (Fletscher and Kittel, 1960), a possible way to qualitatively explain this phenomenon is to consider the magnetostatic energy associated with the excited modes. In Buess *et al*. (2005), it is shown that the magnetostatic energy, which Fletcher and Kittel refer to, are the diagonal elements of our matrix. These diagonal elements are exactly the Coulomb energy of the effective magnetic charge $\frac{1}{r}\frac{\partial}{\partial r} r \psi_{n,m}(r, \varphi)$. They are also indicated in Figure 6 and are clearly quite close to the 'true' eigenfrequencies, confirming the qualitative suggestion by Fletcher and Kittel. The negative dispersion means that when the magnetic charge distribution is partitioned by introducing diametric nodes, the Coulomb energy (and thus the frequency) *decreases*.

4.8 Comparison with acoustic membranes

An analogy can be drawn with eigenmodes of acoustic membranes which resonate in such a way that adding a circular or a diametric node inevitably produces an increase of the vibrational frequency. Chladni's law for sound in a circular membrane (Rayleigh, 1945; Rossing, 1982) states

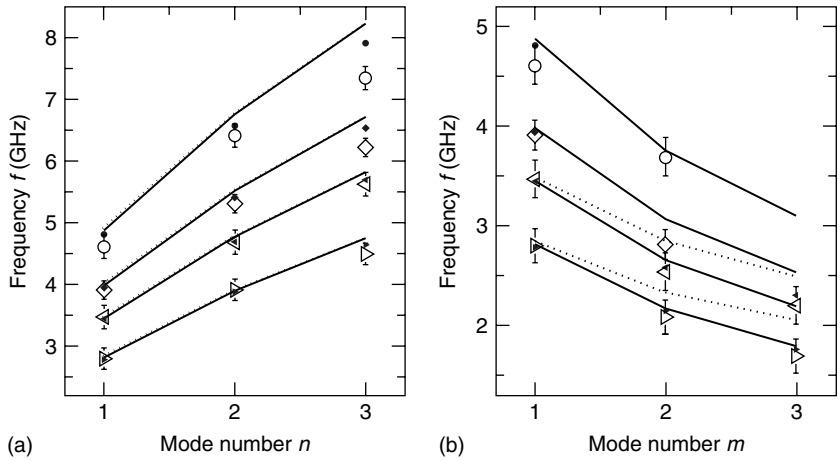

Figure 6. Dispersion relations. (a) The frequency for modes of the type $(n, m = 0)$ as a function of the radial mode number n: $R = 1\,\mu$m; ○, 1.5 µm; ⋄, 2 µm; △, 3 µm; ▽ are displayed as open symbols. The error bars are $\pm\frac{df}{2}$. (b) the frequency for modes of the type $(n = 1, m)$ as a function of the azimuthal mode number m. The corresponding data points of the micromagnetic simulation based on the LLG code LLG, are diagramed as full symbols. Results from the variational model as discussed in the Section 4.9 are represented as solid and the dotted lines. The dotted line is calculated by the diagonal elements and the solid line from the full matrix eigenvalues. (Reprinted with permission from M. Buess *et al*., *Phys. Rev. B*, **71**, 104415 (2005).)

that $f \propto (m + 2n)^2$. This phenomenon is a consequence of the positive dispersion of ordinary waves. It has been shown by imaging the modes and analyzing their corresponding frequencies in Section 4 that Chladni's law is violated by spin excitations in small circular ferromagnetic disks with a vortexlike ground-state configuration. This violation is due to the particular laws governing spin dynamics: in ordinary standing waves residing on a membrane, the change of frequency due to diametric modes is related to the matrix elements of the angular part of the Laplace operator, which scales with the square of the angular momentum, m^2. The relevant operator for spin systems contains the Coulomb interaction, which behaves quite differently with m, as discussed in the preceding text.

4.9 Advanced variational theory

We expand our analytical model from Section 3 to include modes containing diametric nodal lines in order to construct a more thorough theoretical model that also comprises the azimuthal dependence (φ) of the magnetization $\boldsymbol{m}(r, \varphi)$.

In the following text, we suggest a quantitative model that essentially accounts for all the experimental dispersion curves measured, including the lowering of the frequency f with m and the size dependence. We point out that for moderate field pulse excitations and large magnetic elements (e.g., several tens of microns) the highly degenerate excitation spectrum is dominated by magnetostatic modes (Tamaru *et al*., 2002). When the size of the elements is reduced or higher-order modes are excited, the exchange interactions can, in general, no longer be ignored and the dynamic response gradually changes from a purely magnetostatic to an exchange dominated one (Jorzick *et al*., 2002; Park *et al*., 2003; Demokritov *et al*., 2001).

As shown previously in Section 3 the relevant operator governing the dipolar modes is the dimensionless in-plane radial field given by $h_r[m_r]$. The eigenfrequencies of the various modes are related to the eigenvalues N_r of the equation $h_r[m_r] = -N_r m_r$ by the relation $\omega^2 = (\gamma M_s)^2 N_r$. These results were already used to calculate modes with circular nodal lines in a 6 µm Cobalt disk (Buess *et al*., 2003). Here, they are generalized to include modes with diametric nodes as well. The matrix $[h]_{nn',m} = \langle \psi_{n,m}, h_r \psi_{n',m} \rangle$ is evaluated within the trial space consisting of the orthonormal basis functions

$$\psi_{n,m} = \frac{1}{\sqrt{\pi} R\, J_2(x_{1n})} \mathrm{J}_1(k_n r)\, e^{im\varphi} \tag{18}$$

on the disk with radius R (Jackson, 1999). The variational approach comprises a mixing of several radial basis functions $\mathrm{J}_1(k_n r)$ by keeping the azimuthal dependence $e^{im\varphi}$ (the symmetry) fixed. Using a set of 15 basis functions $n, n' = 1, \ldots 15$ within each sector m was found to give good convergence. The details of this calculation are provided in (Buess *et al*., 2005). The $m = 0$ sector provides the eigenvalues for the modes with circular nodes. The $m = 1, 2, \ldots$ sectors provide the eigenvalues for modes with $1, 2, \ldots$ diametric nodes. The frequencies resulting from the matrix diagonalization are plotted as dotted lines in Figure 6. The agreement with the experimental data is remarkable, taking into account that the calculation is a fully analytical one with no

adjustable parameters. In particular, the negative dispersion for the modes with diametric nodes is also well reproduced.

4.10 Size dependence

The time evolution of individual micron-sized permalloy disks with vortex structure has been recorded at time intervals of 25–40 ps and the excitation spectrum has been extracted as described in the preceding text for each magnetic element. In this section, the size dependence of the modal frequencies is analyzed.

The frequencies f^* corresponding to the maxima of the resonance peaks are used for constructing the experimental dispersion curves in Figure 6. The corresponding frequency data (local FT) was used to identify the mode numbers (n, m) and to justify the peak positions f^* where the amplitude was weak (see average spectra in Figure 3). Figure 6 shows all obtained experimental and simulated mode frequencies for different sample sizes together with calculated values.

4.11 Scaling

Our analytical calculations (see equation 17 and (Buess *et al.*, 2005)) suggest a simple scaling law that should be obeyed by all modes, provided they are of magnetostatic origin: all frequencies for different radii should fall onto one single function when $f(n,m)\left(\frac{R}{d}\right)^{1/2}$ is plotted as a function of n at fixed m (radial modes) or m at fixed n (azimuthal modes), this function being only dependent on the number of diametric and circular nodes. The agreement is excellent (see Figure 6). The largest deviations from this scaling law are observed for small radii, where the exchange interaction is expected to become more important. We recall that the frequency depends only on a symmetry function $s(n,m)$ and the aspect ratio of the disk ($f \sim \sqrt{\frac{d}{R}}\, s(n,m)$) for both kind of modes. This is quite a universal behavior for these idealized magnetostatic thin-film vortex structures. The symmetry function reads

$$s(n,m) = \frac{\gamma_0 M_\mathrm{s}}{2\pi}\left(N_{n,m}\right)^{1/2} \tag{19}$$

and uses the eigenvalues of $N^{(15)}_{n,m} = -\{\mathrm{spec}([h]^{(15)}_{\tilde{n}\tilde{n}',m})\}_n$ in (Buess *et al.*, 2005).

4.12 Variational eigenmodes

In Section 4.9 and (Buess *et al.*, 2005) the demagnetizing factors N_r have been calculated by a variational theory where the matrix representation of the radial dipolar operator $\hat{h}_\mathrm{r}$ has been calculated for a given basis system. To each $m = 0, 1, 2\ldots$ belongs a 15×15 matrix $[h]_{nn',m}$ with

$$[h]_{nn',m} = \left\langle \psi_{n,m}, \hat{h}_\mathrm{r}\, \psi_{n',m} \right\rangle \tag{20}$$

The diagonalized matrix $[d] = [s^{-1}][h][s]$ provides the eigenvalues $-N_\mathrm{r}^\mathrm{eig}(n,m)$ and with $(2\pi f)^2 = (\gamma_0 M_\mathrm{s})^2 N_\mathrm{r}$ we obtain the solid lines in Figures 6 and 7. In addition, the transformation matrix $[s]$ contains the coordinates of the optimized eigenfunctions that belong to the eigenvalues. Consequently, we have not only obtained the demagnetizing factors and the resulting frequencies but also an optimized radial part for the eigenmodes. The most striking fact is that the difference between the shape of the basis functions and the optimized functions increases for higher m. This is in correspondence with the deviations of the frequencies in Figure 7 (dotted and solid lines).

To compare the radial dependence of the experimental data with the results of the theory, the frequency domain data (Figure 4) is displayed as line scans of the FT amplitude as a function of distance to the disk center. Figure 9(a) shows this for the experimental data of the 6 µm-diameter disk and Figure 9(b) for a micromagnetic simulation (see Section 5). The FT amplitudes of the modes $(n,m) = (1,1)$, (1,0), (2,0), (3,0) are normalized to unity and plotted. In general, the agreement with the simulation and the theory (Figure 9) is good. It can be seen that the shape of the (1,1) mode differs from the one of the (1,0) mode. The more simple approach (diagonal values of $[h]_{nn',m}$) use the same radial functions J_1 for both modes, but when the optimized radial parts (belonging to the eigenvalues of $[h]_{nn',m}$) are compared

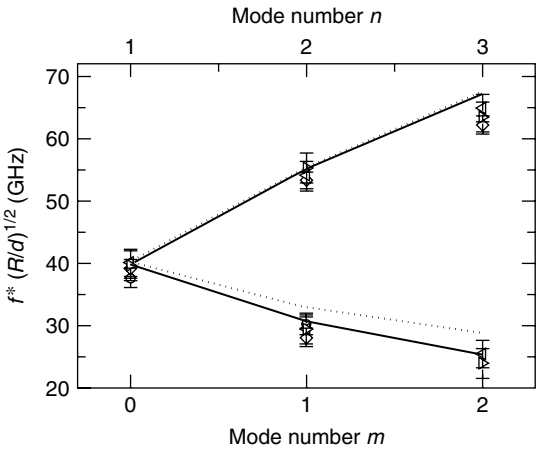

Figure 7. Scaling. When $f(n,m)\left(\frac{R}{d}\right)^{1/2} \doteq \tilde{f}$ is plotted versus m at fixed n or versus n at fixed m, all data points for different radii fall onto one single dispersion curve $\tilde{f}(m)$ and $\tilde{f}(n)$. The symbol and line attributes are the same as in Figure 6. (Reprinted with permission from M. Buess *et al.*, *Phys. Rev. B*, **71**, 104415 (2005).)

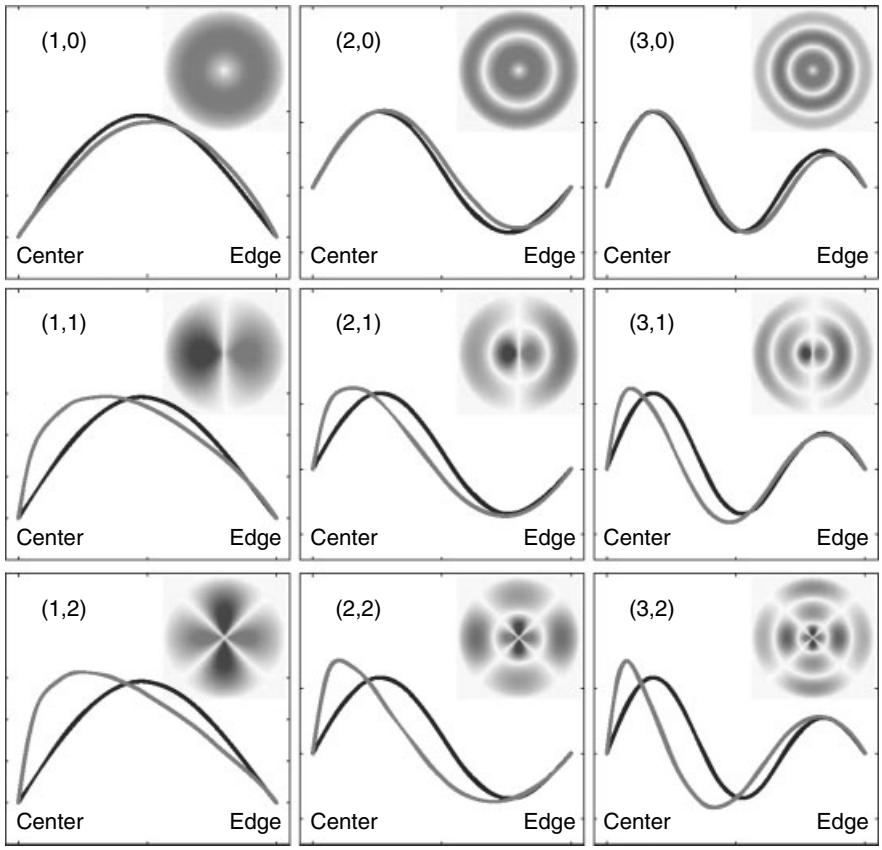

Figure 8. Optimized variational radial parts eigenfunctions (gray lines) compared to Bessel J_1 basis functions (black). For increasing azimuthal mode number m the optimized functions consistently are shifted towards the disk center. The insets show the spatial distribution of M_r amplitude at maximal excursion. The dynamical motion of $\boldsymbol{M}$ forms an elliptical trajectory. Except for ($n = 1$, $m = 0$) the amplitude has regions of both positive and negative sign.

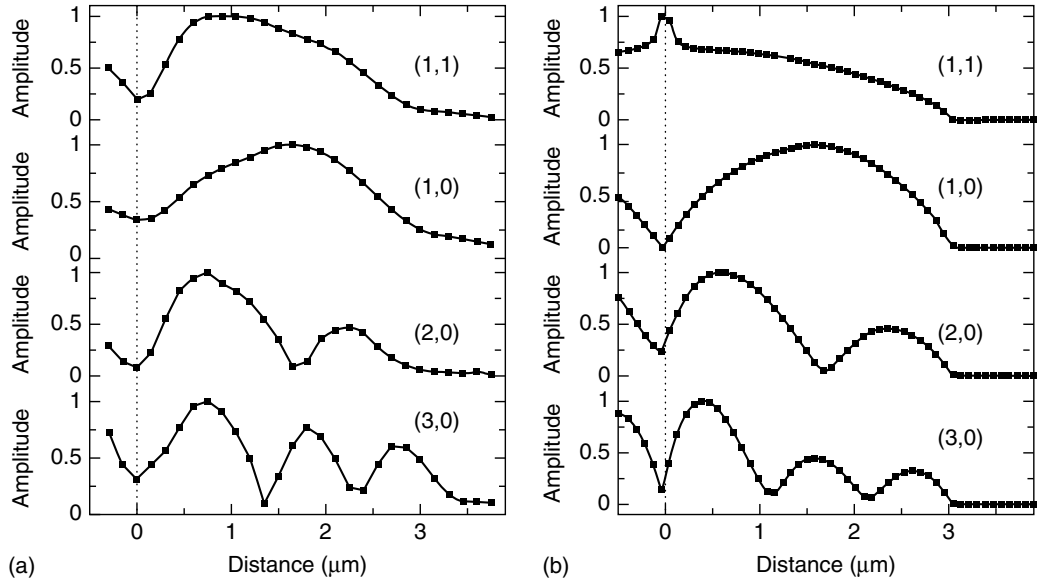

Figure 9. In (a) the FT amplitude for line scans through the center of the disk is extracted from the experimental data for the 6-μm-diameter disk for different modes labeled by (m,n). (b) shows the corresponding data for the micromagnetic simulation.

with the data, they clearly show the same trend: the amplitude is shifted toward the center for $m > 0$.

The curve from the micromagnetic simulation for the mode (1,1) deviates clearly from the experimental one. The reasons are the following: Theoretical considerations ((Ivanov and Zaspel, 2005; Zivieri and Nizzoli, 2005) and references therein) and some experimental data show that the azimuthal mode consists of two modes: one is traveling clockwise and the other anticlockwise around the center. With a real vortex core pointing out of the axis of the film, the frequencies of the two modes are slightly different. The effect grows for smaller disks and its analysis is beyond the scope of this chapter. In fact one of the two modes has high and the other a low amplitude in the center. Note, the limited resolution in the experiment of 300 nm.

4.13 Motion of the vortex core

We now proceed to the motion of the well-defined, circular element seen in some of the images of Figure 2 to reside in the vicinity of the center of the disk. From line scans across the image, this circular element appears as a clear peak (see insets in the bottom part of Figure 10) with a width of the order of the spatial resolution. The location of its maximum can be determined with an accuracy of about 0.2 µm and is seen to move with time (Figure 10a). Furthermore, its z-magnetization is oscillating with time (Figure 10b, circles). Most strikingly, at some times, the 'core' assumes negative M_z values, that is, it is oppositely magnetized with respect to the immediate surroundings (Figure 10b, triangles). Notice that the eigenmodes in this dipolar dominated regime are expected to have zero amplitude at the center of the disk (see Section 3). Thus, we do not have an immediate explanation for the negative M_z magnetization at the center, except that it indicates 'core' switching at some instances. In the ground state, the core of perpendicular magnetization extends over some 10 nm (Shinjo *et al*., 2000; Raabe *et al*., 2000; Wachowiak *et al*., 2002). As our experiment measures deviations from the ground state, the initial state is contrastless but a core dynamics would give rise to a contrast in the M_z component. However, our experiment collects the signal within a spot of 300 nm diameter, and it is not obvious that we can indeed observe the much smaller core. On the other side, our experiment is sensitive to minute ($<2^\circ$) deviations from the ground state. Thus, a reversal of the core magnetization would result in a 30 times stronger Kerr signal and would appear as a strong contrast even with our 'poor' spatial resolution. Notice that our micromagnetic simulations, which include the excitation of nonradially symmetric modes by a nonuniform pulse, appear to reveal this most remarkable process as well. The presence of eigenmodes breaking the axial symmetry of the ground state is thought to be essential for the operation of core switching (Gaididei *et al*., 2003). In fact, we have observed that the central region of the vortex changes its sign with time, suggesting that core switching have taken place.

A more detailed understanding of the generation of azimuthal modes may lead to a concept for controlled ultrafast switching of the vortex core.

5 MICROMAGNETIC SIMULATIONS

In principle, micromagnetic computer simulations solve the Landau–Lifshitz–Gilbert equations (e.g., in the form of equation 21) for each cell of a two- or three-dimensional grid. The effective fields comprise all required interactions acting on the individual cells that also depend on the magnetization $\boldsymbol{M}(r', t)$ of the other cells.

To support our data two different programs were used: LLG (LLG) and OOMMF (OOMMF). The LLG micromagnetics simulator is a three-dimensional simulation tool that integrates the Landau–Lifshitz–Gilbert (LLG) equations. Sample geometries and material parameters, temporally and spatially varying parameters like external fields can be set. The revolution in computer technology has enabled enough calculational power to achieve the relevant cell sizes and time steps for realistic results. There are many publications (Park *et al*., 2002; Hiebert *et al*., 1997; Buess *et al*., 2004) that demonstrate the excellent predictive abilities of the LLG equations of motion in the picosecond time regime for describing magnetization dynamics. The advantage of employing micromagnetic simulations is that all global or position-dependent parameters of the modeled system can be set and the magnetization and energies can be monitored. Unwanted artifacts of the experiment (noise, deviations from ideal system, resolution etc.) are not present. Comparison of the experiment with simulations can justify the proposed bottom lines or yield new results.

Figure 11 is an overview of results for a 4-µm-sized circular platelet with of 15-nm thickness. For the micromagnetic simulation, the sample was divided into $10.6\,\text{nm} \times 10.6\,\text{nm} \times 15.0\,\text{nm}$ pixels in a 375×375 array. The saturation magnetization, exchange stiffness, gyromagnetic frequency, and damping constant are $860\,\text{kA m}^{-1}$ ($860\,\text{emu cm}^3$), $13{\cdot}10^{-12}\,\text{J m}^{-1}$ ($1.3\,\text{micro-erg cm}^{-1}$), $176\,\text{GHz T}^{-1}$ ($17.6\,\text{MHz Oe}^{-1}$), and 0.008, respectively. The equations of motion were integrated in 0.4 ps steps from $t = 0$ to $t = 20$ ns. The data were stored for the entire array and for the average value of each magnetization component. The black line with squares in Figure 11 is the amplitude spectrum of the M_z component averaged over the disk region $S_{\text{ft av}}$. FT was performed by taking the first 6.2 ns of the data and using a Hamming windowing filter. The

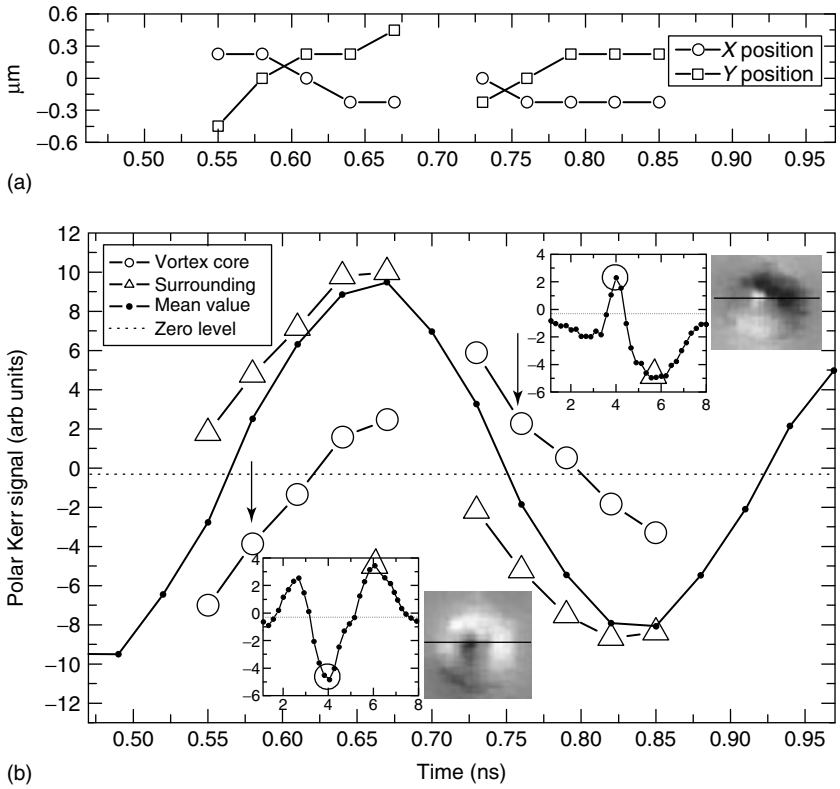

Figure 10. The core region. (a): Plot of the coordinates of the central part with respect to the geometrical image center ($X = 0, Y = 0$), in units of µm. (b): The continuous line indicates the average signal over the disk, and provides us with a check of the zero line (dotted), obtained from the nonmagnetic surroundings. The triangles give the strength of the magnetization surrounding the core, as derived from line scans of the images of the type indicated. The circles give the strength of the magnetization in the core region, which can be seen to become negative and positive. The signal also deviates systematically from the zero line expected for axially symmetric dipolar modes. The data from the line scans shown are marked with arrows. (Reprinted with permission from M. Buess *et al.*, *Phys. Rev. Lett.*, **93**, 077201 (2004).)

fundamental mode (1,1) is dominant and the higher radial modes (2,1), (3,1) . . . are clearly visible. A broad peak is visible below the fundamental mode that is composed of the azimuthal modes $m = 1, 2, 4$ belonging to order $n = 1$. The corresponding local FT modal images (amplitude and phase) are displayed for all peak positions and allow the classification of radial and azimuthal numbers (n,m).

In addition to the average amplitude spectra $S_{\mathrm{ft\ av}} = \mathrm{abs}(\mathrm{FT}(\mathrm{av}(data)))$ where the data was spatially averaged before FT, we can also consider the spatial averaging *after* FT $S_{\mathrm{av\ ft}} = \mathrm{av}(\mathrm{abs}(\mathrm{FT}(data)))$. This is most effective for modes that have regions of different sign because $S_{\mathrm{ft\ av}}$ is compensated fully or partially, though $S_{\mathrm{ft\ av}}$ shows a clear peak. Generally $0 \leq S_{\mathrm{ft\ av}} \leq S_{\mathrm{av\ ft}}$. The dark gray line with circles in Figure 12 is the spatially averaged data after FT $S_{\mathrm{av\ ft}}$.

Notice that $S_{\mathrm{ft\ av}}$ and $S_{\mathrm{av\ ft}}$ are identical for the fundamental modes, as the phase is uniform over the disk in contrast to the other modes. In particular, three modes in the broad low-frequency part are resolved. Moreover, additional modes (n,1) – which show a change of sign across the central line – appear just between the radially symmetric modes (n,0) and ($n - 1$,0).

In summary, we have studied the excitation spectrum of simple magnetic vortex-state structures with high accuracy and have identified several eigenmodes of the system. The spatial distribution and the frequency of the measured eigenmodes can be accounted for by a linear model based purely on dipolar interactions. Micromagnetic simulations show excellent agreement with our experimental findings. The argument developed in the preceding text shows that introducing spatial nodes does not necessarily mean that the frequency increases as expected not only for a large class of phenomena, such as ordinary waves, but also for quantum-mechanical systems, like the hydrogen atom or the harmonic oscillator. In smaller magnetic disks, the exchange interaction should become more important, and it is expected to change the sign of the dispersion (Fletscher and Kittel, 1960) for

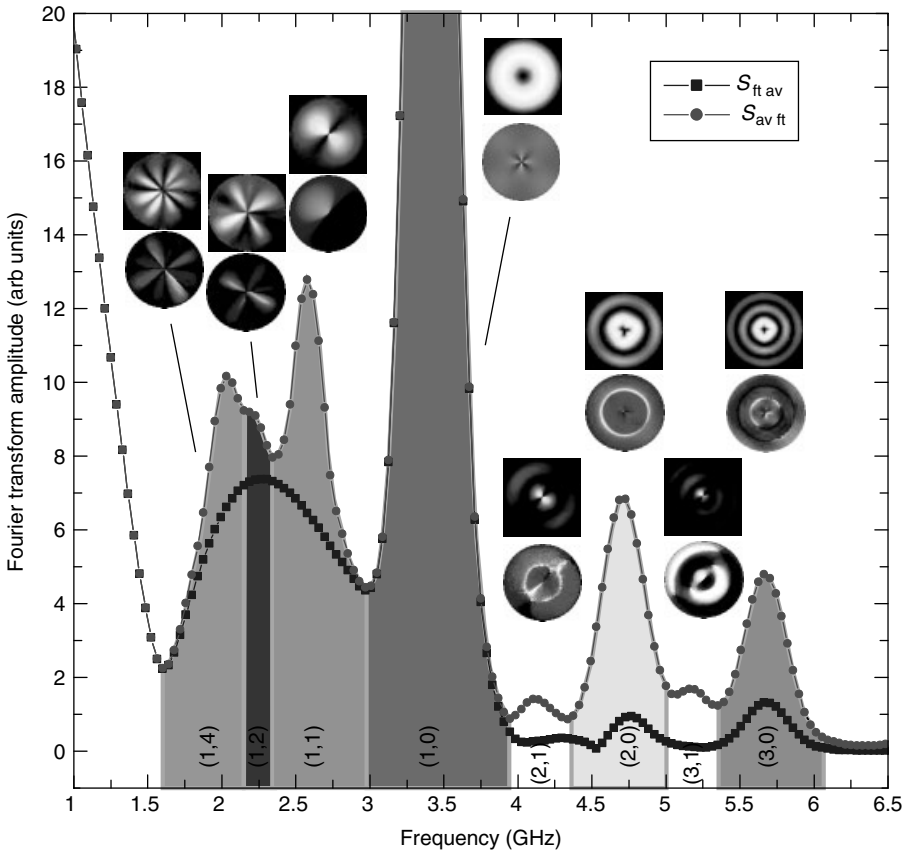

Figure 11. Overview of data obtained by a micromagnetic simulation.

higher m. We can envisage the realization of a new type of junction between elements having opposite dispersion, in analogy to the boundary between left-handed and right-handed photonic crystals (Pendry and Smith, 2004; Pendry and Smith, 2003).

Recall that a spatial asymmetry in the field pulse is needed in order to obtain modes with lower-than-radial symmetry. The low-frequency azimuthal peak in the average amplitude spectra should not be visible at all if the modes had perfect symmetry $e^{im\varphi}$. However, the asymmetry introduced by the field pulse slightly shapes the modes resulting in a nonzero amplitude for these frequencies. The next section uses this data and focuses on the temporal evolution of the modes and compares with the results on the experimental data of the 4 µm platelet.

6 MICROMAGNETIC DISSIPATION, DISPERSION, AND MODE CONVERSION

In the preceding sections of this chapter, the first term of the LLG equation (21), the precessional motion, was investigated by a series of time-resolved Kerr measurements of thin permalloy circular platelets. The focus was on the frequency and the spatial distribution of Fourier amplitude and phase of the observed eigenmodes.

$$\frac{\partial \boldsymbol{M}}{\partial t} = \gamma \boldsymbol{M} \times \frac{\delta \mathcal{E}[\boldsymbol{M}]}{\delta \boldsymbol{M}(\boldsymbol{r})} + \frac{\alpha}{M} \boldsymbol{M} \times \frac{\partial \boldsymbol{M}}{\partial t} \tag{21}$$

In contrast, the succeeding part deals with the second term of equation (21) that accounts for the energy dissipation, an empirical term added to account for the tendency of the system to turn toward an equilibrium state.

6.1 Earlier work

In the precessional regime, optical (Hiebert *et al.*, 1997; Acremann *et al.*, 2000; Buess *et al.*, 2004; Barman *et al.*, 2003; Park *et al.*, 2002) and soft X-ray (Choe *et al.*, 2004; Stoll *et al.*, 2004) pump-probe experiments were employed to examine magnetization dynamics excited by short magnetic field pulses, typically triggered by a laser pulse. Time-dependent measurements are nearly ideal for determining the modal frequencies, the mode structure (Buess *et al.*, 2004;

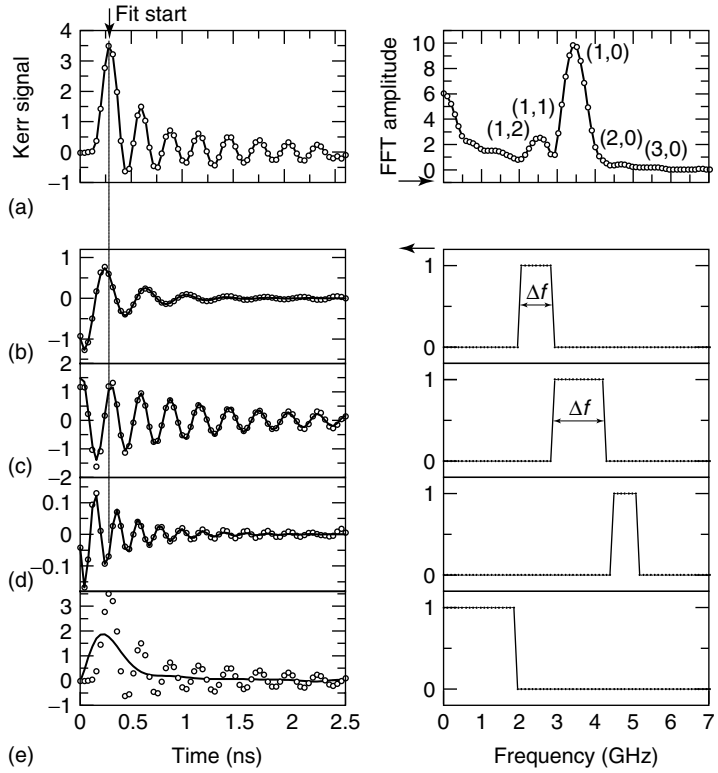

Figure 12. Fourier filtering: Experimental data. (a) shows the average perpendicular magnetization component on the left and its Fourier transform on the right. (b)–(d) By applying the filters on the right before back transformation into the time domain, the temporal evolution (circles) for different modes can be extracted. The solid lines show the fits with $M_i(t) = \sin(2\pi f_i t + \varphi_i)\exp(-t/\tau_i)$ (see text). Δf is the width of the filter. (e) The low-frequency parts up to 2 GHz belong to the transient response on the pulse. (Reprinted with permission from Buess *et al*., *Phys. Rev. Lett.*, **94**, 127205 (2005).)

Hiebert *et al*., 1997; Park *et al*., 2002) and the phenomenological damping parameter (Hiebert *et al*., 2003; Back *et al*., 1999; Tudosa *et al*., 2004; Barman *et al*., 2003) which can be directly compared to measurements using ferromagnetic resonance (FMR) (Celinski and Heinrich, 1991; Ebels *et al*., 2002). When measurements of the damping parameter extracted from quasilinear time-domain measurements do not agree with FMR measurements (Back *et al*., 1999; Tudosa *et al*., 2004; Dobin and Victora, 2004), explanations typically invoke sample and field inhomogeneities (Dobin and Victora, 2004; Belov *et al*., 2004) and higher-order magnon scattering.

In order to probe damping mechanisms typical of the intrinsically nonlinear LLG regime, the modes excited in micron scale permalloy circular platelets presented in the previous sections are examined. Micron-sized disks are ideal systems to study mode excitation, mode conversion, and damping since the small size of the disks provides many well-defined excitations (Buess *et al*., 2004; Gubbiotti *et al*., 2003; Guslienko and Slavin, 2000; Buess *et al*., 2005) within the frequency range easily characterized by stroboscopic time-resolved scanning Kerr microscopy – typically 0–10 GHz (Hiebert *et al*., 1997; Acremann *et al*., 2000; Buess *et al*., 2004; Barman *et al*., 2003; Park *et al*., 2002).

6.2 Eigenmodes of the system

The spin-wave spectrum described in the previous sections was obtained by the resonances of the averaged spectrum and the frequency domain analysis of time sequenced images. Here, we examine mode dispersion and energy channeling between modes which lead to an apparent increase in damping for certain modes.

Our experimental analysis is performed based on the data of a single 4-μm-diameter, 15 nm thick, permalloy disk exhibiting a vortex ground state. Following excitation using a perpendicular magnetic tipping pulse, polar Kerr data are recorded at 40 ps intervals. These data are images encompassing a field of view of 6.5 μm square. A typical trace of the polar Kerr signal as a function of time averaged over the whole element is shown in Figure 12(a) (left frame). Its FT is shown in Figure 12(a) (right frame), and the observed peaks are used to identify the modes. The excited modes

are labeled (*n*,*m*) as in the preceding text; *n* counts the number of axially symmetric nodes and *m* counts the number of azimuthal nodes. We identify the fundamental ((1,0), 3.5 GHz), the second ((2,0), 4.7 GHz), and the third ((3,0), 5.6 GHz) radial modes possessing zero, one, and two additional radial nodes, respectively. We can also identify the dipolar ((1,1), 2.5 GHz) and quadrupolar ((1,2), 2.2 GHZ) azimuthal modes which possess one and two nodes along the equilibrium direction of $\boldsymbol{M}$, respectively. The higher-order azimuthal modes decrease in energy for $m = 0$, 1, 2, consistent with backward volume mode excitations where the $\boldsymbol{k}$-vector is parallel to the magnetization $\boldsymbol{M}$ (Damon and Eshbach, 1960; Buess *et al*., 2004; Buess *et al*., 2005), whereas for the radial modes the opposite is true; $\boldsymbol{k}$ is perpendicular to $\boldsymbol{M}$. The Fourier spectrum does not consist of discrete sharp peaks at the modal frequencies, but of peaks with a finite width (up to 0.7 GHz FWHM). We previously identified these excitations as eigenmodes based upon the linearized LLG equation and the scalar magnetic potential in Section 4.9. The peaks observed in the frequency spectrum as well as those computed from the full LLG equations are not delta functions in frequency due to the presence of dispersion, suggesting that perhaps our earlier terminology might have been misleading. Owing to the finite sampling length and the resulting need of windowing, simple analysis in the frequency domain is not sufficient to illuminate the decay rates and mode conversion. The entire (dispersed) peak contains information about the time evolution of a given mode.

6.3 Linearized equation of motion including damping

We will recall briefly the relevant equations for the precession frequency for this geometry and a decay constant based on a linear, single-α approach: $M_\mathrm{r} = M_\mathrm{s} m_\mathrm{r}$; $M_\varphi = M_\mathrm{s}(1 - O(m_\varphi^2))$; $M_\mathrm{z} = M_\mathrm{s} m_\mathrm{z}$ where m_r and m_z are the direction cosines of the magnetization perturbations, and, $m_\mathrm{r} \ll 1$ and $m_\mathrm{z} \ll 1$. We consider thin micron-sized disks with a ground-state circulating flux-closure configuration ($m_\mathrm{r} = 0$, $m_\varphi = 1, m_\mathrm{z} = 0$), subject to the linearized Landau–Lifshitz–Gilbert equation:

$$\begin{aligned} \dot{m}_\mathrm{r} &= \gamma_0 m_\mathrm{z} N_\mathrm{z} M_\mathrm{s} + \alpha \dot{m}_\mathrm{z} \\ \dot{m}_\mathrm{z} &= -\gamma_0 m_\mathrm{r} N_\mathrm{r} M_\mathrm{s} - \alpha\, \dot{m}_\mathrm{r} \end{aligned} \tag{22}$$

Here, M_s is the saturation magnetization, γ_0 is the absolute value of the gyromagnetic ratio multiplied by μ_0. $N_\mathrm{z} = 1$ is the demagnetizing factor for thin film shape and N_r is defined for a given mode, as defined in Sections 3 and 4.9. N_r is proportional to the averaged effective field for that mode. Inserting oscillatory solutions $\sim e^{i\omega t}$ leads to the result for the decay time τ and the precession frequency f:

$$\tau = \frac{2(1+\alpha^2)}{\alpha\gamma_0 M_\mathrm{s}(N_\mathrm{r} + N_\mathrm{z})} \tag{23}$$

$$2\pi f \cong \gamma_0 M_\mathrm{s} \sqrt{\frac{N_\mathrm{r} N_\mathrm{z}}{(1+\alpha^2)}} \tag{24}$$

With $N_\mathrm{z} = 1$ and in the limit $\alpha \ll 1$ we obtain $\tau = \frac{2}{\alpha\gamma_0 M_\mathrm{s}(N_\mathrm{r}+1)}$ and $2\pi f = \gamma_0 M_\mathrm{s} N_\mathrm{r}^{\frac{1}{2}}$. Thus to evaluate our experimental data, we need to extract the experimental frequencies f and the decay times τ.

6.4 Fourier filtering

In our implementation, the spatially averaged Kerr signal $K(t)$ is used to compute the complex Fourier spectra $S(f)$ as

$$S(f_n) = \frac{1}{N} \sum_{m=1}^{N-1} K(t_m) H(t_m) e^{-2\pi i m n/N} \tag{25}$$

where N is the number of data points of the temporal signal which when acquired over a fixed time interval Δt determines the maximum Fourier frequency in the spectrum and the resolution in the frequency domain and $H(t)$ is the Hamming window function. Windowing is used to reduce the artifacts from the finite sampling length. It is better to extract the damping parameter in the time domain as shown in Figure 14 rather than from the width of the transformed peak, in contrast to FMR, where the time signals are essentially of infinite duration.

We can now back-transform a modal peak after applying a band-pass filter $F(f)$ to the Fourier spectra $S(f)$ since the data are ordered in frequency and the modes are obviously well separated. To compare with the original temporal data, the inverse FT has to be normalized by $H(t)$ in the time domain as

$$M_k(t_m) = \frac{1}{H(t_m)} \Re \sum_{n=1}^{N-1} S(f_n) F_k(f_n)\, e^{2\pi i m n/N} \tag{26}$$

allowing different modal components $M_k(t)$ of $K(t)$ in the time domain to be analyzed. If modal damping were to obey an exponential decay, an effective decay time, τ for each mode can be defined.

6.5 Time-dependent Fourier transform

An alternative method to the Fourier filtering (FF) described in the last section is presented here. Time-dependent Fourier transform (TDF) aims at displaying time and frequency information in the same two-dimensional plot. This is achieved by analyzing only a small section of the time-domain data, a window of length t_{win}. This window is shifted over the whole data and as a function of time displacement Δt, slice by slice of a two-dimensional spectrum is generated by FT. The result is a map of the Fourier amplitude (or phase) as a function of frequency and time displacement Δt. The principle is well known and used for signal processing of audio signals (this is also what a spectrum analyzer of a hi-fi system does: it produces a momentary spectrum of the amplitude of different frequency bands).

TDF should therefore be useful for analyzing the evolution of different frequency components (eigenmodes) in the data of excited ferromagnetic permalloy platelets. It can be described by a formula which is very similar to equation (25):

$$S(f_n, \Delta t) = \frac{1}{N} \sum_{m=1}^{N-1} K(t_m) \tilde{H}_{t_{\text{win}}}(t_m - \Delta t)\, e^{-2\pi i m n/N} \quad (27)$$

For the window function $\tilde{H}_{t_{\text{win}}}$ a Hanning window of length t_{win} is used ($\tilde{H}_{t_{\text{win}}}(t) = 0$ for $t \leq 0$ or $t \geq t_{\text{win}}$). Hence, the FT of $K(t)$ is merely applied in the range $\Delta t \leq t \leq \Delta t + t_{\text{win}}$. The parameter t_{win} is very critical: by construction of S, the frequency resolution is determined by the length t_{win} of the examined signal as $\Delta f = 1/t_{\text{win}}$. In addition, a value $S(f_n, \Delta t)$ corresponds to a range t_{win} within the time domain and therefore determines the time resolution t_{win} of $S(f_n, \Delta t)$. Obviously there is a trade-off between frequency and temporal resolution. The higher the frequency resolution, the smaller the temporal resolution and vice versa. This is important for interpreting the spectra. Figure 13 shows this method applied to the averaged M_z data of the micromagnetic simulation. A window length t_{win} of 2.8 ns was used for the data of 20 ns total length. The Fourier amplitude $S(f_n, \Delta t)$ is plotted on a logarithmic scale. Notice that the amplitude changes by 12 orders of magnitude. The amplitude of the modal peaks above 3 ns drops exponentially and shows an almost perfect linear fit in Figure 13(c). The decay times have been evaluated as $\tau_{(1,0)} = 1.30$ ns, $\tau_{(2,0)} = 1.29$ ns and $\tau_{(3,0)} = 1.30$ ns with errors 0.01 ns. These values are discussed in the subsequent text.

What about the azimuthal modes visible in the spectra of Figure 5 at a frequency below 3 ns? This peak decays much faster and the evaluated decay time is of the order of the time resolution $\Delta t = 0.36$ ns, therefore limited by the TDF window length t_{win}. When t_{win} is decreased, the modes are no longer separated well by the reduced frequency resolution. However, the time evolution of these modes can be analyzed with the FF method as described in the next section. This shows that the TDF method is complementary to FF: a different aspect is that it does not matter for TDF that the higher radial modes are 3 orders of magnitude smaller in amplitude than the fundamental one. The peaks are well separated in frequency and there is no mixing of different frequency components. However, in FF, the small amplitude of the *higher* modes leads to bigger errors for these modes. Hence TDF is used for the evaluation of the radial modes only when we have analysed the whole spectrum with (FF) as shown in the next section.

6.6 Results and discussion

Figure 12(a) shows the averaged Kerr data $K(t)$ (left) and its Fourier transform amplitude $S(f)$ (right). The right side of Figure 12(b)–(e) show the filters $F(f)_k$ used in equation (2) to obtain the modes (1,0), (2,0), the azimuthal mode and the low-frequency residuals corresponding to the modal magnetization curves $M_k(t)$ (left), respectively. Fits to our data using an exponentially decaying sine function (solid lines in Figure 12(b)–(e), left frame) lead to the decay times $\tau_{\text{exp}}^{\text{fit}}$ displayed in Table 1. For the nonradially symmetric azimuthal modes, there are some peculiarities: from the frequency domain data, the peak positions for the (1,1)- and (1,2)-modes are known and a superposition of these modes is seen in the Fourier spectrum from 2 to 2.8 GHz; this is referred to as the *azimuthal peak*. Note that the amplitude of the two components is determined by the spatial and temporal shape of the field pulse. The resulting value obtained by mode filtering and damped-oscillation fit is displayed as $\tau_{\text{exp}}^{\text{fit}}$. This demonstrates the significant result that the symmetry breaking azimuthal modes ($\tau_{\text{azim}} = 0.37$ ns) decay three times faster than the fundamental mode ($\tau_{(1,0)} = 1.1$ ns) for windows whose widths $\Delta f/f_0$ are as good as constant (0.31 versus 0.37 for the azimuthal and fundamental peak, respectively). This is a surprising result, because the calculated $\tau_{\alpha=0.008}^{\text{calc}}$ for all modes is constant within the experimental errors, as the decay constant depends weakly on N_r in $N_z + N_r = 1 + N_r \cong 1$ [3]. Thus, additional mode damping due to energy transfer or mode conversion must occur. Furthermore, despite the large error bar, we observed a significant difference for the decay of the modes (1,0) and (2,0). It is fortuitous to note that the higher radial modes have very small amplitude. Consequently, the decay times of the filtered signals have bigger error for the modes (2,0). The decay time for the mode (3,0) cannot be determined accurately. The error bar was obtained by analyzing the resulting

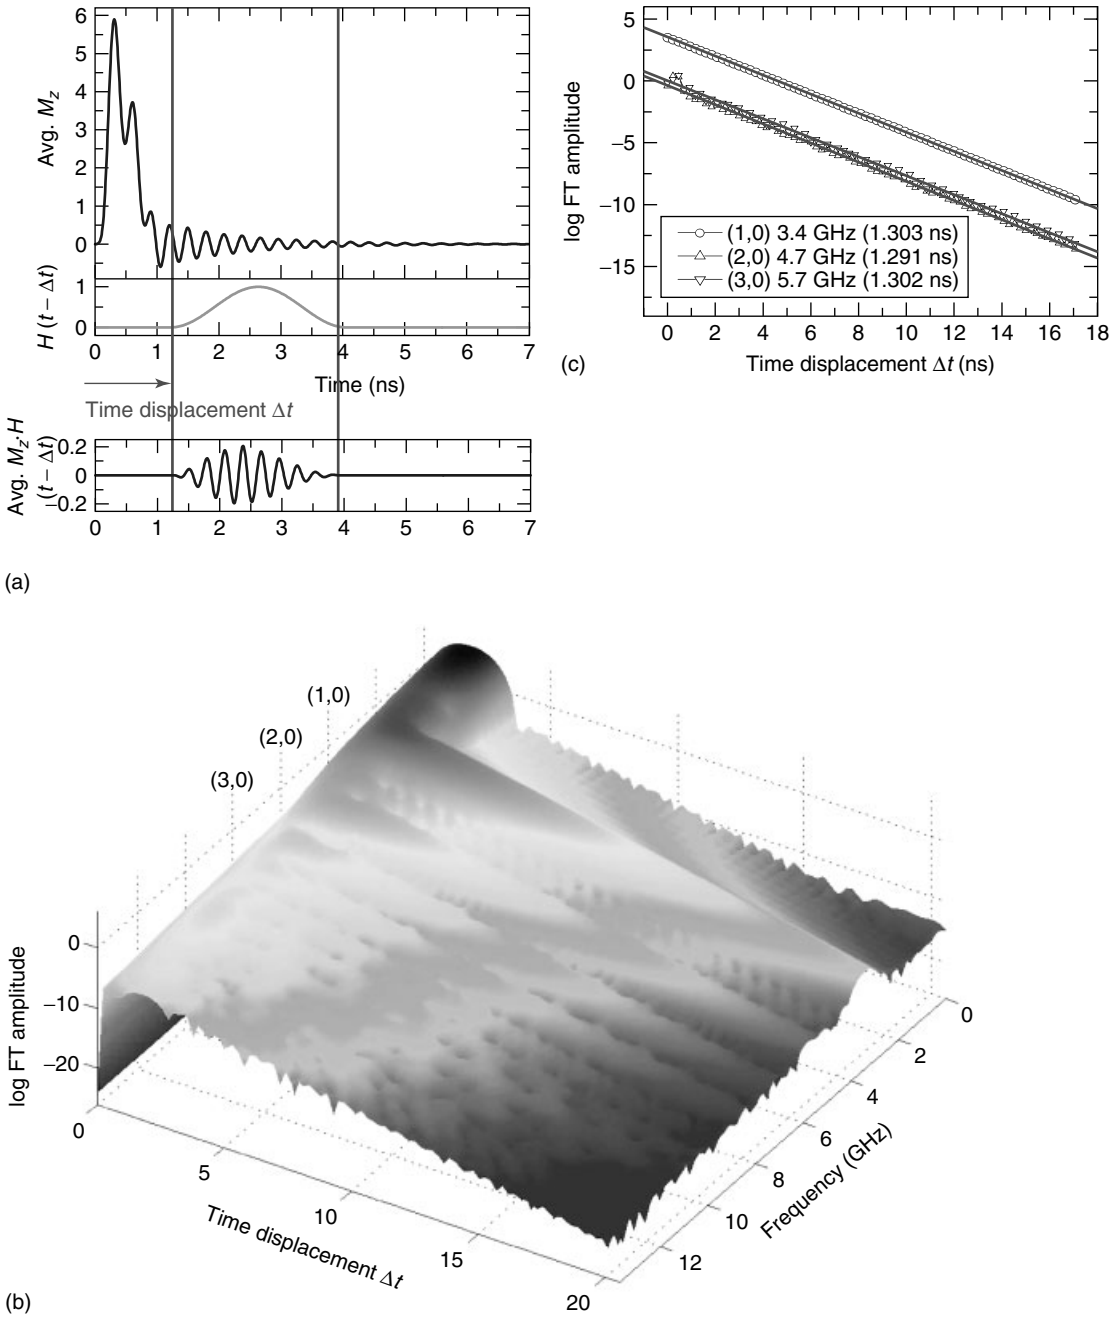

Figure 13. Time-dependent Fourier transform for the 4 µm data of the micromagnetic simulation (see Section 5). (a) Illustration of time-dependent windowing. The spatially averaged M_z is multiplied by the window function H with time displacement Δt before Fourier transformation. (b) The Fourier amplitude as a function of frequency and time displacement Δt is displayed on a logarithmic scale. (c) The time evolution of the modes is analyzed by plotting the amplitude at peak position of the first three radial modes. The decay times of the exponentially decaying values are evaluated as 1.30, 1.29, and 1.30 ns.

decay time by varying the parameters of the filtering process. Unfortunately, experimentally, we cannot separate the effect of the damping of each independent mode from energy that is coupled (nonlinearly) between the modes. However, there are many publications (Buess *et al*., 2004; Park *et al*., 2002; Hiebert *et al*., 1997) that demonstrate the excellent predictive abilities of the LLG equations of motion in the picosecond time regime for describing magnetization dynamics. The advantage of employing micromagnetic simulations is that energies can be monitored and global or position-dependent

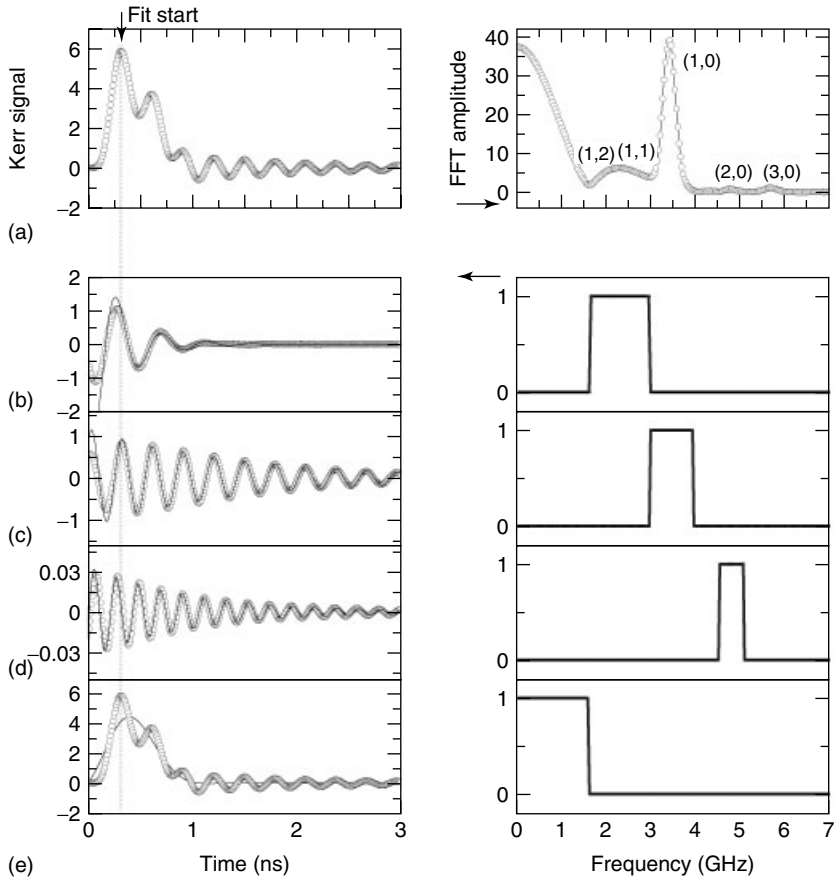

Figure 14. Fourier filtering: Micromagnetic simulation. The same modes are extracted from the computed average M_z component as in Figure 1. The good qualitative agreement with the simulation supports the findings in Figure 1. (Reprinted with permission from M. Buess *et al.*, *Phys. Rev. Lett.*, **94**, 127205 (2005).)

Table 1. Compilation of all relevant parameters for each of the eigenmodes (m,n). The peak frequencies f_{exp} and f_{sim} are obtained from the absolute-FT spectra of the 4-μm disk data and from the micromagnetic simulation, respectively. $N_{\mathrm{r,sim}}$ is calculated from f_{sim} and leads to the values $\tau^{\mathrm{calc}}_{\alpha=0.008}$ (see text). The decay times $\tau^{\mathrm{fit}}_{\mathrm{exp}}$ and $\tau^{\mathrm{fit}}_{\mathrm{sim}}$ are derived by the Fourier filtering (FF) method presented in this section. The decay times $\tau^{\mathrm{TDF}}_{\mathrm{sim}}$ are obtained by Time-dependent Fourier transform (TDF).

parameters can be set. We have reproduced the details of the modal structure including the nonradially symmetric modal response for excitations in circular platelets of permalloy. Shown in Figure 14(a) are the computed LLG (LLG) averaged M_z data (left) and its Fourier amplitude $S(f)$ (right). Figures 14(b)–(d) show the filters $F(f)_k$ used in equation (2) (right frame) to obtain the modes (1,0), (2,0) and the azimuthal modes peak, corresponding to the modal magnetization curves $M_k(t)$ (left frame), respectively. At first glance one observes that in Figure 14 the position of the resonances

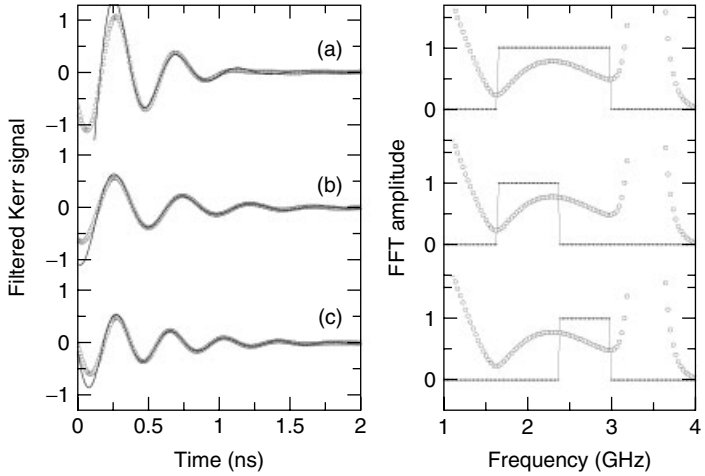

Figure 15. Fourier filtering: Azimuthal mode separation. Detailed analysis of the azimuthal peak in Figure 14(b). The left side shows the filtered signals (circles) with fit (solid), and on the right the filters (circles) and FT of the original curve (solid). We find that the decay time for the whole peak in (a) (0.31 ns) is composed of the two components (b) and (c) with 0.44 and 0.45 ns.

as well as their relative strength is very similar to the data in Figure 12. We also observe that the decay times of the individual modes show the same trend as in Figure 12: fits to our data (see Table 1) demonstrate good agreement in the decay times with the experimental values. Also included in the table are the $N_{\mathrm{r,sim}}$ calculated by equation (24) from the values f_{sim} and the resulting $\tau^{\mathrm{calc}}_{\alpha=0.008}$ by equation (23). Again, the symmetry breaking azimuthal modes decay much faster than the fundamental mode. Finally, in the simulation it was possible to separate the azimuthal peak into the two modes. For this purpose, the average amplitude over the local FT of the magnetic movie was used to determine the separation frequency of 2.35 GHz between the two modes. In Figure 15 the two different filtered and back-transformed components are displayed. The resulting τ^{fit} of 0.44 and 0.45 ns are corrected values and are 45% bigger than the decay time for the total azimuthal peak. However, it quantifies the effect of increased decay rate by superposition of the two overlapping peaks. This is still quite a small correction when compared to the longer decay times of the radial modes. And again we see the same trend on the modes (2,0) and (3,0) as in the experiment, which differ from the calculated values $\tau^{\mathrm{calc}}_{\alpha=0.008}$ (equation 23) only within the uncertainty. Since the LLG simulations use a single phenomenological damping parameter we can immediately rule out different damping of one mode over another as the cause for the extra observed damping in the low-frequency modes. Rather, we can see that since energy is conserved and the global energy loss is governed by α, that mode–mode coupling must channel energy from the low-frequency modes toward the higher frequency modes. Scattering must be consistent with solutions to the nonlinear wave equation and energy conservation (i.e., scattering to higher frequency modes must also reduce the amplitude if the scattering is in one direction in k space).

We conclude that we have presented a method to extract the decay rates for different modes from a single average precession component. For the low-frequency modes we find an increased damping whose possible origin lies in mode conversion. For the radial modes, we find a behavior as expected from the linearized LLG equation. These two important features are closely reproduced in the micromagnetic simulation where the phenomenological Gilbert damping model is implemented with a single α. This demonstrates that for confined single-material ferromagnetic structures no additional theory of dissipation is necessary for exact reproduction of such intricate experimental results: The single α straightforward LLG is all that is required to understand and explain the physics. These measurements are the first clear demonstration that mode–mode coupling plays a significant role in magnetization dynamics, and the data demonstrate how mode conversion could be construed as damping.

NOTES

[1] For modes smaller than 1 μm and higher mode numbers, the stronger effect of exchange interaction leads to deviations between theory and micromagnetic simulation.

[2] Of course, magnetic fields are, strictly speaking, only singular at boundaries in the two-dimensional limit which we have adopted here. In practice, boundaries have a finite thickness and although the fields might become large they remain finite at two-dimensional surfaces. In the present case, $H_{\mathrm{r}}\,|_{z=0,r\to R-\to}\,-2\pi M_{\mathrm{r}}(R)$).

[3] In principle, the sum of the demagnetizing factors adds up to exactly one. However, in our approximation we directly set $N_z = 1$ for a thin-film disk and calculate N_r.

1 INTRODUCTION

The concept of small-amplitude, lowest-lying dynamic eigenmodes of magnetic media called *spin waves* was introduced by Bloch (1930). Early experimental evidence for the existence of spin waves came from measurements of thermodynamic properties, but the first direct observation was made through ferromagnetic resonance (FMR) (Griffiths, 1946) and then through light scattering (Fleury, Porto, Cheesmman and Guggenheim, 1966). In the quantum-mechanical approach the spin-wave quanta (magnons) are similar to the quanta of light (photons) or those of acoustic waves (phonons).

Spin waves provide the basis for describing the spatial and temporal evolution of the magnetization distribution in a magnetic sample under the general assumption that locally the length of the magnetization vector is constant. The length of the magnetization vector is conserved, if, first, the system is in a thermodynamic equilibrium described by a temperature far below the Curie temperature and, second, if no topological anomalies, like vortices, are present. The latter is fulfilled for samples in a single-domain state, that is, samples that are magnetized to saturation by an external applied magnetic field. Then the dynamics of the magnetization vector is described by the Landau–Lifshitz torque equation (Landau and Lifshitz, 1935)

$$\frac{\mathrm{d}\vec{M}}{\mathrm{d}t} = -|\gamma|\vec{M} \times \vec{H}_{\mathrm{eff}} \tag{1}$$

where $\vec{M} = \vec{M}_0 + \vec{m}(\vec{r}, t)$ is the total magnetization, $\vec{M}_0$ and $\vec{m}(\vec{r}, t)$ are the vectors of saturation and variable magnetization, correspondingly, $|\gamma|$ is the modulus of the gyromagnetic ratio for the electron spin ($|\gamma|/2\pi = 2.8\,\mathrm{MHz\,Oe^{-1}}$), and $\vec{H}_{\mathrm{eff}} = -\delta W/\delta\vec{M}$ is the effective magnetic field calculated as a variational derivative of the energy function W, where all the relevant interactions in the magnetic substance have been taken into account (see, e.g., Lvov, 1994; Wigen, 1994; Cottam, 1994). If the amplitude of the variable magnetization $\vec{m}(\vec{r}, t)$ is small compared to the saturation magnetization $\vec{M}_0$, that is, if the angle of magnetization precession is small, one can develop a solution for the variable magnetization in a series of plane waves of magnetization (having a

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*. ISBN: 978-0-470-02217-7.

three-dimensional wave vector $\vec{k}$) or spin waves,

$$\vec{m}(\vec{r}, t) = \sum_k \vec{m}_k(t) \exp(i\vec{k}\vec{r}) \tag{2}$$

Thus, spin waves can be obtained as a solution of equation (1), if the nonlinearity is neglected. Theoretical estimations and experiment show that it can be done if the mean amplitude of the precession is less than 1°.

However, both $\vec{M}$ and $\vec{H}_{\text{eff}}$ are time dependent, and since one has the product of these quantities on the right-hand side of equation (1), this equation is intrinsically nonlinear. This nonlinearity should be taken into account if higher values of the angle of magnetization precession are allowed. From the quantum-mechanic point of view, the nonlinearity describes the interaction between the magnons.

Depending on the particular properties of the described phenomena, the interaction can be either attractive or repulsive. In the framework of a crude but very useful approximation, the nonlinearity can be taken into account by considering the properties of spin waves that are dependent on their amplitude, as is shown in the following sections.

There are several methods of spin-wave excitation in magnetic films. First, spin waves of the frequency ω_k can be excited linearly ($\omega_k = \omega_s$) by a microwave magnetic field of a strip-line antenna when an input microwave electromagnetic signal of the frequency ω_s is supplied to the antenna. A strip-line antenna of the width w and aperture (or length) l can effectively excite spin waves having the wave number component in the direction perpendicular to the antenna aperture in the interval $0 < k < 2\pi/w$, while the range of propagation directions (or the interval of the wave number components parallel to the antenna aperture) is determined by the antenna length l. The magnitude of the wave number of the linearly excited spin wave is determined by the frequency of the input electromagnetic signal ω_s and by the spin-wave dispersion relation $\omega_k(k)$ in a magnetic film.

Second, pairs of contrapropagating spin waves can be excited (or amplified) parametrically by a weakly localized electromagnetic pumping (effective wave number of the pumping $k_p \simeq 0$) having frequency ω_p twice as large as the frequency of the excited spin waves. This process obeys the conservation laws $\omega_p = 2\omega_k$, $k_p \simeq 0 = \mathbf{k} + (-\mathbf{k})$. The magnitude of the wave number of the excited spin-wave pair is determined by the k dependence of the threshold of parametric excitation in a magnetic film (see chapter 10 of Gurevich and Melkov (1996) for details). If a spin-wave packet with a definite carrier wave number k is excited linearly by a strip-line antenna and experiences parametric interaction with the microwave field of double-frequency pumping, this wave packet is amplified and a contrapropagating wave packet with a carrier wave number $-k$ is parametrically excited. This situation is discussed in detail in Section 5.

Third, recently, it has been discovered theoretically (Slonczewski, 1996; Berger, 1996; Slonczewski, 1999) and confirmed experimentally (Tsoi *et al.*, 1998; Kiselev *et al.*, 2003) that there is yet another method of spin-wave excitation in metallic magnetic films due to transfer of the angular momentum of spin-polarized charge carriers. This method of spin-wave excitation is very efficient and leads to very large amplitudes of the excited spin waves, and the nonlinear properties of spin waves play a very important role in this new excitation mechanism. The nature and properties of the spin-wave modes excited by spin-polarized current in metallic ferromagnetic films are discussed in the last section of this chapter.

Finally, very recently an optical approach for spin-wave excitation based on the spin–momentum transfer effect has been developed. It takes advantage of circularly polarized, short laser pulses. A direct transfer of the photon angular momentum to spins in solid states can be used for coherent excitation and absorption of spin waves with frequencies about 100 GHz (Kimel *et al.*, 2004; Hansteen, Kimel, Kirilyuk and Rasing, 2005).

Spin waves in magnetic samples comprise an excellent testing ground to study general properties of nonlinear waves. In many aspects, nonlinear phenomena in magnetic systems supporting spin waves are more easily accessible compared to nonlinear processes in, for example, optics or plasma physics.

First, the nonlinearity in magnetic systems is rather large compared to optical nonlinearities, and this makes the generation of nonlinear waves and wave packets rather easy in experiment. Second, spin waves with velocities in the range of a few kilometers per second are relatively slow compared to the electromagnetic waves in optics or plasma. Therefore, the observation of propagating waves puts less demand on the time resolution of the experimental setup. All these properties of spin waves in bulk magnetic samples were successfully used in early experiments on nonlinear spin-wave dynamics (see, e.g., Lvov, 1994).

Spin waves at microwave frequencies propagating in monocrystalline *ferrite films* and, in particular, in yttrium iron garnet ($Y_3Fe_5O_{12}$, YIG) films with very low losses, characterized by a very narrow FMR linewidth of $2\Delta H_K = 0.4$ Oe at 10 GHz, provide an especially good opportunity to study the general properties of nonlinear wave phenomena. An important advantage of ferrite films as a medium for experimental investigations of nonlinear wave dynamics is the fact that the wave process in the film is directly accessible from the surface for characterization by either inductive probes or magneto-optical methods. For example, using

the recently developed space- and time-resolved Brillouin light-scattering (BLS) technique in YIG films one can visualize and study linear and nonlinear processes involving slow waves (spin waves) by scattering fast waves (light) on slow waves as on a quasistationary diffraction grating. This experimental approach allows us to perform such unique experiments, as direct observation of wave tunneling through a potential barrier created by a local inhomogeneity in the bias magnetic field with the appropriate spatial and temporal resolution (Demokritov *et al*., 2004).

An additional advantage of ferrite films as a medium for experimental investigation of nonlinear waves is the fact that the nonlinear and dispersive characteristics of spin waves in ferrite films can be controlled by changing the magnitude and orientation of the bias magnetic field. Figure 1 shows a typology for different orientations between the in-plane wave vector $\vec{k}$ and the magnetization $\vec{M}_0$ (Damon and Eshbach, 1961). Three different geometries are shown. If $\vec{k}$ and $\vec{M}_0$ are both in the film plane and if $\vec{k}$ is perpendicular to $\vec{M}_0$, the so-called magnetostatic surface wave (MSSW) exists. If $\vec{k}$ and $\vec{M}_0$ are collinear in the film plane, a mode with negative dispersion, the so-called backward-volume magnetostatic spin-wave (BVMSW) mode exists with the group velocity antiparallel to the wave vector. Finally, if the magnetization is perpendicular to the film plane, the existing modes are the so-called forward-volume magnetostatic spin-wave (FVMSW) modes.

A wide variety of nonlinear wave phenomena, like parametric and kinetic instabilities of spin waves, auto-oscillations, chaotic dynamics, strange attractors, formation, propagation, and collision of 'bright' and 'dark' spin-wave envelope solitons, nonlinear diffraction, self-focusing of spin-wave packets, and tunneling of these packets through potential barriers can be observed in ferrite films at moderate input microwave power levels of less than 1 W (see, e.g., Wigen, 1994; Cottam, 1994; Büttner *et al*., 2000; Demokritov, Hillebrands and Slavin, 2001).

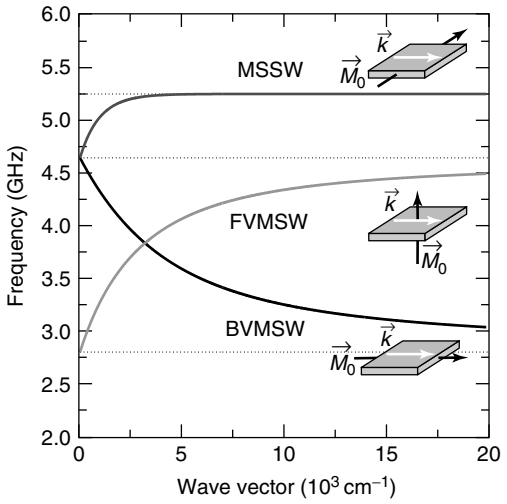

Figure 1. Typology of magnetostatic spin-wave modes for different directions of the magnetization, $\vec{M}_0$, and the in-plane wave vector, $\vec{k}$. MSSW: magnetostatic surface spin waves; FVMSW: forward-volume magnetostatic spin waves; BVMSW: backward-volume magnetostatic spin waves.

Here we present a review of the experimental investigations of nonlinear spin waves in magnetic films, performed using the novel magneto-optical method of space- and time-resolved BLS (Büttner *et al*., 2000).

The outline of the review is as follows. After this introduction (Section 1), in Section 2 we give a theoretical description of nonlinear spin-wave dynamics in magnetic films using the classical Hamiltonian formalism for spin waves in an unbounded ferromagnet (Lvov, 1994), in combination with the dipole-exchange theory of the spin-wave spectrum in magnetic films (see Slavin, 1994, and Chapter 2 in Cottam, 1994) and the elements of the spin-torque theory of spin-wave excitation (Slavin and Kabos, 2005).

Section 3 describes the space- and time-resolved BLS technique – an important tool for the investigation of magnetic dynamics – and compares it with the other techniques for experimental investigation of spin waves.

The following sections describe experiments on the excitation of nonlinear spin-wave modes in magnetic films performed by different experimental methods.

Section 4 is devoted to the experimental study of nonlinear spin-wave excitations generated by an external microwave signal. Here the advantages of the BLS experimental technique are clearly demonstrated by the observation of a two-dimensional counterpart of spin-wave envelope solitons – spin-wave bullets. It is interesting to note that formation of wave bullets was predicted in optics (Silberberg, 1990), but the first experimental observation of this effect has been reported for the system of spin waves using the BLS experimental technique (Bauer *et al*., 1998).

Section 5 describes the experimental study of nonlinear spin-wave excitations, either self-generated from noise in active rings containing ferrite-film delay line and external amplifier or parametrically generated or/and amplified by a weakly localized double-frequency microwave pumping. The experiments described in this section prove that one-dimensional spin-wave solitons and two-dimensional spin-wave bullets are the intrinsic nonlinear excitations of a finite-width spin-wave waveguide and an infinite in-plane magnetic film, respectively. The experiments also show that the combination of an active ring with parametric pumping allows us to observe novel nonlinear symmetry-breaking spin-wave excitations having a rather unusual Möbius topology.

Section 6 demonstrates that the general ideas about nonlinear spin waves formulated in the theoretical Section 2 and illustrated experimentally for spin waves in ferrite films in Sections 3–5 remain in force even in the case when spin-wave modes are excited by the spin torque created by spin-polarized direct current in a very thin magnetic film made of a ferromagnetic metal. It turns out that a large-amplitude, standing spin-wave mode excited by spin-polarized current in an in-plane magnetized metallic film is a two-dimensional standing spin-wave bullet, similar to the propagating spin-wave bullets studied in Sections 3–5.

The conclusions are given in Section 7.

2 THEORETICAL DESCRIPTION OF SPIN WAVES IN MAGNETIC FILMS

It this section we give a brief outline of the general theory of nonlinear spin waves in magnetic films. We consider both the situation when a spin wave or a spin-wave packet propagating in a dielectric ferromagnetic film is linearly excited by a microwave magnetic field $\vec{h}_{\rm s}(\vec{r},t)=\vec{h}_{\rm s}(\vec{r})\exp(i\omega_{\rm s}t)$ and then interacts parametrically with the double-frequency ($\omega_{\rm p}=2\omega_{\rm s}$) microwave pumping $\vec{h}_{\rm p}(\vec{r},t)=\vec{h}_{\rm p}(\vec{r})\exp(i\omega_{\rm p}t)$ (see Bagada, Melkov, Serga and Slavin, 1997; Melkov *et al*., 2000; Serga *et al*., 2005; Melkov *et al*., 2001), and the recently discovered effect of microwave spin-wave excitation in a metallic ferromagnetic film by a spin-polarized direct current traversing the film (Slavin and Kabos, 2005; Slavin and Tiberkevich, 2005).

To describe magnetization dynamics in the presence of a spin-polarized current, the equation of motion for the magnetization $\vec{M}$ in a magnetic film (equation (1)) can be written in the form that includes the spin-transfer torque $\vec{T}_I$ (Slonczewski, 1996; Berger, 1996; Slonczewski, 1999):

$$\frac{{\rm d}\vec{M}}{{\rm d}t}=-|\gamma|\vec{M}\times\vec{H}_{\rm eff}+\vec{T}_I \tag{3}$$

where $|\gamma|=g\mu_{\rm B}/\hbar$ is the modulus of the gyromagnetic ratio for the electron spin; g is the spectroscopic Lande factor; $\mu_{\rm B}=e\hbar/2m_e$ is the Bohr magneton; e and m_e are the modulus of the electron charge and the electron mass, respectively; and $\hbar=h/2\pi$, where h is the Planck constant.

The first term on the right-hand side of equation (3) represents the traditional torque, with $\vec{H}_{\rm eff}=-\delta W/\delta\vec{M}$ being the effective magnetic field in the magnetic film. The free energy W includes, first of all, the Zeeman energy of magnetization interaction with the external magnetic field $h_{\rm e}$, which consists of the external bias magnetic field $\vec{H}_{\rm e}$ and the microwave fields of the input signal $\vec{h}_{\rm s}$ and microwave pumping $\vec{h}_{\rm p}$. It also includes the energies of the dipole–dipole interaction, exchange interaction, and crystallographic anisotropy, together with the Zeeman energy of interaction with the inhomogeneous Oersted field $\vec{H}_{\rm I}(\vec{r})$ created by the spin-polarized current. The explicit expression for the energy W in a magnetic film of a finite thickness L is given in Slavin (1994); Wigen (1994). For simplicity, we will not consider anisotropy and interaction with the field $\vec{H}_{\rm I}(\vec{r})$, which have only a limited influence on the generation of the spin waves.

The second term on the right-hand side of equation (3)

$$\vec{T}_I=\frac{\alpha_I}{M}\vec{M}\times[\vec{M}\times\vec{p}] \tag{4}$$

represents the Slonczewski–Berger torque (Slonczewski, 1996; Berger, 1996; Slonczewski, 1999) of polarized current exerted on the magnetization $\vec{M}$ of the magnetic film, where $\vec{p}$ is a unit vector in the direction of spin polarization of the direct current traversing the magnetic film, while:

$$\alpha_I=\sigma S_{\rm c}J=\sigma I \tag{5}$$

is a linear function of the current density J and the area $S_{\rm c}$ of the contact or a linear function of the magnitude of spin-polarized current I. We would like to stress that the last term in equation (3) is nonconservative and depending on the direction (sign) of the current can contribute to either positive or negative magnetic dissipation in the magnetic film. The modulus of the quantity σ is defined in Slonczewski (1996) as

$$\sigma=\epsilon\frac{g\mu_{\rm B}}{2eMS_{\rm c}L} \tag{6}$$

where ϵ is the spin-polarization efficiency defined in Slonczewski (1996), μ_0 is the magnetic permeability of free space, and L is the magnetic film thickness.

We shall consider solution of equation (3) in the coordinate system where axis z is parallel to the direction of the static saturation magnetization $\vec{M}_0$ ($\vec{e}_z||\vec{M}_0$) in the magnetic film. We shall represent vectors $\vec{M}$ and $\vec{p}$ in equations (3) and (4) as sums of components perpendicular and parallel to the unit vector $\vec{e}_z$:

$$\vec{M}=\vec{m}_\perp+M_z\vec{e}_z;\quad \vec{m}_\perp=m_x\vec{e}_x+m_y\vec{e}_y;$$
$$M_z^2=M_0^2-|\vec{m}_\perp|^2 \tag{7}$$
$$\vec{p}=\vec{p}_\perp+p_z\vec{e}_z;\quad \vec{p}_\perp=p_x\vec{e}_x+p_y\vec{e}_y \tag{8}$$

To consider approximate dynamic solutions of equation (3) in the magnetic film we first find the equilibrium orientation θ of the internal bias magnetic field $\vec{H}$ (and the static magnetization $\vec{M}_0$) in this layer (relative to the plane of the layer) in the absence of current ($\alpha_I=0$) from the usual

electrodynamic boundary conditions for a single magnetic layer:

$$H_e \cos\theta_e = H\cos\theta;$$
$$H_e \sin\theta_e = (H + 4\pi M_z)\sin\theta \tag{9}$$

for given magnitude H_e and orientation θ_e of the external bias magnetic field.

In the following equation we also assume that $p_\perp \ll p_z$ and $m_\perp \ll M_z$. In this case, the expression for the spin-transfer torque equation (4) can be substantially simplified to give

$$\vec{T}_I = \frac{\alpha_I}{M}[\vec{M}(\vec{p}\vec{M}) - \vec{p}M^2] \cong \frac{\alpha_I}{M} p_z M_z \vec{m}_\perp - \alpha_I M \vec{p}_\perp \tag{10}$$

If $p_\perp \ll p_z$ the influence of the second term in equation (10) on the magnetization dynamics is not very significant. For large enough values of current, this term can change only the equilibrium orientation of $\vec{M}_0$, while the first term in equation (10) describes either negative or positive current-dependent dissipation, with sign depending on the current direction. Thus, when describing excitation of spin waves by spin-polarized current, we neglect the second term in equation (10) and write the expression for the spin-transfer torque $\vec{T}_I$ of equation (3) in the simple form

$$\vec{T}_I \cong \frac{\alpha_I}{M} p_z M_z \vec{m}_\perp \tag{11}$$

At first we shall consider a spatially uniform problem, that is, we will neglect spatial localization of the microwave field of parametric pumping and of the spin-polarized current. In this spatially uniform case, it is natural to represent the magnetization as a sum of plane waves propagating in the magnetic film:

$$\vec{m}_\perp(\vec{r}) = \sum \vec{m}_{k\perp} \exp(-i\vec{k}\vec{r}) \tag{12}$$

where $\vec{r}$ is the coordinate vector in the plane of the film and $\vec{k}$ is the wave vector of the excited spin-wave mode directed in the plane of the film at the angle φ to the projection of the bias magnetic field.

Using all these assumptions, we perform in the equation of motion equation (3) the usual series of Holstein–Primakoff and Bogolyubov transformations. First, we introduce the circularly polarized variables a_k:

$$m_k^+ = (m_k^-)^* = m_{kx} + i m_{ky}$$
$$= \sqrt{2|\gamma|M_0}\left(a_k - \frac{|\gamma|}{4M_0}\sum_{k_1,k_2} a_{k_1}^* a_{k_2} a_{k+k_1-k_2}\right) \tag{13}$$

$$M_z = M_0 - |\gamma| \sum_{k_1,k_2} a_{k_1}^* a_{k_2} \tag{14}$$

Next, we introduce the elliptically polarized dimensionless variables b_k :

$$a_k = \sqrt{\frac{M_0\omega_k}{|\gamma|A_k}}(u_k b_k + v_k b_{-k}^*) \tag{15}$$

(for details see Wigen (1994) p. 215–216). The coefficients of the last $u - v$ transformation for the case of spin waves in a magnetic film magnetized at an arbitrary internal angle θ have the form (Wigen, 1994)

$$u_k = \sqrt{\frac{A_k + \omega_k}{2\omega_k}},$$
$$v_k = \frac{B_k}{|B_k|}\sqrt{\frac{A_k - \omega_k}{2\omega_k}} \tag{16}$$

where

$$2A_k = 2\Omega_k + \omega_M \cos^2\theta + \omega_M P(kL)[1 - \cos^2\theta(1 + \cos^2\varphi)] \tag{17}$$

$$B_k = A_k - \Omega_k - \omega_M P(kL)\sin^2\varphi + i(\omega_M/2)P(kL)\sin\theta\sin 2\varphi \tag{18}$$

$$\omega_k^2 = A_k^2 - |B_k|^2 = \Omega_k[\Omega_k + \omega_M F(kL)] \tag{19}$$

$$\Omega_k = \omega_H + (2\gamma A/M_0)k^2 \tag{20}$$

$$F(kL) = (1 - P(kL)\cos^2\varphi)\cos^2\theta + P(kL) \times\left[\sin^2\theta + \frac{\omega_M}{\Omega_k}(1 - P(kL))\cos^2\theta\sin^2\varphi\right] \tag{21}$$

$$P(kL) = 1 - \frac{1 - \exp(-kL)}{kL} \tag{22}$$

where $\omega_M = |\gamma|M_z$, $\omega_H = |\gamma|H$, and H and θ are the magnitude and direction of the internal bias field $\vec{H}$, respectively, found from the boundary conditions (equation (9)), φ is the angle of wave propagation in the film plane; and A is the exchange constant.

In this chapter we will not discuss in detail the process of linear excitation of spin waves by the microwave magnetic field $\vec{h}_s(\vec{r}, t)$ of a strip-line antenna, which is extensively described in literature (see e.g., Chapter 5 in Stancil, 1993), and will only discuss either the spin waves that are excited by parametric pumping or spin-polarized direct current, or the waves propagating in a magnetic film sufficiently far from the input strip-line antenna.

The resulting equation for the amplitude of the spin wave written in the wave number space has the form:

$$\frac{\mathrm{d}b_k}{\mathrm{d}t} = -i\omega_k b_k - iV_{k,-k}h_\mathrm{p}b^*_{-k} - i\sum_{k+k_1=k_2+k_3} T_{k,k_1,k_2,k_3}b^*_{k_1} \times b_{k_2}b_{k_3} - \Gamma_k b_k + \sigma I\sum_{k_1}\frac{M_{k_1 z}}{M_0}b_{k-k_1} \tag{23}$$

where ω_k is the linear spin-wave frequency given by equation (19), $V_{k,-k}$ is the coupling coefficient between the parametrically excited contrapropagating spin waves b_k, b^*_{-k}, and the microwave pumping defined by equation (7) in Melkov *et al*. (2001), h_p is the amplitude of the quasiuniform parametric pumping field, T_{k,k_1,k_2,k_3} is the coefficient of four-wave interaction between spin waves defined in Lvov (1994), Slavin (1994), and Γ_k is the phenomenologically introduced dissipation parameter of spin waves. In the following text we shall consider several particular cases of the general equation (23).

First of all we shall consider excitation of the spin-wave mode in a very thin layer of a ferromagnetic metal by spin-torque $\vec{T}_I$ defined by equation (11). The spin-polarized direct current creating this torque is localized in the circular contact having the radius R_c in the film plane. This situation is realized in the recent experiments conducted by Kiselev *et al*. (2003, 2004); Rippard *et al*. (2004a,b). In these experiments, the thickness L of the magnetic film ("free" layer) is rather small, usually smaller than the exchange length $l_\mathrm{ex} = \sqrt{2A/M_0^2}$ in the ferromagnetic metal, while the in-plane radius of the current-carrying region (nanocontact), R_c, is substantially larger than both the layer thickness and the exchange length $R_\mathrm{c} > l_\mathrm{ex} > L$. In such a situation the nanocontact plays the role of an antenna and excites a spectrally narrow packet of spin waves localized near $\vec{k} = 0$ and having a spectral width in the k space of the order of $\Delta k \sim 2\pi/R_\mathrm{c} \ll 2\pi/L$. Although this wave packet can be considered spectrally narrow compared to the characteristic wave number $k_L \sim 2\pi/L$, the absolute values of spin-wave wave numbers in the packet $k \sim 2\pi/R_\mathrm{c}$ are sufficiently large, so the exchange interaction creates a dominant contribution to the spin-wave spectrum. At the same time, the in-plane anisotropy of the spin-wave spectrum, equation (19) caused by the dynamic dipole–dipole terms (of the order of $kL \sim L/R_\mathrm{c}$) could be ignored, and only the static demagnetization and exchange interaction should be taken into account in the spin-wave dispersion equation. This leads to the following simple approximate expression for the spin-wave dispersion law:

$$\omega_k = \omega_0 + Dk^2 \tag{24}$$

where $\omega_0^2 = \omega_H(\omega_H + \omega_M\cos^2\theta)$ is the spin-wave frequency and spin-wave dispersion $D = \partial^2\omega_k/\partial k^2 = (A/M_0)(\partial\omega_0/\partial H)$ calculated at $k = 0$. Since the excited packet of spin waves is spectrally narrow we can also replace the four-wave coupling coefficient T_{k,k_1,k_2,k_3} and the damping rate Γ_k in equation (23) by their values at $k = 0$: $N \equiv T_{0,0,0,0}$, $\Gamma = \Gamma_0$.

Using the above simplifications and performing the inverse Fourier transformation in equation (23) one derives the Ginzburg–Landau equation for the amplitude of the excited spin-wave mode in the coordinate space $b(\vec{r}, t) = \sum_{\vec{k}} b_k(t)\exp(i\vec{k}\vec{r})$:

$$\frac{\partial b}{\partial t} = -i[\omega_0 b - D\Delta b + N|b|^2 b] - \Gamma b + f(r/R_\mathrm{c})\sigma I b - f(r/R_\mathrm{c})\sigma I|b|^2 b \tag{25}$$

where r is the two-dimensional position vector in the film plane, Δ is radial part of the Laplace operator written in cylindrical coordinate system, and $f(r/R_\mathrm{c})$ is a dimensionless function that describes distribution of the current across the nanocontact area.

Second, we shall consider the case when a spectrally narrow ($\Delta k \ll k_0$) spin-wave packet is linearly excited by an external signal $\vec{h}_\mathrm{s}(\vec{r}, t)\exp(i\omega_\mathrm{s}t)$ created by a microwave pulse having the carrier frequency ω_s and the duration τ and supplied to a strip-line antenna of width w in a rather thick ferromagnetic film $w \geq L \gg l_\mathrm{ex}$. In this case the characteristic carrier wave number $k_0 \leq 2\pi/w$ of the excited spin-wave packet is determined by the carrier frequency ω_s of the input signal, while the spectral width Δk of the excited spin-wave packet is determined by the input pulse duration τ. In the case of a thick ferrite film, the contribution of the exchange interaction to the spin-wave dispersion could be ignored, and the spin-wave spectrum can be described by equation (19) with the exchange constant $A = 0$.

Using the spectral narrowness ($\Delta k \ll k_0$) of the spin-wave packet, we can again assume that the coupling and damping coefficients in equation (23) do not depend on k, $T_{k,k_1,k_2,k_3} \to N \equiv T_{k_0,k_0,k_0,k_0}$, $\Gamma_k \to \Gamma \equiv \Gamma_{k_0}$ and approximate the nonexchange spin-wave dispersion law equation (19) by its Taylor expansion near the point $\vec{k} = \vec{k}_0 = k_0\vec{z}$:

$$\omega_k = \omega_\mathrm{s} + v_\mathrm{g}\Delta k_z + \frac{1}{2}D\Delta k_z^2 + \frac{1}{2}S\Delta k_y^2 \tag{26}$$

where $v_\mathrm{g} = \partial\omega/\partial k_z|_{k_{0z}}$ is the group velocity, $D = \partial^2\omega/\partial k_z^2|_{k_{0z}}$ and $S = \partial^2\omega/\partial k_y^2|_{k_{0z}}$ are the dispersion and diffraction coefficients. For simplicity, we assumed that the central wave vector $\vec{k}_0$ lies along one of the 'principal directions' of the dispersion law (i.e., either parallel or perpendicular to

the direction of the in-plane bias magnetic field $\vec{H}$), so the cross term $\partial^2\omega/\partial k_z \partial k_y|_{k_{0z}}$ vanishes. It should be stressed that, in contrast with equation (24), the approximate dispersion equation (26) contains the term with group velocity (linear in Δk), because the Taylor expansion is performed near a nonzero central (or carrier) wave vector. Introducing a dimensionless slow-varying amplitude of the spin-wave packet envelope:

$$U(y,z,t) = \sum_{|\Delta\vec{k}|\ll k_0} b_{\vec{k}_0+\Delta\vec{k}}(t)\exp(i\Delta\vec{k}\vec{r} + i\omega_0 t) \qquad (27)$$

and performing the inverse Fourier transformation in equation (23), we can obtain the so-called (2+1)-dimensional nonlinear Schrödinger equation (NSE) for the spin-wave packet envelope U (see e.g., Lvov, 1994; Slavin, 1994):

$$i\left(\frac{\partial U}{\partial t} + v_g\frac{\partial U}{\partial z}\right) + \frac{1}{2}D\frac{\partial^2 U}{\partial z^2} + \frac{1}{2}S\frac{\partial^2 U}{\partial y^2} - N|U|^2U = -i\Gamma U \qquad (28)$$

The coefficients v_g, D, S, and N in equation (28) have been calculated for different directions of spin-wave propagation in Chapter 9 of Wigen (1994). A more rigorous calculation of the nonlinear coefficient N is reported in Wigen, 1994 using a classical Hamiltonian formalism for spin waves in magnetic films.

Finally, we shall consider the case when a spectrally narrow spin-wave packet, linearly excited by a strip-line antenna in a ferrite film and propagating far from the antenna, interacts with a quasiuniform magnetic field $\vec{h}_p$ of a double-frequency ($\omega_p = 2\omega_s$) microwave pumping. As a result of such parametric interaction, an additional idle spin-wave packet with opposite wave vectors $-\vec{k}_0 \pm \Delta\vec{k}$ will be generated, that is, in this case the spin waves are localized near two points $\pm\vec{k}_0$ of the k space. Therefore, one can introduce two slow-varying envelopes $U_{1,2}$ for the description of partial spin-wave packets:

$$U_{1,2}(y,z,t) = \sum_{|\Delta\vec{k}|\ll k_0} b_{\pm\vec{k}_0+\Delta\vec{k}}(t)\exp(i\Delta\vec{k}\vec{r} + i\omega_0 t) \qquad (29)$$

The inverse Fourier transformation of equation (23) gives the following system of equations for the spin-wave packet envelopes $U_{1,2}$:

$$i\left(\frac{\partial U_1}{\partial t} + v_g\frac{\partial U_1}{\partial z} + \omega_r U_1\right) + \frac{D}{2}\frac{\partial 2U_1}{\partial z2} + \frac{S}{2}\frac{\partial 2U_1}{\partial y2} - N\left(|U_1|^2 + 2|U_2|^2\right)U_1 = iVh_p(z,t)\,U_2^* \qquad (30)$$

$$-i\left(\frac{\partial U_2^*}{\partial t} - v_g\frac{\partial U_2^*}{\partial z} + \omega_r U_2^*\right) + \frac{D}{2}\frac{\partial^2 U_2^*}{\partial z2} + \frac{S}{2}\frac{\partial^2 U_2^*}{\partial y2} - N\left(|U_2|^2 + 2|U_1|^2\right)U_2^* = -iV^*\,h_p^*\,(z,t)\,U_1 \qquad (31)$$

where the coefficients of nonlinear self-modulation inside the packets $T_{k_0k_0,k_0k_0}$ and $T_{-k_0-k_0,-k_0-k_0}$, as well as the coefficient of nonlinear cross-modulation between the packets $T_{-k_0k_0,-k_0k_0}$ were assumed to be equal to each other $N = T_{k_0k_0,k_0k_0} = T_{-k_0-k_0,-k_0-k_0} = T_{-k_0k_0,-k_0k_0}$.

The system of equations (30) and (31) gives a good description of the process of interaction of two-dimensional nonlinear spin-wave packets propagating in a magnetic film with a quasiuniform microwave magnetic field h_p of a double-frequency parametric pumping.

3 EXPERIMENTAL TECHNIQUES FOR INVESTIGATION OF SPIN-WAVE EXCITATIONS

There are several experimental approaches for the investigation of linear and nonlinear spin-wave processes. The classical approach of microwave spectroscopy has the important advantage of its simplicity. The input microwave signal is supplied to the input antenna, which converts it in a spin-wave packet in the sample. After some propagation time, the packet is detected by the output antenna placed on the sample several millimeters apart from the input one. The characteristics of the output microwave signal (duration, delay time, shape, phase, frequency spectrum etc.) can then be measured and analyzed. The duration of the detected signal, for example, can be brought into connection with the length of the packet along its propagation direction. Using an additional antenna or an open resonator placed between the input and output antennae, one can manipulate the wave packets in the magnetic medium and study their amplification. The disadvantage of the described technique is lack of spatial resolution. One can study the wave packet only at the position of the output antenna. The propagation and development of the packet between the antennae, which is of particular importance for nonlinear phenomena, cannot be studied by means of this technique. Similar problems arise if one tries to investigate two-dimensional effects. Since the antenna integrates the detected signal over its length, important information about the transverse length of the packet is being lost. An inductive scanning probe based on a small wire loop sensitive to the magnetic field caused by the spin waves during their propagation (Vlannes, 1987) brought limited success. Recent attempts to overcome this drawback made Scott, Kostylev, Kalinikos and Patton (2005) raise a hope that the inductive probe approach

would establish a competitive technique for time- and space-resolved observation of spin-wave modes. Direct observation of spin precession is possible by optical probing using the magneto-optical Faraday or Kerr effects (Geisau, Netzelmann, Rezende and Pelzl, 1990; Hiebert, Stankiewicz and Freeman, 1997). By applying a stroboscopic technique, one can measure the time dependence of different components of the magnetization. However, since the measurements are performed in the time domain, the upper frequency limit of such techniques is 3–7 GHz (Perzlmaier *et al*., 2005).

BLS is an optical spectroscopic method for investigation of excitations with frequencies in the GHz regime. From the point of view of classical electrodynamics, the BLS process can be understood as follows: Owing to magneto-optical effects a moving phase grating is created in the medium by a spin wave; this grating propagates with the phase velocity of the spin wave. Light is Bragg-reflected from the phase grating with its frequency Doppler-shifted by the spin-wave frequency.

The quantum-mechanic understanding of the BLS process is illustrated in Figure 2. A photon of energy $\hbar\omega_I$ and momentum $\hbar\vec{q}_I$ interacts with the elementary quantum of spin waves $(\hbar\omega, \hbar\vec{q})$, which is the magnon. The scattered photon gains an increase in energy and momentum:

$$\hbar\omega_S = \hbar(\omega_I + \omega) \tag{32}$$

$$\hbar\vec{q}_S = \hbar(\vec{q}_I + \vec{q}) \tag{33}$$

if a magnon is absorbed as a result of the scattering process. From equation (33) it is evident, that the wave vector $\vec{q}_S - \vec{q}_I$, transferred in the scattering process, is equal to the wave vector $\vec{q}$ of the spin wave. It can be chosen in the experiment by variation of the scattering angle. If spin waves with wave vectors much smaller than the wave vector of the light are under investigation, the small-angle scattering geometry should be used. On the contrary, the backscattering geometry corresponds to the maximum transferred wave vector, $2|\vec{q}_I|$. A magnon can also be created by energy and momentum transfer from the photon, which in the scattered state has the energy $\hbar(\omega_I - \omega)$ and momentum $\hbar(\vec{q}_I - \vec{q})$. For finite temperatures ($T \gg \hbar\omega/k_B \approx 1K$) both processes have about the same probability.

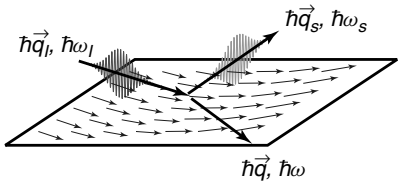

Figure 2. Brillouin light-scattering process from spin waves (magnons). The wave vectors of the incident and the scattered photons as well as that of the magnon are shown. The array of arrows schematically illustrates the orientation of magnetic moments in a spin wave.

However, since for a spin-wave mode propagating in a film the conservation conditions are fulfilled only for the two in-plane components of the wave vector, $\vec{q}_\parallel$. The third component perpendicular to the film, q_x, is not well defined by the conservation law because of a finite width of the film, which results in an essential uncertainty in the wave vector due to the uncertainty principle. Furthermore, if the excitation is not an infinitive plane wave, but a bound, localized state comprising many magnons (soliton or bullet; see the following sections), the in-plane components of the wave vector do not conserve as well. The uncertainty in q_x is, apparently, inversely proportional to the size of the excitation ξ, $\delta q_\parallel \approx 2\pi/\xi$. Thus, it should be taken into account, if $(\vec{q}_S - \vec{q}_I)_\parallel \xi \approx 2\pi$. This effect is of particular importance if excitations in nanocontacts are under investigation.

During the last decades, BLS has developed to a very versatile tool to investigate spin waves in magnetic films with the wave vector in the interval of $0–10^6\,\mathrm{cm}^{-1}$, both thermally driven and excited using an external source (Demokritov, Hillebrands and Slavin, 2001). The tandem Fabry–Pérot interferometer designed by Sandercock is currently widely used as a fairly standard solution (Sandercock, 1978) for the BLS studies. The frequency resolution of the technique of about 200 MHz is usually determined by the flatness of the mirrors of the interferometer, which should be of the highest quality, and their alignment. For example, a typical flatness of the mirrors over the diameter of 50–70 mm is specified as 25–30 nm. For the alignment, an active stabilization procedure continuously analyzing the shape and the measured frequency position of the reference laser beam is obligatory (Hillebrands, 1999). As a result of such a resolution, the detection of waves with frequencies below 1 GHz is questionable. The upper frequency limit of the waves accessible for the BLS technique is determined by the free spectral range of the interferometer, which can hardly be made above 300 GHz, since the distance between mirrors in this case should be below 0.5 mm.

The advantages of the BLS as a technique for investigation of spin waves are (i) high-frequency resolution in the GHz regime and the potential to investigate spin waves with different absolute values and orientations of their wave vectors; (ii) a wide dynamic range, that is, the possibility of detecting both low-amplitude thermal spin waves and high-amplitude spin waves, excited by an external source; and (iii) high spatial resolution defined by the size of the laser beam, which can be focused down to 300 nm in diameter (Perzlmaier *et al*., 2005).

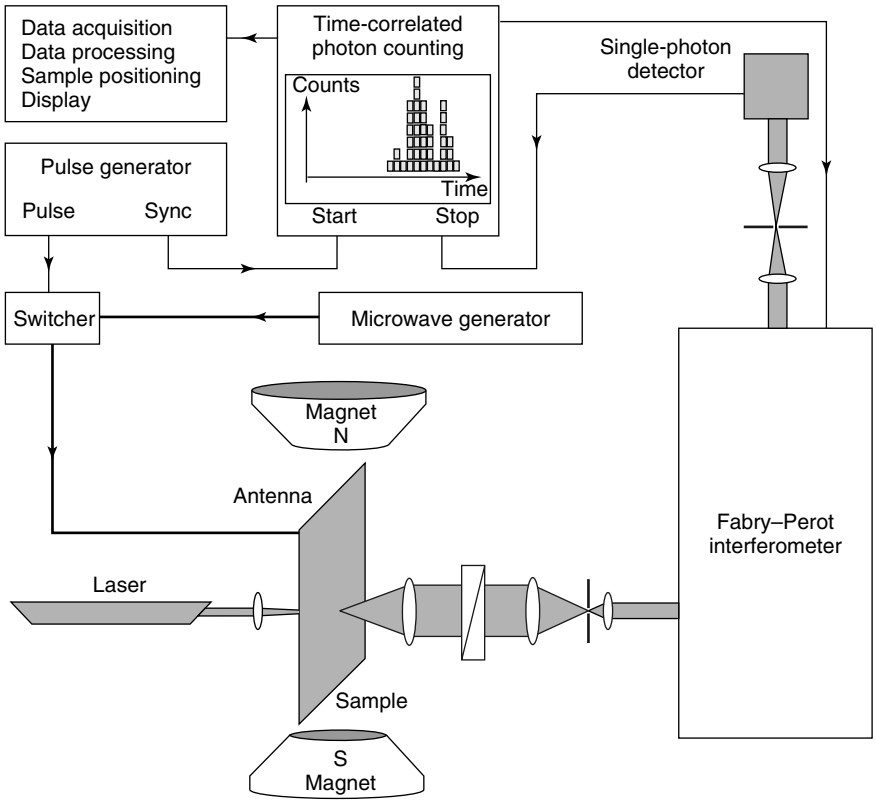

Figure 3. Schematic layout of the Brillouin light-scattering setup in the forward-scattering geometry with space and time resolution. (For a discussion of the components see the main text).

To investigate magnetic excitations simultaneously with spatial and temporal resolutions, an experimental technique based on a standard BLS setup has been developed. It is schematically shown in Figure 3. Similar to the microwave technique, spin waves are generated by an input antenna attached to the sample. The spatial distribution of the wave intensity is measured by scanning the laser beam across the sample, which is performed by a motorized sample mount. Spin waves are effectively excited in a wave vector interval $|\vec{q}| < 300\,\mathrm{rad/cm}$, with the upper bound imposed by the width of the antenna. Thus the light scattered into the forward direction is usually detected to achieve a high sensitivity in this low-wave-vector regime.

Temporal resolution is added by using a time-correlated single-photon counting method similar to time-of-flight measurements in, for example, mass spectroscopy. A pulse generator generates pulses of typically 10–30 ns duration with a repetition rate of typically 1 MHz. The pulse is sent to a microwave switching device to create a pulsed microwave field and to generate a spin-wave pulse. The same pulse is also used to start a 24-bit reference counter counting the output pulses of a 4 GHz time base. If the spin-wave pulse crosses the laser spot, light is inelastically scattered. The scattered light passes through the interferometer and is detected by a single-photon detector. The output signal of the detector is used to stop the reference counter. The counter content is now a measure of the elapsed time between the launch of the spin-wave pulse and the arrival at the position of the laser spot. A cell of a memory array addressed by the content of the counter is incremented by one and the procedure is repeated. After accumulating a large number of events, the content of the memory array represents the temporal variation of the light-scattering cross section (which is proportional to the spin-wave intensity) at the current position of the laser spot. By repeating the procedure for different positions of the laser spot on the sample, two-dimensional maps of the spin-wave intensity are constructed for different values of delay time. The data is arranged in a digital video animation with each frame representing the spatial distribution of the spin-wave intensity for a given delay time. The entire system is built on the basis of a digital signal processing device, which is placed on a PCI computer board. The device can handle up to 2×10^7 events per second continuously. A lower limit of about 1–2 ns on the time resolution is imposed to keep the obtained frequency uncertainty of the at a reasonable level. Typical accumulation times are 5 s per position of the laser spot. A complete measurement of a two-dimensional spin-wave intensity pattern in a film with a sampling area of

$2 \times 6\,\text{mm}^2$ and a mesh size of 0.1 mm takes a little more than 2 h including dead times caused by sample positioning. Using a similar approach, spin waves of different frequencies can be detected simultaneously with a time and space resolution.

The experiments described in the following text usually combine the microwave technique with the BLS one. To investigate nonlinear excitations, high-amplitude spin precession is excited by an external microwave source. To minimize the applied microwave power, media with low damping constants are usually used. As mentioned in the preceding text, rare-earth garnets demonstrate an extremely low damping, YIG ($Y_3Fe_5O_{12}$) having the lowest damping. Excitations with a precession angle of several degrees can be excited in YIG films. Bismuth-substituted-iron garnet ($Lu_{0.96}Bi_{2.04}Fe_5O_{12}$, BIG) films are also an attractive magnetic media for nonlinear studies. Although the dissipation parameter is larger in BIG, this material generates a much higher BLS signal due to its higher magneto-optical activity for green light, commonly used for BLS experiments.

4 NONLINEAR SPIN-WAVE MODES EXCITED BY EXTERNAL MICROWAVE SIGNAL

It has been shown in Section 2 that an intrinsically nonlinear equation of motion for the magnetization Landau and Lifshitz (1935) in the limit of weak nonlinearity can be reduced to the NSE equation (28) describing the evolution of spectrally narrow nonlinear spin-wave packets. The stable or quasistable solutions of this equation describe natural nonlinear spin-wave excitations existing in a magnetic film, and these excitations form a new *nonlinear* basis for the description of microwave dynamics of magnetization in magnetic films.

The most well known of those solutions is a one-dimensional temporal envelope soliton solution, which can be interpreted as a bound state of a large number of linear spin waves (or magnons) (Kosevich, Ivanov and Kovalev, 1988). In contrast to linear wave packets, which spread while propagating in a dispersive medium, the temporal soliton is stable: it preserves its shape during propagation. Moreover, the theory predicts that two solitons can undergo a head-to-head collision without destroying each other (Büttner *et al*., 1999). One distinguishes bright and dark solitons. An envelope dark soliton can be understood as a stable propagating dip in a carrier wave of otherwise constant amplitude in a nonlinear medium. In real experiments, one-dimensional spin-wave envelope solitons can be observed either in the quasi-one-dimensional geometry of a spin-wave waveguide – a narrow strip of a YIG film having a width that is smaller than the characteristic wavelength of transverse modulational instability in the medium (see Demokritov, Hillebrands and Slavin, 2001 for details) – or in the two-dimensional geometry of a wide YIG film where the Lighthill criterion (Lighthill, 1965) of modulational instability in the transverse direction is not fulfilled (e.g., the case of a perpendicularly magnetized YIG film (see Chapter 9 in Wigen (1994)).

In a two-dimensional geometry when the Lighthill criterion is fulfilled in both in-plane directions, it is possible to observe the formation of quasistable two-dimensional self-focused spin-wave packets – wave bullets – that are two-dimensional spatio-temporal analogs of solitons. We would like to stress that bullets existing in a two-dimensional case are only quasistable and do not survive collisions with other bullets (see Demokritov, Hillebrands and Slavin, 2001); nevertheless, they play a very important role in the nonlinear spin-wave dynamics of magnetic films. In fact, bullets give us a convincing example of the general importance of magnetic systems for nonlinear physics. The possibility of 'light bullets', that is, stable optical wave pulses strongly localized in space and time by self-focusing, which is stabilized by saturation of nonlinearity at high wave amplitudes, has been suggested by Silberberg (1990). There exists, however, no clear experimental evidence for this effect in optics, likely because in optical fibers diffraction is much stronger than dispersion and, therefore, both effects cannot be observed simultaneously. On the contrary, the first experimental observation of bullets has been performed in magnetic films (Bauer *et al*., 1998; Büttner *et al*., 1999). The success is mainly based on the fact that the dispersion law of spin waves can be easily manipulated in experiment by changing the magnitude and direction of the bias magnetic field applied to the magnetic film.

The most interesting geometry to study nonlinear spin-wave processes in magnetic films is the case of an in-plane magnetized ferrite (YIG) film. While the exchange-dominated spin-wave spectrum (24) of a very thin metallic film is approximately isotropic in the film plane, in the case of a relatively thick YIG film, the spin-wave dispersion equation (26) is strongly anisotropic in the film plane.

For backward-volume magnetostatic (nonexchange) waves (BVMSW) propagating along the direction of the bias magnetic field in a thick ferrite film, the nonlinear coefficient N is negative, while the coefficients D and S describing dispersion and diffraction are both positive (see Chapter 9 in Wigen (1994)). Thus the Lighthill criterion (Lighthill, 1965) for modulational instability is fulfilled in both in-plane directions ($SN < 0$, $DN < 0$), and the BVMSW are susceptible to both self-modulation in the direction of propagation (z) and self-focusing in the transverse direction (y).

In the case of a sinusoidal input signal supplied to a relatively short input antenna situated on a wide ferrite-film sample, the excited dipolar spin waves are monochromatic, and they propagate in a relatively wide angle in the transverse

(y) direction. These monochromatic waves are not affected by dispersion, but owing to the presence of different directions of wave vectors in the excited beam they are strongly affected by diffraction. Owing to the competition between diffraction and nonlinearity, transverse modulational instability develops, and this leads to stationary self-focusing of the wave beam and to the formation of spatial spin-wave envelope solitons (Boyle *et al*., 1996; Bauer *et al*., 1997; Büttner *et al*., 2000). This effect can be described by a one-dimensional reduction of the NSE equation (28) with $\partial U/\partial t = 0$ and $D = 0$.

In the opposite case, when a wave packet propagates in a narrow strip of a ferrite film (spin-wave waveguide), where the strip width is smaller than the wavelength of the transverse modulational instability (see equations (28) and (29) in Demokritov, Hillebrands and Slavin (2001) for details), the packet is not affected by diffraction, but, owing to the presence of many different spectral components in the packet, it is strongly affected by dispersion. The competition between dispersion and nonlinearity leads to a longitudinal self-modulation of the wave packet and to the formation of 'bright' temporal spin-wave envelope solitons (see, e.g., Kalinikos, Kovshikov and Slavin, 1983; Chen, Tsankov, Nash and Patton, 1994 and references therein).

The properties of MSSW propagating perpendicular to the direction of the bias magnetic field are very different. MSSW modes are modulationally stable and can only form 'dark' spin-wave solitons (Chen, Tsankov, Nash and Patton, 1993). Formation of 'bright' and 'dark' temporal envelope solitons can also be described by a one-dimensional reduction of the NSE equation (28); only in this case we should assume that $S = 0$.

The effects of longitudinal and transverse self-modulation can be observed simultaneously if a pulsed input signal excites a two-dimensional wave packet of BVMSW modes in a wide YIG film sample. In this case, modulational instability takes place in both in-plane directions and leads to a spatio-temporal self-focusing of the wave packet and to initial stages of the wave collapse, when the whole energy of the packet is concentrated in a small spatial region (Bauer *et al*., 1998). The full $(2 + 1)$-dimensional NSE is necessary for the theoretical description of this effect.

Finally, when a two-dimensional linear or nonlinear spin-wave packet propagates in a ferrite film and interacts with a weakly spatially localized field of microwave pumping (Bagada, Melkov, Serga and Slavin, 1997; Melkov *et al*., 2000; Serga *et al*., 2005) the full system of equations (30) and (31) (or its one-dimensional reduction) are needed to describe this interesting and complicated nonlinear wave process.

In this section we shall describe experiments where one- and two-dimensional nonlinear spin-wave packets – solitons and bullets – were excited by an external input microwave pulse launched in the film by a strip-line antenna.

4.1 Bright temporal and spatial solitons

Observation of bright temporal spin-wave envelope solitons in magnetic films using the microwave technique has been reported in Kalinikos, Kovshikov and Slavin (1983) and Kalinikos, Kovshikov and Slavin (1988, 1994) for different orientations of the static magnetization, corresponding to different spin-wave modes. These works have shown that it is in fact possible to create in YIG films nonlinear wave packets, possessing many properties intrinsic to solitons. For example, after some formation time, spin-wave envelope solitons propagate with a constant width. Moreover, it was also shown that the measured phase profile inside the wave packet is flat and corresponds to that of a theoretical soliton solution of equation (28) with $S = 0$.

The first attempt to observe bright spatial solitons of dipolar spin waves in magnetic films was undertaken by Boyle *et al*. (1996). This paper reports the BLS study of the stationary self-channeling of dipolar spin waves in rear-earth garnet films, although the indication of the initial stages of self-focusing was also present in the reported data.

A clear evidence of nonlinear self-focusing of dipolar spin-wave beams and creation of spatial solitons was presented in Bauer *et al*. (1997), where BVMSW beams in a $Lu_{2.04}Bi_{0.96}Fe_5O_{12}$ (BIG) waveguide (width 2 mm) were studied. One of the results was the appearance of a snakelike structure in the beam propagation path, which is caused by the interaction of transverse waveguide modes (Büttner *et al*., 1998). Different width modes of the waveguide, excited by the microwave antenna, propagate with different phase velocities. They interfere with each other creating a snakelike pattern in the spin-wave intensity in the waveguide.

To exclude the effect of self-focusing on measurements, a wide BIG sample (width 18 mm) was used (Büttner *et al*., 2000). The input power in this experiment was varied from $P_{\text{in}} = 10$ mW (linear case) up to $P_{\text{in}} = 600$ mW (nonlinear case). In Figure 4(a) and (b), the measured spin-wave intensity distribution is shown for different values of the input power. The intensity maps are corrected for attenuation, and the data is normalized to the maximum intensity in each map.

In the linear case, as displayed in Figure 4(a), the spin-wave amplitude changes slightly due to the effect of the diffraction, which causes a beam divergence during propagation, so that the spin-wave intensity is distributed over a wider range with increasing distance from the antenna.

In the nonlinear case, the propagation of the spin waves is very different (Figure 4b). The beam no longer diverges. It

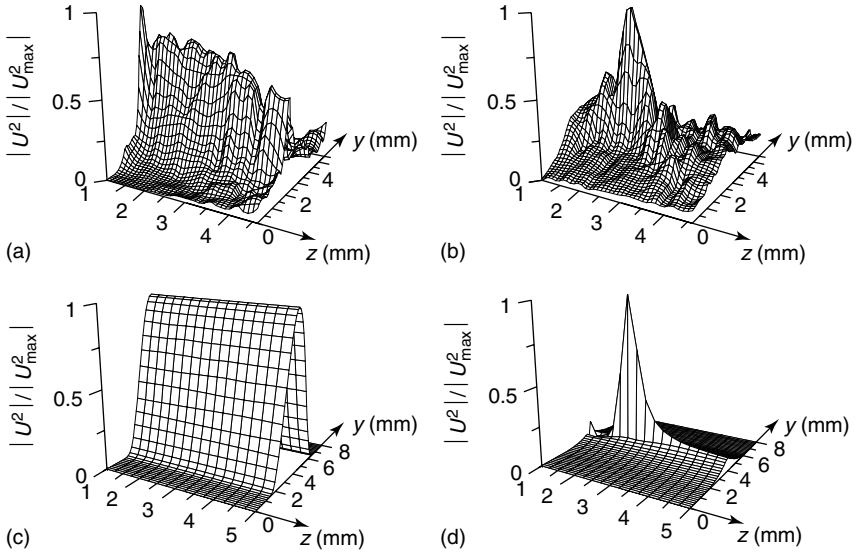

Figure 4. Stationary self-focusing of BVMSW beams in a wide BIG sample. (a) and (b) Experimental distributions of the spin-wave normalized intensity in the film plane for the linear ($P_{in} = 10$ mW) and nonlinear ($P_{in} = 600$ mW) regime, respectively. A clear self-focusing maximum is seen at the point ($z = 2.5$ mm, $y = 3$ mm) in the nonlinear regime. (c) and (d) Results of numerical calculations. (From Büttner *et al*., 2000.)

converges to a small diameter while the spin-wave amplitude increases and a clear focus of spin-wave intensity is observed at the point $z = 2$ mm, $y = 2$ mm. This is the result of the competition between diffraction and nonlinearity, and it can be qualitatively interpreted as the formation of a spatial soliton of a higher order (Agrawal, 1994). In the nonlinear regime, the formation of a narrow wave channel of constant amplitude parallel to the propagation direction z was not observed in these experiments, probably because of the fact that the spatial attenuation in the film is large, and it can play a significant role in the beam-shaping process. Since the spin-wave beam loses energy because of dissipation during propagation, the beam finally diverges when its amplitude becomes so small that the diffraction effect dominates as is the case for $z > 2.6$ mm in Figure 4(b).

4.2 Dark temporal and spatial solitons

As already mentioned, an envelope dark soliton is a stable dip in a carrier wave of otherwise constant amplitude. The dispersion broadening of such a dip is stopped by the influence of nonlinearity, and the actual profile of the completely formed dark soliton, as well as the phase modulation of the carrier wave across the soliton, is a result of a fine dynamic balance between the influences of nonlinearity and dispersion. The characteristic feature of such a dark soliton is a nonzero jump in the phase of its carrier wave as one crosses the dip (Remoissenet, 1999; Slavin, 1995). In the case of a black soliton, if the maximum depth of its dip is equal to the amplitude of the carrier wave, this phase shift is exactly equal to 180°. Thus, to obtain a single dark soliton from an initial wave profile, the phase modulation of the carrier wave should be performed before it enters the nonlinear medium. Without such a modulation, one or several *couples* of dark solitons can be created (Chen, Tsankov, Nash and Patton, 1993; Nash, Kabos, Patton and Staudinger, 1996; Slavin, Kivshar, Ostrovskaya and Benner, 1999). In this case, the phase jumps of successive solitons are added, and the net phase shift across the entire output signal is equal to an integer multiple of 360°.

To create an appropriate phase modulation of the wave, the experimental setup schematically shown in Figure 5 was applied (Serga *et al*., 2004). A similar experimental technique was used in a more-detailed study of dark spin-wave solitons presented in Bischof, Slavin, Benner and Kivshar (2005). Its main difference from a standard setup for investigation of, for example, bright solitons is that the input signal is composed of two coherent rectangular microwave pulses with controlled mutual phase shift in the range $(0, 2\pi)$. The combined pulse is amplified by a power amplifier with controlled gain and is sent to a short-circuited microstrip antenna attached to a strip of a single-crystal YIG film. The input peak power of the microwave signal P_{in} was varied in the range from 0.2 up to 50 mW. The second antenna is used for the detection of the spin-wave packets after their propagation along the YIG film. As shown in Figure 5, the antennae are situated transverse to the long side of the YIG sample and are separated by 8 mm. The sample was magnetized by a static magnetic field of $H_0 = 1745$ Oe applied in the film plane and transverse to the

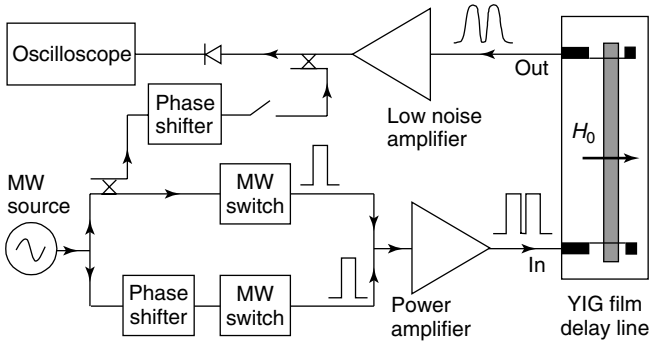

Figure 5. Experimental setup for creation of dark temporal solitons. The YIG film is shown by a shaded rectangle (from Serga *et al*., 2004). (For a discussion of the rest of the components see the main text).

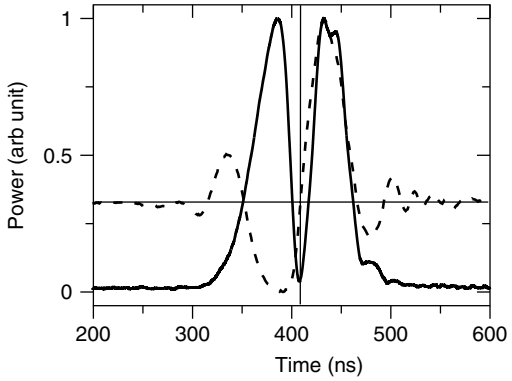

Figure 6. Normalized output signal formed from a nonlinear input rectangular pulse with a dip, demonstrating the formation of a black soliton (solid line). To obtain the black soliton, a phase adjustment between two parts of the initial pulse by 50° was introduced to compensate for the induced nonlinear phase shift. The dashed line shows the result of interference of the black soliton signal with a monochromatic reference signal, illustrating the 180° phase shift over the soliton. (From Serga *et al*., 2004.)

long edge of the strip. In this geometry, MSSW were excited. Such waves have a monotonic dispersion curve $\omega(k)$ with negative dispersion, $D < 0$, and nonlinearity, $N < 0$. The positive product $ND > 0$ (Lighthill, 1965) allows MSSW wave packets to form dark envelope solitons while traveling between the antennae. To analyze the phase jump inside the output signal, the interference between the output signal and a reference signal from the same microwave source was recorded.

Owing to the spin-wave dispersion in the film, the output pulse is broadened and the two initially rectangular pulses forming it acquire bell-like profiles. The width of the central dip decreases with increasing power, providing clear evidence of the dark-soliton formation. However, the dip does not reach the zero level: the intensity at the dip is increasing with increasing power. It means that a 'gray' soliton is created at the initial phase modulation of 180°. This effect is connected with the excitation-induced nonlinear phase modulation (Slavin, Kivshar, Ostrovskaya and Benner, 1999). To obtain a fully 'black' soliton having zero amplitude at the center of the dip, the excitation-introduced phase shift is compensated by the external phase shifter. The envelope shape of the output signal for this case is shown in Figure 6. Thus, an artificial precompensation of the nonlinear phase shift enables one to observe the generation of a single, fundamental black spin-wave envelope soliton having a 180° phase jump.

A similar technique combining two microwave pulses with a phase shift can be used for the formation of dark spatial solitons. Instead of mixing two microwave pulses at one antenna, as was done for the preceding studies of temporal dark solitons, the formation of a spatial dark soliton has been realized by using two axially aligned microstrip antennae (shown by the vertical stripes in Figure 7) attached to the surface of a wide YIG film. Two long (300 ns) coherent microwave pulses with a 180° phase shift between them were supplied to the antennae. Two-dimensional propagating spin waves have been studied using the space-resolved BLS technique. As seen in Figure 7 the antennae excite two almost-parallel beams of MSSW. As a result of a destructive interference of the beams an initial gap is created between them even in the linear case (Figure 7a). This gap plays the role of a soliton seed. Increasing the beam power leads to a sharpening of the gap (see Figure 7b) between them. At the same time, the depth of the gap remains at a constant value. Remarkably and contrary to the linear case, the nonlinear gap preserves its shape for a long propagation distance, as seen in Figure 7(b).

4.3 Spatio-temporal self-focusing: spin-wave bullets

In the experiments discussed in the preceding text, either narrow YIG films were used or stationary effects of the spin-wave propagation were studied. For the investigation of two-dimensional spatio-temporal self-focusing, the propagation of relatively short spin-wave packets in a large YIG film (thickness 7 μm, width 18 mm, length 26 mm) has been studied (Bauer *et al*., 1998). The static magnetic field $H =$ 2098 Oe was applied parallel to the propagation direction. Thus, the BVMSW geometry was realized. The carrier frequency was chosen to be $\omega_s/2\pi = 7970$ MHz, which results in a carrier wave vector $k_{0z} = 50\,\mathrm{cm}^{-1}$.

Figure 8 shows the distribution of the spin-wave intensities for the preceding parameters and for two different input powers: $P_{\mathrm{in}} = 10$ mW in the linear (Figure 8a) and $P_{\mathrm{in}} =$ 460 mW in the nonlinear regime (Figure 8b). The data are

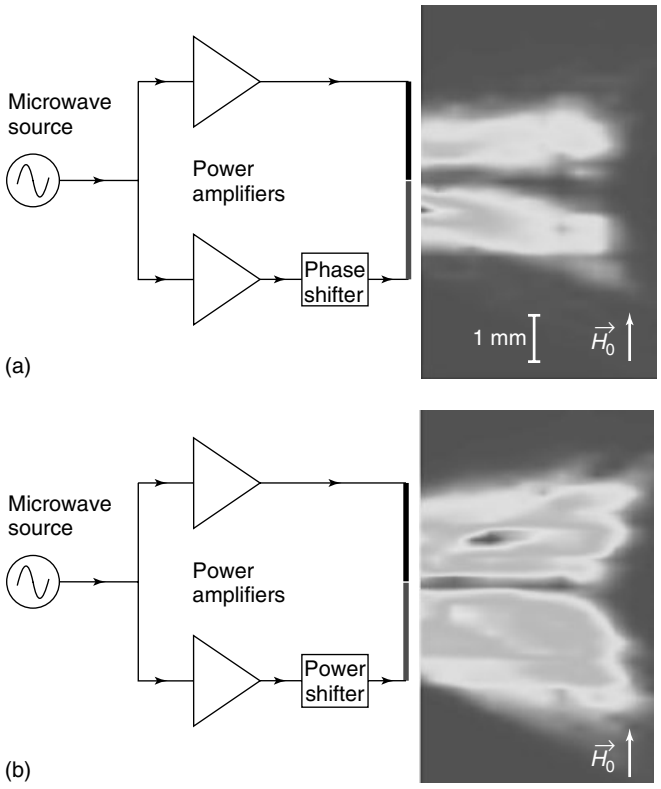

Figure 7. Formation of the dark spatial soliton in a wide YIG sample. Frames (a) and (b) show the normalized two-dimensional distributions of the intensity of spin waves measured in the linear and nonlinear cases, respectively. The orientation of the magnetic field corresponds to the MSSW geometry (Serga, Demokritov and Hillebrands, unpublished).

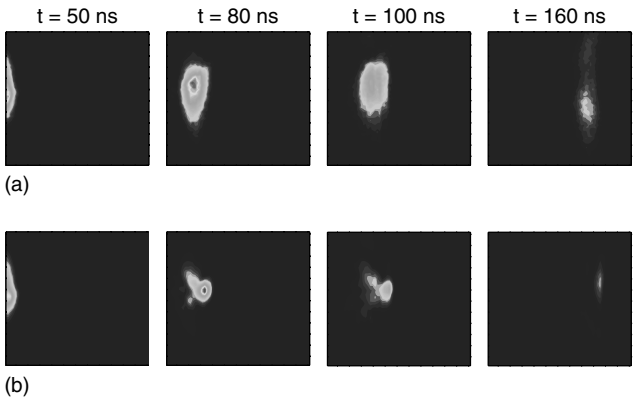

Figure 8. Nonstationary self-focusing of a two-dimensional BVMSW packet. The figure shows the spin-wave intensity distribution in the film created by the propagating pulse of duration 29 ns in a false-color presentation for linear ($P_{\text{in}} = 10$ mW, (a)) and nonlinear ($P_{\text{in}} = 460$ mW, (b)) regimes. Four panels correspond to four successive moments after the moment of a pulse launch from the antenna, as indicated in the figure. Spatio-temporal self focusing is clearly seen for $T = 80$ ns in the nonlinear regime. (Adapted from Bauer *et al*., 1998.)

shown in the false-color presentation. In the linear case, diffraction and dispersion cause a broadening of the initial wave packet both perpendicular to and along the propagation direction, while its amplitude decreases due to dissipation. The propagation of the wave packets in the nonlinear case is quite different. Here the initial high-amplitude wave packet starts to converge, and its amplitude is increasing. Theory predicts that in the two-dimensional case a stable equilibrium between dispersion, diffraction, and nonlinearity is not possible, and nonlinear self-focusing of the wave packets with high-enough initial energy should lead to a wave collapse, that is, all the energy of the packet will be concentrated at one spatial point. In a real medium with dissipation, the complete wave collapse is, of course, avoided, as the wave packet loses its energy. Therefore, in a certain interval of propagation distances, nonlinear collapse is stabilized by dissipation, and a quasistable, strongly localized two-dimensional wave packet, a *spin-wave bullet*, is formed, as predicted in Silberberg (1990).

The effect of bullet formation is further illustrated in Figure 9, where the width of the packet perpendicular to (L_y) and along (L_z) the propagation direction and the peak amplitude of the nonlinear wave packet are shown as functions of the propagation time. For $25\,\text{ns} < t < 40\,\text{ns}$ the packet enters the range of measurement. After the packet enters the measurement region, L_y and L_z rapidly decrease ($40\,\text{ns} < t < 50\,\text{ns}$), while simultaneously the peak intensity P_{peak} increases with a minimum in width and a maximum in intensity at $t = 70$ ns, where a *spin-wave bullet* is formed. For $t > 70$ ns the amplitude of the bullet decays because of the dissipation while L_y and L_z stay constant. At $t > 100$ ns the amplitude is so small that the spatio-temporal focusing effect vanishes and the bullet starts to broaden.

Figure 10 shows the evolution of the spin-wave bullet sizes with increasing input power. It is clear that both in-plane sizes of the bullet decrease with increasing power and become closer to each other. This is a typical behavior of a two-dimensional wave packet approaching the collapse point (see, e.g., Berge, 1998).

5 SELF-GENERATION AND PARAMETRIC EXCITATION OF NONLINEAR SPIN-WAVE MODES

In Section 4 it was shown that spin-wave solitons and bullets are formed from different input microwave signals supplied to the magnetic film from an external source. We would like to stress that the profiles of the formed solitons and bullets are determined by the amplitude of the input signal

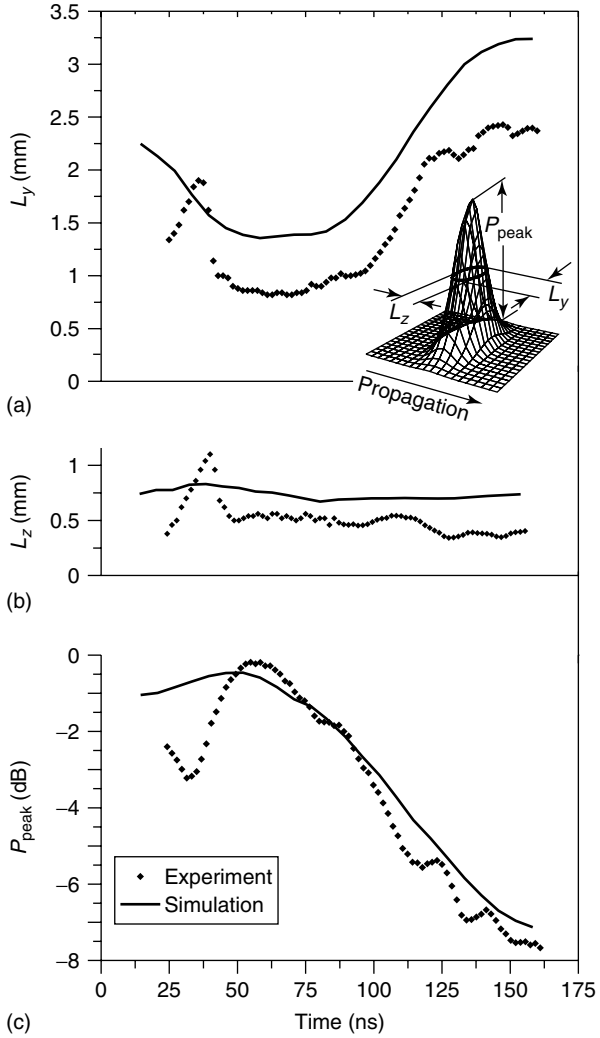

Figure 9. Time evolution of the transverse (L_y) and the longitudinal (L_z) width of the spin-wave packet and the packet amplitude in the nonlinear regime. The symbols show the result of the experiment, the straight line shows the result of a simulation based on the numerical solution of the two-dimensional nonlinear Schrödinger equation. (From Bauer *et al*., 1998.)

and the nonlinear, dispersive, and diffractive parameters of the film and are not closely related to the shape of the excitation signal. In other words, solitons and bullets are the natural intrinsic nonlinear excitation of a nonlinear dispersive medium, and any initial condition of a sufficiently high-amplitude will be reduced to these intrinsic nonlinear excitations in the the process of its evolution in such a medium.

In this section we present an additional experimental confirmation of this fact and demonstrate that spin-wave solitons and bullets can be generated *without any external signal*, directly from the internal noise existing in an active ring. We also demonstrate that spin-wave bullets can be generated

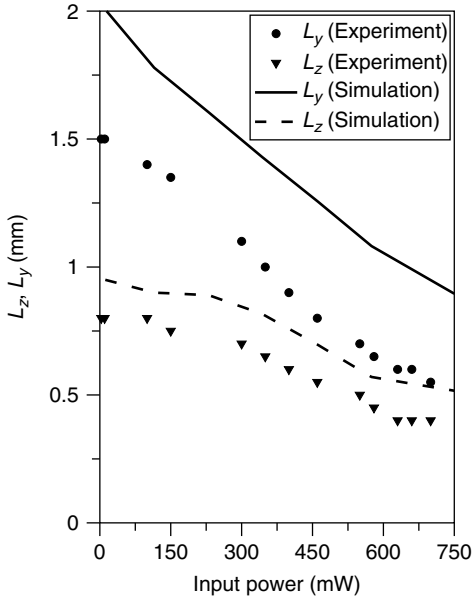

Figure 10. Widths L_y and L_z of the dipolar spin-wave packet of half-maximum power measured at the focal point (point of the maximum peak power) shown as functions of the input power P_{in}. and amplified parametrically, if a microwave pumping of a double frequency is supplied to the magnetic film.

The experiments on self-generation of spin-wave bullets in active rings and their amplification by parametric pumping are of particular importance. As mentioned in the preceding text, the two-dimensional spin-wave bullets, formed as a result of the competition between the effects of nonlinearity, dispersion, diffraction, and linear dissipation are, in contrast with one-dimensional solitons, only quasistable and do not survive collisions with other bullets (Büttner *et al*., 1999). Therefore, it is very interesting to compare the properties of solitons and bullets generated from external input pulses (Section 4) with properties of self-generated solitons and bullets (discussed in the following text).

5.1 Self-generation of quasi-one-dimensional solitons

A magnetic ring for soliton self-generation is usually based on a ferromagnetic film connected to an external amplifier that closes the self-generation ring and provides the energy to compensate the losses in the ring. The amplifier operates in the linear regime and has a wide frequency band of amplification. Therefore, the magnetic film is the only source of nonlinear effects in the ring. As discussed in the previous sections, changing the mutual orientation of the applied field

and the wave vector of the spin wave, one can realize the BVMSW or MSSW geometry. BVMSW, having a positive dispersion coefficient D and a negative nonlinear coefficient N, supports the formation of bright solitons. MSSW, with negative D and N, supports the formation of dark solitons. The self-generation of both bright and dark solitons will be discussed in this subsection.

An active ring consisting of just a magnetic film and an amplifier cannot create solitons, since the self-generation in such a system tends to become chaotic. To stabilize the self-generation of spin-wave solitons, the time-gating Kalinikos, Kovshikov and Patton (1998b, 1998a) and frequency-filtering (Kalinikos, Scott and Patton, 2000; Scott, Kalinikos and Patton, 2001) techniques have been proposed.

The first approach takes advantage of a microwave pulse switch, introduced between the film and the amplifier. The switch periodically closes the ring for a certain period, thus, providing conditions for circulation of a microwave packet of a finite width. If the period of switching is equal to a round-trip circulation time, the frequency spectrum of the wide-band signal allowed by the amplifier and the magnetic film only becomes narrower due to survival of the resonant ring harmonics, which can propagate in the ring only in that particular time window. With successive circulation, the amount of these harmonics is decreased owing to the dispersion effect. Finally, at a given signal amplitude the competition between the dispersion and the four-wave nonlinear interaction results in the longitudinal modulational instability, which is responsible for the energy transition from one frequency mode to neighboring resonant modes and the soliton formation.

The self-generation of magnetic bright solitons was first performed using the time-gating technique in Kalinikos, Kovshikov and Patton (1998b). The ring based on the YIG film in the BVMSW geometry (the applied field is parallel to the wave vector) has a round-trip time $T_s = 100\,\text{ns}$. By adjusting the switching period to match T_s and increasing the gain of the amplifier, the self-generation of a series of narrow wave packets was achieved. By measuring the waveform of the packets and the phase profile inside each packet, the self-generation of bright solitons due to nonlinear interaction of the propagating resonant BVMSW modes was confirmed. From the theoretical point of view, this nonlinear process causes soliton formation if the frequency spacing between neighboring resonance modes, Δf, determined by $T_s : \Delta f = 1/T_s = 10\,\text{MHz}$, is smaller than twice the modulational instability frequency f_m of the waves, $\Delta f < 2f_m$. The latter can be estimated from the NSE (28) with $S = 0$ (see also Remoissenet, 1999) : $f_m = U v_g \sqrt{(|N/D|)}/\pi$, where U is, as usual, the dimensionless amplitude of the spin-wave packet envelope. For the experimental conditions given in Kalinikos, Kovshikov and Patton (1998b) $f_m = 43\,\text{MHz}$. Thus, the preceding condition is in fact fulfilled.

As already mentioned, the self-generation of dark spin-wave solitons can be achieved through MSSW geometry (Kalinikos, Kovshikov and Patton, 1998a). Another key difference from the above described case of bright-soliton generation is that the active ring was periodically broken for a short period of time (switched off) by the switcher. One expects that the dark-soliton pulses will be formed from the dips created by the interruption of the wave circulation. By adjusting the experimental conditions, the circulation time and the frequency spacing between the modes were chosen to be the same as for the experiments with the bright solitons: $T_s = 100\,\text{ns}$, $\Delta f = 1/T_s = 10\,\text{MHz}$. In order to obtain the self-generation, the gain of the amplifier was tuned to compensate the losses and to achieve continuous microwave self-generation. Second, the period of the interruption was adjusted to coincide with T_s. Finally, the soliton duration was varied to obtain the waveform packets and the phase profile inside each packet that correspond to dark solitons. The measured phase characteristic demonstrates two 180° jumps of the phase within each dark wave packet. As discussed in the previous section, this is unambiguous evidence that dark solitons were formed as a pair. This experimental observation is corroborated by theory, predicting the generation of a pair of dark solitons from a dip created by the amplitude modulation only (see, e.g., Kivshar and Luther-Davies, 1998).

5.2 Self-generation of spin-wave bullets

In this subsection, the self-generation of spin-wave bullets from thermal noise in a wide YIG film will be discussed. Characteristics of the self-generated bullets will be compared with those of spin-wave bullets formed from coherent input wave packets.

The realization of the active ring structure for bullet self-generation (Serga, Demokritov, Hillebrands and Slavin, 2004) is similar to that for soliton self-generation with time gating (Kalinikos, Kovshikov and Patton, 1998b, 1998a). As the medium for propagation of the wave packets, a relatively wide YIG film (lateral dimensions $26 \times 18\,\text{mm}$, thickness $d = 7\,\mu\text{m}$) is chosen. A standard delay-line structure consisting of two parallel strip-line antennae is placed on the sample. As is usually the case for bullet studies, the lateral dimensions of the sample are intentionally chosen to be much larger than the length of the input antenna and the distance between the antennae, thus creating the conditions for the existence of a two-dimensional (unrestricted in plane) spin-wave process. The applied field $H_0 = 1735\,\text{Oe}$ is applied parallel to the

propagation direction. Thus, the BVMSW geometry is realized. The two antennae are connected through a microwave switch and a high-gain, wide-band microwave amplifier. The signal from the spin-wave packet is collected at Antenna 2 and, after amplification, brought back into the film by Antenna 1, closing the ring. The microwave switch is used as a mode selector, for details see the following text.

As described in the previous sections, the propagation of two-dimensional spin-wave packets is described by the two-dimensional NSE (28): One should, however, consider Γ as the combined relaxation parameter, comprising the damping in the film, losses in the antennae, and the parameter characterizing the gain of the amplifier ($\Gamma_a < 0$). Let us emphasize again that dissipation plays an important role in the formation of spin-wave bullets. Without dissipation the ongoing self-focusing effect would result in a collapse of the self-focusing packet Sulem and Sulem, 1999. However, the presence of even a weak linear dissipation in the medium stops the self-focusing and results in the formation of a quasistable spin-wave bullet (or bullet of BVMSW) (Bauer *et al*., 1998). On the other hand, the dissipation should be small enough to allow for a sufficient time span for developing the nonlinear two-dimensional instability.

The YIG film with the strip-line antennae forms a transmission line for two-dimensional BVMSW wave packets, but no external coherent input signal was applied to the antennae. Instead, the transmission line is connected to a microwave switch and a wide-band microwave amplifier, closing the active ring. This transmission line plays the role of a resonator in a feedback loop of a standard microwave generator (Tuan and Parekh, 1985). The resonance frequencies of a ring are determined by the phase matching condition

$$k_{nz}(\omega)l + \phi = 2\pi n \tag{34}$$

where n is an integer, l is a distance between the antennae, and ϕ is the additional phase shift associated with the electronic part of the ring. The main qualitative difference between the the soliton-generation experiment and the experiment with a wide film is due to the fact that the wide YIG film sample allows for the generation of substantially two-dimensional BVMSW packets that are affected not only by dispersion, but also by diffraction. To achieve the stable generation of a train of spin-wave packets, it is necessary to fulfill several conditions similar to those necessary for soliton generation (Kalinikos, Kovshikov and Patton, 1998b; Scott, Kalinikos and Patton, 2001). The only additional condition is that Δf should be smaller than the doubled instability frequencies corresponding to the both longitudinal and transverse instabilities. Besides, in two dimensions there exists an additional mechanism of self-limitation associated with diffraction and the partial collapse of the strongly self-focused bullet that manifests itself for large, necessary values of the external amplification gain coefficient.

The time-gating technique described in the preceding text was applied to reach a stable generation of two-dimensional nonlinear wave packets. The switch is opened once during each propagation period of the packet over the ring ($T_0 = 190$ ns) for a time (about $\tau_b = 20$ ns), which is larger than the expected duration of the generated bullet. For small amplification gains, the synchronization of the switch is crucial: a variation of the modulation period, T_0, by more than ± 3 ns leads to a breakdown of the self-generation process.

The described experimental microwave setup allows one to generate a train of short (about 20 ns duration) two-dimensional spin-wave packets and to measure their carrier frequency, duration, and propagation time by monitoring the microwave signals at the input and output antennae of the transmission line. To monitor the propagation of the nonlinear wave packets, the space- and time-resolved BLS technique in the forward geometry is used. As described in the previous sections the BLS technique provides the two-dimensional distribution of the spin-wave intensity $I(y, z)$ (proportional to the squared amplitude of the local dynamic magnetization in the film, $|U|^2$) of the propagating wave packet with a spatial resolution of 0.1 mm and a temporal resolution of 2 ns.

Two series of intensity distributions corresponding to two different values of the external amplification gain at different propagating times as indicated are shown in Figure 11. The first series of profiles (Figure 11a) corresponds to a relatively low value of the amplification gain, yielding a peak power of the generated wave packet at the Antenna 1 of about $P_1 = 1$ mW. This power is not sufficient to cause a pronounced transverse nonlinear self-focusing of the generated wave packet, and a spin-wave bullet is not formed. Nevertheless, the propagating wave packet is almost stationary along most of its propagation path. Here the regime of nonlinear compensation of the dispersive and diffractive spread of the wave packet is achieved. Such a propagation regime was not observed for the coherent excitation of BVMSW packets (Bauer *et al*., 1998) where the propagating packet was either self-focusing or exhibited a relatively strong diffraction spreading. The multiple-pass circulation of the packet in the ring is responsible for the observed stabilization of the wave packet size in this weakly nonlinear regime.

The second series of profiles (Figure 11b) corresponds to a relatively high value of the amplification gain yielding a peak power of the generated wave packet at the input antenna of $P_1 = 220$ mW. Here the generated wave packet is clearly self-focusing in both in-plane directions, and a bullet is formed. The experimentally measured parameters of

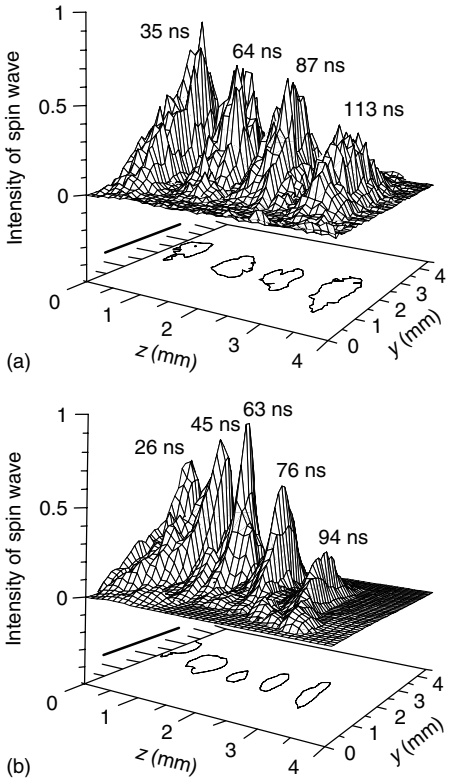

Figure 11. Spatio-temporal self-focusing of two-dimensional self-generated BVMSW packets. The upper part of the panels shows the spin-wave intensity distributions of the packet at successive instants of time, as indicated, after the launch of the packet. The lower part presents the cross sections of the propagating pulse at half-maximum power. Panels (a) and (b) correspond to quasilinear ($P_1 = 1\,\text{mW}$) and strongly nonlinear ($P_1 = 220\,\text{mW}$) spin-wave packets, respectively. The black stripe in the lower part of the panels indicates the position of the antenna. (From Serga, Demokritov, Hillebrands and Slavin, 2004.)

this bullet (width, length, peak power) are very close to the parameters of a BVMSW bullet formed under coherent excitation by an external input microwave pulse. For example, the minimal transverse size of the bullet observed in Bauer *et al*. (1998) is 0.6 mm, while the minimum transverse size of the bullet observed in the self-generation experiment is 0.65 mm, as it show in Figure 12.

5.3 Amplification and parametric generation of spin-wave bullets

The preceding results demonstrate that spin-wave bullets can be self-generated from noise. This proves that, similar to solitons in quasi-one-dimensional systems, wave bullets are intrinsic multidimensional excitations of the nonlinear medium with dispersion, diffraction, and dissipation. It is known (Bagada, Melkov, Serga and Slavin, 1997; Kolodin *et al*., 1998; Melkov *et al*., 2000) that, in a quasi-one-dimensional spin-wave waveguide, parametric interaction of the spin-wave packet with an external pumping may result in a substantial amplification of the initial packet and, in some cases, the parametric generation of a phase-conjugated wave packet propagating in the opposite direction. Therefore, it is important to study parametric interaction of two-dimensional linear and nonlinear spin-wave packets (Serga *et al*., 2005).

Advantages and disadvantages of magnetic films as a medium for nonlinear wave studies, with respect to, for example, optical media, were already discussed in this review. An additional advantage of the magnetic films is the fact that it is possible to realize an effective parametric interaction of a propagating wave packet (having a carrier wave vector $\mathbf{k}$ and frequency ω) with nonstationary (pulsed) electromagnetic pumping (Melkov *et al*., 1999). The conservation laws for such a parametric interaction process have the form

$$\omega + \omega' = \omega_\text{p}, \quad \mathbf{k} + \mathbf{k}' = \mathbf{k}_\text{p} \tag{35}$$

where ω_p, ω, ω' and $\mathbf{k}_\text{p}$, $\mathbf{k}$, $\mathbf{k}'$ are the carrier angular frequencies and carrier wave numbers of the electromagnetic pumping pulse, initial spin-wave packet, and the 'idle' spin-wave packet formed in the interaction process, respectively.

We will see in the following text that from the point of view of parametric amplification the properties of two-dimensional bullets are very similar to those of one-dimensional solitons. In fact, the parametric interaction of a two-dimensional linear spin-wave packet with parametric pumping leads to the formation of pronounced two-dimensional spin-wave bullets from both amplified, forward-propagating and reversed, phase-conjugated packets. These results might be surprising, taking into account the finite width of the studied wave packets in wave vector space and the strong anisotropy of the spin-wave spectrum in a tangentially magnetized magnetic film (see Büttner *et al*., 2000 for details).

The setup for spin-wave amplification experiments is shown in Figure 13. Spin waves were excited in a single-crystal YIG film of 5 μm thickness, $4.1 \times 30\,\text{mm}^2$, using a microstrip antenna of 25 μm width and 2 mm length. The lateral dimensions of the film ($4.1 \times 30\,\text{mm}^2$) were chosen much larger than the characteristic size of a spin-wave bullet (0.2–0.8 mm). The magnetic field H_0 was applied in the film plane along the long side of the film (z axis in Figure 13). As discussed in the preceding text, this geometry corresponds to the excitation of BVMSW. The input BVMSW packets were excited by rectangular electromagnetic pulses of duration 30 ns supplied by a rectangular dielectric resonator with an opening in the middle. The film went through the opening, and the resonator

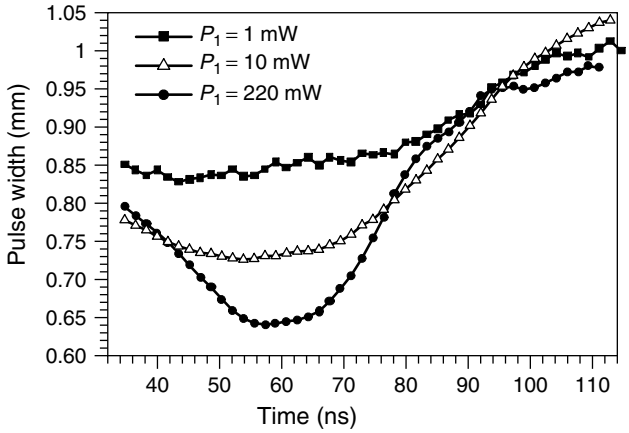

Figure 12. Evolution of the transverse width of the spin-wave packet, L_y, with propagation time t at different amplification gains illustrating the bullet self-generation. (From Serga, Demokritov, Hillebrands and Slavin, 2004.)

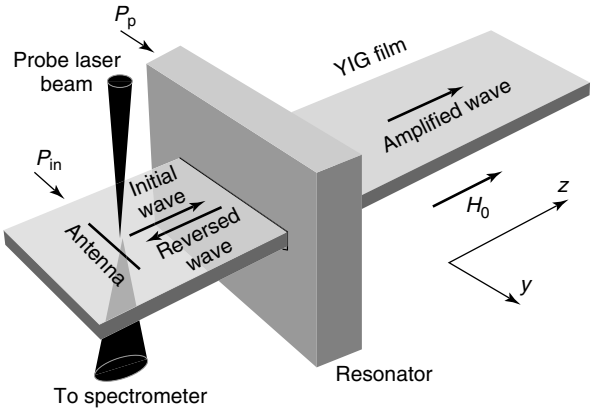

Figure 13. Experimental setup for parametric amplification of spin-wave bullets. Leads feeding the antenna and the resonator are not shown. (From Serga, Demokritov, Hillebrands and Slavin, 2004.)

was placed at a distance of 2.5 mm from the antenna (see Figure 13). The pumping microwave field was parallel to the applied magnetic field. The pumping pulse was supplied to the dielectric resonator at the time when the propagating wave packet was close to the center of the resonator. As a result of the parametric interaction, the forward-propagating amplified and the backward-propagating amplified, reversed, and phase-conjugated spin-wave packets were formed.

A series of maps, showing the two-dimensional distribution of the spin-wave intensities $I(z, y)$ is shown in Figure 14. Figure 14(a) demonstrates the evolution of a two-dimensional wave packet of duration $\tau = 30$ ns after it has been launched from the antenna and until it reaches the pumping area. As seen in Figure 14, the packet spreads along the transverse (y) direction during propagation because of the strong diffraction in the film. The spreading of the packet is

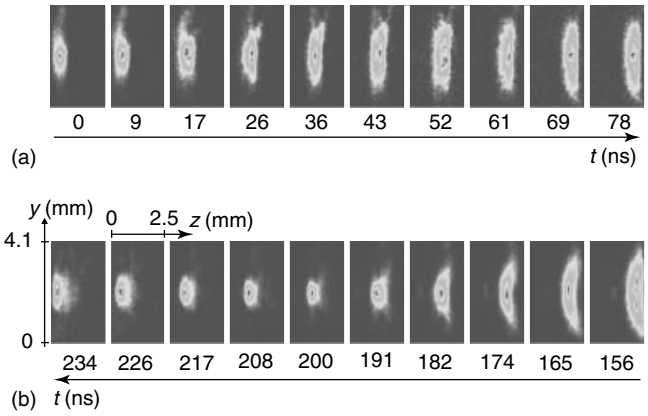

Figure 14. The spatial distributions of the spin-wave intensity captured at successive moments of time both for incident (a) and for reversed (b) spin-wave packets. $P_{in} = 146$ mW, measured by means of time- and space-resolved BLS. (From Serga, Demokritov, Hillebrands and Slavin, 2004.)

illustrated in Figure 15(a), showing its width versus the propagation distance. The three curves correspond to different values of the input power.

Figure 14(b) demonstrates the propagation and evolution of the reversed ($\mathbf{k}' = -\mathbf{k}$) wave packet formed as a result of the parametric interaction. It is clear that the reversed packet experiences a strong nonlinear two-dimensional self-focusing, which leads to the formation of a pronounced spin-wave bullet (see frames corresponding to 191, 200, and 208 ns). The evolution of the bullet width L_y in this reverse propagation is shown by curve (2) in Figure 15(c).

One can see from Figure 14 that the reversed packet undergoes a wave-front reversal (phase conjugation). In fact, frames corresponding to 69 and 78 ns illustrate that the wave packet has a concave front. On the other hand, the reversed packet (165 and 174 ns) has a convex front. Note the reversal of the propagation direction between Figure 14(a) and (b). As seen from Figure 15(d) the front-reversal process due to phase conjugation is more profound for linear, low-power input packet.

Figure 15(b) demonstrates that spin-wave bullet formation also takes place in the forward-propagating amplified wave packet after its interaction with the pumping. However, the bullet formation in the forward-propagating spin-wave packet takes place at a larger distance from the pumping resonator than in the case of the reversed wave packet (1.5 mm compared to 1.0 mm) and the width of the formed bullet L_y is larger (0.3–0.4 mm compared to 0.22–0.25 mm). These differences are connected with the fact that two mechanisms contribute to bullet formation from the reversed packet. The first mechanism is the nonlinear self-focusing effect, characteristic for the four-wave nonlinearity in a focusing medium and responsible for bullet self-formation. The second

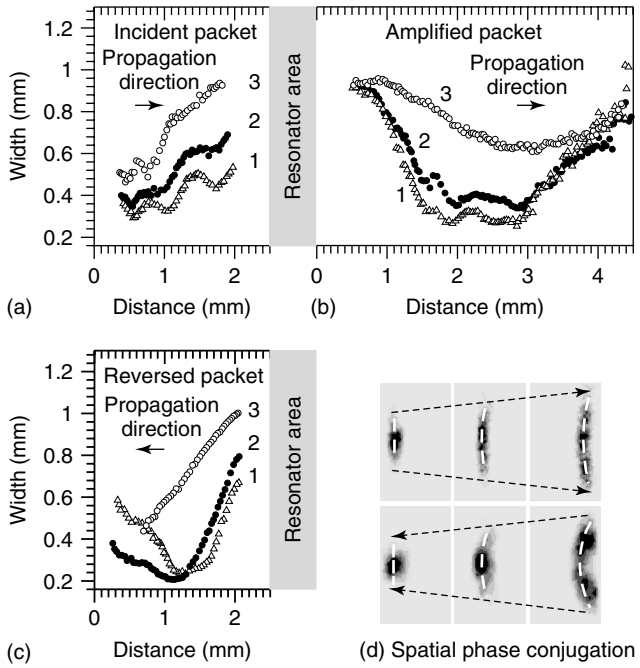

Figure 15. Frames (a) and (b) demonstrate the evolution of the transverse width L_y of the spin-wave packet before its interaction with pumping and after its parametric amplification, respectively. Frame (c) shows the evolution of the width, L_y, of the reversed spin-wave packet. Curves (1), (2), and (3) correspond to the input powers P_{in} of 226 mW (strongly nonlinear), 146 mW (nonlinear), and 22 mW (linear), respectively. Frame (d) illustrates the two-dimensional phase conjugation and front-reversal process of a linear (22 mW) wave packet due to interaction with the pumping. (From Serga, Demokritov, Hillebrands and Slavin, 2004.)

mechanism is the linear self-focusing effect, characteristic for the process of two-dimensional phase conjugation and wave-front reversal (Zeldovich, Pilipetskii and Shkunov, 1985). This linear focusing effect can be observed separately if the power of the input signal is low enough (see curve (3) for $P_{\text{in}} = 22$ mW in Figure 15c). It is clear that curve (3) demonstrating the linear focusing effect has a substantially smaller slope than curves (1) and (2), demonstrating the formation of nonlinear bullets. Thus, owing to the combined action of linear and nonlinear effects the focusing and compression of the reversed wave packet is more pronounced than that of the forward-propagating amplified wave packet, although the amplitude of the forward packet is larger.

As discussed in the previous sections, for description of the parametric interaction of a two-dimensional spin-wave packet with pumping, one needs to use a system of two coupled NLS equations for the envelopes of forward-propagating and reversed wave packets (see equations (30) and (31)). The above described processes of spin-wave packet propagation and interaction with parametric pumping were modeled numerically using those equations. It was assumed that the input linear wave packet has the following profile:

$$U_1^2(y, z, t = 0) = U_0^2 \cosh^{-2}\left[\frac{2(z - z_0)}{L_{z0}}\right] \cos^2\left[\frac{\pi(y - y_0)}{L_{y0}}\right] \tag{36}$$

where L_{y0} and L_{z0} were the same as in the experiment (Figure 15). The initial amplitude of the input pulse U_0 was chosen to be smaller than the minimum threshold of four-wave nonlinearity $U_{\text{th}} = \sqrt{\omega_r / N}$ (see Slavin and Benner, 2003) to guarantee the linear regime of the input wave packet propagation before interaction with pumping. The pumping field of $h_{\text{p}} = 60$ Oe was assumed to be uniform in space and was acting for 40 ns starting at the time when the maximum of the input propagating pulse was at a distance of 3 mm from the antenna.

The two-dimensional distributions of the normalized spin-wave intensity $|U(y, z)/U_0|^2$ calculated for three different times (before, immediately after, and 30 ns after the end of the pumping pulse) are shown in Figure 16(a–c), correspondingly. The numerical model correctly reproduces all the qualitative features of the observed parametric interaction process: Immediately after the interaction with pumping, two counterpropagating wave packets (Figure 16b) are formed from the initial linear wave packet (Figure 16a). This is followed by the formation of bullets in both forward-propagating and reversed wave packets (Figure 16c). Note that the numerical results corroborate the experimental observation that self-focusing of the reversed spin-wave bullet is stronger than self-focusing of the forward-propagating packet.

Thus, the results presented in this section confirm the fact that spin-wave bullets are two-dimensional intrinsic excitations of a nonlinear diffractive and dispersive medium with dissipation. Bullets demonstrate their self-generation from the thermal noise. Besides they can be generated parametrically in magnetic films from linear input wave packets. They are formed from both the forward-propagating and reversed wave packets, and their properties are similar to the properties of wave bullets generated by an external coherent microwave pulse, described in the previous section.

5.4 Self-generation of symmetry-breaking nonlinear spin-wave excitations

In the previous section, solitons and bullets self-generated in active rings have been discussed. The phase matching condition equation (34) was considered as a fundamental condition for the existence of an excitation in a ring. For linear excitations that fill the entire ring, the phase matching condition is the consequence of the unambiguous definition of the wave phase in each particular point of the ring.

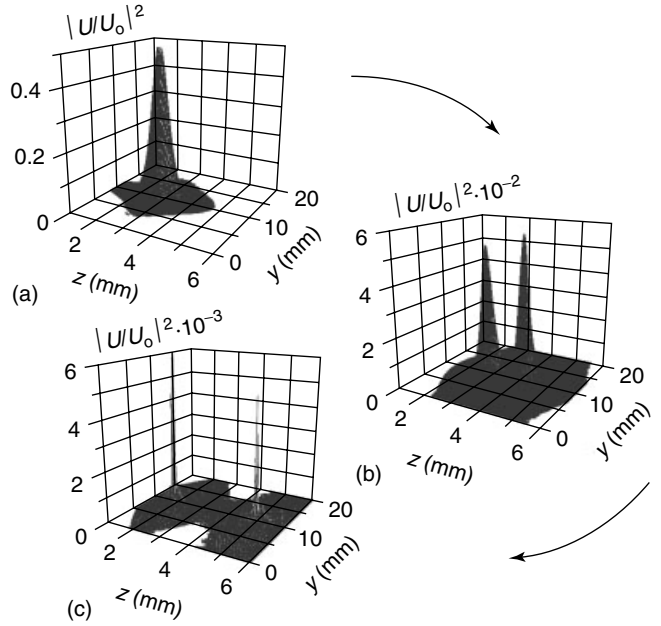

Figure 16. Numerical modeling of bullet formation by parametrically amplified and conjugated spin-wave packets. Frame (a) shows the initial spin-wave packet. Frame (b) shows the amplified and conjugated spin-wave packets just after their parametric interaction with an electromagnetic pumping. In frame (c) a pronounced two-dimensional compression of both spin-wave packets is seen. (From Serga, Demokritov, Hillebrands and Slavin, 2004.)

For nonlinear, localized excitations, the phase matching condition can be broken, since at a given instant of time the phase of such an excitation is defined in the interval of its localization. Thus, the phase matching should be considered as an additional symmetry, which can be broken for some excitations. Although the preceding considerations seem to be very simple, the symmetry-breaking spin-wave excitations have been discovered theoretically (Carr, Clark and Reinhardt, 2000) and experimentally (Demokritov *et al*., 2003) only very recently.

In their pioneering work, Carr, Clark and Reinhardt (2000) have analyzed the solutions of a nonlinear wave equation with attractive nonlinearity in a box with infinitely high walls and, equivalently, in a ring. It was found that the general solution can be described by multisoliton modes, and the modes can be classified by the number of solitons comprising a particular mode. There are, however, two classes of such modes if one takes into account the symmetry connected with the phases of the particular solitons building those modes. The first class covers the nonlinear modes having one-to-one correspondence with the linear solutions. In fact, there is a direct connection between the mode number of a linear mode and its mirror symmetry with respect to the center of the box: odd and even modes are symmetric and antisymmetric, respectively. The standing wave with two half wavelengths fitting the box is antisymmetric with respect to the box center. This linear mode corresponds to a two-soliton nonlinear mode. The nonlinear mode belonging to the first class is also antisymmetric, that is, the phases of the two solitons are opposite. The second class covers the nonlinear modes, having no one-to-one correspondence to linear modes. These modes are called *symmetry-breaking modes*. For example, contrary to the discussed linear mode, there exists a nonlinear mode consisting of two solitons with the same phase, which is symmetric with respect to the box center.

The preceding approach can be adapted for envelope solitons. One needs, however, to define the phase of soliton-like wave packets. In fact, let us consider a one-dimensional spin-wave packet propagating in an unconfined magnetic medium. The dynamic magnetization $m(x,t)$ describing the packet can be written as $m(x,t) = f(x - v_g t)\exp(i\varphi(x,t))$ with $\varphi(x,t) = 2\pi\nu t - kx - \varphi_a(x)$, where f is the envelope function and $\varphi_a(x)$ is an additional phase chirp due to nonlinear effects. One can characterize a propagating soliton by its phase as a whole, for example, at the maximum point of the envelope function: $\varphi(t) = \varphi(x,t)$ for $x = v_g t$. Since the group velocity of a wave can differ from the phase velocity (this is usually the case for spin waves) the defined phase is time dependent, that is, it changes constantly while the soliton is propagating.

As a model system for experimental study of the symmetry-breaking modes, an active nonlinear ring based on spin-wave propagation in a narrow magnetic YIG film waveguide was constructed (see Figure 17). A magnetic field of 1870 Oe is applied parallel to the direction of the spin-wave propagation, realizing the BVMSW geometry corresponding to the waves with an attractive nonlinearity. Therefore, one can expect that the nonlinear eigenmode spectrum of the ring consists of sets of soliton-like wave packets (Carr, Clark and Reinhardt, 2000). A YIG film of 7 μm thickness, 1.5-mm width, and 40-mm length, forms a waveguide. Two short-circuited microstrip antennae for the excitation and detection of spin waves are attached to the film at a distance $l = 8$ mm apart from each other. A linear electronic amplifier, which connects the output and input antennae, compensates the damping of the waves and maintains unidirectionality of the ring, its gain is chosen in such a way that the system is below the self-generation threshold if the phase-sensitive amplifier discussed in the following text is disabled. In the linear regime, that is, for low gains, the ring shows a series of resonant eigenmodes with frequencies in the interval 7.25–7.30 GHz, spaced by $\Delta\nu = 3.2$ MHz, and wave vectors $k = 100$–$150\,\mathrm{cm}^{-1}$. The exact frequencies of the modes are determined by the phase matching condition: $kl = 2\pi n$ with integer n. The time for a full circuit around the ring is $T_0 = 310$ ns.

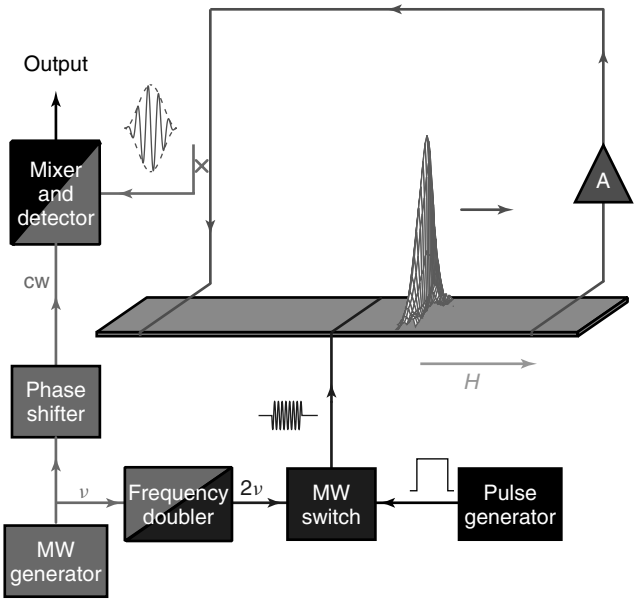

Figure 17. Schematic layout of the active ring for observation of nonlinear symmetry-breaking modes. The ring consists of the film, two antennae, and the linear microwave amplifier (A). Nonlinear modes of the ring are filtered using parametric pumping at double frequency at the position of the center antenna (as described in the text). The ring and the microwave components working at frequency ν are shown in red. The components working at frequency 2ν are shown in blue. The directional coupler, the phase shifter, and the mixer with detector are used for phase-sensitive detection of the modes by mixing them with a continuous wave (CW) reference signal. (From Demokritov *et al*., 2003.)

For the investigation of nonlinear eigenmodes of the ring, it is necessary to have a selection mechanism to individually address each eigenmode. One widely employed approach is the use of a critical threshold mechanism: only the mode with the largest amplification gain is generated at the expense of all others (Agrawal, 1994). Another approach is the use of phase-selective amplifiers, which allows only the modes having a well-defined preset phase at the location of the amplifier in the ring to exist in the active ring. To achieve phase-selective amplification, the technique of parametric parallel pumping is used. A sufficiently strong microwave field with frequency 2ν can parametrically amplify a spin-wave packet of frequency ν (Bagada, Melkov, Serga and Slavin, 1997; Kolodin *et al*., 1998). The pumping microwave field is sent to a microstrip resonator attached to the film centered between the two antennae as shown in Figure 17. For a narrow pumping area, that is, if $k\delta \ll 2\pi$, where δ is the width of the pumping area, the amplification gain is phase sensitive (Melkov *et al*., 2001). Figure 18 illustrates the phase dependence of such an amplification: waves having phases $\pi/4 + n\pi$ with respect to the pumping field are amplified most efficiently. Using this amplification, one

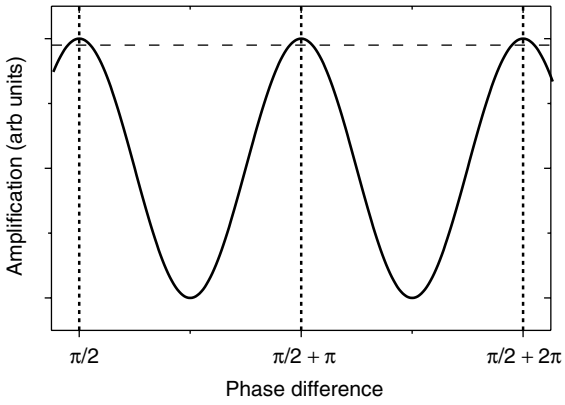

Figure 18. Amplification coefficient of the parametric amplifier as a function of the difference between the phase of the spin wave and the pumping field.

needs to compensate the losses in the ring as shown in the figure by the horizontal dash line. Only the modes having their phases close to the maxima of the amplification coefficient will survive in the ring.

In the experiment, the amplification of the electronic amplifier is chosen in such a way that no nonlinear modes are observed without parametric pumping. Then, the pumping is applied as a single microwave pulse with the duration $\tau = 15{-}35$ ns. Such a pumping results in the creation of a single soliton-shaped microwave packet circulating in the ring. Figure 19 showing the signal detected by the output antenna illustrates the development of the packet in the ring. The packet circulates in the ring with the period T_0, and its amplitude is slowly decreasing. As seen in Figure 19,

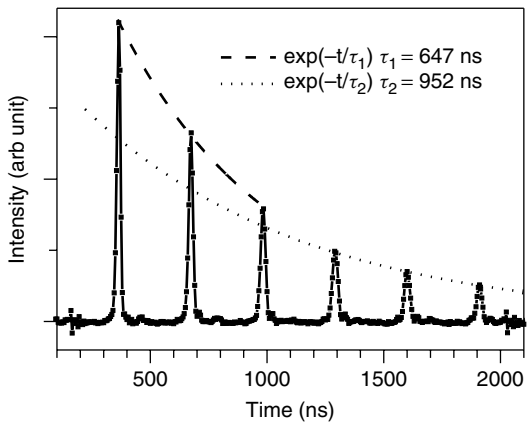

Figure 19. Waveform of a nonlinear wave packet created in the ring by a single pumping pulse. The decay of the packet intensity is due to damping in the magnetic film, which is partially compensated by the electronic amplifier. The soliton nature of the packet is confirmed by a smaller decay time (τ_1) of the packet amplitude with respect to that (τ_2) of the linear packets. (Demokritov, Serga and Hillebrands, unpublished.)

the decay of the amplitude during the first rounds is much faster than that for the small amplitude, confirming the soliton nature of the pulse. More exact analysis of Figure 19 also shows that the wave packet increases its width while decreasing its intensity as one expects from the soliton theory (Remoissenet, 1999). Thus, based on the preceding discussion, one can conclude that the created wave packet has soliton properties, at least during the first two rotations over the ring when the intensity of the wave packet is large enough. By applying pumping pulses periodically, one can keep the intensity of the packet in the soliton regime constant.

Figure 20 illustrates the waveforms of the detected eigenmodes with the curve (a) showing the waveform of the pumping field as a reference. By sweeping the frequency in a narrow interval of 20 MHz, several nonlinear eigenmodes are subsequently observed. Without phase analysis, all modes detected at different frequencies are undistinguishable and consist of a series of soliton-like pulses spaced in time by the time interval T_0 (curve b). The phase-detection technique reveals, however, two different types of single-soliton modes. First, there are soliton modes that keep their phase after traveling around the ring, as demonstrated by the curve (c). They are labeled 'N' for 'normal solitons', since they do not break the phase matching condition. Second, there are soliton modes with the phase difference of π between the two subsequent detections of the soliton, as demonstrated by the curve (d). These modes need to travel twice about the ring to meet the initial phase condition. Since they remind one of the well-known Möbius strip, they are labeled 'M' for 'Möbius mode'. The waveform of the M mode can be reversed by changing the continuous wave (CW) reference phase as shown by the curve (e). Both normal and Möbius modes are observed alternatively at different carrier frequencies, ν_N and ν_M, with $\nu_N - \nu_M = 1.6\,\text{MHz}$, that is, $\Delta\nu/2$. The physical nature of the N modes is easily understood: a soliton is propagating about the ring with the closed-loop phase shift of $2\pi n$. Each of these normal soliton modes has a counterpart among the linear excitations. In a Möbius mode the soliton acquires a phase shift of $2\pi(n + 1/2)$ per loop, that is it breaks the phase matching condition. For this reason it cannot have a counterpart among the linear modes.

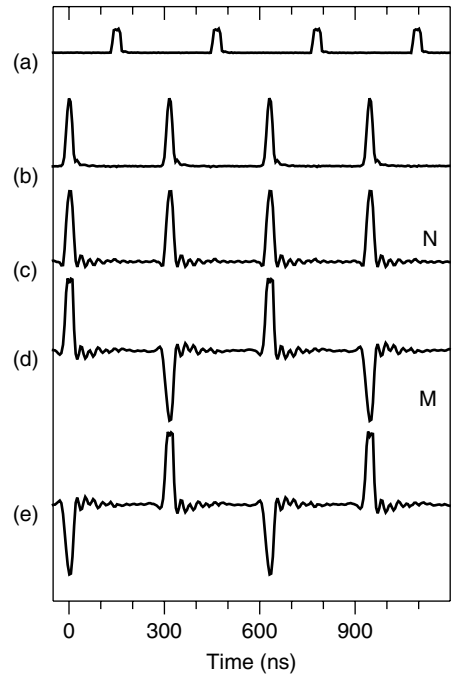

Figure 20. Waveforms of the one-soliton modes observed in the ring, $T_p = T_0$; (a) waveform of the pumping field, (b) waveform of a nonlinear mode obtained without phase-sensitive detection, (c) and (d) waveforms of normal and Möbius modes detected using phase sensitive detection, respectively, (e) is the same as (d) with the phase of the reference wave shifted by π. (From Demokritov *et al*., 2003.)

The possible existence of Möbius modes, that is, eigenmodes with a phase shift per loop that is different from an integer multiple of 2π has not been considered by Carr, Clark and Reinhardt (2000). Instead, soliton modes comprising several solitons and the mutual phase relations between those solitons are discussed in Carr, Clark and Reinhardt (2000). Eigenmodes consisting of several soliton-like wave packets can be also found in the experiment. This happens if the repetition period of the pumping pulses, T_p is a fraction of T_0. Figures 21 and 22 illustrate the cases $T_p = T_0/2$ and $T_p = T_0/3$, that is, a mode with two/three equally spaced solitons rotating in the loop. Similar to Figure 20, the top curves demonstrate the pumping waveforms, while the other curves are the measured waveforms of the different modes detected by phase analysis. The numbers adjacent to the curves in Figure 21 numerate the corresponding values of the mode frequencies in units of GHz. The two vertical dashed lines indicate the time interval T_0, which each of the solitons needs to complete the loop. For $T_p = T_0/2$ one observes two normal modes and one Möbius mode. Although the two normal modes are not completely degenerate, their frequency separation is much smaller than $\delta\nu$. The difference between the Möbius mode and both the normal modes, $\nu_N - \nu_M$, is close to $\Delta\nu/2 = 1.6\,\text{MHz}$. By sweeping the frequency, alternating normal and Möbius modes appear, as demonstrated by the curve at 7.2687 GHz, which, with respect to the observed signal, is identical to the curve at 7.2855 GHz, but separated from the latter in frequency by the amount $\Delta\nu$. As seen in Figure 22, two normal modes and two Möbius modes are found for $T_p = T_0/3$. Again, alternating normal and Möbius modes are observed with the same frequency interval. To summarize these findings: The phase sensitivity of the parametric pumping process constitutes a phase selection rule for the allowed eigenmodes of the ring. The modes with

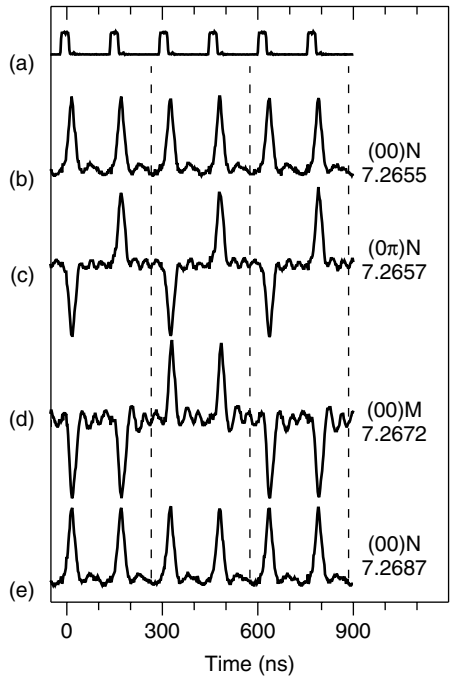

Figure 21. Waveforms of the two-soliton modes observed in the ring, $T_p = T_0/2$; (a) waveform of the pumping field, (b), (c), (d), and (e) waveforms of different modes with the numbers being the frequency of each mode in units of GHz (from Demokritov *et al*., 2003). (The mode nomenclature is explained in the text).

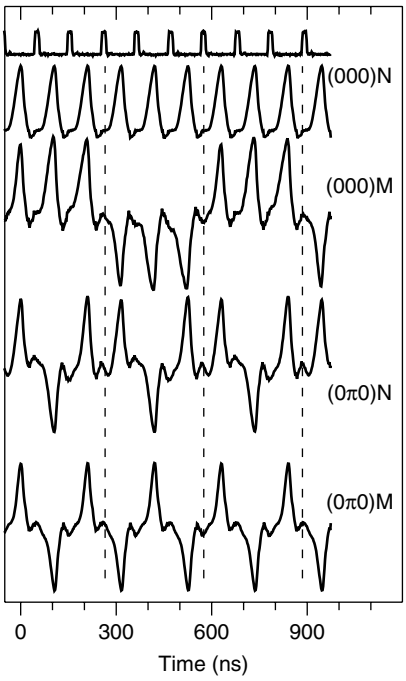

Figure 22. Waveforms of the three-soliton modes observed in the ring, $T_p = T_0/3$; waveforms of the pumping field and of the observed modes (from Demokritov *et al*., 2003). (The mode nomenclature is explained in the text).

phase shifts per loop of $2\pi n$ and $\pi + 2\pi n$ can survive in the ring.

In order to classify the multisoliton modes found, the soliton phase relative to the phase of an arbitrary chosen soliton, which we set to zero without loss of generality, is quoted. A soliton having the same phase will be indicated by '0', one with a phase difference of π, by 'π'. The suffixes 'N' and 'M' for normal and Möbius modes are added. For $T_p = T_0$ only two one-soliton modes exist, a normal mode, (0)N, and a Möbius mode, (0)M. In the case of two-soliton modes one finds, using combinatorics, four possible combinations: (00)N, (0π)N, (00)M, and (0π)M. However, the last two modes are physically identical, as they can be transferred into each other by shifting the origin of the timescale by $T_0/2$. According to Carr, Clark and Reinhardt (2000) some of the N eigenmodes are expected to have broken symmetry, since they cannot evolve monotonously from their linear counterparts. It is found that the (00)N mode has a linear counterpart, while the ($0\,\pi$)N mode has the predicted broken symmetry. A similar analysis for $T_p = T_0/3$ predicts the existence of four nonequivalent three-soliton modes: (000)N, ($0\pi 0$)N, (000)M, and ($0\pi 0$)M. All these modes are observed in the experiment, as demonstrated in Figure 22.

As a conclusion to this section, one should point out that the observation of the symmetry-breaking nonlinear modes is of fundamental importance for nonlinear physics. It opens a new way to create nonlinear objects with new symmetry properties forbidden for linear excitations. As a generalization of the observed Möbius solitons, one can imagine fractal solitons, acquiring the phase shift per loop of $\pi/3$, $2\pi/3$, and so on.

6 STANDING SPIN-WAVE BULLET GENERATED BY SPIN-POLARIZED CURRENT

In the previous sections we discussed nonlinear dynamics of one- and two-dimensional spin-wave packets that were linearly excited by a microwave input signal or self-generated in an active ring containing ferrite (YIG) film, or parametrically excited by the microwave field of double-frequency pumping.

In this section we demonstrate that the nonlinear properties of two-dimensional spin-wave bullets play a critically important role in the process of spin-wave excitation by a spin torque created by spin-polarized current traversing a thin in-plane magnetized film made of a ferromagnetic metal.

It was theoretically predicted (Slonczewski, 1996; Berger, 1996) and experimentally observed (Tsoi *et al*., 1998; Rippard, Pufall and Silva, 2003; Rippard *et al*., 2004a,b; Kiselev

et al., 2003) that spin-polarized current passing through a thin magnetic film ('free' layer of a magnetic layered structure) can excite microwave magnetization oscillations in this layer. A *spatially uniform nonlinear* theory explaining many experimentally observed features of this phenomenon was developed in a series of theoretical papers (Slonczewski, 1999; Rezende, de Aguiar and Azevedo, 2005; Slavin and Kabos, 2005; Bertotti *et al*., 2005). Although it was clear from experiments that the excitation of microwave oscillations has a threshold character (i.e., it is observed for sufficiently large currents $I > I_{\rm th}$), and that the frequency of the excited spin-wave mode is close to the natural FMR frequency of the system, the exact nature of the dynamic mode excited at the threshold in a magnetic nanocontact was not determined in Slonczewski (1999), Rezende, de Aguiar and Azevedo (2005), Slavin and Kabos (2005), Bertotti *et al*. (2005). This is especially true in the case of current-driven nanocontacts (Tsoi *et al*., 1998; Rippard, Pufall and Silva, 2003; Rippard *et al*., 2004a,b) where magnetic layers are not bound in plane, and there are no lateral reflective boundaries that could create an effective magnetic resonator (like in the case of nanopillars, Kiselev *et al*. (2004)).

The most complete theoretical analysis of the nature of the spin-wave eigenmode excited by spin-polarized current in a nanocontact geometry was performed by Slonczewski (1999). He developed a *spatially nonuniform linear* theory of spin-wave excitations in a nanocontact, where the 'free' ferromagnetic layer is infinite in plane, while the spin-polarized current traversing this layer has a finite cross section, $S = \pi R_{\rm c}^2$, where $R_{\rm c}$ is the contact radius. Considering a perpendicularly magnetized nanocontact and using a linearized Landau–Lifshitz equation, Slonczewski was able to show that in the *linear* case the lowest threshold of excitation by spin-polarized current is achieved for an exchange-dominated cylindrical spin-wave mode having frequency determined by equation (24) with wave number $k = k_0 \simeq 1.2/R_{\rm c}$ and traveling out of the region of current localization Slonczewski, 1999. Here ω_0 is the FMR frequency and D is the spin-wave dispersion coefficient determined by the exchange interaction and dependent on the direction of the bias magnetic field (see equation (26)).

It was also shown that the threshold current $I_{\rm th}$ in such a geometry consists of two additive terms: the first one arises from the radiative loss of energy carried by the propagating spin wave out of the region of current localization, while the second one is caused by the usual energy dissipation in the current-carrying region:

$$I_{\rm th}^{\rm lin} \simeq 1.86 \frac{D}{\sigma R_{\rm c}^2} + \frac{\Gamma(H)}{\sigma} \qquad (37)$$

Here, the spin-polarization efficiency σ is given by equation (6) and $\Gamma(H)$ is the spin-wave damping, dependent on the bias magnetic field H. We note that the preceding results of the linear analysis are valid for an arbitrary magnetization orientation if one uses the appropriate expressions for the frequency ω_0 and spin-wave dispersion coefficient D.

For a typical nanocontact of radius $R_{\rm c} \sim 20$–30 nm, the radiative losses are about 1 order of magnitude larger than the direct energy dissipation and should make the main contribution to the threshold current. This result, however, contradicts experimental observations (see, e.g., Rippard, Pufall and Silva, 2003): the experimentally measured magnitude of the threshold current in an in-plane magnetized nanocontact is much smaller than the value predicted by equation (37), although the dependence of this current on the magnetic field H is satisfactory described by this equation.

In this section, following Slavin and Tiberkevich (2005), it is shown that in an in-plane magnetized magnetic film the competition between the nonlinearity and exchange-related dispersion leads to the formation of a stationary two-dimensional self-localized nonpropagating spin-wave mode – standing spin-wave bullet. This bullet is very similar in its structure to the propagating self-localized spin-wave bullets observed on YIG films and discussed in detail in the previous sections of this chapter. The frequency of this standing spin-wave 'bullet' is shifted *below* the spectrum of linear spin waves by the nonlinearity and, therefore, this nonlinear mode has an evanescent character with vanishing radiative losses, which leads to a substantial decrease of its threshold current $I_{\rm th}$ in comparison with the linear propagating mode (equation (37)).

It was demonstrated in Section 2 that the equation describing the amplitude $b(r, t)$ of a spin-wave mode excited by spin-polarized current I in a free layer on an in-plane magnetized magnetic nanocontact can be written in the form of equation (25), where $\omega_0 \equiv \sqrt{\omega_H(\omega_H + \omega_M)}$ is the linear FMR frequency ($\omega_H \equiv \gamma H$, $\omega_M \equiv 4\pi\gamma M_0$, and γ is the gyromagnetic ratio), $D = (2\gamma A/M_0)(\omega_H + \omega_M/2)/\omega_0$ is the dispersion coefficient for spin waves (A is the exchange stiffness), Δ is the two-dimensional Laplace operator in the film plane, $N = -\omega_H\omega_M(\omega_H + \omega_M/4)/\omega_0(\omega_H + \omega_M/2)$ is the coefficient describing nonlinear frequency shift, and $\Gamma \equiv \alpha_{\rm G}(\omega_H + \omega_M/2)$ is the spin-wave damping rate ($\alpha_{\rm G}$ is the dimensionless Gilbert damping parameter). The dimensionless function $f(x)$ describes the spatial distribution of the spin-polarized current. The dimensionless spin-wave amplitude b is connected with the z component of the magnetization by the equation $|b|^2 = (M_0 - M_z)/2M_0$. Equation (25) differs from equation (9) in Slonczewski (1999) (which resulted in the solution (37)) by the presence of two additional nonlinear terms: the term containing the coefficient N and describing a nonlinear frequency shift of

the excited mode, and the last term describing the current-induced positive nonlinear damping that stops the increase of the amplitude of the excited mode at relatively large currents. Also, since the equation (25) was obtained as a Taylor expansion, it is literally correct only for sufficiently small spin-wave amplitudes $|b| < 1$.

Without damping and current terms ($\Gamma = 0$, $I = 0$) equation (25) coincides with the well-known $(2 + 1)$-dimensional NSE (see Akhmediev and Ankiewicz (1997) and equation (28)) written in a cylindrical coordinate system where dispersion and diffraction coefficients are equal to each other, $S = D$, because of the axially symmetric character of the exchange-dominated spin-wave spectrum of a very thin magnetic 'free' layer. In the considered case of an in-plane magnetized film, the nonlinear coefficient N is negative, and the nonlinearity and dispersion satisfy the well-known Lighthill criterion $ND < 0$ (Lighthill, 1965), and the NSE has a nonlinear self-localized radially symmetric standing solitonic solution (or the solution in the form of a *standing spin-wave bullet*)

$$b(t, r) = B_0 \psi(r/\ell) e^{-i\omega t} \tag{38}$$

where the dimensionless function $\psi(x)$, having maximum value of 2.2 at $x = 0$, describes the profile of the bullet. This function is the localized solution of the equation

$$\psi'' + \frac{1}{x}\psi' + \psi^3 - \psi = 0 \tag{39}$$

which has to be found numerically (see e.g., Chiao, Garmire and Townes, 1964; Silberberg, 1990).

In equation (38), B_0, ℓ, and ω are the characteristic amplitude, characteristic size, and frequency of the bullet, respectively. Among these three parameters only one is independent. Taking the amplitude B_0 as an independent parameter, we can express the two other parameters as

$$\omega = \omega_0 + N B_0^2, \quad \ell = \frac{\sqrt{|D/N|}}{B_0} \tag{40}$$

We would like to stress that the frequency of the spin-wave bullet lies *below* the linear frequency ω_0 of the FMR (see equation (40), and note that $N < 0$), that is, outside the spectrum of linear spin waves. This is the main reason for the self-localization of the spin-wave bullet, as the effective wave number of the spin-wave mode with the frequency given in equation (40) is purely imaginary. It also follows from equation (38) and the Taylor expansion condition $|b| < 1$, that the maximum magnitude of B_0 for which the perturbative approach is still correct is $B_0 = 0.46$.

It is well known (Akhmediev and Ankiewicz, 1997) that the bulletlike solutions of $(2 + 1)$-dimensional NSE are unstable with respect to the small perturbations: the wave packets having the bullet shape (38) but amplitudes smaller than B_0 decay because of the dispersion spreading, while the wave packets having amplitudes higher than B_0 collapse because of the nonlinearity. At the same time, equation (25) with both Gilbert dissipation Γ and current I is a two-dimensional analog of a Ginzburg–Landau equation that is known to have stable localized solutions Aranson and Kramer, 2002. In the particular case of an in-plane magnetized nanocontact, the current-induced terms in equation (25) might stabilize spin-wave bullets and might prevent them from both dispersion spreading and nonlinear collapse. One can assume that for a small damping rate Γ and current I the full nonconservative equation (25) can have a bulletlike solution, only slightly different from the exact solution, equation (38), of the conservative NSE equation.

In was shown in Slavin and Tiberkevich (2005) that equation (25), indeed, has a *stable* bullet solution if the bullet amplitude B_0 satisfies the following equation

$$\frac{\sigma I}{\Gamma} = \frac{1.86}{\eta_2(q B_0) - B_0^2 \eta_4(q B_0)} \tag{41}$$

where

$$q \equiv \sqrt{\left| \frac{N}{D/R_c^2} \right|} \tag{42}$$

is the parameter describing the strength of nonlinearity relative to exchange-originated dispersion for the nanocontact of radius R_c, and the function $\eta_n(q B_0)$ is defined as

$$\eta_n(q B_0) \equiv \int_0^\infty f(x/q B_0) \psi^n(x) x \, dx \tag{43}$$

This equation implicitly defines the amplitude B_0 (and, therefore, frequency ω and size ℓ) of the stationary bullet as a function of the system parameters ($\sigma I/\Gamma$ and q). On the other hand, equation (41) can be interpreted as an equation that defines a current magnitude, I, which is necessary to support a stationary spin-wave bullet of amplitude B_0.

The dependence of the normalized bias current $\zeta(B_0) = I(B_0)/I_{\min}$ (where $I_{\min} \equiv \Gamma/\sigma$) for two values of the nonlinearity factor q is shown in Figure 23 for the case of a steplike current distribution ($f(x) = 1$ if $x < 1$ and $f(x) = 0$ otherwise). This dependence has a clear minimum corresponding to the amplitude $B_0 = B_{\text{th}}$ of a bullet formed at the threshold of microwave generation by spin-polarized current. Note that the normalized current $\zeta(B_0)$ shown in Figure 23 was denoted as 'supercriticality' ζ in the spatially uniform theory (Slavin and Kabos, 2005). Note, also, that all the presented formalisms are technically not applicable in the shaded area

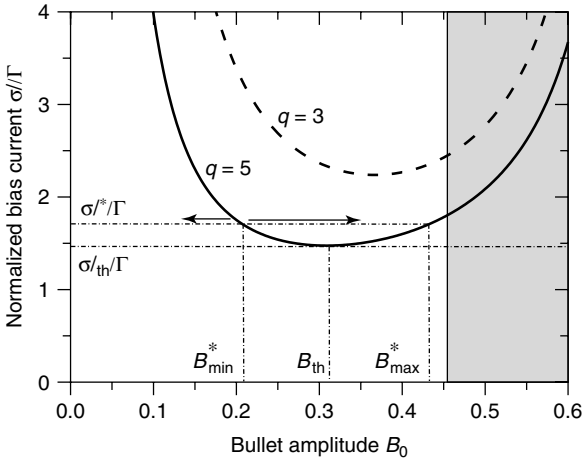

Figure 23. Dependence (41) of the normalized current $\zeta = \sigma I/\Gamma$ on the bullet amplitude B_0 for two values of the nonlinearity factor q: solid line $-q = 5$, dashed line $-q = 3$. Dash-dotted lines indicate the threshold current I_{th}, threshold bullet amplitude B_{th}, and low (B^*_{min}) and high (B^*_{max}) bullet amplitudes for a certain supercritical current $I^* > I_{th}$. The shaded area to the right of the vertical line $B_0 = 0.46$ indicates the region where our perturbative approach is not valid.

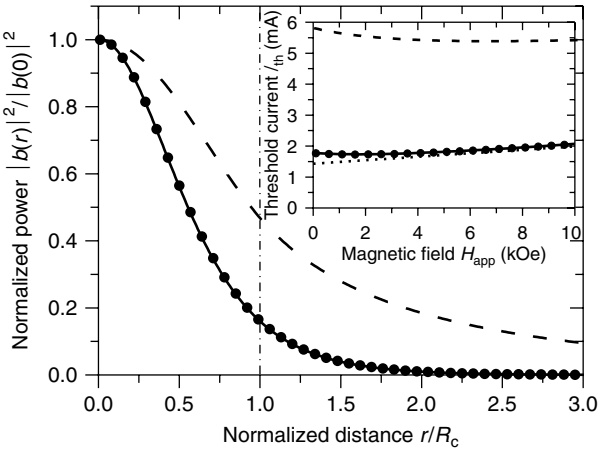

Figure 24. Normalized profiles of the spin-wave mode generated by spin-polarized current at the threshold: solid line – bullet profile (38), circles – result of the numerical solution of equation (25), dashed line – profile of the linear eigenmode calculated from the *linearized* equation (25). The vertical dash-dotted line shows the region of current localization. The inset shows the dependence of the threshold current I_{th} on the applied magnetic field H_{app}: solid line – nonlinear bullet equation (41), dashed line – Slonczewski-like linear mode (37). Dotted line – numerical fit $I\,(\mathrm{mA}) = 1.43 + 0.056\,H_{app}(\mathrm{kOe})$ to the experimental data from. (From Rippard, Pufall and Silva, 2003.)

in the right part of Figure 23 where the Taylor expansion condition $b < 1$ is violated.

The analytical result, equation (41), is heavily based on the assumption that the profile of the spin-wave mode generated at the threshold is approximately the same as the profile of a stationary bullet, equation (38). To check the validity of this assumption, equation (25) was solved numerically. The results of comparison of the spin-wave excitation profiles at the threshold obtained for a typical set of experimental parameters (Rippard, Pufall and Silva, 2003) from the analytical solution equation (38) (solid line) and numerical solution of equation (25) (black dots) are shown in Figure 24.

One clearly sees that the numerical profile of the nonlinear eigenmode is practically indistinguishable from the approximate 'bulletlike' profile, so the 'bullet' model works exceptionally well in this case. For comparison, the spatial profile of the Slonczewski-like (Slonczewski, 1999) linear spin-wave mode is also presented in Figure 24 (dashed line). The amplitude of this linear mode at the threshold is vanishingly small, $|b(r)|^2 \to 0$.

The inset of Figure 24 demonstrates the dependence of the threshold current on the applied magnetic field. One can see that the bullet model gives quantitative description of the threshold current experimentally measured in Rippard, Pufall and Silva (2003) and agrees with experiment much better than the linear threshold equation (37).

Figure 25 demonstrates the comparison of the predictions of the 'bullet' model with the results of the experiment (see

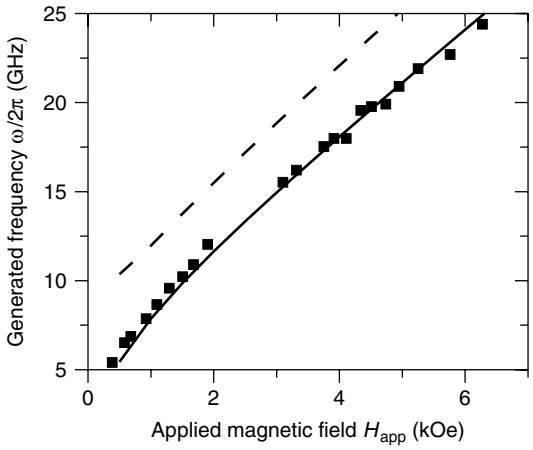

Figure 25. Dependence of the frequency ω, generated at the threshold on the applied magnetic field H_{app}. Solid line – frequency of the nonlinear bullet equation (40), dashed line – frequency of the linear mode (24), symbols – experimental data. (From Rippard *et al*., 2004a.)

Figure 2a in Rippard *et al*. (2004a)) for the magnitude of the spin-wave frequency generated at the threshold as a function of the applied magnetic field. It is again clear that the 'bullet' model gives a quantitative description of the experiment.

We need to mention that the stable bullet solution described above was obtained for the case of the *in-plane*-magnetized magnetic nanocontact. Similar results can be

obtained for the nanocontacts magnetized at such angles to their plane that the nonlinear frequency shift coefficient N is still negative and the Lighthill criterion $ND < 0$ is satisfied (see Figure 8 in Slavin and Kabos (2005) showing the angular dependence of the nonlinear frequency shift coefficient N).

In the case of larger magnetization angles, when $N > 0$ and the Lighthill criterion is not fulfilled, the mechanism of spin-wave self-localization and standing bullet formation described above does not work, and the spin-wave mode excited at the threshold is, most likely, a *propagating* exchange-dominated nonlinear spin wave similar to the one described by the linear solution for a normally magnetized 'free' layer (Slonczewski, 1999). We note, however, that the experiments (Rippard, Pufall and Silva, 2003) show that the measured threshold currents for *normally* magnetized films, for which $ND > 0$ and no standing spin-wave bullets are possible, are also somewhat lower than the values predicted by the linear model (Slonczewski, 1999).

An attempt to create a spatially nonuniform *nonlinear* model of spin-wave excitation by spin-polarized current in a normally magnetized magnetic nanocontact was undertaken in Hoefer *et al*. (2005). Unfortunately, the theoretical results obtained in Hoefer *et al*. (2005) failed to give a quantitative description of the experiments (Rippard *et al*., 2004a,b) for practically reasonable values of the polarization efficiency $\varepsilon = 0.2–0.3$. A qualitative agreement with experiments was obtained in Hoefer *et al*. (2005) for two *different* and rather unrealistic values of $\varepsilon : \varepsilon = 0.8$ in Figure 3 and $\varepsilon = 0.5$ in Figure 4 of Hoefer *et al*. (2005). Thus, the nature of the spin-wave mode excited by spin-polarized direct current in a normally magnetized magnetic nanocontact remains an open question that requires additional investigation.

7 CONCLUSION

In conclusion, stable one-dimensional spin-wave envelope solitons and quasistable two-dimensional spin-wave bullets are, indeed, the natural, intrinsic nonlinear excitations of the dynamic magnetization in magnetic films. The shape and properties of these nonlinear spin-wave modes are practically independent of the method of their excitation and are determined by the dispersive, diffractive, and nonlinear properties of the film. Spin-wave bullets, being unstable in a lossless medium, can be temporarily stabilized by linear dissipation and can propagate for significant distances of several millimeters without substantially changing their shape. Propagating spin-wave solitons and bullets can be self-generated from noise in active rings containing ferrite films and can be parametrically generated and amplified.

The detailed study of the properties of these self-generated nonlinear modes performed using the BLS technique led to experimental discovery of the novel type of symmetry-breaking nonlinear wave excitations – Möbius solitons.

Finally, we demonstrated theoretically that the lowest threshold of spin-wave excitation in an *in-plane* magnetized magnetic nanocontact driven by spin-polarized current is achieved for a two-dimensional nonlinear self-localized spin wave mode – *standing spin-wave bullet*, stabilized by the combined influence of the natural and current-induced nonlinear dissipation.

Thus, the two-dimensional nonlinear self-localization of spin-wave packets, discovered in our previous work for spin waves propagating in ferrite films, turned out to be very important in the process of excitation of nonpropagating evanescent spin-wave modes by spin-polarized current in ultrathin metallic ferromagnetic films.

We believe that the summarized results demonstrate the general nature of multidimensional nonlinear wave excitations described by the NSE (28) and the Ginzburg–Landau equation (25) and will be interesting and important for the investigation of nonlinear wave dynamics in other (e.g., optical) physical systems.

Theory of Spin-transfer Torque

Mark D. Stiles
National Institute of Standards and Technology, Gaithersburg, MD, USA

1 INTRODUCTION

The observation of giant magnetoresistance (Baibich *et al*., 1988; Binasch, Grünberg, Saurenbach and Zinn, 1989) in multilayers of magnetic metals separated by nonmagnetic metals established that electric current in these magnetic multilayers is spin polarized. Eight years later, Slonczewski (1996) and Berger (1996) showed that the angular momentum carried by the spin-polarized current between the magnetic layers exerts torques on the magnetizations. They predicted that when the current is large enough, these *spin-transfer* torques can cause reversal and precession of the magnetization. This prediction has been confirmed in a number of laboratories and in a number of different sample geometries including mechanical point contacts (Tsoi *et al*., 1998; Ji, Chien and Stiles, 2003), lithographically defined point contacts (Myers *et al*., 1999; Rippard, Pufall and Silva, 2003), electrochemically grown nanowires (Wegrowe *et al*., 1999), manganite junctions (Sun, 1999), lithographically defined nanopillars (Katine *et al*., 2000; Grollier *et al*., 2001; Mancoff and Russek, 2002; Urazhdin, Birge, Pratt and Bass, 2003; Özyilmaz *et al*., 2003; Lee *et al*., 2004b; Hayakawa *et al*., 2004; Covington *et al*., 2004; Jiang *et al*., 2004), tunnel junctions (Liu, Zhang, Freitas and Martins, 2003; Huai *et al*., 2004; Fuchs *et al*., 2004; Deac *et al*., 2004), and semiconductor structures (Moriya, Hamaya, Oiwa and Munekata, 2004).

There has been a great deal of research both exploring the variety of behaviors exhibited by these systems and testing the possible explanations that have been offered. Some of these efforts are described in **Spin Angular Momentum Transfer in Magnetoresistive Nanojunctions, Volume 5**, **Microwave Excitations in Spin Momentum Transfer Devices, Volume 5**, and **Spin-transfer in High Magnetic Fields and Single Magnetic Layer Nanopillars, Volume 5**. Spin-transfer torques are not only interesting scientifically but are also potentially important in some commercial applications. In existing implementations of magnetic random access memory (MRAM), bits are switched by the magnetic fields caused by current pulses. This method of switching severely constrains the fabrication of the bits because the magnetic fields are not well localized. The possibility that the bits could be directly addressed and switched by a polarized current is one promising application of spin-transfer torques. Another possible application is based on using the rapid precession observed in these multilayers under suitable conditions. The high frequency oscillating resistance suggests the use of these systems as current controlled high-frequency oscillators (see also **Microwave Generation in Magnetic Multilayers and Nanostructures, Volume 2** for more details). On the other hand, in read heads with perpendicular current flow, precession interferes with the operation of the heads by creating an unwanted noise source. Thus, for some applications, it is desirable to

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*.

understand how to optimize these effects and for others how to minimize them.

Giant magnetoresistance is the dependence of the resistance of a magnetic multilayer on the orientation of the magnetizations in neighboring ferromagnetic layers (see also **Enhanced Magnetoresistance, Volume 1**). Thus, it provides a mechanism for inferring the relative orientations of the magnetizations in a multilayer simply by measuring the resistance. When spin transfer torques change the magnetic configuration of the structure, the resistance of the structure changes as well. To detect these torques, typically one layer, called the *free layer*, responds to the spin-transfer torques, and the other, called the *fixed layer*, is constructed in a way so that it does not. Thus, when the current rotates the magnetization of the free layer, the resistance of the multilayer changes. In the precessing state, a constant input current gives a rapidly varying voltage owing to the time variation in the resistance.

All of the devices studied share some common geometrical attributes, starting with the fact that the current flows perpendicularly to the magnetic layers. Spin-transfer torques are interfacial (see subsequent text) so the free layer is kept thin, usually 3–6 nm thick, because the current necessary to move the magnetization from its ground state is proportional to this thickness. Typically, the fixed layer is much thicker than the free layer so it responds less strongly to the current-induced torques. Cross-sectional dimensions are commonly on the order of 100 nm because of the high current density necessary to move the magnetization. There are two reasons. First, the heating generated by this current density needs to be tied to a relatively large heat sink. Second, the torques due to the current-induced magnetic field become less important as the cross-sectional area decreases.

Tsoi *et al*. observed spin-transfer torques using a point contact to a magnetic multilayer in a high applied magnetic field (Tsoi *et al*., 1998). The signature of a spin-transfer torque in their measurement was the observation of peaks in the differential resistance, peaks that appeared only for one direction of current flow. These peaks were interpreted as evidence of a precessing state. Shortly thereafter, measurements on lithographically defined samples, point contacts by Myers *et al*. (1999) and nanopillars by Katine *et al*. (2000), showed both a similar peak, asymmetric in the current, in high applied magnetic fields, and hysteretic switching between parallel and antiparallel states at lower fields. The crossover field between these behaviors is roughly the zero-current coercive field. The switching was attributed to spin-transfer torques because the behavior was asymmetric. For large currents of electrons flowing from the fixed layer to the free layer, the parallel state was stable, whereas for large currents in the opposite direction, the antiparallel state was stable. If the current-induced switching were due to the magnetic fields produced by the current, the stable state in high currents would be independent of the direction of current flow.

High-frequency measurements of resistance provided more data to interpret the origin of the peak in the differential resistivity at high fields and currents. Urazhdin, Birge, Pratt and Bass (2003) showed that rapid fluctuations between two states with different resistances give rise to peaks in the differential resistance. The dwell times in each state depended strongly on current, so that with increasing current there was a rapid transition from spending most of the time in the low-resistance state to spending most of the time in the high-resistance state. This rapid and reversible rise in the resistance leads to a peak in the differential resistance. Shortly thereafter, measurements at still higher frequencies by Kiselev *et al*. (2003) and Rippard *et al*. (2004a) demonstrated the existence of precession for currents and fields close to the peak, but not clearly associated with it. They observed sharp peaks in the power spectrum density, a measure of the frequency dependent resistance in the devices, characteristic of precession. In some cases, these peaks were extremely sharp, with dimensionless quality factors, $Q \approx 18\,000$ (Rippard *et al*., 2004b). Krivorotov *et al*. (2004) observed the precession through real-time measurements of the resistance and even measured the few precession periods the system undergoes on the way to reversal in lower applied fields.

Finite sample temperatures add additional complications. For low applied fields, the hysteretic switching depends on the measurement time, or the rate at which the field or current is swept (Myers *et al*., 2002). The observed two-level switching is also strongly temperature dependent. There have been a number of studies of this and the associated low frequency noise (Tsoi *et al*., 1998; Myers *et al*., 2002; Urazhdin, Birge, Pratt and Bass, 2003; Fabian *et al*., 2003; Pufall *et al*., 2004). Sometimes the power spectrum density has the Lorentzian form expected for two-level switching, but frequently the low frequency noise has a more general form.

A number of experiments have tested qualitative and quantitative predictions of the models used to describe these systems. The dependence of the switching currents on the thicknesses of the layers confirm that the spin-transfer torque is interfacial (Albert *et al*., 2002). The dependence of the switching current on the angle of the applied field relative to the easy axis of the free layer shows the expected increases as the field becomes perpendicular (Mancoff *et al*., 2003). Comparisons between calculated and measured 'phase diagrams' (Katine *et al*., 2000; Kiselev *et al*., 2004; Koch, Katine and Sun, 2004) in which the behavior of the system is measured as a function of current and applied field show that the models qualitatively reproduce the measurements. For devices that are symmetric, the asymmetric behavior that typically is a signature of the spin-transfer torque becomes symmetric in current, as expected (Tsoi, Sun and Parkin, 2004). Studies of the material dependence show

the expected reduction of switching currents with decreasing saturation magnetization (Pufall, Rippard and Silva, 2003). By choosing appropriate and different materials for each magnetic layer, it is possible to make a device in which the state with antiparallel magnetizations has the lowest resistance, the so called *inverse giant magnetoresistance*. Studies of spin-transfer torques using these material systems (AlHajDarwish *et al*., 2004) show that the stability of the parallel and antiparallel states depends mainly on the properties of the fixed layer, and only weakly on those of the free layer. Again, this result is consistent with the theoretical models described in the subsequent text.

The rest of the chapter describes the theoretical developments put forth to predict and explain the observed behavior. Section 2, reviews spin transport in systems with collinear magnetizations. These calculations show how the current in the nonmagnetic layers becomes spin polarized and what determines how large the polarization is in different devices. However, the magnetizations must be noncollinear for spin-transfer torques to play a role. To understand these torques, it is necessary to calculate the behavior of individual electrons scattering from interfaces with their spin noncollinear with the magnetization, as described in Section 3. Section 4 combines the transport calculations and the scattering calculations to give calculations of the torque as a function of the device geometry and the orientations of the magnetization. The consequences of these torques on the dynamics is briefly discussed in Section 5.

2 COLLINEAR TRANSPORT

The theory of spin transport near interfaces started with Aronov (1976). A macroscopic theory was described by Johnson and Silsbee (1987) and van Son, van Kempen and Wyder (1987) and derived from the Boltzmann equation by Valet and Fert (1993). The history of these developments is discussed in a review article by Žutić, Fabian and Das Sarma (2004). This section discusses charge and spin transport in magnetic multilayers with collinear magnetizations, starting with a single interface between a ferromagnet and a nonmagnet. The results for single interfaces combine to give results for more complicated structures, including the structure of principle interest in this chapter, two ferromagnetic layer separated by a nonmagnetic layer embedded in a nonmagnetic host. The differences in the transport for parallel and antiparallel magnetizations of the two layers gives the giant magnetoresistance.

The negative charge of the electron is a potential source of confusion. For example, charge currents move oppositely to number (and spin) currents. Additionally, the electron's magnetic moment is opposite to its spin, leading to several more possibilities for confusion (Jonker, Hanbicki, Pierce and Stiles, 2004). In this chapter, these issues are addressed by avoiding charge and magnetization and working instead with number densities and currents and spin densities and currents. Multiplying the number current by $-e$ gives the charge current; e is positive by convention. Similarly, multiplying the spin density by $g\mu_B/\hbar$ gives the magnetization density. For free electrons, $g_e \approx -2.002319$. In transition-metal ferromagnets, in which the orbital moment is largely quenched, the g-values are close to -2. In the examples discussed in the subsequent text, one of the magnetic layers has its magnetization in the $-\hat{\mathbf{z}}$ direction, so that the spin density is in the $\hat{\mathbf{z}}$ direction. Majority electrons, referred to as 'spin up', have their spins aligned parallel to the spin density and minority electrons, referred to as 'spin down', antiparallel. The symbols $\uparrow$ and $\downarrow$ refer to majority and minority electrons, respectively.

The main quantities of interest in this section are the spin accumulation and the spin current. The spin accumulation is the excess spin density above the equilibrium amount for each material. For the nonmagnetic material, this is just the spin density itself. The spin current is the net flow of spins. Consider an isolated interface between a nonmagnet and a ferromagnet with a constant and uniform current consisting of electrons flowing from the nonmagnetic layer perpendicularly to the interface into the ferromagnetic layer. Figure 1 shows the behavior of the spin accumulation and the spin current. Far from the interface, both behave as they would in bulk materials. There is no spin accumulation in either material and the spin current is zero in the nonmagnetic material. In the ferromagnet on the other hand, the conductivity for majority electrons, $\sigma_\uparrow$ is greater than that for minority electrons, so the current density is spin polarized. More current is carried by majority electrons compared to minority electrons, $j_\uparrow > j_\downarrow$. The difference

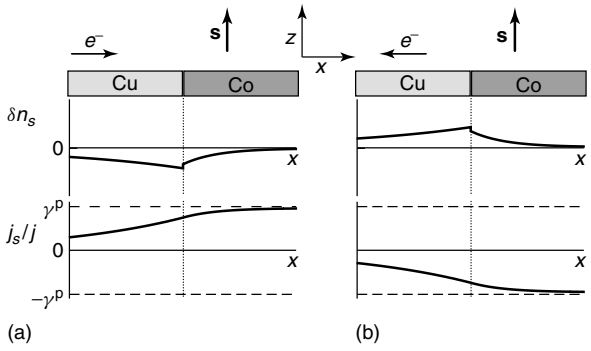

Figure 1. Spin accumulation (δn_s) and spin current (j_s) for electron flow from a nonmagnet into a ferromagnet (a) and vice versa (b). γ^{p} is the polarization of the current in the ferromagnet far from any interfaces. The magnetization in the ferromagnet, **M**, is along the $-\hat{\mathbf{z}}$ direction so that the ferromagnetic spin density **s** is along the $\hat{\mathbf{z}}$ direction.

in the spin dependence of the bulk conductivities between the ferromagnet and nonmagnet means that more majority electrons are extracted from the interface region into the ferromagnet than are delivered to it from the nonmagnet. Thus, a deficit of majority electrons builds up near the interface. Similarly, there is an accumulation of minority electrons near the interface because fewer are extracted into the ferromagnet than are delivered from the nonmagnet.

When the density of spins varies spatially, as it does here, with an excess of minority spins and a deficit of majority spins accumulating near the interface, the spins diffuse in a direction to reduce this variation. Thus, majority electron diffuse into the interface region and minority electrons diffuse away from it. The diffusion of these spins gives rise to the spatially varying parts of the spin current seen in Figure 1. In each material, the spin current for the majority electrons is given by

$$\mathbf{j}_\uparrow = (\sigma_\uparrow/e)\mathbf{E} - D_\uparrow \nabla \delta n_\uparrow \tag{1}$$

where $\delta n_\uparrow$ is the excess density of majority electrons, and $D_\uparrow$ is the spin-dependent diffusion constant, which, like the conductivity $\sigma_\uparrow$, is different in each material. The diffusion constants and the conductivities are related through the Einstein relation $e^2\sigma_\uparrow = D_\uparrow \mathcal{N}_\uparrow$ where $\mathcal{N}_\uparrow$ is the spin-dependent density of states. The density of states also relates the accumulation of each spin to a spin-dependent chemical potential $\delta n_\uparrow = \mathcal{N}_\uparrow \mu_\uparrow$.

The transport equations for majority and minority spins can be combined into an equation describing the net spin current and spin accumulation. The screening length in metals is on the atomic scale, so there is no charge accumulation in the interior of a conductor. This justifies setting $\delta n_\downarrow = -\delta n_\uparrow$ except across interfaces where dipole layers are possible. Summing the transport equations for majority, equation (1), and minority spins, solving for the electric field $\mathbf{E}$ in terms of the current $\mathbf{j}$, and inserting the result into the difference of the two transport equations gives

$$\mathbf{j}_s = \gamma^{\mathrm{p}}\mathbf{j} - D_s \nabla \delta n_s \tag{2}$$

where $\mathbf{j}_s = \mathbf{j}_\uparrow - \mathbf{j}_\downarrow$ and $\delta n_s = \delta n_\uparrow - \delta n_\downarrow$. The first term on the right-hand side of equation (2) is zero in nonmagnets, and gives the current polarization in the bulk of the ferromagnet with $\gamma^{\mathrm{p}} = (\sigma_\uparrow - \sigma_\downarrow)/(\sigma_\uparrow + \sigma_\downarrow)$. The second term describes the net diffusion of spins with $D_s = (D_\uparrow\sigma_\uparrow + D_\downarrow\sigma_\downarrow)/(\sigma_\uparrow + \sigma_\downarrow)$.

The system reaches the steady state shown in Figure 1 because spin-flip scattering, which reduces the number of excess spins by coupling their angular momentum with the lattice, cuts off a limitless increase. The net spin accumulation δn_s decays with a characteristic spin-flip scattering time τ_{sf}

$$\frac{\mathrm{d}\delta n_s}{\mathrm{d}t} = -\nabla\cdot\mathbf{j}_s - \frac{\delta n_s}{\tau_{\mathrm{sf}}} \tag{3}$$

The first term on the right-hand side describes the net flow of spins into and out of a region and the second describes the reduction in the spin density due to spin-flip scattering. In steady state, the left-hand side vanishes so that equations (2) and (3) can be combined to give a diffusion equation for spins. The spin diffusion length $l_{\mathrm{sf}} = \sqrt{D_s\tau_{\mathrm{sf}}}$ is the characteristic length scale in this diffusion equation, it varies from several nanometers in alloys such as $Ni_{80}Fe_{20}$ to around 500 nm in Cu. In Figure 1, the spin accumulation in both materials decays exponentially away from the interface with the spin diffusion length appropriate for each material.

Spin-flip scattering provides an important source of angular momentum for the current carrying electrons. As noted in the preceding text, the current flowing in from the nonmagnet does not carry angular momentum toward the interface, but the current flowing in the ferromagnet does carry angular momentum away from the interface. The angular momentum coupled from the lattice through spin-flip scattering is the source of the difference between the angular momentum flowing in the two leads.

Equations (2) and (3) describe all of the results in Figure 1 except the discontinuity in the spin accumulation at the interface. This discontinuity arises because the interface has a spin-dependent resistance, R_σ associated with it (Schep *et al.*, 1998; Stiles and Penn, 2000; Xia *et al.*, 2001; Bauer, Schep, Xia and Kelly, 2002). For each spin, the current across the interface is related to a discontinuity in the spin chemical potential, described in the preceding text, across the interface

$$R_\uparrow \mathbf{j}_\uparrow\cdot\hat{\mathbf{n}} = \mu_\uparrow^{\mathrm{NM}} - \mu_\uparrow^{\mathrm{FM}} \tag{4}$$

As there is a 'natural' polarization to the bulk current given by γ^{p}, so is there a natural polarization to the spin current through the interface given by $\gamma^{\mathrm{I}} = (R_\downarrow - R_\uparrow)/(R_\downarrow + R_\uparrow)$. The apparent sign reversal comes from the definition in terms of resistances rather than conductances. Whenever the polarization of the current, j_s/j, in the bulk of a material is different from the polarization of the conductivity γ^{P}, there must be a spatially varying spin density to generate a diffusive contribution to the spin density to compensate. Similarly, whenever the polarization of the current crossing an interface differs from the polarization of the interface conductance, γ^{I}, there must be a discontinuity in the spin chemical potential across the interface.

Figure 1(b) shows that when the current direction changes, the spin accumulation and spin currents both change signs. In this case, more majority and fewer minority electrons enter

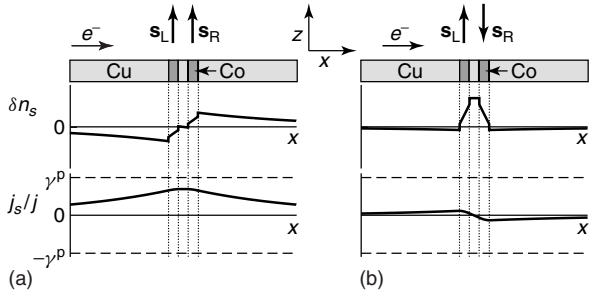

Figure 2. Spin accumulation (δn_s) and spin current (j_s) for electron flow through two ferromagnetic layers embedded in a nonmagnetic host and separated by a thin nonmagnetic spacer layer. The magnetizations of the two layers are parallel along the $\hat{\mathbf{z}}$ direction on the left side and antiparallel on the right. γ^{p} is the polarization of the current in the bulk ferromagnet far from any interfaces.

the interface region than leave it. Hence, there is a positive spin accumulation and a net diffusion of majority electrons away from the interface and minority spins into it.

These ideas describing spin transport through and near interfaces provide the basis for understanding more complicated structures. For example, consider the case of two finite ferromagnetic layers separated by a nonmagnetic spacer layer and embedded in a nonmagnetic host as depicted in Figure 2. Far from the layers, there is no spin current or spin accumulation in the nonmagnetic host. For parallel magnetizations, as depicted to the left, there are more majority electrons flowing through the layers than minority electrons. This flow of electrons leads to minority electrons accumulating to the left of the layers and diffusing to the left and majority electrons accumulating to the right and diffusing to the right. The result is a positive spin current in both cases. The polarization of the current is less than the polarization of the interface conductance, so there are substantial discontinuities in the spin accumulation across the interfaces.

On the other hand, when the two magnetizations are antiparallel, the current flowing through the layers is largely unpolarized, provided the layers are thin compared to the appropriate spin diffusion lengths. The unpolarized current flowing through the ferromagnetic layers requires substantial gradients in the spin accumulation to provide the diffusive spin currents to compensate the bulk-like spin currents. Also, since the current is much less polarized than the interface conductances, there are substantial discontinuities in the spin accumulation as well. This situation leads to an interesting result. In the case of parallel magnetizations, the current flowing through the spacer layer is highly polarized, but the spin accumulation is close to zero. On the other hand, for antiparallel alignment, the spin current in the spacer layer is close to zero but there is substantial spin accumulation.

Figure 2 provides an explanation (Baibich *et al.*, 1988) for giant magnetoresistance. When the magnetizations are parallel, the current carrying electrons are polarized so that more of them flow through the low-resistance majority channel. This polarization of the current lowers the average resistance of the structure and provides a short circuit as compared to the antiparallel case. In the antiparallel case, the current remains largely unpolarized so that close to half of the electrons are forced to flow through the higher resistance minority channel in each layer.

It should be clear from Figure 2 that the spin current depends on the sample geometry, including the leads. In most samples, the leads only have the same cross-sectional area as the rest of the sample for a length much shorter than the spin diffusion length. Then, the structure widens out quickly. In one-dimensional drift–diffusion calculations, this widening is typically modeled by asserting that the spin accumulation goes to zero at the widening point, but the spin current is finite there. This approximation is motivated by the large density of states in the wide part of the sample. Three-dimensional calculations of the transport (Berger, 2004; Hamrle, Kimura, Yang and Otani, 2005) bear out this picture qualitatively, but quantitative differences remain.

There are several key points from this discussion that are important for understanding spin-transfer torques. Spin-dependent conductivities in ferromagnetic layers and spin-dependent conductances at interfaces with ferromagnetic layers lead to spin-polarized current flowing through the nonmagnetic layers in these structures. Spin-flip scattering couples angular momentum from the lattice into the electron system, allowing for apparent nonconservation of angular momentum within the electron system itself. Finally, the spin polarization of the current at particular points in the structure is not a local property. It depends on everything upstream and downstream within a few spin diffusion lengths. It also depends strongly on the alignment of the magnetizations in close-by layers.

3 SPIN-DEPENDENT INTERFACIAL SCATTERING

3.1 Spin currents for noncollinear magnetizations

The last section describes transport in devices with collinear magnetizations, but torques only occur when the magnetizations are noncollinear. Treating the noncollinear case requires understanding the behavior of spins currents at interfaces when the spins are not collinear with the magnetization of the ferromagnet. This section splits the discussion of this behavior into three subsections. The present subsection, Section 3.1, defines spin current in a noncollinear system and describes its equation of motion. Section 3.2 describes the scattering of individual electrons at interfaces as a function

of their spin direction. The result is a torque on the electron spin and a reaction torque on the magnetization. Finally, Section 3.3 describes the behavior of the collection of electrons carrying current. The sum of the reaction torques from the electron spins gives the spin transfer torque for the chosen spin current. These descriptions provide boundary conditions that can be used to generalize the results of the previous section to the case of noncollinear magnetizations. This generalization is taken up Section 4.

When the magnetizations are collinear it is possible to treat the spin accumulation as a scalar and the spin current as a vector. In the presence of noncollinear magnetizations, it is necessary to treat the spin accumulation as a vector to account for variations in the direction of the spins and the spin current as a tensor to account for both the direction of the spins and the direction they are moving. Classically the spin current carried by an individual electron is the outer product of its spin and velocity $(\hbar/2)\hat{\mathbf{s}} \otimes \mathbf{v}$ as illustrated in Figure 3(a). More generally, these quantities are given by the expectation values of the spin operator $\mathbf{S}$ and the velocity operator $\hat{\mathbf{v}}$

$$\mathbf{s}(\mathbf{r}) = \sum_{i\sigma\sigma'} \psi^*_{i\sigma}(\mathbf{r})\, \mathbf{S}_{\sigma,\sigma'}\, \psi_{i\sigma'}(\mathbf{r})$$

$$\mathbf{Q}(\mathbf{r}) = \sum_{i\sigma\sigma'} \mathrm{Re}\left[\psi^*_{i\sigma}(\mathbf{r})\, \mathbf{S}_{\sigma,\sigma'} \otimes \hat{\mathbf{v}}\, \psi_{i\sigma'}(\mathbf{r})\right] \tag{5}$$

In these sums, the index i refers to occupied states, and the index σ to the spinor components of the states. In general, the total spin current need not factor into an outer product of a spin direction and a vector current, but in systems like those considered in the previous section, it does

$$\mathbf{Q} = (\hbar/2)\, \hat{\mathbf{s}} \otimes \mathbf{j}_s = (\hbar/2) P\, \hat{\mathbf{s}} \otimes \mathbf{j} \tag{6}$$

where $\hat{\mathbf{s}}$ is a unit vector in the direction of the spin density. The last form in equation (6) writes the difference of currents carried by each spin as a polarization P times the number current.

The equation of motion for the spin density can be derived in the same way as the familiar continuity equation for the number density

$$\frac{\partial n}{\partial t} = -\boldsymbol{\nabla}\cdot\mathbf{j} \tag{7}$$

which is derived from the commutator of the operator for the number density with the Hamiltonian. The number operator commutes with all terms except the kinetic energy, which gives the right-hand side. The expression shows that the time rate of change of the number of electrons in a volume is given by the net rate of flow of electrons into the volume. For the spin density this procedure gives

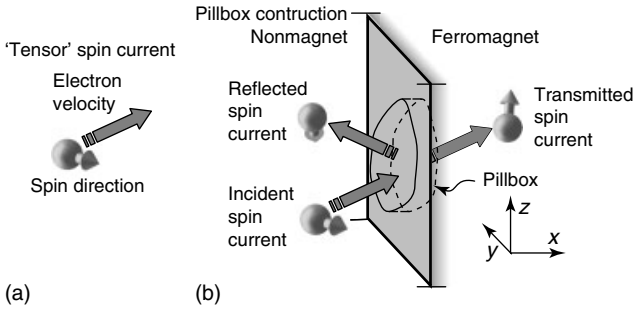

Figure 3. (a) An electron moving in one direction with its spin in another illustrating a tensor spin current. (b) A pillbox around interface for computing the interfacial torque.

$$\frac{\partial \mathbf{s}}{\partial t} = -\boldsymbol{\nabla}\cdot\mathbf{Q} + \mathbf{n}_{\mathrm{ext}} - \alpha\hat{\mathbf{s}} \times \frac{\partial \mathbf{s}}{\partial t} - \hat{\mathbf{s}}\frac{\delta s}{\tau_{\mathrm{sf}}} \tag{8}$$

where $\boldsymbol{\nabla}\cdot\mathbf{Q} = \partial_k Q_{ik}$, summing over the repeated index k. The first term on the right-hand side is similar to the right-hand side of equation (7). It is a contribution to the time rate of change of the spin density given by the net flow of spin into that volume. Unlike the case for the number density, there are other terms that can change the spin density. The second term on the right-hand side of equation (8) comes from the terms in the Hamiltonian in which the energy depends on the orientation of the spin density, terms like the Zeeman interaction with an external field, the magnetocrystalline anisotropy, and the magnetostatic interaction between the magnetizations at different points. These terms tend to cause precession of the spin density around its equilibrium direction and are combined into the effective torque; the last two terms are phenomenological representations of more complicated interactions. The first of these is the damping that tends to reduce the magnitude of the precession and the second is the spin-flip scattering described in equation (3). With just the second and third terms on the right-hand side, equation (8) is the familiar Landau–Lifshitz–Gilbert equation written in terms of the spin density instead of the magnetization. The last term is an addition for cases in which the magnitude of the spin density is allowed to vary owing to flowing current. The first term is the spin-transfer torque of interest in this chapter.

There are two contributions to the spin-transfer term in equation (8), as there are two contributions to the spin current. One contribution to the spin current is carried by all of the electrons and exists whenever the spin density (or magnetization) varies spatially even if there is no current flow. The gradient of this contribution to the spin current gives the micromagnetic exchange interaction discussed in chapter **General Micromagnetic Theory, Volume 2**.

The second contribution is carried by nonequilibrium carriers near the Fermi energy. It only exists in the presence of a current and is the contribution of interest in this chapter. The rest of the chapter deals only with the spin current carried by the nonequilibrium electrons close to the Fermi energy; the contribution from the spin current due to the spatially varying magnetization is included in the torque, $\mathbf{n}_{\text{ext}}$, as is generally done in micromagnetics.

The remainder of the $-\nabla\cdot\mathbf{Q}$ term in equation (8) is the spin-transfer torque and has two important manifestations. The manifestation of principle interest in this chapter is an interfacial contribution in multilayers that is discussed in the subsequent text. There is an additional contribution for spatially varying spin densities in bulk materials originally studied by Berger (1978, 1979). When the spin-density direction varies spatially it exerts a torque on the spins carried along with the current as they move through the variation. These spins tend to rotate to stay aligned with the magnetization. If they stayed perfectly aligned, the spin current would have the form $(\hbar/2)P\hat{\mathbf{u}}(\mathbf{r})\otimes\mathbf{j}$, where $\hat{\mathbf{u}}(\mathbf{r})$ is the local direction of the spin density. Then, the reaction torque on the spin density is $-(\hbar/2)P(\mathbf{j}\cdot\nabla)\hat{\mathbf{u}}(\mathbf{r})$ (Berger, 1984, 1986; Bazaliy, Jones and Zhang, 1998; Ansermet, 2004) for a constant current. If the spins carried by the current do not adiabatically follow the direction of the magnetization, there can be an additional torque of the form $\xi(\hbar/2)P\hat{\mathbf{u}}(\mathbf{r})\times(\mathbf{j}\cdot\nabla)\hat{\mathbf{u}}(\mathbf{r})$ (Waintal and Viret, 2004; Zhang and Li, 2004; Thiaville, Nakatani, Miltat and Suzuki, 2005). However, calculations of this latter quantity are still in a preliminary state.

The rest of this chapter focuses on the interfacial spin-transfer torque of importance in magnetic multilayers (Slonczewski, 1996; Waintal, Myers, Brouwer and Ralph, 2000; Xia *et al*., 2002; Stiles and Zangwill, 2002a). To understand the origin of this torque, it is useful to integrate the spin-transfer torque $-\nabla\cdot\mathbf{Q}$ over the volume of a pillbox surrounding the interface between a nonmagnetic metal and a ferromagnetic metal, as illustrated in Figure 3(b). The volume integral gets converted into the difference in the flux between the two surfaces. For a spin-current incident from the nonmagnetic metal, the net flux can be written as a torque on the enclosed magnetization

$$\mathbf{N}_{\text{c}} = (\mathbf{Q}^{\text{in}} - \mathbf{Q}^{\text{tr}} + \mathbf{Q}^{\text{ref}})\cdot A\hat{\mathbf{x}} \approx \mathbf{Q}^{\text{in}}_{\perp}\cdot A\hat{\mathbf{x}} \qquad (9)$$

where 'in', 'tr', and 'ref' refer to the incident, transmitted and reflected spin currents, respectively. The equality in this equation is the difference in the fluxes through the two interfaces and is an exact result. The approximate result, which states that the transverse component of the incident spin current is absorbed by the ferromagnet at the interface, is developed in the rest of this section.

3.2 Torque due to individual electrons

The behavior of individual electron spins in magnetic multilayers is determined by their interaction with the spin polarized electronic structure of the ferromagnetic metals. Modeling the details of the spin transport requires a model for this electronic structure, which is complicated (Fulde, 1995; Held and Vollhardt, 1998; Yang, Savrasov and Kotliar, 2001) because it is a balance of intra-atomic exchange and correlation effects with interatomic hybridization. In isolated atoms, electrons occupy states in partially filled levels in such a way so as to maximize the total spin (Hund's first rule). Maximizing the spin reduces the Coulomb repulsion between the electrons because parallel spins are naturally kept away from each other by the Pauli exclusion principle. Within partially filled atomic levels, the orbital energies of the different states are the same so there is no penalty for developing this polarization. In solids, the atomic levels hybridize with levels on neighboring atoms forming bands and removing the degeneracy of the states within a level. Since the degeneracy is lifted, there is now a cost for developing a spin polarization as each flipped spin has to be put into a higher energy state. Typically, the Coulomb energy gain from developing a spin polarization is less than that cost, so most solids remain unpolarized. However, in Fe, Co, and Ni, among others, the energy gain is sufficient for ferromagnetism to develop.

Two approaches are commonly used to describe the electronic structure of ferromagnets in the context of magnetic multilayers. One is based on models used to describe magnetic impurities in nonmagnetic hosts (Langreth and Wilkins, 1972). In these models, the d levels on the impurity are treated as localized states that form a local moment. This model ignores the hybridization of the levels forming the moment. In the most common treatment of this model, the local moment becomes a well-defined object in its own right. The moment is then weakly coupled to the moment of the conduction electron spins. This model is referred to as the 's-d' model or the local moment model.

The other approach, adopted in this chapter, is based on the local spin-density approximation (LSDA) (Kohn and Sham, 1965; von Barth and Hedin, 1972; Gunnarsson and Lundqvist, 1976; Jones and Gunnarsson, 1989). This approach was developed for computing the total electronic energy of systems. In metallic solids, it works very well for calculations of properties such as cohesive energies, equilibrium lattice constants, and the magnetic moments (Moruzzi, Janak and Williams, 1978). Alternatively, this method can be thought of as an approximation for the electronic structure in which the interatomic hybridization is treated exactly, but the interactions between the electrons are treated in mean-field theory. This approach does a reasonable job describing the Fermi surfaces of the transition metals.

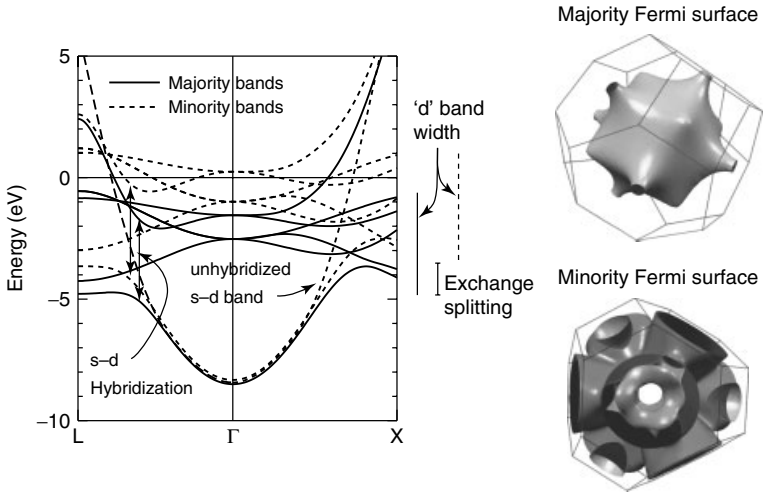

Figure 4. The band structures and Fermi surfaces of face-centered cubic Co. The solid (dotted) curves give the majority (minority) bands along two high symmetry directions through the Brillouin zone center, Γ. The thin dashed curve shows the s-p band if it were not hybridized with the d bands. The bars to the right of the bands show the width of the d bands and the exchange splitting between the majority and minority bands. The arrows in the band structure plots give the width of the gap caused by the hybridization between the s-p and d bands of the same symmetry. The Fermi surfaces are by permission from Choy *et al*. (1995). (Fermi surfaces reproduced from Choy, T.-S., Naset, J., Chen, J., Hershfield, S., and Stanton, C.J. The Fermi Surface Database, 1995, http://www.phys.ufl.edu/fermisurface/.)

Since the transport behavior is dominated by the properties of the electrons at the Fermi energy, this approach is adopted in the rest of this chapter. Calculated band structures and Fermi surfaces for majority and minority electrons in face-centered cubic Co are shown in Figure 4. The fact that the bandwidth of the d-derived states as well as the s-d hybridization are larger than the exchange splitting highlight the importance of treating the hybridization of the d states.

Either approach can describe much of the physics of these systems, largely because so much is unknown about the details of the systems. For example, the spin-dependent conductivity would be difficult to calculate directly even if the details of all of the defects causing the scattering were known. Since these details are not known, the conductivities are usually taken from experiment, allowing either model to correctly describe that aspect of the behavior. However, there are some processes where the details of the Fermi surfaces matter and the two models give different results. As discussed below, the spin-transfer process is an example where this difference is important. Figure 4 shows that when the hybridization of the d-electrons is taken into account, the Fermi surfaces of the majority and minority electrons are quite different. In local moment models, the two Fermi surfaces are almost identical.

Two different aspects of the exchange interaction are discussed in this chapter, the exchange interaction that gives rise to the moments and the micromagnetic exchange. The latter aspect is the additional energy that arises when the direction of the moment varies in space. In this chapter, the magnetization of the layers is generally assumed to be uniform, so references to the exchange interaction refer to the aspect giving rise to the moment. References to micromagnetic exchange refer to the spatially varying aspect.

When electrons scatter from interfaces between a nonmagnetic metal and a ferromagnetic metal, the exchange interaction in the ferromagnet leads to scattering that depends on the spin of the electron. For electrons with moments parallel to the magnetization in the ferromagnet, the reflection amplitude, $R_\uparrow$, is different from the reflection amplitude for electrons with moments antiparallel, $R_\downarrow$. For multilayers with collinear magnetizations, spin-dependent reflection leads to a spin-dependent interface resistance (Schep *et al*., 1998; Stiles and Penn, 2000; Xia *et al*., 2001; Bauer, Schep, Xia and Kelly, 2002). The transmission amplitudes, $T_\uparrow$ and $T_\downarrow$ are similarly spin dependent.

The reflection amplitudes for electrons with moments misaligned with respect to the magnetization can be computed directly from the reflection amplitudes for collinear moments. As discussed in the preceding text, the magnetization is assumed to be in the $-\hat{\mathbf{z}}$-direction so that the ferromagnetic spin density is in the $\hat{\mathbf{z}}$-direction. Then, the spin state of an electron spin pointing in the direction specified by the polar angle θ and azimuthal angle ϕ is given by a coherent superposition of majority- and minority-spin states

$$|\theta, \phi\rangle = \cos(\theta/2)\, e^{-i\phi/2}\, |\uparrow\rangle + \sin(\theta/2)\, e^{i\phi/2}\, |\downarrow\rangle \quad (10)$$

So, an electron in the nonmagnet with a spin pointing in the θ, ϕ direction with wave vector k can be described by the wave function $e^{ikx}\, |\theta, \phi\rangle$. Since quantum mechanics is linear,

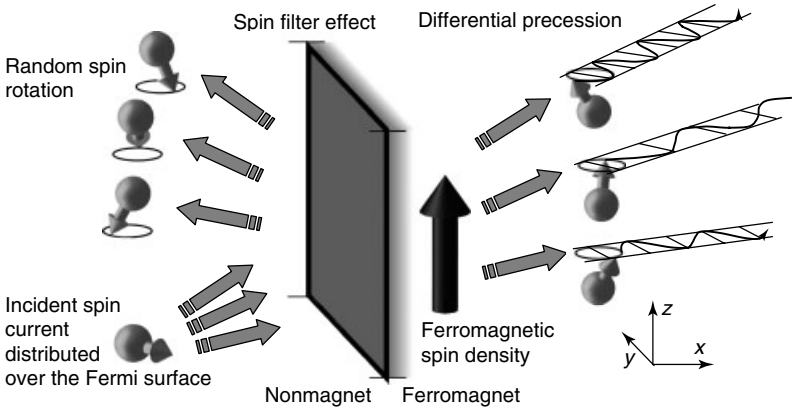

Figure 5. Mechanisms contributing to absorption of incident transverse spin current. Electrons incident from the nonmagnet (lower left) are distributed over states represented here by three different incident directions. All of these electrons are in the same spin state, which is transverse to the ferromagnetic spin density. The reflected electron spins have predominantly minority character and their transverse components are distributed over many directions (random spin rotation) because of the variation over the Fermi surface of the phases of the reflection amplitudes. The transmitted electron spins precess as they go into the ferromagnet because the wave vectors for the majority and minority components are different. Electrons with different initial conditions precess at different rates, leading to classical dephasing (differential precession).

the majority, and minority components of the wave function reflect as they would in the absence of any coherence. The reflected wave function is thus

$$e^{-ikx}\left[R_\uparrow \cos(\theta/2)\, e^{-i\phi/2}\,|\uparrow\rangle + R_\downarrow \sin(\theta/2)\, e^{i\phi/2}\,|\downarrow\rangle\right] \quad (11)$$

The reflected spin is rotated with respect to its incident direction and is pointing in the direction specified by $\tan(\theta'/2) = |R_\downarrow/R_\uparrow|\tan(\theta/2)$ and $\phi' = \phi + \mathrm{Im}[\ln(R_\uparrow^* R_\downarrow)]$. Such rotations are sketched in Figure 5.

Physically, the reflected electron spin precesses during its interaction with the exchange field present in the ferromagnet. Similar effects occur for transmitted electrons with one additional complication. When the electrons go through the ferromagnet they continue to interact with the exchange field and precess around it. This precession manifests itself through the different wave vectors for the two components of the wave function

$$\begin{aligned} &e^{-ik_\uparrow x} T_\uparrow \cos(\theta/2)\, e^{-i\phi/2}\,|\uparrow\rangle \\ &\quad + e^{-ik_\downarrow x} T_\downarrow \sin(\theta/2)\, e^{i\phi/2}\,|\downarrow\rangle \end{aligned} \quad (12)$$

As for the reflected wave function, there is rotation owing to the relative amplitudes and phases of $T_\uparrow$ and $T_\downarrow$. In addition, the different components accumulate additional relative phase from the factor $\exp[i(k_\uparrow - k_\downarrow)x]$ as they propagate. This phase factor describes the precession around the magnetization as the spin propagates through the ferromagnet. There is no such precession for the reflected wave function. In a local moment model, the spatial frequency of the precession is much slower than it is when more realistic Fermi surfaces are considered. Realistic Fermi surfaces give spatial precession periods on the order of several lattice constants.

When the interaction of the spin with the magnetization causes the spin to precess, there is a reaction torque from the spin on the magnetization. This reaction torque is the current-induced torque described in equation (9). The second part of that equation expresses an approximate numerical result for the size of the torque. One of the mechanisms for this result is seen from the following simple argument based on a particular limit (Waintal, Myers, Brouwer and Ralph, 2000), in which the reflection probability for majority electrons is zero and for minority electrons is one. Although this simple behavior is not general, it does occur for some electrons (Stiles, 1996). For a ferromagnetic spin density along $-\hat{\mathbf{z}}$ and an interface normal in the $\hat{\mathbf{x}}$ direction, consider an incident electron with its spin in the $\hat{\mathbf{x}}$ direction. The spin currents on the faces of the pillbox of Figure 3 as in equation (9) are

$$\begin{aligned} \mathbf{Q}_{\mathrm{in}} &= \frac{\hbar}{2}\hat{\mathbf{x}} \otimes v\hat{\mathbf{x}} \\ \mathbf{Q}_{\mathrm{refl}} &= \frac{\hbar}{4}(-\hat{\mathbf{z}}) \otimes (-v\hat{\mathbf{x}}) \\ \mathbf{Q}_{\mathrm{trans}} &= \frac{\hbar}{4}\hat{\mathbf{z}} \otimes v\hat{\mathbf{x}} \end{aligned} \quad (13)$$

This combination gives a current-induced torque of $\mathbf{N}_{\mathrm{c}} = \hat{\mathbf{x}} A v\hbar/2$. There are two features of this result. First, there is no torque along the direction of the magnetization. This is a general result and simply reflects the fact that the component of the spin along the magnetization is conserved during the scattering process. The second feature is that the component of the spin transverse to the magnetization is absorbed by the

magnetization. The mechanism for the torque in this simple model is the spatial separation of the majority and minority components of the wave function. The transverse component of the spin current arises from the interference of these two components of the wave function. When they cease overlapping, the transverse component of the spin current vanishes. The two components of the wave function are separated by the exchange interaction, the ultimate cause for the spin dependence of the reflection amplitudes and hence the torque.

The result that the transverse spin current is absorbed at the interface is exact only for this special limit of complete spatial separation. However, it holds approximately for many transition metal interfaces. Explaining this approximate result requires a discussion of the distribution of electrons that carry a current.

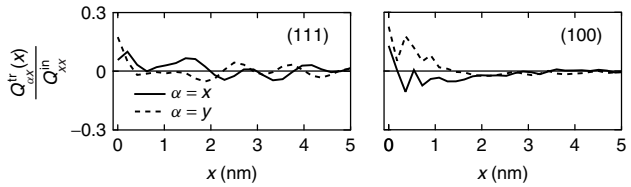

Figure 6. Decay of transverse transmitted spin current as a function of distance from the interface for two orientations of Co/Cu. For a unit incident transverse polarization, the solid curve in each panel is $Q_{xx}(x)$. The dotted curve in each panel is $Q_{yx}(x)$. Asymptotically, the spin current shows decaying oscillatory behavior. The oscillation is due to the precession (see equation (12)) and the decay is due to increasing cancellation of the precession from different parts of the Fermi surface. The amplitude of the asymptotic behavior is smaller for the (111) case than for the (100) case due to the details of the Fermi surface of Co.

3.3 Torque due to an ensemble of electrons

Collinear transport is described in Section 2 using the language of the drift-diffusion approximation in terms of densities and currents, ignoring the behavior of individual electrons. Determining the boundary conditions at the interfaces between different materials requires summing over the behavior of the individual electrons. The electrons carrying the current are spread over the entire Fermi surface and have different properties.

Equation (11) shows that the electron spins rotate when they reflect. First-principles calculations (Xia *et al.*, 2002; Stiles and Zangwill, 2002a; Zwierzycki *et al.*, 2005) show that these rotations vary rapidly over the Fermi surface. A schematic of this distribution of rotations is shown in Figure 5. For most interfaces that have been studied, there is a tendency for a polarization to develop along the direction of the magnetization; either majority or minority reflection is greater on average. However, in all cases, the transverse component of the reflected spin current sums to a value close to zero. Thus, $\mathbf{Q}^{\mathrm{ref}}$ in equation (9) has only a small transverse component.

These same calculations show a similar, but not as complete cancellation of the transmitted transverse spin current. However, the transmitted electrons are rapidly precessing due to the evolving phase difference $\exp[i(k_\uparrow - k_\downarrow)x]$ for the two spin components of the wave function for each electron. The difference in wave vector varies rapidly over the Fermi surface. Thus, there is an increase in the dephasing and concomitant decrease in the transverse component as a function of penetration into the ferromagnet. This precession is illustrated schematically in Figure 5 and the net precession and decay of the spin current is illustrated in Figure 6. If the spin current is considered several layers into the ferromagnet, the transmitted current has only a small transverse component. The small transverse part of the transmitted and reflected spin currents means that the transverse part of the incident spin current is largely transferred to the ferromagnetic magnetization. This result is the approximate second half of equation (9).

Quantitative calculations like those in Figure 6 require keeping track of the distributions of electrons on either side of the interface. One approach is a fully coherent calculation (Zwierzycki *et al.*, 2005; Edwards, Federici, Mathon and Umerski, 2005). Such calculations have the drawback that including all of the coherent multiple scattering between interfaces involves significant computational effort. These coherent effects are not observed experimentally, presumably because disorder in the samples averages them out. An alternate approach, adopted in this chapter, is a generalization of the Boltzmann equation. The Boltzmann equation describes the evolution of the distribution function for electrons when the spatial variations in the system are slow enough that the electrons in a small region can be described as if they were in an infinite bulk region with similar material properties. Coherence between electrons at different wave vectors or positions is ignored. In magnetic multilayers, this approximation can only be valid away from interfaces. However, distributions in two regions away from the interfaces can be joined together through boundary conditions calculated quantum mechanically.

In the ferromagnet, the distribution function $f_s(\mathbf{r}, \mathbf{k})$, depends on position $\mathbf{r}$, wave vector $\mathbf{k}$, and band index (not indicated). The magnetization provides the natural quantization direction and there is a separate function for each spin $s = \uparrow, \downarrow$. Any spin component transverse to this direction tends to rapidly vanish due to dephasing effects similar to those discussed in the preceding text for spin currents injected into a ferromagnet.

In the nonmagnetic layers on the other hand, there is neither a natural quantization direction, nor the rapid

dephasing that is present in ferromagnets. In this case, it is necessary to generalize the Boltzmann equation to keep track of the coherence between electrons in different spin states on each part of the Fermi surface. This can be done by generalizing the two distribution functions to 2×2 distribution matrices

$$f_{s,s'}(\mathbf{r}, \mathbf{k}, t) = f(\mathbf{r}, \mathbf{k}, t)\delta_{s,s'} + \sum_{\alpha=x,y,z} f_\alpha(\mathbf{r}, \mathbf{k}, t)[\sigma_\alpha]_{s,s'} \qquad (14)$$

where σ_α, are Pauli spin matrices ($\alpha = x, y, z$). This construction allows the electron spins to point in arbitrary directions. The four functions that characterize the distribution matrices give the densities and currents

$$\begin{aligned} n_0 + \delta n &= \sum_{\mathbf{k}} f(\mathbf{k}) \qquad j_\beta = \sum_{\mathbf{k}} f(\mathbf{k}) v_\beta(\mathbf{k}) \\ s_\alpha &= \frac{\hbar}{2}\sum_{\mathbf{k}} f_\alpha(\mathbf{k}) \qquad Q_{\alpha\beta} = \frac{\hbar}{2}\sum_{\mathbf{k}} f_\alpha(\mathbf{k}) v_\beta(\mathbf{k}) \end{aligned} \qquad (15)$$

where v_β is a component of the velocity of the state at $\mathbf{k}$, and n_0 is the equilibrium density. Moments of the Boltzmann equation give the drift-diffusion equations in the nonmagnet as shown for the collinear case by Valet and Fert (1993).

The construction in equation (14) is based on including the coherence between majority- and minority-spin states, but only for states at the same point on the Fermi surface. Thus, the possibility of such a construction in ferromagnets depends on the model for the electronic structure of the ferromagnet. Calculations based on local moment models (Heide, 2001; Heide, Zilberman and Elliott, 2001; Zhang, Levy and Fert, 2002; Shpiro, Levy and Zhang, 2003; Hitchon, Chantrell and Rebei, 2004), typically include coherence between majority and minority states because there is little difference between the Fermi surfaces of the majority and minority transport electrons. On the other hand, for realistic models of the electronic structure, such a construction is not possible because states with the same energy do not generally have the same wave vector. Thus Boltzmann equation and drift-diffusion calculations based on realistic band structures do not allow for transverse spins in ferromagnets. It is possible to extend the Boltzmann equation so as to include the coherence that is left out of the Boltzmann equation; this is done in the first-principles calculations (Stiles and Zangwill, 2002a; Zwierzycki *et al.*, 2005). However, it is difficult to include scattering in calculations with coherence between non-overlapping Fermi surfaces.

In the Boltzmann equation, the boundary conditions for each electronic state are determined by the spin-dependent reflection and transmission amplitudes shown in equations (11) and (12). The boundary conditions for reflection can be expressed in terms of four real reflection parameters

$$\begin{aligned} \mathrm{R}_\uparrow &= |R_\uparrow|^2 \qquad \mathrm{R}_\perp = \mathrm{Re}[R_\downarrow^* R_\uparrow] \\ \mathrm{R}_\downarrow &= |R_\downarrow|^2 \qquad \mathrm{R}_\times = \mathrm{Im}[R_\downarrow^* R_\uparrow] \end{aligned} \qquad (16)$$

The two parameters on the left are the reflection probabilities for the majority and minority components, respectively. They determine the reflected number current and the reflected longitudinal spin current. The two quantities on the right, which are not probabilities as they can be negative, determine the reflected transverse spin current. $\mathrm{R}_\perp$ describes reflection of a spin along the same azimuthal axis as the incident state. A negative value implies rotation by 180°. $\mathrm{R}_\times$ describes reflection along an axis rotated by $\pm 90^\circ$. The boundary conditions for transmission are described by the transmission probabilities for majority and minority electrons. Since these models do not include transverse spins in the ferromagnet, any such spins that are transmitted are assumed to be absorbed by the magnetization at the interface. Similarly, the incident electrons from the ferromagnet are assumed to be collinear with the magnetization, so those process are described the majority and minority transmission and reflection probabilities alone.

The transformation from the Boltzmann equation to the drift-diffusion equation requires appropriate averages over these reflection parameters. The result that the incident transverse spin current is absorbed at the interface is equivalent to stating that $\mathrm{R}_\perp$ and $\mathrm{R}_\times$ average to zero. Then, the boundary conditions for transport in multilayers with noncollinear magnetizations are that the transverse spin current and accumulation in the ferromagnet are both zero and the transverse spin accumulation and current in the nonmagnet are proportional to each other

$$\mathbf{Q}_\perp \cdot \hat{\mathbf{n}} = B\mathbf{s}_\perp \qquad (17)$$

The $\perp$ subscript indicates the transverse component. The constant of proportionality is a constant with units of velocity $B = A_{\mathrm{FS}}/(8\pi^3\hbar\mathcal{N})$, where A_{FS} is the Fermi surface area of the nonmagnetic material projected onto a plane in the interface direction.

The spin-transfer torque described here is due to the spin current carried by nonequilibrium carriers at the Fermi energy. Although the spin-transfer torque is interfacial, it is typically treated as spread uniformly throughout the free layer because the free layer is thin enough that the micromagnetic exchange interaction tends to keep the magnetization aligned. It is interesting to see how this comes about in detail. The interfacial spin-transfer torque needs to be balanced by another interfacial torque so as to prevent a diverging response. This balancing torque comes from

the micromagnetic exchange. Normally, the micromagnetic exchange has the boundary condition that the normal gradient of the magnetization vanishes $(\hat{\mathbf{n}} \cdot \nabla)\mathbf{s}(\mathbf{r}) = 0$. This condition is simply the requirement that the interfacial torque vanish. In the presence of an interfacial spin-transfer torque, the gradient is nonzero at the interface. Since the magnetization is differentiable, a finite derivative at the interface gives a finite derivative into the layer. This rotation of the magnetization effectively 'spreads' the interfacial spin-transfer torque over the thin layer. As mentioned after equation (8), the micromagnetic exchange torque can be understood as the gradient of a spin current carried by all of the electrons in the Fermi sea. A finite normal gradient corresponds to a discontinuous spin current. At the interface, both the transport spin current and the micromagnetic spin current are discontinuous. In fact, the total spin current is continuous. At the interface, the incident spin current carried by the nonequilibrium carriers at the Fermi energy is converted into a 'quasiequilibrium' spin current carried by all of the electrons. This conversion is what effectively spreads the interfacial spin-transfer torque over the thickness of the film.

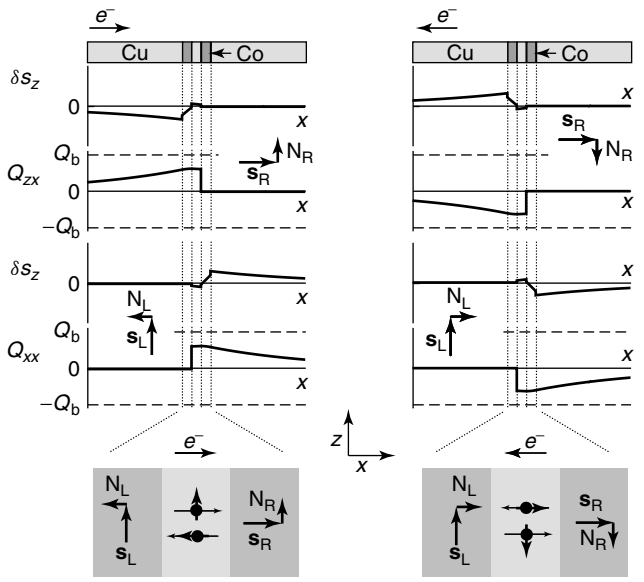

Figure 7. Spin accumulation (δs_α) and spin current ($Q_{\alpha x}$) for electron flow through two ferromagnetic layers embedded in a nonmagnetic host and separated by a thin nonmagnetic spacer layer. The magnetizations of the two layers are perpendicular to each other, for purposes of illustration both are in the plane of the figure. On the left side, the current flows in the $\hat{\mathbf{x}}$ direction and on the right in the $-\hat{\mathbf{x}}$ direction. Q_b is the magnitude of the spin current in the bulk ferromagnet far from any interfaces. The transverse component of the spin current is discontinuous at each interior interface giving rise to torques on the magnetizations of each layer. The directions of the torques are indicated for each of the interfaces. The bottom panel gives a cartoon of the spin current in the spacer layer.

4 NONCOLLINEAR TRANSPORT AND TORQUE

With the boundary condition derived in the previous section, it is now possible to compute the transport for multilayers with noncollinear magnetizations. Such calculations have been undertaken with a variety of different approaches, including the Keldysh formalism (Edwards, Federici, Mathon and Umerski, 2005), the Boltzmann equation (Stiles and Zangwill, 2002b; Shpiro, Levy and Zhang, 2003), the drift-diffusion approximation (Berger, 1998; Grollier *et al*., 2003; Fert *et al*., 2004; Stiles, Xiao and Zangwill, 2004; Barnas *et al*., 2005), random matrix theory (Waintal, Myers, Brouwer and Ralph, 2000), and circuit theory (Brataas, Nazarov and Bauer, 2000; Brataas, Bauer and Kelly, 2006). Although the calculations differ in detail, they all find qualitatively similar results. Here, we describe the physics in the language of the drift-diffusion approach.

A calculation of the spin current and spin accumulation in a magnetic multilayer with perpendicular magnetizations is shown in Figure 7. The behavior is closely related to that shown in Figure 2. Consider the component of spin along $\hat{\mathbf{z}}$, aligned with the spin density in the left layer. Far to the left of the sample, the spin current is unpolarized, but it becomes polarized due to the spin-dependent conductivity of the ferromagnetic layer as described in Section 2. More majority electrons go through the left layer leading to backward diffusion of minority spins in the left lead and a positive spin current. This spin current continues unchanged through the thin spacer layer but goes to zero at the left interface of the right ferromagnet. At this interface, the spins are transverse to the spin density in that layer and the transverse spin current is absorbed as described in Section 3. The abrupt change in the spin current gives a current-induced torque on the right ferromagnet at its left interface.

When the component of the spin along $\hat{\mathbf{z}}$ goes to zero at this interface, components along $\hat{\mathbf{x}}$ are generated by the spin-dependent reflection. The reflected electrons are predominantly antiparallel to the spin density in the right ferromagnetic layer and move away from the interface toward the left ferromagnet. When they hit the right interface of the left ferromagnet, they are again transverse to the spin density and that component of the spin density gets absorbed at that interface. Again, this discontinuity in the spin current give rise to a current-induced torque.

An interesting result of this calculation is that the torques tend to make the two magnetizations pinwheel after each other, apparently violating conservation of angular momentum. This apparent violation is resolved by the role of spin-flip scattering, which couples angular momentum from the

lattice into the electron system, which is then absorbed by the magnetization. Another interesting feature of this figure is that in the spacer layer, the spin-current direction is not aligned with the spin accumulation, but rather is almost perpendicular. Such a result is not entirely unexpected because the spin current is related to the gradient of the spin accumulation rather than the accumulation itself.

The calculation shown in Figure 7 gives the torque and the resistance of the multilayer for a particular magnetic configuration. Similar calculations give the torque and magnetoresistance as a function of angle, see Figure 8. Related calculations done by a number of authors (Vedyayev *et al*., 1997; Slonczewski, 2002; Stiles and Zangwill, 2002b; Huertas-Hernando, Bauer and Nazarov, 2002; Kovalev, Brataas and Bauer, 2002; Bauer, Tserkovnyak, Huertas-Hernando and Brataas, 2003; Manschot, Brataas and Bauer, 2004a,b; Xiao, Zangwill and Stiles, 2004) give similar results. If the spin-current incident on the free layer were independent of the relative orientation of the magnetizations of the two layers and given by $(\hbar/2)\mathcal{P}\,\hat{\mathbf{s}}_0 \otimes \mathbf{j}$, then the torque would be

$$\frac{\mathbf{N}_c}{A} = \frac{\hbar}{2}(\mathbf{j}\cdot\hat{\mathbf{x}})\;\mathcal{P}\;\left[\hat{\mathbf{s}}_0 - (\hat{\mathbf{s}}_0\cdot\hat{\mathbf{s}})\hat{\mathbf{s}}\right] \tag{18}$$

where $\hat{\mathbf{s}}$ is the directions of the ferromagnetic spin density for the free layer. The last factor is simply the transverse part of the spin current. It is more frequently written in terms of the equivalent triple product form, $\hat{\mathbf{s}}\times(\hat{\mathbf{s}}_0\times\hat{\mathbf{s}})$. The magnitude of this vector is $\sin\theta$, where θ is the relative angle between the magnetization $\hat{\mathbf{s}}$ and the direction of the spin current $\hat{\mathbf{s}}_0$. This form of the torque is frequently used in simulations of the magnetic dynamics.

However, calculations show that the spin current *does* depend on the relative angle of the magnetizations, but the changes to equation (18) are simple. The direction of the torque remains the same if $\hat{\mathbf{s}}_0$ is taken to be the direction of the fixed layer magnetization. This replacement works because the direction of spin current is generally some combination of $\hat{\mathbf{s}}$ and $\hat{\mathbf{s}}_0$. Since $\hat{\mathbf{s}}$ does not have a component that is transverse to itself, only the contribution along $\hat{\mathbf{s}}_0$ remains. After that replacement, the rest of the changes in the behavior found in these calculations are captured simply by letting the polarization $\mathcal{P}$ be a function of the relative angle θ between the two magnetizations see Figure 8.

For multilayers with equivalent magnetic layers, Slonczewski (2002) derived an analytic formula for $\mathcal{P}$ by combining a density matrix description of the spacer layer with a circuit theory (Brataas, Nazarov and Bauer, 2000). Extensions of the formula for arbitrary magnetic layers

$$\mathcal{P}(\theta) = \left[\frac{q_+}{B_0 + B_1\cos\theta} + \frac{q_-}{B_0 - B_1\cos\theta}\right] \tag{19}$$

have been described by a number of authors (Kovalev, Brataas and Bauer, 2002; Xiao, Zangwill and Stiles, 2004; Fert *et al*., 2004; Manschot, Brataas and Bauer, 2004a). The four parameters (B_0, B_1, q_+, and q_-) in this expression can be written in terms of layer thicknesses, resistivities, spin diffusion lengths, and so on. The ratio q_-/q_+ depends on the asymmetry between the free layer and the fixed layer and goes to zero for symmetric systems (Slonczewski, 2002). The ratio B_1/B_0 goes to zero when the polarization of the current is independent of the relative angle between the magnetizations. Calculations show that this behavior only occurs in unphysical limits. Xiao, Zangwill and Stiles (2004) have compared solutions of a Boltzmann equation with equation (19) and found very good agreement.

It is difficult to directly compare the form of the torque in equation (19) with experiment because the torque is not directly measurable in the experiment; the only experimental observable is the time-dependent resistance. It is possible to use equation (19) to predict the dynamics, and then to predict the time-dependent resistance to compare with experiment, such simulations are described briefly in Section 5. However, such a comparison requires correctly knowing and treating all of the other factors that contribute to the dynamics. More direct comparisons can be made between the measured and calculated resistances as a function of the relative angle between the magnetizations (Pratt, W.P. Jr. Private Communication), (Urazhdin, Loloee and Pratt, 2005). The measurements show clear deviation from simple $\sin^2(\theta/2)$ behavior. However, the deviations tend to be smaller than those calculated (Manschot, Brataas and Bauer, 2004a) with the models that give results like equation (19).

The torque in equations (18) and (19) is zero for parallel and antiparallel alignments of the magnetization. The existence of transitions out of these configurations is then due to instabilities developing in the configurations as the current is varied, see Sun (2000); Bazaliy, Jones and Zhang

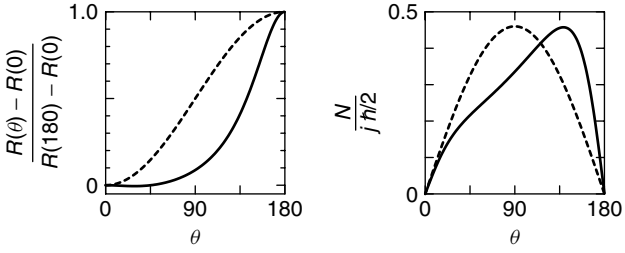

Figure 8. The angular dependence of the torque and magnetoresistance as a function of the relative angle of the two magnetizations. The dashed curves show the simple forms frequently used in micromagnetic simulations, $\sin^2(\theta/2)$ and $\mathcal{P}\sin\theta$ for the relative magnetoresistance and the torque, respectively.

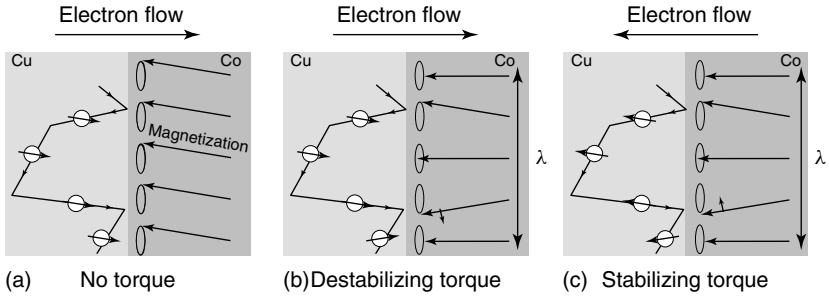

Figure 9. Spin-transfer torque due to lateral diffusion. Each panel shows an electron diffusing in a nonmagnet and reflecting twice from the interface with a ferromagnet. After it scatters, it is oriented *on average* either parallel or antiparallel to the magnetization depending on the direction of the electron flow, see Figure 1. In (a), the ferromagnetic magnetization is uniform laterally so that when the electron scatters the second time, it is aligned with the magnetization and there is no reorientation of either. The electron flow is from the nonmagnet into the ferromagnet, so the accumulated spins are minority spins. In (b), there is a nonuniform magnetization, and the diffusing minority spin is not aligned with the magnetization the second time it scatters. The magnetization exerts a torque on it and it exerts a torque on the magnetization which tends to amplify the spin wave. In (c), the electron flow is in the opposite direction so the diffusing spins are majority spins. In this case, the torque in the second scattering event tends to reduce the amplitude of the nonuniform spin wave.

(2004). For appropriate directions of current flow, the spin-transfer torque tends to amplify small deviations away from the collinear configuration and damping tends to diminish them. For large enough currents, the spin-transfer torque dominates and the system becomes unstable.

A different origin of the instability has been proposed by Berger and studied by a number of authors (Berger, 1996, 1997, 1999, 2002; Tsoi and Tsoi, 2001; Heide, 2001; Tsoi *et al*., 2004). Here, the longitudinal spin accumulation in the ferromagnet drives the instability rather than the transverse spin current. As the current through the structure increases, the spin accumulation eventually becomes large enough that it is possible to flip a spin from minority to majority and excite a magnon. This process is most clearly seen when the spin accumulation is described in terms of a spin-dependent chemical potential. In Berger's model, a particular magnon mode, possibly the uniform mode, gets macroscopically populated through stimulated emission. This instability then gives rise to reversal with a particular critical current density. Tserkovnyak, Brataas and Bauer (2003) have shown that a model without direct magnon excitation but including spin pumping (see below) can give the same critical current density.

When the magnetization varies in space, there are additional considerations. If the magnetization varies along the direction of the current flow, there are torques on the magnetization as the spins in the current precess around the varying magnetizations, as mentioned in Section 3. If the magnetization varies in the plane of the interface, lateral diffusion of spins can tend to increase or decrease these variations depending on the direction of the current flow. If the net electron flow is from a nonmagnet into a ferromagnet, the spins that accumulate in the nonmagnet are, on average, antiparallel to the spin density in the ferromagnet. If the spin density is not uniform, locally, the spins tend to align opposite to the local spin density. These electrons are diffusing, so there is a good chance that some of them diffuse laterally and scatter again from the interface at some different point. If the direction of the spin density at the point is different, the electron, on average, exerts a torque on the magnetization at that point. When the electron flow is from the nonmagnet into the ferromagnet, more minority spins are diffusing, and the torque tends to amplify the variations away from the average, see Figure 9. On the other hand, for electron flow from the ferromagnet into the nonmagnet, more of the diffusing spins are aligned with the spin density, and the resulting torque tends to reduce variations away from the average.

These torques due to lateral diffusion have been discussed (Polianski and Brouwer, 2004; Stiles, Xiao and Zangwill, 2004) in the context of instabilities in single ferromagnetic films and (Brataas, Tserkovnyak and Bauer, 2006) in the context of trilayers. For single films, these calculations show that for the current densities studied experimentally in these systems, nonuniform modes can become unstable. Instabilities have been observed in point contact experiments with single films (Ji, Chien and Stiles, 2003; Chen, Ji, Chien and Stiles, 2004) and also in lithographically defined single films (Özyilmaz *et al*., 2004). The critical currents are close to those found in the calculations and the field dependence of the critical currents is also similar. However, there are still details of the experimental results that are not explained by the calculations.

Finally, before discussing the dynamics that result from the spin transfer torque, there is a correction to the boundary condition, equation (17), when the magnetization is time dependent

$$\mathbf{Q}_\perp \cdot \hat{\mathbf{n}} = B\mathbf{s}_\perp + B'\hat{\mathbf{u}} \times \dot{\hat{\mathbf{u}}} \tag{20}$$

where $\hat{\mathbf{u}}$ is the direction of the magnetization and $\dot{\hat{\mathbf{u}}}$ is its time derivative. This additional term describes the phenomenon called *spin pumping*, an effect originally proposed by Berger (1996, 2001), developed by Tserkovnyak, Brataas and Bauer (2002, 2005) and computed in a number of different models (Tserkovnyak, Brataas and Bauer, 2002; Mills, 2003; Šimánek and Heinrich, 2003; Šimánek, 2003). The two terms in equation (20) are closely related. The first term describes the spin current discontinuity that gives rise to a torque and causes the magnetization to move and the second is the spin current that results from a moving magnetization. Both phenomena are controlled by related parameters

$$B' = \frac{A_{\mathrm{FS}}}{(2\pi)^3}\frac{\hbar}{2} = \frac{\hbar^2}{2}\mathcal{N}B \tag{21}$$

where A_{FS} is projected area of the Fermi surface in the nonmagnet.

Equation (20) shows that even in the absence of a current, a moving magnetization drives a spin current in the nonmagnetic material. When this spin current is absorbed through spin-flip scattering or scattering from another ferromagnetic layer, the spin-pumping process acts like a form of interfacial damping. These effects have been observed in line-width measurements in ferromagnetic resonance (Urban, Woltersdorf and Heinrich, 2001; Mizukami, Ando and Miyazaki, 2002; Ingvarsson *et al*., 2002; Lubitz, Cheng and Rachford, 2003; Heinrich *et al*., 2003; Lenz *et al*., 2004).

5 DISCUSSION

This chapter describes the physics that leads to spin-transfer torques in magnetic multilayers. When the magnetizations of the layers are not collinear with each other, the spin-polarized currents transfer angular momentum to the magnetizations near the interfaces, giving rise to spin-transfer torques. These torques can be computed using a combination of quantum-mechanical calculations of the behavior of spins at interfaces and semiclassical transport calculations to describe the flow of spins in the multilayers.

Quantum-mechanical calculations of spins at interfaces show that a combination of spatial separation of spin components coupled with classical dephasing leads to the approximate absorption of the transverse spin current at the interfaces. This result means that independent of their orientation when approaching the interface, the spins are on average collinear with the magnetization when they leave the interface. In effect, any component of the incoming spins that is transverse to the magnetization is transfered to the magnetization. The angular momentum along the magnetization direction is conserved.

The results of the quantum-mechanical calculations are inserted into semiclassical transport calculations as boundary conditions. These calculations determine the degree of the spin polarization at the interfaces. They show that currents become spin polarized through the combination of spin-dependent conductivities and interface conductances together with spin-flip scattering. Spin-flip scattering couples angular momentum between the electron system and the lattice. The spin-transfer torque couples angular momentum between the electron system and the magnetization.

The transport calculations are done for fixed magnetizations, even when the magnetizations are time dependent. This approximation is justified by a separation of timescales. A typical precession period for the magnetization is about 10^{-9} s and the transit time for a ballistic Fermi surface electron to go through the device (about 100 nm) is about 10^{-13} s. Even though the transport is not ballistic, this difference in timescales argues that treating the electrons as moving through a fixed magnetization should be a good first approximation.

The result of the semiclassical transport calculations is an expression for the spin-transfer torque as a function of the angle between the two magnetizations, equations (18) and (19). These equations summarize the results of the calculations described in this chapter. It is difficult to directly compare this result with experiment. Experimentally, it is the consequences of the torque that are readily measured, for example, the critical currents for switching between parallel and antiparallel configurations. To compare with such experiments, the calculated torque is inserted into the equation of motion for the magnetization, the Landau–Lifshitz–Gilbert equation, and used to compute the dynamics. There are several approaches to such computations.

The simplest approach is to assume that the magnetization of each layer is separately uniform. The model based on this assumption is called the *macrospin model*. The simplicity of the resulting equation of motion lends itself to analytic determination of critical currents (Bazaliy, Jones and Zhang, 2001, 2004; Xi and Shi, 2004) and detailed exploration of behavior as a function of field and current (Katine *et al*., 2000; Kiselev *et al*., 2004; Koch, Katine and Sun, 2004; Xiao, Zangwill and Stiles, 2005). However, the assumption of a uniform magnetization is not always justified. Relaxing this approximation gives a full micromagnetic model. Such calculations (Miltat, Albuquerque, Thiaville and Vouille, 2001; Li and Zhang, 2003; Zhu and Zhu, 2004; Lee *et al*., 2004a,b; Zhu, Zhu and White, 2004; Berkov and Gorn, 2005a,b; Montigny and Miltat, 2005) treat the detailed spatial variation of the magnetization, but the results are sensitive to many of the details of the samples. Since many of these details, like grain sizes, local anisotropies, the detailed shape,

and so on are not measured, it is hard to make definitive comparisons between these calculations and measurements.

A final complication of the comparison between theory and experiment is that experiments are typically done at finite temperature and calculations are most simply done at zero temperature. Under the influence of temperature, transitions between different configurations become statistical rather than deterministic. Several different approaches have been used to analyze the statistics of the switching events (Myers *et al*., 2002; Koch, Katine and Sun, 2004; Li and Zhang, 2004; Apalkov and Visscher, 2005). The most straightforward approach to including thermal effects is to include a fluctuating field in macrospin simulations (Russek *et al*., 2005; Xiao, Zangwill and Stiles, 2005). Such simulations give a reasonably good account of the effects of temperature if allowance is made for the difference in the timescales used in experiments and those achievable in the simulations.

Comparisons between theory and experiment generally give qualitative, but not quantitative agreement. One of the most straightforward predictions of the torque in equations (18) and (19) when inserted into the macrospin model is that the critical currents for the transitions between parallel and antiparallel alignment are determined by the slopes of the torque as a function of angle for 0° and 180° relative angles. Since transport calculations generally give a very different polarization of the current for the two alignments, the critical current for the parallel to antiparallel transition is expected to be larger in magnitude than that for the reverse transition. Although there is wide variation seen experimentally, the trend is that this difference is smaller than what is expected from theory. It is not clear whether this disagreement points to errors in the calculation of the torque or deviations of the reversal process from that expected for a macrospin. Other disagreements between macrospin calculations and experiment appear to explainable by micromagnetic calculations. These are discussed in more detail in other chapters in the volume.

Microwave Generation in Magnetic Multilayers and Nanostructures

William H. Rippard and Matthew R. Pufall
National Institute of Standards and Technology, Boulder, CO, USA

1 INTRODUCTION

The states of magnetic devices are typically controlled and manipulated through applied magnetic fields. The magnetization states of the magnetic elements can be controlled through quasistatic fields, as in the case of magnetic switching, or through time-varying applied fields, as is done in precessional switching (Kaka and Russek, 2002; Gerrits *et al*., 2002) and ferromagnetic resonance (FMR) (Sparks, 1964). In 1996, it was predicted that the magnetization states of thin-film magnetic elements could be similarly controlled through the use of a spin-polarized dc current through the spin-transfer effect (Slonczewski, 1996; Berger, 1996). At that time, typical device dimensions were large enough so that the spin-transfer torque (STT) was much smaller than the torques resulting from applied fields and device anisotropy fields. Hence, the STT did not appreciably alter device performance. However, as device dimensions shrink to below $\approx$100 nm, the STT can be of similar strength to those associated with magnetic fields, and the spin-transfer effects can drastically alter the behavior of the magnetic devices. More specifically, spin-transfer effects have been shown to lead to quasistatic hysteretic switching (Myers *et al*., 1999; Katine *et al*., 2000), high-frequency telegraph switching (Urazhdin, Birge, Pratt and Bass, 2003; Pufall *et al*., 2004), and coherent precessional dynamic excitations (Kiselev *et al*., 2003; Rippard *et al*., 2004a,b). These new effects may find applications in terms of current-induced switching in future generation magnetic random access memory (MRAM) elements and magnetic recording technologies and may enable magnetic nanostructures to be used as *active* circuit elements: for example, high-frequency nanoscale oscillators, mixers, and detectors. However, these same effects may also prove to be problematic in terms of decreasing stability and increasing noise in nanoscale magnetic sensors such as hard-disk read heads (Smith, 2004).

Many of the initial spin-transfer research efforts have focused on characterizing and understanding spin torque–induced switching behaviors of a patterned magnetic element in fields on the order of the device's coercive field. In the case of larger applied fields, these same devices showed anomalies in their transport properties (peaks in the differential resistance of the device for certain values of the dc current I_{dc}), which were often taken as evidence of the onset of spin-transfer-induced dynamics in these structures (Katine *et al*., 2000). Analogous high-field measurements were also performed with mechanical point contacts, which showed similar transport anomalies at high current densities. Although there was one early measurement that showed a relationship between the transport through the

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 2: *Micromagnetism*.

devices and externally applied microwave signals (Tsoi *et al*., 2000), the evidence that the spin torque effect led to coherent microwave precession in these devices remained only indirect until relatively recently (Kiselev *et al*., 2003; Rippard *et al*., 2004a).

Here, we give an overview of the work performed at the National Institute of Standards and Technology (NIST) in studying these coherent precessional dynamics induced in magnetic nanostructures and compare these dynamics in lithographically patterned nanopillar devices and nanocontact devices. In general, the precessional frequency of the magnetic oscillators can be tuned over a range of several gigahertz by varying the dc current applied to the device. The oscillation frequencies also depend on the applied magnetic field, resulting in a nanoscale oscillator that can be tuned from a few gigahertz to greater than 40 GHz. For nanocontact devices, the linewidths of these excitations can be as narrow as a few megahertz. This gives quality factors for the excitations of more than 18 000 at the highest frequencies. As the direction of the field applied to the devices is changed from parallel to perpendicular to the film plane, the power output from the structures increases by several orders of magnitude. For nearly out-of-plane fields, the high-frequency voltage output from the device can be a significant fraction of the maximum voltage expected from the giant magnetoresistance (GMR) effect. The nanoscale oscillators also display a number of attributes that make them attractive for potential technological applications. These include the ability to frequency modulate the devices, phase lock them to external reference signals, and electronically control their phase relative to that of an input signal.

2 SPIN-TRANSFER DYNAMICS

The fundamental concept behind the spin-transfer effect is the transfer of angular momentum from spin-polarized current carrying electrons to the magnetization of a ferromagnetic film. The result of this transfer of angular momentum is that the polarized electron current exerts a torque on the magnetization of the ferromagnetic film, generally referred to as the *spin-transfer torque*. The STT can either add to the intrinsic damping, thereby stiffening the system, or can counteract the dampening in the system, leading to current-induced switching or coherent steady-state precessional dynamics. Here, we will concentrate on the spin-transfer-induced precessional dynamics and generally compare the measured behaviors to those initially predicted by Slonczewski (1999), who described the dynamic behavior of the free layer magnetization $\vec{m}_{\text{free}}$ by

$$\frac{\mathrm{d}\vec{m}_{\text{free}}}{\mathrm{d}t} = -\mu_0\gamma\vec{m}_{\text{free}} \times \vec{H}_{\text{eff}} - \mu_0\gamma\alpha\vec{m}_{\text{free}} \times (\vec{m}_{\text{free}} \times \vec{H}_{\text{eff}}) + \frac{\varepsilon J_{\text{inj}}\hbar}{el_z 2}\frac{\gamma}{M_{\text{s1}}}\vec{m}_{\text{free}} \times (\vec{m}_{\text{free}} \times \vec{m}_{\text{fixed}}) \quad (1)$$

where $\vec{m}_{\text{fixed}}$ is the magnetization of the fixed layer, γ is the gyromagnetic ratio, α is the phenomenological damping term, J_{inj} is the current density through the device, and l_z is the thickness of the free layer. The first term in equation (1) describes typical Larmor precession of the magnetization about the total effective field; the second is the phenomenological damping term which acts to return the magnetization to lie parallel with the total effective field; and the third describes spin-transfer-induced torque, the sign of which is determined by the direction of current flow through the device and can be either positive or negative. By comparing the functional forms of the second and third terms we can see that, for the correct sign of current flow, the STT can counteract that associated with intrinsic damping in the system. For certain ranges of current and applied field, this leads to coherent steady-state precessional motion of the free layer magnetization.

The magnitude of the STT is proportional to the current density passed through the device and, in order for the spin-transfer effects to become significant, high current densities are required. Typical critical currents associated with switching and precessional dynamics are on the order of 10^6–10^7 A cm^{-2}, depending on the device geometry and materials under study. Devices generally have critical dimensions of about 100 nm, so that such high current densities can be achieved with only moderate applied currents of a few milliamperes. Such small dimensions are also required to ensure that the spin-transfer effects dominate over the oersted fields generated by the applied current itself (Katine, Albert and Buhrman, 2000). Experiments have been performed with patterned magnetic pillar structures (Katine *et al*., 2000; Koch, Sun and Katine, 2004; Deac *et al*., 2005; Mancoff *et al*., 2003; Ozyilmaz *et al*., 2003; Urazhdin, Birge, Pratt and Bass, 2003; Kaka *et al*., 2005a; Sun *et al*., 2002; Tulapurkar *et al*., 2004), nanowires (Fabian *et al*., 2003), small electrical contacts made either to or between macroscopic magnetic layers (Rippard *et al*., 2004a; Myers *et al*., 1999), mechanical point contacts (Tsoi *et al*., 2000; Ji, Chien and Stiles, 2003; Pufall, Rippard and Silva, 2003), and patterned magnetic tunnel junctions (Huai *et al*., 2004; Fuchs *et al*., 2005). There is now very good evidence that the spin-transfer effect can be used to induce both switching and precessional motion of the magnetization in the devices in all cases, although the details may vary between the different device geometries.

Cross-sectional views of the typical nanopillar and nanocontact devices we discuss here are shown in Figure 1, along

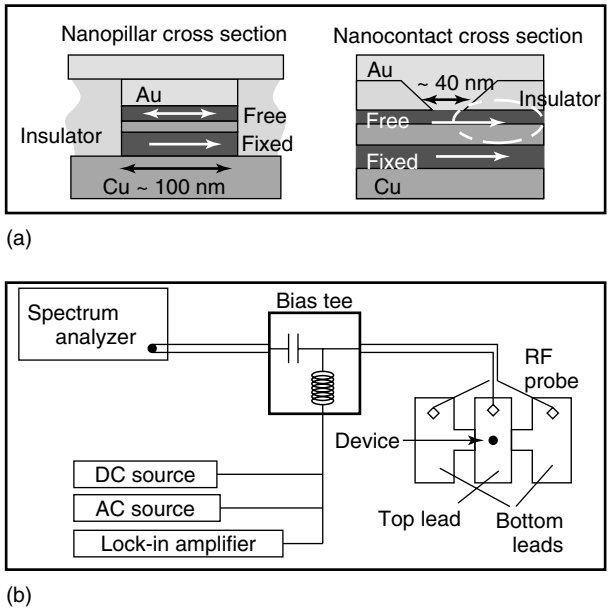

Figure 1. (a) Cross-sectional schematics of both the nanopillar and nanocontact device geometries. (b) Measurement schematic. The bias tee defines the high- and low-frequency legs of the circuit. A spectrum analyzer or a sampling oscilloscope measures the device output. In many measurements, an amplifier is located between the spectrum analyzer and the bias tee.

with a schematic of the measurement geometry. For either device geometry a spin-valve stack such as Ta (5 nm)/Cu (50 nm)/FM1 (20 nm)/Cu (3.5 nm)/FM2 (5 nm)/Cu (1.2 nm)/Au (2.5 nm), where FM is a ferromagnetic material, is first sputter deposited onto an oxidized Si substrate. The thick bottom Cu layer acts as a current shunt to reduce local heating in the active area of the device. To fabricate nanopillar devices, this mesa is then patterned and ion milled to form a pillar structure typically having either an elliptical or elongated hexagonal shape with dimensions of roughly 100 nm (Katine, Albert and Buhrman, 2000). A thick Au layer is used to make electrical contact to the device. Alternatively, a nanocontact device is fabricated by simply making a roughly 50-nm-diameter electrical contact to the top of the spin-valve mesa, which is roughly $8\,\mu\text{m} \times 24\,\mu\text{m}$ on a side. In both cases, the top contact is lithographically patterned into a coplanar waveguide structure and contacted with high-frequency 50 Ω probes. The thicker FM1 layer is typically $Co_{90}Fe_{10}$ while the thinner FM2 layer is typically $Ni_{80}Fe_{20}$. Hence, in these devices the thicker FM1 ('fixed') layer will have a critical current roughly eight times that of the thinner FM2 ('free') layer because of its increased thickness and larger saturation magnetization.

For both device structures the device resistance can range from less than 5 Ω to greater than 30 Ω depending on the materials in use and the lateral dimensions of the structure. The maximum resistance change associated with the GMR effect is typically about 200 mΩ. The structures are contacted with microwave probes and a dc current I_{dc} is passed through the device, along with about a 10 μA ac current, so that both the dc and differential resistances of the device can be simultaneously measured. We use the convention that positive currents correspond to electrons flowing from the free layer into the fixed layer. The devices are current biased so that changes in the relative alignment between FM1 and FM2 result in a voltage across the device through the GMR effect. The output from the device is measured through the high-frequency leg of the measurement circuit by use of either a spectrum analyzer or sampling oscilloscope (Figure 1b). Typically the signal from the device is amplified by 30 dB before measurement. In all cases this is divided out of the presented data. The losses associated with the impedance mismatch between the low resistance device and the 50 Ω load (measurement circuitry) are not taken into account but are expected to be substantial. The measurement circuit has a bandwidth of 0.1 GHz to ≈35 GHz. All measurements discussed here were performed at room temperature. Owing to ohmic heating the device temperature is slightly higher (≈10 °C) than the system temperature (Krivorotov *et al.*, 2004).

2.1 Nanopillar devices

Explicit measurements of coherent spin torque–induced dynamics were first performed in nanopillar devices by a group at Cornell University (Kiselev *et al.*, 2003) and soon afterwards in nanocontact devices by the group at NIST (Rippard *et al.*, 2004a). The evolution of the magnetization dynamics in a typical nanopillar device as a function of current for three different fields applied in the plane of the film is shown in Figure 2(a–c). The individual plots show the current dependence of the microwave precessional frequency f for a given applied field with the power associated, with the precession shown in a linear color scale. Individual spectral traces from the three different fields are shown in the line traces below the two-dimensional plots. The particular device shown here is a nanopillar structure with an elongated hexagonal shape (see Figure 2c) having dimensions of $120\,\text{nm} \times 60\,\text{nm}$, where both FM1 and FM2 are Co films.

As seen in Figure 2(a), precessional dynamics begin to occur in the device at $I_{dc} = 6.5$ mA. The spectral measurements indicate that the device response is composed of a number of harmonically related excitation frequencies and a low-frequency broadband response. Simulations suggest that the precessional magnetization trajectories in this geometry are elliptical in shape and that a number of harmonics will be present. In this case four harmonics can be observed. For

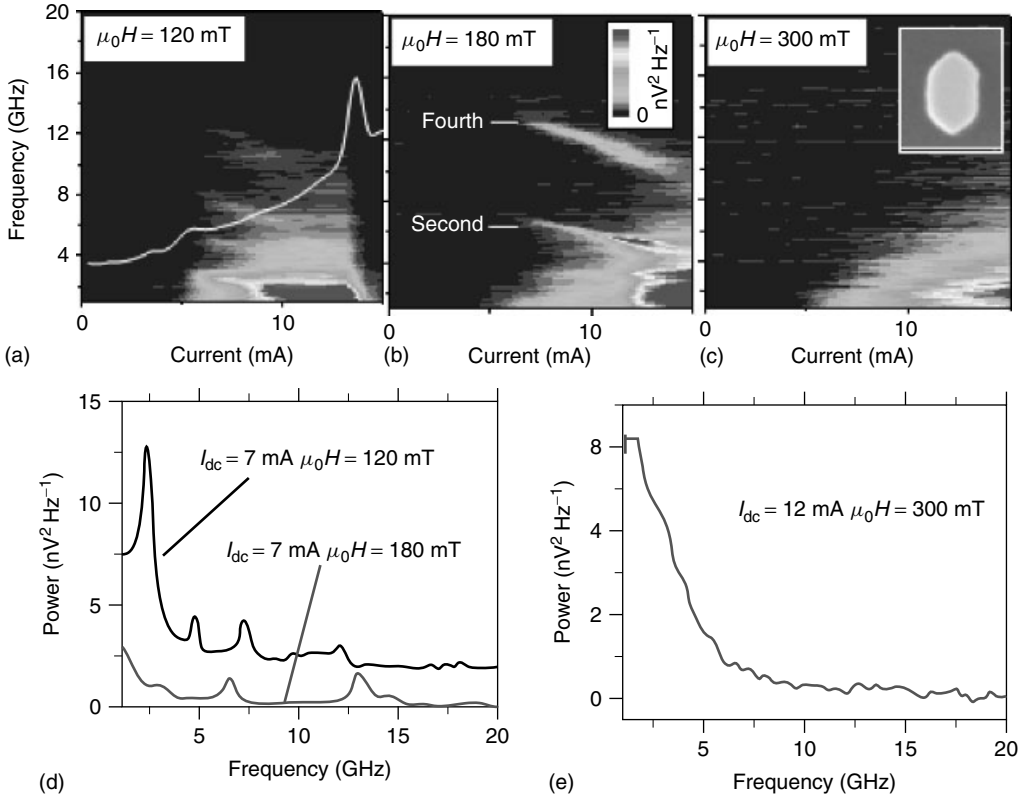

Figure 2. (a–c) Plots showing the spectral output of a nanopillar device as a function of I_{dc} for three different applied fields. The amplitude of the power spectral density is shown in a linear color scale from 0 to 7 $nV^2\,Hz^{-1}$. The corresponding dV/dI_{dc} curve is plotted for the data in (a). A plan view micrograph of the elongated hexagonal (60 nm × 120 nm) ion mill mask used to laterally pattern the nanopillar is shown in the inset of (c). The overlay in (a) shows the differential resistance curve of the device as a function of I_{dc}, and has maximum and minimum values of 17.7 and 16.2 Ω, respectively. (d–e) Spectral traces corresponding to individual current bias point in plots (a–c) showing various harmonically related signals along with the broadband low-frequency output as discussed in the text. In (d) the plots are offset for clarity.

precessional motion of the free layer which is perfectly symmetric about the easy axis of the device, only even-harmonic signals should be observed owing to the signal being generated through the GMR effect, which creates a signal roughly proportional to the cosine of the angle between the fixed and free layer magnetization directions. In most cases, however, odd harmonics are measured as well, indicating that there is some misalignment between the time-averaged magnetization directions of the two ferromagnetic layers. This is perhaps due to a slight misalignment between the applied field direction and the easy axis of the device but could also result from a relative splaying of the layers owing to either the oersted fields generated by the current or the spin-transfer effect itself.

As the current through the device increases, the frequency of oscillation decreases (red shifts) and the linewidth of the oscillations also increases. (The excitation linewidth is taken as the full-width-at-half-maximum (FWHM) of the spectral peak, as determined from a Lorentzian fit to the power spectral density.) The red shift in frequency with I_{dc} agrees well with theoretical expectations based on single-domain simulations of the Slonczewski model, as discussed in the previous sections of this volume and elsewhere (Russek *et al*., 2005; Kiselev *et al*., 2003; Xiao, Zangwill and Stiles, 2005; Berkov and Gorn, 2005; Lee *et al*., 2004; Bertotti *et al*., 2005). The increase in linewidth indicates that, in this geometry, the excitations become less coherent with increasing current. At currents above $I_{dc} = 8.5$ mA for a 120 mT applied field, the linewidths of the spectral peaks become roughly equal to the oscillation frequency and it is no longer possible to clearly identify a distinct oscillation frequency. At still higher currents, the various harmonic signals merge and only a low-frequency broadband response is measured. Above $I_{dc} = 14$ mA, no significant microwave output from the device is measured.

Both the onset and cessation of the precessional dynamics are correlated with features in the differential resistance curve which overlays the plot in Figure 2(a). The largest peaks in these curves are typically correlated with the onset or cessation of the large low-frequency broadband background,

as is the case here. These peaks in the differential resistance curve indicate that the device goes through abrupt and reversible changes in resistance at particular values of I_{dc}. The details of the heights and widths of these peaks in dV/dI_{dc} vary from device to device and can typically be taken as indicating only that the state of the device has been significantly changed at these current values. The overall quasiparabolic shape of the differential resistance curve is due to a combination of ohmic heating in the structure and a change in the average projection of the free layer magnetization onto that of the fixed layer.

As the applied field is increased the frequency of oscillation increases and the even-power harmonics become more pronounced than the odd harmonic signals, indicating that precession of the free layer is more symmetric with respect to the direction of the fixed layer (Figure 2b and d). The precessional oscillations again begin for $I_{dc} = 6.5\,\text{mA}$ and red shift with increasing current. At high-enough currents the spectral signals again become indistinct and only a broad low-frequency signal is measured. As the field is further increased to $\mu_0 H = 0.3\,\text{T}$ (Figure 2c), no distinct spectral frequency can be observed at any current and only the broadband low-frequency signals are measured. This same qualitative behavior is reported in the initial work at Cornell University (Kiselev *et al*., 2003), although the details vary slightly.

The evolution of the coherent spectral signals generally agrees with single-domain simulations based on the theory of Slonczewski (1996), although significant discrepancies between the experimental data and the model also exist (Russek *et al*., 2005; Kiselev *et al*., 2003; Xiao, Zangwill and Stiles, 2005; Berkov and Gorn, 2005; Lee *et al*., 2004; Bertotti *et al*., 2005). Perhaps the most manifest difference is that the single-domain simulations suggest that the precessional motion should neither simply cease nor evolve into a low-frequency broadband signal as the current through the device increases. Instead, numerical integration of equation (1) shows that the precessional modes change from in-plane precession to trajectories in which the time-averaged magnetization $\langle \boldsymbol{M}_{\mathbf{free}} \rangle$ has a component along the direction perpendicular to the plane of the film. In this regime, the frequency of precession is predicted to increase with increasing I_{dc} (blue shift) with current. Typically, this blue-shifting mode is not observed experimentally, but instead a broadband low-frequency output is measured.

The cause of this broadband signal can be understood by measuring the device output in the time domain. An example of this is shown in Figure 3. The time traces show that this broadband microwave signal results from the device undergoing random telegraph switching. As seen in the figure, the dwell times the device spends in the particular states are functions of current, resulting in a spectral signature that changes with I_{dc}, as seen in Figure 2. Initial studies indicated that the

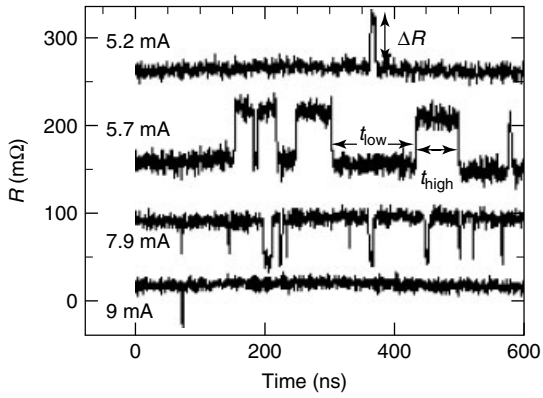

Figure 3. Time-domain measurements showing random telegraph noise occurring in a nanopillar device for several different current values (the curves are offset for clarity). For low currents the device has large dwell times in the low resistance state, whereas for high current values the device has large dwell time in the high resistance state. This switching behavior yields the broadband low-frequency signals discussed in the preceding text. The functional forms of the spectra are expected to be either Lorentzian or f^{-1}, depending on the details of the switching characteristics. (Reproduced from Pufall *et al*., 2004, with permission from the American Physical Society. © 2004.)

switching was between full parallel and antiparallel alignment and that the switching rates ranged between roughly 1 kHz and 1 MHz and the authors proposed an effective temperature model to explain their results (Urazhdin, Birge, Pratt and Bass, 2003; Fabian *et al*., 2003; Wegrowe, 2003). Further investigations found that the states between which the magnetization of the device switches are more complicated and do not necessarily correspond to parallel and antiparallel alignment. Instead, the states can correspond to only partial alignment and the switching rates can exceed 1 GHz (Pufall *et al*., 2004). Switching between numerous states can even occur, depending on the strength and direction of the applied field (Covington *et al*., 2004). The details of the switching behavior are determined largely by whether the applied field is greater than or less than the coercive field of the device under study. We note that this switching behavior can occur even in fields larger than the coercive field of the device. This means that, in the absence of the spin-transfer effect, there exists only one stable energy state for the device – the state having the magnetization pointing in the direction of the applied field. Evidently, the STT allows the device to access states that would not be stable in its absence.

At present, we do not have a full understanding of the states between which the device is switching. It has been suggested that the devices are switching between a static or switched state and a precessional state, or two different precessional states (Li and Zhang, 2003). This is certainly possible. However, spectral measurements show no evidence of a precessional state. This indicates that either the

frequency of any precessional motion, if present, has to be low enough to be overwhelmed by the low-frequency signal associated with the telegraph noise or that the amplitude of the precession is small enough to be below the noise floor of the measurements. Neither of these possibilities seems particularly suitable to explain the observed results. More recent simulations suggest that the two states are associated with the creation and annihilation of vortex states in the devices (Lee *et al*., 2004; Berkov and Gorn, 2005). More detailed comparisons with the experimental observations are still needed in order to verify this possibility. Here, we give an overview of the coherent precessional excitations induced by the spin-transfer effect and we will not discuss this switching behavior in any detail. We instead refer the interested reader to the references just mentioned.

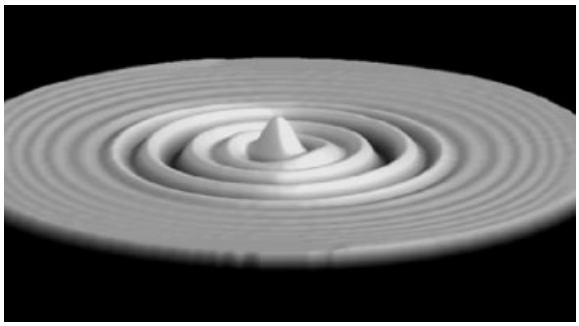

Figure 4. Micromagnetic modeling of the nanocontact geometry. The simulation assumes a dc current of 5 mA injected into a 50-nm area at the center of a 1-μm NiFe disk. The plot shows the local value of m_x in the excited region directly underneath the contact as well as spin waves radiating away from the contact area. The vertical axis is in arbitrary units.

2.2 Nanocontact devices

Throughout much of the remaining part of the chapter, we will concentrate on the precessional dynamics induced in nanocontact devices (see Figure 1b) in which a small ($\approx$50 nm) electrical contact is made to a larger (about 10 μm × 20 μm) magnetic spin-valve structure. The devices discussed will be composed of spin valves having FM1 as $Co_{90}Fe_{10}$ and FM2 as $Ni_{80}Fe_{20}$. In this device geometry, the current is not as well confined to the active area underneath the electrical contact, as in nanopillar devices. Hence, the current densities required to induce a dynamical response are expected to be slightly higher, as the continuous film will act as a slight current shunt away from the device area. However, there are several advantages to this device geometry: the edge defects associated with the patterning of the devices will be mitigated; there is no parasitic dipole coupling between the layers; the device area will be free from oxides that will be present on the sides of the patterned magnetic devices; and the devices are easier to fabricate (particularly for integrated arrays). These topics will be discussed in more detail in the following text.

One potentially important difference between the two device configurations is that in the nanocontact geometry the area undergoing magnetic precession is directly coupled to the surrounding magnetic film through the exchange interaction. As was pointed out by Slonczewski (1999), this naturally leads to spin-wave radiation away from the contact area into the surrounding film. Hence, the nanopillar and nanocontact device geometries have very different boundary conditions, which may play an important role in the nature of the dynamic excitations. An example of a simulated excitation in a nanocontact device, which was obtained using the object oriented micromagnetic framework (OOMMF) program (Donahue and Porter, 2005), is shown in Figure 4. The simulation here assumes a localized current source (40-nm diameter contact) into a 1-μm NiFe/Cu/CoFe disk with an out-of-plane applied magnetic field (1.1 T). As seen in the figure, even though the current is locally injected, the induced excitations have an effectively extended nature and may result in dynamical excitations that are significantly different from those excited in nanopillar devices. More recent theoretical work has even suggested that the exchange coupling between the region directly excited by the STT and the surrounding film in the nanocontact geometry can lead to excitations having fairly complicated mode profiles even directly underneath the contact area (Hoefer *et al*., 2005). The differences between the measured behaviors of the spin-transfer-induced excitations in the two device geometries will be discussed in more detail in the following text.

2.2.1 *In-plane fields*

We will first discuss the dynamics for fields applied in the plane of the film (the same field geometry described in the preceding text for the nanopillar devices). In Figure 5(a) we show the differential resistance of the device as a function of I_{dc}. The curve is similar to those observed for nanopillar devices. There is a quasiparabolic background, on top of which is a small peak in the curve, which occurs here at $I_{dc} = 4$ mA. The spectral output of the device is shown for several values of I_{dc} as indicated in Figure 5(b). For low currents no spectral peaks are observed. At $I_{dc} = 4$ mA, a spectral peak emerges at a frequency of $f = 7.9$ GHz. As seen in the figure, the oscillation frequency red shifts with increasing current, as was observed in the nanopillar devices. The power in the peak initially increases with I_{dc}. However, at higher currents the power output continually decreases until no spectral peaks are observed, as shown by the $I_{dc} = 9$ mA data.

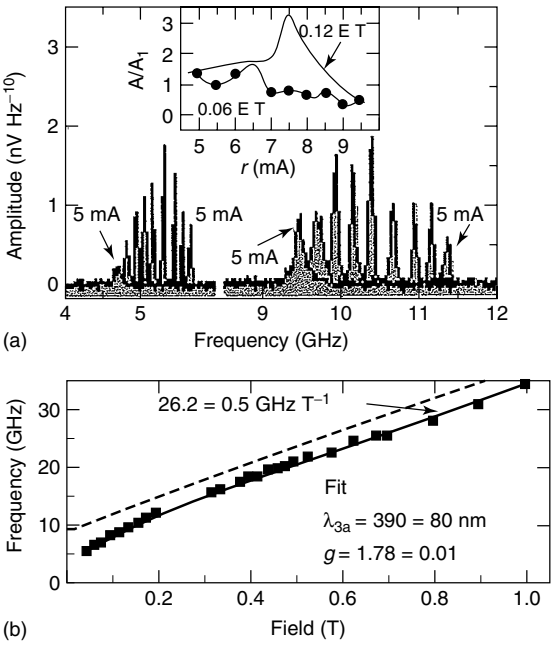

Figure 6. (a) High-frequency spectra for currents from 5 to 9 mA taken in 0.5 mA steps with $\mu_o H = 0.06\,\mathrm{T}$ showing the fundamental response and another at twice that frequency (inset). Amplitude ratios of the peaks as a function of I_{dc} for two different fields. (b) Measured frequency at onset as a function of $\mu_0 H$ along with fit (solid line). The dashed line corresponds to the excitation frequencies predicted by Slonczewski (1999) using the deflated value of $g = 1.8$. Error bars (FWHM) are smaller than the data points. (Reproduced from Rippard *et al*., 2004a, with permission from the American Physical Society. © 2004.)

The oscillation frequency, determined by fitting Lorentzian functions to the spectra, depends linearly on the injected current, as shown in Figure 5(b) (inset). The strength of this red shift depends on the magnitude of the applied field and varies from approximately $0.2\,\mathrm{GHz\,mA^{-1}}$ at low fields ($\approx$50 mT) to approximately $1\,\mathrm{GHz\,mA^{-1}}$ at higher fields of $\approx$0.8 T. For this field geometry, devices can typically be tuned over a range of several gigahertz by varying the current through the device for a fixed field magnitude. As shown in Figure 6(a), both first and second harmonic signals are often observed in these devices, as was the case with the nanopillar structures. Here, the existence of a first-harmonic signal cannot be attributed to a misalignment between the layers being induced by the applied *field*, as the fields are much larger than the film coercivities of a few millitesla. Instead, the misalignment is more likely caused by the applied current either through the generated oersted fields or the spin torque itself.

The frequency of oscillation can also be controlled by the strength of the applied field, as shown in Figure 6(b). The data plotted correspond to the highest precession frequency (lowest current) for a given applied field (see Figure 5(b)). As seen in the figure, the precessional frequency can be tuned from a few gigahertz to greater than 35 GHz by varying the applied field from 50 mT to 1 T, giving an average field tunability of roughly $26\,\mathrm{GHz\ T^{-1}}$. A very similar variation of the oscillation frequency with the applied field is found for nanopillar devices (Kiselev *et al*., 2003). No spectral peaks are measured above $\mu_0 H > 1\,\mathrm{T}$ ($f = 35\,\mathrm{GHz}$). However, this does not necessarily indicate the cessation of precessional dynamics. Measurement of dynamic excitations above 35 GHz is beyond the bandwidth of our present measurement system. The drop in signal strength at these highest frequencies occurs in all measurement geometries and is due to the bandwidth limitation of the measurement system. Furthermore, the signals in Figure 5 correspond to first-harmonic peaks and the strength of the second harmonic signal quite probably increases at high applied fields, as precession becomes more symmetric about the field direction (i.e., the direction of the fixed layer). In fact, output from the devices above 100 GHz is quite possible in the present measurements.

Determination of the precessional mode being excited is clearly of interest. The nanopillar devices are typically small enough to behave largely as single-domain particles and the precessional frequencies at the onset of oscillations are reasonably well described by the standard Kittel equation for FMR (Kittel, 1986). Both of these point to the uniform precession of the free layer in the nanopillar devices, at least at the onset of precession. Recent micromagnetic modeling

results suggest that this single-domain behavior breaks down for currents slightly above the critical current (Lee *et al*., 2004; Montigny and Miltat, 2006, private communication; Berkov and Gorn, 2005). In the nanocontact devices, the mode or the wavelength of the excitation is less clear. Slonczewski (1999) initially predicted that the excitation wavelength would be set by the localized nature of the current passing through the layers and that the device size would roughly equal half of the wavelength of the excited mode.

In order to investigate the excitation wavelength, we fit the data shown in Figure 6(b) to the Kittel equation for in-plane spin-wave generation excluding dipole effects:

$$f(H) = \left(g\mu_B\mu_0/h\right)\left((H + H_{sw} + H_k + M_{eff})\right. \\ \left.\times\ (H + H_{sw} + H_k)\right)^{1/2} \quad (2)$$

where $H_{sw} = Dk^2/(g\mu_B\mu_0)$, D is the exchange stiffness, g is the Landé factor, k is the magnon wave number, M_{eff} is the effective magnetization, H_k is the anisotropy field, μ_0 is the permeability of free space, h is Planck's constant, and μ_B is the Bohr magneton (Kittel, 1986). Equation (2) is strictly valid only in the limit of small-amplitude precession, a limit that is likely not met in the present experiments. We include this fitting procedure as a comparison to the behavior predicted by Slonczewski (1999) and as a beginning point for a discussion of the modes excited in the nanocontact structures.

In fitting the data, k and g are treated as free parameters while fixed values of $\mu_0 M_{eff} = 0.8\,\mathrm{T}$ and $\mu_0 H_k = 0.4\,\mathrm{mT}$ are used, as determined from magnetometry measurements. The fit yields $g = 1.78 \pm 0.01$ and a magnon wavelength of $\lambda = 390 \pm 80\,\mathrm{nm}$. From both the above fit and the linear portion of the data for $\mu_0 H > 0.4\,\mathrm{T}$ we determine $g = 1.78 \pm 0.01$, which is smaller than the accepted value of $g = 2$. This discrepancy is not unexpected. Numerical simulations of the Landau–Lifshitz–Gilbert (LLG) equation show that fitting equation (2) to data corresponding to large-angle precession will give an apparently suppressed value of g. As we will discuss in more detail in the following text, the precessional angles in these devices can be quite large.

The wavelength determined from the fit is much larger than the contact diameter, in contrast to the initial predictions. Although given the above considerations the wavelength determined from the fit can be taken only as a guide, the data do indicate that the excitations approximate the uniform precessional mode, that is, the uniform FMR mode, and that the excitation frequency is not dominated by the spin-wave exchange energy H_{sw}. For comparison, assuming a 40-nm electrical contact, an excitation wavelength predicted by Slonczewski would yield a value of about $\mu_0 H_{sw} = 0.14\,\mathrm{mT}$, making the predicted frequencies (shown as the dashed line in Figure 6b) clearly higher than those observed experimentally. Similar values for g and λ were measured for devices having CoFe as the free layer, although the oscillation frequencies were higher, in accordance with the larger value of the CoFe saturation magnetization.

2.2.2 *Out-of-plane fields*

The dynamics excited by the spin-transfer effect change dramatically with the direction of the applied field. First, we will discuss the dynamics when the field is applied perpendicular to the plane of the films. In this geometry, the applied field will pull the magnetizations of both ferromagnetic layers at least partially out of the plane of the film. The calculated canting angles for both CoFe and NiFe for several different field strengths and angles are shown in Figure 7. This figure shows that over the field range of interest (0.5–1 T) the NiFe layer is canted at a significantly larger angle than the CoFe, particularly for applied values on the order of 1 T.

An example of the evolution of the precessional dynamics as a function of current for an out-of-plane field of $\mu_0 H = 0.9\,\mathrm{T}$ is shown in Figure 8(a). As can be seen in the figure, the oscillation frequencies increase (blue shift) with increasing I_{dc} for this geometry and field range. More complicated behavior is also observed; for example, there are discrete jumps in the precessional frequency with current. These jumps are not typically hysteretic in the current or applied field, although some devices do show hysteretic characteristics at this extreme field angle. The cause of the discontinuous evolution of frequency with current is not

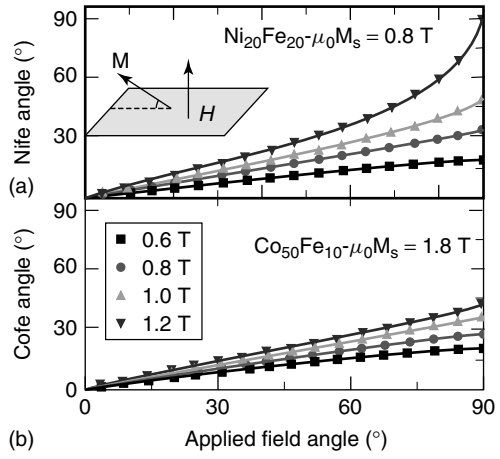

Figure 7. Schematic diagram to define the angles discussed in the text. The plot gives the calculated static angle between the two layers as a function of the angle of the applied field for several different field strengths.

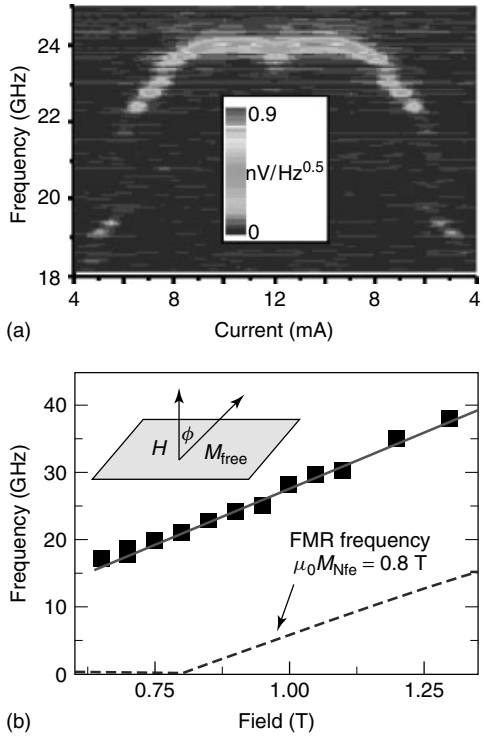

Figure 8. (a) Plot of f as a function of I_{dc} with the amplitude shown in a linear color scale, as shown in the inset. Discretization in the plot results from measuring the frequency spectra in 500 μA intervals. (b) f versus H for H applied out of plane. Data correspond to the highest f. The error bars (FWHM) are smaller than the data points. The fit to the data is discussed in the text. The dashed line gives the calculated FMR precessional frequencies. (Reproduced from Rippard *et al*., 2004a, with permission from the American Physical Society. © 2004.)

certain, although simulations suggest that it might be caused by an abrupt reorientation of the 'fixed' layer, which will be discussed in more detail in the following text.

In Figure 8(b), we plot the excitation frequency as a function of the applied field strength. For clarity, we again plot only the highest measured precession frequency for each given applied field value. The precession frequency is found to vary linearly with a slope of roughly 32 GHz T^{-1}. The data are fit with the Kittel equation for circular magnetization precession about the axis perpendicular to the plane of the film, which correspond to the trajectories predicted by the single-domain simulations

$$f(H) = \left(g\mu_B\mu_0/h\right)\left(H - M_{eff}\cos(\phi)\right) \qquad (3)$$

where ϕ is the angle of precession with respect to the field direction, θ_H. The data are fit using g and ϕ as free parameters to match the slope and intercept of the data, respectively. From the fit we find $g = 2.1 \pm 0.01$ and a precession angle $\phi = 80^\circ$, indicating that these are large-angle precessional modes. For comparison, the dashed line in the figure represents the corresponding small-angle modes typically observed in FMR experiments. The origin of the significant offset between the two curves is the greatly reduced demagnetization factor ($M_{eff}\cos(\phi)$) associated with the large-angle precessional modes. This results in relatively large total applied effective fields as compared to those associated with small precessional angles. As was the case of in-plane applied fields, these precessional excitations can be considered as very large-angle versions of FMR excitations (Bertotti *et al*., 2005), although such modes cannot be accessed through the application of time-varying fields used in FMR experiments (Suhl, 1958).

2.2.3 *Intermediate field angles*

There are clear differences between the precessional dynamics in the two geometries discussed in the preceding text. For the in-plane case, the precessional frequencies linearly decrease with the current through the device, and the frequency of precession evolves in a continuous manner. In the out-of-plane geometry the evolution of the dynamics with current is more complicated. Overall, the excitation frequencies increase with increasing I_{dc}, and there are discontinuous jumps in the excitation frequency as the current through the device is changed. In the following text, we investigate the evolution of the precessional motion as a function of both I_{dc} and $\mu_0 H$ as the direction of the applied field is changed from in-plane to out-of-plane.

In Figure 9, we show the device oscillation frequencies as a function of I_{dc} for several field angles θ_H, given relative to the film plane, for a constant field $\mu_0 H = 0.8$ T. For in-plane fields, the frequency output linearly red shifts with current, as is generally observed in these devices for in-plane fields, as discussed in the preceding text. As the angle of the applied field is increased, the excitations typically appear over a wider range of currents, and the dependence of the frequency f on I_{dc} becomes more complicated. For the data at $\theta_H = 35^\circ$ a linear red shift is found for low currents. However, at $I_{dc} = 5$ mA the slope of the curve $\mathrm{d}f/\mathrm{d}I_{dc}$ changes sharply and, although the current-induced red shift persists, f deviates significantly from a linear dependence on current. As the angle is increased, this initial sharp change in slope becomes an abrupt jump in the excitation frequency, as shown by the data for $\theta_H = 45^\circ$, defining two distinct frequency branches in the f versus I_{dc} curve. For $\theta_H = 55^\circ$ the precession frequency initially decreases but then blue shifts with current for $I_{dc} > 5$ mA. At this angle, as I_{dc} reaches 6.625 mA the excited mode becomes poorly defined (the excitation linewidth is several gigahertz wide and the amplitude strongly decreases), and we were not

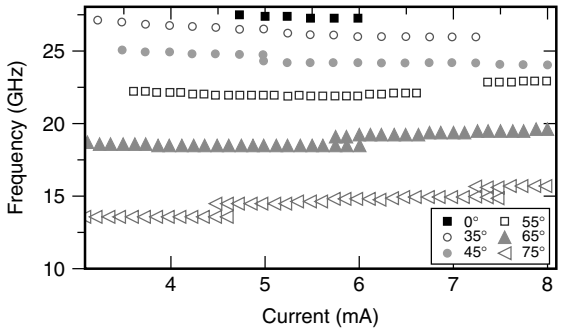

Figure 9. Frequency versus current for several different field angles for $\mu_0 H = 0.8$ T. The FWHM of the spectra are smaller than the data points. Both increasing and decreasing I_{dc} scans are shown but are not visible on this scale range. (Reproduced from Rippard *et al.*, 2004b, with permission from the American Physical Society. © 2004.)

able to uniquely determine f for 6.75 mA $< I_{dc} <$ 7.25 mA. However, as the current increases further the mode again becomes well defined and blue shifts with current.

As the field angle is increased, we again see abrupt jumps in the frequency of the oscillations with increasing current, although the jumps in f are now to higher frequencies instead of to lower frequencies. For instance, for $\theta_H = 65^\circ$ the oscillation frequency red shifts for currents below 6 mA, whereas for higher currents the oscillations abruptly shift to a higher frequency and show a blue shift with increasing current. At higher angles similar multiple jumps in f with I_{dc} are still seen but with the frequency now showing an *overall* blue shift on each of the individual branches of the curves (see $\theta_H = 75^\circ$). However, the frequency does not typically vary linearly, or even monotonically, with I_{dc} over the entire range of the individual branches of these curves. For instance, for the middle branch of the $\theta_H = 75^\circ$ data, f shows a blue shift at low current but a red shift for $I_{dc} > 6.75$ mA. This same discontinuous evolution of frequency with I_{dc} described in the preceding text occur over the range of fields studied (0.5–1.1 T) although the particular current and angle at which two frequency branches are delineated, as well as the detailed dependence of f on I_{dc} over a particular branch, vary with H. For a given angle, f can be tuned, on average, over a range of several gigahertz by varying I_{dc}.

As shown in Figure 9 for $\theta_H = 65^\circ$ and $I_{dc} \approx 5.75$ mA, the frequency output of the device at fixed current and field can be multivalued. This is not hysteretic behavior with f depending on the direction of current sweep. Rather multiple nonharmonically related peaks are observed in the spectral output of the device at this particular current and field. Individual time-sequenced spectra typically show that the powers in the individual peaks change significantly from scan to scan with the power associated with one of the frequencies increasing or decreasing at the expense or benefit of the other. We attribute this to the device hopping between distinct precessional trajectories with different oscillation frequencies. Often each individual peak in a multipeak spectrum has a linewidth less than 50 MHz, indicating that the individual modes are still well defined. In some cases, this hopping behavior is not explicitly observed and is likely due to our $\approx$100 ms spectral acquisition time that limits direct detection of this switching behavior to situations in which one of the precessional states has a dwell time of that order or longer.

The reason for the discontinuous evolution of the precessional frequency with current is not clear, but simulations suggest that it may result from the 'fixed' layer undergoing a reorientation. As no additional precessional modes are observed, it appears that the 'fixed' layer is not entering a precessional state at these frequency jumps. However, other measurements do indicate that there may be precessional motion occurring in the 'fixed' layer over small ranges of $\mu_0 H$ and θ_H. This is shown in Figure 10. In this case, three nonharmonically related spectral peaks occur over a wide range of current. In addition to the main spectral peak there are also peaks symmetrically located at 500 MHz above and below the main peak. The upper and lower sideband peaks are not symmetric in power and only the lower sideband appears in the two-dimensional plot on this color scale. However, both are visible in the line trace in Figure 10(b). This is very reminiscent of a spectral peak undergoing frequency modulation, in which sideband signals appear at frequencies different from that of the main signal (this will be discussed in more detail in the following text). However, in this case, no modulation source is applied, and the two sidebands are symmetric in frequency but not in power. The cause of these sideband signals is not certain, although it possibly results from excitation or reorientation of the 'fixed' layer. The frequency of the modulation signal is quite low and does not correspond to the difference in the precessional excitation frequencies of the two layers induced by the spin-transfer effect, at least according to single-domain modeling using equation (1). However, this may result from a 'scissoring' mode between the two layers. This 'self-modulation' behavior typically occurs for fields of about 0.5–0.6 T applied approximately 60° to the film plane.

2.2.4 *Oscillator output power*

Up to this point, we have focused largely on the dependence of the precession frequency on the strength and direction of the applied field. We will now focus on the power associated with the different mode structures and the linewidths of the excitations. In general, we find that the linewidths of the devices are quite narrow having FWHM values of a few megahertz to a few tens of megahertz. For certain field geometries we have found that the measured voltage output

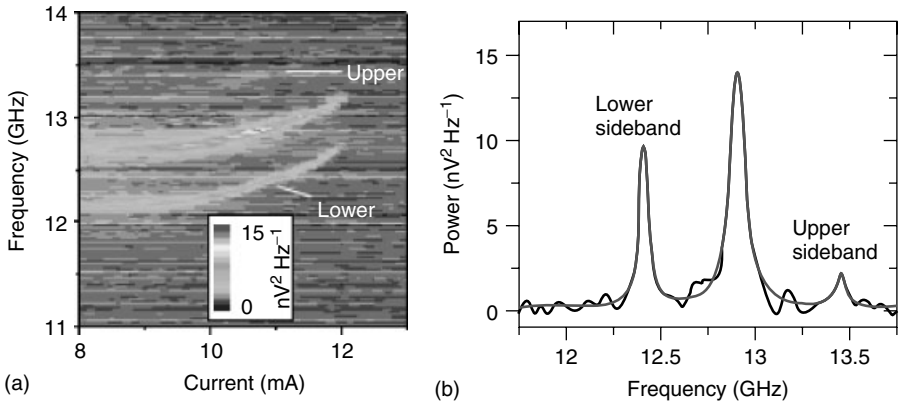

Figure 10. (a) Plot showing the spectral output from a device with $\mu_0 H = 0.5\,\mathrm{T}$ applied at 60° away from the film plane. The main peak has both an upper and lower sideband, reminiscent of frequency modulation. (b) Spectral trace for $I_{\mathrm{dc}} = 11\,\mathrm{mA}$ along with a fit (solid line).

associated with the precessional dynamics can be as much as one-third of the maximum voltage obtainable from the GMR effect.

For a particular field strength and angle the device output power can be a strong function of I_{dc}, Figure 11(a). The power output does not generally scale as I^2 as it would for a constant precession angle and a constant average orientation between $\boldsymbol{M}_{\mathrm{free}}$ and $\boldsymbol{M}_{\mathrm{fixed}}$. Instead, the output power depends more strongly on the particular frequency branch of the excitation, consistent with the relative directions of the fixed and free layers significantly changing when a jump in frequency occurs. Shown in Figure 11(b) is the *maximum* integrated power output of a device versus applied field angle. In general, the current yielding the maximum power output varies with $\mu_0 H$ and θ_H. For this device this current varies between $I_{\mathrm{dc}} = 5$ and 7 mA over the range of fields and angles studied. Hence, normalizing the data by I^2 does not significantly affect the trend in the plot. The maximum power output of the device varies by roughly 2 orders of magnitude, from about 1 pW to 0.1 nW, as the field is changed from in-plane to out-of-plane. This general trend is in accordance with the device output power resulting from the GMR effect, in which the instantaneous resistance of the device is proportional to $\boldsymbol{M}_{\mathrm{free}} \cdot \boldsymbol{M}_{\mathrm{fixed}}$. When the two magnetization directions are parallel, the change in the projection of $\boldsymbol{M}_{\mathrm{free}}$ onto $\boldsymbol{M}_{\mathrm{fixed}}$ during one precessional cycle is relatively small when compared to when they are nearly perpendicular, for a given angle of precession (see Figure 11c). Hence for fields applied perpendicular to the film plane, which will tend to splay $\boldsymbol{M}_{\mathrm{free}}$ relative to $\boldsymbol{M}_{\mathrm{fixed}}$, a larger change ΔR is expected for a given precessional angle, which will in turn lead to a larger output signal from the device.

For simple circular precession, the GMR signal should follow $\Delta R = \Delta R_{\mathrm{max}} \sin(\gamma) \sin(\phi)$ where ΔR_{max} is the maximum GMR signal, γ is the angle between the time-averaged values of $\langle \boldsymbol{M}_{\mathrm{fixed}} \rangle$ and $\langle \boldsymbol{M}_{\mathrm{free}} \rangle$ (generally different

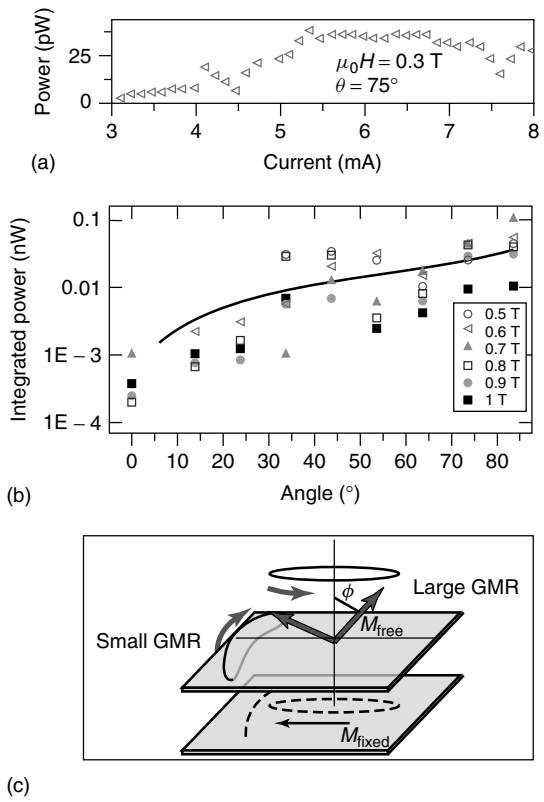

Figure 11. (a) Integrated output power (area under spectral peak) versus I_{dc}. For currents having multiple frequencies the powers in both peaks are included. Data correspond to those of the same symbol in Figure 8(a). (b) Maximum integrated power output versus field angle for several different fields. The line shows the calculated functional form of the power assuming a constant circular precessional angle and $\mu_0 H = 0.8\,\mathrm{T}$. (c) Schematic diagram showing the projection of $\boldsymbol{M}_{\mathrm{free}}$ onto $\boldsymbol{M}_{\mathrm{fixed}}$ (dashed lines) for two different geometries. For similar precessional angles, the change in the projection is much larger for geometries where the two layers are skewed with respect to one another. Figure 12. (a) Schematic defining the variables discussed in the text. (b) Calculated value of the angle γ, the angle between $\boldsymbol{M}_{\text{fixed}}$ and the time-averaged value of $\boldsymbol{M}_{\text{free}}$.

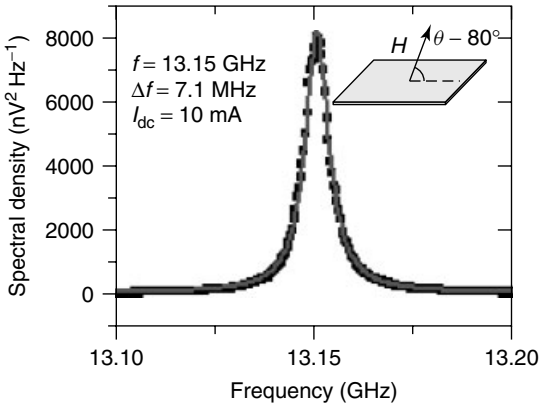

Figure 13. Plot showing the particularly strong output power from a device with $\mu_0 H = 0.6\,\text{T}$, applied 80° away from the film plane, along with a Lorentzian fit. The integrated power in the peak converts to 0.8 mV peak-to-peak signal.

from θ_H, Figure 12b), and ϕ is the precession angle (inset Figure 12a). Hence, for a constant precession angle the device power output should increase with θ_H and roughly scale as $\sin(\gamma)$ at fixed current, over the range of fields and angles studied here. While the measured power output does increase with θ_H, its dependence on angle at fixed H does not follow such a simple relation (solid line in Figure 11b). For instance, the power output generally does not simply increase with H at a given applied field angle, indicating that the excited trajectories are more complicated functions of H and I_{dc}.

The largest power outputs measured are significant fractions of the maximum possible through the GMR effect. In Figure 13, we show the output from a device with $\mu_0 H = 0.65\,\text{T}$ applied 80° out of the film plane and $I_{\text{dc}} = 10\,\text{mA}$. For this particular geometry the integrated output power in the out-of-plane geometry is roughly 1 nW, corresponding to a peak-to-peak voltage of 0.8 mV. This is about 30% of the maximum voltage obtainable through the GMR effect in this device, which has a $\Delta R_{\text{max}} = 230\,\text{m}\Omega$. The voltage measured by the spectrum analyzer represents only a fraction of the signal being generated at the device itself owing to the finite resistance of the device structure and imperfect microwave coupling between the device and the off-chip measurement circuitry. A simple circuit analysis shows that the voltage measured at the spectrum analyzer is

$$V_{\text{spectrum analyzer}} = V_{\text{device}} \left(\frac{Z_{\text{load}}}{Z_{\text{device}} + Z_{\text{load}}} \right) \qquad (4)$$

where Z_{device} is the device impedance and Z_{load} is the impedance of the load circuit (Johnk, 1988). For the 15 Ω device discussed here this indicates that only roughly three-fourths of the actual device output is measured by the spectrum analyzer, assuming that the high-frequency impedance of the device is equal to its dc value. Taking this into account, the peak in Figure 13 corresponds to approximately half of the total possible output from the device, that is, precessional angles of approximately 60°. The additional, and possibly significant, losses due to imperfect coupling between the on-chip and off-chip transmission lines are not included in this model.

2.2.5 *Comparison between linewidth, power, and frequency evolution*

A more complete comparison between the linewidth, power, and their dependencies on current and field are discussed in the following text. In Figure 14, we show the detailed evolution of the precessional frequency, as functions of both I_{dc} and magnetic field strength, for $\theta_H = 75°$. As seen in Figure 14 the precession frequency does not have a simple dependence on either of these parameters. Overall, the precessional frequencies vary from roughly 11 to 24 GHz as the applied field is swept from 0.5 to 1.1 T. The evolution of the dynamics with current is more complicated. However, we can easily observe that the precession red shifts with increasing current at low applied fields and that the oscillations change to blue shifting with increasing I_{dc} as the applied field is increased. The most striking features in the surface plot are the well-defined places where the precessional frequency evolves in a discontinuous manner with either current, applied field, or both, as indicated by the solid lines in the figure. The positions of the steps vary fairly continuously with both field and current, forming a surface consisting of several plateaus separated by steps (when multiple spectral

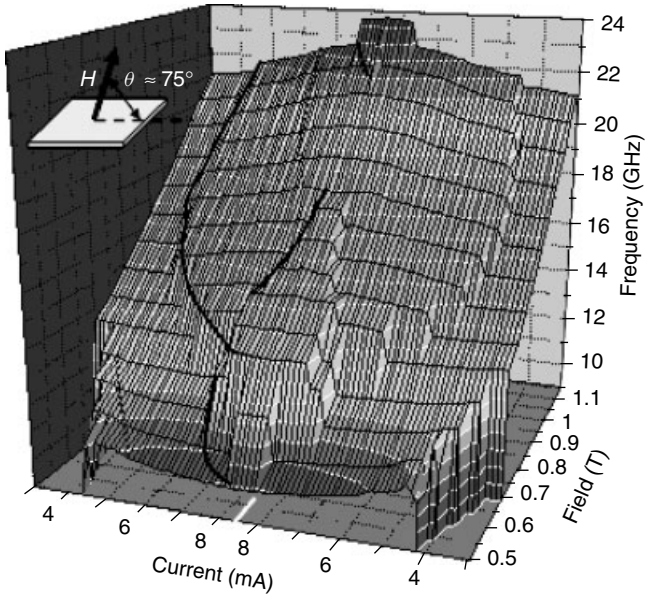

Figure 14. Surface plot showing the evolution of the precession frequency with both current and applied field for an applied field angle of 75°. At the lowest currents and applied fields no precessional dynamics are measured, which appears as the vertical sidewall in the plot. The surface includes data from both increasing and decreasing current scans. The lines discussed in the text are shown only on the increasing current scan for clarity and serve only as visual guides.

peaks are present, see Figure 9, only the peak with the largest integrated power is included in the plot). Within these individual plateaus the evolution of the precessional frequency with current and field is typically very smooth and continuous. However, there are also regions in which the oscillation frequency goes through more rapid changes in one of these variables, as indicated by the dashed lines in the plot. These features, although not as dramatic as the steplike features described in the preceding text, are still distinct from the typical evolution of the dynamics. At the lowest fields and currents no spectral signals are measured for this angle of applied field. For the purposes of this surface plot, the frequency of precession is taken to be zero when no spectral peak is measured, which results in the artificial appearance of a large step where the precessional dynamics first appear.

The overall behavior of the dynamics generally agrees with numerical simulations of equation (1). Simulations of this measurement geometry indicate a red-shifting behavior at low fields and a blue-shifting behavior at higher fields. However, the discontinuous jumps have not been observed in the simulations, nor have the smaller ridges. The jumps may result from the 'fixed' layer undergoing a reorientation or precessional oscillations itself, as discussed in the preceding text. They may also result from the free layer precession changing from a quasiuniform mode to some other normal mode, although the change in frequency associated with the jump are smaller than one would expect for this behavior (McMichael and Stiles, 2005). Other somewhat complicated behavior is also found in the measurements. For instance, for $\mu_0 H = 0.70\,\mathrm{T}$ the oscillations show complex behaviors as I_{dc} is swept from about 7.5 to 8.5 mA. After the discontinuous jump with current, the precession frequency increases, and then decreases, before increasing once again. Such a complicated frequency dependence on current has not been found from numerical integration of equation (1), assuming a constant damping value (Russek *et al.*, 2005; Xiao, Zangwill and Stiles, 2005).

As shown by the plots in Figure 15(a–b), the device output power and the oscillation linewidth vary a great deal over the range of currents and fields studied here. The oscillation linewidth varies from below 5 MHz to greater than 100 MHz while the output power varies from the picowatt to nanowatt range. As seen in the two plots, the parameters giving the higher output power are not simply correlated with the oscillations having larger linewidths. For instance, for fields between 0.6 and 0.8 T the highest powers are found for currents between $I_{\mathrm{dc}} = 7.5$–$8.5\,\mathrm{mA}$, while the oscillations over this region have linewidths of only a few megahertz.

Clear correlations exist between the excitation linewidth and the frequency surface plot. Most notably, a large gradient in the frequency surface (i.e., f varies strongly with either current of applied field) is generally correlated with a corresponding increase in the measured linewidth. This is expected with any tunable oscillator. Noise in any parameter that changes the oscillation frequency will also cause the oscillation linewidth to broaden. Treating fluctuations in the applied field and I_{dc} as independent sources of noise, the simplest description of the noise contribution to the excitation linewidths is

$$\Delta f = \left(\left(\frac{\partial f}{\partial H} \right)^2 (\Delta H)^2 + \left(\frac{\partial f}{\partial I_{\mathrm{dc}}} \right)^2 (\Delta I_{\mathrm{dc}})^2 \right)^{1/2} \qquad (5)$$

where ΔH is the fluctuation of the magnetic field during the measurement interval $\approx 10\,\mathrm{s}$ and ΔI_{dc} is the noise in the current through the device due to Johnson noise, shot noise, and noise in the current source itself. We measure $\Delta(\mu_0 H) = 0.05\,\mathrm{mT}$ and estimate $\Delta I_{\mathrm{dc}} = 1\,\mu\mathrm{A}$. For a typical value of $\mathrm{d}f/\mathrm{d}H = \gamma = 26\,\mathrm{GHz\ T^{-1}}$, the field-noise-induced linewidth amounts to 1.3 MHz, which is approximately equal to the narrowest peaks that we regularly measure. This indicates that the linewidths are limited by the noise in the measurement system and that the linewidths of the oscillations themselves could be substantially narrower than their measured values.

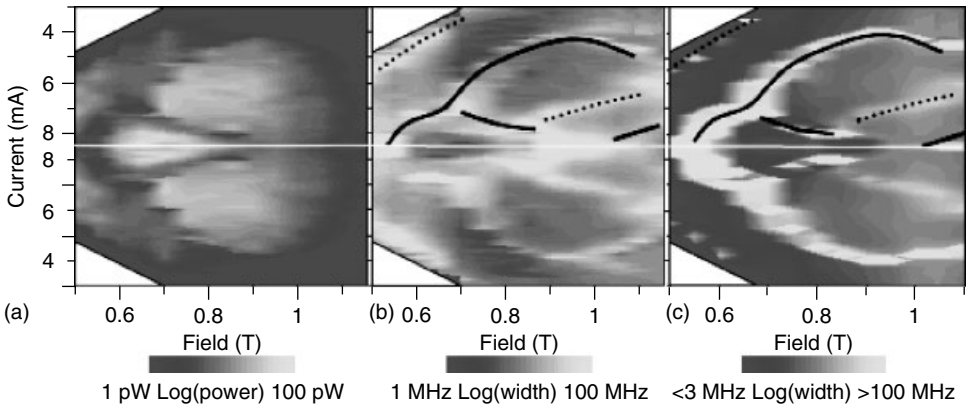

Figure 15. (a) Two-dimensional plot showing the device output power as discussed in the text with the power shown in a logarithmic color scale. (b) Analogous plot of the measured linewidth over the same parameters with the linewidth (FWHM) shown in a logarithmic color scale. (c) Analogous plot of the 'calculated linewidth' over the same range of parameters shown in a logarithmic color scale. In all cases, data from both the increasing and decreasing current scans are included so that the plots are symmetric about the highest bias current. The different lines in (b) and (c) correspond to the analogous lines in Figure 13 and serve only as visual guides for the purpose of comparison.

To directly compare the measured linewidths to the model outlined in the preceding text we have numerically differentiated the surface plot and constructed the resulting calculated noise-induced linewidths in Figure 15(c) using equation (5). Over most of the surface the differentiation process is well defined. However, at the discontinuous jumps in frequency this is not the case and the resulting values for the linewidths will be too large. Hence, at these locations the measured linewidths and calculated 'noise linewidth' can be compared only qualitatively. There are several clear correlations between regions having high measured linewidths and regions having large calculated linewidths. The correlation is particularly strong when there is a discontinuous jump in the oscillation frequency in either current or applied field where the gradient of the frequency surface is strongest. These locations are shown as dashed lines in the figures. Similarly, strong correlation occurs between regions having measured linewidths on the order of a few megahertz, and regions having narrow linewidths in the calculation. These measurements indicate that the largest linewidths result at least partially from a very strong variation of the precession frequency with either current or field and noise fluctuations in these two variables. Similarly, the narrowest measured linewidths are seemingly also limited by systematic noise and may not reflect the actual linewidth of the oscillations themselves.

However, the correlation between the calculated and measured linewidths is not complete. For instance, the calculations give a region of very narrow linewidth for $I_{dc} = 8-8.5$ mA and an applied field of 0.9–1 T, whereas the measured linewidths over this region are actually fairly large. This is also somewhat the case at the lowest fields and current values between 6 and 7 mA. This indicates that the linewidths are not always dominated by the noise characteristics of the current and field but can also perhaps result from instabilities of the magnetization trajectories. Of course, thermal effects will, in general, prevent the magnetization from following a perfectly exact and closed trajectory, which will act to give a finite linewidth to the spectral peaks. However, the data here suggest that, at least for the narrowest peaks, thermal effects are not the dominant source of linewidth broadening in the nanocontact devices.

2.2.6 *Linewidth comparison in nanopillars and nanocontacts*

It is interesting to compare the linewidths in typical nanopillar devices to those of nanocontact devices. At first glance one might expect the nanocontact devices to have broader spectral signals. The region undergoing precession is attached to a continuous ferromagnetic film, which will result in spin waves being shed away from the contact area. This is a loss mechanism and could lead to a broadening of the excitation linewidth. However, as shown in the preceding text, the oscillations associated with the nanocontact devices are typically significantly narrower than those associated with the nanopillar geometry. The room-temperature oscillation linewidths of nanopillar devices typically range from a few hundred megahertz up to several gigahertz, whereas the nanocontact oscillations have linewidths typically ranging from a few megahertz to a several tens of megahertz (see Figures 2 and 15).

The cause of this discrepancy is not presently clear, but there are a number of possibilities. In the pillar structures, the edges of the device structure are formed by lithographically defining a mask in the shape of the desired structure and then ion milling through the magnetic layers to form a pillar.

As with any lithographic process, this will naturally lead to shape defects in the edge of the device. Further processing will also oxidize the sides of the pillar structures. Each of these is expected to broaden the oscillation linewidths. This edge roughness will naturally lead to local variations in the demagnetizing fields. Thus, the magnetization at the edges of a laterally patterned structure will tend to oscillate at slightly different frequencies than the magnetization in the middle of the structure and cause linewidth broadening. This is further exacerbated by defects and perhaps nonuniform oxidation along the device sides. These effects result in the nonuniform precession of the magnetization throughout the device structure and the excitation of incoherent spin waves leading to broadened linewidths (Lee *et al*., 2004; Berkov and Gorn, 2005). In the nanocontact devices there is no patterning of the ferromagnetic film close to the device area, and so the problems associated with devices edges will be lessened, if not resolved. Of course the contact itself will have some edge defects, but these local defects will tend to be washed out by the diffusive nature of the current flowing through the device.

However, it is difficult to attribute the narrow linewidths in the nanocontact geometry solely to the lack of edge defects and oxidation. Single-domain simulations of pillar devices innately lack any of the issues associated with edge defects and preclude the possibility of spin-wave excitations and nonuniform precession. However, thermal effects can be included in the simulations through the use of a fluctuating thermal field term that is proportional to $(T/V)^{1/2}$, where T is temperature and V is the device volume (Brown, 1963; Zhu, 2002). The effect of the thermal field is to perturb the precessional trajectories from being perfectly repeating, which will act to broaden the spectral linewidths. The strength of the thermal field is inversely proportional to the device volume and broadens the oscillation linewidths as the device dimensions are decreased, as shown in Figure 16 (Russek *et al*., 2005). Simulations of devices having dimensions of $50\,\text{nm} \times 50\,\text{nm}$, the nominal size of the nanocontacts discussed here, give linewidths on the order of 1 GHz for room-temperature precession. Hence, in the nanocontact geometry the precessional motion appears to be stabilized against these thermal effects, as compared to the pillar structure. Recent experimental work shows that the linewidths in nanopillar devices are significantly narrowed by reduced temperatures, indicating that thermal effects are at least partially responsible for their comparatively increased linewidths (Sankey *et al*., 2005). This stabilization in nanocontact devices possibly results from the exchange interaction between the precessing magnetization and the surrounding film. It is also possible that the effective volume of the precessing magnetization in the nanocontact geometry is much larger than the contact size, as was discussed in Figure 6, rendering the oscillations more stable against thermal effects. Resolving this question will significantly increase our understanding of the similarities and differences between the two device geometries.

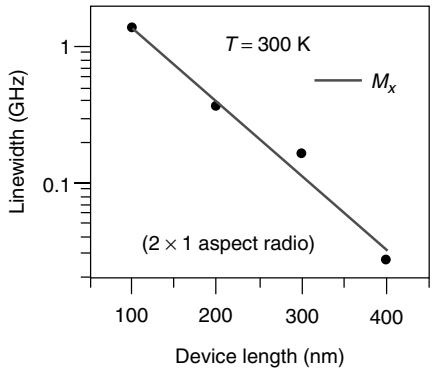

Figure 16. Plot showing the simulated linewidth vs device size for a set of 5-nm-thick $Ni_{80}Fe_{20}$ rectangular devices at room temperature. A 2:1 aspect ratio is used in all simulations. The line is an exponential fit, which gives an 82-nm decay length. (Reproduced from Russek *et al*., 2005, with permission from the American Physical Society. © 2005.)

In the preceding text, we have largely concentrated on the present understanding and experimental results of the spin-transfer-induced excitations in terms of their frequencies, linewidths, and output powers. Although there are still a number of unresolved issues, the excitation frequencies can generally be understood as very large-angle precessional motion approximating the uniform (FMR) mode. The linewidths in the oscillations depend on the device geometry and vary with the particular field and current applied to the device. For the nanocontact devices, the linewidths are typically a few tens of megahertz but can be larger, particularly when the oscillation frequency strongly depends on current or field. The narrowest linewidths are a few megahertz, which appears not to represent the intrinsic linewidth of the devices but instead reflects noise in the measurement system. The device output can be tuned by several orders of magnitude by controlling the geometry between the fixed and free layers, as expected from the GMR effect. At present, the output from the devices is still relatively low for microwave applications, although the device output power is a very significant fraction of that available through the GMR effect. The maximum signals to date are about 1 mV peak to peak. Of course, efforts to increase the ΔR_{max} in these devices are underway, either through the TMR effect, through materials engineering, or alternative device geometries such as coherent arrays (Kaka *et al*., 2005b; Mancoff, Rizzo, Engel and Tehrani, 2005). Impedance matching the devices to the measurement circuitry is also expected to significantly increase the measured output power.

2.3 Modulation effects

These spin-transfer-based nanoscale oscillators have several features making them attractive for potential applications. The devices are back-end CMOS compatible, they have nanoscale 'footprints', the devices are frequency agile, and they do not rely on any particular substrate material. The most obvious potential application for these devices would be as high-frequency clock oscillators or as microwave sources for on-chip signals. However, these devices would have a greater number of potential applications if the oscillation frequencies can be modulated allowing for transmission and reception of information and spectral analysis of microwave signals. In addition, many applications would also require the devices to be phase locked or referenced to either other devices or an external reference signal, such as is done in phase-locked loops and radio communications applications. In the following sections, we discuss recent work investigating these behaviors in the spin-transfer-based oscillators.

2.3.1 Frequency modulation

The measurement setup for the following modulation and phase-locking experiments is shown in Figure 17. The system consists of high- and low-frequency branches defined by the bias tee. A power splitter is inserted into the high-frequency branch and a tunable microwave source is coupled into one leg of the power splitter. This will modulate the current through the device so that

$$I = I_{\mathrm{dc}} + \Delta I_{\mathrm{ac}} \cos\left(2\pi f_{\mathrm{mod}} t\right) \tag{6}$$

where f_{mod} is the frequency of the injected current. Since our devices are not matched to the 50 Ω impedance of the measurement circuitry, we must in general calculate the magnitude ΔI_{ac} using the voltage output from the microwave source and a simple microwave circuit analysis (Johnk, 1988). In this measurement, part of the signal from the microwave source is also parasitically input directly into the spectrum analyzer/oscilloscope. Hence, the signal measured by the spectrum analyzer or oscilloscope will be composed of a signal from the microwave source along with the output from the spin-transfer oscillator. These two different signals are easily distinguished as long as the input frequency is far from the device oscillation frequency, but care needs to be taken with the frequencies that are close to one another or identical.

The spectral output from a typical device when biased only with a dc current is shown in Figure 18 for $\mu_0 H = 0.7\,\mathrm{T}$ and $\theta_H = 80^\circ$. The frequency increases roughly linearly from $I_{\mathrm{dc}} = 6$–$8\,\mathrm{mA}$, and then increases at a more gradual rate up to $I_{\mathrm{dc}} = 9.5\,\mathrm{mA}$. To examine the effects of an ac current on the resonance, the device is first biased to a fixed current and an additional 40 MHz ac current is applied through the power splitter, generating a time-varying resonance frequency, that is, frequency modulation (FM). In Figure 19(a), the spectral outputs at $I_{\mathrm{dc}} = 8.5\,\mathrm{mA}$ are shown for two input ac current amplitudes. The spectra generally show that, with increasing modulation current amplitude ΔI_{ac}, more power is driven into sidebands positioned at $f = f_{\mathrm{center}} \pm n40\,\mathrm{MHz}$ (the sideband order $n = 1, 2, \ldots$), with the specific sideband magnitudes depending on the variation of the precession frequency with current. For example, at a bias point in the linear region of the f versus I_{dc} curve, such as $I_{\mathrm{dc}} = 7.5\,\mathrm{mA}$, the upper and lower sidebands of a given order have approximately the same amplitude. However, when the device is biased at $I_{\mathrm{dc}} = 8.5\,\mathrm{mA}$, where the frequency does not have simple linear dependence on current (Figure 18), the upper and lower sidebands have significantly different magnitudes and vary differently with ΔI_{ac}.

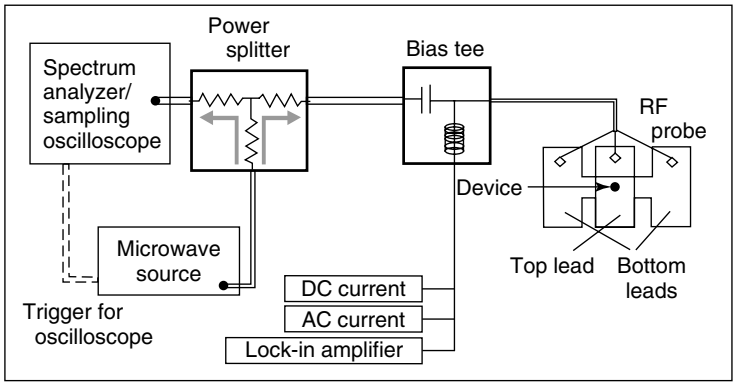

Figure 17. Schematic diagram showing the measurement setup used to allow high-frequency modulation of the current through the device. When a sampling oscilloscope is used in the measurements, the oscilloscope is referenced to a 10 MHz signal from the microwave generator to which the high-frequency output from the generator is phase locked. The arrows show the parallel paths, the signal from the generator follows.

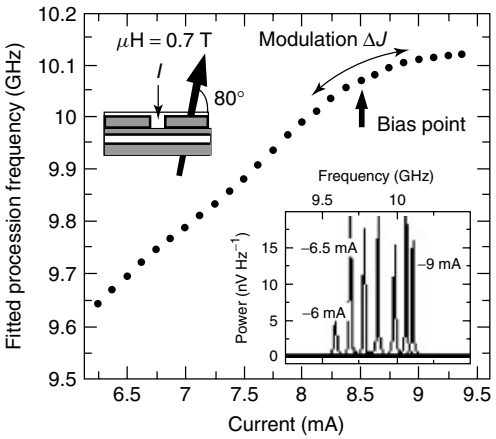

Figure 18. Frequency of spin-transfer-induced precession in a nanocontact as a function of dc bias current. Schematic shows sample measurement geometry. Inset: Spectral output of nanocontact for several dc currents, showing variation of frequency and amplitude with current (Pufall *et al*., 2005). (Reproduced from Pufall *et al*., 2005, with permission from the American Physical Society. © 2005.)

Multiple Lorentzian functions were simultaneously fit to the spectra for $I_{dc} = 8.5\,\text{mA}$ to determine the spectral peak positions and amplitudes for different magnitudes of the modulation current ΔI_{ac} (see Figure 19(b–d)). The upper and lower sideband amplitudes of a given order vary in markedly different ways as a function of ΔI_{ac}. For example, for the first-order sidebands ($f = f_0 \pm 40\,\text{MHz}$, Figure 19c), the upper sideband is larger in magnitude at a given ΔI_{ac} and peaks at a higher ΔI_{ac} than the lower sideband. In contrast, for the second-order sidebands ($f = f_0 \pm 80\,\text{MHz}$, Figure 19d), the lower sideband is larger in magnitude for low ΔI_{ac}, with the upper sideband becoming larger for $\Delta I_{ac} > 0.75\,\text{mA}$. Finally, the central peak (the 'carrier' frequency f_0, see Figure 19b) red shifts significantly with ΔI_{ac}. As will be shown, these effects are due to the nonlinear shape of the f versus I_{dc} transfer curve in the neighborhood of 8.5 mA.

The general form for the output signal from an oscillator is

$$V(I,t) = \text{Re}(V_0 \exp(i\theta(I,t))) \tag{7}$$

where the phase angle is defined as

$$\theta(I,t) = 2\pi \int_0^t f\left(I\left(t'\right)\right) \mathrm{d}t' \tag{8}$$

When $f(I) = \text{constant} = f_0$, the phase angle is simply $2\pi f_0 t = \omega_0 t$, and the oscillator output spectrum is a single peak at f_0. For typical frequency-modulation systems, the frequency varies linearly with the modulation parameter. With such a linear f versus I_{dc} characteristic of slope b, the current will have the form $I(t) = I_{dc,0} + \Delta I_{ac}\cos(2\pi f_{mod} t)$ and the phase angle becomes

$$\theta(I,t) = \omega_0 t + \beta \sin(\omega_{mod} t) \tag{9}$$

in which $\omega_0 = 2\pi f(I_{dc,0})$, $\omega_{mod} = 2\pi f_{mod}$, and the modulation factor $\beta \equiv f_{dev}/f_{mod} \equiv b\Delta I_{ac}/f_{mod}$. The resulting expression for $V(I,t)$ can be expanded in a Bessel series given by

$$V(I,t) = V_0 \mathrm{e}^{i(\omega_0 t + \beta \sin(\omega_{mod} t))} = V_0 \mathrm{e}^{i\omega_0 t} \sum_{l=-\infty}^{\infty} J_l(\beta)\, e^{il\omega_{mod} t} \tag{10}$$

This expression shows the familiar result that the output spectrum has peaks at f_0, $f_0 \pm f_{mod}$, $f_0 \pm 2f_{mod}$, . . . , $f_0 \pm lf_{mod}$, and that the amplitude of the lth sideband is proportional to $J_l(\beta)$ for linear FM. The calculated FM spectrum and a function of drive amplitude is shown in Figure 20, showing that as the modulation amplitude is increased more power is taken from the peak at the center or carrier frequency f_0, and driven into the modulation sidebands (Couch, 2001).

For many values of field and field angle, the precession frequency of the spin-transfer oscillators does not linearly depend on I_{dc} but instead follows a higher-order polynomial in current near the bias point, as is the case for $I_{dc} = 8.5\,\text{mA}$ in Figure 18. This function $f(I)$ can be expanded as a Taylor series of order n:

$$f(I, I_{dc,0}) = \sum_n \frac{1}{n!} \left.\frac{\partial^n f}{\partial I^n}\right|_{I=I_{dc,0}} \left(I - I_{dc,0}\right)^n \tag{11}$$

With this form for $f(I)$, a sinusoidal input current of the form $I(t) = I_{dc,0} + \Delta I_{ac}\cos(2\pi f_{mod} t)$ results in a power series in $\Delta I_{ac}\cos(\omega_{mod} t)$:

$$f(I_{dc,0}, \Delta I_{ac}, t) = f(I_{dc,0}) + \sum_{n=1}^{\infty} \frac{1}{n!} \left.\frac{\partial^n f}{\partial I^n}\right|_{I=I_{dc,0}} \times (\Delta I_{ac}\cos(\omega t))^n \tag{12}$$

This results in several modifications to the linear FM expression (equation 10). First, each factor $\cos^k(\omega_{mod} t)$ can be expanded as a series in $\cos(m\omega_{mod} t)(m \le k)$:

$$\cos^n(\omega t) = \frac{1}{2^n}\binom{n}{n/2} + \frac{1}{2^{n-1}} \sum_{k=0}^{n/2-1} \binom{n}{k} \times \cos\left[(n-2k)\,\omega t\right];\, n \text{ even} \tag{13}$$

$$= \frac{1}{2^{n-1}} \sum_{k=0}^{n-1/2} \binom{n}{k} \times \cos\left[(n-2k)\,\omega t\right];\, n \text{ odd}$$

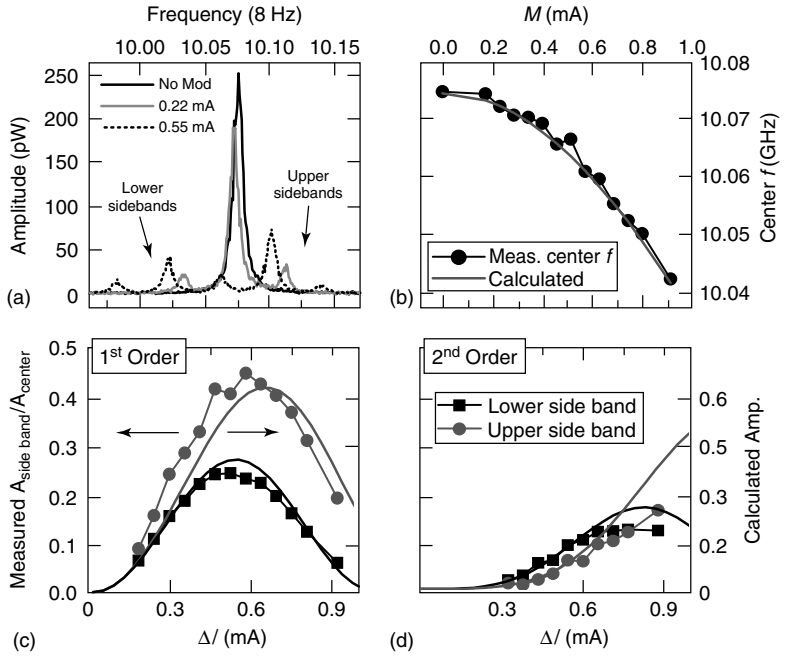

Figure 19. (a–d) Effects of injected ac current on spin-transfer resonance, at a dc current bias of $I_{dc} = 8.5\,\text{mA}$, $f_{mod} = 40\,\text{MHz}$. Solid lines in (b)–(d) are sideband amplitudes, calculated as described in the text. (a) Spectral output of device for several input modulation amplitudes ΔI_{ac}, showing sideband changes and shift of center frequency versus ΔI_{ac}. (b) Shift of center frequency versus ΔI_{ac}. (c) Variation of upper and lower first-order sideband amplitudes versus ΔI_{ac}. (d) Variation of upper and lower second-order sideband amplitudes versus ΔI_{ac}. Figure 20. Simulated FM curves from equation (9), showing growth of sideband amplitudes with increasing $\beta = f_{dev}/f_{mod}$. Carrier frequency $f = 1.1\,\text{kHz}$, $f_{mod} = 50\,\text{Hz}$. Traces are offset for clarity.

Upon substitution of this expansion into the expression for $\theta(t)$ (equation (8)), one finds that a series in $\sin(m\omega_{mod}t)(m \leq n$, the order of the polynomial) now replaces the single sinusoidal term in equation (10). In addition, each even power in the cosine power series also contributes a term linear in t. These terms collectively are the source of the shift of the carrier (center) frequency, reflecting the fact that a sinusoidal drive shifts the average frequency of the device away from $f(I_{dc,0})$ when the frequency dependence on current is not symmetric about the bias point.

Each harmonic of ω_{mod} can be individually rewritten as a Bessel series, as in equation (10). The expression for $V(I_0, \Delta I, t)$ is then a product of Bessel functions with the number of factors set by the order of the polynomial. For example, the third-order expression is

$$V(I_0, \Delta I, t) = \text{Re}\left\{V_0 e^{iA_0 t} \sum_{l=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} \sum_{p=-\infty}^{\infty} \times J_l(A_1)\, J_m(A_2)\, J_p(A_3)\, e^{i(l+2m+3p)\omega_{mod}t}\right\} \tag{14}$$

in which the A_n are linear combinations of the Taylor coefficients, and A_0 is a sum of $\omega_0 = 2\pi f(I_0)$ with contributions from even powers in the Taylor expansion. The A_i are, in general, functions of $I_{dc,0}$, ΔI, and ω_{mod}, and are generalizations of the modulation factor $\beta = f_{dev}/f_{mod}$ in linear FM in equation (10). This sum has terms proportional to $\sin(A_0 t)$, $\sin(A_0 t \pm \omega_{mod}t)$, $\sin(A_0 t \pm 2\omega_{mod}t)$, $\sin(A_0 t \pm 3\omega_{mod}t)$, . . . describing a carrier at a (shifted) frequency $A_0/2\pi$, plus sidebands at integer harmonics of f_{mod}. The

amplitude of a given sideband is a sum of terms such that the sum of the indices $l + 2m + 3p$ is equal to the order of the sideband, that is, $\pm 1, \pm 2$, and so on. Since the indices l, m, p can be either positive or negative, a large number of terms contribute to the amplitude of a given order. Furthermore, Bessel functions with negative indices can themselves be negative (since $J_m(x) = (-1)^m J_m(x)$), and so can produce an amplitude asymmetry between the upper and lower sidebands of a given order.

The computed center frequency shift and sideband amplitudes as functions of drive amplitude are shown as solid lines in Figure 19(b–d), determined using a fifth-order Taylor series expansion about $I_{dc,0} = 8.5\,\text{mA}$. As seen in the figure, the above expressions accurately describe both the red shift of the center frequency and also the relative variations of the sideband amplitudes with the modulation current, up to a constant amplitude factor. The model describes the amplitude difference between the upper and lower sidebands of a given order and also the crossover in their relative magnitudes (for linear FM, the magnitudes of the upper and lower sidebands of a given order are equal). The overall magnitudes of the calculated sidebands (but not the carrier frequency amplitude) are too large by a factor of 1.5, a factor that varies with bias point. This possibly results from nonlinearities in the current–voltage transport characteristics of the device, or from nonlinear amplitude modulation effects not included in the model. The amplitude of the output signal is not constant with current (Figure 18 inset), and on average decreases away from $I_{dc,0}$, which acts to decrease the amplitudes of the sidebands.

Note that these observed FM effects are not simply electrical, that is, the result of signal mixing due to a nonlinear current–voltage relation, but rather correspond to periodic variations in the precessional trajectory of the free layer magnetization. Simulated trajectories of a $100\,\text{nm} \times 100\,\text{nm}$ device for both zero and nonzero modulation amplitudes over one-half period of the modulation are shown in Figure 21 for an applied field $\mu_0 H = 0.7\,\text{T}$ at 80° to the film plane. In this configuration, the simulations predict a roughly linear dependence of frequency on current. The trajectory for nonzero modulation has a larger width in the z direction (perpendicular to the film plane). The modulation drives the magnetization periodically more into and out of the plane, expanding and contracting the cone of precession. This decreases and increases the demagnetizing field, which in turn modulates the net effective field and the precession frequency. The projection onto the y–z plane shows that the average value of the magnetization perpendicular to the plane oscillates at the modulation frequency.

These results show that the spin-transfer-based oscillators can be frequency modulated by modulating the current through the device. The spectral output from the devices can

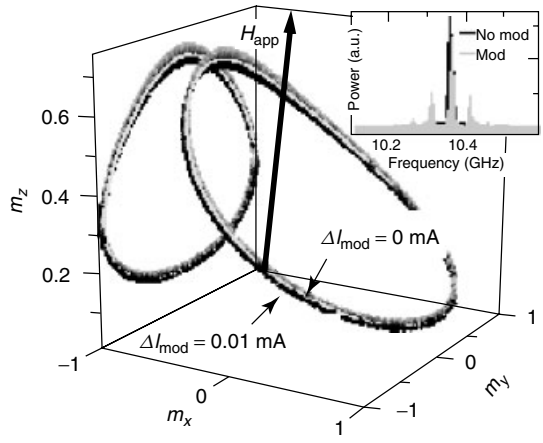

Figure 21. Plot of computed single-domain magnetization trajectory with (grayscale symbols) and without (light gray line) injected ac current modulation, over one modulation period. Color scale on trajectory denotes phase of ac modulation, from gray (ac current at minimum) to black (ac current at maximum). Axes are in units of the saturation magnetization. Trajectories also projected onto y–z plane to show spreading of the orbit in the z direction with drive. Simulations shown are at $T = 0\,\text{K}$, to more easily show the trajectory. AC current values differ from measured values owing to a different slope of calculated f versus I_{dc} curve and uncertainties in the absolute scaling of I_{dc} in the model. largely be understood by the standard frequency-modulation analysis that includes a nonlinear dependence of frequency on I_{dc}. The data indicate that the large-angle precessional modes of the magnetization induced by spin transfer are stable and tolerant of significant (current-induced) perturbations. Further measurements have shown that the devices can be modulated at frequencies approaching that of the current-induced precession. This indicates that the precessional dynamics are not only robust to a large bandwidth of modulation inputs, but that the devices are able to respond to very rapid changes in current. These results indicate that the oscillators may be amenable to high-bandwidth, on-chip transmission and reception applications as well as rapid on-chip spectral analysis of a wide range of frequencies.

2.3.2 *Injection locking*

As mentioned in the preceding text, in many electronics applications oscillators must be phase referenced to a secondary signal. Most modern circuits accomplish this through the use of phase-locked loops. We investigate the ability of these spin-transfer oscillators to phase lock to an external signal using the simpler method of injection locking. In this synchronization scheme, the current through the device is modulated at a frequency close to, but distinct from, the

natural oscillation frequency of the oscillator, inducing the device to sympathetically oscillate at the drive frequency. This general feature of nonlinear oscillators is exploited in many modern technologies such as wireless communications, the American power grid, various power combining architectures, and phased array antennae networks (Strogatz, 2003). We find that the spin-transfer-based oscillators studied here can similarly be injection locked to signals up to several hundred megahertz away from their natural oscillation frequencies and, over this locking range, the phase of the oscillator can be electronically tuned over a range of roughly $\pm 90^{\circ}$ relative to the injected signal.

The output of a nanocontact device as a function of I_{dc} is shown in Figure 22(a) along with the corresponding differential resistance curve (Figure 22b). The small feature in the $\mathrm{d}V/\mathrm{d}I_{\mathrm{dc}}$ curve at 6.25 mA corresponds to the onset of oscillations in the f versus I_{dc} response. The power associated with the oscillations is shown in Figure 22(c) and is represented in a linear color scale in the top part of the figure. In Figure 22(d) and (e), we show the analogous data when an ac current $I_{\mathrm{ac}}^{(\mathrm{rms})} = 410\,\mu\mathrm{A}$ at 10.86 GHz (f_{drive}) is added to I_{dc}. In our measurement, part of this ac signal is parasitically shunted to the spectrum analyzer used to acquire the data, and produces a background signal at 10.86 GHz in Figure 22(d). We have found that in this configuration the spectrum analyzer lacks sufficient dynamic range to repeatably subtract this parasitic background, and so we are unable to directly measure the device output at this particular frequency using this method. At low currents the oscillation frequency is slightly pulled toward the drive frequency f_{drive}. As I_{dc} is increased the deviation between the driven and nondriven frequencies increases as the spin-transfer oscillations are pulled closer to the drive frequency. At $I_{\mathrm{dc}} = 7.4$ mA the device locks to the drive frequency, as we will explicitly show below, and remains so until $I_{\mathrm{dc}} = 7.8$ mA. At larger currents the device oscillation frequency is distinct from the drive frequency but is again pulled toward f_{drive}. Over the locking range of the oscillator a dc-rectified voltage V_{rect} is measured (see Figure 22(f)). This gives indirect evidence of injection locking of the oscillator to the input signal (Tsoi *et al.*, 2000).

When locked, the oscillator is expected to take on the noise characteristics of the injected signal (Razavi, 2004). A frequency stability of $f/\Delta f > 10^9$ is expected in the present case as determined by the microwave source, allowing measurement of the signal using stroboscopic sampling techniques. Direct measurement of the oscillator synchronization is done in the time domain using a sampling oscilloscope instead of the spectrum analyzer (see Figure 17). The oscilloscope is triggered from a 10 MHz signal that is phase referenced to the microwave generator. The signal measured by the oscilloscope is again composed of both a background signal from the microwave generator and the output from the spin-transfer device. To determine the device output, the background signal is first measured with no current running through the device. A second measurement is then taken with I_{dc} through the device and the background signal is subtracted, leaving the device output. Typically about 1000 averages are acquired for each time trace. In principle, this measurement is equivalent to the one using a spectrum analyzer.

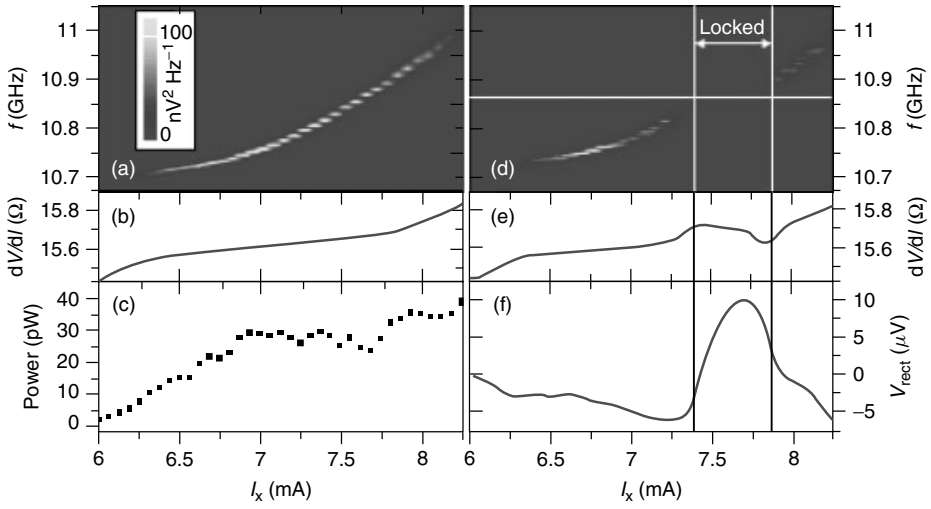

Figure 22. (a) Plot of f versus I_{dc} with amplitude shown in a linear color scale from 0 (black) to 100 $\mathrm{nV^2\,Hz^{-1}}$(light) with (b) corresponding $\mathrm{d}V/\mathrm{d}I_{\mathrm{dc}}$ curve without ac drive. Inset: Device and measurement schematic. (c) Device output power versus I_{dc} without ac drive signal in the same color scale. (d and e) Same as in (a and b) but with an ac drive at 10.86 GHz, 410 $\mu\mathrm{A}^{\mathrm{rms}}$. (f) Plot of V_{rect} versus I_{dc}. Vertical lines indicate the region of locking (Rippard *et al.*, 2005). (Reproduced from Rippard *et al.*, 2005, with permission from the American Physical Society. © 2005.)

However, the dynamic range of the sampling oscilloscope is larger ($1{:}2^{15}$) than that of the spectrum analyzer, permitting repeatable subtraction of the background signal. Such a stroboscopic measurement technique gives a null result unless the output from the device is phase synchronous with the injected microwave signal (i.e., the trigger signal) throughout the entire measurement interval of several minutes.

As indicated in Figure 22(d), the oscillator is locked to the injected signal for $I_{dc} = 7.6\,\text{mA}$. A time trace corresponding to this locked state is shown in Figure 23(a) along with a sinusoidal fit. The fact that we are able to measure the signal in the time domain explicitly shows that the oscillator is phase locked to the injected signal. A fit to the data yields an oscillation frequency of 10.86 GHz and a peak voltage of 44 μV. A spectral measurement of the device output without an ac bias for $I_{dc} = 7.6\,\text{mA}$ is shown in Figure 23(b). The spectral signal is equivalent to a peak voltage of 51 μV, in good agreement with the time-domain signal. Spectral measurements indicate that no significant power is generated at other frequencies (0–40 GHz). The deviation of the signal from a sinusoid is likely the result of imperfect synchronization between the trigger and the injected signal, as similar deviations from a sinusoid are obtained when the microwave generator output is directly measured.

The effect of varying the dc current through the locking range is shown in Figure 24(a). The device is locked to an ac current of $I_{ac}^{rms} = 410\,\mu\text{A}$ at 10.86 GHz and the time-domain signal is measured as I_{dc} is varied from 7.2 to 7.8 mA. As seen in the figure, the phase of the spin-transfer oscillator varies relative to that of the injected signal, allowing electronic phase control of the devices. Over the locking range the phase of the device varies by roughly $\pm 90^\circ$, as shown in Figure 24(b). No time-domain signals are observed outside this range, indicating that the signal is no longer phase coherent with the injected signal, as shown by the $I_{dc} = 7.85\,\text{mA}$ data.

We compare our results to the model of Adler (1973), which treats the oscillator as an active nonlinear circuit element coupled to an RLC circuit. Although simple, this analysis has been found to describe the locking characteristics of a range of oscillator circuits such as those based on diodes, transistors, and klystrons, to name a few (York, 1998 and references therein). The basic result of the analysis is

$$f_{drive} - f_o = \Delta f_{lock} \sin(\phi);\ \Delta f_{lock} = \frac{\Delta f}{2}\frac{V_{inj}}{V_{osc}} \qquad (15)$$

where Δf_{lock} defines the locking range of the device, Δf is the free-running oscillation linewidth, f_o is the free-running oscillation frequency, V_{inj} is the injected ac voltage across the device, V_{osc} is the oscillator voltage output, and ϕ is the phase difference between the oscillator and injected signal. Equation (15) has a solution for $f_{drive} = f_o \pm \Delta f_{lock}$, and over that range the phase of the oscillator relative to the injected signal varies from $-90^\circ < \phi < 90^\circ$, in agreement with the data in Figure 24. This result is derived under the limit that the addition of the injected signal does not significantly alter the output amplitude of the oscillator. In our devices, this criterion is met as long as the oscillator output (amplitude and linewidth) does not depend too strongly on the dc bias current over the locking range. This is often the case, as it is for the data presented here (see Figure 22c). In other cases, significant deviations from the 180° phase shift and the simple linear dependence of the locking range on the injected signal strength are found, as expected when significant power variation is included in the model (Fukumoto, Nakajima and Nakajima, 1983).

The dependence of the oscillation frequency on dc current for several different ac injection amplitudes is shown in Figure 25(a). ΔI_{ac} is estimated using standard microwave circuit analysis and taking the RF device resistance as equivalent to its dc value with no complex components (Johnk, 1988). As was seen in Figure 22, when the device is biased outside of the locking range, the spectral measurements indicate that the oscillation frequency is pulled toward the injected ac signal. The measured frequency is pulled only

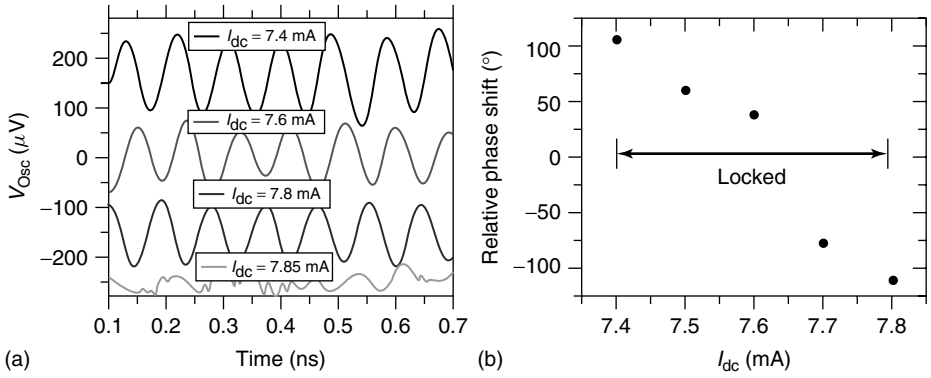

Figure 24. (a) Time-domain measurements of the device output as a function of dc current bias. The data are offset for clarity. (b) Relative phase shift between the device output and the external drive signal. An overall phase of 100° has been subtracted from the data. (Reproduced from Rippard *et al*., 2005, with permission from the American Physical Society. © 2005.)

slightly from its nondriven value far from the locking region. However, when the device is just outside of the locking range, the effect of the frequency pulling is much more significant, with the measured frequency continuously approaching the injection frequency.

This is not a frequency-modulation effect. In modulation schemes, the frequency of the mixed signal is independent of the amplitude of the modulation signal, at least for a linear f versus I_{dc} relationship, as discussed in the preceding text. As seen in Figure 25(a) this is not the case. Instead, the measurements are consistent with the oscillator quasilocking to the injection signal. When the oscillator is close to but outside the locking range, the device undergoes periods of being locked to the injected signal, punctuated by periods when the oscillator undergoes rapid phase slips and oscillates at frequencies different from f_{drive} (Razavi, 2004). The closer the oscillator is to the locking range, the longer the time between these periods of rapid phase change. The result is that the device oscillates not at a single frequency but over a range of frequencies, which appears as the pulling effect shown in Figure 25(a).

In Figure 25(b), the full locking range ($2\Delta f_{lock}$) is shown more explicitly as a function of the drive amplitude. The locking range is taken as the difference between the nondriven device oscillation frequencies at the minimum and maximum dc currents at which the device locks to the injected signal. The device is taken to be locked to the injected signal when more than 90% of the oscillator signal is at the injection frequency. The locking range varies approximately linearly with drive amplitude with a slope of $16\,\mathrm{MHz\,mV^{-1}}$. From equation (15), the full locking range is expected to be linear with a slope of $\Delta f / V_{osc}$ and intersect the origin. The predicted slope can only be estimated since the quantity depends explicitly upon the device output. Whereas the cabling and other component insertion losses can be measured, the coupling coefficient between our low impedance devices and a $50\,\Omega$ microwave line must be calculated. For the device investigated here having $\Delta f = 7\,\mathrm{MHz}$ we estimate that equation (15) predicts a slope of $42\,\mathrm{MHz\,mV^{-1}}$. The remaining discrepancy is possibly accounted for by a difference between the dc device resistance used in our estimate and the actual device impedance at 10.86 GHz.

The quantitative difference between the slope predicted by equation (15) and the measured value is not constant but instead varies with the device studied and the measurement geometry. To date, the values have always been within a factor of 5. For other devices in the same measurement geometry and a given injection amplitude, devices having larger linewidths and lower output powers lock over a wider range of frequencies in accordance with equation (15). In general, the devices can be locked to signals up to several hundred megahertz away from their natural oscillation frequency. The fit to the data indicates that a drive of finite amplitude, $1 \pm 0.2\,\mathrm{mV}$, is required to lock the device. This is in contrast to the predictions of equation (15). We have not yet determined the cause of the nonzero intercept, but it may reflect additional intrinsic losses in the nanocontact devices due to magnon radiation away from the device area (Slonczewski, 1999).

Close to the locking range, spectral measurements of the oscillations are predicted to yield $f = f_{drive} \pm ((f_o - f_{drive})^2 - \Delta f_{lock}^2)^{0.5}$ (Razavi, 2004). The line in Figure 25(a) shows this dependence for the data with $I_{ac}^{rms} = 330\,\mu\mathrm{A}$. As seen in the figure, this qualitatively describes the data close to the locking region. However, as the device frequency gets farther away from the locking regime, the measured frequency pulling is significantly larger than that predicted by the simple model used here. This discrepancy likely results from the amplitude effects that are not taken into account in the simple oscillator model (see Figure 22c).

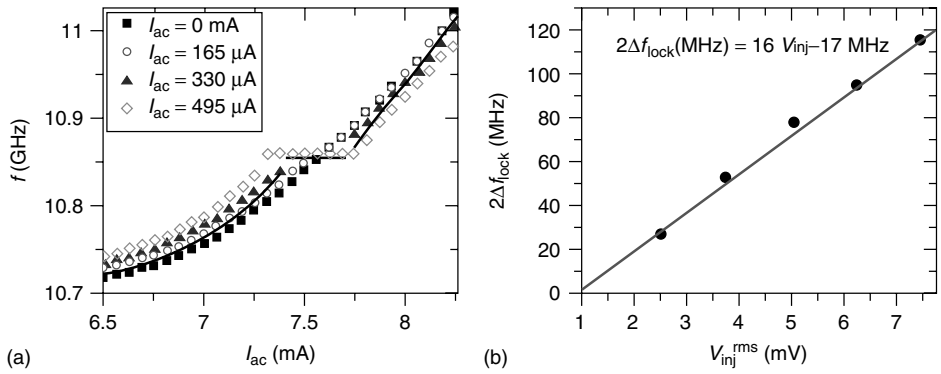

Figure 25. (a) Plot showing the f versus I_{dc} relation for several different amplitudes of drive at 10.86 GHz. The solid line is the predicted oscillation frequency for the drive of 330 μA, as discussed in the text. (b) Plot showing the locking range as a function of ac drive amplitude (ac voltage across the device) along with a linear fit to the data. 3 SUMMARY

As we have shown, the spin-transfer effect can result in a variety of coherent precessional dynamics in magnetic nanostructures. The precessional frequencies depend on both the current and magnetic field and can be tuned over a wide range of frequencies. Present measurements have demonstrated output frequencies up to about 40 GHz, but we expect to be able to generate even higher frequencies. The frequency dependence on magnetic field can be largely understood in terms of large-angle FMR precessional modes. The frequency dependence on the applied current is generally in agreement with the predictions of Slonczewski, although there are significant discrepancies between the theory and experiment. The device output power can be tuned over several orders of magnitude by varying the direction and strength of the applied field. The largest powers occur for nearly out-of-plane applied fields, which is consistent with the predicted magnetization trajectories and the GMR effect. The largest powers can be significant fractions of the maximum available through the GMR effect, and with improved impedance matching, the signals are expected to be nearly equivalent to the maximum values. The linewidths of the excitations can be quite narrow, leading to quality factors commonly in excess of 10^4. The narrowest linewidths are about 2 MHz and are presently limited by the fluctuations in the applied magnetic field and current noise.

The devices show attributes that are promising for potential applications. The spin-transfer oscillators can be frequency modulated at rates approaching the natural oscillation frequency of the device. This potentially allows the devices to be used in localized wireless communication architectures as well as in on-chip high-speed spectral analysis. The oscillators can be injection locked to an external reference signal up to several hundred megahertz away from their natural oscillation frequencies. Over the locking range, the phase of the device can be tuned relative to that of the injection signal by approximately $\pm 90^\circ$. These measurements demonstrate the potential for spin-transfer-based oscillators in practical microwave circuits that require synchronization of multiple oscillators (such as in timing circuits, signal tracking and reception, and signal demodulation) and phase control of multiple oscillators (such as directional beam steering, phased array detection, and localized coherent manipulation of quantum states).

ACKNOWLEDGMENTS

This work was supported by the NIST nanomagnetodynamics program, the NIST Office of Microelectronics Programs, the NIST Advanced Technology Program, and the DARPA SpinS program. We gratefully acknowledge S. Kaka, T. Silva, S. Russek, and J. Katine, with whom much of the experimental work was performed. We also acknowledge M. Stiles and R. McMichael for helpful discussions and S. Wolf for motivating the work on injection locking, as well as R. Goldfarb, A. McCallum, D. Smith, and C. Weil for helpful commentary on this manuscript.

1 INTRODUCTION AND OUTLINE

Technological progress of recent years clearly brings to the forefront the ever-increasing importance of magnetism and magnetic materials in the everyday life. Detailed understanding of microscopic atomic structure and origins of magnetic phenomena now appears as key to further advances in diverse fields of science and technology. Although studies of magnetic structures and excitations form a rapidly expanding area of modern science offering new discoveries and surprises without an end in sight, a large body of experimental material and theoretical work accumulated over the past half a century can be understood in the framework of a simple microscopic description based on semiclassical treatment of systems of localized spins of magnetic ions. This article presents a brief survey of common types of spin structures and excitations found in magnetic crystals that can be described in the framework of such a semiclassical spin-wave approach. Experimental examples of neutron scattering studies, as best known to the author, are presented for each type, and discussed in the context of an up-to-date presentation of the linear spin-wave theory, perhaps, at the undergraduate level.

The article is organized as follows. The introductory second section outlines the fundamental connection between magnetism and the electronic spins from which it arises, spin interactions that are at the origin of cooperative magnetic phenomena are discussed in the third section, the fourth and the fifth sections present survey of different spin structures and spin-wave excitations, respectively, and the last section gives a brief summary.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. © 2007 John Wiley & Sons, Ltd. ISBN: 978-0-470-02217-7.

2 MAGNETISM AND SPIN

Magnetism of many-electron condensed matter systems is a cooperative macroscopic quantum phenomenon originating from the fundamental relationship between the magnetic moment $\boldsymbol{M}$ and the angular momentum $\boldsymbol{J}$,

$$\boldsymbol{M} = \gamma \boldsymbol{J} \tag{1}$$

where, γ is the so-called gyromagnetic ratio (Einstein and De Haas, 1915; Barnett, 1935). This expression is a counterpart of the famous equivalence relation between the magnetic field $\mathbf{H}$ acting on the electron and the rotation with angular velocity $\boldsymbol{\Omega}_L = \frac{|e|}{2m_e c}\mathbf{H}$ known as *Larmor's theorem*, where, e and m_e are the electron's charge and mass and c is the velocity of light in vacuum. If a system interacts with an anisotropic environment, such as an atom in crystal's electric field, $\boldsymbol{M}$ and $\boldsymbol{J}$ might be not co-aligned and the gyromagnetic ratio becomes a tensor quantity, $\gamma_{\alpha\beta}$.

The magnetic moment associated with the Ampere's molecular electric current produced by an electron moving in an atomic orbit can already be derived semiclassically from

the Biot–Savart law,

$$\boldsymbol{\mu}_{le} = -\frac{\mu_{\mathrm{B}}}{\hbar}\left[\mathbf{r}_e \times \mathbf{p}_e\right] = -\frac{\mu_{\mathrm{B}}}{\hbar}\mathbf{l}_e = -\frac{|e|}{2m_{\mathrm{e}}c}\mathbf{l}_e \qquad (2)$$

This establishes the gyromagnetic ratio for the orbital motion, $\gamma_l = -\frac{|e|}{2m_{\mathrm{e}}c}$. This ratio is negative, so the electron's orbital magnetic moment is opposite to its orbital angular momentum. The magnetism of moving electric charges, however, is grossly insufficient for explaining magnetic properties of matter, such as magnetism of the lodestone (magnetite) known since ancient times, which is why it was one of the longest-standing problems in the history of science (Mattis, 1965). Magnetic fields produced by orbital Ampere currents, like artificial magnetic fields from electromagnets, are of electrodynamic origin. They are caused by nonrelativistic motion of electric charges and therefore contain a relativistically small factor, $\sim\alpha \approx 1/137$. The energy of magnetic interaction between two magnetic dipoles associated with Ampere orbital currents of two electrons at a distance $r = 1\,\text{Å}$, each carrying 1 Bohr magneton, $\mu_{\mathrm{B}} = |e|\hbar/(2m_{\mathrm{e}}c) = 0.927{\cdot}10^{-20}$ erg/Gs,

$$V(\mathbf{r}) = -\left\{\frac{8\pi}{3}\,(\boldsymbol{\mu}_1{\cdot}\boldsymbol{\mu}_2)\;\delta\,(\mathbf{r}) - \frac{(\boldsymbol{\mu}_1{\cdot}\boldsymbol{\mu}_2)}{r^3} + \frac{3\,(\boldsymbol{\mu}_1{\cdot}\mathbf{r})\;(\boldsymbol{\mu}_2{\cdot}\mathbf{r})}{r^5}\right\} \qquad (3)$$

is only $\sim \mu_{\mathrm{B}}^2/(k_{\mathrm{B}}r^3) \approx 0.6\,\text{K}$. This is way too small compared with the entropy contribution to the free energy to explain the existence of magnetism at room temperature and above. In addition, a simple theorem, established independently by N. Bohr and J. H. van Leeuwen, in fact prohibits magnetism in a system of classical electrons in thermal equilibrium (Mattis, 1965).

Therefore, fundamentally, room temperature magnetism could not be described by classical electrodymanics and was only explained with the devise of quantum mechanics in the early twentieth century. It is a consequence of the existence of an additional quantum degree of freedom of an electron, its spin (Compton, 1921; Uhlenbeck and Goudsmith, 1925). In quantum mechanics the electron at rest still possesses a quantum of 'internal' angular momentum, $\hbar\mathbf{s}_e$ ($\hbar$ is the Planck's constant), described by the spin angular momentum operator $\mathbf{s}_e$ of magnitude $\mathrm{s}_e = 1/2$,

$$\mathbf{s}_e^2 = s_e(s_e+1) = \frac{3}{2},\ \left[s_e^x, s_e^y\right] = is_e^z,\ \ etc \qquad (4)$$

There is also a magnetic moment of magnitude $\mu_{se} = \mu_{\mathrm{B}}\,(1 + \alpha/2\pi - \cdots) \approx 1.001\mu_{\mathrm{B}}$ associated with the electron's spin (Abragam and Bleaney, 1986). It is aligned opposite to spin angular momentum,

$$\boldsymbol{\mu}_{se} = -g_s\mu_{\mathrm{B}}\mathbf{s}_e = \gamma_s{\cdot}\left(\frac{1}{2}\hbar\mathbf{s}_e\right), \quad \gamma_s = -g_s\frac{|e|}{2m_{\mathrm{e}}c} \qquad (5)$$

where $g_s \approx 2.002$ is Lande g factor and γ_s is spin gyromagnetic ratio for the free electron which, like γ_l, is also negative. Neglecting a $\approx 0.1\%$ relativistic correction, $\gamma_s = 2\gamma_l$. In addition to the orbital angular momentum $\boldsymbol{L}$, magnetic moment of a many-electron atom is determined by its total spin,

$$\mathbf{S} = \sum_e \mathbf{s}_e \qquad (6)$$

where the summation can be restricted only to $2S$ unpaired electrons. Magnetism of condensed matter systems is usually described in terms of interactions between these atomic spins and resulting spin structures and excitations. Within the spin-S ground-state (GS) multiplet of a Hund's atom, electronic spins in the incomplete shell can be expressed as $\mathbf{s}_e = \pm\frac{1}{2S}\mathbf{S}$, with plus sign for the majority and minus for the minority electrons.

For an atomic system with total angular momentum $\boldsymbol{J} = \boldsymbol{L} + \boldsymbol{S}$, atomic gyromagnetic ratio in equation (1) is a combination of γ_s and γ_l and in many cases can be calculated using simple Lande-type formulae (Abragam and Bleaney, 1986). Larmor's equivalence between magnetic field and rotation can be seen in that additional term in the free energy resulting from magnetic field $\mathbf{H}$ and the term arising from Larmor rotation with frequency $\boldsymbol{\Omega}_L = \gamma{\cdot}\mathbf{H}$ are exactly equal,

$$F_M = -\mathbf{M}{\cdot}\mathbf{H} = -\gamma\,\mathbf{J}{\cdot}\frac{\boldsymbol{\Omega}_L}{\gamma} = -\mathbf{J}{\cdot}\boldsymbol{\Omega}_L \qquad (7)$$

and can be interchanged as a matter of convenience. This fundamental equivalence immediately leads to the Lagrangian of spin rotations,

$$L = \frac{1}{2}\chi\left(\frac{\boldsymbol{\Omega}}{\gamma} - \mathbf{H}\right)^2 \qquad (8)$$

which is at the origin of the powerful macroscopic description of long-wavelength, low-energy excitations in magnetic systems with finite magnetic susceptibility χ and in the presence of a magnetic field, in the framework of spin hydrodynamics (Andreev, 1978).

3 SPIN INTERACTIONS AND SPIN HAMILTONIAN

Strong interaction between electronic spins leading to magnetism in condensed matter results from a combination of the electrostatic Coulomb repulsion between electrons and a quantum-mechanical coupling between electron spin and coordinate wave functions established by the Pauli principle

which prohibits electrons with the same orbital wave function from also having parallel spins. Hence, a many-electron wave function minimizing the Coulomb energy corresponds to a particular mutual spin alignment of interacting electrons. As was first established by Heisenberg and Dirac (Dirac, 1926; Heisenberg, 1926, 1928) within the first-order approximation of the perturbation theory the electrostatic Coulomb interaction in the many-electron system can be expressed in the form of a spin Hamiltonian,

$$H = \sum_{e,e'} J_{ee'} \left(\mathbf{s}_e \cdot \mathbf{s}_{e'} + \frac{1}{4} \right) \tag{9}$$

which became known as the *Heisenberg exchange interaction*. Expression in brackets, up to a sign, is just a permutation operator for two electrons, tagged e and e', expressed through their spins. The strength of such direct exchange interaction between two electrons occupying orbital states with wave functions ψ_1 and ψ_2 is given by the overlap integral,

$$J_{ee'} = -\int \psi_1{}^*(\mathbf{r}_e)\ \psi_2{}^*(\mathbf{r}_{e'}) \times \frac{e^2}{r_{ee'}}\ \psi_1(\mathbf{r}_{e'})\ \psi_2(\mathbf{r}_e)\ \mathrm{d}^3\mathbf{r}_e\ \mathrm{d}^3\mathbf{r}_{e'} \tag{10}$$

which measures the frequency with which two electrons exchange their orbital states (Bethe and Jackiw, 1997). For the localized orthogonal orbitals the integral is always positive (Bethe and Jackiw, 1997; Yosida, 1998) and the direct exchange coupling is negative, $J_{ee'} < 0$, favoring parallel, ferromagnetic alignment of electronic spins. This type of interaction is at the origin of the Hund's rule requiring that electrons in an unfilled atomic shell maximize their total spin, and is also involved in the ferromagnetism of 3d metals (Fe, Ni, Co) and other materials. In very few cases, though, straightforward direct exchange is the leading cause of ferromagnetism. In fact, contribution of electron–nuclei Coulomb interaction to the direct electron exchange coupling between two atoms can actually make this coupling positive (e.g., when electron's wave functions have large overlap close to the nuclei), favoring antiparallel, antiferromagnetic spin alignment (Van Vleck, 1945).

In addition to direct exchange, there are a number of indirect exchange mechanisms contributing to coupling between atomic spins in condensed matter systems. The leading cause of the antiferromagnetism in magnetic insulators is the superexchange interaction resulting from the hybridization of wave functions of magnetic 3d ions with those of the intervening nonmagnetic anions (Kramers, 1934; Anderson, 1959). In the second-order perturbation theory, virtual electron hopping between the anion and the cation orbitals lowers the energy of the localized electrons. Depending on the electronic and orbital configuration and the resulting hopping matrix elements, direct exchange on the anion site may either lead to antiferromagnetic, or ferromagnetic superexchange (Kanamori, 1959). While in insulators with localized electrons superexchange interaction is short-range, typically acting only between the nearest cations bonded by an anion, in semiconductors where anion states form band superexchanges interaction can be long range, extending to distant neighbors (White, 1983). In addition to superexchange, electron hopping through anion site between 3d cations with two degenerate states, such as in Mn^{3+}/Mn^{4+} mixed valence systems, can facilitate ferromagnetic coupling, which is known as *double exchange* (Zener, 1951, 1959). Finally, in metals, direct exchange between the localized 3d electrons and itinerant conduction electrons leads to a long-range indirect RKKY interaction whose sign depends on the distance between 3d sites and on the density of delocalized itinerant electrons (Kasuya, 1956; Yosida, 1957).

In view of the fact that spin of each unpaired electron of a Hund's atom is (within the ground-state multiplet) proportional to the total spin $\boldsymbol{S}$, in most cases spin Hamiltonian of a system of magnetic atoms in a crystal can, to a good approximation, be written as,

$$H = \sum_{j \neq j'} J_{jj'} \mathbf{S}_j \cdot \mathbf{S}_{j'} + \sum_j D \left(S_j^z \right)^2 - \sum_{j,\beta} \gamma_\beta H_\beta S_j^\beta \equiv H_E + H_A + H_Z \tag{11}$$

The first term here is the Heisenberg exchange including all direct and indirect exchange interactions, the second term describes the simplest, second-order uniaxial spin anisotropy resulting from electron interaction with the crystal electric field, $\sim A(L^z)^2$, and mediated by the relativistic spin-orbit coupling, $\sim\lambda(\boldsymbol{LS})$, and the third term is Zeeman energy in magnetic field $\mathbf{H}$. The sum is over all atoms tagged by an index j.

While isotropic Heisenberg exchange does select the mutual spin alignment in the GS spin structure, it has a full O(3) spherical symmetry with respect to spin rotations and therefore does not establish any particular spin orientation with respect to positions of atoms (on the lattice) in the coordinate space. Continuum of GS spin configurations that are related by simultaneous rotation of all spins is allowed. Symmetry of the order parameter in the exchange structure can be understood by moving every spin to a single point without changing its direction. As a result, there might be just one spin group with coinciding spin directions as in the ferromagnet, two groups corresponding to two sublattices with opposite spins, this occurs in antiferromagnets and ferrimagnets, a star of n groups of similar spins with C_n

rotational symmetry corresponding to n sublattices in a commensurate spiral magnet, a circle (or ellipse) filled with continuum of spin directions, such as in the incommensurate spin spiral, and so on, see Figures 4 and 5. A complete classification of exchange spin structures was given in Andreev and Marchenko (1980).

Anisotropic interactions sensitive to spin direction with respect to atomic positions arise from several sources. First and perhaps most important is the electron spin interaction with crystal electric field mediated by spin-orbit coupling which was mentioned above. Although spin-orbit interaction is a relativistic, electrodynamic effect, it is an intra-atomic interaction and is only small on an atomic energy scale. With $\lambda \sim 100-1000$ K and more, it is still very significant on the energy scale of condensed matter systems. Crystal-field effects are most pronounced in rare earths and in systems where the atom's orbital moment is unquenched and contributes significantly to the atomic magnetization. In rare earths strong spin-orbit coupling leads to the fine structure of atomic multiplets where total angular momentum $\boldsymbol{J}$ is a good quantum number and magnetism exists in the ground-state $\boldsymbol{J}$ multiplet. In most cases, magnetic moment of an atom can still be described by an effective spin and using equation (1), perhaps with anisotropic gyromagnetic tensor $\gamma_{\alpha\beta}$. Anisotropic spin interaction with crystal electric field on the same site can be described by a single-ion spin Hamiltonian, which is usually expressed in terms of Stevens operators $O_l^m(\mathbf{S})$ (Abragam and Bleaney, 1986; Jensen and Mackintosh, 1991),

$$H_A = \sum_{l \le S} \sum_{m=0}^{2l} B_{2l}^m O_{2l}^m(\mathbf{S}) \tag{12}$$

of which only $O_2^0(\mathbf{S}) = 3(S^z)^2 - S(S+1)$ was included in equation (11). B_{2l}^m are the crystal-field parameters, which, in principle, can be obtained from an *ab initio* calculation of charge distribution in the crystal. These parameters determine spin orientations with respect to the crystal axes and magnetic field. In the absence of magnetic field and for the uniaxial anisotropy of equation (11), spins can minimize their energy by aligning parallel to z axis when the anisotropy constant is negative, $D < 0$, (easy-axis anisotropy) and by being perpendicular to the z axis when D is positive (easy-plane anisotropy).

Electron hopping (i.e., the orbital hybridization) between the cation and surrounding anions can lead to a transferred spin anisotropy, which is determined by the electric field at the anion site. In addition, an account for spin-orbit interaction may add anisotropic part to the exchange interaction, resulting in two-spin anisotropy, $\mathrm{H}_A = \sum_{\alpha,\beta} D_{jj'}^{\alpha\beta} S_j^\alpha S_{j'}^\beta$, $\alpha, \beta = x, y, z$. Another small source of anisotropic two-spin coupling is the magnetic dipole interaction, equation (3). The structure of the diagonal part of anisotropic exchange is similar to equation (3) and is often called the *pseudodipole interaction*. The off-diagonal part is the antisymmetric exchange of Dzyaloshinskii (1958)–Moriya (1960) and is usually written in the form,

$$\mathrm{H}_{\mathrm{DM}} = \mathbf{D}_{jj'} \cdot [\mathbf{S}_j \times \mathbf{S}_{j'}] \tag{13}$$

This interaction is at the origin of weak ferromagnetism of antiferromagnets, Figure 2(b), and incommensurate spiral spin structures such as shown in Figure 4. An expression for vector $\mathbf{D}$ can be derived in the perturbation theory and depends on the matrix elements of the orbital angular momentum of the interacting atoms. Its direction in the crystal can often be determined from the symmetry of atomic orbitals with respect to the line segment connecting spins j and j'. If there is inversion symmetry with respect to the center of this bond, $\mathbf{D}$ vanishes. For $S = 1/2$ ions such as Cu^{2+}, single-ion spin Hamiltonian resulting from the crystal field is just a constant and only two-ion spin anisotropy is possible.

In metals and systems with itinerant electrons, the anisotropy of indirect exchange mediated by these electrons can arise not only from their spin-orbital coupling to the crystal field, but also from the spin and wave vector dependent electron scattering due to Fermi surface anomalies, which is sensitive to the spin polarization of electron bands.

4 SPIN STRUCTURES

While spin Hamiltonian of equation (11) is clearly oversimplified, for example, it assumes localized spins and only includes uniaxial single-ion spin anisotropy, it properly describes a great variety of important cases, some of which are discussed in the subsequent text. It also appears that with some notable exceptions, such as often found in one-dimensional (1D) and two-dimensional (2D) and/or frustrated spin systems where the GS is disordered (Mermin and Wagner, 1966a,b; Haldane, 1983; Chandra and Doucot, 1988), spin structures and excitations of this Hamiltonian can be correctly predicted by adopting a semiclassical description of spin based on $1/S$ expansion. This approach, which is justified for large spins, is known as the *spin-wave theory* (Anderson, 1952; Nagamiya, 1967; Nagamiya, Nagata and Kitano, 1962).

The starting point for spin-wave calculation is finding the GS spin configuration that has the lowest energy, E_{GS}, for classical spins, that is, treating spin operators in equation (11) as classical vector variables. This neglects all fluctuations and is essentially a mean-field approximation. For a system of N identical spins S on a Bravais crystal lattice and without

anisotropy and magnetic field ($D = H = 0$), the general solution for the classical GS of equation (11) is a coplanar spin spiral (Yoshimori, 1959; Villain, 1959; Kaplan, 1959, 1961),

$$\mathbf{S}_j = \mathbf{S}_\mathbf{Q} e^{i\mathbf{Q}\cdot\mathbf{r}_j} + \mathbf{S}^*_\mathbf{Q} e^{-i\mathbf{Q}\cdot\mathbf{r}_j} \tag{14}$$

GS spin configuration is thus specified by the order parameter $\mathbf{S}_\mathbf{Q}$, which is simply a Fourier transform of spin structure. This includes ferromagnetic ($\mathbf{Q} = 0$ and all spins are parallel) and antiferromagnetic (there are two spin positions in the lattice, with $\mathbf{Q}\mathbf{r}_j = 0$ and $\mathbf{Q}\mathbf{r}_j = \pi$, i.e., there are two sublattices with antiparallel spins) collinear spin structures, see Figure 1. In a collinear structure $\mathbf{S}_\mathbf{Q}$ in (14) is a real vector of length $S/2$. In a noncollinear spiral spin structure, $\mathbf{S}_\mathbf{Q}$ is a complex vector satisfying conditions $\mathbf{S}^2_\mathbf{Q} = 0$ and $2\left(\mathbf{S}_\mathbf{Q}\cdot\mathbf{S}^*_\mathbf{Q}\right) = S^2$ that ensure that all spins have equal length S. Consequently, its real and imaginary parts are two mutually perpendicular vectors of length $S/\sqrt{2}$. They define the plane to which all spins are confined. Spins follow circularly polarized rotation in this plane, which propagates in the direction of wave vector $\mathbf{Q}$ and with the rotation angle given by $\mathbf{Q}\mathbf{r}_j$. All spins in a plane perpendicular to $\mathbf{Q}$ are co-aligned. Unlike circularly polarized electromagnetic wave, which is transverse, in the absence of anisotropic interactions spin plane in the exchange spin spiral may have arbitrary orientation with respect to the propagation vector $\mathbf{Q}$ (and the crystal lattice).

If spin ordering wave vector $\mathbf{Q}$ is commensurate with some reciprocal lattice vector $\boldsymbol{\tau}$, that is, there exists a whole number n such that $n\mathbf{Q} = \boldsymbol{\tau}$, then only n different values of spin rotation angle (mod 2π) are possible on the lattice and the spin structure is the commensurate spiral with finite repeat period. In this case there are only n different spin orientations in the crystal and one can divide the spin system into n sublattices with co-aligned spins and define a superlattice with a larger unit cell which contains all differently aligned spins. A simple example is spin structure in a 2D antiferromagnet on triangular lattice. It is a commensurate spin spiral with propagation vector $\mathbf{Q} = (1/3, 1/3)$ consisting of three sublattices directed at 120° to each other, see Figure 5(c). While sublattice description is straightforward, it entails significant complications for spin-wave calculations and for understanding the structure and behavior of spin order parameter and excitations. Existence of n spin species requires n equations of motion; an enlarged unit cell corresponds to a proportionally smaller Brillouin zone into which dispersion of all excitations existing in the system have to be folded. It also implies a number of extinction rules for nuclear Bragg peak intensities prohibiting unphysical peaks, which would be at fractional positions in the real lattice. Finally, sublattice description is not possible for incommensurate spirals.

While in some cases introducing spin sublattices is unavoidable, in many situations spin structure is a weakly distorted exchange spiral (14) and can be best described in terms of the nuclear lattice on which the spin Hamiltonian, for example (11), is defined. In this description all spins in the ordered structure are treated equally, without subdividing them into sublattices. The lattice unit cell is not increased to incorporate translational symmetry breaking by spin order. The corresponding folding of the nuclear Brillouin zone is also avoided. Instead, additional (magnetic) Bragg peaks corresponding to spin superlattices are indexed in the paramagnetic (nuclear) Brillouin zone. For a Bravais lattice there is a single branch of spin-wave excitations, whose properties are determined by spin structure.

A general procedure for finding the GS structure of classical spin Hamiltonian (11) on a simple Bravais lattice was developed in Nagamiya (1967), Nagamiya, Nagata, and Kitano (1962), Yoshimori (1959), Villain (1959), and Kaplan (1959, 1961) and recently discussed in Zaliznyak and Zhitomirsky (1995a,b), Zaliznyak (2003), and Zhitomirsky and Zaliznyak (1996). One has to minimize a function of N classical vector variables $\mathbf{S}_j$, subject to N constraints of equal length, $\mathbf{S}^2_j = S^2$. Employing Lagrange multipliers and switching to Fourier representation, which takes advantage of lattice translational symmetry, the following system of equations for spin configuration, minimizing spin Hamiltonian (11) under the equal-spin constraint is obtained,

$$N J_\mathbf{q}\mathbf{S}_\mathbf{q} + \mathbf{e}_z D S^z_\mathbf{q} - \sum_{\mathbf{q}'} \lambda_{\mathbf{q}'}\mathbf{S}_{\mathbf{q}-\mathbf{q}'} = \frac{\gamma}{2}\mathbf{H}\delta_{\mathbf{q},0},$$
$$\sum_{\mathbf{q}'} \mathbf{S}_{\mathbf{q}'}\cdot\mathbf{S}_{\mathbf{q}-\mathbf{q}'} = S^2\delta_{\mathbf{q},0} \tag{15}$$

Here $\mathbf{e}_z$ is the unit vector along z axis, $\delta_{\mathbf{q},\mathbf{q}'}$ is a 3D Kronekker symbol, and $\mathbf{S}_\mathbf{q}$, $\lambda_\mathbf{q}$ and $J_\mathbf{q}$ are the lattice Fourier transforms of spin $\mathbf{S}_j$, Lagrange multiplier λ_j and exchange coupling $J_{jj'}$ lattice fields, for example,

$$J_\mathbf{q} = \sum_{\mathbf{r}_{jj'}} J_{jj'} e^{-i\,\mathbf{q}\cdot\mathbf{r}_{jj'}} = J_{-\mathbf{q}},\ J_{jj'} = \frac{1}{N}\sum_\mathbf{q} J_\mathbf{q} e^{i\,\mathbf{q}\cdot\mathbf{r}_{jj'}} \tag{16}$$

Result (14) follows immediately from equations (15). In the absence of anisotropy and magnetic field, the GS energy per spin is $E_{GS}/N = J_\mathbf{Q} S^2$, so the ordering wave vector $\mathbf{Q}$ corresponds to the minimum of the Fourier transform of exchange interaction, $J_\mathbf{Q} = \min\{J_\mathbf{q}\}$. When magnetic field $\mathbf{H}$ is turned on in the absence of spin anisotropy ($D = 0$), spins simply tilt toward field, forming a cone. $\mathbf{S}_\mathbf{Q}$ and the plane of spin spiral component align perpendicular to the field, and

the net magnetization, $\gamma \mathbf{S_0} = \chi \mathbf{H}$, is parallel to it. The same simple structure is realized when there is uniaxial anisotropy but the magnetic field is parallel to its axis, although for easy-axis spin anisotropy ($D < 0$) it occurs only for fields above spin-flop transition field, $H > H_{\rm sf} \sim \mathrm{S}\sqrt{|D|J}$. The balance between exchange and Zeeman energy determines spin-canting (cone) angle α, $\sin\alpha = H/H_{\rm s}$, which is valid up to the saturation field, $H_{\rm s} = 2S(J_0 + J_{\rm Q} + D)$. Above $H_{\rm s}$, $\sin\alpha = 1$ and spins are aligned parallel to the magnetic field.

In the general case, when both anisotropy and magnetic field are present, the situation is significantly more complicated. In addition to straightforward spin canting toward magnetic field as in the simple cases mentioned above, a noncollinear classical spin spiral also becomes distorted. This distortion, known as 'bunching', is described by the appearance of Fourier harmonics at integer multiples, $n\mathbf{Q}$, of the spin structure ordering wave vector $\mathbf{Q}$, that is, at $\boldsymbol{S}_{2\mathbf{Q}}$, $\boldsymbol{S}_{3\mathbf{Q}}$, and so on, in addition to $\boldsymbol{S}_{\rm Q}$. When such distortion is weak, for example, for small D and H, it can be calculated using perturbative harmonic expansion, $\lambda_{\mathbf{q}} = \sum_n \lambda_n \delta_{\mathbf{q},n\mathbf{Q}}$, $\mathbf{S_q} = \sum_n \mathbf{S}_{n\mathbf{Q}} \delta_{\mathbf{q},n\mathbf{Q}}$, where $\lambda_{n\neq 0} \sim O\left(\sqrt{\frac{D}{J}}, \frac{\gamma H}{J}\right) \cdot \lambda_{|n|-1}$ and $\left|S_{n\mathbf{Q}}\right| \sim O\left(\lambda_{|n|-1}\right)$ (Zaliznyak, 2003). Alternatively, it can be obtained by considering perturbative corrections to spiral winding angle in the real-space spin structure, $\delta\theta_j = \sum_n \alpha_n \cos\left(n\mathbf{Q}\mathbf{r}_j\right) + \beta_n \sin\left(n\mathbf{Q}\mathbf{r}_j\right)$, where the coefficients α_n and β_n are of the order $\sim O\left(\left(\frac{D}{J}\right)^{\frac{n}{2}}, \left(\frac{\gamma H}{J}\right)^n\right)$ (Zaliznyak and Zhitomirsky, 1995a,b).

Squares of the absolute value of Fourier components of spin density, $|\mathbf{S_Q}|^2$, $|\mathbf{S}_{2\mathbf{Q}}|^2$, and so on, are proportional to the intensity of magnetic Bragg reflections associated with spin order at the corresponding wave vectors, $\mathbf{Q}$, $2\mathbf{Q}$, and so on, which are measured in experiment, for example, by magnetic neutron diffraction (Izyumov and Ozerov, 1970; Zaliznyak and Lee, 2005; see also **X-ray and Neutron Scattering by Magnetic Materials, Volume 1**). For spin structures on a simple Bravais lattice discussed above, where there is only one spin in the crystal unit cell, $\mathbf{S_Q}$ is simply given by the magnitude of that spin S. Higher harmonics, which result from distortion of exchange spin structure, for small distortions can be calculated following the procedure described in the preceding text, see for example Zaliznyak and Zhitomirsky (1995a,b) and Zheludev *et al*. (1998, 1999). For non-Bravais crystal lattices with several spins in the unit cell, $\mathbf{S_Q}$ is the Fourier transform of the spin density of the entire unit cell. When there is more than one atom in the unit cell of the crystal, the above procedure of finding spin GS has to be modified by introducing several spin species. While this situation is actually more common in real materials, it leads to some computational complications, resulting in a system of linear equations for the order parameters of different spin species (Izyumov and Ozerov, 1970). Nevertheless, the result in principle is not much different from that for Bravais lattice. In fact, spin structures can often be easily understood by simply considering bond energies contributing to the Hamiltonian (11).

Some examples of spin structures found in different materials are shown in Figure 1 through Figure 4. The simplest, ferromagnetic structure, most commonly occurs in metals, such as 3d metals of the iron group, Figure 1(a). While electron states in metals form bands and applicability of the localized spin description is questionable, experiments do indicate existence of localized magnetic moments in metals of the iron group and their alloys, persisting well above the Curie temperature (Schurer, Sawatzky and van der Woude, 1971; Brown *et al*., 1982; Lynn, 1975, 1984). This can be visualized by adopting a simple approximate picture called the s–d model, where electrons of the incomplete d shell are localized, while valence s electrons are involved in metallic cohesion and are collectivized and described by Bloch wave functions (Zener, 1959, 1951). They provide long-range indirect exchange between the localized d electrons. First-principle local spin density functional calculations (Liechtenstein, Katsnelson, Antropov and Gubanov, 1986) indicate that effective Heisenberg localized spin Hamiltonian can indeed be used for describing 3d metals, and give effective exchange parameters for iron and nickel which agree well with experimental values. However, experimentally determined magnetic moments in ferromagnetic 3d metals, $\mu_{\rm Fe} \approx 2.2$, $\mu_{\rm Co} \approx 1.7$, $\mu_{\rm Ni} \approx 0.6$, are noticeably smaller than corresponding expected free-atom values arising from spin of unpaired 3d electrons, $S_{\rm Fe} = 2$, $S_{\rm Co} = 3/2$, $S_{\rm Ni} = 1$, which shows that simplistic s–d model is at best a very coarse approximation.

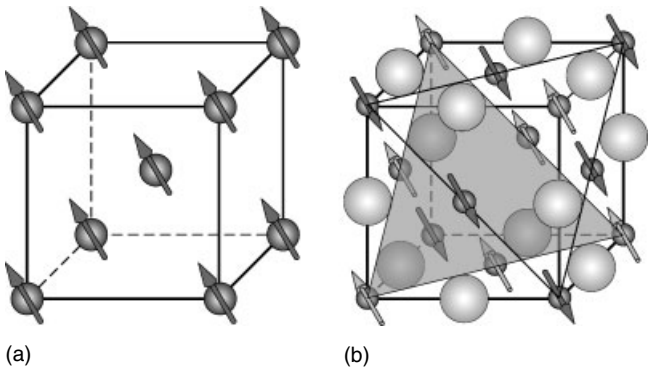

Figure 1. (a) Ferromagnetic spin alignment on the body-centered cubic (bcc) lattice found in simple metals (Fe, Ni, Co, . . .). (b) Antiferromagnetic spin structure on the NaCl-type face-centered cubic (fcc) lattice found in metal monoxides such as FeO, NiO, CoO, MnO. Small darker spheres with arrows show metal ions and their spins, larger spheres are oxygen anions. Structure consists of ferromagnetic sheets perpendicular to (111) diagonal of the cubic unit cell (shown semitransparent in the figure), staggered antiferromagnetically.

Transition-metal monoxides with simple fcc crystal lattice adopt antiferromagnetic spin structure shown in Figure 1(b) (Shull, Strauser and Wollan, 1951). It is driven by strong antiferromagnetic superexchange through 180° M–O–M (M = Fe, Ni, Co, Mn) bond. Propagation vector of such structure is Q = (1/2, 1/2, 1/2), in reciprocal lattice units of the cubic lattice shown in the figure. Spin alignment, however, is different in different oxides, although except for CoO spins tend to be confined to [111] planes. Antiferromagnetic order at T_N is usually accompanied by a slight trigonal distortion arising from magnetostriction associated with anisotropic spin interactions, which makes the symmetry of the crystal consistent with that of the spin structure, (Kugel, Hennion and Carabatos, 1978; Tomiyasu, Inami and Ikeda, 2004; Barbier *et al*., 2004; Goodwin, Tucker, Dove and Keen, 2006). NiO has the highest Neel temperature in the series, $T_N^{(NiO)} \approx 524\,K$, $T_N^{(CoO)} \approx 298\,K$, $T_N^{(FeO)} \approx 198\,K$, $T_N^{(MnO)} \approx 118\,K$.

Apart from simple ferro- and antiferromagnetism shown in Figure 1, there are collinear spin structures where both parallel and antiparallel spin alignments coexist, giving rise to an uncompensated net ferromagnetic, or more precisely ferrimagnetic moment. This can result from existence of atoms with different spins within the unit cell, such as Fe^{3+} and Fe^{2+}, which do not compensate each other when aligned antiferromagnetically, or from the combination of ferro- and antiferromagnetic spin alignment in the spin structure. In fact, both possibilities are realized in magnetite, Fe_3O_4, which is a prototypical ferrimagnet known as *lodestone* since ancient times, Figure 2(a). At room temperature the unit cell of magnetite contains three Fe_3O_4 formula units and 24 spins in total, which are unequally distributed between 8 tetrahedrally coordinated A sites (populated by Fe^{3+}, S = 2) and 16 octahedrally coordinated B sites (equally populated by 8 Fe^{3+}, S = 2 and 8 Fe^{2+}, S = 5/2). Antiferromagnetic superexchange J_{AB} between A and B sites passing through ≈125° A–O–B bond leads to the antiparallel alignment of A and B spins within the unit cell. Unequal population of A and B sites results in the ferrimagnetic structure. Already large unit cell is not further increased by spin structure, and magnetic Bragg reflections appear on top of nuclear Bragg peaks (Shull, Wollan and Koehler, 1951). Despite small value of the superexchange coupling, $J_{AB} \approx 2.35\,meV \approx 27\,K$ (Alperin, Steinsvoll, Nathans and Shirane, 1951), magnetite orders at very high temperature, $T_C \approx 858\,K$. This can be expected for large Fe^{2+}/Fe^{3+} spins and is consistent with spin-wave calculations (Mills, Kenan and Milford, 1966).

In the rhombohedral structure of hematite, Fe_2O_3, (and escolaite, Cr_2O_3) there are four Fe^{3+} (S = 2) ions in the unit cell and two types of bonds between them. In the antiferromagnetic structure below $T_N \approx 950\,K$ spins coupled by the superexchange passing through oxygen anions align antiferromagnetically, while those coupled directly are co-aligned, Figure 2(b). Once again spin order does not break lattice translational symmetry and magnetic and nuclear Bragg peaks overlap (Nathans, Pickart, Alperin and Brown, 1964). Superexchange bond, which couples spins from different sublattices, passes through two oxygen triangles that are rotated by 60° with respect to each other and thus lacks

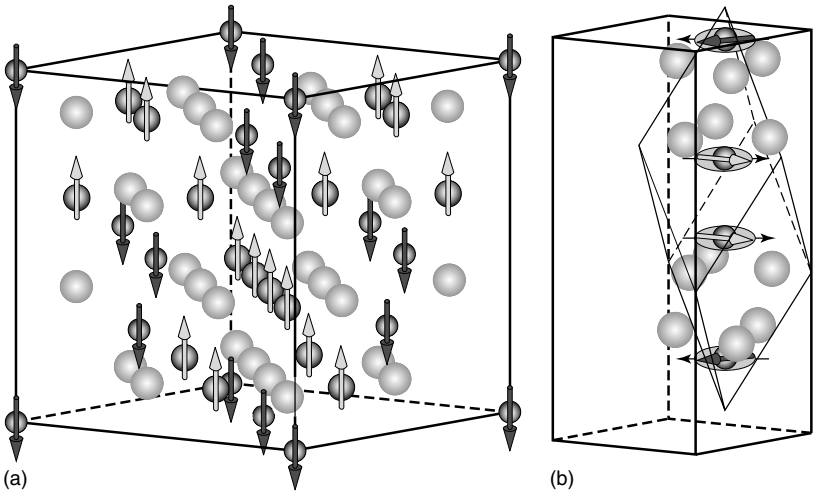

Figure 2. (a) Ferrimagnetic spin structure of magnetite, Fe_3O_4. The unit cell contains 32 O^{2-} anions (larger light-shaded spheres) and 24 Fe cations (smaller dark spheres). 8 Fe^{3+} ions (S = 2) with co-aligned magnetic moments $\approx 4\,\mu_B$ occupy tetrahedrally coordinated sites (down arrows), while 16 octahedrally coordinated sites are occupied by an equal mixture of 8 Fe^{3+} and 8 Fe^{2+} (S = 5/2, $\mu \approx 5\,\mu_B$) ions aligned in the opposite direction (up arrows), resulting in net ferromagnetic moment $\approx 4\,\mu_B$ per unit cell, or $\approx 1/6\,\mu_B$ per iron. (b) Weak ferromagnetism in hematite, Fe_2O_3. Nearly antiferromagnetic spins are shown slightly tilted in the basal plane, resulting in small ferromagnetic moment. Both hexagonal and the rhombohedral unit cell with four Fe^{3+} ions and oxygens bridging them are shown.

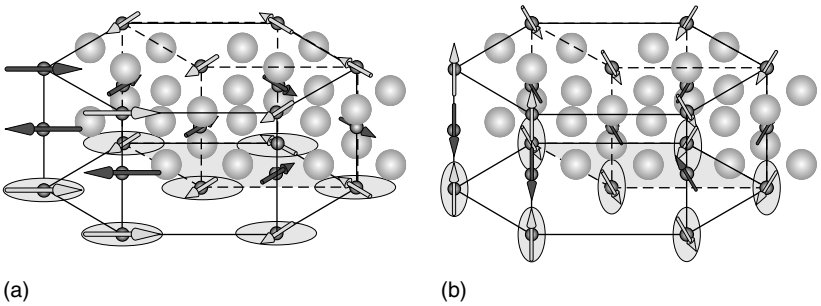

Figure 3. Triangular spin ordering in quasi-one-dimensional ABX_3 hexagonal perovskites; magnetic ordering wave vector is $Q = (1/3, 1/3, 1)$. Dark spheres with arrows show 3d metal ions and their spin. Anions (X) bridging 3d ions (B) in the chains at the corners one unit cell (dashed lines) and providing the exchange coupling are also shown (larger light spheres). (a) Easy-plane anisotropy does not distort 120° spin structure, simply forcing the plane of spin spiral to lie in the $a-b$ basal plane. (b) Easy-axis anisotropy $||\, c$ axis not only forces spin plane to be perpendicular to the basal plane, but also distorts perfect 120° triangular ordering (e.g., in $CsNiCl_3$ the angle between the spin direction in the neighbor chains is ≈119°).

inversion symmetry. This allows DM anisotropic contribution to superexchange, with **D** vector parallel to the threefold rotation axis (z axis). As a result, spins from different sublattices can lower their energy by slightly canting toward each other and producing a weak ferromagnetic component in the basal plane, perpendicular to z axis. The same weak ferromagnetism is also found in many other materials, for example, $MnCO_3$ and $CoCO_3$ (Borovik-Romanov, 1959).

Perhaps, the simplest noncollinear exchange spin structure is a 120° triangular spin ordering occurring in an antiferromagnet on the two-dimensional triangular lattice. It is also an example of the commensurate spin spiral with propagation vector $\mathbf{Q} = (1/3, 1/3)$. Such spin ordering is found in many magnetically quasi-one-dimensional perovskites of ABX_3 family (A = Cs, Rb, K, . . .; B = Ni, Mn, V, . . .; X = Cl, Br, I, . . .) with hexagonal crystal structure. In these compounds antiferromagnetic spin chains consisting of 3d metal sites and running along the hexagonal C_6 axis are arranged on the triangular lattice in the basal plane and form a 120° triangular spin structure in this plane, Figure 3. Easy-plane anisotropy found, for example, in $CsMnBr_3$ and $CsVBr_3$ does not distort 120° exchange structure, simply forcing all spins into the basal plane (Eibshutz, Sherwood, Hsu and Cox, 1972; Inami *et al*., 1995). In the case of easy-axis anisotropy (e.g., in $CsNiCl_3$, $RbNiCl_3$, $CsMnI_3$), spins lie in a plane containing the z axis. Triangular spin ordering of ideal spiral structure is distorted and spin opening angle is less than 120° (Yelon and Cox, 1972, 1973). In $CsMnI_3$, where it is only 100°, magnetic Bragg peak corresponding to third order harmonics of spin spiral structure, $3\mathbf{Q} = (1, 1, 1)$, is readily observed (Harrison, Collins, Abu-Dayyeh and Stager, 1991).

An example of the incommensurate spiral spin structure resulting from Dzyaloshinskii–Moriya interaction is found in quasi-2D $S = 1/2$ antiferromagnet $Ba_2CuGe_2O_7$ shown in Figure 4 (Zheludev *et al*., 1996, 1998, 1999). Absence of the inversion symmetry of the antiferromagnetic bond between nearest-neighbor spins on the centered square lattice in the basal plane allows uniform antisymmetric DM exchange with vector **D** perpendicular to (001) z axis. The spin interaction energy is minimized when all spins are perpendicular to **D**, in which case exchange energy per bond is $2J\cos\varphi + D\sin = \sqrt{4J^2 + D^2}\cos(\varphi - \alpha)$, where J is the antiferromagnetic isotropic Heisenberg superexchange,

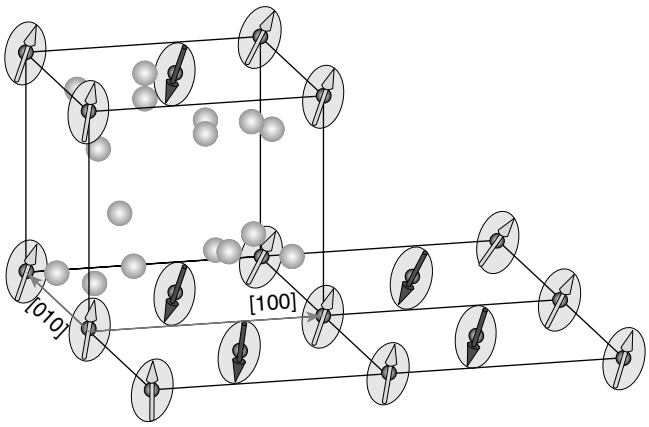

Figure 4. Spiral spin structure in quasi-2D antiferromagnet $Ba_2CuGe_2O_7$. Cu^{2+} ions (dark spheres) with $S = 1/2$ spins (arrows) form ideal square lattice in the $a-b$ plane. Larger, light-shaded spheres show oxygens in one unit cell. Noncentrosymmetric tetragonal crystal structure (space group $P\underline{4}2_1m$) gives rise to Dzyaloshinskii–Moriya interaction which favors spiral spin arrangement with spins confined in $[1, -1, 0]$ xz plane (x axis is directed along the diagonal of the square) and magnetic propagation vector $(1 + \varsigma, \varsigma, 0)$ with $\varsigma \approx 0.0273$. This means that interacting nearest-neighbor spins along the diagonal of the square unit cell rotate by $\alpha = 360^\circ \cdot \varsigma \approx 9.8^\circ$ in xz plane with respect to their antiparallel alignment in the simple collinear antiferromagnetic structure with $\mathbf{Q} = (1, 0, 0)$.

$\alpha = -\arctan(D/J)$ and φ is the angle between the spins. The energy is a minimum for $\varphi = \pi + \alpha$ and the GS spin structure is an incommensurate spin spiral with propagation vector $\mathbf{Q} = (1 + \varsigma, \varsigma, 0)$, $\varsigma = \alpha/(2\pi)$, shown in Figure 4. In this case not only spin alignment, but also spiral propagation vector are both determined by weak anisotropic interactions, and therefore both are equally strongly sensitive to magnetic field (Zheludev *et al.*, 1997).

5 SPIN-WAVE EXCITATIONS

Spin waves are usually understood in the framework of semiclassical description and can be visualized as small oscillations of classical spin vectors around their equilibrium positions in the GS spin structure, as shown in Figure 5. Their wavelike spatial composition results from the translational symmetry of the system. Frequencies of spin-wave oscillations can be calculated from spin Hamiltonian, for example, equation (11), by writing torque equations of motion for classical spins (Mattis, 1965). Such an approach relies entirely on classical mechanics and can be most generally pursued employing Poisson brackets formalism (Dzyaloshinskii and Volovick, 1979). Spin waves are normal modes of the linearized equations of motion. They involve small spin deviations that are perpendicular to the equilibrium spin direction. Hence, spin waves are transversely polarized, with two mutually orthogonal linear polarizations of spin oscillations possible. A circular spin precession around its equilibrium position can have two possible directions, clockwise and counterclockwise; one is shown in Figure 5(a) for a spin wave in ferromagnetic structure.

In an antiferromagnetic spin structure, precession of two sublattices can have the same, Figure 5(b), or the opposite sense, Figure 5(c). In the sublattice description, where the magnetic superlattice contains two spin species, these correspond to two distinct, in-phase and antiphase, spin-wave modes. In the extended, paramagnetic Brillouin zone (BZ) description, where there is only one spin-wave branch for spins on a Bravais lattice, these two modes correspond to spin waves having different wave vectors, $\mathbf{q}$ and $\mathbf{q} \pm \mathbf{Q}$, where $\mathbf{Q}$ is the antiferromagnetic ordering wave vector. For a three-sublattice antiferromagnetic spin structure on a triangular lattice there are two possible choices of sublattice(s) rotating in the 'wrong' sense. Hence, there are three spin-wave modes, Figure 5(d). In general, the total number of spin-wave modes in the sublattice description equals the number of sublattices. For a Bravais nuclear lattice, multiple modes arise from folding of the dispersion surface of a single mode defined in the large nuclear Brillouin zone into a small BZ of magnetic superlattice. Hence, their number is equally given by the volume ratio of these BZ.

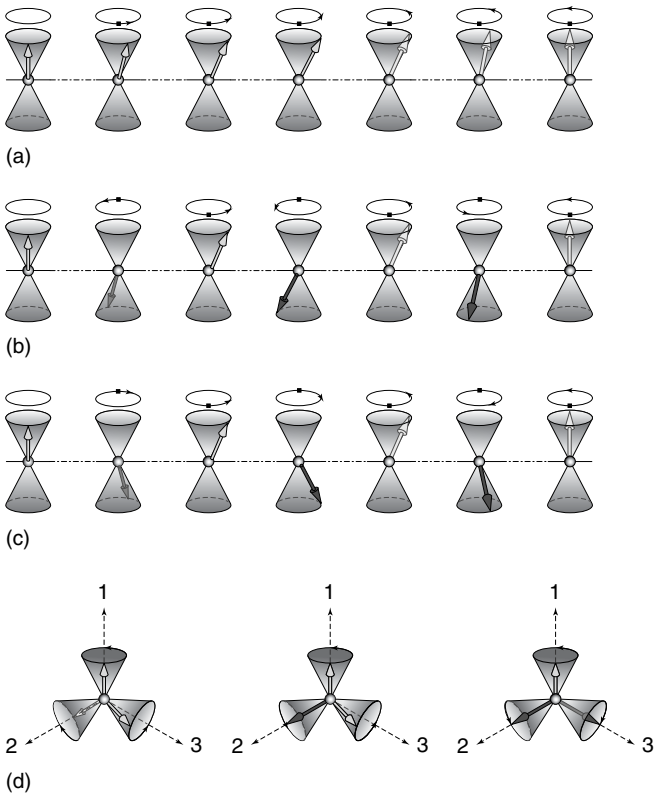

Figure 5. Spin waves in different spin structures. Each spin undergoes precession about its equilibrium direction sweeping out the surface of a cone over a period $2\pi/\omega(q)$, where $\omega(q)$ is frequency of spin wave and q is the wave vector. (a) Ferromagnet, (b) in phase, and (c) antiphase mode in two-sublattice antiferromagnet, (d) in phase and two antiphase (left to right) modes in three-sublattice antiferromagnet on triangular lattice. A half-period of spin-wave oscillation spanning six spins is shown in (a) and (b, c), corresponding to spin wave with wave vector equal to 1/12 of reciprocal lattice unit in the direction of propagation. Antiphase mode in (c) corresponds to wave vector 7/12 in the extended paramagnetic Brillouin zone description.

In quantum-mechanical description of spins, elementary quanta of spin excitation in spin systems, which by virtue of equation (1) are also elementary magnetic excitations, are known as *magnons*. In quantum mechanics, states of an isolated spin system on a lattice are specified by the total spin of the system, S_{tot}, its z component, S^z_{tot}, and wave vector $\mathbf{q}$, which determines the eigenvalue of the lattice translation operator, $\mathrm{T}_{\mathbf{r}}$,

$$\mathrm{T}_{\mathbf{r}} \left|\mathbf{q}, S_{\text{tot}}, S^z_{\text{tot}}\right\rangle = e^{i\mathbf{q}\cdot\mathbf{r}} \left|\mathbf{q}, S_{\text{tot}}, S^z_{\text{tot}}\right\rangle \tag{17}$$

A GS for an isotropic saturated ferromagnet is $\left|0, NS, S^z_{\text{tot}}\right\rangle$, $-NS < S^z_{\text{tot}} < NS$. For an antiferromagnet it is $|0, 0, 0\rangle$ (this implies sublattice description; ordered GS is doubly degenerate). In many cases this set of quantum numbers is sufficient for describing low-energy states of the

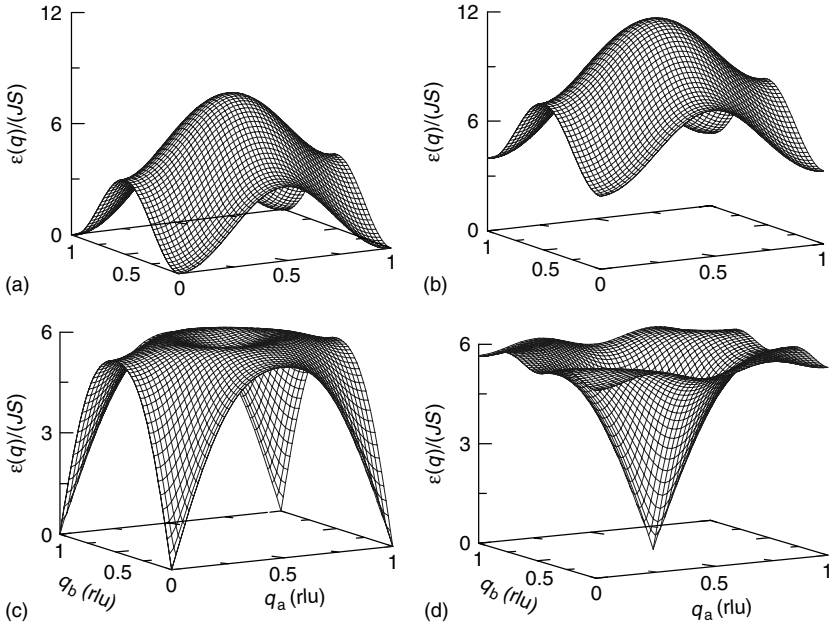

Figure 6. Cuts of the spin-wave dispersion surface in a ferromagnet, $J_a = J_b = J_c = J < 0$, (a), (b) and an antiferromagnet, $J_a = J_b = J_c = J > 0$, (c), (d) on a three-dimensional (3D) Bravais cubic lattice by an (h,k,l_0) reciprocal lattice plane with $l_0 = 0$ (a and c) and $l_0 = 0.5$ (b and d). Wave vector is measured in reciprocal lattice units (rlu), $q_a = h$, $q_b = l$. (a) Spin structure of a ferromagnet has propagation vector Q = (0, 0, 0) and magnetic Bragg peak positions coincide with nuclear structure Bragg peaks at the corners of the Brillouin zone. A cosine-like dispersion is quadratic in q around these points. (b) Dispersion for Q = (h, k, 0.5) does not pass through Q = 0 magnetic ordering vector and has a gap. (c) Dispersion in Q = (h, k, 0) zone does not pass through Q = (1/2, 1/2, 1/2) magnetic ordering vector of an antiferromagnet but still softens for the uniform mode at Q = 0 and has no gap. (d) Dispersion in Q = (h, k, 1/2) zone cuts through the Goldstone mode with sine-like dispersion linear in the vicinity of magnetic ordering vector Q = (1/2, 1/2, 1/2).

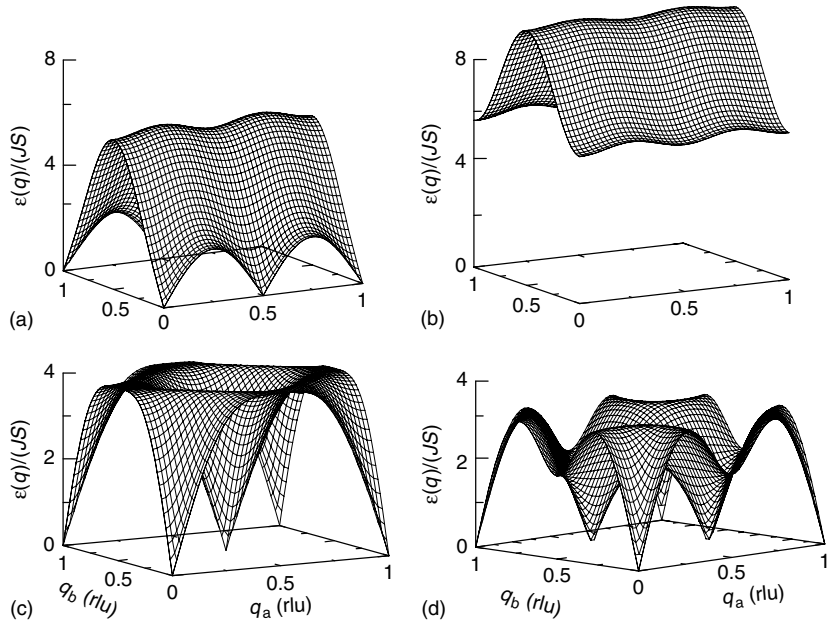

Figure 7. (a, b) Spin-wave dispersion in an antiferromagnet on the 3D cubic Bravais lattice with $J_a = -J_b = -J_c = J > 0$, that is ferromagnetic layers in b–c plane stacked antiferromagnetically along a. (a) cut by a (h,k,0) reciprocal lattice plane showing a Goldstone mode with sine-like dispersion along a arising from magnetic ordering vector Q = (0.5, 0, 0). (b) cut by a (h,k,0.5) plane containing neither Q = 0 nor Q = (0.5, 0, 0) and therefore no soft modes. (c) Spin-wave dispersion in a 2D antiferromagnet on a square lattice. There are two soft modes, at Q = 0 and at the magnetic ordering vector Q = (1/2, 1/2). (c) Spin waves in a triangular lattice antiferromagnet. In addition to soft mode at Q = 0, there are two Goldstone modes at two equivalent spin ordering wave vectors, Q = (1/3, 1/3) and Q = (2/3, 2/3).

system, which can differ from the GS by having a nonzero $\mathbf{q}$ and by the value of the total spin, that is, $\Delta S^z_{\text{tot}} = 0, \pm 1$. Therefore, quantum magnons describing these states are specified by wave vector, $\mathbf{q}$, and spin, $S = 1$, $S^z = 0, \pm 1$, quantum numbers. Clearly, there are three magnon polarizations in quantum theory, as opposed to only two for transverse spin waves in classical description. However, in systems where semiclassical description is valid, for example, for $S >> 1$, and spin order is well developed, only two magnons corresponding to semiclassical spin waves are relevant.

Except for few specific important cases, full quantum-mechanical treatment of spin Hamiltonian presents insurmountable difficulties (Mattis, 1965; see also **Magnetism of Low-dimensional Systems: Theory, Volume 1**, **Spin Waves: History and a Summary of Recent Developments, Volume 1**). The most successful approximate approach to treating quantum spins is the spin-wave theory, which starts from a semiclassical approximation and is based on a perturbative expansion in $1/S$. Semiclassical magnons obtained in the leading, first-order perturbation of spin-wave theory are just classical spin waves.

In spin-wave theory spins are quantized by expanding deviations from their equilibrium directions in the classical spin structure in a series of Bose creation–annihilation operators, using for example, Holstein–Primakoff transformations (Holstein and Primakoff, 1940). Energies of spin excitations and quantum corrections to spin structure can then be calculated using perturbation theory for a system of interacting bosons. A rather complete nonlinear spin-wave theory accounting for second and higher order perturbation corrections has been developed for the isotropic Heisenberg Hamiltonian; some examples are found in Dyson (1956), Chubukov (1984), Rastelli, Reatto, and Tassi (1985), Ohyama and Shiba (1993, 1994), and Veillette, James and Essler (2005), (see also **Spin Waves: History and a Summary of Recent Developments, Volume 1**).

Spin-wave calculations proceed by transforming every spin operator to its own coordinate system with z axis pointing along the spin direction in the classical GS spin structure. For a coplanar exchange spiral (14), such coordinate transformation is achieved by a rotation through an angle $\mathbf{Q}\mathbf{r}_j$. Then, in order to obtain the first $1/S$ correction to classical approximation, in the standard perturbation scheme spin operators are expressed through boson operators, a^+, a, by employing the truncated Holstein-Primakoff transformation, $S^z_j = S - a^+a$, $S^+_j \approx a\sqrt{2S}$, $S^-_j \approx a^+\sqrt{2S}$. The first-order corrections in such a linear, or harmonic spin-wave theory appear in the form of quadratic boson Hamiltonian describing a system of quantum oscillators, which correspond to quantized classical spin waves. Applying this procedure to Hamiltonian (11) for spin spiral without harmonic distortions, the following boson equivalent is obtained, (Zhitomirsky and Zaliznyak, 1996),

$$\mathrm{H} = \sum_{\mathbf{q}} \left\{ \left(A_{\mathbf{q}} + C_{\mathbf{q}}\right)\ a^+_{\mathbf{q}} a_{\mathbf{q}} + \frac{1}{2} B_{\mathbf{q}} \left(a_{\mathbf{q}} a_{-\mathbf{q}} + a^+_{\mathbf{q}} a^+_{-\mathbf{q}} \right) \right\} \tag{18}$$

where

$$\begin{aligned} A_{\mathbf{q}} &= -2SJ_{\mathbf{Q}} + S\cos^2\alpha\left(J_{\mathbf{q}} + D\right) \\ &\quad + S\left(1 + \sin^2\alpha\right)\frac{J_{\mathbf{q}+\mathbf{Q}} + J_{\mathbf{q}-\mathbf{Q}}}{2} \\ B_{\mathbf{q}} &= -S\cos^2\alpha\left(J_{\mathbf{q}} + D - \frac{J_{\mathbf{q}+\mathbf{Q}} + J_{\mathbf{q}-\mathbf{Q}}}{2}\right), \\ C_{\mathbf{q}} &= S\sin\alpha\left(J_{\mathbf{q}+\mathbf{Q}} - J_{\mathbf{q}-\mathbf{Q}}\right) \end{aligned}$$

$A_{\mathbf{q}}$ and $B_{\mathbf{q}}$ are even, while $C_{\mathbf{q}}$ is an odd function of $\mathbf{q}$. Equation (18) is diagonalized by the standard Bogolyubov transformation (which leaves odd-$\mathbf{q}$ terms unchanged), resulting in the Hamiltonian of uncoupled harmonic oscillators, $\mathrm{H} = \sum_{\mathbf{q}} \left\{ \varepsilon\left(\mathbf{q}\right)\left(a^+_{\mathbf{q}} a_{\mathbf{q}} + \frac{1}{2}\right) - \frac{1}{2}A_{\mathbf{q}} \right\}$. The constant term $\sum_{\mathbf{q}} \frac{1}{2}\left(\varepsilon\left(\mathbf{q}\right) - A_{\mathbf{q}}\right)$ gives $1/S$ quantum correction to the classical GS energy. The energy of semiclassical magnons is $\varepsilon\left(\mathbf{q}\right) = \sqrt{A^2_{\mathbf{q}} - B^2_{\mathbf{q}}} + C_{\mathbf{q}}$, or,

$$\begin{aligned} \varepsilon\left(\mathbf{q}\right) = 2S \Bigg(&\sqrt{\left(\frac{J_{\mathbf{q}+\mathbf{Q}} + J_{\mathbf{q}-\mathbf{Q}}}{2} - J_{\mathbf{Q}}\right)} \\ &\times \sqrt{\left(\frac{J_{\mathbf{q}+\mathbf{Q}} + J_{\mathbf{q}-\mathbf{Q}}}{2}\sin^2\alpha + \left(D + J_{\mathbf{q}}\right)\cos^2\alpha - J_{\mathbf{Q}}\right)} \Bigg) \end{aligned} \tag{19}$$

According to Goldstone's theorem, breaking of the continuous symmetry of the Hamiltonian in the GS must entail a zero energy mode(s) in the excitation spectrum. Such modes appear in the spin-wave dispersion of equation (19) at $\mathbf{q} = 0$ and at $\mathbf{q} = \mathbf{Q}$, the latter only has zero energy in the absence of anisotropy and magnetic field.

Dispersion of spin-wave excitations in different spin structures on simple Bravais lattices calculated using equation (19) for $H = D = 0$ and for nearest-neighbor spin interaction are shown in Figures 6 and 7. Fourier transformed exchange is obtained by summing over the neighbor bonds, $J_{\mathbf{q}} = \sum_{\mathbf{d}} 2J_{\mathbf{d}} \cos\left(\mathbf{q}\cdot\mathbf{d}\right)$, which for a simple cubic lattice is just $J_a \cos 2\pi q_a + J_b \cos 2\pi q_b + J_c \cos 2\pi q_c$. For a ferromagnet, where $\mathbf{Q} = 0$, this expression simply has to be shifted upwards by $J_0 = J_a + J_b + J_c$ to obtain the spin-wave spectrum shown in Figure 6(a,b). There is a Goldstone mode with quadratic dispersion at $\mathbf{q} = 0$.

Inelastic neutron scattering provides a direct way of studying spin waves in most magnetic materials. Magnetic neutron scattering cross-section is directly proportional to the dynamic spin susceptibility and exhibits sharp, delta

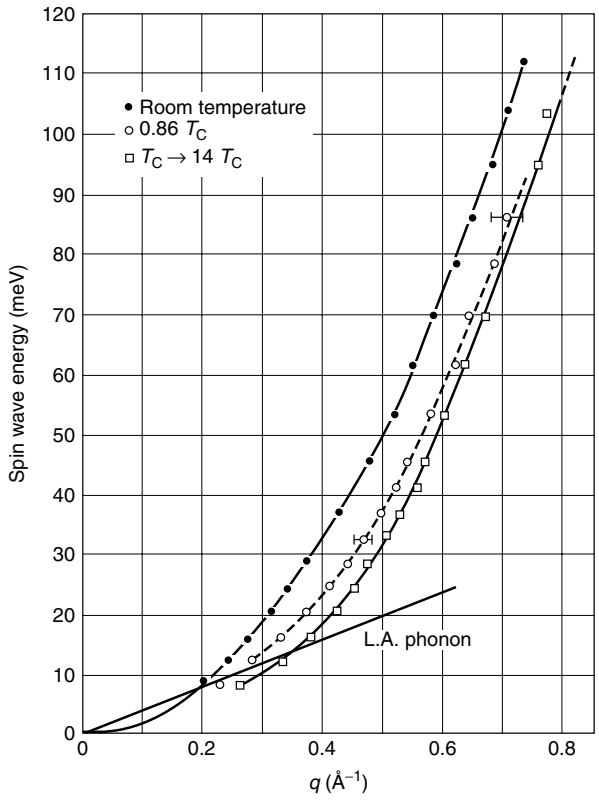

Figure 8. Dispersion of spin waves in Fe with 12 at% of Si at several temperatures, measured by J. W. Lynn using unpolarized inelastic neutron scattering (Lynn, 1975, 1984). With increasing temperature, spin-wave energy somewhat softens, but, outside a small hydrodynamic region, spin-waves neither disappear nor their dispersion renormalizes to zero as $T \rightarrow T_C$, indicating existence of localized spins. (Reprinted figure from permission from J.W. Wynn *et al*., 1975 with permission from the American Physical Society. © 1975.)

function-like peaks at spin-wave energies (Izyumov and Ozerov, 1970; Zaliznyak and Lee, 2005; see also **X-ray and Neutron Scattering by Magnetic Materials, Volume 1**). Quadratic spin-wave dispersion measured by J. W. Lynn in ferromagnetic iron is shown in Figure 8. Spin waves persisting at elevated temperatures, up to and above the Curie temperature, indicate existence of localized spins. Quadratic in q dispersion is, in fact, a very general consequence of the existence of net ferromagnetic moment in the spin system, and therefore it is also observed in ferrimagnets (Alperin, Steinsvoll, Nathans and Shirane 1951).

In antiferromagnets and helimagnets (spin spirals) spin-wave dispersion of Goldstone modes is linear. For an antiferromagnet on a Bravais cubic lattice, cuts of the dispersion surface by planes perpendicular to [001] direction intercept only one Goldstone mode at a time, Figure 6(c,d). The situation is different in ferro-antiferromagnet, which is made of ferromagnetic sheets in $b-c$ plane coupled antiferromagnetically along a, Figure 7(a,b). The antiferromagnetic, sine-like dispersion is pronounced along a axis, while ferromagnetic dispersion in $b-c$ plane is only modified to produce linear spectrum of a Goldstone mode in the vicinity of the ordering wave vector, $\mathbf{Q} = (1/2, 0, 0)$.

A sine-like dispersion of spin waves in the prototypical antiferromagnet NiO measured by Hutchings and Samuelsen (1972) is shown in Figure 9. Data in the figure is indexed in the reduced Brillouin zone of magnetic superlattice, which contains a number of modes whose dispersions coincide.

Spin-wave dispersion in a 2D antiferromagnet on square lattice is shown in Figure 7(c). Such system attracted considerable attention after antiferromagnetism was discovered in the undoped parent materials of high-temperature superconducting cuprates, La_2CuO_4 (Vaknin *et al*., 1987) and $Y_2BaCu_3O_{6+x}$, (Tranquada *et al*., 1988) where weakly coupled layers of Cu^{2+} ions form square lattice in the basal $a-b$ plane of the tetragonal crystal structure. Exchange coupling through 180° Cu–O–Cu bond is extremely strong, reaching ∼0.23 meV in chain cuprates (Zaliznyak *et al*., 2004). Hence, spin excitations are the most energetic eigenmodes and are crucial to understanding properties of cuprate materials. Recent advent of high-power pulsed spallation neutron sources utilizing time-of-flight spectroscopy enabled direct experimental observation of such excitations. Spectacular data on spin excitations in La_2CuO_4 reported in Coldea *et al*. (2001) was successfully described by spin waves, using effective localized spin Hamiltonian with superexchange and additional cyclic exchange induced by electron itinerancy. Similar measurements of high-energy excitations in superconducting $Y_2BaCu_3O_{6+x}$ reported in Stock *et al*. (2005) can also be reasonably well interpreted within the spin-wave framework. These finding are quite surprising in view of the quantum nature of Cu^{2+} spins ($S = 1/2$) and the low-dimensional (2D) character of these systems, undermining the mean-field approach.

Spin-wave dispersion in a 2D antiferromagnet on triangular lattice is shown in Figure 7(d). In addition to $\mathbf{q} = 0$ and $\mathbf{q} = \mathbf{Q} = (1/3, 1/3)$, there is also a Goldstone mode at $\boldsymbol{\tau} - \mathbf{Q} = (2/3, 2/3) = 2\mathbf{Q}$, $\boldsymbol{\tau} = (1, 1)$ is a reciprocal lattice vector. This coincidence (up to $\boldsymbol{\tau}$) between $\mathbf{Q}$ and $2\mathbf{Q}$ makes purely 2D triangular lattice a singular case. For one, harmonic expansion reduces to a single relation and cannot be used to describe bunching of triangular spin structure in magnetic field. Second, spin-wave calculations up to a second order in $1/S$ reveal dramatic modification of spin-wave spectrum (Starykh, Chubukov and Abanov, 2006). These complications are absent in quasi-1D hexagonal ABX_3 antiferromagnets with nearly triangular 120° spin structures, (Eibshutz, Sherwood, Hsu and Cox, 1972; Inami *et al*., 1995; Yelon and Cox, 1972, 1973) where leading interaction is the in-chain exchange perpendicular to triangular lattice and the

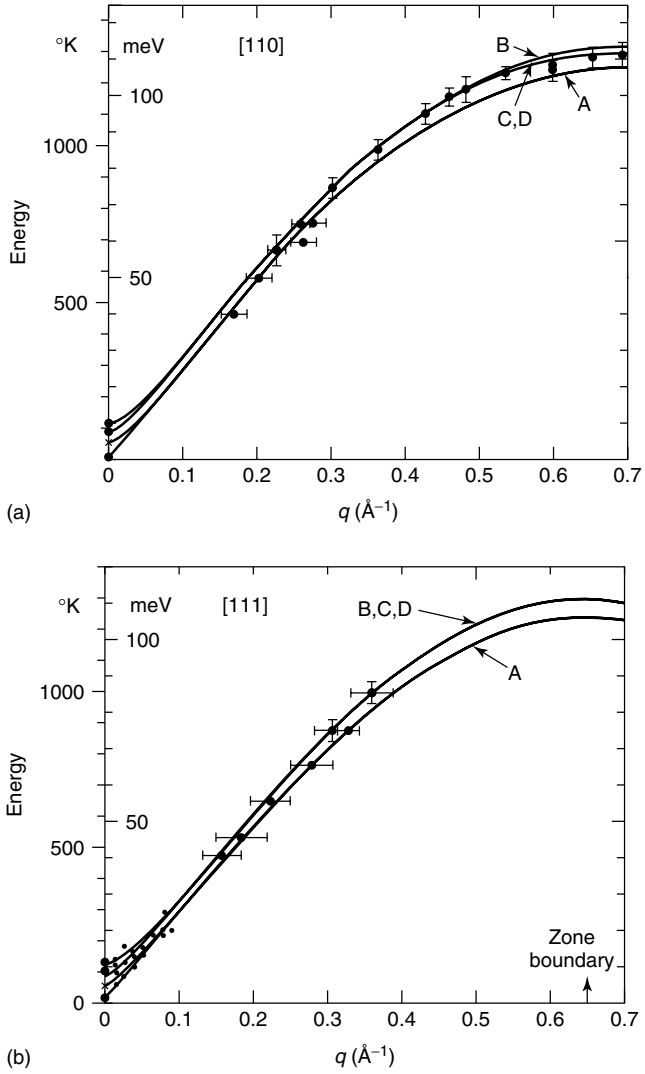

Figure 9. Dispersion of spin waves in antiferromagnetic NiO at $T = 78$ K, (a) along (110) and (b) along (111) reciprocal lattice directions, measured by Hutchings and Samuelsen (1972). Wave vector is indexed in small Brillouin zone of magnetic superlattice with 4 × times enlarged unit cell, such that magnetic ordering wave vector is $Q = (1, 1, 1)$. Different curves marked A, B, C, and D show spin-wave calculation for different magnetic domains corresponding to four possible symmetrically equivalent directions of Q in the cubic lattice. (Reprinted figure from M.T. Hutchings *et al*., 1972 with permission from the American Physical Society. © 1972.)

ordering wave vector is essentially 3D, $\mathbf{Q} = (1/3, 1/3, 1) \neq 2\mathbf{Q} = (2/3, 2/3, 0)$. Numerous neutron scattering studies of spin excitations in these materials indicate that for spin $S > 1$ they are reasonably well described by linear spin-wave theory. Some experimental examples presented in Inami *et al*. (1995) are reproduced in Figure 10. Resemblance of the data with dispersion of equation (19) shown in Figure 7(d) is clearly identifiable.

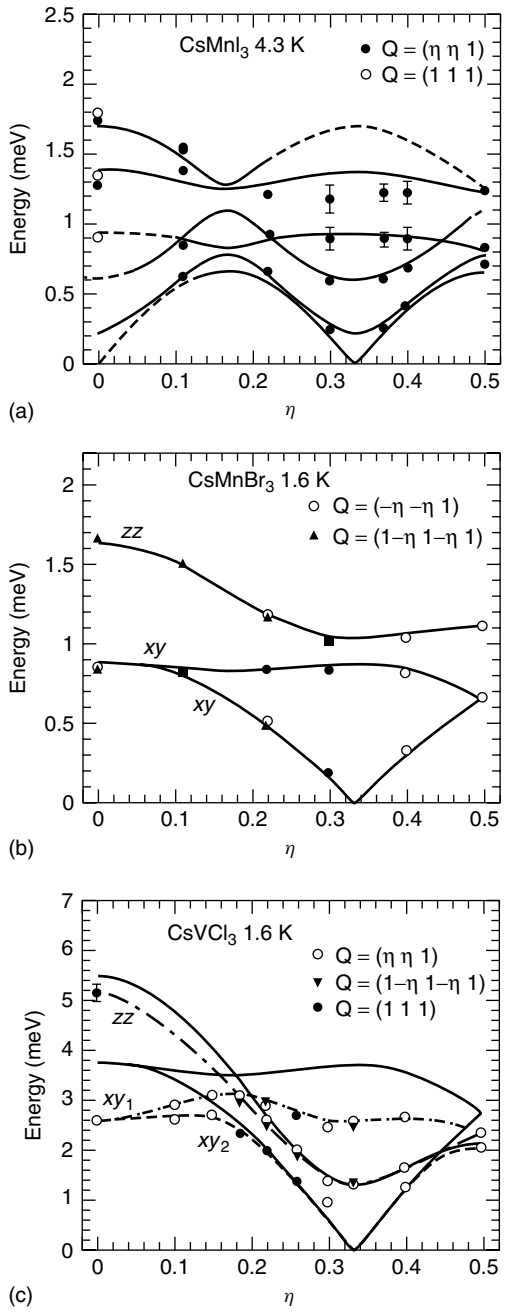

Figure 10. Spin-wave dispersion in the a–b basal plane in several hexagonal quasi-1D antiferromagnets with 120° triangular spin structure measured by Inami *et al*. (1995). (Reprinted figure from A. Zheludev *et al*., 1999, with permission from the American Physical Society. © 1999.)

Perhaps, the most spectacular success of applying spin-wave description to excitations in a spin system is presented in Figure 11. It reproduces spin-wave spectrum in Dzyaloshinskii–Moriya spiral magnet $Ba_2CuGe_2O_7$, whose structure is shown in Figure 4 and was discussed above, measured by Zheludev *et al*. (1998, 1999). Antisymmetric

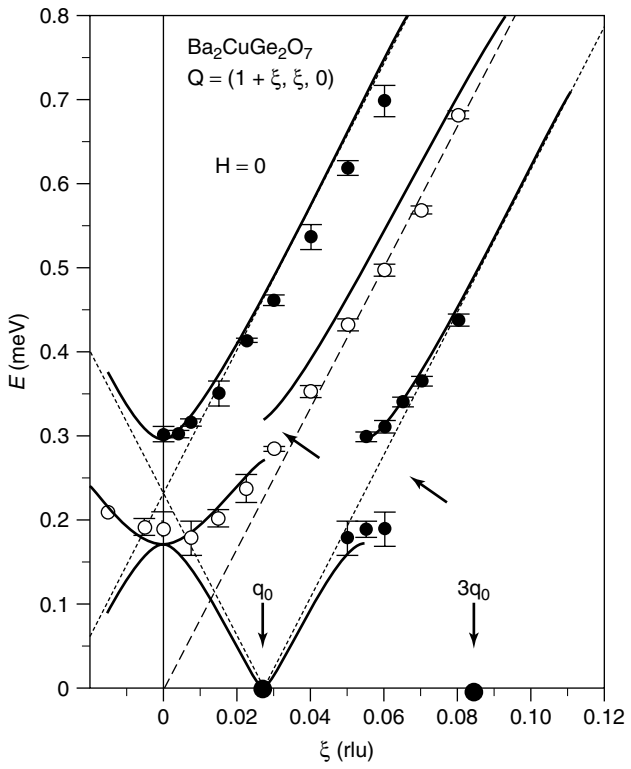

Figure 11. Dispersion of spin waves in Dzyaloshinskii–Moriya spiral spin structure found in $Ba_2CuGe_2O_7$ in zero magnetic field, measured at $T = 0.35\,\mathrm{K}$ by Zheludev *et al*. (1998, 1999). The filled circles on the abscissa axis show positions of the observed magnetic Bragg peaks at Q and 3Q. The solid curves are parameter-free theoretical curves resulting from spin-wave theory calculation. (Reprinted figure with permission from A. Zheludev *et al*., *Phys. Rev. B* Vol 59, 11432. © 1999 by the American Physical Society.)

DM exchange in this material is accompanied by a two-ion anisotropy, and the resulting spin GS is an incommensurate bunched spiral, with clearly observable magnetic Bragg peaks corresponding to third harmonics, $3\mathbf{Q}$, of the ordering wave vector $\mathbf{Q}$. Distortion of spin spiral results in appearance of discontinuities in the spin-wave dispersion at wave vectors $n\mathbf{Q}$, which are clearly observed in experiment.

6 SUMMARY

Although magnetism is rooted in the quantum-mechanical nature of electron's spin, spin structures and excitations in a great variety of magnetic materials can be successfully understood and often accurately described on the basis of semiclassical treatment of a localized spin Hamiltonian. Dispersion of spin excitations predicted by spin-wave theory agrees surprisingly well with neutron scattering experiment even for ordered spin systems with $S = 1/2$, where $1/S$ expansion is clearly not a good approximation. The fundamental reason for this is perhaps simply the fact that while the mapping of spin operators to bosons employed in different flavors of spin-wave theory might not be entirely correct, the fundamental nature of spin excitations as coupled oscillators on a lattice is captured correctly. The resulting equations of motion and corresponding boson Hamiltonian are therefore also correct. However, they may involve effective interaction parameters which can differ significantly from those in the original spin Hamiltonian and which are prescribed by the spin-wave approximation. Therefore, while reasons for the success of semiclassical spin-wave description might be superficial, similar to the Weiss theory of ferromagnetism, it provides a very useful parameterization for describing spin structures and excitations in magnetic materials, for example, in the form of equation (18).

Domain States Determined by Neutron Refraction and Scattering

Axel Hoffmann and Gian P. Felcher
Argonne National Laboratory, Argonne, IL, USA

1 INTRODUCTION

One of the most significant contributions to the understanding of condensed matter made by neutron scattering has been the determination of the magnetic structure of materials. Neutron interaction with matter consists of a 'nuclear' term, resulting from the interaction between the neutron and the each of the nuclei of the atoms, and a magnetic term, due to the interaction between neutron magnetic moment or spin and the magnetic moments in the solids. For a magnetic material like iron, the two interactions have comparable size. The interaction length is also very small, being comparable to the radius of the nucleus, which is smaller by a factor of 10^{-4} than the size of the atom. This means that neutrons may penetrate deeply in matter, sampling a large, and statistically significant volume or area of the material. On the other hand most of the information obtained, in the form of a diffraction or scattering pattern, may require a substantial amount of material because the weakness of interaction is compounded with the limited neutron fluxes emitted from present day sources.

Typical neutron wavelengths are of the order of a few angstroms, comparable to the distance between atoms in a crystalline structure. This explains why neutron diffraction has been a primary tool to determine magnetic structures of single crystals or even polycrystalline samples. Consider for simplicity a ferromagnetic single crystal in which only one magnetic domain is present. In this case, the magnetic structure is identical to the crystalline structure; the intensity of each diffraction peak is composed of a term due to the neutron–nucleus interaction and a magnetic term of the crystalline unit cell. The magnetic intensities diffracted in a given Bragg reflection depend on the angle between the direction of the magnetization and the direction of the momentum transfer of that Bragg reflection. From the diffracted intensities, the collective direction of the magnetic moments aligned in the domain can be obtained. Further information can be obtained if, in addition, the spin of the neutron is known both before and after scattering. For instance, if the polarization axis of the incident neutron beam is parallel to the magnetization, the scattered neutron has the original spin state; but if the two axes are perpendicular, the scattered neutron can have a reversed spin state.

In the case of an antiferromagnetic structure the net magnetization is zero, but still magnetic Bragg reflections are observable, since the crystal may be thought of as being divided in magnetic sublattices, each with its own orientation. For an antiferromagnet, diffraction lines of solely magnetic origin may appear, giving a detailed account of the antiferromagnetic structure. These diffraction lines correspond to lattice planes that in fact have a net magnetization. Even

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

for antiferromagnets, selection rules for intensity and polarization permit, with few exceptions, the determination of the direction of the moments in each sublattice (Bacon, 1975; see also **X-ray and Neutron Scattering by Magnetic Materials, Volume 1**).

Domains are quite common in various physical or chemical systems. They are generally stabilized by competing interactions on different length scales, which in the magnetic case are generally exchange (short-range) and magnetostatic (long-range) interactions (Seul and Andelman, 1995). Within this review we will focus our discussion on magnetic domains, that is, magnetically ordered regions with different orientations of the magnetization. We would also like to note that the techniques discussed in this chapter are also useful to investigate different domain structures, such as the ones occurring due to phase separation in complex oxides, where regions with different magnetic order (i.e., ferromagnetic metallic and antiferromagnetic insulating) coexist. An in depth discussion of these types of domains is beyond the scope of this chapter and the interested reader is referred to a recent review by Dagotto, Hotta and Moreo (2001).

Figure 1 shows how a ferromagnetic material may break down into domains, when the material is in a magnetic field that is weaker than the saturating field. Each domain is characterized by a different orientation of the magnetization. When no magnetic field is applied, in each domain the magnetization is aligned along one of the directions of easy magnetization allowed by the symmetry of the crystal (Birss, 1964). From the *intensities* of the Bragg reflections it is then possible to reconstruct *statistics of the domains*, that is, the fraction of the volume of the sample occupied by domains with each allowed magnetization direction. This is one of the earliest information provided by neutron scattering (Bacon, 1975). Another information that can be obtained from the *width of the Bragg reflections* is the average *size of the domains*. This is because the width of a magnetic Bragg reflection is inversely proportional to the domain size. To be practically detectable in conventional diffraction, the domain size should not exceed 100 nm. Besides the simple relationships between domains and scattered neutrons, one can ask the question if it is possible to obtain further information about domains from neutron scattering experiments? Since in conventional diffraction neutrons determine the pair correlation of atomic moments as a function of their distance, it is natural to ask if they could also be used to measure the pair correlation of the magnetization in adjacent magnetic domains. Unfortunately in general this type of information is difficult to obtain; and some of the reasons will be outlined here. However, such difficulties can be more easily surmounted for samples consisting of very well ordered magnetic nanostructures, or with systems of reduced dimensionality. We note that investigations of nanomagnetic systems with X rays and neutrons have been recently reviewed by Kortright *et al*. (1999) and Fitzsimmons *et al*. (2004), respectively.

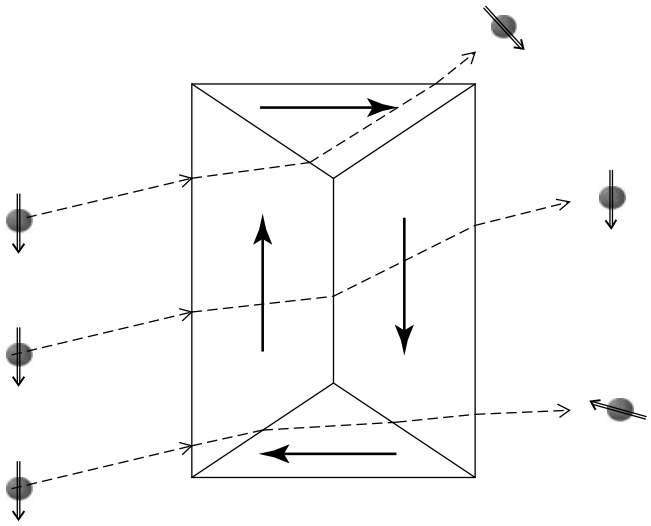

Figure 1. Simple example of a flux-closure domain pattern ('Landau pattern'). Depicted are three different neutron trajectories illustrating the effects of polarized neutron refraction and precession.

1.1 Refraction and scattering

So far we discussed that neutrons can give information about domains via scattering. As we will see in detail later, neutron refraction can also play an important role in the investigation of magnetic domains. Early on it was discovered that a well-collimated beam of thermal neutrons diverges when it is passed through finely divided material. This is attributed to scattering and refraction occurring at each individual particle (Weiss, 1951). Until now we have only considered scattering. In the forward direction, scattering does not depend on the detailed crystalline nature of the material, but only on the size of the grains. The grains scatter the neutrons in a cone with an angular width of $\sim\lambda/d$, where d is the particle's size. The difference between refraction and scattering depends on the difference between the phase change in traversing the particle diameter and the phase change in traversing the same path length in vacuum. A neutron that passes through a slab of material is not scattered by it, but its wavelength inside it is changed by a small amount, which is proportional to the refractive index. If along the flight path the difference in phase is appreciably less than one wavelength, the scattering theory has to be applied, otherwise we apply the refraction theory. For instance in a diamond slab neutrons of 4 Å wavelength experience a lag of one period, with respect to vacuum, after 9 μm. Thus the question as to how the neutron is modified after crossing a slab of material arises. In order

to measure the difference of phase change in the flight path within the medium versus that in vacuum, an interferometric measurement is required. The primary beam needs to be split in two components, the first traveling in vacuum and the second in the medium. Then the phase shift of the neutron in the medium appears as a shift of the interference pattern after the two beams are recombined (Werner and Klein, 1987).

The trajectory of a neutron through an assembly of ferromagnetic domains can be described in a similar way. However, it is much easier to verify magnetic – rather than material – refraction effects. Let us assume that the neutron beam is initially polarized in a certain direction (Figure 1). Within each magnetic domain in which the magnetic induction $\vec{B}$ is not parallel to the initial polarization, the neutron spin precesses around $\vec{B}$. Upon exiting the domain, the spin of the outgoing neutron is rotated by a phase defined by the size of $\vec{B}$ and by the time spent in the domain. This phase shift is equal to the phase shift described above for the neutron passing through a material particle. However, in the magnetic case there is no need for interferometry or a reference beam, because the polarization of the incoming beam is defined by a neutron polarizer and the polarization of the outgoing beam is sorted out by a neutron polarization analyzer.

Are refraction effects important in assessing sizes and orientations of domains? A full rotation of the neutron spin takes place, for an ordinary ferromagnetic material, over a length of a few micrometers. Domains of that size scatter neutrons of wavelength of a few angstroms at angles too small for an easy identification of the scattered neutrons, versus those that are simply transmitted through the sample. Separation between the scattered and transmitted components becomes appreciable for domains below 100 nm: here, refractive effects may be considered in the first instance as unimportant, and the intensity of the neutrons that have interacted with the sample may be treated on the basis of the scattering processes. Conversely, for micrometer-size domains, scattering processes have been neglected and information on the domains has been obtained on the basis of the polarization of the neutrons exiting the sample. The need of reconciling these two points of view has arisen recently in the study of domains in nanostructured materials.

This chapter is organized as follows. In Section 2 we discuss in detail different neutron scattering techniques, such as diffraction, depolarization, and grazing incidence reflectivity, from which information about domain structures can be obtained. Following this we will present in Section 3 several science issues involving magnetic domains, which are suitable to neutron investigations. First we discuss basic domain structures in homogeneous materials, and then we show how modified magnetic domain behavior can come about through confinement or coupling between dissimilar materials. Finally, Section 4 gives a brief summary of this chapter.

2 TECHNIQUES

2.1 Diffraction

In classic magnetostatics the Zeeman interaction energy between a magnetic moment $\vec{\mu}$ and a magnetic field $\vec{B}$ is fully described by the Hamiltonian:

$$E = \vec{\mu} \cdot \vec{B} \tag{1}$$

Starting from this term allows determining both the rotation and translation forces, which the field exerts on the magnetic moment. Thus the torque, $-(\partial E/\partial \zeta)$, where ζ is the angle between $\vec{\mu}$ and $\vec{B}$, leads to the well-known Larmor precession of the magnetic moment around $\vec{B}$ in the limit of constant $\vec{B}$. This relation remains valid for the interaction of the magnetic moment of the neutron inside a magnetic material, provided that the neutron is treated as a quantum particle, $\mu_N \hat{\sigma}$, where μ_N is the neutron magnetic moment and $\hat{\sigma}$ are the Pauli's matrices. Thus in principle this equation can be used directly to study magnetic materials; the neutrons probe the distribution of $\vec{B}$ inside the sample and one could subsequently find appropriate models to reproduce the observed $\vec{B}$ configuration. However, since it is most customary to describe magnetism in terms of atomic magnetic moments, it is preferable to express $\vec{B}(\vec{r})$ by the distribution of the magnetic moment density $\vec{M}(\vec{r})$. The Fourier transformation of the magnetostatic expression reduces to:

$$\vec{B}(\vec{q}) = 4\pi \vec{M}_{\perp}(\vec{q}) \tag{2}$$

where $\vec{M}_{\perp}$ is the component of the magnetic moment density perpendicular to the neutron momentum transfer $\hbar\vec{q}$ of the neutrons, where the absolute value of the scattered wave vector $\vec{q}$ is given by

$$|\vec{q}| = \frac{4\pi \sin\theta}{\lambda} \tag{3}$$

Here θ is the half of the scattering angle and λ the neutron wavelength. The vectors $\vec{q}$ considered here are only those corresponding to a Bragg reflection of the crystalline and magnetic crystal. The term *magnetic crystal* is used for any magnetically ordered crystal. In ferromagnetic crystals the magnetic moments of all equivalent magnetic atoms in the crystalline cell are equal and point in the same direction. These restrictions do not apply for the much wider choice of ferri- or antiferromagnetic configurations (Opechowski and Guccione, 1965). From a crystallographic point of view, a ferromagnetic crystal is distinct from an antiferromagnetic one because only the former allows the (000) reflection, or the scattering in the forward direction. In all cases, the orientation of the magnetic moments (in absence of an external

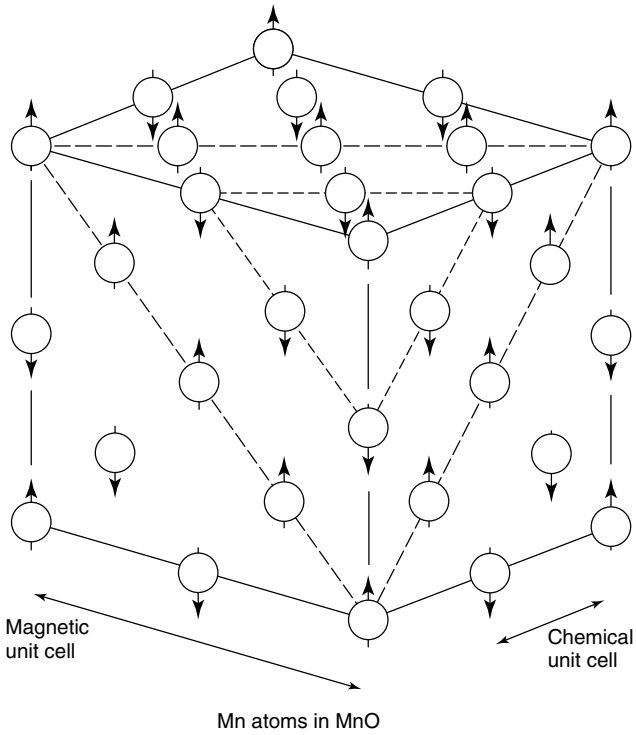

Figure 2. Antiferromagnetic structure of MnO. (Reprinted figure from *Phys. Rev.* Vol. 83, 333 (1951), © 1951 by the American Physical Society.)

magnetic field, which would distort the symmetry) is quite restricted, because certain symmetry operations do not have the result of turning a spin onto itself. In addition, the symmetry of the magnetic crystal is often lower than that of the crystal structure on which it resides; however, the magnetoelastic forces are often too weak to create a detectable distortion of the crystalline lattice. As a result of these effects, in the same single crystal, more than one magnetic domain is possible. By examining the Bragg reflections it is possible to establish what is the population of different domains. A typical example is indicated in Figure 2, illustrating the magnetic structure of the face-centered-cubic oxides of transition elements (Shull, Strauser and Wollan, 1951). The magnetic cell, represented here as a cube with twice the size of the crystalline cell, is distinguished by a propagation axis along the [111] direction. Since the cubic crystal has four equivalent [111] directions, four types of domains are possible (T domains). In addition, we have to consider the direction of the magnetic moments, that in Figure 2 are represented as collinear and parallel to the [001] axis. For each of the [111] propagation axis, we can choose three [001] equivalent directions (S domains). In total, a single crystal of MnO can split into $4 \times 3 = 12$ magnetic domains. The study of antiferromagnetic domain structures and symmetries remained largely of academic interest until the 1980s, when their importance

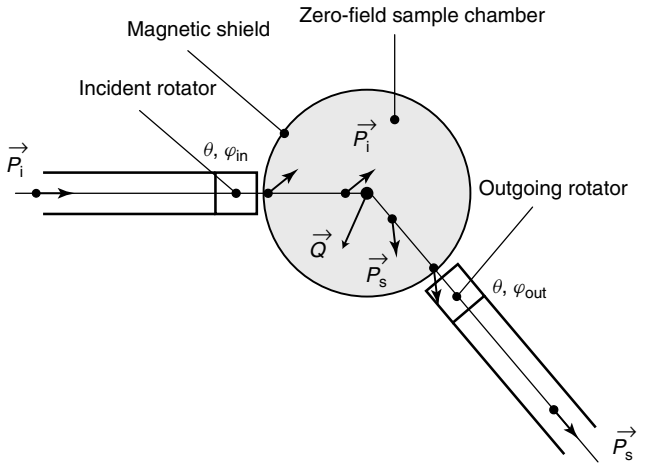

Figure 3. Simple schematic of a neutron scattering experiment with full polarization analysis. Schematic based on the description in Brown, Forsyth and Tasset (1993). (Reproduced from Brown *et al*., 1993, with permission from The Royal Society, London. © 1993.)

in affecting the magnetism of adjacent ferromagnets was recognized (Mauri, Siegmann, Bagus and Kay, 1987).

The most complete diffraction equipment hitherto constructed to study the domain population in zero applied field includes a device, named *Cryopad*, and hitherto has been limited to antiferromagnets (Brown, Forsyth and Tasset, 1993). This device is set in a conventional diffractometer such as schematically represented in Figure 3, and allows spherical polarimetry to be carried out in a neutron scattering experiment. The incoming monochromatic neutron beam is polarized axially, in the direction parallel to its propagation direction. At the entrance of the Cryopad region, the orientation of the neutron spin is turned in a direction characterized by the angular coordinates θ, φ_{in}. After this is accomplished, the neutron enters a region of zero magnetic field. In this region, the orientation of the neutron spin remains unaltered, except during the process of being diffracted by the sample. The sample, at the center of the gray area of Figure 3, consists of a single crystal oriented to reflect neutrons with a certain momentum transfer $\vec{q}$. Along the flight path of the diffracted neutrons, at the exit of the zero-field chamber, magnetic circuits can be tuned to bring the polarization of the diffracted beam in the direction of its propagation: the tuning is tested by a polarization analyzer. This technique has been called *spherical polarimetry* because the polarization axis of the incident and diffracted beams are uniquely and separately determined. In contrast, in conventional uniaxial polarimetry (Moon, Riste and Koehler, 1969) the polarization of the incident and the diffracted radiation are analyzed with respect to a fixed and common axis. The technique is being now used extensively to determine the magnetic structure of complex antiferromagnets (see, for instance,

Zaharko *et al*., 2003) because antiferromagnets are systems for which it is difficult to alter the domain population.

The equations that relate the scattered polarization to the incident polarization and to the physics of the scattering process have been developed by Blume (1963). The polarization P_s of the neutrons scattered by a Bragg reflection with scattering vector $\vec{k}$ from an ordered magnetic structure may be written in terms of the magnetic interaction vector $\vec{M}_\perp$ as:

$$\begin{aligned}\vec{P}_s I = {} & \vec{P}_i N N^* + \vec{M}_\perp N^* + \vec{M}_\perp^* N + I[\vec{P}_i \times \vec{M}_\perp^* N \\ & - \vec{P}_i \times \vec{M}_\perp N^*] + \vec{M}_\perp[\vec{P}_i \cdot \vec{M}_\perp^*] + \vec{M}_\perp^*[\vec{P}_i \cdot \vec{M}_\perp] \\ & - \vec{P}_i[\vec{M}_\perp \cdot \vec{M}_\perp^*] + i[\vec{M}_\perp \times \vec{M}_\perp^*] \end{aligned} \quad (4)$$

In equation (4), I is proportional to the scattered intensity

$$\begin{aligned} I = {} & N N^* + N \vec{P}_i \cdot \vec{M}_\perp^* + N^* \vec{P}_i \cdot \vec{M}_\perp \\ & + \vec{M}_\perp \cdot \vec{M}_\perp^* + \vec{P}_i \cdot \vec{M}_\perp \times \vec{M}_\perp^* \end{aligned} \quad (5)$$

P_i is the incident polarization, N is the nuclear structure factor, and $\vec{M}_\perp$ the magnetic structure factor of the crystalline cell. Equations (4) and (5) may seem quite complicated. However, each term identifies separate and well-defined features of the magnetic structure. For instance, the last terms in equations (4) and (5) are present only if the magnetic structure is noncollinear. For collinear structures, equations (4) and (5) greatly simplify when $\vec{P} || \vec{M}_\perp$. The last terms become important for spiral structures, because they define the direction of propagation of the spiral and its chirality.

Real depolarization of the scattered beam is an indication that a mixed state consisting of more than one magnetic domain is present (see Section 2.2). The ability to distinguish such depolarization from rotation of the polarization away from the unique axis of the conventional technique is one of the features that make zero-field polarimetry very powerful. The different types of antiferromagnetic domains that can occur in antiferromagnetic structures may be classified into configuration domains, 180° and chirality domains, and orientation domains. The type and number of domains that occur depend on the relative symmetries of the paramagnetic and the ordered magnetic phases. In general, if the order of the paramagnetic space group is p and that of the magnetic group is m, the number of different domains is p/m. In a multidomain sample, the quantity $P_s I$ is given by the vector sum of the contributions from the individual domains weighted by their domain fractions. In general, it is easy to distinguish the domain population in the case of 180° and chiral domains. For more complex structures the intensities usually suffice to give the indication of the domain population, if the structures are collinear. A similar approach to diffraction may be possible using resonant X-ray scattering. In general, X-ray magnetic scattering is relatively weak in comparison to charge scattering, becoming sizable only in the proximity of electronic resonances. As a matter of fact, by tuning the wavelength of the X rays it is possible to use element specific resonant scattering, which enables one to obtain magnetic information related to a specific element. For more information about resonant X-ray techniques the reader is referred to **Synchrotron Radiation Techniques Based on X-ray Magnetic Circular Dichroism, Volume 3**.

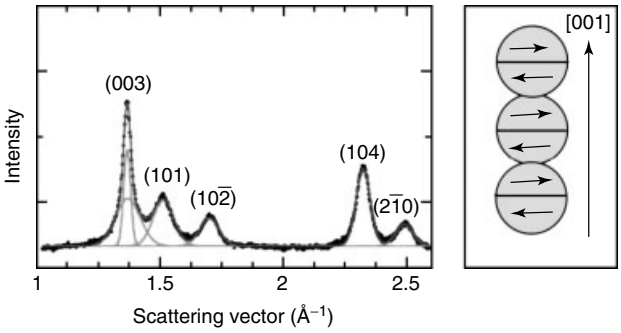

Figure 4. Diffraction of antiferromagnetic α-Fe_2O_3 particles. The (003) and (101) are purely magnetic; the relative sharpness of (003) indicates the presence of magnetic correlations along the [001] direction. (Reprinted figure from *Phys. Rev. B.* Vol. 72, 214406 (2003). © 2003 by the American Physical Society.)

Information on the size of domains can be obtained from the width of the diffraction lines. A representative example of an experiment in this direction is presented in Figure 4, which represents the diffraction pattern from an assembly of α-Fe_2O_3 nanoparticles of 10 nm diameter (Frandsen *et al*., 2005). Each particle is antiferromagnetic and the spins are confined to lie in the low-anisotropy (001) plane. The selective broadening of the (003) and (101) reflections indicates an exchange coupling between particles in the [001] direction. This preferential coupling occurs for assemblies freshly prepared by a solgel method; it disappears by regrinding the sample.

For an assembly of ferromagnetic domains a special 'diffraction' line is broadened, the (000) reflection; that is to say that small-angle scattering takes place around the transmitted beam. Small-angle scattering from domains is easy to detect: Figure 5 shows its earliest observation (Hughes, Burgy, Heller and Wallace, 1949). The beam transmitted through a block of saturated iron has the same shape as the beam without sample. When no magnetic field is applied to iron, the transmitted beam appears much broader. It is tempting to derive, from the increase of the width, the average domain size. Actually, the interpretation of the small-angle scattering is conceptually simpler than the analysis of the broadening of Bragg reflections at finite $\vec{q}$, because it does not depend on the detailed crystalline structure of the sample, that is, as in the case of strain broadening of the Bragg reflection. However, there are

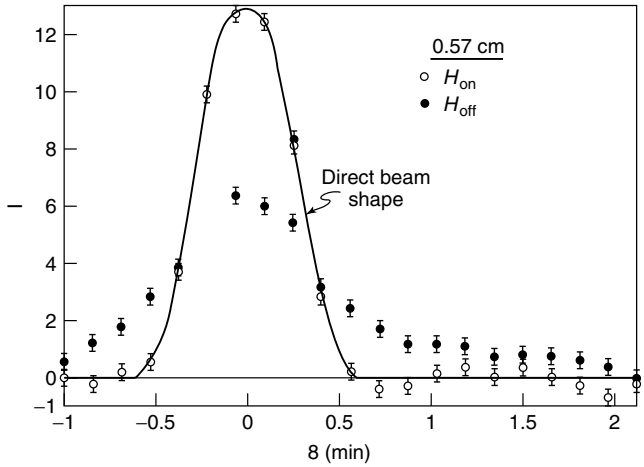

Figure 5. Small-angle scattering of thermal neutrons (wavelength 2.2 ± 0.5 Å) from a block of unmagnetized iron. (Reprinted figure from *Phys. Rev.* Vol. 75, 565 (1949) © 1949 by the American Physical Society.)

genuine difficulties. In its simplest treatment, scattering is assumed to be a minor perturbation of the incident beam; in other words, most of the beam is transmitted through the sample as if no interaction had taken place. This condition is definitely not fulfilled here, since in the scattering pattern of unmagnetized iron no features are recognizable as belonging to the transmitted beam. Multiple scattering then must have taken place, and the broadening is much larger than that due for the single scattering event. Correspondingly, the domain size uncritically inferred from patterns like that presented in Figure 5 is much smaller than the real one. Of course Figure 5 presents the first qualitative observation of magnetic domains; later experiments performed under more exacting conditions were able to provide quantitative information (see, for instance, Löffler, Braun and Wagner, 2000). An inherent difficulty in small-angle scattering is the unambiguous separation of the transmitted from the scattered radiation; a task that becomes progressively more difficult the larger the diameters of the domains are. For domains larger than 100-nm small-angle scattering becomes too hard to detect and alternative techniques have been proposed.

2.2 Neutron beam depolarization

Three-dimensional neutron depolarization is a technique for determining magnetic domain structures in the bulk of magnetic materials for which the typical domain size is in the micrometer range. An experiment consists in determining the change in the polarization of a neutron beam after transmission through a specimen. The polarization change of the neutron beam is related to the micromagnetic state of the medium. The mean magnetic induction results

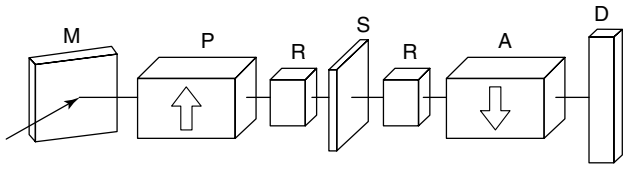

Figure 6. A schematic description of the three-dimensional neutron depolarization system as described by Rekveldt (1973) viewing a continuous wave neutron source. The instrument consists of a monochromator M, a polarizer P, polarization rotators R, a sample S, a polarization analyzer A, and a detector D.

in a net precession of the polarization vector around the mean magnetic induction, while variations in the local magnetic induction result in an effective shortening of the polarization vector, which is called *depolarization*. The neutron depolarization technique in general yields the mean magnetic induction $\vec{B}$, its mean local fluctuation $\Delta\vec{B}$, and the size of the domain (along the neutron's path) over which this fluctuation takes place. This technique has been used to study a variety of topics such as magnetic particulate media and magnetic recording materials (Rekveldt, 1973; Rosman and Rekveldt, 1991; Mitsuda and Endoh, 1985).

A schematic view of a three-dimensional depolarization equipment is given in Figure 6. Most of the instruments have been placed at reactors. A monochromatic beam, of a few angstrom long wavelength, is polarized passing through a polarization cavity. Polarization rotators are placed before and after the sample chamber in order to polarize and analyze the polarization of the beam along three different axes. Each polarization rotator consists of two coils to produce magnetic fields in two directions perpendicular to the transmission direction of the neutron beam. Through the combination of the magnetic fields produced by the coils, the polarization direction can be changed at will. In the sample changer a magnetic field is set on the sample, again in an arbitrary direction. In its handling of the polarization of the neutron, the instrument is quite similar to the Cryopad discussed in Section 2.1. However, here the main difference is that the flight path after the sample is just in transmission geometry. All neutrons have the same flight path at the entrance – before interacting with the sample – as well as at the exit, making polarimetry possible even in the presence of an applied magnetic field.

In a three-dimensional neutron depolarization experiment the polarization vector $\vec{P}$ of a polarized neutron beam is analyzed after transmission through a magnetic sample in all three spatial directions as in spherical polarimetry. The change in $\vec{P}$, caused by Larmor precession of the neutron spin about local magnetic inductions, after passage through a magnetic material can be written in matrix form

$$\vec{P} = \hat{D}\vec{P}_0 \tag{6}$$

In equation (6) $\vec{P}_0$ and $\vec{P}$ are the initial and final polarization vectors respectively, and $\hat{D}$ is the (3×3) depolarization matrix. The elements of $\hat{D}$ are determined experimentally from the measured neutron intensities I_{ij}, where $j = x,\ y,\ z$ represents the direction in which the original beam is polarized and $i = x,\ y,\ z$ represents the spin direction in which the beam is analyzed:

$$D_{ij} = \frac{1 - I_{ij}}{I_s} \tag{7}$$

In equation (7) I_s is the intensity of the fully depolarized beam. The polarization direction transmitted by the analyzer is chosen opposite to that of the polarizer. Therefore, the intensity at the detector is minimal when the polarization direction remains unchanged resulting, under condition of no depolarization, in $D_{ii} = 1$. If the polarization vector rotates π radians, the intensity becomes maximal. The experiment has the beauty and the simplicity of a transport measurement. What remains to be seen is how the matrix $\hat{D}$ can be directly be related to the magnetic structure of the sample in the micrometer range.

In the Larmor approach, the interaction of the polarization vector with a local magnetic induction $\vec{B}$ is described by the equation:

$$\frac{\mathrm{d}\vec{P}(t)}{\mathrm{d}t} = \gamma \left[\vec{P}(t) \times \vec{B}(t)\right] \tag{8}$$

where γ is the gyromagnetic factor of the neutron. The time variable t can be transformed using $t = x/v$ where x is the position variable in the neutron propagation path and v the neutron's velocity. The local magnetic induction can be separated into the mean magnetic induction $\langle\vec{B}\rangle$ and its local fluctuations as experienced by the neutron passing though the material. The mean magnetic induction results in rotation of the polarization vector after transmission through the entire sample. The local fluctuations are responsible for depolarizing the transmitted beam. It is possible to write a correlation function:

$$\alpha_{ij} = \frac{1}{W} \int_W \mathrm{d}^3\vec{r} \int_0^x \mathrm{d}x' \Delta B_i(x, y, z) \Delta B_j(x', y, z) \tag{9}$$

In equation (9), W is a representative subvolume of the medium with size d along the propagation direction of the beam. $\langle d\rangle$, the mean domain size, is supposed to be sufficiently small so that the polarization change in W is small. Within W the magnetization is correlated. In principle, equation (9) also contains terms correlating the magnetization of different domains as seen by the neutron along its path in the x direction. However, a number of assumptions are usually made to permit the evaluation of some physical quantities, such as the mean domain size $\langle d\rangle$. If there is no correlation in the magnetization of different domains, the depolarization matrix element D_{zz} for a magnetic field applied along the z axis becomes:

$$D_{zz} \approx 1 - cL\,\langle d\rangle \left\langle \left(B_s - \overline{B}\right)^2 \right\rangle \lambda^2 \tag{10}$$

In equation (10), c is a constant, λ is the neutron wavelength, L is the total thickness of the sample, and $\langle d\rangle = \sqrt[3]{W}$. This quantity can be derived from the depolarization matrix, if the saturation magnetization and also the magnetization at the field used in the course of the measurements are known. More complex expressions need to be written for systems that are either chemically or magnetically nonhomogeneous.

Neutron depolarization has been used for solving a variety of problems where magnetic domain sizes are of crucial importance. For instance, the compound UGe_2 is both ferromagnetic and superconducting at low temperatures. These two states of matter are considered incompatible with each other. In order to explain the finding, it was suggested that the size of the ferromagnetic domains was less than the coherence length of the superconductor. The latter was estimated to be 20 nm. In a 3D depolarization experiment (Sakarya, van Dijk and Brück, 2005) the average magnetic domain size was found to be of the order of a few micrometers, ruling out that interpretation.

A second example is the investigation of the evolution of the composite structure of iron during the cooling process of carbon steel (Offerman *et al*., 2002). At high temperatures (above 820 °C) the dominant phase is austenite, which has a face-centered-cubic structure and is nonmagnetic. At lower temperatures there is the formation of ferrite, which is body centered and magnetic. This transformation – not only of scientific interest but also of obvious technological importance – has been long studied by neutron depolarization to obtain density and size of the *magnetic* ferrite particles in the course of the cooling process (te Velthuis *et al*., 2001). However, the advent of microbeams at synchrotron light sources permitted a more direct way of observing separately the number and the size of the crystallites. The illuminated volume of material was so small that the diffraction pattern of each crystalline component consisted not of uniform Debye–Sherrer rings but of sequence of spots on the locus of the rings. The number of spots was considered proportional to the density of crystallites in the sample; their intensity proportional to their size. The information that was obtained is presented in Figure 7. The same information in principle could have been obtained by three-dimensional neutron depolarization if the intensity of the source had allowed collimation of the beam to the proper area. Since more powerful neutron sources will be available in the near future, the basic theoretical background

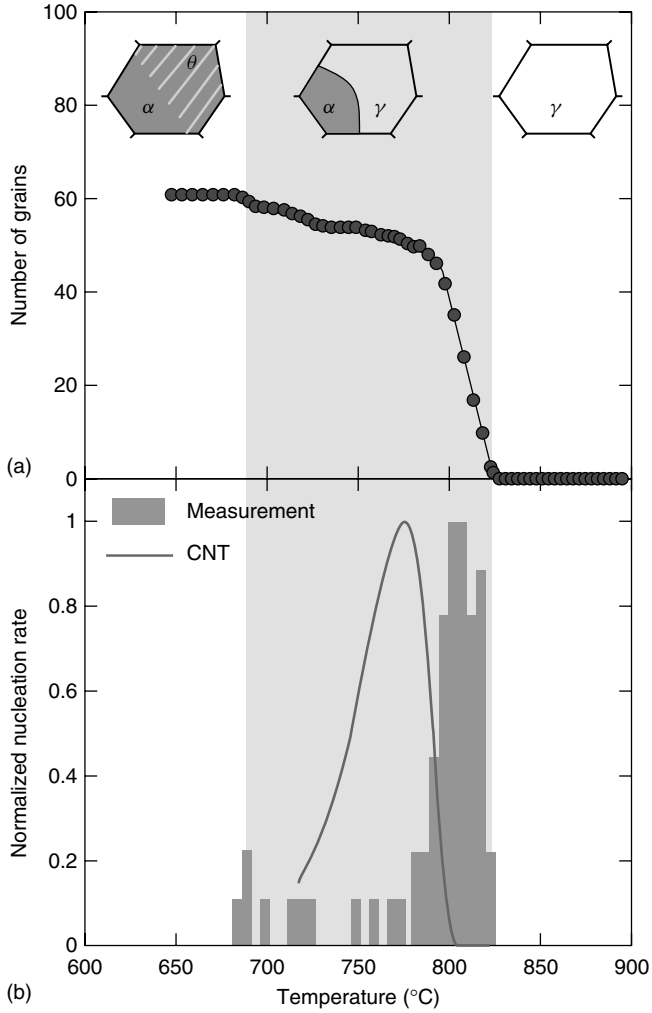

Figure 7. Number of grains of ferrite (α) during cooling of carbon steel. A comparison is made with the classical nucleation theory (CNT). (Reprinted figure with permission from Offerman *et al*., 2002, *Science* **298**:1003–1005. © 2002.)

has been developed in order to evolve neutron depolarization into a tomographic technique (Toperverg, 2002; Badurek, Buchelt, Leeb and Szeywerth, 2003).

2.3 Reflectivity

For the purpose of studying interfaces and surfaces, the neutron-matter interaction and the resulting scattering power may be thought to be in general too weak. This weakness can be overcome by sending the neutron beam at grazing incidence to the surface, in a geometry where the Fresnel reflectivity from the surface cannot be neglected (Werner and Klein, 1987).

In a homogeneous material the neutron–matter interaction may be represented by a smooth pseudopotential whose magnitude is related simply to the scattering density as

$$V^{\pm} = \frac{2\pi h^2}{m} bN + \vec{\mu}\cdot\vec{B} \tag{11}$$

if the neutron spin is aligned parallel (+) or opposite (−) to $\vec{B}$. In equation (11) N is the density of atoms occupying a unit volume, m the neutron mass, and h the reduced Planck constant. In free space ($V = 0$) the component of the incident neutron wave vector normal to the surface is $k_z = 2\pi(\sin\theta_i/\lambda)$ and k_x, k_y are the components in the surface's plane. θ_i is the angle of incidence and λ is the neutron wavelength. In the medium the perpendicular component of the neutron momentum k_{zi} is modified by the optical potential, such that:

$$k_{zi}^{\pm} = \sqrt{k_{z0}^2 - \frac{2m}{h^2}V^{\pm}} \tag{12}$$

Particle and flux conservation at the surface determine the reflectance r and transmittance t. The observable reflectivity R takes the form:

$$R = |r|^2 = \left|\frac{k_{z0} - k_{zi}^{\pm}}{k_{z0} + k_{zi}^{\pm}}\right|^2 \tag{13}$$

For values of $k_{z0}^2 < \left(2m/h^2\right)V^{\pm}$, the neutron wave vector becomes imaginary: the neutron wave decays exponentially in the material and the neutrons are totally reflected. These angles are very small (for 5 Å neutrons the critical angle is less than half a degree). However, at these angles of grazing incidence, surface effects become important. In a neutron reflectivity experiment, the intensity of the neutrons reflected from the surface is measured as a function of the neutron momentum component, which is perpendicular to the surface, $q_z = 2k_{z0}$. Above the critical angle, the reflectivity from a semi-infinite body of homogeneous material decreases as q_z^{-4} (Fresnel reflectivity). Since q_z is a conjugate variable of the depth z from the film surface, a scan over a suitable range of q_z provides excellent information on the chemical and magnetic depth profile $V^{\pm}(z)$ of the film (Lekner, 1987). For instance, if the material is composed of several layers that are periodically repeated, the q^{-4} dependence of the reflectivity is strongly perturbed and maxima occur at the values of $q_{zi} = 2\pi/d$, where d is the repeat distance of the layers. The reflectivity of a periodic multilayer may be easily understood in terms of conventional diffraction: When normalized to the Fresnel reflectivity, the measured reflectivity reduces to a series of peaks whose intensity at large q_z is nearly the square of the scattering length density of the single period. This treatment assumes that the material is chemically and magnetically homogeneous in each plane parallel to the surface.

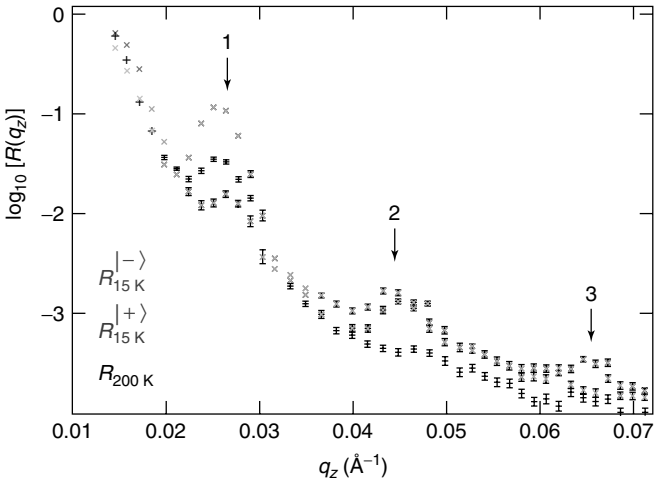

Figure 8. Specular reflectivity of a superlattice composed of a bilayer (LCMO (16 nm)/YBCO (16 nm)) repeated six times: in the paramagnetic region ($T = 200$ K) the indexed diffraction peaks modulating the q^{-4} decay of the reflectivity are well visible. At low temperature, below both $T_C \sim 165$ K and $T_{sc} \sim 75$ K, the reflectivity becomes strongly spin dependent and can be analyzed in terms of a detailed magnetic profile. (Reprinted figure from *Phys. Rev. B.* Vol. 71, 140509® (2005). © 2005 by the American Physical Society.)

For a material with $B \neq 0$, the critical angle is spin dependent; in other words, for neutrons, a ferromagnet is birefringent. Figure 8 presents the reflectivity pattern of a film, composed of the periodic repetition of pairs of layers. At low temperature, one of these is ferromagnetic, the second is a superconductor. In this experiment, the polarization of the incident beam was parallel (R^+) or antiparallel (R^-) to the magnetic field $\vec{H}$ applied to the sample. $\vec{H}$ was in the plane of the sample and was sufficiently high to saturate it. Thus the magnetic induction $\vec{B}$ in the sample was parallel to $\vec{H}$, and no neutron spin flip was expected. This is not generally true in experiments designed to study the magnetization reversal process.

In neutron reflectivity, only uniaxial (and not spherical) polarimetry has been applied. According to this, when the incident neutrons are polarized along an applied magnetic field $\vec{H}$ and the polarization after reflection is analyzed along the same axis, four reflectivities are recorded: R^{++}, R^{+-}, R^{-+}, R^{--}. The first (second) sign refers to the incident (reflected) neutron polarization with respect to $\vec{H}$. For films thinner than the domain-wall thickness, only two-dimensional arrays of domains are possible. In addition, for a majority of magnetic systems shape anisotropy constrains the magnetization to the surface's plane. Specular scattering can give information about the distribution of magnetization directions in lateral domains (Lee *et al.*, 2002). For a single domain, simple and transparent relations link the magnetization to the spin-dependent specular reflectivity. When the direction of magnetization and the applied field are in the film's plane, and $\vec{M}$ is at an angle φ with $\vec{H}$, then:

$$\frac{R^{++}(\varphi) - R^{--}(\varphi)}{R_s^{++}(0^\circ) - R_s^{--}(0^\circ)} = \cos\varphi \tag{14}$$

and:

$$\frac{R^{-+}(\varphi)}{R_s^{-+}(90^\circ)} = \sin^2\varphi \tag{15}$$

provided that the direction of $\vec{M}$ is constant along the thickness of the film. The normalizing quantities, $R_s(0^\circ)$ and $R_s(90^\circ)$, refer to reflectivities measured with $\vec{M}$ saturated and aligned parallel and perpendicular to the neutron polarization, respectively. These relations are valid at all values of q_z above the critical edge for total reflection.

When a film breaks down into lateral domains, the effect on the specular reflectivity depends on the size of the domains. For domains larger than the coherence length the intensities reflected from different domains superimpose incoherently in the specular beam. In this case the terms dependent on φ of equations (14) and (15) can be interpreted as averages across the sample plane. While the term $\langle\cos\varphi\rangle$ may be measured as well by conventional magnetometry, $\langle\sin^2\varphi\rangle$ provides new information leading to the mean square dispersion of the domain orientations $\chi^2 = \langle\cos^2\varphi\rangle - \langle\cos\varphi\rangle^2$. The information on surface magnetic domains as obtained in specular reflectivity is similar to that obtained by observing the magnetic intensities of Bragg reflections from a magnetically ordered solid and consists in providing the statistical distribution of domains. On the other hand, the size of the domains can be determined only if off-specular scattering is detectable.

Any imperfection in the layers parallel to the surface – including domains in the plane of the film – causes some scattering away from the specularly reflected beam, with the geometry illustrated in Figure 9. The scattering may take place in the plane of reflection (defined by the angle of incidence θ_i and reflection θ_f) or else at an angle $\Delta\varphi$ out of the reflection plane. Inhomogeneities in the plane of the film can be represented by a vector $\boldsymbol{\tau}$ with planar projections τ_x and τ_y, where x is chosen in the reflection plane, and y perpendicular to it. When $\boldsymbol{\tau}$ is small in comparison with the incoming wave vector, the laws of conservation of energy and momentum in the plane reduce to:

$$\tau_x = \frac{2\pi}{\lambda}\sin\theta\cdot\Delta\theta; \quad \tau_y = \frac{2\pi}{\lambda}\cdot\Delta\phi \tag{16}$$

where $\Delta\theta$ and $\Delta\phi$ are the observed angles. At grazing incidence fluctuations of $\boldsymbol{\tau}$, which are isotropic in the plane of the film ($\tau_x = \tau_y$), can give scattering at detectable $\Delta\theta$ even

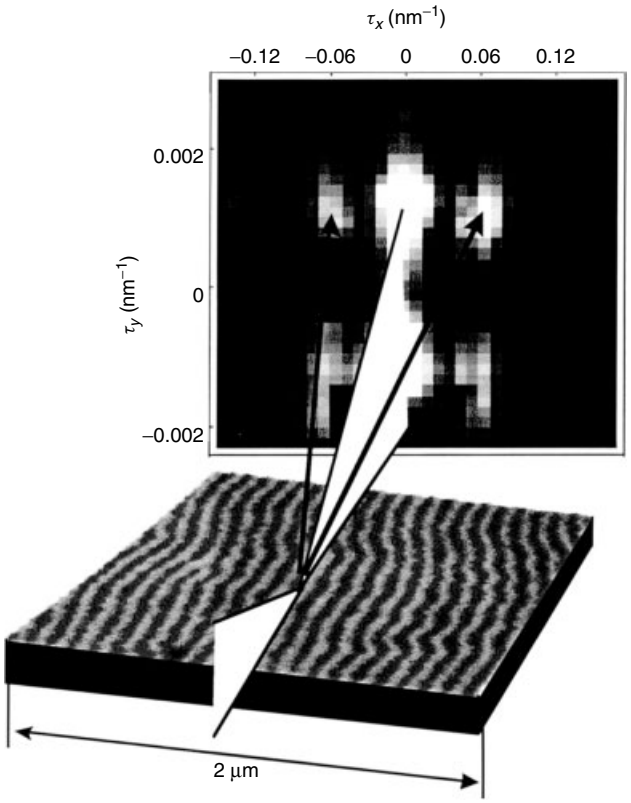

Figure 9. Geometry for scattering at grazing incidence from magnetic stripe domains in a perpendicularly magnetized thin magnetic film. Scattering along τ_y can be observed only because of the large anisotropy of the surface corrugation lengths along x and y. (Reprinted figure from *Physica B: Condensed Matter*, Vol 267–268, Fermon *et al*., © 1999 with permission from Elsevier.)

when $\Delta\phi$ is negligibly small. Reversing the argument, the maximum size of the objects that give rise to lateral scattering (finite $\Delta\phi$ is the same as in transmission geometry and is of the order of a few nanometers). The lateral fluctuations that give rise to a comparable $\Delta\theta$ are instead of the order of a micrometer. The accepted nomenclature is to call the scattering with $\Delta\theta \neq 0$ off-specular reflectivity, while the scattering with $\Delta\phi \neq 0$ is called *scattering at grazing incidence* (Pannetier, Ott, Fermon and Samson, 2003). Most of the experiments carried out on magnetic domains were geared to measure the off-specular reflectivity, integrating the signal along τ_y.

Sizable off-specular reflectivity has been almost universally observed in sputtered samples of magnetic multilayers in the antiferromagnetic state (see also Section 3.3). However, spin-dependent off-specular reflectivity can be observed even in simple systems. Figure 10(a) shows the hysteresis curve of a thin film of ferromagnetic Co covered with CoO. The film has been cooled in a magnetic field through the characteristic temperature at which CoO becomes antiferomagnetic: the effect of field cooling is a displaced hysteresis loop. In addition, a training effect (Hoffmann, 2004) is visible in the repeated hysteresis cycles at low temperature (te Velthuis *et al*., 2000). Except for saturation, a sizable off-specular scattering is observed at all points of the hysteresis cycle. For instance Figure 10(b) shows the spin-dependent intensities of the off-specular scattering obtained at $H = 30$ Oe for the ascending branch of the first hysteresis loop. All the experimental results are well reproduced by calculations based on a simple distribution of the two-dimensional ferromagnetic domains of Co during magnetization reversal (te Velthuis *et al*., 2006). Recently, benchmark neutron experiments have been started on well-defined arrays of nanostructured materials that have been also studied with concurrent techniques such as Kerr microscopy (Lee *et al*., 2003; Theis-Bröhl *et al*., 2005). For these systems it ought to be possible to establish how well the complex scattering patterns obtained by neutron scattering can be interpreted in terms of a statistical ensemble of domains and of their evolution in the presence of a magnetic field.

3 SCIENCE ISSUES

3.1 Homogeneous materials

In order to explain effects, such as different remanent states in ferromagnets, domains were first proposed by Weiss (1907). Subsequently these domains were observed for the first time using a decoration technique by Bitter (1931) and Landau and Lifshitz (1935) were the first to provide a satisfactory explanation. The formation of domains occurs because of the interplay between various energies, such as exchange, anisotropy, magnetostatic, and magnetoelastic energies. In particular magnetostatic energies are important for the understanding of domains in ferromagnets. A magnetization with a component perpendicular to the surface of a ferromagnet, generates magnetic poles and magnetic fields outside of the magnetic material. In general, avoiding these magnetic poles and the concomitant magnetic fields minimizes magnetostatic energies. As shown in Figure 1 the magnetostatic energies can be reduced by the formation of opposite domains and can vanish altogether by the formation of so-called closure domains. It is immediately clear that size and shape, as well as crystalline orientation of the surfaces will influence the domain structures considerably. Some of the basic relationships will be demonstrated below and a much more detailed overview of the properties of ferromagnetic domains can be found in Hubert and Schäfer (1998).

The experimental detection of domains in ferromagnets is based on the fact that each domain has a net nonzero magnetization. This is either measured by detecting the magnetization

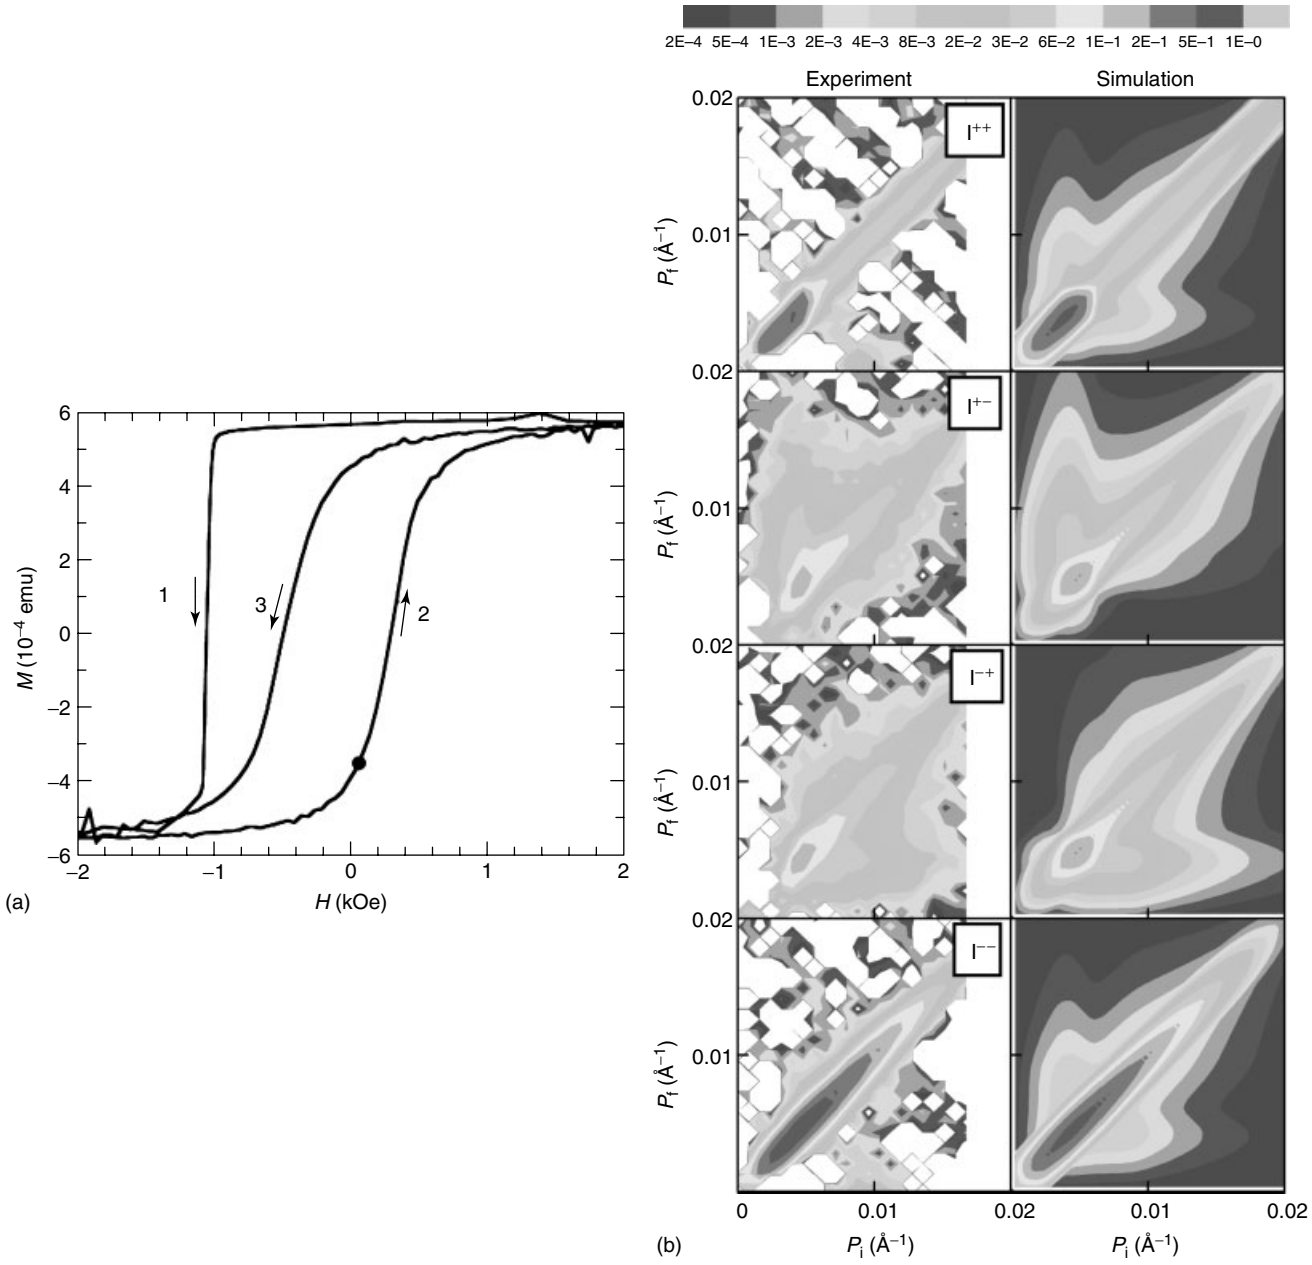

Figure 10. (a) Low-temperature hysteresis loop of a Co/CoO thin film. Cooling in a magnetic field through the ordering temperature of antiferromagnetic CoO causes an exchange bias. A training effect (Hoffmann, 2004) is also visible. (Adapted from te Velthuis *et al*., 2000.) (b) Off-specular neutron reflectivity gives detailed information about size and distribution of the magnetic domains for each point of the hysteresis cycle. Left: Measured spin-dependent reflectivities of the same Co/CoO sample as in (a). The data were collected at $H = 30$ Oe on the ascending curve, marked by a solid dot in (a). $P_i = 2\pi \sin \theta_i$, $P_f = 2\pi \sin \theta_f$. The diagonal line represents the specular scattering. The observed off-specular scattering indicates the presence of finite domains. The spin-flip intensity (I^{+-}, I^{-+}) of the off-specular scattering indicates that the magnetization of these domains is not collinear with the applied magnetic field. Right: simulated off-specular reflectivity based on a simple model for the magnetic domains (te Velthuis *et al*., 2006).

directly or by the stray fields, which occur at the boundaries between domains. The former approach is typically used for scattering (see Section 2) or spectroscopy techniques, while the later is more typical for real space imaging techniques, such as decoration techniques or magnetic force microscopy.

As mentioned in the preceding text, domains form in a ferromagnetic material to balance the different magnetic interactions. From this follows a critical minimum size, below which a magnetic material is single domain since the relatively high increase of exchange energy for a inhomogeneous

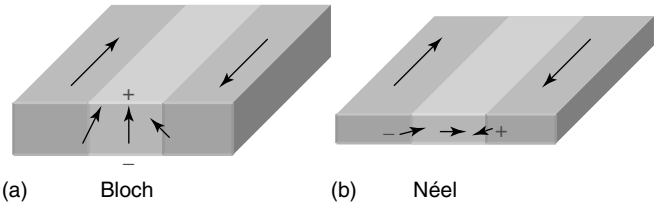

Figure 11. Schematics of Bloch (a) and Néel (b) domain walls. For the Bloch wall the magnetic charges build up at the surface of sample, while for the Néel wall the magnetic charges are contained within the sample.

magnetization state in a small particle is too high (Kittel, 1949). Assuming spherical particles one can determine the following critical radius for low anisotropy

$$r_c = \sqrt{\frac{9A}{\mu_0 M_s^2}\left[\ln\left(\frac{2r_c}{a}\right) - 1\right]} \tag{17}$$

and for high (cubic or uniaxial) anisotropy

$$r_c = \frac{9\sqrt{AK}}{\mu_0 M_s^2} \tag{18}$$

Here A is the exchange stiffness, M_s is the saturation magnetization, a is the lattice constant, and K is the anisotropy constant. The exchange stiffness is given by $A = JS^2/a$, with J being the exchange integral and S the ferromagnetic spin. Typical values for A are $10^{-11}\,\mathrm{J\,m^{-1}}$. In the case of low-anisotropy materials the magnetization forms a so-called vortex state above r_c, while in the case of high anisotropy materials one obtains above r_c well-defined domains with walls separating them.

In general, one can distinguish several types of domain walls in ferromagnetic systems with domains. The two main types of domain walls are Bloch and Néel walls, which are depicted schematically in Figure 11. For a Bloch domain wall the magnetization rotates continuously in the plane of the domain wall. The wall width d_w for the case of opposing domains can be determined from balancing exchange and anisotropy energies (Bloch, 1932):

$$d_w = \pi\sqrt{\frac{A}{K}} \tag{19}$$

One should notice that if the magnetization does not rotate a full 180°, then the domain-wall thickness might also be much less. For example at Co(0001) surfaces, domains have been observed where the relative difference in magnetization direction is about 20° and the domain walls separating these domains are only $1.1 \pm 0.3\,\mathrm{nm}$ wide (Ding, Wulfhekel and Kirschner, 2002).

When the ferromagnetic material becomes very thin, then the magnetic charges associated with the Bloch walls at the surfaces (see Figure 11) create an energetically unfavorable stray field. In this case it may become energetically more favorable to have the magnetization rotate continuously perpendicular to the plane of the domain wall, which is then called a *Néel wall*. Again the width of this wall can be easily determined by balancing exchange and, in this case, magnetostatic energies and in the thin-film limit (O'Handley, 2000) is given by:

$$d_w = \pi\sqrt{\frac{2A}{\mu_0 M_s^2}} \tag{20}$$

Interestingly, since Néel walls have a chirality associated with the sense of magnetization rotation, it is possible for two colliding Néel walls to form a metastable 360° wall, if the individual walls had opposite chirality (Portier and Petford-Long, 2000; Castaño *et al*., 2003).

In general, domain walls are not necessarily just simple Bloch or Néel walls, but the walls can combine aspects of both. For example even films with Bloch walls, may still have Néel caps at their surface. In fact, for films with intermediate thickness one can observe a mixture of Bloch and Néel walls, which is the so-called cross-tie wall (Middlehoek, 1963).

In the following we discuss a few of the typical domain structures that are particularly relevant for thin magnetic films. Magnetic thin films with an anisotropy perpendicular to the film plane tend to form so-called stripe domains in order to minimize magnetostatic energies (see Figure 12a). For the case where the width of the film is much larger than its thickness, the width of the stripe domains can be calculated as (Kittel, 1949):

$$d_d \approx \sqrt{\frac{t\sqrt{KA}}{\mu_0 M_s^2}} \tag{21}$$

where t is the film thickness. Similarly stripes can also be observed for patterned films with in-plane anisotropy, that is, for wires with an anisotropy perpendicular to the wire axis, but in the film plane. In this case the width of the stripes is (O'Handley, 2000):

$$d_d \approx L\sqrt{\frac{\sqrt{KA}}{\mu_0 M_s^2 t}} \tag{22}$$

where L is the width of the wire.

Again in reality the situation can be more complex. The above equations describe the lowest-energy configurations. However, it is also possible that the precise stripe spacing is determined by metastable configurations, which depend

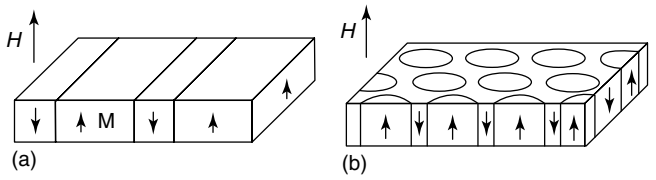

Figure 12. Schematics of stripe (a) and bubble (b) domains. (Reprinted figure from *Phys. Rev. B.* Vol. 26, 325 (1982) © 1982 by the American Physical Society.)

on the magnetic history of the samples (Leaf *et al*., 2006). Furthermore the amount of anisotropy may depend on the film thickness. For example many thin-film systems have a so-called spin reorientation transition, where the anisotropy direction changes as a function of film thickness (Allenspach, 1994). The reason for this is that surface anisotropies can compete with bulk anisotropies and magnetostatic constrains. Therefore, stripe domains close to such a reorientation transition can occur with a complicated wrinkle pattern (Duden and Bauer, 1996). In this case thickness fluctuations can give rise to regions with in-plane and out-of-plane anisotropies, such that the magnetization prefers to be at an intermediate tilt angle with respect to the surface normal. As a consequence the out-of-plane and in-plane magnetization component can set up domain patterns with different length scales, that is, a short-length-scale domain pattern for out of plane (similar to the stripes discussed in the preceding text), while the in-plane component sets up a long-length-scale domain pattern.

Another commonly observed domain pattern is closure domains, which were first suggested by Landau and Lifshitz (1935). Closure domains are more easily obtained in cubic than in uniaxial systems. However, magnetostriction can give rise to strain, which can further complicate the domain structure and actually stabilize stripe domains with reduced elastic strains. In general, closure domains require a minimum sample size and are favored by large magnetization, large sample thickness, small anisotropy, and small wall energy.

Ferromagnetic layers with very high perpendicular anisotropy can develop, in addition to strip domains, so-called bubble domains, which are shown schematically in Figure 12(b) (Malozemoff and Slonczewski, 1979). As the applied field is raised above a critical value there is a transition from stripe to bubble domains (Garel and Doniach, 1982). One interesting consequence of such bubble domains are that small ($<$100 nm) bubble domains can persist to very high field beyond the apparent saturation field obtained from standard magnetometry measurements (Davies *et al*., 2004). Such residual domains can change the magnetization reversal considerably if they are not completely annihilated.

Magnetization reversal can be governed by domain nucleation, domain-wall motion, and magnetization rotation in each domain. In general the reversal can be a complex superposition of all of these mechanisms. Small patterned systems allow looking at simplified model systems, where the reversal is dominated only by a few factors. But even for large samples the field dependence of the hysteresis raises interesting question about the evolution of magnetic domains. For example it is often observed that the value of the magnetization at a given field is reproduced, even if a minor hysteresis loop is applied during the major loop. This observation is referred to as return-point memory. One obvious question is whether this macroscopic return-point memory also corresponds to an identical configuration of magnetic domains. This question was studied by Pierce *et al*. (2003) in Co/Pt thin films with different microstructures using X-ray speckle metrology. They observed that for films with smooth interfaces the nucleation and domain evolution is random and uncorrelated for subsequent hysteresis loops in spite of perfect macroscopic return-point memory. However, for the rougher films the domains show a high degree of correlation during the nucleation, and the correlation becomes reduced further along during the magnetization reversal. This indicates that if there are enough defects present in the magnetic system the nucleation of reversed domains occurs at identical defects, but the motion of domain walls is more random thereafter.

Until now we discussed mainly domains in ferromagnetic systems. While there are also domains possible in antiferromagnetic systems, their behavior tends to be less studied and at the same time very different from ferromagnetic systems. Unlike in ferromagnets, magnetostatic energies are vanishingly small in antiferromagnets and therefore they are not a driving force for domain formation. Furthermore, any gain in configurational entropy is typically not sufficient to overcome the domain-wall energy. Therefore domains in antiferromagnets are generally metastable. However, magnetoelastic interaction, such as piezomagnetism in fluorides (Borovik-Romanov, 1960), may be the dominating energy for domain formation in antiferromagnets. In many cases domains in antiferromagnets may simply originate from random nucleation of long-range order. Applying an external magnetic field during the ordering may influence this domain formation, that is, in MnF_2 fields larger than 150 Oe result in a single-domain state, while smaller fields give rise to multiple domains (Baruchel, Schlenker and Barbara, 1980). In contrast, a field close to that of the spin-flop transition (94 kOe) is required in order to form a single domain at low temperature (Felcher and Kleb, 1996). On the other hand, random defects may also be responsible for establishing a multiple-domain state (Kleemann, 1993). In general, the connection between domains in the antiferromagnet and their macroscopic properties has not been extensively studied. However, domains in antiferromagnets have received increased attention lately

because of their potential role in exchange bias as discussed in more detail subsequently (see Section 3.3).

Owing to the lack of net magnetization for an antiferromagnetically ordered material, the first experimental indications of domains were rather indirect. In a uniaxial antiferromagnet the magnetic susceptibility parallel and perpendicular to the antiferromagnetic anisotropy axis is very different. As a consequence uniaxial antiferromagnets have a spin-flop transition, where the spins suddenly rotate perpendicular to the applied field with a slight canting toward the field in the case where it is applied along the anisotropy axis (Néel, 1936; Foner, 1963). The spin-flop field at which this transition occurs is given by Tanner (1979):

$$H_{\mathrm{f}} = \sqrt{\frac{2K}{\mu_0(\chi_\perp - \chi_{||})}} \tag{23}$$

where K is the anisotropy constant and $\chi_\perp$ and $\chi_{||}$ are the susceptibilities perpendicular and parallel to the anisotropy axis, respectively. This spin-flop transition gives rise to a sudden increase in magnetization. In contrast, for cubic antiferromagnets there is no sudden spin-flop transition (Tanner, 1979). In a cubic antiferromagnet one expects a mixture of domains with spins parallel and perpendicular to the applied field and therefore applying an external field will just result in a spin-flop process via gradual domain-wall motion between these domains (Néel, 1954).

Some antiferromagnetic materials may also have a spin-flip transition as a function of temperature, which typically reflects the temperature evolution of the anisotropy. Examples are Hematite (α-Fe_2O_3), which has the so-called Morin transition at approximately 260 K (Morin, 1950), and chromium, where the direction of the antiferromagnetic spins changes from transverse to longitudinal with respect to the antiferromagnetic ordering vector at 123 K (Werner, Arrott and Kendrick, 1967). As in the case for the field-induced spin-flop discussed in the preceding text, domains in the chromium make this spin-flip transition rather gradual, instead of being first order. Using X-ray microdiffraction it has been recently shown that spin-flipped longitudinal domains nucleate at the domain wall between different transverse domains and subsequently grow gradually until the transverse domains are completely replaced (Evans *et al*., 2002).

Unlike in the case of ferromagnets, the net zero magnetization makes a direct detection of domains in antiferromagnets relatively difficult, which is one of the main reasons they are less studied. However, there are several approaches to directly detect and image antiferromagnetic domains. For example, it is possible that magnetostriction can give rise to strain domains, which are identical to the antiferromagnetic domains (Roth, 1960). In this case, X-ray topography can be used to map out strain domains (Tanner, 1976). It should be noted, however, that the imaging of antiferromagnetic domains via their accompanying strain is only possible in single crystals.

Other possibilities for directly detecting domains are either by utilizing an antiferromagnetic Bragg reflection (reflecting the increased unit cell superstructure) or spectroscopic signatures (i.e., dichroism). Bragg reflections have been used for domain imaging with either polarized neutron diffraction tomography (Schlenker and Baruchel, 1978) or X-ray diffraction microscopy (Evans *et al*., 2002). Examples of imaging with spectroscopic signatures are optical (Eremenko, Kharchenko and Beliy, 1979) or X-ray linear dichroism–based detection (Scholl *et al*., 2000).

Domain structures in antiferromagnets can be much more complex than in ferromagnets, since one can distinguish between domains with different orientations of the ordering vector (T domains, i.e., four different T domains in NiO, which order along (111), see also Section 2.1) and different orientations of the spins along different anisotropy axes (S domains, i.e., for each T domain there are three different S domains, since the anisotropy axes in NiO are the equivalent (112) directions, see also Section 2.1). The nomenclature arises from the fact that T domains are equivalent to different crystallographic twins, while S domains are due to different spin directions. Distinguishing between these different domains may require different approaches. For example, when using neutron scattering T domains can be differentiated by their different Bragg reflections, while S domains can only be detected through polarization selection rules (see Section 2.1).

For completeness we finish the section on homogeneous materials with domains by mentioning that some materials (Tb, Dy, $Tb_{50}Ho_{50}$, $Gd_{60}Y_{40}$, MnP) have a spiral magnetic order. In this case it is also possible to have domains with different chiralities (Palmer, 1975).

3.2 Confined systems

As discussed in the previous section it is clear that geometrical confinement can significantly affect magnetic domain structures. In the following we discuss two types of confined systems, namely, granular systems and well-defined patterned systems, that is, systems obtained via lithography.

Granular systems consist of grains, which are typically sufficiently small to be single domain. In this case the overall magnetic domain behavior is governed by the interactions of the grains. It turns out that at least in the case for ferromagnetic grains as their sizes are reduced, they can start to act collectively, meaning that the domain sizes become bigger than the individual grain sizes. This has

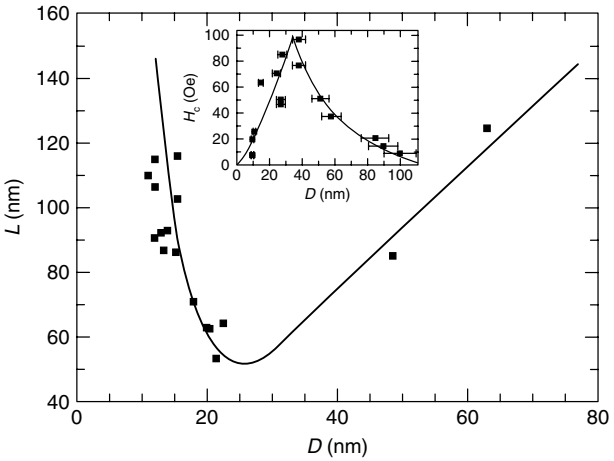

Figure 13. Magnetic correlation length L versus grain size D as determined from small-angle neutron scattering of nanostructured Fe. The inset shows the corresponding coercivity data. (Reprinted figure from *Phys. Rev. Lett.* Vol. 85, 1990 (2000). © 2000 by the American Physical Society.)

been observed by determining magnetic correlations lengths from small-angle neutron scattering (see Figure 13) (Löffler, Braun and Wagner, 2000). The magnetic correlation length is indicative of an average domain size. For large grains the correlation size scales with the grain size, but for very small grains the correlation length increases again. One of the consequences is that in materials with very small grains the crystal anisotropy will be replaced by an effective anisotropy from the superposition of the anisotropies of the magnetically correlated grains. If these grains are randomly oriented, this effective anisotropy can be very small, which makes granular materials very attractive for soft-magnetic applications (Yoshizawa, Oguma and Yamauchi, 1988).

At the same time granular systems can also be used prepare extremely hard magnets. As seen in Section 3.1 there is a critical size below which the magnetization in a grain becomes single domain (see equations (17) and (18)). This also means that the mode of magnetization reversal may change from a domain nucleation and domain-wall motion to either coherent or incoherent rotation. This can give rise to a significant coercivity increase for small grain systems with high crystalline magnetic anisotropy. For example, it has been shown that the coercivity can exceed 10 T for FePt films with grain sizes of 20–30 nm (Shima, Takanashi, Takahashi and Hono, 2004).

Most patterned systems have typical length scales much larger than granular systems. As a consequence, the magnetization of an individual element is often not just a simple single domain. However the limited size often can give rise to very simple domain structures, which tend to 'close the flux' and minimize magnetic strayfields. One of the simplest systems is circular dots, which give rise to a so-called magnetic vortex (Cowburn *et al*., 1999). Similar flux-closure domain configurations can also be observed in other structures, such as rings (Rothman *et al*., 2001; Li *et al*., 2001), rectangular particles (Hubert and Schäfer, 1998), or films with holes. Interestingly, when these systems have a broken in-plane symmetry, that is, either due to shape or magnetocrystalline anisotropy or due to exchange coupling, then the precise remanent domain state may depend on the magnetic history, such as magnitude and direction of previously applied magnetic fields. Examples of such broken symmetries are rectangular patterns (Thomas *et al*., 2000b), elliptical patterns (Vavassori *et al*., 2004), and exchange-biased systems (Sort *et al*., 2005, 2006a).

All the aforementioned examples are systems based on patterned thin films. However 'flux-closure' domain structures can also be observed in other nanopatterned systems. For example flux-closure structures have also been observed for cylindrical Co nanowires with sufficiently large diameter (>50 nm) (Henry *et al*., 2001).

So far there has been only very limited use of scattering techniques for investigating the magnetization behavior in patterned systems. Temst, Van Bael, and Fritzsche (2001) showed that off-specular polarized neutron reflectometry can be used to investigate the field dependence of the magnetization in patterned structures. However, so far there is no detailed information about inhomogeneous magnetization states. In contrast Lee *et al*. (2003) used off-specular neutron scattering to determine the domain structures for magnetic antidot arrays, which have also been suggested for high-density data storage (Cowburn, Adeyeye and Bland, 1997).

In the case of systems with predominantly in-plane anisotropy, flux-closure domain structures, such as a vortex, are stable over a wide range of sizes. But the situation can be markedly different in systems with perpendicular anisotropy, which tend to form stripe domains as discussed in Section 3.1. As long as the lateral size of the pattern is comparable to the stripe width (see equations (21) and (22)), only a few, very simple, well-defined domain patterns are stable consisting of either concentric rings or parallel stripe patterns (Skidmore, Kunz, Campbell and Dahlberg, 2004). But as soon as the lateral dimension of the system becomes larger than $1.5d_d$ the stripe domain patterns become complex and randomly oriented. However, the stripe domains still prefer to be either perpendicular or parallel to the edges of the patterned system.

Aside from confining the possible different domain states, nanostructuring also offers different ways of manipulating domain structures. In bulk systems one generally only investigates how the domain structure is changed by varying external parameters such as applied field and/or temperature. In patterned materials there is also a possibility to change the domain structure through the application of electrical

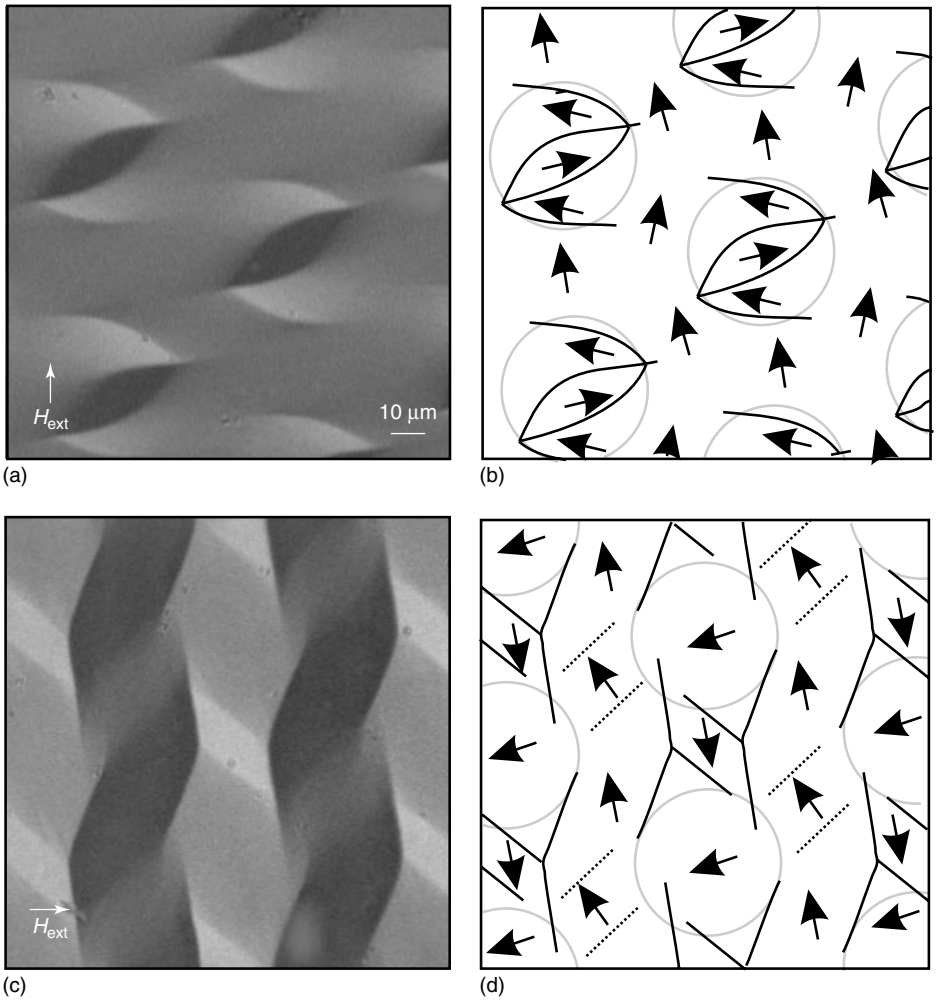

Figure 14. Magneto-optic Kerr microscopy images and deduced domain patterns for FeCoSiB films in which the anisotropies were laterally modified through He-ion irradiation. (Reproduced from J. McCord *et al*., 2005, with permission from American Institute of Physics.)

currents (Gan *et al*., 2000). This current-induced domain-wall motion is either due to spin torque (thin films) (Berger, 1984) and domain drag (thicker films) (Berger, 1978) or due to linear momentum transfer (narrow domain wall) (Tatara and Kohno, 2004).

Recently there have been also approaches using lateral variations of anisotropy to modifying domain patterns besides confining the actual physical size of magnetic systems. The local magnetic anisotropy can be controlled by thickness modulation (Costa-Krämer *et al*., 2003), selective epitaxy (Li *et al*., 2002), or by local ion irradiation (Fassbender, Ravelosona and Samson, 2004). Using a substrate with laterally modulated crystallinity at the surface, Li *et al*. (2002) prepared Ni films with laterally alternating out-of-plane and in-plane anisotropy, which was reflected in a corresponding domain structure. Similarly, Swerts *et al*. (2003) established well-defined domain structures by laterally varying the roughness of the films through regional use of silver buffer layers. Ion irradiation allows changing the microstructure locally (Fassbender, Ravelosona and Samson, 2004), which can be used to tailor both the magnitude of the anisotropy (Chappert *et al*., 1998), as well as the direction (McCord *et al*., 2005). Especially the later possibility of laterally modifying the anisotropy direction allows for the generation of very complex well-defined domain patterns (see Figure 14).

Aside from the static domain patterns in confined magnetic structures, there is an increasing interest in the dynamic behavior of domain patterns and their role for magnetization reversal processes. The dynamic behavior can be complicated, since the magnetization in each domain might show precessional motion, while the domain walls themselves can have excitations analogous to oscillating strings, and intersections of domain walls, such as vortex cores can perform translational motion (Park *et al*., 2003; Perzlmaier *et al*., 2005; Raabe *et al*., 2005; Guslienko *et al*., 2006). Interestingly,

systems with a vortex core (circular disks or squares), may have left or right handedness due to the chirality of the domain pattern and the orientation of the vortex-core magnetization. While in most cases this handedness is unimportant for the static domain patterns, it becomes very important for the dynamic behavior of these systems (Choe *et al*., 2004; Buchanan *et al*., 2005).

3.3 Coupled systems

3.3.1 Antiferromagnetically coupled multilayers

Until now we discussed mainly homogeneous, one-component systems. It is clear that interactions between different magnetic materials can also modify the balance between the different magnetic energies and therefore influence the domain formation considerably. In particular magnetic multilayers were studied extensively in this respect. The interest in magnetic multilayers increased dramatically with the discovery by Grünberg *et al*. (1986) that nonmagnetic layers sandwiched between two ferromagnetic layers can give rise to oscillating ferromagnetic or antiferromagnetic coupling between the ferromagnetic layers depending on the thickness of the nonmagnetic layer (Grünberg *et al*., 1986). Especially the antiferromagnetically coupled multilayers were studied extensively because of the observation of giant magnetoresistance (Baibich *et al*., 1988), which in the meantime has become a key ingredient for many magnetotransport applications (Daugthon, Pohm, Fayfield and Smith, 1999). At the same time antiferromagnetically coupled multilayers are of great basic science interest, since they can be used as model systems for understanding antiferromagnetic behavior in general (Wang *et al*., 1994). Domains in these synthetic antiferromagnetic systems are important for technology driven as well as fundamental science, since the domains may give rise to noise in applications (Hardner, Weissman and Parkin, 1995) and at the same time domains in antiferromagnetic systems have been less studied, as discussed in Section 3.1. Nevertheless, antiferromagnetic coupling may also have beneficial effects for applications, since it can be used for reducing the switching field relative to the thermal stability in antiferromagnetically coupled magnetic recording media (McFayden, Fullerton and Carey, 2006).

Note that in these coupled multilayer systems, there are other possible coupling mechanisms, besides the interlayer exchange coupling. Both structural and magnetic inhomogeneities can result in interlayer coupling. Stray fields due to interface roughness can result in so-called orange peel coupling (Néel, 1962). Similarly stray fields from domains walls can couple the magnetization structure in different ferromagnetic layers (Fuller and Sullivan, 1962; Thomas *et al*., 2000a; Lew *et al*., 2003).

Both polarized neutron (Huang, Felcher and Parkin, 1991; Hahn *et al*., 1994; Borchers *et al*., 1996, 1999; Langridge *et al*., 2000; Nagy *et al*., 2002) as well as X-ray resonant scattering (Idzerda, Chakarian and Freeland, 1999; Spezziani *et al*., 2002; Nefedov *et al*., 2005) have contributed considerably to the present understanding of domains in synthetic antiferromagnetic systems. By analyzing diffuse reflectivity around either the chemical superlattice Bragg reflection or the half-order (antiferromagnetic) Bragg reflections it is possible to obtain information about the ferromagnetically and antiferromagnetically coupled domains respectively (see also Section 2.3).

The first observation of domains in antiferromagnetically coupled multilayers with polarized neutron reflectometry was by Huang, Felcher and Parkin (1991) who studied the Co/Ru system and determined the average domain size to $L_x \approx 4\,\mu$m. Similarly the domain structure was also investigated in Co/Cu (Borchers *et al*., 1999; Langridge *et al*., 2000; Spezziani *et al*., 2002), Fe/Cr (Hahn *et al*., 1994; Nagy *et al*., 2002; Nefedov *et al*., 2005), and $Ni_{80}Fe_{20}$/Ag (Borchers *et al*., 1996) multilayers. In the Co/Cu system it was observed that for the as-prepared samples the domain structures in individual ferromagnetic layers are correlated. However, after subsequent magnetization reversal the domains are uncorrelated (Borchers *et al*., 1999; Langridge *et al*., 2000). This explains directly an experimentally observed decrease of magnetoresistance between the virgin and other remnant configurations. In general, the domain structure in these artificial antiferromagnetic systems is very sensitive to the magnetic history (Hardner, Weissman and Parkin, 1995; Nagy *et al*., 2002). When the domains nucleate after saturation their formation is mostly governed by the competition between Zeeman energy and antiferromagnetic interlayer coupling. This competition can give rise to very small domains ($<1\,\mu$m). On the other hand, during the bulk spin flop, the magnetocrystalline anisotropy becomes very important, resulting in much larger domains ($>10\,\mu$m) (Nagy *et al*., 2002).

Not only the domain structures, but also the domain walls in antiferromagnetically coupled multilayers offer rich research opportunities. This was demonstrated by Hellwig, Berger, and Fullerton (2003) in antiferromagnetically coupled multilayers with perpendicular anisotropy, such that the magnetization is preferentially perpendicular to the interfaces. In this case dipolar interactions also become important and their relative strength with respect to the antiferromagnetic interlayer coupling can be tuned by varying the ferromagnetic layer thickness. Interestingly as long as the antiferromagnetic coupling clearly dominated, the domain walls always had no net magnetization. But when the dipolar coupling became large enough then the domain wall developed a

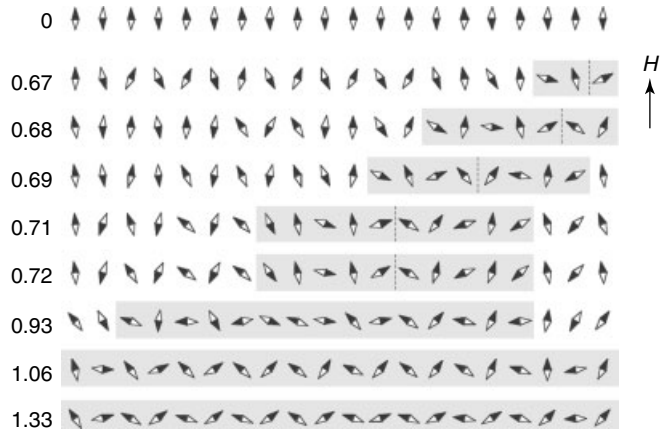

Figure 15. Magnetization direction of each Fe layer in an antiferromagnetically coupled Fe/Cr superlattice as determined with polarized neutron reflectometry. The compass needles indicate the relative direction of the magnetizations in each ferromagnetic layer of the superlattice. The applied fields indicated on the left are normalized by the bulk spin-flop field. (Reprinted figure from *Phys. Rev. Lett.* Vol. 89, 127203 (2002). © 2002 by the American Physical Society.)

striped pattern, by having the domain wall shifted in each ferromagnetic layer. Whether such complex domain walls occur in real antiferromagnets is still an interesting open question.

Besides domain walls, there is another interesting inhomogeneous magnetization structure in synthetic antiferromagnets related to the so-called surface spin flop. As mention in Section 3.1, antiferromagnetic materials can react to an external applied field with a spin-flop transition, where the spins rotate mostly perpendicular to the anisotropy axis. It was realized early on that this transition can be modified at the surface of an antiferromagnet (Mills, 1968; Keffer and Chow, 1973). The experimental verification of this effect was possible only through the use of antiferromagnetically coupled multilayers as model systems for finite antiferromagnets (Wang *et al*., 1994). The actual depth profile of the surface spin flop as a function of applied field has been shown with polarized neutron reflectometry (te Velthuis, Jiang, Bader and Felcher, 2002). Specifically at the surface spin flop, the magnetization of the topmost layers reverses, which gives rise to two antiphase domains as a function of depth into the multilayer. This domain wall moves with increasing field into the center of the superlattice and acts as a nucleation site for the subsequent bulk spin-flop transition (see Figure 15). Furthermore lateral domains can complicate the surface spin-flop effect (Lauter-Pasyuk *et al*., 2002).

The example of the surface spin flop shows that complex noncollinear magnetization structures can occur in multilayers consisting of ferromagnetic layers separated by nonmagnetic spacers because of the intricate balance between different interactions. It should also be noted that noncollinear magnetization structures can be established intentionally during the fabrication of these multilayers. For example, Felcher *et al*. (1998) showed that a helical magnetization structure can be imprinted if the superlattice structure is grown in a continuously rotating field.

3.3.2 Exchange bias

Another extensively studied type of coupled magnetic heterostructures are exchange bias systems (Nogués and Schuller, 1999; Nogués *et al*., 2005). Exchange bias systems were first discovered by Meiklejohn and Bean (1956) and consist of antiferro- and ferromagnetic materials where the coupling between the two gives rise to a symmetry-breaking unidirectional anisotropy resulting in hysteresis loops, which are asymmetrically shifted with respect to the field axis (Meiklejohn and Bean, 1956). This hysteresis loop can be understood intuitively by assuming that the ferromagnet couples only to one sublattice of the antiferromagnet, which remains essentially unaffected by an external field because of the vanishing net magnetization of the antiferromagnet. While this naive model works quantitatively for model systems, which mimic this situation (Jiang *et al*., 2000), it fails to capture many details quantitatively for most real exchange bias systems. In particular the observed loop shift is often several orders of magnitude smaller than theoretically expected (Tsang, Heiman and Lee, 1981). At the same time, exchange bias is observed in systems where the nominal interface of the antiferromagnet is being compensated (Nogués and Schuller, 1999). In this case one would expect that the ferromagnet couples equally to all antiferromagnetic sublattices and thus there should be no net coupling and thus no symmetry breaking. Both observations, the relatively small hysteresis loop shift and the observed bias for compensated antiferromagnetic surfaces, can be possibly reconciled by assuming domains in the antiferromagnet. Domains in the antiferromagnet would reduce the net moment at an uncompensated surface, and at the same time they could generate a net moment at a nominally compensated surface. In either case the bias shift is generally believed to result from a net magnetic moment in the antiferromagnet at the interface. In fact such net magnetizations have been observed recently with polarized neutron reflectometry (Hoffmann *et al*., 2002; Roy *et al*., 2005) and X-ray resonant scattering (Roy *et al*., 2005). Furthermore it has been shown there is a direct correlation between exchange bias and uncompensated spins in the antiferromagnet (Takano *et al*., 1997).

One of the first quantitative theoretical models investigating the role of lateral domains in the antiferromagnet was proposed by Malozemoff (1987). In his model the finite size of the antiferromagnetic domains results in a net moment

simply from a statistical imbalance between the two sublattices. This statistical argument suggests that smaller antiferromagnetic domains give rise to a larger net magnetization per interface area. However, there is so far no direct experimental confirmation of a correlation between exchange bias magnitude and sizes of antiferromagnetic domains.

Another possibility for inhomogeneous magnetization structures in the antiferromagnet of exchange bias structures are domain walls parallel to the interface of the ferromagnet (Mauri, Siegmann, Bagus and Kay, 1987; Stiles and McMichael, 1999), which is very similar to the behavior observed in exchange spring systems discussed further below. Indeed, recent measurements with resonant X-ray reflectivity and polarized neutron reflectivity detected directly such a domain wall parallel to the interface in the uncompensated magnetization of a strained FeF_2 antiferromagnet (Roy *et al*., 2005). However, in this case the domain wall does not necessarily originate from the reversal of the ferromagnetic magnetization, but from different response to external fields of uncompensated moments in the bulk and at the interface of the antiferromagnet. Similarly, Borchers *et al*. (2000) have shown that in Fe_3O_4/NiO the domains in the antiferromagnet depend sensitively on the cooling field, which furthermore underscores the importance of domains in exchange bias systems.

Besides the aforementioned direct observation of domains and domain walls in the antiferromagnet of exchange bias systems, there is also additional indirect evidence of the importance of antiferromagnetic domains. Keller *et al*. (2002) investigated exchange bias as a function of nonmagnetic impurities in the antiferromagnet. They observed that the exchange bias can increase for a moderate concentration of impurities, which could stabilize smaller domains, hence resulting in a larger net moment that couples to the ferromagnet (Nowak *et al*., 2002). However, the situation is more complex, since the precise interfacial microstructure is also very important for determining the influence of impurities in the antiferromagnet on the experimentally observed exchange bias (Shi *et al*., 2003).

Aside from the magnitude of the exchange bias shift, the domain structure in the antiferromagnet may also influence the direction of the shift. Normally the exchange bias shift has the opposite sign of the applied field during field cooling (Nogués and Schuller, 1999). However, a few selected exchange bias systems can exhibit a positive exchange bias shift upon field cooling in very large magnetic fields (Nogués, Lederman, Moran and Schuller, 1996). This crossover from negative to positive exchange bias has been investigated by Kirk, Hellwig, and Fullerton (2002) in model structures based on coupled Co/Pt multilayers, where one of the multilayers was exchange biased by a CoO layer. Interestingly the transition from conventional negative exchange bias to positive exchange bias depends sensitively of the domain structure in the layer responsible for the exchange bias. If the domains in the biasing layer are smaller than those in the biased layer the exchange bias shift changes continuously from negative to positive values. However, if the domains in the biasing layer are larger than typical domains in the biased layer, then the hysteresis loop can become bifurcated with part of the hysteresis loop being biased positively, while the other part is biased negatively. A similar behavior has also recently been observed in a real exchange bias system (Roshchin *et al*., 2005).

Aside from domains in the antiferromagnet, domains in the ferromagnet can also play an important role for exchange bias systems. Some of the unusual aspects of exchange bias systems, such as asymmetries in the magnetization reversal and training effects, can be connected to ferromagnetic domain formation. Using polarized neutron reflectometry Fitzsimmons *et al*. have shown that the magnetization reversal on either side of the hysteresis loops for Fe/Mn_2F (Fitzsimmons *et al*., 2000, 2001) and Fe/Fe_2F (Fitzsimmons *et al*., 2002) can be different, such that with decreasing field the reversal is mostly via a coherent rotation of the magnetization, while for increasing fields the reversal proceeds via domain nucleation and domain-wall motion. More recently it has been shown that this asymmetry in magnetization reversal is a more general consequence due to the competition between different anisotropies in exchange bias systems (Camarero *et al*., 2005). Another unusual property of many exchange bias systems is that after the initial field cooling procedure subsequent hysteresis loops may differ from each other with successively decreasing exchange bias (Hoffmann, 2004). It has been observed that the change in hysteretic behavior is also correlated with domain formation in the ferromagnetic layer (Lee *et al*., 2002; Gierlings *et al*., 2002; Radu *et al*., 2003). For example, Lee *et al*. (2002) observed that domains are differently oriented during different reversals and Radu *et al*. (2003) suggest that after the first reversal interfacial domains form, which remain unchanged during the subsequent reversals. It also should be noted that locally varying exchange coupling can give rise to complex domain structures (Gogol, Chapman, Gilles and Vanhelmont, 2002).

So far we discussed the naturally occurring domains in the ferromagnet. Another aspect of exchange bias systems is that the ferromagnetic layer can be prepared in a well-defined domain configuration in the unbiased state (typically at high temperature), which can be subsequently imprinted into the antiferromagnetic layer. If there are only domains with opposite magnetization orientations, then this can result in two separately shifted subloops (Chien *et al*., 2003). A similar situation exists, when the antiferromagnet owing to its crystalline orientation projects out laterally different field components (Roshchin *et al*., 2005). This idea of

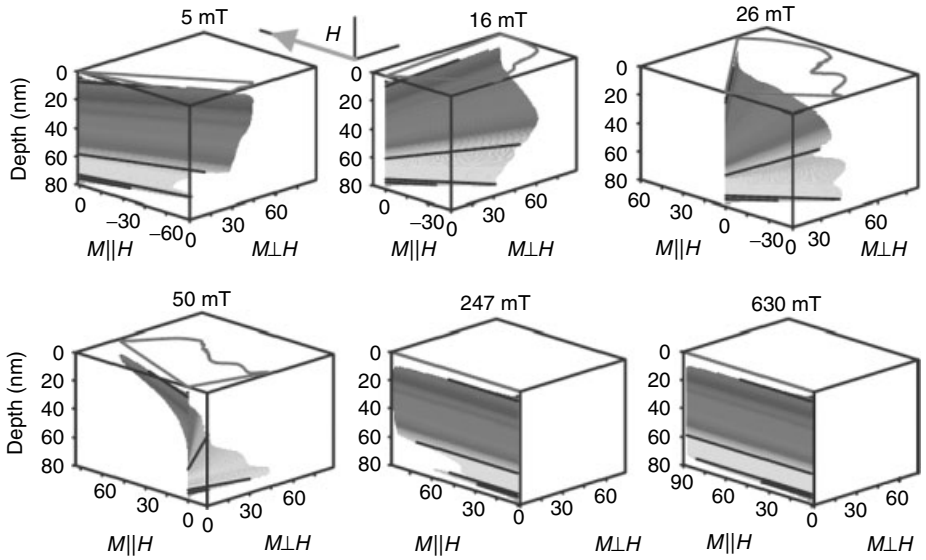

Figure 16. Twist of the magnetization in exchange spring system consisting of a hard magnetic FePt layer (up to the third line from the bottom) and a soft magnetic NiFe layer (upper layers). (Reprinted figure from *Phys. Rev. Lett.* Vol. 88, 067201 (2002). © 2002 by the American Physical Society.)

imprinting magnetization structures can also be utilized to fine tune the shapes of hysteresis loops (Brück *et al*., 2005). More recently, it has also shown that other inhomogeneous magnetization states, such as magnetic vortex states, can be faithfully imprinted into the antiferromagnet (Sort *et al*., 2006a,b).

3.3.3 Exchange spring

Another system of coupled magnetic heterostructures with potential technological applications are exchange spring systems, consisting of coupled hard and soft ferromagnetic materials (Kneller and Hawig, 1991; Fullerton, Jiang and Bader, 1999). For permanent magnet applications the figure of merit is typically the energy product $(BH)_{\max}$, which generally increases with increasing coercivity and increasing saturation magnetization. However, in general, hard magnetic materials have a high anisotropy (thus large coercivity), but relatively low saturation magnetization. At the same time soft-magnetic materials can have a very large saturation magnetization, but typically have a rather low anisotropy. Using hard–soft coupled systems offer the promise of combining the best features of both materials, leading to more powerful permanent magnets.

The limit for improving the energy product in exchange spring systems is determined by how much the interfacial coupling dominates the magnetization behavior of the soft-magnetic component. Once the soft-magnetic layers are thicker than the exchange layer (typically $\approx$10 nm) they can develop a twisted magnetization structure, where the magnetization at the interface is closely aligned with the hard-layer magnetization but away from the interface the magnetization rotates continuously toward the applied magnetic field. Such a twist has been directly observed with polarized neutron reflectometry for $Fe_{55}Pt_{45}/Ni_{80}F_{20}$ bilayer (see Figure 16) (O'Donovan *et al*., 2002). In this particular measurement, the magnetization structure was obtained with high accuracy by combining reflectivity spectra from the front- and backside of the sample, which adds additional constraints to the possible models for fitting the data. Notice that the domain wall extends actually both into the soft and hard magnetic layer.

While the basic behavior of exchange springs can be understood within simple models describing inhomogeneous magnetizations perpendicular to the hard/soft interface, lateral domains may influence the detailed magnetization behavior. For example, in general one would expect only ferromagnetic coupling between the two ferromagnetic constituents of an exchange spring system. However, Vlasko-Vlasov *et al*. (2001) showed that exchange spring systems can also have a biquadratic coupling, meaning that the magnetization in the soft-magnetic layer has a preferred orientation perpendicular to the easy axis of the hard magnetic layer. This effect originates from domains in the hard magnetic layer. In the case of a uniaxial hard magnetic system a partial magnetization reversal of the hard-layer magnetization results in domains with opposite magnetizations. Owing to the high anisotropy, the domains in the hard magnetic layer are in general much smaller than the domains in the soft-magnetic layer. Thus one single soft domain may couple to

multiple hard domains with opposite magnetization. This situation gives rise to a frustration of the interfacial interactions, which then results in the observed biquadratic coupling.

More recent developments show various different interesting aspects of exchange spring systems. For example, contrary to common intuition, a sharp interface between the hard and soft materials does not result in the highest possible energy product. Jiang *et al*. (2004) showed that an intentionally interdiffused (i.e., graded) interface can enhance the energy product, since the field range of reversible magnetization change is significantly extended. Another recent development is an increased interest in lateral exchange spring structures, where the interfacial domain walls change from the Bloch to the Néel type (see also Section 3.1 and Figure 11). The different magnetostatic energies can modify the behavior significantly and depending on the competition between the different interactions there can be the formation of opposite domains or a more coherent magnetization reversal (Fraile Rodríguez *et al*., 2006). Lastly, exchange springs also generated interest for applications beyond the hard magnetic materials, for which they were initially investigated. One new application idea is to use exchange springs, which contain a component with a metamagnetic transition, as possible magnetic recording media, where the switching field can be dramatically reduced by heating past the metamagnetic transition (Thiele, Maat and Fullerton, 2003; Guslienko *et al*., 2004).

3.3.4 Ferromagnet/superconductor hybrids

The last coupled systems to be discussed are ferromagnetic/superconducting hybrids. The interaction between ferromagnets and superconductors has generated a lot of research interest over the years, since the two types of magnetic order are generally mutually exclusive (for a recent review see Lyuksyutov and Pokorovsky, 2005). Their interplay can generate a variety of interesting effects, such as strong vortex pinning (Otani, Pannetier, Nozières and Givord, 1993; Martín, Vélez, Nogués and Schuller, 1997; Morgan and Ketterson, 1998; Van Bael, Temst, Moshchalkov and Bruynseraede, 1999; Martín *et al*., 1999; Hoffmann, Prieto and Schuller, 2000), π phase (Radovic *et al*., 1991; Ryazanov *et al*., 2001), and triplet (Volkov, Bergeret and Efetov, 2003) superconductivity, variations in the superconducting transition temperature (Jiang, Davidovic, Reich and Chien, 1995; Gu *et al*., 2002), and giant magnetoresistance (Peña *et al*., 2005). Most studies ignore the influence of magnetic domain structures or specifically prepare systems with single-domain magnetizations. Nevertheless, there are a few investigations, which specifically target the influence of magnetic domain structures on the superconducting properties of superconducting/ferromagnetic hybrids. Van Bael, Temst, Moshchalkov and Bruynseraede (1999) showed that vortex pinning is stronger for patterned ferromagnetic particles with in-plane single-domain state versus flux-closure state, indicating that the stray field is important. The situation is different for systems where the magnetization of the ferromagnet is perpendicular to the layer, and thus perpendicular to the interface with the superconductor. In this case the formation of a domain state increases the magnetic fields penetrating the superconductor and thus can give rise to increased vortex pinning (Lange, Van Bael, Moshchalkov and Bruynseraede, 2002). However, at the same time the stray field from the magnetic domains can also significantly reduce the superconducting transition temperature (Lange, Van Bael and Moshchalkov, 2003). More recent investigations of Nb thin films grown on ferromagnetic $BaFe_{12}O_{19}$ substrates indicate that the interplay between ferromagnetic domains and superconductivity can be even more complex, resulting in nonmonotonic variations of the superconducting transition temperature as a function of applied magnetic fields (Yang *et al*., 2004). This behavior has been interpreted as evidence for theoretically predicted nucleation of superconductivity at the ferromagnetic domain walls (Aladyshkin *et al*., 2003). Interestingly, so far there has been less investigation into the question how the proximity of a superconductor influences magnetic domain formation. In principle one could expect a strong influence, since the presence of a superconductor changes considerably the magnetostatic energies, which are ultimately often the driving force for domain formation.

4 SUMMARY

From the very beginning of neutron scattering investigations, magnetic materials have been one of the main subjects studied, since neutron scattering is uniquely suited for obtaining atomic-scale magnetic structure. In this chapter we provided an overview about how neutron scattering can also be utilized to obtain information about larger-scale magnetic structures, in particular, magnetic domains. Information about the size, orientation, and population of domains can be determined by neutron diffraction, depolarization, or refraction. Furthermore, neutron scattering can also in principle provide insight about the correlations between domains, similar to its use for studying atomic-scale correlations. However, studies of domain correlations are still in its infancy, but are poised to become more important with the advent of the next generation neutron sources in the near future. Besides introducing the various techniques we also provided a brief overview about different current scientific issues, where magnetic domains play a central role and which lend themselves to neutron investigations. Such a selection of scientific problems from a broad field of research as magnetism has to

be naturally subjective and incomplete; thus we apologize for any oversights. Nevertheless, the examples shown in this chapter should illustrate the role of neutron refraction and scattering in determining magnetic domain states. We are quite confident that based on the solid foundation of the past work, neutrons will continue to play a major role in unraveling magnetic domain structures.

1 INTRODUCTION

Artificial magnetic nanostructures are being intensively investigated because of their intriguing magnetic properties and their specific device applications. By reducing the size in one or more directions new magnetic properties have been observed which are not present in the bulk and which are highly usable for device application. With perpendicular stacked magnetic layers a reduction of size in the out-of-plane direction is accomplished. They allow the investigation of collinear and noncollinear exchange coupling between ferromagnetic (F) layers, exchange bias (EB) between F- and antiferromagnetic (AF) layers, confinement and scaling effects of spin-density wave magnetism, and proximity effects between F and superconducting layers. Reducing the size in the lateral direction results in a plethora of different shapes for F nanostructures such as stripes, dots, antidots, rings, squares, rectangles, triangles, and different ellipsoids. The fabrication of these shapes usually requires lithographic processes or, alternatively, self assembly of magnetic nanostructures. The main interest in magnetic nanostructures is the understanding of the domain structure in the ground state, the reversal mechanism in the space and time domain, and the dipolar interaction between these elements. Here we will review magnetic films and heterostructures, magnetic superlattices, and lateral magnetic nanostructures as they have mainly been investigated via polarized neutron scattering and neutron reflectivity (NR).

During the past 10 years polarized NR has played an increasingly important role for the exploration of magneto- and spintronic nanostructures. Well-known systems extensively studied include exchange-coupled magnetic superlattices, exchange spring valves between soft and hard magnetic films, EB systems between F and AF films, magnetic semiconductors and half-metallic ferromagnets. In addition to studies of layered systems, laterally patterned magnetic systems such as stripes and islands on the submicrometer scale are now being intensively analyzed by neutron scattering.

Although neutron scattering is generally known as a *bulk probe* particularly sensitive to magnetic moments and magnetic excitations by virtue of the chargeless but magnetic particle properties, it is the interface sensitivity which turned

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

out to be most useful in studies of magnetic thin films, multilayers, and lateral magnetic nanotructures. Although the wavelength of cold neutrons can be 1–3 orders of magnitude smaller than the thickness of thin films, the sensitivity is due to the distortion of the neutron wave field near surfaces when potential steps are encountered. The interface sensitivity is exploited in specular NR and off-specular neutron scattering. Often it is advantageous to first fix the neutron polarization vector, that is the neutron magnetic moment with respect to the scattering plane, and to analyze the polarization state of the exit beam before the detector. This variant of neutron reflectivity is called *polarized neutron reflectivity* (*PNR*) and is used mainly for the investigation of magnetic thin films, magnetic superlattices, or any other kind of magnetic heterostructure. Responding to the upsurge of interest in PNR a number of neutron reflectometers for magnetic studies have become available at all major steady-state and pulsed neutron sources around the globe.

A variety of powerful methods are available for the analysis of magnetic nanostructures. In this concert of competing methods, neutron studies have to justify themselves by unique answers to specific questions. Those include:

- magnetic correlation lengths in films and superlattices;
- depth profiles of the magnetization vector;
- quantitative magnetic roughness parameters of buried interfaces;
- magnetic fluctuations and correlations of domain distributions;
- magnetic hysteresis in the presence of superconductivity;
- sensitivity to magnetic induction;
- distinction between different magnetic reversal mechanisms.

In the past PNR was also used for absolute moment determination. This is indeed an important application of PNR, as the cross sections are well known and independent of model assumptions. However, if moments of ultrathin layers are determined other aspects start to play a dominating role, such as growth morphologies, surface roughness, interdiffusion, and so on. In this case, specular and off-specular diffuse scattering has to be analyzed for reliable data analysis and PNR has to be combined with surface science methods. This topic may be revisited in the future when higher intensities and in situ growth capabilities at neutron beam lines become available.

A number of excellent review articles have been published in recent years either focusing on the method of polarized neutron reflectivity (Fermon and Menelle, 1999; Ankner and Felcher, 1999; Majkrzak, 1996; Majkrzak and Donovan, 2006) or on the magnetic film systems (Fitzsimmons *et al*., 2004; Zabel and Theis-Bröhl, 2003; Bland and Vaz, 2005). Here we describe in some detail the method of polarized neutron reflectivity with particular emphasis on the description of perpendicular and lateral micro- anuctures and review recent applications. The distorted wave Born approximation (DWBA) for the description of off-specular diffuse scattering from magnetic domains and nanostructures is described in some detail here for the first time. The outline is as follows. After providing the theoretical framework for PNR, off-specular, and Bragg scattering, experimental considerations for the scattering technique will be discussed. This is followed by a review of NR studies of thin magnetic films, superlattices, and lateral magnetic patterns.

2 METHOD OF POLARIZED NEUTRON REFLECTIVITY

2.1 Unpolarized neutron reflectivity

In the following, we consider first an elastic reflection experiment of unpolarized monochromatic neutrons. Furthermore, we assume that a collimated neutron beam impinges at a glancing angle α_i onto a flat and extended surface separating vacuum (air) and medium (Figure 1). The reflected beam leaves the surface under a glancing angle α_f. In case of specular reflection, the incident and exit angles are identical: $\alpha_i = \alpha_f$. For this reason, we may drop the indices i, f for the moment, but use them again when discussing off-specular scattering. The scattering vector $\boldsymbol{Q}_z$ has the length $Q_z = 2k \sin\alpha$ and points along the z-direction parallel to the surface normal, where $k = 2\pi/\lambda$ is the magnitude of the incident (and/or scattered) wave vector $\boldsymbol{k}$,

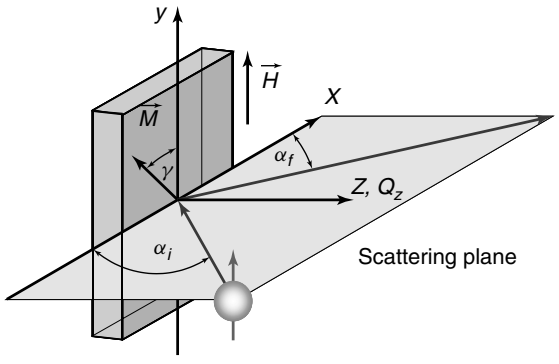

Figure 1. Scattering geometry for polarized neutron reflectivity studies. Neutrons are initially polarized along the y axis. Non-spin-flip reflection is due to the $B_y = |\boldsymbol{B}| \cos\gamma$ projection of the magnetic inductance vector $\boldsymbol{B}$, while $B_x = |\boldsymbol{B}| \sin\gamma$ causes spin-flip reflectivity.

and λ is the neutron wavelength. In vacuum the part of neutron energy corresponding to its propagation in the z-direction is

$$E_z = \frac{\hbar^2 \boldsymbol{Q}_z^2}{8m} \tag{1}$$

where m is the neutron mass. At the interface between vacuum and medium the neutrons experience a potential step of height

$$V = \frac{2\pi\hbar^2}{m} Nb \tag{2}$$

Here N is the atomic number density and b is the coherent scattering length of the neutrons. The product Nb is usually referred to as the scattering length density (SLD). Total reflection occurs for $E_z \leq V$. Thus from equations (1) and (2) one obtains for $E_z = V$ the critical scattering vector for total reflection

$$Q_c = \sqrt{16\pi Nb} \tag{3}$$

Note that total reflection occurs only if the coherent scattering length b is positive, that is if $V > 0$. Then, for $Q < Q_c$ the neutron wave in the medium is exponentially damped within the medium, and for $Q > Q_c$ a Fresnel reflectivity is observed, which drops off with Q^{-4}. In case of thin films, Kiessig fringes are superimposed on the general Fresnel reflectivity due to the constructive (or destructive) interference of the neutron waves reflected from inner and outer interfaces. For multilayers with a chemical periodicity Λ parallel to the z-direction, satellite (Bragg) reflections are observed at positions

$$Q_l \approx \sqrt{Q_c^2 + \left(l\frac{2\pi}{\Lambda}\right)^2} \tag{4}$$

where l is the order of the satellite reflection, and $Q_c \leq (2\pi l/\Lambda)$.

So far unpolarized NR and non-resonant X-ray reflectivity provide essentially the same results. Differences occur due to the fact that the coherent scattering cross section for neutrons is not a smooth function of the atomic number as it is for X rays, and that even different isotopes of the same element can be distinguished. The main difference, however, occurs when investigating magnetic films and multilayers either with PNR or with X-ray resonant magnetic scattering (XRMS). Here we will discuss only PNR, and compare with XRMS later on.

2.2 Basic features of specular polarized neutron reflectivity

Neutrons carry a magnetic moment $\boldsymbol{\mu}$, whose operator

$$\hat{\boldsymbol{\mu}} = \gamma_n \mu_N \hat{\boldsymbol{\sigma}} \tag{5}$$

is proportional to the Pauli spin operator $\hat{\boldsymbol{\sigma}}$ acting in a two-dimensional spin space and being represented by a set of 2×2 matrices: $\hat{\boldsymbol{\sigma}} = \{\hat{\sigma}_x, \hat{\sigma}_y, \hat{\sigma}_z\}$. Here $\gamma_n = -1.913$ is the gyromagnetic ratio of neutron and $\mu_N = e\hbar/2m_p c$ is the nuclear magneton. $\boldsymbol{\mu}$ interacts with the magnetic induction $\boldsymbol{B}$ providing a magnetic (Zeeman) potential for the neutrons. The corresponding operator of magnetic potential energy

$$\hat{V}_m = -(\hat{\boldsymbol{\mu}} \cdot \boldsymbol{B}) \tag{6}$$

is represented by a 2×2 matrix. In general, the magnetic induction $\boldsymbol{B}$ in a magnetic film consists of an external field $\boldsymbol{B}_0$ and a sample magnetization $\boldsymbol{M}$ vectors

$$\boldsymbol{B} = \boldsymbol{B}_0 + \mu_0 \boldsymbol{M} \tag{7}$$

where μ_0 is the permeability of free space.

Usually, the magnetic field is applied parallel to the sample surface, and due to the strong shape anisotropy the magnetization vector $\boldsymbol{M}$ is displayed within the magnetic film plane. Then the first term, $\boldsymbol{B}_0$, is identical inside and outside of the sample and does not contribute to the contrast in the reflection potential. Therefore, it can safely be neglected in the subsequent consideration. This can also be done in the more general case when the vector $\boldsymbol{B}_0$ has an arbitrary direction and the magnetization vector has also a component normal to the surface. The latter contributes to the inductance $\boldsymbol{B}_{\text{ext}}$ outside of the sample. However, the component of the inductance vector $\boldsymbol{B}_z$ normal to the surface is continuous and hence does not make a contrast for magnetic reflection. As a result, considering specular reflection one should neglect the first term in equation (7) and only take into account the neutron interaction with the lateral component $\boldsymbol{M}_L$ of magnetization vector. Below the superscript L will be silently anticipated.

Let us assume that in the z direction a half-infinite sample with a flat surface is in a F, single-domain state. Furthermore, we assume that the incoming monochromatic neutron beam can ideally be polarized collinear with the y axis, as indicated in the schematic outline of the scattering geometry in Figure 1. If the sample is also homogeneously magnetized along the y axis, then the potential energies of the neutron-sample interaction for alternative

polarization directions are the eigenvalues of the interaction operator in equation (6) and they are determined by the equation

$$V_{\pm} = V_n \pm V_m = \frac{2\pi\hbar^2}{m} N(b_n \pm b_m) \tag{8}$$

where V_n is the neutron – nuclei interaction potential, b_n is the nuclear and b_m is the magnetic scattering length, the (+) sign stands for the spin up, that is for neutrons polarized along, and the (−) sign for the spin-down state, that is for the neutrons polarized opposite to the (small) ambient field guiding the polarization directed along the y-axis. If, however, the magnetization makes an angle γ against the y-axis then the matrix of magnetic interaction $\hat{V}_m$ is not diagonal and the 3D Schrödinger equation reads:

$$\left\{-\frac{\hbar^2}{2m}\Delta + \hat{V}(z) - E\right\} |\Psi(\boldsymbol{r})\rangle = 0 \tag{9}$$

where the energy $E = \hbar^2 k^2/2m$ is conserved for elastic scattering. Owing to the fact that $\hat{V}(z)$ depends only on the transverse coordinate z the lateral projection $\boldsymbol{\kappa}$ of the wave vector $\boldsymbol{k}$ is also conserved and the two component wave function $|\Psi(\boldsymbol{r})\rangle$ is factorized into the product $|\Psi(\boldsymbol{r})\rangle = \exp\{i(\boldsymbol{\kappa}\boldsymbol{\rho})\}\,|\Psi(z)\rangle$, where $\boldsymbol{\rho}$ is the lateral projection of the radius-vector $\boldsymbol{r}$. The 2D vector of spin states $|\Psi(z)\rangle$ is represented by a column

$$|\Psi(z)\rangle = \begin{pmatrix} \Psi_+(z) \\ \Psi_-(z) \end{pmatrix} \tag{10}$$

with 2 elements $\Psi_{\pm}$ which denote probability amplitudes to find a neutron with positive, or correspondingly, negative spin projection onto the y-axis. Both spin states of the neutron are partially populated if the interaction matrix

$$\begin{pmatrix} V_{++} & V_{+-} \\ V_{-+} & V_{--} \end{pmatrix} = \frac{2\pi\hbar^2}{m} N \left[\begin{pmatrix} b_n & 0 \\ 0 & b_n \end{pmatrix} + \begin{pmatrix} b_y & b_x \\ b_x & -b_y \end{pmatrix} \right] \tag{11}$$

has non-diagonal elements $V_{\pm\mp} \propto b_x = b_m \sin\gamma$, proportional to the component of magnetic induction perpendicular to the polarization axis. The diagonal elements $V_{\pm\pm} \propto (b_n \pm b_y)$ depend on $b_y = b_m \cos\gamma$, that is on the inductance component parallel to the y-axis. Using equations (10) and (11) the Schrödinger equation in matrix form equation (9) can be explicitly written as a system of two coupled equations

$$\frac{\partial^2}{\partial z^2}\Psi_+(z) + \left[p_0^2 - \frac{2m}{\hbar^2}V_{++}(z)\right]\Psi_+(z) - \frac{2m}{\hbar^2}V_{+-}(z)\Psi_-(z) = 0 \tag{12}$$

$$\frac{\partial^2}{\partial z^2}\Psi_-(z) + \left[p_0^2 - \frac{2m}{\hbar^2}V_{--}(z)\right]\Psi_-(z) - \frac{2m}{\hbar^2}V_{-+}(z)\Psi_+(z) = 0 \tag{13}$$

where $p_0 = Q_z/2 = k\sin\alpha$ is the component of the neutron wave vector normal to the field boundary, and $p_0^2 = k^2 - \kappa^2$ due to the conservation of energy at elastic reflection.

This couple of linear differential equations can readily be solved, but the following first conclusions can be drawn before we present their formal solution in explicit form. When V_{ij} with $i \neq j$ are zero, a set of equations (12) and (13) are decoupled and only non-spin-flip (NSF) scattering occurs, that is the neutrons maintain their spin state upon interaction with the sample.

For NSF scattering, the magnetization vector $\boldsymbol{M}$ has to be oriented along the y axis. Alternatively, if V_{ij} with $i = j$ are zero, the V_{+-} and V_{-+} potentials flip the neutron spin from up to down and vice versa with equal efficiency. The spin-flip (SF) scattering is caused by a magnetization vector $\boldsymbol{M}$ projection M_x onto the x-axis. Thus, by distinguishing between NSF and SF scattering, a quantitative analysis of PNR data yields the x- and y components of $\boldsymbol{M}$, which combine to the magnitude and orientation of the magnetization vector $\boldsymbol{M}$ in the sample plane.

Note that in the configuration shown in Figure 1 only the absolute value of M_x, the magnetization projection, but not its sign, can be determined. In other words, from PNR data one cannot distinguish whether the magnetization is turned to the right or to the left with respect to the polarization analysis axis. This is due to the fact, that in equations (12) and (13) enter only the equal non-diagonal elements $V_{+-} = V_{-+}$. We shall see later that in the more general kinematic case, for example, via a 3D or vector PNR analysis, other matrix elements appear, for example $V_{z\pm}$ and $V_{\pm z}$, allowing a complete projection of the vector $\boldsymbol{M}$.

There are several important points to be noted here

- the effective potentials V_{++} and V_{--} for the y-component contain nuclear and magnetic contributions;
- the potentials V_{+-} and V_{-+} are solely of magnetic origin;
- PNR is not sensitive to any magnetization component parallel to the scattering vector;

- spin and orbital parts, which contribute to the total magnetization of the sample, cannot be distinguished.

Solutions of equations (12) and (13) have been provided by several authors (Felcher *et al.*, 1987; Majkrzak, 1989, 1991), and here we just briefly indicate the main steps leading to the explicit expression for PNR in the simplest case of reflection from a semi-infinite homogeneous film.

For the interaction matrix $V_{ij}(z) = V_{ij}$ constant within the magnetic media the general solution of equations (12) and (13) should, as usual, be written in the form of the superposition of plane waves e^{ipz} and e^{-ipz} with the wave numbers p and the amplitudes to be found. Substitution of this superposition into equations (12) and (13) results in a couple of linear homogeneous algebraic equations with respect to Ψ_+ and Ψ_-

$$[p^2 - p_0^2 + (p_n^2 + p_y^2)]\Psi_+(z) + p_x^2\Psi_-(z) = 0 \quad (14)$$

$$p_x^2\Psi_+(z) + [p^2 - p_0^2 + (p_n^2 - p_y^2)]\Psi_-(z) = 0 \quad (15)$$

where $p_n^2 = 4\pi N b_n$, $p_x^2 = 4\pi N b_x$, and $p_y^2 = 4\pi N b_y$. The couple of equations (14) and (15) may have a nontrivial solution only if its determinant is zero:

$$[(p^2 - p_0^2 + p_n^2) + p_y^2][(p^2 - p_0^2 + p_n^2) - p_y^2] - p_x^4 = 0 \quad (16)$$

This biquadratic equation has two pairs of solutions, $p = p_\pm$ and $p = -p_\pm$, where

$$p_\pm = \sqrt{p_0^2 - [p_n^2 \pm p_m^2]} \quad (17)$$

The first pair with $p = p_\pm$ corresponds to the wave propagation into the medium, while the second one, with $p = -p_\pm$, refers to their propagation in the opposite direction. Amplitudes of these waves will be found from boundary conditions, but now it is important to stress that despite the fact that each of equations (12) and (13) depends on the angle γ, they are only compatible if $p_m^2 = \sqrt{p_x^4 + p_y^4} = 4\pi N b_m$ and the wave numbers in equation (17) are independent of the tilt angle γ. This is the inherent property of the spin 1/2 operator which has only two eigenvalues $\pm 1/2$.

Equation (17) has a transparent physical meaning. Indeed, the neutron wave with the initial wave number p_0 experiences inside the magnetic medium a refraction effect such that the degeneracy with respect to the spin states is lifted. This effect is in analogy with the well-known birefringence in optically active media. For neutrons magnetic media are active due to the Zeeman effect, and spin components of the neutron wave in a magnetic field have different phase velocities $v_\pm = \hbar k_\pm / m$, where $k_\pm = \sqrt{\kappa^2 + p_\pm^2}$, and therefore different refractive indices. Correspondingly, there exist two critical wave numbers of the total reflection

$$p_{c\pm} = \sqrt{p_n^2 \pm p_m^2} \quad (18)$$

and two critical angles $\alpha_{c\pm}$:

$$p_{c\pm} = k \sin\alpha_{c\pm} = \sqrt{4\pi N(b_n \pm b_m)} \quad (19)$$

one for the positive and one for the negative spin projection onto the magnetic inductance direction in the medium. The wave number in and outside the medium and are illustrated in Figure 2.

In contrast to the refraction indices and the wave numbers $p_\pm$, the amplitudes of plane waves inside the magnetic medium vary with the tilt angle γ. Indeed, the general solution for the spin components of the wave function is written as a superposition

$$\Psi_+(z) = t_{++}e^{ip_+z} + t_{+-}e^{ip_-z} + r_{++}e^{-ip_+z} + r_{+-}e^{-ip_-z} \quad (20)$$

$$\Psi_-(z) = t_{-+}e^{ip_+z} + t_{--}e^{ip_-z} + r_{-+}e^{-ip_+z} + r_{--}e^{-ip_-z} \quad (21)$$

of two couples of plane waves with wave numbers satisfying equations (12) and (13) and propagating for $z \geq 0$ with two different phase velocities. The eight amplitudes $t_{\pm\pm}$, $t_{\pm\mp}$, $r_{\pm\pm}$, and $r_{\pm\mp}$ in this equations are to be determined from boundary conditions and hence depend on the initial spin state, which is dictated, in particular, by the angle γ. Owing to equations (14) and (15) not all wave amplitudes are independent, but linked by pairs $t_{-+} = t_{++}\tan(\gamma/2)$, $t_{+-} = -t_{--}\tan(\gamma/2)$, $r_{-+} = r_{++}\tan(\gamma/2)$, and $r_{+-} = -r_{--}\tan(\gamma/2)$. The first two terms in equations (20) and (21) correspond to the propagation of the (transmitted) waves from the front surface into the depth

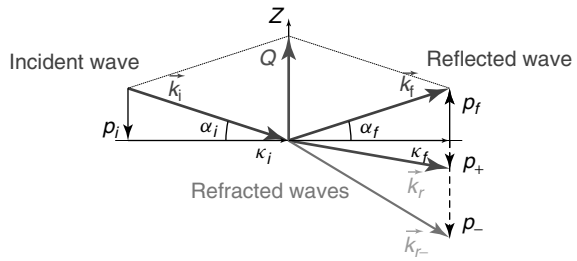

Figure 2. Kinematics of polarized neutron reflection. Owing to the invariance with respect to the lateral shift $\boldsymbol{\kappa}_f = \boldsymbol{\kappa}_i = \boldsymbol{\kappa}$, $p_f = p_i = p_0$, and $\alpha_f = \alpha_i = \alpha$. The wave vector component normal to the surface is split in magnetic medium due to the Zeeman effect.

of the medium. The second couple describes the propagation in the opposite direction, for example, waves reflected from the substrate in the case of the film with finite thickness. For semi-infinite media the latter waves are absent and one should set $r_{\pm\pm} = r_{\pm\mp} = 0$. Then each of the transmitted spin-wave components has to be matched with the corresponding one in free space. For neutrons initially polarized as shown in Figure 1 the spin component with positive spin projection is due to NSF reflection, while those with negative projection may appear due to SF reflection, and for $z \leq 0$ one has:

$$\Psi_+(z) = \mathrm{e}^{ip_0 z} + r_{++}\mathrm{e}^{-ip_0 z} \tag{22}$$

$$\Psi_-(z) = r_{-+}\mathrm{e}^{-ip_0 z} \tag{23}$$

If neutrons are initially polarized opposite to the guiding field, then

$$\Psi_+(z) = r_{+-}\mathrm{e}^{-ip_0 z} \tag{24}$$

$$\Psi_-(z) = \mathrm{e}^{ip_0 z} + r_{--}\mathrm{e}^{-ip_0 z} \tag{25}$$

Matching at $z = 0$ the spin components of the wave function from equations (20) and (21) and their derivatives with the corresponding quantities from either equations (22) and (23), or from equations (24) and (25) one readily obtains a set of equations for the transmission and reflection amplitudes:

$$t_{++} - t_{--}\tan\frac{\gamma}{2} = 1 + r_{++} \tag{26}$$

$$t_{++}\tan\frac{\gamma}{2} + t_{--} = r_{-+} \tag{27}$$

$$p_+ t_{++} - p_- t_{--}\tan\frac{\gamma}{2} = p_0(1 - r_{++}) \tag{28}$$

$$p_+ t_{++}\tan\frac{\gamma}{2} + p_- t_{--} = -p_0 r_{-+} \tag{29}$$

Solution of these equations immediately delivers expressions for the transmission amplitudes. They can be combined into the matrix so that for positive initial polarization one obtains:

$$\begin{pmatrix} t_{++} & t_{+-} \\ t_{-+} & t_{--} \end{pmatrix} = \begin{pmatrix} T_+\cos^2\frac{\gamma}{2} & T_-\sin\frac{\gamma}{2}\cos\frac{\gamma}{2} \\ T_+\sin^2\frac{\gamma}{2} & -T_-\sin\frac{\gamma}{2}\cos\frac{\gamma}{2} \end{pmatrix} \tag{30}$$

where $T_\pm$ are the Fresnel transmission amplitudes

$$T_\pm = \frac{2p_0}{p_0 + p_\pm} = \frac{2p_0}{p_0 + \sqrt{p_0^2 - p_n^2 \mp p_m^2}} \tag{31}$$

For alternative initial polarization one should match the wave function spin component in equations (20) and (21) with the corresponding ones in equations (24) and (25). This results in a set of another four equations similar to equations (26–29)

$$t_{++} - t_{--}\tan\frac{\gamma}{2} = r_{+-} \tag{32}$$

$$t_{++}\tan\frac{\gamma}{2} + t_{--} = 1 + r_{--} \tag{33}$$

$$p_+ t_{++} - p_- t_{--}\tan\frac{\gamma}{2} = -p_0 r_{+-} \tag{34}$$

$$p_+ t_{++}\tan\frac{\gamma}{2} + p_- t_{--} = p_0(1 - r_{--}) \tag{35}$$

Their solutions can also be collected into a matrix

$$\begin{pmatrix} t_{++} & t_{+-} \\ t_{-+} & t_{--} \end{pmatrix} = \begin{pmatrix} T_+\sin\frac{\gamma}{2}\cos\frac{\gamma}{2} & -T_-\sin\frac{\gamma}{2}\cos\frac{\gamma}{2} \\ T_+\sin^2\frac{\gamma}{2} & T_-\cos^2\frac{\gamma}{2} \end{pmatrix} \tag{36}$$

similar to that in equation (30).

Finally, using the equations in the preceding text one obtains a set of explicit expressions for the SF and NSF reflection amplitudes completing a reflectance matrix $\hat{R}$

$$\begin{pmatrix} r_{++} & r_{+-} \\ r_{-+} & r_{--} \end{pmatrix} = \begin{pmatrix} R_+\cos^2\frac{\gamma}{2} + R_-\sin^2\frac{\gamma}{2} & (R_+ - R_-)\cos\frac{\gamma}{2}\sin\frac{\gamma}{2} \\ (R_+ - R_-)\cos\frac{\gamma}{2}\sin\frac{\gamma}{2} & R_+\sin^2\frac{\gamma}{2} + R_-\cos^2\frac{\gamma}{2} \end{pmatrix} \tag{37}$$

In this equation, the amplitudes $R_\pm$ are just eigenvalues of the matrix $\hat{R}$ which is diagonal at $\gamma = 0, \pi$. Owing to equations (26–29) and equations (32–35) $R_\pm = R_\pm^F$, where

$$R_\pm^F = \frac{p_0 - p_\pm}{p_0 + p_\pm} = \frac{p_0 - \sqrt{p_0^2 - p_{c\pm}^2}}{p_0 + \sqrt{p_0^2 - p_{c\pm}^2}} \tag{38}$$

are the Fresnel amplitudes of reflection for neutrons ideally polarized along with, or opposite to the magnetic in-plane induction in the medium, and the critical wave numbers $p_{c\pm}$ are given in equation (19). From equation (38) it immediately follows that if $p_0 \leq p_{c+}$ then $|R_+| = 1$ and neutrons with positive projection of their spins onto the direction of the sample inductance experience the total reflection. If $p_0 \leq p_{c-} \leq p_{c+}$ then $|R_-| = |R_+| = 1$ and neutrons with alternative spin projection are also totally reflected.

With PNR it is possible to measure independently the NSF reflectivities $\mathcal{R}^{++} = |r_{++}|^2$, $\mathcal{R}^{--} = |r_{--}|^2$ and the SF reflectivities $\mathcal{R}^{+-} = \mathcal{R}^{-+} = |r_{\pm\mp}|^2$ which due to equation (37) are explicitly written as

$$\mathcal{R}^{++} = \frac{1}{4}|R_+(1 + \cos\gamma) + R_-(1 - \cos\gamma)|^2 \tag{39}$$

$$\mathcal{R}^{--} = \frac{1}{4}|R_+(1-\cos\gamma) + R_-(1+\cos\gamma)|^2 \quad (40)$$

$$\mathcal{R}^{+-} = \mathcal{R}^{-+} = \frac{1}{4}|R_+ - R_-|^2 \sin^2\gamma \quad (41)$$

Often a simplified version of PNR is used which does not require an analysis of the final spin states of reflected neutrons. Then the measured quantities are:

$$\mathcal{R}^{+} = \mathcal{R}^{++} + \mathcal{R}^{+-} = |R_+|^2 \cos^2\frac{\gamma}{2} + |R_-|^2 \sin^2\frac{\gamma}{2} \quad (42)$$

$$\mathcal{R}^{-} = \mathcal{R}^{--} + \mathcal{R}^{-+} = |R_+|^2 \sin^2\frac{\gamma}{2} + |R_-|^2 \cos^2\frac{\gamma}{2} \quad (43)$$

while one half of their sum,

$$\frac{1}{2}\{\mathcal{R}^{+} + \mathcal{R}^{-}\} = \frac{1}{2}\{|R_+|^2 + |R_-|^2\} = \mathcal{R}_0 \quad (44)$$

determines the reflectivity $\mathcal{R}_0$ of unpolarized neutrons. From the latter equation it is clearly seen that nuclear and magnetic reflection potentials can, in principle, be determined without polarized neutrons. Indeed, the reflectivity curve $\mathcal{R}(p_0)$ should show two plateaus. The one at $p_{c-} \le p_0 \le p_{c+}$, where one half of unpolarized neutrons are reflected. The other half is totally reflected at $p_0 \le p_{c-}$ where $\mathcal{R}_0 = 1$.

In that sense, polarization does not add new insight but allows an independent determination of $|R_+|$ and $|R_-|$. In a particular case $\gamma = 0$, that is when the neutron polarization is collinear with the magnetization direction,

$$\mathcal{R}^{++} = \mathcal{R}^{+} = |R_+|^2, \text{ and } \mathcal{R}^{--} = \mathcal{R}^{-} = |R_-|^2 \quad (45)$$

while $\mathcal{R}^{+-} = \mathcal{R}^{-+} = 0$.

PNR also allows to determine the orientation of the in-plane magnetic induction vector with respect to the neutron polarization axis fixed in the laboratory coordinate system. Indeed, owing to equations (42) and (43) the weights of the positive and negative spin components contributing to the reflectivities $\mathcal{R}^{\pm}$ is controlled by the angle γ, as illustrated in the next section.

2.3 Quantum spin state of neutrons

Here we stress again that there exist only two wave numbers p_{c+} and p_{c-} of the total reflection independent of the angle γ and determined by equation (19). At low angles of incidence α PNR may show two plateaus, at which the reflected intensity does not vary with the wave vector transfer projection $Q_z = 2p_0$. At the first plateau, in accordance with equations (42–43) and equation (38), the values of $\mathcal{R}^{\pm}$ are determined by the angle γ, while at the second one $\mathcal{R}^{\pm} = 1$. Such a behavior is a direct consequence of the splitting of the neutron quantum spin states in a magnetic field of the reflecting medium.

In a recent paper, Radu *et al*. (2005b) have carried out an experiment which provides direct and unambiguous evidence that, indeed, two critical angles $\alpha_{c\pm}$ for the total reflection exist, corresponding to the $\mathcal{R}^{+}$ and to the $\mathcal{R}^{-}$ reflectivity, respectively:

$$Q_c^{\pm} = 2p_{c\pm} = \sqrt{V_n \pm \frac{2m}{\hbar^2}|\boldsymbol{\mu}\|\boldsymbol{B}_s|} \quad (46)$$

The goal was to find a system where the angle between the neutron polarization and direction of the magnetization inside of the film can be fixed and controlled. Then the $\mathcal{R}^{+}$ and $\mathcal{R}^{-}$ reflectivities were measured to determine whether the position of the critical edges changes as a function of the angle γ, or whether the critical edges stay fixed, and only intensity redistributes between reflections $\mathcal{R}^{+}$ and $\mathcal{R}^{-}$ with change of γ. The easiest way to control the angle is to rotate the magnetic film and therefore the magnetization direction with respect to the neutron spin polarization, which remains fixed in space outside of the sample. This requires that the film should have a high remanent magnetization.

As magnetic film, a 100-nm thick Fe layer on a Si substrate was chosen. The results are shown in Figure 3. Two characteristics of the reflectivities are observed: first, the critical edges are fixed and independent of the in-plane rotation angle of the magnetization vector, and second the $\mathcal{R}^{-}$ intensity continuously increases at the expense of the $\mathcal{R}^{+}$ intensity as a function of the γ angle. The plain experimental results as well as a detailed fit unambiguously show that the critical edges Q_c^{+} and Q_c^{-} for total reflection of the two spin states are fixed and are independent of the orientation of the magnetization vector in the film, confirming that the neutron quantum spin states inside of the sample are referred to the quantization axis parallel or antiparallel to the magnetization vector.

The fact that the intensities at the first plateaus in Figure 3 depend on γ in accordance with equations (42) and (43) allows to determine the angle γ, if it is not known in advance. For that purpose it is convenient to use the difference,

$$\mathcal{R}^{+} - \mathcal{R}^{-} = \{|R_+|^2 - |R_-|^2\}\cos\gamma \quad (47)$$

which is directly proportional to $\cos\gamma$. For the same purpose one can also use the so-called spin asymmetry:

$$SA = \frac{\mathcal{R}^{+} - \mathcal{R}^{-}}{\mathcal{R}^{+} + \mathcal{R}^{-}} = \frac{|R_+|^2 - |R_-|^2}{|R_+|^2 + |R_-|^2}\cos\gamma \quad (48)$$

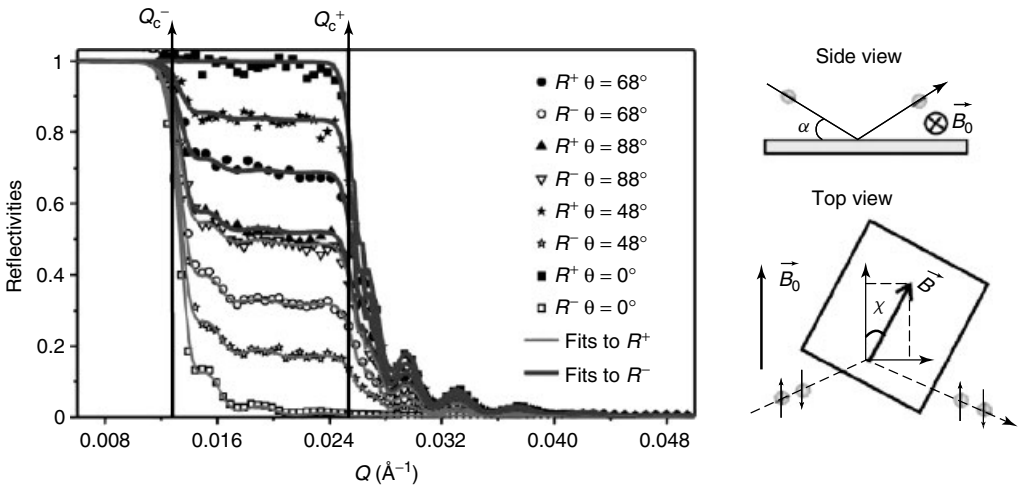

Figure 3. Experimental results of reflectivity curves $\mathcal{R}^+$ and $\mathcal{R}^-$ from a 100-nm-thick Fe film on a Si substrate. The reflectivities are plotted on a linear scale. The two sets of $\mathcal{R}^+$ (solid black symbols) and $\mathcal{R}^-$ (open black symbols) reflectivity curves were measured for four different angles γ (χ in author's (Radu *et al*., 2005b) notations) between the neutron polarization and the film magnetization vector (i.e., the magnetic induction B in the sample plane). The dark gray and light gray lines are the simulated $\mathcal{R}^+$ and $\mathcal{R}^-$ reflectivities, respectively. In panels on the right side, the experimental geometry is shown. The experiment demonstrate that, indeed, the critical edges Q_c^+ and Q_c^- do not depend on the tilt angle. (Reprinted figure with permission from F. Radu *et al*., *Phys Rev. B* Vol. 71, 214423, 2005. © 2005 by the American Physical Society.)

2.4 Phase shift and PNR with total polarization analysis

One can admit that equations (42) and (43) corresponding to the reduced version of PNR, as well as the equation for unpolarized reflectivity equation (44), contain only absolute values $|R_\pm|$ of reflectance amplitudes. On the other hand, below the total reflection edges the wave numbers $p_\pm$ and the amplitudes $R_\pm$ given in equation (38) are complex quantities. The latter ones can be presented as $R_\pm = |R_\pm| \exp(i\chi_\pm)$, where $\chi_\pm$ are phases missing in equations (42–44). They, however, enter the more general equations (39–41) providing at $\gamma \neq 0$ an access to interesting phenomena of the interference between spin states inside a magnetic media.

In order to demonstrate the role of the phases, let us consider the case when the polarization axis is normal to the vector of inductance, that is $\gamma = \pm\pi/2$. Then $\mathcal{R}^{++} = \mathcal{R}^{--}$, $\mathcal{R}^{+-} = \mathcal{R}^{-+}$, and reflectivities

$$\mathcal{R}^{\pm\pm} = \frac{1}{4}|R_+ + R_-|^2 = \frac{1}{4}\{|R_+|^2 + |R_-|^2 + 2|R_+||R_-|\cos\chi_{+-}\} \quad (49)$$

$$\mathcal{R}^{\pm\mp} = \frac{1}{4}|R_+ - R_-|^2 = \frac{1}{4}\{|R_+|^2 + |R_-|^2 - 2|R_+||R_-|\cos\chi_{+-}\} \quad (50)$$

contain the term, proportional to $\cos\chi_{+-}$, where $\chi_{+-} = \chi_+ - \chi_-$. The evolution of the phases $\chi_\pm$ and their difference is sketched in Figure 4(a). For a semi-infinite magnetic media with purely real nuclear SLD, each of the phases turns to zero above the corresponding critical edges, while they reach the maximum value $\chi_\pm = \pi$ at $p_0 = 0$. As a result, within the window $p_{c-} \leq p_0 \leq p_{c+}$ the difference $\chi_{+-} = \chi_+(p_0)$ increases when p_0 decreases. In this range the SF reflectivity, $\mathcal{R}^{\pm\mp}$, also increases and reaches maximum [1] at $p_0 = p_{c-}$, while the NSF reflectivity, $\mathcal{R}^{\pm\pm}$, decreases, but in a way that their sums $\mathcal{R}^{\pm} = \mathcal{R}^{\pm\pm} + \mathcal{R}^{\pm\mp}$ stay almost constant at the level of 0.5, as seen in Figure 4(b). Within the range $p_0 \leq p_{c-} \leq p_{c+}$ one has

$$\mathcal{R}^{\pm\pm} = \cos^2\frac{\chi_{+-}}{2}, \text{ and } \mathcal{R}^{\pm\mp} = \sin^2\frac{\chi_{+-}}{2} \quad (51)$$

This means that due to the constructive interference between spin states, NSF reflectivities at $p_0 \to 0$ increase and tend to one, while SF reflectivities vanish because of destructive interference.

The term containing the phase difference can be separated from other contributions to PNR just by subtraction:

$$\mathcal{R}^{\pm\pm} - \mathcal{R}^{\pm\mp} = |R_+||R_-|\cos\chi_{+-} \quad (52)$$

Therefore, in order to determine both the absolute values and the phase shift one needs to carry out additional measurements with different angles between the polarization axis and the inductance direction.

If neither the angle γ, nor nuclear and magnetic potentials (for instance, in the case of alloys, or complex compounds)

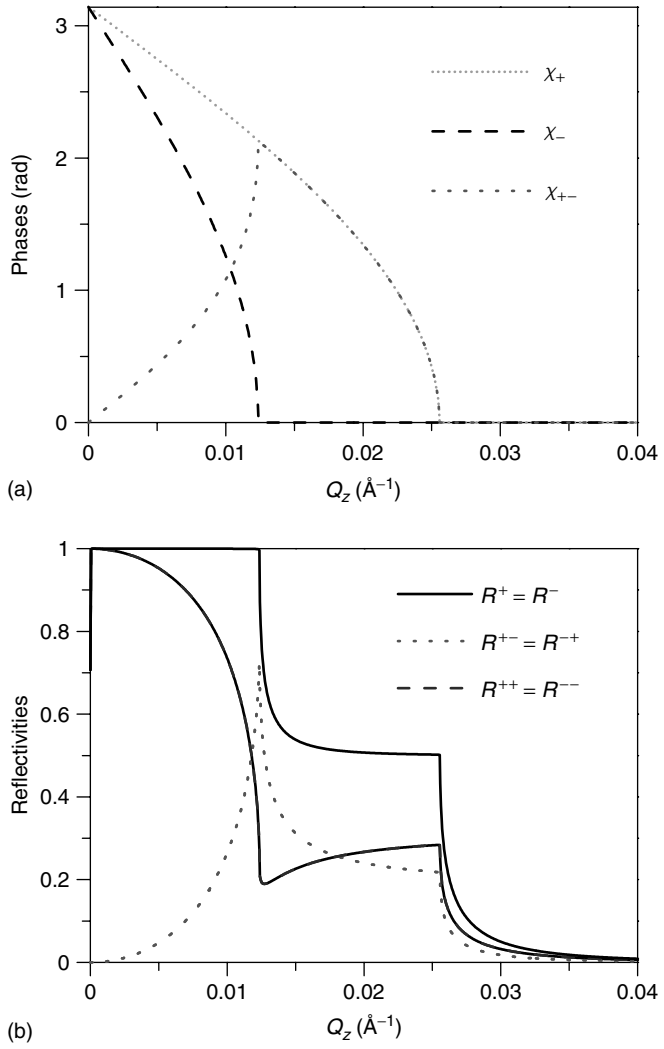

Figure 4. (a): Evolution of phases $\chi_+(Q_z)$, $\chi_-(Q_z)$ of reflection amplitudes $R_\pm = |R_\pm| \exp(i\chi_\pm)$ and the phase difference $\chi_{+-} = \chi_+ - \chi_-$ calculated for reflection from iron. At $Q_z \to 0$ the phases $\chi_\pm \to \pi$. (b): Non-spin-flip (dashed) and spin-flip (dotted) reflectivities calculated for iron with magnetization turned at 90° with respect to the polarization axis. The continuous line shows the sum $R^+ = R^- = R^{++} + R^{+-}$ (middle line in Figure 3). Note the sharp maximum of spin-flip reflectivities at $Q_z = Q_c^-$.

are a priory known, then the parameters can be found via the fitting of data to the theoretical model. For the semi-infinite homogeneous sample the nonlinear fitting routine may be rather stable providing a set of parameters even if only two reflectivities $\mathcal{R}^\pm$ are available. In this case, the phases vary in a restricted range $0 \le \chi^\pm \le \pi$ and are uniquely determined via, for example, the nuclear and magnetic SLDs.

However, this is not the case for more complicated magnetic SLD profiles of interest or even for a single magnetic film of a thickness d placed onto a non-magnetic substrate. In the latter case, all the considerations in the preceding text are valid, and one can easily find the reflection amplitudes $R_\pm$ just by matching the spin components of the wave functions at the outer surface and at the interface with the substrate. This will result in the explicit equation for the reflectances

$$R_\pm = \frac{R_\pm^F + R_{s\pm}^F e^{2i\varphi_\pm}}{1 + R_\pm^F R_{s\pm}^F e^{2i\varphi_\pm}} \tag{53}$$

Here $\varphi_\pm = p_\pm d$, $R_\pm^F$ are the reflection amplitudes from the front face of the sample are given in equation (38), and $R_{s\pm}^F$ are the Fresnel amplitudes for the neutron wave reflected from the interface between the film and the substrate

$$R_{s\pm}^F = \frac{p_\pm - p_s}{p_\pm + p_s} \tag{54}$$

These equations are similar to equation (38), in which the incoming wave number in the vacuum p_0 is substituted by $p_\pm$ in the magnetic film, and $p_s = \sqrt{p_0^2 - p_c^2}$ is the wave number of the neutron propagation in the substrate with the SLD $(Nb)_c = p_c^2/4\pi$.

Traveling through the film from the surface to the substrate each of the neutron spin-wave components now gains the phase factor $\varphi_\pm = p_\pm d$. This leads to interference phenomena manifested in the oscillation of the reflection coefficients (so-called Kiessig fringes). Such oscillations above the total reflection region can be recognized in Figure 3 and are due to the finite thickness of the iron film deposited on a silicon substrate.

Interestingly such oscillations can be observed (te Velthuis, Felcher, Blomquist and Wäppling, 2001; Toperverg, Lauter and Lauter-Pasyuk, 2005a) also in the range $p_{c-} \le p_0 \le p_{c+}$, if the magnetization is not collinear with the polarization axis. In this case, they are due to the interference between different spin components of the neutron wave transmitted into the film and reflected from the substrate. An example of such oscillations is given in Figure 5, where SF and NSF reflectivities are plotted against the wave vector transfer. The experiment (Toperverg, Lauter and Lauter-Pasyuk, 2005a) was carried out on a sample consisting of ^{57}Fe film deposited on a sapphire substrate with the critical wave number $p_c = 8.46 \times 10^{-3}$Å^{-1}. The isotope of iron is chosen due to the fact, that the nominal value for $p_{c+} = 9.35 \times 10^{-3}$Å^{-1} is close to the value of p_c for the substrate, while for the negative spin projection $p_{c-} = i6.13 \times 10^{-3}$Å^{-1} is imaginary. Hence, the positive spin component can totally be reflected from the front face of the sample with almost no account of the interface with the substrate. In contrast, total external reflection of the negative spin component can only be due to the substrate optical potential. But this means that at $p_0 \le p_c$ the negative spin component acquires an additional phase shift with respect to the positive one. In the particular case

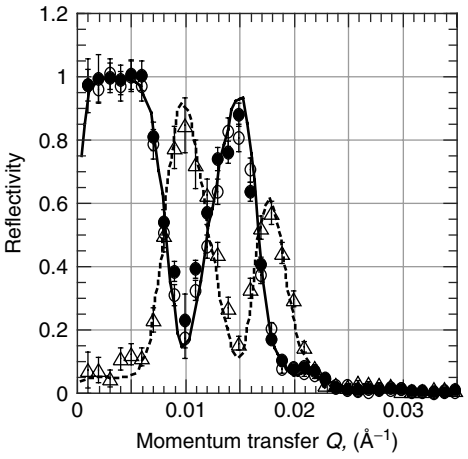

Figure 5. Pseudoprecession oscillations in SF (triangles) and NSF (circles) reflectivities recorded from a ^{57}Fe film magnetized perpendicular to the neutron polarization vector. (Reproduced from Toperverg *et al*., 2005, with permission from Elsevier © 2005.)

of complete compensation, that is if $p_c = p_{c+}$ and $p_{c-} = 0$, the wave number $p_- = p_0$ and $p_+ = p_s$. Then, owing to equation (38) and equation (54) $R_-^F = R_{s+}^F = 0$, while $R_+^F = R_{s-}^F = |R_{s-}^F| \exp(i\chi_s)$. Below the total reflection in accordance with equation (53) this yields $R_+ = \exp(i\chi_s)$ and $R_- = \exp(2i\varphi_0 + i\chi_s)$, where φ_0 is the phase shift due to the film, χ_s is the phase shift due to the substrate, and in equation (51) $\chi_{+-} = -2\varphi_0 = -2p_0 d$.

In Toperverg, Lauter and Lauter-Pasyuk (2005a) the authors argue that at such a reflection the vector of the neutron polarization $\boldsymbol{P}$ rotates around the film inductance $\boldsymbol{B}$ direction for an angle $2\varphi_0$. This phenomenon is called the *Larmor pseudo-precession*.

2.5 Theoretical framework of polarized neutron reflection from multilayers

From the reflected intensities the potential profile along the sample normal can be retrieved and hence PNR provides a tool for layer-by-layer magnetometry (Rücker *et al*., 2002). From general symmetry arguments it follows that equations (39–43) are also valid in the case of any layered structure with collinearly magnetized layers. In this case, each amplitude R_+ and R_- in equations (39–43) can be calculated with a standard Parratt recursion routine (Parrat, 1954), or via the matrix formalism (Born and Wolf, 1975). The net magnetization may certainly make any angle γ with the direction of polarization analysis. Interface roughness, as it occurs in all realistic samples, is best taken into account by a large number of infinitely thin slabs of a gradually varying potential across an interface (Ankner, Majkrzak and Satija, 1993; Schreyer, 1994), or by assuming a specific interface profile, as in the Névot-Croce model (Névot and Croce, 1980).

If, however, the magnetization direction varies as a function of the z coordinate, for example from layer to layer, then equations (39–43) are not valid anymore. This is due to the fact that the reflectivity cannot be characterized by simply a single angle between magnetization and neutron polarization vectors (Toperverg, Rühm, Donner and Dosch, 1999) because of the PNR signal carries an information not only on the total magnetization direction, but also on its vectorial depth profile. This can be illustrated by a simple example of a bilayer with equal layers but with layer inductions $\boldsymbol{B}_1$ and $\boldsymbol{B}_2$ which make a certain angle γ against each other. Then, if $|\boldsymbol{B}_1| = |\boldsymbol{B}_2|$ the net inductance vector $\boldsymbol{B} = \boldsymbol{B}_1 + \boldsymbol{B}_2$ is just the sum of two vectors. However, it is intuitively clear that the reflectivity is sensitive not only to the direction of the vector $\boldsymbol{B}$ but also to the order of $\boldsymbol{B} = \boldsymbol{B}_1$ and $\boldsymbol{B}_2$ in a sequence. Indeed, if for instance, layers are sufficiently thick, so that neutrons can be totally reflected just from the top layer, then namely, the top layer magnetization, but not the net magnetization direction, will determine the reflectivities at the total reflection range. Well above the total reflection, the neutron wave penetrates deep into the system and the role of the bottom-layer magnetization gradually increases for an elevated angle of incidence. This consideration shows that for noncollinear structures the angle γ between the polarization direction and the vector $\boldsymbol{B}$ does not solely determine the behavior of the reflected intensity. Formally, there also exists a direction given by the direct product $[\boldsymbol{B}_1 \times \boldsymbol{B}_2]$. This vector alters its direction if the layers are interchanged and thus it is sensitive to the order of the induction vectors in a sequence.

If the direction of the vector $\boldsymbol{B}(z)$ depends on the z-coordinate, then the way of solving of equations (12) and (13) given in the preceding text has to be reconsidered. In the past, several methods were developed to treat this problem. The earliest matrix formalism was provided by Blundell and Bland (1992), a generalized matrix representation has been described by Radu and Ignatovich (1999) and Rühm, Toperverg and Dosch (1999) have implemented a so-called Supermatrix formalism (Toperverg, Rühm, Donner and Dosch, 1999), and a comprehensive overview of the theoretical treatment of PNR has been provided by Fermon and Menelle (1999).

Usually, in order to analyze experimental data for thin films and multilayers, theoretical reflectivities have to be calculated assuming a potential well structure $V_{ij}(z)$ composed of slabs of constant potential with sharp interfaces. Then a Parratt-type recursion formalism determines all transmitted and reflected amplitudes at each interface. Here we briefly sketch the Parratt routine adjusted for polarized neutron reflection from a sequence of layers with arbitrary arrangement of layer magnetization vectors. This,

so-called superiterative algorithm (Toperverg, 2002a,b) is better suited for numerical calculations (Kentzinger, Toperverg and Rücker, 2003), than those referred to above (Radu and Ignatovich, 1999; Rühm, Toperverg and Dosch, 1999; Fermon and Menelle, 1999).

Following the standard procedure let us divide the slab, as in the preceding text, into slices according to

$$\hat{V}(z) = \sum_{l=1}^{N} \{\hat{V}_{nl} + \hat{V}_{ml}\} \tag{55}$$

where, $\hat{V}_{nl} = \hat{1} V_{nl}$ for $z_{l-1} \leq z < z_l$ and V_{nl} is the nuclear optical potential (if the interaction with the nuclear spin is neglected) of the l^{th} slice, and $\hat{1}$ is the unit matrix in the spin space [2]. The magnetic part of the interaction operator $\hat{V}_{ml} = -\hat{\boldsymbol{\mu}} B_l$ is defined as in the preceding text.

Let us first note, that one can avoid writing down the Schödinger equation (9) in a particular (laboratory) coordinate system as a couple of equations (12) and (13), but instead, represent the solution of equation (9) just above the surface in the following general form

$$|\psi_0(z)\rangle = \{e^{ip_0 z} + e^{-ip_0 z}\hat{R}\}|\Psi_0^i\rangle \tag{56}$$

where $|\Psi_0^i\rangle$ is the initial vector of neutron spin states at the surface, $\hat{R}$ is the 2×2 reflectance matrix transforming spin components of the incoming wave function $|\Psi_0^i\rangle$ into the components of the reflected wave $|\psi_R(0)\rangle = \hat{R}|\Psi_0^i\rangle$.

In the laboratory coordinate system, an explicit expression for the elements $r_{\pm\pm}$ and $r_{\pm\mp}$ of the reflectance matrix $\hat{R}$ and assuming a semi-infinite magnetic sample is given in equation (37).

The boundary conditions at the interfaces between layers can be written in a compact form, if one keeps the interaction potential operator $\hat{V}(z)$ in equation (9) in the vector form of equation (55) independent of the coordinate system and if one applies the algebraic rules of the Pauli operators. To do so, one should just notice that the vector of states $|\psi_l(z)\rangle$ inside any layer l can be written via the vector of initial states $|\Psi^i(0)\rangle$ in the same way as in equation (56) $|\psi_l(z)\rangle = \hat{\mathcal{S}}_l(z)|\Psi_0^i\rangle$, where

$$\hat{\mathcal{S}}_l(z) = \{e^{i\hat{\varphi}_l(z)}\hat{t}_l + e^{-i\hat{\varphi}_l(z)}\hat{r}_l\} \tag{57}$$

and the matrices $\hat{t}_l$ and $\hat{r}_l$ take into account the transformation of the neutron spin-wave components at refraction through and reflection from the interfaces. Here $\hat{\varphi}_l(z) = \hat{p}_l(z - z_{l-1})$ are the phase matrices, and $z_0 = 0$. The wave number matrix $\hat{p}_l = \sqrt{p_0^2 - \hat{p}_{cl}^2}$ is diagonal if the quantization axis is chosen parallel to the vector $\boldsymbol{B}_l$. Then its eigenvalues $p_{l\pm} = \sqrt{p_0^2 - p_{cl\pm}^2}$ are determined by the critical wave numbers $p_{cl\pm}^2 = 4\pi(nb_{nl} \mp nb_{ml})$, where nb_{nl} and nb_{ml} are the nuclear and magnetic scattering length densities within the l^{th} layer. The exponents in equation (57) are generally represented as (Landau and Lifshits, 1977)

$$e^{\pm i\hat{\varphi}_l(z)} = \frac{1}{2}\{[e^{\pm i\varphi_{l+}(z)} + e^{\pm i\varphi_{l-}(z)}] + (\hat{\boldsymbol{\sigma}}\boldsymbol{b}_l)[e^{\pm i\varphi_{l+}(z)} - e^{\pm i\varphi_{l-}(z)}]\} \tag{58}$$

where $\boldsymbol{b}_l = \boldsymbol{B}_l/|\boldsymbol{B}_l|$ and $\varphi_{l\pm} = p_{l\pm}(z - z_{l-1})$. These exponents are also diagonal along with the matrix $\hat{p}_l$.

The transmittance, $\hat{t}_l$, and reflectance, $\hat{r}_l$ matrices are, however, diagonal in the same representation as the matrix $\hat{p}_l$ only for a collinear magnetization arrangement. In general, the components of those matrices are to be found via the continuity conditions for the wave function spin components and their first derivative at subsequent interfaces

$$|\psi_{l+1}(z_{l+1})\rangle = |\psi_l(z_{l+1})\rangle \tag{59}$$

$$|\psi'_{l+1}(z_{l+1})\rangle = |\psi'_l(z_{l+1})\rangle \tag{60}$$

These conditions together with equation (57) immediately deliver the following couple of matrix equations

$$\hat{t}_{l+1} + \hat{r}_{l+1} = e^{i\hat{\varphi}_l}\hat{t}_l + e^{-i\hat{\varphi}_l}\hat{r}_l \tag{61}$$

$$\hat{p}_{l+1}\{\hat{t}_{l+1} - \hat{r}_{l+1}\} = \hat{p}_l\{e^{i\hat{\varphi}_l}\hat{t}_l - e^{-i\hat{\varphi}_l}\hat{r}_l\} \tag{62}$$

where $\hat{\varphi}_l = \hat{p}_l d_l$ is the matrix of the phase shift gained over the layer thickness d_l. The sequence of these coupled equations should, as usual, be completed by adding two more boundary conditions: one for the front interface (usually vacuum) and a second one for the back interface N (usually the substrate):

$$\hat{1} + \hat{R} = \hat{t}_1 + \hat{r}_1 \tag{63}$$

$$p_0(\hat{1} - \hat{R}) = \hat{p}_1(\hat{t}_1 - \hat{r}_1) \tag{64}$$

$$\hat{T} = e^{i\hat{\varphi}_N}\hat{t}_N + e^{-i\hat{\varphi}_N}\hat{r}_N \tag{65}$$

$$\hat{p}_s\hat{T} = \hat{p}_N(e^{i\hat{\varphi}_N}\hat{t}_N - e^{-i\hat{\varphi}_N}\hat{r}_N) \tag{66}$$

where the wave number operator in the substrate is denoted as $\hat{p}_s$.

The set of equations (61–66) look exactly the same as those (Parrat, 1954) for spinless particles and the only difference is that each equation is written as a 2×2 matrix, which actually represents four equations for the matrix elements. However, one may not write them explicitly but rather use general rules of matrix algebra and directly solve the system of equations (61–66) for the reflectance $\hat{r}_l$ matrices and transmittance $\hat{t}_l$ matrices, including $\hat{R}$ and $\hat{T}$.

One of the ways to find a final solution is to apply a customarily used matrix formalism (Born and Wolf, 1975) and express each couple of equations (61–62) as one supermatrix (SM) equation. Then multiplication of supermatrices determined for each layer results in a global supermatrix, linking together $\hat{R}$ and $\hat{T}$ matrices in equations (63–66). This allows to express the elements of $\hat{R}$ and $\hat{T}$ via the elements of the global supermatrix.

Despite of a certain elegancy and transparency for the theoretical analysis, the SM approach is 'ill-conditioned' and may cause numerical problems for a large number and/or large thicknesses of the layers. The source of the problems is indicated in (Toperverg, 2002a) where instead of SM formalism a generalization of the Parratt formalism (Parrat, 1954) was proposed. Such a generalization is based on the same principles, as the SM routine, although it uses another algorithm for calculations. The trick is that the matrix equations (61) and (62) can be immediately solved with respect to the ratio $\hat{R}_l = (\hat{r}_l \hat{t}_l^{-1})$ written as

$$\hat{R}_l = \mathrm{e}^{i\hat{\varphi}_l}\{(\hat{1} - \hat{p}_l^{-1}\hat{p}_{l+1}) + (\hat{1} + \hat{p}_l^{-1}\hat{p}_{l+1})\hat{R}_{l+1}\} \times \{(\hat{1} + \hat{p}_l^{-1}\hat{p}_{l+1}) + (\hat{1} - \hat{p}_l^{-1}\hat{p}_{l+1})\hat{R}_{l+1}\}^{-1}\mathrm{e}^{i\hat{\varphi}_l} \quad (67)$$

These equations can easily be solved via recursion procedures, beginning from the values $\hat{R}_{N+1} = 0$ and ending by finally computing the reflectance matrix $\hat{R} = \hat{R}_0$.

Additionally, one can calculate, if necessary, the transmittance matrices via the recursive solution of the following set of equations

$$\hat{t}_{l+1} = \{\hat{1} + \hat{R}\}^{-1}\{\hat{1} + \mathrm{e}^{i\hat{\varphi}_l}\hat{R}_l\mathrm{e}^{i\hat{\varphi}_l}\}\mathrm{e}^{i\hat{\varphi}_l}\hat{t}_l \quad (68)$$

In this case, the recursion begins with $\hat{t}_0 = \hat{1}$ and ends with $\hat{t}_{N+1} = \hat{T}$. Finally, the reflectance matrices $\hat{r}_l = \hat{R}_l\hat{t}_l$ can also be found via computing the reflectance matrix $\hat{R}_l$ and $\hat{t}_l$. In analogy to the SM approach, this method may be called *Super-Recursion* (*SR*), or Matrix–Recursion (MR) formalism, because it uses recursion routines for solution of coupled matrix equations. The SR formalism allows to compute spin components of the reflectance matrix for arbitrary orientations between magnetization directions in subsequent layers.

In the collinear case, all partial reflectance matrices $\hat{R}_l$ can simultaneously be diagonalized along with the total reflectance matrix $\hat{R}$ via choosing the quantization axis parallel to the sample inductance vector. Then equation (67) reduces to two unlinked sets of equations: one set for eigenvalues R_{l+} and the other for R_{l-} of the reflectance matrices $\hat{R}_l$. Solving these sets of equations one can express the eigenvalues $R_\pm$ of the reflectance matrix $\hat{R}$ via the Fresnel reflectance amplitudes $R^F_{l\pm}$ as given in equation (38) and phases $\varphi_{l\pm}$ for positive and negative spin projections onto the inductance direction. An example of solutions of equation (67) for eigenvalues $R_\pm$ is presented in equation (53).

2.6 Vector polarization analysis

In an arbitrary coordinate system the reflectance matrix $\hat{R}$ contains all four elements $r_{\pm\pm}$ and $r_{\pm\mp}$ which are expressed via the eigenvalues $R_\pm$ and the angle γ as given in equation (37). As soon as those elements are found, one can easily compute the NSF and the SF reflection coefficients: $\mathcal{R}^{\pm\pm} = |r_{\pm\pm}|^2$ and $\mathcal{R}^{\pm\mp} = |r_{\pm\mp}|^2$ as it has been demonstrated in the preceding text in equations (39–41) and in equations (49) and (50) for a single film. However, as it was already pointed out, the reflectivity for the system with noncollinear magnetization arrangement is no longer characterized solely by the angle γ between the net magnetization of the system and the polarization analysis direction. In particular, a SF signal may occur even at $\gamma = 0$ carrying a signature of noncollinearity.

The kinematics depicted in Figure 1 does not exhaust all the capabilities of PNR. Indeed, the classical 3D vector of the neutron polarization $\boldsymbol{P}$ is generally defined as mean value $\boldsymbol{P} = \frac{1}{2}\langle\hat{\boldsymbol{\sigma}}\rangle$ of the neutron spin operator over spin states in the neutron beam. In an arbitrary coordinate system, this vector may have all three Cartesian projections P_x, P_y and P_z being nonzero with $|\boldsymbol{P}| = \sqrt{P_x^2 + P_y^2 + P_z^2} \leq 1$. In the particular case sketched in Figure 1, the polarization vector is initially set along the y axis, and only the projection P_y of the final polarization vector $\boldsymbol{P}$ is assumed to be probed. Two other undetermined components P_z and P_x are, nonetheless, quite important even in the case of reflection from semi-infinite media, or a single magnetic film.

This becomes clear if one admits that the polarization vector of neutrons may not only change its length, but also change direction precessing around a field direction.

The 1D analysis of the polarization vector, which probes neutron spin states along only one direction, cannot unambiguously distinguish between those processes. Then the missing information does not allow to uniquely determine the direction of the vectors $\boldsymbol{B}_l$ in complicated noncollinear structures. In the simplest case covered by equation (37), it is, for example, not possible to discriminate the tilt angle γ from $\gamma + \pi$. This can already be seen from the fact, that equation (37) contains only $\sin^2\frac{\gamma}{2}$ and $\cos^2\frac{\gamma}{2}$, but not $\sin\gamma$. The latter determines whether the magnetization vector in Figure 1 is tilted to the left, or to the right with respect to the y-axis.

The method of 3D vector polarization analysis has been invented by Rekveldt (1971) and Drabkin, Okorokov and

Runov (1972) for spin analysis of neutron spin states in the beam passing through F materials. Later on, the method was extended to small angle by Okorokov and Runov (2001) and inelastic neutron scattering by Tasset (2001), while its application in PNR studies was proposed in Toperverg, Nikonov, Lauter-Passyuk and Lauter (2001).

Here, we consider the general principles of 3D PNR analysis which allows to evaluate all three projections of the outgoing polarization vector by arbitrarily setting the initial polarization vector. The corresponding consideration is based on equations for PNR which can be written down in the tensor form independent of a particular choice of the coordinate system. Such an opportunity is already provided by equation (56), where the reflectance matrix $\hat{R}$ transforms the spin components of the incoming neutron $|\Psi_0^i\rangle$ into the components of reflected wave $|\psi_R(0)\rangle = \hat{R}|\Psi_0^i\rangle$ in the immediate vicinity of the surface. In this range, $|\Psi_0^i\rangle$ is determined by the spin state of the incident polarized neutrons and field conditions on its path to the sample. Observable quantities, for example, spin components of the neutron flux density, are meant as statistical averages over the initial polarized neutron states and over the neutron traces to the sample. Correspondingly, neutrons reflected from the sample propagate trough the analyzing system to the detector. The result of this propagation, analysis, and detection is described by the projection $\langle\Psi_0^f|\psi_R(0)\rangle$ of the reflected vector of neutron states $|\psi_R(0)\rangle$ onto the vector of states $\langle\Psi_0^f|$ possible due to the analyzing system. The latter is also a statistical device, and the reflected flux density has to be considered as a result of statistical averaging of the probability $|\langle\Psi_0^f|\psi_R(0)\rangle|^2$ over the states of the analyzing system and the flight passes taken by the outgoing neutrons. After all averaging, the measurable reflectivity $\mathcal{R}$ is given by the expectation value

$$\mathcal{R} = \overline{|\langle\Psi_0^f|\hat{R}|\Psi_0^i\rangle|^2} = \mathrm{Tr}\{\hat{\rho}^f\hat{R}\hat{\rho}^i\hat{R}^+\} \tag{69}$$

where $\hat{\rho}^i$ and $\hat{\rho}^f$ are the spin-density matrices of incoming and outgoing neutron states at the sample surface

$$\hat{\rho}^i = \overline{|\Psi^i(0)\rangle\langle\Psi^i(0)|} = \frac{1}{2}\left\{1 + (\boldsymbol{P}^i\hat{\boldsymbol{\sigma}})\right\} \tag{70}$$

$$\hat{\rho}^f = \overline{|\Psi^f(0)\rangle\langle\Psi^f(0)|} = \frac{1}{2}\left\{1 + (\boldsymbol{P}^f\hat{\boldsymbol{\sigma}})\right\} \tag{71}$$

Here the 2×2 density matrices are expanded over a set of matrices which includes the unit matrix and three orthogonal Pauli matrices which complete the vector $\hat{\boldsymbol{\sigma}}$. Such the expansion provides a parameterization of the density matrix with the incoming 3D polarization vector, $\boldsymbol{P}^i = \boldsymbol{b}_i|\boldsymbol{P}^i|$, and the 3D vector $\boldsymbol{P}^f = \boldsymbol{b}_f\boldsymbol{P}^f$ of polarization efficiency. The unit vectors $\boldsymbol{b}_i$ and $\boldsymbol{b}_f$ set the directions in which the neutrons are polarized and analyzed, while the absolute values $|\boldsymbol{P}^i| \leq 1$ and $|\boldsymbol{P}^f| \leq 1$ show the degree of the incident neutron beam polarization and efficiency of the analyzing device in corresponding directions.

Parameterizing the 2×2 reflectance matrix $\hat{R} = R(\hat{\boldsymbol{\sigma}})$ in the same manner as in equations (70) and (71) yields an invariant representation:

$$\hat{R} = R + (\boldsymbol{R}\hat{\boldsymbol{\sigma}}) \tag{72}$$

via the complex scalar $R = \frac{1}{2}\mathrm{Tr}\{\hat{R}\}$, and the vector $\boldsymbol{R} = \frac{1}{2}\mathrm{Tr}\{\hat{R}\hat{\boldsymbol{\sigma}}\}$ with three, generally nonzero, complex Cartesian projections R_x, R_y and R_z. These projections, as well as the scalar R, can readily be expressed via the (complex) eigenvalues $R_\pm$ of the matrix $\hat{R}$ and components of the (complex) unit vector $\boldsymbol{r} = \boldsymbol{R}/\sqrt{\boldsymbol{R}^2}$. The latter determines the coordinate system in which the matrix

$$\hat{R} = \frac{1}{2}[(R_+ + R_-) + (\boldsymbol{r}\boldsymbol{\sigma})(R_+ - R_-)] \tag{73}$$

is diagonal. One can also recognize that the scalar R and the length of the vector $\boldsymbol{R}$ are independent of the choice of the coordinate. They are expressed via the matrix invariants: the trace $(R_+ + R_-) = 2R$ and determinant $R^2 - \boldsymbol{R}^2 = R_+R_-/4$ of the matrix $\hat{R}$ so, that $\boldsymbol{R}^2 = (R_+ - R_-)^2/4$.

Note that in a collinear magnetization arrangement the direction of the vector $\boldsymbol{R}$ coincides with that of the inductance. In a more general case, it has all three projections, for example, normal to the surface, and depends on the wave vector transfer. Therefore, the reflectance matrix cannot be diagonalized in any fixed coordinate system independent of Q_z.

One of the advantages of the representation in equation (73) is that it is invariant with respect to the choice of the coordinate system. The other is that one can apply the rules of the Pauli matrix algebra and after substitution of equations (70–72) into equation (69) and calculating the traces, one readily obtains (Toperverg, Rühm, Donner and Dosch, 1999) the following equation for the reflectivity $\mathcal{R} = \mathcal{R}(\boldsymbol{P}^i, \boldsymbol{P}^f)$ in the invariant tensor form:

$$\mathcal{R} = \mathcal{R}(P^i_\mu, P^f_\nu) = \mathcal{R}_0 + \mathcal{R}^i_\mu P^i_\mu + \mathcal{R}^f_\mu P^f_\mu + \mathcal{R}_{\mu\nu}P^i_\mu P^f_\nu \tag{74}$$

where summation over repeating indices μ and ν is assumed. These indices enumerate the Cartesian projections x, y, and z of the vectors $\boldsymbol{P}^i$, $\boldsymbol{P}^f$, $\boldsymbol{\mathcal{R}}^i$, and $\boldsymbol{\mathcal{R}}^f$ as well as of the tensor $R_{\mu\nu}$. Equation (74), together with the procedure for the calculation of the four components of the reflectance matrix $\hat{R}$ (four complex functions R, R_x, R_y, and R_z), totally solves the problem to compute all NSF, $\mathcal{R}^{\pm\pm} = \mathcal{R}(\pm\boldsymbol{P}^i, \pm\boldsymbol{P}^f)$, and SF, $\mathcal{R}^{\pm\mp} = \mathcal{R}(\pm\boldsymbol{P}^i, \mp\boldsymbol{P}^f)$ reflectivities for an arbitrary orientation between the initial polarization and the polarization

analysis directions, and at any distribution of the magnetization directions across the multilayer stack. Equation (74) is exact and general. It is also valid for the transmission coefficient, if one just substitutes the reflectance, $\hat{R}$, for the transmittance, $\hat{T}$, matrices.

The first term in equation (74) is independent of either incoming and outgoing polarization and describes the reflection of unpolarized neutrons. The next two terms are linear with respect to each of the polarization vectors $\boldsymbol{P}^i$ and $\boldsymbol{P}^f$. Together with the first term they determine the reflectivity in the cases when either the neutrons are initially polarized ($\boldsymbol{P}^i \neq 0$), but no analysis (at $\boldsymbol{P}^f = 0$) is assumed, or alternatively, polarization due to reflection of initially unpolarized ($\boldsymbol{P}^i = 0$) neutrons is analyzed. The last term in equation (74) is bilinear with respect to the vectors $\boldsymbol{P}^i$ and $\boldsymbol{P}^f$. It describes that the contribution of the reflection with the evolution of the initial polarization vector caused by magnetic interaction.

The form of equation (74) follows from the basic properties of spin 1/2 particles and can immediately be written down without any preknowledge about a magnetization arrangement in the reflecting system. It uses only the fact that any scalar function of the spin 1/2 operator, for example, $\hat{R} = R(\hat{\boldsymbol{\sigma}})$ in equation (72), is reduced to a linear function (Landau and Lifshits, 1977) of $\hat{\boldsymbol{\sigma}}$.

An explicit expression for the coefficients $\mathcal{R}_0$, $\boldsymbol{\mathcal{R}}^i$, $\boldsymbol{\mathcal{R}}^f$, and $R_{\mu\nu}$ in equation (72) are as follows:

$$\mathcal{R}_0 = \frac{1}{2}\{|R|^2 + |\boldsymbol{R}|^2\} \tag{75}$$

$$\mathcal{R}^i_\mu = \Re\{R^* R_\mu\} + \frac{1}{2}\Im\{[\boldsymbol{R}^* \times \boldsymbol{R}]_\mu\} \tag{76}$$

$$\mathcal{R}^i_\mu = \Re\{R^* R_\mu\} - \frac{1}{2}\Im\{[\boldsymbol{R}^* \times \boldsymbol{R}]_\mu\} \tag{77}$$

$$\mathcal{R}_{\mu\nu} = \frac{1}{2}\{|R|^2 - |\boldsymbol{R}|^2\}\delta_{\mu\nu} + \Re\{R^*_\mu R_\nu\} - \frac{1}{2}\Im\{R^* R_\lambda\}\varepsilon_{\mu\nu\lambda} \tag{78}$$

where $\delta_{\mu\nu}$ is the Kronecker symbol, and $\varepsilon_{\mu\nu\lambda}$ is the Levi–Civita tensor. This tensor is totally antisymmetric with respect to its spatial indices. At first sight the last terms in equations (76–78) violate the reciprocity principle which requires the total invariance of the scattering cross sections with respect to interchange between initial and final states, that is inversion of the scattering process. Owing to this requirement it is expected that $\mathcal{R}^{+-} = \mathcal{R}^{-+}$. In particular, one expects no difference placing the spin analyzer in front, or behind the sample when measuring $\mathcal{R}^{\pm}$. However, due to the last terms in equations (76) and (77), which may exist for noncollinear structures, the first version of the reduced polarization analysis measures reflectivities $\mathcal{R}^{0\pm}$, while the second version provides $\mathcal{R}^{\pm 0} \neq \mathcal{R}^{0\pm}$. From equations (78) and (74) it is also evident that $\mathcal{R}^{+-} \neq \mathcal{R}^{-+}$ if $\boldsymbol{P}^i$ is not collinear with $\boldsymbol{P}^f$ and with the sample magnetization.

Here it is important to recall that polarization and magnetization are pseudovectors which are odd in time, changing sign at time reversal as well as at inversion of the coordinate system. Therefore, the reciprocity principle includes alternation of the magnetization directions in all layers if the initial and final neutron states (including spin states) are interchanged.

The role of the last two terms in equations (76) and (77) can be illustrated by the simplest example of 1D polarization analysis with $\boldsymbol{P}^i$ and $\boldsymbol{P}^f$ parallel with the y-axis, as considered in the preceding text. In this case, the set of equations (74) and (78) reduces to the following form

$$\begin{aligned}\mathcal{R} = \frac{1}{4}\{&|R + R_y|^2(1 + P^i_y)(1 + P^f_y) \\ &+|R - R_y|^2(1 - P^i_y)(1 - P^f_y) \\ &+|R_x - i R_z|^2(1 + P^i_y)(1 - P^f_y) \\ &+|R_x + i R_z|^2(1 - P^i_y)(1 + P^f_y)\}\end{aligned} \tag{79}$$

From this equation it follows that at ideal polarization, that is at $P^i_y = \pm 1$ and $P^f_y = \pm 1$ the difference between $\mathcal{R}^{+-}$ and $\mathcal{R}^{+-}$ is solely due to the term R_z which appears due to noncollinearity in the layer magnetization arrangement.

In the collinear case, the set of equations (75–78) is substantially simplified. In particular, the two last terms in equations (76) and (77) vanish, which distinguish the chirality in the sequence of the layer magnetization vectors. Finally the set of equations (75–78) can be represented via the eigenvalues $R_\pm$ of the reflectance matrix

$$\mathcal{R}_0 = \frac{1}{4}\{|R_+|^2 + |R_-|^2\} \tag{80}$$

$$\mathcal{R}^i_\mu = \mathcal{R}^f_\mu = \frac{b_\mu}{4}\{|R_+|^2 - |R_-|^2\} \tag{81}$$

$$\begin{aligned}\mathcal{R}_{\mu\nu} = \frac{1}{4}\{&(|R_+|^2 + |R_-|^2)b_\mu b_\nu + 2\Re(R^*_+ R_-)(\delta_{\mu\nu} - b_\mu b_\nu) \\ &+2\Im(R^*_+ R_-)\varepsilon_{\mu\nu\lambda} b_\lambda\}\end{aligned} \tag{82}$$

and the projections of the unit vector $\boldsymbol{b}$ pointing in the direction of the net inductance. The first two contributions to the reflectivity, which are due to equations (80) and (81), are symmetric with respect to the interchange of $\boldsymbol{P}^i$ and $\boldsymbol{P}^f$. The tensor $\mathcal{R}_{\mu\nu}$ in equation (82) is decomposed into three orthogonal tensors of different symmetry. The first two terms are symmetric with respect to the interchange of $\boldsymbol{P}^i$ and $\boldsymbol{P}^f$ and acting on the projections of the polarization vectors parallel to $\boldsymbol{b}$ (the first term) and perpendicular (the second term) to $\boldsymbol{b}$. The components of the last tensor in equation (82)

are also perpendicular to $\boldsymbol{b}$, but this tensor is antisymmetric. It contributes to the reflectivity only if all three vectors $\boldsymbol{P}^i$, $\boldsymbol{P}^f$ and $\boldsymbol{b}$ are noncollinear. In contrast to all other contributions, it is sensitive to the sign of $\boldsymbol{b}$. If for example, the vector $\boldsymbol{P}^i$ has the only component P_y^i, while $\boldsymbol{P}^f$ is directed normal to the surface and has the component P_z^f, then this term is proportional to the product $b_x P_y^i P_z^f$ and is sensitive to the sign of the magnetization projection b_x. This allows to determine whether the magnetization vector in Figure 1 is tilted to the left, or to the right with respect to the y axis.

The role of chirality is illustrated in Figure 6 where PNR curves have been calculated for a semi-infinite sample of iron with the magnetization being tilted by $\gamma = +45^\circ$ (Figure 6a) and $\gamma = -45^\circ$ (Figure 6b) with respect to the initial polarization directed along the y axis. The final polarization is analyzed along the z axis normal to the surface. One can clearly see the interchange between the different components of the PNR matrix as the angle γ changes sign.

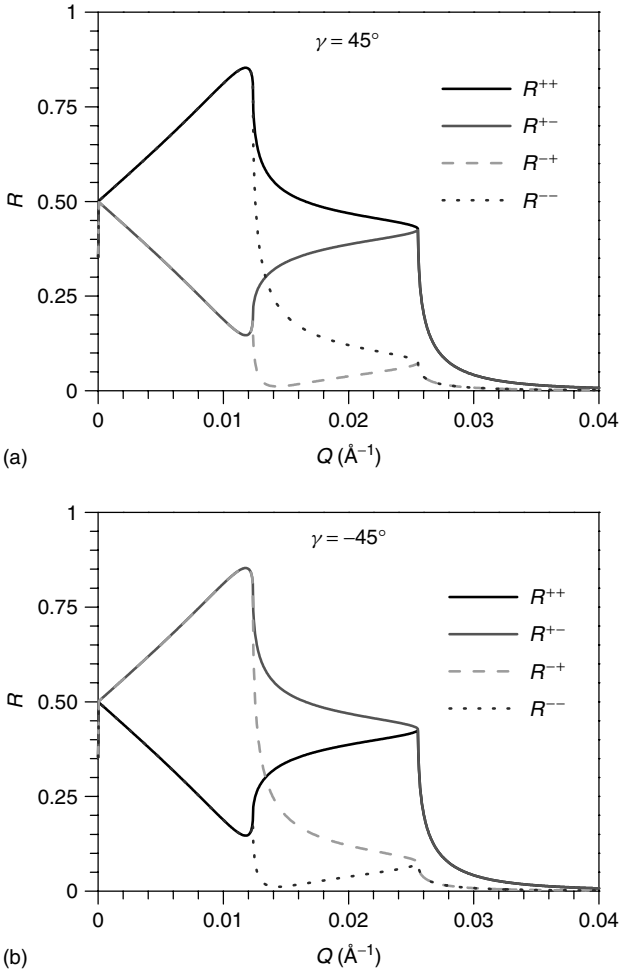

Figure 6. NSF (solid lines) and SF (dashed lines) reflectivities from iron with the magnetization tilted by the angle $\gamma = 45^\circ$ (a) and by the angle $\gamma = -45^\circ$ (b) with respect to the y axis. The initial polarization oriented parallel to the y axis, while the final polarization analyzed is along the z axis.

2.7 Kinematics of off-specular scattering

In the consideration in the preceding text, it was assumed that the surface is laterally infinite and homogeneous. Moreover, we have intentionally ignored the atomic structure of the magnetic media and introduced the optical potential expressed via the SLD, the quantity averaged over a scale much greater than an atomic scale. It is intuitively clear that those approximations are quite reasonable in the range of shallow angles of incidence, $\alpha_i \ll 1$ and reflection $\alpha_f \ll 1$. At these conditions the projection $Q_z = (2\pi/\lambda)(\sin\alpha_i + \sin\alpha_f) \approx 2\pi(\alpha_i + \alpha_f)/\lambda$ of the wave vector transfer $\boldsymbol{Q}$ is much smaller than the reciprocal interatomic spacings. This justifies the continuous medium approximation in the transverse direction, while a crystalline structure can, if necessary, be taken into account via subdividing the medium into a set of atomic scale layers and calculating the reflection coefficient as described in the preceding text.

If at shallow incidence the lateral projection $\boldsymbol{Q}_L = \boldsymbol{\kappa}_f - \kappa_i$ of the vector $\boldsymbol{Q}$ matches a reciprocal vector $\boldsymbol{\tau}_L$ of the crystalline structure, then one may observe so-called grazing incidence neutron Bragg diffraction (GIND) which can, in principle, deliver valuable information (Dosch, 1993) on the atomic and magnetic order in the near surface vicinity. We shall not go into further details of this phenomenon and only mention that it can be described within the framework of the DWBA discussed in the subsequent text. DWBA accounts for optical effects, and in particular, for birefringence of the incident and diffracted neutron waves inside the magnetic medium, while small effects due to lateral crystallinity are treated as a perturbation (Günther, Donner, Toperverg and Dosch, 1998; Toperverg, Rühm, Donner and Dosch, 1999; Toperverg, Lauter-Pasyuk and Lauter, 2005b).

Usually the lateral projection $\lambda_L \approx \lambda$ of the neutron wavelength λ is comparable to the interatomic spacing, and GIND occurs at relatively large angles $\vartheta_y = \vartheta_B$ (Figure 7), where ϑ_B is the angle determined by the Bragg equations $(4\pi/\lambda)\sin(\vartheta_B/2) = \tau_y$ and $(4\pi/\lambda)\cos(\vartheta_B/2) = \tau_x$ via the projections τ_y and τ_x of the 2D reciprocal lattice vectors $\boldsymbol{\tau}_L$. Zeroth order diffraction at $\boldsymbol{\tau}_L = 0$ corresponds to specular reflection, which can be calculated exactly as described in the preceding text where atomic structure was ignored.

Taking into account specular and Bragg reflections, as well as scattering from that lateral heterogeneities of SLD, the cross section of neutron scattering at grazing incidence is conveniently written as a sum of three terms

$$\frac{d\sigma}{d\Omega} = \left(\frac{d\sigma}{d\Omega}\right)_{\text{spec}} + \left(\frac{d\sigma}{d\Omega}\right)_{\text{off-spec}} + \left(\frac{d\sigma}{d\Omega}\right)_{\text{diffuse}} \qquad (83)$$

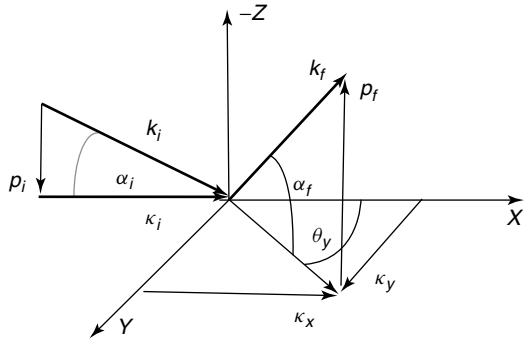

Figure 7. 3D scattering kinematics.

$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)_{\mathrm{spec}} = \mathcal{S}_R \frac{Q_z^2}{4}\mathcal{R}(Q_z)\delta(Q_x)\delta(Q_y) \tag{84}$$

$$\left(\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\right)_{\mathrm{off-spec}} = \mathcal{S}_R \sum_{\boldsymbol{\tau}\neq 0} \mathcal{F}(p_0^i, p_0^f; \boldsymbol{\tau}_L)\delta(Q_x - \tau_x) \times \delta(Q_y - \tau_y) \tag{85}$$

Here the first term is the cross section of the specular reflection expressed via the reflection coefficient $\mathcal{R} = \mathcal{R}(Q_z; \boldsymbol{P}^i, \boldsymbol{P}^f)$, the second term corresponds to off-specular Bragg diffraction and contains a combination $\mathcal{F}(p_0^i, p_0^f; \boldsymbol{\tau}_L)$ of structure factors and form-factors. In the Born approximation it depends on the wave vector transfer $Q_z = p_0^f - p_0^i$, while in DWBA it is a function of two separate variables $p_0^i = k\sin\alpha_i$ and $p_0^f = k\sin\alpha_f$. The last term in equation (84) stands for off-specular diffuse scattering which is due to random domains, roughness and so on, and will be thoroughly discussed later.

The normalization factors in equation (84) can be checked via the sum rule: the integral over the solid angle has to be equal to the sample area $\mathcal{S}_R$ illuminated by the neutron beam. In accordance with the previous consideration, below the critical angle of incidence $\mathcal{R} = 1$ and all neutrons impinging onto the sample should be specularly reflected [3].

We shall here not further calculate the second term in equation (83) for diffraction from atomic structures (Günther, Donner, Toperverg and Dosch, 1998; Toperverg, Rühm, Donner and Dosch, 1999; Toperverg, Lauter-Pasyuk and Lauter, 2005b), but instead consider GIND from laterally nano-patterned layered systems (Toperverg *et al*., 2000). In this case, the lateral spacing is assumed to be much larger than the interatomic distances [4] and GIND contributes to the range of angles $\vartheta_y \ll 1$. Then, at $\alpha_i \ll 1$ and $\alpha_f \ll 1$ the Cartesian projections of the the wave vector transfer can be approximated as follows

$$Q_x \approx \frac{\pi}{\lambda}(\alpha_i^2 - \alpha_f^2 - \vartheta_y^2) \tag{86}$$

$$Q_y \approx \frac{2\pi}{\lambda}\vartheta_y \tag{87}$$

$$Q_z \approx \frac{2\pi}{\lambda}(\alpha_f + \alpha_i) \tag{88}$$

From this equation it follows that at $\alpha_i \sim \alpha_f \sim \vartheta_y \ll 1$ the projection $Q_x \ll Q_y \sim Q_z$.

In the low angle approximation the $\delta-$functions, which determine the Bragg peak positions in equation (85), read

$$\delta(Q_y - \tau_y) = \frac{\lambda}{2\pi}\delta(\vartheta_y - \vartheta_B) \tag{89}$$

$$\delta(Q_x - \tau_x) = \frac{\lambda}{2\pi\alpha_B}\{\delta(\alpha_f - \alpha_B) + \delta(\alpha_f + \alpha_B)\} \tag{90}$$

$$\vartheta_B = \pm\lambda\tau_y/2\pi \tag{91}$$

$$\alpha_B = \sqrt{\alpha_i^2 - \vartheta_B^2 \pm \lambda\tau_x/\pi} \tag{92}$$

where the first term in equation (90) corresponds to reflection into the upper hemisphere, while the second one describes reflection below the horizon. Equation (92) determines two branches of GIND, which can exist at $\alpha_i^2 \geq \vartheta_B^2 \pm \lambda\tau_x/\pi$. In a particular case $\tau_y = 0$ these branches can be observed at low angles $\alpha_f \sim \alpha_i \ll 1$ only for the systems with very large spacing $a \sim \lambda/\alpha_i^2$, typically from micrometer up to submillimeter range. For such huge spacings the term ϑ_B^2 in equation (92) does not play a role and can safely be neglected, except for the case when the period in the y direction is by 3–4 orders of magnitude smaller than that along the x axis. In fact, Bragg reflection can also be observed at low α_B if neither one of the two periods is large enough to be detected. This is achieved (Toperverg *et al*., 2000; Theis-Bröhl, Schmitte, Leiner and Zabel, 2003; Theis-Bröhl *et al*., 2003) by turning the 2D lattice around the sample normal so that the projection τ_x of the reciprocal vector $\boldsymbol{\tau}$ becomes sufficient to fit the position of the Bragg peak at $\alpha_f = \alpha_B$ into the accessible window of detected angles.

2.8 Coherence volume and resolution

It is worth to note that both specular and Bragg reflection are essentially coherent phenomena. They both result from the constructive interference of neutron waves scattered at different points of the sample in either specular, or Bragg directions. Scattering in all other directions is suppressed by destructive interference. Such a description assumes that scattered waves are due to the incident monochromatic plane wave which determines their phase relationship. On the other hand, the neutron source is an incoherent device randomly emitting polychromatic neutron waves diverging from different points in the source volume at uncorrelated moments

in time. Observables, for example, scattered flux density, polarization, and so on, are the result of the statistical averaging of the corresponding quantum-mechanical quantities over neutron emittance events. Further devices of the experimental set up, for example, monochromatization and collimation systems select those events with close phases of emittance so that statistical averaging does not totally eliminate the interference phenomena. Such a filtering reduces the statistical source volume to the so-called *source coherence volume*. It can be considered as a fraction of the source emitting neutron waves with approximately fixed phase relationship. The coherence volume is relatively small so that fronts of irradiated divergent spherical waves at some distance are almost flat. All this justifies the plane wave approximation used in the theoretical consideration in the preceding text. It is constrained by residual dephasing which is taken into account via the *resolution function*.

An intimate relation between resolution effects and coherency of the neutron radiation (Sinha, Tolan and Gibaud, 1998) can be illustrated by the following examples. The first one considers GIND from periodically patterned systems, while the second one concerns PNR from a multidomain F film.

If the periods of a lateral pattern in the x and the y directions are not dramatically different, then due to resolution effects the low angle kinematics generally does not render possible to observe diffraction peaks simultaneously for both angles ϑ_y and α_f. Instead, Bragg angles can be resolved only for the x direction, while in the other direction the Bragg condition is obscured by resolution effects. The uncertainty $\Delta Q_y \sim (2\pi/\lambda)\Delta\vartheta_y$ is mainly due to the angular divergence $\Delta\vartheta_y$ in the y direction, where rather relaxed collimation of the beam is usually provided. The uncertainty ΔQ_x is mostly due to the finite collimation $\Delta\alpha_i$ and finite resolution in detection $\Delta\alpha_f$. It can roughly be estimated as

$$\Delta Q_x \sim \frac{\pi}{\lambda}\sqrt{(\alpha_i\Delta\alpha_i)^2 + (\alpha_f\Delta\alpha_f)^2} \ll \Delta Q_y \qquad (93)$$

A strong asymmetry in the lateral resolution implies a strong anisotropy of the area from which a coherent scattering can be observed. This coherence area [5] is substantially extended along the x-axis for a distance $l_x \sim 1/\Delta Q_x$, while it is relatively short in y-direction in which it is estimated as $l_y \sim 1/\Delta Q_y \ll l_x$. If the period of the lateral structure $a \ll l_x$, then the coherence area may comprise a number of unit cells along x axis, but very few, or even none along the y axis, if $l_y \sim a$. Interference of neutron waves will then result in strong Bragg reflections only at $\alpha_f = \alpha_B$ and a smooth line shape along ϑ_y. The latter is determined by the incident beam collimation in the corresponding direction.

Usually the coherence area covers only a small fraction of the sample surface illuminated by the neutron beam. Therefore, an experimentally recorded (specular and off-specular) Bragg reflection is actually an incoherent sum of intensities coherently reflected from different small areas of the sample. It is often silently assumed that the sample is homogeneous over its total surface so that the reflection coefficients from different parts of the sample, alias different coherence areas, are identical. Then incoherent summation over these areas results in the sample area $\mathcal{S}_R$ in equations (84) and (85). This, however, is not always the case, as can be seen from examples depicted in Figure 8. The first illustration shows two orientations of a lateral stripe array. If the stripes are running along the y axis, then one can observe both: specular reflection, and off-specular Bragg peaks. Rotating the sample around its normal efficiently increases the lateral spacing and the Bragg peaks approach the position at the origin. They finally become unresolvable from the specular reflection. At this point, the coherence area may comprise only one stripe, and each of them as well as the interstripe spaces contribute independently to solely specular reflection.

Another typical situation refers to reflection from a continuous magnetic film broken into a multidomain state as illustrated in Figure 9. If the domains are larger than $l_x \gg l_y$, as assumed in Figure 9(a), then each of the domains reflects independently. The reflectivity has to be calculated for different magnetic domains with different magnetization vectors and finally averaged over all possible domain orientations. Such averaging would not affect the intensity of unpolarized neutron reflection, while only PNR delivers an information

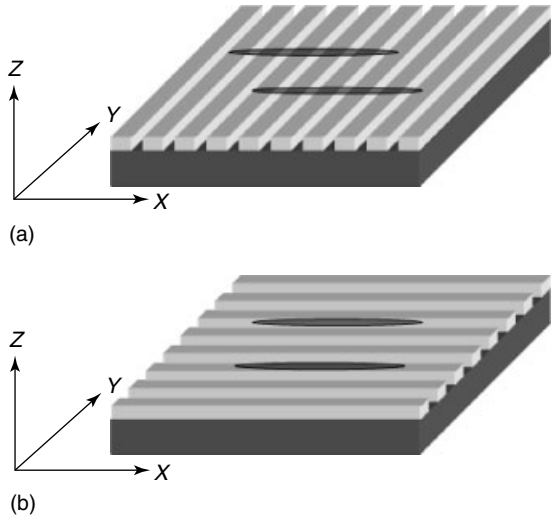

Figure 8. Illustration of the coherence anisotropy. Bragg diffraction can be detected if the coherence ellipse covers a number of stripes (a). Alternatively, each stripe and interstripe spacing contributes to specular reflection and respective intensities are added incoherently (b).

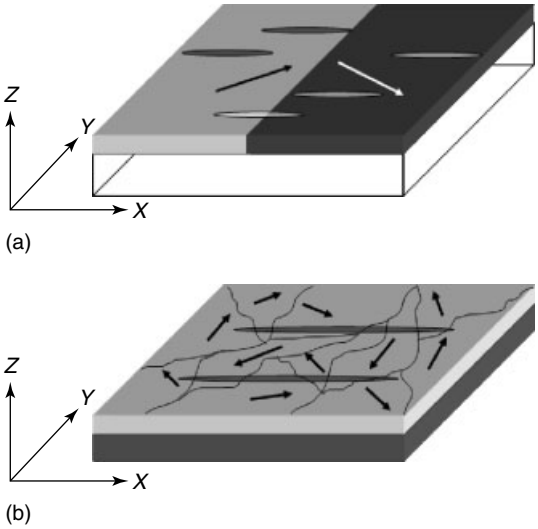

Figure 9. Sketch of lateral magnetic domains with magnetization directions indicated by arrows. In (a) the two large domains are bigger than the coherence area. In most cases, the coherence ellipses are displayed within only one domain, in a few cases the ellipse may cross a common boundary between two of them. In (b) each coherence ellipse covers several domains.

on the magnetization distribution over the reflected surface. Hence, averaging equation (48) one obtains an equation which can be used to find the mean value $\langle \cos\gamma \rangle$ from measurements of the spin asymmetry. This mean value is proportional to the mean magnetization projection onto the polarization analysis axis but it does not allow to discriminate between coherent rotation of the net magnetization for the angle γ and the magnetization reduction due to random domains. For example, SA cannot distinguish between totally demagnetized state and rotation of magnetization perpendicular to the polarization direction, because in both cases $\langle \cos\gamma \rangle = 0$. More certainty can be gained via full 1D-PNR, that is measuring NSF and SF reflectivities. Indeed, averaging of equations (39–41) gives access not only to the mean value $\langle \cos\gamma \rangle$, but also to the mean square $\langle \sin^2\gamma \rangle$. The latter is proportional to the mean square of the magnetization vector projections onto the $x-$axis. Correspondingly, one can determine $\langle \cos^2\gamma \rangle = 1 - \langle \sin^2\gamma \rangle$. In case of a random distribution of domain magnetization directions the dispersion $\Delta = \langle \cos^2\gamma \rangle - \langle \cos\gamma \rangle^2 \neq 0$ is essentially positive. It reaches a maximum value $\Delta_{\max}$ for the totally demagnetized state. In contrast, coherent rotation of the magnetization vector yields $\Delta = 0$. If at the same time $\langle \cos\gamma \rangle = 0$ than sample is in a single-domain state, but with magnetization turned perpendicular to the polarization axis.

As mentioned previously, the 1D polarization analysis cannot distinguish between right and left tilt of the magnetization vector and it is not possible to unambiguously discriminate between rotation of the net magnetization by an angle γ and a multidomain state in which the domain magnetization is equally turned by the angles $\pm\gamma$. This uncertainty is cured by the vector polarization analysis. Owing to the tensorial form of equation (74), corresponding averaging over domain magnetization can easily be performed. Then the limitation of equation (74) is only related to the ratio between characteristic domain sizes and the coherence length. If domains are smaller than the coherence l_x, but still much larger than $l_y \ll l_x$ as sketched in Figure 9(b) then the neutron wave is not only reflected from and transmitted through the mean optical potential, but also scattered in off-specular directions $\alpha_f \neq \alpha_i$. This scattering may be either coherent, as in the case of periodic domain structure, artificial regular patterns and so on, or diffuse, if the domains are randomly distributed over the surface. In all cases, if such scattering is experimentally detected, it serves as a direct evidence in favor of inhomogeneities smaller than l_x. On the other hand, such inhomogeneities, either periodic, or random, also affect the specular reflection reducing the mean value of the reflection potential.

2.9 Cross section of polarized neutron scattering

At shallow incidence angles off-specular scattering, either coherent Bragg reflections or diffuse scattering from lateral inhomogeneities, is usually a much weaker effect than specular reflection. Therefore, it is usually considered within the framework of the perturbation theory as a small correction to the exact solution of the Schrödinger equation for the mean optical potential derived in the preceding text. In most cases, it is sufficient to truncate the perturbation series for the scattering amplitude and take into account only the linear term with respect to the perturbation potential. Such truncation is accomplished either in the Born approximation (BA) or in the DWBA, thoroughly discussed in the next subsections. Here we, however, firstly concentrate on general and independent approximations of the equations for off-specular scattering cross sections of *polarized* neutrons.

Considering a layered systems with a sequence of N layers stacked in the z direction which, in addition, exhibits some lateral inhomogeneity such as a periodic stripe or random domain pattern we decompose the interaction potential in each layer l into two parts

$$\hat{V}(\boldsymbol{\rho}) = \sum_{l=1}^{N} \{\hat{V}_l + \Delta\hat{V}_l(\boldsymbol{\rho})\} \tag{94}$$

Here the main term, $\hat{V}_l = \langle \hat{V}_l(\boldsymbol{\rho}) \rangle_{\mathrm{coh}}$, is independent of the lateral coordinate vector $\boldsymbol{\rho}$, homogeneous across each layer and contributes only to specular reflection and transmission. The choice of the reference potentials $\hat{V}_l$ is constrained

by the condition that after lateral averaging $\langle \Delta \hat{V}_l(\boldsymbol{\rho})\rangle_{\rm coh} = \langle \hat{V}_l(\boldsymbol{\rho}) - \hat{V}_l\rangle_{\rm coh} = 0$. A benefit of such a choice is that it allows to eliminate a contribution to the cross section of specular reflection of the terms linear with respect to $\Delta \hat{V}_l(\boldsymbol{\rho})$. This contribution may cause rather undesirable corrections to the reflectivity which has already been calculated in the preceding text exactly. The terms proportional to $\Delta \hat{V}_l(\boldsymbol{\rho}) = \Delta \hat{V}_l^N(\boldsymbol{\rho}) + \Delta \hat{V}_l^M(\boldsymbol{\rho})$, where $\Delta \hat{V}_l^N(\boldsymbol{\rho})$ and $\Delta \hat{V}_l^M(\boldsymbol{\rho})$ refer to deviations in nuclear and magnetic potentials, are regarded as perturbations to the main potential $\hat{V}_l = \langle \hat{V}_l^N(\boldsymbol{\rho})\rangle_{\rm coh} + \langle \hat{V}_l^M(\boldsymbol{\rho})\rangle_{\rm coh}$ and cause scattering into off-specular directions.

Magnetic off-specular scattering, which is due to the potential deviations $\Delta \hat{V}_l^M(\boldsymbol{\rho}) = -\hat{\boldsymbol{\mu}}\Delta \boldsymbol{B}_l(\boldsymbol{\rho})$, may change the spin state of the incident neutrons, while nuclear scattering leaves them unchanged. Hence the scattering amplitude $F = F(\boldsymbol{k}_i, \boldsymbol{k}_f)$ is represented by the matrix element

$$F(\boldsymbol{k}_i, \boldsymbol{k}_f) = \langle \Psi_0^i | \hat{F}(\boldsymbol{k}_i, \boldsymbol{k}_f; \hat{\boldsymbol{\sigma}}) | \Psi_0^f \rangle \tag{95}$$

of the 2×2 amplitude matrix $\hat{F} = \hat{F}(\boldsymbol{k}_i, \boldsymbol{k}_f; \hat{\boldsymbol{\sigma}})$.

This matrix, as any 2×2 matrix, can formally be decomposed over the orthogonal set of Pauli matrices so that

$$\hat{F} = F_0 + (\hat{\boldsymbol{\sigma}}\boldsymbol{F}) \tag{96}$$

Explicit expressions for the scalar, F_0, and the vector, $\boldsymbol{F}$, components of the scattering amplitude in BA and DWBA are given in corresponding sections in the subsequent text. Here we just mention, that in BA F_0 is due to the nuclear scattering amplitude, while $\boldsymbol{F}$ corresponds to the magnetic scattering amplitude. In DWBA such clear separation of nuclear and magnetic contributions does not hold anymore.

The expansion in equation (96) allows to readily perform an averaging over spin states of the scattering cross section determined by the equation

$$\frac{{\rm d}\sigma}{{\rm d}\Omega} = {\rm Tr}\{\hat{\rho}^f \hat{F} \hat{\rho}^i \hat{F}^+\} \tag{97}$$

which is similar to equation (69).

Substitution of equation (96) and equations (70) and (71) for the density matrices $\hat{\rho}^i$ and $\hat{\rho}^f$ into this equation immediately results in the expression for the scattering cross section,

$$\left(\frac{{\rm d}\sigma}{{\rm d}\Omega}\right) = \Sigma_0 + \Sigma_\mu^i P_\mu^i + \Sigma_\mu^f P_\mu^f + \Sigma_{\mu\nu} P_\mu^i P_\nu^f \tag{98}$$

with the tensor structure being identical to that of equation (74) for the reflection coefficient, if one substitutes the scalar $\mathcal{R}_0$ by Σ_0, the vectors $\boldsymbol{\mathcal{R}}^{i,f}$ in this equation by $\boldsymbol{\Sigma}^{i,f}$ and the tensor $\mathcal{R}_{\mu\nu}$ by tensor $\Sigma_{\mu\nu}$ of scattering cross section. These quantities can be expressed via bilinear combinations of the scalar amplitude F_0 and projections of the amplitude vector $\boldsymbol{F}$ in the same way as $\mathcal{R}_0$, $\boldsymbol{\mathcal{R}}^{i,f}$ and $\mathcal{R}_{\mu\nu}$ are expressed in equations (75–78) via bilinear combinations of the scalar R and projection of the vector $\boldsymbol{R}$. Resulting equations can be used to describe (Toperverg, Nikonov, Lauter-Passyuk and Lauter, 2001) off-specular scattering for arbitrary orientation between directions of incident polarization vector $\boldsymbol{P}^i$ and the vector of polarization analysis $\boldsymbol{P}^f$. These equations are absolutely general and exact. They do not assume any approximations and only exploit the fact that the neutron magnetic moment is associated with its spin 1/2. In particular, they apply either for BA and DWBA providing in the following sections explicit expressions for four complex amplitudes F_0, F_x, F_y, and F_z.

In the most common particular case of a 1D polarization configuration, that is when the incident polarization vector $\boldsymbol{P}^i$ is directed along the y axis and the only projection P_y^f of the outgoing neutron polarization onto the same axis is analyzed, the equation for scattering cross section boils down to the following set of equations for SF and NSF cross sections:

$$\left(\frac{{\rm d}\sigma}{{\rm d}\Omega}\right)_{yy}^{++} = \Sigma_0 + \Sigma_y^i |P_y^i| + \Sigma_y^f |P_y^f| + \Sigma_{yy} |P_y^i||P_y^f| \tag{99}$$

$$\left(\frac{{\rm d}\sigma}{{\rm d}\Omega}\right)_{yy}^{--} = \Sigma_0 - \Sigma_y^i |P_y^i| - \Sigma_y^f |P_y^f| + \Sigma_{yy} |P_y^i||P_y^f| \tag{100}$$

$$\left(\frac{{\rm d}\sigma}{{\rm d}\Omega}\right)_{yy}^{+-} = \Sigma_0 + \Sigma_y^i |P_y^i| - \Sigma_y^f |P_y^f| - \Sigma_{yy} |P_y^i||P_y^f| \tag{101}$$

$$\left(\frac{{\rm d}\sigma}{{\rm d}\Omega}\right)_{yy}^{-+} = \Sigma_0 - \Sigma_y^i |P_y^i| + \Sigma_y^f |P_y^f| - \Sigma_{yy} |P_y^i||P_y^f| \tag{102}$$

Four cross sections Σ_0, Σ_y^i, Σ_y^f, and Σ_{yy} in this set of equations are expressed via various products of four components of the scattering amplitude matrix $\hat{F}$ parameterized in equation (96):

$$\Sigma_0 = \frac{1}{2}\{\langle |F_0|^2 + |F_y|^2 + |F_x|^2 + |F_z|^2\rangle\} \tag{103}$$

$$\Sigma_y^i = \Re\langle F_0^* F_y\rangle + \frac{1}{2}\langle [F_z^* F_x - F_x^* F_z]\rangle \tag{104}$$

$$\Sigma_y^f = \Re\langle F_0^* F_y\rangle - \frac{1}{2}\langle [F_z^* F_x - F_x^* F_z]\rangle \tag{105}$$

$$\Sigma_{yy} = \frac{1}{2}\{\langle |F_0|^2 + |F_y|^2 - |F_x|^2 - |F_z|^2\rangle\} \tag{106}$$

The set of equations (99–102) solves the problem of averaging over spin states separating quantities characterizing a scattering system from instrumental parameters, that is the polarization efficiencies. Indeed, the system of four linear equations (99–102) can easily be solved providing expressions for Σ_0, Σ_y^i, Σ_y^f and Σ_{yy} via combinations of four experimentally measured quantities: two NSF and two SF scattering cross sections. Furthermore, the set of equations (103–106) links together scattering amplitudes calculated below in BA and DWBA for various physical models with experimentally measured cross sections.

On the other hand, the set of equations (103–106) for 1D polarization analysis does not provide all the scope of information which can be gained with polarized neutron off-specular scattering. This is already seen from the fact that equations (103–106) contain seven, generally independent, products of different complex functions F_0, F_x, F_y, and F_z averaged over beam divergency, as well as over possible disorder (domains, roughness, etc.) in the sample. The missing information is, however, available with the complete 3D vector polarization arrangement. Such arrangement would allow to measure all 36, instead of four cross sections in equations (103–106). Aligning $\boldsymbol{P}^i$ and $\boldsymbol{P}^f$ collinear with either x or the z axis one can measure eight additional NSF and SF cross sections diagonal with respect to the Cartesian indices. Another 24 cross section, non-diagonal with respect to x, y and z indices can be measured by setting polarization analysis axis perpendicular to the initial ones. The latter cross sections are not independent and linked via the reciprocity principle. Finally 20 measurable cross sections are, in principle, available altogether to recover all 16 cross sections in equation (98), for example, the scalar Σ_0, six components of two 3D vectors Σ_μ^i and Σ_μ^f, as well as nine components of 3D tensor $\Sigma_{\mu\nu}$ of the second rank. These quantities determined as functions of the incoming and outgoing wave vectors contain all physical information which can be extracted from 3D vector polarization analysis. In the following sections we, however, mainly restrict our consideration to 1D polarization analysis as being well in use in the last decade.

2.10 Off-specular scattering in the Born approximation

In this subsection we, for introductory purpose, concentrate on the most simple approach, that is BA, often used for the description of off-specular scattering of polarized neutrons. In BA optical effects, for example refraction into the mean potential and birefringence due to magnetic interaction are completely ignored. Hence BA is supposed to be valid only far away from the total reflection condition for the incident and scattered neutron waves. Therefore, in case of PNR, BA misses some important polarization effects and may even lead to confusions in the data interpretation. On the other hand, BA allows a simpler discussion of many issues which are common for both BA and DWBA. One of those issues is the general dependency of scattering cross sections on polarization vectors as discussed in the previous section.

In BA the amplitude matrix $\hat{F}(\boldsymbol{k}_i, \boldsymbol{k}_f) = F^N(\boldsymbol{Q}) + \hat{F}^M(\boldsymbol{Q})$ in equations (95–97) is a sum of the unit matrix of nuclear, $F^N(\boldsymbol{Q})$, and the matrix of magnetic, $\hat{F}^M(\boldsymbol{Q})$, scattering. These amplitude matrices in BA depend on the wave vector transfer $\boldsymbol{Q} = \boldsymbol{k}_f - \boldsymbol{k}_i$ and taking into account equation (94) are written as follows:

$$\hat{F}^{N,M}(\boldsymbol{Q}) = -\frac{m}{2\pi\hbar^2}\sum_l \int_{z_{l-1}}^{z_l} \mathrm{d}z\, \mathrm{e}^{i Q_z z} \times \int \mathrm{d}x\, \mathrm{d}y\, \mathrm{e}^{i(Q_x x + Q_y y)} \Delta \hat{V}_l^{N,M}(\boldsymbol{\rho}) \quad (107)$$

where $\boldsymbol{Q}$ has the lateral, Q_x and Q_y, and transverse, $Q_z = p_0^i + p_0^f$, components, $p_0^i = (2\pi/\lambda)\sin\alpha^i$ is the incoming, while $p_0^f = (2\pi/\lambda)\sin\alpha^f$ is the scattered wave vector projection into the normal to the surface.

In BA the first term, $F_0 = F^N(\boldsymbol{Q})$, in equation (96) refers to the nuclear scattering amplitude, while $\boldsymbol{F} = \boldsymbol{b}F^M(\boldsymbol{Q})$ is associated with the magnetic scattering amplitude, and $\boldsymbol{b} = \Delta\boldsymbol{B}(\boldsymbol{Q})/|\Delta\boldsymbol{B}(\boldsymbol{Q})|$ is the unit vector. The scattering amplitude vector $\boldsymbol{F}$ is almost totally displayed within the surface plane. This is due to the fact that in accordance with the Maxwell equations $\boldsymbol{B}(\boldsymbol{Q}) \perp \boldsymbol{Q}$ and the vector $\boldsymbol{Q}$ at glancing angles of incidence and scattering is pointing nearly perpendicular to the surface.

The first terms in equation (103) and equation (106) are responsible for purely nuclear scattering. The three other terms in these equations, as well as the last terms in equation (104) and equation (105) correspond to purely magnetic scattering, while the first terms in the latter equations describe interference between magnetic and nuclear scattering. In BA, $F_z \approx 0$ and therefore the last terms in equations (103–106) can be neglected. Note, this is not the case in DWBA where they may play a role.

The angular brackets in equations (103–106) denote the averaging over the resolution function and hence account for the coherence properties of the neutron radiation. These properties reveal such a strong anisotropy (see, Figures 8 and 9) that even in the case of a pinhole collimation, off-specular scattering in x direction probes lateral length scales exceeding those accessible in the y direction by several orders of magnitude. Moreover, PNR experiments usually use slit-like collimation in z direction, providing simultaneously fine resolution in the Q_x component of the wave vector transfer. On the other hand, almost all neutrons

scattered from large-scale lateral inhomogeneities in the y direction are scattered under unresolved angles. Therefore equation (98) for the scattering cross sections should be integrated over ϑ_y and each term in equations (103–106) is then expressed via the following correlator of the Born partial amplitudes:

$$\langle F_\mu^* F_\nu \rangle = \lambda \int \mathrm{d}y F_\mu^*(Q_z, Q_x; y) F_\nu(Q_z, Q_x; y) \qquad (108)$$

Here μ and ν stand for x, y, z, or 0, and

$$F_\mu(Q_z, Q_x; y) = \sum_l \frac{1}{2\pi} \int \mathrm{d}Q_y \mathrm{e}^{iQ_y y} F_l^\mu(\boldsymbol{Q}) \qquad (109)$$

is the Fourier transform of the corresponding component of the scattering amplitude averaged over Q_y.

Deviations $\Delta\hat{V}_l^N(x, y)$ in the nuclear scattering potential in equation (107) are determined by deviations $\Delta(Nb)_l^N(x, y)$ in nuclear SLDs $(Nb)_l^N(x, y)$ from its mean value $\overline{(Nb)_l^N}$. Decomposition of the SLD into the mean value and deviations is sketched in Figure 10 for the case of a single patterned layer deposited onto a substrate, as depicted in Figure 8. An explicit equations for the amplitude of nuclear scattering from periodic gratings are given in Appendix A. In a more general case of a 2D lateral structure, one can consider the SLD profile in Figure 10 as taken for a fixed y coordinate, bearing in mind that the size of the structural elements along the y axis is much greater than the corresponding width of the coherence ellipsoid [6] in Figure 8.

The particular form of equation (108) is essentially based on the incomparability of coherence ranges in the x and y direction. In fact, the coherence length in the y direction is totally ignored, while in the x direction it is assumed to be very large. If the latter goes to infinity, in the case of nuclear scattering from grating with a period a (see Appendix A) one has the following equations for the first terms in equations (103–106)

$$\langle F_0^* F_0 \rangle = \lambda \int \mathrm{d}y \mathcal{N}_x \mathcal{F}(Q_z, Q_x; y) \frac{2\pi}{a} \sum_\tau \delta(Q_x - \tau) \qquad (110)$$

Here $\mathcal{N}_x = \mathcal{N}_x(y)$ is the number of structural elements and $\tau = 2\pi/a$ in the x direction at fixed y coordinate, while

$$\mathcal{F}(Q_z, Q_x; y) = \left| \sum_l F_l^z(Q_z, y) F_l^L(Q_x, y) \right|^2 \qquad (111)$$

with explicit equations for the transverse, $F_l^z(Q_z, y)$, and lateral, $F_l^L(Q_x, y)$, components of the stripe form-factor given in Appendix A.

In the example of the periodic stripe array sketched in Figure 8 all the functions are independent of the y coordinate and the integral in equation (110) is equal to the length $\mathcal{L}_y$ of the sample in the y direction, while the product $\mathcal{L}_x \mathcal{L}_y = \mathcal{S}$ yields the area factor $\mathcal{S}$ in equation (85), where $\mathcal{L}_x = \mathcal{N}_x a$ is the length of the sample in the x-direction. Owing to the choice of the scattering potential ΔV^N the contribution of the term with $\tau = 0$ in the sum in equation (110) vanishes. Convolution with the resolution function replaces the $\delta-$ by that describes either the line shape of off-specular and specular Bragg reflections.

Note, that starting from the configuration in Figure 8(a) and turning the sample around the normal to the surface by the angle Φ increases efficiently the spacing $a = a_0/\cos\Phi$, where $a_0 = a_1 + a_2$, and decreases τ, that is the distance between Bragg peaks positioned at $Q_x = \tau$. Finally, at $\Phi \to \pi/2$ the Bragg peaks merge the specular reflection at $Q_x = 0$. This effect (Toperverg *et al.*, 2000) will be illustrated in the subsequent text with experimental results (Theis-Bröhl, Schmitte, Leiner and Zabel, 2003; Theis-Bröhl *et al.*, 2003; Theis-Bröhl, 2003). The consideration in the preceding text, however, does not cover a crossover to the limit when the corresponding coherence length becomes comparable with the size of a single structural element as it happens if $\Phi \to \pi/2$. Finally, the specular reflectivity is accounted for as incoherent sum of reflected signals from different stripes and from interstripe spaces. It is a very difficult task to accurately pass the crossover from one regime of averaging to another, while one can match two limiting cases via a weight function controlling respective contributions of coherent and incoherent processes into the measured signal.

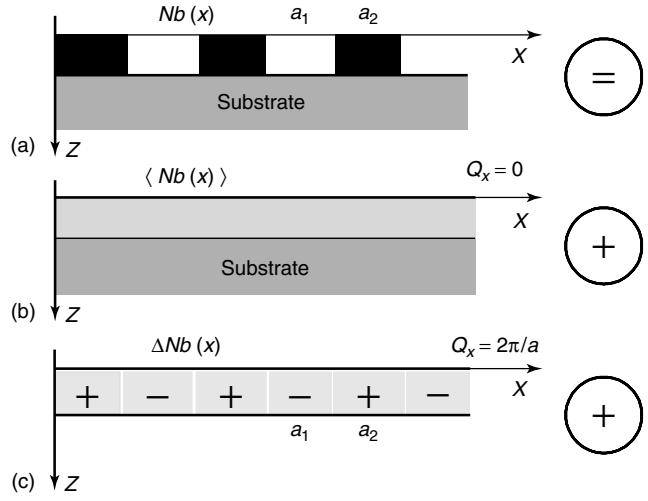

Figure 10. Decomposition of the SLD lateral pattern into a mean layer SLD $\langle Nb \rangle$ (contributing to specular reflection) and SLD deviations $\Delta Nb(x)$, responsible for off-specular diffraction.

Clear discrimination between coherent and incoherent procedures of averaging is especially important for magnetic systems. Magnetic off-specular scattering is due to the potential $\Delta\hat{V}_l^M(\boldsymbol{\rho}) = -(\hat{\boldsymbol{\mu}}\Delta\boldsymbol{B}_l)$ of neutron interaction with deviations $\Delta\boldsymbol{B}_l(\boldsymbol{\rho}) = \boldsymbol{B}_l(\boldsymbol{\rho}) - \overline{\boldsymbol{B}}_l$ of magnetic inductance $\boldsymbol{B}_l = \boldsymbol{B}_l(\boldsymbol{\rho})$ from its mean value $\overline{\boldsymbol{B}}_l = \langle \boldsymbol{B}_l(\boldsymbol{\rho})\rangle_{\rm coh}$ averaged over the coherence range. These deviations have to be classified taking into account the choice of the reference magnetic potential, that is the absolute value and direction of the vector $\overline{\boldsymbol{B}}_l$ pointing along the unit vector $\boldsymbol{b}_l^{\parallel} = \overline{\boldsymbol{B}}_l/|\overline{\boldsymbol{B}}_l|$.

An example of such a classification is shown in Figure 11 for the 'cartoon model' of magnetization distribution over a stripe array in the demagnetized state. The reason for this sort of distribution may be due to the competition between shape anisotropy of the stripes and the sample. This is discussed in the subsequent text in more detail, while for now we concentrate on basic principles of the theoretical description of specular and off-specular PNR from domain patterns such as those shown in Figures 9(b) and 11(c). In the latter figure the stripe magnetization is arranged into two large domains comprising a number of stripes and separated by a domain wall (DW) running across the stripes. In one of the domains the vector $\boldsymbol{B} = \boldsymbol{B}^j$ in each stripe is tilted to the right by the angle γ^j different for even and odd values of the superscript j enumerating the stripes. In the other domain the magnetization is tilted to the left with respect to the shape induced anisotropy directed along the y axis. The mean inductance $\overline{\boldsymbol{B}}$ and, correspondingly, the vector $\boldsymbol{b}^{\parallel}$ is also tilted to the right in one domain and to the left in the other domain by the angles $\overline{\gamma} \approx \pm\pi/2$ as presented in the middle panel. The net inductance of two domains (in the particular example it is zero) may be directed along the y axis, while the alternating vectors of deviations $\Delta\boldsymbol{B}^j(x)$ are directed along and opposite to the stripes, so that the angle $\beta^j = \gamma^j - \overline{\gamma}$ between directions of vectors $\boldsymbol{B}^j$ and $\overline{\boldsymbol{B}}$ alters sign in neighboring stripes, and in Figure 11(c) $\beta^j \approx (-1)^j\pi/2$. In such a configuration of domains the SF specular reflections are accompanied by NSF off-specular Bragg diffraction [7] if the polarization analysis direction is set along the y-axis. At the same time, the deviation angles γ^j decrease the mean value of the magnetic LSD $\overline{(Nb)}^M = (Nb)|\overline{\cos\gamma^j}|$ and the magnetic contribution to the specular reflection is reduced in favor of the off-specular Bragg scattering. If, in particular, $\gamma^j = \pm\pi$, then magnetic scattering does not contribute to specular reflection at all.

Often the angles β^j experience random fluctuations around the mean values $\overline{\beta^j}$ by the angles $\Delta\beta^j(x, y)$. Such fluctuations may be caused by defects, structural roughness, or may develop in a range of parameters where the magnetic structure becomes unstable and tends to rearrange in a more stable domain configuration. These fluctuations reduce both specular and Bragg reflections. By definition the mean value

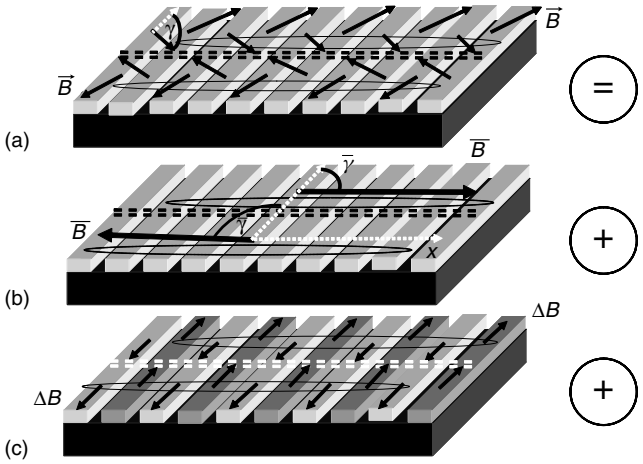

Figure 11. Magnetic domains in striped pattern. Arrows in (a) indicate directions of local inductance $\boldsymbol{B}(x, y)$ within the coherence ellipsoids. In each stripe it is tilted by an angle $\gamma(x, y)$ against the y axis. The wall between two domains is shown by a double dashed line. Thick arrows in (b) represent the mean domain inductance $\overline{\boldsymbol{B}}(y)$ with the tilt angles $\overline{\gamma}(y)$. The lateral distribution over stripe deviations $\Delta\boldsymbol{B}(x, y) = \boldsymbol{B}(x, y) - \overline{\boldsymbol{B}}(y)$ is displayed in (c).

$\overline{\Delta\beta^j} = 0$. However, $\overline{(\Delta\beta^j)^2} \neq 0$, while fluctuations $\Delta\beta^j$ may be correlated so that the mean value $\langle\Delta\beta^j\Delta\beta^{j'}\rangle \neq 0$ for a certain number of neighboring structural elements indexed by $j \neq j'$. If these elements are comprised within the coherence length in the x direction, then such fluctuations cause SF and NSF diffuse off-specular scattering concentrated around each Bragg peak including the one of zeroth order, that is specular reflection.

In the counterexample shown in Figure 9 the domain magnetization is randomly distributed over the layer plane. Then diffuse off-specular scattering is centered around $Q_x = 0$ and its spread over Q_x is determined by their mean size. Both, specular reflection and diffuse scattering may contain NSF and SF components. It is worth to note that random domains with dimensions smaller than the coherence length reduce the mean value $\overline{(Nb)}^M = (Nb)^M\overline{\cos\beta^j}$ of the magnetic SLD and the magnetic contribution to the specular and the Bragg reflections. In particular, the magnetic contribution may vanish if $\overline{\cos\beta^j} = 0$. In this case, random domains mainly scatter in the off-specular directions.

In layered systems the vector $\boldsymbol{b}_l^{\parallel}$ may vary from layer to layer, hence being not necessarily collinear with the direction of the polarization analysis, tilted against this direction by an angle $\overline{\gamma}_l$ and varying also from one coherence spot to another along the layer plane. Within each of such spots the unit vector $\boldsymbol{b}_l^{\parallel}$ together with two other orthogonal unite vectors: $\boldsymbol{b}_l^{\perp} \perp \boldsymbol{b}_l^{\parallel}$, chosen within the layer plane, and $\boldsymbol{b}_l^{\dashv} = [\boldsymbol{b}_l^{\perp} \times \boldsymbol{b}_l^{\parallel}]$, normal to the surface, determines the local Cartesian coordinate system. The vector of the inductance deviations $\Delta\boldsymbol{B}_l = \Delta\boldsymbol{B}_l(x, y)$ can naturally be expanded over

the triad of unit vectors so that,

$$\Delta \boldsymbol{B}_l = \Delta B_l^{\parallel} \boldsymbol{b}_l^{\parallel} + \Delta B_l^{\perp} \boldsymbol{b}_l^{\perp} + \Delta B_l^{\dashv} \boldsymbol{b}_l^{\dashv} \tag{112}$$

where $\Delta B_l^{\parallel} = (\boldsymbol{b}_l^{\parallel} \boldsymbol{B}_l) - \overline{(\boldsymbol{B}_l \boldsymbol{b}_l^{\parallel})}$ describes the deviation of the inductance projection parallel to $\boldsymbol{b}_l^{\parallel}$, while two other terms in the expansion equation (112) correspond to deviations in the local induction directions with respect to its mean orientation within the coherence range. Correspondingly, the scattering amplitude vector of magnetic scattering in equation (96) can be decomposed into three components

$$\boldsymbol{F}(\boldsymbol{Q}) = \sum_l \{F_l^{\parallel} \boldsymbol{b}_l^{\parallel} + F_l^{\perp} \boldsymbol{b}_l^{\perp} + F_l^{\dashv} \boldsymbol{b}_l^{\dashv}\} \tag{113}$$

Here the first term, $F_l^{\parallel} = (\boldsymbol{F}_l \boldsymbol{b}_l^{\parallel})$, is due to longitudinal deviations $\Delta B_l^{\parallel}$. This term, as well as the scalar scattering amplitude represented as a sum

$$F_0(\boldsymbol{Q}) = \sum_l F_l^0 \tag{114}$$

of partial scalar amplitudes $F_l^0 = F_l^0(\boldsymbol{Q})$, do not mix neutron spin states if the quantization axis is chosen along $\boldsymbol{b}_l^{\parallel}$. Hence, in BA the longitudinal components $F_l^{\parallel} = F_l^{\parallel}(\boldsymbol{Q})$, together with $F_l^0 = F_l^N$, which is due to deviations in the nuclear SLD, is responsible for NSF off-specular scattering if the polarization analysis direction is set collinear with the vector $\boldsymbol{b}_l^{\parallel}$. The next two terms in this case mix spin states and create off-specular SF scattering.

Generally, in magnetically inhomogeneous media the inductance vector $\boldsymbol{B}_l = \boldsymbol{B}_l(x, y)$ changes either its direction and its absolute value in accordance with the Maxwell equations. However, in many cases of practical importance the magnetization, and consequently the inductance, are rather homogeneously distributed over relatively large areas, as indicated in Figure 11, while changing their values across relatively narrow regions between those areas. This particularly occurs in continuous films in which narrow DWs separate homogeneously magnetized domains (Figure 9). Each of the latter occupies a substantial volume and, if it is smaller than the coherence ellipsoid, creates quite powerful off-specular scattering. Certainly, DWs also scatter neutrons in off-specular directions. However, this scattering is by several orders of magnitude weaker just due to a very small volume of the sample they occupy. That is why in the first approximation one can safely neglect the DW thickness, set $|\boldsymbol{B}_l| = const$ and equal in each domain to its nominal value, and regard continuity conditions for the magnetic flux components normal to the wall faces. Note, that owing to the continuity conditions across the interfaces between layers the last terms in equations (112) and (113) vanish.

Assuming that the domain magnetization is displayed in the layer plane one concludes that $\Delta B_l^{\parallel} = |\boldsymbol{B}_l|(\cos\beta_l^j - \overline{\cos\beta_l})$, while $\Delta \boldsymbol{B}_l^{\perp} = |\boldsymbol{B}_l| \sin\beta_l^j$, and $\beta_l^j = \beta_l^j(x, y)$ describe deviations $\beta_l^j = \gamma_l^j - \overline{\gamma}_l$ in angles $\gamma_l^j = \gamma_l^j(x, y)$ of the domain magnetization from the mean value $\overline{\gamma}_l(y)$ averaged over domains within the coherence area. Setting $\overline{\gamma}_l = \overline{\gamma}_l(y)$ as a function of only one, for example, the y-coordinate, we, actually, apply the same approximation as in the consideration of nuclear off-specular scattering. This is valid under the assumption that the long axis of the coherence ellipsoid crosses many domains along the x axis, while the short ellipsoid axis is smaller than the domain size in y direction.

Then the amplitudes of magnetic scattering from longitudinal and transverse deviations in BA can be written down explicitly in a form

$$F_l^{\parallel,\perp}(Q_z, Q_x; y) = F_l^z(Q_z, y) \sum_j \mathrm{e}^{i Q_x x_j} \tilde{F}_{lj}^{\parallel,\perp}(Q_x, y) \tag{115}$$

similar to that of equation (A1), in which the transverse form-factor $F_l^z(Q_z, y)$ is determined by equation (A2) in the Appendix A.

The lateral distribution of magnetic inhomogeneities is determined by the functions $\tilde{F}_{lj}^{\parallel}(Q_x, y)$ and $\tilde{F}_{lj}^{\perp}(Q_x, y)$ which can be represented as Fourier transforms

$$\tilde{F}_{lj}^{\parallel,\perp}(Q_x, y) = \int_0^{a_j} \mathrm{d}x\, \mathrm{e}^{i Q_x x} \Delta(Nb)_l^{\parallel,\perp}(x, y) \tag{116}$$

of the longitudinal, $\Delta(Nb)_l^{\parallel}(x, y) = (Nb)_l^M(\cos\beta_l - \overline{\cos\beta_l})$, and transverse, $\Delta(Nb)_l^{\perp}(x, y) = (Nb)_l^M \sin\beta_l$ deviation in magnetic SLD. This equation has exactly the same shape as equation (A3) for the lateral form-factor $F_{lj}^L(Q_x, y)$ of nuclear scattering (see in Appendix A), if one notices that $\Delta(Nb)_l^{\parallel,\perp}(x, y) = (Nb)_l^{\parallel,\perp}(x, y) - \overline{(Nb)_l^{\parallel,\perp}}(y)$ with $(Nb)_l^{\parallel}(x, y) = (Nb)_l^M \cos\beta_l(x, y)$, $(Nb)_l^{\perp}(x, y) = (Nb)_l^M \sin\beta_l(x, y)$, $\overline{(Nb)}_l^{\parallel}(y) = (Nb)_l^M \overline{\cos\beta(y)}$, and $\overline{(Nb)}_l^{\perp}(y) = 0$. Therefore integration in equation (116) results in equations for $F_l^{\parallel,\perp}(Q_x, y)$ which immediately follow from equation (A4) if $\Delta(Nb)_l^m$ in this equation is substituted by $\Delta(Nb)_l^{m\parallel,\perp}$, where the index m enumerates magnetic structural elements in the unit cell along the x axis.

The magnetic unit cells may be different for longitudinal and transverse deviations and either of them may not coincide with the nuclear one. In the example sketched in Figure 11 the integral in equation (116) covers two stripes, where $\Delta(Nb)^{\perp} = \pm(Nb)^M |\sin\beta^j|$, and two interstripe spaces where $\Delta(Nb)^{\perp} = 0$, and the unit cell is doubled with respect to the nuclear one. Longitudinal deviations in

this case are suppressed due to the flux continuity conditions and $\Delta(Nb)^{\parallel} = 0$. For random domains drawn in Figure 9 the structural element coincides with a single domain and both types of deviations are present.

After the coefficients $F_l^{\parallel}$ and $F_l^{\perp}$ in equation (113) are found one can return to the laboratory coordinate system and write down explicitly equations

$$F_x = \sum_l (F_l^{\parallel} \cos\gamma_l + F_l^{\perp} \sin\gamma_l) \tag{117}$$

$$F_y = \sum_l (F_l^{\parallel} \sin\gamma_l + F_l^{\perp} \cos\gamma_l) \tag{118}$$

for F_x and F_y, which together with equation (109) and equation (A1) given in Appendix A for F_0 determine correlators $\langle F_\mu^* F_\nu \rangle$ in equation (108) and finally the scattering cross section in equation (98).

For the case of a single magnetic layer, the first term in equation (98) corresponding to the scattering cross section of unpolarized neutrons is simply a sum,

$$\Sigma_0 = \frac{1}{2}\langle |F^0|^2 + |F^{\parallel}|^2 + |F^{\perp}|^2 + |F^{\dashv}|^2 \rangle \tag{119}$$

of nuclear and all three possible cross sections of magnetic scattering. In BA the last term here vanishes, while the cross sections of scattering on longitudinal and transverse magnetization deviations are given by the equations which follow from equation (110) for $\langle |F_0|^2 \rangle$ if one substitutes $\mathcal{F}(Q_z, Q_x; y)$ in this equation for $\mathcal{F}^{\parallel}(Q_z, Q_x; y)$, or correspondingly, for $\mathcal{F}^{\perp}(Q_z, Q_x; y)$. Equations for the latter quantities can immediately be obtained from equation (111) by substitution the respective magnetic form-factors $F_l^{\parallel,\perp}(Q_x, y)$, given in equation (116), instead of the nuclear one $F_l^L(Q_x, y)$ presented in the Appendix A. The result can be used to evaluate the part of the scattering cross section bilinear with respect to polarizations. In accordance with equation (106) the corresponding equation takes the following shape

$$\Sigma_{yy} = \Sigma_0 - \langle |F_x|^2 + |F_z|^2 \rangle \tag{120}$$

where the last term in BA is neglected.

In contrast to Σ_0, the term Σ_{yy} explicitly depends on the angle $\gamma(y)$. In principle, this angle can also be determined by means of a reduced version of PNR, when either $P^i \neq 0$, but $P^f = 0$, that is incident neutrons are polarized, but no analysis of the final spin state is available, or vice versa, when $P^i = 0$, but $P^f \neq 0$. In both cases, the linear term with respect to P^i, or P^f in equation (98) changes sign if the polarization is flipped. Hence interference between magnetic and nuclear scattering can readily be separated from other contributions. Such interference may contribute into off-specular diffraction if, in accordance to equations (104) and (105), deviations in magnetic and nuclear SLDs are properly correlated. This, unfortunately, is not the case for the example sketched in Figure 11. Correlations, indeed take place for components of magnetic inductance perpendicular to $\overline{\boldsymbol{B}}$. However, according to equation (A4) presented in Appendix A, the nuclear structure factor vanishes at the position of the magnetic superstructure Bragg reflection.

On the other hand, the magnetic structure factor vanishes at the position where the nuclear structure shows a Bragg peak. As a result, the interference term, which is proportional to the real part of the product $\langle F^{\perp}(Q_x, y) F^L(Q_x, y) \rangle$, does not contribute to the Bragg diffraction, as can be seen in Figure 12(a) and (c). In this figure, the results of the calculation in BA are represented in the form of maps of the scattered intensity distribution over the plane with coordinates p_0^i versus p_0^f. For the stripe pattern shown in Figure 11 there are no longitudinal deviations of the magnetization and the magnetic-nuclear interference term affects only the specular SF reflectivity seen as a ridge running along the diagonal in Figure 12(a). The intensity variation along this ridge is calculated exactly, including all interference terms, and together with the NSF reflectivity ridge (Figure 12c) it, in principle, allows the determination of the angle γ. Other parameters of the model and in particular, the magnetization distribution over the stripe array, can be deduced from a quantitative analysis of the intensity distribution between different Bragg diffraction bands seen as curved lines in the maps. There is, however, an appreciable difference between the intensity distributions as calculated in BA (Figure 12a and c) as compared to calculations in DWBA (Figure 12b and d). The differences are visible over a significant area in the maps and are most pronounced for small p_0^i and p_0^f. Only at high values of p_0^i and p_0^f the results of DWBA collapse to those obtained in BA. In this range, the scattered intensity is already reduced due to lateral and transverse form-factors, while superstructure diffraction bands merge with the specular ridge. In conclusion, while BA has an applicability range at high values of p_0^i and p_0^f, it can hardly be used for any quantitative evaluation of data taken with PNR. Moreover, BA may often be misleading even for a qualitative interpretation of experimental results of specular and off-specular scattering from magnetization distributions in thin films and multilayers.

2.11 Distorted wave Born approximation

All general equations which have already been derived in the preceding text for the polarization analysis (e.g.,

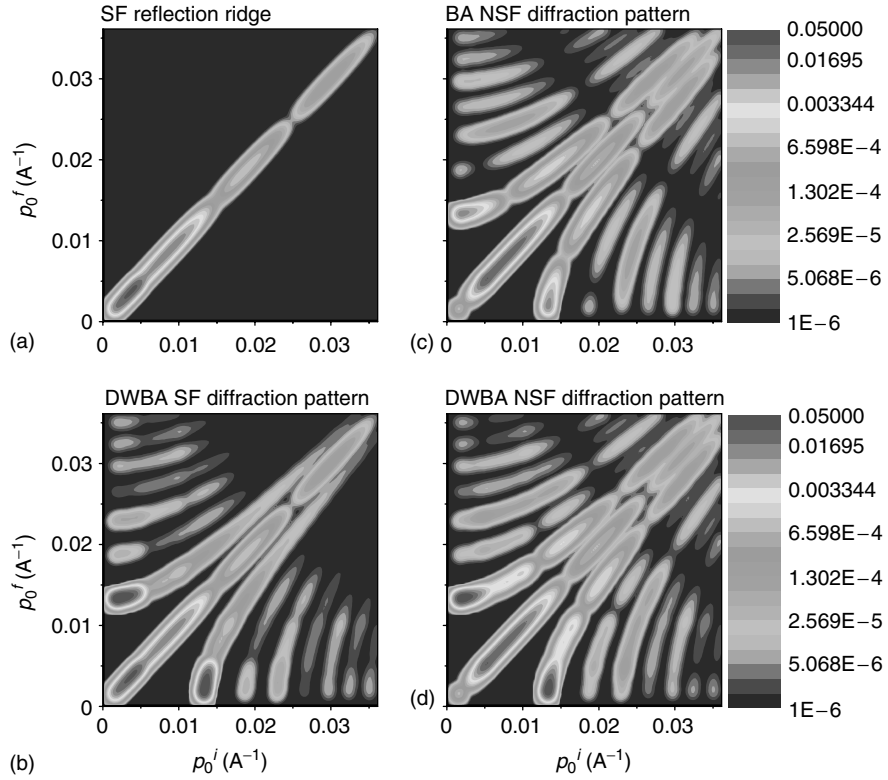

Figure 12. SF (a and b) and NSF (c and d) scattering intensity distribution over incoming, p_0^i versus outgoing, p_0^f wave vector components normal to the surface. Calculations are performed in BA (a and c) and in DWBA (b and d) for the model of a Co/Fe stripe array on a silicon wafer, as depicted in Figure 11. The stripes have a width of 4.75 µm and a height of 270 Å. They are separated by empty space of 0.25 µm. All panels show SF and NSF specular reflection ridges running along diagonals of the maps at $p_0^i = p_0^f$. Sets of Bragg diffraction bands are seen as bent lines in all panels except for the first one. They approach the specular ridge and decay at elevated values of p_0^i and p_0^f where BA becomes valid. High intensity bands correspond to magnetic superstructure due to the antiparallel or antiferromagnetic orientation of the stripe magnetization. Low intensity bands are due to nuclear scattering from the period of the stripe array. Intensity modulation superposed on the specular ridges and the diffraction bands is due to the height of the stripes. Differences in the period of this modulation, as well as absence of SF diffraction in (a) is due to the fact that BA ignores refraction in the mean optical potential. This effect is accounted for in DWBA, as explained in the main text.

equations (98–106)), as well as the discussion concerning the lateral components of structure- and form-factors (lateral averaging, etc.) remain valid and apply also at shallow incidence when the optical effects become important. However, in order to provide a quantitative description of the experimental situation, the equations for the transverse form-factors have substantially to be modified. This will, in particular, result in new polarization effects which are ignored in BA.

DWBA (Mott and Massey, 1965; Sinha, Sirota, Garoff and Stanley, 1988) is also based on the decomposition of the optical potential (equation (94)) into two parts, the averaged optical potential and deviations from the mean. The deviations from the average optical potential are treated as perturbations which cause off-specular scattering. However, the 1D Schödinger equation (9) for the mean potential averaged over those deviations $\hat{\overline{V}}(z) = \langle \hat{V}(\boldsymbol{r}) \rangle_{\text{coh}}$, is solved exactly. The solution $|\Psi(\boldsymbol{r})\rangle$ for layered systems was found in equations (56–58) in the factorized form $|\Psi(\boldsymbol{r})\rangle = \exp(i\kappa_x x + i\kappa_y y)|\psi(z)\rangle$, where

$$|\psi(z)\rangle = \sum_l \hat{\mathcal{S}}_l(z)|\Psi_0\rangle \tag{121}$$

$\kappa_x = \kappa_x^{i,f}$ and $\kappa_y = \kappa_x^{i,f}$ are lateral projections of the incoming and scattered wave vectors $\boldsymbol{k}^{i,f}$ and the $\hat{\mathcal{S}}_l(z) = \hat{\mathcal{S}}_l^{i,f}(z)$ matrices describe the neutron wave propagation inside the l^{th} layer before and after the scattering event on the deviation $\Delta\hat{V}_l$ of the interaction potential.

The $\hat{\mathcal{S}}$ matrices exactly account for refraction and reflection effects in the mean layer potentials, and instead of the equation for the Born amplitude matrix in equation (107)

one has to use the DWBA amplitude matrix in the following form

$$\hat{F}(\boldsymbol{k}^i, \boldsymbol{k}^f) = -\frac{m}{2\pi\hbar^2} \sum_l \int_{z_{l-1}}^{z_l} \mathrm{d}z \int \mathrm{d}\boldsymbol{\rho} \mathrm{e}^{i(Q_x x + Q_y y)} \times \hat{\mathcal{S}}_l^i(z) \Delta \hat{V}_l(x, y) \hat{\mathcal{S}}_l^f(z) \quad (122)$$

Here $\hat{F}(\boldsymbol{k}^i, \boldsymbol{k}^f) = \hat{F}(p_0^i, p_0^f; Q_x, Q_y)$, in contrast to the BA expression in equation (107) depends not only on the transverse wave vector transfer $Q_z = p_0^i - p_0^f$. Owing to the $\hat{\mathcal{S}}$ matrices, it depends also on the incoming, p_0^i, and scattered, p_0^f, wave vector projection normal to the surface.

The substitution of equation (121) into equation (122) results in an expression of the DWBA scattering amplitude matrix,

$$\hat{F}(p_0^i, p_0^f; Q_x, Q_y) = \sum_l \{\hat{F}_l^{tt} + \hat{F}_l^{tr} + \hat{F}_l^{rt} + \hat{F}_l^{rr}\} \quad (123)$$

via the sum of four terms corresponding to all possible partial amplitude matrices $\hat{F}_l^{\tau\rho}$ describing transitions between neutron wave spin components transmitted into and reflected from the layer mean potential. These amplitude matrices are written explicitly as

$$\hat{F}_l^{\tau\rho} = -\frac{m}{2\pi\hbar^2} \int_{z_{l-1}}^{z_l} \mathrm{d}z\, \hat{a}_l^{i\tau} \mathrm{e}^{i\hat{\varphi}_l^{i\tau}(z)} \Delta \hat{V}_l(Q_x, Q_y) \mathrm{e}^{i\hat{\varphi}_l^{f\rho}(z)} \hat{a}_l^{f\rho} \quad (124)$$

where the indices $\tau, \rho = t, r$ enumerate transmission and reflection matrices so that $\hat{a}_l^{it} = \hat{t}_l^i$, $\hat{a}_l^{ft} = \hat{t}_l^f$ are transmittance matrices for incoming and scattered waves, $\hat{a}_l^{ir} = \hat{r}_l^i$, $\hat{a}_l^{fr} = \hat{r}_l^f$ are corresponding reflectance matrices, $\hat{\varphi}_l^{it}(z) = \hat{p}_l^i(z - z_{l-1})$, $\hat{\varphi}_l^{ft}(z) = \hat{p}_l^f(z - z_{l-1})$, $\hat{\varphi}_l^{ir}(z) = -\hat{\varphi}_l^{it}(z)$ and $\hat{\varphi}_l^{fr}(z) = -\hat{\varphi}_l^{ft}(z)$ are phase matrices introduced in equation (57), with $\hat{p}_l^i = \sqrt{(p_0^i)^2 - \hat{p}_{cl}^2}$ and $\hat{p}_l^f = \sqrt{(p_0^f)^2 - \hat{p}_{cl}^2}$. In fact, owing to equations (123) and (124) $\hat{F}^{\tau\rho}$ is a supermatrix whose elements are composed of 2×2 spin matrices.

The DWBA scattering amplitude matrix given in equation (123), as well as each element of the supermatrix in equation (124) can be represented in the same manner as was done in equation (96) for the amplitude matrix in BA. Then substitution of the result into equation (97) yields a set of equations for the scattering cross section in DWBA identical with equations (98–106). In the next step one can use the expansion of the DWBA amplitude vectors $\boldsymbol{F}_l$ over unit vectors, as it has been done in equation (113) for the case of BA, and take into account that either transmission–reflection and phase matrices are diagonal in the representation with the quantization axis parallel to $\boldsymbol{b}_l^{\parallel}$.

This allows to express the scalars, F_l^0, in equation (114) and the corresponding components of the DWBA amplitude vectors $\boldsymbol{F}_l$ in equation (113) in the following compact form (Toperverg, Rühm, Donner and Dosch, 1999; Toperverg, Nikonov, Lauter-Passyuk and Lauter, 2001)

$$F_l^0 = \frac{1}{2}(F_l^{++} + F_l^{--}) \quad (125)$$

$$F_l^{\parallel} = \frac{1}{2}(F_l^{++} - F_l^{--}) \quad (126)$$

$$F_l^{\perp} = \frac{1}{2}(F_l^{+-} + F_l^{-+}) \quad (127)$$

$$F_l^{\dashv} = \frac{i}{2}(F_l^{+-} - F_l^{-+}) \quad (128)$$

In these equations the amplitudes

$$F_l^{++} = \tilde{F}_{l++}^N + \tilde{F}_{l++}^M \quad (129)$$

$$F_l^{--} = \tilde{F}_{l--}^N - \tilde{F}_{l--}^M \quad (130)$$

correspond to nuclear scattering, $\tilde{F}_{l\pm\pm}^N$, and magnetic scattering, $\tilde{F}_{l\pm\pm}^M$, which maintain the neutron spin states after splitting in the mean magnetic field in the layer l. The amplitudes $\tilde{F}_l^{+-} = \tilde{F}_{l+-}^M$ and $\tilde{F}_l^{-+} = \tilde{F}_{l-+}^M$ describe scattering processes, which mix those states.

Owing to equations (123) and (124) each amplitude $\tilde{F}_{l\mu\nu}^{N,M}$, with $\mu = \pm, \nu = \pm$, is represented by the linear combination [8]

$$\tilde{F}_{l\mu\nu}^{N,M} = \frac{1}{2} \sum_{\tau,\rho} a_\mu^{f\tau} F_{l\mu\nu}^{N,M}(Q_{\mu\nu}^{\tau\rho}, Q_x, Q_y) a_\nu^{i\rho} \quad (131)$$

of the Born amplitudes $F_{l\mu\nu}^{N,M}(Q_{\mu\nu}^{\tau\rho}, Q_x, Q_y)$. The latter ones depend on a number of different effective transverse wave vector transfers $Q_{\mu\nu}^{tt} = p_{l\mu}^i + p_{l\nu}^f = -Q_{\mu\nu}^{rr}$, $Q_{\mu\nu}^{tr} = p_{l\mu}^i - p_{l\nu}^f = -Q_{\mu\nu}^{rt}$, relevant to the various matrix elements between transmitted ($\tau, \rho = t$) and reflected ($\tau, \rho = r$) waves with, or without intermixing of the spin states. To shorten the notation for all these wave vector transfers they can be combined in a unique supermatrix $\hat{Q}_z = Q_{\mu\nu}^{\tau\rho}$. In equation (131) the amplitudes $F_{l\mu\nu}^{N,M}(\hat{Q}_z, Q_x, Q_y)$ are decorated by the corresponding amplitudes of transmission, $a_\pm^{it} = t_\pm^i$ and $a_\pm^{ft} = t_\pm^f$, into the layer through its front face, or reflection $a_\pm^{ir} = r_\pm^i$ and $a_\pm^{fr} = r_\pm^f$, from its back interface.

The matrix elements $F_{l\pm\pm}^N$ describe nuclear off-specular scattering of either positive or negative spin components of the neutron wave. They are proportional to the nuclear SLD contrast fluctuations $\Delta\overline{(Nb)_l^N} = (Nb)_l^N - \overline{(Nb)_l^N}$ with respect to its mean value $\overline{(Nb)_l^N}$ and are mostly due to the interfacial roughness, or due to artificial patterning. It

is important to note that $F^N_{l++} \neq F^N_{l--}$ even though SLD and the Born amplitude F^N_l of nuclear scattering given in Appendix A are independent of the spin state. This is a direct consequence of DWBA which describes scattering of neutron waves whose spin states are split due to the Zeeman effect in the mean optical potential. Hence their wave numbers are different. Nuclear scattering, certainly, does not mix those states.

The amplitudes $F^M_{l\pm\pm}$ correspond to off-specular scattering from longitudinal deviations $\Delta(Nb)^{\parallel}_l = \overline{(Nb)^M_l}(b^{\parallel}_l - \langle b^{\parallel}_l\rangle)$ of the projection $b^{\parallel}_l = (\boldsymbol{b}_l\boldsymbol{b}^{\parallel}_l) = \cos\beta_l$ of the local vector $\boldsymbol{b}_l = \boldsymbol{b}_l(x, y)$ onto the direction of $\boldsymbol{b}^{\parallel}_l$ from its mean value $\langle b^{\parallel}_l\rangle = \langle(\boldsymbol{b}_l\boldsymbol{b}^{\parallel}_l)\rangle = \overline{\langle\cos\beta_l\rangle}$ averaged over domains within the coherence range. Scattering from longitudinal magnetic fluctuations also maintains the neutron spin state. Two amplitudes, $F_{l\pm\mp} = F^M_{l\pm\mp}$, are due to fluctuations $\Delta(Nb)^{\pm}_l = (Nb)^M_l[(\boldsymbol{b}_l\boldsymbol{b}^{\perp}_l) \mp i(\boldsymbol{b}_l\boldsymbol{b}^{\dashv}_l)]$ of the field components perpendicular to $\boldsymbol{b}^{\parallel}_l$ and correspond to magnetic scattering which mix the spin states.

Consequently, the calculation in DWBA is reduced to simply a substitution of the Born amplitudes

$$F^{N,M}_{l\mu\nu}(\hat{Q}_z, Q_x, Q_y) = \int \mathrm{d}\boldsymbol{r}\, \mathrm{e}^{i(\hat{Q}_z z + Q_x x + Q_y y)}\Delta(Nb)^{N,M}_{\mu\nu} \tag{132}$$

into equation (131), taking into account that $\Delta(Nb)^N_{\pm\pm} = \Delta(Nb)^N_l$, $\Delta(Nb)^M_{\pm\pm} = \Delta(Nb)^{\parallel}_l$, while $\Delta(Nb)^M_{\pm\mp} = \Delta(Nb)^{\pm}_l$. If $(\boldsymbol{b}_l\boldsymbol{b}^{\dashv}_l) = 0$ then $\Delta(Nb)^M_{\pm\mp} = \Delta(Nb)^{\perp}_l$.

After the DWBA amplitudes have been determined, the lateral averaging can be accomplished in exactly the same way as was done for the BA cross sections in the preceding text. In particular, similar to equation (109) one can define the Fourier transform of equation (132),

$$F^{\lambda}_{l\mu\nu}(\hat{Q}_z, Q_x; y) = \frac{1}{2\pi}\int \mathrm{d}Q_y \mathrm{e}^{-iQ_y y} F^{\lambda}_{l\mu\nu}(\hat{Q}_z, Q_x, Q_y) \tag{133}$$

for each of the three amplitudes indexed by the superscript λ, denoting N, $\parallel$, or $\perp$. Then instead of equation (115) and equation (A1) in Appendix A one has the following set of equations:

$$F^N_l(\hat{Q}_z, Q_x; y) = F^z_l(\hat{Q}_z, y)\sum_j \mathrm{e}^{iQ_x x_j} F^L_{lj}(Q_x, y) \tag{134}$$

$$F^{\parallel,\perp}_l(\hat{Q}_z, Q_x; y) = F^z_l(\hat{Q}_z, y)\sum_j \mathrm{e}^{iQ_x x_j} \tilde{F}^{\parallel,\perp}_{lj}(Q_x, y) \tag{135}$$

These equations differ from the former ones just by the argument of the BA transverse form-factor $F^z_l(Q_z)$, provided in equation (A2) of Appendix A and depending on the transverse projection of the wave vector transfer Q_z. In DWBA Q_z has to be substituted for one of the 16 components of the supermatrix $\hat{\mathcal{Q}}_z = Q^{\tau\rho}_{\mu\nu}$. Then the corresponding results are to be inserted into the sum equation (131) used to calculate the amplitude components determined in equations (125–128), and then in equations (117–118). The latter finally give access to the terms of the cross sections determined in equation (98).

The sketched procedure to determine the scattering amplitudes in DWBA appears cumbersome while comprising all processes of NSF and SF nuclear and magnetic scattering of neutron waves refracted in and reflected from the mean optical potential. However, being well structured the procedure can easily be programmed and, as we shall see, allows to analyze rather complex multilayered systems providing a wealth of information hardly accessible by other means. The effects of each step in DWBA (reflection and transmission amplitudes, birefringence, etc.) can perfectly be classified so that a qualitative interpretation of prominent features detected in properly presented raw data can serve as a solid basis for choosing an adequate theoretical model. The latter, being further refined via, for example, a least square fit routine, would then quantify the information contained in the scattering pattern. Some of those distinct features are illustrated for a few benchmark examples discussed further in the subsequent text.

Before doing so, let us turn back to Figure 12 demonstrating the role of transmission–reflection factors in equation (131) for a simple example of a single periodically patterned film of Co, as sketched in Figure 11. Calculation carried out in BA (Figure 12a and c) and in DWBA (Figure 12b and d) for the same pattern and collected in the maps in Figure 12 show that in BA some essential features are missing. In particular, DWBA calculations for NSF scattering (Figure 12d) reveal noticeable difference as compared to BA results (Figure 12c). Thus, in contrast to BA, the oscillations along diffraction bands in the DWBA map are perfectly in phase with those on the specular ridge, as they should. This improvement of the BA outcome is due to the fact that the transverse form-factor in DWBA depends on the wave numbers $p^i_{\pm}$ and $p^f_{\pm}$ corrected for refraction effects, instead of those in the vacuum used by BA.

However, the most striking result of DWBA is that it provides SF Bragg diffraction. The latter is manifested via strong SF diffraction bands seen in Figure 12(b), which are absent in BA shown in Figure 12(a). This effect is mainly due to the transmission, $t^{i,f}_{\pm}$ and reflection, $r^{i,f}_{\pm}$ amplitudes in equation (131). These amplitudes take into account that the mean magnetic field of the effective layer (sketched in Figure 10b) oriented in accordance with Figure 11(b) not collinear with the polarization analysis axis. In such a

configuration both states with spin projections along and opposite to the mean magnetic field of the neutron wave inside the effective layer are populated. Then each of both spin components is scattered at local (periodic) deviations from the magnetic and nuclear SLD. In short, this example demonstrates that if the mean magnetic field in the layer is noncollinear with the initial polarization, SF off-specular scattering may occur due to *longitudinal* magnetic and *even nuclear* inhomogeneities. Local field projections perpendicular to the direction of the mean magnetic field mix spin states, while those parallel to this direction maintain the neutron spin states, which are split in the mean magnetic field. If the latter is directed perpendicular to the polarization analysis axis, as in Figure 11, then spin states are equally populated and SF scattering intensities $I^{+-} = I^{-+}$. More generally, as we shall see subsequent text for another example, $I^{+-} \neq I^{-+}$, and contribution of magnetic scattering can be separated that arising due to the nuclear scattering.

The role of transmission–reflection amplitudes is not restricted to the mixing of initial neutron spin states in case of noncollinearity between magnetization and polarization directions discussed in the preceding text. These amplitudes may also be responsible for another peculiar and often confusing features observed even for such a simple system as a single F film in a multidomain state. An example of NSF and SF scattering maps from domains in a 200 Å thick Co film on a Si substrate is displayed in a set of maps [9] in Figure 13. In the model system, it was assumed that the domain size is on the average 50 μm, and the domain magnetization is randomly tilted by an angle $\Delta\gamma$ with respect to the mean value averaged over the coherence volume. This mean magnetization itself may vary as a function of the y coordinate yielding an angle $\overline{\gamma}(y)$, as sketched in Figure 9. Short range magnetization fluctuations due to domains reduce the mean magnetic optical potential by a factor $\overline{\cos(\Delta\gamma)}$. In the simulation this value is set to ≈ 0.3. The second effect of these fluctuations is off-specular diffuse scattering, which is due to either magnetization projections perpendicular to the mean magnetization, or due to longitudinal fluctuations. Perpendicular fluctuations are characterized by the mean value $\overline{\sin^2(\Delta\gamma)}$, which here was chosen to be 0.75. For such a choice both perpendicular and longitudinal fluctuations contribute to off-specular scattering. As was mentioned in the preceding text, the contribution of the latter ones is proportional to the dispersion [10] $\tilde{\Delta} = \overline{\cos^2(\Delta\gamma)} - \overline{\cos(\Delta\gamma)}^2 = 0.16$.

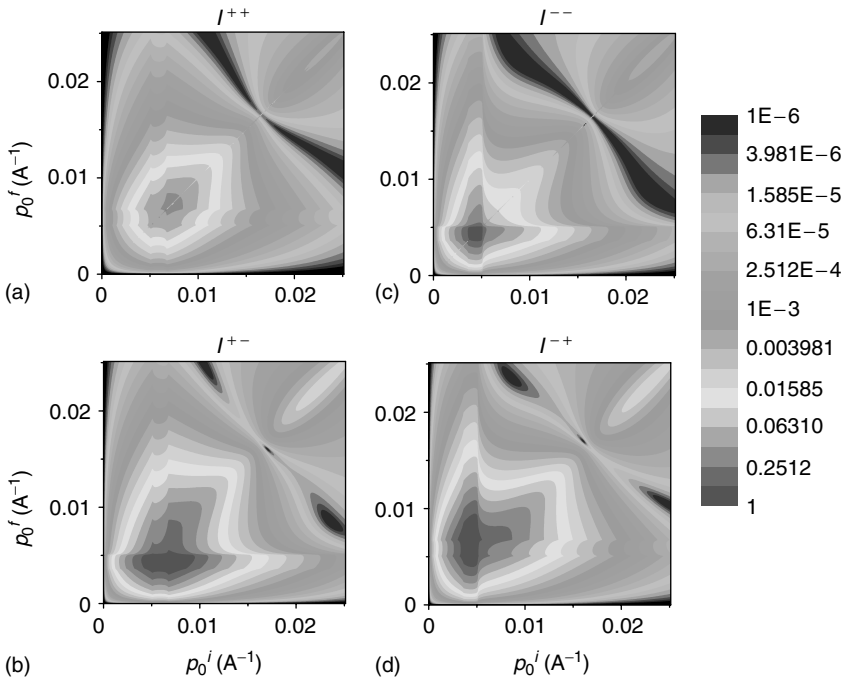

Figure 13. NSF (a) and (c) and SF (b) and (d) off-specular scattering intensity distribution calculated for a ferromagnetic 200 Å thick Co film deposited onto a Si substrate. It is assumed that the Co film is decomposed into a set of random domains with the mean size of 50 μm. The distribution of angles $\Delta\gamma$ between magnetization directions and the y axis is characterized by two parameters: $\langle\cos(\Delta\gamma)\rangle = 0.30$ and $\langle\sin^2(\Delta\gamma)\rangle = 0.75$. The mean magnetization averaged over the coherence length along the x axis is assumed to be independent of the y coordinate and to be collinear with the polarization analysis direction set along the y axis. Specular reflection ridges are eliminated for clarity.

Figure 13(a) and (c) present intensity distributions of NSF diffuse scattering. The dramatic difference between the scattering intensity I^{++} with positive spin projection (a), and I^{--} for negative spin projection (c) demonstrate the sensitivity of the diffuse scattering to the residual magnetization. In the model calculations, the mean magnetization averaged over the coherence range is reduced down to only 30% of its nominal value.

The off-specular diffuse NSF scattering reaches its maximum value at higher angles for neutrons polarized parallel to the mean magnetic magnetization (Figure 13a and b) than for neutrons polarized opposite to it (Figure 13c and d). Such a location of diffuse scattering on the maps is the direct consequence of the particular dependencies of the transmission and reflection amplitudes in equation (131) plotted in Figure 14. There one can clearly recognize a few prominent features. First of all, transmission and reflection amplitudes reveal noticeable singularities at points of the total reflection for this or the other spin components. These singularities substantially enhance the diffuse scattering (up to a factor 16 for a single film). Such enhancement is well known as the *Yoneda effect* (Yoneda, 1963) firstly observed for X-ray scattering from rough surfaces. In the case of off-specular scattering from domains, the neutron field is enhanced in the magnetic film at the critical edges $p_{c\pm}$ and at the critical wave number for the substrate. For our example the neutron field for positive spin projection is enhanced at $p_0 = p_{c+} \approx 6.7 \times 10^{-3}\,\text{Å}^{-1}$, while for both of them at $p_0 = p_s \approx 5.1 \times 10^{-3}\,\text{Å}^{-1}$, that is at the critical wave number for the silicon substrate.

The singularity related to the substrate is quite weak in Figure 14, but it is well expressed in Figure 13(c). This is due to the influence of the transverse form-factor discussed in the subsequent text for a Co film on a sapphire substrate where the effect is even more dramatic. For Co material the nominal magnetic optical potential is almost twice as big as the nuclear one [11]. Therefore, the critical wave number p_{c-} for saturated Co is imaginary and for the negative spin component there is no critical angle for total reflection. Then the first singularity in Figure 14 has to be absent. If, however, the Co film is partially demagnetized due to domains smaller than the coherence range then the mean magnetization may be reduced so that the mean magnetic SLD becomes lower than the nuclear one. Assuming a residual 30% of the nominal magnetization, the critical wave number for the state with negative spin projection is $p_{c-} \approx 3.6 \times 10^{-3}\,\text{Å}^{-1}$ and corresponding singularity is well presented in Figure 14. This figure, certainly, does not provide a full impression on the behavior of the transmission and reflection amplitudes, which are complex quantities. Nonetheless, Figure 14 can qualitatively explain the peculiarities of the diffuse intensity distribution over the maps plotted in Figure 13. For instance,

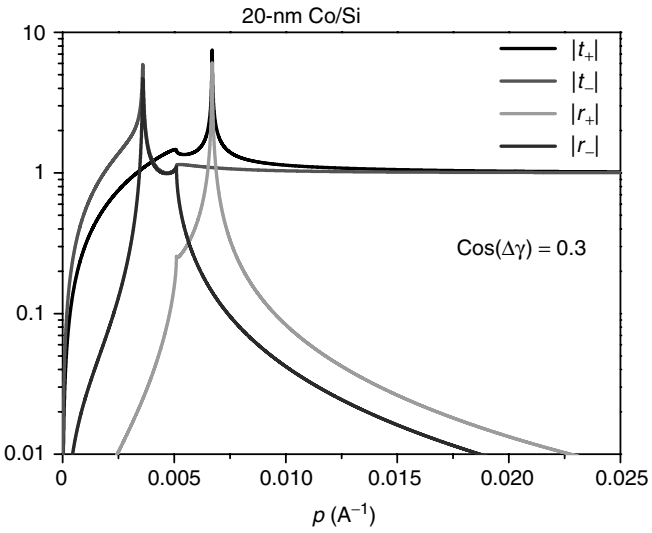

Figure 14. Transmission, $|t_\pm|$, and reflection, $|r_\pm|$ amplitudes of the neutron wave field in the mean optical potentials of the effective ferromagnetic 200 Å thick Co film on a Si substrate.

one can see that the reflection and transmission amplitudes at the critical edges are equal and just this fact doubles the neutron wave field which can be scattered in corresponding off-specular direction. Solely this fact provides an enhancement factor of 16 for the DWBA scattering cross section over the result obtained within BA. In reality, such enhancement factors may reach up to a few orders of magnitude depending on the particular design of the multilayer stack. At the wave numbers smaller than critical edges for the total reflection transmission and reflection amplitudes rapidly decay. This leads to a strong reduction of the scattered intensity when the neutron waves do not penetrate deep into the mean optical potential.

The transmission–reflection amplitudes also explain the substantial asymmetry in the SF scattered intensity distribution as seen in Figure 13. Indeed, SF scattering accounts for the fact that the spin states in the incoming and outgoing neutron waves are inversely populated. As mentioned before we consider here for clarity the case that the mean magnetization is collinear with the neutron polarization axis. Then Figure 13(d) refers to an incoming beam polarized opposite to the magnetization direction (spin-down state) and the corresponding amplitudes t^i and r^i are enhanced only at $p_0^i = p_s$ and at $p_0^i = p_{c-}$. Therefore, each cut of this map at fixed outgoing p_0^f, that is along the abscissa, shows an enhancement of the *incoming* wave field at $p_0^i = p_{c-}$ and at $p_0 = p_s$ (these two singularities are not well resolved in the maps). If at the same time the outgoing neutron is flipped into the up state then the corresponding amplitudes t^f and r^f provide the *scattered* wave field enhancement at $p_0^f = p_{c+}$ and $p_0^f = p_s$. As a result at fixed incoming wave

number p_0^i the scattering intensity reaches a maximum value at $p_0^f = p_{c+}$ and $p_0^f = p_s$. For the I^{+-} in Figure 13(b) the situation is just reversed: the incoming wave reflected from and transmitted into higher optical potential, than its scattered counterpart. Owing to the reciprocity principle both maps in Figure 13(b) and (d) are interchangeable by switching the magnetic field direction. If the magnetic layer is totally demagnetized via formation of small domains so that the mean field becomes zero, then $I^{++} = I^{--}$, $I^{+-} = I^{+-}$, and all maps are perfectly symmetric with respect to interchange p_0^i and p_0^f.

The crucial role of distortions of the incoming and scattered waves is demonstrated in Figure 15. These plots show off-specular scattering maps [12] calculated for a multidomain state of a 200 Å thick cobalt film, deposited onto a sapphire substrate covered with a 2000 Å thick sublayer of titanium. The maps also contain specular reflection ridges running along diagonals of the maps. They were omitted in the previous example for clarity. Specular ridges in the SF channels appear if the mean magnetization averaged over the coherence spot depends on its position on the sample surface. As was mentioned before this is quite a common case due to the strong anisotropy of the coherence ellipsoid whose long axis may cross several domains, while the short one is much smaller than the size of domains. In this case, one can expect quite appreciable fluctuations in angles $\overline{\gamma}(y)$. These fluctuations are characterized by two parameters set-in calculations of the maps in Figure 15 as follows: $\overline{\cos\gamma} = 0.866$ and $\overline{\sin^2\gamma} = 0.125$. Fluctuations on smaller scale cause off-specular scattering, the intensity of which is determined by the domain size (set-in calculations to 5 μm), and by fluctuations $\Delta\gamma$ in angles between domain magnetic moment directions and the magnetization direction of the coherence spot. Calculations in Figure 15 were carried out for $\overline{\cos(\Delta\gamma)} = 0.866$ and $\overline{\sin^2(\Delta\gamma)} = 0.125$.

The maps in Figure 15 display rather rich intensity details, although they possess the same general symmetry properties as the maps plotted in Figure 13. Most of the details are related to the transmission and reflection amplitudes because the film form-factor is kept the same as in the preceding text. The amplitude dependencies plotted in Figure 16, manifest, in contrast to Figure 14, a number of interesting features, which are related to the fact that the Ti nuclear SLD is negative and forms a wide (but shallow) potential well, while the SLD of the sapphire substrate is higher than the SLD of Co for the positive spin projection. Such a SLD profile is responsible for the oscillations of the transmission and reflection amplitudes either above and below the total reflection edge of sapphire. The situation is similar to that discussed above in view of pseudo-precession. Destructive interference of waves passed over the titanium potential well to and reflected from

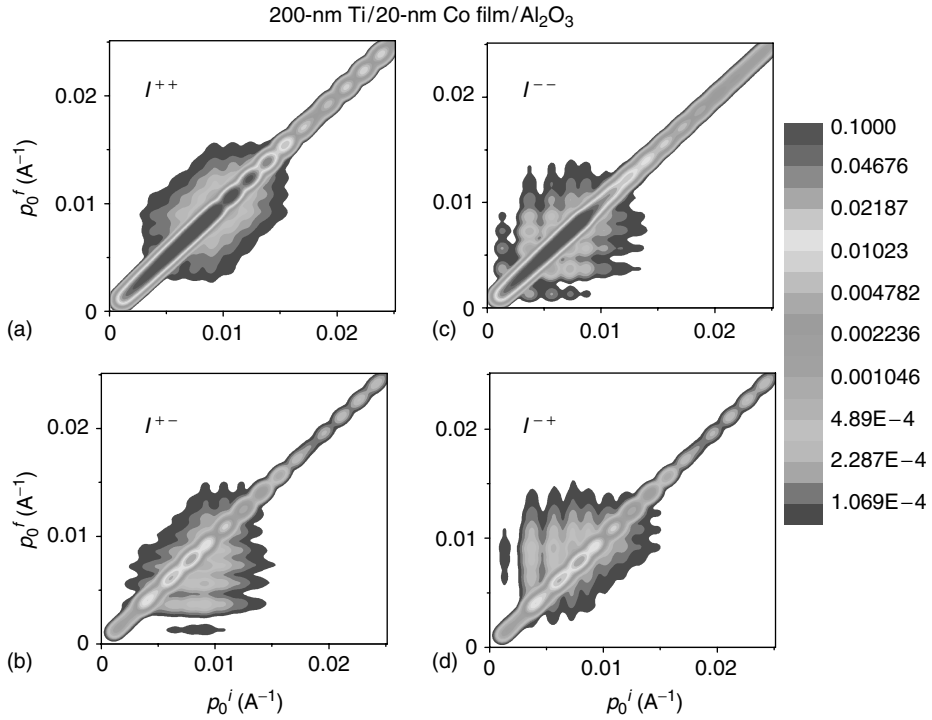

Figure 15. The same as in Figure 13, but for a 200 Å thick multidomain Co layer deposited onto the sapphire substrate covered with a 2000 Å thick titanium sublayer. Maps are calculated for the following set of parameters: $\overline{\cos\gamma} = \overline{\cos(\Delta\gamma)} = 0.866$, $\overline{\sin^2\gamma} = \overline{\sin^2(\Delta\gamma)} = 0.125$.

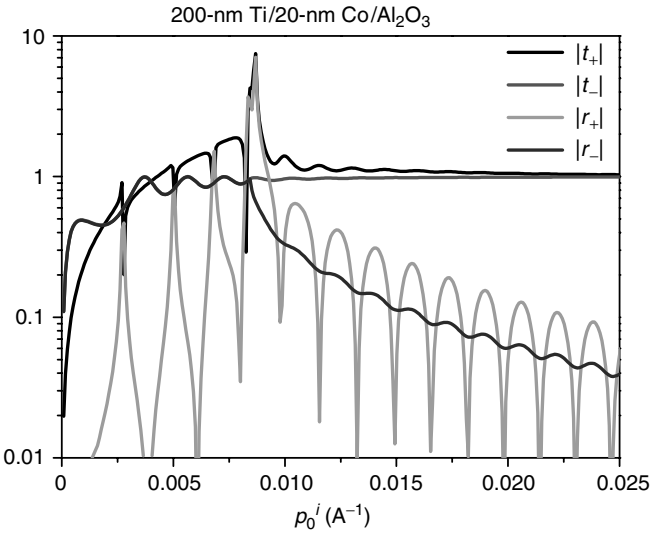

Figure 16. The same as in Figure 14, but for a 200 Å thick Co layer deposited onto a sapphire substrate covered with a 2000 Å thick titanium film with the same set of domain parameters as in Figure 15.

the substrate is expressed in narrow dips in the absolute values $|t^+|$ of the transmission amplitude and antiphase maxima in $|r^+|$ dependence on the wave number p_0^i. Those dips and maxima may exactly compensate each other. However, in equation (131) this compensation is destroyed due to the difference in phases of transmitted and reflected waves, as well as due to the transverse form-factor $F^M(\hat{\mathcal{Q}}_z)$ of the magnetic layer. As a result, the Yoneda wings in the maps of Figure 13 are cut by a set of narrow valleys running either parallel to p_0^i axis or parallel to p_0^f in Figure 15.

In accordance with equation (A2) the transverse form-factor of the film is an oscillating function of the transverse wave vector transfer Q_z with the period matched with the film thickness d. Corresponding oscillations lead to a modulation of scattered intensity along diffraction lines, as was demonstrated in Figure 12. Such a modulation is also present in the maps of Figure 13 where the first minimum in the form-factor $F^M(Q_{\mu\nu}^{\tau\rho})$ is manifested as valleys running across the main diagonal of the maps. Taking a closer look at the maps in the upper row one notices that the locations of the valleys are slightly shifted up in the left and down in the right maps. This shift is due to the difference in refraction effects for neutron waves with positive and negative spin projections. The refraction effects are even better seen in the bottom panels where corresponding valleys are asymmetric. The scattered intensity I^{++} in DWBA is not a function of the unique transverse wave number Q_z, but is rather a bilinear combination of four transverse form-factors $F^M(Q_{++}^{tt})$, $F^M(Q_{++}^{tr})$, $F^M(Q_{++}^{rt})$ and $F^M(Q_{++}^{tt})$. Hence, positions of one set of interference minima for I^{++} and, in particular, for one seen as a valley in Figure 13(a), are determined by the conditions:

$$Q_{++}^{tt} = -Q_{++}^{rr} = p_+^f + p_+^i = n\frac{\pi}{d} \tag{136}$$

if n is an odd number. If n is an even number then the corresponding equations determine the position of the maximum values for matrix elements responsible for transitions between two transmitted or two reflected waves with either the same or different spin states. For the map represented in Figure 13 the scattered intensity I^{--} the valleys run for odd n along the line determined by the equations

$$Q_{--}^{tt} = -Q_{--}^{rr} = p_-^f + p_-^i = n\frac{\pi}{d} \tag{137}$$

while in the maps for I^{+-} and I^{-+} valleys are traced by the equation

$$Q_{+-}^{tt} = -Q_{-+}^{rr} = p_+^f + p_-^i = n\frac{\pi}{d} \tag{138}$$

The scattering processes discussed in the preceding text account for only half of possible transitions described by 16 amplitudes in equation (132). The other half is due to processes which account for transitions between transmitted and reflected waves and depend on off-diagonal components of the wave vector transfers supermatrix $Q_{\mu\nu}^{\tau\neq\rho}$. Transverse form-factors relevant to these processes at odd n show minima if the *anomalous* wave vector transfers

$$Q_{++}^{tr} = -Q_{++}^{rt} = p_+^f - p_+^i = n\frac{\pi}{d} \tag{139}$$

$$Q_{--}^{tr} = -Q_{--}^{rt} = p_-^f - p_-^i = n\frac{\pi}{d} \tag{140}$$

for spin state conserving transitions. If the spin states are changed, then those minima are determined by the equations

$$Q_{+-}^{tr} = -Q_{+-}^{rt} = Q_{-+}^{rt} = -Q_{-+}^{tr} = p_+^f - p_-^i = n\frac{\pi}{d} \tag{141}$$

Related features are not seen in Figure 13. In this case, they are rather week and beyond the range displayed in this figure. Therefore, we will discuss next an example of a thick Co film, where *anomalous* scattering processes dominate [13], as in Figure 17.

In simulations, the mean magnetization was set again along the polarization analysis axis, but in contrast to the previous examples the sample is supposed to be in a multidomain state with a remanence half of the saturation magnetization value. The average size of the domains is set to 50 μm and the magnetic moments of different domains within the coherence volume are randomly tilted so that $\overline{\sin^2 \Delta\gamma} = 0.75$.

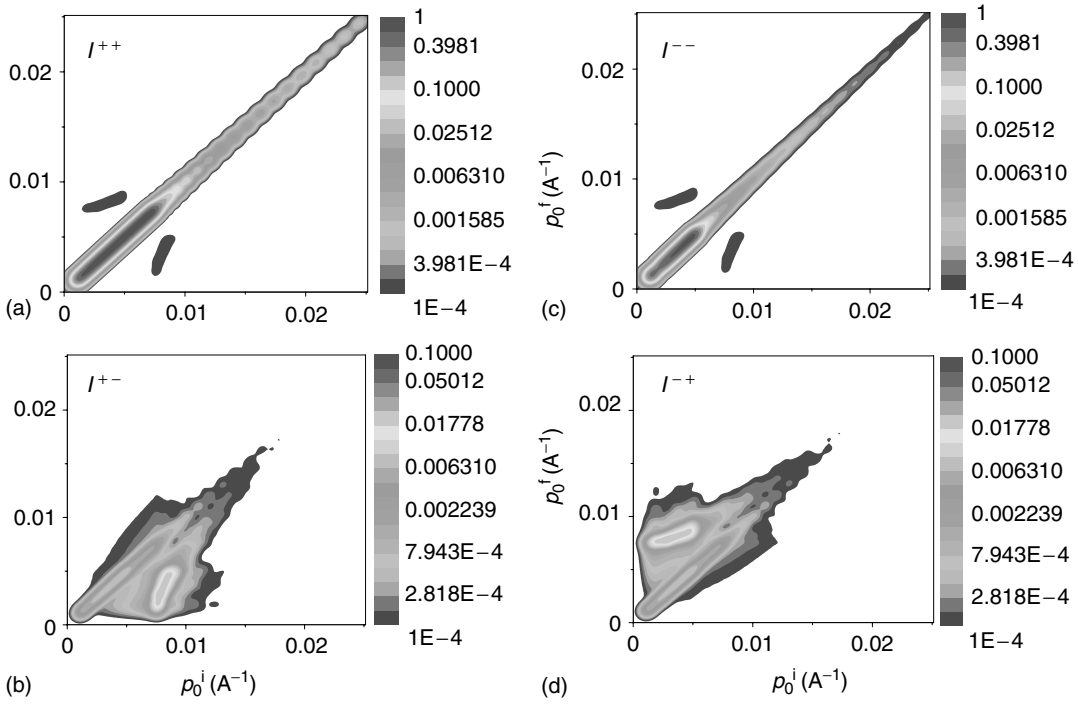

Figure 17. NSF (a and c) and SF (b and d) scattering intensity maps for random magnetic domains in a 2500 Å thick Co film on a Si substrate. Calculations are carried out for the sample in the state relatively close to saturation so that $\overline{\cos \Delta\gamma} = 0.5$, and $\overline{\sin^2 \Delta\gamma} = 0.75$. The mean magnetization is assumed to be perfectly collinear with the polarization analysis axis, while traces of off-specular scattering in the top and specular signal in the bottom panels are due to incomplete polarization efficiency which is set to 99%.

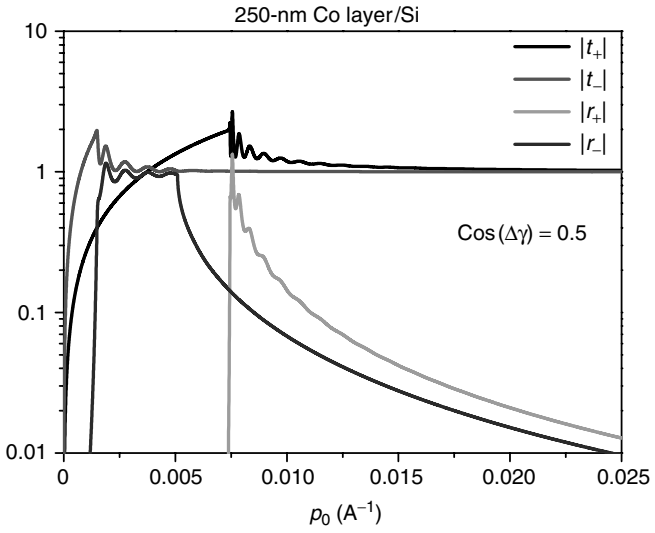

Figure 18. The same as in Figure 16, but for a 2500 Å thick film on Si substrate.

The behavior of the transmission and reflection amplitudes for this case are illustrated in Figure 18 where one can recognize singularities similar to those in Figure 14 and fast total thickness oscillations as in Figure 16. These oscillations in Figure 18 are due to the thick Co layer itself, but not caused by the thick sublayer as in the former case.

Large shifts of the critical edges due to a high magnetization value within a domain provides strong asymmetry in off-specular SF scattering intensity distribution as seen in Figure 17. However, its particular 'banana-like' shape is due to the fact that scattering is mostly contributed by an anomalous process with the wave vector transfers determined by equation (141). This equation for $n = 0$ has the following solutions:

$$p_0^f = \sqrt{(p_0^i)^2 - 2p_{cm}^2} \tag{142}$$

$$p_0^i = \sqrt{(p_0^f)^2 - 2p_{cm}^2} \tag{143}$$

where $p_{cm}^2 = 4\pi (Nb)_m \overline{\cos \Delta\gamma}$ is the critical wave number for the mean magnetic potential and $(Nb)_m$ is the nominal magnetic SLD. The first equation here corresponds to the left, while the second one to the right map in Figure 17. Owing to the large thickness of the film the transverse form-factor at these values has a rather sharp maximum, while the side maxima at $p_+^i - p_-^f = 2\pi n$ are suppressed.

In the preceding discussion, we intentionally concentrated on a few simple examples of single magnetic films in

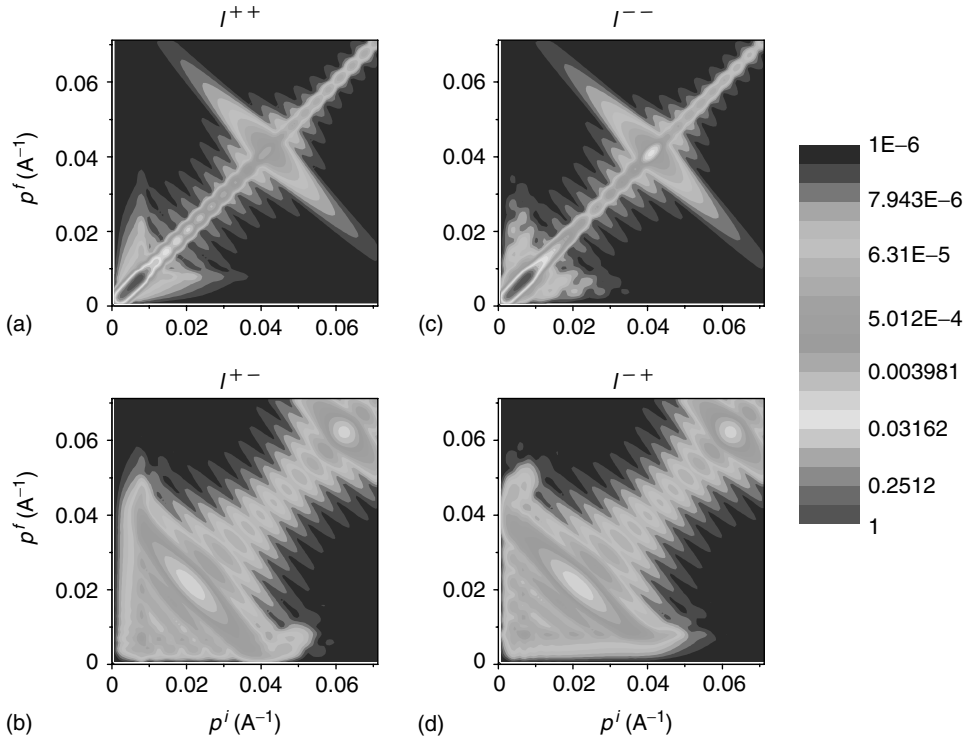

Figure 19. NSF (a) and (c) and SF (b) and (d) scattering intensity maps for magnetic domains in the antiferromagnetically coupled $[^{57}\mathrm{Fe}(67)\mathrm{Cr}(9)]\times 12$ multilayer on sapphire substrate. Calculations are carried out for the model of column-like domains with lateral size of 5 μm and domain magnetization tilted in the neighboring layers to the left and to the right by $\sim 45^\circ$ with respect to the polarization analysis axis. Alternation of the domain magnetization projection perpendicular to this axis result in SF superstructural Bragg sheets in the bottom panels. The mean layer magnetization is assumed to be reduced by the factor $\overline{\cos \Delta\gamma} = 0.5$, so that alternation of the domain magnetization projections onto the y axis causes NSF structural Bragg sheets as seen in the top panels running across the Bragg peak on the specular reflection ridge. The net magnetization is assumed to be perfectly collinear with the polarization and this ridge is only present in NSF channels.

a domain state or with a periodic lateral pattern. These examples show that DWBA provides a deep understanding of the rich details in the NSF and SF scattering maps. Furthermore, DWBA provides a solid framework for correct and quantitative analysis of experimental data, yielding information on the lateral magnetization distribution over the film plane. However, the main advantage of PNR and, in particular, of off-specular scattering is attributed to its sensitivity to the depth profile of the magnetization distribution.

This can already be seen comparing the last three examples for films of different thickness. One more example is still needed to illustrate the case of DWBA for laterally structured periodic multilayers. The magnetization distribution in such system is of a special practical importance, while off-specular scattering of polarized neutrons is a powerful tool to study it in great detail. On the other hand, owing to the transverse periodicity off-specular scattering maps from multilayer structures contain qualitatively new features which need to be discussed separately.

Figure 19 shows an example of a DWBA calculation carried out for a multidomain state of a $[^{57}\mathrm{Fe}(67)\mathrm{Cr}(9)]\times 12$ multilayer deposited onto a sapphire substrate. In this system, atomic spins in neighboring F layers of iron are antiferromagnetically exchange coupled through the metallic chromium spacer layers. Very often, however, F layers are not homogeneously magnetized, but rather fall into a set of lateral domains. Then owing to the exchange coupling the multilayer stack appears to be broken up into lateral domains where magnetic moments are arranged antiferromagnetically across the multilayer. In an applied magnetic field the magnetization of the Fe layers is forced toward the field direction and the system may undergo a transition into the spin-flop phase, as discussed in the subsequent text (Lauter-Pasyuk *et al.*, 2002). In this state the sublayer magnetization, for example, the magnetization in each of the lateral domains, is tiled to the left and to the right with respect to the applied field direction. The net magnetization is directed along the field, while in the sublayers it has alternating projections onto the perpendicular direction to the field.

In Figure 19(a) and (c) we present NSF scattering intensity distributions, which show ridges of specular reflections. Along these ridges one can see the ranges of total reflection at low wave numbers, Kiessig fringes, and Bragg peaks due to the periodicity in the mean optical potential variation across the multilayer stack. Note that in Figure 19(c), corresponding to I^{--}, this peak is stronger than in Figure 19(a), corresponding to I^{++}. This is due to the fact that the nuclear SLD of ^{57}Fe is lower than the magnetic SLD, providing highest optical contrast for reflection of neutrons with negative spin projections onto the field direction. All maps in Figure 19 reveal off-specular scattering justifying that the lateral size of the domains (set to 5 µm) are smaller than the coherence length. Off-specular scattering in the NSF maps may be caused by conformal interfacial roughness and/or deviations from the magnetization projections parallel to the net magnetization. The latter is set along the polarization analysis axis. NSF off-specular scattering is substantially enhanced at the critical edge of the total reflection (Yoneda scattering), and its line shape depends on the spin state of the scattered neutrons. In particular, for I^{++} it is enhanced at $p_0^i \approx p_{c+}$, or $p_0^f \approx p_{c+}$, where p_{c+} is the critical wave number of the total reflection from SLD of ^{57}Fe for neutrons with positive spin projection. For negative projection the critical edge is absent and an enhancement of I^{--} occurs along a set of sheets (Kiessig sheets) determined by equations (140) and (139) with d corresponding to the total thickness of the multilayer. These sheets have similar origin to those in the case of thick Co films discussed in the preceding text. Off-specular scattering is also enhanced along the lines crossing the position of the Bragg peak on the reflectivity ridge. There it forms so-called Bragg sheets along which, in accordance with equations (136) and (137) $Q_z \approx 2\pi/d$, where d is the multilayer period. The extension of the Bragg sheets is mostly determined by the domain size, while their intensity is due to the amplitude of deviations from the mean optical potential and the degree of their conformity through the multilayer stack.

Figure 19(b) and (d) show SF scattering maps In contrast to the NSF maps they do not contain specular ridges. This means that in the model there is no mean magnetization projection onto the direction perpendicular to the polarization analysis axis. But instead, one can see in those maps extensive Bragg (and also Kiessig) sheets running along the lines determined by equation (138) with $n = 1$ and $n = 3$. SF Bragg sheets manifest AF ordering of domain magnetization projections perpendicular to the mean magnetization. Such an ordering doubles the unit cell with respect to the structural cell across the multilayer stack. Owing to nonzero magnetization the intensity distribution I^{+-} and I^{-+} are asymmetric with respect to main diagonal. In particular, one can see strong distortions of the superstructural Bragg sheet when angles of incidence of the incoming or exit beams approach the sample horizon. Close to the critical edges the anomalous scattering becomes very strong resulting in an anomalous Bragg sheet running along the lines determined by equation (141), as was discussed in the example of the thick Co films in the preceding text. In the subsequent text, we present experimental results which use above considerations to interpret data collected from various magnetic films, multilayers, and laterally structured magnetic arrays.

3 EXPERIMENTAL CONSIDERATIONS

As discussed in the preceding text, any y component of a magnetic field distribution or a sample magnetization leads to two critical angles for total neutron reflection with respect to the two possible neutron spin polarizations. If the incident beam is unpolarized, for scattering vectors $\mathbf{Q}_c^- \leq \mathbf{Q} \leq \mathbf{Q}_c^+$, neutrons with polarization parallel to the magnetization are reflected and neutrons with the opposite polarization are transmitted. This property is exploited in supermirrors for polarizing neutron beams, where either the reflected or the transmitted beam can be used for polarizing the incident neutron beam for PNR experiments (Krist *et al*., 1995; Böni, 1997). For practical reasons, it is advantageous to use the transmitted beam and to accept the small absorption. The same scheme is used for the scattered beam if a two-dimensional polarization analysis of the magnetization vector is required.

PNR studies are carried out either in a wavelength or in an angle dispersive mode. In the angle dispersive mode, a monochromator in the incident beam selects a narrow wavelength band of $\Delta\lambda/\lambda = 0.5$ to 5% depending on the resolution required. Instead of a monochromator also a Fermi velocity selector with a continuously tunable wavelength can be placed in the incident beam. However, this requires that an end position for the instrument is available.

In the wavelength dispersive mode the time-of-flight start time is defined by the first chopper, while the second chopper serves for pulse shaping and for eliminating frame overlap problems. In both set-ups supermirrors (SM) and π-spin flip coils (SF_1 and SF_2) are used in the incident and reflected beam for polarizing the beam before the sample and for analyzing the polarization state after the scattering event.

Supermirrors and spin flippers can be integrated into one device if the remanent magnetization of the supermirror is high enough and if its magnetization can be switched from one orientation to the opposite with a pulsed field (Böni, 1997; Böni, Clemens, Senthil Kumar and Pappas, 1999).

The main advantage of the wavelength dispersive mode is a fixed glancing angle to the sample surface. On the other hand, the angle dispersive mode has the advantage of a constant efficiency for the supermirrors and spin flippers, optimized for the particular wavelength used. At steady-state neutron sources both modes of operation are being used, while at pulsed neutron sources only the wavelength dispersive mode is suitable.

A typical setup for a polarized neutron reflectometer is shown in Figure 20. The supermirrors are used in the transmission mode, and in the chosen example the front flipper is turned 'on' to provide a spin-up state, while the back flipper is turned 'off', thus measuring the $(+-)$ cross section in transmission mode of the back analyzer and the $(++)$ cross section in reflection mode. Using two detectors, the $(++)$ and $(+-)$ cross sections can be measured simultaneously. In case of an angle dispersive reflectometer between the source and the first polarizer a monochromater has to be placed, while for wavelength dispersive detection the monochromator is substituted by a chopper system. In Figure 21, the angle dispersive ADAM reflectometer at the Instiut Laue–Langevin is shown in a cut away view.

Instead of taking radial scans in the Q_z direction, that is parallel to the specular ridge, it is often necessary to map out the off-specular diffuse intensity, by using a position-sensitive detector (PSD). The PSD covers the specular reflection as well as collects off-specular intensity.

The simultaneous polarization analysis of the specular and off-specular exit beam requires the use of a wide angle polarization analyzer. Two types of wide angle analyzers are presently being used, either a stack of supermirrors

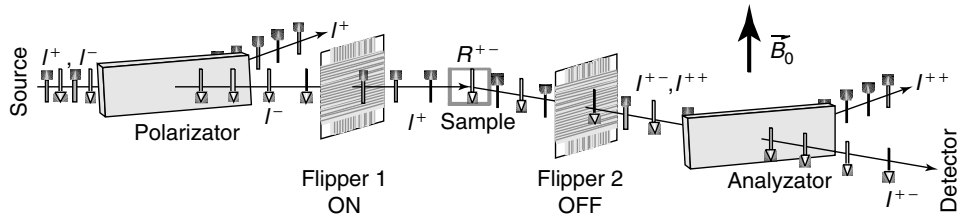

Figure 20. Schematic outline of an angle dispersive neutron reflectometer with polarization analysis. The incident monochromatic and unpolarized beam is polarized by the first supermirror in transmission mode. Spin flippers before and after the sample can change the neutron polarization from up to down and vice versa. The back supermirror analyzes the polarization state of the neutrons after the sample. In the shown configuration with the front spin flipper turned on and the back spin flipper turned off, the SF $R^{+,-}$ reflectivity is measured (Siebrecht, 2001).

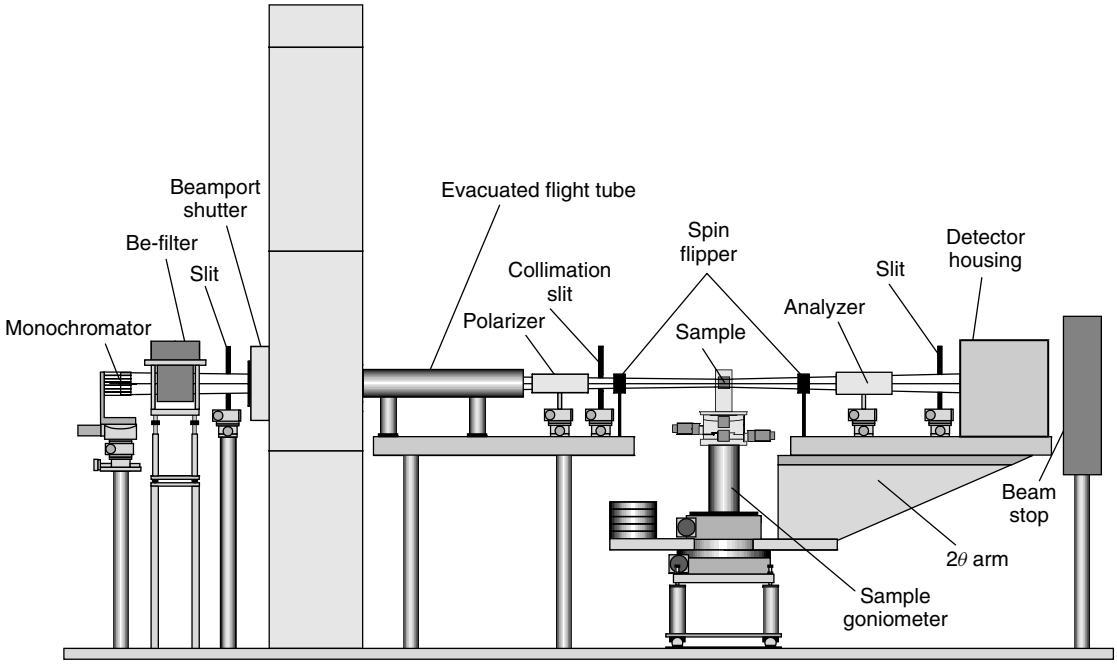

Figure 21. Cut away view of the angle dispersive neutron reflectometer ADAM at the Institut Laue–Langevin, Grenoble.

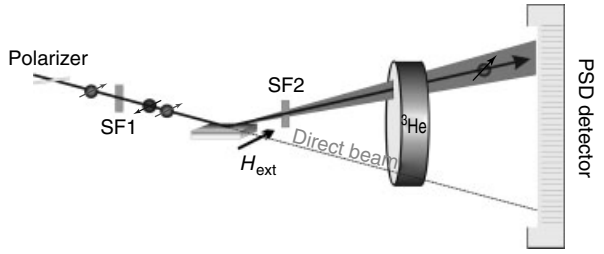

Figure 22. Schematic outline of a scattering experiment using a spin filter for analyzing the polarization of the exit beam and detection with a position-sensitive detector. (Reproduced from M. Wolff *et al*., 2006, with permission from Taylor and Francis. © 2006.)

(Krist, Fritzsche and Mezei, 2002; Syromyatnikov *et al*., 2001) or a polarized ^{3}He transmission spin filter in the exit beam (Zimmer *et al*., 2000; Nickel, Rühm *et al*., 2001). A schematic outline of the scattering geometry with a spin filter analyzer is shown in Figure 22. In recent years, huge progress has been made with respect to lifetime and quality factor of ^{3}He spin filters (Radu, 2005; Wolff *et al*., 2006). While in the past there was some hesitation to use spin filters as a standard tool, recent developments seem to favor the use of spin filters over solid state analyzers. The main advantages being that with polarized ^{3}He spin filters (i) highly divergent beams can be analyzed; and (ii) the analyzing efficiency is homogeneous and predictable with negligible small-angle scattering from the ^{3}He cell. The use of ^{3}He spin filters requires a sophisticated infrastructure for polarizing ^{3}He by optical pumping, which is available at the Institut Laue–Langevin (Grenoble, France) and at the NIST Center for Neutron Research (Gaithersburg, USA), and becomes also available at other neutron sources in the near future. Supermirror stacks are, in contrast, maintenance free, but may cause additional small-angle scattering. Supermirror stacks in reflection mode (Syromyatnikov *et al*., 2001) appear to be operating better than those in transmission mode (Krist, Fritzsche and Mezei, 2002; Syromyatnikov *et al*., 2001).

By designing a neutron reflectometer, three main decisions have to be taken:

- horizontal or vertical scattering plane;
- angle dispersive or wavelength dispersive scattering mode;
- with or without polarization analysis.

For the investigation of magnetic samples, polarization analysis is mandatory. The other two decisions are a question of convenience, floor space available, and investment cost.

Historically, three generations of polarized neutron reflectometers can be distinguished. The first generation of neutron reflectometers were built in the late 1980s, using a polarized beam without polarization analysis (Felcher *et al*., 1987). The second generation of instruments built in the early 1990s included supermirrors for the spin polarization and for spin analysis (Majkrzak, 2001; Siebrecht *et al*., 1997). The third generation starting with the early twenty-first century is equipped with wide angle polarization analyzers, PSD detectors, and an option for grazing incidence small-angle scattering of magnetic in-plane structures (GISANS) (Rücker *et al*., 2001; Pannetiera, Ott, Fermon and Samson, 2003). A fourth generation can be foreseen and developments are taking shape at several places for spin-echo type reflectometers, which accept divergent incident beams (Major *et al*., 2003; Pynn *et al*., 2003). Table 1 provides a non-comprehensive list of typical reflectometers at different neutron sources. Worldwide the total number of polarized and unpolarized neutron reflectometers operational at steady-state and pulsed neutron sources is about 30, and this number is steadily increasing (see http://material.fysik.uu.se/group_members/adrian/reflect.htm for an up-to-date list).

4 PNR INVESTIGATIONS OF MAGNETIC FILMS, HETEROSTRUCTURES, AND SUPERLATTICES

Different magnetic heterostructures are conceivable, such as simple magnetic films on substrates, bilayers, trilayers, or multilayers. These structures are referred to as perpendicular

heterostructures as their extension within the plane is 'infinite', but in the perpendicular direction the layer thicknesses can range from a few monatomic layers up to a few hundred nanometers. In contrast, lateral heterostructures usually require some top–down lithographic processing or, alternatively, some bottom up self assembly.

In Figure 23, some typical magnetic heterostructures are sketched. PNR investigations of magnetic heterostructures include the magnetization profile within single magnetic films and in multilayers (Figure 23a); magnetic states and phase transitions in films of magnetic alloys, compounds, and dilute magnetic semiconductor (Figure 23b); magnetization reversal mechanism and domain formation in exchange-biased systems (Figure 23d); twisting effects of the magnetization vector in spring magnets (Figure 23e); and domain states and stripes (Figure 23c). The theoretical framework for the analysis of these magnetic heterostructures is provided in Section 2.5. Experimental results are discussed in the following sections.

PNR has developed into an essential tool for the analysis of artificial magnetic heterostructures with main emphasis on vector magnetization profiles, magnetic domain distributions and fluctuations, magnetization reversal mechanisms, and on correlation effects. Although the competition with XRMS has increased in recent years (Kortright *et al*., 2003), there are some advantages PNR offers that are hard to challenge. Those include the data analysis using the BA or the DWBA, the well-known cross sections, and the purely magnetic SF scattering that has no counterpart in XRMS.

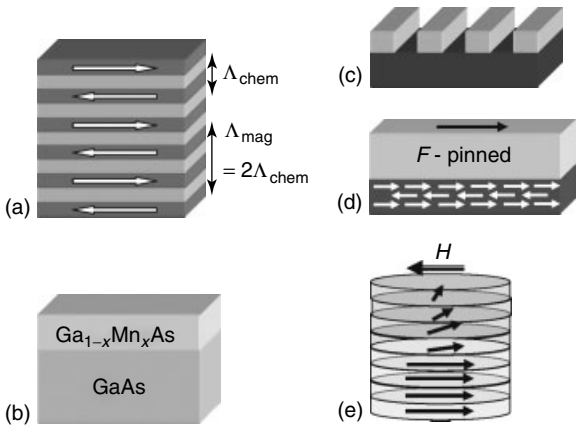

Figure 23. Selection of magnetic nanostructures investigated by polarized neutron reflectivity experiments. Thin F films are important objects in many device applications. They are characterized by a certain thickness, interfacial roughness, domain state within the film plane, and magnetization profile normal to the film surface. Furthermore, magnetic films are characterized by their magnetic hysteresis, including coercivity, remanence, saturation, and magnetic anisotropy. A thin film is never standing alone but is supported by a substrate or is sandwiched between other layers. Even in the case of a self supported thin film, the magnetic film will acquire an oxide cover, unless protected by a cap layer. Whether a thin film is investigated on a substrate or as a film embedded in a multilayer depends on the question asked and on the physics to be analyzed. If at all possible, multilayers are preferable over thin films, not only because they increase the probing volume but mainly because they give rise to Bragg reflections due to the artificial periodicity. Bragg reflections represent the Fourier transform of the real structure and are much more sensitive to small perturbations than reflectivity from single films is.

We will discuss recent experimental developments in the analysis of thin magnetic films, magnetic heterostructures, multilayers, and patterned magnetic films. We will not discuss ultrathin magnetic films, as this topic has recently been reviewed by Bland and Vaz (2005). The following sections are not intended to provide a review on the physics of thin magnetic films, heterostructures, and superlattices, but to discuss PNR applications to these systems.

4.1 Thin ferromagnetic films

4.1.1 Magnetic heterostructures

We start our discussion with a PNR study of a thin F layer on a non-magnetic substrate. Figure 24 shows polarized reflectivity scans from a single 2-nm-thick Fe(110) film on top of a 150-nm-thick Nb(110) film grown on a sapphire substrate. The Fe film is protected by a 5-nm-thick Nb capping layer. The measurements were carried out at the ADAM instrument of the Institut Laue–Langevin, Grenoble, in an angle dispersive mode (Zabel and Theis-Bröhl, 2003).

The Fe film is in a F state and the magnetization vector is aligned parallel to the y axis. Two types of oscillations can be observed. The rapid oscillation is due to the total film thickness including all three layers, the wider oscillation originates from the top Nb protecting layer, while the complete oscillation from the 2-nm-thick Fe film is not visible due to the limited Q-range of the scan. Nevertheless, the special sandwich design for the F film provides a very high sensitivity for neutron scattering. The $\mathcal{R}^{++}$ and $\mathcal{R}^{--}$ intensities are strongly split, with a negligible amount of SF scattering, indicative first for the F state of the sample,

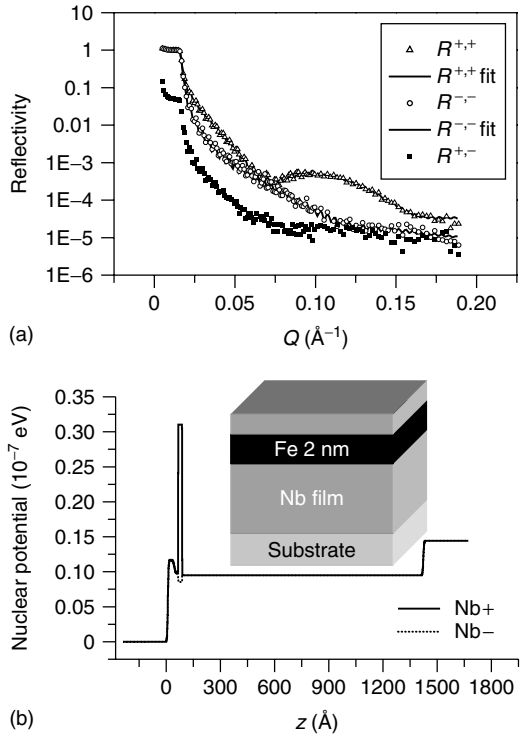

Figure 24. (a) Polarized neutron reflectivities are shown for a ferromagnetic 2-nm thick Fe layer on a non-magnetic Nb film. The intensity splitting between the $\mathcal{R}^{++}$ and $\mathcal{R}^{--}$ reflectivities is a clear sign for the ferromagnetic state of the thin Fe layer. Shown in the lower part of the figure is also the $\mathcal{R}^{+-}$ spin-flip scattering. This scattering is featureless, indicating that any component of the magnetization vector parallel to the x axis is negligible. (b) Nuclear and magnetic profiles for the up and down neutron spin polarization resulting from a fit to the reflectivity curves according to the generalized matrix method. (Reproduced from F. Radu *et al*., 1999, with permission from Elsevier. © 1999.)

and second for the orientation of the magnetization vector being parallel to the y axis. Figure 24(b) shows the nuclear and magnetic density profile resulting from a fit to the $\mathcal{R}^{++}$ and $\mathcal{R}^{--}$ reflectivities, using the generalized matrix method for describing the polarized reflectivity (Radu and Ignatovich, 1999). The profile not only confirms the F state of the Fe layer with a magnetic moment identical to the Fe bulk moment and little interdiffusion at the Fe/Nb interfaces, but also shows that an oxide layer exists at the surface with a slightly enhanced SLD. The solid and dashed lines are the reflectivity profiles for the parallel and antiparallel polarization of the neutrons in relation to the layer magnetization. The antiparallel alignment results in little contrast to the Nb layers, as already recognized by the missing oscillations in the $\mathcal{R}^{--}$ reflectivity curve. The astounding conclusion of this measurement is the very high sensitivity of PNR to thin F layers, corresponding in the present case to only 10^{-3} emu. Obviously this is not the limit and even thinner samples have been investigated in the past (Blundell and Bland, 1992). This is an important result, since PNR provides valuable magnetic information on ultrathin buried films together with structural information as concerns the film thickness, the magnetization profile, and the interfacial roughness.

A number of similar PNR experiments have been performed in the past on magnetic films, in most cases in order to learn about the magnetization profile in buried layers, whenever 'dead' layers are suspected from interdiffusion or interfacial roughness. For instance, Vaz *et al*. (2005) have investigated the magnetization profile of a 5-nm-thick epitaxial Fe layer grown on GaAs(100) with a 1.3-nm-thick AlO_x tunnel barrier and capped with 25 nm Au layer. From the PNR results they conclude that at the interfaces no interdiffusion occurred and that the Fe magnetic moment corresponds to the bulk value in spite of the non-ideal growth properties on the amorphous AlO_x tunnel barrier. Thus, in this case a 'dead' layer does not form at the interface and the full polarization of the Fe layer can be used for spin tunneling into GaAs. The question of a 'dead' layer at the Fe/GaAs interface can also be answered by Mössbauer spectroscopy experiments, using a probing ^{57}Fe layer at the interface (Doi *et al*., 2002). The advantage of PNR over Mössbauer spectroscopy is that no special isotopes are needed nor particular growth conditions to avoid interdiffusion of ^{57}Fe and natural Fe.

Zhengdong *et al*. (2004) have studied the growth of Ni on MgO. When growing metals on oxide surfaces, it can be suspected that an oxide layer forms at the interface. NiO is AF below $T_N = 500$ K and causes an EB when in contact with Ni. This scenario could indeed be observed for Ni grown on MgO(001) after annealing at 573 K. Neutron reflectivity studies have confirmed the existence of a non-magnetic layer at the interface between Ni and MgO with a SLD that matches NiO rather well.

Magnetite (Fe_3O_4) is a highly interesting ferromagnetic oxide with a complex spinel structure. Because of the high moment and half-metallicity it is considered as a suitable material for spintronic applications (Coey and Chien, 2003). Significant values of spin polarization have already been observed in bulk Fe_3O_4 (Bratkovsky, 1998; Kozlowski *et al*., 1993). However, several studies of (001) oriented thin films, usually grown on MgO(001), have exhibited very small magneto-resistive (MR) ratios. These reduced MR values have been attributed to complex magnetic and structural properties at their interfaces. To clarify the magnetic moment of magnetite in thin films grown on MgO, Morall *et al*. (2003) have performed PNR measurements at room temperature, which is far below the Curie temperature of 860 K. For a 5.3-nm-thick film an average magnetic moment of 2.8 μ_B was determined, much less than the expected value of 4 μ_B. The authors could not explain the discrepancy but refer to a

rather high layer roughness of 2.3 nm and a possible reduced Curie temperature. It should be pointed out that for roughness parameters on the order of the film thickness the determination of magnetic moments with the PNR method becomes unreliable.

So far we have discussed F thin films in saturation. The main emphasis of these studies is the depth dependent magnetization profile, which is determined by two reflection coefficients $\mathcal{R}^{++} = \mathcal{R}^{+}$ and $\mathcal{R}^{--} = \mathcal{R}^{-}$. Off-specular and SF scattering is not expected in this case and therefore does not need to be analyzed. The situation is different for F films either in remanence or at the coercive field. If the remanence is less than 100%, magnetic domains are expected which will give rise to new effects thoroughly discussed in the Section 2.11: first the magnetic domains will cause diffuse scattering in case that the domains are smaller than the longitudinal coherence length of the neutron beam, and second the canting of the domain magnetization vectors will cause SF scattering. This effect has recently been studied in some detail by Radu *et al*. (2005a). For this experiment a 2500 Å thick Co film was used, grown by rf-sputtering on a SiO_2 substrate. Growth conditions and substrate choice provided a polycrystalline Co film. A Kerr image taken at a field of 10 Oe, which is comparable to the neutron experimental condition, showed a small-angle ripple domain structure, which is due to the polycrystalline nature of the film combined with the intrinsic magnetocrystalline anisotropy of Co. The magnetization within the ripple domains is partly tilted by the angle $\Delta\gamma$ to the left and to the right with respect to the applied magnetic field (partial spin-flop orientation). The ripple domains are responsible for the reduced remanence observed in the magnetic hysteresis. The neutron intensity maps for all four cross sections from the Co film on Si are shown in Figure 25.

The general features of these maps are well reproduced by DWBA simulations plotted in Figure 17. Off-specular SF scattering is mostly concentrated along the lines determined by equations (141–143), which account for birefringence in the magnetic part of the mean optical potential. These equations allow to experimentally find the mean value $\overline{\cos(\Delta\gamma)}$ averaged over the coherence length. Figure 17 demonstrates that DWBA is able to describe not only the location, but also the absolute intensity of diffuse scattering. The latter is proportional to the mean value $\overline{\sin^2(\Delta\gamma)}$ and fitting the data to the theoretical model one can determine the dispersion $\tilde{\Delta} = \overline{\cos^2(\Delta\gamma)} - \overline{\cos(\Delta\gamma)}^2$, quantifying the domain reversal mechanism, as discussed in the next subsection. On the other hand, some important conclusions on the lateral magnetization distribution in the

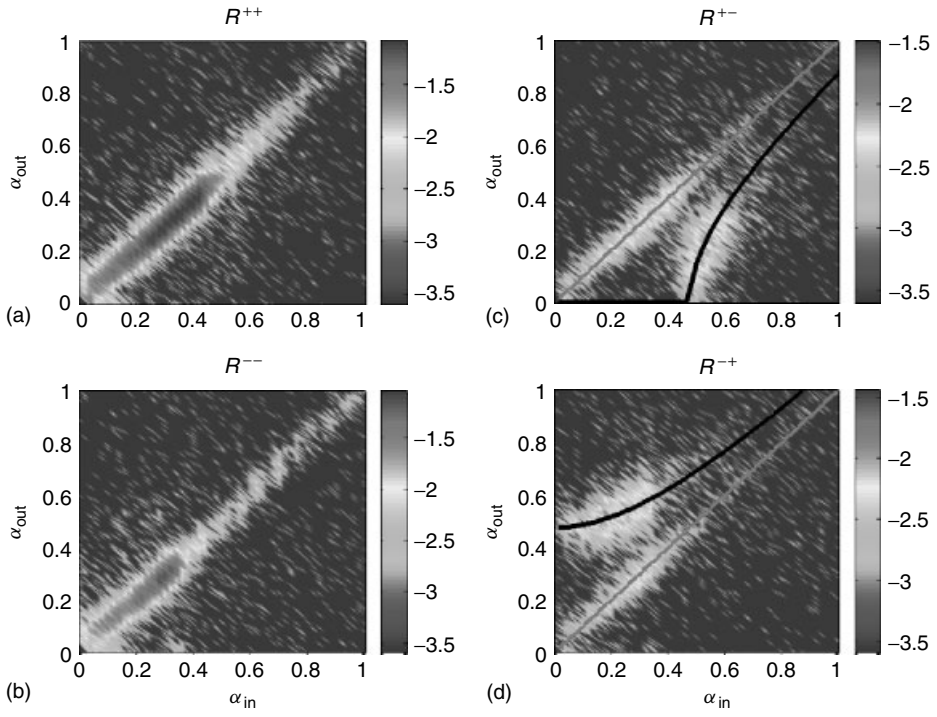

Figure 25. Intensity maps taken from a 2500-Å-thick polycrystalline Co film on a Si substrate. The maps were recorded close to remanence (≈10 Oe). The left column shows intensity maps for the non-spin-flip cross sections $\mathcal{R}^{++}$ (a) and $\mathcal{R}^{--}$ (b), the right column for the spin-flip cross sections $\mathcal{R}^{+-}$ (c) and $\mathcal{R}^{-+}$ (d). The intensities are plotted in terms of exit angles (vertical axis) versus incident angle (horizontal axis). For a discussion of the maps, see main text. (Reproduced from Radu *et al*., with permission from IOP Publishing Ltd, ©.)

domains can already be made even before carrying out a quantitative analysis of the data in Figure 25. First of all one may admit that the intensity distribution in Figure 25(c) and (d) is strongly asymmetric such that (c) becomes identical to (d) if angles of incidence and of scattering are interchanged. Second, almost no off-specular non-spin-flip scattering (Figure 25a and b) is detected. This means that, as explained in the Section 2.11, the ripple domains do not cause any appreciable fluctuations of magnetization projection onto the direction of the mean inductance (e.g., along y axis). This is only possible if the moments in the magnetic domains are tiled to the left and to the right from y axis by about the same angles $\pm\Delta\gamma$, and $\tilde{\Delta} \approx 0$. The other conclusion immediately follows from the SF maps in Figure 25, if one accepts that the intensity along the specular SF reflection ridge (displayed along diagonals) is mainly due to a non-perfect polarization analysis. If corrections for the SF efficiency are applied, the specular SF intensity should vanish and only NSF specular reflection would be left. This means that there is no tilt of the mean magnetization averaged over the coherence length, and $\overline{\gamma} = 0$. At the same time deviations $\Delta\gamma$ due to the ripple domains are not correlated over distances more than the coherence length.

The example in the preceding text shows that investigations of magnetic thin films by PNR provides rich and quantitative statistical information on domain distributions and magnetization fluctuations. An additional twist is gained when studying by PNR the magnetization reversal as a function of applied field. From specular and off-specular scattering the type of reversal (coherent or incoherent) can be distinguished. This has been particularly useful for functionalized thin magnetic films, which are in contact with different F or AF films for the investigation of exchange springs or EB heterostructures, respectively, to be discussed in the next paragraphs.

Exchange springs are magnetic heterostructures consisting of a magnetically soft material in contact with a magnetically hard layer. When the magnetization of the soft layer is reversed in an external field, the spins close to the interface are pinned to the hard magnetic layer, whereas spins further away may be twisted under the action of the external field to form a magnetic spiral, as schematically shown in Figure 23(e). The concept of exchange springs is based on a seminal paper by (Kneller and Hawig, 1991) and has been reviewed in Fullerton, Jiang and Bader (1999). A review of NR studies on exchange-spring heterostructures is provided by Felcher and Hoffmann in this volume (see also **Domain States Determined by Neutron Refraction and Scattering, Volume 3**) and therefore will not be discussed here any further.

4.1.2 Exchange bias

The EB effect refers to a shift of the F hysteresis to negative values when a F system is in contact with an AF system via a common interface and cooled in a positive applied magnetic field through the Néel temperature of the AF system. The EB phenomenon is associated with the interfacial exchange coupling between F and AF spin structures, resulting in a unidirectional magnetic anisotropy (Meiklejohn and Bean, 1956, 1957; Meiklejohn, 1962). The EB effect is essential for the development of magnetoelectronic switching devices (spin valves) and for random access magnetic storage units. Therefore, there is a large interest not only to understand its basic physical mechanism but also to design interfaces with controllable and robust unidirectional anisotropies.

Extensive data have been collected on the EB field H_{EB} and the coercivity field H_c for a large number of bilayer systems, which are reviewed in Berkowitz and Takano (1999), Nogués and Schuller (1999), Stamps (2000a,b), and Kiwi (2001). Because of the asymmetry, the coercivities H_{c1} and H_{c2} for the descending and ascending branches of the hysteresis, respectively, are different. Then $(H_{c1} + H_{c2})/2 = H_{EB}$ is the EB field and $|H_{c1} - H_{c2}| = H_c$ is the coercive field. The details of the EB effect depend crucially on the AF/F combination chosen and on the structure and thickness of the films. However, some characteristic features apply to most systems: (i) H_{EB} and H_c increase as the system is cooled in an applied magnetic field below the blocking temperature $T_B \leq T_N$ of the AF layer, where T_N is the Néel temperature of the AF layer; (ii) the magnetization reversal can be different for the ascending and descending part of the hysteresis loop (Fitzsimmons *et al*., 2000; Radu *et al*., 2002b; Gierlings *et al*., 2002; Lee *et al*., 2002; Radu *et al*., 2003a); (iii) thermal relaxation effects of H_{EB} and H_c indicate that a stable magnetic state is reached only at very low temperatures (Geoghegan, McCormick and Street, 1998; Goodman*et al*., 2000; Radu *et al*., 2002a).

PNR has been instrumental in unraveling the details of the magnetization reversal in EB systems. Using PNR methods statistical information can be gained on the mean magnetization vector, the mean square dispersion of the magnetization in domains, and the reversal mechanism either by rotation or domain wall (DW) motion. This is in contrast to vector magneto-optical Kerr effect (MOKE), which allows to determine the average x and y components of the magnetization vector $\langle M_x \rangle$ and $\langle M_y \rangle$, but not the dispersion $\Delta = \langle \cos^2 \gamma \rangle - \langle \cos \gamma \rangle^2$ (see Section 2.8), where γ denotes the tilt angle of local magnetization averaged over distances greater than the coherence length. Because of this and the possibility to investigate domain formation by off-specular

diffuse scattering, PNR has been applied to a number of EB systems, which are listed in Table 2.

Two types of EB systems have been studied in the past. The first type consists of F layers in contact with natural antiferromagnets such as oxides (CoO, NiO), fluorides (MnF_2, FeF_2) or itinerant antiferromagnets (FeMn, CoMn, IrMn, etc.). The second type consists of F layers in contact with artificial antiferromagnets, such as AF coupled Fe/Cr or Co/Ru multilayers. In the former case with PNR only the F layer can be investigated but not the pinning AF layer, as the reciprocal lattice vector for the AF superstructure is by far bigger than the scattering vectors usually probed in PNR experiments. However, in the latter case with PNR both, the F layer and the antiferromagnetically coupled (AFC) multilayer can be investigated in the same reflectivity experiment, allowing a correlation between the reversal of magnetization in the F layer and the reaction of the pinning AF coupled multilayer. This resembles the situation of the spring magnets where also both, the soft and hard magnetic films are investigated simultaneously by PNR.

The following paragraphs are not intended to provide a comprehensive overview on EB systems studied with PNR, but to discuss a few illustrative examples to demonstrate the capability of the method. Here we will confine the discussion to CoO/Co, which is the original system for which the EB effect was discovered (Meiklejohn and Bean, 1956) and which has been intensively investigated in the past by PNR methods [14].

In order to enhance the signal, Gierlings *et al*. (2002) have grown a multilayer consisting of CoO/Co bilayers separated by Au spacer layers which magnetically isolate neighboring CoO/Co bilayers and at the same time provide Bragg reflections, which can conveniently be analyzed. The neutron data are shown in Figure 26. They have compared the reversal in the unbiased state above the Néel temperature of CoO ($T_N = 280\,K$) and in the field cooled biased state at 10 K. In the unbiased state they find a magnetization reversal via coherent rotation in the descending as well as in the ascending field direction. However, in the biased state, the reversal in descending fields is clearly characterized by nucleation and DW motion, whereas the reversal in the ascending field remains unaffected. Thus it appears that the EB only affects the magnetization reversal in the direction opposite to the bias field direction. This behavior appears to be typical for the CoO/Co system and has also been observed by other groups (Radu *et al*., 2002b; Radu *et al*., 2003a; Lee *et al*., 2002), and may be different for other systems.

The mean magnetization direction characterized by $\langle\cos\gamma\rangle$ and the dispersion $\Delta = \langle\cos^2\gamma\rangle - \langle\cos\gamma\rangle^2$ [15] was used by Lee *et al*. (2002) for the analysis of the reversal mechanism of a CoO/Co bilayer grown on a sapphire substrate. The dispersion offers a powerful tool for analysis of the domain state of magnetic films without requiring a full analysis of the specular reflectivity profile, provided that the diffuse scattering is negligible and that the magnetic domains are larger than the coherence length of the neutrons such that an incoherent averaging over the magnetic domains is allowed. At the coercivity the magnetization component $M_y = 0$. This can be either the result of a coherent rotation, a domain state with equally populated M_y and $-M_y$ domains, or due to a random distribution of magnetic domains. In the first case $\Delta = 0$, in the second case $\Delta = 1$, and for the third case $\leq \Delta \leq 1$. Thus a finite value of Δ indicates an angular spread of domains. The magnetic hysteresis and the corresponding Δ values are reproduced in Figure 27 ($\Delta = \chi^2$ in the authors notations). At temperatures above the blocking temperature the magnetic hysteresis is symmetric and $H_{EB} = 0$. In this case, the $\Delta \equiv \chi^2$ values are close to one for all scattering

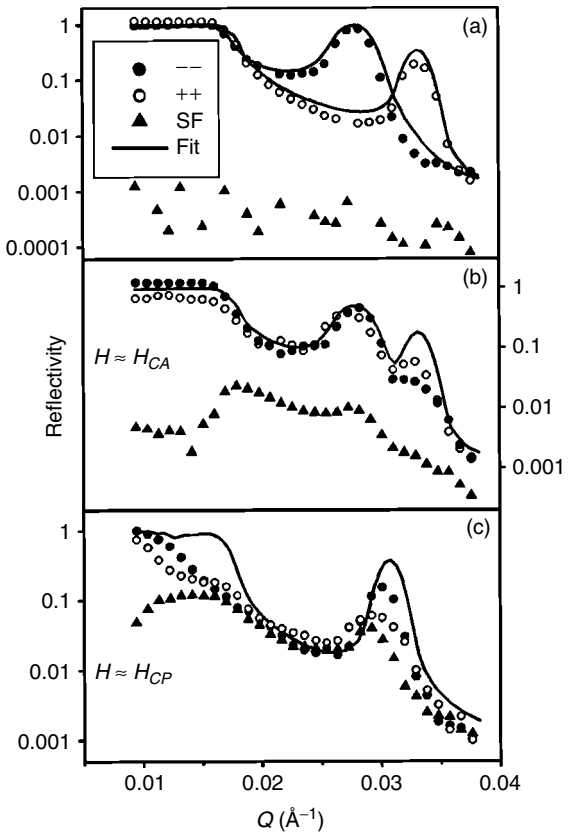

Figure 26. Reflectivity measurements from a CoO/Co/Au multilayer. (a) NSF and SF reflectivities are shown for the sample in saturation. The position of the first Bragg peak is shifted for the $(++)$ and $(--)$ reflectivities due to the different optical potentials. This would also be expressed in different critical scattering vectors, which is, however, here obscured due to the higher potential of the Al_2O_3 substrate for the $(++)$ reflectivity; (b) reflectivities taken in a descending field close to coercivity. The split peaks in both, $(++)$ and $(--)$ reflectivities and the low SF intensity indicates a domain state with parallel and antiparallel domains with respect to the field direction equally populated; (c) reflectivities taken in an ascending field close to the coercive field. All cross section exhibit roughly the same peak position, indicative for a coherent rotation of the magnetization direction into the x direction. (Reprinted figure with permission from M. Gierlings *et al.*, *Phys Rev. B* Vol 65, 092407 (2002). © 2002 by the American Physical Society.)

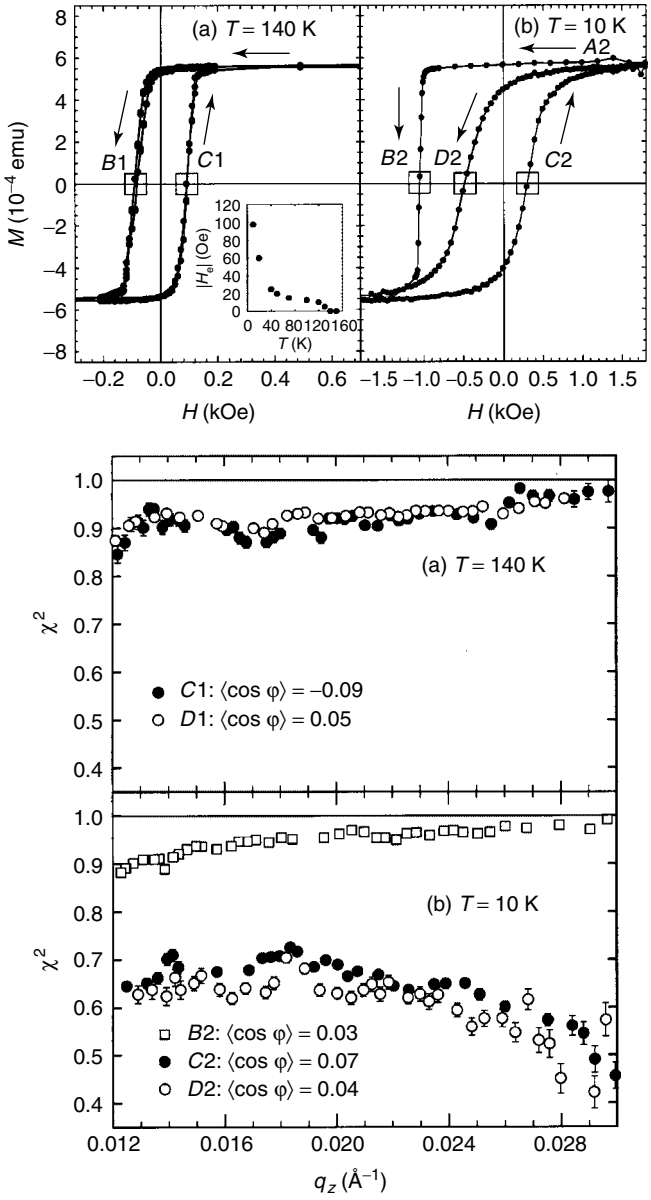

Figure 27. Left panel: Magnetic hysteresis of a CoO/Co bilayer taken at a temperature above the blocking temperature T_b; Right panel: $\chi^2 \equiv \Delta$ values evaluated from PNR measurements taken at the designated remanent points and indicated in the left panel. For temperatures above the blocking temperature, χ^2 is essentially one. After field cooling to 10 K the χ^2 value remains one for the untrained magnetization reversal, but assumes values smaller than one in the trained state, indicative for the development of a angular distribution of domains. (Reprinted figure with permission from W.-T. Lee *et al.*, *Phys. Rev.* Vol. 65, 224417 (2002). © 2002 by the American Physical Society.)

vectors probed, as can be seen in the top right panel of Figure 27. This indicates that for $T > T_B$ the magnetization reversal is characterized by domain nucleation and wall motion. The same behavior is also seen after field cooling below T_B for the first reversal in a descending field. However, after increasing the magnetic field again from negative to positive values, $\Delta \equiv \chi^2$ has clearly dropped below one for all subsequent coercivities in ascending and descending fields. Thus it can be inferred that after the first magnetization reversal of the virgin and field cooled sample, a domain state is created at the CoO/Co interface. This domain state obviously changes the shape of the hysteresis and lowers the EB field.

Radu *et al.* have carried out similar PNR experiments of the magnetization reversal of CoO/Co bilayers, studying not

only the specular reflectivity (Lee *et al*., 2002), but also the off-specular diffuse scattering (Radu *et al*., 2003a). From the spin asymmetry of the specular reflectivity they have evaluated the magnetic hysteresis and compared the neutron results with MOKE measurements. Both hystereses are practically identical (see Figure 28a), neglecting slightly different H_{c1} values due to different temperatures during the MOKE and PNR measurements. Furthermore Radu *et al*. have analyzed the spin flip scattering during the first untrained reversal and during subsequent trained reversals. Similar to Gierlings *et al*. (2002) and Lee *et al*. (2002) they conclude that the first untrained reversal is characterized by nucleation and DW motion. However, all subsequent reversals exhibit some partial coherent rotation. Radu *et al*. emphasize that during the first reversal of the virgin bilayer the CoO/Co interface becomes irreversibly altered, which is manifested mainly in a dramatically enhanced off-specular diffuse scattering in the SF cross sections that cannot be removed even in high magnetic fields. The spin disorder, created during the first reversal can be recognized by the off-specular diffuse SF scattering in Figures 28(d) and (e) and more impressively by the maps shown in Figure 29 for all four cross sections R^{--}, R^{+-}, R^{-+}, R^{++} taken at characteristic points of the hysteresis before and after reversal.

The scattered intensity distribution seen in the maps of Figure 29 can be described in terms of DWBA (Section 2.11). In particular, the asymmetry of the SF off-specular scattering, which is due to a birefringence effect, alters the R^{+-} and R^{-+} maps in the descending and ascending branch of the hysteresis, as it should be in accordance with the reciprocity principle discussed above. The maps in Figure 29 differ from those in Figure 25 in many details [16]. Some of them, for example, the streaks running parallel to the coordinate axis, are not relevant to the physics of the EB system, but are just due to the choice of the sapphire substrate with high optical potential, as explained in the Section 2.11. Those details of the scattered intensity distribution are well reproduced [17] in the maps of Figure 15 calculated in DWBA for the model of F domains. The latter is similar to the one used for the single Co film on the Si substrate. However, the other features carry information which are specific for the EB bilayer system. This is, in particular, the specular SF reflection, which in Figure 29 is much stronger than the off-specular scattering, in contrast to Figure 25.

The presence of *specular spin-flip* intensity may be attributed to the fact that in the trained sample the magnetization within the domains is correlated over distances bigger than the lateral projection of the coherence length. Such long-range correlation lengths occur only because of the interfacial exchange coupling of the F moments to the rigid and frozen-in domains in the AF counterlayer. Without the interfacial exchange coupling the specular SF scattering is expected to be much weaker. The additional and intrinsic disorder is expressed in off-specular scattering and hence in the residual fluctuations of the magnetization vector which persists even in the nominally saturated state.

The restoration of the interface state is only possible by refreshing the field cooling procedure. With PNR the change of the interface is quite obvious. Using the element specificity of the XRMS technique for the investigation of the similar CoO/Fe EB system, it could be shown that the proximity of the F layer induces a small but finite magnetic moment in the AF layer (Radu *et al*., 2006). Furthermore, the F moment in the CoO layer appears to have two components: one is frozen-in and does not follow the applied magnetic field, while the other one follows in phase the F magnetization of the F layer. The 'loose' F component is responsible for the EB field and the shape of the hysteresis after the first reversal has taken place.

4.1.3 Spin valves

Spin valves are functional heterostructures in giant magneto resistance (GMR) and magneto-tunneling resistance (TMR) devices. Two F layers are separated by a non-magnetic layer, one of them being pinned by exchange coupling to an AF layer and the other one is comparatively easy to rotate in an externally applied field. Spin valves play an essential role in GMR heads, in MRAM devices, and in novel AFC hard disks. Analyzing the layer resolved switching is therefore of paramount importance.

Choi *et al*. (2000) have performed a layer selective vector magnetometry study with PNR for analyzing the magnetic configuration of the following layer sequence: Cu/Co/Cu/FeNi/Cu/Co/Cu. The magnetically soft FeNi layer in the middle is exchange coupled to the outer Co layers, acting as a double spin valve system. Instead of one step in the magnetic hysteresis for a single spin valve, two steps are observed. At the first plateau the center FeNi layer reverses by applying a reversing field, then the lower Co layer switches, and saturation is reached when also the upper Co layer is switched. Neutron reflectivity has been used for analyzing the magnetization vectors of the different layers in more detail. The data show that in the plateau region a perfect antiparallel alignment between the Co and the FeNi layers cannot be reached, but that there is always some canting. Layer resolved vector magnetometry provides a much more detailed picture of the reversal mechanism than it is possible with an layer averaging method such as SQUID or VSM.

Toney *et al*. have recently investigated the switching of an AFC trilayer (Toney *et al*., 2005). The upper magnetic layer was a 12-nm-thick $Co_{63}Pt_{11}Cr_{18}B_8$ alloy, while the lower

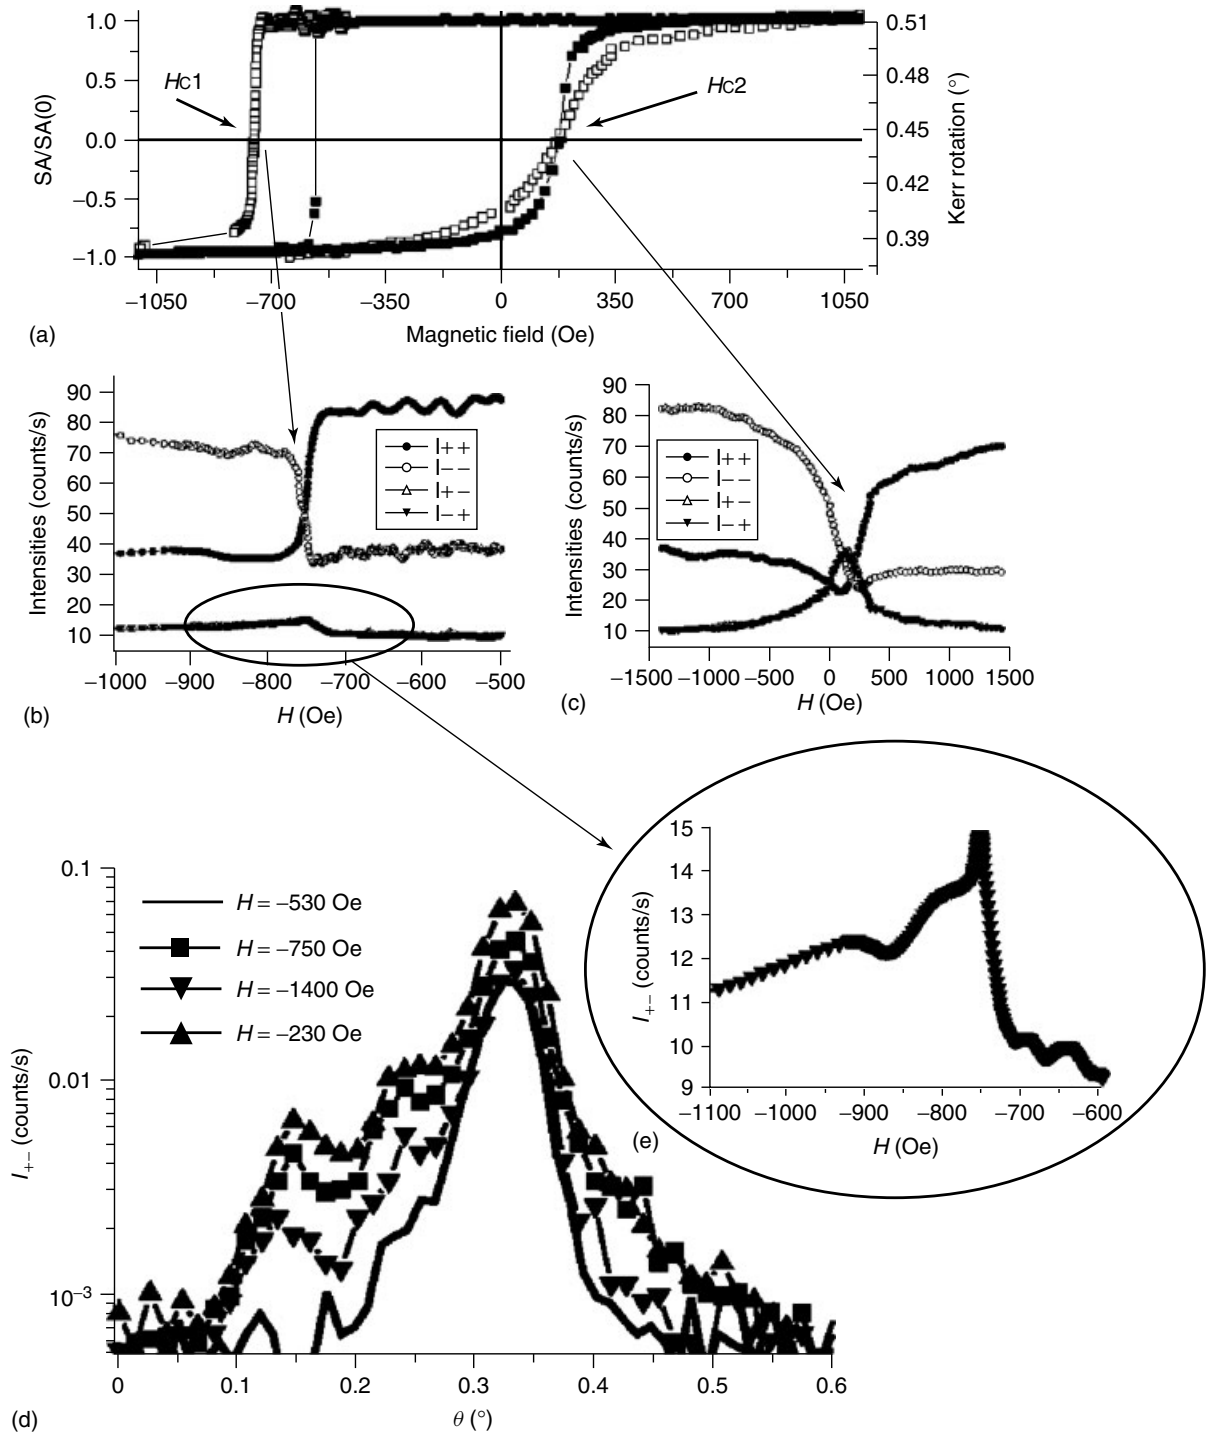

Figure 28. (a) Comparison of MOKE hysteresis loop (full squares) and neutron hysteresis loop (open squares) of a CoO/Co bilayer after field cooling to 50 K (MOKE) and to 10 K (neutrons); (b) and (c) reproduce the specular NSF and SF scattering close to the coercive fields in the descending and ascending branch of the hysteresis; (d) off-specular diffuse spin-flip scattering taken just before magnetization reversal at −530 Oe (line), at $H_{c1} = -750$ Oe (full squares), in saturation at −1400 Oe (down full triangles), and before the second magnetization reversal at −230 Oe (up full triangles); (e) a zoom in from panel (d) showing the weak SF intensity at the first magnetization reversal with a sharp spike from domain wall propagation. The SF scattering at H_{c2} is much more pronounced and indicates a coherent rotation of the magnetization. (Reprinted figure with permission from F. Radu *et al*., *Phys Rev. Figure 29. Intensity maps from a CoO/Co bilayer with exchange bias taken with polarized neutrons and using a ^{3}He spin filter for the spin analysis of scattered neutrons. Always four sets for the four different reflectivities are shown: R^{--}, R^{+-}, R^{-+}, R^{++}. The first set shown on the top right panels (taken at point (2) of the hysteresis loop) shows the sample after field cooling through the Néel temperature of CoO in an external field of 2 kOe and after the first reversal has taken place in the ascending branch of the loop. The R^{++} and R^{--} specular intensities are essentially the same as before the first reversal, but the off-specular spin-flip reflectivities R^{+-} and R^{-+} have dramatically changed. Their asymmetry signals a ferromagnetic domain state or spin disorder at the interface between the ferromagnetic and antiferromagnetic layer. The second reversal occurs at a different coercive field than the first reversal (training effect). However, the off-specular spin-flip reflectivities R^{+-} and R^{-+} shown for point (1) in the top left panels remain the same, only the sign has changed, indicating that the interfacial domain disorder is stable but changes orientation with the field direction. The logarithmic intensity color coding is identical for all maps. (Reproduced from F. Radu *et al*., 2003 with permission from Elsevier. © 2003.)

magnetic layer was a 3-nm-thick $Co_{86}Cr_{14}$ alloy separated by a 0.7-nm-thick Ru layer providing a strong AF coupling of the upper and lower layer. The alloy grains in the polycrystalline F layers are supposed to be magnetically decoupled. Magnetization measurements confirm that at large applied fields, the AF coupling is overcome and the magnetization in the F layers is parallel to the field. As the field is reduced, the thinner lower layer first reverses at $H = H_{ex}$ to become antiparallel to the thick upper layer. As the field is further reversed, the upper layer switches and both layers are again parallel to the field. While this explanation of the magnetic reversal is basically correct, the details are revealed by PNR measurements, as shown in the Figure 30. In particular, the PNR measurements provide information about the depth dependence of the magnetization at the different field values and therefore give a more detailed understanding of the reversal process. Detailed analysis shows that the field dependence of the upper layer magnetization during reversal of the lower layer does not follow simple expectations for a layer with magnetically

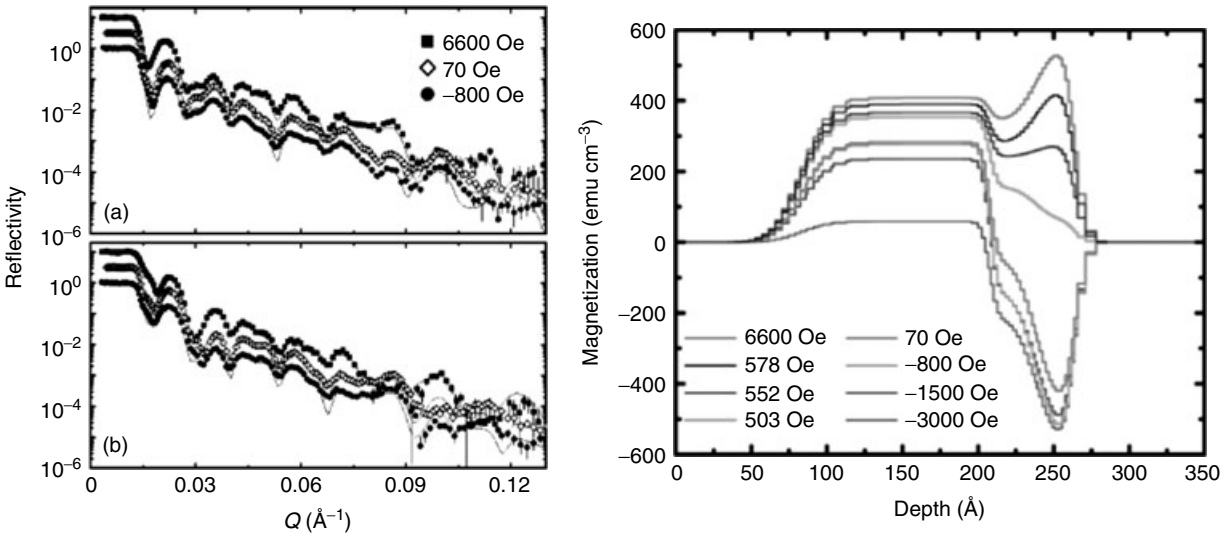

Figure 30. Reflectivity measurements from thick $Co_{63}Pt_{11}Cr_{18}B_8/Ru/Co_{86}Cr_{14}$ trilayer, used for data storage in antiferromagnetically coupled hard disks. (a) R^{++} reflectivity, (b) R^{--} reflectivity and for the respective magnetic field values. In right panel, the magnetization profiles are shown as obtained from best fits to the data. decoupled grains and high anisotropy that is AFC to the lower layer. Near the reversal field for the lower layer at $H_{ex} \leq 500$ Oe, the magnetization of the upper layer abruptly drops from the saturation value of 400 emu cm^{-3} to approximately 300 emu cm^{-3}, and then gradually decreases as the field is decreased to -3000 Oe. This sudden drop was unexpected from SQUID data and is only revealed by the PNR measurements. The authors conclude that the coupling of the upper and lower layers during reversal may be more complex than previously assumed and may include interactions from DWs in the lower layer. These results have a direct impact on the future design of AFC hard disks.

4.2 Magnetic multilayers

Magnetic multilayers and magnetic superlattices are the most rewarding playground for PNR measurements as short and long-range F- and AF correlation effects can easily be revealed, as well as conformal and non-conformal interface roughnesses and layer resolved reversal processes. In this respect, the PNR method is essentially unrivaled. Resonant magnetic X-ray scattering has become a serious competition in recent years. However, the deeper penetration depth of neutrons and the well-known cross sections remain to be strongholds of PNR. Because of this, a large number of magnetic multilayers have been investigated by PNR since the early 1980s, representative examples are listed in Table 3.

The archetypal magnetic superlattices for which interlayer exchange coupling (IEC) was intensely investigated in the past are Fe/Cr and Co/Cu superlattices. In Fe/Cr superlattices the spin density wave (SDW) magnetism of the Cr spacer layer supports the IEC. At the same time, the SDW magnetism interferes with IEC in case of interfacial defects. The interplay between the ferromagnetism of the Fe layers and the SDW order of the Cr spacer layers adds to the complexity of Fe/Cr superlattices. Co/Cu superlattices are comparatively easy objects as the Cu spacer layer does, at first glance, not inflict further complications. Therefore Co/Cu superlattices with [100], [110], and [111] orientations served as testbeds for studies of the oriental dependence of the period and the strength of the IEC. Although the magnetic and electronic properties of Co/Cu superlattices are straightforward, growth problems have inhibited the observation of an oscillatory IEC in the [111] growth direction.

4.2.1 Co/Cu multilayers

Co/Cu multilayers continue to serve as model systems for exchange coupling, domain states, and interfacial magnetic roughness. In the [111] growth direction, however, Cu antiphase domains develop on the Co(111) surface, giving rise to magnetic pinholes. For a long time the oscillatory IEC was obscured in Co/Cu(111) superlattices due to its inherent weakness and due to the fact that domain wall pinning at structural defects inhibit AF alignment of the F layers. Schreyer *et al*. have finally verified with PNR methods the oscillatory character of the IEC for carefully

grown epitaxial Co/Cu(111) (Schreyer *et al*., 1993a). They could clearly identify a half order, albeit weak, Bragg peak signaling AF correlation at the first (Cu thickness 1 nm) and second maximum (Cu thickness 2 nm) of the AF interlayer exchange coupling.

The magnetic arrangement of Co/Cu polycrystalline multilayers has been analyzed by Borchers *et al*. (1999), shown in Figure 31. The Cu spacer was chosen rather thick as to provide only a weak exchange coupling between the adjacent Co layers. The NSF reflectivity curve measured from the Co/Cu multilayer in the as prepared state of the sample shows a half-order AF peak along with a first-order Bragg reflection. The observation of a half-order superstructure reflection provides direct evidence for AF coupling in neighboring layers. Weak SF reflectivity enhanced at the position of the half-order AF periodicity and first order chemical periodicity indicates that the magnetization of the Co layers may not be exactly parallel to the field guiding neutron polarization. Diffuse scattering measured slightly away from the specular ridge indicates that the magnetization is not homogeneous in the lateral direction, but rather is decomposed into a set of F domains. In the domains the magnetic moments keep the antiparallel orientation across the multilayer stack. This alternation appears to be quite perfect as no diffuse scattering contribution at the first-order Bragg peak was detected. In contrast, the intensity of the specular and off-specular half-order superstructure peak is of the same magnitude. From this it can be inferred that the AF order is spread out in the lateral direction over a distance bigger than the coherence length. Indeed, via rocking scans across the half-order AF Bragg position, that is varying Q_x at fixed value of $Q_z = Q_{\mathrm{Bragg}}$, it was found that the diffuse scattering forms Bragg sheets, similar to those
