Advanced Magnetic Microwires

Manuel Vázquez
Instituto de Ciencia de Materiales, Madrid, Spain

1 INTRODUCING AMORPHOUS MAGNETIC MICROWIRES

Amorphous microwires, being among the softest magnetic materials, present outstanding peculiarities. Those with large and positive magnetostriction, exhibit bistable behavior with magnetization reversal through a giant Barkhausen jump originating in the propagation of a single-domain wall. On the other hand, microwires with vanishing magnetostriction show giant magnetoimpedance (GMI) effect. And both types show natural ferromagnetic resonance (NFMR) at microwave frequencies. Recently, a combination of fabrication methods has enabled the design of new bimagnetic multilayer microwire materials with novel properties, thus opening new generation of magnetic microwires. All these properties, and many others, make amorphous magnetic microwires very attractive for unique technological applications, and also provide opportunities for fundamental micromagnetic studies due mainly to their simple magnetic domain structure.

Magnetic microwires with disordered atomic structure belong to the large family of amorphous alloys. From the early development of amorphous metallic alloys, researchers have been looking to obtain amorphous microstructured materials with specific shapes and magnetic properties designed for applications, in particular, devices. Such developments have been running in a parallel way with the development of new techniques of fabrication. In this regard, for example, amorphous alloys are prepared, in the shape of ribbons, by rapid solidification techniques (usually directly labelled as metallic glasses), as thin films by sputtering methods, and as bulk materials, by optimized nonequilibrium techniques. Among these materials, amorphous thin films are readily integrated into thin-film and semiconductor technology but their magnetic character is not as soft as that of the others. Metallic glasses are commonly fabricated in ribbon form with specific applications in cores of small transformers or elements in sensor devices. For general information about amorphous alloys, the reader is referred to the chapter **Amorphous Alloys, Volume 4**. Here, we focus on a particular family of metallic glasses with cylindrical shape. What is actually an amorphous magnetic microwire? and what are the conditions determining their technically exciting behavior? Their same name provides the reader with a detailed description of the nature of microwires: *amorphous magnetic microwires*. Firstly, due to their ferromagnetic behavior, the largest energy term among magnetic interactions to be considered is *exchange coupling*. Secondly, their nature being structurally amorphous, magnetocrystalline anisotropy can be neglected so that *magnetoelastic anisotropy* plays a major role. And thirdly, their

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

cylindrical symmetry induces a very characteristic magnetic *shape anisotropy*.

In fact, all of the above three factors are influenced by the *rapid solidification* method employed in the fabrication. Firstly, composition, as in other magnetic amorphous alloys obtained by melt spinning is mainly restricted to various FeCo-based alloys. Of particular relevance is the fact that the alloy composition determines the *magnetostriction* constant, λ_s. Secondly, the quenching technique determines the possibility to achieve amorphous structure, but in turn introduces unique distribution of strong internal *mechanical stresses*, σ. Thus, magnetostriction and stresses determine the strength of magnetoelastic anisotropy. And finally, the particular fabrication method determines the cylindrical shape. Here, for simplicity, we will consider the term *microwire* for kinds of amorphous and nanocrystalline wires with diameter ranging between 1 and 100 μm.

In summary, the magnetic behavior of amorphous magnetic microwires is determined by exchange interaction, plus shape and magnetoelastic anisotropy energy terms. Major scientific and technological relevance of amorphous alloy microwires are associated either with their characteristic single-domain structure determining their bistable behavior, or with their ultrasoft magnetic behavior in connection with the GMI effect.

Magnetic wires with polycrystalline structure have been fabricated by metallurgical procedures for many years with diameter from millimeter to hundred of microns. Typically, such procedures induce large mechanical stresses that, combined with the shape anisotropy, determine their magnetic response of interest in various sensing applications. In particular, the so-called Wiegand wires were introduced in the beginning of the 1980s exhibiting quite large Barkhausen jump that can be employed for pulse sensors (Wiegand, 1981).

The production of amorphous wires with diameter in the range of hundred microns was first enabled by the development of modified melt-spinning processes in the 1970s. The first successful method to produce amorphous wires, based on a process of liquid solidification into water, was developed by Kavesh (1976). There, the metallic molten alloy was directly injected into a confluent cooling fluid (normally water) with viscosity nearly equal to that of the molten alloy. The first work on the attractive magnetic behavior of such amorphous wires was reported by O'Handley (1975). Further development of quenching technique into rotating water was subsequently achieved in Japan by Ohnaka *et al.* (1982) and Masumoto, Ohnaka, Inoue and Hagiwara (1981) and particularly by technical researchers at Unitika Ltd, allowing the commercialization of amorphous microwires, produced in a continuous way, with a diameter restricted to around 100 μm. Relevant scientific work in the 1980s was performed by the researchers Mohri in Japan and Humphrey *et al.* (1987) in United States. In the 1990s, other groups have been actively involved in the research of these microwires particularly paying attention to preparation and structure characterization by Olofinjana and Davies (1992) in Sheffield, magnetic domain observation by Yamasaki (1992) and Yajako, Yamasaki and Humphrey (1993) in Kyushu, magnetic bistability by Mitra and Vázquez (1990) and Vázquez, Gómez-Polo, Chen and Hernando (1994) in Madrid, magnetoelastic behavior by Squire, Atkinson, Gibbs and Atalay (1994) in Bath, and other groups in Japan mainly involved in development of various sensor devices. Additionally, in 1994, the GMI effect was rediscovered in nonmagnetostrictive amorphous wires simultaneously by Panina and Mohri (1994) in Nagoya and Beach and Berkowitz (1994) in San Diego. Recent activities are mainly related to their adoption as sensing elements by several groups in Europe and particularly in Japan.

The story on the development of the amorphous microwires prepared by quenching and drawing method is even longer. These microwires covered by an insulating Pyrex coat are fabricated by a technique that, in essence, was introduced in the 1920s by Taylor (1924) in United States. After modifications of this method, first glass-coated microwires were prepared in the former Soviet Union in the 1950s by Ulitovsky (1957). First reports on such materials were dealing with their mechanical properties by Nixdorf (1967) in Germany and by Goto (1977) in Japan, and on magnetic properties by a number of researchers in former Eastern Europe (i.e., Schneider in East Germany, and Kraus in Checkoslovakia (Kraus, Schneider and Wiesner, 1976)). The interesting radar absorption properties attracted much interest in the Soviet Union during the 1980s, and the work was developed somehow independently by different groups in Kishinev, Moscow, and Leningrad. By the beginning of the 1990s, first reports in western journals were introduced by Chiriac in Romania and Vázquez in Spain (Chiriac, Pop, Barariu and Vázquez, 1994; Zhukov *et al.*, 1995) through their contacts with Larin and Torcunov in Amotec Ltd in Moldova (Baranov *et al.*, 1989). This interest was related to the fact that exhibiting similar outstanding properties as wires prepared by liquid quenching into water, they offered additional possibilities to be used as sensing elements due to their reduced diameter, ranging between 1 and 30 μm, and protecting insulating glass coating. Additionally, interest was also related to their real possibilities as outstanding materials at microwave frequencies derived from the so-called NFMR effect that make them attractive in radar absorption coatings or even as left-handed materials (LHMs).

From the original studies of the Russian school, other families of similar fibers have been investigated by a group in Montrèal leaded by Ström-Olsen, and then Yelon (Rodkowski *et al.*, 1995), or by Kraposhin in Saint Petersburg. Other works around Moscow have been reported by Shalyguina

(Moscow State University), Antonov (Theoretical and Applied Electrodynamics) and Usov (Troistsky Institute) in Moscow, and by Manov (Advanced Metal Technologies Ltd) in Israel.

Nowadays, various attempts are being performed to fabricate novel microwires with new or optimized properties. In this regard, the recent introduction of so-called multilayered microwires consisting of several cylindrical microlayers with different magnetic behavior offers promising perspectives owing to the observed biphase magnetic behavior of interest for the spin-valve-like magnetic or the asymmetric magnetoimpedance responses (Pirota *et al*., 2004). In parallel, latest attempts are focused on the preparation of magnetically harder, although structurally not amorphous, microwires by introducing anisotropic hard phases. All these attempts are related to the employment of new metallurgical or combined techniques. The present trends can be thus summarized considering the path of methods used to prepare microwire materials: from metallurgical traditional methods enabling the production 'typically' of millimeter diameter fibers, to the rapid solidification techniques for producing micrometric diameter wires, and, in the next stage leading probably to the controlled production of submicrometric and nanometric wires which require different fabrication procedures.

Specific international workshops and meeting have been devoted to amorphous microwires. The first one was organized by Unitika Ltd in London, 1991, chaired by Ogasawara and Humphrey. Next one was held in Albuquerque, New Mexico, in 1994 chaired by Hasegawa and Ramanan, and their proceedings appeared as a special issue of *IEEE Transactions on Magnetics* (1995). In 1999, Mohri organized a symposium at the University of Nagoya. Vázquez, González, Zhukov, and Gómez-Polo chaired in 2001 the International Workshop on Magnetic Wires in San Sebastián, Spain, the papers later appeared in a special issue of the *Journal of Magnetism and Magnetic Materials* (2002).

The general aspects of advanced microwires are described in this chapter to give the reader a general overview with a particular emphasis on the magnetization processes, in which lies the origin of their technological applications.

2 AMORPHOUS MICROWIRES: PRODUCTION AND PROCESSING

Magnetic alloys composition that can be produced with amorphous structure, similarly as for metallic glass ribbons, can be given as $TM_xM_{(1-x)}$ with x typically between 70 and 80%. Transition metals (TMs), Fe, Co, and Ni and their combinations determine the magnetic character. Many other TMs have been investigated, such as Ti, V, Nb, Ta, Cr, Mo, W, Mn, Pd, or Al (Hagiwara, Inoue and Masumoto, 1982). As for the metalloids, those typically considered are Si and B, although others such as C, P, Al, and so on, can be employed.

Intrinsic magnetic properties such as saturation magnetization or Curie temperature exhibit similar values as amorphous alloy in ribbon shape having the same composition. The technical magnetic behavior of microwires can be classified into three groups according to their magnetostriction, λ:

1. FeSiB alloys with large and positive magnetostriction (in the order of $1-3 \times 10^{-5}$).
2. FeSiBCuNb alloys with similar λ, but which notably reduces its value and eventually changes sign upon nanocrystallization process.
3. CoFeSiB alloys with balanced magnetostriction for the Fe/Co rate at around 5%.
4. CoSiB alloys with negative and slightly reduced magnetostriction $\lambda \approx -1 \times 10^{-6}$.

Mechanical or electrical properties are quite similar to those of amorphous ribbons. The reader is referred to review articles (Donald, 1987) for in-water-quenched wires and (Goto, 1980) for glass-coated microwires.

2.1 Fabrication techniques

General information about the fabrication of amorphous microwires can be found in Ogasawara and Ueno (1995) on in-water-quenched wires, (Zhukov *et al*., 2003) on glass-coated microwires, and (Ogasawara and Ueno, 1995; Hagiwara and Inoue, 1993) on both types of amorphous materials. Figure 1 shows views of the in-rotating-water-quenching (1a and 1b) and glass-coating (1c) units at ICMM/CSIC laboratories as well as a glass-coated microwire (1d).

2.1.1 In-rotating-water-quenching production technique

In this method, experimentally introduced and patented by Ohnaka (1980), a molten metal stream is ejected through the orifice of a quartz tube into a water layer formed by centrifugal force on the internal surface of a rotating drum. The equipment and the process itself essentially consists of the following elements and steps:

1. A *rotating drum unit*, typically 0.5 m diameter, which rotates at around 350 rpm. Owing to centrifugal force, water previously bombed at the drum forms a tiny layer approximately 2 mm deep onto its internal surface.
2. A *microwave coil heater* of the metallic mother alloy. This is previously prepared by pressing of powders and preheated for homogenization, or alternatively prepared

by arc melting. Such mother alloy is placed inside a vertical quartz nozzle tube having a small orifice, typically 0.1–0.3 mm diameter, at its bottom. The temperature of the molten alloy can be controlled by means of a thermocouple.

3. An *ejection system* of the molten alloy by argon overpressure, around 0.5 MPa, on the top quartz tube. Once the convenient temperature is reached, in the range between 1250 and 1300 °C, and with the help of a pneumatic system, the whole quartz tube is lowered so that the mentioned orifice gets quite close to the surface of the rotating water layer. This proceeds simultaneously to the injection of the argon overpressure so that a molten lead stream crosses the quartz orifice and plunges into water.
4. A *cooling system* that consists of the rotating water. The quenching rate is of the order of $10^5\,\mathrm{K\,s^{-1}}$.
5. A microwire *collector system*. Typically, a continuous production of several tens of meters can be produced at laboratory scale (depending on the weight of mother alloy). Then the drum stops and the microwire is collected manually. Commercial equipments incorporate an additional winding system to enhance the production of amorphous wire.

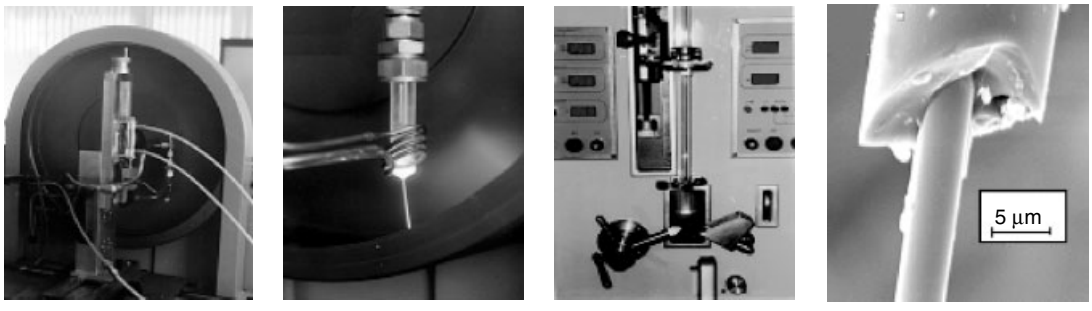
The quenching rate (about $10^5\,\mathrm{K\,s^{-1}}$) required to achieve amorphous structure restricts the diameter in a range typically from 80 to 200 µm. The production of a continuous wire is solved by controlling a number of fabrication parameters such as the following: (i) Diameter of the orifice at the bottom of the quartz tube; allowing for shrinkage during solidification, typically 3–4 vol%, this parameter determines the final wire diameter. (ii) Temperature of molten alloy. (iii) Argon overpressure. (iv) Distance from the orifice to water layer during injection. (v) Tangential velocity at the surface of the rotating drum and drum diameter itself. (vi) Ejection angle between the jet of molten metal and the rotating water layer.

2.1.2 Quenching and drawing procedure: glass-coated microwires

As introduced previously, this technique is based on early works by Taylor, Ulitovsky and others (Ulitovsky, 1957; Goto, 1977; Nixdorf, 1967; Kraus, Schneider and Wiesner, 1976; Donald, 1987; Ohnaka, 1980; Larin *et al*., 2002), and it has had an emerging interest in recent years. By this method, it is possible to fabricate composite microwires consisting of a metallic nucleus with diameter ranging between 1 and 30 µm and an insulating coating 2–10 µm thick (see Figure 1d). The main differences with previously described wires are (i) the smaller diameter of the metallic nucleus with interesting possibilities in miniaturization and (ii) the presence of the insulating coating, which offers protection against corrosion and electrical insulation, but also induces additional strong mechanical stresses to the nucleus.

The main steps of this process of fabrication (see Figure 1c) are as follows:

1. A *vertically moving system* with controlled velocity to ensure the continuous production, at around $400\,\mathrm{m\,min^{-1}}$, of microwire. This allows the vertical displacement of the Pyrex tube that contains the pellet of metallic mother alloy, previously prepared as mentioned earlier.
2. A *microwave coil heater* surrounding the Pyrex tube with the metallic pellet. It induces the melting of the metallic alloy, at 1200–1300 °C, which generates sufficient heating for practical melting of the Pyrex, or similar insulating glass. The metallic alloy and insulating external layer then remain as a very viscous melt.
3. A *drawing and quenching* system that essentially consists in a first starting manual process by which that viscous melt is drawn down. By this procedure, the melt rapidly solidifies into a metallic nucleus with surface Pyrex coating. This rapid solidification is enhanced by a running water jet allowing a quenching rate of about $10^5\,\mathrm{K\,s^{-1}}$. The solidified microwire gets down with a



(a) (b) (c) (d)

Figure 1. In-rotating-water-quenching unit: general view (a), and during the melting process (b). Quenching and drawing unit (c) and glass-coated microwire (d).

total mass vertical displacement coupled to the vertical moving system.

4. A microwire *collector system*, enabling a continuous production of around 400 m min^{-1} with typically several kilometer-long microwire produced at laboratory scale. The system consists of a rotating cylinder collecting the drawn microwire whose rotating velocity is coupled to the vertical displacement mentioned above. It also has a lateral displacement to allow winding of several kilometers of microwires around a bobbin. Additionally, the continuous production of microwire is automatically controlled by a microwave sensor detecting the presence of microwire below the heater units.

A number of parameters determine the geometrical dimensions of the final microwire as, for example: (i) vertical drawing stress and velocity, (ii) insulating tube thickness (typically 0.5–2 mm), (iii) temperature of the melt, (iv) vacuum underpressure inside the Pyrex tube in order to control the diameter of the metallic core.

Usually, the insulating coating is made out of Pyrex, but other insulators as Ursan can be employed. Controlled tailoring of the coating thickness is also important as described later because of the different internal stresses induced in the nucleus during the fabrication process.

Finally, we should mention an alternative method developed by the group in Montréal (Ström-Olsen and Rudkowsky, Piotr, 1991). In this method, the rapid solidification method is based on the melt extraction from a continuous stream of liquid alloy. The molten material wets the edge of a fast rotating metallic wheel. The molten tip is placed under the center of the sharp edge of the wheel to wet symmetrically and finally extract small fibers. The surface below the line of contact transfers heat to the casting wheel and permits a thin layer of liquid to be pulled from the molten tip. The cross section of the fibers is nearly circular, with diameter in the range of 5–25 μm, while their continuous length may reach up to several meters.

2.2 Distributed mechanical stresses due to quenching

Different attempts have been performed to determine the complex distribution of internal mechanical stresses, σ_{int}, arising from the casting technique for both in-water-quenched and glass-coated microwires:

1. *In-water-quenched microwires:* Stresses are frozen in as a consequence of thermal gradient inside the wire during quenching. According to the classical theory of elasticity and considering that the cooling front corresponds to a cylindrical surface, there appears a thermal gradient in the radial direction (Boley and Weiner, 1990). A general assumption is that the cooling process takes place steeply in differential tubular shells inwards from the surface where the cooling rate should be higher. Complex stress distributions have been reported (Madurga and Hernando, 1990; Liu, Malmhäll, Arnberg and Savage, 1990; Costa and Rao, 1991; Velázquez *et al*., 1991). Essentially, three components of stresses: radial, σ_{r}, azimuthal, σ_ϕ, and axial, σ_{z}, appear being radially distributed. Whereas radial stress remains always tensile (positive) in character, circular and axial stresses change sign from tensile at the inner part to negative at the outer part having maximum value at the surface, so defining two main regions within the wires: the *inner core* and the *outer shell* where the interface remains at a radius $r \approx 0.7\,R$(R being the microwire radius). Some refinements of the stress distribution have been considered more recently, in order to account for the stresses around the axis of the wire (Chen *et al*., 2001), the result of which is given in Figure 2. Estimated average value of stresses is in the order of 50–100 MPa.
2. *Glass-coated microwires:* The case of glass-coated microwires is even more complex since now we have to consider the stresses arising from three different contributions: (i) *thermoelastic stresses* from the temperature gradient during quenching, which are essentially similar to those as for in-water-quenched microwires; (ii) *drawing stresses*, tensile in nature, originated by the extraction process; and (iii) stresses coming from the *different thermal expansion coefficients* of metallic nucleus and insulating coating.

Different authors have calculated the stress distributions. Baranov *et al*. (1989) considered that most stresses actually arise from the differential thermal expansion coefficients so

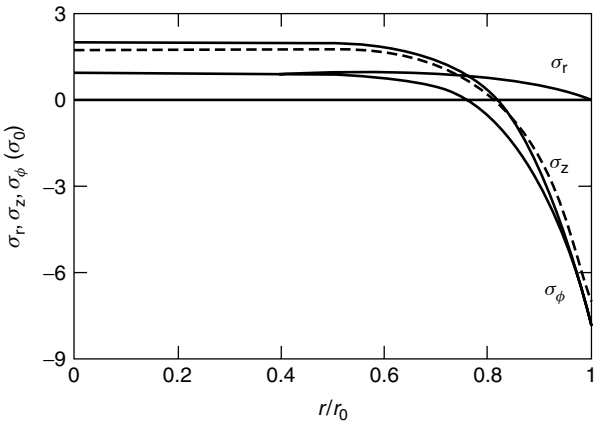


Figure 2. Radial distribution of stresses frozen in during quenching: radial, σ_{r}, azimuthal, σ_ϕ, and axial, σ_{z}. (Reproduced from D.-X. Chen *et al*., 2001, with permission from IEEE. © 2001.)

obtaining complex axial, σ_{zz}, radial, σ_{rr}, and azimuthal, $\sigma_{\phi\phi}$, stress contributions:

$$\sigma_{rr} = \sigma_{\phi\phi} = \frac{3E_r S_r}{(E_r + 3)\, S_r + 4}\varepsilon E_m$$
$$\sigma_{zz} = \sigma_{rr}\frac{(E_r + 1)\, S_r + 2}{E_r S_r + 1} \quad (1)$$

with $\epsilon = (\alpha_g - \alpha_m)\Delta T$, ($\Delta T$ being the temperature change), where $E_r = E_g/E_m$, $S_r = S_g/S_m$, and α denote, Young's modulus, cross section, and thermal expansion coefficient, respectively, and subscripts m and g indicate metallic and glassy coating, respectively. Other models (Chiriac and Ovari, 1996; Velázquez, Vázquez and Zhukov, 1996) consider all three origins for stresses. Nevertheless, the final distribution of stress depends on the prevailing relative contribution either from the drawing stresses or from the coating stresses arising from the differential thermal expansion coefficient. Average value of stresses in glass-coated microwires is of the order of 400–500 MPa.

2.3 Controlled processing: how to tailor properties

In a search to adjust to desired magnetic behavior, as-cast amorphous microstructure can be modified by mechanical, chemical, or thermal processing. Most noticeable methods are given in the following sections.

2.3.1 Cold drawing and chemical etching

These processes are aimed at the modification of the geometry of the microwires. Cold drawing was developed by Unitika Ltd and other groups in Japan (Malmhäll *et al*., 1987; Kakuno, Masuda, Yamada and Mochida, 1987) with a final objective of reducing the diameter of such amorphous wires in order to miniaturize the sensing elements made out of such materials. The diameter of the wires is reduced continuously step by step through a large number of drawing processes. In this way, the microwire diameter can be reduced from around 120 µm down to typically 30 µm. Although the amorphous microstructure is maintained, strong mechanical inelastic stresses are induced by this process which usually hardens its magnetic behavior. Cold-drawn microwires are subjected subsequently to thermal processing that reduces such stresses, thus recovering and even optimizing the soft properties of precursor microwires.

Glass coating of microwires can be either fully or partially reduced by suitable chemical etching (Chiriac, Pop, Bararíu and Vázquez, 1994; Zhukov *et al*., 1995; Catalán *et al*., 1997; Chiriac, Ovari, Marinescu and Nagacevschi, 1996). Diluted acids (i.e., HF, HCl, and others) are employed to proceed with a careful coating removal, which also modifies the stress state of the metallic nucleus resulting in a significant magnetic softening.

2.3.2 Inducing particular short-range ordering: thermal annealing

Amorphous microstructure can be modified by different thermal processes which relax and induce particular short range ordering (Fujimori, 1983; Hernando and Vázquez, 1993; Nielsen, 1985). Further information can be found in the chapter corresponding to amorphous ribbons. For amorphous microwires, simple thermal treatments at low temperatures result in a relaxed more stable amorphous microstructure with partial annihilation of structural defects and significant reduction of the mechanical stresses induced during the quenching fabrication process.

On the other hand, thermomagnetic annealing gives rise to internal stress relaxation and, when annealing below the Curie point, it induces short range ordering with an associated induced magnetic anisotropy with easy magnetization direction lying along the orientation of the field during annealing. The thermal treatment can be done either in a conventional furnace or by current annealing, making an electrical current flow along the microwire. In the latter case, it generates a circumferential field and a circular induced anisotropy by itself when the current is not high enough to overcome the Curie temperature of the alloy. Finally, thermomechanical annealing also induces noticeable anisotropies as for the case of amorphous ribbons. Experimental results concerning all these types of annealing for in-water-quenched microwires and on glass-coated microwires can be found in Gómez-Polo and Vázquez (1993), Zhukov *et al*. (2000) and Zhukov (2006).

3 AXIAL MAGNETIZATION PROCESS AND MAGNETIC BISTABILITY

All the outstanding magnetic characteristics of amorphous microwires and particularly their magnetization processes derive from the unique stress distribution and from the magnetostriction constant, in turn determined by the alloy composition. The corresponding magnetoelastic anisotropy together with the shape anisotropy determines the magnetization process for each type of microwires. A number of review papers dealing with magnetization process of in-water-quenched (Humphrey *et al*., 1987; Vázquez and Chen, 1995; Squire, Atkinson, Gibbs and Atalay, 1994), and glass-coated microwires (Vázquez and Zhukov, 1996; Chiriac and Ovari, 1996; Vázquez, 2001a; Zhukov, 2002)

have been previously reported. Here, most important characteristics are collected and the latest results introduced and discussed. In this first section, we analyze the magnetization process of magnetostrictive microwires exhibiting bistable behavior and its consequences.

3.1 Domain structure and axial hysteresis loops of Fe-based magnetostrictive microwires

3.1.1 Axial hysteresis loops and main domain structure

General information about the distribution of magnetization in the wire can be straightforwardly extracted from combined information from axial loops and domain observation (see Figure 3). The low-frequency low-field longitudinal hysteresis loop of Fe-based microwire, prepared by the techniques described previously, is astonishingly simple. It takes a square shape with a single giant Barkhausen jump at switching field of around 5–30 A m^{-1} for in-water-quenched and glass-coated microwires, respectively. From this simple experimental fact and assuming a domain wall displacement magnetization process (confirmed by additional experiments), we can derive some important information: the axial magnetization reversal takes place by the displacement of *a single-domain wall*.

Complementary information can be obtained from magnetic domain observation in the case of in-water-quenched microwires (i.e., by magnetooptic Kerr effect, or Bitter technique) (Reininger, Kronmüller, Gómez-Polo and Vázquez, 1993): at the surface, domain patterns are relatively complex with a number of zigzag walls denoting some complex distribution of magnetization direction at that region. In turn, the domain structure of the inner part is much simpler as observed after careful polishing of the microwire: at zero field, no domain wall can be detected indicating the homogeneous distribution of magnetization in a large single domain axially magnetized.

At higher applied fields (not observed in Figure 3), magnetization process takes place in a nearly reversible way until approaching magnetic saturation at fields of the order of units or tens of kiloamperes per meter for in-water-quenched and glass-coated microwires, respectively. In fact, for in-water-quenched wires, remanence, M_r, to saturation magnetization, M_s, squareness ratio, $m_r = M_r/M_s$, is nearly $m_r \approx 0.5$ (see Figure 4a) (for an analysis of the correlation between remanence and fractional volumes of core and shell, see Fujimori, 1983; Hernando and Vázquez, 1993; Nielsen, 1985). This

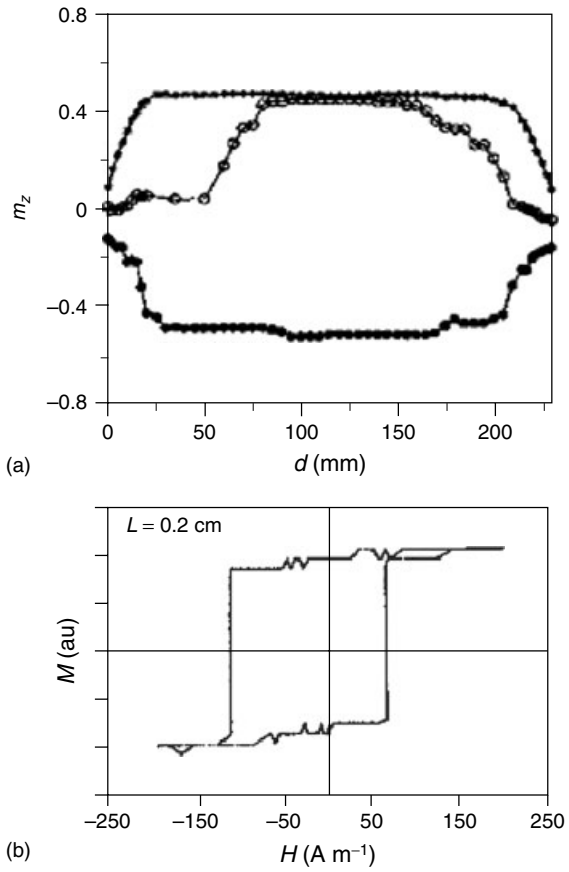

Figure 4. (a) Magnetization profile at the remanence (*), just before (○) and after (●) switching for an Fe-rich amorphous wire (a). (Reproduced from M. Vázquez *et al*., 1995, with permission from IEEE. *copyright* 1995.) The evidence of bistability in glass-coated Fe-rich wires in samples of very short lengths (b). (Reproduced from M. Vázquez *et al*., 1996, with permission from Elsevier. © 1996.)

indicates that the fractional volume involved in the giant Barkhausen jump, that is, the inner core is nearly one-half of the wire and, consequently, its radius is $r \approx 0.7\,R$ (note that this corresponds to the distance to the wire axis in Figure 2 where axial stress is no longer predominant). The outer shell consists of a multidomain structure with magnetization radially oriented and additional closure structures at the very surface (see schematic view in Figure 3), all of that magnetizing reversibly at high field. This is consistent with the distribution of stresses obtained in the previous section. From its analysis, we conclude that the easy magnetization direction from magnetoelastic origin is axial at the core where axial tensile stresses dominate. At the shell, maximum stresses are azimuthal and axial and their compressive character in the surface of the wire results in a Poisson contraction and radial easy axis. This radial easy axis, in competition against the transverse demagnetizing field, gives rise to the complex domain structure at the surface of microwires, as schematically drawn in Figure 3.

The case of glass-coated microwires is very similar, although the domain structure is much more difficult to observe owing to their reduced dimension. Figure 4(b) shows how the bistability is preserved in glass-coated microwires even at very short sample lengths.

3.1.2 Fine domain structure of microwires

Finer domain structure at the inner part of in-water-quenched microwires has been thoroughly studied by Yamasaki (Mitra and Vázquez, 1990; Vázquez, Gómez-Polo, Chen and Hernando, 1994). A careful polishing of microwires allows one to observe a finer domain structure at the border between core and shell.

Closure domain structures also appear at the ends of microwires to reduce the large magnetostatic energy associated with magnetic charges that would otherwise appear (Vázquez, Gómez-Polo and Chen, 1992; Gómez-Polo, Vázquez and Chen, 1993). This fine domain structure has been directly observed by magneto-optic Kerr effect and Bitter technique in in-water-quenched microwires (Reininger, Kronmüller, Gómez-Polo and Vázquez, 1993; Vázquez, Gómez-Polo and Chen, 1992; Gómez-Polo, Vázquez and Chen, 1993; Vázquez, Theuss and Kronmüller, 1999) (see Figure 3, bottom). The existence of those closure structures is also derived from the profiles of magnetization and susceptibility close to the ends in both types of microwires. Figure 4(a) shows the reduced-remanence regions at the ends of the wire. Such reduction is ascribed to the closure structures (note those enlarged regions just before the switching) (Vázquez, Theuss and Kronmüller, 1999; Zhukova, Usov, Zhukov and González, 2002). The length of such closure structures is of about 3 cm and 1 mm for in-water-quenched and glass-coated microwires, respectively, that gives us a hint of half the minimum length of microwires to observe bistable magnetic behavior: around 6 cm and 2 mm for in-water-quenched and glass-coated Fe-rich microwires, respectively. The loop for a 2-mm-long glass-coated microwire is shown in Figure 4(b). Figure 5(a) shows the hysteresis loop for a 5-cm-long in-water-quenched microwire that now consists of two Barkhausen jumps. This indicates that the inner core at its center is not a single-domain structure, which is confirmed by the corresponding domain structure (after careful polishing) showing the presence of two antiparallel domains (Figure 5b).

3.2 Bistable reversal mechanism and its dynamics

The very existence of the closure structure at the microwire ends is very important for understanding the magnetization

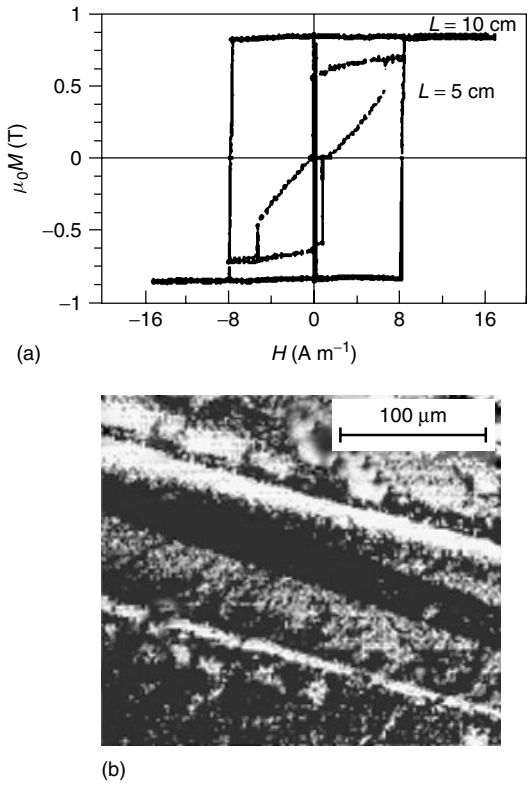

Figure 5. Hysteresis loops for a 10- and 5-cm-long wires (a), and the domain structure of a microwire shorter than the critical length for bistability (b). (Reproduced from T. Reininger *et al*., 1993, with permission from American Institute of Physics. © 1993.)

reversal process under homogeneous axial field. At the bottom of Figure 3, a set of images shows the domain structure at 1-cm distance from the end of a microwire between the remanence and the switching: at the inner core, there is a main single domain (light) and the tip of a closure domain. At the left, only the expanded closure domain (dark) can be observed. As the reverse applied field increases, the closure domain structure increases in size. At a given applied field, the energy stored at the main domain becomes large enough so that, the magnetic configuration becomes unstable and a single wall depins from the closure structure and propagates along the wire until reaching the closure structure at the opposite end. Note that the enlargement of the closure domain before the switching is not detected in the hysteresis loop of Figure 3(a) because the tiny coil is placed at the center of the wire. A simple expression for the switching field, H_{sw}, is

$$H_{sw} \sim [1/(\mu_0 M_s \nu_{cr})](\alpha E_\gamma + \beta E_{sf}) \qquad (2)$$

where E_γ denotes the wall energy and E_{sf} is the stray field energy from the charges at the wire end, ν_{cr} is the fractional volume of the enlarged closure structure at the depinning, and α and β are geometric parameters. The general mechanism of reversal can be seen as nucleation of reverse domain plus depinning and propagation of a single wall, with the particularity, as discussed later, that the reverse domain may exist at any finite field.

The magnetization reversal process and its dynamics has been studied in several works for the two types of microwires from the early work by O'Handley (1975). More recent studies are connected with the investigations on the closure structures at the wire ends for in-water-quenched microwires (del Real *et al*., 1993; Chen, Dempsey, Vázquez and Hernando, 1995), and glass-coated microwires (Zhukov, 2001; Neagu *et al*., 2001a). It was firstly shown that evolution of the reversal process was unidirectional irrespective of the initial remanent state, possibly owing to the slightly different closure structures at each end (Vázquez, Gómez-Polo and Chen, 1992; Gómez-Polo, Vázquez and Chen, 1993). Experimental methods similar to those of Sixtus and Tonks, in which a long solenoid drives the magnetization drives the magnetization process and two peak-up coils where peak signals are induced upon the passing of the propagating wall. A careful analysis of the symmetric shape of the induced peaks (see Figure 6a) revealed that the shape of the wall is rather quasiplanar not only for in-water-quenched (del Real *et al*., 1993; Chen, Dempsey, Vázquez and Hernando, 1995) but also for glass-coated microwires (Varga, García, Vázquez and Vojtanik, 2005) (note that the time constant of the circuit should be shorter than the peak width). Moreover, from the width of the induced peaks it is also possible to deduce the length of the wall to be of the order of few centimeters and millimeters for in-water-quenched and glass-coated microwires, respectively.

The motion equation of the wall during propagation can be written as

$$m\frac{d^2x}{dt^2} + \beta\frac{dx}{dt} + \alpha x = 2\mu_0 M_s H \qquad (3)$$

where β represents the damping coefficient, m is an effective mass of the wall, α the restoring force constant, and $2M_sH$ the driving force supplied by the applied field. Once the wall propagates at constant velocity, equation (3) reduces to $v = (2\mu_0 M_s/\beta)(H - H_0)$, where H_0 is generally taken as the critical propagation field. The velocity of the wall is thus experimentally deduced from the flight time between those two peaks. Figure 6(b) shows the evolution of the wall velocity, v, with the applied field, H, for a range of measuring temperatures. For large enough field, $H \geq H_{sw}$, the velocity increases as expected linearly with the applied field and the switching field, H_{sw}, depends on the measuring temperature. Note the high speed of the propagating wall reaching up to 500 m s^{-1} at applied fields of 200 A m^{-1}.

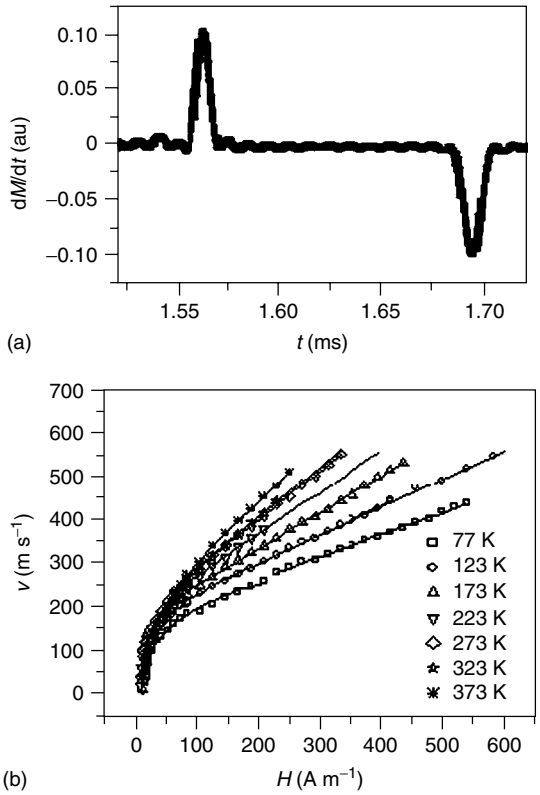

Figure 6. Induced peaks at two coils during wall propagation for a Fe-based glass-coated microwire (a). (Reproduced from L. Sampaio *et al*., 2000, with permission from the American Physical Society. © 2000.) Dependence of the propagating wall on constant applied axial field during propagation for a range of indicated temperatures (b). (After Varga *et al*., to be published.)

A first astonishing fact is that the extrapolation of that linear behavior to zero velocity gives a negative field. According to classical nucleation–propagation theory, square loops are obtained when nucleation field, H_n (typically provided by an extra local exciting coil), is larger than the propagation field, H_p, so that, once the reverse domain is formed, it immediately enlarges and propagates along the entire microwire ($H_n > H_p$): the propagation field is the linear extrapolation value to zero velocity, while the switching field corresponds to the nucleation field. In the present case, something singular happens, at negative fields the closure structures at the ends of the wire existing to reduce the stray fields energy play the role of the reverse domain, but a wall does not depin and propagates until reaching the propagation or switching field. Thus, we reach a reversal mode of square loop by which a reverse domain is first nucleated even at negative applied field but does not move until reaching the propagation field ($H_p > H_n$): the extrapolated figure corresponds to an effective nucleation field while the switching field corresponds to the propagation or depinning field.

Further studies on the domain wall dynamics in glass-coated microwires in the low-field regime have been performed in order to obtain deeper information. As observed in Figure 6(b), in the low-field regime, a nonlinear behavior is observed whose analysis has allowed one the experimental confirmation of the scaling behavior of the single-domain wall propagating on large distance (Varga *et al*., to be published). Three regions can be then distinguished for the propagating wall: (i) Below some critical field, H_{cr}, the domain wall is pinned at the wire end; (ii) just above that field, the domain wall propagates in the adiabatic regime, interacting with the defects during its propagation, with an average velocity that scales as $v \sim (H - H_{cr})^q$, with q the scaling factor; and (iii) at higher fields, $H > H_{sw}$, the domain wall propagates in the viscous regime and its average velocity is proportional to the applied magnetic field as considered above. The scaling law is an universal law valid on a wide range of scales where crackling noise is detected: from meter (earthquake-tectonic plates rub past one to another), decimeter (movement of the car on the landscape full of holes), centimeter (splitting the piece of paper), millimeter (drop of the water moving around the dirty glass) down to the micrometer scale for the domain wall movement or for dislocation propagation under small tension (Sethna, Dahmen and Myers, 2001; Zapperi, Castellano, Colairoi and Durin, 2005; Nakatani, Thiaville and Miltat, 2003). Fitted values of scaling factor to experimental results are close although not exceeding 1/2, and they reflect the correlation length of the domain wall with the defects (the lower the q, the longer is the correlation length).

With regard to the damping of domain wall motion, two mechanisms are commonly considered (O'Handley, 1975; del Real *et al*., 1993; Chen, Dempsey, Vázquez and Hernando, 1995): eddy current and spin relaxation. An additional contribution from structural relaxation/spin origin has been recently experimentally and theoretically introduced (Varga, García, Vázquez and Vojtanik, 2005). A general expression for the temperature dependence of damping coefficient β has been then proposed as the sum of eddy current, β_e, spin relaxation, β_r, and interaction with the mentioned defects, β_s, damping mechanisms:

$$\beta = \beta_e + \beta_r + \beta_s = \frac{k_1 M_s(T)^2}{\rho(T)} + k_2(M_s(T)^3(1 + r\Delta T))^{1/2} + k_3\frac{\tau}{T} \qquad (4)$$

where k_1 is a geometrical parameter, k_2 is proportional to mechanical stresses induced during fabrication, σ_r, and k_3 reflects the interaction between the wall and local structural defects, ρ is the resistivity, $r \approx E(\alpha_g - \alpha_m)/\sigma_r$, and τ the relaxation time.

3.3 Magnetoelastic effects

3.3.1 Influence of applied tensile, torsional, and bending stresses

Magnetoelastic anisotropy plays an important role owing to the relatively high magnetostriction, λ_s, of Fe-based amorphous microwires, of the order of $1-3 \times 10^{-5}$. The application of mechanical stress induces an extra magnetoelastic anisotropy with energy density $K_{m.elas} = (3/2)\lambda_s \sigma_{ap}$ that reinforces or balances the anisotropy arising from stresses frozen in during fabrication. In the case of applied tensile axial stress, it is observed that the remanence increases continuously until saturation as a consequence of the increase of the fractional volume of the inner core with axial easy direction at the expense of the outer shell. This evolution supplies complementary information on the distribution of the internal stresses at the shell. For example, the applied stresses at which remanence saturates are of the order of 100 and 400 MPa for in-water-quenched and glass-coated microwires, respectively.

From equation (2), a simple expression can be derived for the dependence of the switching field on applied stress, σ_{ap}, (Severino, Gómez-Polo, Marín and Vázquez, 1992):

$$H_{sw} = \gamma \sqrt{\lambda(\sigma_{ap} - \sigma_r)} - \mu_0 N_{eff}(L) M_s \qquad (5)$$

where γ is a parameter containing mainly geometrical factors, and the effective demagnetizing factor N_{eff} is a function of the length-to-diameter ratio of the wire. Actually, H_{sw} is determined by a term proportional to the energy stored in the depinned wall which is proportional to the applied stress.

The fitting of that expression to experimental results is very reasonable as observed in Figure 7(a) for several microwires with different lengths (Severino, Gómez-Polo, Marín and Vázquez, 1992). At low applied tensile axial stress, it balances internal stress in the outer shell which reduces the energy stored in the wall and the switching field according to equation (5). Note also, that for the shortest microwire, bistability is only observed after applying large-enough stresses. When applied and internal stresses nearly balance each other, and the effective demagnetizing field becomes more important, the formation of a number of walls is possible. This hinders the formation of a large domain and consequently the observation of bistable behavior.

Application of torsional stresses induces distributed tensile and compressive stresses following a helical path at 45° with the wire axis. Figure 7(b) shows the domain structure of an in-water-quenched wire subjected to torsional stress, where the helical path denotes the easy magnetization direction at 45° (Hernando *et al*., to be published). Torsional

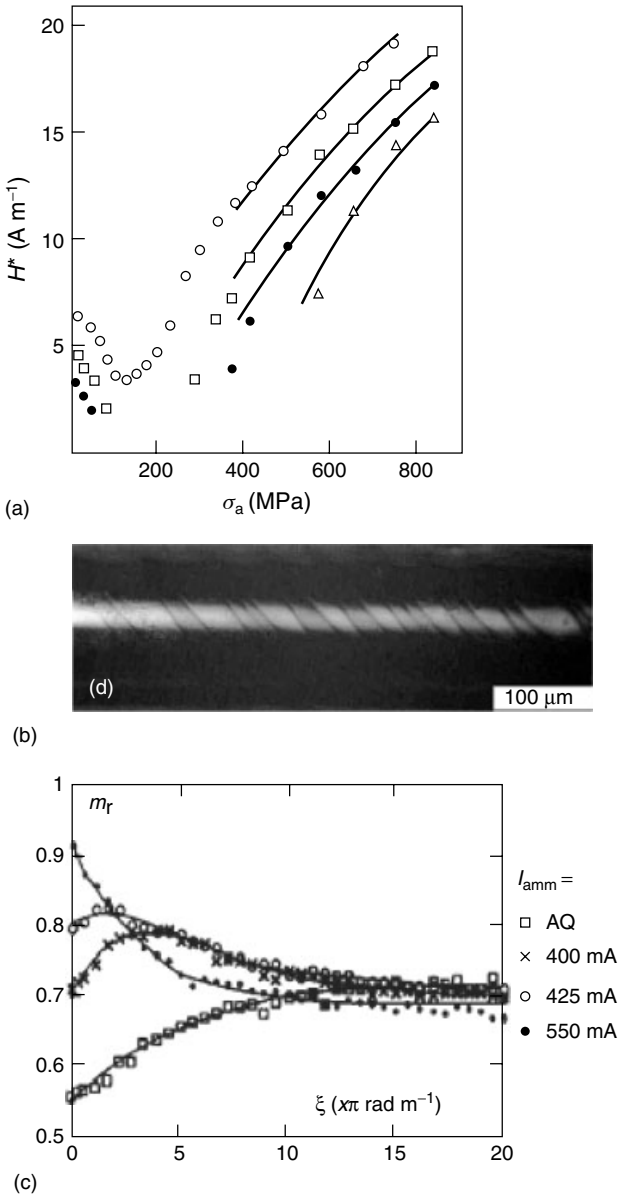

Figure 7. Dependence of switching field on applied tensile stress for a FeSiB in-water-quenched microwire (length = 12, 9.9, 8.4, and 6 cm) (a). (Reproduced from A.M. Severino *et al*., 1992, with permission from Elsevier. © 1992.) Bitter image of the domain structure at the surface of a torqued microwire (after Hernando *et al*., to be published), and torsional dependence of remanence for a bistable Fe-based microwire (b). (Reproduced from M. Vázquez *et al*., 1991, with permission from Elsevier. © 1991.)

stress, $\tau = \mu \xi r$, with μ the shear modulus, and ξ the angular displacement per unit length, induces inhomogeneous stresses so that, the corresponding magnetoelastic anisotropy is given by:

$$K_{m.elas}(r) = \frac{3}{2}\lambda_s \mu \xi r \qquad (6)$$

One should also consider the different response to applied torsion of the inner core and the outer shell because each region exhibits a different internal magnetoelastic easy axis. Upon twisting, ξ, the magnetization rotates toward the helix at 45° from the axial direction in the core and from the transverse direction at the shell. For large enough torsion, the magnetization orientates along the helical direction in the whole microwire, resulting in a reduced remanence of $m_r = 0.7$. An expression for the evolution of reduced remanence, $m_r = M_r/M_s$, with torsion has been proposed elsewhere (Vázquez *et al*., 1991; Chiriac *et al*., 1997) considering the evolution of the fractional volumes of the core and the shell with applied torsion as well as that of the magnetization direction in each region:

$$m_r = \frac{1}{\sqrt{2}} v_{os} \left(\frac{K_\tau}{K_{os}} \right) + \frac{1}{\sqrt{2}} v_{ic} \left[1 + \left(1 + \frac{K_\tau^2}{K_{ic}^2} \right)^{-1/2} \right] \quad (7)$$

Where K_τ, K_{ic}, and K_{os} denote the average magnetoelastic anisotropy constant induced by torsion, and those internally at the inner core and the outer shell, respectively, and v_{ic} and v_{os} are the fractional volumes of the core and shell, respectively. The experimental evolution with applied torsion is fitted to that expression, as observed in Figure 7(b), for a series of microwires that have been thermally treated inducing variations of the fractional volumes.

Applying bending stresses gives rise to distributed tensile and compressive stresses for convex and concave curvature regions of the wire, respectively. For the convex region with tensile component, the magnetization easy axis parallel to the wire axis is reinforced, while the compressive stress at the concave region induces a transverse easy axis. For large enough bending (small radius of curvature) the domain structure consists of an asymmetric inner core with axial magnetization and the residual region with transverse easy axis (Vázquez, Gómez-Polo, Theuss and Kronmüller, 1996; Vázquez, Gómez-Polo, Velázquez and Hernando, 1994). That asymmetric core is then responsible for the bistable behavior in bent microwires (Figure 8).

3.3.2 Thermally induced stresses in glass-coated microwires

An expression for the stresses induced during the fabrication in glass-coated microwires by the coating is given in equation (1). The strength of their effect on the magnetic behavior of microwires can be straightforwardly derived by comparing hysteresis loops (see Figure 9) for microwires with different metallic radius to total radius ratio, $\rho = r_{met}/R_{tot}$

Glass coating plays an important role to determine stresses not only in the as-prepared state, but also as a source of additional stresses when the measuring temperature is modified owing to the different thermal expansion coefficients, α_m and α_g, of metallic nucleus and glass coating, respectively (Vázquez *et al*., 2004b, 2006b). A general expression for the stresses arising from the coating and induced by a temperature change, ΔT, is

$$\sigma(T) = E(\alpha_g - \alpha_m)\Delta T + \sigma_r \quad (8)$$

where σ_r denotes the internal stresses induced during fabrication. An estimation of the effective thermally induced tensile stresses when decreasing temperature down to around 10 K is of the order of 200–300 MPa (Vázquez *et al*., 2004b, 2006b).

Recently, experiments have been performed to evaluate the temperature dependence of the switching field and its fluctuations in glass-coated microwires. In fact, previous studies were reported on the jitter of induced pulses by the reversal of magnetization that in principle should be avoided for technological purposes (Mohri, Humphrey, Yamasaki and Okamura, 1984; Zhukova *et al*., 2002). Figure 10(a) shows the distribution of the switching field as a function of temperature. It can be observed that not only the average switching field but also the width of the distribution decreases with increasing temperature. Such studies have allowed us to evaluate the contributions to the switching field: the magnetostrictive term (mostly relevant at high temperatures and containing the temperature dependence of magnetostriction and that of coating stresses), and the structural fluctuations term (relevant at low temperatures as indicated for the damping parameter) (Varga, García, Vázquez and Vojtanik, 2003, 2005; García, Varga and Vázquez, 2005).

The fitting to this temperature dependence has been done considering the magnetoelastic and structure contributions (see Figure 10b). Note that temperature dependence of magnetoelastic term arises from that of mechanical stresses induced by the coating, and from the magnetostriction. The switching field can be then expressed as (Varga, García, Vázquez and Vojtanik, 2003; García, Varga and Vázquez, 2005):

$$H_{sw} = p\left\{\left[\alpha(x)M_s^3(T) + \beta(x)M_s^2(T)\right](1 + r(\Delta T))\right\}^{1/2} + \frac{nG(T,t)}{M_s(T)} \quad (9)$$

where p is a constant, $r \approx E(\alpha_g - \alpha_m)/\sigma_r$, α and β the relative contributions to magnetostriction from single-ion and two-ion mechanisms, $\lambda(T) = \alpha M_s^3(T) - \beta M_s^2(T)$, n is the density of structural defects interacting with the propagating wall, and G is a relaxation function with relaxation time τ. It should be mentioned that the magnetostriction is sensitive not only to modification of temperature but also to applied mechanical stresses and to thermal treatments in

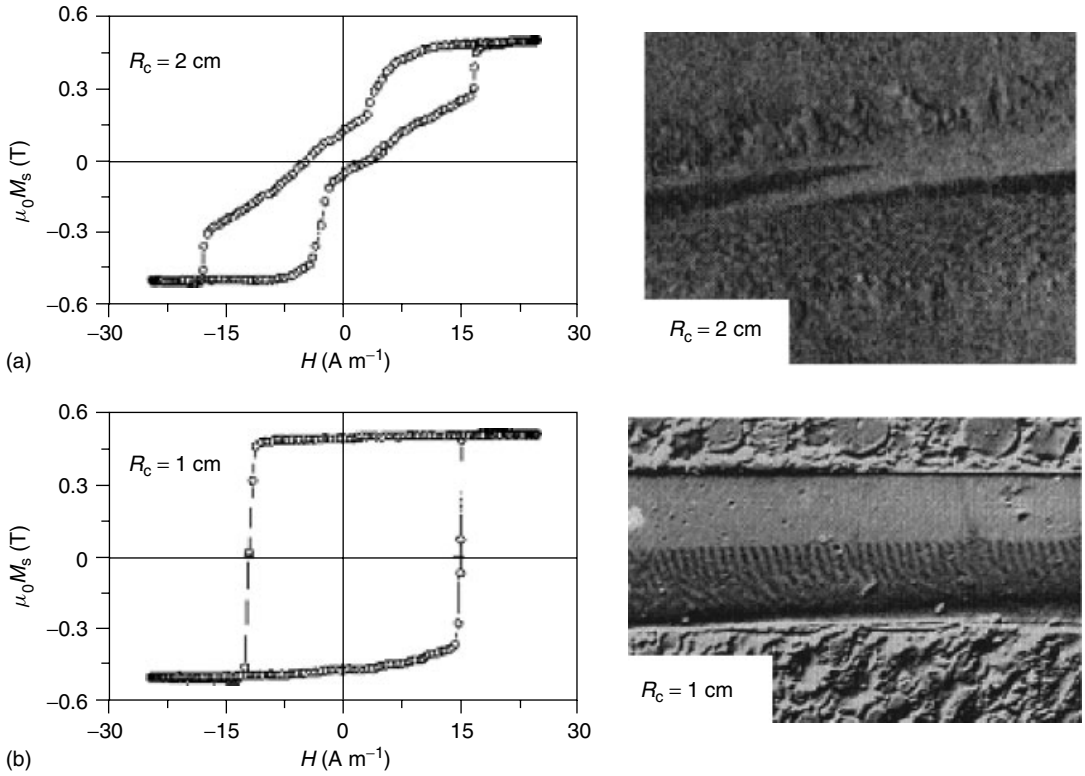

Figure 8. Hysteresis loops and corresponding domain structure images observed by Kerr effect of a 10-cm-long Fe-rich bent mirowires with radius of curvature $R_c = 2$ cm (a) and $R_c = 1$ cm (b). (Reproduced from M. Vázquez *et al.*, 1996, with permission from Elsevier. © 1996.) Note the reappearance of bistability in strongly bent wire.

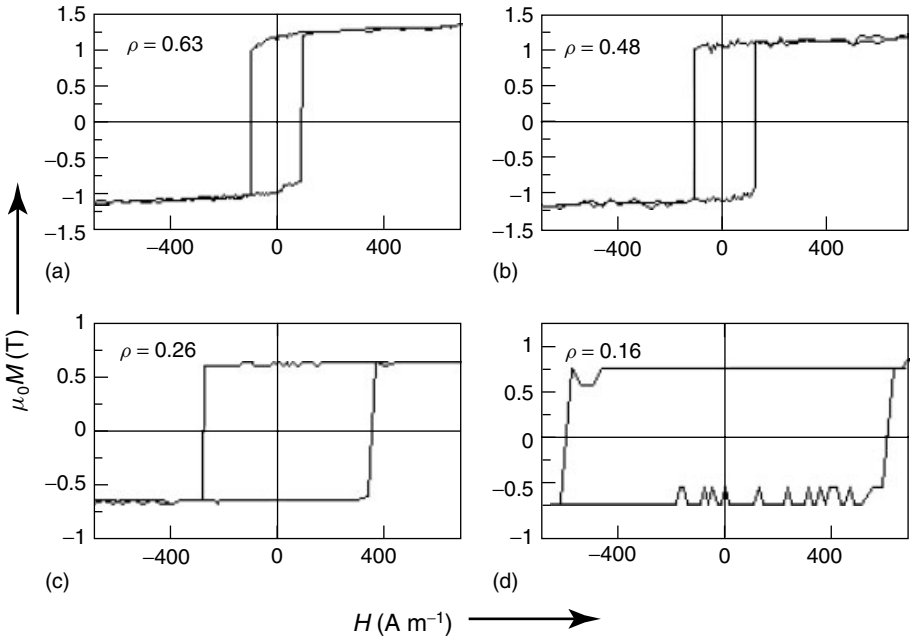

Figure 9. Hysteresis loops for glass-coated microwires as a function of the ratio metallic to total diameter, $\rho = r_{met}/R_{tot}$. (Reproduced from M. Vázquez *et al.*, 1996, with permission from Elsevier. © 1996.)

a similar way as amorphous ribbons (Zhukov *et al*., 2003; Barandiarán *et al*., 1987). Such changes, $\Delta\lambda$, can reach values up to 10^{-7} so that, they are relevant for Co-base non-magnetostrictive alloys.

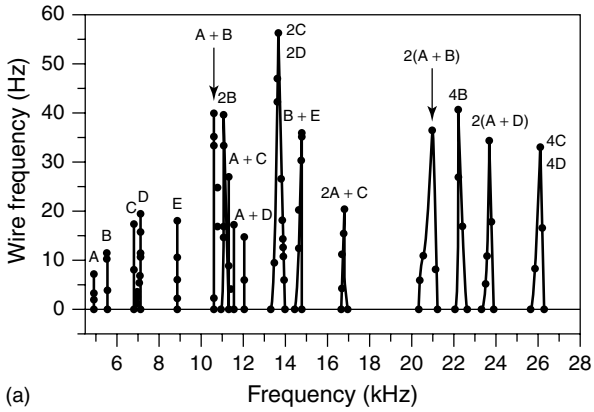
3.3.3 Magnetoelasticity and elastic moduli

Applied magnetic fields produce magnetostrictively induced deformation that gives rise to modification of effective elastic Young and shear *moduli* of magnetostrictive microwires, and to variations of the sound velocity. Several reports have been published on magnetoelastic properties related to ΔE effect and sound velocity effect for both types of microwires, where the role played by thermal treatments and/or the application of stress is shown (Squire, 1994; Kakuno, Masuda, Yamada and Mochida, 1987; Chiriac *et al*., 2000). The induced torsional deformation has also been reported where dc axial and ac circular field were applied simultaneously (Velázquez *et al*., 1995; Navarro, Garcia-Beneytez, Vázquez and Hernando, 1996). Forced and free oscillations are detected for the torsional magnetoelastic resonance where resonant peaks at given frequencies are accounted for by considering the existence of two main domain regions, and its connection to the variations of shear modulus. Complex bifurcation modes have also been detected.

3.3.4 Field-induced rotation of magnetostrictive wires

Exciting a vertically standing Fe-based microwire with a longitudinal ac field (of the order of kilohertz frequency), supplied by a solenoid or coil, results in spontaneous rotation of the wire with frequency of the order of units or tens of hertz. Such a rotation is only observed for given values of the exciting field frequency (see Figure 11a), and the most important characteristics of this unusual effect recently rediscovered in bistable amorphous microwires (Chiriac, Marinescu and Ovari, 1997; Castaño *et al*., 1999; Sugino, Takezawa, Honda and Yamasaki, 2001) are as follows: (i) It is observed for different types of wires (even ribbons) with amorphous or polycrystalline microstructure (e.g., until 3-mm-diameter commercial Ni cylindrical rods (Luna, Raposo, Rauscher and Vázquez, 2002). (ii) A minimum threshold field amplitude is needed for proper rotation the sense of which depends in a complex way on the field itself. (iii) Typical rotation frequency of microwire is of the order of units or tens of hertz, much lower than that of the exciting field, and it depends on mechanical friction to the capillary or tube surrounding the wire. (iv) Such rotation can be accompanied by levitation of the wire, when allowed by the sustaining force from the gradient field acting exerted by the exciting coil (see Figure 11b).

The origin of this phenomenon is quantitatively not well known, but it must be connected with the magnetostrictive character of the samples because the only requirement to be observed is a sufficiently large value of magnetostriction of the wire. Apparently, longitudinal vibrations of the wire, induced by the magnetostrictive elongations due to the exciting field, transform into coherent rotation through the friction with the surrounding tube or capillary. This phenomenon exhibiting some peculiar characteristics related to lack of symmetry and chaos as well as a kind of magnetic



(a)

ratchet was, nevertheless, studied for many years without final full understanding (Barnett and Kenny, 1952).

3.4 Arrays of bistable microwires: magnetostatic interactions and chaotic behavior

An interesting possibility for bistable microwires is its employment as memory units in magnetic labels (Hernando *et al*., 1996). There, a set of parallel bistable microwires are placed in a tag, each one with different switching field so that, when magnetized under an increasing field, each microwire reverses at its characteristic switching field. In order to increase the capability of storing information, it is desirable to reduce the size of sensing units (wire length and interwire separation), place them as close as possible, and reduce, when possible, the differential switching field among all of them. Experimental results indicate, nevertheless, that when they are spaced too closely, the intrinsic switching field of each wire is shifted indicating that some magnetostatic interaction takes place, and the magnetic information can be lost.

Bistable magnetic microwires are characterized by a nearly single-domain structure with a large axial domain with closure structures at the ends that appear to reduce the stray field energy. It seems likely that closure structures are either perturbed and/or they do not close completely their stray fields so that, each microwire can be taken as an effective dipole creating a stray field at the neighboring microwires modifying their switching field. Several studies have been reported on the magnetostatic interactions in sets of magnetic microwires (Velázquez, García, Vázquez and Hernando, 1996, 1999). From the experimental point of view, the hysteresis loop of a set of nearly identical microwires is characterized by as many Barkhausen jumps as the number of microwires, as observed in Figure 12(a) (Sampaio *et al*., 2000).

The modeling to quantify such hysteresis loops has been done considering the total magnetic energy, E_{mag}, that contains the Zeeman, dipolar, and anisotropy contributions and can be given by the general expression:

$$E = -\sum_j \vec{m}_j \cdot \vec{H}_{\mathrm{ap}} - \sum_{i>j} \frac{\vec{m}_i \cdot \vec{m}_j - 3(\vec{m}_i \cdot \vec{n}_{ij})(\vec{m}_j \cdot \hat{n}_{ij})}{r_{ij}^3} - \sum_j k_j \left(\frac{\vec{m}_j}{m_j} \cdot \hat{z}\right)^2 \tag{10a}$$

where m_i denote the dipolar magnetic moment of each microwire, r_{ij} is the distance between neighboring microwires, and k_j is the magnetic anisotropy constant with longitudinal easy axis. The final expression of magnetization and the effective switching field are determined by the Monte Carlo method. Alternatively, the problem can be solved by iteration, considering the expression for the magnetization of each wire as a function of the applied field plus the interactions with the surrounding microwires as

$$M_i(H_i) = M_i\left(H_{\mathrm{ap}} - \sum_{j=1}^{j=N} K_{ij} M_j\right) \tag{10b}$$

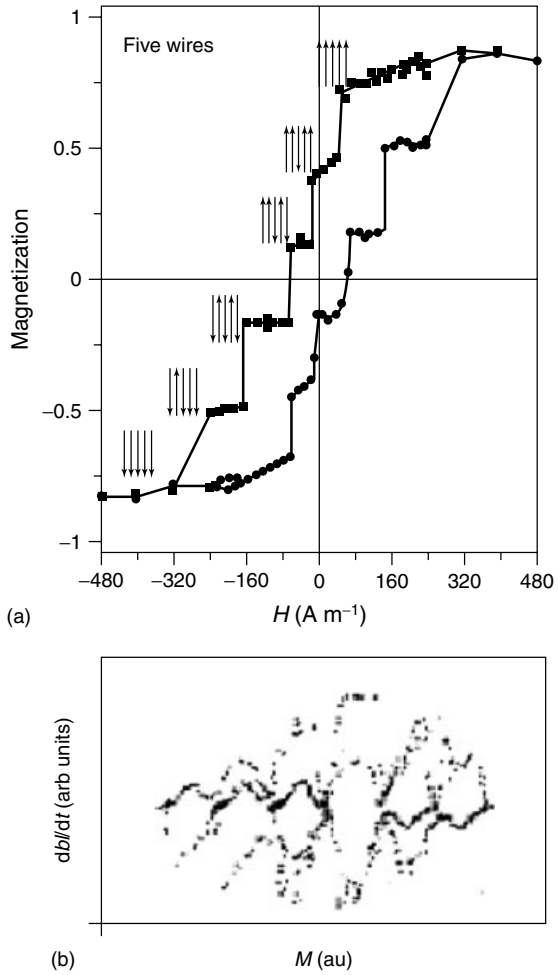

Figure 12. Hysteresis loops for a set of five bistable microwires (a). (Reproduced from L. Sampaio *et al*., 2000, with permission from American Institute of Physics. © 2000.) Reconstruction of the attractor in the magnetization phase diagram of a set of five microwires (b). (Reproduced from J. Velázquez *et al*., 1996, with permission from the American Physical Society. © 1996.)

The later contribution depends on their geometrical arrangement, which being dependent on the distances between individual microwires, r_{ij}, is reflected in the constant K_{ij}. To start the process, initial values are introduced in a first iteration (Vázquez *et al*., 2004a).

Several different modeled configurations of microwires arrays have been considered as linear, cubic, or hexagonal configurations (Vázquez and Velázquez, 2002). Particularly, the hexagonal configuration is of interest regarding the similarities with the case of nanowires in nanoporous alumina membranes.

Finally, it should be mentioned that the switching field of individual microwires, although very close, cannot be taken as identical. As a consequence of that, a complex behavior with weak-chaos characteristics has been found when analyzing the magnetic stability of the set of microwires. The reader is referred to previous references for further details (Velázquez, García, Vázquez and Hernando, 1996, 1999; Vázquez and Velázquez, 2002), and as an example, Figure 12(b) shows the temporal evolution of magnetization of a set of two microwires showing the reconstruction of the corresponding attractor.

3.5 Applications of Fe-based magnetostrictive microwires

3.5.1 Applications based on magnetic bistability

A number of applications can be found from the unique magnetization reversal of bistable microwires (Vázquez and Hernando, 1996). Some of them are related to sharp jitterless voltage induced in pick-up coils wound around the microwires during the magnetization reversal, with improved response with regard to Wiegand wires (Mohri, 1994a; Rauscher and Radeloff, 1989). Applications using bistable microwire as sensing elements include switchers, rotation counters, and position and velocity sensors among others. Sensors employed in security systems making use of the sharp induced voltage also include those based on the high harmonic response (Humphrey, 1987) such as an identification magnetic tag where codification is related to the multipeak induced signal in a set of bistable microwires with different switching fields.

3.5.2 Applications based on magnetoelasticity

The magnetostrictive character of Fe-based microwires is very suitable for various magnetoelastic sensing applications. Among others, some examples are mentioned in the following. Delay lines and sound velocity sensors using magnetostrictive Fe-based microwires have been proposed by Hristoforou (1997) and Hristoforou and Niarchos (1992). Digitizers, dc current sensor, and noncontact torsional stress sensors have been proposed based on inverse Wiedemann effect and torsion (Meydan and Elshebani, 1992; Pulido *et al*., 1991). A thermoelastic sensor makes use of differential thermal expansion coefficients of glass-coated microwires (Vázquez *et al*., 2006a). A novel viscometer is based on the field-induced rotation effect of magnetostrictive wires discussed above (Vázquez *et al*., 2001). A magnetoelastic sensor for signature identification based on the magnetoelastic behavior of magnetostrictive microwires has also been proposed (Zhukov, Vázquez and Beneytez, 1998; Zhukov, Garcia Beneytez and Vázquez, 1996). As an example of its possibilities for signature identification and authentication, a

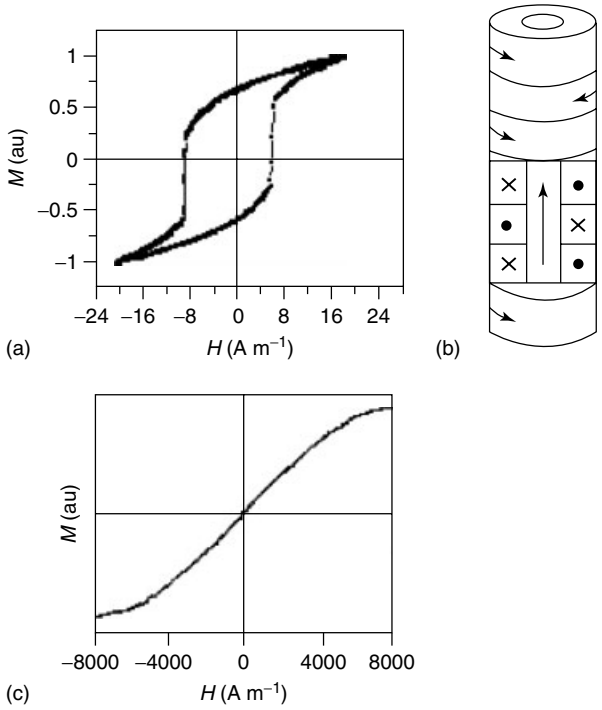

Figure 14. Axial hysteresis loop (a) and schematic view of domain structure (b) for an as-cast negative magnetostriction CoSiB in-water-quenched microwire, and for an as-prepared glass-coated microwire with similar composition (c).

schematic view of the sensor is shown in Figure 13(a). A typical magnetoelastic signature before digitalizing is depicted in Figure 13(b), where the voltage peaks, proportional to the mechanical stress are plotted as a function of time. An individual magnetoelastic signature is characterized by the number of peaks, their trend, and time intervals, while amplitude of peaks typically depend on the mood of the signatory.

4 CIRCULAR MAGNETIZATION PROCESS AND GIANT MAGNETOIMPEDANCE

4.1 Magnetization process of microwires with circumferential easy axis

4.1.1 Axial magnetization process of Co-based negative magnetostriction microwires

The axial hysteresis loop of as-cast negative magnetostriction Co-base CoSiB-like amorphous microwires obtained by in-water quenching consists, as for positive magnetostriction microwires, of a low-field giant Barkhausen jump and a reversible magnetization process at higher fields until reaching saturation (see Figure 14a). While it looks similar to the bistable loops of Fe-based microwires and the coercivity takes similar values, there are some differences: (i) reduced remanence at stable magnetic states takes smaller values of around $m_r \sim 0.36$ and (ii) differential susceptibility around remanence takes higher values of around 1 order of magnitude. These experimental results (Humphrey *et al*., 1987) together with the direct observation of domains by magneto-optical Kerr effect (Yamasaki, 1992; Yajako, Yamasaki and Humphrey, 1993), allow us to assume that the domain structure consists, as for Fe-based microwires, of two main regions: (i) an inner core with easy magnetization direction diverging from the wire axis by a small angle that depends on the radial coordinate and (ii) a shell domain structure with mostly circumferential easy axis giving rise to the so-called bamboolike structure. This domain structure is schematically depicted in Figure 14(b).

Upon applying an axial magnetic field, magnetization reverses at the core with a Barkhausen jump not so large as for Fe-based wires owing to the reduced axial component of the magnetization. A critical length to observe bistability is again observed (Zhukova, Usov, Zhukov and González, 2002). At a higher field, magnetization rotates at the shell toward the axial direction until the disappearance of the circumferential domains.

A typical axial hysteresis loop of Co-based glass-coated microwire is shown in Figure 14(c). In this case, there is no large Barkhausen jump, and magnetization process can be

interpreted as taking place by magnetization rotation from a circumferential orientation toward the longitudinal direction. This denotes the existence of a spontaneous circumferential anisotropy throughout the whole microwire, practically without inner core (Zhukov, 2001; Neagu *et al*., 2001a; Varga, García, Vázquez and Vojtanik, 2005). This indicates that the whole cross section should consist of a circumferentially magnetized shell, with a well-defined transverse magnetic anisotropy, K_ϕ, whose anisotropy field, $H_{\kappa\phi}$, can be experimentally evaluated as the field required to reach saturation in Figure 14(c). The average effective axial stress built in during rapid solidification can be determined from the anisotropy field expression $H_{\phi\kappa} = 2K_\phi/\mu_0 M_s = 3\lambda\sigma/\mu_0 M_s$. Taking the experimental values of the anisotropy field, $H_{\phi\kappa}$, the saturation magnetization, M_s, and the magnetostriction constant of this alloy composition ($\lambda \sim -1 \times 10^{-6}$), one reaches an average effective axial stress of 400 MPa.

A similar all-radii circumferential anisotropy can be also observed in nonmagnetostrictive CoFe-based in-water-quenched microwires induced by suitable stress-annealing treatments (Freijo *et al*., 1999). As observed in Figure 15(a) for the axial hysteresis loop after stress annealing, a circumferential anisotropy with circular anisotropy field of around 6 Oe is deduced. In spite of this circumferential anisotropy, a vortex micromagnetic structure with axial magnetization should appear at the very axis of the wire to reduce the otherwise significant exchange energy that would be stored. An effective radius of that vortex can be calculated by minimization of the total exchange (circular, ϕ, and radial, r, terms) plus circular anisotropy, K_ϕ, energies, leading to the Euler equation:

$$(d^2\Theta/dr^2) + (1/r)(d\Theta/dr) + [K_\Theta/A - 1/2r^2]\sin 2\Theta = 0 \tag{11}$$

In the example shown in Figure 15(a), a vortex diameter of around 0.3 µm is calculated which gives an almost negligible contribution to the whole axial hysteresis loop. A similar evaluation for an as-prepared negative magnetostriction (-2×10^{-6}) Co-based glass-coated microwire results in a vortex diameter of about 0.2 µm.

4.1.2 Crossed nonaxial magnetization processes

In cylindrical coordinates, suitable to the shape of our samples, the magnetization vector (considering axial and circular

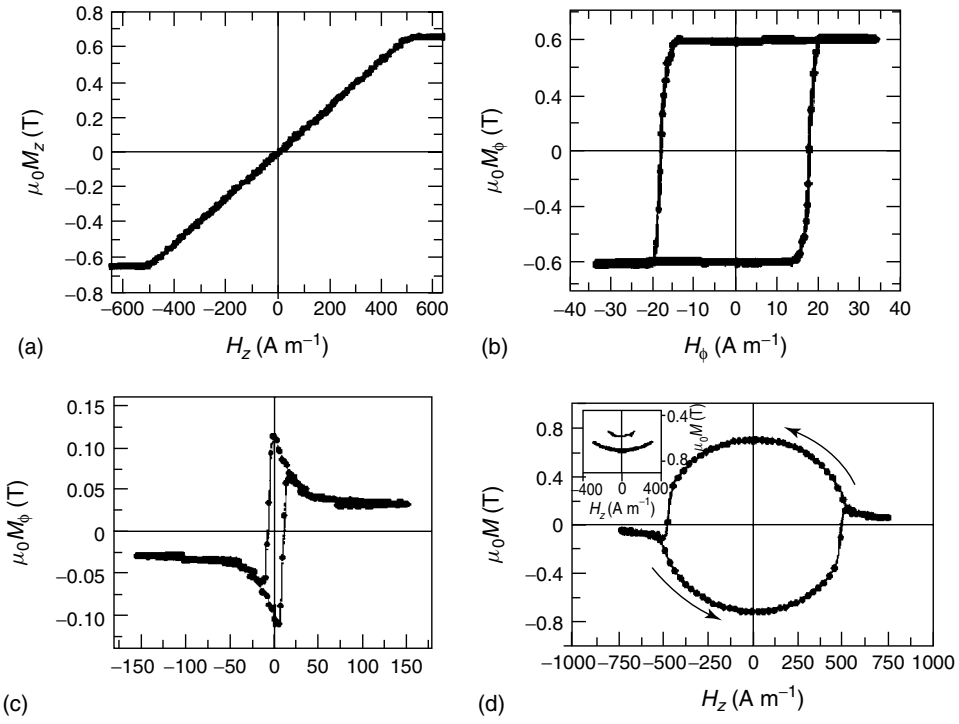

Figure 15. Axial, M_z versus M_z (a), circular, M_ϕ versus M_ϕ, (reproduced from J.J. Freijo *et al*., 1999, with permission from the American Institute of Physics. © 1999) (b), Matteucci, M_ϕ versus H_z, (reproduced from J.J. Freijo *et al*., 1999, with permission from the American Institute of Physics. © 1999) (c) and inverse Wiedemann, M_z versus H_ϕ, (reproduced from *Journal of Applied Physics*, 1999, 5450, with permission from the American Institute of Physics) (d) hysteresis loops corresponding to the four terms of susceptibility tensor in equation 12 for a CoFe-based microwire after annealing under stress. (Reproduced from J.J. Freijo *et al*., 1999, with permission from the American Institute of Physics. © 1999.) Note the induced circular anisotropy.

components) can be expressed through the susceptibility tensor as:

$$\left(M_z M_\phi\right) = \begin{pmatrix} \chi_{zz} & \chi_{z\phi} \\ \chi_{\phi z} & \chi_{\phi} \end{pmatrix} \begin{pmatrix} H_z \\ H_\phi \end{pmatrix} \tag{12}$$

which is useful particularly when the magnetization has nonvanishing components along the two orthogonal directions. Axial and circular hysteresis loops gives rise to χ_{zz} and $\chi_{\phi\phi}$ susceptibility terms, respectively. The Matteucci effect consists of the observation of a circular component of magnetization (or equivalently of a voltage induced at the ends of microwires) when axially magnetizing the wire (the corresponding susceptibility term is $\chi_{\phi z}$). The inverse Wiedemann effect consists of the existence of an axial magnetization component when the wire is subjected to a circular field (susceptibility term $\chi_{z\phi}$).

Figure 15 shows the four hysteresis loops corresponding to the 4 susceptibility terms in equation (12) for a CoFe nonmagnetostrictive wire after stress annealing, inducing a circular anisotropy. Axial, circular, Matteucci and inverse Wiedemann hysteresis loops are given respectively in Figure 15(a–d).

These effects are typically observed when the magnetization exhibits some helical component so that, when magnetizing axially or circularly, crossed circular or axial magnetization processes are observed, respectively (Kraus *et al*., 1994). Such a helical component can be induced by applying torsion or annealing under torsion. In fact, a spontaneous helical component of magnetization is experimentally deduced from both types of crossed loops in as-cast microwires (Velázquez *et al*., 1991), and actually it arises from the departure from parallelism between the magnetization in the core and the shell and/or just from interface between both regions. Recent studies suggest that the core/shell model should be modified with the introduction of some helical component at the core of negative magnetostriction in-water-quenched wires (Chen *et al*., 2001).

4.1.3 Circular magnetization process and magnetoinductive effect

The circular magnetization process, M_ϕ versus H_ϕ, is relevant when the microwires exhibit a circular component of magnetization, and in the case of the GMI effect considered in the next section. The circular magnetic field, H_ϕ, is supplied by the flow of ac current, I, along the microwire (as in the case of the inverse Wiedemann effect), and is radially inhomogeneous, $H_\phi = Ir/R$. Circular magnetization, M_ϕ is evaluated by integration of the voltage induced at the ends of the microwire, as a consequence of the changes in circular component of magnetization after subtracting the voltage coming from the ac current itself, that is, $M_\phi \approx \int \mathrm{d}M_\phi/\mathrm{d}t \approx \int (V - V_I)\mathrm{d}t$. As an example, Figure 15(b) shows the circular hysteresis loop, M_ϕ versus H_ϕ, corresponding to a stress-annealed nonmagnetostrictive CoFe-based in-water-quenched microwire (Pulido *et al*., 1991). Alternatively, circular magnetization reversal can be studied by magneto-optical Kerr effect (Chizhik, González, Zhukov and Blanco, 2002; Kabanov, Zhukov, Zhukva and González, 2005), thus obtaining direct information on the magnetization process at the very surface of the microwires.

The circular hysteresis loop in Figure 15(b) is obtained at a low ac field frequency (at 80 Hz). An increase of the working frequency gives rise to a noticeable enhancement of the voltage induced at the ends arising from the circular magnetization process. This circular magnetization process is sometimes labelled as magnetoinductive effect, which has been studied by several authors specially for in-water-quenched microwires (Mohri *et al*., 1992; Velázquez, Vázquez, Chen and Hernando, 1994). The magnetoinductive voltage, ΔV_{ind}, can be expressed as:

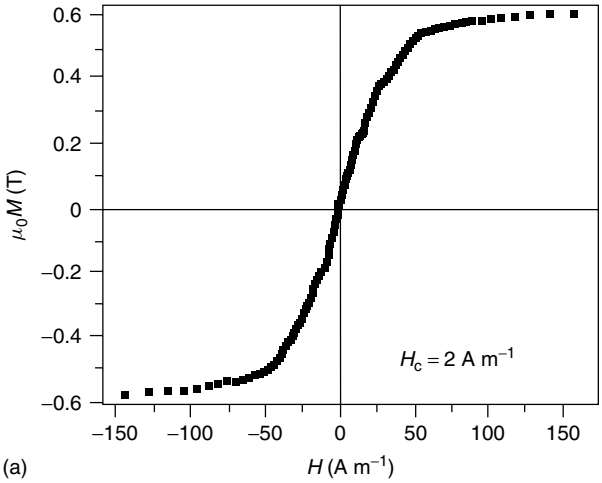
$$\Delta V_{\mathrm{ind}} \approx \sqrt{1 + \left(\pi \mu_0 r^2 \chi_{\phi\,\mathrm{max}} f/2\rho\right)^2} \tag{13}$$

where r and ρ are the radius and resistivity of the microwire, and $\chi_{\phi\mathrm{max}}$ denotes the maximum circular susceptibility, which is achieved for an ac current circulating through the wire that generates a magnetic field corresponding to the circular coercivity. Note that magnetoinductive voltage increases with the frequency, f, of the exciting circular field and with the circular susceptibility, but it decreases with resistivity of the wire. Concerning the later, circular susceptibility shows maximum values just around the circular switching field or circular coercivity. While the frequency range for this magnetoinductive effect is of the order of kilohertz, at higher frequencies it is overcome by a new phenomenon: the magnetoimpedance effect.

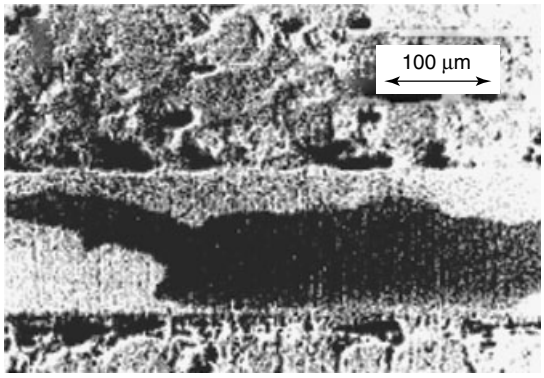
4.2 Giant magnetoimpedance effect

4.2.1 Magnetization process of nonmagnetostrictive CoFe microwires

Nonmagnetostrictive amorphous CoFe-based microwires exhibit the softest behavior when magnetizing along both axial and circular directions. The intrinsic magnetoelastic anisotropy, being now much smaller owing to the reduced magnetostriction (of the order of 10^{-7}), enables the formation of a larger number of walls, and magnetic bistability is no longer observed: within the core, a multidomain structure is present that destroys bistability but in turn, results in the largest values of initial permeability (up to about 10^5).



(a)



(b)

Figure 16. A nearly nonhysteretic loop of a nonmagnetostrictive as-cast CoFe-based in-water-quenched microwire (a). (Courtsey of G.A. Badini Confalonieri, Thesis, University of Sheffield, 2005.) Kerr effect image showing the multidomain structure in its core (b). (Reproduced from H. Theuss *et al*., 1995, with permission from Elsevier. © 1995.)

Figure 16 shows the axial hysteresis loop for an as-prepared in-water-quenched CoFe-based microwire.

Bistability can be, nevertheless, observed at low temperature as a consequence of the increase in magnetostriction (Theuss *et al*., 1995). It should also be mentioned that magnetostriction of such nonmagnetostrictive microwires is significantly modified by thermal treatments as well as by the application of mechanical stress. In fact, as for ribbon-shaped amorphous alloys, magnetostriction decreases linearly with applied stress, and a change of sign can even be observed as has been reported for the two families of microwires (Gómez-Polo and Vázquez, 1993; Zhukov *et al*., 2000; Zhukov, 2006; González *et al*., 2000; Neagu *et al*. 2001b).

4.2.2 Phenomenology of giant magnetoimpedance

The phenomenon of GMI, consists of the modification of impedance, both real and imaginary components, of a metallic conductor upon the action of a static magnetic field. Although this phenomenon was first reported many years ago (Harrison, Turney and Rowe, 1935), it did not attract much attention until its rediscovery in the 1990s (Panina and Mohri, 1994; Beach and Berkowitz, 1994) in nonmagnetostrictive CoFe-based in-water-quenched microwires. The most important characteristics of GMI for microwires are: (i) that they must show a magnetic character as soft as possible, (ii) the largest relative changes of impedance with static field reaches up to around 600%, and (iii) the static field required to observe GMI is typically of the order of few units or tens of oersted, with a maximum sensitivity of around 300% Oe^{-1} at very low fields. A number of review articles have been recently published covering the different aspects of magnetoimpedance (Knobel, Vázquez and Kraus, 2003; Vázquez, 2001b; Mohri *et al*., 2001). Here, we will only summarize some interesting effects related to microwires while further detailed information can be found in those review articles.

The common experimental method to evaluate GMI is very simple: the impedance of a microwire is typically evaluated through the four-points technique by which the voltage at the ends of the microwire is measured as a function of a low-amplitude ac current flowing along the microwire. A modification of the impedance is then observed when the sample is subjected to a static magnetic field. The GMI ratio is usually defined as:

$$\frac{\Delta Z}{Z} = \frac{\left|Z(H_0)\right| - \left|Z(H_{0,\max})\right|}{\left|Z(H_{0,\max})\right|} \tag{14}$$

where the impedance $Z = R + iX$.

Figure 17 shows the frequency dependent GMI effect for two as-cast amorphous microwires. The larger values of GMI are observed for in-rotating-water microwire at frequencies of the order of about 1 MHz or less, while glass-coated microwires show their maxima at higher frequency of around 10 MHz (Vázquez *et al*., 1998; Chiriac, Ovari and Marinescu, 1998).

GMI actually depends not only on frequency but also on a number of additional parameters characterizing the microwire and particularly the circular magnetization process. These factors include: (i) current flowing through the microwire (specially, depending on whether it creates a circular field overcoming the circular coercivity, or not), (ii) alloy composition (and consequently magnetostriction), (iii) the actual magnetic domain structure, and (iv) thermal treatments relaxing the amorphous microstructure or inducing anisotropies. For further information on the phenomenology of GMI the reader is referred to the review articles mentioned earlier.

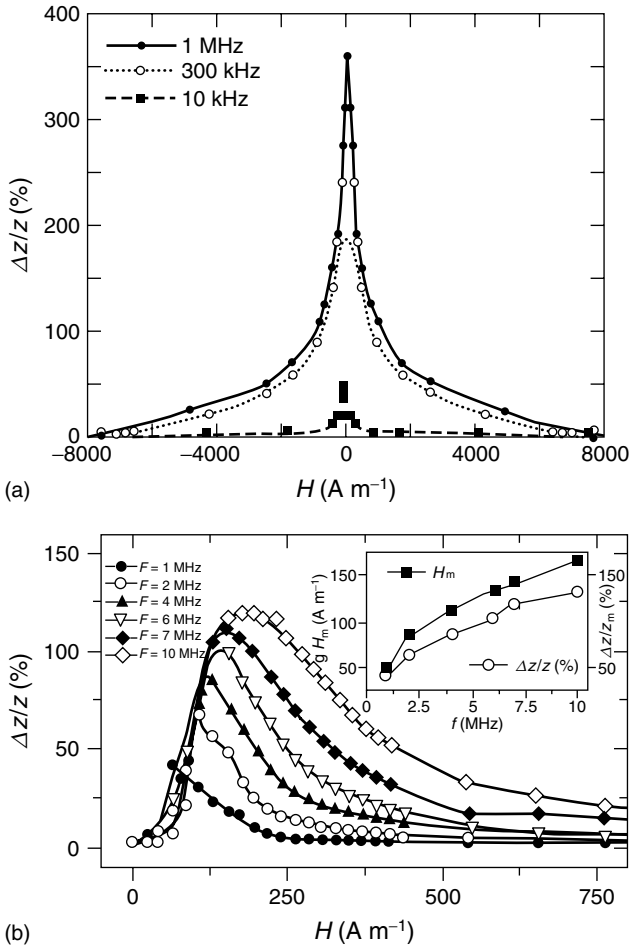


Figure 17. Giant magnetoimpedance ratio (GMI), as a function of static magnetic field for a range of measuring frequencies for a CoFe nonmagnetostrictive in-rotating-water microwire (a) (reproduced from M. Vázquez *et al*., 1996, with permission from IOP Publishing Ltd. © 1996) and for a CoFe based glass-coated amorphous microwire (b). (Reproduced from M. Vázquez *et al*., 2000, with permission from Materials Research Society. © 2000.)

4.2.3 The skin effect and the giant magnetoimpedance: circular permeability

The origin of GMI is related to the classical electromagnetic skin effect (Knobel, Vázquez and Kraus, 2003; Vázquez, 2001b; Mohri *et al*., 2001). When an ac current of sufficient high frequency flows along a metallic sample, it concentrates in a thin layer at the surface as a consequence of the induced eddy currents. The skin depth, δ, over which the current flows is given by

$$\delta = \sqrt{\frac{\rho}{\pi f \mu_\phi}} \tag{15}$$

which in turn determines the impedance of the sample that can be expressed as

$$Z = R_{\mathrm{DC}} \left(\frac{ka}{2}\right) \frac{J_0(ka)}{J_1(ka)} \tag{16}$$

Here, J_i is the Bessel functions, and $k = (1+i)/\delta$. Typically, the penetration depth, δ, in metallic nonmagnetic samples depends only on their conductivity and on the frequency of the ac current. Nevertheless, in ultrasoft magnetic materials, the skin effect is strongly enhanced through the transverse permeability as deduced in equations (14) and (15). The effect of the static applied field is thus simply that of modifying the effective circular permeability of the microwire. Actually, GMI can be regarded as a consequence of the circular magnetization process generated by the high-frequency ac circular field, the circular permeability can be modified and to some extent tailored by the static magnetic field.

Particularly, the domain structure existing in the microwires determines the $Z(H)$ profile of the impedance response to static applied fields. Two main GMI profiles are directly correlated with the domain structure and magnetization process of microwires: (i) single-peak (SP) behavior consists of a continuous decrease of GMI ratio from a maximum nearly at zero applied field, $H_{\max} \approx 0$, and (ii) two-peak (TP) behavior, which maximum GMI is observed at a given static field, $H_{\max} \neq 0$. Figure 18 shows examples of each of those behaviors. SP behavior is observed in those microwires with an effective axial anisotropy, while TP behavior appears in those microwires with an effective circular anisotropy which corresponds to the field, $H_{\max}$, for which maximum GMI is observed. The correlation between GMI shape and the corresponding magnetization process has been discussed further elsewhere (Vázquez, Sinnecker and Kurlyandskaya, 1999).

4.2.4 Stress-impedance and magnetoelastic effects

Because the GMI response is determined by the circular susceptibility, it is clear that it will be modified magnetostrictively by the application of mechanical stresses. A number of works have been published concerning the influence of applied stresses, particularly tensile and torsional stresses, on the GMI response (Knobel, Vázquez, Sánchez and Hernando, 1997; Li, Vázquez and Chen, 2003; Prida *et al*., 2003). An example is given in Figure 19(a) for applied torsion. The stress-impedance (SI) ratio, under a given applied dc field, for any kind of applied mechanical stress, can be defined as

$$\left(\frac{\Delta Z}{Z}\right)_{H_0} = \frac{|Z(\sigma)| - |Z(\sigma_{\max})|}{|Z(\sigma_{\max})|} \tag{17}$$

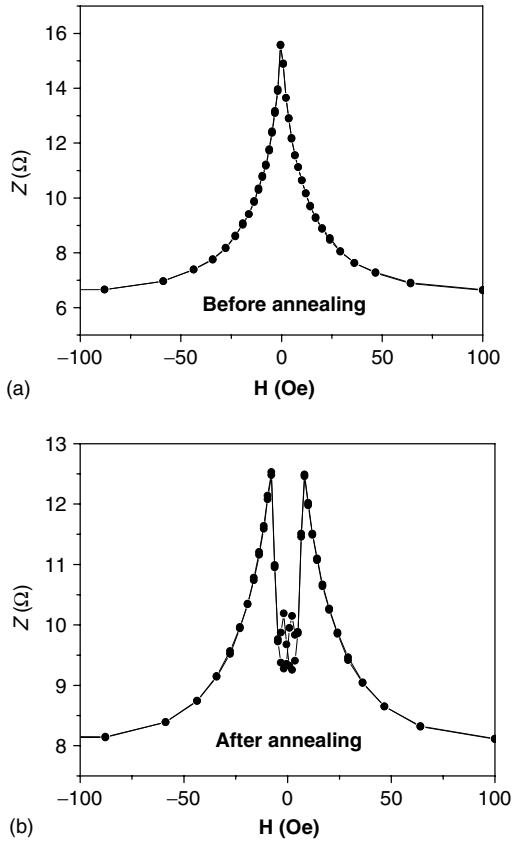

Figure 18. Single peak (a) and two peaks (b) GMI behavior (900 KHz, 5 mA) for a $(Co_{0.947}Fe_{0.053})_{70}Si_{12}B_{18}$ nonmagnetostrictive in-water-quenched microwire in its as-cast state (a), and after thermal annealing (b) exhibiting effective axial and circular anisotropy, respectively. (Reproduced from M. Vázquez *et al*., 1999, Materials Science Forum, pp. 209. © 1999.)

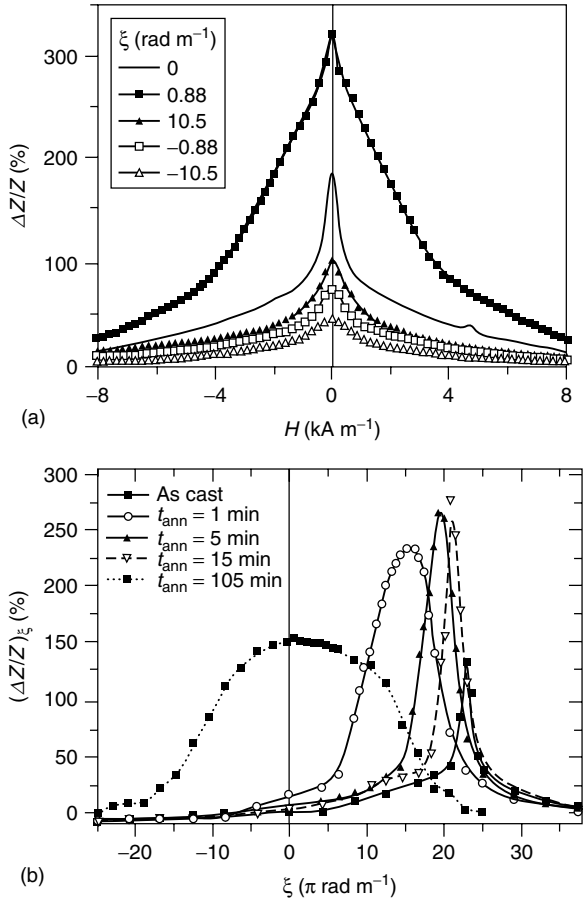

Figure 19. Evolution of magnetoimpedance response of a microwire under applied torque (a). (Reproduced from Y.F. Li *et al*., 2003, with permission from the American Institute of Physics. © 2003.) Asymmetric torsion impedance after a helical anisotropy is induced by torsion annealing (b). (Reproduced from M. Knobel *et al*., 2003, with permission from Elsevier. © 2003.)

Additionally, GMI has also been proved to be a useful tool to determine a number of magnetic characteristics of magnetoimpedive samples. For example, from the dependence on applied stress, σ, of the field, H_{max}, at which maximum GMI is observed, it is possible to derive quantitatively the magnetostriction of the microwire (Knobel, Vázquez, Sánchez and Hernando, 1997) as

$$\lambda_s = -\left(\mu_0 \frac{M_s}{3}\right)\left(\frac{\Delta H_{max}}{\Delta \sigma}\right) \tag{18}$$

There is particular technological interest in the possibility of obtaining asymmetric GMI that enable a continuous reading of impedance with field (Panina, 2002; Kraus, Freit, Pirota and Chiriac, 2003). Such asymmetry can be obtained by superimposing an additional static field, or inducing a helical anisotropy either by applying a torque or by mechanical torsion stress annealing (Zhukov *et al*., 2000; Panina, Mohri and Makhnovskiy, 1999; Kim, Jang, Kim and Yoon, 1999; Gómez-Polo, Vázquez and Knobel, 2001). Figure 19(b) shows the asymmetric GMI obtained after current annealing under torsion for different annealing times. It should be mentioned that particular real enhancement of GMI is to be expected by suitable thermal treatment and smoothening of the sample surface (Kraus, 1999). Another characteristic of GMI is the appearance of hysteresis as a consequence of the irreversibility in the circular magnetization process. Such hysteresis should be avoided as much as possible for technological applications (Knobel, Vázquez and Kraus, 2003; Vázquez, 2001b; Mohri *et al*., 2001).

4.2.5 Giant magnetoimpedance and ferromagnetic resonance

At frequencies higher than few tens of megahertz, the evaluation of impedance is no longer reliable by the four-point technique due to uncertainties in parasitic and cable impedances. To determine the effective impedance at microwave frequencies, several experimental methods

are employed including guided waves in cavities, the insertion of microwires into coaxial lines for determination of transmission coefficients, or through studies on the real and imaginary components of permeability (Lofland, García-Miquel, Vázquez and Baghat, 2002; García-Miquel, García, García-Beneytez and Vázquez, 2001; Jacquart and Acher, 1996). The electromagnetic field configuration at microwave frequencies is the same as for radiofrequencies where orthogonal electrical field and magnetic field are acting on the sample, and now the impedance has to be considered as the relation between both fields. In the microwave frequency range, the magnetoimpedance effect has been theoretically correlated with ferromagnetic resonance phenomena (Yelon, Menard, Britel and Ciureanu, 1996; Melo, Menard, Ciureanu and Yelon, 2002) where one should consider the correlation between surface impedance and the skin effect. Under particular biasing field, H_0, the ferromagnetic resonance frequency can be approximated by García-Miquel *et al*. (2001) and García *et al*. (2000):

$$f_r = \gamma\mu_0\sqrt{(H_0 + M_s)\left(H_0 - \frac{2k}{\mu_0 M_s}\right)} \cong \gamma\mu_0\sqrt{M_s(H_0 - H_k)} \tag{19}$$

where γ is the gyromagnetic ratio and $H_k = 2k/\mu_0 M_s$ is the transverse anisotropy field. The resonance frequency can be experimentally evaluated also through the scattering parameter S_{11} correlating to the incident, P_{in}, reflected, P_{ref}, and absorbed, P_{abs}, powers as: $|S_{11}|^2 = P_{ref}/P_{in} = 1 - P_{abs}/P_{in}$. As an example, Figure 20(a) shows the evolution of the square of the scattering parameter with the frequency for a series of increasing applied field values, allowing us to determine the field dependence of the resonance frequency (as determined from the minimum square scattering parameter). Figure 20(b) shows the field dependence of the square resonance frequency, following equation (19), for a series of glass-coated microwires. Extrapolation of observed linear behavior gives us values of anisotropy fields, while saturation magnetization can be extracted from the corresponding slopes.

Several experiments have been performed on the correlation between absorption spectra and magnetization process for amorphous and nanocrystalline microwires (Ovari, Chiriac, Vázquez and Hernando, 2000; Lofland *et al*., 1999; Montiel *et al*., 2005). In these reports, the observed low-field absorption peak has been ascribed to the magnetization reversal process of the microwires. All the outstanding microwave phenomena are actually a consequence of the so-called NFMR, which in these glass-coated microwires appears in this frequency range. In CoFe and Fe-based microwires NFMR frequencies are of around 2–3 GHz and 8–12 GHz for nonmagnetostrictive CoFe-based and magnetostrictive

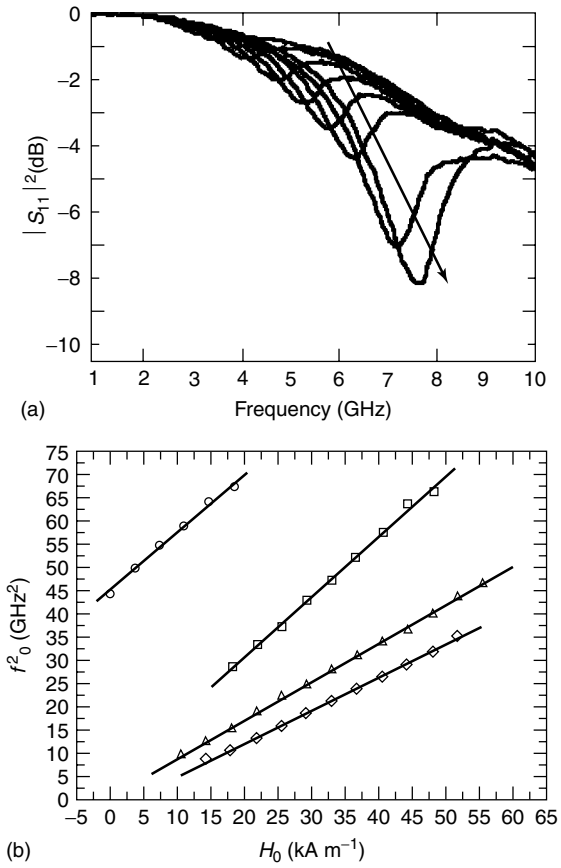

Figure 20. Evolution of the square scattering parameter, $|S_{11}|^2$ with the working frequency for a range of increasing applied field values up to 700 Oe as indicated by the arrow (a). Fe-based microwires, respectively as a consequence of the intrinsic magnetoelastic anisotropy (Baranov, Zotov, Larin and Torkunov, 1991).

4.3 Applications based on ultrasoft behavior and microwave absorption

4.3.1 Ultrasoft magnetic behavior and giant magnetoimpedance

Nonmagnetostrictive CoFe-based amorphous microwires are among the softest magnetic materials and consequently, they can be used in a broad spectrum of sensing devices. A first application of such wires is as magnetic tips for a particular near field microscopy. The CoFe-based in-water-quenched microwire is subjected to a particular chemical

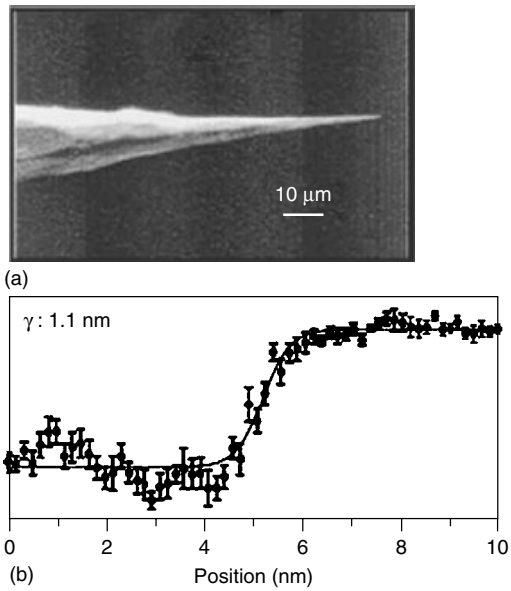

Figure 21. Sharpened microwire (a) used as magnetic tip in spin-polarized scanning tunneling microscopy, and high sensitivity fine structure of the domain wall in a Co sample (b). (Reproduced from W. Wulfhekel *et al*., 2001, with permission from Springer-Verlag. © 2001.)

etching resulting in sharpening of the microwire end (see Figure 21a). As an example, Figure 21(b) shows the high sensitivity fine structure of the domain wall in a Co sample obtained in a spin-polarized scanning tunneling microscope (Wulfhekel *et al*., 2001). An additional advantage of these wires is the significant reduction of magnetostrictively induced vibrations at the tip.

Nevertheless, the large number of applications where non-magnetostrictive microwires are usefully employed include sensing elements based on the GMI effect. They have been extensively developed in Japan mainly around the group led by Mohri (1994b), Mohri, Uchiyama and Panina (1997), and Mohri *et al*. (2002). Most of the sensors use CMOS-type circuitry where tiny pieces of amorphous microwires (1–2 mm long) showing GMI effect are employed as elements to sense static field. Magnetic field sensors are characterized by low power consumption and high low-field sensitivity (around 100% change in impedance, up to 1 nT). Several sensors, as developed by Aichi Steels (3D magnetic field sensors, GPS compass, etc.) (Cai, Yamamoto and Honkura, 2005 Private Communication), are currently used in car industry or car traffic monitoring. Other related applications include the record of the car magnetic signature in parking places and on moving cars (Valenzuela, Vázquez and Hernando, 1996; Uchiyama *et al*., 2000).

Stress-impedance effect is being used as principle of work in other families of sensors (Cobeño *et al*., 2001): in biomedical applications as, for example, to detect cancer tumors, biomechanical movements (as eyelid or articulator movements (Mohri, 1994b; Mohri, Uchiyama and Panina, 1997; Mohri *et al*., 2002; Sonoda, 1995), or as biomolecular labels when coated to specific antibody (Kurlyandskaya and Levit, 2005).

4.3.2 Electromagnetic field absorption

Probably one of the most interesting technological applications of glass-coated microwires is their employment as absorbers to the electromagnetic radiation, as has been theoretically studied and experimentally demonstrated (Baranov, 1998, 2003; Belozorov, Derkach and Tarapov, 2002). This is very important for electromagnetic shielding of military and civil vehicles, planes, and ships, in civil airports or for mobile phones and similar technologies. These types of experiments were already performed years ago but not well publicized. Particularly, arrays of glass-coated microwires in suitable dielectric matrix are most interesting for such shielding. As can be observed in Figure 22(a), there is a broad frequency spectrum for the absorption, with maximum value of around 30 dB (equivalent to 99.9% absorption). Recent studies (Makhnovskiy, Panina and Sandacci, 2005; Makhnovskiy *et al*., 2006; Acher *et al*., 2000) show that the microwave behavior (i.e., scattering spectra) of this type of composite materials based on glass-coated microwires can be suitably tuned by relatively small applied field and mechanical stress. This is particularly relevant for applications in remote non-destructive evaluation of structural materials.

Finally, the potential exists to use glass-coated microwires to develop *LHMs*, where the wave vector, k, the electric field, E, and the magnetic, H, field would form a left-handed rather than a right-handed vectors set. Such materials exhibit negative index of refraction as proposed in Veselago (1967), and this behavior has attracted much attention owing to recent theoretical and experimental reports (Pendry, 2000; Smith, Pendry and Wiltshire, 2004). Particularly, such phenomenon is predicted in the case when both permeability and permitivity show negative values simultaneously, which can be achieved in arrays of glass-coated microwires under particular conditions of frequency and field (Baranov and Vázquez, to be published; Engelvin-Adenot, Dudek, Toneguzzo and Acher, 2007). As shown in Figure 22(b), negative permeability can be found just above the FMR frequency, which combined with appropriate dielectric matrix would result in an LHM.

5 NOVEL ADVANCED MICROWIRES

Until now, we have been considering microwires with amorphous microstructure. They exhibit outstanding properties

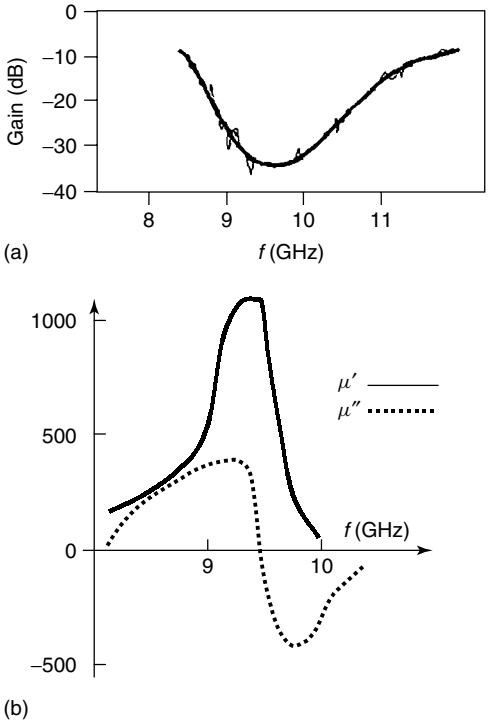

Figure 22. Electromagnetic absorption spectrum of a composite radioabsorbing screen containing short pieces of glass-coated microwires, (a) and frequency dependence of real, μ and imaginary, μ components of permeability in a Fe-based glass-coated microwire (b). (After Baranov and Vázquez, to be published.)

derived from the out-of-equilibrium fabrication processes. Once these rapid solidification methods have been completed, further processing can be done to achieve extraordinary properties of interest, in particular, appreciations. In this section, we review information on different processing methods used to optimize some particular properties or even resulting in a novel family of microwire material with unique magnetic behavior. First, we analyze microwires exhibiting inhomogeneous structure, with a characteristic structure length of the order of nm (e.g., either nanocrystals or grains embedded in matrix). Later on, we consider multilayer microwires with homogeneous characteristics within each layer.

5.1 Composite microwires

5.1.1 Nanocrystalline microwires: optimizing soft magnetic behavior

Owing to their metastable nature, amorphous microwires thermally treated at elevated temperature can crystallize, which often results in drastic magnetic hardening. However, as shown by Yoshizawa, Oguma and Yamauchi (1988) for FeSiB amorphous alloy ribbons with small addition of elements as Cu and Nb, a stable and homogeneous microstructure with soft magnetic properties can be attained after suitable thermal treatments (for detailed information, see chapter **Soft Magnetic Materials – Nanocrystalline Alloys, Volume 4**). A similar effect has been reported for in-water-quenched microwires (Gómez-Polo *et al*., 1993; Vázquez, Marín, Davies and Olofinjana, 1994) and glass-coated microwires (Arcas *et al*., 1996; Chiriac, Ovari, Pop and Bararіu, 1997).

Microwires showing high magnetostriction exhibit bistable behavior in their as-cast state, which is later destroyed by the thermal treatments. Figure 23(a) shows the evolution of coercivity for a $Fe_{75}Si_{11}B_{10}Cu_1Nb_3$ in-water-quenched microwire (Gómez-Polo *et al*., 1993; Vázquez, Marín, Davies and Olofinjana, 1994), where different magnetic stages can be detected: (i) a first reduction after annealing up to 440 °C is ascribed to the relaxation of internal

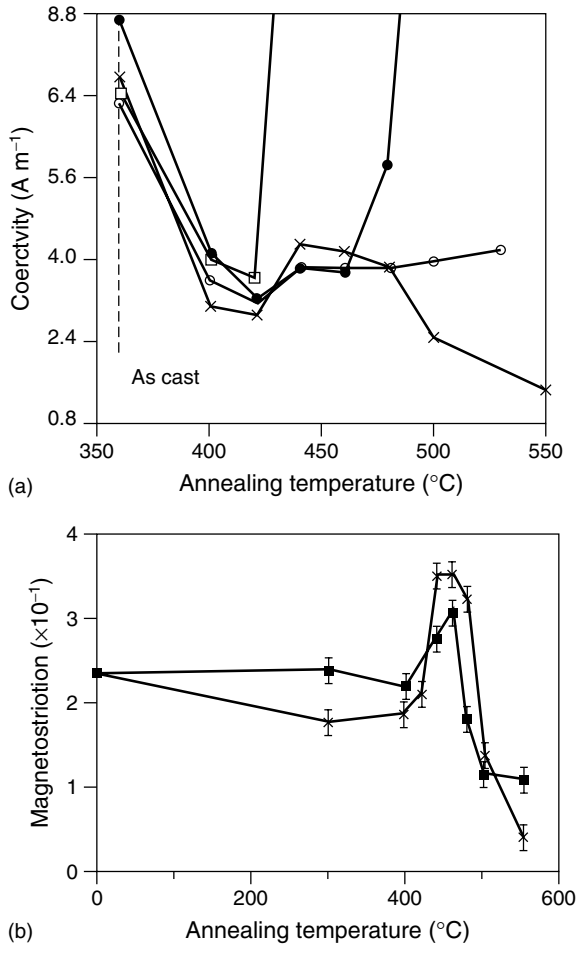

Figure 23. Annealing temperature dependence of coercivity for $Fe_{73.5}Si_{13.5}B_{13}$ (●), $Fe_{73.5}Si_{13.5}B_{13}Cu_1$ (□), $Fe_{73.5}Si_{13.5}B_{10}Nb_3$ (○), and $Fe_{73.5}Si_{13.5}B_9Cu_1Nb_3$ (×) microwires (a); and of magnetostriction for a FeSiBCuNb ribbon (×) and nanocrystalline microwires (○) (b). (Reproduced from C. Gómez-Polo *et al*., 1994, with permission from the American Institute of Physics. © 1994.)

mechanical stresses in the amorphous structure, (ii) annealing near 460 °C results in a relative increase in coercivity, which is ascribed to a first nucleation of Cu-rich clusters that act as pinning centers, (iii) optimum ultrasoft behavior is obtained by annealing at 530 °C when the composite nanostructure consists of α-Fe(Si) nanograins, around 10 nm in grain size, embedded in a residual amorphous matrix, and (iv) further crystallization with the growth of grain size and appearance of new phases (borides) with harder character results in increased coercivity. For glass-coated microwires, a similar evolution of coercivity is observed although at slightly more elevated temperatures, perhaps due to a difference in the effective temperature of the microwire owing to the protective coating (Arcas *et al*., 1996; Chiriac, Ovari, Pop and Bararíu, 1997).

A general expression for the coercivity considering its proportionality with the energy stored in a wall is:

$$H_c \propto \frac{\sqrt{A(3\lambda\sigma + \langle K_{crys}\rangle)}}{\mu_0 M_s} \tag{20}$$

Here, all λ, σ and $\langle K_{crys}\rangle$ (the average magnetocrystalline anisotropy of treated microwire) are modified by the thermal treatments. The ultrasoft character is ascribed to reduction of the average anisotropy constant, $\langle K_{crys}\rangle$, due to the reduced size of nanocrystals, 10–12 nm in average, smaller than the exchange correlation length, as well as to the significant reduction of the magnetostriction. The evolution of the magnetostriction with annealing temperature can be observed in Figure 23(b). Here, the final reduction of magnetostriction after annealing at 540 °C has been ascribed to the balance between contribution between nanocrystalline and residual amorphous phases, while intermediate relative increase seems to be related to first structural modifications as mentioned previously.

It is to be mentioned that besides ultrasoft magnetic character, nanocrystalline microwires exhibit improved mechanical behavior with respect to ribbon-shaped samples (Olofinjana and Davies, 1995). Because the bistability is lost at the optimum nanocrystalline state owing to the reduced effective anisotropy, the most interesting issue is that of improved magnetoimpedance behavior due to its soft character (Knobel *et al*., 1996). Nevertheless, optimum GMI does not reach the results obtained with soft amorphous microwires.

5.1.2 Nanocomposite hard and granular microwires

Whereas the amorphous state results in magnetic softening, some different attempts have been made to prepare hard magnetic microwires. First attempts have been done simply by crystallizing precursors soft amorphous microwires for the alloy compositions considered so far. This gives rise to magnetic hardness and enhanced coercivity of the order of 100 Oe.

Later attempts have been made by adding suitable elements in order to induce magnetic hardening either by forming new hard phases or just by enhancing pinning mechanism of magnetization reversal (Wang *et al*., 1997; Sinnecker *et al*., 1999; Zhukov *et al*., 1999). Several glass-coated microwires containing immiscible elements have been prepared by quenching and drawing technique followed by thermal treatments so that final granular systems are formed. We mention three series of alloys Fe–Co–Cr (with coercivity of 16 kA m^{-1}), Fe–Ni–Cu (50 kA m^{-1}), or Co–Ni–Cu–Mn (60 kA m^{-1}). Some technical difficulties arise, nevertheless, to fabricate these microwires owing to the higher temperature required to melt such alloys as well as their high tendency toward oxidation. Despite these works, reported values of coercivities of several hundreds of oersted, the net magnetization is unfortunately significantly reduced in comparison with that of soft phases. Latest results performed on FePt rich microwires have allowed coercivities of around 100 kA m^{-1} (Badini, Torcunov, García and Vázquez, to be published).

Finally, some recent works have been reported in granular microwires showing that they exhibit some magnetotransport properties, particularly magnetoresistance, which are of interest for sensing applications although so far being relatively modest in amplitude (Zhukov *et al*., 2004a,b; Zhukov, González and Zhukova, 2005).

5.2 Multilayer microwires

Owing to the cylindrical symmetry, the preparation of multilayered microwires by adding external layers or microtubes to existing wires has been studied. First, attempts were reported in Rauscher and Radeloff (1991) where composite microwires were prepared consisting of a soft NiFe-based core and a hard CrCoFe shell. There, the magnetic interactions between components play an important role to determine the bistable magnetic behavior of the core.

Attempts were performed by electrochemical deposition of CoP, CoFeNi, and CoNi alloys onto Cu-rich microwires which was used as electrode (Kurlyandskaya *et al*., 1999; Vázquez *et al*., 2000; Sinnecker *et al*., 2000; Atalay and Atalay, 2005). The objectives for fabrication of these microtubes onto metallic nonmagnetic microwires were related to their magnetoimpedance properties. Owing to the differential conductivity and especially their permeability, the magnetoimpedance behavior was expected to show a particular response. In fact, quite large variations of the imaginary component of impedance were reported (see Figure 24a). Additionally, interest lies in the preparation technique itself

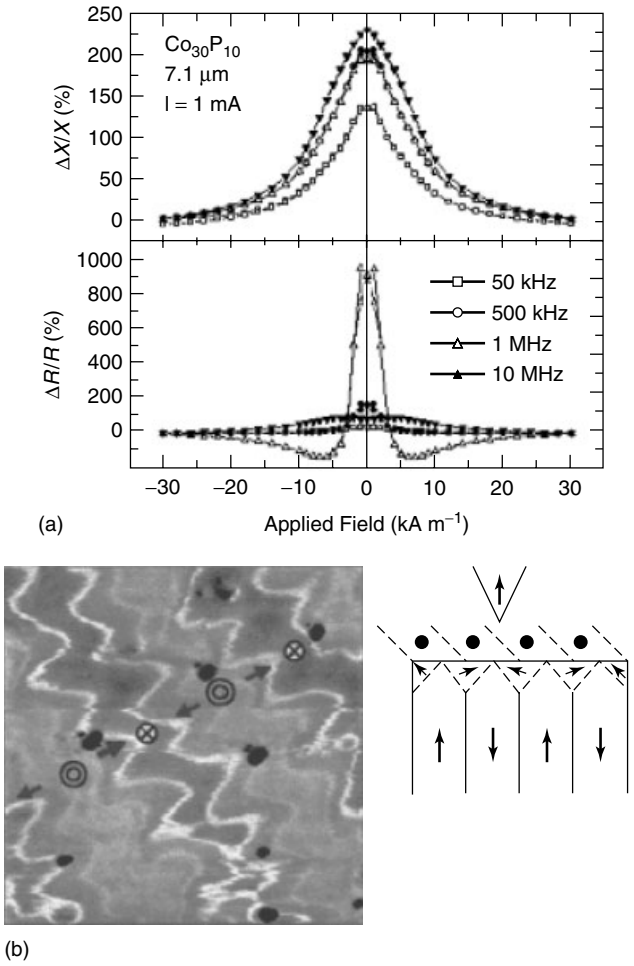

Figure 24. Large giant magnetoimpedance (GMI), effect in a CoP microtube electroplated onto a Cu microwire (a) (reproduced from J.M. García *et al*., 2000, with permission from the American Institute of Physics. © 2000) with corresponding schematic interpretation of domains (b). (Reproduced from J.M. García *et al*., 2001, with permission from the American Institute of Physics. © 2001.)

that allowed the fabrication of novel materials with nonstandard properties. Electrodeposition of outer layers to microwires opens new possibilities for controlled behavior such as modifiable easy magnetization axis (from radial to in plane of the layer) depending on thickness and electroplating parameters. Figure 24(b) shows the domain structure at the surface of a Co microlayer onto Cu microwire where the existence of radial anisotropy is deduced. A correlation between the frequency dependence of the impedance and the penetration of the surface closure structure was found that enabled the evaluation of the thickness of such closure structure (García *et al*., 2001).

More recently, multilayered microwire structure has been achieved employing the two families of amorphous microwires considered in previous sections as precursors and combining sputtering and electrodeposition techniques. For this purpose, a specific electrodeposition cell is to be designed because of the particular geometry of the electroplating (Pirota *et al*., 2004). Sputtering of a nanolayer by commercial sputtering is first required in the specific case of glass-coated microwires to provide a conducting path for electroplating. For example, Ti, Ag, or Au layer, several tens of nanometer thickness, is first sputtered onto the Pyrex-like coating. This nanotube actually acts as an electrode for the subsequent electrodeposition of metallic elements and alloys, magnetic or nonmagnetic, thus obtaining a multilayered microwire.

The influence of these additional coatings on the magnetic behavior of multilayer microwire is really impressive as is given in Figure 25 as an example. The shape of a hysteresis loop can be tailored for particular purposes: after just sputtering a Ti nanolayer in Figure 25(a), the nearly nonhysteretic

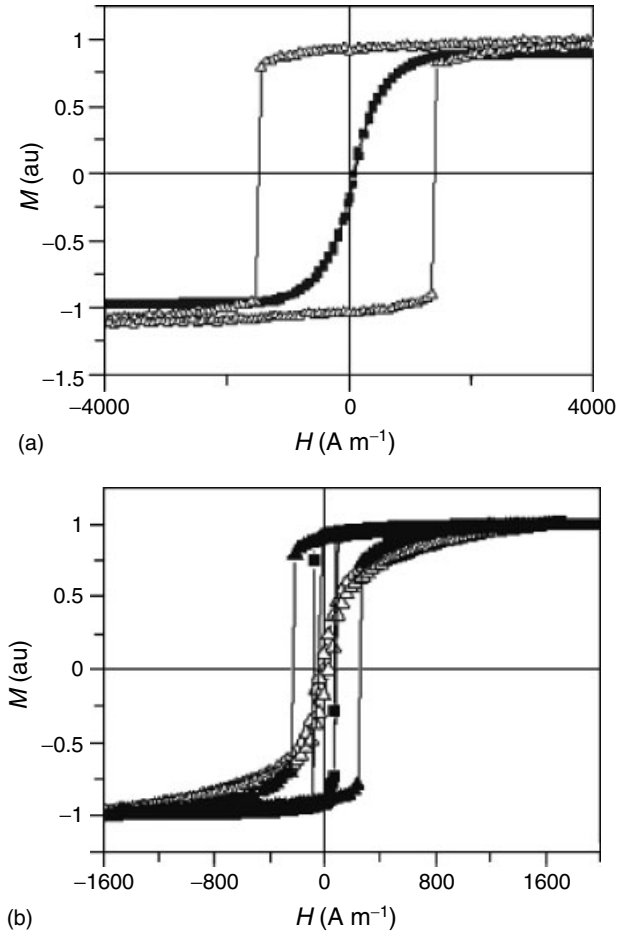

Figure 25. Hysteresis loops of multilayer microwires consisting of a $(CoFeNi)_{75}Si_{10}B_{15}$ glass-coated microwire (■) and after (△) sputtering a 10-nm-thick Ti nanolayer (a), and for a $Fe_{72.5}Si_{12.5}B_{15}$ glass-coated microwire (■), after sputtering a 30-nm-thick Au nanolayer (▲) and after subsequent electroplating (△) of a 14-m-thick Ag microlayer (b). (Reproduced from K. Pirota *et al*., 2005, with permission from Elsevier. © 2005.)

loop of a CoFeNi-based nonmagnetostrictive microwire, typical of a circular anisotropy becomes square denoting the axial anisotropy ascribed to the compressive stresses induced by the Ti nanolayer. In turn, in Figure 25(b), the square loop of a Fe-based magnetostrictive microwire becomes finally nearly nonhysteretic after sputtering and subsequent electroplating two nano- and microlayers, respectively.

An interesting possibility is to obtain multiphase magnetic microwires by suitable electroplating of magnetic material (Pirota *et al*., 2005), which was recently exploited in the production of biphase magnetic multilayer microwires. In the case shown in Figure 26(a), the internal core is a nonmagnetostrictive ultrasoft Co-rich alloy, and the externally electroplated microlayer consists of a magnetically harder CoNi alloy. The hysteresis loops show the biphase hysteresis loop characterized by two giant Barkhausen jumps: the first one at the very low-field region (observed at around $20\,\mathrm{A\,m^{-1}}$) corresponding to the magnetization reversal at the magnetically ultrasoft Co-rich ultrasoft amorphous alloy, while the second one is observed at higher field (of around $20\,\mathrm{kA\,m^{-1}}$) and is ascribed to magnetization reversal at the external semihard CoNi microlayer.

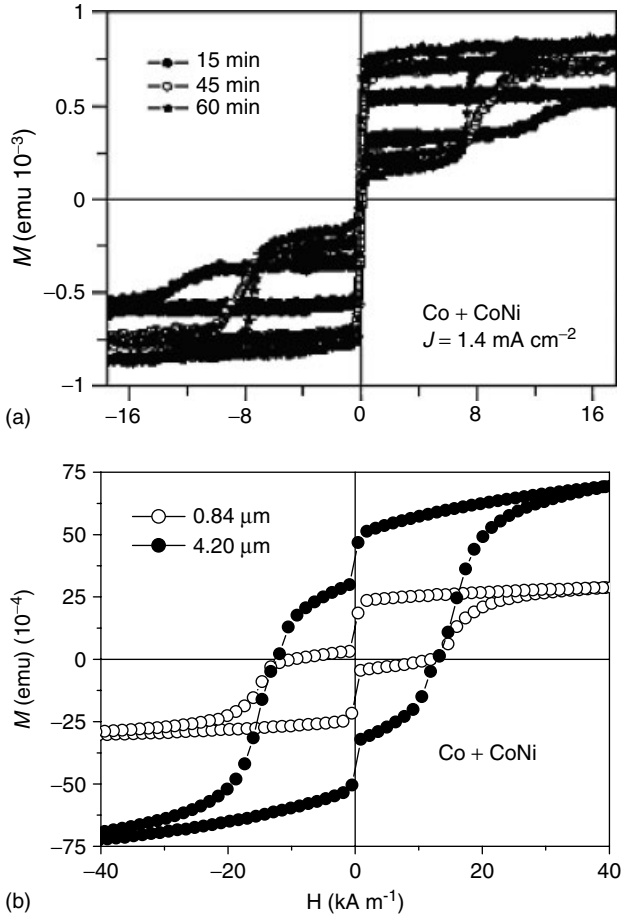

Figure 26. High-field hysteresis loops for a soft/hard biphase magnetic multilayer microwire consisting of an ultrasoft Co-based nonmagnetostrictive glass-coated microwire, coated by an intermediate sputtered 10-nm-thick Au nanolayer, and an outer electroplated CoNi microlayer shell with increasing thickness (a) (reproduced from K. Pirota *et al*., 2005, with permission from Elsevier. © 2005), and one branch of the low-field hysteresis loops after premagnetizing to saturation (b). (After Torrejón, Badini, Pirota and Vázquez, 2007.)

The existence of a magnetic coupling between the soft core and the hard layer has been recently confirmed (Torrejón, Badini, Pirota and Vázquez, 2007). Figure 26(b) shows the shifted low-field magnetization curves of the ultrasoft core after premagnetizing in a saturating magnetic field for a range of thicknesses of the electroplated hard shell. This shifting or bias field, H_b, is parallel to the premagnetizing field direction similar to antiferromagnetic-like coupling in exchange FM/AFM biased thin films used in spin valves. In the present case, where the bias field depends on the geometrical characteristics (i.e., length and thickness of each phase), its origin has been ascribed to the magnetostatic field created by unbalanced charges at the ends of the hard layer which remains in its remanence state after premagnetizing. A similar effect has been found in the case of electroplating directly onto an in-water-quenched microwire (Vázquez *et al*., 2006a,b, 2007; Torrejón, Badini, Pirota and Vázquez, 2007).

The possibility of tailoring multilayer microwires is particularly interesting regarding some technological applications. One, based on the magnetoelastic behavior of the multilayer microwires, makes use of the mechanical stresses induced by the new coatings and of their different magnetic response upon temperature changes. This principle has been used for sensitive quick-response thermal sensors (Vázquez *et al*., 2001).

Other applications are based on the magnetic coupling between phases. The field created by the hard phase can be employed as the additional dc field required to obtain asymmetric magnetoimpedance which is used for magnetic field sensing. The magnetostatic bias between soft and hard phases giving rise to a spin-valve effect, similar to exchange coupling in planar multilayer structures, opens new applications deriving from the cylindrical symmetry of the multilayer microwires.

6 FINAL REMARKS

We conclude the chapter with a mention of the large number of fields where magnetic microwires are relevant, from fundamental aspects as exhibiting simple, nearly ideal domain structure for suitable micromagnetic static and dynamic calculations, weak-chaos behavior induced by magnetic interaction, or the scaling law in low-field propagating

single-domain wall, to interesting fabrication and processing techniques, to engineering materials, or to a variety of sensor applications profiting, for instance, of their excellent magnetoelastic or microwave properties. Present challenges are related to the search of novel microwires with optimized hard, soft, or multiphase magnetic behavior, as well as to fabricate, in a controlled way, wires with more reduced dimensions, that is, nanoscale diameter which is the topic of the next chapter.

1 INTRODUCTION

Nanoscale arrays of ferromagnetic materials have an exciting future in a wide range of applications, including magnetic storage and nanoelectromechanical systems (NEMS) sensors and actuators. The motivation for studying nanowire arrays is that they hold much promise in fast-moving technologies such as magnetic storage. In addition, nanowire arrays inherently provide a high density of sensors, which will enable completely new applications, such as compact, high-bandwidth NEMS sensors. Several of these applications are discussed in this introduction, but the principles can be applied to many other important technologies.

One of the best examples of a fast-moving technology is magnetic storage, which has played a key role in the development of information technology since IBM built the original hard disk drive, known as random access method of accounting and control (RAMAC), in 1956. RAMAC had an areal density of 2 kbit $in.^{-2}$ and stored 5 MB of information on 50 24-in. disks. From 1956 to 1991, the areal density progressed at an average rate of 23% per year. After 1991, the annual increase in storage density for commercially available hard disks increased to 60%. By 2006, IBM was selling 2.5-in. hard disks with areal densities of 30 Gbit $in.^{-2}$, and a number of companies had demonstrated densities ranging up to 120 Gbit $in.^{-2}$ in their laboratories. If nanowire arrays were used as perpendicular magnetic storage media (O'Barr *et al*., 1997; Ross *et al*., 1999), an areal density of about 1 Tbit $in.^{-2}$ could be achieved using a hexagonally arranged array of nanomagnets with a lattice constant of about 25 nm (Figure 1; see also Section 7).

Nanowire arrays can be fabricated more cost-effectively by electrodeposition into nanoporous templates than by traditional fabrication methods, such as nanopatterning using focused ion beam or electron-beam lithography (Routkevitch *et al*., 1996). Moreover, these arrays of magnetic nanowires can be easily fabricated over areas of several square centimeters. Although a variety of nanoporous templates are reviewed here, hexagonally arranged porous

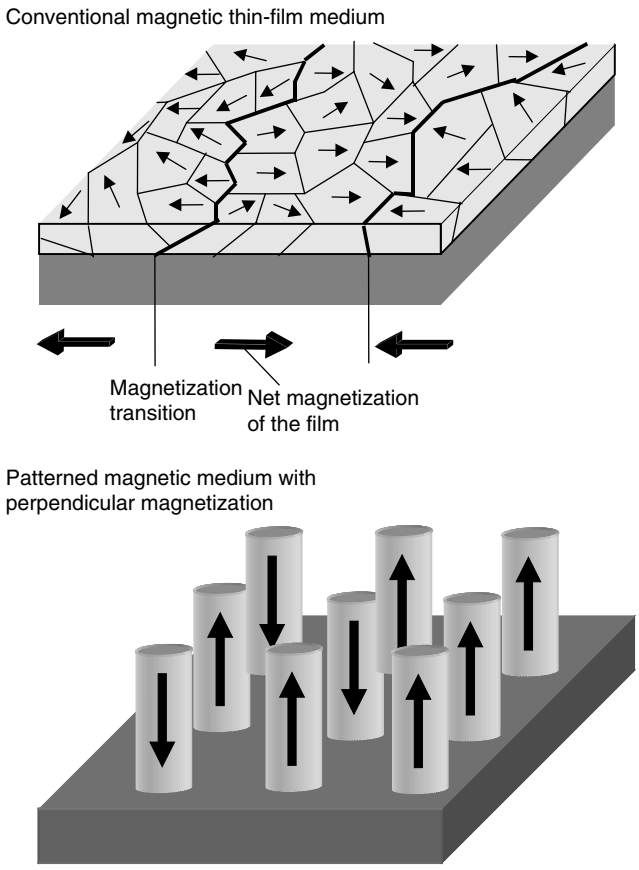

Figure 1. Principle of a conventional magnetic media based on longitudinal thin films and the principal of a patterned magnetic media based on single-domain nanowires.

alumina templates are most important for the following discussion on nanowire arrays.

Since 1975, numerous articles on disordered porous alumina templates filled with ferromagnetic materials have been published (Kawai and Ueda, 1975; Kaneko, 1981; Almawlawi, Coombs and Moskovits, 1991; Feiyue, Metzger and Doyle, 1997; Strijkers *et al*., 1999; Zeng *et al*., 2000). These structures had large distributions in both their pore sizes and their interpore spacings, and the degree of pore filling was usually not specified in the literature. On the basis of an approach by Masuda and Fukuda (1995) (see also Section 3), several groups have obtained ordered porous alumina arrays with sharply defined pore sizes and interpore spacings using two-step electrochemical anodization of aluminum (Li *et al*., 1998; Nielsch *et al*., 2002a; Stadler *et al*., 2005). Using this technique, the pores had excellent short-ranged order, leading to a polydomain structure where typical domain sizes were on the microscale. Monodomain pore arrays have also been obtained by electron-beam lithography (Li, Müller and Gösele, 2000) and nanoimprint techniques (Masuda *et al*., 1997; Tan, 2005; Stadler *et al*., 2005; McGary *et al*., 2006).

The first attempts at developing metal-filled alumina membranes for magnetic media were made by a Japanese company in the middle 1970s (Kawai and Ueda, 1975; Kaneko, 1981). At that time, disordered membranes were used and information was stored like conventional media (1 bit $\equiv$ 10–100 magnetic wires). At the turn of the century, two major Japanese companies (Canon and Fujitsu Technology) restarted research activities on the development of a high-density magnetic media based on perfectly ordered alumina membranes with the hope of obtaining patterned magnetic media with a storage capacity in the terabits per square inch range, where each magnetic nanowire could be addressed and store 1 bit of information.

In sensor applications, clusters of nanowires have often been used in order to make contact between the wires and microfabricated electronics (Lindeberg and Hjort, 2003). Track-etched, templated Ni nanowire clusters have been used in this way to measure magnetoresistance (MR) as high as 1% ($\Delta R/R$) caused by a strong field (7 kOe). Because of the potential of individual nanowire sensors, many groups have made magnetic nanowires and are studying the magnetic properties of the wires as a function of size, template, composition, temperature, and external fields (Liu, Wang, Yan and Xue, 2004; Chiriac, Moga, Urse and Ovari, 2003; Nielsch *et al*., 2002b,c; Skomski, 2003; Kelcher, Park, Yoo and Myung, 2005). Magnetotransport in Bi nanowires has also been studied at low temperatures (Zhang *et al*., 1998). In addition to the cluster measurements, copolymer templates have been made with sufficiently spaced wires to allow MR measurements of single wires at a time (Gravier *et al*., 2004).

However, for some innovative sensor applications, such as artificial cilia transducers which mimic the cilia in the ear, it is essential to have dense arrays of parallel wires that are perpendicular to the substrate (Figure 2a). This requirement is also present in magnetic random access memory in order to achieve high density (each bit a single nanowire) combined with thermal stability (Figure 2b). For applications like these, template-based nanomagnets are the best option.

This article discusses several templates that can be used in the fabrication of nanomagnet arrays in Section 2, with an emphasis on nanoporous anodic alumina. Next, two methods for the fabrication of nanomagnets are explained in Section 3. The magnetic properties of Co, Ni, and permalloy nanowires arrays are described in Section 4, followed by some modeling results of these properties in Section 5. Sections 6 and 7 present arrays with perfect large-scale order and some key applications. Finally, a summary of the fundamentals presented here is given in the concluding remarks.

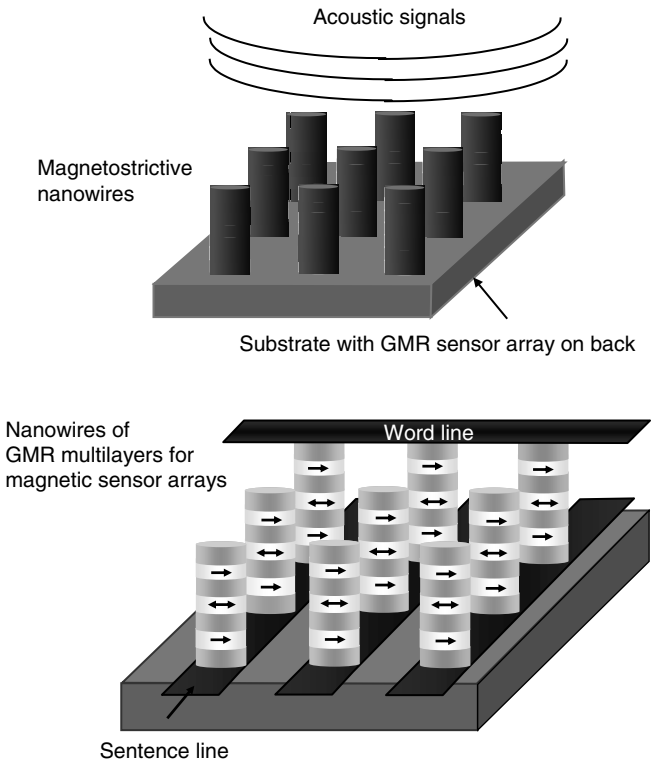

Figure 2. Schematics of acoustic and magnetic sensors based on magnetic nanowire arrays.

2 GENERAL SYNTHESIS TECHNIQUES FOR MAGNETIC NANOWIRE ARRAYS

Although this chapter primarily focuses on fabrication using anodic alumina templates, several nanoporous templates can be used to make nanowires. Self-assembled nanoporous templates include both anodic alumina and diblock copolymers. Another template involves pores that are defined inside certain polymers using ion tracks. Once a nanoporous template is obtained, nanowires can be grown inside the pores via electrochemical deposition. If the nanowires are grown to extend out of the pores, the exposed sides will induce lateral growth, which may be undesirable. For example, in many applications, the nanowires are removed from their template, and lateral outgrowths on the surface will inhibit the template etching. In magnetic nanowires, outgrowth will also alter the measured magnetic properties of the sample, such as anisotropy.

For completeness, the reader should be aware that there are several other methods of growing nanowires that do not involve templates, including fabrication of individual nanowires via step-edge decoration (Petrovykh, Himpsel and Jung, 1988; Tokuda *et al*., 2004), aqueous growth using electrical fields (Cheng, Gonela, Gu and Haynie, 2005), and the vapor–liquid–solid technique (Morales and Lieber, 1998). Also, in addition to the 'bottom-up' approaches of self-assembly discussed here, some experimentalists have fabricated ferromagnetic nanowires using 'top-down' approaches such as lithography. Although some interesting studies on ferromagnetic nanowires fabricated this way have been reported (Florez, Krafft and Gomez, 2005; Dumpich, Krome and Hausmanns, 2002; Castano *et al*., 2002), the nanowires are strictly limited to parallel configurations with the substrate in order to obtain high aspect ratios (10–100). Therefore, two-dimensional arrays, such as those discussed here, are not possible.

The most common nanoporous templates are discussed in detail below, including anodic aluminum oxide, selectively etched block copolymers, and ion-track-etched polymers. Another template that is less common involves phase-separated Al–Si alloys from which the Al has been etched (Fukutani, Tanji, Motoi and Den, 2004).

2.1 Anodic alumina templates

The main advantage of anodic alumina nanoporous templates is that the nanopores can be made to self-assemble strictly parallel to each other and perpendicular to the substrate (Figure 3), using a two-step anodization process that was developed initially by Masuda and Satoh (Masuda and Fukuda, 1995; Masuda, Tanaka and Baba, 1990). The pores are grown inside an oxide that forms during the anodization of either Al foil or Al films for integrated nanopores (Rabin *et al*., 2003). The process of anodization involves applying

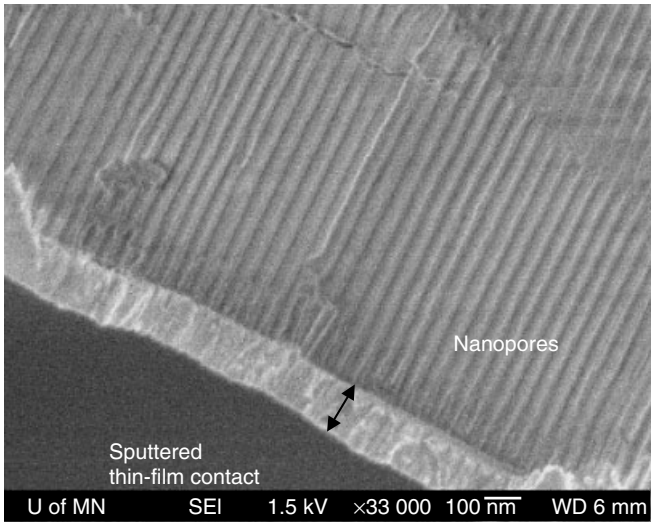

Figure 3. As seen in this fractured side view of anodic alumina nanopores, the pores are strictly parallel to each other. A Cu contact has been sputtered onto one side for electrodeposition of wires into the other side of the pores.

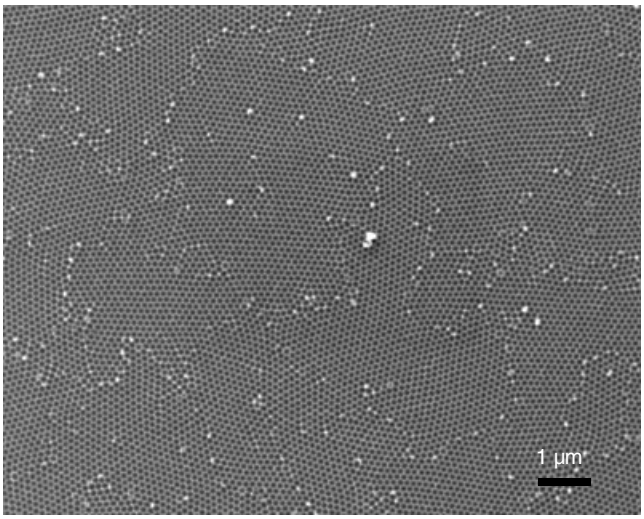
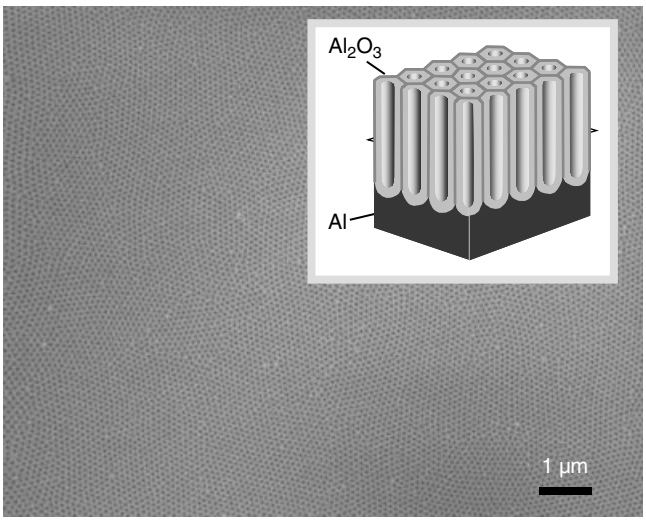


(a)



(b)

Figure 4. Self-assembled anodic alumina nanopores with typical short-range order: (a) Al surface after first oxide is etched away and (b) top of oxide after second anodization.

a voltage to a clean, smooth surface of aluminum while exposing it to an acid. The pores appear to form owing to mechanical stresses in the thickness-limited passive oxide that grows as a result of the anodization (Li *et al*., 1998). The pore ordering occurs at the oxide/Al interface, so the electrolyte/oxide interface, or top interface, will be less ordered than the bottom interface in self-assembled pores. Also, the bottom of the as-grown pores will be closed off by the passive oxide layer, which is called the *barrier layer*.

The two-step process (Masuda and Fukuda, 1995; Masuda, Tanaka and Baba, 1990) involves an initial, long anodization (∼16 h) to establish order at the oxide/metal interface. This nanoporous oxide is then etched away, leaving a clean Al

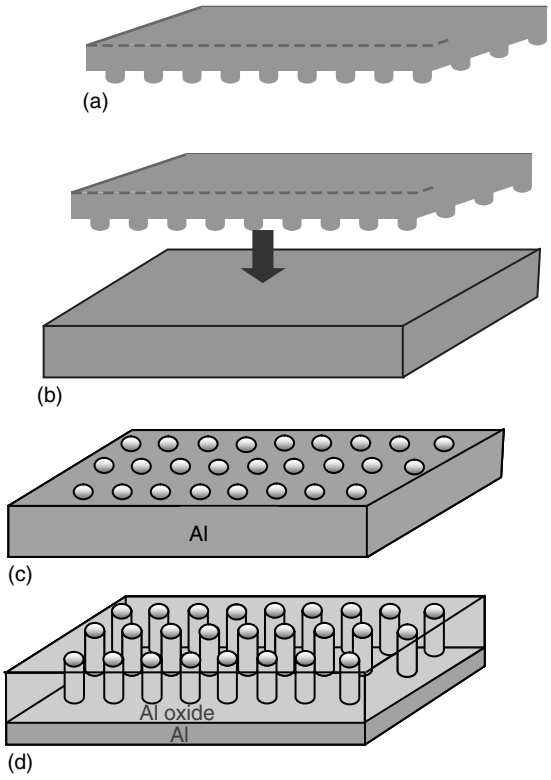


Figure 5. Process for directed self-assembly of nanopore arrays by nanoimprint method: (a) master stamp with ordered array of posts, (b) molding on the Al using an oil press, (c) patterned Al sheet, (d) anodization and growth of high-order nanopore arrays.

substrate that is textured where the bottoms of the now-etched nanopores had been (Figure 4a). A second oxide is then grown under the same conditions, and the new pores form at the already organized sites of the first anodization because of variations in mechanical stress at the textured Al surface (Figure 4b). These nanopores are parallel to each other since they will grow at the same location from top to bottom.

The dimensions of the nanoporous arrays are determined by the temperature of the electrochemical bath, the choice of electrolyte, and the voltage. The latter two parameters are especially important, and it has been shown that the interpore spacing (a) varies linearly from 10 to 500 nm with applied voltage (V) from 5 to 195 V according to

$$a(\text{nm}) \sim -b + mV(V) \tag{1}$$

where researchers have found values of b and m to be in the range of 0–1.7 and 2.5–3, respectively (Li *et al*., 1998; Cobian, 2004). Sulfuric acid is the common electrolyte for a less than 30 nm, oxalic acid is used for $30 < a < 70$ nm, and phosphoric acid is used for $a > 100$ nm. Pore diameters are typically a third to a half of the interpore spacings.

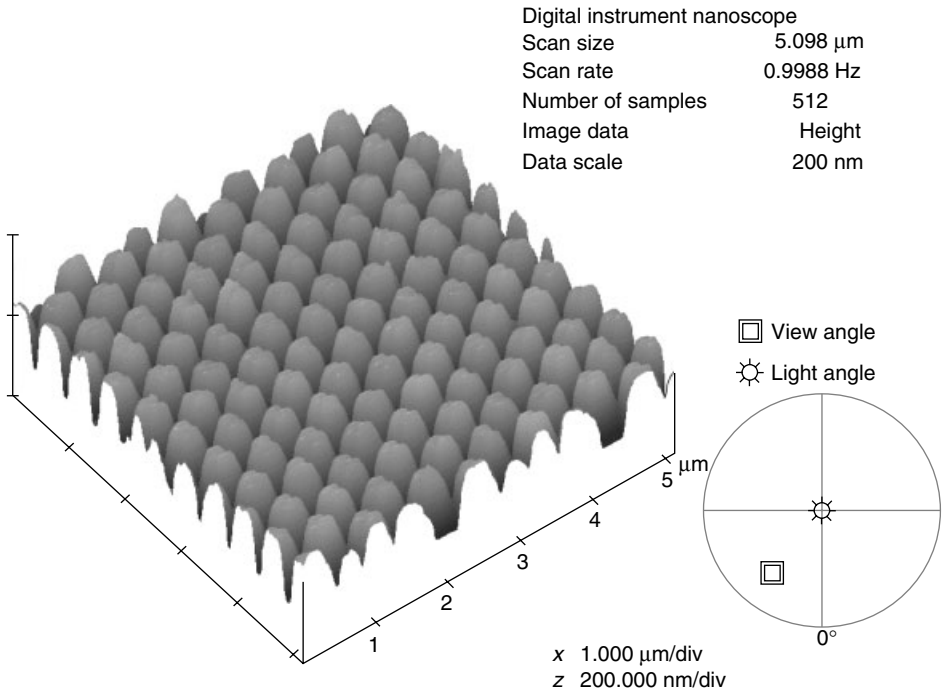

Figure 6. Atomic force micrograph of Si_3N_4 posts defined by electron-beam lithography for use as an imprint nanostamp.

With self-organization, the nanopores are hexagonally ordered with short-range order (Figure 4) (Tan, 2005; Stadler *et al*., 2005). However, a mechanical texture to the surface of the aluminum prior to anodization can be introduced to encourage long-range order (Figure 5). This has been done either by direct nanolithography and etching of the Al surface (Li *et al*., 1998) or by imprinting the Al with lithographically defined stamps of either SiC (Masuda *et al*., 1997; Masuda, Nishio and Baba, 1993) or Si_3N_4 (Stadler *et al*., 2005; Nielsch *et al*., 2003; Choi *et al*., 2003). Figures 6–8 show atomic force micrographs of a nitride stamp and an imprinted Al surface, and an scanning electron microscopy (SEM) photo of the resulting pores with long-range order, respectively (Tan, 2005; Stadler *et al*., 2005; McGary *et al*., 2006). Another stamp, and the resulting array of perfectly ordered Ni nanowires, is described in Section 6.

After growing the nanopores, the barrier layer is etched in phosphoric acid and a metallic contact is deposited on one side for electrodeposition of metal into the other end of the pores, Section 3.1. However, the barrier oxide presents a difficulty when trying to integrate nanowires onto convenient substrates, such as Si or glass (Rabin *et al*., 2003). Some researchers have tried to etch the whole sample in phosphoric acid, but the pores widened and lost their shape when the barrier layer was being removed. For short pores, for example those used for nanopattern transfer, the barrier layer can be removed by reactive ion etching with an inductively coupled plasm head (Zou, Qi, Tan and Stadler, 2006). This technique combines the speed of reactive ion etching (RIE) with the directionality of ion milling (Horst *et al*., 1997). Alternatively, electrodeposition techniques have also been used with a thinned barrier layer, see Section 3.2. In this case the barrier layer was not removed, but by an exponential reduction of the anodization potential over time the barrier layer was thinned down to less than 5 nm and dendrite pores were formed at the pore bottoms.

2.2 Diblock copolymer templates

Diblock copolymer membranes are an alternative to anodic alumina templates. Their advantages include the lack of a barrier layer and the ease of dissolution of the template to expose the wires, if desired for a specific application. However, the possible diameters (14–50 nm with $a = 24$–89 nm) are limited, and they are more difficult to align completely perpendicular to the substrate for subsequent electrodeposition of nanowires.

Diblock copolymers have two different types of polymers (e.g., polystyrene and polymethylmethacrylate) that are attached at one end (Xu *et al*., 2001; Gates, Mayers, Cattle and Xia, 2002; Thurn-Albrecht *et al*., 2000). Close-packed arrays can be achieved when the ratio of the minor to the major component is 0.3:0.7, then the minor phase is removed to make a nanoporous membrane (Olayo-Valles *et al*., 2005; Guo *et al*., 2006). An electric field can be used to help

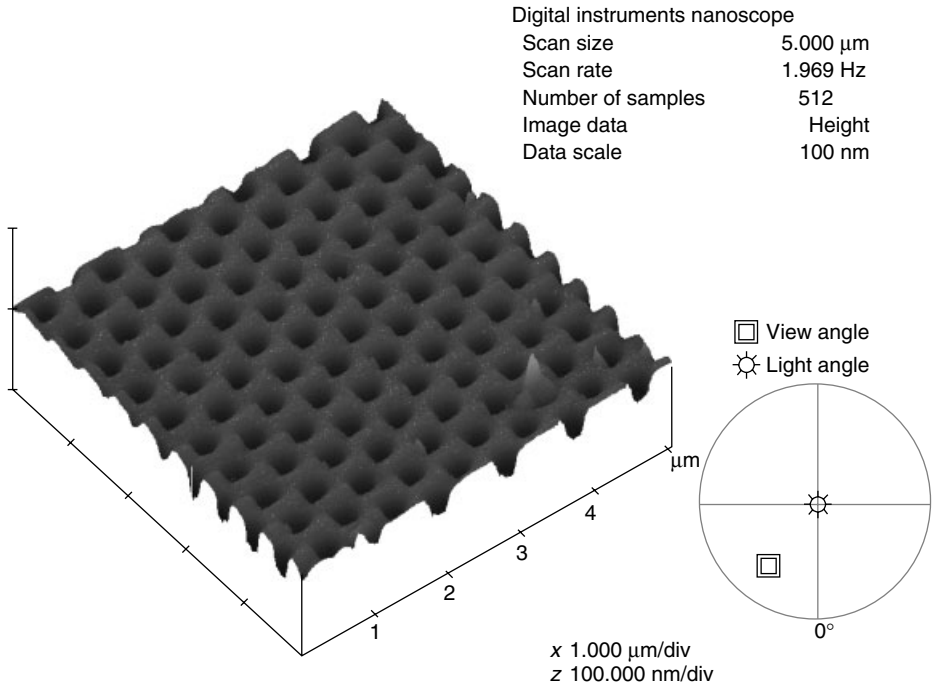

Figure 7. Atomic force micrograph of a polished Al surface that has been imprinted using a nanostamp.

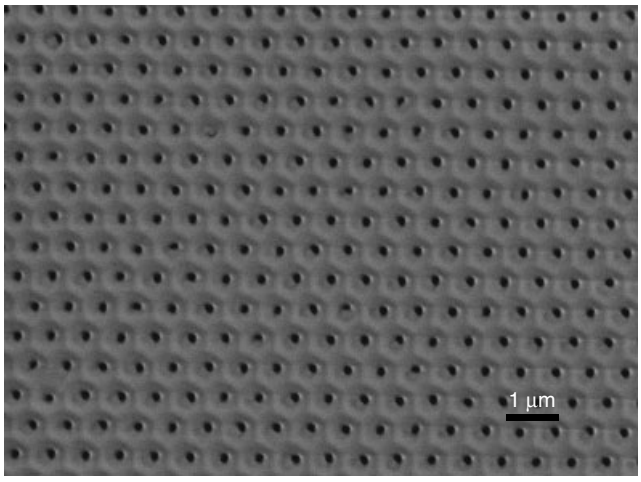

Figure 8. Scanning electron micrograph of nanopores that grew inside the oxide as an imprinted Al surface was anodized. The stamp was used to induce long-range order.

align the columns perpendicular to the substrate using surface charges between the blocks (Morkved *et al*., 1996; Amundson *et al*., 1994). However, the substrate can introduce competing interfacial interactions that encourage the cylindrical nanodomains to align parallel to the substrate if the voltage is not above a specific threshold (Thurn-Albrecht, DeRouchey, Russell and Jaeger, 2000).

Interestingly, nanowires can be grown directly by phase separation of a mixture of metal salt and polymer, but they will not be aligned. Au nanowires have been embedded directly into poly(ethylene oxide)–poly(propylene oxide)–poly(ethylene oxide) block copolymer by mixing gold salt ($HAuCl_4$) into the block copolymer medium and reducing the salt via UV irradiation and thermal reduction (Kim *et al*., 2004). Variations of styrene and vinylpyridine diblock copolymers have produced cylindrical nanostructures which have either been coated with metals or semiconductors or have been filled with metals through photoreduction (Fahmi, Braun and Stamm, 2003; Djalali, Li and Schmidt, 2002).

2.3 Etched ion-track templates

Nanowires can also be grown in ion tracks that have been etched in polycarbonate (Whitney, Jiang, Searson and Chien, 1993; Ferain and Legras, 1997; Schonenberger *et al*., 1997; Mbindyo *et al*., 2002; Dauginet-De Pra, Ferain, Legras and Demoustier-Champagne, 2002; Attenborough *et al*., 1995; Valizadeh, George, Leisner and Hultman, 2002). This technique produces a lower density of nanopores, even down to a single nanopore (Enculescu *et al*., 2003; Chtanko, *et al*., 2004; Toimil Molares *et al*., 2003), so that single wires can be measured. For this, 10–50-μm-thick polymer membranes are irradiated with heavy ions, such as Ar, Xe, Au, or Pb, with energies of 8–12 MeV/nucleon for single-ion tracks or 0.2–2 GeV with fluences between 10^6 and 10^9 ions/cm^2 for multiple tracks. The tracks left by the ions can

then be chemically etched in aqueous NaOH, sometimes after UV irradiation, to make pores as small as 15 nm. Occasionally, the polycarbonate membrane is spun-coated onto a substrate for convenient integration (Dauginet-De Pra, Ferain, Legras and Demoustier-Champagne, 2002), but the resulting pores tend to be conically shaped.

3 PREPARATION OF MAGNETIC NANOWIRES

Two approaches will be presented for the electrodeposition of magnetic nanowires in alumina membranes. First, electroplating directly onto a metallic electrode will be discussed where the barrier layer at the bottom of the pores has been removed. Second, a pulsed plating technique will be described in which the nanowires can be grown onto a thinned barrier layer.

3.1 Deposition directly onto contact electrodes

Once the nanoporous templates discussed above are fabricated, electrochemical deposition is the best method for nanowire growth due to the high aspect ratios involved. For direct deposition, the barrier oxide at the bottom of the pores is removed by floating the template on phosphoric acid with the bottom down in order to avoid pore widening. A contact film can then be sputtered onto one side of the template, but care must be taken that the film covers up the pores. Sometimes, rf sputtering can yield films that penetrate the pores a short distance, and they will not provide good electrical contact for growing wires. The use of oblique-angle sputtering can provide a solution. Films of copper, silver, gold, or any metal can be used, but precious metals usually require a thin initial coating of Ti or Cr to provide adhesion to the nanoporous oxide because of the high surface energetics. Contact-coated nanopores are submerged into an electrolyte containing metal ions and a voltage is applied that is sufficient to reduce the ions (Figure 9). The back of the sample is insulated so that only the contact at the bottom of the nanopores is exposed to the electrolyte, and wires grow as the metal reduces there.

The nanowires grow most evenly using potentiostatic deposition, where a constant voltage is applied to the electrode with respect to a reference electrode that is placed in close proximity to the working surface. This voltage must be less than the reduction potential of the metal, and overpotentials (η) increase current density (J) according to Erying's equation:

$$J = nFA\left(C_O e^{-\alpha nF\eta/k_B T} - C_R e^{(1-\alpha)nF\eta/k_B T}\right) \qquad (2)$$

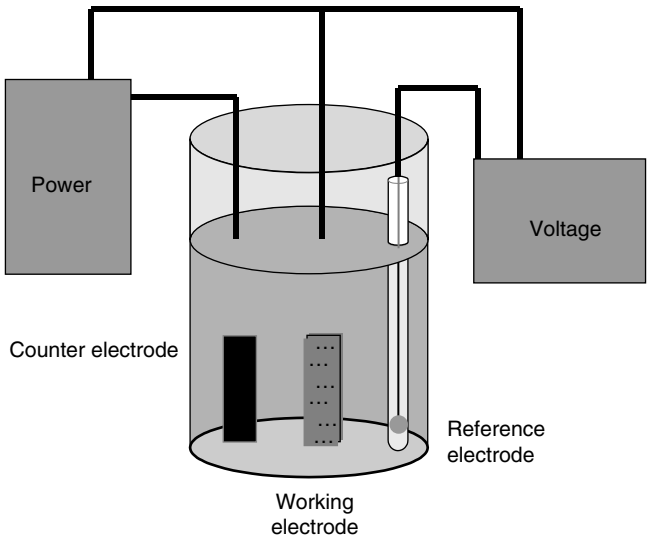

Figure 9. Schematic of electrodeposition apparatus used to grow nanowires inside templates.

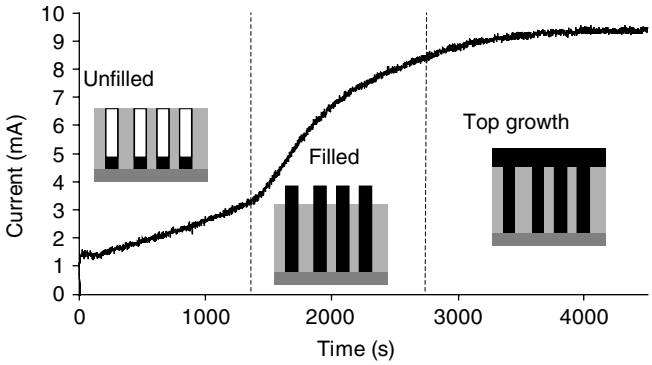

Figure 10. A plot of the current density versus growth time for potentiostatic electrodeposition of nanowires. The schematics show the progress of the growth of the nanowires with time.

where F is Faraday's constant, A is the electrode area, α is an empirical constant, k_B is Boltzmann's constant, and T is the temperature. The deposition rate is proportional to J, so it will scale exponentially with overpotential, so this overpotential can dramatically affect the resulting morphology, for example, grain size (Paunovic and Schlesinger, 1998). Also, the current density can be monitored during the growth in order to reach the desired lengths of the nanowires (Figure 10).

The most common electrolyte is a Watts bath, which is composed of metal sulfates and boric acid (a Lewis acid) to control the pH both in the bulk electrolyte and at the working surface. A typical recipe for Ni nanowires is $26\,g\,l^{-1}$ nickel sulfate heptahydrate, $45\,g\,l^{-1}$ boric acid (using -1.5 V vs a Ag/AgCl reference electrode at room temperature (RT) and sonication). For Fe nanowires, $80\,g\,l^{-1}$

$FeSO_4 \cdot 7H_2O$, 30 g l^{-1} H_3BO_3 can be used, and a new magnetostricitve alloy, $Fe_{1-x}Ga_x$ or Galfenol, can be obtained by adding 25 g l^{-1} $Ga_2(SO_4)_3 \cdot 18H_2O$. Voltages of -1 to -1.5 V versus Ag/AgCl can be used at RT with sonication, and sometimes complexing agents are added to the electrolyte (McGary, 2006). For growth of alloy nanowires, the overpotential for the two constituents will be different at a specific growth voltage. This is a good thing when one wants to control composition according to equation (2) using the standard reduction potentials. However, for nanowires, it can lead to great variations in nanowire composition as the wire grows closer to the reference electrode. Therefore, somewhat dilute electrolytes can be advantageous (McGary, 2006). X-ray diffraction (XRD) has shown that these bcc metals grow with the [110] direction parallel to the wire axis, and energy dispersive spectroscopy (EDS) or wavelength dispersive spectroscopy (WDS) can be used to study compositional variations along the wires.

A typical bath for Co nanowires is 75–250 g l^{-1} $CoSO_4$ with 0–50 g l^{-1} H_3BO_3 and sometimes NaOH is used to adjust the pH (3.3–6.5) (Cobian, 2004). As discussed in Section 4, the crystallography of several electrodeposited metals, especially hcp Co, has been shown to be dependent on pH. A high pH yields wires with the *c* axis parallel to the wire axes and low pH yields wires with the *c* axis perpendicular to the wire axes, as shown by XRD and ferromagnetic resonance (Cobian, 2004; Darques, Encinas, Vila and Piraux, 2004). This makes titration and the choice of whether to use Lewis acids matters of importance because the magnetocrystalline anisotropy of Co is large. Finally, for Co/Cu multilayered nanowires, 250 g l^{-1} $CoSO_4$ and 12.5 g l^{-1} $CuSO_4$ can be used. The reduction potential of copper (+0.14 V vs Ag^+/AgCl) is much higher than the reduction potential of cobalt (−0.48 vs Ag^+/AgCl). Therefore a dilution of Cu^{2+} in the bath enables deposition of Co primarily at more negative overpotentials and Cu primarily at potentials between the standard reduction potentials. The optimal potentials for depositing cobalt and copper were determined by cyclic voltammetry to be -1 and -0.5 V, respectively (Cobian, 2004; Tan and Stadler, 2006). For the thin multilayers required to produce MR (1–20 nm), transmission electron microscopy (TEM) must be used to analyze the layers (Tan and Stadler, 2006).

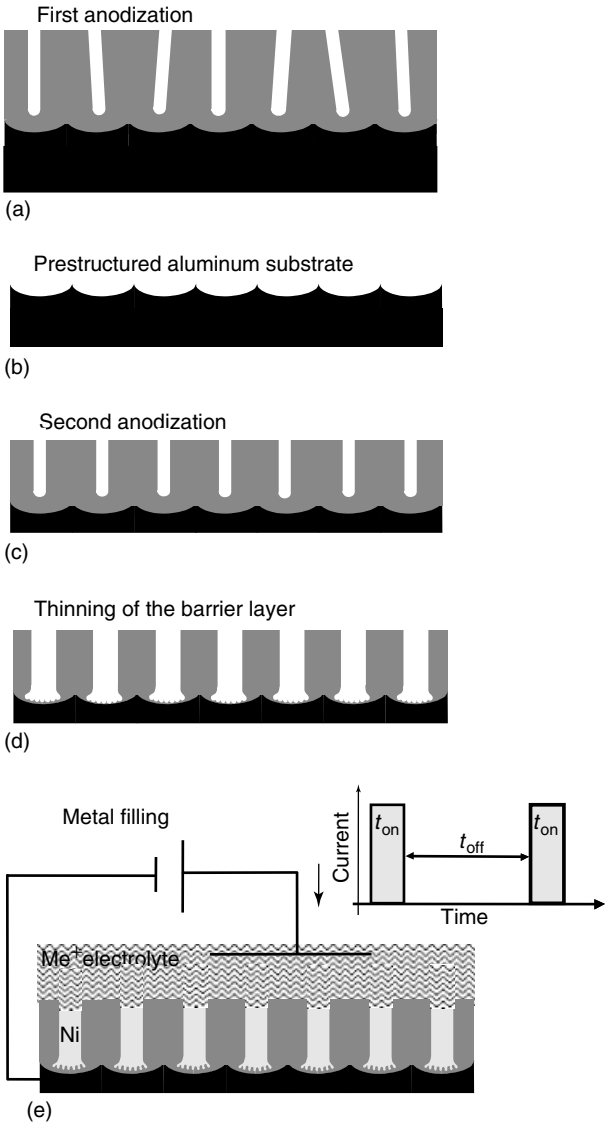

Figure 11. Schematic diagram demonstrating the fabrication of a highly ordered porous alumina matrix and the preparatory steps necessary for the subsequent filling of the structure. The Al substrate was prestructured by a long-time anodization and by removing the oxide (a,b). A second anodization step yielded a highly ordered alumina pore structure (c). The barrier layer was thinned and the pores were widened by isotropic chemical etching (d). To thin the barrier layer further, two current-limiting anodization steps followed, with dendrite pores forming at the barrier layer. Pulsed electrodeposition of nickel in the pores is shown in (e).

3.2 Pulsed electrodeposition on the oxide barrier

As mentioned above, the alumina membranes can be prepared via a two-step anodization process (Figure 11). When depositing wires without removing the barrier layer (e.g., for integrated templates), the quality and homogeneity of the deposition process has been significantly improved by thinning the barrier layer (Figure 11d). This thinning is done by chemical pore widening and by current-limited anodization (Nielsch *et al.*, 2000a). Firstly, growth electrolyte (oxalic acid) is heated to 30 °C to decrease the thickness of the barrier layer and to widen the pores chemically. After 3 h, the barrier layer is decreased from 45 to 30 nm and the mean pore diameter is increased from 30 nm to approximately 50 nm.

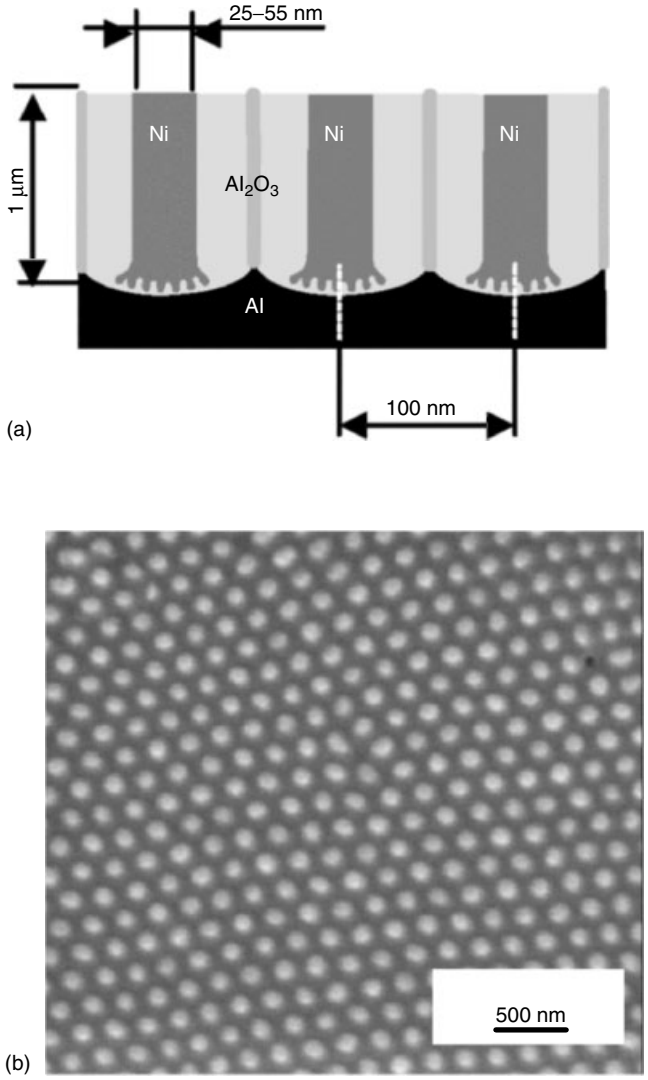

Figure 12. (a) Sketch of the magnetic structure. Nickel nanowires are arranged in a hexagonal array perpendicular to a silicon substrate and embedded in an aluminum oxide matrix. (b) Top-view SEM micrograph of a nickel-filled alumina matrix, with an interpore distance of 105 nm, fixed on a silicon substrate. The Ni columns have a diameter $D_P = 35$ nm and a length of ∼700 nm.

Afterward, the electrolyte is cooled down to 2 °C to interrupt the widening process. Secondly, the structure is anodized twice for 15 min using constant-current conditions of 290 and 135 mA cm^{-2}, respectively. During these anodization steps, the anodization potential decreases and the pores branch out at the formation front such that the thickness of the barrier layer is significantly reduced. Finally, the anodizing potential reaches 6–7 V, which corresponds to a barrier oxide thickness of less than 10 nm (Figure 11d) (Nielsch *et al*., 2000a).

Ferromagnetic materials can then be electrodeposited from aqueous electrolytes at the pore tip of these high-aspect-ratio porous templates (Figure 11e). A highly concentrated Watts-bath electrolyte is used to achieve a high concentration of metal ions in each pore. For example, a typical recipe for a nickel electrolyte is 300 g l^{-1} $NiSO_4 \cdot 6H_2O$, 45 g l^{-1} $NiCl_2 \cdot 6H_2O$, 45 g l^{-1} H_3BO_3, pH = 4.5, $T = 35$ °C (Nielsch *et al*., 2000a,b). The typical electrolyte for a cobalt deposition is similar, except that it contains Co salts and has a pH of 4.3 (Nielsch *et al*., 2000a,b). Frequently, an alternating current (AC) signal is used for the deposition (Almawlawi, Coombs and Moskovits, 1991; Feiyue, Metzger and Doyle, 1997; Choi *et al*., 2003; Nielsch *et al*., 2000a) when a porous alumina structure is kept on its aluminum substrate for the filling process. The metal is directly deposited onto the nearly insulating oxide barrier layer at the pore tips. It has been demonstrated that a pulsed electrodeposition (PED) is more suitable for a direct and homogeneous filling of the porous alumina structures, as described briefly in the following text (Nielsch *et al*., 2002a).

Nielsch found that pore filling was based on modulated pulse signals in the milliseconds range. During a relatively long pulse of negative current (8 ms, $I_{pulse} = -70$ mA cm^{-2}), metal was deposited in the bottom of the pore (Nielsch *et al*., 2002a). The measured voltage varied between −8 and −12 V. After the deposition pulse, a short pulse of positive polarization (2 ms, $U_{pulse} = +4$ V) followed to interrupt the electric field at the deposition interface immediately. A relatively long break time (0.3–1 s) was allowed between the deposition pulses to refresh the ion concentration at the deposition interface, to let the deposition by-products diffuse away from the pore bottoms, and to ensure a stable pH in each pore during the deposition. Consequently, the delay time t_{off} improved the homogeneity of the deposition. For the deposition of nickel $t_{off} = 990$ ms was selected. The deposition continued until the nanowires began to grow out of the pores.

For the characterization of these metal-filled templates (Figure 12a) and their magnetic properties, the tips of the nanowires closest to the substrate must be removed. To do this, the top of the template structure is fixed to a silicon substrate by conducting glue. Next, the aluminum substrate is removed by a saturated solution of HgCl and the structure is turned upside down. After removing ∼200 nm from the top of the sample using a focused ion beam, the top ends of the nanowires become visible at the surface and a relatively smooth surface can be obtained.

As an example, Figure 12(b) shows an SEM image of a nickel sample with a nanowire diameter of 35 nm and a 105-nm interpore distance (Nielsch *et al*., 2000a). Ferromagnetic nanowires (white) with a monodisperse diameter were embedded in the porous alumina matrix (black). Because of the self-organization process, the nanowires were arranged in a hexagonal pattern. Nearly 100% pore filling was obtained for all of the samples, demonstrating that the metallic filling extended over the whole length of the pores.

The crystallinity of these samples was further analyzed by XRD. From the 2θ scan, the average crystallite size was estimated using the Scherrer equation for round particles, yielding an average grain size $D_{Gr} = 10–15$ nm. Analysis by transmission electron microscopy has been performed on individual Ni nanowires that have been released from the alumina matrix by selective chemical etching. The nanowires consist of nanocrystallites of between 20 and 100 nm most of which have tetrahedral shapes, a face-centered cubic (fcc) lattice, and preferential ⟨110⟩ orientation perpendicular to the nanowire axis (Nielsch *et al*., 2001). Before magnetic characterization, the nanowire arrays embedded in the alumina matrix were transferred onto a silicon substrate and the dendrite structure of the magnetic nanowire was removed by ion bombardment (Nielsch *et al*., 2002c).

4 MAGNETIC PROPERTIES OF MAGNETIC NANOWIRE ARRAYS

Although many magnetic materials have been grown in nanoporous templates, the following discussion focuses on Co, Ni, and permalloy in order to review several different aspects of magnetic nanowires. In particular, magnetic anisotropy is best studied using Co because the crystallographic and shape anisotropies are comparable. Controlling coercivity is particularly interesting in Ni and permalloy. These chosen properties are interesting for applications in sensors and recording applications, respectively, but they also give the reader a sense of what properties are present in magnetic nanowires for many applications.

4.1 Arrays of cobalt nanowires

Cobalt is an especially interesting ferromagnetic material for nanowires because it has a large magnetocrystalline anisotropy. In fact, when comparing energy densities, this anisotropy ($K_u = 4.1 \times 10^5\ J\,m^{-3}$) is comparable to the magnetostatic shape anisotropy ($\mu_0 M_s^2/2 = 1.3 \times 10^6\ J\,m^{-3}$) (O'Handley, 2000). Therefore, aligning the *c* axis of the unit cell parallel and perpendicular to the wire axis enables control of a variety of interrelated magnetic properties, such as effective anisotropy, coercivity, and remanent magnetization.

This crystallographic alignment can be controlled using deposition parameters such as the pH of the solution, including the local pH at the growth surface, the deposition rate, applied magnetic fields, and the nanowire size. For example, Co will deposit in either the fcc or hcp phase depending on pH, where very low pH (<2.3) yields fcc (Cobian, 2004). Crystallographic alignment of magnetic hcp cobalt has been shown through the use of a magnetic field (Cobian, 2004; Stadler *et al*., 2005), but the pH is a stronger determinant of crystallographic alignment. For this reason, if Lewis acids, such as boric acid, are used to buffer the local pH, an applied magnetic field will have little effect on the crystallographic alignment. This has been shown in electrolytic solutions that contain boric acid, but are subsequently titrated to achieve controlled pH (Cobian, 2004; Darques, Encinas, Vila and Piraux, 2004). As mentioned in Section 3.1, low pH (3.3–5.3) will yield (100) alignment and high pH (>5.8) will yield (002) alignment, which means the hcp *c* axis is aligned perpendicular and parallel to the wire axis, respectively. Finally, deposition rate can be controlled using the Co^{2+} ion concentration in the electrolyte. If the rate is too fast, or too slow, an applied field will not affect the alignment. For example, with no boric acid (pH = 3.5) and 250 g l^{-1} $CoSO_4$, the alignment was (002) as expected for high pH solutions for all applied magnetic fields (Figure 13a). However, with a medium concentration of $CoSO_4$ (155 g l^{-1}) and no boric acid, a perpendicular applied field caused (100) alignment as the Co nanowires grew (Figure 13b) (Cobian, 2004).

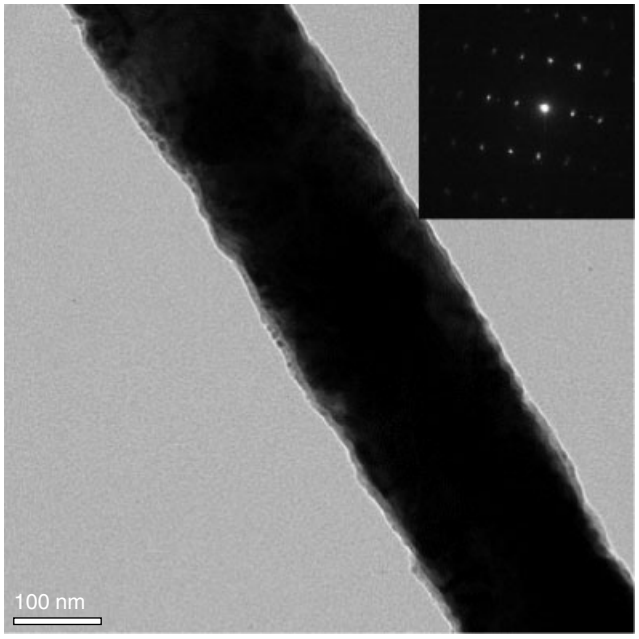
The effects of the crystallographic alignment on magnetic properties can be seen from the hysteresis loops taken by vibrating sample magnetometry (VSM) of the resulting nanowires arrays. Although shape anisotropy will dominate, as predicted by the energy densities, a fivefold increase in the remnant magnetization and a threefold increase in the coercivities of the nanowires whose anisotropy axes were aligned parallel to each other can be obtained (Figure 14a).

Magnetostatic interactions between the nanowires can limit the overall control of the magnetic properties of the array, and templates that enable larger spacing between the nanowires may extend control. Also, if Co/Cu multilayers are grown along the nanowires, the shape anisotropy of each Co layer can be controlled when its thickness is comparable to the diameters of the nanowires (Stadler *et al*., 2005; Tan and Stadler, 2006). Finally, the parameters discussed in the preceding text have similar affects on crystallography over a wide range of diameters. However, the diameter itself will have a large effect on the magnetic properties, with the coercivity increasing with decreasing diameter until the diameter reaches about 30 nm, after which the coercivity will sharply decrease (Figure 14b) (Stadler *et al*., 2005).

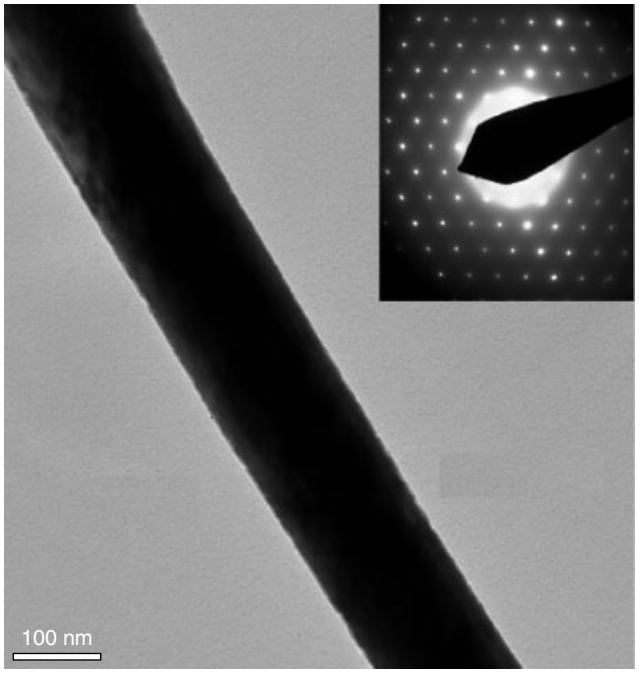
4.2 Nickel and permalloy nanowire arrays

4.2.1 SQUID characterization and effects of Ni volume fraction

In addition to the vibration sample magnetometer (VSM) mentioned above, a superconducting quantum interference device (SQUID) magnetometer can also be used to measure



(a)



(b)

Figure 13. TEM micrographs and diffraction patterns of Co nanowires grown from a solution (pH $\sim$ 3.5) with no pH buffering agent. (a) High concentrations of Co^{2+} ions yielded expected [001] alignment along the wire axis, so side view is (100). (b) Slower deposition rates enabled the crystallographic alignment to be controlled by an applied magnetic field, and perpendicular fields caused the *c* axis to be aligned perpendicular to the nanowires axis (Cobian, 2004). (Reprinted with permission T. Xu *et al*., copyright 2001, Eslevier.)

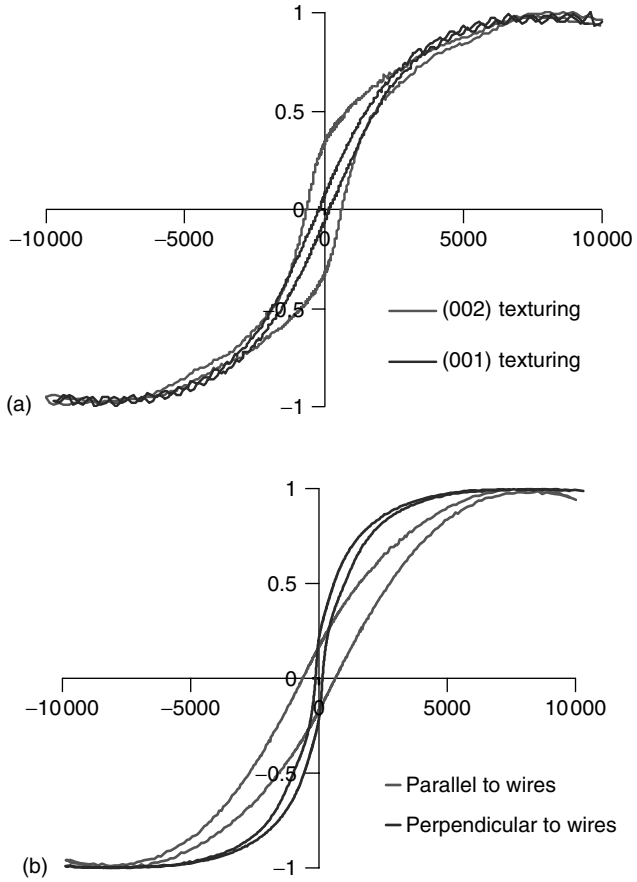


Figure 14. (a) Hysteresis loops parallel to the nanowire axes ((002) texturing: $H_c = 630\,\text{Oe}$, $M_r/M_s = 0.33$; (100) texturing: $H_c = 190\,\text{Oe}$, $M_r/M_s = 0.065$). (b) Hysteresis loops for (100) 40-nm-diameter nanowires (parallel: $H_c = 650\,\text{Oe}$, $M_r/M_s = 0.167$; perpendicular: $H_c = 130\,\text{Oe}$, $M_r/M_s = 0.21$).

the magnetic properties of nanowire arrays. Figure 15 shows a hysteresis loop for a sample with an interpore distance $D_{\text{int}} = 65\,\text{nm}$, a nanowire diameter $D_P = 25\,\text{nm}$, and a column length $L = 700\,\text{nm}$ (Nielsch *et al*., 2002c). When an applied field was parallel to the axis of these Ni nanowires, the hysteresis loop exhibited a coercivity $H_c^{\parallel} \approx 1100\,\text{Oe}$ and a squareness of 96%. In the perpendicular direction, the coercivity was small ($H_c^{\perp} \approx 150\,\text{Oe}$), large magnetic fields were required for a complete magnetization, and the loop showed a nearly reversible behavior. Therefore, this sample had its preferential magnetic orientation along the wire axis.

For this arrangement each Ni nanowire was a single-domain particle, and its anisotropy was determined by the particle shape (Nielsch *et al*., 2001). When this magnetic array was saturated along the magnetic easy axis, the average internal stray field between the nanowires was $H_D^{\parallel} = 2\pi^{3/2}(D_P/D_{\text{int}})^2 \cdot M_s = 770\,\text{Oe}$ (Nielsch *et al*., 2001) and thus it was smaller than $H_c^{\parallel}$. Each Ni nanowire had

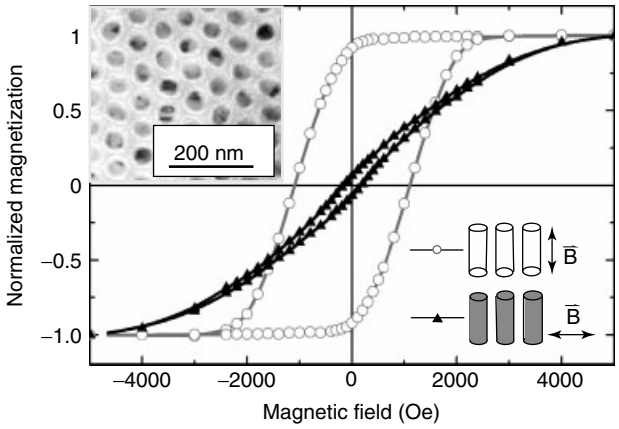

Figure 15. SQUID hysteresis loops of the nickel nanowire array with a pitch of 65 nm, a column length of about 700 nm, and a wire diameter of 25 nm measured with an applied field parallel (○) and perpendicular (▲) to the column axis. The inset shows a micrograph image of the corresponding sample recorded by transmission electron microscopy. The Ni nanowires embedded in the alumina matrix can be clearly seen.

on average a switching field $H_{sw} \approx H_c^{\parallel}$ with a standard deviation ΔH_{sw}, due to the diameter variation. After the sample had been saturated along the nanowire axis and the magnetic field had been switched off, a very small fraction of nanowires reversed their magnetization, because locally $(H_{sw} - \Delta H_{sw}) < H_D$. This explains the small deviation of the measured squareness (96%) from the expected value of 100% for $H_D^{\parallel} < H_c^{\parallel}$.

In these Ni samples, the volume fraction of the ferromagnetic material in the oxide matrices was usually around 10% (Nielsch *et al*., 2001). Even with this relatively low volume fraction, the dipolar interaction seemed to have significant impact on total magnetic anisotropy of the nanowire arrays. The effect of the volume fraction of magnetic material in the alumina membrane on the total magnetic anisotropy and the hysteresis loops was investigated in detail (Nielsch *et al*., 2001). A set of three Ni samples with fixed interpore distances of 105 nm and column lengths of about 800–1000 nm was prepared. Figure 15 shows the hysteresis loops for the nickel arrays measured with an applied field parallel (∥) and perpendicular (⊥) to the wire axis. In this experiment, the Ni nanowire arrays had wire diameters of 55 (sample A), 40 (B), and 30 nm (C), which corresponded to volume fractions of magnetic material of $P = 24.5$, 13, and 7.5%, respectively.

The hysteresis loop for sample A measured in the ∥ direction showed a coercive field of $H_c^{\parallel} \approx 600$ Oe and squareness of about 30% (Figure 16a). For the ⊥ direction, the hysteresis showed a low coercive field of $H_c^{\perp} \approx 100$ Oe. The hysteresis for both directions exhibited similar saturation fields ($H_s \approx 4000$ Oe). Therefore, this sample did not have a preferential magnetic orientation. In contrast, sample

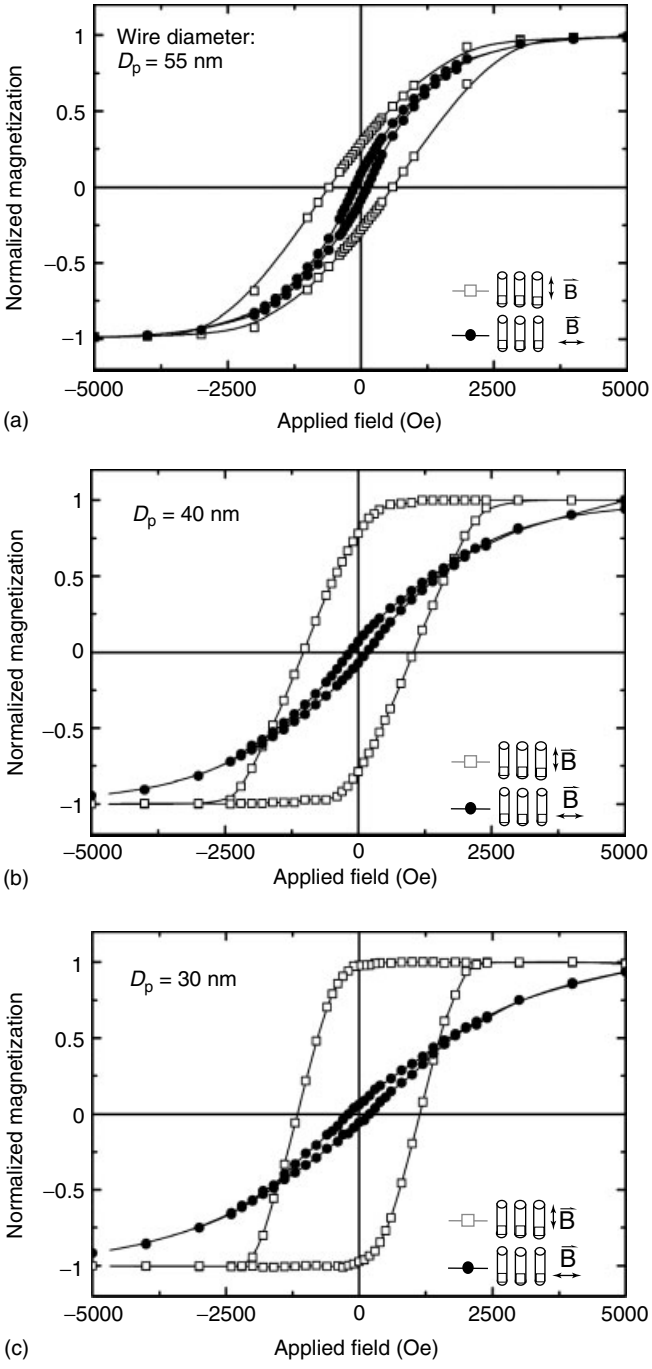

Figure 16. SQUID hysteresis loops for hexagonally ordered Ni nanowire arrays with a pitch of 105 nm and pore diameters of D_P 55 nm (a), 40 nm (b), and 30 nm (c).

B ($D_P = 40$ nm; Figure 16b) exhibited increased coercive fields of about $H_c^{\parallel} \approx 1000$ Oe and improved magnetic hardness, ∼80% squareness. This sample had a magnetic easy axis along the wire axis ($H_s^{\parallel} \approx 2500$ Oe, $H_s^{\perp} \approx 5500$ Oe, and $H_c^{\parallel} \gg H_c^{\perp}$). For sample C ($D_P = 30$ nm), a squareness of 98% and the highest coercive field $H_c^{\parallel} \approx 1200$ Oe

(Figure 16c) were measured. This is the highest reported coercivity for a high-density ($D_{\text{int}} < 120\,\text{nm}$) Ni nanowire array (Kawai and Ueda, 1975; Kaneko, 1981; Zeng *et al*., 2000; Hwang *et al*., 2000a; Chou, Wie, Krauss and Fischer, 1994). Samples B (40 nm) and C (30 nm) had similar magnetic anisotropies. The bulk value of the saturation magnetization $M_s \approx 484\,\text{emu cm}^{-3}$ was used. By determining the absolute amount of nickel in the pores using atomic absorption spectroscopy and relating it to the absolute magnetization by SQUID magnetometry, these samples were determined to have $M_s = 480\,\text{emu cm}^{-3}$.

The magnetic anisotropy of arrays of thin magnetic wires results from the interplay of a series of effective fields. In the case of a single-domain wire, which is expected for Ni with diameters smaller than 55 nm, three contributions must be considered. First is the macroscopic demagnetization field due to the average magnetic charges of the wires at the surface. For Ni in the geometry of a hexagonal pore structure, the average derived demagnetization field ($-4\pi M_s P$; $P >$ porosity of the template structure) is about -1750 Oe for 55 nm pores, -920 Oe for 40 nm pores, and -520 Oe for 30 nm pores. Second, the shape anisotropy of the individual wire if magnetized parallel to the pore axis is of the order of $2\pi M_s \approx 3200$ Oe. Third, a contribution results from the magnetocrystalline anisotropy energy, given by ($-4K_1/3M_s > 120$ Oe for Ni where K_1 is the magnetocrystalline anisotropy. When reducing the pore diameter from 55 to 30 nm while keeping the interpore distance constant ($D_{\text{int}} = 105$ nm), the remanence increased up to nearly 100% and the coercive field shifted toward 1200 Oe. Sample B with $D_P = 40$ nm and sample C with $D_P = 30$ nm, mentioned above, were single-domain wires, which were preferentially magnetized in the $\parallel$ direction because the shape anisotropy of 3200 Oe easily overcame the crystal field of 120 Oe. Theoretically, the effective coercive field of a single infinitely extended cylinder magnetized parallel to the $\langle 111 \rangle$ easy direction of the Ni cylinder axis for homogeneous rotation is given by $H_c = 4K_1/3M_s - 2\pi M_s$. This holds if the cylinder diameter is smaller than the critical diameter D_{crit} for the curling process (Aharoni and Shtrikman, 1958), $D_P < D_{\text{crit}} \approx 3.68 \times \sqrt{(\pi M_s^2)}$ ($A = 8.6 \times 10^7$) erg cm^{-1} for Ni yielding for Ni $D_{\text{crit}} = 40$ nm. Therefore, the curling mode is not an appropriate description for the magnetization of samples with $D_P = 40$ and 55 nm (Nielsch *et al*., 2001).

As single-domain particles, the magnetic reversal process of these Ni nanomagnets appears to occur by inhomogeneous switching modes, as discussed in the micromagnetic modeling by Hertel (2001, 2002). The small size distribution in the pore diameter ($\Delta D_P/D_P < 10\%$) (Nielsch *et al*., 2002a; Masuda and Fukuda, 1995) has a positive impact on the magnetic properties. The highest measured coercive field ($H_c \sim 1200$ Oe for a close-packed nickel nanowire array embedded in a membrane matrix) has been reported when $P = 7.5\%$. Earlier work on unarranged nickel nanowire arrays demonstrated lower coercive fields, about 1000 Oe or less along the easy axis (Kawai and Ueda, 1975; Kaneko, 1981; Zeng *et al*., 2000; Ounadjela *et al*., 1997). The large size distributions (up to $\Delta D_P/D_P > 50\%$) (Strijkers *et al*., 1999) in the pore diameters and the interwire distances enhanced the magnetic interactions in the nanowire arrays and reduced the squareness of the hysteresis loop.

4.2.2 Dynamic properties of nickel nanowires

The dynamic properties of Nickel nanowires have been investigated by a few groups. M.H. Kuok *et al*. from the National University of Singapore have investigated spin-wave modes in Ni nanowire arrays by inelastic Brillouin light scattering experiments in zero magnetic fields (Wang *et al*., 2003). They detected three so-called bulk magnon modes in Ni nanowires and observed an increase in the mode frequencies with decreasing nanowire diameter ($f \sim 1/D_P^2$), which can be labeled as a magnetic quantum size effect. In contrast, on lithographically patterned magnetic films, only surface spin-wave modes have been detected (Jorzick *et al*., 1999a,b; Mathieu *et al*., 1998).

Riccardo Hertel from the Max Planck Institute in Halle has simulated the dynamic properties and the switching modes of Ni nanowires by micromagnetic simulations. He showed that magnetic switching does not occur via coherent rotation (Stoner–Wohlfarth model) or via classic curling. If a nanowire is 60 nm in diameter and more than 1 μm in length, the switching event happens at a timescale of a few hundred picoseconds after a reversed field is applied. In this case switching happens by the propagation of a vortex domain wall (local curling mode) along the nanowire axis (Hertel, 2002; Hertel and Kirschner, 2004). If the nanowire diameter is reduced, the magnetic stiffness increases, for example, for 40 nm diameter the switching process is accomplished after a few nanoseconds. In this case, a 180° head-to-head wall starts at one end of the nanowire and propagates along the length of the wire (Hertel and Kirschner, 2004). The writing speed of conventional magnetic media is currently in the range of a few hundred picoseconds. We can assume that Ni nanowires with sub-30 nm diameter will experience slower switching (>5 ns), and therefore their application to patterned magnetic media, may be restricted.

4.2.3 Permalloy nanowire arrays

A further enhancement of the coercive fields of the Ni nanowire arrays was obtained by adding a small amount of iron sulfate (0.8 g l^{-1} $FeSO_4 \cdot 7H_2O$) to the Ni electrolyte, see Section 3.2. The resulting magnetic nanowire contained

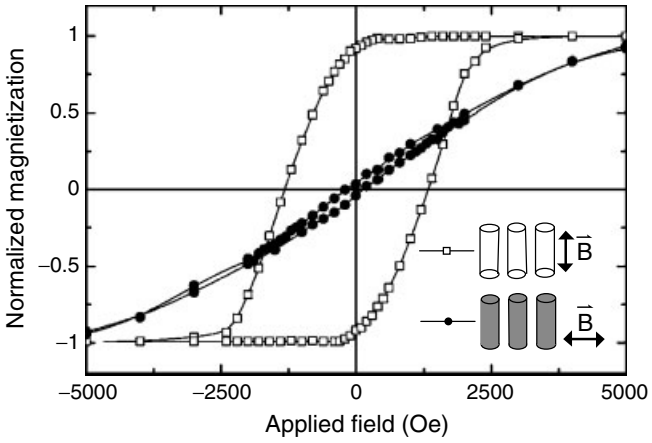

Figure 17. SQUID hysteresis loops of the permalloy ($Ni_{83}Fe_{17}$) nanowire array with a pitch of 105 nm, a column length of about 1000 nm, and a wire diameter of 30 nm measured with an applied field parallel (□) and perpendicular (●) to the column axis.

83% Ni and 17% Fe, which is the nearly ideal composition for permalloy (80% Ni, 20% Fe). Although there was a negligible effect of magnetic anisotropy in the Ni nanowires, this will be even smaller for permalloy nanowires than for Ni nanowires. On the other hand permalloy (M_s = 800–900 emu cm^{-3}) has a higher saturation magnetization than nickel (480 emu cm^{-3}). For a permalloy nanowire array with 30 nm wire diameter, 105 nm interwire distance, and 800 nm wire length, the preferential magnetic orientation was parallel to the wire axis (Figure 17). This hysteresis loop for the parallel direction (∥) had coercive fields of 1350 Oe and a squareness of 96%. The hysteresis loop for the perpendicular direction (⊥) exhibited a small coercive field (100 Oe) and higher saturation fields, up to 7500 Oe. If Figure 17 is compared with Figure 14(a), the permalloy nanowire array had a higher coercivity but a slightly reduced remanence. The additional amount of iron led to an enhancement of the total saturation magnetization M_s of each nanowire. The coercivity and the saturation field increased because of the rise of the theoretical shape effect factor for a nanowire ($2\pi M_s$). On the other hand, the interactions between the nanowires increased because of the enhancement of the average demagnetization fields ($-4\pi M_s \cdot P$: $P \equiv$ metal filling fraction in the oxide matrix), which led to the reduction of the remanence. In conclusion, all these investigations suggest that Ni nanowires and permalloy nanowires are suitable for patterned perpendicular magnetic media. Although, coercive fields of $H_c^{\parallel} = 1200–1350$ Oe were obtained, and the squareness of the hysteresis loop was in the range of 95 to 100%, the estimated demagnetization field inside the magnetic array was still in the range $H_D = 0.5 - 0.7 \times H_c^{\parallel}$. For application as storage media, the dipolar interactions inside the nanowire arrays have to be further reduced, for example, $H_D = 0.1 - 0.2 \times H_c^{\parallel}$. In principle, this can be obtained by reducing the ratio between nanowire diameter (D_P) and interpore distance (D_{int}) by 50–65%, whereby the filling fraction of magnetic material inside the oxide matrix will decrease to less than 3%.

5 MODELING OF THE MAGNETIC PROPERTIES

5.1 Switching field of individual nanowires

Ideally nanowires have a uniaxial anisotropy and the magnetization prefers to align parallel to the nanowire axis (z direction). This anisotropy depends on the aspect ratio of these one-dimensional nanostructures. Here, two simple analytical models for the calculation of the switching field and coercive field for an isolated magnetic nanowire are described.

5.1.1 Stoner and Wohlfarth model

In the classical model based on (Stoner, Wohlfarth and Wohlfarth, 1948), a homogeneously magnetized 3D ellipsoid is used as an approximation for a cylindrical shaped nanowire (Figure 18). In this simple model, any effects related to the crystal structure of the nanowires are excluded. The energy term of the stray field E_D is determined by the aspect ratio $a = L/D_P$ (length/diameter) and the alignment (ϑ) of the magnetization toward the nanowire axis.

$$E_D = \pi M_s^2 \left[1 + \frac{3}{a^2}\left[1 - \ln(2a)\right]\right] \sin^2 \vartheta \qquad (3)$$

When the magnetic dipole is aligned along the nanowire axis, the stray field is in the lowest energetic state. On the basis of the energy term E_D, the maximum switching field H_D of a homogeneous magnetized cylinder can be calculated.

$$H_D = 2\pi M_s \left[1 + \frac{3}{a^2}\left[1 - \ln(2a)\right]\right] \qquad (4)$$

Most of the experimental data presented in the Chapter 4 were taken from magnetic nanowires that exhibited aspect ratios >10. Therefore equation (2) can be simplified for the case $a \gg 1$. The approximated switching field for 180° rotation of the magnetization is given by equation (3).

$$H_D = 2\pi M_s \qquad (5)$$

For Ni, Co, and Fe nanowires, the theoretic switching fields have been calculated on the basis of the model of Stoner and Wohlfarth as H_D = 3260, 8900, and 10 800 Oe, respectively.

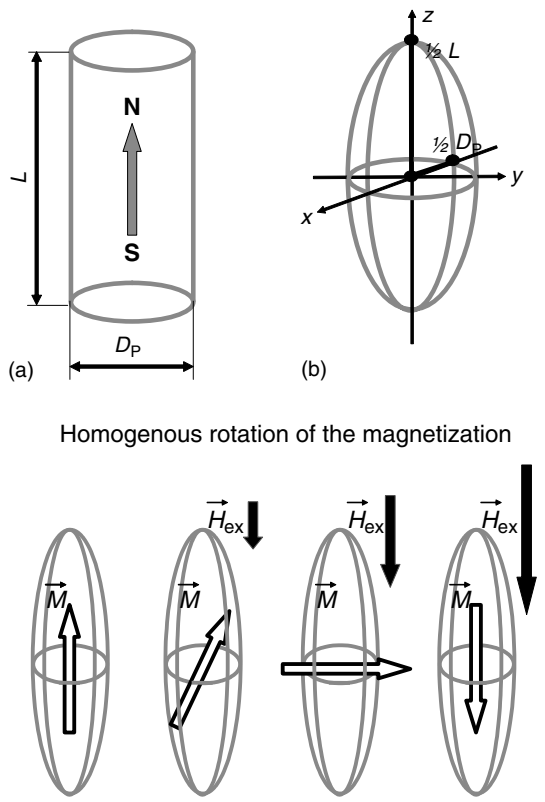

Figure 18. In Stoner–Wohlfarth model a homogeneous magnetized cylinder (a) is approximated by a elongated ellipsoid (b). During the switching process the magnetization is homogenous at any stage of the rotation process.

These values are more than two times higher than the maximum coercivities measured on magnetic nanowires up to now. Contrary to the Stoner–Wohlfarth model, the magnetic nanowires tend to be inhomogeneously magnetized. Micromagnetic simulations provide a more realistic picture of the magnetization inside the nanowire and their switching behaviors. An alternative analytic model has been suggested by Jacobs and Bean (1955).

5.1.2 Jacobs and Bean model

In the simple model by Jacobs and Bean (1955) a chain of an integer number a, of magnetic spheres is used for the calculation of the switching field (Figure 19). Each sphere

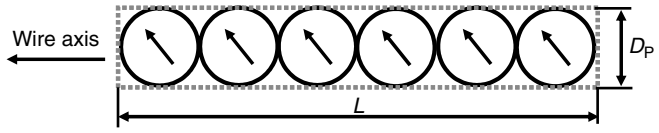

Figure 19. Jacobs and Bean Model: A chain of homogeneous magnetized spheres is used as an approximation for a single-domain nanowire.

is homogeneously magnetized and the magnetization vector in each sphere is pointing in the same direction. On the basis of the dipolar interactions between the magnetic spheres the stray field energy E_D is calculated depending on the orientation angle (ϑ) of the magnetization M toward the nanowire axis.

$$E_D = \frac{1}{2}\pi M_s^2 \left(\sum_{j-1}^{a} \frac{a-j}{aj^3} \right) \sin^2 \vartheta \tag{6}$$

On the basis of (6) the coercive field H_D for an infinitely long nanowire ($a \to \infty$) has been calculated as follows:

$$H_D \approx 1.2\pi M_s \tag{7}$$

The calculated switching field for an isolated nanowire based on the model of Jacobs and Bean is about 40% lower than the Stoner–Wohlfarth approximation.

5.1.3 Curling model

The Curling model (Aharoni, 1999) is a noncoherent calculation that minimizes the total magnetic energy. Curling is often suggested as the reversal mechanism for ferromagnetic nanowires when their diameters are several times larger than the magnetic exchange length $\lambda_{ex} = (2A/\mu_0 M_s^2)^{1/2}$ (where A is the exchange stiffness constant, M_s is the saturation magnetization of the ferromagnetic material, and μ_0 is the permittivity of free space). For Ni, Co, permalloy, and Fe the magnetic exchange lengths are $\lambda_{ex} = 8.3$, 2.9, 5, and 2.3 nm, respectively. When magnetic reversal occurs via curling, a magnetic vortex structure is formed at the nanowire ends and for magnetic cylinders with an infinite length, an analytic solution can be calculated. In contrast to the Stoner–Wohlfarth model where the exchange energy is minimized, in curling the stray field energy is minimized and this leads to an inhomogeneous and vortex-type magnetization. The analytic solution for the nucleation field, H_{sw}, is given as

$$H_{sw} = \frac{27A}{M_s \cdot D_P^2} - \frac{2K_1}{M_s} \tag{8}$$

where K_1 is the magnetocrystalline anisotropy constant. If the nanowire diameters are $D_P \geq \sqrt{27A/2\pi \cdot M_s^2}$ the Curling approximation is a very useful approximation for the theoretic switching field. At smaller diameters the Stoner–Wohlfarth approximation is a more suitable model. If we calculate the theoretic switching field for nickel nanowires with 40 nm (55 nm) diameters and zero magnetocrystalline anisotropy ($K_1 = 0$), the results with Stoner–Wohlfarth, Jacobs–Bean, and Curling are 3200 Oe

(3200 Oe), 1795 Oe (1778 Oe), and 2650 Oe (1310 Oe), respectively. Unfortunately, these theoretic values all have large discrepancies with each other and the experimental data (Figure 16): 1000 Oe (600 Oe) coercivity for $D_P = 40$ nm ($D_P = 55$ nm).

5.2 Dipolar interactions inside the nanowire arrays

Each saturated nanowire produces a dipolar magnetic field, which interacts with the neighboring nanowires. The sum of the dipolar fields from each nanowire inside a magnetic array is called stray or demagnetization field. When an external magnetic field $\vec{H}_{ex}$ is applied, the effective field $\vec{H}_{eff}$, which acts on each nanowire, is the difference between $\vec{H}_{ex}$ and the sum of the dipolar fields originated by the neighboring nanowires.

$$\vec{H}_{eff} = \vec{H}_{ex} - \sum_i \vec{H}_{D,i} \tag{9}$$

In the case that the whole magnetic nanowire array is saturated parallel to the nanowire axis and the external magnetic field is pointing in the same direction, the effective magnetic field $\vec{H}_{eff}$ within the nanowire array is lower than the applied external magnetic field $\vec{H}_{ex}$.

The average demagnetization field of a nanowire array can be calculated under the assumption that the nanowire array is a magnetic thin film with an effective saturation magnetization per volume M_{eff}. When a porous alumina membrane with a pore diameter D_P and an interpore distance D_{int} is filled completely with a ferromagnetic material, M_{eff} can be calculated on the basis of the ratio of the volume of the ferromagnetic material versus the matrix volume.

$$M_{eff} = \frac{\pi}{\sqrt{12}} \left(\frac{D_P}{D_{int}} \right)^2 M_s \tag{10}$$

The average dipolar field H_D inside a saturated nanowire array (magnetic field parallel to nanowire axis) can be estimated as shown in equation (11):

$$H_D = 4\pi M_{eff} = \frac{2\pi^2}{\sqrt{3}} \left(\frac{D_P}{D_{int}} \right)^2 M_s \tag{11}$$

A more accurate model for the demagnetization field inside a saturated nanowire array with a hexagonal arrangement has been proposed by Samwel, Bissel and Lodder (1992). A magnetostatic field $H_{A\to B}$ acts from nanowire A toward nanowire B from a distance D_{int}, and both nanowires have length L. The dipolar field at the top of nanowire B, which is pointing parallel to the nanowire axis, can be calculated by the following equation:

$$H_{A\to B} = \frac{\pi D_P^2 M_s}{2L} \left[\frac{1}{D_{int}} - \frac{1}{\sqrt{D_{int}^2 + L^2}} \right] \tag{12}$$

For a hexagonal arrangement of an infinite large nanowire array the average stray field has been calculated on the basis of the approach of Samwel, Bissel and Lodder (1992).

$$H_D = \frac{3\pi D_P^2 M_s}{L D_{int}} \sum_{i=1}^{\infty} \sum_{j=0}^{i-1} \left(\frac{1}{\sqrt{\left(i^2 - ij + j^2\right)}} - \frac{1}{\sqrt{\left(i^2 - ij + j^2 + (L/D_{int})^2\right)}} \right) \tag{13}$$

The indices i and j are explained by Figure 20. In equation (13), the total dipolar field is summed for a 60° section of the magnetic array and is multiplied by 6. Equation (13) can be written as a function of the average demagnetization H_D:

$$H_D = 4\pi M_{eff} \gamma \tag{14}$$

in this case γ can be interpreted as a correction factor for equation (11):

$$\gamma = \frac{3\sqrt{3}}{2\pi} \frac{D_{int}}{L} \sum_{i=1}^{\infty} \sum_{j=0}^{i-1} \left(\frac{1}{\sqrt{\left(i^2 - ij + j^2\right)}} - \frac{1}{\sqrt{\left(i^2 - ij + j^2 + (L/D_{int})^2\right)}} \right) \tag{15}$$

For magnetic arrays with a high-aspect-ratio nanowires ($L/D_P > 10$) the correction factor γ is in the range of 0.95–0.98. Therefore we can conclude that equation (10) is a relatively accurate approximation for the calculation of the average stray field inside a saturated nanowire array (nanowire axis parallel to applied field).

5.3 Monte Carlo simulation of the hysteresis loop

In the past Hwang *et al*. (2000b) and Zheng, Pardavi-Horvath and Vertesy (1997) have worked on the numerical simulation of the hysteresis loops when the magnetic field is applied parallel to the nanowire axis. An Ising-type approach is used, where each nanowire is a single-domain magnet (i) with a

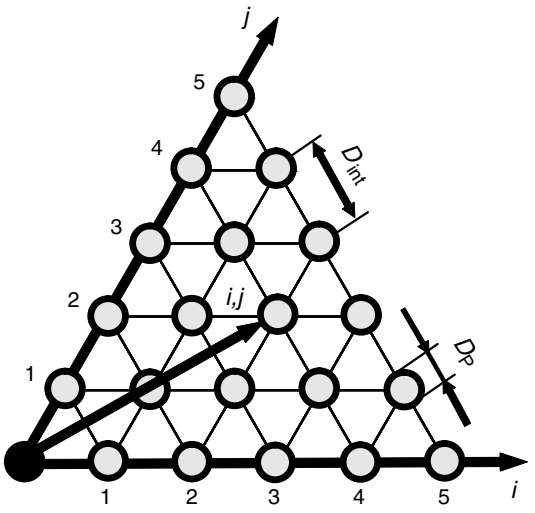

Figure 20. Map of a magnetic nanowire array for the calculation of the dipolar interactions. On the basis of the hexagonal symmetry only one-sixth part of the array is plotted, which is sufficient for the calculations.

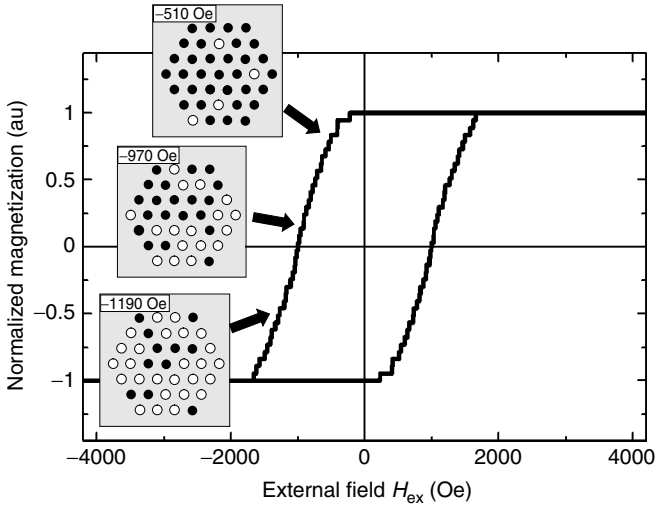

Figure 21. As an example, a numerical simulation of the hysteresis loop is shown for an array of 37 Ni nanowires with a nanowire diameter of 45 nm, an interwire distance of 105 nm, and a wire length of 800 nm.

boxlike hysteresis loop, when the magnetic field is applied parallel to the wire axis, and an individual switching $H_{sw}(i)$. The average switching field $\overline{H_{sw}}(i)$ of the whole magnetic array corresponds to the measured coercive field H_c of a nanowire array with identical geometrical parameters, for example, L, D_{int}, D_P. The variation of $H_{sw}(i)$ follows a classical Gaussian distribution. $\Delta H_{sw}(i)$ is used as a fitting parameter for the simulation and defines the variation width of $H_{sw}(i)$.

Usually, Monte Carlo simulations are started with a saturated array of nanomagnets ($M_{(i)} = +M_s$). At the beginning, the external magnetic field H_{ex} is significantly larger than the saturation field of the whole array. The effective field $H_{eff}(i)$ is calculated by adding up the stray field contributions for each nanomagnet i from all neighboring nanowires j with the magnetic polarization $p(j) = +1$.

$$H_{eff}(i) = H_{ex} - \frac{\pi D_P^2 M_s}{2L} \sum_{j \neq i} \left[\frac{1}{D(i,j)} - \frac{1}{\sqrt{D(i,j)^2 + L^2}} \right] p(j) \qquad (16)$$

The external field H_{ex} is reduced in infinitely small steps until the first nanowire is found where the local effective field is smaller than the individual switching field: $|H_{eff}(i)| > |H_{sw}(i)|$. After that the polarization of the nanomagnet i becomes negative ($p(i) = -1$), the local effective magnetic field $H_{eff}(j)$ is recalculated for each nanomagnet j and the external field H_{ex} is reduced until another nanomagnet k is found that fulfills the criteria $|H_{eff}(k)| > |H_{sw}(k)|$. This iterative procedure is repeated until the whole array of single-domain magnets has totally changed its polarization ($p(i) = -1$). The complete hysteresis loop is simulated by varying the external field H_{ex} from $+H_s \rightarrow -H_s \rightarrow +H_s$ stepwise and calculating the magnetization of the entire magnetic array as a function of the external field.

As an example, the hysteresis loop (nanowire parallel to H_{ex}) of a miniarray composed of 37 magnetic nanowires was simulated. For the simulation an average switching field $\overline{H_{sw}} = 1000$ Oe and a distribution width of $\Delta H_{sw} = 250$ Oe were selected. The following geometric parameters were used for this calculation: nanowire diameter $D_P = 45$ nm, interwire distance $D_{int} = 105$ nm, and nanowire length $L = 800$ nm. The simulated hysteresis loop and the domain pattern for three different external fields $H_{ex} = 510$, 970, and 1190 are plotted in Figure 21. Since the number of nanowires in this test simulation was small, the Barkhausen jumps, which originate from the switches of single wires, can be detected in this hysteresis loop.

In these Monte Carlo simulations (Figure 22) the distribution width of the switching field ΔH_{sw} was a very essential parameter. In order to visualize the effect of ΔH_{sw} on the simulated hysteresis loops, a second test calculation was performed for an array composed of 37 nanowires (with the same geometric parameters, $\overline{H_{sw}} = 1000$ Oe, and $\Delta H_{sw} = 20$, 100, 250, and 400 Oe). For low ΔH_{sw} the hysteresis loop looked similar to a parallelogram. When the distribution width ΔH_{sw} was enhanced, the shearing effect on the hysteresis loop increased and the edges of the loop became rounded. In the past, only the stray field interactions

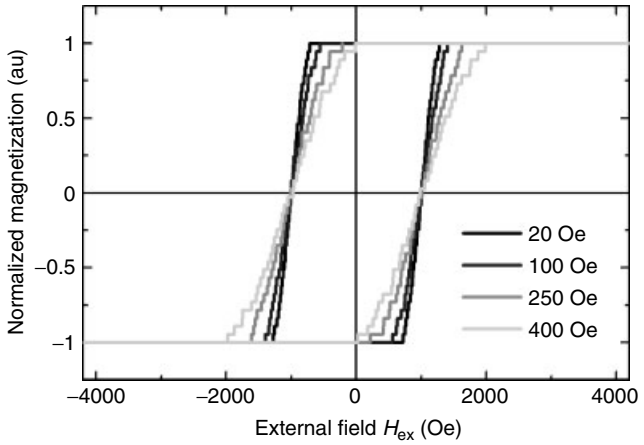

Figure 22. This simulation demonstrates the influence of the switching field distribution on the hysteresis loop when the magnetic field is applied parallel to the nanowire axis. The geometric parameters of this simulation are identical to the simulation shown in Figure 21.

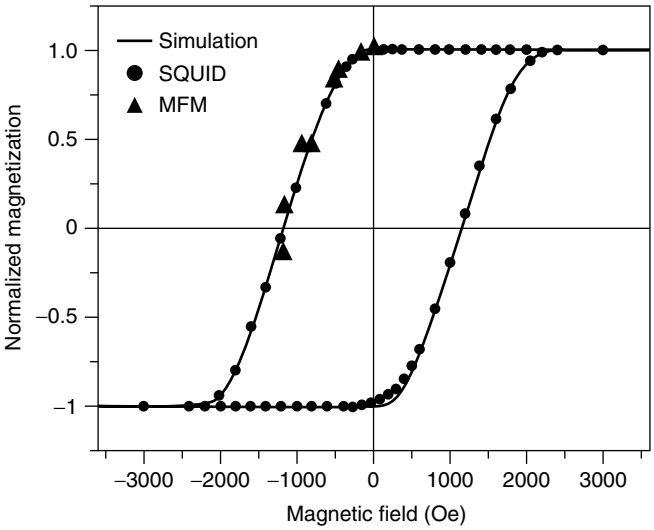

Figure 23. Comparison of a numerical simulation and a SQUID hysteresis loops of a nickel nanowire array with a pitch of 100 nm, column length of about 700 nm, and a wire diameter of 30 nm measured with an applied field parallel and perpendicular to the column axis. Additionally the statistical results from MFM investigations while an external magnetic field H was applied to the sample are also plotted in this figure.

have been considered, but shearing effects in the hysteresis loops of magnetic nanowires have been discussed in the literature (Hwang *et al*., 2000b). As demonstrated in Section 6, the ordering degree of the nanowire array has an important influence on the coercive fields and the shearing effect of the hysteresis. Disordered nanowire arrays have a broad distribution in nanowire diameter. Therefore less-ordered nanostructures have a broader distribution of the switching field ΔH_{sw} and their hysteresis loops exhibit stronger shearing effects. Briefly, the dipolar interactions between the nanomagnets and the distribution width of the switching field are responsible for the shearing of the hysteresis loops.

For comparison with the experimental measurement, Monte Carlo simulations were performed on magnetic arrays with up to 65 269 nanowires. In Figure 23, the experimental data of a nickel nanowire array (wire diameter $D_P = 30$ nm, periodicity $D_{int} = 105$ nm, wire length $L = 800$ nm, $H_c = \overline{H_{sw}} = 1150$ Oe) was measured by a SQUID magnetometer and the statistical analysis of the magnetic force microscopy (MFM) investigations (Nielsch *et al*., 2001, 2002b) were compared with the corresponding Monte Carlo simulation. Here an excellent fit to experimental data was obtained for $\Delta H_{sw} = 150$ Oe. ΔH_{sw} corresponds to 13% of H_c.

In this analysis, a Ni nanowire array within a self-ordered alumina template with an average deviation in pore diameter of about 8% was used. If we assume further that $2\Delta D_P/\overline{D_P} \approx \Delta H_{sw}/\overline{H_{sw}} \approx 16\%$, we can presume that the factor ΔH_{sw} in this simulation is in good agreement with the variation of the cross-section area of the magnetic nanowires. The experimental data presented by Nielsch *et al*. (2001, 2002b) and the Monte Carlo simulations give clear evidence that a perfectly ordered nanowire array with a well-defined pore diameter will have a higher magnetic anisotropy than a self-ordered nanowire array with a larger distribution in pore diameter.

6 FERROMAGNETIC NANOWIRE ARRAYS WITH PERFECT ARRANGEMENT ON LARGE (CM^2)-SCALE ORDER

For the application of magnetic nanowire arrays as a magnetic media and as magnetic field sensors, a perfect arrangement of the array on a large scale is necessary in order to be able to address each individual nanowire. Additionally, a perfect arrangement narrows the distribution of the nanowire diameters and interpore distances, and this will reduce the switching field distribution of the individual nanowires ΔH_{sw}. As demonstrated in Section 5.3, a low ΔH_{sw} will improve the total anisotropy of the whole magnetic array. This assumption has been proved experimentally, by measurement of the hysteresis loops of nickel-filled alumina membranes with a different degree of self-ordering (Nielsch *et al*., 2002c; Vázquez *et al*., 2004).

Using imprint lithography as a tool for prepattering aluminum surfaces, alumina templates with a perfect hexagonal pore arrangement on a square centimeter scale can be achieved using a single anodization process. Initially,

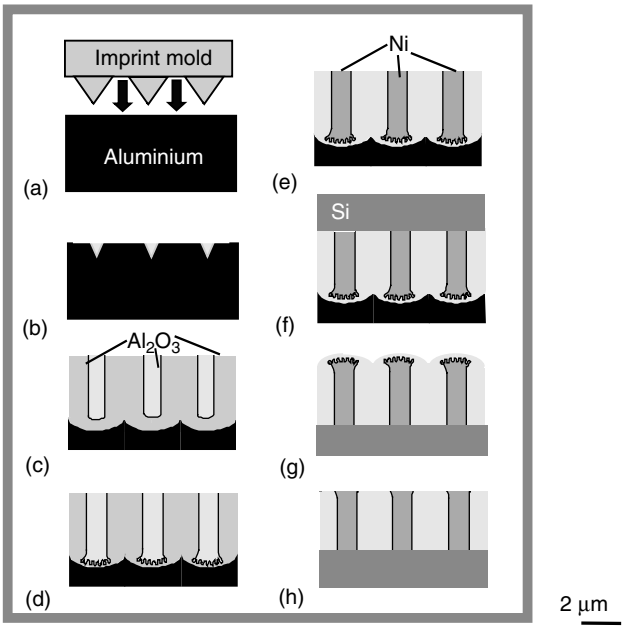

Figure 24. The sketch shows the fabrication process for a perfect ordered magnetic nanowire array.

Masuda *et al*. (1997) used this technique for the fabrication of perfectly ordered, unfilled alumina membranes on a small scale.

In this section, the fabrication of Ni nanowire arrays on a square centimeter scale based on imprint lithography is presented. First, mechanically polished Al substrates were patterned by an imprint master mold, or stamp, described elsewhere (Choi *et al*., 2003). The stamp consisted of hexagonal arrays of Si_3N_4 pyramids with a pitch of $a = 500\,\text{nm}$ (Figure 24a). The imprinted etch pits on the Al surface acted as nucleation sites for pore formation (Figure 24b). The prestructured Al surface was anodized with 1 wt% H_3PO_4 at 195 V for 75 min. Alumina templates (Figure 24c) with a perfect hexagonal arrangement of pores on a square centimeter scale were obtained. Subsequently, the barrier layer was thinned at the pore bottom (Figure 24d) from about 250 nm to less than 7 nm, which resulted in the formation of small dendrite pores at the pore bottom, as described in Section 3.2. Nickel was directly plated onto the nearly insulating barrier by current pulses (Figure 24e). Subsequently, Si substrates were fixed on top of the area (Figure 24f), the Al substrate was selectively removed by chemical etching and the sample was turned upside down (Figure 24g). Finally, the barrier layer and the dendritic part of the nanowires were removed by etching with a focused ion beam (Figure 24h), in order to reduce the stray field interactions between the nanowires. Scanning electron images (Figure 25a) of the nanowire structure revealed $h \approx 4\,\mu\text{m}$, $a = 500\,\text{nm}$, and $D_\text{P} = 180\,\text{nm}$ with a dispersion $\Delta D_\text{P}/D_\text{P} < 2\%$. In comparison, Figure 25(b)

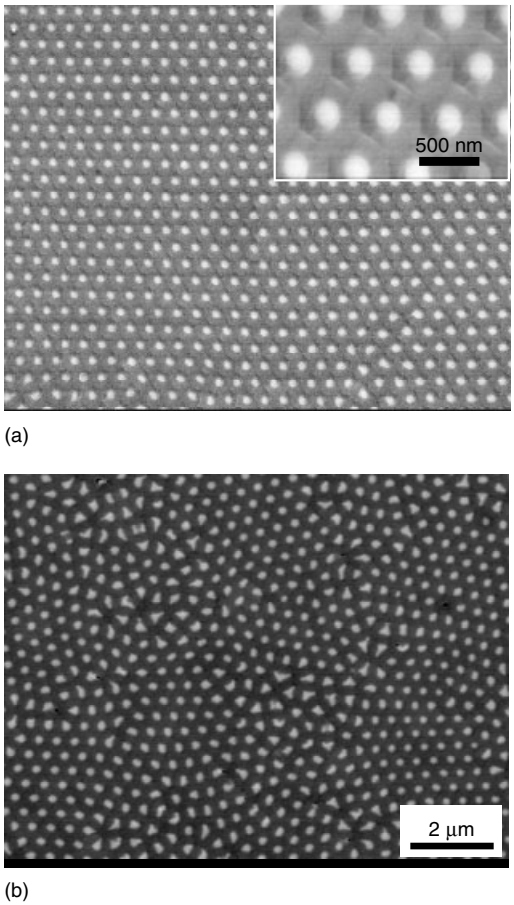

Figure 25. SEM micrographs of nickel nanowire arrays with a 2D monocrystalline (a) and 2D polycrystalline (b) arrangement of the magnetic columns fabricated by imprint lithography and self-organization, respectively. Both arrays have 500-nm interwire distance and 180-nm column diameter. The length of the magnetic columns is ∼5 μm. The inset in (a) shows a higher magnification of the same Ni nanowire array with the perfect arrangement.

shows a nickel nanowire array with a 2D polycrystalline arrangement. The latter array, which was fabricated by the classical two-step anodization process, had a medium-range ordering and a larger dispersion $\Delta D_\text{P}/D_\text{P} \approx 10\%$. Both samples were fabricated under identical electrochemical conditions.

The hysteresis loops were measured for both samples in the direction of nanowire axes and perpendicular to the nanowire axes (Figure 26). In the case when the nanowires had a monodisperse pore diameter and monocrystalline arrangement, a coercive field of 250 Oe and a remanence of 42% were detected. The second sample exhibited a reduced coercivity of 160 Oe and a remanence of 30% because of larger dipolar interactions caused by larger deviations in the nanowire diameters and higher disorder in the magnetic array. In contrast to earlier results on Ni nanowires with

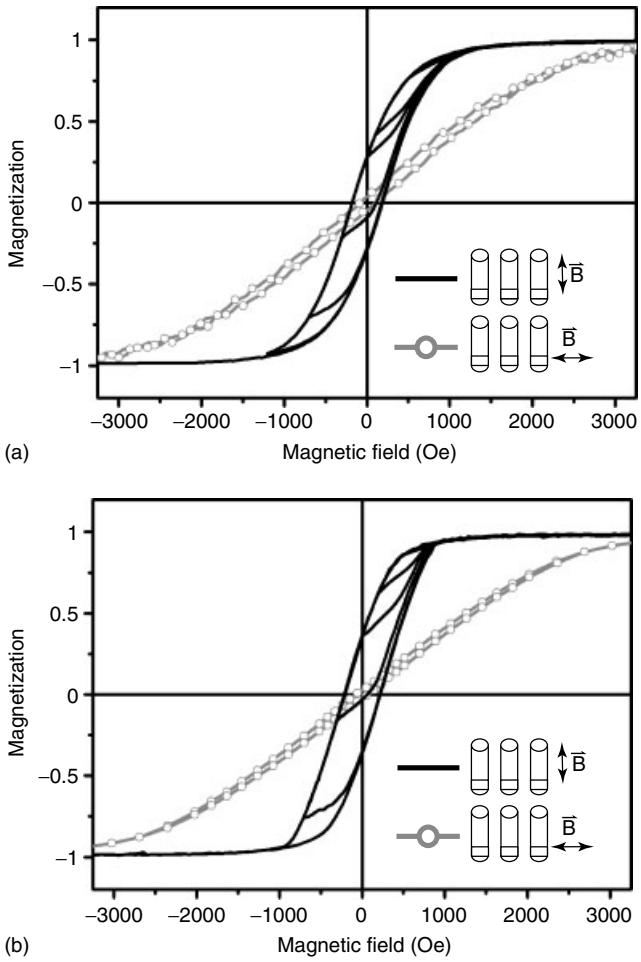

Figure 26. SQUID hysteresis loops of the nickel nanowire arrays with a 2D monocrystalline (a) and 2D polycrystalline (b) arrangement measured with an applied field parallel and perpendicular to the column axis.

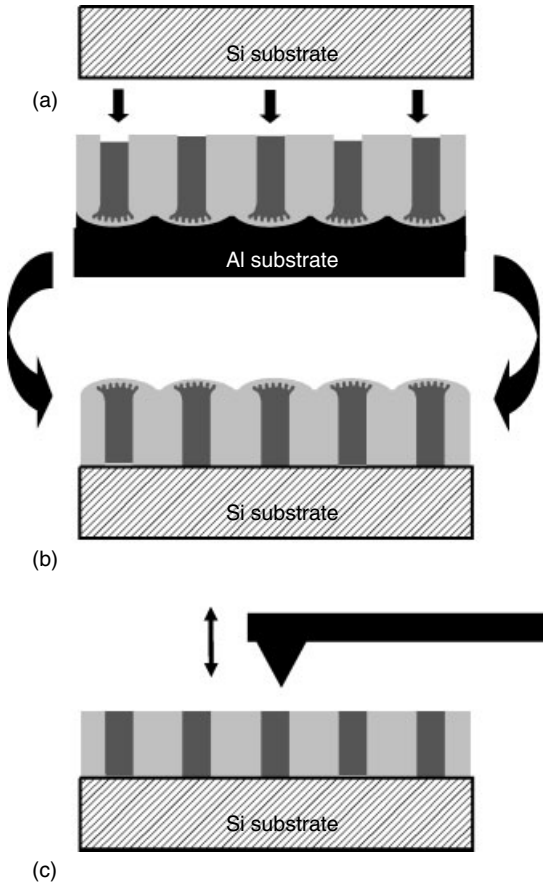

Figure 27. Schematic diagram demonstrating the preparation steps for the subsequent magnetic force microscopy. The filled template was attached to a Si substrate (a). The Al substrate was removed by selective chemical etching (b) and the structure was turned upside down. By focussed ion beam milling the barrier layer and dendrite structure were removed and a smooth surface was obtained (c).

$D_P < 55$ nm (Figure 26a), a single Ni nanowire with $D_P = 180$ nm diameter does not exhibit a boxlike magnetization loop. The reduced remanence of an array of nanowires appears to be due to dipolar interactions, and the sample with the 2D monocrystalline arrangement (Figure 26a) has a narrower distribution of the nanowire switching fields ($\Delta H_{sw}/H_{sw} \approx 2\Delta D_P/D_P$).

7 APPLICATIONS

7.1 Recording application and magnetic force microscopy

One of the promising applications of nanowire arrays is in recording, where one bit of information would correspond to one single-domain, nanosized particle, or one nanomagnet. These nanomagnets would have large aspect ratios to maintain thermal stability rather than the ∼1000 grains required by longitudinal media as discussed in Section 1. The following section discusses an atomic probe technique that can be used in evaluating these nanowire arrays for recording.

In contrast to the bulk measurements of VSM and SQUID, MFM can be used to image the magnetic polarization at the top end of each magnetic nanowire (Figure 27) (Nielsch *et al.*, 2001, 2002b). Figure 28 demonstrates the domain structure of an array of nickel columns in the demagnetized state. First, the topographic image of the Ni nanowire array embedded in the alumina matrix was measured by atomic force microscopy as shown in Figure 28(a). The geometric parameters of the sample were the same as in Figure 16(b) ($D_P = 40$ nm). Dark spots in the magnetic image (Figure 28b) imply that the magnetization was pointing up and bright spots imply that the magnetization was pointing down. Up magnetization may be interpreted as a binary '1', and down magnetization as a binary '0'. It can

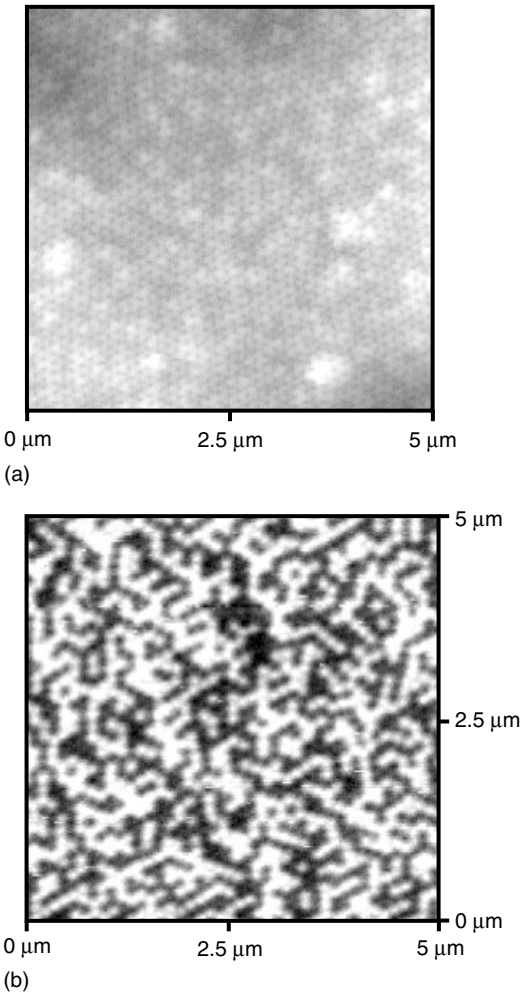

Figure 28. (a) Topographic image recorded by atomic force microscope of an array of magnetic nanowires with 105 nm interwire distance and 40 nm wire diameter embedded in the alumina membranes. (b) Magnetic force microscopic image of the corresponding nanowire array in the demagnetized state, showing the magnetic polarization of the pillars alternately 'up' (white) and 'down' (black).

be deduced from the picture that the Ni pillars were single-domain nanomagnets aligned perpendicular to the surface. The patterned domain structure was due to an antiferromagnetic alignment of pillars influenced by the weak magnetic interaction between these nanomagnets.

The labyrinth pattern (Figure 28b) of the domain structure was characteristic for hexagonally arranged single-domain magnetic particles with a perpendicular magnetic orientation in the demagnetized state. In the case of a quadratic lattice, each of the four nearest neighbors will be aligned antiparallel, and the domain structure exhibits a checkerboard pattern (Ross *et al*., 1999). In a hexagonal lattice, two of the six nearest neighbors will align their magnetization parallel and four will be magnetized antiparallel if the stray field has only nearest-neighbor interaction. In Figure 28(b), it can be seen that an average of 2.5 nanomagnets were aligned parallel and that 3.5 were magnetized antiparallel. Therefore, the stray field interaction appeared to extend over several lattice periods D_{int}, because of the high aspect ratio of the magnetic nanowires. The stray field interactions for sample B with $D_{\text{P}} = 40\,\text{nm}$ therefore appeared moderate, as has been shown using the simple approximation of the demagnetization field H_{D}.

Additionally, MFM investigations with applied magnetic field can be used to study the switching behavior of the individual nanowires in the array (Nielsch *et al*., 2002b). Low moment magnetic tips should be used for MFM scans, in order to prevent switching of the magnetization in the nanowires by the dipole field of the magnetic tip ($H_{\text{tip}} \approx 50\,\text{Oe}$). Here, the sample was saturated by an external magnetic field of about 5000 Oe along the wire axes. The first scan was performed without an external field (Figure 29a). In order to get a better impression of the magnetic polarization of each pillar, the MFM images were numerically enhanced. Even though $H_{\text{ex}} = 0\,\text{Oe}$ and the maximum demagnetization field of $H_{\text{D}} = -920\,\text{Oe}$ was smaller than the coercive field, a few pillars had already switched their polarization, because of the dipolar interactions between the nanowires and the distribution of the switching field of the individual nanowires. Next the external magnetic field was increased to -300, -600, and $-900\,\text{Oe}$ (Figure 29b–d) in the direction opposite to the magnetization. The stray field of the sample appeared to increase, $H_{\text{eff}} = H_{\text{D}} + H_{\text{ex}}$. For $H_{\text{ex}} = -300\,\text{Oe}$, the effective field in the nanowire array was already smaller than the coercive field, therefore a significant number of nanowires had reversed their magnetizations. Increasing the external field led to an increased number of reverse-magnetized pillars (Figure 29b–d). The enhancement of H_{eff} was partly compensated by the reduced dipole interactions from the reversed pillars. In the final image (Figure 29d), the applied external field had nearly reached the coercive field $H_{\text{c}}^{\parallel} = 1000\,\text{Oe}$. The number of switched (black) and unswitched (white) nanowires was nearly equal. In this case, the average demagnetization field in the sample was reduced nearly to a minimum and $H_{\text{ex}} \approx H_{\text{eff}} \approx H_{\text{c}}^{\parallel}$.

The suitability of nickel nanowire arrays for patterned perpendicular magnetic media has been studied in more detail. For this experiment sample A ($D_{\text{P}} = 30\,\text{nm}$) with the best magnetic performances in terms of squareness (100%) and coercivity (1200 Oe) was used (see Figure 16c). An attempt was made to saturate a defined area of a demagnetized sample by a strong magnetic MFM tip ($H_{\text{tip}} \approx 250\,\text{Oe}$) and an external magnetic field ($H_{\text{ex}} = -1200\,\text{Oe}$). The amount of the applied external field was nearly equal to the average switching field (H_{sw}) of the individual nanowire ($H_{\text{c}}^{\parallel} = 1200\,\text{Oe}$)

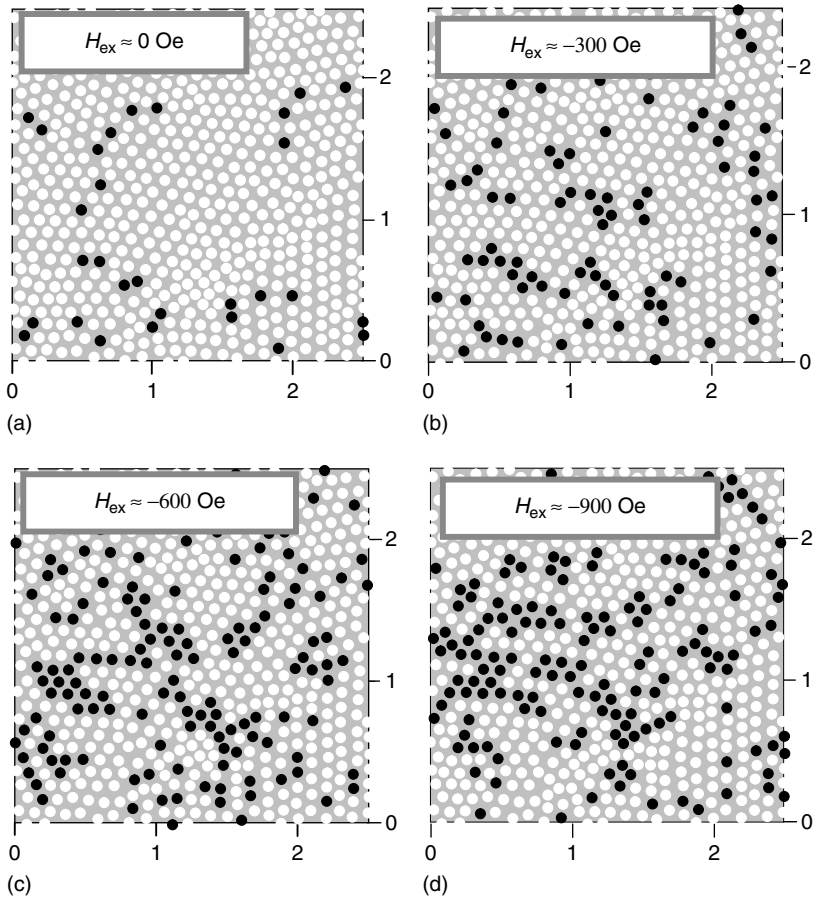

Figure 29. An external magnetic field was applied perpendicular to the sample surface. (a) The MFM image of the saturated nanowire array. Numerically enhanced MFM images recorded with an applied magnetic field of $H_{ex} = 0$ (a), -300 (b), -600 (c), and -900 Oe (d).

and was applied in the direction of the nanowire axis. Starting in the upper region of Figure 30 the strong magnetic tip was scanned over an area of $5 \times 5\,\mu m^2$. Hereby, a total external field of about $H'_{ex} = H_{ex} + H_{tip} = -1450$ Oe was locally applied on this selective area. Subsequently, the external magnetic field was switched off. An enlarge area of $10 \times 10\,\mu m^2$ (Figure 30) was scanned with the magnetic tip in order to measure the domain pattern of the manipulated area in the nanowire array. Inside the area of the first scan, nearly every nickel column ($\sim$93%) was magnetized in the same direction. Figure 30 shows the local impact (dark quadratic region) of the external magnetic field and the strong magnetic tip during the first MFM scan on the magnetization of nanowires. Around the magnetized region of $5 \times 5\,\mu m^2$, the nickel nanowire array remained in the demagnetized state and exhibited the labyrinth-like domain pattern (Figure 28). The border between the magnetized area and the surrounding demagnetized area is clearly visible. From this picture, it can be concluded that the applied magnetic field ($H_{sw} \approx H_c$) alone was not strong enough for the switching of magnetic polarization in the Ni columns. Hence, the additional field contribution from the strong MFM tip (H_{tip}) enabled the local switching process in the Ni nanowire array. The probability for a nickel nanowire to remain unswitched (light spots) increased in the lower region of the magnetically manipulated area (Figure 30, first scan). In the upper region, where the first magnetic scan procedure was started, the first five or six horizontal nanowire rows had been saturated in the same direction. During the first scan procedure when the area of the saturated nanowires was growing, the probability for a nanomagnet to remain unswitched increased. It can be assumed that the stray field interactions between the demagnetized and the magnetized area can be neglected and the net stray field in the demagnetized area is zero. By increasing the area of parallel-magnetized nanowires, the dipole interactions between the magnetic elements were enhanced and the applied local field ($H_{tip} + H_{ex}$) was becoming less sufficient for a complete magnetic alignment of magnetization in a horizontal row of nickel columns. At the left and right border of the magnetically manipulated area, the stray field interactions were weak and a lower number of unswitched magnetic columns were observed there. From this experiment, it can

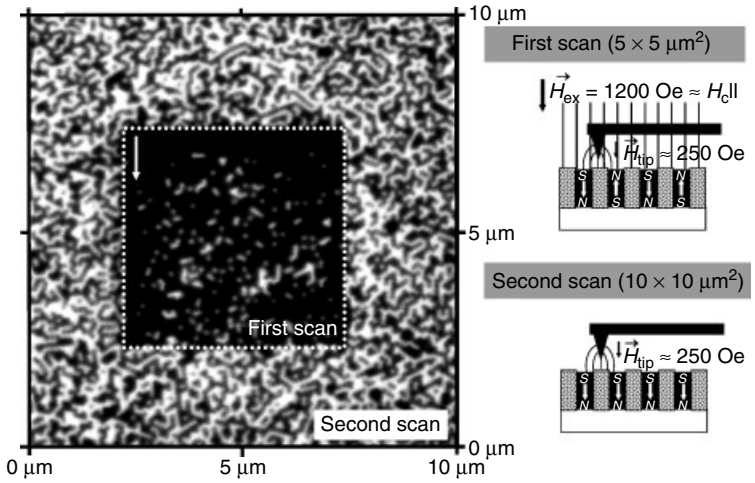

Figure 30. Local magnetic switching of a demagnetized sample area ($5 \times 5\,\mu m^2$, first scan) by a strong magnetic MFM tip ($H_{tip} \approx -250$ Oe) and an external magnetic field ($H_{ex} = -1200$ Oe). This image of the domain pattern ($10 \times 10\,\mu m^2$) was recorded by a second subsequent MFM scan without an external magnetic field.

be concluded that the stray field dipole interactions between the nanowires were extended over several interwire distances because of their high aspect ratio (nanowire length to interwire distance $L/D_{int} \approx 7$). In principle, a single nanowire can store 1 bit of information and can be locally switched independently of the magnetization of its nearest neighbors.

Researchers from Fujitsu Laboratories in Japan (Kikuchi *et al*., 2005) have preformed reading and writing tests on cobalt-filled porous alumina structures with 63-nm pitch on 2.5-in. disks, recently. Although they performed these experiments on disordered porous alumina structures, they demonstrated the data readout of the magnetic polarization of individual nanowires with a standard head for perpendicular recording. Currently, the Fujitsu researchers performing these tests on ferromagnetic materials filled alumina pore arrays with short and long range ordering.

7.2 Nanoelectromechanical systems (NEMS) and magnetic sensors

Other applications for magnetic nanowires include magnetic and mechanical sensors, where the nanowires can essentially be used as magnetoelectronic systems and/or NEMS with advantages that scale indirectly with size. In particular, NEMS sensors involve nanowire motion. Typically the force to be sensed moves the nanowires, and this motion is then detected by another means. Similar size advantages are already commercially achieved with microelectromechanical systems (MEMS), which began to attract interest in the middle of the last century (Feynman, 1992). Advantages of MEMS include reduced mass, increased resonant frequencies, lower force constants, and ease of 'manufacturing' large numbers of devices simultaneously using silicon (Si) planar processing. MEMS are now seen commercially in applications such as mirrors for optical communications (Lin and Goldstein, 2002; Ermolov *et al*., 2002), accelerometers (Beliveau, Spencer, Thomas and Roberson, 1999), medical devices (Maluf, Gee, Petersen and Kovacs, 1996), and flow control in ink-jet printers (Brünahl and Grishin, 2002; Lee, Kim, Kuk and Oh, 2002), and acoustic sensor arrays (Arnold, Nishida, Cattafesta and Sheplak, 2003).

Several groups are taking the MEMS-like 'top-down' approach to new limits in the nanoscale through novel lithography techniques using ion and electron-beam etching (Abadal *et al*., 1999; Yang *et al*., 2001; Roukes, 2001; Sundararajan and Bhushan, 2002). These novel non-silicon-specific techniques enable new materials to be used, which further increases the potential functionality of NEMS. However, owing to the limitations of lithography, they are limited in that the devices must usually have their largest dimension in plane and, as mentioned above, the processing is expensive with small areal coverage. Arrays of magnetic nanowires enable 'bottom-up' fabrication of NEMS, which offers the advantage of low-cost, high-density arrays.

Two applications of magnetic nanowire sensors can be classified as NEMS. The first involves layered nanowires to be used for atomic resolution in magnetic resonance force microscopy using layers of Ni, Au, and Pt (Valizadeh, George, Leisner and Hultman, 2002). A nanoreflector of Ag is preferentially grown on top of the Au layers at various locations along the wire depending on the sensor design (Barbic and Scherer, 2005). The resonance of such wires has been studied as well (Husain *et al*., 2003).

The second NEMS application of magnetic nanowires involves magnetostrictive nanowires for acoustic sensors (Stadler *et al*., 2005; McGary and Stadler, 2005; McGary *et al*., 2006; Downey and Flatau, 2005). These magnetostrictive nanowires are being tailored to dimensions that will resonate at a variety of frequencies for applications in sonar, hearing, and ultrasound. Because they are magnetostrictive, the nanowires will generate a magnetic field when they change dimension because of the acoustic signal. This field will then be detected by a magnetic sensor, ideally this sensor will be a nanowire giant magnetoresistance (GMR) sensor that is integrated directly into the base of each nanowire. In this way, a very small array will be produced for sensing the magnitude and phase of the incoming sound. Resonant frequencies can range from kilohertz to gigahertz for 20 nm nanowires by varying the lengths from 0.5 to 100 μm (Stadler *et al*., 2005). Arrays of shorter wires will therefore be useful in medical applications, for example, in echocardiography, and the arrays can be polished at an angle to produce varying lengths, which will enable high spatial resolution imaging. Longer nanowires will be useful in applications such as ultrasound, sonar, and hearing.

In addition to NEMS, nanowires can be used as magnetic sensors, which use MR to sense external fields. This property can be intrinsic to the nanowire material, for example, Ni, or it can be optimized by designing multilayers inside the wires. An example of the latter is Co/Cu/Co stacks in which one of the Co layers is fabricated to have a higher coercivity than the other, perhaps by altering its thickness. Most magnetic nanowires studies involve template-grown arrays, although sometimes step decoration has been used, for example, Fe wires on sapphire steps (Westphalen, Zabel and Theis-Brohl, 2004).

These Co/Cu/Co multilayers are an example of GMR structures. These structures involve passing current through two ferromagnetic layers that have different coercivities (such as Co), and they are separated by a nonmagnetic spacer (such as the Cu). The ferromagnetic layer that is more coercive is considered to have a 'fixed' magnetization direction and the magnetization of the other ferromagnet is designed to be soft so that it can point in the direction of the magnetic field to be sensed. When these two layers are aligned (which occurs when the sensed field is aligned with the fixed layer), the resistance of the structure is low. However, when the ferromagnets are not aligned, the electrons become polarized in one layer, and they are less likely to be able to conduct through the other layer due to interfacial scattering.

This phenomenon of GMR is mostly studied using Co/Cu/Co layers (McGary, 2006; Piraux *et al*., 1997; Blondel, Meir, Doudin and Ansermet, 1994; Liu, Nagodawithana, Searson and Chien, 1995), which have yielded MR of 20% or higher at RT (Liu, Nagodawithana, Searson and Chien, 1995; Doudin, Blondel and Ansermet, 1996). The exact MR ratio depends on the total length of the nanowire, which often includes long Cu ends that contribute to the total resistance, but not to the MR, so the absolute MR of the multilayers will be higher than the measured MR. Figure 31 shows a 100-nm nanowire from an array grown with the recipe given in Section 3 with (30 nm) Co/(50 nm) Cu layers. Similar wires with 150 nm diameters and (5 nm) Co/(5 nm) Cu yielded 7% MR at RT using the recipe given (Stadler and Tan, 2006). Several other configurations have been studied in which the pure Co ferromagnetic layers are replaced by CoNiCu (Heydon *et al*., 1997), NiFe (Blondel, Meir, Doudin and Ansermet, 1994; Dubois *et al*., 1997), CoNi (Attenborough *et al*., 1995), Ni (Wang *et al*., 1996; Chen, Searson and Chien, 2003), and Fe (Piraux *et al*., 1997). The Cu nonmagnetic spacer can also be replaced by other metals, such as Ag (Valizadeh, George, Leisner and Hultman, 2002), Pt (Chu, Inoue, Wada and Kurashima, 2004), or Pb (Dubois *et al*., 1999). Most groups use single electrochemical baths which contain sulfates or other salts of all of the desired metals, but some groups use separate baths for each layer (Blondel, Doudin and Ansermet, 1997). In growing these GMR structures, it is difficult to obtain ferromagnetic layers with the required differences in coercivity. In patterned thin-film sensors, this is usually done using an antiferromanget next to one of the ferromagnets in order to fix its magnetization. However, antiferromagnets are often oxides or alloys that are difficult to deposit (e.g., IrMn), and the other option, synthetic antiferromagnets, involves stacks of up to five elements which can require additional metal ions in the electrolyte, and hence complicate the deposition of each layer. As mentioned above, the coercivity can be altered by varying the thickness of one of the ferromagnetic layers, but this has a limited effect.

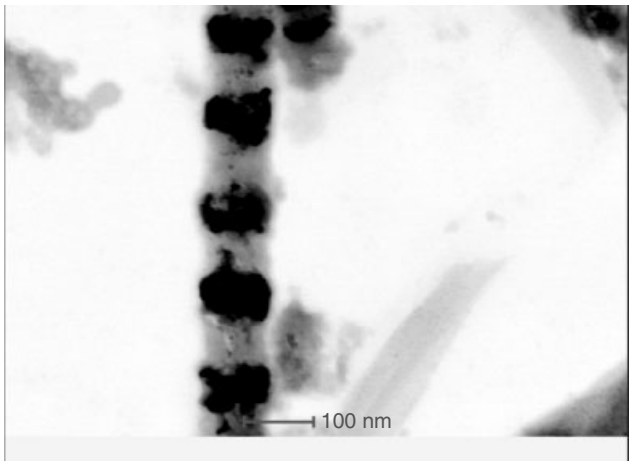

Figure 31. High-resolution TEM image of a Co/Cu/Co multilayered nanowire.

Another method is to vary the crystallographic alignment of Co in the various layers using an external applied magnetic field as shown in Figure 13 (Cobian, 2004). This allows one bath for all of the layers as long as the nanowires can be deposited inside a double-axes magnet.

8 CONCLUSIONS

About 10 years ago, Masuda and Fukuda discovered the self-ordered growth of nanoporous alumina membranes via anodization. Since this time, highly ordered anodized alumina has attracted many international groups as a template material for the synthesis of magnetic nanowires. Classical ferromagnetic materials, such as iron, cobalt, and nickel, as well as novel magnetic materials, such as CoPt and GaFe alloys, have been electrodeposited by constant or pulsed electrical signals inside the nanopores of these alumina membranes. The monodisperse nanowires are then in a strictly parallel hexagonal arrangement that is perpendicular to the substrate. The diameters have been tailored from 10 to 350 nm by varying the anodization conditions, such as electrolyte, voltage, and temperature.

The magnetic properties of the nanowires and arrays have been modified through the choice of material, diameter, spacing, and applied fields during growth. For Co nanowires the anisotropy has been controlled by balancing the strong crystallographic anisotropy of Co with the shape anisotropy of the wires. Multilayered nanowires of Co/Cu/Co with controlled anisotropy in the Co are well suited for magnetic sensors and magnetic random access memory (MRAM). For $Fe_{1-x}Ga_x$ alloys (Galfenol), the magnetostriction varies with composition, which has been controlled via deposition parameters. Nanowire arrays of Galfenol are essentially NEMS that can be used as cilia for sensors of acoustic and other mechanical signals. For Ni and NiMn nanowires, large coercivities have been obtained with weak dipolar interactions between wires due to small magnetocrystalline anisotropy and small magnetic moment. These materials are therefore particularly suitable for patterned perpendicular magnetic media.

Numerical simulations were presented that showed that the independent magnetization reversal of individual nanowires inside a close-packed array was possible. Also, perfectly ordered magnetic nanowire arrays have been demonstrated on the square centimeters scale by nanoimprinting the Al precursor prior to anodization. Significant improvement of the magnetic performance was obtained, because the nanomagnets had a very narrow size distribution, as well as perfect order.

The fabrication of large-scale, perfectly ordered nanowire arrays with sub-100 nm periodicity and very monodisperse magnetic nanowires with sub-10 nm diameters are still a great challenge, and further developments of these nanostructures are necessary. Also, the growth of novel magnetic materials, especially new alloys, will be a frontier for this field that must be reached in order to realize the potential of many applications. New applications continue to be developed, including multilayer nanotubes, self-assembled 3D nanostructures based on multilayer magnetic nanowires, nanowires with specific binding sites for molecules or DNA, and more. With many fundamentals understood, we are only seeing the tip of the iceberg in the impact of magnetic nanowires.

ACKNOWLEDGMENTS

We are grateful to T. Schweinböck, H. Kronmüller, S. F. Fischer, D. Weiss, D. Navas, M. Vazquez, Ryan Cobian, Patrick McGary, Liwen Tan, and Na hyoung Kim for support, experimental measurements, or fruitful discussions. We also like to thank Professor U. Gösele and Professor J. Kirschner for supporting this activity. Partial funding of some results was provided by the US Office of Naval Research and the US National Science Foundation, including the University of Minnesota's Materials Research Science and Engineering Center.

Magnetic Carbon

Pablo Esquinazi
University of Leipzig, Leipzig, Germany

1 INTRODUCTION

Not long ago, carbon allotropes like graphite, diamond, carbon nanotubes, and fullerenes were accepted to be basically diamagnetic. In Short, the diamagnetic signal is the counter-response to an applied magnetic field from localized electrons, as in diamond, or from delocalized π-band electrons, as in graphite for fields normal to the graphene layers, or from a mixture of the diamagnetism of localized electrons and the so-called van Vleck paramagnetic (magnetic dipole interband transitions due to the asymmetry of the chemical bond) contributions, as in fullerenes and nanotubes. This magnetic response was reviewed some years ago by Haddon (1995). On the other hand, it was a common belief that any ferromagnetic-like signal measured at room temperature in a carbon structure is due to magnetic impurities. Apart from a few publications at the end of the 1980s and in the 1990s (some of them will be reviewed in Section 2), the scientific community did not take the possibility that a carbon structure could show magnetic order at room temperature seriously. The main problem scientists have to convince themselves on such a phenomenon in a material with only s and p electrons is that magnetic impurities, like Fe or Ni, may contribute to the magnetic response substantially in case the 'intrinsic' magnetic signals are relatively small.

Paradoxically, the overall success of the pioneer model of ferromagnetism in metals contributed substantially to create some kind of 'magnetic prejudice' for more than 60 years. In his original article, Heisenberg (1928) rejected the possibility of magnetic order in elements with main quantum number $n < 3$ (for the electrons responsible for the ferromagnetism). Elements like Fe, Ni, or Co have a net magnetic moment $\mathbf{m}$ in the solid state due to unpaired 3d electrons. Through exchange interactions between them characterized by a constant J, compounds based on these elements belong to the restricted family of ferromagnets with Curie temperature above room temperature. In contrast, carbon in the atomic state has $\mathbf{m} = 0$ and in the solid state shows strong covalent bondings that suppress any unpaired-electron spin. It is therefore understandable that judging the 'sometimes unclear' experimental evidence in the past the possibility of magnetic order in carbon-based materials was tacitly denied by the main stream of scientists working in magnetism.

From the basic research point of view the existence of a room-temperature magnet containing only s and p electrons is of great significance for the physics of magnetism, especially because of the expected interesting correlation effects between electrons. We note that macroscopic magnetic order in metal-free organic materials has been reported in 1991 in the open-shell radical *p*-nitrophenylnitronyl nitroxide (*p*-NPNN) (Turek *et al*., 1991; Tamura *et al*., 1991) and

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

in tetrakis(dimethylamino)ethylene (TDAE) + C_{60} charge-transfer salt (Allemand *et al*., 1991) with Curie temperatures $T_c = 0.6$ and 16 K, respectively. These findings were recognized by the community, in clear contrast to the few, rather unnoticed works where evidence for magnetic order in carbon was reported before 1991 (see Section 2). A number of studies on molecular magnets with low Curie temperatures ($T_c < 30$ K) have been done in the last 10 years (Veciana, 2001; Blundell and Pratt, 2004). We also note that antiferromagnetic order has been observed in a material with only s or p electrons, as probably the first example for an s-electron antiferromagnet reported in the compound $(Na/K)_8(AlSiO_4)_6$ below 50 K by Srdanov, Stucky, Lippmaa and Engelhardt (1998) indicates; see also Madsen, Iversen, Blaha and Schwarz (2001).

To the best of our knowledge, we are not aware of any physical law that prohibits the existence of a room-temperature ferromagnet in a compound with only s or p electrons. Therefore, and taking into account experimental data, there are no reasons to deny *a priori* its existence. In this article we review in Section 2 a few early publications that indicate the possible existence of unusual magnetic order in carbon. In Section 3, we discuss the characterization of the magnetic impurities, an important issue when the intrinsic magnetic signals of the studied compounds are relatively weak. In Section 4, we review different magnetic phenomena observed in carbon structures, that is, diamagnetism (Section 4.1), paramagnetism (Section 4.2), as well as recent observations of magnetic order in well-characterized carbon-based samples prepared under special conditions (Section 4.3). In the last section of this article, we review the possible origins for a magnetic order in carbon, discussed nowadays in the literature.

2 EARLY REPORTS ON FERROMAGNETIC-LIKE BEHAVIOR IN CARBON STRUCTURES

Till the end of the last millennium nearly 100 papers and 30 patents describing ferromagnetic structures containing either pure carbon or carbon combined with first-row elements were published. Many of these publications, some of them unknown to the main stream of magnetism experts, was reviewed recently by Makarova (2003, 2004). Unfortunately, in several of these early published studies the concentration of impurities is not clarified, perhaps not even determined. Therefore, it is not easy to provide a rigorous evaluation for most of them, also because the reproducibility of those results was apparently not reported in later work. Taking into account the experience of the author with the contribution of magnetic impurities (mainly Fe), we cannot assume that those early observations were free from systematic errors. Nevertheless, some of these results attract our attention. In this section, we restrict ourselves to discuss chronologically only a few of them.

Apparently, one of the first room-temperature organic ferromagnets was synthesized by Oostra and Torrance (1984) and reported in a symposium that took place in Honolulu. Three years later, these authors published a paper in which they showed that the reaction of symmetrical triaminobenzene ($C_6H_9N_3$) with iodine produces a black, insoluble polymer. This polymer showed, in some of the runs, ferromagnetism up to ∼600–700 K, which is near its decomposition temperature (Torrance, Oostra and Nazzal, 1987). The observed magnetization in that sample remains unknown since only the magnetic moment was reported without providing any information on the sample mass or volume. Although some trace quantities of Fe were found, neither its amount nor the irreversibility observed with temperature, implies that magnetic impurities may be the possible source for the magnetism. Apparently, a lack of reproducibility of the results reported by these authors remained in the years to come.

Korshak *et al*. (1986) (see also Korshak, Medvedeva, Ovchinnikov and Spektor, 1987) found a spontaneous magnetization $M = 0.02\,\text{emu g}^{-1}$ ($1\,\text{emu g}^{-1} = 1\,\text{Am}^2\,\text{kg}^{-1}$) in a chain of interacting radicals obtained by polymerization of a BIPO polydiacetylene crystal (BIPO: 1,4-bis-(2,2,6,6-tetramethyl-4-oxy-4-piperidyl-1-oxyl)-butadiene). The apparent magnetic order vanished at temperatures between 420 and 460 K. The value reported for the spontaneous magnetization is not high enough to assure negligible contributions from transition-metal impurities. However, the relatively low, apparent Curie temperature of less than 500 K does not imply pure iron or iron oxide (magnetite) magnetic contribution. One cannot rule out, however, that an Fe–C or another magnetic element–C alloy may show such a Curie temperature.

An extraordinary saturation magnetization value of $M_s \sim 150\,\text{emu g}^{-1}$ was reported [1] by Ovchinnikov and Spector (1988) for the pyrolytic decomposition at 1300 ± 100 K of polyacrylonitril (PAN) with a Curie temperature near 800 K. The impurity concentration reported in that publication does not seem to account for the large magnetization value. To the best of our knowledge, apparently nobody could reproduce those results.

Murata, Ushijima, Ueda and Kawaguchi (1991) measured the magnetization of amorphous-like carbons prepared from tetraaza compounds by chemical vapor deposition (CVD) method. The starting, commercially available materials (tetraaza) were organic monomers with different amounts of carbon, hydrogen, and nitrogen. The carbon-based material was heated in vacuum at 950 °C for 30 min. The aza-carbon

showed a remnant magnetization value (measured not at 0 but at 50 Oe applied field) $M_r \simeq 0.45\,\text{emu g}^{-1}$ at room temperature. Murata, Ushijima, Ueda and Kawaguchi (1991) further showed that at room temperature M_s increased as a function of the ratio between hydrogen and carbon (H/C) of the starting material. For H/C $\simeq$ 2.8 the authors obtained $M_s \simeq 2\,\text{emu g}^{-1}$. Although this work gave no information on the impurity concentration in the final samples, the systematic increase of M_s with H/C does not seem to support an impurity magnetic contribution. The role of hydrogen on the magnetic order was not clear.

The same authors (Murata, Ushijima, Ueda and Kawaguchi, 1992) later showed that the amorphous-like carbon compound prepared by direct pyrolysis of 1,2-diaminopropane (H/C = 3.3) was ferromagnetic with $M_s \simeq 10\,\text{emu g}^{-1}$ at room temperature (a factor 10 smaller than magnetite Fe_3O_4) (see Figure 1). A complete elemental analysis of impurities for the magnetic sample was not reported in that work, but only 3 wt% nitrogen and an unknown amount of hydrogen. If we assume that the signal is due to Fe impurities, then to obtain a magnetization at saturation of $10\,\text{emu g}^{-1}$ the carbon sample should have several weight percent of Fe! Not only does this number appear to be too large but the temperature dependence of the magnetization (see Figure 1) does not also show any sign of magnetism of small ferromagnetic particles, nor a Curie or Curie–Weiss behavior. The superparamagnetism effect is expected in case the Fe (or Fe_3O_4) grains are small enough and are randomly distributed in the sample. It shows a strong temperature dependence in the magnetization for fields of the order of those shown in Figure 1. As an example for superparamagnetism of Fe in carbon, see Figure 9 in Esquinazi *et al*. (2002) where a graphite crystal with an average Fe concentration of $500\,\mu\text{g g}^{-1}$ has been measured. The observed dependence is in clear contrast to that in Figure 1 as well as in highly oriented pyrolytic graphite samples with concentrations of Fe impurities in the $10\,\mu\text{g g}^{-1}$ region (Esquinazi *et al*., 2002).

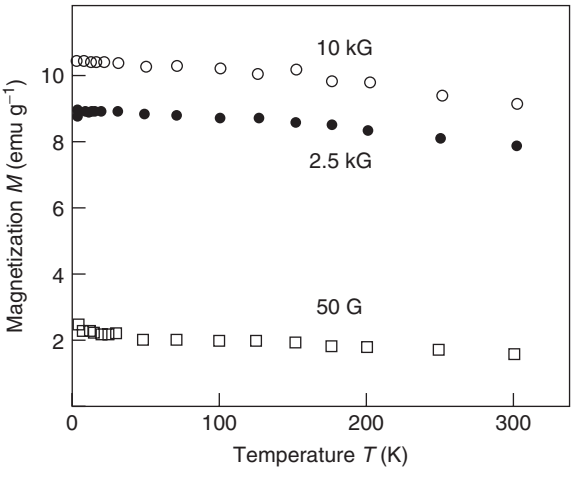

Figure 1. Temperature dependence at three different applied fields of the magnetization of an amorphous-like carbon compound prepared by direct pyrolysis of 1,2-diaminopropane with a ratio between hydrogen and carbon, H/C = 3.3. (Reproduced from Murata *et al*. 1992, with permission from the Royal Society of Chemistry. © 1992.)

Murata, Ushijima, Ueda and Kawaguchi (1992) speculated that atomic hydrogen may have led to the formation of a three-dimensional network of both sp^3- and sp^2-carbons, which according to theoretical predictions (Ovchinnikov and Spector, 1988) (see also Section 5) may originate a spin-ordered state in the (dangling) π electrons from the sp^2-carbons. As Murata, Ushijima, Ueda and Kawaguchi (1991) and Mizogami, Mizutani, Fukuda and Kawabata (1991) observed, ferromagnetic behavior in pyrolytic carbon is obtained from adamantane as a raw material by CVD method under low-temperature growth. Clear hysteresis loop was observed at room temperature. The authors stressed that the highly oriented structure and a large number of unpaired electrons appeared to play an important role in the observed ferromagnetism. Ferromagnetic impurities like Fe were not detected within experimental accuracy.

An interesting experiment was performed by Murakami and Suematsu (1996) inducing magnetic ordering in fullerene C_{60} crystals exposing them to light irradiation from a xenon lamp in the presence of oxygen. Before irradiation the pristine fullerene crystals showed the usual temperature-independent diamagnetic signal with a susceptibility $\chi \simeq -2.7 \times 10^{-7}\,\text{emu (gOe)}^{-1}$, state (a) in Figure 2. This diamagnetism is overwhelmed by a para- and ferromagnetic response after irradiation of the sample under xenon light in oxygen for 2.5 h, state (b) in Figure 2. After annealing the sample (after state (b)) at 400 °C in vacuum to remove physisorbed oxygen (O_2, usually the origin for the paramagnetic response in some carbon-based samples) the paramagnetic contribution decreased but an enhancement of the ferromagnetic-like contribution was observed, state (c) in Figure 2. After leaving the sample in air for three months, the ferro- and paramagnetic contributions increased as can be seen in Figure 2, state (d). Figure 3 shows in more detail the ferromagnetic hysteresis loop of the C_{60} crystal in the state (c) at room temperature. Note that the magnetization plotted in the figures were calculated by dividing the measured magnetic moment by the total sample mass and not by the ferromagnetic mass of the sample. The authors separated the ferromagnetic part from the sample and obtained an increase of 100 in the magnetic moment ($0.1\,\mu_B$) per C_{60} molecule.

From the work of Murakami and Suematsu (1996) the following is worth noting. (i) The temperature dependence of the saturation magnetization indicates an extraordinarily high

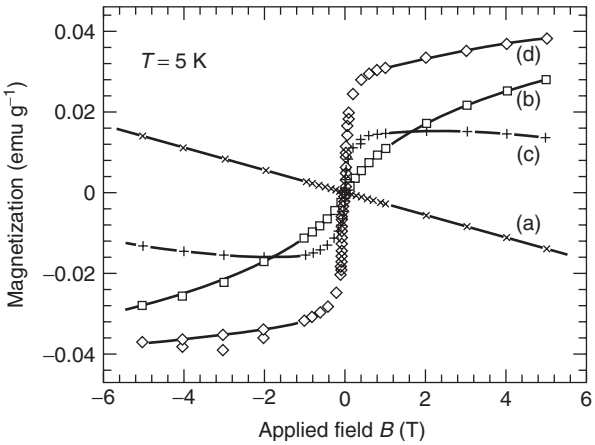

Figure 2. Magnetic field dependence of the magnetization at 5 K for (a) a pristine C_{60} powder crystals, (b) the same sample exposed to xenon light in oxygen for 2.5 h, (c) after annealing it at 400 °C for 2.5 h and (d) after leaving it in air for three months. Curie temperature $T_c \sim 800$ K. (ii) No elemental analysis of the samples at the different preparation steps were reported in that work, although with the used procedure one does not expect the introduction of impurities. On the other hand Makarova *et al*. (2003) recently reported similar effects by photopolymerization of fullerene films (see Section 4.3.2). (iii) The temperature dependence of the magnetic moment at fixed fields shows the contribution of small particle magnetism, which is in part the origin for the Curie-like term measured at low temperatures ($T < 40$ K). (iv) The room-temperature hysteresis loops (see Figure 3) indicate a saturation field of the order of 2 kOe and a remanence magnetization of the order of 10% of its saturation value. It is remarkable that similar values are also obtained for different ferromagnetic carbon-based samples produced by different methods (see Section 4.3). From this study it remains unclear whether polymerized fullerene or a disordered graphitic structure is responsible for the observed magnetic order.

For completeness we also note the reports on the ferromagnetic behavior of micrographitic structures with high surface area ($\sim 3110\ m^2\ g^{-1}$) (Ishii, Matsumura and Kaneko, 1995; Ishii, Shindo and Kaneko, 1995). The magnetic properties of activated mesocarbon microbead (a-MCMB) were examined over the temperature range 1.7–285 K. Magnetic hysteresis and a saturation and residual magnetization of 0.032 and 0.016 emu g^{-1} at 1.7 K were observed. Although the magnetic hysteresis loop became small while increasing temperature, it still remained at 285 K. The Fe impurity concentration was 80 ppm. In the case that this quantity of Fe would be ferromagnetic at low temperatures one expects a saturation magnetization at least two times larger than the measured one. Therefore, neither the absolute values of the measured magnetization nor its temperature dependence (Ishii, Matsumura and Kaneko, 1995) can be taken as evidence against an extrinsic origin for the observed magnetism. Although low-surface-area carbon ($570\ m^2\ g^{-1}$) showed no ferromagnetism (Ishii, Shindo and Kaneko, 1995), the unknown impurity contribution always casts a doubt and this is the main reason for the scepticism and the lack of interest that the scientific community showed in the past on all the results involving magnetic order in metal-free materials.

3 MEASUREMENT OF THE IMPURITY CONCENTRATION

There are several methods for a quantitative determination of the impurity concentration of a sample. They are as follows: (i) Particle-induced X-ray emission (PIXE). This is a standard-free, quantitative, nondestructive multielemental analysis, which provides a 0.1–100 μg g^{-1} detection limit depending on the matrix and element to be analyzed. It requires a proton beam in the megaelectron volt energy range. (ii) Energy dispersion X-ray (EDX) analysis spectroscopy using electrons. This method is similar to PIXE. However, its detection limit is at least a factor of 100 larger due to strong bremsstrahlung background. (iii) X-ray fluorescence (XRF) analysis. This method is similar to PIXE; however, for bulk analysis a large sample mass >100 mg is required for good sensitivity. XRF microbeam usually requires a synchrotron.

(iv) Methods like Inductively-Coupled-Plasma-Spectrometry (ICP-MS), Secondary Neutral Mass Spectrometry (SNMS), and Secondary Ion Mass Spectroscopy (SIMS) need standard samples for quantification. Very low detection limits can be achieved, depending on the element to be analyzed. The disadvantage is, however, that these methods are destructive. (v) Neutron activation analysis (NAA) is a very sensitive method but needs a relatively large amount of sample and a (large) neutron source to make the nucleus of the impurities radioactive. A study that was recently done has checked the accuracy of the PIXE method by comparing its results with those obtained from XRF and NAA on the same samples. Very good agreement has been found between the three methods (Barzola-Quiquia *et al*., 2007).

For carbon-based materials the preferred method is PIXE. It uses protons to get a map for all relevant impurity elements within a sample depth of 30 µm for a proton energy of ∼2 MeV in carbon. A systematic and full characterization of the magnetic impurity content in each of the samples, and after each treatment or handling (it makes no sense to start with a highly pure sample and then cut it with a steel knife afterwards), is of primary importance and absolutely necessary specially because in several samples, due to their small magnetization and/or small mass, the magnetic moment at saturation is very small ($m_s \lesssim 10^{-5}$ emu). The reader can get more details on this method in the papers by Butz *et al*. (2005) and Esquinazi *et al*. (2006). Here we would like to make a few remarks. A total charge of 0.5 µC suffices to obtain with a proton microbeam a minimum detection limit for Fe impurities below 1 µg g^{-1}. The advantage of using a microbeam for PIXE analysis, compared to a broad beam, is that a distribution map for all relevant impurity elements can be obtained contrary to the integral value from the broad-beam method, which is a rather important issue considering the grossly inhomogeneous distribution of impurities like Fe which we have encountered in some samples (see, e.g., Figure 1 in Spemann *et al*., 2003). A typical broad-beam PIXE spectrum for a highly oriented pyrolytic graphite (HOPG) sample is shown in Figure 4. It shows the presence of a number of impurities, the Fe content being (0.45 ± 0.04) ppm. Taking into account experimental (see Sections 2 and 4.3) as well recent theoretical studies (see Section 5), hydrogen, as well as oxygen, may be related to the origin of the magnetic signals in carbon-based materials. However, hydrogen content measurements with a sensitivity in the parts per million range are a rather difficult experimental task. Butz *et al*. (2005) briefly discuss the methods available for this kind of measurement.

A recent study done by Reichart *et al*. (2006) using a proton–proton scattering method analyzed the hydrogen distribution of pristine as well as irradiated HOPG samples, which were implanted with micrometer-sized spots and

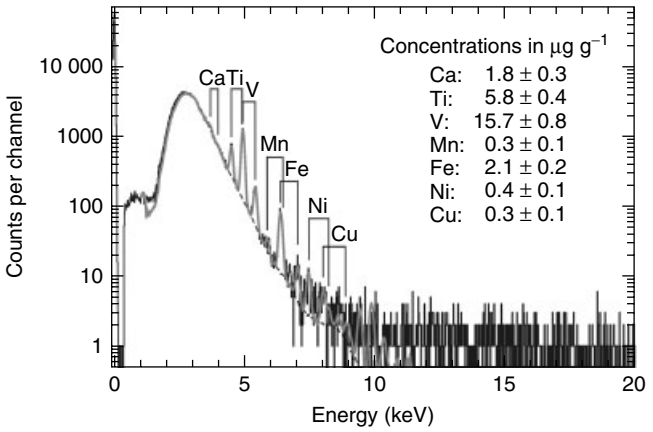

Figure 4. Typical broad-beam PIXE spectrum from a HOPG sample. The main impurities are Ti, V, and Fe. The minimum detection limit for other elements heavier than Si is ∼0.3 µg g^{-1}. Note that 2.1 µg g^{-1} iron in the carbon matrix means a concentration of 0.45 ppm Fe. (Reproduced from T. Butz *et al*., 2005, with permission from Springer. © 2005.)

extended areas with various doses of 2.25 MeV protons at the Leipzig microprobe LIPSION (see Section 4.3.3). For this study a sensitive three-dimensional hydrogen microscopy system at the Munich microprobe SNAKE was used. The background hydrogen level in pristine HOPG was determined to be about 0.3 at-ppm. About 4.8×10^{15} H atoms/cm^2 were observed in the near-surface region (∼4 µm-depth resolution). The depth profiles of the implants showed hydrogen located within a confined peak at the end of the penetration range, in agreement with SRIM Monte Carlo simulations and no evidence of diffusion broadening along the *c* axis. For the sample with microspots, up to 36 at-% of the implanted hydrogen was not detected, providing support for a lateral hydrogen diffusion.

3.1 The role of iron

Iron is usually the main magnetic impurity that one finds in carbon-based materials. Owing to its relatively large para- and ferromagnetic contributions, the measurement of its concentration is of main importance. As an example and assuming that 1 µg Fe per gram carbon for a sample with the density of graphite would be ferromagnetic, its contribution would be $\simeq 2.2 \times 10^{-4}$ emu g^{-1} to the magnetization in the case of Fe clusters or $\simeq 1.4 \times 10^{-4}$ emu g^{-1} in the case of Fe_3O_4 clusters. Usually such small amounts of impurities are diluted in the sample and one does not measure a ferro- but a paramagnetic or superparamagnetic behavior because of small particle magnetism. For an example see Figure 9 in Esquinazi *et al*. (2002) where the magnetization of a graphite sample with an average concentration of Fe ∼500 µg g^{-1}

has been measured. Instead of a ferromagnetic behavior, a superparamagnetic-like behavior was measured with a strong temperature dependence. From the saturation of the magnetic moment at very high fields and low temperatures one can estimate that $\sim 840\,\mu g\,g^{-1}$ Fe in the graphite matrix contributes to the magnetic response. Interestingly, this relatively large amount of Fe in carbon did not show ferromagnetism. Nevertheless, the influence of ferromagnetic impurities, specially that of Fe and magnetite (Fe_3O_4), has to be carefully checked because the ferromagnetic signals of the carbon-based samples are (still) relatively small.

Measurements of the magnetization of graphite nodules from a meteorite (Coey *et al*., 2002) and of the magnetic force gradients of carbon nanotubes in contact with ferromagnetic substrates (Cespedes *et al*., 2004) suggest that magnetic ordering in graphite might be induced by a proximity effect. A relatively large magnetization-decay length (identical to the spin-diffusion length) $\lambda_s \approx 5\,nm$ was estimated for the graphite–magnetite interface by Coey *et al*. (2002). However, there is no direct evidence yet for such a large magnetization-decay length. Local ferromagnetism in C/Fe multilayers was observed by resonant magnetic reflectivity of circularly polarized synchrotron radiation (Mertins *et al*., 2004). The thickness of the carbon layers was 0.55 nm in comparison with 2.55 nm for the Fe layers. Taking into account an average roughness of 0.35 nm at the interface where a mixture of C and Fe exists, the induced ferromagnetism appears within a penetration depth of less than 0.5 nm. This result would agree with the results of Höhne, Ziese and Esquinazi (2004) in which by studying the magnetization of graphite–magnetite composites a $\lambda_s \lesssim 0.4\,nm$ was inferred with no indication of an induction of bulk ferromagnetism in graphite through the contact with magnetite. More experiments are necessary for a conclusion about the existence of a large magnetic proximity effect in certain carbon structures.

4 MAGNETIC STATES IN CARBON STRUCTURES

4.1 Diamagnetism

Usually, a diamagnetic signal is measured in carbon-based materials. The absolute value of this signal depends on the contribution of the core electrons, valence electrons, and a van Vleck paramagnetic term mentioned in the introduction. The total susceptibility of natural IIa diamond single crystal at room temperature is $\chi \simeq -5.9 \times 10^{-7}\,emu\,(gOe)^{-1}$. This value is only a few percent from that of oriented graphite, which shows the largest diamagnetic susceptibility for fields applied parallel to the *c* axis. In a simple but successful model the diamagnetic response is proportional to an effective area of the electronic current loop (see Haddon (1995) and references therein). Therefore, one can derive an effective radius for the electronic circulation, which goes from the closed-shell atom confinement as in diamond to current flows along several bonds in conjugated rings. With this concept it is possible to understand the increase in the ring π electron's current diamagnetic response for planar aromatic organic compounds. To understand the susceptibility of fullerenes, however, a constrained movement of the π electrons and the van Vleck paramagnetic contribution should be taken into account.

Owing to the increasing importance of single-wall and multiwall carbon nanotubes in basic and applied research, there has been a renewed interest in the properties of oriented graphite. Interestingly, the transport and magnetic properties of graphite are still not well understood (see, e.g., Kopelevich *et al*. (2003a) and references therein). Measurements of highly oriented pyrolytic graphite samples with rocking curve width at half maximum full-width half-maximum (FWHM) $\leq 0.4^\circ$ provide a value for the susceptibility $\chi_{||} = -(2.4 \pm 0.1) \times 10^{-5}\,emu\,(gOe)^{-1}$ at 300 K and for fields applied parallel to the *c* axis (Esquinazi *et al*., 2002). This large diamagnetism stems from 'fast-moving' electrons (McClure, 1956) with a small effective mass $m^* \sim 0.05\,m_0$ (here m_0 is the free electron mass). Within a tight-binding picture the small effective mass is due to the large π-bonding overlap of the neighboring C atoms in a single layer given by the band parameter $\gamma_0 \propto 1/m^*$. For the calculation of χ the linear dispersion relation for two-dimensional (2D) graphene $E(k) \propto k$ was assumed (Wallace, 1947). The main contribution to the T-dependence of $\chi(T)$ at $T \gtrsim 150\,K$ is given by $\partial f/\partial E|_{E=E_F}$ (f is the Fermi–Dirac distribution function) due to the condensation of fermions into the Landau level with $n = 0$ after the application of a magnetic field (McClure, 1956). Although experimental results are, in general, in agreement with this theory, to explain the saturation of $\chi(T)$ at low T a series of additional band parameters has to be included (see Dresselhaus *et al*. (1988) and references therein). We note, however, that this further developed theory does not account for the measured anisotropy of the g factors (Dresselhaus *et al*., 1988).

High-resolution magnetization measurements in different HOPG samples indicate that at low temperatures χ does not saturate but has a shallow, well-defined and field-dependent minimum at $T \lesssim 30\,K$ (see, e.g., Kopelevich, Lemanov, Moehlecke and Torres, 1999; Huber, Urbano, Sercheli and Rettori, 2004). This minimum is not due to magnetic impurities. The origin for this minimum is not yet clarified and no attempt has been made to check whether it is compatible with elaborate theories for the diamagnetism in graphite.

Owing to the available sample quality, the measurement of the anisotropy in the carrier diamagnetism of graphite is difficult. Taking into account recent measurements of the electrical anisotropy that indicates a ratio (parallel to perpendicular to the c axis) of the order of or larger than 10^4 for well-ordered samples, we expect to have a susceptibility $|\chi_\perp|$ smaller than the atomic susceptibility $|\chi_{at}|$ of carbon in graphite, which is of the order of $|-5 \times 10^{-7}|$ emu (gOe)$^{-1}$ according to literature. We have to also take into account internal misalignments of the crystallites in the sample. At room temperature and for a sample with FWHM $= 0.4^\circ$, owing to the $\chi_{||}$ component a value of the order of $|-1.7 \times 10^{-7}|$ emu (gOe)$^{-1}$ would be measured for fields applied nominally parallel to the planes. The effect of this internal misalignment has been verified by electrical conductivity measurements (Kempa, Semmelhack, Esquinazi and Kopelevich, 2003).

4.2 Paramagnetism in disordered carbon

The response of free, independent magnetic moments under an applied magnetic field B and without interaction between them gives rise to paramagnetism. As a function of field and temperature the magnetization M due to this effect follows the Brillouin function $B_J(y)$ where J is the total angular moment of the magnetic ion and $y \propto B/k_B T$. For $y \ll 1$ the susceptibility $\chi = M/B$ follows the Curie law $\chi = C/T$, C, being the Curie constant. At low-enough temperatures the paramagnetic response follows a s-like curve with saturation of M at high-enough magnetic fields, that is, at $y \gg 1$. This kind of behavior is observed in carbon samples when some kind of disorder exists. In disordered carbon structures, apart from the intrinsic van Vleck paramagnetism due to nonspherical potential, paramagnetic signals due to localized spins from unpaired electrons associated with the existence of broken σ-dangling bonds or the mixture of sp^2–sp^3 bonds are measured. In this case the density of paramagnetic centers is related to the disorder of the carbon structure. Interestingly, in earlier work (see Delhaès and Carmona (1981) and references therein) this density was also correlated with the hydrogen concentration. Although this paramagnetic phenomenon is well known one should not confuse it with the s-like response of ferromagnets. In general the paramagnetic response follows a Curie law (it scales with H/T) and shows no hysteresis in the magnetization loop.

According to theoretical work zigzag (Fujita) edges of ordered graphene layers may also contribute to the paramagnetic response due to electron spin localization at the sp^2 free bond of the edge carbon atoms (Fujita, Wakabayashi, Nakada and Kusakabe, 1996). Although no direct evidence for this contribution has been reported yet, scanning tunneling microscopy (STM) measurements on this kind of edges indeed indicate an increase in the electronic density of states (Esquinazi *et al*., 2002; Kobayashi, Fukui, Enoki and Kusakabe, 2006) as predicted.

If we increase the disorder in a graphite structure the main diamagnetic signal decreases in absolute value and turns paramagnetic when the disorder is large enough. An example of this behavior can be seen in Figure 5 where the temperature dependence of the magnetization of a target made of an ultrapure graphite powder and of the material obtained from disordered carbon films prepared by pulsed-laser deposition (PLD) on Si substrates are shown (Höhne *et al*., 2004b; Esquinazi and Höhne, 2005).

In general, disordered carbon material shows a Curie-like dependence added to a Pauli-like contribution (T-independent paramagnetism) (see Figure 5). The inset in Figure 5 shows the field dependence of the magnetization for the carbon film material at 5 K. These data can be described by the classical Langevin expression from which we obtain a spin density $n_s \sim 10^{19}\,g^{-1}$. Annealing the disordered carbon material at 1000 °C for 10 h in vacuum clearly reduces the temperature-dependent paramagnetic part (see Figure 5). Note that the observed behavior with annealing is not in favor of a magnetic impurity contribution. Within experimental

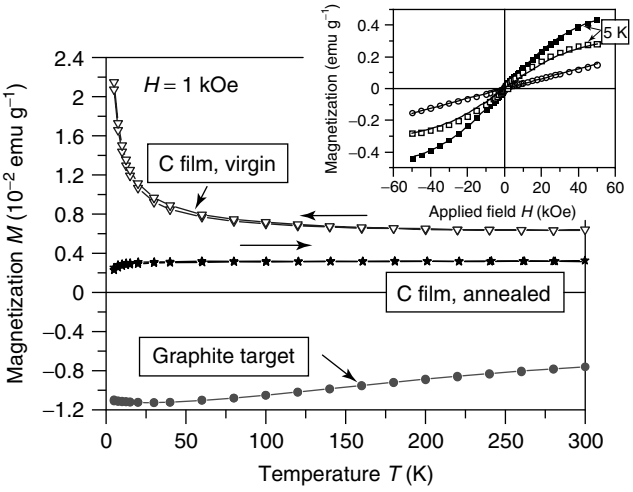

Figure 5. Temperature dependence of the magnetization at 1 kOe obtained for graphite target made from an ultrapure graphite powder and disorder carbon films, before and after annealing at 1000 °C for 10 h in vacuum. Inset: Field dependence of the magnetization of the carbon films at 5 K (■), and after subtraction of the Pauli-like term (□) given by the straight line through the points (○) $M = 3.1 \times 10^{-6} H$ emu (gOe)$^{-1}$ where H is the applied field in oersted. In the scale of the figure the Pauli-like magnetization curves measured at 300 K (before and after annealing) and at 5 K (after annealing) (○) practically coincide. The continuous lines through the points (■, □) are fits to the classical Langevin expression. (Reproduced from Esquinazi *et al*., 2005, with permission from Elsevier. © 2005.)

Table 1. Paramagnetic-like properties of disordered carbon samples at different years. The samples are (a) different noncrystalline carbons (Delhaès and Carmona, 1981), (b) activated carbon fibers (low-T annealing) (Shibayama, Sato, Enoki and Endo, 2000), (c) PLD-carbon films (nonannealed) (Höhne *et al*., 2004b), (d) Nanofoam (Rode *et al*., 2004), and (e) PLD-carbon films (nonannealed) (Takai *et al*., 2004).

Year	. . .1981	2000	2003	2003	2004
Sample	(a)	(b)	(c)	(d)	(e)
$n_s(g^{-1})$	10^{19}–10^{20}	$\sim 4 \times 10^{19}$	$\sim 2 \times 10^{19}$	$\sim 10^{20}$	$\sim 2 \times 10^{20}$
M_s(emu g^{-1})	$\lesssim 0.5$	~ 0.2	~ 0.4	~ 0.35	~ 1.5

n_s: spin density; M_s: magnetization at saturation measured at $T < 10$ K.

error the hysteresis loops for the disordered carbon films above 5 K are reversible. This indicates that a disordered mixture of sp^2–sp^3 bonds, which exists in the disordered carbon films, does not automatically trigger ferromagnetism.

A quick look at the published literature shows that the paramagnetic response of disordered carbon is a 'time-independent' general phenomenon. Table 1 shows the spin density n_s and the magnetization at saturation M_s of very different disordered carbon samples. In their virgin, nonannealed states, carbon fibers, nanofoams, or amorphous carbon films prepared by PLD, show similar values for both n_s and M_s and their overall behavior as a function of temperature follows a Curie-like dependence added to a Pauli-like contribution. One should be careful to associate magnetic ordering to this paramagnetic response. Nevertheless, at low-enough temperatures and for high-enough spin density nonsimple magnetic behavior was reported in nanofoams (Rode *et al*., 2004; Arčon *et al*., 2007) where a small ferromagnetic-like hysteresis loop was superposed to the main paramagnetic response. Also, the observed behavior of some activated carbon fibers (Shibayama, Sato, Enoki and Endo, 2000) or nanographite (Enoki and Takai, 2006) suggests that interactions between localized spins may exist. The localized spins at the edges can have an exchange interaction between them mediated by π electrons. The paramagnetic response of disordered carbon is being rediscovered nowadays owing to its sensitivity to guest molecules. It is believed that physisorption of guest molecules in the micropore space of nanographite (or nanofoam) network can produce a magnetic switching effect of the edge-state spins, an effect that can be used for molecular device applications of nanographite as gas-sensing probe (Enoki and Takai, 2006).

4.3 Magnetic order

At the beginning of this millennium there were a few new reports on magnetic order in carbon-based structures that began to finally attract the interest of the community. In this section we will review mainly those works published since the year 2000.

4.3.1 In highly oriented pyrolytic graphite

According to theoretical ideas that are described in Section 5 a perfect graphite sample should show nil or at most very weak ferro- or ferrimagnetic signal. In fact well-annealed graphite powder of high purity and high degree of orientation (which indicates a small defect density) does not show any evidence for such a phenomenon within experimental accuracy. Most, but not all, of the oriented bulk graphite samples, however, show weak ferromagnetic-like signals. It should not be surprising if somebody measures a non-ferromagnetic-like signal in an oriented graphite sample, because this signal depends on the properties of each sample. In general, the measurement of these signals is not simple since their magnitude is overwhelmed by the giant diamagnetic one. The subtraction of this diamagnetic contribution is, in general, simple since it depends linearly on applied field. However, for the signal levels we are discussing (ferromagnetic-like magnetic moment of the order of 10^{-5} emu or less; see, e.g., Esquinazi *et al*. (2002)) the available magnetometers (in general superconducting quantum interference devices, SQUIDs) may produce in some cases hysteresis curves that do not come from the samples but are artifacts of different origins. One should spend enough time to characterize those artifacts.

After a first report on ferromagnetic- and superconducting-like behavior in the magnetization of some HOPG samples by Kopelevich, Esquinazi, Torres and Moehlecke (2000) Esquinazi *et al*. (2002) studied in detail several HOPG samples from different sources with concentration of Fe impurities between $<0.3\,\mu g\,g^{-1}$ and $\sim 19\,\mu g\,g^{-1}$. The concentration of other magnetic metallic impurities were below $2\,\mu g\,g^{-1}$. Figure 6(a) shows that the magnetization at 2 kOe, after subtraction of background contributions, does not show a correlation with the Fe concentration. The results also indicate that the ferromagnetic-like hysteresis loops are weakly temperature dependent between 5 and 300 K, see inset in (b). A naive estimate assuming that the Fe concentration behaves as ferromagnetic Fe- or Fe_3O_4-bulk in the carbon matrix would give the two lines shown in Figure 6(a). Except for three HOPG samples the others show magnetization values below the ones expected from those lines. This figure clearly shows how much care is needed with the sample handling in all these studies. The assumption that such a small amount of Fe distributed in the carbon matrix behaves ferromagnetically is not consistent with the behavior we observed in graphite samples with much larger Fe concentrations (Esquinazi *et al*., 2002) nor in 4d–5d metals, where paramagnetism as well as

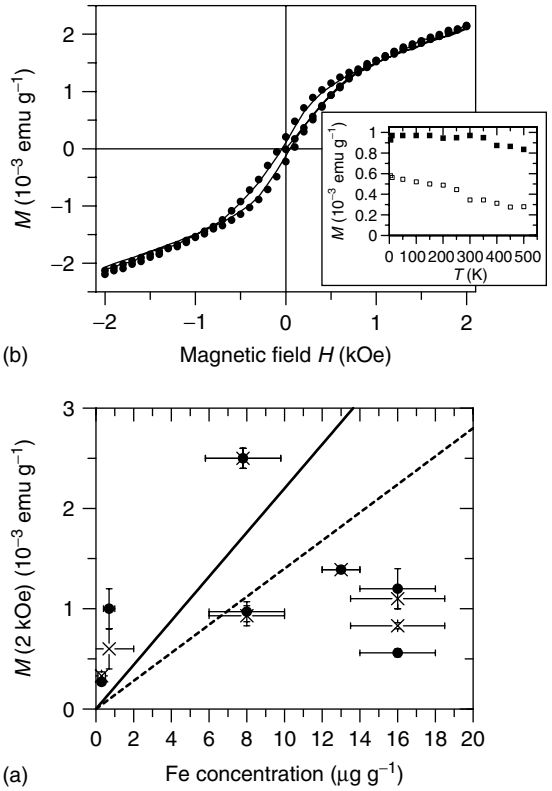

Figure 6. (a)Magnetization at 2 kOe as a function of Fe concentration at two temperatures ((*X*): 300 K, (●): 5 K) for different HOPG and Kish graphite samples. The solid line represents the expected magnetization if Fe contained in the samples was in a ferromagnetic state. The dashed line represents the analogous relation for Fe_3O_4. (b) Hysteresis loops at 5 K (●) and 300 K (continuous line) of a HOPG sample (FWHM $\sim 1.3^\circ$) for fields applied parallel to the graphene planes. No background was subtracted from the data. The inset shows the T-dependence of the magnetization at saturation (■) and its remanence (□) after annealing for 16 h at 700 K. (Reproduced from Esquinazi *et al*., 2005, with permission from Elsevier. © 2005.)

spin glass behaviors are measured for Fe concentrations of $\sim$100 ppm or larger (Peters *et al*., 1984).

Figure 6(b) shows two hysteresis loops for a HOPG sample. We note that in this field range no sign of diamagnetism is measured but a paramagnetic behavior is added to the hysteresis. This is one of some fortuitous cases where the diamagnetic component is small enough owing to the small misalignment of the sample in the SQUID. The observed behavior in Figure 6 is in clear contrast with the T-dependent paramagnetic contribution measured in samples with a larger amount of Fe impurities (Esquinazi *et al*., 2002). The reason for the temperature-independent (between 5 and 300 K) Pauli-like paramagnetism is probably related to the intrinsic lattice disorder as in disordered carbon samples (see Section 4.2). The results shown in Figure 6 belong to a relatively disordered HOPG sample with FWHM $\simeq 1.3^\circ$ and a Pauli-like susceptibility $\chi \sim 5 \times 10^{-7}$ emu (gOe)$^{-1}$, smaller than that obtained for disordered carbon $\chi \sim 3 \times 10^{-6}$ emu (gOe)$^{-1}$ (Höhne *et al*., 2004b). We expect that by increasing the lattice disorder a Curie-like paramagnetic contribution will appear. The overall results suggest that special lattice disorder and probably the influence of a light atom like hydrogen may be related to the origin of the observed ferromagnetism. A review of the recent theoretical ideas on this topic is given in Section 5.

4.3.2 In fullerenes

Reports on magnetic order in fullerenes, either pressure polymerized (Makarova *et al*., 2001; Wood *et al*., 2002; Narozhnyi *et al*., 2003), hydrofullerite $C_{60}H_{24}$ (Antonov *et al*., 2002) or photopolymerized fullerene powder and films in the presence of oxygen (Makarova *et al*., 2003) triggered a renaissance of interest in the magnetism in carbon structures. Neutral C_{60} can be polymerized into phases in which the cages are linked by cyclic C_4 units by photoirradiation, an electron beam, or by pressure. Polymerized fullerenes can exist in a variety of one-, two-, or three-dimensional phases. According to the original reports, polymerization of C_{60} at temperatures and pressures near the cage collapse and graphitization of the anisotropic 2D rhombohedral Rh-C_{60} phase leads to ferromagnetism with $T_c \gtrsim 500$ K (Makarova *et al*., 2001; Wood *et al*., 2002; Narozhnyi *et al*., 2003). The systematic work of Wood *et al*. (2002) indicates a maximum in the magnetization for samples prepared at conditions near the cage collapse. We should note, however, that neither the amount of magnetic samples nor the studied condition-parameters range (temperature, pressure, and time) are sufficient to give a clear phase diagram for the occurrence of ferromagnetism in polymerized fullerenes. There is not enough experimental evidence that assures that the magnetic order does depend primordially on a specific lattice structure of the polymerized fullerene. This fact added to the non-negligible impurity concentration (see below in this section) found in those samples (Spemann *et al*., 2003) casts doubts about the intrinsic nature of most of the ferromagnetic signals (Höhne and Esquinazi, 2002). The measured Curie temperature for the pressure-polymerized samples E16 and E17 was 500 K (Makarova *et al*., 2001; Höhne and Esquinazi, 2002). Samples prepared in a similar way, however, revealed Curie temperatures above 800 K (Wood *et al*., 2002; Narozhnyi *et al*., 2003).

Four pressure-polymerized phases have been identified as rhombohedral (Rh), tetragonal (T), orthorhombic (O), and dimeric (D) phases (Davidov *et al*., 2000). The details of the $p - T$ phase diagram are rather complicated and can be seen in Figure 18 in the review of Makarova (2004). The R phase is thought to be stabilized between 700 and $\sim$1100 K in the

pressure range between ∼3 and ∼9 GPa. The speculation that the magnetism in polymerized fullerene is related to the Rh structure near the cage collapse at the phase transition line between rhombohedral and disordered structure, as depicted in Makarova *et al*. (2003) and Makarova (2003, 2004), cannot be confirmed at present. The polymerized samples studied by Makarova *et al*. (2001) and Höhne and Esquinazi (2002) (with the names E16, E17, and E20) were actually produced at 1125 K (T phase with disordered graphite), 973 K (mostly Rh phase), and 1073 K (Rh phase with disordered graphitized fullerite) and at pressures of 2.5 and 6 GPa where this last pressure corresponds to the last two samples; see also Makarova *et al*. (2005).

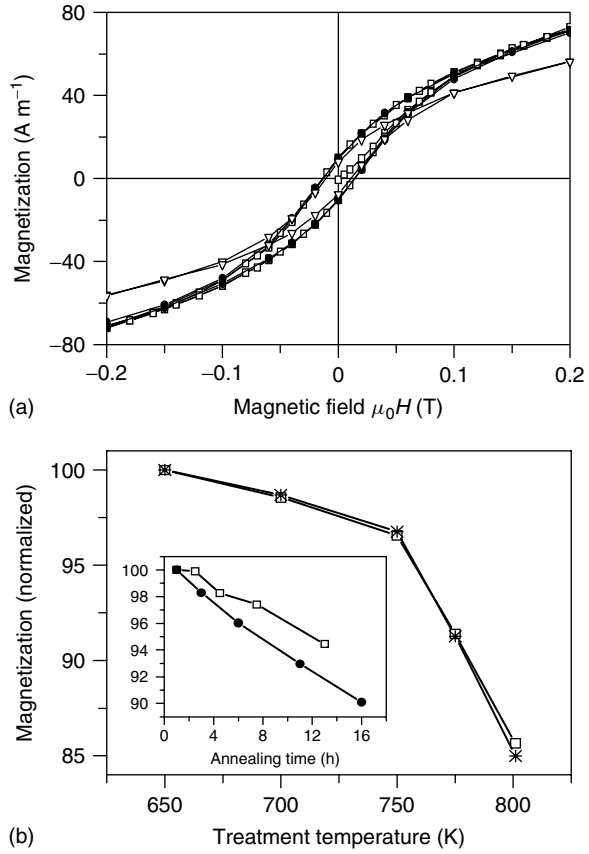

Figure 7. (a) Hysteresis loops of the magnetization measured at $T = 400$ K in the virgin state (□), and after heat treatment for 3 h at 700 K (●) and for 16 h at 800 K (▽). To convert the magnetization unit A m^{-1} into emu g^{-1} divide the first by the density of the sample $\sim 1.75 \times 10^3$ kg m^{-3}. (b) Magnetization values measured at 400 K in magnetic fields of 0.2 (□) and 1 T (∗) after heat treatment for 3 h at different temperatures. The values measured after treatment at 650 K were set to 100. Inset: Normalized magnetization values measured at 400 K and a magnetic field of 0.2 T as a function of annealing time at 750 K (□) and 800 K (●); these annealing studies were performed first at 750 K and then at 800 K. All measurements were done on sample E17. (Reproduced from R. Höhne *et al*., 2002, with permission from Wiley VCH-Verlag. © 2002.)

Indirect evidence for the absence of a correlation between the Rh phase and the magnetism in fullerenes is given by the annealing behavior of the samples studied by Höhne and Esquinazi (2002). Figure 7(a) shows the magnetization loop at 400 K of sample E17 (the same sample included in Makarova *et al*., 2001) at different annealing stages. Figure 7(b) shows the evolution of the magnetization (at fixed applied field of 2 kOe and a temperature of 400 K) with annealing temperature (after leaving the sample for 3 h at each temperature). There are no changes of the magnetic state after treatments up to 650 K even after 10 h. After a treatment at 700 K weak changes on the magnetic state were observed. After 3 h treatment at 700 K the magnetization (at 400 K and at a field of 1 T) had 98.5% of the virgin value, decreasing to 79% after 16 h at 800 K.

Korobov *et al*. (2003) showed that the Rh phase prepared at $T = 1025-1050$ K and $p = 6$ GPa rapidly decomposed at 520–570 K for 5 min and did not demonstrate additional thermal stability. Comparing this result with the evolution with annealing shown in Figure 7 we conclude that there is no evidence of a relation between the Rh phase and the magnetic signal. Recently published band structure calculations of Rh-C_{60} performed in the local-spin-density approximation found no magnetic solution for Rh-C_{60} and energy bands with different spins are found to be identical and not split, concluding that the rhombohedral distortion of C_{60} itself cannot induce magnetic ordering in polymerized fullerene in agreement with magnetization, X-ray emission, and absorption spectra measurements performed in Rh-C_{60} samples (Boukhvalov *et al*., 2004). These results suggest that the magnetic ordering is related to other carbon structures that are formed before the fullerene cages collapse, as the work of Wood *et al*. (2002) indicates; see Figure 8.

An important issue is the impurity concentration in the fullerene samples polymerized under pressure. Apparently the pressure cells used by Makarova *et al*. (2001) were not clean enough according to the measured impurity concentration through PIXE measurements (Höhne and Esquinazi, 2002; Spemann *et al*., 2003) that reaches values of the order of 400 μg g^{-1} of iron, nonhomogeneously distributed across the sample within 30 μm depth from the surface. Because the pristine C_{60} powder has a much smaller impurity concentration, the impurities should have been incorporated during some sample preparation steps. Owing to the iron concentration one may speculate that Fe_3C may have been synthesized during the preparation conditions. Such an alloy shows a Curie temperature of the order of 500 K similar to the measured one in some of the samples (Makarova *et al*., 2001). In fact, polymerized C_{60} samples mixed with iron before polymerization show a similar Curie temperature (500 K) as those reported by Makarova *et al*. (2001), owing to the presence of the compound Fe_3C (Talyzin *et al*., 2007). Taking into

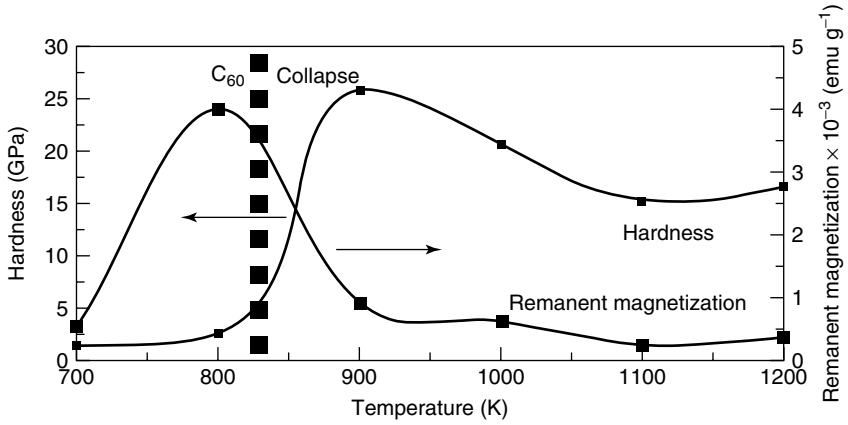

Figure 8. Hardness and remanent magnetization as a function of the preparation temperature for fullerene samples treated at 9 GPa, indicating the region of radical center generation. According to Wood *et al*. (2002) a pressure of 9 GPa was applied to all the samples before heating. The samples were then heated to preparation temperatures in the range 700–1200 K where they were held for 1 min. X-ray diffraction work (Bennington *et al*., 2000) indicates that this isobar will go through an almost pure rhombohedral phase straight into the graphitic hard carbon phase. Note that a maximum remanent magnetization was obtained near the cage collapse. (Reproduced from R.A. Wood *et al*., 2002, with permission from IOP Publishing Ltd. © 2002.)

account this result and the amount of Fe found in the original samples (Höhne and Esquinazi, 2002; Spemann *et al*., 2003), one concludes that the main magnetic signal and the ferromagnetic transition reported by Makarova *et al*. (2001) likely originated from Fe_3C (Makarova *et al*., 2006). We note that recent experimental study (Han *et al*., 2005) performed on samples prepared from fullerenes with lower impurity content and after high pressure high temperature (HPHT) treatment showed vanishingly small bulk magnetization, indicating that the pressure polymerization of fullerenes is not an appropriate method to produce magnetic carbon.

In spite of the results discussed above we would like to comment on a combined experiment with PIXE and magnetic force microscopy (MFM) done in the pressure-polymerized fullerenes (Han *et al*., 2003b; Spemann *et al*., 2003). In one piece of the E16 sample described above, a region of area $\sim 500 \times 250\,\mu m^2$ with a concentration of magnetic impurities below $1\,\mu g\,g^{-1}$ was selected and characterized with MFM. Around 30% of the pure region showed magnetic domains, indicating that only a small fraction ($\sim$10%) of the sample contributes to the magnetic signal measured by the SQUID. Figure 9 shows one kind of MFM images obtained in such pure region where apparent magnetic domains were observed (Han *et al*., 2003b, 2003c). The MFM image changes clearly when it is measured under a magnetic field; see Figure 9. It remains unclear, however, how large the total magnetic moment and mass of the impurity-free magnetic region are.

We should note that in the work of Wood *et al*. (2002) no detailed impurity measurements were provided although we would naively rule out such a contribution because a maximum in the magnetization is obtained only at a particular

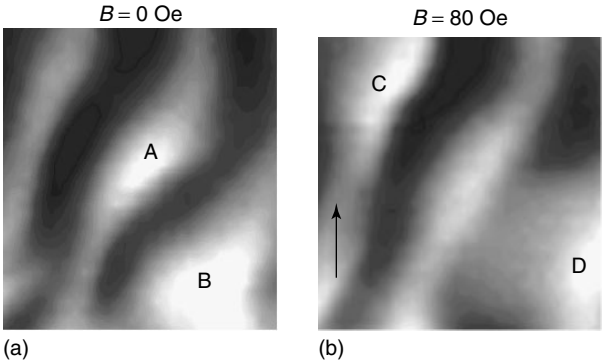

Figure 9. Magnetic force gradient images taken at room temperature from the pure region of the E16 bulk sample without (a) and with (b) magnetic field of 80 Oe. The scan size was $2.5 \times 2.5\,\mu m^2$ and the tip-sample distance was 100 nm. The arrow shows the direction of applied magnetic field. Note the clear change in the phase shift signal at the regions denoted by letters before and under a magnetic field. (Reproduced from Han *et al*., 2003, with permission from Elsevier. © 2003.)

point of the phase diagram; see Figure 8. However, as the work of Talyzin *et al*. (2007) indicates, there appears to be a chemical reaction of Fe with C_{60} at the used temperature and pressure treatment, which forces the cage structure to collapse with a $\sim$15% volume shrinking. Owing to this collapse it is possible that the pressure cell breaks and contamination from outside penetrates the sample. This may be a possible explanation for the behavior shown in Figure 8.

In Section 2 we have noted that Murakami and Suematsu (1996) produced magnetic order in C_{60} crystals exposing them to xenon-light radiation in the presence of oxygen. Similar to polymerization by pressure, oxygen-free C_{60} films

and crystals can be photopolymerized under the action of UV and visible light (Rao *et al*., 1993a,b). Two processes occur when C_{60} is simultaneously exposed to oxygen and light: a photoassisted diffusion of molecular oxygen into solid C_{60} and oxidation of C_{60} (Rao *et al*., 1993a). The oxygen phototransformed phase has, in general, the formula $C_{60}(O_2)_x$ with x depending on the light wavelength and intensity as well as the crystallinity of the sample. There is indirect evidence that the photoassisted reaction of oxygen with C_{60} may lead to the opening and breaking of the C_{60} cages (Wohlers, Bauer and Schlögl, 1997; Matsuishi *et al*., 1997). Whether after the opening of the cages the oxygen atoms or other light atoms like hydrogen play a main role in the magnetic order remains to be studied.

Makarova *et al*. (2003) repeated the experiment of Murakami and Suematsu (1996) transforming C_{60} bulk samples by white light for several days and C_{60} films by Ar-ion laser and electron beam with different wavelengths. More details on the preparation conditions as well as the penetration depths of the irradiation can be found in the original publication. The change in the magnetic signal has been characterized by ac susceptibility and SQUID measurements for the bulk samples and through MFM measurements of the fullerene films. Fullerene irradiated in the presence of oxygen showed clear ferromagnetic hysteresis loops with a saturation magnetization that increased with the exposition time. Figure 10 shows the topography and the magnetic field gradient images of the laser-illuminated spot region of a fullerene film. The magnetic signals (maxima and minima in the force gradient) coincide with the topography. The irradiation-driven transition from a van der Waals–bonded solid to a chemically bonded one contracts the lattice, creating grains as seen in the atomic force microscopy (AFM) images (see Figure 10). These grains or the surface of the grains turned out to be magnetic. No magnetic signals are measured at the nonexposed areas even when topography irregularities exist (Makarova *et al*., 2003). A nonexposed region of the same C_{60} film was irradiated with protons (20 spots pairwise separated by 20 μm at different fluences and 2.5 MeV energy); see Figure 10. Although no change in topography was observed, the irradiated region reveals clear phase constrast. Since the penetration depth of the protons at the energy used is much larger than the thickness of the C_{60} film (∼0.25 μm) it is not expected that those protons remain in the film. As we will discuss in the next sections, the defects produced by the proton irradiation and the hydrogen atoms already in the sample may trigger magnetic order. In summary, we may conclude that fullerenes do not show magnetic order and serve only as an auxiliary unit for the formation of magnetic carbon defects.

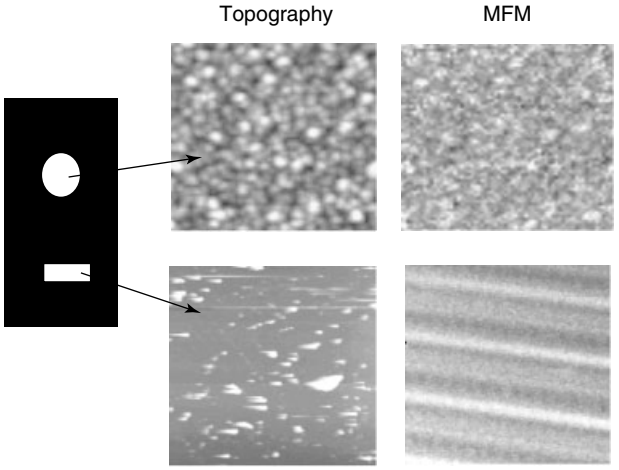

Figure 10. Left-side sketch shows the fullerene film with the two irradiated regions: the upper ellipse corresponds to the laser-illuminated region in air (2.6 eV and 200 mW cm^{-2} intensity) (Makarova *et al*., 2003) and the lower rectangle, to the region where 20 spots of 1.8 μm diameter each where irradiated with a proton microbeam with a current of 500 pA and fluences between 0.068 and 68 nC μm^{-2}. In contrast to the clear change in topography at the laser-irradiated spot (due to the grain formation) and at the proton-irradiated spots in HOPG (see Section 4.3.3) no change in the topography is detected after proton irradiation of the spots in the fullerene film. All images correspond to an area of $5 \times 5\,\mu m^2$. (Reproduced from Esquinazi *et al*., 2005, with permission from Elsevier. © 2005.)

4.3.3 In proton-irradiated carbon structures

Although irradiation effects in graphite were a major research area in the past, their influence on the magnetic properties were only noted through the increase in the spin density and a decrease in the diamagnetism owing to the introduction of lattice defects (Kelly, 1981). Recently, induced magnetic order by proton irradiation was found in graphite and disordered carbon and fullerene films (Esquinazi *et al*., 2003; Höhne *et al*., 2004a; Han *et al*., 2003a; Esquinazi *et al*., 2006). In this section we will briefly review some of the obtained results, mainly on the effects produced by proton irradiation in HOPG samples. For a detailed review on these effects in carbon structures and other irradiation characteristics, the reader should refer to a recently published article (Esquinazi *et al*., 2006).

The early literature on magnetism in carbon structures tends to indicate that apparently hydrogen (or maybe another light atom like oxygen) plays a role in the reported ferromagnetism. As we have described in Section 2, especially the work of Murata, Ushijima, Ueda and Kawaguchi (1991, 1992) suggests a correlation between hydrogen concentration and magnetic order in carbon. Proton irradiation provides us with the unique possibility to implant hydrogen, produce lattice defects in the carbon structure, and simultaneously

have a complete elemental analysis of the sample. Protons in the megaelectron volt energy range have a penetration depth of several tens of micrometers inside a carbon structure (Spemann *et al*., 2004). The defect formation process by high-energy protons is a nonequilibrium athermal process and it appears rather unlikely that ordered arrays of defects are formed by migration of interstitial carbon atoms or vacancies, maybe with the exception of interstitials across the gallery. According to Banhart (1999) and from electron irradiation studies, the essential types of radiation damage up to intermediate temperatures are the rupture of basal planes (due to shift of the C atoms out of the plane) and the aggregation of interstitials into small dislocation loops between the graphene layers. The protuberances measured at the irradiated surface of microspots (Han *et al*., 2003a) result from the creation of interstitials. The migration energy of the interstitial depends on whether it is bounded. Di-interstitials were proposed to explain the irradiation-induced amorphization of graphite with a migration energy of 0.86 eV (Niwase, 1995). The interstitial loops are stable up to rather high temperatures, probably to 1000 °C (Banhart, 1999).

Irradiation changes the ratio of sp^2 to sp^3 bonding leading to cross-links between the graphene layers and the formation of sp^3 clusters (Tanabe, 1996). These clusters appear to be stable and do not anneal at high temperatures. Raman and X-ray photoemission spectroscopy (XPS) measurements indicate an additional disorder mode peak 'D' at 1360 cm^{-1}. Experimental results after proton irradiation in HOPG samples indicate that with increasing fluence the E_2g_2 and D modes become broader and the ratio of their intensities $I(D)/I(E_2g_2)$ increases as a measure of the degree of disorder (Höhne *et al*., 2004a). Monte Carlo simulations (Ziegler, 1977–1985) indicate that the vacancy and interstitial number produced by the megaelectron volt protons is about 15 times larger than the number of implanted ions. For fluences 0.001–75 nC μm^{-2} we get in the near-surface region between 4.7×10^{-6} and 0.35 displacements per carbon atom, that is, complete amorphization for the highest fluence, using a displacement energy of 35 eV for Frenkel pairs in HOPG, in agreement with recently published studies of the damage cascades by irradiation on graphite (Abe, Naramoto, Iwase and Kinoshita, 1997). For a fluence of 75 nC μm^{-2} we have $\sim 5 \times 10^{11}$ protons/μm^2, that is, the regions where defects are created by each individual proton overlap heavily. A dangling bond at the vacancy position in the carbon structure could trap a hydrogen atom – not necessarily from the proton implantation but already present as impurity in the sample. Theoretical estimates (Lehtinen *et al*., 2004) indicate (see Section 5) that certain H-vacancy complexes as well as hydrogen bonded to carbon adatoms (just above a graphene layer) have a magnetic moment; each hydrogen would provide an average magnetic moment of $\sim 1\,\mu_B$.

'Magnetic spots' of micrometer size

With a proton microbeam of energy in the megaelectron volt range directed onto the HOPG surface parallel to the *c* axis of the sample without beam scanning (excepting line scans, see the following text) it is possible to 'magnetically write' on a graphite surface, leading to the formation of micron-sized spots with enhanced defect density, as measured by micro-Raman (Höhne *et al*., 2004a; Esquinazi *et al*., 2006). In general, two spots separated by a distance of 20 μm were irradiated with the same ion fluence and several ion fluences were used. For large-enough fluences the swelling at the spots can be directly observed with an optical microscope (Spemann *et al*., 2004; Esquinazi *et al*., 2005). The height of this swelling depends on the irradiated fluence and on the mass of the ions. The swelling in the *c* direction occurs together with the contraction in the graphene layer; the newly formed interstitial planes push the existing planes apart leading to a protuberance at the sample surface. The dependence of the maximum swelling height h, measured by AFM (see Figure 11), with the fluence for proton irradiation f follows the function $h = 27.5 f^{0.61}$ nm with f in nC μm^{-2}. With an MFM one can measure the phase change of the, eventually magnetic, signal on the spots; see Figure 11. Whether these phase changes at the surface of the spots are of magnetic origin should be further checked since electrostatic effects, partially related to changes in the work function of the irradiated area, may provide a nonnegligible contribution.

The maximum amplitude of the signal (maximum phase shift) as a function of the fluence has a more complicated, nonmonotonic dependence, which depends also on the proton current used (Esquinazi *et al*., 2006). The units of the phase signal from the MFM are 'degrees'; a relation of this phase shift of the tip vibration to the force gradient can be found in Lohau *et al*. (1999, 2000). Examples for the magnetic moment calculated from measurements of the phase shift in carbon samples can be found in Han *et al*. (2003b, 2003c); Han and Esquinazi (2004). The dependence of the phase signal amplitude with the tip-to-sample distance can be used to estimate roughly the local magnetization of a micrometer region assuming a specific thickness (usually of the order of 1 μm). For the magnetic spots a relatively large magnetization was estimated (Han and Esquinazi, 2004). However, in those measurements the influence of electric potential differences (e.g., difference in contact potentials (work functions) between tip and sample surface or circuit-induced potential differences) was not taken into account and appropriately checked. Therefore, we may doubt the estimated values as well as the magnetic origin of the phase contrast at and in the surroundings of an irradiated spot till clear evidence from other experimental techniques is obtained. SQUID measurements done on thousands of

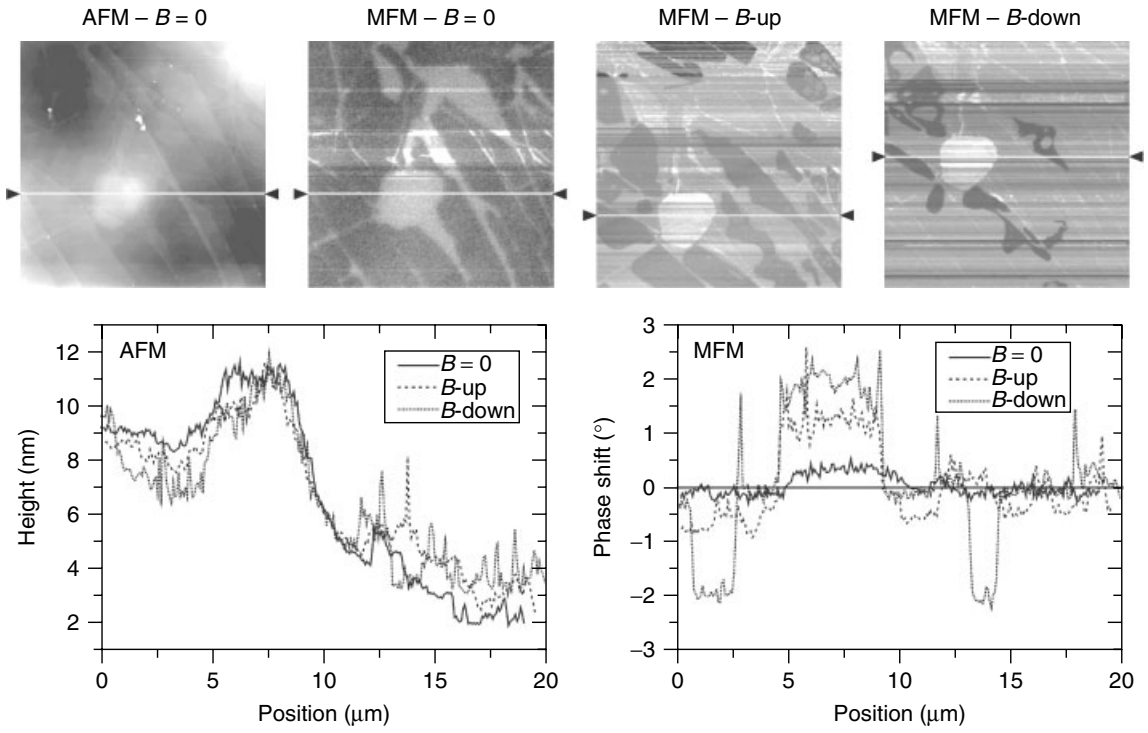

Figure 11. AFM (top left) and MFM images (scan size: $20 \times 20\,\mu m^2$) for a $2 \times 2\,\mu m^2$ spot irradiated with 2.25 MeV protons at a fluence of $7.5 \times 10^{16}\,cm^{-2} \simeq 0.115\,nC\ \mu m^{-2}$. The AFM and MFM line scans shown below were extracted from the images as indicated by the black triangles. The images show the results of the spot measured after irradiation ($B = 0$), after exposing it to a field of $\sim$1 kOe in the c direction (B-up) or $-c$-direction (B-down). The measurements were done, however, at zero applied field. Since the sample had to be removed from the MFM for the exposure to an external magnetic field, the subsequent repositioning of the spot in the MFM was accurate to $\sim$2 μm. Note that the phase changes in these images may be partially influenced by electrostatic as well as aging effects, since there was a certain time lag between the measurements at different applied magnetic fields. (Reproduced from Han *et al*., 2003a, with permission from Wiley VCH-Verlag. © 2003.)

spots in HOPG confirm that there show magnetic order (Barzola-Quiquia *et al*., 2007) The recently performed X-ray circular dichroism absorption measurements at proton-irradiated spots produced on 200-nm-thick carbon films suggest the presence of magnetic order at the carbon K-edge (Ohldag, *et al*., 2006). These kinds of experiments are very important to rule out impurity contributions as well as to confirm the magnetic order at the proton-irradiated regions.

With an α particle microbeam of 1.5 MeV energy similar topological spots were produced on HOPG surfaces (Han *et al*., 2003a). In contrast to the phase contrast obtained at the spots produced with the proton microbeam, those spots showed a much smaller contrast indicating that disorder alone does not trigger the observed signals. Nevertheless, more experiments using α particles in a broader range of parameters are still necessary because we cannot rule out that other effects, like local annealing, adversely influence the development of the observed phenomena.

Proton irradiation of large areas

Eventually, in order to visualize magnetic domain patterns as well as to increase the induced magnetization to reach the minimum range of commercial SQUIDs (typical magnetic moment resolution $\sim 10^{-7}$ emu or better) it is necessary to increase the irradiation area as well as the total irradiated charge. Figures 12 and 13 show the magnetic moment data and magnetic images obtained for a HOPG sample irradiated in a broad area (Esquinazi *et al*., 2003).

The increase of the saturation magnetic moment with the total irradiated charge has been reproduced in other HOPG samples (Esquinazi *et al*., 2003, 2006; Barzola-Quiquia *et al*., 2007). However, irradiation can lead also to negligible change or even to a reduction of the total magnetic moment upon the selected irradiation parameters and sample characteristics. The parameters that influence the magnetic order are (i) the total implanted charge; (ii) the input energy; (iii) the fluence, the irradiated charge per unit area; (iv) the ion current, large currents might heat the sample and nonsystematic effects are then possible; (v) micro- or

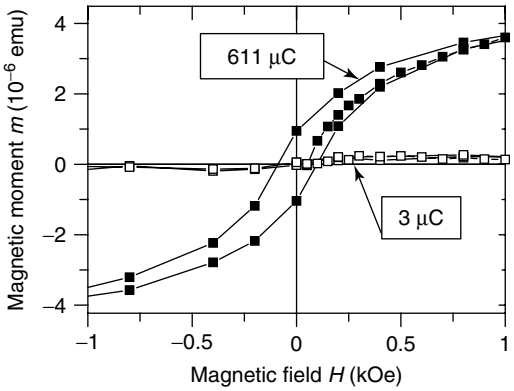

Figure 12. Magnetic moment as a function of applied field of a HOPG sample proton irradiated with a total charge of 3 μC and 611 μC (stage No. 1 and 2 + 3, respectively, described in Esquinazi *et al*. (2003)). The field was applied parallel to the graphene planes. (Reproduced from Esquinazi *et al*., 2004, with permission from Elsevier. © 2004.)

macroirradiation; (vi) sample temperature; and (vii) the initial state of the sample, namely, the density and type of defects, as well as the concentration of hydrogen before irradiation. Computer simulation results of the effects of adsorbed hydrogen on the band structure of a graphene layer indicate that metallization caused by specific defects can quench a spin-polarized state (Duplock, Scheffler and Lindan, 2004).

Clear proton irradiation effects on the magnetic response of thin carbon and fullerene films were reported (see Höhne *et al*. (2004a) and Esquinazi *et al*. (2006) and Figure 10), although the thickness of those films ($\lesssim 1\,\mu m$) were much smaller than the proton penetration depth at the used energies, that is, most of the protons should go through the material. These experimental facts indicate either that the hydrogen concentration in the sample or surrounding before irradiation might be relevant (the measured H concentration at the surface of HOPG samples is rather high; see Reichart *et al*. (2006)) and/or that the defect concentration in the first micrometer from the sample surface and produced by the proton beam is not negligible.

4.3.4 In other carbon-based structures

Kapton® is a tough, aromatic polyimide material, generally used in the form of a composite film (of amber color) in a wide variety of applications. The molecular structure is composed of an imide part, polymellitic dianhydride, and a bridging part, 4,4′-oxydianiline, that is, it contains basically the elements C, N, O, and H. Kapton has been (and apparently is still) used as wiring insulation, although it is suspected to be involved in several aircraft disasters owing to its tendency to arc. Kapton and some other polymer films with heat resistance transform into graphite films with high crystallinity after heat treatment at high temperatures ($T >$ 2000 K). For polyimide films the degree of graphitization increases for thinner films (Hatori, Yamada and Shiraishi, 1992, 1993). Low-temperature annealing of polymers leads to the formation of porous structures with a high density of radical molecules. Therefore, it is tempting to think that through the exchange interaction between unpaired electrons on free radicals one may trigger magnetic order. Note, however, that this assumption does not always work as the magnetization of disordered carbon revealed; see Section 4.2.

Kaburagi and Hishiyama (2002) observed an interesting behavior of the magnetization of Kapton when it starts decomposing around 770 K. Figure 14 shows the magnetization loops at 300 K measured for Kapton samples kept for 1 h at each of the temperatures shown in the figure and under nitrogen flow. The results clearly show that Kapton's magnetization behavior changes from the usual diamagnetic one to a ferromagnetic one at annealing temperatures around 500 °C. A maximum saturation magnetization at room temperature of 0.06 emu g^{-1} (coincidentally a value observed for some of the polymerized fullerene samples) was reached after an annealing temperature of 520 °C. Note that the ferromagnetic behavior vanishes for annealing temperatures above 520 °C. Taking into account that annealing dramatically decreases the concentration of light elements (a 70% weight loss was measured after a heat treatment at 540 °C (Kaburagi and Hishiyama, 2002)) the results suggest that a specific balance between graphitic-like order plus a certain amount of light atoms are necessary to trigger the magnetic order. The coercive field at 300 K was of the order of 0.005 T and a remanent magnetization of the order of a few percent of its saturation value. The magnetic response of the annealed samples shows the contribution of three components, that is, diamagnetism, paramagnetism (clearly observed when M is measured as a function of temperature at fixed field), and ferromagnetism. We expect that the magnetic order is not homogeneously distributed in the annealed sample. In spite of the clear magnetic order demonstrated by the SQUID measurements, the authors did not find evidence of magnetic domains using MFM, nor any sign for an anisotropic response within experimental error. Measurements done after five months revealed a slight decrease of M and increase of the paramagnetic part. This aging effect of the magnetic order appears to be a general feature observed in different carbon-based samples; see Section 4.3.5. We should note, however, that several groups could not still reproduce the results of Kaburagi and Hishiyama (2002) shown in Figure 14. Therefore we may doubt whether the observed effects are intrinsic to the measured samples.

Kopelevich *et al*. (2003b) reported on local ferromagnetism in microporous carbon with the structural regularity of zeolite Y. The authors observed clear hysteresis loops

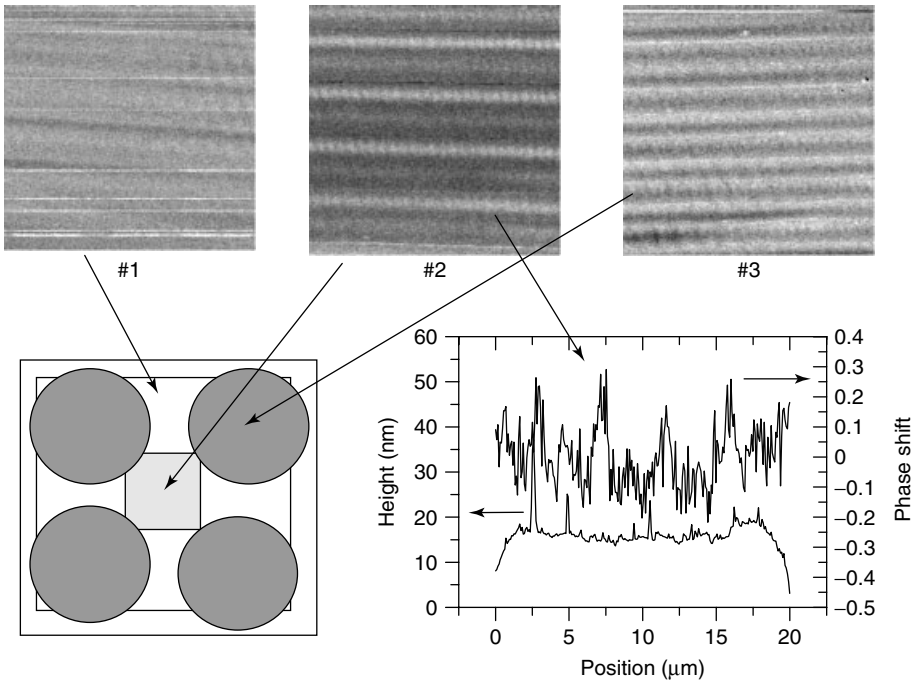

Figure 13. Top: Phase gradient images obtained at room temperature from MFM at three surfaces of a HOPG sample at three irradiation stages as described in Esquinazi *et al*. (2003). Bottom right: Topography and phase gradient line scans of the MFM image at the stage No. 2. As in Figure 11 the possible influence of electrostatic effects may play a role in the observed phase contrast and should be checked in future experiments. (Reproduced from Esquinazi *et al*., 2003, with permission from the American Physical Society. © 2003.)

added to a paramagnetic contribution. Subtracting this contribution at low temperatures, the saturation magnetization of this sample is $\lesssim 0.04\,\mathrm{emu\,g^{-1}}$. This value should be compared to $\sim 0.06\,\mathrm{emu\,g^{-1}}$, which is the maximum expected saturation magnetization due to the Fe concentration in the samples (Kopelevich *et al*., 2003b). In contrast to the behavior observed in most of the carbon-based samples reported above, this microporous carbon revealed a rather complicated temperature and field dependence added to clear difference between field and zero-field cooled samples at low-enough temperatures and fields. Following the experimental work of Harris, Burian and Duber (2000) that indicates that microporous carbon may have a fullerene-related structure, in which pentagons and heptagons are distributed randomly throughout a hexagonal network, Kopelevich *et al*. (2003b) proposed that the origin of magnetism may be related to topological disorder and curved graphene sheets, whereas the behavior at low temperatures may be due to a percolative-type transition of isolated magnetic clusters. This proposal agrees with the *ab initio* density functional theoretical calculations on carbon nanostructures with negative Gaussian curvature and without undercoordinated carbon atoms that reveal a net magnetic moment in the ground state of these structures (Park *et al*., 2003). It would be interesting to repeat these measurements with samples of higher purity and to study the evolution with annealing.

4.3.5 Aging and annealing effects

Depending on the sample and the origin of the magnetic order, it is possible to observe aging effects in the magnetization. Taking into account previous reports on the behavior and diffusion of hydrogen in graphite (Atsumi, 2002) one may expect to observe some time dependence in the magnetic response in some of the magnetic samples if hydrogen is involved in its origin. We note, however, that in general it is not simple to separate a pure hydrogen diffusion effect from structural relaxation because both may always be correlated.

Aging effects at room temperature in the magnetization has been observed in the fullerene $C_{60}H_{24}$ by Antonov *et al*. (2002). Hydrofullerites $C_{60}H_x$ synthesized at hydrogen pressures of 0.6 and 3 GPa were found to be ferromagnetic at room temperature (Antonov *et al*., 2002) with a magnetization at saturation of the order of $1\,\mathrm{emu\,g^{-1}}$. Figure 15 shows that the magnetization of a ferromagnetic sample decreases when the sample is stored at ambient conditions.

Different measurements were done in irradiated samples to test the possible influence of hydrogen diffusion in the observed magnetism. Measurements were done in irradiated spots in HOPG as well as in disordered carbon films just after irradiation and after several months of leaving the sample at ambient conditions. After a period of more than six months the magnetic signals decreased (Esquinazi *et al*.,

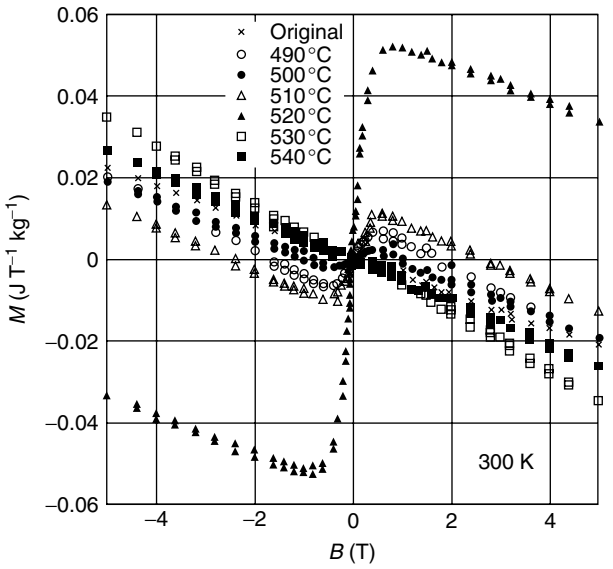

Figure 14. Magnetization ($J\,T^{-1}\,kg^{-1} = emu\,g^{-1}$) as a function of magnetic field at room temperature for Kapton after annealing for 1 h at the indicated temperatures in a nitrogen flow. (Reproduced from Y. Kaburagi *et al*., 2002, with permission from Materials Research Society. © 2002.)

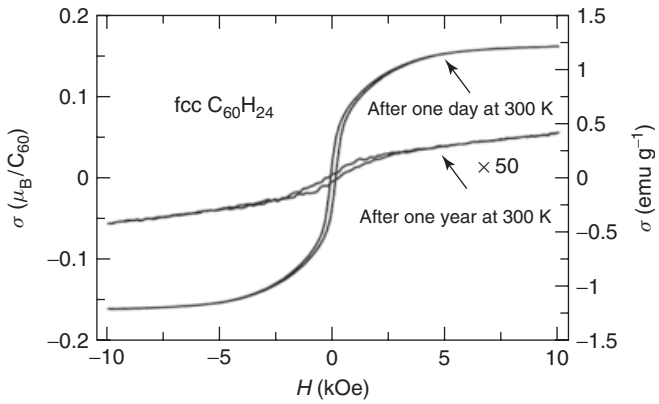

Figure 15. Magnetization as a function of magnetic field at room temperature for a $C_{60}H_{24}$ sample synthesized at a hydrogen pressure of 0.6 GPa and at $T = 350\,^{\circ}C$ and exposed to ambient conditions for 1 day and 1 year. (Reproduced from Antonov *et al*., 2002, with permission from Elsevier. © 2002.)

2006). Figure 16 shows the magnetic moment of a disordered carbon sample before, just after proton irradiation, and after one year at room temperature (after irradiation). It is clearly seen that the ferromagnetic-like hysteresis vanishes after one year. A clear decrease of the maximum phase shift of the MFM signal at the magnetic spot positions as well as changes in the topography with time have also been observed (Esquinazi *et al*., 2006). Annealing irradiated samples at high temperatures (∼1000 °C) makes the phase contrast vanish at room temperature (Esquinazi *et al*., 2006).

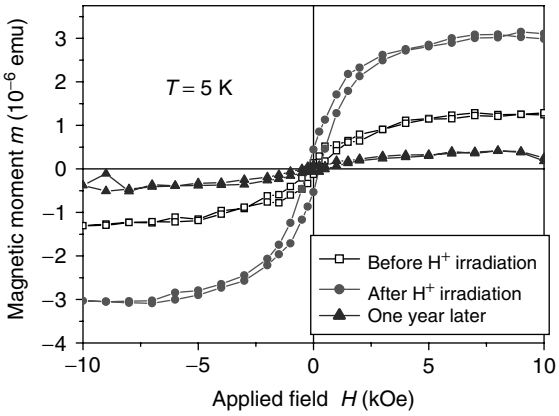

Figure 16. Magnetic moment (the diamagnetic background was subtracted) as a function of applied field for the disordered carbon film CH577a after preparation by PLD (before irradiation (□)), after irradiation (●) and one year later, leaving the sample at room temperature (▲). (Reproduced from Esquinazi *et al*., 2005, with permission from Elsevier. © 2005.)

The oxygen effect on the magnetic properties of graphite has been explored by Kopelevich, Moehlecke and da Silva (2006). In their experiments, an activated graphite powder was prepared by cutting and grinding an ultraclean graphite rod at $T = 300$ K in oxygen atmosphere by means of a virgin diamond saw blade. It is found that whereas the starting sample demonstrated a diamagnetic (nonhysteretic) response, measurements performed on the oxidized graphite powder revealed a pronounced ferromagnetic signal. It has also been found that the ferromagnetism vanishes with time after taking the sample out from the oxygen atmosphere, providing indirect evidence that the ferromagnetism is triggered by the adsorbed oxygen and not by a possible trace of magnetic impurities.

5 POSSIBLE ORIGINS OF THE MAGNETIC ORDER

In general, magnetic order in solids at low-enough temperatures, that is, below the Curie temperature, is characterized by a microscopic arrangement of magnetic moments, which are related to atoms containing partially filled electron shells, like in elements (and their alloys) with 3d or 4f electrons. To account for the 'order' one needs an exchange interaction (given by a constant J) of electrostatic origin between the localized magnetic moments or, in case of itinerant electron magnetism, an effective exchange energy for the unpaired, delocalized electrons. What makes the room-temperature carbon-based magnetic order unusual is the absence of d and f electrons, that means an apparent absence of localized magnetic moments. In this section we review several

proposals for a magnetic order in carbon structures and their correlations with experimental results. We would like to mention that due to the still inhomogeneous distribution (actually unknown) of magnetic material in the reported carbon structures, it makes little sense to speak about a specific amount of Bohr magneton per carbon atom or per fullerene cage. Any correlation of this number with theoretical predictions should be dealt with carefully.

(a) Can ferromagnetism occur in a perfect graphene layer? Itinerant ferromagnetism in graphite: It has been pointed out that the low dimensionality and density of carriers in graphite ($n_{2D} = 1 \ldots 2.4 \times 10^{11}\,\mathrm{cm}^{-2}$) may give rise to itinerant ferromagnetism (Khveshchenko, 2001a,b). This phenomenon is related to the large electron–electron interaction expected for a two-dimensional system with a low density of carriers. The strength of this interaction can be estimated through the Coulomb coupling constant

$$r_\mathrm{s} = \frac{e^2 m^*}{\hbar^2 \epsilon \epsilon_0 \sqrt{\pi n_{2D}}} \tag{1}$$

where $m^* = 0.04$–$0.06\,m$ (Sharma, Johnson and McClure, 1974) is the effective mass of the carriers (m is the free electron mass), $\epsilon = 12$–15 the dielectric constant. Using these values we get $r_\mathrm{s} = 7$–21. The constant r_s is given by the ratio between potential Coulomb energy (between carriers) and the Fermi (kinetic) energy. If $r_\mathrm{s} \gtrsim 1$ and within a rough picture, it may be possible that the ground state of an electron pair is not given by spin-up and spin-down but both with the same spin direction because in this case the Coulomb interaction decreases (the effective distance between the two electrons increases) and therefore a magnetic order appears.

In case the main carriers are massless Dirac fermions, as it is assumed for graphite due to the linear dispersion relation of the carriers near the Fermi energy, then the strength of the Coulomb interaction is characterized by

$$g = \frac{e^2}{\epsilon_0 v_\mathrm{F} \hbar} \tag{2}$$

With $v_\mathrm{F} \sim 2 \times 10^6\,\mathrm{m\,s}^{-1}$, $g \sim 10$ and therefore the strong Coulomb interaction can open an excitonic gap in the spectrum of the Dirac fermions (Khveshchenko, 2001a,b). Theory indicates that the occurrence of a gap is accompanied by the appearance of a small magnetic moment due to the band anisotropy.

Indirect experimental evidence for the importance of the Coulomb interaction between carriers and the opening of a gap with field may be given by the field-induced metal-insulator transition in the magnetoresistance of HOPG for fields applied normal to the layers (Kempa *et al*., 2000, 2003; Kopelevich *et al*., 2003a). Direct experimental evidence for the existence of a gap in the band structure of graphite is still missing and therefore the existence and further details of the long-range itinerant ferromagnetic order remain unclear.

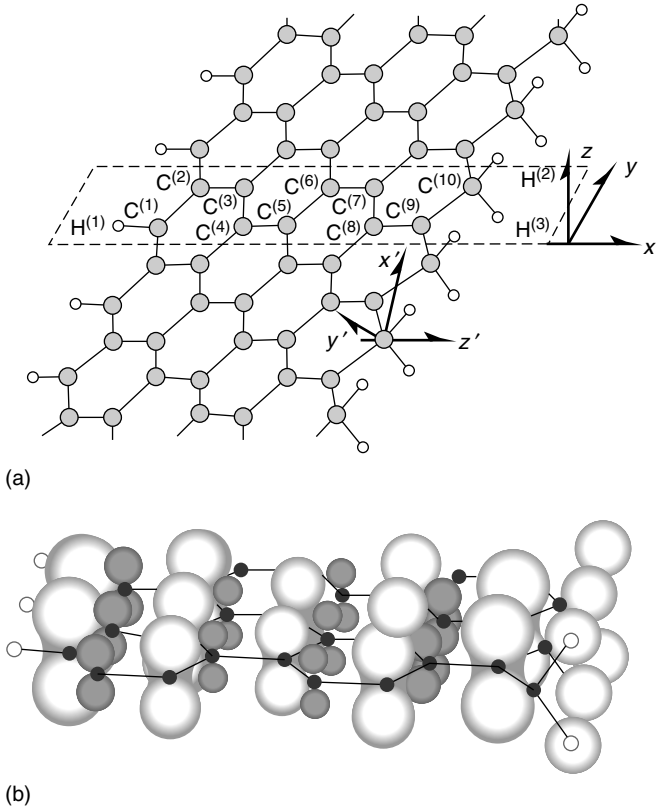

Figure 17. (a) The structure of a magnetic graphene ribbon. Dark circles represent carbon atoms and open circles, hydrogen. The unit cell contains 10 carbon and 3 hydrogen atoms, represented by dashed lines in the x, y plane. The monohydrogenated $C^{(1)}$ carbon atom forms sp^2 bonding, whereas the dihydrogenated $C^{(10)}$ carbon atom, an sp^3 bonding. (Reproduced from Kusakabe *et al*., 2003, with permission from the American Physical Society. © 2003.) (b) Spin density represented by isosurfaces. Bright and gray surfaces represent spin-up and spin-down densities. (Reproduced from Kusakabe *et al*., 2003, with permission from the American Physical Society. © 2003.)

(b) Magnetic properties of graphene with zigzag edges: Fujita, Wakabayashi, Nakada and Kusakabe (1996) categorized two-dimensional graphitic structures in nanometer scale as a novel graphitic material with properties different from bulk graphite or small aromatic molecules due to the influence of the open edges. Depending on the shape and termination of the edges a magnetic instability may occur in the graphitic structure. One distinguishes between three types of edges: zigzag (monohydrogenated Fujita's edge, edges similar to the position $C^{(1)}$ in Figure 17(a), dihydrogenated zigzag edges, Klein's edge (Klein, 1994), edges similar to the

position $C^{(10)}$ in Figure 17(a)), or armchair edges. Theoretical predictions (Fujita, Wakabayashi, Nakada and Kusakabe, 1996) indicate that the electronic states at Fujita's zigzag edges (terminated with one hydrogen atom, i.e., sp^2-bonded carbon atoms) are strongly localized with the nonbonding unpaired electrons having a localized magnetic moment with $S = 1/2$. These states, characterized by nearly flat dispersion in a certain range of momentum space and whose density of states has a sharp peak around the Fermi energy, would decay exponentially into the bulk of the 2D sheet (Nakada, Fujita, Dresselhaus and Dresselhaus, 1996). The edge states are believed to be responsible for the paramagnetic as well as the unconventional behavior observed in activated carbon fibers by Shibayama, Sato, Enoki and Endo (2000) (see also Enoki and Takai (2006)). Evidence for an increase of the density of states at the Fermi level at zigzag edges has been obtained by STM studies (Giunta and Kelty, 2001; Esquinazi *et al*., 2002; Kobayashi, Fukui, Enoki and Kusakabe, 2006).

Although a dihydrogenated zigzag edge behaves as Klein's edge and becomes magnetically ordered as Fijuta's edge (Kusakabe and Maruyama, 2003), a graphene ribbon with both edges either mono- or dihydrogenated *cannot* be magnetic, unless they are uncompensated. This is expected because of the effective antiferromagnetic compensation (net moment zero) of the localized magnetic moments at the opposite edges of the graphene ribbon. This situation agrees with the so-called Lieb's theorem (Lieb (1989b) see also Lieb (1989a)), which states that the ground state of a lattice like graphene is magnetic with a total spin given by $S = |N_A - N_B|/2$, where $N_A(N_B)$ is the number of A (B) sites or stared (unstared) carbon atoms, if a short-range interelectron repulsion U is assumed. A similar result has been obtained already for hydrocarbon molecules by Ovchinnikov (1978). If the π-electron system is described by this bipartite network with only nearest-neighbor electron transfer paths (electrons hop from a lattice position A to B without direct A–A or B–B hopping) then a flat band appears at E_F if the orbital energy is the same for every site. A couple of examples on how to estimate S for two hydrocarbon networks are given by Maruyama *et al*. (2004).

A finite magnetic moment per unit cell is obtained in graphene if both Fujita's and Klein's edges exist in the same ribbon. In this case the spin balance cancels owing to the existence of an sp^2- and an sp^3-bonded carbon atoms ($C^{(1)}$ and $C^{(10)}$ in Figure 17(a)) at the edges. The flat band is destroyed and an energy difference appears between the spin-up and spin-down bands. This spin gap is estimated with local-spin-density-approximation (LSDA) to be of the order of 0.2 eV for the unit cell of Figure 17(a) (Kusakabe and Maruyama, 2003) (note that the calculation is done at $T = 0$ K). The LSDA results indicate a net magnetic moment of $1\,\mu_B$ per unit cell of the ribbon. Similar calculations substituting hydrogen by fluor and oxygen as well as the addition of methylene indicate that the net magnetic moment depends on the bonded atom at the edges (Maruyama and Kusakabe, 2004; Maruyama *et al*., 2004). Note that the sp^2–sp^3 unbalance of carbon-bonded atoms plays a crucial role in triggering the finite magnetic moment. Note that this is not localized at the edges but distributed in the whole cell. The structure and energy spectra of different classes of large hydrocarbons ($\sim 10^4$ carbon atoms) with different edge structures and semiconducting properties have been studied theoretically by Dietz, Tyutyulkov, Madjarova and Müllen (2000). The main results of this work indicate that defects in polycyclic aromatic hydrocarbons change their energy spectra and in some cases the defect state energy levels are situated within the energy gap as n or p state in conventional semiconductors. In some cases the defects can lead to a high-spin state (ferro- or antiferromagnetic order) in the aromatic hydrocarbon.

Since electron–electron interactions play a main role in the development of a spontaneous spin-polarized state at the zigzag edges, one may doubt the use of certain theoretical approximations to solve this problem. Therefore, controlled approximations are always necessary to understand and clarify their influence on the calculated low-energy properties of the small graphitic structures. Hikihara, Hu, Lin and Mou (2003) studied the effects of the electron–electron interactions and showed that (i) in the presence of a Hubbard interaction the ground state is a spin singlet with finite charge and spin gaps without spontaneous spin polarization. (ii) Electrons at the zigzag edges correlate ferromagnetically composing effective spins that are easily polarizable by an external field. (iii) The localization at the zigzag edges of the effective spins are robust against electron–electron interactions. Regarding the question of interaction between graphene layers (interlayer interaction) in a 3D graphite structure, Harigaya (2001) showed that the magnetic properties change drastically depending on the type of stacking geometry; for the simple stacking there is apparently no magnetic solution.

(c) Three-dimensional structures of full carbon magnets: Mataga (1968) and Tyutyulkov and Bangov (1974) were probably the first authors to propose organic ferromagnets with unpaired electrons in nonbonding π-molecular orbital, in particular, in hydrocarbon molecules and nonclassical π-conjugated polymers. A few years later Ovchinnikov (1978) published similar ideas. A magnetic all-carbon structure with a mixture of sp^2 and sp^3 bonds was proposed by Ovchinnikov and Shamovsky (1991) (see also the references therein). These authors suggested that a three-dimensional all-carbon structure with the highest magnetization would contain an equal number of sp^2 and sp^3 hybridized carbon

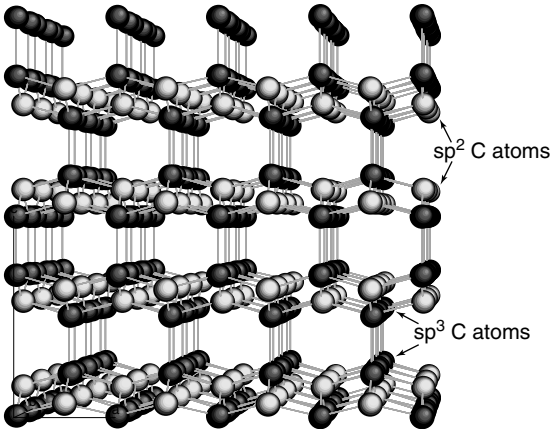

Figure 18. The theoretical structure of 'ferrocarbon' that contains equal numbers of sp^2 and sp^3 hybridized carbon atoms. This structure is intermediate between the graphite and diamond structures and contains 50% of unpaired-electron carriers. The lattice parameters were determined by energy minimization by Ovchinnikov and Shamovsky (1991). (Reproduced from A.A. Ovchinnikov *et al*., 1991, with permission from Elsevier. © 1991.)

atoms, that is, a mixture of the diamond and graphite structures. Note that the structure is obtained by shifting some of the sp^2 carbon atoms out from the planar graphene layer and hybridizing them to an sp^3 state with the next carbon neighbors from the top or bottom graphene layers. Through this sp^3 hybridization a singlet state is achieved for the former π electrons. Every sp^2 carbon atom with one unpaired electron is surrounded by three sp^3 carbon atoms. The elementary cell of the structure proposed by Ovchinnikov and Shamovsky (1991) and shown in Figure 18 has eight carbon atoms with a maximum magnetic moment of $4\,\mu_B$ per unit cell. The authors' estimations suggest that an exchange interaction between all pairs of nearest unpaired electrons localized on the sp^2 carbon atoms might be possible and the triplet, ferromagnetic electronic configuration should be the ground state of the structure. In spite of some reports in literature (see Shulg'a, Boldyrev and Ovchinnikov (1992) and references therein) it is unclear whether such a structure has been realized and how large its intrinsic magnetization was since nobody apparently could reproduce those results.

Unpaired spins in an all-carbon structure can be also found in special cases like nanostructures with negative Gaussian curvature, see Figure 19(a), as suggested by Park *et al*. (2003). The carbon radicals are those depicted by the gray spheres in one of the four phases of the tetrapod, see Figure 19(b). Note that in this structure the radicals are not undercoordinated but sterically protected by heptagons (gray areas in Figure 19(b)) and hexagons. These radicals are the source for the spin polarization. According to Park *et al*. (2003) the decomposition of the calculated electronic density of states for the sp^2 terminated tetrapod suggests that 4 of 12 unpaired spins are not localized and originate a magnetic ground state. Although such negative Gaussian curvatures are unlikely to be the origin of the magnetic order in graphite structures, the authors speculate that this building block may exist in carbon foams giving rise to its anomalous magnetic behavior (Rode *et al*., 2004).

(d) Magnetic properties of vacancies and adatoms on certain carbon structures: Till the end of the 1990s there was basically consensus that disorder in a graphite or other carbon-based structure produces a paramagnetic behavior due to the formation of nonbonding electrons (dangling bonds). Owing to the expected electron–electron interactions in graphene, González, Guinea and Vozmediano (2001) suggested that topological defects enhance the density of states and induce electronic instabilities, giving rise to the possibility of ferromagnetism as well as *p*-wave superconductivity. Quantitative treatments of the magnetic properties of vacancies and adatoms using spin-polarized density-functional simulations have been published recently. Experimental evidence for ferromagnetic behavior in carbon structures with some kind of disorder, like proton-irradiated graphite (Esquinazi *et al*., 2003), suggests that vacancies and adatoms, possibly with the influence of light atoms like hydrogen or oxygen, play an important role in the magnetic order. *Ab initio* calculations indicate that a carbon adatom on a graphene sheet can have equilibrium positions with a finite magnetic moment of the order of $0.5\,\mu_B$ (Lehtinen *et al*., 2003). This moment can be understood if we consider that the hybridization state is different for the two surface atoms attached to the adatom and this last one (sp^2–sp^3 vs sp^2 hybridization, respectively); the half p_z electron of the adatom provides the $0.5\,\mu_B$.

(b) Three trivalent carbon radicals are represented by the gray spheres. The tetrapod contains 12 trivalent radicals. The gray areas indicate the heptagons to which the radicals are associated. (Reproduced from Park *et al*., 2003, with permission from the American Physical Society. © 2003.)

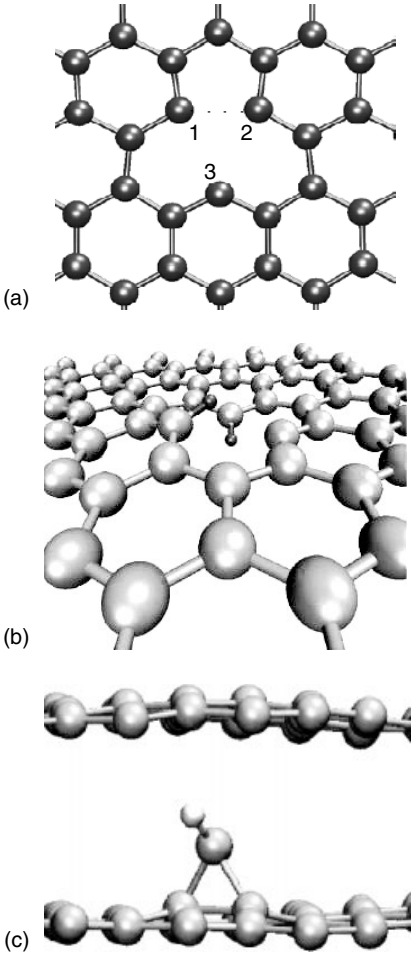

Figure 20. (a) Atomic structure of a vacancy in a graphene layer. (Reproduced from Y. Ma *et al*., 2004, with permission from IOP Publishing Ltd. © 2004.) (b) Structure of a vacancy surrounded by two hydrogens. (Reproduced from Lehtinen *et al*., 2004, with permission from American Physical Society. © 2004.) (c) Structure of a C–H group adsorbed between two graphene layers. (Reproduced from Lehtinen *et al*., 2004, with permission from American Physical Society. © 2004.)

Ma, Lehtinen, Foster and Nieminen (2004) analyzed the magnetic state of a vacancy in a graphene sheet as that shown in Figure 20(a). Their result indicates that the vacancy undergoes a Jahn–Teller distortion moving the atoms 1 and 2 together in Figure 20(a). This deformed pentagon saturates the sp^2 electrons of the atoms 1 and 2, leaving number 3 with a dangling bond that is responsible for the $1.04\,\mu_B$ magnetic moment. Ma, Lehtinen, Foster and Nieminen (2004) also studied the dependence of the electronic structure and magnetic properties on the vacancy concentration of carbon nanotubes. Their results indicate that vacancies can change the electronic structure of the nanotube and, in case it is metallic, the vacancy may trigger ferro- or ferrimagnetism.

The calculations of Lehtinen *et al*. (2004) indicate that if an hydrogen encounters an empty vacancy, then it compensates the dangling bond, and the magnetic moment of Figure 20(a) vanishes. However, if a vacancy is saturated by a hydrogen atom, a second hydrogen atom can bond to the other side of the vacancy (see Figure 20(b)). This configuration with one H-atom above the graphene plane and one below has a magnetic moment of $1.2\,\mu_B$ localized on the dangling sp^2 bond. The other possibility to have a magnetic moment of the order of $0.9\,\mu_B$ is when the hydrogen atom bonds to the C adatom in between two graphene layers (see Figure 20(c)). Lehtinen *et al*. (2004) estimated the total magnetic moment produced in the irradiation experiments made by Esquinazi *et al*. (2003) taking into account the amount of hydrogen atoms, vacancies, and C adatoms obtaining reasonable agreement. We note, however, that the magnetic order is not demonstrated by these calculations but is implicitly assumed through defect–defect interactions.

Chan *et al*. (2004) used density-functional theory and reactive force field molecular dynamics to study the magnetic order in fullerenes with defect rhombohedral structure. They found that if a hydrogen bonds a C atom near a vacancy of the C_{60} cage, a ferromagnetic ground state is found with a moment of $3.0\,\mu_B$ per cage. In contrast to the graphene case mentioned above, this bonding of hydrogen in the curved fullerene structure does not quench the magnetic moment but one of two possible states, destroying the spin balance. To account for the measured magnetization the authors estimated a ratio $H{:}C_{60} \sim 10\%$. Inelastic neutron scattering experiments performed by the same authors indicated a similar concentration of hydrogen as the theoretical estimate.

(e) The influence of hydrogen: In the previous section we saw that bonding of hydrogen with carbon atoms near vacancies or at the edges of graphene layers may be of advantage for the formation of a magnetically ordered state in certain carbon structures. In this section we would like to emphasize some results from literature that indicate that the coupling of hydrogen to carbon atoms in graphite-like structures can have a strong influence in the electric and magnetic properties of the carbon structure.

Ruffieux *et al*. (2000) combined AFM and STM measurements to study the topography and the electronic changes in the vicinity of defects produced by chemisorbed hydrogen or atomic vacancy formation on the basal plane of graphite. HOPG samples were irradiated with a low proton flux of $10^{12}\,cm^{-2}\,s^{-1}$ and 10 eV energy. In the region where chemisorbed hydrogen was present, these authors found superlattice-type modifications of the electronic properties over a distance of 25 lattice ($\sim$6 nm range) constants without modifications in the topography. These results are the first to show a long-range modification of the electronic structure produced by a hydrogen atom.

A positive muon (μ^+) is an elementary particle with a mass (1/9)th that of a proton and therefore much larger than that of an electron. The electronic structure around a (μ^+) in a solid is virtually identical to that of hydrogen in the same solid. After implantation in a solid these particles occupy interstitial sites and are a convenient way to simulate the behavior of hydrogen impurity. The study of the spin-relaxation rate and Knight shift, within the 2.2 μs lifetime of the muon, provides a valuable way to characterize the local electronic structure one would expect around a hydrogen atom in the implanted solid structure. Evidence for local magnetic moment formation on the carbon atoms of a graphene layer around a positive muon in graphite was obtained by Chakhalian *et al*. (2002) supported by the unusually large and temperature-dependent Knight shift. The muon-spin-relaxation rate is also anomalously large and deviates from the Korringa relaxation for normal metals. Chakhalian *et al*. (2002) noted that this result is compatible with the strong energy dependence in the density of states and the small Fermi energy of graphite.

First-principles calculations of the electronic density of states of graphene done by Duplock, Scheffler and Lindan (2004) showed that the adsorption of atomic hydrogen opens a substantial gap of 1.25 eV inducing a spin-polarized state. This result agrees, in principle, with the experimental results from Chakhalian *et al*. (2002) described above. The results of Duplock, Scheffler and Lindan (2004) further showed that the spin state is quenched when hydrogen is adsorbed either on a Stone–Wales defect (pentagon and a heptagon pair on the graphene layer) or on a layer containing this defect. This amazing result appears to be due to the metallization induced by this kind of defect on the band structure of the graphene layer.

6 CONCLUSION

Defects undoubtedly alter the magnetic properties of carbon-based structures. The simplest, well-reproducible example is the increase of the paramagnetic contribution with disorder in a graphite structure. There are several publications that indicate that in certain carbon-based structures a magnetic order exists, which remains even above room temperature and without the influence of metal ions. This interesting behavior was overseen by the main stream of experts in magnetism partially because of the unclear characterization of the magnetic impurity contribution in several, earlier publications and also due to the lack of sensitivity in earlier studies. This situation has been improved by systematic and careful studies of the magnetism in graphite, disordered carbon, and fullerenes, especially after proton irradiation in which an overall impurity characterization was performed. On the basis of the results obtained recently, the author is convinced that room-temperature ferromagnetism in metal-free carbon-based materials is a much more general phenomenon than one ever thought. Impurities remain a problem because in several of the not-yet optimized materials the signals are rather weak and can be easily overwhelmed by a few tens of parts per million of ferromagnetic iron or other magnetic ion. This unwanted contribution added to aging effects and poor reproducibility of the methods used to produce magnetic order in carbon systems are the main problems faced by researchers nowadays. A large number of open questions will keep researchers busy in the years to come, namely, the origin for the magnetic order; the range of Curie temperature; the maximum achievable saturation magnetization in carbon structures; the contribution to the magnetic order from lattice defects and their influence as H-trapping centers; the electrical conductivity of the ferromagnetic structures; the influence of the ion current, fluence, and energy of the irradiated particle and the sample temperature on the magnetic order; the hydrogen and oxygen coverage in the first micrometers from the surface before and after irradiation; the defect relaxation and hydrogen, or other light element, diffusion, and their influence on the magnetic order.

NOTES

[1] In the manuscript from Ovchinnikov and Spector (1988) the absolute value of magnetization is in units of $\mathrm{G\,g^{-1}}$, a unit that does not match the usual magnetization units. In that publication, however, there is a figure where the magnetization in G and in $\mathrm{emu\,g^{-1}}$ for the same sample are given. From that figure we infer that the used '$\mathrm{G\,g^{-1}}$' should be equivalent to $\mathrm{emu\,g^{-1}}$.

Magnetic Ultrathin Films

Bretislav Heinrich and John Francis Cochran
Simon Fraser University, Burnaby, British Columbia, Canada

1 THIN-FILM GROWTH

Ultrathin magnetic films have been extensively investigated since early 1980. In ultrathin films the interfaces play a crucial role. In ultrathin structures, the exchange energy between electrons maintains the same orientation of the atomic magnetic moments across the film. The magnetic properties of interface atoms are often different from those in the bulk. These properties in ultrathin films are shared by the atoms inside the film because of the very strong exchange forces. As a result, ultrathin films behave like giant magnetic molecules that are characterized by unique magnetic properties absent in the bulk. In order to fully benefit from the unique behavior of interface atoms on thin-film magnetic properties, one is compelled to prepare ultrathin-film structures having the best possible quality of interfaces. The deposition of the film material on a suitable substrate is usually carried out close to room temperature (RT) where the film growth is controlled by the interplay of thermodynamics and kinetics. The atomic layers are formed by nucleation of flat atomic islands and the deposited atoms are incorporated into these islands by surface diffusion. However, this is a nonequilibrium kinetic process that affects the growth mode. In general, one can say that perfect interfaces cannot be achieved, but by choosing suitable growth conditions one can create ultrathin-film structures in which the interfaces have a dominant effect. In fact, a reasonable degree of interface roughness can result in novel magnetic properties which would be absent in structures having perfect interfaces. In the following, we will demonstrate the wealth and depth of studies obtained by using ultrathin-film homoepitaxial and heteroepitaxial structures grown in a quasi layer by layer mode where the interface roughness is mainly limited to a few atomic layers.

The growth of ultrathin metallic structures has been mainly carried out using three major deposition techniques: thermal deposition (TD), laser pulse deposition (LPD), and sputtering.

1.1 Thermal deposition (TD)

Deposition rates are usually between 1 and 10 atomic layers/min. That slow rate automatically requires that the growth be carried out in stringent ultrahigh vacuum (UHV) conditions: a vacuum pressure lower than a few times 10^{-10} Torr is a necessity which can't be compromised. Interface diffusion and segregation usually limits the substrate temperatures to the vicinity of 300–400 K, but in some cases one has to resort to the use of cryogenic substrate temperatures at the initial stages of the growth. In that case, it has been found useful to eventually increase the substrate temperature to the highest allowable temperature in order to avoid excessive lattice defects, achieve large atomic terraces, and improve the overall interface roughness. One has to realize that interface diffusion and intermixing are characterized by significantly lower energy barriers compared with the bulk.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

Therefore once several atomic layers have been deposited the substrate temperature can be increased without having an adverse effect on the interface quality. There are no universal rules to follow. It depends on the individual substrates and deposited films. It is crucial to be able to follow the film growth *in situ* by means of some surface science techniques. Scanning tunneling microscopy (STM), reflection high-energy electron diffraction (RHEED), low-energy electron diffraction (LEED), angular resolved Auger electron spectroscopies (ARAES), and X-ray photoelectron spectroscopies (XPS) are most commonly employed as *in situ* UHV tools. The growth of heteroepitaxial structures can be affected by a number of problems related to interface thermodynamics and lattice mismatch.

1.1.1 Surface segregation and interdiffusion

Surface segregation can be important in the growth of heteroepitaxial structures especially at elevated temperatures. It is often thought that alloys like CoCu or FeAu are not formed naturally because their heats of alloying is endothermic. This does not necessarily apply to surfaces. In many cases, the thermodynamics favors surface segregation (mixing of film and substrate atoms) on a low surface free energy substrate and as a result metastable alloys can be formed (Steigerwald, Jacobs and Egelhoff, 1988). The effect of segregation was nicely demonstrated by Egelhoff (1989) using Ni grown on a Cu(001) substrate. Rapid segregation was observed at 450 K. Bulk diffusion was not possible at these temperatures. A lattice site hop via the vacancy mechanism would happen on a timescale of 10^7 years at 450 K. The Cu/Ni interface provides a much lower activation energy allowing an effective segregation of Cu on the top of the deposited Ni film (Egelhoff, 1994a). A possible process is exchange diffusion often referred to as the place-exchange atomic mechanism. In this process, surface diffusion proceeds by the combined motion of an adatom moving down into the substrate surface at the same time that a substrate surface atom moves up to form a new film atom (Chambliss, Wilson and Ching, 1992; Grass, 2003). Interface exchange diffusion can dramatically affect the magnetic properties. A typical example is an Fe-whisker/Cr/Fe(001) structure which has played a crucial role in the study of exchange coupling between two ferromagnets separated by a spin density wave (SDW) Cr(001) layer. Scanning electron microscopy with polarization analysis (SEMPA) (Unguris, Celotta and Pierce, 1991; Unguris, Celotta and Pierce, 1992) and magneto-optic Kerr effect (MOKE) measurements (Purcell *et al.*, 1991) showed that the exchange coupling oscillates with the thickness of the Cr film with a short-wavelength period of $\sim$2 atomic layers. Heinrich and coworkers have carried out quantitative studies (Heinrich and Cochran, 1993; Heinrich, Cochran, Monchesky and Urban, 1999). They found that the coupling is extremely sensitive to small variations in the growth conditions. In addition it was also established that the phase of the coupling in this system was shifted by 180°. The bilinear exchange coupling strength was found to oscillate between ferromagnetic and antiferromagnetic for an even and odd number of the Cr atomic layers. This is exactly opposite to that expected for a SDW in Cr(001). This study showed that the strength of the bilinear coupling constant J_1 was very sensitive to the initial growth conditions: a lower initial substrate temperature resulted in a larger exchange coupling strength. This behavior indicated that the atomic formation of the Cr layer is more complex than had been previously acknowledged. ARAES (Venus and Heinrich, 1996), STM (Davis, Stroscio, Pierce and Celotta, 1996), and proton induced AES (Pfandzelter, Igel and Winter, 1996) have shown that the formation of the Fe/Cr(001) interface is strongly affected by an interface exchange atom diffusion. The ARAES studies showed that interface alloying during the growth starts at the low temperature of 100 °C. Interface alloying increases with increasing temperature. It is driven by the difference in binding energies between the substrate and the adatoms. Interface alloying has been observed in those systems for which the substrates have a lower melting point than the adatom solids. Therefore this effect is not symmetric. It happens at the Fe/Cr interface but it is absent at the Cr/Fe(001) interface (Heinrich, Cochran, Monchesky and Urban, 1999). Freyss, Stoeffler and Dreysse (1997) used a tight-binding d-band Hamiltonian to show that the interface alloying indeed results in the reversal of the phase of the bilinear exchange coupling in agreement with the experimental studies. The interface roughness of Fe/Cr/Fe(001) and Fe/Cr(001) structures has a profound effect on the SDW even in thick Cr layers. In Fe/Cr/Cr(001) superlattices grown on MgO(001) substrates (Fullerton, Bader and Robertson, 1996), the neutron scattering data have shown that the transverse SDW (with the magnetic moment parallel to the film and the single Q wave vector oriented perpendicular to the layers) orders symmetrically in the Cr layers with the nodes near the Fe–Cr interfaces. This is in agreement with the Stoeffler and Gautier theoretical calculations (Stoeffler and Gautier, 1995) showing that the magnetic moment in Cr is primarily stabilized by SDW order. The magnetic moment in Cr can be easily decreased, even quenched, by interface disorder. The SDW in Cr depends strongly on the degree of interface roughness. Cr(001) films grown on $(1\bar{1}02)$ oriented Al_2O_3 substrates having a Nb(001) buffer layer (Boedeker, Schreuer and Zabel, 1999) and covered by an Fe(001) layer showed a different behavior. For thicknesses less than 25 nm a transverse incommensurate SDW with the magnetic moment of Cr perpendicular to the film was

observed. In this case, the interface disorder was accommodated by orienting the magnetic moment of the Cr atoms perpendicular to the in-plane Fe magnetic moments. There is no preference for the Cr moments to be parallel or antiparallel to the surrounding Fe atomic moments. Commensurate SDWs were obtained by limiting the Cr thickness to values less than the SDW wavelength, see further details in Boedeker, Schreuer and Zabel (1999).

1.1.2 Surfactants in epitaxy

An absorbate can modify the balance of surface and interface free energies and can have a pronounced effect on surface morphology. That was nicely demonstrated by the Egelhoff and Chambliss groups (Steigerwald, Jacobs and Egelhoff, 1988; Chambliss, Wilson and Ching, 1992). Transition metals (TMs) such as Fe and Ni have the tendency to conglomerate and intermix on Cu(001) substrates. An absorbate such as oxygen forms stronger bonds with Fe and Ni than with Cu. This significantly decreases the TM surface energy and leads to an appreciable reshuffling of the Ni and Fe atoms resulting in a flattening of the Fe, Ni/vacuum interface (Egelhoff, 1994b). Egelhoff *et al*. (1997) have used oxygen as a surfactant in the growth of Co/Cu/Co spin valve structures. Their spin valve structures were fabricated using sputtering (see Section 1.3 below). Single Co/Cu/Co specimens grown on a NiO substrate in 2 mTorr of Ar, oxygen free, exhibited a giant magnetoresistance (GMR) effect of 14%: Egelhoff *et al*. refer to this structure as a 'bottom spin valve'. Bottom spin valves grown in an atmosphere of 2 mTorr Ar plus 5×10^{-9} Torr of oxygen exhibited an increase in GMR from 14 to 19%. This increase in GMR is thought to be due to the growth of smoother Co/Cu interfaces resulting in an increased specular scattering of the conduction electrons at those interfaces. The GMR effect could be further increased by postgrowth oxidation of the top Co layer. A surface film of oxidized Co led to a smoother Co/CoO interface which further increased the level of specular scattering of electrons. The Egelhoff *et al*. procedure (Egelhoff *et al*., 1997), considerably increased the efficiency of GMR sensors and has become a part of the processing steps for commercially made spin valve sensors.

Not all surfactants lead to smooth interfaces. Fe films grown on GaAs(001) substrates are known to incorporate approximately 0.6 monolayer (ML) of As as a surfactant. This limits the size of Fe terraces to 3 nm. In this particular case the As likes to become attached to the Fe atomic steps. In fact, the As floats on the top of metallic layers deposited over the Fe films. The surface reconstruction of Au(001) (grown on Fe(001)) is 2×2 instead of the well-known 5×1 reconstruction of a clean Au(001) surface, see Figure 1. STM images have shown that the Au terraces are

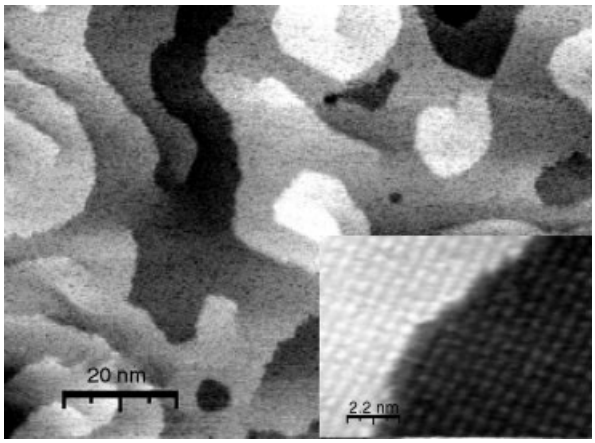

Figure 1. STM image of the top Au(001) layer in a GaAs/Fe/Au(001) structure prepared by thermal deposition. Lower right inset: Note that the Au(001) film has a 2×2 surface reconstruction. This reconstruction is triggered by surfactant As. Notice that the atomic terraces are rounded and decorated by 2×2 atomic kinks.

not of a rectangular shape as is the case of a clean Au surface, but are rounded and are terminated by a high density of atomic kinks consisting of 2×2 Au atoms: the surface of the 5×1 reconstruction consists of rectangular shaped terraces. (Recent measurements carried out together with the Max Planck Institute, Halle, and the Technical University, Krakow.) A well-known 5×1 reconstruction of Au(001) was observed in GaAs/Fe/Au(001) structures prepared by LPD, see Figure 2. This suggests that LPD does not allow surfactant As to float on the top of the metallic layers.

It was found possible to increase the size of atomic terraces of Fe grown on GaAs(001) by removing the surfactant As by sputtering using grazing incidence 500 eV Ar^+ ions. Subsequent annealing and the growth of Fe at 200 °C markedly improved the film conductivity (Monchesky *et al*., 1999). This indicated that the removal of As and subsequent annealing and growth at 200 °C repaired the defects created by the sputtering and improved the surface smoothness: this resulted in a greater specular electron reflectivity at the Fe/vacuum interface (Enders *et al*., 2001).

1.1.3 Lattice strain

In heteroepitaxy the lattice mismatch can be significant and can result in ordered structural defects which can profoundly modify the magnetic properties of ultrathin-film structures.

Pd/Fe(001)

A typical example is Pd grown on Fe(001) templates. Because of a high density of states at the Fermi surface, the magnetic properties of Pd are sensitive to structural changes. Several authors have predicted the onset of ferromagnetism

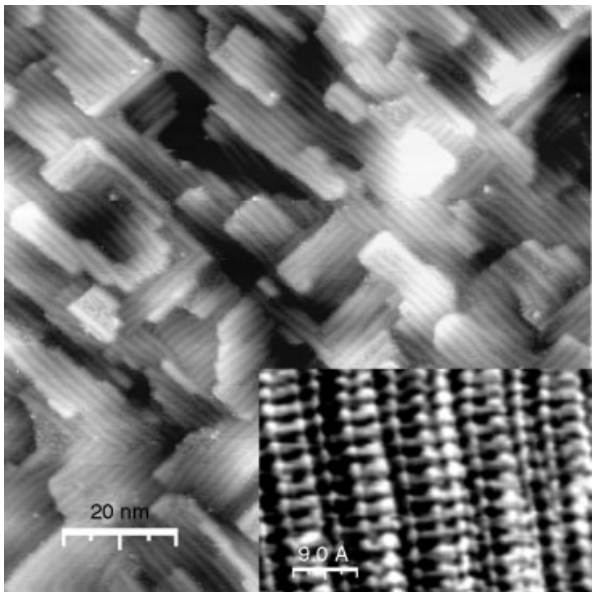

Figure 2. STM image of the top Au(001) layer in a GaAs/Fe/Au(001) structure prepared by laser pulse deposition (LPD). The STM image corresponds to a well-known 5×1 reconstruction of a clean Au(001) surface. The Au(001) surface is terminated by a corrugated atomic (111) plane, see the lower right inset. Notice that the atomic terraces are square shaped with the atomic steps oriented along the ⟨110⟩ crystallographic directions.

in fcc Pd having a lattice expanded by 6% (Moruzzi and Marcus, 1989a,b). Molecular beam epitaxy (MBE) makes it possible to explore the interplay of structure and magnetism in ultrathin Pd layers by creating metastable phases and manipulating the atomic structure via epitaxial strain. In the Fe/Pd(001) system, the lattice strain results from the 4.2% mismatch between the bcc Fe(001) and the Pd(001) surface nets. Ultrathin Pd(001) films grown on Fe(001) are expanded laterally to match the Fe mesh (Celinski *et al*., 1990). The structure and magnetism of Pd in Fe/Pd/Fe (001) trilayers grown on Ag(001) substrates were studied in Celinski *et al*. (1990). The main result of the magnetic measurements was that the Pd was ferromagnetic only for two adjacent Pd atomic layers at the Fe/Pd and Pd/Fe interfaces. By increasing the thickness of Pd by one additional atomic layer (a total thickness of 5 ML) the long-range ferromagnetic order in Pd was lost. Using RHEED and X-ray diffraction it could be shown that the Pd ultrathin films grew on Fe(001) with a 4.2% latterly expanded lattice accompanied by an out-of-plane contraction of 7.2% ($c/a = 0.89$). The ultrathin films of Pd grown on Fe(001) had a pronounced face-centered tetragonal (fct) structure (Fullerton *et al*., 1995). Theoretical *ab initio* studies of the interfacial structure showed that the structural ground state of the epitaxially strained Pd layer was well described by a fct structure which maintained the bulk Pd atomic volume (Fullerton *et al*., 1995). This was in agreement with the results of RHEED and X-ray diffraction measurements.

Ab initio theoretical studies of Fe_3Pd_n superlattices (where n is the number of Pd atomic layers) with fct Pd found that indeed the first two atomic layers of Pd at the Fe/Pd and Pd/Fe interfaces are ferromagnetic but the magnetic moment in the third atomic layers abruptly disappears (Fullerton *et al*., 1995). The spin polarization in Pd is mainly induced by the Fe moments and does not have an intrinsic character. The magnetic moment in the Pd atomic layer adjacent to Fe was found to be 0.29 Bohr magnetons (μ_B). Polarized neutron reflectivity results on an Fe(5.6 ML)/Pd(7 ML)/Au(20 ML) sample determined the average moment per Fe atom to be $2.66\,\mu_B$ (Fullerton *et al*., 1995). Calculations for the same structure showed that this value is consistent with the observed induced Pd polarization. It is interesting to point out that metallic fcc Pd having a lattice expansion of 4.2% would result in long-range ferromagnetic order (Fullerton *et al*., 1995). Clearly the lattice vertical relaxation has to be taken into account in order to explain the real magnetic properties of strained epitaxial structures.

Lattice strain is eventually relaxed by the introduction of a network of misfit dislocations. Crystalline Au/Pd/Fe(001) and Au/Fe/Pd/Fe(001) epitaxial layers grown on GaAs(001) represent typical cases. Pd has a lateral lattice mismatch of 4.2% with respect to the Fe(001) and 4.9% with respect to the Au(001) atomic meshes, and therefore samples with a sufficiently thick Pd layer are influenced by the presence of lattice strain induced defects. Using plan view transmission electron microscopy (TEM), (Woltersdorf, Heinrich, Woltersdorf and Scholz, 2004), a self-assembled network of misfit dislocations was found to be oriented along the ⟨100⟩ crystallographic axes of Fe, see Figure 3.

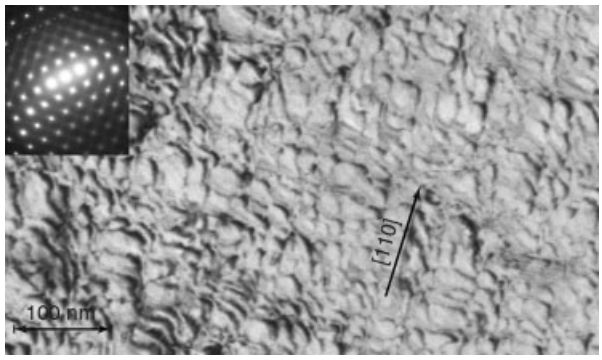

Figure 3. Plan view TEM image of the 90Au/9Pd/16Fe/GaAs(001) sample exposing the misfit dislocation network (Woltersdorf, Heinrich, Woltersdorf and Scholz, 2004). The upper left inset shows the corresponding diffraction pattern. The fourfold symmetry of defects is evident in the presence of reciprocal sheets. The mean separation between dislocation lines was ∼15 nm. (Reprinted with permission B. Heinrich *et al*., copyright 2004, American Physical Society.)

The onset of a rectangular network of misfit dislocations resulted in a strong extrinsic magnetic damping. This damping could be described by a two-magnon scattering process (Woltersdorf, Heinrich, Woltersdorf and Scholz, 2004; Woltersdorf and Heinrich, 2004). The lattice defects associated with misfit dislocation slip planes created a rectangular network of uniaxial anisotropies having an overall fourfold in-plane symmetry oriented along the ⟨100⟩ axes of the Fe(001) template. No overall average uniaxial anisotropy was observed indicating that the distribution of the uniaxial anisotropies along the misfit dislocation slip planes was highly symmetric. Due to inhomogeneities in the induced in-plane network of uniaxial anisotropies the ferromagnetic resonance (FMR) linewidth exhibited a strong fourfold angular dependence on the direction of the saturation magnetization with respect to the Fe crystallographic axes. The maximum two-magnon scattering occurred with the magnetization directed along the ⟨100⟩ axes, while the two-magnon scattering contribution was absent when the magnetization was directed along the ⟨110⟩ axes.

An angular dependent extrinsic damping created by a rectangular network of defects appears to be a common phenomenon.

Ni/Fe and Heusler alloy films

The creation of a network of lattice defects satisfying the in-plane crystalline fourfold symmetry has also been observed in metastable bcc Ni/Fe(001) bilayers grown on Ag(001) substrates (Heinrich *et al*., 1988), Fe(001) films grown on bcc Cu(001) (Celinski and Heinrich, 1991), and in Fe/V superlattices (Lindner *et al*., 2003). After depositing 3 ML of Ni on Fe(001) to form a Ni/Fe(001) bilayer the bcc Ni went through a major structural change. Mijiritskii *et al*. (1998), showed that the Ni underwent a bcc to fcc martensitic transition creating a mosaic of four fcc Ni domains with the fcc Ni{110} planes parallel with the bcc Fe{110} planes and the Ni⟨211⟩ crystallographic directions along the Fe⟨110⟩ axes. The lattice defects created by the martensitic transition again resulted in local anisotropies having the overall symmetry of the Fe(001) template (Lindner *et al*., 2003). This resulted in two strong magnetic effects: firstly, an additional average in-plane fourfold anisotropy field in Ni/Fe, $2K/M_s$, was created and exceeded the cubic anisotropy field of the bulk Fe by nearly an order of magnitude. Secondly, the inhomogeneous part of the magnetic anisotropy resulted in a strong extrinsic damping with the damping maxima occurring when the magnetization was directed along ⟨110⟩ and the damping minima occurring when the magnetization was directed along the ⟨100⟩ crystallographic axes of the Fe. Coercive fields of several hundred oersted were observed due to the enhanced anisotropy and lattice defects (Heinrich *et al*., 1993; Przybylski *et al*., 2002).

A similar situation occurs for semimetals. Half-Heusler compound NiMnSb(001) films were grown in UHV, MBE, on (In,Ga)As/InP (001) wafers for possible applications in spin injection devices, (Bach *et al*., 2003). A quasicontinuous network of defects closely aligned with the ⟨100⟩ in-plane directions (Koveshnikov *et al*., 2005) resulted in strong two-magnon scattering which led to an extrinsic magnetic damping exceeding the intrinsic damping by two orders of magnitude (Heinrich *et al*., 2004). The ability to control the damping by means of a network of misfit dislocations could be attractive to promote a fast convergence to the steady state of magnetic memory pixels where the rotation of the magnetic moment in the time domain is of the order of nanoseconds.

Fe/MgO

The role of lattice mismatch and chemistry at interfaces is exemplified by the growth of MgO on Fe(001). The growth of high quality crystalline layers of MgO on Fe is attractive for use in Fe/MgO/Fe(001) spin polarized tunneling junctions (Klaua *et al*., 2001). It also represents an interesting case of interface formation involving a TM (Fe), and an oxide (MgO) having a large tunneling barrier. The structural studies were particularly simplified by using perfect Fe whiskers for substrates: the Fe whiskers were prepared by chemical vapor deposition (CVD). Single-crystal Fe(001) discs were also used. The MgO layers were deposited on a substrate at 295 K using electron beam evaporation. MgO grows pseudomorphically on Fe(001) for thicknesses up to 6 ML with the epitaxial relationship of Fe(001)[110]/MgO(001)[100] and a 3.8% compression of the MgO lattice. A partial lattice relaxation sets in for MgO films thicker than 6 ML, resulting in an increased lattice spacing. The most convincing indication of the pseudomorphic growth and subsequent sharp onset of misfit dislocations can be seen in the LEED patterns.

The LEED and RHEED spots were very sharp on a clean bcc Fe(001) whisker indicating a superb surface quality. Similar sharp spots were observed from the MgO(001) surface after the growth of 6 ML of MgO. For thicknesses greater than 7 ML the MgO LEED pattern showed four additional satellite spots around each main MgO diffraction spot, see Figure 4. The four lines connecting any given set of satellite spots and their central diffraction spot were directed along equivalent ⟨100⟩ in-plane crystallographic directions of the MgO lattice. This splitting decreased with increasing thickness of MgO. This behavior can be explained using a model which includes edge dislocation formation at the Fe/MgO interface. The MgO lattice warps in a narrow region above the misfit dislocation lines. The warped surfaces created tilted reciprocal-space rods which satisfied the fourfold in-plane symmetry of the Fe(001) template. The LEED satellite

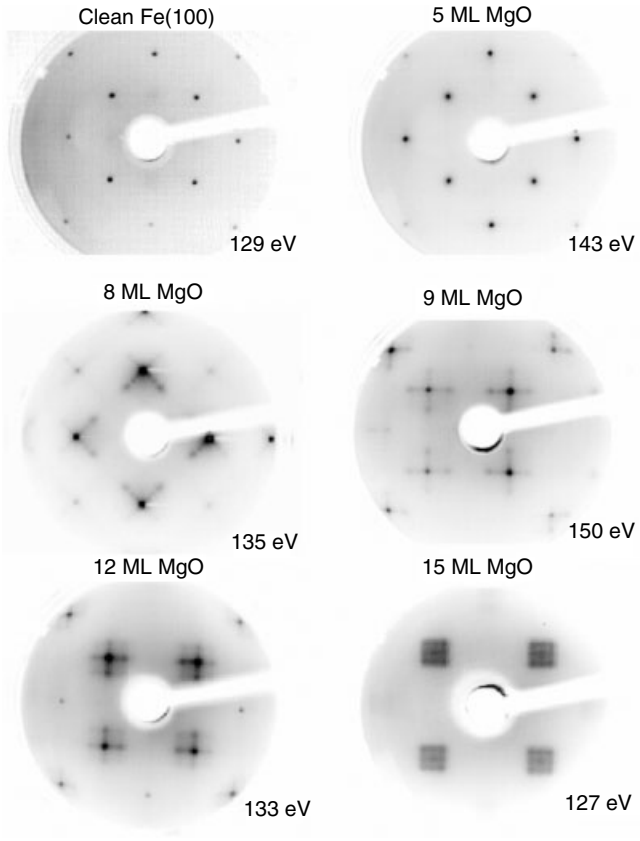

Figure 4. LEED patterns of MgO(001) films grown on a nearly perfect Fe(001) whisker template (prepared by chemical vapor deposition). Notice that the MgO(001) starts to grow with the lattice spacing of Fe and having nearly perfect LEED diffraction spots like those of the Fe(001) whisker. At 8 ML the MgO(001) partly releases its lattice strain (compression) by creating a network of misfit dislocations. The dislocation glide planes result in surface corrugations leading to inclined reciprocal rods. Each main diffraction spot is surrounded by four satellite spots reflecting the fourfold symmetry of the Fe(001) template, see the text. Notice that the satellite spots decrease their separation with increasing thickness of the MgO film which indicates that the core of the dislocation network remains confined to the Fe/MgO(001) interface.

spots were caused by the tilted reciprocal-space rods. STM images revealed nearly perfect layer-by-layer growth. Electron diffraction and STM studies revealed an overall surface topography and orientation but they did not provide one with details of the chemistry at the Fe/MgO interface. *Ab initio* calculations by Butler, Zhanh, Schulthess and MacClaren (2001) for Fe/MgO/Fe(001) trilayers have provided evidence for the importance of lattice perfection at the Fe/MgO interface. They showed that tunneling magnetoresistance (TMR) can become as large as several 1000% due to a strongly peaked conductance in the majority channel for a parallel alignment of the Fe magnetic moments, while the minority channel conductance is dominated by interface states. Clearly the transmission magnetoresistance, the TMR ratio, will be strongly affected by the chemistry and lattice configuration at the Fe/MgO interface. Meyerheim *et al*. have addressed this question by using surface X-ray diffraction (SXRD) measurements (Meyerheim *et al*., 2001). They found that, contrary to common belief, MgO is not formed in direct contact with the Fe. They found that a FeO interface layer is formed between the Fe substrate and the growing MgO layer, see Figure 5. This oxide layer clearly must affect the formation of interface states and the corresponding TMR ratio.

The Fe-whisker/MgO/Fe/Au(001) structure provided an ideal opportunity to investigate tunneling through a nearly perfect crystalline tunneling junction. The tunneling in Fe-whisker/MgO and Fe-whisker/MgO/Fe/Au(001) structures was investigated by means of an STM tip (Klaua *et al*., 2001). The tunneling *I–V* characteristics were found to be very asymmetric. For a negative bias no tunneling current was observed due to the large tunneling barrier in MgO. The *I–V* curves for a positive bias showed an abrupt increase in the tunneling current when the Fermi level of the STM tip was lined up with the conduction band states of MgO. In fact in that way it was possible to determine the potential barrier of the Fe/MgO/Fe system. For 2 ML of MgO the tunneling barrier was already 2.5 eV. The tunneling barrier reached the bulk value of 3.5 eV at an MgO thickness of 5 ML. The relationship between the MgO layer thickness and the electron transport

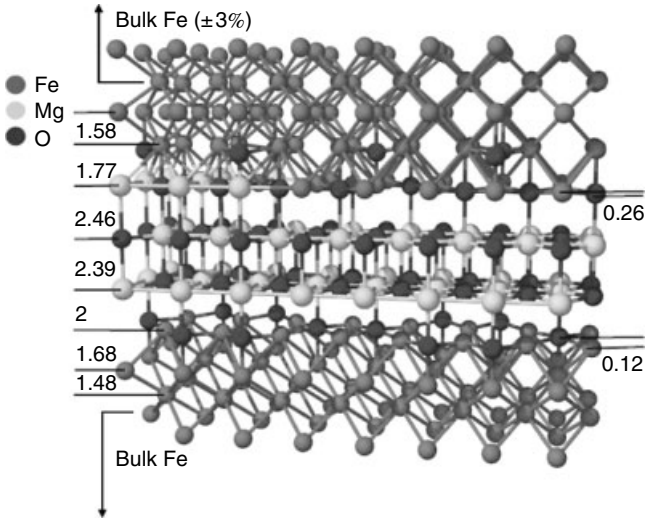

Figure 5. A model of atomic layers of a crystalline Fe/MgO/Fe(001) structure prepared on a Fe(001) whisker. This model was obtained by interpreting the surface X-ray diffraction (SXRD) measurements, see Meyerheim *et al*. (2001). Notice that the first oxide layer is mostly FeO with the oxygen atoms located on the fourfold hollow sites of the top Fe(001) atomic layer. The integers on the left side describe the interplanar distances in angstroms. (Reprinted with permission Meyerheim *et al*., copyright 2001, American Physical Society.)

through the MgO layers was obtained by taking STM topographic images and acquiring tunneling *I–V* characteristics simultaneously. These images showed that the tunnel barriers were homogeneous across a large area of the sample, and they revealed a low density of localized defects (a few nanometers across) that correlated neither with substrate steps nor with misfit dislocations. These defects were most likely caused by localized defect states located midway between the valence and conduction bands of MgO (Klaua *et al*., 2001). The same *I–V* images were obtained for the Fe/MgO and the Fe/MgO/Fe/Au samples. Both samples exhibited mainly perfect tunneling characteristics and a low density of localized defects. This was an important observation. It can be concluded that the electron transport in high quality crystalline MgO tunneling junctions proceeds by ballistic tunneling.

The magnetization behavior of single crystalline Fe-whisker/20MgO/20Fe/20Au(001) films was investigated by depth-selective Kerr microscopy (Schaefer *et al*., 2002). No magnetic coupling through the MgO was observed. It was demonstrated that a moving 180° whisker domain wall acts on the Fe film by writing domains in the film that are magnetized transverse to the wall direction. The sign of the transverse domains depends on the internal rotation sense of the whisker wall, not on its surface rotation. The change in sign of the transverse domains was always accompanied by a Bloch line. This clearly indicated that the residual fringing fields emerging from the whisker wall must be responsible for the interaction. The sign of these fringing fields depends on the internal rotation alignment of the whisker wall.

Fe/GaAs

The importance of growth of metallic structures on semiconductor substrates has been realized right at the advent of MBE studies of 3d TM elements. The early development in this field is well described in Prinz (1994). The Fe/GaAs(001) interfaces became very attractive for spintronics devices using electrical spin injection into semiconductors. See review chapters on Spin-Light Emitting Diodes (SLED) by Jonker (2005) and Optical Studies of Electron Spin Transmission by Bland, Steinmueller, Hirohata and Taniyama (2005). The magnetic properties of GaAs/Fe(001) will be further discussed in Section 2.5. The Naval research laboratory (NRL) group has carried out extensive studies of GaAs/Fe(001) and GaAs/AlGaAs/Fe(001) interfaces. They were able to find plausible Fe/AlGaAs(001) interface structures (Zega *et al*., 2006) by employing high-angle annular-dark-field (HAADF) imaging, the highest resolution chemically sensitive TEM technique. The results were interpreted by means of using computer simulations based on density-functional theory. It was found that the Fe films grown at the substrate temperature of 10–15 °C results in a structurally disordered Fe_3GaAs compound interface that is about 5 atomic layers in thickness. By means of low temperature annealing at 200 °C the interface becomes ordered and coherent with intermixing of the Fe and AlGaAs occurring on a single atomic plane. This marked improvement in the interface structure results in an appreciable increase in spin injection polarization going from 18% for grown samples to 25% for annealed samples. The interface structure strongly affects carrier lifetimes and perfectness of Schottky barriers. The Fe films grown at 175 °C on a GaAs(001) template terminated by an As rich 2×4 reconstruction resulted in an appreciable enhancement of carrier lifetimes and a decrease in the density of midgap states (depinning of the Fermi level) compared to the Fe films grown on S-passivated, AlGaAs, and native oxide GaAs(001) templates (Jonker, Glembocki, Holm and Wagner, 1997). The STM study of a submonolayer growth of Fe on a (2×6) reconstructed GaAs(001) template was carried out by Ionescu *et al*. (2005). The (2×6) reconstruction is a Ga-rich As terminated surface. They have shown that in the early stages the growth of Fe clusters mainly occurs atop the As-dimer rows. At 0.3 ML of Fe a transition from the 3D cluster growth to a 2D island nucleation takes place. At 1 ML the coalescence of several islands leads to a large distribution of island sizes and decreased island density. The STM images indicated that during deposition some of the Fe penetrates into the GaAs(001) substrate. Fe atoms substitute for Ga atoms in the second layer displacing them into an interstitial position. In addition, it is suggested that the Fe atoms inside the top As layer together with the top Fe layer form Fe_2As antiferromagnetic compound seed crystals for the bcc Fe growth. The following Fe growth is GaAs(001)‖Fe_2As(001)‖Fe(001) and within the plane GaAs[110]‖Fe_2As[100]‖Fe[110]. The substitution of Ga atoms by Fe is in agreement with the recent Mössbauer studies (Kardasz *et al*., 2007). A low hyperfine field component was found in the TD Fe films on GaAs(001) − (2×6). The low hyperfine field (0.65 T) component corresponds to approximately 6% of the relative intensity.

1.2 Laser pulse deposition (LPD)

LPD turned out to be particularly useful for the growth of high T_c material compounds (Chrisey and Hueber, 1994). The main advantage of this method is that any material can be deposited, and the stoichiometry of any material is preserved. It turns out that the popular view is not always true. In magnetically doped TM oxides, such as Co-doped TiO_2, when the film composition has been independently measured, it has been found to be different from that in the target. In the LPD method repeatable short pulses from a high-power laser impinge on the surface of a target material. The evaporation takes place within the very short time of

a few nanoseconds. The material does not melt but it is ablated. The resulting vapor consists mostly of atoms and dimers. The laser pulse is usually longer than the time required for evaporation and this results in absorption of the light by the vapor. The absorption of light leads to ionization of the evaporated atoms and the formation of a visible so-called plasma plume which expands toward the target. The evaporated material in the plasma reaches an energy of $\sim$1 eV, much higher than that obtained by thermal evaporation. A recoil plasma plume and target macroscopic and microscopic surface irregularities after repeated exposure to high-energy laser pulses lead to the so-called splashing in which particles and droplets are deposited on the substrate. The particles and droplets are of the order of a micron in size and are absolutely undesirable in the growth of ultrathin films. There are a number of modifications of the LPD system that allow one to minimize the effect of splashing (Gavignan, 1991; Holzapfel *et al*., 1996). Generally a large distance between the target and the substrate, rotation of the target during deposition, and keeping the laser power slightly above the ablation threshold help to minimize the role of splashing (Jenniches *et al*., 1999).

The LPD average deposition rate is not high: usually a fraction of a monolayers per minute, similar, but even lower than the deposition rate for TD films. However, during the laser pulse the evaporation rate is very high and one obtains the so-called instantaneous deposition (Cheung and Sankur, 1988). The deposition rate during the pulse can be in the range of 10^4 ML s^{-1} which is 6–7 orders of magnitude higher than the deposition rate associated with TD (Jenniches *et al*., 1999). This large deposition rate leads to a substantial increase in the density of condensation nuclei compared with TD. After applying the laser pulse the atoms in the plasma plume are deposited over a period of the order of 1 μs, the duration time of the plasma plume. This leads to a very high rate of deposition. Each laser pulse deposits between 10^{-3} and 10^{-2} ML of atoms/μs. It is known that the number of nuclei scales with the flux as $(F/D)^c$, where F is the flux, D is the diffusion constant, and $c \sim 0.5$ (Villain, Pimpinelli and Wolf, 1992). Therefore during the first laser pulse a significantly larger density of nuclei is formed than is established during TD. Small critical nuclei consist only of two atoms. After the next laser pulse the burst of deposited single atoms is available to participate in the growth. Between laser pulses the deposited adatoms have time to diffuse and to become attached to the closely spaced nuclei. In this way a full atomic layer is slowly filled. In TD the deposition is continuous and the flux is 6–7 orders of magnitude smaller than that obtained using LPD. This means that the density of TD nuclei is much lower. The nuclei are larger and more separated. The deposited atoms have a much longer time to get attached to existing nuclei than is the case for LPD. This can profoundly affect the growth of structures where it can be expected that a fast incorporation of atoms into a continuous layer is important for maintaining a metastable structure.

Jenniches *et al*. (1999) found that using LPD one can grow metastable fcc Fe(001) on Cu(001) layer by layer up to 10 ML. The growth was carried out at RT. The fcc Fe(001) films thicker than 10 ML underwent a phase transition to bcc Fe. Fcc Fe forms a high magnetic moment state that increases with thickness up to 3 ML. Between 5 and 7 ML the film experiences an inverse spin reorientation from a magnetization oriented in plane to an out-of-plane magnetization orientation in which the easy axis is perpendicular to the film plane. The TD films showed no layer-by-layer growth for the first 2 ML: a layer-by-layer growth appeared only after an average thickness of 2 ML. The LPD films grew in the fcc structure, whereas the TD films grow in a fct structure. The LPD films have the lattice constant of Cu in both directions. The fct films were found to be unstable with increasing temperature (Zharnikov *et al*., 1997), while the LPD films were found to be stable. Improved morphology and structure for films grown by LPD was also observed in the growth of Fe(111) on a Cu(111) substrate. The deposition was carried out at 220 K in order to eliminate a significant interdiffusion of Cu and Fe. Two monolayers thick Fe/Cu(111) films grown by TD exhibited a conglomerated structure where the surface coverage ranged from 0 to 5 ML with a considerable presence of ridgelike features (Ohresser *et al*., 1999). TD deposited films of Fe on Cu(001) had a critical thickness of 3 ML for the fcc to bcc lattice transformation. The LPD films grew with a better structural quality than the TD grown films. In the low thickness range, 3 ML, the LPD films have a long-range order and a large magnetic moment while the TD films have a short range order and low magnetic moment (Ohresser *et al*., 1999).

LPD is not always a winner. The bcc Fe(001) films grown by TD on a GaAs(001) substrate exhibit a smoother GaAs/Fe interface than those grown by LPD. Mössbauer studies have shown that the LPD films have a high degree of Fe incorporated into the GaAs while the TD films incorporated only a small amount of Fe into the GaAs substrate and these incorporated atoms exhibited a small hyperfine field (Kardasz *et al*., 2007). The rough Fe/GaAs interface obtained using LPD is most likely caused by the high kinetic energy of the LPD atoms. Layer-by-layer growth is only observed using TD, but the average size of terraces is similar in the LPD and TD grown films. The interface magnetic properties are profoundly affected by the method of deposition. The LPD deposited films exhibit nearly zero in-plane uniaxial anisotropy, whereas the TD deposited films exhibit a large uniaxial anisotropy of 1 KOe for Fe(001) films 10 ML thick (Monchesky *et al*., 1999).

1.3 Magnetron sputtering

Sputtering differs from MBE growth techniques due to the difference in the kinetic energy of the deposited atoms. The energy of the sputtered atoms depends on many factors (Eric E. Fullerton private communication). It depends on the relative potential of the target, the masses of the sputtering gas, target atoms, the product of the gas pressure and the target-to-substrate distance. The latter is particularly important because the sputter gas thermalizes the sputtered atoms. The greater the gas pressure and/or target-to-substrate distance the more the atoms are thermalized and can be characterized by a temperature that approaches ambient temperature, see Schuller and Falco (1981), Fullerton (1993), and Windischmann (1992). The energy of the adatoms impinging on a substrate in sputtering can have a profound effect on the deposited film morphology. Crystalline TM films, rare-earth (RE) and oxide epitaxial layers have been grown using sputtering in which the sputtered atoms are deposited on epitaxial buffer layers grown on single-crystal substrates. Epitaxial crystalline films prepared by the use of sputtering include Fe (Yaegashi, Kurihara and Segawa, 1993; Fuke, Sawabe and Mizoguchi, 1993; Fullerton *et al*., 1993; Mattson, Fullerton, Sowers and Bader, 1995); Pt and FePt (Lairson *et al*., 1992; Lairson, Visokay, Sinclair and Clements, 1993); Co (Morawe *et al*., 1991); Cu (Giron *et al*., 1993); $SmFe_{12}$, Sm_2Co_7, Sm_2Co_{17} (Fullerton, Sowers, Pearson and Bader, 1997) and MgO (Park, Fullerton and Bader, 1995).

MgO(111), MgO(110), and MgO(001) substrates have been employed to grow different orientations of the bcc TMs Nb, Mo, Fe, and Cr (Mattson, Fullerton, Sowers and Bader, 1995). Nb, Mo, Cr, and Fe films have been grown with the (001), (112), and (110) crystallographic orientations on MgO(001), MgO(110), and MgO(111) substrates, respectively. Fe/Cr(001) and Fe/Cr(211) superlattices have been grown on MgO(001) and MgO(110) substrates covered by a 10-nm Cr buffer layer which was deposited at 600 °C (Fullerton *et al*., 1993). The subsequent Fe/Cr superlattices were grown at 180 °C. The epitaxial orientation of the Fe/Cr(211) superlattices was found to be $\mathrm{Fe/Cr}\left[0\bar{1}1\right] \| \mathrm{MgO}\left[1\bar{1}0\right]$ while for Fe/Cr(001) the epitaxial orientation was found to be Fe/Cr[001]||MgO[011]. These orientations correspond to a 3.8 and a 16.7% lattice mismatch of the Cr with MgO, respectively. The crystalline lattice coherence was found to be ∼43 nm. A 10-nm Cr buffer layer was found to be sufficiently thick to relieve most of the epitaxial strain prior to the growth of the superlattice films. XRD measurements showed that the Fe/Cr superlattices sputtered on MgO appeared to be comparable in crystalline quality to those grown on MgO using MBE. The Fe/Cr superlattices were used to investigate the strength of the exchange coupling between the iron films. The exchange coupling exhibited an oscillatory dependence on the Cr film thickness. Only long wavelength oscillations were observed indicating that the interface roughness of the sputtered films was worse than those prepared on good single crystalline lattice matched substrates using MBE (Heinrich and Cochran, 1993; Heinrich, Cochran, Monchesky and Urban, 1999 and references within). In the sputtered Fe/Cr superlattices the strength, oscillation period, and phase of the long wavelength exchange coupling strength were found to be identical for both superlattice orientations. The crystalline magnetic volume anisotropies were found to be nearly the same as those observed for bulk Fe.

Ultrathin films of MgO (5–30 nm) were grown epitaxially onto 15-nm-thick Fe(001) which was used as a seed layer on MgO(001). The LEED spot patterns were observed to be broad and diffused even for 0.5-nm-thick MgO. This indicated that sputtering results in a more disordered MgO(001) lattice structure than that observed for MgO films grown on bulk Fe(001) substrates using TD, see the preceding text. However, the long-range lattice order improved with an increasing MgO thickness. This suggested that the lattice strain in the sputtered films was released already in the initial stages of growth. X-ray forward scattering measurements on sputtered MgO films revealed peaks corresponding to the main crystallographic directions of bulk crystalline MgO.

Epitaxial RE-TM thin films were grown using sputtering onto a buffer layer of 10–20-nm-thick W deposited on MgO(001) (Fullerton, Sowers, Pearson and Bader, 1997). The W(001) buffer layer was sputtered onto a substrate held at a temperature of 600 °C. The W mosaic spread was found to be ∼1°. The epitaxial relationship was found to be W[100]||MgO[110]. This resulted in *c*-axis tetragonal $SmFe_{12}$ films and a *c*-axis growth of hexagonal Sm–Co films. The magnetization in Co-rich Sm_2Co_{17} films was found to be reversible on thermal cycling to 800 K and showed only a 13% reduction in magnetic moment from RT to 800 K. The in-plane coercivity was observed to be 1 T at 300 K and retained the quite high value of 0.42 T at 500 K.

Sputtering has been extensively employed in the preparation of spintronics devices. These systems will be described in separate Chapters.

2 MAGNETIC ANISOTROPIES IN FERROMAGNETIC THIN FILMS

2.1 Anisotropies in bulk single-crystal ferromagnets

Most of our understanding of the properties of ultrathin ferromagnetic films is derived from experimental studies carried

out on films of the TMs Fe, Co, and Ni. Consequently this article will concentrate on a discussion of films composed of those three metals and their alloys. In their bulk form, and in thermal equilibrium at RTs, iron is a body-centered cubic metal (bcc), cobalt is a hexagonal close-packed metal (hcp), and nickel is face-centered cubic metal (fcc). The ferromagnetic state is characterized by a magnetic moment per unit volume, M_s, that is independent of an applied magnetic field to a good approximation (Chikazumi, 1964; Brown, 1978). This magnetization density does depend upon the temperature, and obtains its maximum value at $T = 0\,\mathrm{K}$. The magnetization vanishes at the Curie temperature in zero applied magnetic field. The Curie temperatures of iron, cobalt, and nickel are 1044, 1390, and 631 K (Crangle and Goodman, 1971). It is known from experiment that the free energy of a ferromagnet depends upon the orientation of the magnetization, M_s, with respect to the crystalline axes that define its crystal structure. The origin of this magnetic anisotropy is spin-orbit coupling between the atomic spin moment and the atomic orbital moments (Kittel, 1949; Chikazumi, 1964). On the basis of symmetry arguments the variation of the free energy contribution due to anisotropy in a cubic crystal can be written, to lowest order in the magnetization components,

$$F_a = -\frac{K_1}{2}\left[\left(\frac{M_x}{M_s}\right)^4 + \left(\frac{M_y}{M_s}\right)^4 + \left(\frac{M_z}{M_s}\right)^4\right] \tag{1}$$

where K_1 is an empirical temperature dependent parameter and M_x, M_y, and M_z are the components of $\vec{M}_s$ along the three cube axes. Note that the dependence of F_a on the magnetization components can also be written in the form

$$F_a = \frac{K_1}{M_s^4}\left[M_x^2 M_y^2 + M_x^2 M_z^2 + M_y^2 M_z^2\right] \tag{2}$$

The equivalence of equations (1) and (2) follows from the relation $M_s^2 = M_x^2 + M_y^2 + M_z^2$.

For hexagonal crystal symmetry the anisotropic free energy can be expressed in lowest orders by

$$F_a = K_2 \sin^2(\phi) + K_4 \sin^4(\phi) \tag{3}$$

where

$$\sin^2(\phi) = 1 - \left(\frac{M_z}{M_s}\right)^2$$

and ϕ is the angle between $\vec{M}_s$ and the c axis of the crystal. K_2 and K_4 are temperature dependent parameters, see Chikazumi (1964).

The variation of the free energy density with magnetization direction in the crystal results in a torque density that acts so as to align the magnetization along a direction that minimizes the free energy density. This torque density can be written as

$$\vec{L} = \vec{M}_s \times \vec{H}_a \tag{4}$$

where

$$\vec{H}_a = -\left(\frac{\partial F_a}{\partial M_x}\right)\hat{u}_x - \left(\frac{\partial F_a}{\partial M_y}\right)\hat{u}_y - \left(\frac{\partial F_a}{\partial M_z}\right)\hat{u}_z \tag{5}$$

is an effective magnetic field that exerts the same torque on the magnetization as does a real magnetic field (Brown, 1978).

2.2 Ultrathin ferromagnetic crystals

Consider a very thin crystal whose thickness t is very small compared with its lateral dimensions and which is uniformly magnetized. The magnetization in such thin films is uniform for internal magnetic fields that are comparable to, or larger than, typical anisotropy fields: the same exchange interaction between spins that results in the ferromagnetic state makes any spatial variation of the magnetization density relatively costly in free energy (Brown, 1978). It is clear that the free energy density of this film is likely to be quite different when the magnetization is directed along the film normal as compared with the case in which the magnetization lies in the film plane. The most important source of this free energy difference is due to the magnetic fields generated by the shape of the film. When the magnetization lies in the plane of a film a few mm in lateral dimensions but a few nm thick the magnetic field generated by the magnetization density, discontinuity at the film edges can be ignored (the approximation of infinite lateral dimensions). However, when this same uniform magnetization has a component, M_z, directed along the film normal the discontinuity in magnetization at the film surfaces generates an internal demagnetizing field $H_d = -4\pi M_z$. The interaction between this demagnetizing field and the magnetization density contributes a term to the free energy density having the form

$$F_d = 2\pi M_z^2 \tag{6}$$

Another important source of difference between a bulk magnetic crystal and a magnetic thin film comes about because the thin film must necessarily be supported on a substrate. If the crystal structure of the thin film is not exactly matched to the crystal structure of the substrate, the bonding between the film and substrate must result in deformation of the film. In general, the film structure becomes distorted both in plane and out of plane. The simplest case is that in which the film retains fourfold symmetry in plane but the lattice

spacing in the perpendicular direction becomes different from the in-plane spacing so that the thin film adopts a tetragonal symmetry. For tetragonal symmetry the magnetocrystalline free energy density can be written as

$$F_{\mathrm{a}} = -\frac{K_1^{\mathrm{par}}}{2}\left[\left(\frac{M_x}{M_{\mathrm{s}}}\right)^4 + \left(\frac{M_y}{M_{\mathrm{s}}}\right)^4\right] - \frac{K_1^{\mathrm{perp}}}{2}\left(\frac{M_z}{M_{\mathrm{s}}}\right)^4 - K_{\perp}\left(\frac{M_z}{M_{\mathrm{s}}}\right)^2 \tag{7}$$

where K_1^{par}, K_1^{perp}, and $K_{\perp}$ are anisotropy parameters having the dimensions of energy per unit volume. An example of this case is that of a thin crystal of Fe(001) grown on the (001) surface of a silver substrate (Heinrich *et al*., 1988, 1991; Heinrich and Cochran, 1993, Section 1.4.1). The atoms in the fcc Ag(001) surface net form a square array 2.889 Å on a side. The atoms on the bcc Fe(001) surface planes form a square array 2.866 Å on a side. Thus the fourfold hollows on the silver surface can accommodate the Fe(001) surface atoms if the iron net is expanded by 0.8% in plane. At the same time the spacing between iron atomic layers is reduced by 1.5%: see Section 1.4.1 Heinrich and Cochran (1993).

It may happen that the thin ferromagnetic film is grown on a substrate template that does not exhibit in-plane fourfold symmetry. In that case the free energy density should include a term of lower symmetry having the form of an in-plane uniaxial anisotropy in addition to the terms of equation (7):

$$F_{\mathrm{u}} = -\frac{K_{\mathrm{u}}}{M_{\mathrm{s}}^2}\left(\vec{M}_{\mathrm{s}}\cdot\hat{u}\right)^2 \tag{8}$$

In equation (8) K_{u} is a uniaxial anisotropy parameter and $\hat{u}$ is a unit vector that specifies the orientation of the in-plane twofold axis.

It is an experimental fact that the magnetocrystalline anisotropy parameters of equations (7) and (8) depend upon thickness and temperature. It has been observed that each of the parameters in equations (7) and (8) usually exhibits a thickness dependence such that

$$K_i = K_{iV} + \left(\frac{K_{iS}}{t}\right) \tag{9}$$

where K_{iV} is a thickness independent volume coefficient that has the units of energy per unit volume, and K_{iS} is a coefficient that has the units of energy per unit area, (Heinrich and Cochran, 1993). K_{iS} has the dimensions of a surface anisotropy term. In fact the anisotropy coefficients K_{iS} are found to be sensitive to the structure and chemical composition of the film surfaces and their interfaces with the substrate and any cover layer that may be present: often the film is covered by a nonmagnetic layer either because it forms part of a multilayer, or because the film is covered by an inert film such as gold in order to protect the magnetic film from corrosion if the specimen must be removed from the vacuum system. It should be noted, however, that an inverse dependence of the anisotropy parameter on thickness can also result from the inclusion in the film of a network of dislocations generated in order to relieve stresses in the magnetic film due to lattice mismatches between film and substrate (Chappert and Bruno, 1988, Section IVB).

2.3 The measurement of ultrathin-film anisotropies

The variation of the film free energy with magnetization orientation means that torques are exerted on the magnetization vector due to the effective fields of equation (5). Thus any experimental technique that permits one to measure torques on the magnetization can be used to obtain the anisotropy coefficients of equations (7) and (8). There are two main methods for the investigation of these torques: (i) FMR experiments and (ii) experiments designed to measure the orientation of the magnetization vector as a function of the strength and orientation of an applied magnetic field.

FMR is a dynamic technique in which the frequency is measured when the magnetization, having been perturbed from equilibrium, precesses around its equilibrium orientation. The precessional frequency depends upon all of the magnetic fields to which the magnetization is subject, including the dipolar and anisotropy effective fields:

$$H_\alpha = -\frac{\partial F_{\mathrm{sum}}}{\partial M_\alpha} \tag{10}$$

where $F_{\mathrm{sum}} = F_{\mathrm{d}} + F_{\mathrm{a}} + F_{\mathrm{u}}$ from equations (6–8). A study of how the precessional frequency depends upon applied magnetic field strength and orientation enables one to determine the effective fields due to magnetocrystalline anisotropy. In FMR experiments the precessional frequencies are determined from the resonant absorption of microwave radiation; see the review articles by Heinrich (1994), Farle (1998), and Poulopoulos and Baberschke (1999).

A related technique is Brillouin light scattering (BLS). In BLS the magnetization oscillates around its equilibrium orientation as the result of thermal agitation. The optical constants of the magnetic thin-film material are modulated at the magnetization precessional frequency, ω, and this modulation results in a frequency shift of $\pm\omega$ in the frequency of light reflected from the film; see the articles by Cochran (1994), and by Hillebrands and Güntherodt (1994). FMR and BLS have approximately the same sensitivity.

FMR requires larger specimens than does BLS, but the frequency discrimination is so fine that one can measure effective fields with a precision of 1 Oe in a 10 Å thick iron film having an area of 1 mm^2. The frequency resolution of the BLS technique is between 10 and 100 times less than that for FMR but it can be used to investigate specimens whose dimensions are as small as a few microns on a side. Note that both FMR and BLS measurements yield effective fields. It is therefore necessary to know M_s in order to obtain the anisotropy coefficients K_i. Usually the saturation magnetization must be measured in a separate experiment using a sensitive magnetometer such as a superconducting quantum interference device (SQUID). However, the strength of the FMR absorption signal is proportional to M_s, and it proves to be possible to obtain M_s with an accuracy of a few percent by means of very careful absorption measurements (Celinski, Urquhart and Heinrich, 1997).

A second class of experiments designed to evaluate anisotropy coefficients is based upon the measurement of magnetization curves. Anisotropy coefficients can be deduced from a series of measurements of the magnetization component directed along the applied magnetic field, M_H, as the applied field is varied from zero to a field large enough to ensure that $M_H = M_s$. The free energy difference between the zero field state and the saturated state is given by

$$\Delta F = \int_0^{M_s} H \, \mathrm{d}M_H \tag{11}$$

The change in ΔF with the direction of the applied magnetic field is a direct measure of the variation of the free energy density with the orientation of the magnetization vector, and therefore it can be used to determine the various anisotropy parameters. A very sensitive magnetometer is required to measure the magnetization density in ultrathin magnetic films. Usually the magnetic moment of a specimen of known thickness and area is measured using a SQUID or an alternating-gradient magnetometer (AGM): see Flanders (1988). Absolute magnetic moment measurements are difficult and rather slow, therefore in most cases the magnetometer is used only to measure the saturation magnetization, M_s, and the magneto-optic Kerr effect, MOKE, is used to measure the ratio M_H/M_s as a function of applied magnetic field. For a discussion of the physics of MOKE see Bader and Erskine (1994). These authors also discuss the use of MOKE to investigate anisotropy in ultrathin films. MOKE is a particularly convenient tool for finding the orientation of easy and hard magnetic axes. The optical beam used to measure MOKE can be focused to a very small spot a few microns in diameter so that MOKE can be used to investigate specimens having small lateral dimensions. The use of MOKE to measure anisotropy coefficients is discussed by de Jonge, Bloeman and den Broeder (1994), and by Johnson, Bloeman, den Broeder and de Vries (1996). Bayreuther *et al.* (2003), have discussed the use of hard axis magnetization curves to deduce the in-plane magnetic anisotropy coefficients for Fe(001) films grown on GaAs(001) substrates. They were able to evaluate K_1^{par} and $K_\perp$ (see equation (7)) from a comparison of the M_H versus H data with a theory based upon continuous rotation of the magnetization vector, $\vec{M}_s$.

A very useful modification of the M_H versus H technique has been described by Weber, Allenspach and Bischof (1997). These authors provide a fixed bias magnetic field, H_b, applied along a direction perpendicular to the variable magnetic field, H. The bias field guarantees a reversible rotation of the magnetization vector over an extended range of the field, H. The method has been shown to be particularly useful for the measurement of in-plane anisotropy coefficients when the variable field is aligned with an in-plane easy axis.

Finally, Gradmann and his coworkers have developed a torsion magnetometer that can be used to measure the magnetic properties of thin magnetic films in the UHV system in which the films are grown (Gradmann, Kümmerle and Tham, 1976). These authors have shown that the torsion data can be used to measure the specimen magnetic moment and the anisotropy parameters at the same time. This technique has been used to measure the magnetic moment of Ni(111) films, in UHV, grown on a Re(0001) crystal, (Gradmann and Bergholz, 1984). The magnetic moment of a Ni film only 2.5 MLs thick and having an area of 0.1 cm^2 could be measured with an uncertainty of approximately 1%. See also the review article by Gradmann (1993).

2.4 The origin of magnetocrystalline anisotropy

2.4.1 First-principles electronic band calculations

First-principles calculations of magnetic anisotropies are based upon the solution of Schrödinger's equation for interacting electrons with spin. The forms of the equations to be solved are discussed by Gay and Richter (1994). In order to calculate anisotropies it is necessary to calculate the ground state energy of the system under investigation for various orientations of the magnetization vector with respect to the crystalline axes. This is a formidable task since the energy differences in question, in the order of millielectron volts per atom, are very small compared with the total ground state energy of the order of Volts per atom. Nevertheless, in their pioneering articles Gay and Richter (1986, 1987), calculated the magnetic anisotropy coefficients for Fe, Ni, V, and Co monolayers having the lattice spacing of the

Ag(001) surface. They also calculated the perpendicular uniaxial anisotropy coefficients for freestanding (001) iron films 3, 5, 7, and 9 layers thick. The calculations indicated that Fe and V monolayers should have a magnetization vector oriented perpendicular to the film plane, whereas Ni and Co film magnetizations should lie in the film plane. The success of these calculations in predicting a perpendicular magnetization for Fe(001) in agreement with experiment stimulated a great deal of theoretical and experimental work on thin-film magnetic anisotropies. The precision with which the ground state energies could be calculated improved with time until it is now claimed that anisotropy energies for Fe, Ni, and Co monolayers, which are of the order of 1 meV/atom, can be calculated with an uncertainty of the order of 0.001 meV/atom. (1 meV/atom corresponds to a surface energy of 2.45 ergs cm^{-2} for atoms arranged on a Cu(001) surface net – a square net 2.56 Å on a side.) See the review article by Wu and Freeman (1999).

In all of the above calculations the variation of the ground state energy with orientation of the magnetization is due to spin-orbit coupling. In many cases the calculated thin-film perpendicular anisotropy coefficients are in agreement with experimental observations. However, the calculations are usually carried out for smooth and perfect surface interface planes, whereas in real specimens these interface planes are usually rough on a scale of at least ±1 atomic layer. Moreover, in many cases of interest there is some intermixing between substrate or overlayer atoms with the thin magnetic film atoms (Schurer, Celinski and Heinrich, 1995). Therefore, one cannot expect perfect agreement between calculated and observed anisotropy coefficients no matter how exactly solved the theoretical model may be.

2.4.2 *The Néel model*

In 1954 L. Néel introduced a phenomenological model for the ferromagnetic state based upon the sum of pairwise interactions between ferromagnetic atoms. This model was meant to help understand the origin of surface anisotropies as well as to elucidate the physics of magnetoelastic phenomena (Néel, 1954). The pair interaction was written as the sum of Legendre polynomials:

$$W(r,\theta) = L(r)P_2(\cos\theta) + g(r)P_4(\cos\theta) + \cdots \tag{12}$$

where r is the separation of the atom pair, $L(r)$ and $g(r)$ are phenomenological parameters, and θ is the angle between the magnetization direction and the line that joins the atom pair. Usually only the first term of the above series is used to discuss magnetic anisotropies and magnetoelastic effects. Thus, ignoring the constant term, the pair interaction can be written as

$$W(r,\theta) = L_f(r)\left(\hat{u}_r \cdot \hat{m}\right)^2 \tag{13}$$

where $\hat{u}_r$ is a unit vector directed along the line joining the atom pair, and $\hat{m}$ is a unit vector in the direction of the magnetization vector. This simple model can be used to calculate the free energy density for an ultrathin film in terms of the parameter L_f. Such a free energy function will consist of the sum of a term proportional to the film thickness, a volume term, plus a term independent of film thickness, a surface term. It is clear that the free energy density must depend upon any strains introduced by film growth on a lattice mismatched substrate because it depends upon the angles between magnetization direction and the orientation of the lines joining nearest-neighbor atoms. Chapter 8 of Chikazumi (1964) demonstrates the use of the Néel model to deduce the form of the magnetoelastic coupling energy for cubic crystals. For a (001) oriented cubic lattice whose in-plane lattice parameter has been altered by $\epsilon_1 = \Delta a/a$, and whose lattice parameter perpendicular to the plane has been altered by $\epsilon_2 = \Delta c/a$ the magnetoelastic energy density is given by:

$$F_{\text{me}} = \text{const} + B_1\left[\epsilon_1\left(\frac{M_x}{M_s}\right)^2 + \epsilon_1\left(\frac{M_y}{M_s}\right)^2 + \epsilon_2\left(\frac{M_z}{M_s}\right)^2\right] \tag{14}$$

B_1 is a magnetoelastic coupling constant. From the condition that the film must be stress free along the film normal one has

$$\frac{\epsilon_2}{\epsilon_1} = -\frac{2C_{12}}{C_{11}} \tag{15}$$

where C_{11}, C_{12} are elastic constants such that the elastic energy density is given by

$$F_{\text{el}} = \frac{C_{11}}{2}\left(2\epsilon_1^2 + \epsilon_2^2\right) + C_{12}\left(\epsilon_1^2 + 2\epsilon_1\epsilon_2\right) \tag{16}$$

see Sander (1999). From equations (14) and (15), and the condition $M_x^2 + M_y^2 + M_z^2 = M_s^2$ the strain contribution to the free energy density can be written as

$$\begin{aligned} F_{\text{me}} &= \text{const} + B_1\left[\epsilon_2 - \epsilon_1\right]\left(\frac{M_z}{M_s}\right)^2 \\ &= \text{const} - B_1\left(1 + \frac{2C_{12}}{C_{11}}\right)\epsilon_1\left(\frac{M_z}{M_s}\right)^2 \end{aligned} \tag{17}$$

For iron $C_{11} = 2.41 \times 10^{12}$ ergs cm^{-3}, $C_{12} = 1.46 \times 10^{12}$ ergs cm^{-3}, and $B_1 = -34.3 \times 10^6$ ergs cm^{-3}. Therefore, if an iron film is stretched in plane, the magnetoelastic coupling acts so as to orient the magnetization in the film

plane. For a strain of 1% the magnetoelastic contribution to the effective perpendicular uniaxial anisotropy would be $-K_\perp = 7.6 \times 10^5\,\mathrm{ergs\,cm^{-3}}$, see equation (7). This can be compared with the dipole–dipole energy $F_\mathrm{d} = 2\pi M_\mathrm{s}^2 = 18.2 \times 10^6\,\mathrm{ergs\,cm^{-3}}$. Sander (1999) describes in detail how to calculate the magnetoelastic contribution to the effective uniaxial anisotropy coefficient for cubic and hexagonal films having various surface plane orientations.

The above Néel model results in an anisotropic free energy density that is independent of the substrate or overlayer materials. In order to correct this defect MacLaren and Victora (1993) and Victora and MacLaren (1993a,b) have proposed an extension of the Néel theory that includes a pair interaction between ferromagnetic atoms and nonmagnetic nearest-neighbor atoms having the form

$$W(r,\theta) = L_m(r)\left(\hat{u}_r \cdot \hat{m}\right)^2 \tag{18}$$

where $\hat{u}_r$ is a unit vector in the direction of the line joining a ferromagnetic atom with a nonmagnetic atom, and $\hat{m}$ is a unit vector parallel with the magnetization vector. In this version of the theory at least two interaction parameters are required, L_f and L_m. MacLaren and Victora have determined these two parameters for the Co(001)/Pd system by comparison of the resulting anisotropic free energy expression with the free energy obtained from first-principles calculations using the experimentally observed strained lattice spacings as measured by Engel *et al*. (1991). The results of their first principles calculations were in good agreement with experiment. They used the values of L_f, L_m so determined to calculate the anisotropy coefficients for (111) and (110) oriented Co/Pd surfaces. The results were in reasonable agreement with the experimental data of Engel *et al*. (1991).

The Victora and MacLaren extension of the Néel model has been applied to Co/Cu(001) and Co/Pd(001) structures by Heinrich, Kowalewski and Cochran (1998). These authors used measured lattice strains and measured surface anisotropy energies to deduce that $L_f = 9.0 \times 10^{-16}$ and $L_m = 2.3 \times 10^{-16}$ ergs for the Cu/Co interface compared with $L_f = 7.1 \times 10^{-16}$ and $L_m = 6.9 \times 10^{-16}$ ergs for the Co/Pd interface. Thus the interaction energy between Co and Pd atoms was found to be approximately three times larger than the interaction energy between Co and Cu atoms. This difference is not unexpected given the tendency of Pd to form a magnetic moment when placed at an interface with a ferromagnet.

In an interesting application of the Néel model, equation (12), Bayreuther *et al*. (2003) were able to show that the fourth order in-plane volume anisotropy coefficient should be correlated with the fourth order in-plane surface anisotropy coefficient (see the notation of equations (7) and (9)). Indeed, the ratio $\left(K_{1S}^\mathrm{par}/K_{1V}^\mathrm{par}\right)$ was found to be independent of composition for a series of $Fe_{1-x}Co_x$ alloy films grown on a GaAs(001) substrate. The experimental ratio was found to correspond to a thickness of 6 MLs.

2.4.3 Vicinal surfaces

If a crystal is cut so that the surface plane makes a small angle with respect to a principle crystallographic plane the result is a surface containing many monatomic steps. Such a surface is called a vicinal surface. In a series of experiments in which Fe films and Fe films covered by Ni films were grown on vicinal Ag substrates it was discovered that the specimens exhibited an in-plane twofold magnetic anisotropy in which the direction of the uniaxial anisotropy axis was correlated with the orientation of the vicinal surface steps (Heinrich *et al*., 1988). A few years later systematic studies of the anisotropies introduced by growing Fe and Co films on deliberately miscut vicinal substrates were initiated by Chen and Erskine (1992), who studied Fe films grown on W substrates, and by Krams *et al*. (1993), who studied Co films grown on Cu substrates. In these studies the substrates exhibited a well-defined surface roughness consisting of parallel monatomic steps separated by a distance that depended on the relatively small angle between the surface normal and the crystalline [001] direction. In the case of Fe grown on a W(1 1 14) surface the uniaxial easy axis was found to be perpendicular to the step edges. In the case of Co grown on Cu(1 1 13) the easy axis was found to be parallel with the step edges. In the case of Co/Cu the uniaxial anisotropy parameter was found to be quite strong: $K_\mathrm{u} = 6 \times 10^5\,\mathrm{ergs\,cm^{-3}}$ and therefore comparable in strength with the in-plane fourfold anisotropy parameter $K_1^\mathrm{par} = -6.5 \times 10^5\,\mathrm{ergs\ cm^{-3}}$. Albrecht *et al*. (1992), also studied anisotropies deliberately introduced by substrate steps for Fe(110) films grown on W(110). They showed that their experimental results were in good agreement with calculations based upon the Néel pair model of anisotropies (Néel, 1954).

According to Krams *et al*. (1993) and Krams, Hillebrands, Güntherodt and Oepen (1994), the uniaxial anisotropy due to a stepped surface is a consequence of the lattice mismatch between the magnetic thin film and the substrate upon which it has been grown. Chuang, Ballentine and O'Handley (1994), ascribe the step-induced uniaxial anisotropy partly due to magnetoelastic effects and partly due to the missing bonds at the step edges and corners. The latter authors have applied the Néel model (Néel, 1954), to derive expressions for the effect of steps on the (001), (110), and (111) surfaces of simple cubic, bcc, and fcc crystals. Their models do correctly predict the orientation of the easy in-plane magnetic anisotropy axes, but they tend to overestimate the strength of the anisotropy parameters for the Co/Cu and Fe/W systems.

Arias and Mills (1999), have also discussed the problem of step-induced anisotropies, see Section 2.4.4. They have concluded that the contribution of surface steps to the in-plane uniaxial anisotropy energy due to stray magnetic fields is consistent with observations on Fe(001) films grown on a vicinal substrate.

More recent studies carried out on Co and Fe films grown on vicinal substrates can be found in the articles by Mikuszeit, Pütter and Oepen (2004), and by Rickart *et al*. (2004).

2.4.4 Surface roughness

1. The expression for the magnetostatic contribution to the free energy density, $F_{\rm d}$ of equation (6), has been written for a uniformly magnetized continuum. In a real thin film the magnetization density is localized near atomic positions. This nonuniform magnetization distribution may be better modeled by a collection of point dipoles situated at the atomic positions. The magnetostatic energy density of a lattice of point magnetic dipoles has been studied by Draaisma and Draaisma and de Jonge (1988), and is dealt with in the appendix of Heinrich *et al*. (1988). These authors have shown that the correction to $F_{\rm d}$ can be described as a surface contribution to the perpendicular uniaxial anisotropy having the form

$$F_{\rm corr} = -\frac{K_{\rm s}}{t}\left(\frac{M_z}{M_{\rm s}}\right)^2 \tag{19}$$

per surface, where $K_{\rm s}$ depends upon the crystal structure and upon the surface plane of the film. For cubic structures the correction is largest for the bcc(001) surface, and amounts to $0.05\,{\rm ergs\,cm^{-2}}$ per surface for iron. The correction, equation (19), favors alignment of the magnetization vector along the film normal. This contribution to the perpendicular uniaxial surface anisotropy parameter is approximately a factor of 10 smaller than the surface energy parameter measured for the Fe(001)/Au interface (Heinrich and Cochran, 1993).

2. The above correction to the uniaxial surface free energy contribution treats surface roughness whose dimensions are the interatomic spacing. Any real thin-film specimen will exhibit surface roughness on a much larger lateral scale as a result of the mode of growth, or as a result of growth on a substrate whose chemical composition varies from place to place on the surface, or as a result of growth on a substrate whose surface consists of flat smooth areas bounded by steps. Dieny and Vedyayev (1994), have pointed out that lateral variations of the uniaxial surface energy parameter around the average value, $\Delta K_{S\rm perp}$, will generate a fourfold surface free energy term having the form

$$\Delta F_{S\rm perp} = -K_{4S}\ \sin^2(\theta)\cos^2(\theta) \tag{20}$$

where θ is the angle between the average magnetization vector and the normal to the film plane. Note that the angular variation of $\Delta F_{S\rm perp}$ corresponds to a fourfold variation of the anisotropy energy with angle. Dieny and Vedyayev have calculated the surface energy parameter K_{4S} for a periodic array consisting of square mesas of length on a side and repeated with a two-dimensional spatial period of length L. The key finding is that K_{4S} is proportional to the square of the fluctuation of the uniaxial surface energy parameter around the average value. This means that the easy axes of the fourfold surface energy term are oriented at 45° to the film normal. They have also shown that for reasonable estimates of the uniaxial surface energy parameter fluctuations the effective anisotropy field, $2K_{4S}/M_{\rm s}D$, where D is the film thickness, can become comparable to fourfold volume anisotropy effective fields, $2K_1^{\rm par}/M_{\rm s}$, for films a few monolayers thick. Thus the fourfold free energy term generated by the lateral variation of the twofold surface energy term may be expected to play an important role in specimens for which the dipolar field, $4\pi M_{\rm s}$, is nearly cancelled by the uniaxial surface energy effective field $2K_{\perp S}/M_{\rm s}D$. Under those circumstances the magnetization vector may be canted so that it is neither oriented perpendicular to the film nor parallel with the film surface: see Allenspach, Stampanoni and Bischof (1990).

Heinrich, Monchesky and Urban (2001), have also investigated the effect of lateral variations of any of the magnetic anisotropy parameters. Their calculation was modeled on the Slonczewski treatment of the effect of spacer thickness variations on the interlayer exchange coupling between two ferromagnetic films separated by a nonmagnetic spacer layer (Slonczewski, 1991). They concluded that any system that exhibits a lateral variation of the anisotropic free energy characterized by a particular angular power will exhibit an effective anisotropic free energy corresponding to a higher angular power as a consequence of exchange averaging over the lower order term. Specifically, Heinrich *et al*. have shown that, under simplifying but reasonable assumptions, lateral variations of the uniaxial anisotropy parameter $K_{\rm u}$ results in a fourfold anisotropy energy having the form

$$\Delta F_4 \cong -2\Delta K_{\rm u}\left[\frac{\Delta K_{\rm u}/M_{\rm s}}{(2A/M_{\rm s})\,k_{\rm eff}^2}\right]\sin^2(\phi)\,\cos^2(\phi) \tag{21}$$

where ϕ is the average angle that the magnetization direction makes with the direction of the uniaxial axis, A is the exchange stiffness parameter, $k_{\rm eff} = \pi/L$, and L is the characteristic spatial period of the inhomogeneities. Note that the above expression is proportional to $(\Delta K_{\rm u})^2$ so that

fluctuations of either sign contribute to easy axes that are oriented 45° to the original twofold axis. This is in agreement with the calculations of Dieny and Vedyayev. Note that if K_u is the average uniaxial surface energy parameter then $\Delta K_u/M_s$ in the brackets in equation (21) must be replaced by the effective field $(\Delta K_u/M_s D)$. For the case in which the thickness of the film fluctuates around the mean thickness, D, by an average value ΔD the fluctuations in the surface free energy parameter can be written $\Delta K_u = K_u(\Delta D/D)$. It follows that the resulting fourfold surface free energy term will not be independent of film thickness as is required of a true surface energy term unless $(\Delta D/D)$ is proportional to $\sqrt{D}$.

It should be noted that the fourfold in-plane anisotropy measured by Bayreuther *et al*. (2003), in Fe/Co alloy films grown on GaAs(001) can also be explained as the result of fluctuations in the strength of the in-plane twofold anisotropy parameter; see the last paragraph of Section 2.4.2.

3. It has been pointed out by Bruno (1988), that the magnetostatic contribution to the free energy density, F_d, see equation (6), must be corrected to take into account stray fields when the film thickness varies from place to place. Any film roughness may be expected to affect the magnetostatic energy density which is calculated from the expression

$$F_d = -\frac{1}{2}\int_{\text{Volume}} \vec{M}\cdot\vec{H}\,dV \tag{22}$$

where $\vec{H}$ is the magnetic field generated by the magnetization distribution. Bruno finds that for a stepped surface the correction to F_d of equation (6) can be described as a contribution to the uniaxial surface anisotropy parameter corresponding to a free energy contribution proportional to $\sin^2(\theta)$, where θ is the angle between the magnetization vector and the film normal. For a step height of one atomic layer separating flat areas 10 atomic spacings wide, this contribution to the surface energy parameter can be as large as $0.15\,\text{ergs cm}^{-2}$, per surface, for a Fe(110) interface. This form of surface roughness favors alignment of the magnetization along the film normal. Arias and Mills (1999), discuss in detail the calculation of the contribution to the free energy density for the case of an external magnetic field, H_0, applied in the film plane so that in the absence of surface roughness the magnetization density, M_s, would everywhere be parallel to the applied magnetic field and the contribution to the free energy density would be $-M_s H_0$. For an external magnetic field applied along the z direction in the film plane these authors show that the correction to the free energy density caused by surface roughness is given by

$$\Delta F = -\frac{M_s}{2}\int_{\text{Volume}} dV\; h_z(\vec{r}) \tag{23}$$

where h_z is the z component of the magnetic field generated by the surface roughness, and the integral is taken over the volume of the film taking the roughness into account. Arias and Mills applied their theory to the case of equally spaced steps generated by growth of the film on a vicinal surface. They show that the correction to the magnetostatic energy density is a uniaxial anisotropy in which the easy axis is parallel with the step edges. The strength of the step-induced uniaxial free energy calculated for Fe(001) and a vicinal angle of a few degrees was found to be in the range $0.02-0.04\,\text{ergs cm}^{-2}$, values similar to those found experimentally.

2.5 Anisotropy data

RT uniaxial perpendicular anisotropy coefficients, plus references to the relevant articles, are listed in the review article by Johnson, Bloeman, den Broeder and de Vries (1996). Their Table 3 lists data for Fe films grown on various substrates; Table 4 lists data for Co films grown on various substrates; and Table 5 lists data for Ni films grown on various substrates. More detailed data and discussion are provided in the review article by Heinrich and Cochran (1993): in particular, refer to their Table 1 for anisotropy parameters measured for the interface between Fe(001) and vacuum, Ag, Cu, Au, and Pd. The review article by Farle (1998), contains extended discussions of the Ni/Cu(001) and the Gd/W(001) systems. The case of Fe grown on GaAs(001) has become very interesting because the small mismatch between the Fe(001) and the GaAs(001) interface makes this combination an obvious choice for devices based on a hybrid ferromagnetic/semiconductor system. The Fe/GaAs(001) system is exhaustively discussed in the monumental review article by Wastlbauer and Bland (2005). Their article includes a compilation of measured anisotropy coefficients plus relevant references.

It is interesting to point out complexities related to the in-plane uniaxial anisotropy in GaAs(001) structures. The origin of the large in-plane interface uniaxial anisotropy in GaAs/Fe(001) has so far not been clearly understood. The hard magnetic axis lies along the $[1\bar{1}0]$ crystallographic direction which is parallel to the dangling bonds of As terminated (2×6) and pseudo (4×6) reconstructed GaAs(001) substrates (Monchesky *et al*., 2000). However Moosbuehler, Bensch, Dumm and Bayreuther (2002) have shown that the strength and sign of the in-plane uniaxial surface anisotropy is not affected by a particular reconstruction of the GaAs template. A genuine Ga rich (4×6) reconstruction results in almost the same uniaxial anisotropy as that observed in the (2×6) As rich reconstruction. Therefore it is hard to believe that the source of this anisotropy lies in chemical

bonding between the dangling bonds of As and the Fe. This point of view is further supported by recent results obtained by Aktas *et al*. (submitted). They found that a Cr(001) layer grown over a 15 ML thick Fe(001) film grown on GaAs(001) can significantly decrease, or even entirely remove, the in-plane uniaxial anisotropy. This observation implies that the interface chemistry between As and Fe cannot be the source of the in-plane anisotropy. Calculations by Mirbt, Sanyal, Isheden and Johansson (2003), have suggested that an interface in-plane shear (of the order of 2%) can be stabilized at the GaAs/Fe(001) interface. A significant interface shear was observed in InAs/Fe(001) structures by Xu, Freeland, Tselepi and Bland (2002). However, recent work by Gordon and Crozier (2006), using the technique of polarization dependent X-ray absorption fine structure (XAFS) has shown that an interface shear of approximately 1% is present in 2 ML thick Fe films grown on GaAs(001) substrates and, without a capping layer, measured *in situ* at pressures in the mid-10^{-10} Torr. The in-plane shear strain was found to be $\epsilon_6 = -0.013$ (The notation used here is that used by Sander (1999), and by Thomas *et al*. (2003), in which the displacement of an atom originally at (x_1, x_2, x_3) in a Cartesian coordinate system is given by $dx_m = \sum_{n=1}^{3} \epsilon_{m,n} x_n$ where $\epsilon_{m,n}$ are the components of the strain tensor. In the present application to a strained Fe(001) film in which x_1, x_2 are taken to be along the in-plane cube axes, and following Thomas *et al*. (2003), $\epsilon_{11} = \epsilon_{22} = \epsilon_1$, $\epsilon_{33} = \epsilon_3$, $\epsilon_{12} = \epsilon_{21} = \epsilon_6/2$, and $\epsilon_{13} = \epsilon_{31} = \epsilon_{23} = \epsilon_{32} = 0$. The in-plane uniaxial anisotropy contribution to the free energy density is given by $(B_2\epsilon_6/2)\sin(2\phi)$ where ϕ is the angle between the magnetization vector and the [100] direction and, following Thomas *et al*., $B_2 = 7.62 \times 10^6\,\mathrm{J\,m^3}$.) Thus the surface cell length along [110] was observed to be smaller than the surface cell length along $[1\bar{1}0]$. No interface shear could be detected within experimental error in a 5 ML thick Fe sample: this observation suggests that in their samples the lattice shear was located only at the GaAs/Fe interface. The in-plane lattice shear leads to a uniaxial anisotropy due to the magnetoelastic parameter B_2, (Sander, 1999), with the uniaxial magnetic axis oriented along one of the $\langle 110 \rangle$ directions, (Urban, Woltersdorf and Heinrich, 2001). Thomas *et al*. (2003) have observed in-plane shear in relatively thick Fe(001) layers grown on GaAs(001) and capped with aluminum. The in-plane shear component ϵ_6 was clearly resolved for films thicker than 4 nm. The shear component $\epsilon_6 = 0.002$ at 13 nm, became unobservably small at a film thickness of 2 nm. In this case the sign of the in-plane shear was reversed compared to that in the ultrathin films investigated by Gordon and Crozier (2006). In the measurements reported by Thomas *et al*. (2003), the strength and sign of the in-plane uniaxial anisotropy energy associated with the in-plane shear follows closely the predictions of the equation

$$f_{\mathrm{me}} = \left(\frac{B_2\epsilon_6}{2}\right)\sin(2\phi) \tag{24}$$

where ϕ is the angle between the magnetization vector and the [100] direction and, following Thomas *et al*., $B_2 = 7.62 \times 10^6\,\mathrm{J\,m^{-3}}$. In this case the easy in-plane uniaxial anisotropy axis was directed along the $[1\bar{1}0]$ crystallographic direction.

Using the interface shear from the XAFS measurements and the value $B_2 = 7.62 \times 10^7\,\mathrm{ergs\,cm^{-3}}$ for bulk iron (Thomas *et al*., 2003), multiplied by 2.87×10^{-8} cm results in an interface anisotropy of approximately $-0.014\,\mathrm{ergs\,cm^{-2}}$: this surface energy is approximately a factor of 5 smaller than the observed anisotropy (Urban, Woltersdorf and Heinrich, 2001; Moosbuehler, Bensch, Dumm and Bayreuther, 2002). However it leads to the correct orientation for the easy magnetic axis, (Rickart *et al*., 2004). In order to explain the strength of the observed in-plane uniaxial anisotropy at the GaAs/Fe[001] interface one would require a larger interface shear and perhaps an enhanced value of the magnetoelastic coefficient B_2.

Seki *et al*. (2003), have shown that thin films of the alloy $Fe_{38}Pt_{62}$ having a uniaxial perpendicular anisotropy parameter as large as $K_\perp = 1.8 \times 10^7\,\mathrm{ergs\,cm^{-3}}$ can be grown on an MgO(001) substrate at substrate temperatures as low as 300 °C. These films, 18 nm thick, were grown by means of codeposition of Fe and Pt by sputtering on a (1-nm Fe + 40-nm Pt) buffer layer deposited on the MgO(001) crystal at RT. The films exhibited long-range intermetallic order having the $L1_0$ structure. Such films may be useful for ultrahigh density recording media. It is very interesting that Fe and Pt codeposited on a clean MgO(001) substrate at temperatures ranging from 500 to 700 °C formed isolated islands of the alloy $Fe_{52}Pt_{48}$ consisting of crystals having a tetragonal structure with the *c* axis oriented along the normal to the substrate (Shima *et al*., 2003). Films composed of islands 10 nm thick not only exhibited a very large uniaxial perpendicular anisotropy but they were characterized by coercive fields as large as 40 KOe!

Finally, the attention of the reader is directed to the article by Tian *et al*. (2005). These authors have discovered how to grow films of bcc Ni up to a thickness of 3.5 nm on GaAs(001). Body-centered Ni does not occur in nature. Their bcc(001) Ni films are characterized by a Curie temperature of 456 K, a lattice constant of $a = 0.282$ nm, and an atomic magnetic moment of $0.52\,\mu_{\mathrm{B}}$. Their films exhibited an in-plane fourfold anisotropy parameter of strength $K_1^{\mathrm{par}} = 4.0 \times 10^5\,\mathrm{ergs\,cm^{-3}}$, with the easy axis along $\langle 100 \rangle$.

ACKNOWLEDGMENTS

The authors would like to thank their colleagues Dr G. Woltersdorf, Dr H. Meyerheim, Mr B. Kardasz, and O. Mosendz for their invaluable help in the preparation of this chapter. We would like to thank to Dr Eric E. Fullerton for his input in the section on magnetron sputtering, and Dr Berend T. Jonker and Dr Daryl Crozier for their input on the atomic formation of Fe/GaAs interfaces. We would like to thank especially the Natural Science Engineering Research Council (NSERC) of Canada, and the Canadian Institute for Advanced Research (CIAR) for continued research funding which makes our work possible.

Hard Magnetic Films

Toshiyuki Shima[1] and Koki Takanashi[2]

[1] *Tohoku Gakuin University, Sendai, Japan*
[2] *Tohoku University, Sendai, Japan*

1 INTRODUCTION

Future development of magnetic devices strongly depends on the progress of the performance of hard magnetic films. Recently, a lot of work has been reported for nanoscale patterned or particulate magnets (Carl *et al*., 1999; Sun *et al*., 2000; Chen *et al*., 2003), since they are believed to be good candidates for future magnetic devices such as next-generation ultra-high-density magnetic storage media and biasing nanomagnets in micro-electromagnetic devices. However, all ferromagnetic materials are characterized by a critical grain size where thermal fluctuations become dominant at room temperature. In order to reduce this critical grain size, materials with high magnetocrystalline anisotropy (K_u) have attracted much attention. In this chapter, firstly, the fundamental phenomena and models which are important for the understanding of hard magnetic properties in thin films will be described. Secondly, the recent developments of hard magnetic films and their potential applications will be mentioned.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

1.1 High K_u materials

It is well known that the magnetocrystalline anisotropy is a key factor to determine the nature of magnetic materials. For soft magnetic materials (SMs), many studies have been made to reduce the effective magnetic anisotropy by amorphization (Hoffmann, 1964) or nanocrystallization (Yoshizawa, Oguma and Yamauchi, 1988; Hasegawa and Saito 1992; Suzuki *et al*., 1991; Herzer, 1989). On the other hand, for hard magnetic materials (HMs), a lot of effort has been made for exploring new materials, since the origin for a large magnetocrystalline anisotropy is due to the asymmetry of crystal structure. For instance, Sm–Co alloy (Buschow, 1969; Senno and Tawara, 1975; Ojima, Tomizawa, Yoneyama and Hori, 1977) and Nd–Fe–B alloy (Sagawa *et al*., 1984; Croat, Herbst, Lee and Pinkerton, 1984) magnets with complex crystal structures, which were discovered in the last few decades, exhibit a large uniaxial magnetic anisotropy K_u. Representative high K_u materials are summarized in Figure 1 (Weller and Moser, 1999). It is well known that $L1_0$ ordered alloys (CuAu-type crystal structure) such as MnAl, CoPt, FePd, and FePt possess large K_u, which arise from a breakdown of the crystal symmetry from a cubic structure to a tetragonal one. For example, it has been reported that the K_u of $L1_0$ FePt almost reaches a value of the order of $10^8\,\mathrm{erg\,cm^{-3}}$ which is close to that of Sm–Co alloy and about 20 times larger than that of pure Co. The large K_u of $L1_0$ FePt offers thermally stable grains with diameters down to a few nanometers, as compared with about 10 nm for pure Co.

1.2 Magnetization process and coercivity

A lot of features of magnetic materials are implied in the magnetization curves (M–H curves); in other words, the

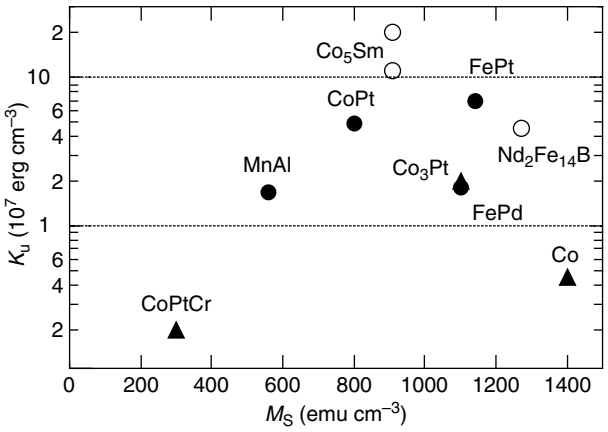

Figure 1. Saturation magnetization (M_S) and magnetocrystalline anisotropy energy (K_u) in representative high K_u materials; ●: $L1_0$ ordered alloys, ○: rare-earth–transition-metal alloys, ▲: Co and Co alloys (Weller and Moser, 1999).

response of the magnetization of the material to an applied field. The curves with the field applied along either the hard or easy axis contain important information regarding the behavior of hard magnets. This may be associated with the concept of nucleation and domain wall displacement. By measuring the initial magnetization curve (virgin magnetization curve) after demagnetization, two different kinds of qualitative behavior are observed. These are classified into nucleation-type (a) and pinning-type (b) magnets as shown in Figure 2. In a nucleation-type magnet, the initial curve is steep and the saturation of magnetization is reached at a field much lower than the coercive field (H_c). Domain walls are present in the initial state and they are free to move and do not feel pinning effects, leading to the easy saturation of magnetization. Once the domain walls are swept away from the specimen, it is difficult to nucleate reversed domains. In a pinning-type magnet, on the other hand, a field of the order of the coercive field ($H \approx H_c$) is required to saturate the magnetization of the specimen from the initial state. This indicates that domain wall pinning is the main mechanism for coercivity.

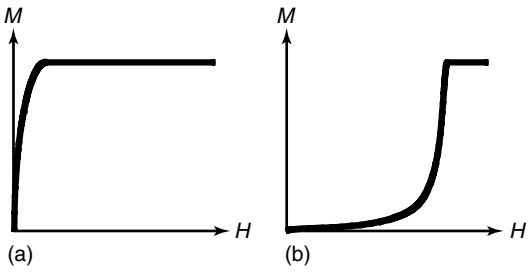

Figure 2. Schematic illustration of initial magnetization curves in (a) nucleation-type and (b) pinning-type magnets.

When the specimen size is reduced, single domain (SD) states become stable, and then, the magnetization rotation becomes a dominant process. However, an SD particle does not necessarily reverse the magnetization by coherent rotation, because incoherent rotation such as curling and buckling owing to morphological defects is not excluded. The transition from coherent rotation to incoherent rotation occurs at a particle diameter of about 10 nm, which is of the order of 5 $(A/\mu_0 M_S^2)^{1/2}$, independent of the magnetic anisotropy energy K. With increasing particle size, multidomain (MD) particles are formed. The critical boundary between MD and SD particles with a spherical shape is given by the critical diameter of particles $D_{crit} = 9\gamma_B/\mu_0 M_S^2$, where γ_B is the specific wall energy ($E4(AK)^{1/2}$) (Kronmüller and Fähnle, 2003). A qualitative relation between H_c and the particle diameter D is given in Figure 3.

1.3 Exchange-spring magnet

Kneller and Hawig (1991), proposed the exchange-spring magnet as a way to create a next-generation, high-performance permanent magnet. Such systems are based on the interfacial exchange coupling of two suitably dispersed nanostructured ferromagnetic phases. One of the two phases is an HM in order to provide a high coercive force, while the other is an SM to provide high saturation magnetization. Theoretical treatment of such systems predicts the improvement of hard magnetic properties such as a high maximum energy product ($(BH)_{max}$), a reversible demagnetizing curve (exchange spring) and high remanence (B_r) ratio. For instance, such exchange-spring characteristics can be realized by preparing a nanostructured composite of fine HM grains separated by a thin SM layer. However, it is noted that particles must not be exchange coupled to each other in order not

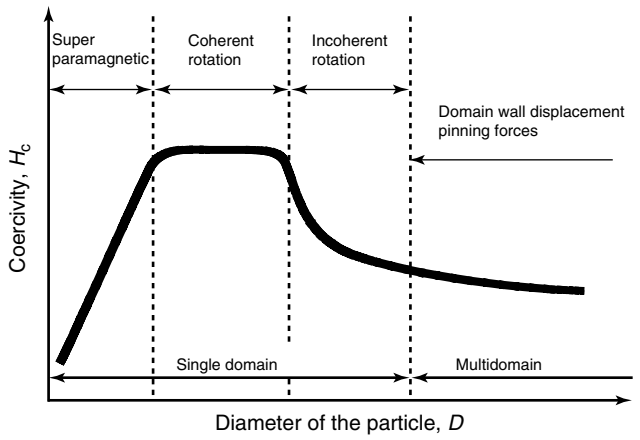

Figure 3. Schematic qualitative relation between coercivity H_c and particle diameter.

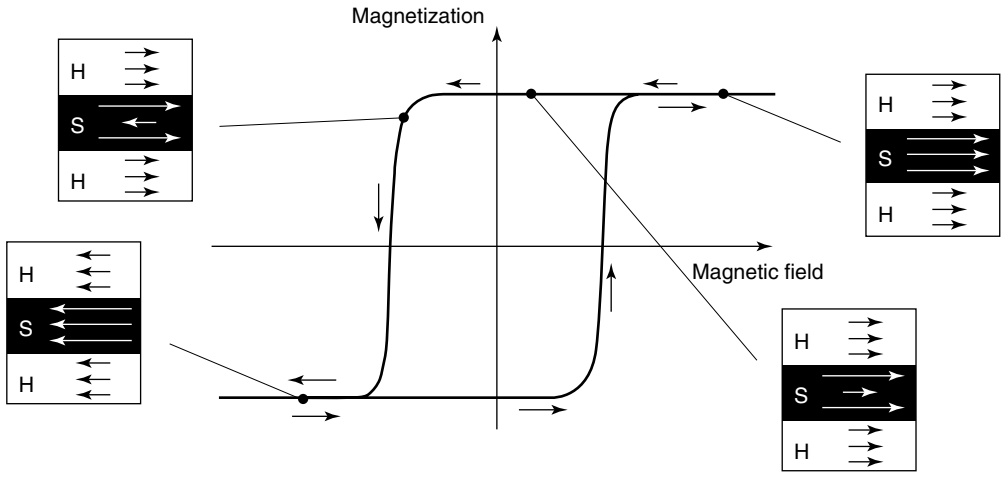

Figure 4. A schematic illustration of the exchange-coupling behavior of the magnetization curve. H: hard magnetic layer; S: soft magnetic layer.

Table 1. K and exchange length l_{ex} of Fe, Co, and Ni. $l_{ex} = (A/K_u)^{1/2}$, $A = 10^{-11}$ (J m^{-1}).

	K (10^3 J m^{-3})	l_{ex}(nm)
Fe	48	14
Ni	4.5	47
Co	410	5

to switch collectively. In appropriate systems, the magnetization of SM may be exchange coupled to that of magnetically hard nanocrystalline grains; the coupling then tends to hold the moment of SM parallel to those of the nearest grain over an exchange length (l_{ex}). A schematic illustration of exchange-coupled behavior in magnetization curves is shown in Figure 4. The values of K and l_{ex} are summarized for representative SM such as Fe, Ni, and, for reference, also Co in Table 1. If the thickness of the SM layer is larger than l_{ex}, no additional moment enhancement is expected. In order to realize high-performance permanent magnets that are greater than existing magnets, magnetic thin-film multilayers may be a promising candidate as an exchange-spring system. Skomski and Coey (1993) predicted that the remanent enhanced magnets, in other words, materials with giant $(BH)_{max}$, of 1090 kJ m^{-3} (137 MGOe) could be realized for $Sm_3Fe_{17}N_3/Fe_{65}Co_{35}$ multilayer films, assuming alignment of the hard-phase easy axes and development of sufficient coercivity.

2 FABRICATION OF THIN FILMS

In order to prepare hard magnetic films, many kinds of deposition techniques are used. Here, conventional and typical deposition techniques such as sputtering and thermal evaporation are briefly described.

2.1 Sputtering

Sputtering is a most widely used technique for preparing thin films. The benefit of this method is that both metals and insulators can easily be deposited. Besides, a lot of sputtering parameters, such as pressure during deposition, distance between target and substrate, input power, deposition rate, and so on, can easily be changed. Since the operation of a sputtering system is simple, it has become a conventional and convenient technique for thin-film preparation, not only for academic but also for practical use. Moreover, if an important report on the process is revealed, it can be mutually transferred between the laboratory and the industry. The definition of sputtering is as follows:

Sputtering is the process in which atoms are ejected from the surface of a material (target) when the surface is bombarded by energetic particles (ions). Sputtering can often be operated using inert gases like Ar, Kr, or Xe, since there is no chemical reaction between the sputtering gas and the target. The inert gas is ionized in a strong electric field, creating a plasma above the target. When a subtle amount of reactive gas such as oxygen or nitrogen is mixed with the sputtering gas and introduced into the sputtering chamber during deposition, compound films of oxide or nitride can be prepared. This process is called *reactive sputtering*. When a composite (multicomponent) target or multiple targets are used, alloy films can be prepared. Several sputtering systems are proposed for thin-film deposition including dc diode, RF diode, magnetron, and ion-beam sputtering. The basic construction of sputtering is shown in Figure 5(a). The

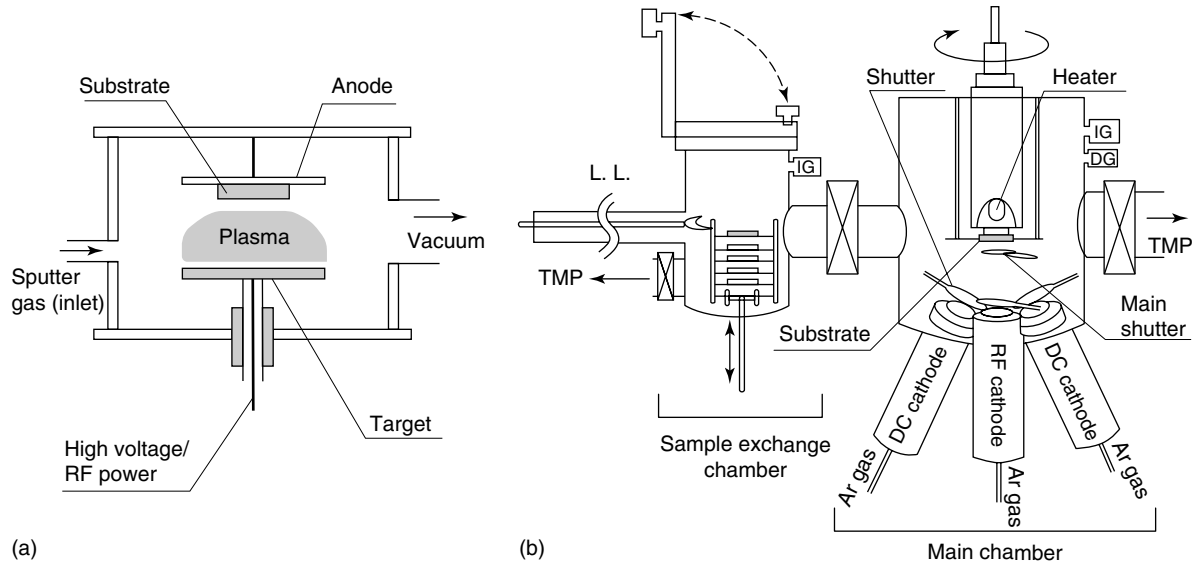

Figure 5. A schematic illustration of sputtering systems.

base pressure for most sputtering systems is in the range from 10^{-6} to 10^{-4} Pa. This relatively high vacuum (HV) is achieved with diffusion, turbo molecular, or cryogenic pumps. Recently, in order to improve the quality of films, sputtering systems with a base pressure in ultrahigh vacuum (UHV) region are being used. The working pressure during deposition is in the range of 10^{-2}–1 Pa. A typical sputtering system with a UHV chamber is illustrated in Figure 5(b).

2.2 Thermal evaporation

Materials to be deposited are thermally evaporated and then deposited onto a substrate. The thermal evaporation process is conventionally called *vacuum evaporation*. There are a lot of ways to evaporate the material. The simplest way is to heat the source materials in a crucible up to approximately its evaporation temperature by passing electrical current through a filament, which surrounds the crucible. The filament is generally made of refractory metals such as W, Mo, or Ta, with or without ceramic coating. Another method consists of bombarding the surface of the material with electron beam (EB) created by an electron gun (EB deposition). The heating of the material is much more localized in this case. Crucibles of graphite, alumina, beryllia, boron nitride, zirconia, and some refractory metals are used with indirect heating.

EB evaporation is carried out in a vacuum chamber with a pressure of the order of 10^{-4}–10^{-6} Pa. The operation pressure during deposition depends strongly on the quality of the equipment and deposition materials. Figure 6 shows a schematic illustration of a typical EB evaporation system with three independent EB guns. Ingots (source material)

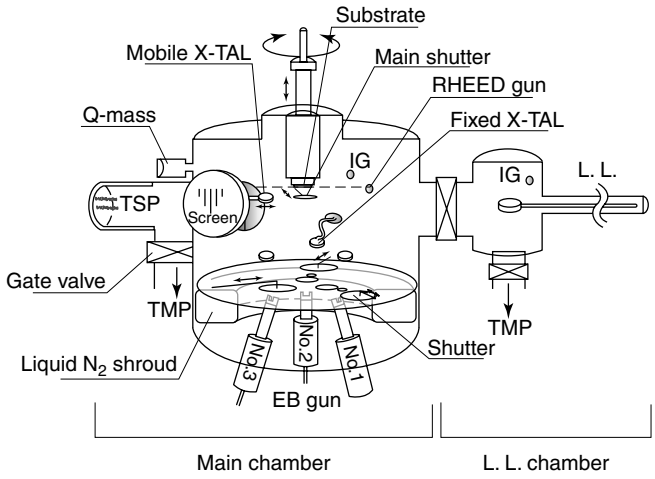

Figure 6. Schematic representation of an EB deposition system.

are melted by the EB created by an electron gun powered from several kilowatts to several hundred kilowatts. The high-energetic EB is directed onto the melting crucible, where the source material is located. The multilayered structure is prepared by controlling shutters above crucibles. If necessary, the thickness is controlled in the unit of monatomic layer and monitored by reflection high-energy electron diffraction (RHEED) oscillation. A thin film is then deposited on a substrate with a variety of temperatures by heating the substrate.

Another method is pulsed-laser deposition (PLD, also known as *laser molecular-beam epitaxy*, *MBE*), in which the material is locally heated with a laser beam. PLD is an improved process used for the deposition of alloys

and/or compounds with a precisely controlled chemical composition. A high-power pulsed laser such as KrF excimar laser or YAG laser is irradiated onto the target of source materials through the quartz window.

The MBE system is a complicated but most reliable deposition process in thermal evaporation and it works at relatively higher vacuum, in other words, UHV atmosphere (i.e., 10^{-9}–10^{-7} Pa). In order to get high-quality samples, the growth chamber is usually combined with *in situ* characterization equipment. This is an excellent preparation technique for fundamental studies; however, it is now difficult to transfer the fundamental results directly into industry except for semiconductor fields.

2.3 Thin-film growth process

In general, depending on the thermodynamic parameters of the deposit and the substrate surface, film growth processes are classified as follows: (a) Volmer-Weber mode (island growth), (b) Frank-van der Merwe mode (layer growth), and (c) Stranski-Krastanov mode (mixed growth). The Volmer-Weber mode is schematically described in Figure 7. In the first stage, a thin film is grown with the island-growth mode (island state). The lateral grain size is expected to increase with increasing the surface mobility of the adsorbed species; in other words, large grains are formed at high substrate temperature. With increasing the volume fraction of the material, that is, increasing the nominal thickness of the film, the islands grow and coalesce forming an interconnected mazelike pattern (discontinuous state). Finally, percolation occurs and the film changes from a discontinuous to a continuous state, and leads to the reduction of the bare substrate surface. However, the coalescence is strongly affected by the deposition temperature. The morphology tends to show the continuous state when the film is fabricated at low temperature, while it tends to show the island state at high deposition temperature. The tendency to form an island state is enhanced by increasing the surface mobility of the adsorbed species by increasing the substrate temperature.

The understanding of magnetization processes in the magnets of nanometer scale is of great technological and scientific interest. Since the early work of Kittel (1946) and Stoner and Wohlfarth (1948), the magnetization processes of fine particles and their assemblies have been investigated extensively (Jacobs and Bean, 1995). The magnetization reversal process, and therefore the coercivity should depend strongly on the characteristic size and the morphology of materials. Up to now, only a few studies have been devoted to the discussion about the relationship between experimentally measured magnetization behavior and actual nanostructural observations of thin films. However, recent development of the fabrication technique for thin films has enabled the preparation of nanoscaled magnetic materials and recent progress of the characterization technique also has enabled the evaluation of magnetic properties on the nanoscale.

Figure 7. Growth process of thin film.

3 RARE-EARTH–TRANSITION-METAL ALLOY THIN FILMS

3.1 High-performance rare-earth magnets

Hard magnets based on $SmCo_5$ possess the highest uniaxial anisotropy $K_u \approx 10^8\,\mathrm{erg\,cm^{-3}}$ of all the magnets, as shown in Figure 1. On the other hand, magnets based on Sm_2Co_{17} phase exhibit higher saturation magnetization and Curie temperature. Besides, recently developed magnets based on $Nd_2Fe_{14}B$ exhibit the highest energy products $(BH)_{max}$. These permanent magnets are called *high-performance permanent magnets* and their magnetic properties are summarized in Table 2 (Evetts, 1992; Schrefl and Fidler, 1992; Skomski and Coey, 1993; Hu, Li, Gavigan and Coey, 1989).

It is well known that a particular nanostructure is required to obtain the hard magnetic properties in these materials. Important aspects of this structure involve the size, shape, and crystal orientation of grains, and the intergrain coupling. Recent improvement of microfabrication and thin-film preparation technique enables these permanent magnets to have reduced dimensions down to a micrometer region to fit the

micromagnetic device applications. One potential application of hard magnetic films is micro-electromechanical systems (MEMS), that are prepared from relatively thick films of the order of several micrometers and the high $(BH)_{max}$ of rare-earth magnets promises small lateral dimensions. Several MEMS components such as a submillimeter electric motor and a stepper motor were successfully prepared (Yamashita, Yamasaki, Ikeda and Iwabuchi, 1991; Lemke, Lang, Göddenhenrich and Heiden, 1995). Another application is the creation of a bias magnetic field on the monolithic microwave integrated circuits (MMICs).

Furthermore, there is a huge application area of hard magnetic films for consumer electronics, such as a magnetic data storage on computer hard disks (HDs), HD video recorders, portable music players, and so on. The present conventional CoCr-based materials are facing the superparamagnetic limit, where the information stored in the small magnetic dots tends to become thermally unstable. In order to overcome the limit of areal recording density, the substitution of present recording system to a perpendicular regime is being implemented and materials with a higher K_u are of great interest. Compared to other applications, small film thicknesses ($5 \sim 20$ nm) are required for magnetic recording.

In this section, the magnetic properties of rare-earth-based permanent magnet films are briefly reviewed particularly focusing on their improvement through the introduction of underlayers and the adoption of the concept of an exchange-spring magnet.

3.2 Sm–Co thin films

The first report on the fabrication of rare-earth-based permanent magnet films was performed by Theuerer, Nesbitt and Bacon (1969). A getter sputtering technique was used to prepare $SmCo_5$ thin films and a large coercivity exceeding 20 kOe was obtained in the in-plane direction at the substrate temperature T_S of 600 °C. They also reported that a large coercivity of 30 kOe was obtained for $SmCo_{3.65}Cu_{1.35}$ thin films at $T_S = 500$ °C. Cadieu *et al*. investigated the synthesis and the magnetic anisotropy of $SmCo_5$ and $Sm_2(Co, Fe, Zr)_{17}$ thin films (Cadieu *et al*., 1982; Cadieu, Cheung and Wickramasekera, 1985; Cadieu, 1987; Hegde *et al*., 1994; Rani *et al*., 1997). In order to apply these films to recording media, the effect of Cr underlayer on the magnetic properties and microstructure were investigated, firstly by Velu and Lambeth (1992) and Okumura *et al*. (1995). They reported that the introduction of Cr underlayer plays an important role for getting high coercivity on Sm–Co films. Fullerton *et al*. (1996, 1997) studied the microstructures and the magnetic properties of epitaxial rare-earth–transition-metal films on a Cr underlayer and its effects were investigated (Mishra *et al*., 1981). They observed strong in-plane anisotropies that reflect the symmetry of the Cr buffer layers. Malhotra *et al*. (1996) reported that H_c as high as 31 kOe was obtained for 100-nm-thick Sm–Co films with a Cr underlayer of 20 nm after annealing at 500 °C. They also reported that high H_c of 20 kOe was obtained for several 10-nm-thick Sm–Co films with a Cr underlayer. They concluded that the reason for the large enhancement in coercivity after annealing is due to the crystallization of SmCo grains. Many studies on $SmCo_5$ films exhibiting in-plane magnetic anisotropy have been carried out. However, in order to influence the progress on high-density magnetic recording, the study of Sm–Co films with perpendicular magnetic anisotropy is strongly needed. Recently, Chen, Hegde, Jen and Cadieu (1993) reported that Sm–Co films, which were sputter deposited at a high Ar pressure and postannealed at a high temperature, showed perpendicular magnetic anisotropy, but these Sm–Co films were amorphous and the perpendicular magnetic anisotropy was insufficient. Recent investigation enabled the improvement of the perpendicular magnetic anisotropy by controlling the crystal orientation (Sayama, Mizutani, Asahi and Osaka, 2004).

3.3 NdFeB thin films

The fabrication of NdFeB thin films was firstly demonstrated by Cadieu, Cheung and Wickramasekara (1986). They prepared NdFeB films by using a slow deposition rate together with applying bias field in the in-plane direction, and high H_c of 16 kOe was achieved. However, in order to consider a practical use, some drawbacks were pointed out: the substrate temperature during deposition, 750 °C, was too high and the easy magnetization axis was aligned in the in-plane direction. Since then, many studies have been made in order to control the crystal orientation and to improve the magnetic properties. Table 3 summarizes representative studies on NeFeB thin films reported so far (Aylesworth, Zhao, Sellmyer and Hadjipanayis, 1988; Yamashita, Yamasaki, Ikeda and Iwabuchi, 1991; Lemke, Muller, Göddenhenrich and Heiden, 1995; Shindo *et al*., 1996; Parhofer, Gieres, Wecker and Schultz, 1996; Shima, Kamegawa, Hono and Fujimori, 2001).

Aylesworth, Zhao, Sellmyer and Hadjipanayis (1988) studied the effect of an Fe underlayer on NdFeB films and a coercive field of 5 kOe measured in the perpendicular direction was obtained. They concluded that Fe underlayer plays an important role for suppressing the formation of Nd–O phase. Yamashita, Yamasaki, Ikeda and Iwabuchi (1991) studied the effect of composition and substrate temperature during deposition. High H_c of 7 kOe measured in the perpendicular direction and large $(BH)_{max}$ of more than 20 MGOe were obtained. Furthermore, by using the NdFeB films, the

operation of small-sized pulsed motors was demonstrated as one of the possible applications. Shindo *et al*. (1996) studied the effect of postannealing for the films consisting mainly of the $Nd_2Fe_{14}B$ phase and a coercive field of 5 kOe in the in-plane direction was obtained. Parhofer, Gieres, Wecker and Schultz (1996) studied the relationship between the magnetic properties and the composition and high H_c of 18 kOe in the perpendicular direction was achieved. In order to achieve hard magnetic properties, the $Nd_2Fe_{14}B$ phase should be sufficiently crystallized. Here, two methods have been considered: one is the postannealing that transforms the amorphous phase into the crystallized phase; the other is the deposition on heated substrates. However, it is hard to change the in-plane oriented *c* axis of the NdFeB phase to the perpendicular oriented one by postannealing. Shima, Kamegawa, Hono and Fujimori (2001) studied the effect of Cr overlayer on NdFeB films and the highly oriented $Nd_2Fe_{14}B$ phase was achieved on a glass substrate. They concluded that Cr overlayer plays a significant role in developing crystallographically textured $Nd_2Fe_{14}B$ grains, and they also assume that the developed texture is due to the seeding effect of the overlayer to induce the crystallization of the amorphous underlayer.

4 FePt THIN FILMS

As described in Section 1, many studies have been focused on the $L1_0$ ordered alloys such as MnAl, CoPt, FePd, and FePt, because they possess large uniaxial magnetocrystalline anisotropy K_u. Among them, $L1_0$ ordered FePt alloy has attracted much attention in recent years as a candidate material for applications such as next-generation high-density magnetic storage, because of large K_u of the order of 10^7 erg cm^{-3} and high corrosion resistance compared to rare-earth-based alloys described in Section 3. In this section, the basic properties and recent topics of FePt thin films are described.

4.1 $L1_0$ ordered structure

The key feature which is essential for remarkable magnetic properties of FePt alloys is the chemically ordered $L1_0$ phase around the equiatomic composition in the thermal equilibrium phase diagram as shown in Figure 8 (Okamoto, 2000). Although the thermodynamic ordering temperature of $L1_0$ FePt phase is 1300 °C, the FePt films fabricated by sputtering or vacuum evaporation methods usually have disordered face centered cubic (FCC) structure. In general, high-temperature postannealing above 500 °C is necessary to transform the disordered FCC phase to the $L1_0$ structure. The crystal structure of $L1_0$ structure is basically face centered tetragonal (FCT), composed of alternating atomic planes of Fe and Pt along the *c* axis (Figure 9). The $L1_0$ ordered phase of FePt alloy exhibits a large uniaxial magnetocrystalline anisotropy along the *c* axis, with a reported bulk value of 7×10^7 erg cm^{-3} (Ovanov, Solina and Demshina, 1973). This value is the highest of all the materials including no rare-earth elements as described in Figure 1.

4.2 Film morphology and magnetization process

The magnetization process of hard magnetic films depends strongly on the film morphology. It was clearly demonstrated in FePt thin films epitaxially grown on a MgO(001) substrate (Shima, Takanashi, Takahashi and Hono, 2002a, 2004). The film morphology may be changed by deposition parameters. Here, as two representatives, the results obtained by changing the substrate temperature T_S or the nominal thickness t_N will be described.

4.2.1 Substrate temperature (T_S) dependence

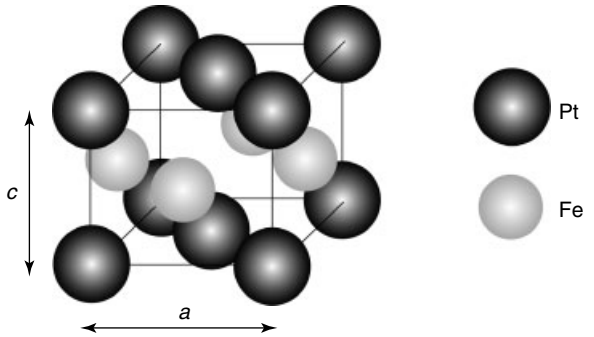

Figure 9. Crystal structure of $L1_0$ phase.

FePt films deposited on a MgO(001) substrate at various T_S in the range from 200 to 700 °C are shown in Figure 10. The nominal thickness t_N is fixed at 10 nm. In the diffraction pattern for $T_S = 200$ °C, only A1 diffraction spots are observed to be overlapped with the MgO diffraction spots from the substrate. Very weak superlattice spots are observed in the diffraction pattern for $T_S = 300$ °C, suggesting that the degree of order is still very low. The intensities of superlattice spots increase with T_S. The SAED patterns show the epitaxial growth with cube–cube orientation relationship between the FePt film and the MgO substrate, that is, $(001)_{FePt}||(001)_{MgO}$ and $<100>_{FePt}||<100>_{MgO}$.

Figure 11 shows a TEM image for $t_N = 10$ nm ($T_S = 700$ °C). The film was grown with the island-growth mode. Strongly faceted islands of FePt particles are observed with large size distribution. The major facet planes are (100) and (010), and the minor facet plane is (110), indicating that the surface energy of (100) and (010) planes is the lowest. When particles are small, the surface energy is large compared to the volume free energy, and thus the small particles would show clear faceting. The stripe contrast observed in the particles are the Moiré pattern originating from the lattice parameter difference between FePt and MgO, and the distance between neighboring stripes is approximately 2.2 nm as expected from the lattice mismatch between FePt and MgO with $a_{FePt} = 0.40$ nm and $a_{MgO} = 0.42$ nm, respectively. In cross-sectional TEM images, no structural defects, such as twins are observed and the surfaces of the particles are atomically flat. The sizes of particles are widely distributed with a typical lateral size of about 50 nm. In addition to these particles, much smaller particles are also observed. This suggests that a number of small particles were formed in the initial stage of the film deposition, and then they coalesced to form big particles.

Magnetization curves taken at 295 K for different substrate temperature T_S are shown in Figure 12. The solid and broken curves represent the magnetization measured in the direction perpendicular and parallel to the film plane, respectively. The film prepared at $T_S = 200$ °C is magnetically soft because of the low magnetocrystalline anisotropy of disordered FePt. With increasing T_S, at $T_S = 450$ °C, the easy magnetization axis changes from in plane to the direction perpendicular to the film plane. The coercivity H_c of the film increases

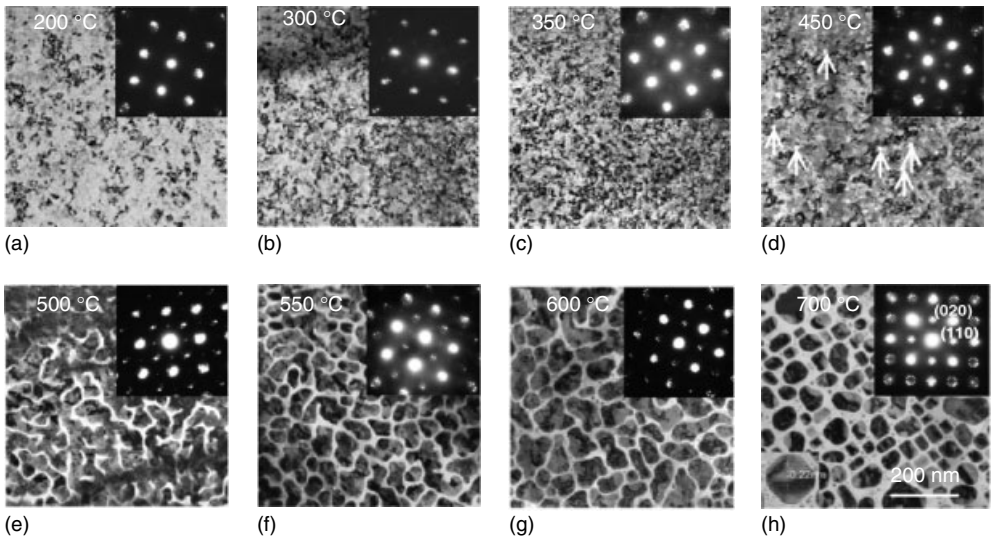

Figure 10. Bright field TEM images and SAED patterns of FePt films fabricated on MgO(001) substrates at various T_S. (Reprinted with permission Y.K. Takahashi *et al*., copyright 2003, Elsevier.)

from 0.85 kOe to about 42 kOe with increasing T_S from 450 to 700 °C. The in-plane magnetization of the film prepared at $T_S = 450$ °C saturates at 20 kOe. In the film deposited above 500 °C, however, the in-plane magnetization does not saturate even at 55 kOe, indicating high uniaxial magnetic anisotropy. Since the maximum magnetic field of 55 kOe in the super conducting quantum interence device (SQUID) is not sufficient to saturate the magnetization, the real value of H_c and saturation magnetization (M_S) are even higher. From the change of the magnetization curves, it is noted that the magnetocrystalline anisotropy increases with the progress of the $L1_0$ ordering as T_S is increased.

4.2.2 Nominal thickness (t_N) dependence

A remarkable change in the morphology of the film is observed for the films with different nominal thicknesses (t_N) deposited at 700 °C. Figure 13 shows TEM images for different t_N values. With increasing t_N, the typical size of particles increases from ∼50 nm for $t_N = 10$ nm to about ∼400 nm for $t_N = 20$ nm because of the coalescence. With further increase of t_N, particles grow to form an interconnected isotropic mazelike pattern. However, the mazelike structure does not percolate for $t_N \leq 45$ nm. The percolation occurs for $t_N = 50$ nm, and the film changes from discontinuous to continuous morphology. The electronic transport measurement also reveals that there is a drastic change in electrical resistance between $t_N = 45$ and 50 nm. The resistances are 800 MΩ and 810 Ω for $t_N = 45$ and 50 nm, respectively. With further increase of t_N, the percolated network expands at the expense of the voids, and the free space between FePt diminishes.

Figure 14 shows magnetization curves for different values of t_N. The easy magnetization axis is perpendicular to the film plane for all the samples, since the [001] axis of the tetragonal $L1_0$ ordered structure is perpendicular to the film plane as shown in Figure 1. Huge H_c of about 40 kOe, measured in the direction perpendicular to the film plane, was obtained for $t_N = 10$ nm at room temperature. With increasing t_N, the coercivity decreases slowly, but still keeps a quite large value of about 25 kOe for $t_N = 45$ nm. However, a drastic change of the magnetization curves is observed (Thiele, Folks, Toney and Weller, 1998; Kooy and Enz, 1960) between $t_N = 45$ and 50 nm. This critical region corresponds to the change in the morphology of the films from a particulate to a continuous state. With further increasing t_N, the magnetization becomes easier to be saturated in the perpendicular direction.

In Figure 15, the magnetic properties obtained from the magnetization curves and electrical resistance as a function

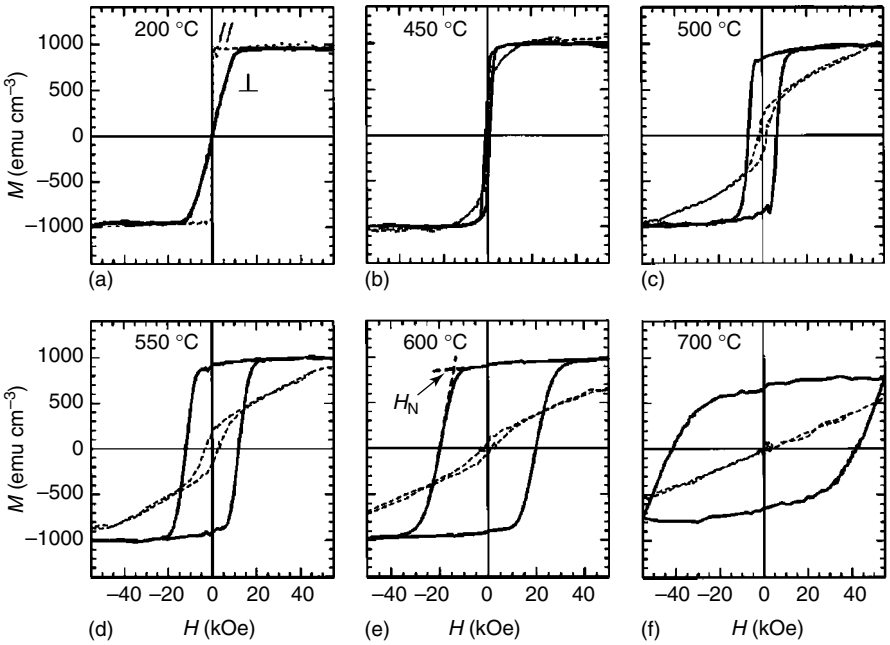

Figure 12. Magnetization curves taken at 295 K of FePt films with various T_S. Solid and broken curves represent the data with the applied field perpendicular and parallel to the film plane, respectively. (Reprinted with permission Y.K. Takahashi *et al*., copyright 2003, Elsevier.)

(Reprinted with permission Shima *et al*., copyright 2002, American Institute of Physics.)

of t_N are summarized. Large coercivites are obtained for $t_N \leq 45$ nm, and a drastic change by 1 order of magnitude is observed between $t_N = 45$ and 50, where the electrical resistance also reveals a drastic drop showing the onset of percolation. The nucleation field (H_N), at which the magnetization begins to drop with decreasing the field after saturation, is also evaluated. In the case of the films with large coercivity, the nucleation fields are defined from the

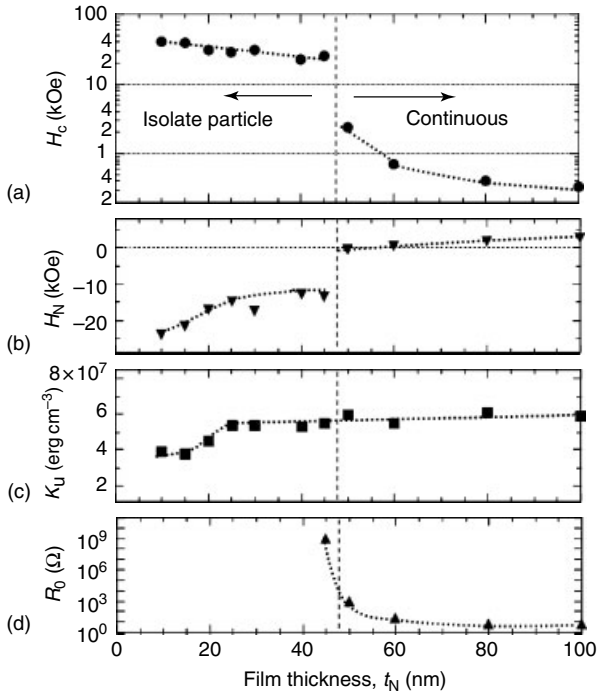

Figure 15. Magnetic properties and electrical resistance for FePt thin films as a function of the film thickness t_N. (Reprinted with permission Shima *et al*., copyright 2002, American Institute of Physics.)

cross point of the extrapolation of the values of saturation magnetization and the tangential line at the coercivity. The behavior of H_N shows a tendency similar to that of the coercivity: H_N also changes drastically between $t_N = 45$ and 50 nm. The uniaxial magnetic anisotropy K_u determined from the area enclosed between the magnetization curves in applied fields parallel and perpendicular to the film plane are also shown in Figure 15(c). The films with $t_N \geq 25$ nm showed a large value of $6.0 \pm 0.5 \times 10^7$ erg cm^{-3} which is very close to the value of the fully ordered FePt alloys (7×10^7 erg cm^{-3}). No jump is seen between $t_N = 45$ and 50 nm. For $t_N \leq 25$ nm, K_u decreases gradually with t_N. This is thought to be due to the lack of magnetization saturation associated with the fact that for very small t_N, the coercivity is larger than the maximum applied field (55 kOe).

Magnetic force microscope (MFM) images superimposed with atomic force microscope (AFM) images for different t_N are shown in Figure 16. For $t_N = 10$ nm, most particles have an SD state. With increasing t_N, MD particles, which correspond to a black and white contrast inside a particle, appear. The critical size from an SD to an MD particle is estimated to be approximately 200 nm. Almost all particles have the MD state for $t_N = 45$ nm; nevertheless, the coercive force is still quite high. There is no remarkable difference in the domain structure between $t_N = 45$ and 50 nm, that is, at the percolation boundary where the coercivity shows a noticeable drop. In other words, the drastic decrease in coercivity is not associated with a change in the domain structure, but it depends only on the percolation of particles. The origin for this behavior might be considered in the following way: there are some nucleation sites where reversed domains are easily generated at a very low magnetic field. However, such nucleation sites are very few. For a discontinuous film that is not percolated, domain walls created around the nucleation site cannot propagate all over the film, resulting in high coercivity. For a percolated continuous film, on the other hand, the domain walls can propagate all over the film, once the nucleation has occurred. Therefore, the coercivity becomes very small.

The drastic change in H_c is clearly observed at the percolation boundary in association with the morphology change from discontinuous to continuous state, where the magnetic domain structure shows no remarkable change. Transition from SD to MD particles proceeds gradually for even smaller t_N below the percolation limit. The detailed magnetization process of the samples in the region $t_N <$ 40 nm is given in the case where a field high enough to saturate the magnetization is applied.

Figure 17 shows H_c as a function of t_N at room temperature and 4.5 K. H_c was obtained from the magnetization curves measured with the applied magnetic field perpendicular to the substrate plane, using a vibrating sample magnetometer (VSM) equipped with a superconducting magnet (maximum magnetic field of ±140 kOe). Huge H_c values of 70 kOe at room temperature and 105 kOe at 4.5 K are obtained for $t_N = 5$ nm. In addition, the maximum energy product $(BH)_{max}$ at room temperature reaches about 50 MGOe, which is almost equal to the ideal value $(2\pi M_S)^2$. At both room temperature and 4.5 K, H_c decreases gradually with t_N. However, it remains large (42 and 59 kOe at room temperature and 4.5 K, respectively) even for $t_N = 40$ nm. A rapid decrease of H_c for $t_N \leq 3$ nm at room temperature is caused by poor chemical order in small particles with a diameter less than a few nanometers and also by thermal instability. It has been found from MFM observation that most of the particles have the SD state for $t_N \leq 5$ nm where the particle sizes are a few tens of nanometers or smaller. As t_N increases, MD particles appear with increasing average size, and most of the particles have the MD state for $t_N \geq 25$ nm where the particle sizes are typically of the order of hundreds of nanometers. SD and MD particles are mixed in the intermediate region between $t_N = 5$ and 25 nm.

The t_N dependence of H_c shows different behavior depending on the microstructure of the film (Takahashi, Hono, Shima and Takanashi, 2003). Figure 18 shows H_c measured

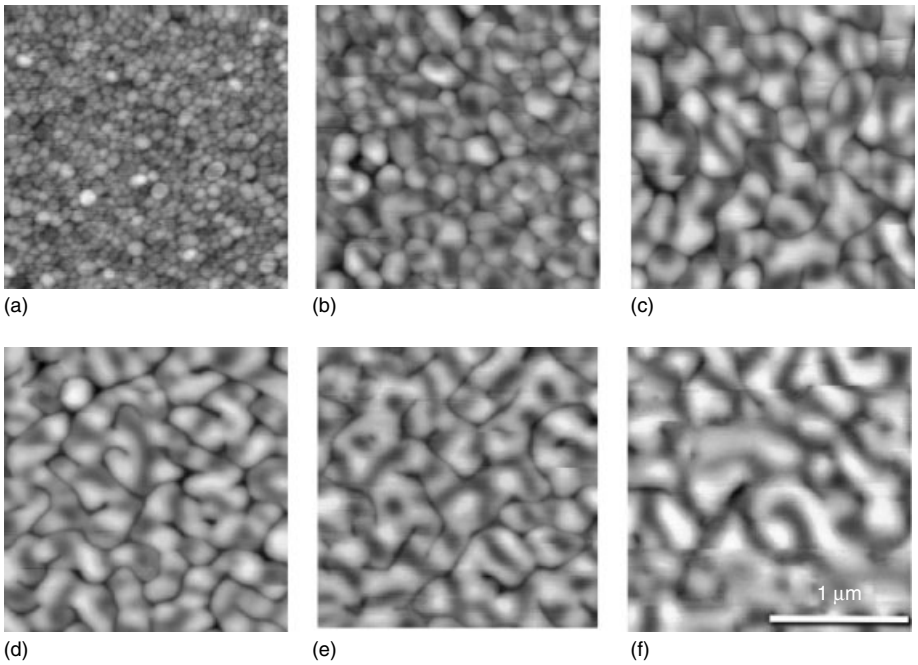

Figure 16. MFM images superimposed with AFM images of FePt thin films for different film thicknesses, $t_N = 10$ nm (a), 20 nm (b), 45 nm (c), 50 nm (d), 60 nm (e), and 100 nm (f). (Shima, Takanashi, Li and Ishio, 2003). (Reprinted with permission T. Shima *et al*., copyright 2003, Elsevier.)

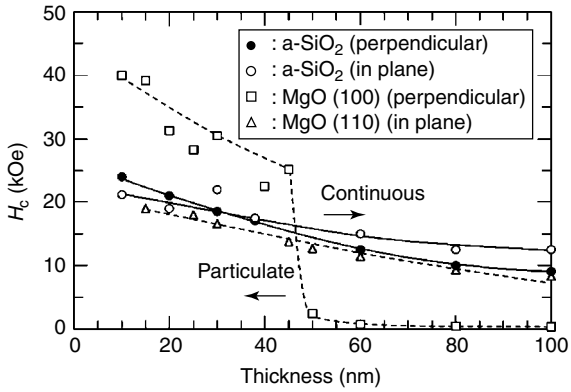

Figure 18. H_c as a function of t_N for the film on various substrates: MgO(100), MgO(110) single crystal and SiO_2 amorphous substrates. Each H_c was measured in the easy magnetization axis. (Reprinted with permission Takahashi *et al*., copyright 2004, American Institute of Physics.)

in the easy magnetization axis as a function of t_N for films deposited on various substrates: MgO(001), MgO(110) single crystal, and SiO_2 amorphous substrates (Takahashi *et al*., 2004b). The substrate temperature T_S was fixed at 700 °C. Electrical resistance measurements and TEM observations indicate that the percolation occurs between $t_N = 45$ and 50 nm for the film on any substrate. Nevertheless, in contrast to the behavior for the films on MgO(001) substrate, a gradual change of H_c was observed and no jump was seen at the critical thickness for the films on MgO(110) and SiO_2. The former indicates low resistance to the movement of the nucleated domain walls for the films on MgO(001), while the latter indicates the presence of pinning for the domain wall movement for the films on MgO(110) and SiO_2. X-ray diffraction (XRD) and TEM measurements revealed that FePt films grown on MgO(110) substrates consist dominantly of (101) texture, where twins with two different directions of the *c* axis, that is, the easy magnetization axis, exist. FePt

films grown on SiO_2 glass substrates show polycrystalline structure consisting of grains with different directions of the *c* axis. The pinning is then thought to be due to structural defects like twins and/or grain boundaries.

4.3 Magnetization process for highly oriented FePt(001) particles

FePt(001) island films grown on MgO(001) substrates at high T_S provide model systems for the assembly of hard magnetic particles because of their defect-free highly oriented structure. Figure 19 shows the initial magnetization curves starting from the demagnetized state for different values of t_N, clearly showing the difference between the magnetization processes in SD and MD particles. All the magnetization curves were measured at 295 K in the direction perpendicular to the film plane. The vertical axis indicates the magnetization normalized by the magnetization value at 140 kOe. t_N is 3, 5, 8, 10, 12, 15, 18, 20, 25, 30, and 40 nm. The films with $t_N = 3$ and 5 nm are very difficult to be magnetized, because they contain only SD particles with sizes from ten to a few tens of nanometers. Hence, the magnetization progresses only by the magnetization rotation in the particles. However, with increasing t_N (10 and 12 nm), that is, with increasing particle size, a steep increase of the magnetization at low magnetic field is observed although the complete saturation is still hard. The fractional magnetization at low magnetic field corresponds to the magnetic domain wall displacement; in other words, particles larger than 200 nm with MD structure are first magnetized at low magnetic field. With further increasing t_N (15 and 20 nm), the volume fraction of MD particles increases, and consequently, the fraction of the magnetization that is magnetized at low magnetic field increases. This figure also indicates that the particles smaller than 200 nm, that is, with SD structure, still exist for the film with $t_N = 20$ nm because a small fraction of the magnetization is still hard to saturate. However, they disappear for the films with $t_N \geq 25$ nm. In this case, the magnetization can easily be saturated at a field lower than 10 kOe by domain walls displacement process. Such initial magnetization curves are usually classified as 'nucleation type'. The coexistence of both SD and MD structures is clearly elucidated from the initial magnetization process, and is consistent with the MFM observations.

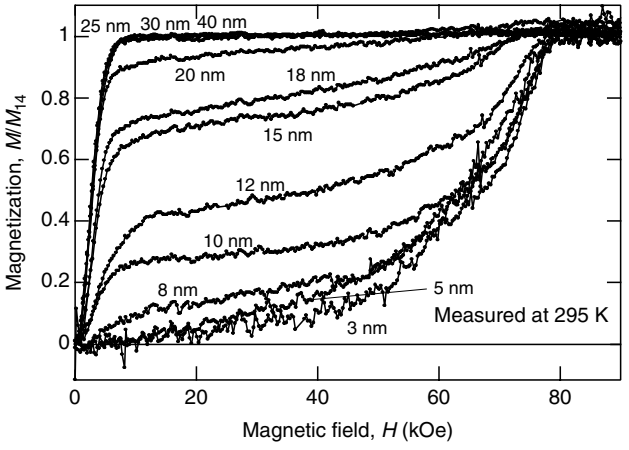

Figure 19. Initial magnetization curves for FePt films with different t_N. t_N is 3, 5, 8, 10, 12, 15, 18, 20, 25, 30, and 40 nm. (Reprinted with permission Shima *et al*., copyright 2004, American institute of Physics.)

Even in hard magnets showing so-called nucleation-type behavior to date, it is well known that a high magnetic field comparable to or larger than H_c is generally required to fully magnetize the material, because the existence of multiple phases and/or grain boundaries and interparticle dipolar interaction prevents the complete disappearance of reversed domains. However, the FePt nanoparticles are clearly different from these. Figure 20 shows the magnetization curves for $t_N = 25$ nm, with variation of the initial applied field (H_{in}) from the virgin state. H_{in} is 2 kOe (a), 3 kOe (b), 4 kOe (c), 5 kOe (d), and 6 kOe (e). The magnetic field is first increased to H_{in} from the virgin state and then reversed to −55 kOe. It is then increased again through zero to +55 kOe, and finally reversed through zero to −55 kOe. In the case of $H_{in} = 2$ kOe (Figure 20a), most of the particles have their magnetization easily reversed at low negative magnetic fields of a few kilooersteds when the magnetic field is reversed. With increasing H_{in}, the fraction of the particles showing easily reversed magnetization decreases (Figure 20b,d), before finally disappearing at $H_{in} = 6$ kOe (Figure 20e). This result indicates that 6 kOe alone is enough to fully magnetize the sample and obtain a high H_c value of more than 50 kOe. In other words, domain walls are completely wiped out from each particle at a low magnetic field, and the nucleation of reversed domains becomes very difficult; a high magnetic field is then required for magnetization reversal (Shima *et al*., 2006).

This remarkable nucleation-type behavior may be attributed to the ideal structure with defect-free, perfectly aligned, monocrystalline FePt nanoparticles, and weak dipolar interaction between particles. The wipeout of domain walls is thought to be dominated by the competition between the applied magnetic field and interparticle dipolar interaction (Durst and Kronmüller, 1987; Givord, Tenaud and Viadieu, 1988; Givord *et al*., 1992) in sintered NdFeB magnets where NdFeB grains are densely packed. Conversely, for FePt nanoparticles shown in this section, the particle density is low and the interparticle distance is considerably larger. Therefore, the interparticle dipolar interaction is significantly reduced compared to that in sintered NdFeB.

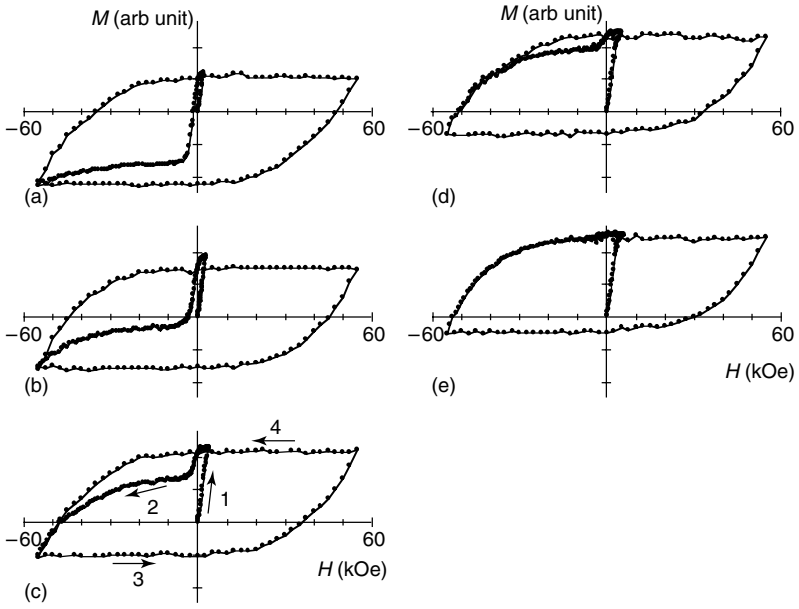

Figure 20. Magnetization curves for nominal thickness $t_N = 25$ nm, with varying the initial applied field (H_{in}) from the virgin state. H_{in} is 2 kOe (a), 3 kOe (b), 4 kOe (c), 5 kOe, (d), and 6 kOe (e). (Reprinted with permission Shima *et al*., copyright 2006, American Institute of Physics.)

4.4 Low-temperature fabrication of $L1_0$ phase

It is well known that the substrate temperature during deposition and/or the postannealing temperature are required to be high (usually more than 500 °C) for the preparation of highly ordered Fe–Pt alloy films. However, for practical use, it is essential to reduce the growth temperature. Recently, a lot of studies have focused on the reduction of the ordering temperature by several approaches as summarized in Table 4.

Maeda *et al*. (2002) reported that the addition of Cu to FePt is an effective way to reduce the ordering temperature, and H_c of about 5 kOe was obtained after annealing at 300 °C. A similar result was also reported by Takahashi, Ohnuma and Hono (2002). They confirmed that the Fe site was substituted by Cu in a FePtCu system and the decrease of the ordering temperature was thought to be attributed to faster diffusion in Cu-containing FePt alloy, owing to the depression of the melting temperature. Besides the addition of Cu, Platt *et al*. (2002) studied the effect of Au and Ag in the FePt films. The reduction of the annealing time by Zr addition (Lee, Yang, Kim and Na, 2001) and the control of the particle size by C addition were also reported (Ko, Perumal and Shin, 2003).

Ravelosona, Chappert, Mathet and Bernas (2000) actively studied the effect of ion irradiation. They have shown that the long-range order in FePt films, grown by sputtering at moderate temperatures, was enhanced by He ion irradiation. After irradiation, the perpendicular magnetic anisotropy was observed to increase. Authors believe that this irradiation technique could be a candidate for the fabrication of partially ordered granular media based on the weakly ordered alloys.

Luo and Sellmyer (1995) and Endo, Kikuchi, Kitakami and Shimada (2001) found that the rapid diffusion at Fe/Pt interface occurred at temperatures around 300 °C and the multilayer structure directly transforms to the ordered FCT phase when Fe and Pt layer thicknesses are almost equal. They also confirmed that the rapid formation of the FCT phase in the multilayers with Fe/Pt ≈1 was due to relatively rapid diffusion at the interface. Ultimate multilayer structure is an alternate stacking of monatomic layers of Fe and Pt. Shima, Moriguchi, Mitani and Takanashi (2002b) reported that the $L1_0$ phase could artificially be produced by alternating Fe(001) and Pt(001) monatomic layers on a MgO(001) substrate at temperatures below 230 °C. The samples prepared by this technique exhibited perpendicular magnetization with a large uniaxial magnetic anisotropy K_u of 3×10^7 erg cm^{-3} and high chemical ordering (long-range order parameter $S = 0.7 \pm 0.1$) even at $T_S = 200$ °C.

Furthermore, Suzuki, Harada, Honda and Ouchi (1999) reported that a high Ar pressure during deposition was very effective in promoting the chemical ordering. On the other hand, Takahashi, Ohnuma and Hono (2001) reported that the combination of the elevated substrate temperature during the deposition and postannealing was effective for the promotion of ordering even at 300 °C.

Numerous studies were made for the samples with compositions around $Fe_{50}Pt_{50}$ (in at%). However, Seki *et al*. (2003) found that $L1_0$ ordered FePt(001) films with large magnetic

Table 4. Recent studies on the reduction of the ordering temperature for FePt films (Hsu, Jeong, Laughlin and Lambeth, 2001; Maeda *et al*., 2002; Takahashi, Ohnuma and Hono, 2001, 2002; Platt *et al*., 2002; Lee, Yang, Kim and Na, 2001; Ko, Perumal and Shin, 2003; Ravelosona, Chappert, Mathet and Bernas, 2000; Luo and Sellmyer, 1995; Endo, Kikuchi, Kitakami and Shimada, 2001; Shima, Moriguchi, Mitani and Takanashi, 2002; Suzuki, Harada, Honda and Ouchi, 1999; Seki *et al*., 2003).

anisotropy could successfully be prepared at $T_S = 300\,^{\circ}C$ by decreasing the Fe concentration from the equiatomic composition. This is quite a simple method for the reduction of ordering temperature, although the detailed mechanism is not elucidated yet.

4.5 Self-assembly of FePt nanoparticles

The demand for higher magnetic recording density with a low system noise stimulates the need for a medium consisting of magnetically isolated particles with a size below 10 nm. Besides, the size of ferromagnetic particles dispersed in a nonmagnetic matrix is expected to become a few nanometers even for a bit size of a 10–20 nm. This size almost reaches the superparamagnetic limit for existing materials that are unsuitable for such applications. Besides, in order to overcome thermal fluctuation and demagnetizing fields that make the magnetization of the recording bit unstable, high K_u materials are needed. A lot of studies on granular-type films consisting of $L1_0$ ordered FePt particles dispersed in a nonmagnetic matrix have been performed. Recent reports on FePt granular films, where FePt nanoparticles are embedded in the matrix materials are indicated here; oxide (MgO: Mukai, Uzumaki and Tanaka, 2003; Shima, Takanashi, Takahashi and Hono, 2006; Al_2O_3: Bian *et al*., 1999; White *et al*., 2003; Al–O: Watanabe, Masumoto, Ping and Hono, 2000; Ping *et al*., 2001; SiO_2: Saito, Kitakami and Shimada, 2002; Luo and Sellmyer, 1999; B_2O_3: Luo *et al*., 2000), nitride (BN: Daniil *et al*., 2002; Christodoulides *et al*., 2001; AlN: Chen, Luo, Lie and Hua, 2001; Si_3N_4: Kuo and Kuo, 2000), metal, and so on (Ag: Chen *et al*., 2002; Ping *et al*., 2001; C: Christodoulides *et al*., 2001; Lee *et al*., 2005). Generally, the granular structure is obtained by following preparation techniques: one of them is codeposition of Fe, Pt, and matrix material. The other consists of first depositing FePt/matrix films in a multilayer form and subsequently annealing the samples at high temperature to form granular structure. Sputtering and ion implantation techniques are used.

Among a lot of investigations on FePt granular films, Takahashi *et al*. (2004a) revealed that there exists a size dependence of the degree of chemical order in FePt–Al_2O_3 granular films. In other words, when the particle size becomes less than a few nanometers, the ordered phase becomes unstable with respect to the disordered phase. Since FePt nanoparticles cannot be coarsened when the volume fraction of FePt is low in the oxide matrix, they may not be able to be ordered to the $L1_0$ structure owing to the size effect.

Figure 21 shows a self-organized magnetic assembly (SOMA) of FePt nanoparticles (Sun *et al*., 2000) which has given a great influence on research direction as a promising candidate for an advanced future magnetic recording media. The chemically processed FePt particles are initially in the disordered state, so they must be ordered to the $L1_0$ phase by annealing. However, several problems are still to be overcome. One of these problems is that the ordered arrays of nanoparticles are deteriorated by the coalescence of the particles. The other is that aligning the *c* axis of the particles by the chemical synthesis method is not easy. Recent progress of chemical synthesis may have an answer to the first problem: it was revealed that SiO_2-coated FePt nanoparticles, which were prepared by chemical synthesis, suppress the coalescence of the particles after annealing at high temperature (Yamamoto, Morimoto, Ono and Takano, 2005). In

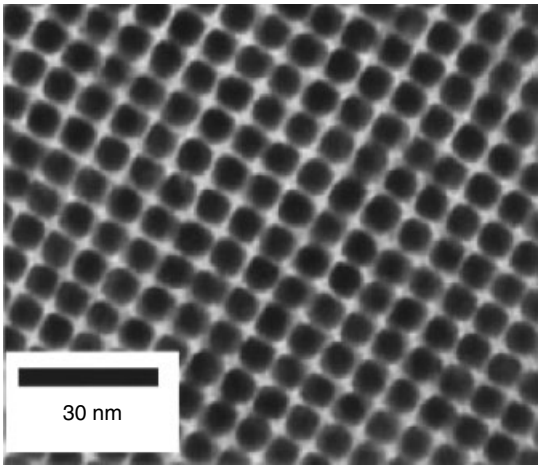

Figure 21. TEM image of a 3-D assembly of FePt nanoparticles with a diameter of 6 nm (Sun *et al*., 2000).

addition, the direct synthesis of $L1_0$ nanoparticles at low temperature using 'modified polyol method' was demonstrated and was found to be effective for reducing the ordering temperature and suppressing the coarsening (Takahashi, Ogawa, Hasegawa and Jeyadevan, 2005).

5 NANOCOMPOSITE MAGNET FILMS

Several attempts to realize an exchange-spring magnet, in other words, a nanocomposite magnet, have been performed by the mixture of a hard magnetic layer and a soft magnetic layer as described in Section 1.3. A possible combination for the nanocomposite structure is constituted by Sm–Co, Sm–Fe, Nd–Fe–B, Fe–Pt as the hard phase and α-Fe, Fe_3B, NiFe, Co as the soft phase. Theoretical energy products $(BH)_{max}$ of some nanocomposite magnets and bulk $Nd_2Fe_{14}B$ alloy, as a reference, are shown in Table 5 (Skomski 1994; Sabiryanov and Jaswal, 1998a). 'Megajoule magnet' can possibly be achieved when $Sm_2Fe_{17}N_3$ and $Fe_{65}Co_{35}$ alloys are selected. Several papers on the experimental work were published on Co/Sm–Co (Liu, Skomski, Liu and Sellmyer, 2000), Fe/FePt (Liu *et al*., 1997), Fe/Pt (Liu, Luo, Liu and Sellmyer, 1998), FePt/Fe_3Pt (Zeng *et al*., 2002), and $Ni_{80}Fe_{20}/Sm_{40}Fe_{60}$ (Yan *et al*., 2001). However, to date, magnetic properties such as remanence enhancement and energy product have not succeeded those of the best aligned 'single-phase' magnets such as $Nd_2Fe_{14}B$ with $(BH)_{max} \simeq 55$ MGOe. The key technology to achieve the improvement of magnetic properties is thought to be in the control of the direction of the easy magnetization axis and the epitaxial growth of each layer.

Table 5. Theoretical energy product $(BH)_{max}$ of some nanocomposite magnets and bulk $Nd_2Fe_{14}B$ alloy (Skomski, 1994; Sabiryanov and Jaswal, 1998a).

Material		$(BH)_{max}$	
Hard phase	Soft phase	(MGOe)	(kJ m^{-3})
$Sm_2Fe_{17}N_3$	$Fe_{65}Co_{35}$	137	1090
$Sm_2Fe_{17}N_3$	Fe	110	880
FePt	Fe	90	720
$Nd_2Fe_{14}B$	Fe	90	720
Sm_2Fe_{17}	Fe	74	592
$SmCo_5$	$Fe_{65}Co_{35}$	65	520
$Nd_2Fe_{14}B$ (bulk)		55	440

Magneto-optical Materials

Wolfgang Kleemann
Universität Duisburg-Essen, Duisburg, Germany

1 INTRODUCTION

Magneto-optics was discovered in the nineteenth century. *Michael Faraday* (1791–1867) observed the rotation of the plane of light polarization in a piece of longitudinally magnetized glass in 1845 (Faraday, 1846), while *John Kerr* (1824–1907) realized the complementary effect in reflection from the poles of a magnet in 1876 (Kerr, 1877). More precisely, the magneto-optical *Kerr* effect (MOKE) is the change of polarization (ellipticity and/or rotation of the polarization axes) and/or intensity of the light being reflected by a magnetized surface. Three different geometries are distinguished (Figure 1): the polar (a), the longitudinal (b), and the transversal MOKE (c). All of these effects are linear in the magnetization and/or the magnetic field (quadratic contributions may superimpose at very high fields). Both Faraday rotation and MOKE may be classified as magnetic circular birefringence (MCB) effects, which are Kramers–Kronig related to magnetic circular dichroism (MCD). They have to be distinguished from transverse magneto-optical (MO) effects being quadratic in magnetization and/or magnetic field. The *Voigt* or *Cotton–Mouton* effect (Voigt, 1898, 1908; Cotton and Mouton, 1907) is commonly known as *magnetic linear birefringence* (MLB), which is related to the magnetic linear dichroism (MLD).

Today, the theory of magneto-optics is well understood and the development of MO materials and devices is an extremely vivid field of research. This has been documented in the last 20 years from various points of view, either focusing on materials (Buschow, 1988) or on theory (Oppeneer, 2001), or on both of them in an excellent monograph (Zvezdin and Kotov, 1997). Aspects of applications were in the focus of other reviews or monographs. Ever since, Faraday rotation and MOKE have been most popular methods to image ferro- and ferrimagnetic domain structures (Dillon, 1963; Craik and Tebble, 1965; Dillon, 1971; Hubert and Schäfer, 1998). Although MO recording materials and devices have been developed since more than 30 years, they reached maturity only in the last 10 years. In particular, the preparation of high performance MO materials and their heterostructures allowing the storage, readout, and erasure of data at very high densities were sensitively improved. This has been documented in various extensive reviews (Mansuripur, 1995; Gambino and Suzuki, 1999; Röll 2003). Thin films and nanostrucures are, meanwhile, probably the most investigated materials in MO research and development (Ferré, 1992). Even more sophisticated structures like MO light waveguides and magnetophotonic crystals (Lyubchanskii *et al*., 2003) are at the dawn of applications.

In parallel to the development of appropriate materials, the search for optimized light sources has become increasingly important. The development of the MO disc technology is intimately connected with the development of novel laser diodes emitting at shorter light wavelengths. On the

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

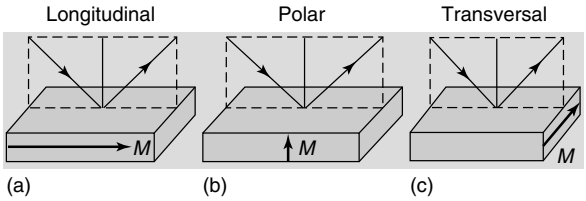

Figure 1. Schematic longitudinal (a), polar (b), and transversal Kerr effect (c) configurations.

other hand, high-power mode-locked solid-state lasers with ultrashort pulses are now playing a major role in modern materials research, where MOKE has become an indispensable tool for investigating novel nanostructured and/or very thin-film materials at high temporal resolution (Hillebrands and Ounadjela, 2002, 2003). Owing to its very fast response, high accuracy, and high temporal and spatial resolution, the MO probe has proved to be probably the most powerful method to study magnetic properties at extreme length and timescales (Rasing *et al*., 2003). The novel term *femtomagnetism* stands for temporal magnetic response on a subpicosecond timescale and substantially relies on MO spectroscopical techniques (Bigot, Guidoni, Beaurepaire and Saeta, 2004). The excellent time resolution of MOKE is also absolutely essential in spintronics research, where spin states of magnetic semiconductors are investigated at the picosecond timescale (Kimel *et al*., 2004). Finally, the development of powerful and versatile synchrotron-based light sources in the X-ray regime opened another extremely fruitful branch of magneto-optics. Magnetically dichroic signals (X-ray magnetic circular dichroism, XMCD, X-ray magnetic linear dichroism, XMLD) at resonance with spin-polarized transitions from K and L edges (Schütz *et al*., 1987) have proven to be extremely sensitive and have become widely used for investigations of quantitative aspects of magnetism, meanwhile also connected with microscopic imaging at high spatial resolution (Stoehr *et al*., 1993, Fischer *et al*., 1996).

When talking about *magnetic domains* intuitively the topography of ferromagnetic and ferrimagnetic magnetization is normally considered (Hubert and Schäfer, 1998). This view is, however, incomplete, since there are at least as many antiferromagnetic materials in nature as ferromagnetic ones. For thermodynamic reasons, they also decay into domains, the structure of which is, however, less evident than in the ferroic case. It is usually not accessible by MOKE or Faraday rotation and has never been considered as useful as the ferromagnetic one. This opinion has changed in recent years, since antiferromagnetic materials gained appreciable technological interest within the context of spin electronics (Prinz, 1998), exchange bias (Nogués and Schuller, 1999), magnetoelectric, and multiferroic systems (Fiebig, 2005). While the cumbersome method of neutron topography was previously the only direct method to verify the $\pm 180^\circ$ orientation of an antiferromagnetic uniaxial order parameter (Tanner, 1979), nonlinear MO spectroscopy is now an alternative to image antiferromagnetic domain topography at higher resolution using second harmonic generation (SHG) (Fiebig, Fröhlich, Krichevstov and Pisarev, 1994). Another very promising method utilizes the XMLD of antiferromagnets with appropriate symmetry (Nolting *et al*., 2000).

In this contribution, we shall give brief overviews on the theoretical aspects (Section 2) and the experimental techniques (Section 3) presently involved in magneto-optics. Section 4 will then deal with some MO materials and their applications, which are presently in the focus of interest: magneto-optical storage materials, magnetic semiconductors, antiferromagnets, and magnetophotonic crystals.

2 THEORETICAL ASPECTS

2.1 Linear magneto-optics

In the spectral range of visible and UV light, MO effects are linked to the dielectric permittivity tensor being perturbed by magnetic contributions. Being far above the frequencies of magnetic resonances, there is virtually no contribution from the magnetic permeability. Let us first consider a simple quasiclassic model of the axial (polar) MO effects based on the Drude–Lorentz model of elastically bound electrons (spatial coordinate $\mathbf{r} = (x, y)$, mass m, charge e, damping constant γ, eigenfrequency ω_o) under the combined action of the electrical field of the light wave, $\mathbf{E} = (E_x, E_y)\exp(i\omega t)$ and an axial external magnetic field, $\mathbf{B} = B\hat{z}$. The equation of motion reads

$$m\ddot{\mathbf{r}} + \gamma\dot{\mathbf{r}} + m\omega_o^2\mathbf{r} = e\mathbf{E} + e(\dot{\mathbf{r}} \times \mathbf{B}) \tag{1}$$

and is solved by harmonically oscillating coordinates $x = x_o \exp(i\omega t)$ and $y = y_o \exp(i\omega t)$ which enter circular coordinates,

$$x_\pm = \alpha_\pm E_\pm / e \tag{2}$$

with $x_\pm = (x_o \pm i y_o)\exp(i\omega t)$ and $E_\pm = (E_x \pm i E_y)\exp(i\omega t)$. The electric dipole moment $p_\pm = e x_\pm = \alpha_\pm E_\pm$ involves the polarizabilities

$$\alpha_\pm = \frac{e^2}{m\left(\omega_o^2 - \omega^2\right) + i\omega\gamma \mp e\omega B} \approx \frac{e^2}{m\left(\omega_o^2 - \omega^2\right) + i\omega\gamma} \times \left\{1 \pm \frac{e\omega B}{m\left(\omega_o^2 - \omega^2\right) + i\omega\gamma}\right\} \tag{3}$$

such that finally

$$\vec{p} = \begin{pmatrix} p_x \\ p_y \end{pmatrix} = \frac{1}{2} \begin{pmatrix} \alpha_+ + \alpha_- & i\,(\alpha_+ - \alpha_-) \\ -i\,(\alpha_+ - \alpha_-) & \alpha_+ + \alpha_- \end{pmatrix} \times \begin{pmatrix} E_x \\ E_y \end{pmatrix} = \vec{\alpha}\vec{E} \tag{4}$$

The tensor of the dielectric permittivity

$$\varepsilon_{ij} = \frac{N\alpha_{ij}}{\varepsilon_o} + \delta_{ij},$$
$$\vec{\varepsilon} = \frac{1}{2} \begin{pmatrix} N(\alpha_+ + \alpha_-)/\varepsilon_o + 1 & iN(\alpha_+ - \alpha_-)/\varepsilon_o \\ -iN(\alpha_+ - \alpha_-)/\varepsilon_o & N(\alpha_+ + \alpha_-)/\varepsilon_o + 1 \end{pmatrix} \tag{5}$$

is diagonal in circular polarization and yields the complex refractive indices

$$\tilde{n}_\pm = \sqrt{\varepsilon_\pm} = \sqrt{N\alpha_\pm/\varepsilon_o + 1} \equiv n_\pm + i\kappa_\pm \tag{6}$$

The *Faraday* rotation angle is readily found from the circular birefringence $n_+ - n_-$ and yields

$$\Theta_{\mathrm{F}} = \frac{\pi}{\lambda_{\mathrm{o}}} (n_+ - n_-)\, t \propto Re\,(\alpha_+ - \alpha_-) \propto B \tag{7}$$

where t is the sample thickness. The *Faraday* ellipticity is related to the circular dichroism $\kappa_+ - \kappa_-$ via

$$\varepsilon_{\mathrm{F}} = \frac{\pi}{\lambda_{\mathrm{o}}} (\kappa_+ - \kappa_-)\, d \propto \mathrm{Im}\,(\alpha_+ - \alpha_-) \propto B \tag{8}$$

In a ferromagnet, one has to replace B by the magnetization M such that

$$\Theta_{\mathrm{F}}, \varepsilon_{\mathrm{F}} \propto M \tag{9}$$

Kerr rotation and ellipticity in the polar geometry (Figure 1a) is calculated by starting from an x polarized incident wave, which contains two circularly polarized eigenmodes at longitudinal propagation,

$$\mathbf{E}_i^{\pm} = \begin{pmatrix} 1 \\ \pm i \end{pmatrix} \frac{E_i}{2} \text{ with } \mathbf{E}_i = \mathbf{E}_{\mathrm{o}} \mathrm{e}^{i(\omega t - kz)} \tag{10}$$

Making use of the dielectric tensor, equation (5), which may be written as

$$\boldsymbol{\varepsilon} = \begin{pmatrix} \varepsilon_{xx} & i\varepsilon_{xy} & 0 \\ -i\varepsilon_{xy} & \varepsilon_{xx} & 0 \\ 0 & 0 & \varepsilon_{zz} \end{pmatrix} \tag{11}$$

and of Fresnel's formulae, one obtains the reflected field components

$$\mathbf{E}_{\mathrm{r}}^{+} = \frac{1 - n_+}{1 + n_+} \begin{pmatrix} 1 \\ i \end{pmatrix} \frac{E_e}{2} \tag{12}$$

where $\mathbf{E}_{\mathrm{r}}^{-} = \frac{1-n_-}{1+n_-} \begin{pmatrix} 1 \\ -i \end{pmatrix} \frac{E_i}{2}$ and $n_\pm = \left(\varepsilon_{xx} \mp \varepsilon_{xy}\right)^{1/2}$. One thus obtains

$$E_{\mathrm{r}x} = \frac{1}{2} \left(\frac{1 - n_+}{1 + n_+} + \frac{1 - n_-}{1 + n_-} \right) E_i = \frac{-n_+ n_- + 1}{(1 + n_+)\,(1 + n_-)} E_i = A_x \mathrm{e}^{i\Phi_x} \tag{13}$$

$$E_{\mathrm{r}y} = \frac{i}{2} \left(\frac{1 - n_+}{1 + n_+} - \frac{1 - n_-}{1 + n_-} \right) E_i = i \frac{-n_+ + n_-}{(1 + n_+)\,(1 + n_-)} E_i = A_y \mathrm{e}^{i\Phi_y} \tag{14}$$

and the ratio

$$\frac{E_{\mathrm{r}y}}{E_{\mathrm{r}x}} = i \frac{n_+ - n_-}{n_+ n_- - 1} = \frac{A_y}{A_x} \mathrm{e}^{i(\Phi_y - \Phi_x)} = \frac{A_y}{A_x} \left[\cos\left(\Phi_y - \Phi_x\right) + i \sin\left(\Phi_y - \Phi_x\right) \right] \tag{15}$$

For $\Phi_y - \Phi_x = 0$ one solely obtains Kerr rotation,

$$Re \frac{E_{\mathrm{r}y}}{E_{\mathrm{r}x}} = \frac{A_y}{A_x} = \tan\theta_{\mathrm{K}} \approx \theta_{\mathrm{K}} \tag{16}$$

while for $\Phi_y - \Phi_x = \frac{\pi}{2}$ mere Kerr ellipticity is observed,

$$Im \frac{E_{\mathrm{r}y}}{E_{\mathrm{r}x}} = \frac{A_y}{A_x} = \varepsilon_{\mathrm{K}} \tag{17}$$

Since in general $0 \neq \Phi_y - \Phi_x \neq \frac{\pi}{2}$, both components as defined by equations (16) and (17) are simultaneously observed. Under the constraint $|\varepsilon_{xy}| \ll |\varepsilon_{xx}|$ a compact final formula is derived,

$$\frac{E_{\mathrm{r}y}}{E_{\mathrm{r}x}} = i \frac{n_+ - n_-}{n_+ n_- - 1} \approx \frac{\varepsilon_{xy}}{i\,(\varepsilon_{xx})^{1/2}\,(\varepsilon_{xx} - 1)} \tag{18}$$

Interestingly, a transparent solid with real tensor components ε_{xx} and ε_{xy} lacks any Kerr rotation, $\mathrm{Re}\frac{E_{\mathrm{r}y}}{E_{\mathrm{r}x}} = 0$, but reveals nonvanishing Kerr ellipticity,

$$\mathrm{Im} \frac{E_{\mathrm{r}y}}{E_{\mathrm{r}x}} = \varepsilon_K = \frac{-\varepsilon_{xy}}{(\varepsilon_{xx})^{1/2}(\varepsilon_{xx} - 1)} \tag{19}$$

Since the secondary motion of the electrons due to the Lorentz field in equation (1) is perpendicular to both the

direction of the magnetization and to the primary motion, a secondary amplitude is superimposed to the primary beam of the reflected light. This explains qualitatively the differences between the three general MOKE geometries shown in Figure 1. In the *polar* geometry, P-MOKE (a) the magnetization is perpendicular to the reflecting surface; hence, a linearly polarized wave generates a secondary component, which is strongest at perpendicular incidence. There is no dependence on the initial direction of the polarization. In the *longitudinal* configuration, L-MOKE (b) the magnetization is parallel to both the plane of incidence and to the reflecting surface. This generates a rotation of the polarization of the reflected beam both for s (= perpendicular) and p (= parallel) polarized light with respect to the plane of incidence, however, with different signs of the Kerr rotation. It vanishes for perpendicular incidence and maximizes at intermediate angles of incidence. General results for arbitrary angles of incidence have been derived by explicit use of the corresponding Fresnel's formulae (see e.g., Metzger, Pluvinage and Torguet, 1965; Dillon, 1971; Zvezdin and Kotov, 1997).

For the *transversal* geometry, T-MOKE (c) does not involve any rotation or ellipticity as is the case for P-MOKE or L-MOKE, since the secondary amplitude either vanishes (in s-wave polarization, where **M** is parallel to $\dot{\mathbf{r}}$) or adds along the propagation vector (in p-wave polarization). However, in the latter case, the reflectivity changes at oblique incidence when inverting the magnetic field (or magnetization), since the component of the electric polarization **P** perpendicular to the direction of the reflected beam changes. Thus, the *transversal* 'Kerr' effect is quite useful for observing or measuring magnetization contrast by simple intensity measurements (Voigt, 1908; Yang and Scheinfein, 1993). T-MOKE was first observed by Zeeman (1897) and is particularly suited to visualize surface magnetic domain structures (Hubert and Schäfer, 1998).

It should be mentioned that second-order contributions, that is, quadratic in the components of **M**, may be quite sizeable. They are natural ingredients from the beginning in the sense of perturbation expansions like those used in equation (3) and dominate in the transverse *Voigt* geometry. The linear dielectric tensor, equation (11), has to be supplemented by a quadratic one and reads as follows for cubic crystals (Hubert and Schäfer, 1998):

$$\boldsymbol{\varepsilon} = \varepsilon \begin{pmatrix} 1 & -iQm_z & iQm_y \\ iQm_z & 1 & -iQm_x \\ -iQm_y & iQm_x & 1 \end{pmatrix} + \begin{pmatrix} B_1 m_x^2 & B_2 m_x m_y & B_2 m_x m_z \\ B_2 m_x m_y & B_1 m_y^2 & B_2 m_y m_z \\ B_2 m_x m_z & B_2 m_y m_z & B_1 m_z^2 \end{pmatrix} \quad (20)$$

Here, **m** is the unit vector of the magnetization, $Q \propto \varepsilon_{xy}$ (*Voigt constant*), and B_1 and B_2 are material parameters. In the Faraday configuration with $m_x = m_y = 0$, Faraday effect and P-MOKE emerge linearly in m_z as anticipated above, whereas in the L-MOKE configuration with $m_x \neq 0 \neq m_y$, the Kerr rotation angle may effectively contain quadratic contributions formally described as

$$\theta_{\mathrm{K}} \propto m_y + \alpha m_x m_y + \beta m_x^2 \quad (21)$$

They were shown to depend on the angle of incidence and to give rise to asymmetric hysteresis loops as reported, for example, for the case of thin films of Fe (Postava *et al*., 1997; Yan, Schreiber, Grünberg and Schäfer, 2000) and discussed within an extended MOKE theory (Osgood, Clemens and White, 1997; Osgood, Bader, Clemens and White, 1998).

All MO spectroscopies are based on the coupling of electromagnetic waves to the orbital states of spin-polarized electron states. Since these are coupled by the spin-orbit interaction, techniques like MOKE are intimately probing the very heart of magnetism within the electronic structure of materials (Schoenes, 2003). In order to understand MOKE theoretically, basically the nondiagonal element of the dielectric tensor, ε_{xy}, which enters the pertinent formulae, equations (18) and (19), has to be calculated in a reasonable approximation. Attempts to do this without taking into account the spin-orbit interaction (Bennett and Stern, 1965) virtually failed, and an early perturbation theory (Argyres, 1955) including spin-orbit coupling was finally acknowledged to be basically correct. Direct calculations of MOKE spectra (Misemer, 1988; Oppeneer, Sticht, Maurer and Kübler, 1992) confirmed that the Kerr effect scales linearly with the spin-orbit coupling strength. Here, we restrict ourselves to give a simple picture, starting with the imaginary part of the optical conductivity, σ_{xy}, which is Kramers–Kronig related to the dielectric tensor component ε_{xy} (Bruno, Suzuki and Chappert, 1996),

$$\sigma''_{xy}(\omega) \propto \frac{1}{\omega} \sum_{i,f} f(E_{\mathrm{i}}) \left[1 - f(E_{\mathrm{f}})\right] \times \left[|\langle i|p_-|f\rangle|^2 - |\langle i|p_+|f\rangle|^2\right] \delta(\omega_{if} - \omega) \quad (22)$$

where $f(E)$ is the Fermi function, $\langle i|p_\pm|f\rangle$ the dipole matrix elements for left and right circularly polarized light, and $\hbar\omega_{if} = E_{\mathrm{f}} - E_{\mathrm{i}}$ photon energies connecting initial and final electronic states of the system under inspection. Figure 2 (Bruno, Suzuki and Chappert, 1996) shows a simplified quasiatomic energy scheme of a ferromagnetic metal, where optical absorption in the visible region is due to dipolar allowed d–p transitions. Two level splittings are essential: (i) the exchange splitting $\Delta_{\mathrm{ex}} \approx 1\text{–}2\,\mathrm{eV}$ between the

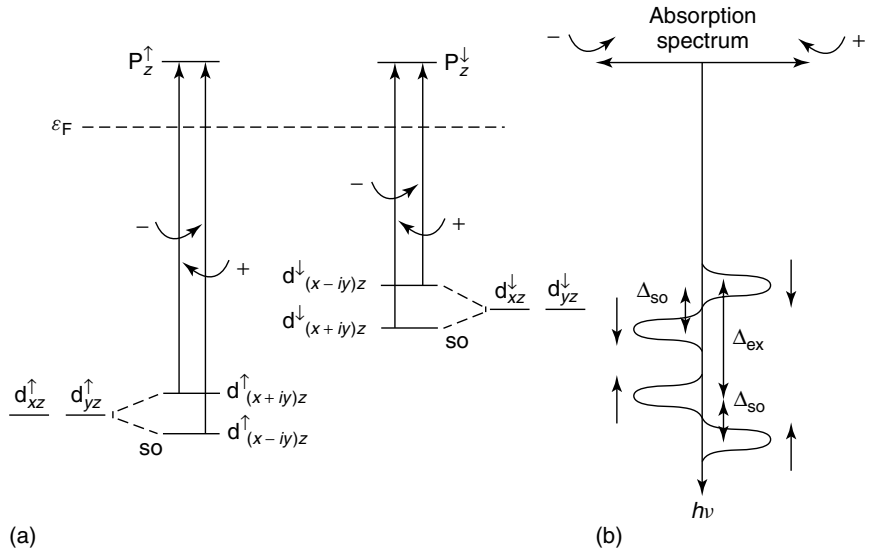

Figure 2. Energy levels of a ferromagnet, showing the electric dipolar optical transitions for left and right circular light (a) and the corresponding absorption spectra (b). (Reproduced from Bruno *et al*., 1996, with permission from the American Physical Society. © 1996.)

spin-up and spin-down electrons and (ii) the spin-orbit splitting $\Delta_{so} \approx 10-20\,\text{meV}$ between the $d_{xz,yz}$ states. The transitions from the spin-orbit split levels into the p_z state are distinguished by their photon polarization, σ_+ and σ_-, respectively. This explains the dichroism within the absorption spectrum as depicted in Figure 2(b), which reveals four differently polarized absorption lines. Clearly, this MCD would be absent without spin-orbit splitting, viz in case of degeneracy of the $d_{xz,yz}$ states. It would also be absent without the exchange splitting, since the two spin-orbit split doublets would collapse and annihilate any dichroism. It should be remarked that the spin-orbit splitting does not necessarily occur in the ground state (Schoenes, 2003). For example, the largest ever reported Faraday rotation exceeding $2 \times 10^6\,\text{deg}\,\text{cm}^{-1}$ is observed in thin films of europium monochalcogenides EuS, EuSe, and EuTe, which have a $4f^7(^8S_{7/2})$ ground state without any orbital moment. Hence, there is no spin-orbit splitting in the initial state, but in the final ones.

Realistic calculations of MOKE spectra have to take into account the full band structure of the systems involved. They require the knowledge of the single particle electron wave functions and their energies. The dielectric permittivity tensor components or, equivalently, the components of the optical conductivity are usually calculated within the Kubo formalism (Kubo, 1957), while its principal ingredients (energies and wave functions) are provided within density-functional theory (DFT) (Kohn and Sham, 1965), for example, in local spin density approximation (LSDA). Figures 3–5 show three examples of *ab initio* calculated MOKE spectra of ferromagnetic Co, CoPt (Oppeneer and Antonov, 1996), and MnBi (Oppeneer *et al*., 1996), respectively. All of them (solid lines) compare reasonably well with experimental results (Weller *et al*., 1994; Weller, 1996; Di, 1992; Harder, Menzel, Widmer and Schoenes, 1998, respectively) on bulk samples. Interestingly, the cobalt spectra turn out to depend substantially on the crystallographic directions, that is, on the magnetocrystalline anisotropy (left: fcc-Co, right: hcp-Co $[11\bar{2}0]$ and [1000]). This is another manifestation of the spin-orbit interaction. The spectra of MnBi give an example of the difficulties in obtaining reliable experimental results on a material, which is not easily prepared in perfect stoichiometry and where vacuum conditions may play a role on the absolute values of the MOKE components of Φ_K. We remark that the magnitude of Φ_K increases from Co to CoPt and MnBi. Even larger values have been found for other rare-earth (RE) elements, in particular, for Ce compounds. Record values as high as $\theta_K = 90^\circ$ were found, for example, in CeSb (Pittini, Schoenes, Vogt and Wachter, 1996). This is a consequence of the strong localization of the 4f electrons, where the 100% effects shown in Figure 2 are approximately realized. As a tribute to the high correlation of the 4f electrons, however, precise calculations of the MO spectra require the introduction of an additional Hubbard-like Coulomb interaction U (Yaresko *et al*., 1996; Oppeneer, 2001).

2.2 X-ray magneto-optics

XMCD is closely related to conventional MOKE or MCD, but is shifted down to the subnanometer wavelength regime, that is, 2 orders of magnitude smaller than visible light (Schütz *et al*., 1987). The dichroic effect occurs in the

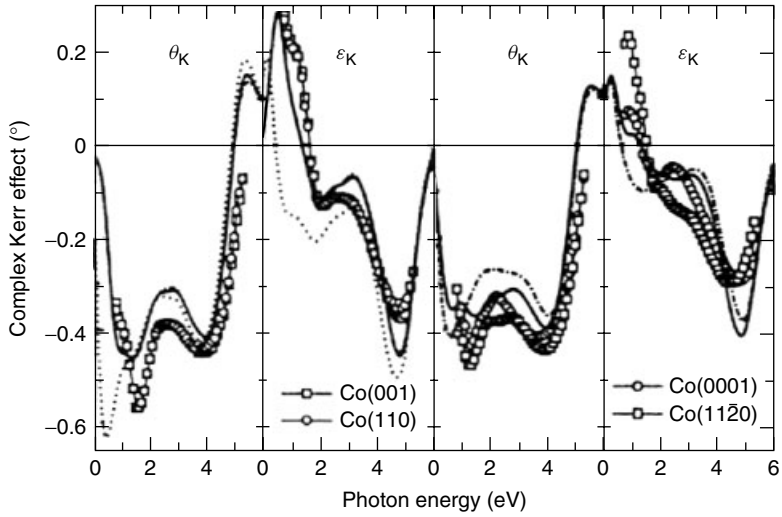

Figure 3. Polar Kerr rotation θ_K and ellipticity ε_K of (001) and (110) fcc-Co (left) and hcp-Co (0001) and (11$\bar{2}$0) (right) obtained from theory (solid lines; only interband contributions: dotted lines) and experiments (symbols: after Weller *et al*., 1994). vicinity of element-specific inner-core absorption edges and denotes the dependence of the absorption of circularly polarized X rays on the ferromagnetic magnetization component onto the photon wave vector (Ebert and Schütz, 1996; Starke, 2000). At L edges in 3d transition metals (TMs) relative changes in the absorption constant as large as up to 50% occur. Very similar to MOKE, as observed in the NIR/visible/UV regime (Figure 2), the physical origin of XMCD in the X-ray absorption is based on angular momentum conservation and spin-orbit interaction basically in the initial state. If the energy of the absorbed photon equals the binding energy of a particular inner-core level (e.g., $p_{3/2}$), the photoelectron is excited into an unoccupied state of d symmetry above the Fermi level, obeying dipolar selection rules. In the case of a circularly polarized absorbed photon, the emitted photoelectron acquires both an expectation value of the spin and the orbital momentum projected onto the direction of propagation of the incoming photon obeying the constraint $\Delta m_l = \pm 1$. The spin and orbital polarizations as calculated via Clebsch–Gordan coefficients are $\langle \sigma_z \rangle = 50$ and 25% at the L_2 and L_3 edges, whereas $\langle l_z \rangle = 75\%$ at both L edges. According to the Pauli principle, the photoelectron can be considered as a local probe for the spin and

orbital polarization of the absorbing atom. Just like in a spin ferromagnet, the final density of states exhibits a spin polarization owing to the exchange interaction, and the transition probability of the absorption process depends on the polarization of the final d states, which is directly related to the magnetization of the absorbing atom. In the ideal case of a completely spin-polarized final state, that is, one spin band is completely shifted below the Fermi level and the magnetic moments are fully aligned, the difference between the absorption coefficients for the direction of the magnetization parallel μ_+ and antiparallel μ_- to the photon propagation direction $(\mu_+ - \mu_-)$ normalized with respect to the unpolarized absorption $(\mu_+ + \mu_-)$ corresponds directly to $\langle \sigma_z \rangle$ provided that the corresponding orbital polarization can be neglected. Taking into account also the orbital contribution, a further increase or decrease of the dichroic signal at the L_3 and L_2 edges has to be expected.

As an example, Figure 6 shows the XMCD of Fe at the levels $2p_{3/2}$ and $2p_{1/2}$ (c), obtained as a difference spectrum of the two circularly polarized X-ray absorption spectra (XAS) (b), and after subtracting the nonmagnetic substrate background (a) (Chen *et al*., 1995). Further, the summed and the integrated XAS are shown (d). In principle, the comparison of the magnetic contrast taken at the L_3 and L_2 edges yields information on the lateral spin and orbital contributions. By applying sum rules (Thole *et al*., 1992; Carra *et al*., 1993) one can extract separately the spin and the orbital moments, whose ratio is $m_{\mathrm{orb}}/m_{\mathrm{spin}} \approx 0.04$ in the case of bcc-Fe (Figure 6). This unique feature of XMCD spectroscopy has revived appreciable interest in the orbital moments, whose role, for example, in the origin of the magnetocrystalline anisotropy energy of ferromagnets is of paramount importance (Weller *et al*., 1995; Weller, 1996). The other great advantage of XMCD is its element specificity. For example, experiments on multilayers are selective with respect to the elements involved and can reveal individual magnetic moment distributions of individual layers or at interfaces (cf. Section 3.6).

The realization of XMLD being quadratic in **M** and occurring on transversely magnetized samples in absorption geometry was demonstrated by Kuiper *et al*. (1993) on Fe_2O_3, while its dispersive counterpart, the X-ray MO Voigt effect, was first observed by Mertins *et al*. (2001) on an amorphous Co film. The ellipticity, which corresponds to the MLB in the visible region, was analyzed using the dichroic reflection at an analyzer plate. Its value agrees excellently with *ab initio* caculations, which crucially have to take into account the exchange splitting of the 2p core states. While the observed Voigt ellipticity is quite small ($\theta_V = 7.5\,\mathrm{deg}\,\mu\mathrm{m}^{-1}$), much larger effects ($\Delta R/R \approx 20\%$) were observed in reflection on antiferromagnetic NiMn and NiO (Oppeneer *et al*., 2003). Thus, reflection XMLD promises to become a versatile tool to image antiferromagnetic domains, which may sustain external magnetic fields in contrast to conventional XMLD–PEEM (photoelectron emission microscope) (Section 3.6).

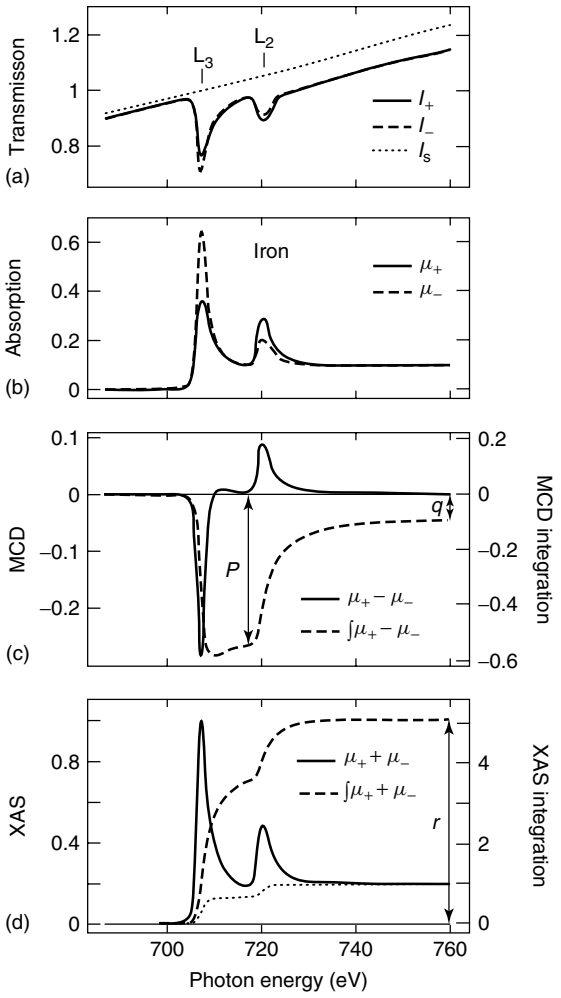

Figure 6. X-ray transmission (a), absorption (b), MCD (c), and XAS (d) spectra of Fe/parylene thin films taken at two opposite saturation magnetizations. Integrated spectra for sum-rule analysis are shown as dotted lines in (c) and (d). (Reproduced from Chen *et al*., 1995, with permission from the American Physical Society. © 1995.)

2.3 Nonlinear magneto-optics

Usually MOKE signals are observed at the same frequency as that of the incident light, hence, the name *linear* MO response. Under favorable circumstances there is, however, also a measurable fraction of frequency-doubled light due to SHG. This effect is referred to as *nonlinear,* because of its origin due to the nonlinear optical

susceptibility, which generates light at second harmonic (SH) frequency, but not on the dependence on the magnetization, which remains linear to first order as in the ordinary MOKE. SHG appears when inversion symmetry is broken (Shen, 1984) as is usually the case for every solid at its surface. A simultaneous change of the state of polarization of SH reflected light was predicted (Pan, Wei and Shen, 1989; Hübner and Bennemann, 1989) and first been observed on an Fe surface (Reif, Zink, Schneider and Kirschner, 1991). The determination of a magnetic structure from SHG is based on the relation $P_i(2\omega) = \varepsilon_0[\chi_{ijk}(i) + \chi_{ijk}(c)]E_j(\omega)E_k(\omega)$ between the induced nonlinear polarization $P_i(2\omega)$ at the doubled frequency 2ω and the electric fields $E_j(\omega)$ and $E_k(\omega)$ of the incident light at frequency ω. $\chi_{ijk}(i)$ and $\chi_{ijk}(c)$ are the nonlinear susceptibility tensor components, which couple to the crystallographic and magnetic structure, respectively. From the nonvanishing components $\chi_{ijk}(c)$ it is possible to determine the magnetic structure and interactions of a system (Birss, 1966). The theory of nonlinear MO effects was considered for metal surfaces (Pustagowa, Hübner and Bennemann, 1993; Hübner and Bennemann, 1995; Bennemann, 1998), insulating antiferromagnets (Fiebig, Fröhlich, Krichevstov and Pisarev, 1994; Qian, Dong and Xing, 2001; Iizuka-Sakano, Hanamura and Tanabe, 2001), and magnetic granular alloys (Granovsky, Kuzmichov and Clerc, 2003). The best-known phenomenon is NOMOKE (occasionally also termed *SHMOKE* = second harmonic magneto-optical Kerr effect; Crawford, Silva, Teplin and Rogers, 1999). This counterpart to MOKE has meanwhile become a popular instrument in order to characterize magnetic surfaces and interfaces, in particular, of thin films and multilayers (Rasing, 1998). Nonlinear MO spectroscopy benefits from its 'additional degrees of freedom' (Bennemann, 1998), since it can clearly distinguish between transitions of magnetic and nonmagnetic origin. In centrosymmetric materials, SHG is restricted to the symmetry-breaking surfaces and interfaces. It is therefore a highly selective sensor for surface or interface magnetism.

An illustrative comparison is drawn in Figure 7 between MOKE and NOMOKE properties obtained on a thin-film sample of Co with variant thickness t (in monolayer units, ML) (Vollmer, Jin, Regensburger and Kirschner, 1999). While the MOKE signal increases linearly with t as predicted (see Section 3 Visnovsky, 1995), the intensity $I(2\omega)$ maximizes already for 2 ML with a slightly decreasing asymmetry A between the components $I(2\omega, +B)$ and $I(2\omega, -B)$. Unfortunately, the efficiency of the SHG is very small, $I(2\omega)/I(\omega) \approx 10^{-12}$. Hence, in contrast with linear MOKE, the use of nonlinear MOKE presently rather lies in its fundamental ability to explore surfaces and interfaces, than in practical applications.

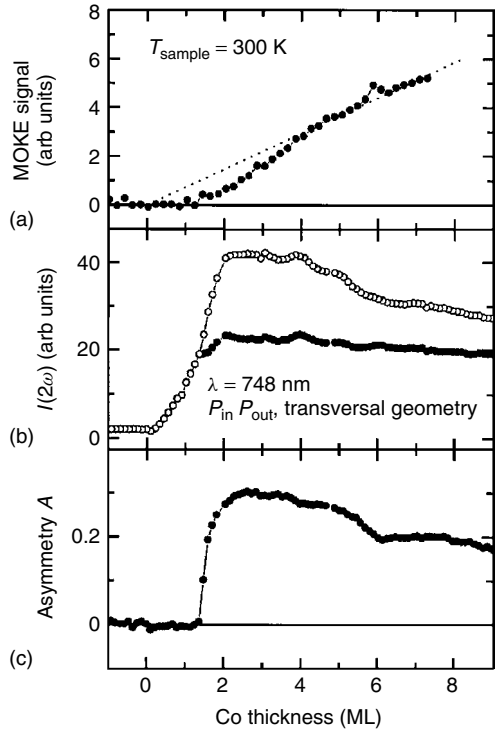

Figure 7. L-MOKE (a), SH intensity (b), and nonlinear asymmetry (c) measured on Co/Cu(001) at variant Co thickness under an angle of incidence $\alpha = 38^\circ$ with $\lambda = 633$ nm. (Reproduced from Vollmer *et al.*, 1999, with permission from Elsevier. © 1999.)

3 EXPERIMENTAL TECHNIQUES

3.1 Magneto-optic ellipsometry

In addition to conventional ellipsometry aiming at determining Kerr rotation angle θ_K and ellipticity ε_K, domain imaging by polarization optical techniques has become very important in recent years (Hubert and Schäfer, 1998). High performance experimental techniques are now available for both MO ellipsometry and domain imaging. Kerr microscopes have been developed to achieve satisfying contrast also in the case of weak MO effects ($\theta_K \approx 0.1^\circ$) by using sensitive charge coupled device cameras and sophisticated image processing (Meyer, Pommier and Ferré, 1989; Hubert and Schäfer, 1998). The measurement of rotations and ellipticities with a resolution of a few microradians is achieved, for example, with the help of a photoelastic modulator (PEM) (Jasperson and Schnatterly, 1969) driven at a fairly high frequency of $f \approx 0$ kHz. The signals at both the fundamental and the first harmonic frequency of the emerging light intensity are detected by using lock-in detection. Linear detection of the signal is achieved when placing the reflecting sample between polarizers, which are oriented 45° with respect to

each other. As a rule, ellipticity is observed at frequency f, whereas rotation emerges at $2f$. Instead of a PEM a Faraday rotation modulator may also be used. It is much easier to assemble than the photoelastic one, however, at the price of a reduced signal-to-noise ratio owing to the lower modulation frequency, $f \approx 1\,\text{kHz}$. Moreover, sensitivity to Kerr ellipticity is achieved here only when placing an additional birefringent $\lambda/4$ retarder plate into the reflected beam.

Analyses of MOKE measurement techniques utilizing different modulators, retarders, polarizing beam splitters, and so on, have been presented by various authors (Sato, 1981; Nederpel and Martens, 1985; Bader and Moog, 1987; Sato *et al*., 1993; Kim, Aderholz and Kleemann, 1993; Yang and Scheinfein, 1993; Zeidler *et al*., 1996; Berger and Pufall, 1997; Pufall, Platt and Berger, 1999; Vavassori, 2000; Teplin and Rogers, 2001; Allwood, Xiong, Cooke and Cowburn, 2003). They are usually based on the Jones matrix calculus (Azzam and Bashara, 1979) using homogeneous dielectric permittivity tensors as in our classical example of Section 2. In the following, we briefly present two methods, one being extremely simple and easy to mount, while the other one is more sophisticated, highly precise, and prepared for absolute calibration.

For many purposes, very low-cost MOKE apparatus without any polarization modulation and lock-in technique is sufficient. After deleting the PEM and one of the orthogonal magnetic fields, M(T) or M(L), in the setup shown in Figure 8, one remains with a laser diode or a HeNe laser as a light source, while a Si photodiode or a phototransistor serves as a detector (D). When orienting the analyzer (P_2) for the reflected light nearly crossed to the incident p polarization (angular mismatch $0 < \alpha \ll \pi/2$) and measuring the transmitted light intensity for both magnetization directions, I_+ and I_-, one can easily determine the Kerr angle from the asymmetry $A_K = (I_+ - I_-)/(I_+ + I_- - 2I_\text{u})$ by setting $\theta_\text{K} \approx \alpha A_\text{K}/2$ provided that $\theta_\text{K} \ll \alpha$. Here, I_u is the leakage intensity measured at $\alpha = 0$. A p-oriented quarter wave plate placed in the reflected beam makes Kerr ellipticity accessible via a related formula, $\varepsilon_\text{K} \approx \alpha A_\text{K}/2$.

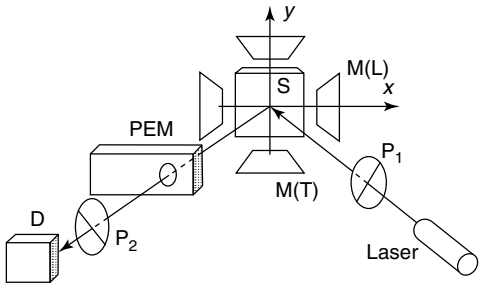

Figure 8. L- and/or T-MOKE experiment with light source (laser), polarizer (P_1), sample (S), magnet (M), photoelastic modulator (PEM), analyzer (P_2), and photodetector (D). Two pairs of magnetic pole shoes are shown for L- and T-Moke, M(L) and M(T), respectively. (Reproduced from P. Vavassori *et al*., 2000, with permission from the American Institute of Physics. © 2000.)

A spectroscopical setup for measuring θ_K and ε_K in P-MOKE configuration quantitatively and employing photoelastic polarization modulation is shown in Figure 9 (Kim, Aderholz and Kleemann, 1993). Two arrangements for light source (L) and detector (D) are in use. For routine investigations, a 5-mW HeNe laser or a laser diode is placed directly in front of the polarizer P_1 and behind the analyzer P_2, respectively. In the second case, for measurements of the spectral dependences as a function of the light wavelength $350 \leq \lambda \leq 800\,\text{nm}$, the light source L is a 50-W tungsten filament lamp, and D is a photomultiplier. Fiber optical attachments F_1 and F_2 are interfaced in order to produce a parallel white beam with diameter $d \approx 3\,\text{mm}$ at the entrance (F_1) and to collect it at the exit (F_2). Thereafter, the light is dispersed by a grating monochromator G with a spectral bandpass $\Delta\lambda \approx 2\,\text{nm}$ before reaching the photomultiplier D. The optical elements consist of two Glan air polarizing prisms (P_1, P_2), an elasto-optic modulator (M), a calcite wedge Babinet-Soleil-type phase compensator (C) and quartz lenses L_1 and L_2 for focusing the light beam onto the sample S and F_2 or D, respectively. S is placed with its surface plane perpendicular to the field **B** of an electromagnet ($|\mathbf{B}| \leq 2\text{T}$). It is hit by the light beam at near normal incidence, $\alpha_i < 3^\circ$. The light intensity emerging at D is Fourier analyzed by two lock-in amplifiers, A_1 and A_2, tuned to the first and second harmonics of the modulator frequency ω, I_1 and I_2, while a third amplifier measures the dc component, I_0. When properly setting the orientations of the light vector components and of the optical elements, I_1 and I_2 measure

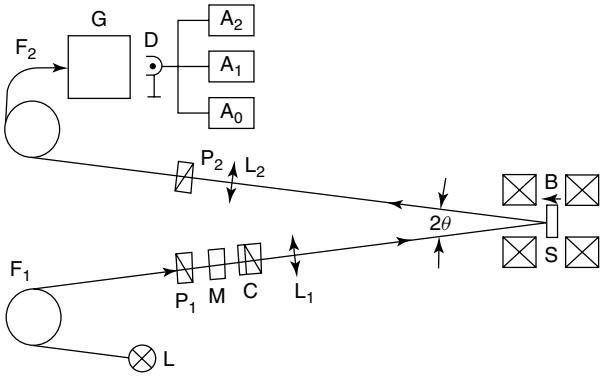

Figure 9. P-MOKE spectrometer with light source (L), optical fibers (F_1 and F_2), polarizers (P_1 and P_2), lenses (L_1 and L_2), photoelastic modulator (M; frequency ω), Babinet-Soleil compensator (C), sample (S), monochromator (G), photomultiplier (D), and amplifiers tuned to dc (A_0), ω (A_1), and 2ω (A_2). (Reproduced from W.S. Kim *et al*., 1993, with permission from Institute of Physics Publishing Ltd. © 1993.)

directly the Kerr ellipticity and the rotation, respectively, while I_0 serves for normalizing the signals and filtering noise. Absolute calibration of the signals is achieved by normalizing I_1 and I_2 to amplitudes obtained at certain calibration settings of the compensator (C) and of the analyzer (P_2), respectively (Kim, Aderholz and Kleemann, 1993). It should be noticed that the Kerr ellipticity is often the best option for measuring the magnetization of a reflecting material. On one hand, it might provide a spectral advantage with respect to rotation, as is the case, for example, for the widely used MO material Co at photon energies around 5 eV (Figure 3) (Weller *et al*., 1994). On the other hand, very often the large Faraday rotation in the windows of the vacuum vessel or cryogenic setup risks to mask tiny Kerr rotation signals.

Another problem to be addressed are interference effects owing to surface layers at bulk samples or in multilayer samples with individual layer thicknesses in the order of the optical wavelength used. The theory as sketched in Section 2.1 applies to the reflection at only one optical interface. In order to describe the MO response of layered systems, one has to account for the reflections at the inner surfaces. To this end a transfer matrix formalism has been developed, which considers the amplitude and phase conditions at the interfaces. The theory was originally developed (Yeh, 1980) for nonmagnetic birefringent multilayers. In order to include the description of magnetic anisotropic media, the dielectric tensor becomes, in general, asymmetric (due to broken time inversion symmetry) and complex (i.e., containing refraction and absorption indices). At the interfaces, continuity of amplitudes and phases has to be properly accounted for. Transfer matrices have been developed for various magnetic symmetries (polar, longitudinal, and transversal) and film sequences (Sprokel, 1984; Visnovsky, 1986a; Zak, Moog, Liu and Bader, 1990), and applied to pertinent thin-film and multilayer configurations with remarkably good success (Visnovsky, 1986b; Visnovsky *et al*., 1995).

It turns out that the multiple reflections not only inside the active MO layers but also at adjacent buffer or cap layers have to be taken into account. This may become crucial, in particular, in the vicinity of the plasma frequency of adjacent nonmagnetic metallic layers (Visnovsky *et al*., 1995). Figure 10 shows saturated P-MOKE spectra of trilayers Au(5 nm)/Co(t_{Co})/Au(25 nm)/glass for different thicknesses of the Co layer, which agree well in experiment (a,c) and theory (b,d). It has to be stressed that these caculations rely on bulk optical constants of all components, Au, Co, and even float glass, which absorbs strongly at photon energies $E > 3.8$ eV. Comparison with P-MOKE data obtained on bulk Co (Figure 3) clearly shows that the multilayer structure and its nonmagnetic components strongly suppress the Kerr angle, $|\theta_K|$ at high photon energies, $\approx$3.8 eV. This is, again, primarily due to the glass substrate, while the Au layers exert their main influence at low energies, $\approx$1.5 eV. Remarkably, in the ultrathin limit, $t < 20$ nm, the MOKE parameters depend linearly on the thickness, t, as shown in Figure 7 for the longitudinal Kerr angle of s-polarized light of wavelength $\lambda = 633$ nm incident under 38° (longitudinal) on a thin film of Co (Vollmer, Jin, Regensburger and Kirschner, 1999). This result is not intuitively expected, since reflection properties should *by definition* not depend on the thickness of the mirror. However, this is not true at thickness scales $t \ll \lambda$, because of the finite penetration length of electromagnetic waves even into strongly absorbing metals.

3.2 Vector MOKE

It is often desirable to measure not only the component of **M** along the applied field but also the orthogonal magnetization component(s) in order to reconstruct the complete magnetization vector. To this end, various 'vector MOKE' (V-MOKE for short) strategies have been developed (Florczak and Dahlberg, 1991; Yang and Scheinfein, 1993; Daboo *et al*., 1993; Berger and Pufall, 1999; Vavassori, 2000; Schmitte *et al*., 2002). In the setup chosen by Vavassori (2000) (Figure 8), complete vector magnetometry is possible without any moving element in a conventional MOKE setup. It involves a HeNe laser, whose beam passes a rotatable glan-Thomson polarizer P_1, hits the sample S under an angle of incidence of 25°, after reflection passes a *PEM* with frequency ω (Jasperson and Schnatterly, 1969), a second polarizer P_2 and is detected by a photodiode D. A magnetic field can be applied both parallel and perpendicular to the plane of incidence by means of a double-axis electromagnet M. By choosing both polarizations, s and p, detecting the modulated signal under both ω and 2ω, and rotating all optical elements (except the sample) in a second set of measurements by $\pm$45°, one can find all the data, which suffice to calculate all three vectorial components of the normalized magnetization, m_x, m_y, and m_z, as shown for the magnetic hysteresis curve of a 180-nm-thick film of CoNiO in Figure 11. This sample was prepared with an oblique out-of-plane anisotropy axis. This explains the occurrence not only of a finite transverse in-plane component m_y but also of a perpendicular component m_z while reverting the magnetization with a field parallel to the x axis.

Other setups use L-MOKE exclusively with s-polarized light, $\boldsymbol{E} \parallel y$ (coordinates as in Figure 8), while the external field **H** lies in the (xz) plane of incidence (Schmitte *et al*., 2002). Let the magnetization **M** be a vector lying in the (xy) plane. Then the MOKE signal is proportional only to its x component, M_x. The y component M_y would yield a T-MOKE signal in p polarization, but remains undetected in s polarization. It can be registered, however, by its s-polarized

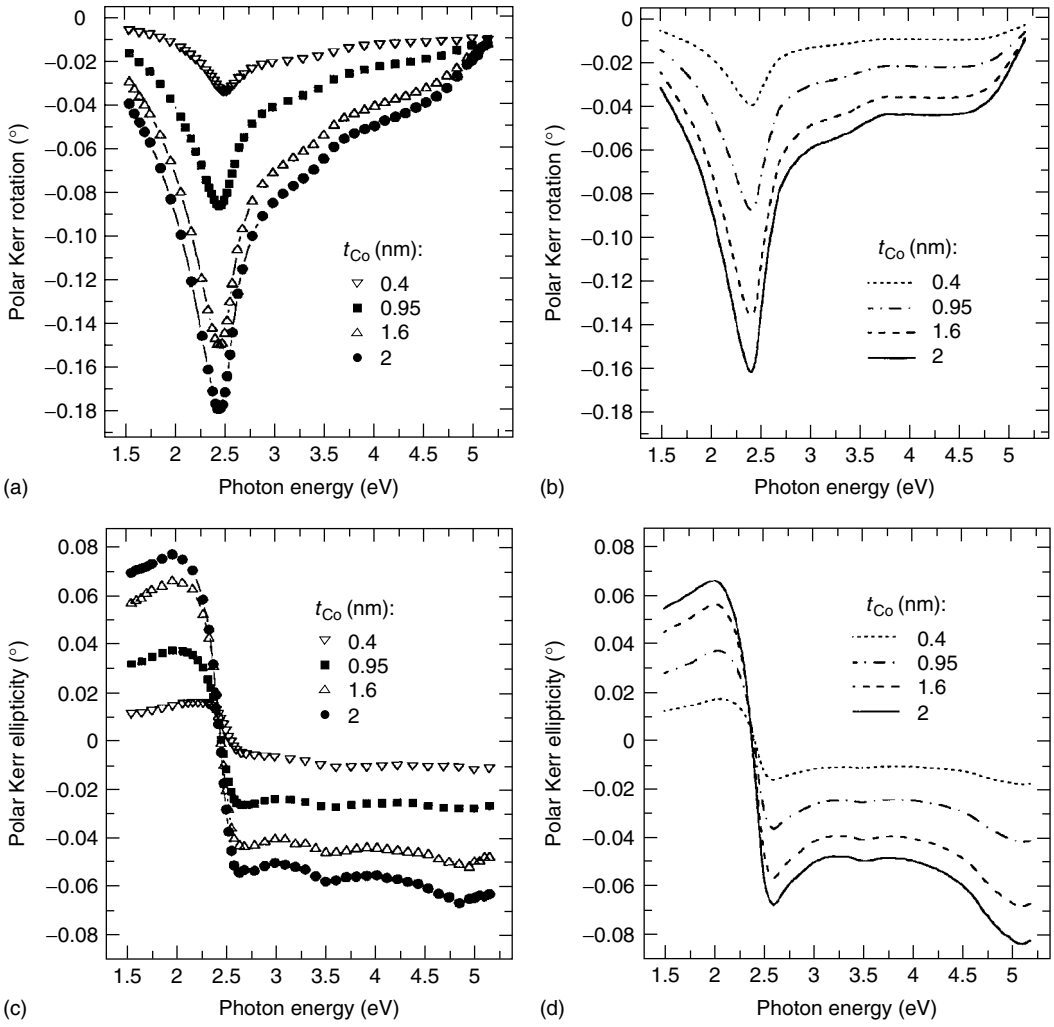

Figure 10. Saturated P-MOKE spectra of [Au (5 nm)/Co (t_{co})/Au (25 nm)]$_n$/glass (1 mm) samples for different values of t_{co} from experiments (a,c) and matrix calculations (b,d). (Reproduced from Visnowsky *et al*., 1995, with permission from the American Physical Society. © 1995.)

L-MOKE signal upon rotating the plane of incidence by 90° into the (*yz*) orientation, while keeping the sample and the field fixed. In practice, the same target is reached by keeping the plane of incidence fixed, but rotating the sample and the field together by 90°.

The rotation of the optical and magnetic components can be avoided by mounting two orthogonal s-polarized L-MOKE setups, thus realizing simultaneous vector magnetometry. Alternatively one may use a combination of L- and T-MOKE. Since the transverse Kerr effect implies an intensity change of the reflected p-polarized light, while the longitudinal Kerr effect provokes a rotation of its plane of polarization, one can unambiguously extract both quantities in a simultaneous experiment. The fact that there are no moving parts of the setup is clearly the advantage of this technique (Flocrzak and Dahlberg, 1991), but enhanced calibration efforts have to be taken, since both measured signals are not commensurate.

3.3 Diffracted MOKE

MOKE experiments are very advantageous in performing locally resolved magnetometry on a submicron level by simply focusing the light onto the desired area. Hence, Kerr magnetometry has become an indispensable tool for investigating small magnetic structures. If these structures have some periodicity, for example, either as a mechanical or a magnetic (i.e., domain) stripe pattern, another piece of information can be drawn from the reflected light. The material acts like a diffraction pattern, where the diffraction orders may contain magnetic information via the

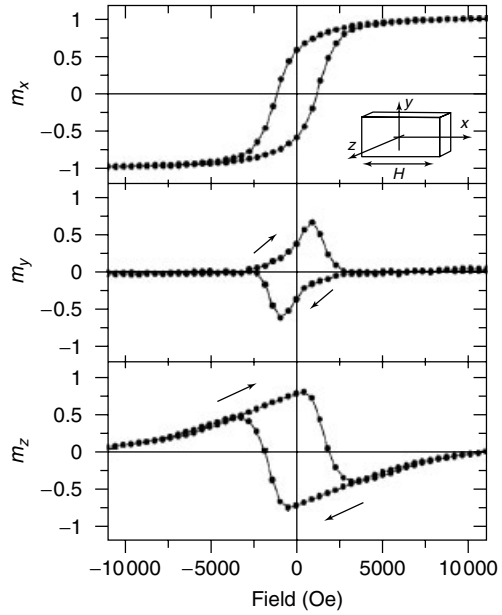

Figure 11. Normalized magnetization components m_x, m_y, and m_z obtained from V-MOKE on a CoNiO thick film as a function of the applied field H_x. (Reproduced from P. Vavassori *et al*., 2000, with permission from the American Institute of Physics. © 2000.)

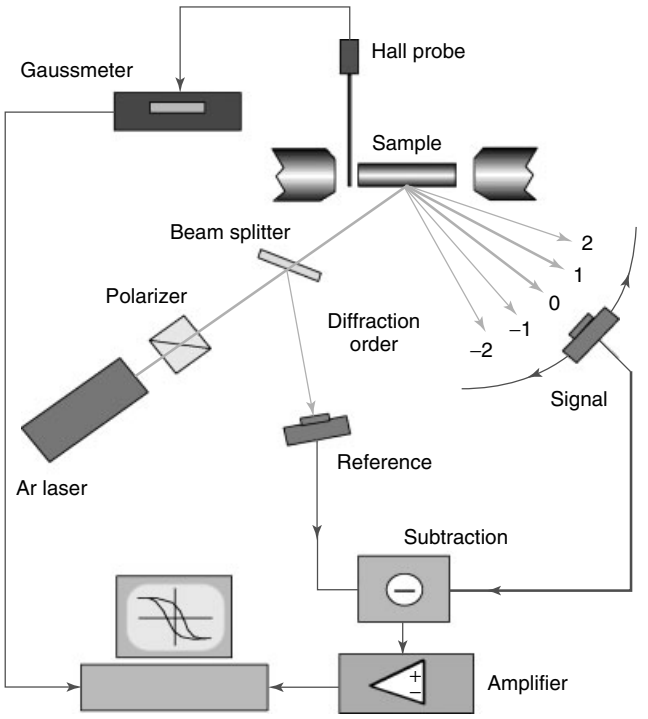

Figure 12. Block diagram of a D-MOKE setup. (Reproduced from M. Grimsditch *et al*., 2004, with permission from Institute of Physics Publishing Ltd. © 2004.)

rotation or ellipticity of the emerging light, hence, the name D-MOKE (Grimsditch and Vavassori, 2004) or, occasionally, Bragg-MOKE (Schmitte, Schemberg, Westerholt and Zabel, 2000). Figure 12 shows schematically the D-MOKE setup of Grimsditch and Vavassori (2004), where the incident beam is chosen to hit the grating under a typical L-MOKE angle α_0 and various positive and negative diffraction orders n are expected to appear at angles $\alpha_f = \alpha_0 \pm \alpha_n$. While the mechanical shape of the grating and the periodicity of its reflectivity determine the distribution of diffracted spots via Fourier transformation of the intensity distribution function, the underlying magnetization pattern contributes a magnetic form factor. The MOKE signal reflects the Fourier transform of the magnetization pattern according to

$$f_n^{(m)} = \int m(r) \exp(2\pi nir/d) \mathrm{d}S \tag{23}$$

where $m(r)$, d, and r are the normalized magnetization profile, its period, and the position inside the unit cell area, respectively (Geoffroy *et al*., 1993; Vial and van Labeke, 1998; Vavassori *et al*., 1999; Schmitte, Schemberg, Westerholt and Zabel, 2000; Schmitte, Westphalen, Theis-Bröhl and Zabel, 2003; Grimsditch and Vavassori, 2004). The electric field in the nth-order diffracted beam from a magnetic patterned surface may be written as

$$E_n = E_0 \left(r_{\mathrm{pp(ss)}} f_n + r_{\mathrm{pp(ss)}}^{(m)} f_n^{(m)} \right) \tag{24}$$

where E_0 is the incident electric field, $f_n = \int \exp(2\pi nir/d)\, \mathrm{d}S$ the structural form factor of the grating, and $r_{\mathrm{pp(ss)}}$ and $r_{\mathrm{pp(ss)}}^{(m)}$ the nonmagnetic and magnetic p(s)-polarized reflectivities of the material, respectively. It has to be noticed that both $r_{\mathrm{pp(ss)}}$ and $r_{\mathrm{pp(ss)}}^{(m)}$ are, in general, differently angular dependent according to their individual Fresnel's coefficients. Hence, it turns out that a good agreement between observed and calculated D-MOKE usually requires micromagnetic calculations (Brown, 1978). As an example, Figure 13 (Grimsditch and Vavassori, 2004) shows hysteresis curves up to diffraction order $n = 2$ obtained experimentally (upper row) on a two-dimensional periodic arrangement of square rings of permalloy, in comparison with theoretical magnetization curves (lower row) calculated on the basis of object oriented micromagnetic framework (OOMMF) (Donahue and Porter, 2000). D-MOKE is considered as a novel technique, which can yield information on the magnetic spin structure within micro- or even nanosized particles. As with every diffraction method, D-MOKE requires a periodic arrangement of exactly equal elements. Micromagnetic calculations are indispensable for a detailed understanding of the magnetic form factors. Hence, any transformation of the D-MOKE signal from Fourier space into the real space should be accompanied by simulations. If successful, the method might compete with or even surpass other magnetic imaging methods like PEEM

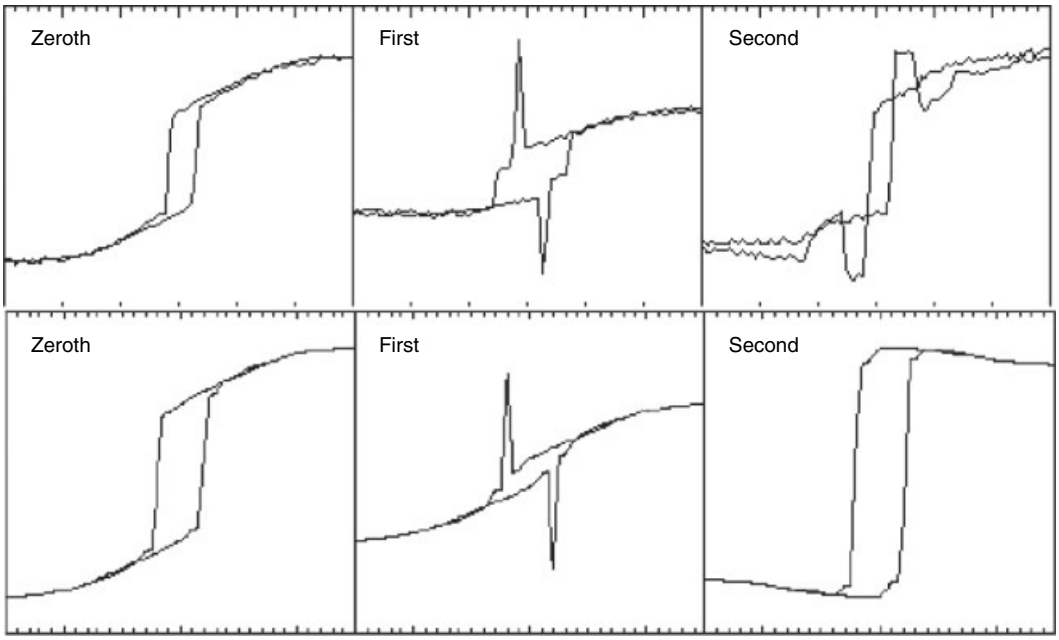

Figure 13. D-MOKE hysteresis loops of zeroth-, first-, and second-order for square rings of permalloy, periodically arranged on a square lattice obtained with an edge-parallel magnetic field (upper panels: experimental; lower panels: calculated). (Reproduced from M. Grimsditch *et al*., 2004, with permission from Institute of Physics Publishing Ltd. © 2004.)

(Section 3.6). Recently, it could be shown that periodic magnetic structures may also serve as diffraction gratings for soft X rays (Remhof *et al*., 2005). Analogous to D-MOKE, one finds diffracted beams in reflection, whose XMCD contrast mirrors the magnetic form factor (equation (23)). In combination with micromagnetic simulations, this opens another possibility to transform the element-specific magnetization patterns from Fourier into real space, with no restrictions on magnetic fields to be applied and no need for sophisticated X-ray optics.

3.4 Dynamic MOKE

The dynamics of magnetization reversal is of prime importance in magnetic and MO recording and in the context of modern magnetoelectronics (Ferré, 2001). MO diagnostics has become a leading technique being involved in three types of magnetization reversal phenomena: (i) thermomagnetic effects induced by local laser heating of the sample, (ii) photoinduced effects, which are not based on thermal heating and open a new field of research called *femtomagnetism*, and (iii) magnetic field–induced effects as evidenced by magnetization reversal or full hysteresis loops. In the latter category, MO techniques are indispensable in order to observe the field-driven dynamics of magnetization reversal from the milli- to the gigahertz region. At very low frequencies, Kerr microscopy was successfully employed, for example, on ultrathin Pt/Co/Pt trilayers in order to observe the creep of pinned domain walls under near-coercive magnetic fields, and to determine the stationary wall velocity v as a function of the field H (Lemerle *et al*., 1998) and the local wall roughening (Repain *et al*., 2004). Figure 14 shows a double exposure of a domain-wall contrast before and after a magnetic

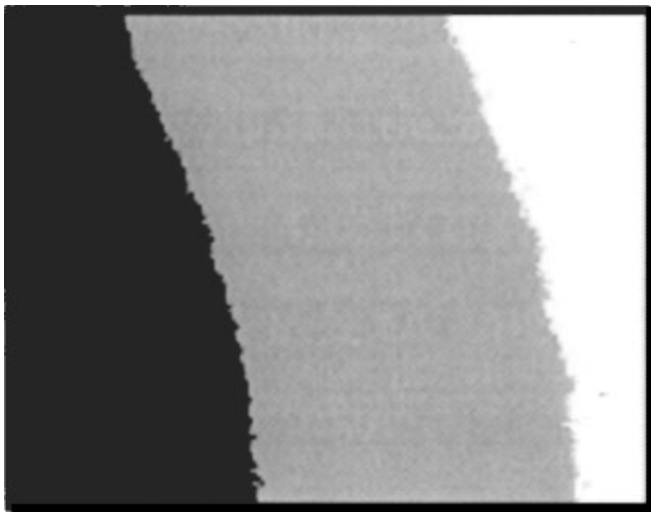

Figure 14. P-MOKE image (size $90 \times 72\,\mu m^2$) of a domain wall in Pt(1.2 nm)/Co(0.5 nm)/Pt(1.2 nm)/glass before (black) and after (gray) being swept by a perpendicular field of 46 mT during 111 µs. (Reproduced from Lemerle *et al*., 1998, with permission from the American Physical Society. © 1998.)

field pulse of 460 Oe during a time of 111 μs. Excellent agreement with creep theory (Feigel'man, Geshkenbein, Larkin and Vinokur, 1989) was obtained.

At intermediate frequencies, dynamic ferromagnetic hysteresis loops are known to broaden as the frequency f increases. In simple Ising-type systems with one leading relaxation time, τ, one even expects a dynamic phase transition at a critical frequency f_0 in the sense that the dynamic order parameter, $Q = (1/2\pi)\oint M\mathrm{d}t$, changes discontinuously from $Q = 0$ at $f < f_0$ to $Q \neq 0$ at $f > f_0$ (shift of the loop, e.g., to the upper two quadrants in the M–t plane) (Chakrabarti and Acharyya, 1999). Such processes have been studied, for example, at frequencies up to $f = 2\,\mathrm{kHz}$ on thin films of Fe/GaAs (Moore and Bland, 2004). Figure 15(g) shows the dynamic broadening of hysteresis loops recorded with L-MOKE on a *superferromagnetic* (i.e., predominantly dipolarly coupled) discontinuous multilayer of CoFe nanoparticles embedded in amorphous alumina at frequencies from 5 mHz up to 10 Hz (Bedanta *et al*., 2006). The very weak coercive field increases power law–like, $H_c = H_{c0} + b\,f^{\alpha}$, where $\mu_0 H_{c0} \approx 0.2\,\mathrm{mT}$ and $\alpha \approx 0.5$ (Figure 15h). The dynamic contribution reflects the presence of nucleation processes and domain-wall sliding motion, as confirmed by L-MOKE microscopy for $f \approx 0.1\,\mathrm{Hz}$ in Figure 15(a–f) (Bedanta *et al*., 2006) in close agreement with observations in continuous ferromagnetic films (Lee *et al*., 2000).

Finally, at high frequencies, MO techniques are indispensable either as touchless transient methods, if high magnetic field pulses are involved (Takeyama, Osada and Miura, 2004; Singleton *et al*., 2004) or as unrivaled fast speed methods, if timescales at or below the nanosecond level are to be resolved. Here, questions are posed like 'how fast can the magnetization of a magnetic medium or element be changed?' and 'what are the fundamental and practical limits of the speed of magnetic writing and reading?'. They are of paramount interest with far reaching consequences for the future of data storage and retrieval. Surely, there is large economical and technical interest in finding answers, which hopefully guarantee further applicability of Moore's law with respect to the acceleration of data transfer. However, there is also a lot of exciting fundamental research, which greatly profits from ultrafast laser pulse sources and MO pump-probe techniques.

Since the invention of the first magnetic memory disk in 1954, much effort has been put into enhancing the speed, bit density, and reliability of magnetic memory devices. Modern magnetic random access memory (MRAM) devices aim at fast coherent magnetization rotation by precession of the entire memory cell (Hiebert, Stankiewicz and Freeman, 1997; Back *et al*., 1998; Choi *et al*., 2001; Hiebert, Ballentine and Freeman, 2002; Kaka and Russek, 2002), since conventional reversal by domain-wall motion is much too slow. In principle, the fundamental limit of the switching speed via precession is given by half of the precession period. The dynamics of the magnetization then follows the Landau–Lifshitz–Gilbert equation of motion,

$$\frac{\mathrm{d}\mathbf{M}}{\mathrm{d}t} = -|\gamma|\,(\mathbf{M}\times\mathbf{H}_{\mathrm{eff}}) - \lambda\,[\mathbf{M}\times(\mathbf{M}\times\mathbf{H}_{\mathrm{eff}})] \qquad (25)$$

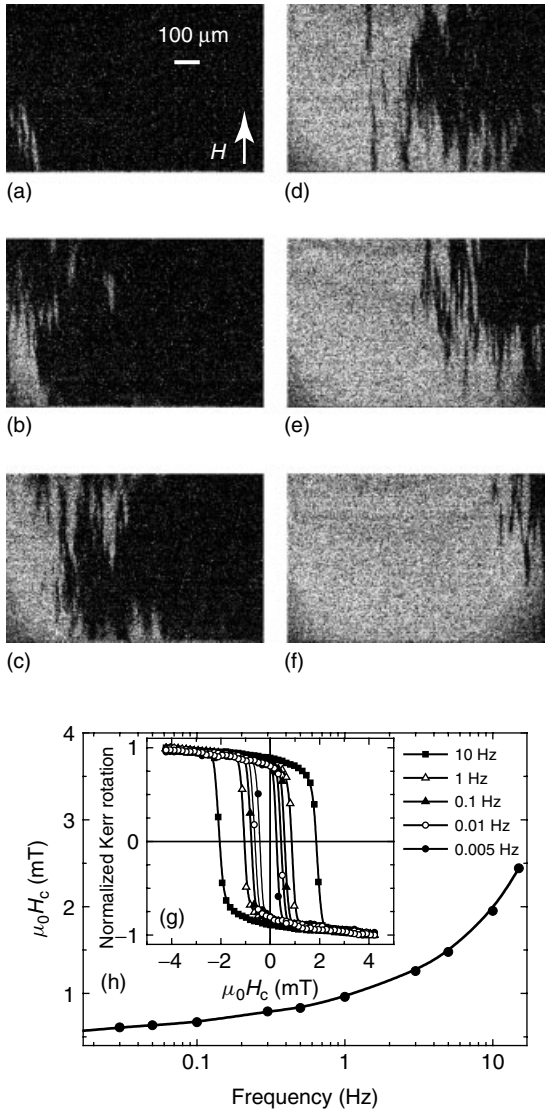

Figure 15. (a–f) Longitudinal Kerr microscopy domain images at room temperature of initially remanent $[Co_{80}Fe_{20}(1.3\,\mathrm{nm})/Al_2O_3(3\,\mathrm{nm})]_{10}$ (size $980 \times 700\,\mu\mathrm{m}^2$) under a supercoercive field, $\mu_0 H = 0.65\,\mathrm{mT}$, at $t = 1.5$ (a), 2.5 (b), 3.5 (c), 4.5 (d), 5.5 (e), and 7 s (f). (g) Normalized L-MOKE loops obtained on the same sample at $T = 294\,\mathrm{K}$ and $f = 0.005$ (1), 0.01 (2), 0.1 (3), 1 (4), and 10 Hz (5), and (h) frequency dependence of the coercive field, best fitted to power laws $H_c = H_{c0} + \mathrm{b}\,f^{\alpha}$ with $\mu_0 H_{c0} = 0.2\,\mathrm{mT}$ and $\alpha = 0.5 \pm 0.1$ (solid line). (From Bedanta *et al*., 2007.)

where the gyroscopic constant γ represents the precession frequency. The phenomenological damping factor λ drives the system toward an energy minimum. $\mathbf{H}_{\text{eff}}$ is the sum of the external field $\mathbf{H}_{\text{bias}} \cdot \mathbf{H}_{\text{pulse}}$, the anisotropy $\mathbf{H}_{\text{ani}}$ and the demagnetizing field $\mathbf{H}_{\text{dem}}$, and is decisive for the path on which the magnetization reaches a new equilibrium. Methods have been developed to reverse the magnetization in undercritically damped systems by coherent rotation of the magnetization at switching times of about 200 ps while avoiding any ringing. Here, we show one example of how to achieve this by applying specifically shaped magnetic field pulses that match the intrinsic properties of the magnetic elements. Figure 16 shows the apparatus (Gerrits *et al.*, 2002) containing a sequence of two pump-laser pulses, which are separated by a distinct time delay and excite two GaAs-photoconductive switches. The generated current pulses are superimposed to produce one short and squarelike magnetic field pulse. The field pulse is launched down a coplanar waveguide structure and excites the thin-film permalloy ($Ni_{81}Fe_{19}$) element at the end of the tapering. The inset is a micrograph of the 8-nm-thin permalloy magnetic element that has an elliptical shape with dimensions of 8×16 mm. The vector- and time-resolved element response is measured by magnetization-induced second harmonic generation (MSHG) (see Section 3.5) and P-MOKE. A high-reflectance infrared mirror (HRIR) is used to split the fundamental and SH part of the beam. A photomultiplier tube (PMT) is used to detect the SH photons. By applying proper pulse shaping the authors succeeded in achieving writing frequencies of 5 GHz.

Which kind of spin dynamics has to be expected at times far below the precession period? Again, ultrashort laser pulses are the ultimate solution for all kinds of dynamic

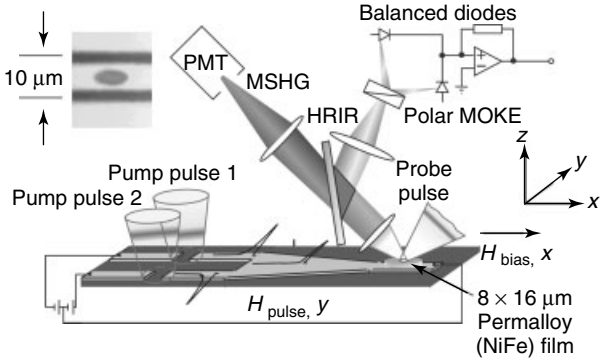

Figure 16. Experimental setup of a pump-probe experiment for measuring the *xy*- and time-resolved magnetization of a thin-film permalloy element with dimensions $8 \times 16\,\mu m^2$ (micrograph upper left corner) using 150 fs Ti:Sapphire laser pulses for switching the field and probing the magnetization by MOKE and MSHG. investigations in the subnanosecond regime. Mode-locked pulse lasers, which deliver light pulses with duration $\approx$10 fs, are predestinated to probe spin dynamics on this timescale. Surprisingly, at the very beginning of a typical magnetization reversal (or spin-flip?) experiment a tremendous increase of the spin temperature is observed. This was apparent with time-resolved L-MOKE on a polycrystalline Ni film (Beaurepaire, Merle, Daunois and Bigot, 1996), in which a 60-fs dye laser pulse heats the spin temperature up to nearly 600 K within 2 ps, hence, much faster than predicted for conventionally precessing spins. The dynamics of the spin excitation (demagnetization) and recovery was measured with an all-optical pump-probe experiment. In parallel, the increase of the electron temperature was measured by the dynamics of the optical transmission. It rises differently than the spin temperature in the first 2 ps, thus corroborating early 'two-temperature' models (Anisimov, Kaspeliovitch and Perel'man, 1974a,b). These findings were confirmed by spectrotemporal magneto-optics using a Ti:Sapphire pulse laser (Bigot, Beaurepaire, Guidoni and Merle, 2002; Bigot, Guidoni, Beaurepaire and Saeta, 2004). Obviously, *femtomagnetism*, that is, magnetism on a femtosecond timescale, seems to behave quite differently than conventional demagnetization processes (spin precession, magnetic domain motion and rotation). These become relevant only on the nanosecond timescale of spin-lattice, magnetic dipole, and spin–spin interactions (Zhang, Hübner, Beaurepaire and Bigot, 2002). In other experiments (Koopmans, van Kampen, Kohlhepp and de Jonge, 2000), a disproportionality of θ_K and ε_K was observed, although both quantities should be proportional to **M**. Hence, the question arises, if really the magnetization vector **M** is measured in ultrafast pump-probe demagnetization experiments? The new data seem to reveal the blocking of spin-excitation channels rather than a true change of **M**. Hence, alternatively, dichroic bleaching and nonequilibrium MOKE response have been proposed for an adequate description (Oppeneer and Liebsch, 2004). Further theoretical and experimental research is clearly needed in this novel field of magnetism.

3.5 Nonlinear MOKE

NOMOKE is a typical surface effect and in metals it is dominating, even if the material underinspection has broken inversion symmetry (Pan, Wei and Shen, 1989). Hence, it appears tempting to measure both MOKE and NOMOKE with the same apparatus and thus provide both magnetic volume and surface information simultaneously as shown in Figure 7 (Vollmer *et al.*, 1995). One apparatus toward this end was shown in Figure 16. A similar setup of Teplin and Rogers (2001) contains the V-MOKE option, in addition.

It allows to measure both L- and T-MOKE for achieving the magnetization vector components both in the bulk (via fundamental wave ellipticity) and at the surface or interface (via second harmonic wave ellipticity). Images of the spatial magnetization distribution can be measured by moving the sample across the laser focus using an *xy*-piezo scanner. The light pulses of the Ti:Sapphire laser ($\tau = 50$ fs) are further utilized to investigate bulk and surface magnetodynamics by simultaneous pump-probe strategies. As an example, Figure 17 shows the magnetization components of a permalloy film, which are precessing synchronously in a static field after application of a 100-ps field pulse (Teplin and Rogers, 2001).

3.6 Magneto-optic X-ray microscopy

The magnetic contrast occurring in XMCD can be applied to imaging techniques in the absorption mode. XMCD microscopy has been developed utilizing either (i) the primary absorption process or (ii) the subsequent emission of secondary electrons. In the latter mode, XMCD has been coupled to a PEEM, which gains a spatial resolution on samples at remanence from a few micrometers (Stöhr *et al*., 1993) to 300 nm (Schneider *et al*., 1997). Basic features of these experiments are the element specificity and the surface sensitivity, but they are restricted to studies in virtually zero magnetic field. As an example, Figure 18 shows two X-PEEM micrographs obtained on a bilayer of ferromagnetic cobalt (XMCD contrast at the Co L_3 edge) deposited on antiferromagnetic $LaFeO_3$ (XMLD contrast at the Fe L_3 edge) (Nolting *et al*., 2000). The images reveal clear correlations between the domains in both layers, which are exchange coupled and exhibit local exchange bias (Nogués and Schuller, 1999) domain by domain. The very origin of the global exchange bias, that is, the solid shift of the ferromagnetic hysteresis loop along the field axis as induced by magnetic field cooling was unraveled on the bilayer system $Ir_{20}Mn_{80}$/Co by using XMCD–PEEM in the total electron yield mode, which tolerates nonzero magnetic fields (Ohldag *et al*., 2003). Here, a fraction of about 4% of pinned excess magnetic moments on the antiferromagnetic $Ir_{20}Mn_{80}$ interface were clearly observed by Mn L_3-edge XMCD and attributed to the very heart of the observed exchange bias.

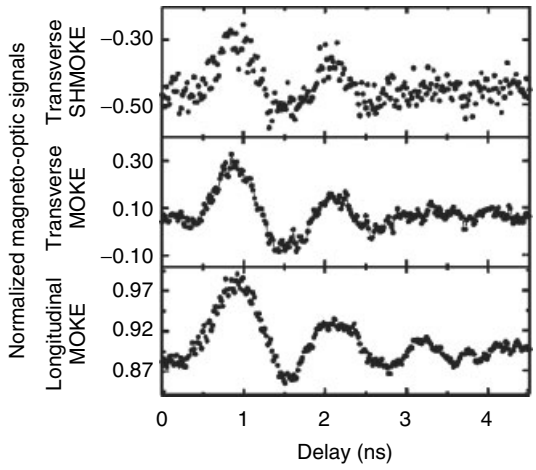

Figure 17. Normalized dynamic MOKE and NOMOKE (= SHMOKE) response of a $Fe_{80}Ni_{20}$ thin-film sample to a magnetic field pulse with 100 ps rise time in the transverse direction. Static transverse and longitudinal fields are applied so that the magnetic response of each magnetization component is linear and not hysteretic. (Reproduced from C.W. Teplin *et al*., 2001, with permission from the American Institute of Physics. © 2001.)

An alternative approach to image magnetic domains with improved parameters, viz on the nanometer length scale and permitting the application external magnetic fields uses microzone plates for lensless imaging of X rays in transmission. This was first realized at the synchrotron source BESSY I using the XMCD effect used in the complementary transmission mode (Fischer *et al*., 1996). Figure 19 shows some of the recorded magnetic X-ray micrographs of a multilayer $[Gd(0.4\,nm)/Fe(0.4\,nm)]_{75}$ (Fischer *et al*., 1998). The domain structures observed indicate magnetization vector components parallel and antiparallel to the light wave vector, respectively, at an approximate resolution of 30 nm. Different stages of the reverting magnetization from nucleation (N) to saturation (S) while passing relatively hard wormlike structures (W) are indicated. In the nucleation regime, a time-dependent magnetic aftereffect (= creep (C); cf. Figure 14 (Lemerle *et al*., 1998)) could be studied on a timescale of seconds.

4 MAGNETO-OPTICAL MATERIALS

Since more than 20 years, the two most prominent technological applications for MO effects have been optical isolators for fiber optical data transmission and MO memories. Both fields have intensely triggered the research of MO materials, whose state of the art has variously been reviewed (Dillon, 1991; Schoenes, 1992; Mansuripur, 1995; Zvezdin and Kotov, 1997; Gambino and Suzuki, 1999; Oppeneer, 2001; Röll, 2003). In the following sections, the established experience will briefly be recalled, while the focus will rather be laid onto the more recent developments.

4.1 Magneto-optical storage materials

The success of modern optical data storage devices started in 1982 with the introduction of the audio compact disc (CD).

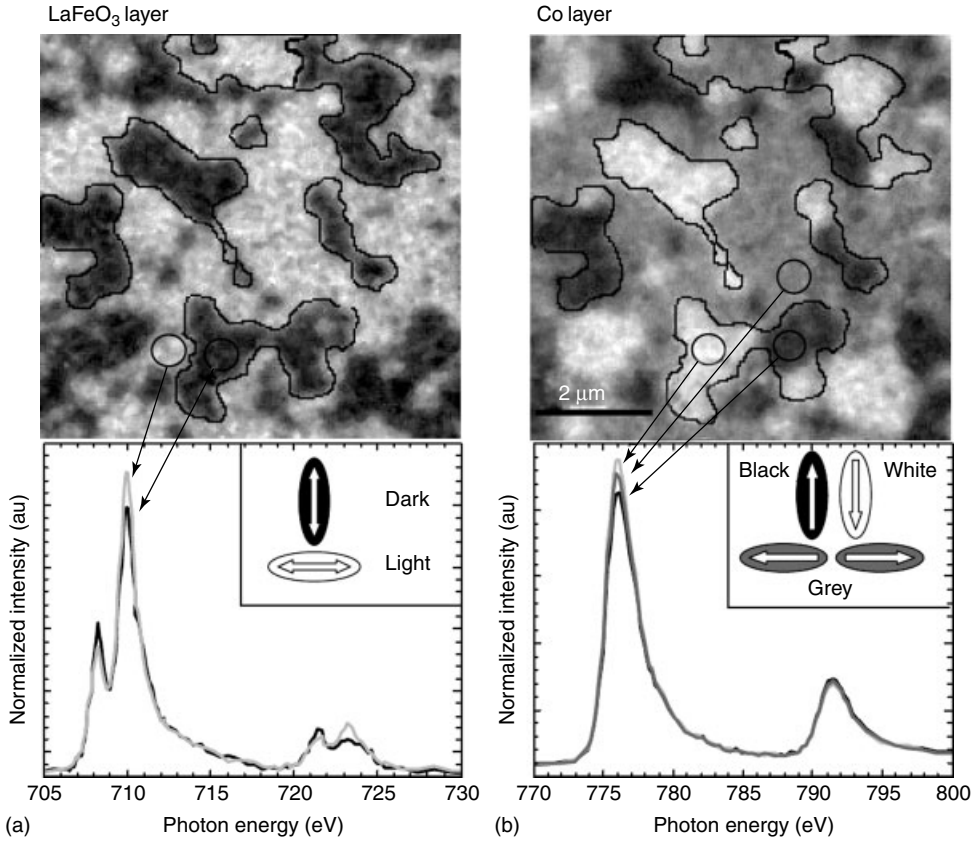

Figure 18. Fe L-edge XMLD (a) and Co L-edge XMCD images (b) and local spectra from the antiferromagnetic and ferromagnetic layers for Co(1.2 nm)/$LaFeO_3$/$SrTiO_3$(001). The contrast in the images arises from antiferromagnetic domains in (a) and ferromagnetic domains in (b) with in-plane orientations of the antiferromagnetic axis and ferromagnetic spins as indicated below the images. The X-ray spectra were recorded in the indicated areas and illustrate the origin of the intensity contrast in the PEEM images. (Reproduced from F. Nolting *et al*., 2000, with permission from Nature Publishing Group. © 2000.)

The erasable MO disc became available in 1988. The binary information is stored in small magnetic domains which are formed or erased in a magnetic layer by laser pulses in the presence of a magnetic field (thermomagnetic writing/erasing). Readout is obtained from intensity modulations of the reflected laser light caused by P-MOKE at the written domains (Mansuripur, 1995; Gambino and Suzuki, 1999; Röll, 2003).

MO storage materials are expected to undergo a very large ('unlimited') number of write/erase operations without any loss in recording/reading quality. The MO media write magnetically with thermal assist and read optically. Presently there are two standard formats, 5.5 and 3.5 in., which are protected by hard envelopes. The larger format MO disks have been capable of holding about as much as the standard CD-ROM, but under the pressure from inexpensive and relatively fast CD-R and CD-RW, more recently also DVD-RW disks, MO drives seemed to be losing ground. However, novel principles of MO recording technology like *direct overwrite* (Saito, 1999) and *magnetically induced superresolution* (MSR) (Kaneko, 1999, 2000) are now promising again to find their way back into the group of most advanced magnetic storage devices of the future.

Above their Curie temperature, T_C, any magnetic material loses its spontaneous magnetization and thus all magnetic information due to a complete disordering of their magnetic domains. Even more importantly, the material's coercivity, H_c, decreases as the temperature approaches the Curie point, and becomes zero when this temperature is exceeded. Modern MO recording systems use materials with $T_C \approx 200\,^{\circ}C$, low enough to enable the disk not to be damaged by many heating and cooling cycles, but high enough not to risk a loss of data under ambient conditions.

The fact that H_c drops at higher temperatures allows thermally assisted magnetic recording with relatively weak magnetic fields, which simplifies the drive's design. Even a relatively weak laser, $P \approx 1$ mW, can generate a high local temperature when focused onto a small spot of the order of 1 μm. When the material is heated, the magnetization of the material can easily be changed by applying a magnetic

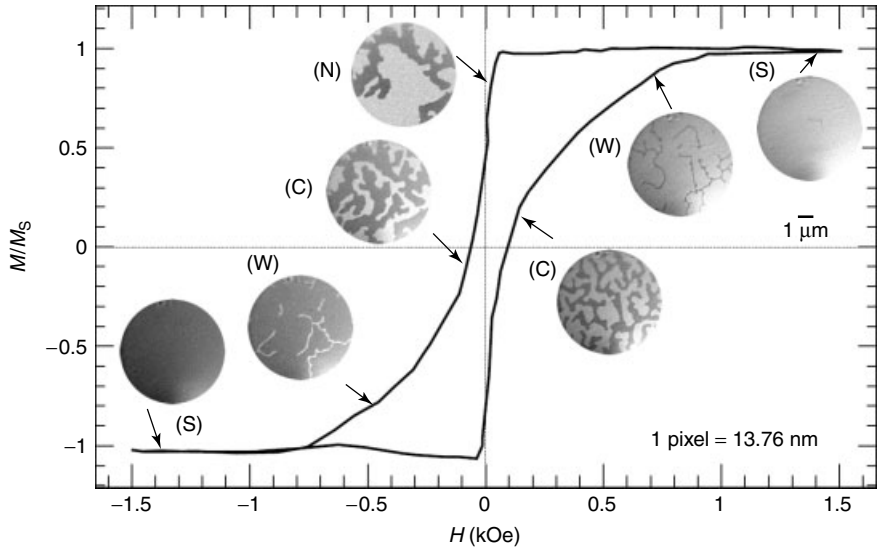

Figure 19. A sequence of XMCD micrographs at the Fe L_3 edge of a layered Gd–Fe system in an applied magnetic field covering the complete hysteresis loop. The different stages saturation (S), nucleation (N), and wormlike domains (W) are marked. The hysteresis loop, M/M_s versus H (solid line), was determined from MOKE measurements. (Reproduced from P. Fischer *et al*., 1998, with permission from Institute of Physics Publishing Ltd. © 1998.)

field from a permanent magnet. When the material is cooled to room temperature, H_c rises back to such a high level that the magnetic data cannot easily be affected by magnetic fields, which may accidentally approach the MO device from outside. The basic schematic of the recording process is illustrated in Figure 20. The disk inserted into the drive will face the magnet from the label side, whereas the transparent face will face the laser. Although longitudinal recording as is customary in most present days' hard disks might be feasible by using L-MOKE readout, MO recording has always used the perpendicular direction of the magnetization with P-MOKE readout and potentially higher density of data storage.

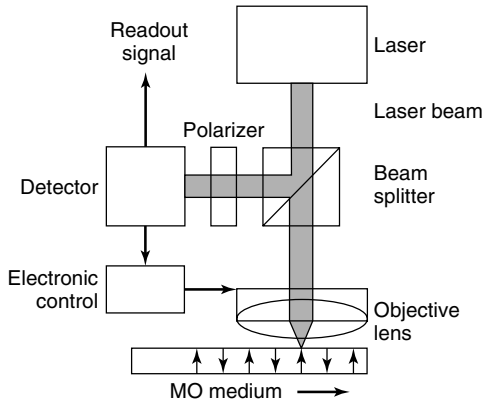

Figure 20. Optical paths and electronic control of the MOKE write and read head. (Reproduced from H. Röll *et al*., 2003, with permission from Wiley VCH. © 2003.)

For readout, the laser is operated at sufficiently low power, which does not change the stored information, viz the domain structure. The state of polarization of the reflected light is changed by P-MOKE, that is, the incident, linearly polarized light becomes elliptical with a slight tilt of the long polarization axis, $\theta_K \leq 0.5^\circ$. For opposite magnetization directions, $\pm\theta_K$ is obtained such that the light passing an analyzing polarizer encounters an intensity modulation between differently magnetized bubble domains ('bits'). The electronic control of the lens position in Figure 20 is to focus and to track the laser beam along the 'land' areas, which carry the storage material loaded with information. Usually quadrilayer stacks are used in the design of MO disks. In order to increase the optical absorption of the MO layer (thickness ≈30 nm) and thus to reduce the laser power for recording, it is coated by thin (≈100 nm) dielectric antireflection layers made from AlN or SiN. Another thin Al layer (≈50 nm) is introduced to serve both as a light reflector and as a heat sink.

The polar Kerr effect used for the readout procedure is sensitive to the magnetization component perpendicular to the film plane. In order to obtain a complete perpendicular orientation, a sufficiently large uniaxial anisotropy K_u is necessary. It must be larger than the shape anisotropy which is proportional to M_s^2,

$$K_u \geq (1/2)\mu_0 M_s^2 \tag{26}$$

Further, a large product $M_s H_c$ is required to ensure high recording density. Very low medium noise, large P-MOKE

signals and a large domain-wall stiffness minimizing wall jaggedness are to optimize the signal-to-noise ratio. Finally, high corrosion resistance is desirable.

Many different materials have been considered because of their individual promising features. For example, MnBi with its large MOKE signal, $\theta_K > 1^\circ$, has always appeared to be a good candidate. However, it was finally abandoned for MO recording purposes because of the high media noise owing to its polycrystalline structure. Only when being in a single crystalline state the MO properties of MnBi still attract interest (Brammeier *et al.*, 2004). Amorphous RE–TM alloys with extremely low media noise have finally served for the development of MO data storage systems passing three generations of media with increasing complexity:

1. binary RE–TM amorphous alloy films
2. ternary or quaternary RE–TM amorphous alloy films
3. exchange coupled ternary RE–TM alloy bilayers.

The first generation started with RE-rich RE–TM amorphous alloy films (RE = Tb, Gd and TM = Fe, Co) (Chaudhari, Cuomo and Gambino, 1973; Gambino and Suzuki, 1999). These materials, for example, $Tb_{75}Fe_{25}$, are widely used as relatively thin films (20–50 nm) in current commercial MO disks. Even better quality was obtained by materials of the second generation, ternary RE–TM alloys, where Tb and Fe can be partially substituted by other RE or TM atoms, for instance, Gd, Dy or Co, Ni, respectively. Since the films reveal antiferromagnetic coupling between the RE and the TM components, the net magnetization M_s can be small in spite of the fact, that the magnetizations of the RE and TM subnetworks are high. As the temperature dependencies of the two subnetwork magnetizations are different often a compensation temperature, T_{comp}, exists where the net magnetization is even zero (Figure 21). At T_{comp} the coercivity of the material becomes very large, since an external field cannot turn the magnetization into any given direction. This is important for the stability of the domains. At a high temperature near T_C, the coercivity is sufficiently small to form a domain by the external bias field H_b. During cooling to room temperature the coercivity increases rapidly and, as a consequence, a written domain will not be destroyed by any external stray field.

Magnetization data for different TbFeCo films are shown in Figure 22 (Greidanus, Jacobs, Spruit and Klahn, 1989). Within a small range of composition the compensation temperature changes from zero to a value above Curie temperature. For the stability of the domains a compensation temperature near room temperature is favorable. It can be obtained by a Tb content of approximately 25%. The composition influences also the Curie temperature, T_C, but in a much smaller range. A Curie temperature near 200 °C is convenient for the writing process. For a given Tb content, the

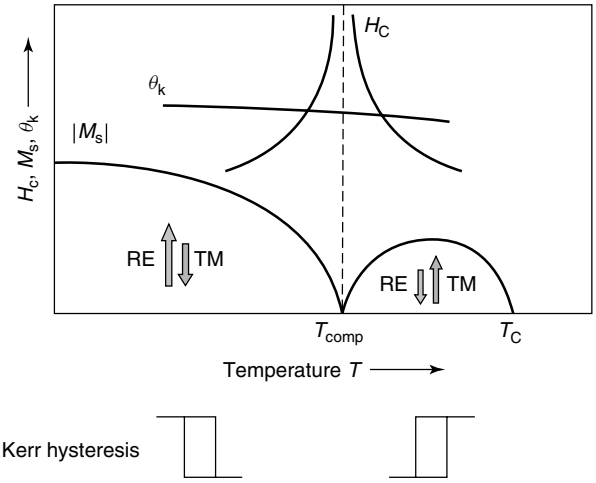

Figure 21. Magneto-optical properties of rare-earth (RE) and transition-metal (TM) thin films (M_s: saturation magnetization, θ_K: Kerr rotation angle, H_c: coercivity). (Reproduced from H. Röll *et al.*, 2003, with permission from Wiley VCH. © 2003.)

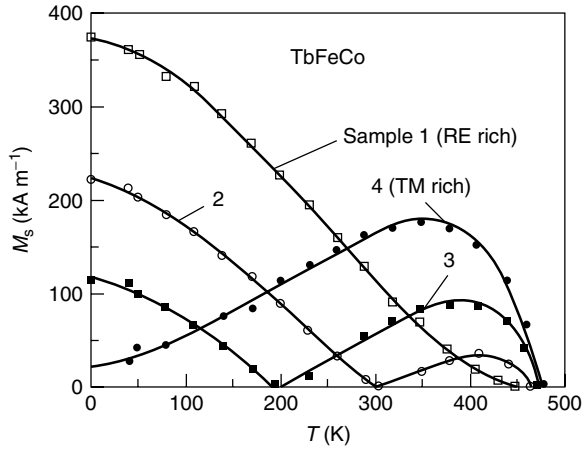

Figure 22. Magnetization curves M_s versus T of films of $Tb_{29.9}Fe_{62.6}Co_{7.5}$ (1), $Tb_{27.2}Fe_{63.5}Co_{7.3}$ (2), $Tb_{23.6}Fe_{67.6}Co_{8.8}$ (3), and $Tb_{21.2}Fe_{71.9}Co_{6.9}$ (4). (Reproduced from F.J.A.M. Greidanus *et al.*, 1989, with permission from IEEE. © 1989.)

Curie temperature can be slightly shifted to higher values by substitution of Fe by Co (Hansen, 1991). For TbFeCo films being near to the compensation point at room temperature (comparable to Figure 22, curve 2), excellent recording parameters have been achieved: $\theta_K = 0.43^\circ$ at $\lambda = 830$ nm with a carrier-to-noise ratio of greater than 60 dB at a bandwidth of 30 kHz (Hatwar, Genova and Stinson, 1990).

The Kerr effect required for readout is related to inter- and intraband transitions of the RE/TM alloy. For wavelengths between 620 and 780 nm, which are still commonly used for readout, the main contribution comes from the 3d electrons of the TMs. In the temperature range near the compensation temperature, the Kerr rotation θ_K varies only

slightly according to the variation of the magnetization of the TM subnetwork. An external field, however, acts on the net magnetization, which changes from a RE-dominated behavior below the compensation temperature to a TM dominated behavior above the compensation temperature. Hysteresis loops determined by MOKE, therefore change their sign when the temperature passes the compensation temperature T_{comp} (Figure 21).

A very important contribution to noise comes from irregularities of the written domains. They depend on the composition as well as on the writing conditions. In Figure 23, this is demonstrated for some test structures observed in Tb/Fe multilayers. Domains which are spontaneously formed usually have an irregular shape (Figure 23a). By using laser pulses of 20 µs length and various power levels, circular domains can be written in a film with $H_c = 170\,\mathrm{kA\,m^{-1}}$. Depending on the power level the diameter can be varied between 5 and 1 µm (Figure 23b). The regularity of the domains depends also on the magnitude of the bias field during the writing process (Figure 23c). For a pulse length of 10 µs and a power level of 1.8 mW, the field must exceed $15\,\mathrm{kA\,m^{-1}}$, otherwise a granular substructure is observed within the domains. In Figure 23(d), a domain structure is shown which is obtained by magnetic field modulation. A circular domain can be partially overwritten when the laser spot is slightly shifted and the bias field is reversed from one direction to the opposite. The result is a track of crescentlike domains. It is obvious, that a high recording density along the track can be obtained in spite of a relatively large diameter of the individual domain. This type of recording is applied in the present generation of the MiniDisc.

A principal limitation for the recording density is set by optical diffraction. The diameter d of the diffraction pattern produced by the objective lens during writing and reading is given by

$$D = 1.22\lambda/NA \tag{27}$$

where λ is the wavelength of the radiation (at present between 780 and 620 nm) and NA is the numerical aperture of the

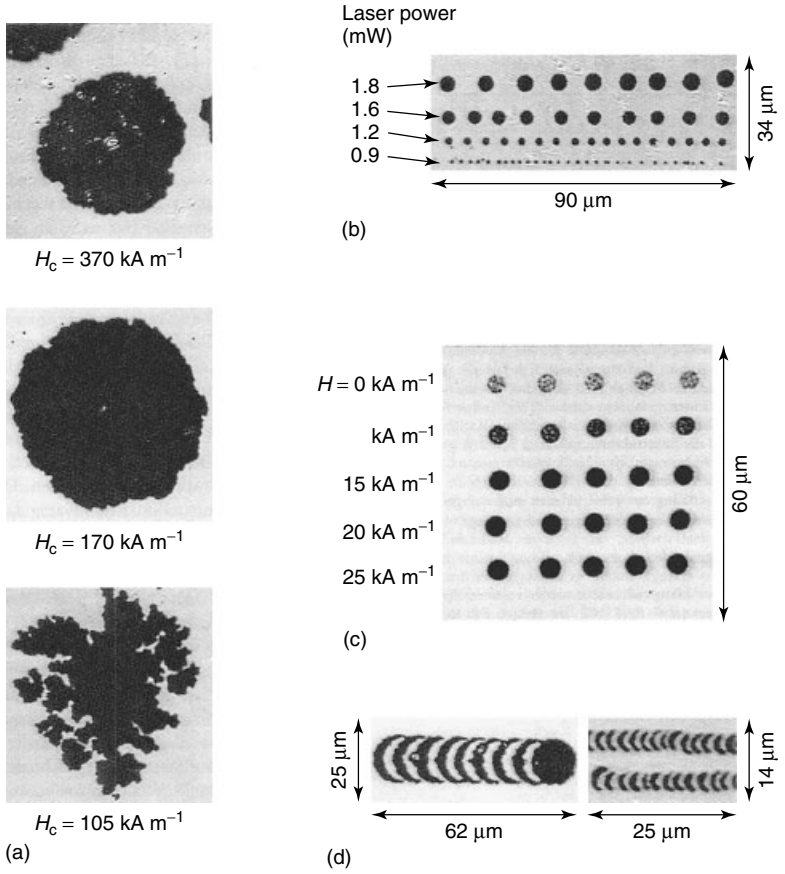

Figure 23. Magnetic domains in Tb/Fe multilayers observed by Kerr microscopy. (a) Spontaneously formed domains in films with different coercivities; (b) thermomagnetically written domains in the film with $H_c = 170\,\mathrm{kA\,m^{-1}}$ at pulse length 20 µs and variant laser power; (c) domains thermomagnetically written with laser power 1.8 mW, pulse length 10 µs, and variant bias field H_b; (d) domains written by magnetic field modulation. (Reproduced from H. Röll *et al.*, 2003, with permission from Wiley VCH. © 2003.)

objective lens of the optical head. The writing process is not so critical, because the size of the written domain depends mainly on the relation between the applied bias field H_b and the temperature distribution of H_c produced by the laser pulse (cf. Figure 23b). By appropriate conditions, domains smaller than the optical limit d can be created. The main problem originates from the reading process, since it is not possible to distinguish very small domains in a distance below (d/2). It is assumed, that the problem can be overcome in near future by MSR or related techniques (Kaneko, 1999; 2000). This principle is related to optical near-field techniques, where a narrow aperture is shifted over the sample in a very close distance and reads out the information from the center of a diffraction-broadened domain ('bit'). Its realization is closely coupled to the use of MO recording materials of the third generation, viz exchange coupled RE–TM ternary alloy films.

The original procedure to write, erase, and read out information from a MO disc is discontinuous (see the preceding text) and excludes the direct overwrite function for very high-speed real-time recording. Here exchange-coupled RE–TM alloy bilayers can help very elegantly (Saito, 1999). Figure 24 shows schematically the bilayer consisting of a TM dominated memory layer (1; e.g., sample 3 from Figure 22) and a RE-dominated reference layer (2; e.g., sample 1 from Figure 22). Layer (2) has low coercivity at room temperature and is initialized by H_{ini} (left-hand side). Interfaces appear between up-magnetized parts of layer (1) (logic '1'). Then a low-level laser pulse heats the layer (1) to T_L close to its Curie temperature such that the antiparallel ground state forms by virtue of the interlayer exchange. This sets the disc to logic '0'. Alternatively, a high-level laser pulse heats the disc to T_H close to the Curie temperature of layer (2). Now an inverted weak bias field H_b switches layer (2) down, while layer (1) being above its Curie temperature loses its information. On cooling, however, layer (1) is switched up via exchange coupling and now carries the information '1'. Thus, by low-level and high-level modulation of the laser power an arbitrary bit pattern can be recorded by direct overwrite. This principle, together with the concept of superresolution (only the center of the laser spot is used for reading and writing), has opened the breakthrough to very high density MO recording. Presently (year 2005), the highest storage levels of commercial MO discs are 9.1 GB (5.5 in.) and 2.3 GB (3.5 in.).

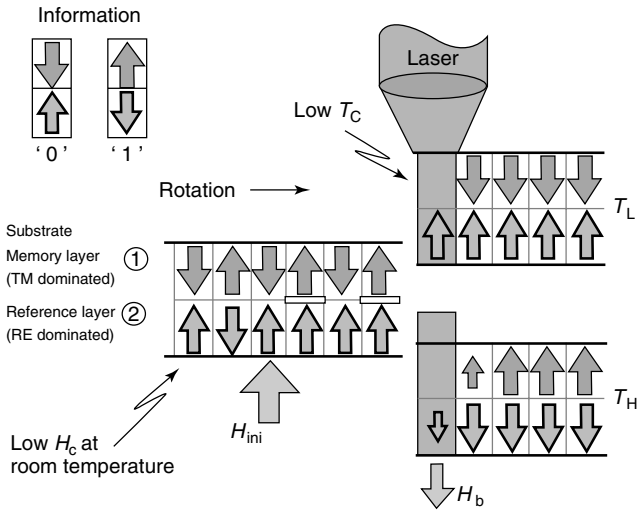

Figure 24. Principle of direct overwrite by laser intensity modulation (see text). (Reproduced from H. Röll *et al.*, 2003, with permission from Wiley VCH. © 2003.)

A more straightforward solution toward even higher storage densities would be the application of a green or blue laser instead of the present red and infrared lasers. In near future, GaInN-based semiconductor lasers will be used at wavelengths of 428 nm (blue), which would allow an increase of recording density by a factor 3.8 by a linear reduction of the dimensions. However, for the presently available RE/TM media, the figure of merit drops rapidly with decreasing wavelengths. The most promising candidates for green and blue laser radiation are Co/Pt or Co/Pd multilayer structures, for example, with a composition $25\times$ (0.4-nm Co + 1.9-nm Pt) (Carcia and Suzuki, 1999; Kaneko, 2000). Studies on TbFeCo/Pt multilayers (Itoh, Suzuki and Birukawa, 1999) have shown that the Pt component is essential for the enhanced P-MOKE angles in the violet region ($\approx$3 eV, Figure 4) and high perpendicular anisotropy. Although laboratory experiments have been successfully performed, it is an open question, if large numbers of discs with such a complicated structure can be produced on an industrial scale.

4.2 Magneto-optical semiconductors

Three classes of magnetic semiconductors have to be distinguished:

1. magnetic insulators
2. semimagnetic semiconductors
3. ferromagnetic semiconductors.

Magnetic insulators, which can also be considered as 'large gap magnetic semiconductors', comprise all magnetic ionic crystals, for example, the cubic europium chalcogenides (EuO, EuS, EuSe, and EuTe), the cubic garnets like yttrium-iron-garnet, $Y_3Fe_5O_{12}$, YIG, the (quasi)tetragonal rutile-type compounds like MnF_2, NiF_2, FeF_2, and CoF_2, the cubic TM oxides like MnO, NiO, FeO, and CoO, and the layered halides like $FeCl_2$, $FeBr_2$, and $CrCl_3$. All of these and

many more insulating compounds are well known from their magneto-optic behavior, which has been described in some detail in previous reviews (Dillon, 1971; Ferré and Gehring, 1984; Eremenko and Kharchenko, 1992; Oppeneer, 2001).

Considerable interest has recently been devoted to antiferromagnets like FeF_2 and CoO because of their key role in the appearance of exchange bias, which occurs when being exchange coupled to an adjacent ferromagnet (Meiklejohn and Bean, 1956; Nogués and Schuller, 1999) (see Section 4.3). Both constituents – the ferro- and the antiferrmagnetic component – and the evolution of domains at their interface are subject to detailed MO investigations, both in the visible (Roshchin *et al*., 2005) and in the soft X-ray regime (Ohldag *et al*., 2003). Two further classes of insulating magnets came recently into the focus of interest, the so-called magnetoelectrics and multiferroics (Fiebig, 2005; Eerenstein, Mathur and Scott, 2006). While multiferroics experience the coexistence of two types of long-range order (e.g., $TbMnO_3$ has antiferromagnetic order below $T_N = 44\,K$ and ferroelectric order below $T_C = 27\,K$ (Kimura *et al*., 2003)), magnetoelectrics have only one type of long-range order (mostly antiferromagnetic). In these compounds, magnetoelectric coupling denotes the induction of a dielectric polarization by a magnetic field and – concomitantly – the appearance of a magnetic moment induced by an electric field (O'Dell, 1970). This is prototypically realized in the antiferromagnetic insulator Cr_2O_3, whose antiferromagnetic 180° domains were imaged magneto-optically (Fiebig, Fröhlich, Krichevstov and Pisarev, 1994, see Section 4.3).

Semimagnetic semiconductors, SMS (also: diluted magnetic semiconductors, DMS) are usually II–VI semiconductors, in which TM ions of magnetic semiconductors (preferentially chalcogenides of Cr, Mn, Fe, and Co) substitute cations of the host semiconductor material (preferentially chalcogenides of Zn, Hg, and Cd) at concentrations $x \lesssim 50\%$. The fundamental difference between SMS and ordinary semiconductors, for example, between $Cd_{1-x}Mn_xTe$ and $Cd_{1-x}Zn_xTe$, is the strong field-induced magnetism in SMS, which is not observed in the absence of a magnetic field. The localized d electrons of the dopant ions strongly couple to the delocalized sp carriers of the host semiconductor. By virtue of sp–d exchange large MO effects are induced as first observed by Komarov, Ryabchenko and Terletskii (1977a,b) on $Cd_{1-x}Mn_xTe$ at microwave frequencies. Verdet constants as large as $10\,deg\,Oe^{-1}cm^{-1}$ were observed at a temperature $T = 77\,K$ and photon energy $W = 1.8\,eV$ for $x = 0.2$ (Gaj, Galazka and Nawrocki, 1978). These effects are due to a giant band splitting of the electrons, holes, and excitons, and may be observed both via MCD or via MCB (Faraday rotation). Recently, Verdet constants in the same order of magnitude were also observed in a large gap SMS, $Zn_{1-x}Co_xO$, $x = 0.042$, at UV wavelengths, $W = 3.4\,eV$, and temperature $T = 5\,K$ (Ando *et al*., 2001). These effects vanish at room temperature, but should be regained in ferromagnetically ordering $Zn_{1-x}Co_xO$ (Sato and Katayama-Yoshida, 2000).

A large amount of experimental results and steps toward a theory of the carrier-ion exchange in SMS have been compiled by Gaj (1988) and Kossut and Dobrowolski (1993). The s–d exchange is a direct ferromagnetic exchange between s and d one-electron orbitals centered at the same ion core and is virtually independent of the host and magnetic ions. On the contrary, the p–d exchange is kinetic due to p–d hybridization and can have either sign. As a rule, it is ferromagnetic for less than half-filled d shells as for $Cr(d^4)$, but antiferromagnetic for more than half-filled d shells as for $Mn(d^5)$, $Fe(d^6)$, or $Co(d^{7+})$. They have been determined in $Cd_{1-x}Cr_xS$ by free exciton spectroscopy (Twardowski *et al*., 1996). At larger concentrations, d–d exchange may give rise to collective states, for example, spin glass or antiferromagnetic, which have extensively been investigated using the MO probe (Ayadi, Ferré, Mauger and Triboulet, 1986).

The giant Faraday rotation in SMS is used to study the magnetization of the Mn^{2+} ions optically. At low x it is given by

$$\theta_F = \theta_0(\hbar\omega)B_S(H,T) + \chi(\hbar\omega) \tag{28}$$

where $\theta_0(\hbar\omega)$ and $\chi(\hbar\omega)$ are the paramagnetic contribution of Mn^{2+} and the diamagnetic contribution of the interband transitions, respectively, while $B_S(H,T)$ is the Brillouin function referring to the spin quantum number $S(= 5/2$ for $Mn^{2+})$ at the magnetic field H and the temperature T. The first term in equation (28) saturates at high fields ($\mu_0 H > 7$ T) such that only the negative second term remains. For $x > 0.01$, the d–d interaction between the magnetic ions becomes important and gives rise to quantized nearest-neighbor pair states with corresponding Zeeman levels and steps in the Faraday rotation θ_F versus B (Matsuda and Kuroda, 1996).

By exciting SMS with intense femtosecond laser pulses with circular polarization and measuring the time-resolved MOKE rotation, the Larmor precession of the Mn^{2+} spins initiated by photoinjected carriers can be observed. The pump pulse, tuned to the heavy-hole (HH) exciton resonance creates magnetic moments of electrons and HH along the growth direction in $CdTe/Cd_{1-x}Mn_xTe$ quantum wells, which is perpendicular to both the magnetic field and the sample surface (Voigt geometry). After pumping, the conduction electron spins precess with Larmor frequency amplified by the s–d exchange. In contrast, HH being quantized along the growth direction cannot precess and decay. Interestingly, as shown in Figure 25, a slower weak θ_K oscillation appears superimposed. It is due to the Mn^{2+} spins being subject to additional

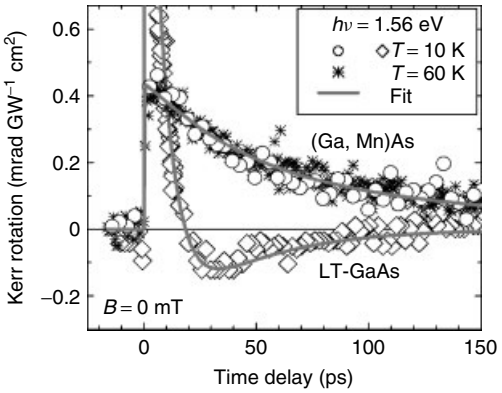

Figure 26. Temporal decay of the Kerr rotation of $Ga_{0.98}Mn_{0.02}As$ after circularly polarized excitation with 100-ps laser pulses of power 0.1 GW cm^{-2} at a photon energy of 1.56 eV and $T = 10$ and 60 K, respectively, in comparison with the behavior of a reference film of low-temperature grown-GaAs. (Reproduced from Kimel *et al.*, 2004, with permission from the American Physical Society. © 2004.)

tipping owing to the HH exchange field (Akimoto *et al.*, 1998).

Picosecond spin dynamics of photoinduced (nonequilibrium) spin polarization is also of major interest in *ferromagnetic semiconductors* of the type $Ga_{1-x}Mn_xAs$, which have recently been shown to reach Curie temperatures up to $T_C \approx 250$ K in suitable heterostructures (Nazmul *et al.*, 2005). This technique is believed to contribute to the development of ultrafast magnetic devices in spintronics. The hole-mediated ferromagnetic exchange in semiconductors opens the possibility to change the magnetic properties of $Ga_{1-x}Mn_xAs$ by modulating the hole concentration (Ohno, 1998). The magnetization dynamics of an epitaxially grown $Ga_{0.98}Mn_{0.02}As$ film of 350 nm thickness was measured by using a pump-probe MOKE technique (Kimel *et al.*, 2004). At a fluence of 10 μJ cm^{-2} the photoinduced magnetization turned out to correspond to the application of an external field of about 1 mT. The observed relaxation time of 30 ps (Figure 26) was attributed to intraconduction band relaxation and – surprisingly – was independent of the Mn^{2+} ordering.

Magneto-optics is also the proper instrument for testing the efficiency of spin-injection devices. Spin transmission across ferromagnet/semiconductor interfaces is one of the key goals for the realization of the spin transistor (Datta and Das, 1990). In order to evaluate the actual degree of spin transmission, up to 32% were reported on Fe/AlGaAs/GaAs–Schottky diodes (Hanbicki *et al.*, 2003), it was proposed to measure the changes of the magneto-optic response of the ferromagnetic component, for example, via P-MOKE while injecting charge carriers. Experiments carried out on bilayers of Co/GaAs and $Ni_{0.8}Fe_{0.2}$/GaAs (Ruggiero *et al.*, 2003) showed, however, that any change of the MOKE signal coming from the spin injection was masked by the dominating intrinsic MO activity of the bare ferromagnetic layer. More adequate are attempts analyzing the spin polarization of the current through the semiconductor component directly via the circular polarization of the light emitted at a sensing pn contact. Recently, it was demonstrated that the circular polarization of the emission from an optically pumped vertically emitting multiquantum well laser (VCSEL) is very sensitive to the spin polarization of the driving current. For example, by generating 30% spin polarization of the photoelectrons via the circular polarization of the pump light, 100% polarization of the laser radiation was obtained, thanks to the nonlinearity of the laser threshold (Hövel *et al.*, 2005). Using this sensitive MO diagnostics tool, 0.75% spin polarization could be observed at $T = 90$ K in an electrically pumped spin VCSEL when using a perpendicularly magnetized Fe/Tb multilayer in remanence as an injecting electrode (Gerhardt *et al.*, 2005).

4.3 Antiferromagnets

Only recently, the majority of the magnetism community has acknowledged antiferromagnets to be worth studying and to pay attention about. The opinion changed radically, since

antiferromagnetic materials gained appreciable technological interest with regard to the concepts of spin electronics (Prinz, 1998), exchange bias (Nogués and Schuller, 1999), magnetoelectric and multiferroic systems (Fiebig, 2005; Eerenstein, Mathur and Scott, 2006). However, although only in recent years advanced MO spectroscopical methods became available in order to determine antiferromagnetic domain topograhy (see the following text), the benefits of magneto-optics toward understanding antiferromagnetic crystals became obvious already more than 30 years ago. The quadratic MO effects, in particular, the MLB was found to be an excellent tool to determine the magnetic specific heat c_m of optically transparent materials, for example, rutile type antiferromagnets like MnF_2 and FeF_2 (Jahn and Dachs, 1971). It was soon understood (Smolenskii, Pisarev and Sinii, 1975, 1976) that the optical refractive index and the corresponding linear birefringence are sensitive to spin-correlation functions. One may consider (Borovik-Romanov, Kreines and Talaev, 1974a,b) the dependence of the electrical energy of radiation per unit volume on the spin correlations according to

$$w_e = \frac{1}{2} \sum_{i,j=x,y,z} \left[\varepsilon_{ii} E_i E_i + \frac{1}{2} \sum_{l,l'\gamma,\delta} R_{i,j,\gamma,\delta} \langle S_i^{\gamma} S_j^{\delta} \rangle E_i E_j \right] \tag{29}$$

In this relation, ε_{ii} represents the unperturbed optical permittivity tensor components, E_i the electric field of the radiation, $R_{i,j,\gamma,\delta}$ the magneto-optic tensor components, and $\langle S_i^{\gamma} S_j^{\delta} \rangle$ the spin-correlation functions, respectively. Single ion ($l = l'$) and two-ion ($l \neq l'$) contributions are included. From this one readily obtains the magnetically perturbed permittivity components

$$\varepsilon'_{ii} = \frac{\partial w_e}{\partial E_i \partial E_i}, \varepsilon'_{ij} = \frac{\partial w_e}{\partial E_i \partial E_j} \tag{30}$$

which are linear functions of the spin-correlation functions. This applies equally to the refractive indices and to the linear birefringence, when expanding the Fresnel ellipsoid given by equation (30). Thus, a comparatively simple optical method provides access to spin correlation functions, which are usually measured by neutron scattering. Surprisingly, it turned out that MLB method was capable of determining an important thermodynamic quantity, namely, the magnetic energy, $U \propto J \langle S_i S_{i+1} \rangle$. Here J and $\langle S_i S_{i+1} \rangle$ stand for the nearest-neighbor spin exchange interaction and the corresponding spin–spin correlation function. Empirically, MLB is very often dominated by the same correlation function, $\Delta n_m \propto \langle S_i S_{i+1} \rangle$, thus giving access to the magnetic specific heat $(d\Delta n_m/dT) \propto (dU/dT) \propto c_m$. It should be stressed that the same information is basically contained in the refractive indices (Markovin, Pisarev, Smolensky and Syrnikov, 1976), which are, however, usually much harder to measure at sufficient accuracy than linear birefringence. The ease of measuring MLB at very high accuracy made it an extremely popular MO method (Ferré and Gehring, 1984). It is often superior to caloric methods, where phonon contributions may mask the tiny magnetic anomalies.

By using proper modulation methods, the MLB can be measured with an utmost accuracy in the order $\delta(\Delta n) \approx 10^{-8}$ on a crystal of thickness 1 mm (Ferré and Gehring, 1984). Similarly, changes of refractive indices may be determined at an accuracy up to the order $\delta n \approx 10^{-6}$ when employing photoelastically modulated two-beam interferometry (Schäfer and Kleemann, 1985). In conjunction with polarization microscopy, the modulation method is able to determine crystal optical anisotropy with high accuracy at domains on the micrometer scale. As an example, Figure 27 shows the temperature dependence of the MLB in α-MnS, a crystal isomorphic in the cubic phase to NiO. Two anomalies are observed, where the magnitude of the MLB sharply rises in an order parameter fashion, $\Delta n_m \propto \langle S^2 \rangle$, at $T_{C1} = 152.7\,\mathrm{K}$ and at $T_{C2} = 129.5\,\mathrm{K}$ (Kleemann, Schäfer and van der Heide, 1982). Obviously two successive phase transitions occur, from the cubic into a rhombohedrally compressed (as in NiO) at T_{C1}, and into a rhombohedrally elongated phase – very probably with multi-**k** antiferromagnetic ordering due to biquadratic exchange – at T_{C2}. This conjecture is corroborated by a comparison with strain data (Figure 27). Owing to a decay of the cubic single crystal into an antiferromagnetic multidomain sample at the phase transition, which transforms

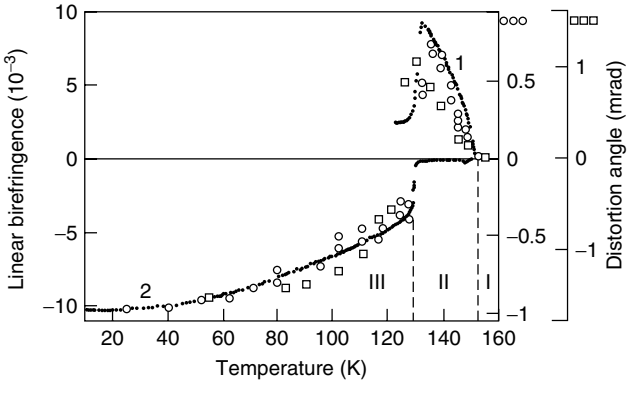

Figure 27. Linear birefringence Δn versus T (solid points) of α-MnS measured at $\lambda = 560\,\mathrm{nm}$ on single T domains selected in phase I (curve 1) and III (curve 2), respectively. Comparison is made with lattice distortion data fitted to the MLB data at low T. (Reproduced from Kleeman *et al.*, 1982, with permission from Elsevier. © 1982.)

into yet another domain network at the second one, the microscopic MLB technique is indispensable.

Antiferromagnetic domains were first postulated by Néel (1948) and first evidenced by MO methods in 1960 on NiO (Slack, 1960; Roth, 1960). These latter authors were able to map domains exhibiting MLB of different sign owing to coupling of strain to spin-pair correlation functions, which give rise to magnetostrictive distortion of the cubic lattice. Figure 28 shows the so-called T (= trigonal) domain pattern of a (111) oriented crystal plate of α-MnS under the polarizing light microscope at $T = 74\,\mathrm{K}$ (Kleemann, Schäfer and van der Heide, 1982). The pattern appears with different contrast depending on the choice of three different orientations of the crossed polarizers, $[\bar{2}11]$, $[1\bar{2}1]$, and $[11\bar{2}]$. These are projections of the three trigonal $\langle 111\rangle$ axes, which are orthogonal to the magnetic easy planes similar to the situation found in NiO (Slack, 1960; Roth, 1960), but not orthogonal to the sample plane. The T_1 domain (optically neutral for all polarizer settings) is missing because of surface compressive stress along [111] arising at the phase transition at $T_N = 129.5\,\mathrm{K}$. According to minimum strain conditions, the crystallographic orientations of the twin walls are restricted to the 110 and 100 planes. Only the walls parallel to $(\bar{1}10)$, $(10\bar{1})$, and $(0\bar{1}1)$ intersect the habit plane perpendicularly along $[\bar{2}11]$, $[1\bar{2}1]$, and $[11\bar{2}]$ (sharp borders), while all other walls are oblique with respect to the habit plane (diffuse borders). It should be noticed that the possibilities of antiferromagnetic domain topography were recently rediscovered using resonant XMLD techniques with polarized synchrotron radiation. Essentially under the same polarization selection rules as applicable to MLB (Roth, 1960), the 12 intraplanar $\langle 11\bar{2}\rangle$ oriented S (= spin) domains within the four T domains have been imaged by XMLD/PEEM on NiO (Hillebrecht *et al.*, 2001).

The intimate interplay between MO permittivity and spin correlations makes magneto-optics a versatile tool to tackle more sophisticated problems of statistical physics. For example, the famous random-field Ising model, one of the standards for microscopic disorder in spin systems (Imry and Ma, 1975), has been studied on diamagnetically diluted uniaxial antiferromagnets like $Fe_{1-x}Zn_xF_2$, $x \lesssim 0.5$, using both MLB (Belanger, Jaccarino and King, 1983) and Faraday rotation (Kleemann, King and Jaccarino, 1986). Peculiarly, both MO techniques reveal the same critical dependence, namely, $(\mathrm{d}\Delta n_\mathrm{m}/\mathrm{d}T) \propto (\mathrm{d}\theta_\mathrm{F}/\mathrm{d}T) \propto c_m$. This is in accordance with field-scaling properties of the leading singularities of all second derivatives of the free energy with respect to T and H. All of them, $(\partial^2 F/\partial H\partial T)$, $(\partial^2 F/\partial H^2)$, $(\partial^2 F/\partial T^2)$, diverge as $H^y|T - T_\mathrm{C}|^{-\alpha}$, with the same $\alpha \approx 0$, but different exponents y emerging from scaling theory (Kleemann, King and Jaccarino, 1986). This is illustrated by Figure 29, which shows the logarithmic

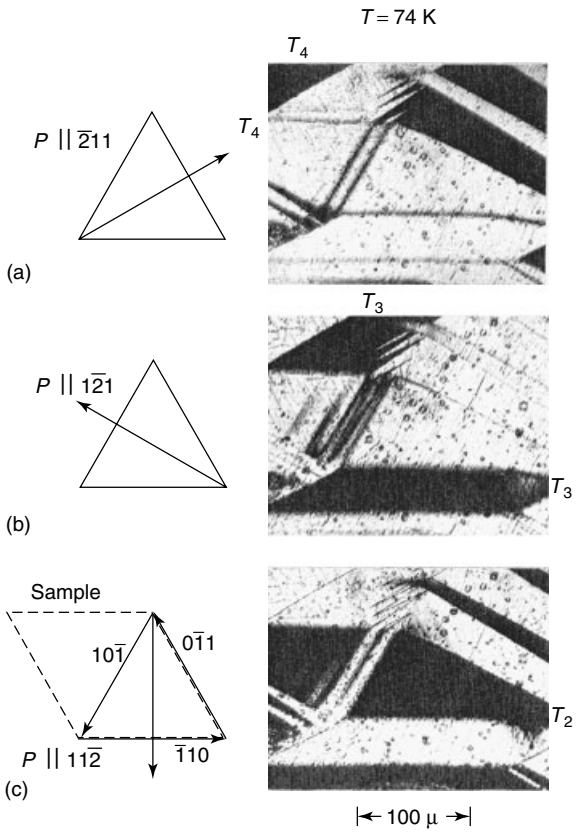

Figure 28. MLB contrast of T domains in phase III of as-grown (111) platelets of α-MnS with thickness 25 μm observed at various settings of the polarizers (left-hand panel). Optically neutral T_j domains ($j = 2$, 3, and 4) are indicated. (Reproduced from Kleeman *et al.*, 1982, with permission from Elsevier. © 1982.)

divergences of $(\mathrm{d}\Delta n_\mathrm{m}/\mathrm{d}T)$ (Belanger, Jaccarino and King, 1983) and $(\mathrm{d}\theta_\mathrm{F}/\mathrm{d}T)$ (Pollak, Kleemann and Belanger, 1988) obtained on $Fe_{0.47}Zn_{.53}F_2$ in different external magnetic fields.

MLB – or its Kramers–Kronig complement MLD – is applicable to domain topography only, whenever the spatial symmetry is broken in the antiferromagnetic phase. For example, all cubic systems become optically anisotropic as collinear spin ordering takes place. This does not hold in uniaxial single crystals, if the magnetic order parameter conserves the axial symmetry. Contrary to frequent belief, this is also valid for the resonant XMLD technique (the XMLD contrast observed on a thin film of $LaFeO_3$ in Figure 18 becomes possible only because of its inherent 'twin' structure containing crystallites with alternate in-plane c axes!). In the case of antiferromagnetic 180° domains, linear MO methods are applicable only if a magnetic field induces a net magnetization and time inversion symmetry becomes broken (Eremenko and Kharchenko, 1987; Dillon, 1991). Figure 30 shows a drastic example, namely, the metamagnetic domain

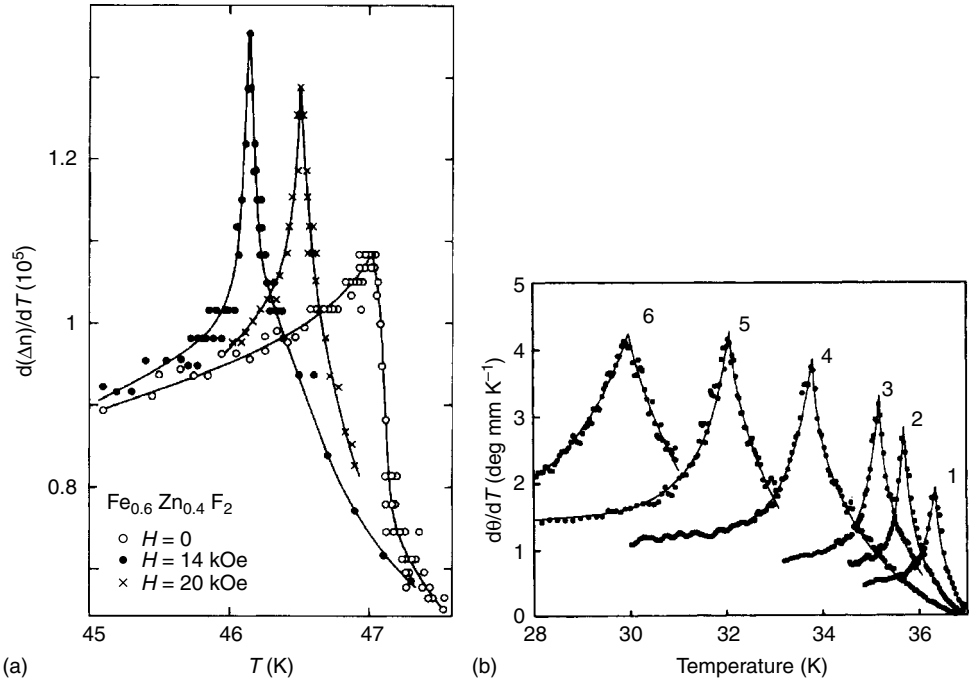

Figure 29. $d(\Delta n)/dT$ (a) and $d(\theta_F)/dT$ of $Fe_{1-x}Zn_xF_2$, $x = 0.40$ (a) and 0.53 (b) as functions of the temperature for magnetic fields $B = 0$, 1.4 and 2.0 T (a), and 1, 1.5, 2, 3, 4, and 5 T (b) applied parallel to [001]. (Reproduced from Belanger *et al.*, 1983, with permission from the American Physical Society. © 1983 (a) and Reproduced from Pollack *et al.*, 1988, with permission from the American Physical Society. © 1988 (b).)

pattern of the uniaxial antiferromagnet $FeCl_2$ in its 'mixed phase', that is, when exposed to sufficiently high axial magnetic field (Kushauer, 1995). The domains show Faraday rotation contrast between strongly magnetized metamagnetic (= paramagnetically saturated) domains (white) embedded in weakly magnetized antiferromagnetic background (black) induced by fields between the critical values, $H_{c1} = 841\,\text{kA/m} < H < H_{c2} = 1420\,\text{kA m}^{-1}$. Magnetostatically stabilized stripe domains are observed, which nucleate as bubbles close to the critical fields (a,t) and form maze-type patterns with minimal mutual distances (h–j) at intermediate fields, $H \approx 1100\,\text{kA m}^{-1}$. Similarities with stripe and bubble domain patterns in ferrimagnetic garnets and strongly perpendicular anisotropic films are obvious (Kooy and Enz, 1960; Thiele 1970; Bobeck and della Torre, 1975; Hubert and Schäfer, 1998).

Domain visualization of uniaxial antiferromagnets in its zero-field ground state has long time been possible only via neutron topograhy (Alperin, Brown, Nathans and Pickart, 1962; Schlenker and Baruchel, 1978), a tedious and time consuming technique (exposure times up to 24 h!), which has a poor spatial resolution in the order of 0.1 mm. Only recently, a purely MO technique was discovered, which is applicable to uniaxial antiferromagnetic crystals, which are based on nonreciprocal properties of the point group involved (Fiebig, Fröhlich, Krichevstov and Pisarev, 1994). It is possible by using nonlinear resonant sum frequency spectroscopy, viz by mapping the interference patterns of time-inversion and non-time-inversion symmetrical contributions to the nonlinear polarization. A model system fulfilling the above symmetry conditions is the axial magnetoelectric antiferromagnet Cr_2O_3, a sample of which shows its domain structure in Figure 31 in right (a,c) and left (b) circular SH light at a photon energy of 2.1 eV (Fiebig, 1995). The technique, although involving a setup with an optical parametric oscillator (OPO) for two-photon spectroscopy in a suitable spectral region, is less expensive than the spin-polarized neutron probe and reveals a much better spatial resolution in the order of 1 µm. It has been applied to a number of nonreciprocal materials. Presently, attention is focused on magnetoelectric and multiferroic materials (Fiebig, 2005) like $HoMnO_3$ (Goltsev, Pisarev, Lottermoser and Fiebig, 2003) and $YMnO_3$ (Fiebig *et al.*, 2002), where access to antiferromagnetic and ferroelectric domain structure was enabled by SHG spectroscopy.

4.4 Magnetophotonic crystals

Starting with the pioneering work of Yablonovich (1987) and John (1987) photonic band gap (PBG) materials or photonic crystals (PCs) have been of utmost interest among theoreticians and experimentalists because of their promising potential in applications in micro- and optoelectronics.

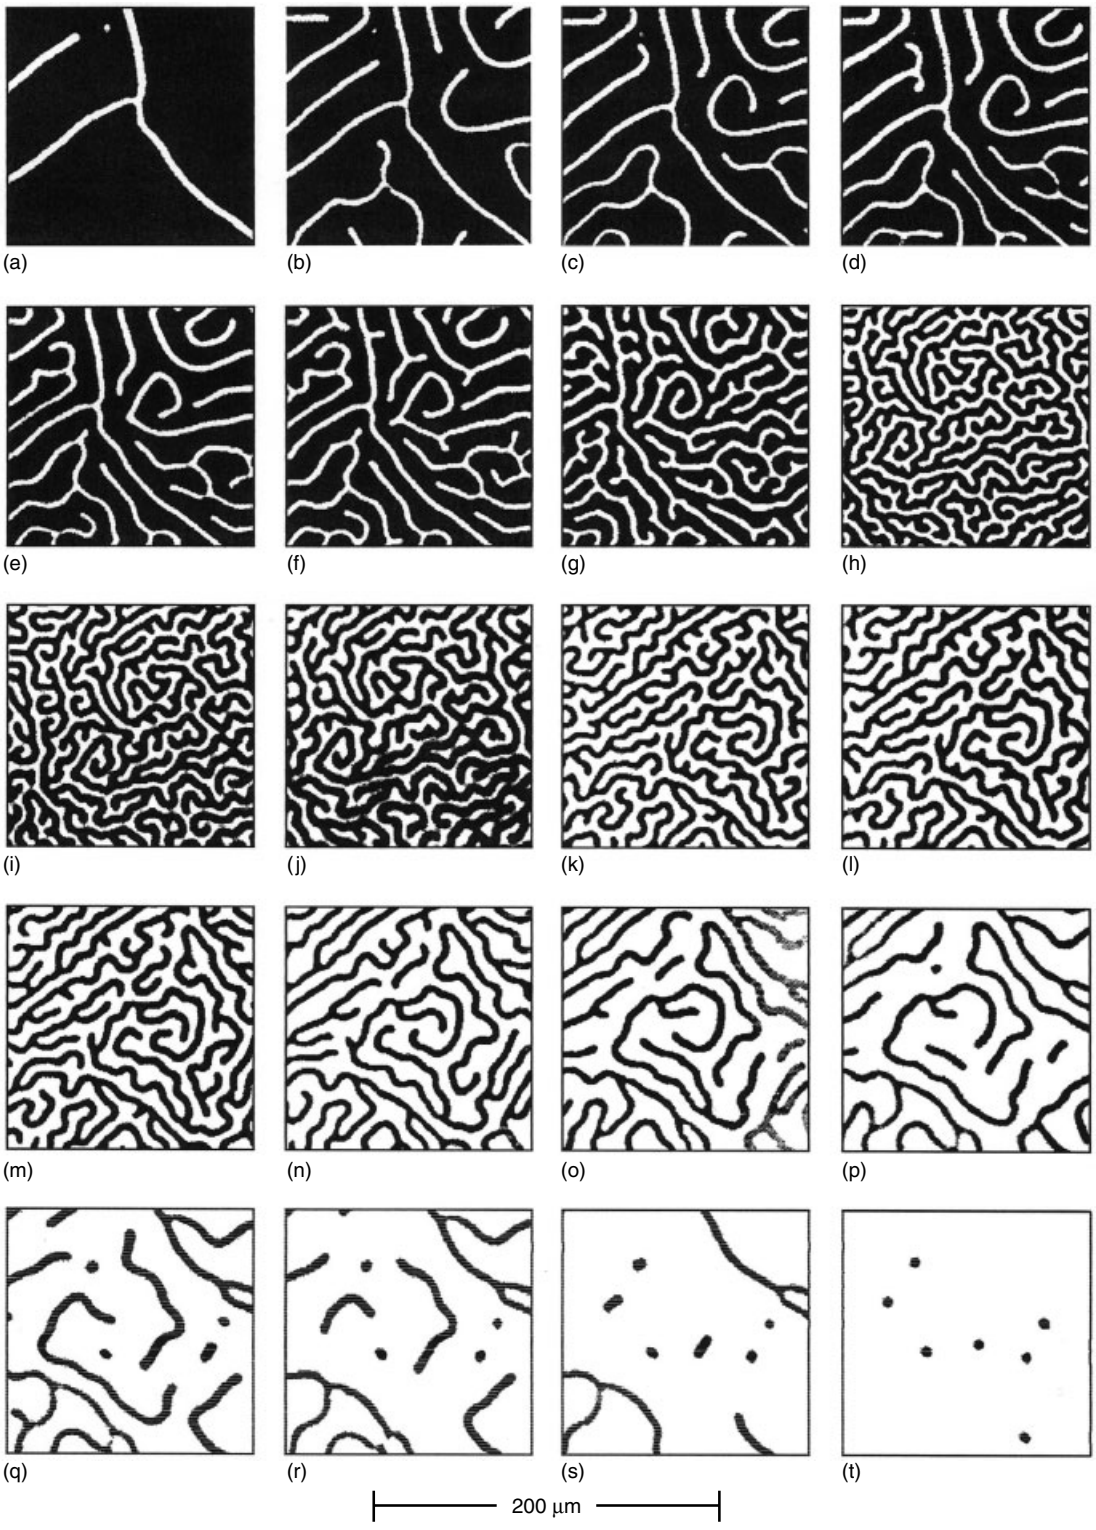

Figure 30. Faraday rotation contrast of metamagnetic domains (white) observed in a (111) platelet (thickness 170 μm) of antiferromagnetic $FeCl_2$ (black) at $T = 10\,\mathrm{K}$ under various axial magnetic fields $481.4 \leq H \leq 1407.3\,\mathrm{kA\,m^{-1}}$. (From Kushauer, 1995.)

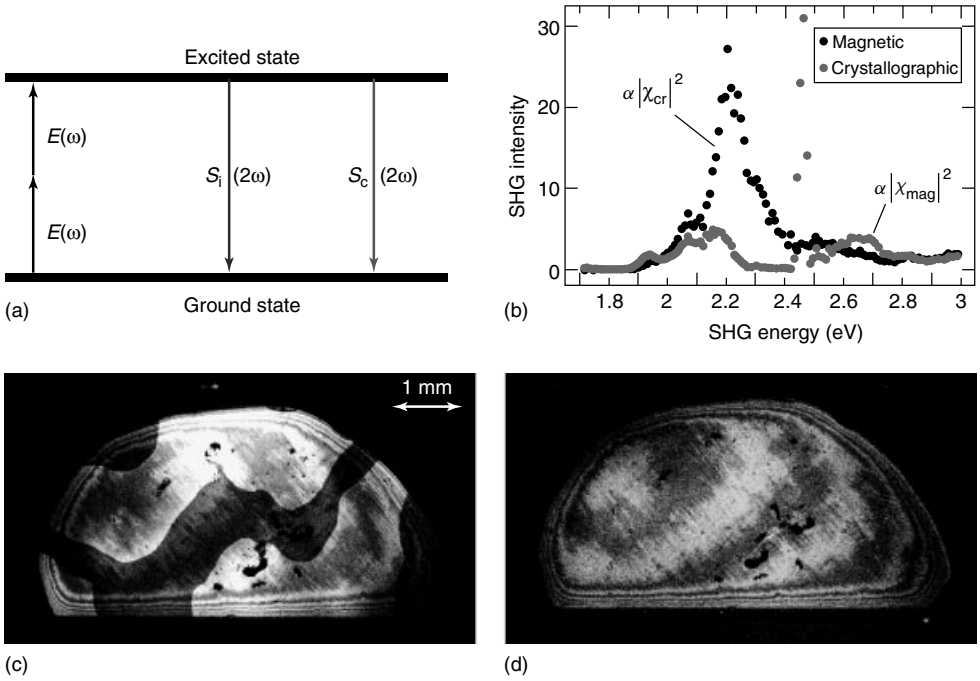

Figure 31. Antiferromagnetic domains in Cr_2O_3 (c) imaged by second harmonic generated intensity contrast due to interference of the crystallographic and magnetic two-photon scattering fields, S_i and S_c (a), respectively, at appropriate resonant frequencies (b). Above $T_N = 308$ K (d) the domain contrast vanishes. (Reproduced from M. Fiebig *et al*., 2001, with permission from Institute of Physics Publishing Ltd. © 2001.)

PCs are one- (1D), two- (2D), or three-dimensional (3D) periodically ordered structures made from materials with different refractive indices. The periods being in the order of the wavelengths of the impinging electromagnetic radiation (microwaves, infrared, or visible light) give rise to interference effects, which finally lead to band formation in the electromagnetic spectrum. A PBG may finally inhibit light propagation for certain frequencies and selected or even arbitrary polarization.

PCs, even those without a PBG, have multiple interesting and useful properties related to the dispersion, anisotropy, and polarization properties of the photonic bands (Joannopoulos, Meade and Winn, 1995). They have, for example, been demonstrated to create efficient dispersion compensation, enhanced nonlinear frequency conversion, to operate as highly efficient Bragg mirrors and to realize the localization of light (Yablonovitch, 1987). The tunability of the optical properties of PCs can open new applications of these materials in integrated-optics devices. Tunability in semiconductor structures may, among others, be achieved by use of magnetic constituents. This leads to the fabrication of magnetic photonic crystals (MPCs), which have attracted much interest in the past 10 years. Review articles about the theory and the experimental realizations of MPCs were published by Lyubchanskii *et al*. (2003), Zvezdin and Belotelov (2004), and Inoue (2006).

Incorporation of magnetic components into PCs can lead to new and interesting phenomena of magneto-optics such as enhanced MCB and MLB (Inoue and Fujii, 1997; Steel, Levy and Osgood, 2000; Levy, Yang and Steel, 2001; Saado, Golosovsky, Davidov and Frenkel, 2002; Dolgova *et al*., 2004). The first PC structures were one-dimensional multilayers with dielectric mirrors ($\lambda/4$ stacks of materials with high and low refractive index) and a transparent magnetic $\lambda/2$ Fabry–Pérot cavity (Figure 32). These '1D MPCs with stacking faults' were designed as to fulfill the optical isolator conditions, viz 45° Faraday rotation and 100% transparency at a given wavelength. This aim could be reached in a very good approximation by Kato *et al*. (2003) with a bilayer number $k = 6$, an enhancement of θ_F by a factor of 150, and an absorption in the order 10^{-6}. Figure 33 (inset) gives an impression of the high finesse of the spectral enhancement of both the optical transmission and the Faraday rotation (enhancement factor 50) of a related MPC, $(SiO_2/Ta_2O_3)_5$/Bi:YIG/$(SiO_2/Ta_2O_3)_5$ (Murzina *et al*., 2004).

The theory of 1D MPCs is related to that of magnetic multilayers (Visnovsky *et al*., 1995), although the layers are coarsened toward micrometer thickness instead of the 'conventional' nanometric periods. However, the matrix formalism to be applied is very similar. A 4×4 transfer-matrix formalism is applicable, which describes the circularly

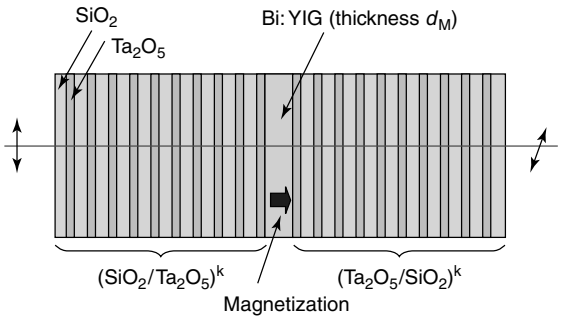

Figure 32. Schematic 1D magnetophotonic crystal containing a Bi:YIG layer as a defect and acting as a Fabry–Pérot resonator with enhanced Faraday rotation of Bi:YIG.

polarized eigenmodes with clock- and anticlock-wise rotation of the electric-field vector (Belotelov and Zvezdin, 2005). In 2D and 3D, the full eigenvalue problem has to be resolved as in classical PC theory (Sakoda, 2004). This means to solve the Helmholtz equation under the constraint of a spatially periodic dielectric constant, $\varepsilon(\mathbf{r})$, a problem which reminds of the equation of motion of electrons in the periodic potential of a crystal. Dispersion relationships, $\omega(\mathbf{k})$, and a band structure emerge for (nonexisting) quasi-longitudinal and (existing) quasitransverse modes, which are vectorial Bloch functions. Taking into account the periodic magneto-optic Voigt parameter (see equation (20)), $Q(\mathbf{r})$ changes the mode behavior in the sense that transverse electric (TE) modes adiabatically transform into transverse magnetic (TM) ones and vice versa. This is a consequence of the gyrotropy of the medium. Peculiarly for the MPC structure, it turns out that the specific Faraday rotation grows sharply, when the frequency approaches the band gap. This can be understood by the fact that the group velocity of the light decelerates appreciably close to the gap. This leads to an increased light-matter interaction (similarly as for the light in the Fabry–Pérot cavity of a 1D MPC) with enhanced MO effects. This was evidenced on a 3D colloidal MPC containing a Faraday active transparent liquid, where the Faraday rotation increases by a factor of 5 within the stop band, whereas it is virtually unaffected outside the stop band (Koerdt, Rikken and Petrov, 2003).

Self-organizing colloidal crystals with magnetic components (Xu *et al*., 2002), inverted magnetically filled opals (Gates and Xia, 2001), and structured ferrofluids(Richardi *et al*., 2002) are presently the most popular candidates of MPC growth. Apart from these artificially prepared magnetic superlattices, natural or artificially prepared magnetic domain structures have been investigated. They may occur as 1D stripe domain patterns or as 2D bubble lattices (Bobeck and della Torre, 1975; Hubert and Schäfer, 1998). Again, as in structural MPCs, mode conversion TE → TM is

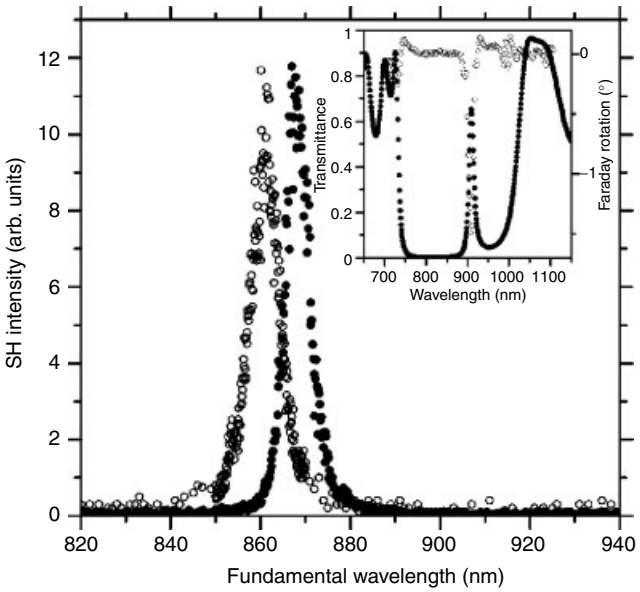

Figure 33. SHG spectra of the MPC with $\lambda_{PBG} \approx 900$ nm measured in the p-in, p-out and s-in, p-out polarization combinations, open and solid circles, respectively. Inset: Transmittance spectra (solid circles) and Faraday rotation angle (open circles) measured at normal incidence. (Reproduced from Murzina *et al*., 2004, with permission from the American Physical Society. © 2004.)

expected (Nikitov and Tailhades, 2001). Applications in MO waveguides (Dötsch *et al*., 2005) are envisaged.

A new aspect of MPCs is the use of optical nonlinearity because of their ability to enhance small effects significantly (Aktsipetrov *et al*., 2005). For example, the modification of the electromagnetic wave dispersion near to the PBG edges allows one to effectively fulfill the phase matching conditions for SHG, if either the fundamental or the SH wave is tuned toward the gap (Dumeige *et al*., 2001). A new domain of nonlinear optics appears as the second- and third-order structural nonlinearities that are combined with the broken time-reversal symmetry owing to the magnetization of ferromagnetic materials. As a result of this combination, SHG and third-harmonic generation (THG) become very sensitive to control by external magnetic impacts. MSHG has, for example, been observed in MPC microcavities formed from a half-wavelength-thick Bi:YIG film sandwiched between two high-finesse dielectric Bragg reflectors (Murzina *et al*., 2004; Fedyanina *et al*., 2004). Apart from the well-known enhancement of the Faraday rotation (Figure 33, inset), this 1D MPC reveals SHG for both s- and p-polarized fundamental radiation, which is resonance enhanced at least by a factor of 10^3 as compared to the intensity outside the PBG (Figure 33, main panel). Magnetization-induced changes of the relative phase of the SH wave are observed using SHG interferometry and reach the factor of 4 in intensity and 180° in phase for directions

opposite to the dc magnetic field. The longitudinal and polar nonlinear MOKEs manifest themselves in a considerable rotation, up to $\theta_K \approx 50^\circ$, of the SH wave polarization. This enhancement is attributed to the fulfillment of the phase-matching conditions for the MSHG effect in layered structures with periodic modulation of both optical (MO) and nonlinear optical parameters. Recently, also a 2D magnetophotonic crystal, viz a hexagonal magnetic bubble lattice, has been shown to reveal enhanced MSHG at the PBG with noticeable influence of an external magnetic field (Dadoenkova *et al*., 2005).

5 CONCLUSION

Magneto-optics in solid-state research and applications has reached a new level as an indispensable tool for magnetic research and applications. Although the traditional tasks are still vivid and most useful, viz applications in MO recording and optical isolators, new techniques have matured in the last 10 years. Partially they are based on sophisticated light sources, which make magneto-optics extremely important, if not irreplaceable. Together with ultrafast laser light sources the limits of magnetic dynamics can now be explored. In conjunction with intense, polarized, and highly resolved synchrotron radiation core level, X-ray spectroscopy has become a routine tool to separate spin from orbital magnetism, to distinguish between contributions of different magnetic elements, and to image magnetic nanodomains both in real and Fourier space. Intense laser light sources are the key to real surface sensitive magnetic explorations via MSHG and to unprecedented possibilities for MO SHG imaging of 180° domains in antiferromagnets. New materials for spintronics and magnetic storage purposes like ultrathin films, multilayers, and patterned nanostructures are preferably investigated by magneto-optic methods for obvious reasons. But there are also new devices like magneto-optic waveguides and magnetophotonic crystals, which are specially designed for magneto-optics and will certainly soon enter the market for tele and data communications. It is probably not too optimistic to predict that (Lyubchanskii *et al*., 2003) 'the use of magnetic materials in combination with dielectrics, metals, and semiconductors can lead to the creation of a new class of devices for photonics applications, and a new direction in photonics called *magnetophotonics*'.

Magnetocaloric Materials

Vitalij K. Pecharsky and Karl A. Gschneidner, Jr.
Iowa State University, Ames, IA, USA

1 INTRODUCTION

Modern society is highly dependent on reliable refrigeration technology. Without this technology: the food supply would be seasonal and limited to locally produced nonperishable items; comfortable living conditions would be impossible everywhere; and many medical advancements, for example, MRI, organ transplantation, organ and tissue cryostorage, and cryosurgery would be impossible. It is startling that all these and other developments in achieving and maintaining temperatures lower than ambient are supported by the technology which remains essentially unchanged from the time it was invented more than a century ago.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

Near-room-temperature refrigeration today is almost entirely based on a vapor-compression refrigeration cycle. Over the years, all parts of a commercial refrigerator, that is, the compressor, heat exchangers, refrigerant, and packaging, were considerably improved due to extended research and development efforts carried out by the academia and industry. Both recently achieved and anticipated improvements in the technology, however, are incremental since conventional refrigeration is already near its fundamental limit of energy efficiency. Furthermore, chlorofluorocarbons (CFCs), hydrofluorocarbons (HFCs), and other chemicals used as refrigerants eventually escape into the environment promoting ozone layer depletion and global warming, and therefore, liquid chemical–based refrigeration is a major factor contributing to deleterious, cumulative changes in the global climate.

Refrigeration is defined as the use of a working body that changes its temperature in response to certain thermodynamic triggers to cool an object. These variations must be achieved quickly, repeatedly, reversibly, and with minimum energy losses. Since a magnetic field easily and effectively couples to magnetic moments of individual atoms in a solid, the magnetic field is one of the common thermodynamic variables that can alter the temperature of a magnetic solid. For instance, heating (but not cooling) of ferromagnetic materials having a measurable hysteresis by a low frequency ac magnetic field is a well-known magnetothermal effect, and this so-called hysteresis heating has been successfully utilized in treating certain tumors by hyperthermia (Borelli, Luderer and Panzarino, 1984). Both heating and cooling of soft ferromagnetic materials in response to increasing and decreasing magnetic fields, respectively, has been known since the latter part of the nineteenth century when Warburg (1881) reported a small but measurable, reversible temperature changes in pure iron in response to magnetic field changes. Today,

this phenomenon is recognized as the *magnetocaloric effect* (MCE) and materials exhibiting large, reversible temperature changes in response to changing magnetic fields are usually referred to as *magnetocaloric materials*.

2 THE MAGNETOCALORIC EFFECT AND ITS SIGNIFICANCE

The magnetocaloric effect – commonly abbreviated as MCE – is one of the most fundamental physical properties of magnetic materials. The MCE describes the behavior of a magnetic solid when it is exposed to a changing magnetic field: its temperature may be appreciably increased or decreased, with both the sign and the extent of the temperature difference between the final and the initial states of the material being dependent on numerous intrinsic and extrinsic factors. The chemical composition, the crystal structure, and the magnetic state of a compound are among the most important intrinsic material parameters that determine its MCE. The extrinsic factors include the temperature, the surrounding pressure, and the sign of the magnetic field change, that is, whether the magnitude of the magnetic field has been raised or lowered. These variables affect the magnetic field–induced temperature changes and therefore play a role in defining the MCE.

The MCE is inherent to every magnetic solid, and has extraordinary fundamental importance because it spans many orders of magnitude over length, energy, and timescales: from quantum mechanics to micromagnetics, from statistical to macroscopic thermodynamics, and from spin dynamics to bulk heat flow and thermal conductivity. Understanding and, ultimately, controlling this vast, many-body and many-parameter landscape is an enormously challenging task, yet even partial successes along the way facilitate greater precision and better control over the design of novel magnetocaloric solids. In other words, knowing how changes in the chemical composition, the crystal structure, and the microstructure affect the physical behavior of solids helps to create an environment in which a material could be tailored to exhibit a specific combination of magnetic and thermal properties.

In addition to its basic scientific significance, the MCE is the cornerstone of near-room-temperature magnetic cooling, which is poised for commercialization in the foreseeable future and may soon become an energy efficient and environmentally friendly alternative to vapor-compression refrigeration technology (Pecharsky and Gschneidner, 1999a; Zimm *et al*., 1998; Zimm, 2003, Tishin and Spichkin, 2003; Gschneidner, Pecharsky and Tsokol, 2005). Practical applications of the MCE, therefore, have the potential to reduce the global energy consumption, and eliminate or minimize the use of ozone depleting compounds, greenhouse gases, and hazardous chemicals.

Among several alternatives to conventional refrigeration (thermoelectric cooling is probably the best known and well developed, yet it remains an energy inefficient technology), *magnetic cooling* has been in and out of the limelight for many decades. Its first application was suggested in late 1920s by Debye (1926) and, independently, by Giauque (1927). One-step cooling from 1.5 to 0.25 K by adiabatically demagnetizing gadolinium sulfate octahydrate was successfully demonstrated by Giauque and MacDougall (1933). Since then, adiabatic demagnetization refrigeration has been and still remains a great tool in achieving ultralow temperatures in many research laboratories. The potential of the magnetic cooling for the near-room-temperature applications, however, remained uncertain before the late 1990s despite two well-known demonstrations that were undertaken in the last quarter of the twentieth century, that is, those by Brown (1976) and Green, Chafe, Stevens and Humphrey (1990).

Today, following a seminal work of Zimm *et al*. (1998), near-room-temperature magnetic refrigeration has quickly caught the attention of both scientists and engineers, and by the end of 2006 more than 20 laboratory-scale magnetic cooling units have been built and tested. Various degrees of success in implementing magnetic refrigeration as a near-room-temperature cooling technology have been reported by Bohigas *et al*. (2000), Hirano *et al*. (2002), Rowe and Barclay (2002a,b), Blumenfeld, Prenger, Sternberg and Zimm (2002), Hirano (2003), Wu (2003), Zimm (2003), Richard, Rowe and Chahine (2004), Clot *et al*. (2004), Shir *et al*. (2005), Lu, Xu, Wu and Jin (2005), Okamura, Yamada, Hirano and Nagaya (2005), Rowe, Dikeos and Tura (2005), Vasile and Müller (2005), and Zimm, Boeder and Chell (2005). Furthermore, as far as the authors of this chapter are aware, a few more units have been built and either tested or are undergoing rigorous evaluation as of the time of writing this article, yet to date there have been no publication concerning these units in any kind of broadly available medium.

Among the many components that need to come together in order to make a successful operating magnetic refrigerator shown schematically in Figure 1 (for more information see recent reviews by Pecharsky and Gschneidner 1999a; Gschneidner, Pecharsky and Tsokol 2005 and a monograph by Tishin and Spichkin 2003), the magnetocaloric compound (the magnetic refrigerant material) is of utmost importance. First, its MCE must be large for a given, usually relatively small magnetic field change, and it should occur in the temperature range between that of the hot and cold heat exchangers of a device. Second, the magnetocaloric material must be chemically stable, noncorrosive, nonflammable, and nontoxic. Third, the compound or alloy must be composed

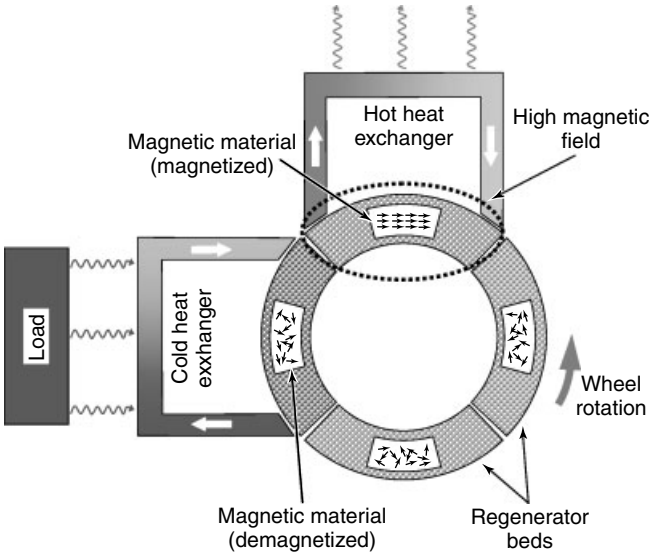

Figure 1. Schematic of a magnetic refrigerator. The wheel consists of regenerator beds packed with a magnetic material. As the wheel rotates, one of the beds (top) enters the high-magnetic-field volume, heating up due to the magnetocaloric effect. Heat exchange fluid flows through the bed removing heat via hot heat exchanger. Previously magnetized and already cooled by the heat exchanged fluid bed exits the high-magnetic-field area (left), cooling down due to reverse magnetocaloric effect. Heat exchange fluid flows through the bed, thereby removing heat from a load.

from readily available, inexpensive components. Fourth, the manufacturing of the material should be economical without adding too much to the cost of the final product, which is a regenerator bed. Finally, in addition to chemical stability, the magnetocaloric material should exhibit sufficient mechanical stability to ensure that the life span of a magnetic refrigerator is comparable to the life span of a modern conventional refrigeration device.

Over the last decade, basic research on the magnetocaloric materials enjoyed nearly explosive growth (Gschneidner, Pecharsky and Tsokol, 2005). As a result, a variety of advanced magnetocaloric materials have been discovered and we are certain that more exciting breakthroughs lie ahead. Magnetocaloric compounds have extended far beyond the prototypical elemental Gd to include binary rare-earth-based alloys, oxide perovskite materials, complex intermetallics, and chalcogenides and pnictides. Recently, novel magnetocaloric materials have been reviewed in detail by Gschneidner, Pecharsky and Tsokol (2005), and therefore, we refer the reader to this review for an exhaustive list of materials along with a large body of numerical MCE data. Instead, this chapter is intended as a primer about the current state of the art in magnetocaloric materials, concentrating on compounds that have a good chance of commercial success in the near future. Even though predictions in science maybe quite unreliable, we will conclude this work with our thoughts on how the science of near-room-temperature magnetocaloric materials will develop and where we are most likely to see the biggest breakthroughs in the next few years to a decade.

3 MAGNETOCALORIC EFFECT: THE FUNDAMENTALS

The MCE arises from the coupling of a magnetic sublattice with an external magnetic field, which affects the magnetic part of the total entropy of a solid. Similar to isothermal compression of a gas, during which positional disorder and the corresponding component of the total entropy of a gaseous system are suppressed, exposing a paramagnet near absolute zero temperature or a ferromagnet near its Curie temperature, T_C, to a change of a magnetic field (B) from zero to any nonzero value, or in general, from any initial value B_i to a final higher value $B_f(\Delta B = B_f - B_i > 0)$ greatly reduces disorder of a spin system. Thus, the magnetic part (S_M) of the total entropy (S) is substantially lowered. In a reversible process, which resembles the expansion of a gas at constant temperature, isothermal demagnetization ($\Delta B < 0$) restores the zero-field magnetic entropy of a system. The MCE, therefore, can be quantified as an extensive thermodynamic quantity, which is the isothermal magnetic entropy change, ΔS_M. The latter is illustrated in Figure 2 as the difference between entropy functions determined at a common given temperature and is marked by a vertical arrow.

When a gas is compressed adiabatically, its total entropy remains constant, whereas velocities of the constituent molecules, and therefore, the temperature of the gas both increase. Likewise, the sum of the lattice and electronic entropies of a solid must change by $-\Delta S_M$ as a result of adiabatic magnetization (or demagnetization) of the material, thus leading to an increase (decrease) of the vibrational entropy of the lattice. This brings about an adiabatic temperature change, ΔT_{ad}, which is an intensive thermodynamic quantity that is also used to measure and quantify the MCE.

In Figure 2, ΔT_{ad} is illustrated as the difference between the two entropy functions determined at the same entropy and is indicated using a horizontal arrow. It is worth noting that in the case of a refrigeration cycle employing a gas, it is a *change of pressure* that results either in the adiabatic temperature change, or the isothermal entropy change, while in the case of a magnetic solid it is a *change of magnetic field* that brings about the entropy or temperature change. No matter how strong the magnetic field is around the sample, the MCE will remain zero as long as the field is kept constant.

For a given material at a constant pressure, the two quantitative characteristics of the MCE, ΔS_{M} and ΔT_{ad}, are functions of the absolute temperature, T, and the magnetic field change, ΔB. The MCE can be easily computed provided the behavior of the total entropy of a compound is known as a *function of temperature* in both the initial and final magnetic fields, for example, see Figure 2:

$$\Delta S_{\mathrm{M}}(T,\Delta B)_{\Delta B} = S(T,B)_{B=B_{\mathrm{f}}} - S(T,B)_{B=B_{\mathrm{i}}} \quad (1)$$

$$\Delta T_{\mathrm{ad}}(T,\Delta B)_{\Delta B} = T(S,B)_{B=B_{\mathrm{f}}} - T(S,B)_{B=B_{\mathrm{i}}} \quad (2)$$

Equation (2), in which the entropy is the independent variable and the temperature is the dependent variable, is straightforwardly employed in direct measurements of the adiabatic temperature change ΔT_{ad}. The temperature of a sample is measured in both B_{i} and B_{f}, that is, before and after the magnetic field has been altered. The difference between the two temperatures yields the intensive MCE value, for example, see Gopal, Chahine, Földeaki and Bose (1995), Gopal, Chahine and Bose (1997), and Dan'kov, Tishin, Pecharsky and Gschneidner (1997), which is usually reported as a function of temperature for $B_{\mathrm{i}} = 0$.

At equilibrium, both ΔS_{M} and ΔT_{ad} are correlated with the magnetization (M), magnetic flux density (B), heat capacity at constant pressure (C_P), and absolute temperature by one of the following fundamental equations derived from the well-known Maxwell relationships and general thermodynamics:

$$\Delta S_{\mathrm{M}}(T,\Delta B)_{\Delta B} = \int_{B_{\mathrm{i}}}^{B_{\mathrm{f}}} \left(\frac{\partial M(T,B)}{\partial T}\right)_B \mathrm{d}B \quad (3)$$

$$\Delta T_{\mathrm{ad}}(T,\Delta B)_{\Delta B} = -\int_{B_{\mathrm{i}}}^{B_{\mathrm{f}}} \left(\frac{T}{C_P(T,B)} \times \frac{\partial M(T,B)}{\partial T}\right)_B \mathrm{d}B \quad (4)$$

As immediately follows from equations (1)–(4), materials whose total entropy is strongly influenced by a magnetic field and whose magnetization varies rapidly with temperature in any magnetic field are expected to exhibit an appreciable MCE. The MCE usually peaks when $|(\partial M(T,B)/\partial T)_B|$ is the greatest, that is, around T_{C} in a conventional ferromagnet or near absolute zero temperature in a paramagnet. The MCE of a simple ferromagnet is gradually lowered both below and above T_{C}, as is clearly seen in Figure 3.

Equations (3) and (4) are applicable to ferromagnets that magnetically order via a second-order phase transformation and they give correct estimates of the MCE for the first-order phase transition materials, yet both equations fail to describe the MCE in the vicinity of a truly discontinuous first-order phase transition when either or both $|[\partial M(T,B)/\partial T]_B|$ and $[T/C_P(T,B)]_B$ do not exist or cannot be accurately measured [1]. Equations (1) and (2), on the other hand, define

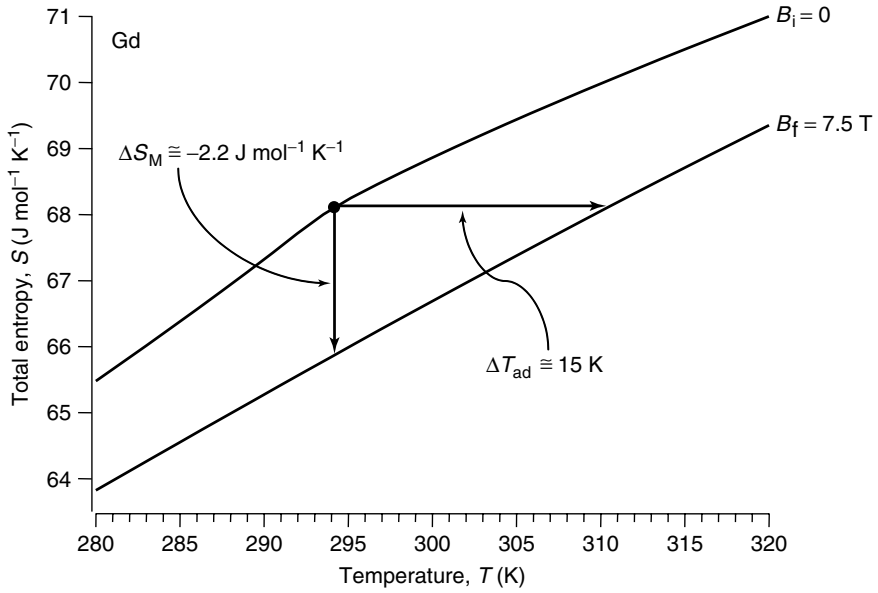

Figure 2. The total entropies of Gd shown as functions of temperature in 0 and 7.5 T magnetic fields near the Curie temperature of the metal ($T_{\mathrm{C}} = 294$ K). The vertical arrow represents the isothermal magnetic entropy change, ΔS_{M}, while the horizontal arrow is the adiabatic temperature change, ΔT_{ad}, both for the case when Gd is magnetized at T_{C}.

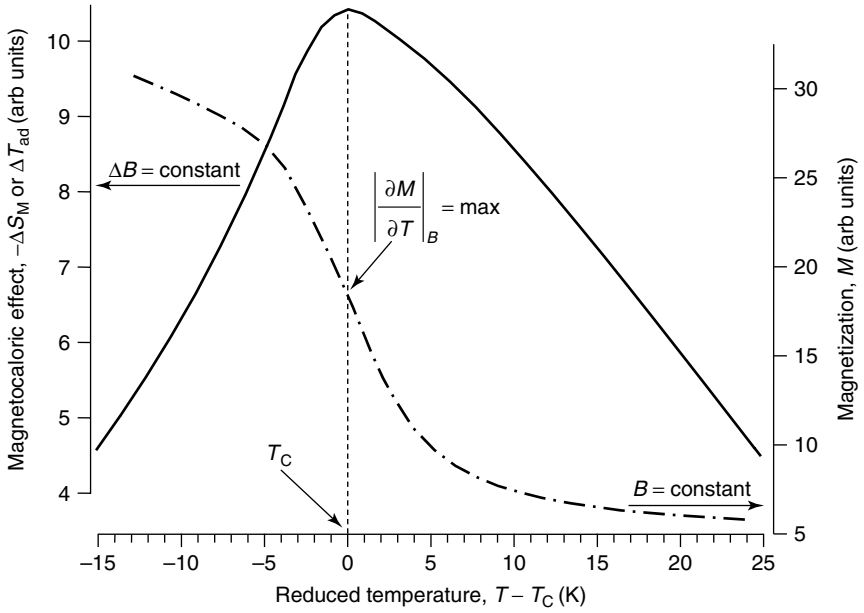

Figure 3. The characteristic temperature dependencies of the magnetocaloric effect (for a fixed magnetic field change ΔB, solid line, left-hand scale) and the magnetization (for a constant magnetic field B, dash-dotted line, right-hand scale) of a soft ferromagnetic material near its Curie temperature, T_C.

the MCE regardless of the thermodynamic nature of the phase transformation that occurs, if any, in a material.

For a first-order phase transition, it is also possible to employ an approximation, which is based on the Clausius–Clapeyron equation to determine the entropy change, ΔS:

$$\left(\frac{\mathrm{d}B}{\mathrm{d}T}\right)_{\mathrm{eq}} = -\left(\frac{\Delta S}{\Delta M}\right)_T \tag{5}$$

In equation (5), the left-hand-side derivative is taken under equilibrium conditions, that is, when the Gibbs free energies of the two phases are identical. For the right-hand side, $\Delta S = S_2 - S_1$ and $\Delta M = M_2 - M_1$, where the subscripts 1 and 2 correspond to the states of the material in the initial and final magnetic fields, respectively. Obviously, equation (5) is only applicable when B_f is strong enough to complete the transformation from state 1 to state 2 and when the quantity $\mathrm{d}B/\mathrm{d}T$ at equilibrium is known. In other words, the $B - T$ phase diagram for the system must be well established. By combining equations (3) and (4) with equation (5) and postulating that $T/C_P(T,B)$ is constant (for a true first-order phase transition the magnetic field has no effect on the heat capacity other than shifting the transition temperature), the following proportionality can be written for the adiabatic temperature change:

$$\Delta T_{\mathrm{ad}} \propto \left(\frac{T}{C_P(T,B)}\right)_B \left(\frac{\mathrm{d}B}{\mathrm{d}T}\right)_{\mathrm{eq}} \Delta M \tag{6}$$

The extensive measure of the MCE is indeed an irreplaceable tool enabling a quick and reasonably accurate way of gauging whether or not a compound is suitable as a magnetocaloric material (e.g., see Földeaki, Chahine and Bose, 1995). In this context, it is worthwhile to remind the reader that while a good magnetocaloric material must have as large ΔS_M as possible, it must also have the largest possible ΔT_{ad} to be competitive with known prototypic MCE materials. In other words, one must be careful when comparing the cooling potential of closely related materials (e.g., two metallic alloys containing different lanthanides or two perovskite-type oxide materials) exhibiting similar ΔS_M over vastly different temperature ranges or chemically dissimilar materials (such as a lanthanide-containing intermetallic compound with a perovskite-type oxide) over the same range of temperatures based solely on the magnitudes of ΔS_M. Caution should be exercised because absolute temperature and heat capacity are both factored in the definition of the adiabatic temperature change, see equations (4) and (6). Furthermore, one should always be aware of both random and systematic errors, which when combined may reach 25%, depending on the temperature range and the experimental technique that was employed to measure the magnetocaloric properties of a material. These and other related subjects have been extensively discussed in the past and we refer the reader to critical assessments written by Pecharsky and Gschneidner (1999b, 2001) and Pecharsky, Gschneidner, Pecharsky and Tishin (2001).

4 THE BENCHMARK MCE MATERIAL – GADOLINIUM

As far as near-room-temperature applications are concerned, the rare-earth metal Gd is truly a benchmark magnetic refrigerant material. It exhibits excellent magnetocaloric properties, which are difficult to improve upon. Not surprisingly, the metal has been employed in each of the early demonstrations of near-ambient cooling by the MCE (Brown, 1976; Green, Chafe, Stevens and Humphrey, 1990). Gadolinium was indeed used as the refrigerant powering the first successful proof-of-principle refrigerator device (Zimm *et al*., 1998). Metallic gadolinium has constituted the whole or at least a major part of every magnetic regenerator bed in every near-room-temperature magnetic cooling machine built and tested to date (Bohigas *et al*., 2000; Hirano *et al*., 2002; Rowe and Barclay, 2002a,b; Blumenfeld, Prenger, Sternberg and Zimm, 2002; Hirano, 2003; Wu, 2003; Zimm, 2003; Richard, Rowe and Chahine, 2004; Clot *et al*., 2004; Shir *et al*., 2005; Lu, Xu, Wu and Jin, 2005; Okamura, Yamada, Hirano and Nagaya, 2005; Vasile and Müller 2005; Zimm, Boeder and Chell, 2005).

Pure Gd metal adopts the simplest, hexagonal close-packed crystal structure, and it orders ferromagnetically at $T_C = 294\,K$ (this value is representative of a 99.95+ wt% pure metal, but can be lower in an impure metal (see Dan'kov, Tishin, Pecharsky and Gschneidner, 1998). Below its Curie temperature, the magnetic moments of all Gd atoms align parallel to the c axis of the crystal (the easy magnetization direction) but for $T < 232\,K$ the moment direction begins to deviate from the c axis reaching a maximum of $\sim 65^\circ$ for $T = 180\,K$ (Cable and Wollan, 1968). The moments can be realigned with the c axis by a weak magnetic field. Since magnetization and heat capacity are two most relevant physical properties defining the MCE, see equations (1)–(4), these are displayed for reference in Figures 4 and 5, respectively, for a Gd single crystal (Dan'kov, Tishin, Pecharsky and Gschneidner, 1998). Even though, the magnitude of $|\partial M/\partial T|_B$ decreases with the increasing magnetic field (Figure 4), the absolute value of the derivative is always maximized in the immediate vicinity of T_C and remains substantial in magnetic fields of 5 T and higher. The zero-field heat capacity (Figure 5) exhibits a λ-type maximum, which is typical for many second-order ferromagnetic ordering transitions. As the magnetic field increases, the sharp peak in heat capacity becomes more and more rounded, that is, the heat capacity below the zero-field peak is suppressed, while it becomes enhanced above T_C.

Large $|\partial M/\partial T|_B$ and large changes of the heat capacity induced by the magnetic field imply the presence of the large MCE in Gd. The isothermal magnetic entropy change, calculated using equations (1) and (3) from the heat capacity and magnetization data, respectively, is shown in Figure 6. This figure indicates that the MCE computed from the two different types of experimental data (compare the results for a 2 and 5 T magnetic field changes) match well, provided experimental measurements have been performed with sufficient accuracy. Furthermore, the results of Figure 6 clearly show that as the magnetic field increases, the derivative of the MCE with respect to the magnetic field decreases (both ΔT_{ad} and ΔS_M are nearly proportional to

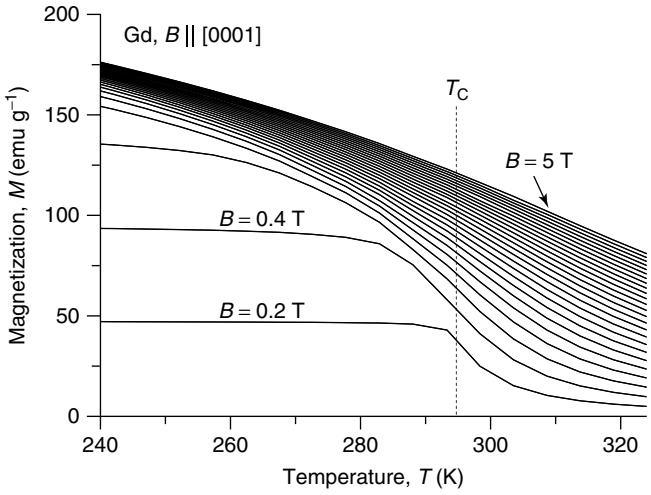

Figure 4. The magnetization of Gd single crystal measured in magnetic fields ranging from 0.2 to 5 T. Every $M(T)$ curve is separated from its nearest neighbor(s) by a fixed difference in the magnetic field, that is, $\Delta B = 0.2\,T$. The magnetic field vector was parallel to the [0001] direction during each measurement.

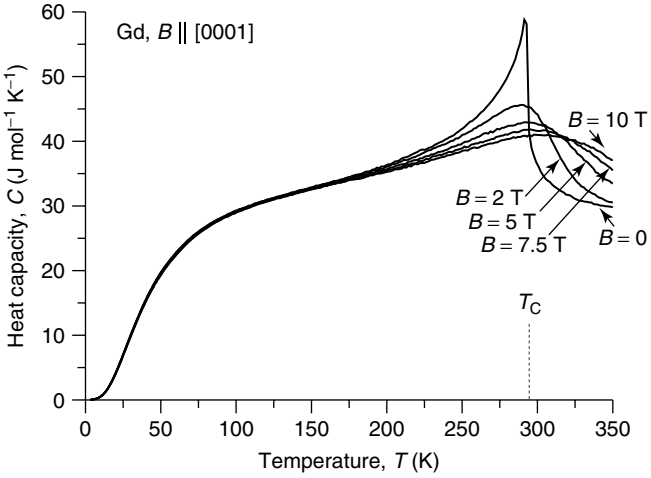

Figure 5. The heat capacity of single crystal Gd measured in various constant dc magnetic fields with the magnetic field vector parallel to the [0001] direction.

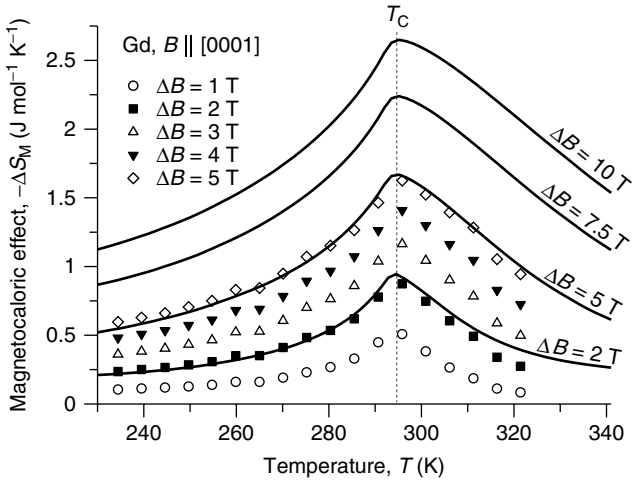

Figure 6. A comparison of the magnetocaloric effect (isothermal magnetic entropy change) of single crystalline Gd calculated from the magnetization data shown in Figure 4 (symbols) and the heat capacity data shown in Figure 5 (solid lines).

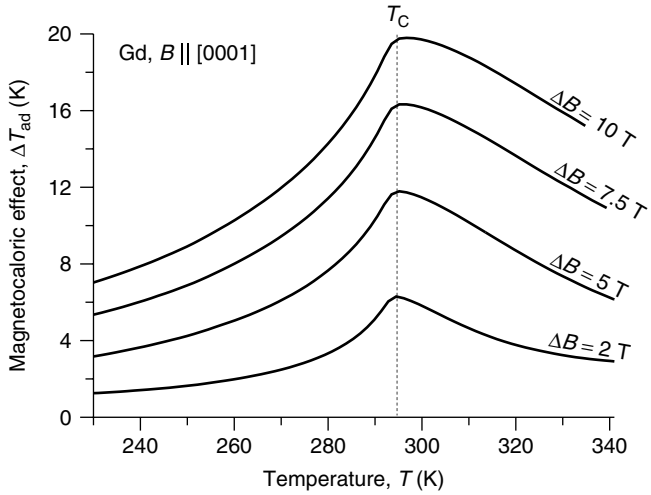

Figure 7. The magnetocaloric effect (adiabatic temperature change) of single crystalline Gd calculated from the heat capacity data shown in Figure 5.

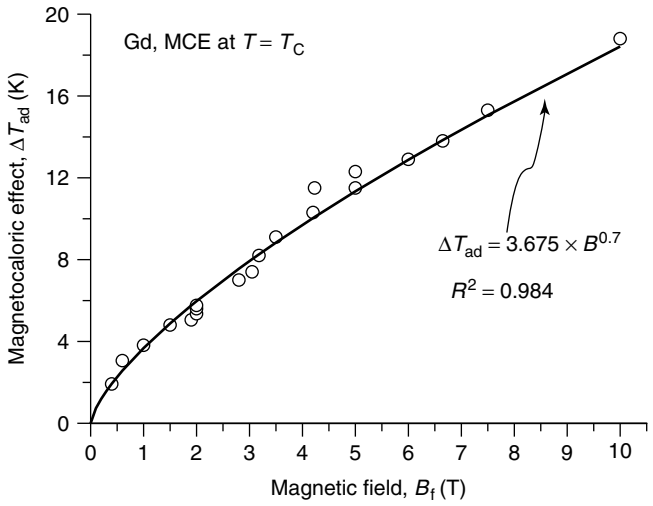

Figure 8. The magnetocaloric effect of Gd at its Curie temperature, shown as a function of the final magnetic field, B_f, for $B_i = 0$, both measured directly and calculated from heat capacity data by different authors (symbols) and the least squares fit assuming power-law dependence of the MCE on the magnetic field. See Dan'kov, Tishin, Pecharsky and Gschneidner (1998) and Gschneidner and Pecharsky (2000) for a list of references and sources of the experimental MCE data.

$B^{2/3}$, that is, d(MCE)/d$B \propto B^{-1/3}$, see Oesterreicher and Parker, 1984). In other words the highest specific MCE (i.e., the MCE per unit field change) always occurs near zero magnetic field. The intensive MCE of Gd, calculated using equation (2) from the data presented in Figure 5, is illustrated for four different magnetic field changes in Figure 7. Similar to ΔS_M, ΔT_{ad}, peaks at T_C and d(ΔT_{ad})/dB is also substantially reduced as B increases. The nearly $B^{2/3}$ dependence of the ΔT_{ad} of Gd is illustrated in Figure 8, where experimental measurements reported by numerous authors (see Dan'kov, Tishin, Pecharsky and Gschneidner, 1998; Gschneidner and Pecharsky, 2000) exhibit an excellent fit of the MCE data to the $B^{0.7}$ behavior.

It is worth noting that the magnetocrystalline anisotropy of Gd in fields exceeding a few tenths of a tesla is negligible (Dan'kov, Tishin, Pecharsky and Gschneidner, 1998), and therefore, the results shown in Figures 4–7 change little when the magnetic field is applied along a different crystallographic direction, or even for a polycrystalline Gd, provided the latter is as pure as the single crystal used to collect these data (the purity of the metal was 99.98 wt%). The behavior of the MCE of Gd illustrated in Figures 6 and 7 is quite universal for materials with second-order paramagnetic–ferromagnetic phase transformations. The differences between the MCE of Gd and those of other second-order phase transition materials mainly lie in differences in the absolute values of the MCE for the same magnetic field change, the temperature of the peak, and how quickly the derivative, d(MCE)/dB, is suppressed by the increasing magnetic field. To illustrate this universality, we show in Figure 9 the adiabatic temperature change of five different magnetocaloric materials, all of which order magnetically via second-order transformations at various temperatures ranging from ∼14 to ∼294 K. One of the five materials – elemental dysprosium – orders antiferromagnetically but magnetic fields exceeding ∼2 T transform the metal into a collinear ferromagnet, thus the behavior of the MCE

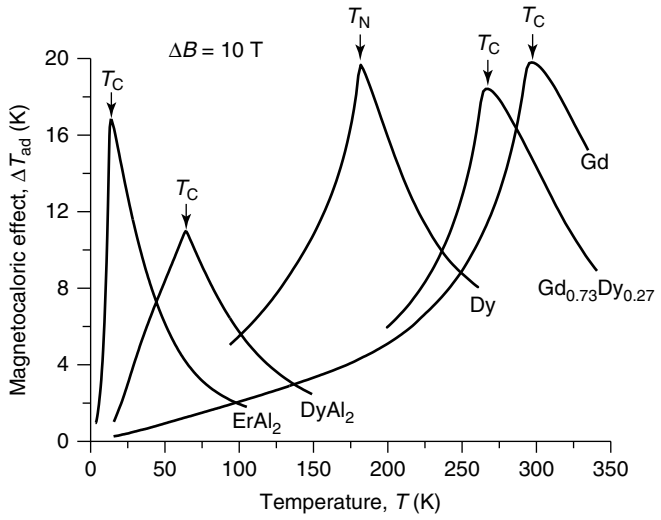

Figure 9. The magnetocaloric effect of polycrystalline $ErAl_2$ (Gschneidner, Pecharsky and Malik, 1996), polycrystalline $DyAl_2$ (Gschneidner, Pecharsky and Malik, 1996), single crystalline Dy with the magnetic field vector parallel to the *a* axis (Chernyshov *et al*., 2005), polycrystalline $Gd_{0.73}Dy_{0.27}$ (Pecharsky and Gschneidner, 1995), and single crystalline Gd with the magnetic field vector parallel to the *c* axis (Dan'kov, Tishin, Pecharsky and Gschneidner, 1998) as calculated from heat capacities measured in a 0 and 10 T magnetic field.

near the Neél temperature of Dy is nearly identical to that of other ferromagnets [2].

5 THE GIANT MAGNETOCALORIC EFFECT

Rising interest in both the fundamental science and potential applications of advanced magnetocaloric materials has been sparked by recent discoveries of new compounds exhibiting a MCE much larger than those found in the vast majority of previously known compounds, including elemental Gd. The most notable examples that originated a modern pool of advanced magnetocaloric materials are FeRh (Annaorazov *et al*., 1992), $La_{0.8}Ca_{0.2}MnO_3$ (Guo *et al*., 1997), and $Gd_5Si_2Ge_2$ and related $Gd_5(Si_xGe_{4-x})$ alloys (Pecharsky and Gschneidner, 1997a,b,c); the latter references also coined the phrase 'the giant magnetocaloric effect' (GMCE) materials. A few years later, several other families of materials have been shown to also exhibit a GMCE at temperatures close to ambient. These include $Tb_5Si_2Ge_2$ (Morellon *et al*., 2001), MnAs and $MnAs_{1-x}Sb_x$ compounds (Wada and Tanabe, 2001; Gama *et al*., 2004), $La(Fe_{1-x}Si_x)_{13}$ alloys (Hu *et al*., 2001) and their hydrides $La(Fe_{1-x}Si_x)_{13}H_y$ (Fujita, Fujieda, Hasegawa and Fukamichi, 2003), $MnFeP_{0.45}As_{0.55}$ and related $MnFeP_xAs_{1-x}$ alloys (Tegus, Brück, Buschow and de Boer, 2002; Brück *et al*., 2003), and $Ni_{2\pm x}Mn_{1\pm x}Ga$ ferromagnetic shape memory alloys (Albertini *et al*., 2004; Pasquale, Sasso and Lewis, 2004; Zhou, Li, Kunkel and Williams, 2004).

Today, it has been well established that the GMCE arises from magnetic field–induced magnetostructural first-order transformations. Upon the application of a magnetic field, the magnetic state of a compound changes from a paramagnet or an antiferromagnet to a nearly collinear ferromagnet simultaneously with either a martensitic-like structural change (e.g., see Morellon *et al*., 1998; Choe *et al*., 2000), or is accompanied by a phase volume discontinuity but without a clear crystallographic modification (Fujita, Fukamichi, Koyama and Watanabe, 2004). When the system undergoes a first-order phase transition, then the behavior of the total entropy as a function of temperature reflects a discontinuous (in reality almost always continuous except for some ultrapure lanthanides, see Pecharsky, Gschneidner and Fort, 1996; Gschneidner, Pecharsky and Fort, 1997) change of entropy at a critical temperature, T_t. Figure 10 shows a schematic $T - S$ diagram modeling discontinuous entropy changes in a $Gd_5Si_2Ge_2$ compound near the magnetostructural transition in a 0 and 2 T magnetic fields. A magnetic field has a small effect on the heat capacity both below and above the first-order phase transition temperature, but T_t increases with the increasing magnetic field at a rate of approximately $4\,K\,T^{-1}$ (Pecharsky, Gschneidner and Pecharsky, 2003). The phase transition in the magnetic field B_i occurs at temperature T_{t,B_i}, and the enthalpy of this transformation is ΔH_{B_i}. The discontinuous equilibrium change of the entropy at T_{t,B_i} totals $\Delta S_{B_i} = \Delta H_{B_i}/T_{t,B_i}$. Likewise, the phase transition in the magnetic field B_f occurs at T_{t,B_f}, the enthalpy of this transformation is ΔH_{B_i}, and the equilibrium entropy change is $\Delta S_{B_f} = \Delta H_{B_f}/T_{t,B_f}$. It was shown by Pecharsky, Gschneidner, Pecharsky and Tishin (2001) that for relatively small magnetic fields, that is, those that are most suitable for commercial near-room-temperature magnetic refrigeration applications, the maximum MCE in a first-order phase transition material can be defined as follows:

$$\Delta S_M \cong \frac{\Delta H_{B_i}}{T_{t,B_i}} \cong \frac{\Delta H_{B_f}}{T_{t,B_f}} \tag{7}$$

$$\Delta T_{ad} \cong \frac{\partial T_t}{\partial B}(B_f - B_i) \tag{8}$$

Equation (8) additionally assumes that the derivative, $\partial T_t/\partial B$, is constant.

Comparing the schematics presented in Figures 10 and 2 and considering equations (7) and (8) it is easy to see that for *first-order system*s one has to be careful when evaluating the magnetocaloric properties of different materials in relatively small magnetic fields. Thus, a compound with a large ΔS_M

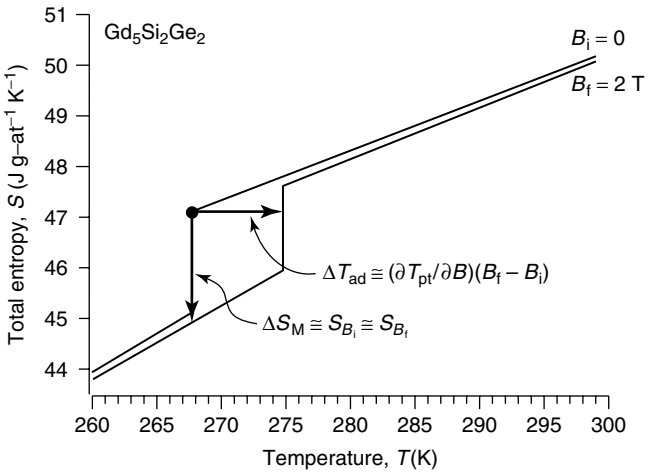

Figure 10. The idealized schematic of the $S-T$ diagrams of $Gd_5Si_2Ge_2$ in the vicinity of the magnetostructural transition in magnetic fields of 0 and 2 T. The thick arrows designate two measures of the magnetocaloric effect at T_C.

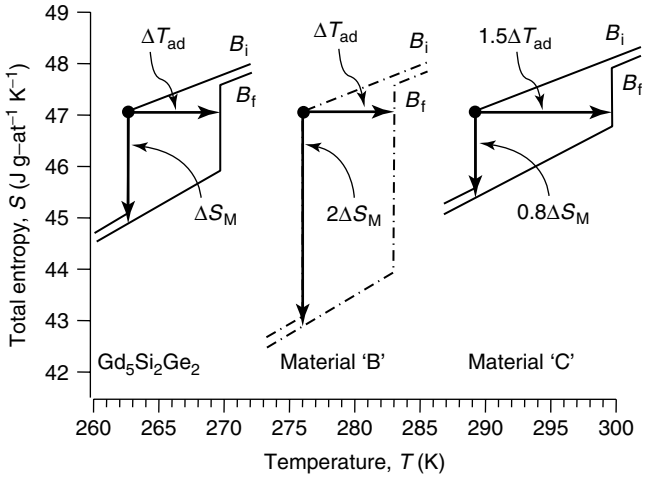

Figure 11. Schematic $S-T$ diagrams of three different materials illustrating independence of both the extensive and intensive magnetocaloric effects in small magnetic fields.

may not necessarily be a compound with a large ΔT_{ad}. Quite to the contrary, it is possible that among the two, the compound exhibiting a smaller ΔS_M has a larger ΔT_{ad}. To illustrate these situations, we show in Figure 11 schematic $T-S$ diagrams of two hypothetical materials 'B' and 'C' together with the same for $Gd_5Si_2Ge_2$. Material 'B' has ΔS_M twice as large as that of the $Gd_5Si_2Ge_2$, yet the adiabatic temperature changes of both materials are identical. Material 'C' has a ΔS_M, which is smaller by 20% but its ΔT_{ad} is 1.5 times that of $Gd_5Si_2Ge_2$.

The behavior of both the extensive and intensive measures of the GMCE in first-order phase transition materials is different when compared to the conventional MCE in second-order phase transition compounds, as can be easily seen from Figure 12 when compared to Figures 3, 6, 7 and 9. First, especially for small magnetic fields, the GMCE is much larger than the conventional MCE (also see Figure 3 in a review by Gschneidner, Pecharsky and Tsokol, 2005). Second, the width of the GMCE becomes broader as ΔB increases, but it broadens asymmetrically toward one side, away from the phase transition temperature. Third, as ΔB increases, both the ΔS_M and the ΔT_{ad} increase rapidly for small fields with the corresponding derivatives ($\partial \Delta S_m/\partial \Delta B$ and $\partial \Delta T_{ad}/\partial \Delta B$) exhibiting a clear tendency toward saturation. As a matter of fact, when the magnetic field is strong enough to complete the transformation, the magnitudes of the ΔS_M discontinuities remain truly identical (see the left-hand sides of the peaks in Figure 12(a) at $\Delta B = 5$ and 7.5 T). Considering Figure 10, these discontinuities correspond to $\Delta S_{B_i} = \Delta H_{B_i}/T_{t,B_i}$ and the observed modest rise of the background under ΔS_M peaks is due to magnetic field effects on the magnetic entropy of the material in the ferromagnetic state, just as in other materials exhibiting conventional MCE. As was shown recently by Chernyshov *et al.* (2005), the calculated magnetic entropy change in Dy in the vicinity of its first-order magnetic phase transition at $T = 90$ K matches the entropy change of the spontaneous ferromagnetic FM $\rightarrow$ antiferromagnetic AFM phase transformation measured directly in a zero magnetic field (Pecharsky, Gschneidner and Fort, 1996) to within 2%.

6 ROLE OF THE STRUCTURAL CHANGE IN THE GMCE

Although crystallographic details of the magnetic field–induced structural changes are well-documented at least for some of the GMCE materials (Pecharsky, Holm, Gschneidner and Rink, 2003; Holm *et al.*, 2004), the contribution of crystallographic changes to the MCE presents an interesting basic science question. *Ab initio* calculations of the entropies involved in the magnetostructural phase changes are difficult, to say the least, and therefore, we will provide insight into this question using some of the available experimental data. We concentrate on $R_5(Si_{4-x}Ge_x)$ compounds, where R is a rare-earth element, because alloys with R = Gd that have nearly the same composition (x), and therefore, have closely spaced Curie temperatures, can be prepared in two different crystal structures around $x = 2$ in the paramagnetic state (Pecharsky *et al.*, 2003). The magnetic ordering in these materials occurs via a second-order phase transformation when $x < 1.91$ because both the paramagnetic and ferromagnetic $Gd_5(Si_{4-x}Ge_x)$ phases have the same orthorhombic Gd_5Si_4-type structure and these alloys exhibit

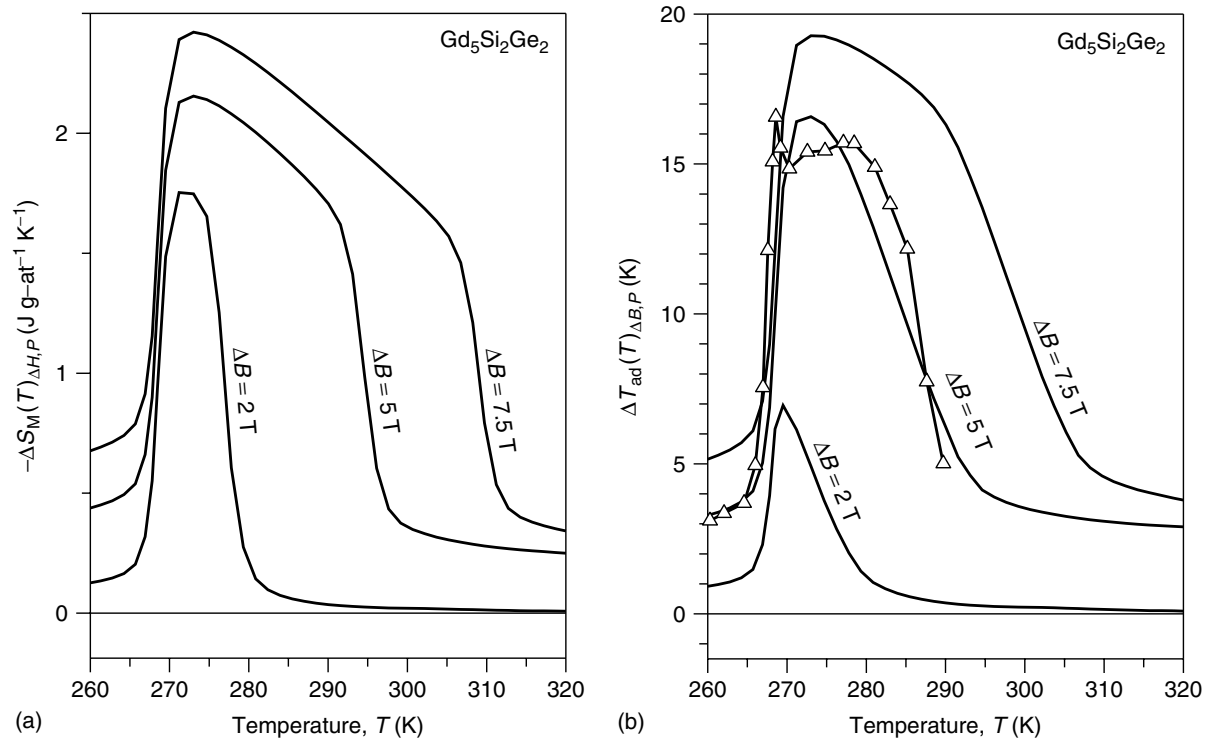

Figure 12. The magnetocaloric effects of $Gd_5Si_2Ge_2$ shown as functions of temperature for three different magnetic field changes: from 0 to 2 T, from 0 to 5 T, and from 0 to 7.5 T calculated from heat capacity data. The open triangles represent the MCE measured directly for a magnetic field change from 0 to 5 T.

a conventional MCE. When $x \geq 1.91$, the paramagnetic $Gd_5(Si_{4-x}Ge_x)$ phases adopt the monoclinic $Gd_5(Si_2Ge_2)$-type structure and order ferromagnetically concurrently with a structural change to the orthorhombic Gd_5Si_4-type structure. This results in a first-order paramagnetic to ferromagnetic transformation and yields the GMCE, see Figure 12.

Taking into consideration this difference in the thermodynamic nature of phase transitions occurring in closely related intermetallic phases, in Figure 13 we illustrate the behavior of the total entropies of $Gd_5(Si_{2.5}Ge_{1.5})$ and $Gd_5(Si_2Ge_2)$ in 0 and 7.5 T magnetic fields. The former compound orders ferromagnetically in a conventional second-order manner at $T_C = \sim 312$ K, while the latter material undergoes a first-order magnetostructural transition at $T_C = \sim 270$ K. Since the Curie temperatures of the two materials are slightly different, all data in Figure 13 are plotted as functions of the reduced temperature, $T - T_t$, where T_t is taken just above T_C as the temperature at which the magnetostructural transformation in $Gd_5(Si_2Ge_2)$ is complete. For clarity, the total entropy functions of $Gd_5(Si_{2.5}Ge_{1.5})$ were also reduced by subtracting a constant value of ~ 5.5 J/g-at K to match the total zero magnetic field entropy of $Gd_5(Si_2Ge_2)$ just below the magnetostructural transition temperature.

As expected from the similarity of the chemical compositions, identical crystallography, and ferromagnetism, the total entropy functions of the two materials after normalization show nearly indistinguishable behavior in a zero magnetic field immediately below their respective Curie temperatures. A major deviation between the two entropy functions occurs in the vicinity of T_C, where the entropy of $Gd_5(Si_2Ge_2)$ is increased by the change in structural entropy $\Delta S_{str} = \Delta H_{str}/T_t$, where ΔH_{str} is the enthalpy or latent heat of a first-order structural phase transformation. As is easily seen from Figure 13, the two zero magnetic field entropy functions continue to behave very similarly above the T_C; in fact, the difference between them remains nearly constant and is equal to ΔS_{str}. Once again, we relate this similarity in the behavior of the two entropies to close relationships between crystallography and magnetism of these two compounds.

The total entropies of the two materials after the application of the magnetic field do not match as well as the zero magnetic field entropies do, as is also clearly seen in Figure 13. This mismatch is related to different effects of the magnetic field on conventional ferromagnets, such as $Gd_5(Si_{2.5}Ge_{1.5})$, when compared to $Gd_5(Si_2Ge_2)$, which has a first-order magnetic-martensitic phase change. In fact, since

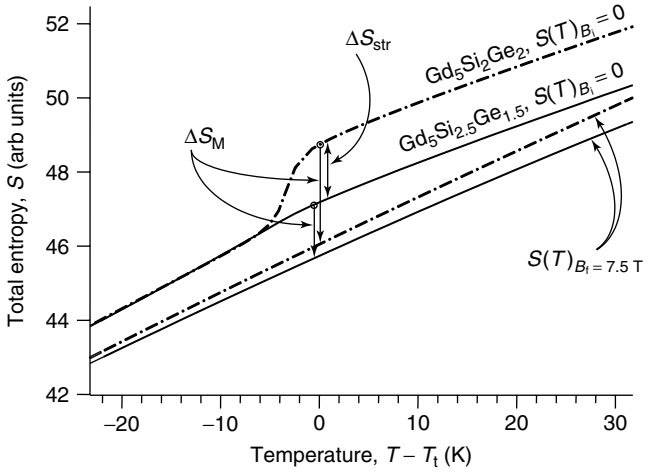

Figure 13. The behavior of the total entropies of $Gd_5Si_{2.5}Ge_{1.5}$, where ferromagnetic ordering at T_C is a second-order phase transformation (solid lines), and of $Gd_5Si_2Ge_2$ where ferromagnetic ordering is a first-order phase transformation (dash-dotted lines) in the vicinities of their respective Curie temperatures in 0 and 7.5 T magnetic fields. The three vertical arrows around T_t indicate the magnitudes of the magnetocaloric effects of the two materials, and entropy of the first-order phase transition in $Gd_5Si_2Ge_2$, all at $T = T_t$.

the crystal structure is decoupled from a magnetic sublattice in the case of $Gd_5(Si_{2.5}Ge_{1.5})$, the magnetic field does not actually transform the system into a nearly collinear ferromagnet, nor does it raise the Curie temperature of the material. Conversely, in the case of $Gd_5(Si_2Ge_2)$, where the magnetic field induces a magnetostructural phase change, the Curie temperature is increased nearly linearly with the field. Furthermore, first-principles calculations indicate that the conventional ferromagnetic ordering of the orthorhombic paramagnetic $Gd_5(Si_2Ge_2)$ occurs at a much higher temperature than a conventional ferromagnetic ordering of the monoclinic paramagnetic $Gd_5(Si_2Ge_2)$ if the monoclinic structure can be maintained in a ferromagnetic state (Pecharsky *et al*., 2003; Paudyal, Pecharsky, Gschneidner and Harmon, 2006). This difference in the Curie temperatures of the two structures and the fact that the magnetostructural transition between the monoclinic paramagnetic and orthorhombic ferromagnetic phases of $Gd_5(Si_2Ge_2)$ occurs at $T_C^{\text{monoclinic}} < T_t < T_C^{\text{orthorhombic}}$ may explain the suppression spin fluctuations and ferromagnetic clustering above T_t in the case of $Gd_5(Si_2Ge_2)$, while both should be present in $Gd_5(Si_{2.5}Ge_{1.5})$.

The MCEs at T_C are shown in Figure 13 as arrows for both compounds (the arrows are offset along the temperature axis for clarity). Obviously, the two MCEs are considerably different and the difference between them should be primarily ascribed to the absence and the presence of a structural change in $Gd_5(Si_{2.5}Ge_{1.5})$ and $Gd_5(Si_2Ge_2)$, respectively. Even though the magnetic field has slightly different effect on the total entropies of the two compounds, the difference in ΔS_M at the T_C is nearly identical to ΔS_{str}. The large magnetic field–induced phase volume and chemical bonding changes, observed in $Gd_5Si_2Ge_2$ and other $R_5Si_{4-x}Ge_x$ materials, therefore, indicate that the GMCE is achieved due to the concomitant change of the entropy during the structural transformation, designated in Figure 13 as ΔS_{str}. As a result, it is possible to speculate that the observed GMCE is the sum of the conventional magnetic entropy-driven process (ΔS_m, which is the same as ΔS_M in a material without a structural change as defined by equation (3) and the difference in the entropies of the two crystallographic modifications (ΔS_{str}) of a solid:

$$\Delta S_M(T, \Delta B)_{\Delta B = B_f - B_i} = \Delta S_{str} + \Delta S_m \tag{9}$$

Although the first factor in the right-hand side of equation (9) is a hidden parameter in conventional magnetization, heat capacity, and direct MCE measurements because any of these properties reflect both the magnetic and crystallographic states of the material, an estimate of ΔS_{str} based on comparing the MCEs exhibited by these two members of the $Gd_5(Si_{4-x}Ge_x)$ family is possible. This situation is illustrated in Figure 14, where we plot the isothermal magnetic entropy changes of $Gd_5Si_2Ge_2$ and of $Gd_5(Si_{2.5}Ge_{1.5})$ for field changes from 2 to 10 T (both sets of data have been taken from Pecharsky, Gschneidner and Pecharsky, 2003). Considering equation (9) and recalling that ΔS_{str} is independent of the magnetic field, provided that the entire volume of the material retains the low field crystal structure at B_i and it is completely converted into the high-field allotrope by B_f, the difference between the peak values of ΔS_M should remain constant regardless of the field change. This constant difference, indeed, is approximately equal to ΔS_{str}. A simple calculation based on the data presented in Figure 14 results in $\Delta S_{str} = 1.08(4)\ \text{J/g–at}^{-1}\,\text{K}^{-1}$ (or $9.8 \pm 0.3\ \text{J kg}^{-1}\,\text{K}^{-1}$) for $Gd_5Si_2Ge_2$.

Recently, Morellon *et al*. (2004) were able to establish the role of the lattice in bringing about the GMCE by using a different approach. They employed a single compound – $Tb_5Si_2Ge_2$ – in which the magnetic and structural transitions are separated by about 10 K under normal pressure. After applying hydrostatic pressure, the two transition temperatures were superimposed and the two transformations were recoupled, resulting in a GMCE and in an estimated ΔS_{str} on the order of $9\ \text{J kg}^{-1}\,\text{K}^{-1}$ (or $\sim 1\ \text{J/g–at}^{-1}\,\text{K}^{-1}$). Considering that the structural transition in $Tb_5Si_2Ge_2$ (Ritter *et al*., 2002) is the same as that found in the $Gd_5Si_2Ge_2$ the agreement between the two values was expected and is indeed very good.

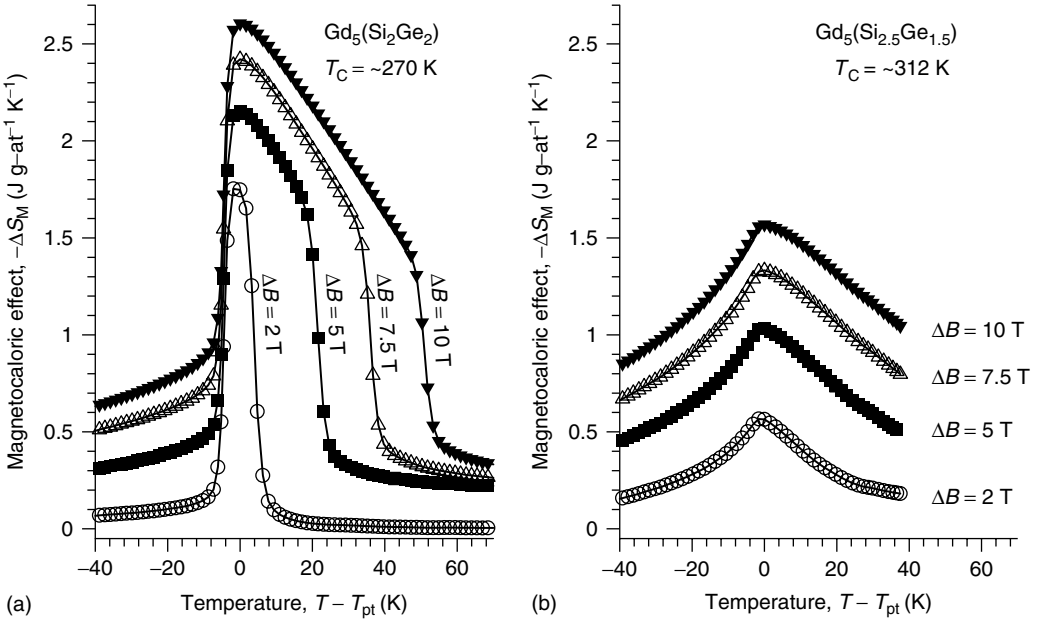

Figure 14. The magnetocaloric effects of $Gd_5Si_2Ge_2$ (a) $Gd_5Si_{2.5}Ge_{1.5}$ (b) calculated from heat capacity data allowing for the calculation of the contribution from the structural transition to the observed isothermal magnetic entropy change of $Gd_5Si_2Ge_2$.

7 CONCLUSIONS: WHAT DOES THE FUTURE HOLD?

The discovery of the GMCE and extensive characterization of multiple families of GMCE materials are indeed extremely important developments both in the science of the MCE and, potentially, in its application to near-room-temperature cooling. As described above, the overlapping contribution from the crystallographic and related electronic changes in the lattice may account for 50% or more of the total MCE (as quantified by the isothermal magnetic entropy change) in magnetic fields of 5 T and below. More significantly, the relative contribution from the structural entropy change ΔS_{str} to ΔS_M increases as the magnetic field decreases so long as the final magnetic field (B_f) is strong enough to complete the magnetostructural transition. A chart schematically comparing the MCEs in first-order phase transition compounds (GMCE materials) and second-order phase transition compounds (MCE materials) is shown in Figure 15. At any temperature, the GMCE materials have much larger magnetic field–induced entropy changes compared to conventional MCE compounds. As far as near-room-temperature applications are of concern, elemental Gd and $Gd_5Si_2Ge_2$ remain the leaders in their respective groups of compounds.

Advanced magnetocaloric materials, no doubt, should exist in other solid systems where structural changes are coupled with ferromagnetic ordering, and therefore, can be triggered by a magnetic field. Considering equation (9), the strongest MCEs in the weakest magnetic fields are anticipated to be found in novel materials designed to maximize the entropy differences of the low-magnetic-field and high-magnetic-field phases that includes the large entropy of a structural transformation, ΔS_{str}, in addition to a large magnetic entropy change ΔS_m. Furthermore, it is important that these materials also have a large ΔT_{ad}, which can be achieved by maximizing the effect of a magnetic field on the phase transition temperature.

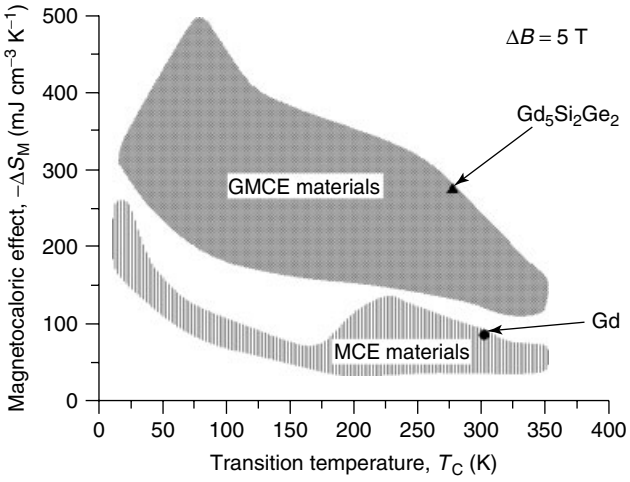

Figure 15. A map showing the magnitudes of the magnetocaloric effect in first-order (GMCE materials) and second-order (MCE materials) phase transition materials. (Adopted from Gschneidner, Pecharsky and Tsokol 2005, Figure 3.)

Where shall one look for such materials? Although no one at this point can give a definitive recipe, we believe that the most useful magnetocaloric materials

- will have large densities in order to support maximum cooling power in a small volume;
- will be first-order phase transition materials exhibiting GMCEs to provide maximum cooling power at the lowest energy cost;
- will order ferromagnetically to minimize internal entropy losses from realignment of spins in ferromagnets, antiferromagnets, spin glasses, and so on;
- will be metals because metals usually have much better thermal conductivities than ceramics;
- will contain a lanthanide, most likely Gd, and will have 50% or more magnetic atoms in order to minimize inactive thermal mass of the solid;
- and will finally, likely be crystalline bulk materials, not nanostructures or amphorous materials for near-room temperature.

Although nanostructures offer numerous potential benefits, such as large surface areas, control of geometry, and good thermal conductivity, nanoparticles normally do not order magnetically since the blocking temperatures are usually well below the temperature range useful for consumer applications. Amorphous alloys, which offer superior mechanical properties over brittle intermetallic alloys, have magnetocaloric properties which are distinctly inferior to the crystalline materials, primarily because the atoms and thus the spins of the magnetic atoms are randomly orientated causing an entropy loss due to the energy required to align the spins by the applied magnetic field (Gschneidner and Pecharsky, 2000).

In summary, much remains to be done to better understand, and therefore, achieve a better control over known magnetic materials to maximize their magnetocaloric properties and performance. A clear path forward will remain highlighted by thorough experiments coupled with theory, where the latter is tested and refined against the former, thus resulting in discoveries of new and improved materials and bringing near-room-temperature magnetic refrigeration technology to fruition in the not-so-distant future.

NOTES

[1] By definition, partial first derivatives of the Gibbs free energy with respect to intensive thermodynamic variables, for example, T, P, or B, vary discontinuously at the first-order phase transition. As a result, the bulk magnetization is expected to undergo a discontinuous change at constant temperature, and the heat capacity is expected to be infinite during a first-order phase transformation. Thus, in theory, $[\partial M(T,B)/\partial T]_B$ and $[T/C_P(T,B)]_B$ do not exist at the temperature of the first-order transition. In reality, these changes occur over a few kelvin wide temperature range and both functions can be measured experimentally.

[2] When a magnetic field varies between zero and a certain nonzero value that is lower than the critical field needed to induce a metamagnetic transition in an antiferromagnetic system, a 'negative' of 'reverse' magnetocaloric effect is commonly observed, specifically, ΔT_{ad} becomes negative and ΔS_{M} positive when $\Delta B > 0$.

Chalcogenides and Pnictides

Daniel Fruchart and Pierre Wolfers
CNRS, Grenoble, France

1 PNICTIDES

Transition-metal-rich phosphides and arsenides or antimonides (X = P, As, Sb) exhibit very peculiar but strongly related crystal structures, leading to fairly marked magnetic characteristics. Both the magnetic ordering temperatures and the local magnetic moments of transition elements (T) usually do not range very far from those of the metals and alloys, respectively. In fact, the main series of TT′X and TX metal–type compounds display nearest metal–metal distances 10–20% larger than only those in pure metal compounds (Fruchart, 1982). Contrary to halides, oxides, and chalcogenides, the size of the nonmetal element X in this case is effectively smaller, the ionic–covalent character of the T–X bonds is less marked, to the benefit of the metal character of phosphides and arsenides. This peculiarity stands for the classes of closely structured TT′X and TX compounds as well, where X = Si, Ge, Sn, Sb,. . ., for example, with MnAlGe on one side and MnSb on the other.

It also exists as a ternary pnictides series, for example, as skutterudites phosphides or antimonides (Leithe-Jasper *et al*., 2004), or more complex systems, for example, $Zr_2Fe_{32}P_8$ (Le Sénéchal *et al*., 1999) of the generic formula $\square_{n(n+1)}R_{n(n-1)}T_{6(n^2+1)}X_{2(2n^2+1)+1}$ (where R is a rare-earth element and $\square$ is a vacancy), that most of the time exhibit either magnetic properties at low temperature only or are weakly polarized with a small moment, if any. These are not discussed here since they exhibit weak magnetic characteristics, often disperse and also peculiar magnetic components and couplings. Also, the binary and ternary transition-metal nitrides are not considered here since the marked interstitial character of X = N in many metal lattices is better compared to those in parent metal carbides, even borides. The coordination polyhedron of nitrogen in transition-metal nitrides is quite different from that in compounds with a less metallic type such as phosphides, arsenides, antimonides.

Nevertheless, the magnetic properties of the two main series TX and TT′X considered here remain dominated by direct metal–metal interactions (Fruchart, 1982); however, the T–X bonds lead to a reduction in the magnetic polarization reference to the orbital scheme of a pure ionic state and support marked competition of exchange forces. Additionally, for several compounds, rather strong magnetic moments (larger than $\sim 3\,\mu_B$ for Mn) have been measured. In fact, the classes of TX and TT′X materials are also characterized by instabilities of the local magnetic polarization, with a possible impact on long-range magnetic ordering that, in most cases, are accompanied by structural transitions.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

Earlier, J.B. Goodenough had focused his interest on these two series of peculiar compounds, thus establishing conceptual phase diagrams (Goodenough, 1973, 1976) and had proposed a general analysis of the subtle physical and magnetic aspects of T-metal pnictides in terms of electron filling orbitals, with regard to characteristics that were intermediate between metal and ionic types.

Such singular behaviors led to the renewal of a marked interest in both series of TT′X and TX metal phosphides and arsenides since high-performance magnetocaloric properties have been revealed quite recently. Promisingly, their corresponding magnetic transitions spread over a wide range of temperature for large changes in magnetization, moreover being induced by moderate magnetic fields, as delivered by the modern permanent magnet, for example, the NdFeB-type of magnet.

2 CRYSTAL STRUCTURE RELATIONSHIPS

The TT′X series of compounds exhibit peculiar structural arrangements as a consequence of sensitive T–T′ metal interactions. From a unique pseudo unit cell (block) containing one formula unit (fu), the very rich series of polytype structures labeled T2 (tetragonal, 2 fu/cell), H3 (hexagonal, 3 fu/cell), O4 (orthorhombic, 4 fu/cell), O8, H12, and so on, are derived (Artigas, Fruchart, Boursier and Fruchart, 1990). The elementary block is defined as a pseudorhombic unit cell, where the X atoms form two types of interstices, two with tetrahedral coordination, *T*, and two of fivefold coordination with the shape of square-based pyramids, *P*. The three fundamental polytype members crystallize with the Cu_2Sb (SG: P4/*nmm*), the Fe_2P (SG: P$\bar{6}$2*m*), or the Co_2P (SG: P*nma*)-type of structure. These structures are strongly related since the different point symmetry groups allow one to build compact but different arrangements of blocks with respect to the fourfold, threefold, and twofold symmetries, respectively. The three main TT′X structures are represented in Figure 1, along with the rhombic pseudo unit cell containing one formula unit that is defined from a triangular channel formed by the X atoms.

Analogies can be established between the different crystal structures of the former series and those of the T′X one. Here, one of the metal atoms (T′) is 'missing', the corresponding tetrahedron, *T*, being empty; thus the T-metal atom occupies the center of the octahedron formed from two neighboring pyramids, *P*. The corresponding crystal structures are of the NiAs hexagonal type (H2, SG: P-3/*mmc*) and the MnP orthorhombic type (O4, SG: P*nma*), as seen in Figure 2. Both the TX crystal structures are directly related since the second

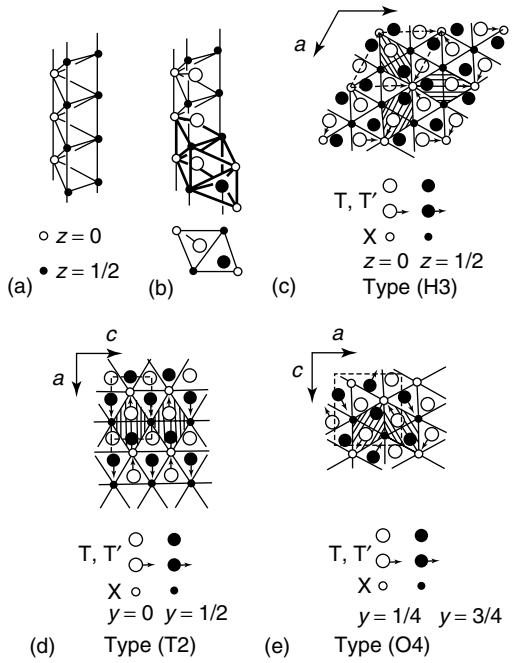

Figure 1. Structures (c) – type Fe_2As (T2), (d) – type Fe_2P (H3), and (e) – type Co_2P (O4) of the TT′X compounds as projected along axes to evidence the *T* (tetrahedral) and *P* (pyramidal) sites, the latter identified by arrows toward the apical X site. Above are represented fragments illustrating the triangular channel (a), hosting the pseudorhombohedral TT′X cell (b). (Fruchart, R., 1982, *Annales De Chimie*, **7**(6–7), 572; Artigas, M., PhD, Grenoble, 1992, p. 30.)

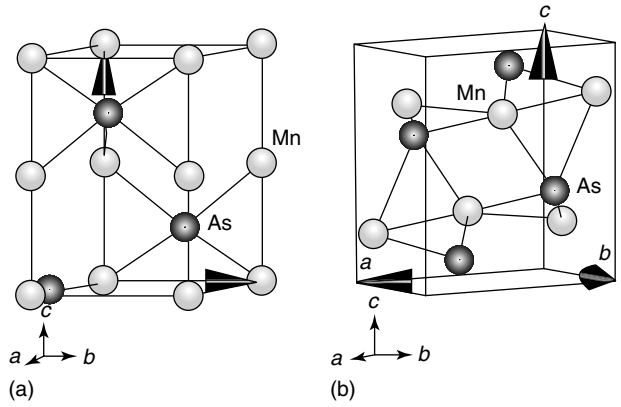

Figure 2. MnAs crystal structures in hexagonal (a) and orthorhombic (b) types. (Nascimento, F.B., *Materials Research*, **9**(1), (2006) 113.)

one can be considered to be the orthohexagonal distorted variant, the T atom being shifted from the center of the octahedron as a bipyramid, alternately in one or the other of the two pyramids. In fact, the series of TX and TT′X pnictides derive from the NiAs or are filled from Ni_2In via displacive or distortive types of transformations.

For both series TT′X and TX, more dense structures (shorter and shorter metal–metal distances) are obtained by application of external pressure or chemical pressure (Krumbugel-Nylund *et al*., 1974) following the succession T2 (TT′X) to H3 (TT′X and TX) to O4 (TT′X and TX). Since the magnetic coupling forces are intimately related to the metal-to-metal distances and directly depend on the crystal structure taken by the TT′X or TX compounds, magnetoelastic transitions take place systematically with changes in both the crystal and magnetic structures (e.g., ferro to antiferro (AF) in the MnAs–FeAs system Krumbugel-Nylund, 1974). The competing magnetic interactions promote the presence of metastable noncollinear, long-range ordering arrangement, leading to metamagnetic behavior versus the applied magnetic field. Also, instabilities of the electronic origin are commonly observed, and abrupt changes in the metal atom magnetization level can accompany the structure transition, which is often of the first-order type.

3 GENERAL OVERVIEW ON MAGNETIC PROPERTIES

The structural and magnetic characteristics of most intermetallic compounds of transition elements, namely, the pnictides formed with P, As, and Sb, had been extensively reviewed 15 years ago by Beckman and Lundgren (1991). The reader is invited to refer to this excellent review for information on most of the compounds mentioned earlier. As mentioned in the preceding text, one can easily recall the most pertinent phase diagrams, as reported versus composition, stoichiometry, or external pressure, thus well illustrating the dramatic interplays between crystal structures and opposite magnetic couplings.

Both the series of pnictides discussed here reveal optimal magnetic properties corresponding well to a peculiar valence electron concentration (VEC) that leads to extreme ordering temperatures or (and) large magnetization levels. Whatever the crystal structure of the considered TT′X polytypes may be, the maximum T_C of most compounds takes place close to the d^6 configuration (Fe), as for Fe_2P, MnCoP, MnCoAs, CrNiAs, and so on (Fruchart, 1982). This also applies to the solid solutions and multinaries. For example, Figure 3 presents the huge variation of both Curie temperature in the $Mn_{1-x}Co_xP$ system and magnetization, as reported earlier (Fruchart, Martin-Farrugia, Rouault and Sénateur, 1980). For the optimized VEC value, ferromagnetic couplings are, most of the time, dominating but with a slight change in composition or application of pressure (chemical or external pressure), dramatic changes take place with abrupt drops in magnetization. Then, AF couplings control the long-range magnetic ordering, which is often incommensurate

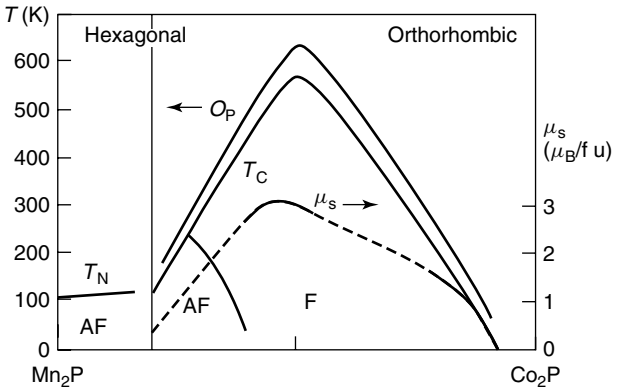

Figure 3. Magnetic phase diagram of the system Mn_2P–Co_2P. (After Fruchart, D., *et al*. Phys. Stat. Sol. (a) 57 675–682. *Handbook of Magnetic Materials*, Buschow (Ed.), Vol. 6, O. Beckman and L. Lundgren, p. 236.)

with the crystal cell. The situation is perfectly illustrated in Figure 4(a–c), all related to Fe_2P. In the vicinity of the change in ordering, both the ferro-antiferromagnetic and the ferro-paramagnetic transitions are accompanied either by a change in the crystal structure or at least by discontinuities of the cell parameters. Simultaneously, the magnetic moment of the T (T′) element can vary abruptly as the electronic state becomes modified (Bacmann *et al*., 1994). Additionally, in the paramagnetic state, short-range magnetic ordering effects have been observed with a regime of high-temperature correlation of up to $3T_C$ (Zach *et al*., 1994, 1995; Zach, Guillot, Picoche and Fruchart, 1995a).

Very similar instability effects, also of electronic origin, have been pointed out in the TX series, as illustrated in Figure 5 for the CrP–MnP–FeP system (Sénateur, Roger, Fruchart and Chappert, 1969; Beckman and Lundgren, 1991). The well-known lattice and magnetic instability of MnAs (Goodenough and Kafalas, 1967) versus temperature, composition, and application of pressure are more particularly illustrated in Figure 6(a) versus composition and Figure 6(b) versus application of an external pressure.

More recent fundamental investigations on the properties of the TT′X series have been reported from the 1990s up to now, mostly by T. Kanomata *et al*. in Japan, R. Zach *et al*. in Poland, D. Fruchart *et al*. in France, J. Bartolomé *et al*. in Spain, for a part under crossed collaborations, and by E. Brück *et al*. in The Netherlands. After the discovery of the very important magnetocaloric effect (MCE) in MnAs by H. Wada *et al*. in Japan, S. Gama *et al*. in Brazil have evidenced colossal MCE properties of $MnAs_{1-x}Sb_x$ systems under pressure.

These contributions can be classified relative to their main objectives and interests as follows:

1. Investigation of the magnetic and electronic structures.

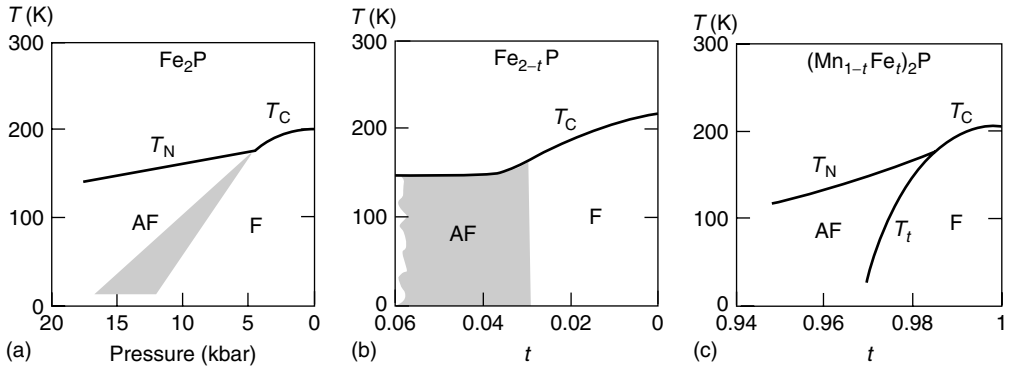

Figure 4. (a) (T, P) Phase diagram for Fe_2P, (b) (T, t = □) diagram for $Fe_{2-x}P$, (c) diagram for $(Mn_{1-x}Fe_x)_2P$. (After Roger, A. PhD Thesis, Paris–Orsay, (1970); or *Handbook of Magnetic Materials*, Buschow (Ed.), Vol. 6, Beckman, O. and Lundgren, L. p. 230.)

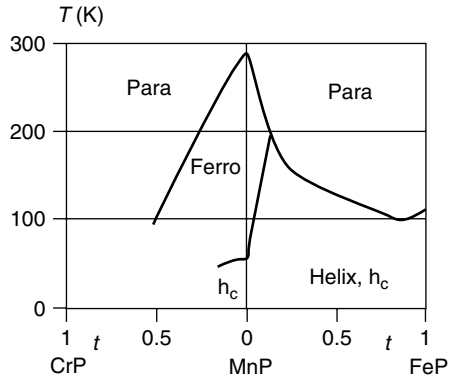

Figure 5. Magnetic phase diagram of the systems CrP–MnP–FeP. (After Sénateur, Roger, Fruchart and Chappert, 1969; *Handbook of Magnetic Materials*, Buschow Ed., vol. 6, Beckman, O. & Lundgren, L. p. 203.)

2. Correlation of the typical magnetoelastic behaviors with the crystal and magnetic transformations at specific transitions.
3. Transformations induced by applying external pressure or high magnetic fields.
4. Specific analysis of the change in entropy at transition in terms of MCE.

3.1 Investigation of the magnetic and electronic structures

3.1.1 TT′X pnictides

Fe_2P remains a material of reference because of the multiple magnetic and physical sensitive characteristics obtained with the pure and substituted compounds. Band structure calculations using a KKR-CPA (Korringa Kohn Rostoker-Coherent Potential Approximation) method were performed to compare with the experimental results obtained by a combination of magnetization and neutron diffraction measurements on Fe_2P (Koumina *et al.*, 1998) and on $FeMnP_{1-x}As_x$ compounds (Tobola *et al.*, 1996). A fairly good agreement was reached in determining the magnetic moments from experience and calculations. The reentrant spin glass SP (Spin Glass)–type transition at T ∼ 125 K of Fe_2P substituted with small amounts (5%) of both Cr and Ni was studied by dc magnetization and ac susceptibility (Srivastava *et al.*, 1994). The critical exponent of the freezing phenomenon was determined, thus ranging well with values observed for ordinary paramagnetic SP transitions. The magnetic phase diagram of slightly Cr-substituted Fe_2P samples was determined from magnetization and neutron diffraction experiments. Three different regions were identified with reference to an intermediate range ($50 < T < 120$ K), where negative interaction forces reveal an important comparison made with low and high ranges of temperatures respectively, both exhibiting ferromagnetic-type orderings (Sudish-Kumar, Srivastava, Krishnamurthy and Sahni, 1999).

The dependence of the thermopower Seebeck coefficient S(T) (Nakama *et al.*, 1998) was measured versus polarization of the magnetic structure by application of high magnetic fields up to 15 T. A large field dependence was found with a shoulder between 60 and 70 K and a discontinuity at 'T_C'; a first-order-type transition.

The magnetic phase diagram of MnRhAs (H3 type) was reanalyzed using single-crystal and ac susceptibility technique in order to make the metastable character of a so-called *ferro-AF multistep transition* taking place between 127 and 176 K more precise. Three zones with different behaviors were evidenced to relate to the spin canting phenomena (Rillo *et al.*, 1992).

The ferromagnetic $(Fe_{1-x}Ru_x)_2P$ (H3 type) system was investigated using the same technique as in the preceding text, thus revealing two magnetic transitions, the role of increasing Ru content being interpreted similar to the application of high pressure on the binary Fe_2P (Artigas *et al.*,

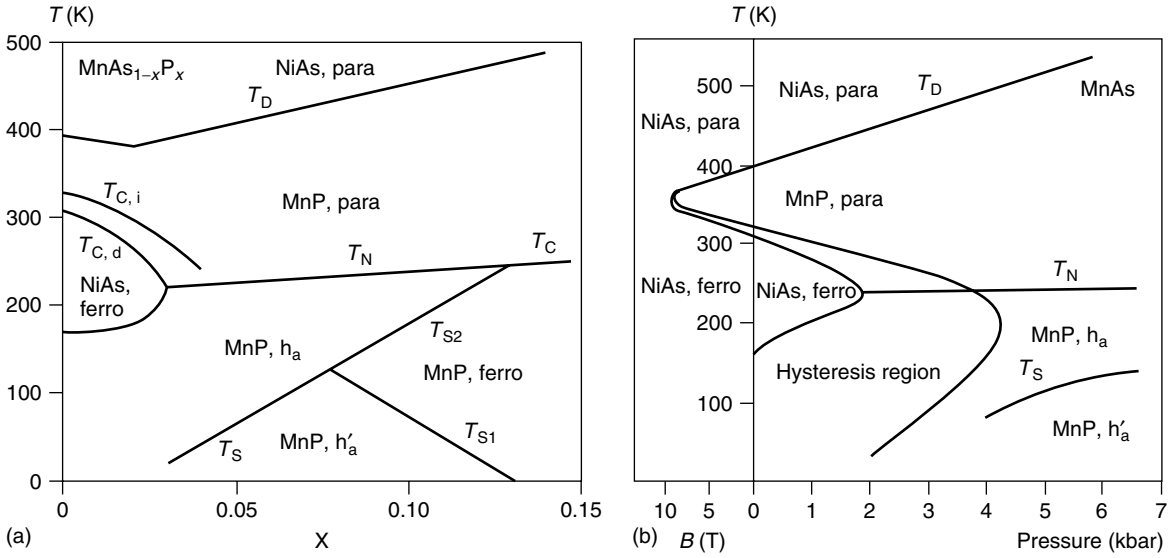

Figure 6. (a) Phase diagram of the pseudobinary compounds $MnAs_{1-x}P_x$ on the MnAs rich side, indicating the transition lines from NiAs to MnP-type structure, and first-order transition from ferromagnetic NiAs to paramagnetic MnP. (*Handbook of Magnetic Materials*, Buschow (Ed.), Vol. 6, Beckman, O. and Lundgren, L. p. 209.) (b) Influence on magnetic field and pressure on the crystal and magnetic structure of MnAs. (*Handbook of Magnetic Materials*, Buschow (Ed.), Vol. 6, Beckman, O. and Lundgren, L. p. 205.)

1992), the latter being reanalyzed by neutron diffraction and band structure calculations (Tobola *et al*., 1996). A comparison was established with the parent $MnFeP_{0.7}As_{0.3}$ where a drop in the magnetic moment of Fe was evidenced earlier at ferro-AF transition.

Following the phase diagram reinvestigation (Bacmann *et al*., 1990) of the $(Mn_{1-x}Fe_x)_2P$ (H3 type) by ac susceptibility, new magnetic phases were detected, in agreement with a parallel neutron diffraction analysis. The system $(Mn_{1-x}Co_x)_2P$ (O4 type) isoelectronic to Fe_2P (H3 type) for $x = 0.5$ was analyzed parallel to magnetization measurements and band structure calculations (Sredniawa *et al*., 2002). In agreement with the magnetic arrangements, as determined elsewhere by neutron diffraction, the rapid drop in phase transitions induced by much higher Mn contents was correlated with a marked enhancement of density of states (DOS) close to the Fermi level. Complementary to the two preceding ternary systems, analysis of the pseudo-quaternary $MnFe_{1-x}Co_xP$ systems by different experimental techniques and band structure calculations (Sredniawa *et al*., 2001) reveals a very interesting phase diagram with a first-order AF-ferro transition sensitive to composition. This orthorhombic phase diagram appears quite similar to the hexagonal part of the MnFeP–MnFeAs hexagonal system (Bacmann *et al*., 1994; Tobola *et al*., 1996). Substitution of Si to P in MnFeP was shown to be possible up to $x \sim 0.4$; however, the thermal treatment history dependence reveals unexpected and puzzling effects in terms of Curie temperature (Zhang *et al*., 2005).

Magnetization curves measured in an H3 (MnRuP) and in T2 (MnZnSb and MnGaGe) systems around Curie temperature to determine the critical exponents (Ono *et al*., 2001) lead to the conclusion that the two-dimensional magnetic character applies well for the later T2-type compounds, contrary to the H3-type MnRuP. Systematic computational KKR-CPA analyses of tetragonal arsenides, binary, and ternary antiferromagnets (Cr_2As, CrMnAs, Mn_2As, CrNiAs) were performed (Tobola *et al*., 1997), revealing an excellent agreement with the previous magnetic structure determination, namely, using neutron diffraction. However, the hexagonal CrNiAs compound, isoelectronic to Fe_2P, reveals strong competition between AF and ferromagnetic couplings, and it was anticipated that pressure effects or substitution should increase the magnetic moment of Cr up to more than $2\,\mu_B$. The pressure effects have been studied in detail by Ohta *et al*., as reported in Section 3.3. The reports given by this group are parallel to the high-field magnetization performed on $(Cr_{1-x}Ni_x)_2As$ with $x = 0.5$, 0.7, concluding that the low temperature anomalous magnetization attributed to the spin glass–like behavior related to band magnetism (Ohta *et al*., 1995a). From a band structure analysis, they concluded that CrTX systems with T = Fe, Co, Ni, X = P, As, Cr are magnetically ordered but Cr carries only a magnetic moment (Ishida, Takiguchi, Fujii and Asano, 1996). Finally, a study based on neutron diffraction (Bacmann, Fruchart, Koumina and Wolfers, 2004) revealed that the low-temperature phase of CrNiAs (up to ∼110 K) consists of a sine-modulated structure with moments on both Cr

and Ni, but up to $T_C \sim 210$ K, only Cr carries a moment, forming a simple collinear structure.

More recently, all possible magnetic exchange couplings that could take place in the tetragonal series of TT′X pnictides were reviewed from theoretical symmetry approaches (Fruchart, 2005). Contrary to most magnetic arrangements established up to now, which form AF collinear magnetic structures, long-range noncollinear structures are basically allowed in complete agreement with a first experimental result (Yamagishi *et al*., 1999). Here also, potential magnetoelastic couplings must be accounted to fully understand the magnetic phase diagram, as anticipated earlier (Shirakawa and Ido, 1976).

Definitively, a systematic analysis of the magnetic couplings versus the metal–metal distances in some TT′X with T = Cr and Mn, T = 4d elements (Ru, Rh, Pd) phosphides and arsenides leads to the conclusion that the physical behavior should also be interpreted in terms of itinerant–electron magnetism (Ohta, Kanomata and Kaneko, 1990; Kanomata *et al*., 1991), as revealed by fitting the susceptibility traces.

3.1.2 TX pnictides

For TX pnictides, similar fundamental analyses were performed in order to better understand the subtle equilibrium state between ferromagnetic and AF phase regions.

Symmetric and antisymmetric anisotropic exchange energies were considered for the relative stability of the different modulated magnetic phases existing in the monopnictides MnP, FeP, CrAs, MnAs (Sjöstrøm, 1992). The results, based on a band model analysis, confirm that the shape of the Fermi surface and the antisymmetric interactions is crucial for the stability of the helical magnetic structure, for example, in MnP.

The magnetic couplings supported by conduction carriers were demonstrated to be of relative importance in correlating the transport and magnetic properties (Barner, 1987). Also, the canted and helicoidal equilibrium spin structure was attributed to mixed couplings, with peculiar field and temperature dependence in MnP_xAs_{1-x} and $Cr_xMn_{1-x}Sb$ systems (Kohnke *et al*., 1996).

MnP (O4 type) is one of the few magnetic systems in which a uniaxial Lifshitz point (LP) has been identified, occurring at the confluence of modulated, ferromagnetic, and paramagnetic phases. Experiments were performed by applying the magnetic field along the main direction of the orthorhombic cell, thus allowing the evaluation of the critical exponent parameters, for example, susceptibility and specific heat (Becerra, Bindilatti and Oliveira, 2000). The results have been successfully interpreted in terms of a 3-D Ising model. Besides, from the analysis of the wave vector dependence q(H) with the applied field of all the modulated magnetic structures (helix, fan, cone), the shape of the magnetization curves realized while applying the field along the lattice vectors was explained along with the nature of the cone-phase-type transition (Zieba, Slota and Kucharczyk, 2000). The characteristics of the LP, triple point, and critical end point were derived on the basis of an axial next nearest-neighbor Heisenberg model (ANNNH), thus appearing in semiquantitative agreement with the experiments. Effective values for the crossover exponent, wave vector exponent, and magnetization discontinuity provide explanations of the deviation to experimental results. Apart from the mechanisms of phase transformation, the nature of the O4–MnP-type magnetic structure was requestioned theoretically by density-functional determination (Niranjan, Sahu and Kleinman, 2004). The high-temperature magnetic state was shown to be antiferromagnetic and the absence of any Curie–Weiss-type magnetic susceptibility was justified by the lack of long-range ordering, according to the model.

3.2 Typical magnetoelastic behaviors

A peculiar system $MnFeP_{1-x}As_x$ revealed to be very interesting since it contains the three main structure polytypes O4 for the P-rich side, T2 for the As-rich side, and H3 for intermediate compositions, as shown in Figure 7. By analyzing the dependence of magnetic couplings versus the metal–metal distances ('densification' effect from T2 to H3 to O4), the intermediate H3 part of the phase diagram reveals

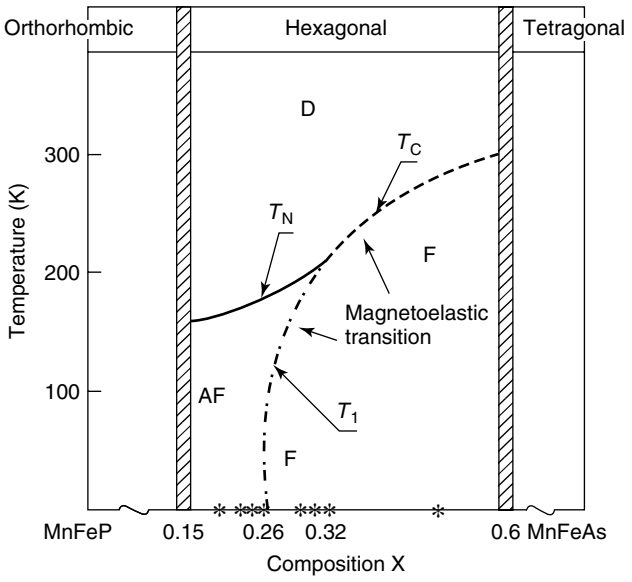

Figure 7. Magnetic phase diagram of the MnFeP–MnFeAs system. (A., Krümbugel-Nylund PhD University of Paris–Orsay, 1974; M., Bacmann *et al*. *Journal of Magnetism and Magnetic Materials* **134**, (1994), 59–67.)

the existence of a singular transition T_T at $x \sim 0.27$ between a ferromagnetic domain and an antiferromagnetic one. The so-called *Curie temperature* 'T_C' from ferro to 'paramagnetic' *P* state appeared to have similar trends: first-order transition type with a magnetoelastic character, as the F–AF transition. The influence of high magnetic fields was measured in the range 0–20 T from 4 to 400 K, thus inducing magnetic phase transformations with magnetoelastic characters (Zach, Guillot and Fruchart, 1990). Then the magnetic ordering was checked for using several complementary techniques such as X-ray and neutron diffraction versus temperature, Mössbauer spectroscopy, and magnetic measurements (Bacmann *et al*., 1994; Zach *et al*., 1995). The ***a*** cell parameter drops down by ∼1% at the F–AF and F–P transitions T_T and 'T_C'; conversely, the ***c*** cell parameter increases by ∼2.5%, thus almost no change in volume is observed. Crystal structure refinements indicate that, starting from the ferromagnetic state, the magnetoelastic transitions T_T and 'T_C' led to the mean ⟨Mn–Mn⟩ (pyramidal sites) distance remaining unchanged, the ⟨Fe–Fe⟩ (tetrahedral sites) distance dropped by 0.1 Å, conversely to the ⟨Mn–Fe⟩, which increased by the same value. A high-field X-ray diffraction investigation performed on $MnFeP_{0.5}As_{0.5}$ confirms the same change in the ***a*** and ***c*** cell parameters when applying high field just above 'T_C'; however, the cell volume slightly and continuously decreases with increasing magnetic field through the transformation (Koyama, Kanomata, Matsukawa and Watanabe, 2005), thus realizing the reverse behavior of the volume expansion when temperature increases. Solving the complex noncollinear and incommensurate AF structure using both neutron diffraction and ^{57}Fe Mössbauer spectroscopy indicate that at T_T (and accordingly at 'T_C') the magnetic moment drops down by ∼50% (0.6 μ_B), the magnetic moment of Mn remaining unaffected, close to 3 μ_B. All these trends were confirmed later by KKR-CPA electronic structure calculations. The confirmation of most of the characteristics of the $MnFeP_{1-x}As_x$ magnetic system was achieved more recently using ^{57}Fe Mössbauer spectroscopy, but applied to close compositions as those previously analyzed (Hermann *et al*., 2004).

Both competing positive and negative interactions and a reduction in the Fe–M exchange forces induce a ferromagnetic–paramagnetic magnetoelastic transition with a marked loss of long-range correlation just above 'T_C', as indicated by the important diffuse scattering at large ***q*** vectors (Bacmann *et al*., 1994). A magneto-resistance study was realized on $MnFeP_{0.55}As_{0.45}$ on a polycrystalline sample prepared by a solid-state reaction (Tegus, Brück, Buschow and de Boer, 2002). The extremum of the derivative of $\rho(T)$ coincides well with 'T_C'. The increase in resistivity, which is almost constant in the room-temperature (RT) range, approaching the magnetic ordering temperature may be related to the existence of AF spin fluctuations. This appears in agreement with what was proposed by Zach *et al*. (1995).

The critical field behavior was investigated experimentally (Zach, Guillot, Picoche and Fruchart, 1995a), allowing to propose a Landau type of thermodynamic model as seen in Figure 8(a–c). This model was shown to be supported well by systematic magnetic measurements under pressure, allowing to build a (T, B, P) diagram (Zach, 1997).

Recently, a model description of the first-order phase transition in $MnFeP_{1-x}As_x$ was proposed (Tegus *et al*., 2005b) on the basis of the Bean–Rodbell model. Exchange interactions, elastic energy, entropy, pressure terms and, finally, the Zeeman energy were used to minimize the Gibbs free energy with respect to the volume and magnetization. The fit of pertinent parameters to experimental data confirms that the magnetoelastic couplings play a very important role in the mechanism of the phase transition.

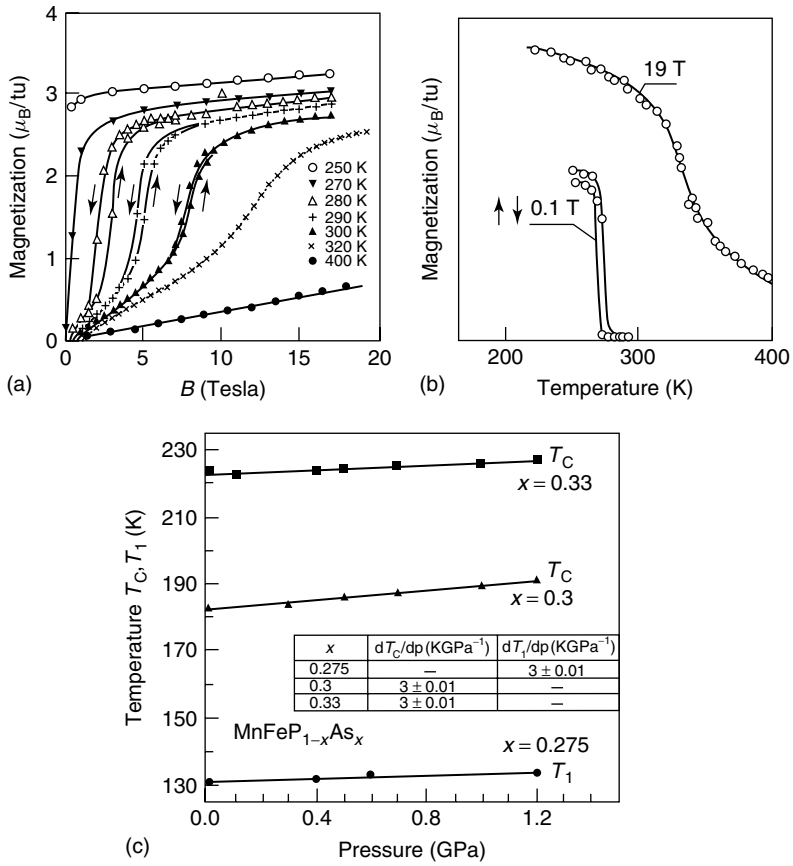
Besides, the magnetoelastic properties and electronic structure analysis for a similar H3 system $(Fe_{1-x}Ni_x)_2P$ were determined recently (Zach *et al*., 2004). Once more, the tetrahedral site where preferentially Ni substitutes for Fe loses its magnetic polarization rapidly.

In both cases, similar to the other ones of the TT′X series, the magnetoelastic character of the first-order-type transitions is directly related to magnetic instabilities of electronic origin, induced by chemical pressure effects.

3.3 Transformations induced by external pressure or high magnetic fields

Since the TT′X (and TX) systems of magnetic transition-metal pnictides reveal very dramatic competitions of coupling forces, with correlated magnetoelastic phenomena, an external pressure technique was used along with a high magnetic field to better understand the nature of the transitions.

The MnRhAs (H3 type) compound first proved to be very attractive with regard to the successive complex noncollinear structure, AF at low temperature, transforming to a F + AF state via a first-order transition at $T_T = 158$ K, then losing long-range ordering at $T_C \sim 200$ K (Chenevier *et al*., 1984; Bacmann *et al*., 1986). Moreover, antiphase magnetic arrangements occurred immediately down to T_T, as specially confirmed later by neutron diffraction and topography (Chenevier *et al*., 1992). The pressure dependence of the different transitions was first investigated by Kanomata, Shirakawa and Kaneko (1987), indicating the stabilization of the AF domain at the expense of the F + AF one. This was confirmed in more detail with the (T, B, P) phase diagram determined on the extended $MnRhAs_{1-x}P_x$ system (Zach *et al*., 1992, 1995; Zach, 1997). Critical field exponent as well as triple point and end point were evidenced



x	dT_C/dp (KGPa^{-1})	dT_1/dp (KGPa^{-1})
0.275	–	3 ± 0.01
0.3	3 ± 0.01	–
0.33	3 ± 0.01	–

Figure 8. (a) Isothermal $M_T(B)$ magnetization of $MnFeP_{0.5}As_{0.5}$; (b) isofield $M_B(T)$ magnetization of $MnFeP_{0.5}As_{0.5}$; (c) (P, T) magnetic phase diagram of $MnFeP_{1-x}As_x$, $x = 0.275$ (T_{F-AF}), $x = 0.3$ ('T_C'), $x = 0.33$ ('T_C'). (Zach, R., Hab Thesis, D., Politecknika Krakowska, Zeszyt Naukowy NR 2 Krakow 1997.)

and interpreted using a Landau-type thermodynamic model as for the $MnFeP_{1-x}As_x$ system (Zach, 1997).

Pressure-induced structural transition in the ferromagnet MnRhP (H3 type) and MnRhAs at RT by using an *in situ* experiment (Eto *et al*., 2000). A transformation to an orthorhombic (more dense) structure occurred under 34 GPa. Another unidentified transformation also occurred for MnRhAs under 25 GPa. The Curie temperature dependence of the former and ferromagnetic compound was checked under pressure, revealing a c-plane dependence of the exchange forces (Nishino *et al*., 2000). The magnetic characteristics of the second compound, as submitted to external pressure, but in a weaker pressure range than for the X-ray investigation, were determined by Fujii *et al*. (2001). This experiment has allowed to establish a singular behavior, as reported in Figure 9, but in good agreement with earlier studies (Zach *et al*., 1997). For a pressure larger than 5 GPa, an almost ferromagnetic phase was stabilized. Similarly, a ferromagnetic state was stabilized under pressure up to 12 GPa in the $MnRhAs_{0.5}P_{0.5}$as a part of reanalysis of the $MnRhAs_{1-x}P_x$ system with $x = 0.4$, 0.5, 0.6 (Zach *et al*., 1992; Fujii *et al*., 2002a). Finally, the related but more complex system $MnRh_{1-x}Co_xAs$ was investigated up to 8 GPa for magnetic properties and using *in situ* experiments for X-ray analysis (Fujii *et al*., 2002b). MnCoAs (O4 type) is a ferromagnet and from substitution of Rh to Co, a reinforced ferromagnetic state can be expected at the expense of the low-temperature AF state. A comparison of the results in terms of magnetic couplings acting along the *c* axis with those recorded on parent compounds (MnRhP, MnRuP, MnRhAs, $MnRhAs_{1-x}P_x$, MnZnSb) allowed the authors to conclude that RKKY-type interactions play an important role in the exchange mechanism in the TT′X system, as illustrated in Figure 10.

Other sensitive TT′X systems were investigated under pressure, with CrNiAs and CrRhAs (both H3 type) for a similar phenomenology anticipated with both the $Co_xMn_{1-x}P$ and $MnRhAs_{1-x}P_x$, systems. A decrease in the ordering temperature T_C and T_N respectively was induced by application of pressure (Ohta *et al*., 1995b; Ohta and Onmayashiki, 1998).

Interestingly, MnFeAs (T2 type) transforms and is stabilized to MnFeAs (H3 type) by using high pressure (6 GPa)

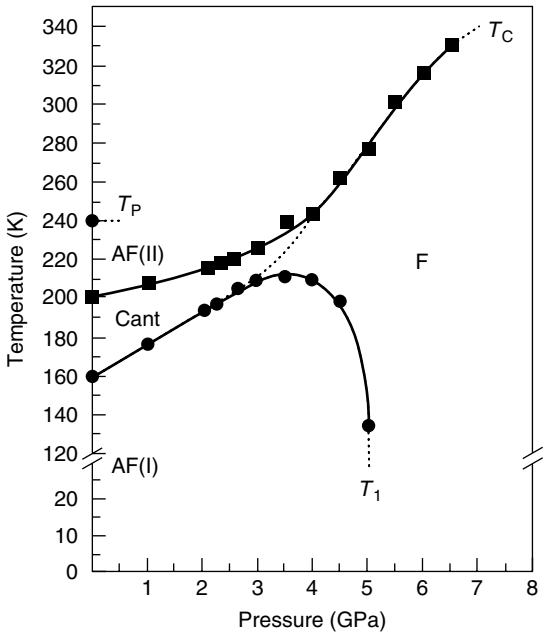


Figure 9. The (P–T) phase diagram determined from the present experiment. A pressure-induced phase transition from AF(I) to F takes place at around 5 GPa. T_P was not detected in this experiment. The dotted line was drawn according to Kanomata, Shirakawa and Kaneko, (1987). (Fujii, N., *et al*. *Journal of Magnetism and Magnetic Materials*, **224**(1) (2001) 15.)

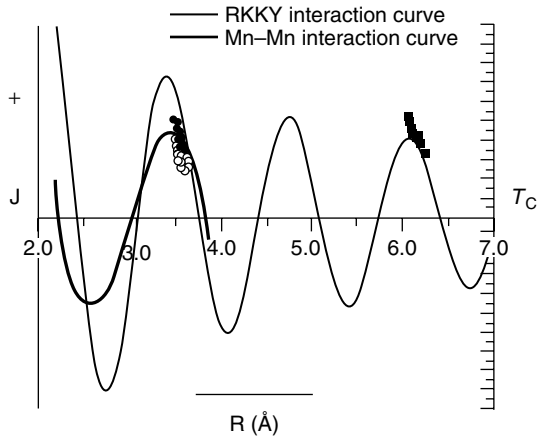

Figure 10. Mn–Mn interaction curves in MnMX-type intermetallic compounds calculated from RKKY theory and estimated from refs. (30–32) in Fujii *et al*., (2002b) for Mn alloys. Observations of T_C for MnRuP (●), MnRhAs (○), MnZnSb (■) are also plotted. (Fujii, N., *et al*. *Journal of Alloys and Compounds*, **345**, (2002b), 66.)

at a temperature of 800 °C. X-ray analysis of the cell parameters, neutron diffraction to analyze both the crystal and magnetic structures, ^{57}Fe Mössbauer spectroscopy studies, and KKR-CPA electronic structure calculations were undertaken (Tobola *et al*., 2001). All results were in fair agreement

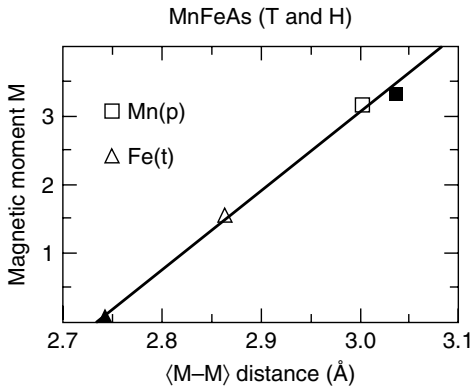

Figure 11. Experimental magnetic moments of Fe (triangle) and Mn (square) in tetragonal (T2-filled symbols) and hexagonal (H3-empty symbols) structures of MnFeAs. (Tobola, J., *et al*. *Journal of Alloys and Compounds*, 317–318, (2001), 279.)

with the fact that the Mn magnetic moment (pyramidal site) was weakly reduced from T2 to H3 type, but, for Fe (tetrahedral site), it was almost zero as T2 was comprised between 1.1 and 1.54 μ_B, respectively, deduced from the calculations and the experiments. This supports well the specific instable character of the magnetic moment of Fe sitting in the tetrahedral site of the TT′X compounds similar to $MnRhAs_{1-x}P_x$ in the H3 range of compositions. Figure 11 represents the position of the Mn and Fe magnetic moment versus the mean metal–metal distance.

Niziol *et al*. have primarily studied the $(Co_{1-x}Mn_x)_2P$ system ($x = 0.6$ and 0.75), namely, using ac susceptibility measurement under external pressure (Niziol *et al*., 1993). The metastable character of the ferromagnetic state with reference to the low-temperature incommensurate AF structure was correlated with a magnetovolume effect. The results led to the proposition of a localized/delocalized picture of magnetism.

In the past, the tetragonal compound Mn_2Sb (T2 type) has got attention for its ferrimagnetic characteristics up to relatively high temperature, as reported in Beckman and Lundgren (1991). Under external pressure and using neutron diffraction, the ferri-antiferromagnetic transition initiated when applying pressure for many of the parent-substituted compounds was not evidenced in pure Mn_2Sb (Ryzhkovskii *et al*., 2002). Under a pressure of 2.8 GPa, the pure binary antimonide is only characterized by a spin reorientation phenomenon. Besides, it was shown earlier on a parent system (Val'kov and Khapalyuk, 1997) that cycles of thermal treatments applied on substituted $Fe_{0.5}Mn_{1.1}As$ (T2 type) allowed to suppress the low-temperature phase down to 77 K, the material still being ferromagnetic, contrary to the sample prepared in a conventional way.

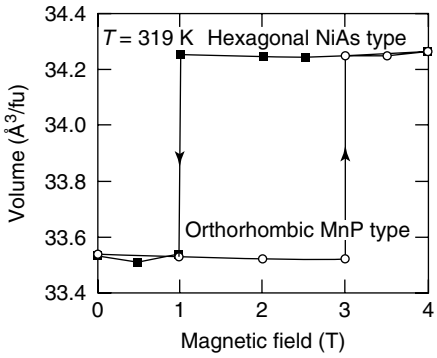

Figure 12. Field dependence of the lattice volume/fu for MnAs. (○) and (■) indicate the volume in increasing and decreasing fields, respectively. (Ishikawa, F., *et al*. *Journal of Applied Physics*, **42**, (2003), L 920.)

In terms of field-induced structural and magnetic transformations, the monopnictide series provides a very interesting result with MnAs (Ishikawa, Koyama, Watanabe and Wada, 2003; Ishikawa, Koyama and Watanabe, 2004). From both magnetization measurements and X-ray diffraction performed under a magnetic field, a metamagnetic transition from paramagnetic to ferromagnetic state was induced above T_C. From the X-ray profile analysis, the forced magnetic state was stabilized at ∼3.5 T, and the first-order crystalline and magnetic transition was deduced from a particularly squared hysteresis loop, as reported in Figure 12.

4 MAGNETOCALORIC PROPERTIES OF THE TT′X AND TX SERIES

4.1 Thermodynamics of magnetocaloric materials

In order to understand the physical origin of the MCE, it is useful to recall briefly the thermodynamic properties of a magnetic material plunged in a magnetic field B. Under constant pressure, the full entropy is given by

$$S(T, B) = S_{\text{lat}}(T) + S_{\text{e}}(T) + S_{\text{m}}(T, B) \tag{1}$$

where S_{lat}, S_{e}, and S_{m} represent respectively the lattice entropy, the electronic entropy, and the magnetic entropy. The MCE can be related to the magnetic properties of the material through the thermodynamic Maxwell's equation

$$\left(\frac{\partial S}{\partial B}\right)_T = \left(\frac{\partial M}{\partial T}\right)_B \tag{2}$$

According to the magnetization measurements versus temperature and applied magnetic field, the magnetic-entropy change of a material can be calculated using this relation as

$$\Delta S_{\text{m}}(T, 0 \rightarrow B) = \int_0^B \left(\frac{\partial M}{\partial T}\right)_{B'} \mathrm{d}B' \tag{3}$$

Considering the temperature variation $M(T)$ and equation (3), it is concluded that a homogeneous magnetic material having a definite magnetic phase transition temperature is not suitable for use as the refrigerant because $(\partial M/\partial T)$ varies considerably with temperature change near T_C and, as a result, entropy change is maximum accordingly.

Using magnetization measurement made at discrete temperature intervals and by numerical integration of equation (3), ΔS_{m} can be approximated as

$$\Delta S_{\text{m}} = \sum_i \frac{M_{i+1} - M_i}{T_{i+1} - T_i} \Delta B_i \tag{4}$$

where M_{i+1} and M_i are the magnetization values measured in a field B, at temperature T_{i+1} and T_i respectively.

In the classical mean-field theory, the relative magnetization is given by

$$\sigma = B_j(y) = \frac{2j+1}{2j} \coth\left(\frac{2j+1}{2j} y\right) - \frac{1}{2j} \coth\left(\frac{1}{2j} y\right) \tag{5}$$

where B_j is the Brillouin function and j is the total angular momentum. The argument y is the solution to the simultaneous equations

$$\sigma = B_j(y)$$

$$y = \frac{1}{T}\left[3T_C\left(\frac{j}{j+1}\right)\sigma + \frac{g\mu_B j}{k} B\right] \tag{6}$$

where k is the Boltzmann constant, g the Landé factor, and μ_B the Bohr magneton.

According to principles of magnetism, the magnetic entropy is derived from

$$S_{\text{m}} = R\left[\ln\left(\frac{\sinh\left(\frac{2j+1}{2j} y\right)}{\sinh\left(\frac{y}{2j}\right)}\right) - y B_j(y)\right] \tag{7}$$

where R is the universal gas constant, and the changes of magnetic entropy caused by a variation of magnetic field $\Delta B = B_f - B_i$ are given by

$$\Delta S_{\text{m}}(T, \Delta B = B_f - B_i) = S_{\text{m}}(T, B_f) - S_{\text{m}}(T, B_i) \tag{8}$$

For deeper analyses, one can refer, for example, to the analytical model developed by von Ranke *et al*. (2005) to

understand the colossal MCE, or, more extensively, to the recent book by Tishin and Spichkin (2003).

From the preceding considerations, it can be expected that the best magnetocaloric materials in terms of application for refrigeration close to RT must undergo first-order-like magnetic transition that is easy to handle under rather low magnetic fields (e.g., 1–2 T), with a limited hysteresis effect to be effectively activated reversibly, with a high density of atom magnetization. Transition-metal-rich magnetic materials, such as the T-pnictides, herein reviewed can fulfill these specifications, since they often exhibit tunable both lattice and ferromagnetic characteristics, along with being good thermal conductors and being formed with rather inexpensive elements.

Reports with more technical details and systems are available in more specific papers such as (Lebouc, Allab, Fournier and Yonnet, 2005).

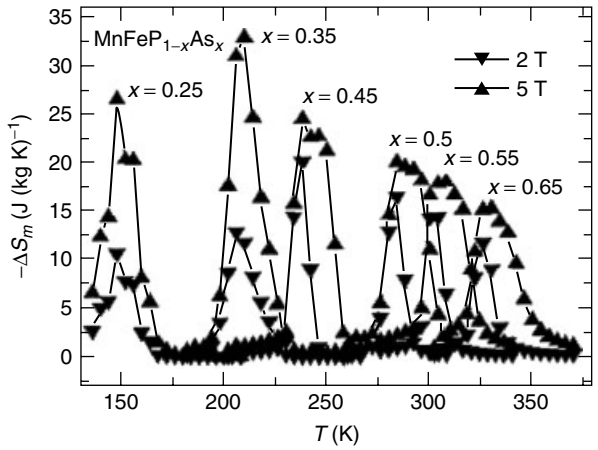

Figure 13. Magnetic-entropy change for different compounds of the $MnFeP_{1-x}As_x$ system for applied field change of 2 and 5 T. (Brück, E., *et al*. *Journal of Alloys and Compounds*, **383**, (2004), 34.)

4.2 Magnetocaloric properties in the TT′X series

Up to 2002, the best promising magnetocaloric material close to RT belonged to the series deriving from the $Gd_5(Si_{1-x}Ge_x)_2$-type compounds (Pecharsky and Gschneidner, 1997).

The $MnFeP_{1-x}As_x$ series was revealed by Tegus, Brück, Buschow, and de Boer (2002) as a performing MCE challenger of the gadolinium intermetallics in terms of effectiveness, also with reference to the cost of elements. Tunability of their MCE characteristics in interesting temperature ranges for application was demonstrated soon after by the same group when selecting different compositions by substitution of As to P (Tegus, Brück, de Boer and Buschow, 2002) or of Mn to Fe (Brück *et al*., 2003; Tegus, 2003). Interestingly, high values of magnetic-entropy changes for different compounds of the $MnFeP_{1-x}As_x$ series were measured up to $-\Delta S_m \sim 35\,J\,kg^{-1}\,K^{-1}$, in rather moderate applied magnetic field, the temperature of activation ranging from ∼150 to 350 K, as shown in Figure 13. However, the best performances remained a little far from RT, better results were recorded close to RT when a moderate part of Ge to As was substituted, thus forming $MnFeP_{0.5}As_{0.5-x}Ge_x$ with a smaller c/a ratio of the hexagonal cell parameter (Brück *et al*., 2004). This point proved to be of importance for the corresponding increase in the corresponding so-called *Curie temperature* 'T_C' and amplitude of the magnetoelastic effect at transition. Further, the maximal magnetic-entropy change was derived from little more complicated formulas such as $Mn_{1.1}Fe_{0.9}P_{0.7}As_{0.3-x}Ge_x$ (Tegus *et al*., 2005a). A more overall analysis of the properties of the MnFeX series was established first by E. Brück *et al*. (Brück *et al*., 2004; Brück, Ilyn, Tishin and Tegus, 2005). Complementary to these specific papers, reports were made on the same series of TT′X materials (Fruchart *et al*., 2005). This particularly concerns systems exhibiting sensitive magnetic properties with magnetoelastic transitions $(Mn_{1-x}Co_x)_2P$, $Fe(Fe_{1-x}M_x)P$, MnRhAs, as well as MnAs.

Besides, a model description of the first-order phase transition in $MnFeP_{1-x}As_x$ was built by the same group (Tegus *et al*., 2005b), based on the Bean–Rodbell model. Another type of approach was proposed a little earlier (von Ranke *et al*., 2004) based on the Landau theory as well as in (Zach, Guillot and Tobola, 1998; Zach *et al*., 1997) to derive the conditions of a first-order transition and then to evaluate ΔS_m and ΔS_{lat}, the magnetic and lattice contribution to change in entropy. All the results appear to fit correctly with the experimental data (Tegus *et al*., 2005b; von Ranke *et al*., 2004; Zach, 1997; Zach, Guillot and Tobola, 1998). However, the electronic part of entropy change at transition ΔS_e was not accounted for.

4.3 Magnetocaloric properties in the TX series

The discovery of giant MCE in $MnAs_{1-x}Sb_x$ samples was made by Wada and coworkers and was reported in 2001–2002. This was a major step in the utilization of T-intermetallics as magnetic refrigerant materials (Wada and Tanabe, 2001; Wada, Taniguchi and Tanabe, 2002). The magnetic-entropy change was rapidly fixed up to $-\Delta S_m \sim 30\,J\,kg^{-1}\,K$ for $x \sim 0.3$ (Wada *et al*., 2003). These were unusual characteristics in the vicinity of the first-order phase transition between the ferromagnetic low-temperature NiAs-type structure and the nonmagnetic MnP-type structure, as illustrated in Figures 2 and 14. Substitution of Sb to As

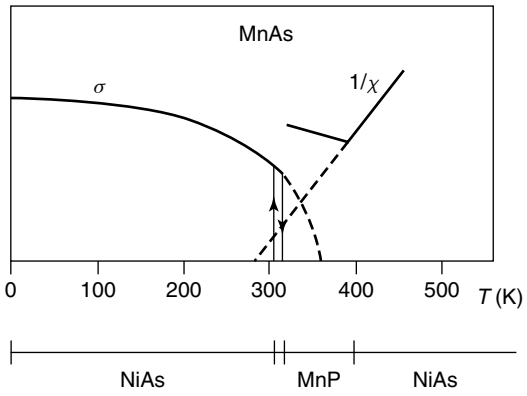

Figure 14. Magnetization and inverse susceptibility of MnAs showing the temperature region of different NiAs and MnP crystal structures. (*Handbook of Magnetic Materials*, Buschow (Ed.), Vol. 6, Beckman, O. and Lundgren, L. p. 204.)

appeared interesting since this decreases the transition temperature, with a reduction of the strong hysteresis effect related to the very abrupt character of the first-order transition of MnAs. A theoretical analysis of the giant MCE in $MnAs_{1-x}Sb_x$ compounds, based on the Landau theory of phase transition, using a Bean–Rodbell-type model, the critical dependence of the transition temperature first versus second order was deduced and also the temperature dependence of ΔS_m was derived in a fair agreement with experience (von Ranke *et al*., 2004). Then a composite system was anticipated for an optimal design and process to work in an Erickson mode near RT.

The parallel effect of deviation from stoichiometry of $MnAs_{1-x}Sb_x$ materials was analyzed on the magnetic and MCE properties, and excess iron content was related to some decrease in the optimal magnetization level (Morikawa and Wada, 2004). Interstitial iron resulting from excess composition was proposed as the parameter controlling the 'T_C' well, the nature (order) of the phase transition, the amplitude of the hysteresis at transition, and finally the force of the MCE, in relation to the increase in the c/a cell parameter ratio. Because of a certain lack of miscibility with Sb additions, the single-phase region was ascribed to compositions $Mn_{1+\delta}As_{1-x}Sb_x$ with δ ranging from 0.05 to 0.11 (Morikawa, Wada, Kogure and Hirosawa, 2004). Then a specific heat treatment determined to get the best composition and element distribution, parallel to the high value of $-\Delta S_m \sim 34\,J\,kg^{-1}\,K$ field ranging in (0–5 T), and a Clausius–Clapeyron analysis (first-order transition) was demonstrated to fit fairly well to the estimate of $-\Delta S_m$ plotted versus T built according to the Maxwell relation (Wada and Asano, 2005). A further analysis of the heat treatment process was made more recently, thus allowing to determine the condition for homogeneous materials with sharp transition (Wada, Funaba and Asano, 2006), when quenching the $Mn_{1+\delta}As_{1-x}Sb_x$ samples directly from the melt instead of slow cooling down as done earlier. Besides, using a high-pressure resistive furnace (5.5 MPa applied during synthesis), high quality MnAs samples were prepared (Nascimento *et al*., 2006), thus exhibiting high variation of entropy well, up to $-\Delta S_m \sim 47\,J\,kg^{-1}\,K$ for 0–5 T applied field.

Application of external pressure on MnAs was experienced, leading to colossal MCE levels, the change in entropy at transition exceeding $-\Delta S_m \sim 260\,J\,kg^{-1}\,K$ from 0 to 5 T under 0.223 GPa as shown on Figure 15, effectively more than six times stronger than without application of pressure (Gama *et al*., 2004). From such experiments and analysis, the authors have concluded that, if generally admitted, the assumption of field independence of Δ_l and Δ_e is certainly not valid. Similar pressure experiences were undertaken on well-known $Gd_5Si_2Ge_2$-type compounds by the same group (Magnus *et al*., 2005), with a reverse behavior for the entropy variation in spite of preserving the magnetization level, even increasing the transition temperature. A complete model allowing the description of the colossal entropy variation of MCE material was developed and specifically applied to MnAs (von Ranke *et al*., 2006). It includes the exchange interactions (β-parameter), the magnetoelastic contributions (η-parameter), the external pressure effects (via the Grünesein relation, γ-parameter), the magnetic field dependence of the lattice entropy, but neglecting the electronic contribution. By adjusting the phenomenological parameters β, γ, η to experimental results, the model allows to determine the temperature dependence without and under applied field of the total entropy Δ_T. However, the authors consider that if the model does not reproduce exactly the shape of the ΔT traces versus temperature and pressure, the fair agreement in

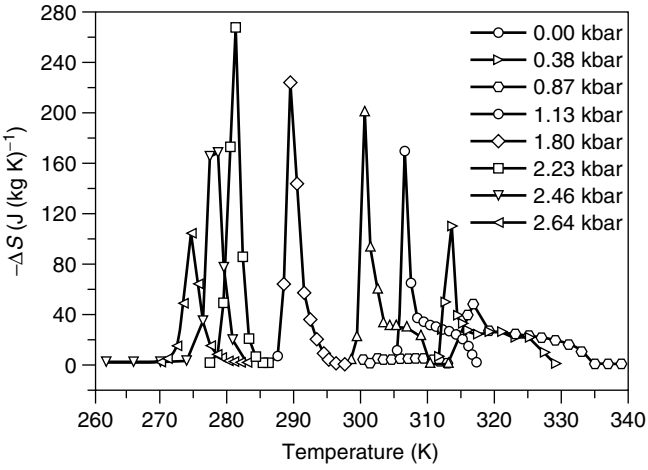

Figure 15. The MCE of MnAs as a function of temperature and pressure. (Gama, S., *et al*. PRL 93, 237202 (2004) p. 3.)

amplitude value leads to ascribe the colossal MCE effect to marked increase in the lattice entropy under pressure. Theoretical analyses of the fundamental behavior and of the (T, H, P) phase diagram of MnAs have been made parallel to the experimentations of the S. Gama's group by de Oliveira (2004) and Nascimento *et al*. (2006).

4.4 Magnetocaloric properties in another series of pnictides

Another series of intermetallic compounds also reveals interesting features in terms of sensitivity to temperature, magnetic field, pressure, chemical composition. . . ferromagnetic phases, with first- or second-order magnetoelastic coupled transitions, as, for example, related to Mn_3GaC, $LaSi_{13-x}Si_x$, $Ce(Fe_{1-x}Co_x)_2$, MnTGe, $MnCoSi_{1-x}Ge_x$. . . all different type compounds. Also, in the series of transition-metal compounds, other families were checked for, as part of an extended list, for example, $Mn_5Ge_{3-x}Sb_x$ (Songlin *et al*., 2002a), $Mn_{5-x}FeSi_xSi_3$ (Songlin *et al*., 2002b), NdP and NdAs (Plaza *et al*., 2004). . . with medium to rather high variations of magnetic entropy at transition. However, the reference book by Tishin and Spichkin (2003) exposes deeply the basic concepts and displays unique sets of data on all of the known systems exhibiting MCE properties. A comparative review of the main characteristics of the most promising MCE alloys and compounds has been reported more recently by Brück (2005).

Other types of materials are interesting to consider in terms of potentially high ferromagnetic but switchable properties, for example, the ternary iron germanium pnictides (X = P, As, Sb) where, apart from MnP and NiAs-type compounds, the systems reveal rich ferromagnetic but switchable properties with different types of structures (Mills and Mar, 2000).

5 CONCLUSION

Two main series of transition-metal-rich pnictides, TT′X and TX, reveal a wide panel of various magnetic properties, but critical situations are confronted owing to strong magnetoelastic couplings associating crystal structure peculiarities and instabilities of magnetic configurations. These series prove to be very attractive with the recent evidence of a marked magnetocaloric character to the many existing transitions. Presently, the renewed interest in the TT′X and TX pnictides covers large fields from fundamental analyses to performances of materials and systems. In fact, the need of alternative solutions to solve the double problem of energy and of environment preservation promotes more research efforts, for example, for room-temperature refrigeration and air conditioning. Anyway, it is worth noting that, exactly 40 years ago, early but determining fundamental characterizations devoted to the just-discovered series of transition-metal pnictides were thus achieved (Goodenough and Kafalas, 1967). This made a milestone lecture of very unusual physical properties versus temperature, magnetic field, and pressure, exhibited by the herein discussed series. The need for a deeper but detailed knowledge led to renewed investigations on magnetic pnictides to better understand the various but interdependent overall contributions to MCE.

6 CHALCOGENIDES

The following part of the chapter is a short review of the knowledge of magnetic chalcogenides compounds. We limit the field of this review to the really new and unusual properties of compounds. The most important event in magnetic compounds is the new interest on the diluted ferromagnetic semiconductors (DMSs) compounds that should be the basic materials for a new kind of electronic components: the 'spintronic' components, in which information is carried by the spins of charge carriers. The first compound family is a zinc-blende compound family in which the metal can be substituted by a magnetic ion. These materials are intensively studied for their epitaxial compatibility with the more classical semiconductors such as GaAs or Si. In complement, the half-metallic ferromagnetic compounds can help to create a basic set of spintronic materials.

After a brief presentation on some layered ferromagnetic compounds and on a 'new class of alkali metal–transition metal chalcogenides', we present recently studied rare-earth and copper chalcogenides that exhibit some structural similarity with high T_C superconductor structures. We finish our discussion of magnetic chalcogenides with two studies on magnetic actinide (essentially uranium) compounds that always constitute an important research activity.

7 NEW MATERIALS FOR SPINTRONICS

Experimental studies on Fe/Cr multilayers (Baibich *et al*., 1988) have made it obvious that the spin drives the conductivity in these structures and led to a new solid state physic concept: spin-based electronic, so-called spintronic, is presently the subject of intensive developments in the world. The first applications, for the magnetic hard disk reading heads, use the giant magnetoresistance (GMR) and tunneling magnetoresistance (TMR) (Barthélémy, Fert and Petroff, 1999; Tsymbal, Mryasov and LeClair, 2003) allowing the actual data storage capacities being reached.

The actual spintronic challenge is now to find convenient materials to construct a real spin-based electronic device in parallel with the conventional ones based on IV, III–V, and II–VI semiconductors. For this purpose, both ferromagnetic semiconductors and half-metallic ferromagnetic compounds are explored.

7.1 The diluted ferromagnetic semiconductors (DMS)

This materials class is derived from the classical semiconductors III–V and II–VI with zinc-blende or wurtzite crystallographic structure. The ferromagnetism is obtained with a partial substitution of the cations by magnetic ions as 3d or 4f metal where the ferromagnetic interaction will be mediated by the holes (Dietl, Haury and Merle d'Aubigné, 1997; Dietl, Ohno and Matsukura, 2001). These material series constitute the diluted magnetic compounds, called *DMS*.

The most relevant feature of DMS, which attracted considerable interest, is the coexistence and interaction of two different electronic subsystems: unlocalized conduction (s type) and valence (p type) band electrons and localized (d or f type) electrons of magnetic ions. In particular the s, p–d exchange interaction leads to strong band splittings, which result in giant magneto-optical effects (Chang and Xia, 2002). On the other hand, the randomly distributed magnetic ions with the d–d exchange interaction can induce formation of antiferromagnetic or spin-glass phases instead of the ferromagnetic one, depending on the magnetic ion concentration and temperature (de Jonge and Swagten, 1991; Twardowski, 1995).

After about three decades of investigation, many devices were synthesized by molecular-beam epitaxy (MBE) technology for DMS growth with various magnetic ions (like Mn, Fe, Co, and recently Cr). Figure 16 displays computed ferromagnetic ordering temperatures (Dietl, Haury and Merle d'Aubigné, 1997) and evidences a possibility to reach room-temperature ferromagnetism for some compounds. This prediction was confirmed by the observed ordering temperature of (Ga,Mn)As that has reached 100 K on one hand (Ohno *et al*., 1996) and, on the other hand, the recent studies starting from the ZnO thin films present some ferromagnetic properties at room temperature (Yan, Ong and Rao, 2004; Shi-Shen e*t al*., 2004) as displayed in Figure 17. Table 1, displays some recent experimental results collected by Hebard *et al*. (2004). It includes the results for the (Ga,Mn)As sample (Ohno *et al*., 1996).

Hebard *et al*. (2004), in their paper, discuss the meaning of high T_C ferromagnetism in DMS and make clear the various disturbing effects during the sample synthesis and their consequences on the final apparent properties.

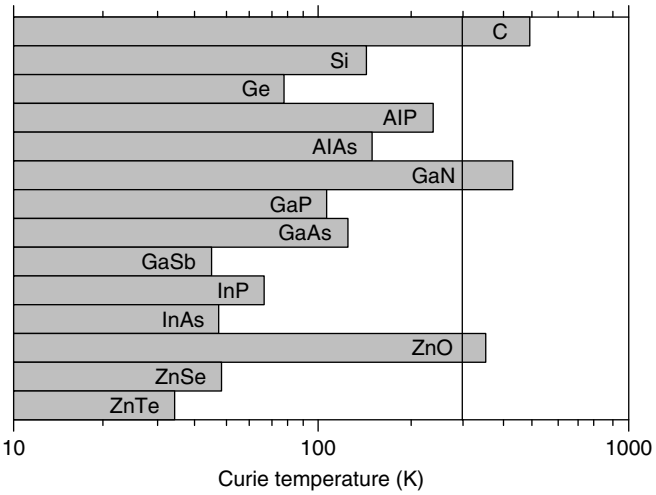

Figure 16. Computed values of the Curie temperatures T_C for various p-type IV, III–V, and II–VI semiconductors containing 5% of Mn by cation and 3.5×1020 holes/cm^3. (After Dietl, T. *et al*., 2001 and Dietl, T., 2002.)

The electronic structure of these compounds was intensively studied by several authors with various methods. Two recent papers (Sanyal, Bengone and Mirbt, 2003; Erikson *et al*., 2004) present a fine analysis of the electronic structure of these compounds. In the first step, starting from self-consistent electronic structure calculation, including a collinear spin arrangement, an electronic structure is determined. Then, the deduced exchange interactions are used in Monte Carlo simulations to take into account the statistical mechanics part of the problem. The results for several representative groups III–V and II–VI DMSs are found to agree nicely with the experimental data particularly for the ordering temperatures.

As pointed out by many authors in recent studies of these materials, it is difficult to get reproducible results which are very sensitive to the methods (MBE, pulsed-laser deposition, metallo organic chemical vapour deposition, etc.) and conditions of compound film elaboration. It seems that it is rather difficult to obtain homogeneous distributions of the magnetic cations in the sample and, the observed Curie temperature is often markedly lower than the predicted one. Finally, the semiconductor properties are depending of the nature and the magnetic ions concentration which affect the strength of exchange interactions that stabilize the ferromagnetic state.

In conclusion, it seems, these semiconductors are actually difficult to use for electronic application so that a very important characteristic of these compounds is the possibility to insert them in devices using standard III–V or II–VI semiconductors. In addition, as known from Tomasz Dietl: 'With no doubt, search for functional ferromagnetic semiconductor

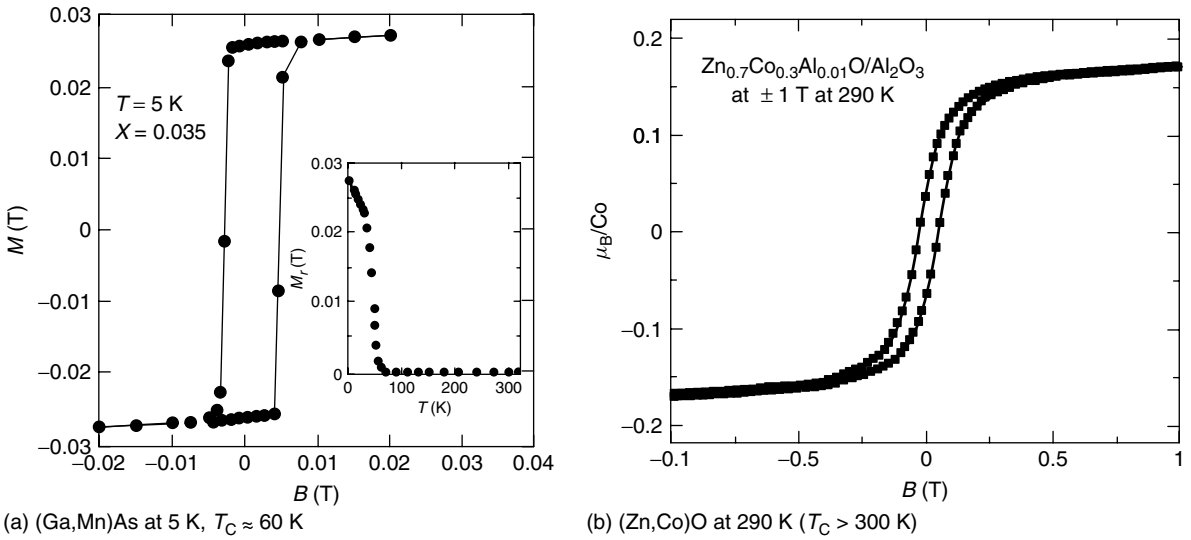

Figure 17. Two Hysteresis cycles for (a) (Ga,Mn)As and (b) (Zn,Co)O films. (After (a) Ohno *et al*., 1996 and (b) Yan *et al*., 2004.)

Table 1. Experimental results on some diluted magnetic semiconductors $A_xM_{1-x}B$ samples as collected by Hebard *et al*. (2004), except for GaAs line that was given by Ohno *et al*. (1996). T_C denotes, the observed Curie temperature by field (H_a) cooling and H_{co} is the coercitive field as observed at the temperature T_o.

Host material	Carrier concentration (cm^{-3})	Magnetic ion	T_C (K)/H_a (Oe)	H_{co} (Oe)/T_o (K)

nanostructures and their theoretical modeling have evolved into an important branch of today's materials science and condensed matter physics.'

7.2 The half-metallic ferromagnetic compounds

Half-metallic ferromagnets (HMFs) are metals having 100% spin-polarized electrons at the Fermi level. The high Curie temperature and very small lattice mismatch with widely employed semiconductors are the useful features that are suitable for spintronic applications.

Some Heusler compounds, like NiMnSb, PtMnSb, PdMnSb, or PtMnSn, were found to possess this necessary combination of properties with a ground state (de Groot, Mueller, van Engen and Bushow, 1983) characterized by a 100% spin polarization of charge carriers.

Recently, Akinaga and coworkers (Akinaga, Manago and Shirai, 2000) have grown a new zinc-blende phase of CrAs. The epitaxial growth was performed by MBE on a GaAs substrate. This zinc-blende CrAs layer was identified as a room-temperature ferromagnet (Figure 18). Studies by several authors seem to indicate that this metastable zinc-blende structure is possible for thin layers

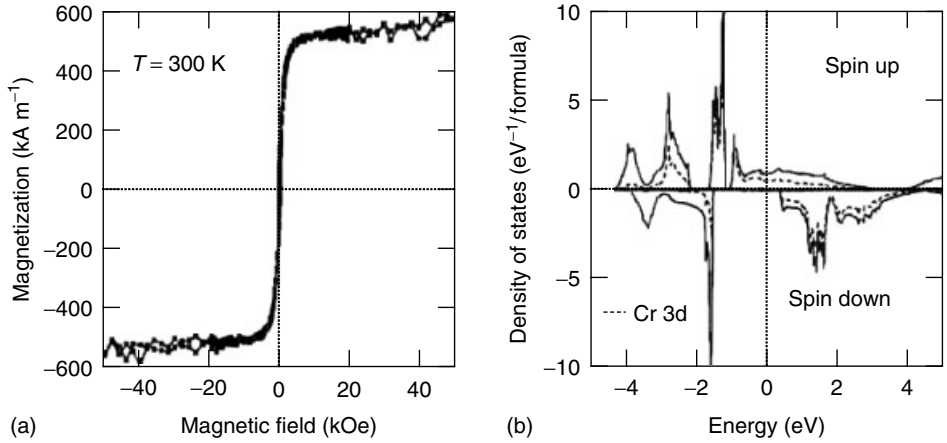

Figure 18. Film of zinc-blende film zb-CrAs/GaAs: Magnetization hysteresis loop at 300 K with applied magnetic field in the film plane (a), and density of states (DOS) where the broken lines denotes the Cr 3d component. The vertical dotted line denotes the Fermi energy (b) (Akinaga *et al*., 2000).

of other similar compounds such as VAs, CrAs, CrSb, MnAs (Kübler, 2003 and their referenced papers). The zinc-blende HMFs would exhibit a high Curie temperature of the same order as the Heusler HMF NiMnSb with $T_C = 701$ K (Kübler, 2003). As for DMS compounds previously described, the main interest of these zinc-blende HMFs is their ability to form thin films (few nanometers) by epitaxy on the traditional III–V and II–VI semiconductors which is combined with their high Curie temperatures.

These half-metallic ferromagnetic compounds should be difficult to use because there are basically instable phases that can be stabilized only by the constraints of substrate with the zinc-blende structure. This fact can make the design of future spintronic devices complicated and therefore, to date, it is difficult to evaluate their future impact on applications.

8 TRANSITION-METAL CHALCOGENIDES

8.1 Magnetic properties of the lamellar compound $Cr_2Ge_2Te_6$

$Cr_2Ge_2Te_6$ is a recently studied layered material belonging to the lamellar ternary $M_2X_2Te_6$ chalcogenides family (where M is a +3 oxidation state metal such as V, Mn, Fe, Co, Ni, Zn, Cd, or Hg and X_2 a silicon or a germanium pair). The crystallographic structures of these compounds can be described as hexagonal compact stackings of Te atoms in which M atoms and the X_2 pair occupy octahedrons in the different layers. The different layers are attached by empty slabs, so-called van der Walls gap. As some other compound family member, $Cr_2Ge_2Te_6$ exhibits a ferromagnetic state at low temperature with a Curie point of 61 K that is significantly higher than for other compounds as $Cr_2Si_2Te_6$ ($T_C = 32$ K) (Carteaux, Brunet, Ouvrard and André, 1995).

8.2 New class of alkali metal–transition metal chalcogenides

The chalcogenides $A_xM_yX_z$ (A = alkali metal, M = transition metal, X = S, Se, or Te) crystallize in structures that, depending upon the stoichiometry, contain isolated groups, dimers, chains, or layers, where the anionic building units M_yX_{zx} are formed by linkage of the $[MX_4]$ tetrahedrons via their edges. The particularity of this study is the use of magnetic properties as an indication of transition between separated or linked together building units (Bronger and Müller, 1997). When the building units are linked together, the compound exhibit some antiferromagnetic orderings while in the other case the paramagnetic susceptibilities are exhibited (Bronger and Müller, 1997).

9 R(4f), X COMPOUNDS

The ternary R–T–X (R = rare earth, T = transition metal, X = chalcogen) including rare-earth and transition-metal (3d or 4d) elements form a very wide space of formulas that exhibit a large panel of physical properties. To illustrate a typical series of compounds, we briefly present the properties of rare-earth with copper chalcogenides.

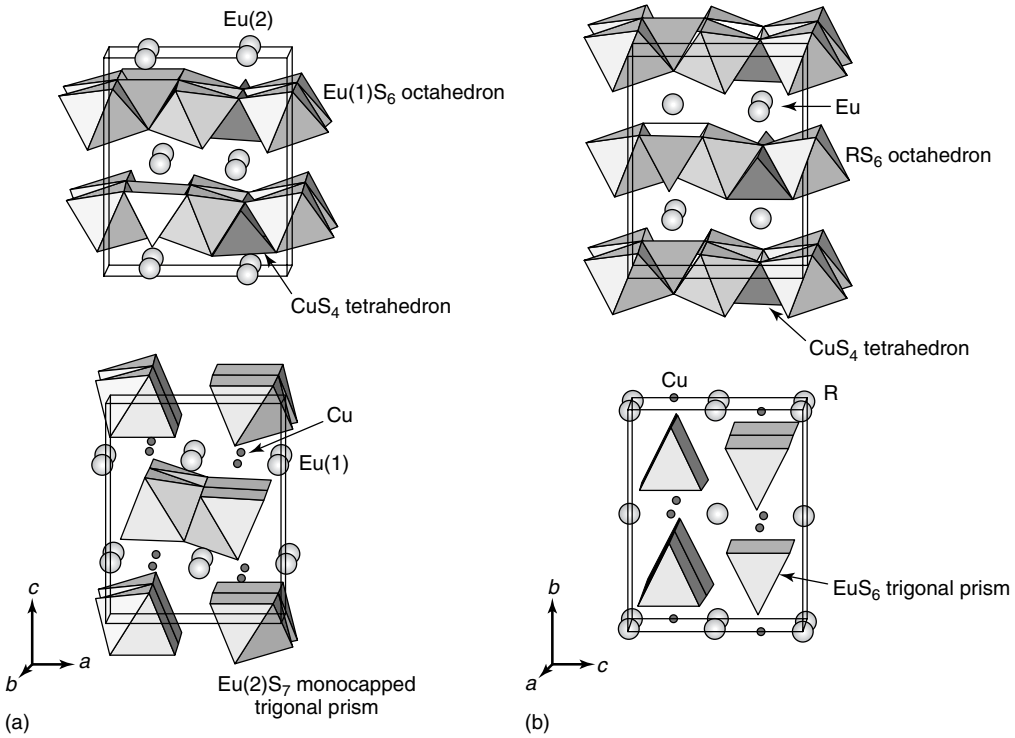

Figure 19. Polyhedral representations of the two types of structures: $EuRCuS_3$ crystallize in the Eu_2CuS_3 (a) except for R = Tm, Yb, and Lu where the type structure is $KZrCuS_3$ (b).

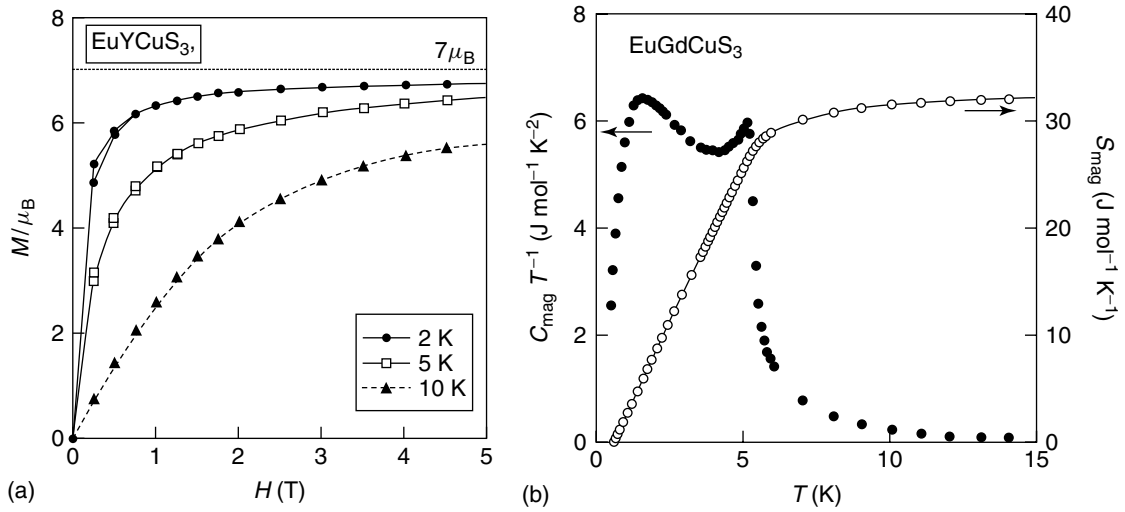

Figure 20. Magnetization curves of (a) $EuYCuS_3$ and (b) $EuGdCuS_3$.

9.1 The $EuRCuS_3$(R = Y, Gd–Lu) compound series

The $EuRCuS_3$ (R = Y, Gd–Lu) compounds series (Wakeshima, Furuuchi and Hinatsu, 2004) is derived from europium sulfide Eu_2CuS_3 (space group *Pnma*) (Lemoine, Carré and Guittard, 1986) in which the Eu^{3+} cations (not magnetic at ground state) are replaced by other rare-earth atoms while the magnetic Eu^{2+} are kept. These substitutions do not change the crystallographic structure except for the smallest atoms, R = Tm, Yb, and Lu, for which the structural type is $KZrCuS_3$ (space group *Bbmm*) that is a supergroup of *Pnma*. The structure of these compounds can be displayed as stack of layers of CuS_4 tetrahedrons and RS_6 octahedrons spaced

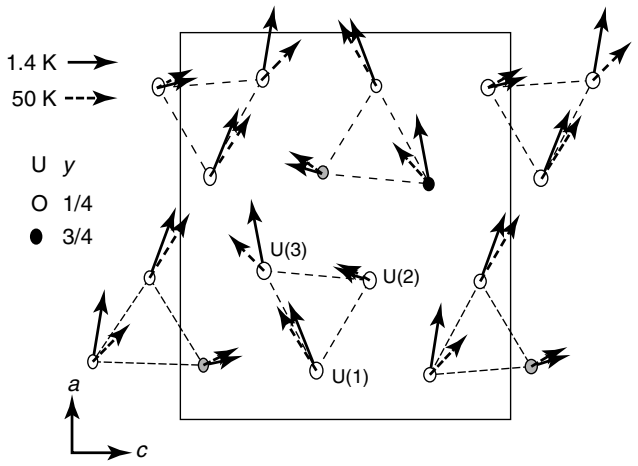

Figure 21. Superposition of the magnetic structures of U_3Te_5 at 1.4 and 50 K in the (a, c) projection plane.

by Eu planes (Figure 19). These systems of layers can be considered as close to high-T_C superconductor compounds with the substitution of oxygen by the sulfur atoms.

These compounds exhibit ferromagnetic behavior for R = Y or Lu (nonmagnetic rare-earth atoms) and ferrimagnetic ones for the magnetic rare-earth atoms. The ordering temperature is close to 5 K for all compounds. The susceptibility, magnetization (Figure 20a) and specific heat (C_p) measurements on the Y and Lu compounds reveal that the ferromagnetic ordering is induced only by the Eu^{2+} (in the eightfold degeneracy ground state). In Figure 20 the magnetization curves for $EuYCuS_3$ and $EuGdCuS_3$ show the contribution of the gadolinium atom as equal to that the europium atoms. This is consistent with the same state $4^8S_{7/2}$ for both atoms and for all these compounds the magnetic moments are close to the classical ionic values if we take in account the crystal-field anisotropy for an isotropic powder sample.

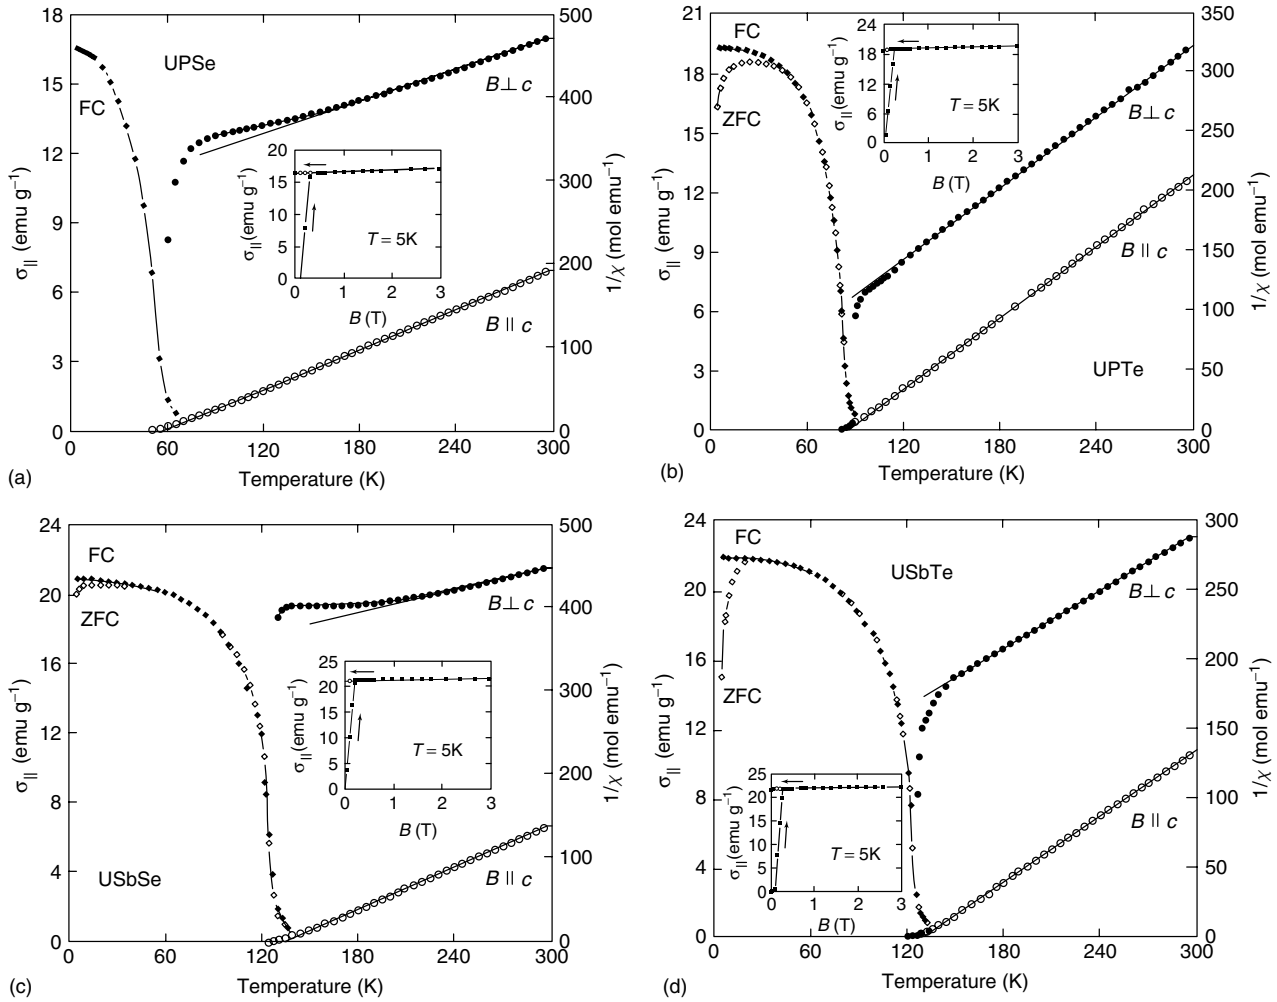

Figure 22. Spontaneous magnetizations and reciprocal of magnetic susceptibility versus the temperature for single crystals of (a) UPSe, (b) UPTe, (c) USbSe, and (d) UsbTe. The magnetic susceptibility was measured in parallel and perpendicularly of c axis that is the spontaneous magnetization direction.

10 Ac(5f), X COMPOUNDS

Actually, the chalcogenides including uranium (and also some other actinides, particularly thorium) form a significant part of the recent metal chalcogenides studies. Here, we briefly describe some typical studies of magnetic uranium chalcogenides: U_3Te_5, U_2Te_3. Moreover the compounds of formula UXY (X = chalcogen, Y = P, As, or Sb) form an other family which displays particularly high anisotropy of uraniums compounds, even in the paramagnetic state.

U_3Te_5, U_2Te_3

As detailed in the previous reference, the U_3Te_5 compounds crystallize in the orthorhombic space group *Pnma* with three uranium nonequivalent atom sites U(1), U(2), U(3). Their respective magnetic moments lie in the $a-c$ plane with a F_xC_z-type structure, with different magnetic moments for U(1), U(2), U(3). A spin reorientation toward the c direction occurs around $T = 45$ K. Both magnetic structures are displayed in Figure 21 (Tougait, André, Bourée and Noel, 2001).

Neutron diffraction data for U_2Te_3 (*Pnmn* space group) are consistent with an antiferromagnetic not collinear G_xA_z-type structure. The magnetic moments of uranium atoms in both crystallographic sites U(1) and U(2) are in the $a-c$ plane with different magnitudes. A slight spin reorientation on the U(2) site occurs also around $T = 45$ K. Close to the ordering temperature ($T = 95$ K, $T_N = 95$ K), some small neutron diffraction lines indicate a complex magnetic structure.

In both compounds, these results are correlated with the macroscopic magnetic measurements.

10.1 UXY compounds

The compounds UPSe, UPTe, USbSe, and USbTe are ferromagnetic with the ordering temperature of $T_C = 55$, 85, 128, and 127 K respectively (Kaczorowski, Noël and Zygmunt, 1995). The authors have measured the susceptibilities and magnetizations on single crystals that display a very large anisotropy of uranium (Figure 22).

The compound UAsSe is ferromagnetic with a ordering temperature T_C close to 113 K (Henkie, Fabrowski, Wojakowski and Zaleski, 1995). This magnetic state disappears at low temperature while the resistivity increases (Kondo effect).

Magnetostrictive Materials and Magnetic Shape Memory Materials

Robert C. O'Handley
Massachusetts Institute of Technology, Cambridge, MA, USA

1 INTRODUCTION

Among the most interesting and technically important properties of any class of materials are its couplings with other phenomena. Examples include piezoelectricity, thermoelectricity, electro-optics, magneto-optics, and magnetomechanical effects. Magnetostriction refers to the deformation of a material owing to changes in its state of magnetization. The magnetostrictive deformation can be isotropic (magnetovolume effect), or anisotropic (Joule magnetostriction). A large volume change is often observed on cooling a magnetic material through its Curie temperature (Figure 1). In the case of Ni, this volume expansion is over 4% (Gschneider, 1964; Stoelinga, Gersdorf and deVries, 1965; Kollie, 1977).

This volume change allows the material to accommodate the increased energy of the spins in the magnetically ordered state; when electrons are no longer equally distributed between spin-up and spin-down states, their kinetic energy increases (Janak and Williams, 1976). In the ferromagnetic state, increasing a field beyond the anisotropy field may also induce a small isotropic strain associated with the high-field susceptibility. This chapter will focus more on the Joule magnetostriction, an anisotropic strain of lower symmetry than the crystal itself that arises from a *change in direction of the magnetization* (Figure 1, inset circle) as well as on a related phenomenon, the large field-induced strain in magnetic shape-memory alloys such as Ni–Mn–Ga. This latter effect is *not* due to the rotation of the magnetization but rather to *field-induced twin-boundary motion*.

Magnetostrictive strains are typically less than 10^{-4} except for certain rare-earth and rare-earth/transition-metal alloys. The net volume change during anisotropic magnetostriction is often close to zero, so $\lambda_\perp \approx -0.5\lambda_\parallel$, where $\lambda_\perp(\lambda_\parallel)$ is measured in the direction perpendicular (parallel) to the field-induced, saturation magnetization. Not only is the magnetostrictive strain tensor anisotropic about the magnetization direction but it can also have very different components depending on the crystallographic direction in which the magnetization is oriented. The inverse effect, whereby an imposed stress changes the state of magnetization, is important for a variety of sensors. In addition, magnetostrictive materials under certain conditions can appear to have a reduced elastic stiffness, called the ΔE effect, and hence reduced sound velocity. These phenomena will be discussed. Other useful references on magnetostriction include the following: Del Moral (2006); O'Handley (2000); Cullen, Clark and Hathaway (1997); Lacheisserie (1993); Kittel and Galt (1967); Kanamori (1963); and Kittel (1949).

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

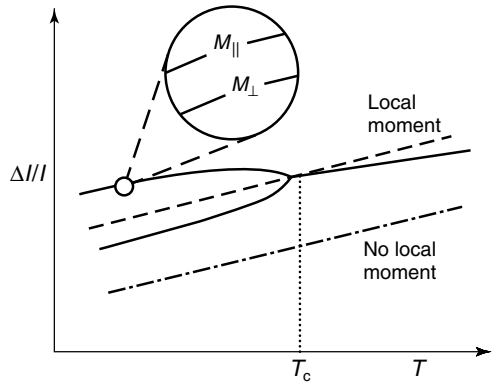

Figure 1. Schematic of the thermal expansion of a magnetic material as a function of temperature illustrating the increased volume due to the presence of a local magnetic moment and the onset of magnetic anomalies below the Curie temperature. A small anisotropic strain, depending on the direction of magnetization (circled inset), is also observed below T_C. The latter is usually referred to as *anisotropic magnetostriction*. (Reprinted with permission O'Handley R.C., copyright 2000, John Wiley & Sons Inc.)

Magnetostriction is an *elastic* deformation. Time-reversal invariance of physical phenomena requires that the strain be the same if the magnetization direction reverses along the same axis. Hence, there is no change in strain for 180° domain-wall motion. There is change in magnetostrictive strain for 90° domain-wall motion and for magnetization rotation.

Historically, Ni was the most widely used magnetostrictive material. Though it has a magnetostrictive strain of only 30 or 40×10^{-6}, the low magnetic anisotropy of Ni allows this strain to be achieved in relatively weak fields. In the 1960s and 1970s, the magnetostriction of many rare-earth transition-metal intermetallic compounds and alloys was studied. This led to the development of the highly magnetostrictive alloy, $Fe_2(Tb_{0.3}Dy_{0.7})$, called *Terfenol-D*, having $\lambda_{\|} - \lambda_{\perp} \approx 2400 \times 10^{-6}$ and relatively low magnetic anisotropy, $\mu_0 H_a \approx 0.1$T (Abbundi and Clark, 1977; Clark, 1980). But these intermetallic compounds are brittle and hard to grow with the proper texture. A new class of ductile, high-magnetostriction alloys based on BCC solid solutions of Fe–Ga has shown $\lambda_{100} \approx 400 \times 10^{-6}$ in fields of order 0.01 T (Clark *et al*., 2000; Guruswamy *et al*., 2000). (λ_{100} is the change in length relative to the dimensions of the demagnetized crystal, measured parallel to the crystallographic [100] direction when $\boldsymbol{M}$ is saturated in that direction.)

In was noted three decades ago that the large field-induced strain in Dy appears to be associated with twin-boundary motion (Liebermann and Graham, 1976). It had long been speculated that similar large strains could be observed in a subclass of shape-memory alloys that are also ferromagnetic shape memory alloys (FSMAs). Examples of such materials include Fe–Pd and Ni_2MnGa. It was expected that an applied field could either move crystallographic twin boundaries in the martensitic state to produce a large strain, or change the temperature of the transformation from the untwined, high-symmetry (austenite) phase to the twinned, low-symmetry (martensite) phase. Thus, application of a field at a temperature close to the transformation could control the large deformation energy there (Ullakko 1996; James and Wuttig, 1996). Experimental evidence of magnetic-field-induced strain by motion of twin boundaries began to accumulate (Ullakko *et al*., 1996; James and Wuttig, 1998; Tickle *et al*., 1999). The full field-induced strain of $1 - c/a = 6\%$ in tetragonal Ni–Mn–Ga (Murray *et al*., 2000) and 10% in its orthorhombic phase (Sozinov, Likhachev, Lanske and Ullakko, 2002) have been observed.

Field-induced strain in FSMAs has two components. First, there is the usual *elastic* magnetostrictive strain that increases quadratically with applied field as the magnetization direction changes; it is of the order -150×10^{-6} in Ni–Mn–Ga alloys (Tickle *et al*., 1999). Second, when mobile twin boundaries are present, there is a much larger *plastic* strain, of order 6 or 10% in tetragonal or orthorhombic Ni–Mn–Ga, respectively. This strain starts to appear when the applied field exceeds a threshold field, and initially increases linearly with the field, then saturates gradually as H approaches $H_a \approx 0.55 \times 10^6\,\mathrm{A\,m^{-1}}$. There are several recent review articles on FSMAs (O'Handley and Allen, 2000; O'Handley *et al*., 2000; Kostorz and Müllner, 2005; Söderberg *et al*., 2006).

This article reviews the phenomenology and range of observed anisotropic magnetostricitve strains. It also summarizes some aspects of the current understanding of magnetic-field-induced strains in FSMAs. The two phenomena, magnetostriction and field-induced strain in FSMAs, are compared and contrasted.

2 ANISOTROPHIC MAGNETOSTRICTION

Changing the direction of magnetization in a magnetic material for $T < T_C$ generally causes it to strain anisotropically (Figure 1, circled inset); that is, the magnetization vector has associated with it a stress tensor with principal axes directed along $\boldsymbol{M}$ that causes a mechanical deformation. The field dependence of this *anisotropic strain* is shown schematically in Figure 2 for an isotropic material ($\varepsilon_{\|}$ for strain measured parallel to the field and $\varepsilon_{\perp}$ for strain measured perpendicular to the field). This anisotropic strain was first observed in 1842 by Joule in iron and is often called *Joule magnetostriction*. The fact that the magnetostrictive strain, $\varepsilon(H) = \Delta l(H)/l \equiv \lambda(H)$, saturates above a certain field, $\lambda\ (H_{sat}) \equiv \lambda_s$, indicates that the anisotropic strain is due to a field-induced change in the direction of the magnetization, not the change in the field itself.

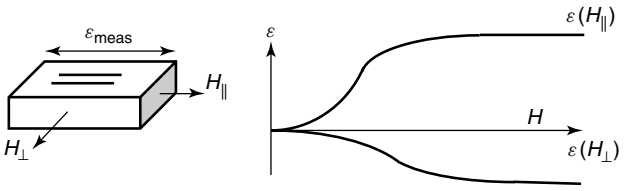

Figure 2. When a demagnetized sample is magnetized by an external field, the sample strains anisotropically. The strain in the direction of magnetization, $\varepsilon(H_\parallel)$, will be opposite in sign to the strain measured perpendicular to the direction of magnetization, $\varepsilon(H_\perp)$. The strains depicted above are those for a material with a positive magnetostriction constant: $(\Delta l/l)_\parallel > 0$.

Values of the saturation magnetostriction, λ_s, can range from zero (effectively, $\varepsilon < 10^{-7}$) to nearly $\pm 10^{-4}$ in 3d metals and alloys and to over $\pm 10^{-3}$ in some 4f metals and alloys. For Ni, which has a principal magnetostrictive stress, $B_1 = +6.2\,\text{MPa}$ and, given its Young's modulus, $E = 2 \times 10^{11}\,\text{N m}^{-2}$, we would expect to observe magnetostrictive strains of the order 30×10^{-6}. This is indeed close to the magnetostriction of polycrystalline Ni, $\lambda_s = -34 \times 10^{-6}$. The minus sign indicates that Ni tends to contract in the direction of magnetization and shows a nearly volume-conserving expansion in the two orthogonal directions, $\varepsilon_\perp = -\varepsilon_\parallel/2$.

The inverse effect is also important. Stressing or straining a magnetic material can produce a change in its preferred magnetization direction or in its M–H curve (Figure 3). These phenomena are called *inverse Joule effects*, *Villari effects*, or *piezomagnetism*. *If the saturation magnetostriction coefficient*, λ_s, *is positive, it is easier to magnetize the material in the tensile strain direction*. It is harder to magnetize a material in a direction for which $\lambda_s < 0$ and the imposed strain $\varepsilon > 0$ or for which $\lambda_s > 0$ and $\varepsilon < 0$. This implies the existence of terms in the magnetic anisotropy energy, which depend on strain as well as on the direction cosines of the magnetization: $\boldsymbol{M} = M_s(\alpha_x, \alpha_y, \alpha_z)$. These magnetic–elastic coupled terms describe the magnetoelastic (ME) anisotropy energy. The anisotropic strain effects arising from terms in the free-energy containing products of strain and magnetization direction are the focus of this chapter.

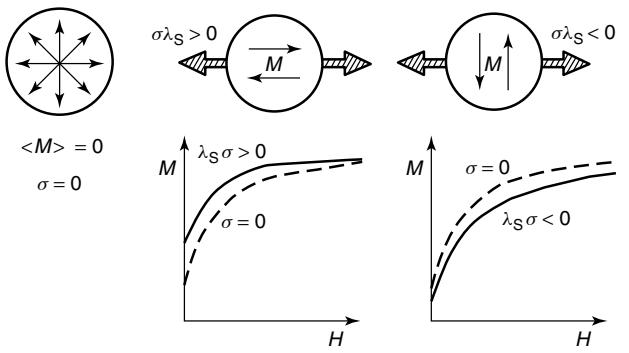

Figure 3. Imposing a strain on a magnetic material by an external mechanical stress can alter the change direction of magnetization (magnetic anisotropy) and thus alter the shape of the M–H curve below saturation. The cases above illustrate the changes observed for a polycrystalline material with a positive magnetostriction constant. (Reprinted with permission O'Handley R.C., copyright 2000, John Wiley & Sons Inc.)

2.1 Phenomenology

2.1.1 Field dependence of Joule magnetostriction

The *anisotropic magnetostrictive strain* relative to the direction of magnetization may be described for an *isotropic material* comprised of a single domain (i.e., one magnetization direction) by the relation

$$\varepsilon = \frac{3}{2}\lambda_s\left(\cos^2\theta - \frac{1}{3}\right) \tag{1}$$

Here $\varepsilon = \Delta l/l$ is the strain measured at an angle θ relative to the saturation magnetization direction and λ_s, the saturation magnetostriction coefficient, is the measure of the magnitude of the strain on changing the direction of magnetization in the material. The strain ε is sometimes called the *magnetostriction*, λ, but clearly, from equation (1), ε is a function of the direction of $\boldsymbol{M}$ or of the applied field so it should not be confused with the saturation magnetostriction λ_s which is a material constant. Figure 2 shows the variation of strain in a given direction in a material as an external field is increased either parallel or perpendicular to the strain-measuring direction.

For a uniaxial material in the absence of an external field, the magnetization lies along the 'easy axis' direction (defined by the uniaxial magnetic anisotropy). A 'hard-axis' magnetization process (in which the field is applied orthogonal to the preferred direction of magnetization) is known to be linear in the field, H and to scale with the ratio of the saturation magnetization, M_s, to the anisotropy field, H_a: $M(H) = M_s H/H_a$. This relation can be expressed in terms of the reduced magnetization, $m(H) = M(H)/M_s$, and reduced field, $h = H/H_a$ giving $m = h$. (The anisotropy field is the field at which a linear, hard-axis magnetization process saturates.) From Figure 4(a), and $m(H) = \cos[\theta(H)]$, we may write equation (1) as

$$\varepsilon = \frac{3}{2}\lambda_s\left(m^2 - \frac{1}{3}\right) \tag{2}$$

That is, the magnetostrictive strain in a hard uniaxial direction is quadratic in $m = h$, so ε is proportional to H^2 (Figure 4b), saturating at $h = 1$.

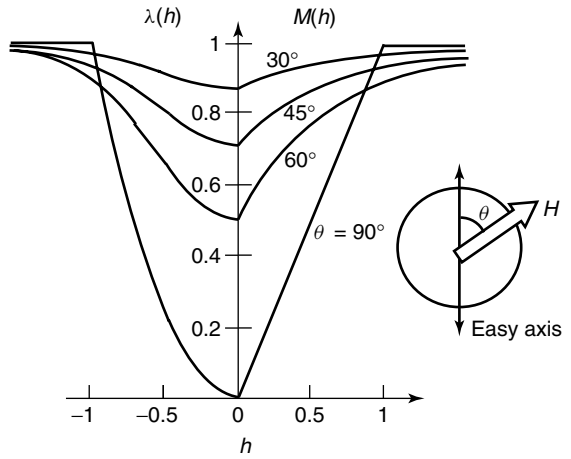

Figure 4. Reduced magnetization (b) and magnetostriction (a) versus reduced field, h, calculated for different orientations of applied field relative to easy axis. Application of a magnetic field perpendicular to the easy axis of a material causes a rotation of the magnetization direction and results in a linear M–H characteristic and a quadratic dependence of strain on field. The field-dependent strain is shown here as positive along the field direction as is the case for $\lambda_s > 0$ (O'Handley, 2000).

Above saturation, the two strain curves in Figure 2 are essentially parallel to each other (except for the presence of any high-field-susceptibility-induced volume magnetostriction) and their difference defines λ_s. From equation (1)

$$\varepsilon_{\parallel} = \frac{3}{2}\lambda_s\left(1 - \frac{1}{3}\right) = \lambda_s \; \varepsilon_{\perp} = \frac{3}{2}\lambda_s\left(0 - \frac{1}{3}\right) = -\frac{\lambda_s}{2} \quad (3)$$

That is, the saturation magnetostriction λ_s is the strain measured in the field direction relative to the randomly magnetized state ($\langle\cos^2\theta\rangle = 1/3$). However, because a completely demagnetized state is not easily achieved with certainty, measurement of *both* $\varepsilon_{\parallel}$ and $\varepsilon_{\perp}$ in equation (3) is recommended to determine λ_s in isotropic materials:

$$\varepsilon_{\parallel} - \varepsilon_{\perp} = \frac{3}{2}\lambda_s \quad \text{so that} \quad \lambda_s = \frac{2}{3}(\varepsilon_{\parallel} - \varepsilon_{\perp}) \qquad (4)$$

The significance of equation (4) for measurement of λ_s in isotropic materials can be appreciated by referring to Figure 2. Changes in the zero-field magnetization distribution may shift the origin up or down between the limits of $\varepsilon_{\parallel}$ and $\varepsilon_{\perp}$, but the difference between the two high-field strains remains fixed at $(3/2)\lambda_s$. Thus, two strains should be measured to specify λ_s in an isotropic material. More than two measurements are required to fully specify λ_{ij} for lower-symmetry materials.

The magnetostrictive strain is the same in each of two magnetic domains separated by a 180° domain wall because $\cos^2\theta$ is the same in each domain. This is due to time-reversal invariance; the energy is the same whether the microscopic currents rotate to give $\boldsymbol{M}$ in one direction or they reverse sign to give $\boldsymbol{M}$ in the opposite direction. Therefore, there is no magnetostrictive shape change associated with a magnetization process involving only 180° domain walls. (There may be a local strain about a 180° domain wall owing to the change in orientation of $\boldsymbol{M}$ there, but the elastic constraint of the material reduces this strain relative to the magnetostrictive strain of an unconstrained, saturated sample.)

2.1.2 Some data

For materials that are not isotropic, the magnetostriction constant can be different in different directions and higher-order distortions than the dipolar strain in equation (1) may also play a role. For example, magnetizing an iron crystal along ⟨100⟩ causes an elongation along ⟨100⟩ relative to the demagnetized state. Magnetizing it along ⟨111⟩ causes a contraction along the ⟨111⟩ direction relative to the demagnetized state. Nickel contracts in the direction of magnetization for any crystal orientation. This is reflected in the principal magnetostriction coefficients of Fe and Ni:

$$\text{BCC iron} \;\; \lambda_{100} = 20.5 \times 10^{-6} \;\; \text{and} \;\; \lambda_{111} = -21.5 \times 10^{-6}$$

$$\text{FCC nickel} \;\; \lambda_{100} = -46 \times 10^{-6} \;\; \text{and} \;\; \lambda_{111} = -25 \times 10^{-6}$$

It should be noted that the ⟨100⟩ directions are the easy directions of magnetization for BCC-Fe and the ⟨111⟩ directions are easy for FCC-Ni (O'Handley, 2000, Ch. 5; Lacheisserie and Monterroso, 1983). Rotating the magnetization of an iron crystal from one easy axis to a different easy axis causes an increase in length along the field axis of $(3/2)\lambda_{100} \approx 31 \times 10^{-6}$. The field at which the magnetostriction saturates is the anisotropy field (see Figure 4).

Many of the rare-earth metals and rare-earth intermetallic compounds are characterized by very strong magnetic anisotropy which makes it difficult to get an accurate measurement of saturation magnetostriction values. Some data for these materials are given in Table 1. Further data on these systems can be found in Cullity (1973) and O'Handley (2000) and in review articles (Clark, 1980; Morin and Schmitt 1990; Cullen, Clark and Hathaway, 1997). An alloy having nearly zero magnetic anisotropy at room temperature, Terfenol-D ($Fe_2[Dy_{0.7}Tb_{0.3}]$) was developed at the Naval Ordinance Laboratory (hence the name *Ter-Fe-NOL*) (Clark, 1980; Cullen, Clark and Hathaway, 1997) by combining appropriate ratios of the cubic Laves compounds Fe_2Tb ($K_1 = -7 \times 10^7\,\mathrm{J\,m^{-3}}$) with Fe_2Dy ($K_1 = 3 \times 10^7\,\mathrm{J\,m^{-3}}$).

The highly magnetostrictive rare-earth compounds are prone to oxidation and are relatively brittle (poor tensile behavior and not easily machined). Favorably textured

Table 1. Magnetostriction constants λ_{100} and λ_{111} in parts per million at 4.2 K and at room temperature for several materials. Some polycrystalline room-temperature values are also listed. The prefix *a* designates an amorphous material. For uniaxial materials (denoted by superscript 'u') where $\lambda^{\gamma,2}$ or $\lambda^{\varepsilon,2}$ was reported, their values are given in parentheses in the λ_{100} and λ_{111} column, respectively.

	$T = 4.2$ K		Room temperature		
	$\lambda_{100}(\lambda^{\gamma,2})$	$\lambda_{111}(\lambda^{\varepsilon,2})$	$\lambda_{100}(\lambda^{\gamma,2})$	$\lambda_{111}(\lambda^{\varepsilon,2})$	Polycrystal λ_s

polycrystalline boules ([211] parallel to the boule axis) can be grown with modest yield. There remained a need for a less expensive and more ductile high-magnetostriction Fe-based alloy. It appears to have been found in the BCC-Fe–Ga solid solutions (appropriately named *Galfenol*) (Clark *et al*., 2000, Guruswamy *et al*., 2000). The variation of λ_{100} with Ga content is shown in Figure 5 (λ_{111} is less than 10% of λ_{100}) due, in part, to the large value of $C_{44} \approx 1.2 \times 10^{11}$ Pa over most of the Ga range studied) (Wuttig, Dai and Cullen, 2002). The peak in λ_{100} at $x_{Ga} = 26$ at% is because of the vanishing of $C_{11} - C_{12}$ there. The peak in λ_{100} at 19% Ga occurs in the solid solution range and is of technical importance; its origin is possibly due to directional ordering of Ga over a short range.

Field-dependent data are not presented here because the form of the strain versus field can depend on many factors such as sample shape, microstructure, and stress, which may obscure the predicted quadratic dependence on field for magnetization along a hard axis (Figure 4). The *typical* field dependence of magnetostriction in a variety of magnetic alloys are compared in Figure 6 on a Log–Log scale. It includes representative behavior for the very low anisotropy Fe-rich amorphous magnetic alloys (such as $Fe_{80}B_{20}$, for which $\lambda_{100} = 32 \times 10^{-6}$ (O'Handley, 1978)), BCC $Fe_{81}Ga_{19}$ and $Fe_2(Dy_{0.7}Tb_{0.3})$, Terfenol-D®. Also included in Figure 6 is the field dependence of the magnetostriction (solid line) and field-induced twin-boundary motion (dashed line) for Ni–Mn–Ga (see next section). In all cases, the magnetostriction is shown as quadratic in

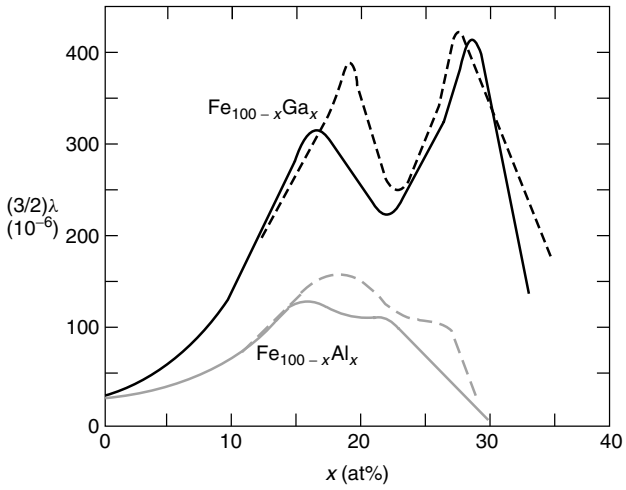

Figure 5. Dependence of λ_{100} on composition for a variety of $Fe_{1-x}Ga_x$ alloys compared with the behavior of $Fe_{1-x}Al_x$ (Hall, 1959). The solid lines are for furnace-cooled samples and the dashed lines are for quenched samples. Data for $Fe_{1-x}Be_x$ alloys is available up to 12 at% and follows that for Fe–Ga in that range. (Data assembled by M. Wun Fogle and J. Restorff, unpublished.) (Reprinted with permission R.C. Hall, copyright 1959, American Institute of Physics.)

the field up to its saturation value. Note the difference in saturation fields for the various materials. The diagonal dotted line is a guide to the eye with a slope of unity; it indicates that the saturation magnetostriction is not achieved at a field that is proportional to the saturation magnetostriction.

A quality factor for many applications is the ratio strain per unit field, λ/H. Amorphous magnetic alloys have advantage on that basis because they typically saturate in fields of order $10-100\,\mathrm{A\,m^{-1}}$ though they produce far less strain than the other materials. Terenol-D® shows about six times the magnetostrictive strain of Fe–Ga ($2400 \times 10^{-6}/400 \times 10^{-6}$) but Galfenol® magnetostriction saturates in a field of approximately about $8\,\mathrm{kA\,m^{-1}}$ while Terfenol-D requires about $80\,\mathrm{kA\,m^{-1}}$ to saturate.

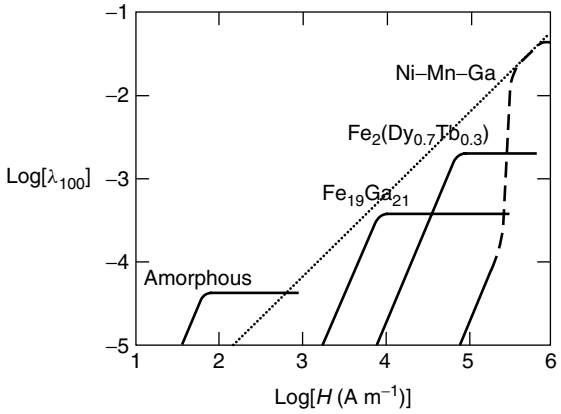

Figure 6. Log–Log representation of λ_{100} versus H typical of various classes of magnetostrictive materials. Amorphous magnetic alloys are represented by $Fe_{80}B_{20}$ and the Ni–Mn–Ga behavior is typical of its tegragonal phase (see below). The fine diagonal line represents a linear dependence of saturation magnetostriction on field indicating an advantage for amorphous alloys in terms of the quality factor, λ/H.

2.2 Cubic systems

The ME contribution to the magnetic anisotropy of a cubic material is expressed to first order as

$$f_{\mathrm{ME}} = B_1\left[e_{xx}\left(\alpha_1^2-\frac{1}{3}\right)+e_{yy}\left(\alpha_2^2-\frac{1}{3}\right)+e_{zz}\left(\alpha_3^2-\frac{1}{3}\right)\right] + B_2\left[e_{xy}\alpha_1\alpha_2+e_{yz}\alpha_2\alpha_3+e_{zx}\alpha_3\alpha_1\right]+\cdots \qquad (5)$$

Here, the direction cosines specify the direction of magnetization and the B_i's are the stresses of magnetic origin, which give rise to the components of the magnetostrictive strain tensor, ε_{ij}, by minimization of the total free energy including elastic terms:

$$(\varepsilon_{ii}) = \begin{pmatrix} -\dfrac{B_1}{(c_{11}-c_{12})}\left(\alpha_1^2-\dfrac{1}{3}\right) & -\dfrac{B_2}{c_{44}}\alpha_1\alpha_2 & -\dfrac{B_2}{c_{44}}\alpha_1\alpha_3 \\ -\dfrac{B_2}{c_{44}}\alpha_1\alpha_2 & -\dfrac{B_1}{(c_{11}-c_{12})}\left(\alpha_2^2-\dfrac{1}{3}\right) & -\dfrac{B_2}{c_{44}}\alpha_3\alpha_2 \\ -\dfrac{B_2}{c_{44}}\alpha_1\alpha_3 & -\dfrac{B_2}{c_{44}}\alpha_3\alpha_2 & -\dfrac{B_1}{(c_{11}-c_{12})}\left(\alpha_3^2-\dfrac{1}{3}\right) \end{pmatrix} \qquad (6)$$

Equation (6) makes it clear that the magnetostrictive strain, ε_{ij}, results from the action of components of the ME stress tensor, B_{ij}, on the material whose stiffness is characterized by the elastic constants, c_{ij}. The strain in any direction, β, is specified by projecting ε_{ij} on the vector $(\beta_1, \beta_2, \beta_3)$:

$$\frac{\partial \ell}{\ell} = (\beta_1,\beta_2,\beta_3)(e_{ii})\begin{pmatrix}\beta_1\\ \beta_2\\ \beta_3\end{pmatrix} = \sum e_{ii}\beta_i^2 + \sum_{i<j} e_{ij}\beta_i\beta_j \qquad (7)$$

Substituting the values of ε_{ij} given in equation (5) into equation (7), gives the strain in direction β for magnetization in direction α:

$$\frac{\partial \ell}{\ell} = -\frac{B_1}{c_{11}-c_{12}}\left(\alpha_1^2\beta_1^2+\alpha_2^2\beta_2^2+\alpha_3^2\beta_3^2-\frac{1}{3}\right) - \frac{B_2}{c_{44}}\left(\alpha_1\alpha_2\beta_1\beta_2+\alpha_2\alpha_3\beta_2\beta_3+\alpha_3\alpha_1\beta_3\beta_1\right) \qquad (8)$$

Equation (8) shows how the deformation of a magnetic sample depends on the direction of magnetization through the α's and on the strain-measuring direction through the β's. The factor of $-1/3$ in equation (8) reflects the fact that a demagnetized crystal with a perfectly random distribution of domain magnetizations is taken by convention to be in a state of zero strain, $dl/l = 0$.

For a sample *magnetized in the* [100] *direction*, the *strain measured in that direction* is defined as λ_{100}. In that case, $\alpha_1 = \beta_1 = 1$ and $\alpha_2 = \alpha_3 = \beta_2 = \beta_3 = 0$, giving:

$$\lambda_{100} = -\frac{2}{3}\frac{B_1}{c_{11}-c_{12}} \qquad (9)$$

For λ_{111}, $\alpha_i = \beta_i = (1/3)$ giving:

$$\lambda_{111} = -\frac{1}{3}\frac{B_2}{c_{44}} \tag{10}$$

Similarly, for λ_{110} we get,

$$\varepsilon_{110} = \lambda_{110} = -\frac{1}{6}\frac{B_1}{(c_{11} - c_{12})} - \frac{1}{4}\frac{B_2}{c_{44}} = \frac{1}{4}\lambda_{100} + \frac{3}{4}\lambda_{111} \tag{11}$$

For an *isotropic material*, all reference to crystallographic direction is gone, so we expect $\lambda_{100} = \lambda_{111} = \lambda_s$, and thus equation (8) reduces to equation (1).

2.3 Polycrystalline materials

For a random polycrystalline material, rotating $\boldsymbol{M}$ produces the full ME stress, B_i, in each grain, but the local strain of each grain may be incompatible with the strains of adjacent grains. The macroscopic material expresses the magnetostrictive strain that is the sum of those of its grains that are constrained and have different orientations.

When magnetostrictive strains are small, it may be adequate to neglect elastic interaction of various grains (O'Handley and Grant, 1985). For a completely *random 3-D polycrystalline material* Callen and Goldberg (1965) obtained:

$$\lambda_s = \frac{2}{5}\lambda_{100} + \frac{3}{5}\lambda_{111} \tag{12}$$

The λ_s values measured for polycrystalline nickel and iron are -34×10^{-6} and -7×10^{-6}, respectively. Use of equation (12) is justified only for an *untextured* polycrystalline material and for amorphous alloys. If a polycrystalline material is crystallographically textured or if the grains are more nearly isotropic magnetoelastically (i.e., $\lambda_{100} \approx \lambda_{111}$), then a net strain closer to the true magnetostriction value can be realized.

Values of saturation magnetostriction for several materials are listed in Table 1. The experimental notation (λ_{100}, λ_{111}) is used because of its prevalence in the literature. More universal definitions of λ, namely, $\lambda^{\alpha,2} \approx 3\lambda_{100}/2$, $\lambda^{\varepsilon,2} \approx 3\lambda_{111}/2$ (Lacheisserie, 1993), are described in the following text. Where the literature indicates that $\lambda^{\gamma,2}$ or $\lambda^{\varepsilon,2}$ was measured, those values are listed in parentheses in Table 1.

2.4 Magnetoelastic contribution to anisotropy

For a cubic material, the magnetocrystalline anisotropy energy density can be written as $f_a = K_1(\alpha_1^2\alpha_2^2 + \alpha_2^2\alpha_3^2 + \alpha_3^2\alpha_1^2) + K_2\alpha_1^2\alpha_2^2\alpha_3^2 + \cdots$. The direction cosines of the magnetization are arranged in a way that defines an energy function that reflects the crystal symmetry. The anisotropy coefficients, K_i, describe the strength of the preference for M to orient in specific crystallographic directions. Inspection of equation (5) shows that for a given value of strain, the ME energy resembles a magnetic anisotropy energy inasmuch as it is a function of the magnetization orientation. However, the first two ME terms for a *cubic* material are of lower symmetry, than the cubic magnetocrystalline anisotropy terms, K_1 and K_2. ME energy is simply that part of the magnetic anisotropy that depends on strain; it can be of lower symmetry than the strain-independent part because of the small change in symmetry imposed by the strain. Thus, isolation of the strain-dependent part of the anisotropy provides a measure of the ME coupling coefficients, B_i.

The ME contribution to the anisotropy is responsible for the inverse magnetostrictive effect illustrated in Figure 3. Inverse ME effects appear in two situations. First, an *imposed mechanical strain* alters the energy density function, $f_a(\theta, \phi)$, and hence changes the magnetization process below saturation. Second, a *magnetostrictive strain* (resulting from a change in magnetization direction) alters the free energy and hence changes the approach to saturation. The latter is a second-order effect and is most apparent in high-magnetostriction materials such as some rare-earth-containing materials.

An example of stress or strain-induced anisotropy can be found in O'Handley (2000). Essentially, tension in a positive magnetostriction material ($\lambda_s \varepsilon_{xx} > 0$ or $B_1 \varepsilon xx < 0$) makes the magnetization process easier in the tensile direction. The area to the left of a hard-axis magnetization curve gives the anisotropy energy density, K^{eff}. If one measures the magnetization curve of a sample in different known states of strain, then the change in that area indicating the energy needed to magnetize the sample changes by $B_1\varepsilon(1 + \upsilon)$. This is true even for an arbitrarily shaped magnetization curve – the strain-induced change in energy needed to magnetize a sample is the ME energy (O'Handley, Song and Ballentine, 1993).

2.5 Symmetry-invariant notation

It is important to know the form that the magnetostriction must take in hexagonal and in other low-symmetry magnetic structures. Materials with hexagonal structures include cobalt and many cobalt-rich alloys, rare-earth metals, and some rare-earth intermetallic compounds, as well as barium

hexaferrite. Presented here are the results of the general formalism for magnetic anisotropy and magnetostriction introduced by Callen and Callen (1960, 1963, 1965) and reviewed by Lacheisserie (1993).

Legendre polynomial expansions of the magnetic free energy are used widely for cubic materials; the simple expansion $f_a = \sum_{n=0,\ldots} C_n \sin^{2n}\theta$ is often used for uniaxial materials. It was noted by Callen and Callen in 1960 that it is appropriate to expand the magnetic anisotropy energy in a set of orthogonal, normalized functions based on Legendre polynomials,

$$g_\ell(\alpha) = \sum_{m=-\ell}^{\ell} A_\ell^m Y_\ell^m(\alpha) \tag{13}$$

The argument α is the direction cosine of the magnetization. The coefficients, A_l^m, of the spherical harmonics, Y_l^m, are defined so the polynomials, $g_l(\alpha)$, belong to the irreducible representation of the crystal point group to be described. The anisotropy energy density is then written:

$$f_K^{\text{hex}} = \sum_{\ell=0} k_\ell g_\ell(\alpha) = k_o + k_2\left(\alpha^2 - \frac{1}{3}\right) + k_4\left(\alpha^4 - \frac{6}{7}\alpha^2 + \frac{3}{35}\right) + \cdots \tag{14}$$

The anisotropy coefficients, k_l, based on such expansions are found more often in the literature on rare-earth materials. When these functions are used, the ME energy expression is a sum of products of strain components and direction cosines, each of which has the same symmetry. This is illustrated in Figure 7 for the cubic system where the strains and direction-cosine terms are both seen to have the familiar forms of the atomic d orbitals in cubic symmetry. These are the five irreducible representations of the cubic point group.

The form of the ME energy in cubic and uniaxial symmetry is given below to lowest order in these symmetry-invariant polynomials. This is followed by the formula for the magnetostriction. Higher-order terms and forms for other symmetries can be found in (Lacheisserie, 1993).

For cubic symmetry, the ME free energy is

$$\begin{aligned} f_{\text{me}}^{\text{cubic}} = {} & \frac{\varepsilon_{xx}+\varepsilon_{yy}+\varepsilon_{zz}}{3}[b^{\alpha,0} + \cdots] \\ & + \frac{3}{2}\left(\varepsilon_{zz} - \frac{\varepsilon_{xx}+\varepsilon_{yy}}{2}\right)\left[b^{\gamma,2}\left(\alpha_3^2 - \frac{\alpha_1^2+\alpha_2^2}{2}\right) + \cdots\right] \\ & + \frac{1}{2}(\varepsilon_{xx} - \varepsilon_{yy})\ \left[b^{r,2}(\alpha_1^2 - \alpha_2^2) + \cdots\right] \\ & + 2\varepsilon_{xy}\alpha_1\alpha_2\left\{b^{\varepsilon,2} + \cdots\right\} + \text{cycl.} \end{aligned} \tag{15}$$

The terms $b^{l,m}$ and ε_{ij} are the ME coupling (stress) coefficients and strains, respectively, in the irreducible representation. The magnetostriction for cubic crystals, to fourth order in α_i is

$$\begin{aligned} \lambda^{\text{cubic}} = {} & \frac{1}{3}\lambda^{\alpha,4}\left(\alpha_1^4 + \alpha_2^4 + \alpha_3^4 - \frac{3}{5}\right) + \sum_{i=1,2,3}\left(\beta_i^2 - \frac{1}{3}\right) \\ & \times \alpha_i^2\left[\lambda^{\gamma,2} + \lambda^{\gamma,4}\left(\alpha_i^2 - \frac{6}{7}\right) + \cdots\right] \\ & + \sum_{i<j=1,2,3} 2\beta_i\beta_j\alpha_i\alpha_j\left[\lambda^{\varepsilon,2} + \lambda^{\varepsilon,4}\left(\alpha_k^2 - \frac{1}{7}\right) + \cdots\right] \end{aligned} \tag{16}$$

The superscript α on the magnetostriction denotes volume strains, which preserve crystal symmetry. The γ and ε exponents come from the molecular-orbital notation that describe 3d orbitals as either the doublet d^γ (d_{z^2} and $d_{x^2-y^2}$) or the triplet d^ε (d_{xy}, d_{yz} and d_{zx}); see Figure 7. They are volume-conserving uniaxial strains. The index after the Greek superscript indicates the order in direction cosines (2 = uniaxial, 4 = cubic, etc.). These symmetry-based cubic magnetostriction coefficients can be expressed in terms of the older coefficients by the relations:

$$\lambda_{100} = \frac{2}{15}\lambda^{\alpha,4} + \frac{2}{3}\left(\lambda^{\gamma,2} + \frac{1}{7}\lambda^{\gamma,4} + \cdots\right) \approx \frac{2}{3}\lambda^{\gamma,2} \tag{17}$$

$$\lambda_{111} = -\frac{4}{45}\lambda^{\alpha,4} + \frac{2}{3}\left(\lambda^{\varepsilon,2} + \frac{4}{21}\lambda^{\varepsilon,4} + \cdots\right) \approx \frac{2}{3}\lambda^{\varepsilon,2} \tag{18}$$

For hexagonal symmetry, the free-energy density is given by

$$\begin{aligned} f_{\text{me}}^{\text{uniaxial}} = {} & b_1^{\alpha,0}\frac{\varepsilon_{xx}+\varepsilon_{yy}+\varepsilon_{zz}}{3} + b_2^{\alpha,0}\frac{\sqrt{2}}{3} \\ & \times\left(\varepsilon_{zz} - \frac{\varepsilon_{xx}+\varepsilon_{yy}}{2}\right) + \left[b_1^{\alpha,2}\frac{\varepsilon_{xx}+\varepsilon_{yy}+\varepsilon_{zz}}{\sqrt{2}}\right. \\ & \left. + b_2^{\alpha,2}\left(\varepsilon_{zz} - \frac{\varepsilon_{xx}+\varepsilon_{yy}}{2}\right)\right]\left(a_3^2 - \frac{1}{3}\right) \\ & + b^{\varepsilon,2}\left[\frac{1}{2}\left(\varepsilon_{xx} - \varepsilon_{yy}\right)\left(\alpha_1^2 - \alpha_2^2\right) + 2\varepsilon_{xy}\alpha_1\alpha_2\right] \\ & + 2b^{\zeta,2}\left(\varepsilon_{yz}\alpha_2\alpha_3 + \varepsilon_{xz}\alpha_1\alpha_3\right) + \cdots \end{aligned} \tag{19}$$

For crystals of hexagonal symmetry, the magnetostriction is

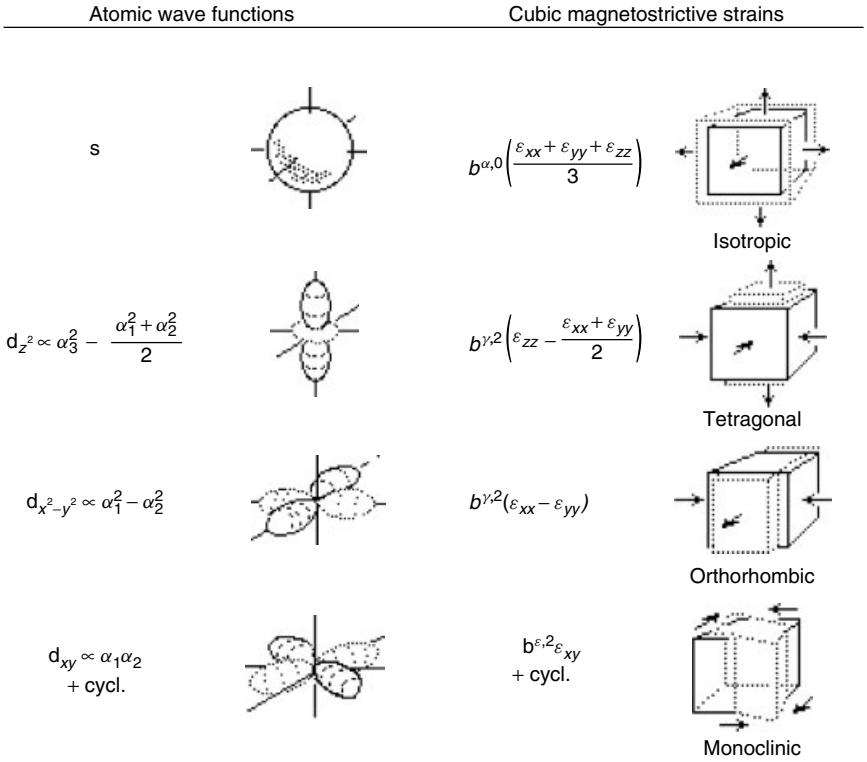

Figure 7. The first line shows the form of the isotropic s-wave function and the isotropic, volume magnetostriction. In the next three rows, the symmetry and amplitude (solid line, $\psi_d > 0$, dotted lines, $\psi_d < 0$) of the five atomic d functions are seen to be isomorphic with the five cubic Joule magnetostriction strains (equation (15)). This is because both are examples of irreducible representations of the cubic group. (Adapted from O'Handley, 2000.)

$$\begin{aligned}\lambda^{\text{hex}} = {} & \frac{1}{3}\lambda_1^{\alpha,0} + \lambda_2^{\alpha,0}\left(\beta_3^2 - \frac{1}{3}\right) \\ & + \left[\frac{1}{3}\lambda_1^{\alpha,2} + \lambda_2^{\alpha,2}\left(\beta_3^2 - \frac{\beta_1^2+\beta_2^2}{3}\right)\right]\left(\alpha_3^2 - \frac{1}{3}\right) \\ & + \lambda^{\varepsilon,2}\left[\frac{1}{2}\left(\beta_2^1 - \beta_2^2\right)\left(\alpha_1^2 - \alpha_2^2\right) + 2\beta_1\beta_2\alpha_1\alpha_2\right] \\ & + 2\lambda^{\zeta,2}\left(\beta_2\beta_3\alpha_2\alpha_3 + \beta_1\beta_3\alpha_1\alpha_3\right) + \ldots \end{aligned} \tag{20}$$

The α- and ε-labeled magnetostriction coefficients describe the same distortions in a hexagonal system as they do in cubic symmetry. ε-labeled terms distort the symmetry in the base plane; ζ terms shear over the c axis (Clark, 1980).

2.6 Temperature dependence

Proper measurement and analysis of the temperature dependence of magnetostriction can indicate a great deal about the nature of the strain-dependent, anisotropic interactions in a material and about the symmetry of the local atomic environment of the magnetic species.

Figure 8 shows the temperature dependence of the two principal magnetostriction constants in Ni. The shaded area shows the trend and scatter in data from numerous sources. The solid lines are theoretical fits that are based on the assumption of localized magnetic moments as will be described below.

The temperature dependence of magnetostriction in iron is quite different from that of nickel, with λ_{100} showing a maximum below room temperature then decreasing at lower temperatures (Tatsumoto and Okamoto, 1959; Lacheisserie and Monterroso, 1983). The temperature dependence of the magnetostriction of Ni comes closer to the theoretical than does that of iron. It is believed this is due to the lower energy of the Ni d bands (thus, more localized magnetic moment) compared to those of Fe.

In rare-earth metals, the metallic character comes from the 5d and 6s valence bands whereas the magnetic moments arise from the partially filled 4f states, which are more atomiclike, more localized; thus the magnetostriction of rare earths should be well described by theory. Figure 9 shows the temperature dependence of λ^{A} and $\lambda^{\text{C}} = \lambda^{\varepsilon,2}/2$ for single-crystal Tb. Note the steep decrease with increasing temperature for λ^{A} (cubic symmetry strain with temperature

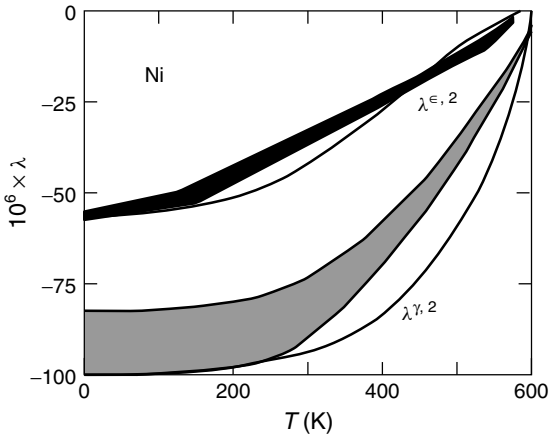

Figure 8. The shaded areas show range of experimental magnetostriction of Ni single crystals (Franse and Stolp, 1970; Lee and Asgar, 1971) and solid lines show calculated temperature dependence (Lacheisserie, 1972; Lacheisserie and Roucy, 1982).

dependence proportional to m^{10}) compared to λ^{C} (uniaxial strain with temperature dependence proportional to m^3). See theory in the following text.

In these examples, just as for magnetocrystalline anisotropy, $\lambda(T)$ drops much more sharply with increasing temperature than does $M(T)$. Here, the results of the theory developed by Callen and Callen (1966) for the temperature dependence of anisotropy and magnetostriction are outlined. To describe the *strain dependence* of the energy, the anisotropic Hamiltonian is expanded in powers of strain to first order:

$$H_{\mathrm{ME}} = \varepsilon_\mu \mathbf{S}_i \cdot \frac{\partial \mathbf{J}_{ij}}{\partial \varepsilon_\mu} \cdot \mathbf{S}_j + \varepsilon_\mu \mathbf{S}_i \cdot \frac{\partial \mathbf{D}}{\partial \varepsilon_\mu} \cdot \mathbf{S}_i + \cdots \qquad (21)$$

Here, $\mathbf{S}_i$ is a spin vector at site i. The elastic Hamiltonian is added to equation (21) and the expectation value of this strain-dependent Hamiltonian, $E = \langle H \rangle$ is minimized to allow solution for the strain components ε_u. The *two-ion* term expresses the strain dependence of the *anisotropic-exchange* interaction, $\mathbf{J}_{ij}$, between the z components of *spins at two different sites*. It gives rise in the solution to correlation functions $\langle S_i^z\, S_j^z \rangle$. (The usual Heisenberg exchange interaction, which is most responsible for the value of the Curie temperature, is an *isotropic* interaction between two spins). The *single-ion* term expresses the effect of strain on the *crystal-field anisotropy*, **D**, seen by a single magnetic ion. It leads to terms in the solution proportional to $\langle (S_i^z)^2 \rangle$. These spin-correlation functions play a central role in understanding the temperature dependence of anisotropy and magnetostriction (Callen and Callen, 1960, 1963, 1965; Lacheisserie, 1993; O'Handley, 1978; Legvold, Alstad and Rhyne, 1963; Rhyne and Legvold, 1965).

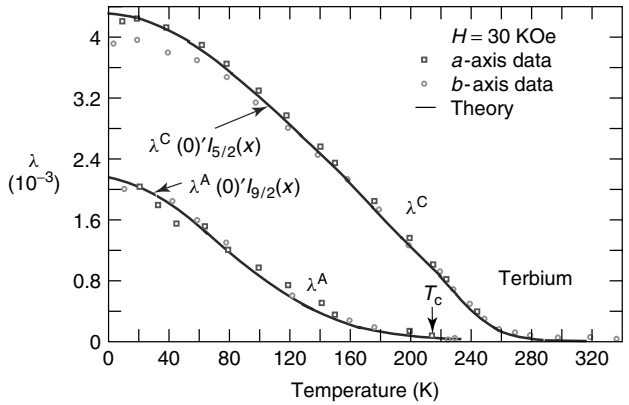

Figure 9. Temperature dependence of λ^{A} and $\lambda^{\mathrm{C}} = \lambda^{\varepsilon,2}/2$ for Tb single crystal (Rhyne and Legvold, 1965).

The exact results of the quantum statistical mechanical model of temperature dependence of ME effects owing to *single-ion effects* can be summarized as follows:

$$\frac{\lambda_\ell(T)}{\lambda_\ell(0)} \quad \text{or} \quad \frac{K_\ell(T)}{K_\ell(0)} = \kappa_\ell(T) = \frac{\left\langle [\mathbf{S}_i^z(T)]^2 \right\rangle}{\left\langle [\mathbf{S}_i^z(0)]^2 \right\rangle}$$

$$\Rightarrow \frac{I_{\ell+1/2}(X)}{I_{1/2}(X)} \equiv \hat{I}_{\ell+1/2}(X) \qquad (22)$$

Here, $I(X)$ is a modified Bessel function and $\hat{I}(X)$ is a reduced, modified Bessel function (Callen and Callen, 1960, 1963, 1965). The argument X is defined by the temperature dependence of magnetization $m(T) = I_{3/2}(X)$ so that X can be formally written as $X = I_{3/2}^{-1}(m)$.

Approximate temperature dependences of the modified Bessel functions have been calculated (Callen and Callen, 1963, 1965); they are characterized by different dependences on the reduced magnetization, m, above and below approximately 0.6 T_{C}. Table 2 shows the low-T and high-T approximations for *single-ion anisotropy* for $l = 2$ and 4.

The temperature dependence of the magnetization for the *two-ion exchange* mechanism is given more simply by the square of the reduced magnetization:

$$\frac{\left\langle S_i^z(T) S_j^z(T) \right\rangle}{\left\langle S_i^z(0) S_j^z(0) \right\rangle} \equiv m^2 \qquad (23)$$

Table 2. Approximate *single-ion* magnetization power law dependences for uniaxial ($l = 2$) and cubic ($l = 4$) systems at low and high temperatures.

Approximations to $\hat{I}_{l+1/2}(X)$		$l = 2$	$l = 4$
Low T	$\sim m^{l(l+1)/2}$	m^3	m^{10}
High T	$\sim m^l$	m^2	m^4

The two-ion exchange is sometimes weaker than the single-ion anisotropy but does play a role in many dipole-coupled rare-earth systems (Morin and Schmitt, 1990).

Lacheisserie (1972) has shown that the nickel data available in 1971 can be fit up to 300 K with a combination of single-ion and two-ion terms (solid lines, Figure 8)

$$B^{\gamma,2} = 110\{0.13\hat{I}_{5/2}(X) + 0.87m^2\} \times 10^6 \text{ erg cm}^{-3}$$
$$B^{\varepsilon,2} = 149\{2.54\hat{I}_{5/2}(X) - 1.54m^2\} \times 10^6 \text{ erg cm}^{-3} \quad (24)$$

Equation (24) indicates that the magnetostriction of nickel contains a two-ion, anisotropic-exchange term in addition to a single-ion contribution. The former plays a significant role as T/T_C approaches unity because there the more-strongly temperature-dependent, single-ion terms are very small. These nickel magnetostriction functions, equations (22) and (24), at room temperature and 4.2 K agree with the data in Table 1. The temperature dependence of magnetostriction in iron is more complex than that of Ni. This is believed to be because of the more itinerant nature of the 3d states (delocalized magnetic moments) in Fe compared to Ni (Lacheisserie and Monterroso, 1983).

The temperature dependence of $\lambda^{\gamma,2}$ in Gd follows that of a sum of single-ion and two-ion terms (Callen and Callen, 1965). Here, the two-ion term is strong enough to account for a change in sign of λ above 220 K.

A particularly simple case is that of amorphous metallic alloys. Although these materials are macroscopically isotropic, they are characterized locally by uniaxial anisotropy. The measured temperature dependence of magnetostriction in several different amorphous alloys is quite well described by the uniaxial, single-ion form of equation (22), $\hat{I}_{5/2}(X)$. Some cobalt-rich amorphous alloys show a change in sign of λ_s with increasing temperature that, as in the case of Gd, may be associated with a significant two-ion contribution (O'Handley, 1978; Lacheisserie, 1987).

2.7 Second-order effects

There are two second-order ME effects that are important to note. One is a change in the ME constants, either λ_s or B_i, when a material is strained to a significant level. In this effect, the ME energy density contains terms that are quadratic in strain and also have direction cosines of the magnetization as coefficients. The other second-order effect is a change in the elastic constant of a material owing to the presence of a magnetostrictive strain in addition to the strain produced by an external stress. This is referred to as the ΔE *effect*.

2.7.1 Strain-induced changes in ME coefficients

In highly strained materials, such as epitaxial thin films with significant lattice mismatch between the film and substrate, the ME coupling coefficient, B_1, can assume values different from bulk. Just as an external strain or stress can alter the magnetocrystalline anisotropy (equation (5)), it can also alter the ME coupling coefficient or the magnetostriction coefficient. This may be appreciated by recognizing that equation (5) is the first-order term in an expansion of the magnetic anisotropy in strain. If terms of second order in strain, such as $D_{ij}\alpha_i\alpha_j\varepsilon_{ij}$, are added to the free energy, then the terms may be regrouped to express an effective ME coupling coefficient, $B_1^{\text{eff}} = B_1 + D_1\varepsilon_{ij}$ (O'Handley and Sun, 1992; Sander, 1999).

Such second-order changes in ME coupling coefficients have been measured directly by straining a bulk material (Lacheisserie and Roucy, 1982) as well as in epitaxial thin film of Ni/Cu, (Ha and O'Handley, 1999; Ciria and O'Handley, 2002), or in polycrystalline thin films of Fe (Koch, Weber, Thürmer and Rieder, 1996; Sander, 1999). A detailed theory of these effects is under development (Fahnle and Komelj, 2002).

Values of D_1 for Ni films (Lachaeisserie, 1993; Sander, 1999; Ciria *et al.*, 2003) are of the order -2.3×10^8. Clearly when these values are multiplied by a strain of order 1%, the product is comparable to the magnitude of the first-order ME coupling coefficient, B_1, namely, 6.2×10^6 Pa and -3.4×10^6 Pa for Ni and Fe, respectively. In both of the cases cited, the second-order effect changes the sign of the ME energy density, $B_1^{\text{eff}}\varepsilon$, for positive strain but not for negative strain.

2.7.2 ΔE Effect

Application of an external mechanical stress to a magnetostrictive material induces a strain which in turn, tends to rotate the magnetization; $\boldsymbol{M}$ moves toward a tensile stress direction for $\lambda > 0$, $B < 0$ (Figure 3). The stress-induced rotation of $\boldsymbol{M}$ brings with it the *magnetostrictive strain in addition to the mechanically induced strain*. In the weak stress regime, the Joule magnetostriction makes a material appear mechanically softer than if the magnetization were not free to respond to the stress. This is illustrated in Figure 10 (from Lacheisserie, 1993). The material appears mechanically softer regardless of the sign of the magnetostriction indicating that this effect is quadratic in λ_s. The added magnetic strain, $\varepsilon_M \approx \lambda_s$, is generally insignificant compared to the elastic strain for large stresses. Thus, this ΔE effect, as it is called, is more important for acoustic waves, vibrations, and damping, than it is for mechanical strength.

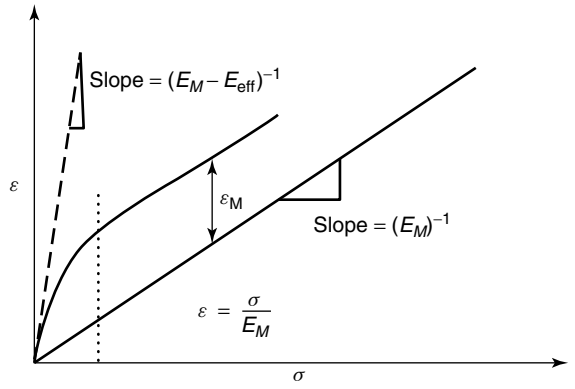

Figure 10. Strain versus stress in a magnetic material in the elastic regime. When the magnetization is fixed, the small strain behavior is purely linear. When the magnetization is free to respond to the applied stress, the material appears softer because of the additional magnetostrictive strain, ε_M. (Adapted from Lacheisserie, 1993.)

The total strain ε_{tot} that the ferromagnetic sample experiences understress, σ, can be written as a sum of the mechanical strain and the magnetostrictive strain:

$$\varepsilon_{\text{tot}} = \frac{\sigma}{E_M} + \frac{3}{2}\lambda_s\left[\cos^2\theta - \frac{1}{3}\right] \tag{25}$$

Here, E_M is the Young's modulus for *fixed magnetization* (no magnetostrictive contribution). The magnetostrictive contribution to total strain is taken from equation (1) where θ is the angle between the magnetization and the strain-measuring direction. Because $\cos\theta = m = H/H_a^{\text{eff}}$ for a hard-axis magnetization process, we can eliminate $\cos\theta$ from equation (25). The apparent modulus, $E_{\text{apparent}} = E_H = \partial\sigma/\partial\varepsilon_{\text{tot}}$, in the presence of this magnetostrictive strain is then obtained from equation (25) as:

$$\frac{1}{E_{\text{apparent}}} \equiv \frac{1}{E_H} = \frac{\partial e_{\text{tot}}}{\partial\sigma} = \frac{1}{E_M} - \frac{3\lambda_s H^2}{(H_a^{\text{eff}})^3}\frac{\partial H_a^{\text{eff}}}{\partial\sigma} \tag{26}$$

The ME contribution to the effective anisotropy field, H_a^{eff}, can be written as $3\lambda_s\sigma/M_s$ to first order, giving

$$\frac{E_M - E_H}{E_H} \equiv \frac{\Delta E}{E} = \frac{9\lambda_s^2 H^2}{M_s(H_a^{\text{eff}})^3}E_M \tag{27}$$

This formula applies when the magnetization is initially orthogonal to the stress direction.

Figure 11 shows the variation with temperature of the ΔE effect in amorphous Fe–P–C ribbons as a function of annealing condition: Z indicates zero field annealed, L and T indicate field annealed, longitudinal, and transverse to the ribbon direction, respectively. The experiments were done by measuring variations in the vibration frequency of the ribbon near 400 Hz (Berry and Pritchet, 1975). Clearly the ΔE effect

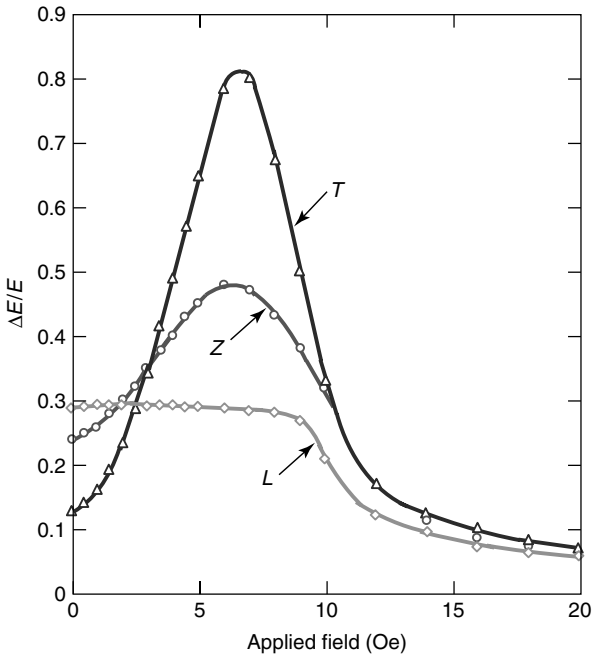

Figure 11. ΔE effect measured by the vibrating reed technique on an amorphous Fe–P–C ribbon in three annealing conditions: Z, no field, L, longitudinal field; T, transverse field. (Reprinted with permission Berry *et al*., copyright 1975, American Physical Society.)

is a function of the initial magnetization configuration of a sample. Annealing in the transverse direction gives an initial magnetization state that produces the most magnetostrictive strain under longitudinal flexure. At these low strain levels, the modulus of the amorphous ribbon is reduced by 80% in a field of about 6 Oe.

The ΔE effect is used in many magnetoacoustic devices where the resonance frequency, proportional to $E_H^{1/2}$, can be modulated by an applied field.

The relative strength of the ΔE effect is measured by a magnetomechanical coupling factor, k, which is defined as the ratio of the energy in coupled ME modes to the geometric mean of the pure elastic and pure magnetic energies:

$$k = \frac{2\mathbf{d}H\sigma}{\sqrt{\frac{1}{2}s^H\sigma^2\frac{1}{2}\chi H^2}} = \frac{4\mathbf{d}}{\sqrt{s^H\chi^\sigma}} = 4\mathbf{d}\sqrt{\frac{E^H}{\chi^\sigma}} \tag{28}$$

Here the free-energy density has the form,

$$g = \frac{1}{2}s^H\sigma^2 + 2\mathbf{d}H\sigma - \frac{1}{2}\gamma^\sigma H^2 \tag{29}$$

In equation (29), s^H is the mechanical compliance at constant field, $s^H = E_H^{-1}$, and χ^σ is the magnetic susceptibility at constant stress. This energy form expresses the partition of energy between pure elastic modes $(1/2)s^H\sigma^2$, pure

magnetic modes $(1/2)\chi^{\sigma}H^2$, and coupled ME modes, $\mathbf{d}H\sigma$. The magnetic and elastic responses for a *coupled* ME system are expressed:

$$-\partial g/\partial H = M = \chi^{sH} + \mathbf{d}\sigma$$
$$\text{and} \quad -\partial g/\partial \sigma = \varepsilon = \sigma s^{H} + \mathbf{d}H \tag{30}$$

The parameter **d**, called the *magnetostrictivity*, is defined as

$$\frac{1}{V}\frac{\partial^2 G}{\partial H \partial \sigma} = -\frac{\partial M}{\partial \sigma} = \frac{\partial e}{\partial H} \equiv \mathbf{d} \tag{31}$$

It describes the magnitude of magnetic-field-induced strain or stress-induced changes in M in a material. If the isotropic magnetostrictive strain expression in equation (1) is substituted for ε in equation (30), and $m = H/H_a$ for hard-axis magnetization is used, the magnetostrictivity can be expressed below saturation as

$$\mathbf{d} = 3\lambda_s \frac{H}{{H_a}^2} \tag{32}$$

where $\mathbf{d} = 0$ for $H > H_a$ (Livingston, 1982). Figure 12 shows the variation of $\mathbf{d}(H)$ for a material with pure transverse anisotropy (solid line) and for a more realistic M–H loop (dashed). Note that $\mathbf{d}(H)$ is the field derivative of $\lambda(H)$ shown in Figure 4 or from equation (1). Equations (27) and (32) indicate that the ΔE effect reaches a maximum when $\mathbf{d}^2$ is a maximum; **d** reaches a peak at or below the effective anisotropy field, H_a^{eff}.

The magnetostrictivity is important for transducer applications because it describes the stress sensitivity of magnetization (magnetoacoustic microphone) or the field sensitivity of strain (ME speaker or sonar projector) (equation (31)). What is needed for these applications is a material with a large value of λ_s but more importantly, a small value of H_a so that saturation is achieved in a relatively weak field. Hence, a useful figure of merit for transducer materials is the ratio $\lambda_s/K_{\text{eff}}^2$ as suggested by equation (32). Keeping in mind that the area under $\mathbf{d}(H)$ is fixed by λ_s (equation (30)), it is clear that decreasing the anisotropy field tends to increase the peak value of $\mathbf{d}(H)$.

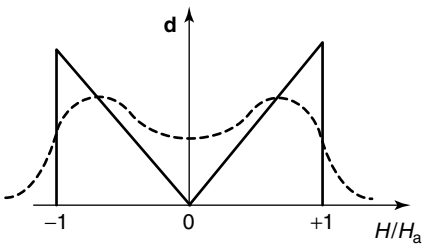

Figure 12. Magnetostrictivity versus field applied transverse to an easy axis (solid line) and for a more rounded magnetization curve (dashed line).

The magnetomechanical coupling factor, k, can take on values between zero and unity, the latter being the condition of complete coupling. In tensor notation, k_{33} pertains to longitudinal mode coupling. Similar expressions apply for shear mode coupling constants.

In terms of the ΔE effect, it can be shown that

$$k^2 = \frac{E_M - E_H}{E_M} = \frac{\Delta E}{E} \tag{33}$$

Thus, the ΔE effect can be expressed in terms of k, **d**, or the magnetostrictive strain.

2.8 Measurement techniques

The techniques for measuring magnetostriction fall into three broad categories.

1. When the sample is free to strain, that is, it is not constrained by adhesion to another material, the true magnetostrictive strain may be measured directly by a variety of means including the use of strain gauge, dilatometer, or capacitance techniques (in which the straining material displaces a capacitor plate). These are direct measurements of free strain.
2. When the magnetic sample is constrained by another body having appreciable bending modulus, Et (E is the elastic stiffness and t is the thickness of the second component), then the magnetostrictive *stress*, B_i can sometimes be measured by the deforming effect that an applied field has on the composite. Rotating $\boldsymbol{M}$ from an easy to a hard axis in a cubic material (equation (5)) generates the full ME stress, B_i. In this case, a strain less than the free magnetostriction, $|\varepsilon| < |\lambda_{ijk}|$, is generated in the constrained magnetostrictive material.

   The ME coupling coefficients of thin films on substrates have been determined from the deflection of the film-substrate cantilever upon change of the magnetization direction (Klokholm, 1976; Tam and Schroeder, 1989; Weber, Koch and Rieder, 1994). The displacement, Δy, of the end of the substrate of length L, fixed at one end (Figure 13), depends on the net in-plane stress, σ_f, generated by the appropriate ME coupling coefficient, B_f, exerted by the film as described by Stoney's equation (valid for $L > 3w$, with w being the width of the cantilever):

$$\Delta y = \frac{3t_f L^2 B_f (1 - \upsilon_s)}{t_s^2 E_s} \approx \frac{2t_f L^2 B_f}{t_s^2 E_s} \tag{34}$$

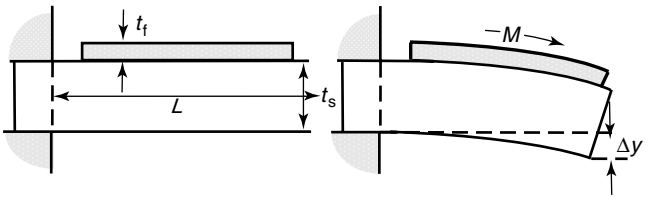

Figure 13. Schematic representation of cantilever bending owing to ME stress as the magnetization direction is changed. The case shown here is for $\lambda_s > 0$, or $B_1 < 0$.

Here t_i, E_i, and υ_i are the thickness, modulus, and Poisson's ratio of the film, $i = f$, or substrate, $i = s$, respectively. The magnetostriction constant can be determined from B_f using equations (8–10) if the elastic constants of the film are also known (but it is the *stress*, B_i, that is actually measured).

The cantilever deflection can be measured by a change in capacitance with the film acting as one plate of the capacitor (Klokholm, 1976), by differential capacitance technique with the film between two capacitor plates (Koch, Leonhard, Thurner and Abermann, 1990), or by deflection of a laser beam reflected from a point on the sample (Betz, Lachiesserie and Baczewski, 1996; Sander, Enders and Kirschner, 1995). This is a direct measurement of ME stress or of constrained strain.

The simple form of equation (34) overlooks more complex aspects of the deformation of a single-crystal cantilever such as the impact that clamping has on the deformation tensor and, particularly in shorter cantilevers, the opposite curvature across the width (due to the Poisson effect of the composite beam). Dahmen, Lehwald and Sander (2000) used analytic and finite element models to address these issues and arrived at a generalized Stoney equation that includes the effects of the dimensionality of the curvature due to an applied surface stress. These results were extended to the case of a cantilever deformed by the magnetostrictive stress due to a 90° rotation of the magnetization; the components of the ME stress tensor measured in such a case were determined for cubic, tetragonal, trigonal, and hexagonal symmetry (Dahmen, Ibach and Sander, 2001).

3. If free or bonded magnetic samples are subjected to known *strains*, then the ME coefficient, B_i, can sometimes be determined from the *strain-induced change in anisotropy* (perhaps measured from the M–H curve) of the magnetic sample of interest. This is the inverse method of measuring the ME coupling. This method can be applied to bulk (Sun and O'Handley, 1991) or thin-film samples but it is most commonly used for the latter (O'Handley, Song and Ballentine, 1993; Song, Ballentine and O'Handley, 1994; Baril, Gurney, Wilhoit and Speriosu, 1999).

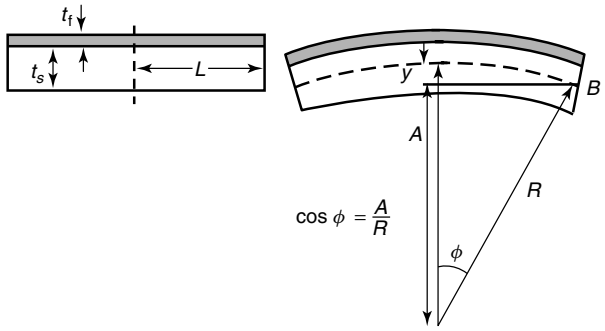

Figure 14. Geometry for determining strain in a thin film on a substrate at the circularly curved, central portion of a four-point bending jig. (Reprinted with permission O'Handley R.C., copyright 2000, John Wiley & Sons Inc.)

The magnitude of the strain in a film of thickness t_f on a substrate of thickness $t_s > t_f$ can be related to the vertical displacement, y, in a four-point bending geometry. In a four-point fixture, the bending is circular inside the inner two pressure points separated by a distance $2L$ (Figure 14). It can be shown that in the limit of circular curvature of radius R, the film strain is $\varepsilon = t_s/(2R)$. Using $\cos\,\phi = A/R = (R - y)/R$ and $\phi = L/R$, the parameters R and ϕ can be eliminated to give:

$$y = \frac{t_s}{2\varepsilon_f}\left[1 - \cos\left(\frac{2\varepsilon_f L}{t_s}\right)\right] \xrightarrow{2\varepsilon_f L/t_s \ll 1} \frac{L^2}{t_s}\varepsilon_f \qquad (35)$$

Thus, knowing the vertical displacement at a given distance, L, from the center of a film on a substrate gives the magnitude of the strain imposed on the film. In such a bending geometry, the film is essentially constrained (by the substrate) across its width, $\varepsilon_{yy} = 0$, and is free to strain normal to its surface, $\varepsilon_{zz} \neq 0$. It can be shown (O'Handley, 2000) that $\varepsilon_{zz} = -\upsilon\varepsilon_{xx}(1 - \upsilon) \approx \varepsilon_{xx}/2$. Thus, the ME contribution to the anisotropy energy of the film strained by $\varepsilon_{xx} = \varepsilon_f = yt_s/L^2$ is, from equation (5):

$$f_{\mathrm{ME}} = B_1 e_{xx}\left[\alpha_x^2 - \frac{1 - 2\upsilon}{3(1 - \upsilon)}\right] \approx B_1 e_{xx}\left(\alpha_x^2 - \frac{1}{6}\right) \qquad (36)$$

Details for various geometries are given in O'Handley, Song and Ballentine (1993).

3 MAGNETIC SHAPE-MEMORY ALLOYS

3.1 Introduction

Ni–Mn–Ga and other FSMAs show large magnetic-field-induced strains owing to twin-boundary motion in the

martensitic phase (Ullakko *et al*., 1996; James and Wuttig, 1998). The stoichiometric compound, Ni_2MnGa, transforms from a cubic austenite phase to tetragonal martensite below about 250 K. It was shown (Chernenko, Cesari, Kokorin and Vitenko, 1995; Murray *et al*., 1998; Vasil'ev *et al*., 1999) that compositions having higher electron-per-atom ratios such as $Ni_{49}Mn_{29}Ga_{22}$ have T_{mart} above room temperature and, thus, can show magnetic-field-induced twin-boundary motion at room temperature. It is in these compositions that magnetic-field-induced strain has most often been studied (Murray *et al*., 1998; O'Handley *et al*., 2000; Tickle *et al*., 1999; Wu *et al*., 1999; Heczko, Sozinov and Ullakko, 2000); the maximum field-induced strain in tetragonal martensite, given by $1 - c/a = 6\%$, was reported in 2000 (Murray *et al*., 2000). Compositions with slightly higher Mn/Ga ratios transform from the cubic austenite to *orthorhombic* martensite and can show a field-induced strain of 10% (Sozinov, Likhachev, Lanske and Ullakko, 2002).

In order to understand the magnetic-field-induced strain in these materials, it is important to clarify (i) the nature of the structure across a twin plane, (ii) the effects of an externally applied magnetic field (or stress) on the energy of two martensite variants having different orientations of their *c* axes (the magnetic easy axis), and (iii) perhaps most importantly, the relative magnitudes of the yield stress that must be overcome to initiate twin-boundary motion, the magnetic mechanism that drives the growth of a particular variant, and the thermal energy at the operating temperature.

3.1.1 Crystal structure

Figure 15 shows the evolution of the X-ray powder diffraction pattern with decreasing temperature from cubic austenite to tetragonal martensite for $Ni_{49.5}Mn_{29.5}Ga_{21}$ (Richard, 2005). For diffraction peaks satisfying $h + k + l = 4n$ (n is an integer), the splitting from single lines to doublets (with the appearance of some modulation peaks) is the important characteristic of the transformation that makes twinning and field-induced twin-boundary motion possible. The inset shows the variation of the magnetic susceptibility with temperature indicating T_C at about 360 K and the first-order martensite transformation centered at 306 K.

Well below the martensite finish temperature, the sample is fully transformed to tetragonal martensite. This single-phase, martensitic regime is of interest here; it can be twinned. Single crystals of $Ni_{50}Mn_{29}Ga_{21}$ can show large-scale twins separated by a twin boundary (Figure 16c) across which a shear displacement is observed (Murray *et al*., 1998). Ni–Mn–Ga particles of similar composition made by spark erosion (Tang *et al*., 2003) show abundant nanometer-scale twinning after annealing (Figure 16, Solomon, Smith, Tang and Berkowitz, 2004; Solomon *et al*., 2005).

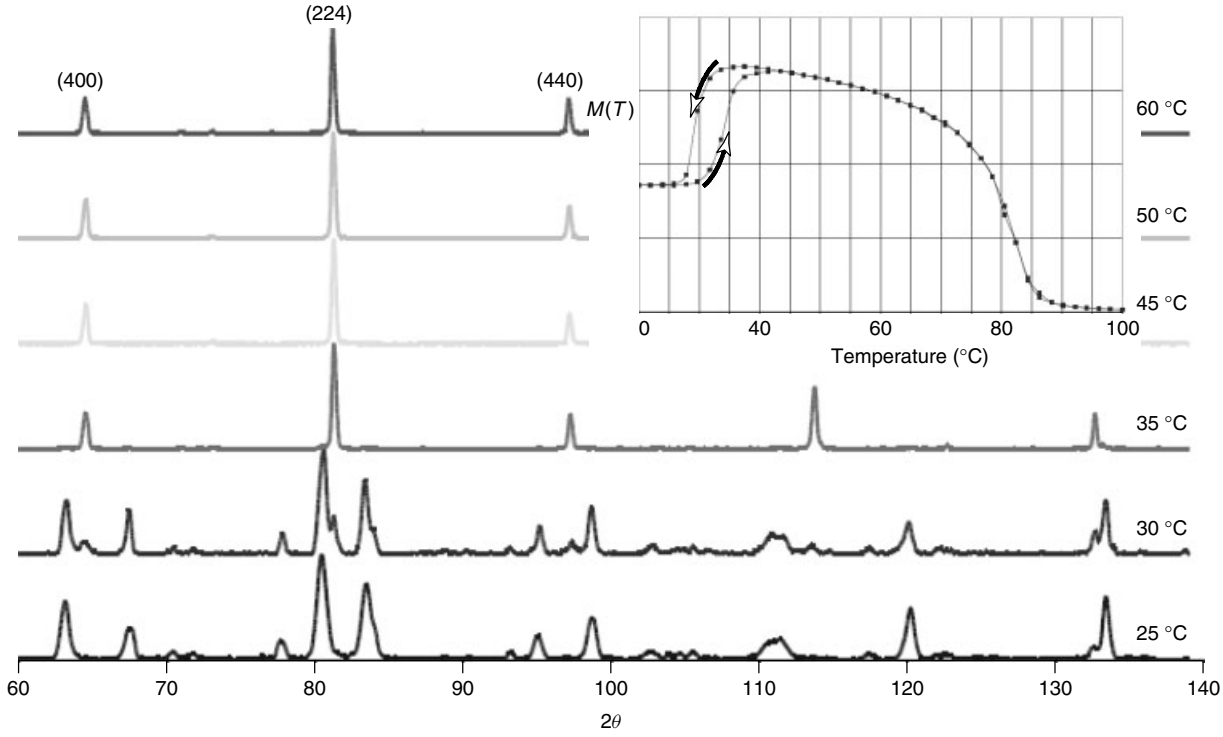

Figure 15. X-ray powder diffraction patterns for Ni–Mn–Ga alloy at selected temperatures. Splitting of peaks below 306 K indicates the transformation to tetragonal martensite. Inset: susceptibility versus temperature (Richard, 2005).

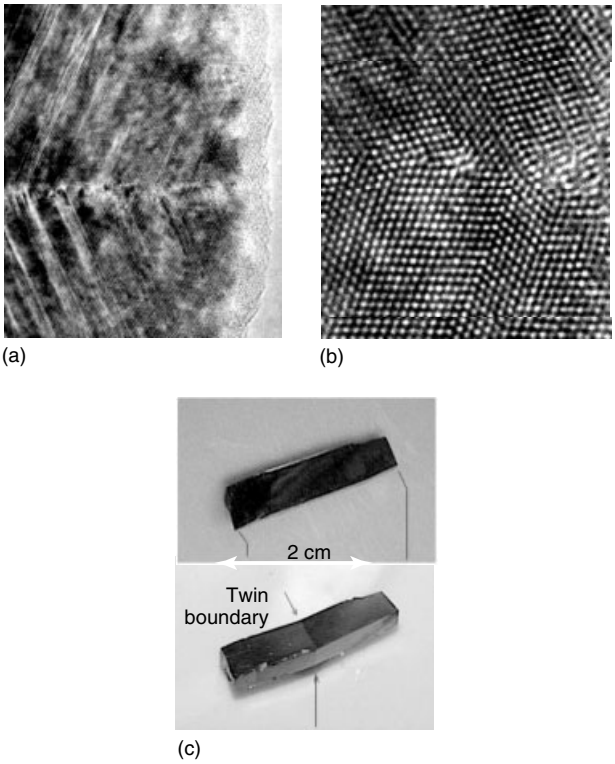

Figure 16. (a) High-resolution transmission electron microscopy images Ni–Mn–Ga particles made by spark erosion. (b) Atomic-scale five-layered martensite reflects the atomic instability along $\langle \underline{1}01 \rangle$ in {101} (Solomon, Smith, Tang and Berkowitz, 2004; Solomon *et al*., 2005). The twinning evident as a horizontal interface in (a) can also be seen in some samples on a macroscopic scale (c) (Murray *et al*., 1998). (Reprinted with permission Solomon *et al*., copyright 2004, American Institute of Physics.)

Three different twin variants (different *c*-axis orientations) are possible in tetragonal martensite; two are depicted schematically in Figure 17. The elastic energy associated with a twin plane in the martensitic phase is minimized if the plane is arranged with mirror symmetry as shown in Figure 17(a). There are only two stable positions for the atoms along the twin-plane {101} in a $\langle \underline{1}01 \rangle$ direction. The energy barrier between these two states is critical for understanding the motion of twin boundaries; the barrier height reflects changes in the lattice potential with position near defects. In fact, the atomic structure of the twin plane is more complicated than the planar form shown here. Evidence suggests that the twin plane consists of a series of terraces and steps that define not only dislocations (with a burgers vector, **b**, in the plane of the terrace) but also disconnections characterized by a height, **h**, due to the steps (Hirth and Pond, 1996). Clearly, the horizontal twin interface in Figure 16(a) shows an irregular form. For the purpose of understanding magnetic-field-induced twin-boundary motion, it is assumed here that the longer-range structure of the

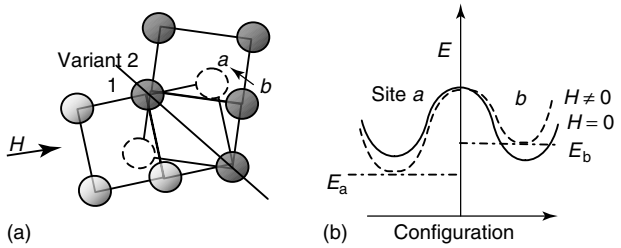

Figure 17. At temperatures below T_0, the martensitic phase is stable; it can form crystallographic twins (a) to minimize strain energy that accumulates during transformation. Panel (b) shows two possible atomic positions exist parallel to and near the twin boundary. Application of a magnetic field lowers the energy of the potential well corresponding to the variant having its *c* axis more nearly parallel to H.

twin plane depicted in Figure 17 is an adequate model because the magnetic exchange interaction ensures that the magnetization is relatively uniform over a longer range than the distance between the steps; the exchange length can be calculated from the magnetic anisotropy to be of order 14 nm (O'Handley *et al*., 2001). The external magnetic field shown as parallel to variant 1 and its effects on the free energy will be discussed in the following text.

If a tetragonal Ni–Mn–Ga crystal is cut so that the sample faces are parallel to its cubic austenite {100} planes, then it can generally be trained so that a single set of {101} twin planes is active. After suitable heat treatment to homogenize the composition, the crystal is prepared for actuation by application of a compressive bias stress, $\sigma > \sigma_0$, in the direction shown in Figure 18(a); this favors growth of twin variants having *c* parallel to the compression axis. If a second stress, orthogonal to the first, is briefly applied as in Figure 18(b) but not fully detwinning the crystal, then a twin structure like that in Figure 18(b) can be achieved. This stress is reduced (Figure 18d); then a magnetic field is applied as shown in Figure 18(d) with a weak, orthogonal bias stress; twin boundaries move back and forth as the ratio of the field energy to the stress energy, $\mu_0 M_s H/\sigma\varepsilon_0$, is greater or less than unity.

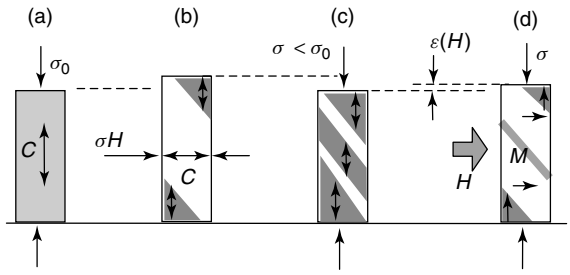

Figure 18. Panels (a) and (b) show crystal training, (c) and (d) crystal actuation. The shaded and clear regions distinguish variants having *c* axis vertical and horizontal, respectively.

3.2 Actuation

3.2.1 Strain versus field

After setting the sample in an initial state with the c axis perpendicular to the field direction, *one-time* field actuation was reported to produce the maximum field-induced strain in tetragonal martensite, $1 - c/a$ (Murray *et al*., 2000). It was demonstrated that *cyclic* actuation of FSMA crystals is possible in a system that contains a reset mechanism, such as a spring that is compressed as the sample deforms by twin-boundary motion under the action of a field directed orthogonal to the spring axis. The field-induced strain observed in such cyclic actuation is often only 2.5 or 3% (Figure 19) (Henry *et al*., 2002) in contrast to the 6% achieved under low static load. There are two reasons for this. First, when the sample ends are constrained, twin boundaries are generally inhibited from entering the constrained regions, reducing the active sample length. Second, the presence of the back stress from the spring as the sample is actuated decreases the effectiveness of the magnetic driving force.

Note also the evidence in Figure 19 of a *threshold magnetic field* below which little twin-boundary motion occurs. (The threshold field is more evident in quasistatic measurements (Murray *et al*., 2000); it is somewhat rounded out in these 2 Hz, cyclic measurements.) The threshold field is a stochastic magnetomechanical parameter, much like the coercive field below which no irreversible domain-wall motion occurs. A related threshold or *yield stress* appears in stress–strain measurements on these materials and the two are related by $\mu_0 M_s H_i = \sigma_{yield}\varepsilon_0$, where H_i is the *internal* field (applied field corrected for demagnetizing effects) above which gross twin-boundary motion initiates. In a perfect crystal, H_{thresh} depends on the local energy change when a twin boundary interacts with the Peierls potential; in a real crystal, it also depends on the much larger energy change when the twin boundary interacts with a distribution of defects (Marioni, Allen and O'Handley, 2004; Paul, O'Handley and Peterson, 2005). Threshold fields of 0.1–0.3 T are typically observed in active Ni–Mn–Ga crystals, and the field-induced strain saturates when the applied field reaches about 0.7 T.

The behavior in Figure 19 should be compared and contrasted with that of magnetostriction. Beyond the obvious difference in the magnitude of the field-induced strain in the two cases, there are two features of the FSMA behavior in Figure 19 that are different from that in magnetostriction. These are (i) the presence of a threshold field below which the large strain does not appear in FSMAs and (ii) the large hysteresis of FSMAs (magnetostriction is anhysteretic, especially in the ideal hard-axis magnetization process). Further differences will be pointed out in the following text.

3.2.2 Frequency dependence

These cyclic actuation experiments were extended to higher frequencies in order to understand the operational bandwidth of Ni–Mn–Ga crystals having a volume of about a cubic

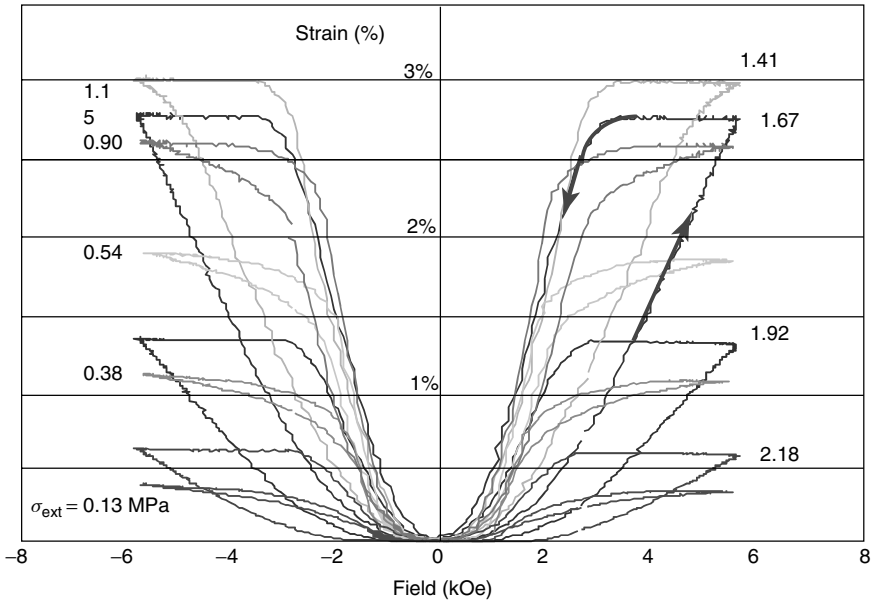

Figure 19. Cyclic strain versus field at 1 Hz for different bias stresses in Ni–Mn–Ga crystal. The bias stress values indicated are initial values and increase by as much as 20% during actuation. (Reprinted with permission Henry *et al*., copyright 2002, American Institute of Physics.)

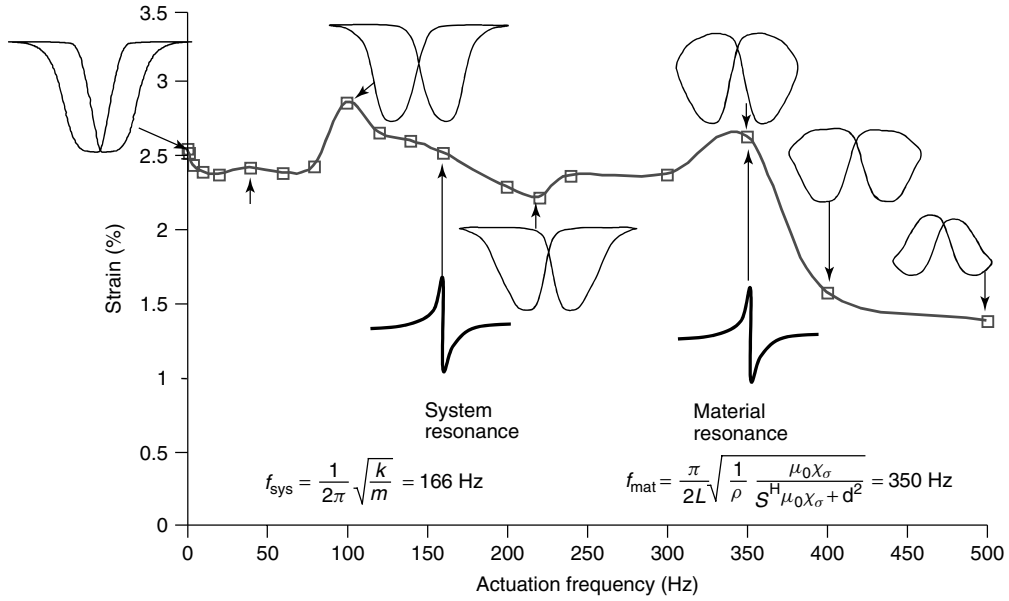

Figure 20. Field-induced strain at 4.6 kOe versus actuation frequency with overlaid ε-H loops. (Reprinted with permission C.P. Henry *et al*., copyright 2003 International Society for Optical Engineering.)

centimeter. Figure 20 shows the field-induced strain achieved at 4.6 kOe versus frequency for $Ni_{49.5}Mn_{29.5}Ga_{21}$ (Henry *et al*., 2003). Overlaid on the curve are the strain versus field loops at selected frequencies. The maximum field that could be achieved with the power supply used in these experiments drops off above 300 Hz because of the increased inductive reactance of the field coils. What is clear from the data is that (i) there is considerable structure in the strain versus frequency curve, (ii) there is a clear decrease in strain above about 350 Hz (actuation frequency is twice the drive frequency), and (iii) the strain versus field loops show more hysteresis with increasing frequency and the phase of the strain changes dramatically relative to that of the field above about 350 Hz.

The structure in the $\varepsilon(f)$ curve between 100 and 200 Hz has been determined to arise from mechanical resonances in the measuring system. The decrease in output strain above 300 Hz is due to the decreasing strength of the applied field as well as to a material resonance, as evidenced by the 180° change in phase of the strain relative to the field. The resonance centered near 350 Hz appears to be the material resonance.

Pulse field actuation experiments were carried out to probe the details of twin-boundary kinetics (Marioni, O'Handley and Allen, 2003). It was observed that the field-induced strain lags the initiation of the magnetic-field pulse by more than that expected from the need to exceed the threshold field for twin-boundary motion. An additional lag is found to be due to the inertia of the sample under the appreciable acceleration (3×10^4 m s^{-2}) it experiences in these experiments. It is also observed that the free end of the sample does not achieve a velocity greater than 6.2 m s^{-1}, regardless of the peak field strength or its rise time. This is now understood to be a consequence of the fact that the magnetic energy applied to the sample cannot exceed $K_u V$ and this limits the FSMA kinetic energy and thus, $v \leq (2K_u/\rho)^{1/2} \approx 6$ m s^{-1}. So the large displacement of actuated FSMA crystals appears to limit their bandwidth to $f < 2500$ Hz for samples of any size.

3.3 Models

Of the many models describing the field-induced motion of twin boundaries in FSMAs, four are briefly compared. They are (i) numerical micromagnetic models (James and Wuttig, 1996), (ii) thermodynamic models (O'Handley, 1998; L'vov, Gomonaj and Chernenko 1998; Likhachev and Ullakko, 2000; Kiefer and Lagoudas, 2005), (iii) analytic, micromagnetic model (Paul, Marquiss and Quattrochi, 2003; Paul, O'Handley and Peterson, 2005), and (iv) kinetic models (Paul, O'Handley and Peterson, 2005; O'Handley *et al*., 2006). These models generally include the Zeeman energy, magnetic anisotropy energy, and an external stress for each of two or sometimes three variant types. They may also include a magnetostatic energy that tends to restore the net magnetization to zero when the field vanishes or, with similar effect, an internal elastic energy that tends to restore the field-induced strain to zero when the field is removed. Energies associated with the yield stress, σ_{yield} can also be added.

Likhachev and Ullakko (2000) have taken a more general analytic approach to the problem in three dimensions. They integrate the Maxwell relation, $(\partial\varepsilon/\partial H) = -(\partial M/\partial\sigma)$, to arrive at the field-dependent strain. Experimental $M(H)$ and $\sigma(\varepsilon)$ data are used as input to allow prediction of $\varepsilon(H, \sigma)$ that includes magnetostatic effects without the need to describe them analytically.

3.3.1 Thermodynamics

A phenomenological, free-energy model for the field and temperature dependence of the magnetization in ferromagnetic martensites has been described (L'vov, Gomanaj and Chernenko, 1998). In their model, the free energy of the large strain due to twin-boundary motion is combined with the much smaller magnetostrictive strain, both as coefficients of the direction cosines of the magnetization. While the magnetostrictive strain does depend only on the direction of magnetization, the strain due to twin-boundary motion does not necessarily appear as the magnetization is rotated if the twin boundaries are pinned. Nevertheless, this model was successfully extended to describe the field dependence of stress–strain curves as well as the field dependence of the magnetostrictive stress (see Figure A1) that accumulates in a twin variant as its magnetization is rotated by the applied field even before twin-boundary motion.

Models of Paul, Marquiss and Quattrochi (2003) and Paul, O'Handley and Peterson (2005) are analytic micromagnetic treatments (exchange energy is included) that describe (i) the field-induced displacement of the 90° domain wall from the twin boundary at fields below threshold in the presence of an elastic defect, (ii) the field-induced acceleration of the twin dislocation between pinning events, and (iii) the interaction of the twin boundary with a localized, elastic defect.

In one variation of the second class of models (O'Handley, 1998), the free-energy density of a two-variant crystal takes the form:

$$\begin{aligned} g(\theta, f_1) = &-\mu_0 M_s H\left[1 + (1 - f_1)\cos\theta\right] \\ &+(1 - f_1)K_u \sin^2\theta + \frac{1}{2}C^{\text{eff}}\left[(f_1 - f_2)\varepsilon_0\right]^2 \\ &+\sigma_{\text{ext}}\varepsilon_0\left[f_1 - (1 - f_1)\cos\theta\right]\cdots \end{aligned} \tag{37}$$

Here, f_1 and $f_2 = 1 - f_1$ describe the *equilibrium* variant distribution and the term proportional to an effective elastic constant, C^{eff}, describes the effect of elastic energy stored in the crystal when twin-boundary motion occurs from the equivariant state. θ is the angle between the applied field direction and the magnetization in variant 2. The external stress term was added later (Murray *et al*., 2000). The resulting field-induced strain is given by

$$\varepsilon(H) \equiv \varepsilon_0 \delta f = \frac{2K_u h(1 - h/2) - \sigma\varepsilon}{C_{\text{eff}}\varepsilon_0} \tag{38}$$

and the field-induced magnetization is

$$m(H) \equiv \frac{M(H)}{M_s} = f_1 + hf_2 = \delta f + \frac{1}{2} + h\left(\delta f - \frac{1}{2}\right) \tag{39}$$

Here, $\delta f = f_1 - 1/2$ is the imbalance in the volume fraction of variants 1 and 2 and $h = \mu_0 M_s H/(2K_u) = \cos\theta_2$ (O'Handley, 1998).

When the field is small compared to the anisotropy field, the analytic models predict a linearly increasing twin-rearrangement strain. If an *ad hoc* yield stress is included (Murray *et al*., 2000) or if defects are incorporated in a microscopic way (Paul, Marquiss and Quattrochi, 2003), then the observed threshold behavior is accounted for. When the applied field approaches the anisotropy field, the Zeeman energy difference across the twin boundary is decreased (***M***.***H*** approaches zero everywhere in the sample) and the achievable strain saturates. The normalized driving force that describes field-induced strain (δf from the rhs of equation (38) normalized to K_u) is plotted in Figure 21 without (solid line) and with (dashed line) twin-boundary yield stress included. The effect of compressive bias stress orthogonal to the field axis would be to increase the field at which actuation initiates and decrease the strain at which actuation saturates.

A closer examination of the assumptions of the equilibrium thermodynamic models is informative. The dependence of the free-energy densities of two adjacent variants in an external magnetic field applied parallel to the c axis of one of them (variant 1 in Figure 17) is shown in Figure 22. Note

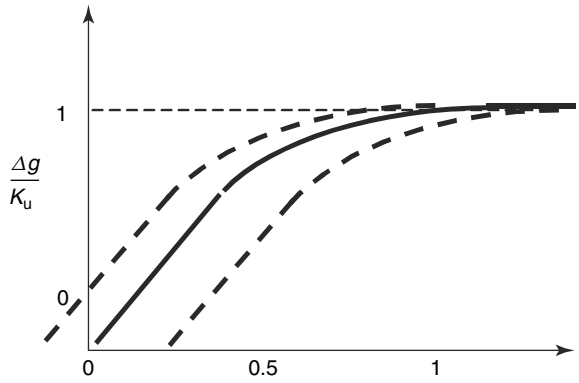

Figure 21. Output of equation (38), ε versus h with zero bias stress is shown passing through the origin. The displaced dashed lines show the effects of an *ad hoc* addition of a twin-boundary yield stress of order 1 MPa, which is equivalent to a field of 100 kA m^{-1} or 0.2 H_a.

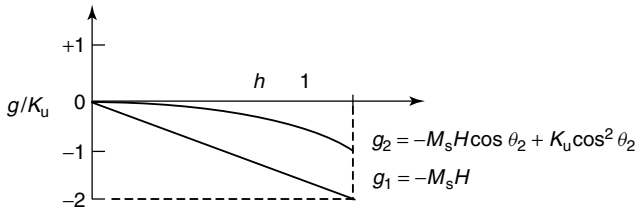

Figure 22. Variation of magnetic free energy density with field strength for two martensite variants, variant 1 having its magnetic easy axis, *c*, parallel to *H* (O'Handley *et al*., 2006).

that above h = 1, the free energy difference between the two variants does not change; the thermodynamic driving force for twin boundary motion is constant for h > 1.

3.3.2 Kinetics

While it is clear from Figure 22 that application of a magnetic field stabilizes variant 1 relative to variant 2, an energy barrier must exist between these two states because the twin boundary does not spontaneously move to expand the volume of variant 1 at the expense of variant 2 under application of a field below the threshold value. Further, the application of magnetic field also exerts *a mechanical shear stress* or torque, τ_{mag}, on the atoms along the twin plane in a direction that moves the twin plane into the unstable variant (Figure 23). This magnetic energy density difference, $g_2 - g_1$, and the torque energy density, $\tau_{\text{yield}}\gamma_0$, where γ_0 is the shear strain involved in the process ($\gamma_0 = 0.122$ for Ni–Mn–Ga (O'Handley *et al*., 2001)) are each of the order $10^5\,\text{J m}^{-3}$ corresponding to about $10\,\mu\text{eV atom}^{-1}$. These magnetic energies are much less than thermal energy per atom at room temperature $\Delta g_{\text{mag}} \leqslant K_{\text{u}} \ll (k_{\text{B}}T/V)$. Thus, it is expected that at room temperature, thermal fluctuations are capable of causing a cluster of several hundred atoms to surmount the barrier, allowing the system to sample both potential wells. But the thermal energy has no preference for direction when the two energy minima have the same potential; to change the variant configuration, the energy wells should have different energies or a shear stress must act on the atoms. The magnetic field provides the difference in energy minima as shown in Figure 22. In Figure 17, variant 1 is favored by a shear stress along [10$\underline{1}$] in (101) that acts to move some of the atoms of variant 2 into the dashed position. At $T = 0\,\text{K}$, the magnetic shear stress, τ_{mag}, would have to exceed the yield stress for twin-boundary motion (Murray *et al*., 2000; Ullakko, 1996; Müllner and Ullakko, 1998; Heczko and Ullakko, 2001):

$$\tau_{\text{mag}} \equiv \frac{K_{\text{u}}}{\gamma_0} > \tau_{\text{yield}} \tag{40}$$

Here τ_{yield} is the threshold shear stress across the twin boundary that initiates twin-boundary motion. This condition may not be met at low temperature. At nonzero temperatures, the magnetic field provides a direction for the transition between the energy minima while the thermal energy provides most of the activation energy to get over the barrier:

$$g_{\text{mag}} + \frac{k_{\text{B}}T}{V} > \tau_{\text{yield}} \tag{41}$$

Here, g_{mag} includes both the Zeeman energy difference between the two states and the magnetic torque on the atoms. Thus, the role of *thermal* activation must be considered when modeling the actuation of FSMAs. The fourth category of models (analytic micromagnetics) has begun to describe the temperature dependence of field-induced strain in FSMAs, which is now considered (Paul, O'Handley and Peterson, 2005).

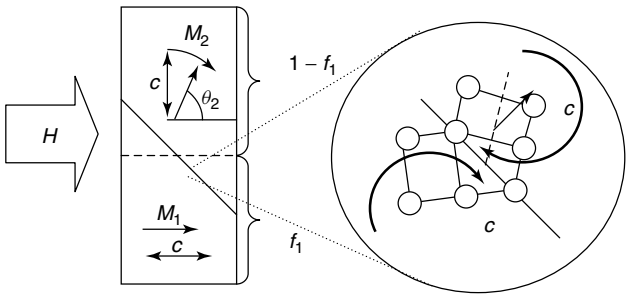

Figure 23. Simple two-variant model of twinned tetragonal martensite. Panel at right represents the change in crystallography across the twin plane and the torque on each variant for a sample constrained from rotating (O'Handley *et al*., 2006).

3.4 Temperature dependence

Magnetic-field-induced strain is generally observed to occur over a limited temperature range below the martensite transformation and above a lower cutoff temperature. Early studies on polycrystalline compositions indicated a very narrow operating range below the transformation (Murray *et al*., 1998; Heczko, Sozinov and Ullakko, 2000). Other temperature-dependent measurements on single crystals are summarized in Figure 24 (Wu *et al*., 1999; Liu *et al*., 2002); they indicate that the temperature range depends on the alloy composition, with one sample being actuated down to 160 K.

Heczko and Straka (2003) described a model that attributes the temperature dependence of field-induced twin rearrangement to the condition in equation (40). They measured the temperature dependence of the magnetic anisotropy, the lattice constants, and twin-boundary yield stress of a Ni–Mn–Ga alloy. They find that the yield stress increases sharply with decreasing temperature. Their model does

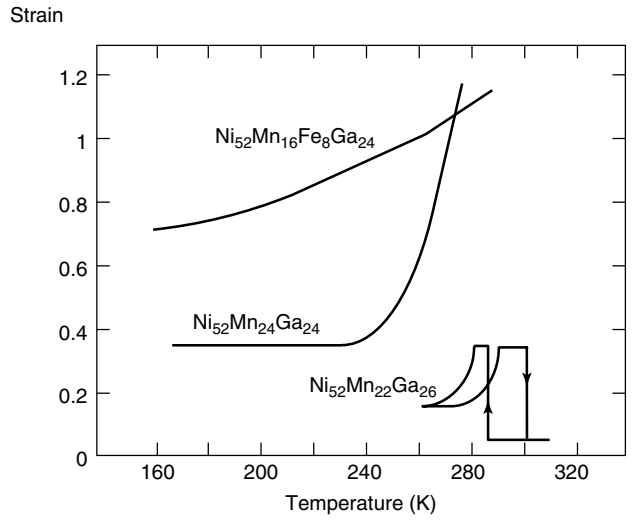

Figure 24. Experimental results for temperature dependence of field-induced strain in three different Ni–Mn–Ga martensites (Liu *et al*., 2002).

provide a basis for understanding the limited range of activation. However, the condition in equation (40) contains no magnetic-field dependence even though twin-boundary motion is observed to proceed at fields below H_a. Further, this model, like all thermodynamic models, does not contain a real physical driving mechanism between the states of the double well, nor does it account for the role of thermal activation in the twin-boundary actuation process.

More recently the temperature dependence of the mechanical torque exerted on the unfavorably oriented variants by application of a field, $T = -(\partial G_{\text{Zeeman}}/\partial\theta)$ where G_{Zeeman} is the first term in equation (37), has been considered to describe the temperature dependence at various fields of the twin-boundary activated strain (O'Handley *et al*., 2006). This model includes thermal activation and the difference in rates of transition between the two potential wells in the presence of an applied field. For Ni–Mn–Ga martensite variants having their crystallographic c axis perpendicular to the applied field (variant 2 in Figure 17), the field-dependent torque per unit volume, $\tau = \mathrm{T}/\Omega$, is given by

$$\tau_2 = -\frac{\partial(-M_s H\cos\theta_2)}{\partial\theta} = -2K_u h\sqrt{1-h^2} \qquad (42)$$

Here M_s, K_u, and h are temperature dependent. This torque on the magnetization is clockwise about the center of mass of variant 2 in Figure 17, generates a mechanical torque on variant 2 that is also clockwise. There is no torque on variant 1 because $\theta_1 = 0$, except that which is transferred from variant 2 in the presence of a physical constraint against rotation of variant 1. The shear across the twin boundary is in a direction that drives the atoms near the twin plane in variant 2 in a direction that grows variant 1 (cf. Figures 17 and 21).

The temperature dependence of the shear stress at the twin boundary is expressed in general terms by making use of the relation for uniaxial anisotropy (Akulov 1936; Callen and Callen, 1966) expressed in equation (23) for two-ion interactions and in Table 2 ($l = 2$, high T) for single-ion mechanisms. (This relation would not hold through an intermartensitic transformation in which the nature of the anisotropy changes; such transformations are often observed in the Ni–Mn–Ga system.) Further, the temperature dependence of the reduced magnetization is approximated with the scaling relation, $m = 1 - t^2 = 1 - (T/T_C)^2$. In this case, the temperature dependence of the torque density reduces to:

$$\tau(T) = -2K_u(0)h(T)(1-t^2)^2\sqrt{1-h(T)^2} \qquad (43)$$

The field dependence of the torque density rises from zero at $h = 0$ to a maximum of K_u at $h = 1/\sqrt{2}$ then decreases to zero again when the applied field reaches the temperature-dependent anisotropy field ($\theta_2 = 0$).

Figure 25 plots the thermally activated torque density, $\tau(T)\Delta R(T)$ versus t, for different values of $h(T)$. $\Delta R(T)$ is the net thermally activated transition rate for atoms moving from positions favoring variant 2 to those favoring variant 1:

$$\Delta R = A_{1\to2}\exp\left[-\frac{\Delta G_0 - \mu_0 M_s H\cos\theta}{k_B T}\right] - A_{2\to1}\exp\left[-\frac{\Delta G_0 + \mu_0 M_s H\cos\theta}{k_B T}\right] \qquad (44)$$

Here, A_{i-j} is a preexponential factor for attempt rate in the double well potential and $\Delta G_0 = 0.015\,\text{eV}$ is the defect energy barrier height in the absence of a magnetic field. An activation barrier close to this value, and the approximate

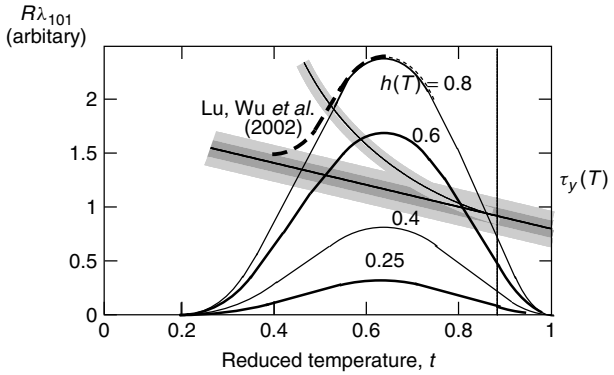

Figure 25. Dependence of thermally activated torque on reduced temperature for $\Delta G = 15\,\text{meV}$ and various values of $h(T)$. Two assumed forms for $\tau_y(T)$ are shown. (Adapted from O'Handley *et al*., 2006.)

range of the strain field about a Ni–Mn–Ga twin boundary, 2 nm, were estimated earlier (O'Handley *et al*., 2001). (See (O'Handley *et al*., 2006), for numerical values used.) Here, a preexponential factor of unity has been used in the thermal activation so the vertical scale is arbitrary. Note that the thermally activated torque is quenched as the reduced temperature, t, approaches zero and vanishes at $t = 1$ (or below $t = 1$ upon transformation to austenite where the two wells become one). The very weak thermal activation at low temperatures does not allow the relatively small magnetic energy to effect twin-boundary motion. Two forms of *threshold* shear stress are also shown in Figure 25, one a simple linear relation based on the weak temperature dependence of the elastic constants, and the other a representation of the exponential temperature dependence observed in one Ni–Mn–Ga alloy (Heczko and Straka, 2003). The shaded area around these yield-stress lines suggests the distribution of pinning strengths that is inherent in the stochastic process of twin-boundary actuation (Marioni, Allen and O'Handley, 2004). Equations (43) and (44) then indicate that field-induced twin-boundary motion occurs over a limited temperature range (between about $h = 0.5$ and 0.8 here) below the martensitic transformation temperature, T_0 (vertical dashed line), or even lower if the applied field decreases below the anisotropy field for $T < T_0$. Actuation vanishes in the temperature range where the temperature-dependent torque drops below the temperature-dependent threshold stress.

Superimposed on the calculated curves are data from Liu *et al*. (2002) showing the decrease in field-induced strain at temperatures below the maximum field-induced strain. The horizontal range of the data was scaled based on the Curie temperature; the vertical axis of the data was scaled to fit the general curve. This is not intended to be a quantitative confirmation of the model but an indication of how it is able to predict the vanishing of thermally activated, field-induced strain at low temperatures. These temperature-dependent models provide new insights into the complex processes that govern the temperature dependence of magnetic-field-induced twin-boundary motion, and show that it contrasts starkly with the temperature dependence of magnetostriction.

4 SUMMARY

ME effects arise from the strain dependence of spin-orbit and anisotropic-exchange interactions. Joule magnetostriction can be described by at least five related parameters: the ME coupling coefficients B_i (stresses of magnetic origin), the magnetostriction constants λ_i (strains of magnetic origin), the magnetostrictivity, **d** (the change in magnetization per unit stress or the change in strain per unit field), the ΔE effect, or magnetomechanical coupling factor, k. The Joule magnetostriction is the strain associated with the direction of magnetization. In an unconstrained sample, λ is proportional to a component of the magnetic stress, B_i, divided by the appropriate stiffness modulus. The inverse Joule effect brings about a change in the magnetization process or change in the anisotropy field, upon straining a sample.

The temperature dependence measured for Joule ME effects is generally steeper than that of the magnetization itself. (The same is true as for magnetic anisotropy.) The reduced magnetostriction, $\lambda^{\gamma,\alpha}(T)/\lambda^{\gamma,\alpha}(0)$, varies as the $l(l+1)/2$ power of the reduced magnetization in materials whose magnetic moments are well localized. Rare-earth metals and alloys with $L_z \neq 0$ can show much larger ME effects than most 3d transition metals and their alloys.

The large field-induced strains observed in FSMAs are due to torque-induced twin-boundary motion and hence are more closely related to (i) martensite crystallography, including compatibility between parent austenite and martensite (James

Table 3. Comparison of Joule magnetostriction and field-induced twin-boundary motion.

	Anisotropic magnetostriction	Field-induced twin-boundary motion
Strain and symmetry	Magnetostrictive strain lowers symmetry of crystal by small elastic distortion	Large strain results from reorientation of low-symmetry crystallographic twins by twin-boundary motion
Strain reference	Direction of $\boldsymbol{M}$	Crystal axes
Strain mechanism	Spin-orbit interaction or anisotropic exchange	Field-induced torque on crystal, thermal activation
Range of strain	$<10^{-4}$ in transition metals, 2×10^{-3} in rare-earth/transition metal alloys	$1 - c/a = 6\%$ tetragonal, 10% in orthorhombic Ni–Mn–Ga
Reversibility	Elastic; small hysteresis due to 90° domain-wall motion	Plastic; large hysteresis due to twin boundary threshold
Role of domain walls	Motion of 90° walls gives strain; motion of 180° walls does not	90° walls follow twin boundary 180° walls produce no strain
Temperature dependence	$\lambda(T)/\lambda(0) = m^{l(l+1)/2}$ $\lambda(0)$ generally $>$ λ (room temperature)	$\varepsilon(H)$ observed below martensite transition but not below thermal cutoff

and Hahn, 2000) as well as $1 - c/a$, which limits the strain in tetragonal martensites, (ii) defect structure, which governs the mobility of twin boundaries, and (iii) the magnetic anisotropy, which limits the torque and hence the shear stress that can be applied along a twin boundary. Table 3 summarizes some of the salient characteristics of Joule magnetostriction and magnetic-field-induced strain in FSMAs that distinguish these two magnetic-field-induced strains that arise from very different mechanisms.

In Fe, 90° domain walls separate two magnetic domains that are weakly strained by Joule magnetostriction in a twinning relation across the domain wall. Application of a field favoring one of the domains may move the domain wall; rotation of the magnetization via domain-wall motion results in a change in magnetostriction in that 'transformed' region and hence a small change in the gross shape of the crystal. In FSMAs the twin boundary is a crystallographic feature, not a result of magnetostriction. The 90° domain wall that is located at the twin boundary in zero field can be separated from the twin boundary by application of a field below the threshold for twin-boundary motion without the large strain that distinguishes these materials; a small magnetostrictive strain accompanies the rotation of the magnetization.

ACKNOWLEDGMENTS

The work from MIT on magnetostriction has been generously supported over the years by the Office of Naval Research (N00014-90J1174), Army Research Office and the National Science Foundation (DMR 94-10943). The work from MIT on FSMAs has been supported by ONR and DARPA and most recently by a Multi-University Research Initiative from ONR. Many students and colleagues have contributed to this work with their research and comments.

APPENDIX

It is important to consider the possible role of conventional magnetostriction in the actuation process of magnetic martensites. Anisotropic magnetostriction is observed to be about -100 to -150×10^{-6} in Ni–Mn–Ga (Tickle *et al*., 1999). This small strain, quadratic in the applied field, is indicated schematically in Figure A1 for Ni–Mn–Ga by the solid line below a typical threshold field of $200\,\mathrm{kA\,m^{-1}}$. In a multivariant martensite, as the magnetization is rotated, the domains are not free to fully express their magnetostrictive strain because of the constraints of adjacent variants, sample clamping, and any imposed bias stress. In these cases, the magnetic stress (the magnetoelastic coupling coefficient, B_1 in this case) builds up inside the constrained variant. This stress can be as large or larger than the yield stress for twin-boundary motion; for Terfenol-D, $B_1 \approx 60\,\mathrm{MPa}$ and in most other magnetic materials it is of the order of 1–10 MPa. The question here concerns the role of this stress accumulation on twin-boundary motion as a field is applied to a multivariant magnetic martensite. The large field-induced strain of certain magnetic martensites is due to twin-boundary motion. Twin-boundary motion may or may not occur in a multivariant crystal upon field-induced rotation of the magnetization in unfavorably oriented variant. However, once twin-boundary motion is initiated, it will proceed to minimize the energy in the presence of the applied field and the accumulated magnetostrictive stress.

In an actuation experiment configured as in Figure 18 but having the external stress provided by a compression spring, one would expect the stress in the load path to be proportional to the strain. Figure A1 shows the output of a load cell during cyclic actuation of the Ni–Mn–Ga sample whose field-induced strain is similar to that shown in Figure 19 (O'Handley *et al*., 2003). Note that the stress increases quadratically by as much as 0.5 MPa even at fields below the threshold for twin-boundary motion. Once twin-boundary motion is initiated (the range over which hysteresis is observed), this motion proceeds with no increase in load-path stress until the magnetic driving stress exceeds the load-path stress (spring plus ME stress). There is no increase in stress above saturation at about $H_a \approx 500\,\mathrm{kA\,m^{-1}}$.

It is possible quantitatively to explain the stress versus field data in Figure A1. The free energy in equation (1) must be supplemented with the ME anisotropy energy density in cubic systems, which has the form (O'Handley, 2000):

$$g_{\mathrm{ME}} = B_1\left[\varepsilon_{xx}(\alpha_x^2 - \tfrac{1}{3}) + \varepsilon_{yy}(\alpha_y^2 - \tfrac{1}{3}) + \varepsilon_{zz}(\alpha_z^2 - \tfrac{1}{3})\right] \tag{A1}$$

Here, the ε_{ii} are the principal magnetostrictive strains and α_i are the direction cosines of the magnetization. Because the ME energies are small ($B_1\varepsilon \approx 10^3\,\mathrm{J\,m^{-3}}$) compared to the magnetic anisotropy, the magnetization direction, determined from $\mathrm{d}g/\mathrm{d}\theta = 0$, is only weakly affected by ME energy. However, to determine the stress inside a constrained crystal, the derivative of the free energy with respect to strains is taken, and the magnitude of B_1 is such that it cannot be neglected relative to the other stresses in the problem that affect twin distribution. When the magnetization in variant 2 rotates in the presence of a field, it exerts a compressive (Tickle *et al*., 1999a,b)

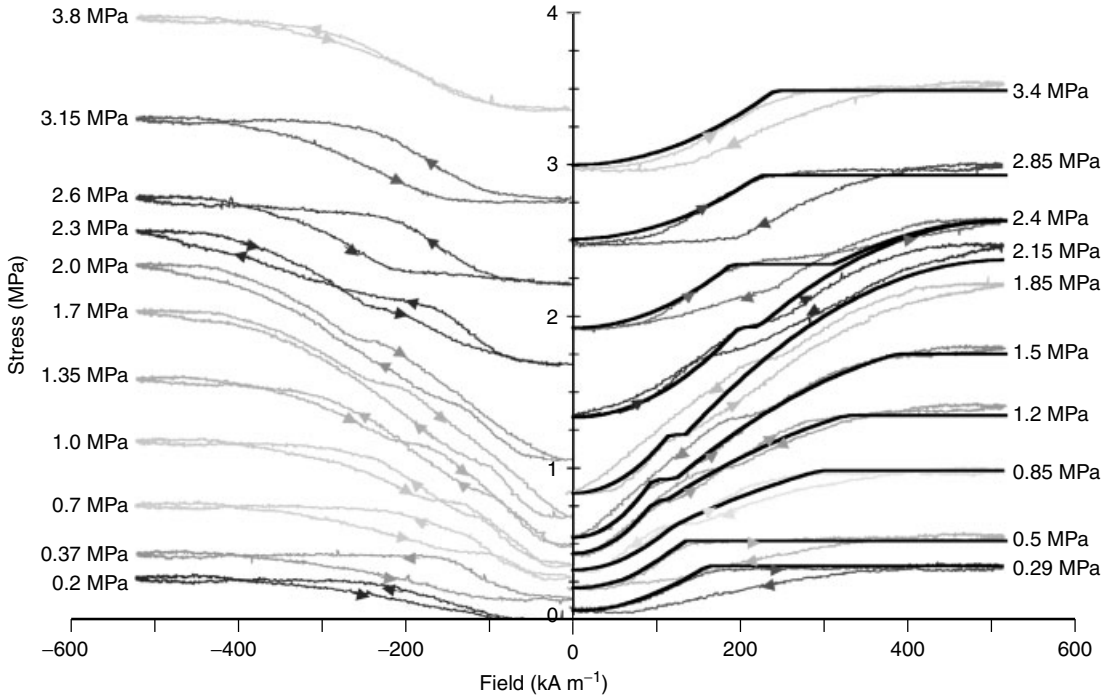

Figure A1. Magnetic-field dependence of stress measured by a load cell during actuation of Ni–Mn–Ga crystal. Theoretical results of equation (4) are plotted for the increasing field branch on half of the data set using different values of σ_0 that correspond to the initial bias stress as labeled. (Reprinted with permission R.C. O'Handley *et al*., copyright 2003 International Society for Optical Engineering.)

magnetostrictive stress on variant 1 proportional to $B_1\varepsilon \approx 10^3\,\mathrm{J\,m^{-3}}$. When the total energy density is written and minimized to find the stress, σ_y, the result is (O'Handley *et al*., 2003):

$$\sigma_y = \frac{\partial g}{\partial \varepsilon_{2y}} + \sigma_{\mathrm{ext}} = \sigma_{2y} + \sigma_{\mathrm{ext}} \tag{A2}$$

$$= \tfrac{3}{2}[B_1(f_1 - h^2) - \sigma_{\mathrm{ext}}(y_0, h)] + \sigma_{\mathrm{ext}}(y_0, h) \tag{A3}$$

The stress predicted by equation (A2) is plotted as a solid line in Figure A1. The model results correctly predict the quadratic increase in stress approaching 1 MPa before twin-boundary motion initiates. This stress is due to magnetostriction in the constrained sample. This model also expresses the absence of an increase in stress during twin-boundary motion. Finally, the saturation of magnetostrictive stress above the anisotropy field is also properly described.

Ferroelectricity in Incommensurate Magnets

1 INTRODUCTION

The interactions between long-range magnetic order and long-range ferroelectric order have been studied in depth since the first experimental confirmation of the magnetoelectric effect in the late 1950s (Dzyaloshinskii, 1959; Astrov, 1960; Folen, Rado and Stalder, 1961). We note the existence of several reviews (Smolenskii and Chupis, 1982; Schmid, 1973; Fiebig, 2005; Eerenstein, Mathur and Scott, 2006) and monographs (Birss, 1954), which give a general overview of the subject.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*.

ISBN: 978-0-470-02217-7.

Of particular interest for this review are those materials which that exhibit a combined magnetic and ferroelectric transition. Perhaps the best known of these is Ni–I boracite ($Ni_3B_7O_{13}I$) which shows coupled ferromagnetic (FM), ferroelectric, and ferroelastic properties at a single phase transition at $T = 61.5\,\mathrm{K}$ (Ascher, Rieder and Stoessel, 1966; Toledano, Schmid, Clin and Rivera, 1985). The multiferroic behavior in this boracite arises from the fact that the magnetic transition is connected to a structural distortion, which in turn allows the development of ferroelectric order (Toledano, Schmid, Clin and Rivera, 1985). This transition can be understood in terms of a phenomenological Landau theory that couples the FM, ferroelectric, and ferroelastic order parameters to a primary antiferromagnetic (AFM) order parameter (Toledano, Schmid, Clin and Rivera, 1985). The strong coupling between magnetic and ferroelectric order parameters in systems having a simultaneous phase transition is demonstrated by the observation that in $Ni_3B_7O_{13}I$ it is possible to reverse the direction of the spontaneous polarization by applying an external magnetic field perpendicular to the direction of magnetization (Ascher, Rieder and Stoessel, 1966).

Cr_2BeO_4 also develops magnetic and ferroelectric order at a single phase transition (Newnham, Kramer, Schulze and Cross, 1978). Below $T = 28\,\mathrm{K}$, Cr_2BeO_4 orders antiferromagnetically into a state with spiral spin structure, and this AFM state shows an extremely small spontaneous polarization (approximately one million times smaller than that of $BaTiO_3$). The coupling between magnetic and ferroelectric order is expressed by a model proposing a mechanism in which the electric polarization is induced solely by the AFM order (Stefanovskii and Yablonskii, 1986). A similar model for magnetically induced ferroelectric order will be discussed in detail in the following sections.

The multiferroic behavior of $BaMnF_4$ is useful for illustrating the importance of symmetry considerations in determining magnetoelectric properties. Pyroelectric $BaMnF_4$ orders antiferromagnetically when cooled below $T = 26\,\mathrm{K}$, and there is a dielectric anomaly at this magnetic transition temperature (Samara and Richards, 1976). This decrease in dielectric constant below T_N varies like the square of the sublattice magnetization, and clearly indicates a coupling between the magnetic and ferroelectric properties of the sample. This interaction between magnetic and ferroelectric order is attributed to a magnetoelectric coupling, which causes a polarization-induced spin canting of 3 mrad (Fox and Scott, 1977). This spontaneous magnetoelectric effect is allowed by the $2'$ magnetic point group of $BaMnF_4$. Substituting 1% Co for Mn changes the magnetic point group to 2, which does not allow a spontaneous magnetoelectric effect, and no dielectric anomaly is observed in $BaCo_{0.01}Mn_{0.99}F_4$ (Fox, Tilley and Scott, 1980). While the magnetic structure in $BaMnF_4$ is strongly affected by the ferroelectric order, the very large coercive field precludes controlling the magnetization using an external electric field (Fiebig, 2005).

Until quite recently, the theoretical and experimental studies have focused on ferroelectricity in systems with simple FM or AFM order (Fox, Tilley and Scott, 1980; Toledano, Schmid, Clin and Rivera, 1985) (with studies on Cr_2BeO_4 being the notable exception). These systems are tractable from a theoretical standpoint, and allow a comparison to be made between experimental results and straightforward models based on magnetic space groups. However, limiting the scope of investigation to systems with FM or AFM order neglects a large class of materials that have more complex magnetic structures. Here, we will not consider systems (several of which are listed in Table 1 of Smolenskii and Chupis, 1982) which are ferroelectric at high temperature and then have a lower temperature magnetic phase transition (Fiebig *et al*., 2002). Instead, in this brief review article we will focus on the more recent studies in which ferroelectricity appears simultaneously (in a single combined phase transition) with long-range sinusoidally modulated magnetic order (Kimura *et al*., 2003; Hur *et al*., 2004), which we will refer to generically as 'incommensurate' magnetic order. (Commensurate systems have a wave vector q such that $aq = n/m$, where n and m are integers. If this condition is not satisfied, the system is incommensurate.) Accordingly, we will briefly summarize the experimental situation for the systems $TbMnO_3$ (TMO) (Hur *et al*., 2004; Kenzelmann *et al*., 2005) and $Ni_3V_2O_8$ (NVO) (Lawes *et al*., 2004, 2005; Kenzelmann *et al*., 2006). Then we will describe in detail the symmetry analysis developed in Lawes *et al*. (2005), Kenzelmann *et al*. (2006), and Harris (2006a) to understand the phenomenology of these systems. We believe that this theoretical approach is simple enough that it can easily be applied

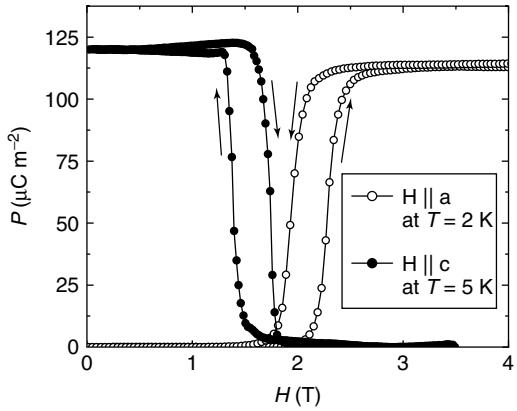

Figure 1. Experimental results for the spontaneous (i.e., in zero applied electric field) polarization **P** versus applied uniform magnetic field **H** applied along different crystallographic directions at selected temperatures for NVO. Only the *b*-component of the spontaneous polarization vector is nonzero. The arrows indicate the directions of increasing and decreasing magnetic field. (Reprinted with permission G. Lawes *et al*., copyright 2005, American Institute of Physics.)

to the ever increasing number of systems like NVO or TMO in which ferroelectricity is induced by incommensurate magnetic long-range order (For a symmetry analysis of several other systems, see Harris, 2006b).

To illustrate this phenomenon, we show, in Figure 1 some intriguing data from (Lawes *et al*., 2005) showing that the spontaneous polarization **P** depends strongly on the applied magnetic field **H**. At first glance, this data seems to have no obvious explanation. However, when viewed in combination with the magnetic phase diagram (see Figure 6) we will see that this data indicates that the spontaneous polarization is nonzero only in the magnetic phase we will call the 'low-temperature incommensurate phase'. The hysteresis is a consequence of passing through a first-order phase boundary between this phase and an AFM phase in which a spontaneous polarization is not allowed. Thus, the dramatic dependence of polarization on magnetic field has a simple explanation: ferroelectric order appears only in one specific magnetic phase whose existence depends in the value of the magnetic field. This strong coupling between magnetic and ferroelectric order is potentially important for device applications, as we will discuss in the following section. From a basic physics standpoint, these systems that exhibit a coupling between the ferroelectric moment (a polar vector) and the magnetic moment (an axial vector) are very interesting. (As we will see, such systems have order parameters whose response to both electric and magnetic fields becomes large especially near a phase transition.) A complete understanding of this coupling from a microscopic theory is not yet available. Here, we will show that the Landau expansion explains the observed phenomenology

of this interaction and that these results follow from the microscopic symmetry of the strain dependence of the exchange tensor. This explanation will serve as a guide to constructing a fully microscopic theory of magnetoelectric coupling.

Briefly, this review is organized as follows. In Section 2, we discuss some general types of applications in which the magnetoelectric coupling may be exploited to develop new types of devices. It should be emphasized that these applications are speculative, and are intended to illustrate the types of new devices that could be developed using these new materials. In Section 3, we review the Landau description of ferroelectricity. In Section 4, we give a simplified theoretical analysis of incommensurate magnetic ordering and in Section 5, we discuss how Landau theory leads to a symmetry-based description of incommensurate magnetic ordering. It is our aim to demystify the use of representation theory for the determination of magnetic structure by diffraction techniques. Understanding these incommensurate magnetic structures is crucial to developing a model for the coupling between magnetic and ferroelectric order in these systems. In Section 6, we use the results of Section 5 to analyze how symmetry restricts the form of the coupling between electric and magnetic order parameters and thereby explain the simultaneous appearance of these two kinds of order parameters in a single phase transition. The construction of this interaction is greatly simplified by the fact that it involves an expansion in powers of the order parameters relative to the paramagnetic paraelectric phase. Thus the interactions have to satisfy the invariances of the disordered paramagnetic/paraelectric phase (Dzyaloshinskii, 1957; Landau and Lifshitz, 1958) and we do not need to broach the more complicated question of analyzing the symmetry of interaction within an ordered phase. In Section 7, we analyze the symmetry of the strain dependence of the exchange tensor and show that it leads to results identical to those of Landau theory. In Section 8 we summarize the main points of this review and speculate on some future directions of research. We will discuss how our results on ferroelectric order in incommensurate magnets may offer guidance in searching for new magnetoelectric materials. Finally in Section 9, we briefly discuss results which appeared subsequent to the writing of this review.

2 DEVICE APPLICATIONS

The development of devices incorporating both charge and spin degrees of freedom, often referred to as *spintronics*, has already led to significant technological breakthroughs (Wolf *et al*., 2001). Magnetic sensors based on giant magnetoresistance (GMR) are widely used as the read heads in modern hard drives, and magnetic random access memory also relies strongly on couplings between charge and spin. Additionally, there are a wide range of proposals for devices based on controlling the spin degree of freedom in FM semiconductors, including spin valves and qubits for quantum computing. Much of the research on materials in which charge and spin are coupled has focused on metallic and semiconducting systems. However, dielectric materials exhibiting couplings between electric polarization and magnetization may also play an important role in developing the next generation of spintronic devices.

Magnetoelectrics are systems in which either applying an external magnetic field produces an electric polarization or applying an external electric field produces a magnetization. This type of coupling between charge and spin was postulated by Pierre Curie at the end of the nineteenth century (Curie, 1894), but not observed experimentally until the late 1950s (Astrov, 1960; Folen, Rado and Stalder, 1961). Materials in which two or more of ferroelectric, FM, and ferroelastic order coexist are referred to as multiferroics. This strict definition of multiferroics is often relaxed to include systems that exhibit combinations of any type of long-range magnetic, ferroelectric, or ferroelastic order. Furthermore, a fourth class of ferroic order, *ferrotoroidicity*, has been included in discussions of multiferroic materials (Fiebig, 2005; Schmid and Rivera, 1994; Ye *et al*., 1994). This review will concentrate specifically on magnetoelectric multiferroics, where the coexistence of long-range magnetic and long-range dielectric order leads to a pronounced coupling between the charge and spin degrees of freedom in these systems.

We consider two classes of devices based on magnetoelectric multiferroics. The first class of devices depend on the magnetoelectric effect – the induction of a magnetization (polarization) by an applied electric (magnetic) field. Using the magnetoelectric effect, it is possible to design a range of devices from sensors to transducers to actuators, in which magnetic and electric properties are coupled. The second class of devices exploits the fact that these materials have simultaneously appearing long-range magnetic and ferroelectric order. The underlying assumption is that multiferroics exhibit both charge and spin ordering, and because of the coupling between the two, both magnetic and ferroelectric order will be strongly affected by either magnetic or electric fields. Strictly speaking, only magnetic field control of the electric polarization has been demonstrated for the multiferroic materials with incommensurate magnetic structures discussed in this review, but magnetic phase control by an external electric field has been demonstrated in other multiferroic materials (Lottermoser *et al*., 2004). Very recently, Ederer and Spaldin have discussed the materials requirements for electrically switchable magnetic properties in thin-film multiferroics (Ederer and Spaldin, 2005).

The investigation of magnetoelectric devices is an active area of research. Prototype devices fabricated using piezoelectric–magnetostrictive composite materials to produce magnetoelectric coupling have already been tested (Bayrashev, Parker, Robbins and Ziaie, 2003; Srinivasan *et al*., 2002), and there are a range of proposals for other magnetoelectric devices. These include utilizing magnetoelectric materials as the pinning layer in GMR devices (Binek and Doudin, 2005), for low-frequency wireless power applications (Bayrashev, Parker, Robbins and Ziaie, 2003), and for developing tunable dielectric materials (Katsufuji and Takagi, 2001). One key feature of magnetoelectric materials is that they allow the design of devices controlled magnetically or electrically, as desired. Controlling the magnetic properties of materials using an *electric* field offers significant benefits in designing new devices. Using current-based methods to switch magnetic devices is relatively slow and power intensive. Voltage control of the magnetic properties is expected to offer significantly faster switching (thin-film ferroelectrics can show switching times of less than 200 ps (Li *et al*., 2004)) in a low-power device. Magnetoelectric materials offer the potential for fabricating highly tunable, fast switching, low-loss/low-power devices having very small form factors, which would be suitable for a wide range of commercial and industrial applications.

The materials property most relevant in determining the suitability of a compound for applications in magnetoelectric devices is the magnitude of the magnetoelectric susceptibility, χ_{ME}. For homogeneous materials, χ_{ME} satisfies the bound,

$$\left(\chi_{\mathrm{ME}}^2 \leq \chi_{\mathrm{E}}\chi_{\mathrm{M}}\right) \tag{1}$$

where χ_{E} and χ_{M} are the electric and magnetic susceptibilities of the system, respectively (Smolenskii and Chupis, 1982). Therefore, in order to maximize the magnitude of the magnetoelectric coupling, one should attempt to maximize the magnitudes of *both* χ_{M} and χ_{E}. Since ferroelectrics typically have large values of χ_{E} and ferromagnets typically have large values of χ_{M}, multiferroics are expected to have large values of χ_{ME}. Furthermore, since susceptibilities are largest at the ordering transition, systems developing magnetic and ferroelectric order at the same temperature should show exceptionally large magnetoelectric couplings. Understanding the microscopic origins of the magnetoelectric coupling in these multiferroic systems will have important ramifications for developing novel magnetoelectronic devices.

Beyond simply exhibiting very large magnetoelectric couplings, intrinsic multiferroics also have both long-range magnetic order and long-range ferroelectric order. The coupling between magnetization and polarization offers new possibilities for designing devices. The ability to control the magnetic or ferroelectric state of a system using either a magnetic field or an electric field would offer the ability to develop multifunctional memory elements, for example, ferroelectric memory that can be written to using magnetic fields. We will discuss two proposals for new technologies that explicitly utilize the ferroelectric and magnetic characters of magnetoelectric multiferroics. It should be emphasized that this discussion is meant only to illustrate some of the potential applications arising from the incorporation of multiferroic materials into new devices. More investigation on the specific properties of these multiferroics is required before proof-of-principle devices could be designed on the basis of these speculations. Because the spontaneous polarization in incommensurate multiferroics is small, these materials are not expected to replace conventional ferroelectrics in any type of current devices. Therefore, we will concentrate on discussing novel applications which would only be possible using multiferroic materials.

As the bit density of modern hard drives increases, the characteristic size of the magnetic structures used to store the information is decreasing. As the physical size of the bit is reduced, the anisotropy energy decreases, and the magnetic moment can begin to thermally fluctuate. Controlling these thermal fluctuations is necessary to ensure the long-term stability of stored information in ultradense magnetic recording material. For long-term magnetic storage (5+ years), the ratio of the energy barrier against these thermal fluctuations to k_{BT} should be large, roughly 55. In current devices, this is often accomplished by using materials with very large magnetic anisotropy energies or by exploiting the anisotropic difference between FM and AFM layers. One possible application for multiferroic materials is to use the coupling between ferroelectric and magnetic order in these systems to stabilize the magnetic moment against thermal fluctuations in nanoscale magnets.

In many magnetoelectric multiferroics, there is a strong coupling between the ferroelectric and magnetic order parameters. In such systems, fixing the polarization (magnetization) direction will fix the axis of the magnetization (polarization). This coupling is observed in measurements showing that the sign of the magnetically induced polarization is independent of the sign of the applied magnetic field, although the development of ferroelectric order depends strongly on the magnetic field axis. In such multiferroics, fixing the electric polarization would also fix the magnetization axis. This ferroelectrically induced magnetic anisotropy would inhibit thermally activated switching of the magnetic moments by significantly increasing the magnitude of the energy barrier to magnetization reversal. This could be accomplished, for example, by assembling multiferroic nanoparticles on a ferroelectric substrate. In this geometry, the very large ferroelectric anisotropy energy would provide a tunable

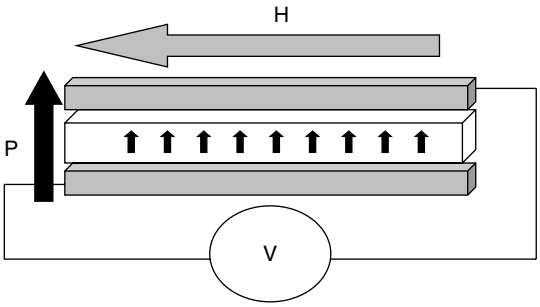

Figure 2. Schematic illustration of a device to measure magnetic fields by using the induced polarization. The middle layer (white) is a multiferroic material with strong magnetoelectric couplings and the outer layers (gray) are ferromagnetic metals. In this example, the polarization is induced in a direction perpendicular to the applied magnetic field.

barrier against thermal fluctuations of the *magnetic* moment as well.

Multiferroics may also have important applications in developing magnetic field sensors. There are a range of proposals for incorporating magnetoelectric materials in exceptionally sensitive magnetic field detectors. Even relatively small external magnetic fields will produce a voltage change in materials with very large magnetoelectric couplings. Since it is often better to measure small voltages at zero applied current rather than small magnetizations or small changes in resistivity, magnetoelectric materials offer the potential for developing greatly improved magnetic field sensors. Because multiferroics exhibiting simultaneous magnetic and ferroelectric transitions offer exceptionally large magnetoelectric couplings, these materials are particularly interesting in the context of improved sensors. Figure 2 shows a schematic for such a device (http://www.nasatech.com/Briefs/May00/NPO20523.html). The magnetization produces a spontaneous polarization directed perpendicular to the plane of the sensor. This magnetically induced voltage can be measured to a high degree of accuracy, either directly or by measuring the dielectric response of the compound. This device could also be configured to extract energy from an *alternating* magnetic field – the magnetically induced alternating voltage could be used as a supply for very low-power applications (Bayrashev, Parker, Robbins and Ziaie, 2003).

Beyond simply being used as a passive magnetic field sensor, the device illustrated in Figure 2 could also be configured as a voltage-biased magnetic memory element. One of the difficulties facing current magnetic random access memory (MRAM) devices lies in producing magnetic fields that are strong enough to cause a moment reversal in the memory element but also sufficiently localized to affect only one specific element. While identifying multiferroic materials in which applying a voltage could reverse the direction of the magnetization would certainly be beneficial for developing MRAM devices, a more modest type of voltage-assisted magnetization reversal could also be implemented in memory elements. As will be discussed in the following section, ferroelectric order can be promoted or suppressed by the application of an external magnetic field in many multiferroic materials. We expect that in these materials, applying an electric field could then suppress or promote magnetic ordering. In such a system, the coercivity of the magnetic memory element could be tuned by applying an electric field. Incommensurate multiferroics may be more suitable for devices based on voltage-tunable coercivity, rather than voltage-tunable magnetization, because of the very small spontaneous polarization typically developing in these systems.

Consider the multiferroic memory element in a FM state, which can be suppressed by applying a sufficiently large voltage. In the absence of an electric field, the coercivity of the memory element is large, so the magnetization is unaffected by stray magnetic fields. In order to reverse the magnetization direction, a bias voltage is applied to the multiferroic element, bringing the system closer to the magnetic transition, reducing the magnitude of the coercive field. In this state, the magnetization can be reversed by a relatively small external magnetic field, smaller than the coercive field of the unbiased multiferroic. When the voltage is removed, the new magnetization will be stable. This type of voltage-assisted magnetization reversal could be used to produce arrays of magnetic memory elements that could be switched by the same external magnetic field. Only those elements that have a bias voltage applied will have a sufficiently small coercivity to be switched by the magnetic field. This technique may offer advantages over transitional MRAM devices, such as a smaller sensitivity to stray fields (allowing higher bit density) and potentially faster switching times. This is schematically illustrated in Figure 3.

While multiferroics offer many exciting possibilities for designing novel magnetoelectric and magnetodielectric devices, there are several materials limitations that need to be overcome, specifically for incommensurate multiferroics. All incommensurate multiferroics identified to date have transition temperatures well below room temperature, with the possible exception of $Ba_{0.5}Sr_{1.5}Zn_2Fe_{12}O_{22}$ (T. Kimura, private communication). Additionally, the magnitude of the spontaneous polarization in incommensurate multiferroics is very small, with typical polarizations on the order of only $10^{-3}\,\mathrm{Cm}^{-2}$. Finally, incommensurate multiferroics often have a small or negligible net magnetization in the ordered state. These limitations make it difficult to identify applications in which incommensurate multiferroics could replace conventional FM or ferroelectric materials. However, the strong spin-charge coupling in multiferroic materials does

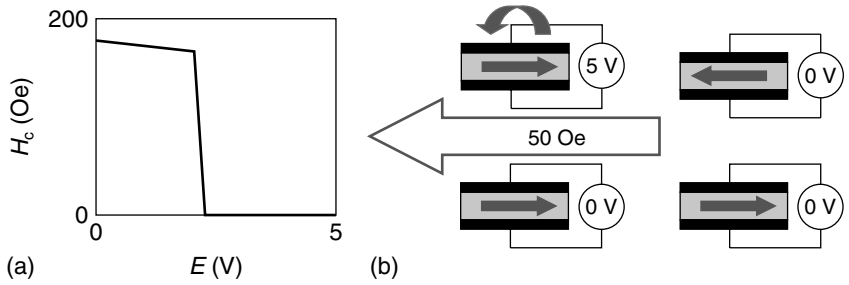

Figure 3. Voltage-assisted MRAM. (a) Schematic diagram showing a *model curve* for how the coercive magnetic field is expected to vary with voltage. (b) With the magnetization of the bits originally directed to the right, a small (50 Oe) writing field is applied. At zero voltage, this is smaller than the coercive field, so that the magnetization does not switch. However, applying 5 V across the multiferroic layer reduces the coercive field to almost zero, so that this small magnetic field is sufficient to reverse the direction of magnetization.

offer the possibility of designing new classes of devices, which would be impossible with conventional materials. Identifying incommensurate multiferroics having higher transition temperatures and larger ordered moments (both electric and magnetic) is one of the major current research objectives for multiferroic materials. Furthermore, there is some hope that the ferroelectric properties of incommensurate multiferroics may be enhanced in thin films. Recent work on $BiFeO_3$ films has shown that the magnitude of the polarization in thin films is approximately an order of magnitude larger than in bulk samples (Wang *et al*., 2003). This has been explained in terms of epitaxial strain (Li *et al*., 2004) and allows the possibility that the spontaneous polarization of incommensurate multiferroics may be enhanced in thin films.

3 FERROELECTRICITY

We start by making a few observations concerning the symmetry properties of ferroelectric systems for which magnetic ordering plays no role. In the most common scenario, ferroelectrics exhibit a high-temperature phase having spatial inversion symmetry which prevents the existence of a vector order parameter. Then, as the temperature is reduced through a critical value, T_F, a lattice instability develops in which inversion symmetry is broken cooperatively via a continuous phase transition at which a spontaneous polarization appears. Within a Landau theory this transition is described by a free energy as a function of the polarization $\mathbf{P}$ which is of the form

$$F = \frac{1}{2}\chi_E^{-1}\mathbf{P}^2 + \mathcal{O}(\mathbf{P})^4 = \frac{1}{2}a(T - T_F)\mathbf{P}^2 + \mathcal{O}(\mathbf{P})^4 \quad (2)$$

At the transition, the fact that the quadratic term in $\mathbf{P}$ becomes unstable (negative) reflects the divergence in the electric susceptibility at the ferroelectric transition. This instability is sometimes traced to a soft phonon, but whatever the mechanism, the appearance of ferroelectricity represents a broken symmetry. Conversely, as will become relevant in the following, ferroelectricity can only occur if the symmetry is broken to permit the ordering of the polarization vector. We will use this criterion to determine which types of magnetic order can possibly induce ferroelectric order. If one takes the quartic terms in equation (2) to be of the form $(b/4)[\mathbf{P}^2]^2$ (with $a > 0$ for stability), then minimization of F with respect to $\mathbf{P}$ shows that for $T < T_F$ one has $P \sim [a(T_F - T)/b]^{1/2}$, which is expected to hold as long as $T_F - T$ is not so large that sixth- and higher-order terms in F are important. Mean-field theory ignores spatial correlations that lead to modifications of critical exponents, but the scope of this review does not permit consideration of such corrections (Domb and Green, 1976).

As the temperature is further lowered it is possible for this ferroelectric system to develop long-range magnetic order (Fiebig *et al*., 2002). In this case, one does not expect significant interaction between electrical and magnetic properties because the two phenomena are essentially independent of one another. In these systems, the spontaneous polarization will depend only weakly on the applied magnetic field. In this scenario, it is well known (Lawes, Ramirez, Varma and Subramanian, 2003) that one can expect anomalies in the dielectric response of the system when the ferroelectric develops (independently) long-range magnetic order. This review is *not* concerned with such an 'accidental' superposition of electric and magnetic properties. Instead, we focus our attention on the situation when the appearance of long-range magnetic order induces ferroelectricity. Furthermore, we will consider an interesting subclass in which the long-range magnetic order is modulated with an apparently incommensurate wave vector. We will develop a Landau theory for this combined phase transition in which the fact that the wave vector does not have high symmetry (and is thus neither FM or AFM) is crucial to our analysis. Thus the development here cannot be obtained by a trivial extension of theories applicable to FM or AFM ferroelectrics. A simplifying feature of this formulation is that it is based on an expansion of the free energy in powers of the various order parameters relative

to the *paramagnetic* phase. Accordingly, each term in this expansion has to have the full symmetry of the disordered phase (Dzyaloshinskii, 1957; Landau and Lifshitz, 1958). In contrast, it is less straightforward to analyze whether the symmetry of a magnetically ordered phase permits an induced ferroelectric order. Also, the Landau formulation correctly predicts which components of the spontaneous polarization vector are induced by the magnetic ordering. In addition, the Landau expansion indicates that the spontaneous polarization is proportional to the nth power of the emerging magnetic order parameter. In the cases considered here $n = 1$, as we shall see.

4 TOY MODELS FOR INCOMMENSURATE MAGNETISM

4.1 Review of mean-field theory

In this section we review the description and phenomenology of incommensurate magnets, because the characterization of their symmetry is essential to understanding the coupling between magnetic and electric long-range order.

For the purposes of this review, it suffices to consider the description of incommensurate magnets within mean-field theory. For a system consisting of quantum spins of magnitude S on each site, we write the trial free energy as

$$F \equiv U - TS = \mathrm{Tr}[\boldsymbol{\rho}\mathcal{H} + kT\boldsymbol{\rho}\ln\boldsymbol{\rho}] \tag{3}$$

where $\mathcal{H}$ is the Hamiltonian, T the temperature, U the internal energy, S the entropy, and the actual free energy is the minimum of F with respect to the choice of $\boldsymbol{\rho}$ subject to the conditions that $\boldsymbol{\rho}$ is Hermitian with unit trace. Within mean-field theory we take the density matrix to be the product of independent single particle density matrices $\boldsymbol{\rho}(i)$ for each site i:

$$\boldsymbol{\rho} \equiv \prod_i \boldsymbol{\rho}(i) \tag{4}$$

This approximation corresponds to the intuitive idea that when correlations between spins are neglected, each spin reacts to the mean field of its neighbors.

In equation (3), the trace of $\boldsymbol{\rho}\mathcal{H}$ gives the internal energy U and that of $-k\boldsymbol{\rho}\ln\boldsymbol{\rho}$ gives the entropy S. In the absence of anisotropy it suffices to set

$$\boldsymbol{\rho}(i) = \frac{1}{2S+1}[\mathcal{I} + c\boldsymbol{\sigma}(i)\cdot\mathbf{S}_i] \tag{5}$$

where $\mathcal{I}$ is the unit matrix of dimension $(2S+1)$, c is a constant of order unity, chosen to make equation (6) true, and $\mathbf{S}_i$ is the vector spin operator for site i (here $\mathbf{S}_i$ is a $(2S+1)$ dimensional matrix). The free energy is then minimized with respect to the trial parameters $\boldsymbol{\sigma}(i)$, which physically are identified as the average spin vectors:

$$\langle\mathbf{S}(i)\rangle \equiv \mathrm{Tr}[\boldsymbol{\rho}(i)\mathbf{S}(i)] = \boldsymbol{\sigma}(i) \tag{6}$$

Thus, $\boldsymbol{\sigma}(i)$ is the vector *order parameter* at the ith lattice site. In this formulation the internal energy is quadratic in the order parameter $\boldsymbol{\sigma}$, whereas the entropic term involves both quadratic and higher powers of the order parameter. As we shall see, even without explicit calculations much information can be inferred from the symmetry of the trial free energy as a function of the order parameter(s).

As mentioned in the introduction, we will focus our attention on systems which display incommensurately modulated magnetic long-range order. We refer the reader to a comprehensive survey of such systems by Nagamiya (1967). Here we give a simplified review. To characterize an incommensurate state we consider a toy model consisting of a one-dimensional system with interparticle separation a and having isotropic AFM exchange interactions J_1 and J_2 between nearest and next-nearest neighbors, respectively. If J_2 is AFM and large enough, these two interactions compete and produce an incommensurate spin structure. Thus we are led to consider the Hamiltonian

$$\mathcal{H} = \sum_n \mathbf{S}_n \cdot [J_1\mathbf{S}_{n+1} + J_2\mathbf{S}_{n+2}] \tag{7}$$

with $J_2 > 0$. The corresponding trial free energy is

$$F = \frac{1}{2}dkT\sum_i \boldsymbol{\sigma}(i)^2 + \sum_{n=1,2} J_n\boldsymbol{\sigma}(i)\cdot\boldsymbol{\sigma}(i+n) + \mathcal{O}(\boldsymbol{\sigma}^4) \tag{8}$$

where the entropic term is scaled by a constant of order unity, d.

4.2 Wave vector selection

It is instructive to write the free energy per spin, f, in terms of Fourier variables, $\boldsymbol{\sigma}(q) = (1/N)\sum_i e^{iqx_i}\boldsymbol{\sigma}(i)$, where N is the total number of spins as

$$f \equiv \frac{F}{N} = \frac{1}{2}\sum_q \chi(q)^{-1}\boldsymbol{\sigma}(q)\cdot\boldsymbol{\sigma}(-q) + \mathcal{O}(\boldsymbol{\sigma}^4) \tag{9}$$

where $\chi(q)^{-1} = dkT + J_1\cos(qa) + J_2\cos(2qa)$ is the wave vector-dependent susceptibility. At high temperature (when $kT \gg |J_1|$ and $kT \gg |J_2|$), $\chi(q)^{-1}$ is positive for all q and the free energy is minimized by setting all the order

parameters $\boldsymbol{\sigma}(q)$ to zero. In Figure 4, we show $\chi(q)^{-1}$ as a function of wave vector q for a sequence of temperatures. As the temperature is lowered through a critical value T_c, $\chi(q)^{-1}$ becomes zero for the wave vector $q \equiv q_0$ which minimizes $\chi(q)^{-1}$:

$$\cos(q_0 a) = \frac{-J_1}{(4J_2)} \tag{10}$$

This determination of the value of q_0 is called *wave vector selection*. As the temperature is reduced through T_c the paramagnetic phase becomes unstable against the formation of long-range order at the selected wave vector q_0. If q_0 is commensurate, that is, if $q_0/(2\pi)$ is rational, then the magnetic unit cell has length $2\pi/q_0$. Otherwise the periodicity of the magnetic structure is incommensurate with the periodicity of the lattice. However, it is essentially impossible to distinguish whether a system is truly incommensurate or merely has a very large magnetic unit cell. Since the properties of systems depend very weakly on whether the magnetic unit cell is infinite, the question whether the magnetic structure is truly incommensurate is an academic one.

For $T < T_c$ the order parameter $\boldsymbol{\sigma}(q_0)$ assumes a nonzero value determined by the (negative) quadratic terms in the free energy in combination with the (positive) terms of order $\boldsymbol{\sigma}^4$, so that

$$f \sim \frac{1}{2} r\sigma(q_0)^2 + u\sigma(q_0)^4 \tag{11}$$

Within mean-field theory $r \sim a(T - T_c)$, in which case $|\boldsymbol{\sigma}(q_0)| \sim (T_c - T)^{1/2}$. Once order develops at one wave vector, other terms of order $\boldsymbol{\sigma}^4$ prevent order developing at other wave vectors. This scenario is realistic for a three-dimensional system (for which long-range order is not destroyed by thermal fluctuations). The eigenvector associated with the eigenvalue of the quadratic form which passes through zero is called the *critical eigenvector*. The critical eigenvector contains the form factor of the ordering, that is, it completely describes the pattern of spin ordering within a unit cell. In this simple model there is only one spin per unit cell, so the eigenvector specifies the spin direction, that is, the component of spin which condenses. (This concept will be better illustrated when we consider real systems that often have more than one magnetic site per unit cell.) In the present case when there is no anisotropy, the spin structure when $\boldsymbol{\sigma}(q)$ becomes nonzero for $q = q_0$ is a modulated one in which the x component of spin has a complex amplitude, A_x, so that

$$\sigma_x(i) = A_x e^{iq_0 x_i} + A_x^* e^{-iq_0 x_i} \tag{12}$$

and similarly for the other spin components. If these complex amplitudes A_x, A_y, and A_z all have the same phase (We say that two complex-valued quantities, z_1 and z_2, have the *same phase* if z_1/z_2 is *real*, but is not necessarily *positive real*.), then the spin is linearly polarized with respect to an axis determined by the ratios of A_x, A_y and A_z and with an amplitude that varies sinusoidally with position. If the complex amplitudes do not have the same phase, then the spin structure will be a helix, a spiral, or a fan, and so on.

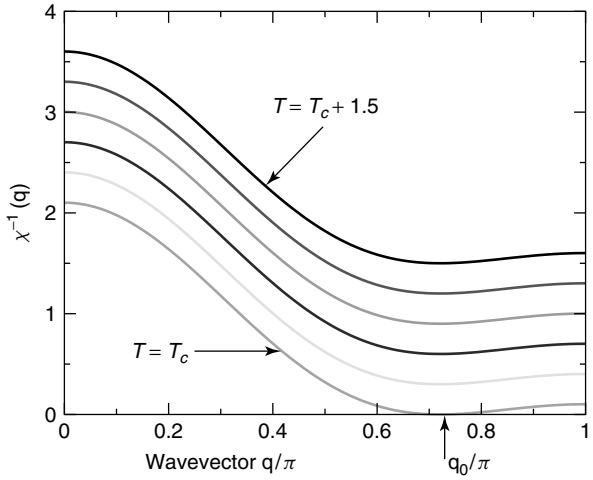

Figure 4. $\chi(q)^{-1}$ at a sequence of temperatures, $T = T_c + 0.3n$ for $n = 0, 1, 2, 3, 4, 5$ with $J_1 = 1.0$ and $J_1/J_2 = 2.56$ (as is appropriate for NVO). Here $T_c = 0.711$.

4.3 Effects of anisotropy

This toy model will not accurately capture the behavior of real magnetic systems because we have not yet included any magnetic anisotropy. As can be seen from Figure 5, the sequence of phases which appear as the temperature is reduced for zero anisotropy ($K = 0$) is not characteristic of the case when K is nonzero, even if K is small. So $K \neq 0$ is the generic scenario. In the presence of single-ion easy-axis anisotropy, the trial free energy at quadratic order assumes the form

$$f = \frac{1}{2}\sum_q \chi(q)^{-1}\boldsymbol{\sigma}(q)\cdot\boldsymbol{\sigma}(-q) - K\sum_q \boldsymbol{\sigma}_x(q)\boldsymbol{\sigma}_x(-q) + \mathcal{O}(\boldsymbol{\sigma}^4) \tag{13}$$

where K is an anisotropy energy that favors alignment of spins along the easy axis, here the x axis, and f denotes the free energy per spin. In this case, the instability (at which long-range order first appears) is one in which the spins are confined to the easy axis and have a sinusoidally varying amplitude. This type of ordered phase will be referred to as

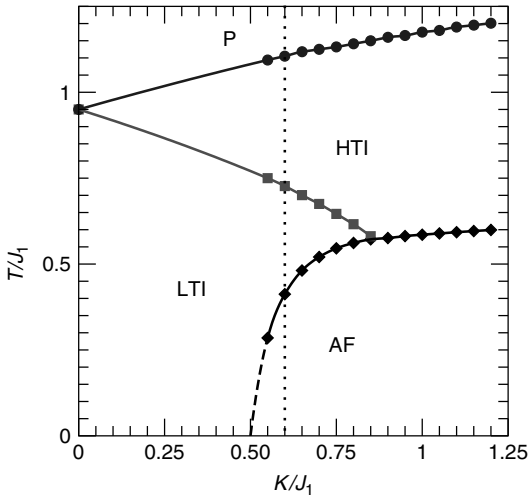

Figure 5. Zero-temperature phase diagram for the $J_1 - J_2$ ($S = 1$) model with easy-axis anisotropy scaled by K (Kenzelmann *et al.*, 2006). The points represent numerical implementation of mean-field theory except for $K = 0$ where analytic results are used. Here, 'HTI' denotes a longitudinally polarized incommensurate phase and 'LTI' an elliptically polarized incommensurate phase. In both phases, the modulation vector is given by equation (10). 'AF' denotes a two-sublattice collinear antiferromagnetic phase. For large anisotropy this model reduces to the anisotropic nearest–next-nearest neighbor Ising (ANNNI) model (Fisher and Selke, 1980a,b). The dashed line is drawn for a value of the anisotropy energy that reproduces the evolution of magnetic phases in NVO as a function of T for $H = 0$. (Reprinted with permission G. Lawes *et al.*, copyright 2006, American Physical Society.)

the high-temperature incommensurate (HTI) phase and the associated critical temperature will be denoted T_{HTI}. If the anisotropy is not too large, then, as the temperature is further reduced, the fourth-order terms in the free energy (which we have so far neglected) become important. One effect of these terms can be visualized as incorporating the constraint of 'fixed length'. In the HTI phase, the spins have a length that varies sinusoidally with position. However, in the ground state, we expect each spin to have its maximum length S but to be oriented in a direction to optimize the energy. Thus, in the extreme limit of zero temperature, the constraint of fixed spin length is fully enforced. Although the constraint is less fully realized at higher temperature, the qualitative effect is clear: when the temperature is sufficiently reduced, one has a continuous phase transition into a phase we refer to as the low-temperature incommensurate (LTI) phase. In this phase, the spins develop transverse order (in addition to the preexisting longitudinal order along the easy axis) to more nearly achieve fixed spin length. If the easy-axis anisotropy is small, the range of temperature over which the HTI phase is stable is also small. The phase diagram of such a model as a function of anisotropy energy K and temperature is shown in Figure 5 (Lawes *et al.*, 2004; Kenzelmann *et al.*, 2006).

We will mainly be concerned with the two incommensurate phases, the longitudinally modulated HTI phase and the elliptically polarized low-temperature incommensurate LTI phase. Although the details of the unit cell complicate the picture, the phenomenology of the HTI and LTI phases are usually roughly similar to that of the simplified case discussed here. In Figure 6, we show the experimentally determined phase diagrams of NVO and TMO as a function of applied magnetic field H and temperature T, with the HTI and LTI phases labeled.

4.4 Wave vector locking

From equation (10), it would seem that the wave vector q is a continuous and smooth function of J_2/J_1. Although our toy model does not give any simple explanation for the observed temperature dependence of q, a more complete analysis (as in Harris *et al.*, 2006 and Kajimoto *et al.*, 2004) leads to a small dependence on temperature which, like the dependence on J_2/J_1, might be thought to be smooth and continuous. However, there are terms which favor commensurate values of q. These terms in the free energy must conserve wave vector, but only to within a reciprocal lattice vector G (which for our one-dimensional toy model can assume the values $G_m = (2m\pi/a)$, where a is the nearest-neighbor separation). Thus one has the so-called Umklapp terms such as $\delta f = w\sigma(q)^4$, when $4q = \mathbf{G}_m$. More generally the Umklapp terms give a contribution to the free energy of the form

$$\delta f = \sum_{m,n} w_{m,n}\sigma(q)^{2n}\delta_{nq-2m\pi/a} \tag{14}$$

where the coefficient w_m is of order unity and δ_x is unity if $x = 0$ and is zero otherwise. (Within the present formulation these terms come from expanding $\mathrm{Tr}\boldsymbol{\rho}\ln\boldsymbol{\rho}$ to higher than quadratic order in the order parameter.) The effect of these Umklapp terms is to cause the wave vector to 'lock' onto a commensurate value $q = 2(m/n)\pi/a$ as J_2/J_1 is varied. Since $\sigma(q)$ is smaller than one, especially near the ordering transition, these terms become much less important as the integer denominator n increases. Thus the effect of the Umklapp terms is that the variation of q as a function of a control parameter (such as the temperature) becomes a so-called devil's staircase, which may either be complete or (if σ is small enough) incomplete, as shown in Figure 7. In the systems we will discuss here, there is no clear evidence of a devil's staircase as a function of temperature. Accordingly, we find it convenient to imagine that q is incommensurate, and does not get stuck on commensurate values by Umklapp terms. Even if this is not strictly true, the difference in properties between an incommensurate system and a commensurate system with a large integer denominator

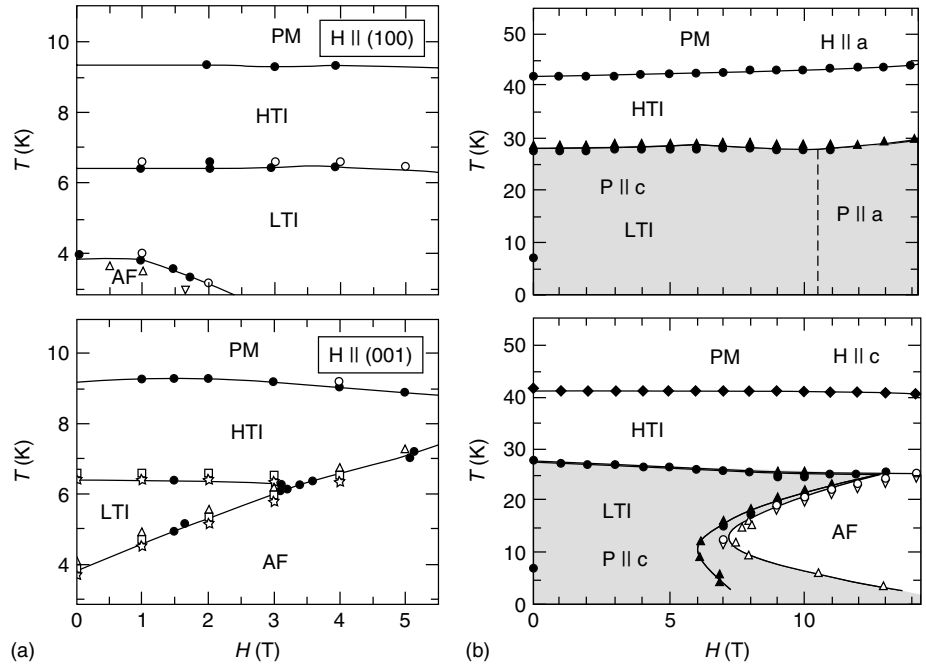

Figure 6. Phase diagram for NVO (a) and TMO (b) as a function of H and T. The HTI and LTI phases will be discussed in more detail, but correspond roughly to the scenario of our toy model. The interpretation of the H dependence of the phase boundaries for NVO is given in Kenzelmann *et al*. (2006). For NVO, AF indicates a commensurate antiferromagnetic phase with a weak ferromagnetic moment. (The NVO phase diagram is adapted from Lawes *et al*., 2004 and the TMO phase diagram is adapted from Kimura *et al*., 2005.) (Reprinted with permission T. Kimura *et al*., copyright 2005, American Physical Society.)

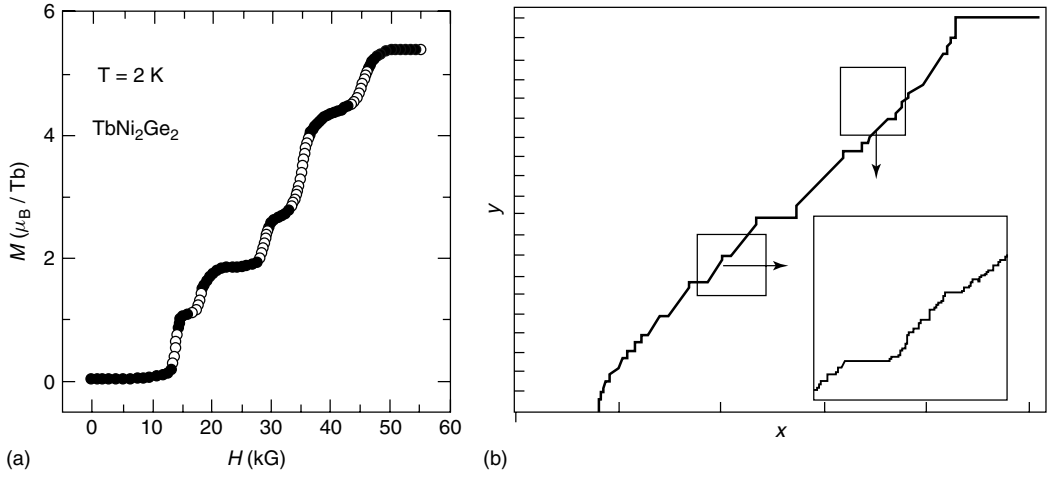

Figure 7. The devil's staircase (DS). (a) An *incomplete* DS for the dependence of the magnetization of $TbNi_2Ge_2$ as a function of magnetic field (Bud'ko *et al*., 1999). (b) Schematic example of a *complete* DS function $Y = f(X)$. In a complete DS, the function is nonconstant on a set of measure zero. For an incomplete DS, the function is nonconstant on a set of nonzero measure. (Reprinted with permission S.L. Bud'ko *et al*., copyright 1999, Elsevier.)

n is experimentally irrelevant for the large values of n ($n \sim 50$), for the systems we will discuss. Accordingly, we will refer to the systems as 'incommensurate' even though this may not be strictly accurate.

In principle, the symmetry of real systems is usually such that anisotropy also occurs in the exchange interaction, in which case the trial free energy assumes the form

$$f = \frac{1}{2}\sum_{q}\sum_{\alpha=x,y,z}\chi(q)_{\alpha}^{-1}\boldsymbol{\sigma}_{\alpha}(q)\cdot\boldsymbol{\sigma}_{\alpha}(-q) + \mathcal{O}(\boldsymbol{\sigma}^4) \tag{15}$$

where $\chi(q)_{\alpha}^{-1} = dkT + J_{1\alpha}\cos(qa) + J_{2\alpha}\cos(2qa)$. If $J_{n\alpha}$ is isotropic (i.e., if it does not depend on α), then the wave vector selected for the ordering of the α component

of spin also will not depend on α. However, in principle $J_{n\alpha}$ depends weakly on α, and therefore the selected wave vector q_0 will also depend weakly on α and the ordering will involve $\sigma_x(q_x)$, $\sigma_y(q_y)$, and $\sigma_z(q_z)$, where q_x, q_y, and q_z differ slightly from one another. Thus in the LTI phase it is possible that the two components of spin might have slightly different wave vectors, which we denote $q_{\rm HTI}$ and $q_{\rm LTI}$. But as with the Umklapp contributions, there will be quartic terms in the free energy (in this formulation coming from the entropic terms) which favor locking the two wave vectors to be equal. These terms can be of the form

$$f_{\rm lock} = a[\boldsymbol{\sigma}_{\rm HTI}(q_{\rm HTI})^2\boldsymbol{\sigma}_{\rm LTI}(-q_{\rm LTI})^2 + \boldsymbol{\sigma}_{\rm HTI}(-q_{\rm HTI})^2\boldsymbol{\sigma}_{\rm LTI}(q_{\rm LTI})^2]\delta_{q_{\rm HTI},q_{\rm LTI}} \quad (16)$$

where $\sigma_{\rm HTI}e^{i\phi_{\rm HTI}} \equiv \boldsymbol{\sigma}_{\rm HTI}(q_{\rm HTI})$ ($\sigma_{\rm LTI}e^{i\phi_{\rm LTI}} \equiv \boldsymbol{\sigma}_{\rm LTI}(q_{\rm LTI})$) is an order parameter characterizing the appearance of the HTI (LTI) phase, and for simplicity we have assumed that the constant a is real valued. This interaction only satisfies wave vector conservation if the two wave vectors are exactly equal. If, in the absence of this term, the two wave vectors are sufficiently close to one another, then this locking energy will cause the wave vectors of the two order parameters to be locked into equality with one another. (In this case, minimization of δf will also fix the relative phase $\phi_{\rm HTI} - \phi_{\rm LTI}$.) Since exchange anisotropy is usually not large, the wave vectors associated with different spin components are normally almost equal to one another. In that case, $f_{\rm lock}$ will be large enough to lock the HTI and LTI wave vectors to a common value. This 'locked' scenario is quite common and we assume it to be the case here. Indeed for the systems discussed below, the data suggests that the HTI and LTI order parameters involve a single wave vector.

5 MAGNETIC SYMMETRY

5.1 Nontrivial unit cell

There is one final refinement of our toy model which we must consider, that is the structure of the crystallographic unit cell. In the toy model considered above, the entire spin structure is characterized by a wave vector and a single complex vector amplitude. Note that the wave vector determines only how the spin wave function evolves from one unit cell to the next. However, to date, almost all magnetically incommensurate systems which have been identified as multiferroics have two or more magnetic ions per crystallographic unit cell. To describe such more general structures, one must introduce a spin wave function for the unit cell. Accordingly, we now discuss how this spin wave function for the unit cell is restricted by the symmetry of the crystal lattice. As a preliminary, we start by discussing the crystal structure of the two systems, NVO and TMO. In Table 1, we list the general equivalent positions which define the space group operations. For NVO we choose the generators of the space group to be the identity, E, a twofold rotation about the x axis, $(x, y, z) \rightarrow (x, \overline{y}, \overline{z})$, the $x - y$ glide plane, $(x, y, z) \rightarrow (x, y + \frac{1}{2}, \overline{z} + \frac{1}{2})$, spatial inversion, $(x, y, z) \rightarrow (\overline{x}, \overline{y}, \overline{z})$, and translations. For TMO, the generators are taken to be E, a mirror z plane, $(x, y, z) \rightarrow (x, y, \frac{1}{2} - z)$, the $y - z$ glide plane, $(x, y, z) \rightarrow (\frac{1}{2} - x, y + \frac{1}{2}, z)$, spatial inversion, and translations. The magnetic sites are at the positions listed in Table 2 and shown in Figure 8.

5.2 Representation theory

If there are $n_{\rm u}$ spins in a unit cell, then an incommensurate state will be described by a wave vector $\mathbf{q}$ and the complex-valued Fourier amplitudes $\mathcal{S}_{\alpha,\tau}(\mathbf{q})$, where $\alpha = x, y, z$ and $\tau = 1, 2, \ldots n_{\rm u}$, in terms of which we write the spin wave functions in the form

$$S_{\alpha,\tau}(\mathbf{R}) = \mathcal{S}_{\alpha\tau}(\mathbf{q})e^{i\mathbf{q}\cdot(\mathbf{R}+\mathbf{r}_\tau)} + \mathcal{S}_{\alpha\tau}(\mathbf{q})^*\ e^{-i\mathbf{q}\cdot(\mathbf{R}+\mathbf{r}_\tau)} \quad (17)$$

where $\mathbf{r}_\tau$ is the position of the τth site within the unit cell. For NVO $\tau = 1, s; 2, s; 3, s;$ or $4, s$ for spine (s) sites and $1, c$, or $2, c$ for cross-tie (c) sites. Thus, apart from the wave vector $\mathbf{q}$, the determination of the spin structure requires fixing the $6n_{\rm u}$ real-valued parameters that are needed to specify the $3n_{\rm u}$ complex-valued parameters $\mathcal{S}_{\alpha\tau}(\mathbf{q})$. Note that the complex amplitudes $\mathcal{S}(q)$ are defined relative to the phase, $\mathbf{q}\cdot(\mathbf{R} + \mathbf{r}_\tau)$ which would obtain if the wave were perfectly sinusoidal. (For NVO and TMO this convention will simplify later results.) One should think of the spin wave function as consisting of a superposition of sinusoidal spin distributions for each of the three Cartesian components of spin on each of the $n_{\rm u}$ sublattices. Each distribution is characterized by an amplitude and phase as encoded in the complex amplitude $\mathcal{S}_{\alpha\tau}(\mathbf{q})$.

We now discuss how symmetry restricts the possible values of the amplitudes $\mathcal{S}_{\alpha,\tau}(q)$ and how these variables are determined via diffraction experiments. The analysis of the symmetry of such systems in terms of their point groups is not developed. Accordingly, a model-independent (representation) analysis (Bertaut, 1971; Rossat-Mignod, 1987) is customarily invoked in such cases when it is assumed (as is generally the case) that the magnetic ordering transition is a continuous one. As we shall see in examples discussed later, it is essential to correctly characterize the symmetry properties of the magnetic ordering in order to understand how this ordering induces ferroelectricity. However, perhaps surprisingly, a crucial point in connection with representation

Table 1. General positions of the space groups for NVO (top), Cmca (#64 in Hahn, 1983) and for TMO (bottom), Pbnm (#62 in Hahn, 1983). For Cmca, the primitive translation vectors are $\mathbf{a}_1 = (a/2)\hat{i} + (b/2)\hat{j}$; $\mathbf{a}_2 = (a/2)\hat{i} - (b/2)\hat{j}$; and $\mathbf{a}_3 = c\hat{k}$. For Pbnm they are $\mathbf{a}_1 = a\hat{i}$; $\mathbf{a}_2 = b\hat{j}$, and $\mathbf{a}_3 = c\hat{k}$.

$\mathbf{r} = (x, y, z)$	$2_z\mathbf{r} = (\overline{x}, \overline{y} + \frac{1}{2}, z + \frac{1}{2})$	$2_y\mathbf{r} = (\overline{x}, y + \frac{1}{2}, \overline{z} + \frac{1}{2})$	$2_x\mathbf{r} = (x, \overline{y}, \overline{z})$
$\mathcal{I}\mathbf{r} = (\overline{x}, \overline{y}, \overline{z})$	$m_{xy}\mathbf{r} = (x, y + \frac{1}{2}, \overline{z} + \frac{1}{2})$	$m_{xz}\mathbf{r} = (x, \overline{y} + \frac{1}{2}, z + \frac{1}{2})$	$m_{yz}\mathbf{r} = (\overline{x}, y, z)$

$\mathbf{r} = (x, y, z)$	$m_{xy}\mathbf{r} = (x, y, \frac{1}{2} - z)$	$2_x\mathbf{r} = (x + \frac{1}{2}, \overline{y} + \frac{1}{2}, \overline{z})$	$m_{xz}\mathbf{r} = (x + \frac{1}{2}, \overline{y} + \frac{1}{2}, \frac{1}{2} + z)$
$\mathcal{I}\mathbf{r} = (\overline{x}, \overline{y}, \overline{z})$	$2_z\mathbf{r} = (\overline{x}, \overline{y}, \frac{1}{2} + z)$	$m_{yz}\mathbf{r} = (\frac{1}{2} - x, y + \frac{1}{2}, z)$	$2_y\mathbf{r} = (\frac{1}{2} - x, y + \frac{1}{2}, \frac{1}{2} - z)$

Table 2. Left: Unit cell lattice positions in NVO of the Ni^{2+} ions carrying $S = 1$ (given as fractions of the cell dimensions a, b, and c). The 'spine' sites are r_n^s and the cross-tie sites are r_n^c. Right: Positions of the Mn and Tb ion sites in the unit cell of TMO as fractions of the cell sides a, b, and c.

r_1^s	(0.25, −0.13, 0.25)
r_2^s	(0.25, 0.13, 0.75)
r_3^s	(0.75, 0.13, 0.75)
r_4^s	(0.75, −0.13, 0.25)
r_1^c	(0, 0, 0)
r_2^c	(0.5, 0, 0.5)

	$n = 1$	$n = 2$	$n = 3$	$n = 4$
Mn	$(0, \frac{1}{2}, 0)$	$(\frac{1}{2}, 0, 0)$	$(0, \frac{1}{2}, \frac{1}{2})$	$(\frac{1}{2}, 0, \frac{1}{2})$
Tb[a]	$(x, y, \frac{1}{4})$	$(x + \frac{1}{2}, \overline{y} + \frac{1}{2}, \frac{3}{4})$	$(\overline{x}, \overline{y}, \frac{3}{4})$	$(\overline{x} + \frac{1}{2}, y + \frac{1}{2}, \frac{1}{4})$

[a] $x = 0.9836$ and $y = 0.0810$ from Blasco *et al*. (2000).

theory that seems to have been universally overlooked until recently (Lawes *et al*., 2005; Kenzelmann *et al*., 2005, 2006) is that for systems such as the family of multiferroics we consider here inversion symmetry places additional constraints on the allowed magnetic structures that can appear at the ordering transition.

To explain this recent development, we first give a much simplified review of representation theory. *If the magnetic ordering transition is assumed to be continuous*, then the phase transition is signaled by an instability in the susceptibility that occurs as the temperature is lowered into the magnetically ordered phase. Alternatively, one may see this instability in the quadratic terms when the free energy is expanded in powers of the order parameters. As we have already noted, we may confine our attention to the order parameters associated with the selected wave vector **q** which first becomes unstable as the temperature is lowered. In order to conserve wave vector the quadratic terms in the Landau

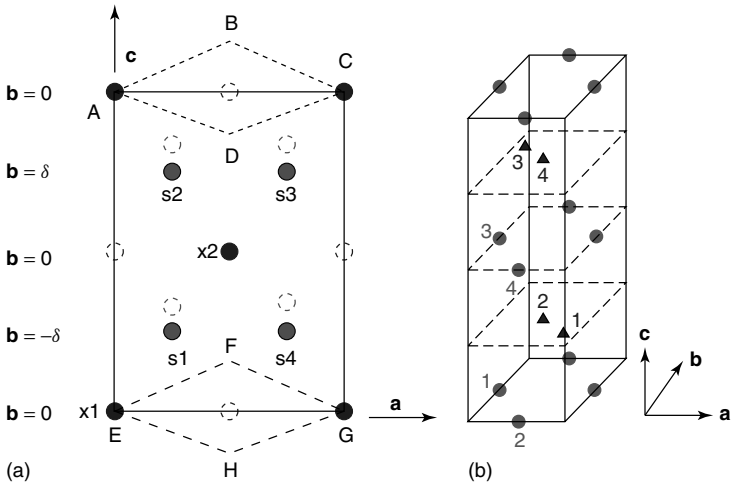

Figure 8. (a) The unit cell (ABCDEFGH) showing only Ni ions numbered as in Table 2. The **b** axis is perpendicular to the plane of the paper. Dashed circles represent spins in adjacent planes displaced from the solid symbols by $\pm\mathbf{b}/2$. (b) The unit cell of $TbMnO_3$ showing only the Mn ions (filled circles) and the Tb ions (filled triangles), numbered as in Table 2.

expansion associated with the selected wave vector **q** must be of the form

$$f_2 = \sum_{\alpha,\beta,\tau,\tau'} c_{\alpha,\tau;\beta,\tau'}(\mathbf{q})\mathcal{S}_{\alpha,\tau}(-\mathbf{q})\mathcal{S}_{\beta,\tau'}(\mathbf{q}) \qquad (18)$$

where $\mathcal{S}_{\alpha,\tau}(-\mathbf{q}) = \mathcal{S}_{\alpha,\tau}(\mathbf{q})^*$. For f_2 to be real for any choice of the complex-valued Fourier amplitudes, it is required that $c_{\alpha,\tau;\beta,\tau'}(\mathbf{q})^* = c_{\beta,\tau';\alpha,\tau}(\mathbf{q})$. Within a simple theory, such as mean-field theory, the coefficient $c_{\alpha,\tau;\beta,\tau'}$ in equation (18) is such that

$$f_2 = \sum_{\alpha,\beta,\tau,\tau'} \left[dkT\delta_{\alpha,\beta}\delta_{\tau,\tau'} - \tilde{c}_{\alpha,\tau;\beta,\tau'}(\mathbf{q})\right]\mathcal{S}_{\alpha,\tau}(-\mathbf{q})\mathcal{S}_{\beta,\tau'}(\mathbf{q}) \qquad (19)$$

where d is a constant of order unity of entropic origin, $\delta_{\alpha,\beta}$ is unity if $\alpha = \beta$ and is zero otherwise, and the $\tilde{c}_{\alpha,\tau;\beta,\tau'}(\mathbf{q})$ are temperature-independent coefficients determined by the spin–spin interactions of the system. When kT is much larger than the characteristic interaction energy, all the eigenvalues of f_2 are positive and the paramagentic phase is stable. As the temperature is lowered, one eigenvalue will become nonpositive although we do not rely on the specific form of equation (19). The stability of the resulting ordered phase is then ensured by the quartic terms of order uS^4, which were not included in equation (18).

Note that the pattern of spin ordering within the unit cell is determined by the eigenvector associated with the first eigenvalue of the quadratic free energy, which passes through zero as the temperature is lowered. (We call this eigenvalue the 'critical eigenvalue' and the associated eigenvector the 'critical eigenvector'.) This phenomenon was discussed briefly earlier in connection with wave vector selection. As we shall see, this analysis of the symmetry of the critical eigenvector is essential when one constructs the allowed couplings between magnetic and ferroelectric order parameters. (A similar, but more complicated analysis, has been developed to describe second-harmonic generation by Sa, Valenti and Gros, 2000.)

As in the case of phonons or other normal modes, the eigenvectors of this quadratic form can be labeled according to the irreducible representations (irreps) Γ_n of the paramagnetic phase, which leave invariant the selected wave vector for ordering. (This group of symmetry operations is called the *group of the wave vector* or the *little group*.) The relevant symmetry is that of the paramagnetic phase because the expansion of the free energy in powers of the order parameters is relative to this phase (Dzyaloshinskii, 1957; Landau and Lifshitz, 1958). For the orthorhombic systems, NVO and TMO, considered in this review, all the irreps are one dimensional. In such cases, the eigenvectors of f_2 must also be eigenvectors of the rotation or mirror (or glide) operations of the little group with eigenvalues of unit magnitude. (To illustrate the principles involved in the complete symmetry analysis of magnetic structures, we focus on the simplest scenario, namely when the irreps are one dimensional and each wave vector is an eigenvector of all the symmetry operations of the group of the wave vector. To use the point of view expressed here for a two-dimensional irrep, see Harris, 2006b.) We now enumerate the symmetry operations for NVO and TMO, which leave the wave vector invariant. For NVO the ordering wave vector lies along the crystal **a** axis, and the symmetry operations of the little group are 2_x, a twofold rotation about the x axis (we often refer to **a**, **b**, and **c** as x, y, and z, respectively) and m_{xy}, a glide operation which takes z into $-z$ followed by a translation of $(\mathbf{b}+\mathbf{c})/2$. For TMO the ordering wave vector lies along the crystal **b** axis and the symmetry operations are a twofold screw rotation about the y axis, 2_y and the mirror plane m_{xy}. These operations are defined in Table 1. Technically speaking, the eigenvalues of these symmetry operations (which characterize the symmetry of the irrep) are known as *characters* and their values for each irrep Γ_p and for each symmetry operation $\mathcal{O}$ are given in the so-called 'character table', which we give for NVO and TMO in Table 3. We see that (apart from a phase factor for TMO) we have four irreps, that is, four symmetries, depending on whether the spin wave function is chosen independently to be even or odd under the two mirror operations.

The result of the group theoretical analysis is that one expresses the Fourier amplitudes $\mathcal{S}_{\alpha\tau}(\mathbf{q})$ in terms of *symmetry adapted coordinates* $m_r^{(n)}$ associated with the irrep Γ_n. Thus if the spin distribution is that of irrep Γ_n, we write

$$S_{\alpha,\tau}^{\Gamma_n}(\mathbf{q}) = \sum_r m_r^{(n)} U_{\alpha,\tau}^{n,r} \qquad (20)$$

where the symmetry adapted basis functions $U_{\alpha,\tau}^{n,r}$ give the α component of spin on the τth sublattice for the rth basis function associated with irrep Γ_n. Although the symmetry adapted coordinates and basis functions are allowed to be complex, the spin vectors given by equation (17) are, of course, real valued.

To make the analysis more intuitive, we may liken it to the problem of determining allowed wave functions for a particle in a spherically symmetric potential. For illustrative purposes we consider a Coulomb potential with a weak spherically symmetric perturbation (for example, a perturbation of the form ar^4). To solve this problem, one introduces symmetry adapted basis functions for the various irreps, which in this case are s functions $\psi_n^{(s)}$, p functions $\psi_n^{(p_x)}$, $\psi_n^{(p_y)}$, $\psi_n^{(p_z)}$, and so on, where n labels the principal quantum number. As is well known, as a consequence of spherical symmetry, the potential has nonzero matrix elements only between symmetry adapted basis functions having the same symmetry label,

Table 3. Character table for the symmetry operations $\mathcal{O}$ of the group[(a)] $G_{\mathbf{k}}$ for the irreps Γ_n for incommensurate magnetic structure of (left) NVO with $\mathbf{k} = (q, 0, 0)$ and (right) TMO for $\mathbf{k} = (0, q, 0)$.

$\mathcal{O}^{a} =$	1	2_x	m_{xy}	m_{xz}
Γ^1	1	1	1	1
Γ^2	1	1	−1	−1
Γ^3	1	−1	−1	1
Γ^4	1	−1	1	−1

$\mathcal{O}^{a,b} =$	E	$\tilde{2}_y$	m_{xy}	$\tilde{m}_{yz}$
Γ_1	1	1	1	1
Γ_2	1	1	−1	−1
Γ_3	1	−1	1	−1
Γ_4	1	−1	−1	1

[a]Operators (without tildes) are defined in Table 1.
[b]For an operator $\mathcal{O}$ we define $\tilde{\mathcal{O}} = e^{iqa/2}\mathcal{O}$.

q, where q denotes (s), (p_x), and so on. Thus eigenfunctions Ψ can be characterized by a symmetry (irrep) label q and, in analogy with equation (20), $\Psi^{(q)}$ can be expressed as a linear combination of symmetry adapted basis functions $\psi_m^{(q)}$, for $m = 1, 2 \ldots$ having a given symmetry label:

$$\Psi^{(q)} = \sum_m c_m \psi_m^{(q)} \tag{21}$$

The symmetry adapted basis functions $\psi_m^{(q)}$ are determined solely by the symmetry of the system. In contrast, the coefficients c_m (which we have called the symmetry adapted coordinates, $m_r^{(n)}$) depend on the specific details of the potential. Analogously, in our magnetic structure problem, the possible eigenvectors will be linear combinations of the symmetry adapted basis functions $U_{\alpha\tau}^{nr}$ with coefficients $m_r^{(n)}$. The U's can be constructed on the basis of symmetry considerations, whereas the m's depend on the specific details of the system. An intuitive picture of the nth symmetry adapted basis function associated with irrep Γ can obtained as follows. Consider the family of symmetry operations $\mathcal{O}_p$ of the little group (which conserves the wave vector). We arbitrarily assign an amplitude $U_{\alpha\tau}^{\Gamma,n}$ to one $S_{\alpha,\tau}(\mathbf{q})$. Then, the condition that the spin wave function is to have a given symmetry under the operations $\mathcal{O}_p$, will fix the amplitude of the other sublattices that are related to the initial one (α, τ) by the operations $\mathcal{O}_p$. For NVO, for instance, if we fix the x component of the spine site $s, 1$ to be $U_{x,\tau}^{p,1}(\mathbf{q})$ (assuming irrep Γ_p to be the active irrep), then in order to have a given symmetry, the amplitudes of all the other spine sites will be given by

$$S_{x,\tau'}(\mathbf{q}) = \pm U_{x,\tau'}^{p,1}(\mathbf{q}) \tag{22}$$

with the sign chosen according to the symmetry of the basis function being constructed. As a result, in constructing allowed eigenfunctions to describe the ordered phase we generally will find that spin functions for each family of crystallographically equivalent sites will be specified by a single parameter. Using the above procedure, one can construct the spin distribution in the form of equation (20) and the results for the spin distribution on the magnetic sublattices assuming a given irrep are given subsequently in the tables.

We now give a short explanation on how to read these tables. For NVO, the first column of Table 4 gives the spin distribution $\mathbf{S}_{\alpha,\tau}^{\Gamma_1}$ for the irrep Γ_1. To specify a spin distribution we have to specify the complex amplitudes for 3 Cartesian spin components of 6 magnetic sublattices, which requires a total of 18 complex parameters. Symmetry indicates that if irrep Γ_1 is assumed to be the active irrep, then the distribution is in fact completely specified by fixing the values of the four complex amplitudes (which we have called symmetry adapted coordinates, $m_r^{(n)}$) $m_{s_x}^{(1)}$, $m_{s_y}^{(1)}$, $m_{s_z}^{(1)}$, and $m_{c_x}^{(1)}$. (Notice that here the index r assumes the values s_x, s_y, s_z, and c_x.) In our language, the symmetry adapted basis functions are the functions which multiply the m's. Thus

$$U_{x,\tau=ns}^{1,r=s_x} = \frac{\partial S_{x,\tau=ns}^{\Gamma_1}}{\partial m_{s_x}^{(1)}} = (i, i, -i, -i) \tag{23}$$

where, on the right-hand side of the equation are given the values for the x components of spin on the sublattices $\tau = 1s, 2s, 3s, 4s$. In the same way, for the y and z components one has

$$U_{y,\tau=ns}^{1,r=s_y} = \frac{\partial S_{y,\tau=n_s}^{\Gamma_1}}{\partial m_{s_y}^{(1)}} = (1, -1, 1, -1) \tag{24}$$

$$U_{z,\tau=ns}^{1,r=s_z} = \frac{\partial S_{z,\tau=n_s}^{\Gamma_1}}{\partial m_{s_z}^{(1)}} = (i, -i, -i, i) \tag{25}$$

Similarly, irreps Γ_2, Γ_3, and Γ_4 require fixing respectively four, five, and five symmetry adapted coordinates. Clearly, the fitting procedure is to try each irrep in turn and see which irrep best fits the data. Often one irrep will be vastly superior to all the others. Normally, one does not include phase factors i into the complex amplitudes, as is done in Table 4 for $m_{s_x}^{(1)}$, for instance. This inclusion cannot affect the structure determination because the best fit will determine the same value of $im_{s_x}^{(1)}$ as it would have done for $m_{s_x}^{(1)}$ had

Table 4. Symmetry adapted basis functions $U^{nr}_{\alpha\tau}$ which transform according to the irreducible representation Γ_n for the incommensurate phase associated with $\mathbf{q} = (q, 0, 0)$ for the Ni spine (s) and cross-tie (c) sites of NVO in the notation of equation (20). So $U^{nr}_{\alpha\tau} = \partial \mathbf{S}^{\Gamma_n}_{\alpha\tau}/\partial m^{(n)}_r$ The symmetry adapted coordinates $m^{(n)}_r$, where $r = s_x, s_y, s_z, c_x, c_y, c_z$, assume complex values, as discussed in the text. The numbering of sites is given in Table 2. The phase factors of i are chosen to simplify the transformation properties under spatial inversion, as is discussed later.

3T	$(0, 0, m^{(1)}_{T_{1z}})$	$(m^{(2)}_{T_{1x}}, m^{(2)}_{T_{1y}}, 0)$	$(0, 0, m^{(3)}_{T_{1z}})$	$(m^{(4)}_{T_{1x}}, m^{(4)}_{T_{1y}}, 0)$
4T	$(0, 0, -m^{(1)}_{T_{2z}})$	$(-m^{(2)}_{T_{2x}}, m^{(2)}_{T_{2y}}, 0)$	$(0, 0, m^{(3)}_{T_{2z}})$	$(m^{(4)}_{T_{2x}}, -m^{(4)}_{T_{2y}}, 0)$

we not included the factor of i. Inclusion of the factor of i may appear to be an unwanted complexity. However, its inclusion will prove to be convenient later in equation (37). One can verify that the symmetry adapted basis functions given in equations (23–25) transform into themselves (with a + or − sign) under 2_x or m_{xy}, as indicated in the character table.

As for NVO, we can use Table 5 to write down the symmetry adapted basis functions for TMO. For instance,

$$U^{1,r=M_x}_{x,\tau=nM} = \frac{\partial S^{\Gamma_1}_{x,\tau=nM}}{\partial m^{(1)}_{M_x}} = (1, 1, -1, -1) \tag{26}$$

$$U^{1,r=M_y}_{y,\tau=nM} = \frac{\partial S^{\Gamma_1}_{y,\tau=nM}}{\partial m^{(1)}_{M_y}} = (1, -1, -1, 1) \tag{27}$$

$$U^{1,r=T_{2z}}_{z,\tau=nT} = \frac{\partial S^{\Gamma_1}_{z,\tau=nT}}{\partial m^{(1)}_{T_{2z}}} = (1, 0, 0, -1) \tag{28}$$

To further illustrate this, we write an explicit formula for the distribution of magnetization in NVO assuming Γ_4 to be the active irrep. Then using equations (17) and (20) we write the distribution of the x component of spin on the 1,s sublattice as

$$S_{x,1s}(\mathbf{r}) = m^{(4)}_{s_x} e^{i\mathbf{q}\cdot\mathbf{r}} + [m^{(4)}_{s_x}]^*\ e^{-i\mathbf{q}\cdot\mathbf{r}} \tag{29}$$

where $\mathbf{r} \equiv \mathbf{R} + \boldsymbol{\tau}_{1,s}$ is the actual position of the spin in the 1,s sublattice. The complex-valued symmetry adapted coordinate $m^{(4)}_{s_x}$ incorporates the amplitude and phase of the sinusoidal wave for the x component of spin on the spine sublattices. We give some (but not all) of the other results assuming Γ_4 to be the active irrep, namely,

$$S_{y,1s}(\mathbf{r}) = im^{(4)}_{s_y} e^{i\mathbf{q}\cdot\mathbf{r}} - i[m^{(4)}_{s_y}]^*\ e^{-i\mathbf{q}\cdot\mathbf{r}} \tag{30}$$

$$S_{z,1s}(\mathbf{r}) = m^{(4)}_{s_z} e^{i\mathbf{q}\cdot\mathbf{r}} + [m^{(4)}_{s_z}]^*\ e^{-i\mathbf{q}\cdot\mathbf{r}} \tag{31}$$

$$S_{x,2s}(\mathbf{r}) = -m^{(4)}_{s_x} e^{i\mathbf{q}\cdot\mathbf{r}} - [m^{(4)}_{s_x}]^*\ e^{-i\mathbf{q}\cdot\mathbf{r}} \tag{32}$$

$$S_{y,1c}(\mathbf{r}) = m_{c_y}^{(4)} e^{i\mathbf{q}\cdot\mathbf{r}} + [m_{c_y}^{(4)}]^* \; e^{-i\mathbf{q}\cdot\mathbf{r}} \tag{33}$$

and so forth. Thus, the incommensurate state is parameterized as consisting of sinusoidal waves having arbitrary amplitudes and phases for each spin component of each crystallographically inequivalent set of sites (i.e., spine sites or cross-ties, respectively). As we shall see in a moment, the recent new development (Lawes *et al*., 2005; Kenzelmann *et al*., 2005) for crystals whose paramagnetic phase is inversion symmetric is to invoke this symmetry to fix the relative phases or, in cases like TMO, the amplitudes of crystallographically inequivalent (with respect to the little group) Tb sites that are related to one another by spatial inversion.

In the above analysis, we assumed that ordering occurs via a single irrep. One might wonder if two irreps could accidentally have an instability at the same temperature. We reject the possibility of such an accidental degeneracy. However, if one adjusts an additional control parameter, such as the pressure, it is possible to reach a multicritical point where two irreps simultaneously become active. A simple example of this principle arises when one treats a ferromagnet on a tetragonal lattice. In that case, one irrep is one dimensional and corresponds to the FM order lying along the fourfold crystal (**c**) axis and the other irrep is two-dimensional and corresponds to ordering in the plane perpendicular to the **c** axis. Clearly, the mean-field transition temperatures for these two distinct orderings should be assumed to be different. If the anisotropy is easy axis, the FM moment will lie along the **c** axis and if the anisotropy is easy plane the moment will be perpendicular to the **c** axis. It is possible for the anisotropy to vanish, but only by adjusting another thermodynamic variable, such as uniaxial stress. One therefore concludes that criticality is associated with a *single* irrep. Since the transformation to symmetry adapted coordinates can be determined using only symmetry considerations, the possible patterns of spin ordering within the unit cell are strongly restricted.

When, for NVO or TMO, the temperature is lowered further and the LTI phase is entered (see Figure 6), then an additional irrep will become active via a second continuous phase transition. For NVO, the new LTI representation (in addition to Γ_4 already present in the HTI phase) is (Lawes *et al*., 2004) Γ_1 and for TMO the new LTI representation (in addition to Γ_3 already present in the HTI phase) is (Kenzelmann *et al*., 2005) Γ_2. In an appendix we discuss that when two different irreps are active, their presence does not induce the development of a third irrep. However, had there been a further phase transition from the LTI phase into yet another incommensurate phase with three irreps, then the presence of three different irreps would induce the presence of a fourth one.

As an illustration of how to apply the above results, we show, in Figure 9, typical spin configurations for NVO which result from the spin wave functions which transform according to irrep #4. The configuration shown in (a) is not allowed because, as we discuss below, it is not consistent with the inversion symmetry of the paramagnetic phase.

5.3 Effect of inversion symmetry for NVO

Until now we only used the consequences of the symmetry of the group of transformations that leave the wave vector invariant at a continuous magnetic ordering transition. According to the usual formalism (Bertaut, 1971; Rossat-Mignod, 1987), one can only exploit symmetries that conserve the wave vector. (If the wave vector were on a face of the Brillouin zone, it could be invariant under inversion). Recently (Lawes *et al*., 2005; Kenzelmann *et al*., 2005, 2006; Schweizer, Villain and Harris, 2007), it has been shown that in such systems spatial inversion plays a crucial role in reducing the number of parameters (symmetry adapted coordinates) needed to specify the magnetic structure. We now give a simplified description of how inversion symmetry restricts the allowed spin structures.

As we have observed previously, the quadratic free energy of equation (18) must be invariant under all the operations of the paramagnetic space group. In particular, the operations for the systems we consider here which are *not* in the little group of the wave vector are those generated by spatial inversion, $\mathcal{I}$. Usually when one introduces an additional symmetry, the matrix for the quadratic free energy becomes block diagonal. Here, the result of the additional symmetry is not to reduce the size of the submatrices for the quadratic free energy, but rather it places additional constraints on the symmetry adapted coordinates m which appear in Tables 4 and 5.

We first analyze the situation for NVO. We need to determine the effect of $\mathcal{I}$ on the spin wave functions listed in Table 4. Recall that the magnetic moment is a pseudovector. That means that under spatial inversion the orientation of the moment is unchanged, but it is simply transported from its initial location at $\mathbf{r}$ to the transformed location, $-\mathbf{r}$. Looking at equation (17) we see that spatial inversion interchanges $\mathcal{S}$ and $\mathcal{S}^*$, but since the orientation is unchanged, spatial inversion will not affect the spin component label α. However, spatial inversion does interchange Ni sublattices #1 and #3 and also #2 and #4. In other words, in the notation of Table 4, we have

$$\mathcal{I}\mathcal{S}_{x,s1} = \mathcal{S}^*_{x,s3}, \;\; \mathcal{I}\mathcal{S}_{x,s2} = \mathcal{S}^*_{x,s4} \tag{34}$$

and similarly for the y- and z-components. To see the consequences of these relations, consider the effect of the first of these two relations acting on the spin distribution for

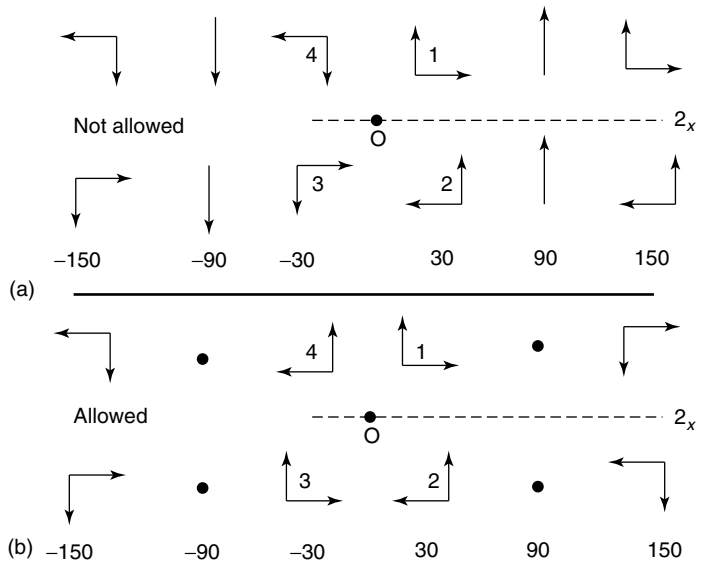

Figure 9. Two structures for spine spins in an **a**–**c** plane for NVO obtained using spin components from Table 4 which transform according to irrep Γ_4. For simplicity this figure is for the wave vector $k = 2\pi/(3a)$, where $a/2$ is the distance between sites. The axis for the twofold rotation 2_x is indicated. The glide plane, which relates spins in adjacent layers is not shown. The sites are numbered as in Table 2. At the bottom of each panel, we give (in degrees) the phase $\theta = \mathbf{q} \cdot \mathbf{r}$ of the propagation factor $\exp(i\mathbf{q} \cdot \mathbf{r})$ at each site. (a) For $m_{s_x}^{(4)} = 1$, $m_{s_z}^{(4)} = -i$ and the other parameters equal to zero. (b) For $m_{s_x}^{(4)} = m_{s_z}^{(4)} = 1$ and the other parameters equal to zero. As we shall see in equation (43), the order parameters $m_{s_x}^{(4)}$ and $m_{s_z}^{(4)}$ must have the same phase, that is, $m_{s_x}^{(4)}/m_{s_z}^{(4)}$ must be real. Only the configuration in (b) satisfies this constraint.

irrep Γ_1 given in the first column of Table 4, for instance. The first relation of equation (34) implies that

$$\mathcal{I}(im_{s_x}^{(1)}, m_{s_y}^{(1)}, im_{s_z}^{(1)}) = (-im_{s_x}^{(1)}, m_{s_y}^{(1)}, -im_{s_z}^{(1)})^* \tag{35}$$

which can be written as

$$\mathcal{I}(m_{s_x}^{(1)}, m_{s_y}^{(1)}, m_{s_z}^{(1)}) = (m_{s_x}^{(1)}, m_{s_y}^{(1)}, m_{s_z}^{(1)})^* \tag{36}$$

This same analysis can be repeated for the other representations and also for the second relation of equation (34). Then we see that the choices of the phase factors i in Table 4 leads to the simple result that for $\alpha = x$, y, or z, and independent of representation Γ_n

$$\mathcal{I}\mathbf{m}_{s_\alpha}^{(n)}(q) = \mathbf{m}_{s_\alpha}^{(n)}(q)^* \tag{37}$$

(Had we not included the phase factors i in Table 4, we would have had to keep track of which m's obey $\mathcal{I}m = m^*$ and which obey $\mathcal{I}m = -m^*$.) For the cross-tie sites, the situation is similar except that under spatial inversion each sublattice is transformed into itself. Thus, we find that

$$\mathcal{I}\mathbf{m}_{c_\alpha}^{(n)}(q) = \mathbf{m}_{c_\alpha}^{(n)}(q)^* \tag{38}$$

So, generally for NVO we have for *any representation* Γ_n

$$\mathcal{I}m_r^{(n)}(q) = m_r^{(n)}(q)^* \tag{39}$$

where $r = s_x, s_y, s_z, c_x, c_y, c_z$. (Note that this relation does not imply inversion symmetry. If the system has inversion symmetry about the origin, then $\mathcal{I}m_r^{(n)}(q) = m_r^{(n)}$, and magnetic order cannot induce ferroelectric order. Thus one cannot have ferroelectric order if all the m's are real.)

Now we invoke the invariance of the free energy with respect to spatial inversion (which, for NVO, is a symmetry of the paramagnetic lattice). For this purpose, we consider the form of the quadratic free energy written in equation (18). Since f_2 is quadratic in the $\mathcal{S}$'s, it can also be written as a quadratic form in the symmetry adapted coordinates m:

$$\begin{aligned} f_2 &= \sum_{jkn} F_{j,k}^{(n)} m_j^{(n)}(-\mathbf{q}) m_k^{(n)}(\mathbf{q}) \\ &= \sum_{jkn} F_{j,k}^{(n)} m_j^{(n)}(\mathbf{q})^*\, m_k^{(n)}(\mathbf{q}) \end{aligned} \tag{40}$$

where n refers to the irrep Γ_n. Note that there are no matrix elements connecting coefficients of different irreps. Also we used wave vector conservation which implies that $\mathbf{q}$ couples to $-\mathbf{q}$. For f_2 to be real no matter what the m's might be, one requires that the matrix $\mathbf{F}$ be Hermitian:

$$F_{j,k}^{(n)} = F_{k,j}^{(n)*} \tag{41}$$

Now we use equation (39) to see the consequence of f_2 being inversion invariant. We have that

$$\begin{aligned}\mathcal{I}f_2 &= \sum_n \sum_{jk} F_{j,k}^{(n)} \left[\mathcal{I}m_j^{(n)}(q)^* \right]\left[\mathcal{I}m_k^{(n)}(q)\right] \\ &= \sum_n \sum_{jk} F_{j,k}^{(n)} m_j^{(n)}(q) m_k^{(n)}(q)^* \\ &= f_2 = \sum_n \sum_{jk} F_{k,j}^{(n)} m_k^{(n)}(q)^* \, m_j^{(n)}(q) \end{aligned} \tag{42}$$

Thus we see that inversion invariance of $f_2^{(n)}$ implies that $F_{j,k}^{(n)} = F_{k,j}^{(n)}$. Combining this with equation (41) we see that all the coefficients of the quadratic form must be real valued. This means that all the components of the eigenvectors of the quadratic free energy, when written in terms of the variables of equation (40), can be taken to be real valued. However, this does not mean that these variables *must* be real. Rather, since these variables are allowed to be complex, we may initially take them to be real valued, but more generally one may then introduce an overall complex phase factor. So, the critical eigenvector of irrep Γ_n (which, when normalized, has components $x_j^{(n)}$), has an arbitrary overall phase, in which case the symmetry adapted coordinates in the HTI phase are given as

$$m_j^{(4)} = \boldsymbol{\sigma}_{\rm HTI} x_j^{(4)} = |\boldsymbol{\sigma}_{\rm HTI}| \, e^{i\phi_{\rm HTI}} r_j^{(4)} \tag{43}$$

in terms of the real-valued eigenvalue components $r_j^{(4)}$. As mentioned above, since the r's depend on the details of the interactions, we do not say anything about their explicit form. Also, because we have introduced an overall scale factor $\boldsymbol{\sigma}_{\rm HTI}$, we may require that $\sum_j \left[r_j^{(4)}\right]^2 = 1$. Notice that the phase of all variables of a given irrep are the same. In other words, the phases of the m's in equations (30–33) are all the same. Equation (43) shows that we are dealing with an x–y-like order parameter $\boldsymbol{\sigma} \equiv \sigma_{\rm HTI} e^{i\phi_{\rm HTI}}$ which has an amplitude and a phase. (As the temperature is varied near $T_{\rm HTI}$, Landau theory gives the approximate result $\sigma_{\rm HTI} \sim (T_{\rm HTI} - T)^{1/2}$.) In the appendix, this argument (showing that the $x_j^{(n)}$ are real apart from an overall phase factor) is extended to include fourth-order terms in the free energy. In analyzing experimental data, it is very helpful to realize that apart from the overall phase, $\phi_{\rm HTI}$, all the phases of the of the symmetry adapted coordinates $m_j^{(4)}$ are fixed. When speaking in terms of the spin components, $\mathcal{S}_{\alpha\tau}(q)$, the listing of Table 4 indicates that (for irrep #4, for instance), $\mathcal{S}_{x,1s}(q)$, $\mathcal{S}_{z,1s}(q)$, $\mathcal{S}_{y,1c}(q)$, and $\mathcal{S}_{z,1c}(q)$ will all have the same phase, but (due to the factor i), $\mathcal{S}_{y,1s}(q)$ will be out of phase with the other variables, as one sees in equation (30). As it happens, unless a huge number (several thousand) of reflections are monitored, it is impossible to use diffraction data to fix the relative phases with any degree of certainty. Thus, this theoretical development is useful to completely determine the spin structure of complicated systems such as NVO or TMO. (See note added in publication.)

We now check to see whether the HTI phase has a center of inversion symmetry, in which case, a spontaneous polarization cannot be induced in this phase. We will show that for NVO a phase with a single representation has inversion symmetry. First of all, because we assume incommensurability, we can redefine the origin to be arbitrarily close to a lattice site at R, such that $\phi - qR$ is a multiple of 2π. We have already noted that $\mathcal{I}m_\alpha^\tau = m_\alpha^{\tau *}$. But if ϕ in equation (43) is redefined to be zero, this implies that $\mathcal{I}m_\alpha^\tau = m_\alpha^\tau$, which means that the spin structure has inversion symmetry about the redefined origin. In Figure 9, we show an example of a system obeying equation (43) which does have inversion symmetry and one having an arbitrary set of parameters out of Table 4 which does not satisfy equation (43) and is therefore not allowed. This latter structure does not display inversion symmetry. Note that, as exemplified in Figure 9(b), it is possible for a structure to be noncollinear, but to have a center of inversion symmetry. So noncollinearity, in and of itself, does not guarantee having a spontaneous polarization.

The analysis of the LTI phase is similar. Here again, one can use the transformation properties of the order parameters under inversion to fix the phases of the spin amplitudes. Again, at quadratic order, one has the same result as for the HTI phase: all the LTI order parameters m_α^s for the LTI irrep Γ_1 have the same phase, $\phi_{\rm LTI}$ (which generally is not equal to $\phi_{\rm HTI}$). The analysis is extended to quartic order in the appendix. When two order parameters are nonzero, inversion symmetry will be broken if the centers of symmetry of the two irreps do not coincide, that is, if $\phi_{\rm LTI} \neq \phi_{\rm HTI}$, as is expressed in equation (61).

5.4 Effect of inversion symmetry for TMO

For TMO the nth Mn sublattice (denoted nM) is transformed into itself, so, using Table 5, we have

$$\mathcal{I}S_{\alpha,nM}^{\Gamma_n} = \left[S_{\alpha,nM}^{\Gamma_n}\right]^* \tag{44}$$

which implies that

$$\mathcal{I}m_{M_\alpha}^{(n)}(q) = \left[m_{M_\alpha}^{(n)}(q)\right]^* \tag{45}$$

For the Tb spins, inversion transforms sublattice #1 (denoted $T1$) into sublattice #3 (denoted $T3$) and #2 (denoted $T2$) into #4 (denoted $T4$), so that for them one has

$$\mathcal{I}S_{\alpha,T1}^{\Gamma_n}(q) = \left[S_{\alpha,T3}^{\Gamma_n}(q)\right]^* \ , \ \mathcal{I}S_{\alpha,T2}^{\Gamma_n}(q) = \left[S_{\alpha,T4}^{\Gamma_n}(q)\right]^* \tag{46}$$

These relations imply that

$$\mathcal{I}m^{(n)}_{T_{1\alpha}} = \left[m^{(n)}_{T_{2\alpha}}\right]^* \tag{47}$$

The situation for TMO is slightly more complicated than it was for NVO because of the presence of the lower-symmetry Tb sites. In the HTI phase, the irrep for TMO was determined to be Γ_3. One can repeat the argument used for NVO to show that all the symmetry adapted coordinates on the Mn sites, $m^{(3)}_{M_\alpha}$, have the same phase. To proceed further, we now study the quadratic free energy $f_2^{(3)}$ associated with the irrep Γ_3. In matrix notation we have the quadratic free energy in terms of symmetry adapted coordinates as

$$f_2^{(3)} = \left[m^{(3)\,*}_{M_x},\ m^{(3)\,*}_{M_y},\ m^{(3)\,*}_{M_z},\ m^{(3)\,*}_{T_{1z}},\ m^{(3)\,*}_{T_{2z}}\right] \times \begin{bmatrix} a & b & c & z_1 & z_2 \\ b & d & e & z_3 & z_4 \\ c & e & f & z_5 & z_6 \\ z_1^* & z_3^* & z_5^* & g & z_7 \\ z_2^* & z_4^* & z_6^* & z_7^* & h \end{bmatrix} \begin{bmatrix} m^{(3)}_{M_x} \\ m^{(3)}_{M_y} \\ m^{(3)}_{M_z} \\ m^{(3)}_{T_{1z}} \\ m^{(3)}_{T_{2z}} \end{bmatrix} \tag{48}$$

In writing this form, we have used the fact that the reality of $f_2^{(3)}$ requires the matrix to be Hermitian. Also the matrix elements b, c, and e are real, as can be shown from the arguments used previously for NVO. We now consider complex-valued matrix elements z_n, which have no analog for NVO. (An analogous formulation would be needed for NVO if we were to consider the effect of the minuscule moments which are induced on the lower-symmetry oxygen sites.) We see that the form of equation (48) implies a contribution to $f_2^{(3)}$ of the form

$$\delta f_2^{(3)} = z_1 \left[m^{(3)}_{M_x}\right]^*\ m^{(3)}_{T_{1z}} \tag{49}$$

Using equations (45) and (47), we have that

$$\mathcal{I}\delta f_2^{(3)} = z_1 m^{(3)}_{M_x} \left[m^{(3)}_{T_{2z}}\right]^* \tag{50}$$

Invariance under inversion symmetry indicates that this term must be the same as that, $z_2^*\ [m^{(3)}_{T_{2z}}]^*\ m^{(3)}_{M_x}$, given by equation (48). We thus conclude that $z_2^* = z_1$. Similarly, one can show that $z_4^* = z_3$ and $z_6^* = z_5$. Inversion symmetry gives no information on the phase of z_7. Thus the matrix for $f_2^{(3)}$ is of the form

$$\begin{bmatrix} a & b & c & y_1 & y_1^* \\ b & d & e & y_2 & y_2^* \\ c & e & f & y_3 & y_3^* \\ y_1^* & y_2^* & y_3^* & g & y_4 \\ y_1 & y_2 & y_3 & y_4^* & h \end{bmatrix} \tag{51}$$

where only the y's are complex valued. One can then show that any eigenvector of this matrix must be of the form

$$\psi = [M_x, M_y, M_z, T_1, T_2] = \sigma_{\rm HTI}[r_x, r_y, r_z, c, c^*\ ]e^{i\phi_{\rm HTI}} \tag{52}$$

where r_α is real, c can be complex, and we require the normalization $2|c|^2 + \sum r_\alpha^2 = 1$. As for NVO, we introduced an arbitrary overall phase $\phi_{\rm HTI}$. Note that $m^{(3)}_{M_\alpha}(q) = \sigma_{\rm HTI} r_\alpha e^{i\phi_{\rm HTI}}$, $m^{(3)}_{T_{1z}}(q) = \sigma_{\rm HTI} c e^{i\phi_{\rm HTI}}$, and $m^{(3)}_{T_{2z}}(q) = \sigma_{\rm HTI} c^*\ e^{i\phi_{\rm HTI}}$. Thus, as a result of inversion symmetry, the amplitudes of the two Tb sublattices (c and c^*), which without considering inversion symmetry were unrelated, are now equal in magnitude and have equal and opposite phases relative to the Mn sites. The value of this relative phase (of c) is not fixed by symmetry. As for NVO, one can verify that ψ is inversion invariant if ϕ is redefined to be zero, since then $\mathcal{I}r_\alpha = r_\alpha$ and $\mathcal{I}c = (c^*)^*\ = c$. (The latter relation follows from equation (47).)

5.5 Summary

Finally, we should emphasize that although we do not have a quantitative treatment of the development of magnetic long-range order, we can certainly determine the magnetic symmetry. This information is encoded in Table 3. For NVO, $\sigma_{\rm HTI}$ is associated with irrep #4 and therefore is odd under a twofold rotation about x and even with respect to the mirror plane taking z into $-z$. Likewise, $\sigma_{\rm LTI}$ is associated with irrep #1 and is therefore even with respect to both these operations. For future reference, we also give the transformation properties of $\boldsymbol{\sigma}_{\rm HTI}\boldsymbol{\sigma}_{\rm LTI}$. These results are summarized in Table 6. The symmetry of the LTI phase of NVO is illustrated in Figure 10.

For TMO, the HTI order parameter $\boldsymbol{\sigma}_{\rm HTI}$ is odd with respect to the mirror taking z into $-z$ and is even with respect to the mirror taking x into $-x$. Likewise, $\boldsymbol{\sigma}_{\rm LTI}$ is associated with irrep #2 and is even with respect to the mirror taking z into $-z$ and is odd with respect to the mirror taking x into $-x$ and these results are summarized in Table 6.

In Table 7, we give the experimentally determined values of the symmetry adapted parameters that describe the HTI and LTI phases of NVO and TMO. The results for NVO are analyzed in detail in Kenzelmann *et al.* (2006). We will make a few brief observations here. For NVO, the spine spins dominantly have order in the x direction in the HTI phase from irrep Γ_4 indicating that the x axis is the easy axis. The additional order in the LTI phase due to irrep Γ_1 is along the y direction, and the phase difference

Table 6. Transformation properties of order parameters for NVO (left) and TMO (right). In this table, $\boldsymbol{\sigma} \equiv \sigma e^{i\phi}$. and 'c.c.' denotes complex conjugation. Each column gives the result of applying the operator at the top of the column to the order parameter listed in the row.

Order Parameter	2_x	m_{xy}	$\mathcal{I}$
$\boldsymbol{\sigma}_{\rm HTI}(q)$	-1	1	c.c.
$\boldsymbol{\sigma}_{\rm LTI}(q)$	1	1	c.c.
$\boldsymbol{\sigma}_{\rm LTI}(q)\boldsymbol{\sigma}_{\rm HTI}(-q)$	-1	1	c.c.

Order Parameter	$\tilde{2}_y$	m_{xy}	$\mathcal{I}$
$\boldsymbol{\sigma}_{\rm HTI}(q)$	-1	1	c.c.
$\boldsymbol{\sigma}_{\rm LTI}(q)$	1	-1	c.c.
$\boldsymbol{\sigma}_{\rm LTI}(q)\boldsymbol{\sigma}_{\rm HTI}(-q)$	-1	-1	c.c.

Table 7. Values of the symmetry adapted parameters that describe the HTI and LTI phases of NVO (see Lawes *et al*., 2004) and TMO (see Kenzelmann *et al*., 2005). The uncertainty in the last digit quoted is given in parenthesis. Where there is no parenthesis, the entry is fixed by symmetry to be zero. For TMO, the two Tb order parameters were assumed to have the same magnitude (as predicted by Landau theory) and the phase difference between the Tb parameters $m^{(2)}_{T_{1\alpha}}$ and $m^{(2)}_{T_{2\alpha}}$ in the LTI phase was found to be $1.3(3)\pi$. For NVO, $T = 7$K is in the HTI phase and $T = 5$K is in the LTI phase. For TMO, $T = 35$K is in the HTI phase and $T = 15$K is in the LTI phase.

NVO					TMO				
T(K)	Variable	$\alpha = x$	$\alpha = y$	$\alpha = z$	T(K)	Variable	$\alpha = x$	$\alpha = y$	$\alpha = z$
7	$m^{(4)}_{s_\alpha}$	1.93(5)	0.20(5)	0.10(4)	35	$m^{(3)}_{M_\alpha}$	0.0(8)	2.90(5)	0.0(5)
7	$m^{(4)}_{c_\alpha}$	0	$-0.2(2)$	0.00(2)	35	$\lvert m^{(3)}_{T_{n\alpha}}\rvert$	0	0	0.0(4)
5	$m^{(4)}_{s_\alpha}$	2.0(1)	0.16(9)	0.01(5)	15	$m^{(3)}_{M_\alpha}$	0.0(5)	3.9(1)	0.0(7)
5	$m^{(1)}_{s_\alpha}$	0.5i(5)	-0.5i(1)	0.00i(3)	15	$m^{(2)}_{M_\alpha}$	0.0i(1)	0.0i(8)	2.8i(1)
5	$m^{(4)}_{c_\alpha}$	0	$-2.1(2)$	$-0.03(9)$	15	$\lvert m^{(3)}_{T_{n\alpha}}\rvert$	0	0	0(1)
5	$m^{(1)}_{c_\alpha}$	0.9i(5)	0	0	15	$\lvert m^{(2)}_{T_{n\alpha}}\rvert$	1.2(1)	0(1)	0

$\phi_{\rm LTI} - \phi_{\rm HTI} = \pi/2$ indicates that the spin structure is a spiral, as illustrated in Figure 10. From this figure, one sees that interactions between nearest neighboring spins in adjacent spines displaced from one another along either **c** or **b** are AFM. Since the wave vectors are the same for both types of order, we infer that the exchange interactions are nearly isotropic.

For the Mn spins in TMO, the situation is much the same. In the HTI phase, the Mn spins dominantly have order in the y direction, indicating that this axis is the easy axis. In the HTI irrep (Γ_3) one sees, from Table 5, that sites #1 and #2 (in one basal plane) have positive y components of spin and that sites #3 and #4 (in the adjacent basal plane) have negative y components of spin indicating FM in-plane interactions and AFM out-of-plane interactions. In the LTI phase of TMO, the additional irrep Γ_2 involves spins along z axis and Table 5 shows that for irrep #2 the components are again arranged ferromagnetically within basal planes but antiferromagnetically between adjacent basal planes. The fact that both components of spin are organized similarly suggests that the exchange interactions are probably nearly isotropic. As for NVO the difference in phase between the LTI and HTI order parameters is characteristic of a spiral spin structure.

6 MAGNETOELECTRIC COUPLING

6.1 Landau theory with two order parameters

Now we consider the Landau expansion for the free energy, $f_{\rm ME}$, of the combined magnetic and electric system. One might be tempted to write

$$f_{\rm ME} = a(T - T_F)\mathbf{P}^2 + b(T - T_M)|\sigma|^2 \qquad (53)$$

where σ is a magnetic order parameter and, if we wish to describe a phase transition in which both electric and magnetic order appear simultaneously, we would set $T_{\rm F} = T_{\rm M}$. There are several reasons to reject this scenario. First of all, it is never attractive to assume an accidental degeneracy ($T_F = T_M$). This degeneracy can happen, of course, but normally one would have to adjust some addition control parameter (such as pressure) to reach such a higher-order critical point. In addition, in this type of scenario magnetic and electric properties would not be interrelated. In NVO and TMO, in contrast, as shown in Figure 1, the electric polarization has a dramatic dependence on the applied magnetic field (Lawes *et al*., 2005), which such an independent scenario could not explain.

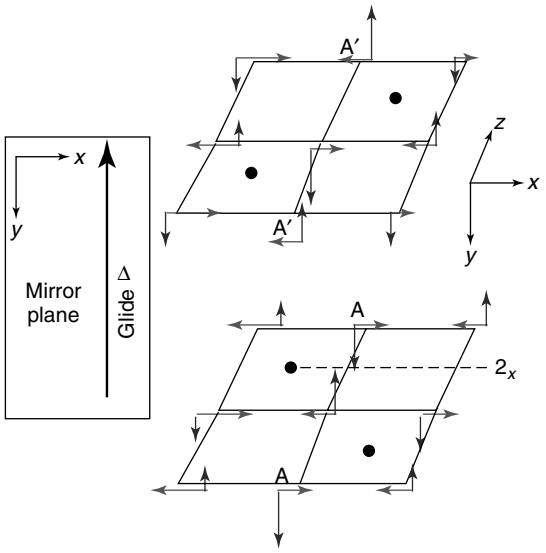

Figure 10. Schematic representation to show the symmetry of spin components for NVO. Here, we show sections of two adjacent **a**–**c** planes. The filled circles indicate the cross-tie sites whose spin components are not shown, for simplicity. The x components transform according Γ_4: they are odd under the twofold rotation 2_x about the x axis and are even under the x–y glide plane (the mirror plane is shown on the left with a subsequent displacement $\vec{\Delta}$ along $\hat{y}$). (Remember that the magnetic moment vector involves a cross product and therefore is an axial vector: under a mirror operation it picks up an extra minus sign.) The y components transform according to Γ_1: they are even under both operations. Although the x and y components have different symmetry, they can plausibly result from nearly isotropic exchange interactions.

6.2 Landau theory with two coupled order parameters

Accordingly, we turn to a formulation in which the appearance of magnetic order induces ferroelectric order. (The possibility that electric order induces magnetic order is not allowed by symmetry, by the argument in footnote 87 of Toledano, Schmid, Clin and Rivera (1985).) So we write

$$f_{\rm ME} = a\chi_{\rm E}^{-1}\mathbf{P}^2 + a(T - T_M)|\sigma|^2 + V_{\rm ME} \tag{54}$$

where $\chi_{\rm E}^{-1}$ does not approach zero and the simultaneous appearance of magnetic and electric order is due to the term $V_{\rm ME}$. As we have seen, the magnetic order is associated with a nonzero wave vector, whereas the ferroelectric order is a zero wave vector phenomenon. Accordingly, we are constrained to posit a magnetoelectric coupling of the form

$$V_{\rm ME} \sim \sigma(q)\sigma(-q)P \tag{55}$$

This term will do what we want: when magnetic order appears in $\sigma(q)$, it will then give rise to a linear perturbation in P, so that $P \sim \chi_{\rm E}|\sigma(q)|^2$. This argument is schematic, of course, and we will have to fill in the details, which must be consistent with the crystal symmetry of the specific systems involved.

The minimal phenomenological model that describes the magnetic and electric behavior of the HTI and LTI phases is therefore written as

$$\begin{aligned} f = {} & \frac{1}{2}(T - T_{\rm HTI})\boldsymbol{\sigma}_{\rm HTI}(q)\boldsymbol{\sigma}^*_{\rm HTI}(q) \\ & + \frac{1}{2}(T - T_{\rm LTI})\boldsymbol{\sigma}_{\rm LTI}(q)\boldsymbol{\sigma}^*_{\rm LTI}(q) \\ & + \mathcal{O}(|\sigma|^4) + \frac{1}{2}\chi_{\rm E}^{-1}\mathbf{P}^2 + V_{\rm ME} \end{aligned} \tag{56}$$

where

$$V_{\rm ME} = \sum_{\rm A,B\,=\,LTI,\,HTI} \sum_{\gamma=x,y,z} a_{A,B,\gamma}\boldsymbol{\sigma}_A(q)^*\,\boldsymbol{\sigma}_B(q)P_\gamma \tag{57}$$

6.3 Symmetry of magnetoelectric coupling

We now show that this free energy reproduces the observed phenomenology of ferroelectricity in NVO and TMO. First, of all, in the HTI phase (where $\boldsymbol{\sigma}_{\rm LTI} = 0$) $V_{\rm ME}$ is of the form

$$V_{\rm ME} = \sum_\gamma b_\gamma |\boldsymbol{\sigma}_{\rm HTI}(q)|^2 P_\gamma \tag{58}$$

where b_γ is real. Now we use the fact that $V_{\rm ME}$ has to be inversion invariant, since it arises in an expansion relative to the paramagnetic phase, which is inversion invariant (Dzyaloshinskii, 1957; Landau and Lifshitz, 1958). We use $\mathcal{I}\sigma_{\rm HTI}(q) = \sigma_{\rm HTI}(q)^*$ and $\mathcal{I}P_\gamma = -P_\gamma$ to show that b_γ must vanish. Indeed, we have already seen, the HTI phases of NVO and TMO are inversion invariant. So, for these situations b_γ in equation (58) must be zero and no polarization can be induced in the HTI phase.

Now we consider the situation in the LTI phase when the two order parameters $\sigma_{\rm HTI}$ and $\sigma_{\rm LTI}$ are both nonzero. The argument which indicated that $a_{\rm HTI,HTI,\gamma} = 0$ can be used to establish that $a_{\rm LTI,LTI,\gamma} = 0$. Then we write

$$\begin{aligned} V_{\rm ME} = \sum_\gamma \big[& c_\gamma \boldsymbol{\sigma}_{\rm HTI}(q)^*\,\boldsymbol{\sigma}_{\rm LTI}(q) \\ & + c^*_\gamma\,\boldsymbol{\sigma}^*_{\rm LTI}(q)\boldsymbol{\sigma}_{\rm HTI}(q)\big] P_\gamma \end{aligned} \tag{59}$$

This interaction has to be inversion invariant, so we use the transformation properties of the order parameters under inversion to write

$$V_{\rm ME} = \mathcal{I} V_{\rm ME} = -\sum_{\gamma} \left[c_\gamma \boldsymbol{\sigma}_{\rm HTI}(q) \boldsymbol{\sigma}_{\rm LTI}(q)^* + c_\gamma^* \, \boldsymbol{\sigma}_{\rm LTI}(q) \boldsymbol{\sigma}_{\rm HTI}(q)^* \right] P_\gamma \qquad (60)$$

Comparison with equation (59) indicates that c_γ must be pure imaginary: $c_\gamma = i r_\gamma$, where r_γ is real. Then

$$V_{\rm ME} = 2 \sum_{\gamma} r_\gamma \sigma_{\rm HTI}(q) \sigma_{\rm LTI}(q) P_\gamma \sin[\phi_{\rm HTI} - \phi_{\rm LTI}] \qquad (61)$$

This result shows that to get a nonzero spontaneous polarization it is necessary that two order parameters be nonzero. (A similar interaction was proposed by Frohlich, Leute, Pavlov and Pisarev, 1998 in their analysis of second-harmonic generation.) Furthermore, these two order parameters must *not* have the same phase. In fact, a more detailed analysis of Landau theory shows that the phase difference $\phi_{\rm HTI} - \phi_{\rm LTI}$ is expected to be $\pi/2$. (This result comes from an analysis of the quartic terms. As we observed earlier, the function of the quartic terms is to enforce the constraint of fixed spin length. This constraint usually means that the ordering in two representations should be out of phase, so that when one representation gives a maximum of spin lengths, the other gives a minimum of spin lengths.) The reader should be alerted to the fact that there are systems such as $TbMn_2O_5$ and YMn_2O_5 which have a magnetoelectric interaction of the form

$$V_{\rm ME} = \sum_{\gamma} r_\gamma [|\sigma_1(q)|^2 - |\sigma_2(q)|^2] P_\gamma \qquad (62)$$

and which therefore can support a ferroelectric phase in the presence of a *single* incommensurate magnetic order parameter (Harris, 2006b). (A similar magnetoelectric interaction was found in Cowley, 1980, and Sergienko, Sen and Dagotto, 2006, for *commensurately* ordered magnetic systems.)

Finally, we consider how the symmetry properties constrain the spontaneous polarization. Look at Table 6. There we see how the magnetic order parameters transform under the various symmetry operations of the paramagnetic phase. For $V_{\rm ME}$ to be an invariant, we see that for NVO, **P** must be odd under 2_x (which restricts **P** to be along y or z) and it must be even under m_{xy} (which restricts **P** to be along x or y). Thus, symmetry restricts **P** to be only along y. This is exactly what experiment shows. For TMO, **P** must be odd under both $\tilde{2}_y$ and m_{xy}. Thus, symmetry restricts **P** to lie along z at $H = 0$, as is observed in experiment. (At higher magnetic fields, the magnetic symmetry must change to explain why the polarization switches from the z axis to the x axis.) Furthermore, the temperature variation of **P**, shown in Figure 11 looks very much like that for an order parameter. But that is to be expected because if we minimize the total free energy with respect to **P**, using equation (61), we see that the spontaneous polarization is given as

$$P_\gamma \sim \chi_{\rm E} \sigma_{\rm HTI} \sigma_{\rm LTI} \qquad (63)$$

When the LTI phase is entered, $\sigma_{\rm HTI}$ is already well developed and is therefore essentially independent of temperature. Thus we expect that crudely $P_\gamma \sim \sigma_{\rm LTI}$. Indeed, although we have not undertaken a quantitative analysis, the experimental curves of P versus T look quite similar to those for an order parameter.

Finally, for TMO for a large magnetic field along **a** (see Figure 6) or along **b** (see Kimura *et al*., 2005), there is a change of orientation of the spontaneous polarization **P** to lie along **a**. Since there seems to be no analogous phase transition within the HTI phase, we attribute this reorientation to a change in the LTI spin state. Instead of the additional irrep of the LTI phase being Γ_2 (as it is at low field), we infer that the new LTI irrep is Γ_1, since this combination of irreps is consistent with having **P** along **a**. Furthermore, if we assume that the exchange coupling is isotropic, then we would expect that Γ_1 ordering would be FM within basal planes and AFM between planes. From Table 5, this constraint can only be satisfied if the ordering involves the x component of spin. So, from the polarization data we

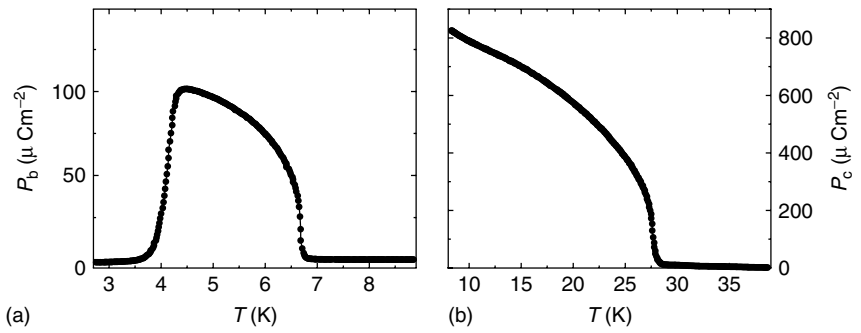

Figure 11. Temperature dependence of the spontaneous polarization at zero applied magnetic field for NVO (a) and for TMO (b). Note the different scales for **P**. (Reprinted with permission G. Lawes *et al*., copyright 2005, American Institute of Physics (a) and Reprinted with permission T. Kimura *et al*., copyright 2003, Nature Publishing Group (b).)

speculate that the Mn spin structure (which at low field is in the **b**–**c** plane) is rotated, at high field, into the **a**–**b** plane.

6.4 Spin-current model

A microscopic explanation of ferroelectricity occurring simultaneously with spiral order of the type seen in TMO or NVO was given by Katsura, Nagaosa and Balatsky (2005). (Subsequently, a similar result was obtained phenomenologically Mostovoy, 2006.) In this theory, a microscopic mechanism is invoked in which a spontaneous polarization $\mathbf{P}_{ij}$ can be induced by spins $\mathbf{S}_i$ and $\mathbf{S}_j$ which are located at respective positions $\mathbf{r}_i$ and $\mathbf{r}_j$. Assuming a noncollinear spin ordering (presumably established by competing exchange interactions), they found that

$$\mathbf{P}_{ij} = a\left[\frac{\mathbf{r}_{ij} \times (\mathbf{S}_i \times \mathbf{S}_j)}{r_{ij}}\right] \tag{64}$$

where a is a constant and $\mathbf{r}_{ij} = \mathbf{r}_i - \mathbf{r}_j$. This model successfully predicts the magnetically induced spontaneous polarization in both NVO and TMO. First of all, in the HTI phases if the spins are assumed to be collinear, this mechanism predicts that $\mathbf{P}_{ij} = 0$. In a phase in which the spins rotate a plane perpendicular to $\mathbf{n}$, one see that the vector $\mathbf{S}_i \times \mathbf{S}_j$ must be parallel to $\mathbf{n}$. If one averages over spins in planes perpendicular to the wave vector $\mathbf{q}$, one see that the net polarization must be in the direction $\mathbf{n} \times \mathbf{q}$. For the LTI phase of NVO, for instance, the vector $\mathbf{n}$ is parallel to the $\mathbf{b}$ direction and $\mathbf{q}$ is along the $\mathbf{a}$ direction. This model therefore correctly predicts a spontaneous polarization along the $\mathbf{c}$ direction. However, the predictions of this mechanism are less obvious when there are small transverse components of magnetization which are allowed within the observed irrep.

The same argument also correctly predicts the direction of the spontaneous polarization in TMO and gives the same prediction for the rotation of the plane of the magnetization when TMO is subject to a large magnetic field that rotates the direction of the spontaneous polarization.

6.4.1 Note added in Proof

Recently, the stacked triangular antiferromagnet $RbFe(MO_4)_2$ with spins confined to the plane perpendicular to the threefold axis, with each such plane forming a 120° antiferromagnet has been shown to be ferroelectric (Kenzelmann *et al*., 2007). Since the spins are perpendicular to the threefold axis, the vector $\mathbf{S}_i \times \mathbf{S}_j$ must lie along the threefold axis. The observed spontaneous polarization along the threefold axis contradicts the prediction of the spin-current model that there be no ferroelectricity induced by antiferromagnetism. So, while the spin-current model is appealing in the simplicity of its conclusion, it cannot be a universal explanation of magnetically induced ferroelectricity. In this system equation (62) is verified by showing that P_γ goes like $|\sigma_1(q)|^2$ when $\sigma_2(q)$ vanishes.

We also point out a recent paper of Sergienko and Dagotto (2006) (SD) who show that the Dzyaloshinskii–Moriya (DM) interaction can induce a combined magnetic and ferroelectric phase transition. However, in the model explicitly considered in their paper, the phenomenology seems inappropriate since the transition requires a threshold strength of the DM interaction, whereas the phenomenology we have developed here always gives ferroelectricity independent of the strength of the magnetoelectric coupling providing the symmetry is appropriate.

6.5 Broken symmetry

We should also mention some considerations concerning broken symmetry for NVO. (Clearly, a similar discussion applies to other similar systems.) Since both transitions involving the HTI phase involve broken symmetry, we assert the following. At the level of the present analysis when the temperature is reduced to enter the HTI phase, the modulated order appears with an arbitrary phase ϕ_{HTI}. Of course, if this state is truly incommensurate, then this phase will remain arbitrary. Normally, however, we would expect some perturbation to break this symmetry and this continuous symmetry should be removed. However, we do expect a degeneracy with respect to the time-reversed version of the ordered HTI phase. In that case upon performing many runs of the same experiment, both time-reversed versions of the HTI ordered phase should occur with equal probability.

One can make much the same observation about the HTI→LTI phase transition. Here, one has the additional broken symmetry associated with the irrep Γ_1. When the temperature is reduced to enter the LTI phase, the system will have two symmetry-equivalent states into which it can condense. As with the usual magnetic phase transitions, one can (in principle) select between these two phases by applying a suitably spatially modulated magnetic field. Such an experiment does not seem currently feasible (because modulation of an applied field on an atomic scale is difficult to produce). However, because the magnetic order parameters are coupled to the ferroelectric moment, one can select between the two symmetry-equivalent possibilities for the LTI order parameter by applying a small *electric* field. An interesting experiment suggests itself: compare the magnetic state as determined by, say, neutron diffraction for the two cases of a small applied electric field in the positive and negative $\mathbf{b}$ directions. According to the magnetoelectric trilinear coupling, application of such an electric field should select the sign of the product $\sigma_{\mathrm{HTI}}\sigma_{\mathrm{LTI}}$. In this context, we

remark that measurement of the spontaneous polarization **P** (as in Figure 1) is made by preparing the sample in a small symmetry-breaking electric field $\mathbf{E}_0$, which is removed once **P** becomes nonzero. The ferroelectric order is confirmed by verifying that **P** changes sign when the sign of $\mathbf{E}_0$ is changed.

7 MICROSCOPICS

Since the spontaneous polarization **P** must result from a spontaneous condensation of an optical phonon having a dipole moment, we are led to study the symmetry of the phonon excitations at zero wave vector. Neglecting nonzero wave vectors, we write the α component of the displacement of the τth ion in the unit cell at **R** as

$$u_\alpha(\mathbf{R}, \tau) = \sum_i Q_i \xi_\alpha^{(i)}(\tau) \tag{65}$$

where $\xi_\alpha^{(i)}(\tau)$ is the normalized form factor of the ith generalized displacement whose amplitude is Q_i. A comprehensive analysis is given elsewhere (Harris, Yildirim, Aharony and Entin-Wohlman, 2006), but here we confine our attention to generalized displacements in NVO which transform appropriately (like a displacement along **b**) to explain experiments. Such a (y-like) generalized displacement Q_i must be invariant under the operations (see Table 2) E, $\boldsymbol{\sigma}_x$, $\boldsymbol{\sigma}_z$, and 2_y and change sign under $\boldsymbol{\sigma}_y$, 2_x, 2_z, and $\mathcal{I}$. There are 12 such generalized displacements of the 13 ions in the primitive unit cell. Six of these are the uniform displacements along **b** of all crystallographically equivalent sites of a given type, that is Ni spine sites, Ni cross-tie sites, V sites, O_1, O_2, and O_3 sites, and these uniform displacements, denoted Q_1, $Q_2, \ldots Q_6$, give rise to a dipole moment along the **b** axis. Other generalized displacements involve, perhaps surprisingly, oppositely oriented displacements along the **a** or **c** axis within a group of crystallographically equivalent sites. We illustrate one of these (Q_7 involving Ni cross-tie sites) along with Q_2 in Figure 12. Since Q_7 has the same symmetry as $Q_1 \ldots Q_6$, it must couple to these modes. One can easily visualize this by imagining the ions to act like hard spheres. In that case, as the cross-tie ions approach spine sites #1 and #4, they cause these site (which initially were at negative y) to move to more negative y. Similarly, as the cross-tie sites move away from sites #2 and #3, these ions have more room to move closer to $y = 0$. In other words, the opposing motion of the cross-tie sites in mode Q_7 along the **c** axis interacts with the uniform motion in mode Q_1 of the spine sites along **b**. In summary, the elastic free energy as a function of displacements can be written as

$$f(\{Q_i\}) = \frac{1}{2} \sum_{i,j=1}^{12} V_{ij} Q_i Q_j \tag{66}$$

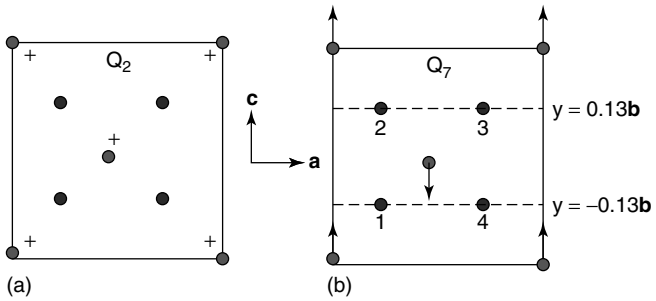

Figure 12. Pattern of two generalized displacements, Q_2 (a) and Q_7 (b), which transform under the symmetry operations of the crystal like a displacement along **b**. In (a), '+' indicates motion along the positive **b** axis. In Q_2, all the cross-tie sites move in parallel along the **b** axis and therefore this motion induces a dipole moment. As discussed in the text, the nonuniform motion of the cross-tie sites in the generalized displacement Q_7 induces uniform motion of the spine site in the **b** direction which in turn produces a dipole moment.

At the time of this writing, no calculation or neutron experiments to determine V_{ij} have appeared. Instead we have recourse to a very crude toy model, obtained by setting

$$f(\{Q_i\}) = \sum_i \frac{1}{2} M_i \omega_D^2 Q_i^2 \tag{67}$$

where M_i is the mass of ions in mode Q_i and ω_D is the Debye frequency, characteristic of phonons.

We now consider the effect of a generalized y-like displacement Q_i on the exchange interaction between nearest neighbors in the same spine. Then for spins numbered 1 and 4 in a unit cell we have the exchange interaction as a function of displacement as

$$\mathcal{H}_{14}(Q_i) = \mathcal{H}_{14}(0) + Q_i \sum_{\alpha\beta} S_\alpha(1) \frac{\mathrm{d}M_{\alpha\beta}(1,4)}{\mathrm{d}Q_i} S_\beta(4) \tag{68}$$

The existence of a mirror plane perpendicularly bisecting the 1–4 bond ($m_{\mathbf{bc}}$) implies that

$$\mathcal{H}_{14}(Q_i) = m_{\mathbf{bc}} \mathcal{H}_{14}(Q_i) \tag{69}$$

which is

$$\mathcal{H}_{14}(Q_i) = Q_i [S_{1x}, S_{1y}, S_{1z}] \frac{\mathrm{d}}{\mathrm{d}Q_i} \times \begin{bmatrix} M_{xx} & -M_{yx} & -M_{zx} \\ -M_{xy} & M_{yy} & M_{zy} \\ -M_{xz} & M_{yz} & M_{zz} \end{bmatrix} \begin{bmatrix} S_{4x} \\ S_{4y} \\ S_{4z} \end{bmatrix} \tag{70}$$

where we used $m_{\mathbf{bc}} Q_i = Q_i$, $m_{\mathbf{bc}} S_{1x} = S_{4x}$, $m_{\mathbf{bc}} S_{1y} = -S_{4y}$, and $m_{\mathbf{bc}} S_{1z} = -S_{4z}$ (the spin is a pseudovector). Thus,

to satisfy equation (69) the derivatives must satisfy the conditions

$$\frac{\mathrm{d}M_{yx}}{\mathrm{d}Q_i} = -\frac{\mathrm{d}M_{xy}}{\mathrm{d}Q_i}, \frac{\mathrm{d}M_{zx}}{\mathrm{d}Q_i} = -\frac{\mathrm{d}M_{xz}}{\mathrm{d}Q_i}, \frac{\mathrm{d}M_{zy}}{\mathrm{d}Q_i} = \frac{\mathrm{d}M_{yz}}{\mathrm{d}Q_i} \quad (71)$$

Thus the gradient of the exchange tensor must assume the form

$$\frac{\mathrm{d}M_{\alpha\beta}(1,4)}{\mathrm{d}Q_i} = \frac{\mathrm{d}}{\mathrm{d}Q_i}\begin{bmatrix} J_{xx} & D_z & -D_y \\ -D_z & J_{yy} & J_{yz} \\ D_y & J_{yz} & J_{zz} \end{bmatrix} \quad (72)$$

where $J_{\alpha\beta}$ is the symmetric exchange tensor and **D** is the Dzyaloshinskii–Moriya vector, which specifies the antisymmetric component of the exchange tensor.

We determine the other similar interactions in the unit cell using the appropriate symmetry operations. If 2_y is a rotation about an axis parallel to **b** and which passes through site #4, then

$$\mathcal{H}(4,1';y) = 2_y\mathcal{H}(1,4;y) = Q_i[S_{4x}, S_{4y}, S_{4z}]\frac{\mathrm{d}}{\mathrm{d}Q_i} \times \begin{bmatrix} J_{xx} & D_z & D_y \\ -D_z & J_{yy} & -J_{yz} \\ -D_y & -J_{yz} & J_{zz} \end{bmatrix}\begin{bmatrix} S_{1'x} \\ S_{1'y} \\ S_{1'z} \end{bmatrix} \quad (73)$$

where we used $2_y Q_i = Q_i$, and site #4′ is one unit cell to the right of site #4 in Figure 12. Also, if 2_x is a rotation about the **a** axis, then

$$\mathcal{H}(2,3;y) = 2_x\mathcal{H}(1,4;y) = Q_i[S_{2x}, S_{2y}, S_{2z}]\frac{\mathrm{d}}{\mathrm{d}Q_i} \times \begin{bmatrix} -J_{xx} & D_z & -D_y \\ -D_z & -J_{yy} & -J_{yz} \\ D_y & -J_{yz} & -J_{zz} \end{bmatrix}\begin{bmatrix} S_{3x} \\ S_{3y} \\ S_{3z} \end{bmatrix} \quad (74)$$

where we used $2_x Q_i = -Q_i$ and

$$\mathcal{H}(3,2';y) = 2_y\mathcal{H}(2,3;y) = Q_i[S_{3x}, S_{3y}, S_{3z}]\frac{\mathrm{d}}{\mathrm{d}Q_i} \times \begin{bmatrix} -J_{xx} & D_z & D_y \\ -D_z & -J_{yy} & J_{yz} \\ -D_y & J_{yz} & -J_{zz} \end{bmatrix}\begin{bmatrix} S_{2'x} \\ S_{2'y} \\ S_{2'z} \end{bmatrix} \quad (75)$$

where site #2′ is one unit cell to the right of site #3 in Figure 12.

When we consider equation (67) and neglect fluctuations, the spin–phonon interactions lead to the result

$$\langle Q_i\rangle = \left(M_i\omega_{\mathrm{D}}^2\right)^{-1}\sum_{\alpha\beta}\sum_{n,m}\langle S_\alpha(n)\rangle\frac{\mathrm{d}M_{\alpha\beta}(n,m)}{\mathrm{d}Q_i}\langle S_\beta(m)\rangle \quad (76)$$

where $\langle\ \rangle$ indicates a thermal average and (n, m) are summed over the four nearest-neighbor spine–spine interactions in a unit cell. Assuming the spins are characterized by spine spin components scaled by **a** for irrep 4 and by **b** for irrep #1, we write the spin components as

$$\begin{aligned} S_x(x_1) &= (a_x + ib_x)\mathrm{e}^{iqx_1} + (a_x^* - ib_x^*)\mathrm{e}^{-iqx_1} \\ S_x(x_2) &= (-a_x + ib_x)\mathrm{e}^{iqx_1} + (-a_x^* - ib_x^*)\mathrm{e}^{-iqx_1} \\ S_x(x_3) &= (a_x - ib_x)\mathrm{e}^{iqx_4} + (a_x^* + ib_x^*)\mathrm{e}^{-iqx_4} \\ S_x(x_4) &= (-a_x - ib_x)\mathrm{e}^{iqx_4} + (-a_x^* + ib_x^*)\mathrm{e}^{-iqx_4} \end{aligned} \quad (77)$$

$$\begin{aligned} S_y(x_1) &= (ia_y + b_y)\mathrm{e}^{iqx_1} + (-ia_y^* + b_y^*)\mathrm{e}^{-iqx_1} \\ S_y(x_2) &= (ia_y - b_y)\mathrm{e}^{iqx_1} + (-ia_y^* - b_y^*)\mathrm{e}^{-iqx_1} \\ S_y(x_3) &= (-ia_y + b_y)\mathrm{e}^{iqx_4} + (ia_y^* + b_y^*)\mathrm{e}^{-iqx_4} \\ S_y(x_4) &= (-ia_y - b_y)\mathrm{e}^{iqx_4} + (ia_y^* - b_y^*)\mathrm{e}^{-iqx_4} \end{aligned} \quad (78)$$

$$\begin{aligned} S_z(x_1) &= (a_z + ib_z)\mathrm{e}^{iqx_1} + (a_z^* - ib_z^*)\mathrm{e}^{-iqx_1} \\ S_z(x_2) &= (a_z - ib_z)\mathrm{e}^{iqx_1} + (a_z^* + ib_z^*)\mathrm{e}^{-iqx_1} \\ S_z(x_3) &= (a_z - ib_z)\mathrm{e}^{iqx_4} + (a_z^* + ib_z^*)\mathrm{e}^{-iqx_4} \\ S_z(x_4) &= (a_z + ib_z)\mathrm{e}^{iqx_4} + (a_z^* - ib_z^*)\mathrm{e}^{-iqx_4} \end{aligned} \quad (79)$$

Using these evaluations one can carry out the sum over (n, m) in equation (76) to get

$$\langle Q_i\rangle = 16(M_i\omega_{\mathrm{D}}^2)^{-1}\left[F_i^{(s)}\sin(qa/2) + F_i^{(c)}\cos(qa/2)\right] \quad (80)$$

where

$$F_i^{(c)} = \Im\left[a_x^*\, b_z + a_z^*\, b_x\right]\mathrm{d}D_y/\mathrm{d}Q_i + \sum_\alpha \pi_\alpha \Im\left[a_\alpha b_\alpha^*\right]\mathrm{d}J_{\alpha\alpha}/\mathrm{d}Q_i \quad (81)$$

and

$$F_i^{(s)} = \Im\left[a_z b_y^* + b_z a_y^*\right]\mathrm{d}J_{yz}/\mathrm{d}Q_i + \Im\left[a_x b_y^* + b_x a_y^*\right]\mathrm{d}D_z/\mathrm{d}Q_i \quad (82)$$

where $-\pi_x = \pi_y = \pi_z = 1$. Note that these terms require the presence of both order parameters **a** and **b** and hence they can only be nonzero in the LTI phase. Also these terms are only nonzero if **a** and **b** have different phases. For displacements that could give rise to a spontaneous polarization along the **a** or **c** axes, the sum over (n, m) in equation (76) gives zero (Harris, Yildirim, Aharony and Entin-Wohlman, 2006). These conclusions agree with the

result found using Landau theory. This magnon–phonon coupling also contributes to the temperature dependence of the wave vector q (Kenzelmann *et al*., 2006; Harris *et al*., 2006).

To get an order-of-magnitude estimate of the various quantities, we consider the effect of the motion of the oxygen ions, which are the lightest atoms and therefore have the largest displacements. Crudely speaking, the dipole moment, P_Q of the generalized displacement Q is given by $P_Q = q_Q \sum_{i\in Q} u_i$, where q_Q is the charge of the ions of Q and u_i is the displacement of ion i in Q. More accurately, q_Q should be replaced by an effective charge q_Q^* which takes account of the electrical relaxation that occurs as the ions move. (This is analogous to the discussion given at the end of the preceding paragraph.) Thus, even Q_7 will develop a (probably small) dipole moment in the **b** direction. However, for simplicity we set

$$\langle P\rangle = \frac{q_i\langle Q\rangle}{v_{\rm uc}} = \frac{2e\langle Q\rangle}{v_{\rm uc}} \tag{83}$$

where $v_{\rm uc} \approx 275\times 10^{-30}\mathrm{m}^3$ is the volume of the unit cell. More accurately, $\langle Q\rangle$ should be replaced by $\langle Q\rangle\sqrt{n}$, where n is the number of ions involved in the mode generalized displacement Q (So $n = 4$ or $n = 6$). So, in meters, $\langle Q\rangle \approx (275\times 10^{-30})(5\times 10^{-4})/(3.2\times 10^{-19}\sqrt{n})$, where we took $P = 5\times 10^{-4}\,\mathrm{C\,m^{-2}}$ as a typical value. Thus we estimate the ionic displacement to be of order $\langle Q\rangle \sim 0.001$ Å. (Actually, neutron diffraction indicates that the ionic displacement ought to be at most 0.001 Å.) (We thank Prof. C. Broholm for communicating this bound to us.) If $\partial J/\partial Q$ represents a typical value for $\partial M_{\alpha\beta}/\mathrm{d}Q$, then

$$\langle Q_i\rangle \sim \frac{(\hbar c)^2}{(M_i c^2)(\hbar\omega_{\rm D})^2}\frac{\partial J}{\partial Q} \tag{84}$$

Working in Åand eV and taking $\langle Q_i\rangle = 0.001$ Å, $\hbar\omega_{\rm D} \approx 0.05$ eV, $M_i c^2 \approx 1.6\times 10^{10}$ eV, and $\hbar c \approx 2000$ eV Å, we find that this mechanism requires that

$$\frac{\partial J}{\partial Q} \sim 0.01\ \mathrm{eV/Å} \tag{85}$$

This seems to be a plausible value. Obviously a first-principles calculation of $\partial M_{\alpha\beta}/\partial Q_i$ would be of interest to make this analysis more concrete.

8 SUMMARY AND OUTLOOK

The development of multiferroic materials having very large magnetoelectric couplings offers the possibility of designing new types of devices that exploit the coupling between magnetic and ferroelectric order. Furthermore, investigating the nature of the coupling between magnetic and ferroelectric order parameters in these compounds may be important in understanding other systems displaying significant interactions between different types of long-range order. We will briefly summarize the main results of the model we have presented coupling ferroelectricity with incommensurate magnetic order, and then discuss what this implies for future research on magnetoelectric multiferroics.

8.1 Summary of this review

As many of the recently identified materials exhibiting simultaneous magnetic and ferroelectric order are incommensurate magnets, we have focused on these systems. We discussed a toy model for incommensurate magnetism. In this model, we saw that, under the assumption that the magnetic anisotropy is not too large, the magnetic system will undergo a paramagnetic to a longitudinally ordered incommensurate phase we refer to as the HTI phase. On further lowering the temperature, the is another transition to a distinct incommensurate phase with additional transverse spin ordering, which we call the LTI phase.

Because knowing the detailed symmetry of the incommensurate magnetic structure is crucial for determining whether ferroelectric order is allowed, we considered the extension of this toy model to systems with nontrivial unit cells. We addressed this problem by expressing the spin order parameters in terms of irreducible representations consistent with the symmetry restrictions of the unit cell. The central observation for understanding the magnetoelectric coupling is that the free energy must be invariant under all symmetries of the paramagnetic phase, and in particular, if the paramagnetic crystal has inversion symmetry, it must be invariant under spatial inversion. This requirement was used to determine whether a particular incommensurate magnetic structure allowed the possibility of ferroelectric order. Using this approach, we are able to qualitatively explain the multiferroic behavior of both NVO and TMO, including the absence of ferroelectric order in the HTI phase, the development of ferroelectricity in the LTI phase, and the qualitative features of the spontaneous polarization (direction and temperature dependence).

It is worth noting that the magnetoelectric coupling we have described here does not reduce to the analogous coupling that can occur in a ferromagnet or in an antiferromagnet. As remarked in the review of Smolenskii and Chupis (1982), such a trilinear coupling cannot exist in structures that (like NVO or TMO) have inversion symmetry in the paramagnetic phase. Indeed, the mechanism we invoke requires that $q \neq 0$, as one can see from equation (61). (If $q = 0$, then the

order parameters are real, $\phi_{\mathrm{HTI}} = \phi_{\mathrm{LTI}} = 0$ and $V_{\mathrm{ME}} = 0$.) In that review, they also mention a coupling that involves gradients of the magnetic order parameter. That type of coupling may be related to the one used here, although in our case the symmetry properties of the unit cell play a crucial role that cannot be replaced by a continuum vector field.

We also showed that the microscopic symmetry of the derivative of the exchange tensor with respect to ionic displacement leads to results in complete agreement with the symmetry arguments based on the Landau expansion. This symmetry will have to be respected by any truly microscopic theory of magnetoferroelectrics.

8.2 Outlook for device applications

The success of the theory described in this review suggests that it may be valuable both in understanding the origins of multiferroic behavior in presently identified systems, and well as in guiding the search for new multiferroic compounds having desirable materials properties. We briefly discussed the technological drivers motivating the search for magnetoelectric materials, by illustrating the types of devices that might be possible using multiferroics. However, there are two main difficulties that must be resolved before these materials could be incorporated into fabricating next generation magnetoelectric devices. Firstly, the very low transition temperatures into the ferroelectric LTI phase (6.4 K for NVO and ∼27 K for TMO) make these materials unsuitable for many applications. Secondly, the spontaneous polarizations in these systems are typically several orders of magnitude smaller than what is found in conventional ferroelectrics. Before incommensurate multiferroics can be considered for applications, it will be necessary to engineer materials having larger spontaneous polarizations developing at higher temperatures. We discuss in the following some of the general ideas extracted from our model which may help guide the search for new multiferroics more suitable for applications.

Extending the search for multiferroics from simple ferromagnets to systems with incommensurate magnetic order is an important first step in finding materials that have a room-temperature transition into a phase, developing magnetic and ferroelectric order simultaneously. Insulating ferromagnets tend to have very low transition temperatures, but many incommensurate magnets have ordering temperatures well above room temperature (Sosnowska, Newmaier and Seichle, 1982). In fact, the incommensurate magnetic structure associated with ferroelectric order in one recently identified multiferroic (T. Kimura, private communication) persists up to $T = 320$ K. Our results suggest that insulating incommensurate magnets with high magnetic ordering temperatures may be prime candidates in the search for strongly coupled magnetoelectric multiferroics at room temperature.

The second shortcoming of currently known incommensurate multiferroics for device applications is the small value of the spontaneous polarizations. As we develop a better understanding of the microscopic mechanisms giving rise to multiferroic order, it should be possible to engineer materials with larger ferroelectric moments. Additionally, several recent studies suggest that the spontaneous polarization of certain multiferroic materials may be significantly enhanced in thin-film geometries (Wang *et al*., 2003). This offers the possibility of improving the properties of incommensurate multiferroics by preparing the thin-film samples that would be required for device applications.

8.3 Experimental outlook

Both of the systems we have considered in detail (NVO and TMO) are inversion symmetric in the paramagnetic phase, and only develop ferroelectric order by coupling the polarization to two distinct magnetic order parameters. On the surface, this might suggest that the search for new multiferroic materials should focus on systems with multiple magnetically ordered phases developing in zero field. However, as pointed out in equation (62) ferroelectricity can appear within a scenario involving the condensation of a single magnetic order parameter and very recent experiments on $RbFe(MoO_4)_2$ have shown this unambiguously (Kenzelmann *et al*., 2007).

This specific example raises the general problem of producing multiferroic order in a system that has neither magnetic nor ferroelectric order in the high-temperature phase. In particular, consider systems that lack inversion symmetry, but whose rotational symmetry elements preclude a nonzero vector order parameter. We give two families of such crystal structures. The first is that of the point group D_2 (orthorhombic space groups #16–#24 in Hahn, 1983) and the second is that of point group T (cubic space groups #195–#199 in Hahn, 1983). In the para phase, these systems have no magnetic long-range order and, because these crystal structures do not allow vector ordering, they do not display ferroelectric order. When such a system develops long-range incommensurate order with a wave vector along one of the crystallographic directions, then only rotations about this direction remain symmetric and a spontaneous polarization along the direction of the wave vector is permitted, at least in principle. This mechanism would therefore allow the development of multiferroic order at a single phase transition.

These results suggest that there are many more multiferroic materials than previously considered, and offer guidelines to identifying new multiferroics. The magnetic transition giving rise to ferroelectric order should produce a noncollinear

spin structure. Because magnetic order in geometrically frustrated magnets is often driven by anisotropic interactions, such complex spin structures often arise on frustrated triangular lattices. Furthermore, because the magnetic exchange energies at the ordering temperatures are typically large in frustrated systems (with the order temperature T_c an order of magnitude smaller than the Weiss temperature), these systems often show significant magnetoelectric coupling. Systems having low-energy phonon modes may be more susceptible to magnetically induced ferroelectric distortions, although other typical requirements for conventional ferroelectrics, specifically empty d orbitals (Seshadri and Hill, 2001), are apparently unimportant in multiferroics. Finally, while many of the magnetically induced multiferroics studied so far are in fact incommensurately ordered, it is not a necessary prerequisite, but is simply a consequence of the geometrical frustration in these systems (Kenzelmann *et al*., 2007). A recently studied commensurately ordered multiferroic is discussed in Sergienko and Dagotto (in press).

We also refer the reader to Section 6.5 where we suggest an experiment to test our assertions about broken symmetry, namely that the application of a small symmetry-breaking electric field should select states for which $\sigma_{\mathrm{HTI}}\sigma_{\mathrm{LTI}}$ has a fixed sign, although neither order parameter individually has a fixed sign.

Another experimental program which this study suggests concerns the phase diagram of these systems in the $T-E$ plane, where E is the uniform applied field. Since only the LTI phase of NVO or TMO has a spontaneous polarization, this phase is favored (relative to the HTI or AF phases) in the presence of an electric field. So we propose the schematic phase diagram shown in Figure 13. We have not specified the scale of the horizontal axis in this schematic figure, but at least for the LTI–AF transition in NVO we can estimate how thin a film would have to be to produce a 5% shift in the transition temperature for an applied voltage of 5 V. The analog of the Clausius–Clapeyron equation for the LTI–AF phase boundary in the $T-E$ plane is

$$\frac{\mathrm{d}T}{\mathrm{d}E} = \frac{-V(P_{\mathrm{LTI}} - P_{\mathrm{AF}})}{(S_{\mathrm{LTI}} - S_{\mathrm{AF}})} \tag{86}$$

Now take V to be the volume per Ni ion. The volume of the conventional unit cell is $v = abc$, so $V = abc/12$, because there are 12 Ni's per conventional unit cell. $a = 5.9$, $b = 11.4$, and $c = 8.2$, all in 10^{-10} m. For one Ni ion, the total entropy change from zero to infinite temperature is $k \ln 3$. Guided by specific heat measurements (Lawes *et al*., 2004) we set

$$(S_+ - S_-) = 0.01k \ln 3 \tag{87}$$

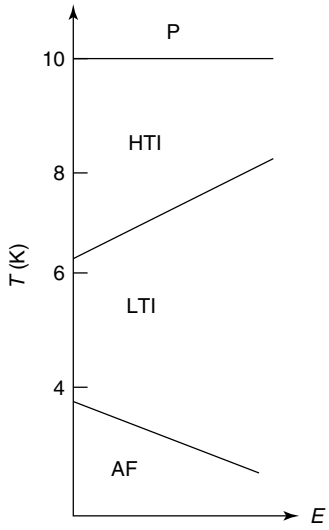

Figure 13. Schematic phase diagram for a system like NVO in the $T-E$ plane. (We do not give the scale of the E axis.)

and take $P = 5 \times 10^{-4}\,\mathrm{C\,m^{-2}}$ as a typical value. Then we find

$$\frac{\mathrm{d}T}{\mathrm{d}E} = -[(540 \times 10^{-30}\,\mathrm{m^3}/12)](5 \times 10^{-4}\,\mathrm{C\,m^{-2}})/ [1.4 \times 10^{-25}\,\mathrm{JK^{-1}}] = 1.5 \times 10^{-7}\,\mathrm{Km\,V^{-1}} \tag{88}$$

To see roughly what this means, set $\mathrm{d}T = 0.05\,T_c = 0.2\,\mathrm{K}$ and $\mathrm{d}E = 5\mathrm{V}/t$, where t is the thickness of the sample. This gives $0.2t \times 10^{-8}$, or $t \approx 1\,\mu$.

Finally, we emphasize that it would be desirable to determine the magnetic structure of TMO for high magnetic fields along the **a** or **b** direction to test whether the magnetic structure proposed below equation (63) is realized.

8.4 Theoretical outlook

It is clear that the next step for theorists is to construct a fully microscopic theory to explain the phenomenological trilinear interaction highlighted in this review. Here, we indicated how the dependence of the exchange interaction on ionic displacements gives rise to the symmetries expected from Landau theory. What is clearly missing is a microscopic calculation of the exchange constants. This sort of calculation as a function of bond angles has been pursued for Cu–O–Cu bonds (Tornow, Entin-Wohlman and Aharony, 1999). However, what is needed here is the more complicated calculation for Ni–O–Ni bonds and furthermore, it would seem that this is going to require some sort of calculation based on the local density approximation to determine the dependence of the exchange tensors on ionic displacements. Calculations of this type are being carried out.

9 RECENT DEVELOPMENTS

Subsequent to preparation of this review there have been several important studies of optical and dynamical properties of multiferroic systems. We give a very brief overview of work in these two areas.

We first consider the optical properties of phonon modes. We remind the reader of the crucial fact that for systems with inversion symmetry the modes at zero wave vector can be classified as being either even or odd under inversion symmetry. Only odd modes can be detected by absorption of electromagnetic radiation and only even modes contribute to Raman scattering (in which an outgoing photon is observed with a small shift in energy from the incoming photon due to creation or destruction of an elementary excitation of the system). Of course, when the system develops a spontaneous polarization, this selection rule is broken in a way that one can analyze by asking what ferroelectric subgroups are contained in the original centrosymmetric space group. Here, we give a simple approach to elucidate the mechanisms involved in breaking inversion symmetry. For this purpose, we construct an effective linear coupling between even and odd modes which leads to their mixing and concomitant breakdown of the even–odd selection rule due to the presence of a spontaneous polarization. We consider the expansion in terms of displacements relative to the inversion symmetric structure. In that expansion inversion symmetry does not permit the existence of a linear even–odd phonon coupling of the form

$$V = \sum_{m,n} c_{nm} Q_{\mathrm{odd},n} Q_{\mathrm{even},m} \tag{89}$$

where $Q_{\mathrm{odd},n}$ is the amplitude of the nth odd phonon mode at zero wave vector and $Q_{\mathrm{even},m}$ is that of the mth even phonon mode at zero wave vector. So we consider the anharmonic perturbation V_3 due to the interaction of three phonons:

$$V_3 = \sum_{\mathbf{k}_1,\mathbf{k}_2\mathbf{k}_3} \sum_{r,s,t} c_{rst} Q_r(\mathbf{k}_1) Q_s(\mathbf{k}_2) Q_t(\mathbf{k}_3) \times \Delta(\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3) \tag{90}$$

where $Q_n(\mathbf{k})$ is the amplitude of the nth phonon at wave vector $\mathbf{k}$ and Δ expresses the conservation of wave vector modulo a reciprocal lattice vector. We replace one of these phonon amplitudes by its equilibrium value in the ferroelectric phase. For concreteness we specialize to the case of NVO where the condensed phonons which give rise to the observed spontaneous polarization along the y axis are $Q_{y_n}(0)$, the nth y like mode at zero wave vector. Thus, the coupling we seek is of the form

$$V \sim \sum_{\mathbf{k}} \sum_{r,s,t} c_{rst} Q_r(\mathbf{k}) Q_s(-\mathbf{k}) \langle Q_{y_t}(0) \rangle \tag{91}$$

where $\langle Q_{y_t}(0) \rangle$ is the amplitude of the static distortion in the phonon coordinate $Q_{y_t}(0)$. We then see that the coupling at zero wave vector is of the form

$$V \sim P_y \sum_{m,n} d_{mn} Q_{\mathrm{even},m}(0) Q_{\mathrm{odd},n}(0) \tag{92}$$

As a result of this coupling absorption active (odd) modes that transform like x, y, or z will be mixed into Raman active (even) modes that transform like xy, y^2 (A_g), and yz respectively. What this means is that Raman modes of symmetry, say, xy, will now be absorption active for radiation polarized with the electric field along x. Likewise Raman active modes that transform like xy, yz, or A_g will be mixed into absorption active modes that transform like x, z, or y, respectively. (xz Raman modes will get mixed into xyz modes that are silent modes.) As a result, modes that are absorption active with radiation polarized so that the electric field is along x will be weakly Raman active with xy symmetry. For xz symmetry Raman scattering, the polarization will not induce and new modes. This argument explains which modes may now be observed in the presence of the ferroelectric distortion. (Similar conclusions for the optical selection rules for $TbMn_2O_5$ were obtained in Aguilar *et al.*, 2006.) The cross section for distortion-induced absorption or Raman scattering is proportional to the square of the wave function induced by the distortion. Thus the induced cross sections will be proportional to the square of the spontaneous polarization, as is observed (Aguilar *et al.*, 2006). In addition, as the ferroelectric phase is entered there should also appear an anomalous temperature-dependent shift in frequency of the modes proportional to the square of the order parameter.

In addition to the mechanism of equation (90), one may have similar effects from a spin-phonon interaction treated by Fennie and Rabe (2006). This interaction is schematically of the form

$$V = \sum_{\mathbf{r},\,\mathbf{r}',\alpha\beta} \sum_{m,n} Q_m Q_n S_\alpha(\mathbf{r}) S_\beta(\mathbf{r}') Q_m Q_n \frac{\partial^2 J_{\alpha,\beta}(\mathbf{r},\mathbf{r}')}{\partial Q_m \partial Q_n} \tag{93}$$

where the Q's are phonon amplitudes and $J_{\alpha\beta}(\mathbf{r},\mathbf{r}')$ is an exchange tensor which couples the α component of spin at site $\mathbf{r}$ to the β component of spin at site $\mathbf{r}'$. When $S_\alpha(\mathbf{r}) S_\beta(\mathbf{r}')$ is replaced by its thermal expectation value, a result of the form of equation (92) is obtained, except that P_y is replaced by a spin–spin correlation function, *which has the same symmetry as* P_y.

The spontaneous polarization also has a dramatic effect on the absorption because of magnon creation or excitation. This process, which, in the absence of a spontaneous polarization, is only allowed because of magnetic dipole excitation, now has a strongly enhanced cross section due to admixing of the wave function which allows the highly dominant electric dipole excitation process (Pimenov *et al*., 2006a,b). Thus, even though the wave function of the magnon only suffers a tiny perturbation and energy shift due to magnetoelectric interaction, its absorption cross section is significantly increased because of the possibility of electric dipole excitation. A detailed calculation of this effect has appeared (Katsura, Balatsky and Nagaosa, 2007). However, a simple effective magnon-polarization coupling can be intuited from the trilinear magnetoelectric interaction which is schematically of the form

$$V \sim \sum_{\alpha\beta\gamma} c_{\alpha\beta\gamma}^{\tau\tau'} S_{\alpha\tau}(\mathbf{q}) S_{\beta\tau'}(-\mathbf{q}) P_{\gamma} \tag{94}$$

In a magnetically ordered phase (even one without a spontaneous polarization), we have the effective interaction

$$V \sim \sum_{\alpha\beta\gamma} c_{\alpha\beta\gamma}^{\tau\tau'} \langle S_{\alpha\tau}(\mathbf{q}) \rangle S_{\beta\tau'}(-\mathbf{q}) P_{\gamma} \tag{95}$$

This indicates an effective coupling that mixes the spontaneous polarization (at zero wave vector) into the spin excitation (magnon) at wave vector $\mathbf{q}$ or $-\mathbf{q}$. This would be observed by a huge enhancement of the cross section for absorption of electromagnetic radiation by magnon creation caused by the possibility of an electric dipole process in which radiation at zero wave vector couples to the low-energy magnon at wave vector $\mathbf{q}$. By the Kramers–Kronig relation, this coupling also explains (Sushkov *et al*., 2007) the anomalous enhancement which is seen in some multiferroics when spin ordering takes place.

ACKNOWLEDGMENTS

We have greatly profited from many discussions with A. Aharony, C. Broholm, H. D. Drew, O. Entin-Wohlman, M. Kenzelmann, T. Kimura, A. P. Ramirez, and T. Yildirim. We acknowledge help from B. Adhikary in preparing the figures. ABH thanks the US–Israel BSF for partial support.

APPENDICES

A QUARTIC TERMS

A.1 HTI phase of NVO

Since irrep #4 cannot induce any other irrep, the free energy only involves order parameters of that irrep. (So we will omit the superscript $n = 4$ which labels that irrep.) Then, correct to quartic order we write the free energy associated with irrep #4 as

$$\mathcal{H} = \mathcal{H}^{(2)} + \mathcal{H}^{(4)} + \ldots \tag{A1}$$

where

$$\mathcal{H}^{(2)} = \sum_{\tau\tau'} v_{\tau,\tau'} m_\tau(q)^*\, m_{\tau'}(q) \tag{A2}$$

and

$$\mathcal{H}^{(4)} = (1/4) \sum_{\tau_1,\tau_2,\tau_3,\tau_4} w_{\tau_1,\tau_2,\tau_3,\tau_4} m_{\tau_1}(q)^* \times m_{\tau_2}(q)^*\, m_{\tau_3}(q) m_{\tau_4}(q) \tag{A3}$$

where $m_{\tau=1}(q) = m_{s_x}(q)$, $m_{\tau=2}(q) = m_{s_y}(q)$, $m_{\tau=3}(q) = m_{s_z}(q)$, $m_{\tau=4}(q) = m_{c_y}(q)$, and $m_{\tau=5}(q) = m_{c_z}$, and the spin components at all the sites in the unit cell are given in Table 4 in terms of these variables. Hermiticity implies that $v_{\tau,\tau'} = v^*_{\tau',\tau}$ and

$$w_{\tau_1,\tau_2,\tau_3,\tau_4} = w^*_{\tau_3,\tau_4,\tau_1,\tau_2} \tag{A4}$$

and $\mathbf{w}$ can be taken to be symmetric under interchange of τ_1 and τ_2 and of τ_3 and τ_4. Since $\mathcal{H}^{(4)}$ must be invariant under inversion we have that

$$\begin{aligned}\mathcal{H}^{(4)} &= \frac{1}{4} \sum_{\tau_1,\tau_2,\tau_3,\tau_4} w_{\tau_1,\tau_2,\tau_3,\tau_4} \left[\mathcal{I}m_{\tau_1}(q)^*\right]\left[\mathcal{I}m_{\tau_2}(q)^*\right] \\ &\quad \times \left[\mathcal{I}m_{\tau_3}(q)\right]\left[\mathcal{I}m_{\tau_4}(q)\right] \\ &= \frac{1}{4} \sum_{\tau_1,\tau_2,\tau_3,\tau_4} w_{\tau_1,\tau_2,\tau_3,\tau_4} m_{\tau_1}(q) m_{\tau_2}(q) \\ &\quad \times m_{\tau_3}(q)^*\, m_{\tau_4}(q)^*\end{aligned} \tag{A5}$$

For this to reproduce $\mathcal{H}^{(4)}$ we must have that

$$w_{\tau_1,\tau_2,\tau_3,\tau_4} = w_{\tau_3,\tau_4,\tau_1,\tau_2} \tag{A6}$$

In conjunction with equation (A4), this indicates that all the matrix elements of $\mathbf{w}$ are real.

Now we transform to normal modes:

$$m_\tau(q) = \sum_\rho r_{\tau,\rho} \xi_\rho e^{i\phi_\rho} \tag{A7}$$

$$\boldsymbol{\xi}_{\rho'} = \sum_{\tau'} r_{\tau'\rho'} m_{\tau'}(q) e^{-i\phi_{\rho'}} \equiv \xi_{\rho'} e^{-i\phi_{\rho'}} \tag{A8}$$

where $\rho = 0, 1, 2, 3, 4$ labels the normal mode, the r's are real, and the critical mode (ρ_0) has an amplitude ξ_0 which heretofore we called σ_{HTI}. The quartic Hamiltonian is

$$\mathcal{H}_4 = \frac{1}{4} \sum_{\tau_1,\tau_2,\tau_3,\tau_4} \sum_{\rho_1,\rho_2,\rho_3,\rho_4} w_{\tau_1,\tau_2,\tau_3,\tau_4} r_{\tau_1,\rho_1} r_{\tau_2,\rho_2} r_{\tau_3,\rho_3} \times r_{\tau_4,\rho_4} \xi_{\rho_1} \xi_{\rho_2} \xi_{\rho_3} \xi_{\rho_4} e^{i\left(\phi_{\rho_3} + \phi_{\rho_4} - \phi_{\rho_1} - \phi_{\rho_2}\right)} \tag{A9}$$

This quartic term will involve contributions proportional to $\xi_0^p \equiv \sigma_{\mathrm{HTI}}^p$, where p ranges from zero to four. If we were to omit the quartic terms with $p = 3$, then the minimum of the trial free energy would be realized for $\sigma_{\mathrm{HTI}} \neq 0$, but with the other ξ_ρ's being zero. Therefore, the most important term to consider is the one cubic in σ_{HTI}, which is

$$\begin{aligned}\delta\mathcal{H}_4 &= \frac{1}{2}\sum_{\tau_1,\tau_2,\tau_3,\tau_4}\sum_{\rho=1}^{3} w_{\tau_1,\tau_2,\tau_3,\tau_4} r_{\tau_1,0} r_{\tau_2,0} r_{\tau_3,0} r_{\tau_4,\rho} \\ &\quad\times\ \xi_\rho \sigma_{\mathrm{HTI}}^3 e^{i(\phi_\rho - \phi_{\mathrm{HTI}})} + \text{c. c.} \\ &= \sum_{\rho=1}^{3} A_\rho \xi_\rho \sigma_{\mathrm{HTI}}^3 \cos[\phi_\rho - \phi_{\mathrm{HTI}}] \end{aligned} \tag{A10}$$

where A_ρ is real. The quadratic terms for the noncritical variables can be written as

$$\delta\mathcal{H}_2 = \frac{1}{2}\sum_{\rho=1}^{3} \chi_\rho^{-1} \boldsymbol{\xi}_\rho^* \, \boldsymbol{\xi}_\rho = \frac{1}{2}\sum_{\rho=1}^{3} \chi_\rho^{-1} \xi_\rho^2 \tag{A11}$$

where χ_ρ is the susceptibility of the ρth mode. Then, after minimization with respect to the noncritical variables ξ_ρ for $\rho > 0$, we see that $\cos[\phi_\rho - \phi_{\mathrm{HTI}}] = \pm 1$ (so that σ_{LTI} and σ_{LTI} are in phase) and

$$\xi_\rho = \pm \chi_\rho A_\rho \sigma_{\mathrm{HTI}}^3 \tag{A12}$$

Thus the effect of the quartic terms is to induce nonzero values for the noncritical normal modes and thereby slightly change the components of the critical eigenvector, but the quartic terms do not change the fact that all the order parameters m_τ belong to irrep #4 and that they all have the same relative phase.

A.2 LTI phase of NVO

Now we consider the LTI phase, where we have two irreps simultaneously present. There are various types of quartic terms. First, consider those quartic terms which only involve a single irrep. We can apply the analysis of the HTI phase, to state that such terms do not modify the conclusion that all the symmetry adapted coordinates of irrep #4 have the same phase, ϕ_4, and all the symmetry adapted coordinates of irrep #1 have the same phase ϕ_1.

Next consider the more general quartic terms which involve both irreps. Terms of the type $[m^{(4)}]^* \, [m^{(1)}]^* \, m^{(4)} m^{(1)}$ are independent of the phases and therefore after minimization of the trial free energy these terms do not modify the phases. There are no terms that involve three order parameters of one irrep and one order parameter of the other irrep. So the only terms that might affect the phases are terms of the form $[m^{(4)}]^* \, [m^{(4)}]^* \, m^{(1)} m^{(1)}$ and its complex conjugate. So, we consider quartic terms of the form

$$\begin{aligned} F_4 = &\sum_{\tau_1\tau_2\tau_3\tau_4} w^{(4)(4)(1)(1)}_{\tau_1\tau_2\tau_3\tau_4} m^{(4)}_{\tau_1}(q)^* \, m^{(4)}_{\tau_2}(q)^* \\ &\times\ m^{(1)}_{\tau_3}(q) m^{(1)}_{\tau_4}(q) + \text{c. c.} \end{aligned} \tag{A13}$$

Hermiticity requires that $w^{(4)(4)(1)(1)}_{\tau_1\tau_2\tau_3\tau_4} = [w^{(1)(1)(4)(4)}_{\tau_3\tau_4\tau_1\tau_1}]^*$. Then inversion symmetry indicates that the w coefficients are real. Thus these quartic terms give

$$\begin{aligned} F_4 = A\cos\big[2(\phi_4 - \phi_1)\big] &\sum_{\tau_1\tau_2\tau_3\tau_4}\sum_{\rho_1\rho_2\rho_3\rho_4} r^{(4)}_{\tau_1\rho_1} r^{(4)}_{\tau_2\rho_2} r^{(1)}_{\tau_3\rho_3} \\ &\times\ r^{(1)}_{\tau_4\rho_4} \xi^{(4)}_{\rho_1} \xi^{(4)}_{\rho_2} \xi^{(1)}_{\rho_3} \xi^{(1)}_{\rho_4} \end{aligned} \tag{A14}$$

where the r's are the real-valued transformation coefficients determined in quadratic order. All the quantities in F_4 are real. So F_4 is minimized by either setting $\cos[2(\phi_4 - \phi_1)] = \pm 1$. An explicit calculation for the actual experimentally determined values of the order parameters indicated that the correct choice of sign is the negative sign, and therefore that the two irreps are out of phase with one another. This conclusion agrees with the intuitive argument based on the idea that quartic terms tend to enforce the fixed spin length constraint. When the coordinates of one irrep are maximal, then those of the other irrep should be minimal. Thus, we conclude that $|\sin(\phi_{\mathrm{HTI}} - \phi_{\mathrm{LTI}})| = 1$ in equation (61).

B DO TWO IRREPS INDUCE A THIRD ONE?

When two irreps, $\Gamma_x(q)$ and $\Gamma_y(q)$ are simultaneously present (as happens in the LTI phase), one might ask whether their combination could then induce a third representation, $\Gamma_a(q)$, all of which are assumed to be associated with the selected wave vector q. Since $\Gamma_y(q)\Gamma_y(-q)$ is unity, it is equivalent to ask whether for some k, products like $\Gamma_x(q)^{k-1} \otimes \Gamma_y(-q)^k \otimes \Gamma_a(q)$ or $\Gamma_y(q)^{k-1} \otimes \Gamma_x(-q)^k \otimes \Gamma_a(q)$ transform like unity. (The form of this product is dictated by wave vector conservation. In this connection, we neglect the possible effects of Umklapp terms.) If one of these products satisfies this condition, then the existing order parameters can give rise to a linear field acting on $\Gamma_a(q)$, thereby inducing a nonzero value for this representation. By explicit enumeration of the various cases, one can verify that the condition to induce a third irrep cannot be satisfied. If, hypothetically, there existed a third phase transition in which a third irrep condensed, then the presence of these three irreps would induce the fourth irrep.

Magnetism and Quantum Criticality in Heavy-Fermion Compounds: Interplay with Superconductivity

Oliver Stockert[1], Michael Nicklas[1], Peter Thalmeier[1], Philipp Gegenwart[2] and Frank Steglich[1]

1 INTRODUCTION

Intermetallic systems with strong electronic correlations continue to be of interest since these systems can serve as model systems to study electron interactions. The strong electron interactions result in a largely enhanced effective mass of the quasiparticles, hence the name heavy-fermion (HF) systems. The electronic interactions can lead to a variety of different ground states: paramagnetic, magnetically ordered, or superconducting. Most ordered systems show antiferromagnetic (AF) order, only a few compounds order ferromagnetically. Especially the interplay between magnetic order and superconductivity (SC) attracts special interest.

Research in the two decades after first observations in $CeAl_3$ in 1975 (Andres, Graebner and Ott, 1975) and following the discovery of HF SC in $CeCu_2Si_2$ in 1979 (Steglich *et al*., 1979), by which it was verified that the low-temperature anomalies found in $CeAl_2$ are indeed due to charge carriers with very large effective mass ($m \approx 1000 m_e$ with m_e being the free electron mass, 'heavy fermions'), was driven by the discovery of new systems and the investigation of their properties. In contrast, during the last decade the research focused mainly on two topics: (i) the interplay between magnetic order and SC, and (ii) the behavior at magnetic instabilities at $T = 0$, that is, at a so-called quantum phase transition (QPT). Interplay between SC and magnetic order is an important issue since in classical superconductors magnetic impurities suppress SC while in HF superconductors the magnetic f electrons are essential and are involved in the superconducting pairing mechanism and form Cooper pairs. In contrast to phonon-mediated SC there seems to be growing evidence that in HF superconductors spin fluctuations play the role as superconducting glue. HF superconductors usually do not show an isotropic superconducting energy gap, but have unusual order parameters with an anisotropic gap and line or point nodes where the gap vanishes. Coexistence and/or competition of both phenomena, magnetism and SC, can also have important implications for the order parameters which might have to be compatible with each other. The appearance of SC is closely related to QPTs. At a

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

QPT a magnetically ordered phase vanishes as a function of an external parameter, the ordering temperature is suppressed to $T_{N/c} = 0$. In the case of a continuous phase transition tuned to occur at $T = 0$, this $T = 0$ QPT is then called a *quantum critical point* (QCP). In the vicinity of such a magnetic instability unusual low-temperature behavior in thermodynamic and transport properties is observed, called *non-Fermi-liquid behavior*. Sometimes these systems become superconducting close to the QPTs. Since the transition from a nonmagnetic to a magnetically ordered state occurs at $T = 0$, quantum rather than thermal fluctuations become critical at the QPT. It is this nature of these quantum fluctuations that attracts experimentalists as well as theorists.

We focus our review on only a few typical model systems. They are prominent examples for the interplay between SC and magnetic order or for systems close to a QCP. We will present thermodynamic and transport properties and show in addition microscopic measurements like nuclear magnetic/quadrupole resonance, muon spin rotation or neutron scattering.

General reviews about the experimental situation in HF systems can be found in (Grewe and Steglich, 1991; Kuramoto and Kitaoka, 2000; Stewart, 2001) while an overview of theoretical concepts, especially on the interplay between magnetism and SC is given in (Thalmeier *et al*., 2005).

This overview is organized as follows. We first introduce the basic concept of QPTs and QCPs and present a simple microscopic model to describe HF systems (Section 2). We will then move on to the archetypal system $CeCu_2Si_2$ in Section 3. A relatively new class of materials is derived from the classical $CeIn_3$, the Ce115 systems, being close to quantum criticality and exhibiting a rich variety of magnetically ordered phases and SC. They can be described within a conventional picture of QCPs. Then theoretical aspects about different behavior at QPTs are presented. While systems showing a conventional behavior at a QCP sometimes exhibit SC, unconventional behavior seems to exclude the appearance of SC. We restrict ourselves to one important member with unconventional behavior which will be presented in Section 4: $YbRh_2Si_2$. This compound was only discovered a few years ago in contrast to the system $CeCu_{6-x}Au_x$, which has been known for roughly two decades. We end with a short summary and outlook (Section 5).

2 QUANTUM PHASE TRANSITIONS

Many strongly correlated electron (HF) systems, usually intermetallic rare-earth compounds containing mainly cerium (Ce) or ytterbium (Yb), can be tuned continuously from a magnetically ordered to a nonmagnetic ground state by means of an external control parameter such as doping x, hydrostatic pressure p, or magnetic field B. This offers the possibility to induce a $T = 0$ phase transition, a so-called QPT, separating a magnetically ordered state from a nonmagnetic ground state at $T = 0$. Instead of being driven by thermal fluctuations as for finite temperature phase transitions, a magnetic–nonmagnetic transition as a function of the control parameter at absolute zero is driven by quantum fluctuations. If a continuous phase transition is tuned to $T = 0$, we will call this special QPT in the following a QCP. Around the critical value of the control parameter where the magnetic order vanishes, that is, for $T_{N/c} = 0$ at the QCP, these systems no longer behave as Fermi liquids (FLs) like usual metals but exhibit strong deviations from FL behavior in thermodynamic and transport properties at low temperatures, called *non-Fermi-liquid* (NFL) behavior. This NFL behavior is visible for example, in the specific heat showing a specific heat coefficient $\gamma = C/T$ quite often diverging as the logarithm of the temperature, $\gamma = C/T \propto -\ln T$, or an electrical resistivity varying with temperature as $\Delta\rho \propto T^n$, $n < 2$. These T dependences are in marked contrast to the predictions for a Landau–Fermi liquid (LFL) with $\gamma = \text{const}$ or $\Delta\rho = T^2$. The general phase diagram of systems close to a QCP is displayed in Figure 1. Some compounds even become superconducting in the vicinity of the QCP with indications for unconventional SC.

However, the concept of QCPs is not restricted only to magnetic and HF systems but is a more general concept for systems where a second-order phase transition separates an ordered phase from a nonordered one and where the phase transition can be tuned to $T_c = 0$. While for finite temperature phase transitions the critical fluctuations are restricted to a region just around the ordering temperature or a small fraction in reduced temperature given by the energy scale of the transition temperature, such an energy scale does not

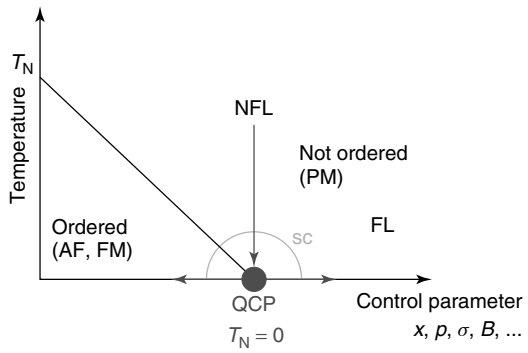

Figure 1. General phase diagram of magnetic systems close to a quantum critical point (QCP) where $T_N \to 0$. At the QCP, unusual temperature dependences in thermodynamic properties are observed (NFL). Sometimes superconductivity (SC) occurs in the vicinity of the QCP.

exist at the QCP and the temperature itself is the scale for spin excitations. These low-energy spin excitations becoming critical at the QCP are discussed as the possible origin for the NFL behavior. Here the nature and dimensionality of these critical fluctuations play a crucial role. Their character may also be responsible for the occurrence of SC in the vicinity of a QCP in some of the systems.

A simple microscopic approach to understand the physics at a QCP is the so-called Doniach model (Doniach, 1977), which starts from the competition between the Kondo effect and the Ruderman–Kittel–Kasuya–Yosida (RKKY) interaction. Here the Kondo effect describes the exchange interaction between a magnetic impurity and conduction electrons. For an AF coupling with coupling constant J the impurity spin is completely screened by conduction electrons at low temperatures, resulting in the formation of a nonmagnetic Kondo-singlet ground state. This Kondo singlet is accompanied by an energy gain of $k_{\mathrm{B}}T_{\mathrm{K}} \propto e^{-1/JN(E_{\mathrm{F}})}$ with T_{K} the Kondo temperature. In HF systems however, independent magnetic impurity spins are no longer present, but they form a periodic array of f electrons (Kondo lattice). This slightly modifies the effective T_{K}. On the other hand, the f electrons can interact with each other through the RKKY interaction. This interaction is mediated via the conduction electrons and favors a magnetically ordered ground state. As for the Kondo effect, the coupling constant between local spin and conduction electrons is important. However, it enters into the energy gain of the system in a different way from that for the Kondo effect. For the RKKY interaction the energy is then lowered by $k_{\mathrm{B}}T_{\mathrm{RKKY}} \propto J^2N(E_{\mathrm{F}})$. The ground state in HF systems is now determined by the competition between Kondo effect and RKKY interaction. If the Kondo interaction dominates, the system orders magnetically. In the case of a stronger Kondo effect, a nonmagnetic ground state is formed and usually FL behavior is observed. Since both interactions depend on the coupling constant J between the local moments and the conduction electrons and J can be changed by hydrostatic pressure, magnetic field, or chemical substitution, the ground state in these systems can be tuned from magnetically ordered to a nonmagnetic ground state. At the QCP where both interactions cancel each other, interactions that are usually weaker can become dominant and for example, SC can occur.

3 CONVENTIONAL QUANTUM CRITICALITY

3.1 $CeCu_2Si_2$

$CeCu_2Si_2$ is one of the prototypical HF compounds exhibiting antiferromagnetism and SC at low temperatures. Both phenomena are observed below 1 K and the interplay can be adjusted sensitively by very small changes in sample composition or by applying hydrostatic pressure. Especially this interplay between both ground states and the vicinity of the compound to a QCP at the disappearance of the AF order attract both experimentalists and theorists.

Although the superconducting properties of $CeCu_2Si_2$ ($T_{\mathrm{c}} \approx 600\,\mathrm{mK}$, $B_{\mathrm{c}2} \approx 1\,\mathrm{T}$) were already discovered more than 25 years ago (Steglich *et al.*, 1979), the nature of the HF SC still remains unclear. The compound forms only in a very narrow range of the ternary phase diagram Ce:Cu:Si around the 1:2:2 composition (Steglich *et al.*, 1996) and crystallizes in the tetragonal $ThCr_2Si_2$ structure (space group $I4/mmm$) with lattice constants $a = 4.1\,\text{Å}$ and $c = 9.9\,\text{Å}$. However, the ground state depends very delicately on the actual composition. Thus, Cu-rich samples exhibit only SC (S phase) and Si-rich ones only show magnetic order (A phase), while in stoichiometric samples (A/S-type) a complex interaction between SC and magnetic order occurs (Steglich, Gegenwart and Geibel, 2001). The origin of the AF order was unraveled only very recently (Stockert *et al.*, 2004). First indications of magnetic order in $CeCu_2Si_2$ were already given in the late 1980s by muon spin rotation (μSR) and nuclear magnetic resonance (NMR) measurements (Nakamura, Kitaoka, Yamada and Asayama, 1988; Uemura *et al.*, 1989). Both techniques found order with static or slowly fluctuating moments of the order of $0.1\mu_{\mathrm{B}}$. Successive neutron-scattering studies failed in detecting any magnetic intensity. Therefore this unusual ordered state, called *A phase*, was thoroughly investigated by thermodynamic and transport properties in the 1990s. The A phase forms below $T \approx 600-800\,\mathrm{mK}$ and upon applying a magnetic field at low temperatures the magnetic A phase is suppressed in a field of $B \approx 7-8\,\mathrm{T}$ giving rise to another ordered phase, called *B phase*, which first detected by ultrasound attenuation measurements (Bruls *et al.*, 1994). All these measurements revealed a complex (B, T) phase diagram (Bruls *et al.*, 1994; Steglich *et al.*, 1996; Gegenwart *et al.*, 1998) with different magnetically ordered and superconducting phases depending on the actual stoichiometry. Electrical resistivity measurements gave first hints about the origin of the A phase in $CeCu_2Si_2$ (Gegenwart *et al.*, 1997, 1998). The relative increase of the resistivity below the ordering temperature along a certain direction, while along another direction a drop in the resistivity was observed, suggested the opening of a gap. Hence, it was speculated that the A phase was a spin-density wave.

For a better understanding of the ground-state properties initial experiments have been performed under hydrostatic pressure (Yuan *et al.*, 2003; Holmes, Jaccard and Miyake, 2004; Lengyel *et al.*, 2006) in addition to experiments on the Ge-substituted system $CeCu_2(Si_{1-x}Ge_x)_2$ (Knebel *et al.*, 1996; Trovarelli *et al.*, 1997; Deppe *et al.*, 2004; Oeschler

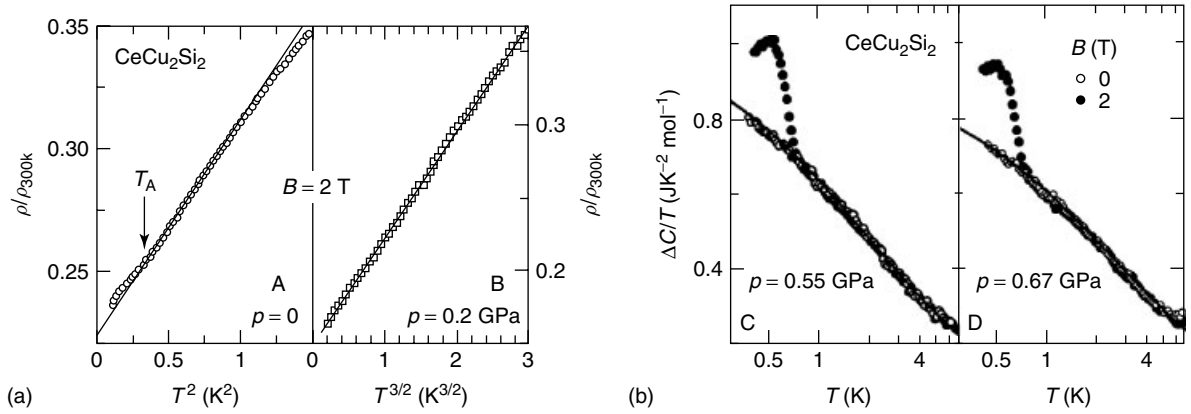

Figure 2. Non-Fermi-liquid behavior of the electrical resisitivity (A, B) and the specific heat (C, D) in pressure-tuned $CeCu_2Si_2$ when applying an overcritical magnetic field to kill superconductivity (Sparn *et al.*, 1998). At the QCP the resistivity varies as $\Delta\rho \propto T^{3/2}$, while the specific heat $\Delta C/T$ follows a $\sqrt{T}$ behavior. Note the relative increase of ρ below the ordering temperature at ambient pressure indicating the opening of a charge gap.

et al., 2005). They suggest that $CeCu_2Si_2$ is located quite close to a QCP at the disappearance of the A phase. While Ge doping expands the lattice and thus stabilizes the magnetic A-phase order (Knebel *et al.*, 1996; Trovarelli *et al.*, 1997), hydrostatic pressure acts in the opposite way, suppressing the A phase (Yuan *et al.*, 2003; Lengyel *et al.*, 2006). A-phase magnetism disappears continuously as a function of pressure and, around the QCP, SC appears in $CeCu_2Si_2$. When applying a magnetic field to kill SC, NFL behavior is observed, for example, in the specific heat or the electrical resistivity (Gegenwart *et al.*, 1998). Thus, the specific heat exhibits a temperature dependence $C/T = \gamma_0 - \alpha\sqrt{T}$ for $T \to 0$ and the electrical resistivity varies with temperature as $\Delta\rho \propto T^{3/2}$ (cf. Figure 2). These results are compatible with a three-dimensional spin-density-wave instability within the Hertz–Millis theory.

However, SC is not only detected in a narrow range around the critical pressure to suppress magnetism (up to a few tenths of GPa), but extends to very high pressures (more than 7 GPa) (cf. Figure 3). This behavior is similar to the related compound $CeCu_2Ge_2$ (Jaccard, Wilhelm, Alami-Yadri and Vargoz, 1999), but in marked contrast to other Ce-based HF systems, like $CePd_2Si_2$ or $CeIn_3$ (Mathur *et al.*, 1998), which can be tuned to a QCP by pressure. In these systems, SC is detected only in a narrow pressure range around the critical pressure, necessary to suppress magnetic order. Pressure experiments on pure $CeCu_2Si_2$ (Holmes, Jaccard and Miyake, 2004) and lightly Ge-doped $CeCu_2(Si_{1-x}Ge_x)_2$ (Yuan *et al.*, 2003) to reduce the mean free path and therefore weaken the SC, established in fact two distinct superconducting regimes at low and at high pressure. In pure $CeCu_2Si_2$ both superconducting regions merge to form one superconducting phase extending from low to high pressure. The superconducting high-pressure regime seems to coincide with a weak first-order valence transition of cerium in $CeCu_2Si_2$. Such a transition has been reported in the related compound $CeCu_2Ge_2$ by X-ray diffractometry (Onodera *et al.*, 2002). For the moderately Ge-doped $CeCu_2Si_2$ single crystals this was concluded from recent resistivity data (Yuan *et al.*, 2006). Since the critical endpoint of this first-order valence-transition phase boundary is very low ($T < 20$ K) for these alloys (Yuan *et al.*, 2006), some sufficiently soft valence fluctuations are likely to exist under the high-pressure superconducting dome where they

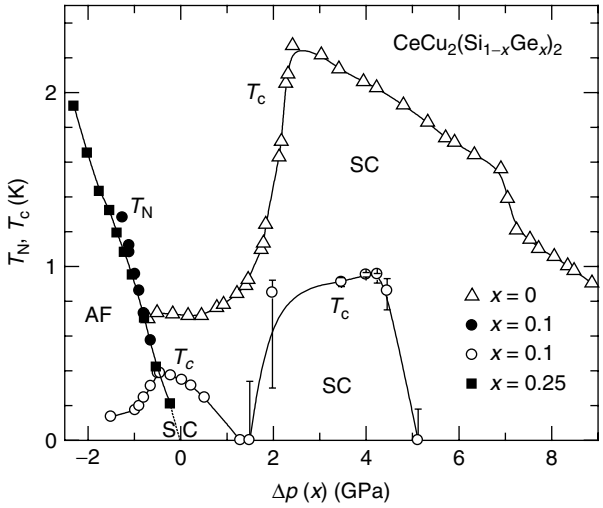

Figure 3. Temperature–pressure phase diagram of $CeCu_2(Si_{1-x}Ge_x)_2$ indicating the pressure dependence of the transitions into the antiferromagnetically ordered state (closed symbols) and the superconducting states (open symbols). The data are plotted as a function of relative pressure $\Delta p = p - p_c$ in a way that the magnetic transition lines for all Ge concentrations coincide. (Reprinted with permission Stockert *et al.*, copyright 2004, American Physical Society.)

may mediate Cooper-pair formation (Miyake, Narikiyo and Onishi, 1999). Therefore, the two distinct superconducting regimes in $CeCu_2Si_2$ may indeed arise owing to different pairing mechanisms, related to fluctuations of the spin density at low pressure and of the charge density at high pressure.

The recent availability of large $CeCu_2Si_2$ single crystals with well-defined physical properties allowed single crystal neutron diffraction to be performed for the first time (Stockert *et al.*, 2004). Incommensurate AF order was found in an A-type single crystal with a propagation vector $\mathbf{Q} = (0.215, 0.215, 0.530)$ at $T = 50\,\mathrm{mK}$ as displayed in Figure 4(a) (Stockert *et al.*, 2004). The magnetic intensity vanishes at $T_\mathrm{N} = 800\,\mathrm{mK}$ in close accordance with thermodynamic measurements and the ordered moment has been estimated to be $m_0 \approx 0.1\,\mu_\mathrm{B}$ assuming a sinusoidal modulation of the magnetic moments lying in the basal plane.

The incommensurate magnetic order is determined by nesting properties of Fermi surface as suggested by renormalized band structure calculation (Zwicknagl and Pulst, 1993; Stockert *et al.*, 2004). The Fermi surface of the heavy quasiparticles ($m^* \approx 500\,m_0$) has been calculated with the renormalized band method (Zwicknagl, 1993) and indicates nesting for the incommensurate wave vector $\mathbf{q} \approx (0.21, 0.21, 0.55)$ (Stockert *et al.*, 2004). Further hints are given by the direct calculation of the wave vector–dependent static susceptibility $\chi(\mathbf{q})$. The maximum of $\chi(\mathbf{q})$ coincides with the propagation vector observed in the neutron experiments as shown in Figure 4(b) (Stockert *et al.*, 2004). Therefore at low temperatures the renormalized Fermi surface is indeed unstable with respect to the formation of a spin-density wave. This observation of a low-moment spin-density wave explains why the pronounced NFL behavior in normal-state $CeCu_2Si_2$ satisfactorily agrees with the predictions of the Hertz–Millis–Moriya theory for three-dimensional critical AF spin fluctuations.

With the knowledge of the A-phase magnetism, A/S-type single crystals have been investigated. These crystals are located closer to the QCP as the Néel temperature is already reduced to $T_\mathrm{N} \approx 700\,\mathrm{mK}$. In elastic neutron-scattering experiments (Stockert *et al.*, 2005; Thalmeier *et al.*, 2005) magnetic intensity has been detected below T_N at the same positions as for pure A-type crystals showing that the incommensurate magnetic order is quite unaffected by slight changes in the stoichiometry. Surprisingly, the magnetic intensity vanishes inside the superconducting state well below $T_\mathrm{c} \approx 550\,\mathrm{mK}$ (cf. Figure 5). Therefore, SC and AF order do not coexist on a microscopic scale. Instead, SC expels magnetism at low temperatures. These findings are confirmed by a μSR measurements on the same A/S-type single crystal (Stockert *et al.*, 2006). The new results are in line with previous μSR and nuclear quadrupole resonance (NQR) experiments

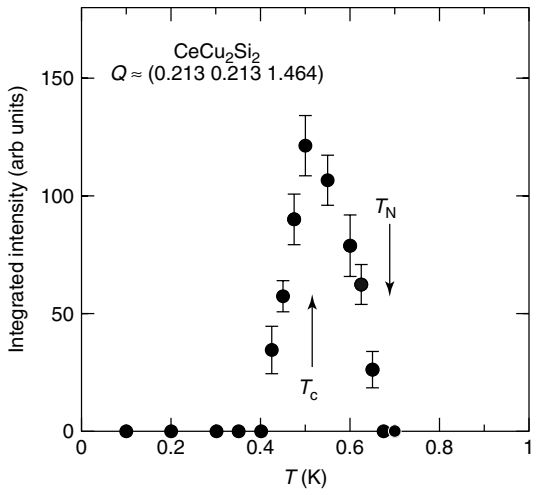

Figure 5. Temperature dependence of the intensity of a magnetic superstructure reflection in A/S-type $CeCu_2Si_2$. (Reprinted with permission Thalmeier *et al.*, copyright 2005, Springer Verlag, Berlin.)

(Feyerherm *et al*., 1997; Ishida *et al*., 1999), which were restricted at that time to polycrystalline samples, but also found phase separation between AF and superconducting phases.

Current studies on $CeCu_2Si_2$ focus on the nature of the superconducting pairing mechanism aiming to detect the charge and/or spin excitation gap and the symmetry of the order parameter in the superconducting state.

3.2 $CeTIn_5$ (T = Co, Rh, Ir)

The discovery of SC in the new class of HF compounds with the general formula $Ce_nT_mIn_{3n+2m}$ (T = Co, Ir, Rh) extended the number of unusual HF systems showing an intensive interplay of magnetism and SC.

This family of materials is composed of alternating n-fold layers of $CeIn_3$ and m-fold layers of TIn_2 crystallizing in the tetragonal $HoCoGa_5$ structure-type (space group $P4/mmm$) (Grin, Yarmolyuk and Gladyshevskii, 1979). The parent compound $CeIn_3$ ($n = \infty$), orders in a commensurate AF structure below $T_N = 10\,K$. Magnetism is suppressed to $T_N = 0\,K$ at a critical pressure of $p_c \approx 2.5\,GPa$, and right in the vicinity of p_c SC is developing below $T_c = 200\,mK$ (Mathur *et al*., 1998). At the critical pressure the low-temperature normal-state resistivity can be described by a power law $\rho = \rho_0 + A'T^{\varepsilon}$, where ρ_0 is the residual resistivity and the exponent $\varepsilon \approx 1.6$ is indicative of NFL behavior (Mathur *et al*., 1998; Knebel *et al*., 2001). The single-layered descendants consisting of $CeIn_3$ layers separated by TIn_2 exhibit a variety of fascinating physical properties caused by the intimate interrelationship of magnetism, SC, and dimensionality. $CeCoIn_5$ and $CeIrIn_5$ are superconducting below $T_c = 2.3\,K$ (Petrovic *et al*., 2001) and $T_c = 0.4\,K$ (Petrovic *et al*., 2001), respectively. $CeCoIn_5$ exhibits the highest T_c among the Ce-based HF superconductors at ambient pressure. $CeRhIn_5$ orders antiferromagnetically below $T_N = 3.8\,K$ (Hegger *et al*., 2000) at atmospheric pressure, and SC develops under hydrostatic pressure ($p > 0.9$ GPa) (Hegger *et al*., 2000; Llobet *et al*., 2004) with a maximum $T_c = 2.12\,K$ at 2.1 GPa, similar to the parent compound $CeIn_3$, but with a maximum T_c being one order of magnitude higher.

We want to start our discussion with the magnetic properties of $CeRhIn_5$. Without the existence of this magnetic representative of the $CeTIn_5$ family the role of magnetism in its nonmagnetic, superconducting compounds Co and Ir homologs would be even more in disguise. $CeRhIn_5$ orders in an incommensurate structure with a propagation vector $(0.5, 0.5, \delta = 0.297)$ (Bao *et al*., 2000, 2001) corresponding to a simple AF structure in the basal plane and a tilting by $\delta = 107^{\circ}$ between the moments in different planes along the c axis. The magnetic moment ($\mu \approx 0.8\,\mu_B$) (Llobet *et al*., 2004) (the originally published value (Bao *et al*., 2000, 2001) was corrected in (Llobet *et al*., 2004)) is only 20% smaller than the full moment obtained from crystal-electric-field (CEF) calculations ($\mu = 0.92\,\mu_B$) not taking into account the reduction of the measured moment by the Kondo effect. The ordered moment in $CeRhIn_5$ is much larger than that, for example, in $CeCu_2Si_2$ ($\mu = 0.1\,\mu_B$) (Stockert *et al*., 2004).

$CeRhIn_5$ has localized 4f electron states which are CEF split into three Kramers doublets $\Gamma_7^1(0)$, $\Gamma_7^2(6.9\,meV)$, and $\Gamma_6(23.6\,meV)$ (Christianson *et al*., 2004). Therefore, the low-temperature properties are determined exclusively by the ground-state doublet. De Haas–van Alphen (dHvA) studies and local density approximation (LDA) calculations have been carried out showing that $CeRhIn_5$ has indeed, as expected for localized 4f electrons, a Fermi surface similar to that of the reference compound $LaRhIn_5$ (Shishido *et al*., 2002; Hall *et al*., 2001a). On the other hand, the low-temperature Fermi surface in $CeCoIn_5$ (Hall *et al*., 2001b; Shishido *et al*., 2002) and $CeIrIn_5$ (Haga *et al*., 2001; Shishido *et al*., 2002) is best described by including the 4f electrons and considering them as itinerant. The layered structure produces an anisotropic electronic structure reflected in the Fermi surface by almost cylindrical shapes. Though these compounds should not be considered as purely two dimensional, their structural (electronic) anisotropy has an essential influence on their ground-state properties.

Applying pressure in $CeRhIn_5$ first leads to a slight increase of the Néel temperature T_N to a maximum value of $T_N \approx 3.9\,K$ at 0.8 GPa, before the magnetic ground state becomes less favorable and T_N drops, typical for a Ce-based magnetically ordered HF compound near its magnetic instability. The staggered magnetic moment decreases little with increasing pressure (Llobet *et al*., 2004; Majumdar *et al*., 2002). Llobet *et al*. (2004) find only a slight enhancement of the discommensuration. No magnetic order is evident at $p = 1.85\,GPa$ and $T = 1.8\,K$ in their data anymore. In contrast, a marked change of the wave vector at 1 GPa is reported by Majumdar *et al*. (2002). Zero resistance and the onset of a diamagnetic response in the susceptibility indicating the development of SC is already observed deep inside the AF phase for $p \gtrsim 0.9$ (Nicklas *et al*., 2004), while clear evidence for *bulk* SC from specific heat experiments inside the AF phase is reported only close to the pressure where T_N meets T_c (Knebel *et al*., 2004). No trace of the Néel transition appears inside the superconducting phase at zero magnetic field for $T_N < T_c$ suggesting that AF order disappears abruptly as a function of pressure. It is remarkable that at about $p_c \approx 2.3\,GPa$ a drastic change of the 4f electron nature from localized to itinerant takes place as evidenced by the disappearance of the dHvA frequencies for the main branches together with those characteristic for

the antiferromagnetism and the appearance of new branches ($p > 2.3$ GPa) (Shishido, Settai, Harima and Ōnuki, 2005). These new branches are qualitatively the same as those in $CeCoIn_5$, consistent with LDA calculation taking the 4f electrons as part of the Fermi surface (Shishido *et al.*, 2002). A magnetic field $B > 2$ T induces a magnetic transition inside the SC state which evolves smoothly from $T_N(p)$ with increasing pressure (Park *et al.*, 2006; Knebel *et al.*, 2006). The temperature, where the line of field-induced transition crosses the superconducting upper critical field in the $H-T$ phase diagram [$T_M(H = H_{c2})$], extrapolates to zero at $p_c \approx 2.25$ GPa at about the pressure where the size of the Fermi surface changes (Shishido, Settai, Harima and Ōnuki, 2005). This might be taken as evidence for a locally critical QCP (Si, Rabello, Ingersent and Smith, 2001). However, dHvA experiments are carried out at a magnetic field of the order of 10 T. At atmospheric pressure, the Kondo temperature is of the order of the Néel temperature ($T_N = 3.8$ K) corresponding to a Kondo field of about $B_K \sim 1$ T (Hegger *et al.*, 2000; Curro *et al.*, 2003). B_K is usually increasing with pressure in Ce-based HF systems and, therefore, it is conceivable that $B_K(p)$ will reach the measuring field of the dHvA experiments close to p_c. Here, it is worth noting that in HF compounds commonly both *local* Kondo and *nonlocal* magnetic (AF or ferromagnetic (FM)) correlations become frozen below $T \approx T_K(B = 0)$ and $B \approx B_K(T = 0)$, respectively (Grewe and Steglich, 1991). Thus for instance, in $CeRu_2Si_2$ (AF correlations) the Kondo temperature and the metamagnetic field show the same pressure-dependent increment (Mignot *et al.*, 1988). A similar observation was recently made for $YbRh_2Si_2$ with dominating FM correlations in wide parts of the $B-T$ phase diagram (cf. Section 4.1) (Tokiwa *et al.*, 2005). It is therefore possible that the measuring field of the dHvA experiments performed on $CeRhIn_5$ under $p \approx p_c$ has the meaning of a metamagnetic field. This would in a natural way explain the observed change of the Fermi surface: for $p < p_c$ the measuring field would be greater than B_K explaining the local character of the 4f electrons, while for $p > p_c$, with further increasing B_K the 4f electrons in dHvA experiments would appear to be part of a larger Fermi surface because of the Kondo screening. Alternatively, the divergence of the cyclotron mass when approaching the critical pressure p_c from either side (Shishido, Settai, Harima and Ōnuki, 2005) may well be taken as evidence for unconventional quantum criticality (cf. Section 4).

Substituting Rh by the isoelectronic Co or Ir, $CeRhIn_5$ slowly looses the AF phase (Pagliuso *et al.*, 2002; Zapf *et al.*, 2001). As a consequence of replacing Rh by Co the unit-cell volume shrinks and one, therefore, expects a suppression of the AF order. For $x \gtrsim 0.70$ in $CeRh_{1-x}Co_xIn_5$ no magnetic order is indeed present anymore (Zapf *et al.*, 2001). Already at a doping level of $x \gtrsim 0.35$, bulk SC occurs coexisting with AF order, and persists up to stochiometric $CeCoIn_5$. Ir doping suppresses T_N in $CeRh_{1-x}Ir_xIn_5$ at concentration $x \approx 0.65$, and an extended range of microscopic coexistence of SC and AF ($0.35 \leq x \leq 0.65$) exists (Pagliuso *et al.*, 2002). The microscopic coexistence was confirmed by susceptibility measurements conducted simultaneously with NQR (Zheng *et al.*, 2004) and μSR (Morris *et al.*, 2003) experiments. However, the SC phase does not represent an ideal dome-shape as, for example, in $CeIn_3$. In contrast to Co substitution, the unit-cell volume increases slightly on Ir-doping showing that volume is not the only relevant control parameter. A cusplike minimum in $T_c(x)$ appears at $x = 0.9$ in (Pagliuso *et al.*, 2001; Pagliuso *et al.*, 2002; Nicklas *et al.*, 2004). Under the application of hydrostatic pressure, this minimum evolves in a region where SC is removed from the $x-T$ phase diagram leaving two distinct superconducting phases, SC1 and SC2 (see Figure 6) (Nicklas *et al.*, 2004). Upon applying pressure, AF order is giving away for SC, while the maximum of T_c is roughly tracking the critical pressure p_c on the Rh-rich side of the phase diagram. At 1.75 GPa, AF order has nearly completely disappeared from the $x-T$ phase diagram and the SC1 phase extends in the whole range from $CeRhIn_5$ up to $x \approx 0.75$. This is taken as a hint to spin-fluctuation-mediated SC, whereas the nature of the SC2 phase in the immediate proximity to $CeIrIn_5$ remains unclear.

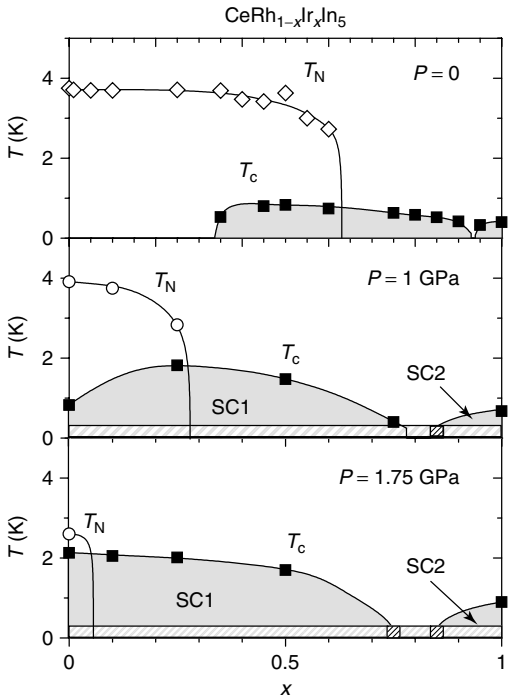

Figure 6. Evolution of the concentration–temperature ($x-T$) phase diagram of $CeRh_{1-x}Ir_xIn_5$ with pressure. (Reprinted with permission Nicklas *et al.*, copyright 2004, American Physical Society.)

$CeIrIn_5$ seems to be far away from any magnetism. No evidence for a magnetic phase transition appears in specific heat, magnetization, or susceptibility data. μSR experiments confirm the absence of any long-range magnetic order down to $T = 20\,\mathrm{mK}$ (Higemoto *et al.*, 2002; Morris *et al.*, 2003). However, strong AF spin fluctuations play an important role, and NQR studies are consistent with $CeIrIn_5$ being in the nearly AF region close to magnetic ordering (Zheng *et al.*, 2001; Kohori *et al.*, 2001). In the normal state, T_1^{-1} does not follow a Korringa law as expected from LFL theory, pointing to the NFL character of $CeIrIn_5$. Zheng *et al.* (2001) explain the unusual temperature dependence of $1/T_1T$ by the existence of anisotropic AF spin fluctuations. Recent NMR data show that hydrostatic pressure rapidly suppresses the AF spin fluctuations but enhances the superconducting transition temperature T_c (Kawasaki *et al.*, 2005). At 2.1 GPa, $T_c = 0.8\,\mathrm{K}$ is twice the value at ambient pressure. It is important to note that SC in $CeIrIn_5$ is robust over a wide pressure range where AF fluctuations are absent (Kawasaki *et al.*, 2005). These results are consistent with pressure studies of the doping series $CeRh_{1-x}Ir_xIn_5$ showing that the SC phase on the Ir-rich side close to $CeIrIn_5$ is disconnected from a second SC phase coexisting with AF in a wide range for higher Rh concentrations (Nicklas *et al.*, 2004). Recently, AF order has been reported in slightly Cd-doped $CeIrIn_5$ (Pham *et al.*, 2006), where In is partly replaced by Cd leading to a lattice contraction. This puts up the question, what provides the glue for the Cooper pairing in $CeIrIn_5$ and the role of AF spin fluctuations. In magnetic fields, LFL behavior occurs between T_c and the crossover temperature T_{LFL} (Capan *et al.*, 2004), suggesting that SC also at zero magnetic field and at ambient pressure develops in the background of a LFL state. With increasing field T_{LFL} is suppressed continuously and can be extrapolated to $T = 0$ at a critical field of $B_c \approx 26\,\mathrm{T}$. Close to this (Kim, Alwood, Kumar and Stewart, 2002) extrapolate the existence of a metamagnetic quantum critical endpoint (QCEP) inferred from (i) specific heat measurements performed at $B \geq 30\,\mathrm{T}$ and $T > 1.4\,\mathrm{K}$ and (ii) from magnetization measurements which reveal a metamagnetic transition around 42 T at 1.3 K (Takeuchi *et al.*, 2001). Detailed studies in the vicinity of this critical field are still missing, and the detailed nature of the QCEP is waiting to be unraveled. The relationship of this QCEP with the *substitution-controlled* QCP in $CeIr(In_{1-x}Cd_x)_5$ and SC in $CeIrIn_5$ is still to be explored.

$CeCoIn_5$ is the most extensively studied compound in this series. As for $CeIrIn_5$, no proof for any long-range magnetic order has yet been reported. The μSR relaxation rate is temperature independent, clearly showing the absence of magnetic order (Higemoto *et al.*, 2002). The resistivity data in the normal state exhibit a linear temperature dependence up to $T = 20\,\mathrm{K}$ (Petrovic *et al.*, 2001). Also, the coefficient of the electronic specific heat shows a logarithmic divergence (Petrovic *et al.*, 2001). The NFL behavior in both the resistivity and the specific heat extending to the lowest temperatures in the normal-state point to the presence of strong AF fluctuations in $CeCoIn_5$ usually explained in a QCP scenario. In addition, NMR and NQR experiments show the existence of strong AF spin fluctuations (Kohori *et al.*, 2001; Kawasaki *et al.*, 2003; Yashima *et al.*, 2004). Substitution studies on $CeRh_{1-x}Co_xIn_5$ substantiate the closeness of magnetic order in $CeCoIn_5$. Similar conclusions can be drawn from the comparison of the pressure–temperature ($p-T$) phase diagram of $CeRhIn_5$ (Hegger *et al.*, 2000; Llobet *et al.*, 2004; Nicklas *et al.*, 2004) and $CeCoIn_5$ (Nicklas *et al.*, 2001; Sidorov *et al.*, 2002): $CeCoIn_5$ can be considered as under an effective pressure of $p_{eff} \approx 1.6\,\mathrm{GPa}$ compared to the AF $CeRhIn_5$ (see Figure 7). This is further supported by a Cd-substitution study where, as in $CeIrIn_5$, In is partly replaced with Cd imposing a small negative chemical pressure inducing AF (Pham *et al.*, 2006). Therefore, $CeCoIn_5$ at atmospheric pressure can be considered situated close to a QCP existing at a small hypothetical negative pressure.

A detailed analysis of specific heat and resistivity data obtained on $CeCoIn_5$ in magnetic fields suggests the presence of a field-induced QCP in immediate proximity to the upper critical field for SC [$B_{c2}(T = 0)$] (Bianchi *et al.*, 2003; Paglione *et al.*, 2003; Ronning *et al.*, 2005). The temperature dependence of the normal-state specific heat and the resistivity taken to the lowest temperatures in fields $B \gtrsim B_{c2}(T = 0)$ exhibit NFL behavior for the magnetic-field orientations, parallel to the c axis (Bianchi *et al.*, 2003; Paglione *et al.*, 2003) and within the basal plane ($B \parallel ab$) (Ronning *et al.*, 2005). With further increasing field, crossovers in $C(T)/T$ from

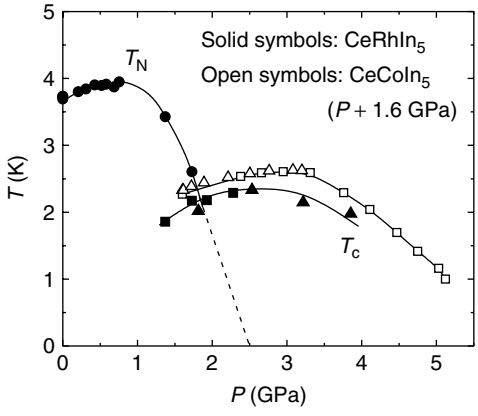

Figure 7. Pressure–temperature ($p-T$) phase diagram of $CeRhIn_5$ (solid symbols) and $CeCoIn_5$ (open symbols). $CeRhIn_5$: T_N (●) from (Llobet *et al.*, 2004) and T_c from (Llobet *et al.*, 2004) (■) and (Muramatsu *et al.*, 2001) (▲). ($CeCoIn_5$ data shifted by $\Delta p = 1.6\,\mathrm{GPa}$, T_c taken from Nicklas *et al.*, 2001 (△) and Sidorov *et al.*, 2002 (□).)

$-\ln T$ to constant behavior and in $\rho(T)$ from a linear to a quadratic temperature dependence indicate the establishment of a field-induced LFL state. An analysis of the data leads to the conclusion that an AF QCP exists close to $B_{c2}(T=0)$ for the field applied within the basal plane (Bianchi *et al.*, 2003; Paglione *et al.*, 2003) as well as in the c direction (Ronning *et al.*, 2005). This holds true despite a factor of 2.4 difference between $B_{c2}(T=0)$ for $B \parallel c$ and $B \parallel ab$. However, the existence of AF ordering at $B \lesssim B_{c2}(T=0)$ has yet to be demonstrated. The normal-state thermal-expansion coefficient $\alpha(T)$ measured at $B \gtrsim B_{c2}(T=0)$ is actually independent of temperature, $300\,\mathrm{mK} < T < 6\,\mathrm{K}$ (Donath *et al.*, 2007) (see Figure 8). These results as well as the logarithmic decrease of $C(T)/T$ (Bianchi *et al.*, 2003) and the linear T dependence of the electrical resistivity (Petrovic *et al.*, 2001) are compatible with 2D quantum critical fluctuations within the Hertz–Millis theory. Below $T^* = 300\,\mathrm{mK}$ down to 100 mK $\alpha(T)$ follows a $T^{1/2}$ dependence (Donath *et al.*, 2007), predicted for 3D quantum critical fluctuations within this itinerant theory.

In conclusion, the $CeTIn_5$ compounds are located close to QCPs, exhibit SC around the QCP, and can be described within an itinerant spin-density-wave scenario by the Hertz–Millis theory.

3.3 Theoretical concepts

The idea that tuning of a control parameter may change the magnetic state of an insulator or metal at zero temperature is indeed a very old one. The classical Stoner–Wolfarth theory of itinerant ferromagnetism (Stoner, 1938) identifies this control parameter as $x = IN(E_F)$, where I is the exchange integral of itinerant conduction electrons and $N(E_F)$ the conduction-electron density of states (DOS). For $x > x_c = 1$ a spontaneous FM moment and exchange splitting of conduction bands sets in. For x only marginally above the FM QCP $x_c = 1$ one therefore has only weak ferromagnetism (WFM) and anomalous thermodynamic and transport behavior due to paramagnon excitations (Berk and Schrieffer, 1966; Doniach and Engelsberg, 1966) was observed. The first theory to address such quantum critical phenomena were Moriya's self-consistent renormalization (SCR) theory (Moriya and Kawabata, 1973a,b; Moriya, 1985) for the WFM and the theory by Hertz (1976) on which much of the later developments are based. An alternative scenario describes lanthanide or actinide intermetallics with localized f-electron states showing a singlet–singlet CEF splitting Δ (e.g., Pr compounds) and effective RKKY exchange $J(\mathbf{Q})$ where a transition from the nonmagnetic singlet ground state to an induced moment magnetic state with modulation vector $\mathbf{Q}$ may occur. This happens if the control parameter $x = \alpha^2 J(\mathbf{Q})^2/2\Delta$ is larger than the critical $x_c = 1$ (Jensen and Mackintosh, 1991). The induced moment scenario is very similar to the Bose–Einstein condensation (BEC) picture for the field-induced AF transition below a critical field in some quasi-one-dimensional spin chain compounds (Rüegg *et al.*, 2003).

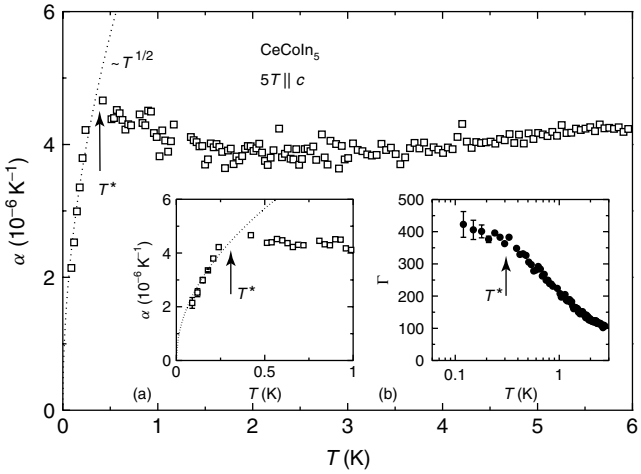

Figure 8. Temperature dependence of the linear thermal-expansion coefficient of $CeCoIn_5$ at $B = 5\,\mathrm{T}$ ($B \parallel$ c). Dotted line and arrow indicate $\alpha \propto \sqrt{T}$ and crossover temperature $T^\star$, respectively. Inset (a) enlarges low-temperature regime. Inset (b) displays temperature dependence of Grüneisen parameter $\Gamma = V_m/\kappa_T \times \alpha/C$ using $V_m = 9.57 \times 10^{-5}\,\mathrm{m^3\,mol^{-1}}$ and $\kappa_T = (3.43 \pm 0.16) \times 10^{-3}\,\mathrm{GPa^{-1}}$ (Kumar, Cornelius and Sarrao, 2004). (From Donath *et al.*, 2007.)

In this section we focus exclusively on quantum critical phenomena in HF compounds. First we discuss the basics of an empirical scaling ansatz based on naive ideas of universality and then discuss a phenomenological Gaussian type spin-fluctuation model for the nearly AF FL. Finally we briefly mention the implications of impurity effects.

The families of Ce-HF compounds discussed before show that a magnetically ordered, SDW phase may evolve continuously out of a disordered LFL phase by applying hydrostatic pressure, by varying chemical pressure via doping, or by varying an applied magnetic field. At zero temperature, pressure (or field) may be considered as control parameter of a QPT between LFL and SDW phases which meet at a QCP at the critical pressure p_c (or critical field B_c) where the total energies of the two phases become equal (Continentino, 2001; Sachdev, 1999). The notion of a QPT implies that the total energy is indeed dominated by the quantum fluctuations of the order-parameter field, the effective phase-space dimensionality is then $d_{\mathrm{eff}} = d + z$ rather than just the spatial dimensionality d because at the QCP with $T_N = 0$ quantum fluctuations develop long-range correlations in both space and time. Here z is the dynamic exponent which characterizes the rescaling of energies of quantum fluctuations with system size ($\tau \propto \xi^z$). On the other hand for a phase transition

at finite $T_N > 0$ the coherence of quantum fluctuations is destroyed by thermal fluctuations for times longer than the timescale $\tau_T = \hbar/k_B T_N$ and hence classical phase transitions are driven by thermal fluctuations of the order parameter in real space with dimension d. As a consequence right along the quantum critical line ($r = 0$) in Figure 9 anomalous NFL temperature dependence of physical quantities like $\chi(T)$, $C(T)/T$, and $\rho(T)$ emerges. Its origin and theoretical description has been the subject of much controversy. Here we briefly outline the most important predictions of those frequently applied models which treat QPT as classical ones in higher dimensions, that is, scaling theory and theories of critical spin fluctuations including disorder effects. Finally concepts of so-called local criticality are mentioned.

3.3.1 Scaling theories for the quantum critical point

A Kondo impurity in a metallic host shows all the signatures of a local LFL state (Hewson, 1993) at temperatures $T \ll T^*$, notably a scaling of the free-energy density with T/T^*. This idea has been successfully extended to the LFL phase of HF and mixed valence compounds in a phenomenological scaling ansatz (Takke *et al.*, 1981; Thalmeier and Fulde, 1986) to explain observed relations between quantities like specific heat, thermal expansion, magnetostriction, and others. It is natural to apply these ideas to the vicinity of the QCP also, where the characteristic energies $T^*(p)$ and $T_c(p)$ themselves depend on the distance r to the QCP which then appears as a further scaling variable. The associated correlation length, ξ, and timescales of quantum fluctuations, τ, diverge on approaching the phase transition. Their critical exponents are universal, depending only on dimension and the degrees of freedom of the order parameter. Defining

$$r = \frac{X - X_c}{X_c}, \qquad t = \frac{T - T_c}{T_c} \qquad (X = p \text{ or } H) \quad (1)$$

where t, r measure the distance to the transition temperature T_c and critical control parameter X_c respectively. On approaching the QCP ($T = 0$, $r = 0$) the correlation length, fluctuation time, and free-energy scale as

$$\xi \sim |r|^{-\nu}, \quad \tau \sim |r|^{-\nu z}, \quad f \sim |r|^{2-\alpha} \tilde{f}\left(\frac{T}{T^*}, \frac{H}{H^*}\right) \quad (2)$$

Here H^* has the meaning of 'metamagnetic' field scale, for fields $H \gg H^*$ the HF state is destroyed by breaking the Kondo-singlet state. For QPT the hyperscaling relation, which relates critical exponents to the effective dimension, is given by

$$2 - \alpha = \nu d_{\text{eff}}, \quad d_{\text{eff}} = d + z \quad (3)$$

In the case of the Gaussian fixed point appropriate for $d_{\text{eff}} > 4$ one has $\nu = \frac{1}{2}$. In the free energy of equation (2), which is a generalization of the one used in (Takke *et al.*, 1981; Thalmeier and Fulde, 1986), the characteristic temperature, T^*, and metamagnetic field, H^*, have scaling relations

$$T^* \sim |r|^{\nu z}, \qquad H^* \sim |r|^{\phi_h} \quad (4)$$

In the magnetically ordered regime T^* has to be replaced by the magnetic transition temperature which scales as $T_N \sim |r|^{\psi}$ where ψ is the shift exponent. Below the upper critical dimension $d_{\text{eff}} = 4$ one has $\psi = \nu z$, that is, $T_N(r)$ and $T^*(r)$ scale symmetrically around the QCP (Figure 9), however, for $d_{\text{eff}} > 4$ in general one has $\psi \neq \nu z$. This is known as *breakdown of hyperscaling*. Within a generalized Landau–Ginzburg–Wilson approach this may be understood as the effect of a dangerously irrelevant quartic interaction u (equation (6)) which, although it scales to zero for $d_{\text{eff}} > 4$, nevertheless changes the scaling behavior at finite T leading to a modified shift exponent $\psi = z/(d_{\text{eff}} - 2)$ for $d_{\text{eff}} > 4$. The zero-temperature critical exponent α in equation (3) satisfies the scaling relation $\alpha + 2\beta + \gamma = 2$ while ϕ_h is independent.

From the experimental view the most interesting aspect is the temperature dependence of physical properties at the QCP ($r = 0$) in the NFL regime. Very useful quantities are specific heat $C = (T/V)(\partial S/\partial T)_p$ and thermal expansion $\alpha = (1/V)(\partial V/\partial T)_p$ (Küchler *et al.*, 2003; Zhu, Garst, Rosch and Si, 2003). At the QCP ($r = 0$) they scale with

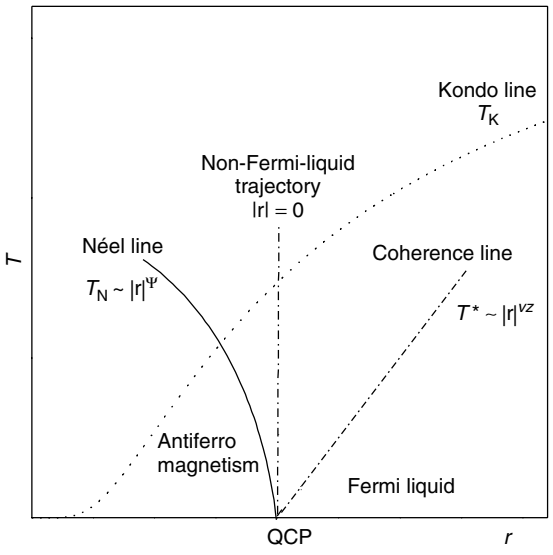

Figure 9. Schematic phase diagram for Kondo compounds with a QCP separating AF (left) and LFL (right) phases. Scaling of the characteristic temperatures is indicated (Continentino, 2004b).

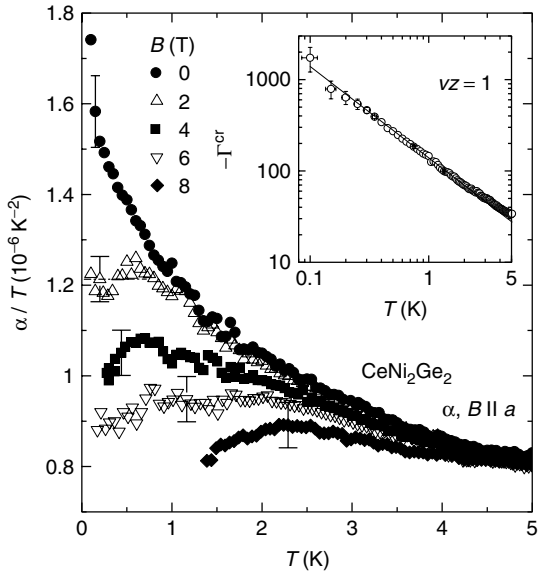

Figure 10. Thermal expansion showing the suppression of NFL behavior as a function of the field. The inset shows that for $B = 0$, the critical contribution to the Grüneisen ratio Γ of $CeNi_2Ge_2$ scales as $\Gamma \sim 1/T^{\nu z}$ with $\nu z = 1$. After equation (5), this means (assuming $z = 2$ for AF SDW) a mean-field correlation length exponent $\nu = 1/2$ which is in agreement with $d_{\text{eff}} = d + z = 5$ for the effective dimension. (Reprinted with permission Küchler *et al.*, copyright 2003, American Physical Society.)

temperature as

$$C(T) \sim T^{d/z}, \quad \alpha(T) \sim T^{(d-\frac{1}{\nu})/z} \quad \text{and}$$
$$\Gamma = \frac{\alpha}{C} \sim T^{-\frac{1}{\nu z}} \tag{5}$$

This means that the temperature dependence of the critical 'Grüneisen ratio' $\Gamma(r = 0)$ is controlled by the exponent which directly determines the timescale of quantum fluctuations (equation 2). Using this important relation a consistent explanation of experiments in the NFL compound $CeNi_2Ge_2$ can indeed be given (Figure 10). Tables of the scaling behavior of the quantities in equation (5) for various d, z have been given in (Küchler *et al.*, 2003).

The exponent νz at the same time determines the pressure scaling (equation 4) of the characteristic temperature T^* on the nonmagnetic side of the QCP. On the other hand the pressure scaling exponent of the characteristic field H^* is an independent quantity within the scaling ansatz. Experimentally it has been investigated in detail for $CeRu_2Si_2$, which has a metamagnetic field scale $H^*(p = 0) = 7.8\,\text{T}$ ($\mathbf{H} \parallel c$). It was found that empirically $\phi_h = 2 - \alpha = \nu z$ is fulfilled. According to the free energy in equation (2) this implies with $m = (\partial f/\partial H)$ that $m(H^*) =$ const independent of pressure. This was indeed found experimentally (Lacerda *et al.*, 1989). The empirical relation $2 - \alpha = \nu z$ may be interpreted as hyperscaling with dimension $d = 0$ according to equation (3). The empirical validity of such a relation points to a dimensional crossover as function of pressure close to the QCP which is caused by the different divergence of spatial and temporal correlations (Continentino, 2004a).

3.3.2 Nearly antiferromagnetic Fermi liquid

The quantum critical behavior in the nearly AF FL has been studied within two closely related approaches. Firstly the SCR theory of WFM may be extended to the weakly AF case often observed in HF compounds (Moriya and Takimoto, 1995). It starts with a parameterized phenomenological ansatz for the dynamical conduction-electron susceptibility which is expanded around the AF wave vector $\mathbf{Q}$. The moment size and spin-fluctuation spectrum is then self-consistently determined via sum rule requirements as function of microscopic model parameters and temperature. This approach has the advantage of keeping the connection to the original microscopic degrees of freedom and being also applicable away from the QCP.

For understanding only the scaling behavior close to the QCP (for $r > 0$, i.e., on the nonmagnetic side) one may start from an even more phenomenological model based on a Landau–Ginzburg–Wilson functional that contains only the spatial and temporal fluctuations $\Phi(\mathbf{q}, \omega)$ of the incipient magnetic order parameter treated within an renormalization group (RNG) approach. At this stage the fermionic degrees of freedom have already been integrated out and the frequency dependence of the Gaussian (quadratic) term of the action and the strength of the quartic interaction term of fluctuations are determined. This elimination is possible only when the Fermi surface has no nesting features for the $\mathbf{Q}$-vector of incipient magnetic order. In uranium-based HF systems this is probably the case since $\mathbf{Q}$ is mostly that of commensurate AF unrelated to nesting vectors. However for the $CeCu_2(Si_{1-x}Ge_x)_2$ series the magnetism is clearly related to nesting properties and the model described in the subsequent text may not be applicable. It was first proposed by Hertz (1976) for QPTs and extended later (Millis, 1993). The effective action functional is given by

$$S[\phi] = \sum_{\mathbf{q}, i\omega_n} (r + q^2 + \frac{|\omega_n|}{\Gamma_q}) |\Phi_{\mathbf{q}, i\omega_n}|^2$$
$$+ u \int_0^\beta d\tau \int d^d\mathbf{r} |\Phi(\mathbf{r}, \tau)|^4 \tag{6}$$
$$\text{with} \quad \Gamma_{\mathbf{q}} = \Gamma_0 q^{z-2} \tag{7}$$

An essential ingredient of the theory is the assumption of overdamped order-parameter fluctuations in the AF case which means $z = 2$ as opposed to quasi-propagating fluctuation modes in the FM case ($z = 3$) which are protected by conservation laws. The dominant mechanism is Landau damping of fluctuations via excitation of electron-hole pairs. Solution of renormalization group equations for the preceding model shows that the quartic interaction term scales with $u'/u = b^{4-(d+z)}$ ($b = L/L'$). This means that for $d_{\text{eff}} > 4$ the low-temperature behavior is determined by a Gaussian fixed point with exponent $\nu = \frac{1}{2}$ leading to ($H = 0$) scaling relations for free energy, specific heat, and so on, as described before within the scaling ansatz whose foundation becomes now clear.

It was tacitly assumed in the preceding text that the tuning to the QCP happens via application of hydrostatic or chemical pressure, that is, without breaking spatial or other symmetries. This raises the question what happens when the QCP is reached via magnetic-field tuning (Fischer and Rosch, 2004). Because the field introduces anisotropy and breaks time reversal symmetry, a different nonuniversal scaling behavior may result. It is caused by precession terms present for nonzero field that modify the dynamics of the order-parameter fluctuations and compete with the Landau damping. The relative importance of the two effects has been parameterized in (Fischer and Rosch, 2004) and the resulting nonuniversal quantum critical scaling has been studied for the thermodynamic coefficients. One interesting result of this analysis is that at the QCP ($H = H_c$) the temperature scaling of the uniform susceptibility is given by

$$\frac{1}{T}[\chi(T) - \chi(0)] \sim \xi(T) \tag{8}$$

which would be a direct experimental method to extract the (temperature) scaling exponent of the correlation length in the quantum critical regime.

3.3.3 *Impurity effects on quantum critical behavior*

Resistivity measurements are a versatile method to investigate the vicinity of a QCP. Theoretically this poses the inverse problem compared to thermodynamics. One has to eliminate the order-parameter fluctuations and study their effect on the quasiparticle scattering rate. At the same time the ordinary impurity scattering and the interference of both mechanisms has to be included. Naturally this leads to nonuniversal behavior of $\rho(T)$ above the QCP and a wide range of temperature exponents has indeed been observed. Using a phenomenological ansatz for the spin-fluctuation propagator, this problem may be treated with a standard Boltzmann equation approach (Rosch, 1999; Rosch, 2000) where the total quasiparticle scattering probability is given by

$$P(\mathbf{k}, \mathbf{k}') = g_i^2 \delta(\epsilon_{\mathbf{k}} - \epsilon_{\mathbf{k}'}) + \frac{2g_s^2}{\Gamma} n(\epsilon_{\mathbf{k}} - \epsilon_{\mathbf{k}'}) \text{Im}\chi(\epsilon_{\mathbf{k}} - \epsilon_{\mathbf{k}'}) \tag{9}$$

where g_i and g_S denote the strength of scattering by impurities or fluctuations respectively, their dimensionless ratio is defined by $x = \pi g_i^2 / 2g_S^2$. Furthermore $n(\epsilon_{\mathbf{k}} - \epsilon_{\mathbf{k}'})$ is the Bose function and $\epsilon_{\mathbf{k}}$ the quasiparticle energies. The ansatz for the order-parameter fluctuation spectrum is defined by

$$\chi_{\mathbf{q}}(\omega) \simeq \frac{1}{1/(q_0\xi)^2 + (\mathbf{q} \pm \mathbf{Q})^2/q_0^2 - i\omega/\Gamma};$$
$$1/(q_0\xi)^2 = r + c\left(\frac{T}{\Gamma}\right)^{\frac{3}{2}} \tag{10}$$

where the parameters q_0, Γ denote characteristic momentum and energy scales of fluctuations which are related via the second equation in the preceding text. The results for the scaled resistivity as a function of the reduced temperature $T/\Gamma x$ are shown in Figure 11 for various ratios of the two scattering strengths. In the pure limit $x \ll 1$ the scattering is dominated by exchange of spin fluctuations with momentum $\mathbf{Q}$, this affects only quasiparticles in the 'hot lines' of the Fermi surface (FS) shown in Figure 11(inset). In the dirty limit $x \gg 1$ where impurity scattering dominates, all quasiparticles are affected equally. For $x \simeq 1$ the two mechanisms interfere. As a consequence, the exponent α of the resistivity $\Delta\rho(T) \sim T^{\alpha}$ is nonuniversal and depends on x. As seen in Figure 11 it varies between $\alpha \sim 1$ in the pure limit and $\alpha \sim 3/2$ in the dirty limit. This is indeed the range of observed exponents for Ce-compounds near the QCP.

In the scenario of the previous sections the scattering by spin fluctuations is localized in $\mathbf{k}$ space, only quasiparticles on hot lines are affected. This is due to the construction of the model where it is assumed that the wave vector $\mathbf{Q}$ of critical fluctuations is in no way related to the FS geometry. Therefore only 'hot lines' but no finite 'nested' areas in $\mathbf{k}$-space are involved in the scattering. For this reason the QCP anomalies of specific heat and resistivity in the model discussed in the preceding text are not strong enough to explain experimental results in compounds like $YbRh_2Si_2$ and $CeCu_{6-x}Au_x$. An alternative approach of 'local quantum criticality' where all electrons on the FS develop singular scattering by construction has been proposed in (Si, Rabello, Ingersent and Smith, 2001).

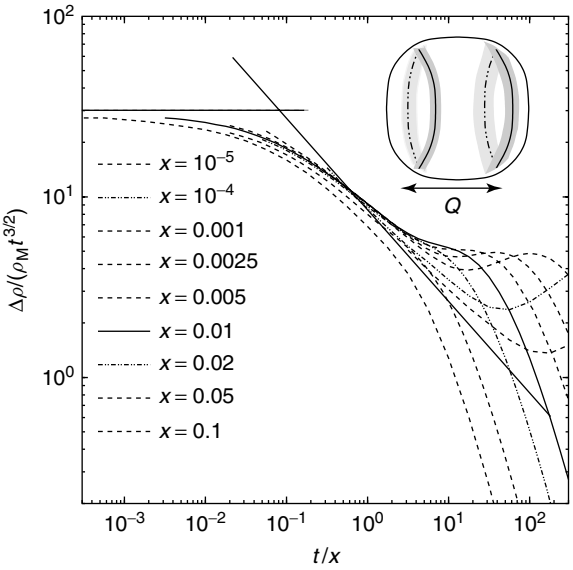

Figure 11. Temperature ($t/x = T/\Gamma x$) dependence of the scaled resistivity $\Delta\rho(t/x)/t^{3/2}$ at the QCP ($r = 0$, $d = 3$) for various scattering ratios x. Straight solid lines show $\Delta\rho \sim t^{3/2}$ for $t \ll x$ and $\Delta\rho \sim t$ for $x \ll t \ll \sqrt{T}$. Inset shows hot lines on the FS with strong quasiparticle scattering by spin fluctuations with momentum **Q**.

4 UNCONVENTIONAL QUANTUM CRITICALITY IN HEAVY-FERMION SYSTEMS

Quantum criticality in f-electron-based heavy fermion systems arises from the competition of the on-site Kondo effect with intersite RKKY exchange interaction as already stated earlier. Whereas the Kondo interaction leads to a screening of the local moments resulting in a paramagnetic ground state with itinerant f electrons, the indirect exchange coupling (RKKY interaction) can mediate long-range ordering between the local moments. By variation of the f-conduction-electron hybridization, these systems can be tuned continuously from the nonmagnetic HF state through a magnetic QCP into a long-range magnetically ordered state. The important question arises whether the heavy quasiparticles retain their itinerant character and form a spin-density wave at the QCP as for $CeCu_2Si_2$ or $CeTIn_5$ or, alternatively, decompose due to the destruction of the Kondo screening (Coleman, Pépin, Si and Ramazashvili, 2001). The first approach to capture the breakdown of the lattice Kondo effect due to quantum critical fluctuations employs an extension of the dynamical mean-field theory (DMFT) and has been worked out by Si *et al.* (2001). On the basis of the idea that the breakdown of the Kondo screening is a local phenomenon, that is, it affects each spin on the Kondo lattice independently, a 'locally critical' QCP scenario, implying Kondo-singlet destruction (Si, Rabello, Ingersent and Smith, 2001) and an electron fractionalization (Coleman, Pépin, Si and Ramazashvili, 2001; Pépin, 2005), has been proposed. An alternative proposal concerns fractionalized FLs (Senthil, Sachdev and Vojta, 2003, 2005). Details on such unconventional scenarios can be found in **Heavy Fermions: Electrons at the Edge of Magnetism, Volume 1**.

4.1 $YbRh_2Si_2$

The tetragonal $YbRh_2S_2$ has recently attracted much interest as a prototype for a clean HF compound located very close to a magnetic QCP (Trovarelli *et al.*, 2000). The low-temperature properties are determined by the CEF-derived doublet ground state which is well separated from the excited levels (Stockert *et al.*, 2006). The analysis of the magnetic entropy reveals a single-ion Kondo scale of 25 K for this lowest lying doublet (with effective spin $\frac{1}{2}$). Upon cooling to below T_K, the electronic specific heat coefficient $C_{el}(T)/T$ displayed in Figure 12(a), shows a pronounced increase which can be described by a $-\ln T$ dependence between 0.3 and 10 K. This is followed by a steep upturn which ends in a sharp phase transition at $T_N = 70$ mK (Custers *et al.*, 2003b). Magnetic measurements have proved the AF nature of this transition (Trovarelli *et al.*, 2000; Gegenwart *et al.*, 2002).

The electrical resistivity of $YbRh_2Si_2$ follows a quasilinear temperature dependence from 10 K down to T_N, below

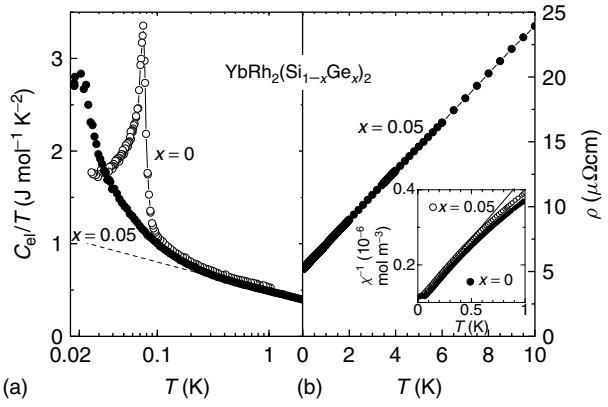

Figure 12. (a) Electronic specific heat of $YbRh_2(Si_{1-x}Ge_x)_2$ as C_{el}/T versus T (on a logarithmic scale) for $x = 0$ and $x = 0.05$ (Custers *et al.*, 2003b). C_{el} denotes the specific heat after subtraction of the nuclear and phonon contributions. (b) Electrical resistivity of $YbRh_2(Si_{0.95}Ge_{0.05})_2$ as ρ versus T (Custers *et al.*, 2003a). The inset displays the inverse susceptibility χ^{-1} versus T for $x = 0$ and $x = 0.05$. The dotted line indicates Curie–Weiss behavior $\chi^{-1} \sim (T - \Theta)$ with $\Theta - 0.3$ K. (Reprinted with permission Custers *et al.*, copyright 2003, Nature Publishing Group & Custers *et al.*, copyright 2003, IOP.)

which a sharp decrease, independent of the current direction, is observed (Gegenwart *et al.*, 2002). The AF order is very weak; muon-spin-rotation experiments have revealed an ordered moment of $2 \times 10^{-3}\,\mu_B$ (Ishida *et al.*, 2003) in accordance with the tiny entropy gain at T_N. The weakness of the AF order is also evidenced by the small critical magnetic field of 0.06 T in the easy tetragonal plane and 0.7 T along the magnetic hard direction parallel to the c axis (Gegenwart *et al.*, 2002).

Hydrostatic pressure causes an increase of T_N as expected in the case of Yb systems for which the ionic size of the magnetic Yb^{3+} configuration is smaller than that of the nonmagnetic Yb^{2+} one. Extrapolating $T_N(p)$ toward zero temperature reveals a small negative critical pressure of −0.3 GPa (Mederle *et al.*, 2002). Thus, a volume expansion induced by the partial substitution of Si with the larger but isoelectronic Ge tunes the system closer to the zero-field QCP. For a single crystal with a nominal composition $YbRh_2(Si_{0.95}Ge_{0.05})_2$, the Néel temperature is suppressed to 20 mK (cf. Figure 12a), and the electrical resistivity follows a linear temperature dependence down to lowest temperatures (Figure 12b) (Custers *et al.*, 2003b). Correspondingly, the critical magnetic field H_c within the easy plane has been reduced to about 0.025 T. At $H = H_c$ and below $T \approx 0.3$ K, the electronic specific heat coefficient follows a power-law divergence $C_{el}(T)/T \sim T^{-1/3}$. This behavior is incompatible with a SDW-type QCP, which at most (i.e., in the case of 2D critical fluctuations) could result in a logarithmic divergence (Millis, 1993; Moriya and Takimoto, 1995). The application of magnetic fields $H > H_c$ results in an LFL ground state which allows to determine the Sommerfeld coefficient $\gamma_0(H)$, Pauli susceptibility $\chi_0(H)$, as well as $A(H)$, which denotes the T^2 coefficient of the electrical resistivity contribution $\Delta\rho = AT^2$. All these properties have been studied systematically starting close to H_c up to very large fields (Custers *et al.*, 2003b; Gegenwart *et al.*, 2005). Figure 13(a) displays the evolution of the Sommerfeld coefficient as a function of the distance from the QCP, $b = B - B_c$. Its power-law dependence proves the divergence of the heavy quasiparticle mass at the QCP in this system.

As outlined before, the Grüneisen ratio, $\Gamma(T) \sim \beta(T)/C(T)$, of thermal expansion, $\beta(T)$, to specific heat, $C(T)$, is a most sensitive thermodynamic probe of quantum criticality as it has to diverge in the approach of any (pressure sensitive) QCP. The critical exponent ϵ in the divergence $\Gamma(T) \sim 1/T^{\epsilon}$ is given by $\epsilon = 1/\nu z$ (Zhu, Garst, Rosch and Si, 2003). Here ν and z are the related critical exponents for the correlation length and correlation time, respectively. For a three-dimensional (3D) AF QCP (in the 2D case, logarithmic corrections are present), the itinerant theory predicts $\nu = 1/2$ and $z = 2$ yielding $\epsilon = 1$. This was, in fact, observed for $CeNi_2Ge_2$ (Küchler *et al.*, 2003). For

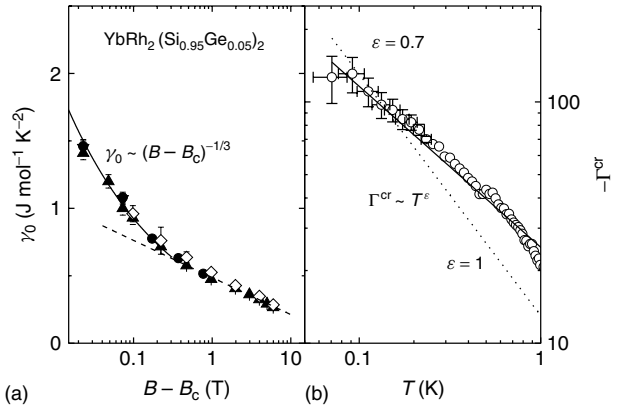

Figure 13. Magnetic-field dependence of the Sommerfeld coefficient $\gamma_0 = C_{el}(T \longrightarrow 0)/T$ of $YbRh_2(Si_{0.95}Ge_{0.05})_2$ as γ_0 versus $B - B_c$ (applied within the easy magnetic plane) with $B_c = 0.027$ T (a). Dashed and solid lines indicate logarithmic and power-law divergences, respectively (Custers *et al.*, 2003b). (b): Double-logarithmic plot of the critical Grüneisen ratio $\Gamma^{cr} = V_m/\kappa_T \cdot \beta^{cr}/C^{cr}$. Here V_m and κ_T denote the molar volume and isothermal compressibility, respectively. A normal contribution to thermal expansion, β, has been subtracted from the raw data, to determine β^{cr} (Küchler *et al.*, 2003). The critical contribution to the specific heat is obtained by subtracting nuclear and phonon contributions from the raw data. The solid and dotted lines represent $\Gamma^{cr} \sim T^{-\epsilon}$ with $\epsilon = 0.7$ and 1, respectively. (Reprinted with permission Custers *et al.*, copyright 2003, Nature Publishing Group.)

$YbRh_2(Si_{0.95}Ge_{0.05})$, by contrast, the measured Grüneisen exponent is fractional: $\epsilon = 0.7 \pm 0.1$ (Küchler *et al.*, 2003) (cf. Figure 13b). This observation provides further evidence for the failure of the itinerant theory and may hint at a locally critical QCP in this system (Küchler *et al.*, 2003). In this latter scenario, the heavy quasiparticles decompose, leading to unscreened f moments in close vicinity to the QCP (Coleman, Pépin, Si and Ramazashvili, 2001; Si, Rabello, Ingersent and Smith, 2001). Indeed, below 0.3 K the ac susceptibility (cf. inset of Figure 12b) follows a Curie–Weiss law, with negative Weiss temperature $\theta = -0.3$ K and with a surprisingly large effective moment $\mu_{eff} \approx 1.4\,\mu_B$ per Yb^{3+}. This indicates the emergence of correlated, non-Kondo-quenched spins at finite temperatures above the QCP (Custers *et al.*, 2003b). In the same temperature range, the electronic specific heat coefficient deviates toward larger values from the $-\ln T$ dependence observed above 0.3 K. For the Ge-doped system, this 'upturn' continues down to the lowest accessible temperature when the critical field H_c is applied. This intrinsically electronic feature can be attributed to the QCP as it disappears in the LFL regime at $H > H_c$. The unique power-law temperature dependence of $C_{el}(T)/T$ for $T < 0.3$ K is disparate from the linear temperature dependence of the electrical resistivity which holds all the way from 10 K to 10 mK (Figure 12b): In case of a q-independent self energy, the linear $\rho(T)$ dependence

would correspond to $C_{\rm el}(T)/T \sim -\ln T$, as in fact observed for $0.3\,K < T < 10\,{\rm K}$. Assuming that the thermodynamic quantity $C_{\rm el}(T)/T$ is probing mainly the dominating local 4f ('spin') part of the composite heavy quasiparticles, while the latter (transport) quantity is mainly probing the itinerant conduction-electron ('charge') part, the disparity between $\rho(T)$ and $C_{\rm el}(T)/T$ observed in the paramagnetic state for $T < 0.3\,{\rm K}$ may be viewed as a direct manifestation of the breakup of the heavy quasiparticles in the approach of the QCP (Custers *et al.*, 2003b).

Bulk magnetic susceptibility (Gegenwart *et al.*, 2005) as well as NMR measurements (Ishida *et al.*, 2002) have revealed strong FM fluctuations for $H > H_{\rm c}$. The Pauli susceptibility follows a power-law divergence $\chi_0(H) \sim (H - H_{\rm c})^{0.6}$ and the dimensionless Sommerfeld–Wilson ratio $R_{\rm W}$ is strongly enhanced (cf. Figure 14a). Whereas typically $R_{\rm W} \sim 2$ for HF systems, in $YbRh_2(Si_{0.95}Ge_{0.05})_2$ it equals 17.5 ± 2 away from the critical field and increases upon lowering the field toward $H_{\rm c}$ (Gegenwart *et al.*, 2005). NMR measurements, while signaling the dominance of AF fluctuations in the quantum critical regime, have also revealed enhanced FM fluctuations: the Korringa ratio $S = 1/T_1T_{\rm K}^2$, with the 4f contribution to the spin-lattice relaxation rate T_1 and isotropic Knight shift K reaches only 10% of the free electron value (Ishida *et al.*, 2002). In $YbRh_2Si_2$, a sharp electron spin resonance (ESR) has been observed at low temperatures (Sichelschmidt *et al.*, 2003). Typically, the spin-fluctuation rates of Kondo ions cause much too large ESR linewidths making ESR signals undetectable. For $YbRh_2Si_2$, the ESR signal occurs well *below* $T_{\rm K}$, and its intensity follows the temperature dependence of the bulk susceptibility which strongly increases upon cooling to low temperatures. The possible relation between the strong FM fluctuations and the occurrence of the ESR signal needs to be clarified. One may argue, that (2D) FM fluctuations explain the fractional Grüneisen exponent of $1/\nu z = 2/3$ within the itinerant theory. This picture is problematic as both the coefficient of the T^2 component of the resistivity, $A(H)$, as well as $\chi_0(H)$ diverge in the approach of the critical field. The ratio A/χ_0^2 is nearly constant (cf. Figure 14b). Since FM spin fluctuations are inefficient in affecting charge transport, the A/χ_0^2 scaling implies that the $q = 0$ fluctuations are a part of overall critical fluctuations in an extended range of wave vector scales (Gegenwart *et al.*, 2007).

The Hall-effect evolution across the field-tuned QCP in $YbRh_2Si_2$ has been studied in great detail at low temperatures (Paschen *et al.*, 2004). Most remarkably, the magnetic field-induced suppression of the weak magnetic ordering with a tiny ordered moment of $2 \times 10^{-3}\,\mu_{\rm B}$/Yb (Ishida *et al.*, 2003) leads to a large (about 30%) change of the Hall coefficient. A new line in the temperature–field phase diagram has been discovered, across which the isothermal Hall resistivity as a

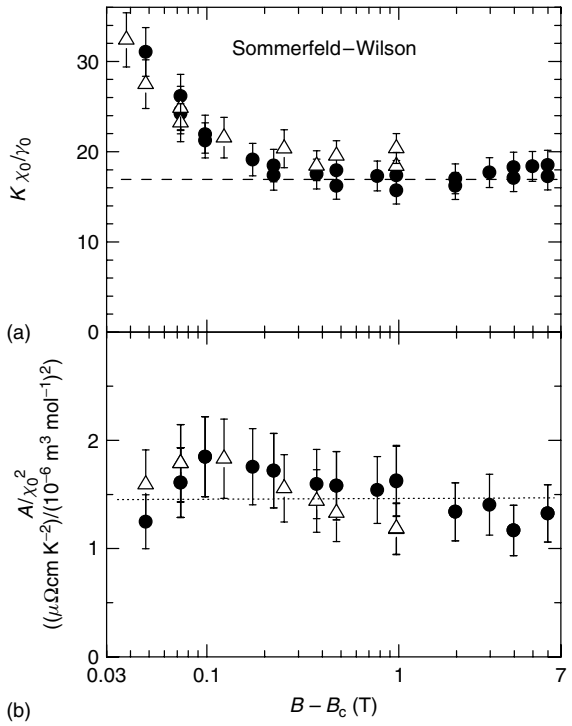

Figure 14. Field dependence of the dimensionless Sommerfeld–Wilson ratio $R_{\rm W} = K\,\chi_0/\gamma_0$, $K = \pi^2 k_{\rm B}^2/(\mu_0\mu_{\rm eff}^2)$ (a) and A/χ_0^2 (b) of $YbRh_2(Si_{0.95}Ge_{0.05})_2$ (Gegenwart *et al.*, 2005), with $A = \Delta\rho(T)/T^2$. (Reprinted with permission Genenwart *et al.*, copyright 2005, American Physical Society.)

function of the applied magnetic field changes from a phase with small Fermi-surface volume (at low fields) to a phase with larger Fermi-surface volume (at elevated fields). Upon decreasing the temperature, this crossover sharpens its width obeying a T-power-law dependence. This suggests that the crossover ends up in a sudden jump of the Fermi-surface volume at the QCP (Paschen *et al.*, 2004).

Very recently, a comparison of thermodynamic measurements with the transport properties has been performed. Figure 15(a) displays the remarkable similarity of the field dependence of the Hall resistivity with both that of the magnetostriction and magnetization. All properties can be fitted by an empirical 'crossover' function yielding a characteristic field scale $H_0(T)$ which defines a scale $T^*(H)$ in the $T-H$ phase diagram (cf. Figure 15b). This scale is seen to be distinct from either the transition temperature ($T_{\rm N}$) for the magnetic ordering at $H < H_{\rm c}$ or the scale ($T_{\rm LFL}$) for the establishment of the coherent LFL state at $H > H_{\rm c}$. For all three quantities, the width of the crossover extrapolates to zero at $T = 0$, implying that the differentials of the magnetostriction, magnetization, and Hall resistivity exhibit a jump in the zero-temperature limit (Gegenwart *et al.*, 2007). These findings contradict the conventional order-parameter fluctuation theory in at least two respects. First, the only

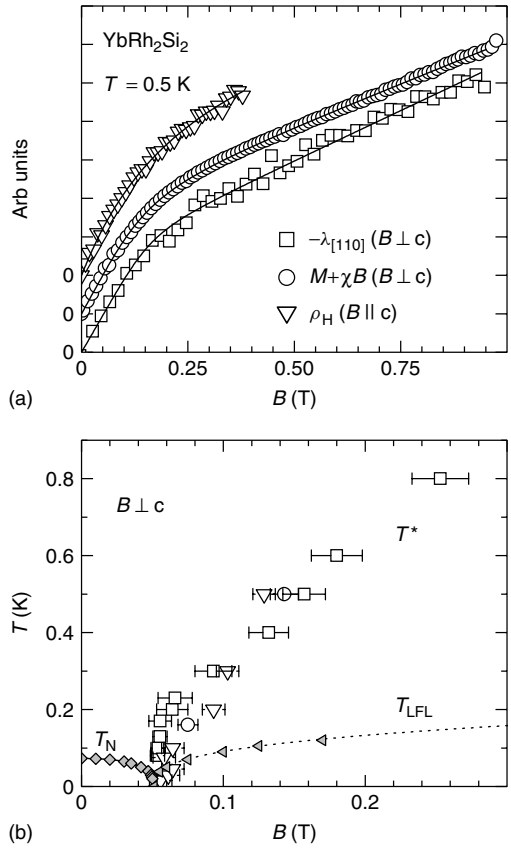

Figure 15. Comparison of the magnetic-field dependence of the Hall resistivity ($H \parallel c$), magnetostriction $\lambda(H) \perp c$), and $M + \chi H(H \perp c)$ which is the field derivative of the magnetic free-energy contribution ($-MH$), all at $T = 0.5\,\mathrm{K}$; similar behavior is observed at other temperatures (a). The solid lines indicate fits of a crossover function $f(H, T)$. (Reprinted with permission Gegenwart *et al*., copyright 2007, AAAS.) Each data set has been normalized by its initial slope. For clarity, the three data sets have been shifted by different amounts vertically. (b) Temperature versus magnetic field diagram for $YbRh_2Si_2$ ($H \perp c$). The gray diamonds and triangles represent respectively the Néel ordering temperature (T_N) and the crossover temperature (T_{LFL}) below which the electrical resistivity varies like T^2. T^* marks the characteristic energy scale determined by the crossovers in Hall resistivity, magnetization, and magnetostriction using the same symbols as in (a). For $\rho_H(T, H)$, the fields $H \parallel c$ were multiplied with the anisotropy factor 1/11. (Reprinted with permission Custers *et al*., copyright 2003, Nature Publishing Group.)

low-energy scale in that theory is associated with magnetic slowing down, which for $H > H_c$ is T_{LFL}. Second, within that theory, only kinklike features, rather than jumps, are expected in the differentials of the aforementioned thermodynamic and transport quantities. The results of Figure 15 indicate that quantum criticality in HF systems may invoke effects of Kondo disentanglement which are manifested through vanishing energy scales that add to those associated with the slowing down of the order-parameter fluctuations.

To summarize, the observed properties of $YbRh_2Si_2$ are incompatible with the predictions of the itinerant (Hertz–Millis) theory and hint at unconventional quantum criticality with multiple vanishing energy scales. Detailed inelastic neutron-scattering experiments are highly desirable to characterize the complicated magnetic fluctuation spectrum which consists of both AF and FM components. The absence of SC even in high-quality single crystals with residual resistivity of less than $0.5\,\mu\Omega\,\mathrm{cm}$ for temperatures $T > 10\,\mathrm{mK}$ is particularly striking. It is likely that SC still occurs below 10 mK. On the other hand, the formation of Cooper pairs may be prevented either by those FM quantum critical fluctuations that are dominating at elevated frequencies or by the very nature of this type of unconventional quantum criticality.

5 OUTLOOK

In contrast to several of the U-based HF compounds whose low-temperature behavior is characterized by the coexistence of AF order and SC, their Ce-based counterparts often show SC to be intimately related to an AF instability or QCP. For the prototypical system $CePd_2Si_2$ it was proposed first that the AF quantum critical fluctuations as main scatterers for the heavy-mass charge carriers not only cause the pronounced NFL effects in the normal state (e.g., $\Delta\rho \propto T^{1.2}$ below $T \approx 20\,\mathrm{K}$) but also mediate the formation of Cooper pairs (Mathur *et al*., 1998): Paramagnon-mediated SC in Ce-based NFL superconductors has meanwhile been widely accepted, although it has not yet been verified experimentally. The proposal by Mathur *et al*. implies charge carriers that keep their integrity at the QCP like 3d electrons in transition metals do, to which the theoretical models described in Section 3 had been originally applied. Since inelastic neutron-scattering and quasiparticle-tunneling experiments to directly demonstrate paramagnon-mediated SC are yet lacking in these kind of superconductors, it appears most desirable to check the *itinerant* nature of their AF ordering. In fact, in the case of $CeCu_2Si_2$ neutron-diffraction experiments, performed at ambient pressure, revealed an incommensurate SDW phase with very small ordered moment. Recalling the anomalous T-power-law dependencies of the resistivity and the Sommerfeld coefficient in the low-temperature state of $CeCu_2Si_2$ close to its QCP, the quantum critical fluctuations in this material are safely of the 3D-SDW type. Of course, neutron-diffraction measurements in other Ce-based NFL superconductors are badly needed to reveal deeper insight into the microscopics underlying Cooper-pair formation in these most interesting materials. In the case of $CeCoIn_5$, thermal-expansion measurements conducted in overcritical

magnetic fields also point to a field-induced QCP of 3D-SDW type at $B_{QCP} \leq B_{c2}(0)$. However, AF order masked by SC could not be established for this compound until now.

Turning to the nonsuperconducting lanthanide-based systems $CeCu_{5.9}Au_{0.1}$ and $YbRh_2Si_2$, it is fair to say that their QCP is indeed of an unconventional nature, that is, it differs strongly from the 3D-SDW-type QCP. It, thus, appears straightforward to relate the lack of SC in these materials to this very fact. On the other hand, it may be argued that the degree of disorder introduced into $CeCu_6$ by doping with 10 at% Au is too high for an unconventional superconducting order parameter to survive. Interestingly, this type of reasoning fails completely in the case of $YbRh_2Si_2$. Here, new high-quality single crystals with residual HRRR resistivity ratios $H \geq 140$ (residual resistivities $\rho_0 \leq 0.5\,\mu\Omega\,\mathrm{cm}$), that is, substantially smaller than those of the best superconducting $CePd_2Si_2$ single crystals (Mathur *et al*., 1998) do not show SC at least for $T > 10\,\mathrm{mK}$. Experiments at much lower temperatures are presently in preparation to check for the possible existence of SC in $YbRh_2Si_2$.

At the current state of the art the following conclusion may be formulated which should also motivate future experimental and theoretical research on strongly correlated matter: paramagnon-mediated SC is favored by a 3D-SDW QCP [1]. However, so far no SC has been observed at unconventional AF QCPs, as in $YbRh_2Si_2$, which is characterized, for example, by the destruction of the Kondo singlets and by FM quantum critical fluctuations in wide parts of the phase diagram. Therefore an unconventional AF QCP might be detrimental to SC. Undoubtedly, the interplay between SC and quantum criticality will remain in the focus of future theoretical and experimental studies of correlated matter.

NOTE

[1] This does not exclude SC in compounds that are lacking a QCP, due to the fact that the $T = 0$ transition from AF ordered to LFL, induced by varying hydrostatic pressure, is of first order. In this case, low-energy quantum critical fluctuations are absent, but SC may nevertheless occur because of higher-frequency AF spin fluctuations. Prime candidates for such a scenario are $CeCu_2Ge_2$ (Jaccard, Wilhelm, Alami-Yadri and Vargoz, 1999) and $CeRh_2Si_2$ (Movshovich *et al*., 2001).

Molecular Nanomagnets

Wolfgang Wernsdorfer
CNRS/UJF, Grenoble, France

1 INTRODUCTION

The interface between classical and quantum physics has always been an interesting area, but its importance has nevertheless, grown with the current explosive thrusts in nanoscience. Taking devices to the limit of miniaturization (the mesoscale and beyond) where quantum effects become important makes it essential to understand the interplay between the classical properties of the macroscale and the quantum properties of the microscale. This is particularly true in nanomagnetism, where many potential applications require monodisperse, magnetic nanoparticles.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

In order to put this review into perspective, let us consider Figure 1, which presents a scale of size ranging from macroscopic down to nanoscopic sizes. The unit of this scale is the number of magnetic moments in a magnetic system. At macroscopic sizes, a magnetic system is described by magnetic domains (Weiss, 1907; Hubert and Schäfer, 1998) that are separated by domain walls. Magnetization reversal occurs via nucleation, propagation, and annihilation of domain walls (see the hysteresis loop in Figure 1a, which was measured on an individual elliptic CoZr particle of $1 \times 0.8\,\mu m^2$ and a thickness of 50 nm (Wernsdorfer *et al.*, 1995)). Shape and width of domain walls depend on the material of the magnetic system, on its size, shape, and surface, and on its temperature (Aharoni, 1996; Wernsdorfer, 2001).

When the system size is of the order of magnitude of the domain-wall width or the exchange length, the formation of domain walls requires a large amount of energy. Therefore, the magnetization remains in the so-called single-domain state. Hence, the magnetization might reverse by uniform rotation, curling, or other nonuniform modes (see hysteresis loop in Figure 1b). For system sizes well below the domain-wall width or the exchange length, one must explicitly take the magnetic moments (spins) and their couplings into account. The theoretical description is complicated by the particle's boundaries.

Magnetic molecular clusters (also called *molecular nanomagnets* or *single-molecule magnets* (*SMMs*)) are the final point in the series of smaller and smaller units from bulk matter to atoms (Figure 1). Till date, they have been the most promising candidates for observing quantum phenomena because they have a well-defined structure with well-characterized spin ground-state and magnetic anisotropy. These molecules can be regularly assembled in

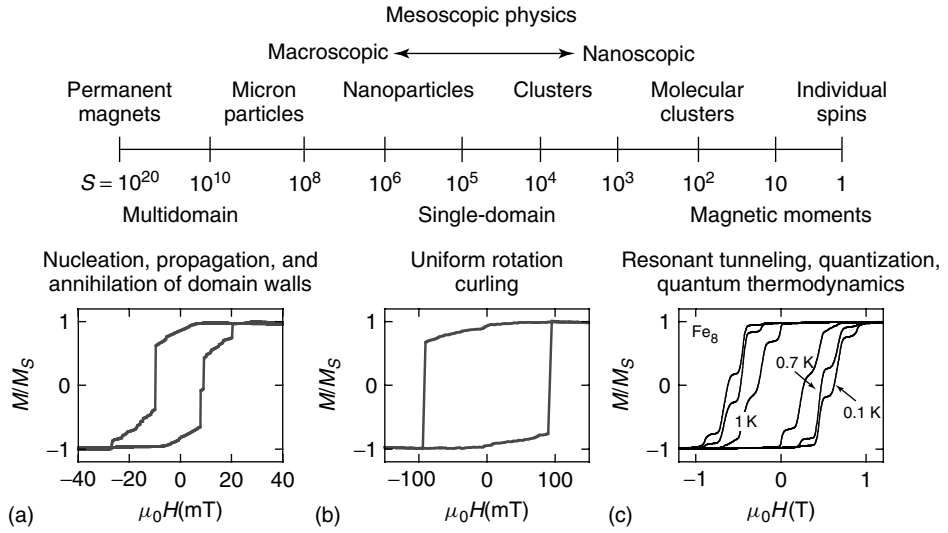

Figure 1. Scale of size that goes from macroscopic down to nanoscopic sizes. The unit of this scale is the number of magnetic moments in a magnetic system (roughly corresponding to the number of atoms). The hysteresis loops are typical examples of magnetization reversal via nucleation, propagation, and annihilation of domain walls (a), via uniform rotation (b), and via quantum tunneling (c).

large crystals where all molecules often have the same orientation. Hence, macroscopic measurements can give direct access to single-molecule properties.

This chapter introduces the basic concepts that are needed to understand the quantum phenomena observed in molecular nanomagnets. Most tunneling studies presented here were performed by magnetization measurements on single crystals using an array of micro-superconduting quantum interference devices (micro-SQUIDs) (Wernsdorfer, 2001). This chapter concludes by mentioning new trends toward molecular spintronics using junctions and nano-SQUIDs (Cleuziou *et al.*, 2006).

2 OVERVIEW OF MOLECULAR NANOMAGNETS

Molecular nanomagnets or SMMs are mainly organic molecules that have one or several metal centers with unpaired electrons. These polynuclear metal complexes are surrounded by bulky ligands (often organic carboxylate ligands). The most prominent examples are a dodecanuclear mixed-valence manganese-oxo cluster with acetate ligands, short Mn_{12} acetate (Lis, 1980), and an octanuclear iron(III) oxo-hydroxo cluster of formula $[Fe_8O_2(OH)_{12}(tacn)_6]^{8+}$ where tacn is a macrocyclic ligand, short Fe_8 (Wieghardt, Pohl, Jibril and Huttner, 1984). Both systems have a spin ground state of $S = 10$ and an Ising-type magnetic anisotropy, which stabilizes the spin states with $m = \pm 10$ and generates an energy barrier for the reversal of the magnetization of about 67 K for Mn_{12} acetate (Caneschi *et al.*, 1991; Sessoli *et al.*, 1993; Sessoli, Gatteschi, Caneschi and Novak, 1993) and 25 K for Fe_8 (Barra *et al.*, 1996).

Thermally activated quantum tunneling of the magnetization was first evidenced in both systems (Novak and Sessoli, 1995; Paulsen and Park, 1995; Friedman, Sarachik, Tejada and Ziolo, 1996; Thomas *et al.*, 1996; Sangregorio *et al.*, 1997). Theoretical discussion of this assumes that thermal processes (principally phonons) promote the molecules up to high levels with small quantum numbers $|m|$, not far below the top of the energy barrier, and the molecules then tunnel inelastically to the other (Abragam and Bleaney, 1970; Villain, Hartmann-Boutron, Sessoli and Rettori, 1994; Politi, Rettori, Hartmann-Boutron and Villain, 1995; Hartmann-Boutron, Politi and Villain, 1996; Villain, Wurger, Fort and Rettori, 1997; Garanin and Chudnovsky, 1997; Fort *et al.*, 1998; Leuenberger and Loss, 2000b). Thus the transition is almost entirely accomplished via thermal transitions and the characteristic relaxation time is strongly temperature dependent. For Fe_8, however, the relaxation time becomes temperature independent below 0.36 K (Sangregorio *et al.*, 1997; Ohm, Sangregorio and Paulsen, 1998a), showing that a pure tunneling mechanism between the only populated ground states $m = \pm S = \pm 10$ is responsible for the relaxation of the magnetization. On the other hand, in the Mn_{12} acetate system, one sees temperature-independent relaxation only for strong applied fields and below about 0.6 K (Perenboom *et al.*, 1998; Kent *et al.*, 2000). During the last few years, many new molecular nanomagnets were presented (see, for instance, Caneschi *et al.*, 1999; Aubin *et al.*, 1998; Price *et al.*, 1999; Yoo *et al.*, 2000), which also show tunneling at low temperatures. The largest molecular nanomagnet is currently a

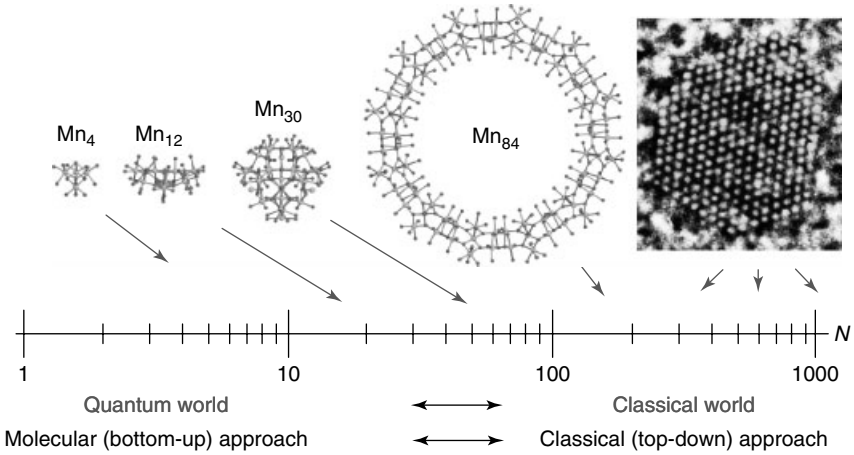

Figure 2. Size scale spanning atomic to nanoscale dimensions. On the far right a high-resolution transmission electron microscopy view along a [110] direction of a typical 3-nm-diameter cobalt nanoparticle exhibiting a face-centered cubic structure and containing about 1000 Co atoms (Jamet *et al*., 2001) is shown. The Mn_{84} molecule is a 4.2-nm-diameter particle. The indicated smaller Mn nanomagnets, which are drawn to scale, are also shown for comparison. An alternative means of comparison is the Néel vector (N), which is the scale shown. The arrows indicate the magnitude of the Néel vectors for the indicated SMMs, which are 7.5, 22, 61, and 168 for Mn_4, Mn_{12}, Mn_{30}, and Mn_{84}, respectively. (Reproduced from A. Tasiopoulos *et al*., 2004, with permission from Wiley VCH. © 2004.)

Mn_{84} molecule (Tasiopoulos *et al*., 2004) that has the size of a magentic nanoparticle (Figure 2).

3 GIANT SPIN MODEL FOR NANOMAGNETS

A magnetic molecule, which behaves like a small nanomagnet, must have a large uniaxial easy-axis-type magnetic anisotropy and a large ground-state spin. A typical example is the octanuclear iron(III) oxo-hydroxo cluster of formula $[Fe_8O_2(OH)_{12}(tacn)_6]^{8+}$, where tacn is a macrocyclic ligand (1,4,7-traiazcyclononane), short Fe_8 (Figure 3) (Wieghardt, Pohl, Jibril and Huttner, 1984).

The internal iron(III) ions are octahedrally coordinated to the two oxides and to four hydroxo bridges. The outer iron(III) ions coordinate three nitrogens and three hydroxyls. Spin polarized neutron scattering showed that all Fe ions have a spin 5/2, six spins up and two down (Pontillon *et al*., 1999). This rationalizes the $S = 10$ spin ground state that is in agreement with magnetization measurements.

In principle, a multispin Hamiltonian can be derived taking into account all exchange interactions and the single-ion magnetic anisotropies. However, the Hilbert space is very large ($6^8 \approx 10^6$) and the exchange coupling constants are not well known. Therefore, a giant spin model that describes the ground spin-state multiplet in an effective way is often used. For a nanomagnet like the Fe_8 molecular cluster, it has the following Hamiltonian:

$$\mathcal{H} = -DS_z^2 + E\left(S_x^2 - S_y^2\right) - g\mu_B\mu_0\vec{S}\cdot\vec{H} \qquad (1)$$

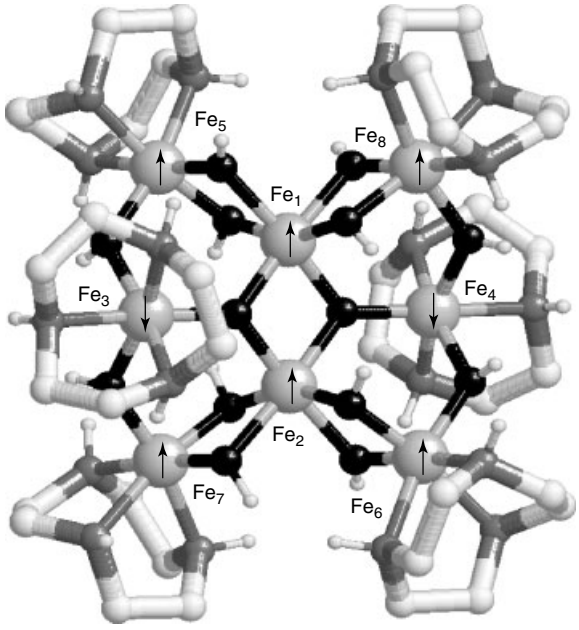

Figure 3. Schematic view of the magnetic core of the Fe_8 cluster. The oxygen atoms are black, the nitrogen atoms are gray, and carbon atoms are white. The arrows represent the spin structure of the ground state $S = 10$. (Reproduced from W. Wernsdorfer *et al*., 2000, with permission from the American Physical Society. © 2000.)

S_x, S_y, and S_z are the three components of the spin operator, D and E are the anisotropy constants, which are determined via high-frequency electron paramagnetic resonance (HF-EPR) ($D/k_B \approx 0.275$ K and $E/k_B \approx 0.046$ K (Barra *et al*., 1996)), and the last term of the Hamiltonian describes

the Zeeman energy associated with an applied field $\vec{H}$. This Hamiltonian defines hard, medium, and easy axes of magnetization in x, y, and z directions, respectively (Figure 4). It has an energy-level spectrum with $(2S+1) = 21$ values, which, to a first approximation, can be labeled by the quantum numbers $m = -10, -9, \ldots, 10$ choosing the z-axis as quantization axis. The energy spectrum, shown in Figure 5, can be obtained by using standard diagonalization techniques of the $[21 \times 21]$ matrix describing the spin Hamiltonian $S = 10$. At $\vec{H} = 0$, the levels $m = \pm 10$ have the lowest energy. When a field H_z is applied, the energy levels with $m < -2$ increase, while those with $m > 2$ decrease (Figure 5). Therefore, energy levels of positive and negative quantum numbers cross at certain fields H_z. It turns out that for Fe_8 the levels cross at fields given by $\mu_0 H_z \approx n \times 0.22\,\mathrm{T}$, with $n = 1, 2, 3, \ldots$. The inset of Figure 5 displays the details at a level crossing where transverse terms containing S_x or S_y spin operators turn the crossing into an 'avoided level crossing'. The spin S is 'in resonance' between two states when the local longitudinal field is close to an avoided level crossing. The energy gap, the so-called tunnel spitting Δ, can be tuned by an applied field in the xy plane (Figure 4) via the $S_x H_x$ and $S_y H_y$ Zeeman terms (Section 3.2).

The effect of these avoided level crossings can be seen in hysteresis loop measurements (Figure 6). When the applied field is near an avoided level crossing, the magnetization relaxes faster, yielding steps separated by plateaus. As the temperature is lowered, there is a decrease in the transition rate due to reduced thermal-assisted tunneling.

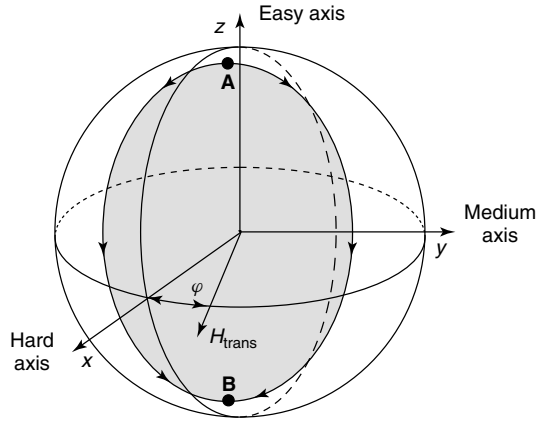

Figure 4. Unit sphere showing degenerate minima **A** and **B**, which are joined by two tunnel paths (heavy lines). The hard, medium, and easy axes are taken in x-, y-, and z-direction, respectively. The constant transverse field H_{trans} for tunnel splitting measurements is applied in the xy plane at an azimuth angle φ. At zero applied field $\vec{H} = 0$, the giant spin reversal results from the interference of two quantum spin paths of opposite direction in the easy anisotropy yz plane. For transverse fields in the direction of the hard axis, the two quantum spin paths are in a plane that is parallel to the yz plane, as indicated in the figure. By using Stokes'theorem it has been shown (Garg, 1993) that the path integrals can be converted in an area integral, yielding that destructive interference–that is a quench of the tunneling rate–occurs whenever the shaded area is $k\pi/S$, where k is an odd integer. The interference effects disappear quickly when the transverse field has a component in the y-direction because the tunneling is then dominated by only one quantum spin path. (Reproduced from A. Garg, 1993, with permission from EDP Sciences. © 1993.)

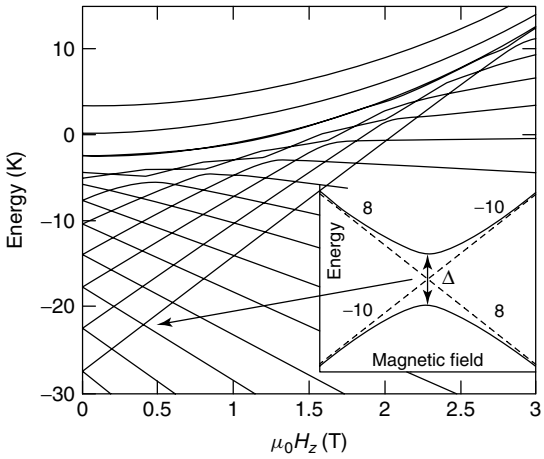

Figure 5. Zeeman diagram of the 21 levels of the $S = 10$ manifold of Fe_8 as a function of the field applied along the easy axis (equation (1)). From bottom to top, the levels are labeled with quantum numbers $m = \pm 10, \pm 9, \ldots, 0$. The levels cross at fields given by $\mu_0 H_z \approx n \times 0.22\,\mathrm{T}$, with $n = 1, 2, 3, \ldots$. The *inset* displays the detail at a level crossing where the transverse terms (terms containing S_x or/and S_y spin operators) turn the crossing into an avoided level crossing. The greater the tunnel splitting Δ, the higher the tunnel rate.

3.1 Landau–Zener tunneling in Fe_8

The nonadiabatic transition between the two states in a two-level system was first discussed by Landau (1932), Zener (1932), and Stückelberg (1932). The original work by Zener concentrates on the electronic states of a biatomic molecule, while Landau and Stückelberg considered two atoms that undergo a scattering process. Their solution of the time-dependent Schrödinger equation of a two-level system could be applied to many physical systems and it became an important tool for studying tunneling transitions. The Landau–Zener model has also been applied to spin tunneling in nanoparticles and clusters (Miyashita, 1995,1996; Rose and Stamp, 1998; Thorwart, Grifoni and Hänggi, 2000; Leuenberger and Loss, 2000a). The tunneling probability P when sweeping the longitudinal field H_z at a constant rate over an avoided energy level crossing (Figure 7) is given by

$$P_{m,m'} = 1 - \exp\left[-\frac{\pi \Delta_{m,m'}^2}{2\hbar g \mu_{\mathrm{B}} |m - m'| \mu_0 \mathrm{d}H_z/\mathrm{d}t}\right] \qquad (2)$$

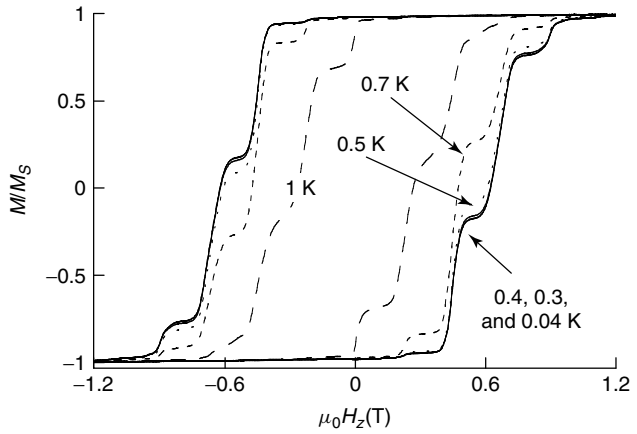

Figure 6. Hysteresis loops of a single crystal of Fe_8 molecular clusters at different temperatures. The longitudinal field (z-direction) was swept at a constant sweeping rate of $0.014\,\mathrm{T\,s^{-1}}$. The loops display a series of steps, separated by plateaus. As the temperature is lowered, there is a decrease in the transition rate due to reduced thermal-assisted tunneling. The hysteresis loops become temperature independent below 0.35 K, demonstrating quantum tunneling at the lowest energy levels. (Reproduced from W. Wernsdorfer *et al*., 1999, with permission from The American Association for the Advancement of Science. © 1999.)

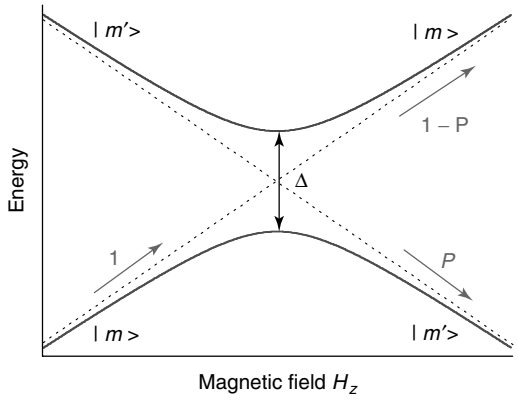

Figure 7. Detail of the energy-level diagram near an avoided level crossing. m and m' are the quantum numbers of the energy level. $P_{m,m'}$ is the Landau–Zener tunnel probability when sweeping the applied field from left to right over the anticrossing. The greater the gap Δ and the slower the sweeping rate, the higher is the tunnel rate (equation (2)).

Here, m and m' are the quantum numbers of the avoided level crossing, $\mathrm{d}H_z/\mathrm{d}t$ is the constant field sweeping rates, $g \approx 2$, μ_B is the Bohr magneton, and $\hbar$ is Planck's constant.

With the Landau–Zener model in mind, we can now start to understand the hysteresis loops qualitatively (Figure 6). Let us start at a large negative magnetic field H_z. At very low temperatures, all molecules are in the $m = -10$ ground state (Figure 5). When the applied field H_z is ramped down to zero, all molecules stay in the $m = -10$ ground state. When ramping the field over the $\Delta_{-10,10}$–region at $H_z \approx 0$, there is a Landau–Zener tunnel probability $P_{-10,10}$ to tunnel from the $m = -10$ to the $m = 10$ state. $P_{-10,10}$ depends on the sweeping rate (equation (2)), that is, the slower the sweeping rate, the larger the value of $P_{-10,10}$. This is clearly demonstrated in the hysteresis loop measurements showing larger steps for slower sweeping rates (Wernsdorfer and Sessoli, 1999). When the field H_z is now further increased, there is a remaining fraction of molecules in the $m = -10$ state that become a metastable state. The next chance to escape from this state is when the field reaches the $\Delta_{-10,9}$ region. There is a Landau–Zener tunnel probability $P_{-10,9}$ to tunnel from the $m = -10$ to the $m = 9$ state. As $m = 9$ is an excited state, the molecules in this state desexcite quickly to the $m = 10$ state by emitting a phonon. An analogous procedure takes place when the applied field reaches the $\Delta_{-10,10-n}$ regions ($n = 2, 3, \ldots$) until all molecules are in the $m = 10$ ground state, that is, the magnetization of all molecules is reversed. As phonon emission can only change the molecule state by $\Delta m = 1$ or 2, there is a phonon cascade for higher applied fields.

In order to apply the Landau–Zener formula (equation (2)) quantitatively, we first saturated the crystal of Fe_8 clusters in a field of $H_z = -1.4\,\mathrm{T}$, yielding an initial magnetization $M_\mathrm{in} = -M_\mathrm{s}$. Then, we swept the applied field at a constant rate over one of the resonance transitions and measured the fraction of molecules that reversed their spin. This procedure yields the tunneling rate $P_{-10,10-n}$ and thus the tunnel splitting $\Delta_{-10,10-n}$ (equation (2)) with $n = 0, 1, 2, \ldots$.

We first checked the predicted Landau–Zener sweeping field dependence of the tunneling rate. We found a good agreement for sweeping rates between 10 and $0.001\,\mathrm{T\,s^{-1}}$ (Wernsdorfer and Sessoli, 1999). The deviations at lower sweeping rates are mainly due to the *hole digging mechanism* (Wernsdorfer *et al*., 1999), which slows down the relaxation (Section 7.2). Our measurements showed for the first time that the Landau–Zener method is particularly adapted for molecular clusters because it works even in the presence of dipolar fields, which spread the resonance transition provided that the field sweeping rate is not too small.

3.2 Oscillations of tunnel splitting

An applied field in the xy plane can tune the tunnel splittings $\Delta_{m,m'}$ via the S_x and S_y spin operators of the Zeeman terms that do not commute with the spin Hamiltonian. This effect can be demonstrated by using the Landau–Zener method (Section 3.1). Figure 8 presents a detailed study of the tunnel splitting $\Delta_{\pm 10}$ at the tunnel transition between $m = \pm 10$, as a function of transverse fields applied at different angles φ, defined as the azimuth angle between the anisotropy

hard axis and the transverse field (Figure 4). For small angles φ, the tunneling rate oscillated with a period of $\sim$0.4 T, whereas no oscillations were present for large angles φ (Wernsdorfer and Sessoli, 1999). In the latter case, a much stronger increase of $\Delta_{\pm 10}$ with transverse field was observed. The transverse field dependence of the tunneling rate for different resonance conditions between the state $m = -10$ and $(10 - n)$ can be observed by sweeping the longitudinal field around $\mu_0 H_z = n \times 0.22\,\mathrm{T}$ with $n = 0, 1, 2, \ldots$. The corresponding tunnel splittings $\Delta_{-10,10-n}$ oscillated with almost the same period of $\sim$0.4 T (Figure 8). In addition, a comparison of quantum transitions between $m = -10$ and $(10 - n)$, with n even or odd, revealed a parity (or symmetry) effect that is analogous to the Kramers' suppression of tunneling predicted for half-integer spins (Loss, DiVincenzo and Grinstein, 1992; von Delft and Henley, 1992). A similar strong dependence on the azimuth angle φ was observed for all studied resonances.

3.2.1 Semiclassical descriptions

Before showing that the preceding results can be derived by an exact numerical calculation using the quantum operator formalism, it is useful to discuss semiclassical models. The original prediction of oscillation of the tunnel splitting was done by using the path integral formalism (Feynman, Leighton and Sand, 1970). Here (Garg, 1993), the oscillations are explained by constructive or destructive interference of quantum spin phases (Berry phases) of two tunnel paths (instanton trajectories) (Figure 4). After our experiments were reported, the Wentzel–Kramers–Brillouin theory has been used independently by Garg (1999) and Villain and Fort (2000). The surprise is that although these models (Garg, 1993,1999; Villain and Fort, 2000) are derived semiclassically, and should have higher-order corrections in $1/S$, they appear to be exactly as written! This has first been noted in Garg (1999) and Villain and Fort (2000) and then proved in Kececioglu and Garg (2001). Some extensions or alternative explications of Garg's result can be found in Barnes (1999), Liang, Mueller-Kirsten, Park and Pu (2000), Yoo and Lee (2000), and Rong *et al.* (2000).

The period of oscillation is given by (Garg, 1993)

$$\Delta H = \frac{2k_\mathrm{B}}{g\mu_\mathrm{B}}\sqrt{2E(E+D)} \tag{3}$$

where D and E are defined in equation (1). We find a period of oscillation of $\Delta H = 0.26\,\mathrm{T}$ for $D = 0.275\,\mathrm{K}$ and $E = 0.046\,\mathrm{K}$ as in Barra *et al.* (1996). This is somewhat smaller than the experimental value of $\sim$0.4 T. We believe that this is due to higher-order terms of the spin Hamiltonian, which are neglected in Garg's calculation. These terms can easily be included in the operator formalism as shown in the next section.

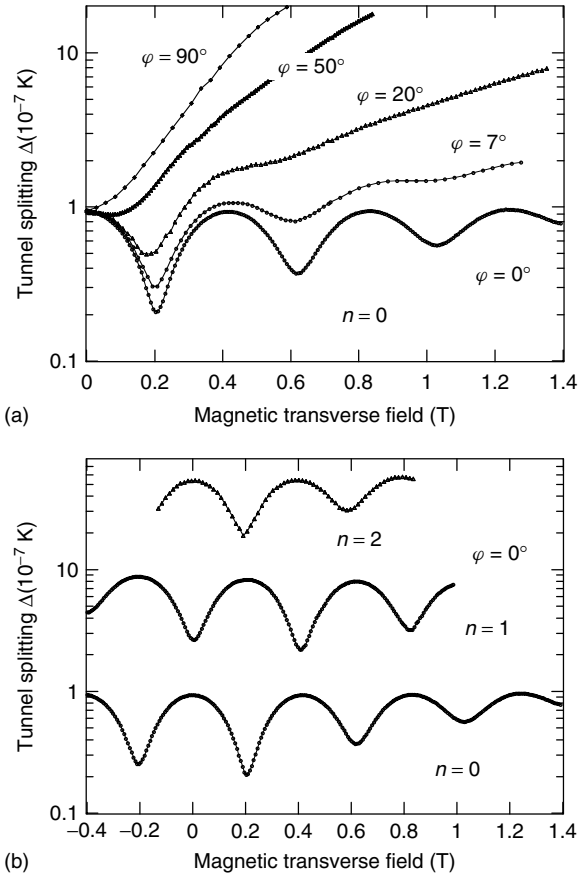

Figure 8. Measured tunnel splitting Δ as a function of transverse field for (a) several azimuth angles φ at $m = \pm 10$ and (b) $\varphi \approx 0^\circ$, as well as for quantum transition between $m = -10$ and $(10 - n)$. Note the parity effect that is analogous to the suppression of tunneling predicted for half-integer spins. It should also be mentioned that internal dipolar and hyperfine fields hinder a quench of Δ, which is predicted for an isolated spin. (Reproduced from W. Wernsdorfer *et al.*, 1999, with permission from The American Association for the Advancement of Science. © 1999.)

3.2.2 Exact numerical diagonalization

In order to quantitatively reproduce the observed periodicity we included fourth-order terms in the spin Hamiltonian (equation (1)) as employed in the simulation of inelastic neutron scattering measurements (Caciuffo *et al.*, 1998; Amoretti *et al.*, 2000) and performed a diagonalization of the $[21 \times 21]$ matrix describing the $S = 10$ system. For the calculation of the tunnel splitting we used $D = 0.289\,\mathrm{K}$, $E = 0.055\,\mathrm{K}$ (equation (1)), and the fourth-order terms as defined in Caciuffo *et al.* (1998) with $B_4^0 = 0.72 \times 10^{-6}\,\mathrm{K}$, $B_4^2 = 1.01 \times 10^{-5}\,\mathrm{K}$, and $B_4^4 = -0.43 \times 10^{-4}\,\mathrm{K}$, which are close to the values obtained by EPR measurements (Barra,

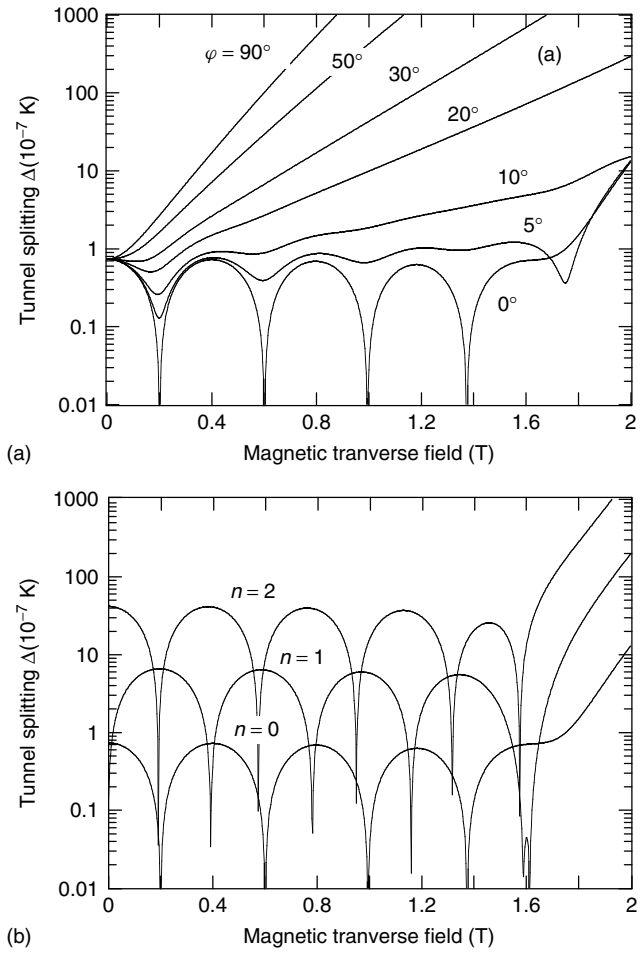

Figure 9. Calculated tunnel splitting Δ as a function of transverse field for (a) quantum transition between $m = \pm 10$ at several azimuth angles φ and (b) quantum transition between $m = -10$ and $(10 - n)$ at $\varphi = 0^{\circ}$ (Section 3.2.2). The fourth-order terms suppress the oscillations of Δ for large transverse fields $|H_x|$. (Reproduced from W. Wernsdorfer *et al.*, 1999, with permission from The American Association for the Advancement of Science. © 1999.)

Gatteschi and Sessoli, 2000) and neutron scattering measurements (Amoretti *et al.*, 2000).

The calculated tunnel splittings for the states involved in the tunneling process at the resonances $n = 0$, 1, and 2 are reported in Figure 9, showing the oscillations as well as the parity effect for odd resonances.

3.2.3 Spin-parity effect

The spin-parity effect is among the most interesting quantum phenomena that can be studied at the mesoscopic level in SMMs. It predicts that quantum tunneling is suppressed at zero applied field if the total spin of the magnetic system is half-integer but is allowed in integer spin systems. Enz and Schilling (1986), and van Hemmen and Süto (1986) were the first to suggest the absence of tunneling as a consequence of Kramers degeneracy [1].

The predicted spin-parity effect can be observed by measuring the tunnel splitting as a function of transverse field (Wernsdorfer *et al.*, 2002a). An integer spin system is rather insensitive to small transverse fields, whereas a half-integer-spin system is much more sensitive. However, a half-integer-spin system also undergoes tunneling at zero external field as a result of environmental degrees of freedom such as hyperfine and dipolar couplings or small intermolecular exchange interaction.

The best observation of the spin-parity effect has been seen for two molecular Mn_{12} clusters with a spin ground state of $S = 10$ and $S = 19/2$ showing oscillations of the tunnel probability as a function of a transverse field being due to topological quantum phase interference of two tunnel paths of opposite windings (Section 3.2.1). Spin-parity-dependent tunneling was established for the first time in these compounds by comparing the quantum phase interference of integer and half-integer-spin systems (Wernsdorfer, Chakov and Christou, 2005).

3.3 A classical approach with applications to the quantum regime

Recently, the molecular (or bottom-up) approach has reached the size regime of the classical (or top-down) approach to nanoscale magnetic materials (Tasiopoulos *et al.*, 2004). Indeed, a giant Mn_{84} SMM was reported with a 4-nm-diameter torus structure, exhibiting both magnetization hysteresis and quantum tunneling. The study of such large systems is greatly complicated by the fact that the spin Hilbert space is huge and it is impossible to treat such systems with exact matrix diagonalization methods. However, since some SMMs are now as large as some classical nanoparticles, it raises the interesting possibility that classical models commonly employed to study the latter may be used to obtain a first-order understanding of large molecular systems. Indeed, we herein propose the use of the classical Néel–Brown model (Néel, 1949; Brown, 1963; Coffey *et al.*, 1995) of thermally activated magnetization reversal of a magnetic single-domain particle in order to study large SMMs. This method allows us to determine important parameters that characterize the magnetic properties of the SMM: the energy barrier, the magnetic anisotropy constant, the spin, τ_0, and the crossover temperature from the classical to the quantum regime. The method is particularly useful for SMMs having low-lying energy states and not showing quantum tunneling steps in hysteresis loops. In such systems, electron paramagnetic resonance (EPR) measurements often exhibit

only very broad absorption peaks, which do not allow the determination of the magnetic anisotropy.

3.3.1 The Néel–Brown model of thermally activated magnetization reversal

The method is based on the Néel–Brown model of thermally activated magnetization reversal of a magnetic single-domain particle, which has two equivalent ground states of opposite magnetization separated by an energy barrier due to magnetic anisotropy (Néel, 1949; Brown, 1963; Coffey *et al.*, 1995). The system can escape from one state to the other either by thermal activation over the barrier at high temperatures or by quantum tunneling at low temperatures. At sufficiently low temperatures and at zero field, the energy barrier between the two states of opposite magnetization is much too high to observe an escape process. However, the barrier can be lowered by applying a magnetic field in the direction opposite to that of the particle's magnetization. When the applied field is close enough to the reversal field, thermal fluctuations are sufficient to allow the system to overcome the barrier, and the magnetization is reversed.

This stochastic escape process can be studied via the relaxation time method consisting of the measurement of the probability that the magnetization has not reversed after a certain time. In the case of an assembly of identical and isolated particles, it corresponds to measurements of the relaxation of magnetization. According to the Néel–Brown model, the probability that the magnetization has not reversed after a time t is given by

$$P(t) = e^{-t/\tau} \tag{4}$$

and τ (inverse of the reversal rate) can be expressed by an Arrhenius law of the form:

$$\tau(T, H) = \tau_0 e^{\Delta E(H)/k_B T} \tag{5}$$

where $\Delta E(H)$ is the field-dependent energy barrier height and τ_0 is the inverse of the attempt frequency. In most cases, $\Delta E(H)$ can be approximated by

$$\Delta E(H) \approx E_0 \left(1 - \frac{H}{H_c^0}\right)^{\alpha} \tag{6}$$

where H_c^0 is the reversal field at zero temperature, E_0 is the barrier height at zero applied field, and α is a constant of the order of unity (for most cases $1.5 \leq \alpha \leq 2$). In the case of a Stoner–Wohlfarth particle (Néel, 1947; Stoner and Wohlfarth, 1948) with uniaxial anisotropy and the field applied along the easy axis of magnetization, all constants can be determined analytically (Néel, 1947,1949): $\alpha = 2$, $E_0 = KV$, and $H_c^0 = 2K/M_s$, where K is the uniaxial anisotropy constant, V is the particle volume, and M_s is the saturation magnetization. For SMMs with dominating uniaxial anisotropy, $\alpha = 2$, $E_0 = DS^2$, and $H_c^0 = 2DS/g\mu_0\mu_B$. However, in general, all constants depend to some degree on the fine details of the magnetic anisotropy and the direction of the applied field H (Thiaville, 1998, 2000).

In order to study the field dependence of the relaxation time $\tau(T, H)$ and to obtain the parameters of the model, the decay of magnetization has to be studied at many applied fields H and temperatures T. This is experimentally very time consuming and complicated by the fact that the equilibrium magnetization is temperature dependent and difficult to obtain for long relaxation times. In addition, for fast relaxation times the initial magnetization depends on the field sweep rates to apply to the field. The number of exploitable decades for τ values is therefore limited for relaxation time measurements.

A more convenient method for studying the magnetization decay is by ramping the applied field at a given rate (Wernsdorfer *et al.*, 1997a) and measuring the coercive field H_c (the field value to obtain zero magnetization), which is then measured as a function of the field sweep rate and temperature.

The mathematical transformation from a reversal time probability (equations (4) and (5)) to a reversal field probability was first given by Kurkijärvi (1972) for the critical current in SQUIDs. Later, Gunther and Barbara calculated similar expressions for magnetic domain-wall junctions (Gunther and Barbara, 1994). A more general calculation was evaluated by Garg (1995). Here, we use a simplified version (Wernsdorfer *et al.*, 1997a) [2] and approximate the mean reversal field of an assembly of identical particles or SMMs by the coercive field H_c:

$$H_c(T, v) \approx H_c^0 \left(1 - \left[\frac{kT}{E_0} \ln\left(\frac{c}{v}\right)\right]^{1/\alpha}\right) \tag{7}$$

where the field sweeping rate is given by $v = \mathrm{d}H/\mathrm{d}t$; H_c^0 is the coercive field at zero temperature, and $c = H_c^0 k_B T / [\tau_0 \alpha E_0 (1 - H_c/H_c^0)^{\alpha-1}]$ (Wernsdorfer *et al.*, 1997a).

3.3.2 Application to Mn_{12} SMMs

The method is applied here to Mn_{12} SMMs with a spin ground state of $S = 10$ (Murugesu *et al.*, 2005). Figure 10 shows typical hysteresis loops with a series of quantum steps separated by plateaus. In order to apply the preceding method, the temperature and field sweep rate dependencies of the coercive fields H_c were measured and plotted in Figure 11. As expected for a thermally activated process, H_c increases with decreasing temperature and increasing field

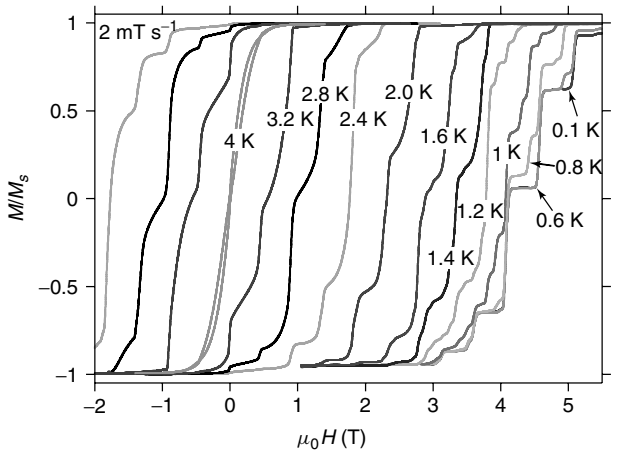

Figure 10. Hysteresis loops of single crystals of a Mn_{12} molecular cluster at different temperatures and a constant field sweep rate indicated in the figure. The loops display a series of steps, separated by plateaus. As the temperature is lowered, there is a decrease in the transition rate due to reduced thermal-assisted tunneling. The hysteresis loops become temperature independent below 0.6 K, demonstrating quantum tunneling at the lowest energy levels. (Reproduced from W. Wernsdorfer *et al.*, 2006, with permission from the American Physical Society. © 2006.)

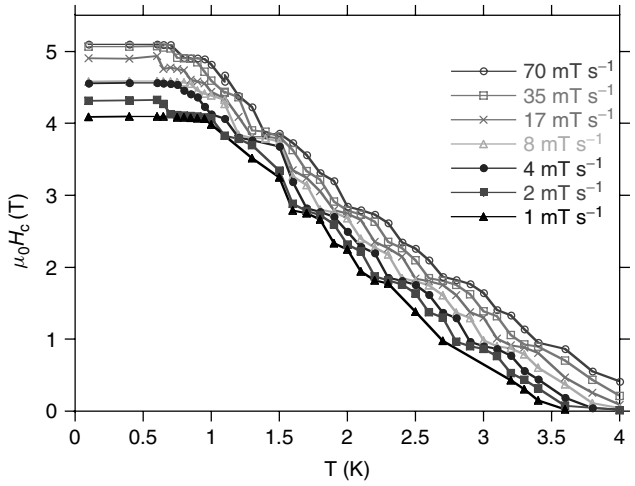

Figure 11. Coercive field H_c for Mn_{12} as a function of temperature. Note the steps of H_c coming from the resonant tunneling steps in the hysteresis loops (Figure 10). (Reproduced from W. Wernsdorfer *et al.*, 2005, with permission from the American Physical Society. © 2005.)

sweep rate. Furthermore, all measurements show an almost logarithmic dependence of H_c on the field sweep rate. H_c becomes temperature independent below about 0.6 K.

The validity of equation (7) was tested by plotting the set of $H_c(T, v)$ values as a function of $[Tln(c/v)]^{1/2}$ where $c = H_c^0 k_B T/[\tau_0 2E_0(1 - H_c/H_c^0)]$. If the underlying model is sufficient, all points should collapse onto one straight line by choosing the proper values for the constant τ_0. We found

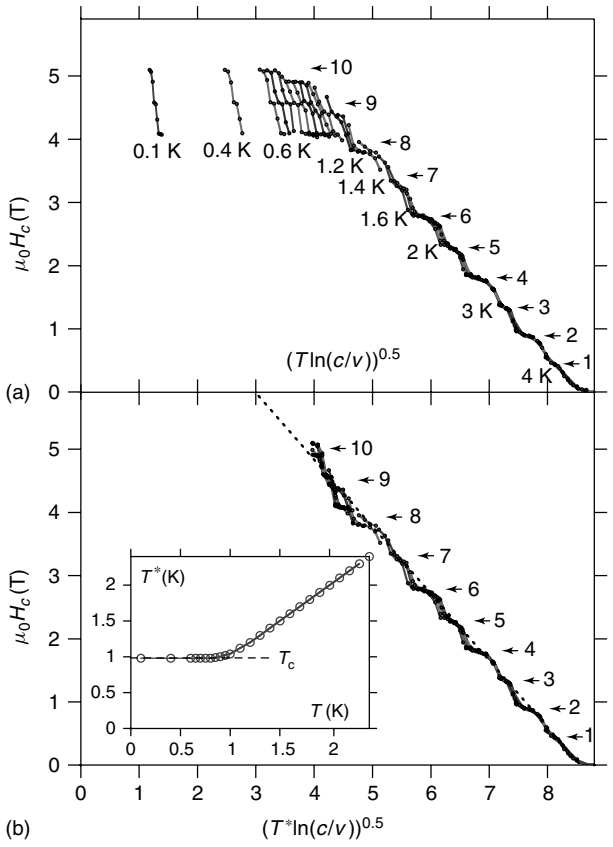

Figure 12. (a) Scaling plot of the coercive field $H_c(T, v)$ of Mn_{12} for field sweep rates between 0.0001 and 0.1 T s^{-1} and several temperatures: 0.1 K, 0.4 K, from 0.6 to 1 K in steps of 0.05 K, and from 1 to 4 K in steps of 0.1 K. The arrows indicate the step index $n = -(m + m')$ where m and m' are the quantum numbers of the corresponding level crossing. Note the parity effect of the steps: even n have larger steps than odd n. (b) Same data of $H_c(T, v)$ and same scales but the real temperature T is replaced by an effective temperature T^* (see inset), which restores the scaling below 1.1 K. (Reproduced from W. Wernsdorfer *et al.*, 2005, with permission from the American Physical Society. © 2005.)

that the data of $H_c(T, v)$ fell on a master curve provided $\tau_0 = 2.1 \times 10^{-7}$ s.

At low temperatures, strong deviations from the master curves are observed. In order to investigate the possibility that these low-temperature deviations are due to escape from the metastable potential well by tunneling, a common method for classical models is to replace the real temperature T by an effective temperature $T^*(T)$ in order to restore the scaling plot (Wernsdorfer *et al.*, 1997b). In the case of tunneling, $T^*(T)$ should saturate at low temperatures. Indeed, the ansatz of $T^*(T)$, as shown in the inset of Figure 12(b), can unequivocally restore the scaling plot demonstrated by a straight master curve (Figure 12b). The flattening of T^* corresponds to a saturation of the escape rate, which is a necessary signature of tunneling. The crossover temperature T_c can be defined as

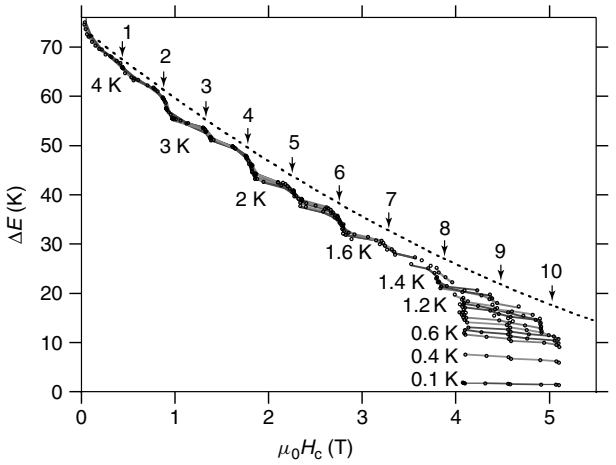

Figure 13. Field dependence of the energy barrier of Mn_{12} obtained from [2] and the set of $H_c(T, v)$ data from Figure 12. The arrows indicate the step index $n = -(m + m')$, where m and m' are the quantum numbers of the corresponding level crossing. Note the steplike reduction of the energy barrier due to resonant tunneling and the parity effect of the steps: even n have larger steps than odd n. The dotted line gives the classical barrier $\Delta E = E_0(1 - H/H_a)^2$ with $E_0 = 74\,\mathrm{K}$ and $H_a = 9.8\,\mathrm{T}$. (Reproduced from W. Wernsdorfer *et al.*, 2005, with permission from the American Physical Society. © 2005.)

the temperature where the quantum rate equals the thermal one. The inset of Figure 12(b) gives $T_c = 0.97\,\mathrm{K}$. The slopes and the intercepts of the master curves give $E_0 = 72.4\,\mathrm{K}$ and $H_c^0 = 9.1\,\mathrm{T}$. The E_0 values are in good agreement with those extracted from Arrhenius plots (69 K) (Murugesu *et al.*, 2005). This result allows us to estimate the spin ground state using $S = 2E_0/(g\mu_B\mu_0 H_c^0)$: $S = 11$. This differs slightly from $S = 10$ determined via magnetization measurements. This deviation is due to quantum effects in the thermally activated regime and is considered further in the subsequent text.

Several points should be mentioned: (i) The classical regime of the model corresponds in most SMMs to the thermally activated tunneling regime with tunneling close to the top of the energy barrier. Because all parameters are deduced from this regime, small deviations from the exact values are expected. (ii) The field dependence of the energy barrier can be obtained directly using [2] and is plotted in Figure 13. (iii) Equation (7) is not valid for fields that are close to $H = 0$ because the model only takes into account the transitions from the metastable to the stable well. However, close to $H = 0$, transitions between both wells are possible, leading to a rounding of the master curve at small fields. (iv) The method can be applied to powder samples with random orientations of the molecules. In this case, $\alpha \approx 1.5$, $vE_0 = DS^2$ where v can be calculated (Thiaville, 1998,2000), and the intercept of the master curve gives $H_c^0/2$. (v) In the case of a distribution of anisotropies, different parts of the distribution can be probed by applying the method at different M values. (vi) This method is insensitive to small intermolecular interactions when H_c is larger than the typical interaction field. (vii) The method can be generalized for 1D, 2D, and 3D networks of spins. In this case, equation (6) describes a nucleation barrier.

4 QUANTUM DYNAMICS OF A DIMER OF NANOMAGNETS

We present here a new family of dimers of nanomagnets (Wernsdorfer, Aliaga-Alcalde, Hendrickson and Christou, 2002) in which antiferromagnetic coupling between two SMMs results in quantum behavior that is different from that of the individual SMMs. Each SMM acts as a bias on its neighbor, shifting the quantum tunneling resonances of the individual SMMs. Hysteresis loop measurements on a single crystal of SMM dimers established quantum tunneling of the magnetization via entangled states of the dimer. This shows that the dimer really does behave as a quantum-mechanically coupled dimer, and also allows the measurement of the longitudinal and transverse superexchange coupling constants (Tiron *et al.*, 2003). The experimental evidence for entangled states was confirmed by an EPR study (Hill, Edwards, Aliaga-Alcalde and Christou, 2003).

The compound $[Mn_4O_3Cl_4(O_2CEt)_3(py)_3]$ crystallizes in the hexagonal space group $R3$(bar) with two Mn_4 molecules per unit cell lying head to head on a crystallographic S_6 symmetry axis (Wernsdorfer, Aliaga-Alcalde, Hendrickson and Christou, 2002) (Figure 14). Each Mn_4 monomer has a ground-state spin of $S = 9/2$, well separated from the first excited state $S = 7/2$ by a gap of about 300 K (Hendrickson *et al.*, 1992). The Mn−Mn distances and the Mn-O-Mn angles are similar, and the uniaxial anisotropy constant is expected to be the same for the two dimer systems. These dimers are held together via six C−H···Cl hydrogen bonds between the pyridine (py) rings on one molecule and the Cl ions on the other, and one Cl···Cl Van der Waals interaction. These interactions lead to an antiferromagnetic superexchange interaction between the two Mn_4 units of the $[Mn_4]_2$ dimer (Wernsdorfer, Aliaga-Alcalde, Hendrickson and Christou, 2002). Dipolar couplings between Mn_4 molecules can be easily calculated and are more than one order of magnitude smaller than the exchange interaction.

Before presenting the measurements, we summarize a simplified spin Hamiltonian describing the $[Mn_4]_2$ dimer (Wernsdorfer, Aliaga-Alcalde, Hendrickson and Christou, 2002). Each Mn_4 SMM can be modeled as a *giant spin* of $S = 9/2$ with Ising-like anisotropy (equation (1)). The corresponding Hamiltonian is given by

$$\mathcal{H}_i = -DS_{z,i}^2 + \mathcal{H}_{\mathrm{trans},i} - g\mu_B\mu_0\vec{S}_i \cdot \vec{H} \qquad (8)$$

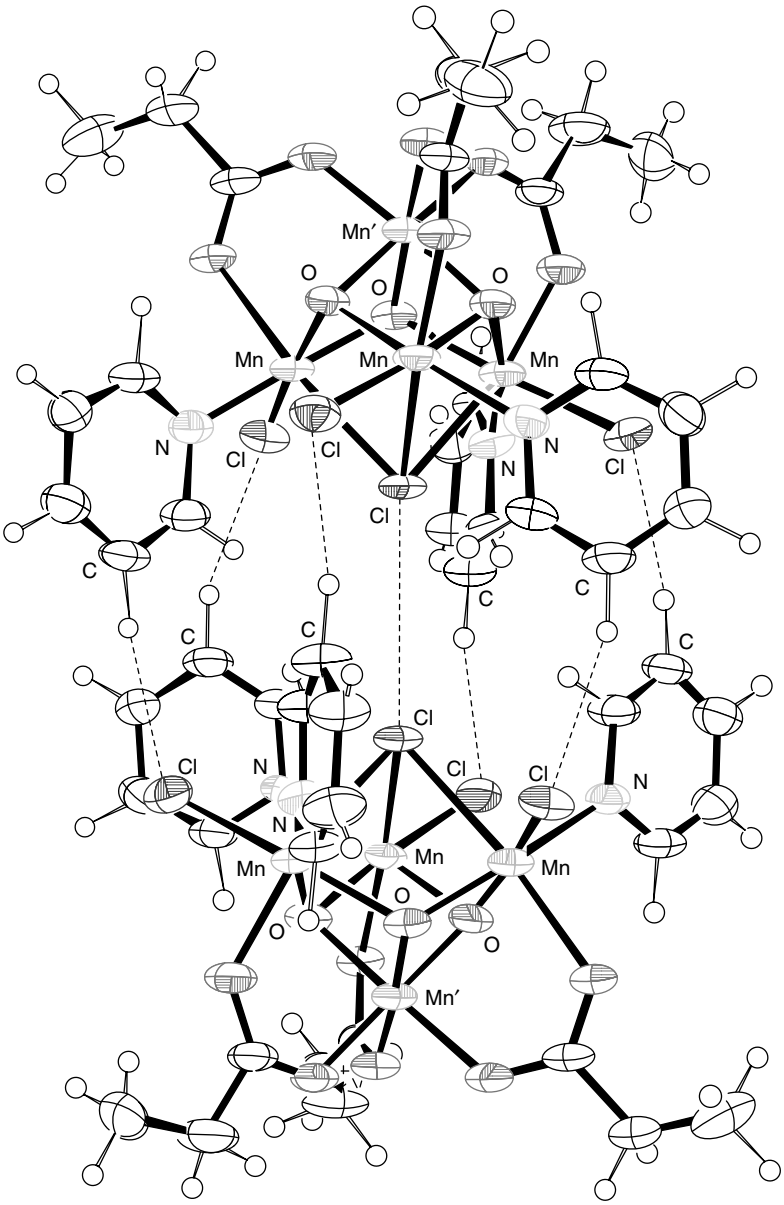

Figure 14. The structure of the $[Mn_4]_2$ dimer of $[Mn_4O_3Cl_4(O_2CEt)_3(py)_3]$. The small circles are hydrogen atoms. The dashed lines are C–H···Cl hydrogen bonds and the dotted line is the close Cl···Cl approach. The labels Mn and Mn^1 refer to Mn^{III} and Mn^{IV} ions, respectively.

where $i = 1$ or 2 (referring to the two Mn_4 SMMs of the dimer), D is the uniaxial anisotropy constant, and the other symbols have their usual meaning. Tunneling is allowed in these half-integer ($S = 9/2$) spin systems because of a small transverse anisotropy $\mathcal{H}_{\text{trans},i}$ containing $S_{x,i}$ and $S_{y,i}$ spin operators and transverse fields (H_x and H_y). The exact form of $\mathcal{H}_{\text{trans},i}$ is not important in this discussion. The last term in equation (8) is the Zeeman energy associated with an applied field. The Mn_4 units within the $[Mn_4]_2$ dimer are coupled by a weak superexchange interaction via both the six C–H···Cl pathways and the Cl···Cl approach. Thus, the Hamiltonian ($\mathcal{H}$) for $[Mn_4]_2$ is

$$\mathcal{H} = \mathcal{H}_1 + \mathcal{H}_2 + J_z S_{z,1} S_{z,2} + J_{xy}(S_{x,1} S_{x,2} + S_{y,1} S_{y,2}) \quad (9)$$

where J_z and J_{xy} are the longitudinal and transverse superexchange interactions, respectively. $J_z = J_{xy}$ is the case of isotropic superexchange. The $(2S + 1)^2 = 100$ energy states of the dimer can be calculated by exact numerical diagonalization and are plotted in Figure 15 as a function of applied field along the easy axis. Each state of $[Mn_4]_2$ can be labeled by two quantum numbers (M_1, M_2) for

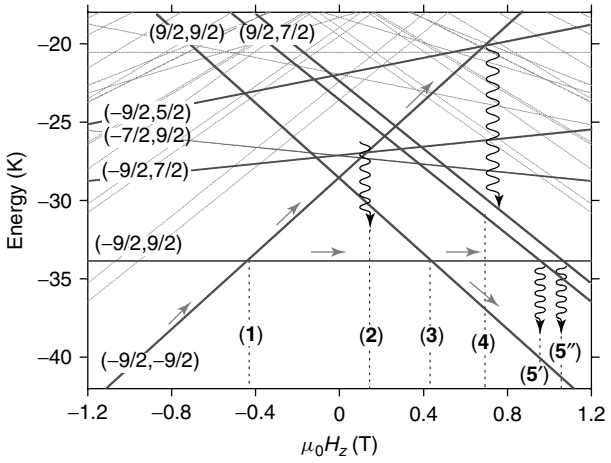

Figure 15. Low-lying spin-state energies of the $[Mn_4]_2$ dimer, calculated by exact numerical diagonalization using equation (9) with $D = 0.77$ K and $J = 0.13$ K, as a function of applied magnetic field H_z (Zeeman diagram). The bold energy levels are labeled with two quantum numbers (M_1, M_2). Dotted lines, labeled 1 to 5, indicate the strongest tunnel resonances: **1**: (−9/2,−9/2) to (−9/2,9/2); **2**: (−9/2,−9/2) to (−9/2,7/2), followed by relaxation to (−9/2,9/2); **3**: (−9/2,9/2) to (9/2,9/2); **4**: (−9/2,−9/2) to (−9/2,5/2), followed by relaxation to (−9/2,9/2); **5**: (−9/2,9/2) to (7/2,9/2), followed by relaxation to (9/2,9/2). For clarity, degenerate states such as (M, M′) and (M′, M) and lifted degenerate states such as $(M, M \pm 1)$, $(M, M \pm 2)$, and so on, are not listed. For example, the $(9/2, 7/2)$ and $(7/2, 9/2)$ states are strongly split into a symmetric (labeled **5″**) and antisymmetric (labeled **5′**) combination of $(9/2, 7/2)$ and $(7/2, 9/2)$ states. This splitting is used to measure the transverse superexchange interaction constant J_{xy}. Cotunneling and other two-body tunnel transitions have a lower probability of occurrence and are neglected (Wernsdorfer *et al*., 2002b). (Reproduced from R. Tiron *et al*., 2003, with permission from the American Physical Society. © 2003.)

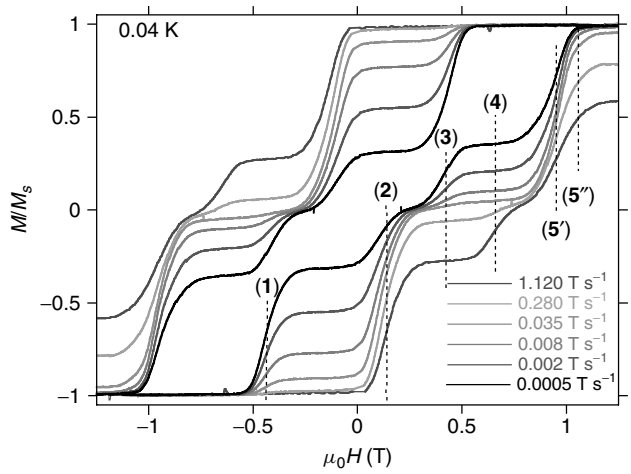

Figure 16. Hysteresis loops for the $[Mn_4]_2$ dimer at several field sweep rates and 40 mK. The tunnel transitions (manifested by steps) are labeled from **1** to **5** (see Figure 1). (Reproduced from R. Tiron *et al*., 2003, with permission from the American Physical Society. © 2003.)

the two Mn_4 SMMs, with $M_1 = -9/2, -7/2, \ldots, 9/2$ and $M_2 = -9/2, -7/2, \ldots, 9/2$. The degeneracy of some of the (M_1, M_2) states is lifted by transverse anisotropy terms. For the sake of simplicity, we mainly discuss the effect of the transverse superexchange interaction $\mathcal{J}_{\text{trans}} = J_{xy}(S_{x,1}S_{x,2} + S_{y,1}S_{y,2}) = J_{xy}(S_{+,1}S_{-,2} + S_{-,1}S_{+,2})/2$, where $S_{+,i}$ and $S_{-,i}$ are the usual spin raising and lowering operators. Because $\mathcal{J}_{\text{trans}}$ acts on $(M, M \pm 1)$ states to first order of perturbation theory, the degeneracy of these states is strongly lifted. For example, the $(9/2, 7/2)$ and $(7/2, 9/2)$ states are strongly split into a symmetric (labeled **5″**) and antisymmetric (labeled **5′**) combination of $(9/2, 7/2)$ and $(7/2, 9/2)$ states. Similar results hold for the $(-9/2, -7/2)$ and $(-7/2, -9/2)$ states. Measurement of this energy splitting allows us to determine the transverse superexchange interaction constant J_{xy} because the latter is proportional to the former.

Figure 16 shows typical hysteresis loops (magnetization vs magnetic field scans) with the field applied along the easy axis of magnetization of $[Mn_4]_2$, that is, parallel to the S_6 axis. These loops display steplike features separated by plateaus. The step heights are temperature independent below ∼0.35 K (Wernsdorfer, Aliaga-Alcalde, Hendrickson and Christou, 2002). The steps are due to resonant quantum tunneling of magnetization (QTM) between the energy states of the $[Mn_4]_2$ dimer (see captions of Figures 15 and 16 for a discussion of five tunnel transitions). QTM has been previously observed for most SMMs, but the novelty for $[Mn_4]_2$ dimers is that the QTM is now the collective behavior of the complete $S = 0$ dimer of exchange-coupled $S = 9/2$ Mn_4 quantum systems. This coupling is manifested as an exchange bias of all tunneling transitions, and the resulting hysteresis loop consequently displays unique features, such as the absence for the first time in an SMM of a QTM step at zero field (Wernsdorfer, Aliaga-Alcalde, Hendrickson and Christou, 2002).

Even though the five strongest tunneling transitions are observed in Figure 16, fine structure is not observed. For example, the hysteresis loops do not show the splitting of the $(9/2, 7/2)$ states (labeled **5′** and **5″**), which we suspected might be due to line broadening. Usually, line broadening in SMMs is caused by dipolar and hyperfine interactions (Prokof'ev and Stamp, 1998), and distributions of anisotropy and exchange parameters. In most SMMs, the zero-field resonance is mainly broadened by dipolar and hyperfine interactions because distributions of anisotropy parameters do not affect the zero-field resonance. For an antiferromagnetically coupled dimer, however, this resonance is shifted to negative fields. Therefore, a distribution of the exchange coupling parameter J_z can further broaden this resonance. In fact, we showed that the latter is the dominant source of broadening (Tiron *et al*., 2003). We used the 'quantum hole

digging' method (see Section 7.2) (Prokof'ev and Stamp, 1998; Wernsdorfer *et al*., 1999, 2000; Alonso and Fernandez, 2001; Tupitsyn, Stamp and Prokof'ev, 2004) to provide direct experimental evidence for the transitions **5′** and **5″**, which established tunneling involving entangled dimer states and allowed us to determine J_{xy} (Tiron *et al*., 2003).

5 RESONANT PHOTON ABSORPTION IN Cr_7Ni ANTIFERROMAGNETIC RINGS

Magnetic molecules are currently considered to be among the most promising electron-spin-based quantum systems for storing and processing quantum information. For this purpose, ferromagnetic (Leuenberger and Loss, 2001) and antiferromagnetic (Meier, Levy and Loss, 2003a,b) systems have attracted an increasing interest (Troiani *et al*., 2005a,b). In the latter case, the quantum hardware is thought of as a collection of coupled molecules, each corresponding to a different qubit. The main advantages would arise from the fact that they are extremely small and almost identical, allowing to obtain, in a single measurement, statistical averages of a large number of qubits. The magnetic properties can be modeled with an outstanding degree of accuracy. And, most importantly, the desired physical properties can be engineered chemically.

The suitability of Cr-based antiferromagnetic molecular rings for the qubit implementation has been proposed (Troiani *et al*., 2005a,b). The substitution of one metal ion in a Cr-based molecular ring with dominant antiferromagnetic couplings allows its level structure and ground-state degeneracy to be engineered (Overgaard *et al*., 2002; Larsen *et al*., 2003). A Cr_7Ni molecular ring was characterized by means of low-temperature specific-heat and torque-magnetometry measurements, thus determining the microscopic parameters of the corresponding spin Hamiltonian. The energy spectrum and the suppression of the leakage-inducing S-mixing render the Cr_7Ni molecule a suitable candidate for the qubit implementation (Carretta *et al*., 2005; Troiani *et al*., 2005a,b).

In this section, we report the first microsuperconducting quantum interference device (micro-SQUID) (Wernsdorfer, Müller, Mailly and Barbara, 2004) studies of the Cr_7Ni molecular ring (Wernsdorfer, Mailly, Timco and Winpenny, 2005). EPR methods are combined with high-sensitivity magnetization measurements. We found very narrow resonant photon absorption lines, which are mainly broadened by hyperfine interactions. Similar measurements were performed on Ni_4 molecules (del Barco, Kent, Yang and Hendrickson, 2004) but quantum coherence was not directly observed.

The Cr_7Ni molecular ring is based on a homometallic ring with formula $[Cr_8F_8(O_2CCMe_3)_{16}]$. The eight chromium(III) ions lie at the corners of a regular octagon (Overgaard *et al*., 2002). Each edge of the octagon is bridged by one fluoride ion and two pivalate ligands. There is a large cavity at the center of the ring. If a single chromium(III) ion is replaced by a metal(II) ion, for example, nickel(II), this makes the ring anionic and a cation can be incorporated in the cavity. Thus, we can synthesize the compound $[H_2NMe_2][Cr_7NiF_8(O_2CCMe_3)_{16}]$ (Larsen *et al*., 2003). If crystallized from a mixture of THF and MeCN, the Cr_8 and Cr_7Ni compounds are isostructural, crystallizing in the tetragonal space group, $P4$.

The measurements were made in a dilution cryostat using a single crystal of Cr_7Ni of size 20 µm. The magnetic probe was a micro-SQUID array (Wernsdorfer, 2001; Wernsdorfer, Müller, Mailly and Barbara, 2004) equipped with three coils allowing the application of a field in any direction and with sweep rates up to $10\,\mathrm{T\,s^{-1}}$. The electromagnetic radiation was generated by a frequency synthesizer triggered with a nanosecond pulse generator. This setup allows continuous variation of the frequency from 0.1 Hz to 20 GHz, with pulse lengths ∼1 ns to continuous radiation (Thirion, Wernsdorfer and Mailly, 2003). Using a gold radio frequency (RF) loop of size 50 µm, the RF radiation field was directed in a plane perpendicular to the applied static field $\mu_0 H$. The microwave power of the generator could be varied from −80 to 20 dBm (10^{-11} to 10^{-1} W). The sample absorbs only a small fraction of the generator power. This fraction is, however, proportional to the microwave power of the generator. The microwave amplitude B_{RF} can be estimated with the method described in Wernsdorfer, Müller, Mailly and Barbara (2004). We found $B_{\mathrm{RF}} \approx 1$ mT at 4 GHz and 15 dBm, which is more than 1000 times larger than that obtained in our previous work on V_{15} (Wernsdorfer, Müller, Mailly and Barbara, 2004).

Figure 17(a) shows magnetization versus applied field curves for several field sweep rates at a cryostat temperature of 0.04 K. The magnetization loops exhibit a clear hysteresis, which is characteristic of the phonon-bottleneck regime with a spin−phonon relaxation time to the cryostat of a few seconds (Chiorescu *et al*., 2000b). Note that the degeneracy of the Kramers doublet is lifted owing to internal transverse fields (mainly the transverse hyperfine fields). In order to quantify the out-of-equilibrium effect, Figure 17(b) presents the same data as in Figure 17(a) but the magnetization M is converted into a spin temperature T_S using the equation (Abragam and Bleaney, 1970)

$$M(T_S)/M_{\mathrm{s}} = \tanh\left(\frac{g\mu_{\mathrm{B}} S\mu_0 H}{k_{\mathrm{B}} T_S}\right) \tag{10}$$

with $S = 1/2$ and $g = 2.1$ (Larsen *et al*., 2003). Figure 17(b) shows clearly a strong adiabatic cooling when sweeping the

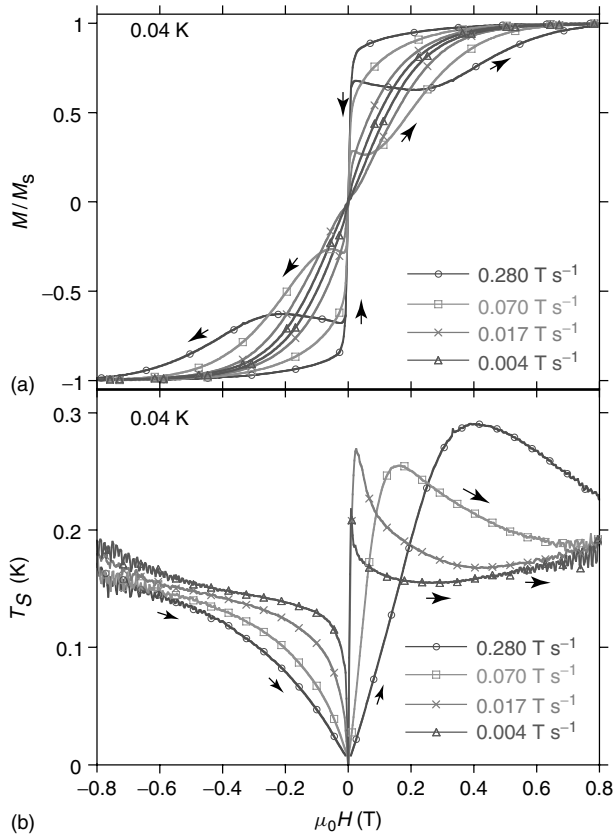

Figure 17. (a) Magnetization (M) hysteresis loops for several field sweep rates at a cryostat temperature of 0.04 K. The loops are normalized by the saturation magnetization M_s at 1.5 T. (b) Spin temperature T_S for field sweeps from negative to positive fields, obtained by inversion of equation (10), where $M(T_S)$ are the data in (a). (Reproduced from W. Wernsdorfer *et al*., 2005, with permission from the American Physical Society. © 2005.)

field down to zero field. Note that this cooling mechanism might be used before qubit operations to reach extremely low temperatures even at relatively high cryostat temperatures. High-frequency noise from the RF-loop around the sample leads to spin temperatures at 1 T being higher than the cryostat temperature.

Figure 18 shows magnetization curves $M(H)$ in the quasi-static regime with a field sweep rate slow enough ($0.14\,\mathrm{mTs^{-1}}$) to keep the system at equilibrium. During the field sweep, RF pulses are applied to the sample with a pulse length of 1 µs and a period of 4 s between each pulse. Depending on the RF frequency, clear dips are observed, which result from resonant absorptions of photons associated with spin transitions between the quantum numbers $m_s = 1/2$ and $-1/2$. After each pulse, the magnetization relaxes back to the equilibrium magnetization (see the fine structure in the inset of Figure 18).

Typical relaxation measurements at a constant applied field after RF pulses of different durations are shown in Figure 19.

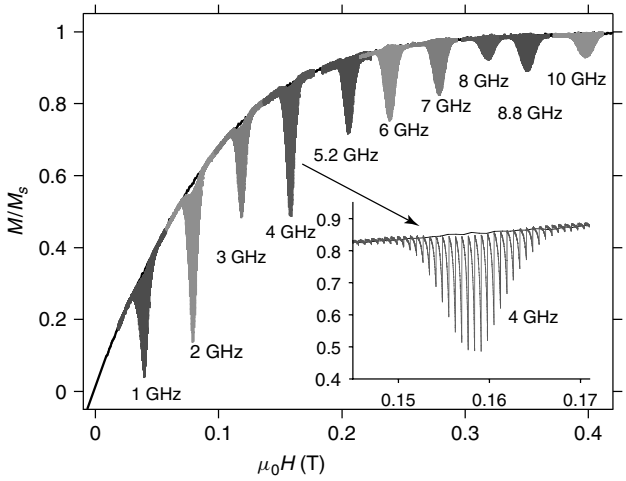

Figure 18. Magnetization curves measured with and without irradiation. The cryostat temperature was 40 mK and the field sweep rate of $0.14\,\mathrm{mT\,s^{-1}}$ was slow in order to keep the system at equilibrium. The electromagnetic radiation was pulsed with a period of 4 s and a pulse length of 1 µs. The RF frequencies are indicated and the RF amplitude is slightly frequency dependent. Inset: Enlargement of the 4 GHz resonance. The fine structure is due to the RF pulses. (Reproduced from W. Wernsdorfer *et al*., 2005, with permission from the American Physical Society. © 2005.)

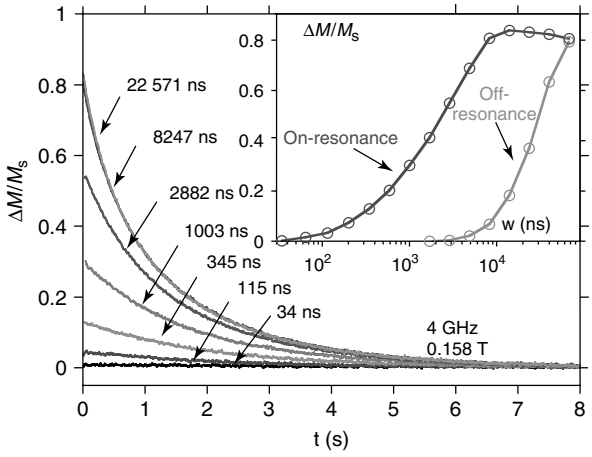

Figure 19. Relaxation of magnetization after an RF pulse of 4 GHz. The pulse lengths w are indicated. Inset: magnetization variation ΔM after a RF pulse versus the pulse length w for an on-resonance field (0.1582 T) and off-resonance field (0.1722 T). (Reproduced from W. Wernsdorfer *et al*., 2005, with permission from the American Physical Society. © 2005.)

The relaxation is exponential with the rate being independent of the pulse length. Detailed studies show that the relaxation rate is dominated by the phonon-bottleneck regime, that is, the spin–phonon relaxation time to the cryostat.

The inset of Figure 19 presents the change of magnetization ΔM between the magnetization before and after the pulse as a function of the pulse length w. ΔM increases linearly with w for short pulses of few tens of nanoseconds.

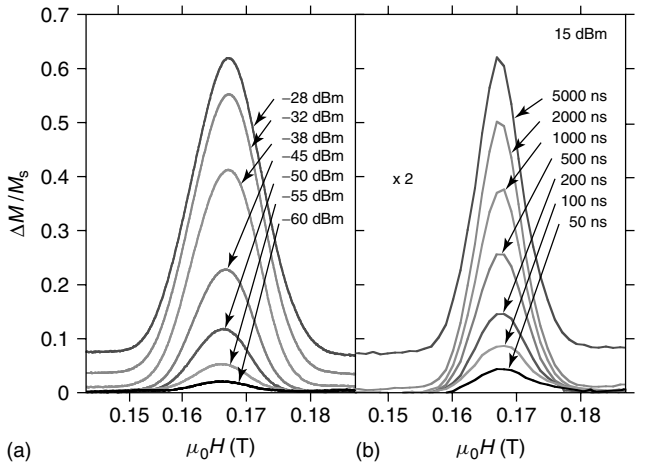

Figure 20. (a) Magnetization variation ΔM between the equilibrium curves measured without and with continuous irradiation. The microwave frequency was 4.2 GHz. The microwave powers of the generator are indicated. (b) Magnetization variation ΔM after a RF pulse of 4.2 GHz and several pulse lengths. The cryostat temperature was 40 mK. ΔM is multiplied by a factor two. (Reproduced from W. Wernsdorfer *et al.*, 2005, with permission from the American Physical Society. © 2005.)

It saturates for $w \approx 10\,\mu$s and decreases for very long pulses because of cryostat heating effects. Nonresonant photon absorption is also observed for very long pulses.

The resonant photon absorption lines are often taken to estimate a lower bound on the decoherence time of a qubit. We therefore investigated the linewidth observed in Figure 18 in more detail. Figure 20(a) presents a typical power dependence of the linewidth for continuous irradiation at 4.2 GHz. Resonant photon absorption is clearly visible for a generator power larger than −60 dBm (1 nW). The line saturated at about −20 dBm (10 μW). Figure 20(b) presents the absorption line for the pulsed technique (see Figure 18) for several pulse lengths and a generator power of 15 dBm (32 mW, $B_{\mathrm{RF}} \approx 1$ mT). The resonant photon absorption is clearly visible for pulse lengths longer than 10 ns. Note that the linewidths in Figure 20(a) are nearly twice as large as those in Figure 20(b).

In our case of an assembly of identical spins, the line broadening is mainly due to dipolar and hyperfine interactions. The dipolar coupling energy can be estimated with $E_{\mathrm{dip}}/k_{\mathrm{B}} \approx (g\mu_{\mathrm{B}}S)^2/V \approx 0.1$ mK ($S = 1/2$ and $V = 6.3\,\mathrm{nm}^3$) (Troiani *et al.*, 2005b). The hyperfine coupling with the nuclear spins can be obtained by considering the dipolar interaction of one Cr ion ($S = 3/2$) with the neighboring F nucleus having a nuclear spin $I = 1/2$. With $g_{\mathrm{F}} = +5.26$ and the distance of $d = 0.2$ nm between F and Cr ions, the interaction energy is about 0.4 mK for each of the eight F nuclear spins (Troiani *et al.*, 2005b). The hyperfine line broadening of all eight F nuclear spins is about 3 mK, which corresponds to 5 mT, in good agreement with the observed Gaussian linewidths of about $\sigma = 4$ mT in Figures 18 and 20.

Finally, we discuss the possibility of observing Rabi oscillations with the present setup. Owing to inhomogeneous broadening, only a lower bound of the coherence time τ_{c} can be estimated from the resonance lines in Figure 20: $\tau_{\mathrm{c}} \approx B_\nu/(\sigma\nu) \approx 10$ ns with $B_\nu = 0.166$ T, $\sigma = 4$ mT, and $\nu = 4.2$ GHz. The corresponding number of coherent flips of the spin system is given by $N = \tau_{\mathrm{c}}/\tau_{\mathrm{Rabi}}$ with $\tau_{\mathrm{Rabi}} = 2\pi/(\gamma B_{\mathrm{RF}}) \approx 40$ ns for $B_{\mathrm{RF}} \approx 1$ mT. We obtain $N \approx 0.25$, showing that there is possibility of seeing Rabi oscillations in the present conditions. In order to obtain $N \gg 1$, it will be necessary to further increase the radiation field B_{RF}, to substantially reduce the hyperfine broadening by substituting the F ions with OH groups, and to minimize the dipolar coupling by doping the crystal of Cr_7Ni molecules with Cr_8 molecules [3].

6 PHOTON-ASSISTED TUNNELING IN SINGLE-MOLECULE MAGNET

It has also been proposed that molecular nanomagnets could be used as quantum computers by implementing Grover's algorithm (Leuenberger and Loss, 2001). For this, it is necessary to be able to generate an arbitrary superposition of eigenstates of these systems. The method suggested was through the use of multifrequency coherent magnetic radiation in the microwave and radiofrequency range. This would first introduce and amplify the desired phase for each m_S state and this information could be finally read out by standard magnetic resonance techniques. In this approach advantage is taken from the non-equidistance of the m_S levels of the ground multiplet (arising from the large axial anisotropy of these systems), which allows coherent populations of the different m_S levels. A theoretical work pointed out that a very accurate control of pulse shape technique, both in amplitude, duration, and choice of frequency is needed to fulfill the condition to design quantum computing devices in molecular nanomagnets (Zhou, Tao, Shen and Liang, 2002). In addition to such basic difficulties, we see in the subsequent text that the total microwave power convoyed onto the samples cannot exceed a critical value above which nonlinear effects occur.

In order to investigate the feasibility of the proposed Process, any preliminary experiment should aim to understand the effects of microwave absorption on the spin dynamics of these systems at low temperatures. The measurements were performed using micro-Hall bars (Sorace *et al.*, 2003). Continuous microwave radiation was generated by a couple of Gunn diodes equipped with calibrated attenuators.

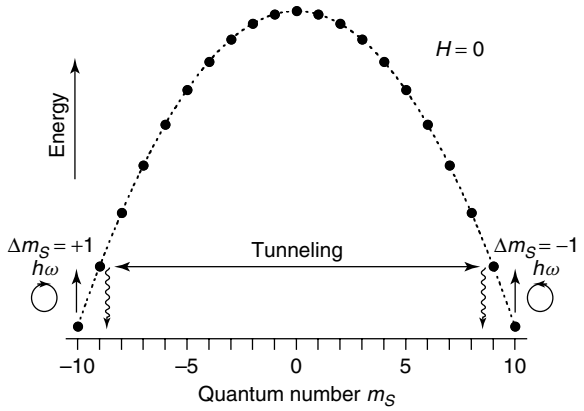

Figure 21. Schematic representation of photon-assisted tunneling. On irradiating an Fe_8 sample with a radiation of wavelength corresponding to the $m_S = -10$ to -9 splitting (vertical arrow), an enhancement of the fraction of molecules that tunnel from the first excited state is expected (horizontal arrow). The use of circularly polarized radiation allows selecting only one side of the well and distinguishing between spin–phonon and spin–photon transitions. (Reproduced from L. Sorace *et al.*, 2003, with permission from the American Physical Society. © 2003.)

With this experimental setup, which has very good stability of emitted power and a narrow bandwidth (100 kHz), only relative powers at the output of the diode can be known, which will be referred to as ρ in the following discussion. We irradiated the sample using a 6-mm waveguide equipped with infrared filters in order to reduce heating. The circular polarization was maximized around 97%. The study was performed on a 0.1-mm Fe_8 single crystal.

As schematically depicted in Figure 21, microwave radiation with a frequency of 115 GHz corresponds to the energy separation between the ground states $m_S = \pm S$ and the first excited states $m_S = \pm(S-1)$ of Fe_8 in zero applied magnetic field (Barra *et al.*, 1996; Hill *et al.*, 2002). If the radiation is linearly polarized, the populations of the first excited states ($m_S = \pm(S-1)$) in both wells will be enhanced equally (equal transition probability for $\Delta m_S = \pm 1$). On the other hand, the use of circular polarization has the advantage of distinguishing between $\Delta m_S = +1$ (left polarization, σ^- photons) or $\Delta m_S = -1$ (right polarization, σ^+ photons) (Abragam and Bleaney, 1970), and the population of only one of the two excited states will be enhanced (Figure 21). An excess of tunneling from one well to the other is then expected. Therefore, circular polarization can help distinguish between spin–phonon relaxation, and spin-phonon relaxation modified by the absorption of photons. The former equally affects the two sides of the barrier, that is, the two branches of the hysteresis loop, while the latter modifies the population of only one side of the barrier, that is, one branch of the hysteresis loop. Any difference observed between the two branches of the hysteresis loop has to be traced back to photon absorption.

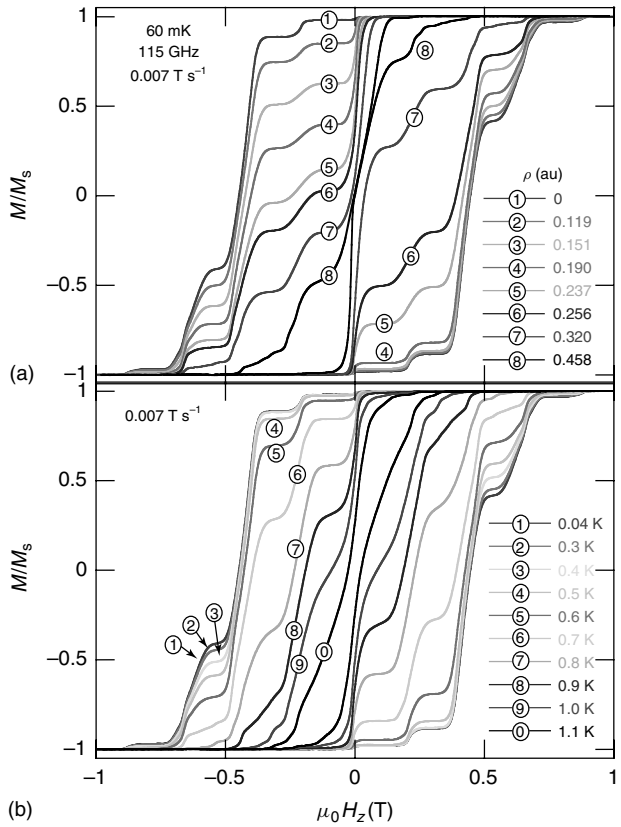

Figure 22. Magnetic hysteresis loops of Fe_8 at a field sweep rate of $0.007\,T\,s^{-1}$ and at 60 mK under irradiation with microwaves at 115 GHz and for several microwave powers ρ (a). The easy axis of the crystal is oriented along the applied field and perpendicular to the radiation oscillating magnetic field. The observed increasing of the tunneling rate at zero field, as a consequence of the absorption of photons induced by circularly polarized radiation, becomes evident by comparing the zero-field steps after positive or negative saturation. For comparison, the thermal behavior is presented in (b). (Reproduced from L. Sorace *et al.*, 2003, with permission from the American Physical Society. © 2003.)

Figure 22(a) shows the hysteresis loops of an Fe_8 single crystal with the easy axis parallel to the applied field, measured at 60 mK under irradiation. The tunneling transition near zero field is strongly enhanced for a radiation at 115 GHz. This is in agreement with a photon-induced population transfer from $m_S = 10$ to $m_S = 9$, and agrees with earlier HF-EPR studies showing strong zero field absorption at about 116 GHz (Barra *et al.*, 1996; Hill *et al.*, 2002). Figure 22(a) also shows the expected asymmetry of the hysteresis loops in the presence of circularly polarized radiation. In particular, the height of the zero-field step (first tunnel resonance, $n = 0$) obtained when sweeping the field from negative saturation is much less affected than when sweeping

from positive saturation. This behavior is completely different from phonon-assisted tunneling (Figure 22b) and clearly establishes that tunneling is assisted by photons for the matching frequency of 115 GHz. The observation of a more symmetric shape of the hysteresis curve at high microwave power can be explained both by the incomplete microwave polarization and by phonon emission, leading to relaxation on both sides of the barrier.

A detailed study showed that at lowest powers the tunnel probability increases linearly with power, whereas at higher powers a strongly nonlinear regime is observed (Sorace *et al*., 2003). The latter might be due to multispin and coherent photon transitions.

7 ENVIRONMENTAL DECOHERENCE EFFECTS IN NANOMAGNETS

At temperatures below 0.36 K, Fe_8 molecular clusters display a clear crossover from thermally activated relaxation to a temperature-independent quantum regime, with a pronounced resonance structure of the relaxation time as a function of the external field (Section 3). It was surprising, however, that the observed relaxation of the magnetization in the quantum regime was found to be nonexponential and the resonance width orders of magnitude too large (Sangregorio *et al*., 1997; Ohm, Sangregorio and Paulsen, 1998a). The key to understand this seemingly anomalous behavior involves the hyperfine fields as well as the evolving distribution of the weak dipole fields of the nanomagnets themselves (Prokof'ev and Stamp, 1998). Both effects were shown to be the main source of decoherence at very low temperature. At higher temperatures, phonons are another source of decoherence.

In the following sections, we focus on the low temperature and low field limits, where phonon-mediated relaxation is astronomically long and can be neglected. In this limit, the $m = \pm S$ spin states are coupled owing to the tunneling splitting $\Delta_{\pm S}$, which is about 10^{-7} K for Fe_8 (Section 3.2) with $S = 10$. In order to tunnel between these states, the longitudinal magnetic energy bias $\xi = g\mu_B S H_{\text{local}}$ due to the local magnetic field H_{local} on a molecule must be smaller than $\Delta_{\pm S}$, implying a local field smaller than 10^{-8} T for Fe_8 clusters. Since the typical intermolecular dipole fields are of the order of 0.05 T, at first it seems that almost all molecules should be blocked from tunneling by a very large energy bias. Prokof'ev and Stamp have proposed a solution to this dilemma by proposing that fast dynamic nuclear fluctuations broaden the resonance, and the gradual adjustment of the dipole fields in the sample caused by the tunneling brings other molecules into resonance and allows continuous relaxation (Prokof'ev and Stamp, 1998). Some interesting predictions are briefly reviewed in the following section.

7.1 Prokof'ev–Stamp theory

Prokof'ev and Stamp were the first to realize that there are localized couplings of environmental modes with mesoscopic systems that cannot be modeled with an 'oscillator bath' model (Feynman and Vernon, 1963) describing delocalized environmental modes such as electrons, phonons, photons, and so on. They found that these localized modes such as nuclear and paramagnetic spins were often strong and described them with a spin bath model (Prokof'ev and Stamp, 1996). We do not review this theory (Prokof'ev and Stamp, 2000) but focus on one particular application that is interesting for molecular clusters (Prokof'ev and Stamp, 1998). Prokof'ev and Stamp showed that, at a given longitudinal applied field H_z, the magnetization of a crystal of molecular clusters should relax at short times with a square-root time dependence, which is due to a gradual modification of the dipole fields in the sample caused by the tunneling

$$M(H_z, t) = M_{\text{in}} + (M_{\text{eq}}(H_z) - M_{\text{in}})\sqrt{\Gamma_{\text{sqrt}}(H_z)t} \qquad (11)$$

Here, M_{in} is the initial magnetization at time $t = 0$ (after a rapid field change), and $M_{\text{eq}}(H_z)$ is the equilibrium magnetization at H_z. The rate function $\Gamma_{\text{sqrt}}(H_z)$ is proportional to the normalized distribution $P(H_z)$ of molecules that are in resonance at H_z:

$$\Gamma_{\text{sqrt}}(H_z) = c\frac{\xi_0}{E_D}\frac{\Delta_{\pm S}^2}{4\hbar}P(H_z) \qquad (12)$$

where ξ_0 is the linewidth from the nuclear spins, E_D is the Gaussian half-width of $P(H_z)$, and c is a constant of the order of unity, which depends on the sample shape. If these simple relations are exact, then measurements of the short time relaxation as a function of the applied field H_z directly give the distribution $P(H_z)$, and they allow one to measure the tunnel splitting $\Delta_{\pm S}$, which is described in the next section.

7.2 Hole digging method to study dipolar distributions and hyperfine couplings

Motivated by the Prokof'ev–Stamp theory (Prokof'ev and Stamp, 1998), we developed a new technique–which we call the *hole digging method*–that can be used to observe the time evolution of molecular states in crystals of molecular clusters. It allowed us to measure the statistical distribution of magnetic bias fields in the Fe_8 system that arise from the weak dipole fields of the clusters themselves. A hole can be 'dug' into the distribution by depleting the available spins

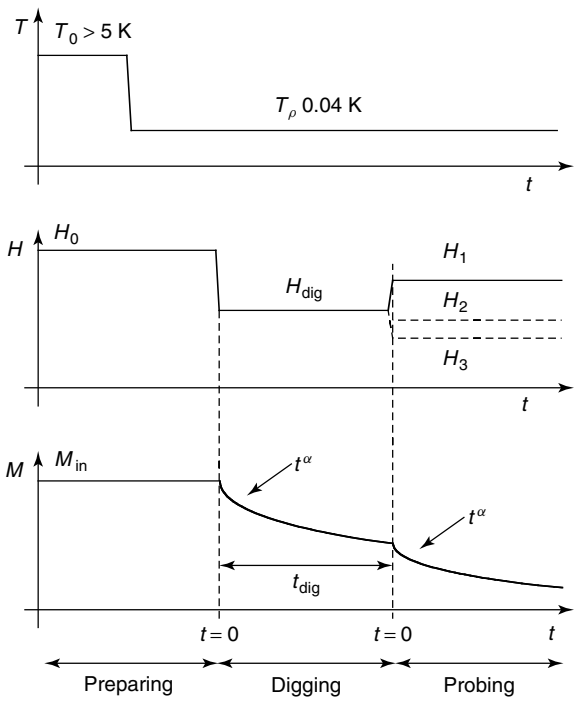

Figure 23. Schema of the hole digging method presenting the time dependence of temperature, applied field, and magnetization of the sample.

at a given applied field. Our method is based on the simple idea that, after a rapid field change, the resulting short time relaxation of the magnetization is directly related to the number of molecules that are in resonance at the given applied field. Prokof'ev and Stamp have suggested that the short time relaxation should follow a $\sqrt{t}-$relaxation law (equation (11)). However, the hole digging method should work with any short time relaxation law–for example, a power law

$$M(H_z, t) = M_{\text{in}} + (M_{\text{eq}}(H_z) - M_{\text{in}})(\Gamma_{\text{short}}(H_z)t)^{\alpha} \quad (13)$$

where Γ_{short} is a characteristic short time relaxation rate that is directly related to the number of molecules that are in resonance at the applied field H_z, and $0 < \alpha < 1$ in most cases. $\alpha = 0.5$ in the Prokof'ev–Stamp theory (equation (11)) and Γ_{sqrt} is directly proportional to $P(H_z)$ (equation (12)). The *hole digging method* can be divided into three steps (Figure 23):

1. *Preparing the initial state:* A well-defined initial magnetization state of the crystal of molecular clusters can be achieved by rapidly cooling the sample from high down to low temperatures in a constant applied field H_z^0. For zero applied field ($H_z = 0$) or rather large applied fields ($H_z > 1\,\text{T}$), a demagnetized or saturated magnetization state of the entire crystal can be obtained, respectively. When quenching the sample in a small field of few milliteslas, any possible initial magnetization M_{in} is achieved. When the quench is fast (<1 s), the sample's magnetization does not have time to relax, either by thermal or by quantum transitions. This procedure yields a frozen thermal equilibrium distribution, whereas for slow cooling rates the molecule spin states in the crystal might tend to a certain dipolar ordered ground state. Finally, a randomly disordered state can be achieved by sweeping the field back and forth over the zero-field resonance. During each sweep, few spins tunnel randomly back and fourth. When the Landau-Zener tunnel probability is small ($P_{\text{LZ}} \ll 1$), and a large number of back and forth sweeps is performed, the randomly disordered state can be complete (Wernsdorfer, Bhaduri, Vinslava and Christou, 2005).
2. *Modifying the initial state–hole digging:* After preparing the initial state, a field H_{dig} is applied during a time t_{dig}, called *digging field* and *digging time*, respectively. During the digging time and depending on H_{dig}, a fraction of the molecular spins tunnel (back and/or forth), that is, they reverse the direction of magnetization [4].
3. *Probing the final state:* Finally, a field H_z^{probe} is applied (Figure 23) to measure the short time relaxation from which one yields Γ_{short} (equation (13)), which is related to the number of spins that are still free for tunneling after step (2).

The entire procedure is then repeated many times but at other fields H_z^{probe}, yielding $\Gamma_{\text{short}}(H_z, H_{\text{dig}}, t_{\text{dig}})$, which is related to the distribution of spins $P(H_z, H_{\text{dig}}, t_{\text{dig}})$ that are still free for tunneling after the hole digging. For $t_{\text{dig}} = 0$, this method maps out the initial distribution.

7.3 Intermolecular dipole interaction in Fe_8

We applied the hole digging method to several samples of molecular clusters and quantum spin glasses. The most detailed study has been done on the Fe_8 system. We found the predicted $\sqrt{t}$ relaxation (equation (11)) in experiments on fully saturated Fe_8 crystals (Ohm, Sangregorio and Paulsen, 1998a,b) and on nonsaturated samples (Wernsdorfer *et al.*, 1999). Figure 24 displays a detailed study of the dipolar distributions, revealing a remarkable structure that is due to next-nearest-neighbor effects (Wernsdorfer *et al.*, 1999). These results are in good agreement with simulations (Cuccoli *et al.*, 1999; Tupitsyn, Stamp and Prokof'ev, 2004).

For a saturated initial state, the Prokof'ev–Stamp theory allows one to estimate the tunnel splitting $\Delta_{\pm S}$. Using equations (3), (9), and (12) of Prokof'ev and Stamp (1998),

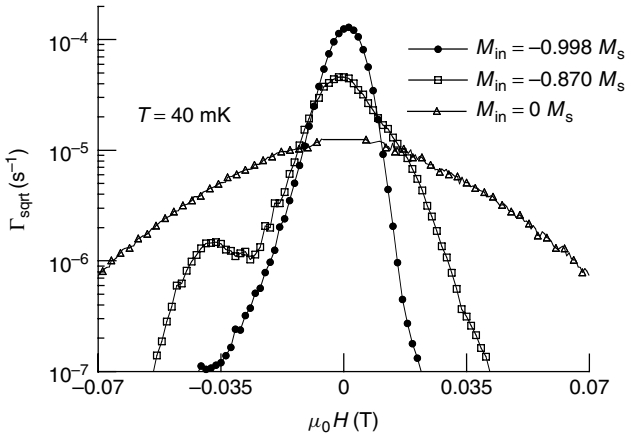

Figure 24. Field dependence of the short time square-root relaxation rates $\Gamma_{sqrt}(H_z)$ for three different values of the initial magnetization M_{in}. According to equation (12), the curves are proportional to the distribution $P(H_z)$ of magnetic energy bias due to local dipole field distributions in the sample. Note the logarithmic scale for Γ_{sqrt}. The peaked distribution labeled $M_{in} = -0.998 M_s$ was obtained by saturating the sample, whereas the other distributions were obtained by thermal annealing. $M_{in} = -0.870 M_s$ is distorted by nearest-neighbor lattice effects. The peak at −0.04 T as well as the shoulder at 0.02 T and 0.04 T are originated by the clusters that have one nearest-neighbor cluster with reversed magnetization: the peak at −0.04 T corresponds to the reversal of the neighboring cluster along the **a** crystallographic axis, which almost coincides with the easy axis of magnetization, while the shoulder at 0.02 and 0.04 T is due to the clusters along crystallographic axes **b** and **c**. (Reproduced from W. Wernsdorfer *et al.*, 1999, with permission from the American Physical Society. © 1999.)

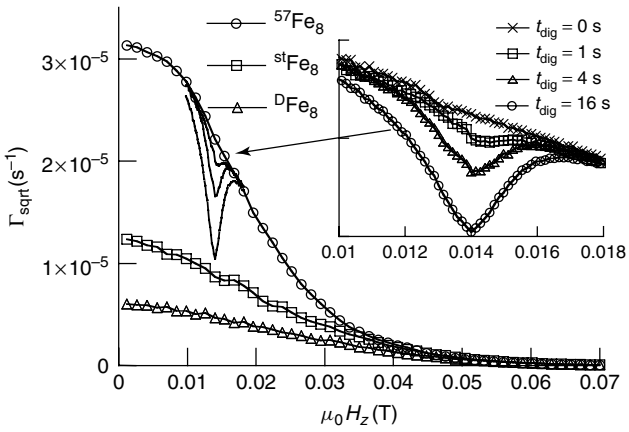

Figure 25. Comparison of the short time relaxation rates of three different Fe_8 samples at $T = 40$ mK with $H_{trans} = 0$ and $M_{init} = 0$. The inset displays a typical example of a hole that was dug into the distribution by allowing the sample to relax for the time t_{dig} at $\mu_0 H_{dig} = 14$ mT. (Reproduced from W. Wernsdorfer *et al.*, 2000, with permission from the American Physical Society. © 2000.)

along with integration, we find $\int \Gamma_{sqrt} d\xi = c \frac{\xi_0}{E_D} \frac{\Delta_{\pm S}^2}{4\hbar}$, where c is a constant of the order of unity that depends on the sample shape. With $E_D = 15$ mT, $\xi_0 = 0.8$ mT, $c = 1$, and Γ_{sqrt} (Wernsdorfer *et al.*, 1999, 2000), we find $\Delta_{\pm 10} = 1.2 \times 10^{-7}$ K, which is close to the result of $\Delta_{\pm 10} = 1.0 \times 10^{-7}$ K obtained by using a Landau–Zener method (Section 3.1) (Wernsdorfer and Sessoli, 1999).

Whereas the hole digging method probes the longitudinal dipolar distribution (H_z direction), the Landau–Zener method can be used to probe the transverse dipolar distribution by measuring the tunnel splittings Δ around a topological quench.

7.4 Hyperfine interaction in Fe_8

The strong influence of nuclear spins on resonant quantum tunneling in the molecular cluster Fe_8 was demonstrated for the first time (Wernsdorfer *et al.*, 2000) by comparing the relaxation rate of the standard Fe_8 sample with two isotopic modified samples: (i) ^{56}Fe is replaced by ^{57}Fe, and (ii) a fraction of ^{1}H is replaced by ^{2}H. By using the hole digging method, we measured an intrinsic broadening that is driven by the hyperfine fields (Figure 25). Our measurements are in good agreement with numerical hyperfine calculations (Wernsdorfer *et al.*, 2000; Tupitsyn, Stamp and Prokof'ev, 2004). For $T > 1.5$ K, the influence of nuclear spins on the relaxation rate is less important, suggesting that spin–phonon coupling dominates the relaxation rate.

8 CONCLUSION

In conclusion, we presented detailed measurements that demonstrated that molecular nanomagnets offer a unique opportunity to explore the quantum dynamics of a large but finite spin. We focused our discussion on the Fe_8 molecular nanomagnet because it is the first system where studies in the pure quantum regime were possible. The tunneling in this system is remarkable because it does not show up at the lowest orders of perturbation theory.

A new family of supramolecular, antiferromagnetically exchange-coupled dimers of SMMs has recently been reported (Wernsdorfer, Aliaga-Alcalde, Hendrickson and Christou, 2002). Each SMM acts as a bias on its neighbor, shifting the quantum tunneling resonances of the individual SMMs. Hysteresis loop measurements on a single crystal of SMM dimers have established quantum tunneling of the magnetization via entangled states of the dimer. This showed that the dimer really does behave as a quantum-mechanically coupled dimer. The transitions are well separated, suggesting long coherence times compared to the timescale of the energy splitting (Tiron *et al.*, 2003). This result is of great importance if such systems are to be used for quantum computing.

Molecules with small spin have also been studied. For example, time-resolved magnetization measurements were performed on a spin 1/2 molecular complex, the so-called V_{15} (Chiorescu *et al*., 2000a). Despite the absence of a barrier, magnetic hysteresis is observed over a timescale of several seconds. A detailed analysis in terms of a dissipative two-level model has been given, in which fluctuations and splittings are of the same energy. Spin–phonon coupling leads to long relaxation times and to a particular 'butterfly' hysteresis loop (Chiorescu *et al*., 2000b; Dobrovitski, Katsnelson and Harmon, 2000). We presented magnetization measurements on a crystal of Cr_7Ni antiferromagnetic rings with a spin 1/2. Irradiation with microwaves at frequencies between 1 and 10 GHz leads to the observation of very narrow resonant photon absorption lines, which are broadened by hyperfine and spin–spin interactions.

The use of circularly polarized microwaves allowed us to show for the first time the phenomenon of photon-assisted tunneling in magnetism, using an SMM Fe_8 (Sorace *et al*., 2003). In accordance with the selection rules for EPR spectroscopy (Abragam and Bleaney, 1970), circularly polarized radiation promotes the transition $m_S = 10$ to 9 with $\Delta m_S = -1$, giving an effect of magnetic dichroism at millimeter wavelengths. At lowest powers, the tunnel probability increases linearly with power, whereas at higher powers a strongly nonlinear regime is observed. The latter might be due to multispin and coherent photon transitions.

What remains still debated is the possibility of observing quantum coherence between states of opposite magnetization. Dipole–dipole and hyperfine interactions are source of decoherence. In other words, when a spin has tunneled through the barrier, it experiences a huge modification of its environment (hyperfine and dipolar), which prohibits the back tunneling. Prokof'ev and Stamp suggested three possible strategies to suppress the decoherence (Prokof'ev and Stamp, 1995). (i) Choose a system where the nuclear magnetic resonance (NMR) frequencies far exceed the tunnel frequencies making any coupling impossible. (ii) Isotopically purify the sample to remove all nuclear spins. (iii) Apply a transverse field to increase the tunnel rate to frequencies much larger than hyperfine field fluctuations. Several groups are currently working on such proposals.

With reference to the perspectives of the field of SMMs, we expect that chemistry will play a major role through the synthesis of novel larger spin clusters with strong anisotropy. We want to stress that there are already many other molecular nanomagnets (the largest is currently an Mn_{84}, Figure 2) that are possible model systems. We believe that more sophisticated theories that describe the dephasing effects of the environment onto the quantum system are needed. These investigations are important for studying the quantum character of molecular clusters for applications like 'quantum computers'. The first implementation of Grover's algorithm with molecular nanomagnets has been proposed (Leuenberger and Loss, 2001). Antiferromagnetic systems have attracted much interest. In this case, the quantum hardware is thought of as a collection of coupled molecules, each corresponding to a different qubit (Meier, Levy and Loss, 2003a,b; Troiani *et al*., 2005a,b). In order to explore these possibilities, new and very precise setups are currently being built and new methods and strategies are being developed. The field of molecular nanomagnets is evolving toward molecular electronics and spintronics, which are both rapidly emerging fields of nanoelectronics with a strong potential impact for the realization of new functions and devices helpful for information storage as well as quantum information. New projects aim at the merging of the two fields by the realization of molecular junctions that involve a molecular nanomagnet. In order to tackle the challenge of controlled connection at the single-molecule level, molecular self-assembly on nanojunctions obtained by the technique of electromigration was used (Heersche *et al*., 2006; Jo *et al*., 2006). Furthermore, a new nano-SQUID with carbon nanotube Josephson junctions has been developed (Cleuziou *et al*., 2006), which should be sensitive enough to study individual magnetic molecules that are attached to the carbon nanotube. Such techniques will lead to enormous progress in the understanding of the electronic and magnetic properties of isolated molecular systems and will reveal intriguing new physics.

NOTES

[1] The Kramers theorem asserts that no matter how unsymmetric the crystal field is, an ion possessing an odd number of electrons must have a ground state that is at least doubly degenerate, even in the presence of crystal fields and spin–orbit interactions (Kramers, 1930).

[2] The probability density of reversal of a stochastic process is $-\mathrm{d}P/\mathrm{d}t = P/\tau$ and the maximum of the probability density can be derived from $\mathrm{d}^2P/\mathrm{d}t^2 = P(1 + \mathrm{d}\tau/\mathrm{d}t)/\tau^2 = 0$. This gives $\mathrm{d}\tau/\mathrm{d}t = -1$. The application to equation (5) leads to $\Delta E(H) = k_\mathrm{B}T \ln\left[k_\mathrm{B}T/\left(\tau_0 \frac{\mathrm{d}E}{\mathrm{d}H}\frac{\mathrm{d}H}{\mathrm{d}t}\right)\right]$. Using equation (6) we find equation (7).

[3] Very recently measurements (Ardavan *et al*., 2007) of the dephasing time of the Cr_7Ni molecular magnets showed values up to three orders of magnitude higher than originally thought (Wernsdorfer, Mailly, Timco and Winpenny, 2005). Such a long timescale gives enough time for about a hundred manipulations, which is a promising figure for quantum computing (Wernsdorfer, 2007).

[4] The field sweeping rate to be applied $H_{\rm dig}$ should be fast enough to minimize the change of the initial state during the field sweep.

1 INTRODUCTION

The past few years have witnessed a continuously growing interest in the use of magnetic-field sensors for biological applications and, in particular, for the detection of biomolecular recognition.

Biomolecular recognition can be understood as the interaction between biomolecules that show affinity toward each other or present some sort of complementarity between them. This translates into the establishment of intermolecular forces of varying intensity either they are Van der Waals forces, salt bridges or hydrogen bonds. Examples of these interactions can be DNA–DNA hybridization, antibody–antigen recognition and general ligand–receptor binding (Voet, Voet and Pratt, 1999).

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

Biomolecular recognition is in fact ubiquitous in life as it is the means through which cell 'machinery' works: the replication of the genetic code; the translation of this code into functional units, the enzymes; the fabrication and modification of biomolecular structures such as proteins, lipids, glycids, and nucleic acids; the intra and extracellular transport; cell metabolism; cell sensing and signaling pathways; just to name a few of general biological processes (Voet, Voet and Pratt, 1999; Cooper, 2000). More familiar uses of biomolecular recognition, on the other hand, include, for instance, pregnancy tests, blood type testing, genetic screening, and site-directed cancer treatments presently being developed.

It is then understandable that the detection of biomolecular recognition is becoming even more important in areas such as healthcare, pharmaceutical industry, environmental analysis, detection of biological warfare agents, and in broad biotechnological applications.

Generally, the detection of biomolecular recognition involves the use of a known biomolecule that probes a testing sample for a specific target analyte. Hence, they are given the names of probe biomolecule and target biomolecule, respectively. For instance, in pregnancy tests the presence of a specific hormone, the human Chorionic Gonadotropin (hCG), in urine indicates that the woman is most probably pregnant. In this case, the target molecule is hCG and the probe biomolecule is an antibody for hCG.

Conventional methods of detecting biomolecular recognition involve the labeling of biomolecules such that a distinct physical property can be detected or measured in the event of biomolecular recognition. As so, biomolecules are usually labeled with radioactive, colorimetric or fluorescent markers, which can be a small chemical moiety, a biomolecule, an

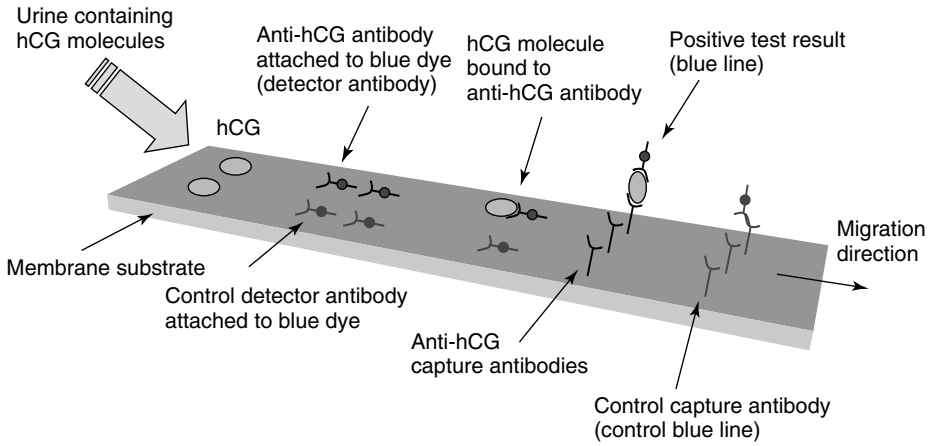

Figure 1. A familiar example of biomolecular recognition: the pregnancy test. Human Chorionic Gonadotropin (hCG) molecules present in the urine of a pregnant woman migrate through a membrane by capillarity. These molecules are first recognized by antibodies labeled with a colored dye, which are adsorbed to the membrane. The antibody-protein moves in the membrane support and are recognized by antibodies immobilized in a narrow region of the membrane. The result is a thin colored line in the test indicating that the woman is pregnant. At the same time, control antibodies also labeled with a similar dye move through the membrane and are bound to the control antibodies immobilized in the membrane indicating that the test proceeded reasonably.

enzyme, a particle or even a conjugation of several of these elements.

Again, in present pregnancy home tests the detection of the hCG hormone proceeds more or less as follows: the hCG molecules carried by the urine move by capillarity through a membrane which contains antibodies labeled with a colored dye (detector antibody). The antibodies recognize the hormone and the complex migrates along the membrane. The hCG molecule complexed with the detector antibody is then recognized by secondary antibodies immobilized in a narrow region of the membrane (capture antibodies) forming a 'sandwich' like structure. Finally, a thin colored line in the test strip appears as a result of increased concentration of blue dyes at that region (Unipath, http://www.unipath.com). The pregnancy test referred in the preceding text is an example of immunoassay, as the target is recognized by an antibody (Figure 1).

The conventional labeling methods present a series of disadvantages. In the case of biomolecular radioactive labeling, although being a sensitive technique, expensive scintillators are required for quantitative measurement. Furthermore, the great care necessary when working with radioactive compounds limits the use of this technique. These systems are presently being replaced by colorimetric- and fluorescent-based ones, which do not show this drawback.

Enzyme-label-based systems usually produce a colored compound that indicates biomolecular recognition. They offer high sensitivity and enable multiplex analysis but require additional reagents (the substrate that produces a colored compound when catalyzed by the enzyme) and the enzyme activity is sensitive to changes in the environment, namely temperature and pH, which limits the range of use of the method. The most widely used colorimetric system is the enzyme-linked immunosorbent assay (ELISA) of which the presented pregnancy test is a variation (Peruski and Peruski, 2003).

The systems that make use of fluorescent labels are also quite sensitive and also enable multiplexing but they often require expensive optical systems for signal detection, and furthermore, the labels photo bleach when exposed to light. This then limits the generalized use of these systems and limits the reproducible retesting of the assays. The most familiar systems of this kind are the real-time polymerase chain reaction (RT-PCR) systems (Cirino, Musser and Egan, 2004) and the so-called DNA chips or DNA microarrays (Ramsay, 1998) which will be discussed in more detail further in Figure 2.

Recent advances on particle synthesis and preparation, such as metal and semiconducting nanoparticles, have overcome some of the limitations of the traditional labels: radioactive, chemical, and biomolecular, such as the dangerous handling and the stability. These labels are also enabling higher biomolecular detection sensitivities and conferring new functionalities to bioanalytical assays (Katz and Willner, 2004).

Magnetic particles have been traditionally used in biological applications for biomolecular and cell separation; has a contrast agent in nuclear magnetic resonance (NMR) imaging; in hyperthermia studies for cancer treatment or even for drug, gene, or radionuclide delivery (Häfeli, Schutt, Teller and Zborowski, 1997; Pankhurst, Connolly, Jones and Dobson, 2003). More recently, they started to be used as labels

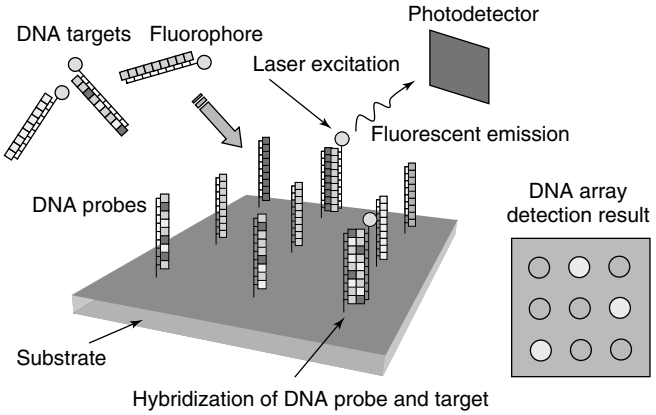

Figure 2. DNA chips or DNA microarrays are comprised of a substrate (usually glass slides) patterned with different DNA probes. These regions usually are circular spots of varying diameters (∼50 to 100 μm or more) that contain millions of copies of the same DNA sequence. In these systems, sample DNA targets are usually labeled with fluorophores and are incubated with the microarrays for several hours for hybridization to occur. DNA target and probe hybridization is detected by measuring the fluorescent emission of the labels with complex optical systems and photodetectors.

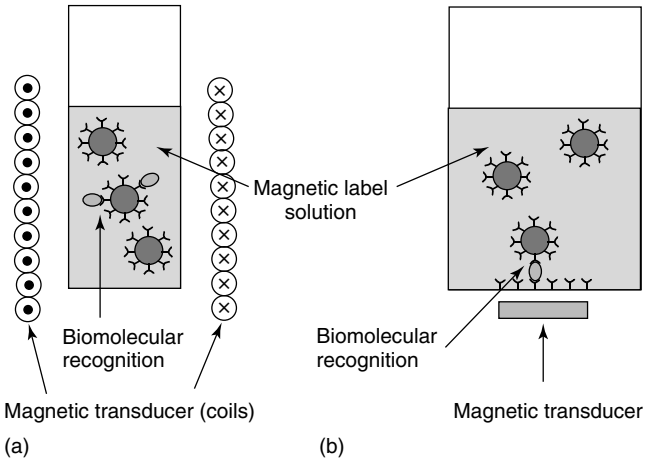

Figure 3. Two types of assays for biomolecular recognition using magnetic labels. (a) In volume detection assays, biomolecular recognition is detected by measuring the magnetic properties of a bulk solution comprised of magnetic labels functionalized with probe molecules that recognize particular targets. (b) In surface detection assays, magnetic labels bound to a surface through biomolecular recognition of probe and target molecules are detected by a nearby magnetic transducer.

or markers for the detection of biomolecular recognition. They offer a number of advantages over colorimetric or fluorescent labels: they are more stable over a broader range of experimental conditions (in temperature and pH) and more stable over time (do not photo bleach, like fluorescent labels); they enable more sensitive measurements as biological samples usually do not contain magnetic material, but often show a color or fluorescent background; they can be used to discriminate between specifically and unspecifically bound biomolecules through the application of a magnetic field (Lee *et al*., 2000); they can be transported and manipulated on chip (Gijs, 2004; Yellen, Hovorka and Friedman, 2005); and they can be readily detected using magnetic-field sensors.

The idea behind magnetic biosensors and biochips is then to use the magnetic labels instead of the conventional ones: biomolecular recognition between target and probe biomolecules is detected by a magnetic-field transducer that senses the magnetic labels bound to the target–probe complexes.

Since magnetic biosensors were first proposed as a simple and sensitive biomolecular recognition detection technique, by making use of coils and ferrofluids (Kriz, Radevik and Kriz, 1996; Kriz, Gehrke and Kriz, 1998), different assay types with different magnetic sensors and labels have been proposed and developed. Basically, two types of assays can be considered with respect to where biomolecular recognition is detected: the volume detection and the surface detection assays (Figure 3).

In volume detection assays (Figure 3a), biomolecular recognition is detected in the bulk of a solution comprised of a suspension of magnetic particles functionalized with the probe molecules of interest. Upon binding of the target analytes to the probes, the hydrodynamic radius of the magnetic particles increases causing a change in their magnetic relaxation times. As a consequence, a shift in the frequency-dependent magnetic susceptibility is observed (Connolly and St. Pierre, 2001; Astalan *et al*., 2004; Chung *et al*., 2004). In these assays, measurement devices such as ac magnetic susceptometers, that measure changes in both the inductance and resistance of an induction coil, are used.

In surface detection assays (Figure 3b), on the other hand, probe biomolecules are immobilized on a solid phase. In these assays, target biomolecules move from the bulk solution to the solid phase surface where they are recognized by the probes. Magnetic carriers bound to the target–probe complexes are then immobilized to the surface. In this case, the magnetic relaxation processes are distinct from when the carriers are free in solution (this will be discussed later on). This difference in relaxation times is used on surface detection assays based on super quantum interfering devices (SQUIDs) (Kötitz *et al*., 1997; Chemla *et al*., 2000).

Nevertheless, the generality of surface detection assays, which correspond to the majority of biosystems being developed, do not rely on measuring changes in the magnetic relaxation of carriers but simply uses the fact that the magnetic carriers create a magnetic field that can be sensed by a transducer.

Several transducers have been used so far, which vary both on physical mechanisms, geometries, properties, and applications: coils (Richardson, Hawkins and Luxton, 2001; Richardson, Hill, Luxton and Hawkins, 2001); giant magnetoimpedance (GMI) sensors (Kurlyandskaya *et al*., 2003; Kurlyandskaya and Levit, 2005; Chiriac, Tibu, Moga and Hera, 2005); SQUID magnetometers (Enpuku *et al*., 1999; Katsura *et al*., 2001); complementary metal–oxide semiconductor (CMOS) Hall-effect sensors (Besse *et al*., 2002); quantum-well Hall effect devices (Landry *et al*., 2004; Sandhu *et al*., 2004; Sandhu and Handa, 2005); and finally, magnetoresistive sensors (Graham, Ferreira and Freitas, 2004; Freitas *et al*., 2004), which are the focus of this chapter.

Coils and giant magnetoimpedance devices assess the presence of magnetic markers by changes in magnetic susceptibility, in the resonance frequency, and in the impedance of the sensing elements, respectively. These devices are simple to fabricate and are better suited for volume magnetic label detection. SQUIDs quantify the magnetic flux created by the labels and are the most sensitive of the magnetic-field sensors developed to date; they are able to sense fields in the order of 100 fT (10^{-13} T). Nevertheless, for high-transition temperature SQUID devices, they require liquid nitrogen (77 K) and vacuum to operate. As a consequence of the necessary apparatus, the separation between the sensor and the sample is usually of tens of micrometers, which results in a smaller effective sensitivity of the device. Hall effect devices do not show these constraints; they measure a voltage drop built in a transversal direction to the sense current due to the Lorentz force induced by the magnetic stray fields originated from the markers. CMOS-based sensor fabrication is relatively straightforward and CMOS-amplification circuitry can be easily integrated with the sensing component. Quantum-well based Hall devices although show a higher sensitivity than CMOS based ones, their fabrication is also more complex, and is comparable to more advanced spintronic devices. Briefly, magnetoresistive sensors are electrical resistors whose resistance value varies with an applied magnetic field, and as so they can be measured using a simple two-point probe measurement scheme. In addition, they operate at room temperature and can be made to have sensitivities down to the pT (10^{-12} T). Furthermore, there is a firmly established technology, as magnetoresistive sensors are used in magnetic reading heads, in several sensing applications (Freitas *et al*., 2000) and most recently on magnetic random access memories (MRAM) and novel magnetoelectronic devices, including biosensors (Freitas *et al*., 2006).

Magnetoelectronic sensors enable then a direct transduction of biomolecular recognition events into electrical signals, which is a considerable advantage over the systems that use colorimetric or fluorescent labels. These optical systems, in their simplest form, provide a qualitative result (yes or no), or a semiquantitative answer based on predefined scales, where interpretation most often depends on the person analyzing the test. On the other hand, more complex systems that often include multiplex testing require bench-top, complex, and expensive optical instrumentation coupled with electrical transduction mechanisms and specialized data-analysis software. Furthermore, these latter systems are usually not portable and cannot be used at the point of care.

This chapter will then review the latest developments on spintronic biosensors and biochips, which show that these devices have the potential to become highly specific and sensitive platforms for low cost, high throughput and portable bioassays. The chapter is organized as follows: first the several types of magnetoresistive sensors will be discussed, together with a comparison of their performance; second the discussion will focus on the magnetic labels or markers used and their properties; afterwards a brief discussion on biomolecular functionalization will be given, and the architectures and detection schemes will be shown next; some applications that have been targeted by several groups will be present together with detection results, while some particular considerations on the detection will be given; finally some conclusions will be drawn at the end.

2 MAGNETORESISTIVE SENSORS

The first magnetoresistive biochip platform was developed at the Naval Research Laboratory (NRL) and was called *bead array counter* (BARC) (Baselt *et al*., 1998). The BARC chip was comprised by 66 giant magnetoresistance (GMR) sensor traces of dimensions of $5 \times 80\,\mu m^2$. Sensors were grouped into eight sensing zones each comprised of eight GMR sensors, these account for 64 sensors while the remaining 2 where used as reference sensors in a half-Wheatstone bridge arrangement. The different sensing zones where later used to detect different biological warfare agents (Edelstein *et al*., 2000).

Since then, a number of research groups worldwide have been developing spintronic biochip platforms based on different magnetoresistive sensors and on distinct sensor geometries, performances, and applications: anisotropic magnetoresistance (AMR) rings (Miller, Prinz, Cheng and Bounnak, 2002); planar Hall effect (PHE) sensors (Ejsing, Hansen and Menon, 2003; Ejsing *et al*., 2004); GMR multilayer traces (Miller *et al*., 2001), serpentines (Rife *et al*., 2003) and spirals (Schotter *et al*., 2002); spin valve (SV) traces (Graham *et al*., 2002; Lagae *et al*., 2002; Li *et al*., 2003), u-shaped (Ferreira *et al*., 2005b, 2005c), or serpentine (Anguelouch, Reich, Chien and Tondra, 2004); and magnetic

tunnel junctions (MTJs) (Shen, Liu, Mazumdar and Xiao, 2005; Cardoso *et al*., 2006).

2.1 Anisotropic magnetoresistance (AMR) based sensors

AMR-based ring sensors were designed and fabricated by NRL for single micron-sized magnetic label detection (Miller, Prinz, Cheng and Bounnak, 2002). The ring sensor was fabricated in NiFe with inner and outer diameters of 3.2 and 5 µm, respectively. The ring was designed to detect the radial component of fringe field created by a single 4.3-µm-diameter $Ni_{70}Fe_{30}$ microsphere, when excited by an out-of-plane alternate current (ac) magnetic field (Figure 4a).

In the setup from NRL, two AMR ring structures (separated by 50 µm) constitute half of a Wheatstone bridge, with the other half completed off chip with resistors of approximately the same value of the resistances of the rings.

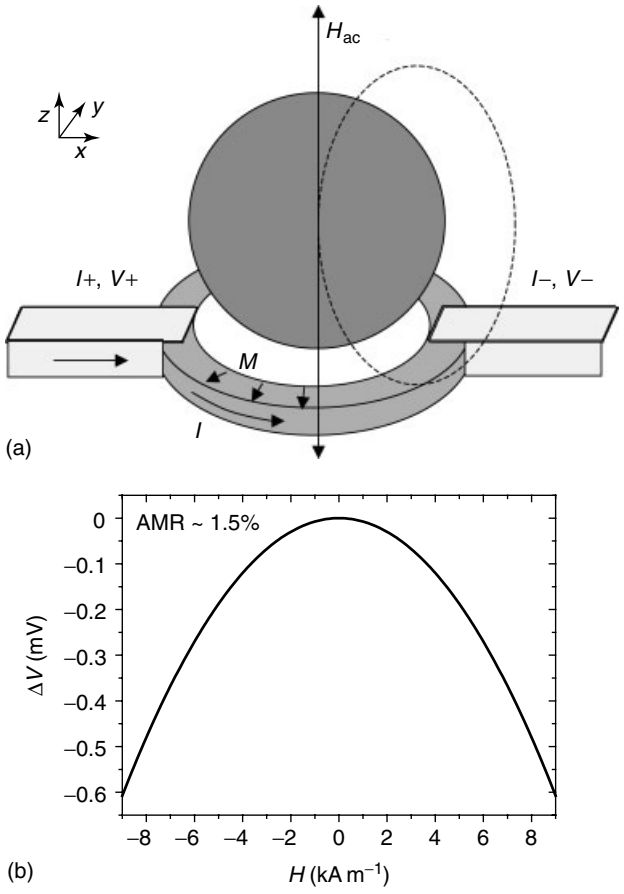

Figure 4. (a) Schematic showing an AMR ring sensor geometry, current flow, voltage measure points, and external magnetic excitation field directions. (b) Typical AMR sensor transfer curve as calculated from equation (1) and using data from Miller, Prinz, Cheng and Bounnak (2002).

An ac driven homopolar electromagnet was used to create a perpendicular-to-plane magnetizing field with typical field amplitudes H_0 between 0 and 4 kA m^{-1} (or 50 Oe), and frequencies f of 200 Hz. In most magnetic-field sensor platforms, paramagnetic or nonremanent magnetic labels are used, such that only in the presence of a magnetizing field they have a moment and thus create a field that is sensed by a particular transducer (this will be further discussed on the section on magnetic labels).

A direct current (dc) bias of ~1 V was applied to the bridge and a single microsphere was measured by scanning the label over one of the rings using an atomic force microscope (AFM) tip (to where the particle was previously glued).

The magnetoresistance of the AMR rings have roughly quadratic magnetic-field dependence around zero applied field, as can be seen from the equation for the electrical response (ΔV) of a single ring structure (Figure 4b).

$$\Delta V = -\left(\frac{\Delta R}{R}\right)_S \mathrm{I} R_{sq} \left(\frac{2\pi r_{av}}{h}\right) \left(\frac{\langle H_{labels}\rangle}{H_k}\right)^2 \qquad (1)$$

In equation (1), $(\Delta R/R)_S$ is the magnetoresistance ratio of the ring structure, which is defined by the difference in resistance between the maximum resistance state (in which the current is parallel or antiparallel to the circumferential magnetization) and the minimum resistance state (in which the current is normal to the magnetization), all divided by the minimum resistance. In this case, the AMR of the NiFe ring structures was ~1.5% (for a film thickness of 20 nm), but as a two-terminal device, the lead/contact resistances reduce the effective AMR to ~1%.

Also in equation (1), I is the sense current and R_{sq} is the sheet resistance defined as $R_{sq} = \rho/t$, with ρ the resistivity and t the thickness of the sensing layer. r_{av} is the average radius of the ring, $(r_{max} + r_{min})/2$, and h is the height of the sensor, $r_{max} - r_{min}$, with r_{max} and r_{min} being the outer and inner radius of the ring structures, respectively. $\langle H_{label}\rangle$ is the radial component of the field created by a magnetic particle averaged at the sensing layer (this issue will be discussed later on). Finally, H_k is the effective anisotropy field that include the crystalline anisotropy and shape demagnetizing fields.

Given the quadratic response of the sensor to the field created by the label, the detection was realized at $2f$, as the expansion of the magnetoresistance yields the dominant term.

Finally, this sensor was designed for the single label detection and was proposed as a sensing unit of a MRAM-like biosensor.

2.2 Planar Hall effect (PHE) based sensors

The use of PHE sensors for magnetic label detection was first proposed by the Mikroelectronik Centret (MIC) of the Technical University of Denmark (DTU) (Ejsing, Hansen and Menon, 2003). These devices are based on the spontaneous resistance anisotropy occurring in ferromagnets, just like the AMR rings.

The fabricated sensors were simple Ni crosses ($20 \times 20\,\mu m^2$ sensing area) and were used to detect 2.8-μm-diameter superparamagnetic polystyrene microspheres (Dynabeads M-280, DynalBiotech, http://www.dynalbiotech.com).

Using this cross geometry, two leads were used for driving current through a sensor, while measuring the voltage drop developed transversally to the current direction, with the other two leads (Figure 5). This voltage drop changed as a result of field created by the labels changing the direction of the magnetization of the ferromagnetic sensing layer with respect to the direction of the current, as shown in equation (2).

$$\Delta V = -\frac{1}{2}\Delta R I \frac{\langle H_{\text{labels}} \rangle}{H_{\text{k}}} \tag{2}$$

Here, $\Delta R = (\rho_{\parallel} - \rho_{\perp})/\text{t}$, with $\rho_{\parallel}$ and $\rho_{\perp}$ being the resistivity of the magnetic material with the sense current parallel or perpendicular to the material magnetization, respectively. For Ni, the resistivity variation is ∼2% (20-nm thick film). Again t is the thickness of the sensing layer, $\langle H_{\text{labels}} \rangle$ is the field created by the magnetic label averaged over the sensing area and H_{k} is the crystalline anisotropy field.

In the MIC platform, a dc sense current of 0.25 mA was used together with an in-plane magnetizing field up to $4.8\,\text{kA m}^{-1}$ (60 Oe) perpendicular to the sense current direction (Figure 5b). Particle detection was realized by measuring the sensor transfer before and after adding a magnetic label solution.

A further improvement, in collaboration with the Institute of Engineering of Systems and Computers – Microsystems and Nanotechnologies (INESC–MN), consisted of the design and fabrication of exchange-biased permalloy planar Hall sensors (Ejsing *et al*., 2004, 2005). Here a MnIr antiferromagnetic layer was used to control the anisotropy and to achieve a well-defined single-domain initial magnetization state. As a consequence, H_{k} in equation (2) represents the sum of the crystalline anisotropy field with the exchange field created by the antiferromagnetic layer.

In this case, PHE crosses of dimensions of $10\,\mu m^2 \times 10\,\mu m^2$ were used to detect in real-time 2-μm-diameter microspheres and 250-nm-diameter particles (Micromer-M and Nanomag-D labels, Micromod, http://www.micromod.de). Direct sense currents ranging from 1 to 10 mA were used together with an in-plane magnetizing field of $1.2\,\text{kA m}^{-1}$ (Ejsing *et al*., 2004); in addition, it was shown that using the sense current alone, without any external field, was sufficient to magnetize the nonremanent magnetic particles tested (Ejsing *et al*., 2005).

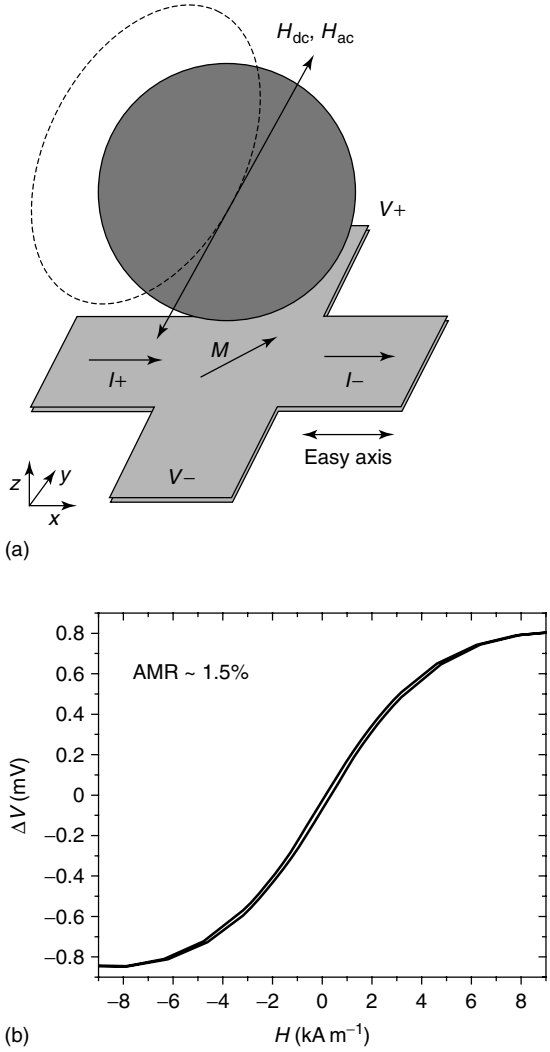

Figure 5. (a) Schematic showing a planar Hall cross sensor geometry, current flow, voltage measure points, and external magnetic excitation field directions. (b) Typical planar Hall effect sensor transfer curve. Data from INESC MN, for a $10 \times 10\,\mu m^2$ sensor with the structure Ta70Å/NiFe300Å/MnPt300Å/Ta70Å.

2.3 Giant magnetoresistance (GMR) multilayer based sensors

GMR multilayer sensors, together with SVs, are the sensing components used in the most developed biochip and

biosensing platforms. These devices are based on the spin-dependent transmission of conduction electrons between magnetic layers coupled through a nonmagnetic spacer. This transmission depends on the relative orientation of the magnetic moments of the magnetic layers (Baibich *et al.*, 1988).

GMR sensors are comprised of a multilayer of magnetic layers separated by nonmagnetic spacer layers and show typical magnetoresistance ratios $(\Delta R/R)_S$ from 5 to ~15%. The output for these sensors is given by equation (3) as is shown in Figure 6:

$$\Delta V = -\left(\frac{\Delta R}{R}\right)_S IR_{sq}\left(\frac{W}{h}\right)\frac{\langle|H_{labels}|\rangle}{H_k} \qquad (3)$$

Here $(\Delta R/R)_S$ is the magnetoresistance ratio, defined as the difference between the maximum resistance of the sensor (when the magnetic layers are antiparallel) and the minimum resistance of the sensor (when the magnetic layers are parallel), divided by the minimum resistance. W is the width of the sensor and h is its height. $|H_{labels}|$ is the absolute value of the component of the field created by the labels in the sensing direction, as the sensor response is unipolar (symmetrical with respect to the applied field, Figure 6b). Again the field created by the labels is averaged on the sensing layer and H_k is the effective anisotropy field that include the crystalline anisotropy and shape demagnetizing fields.

The BARC platform mentioned in the preceding text was the first system to be developed. In an earlier version it was comprised of $5 \times 80\,\mu m^2$ GMR sensor traces. These were arranged in a half-Wheatstone bridge, with a sensor for magnetic label detection in one arm of the bridge and one reference sensor at the other arm. The full bridge was completed with external resistors. Direct sense currents of 5 to 10 mA were used together with a perpendicular-to-plane external magnetizing field of $4\,kA\,m^{-1}$ rms at a frequency of 200 Hz was to enable lock-in detection at 400 Hz, just as in the AMR rings setup (Baselt *et al.*, 1998). The system was then used to detect biological warfare agents through the fringe field created by 2.8-μm-diameter Dynabeads that recognized the specific analytes (Edelstein *et al.*, 2000; Miller *et al.*, 2001).

In a later version, in collaboration with nonvolatile electronics (NVE), the BARC system encompassed serpentine GMR sensors, 1.6 μm wide on a 4 μm pitch, with a total length of 8 mm within a 200-μm-diameter circular zone. This was used to better fit the surface functionalized area to the sensor area (this issue will be discussed later on). A bias voltage across the bridge of 4 V was used together with magnetizing fields of 9.6 an $6.8\,kA\,m^{-1}$ rms at the same frequencies and in the same configuration as previously. Dynal

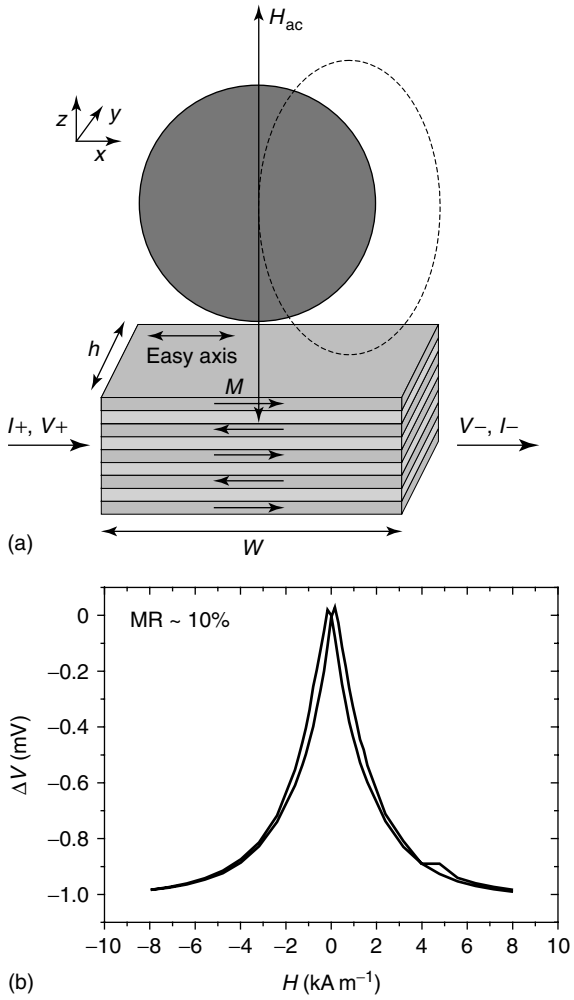

Figure 6. (a) Schematic showing a GMR sensor trace geometry, current flow, voltage measure points, and external magnetic excitation field directions. (b) Typical transfer curve for a GMR sensor. Data from INESC MN for a $2 \times 6\,\mu m^2$ GMR sensor with the stack NiFe60Å/[Cu19Å/NiFe13Å/CoFe4Å]20.

M-280 microsphere and $Ni_{30}Fe_{70}$ were detected (Rife *et al.*, 2003).

The GMR approach was followed by group at Universität Bielefeld, which used 1 μm wide spiral-shaped GMR sensors of a total of 70 μm in diameter (Schotter *et al.*, 2002, 2004). In this platform, smaller 0.35- and 0.86-μm magnetic microspheres Bangs Laboratories (http://www.bangslabs.com) were detected. As in the NRL biosystem, an out-of-plane magnetizing field is used and the sensor response is due to the in-plane components of the fringe field created by the magnetic labels. Particle detection is achieved by recording the dc sensor response from -12 to $12\,kA\,m^{-1}$ (or from -40 to $40\,kA\,m^{-1}$) with respect to a neighboring reference element in a half-Wheatstone

bridge arrangement. These platforms will be discussed more in detail later on Section 5.

2.4 Spin-valve (SV) sensors

SV based biochips were first introduced by INESC–MN (Graham *et al*., 2002) and were followed, in collaboration, by a group at Interuniversitair Micro-Elektronica Centrum (IMEC) (Lagae *et al*., 2002). Later on research laboratories at Standford University (Li *et al*., 2003) and at John Hopkins University (Anguelouch, Reich, Chien and Tondra, 2004) started independent projects on SV based biosensors.

SV sensors, in its simplest form, are comprised of only a single trilayer: two ferromagnetic layers separated by a non-ferromagnetic spacer, and they are also based on the GMR effect (Dieny *et al*., 1991). One of these ferromagnetic layers is called the *reference layer* as it is pinned by exchange coupling to an antiferromagnetic layer, and consequently is not sensitive to low applied magnetic fields. The other ferromagnetic layer is called the *free layer* as it senses even very small magnetic fields. As in GMR multilayer sensors, the spin-valve sensor resistance depends on the relative orientation of the magnetic moments of the magnetic layers. If carefully engineered, SVs can show a linear response to near zero applied fields. Shape demagnetizing effects or perpendicular easy-axis definition for the free and pinned layers during SV deposition are some means to accomplish that, for instance. The sensor response in this case is said to be bipolar and is given by equation (4) (Figure 7).

$$\Delta V = -\left(\frac{1}{2}\right)\left(\frac{\Delta R}{R}\right)_{\mathrm{S}} I R_{\mathrm{sq}} \left(\frac{W}{h}\right) \frac{\langle H_{\mathrm{labels}} \rangle}{H_{\mathrm{k}}} \qquad (4)$$

Here, symbols are the same as for the GMR sensors. Typical values for the magnetoresistance ratio for SV sensors are 7 to 15% (Dieny, 2004). Specular SVs on the other hand show higher $(\Delta R/R)_{\mathrm{S}}$ values from 15 to 20% (Dieny, 2004).

At INESC–MN $2 \times 6\,\mu\mathrm{m}^2$ SV sensors (with a full sensor length of 14 µm) were fabricated to detect single 2-µm microspheres (Micromer-M) (Graham *et al*., 2002) and several magnetic labels of different iron oxide compositions and different sizes ranging from 50 nm up to 1.5 µm (Ferreira, Graham, Freitas and Cabral, 2003). Shape demagnetization effects were used to obtain a sensor linear response (Figure 7b). Typical dc sense currents of 5 to 8 mA were used together with small $1.2\,\mathrm{kA\,m^{-1}}$ dc magnetizing fields applied in the SV sensing direction (see Figure 7a). Measurements were done in real time in a liquid medium using a simple multimeter.

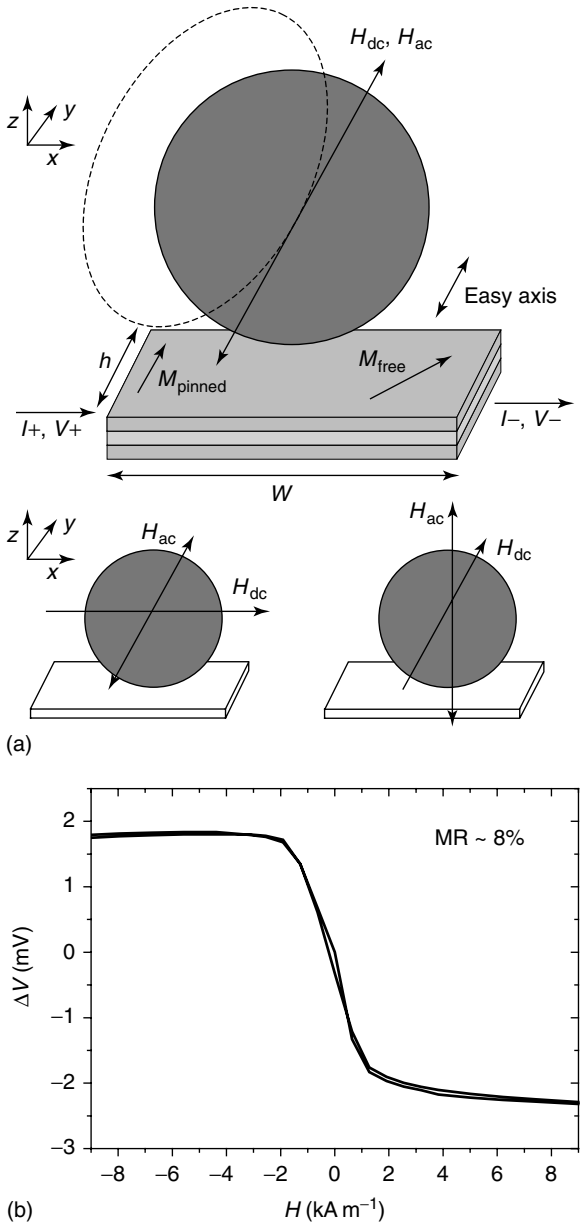

Figure 7. (a) Schematic showing a spin-valve sensor geometry, current flow, voltage measure points, and used external magnetic excitation field directions (larger scheme, INESC; smaller schemes, Stanford). (b) Typical spin valve sensor transfer curve. Data from INESC MN, for a $6 \times 2\,\mu\mathrm{m}^2$ sensor (Graham *et al*., 2005).

A differential dc measurement setup comprised of $2 \times 6\,\mu\mathrm{m}^2$ sensors in a half-Wheatstone bridge (with external resistors completing the other half) was used for detection of biomolecular recognition in the model system biotin–streptavidin (Graham, Ferreira, Freitas and Cabral, 2003). In this case, a SV sensor was functionalized with biotin and was then able to detect bound streptavidin-coated magnetic labels. Another sensor (75 µm away) was

covered with a photoresist mask and was used as a reference sensor, as biomolecular recognition was not observed over the photoresist layer (see details in Sections 5 and 6).

More recently, larger $2.5 \times 80\,\mu m^2$ u-shaped SVs were used for an increased dynamic range (higher number of particles to be detected), in applications for genetic disease diagnostics (Ferreira *et al*., 2005c; Ferreira *et al*., 2006) and for detection of pathogenic microorganisms (Martins *et al*., 2005) (see Section 6). Magnetic label detection in this case was done using a lock-in amplifier for lower noise and decreased thermal drift dependence. Direct sense currents of 1 mA were used together with a combination of external ac magnetizing fields ($\sim 1\,kA\,m^{-1}$ rms at 30 Hz) and dc bias fields (0.8 to $1.2\,kA\,m^{-1}$) applied in the sensing direction of the SVs.

Additionally, some INESC–MN sensing platforms made use of on-chip biomolecule transport using magnetic particles as carriers.

IMEC used $2 \times 16\,\mu m^2$ spin-valve sensors to detect ensembles of nanometer-sized particles. Sensors were linearized by shape anisotropy as in the INESC–MN approach. A sense current of 10 mA was used, and the magnetization of the superparamagnetic labels was achieved by the field created by two metal conductors adjacent to sensor. Current passes alternatively to one or the other conductor, resulting in particle movement over the sensor and, consequently, on label detection (Lagae *et al*., 2002).

In that respect, both approaches from INESC–MN and IMEC are unique with respect to other magnetoresistive biochip platforms and even to more general magnetic-field biosensors. Both research groups make use of on-chip conductors combined with a magnetic transducer to be able to manipulate and move magnetic labeled biomolecules on chip and to detect biomolecular recognition in almost real time.

In the case of INESC–MN, the use of tapered metal conductors (Graham *et al*., 2002) or u-shaped lines (Ferreira *et al*., 2005a) enabled the acceleration of biomolecular recognition between complementary DNA strands (Graham *et al*., 2005; Ferreira *et al*., 2005b). IMEC proposes to use on-chip tapered conductors (Lagae *et al*., 2002) for the detection of biomolecular recognition using a magnetic label cleaving process (Lagae *et al*., 2005). These issues will be further discussed in Sections 5 and 6.

Stanford University research group first used SV sensors of 2.5 to 3 μm height and ∼4 μm width (active areas) to detect a single 2.8-μm-diameter Dynabead (Li *et al*., 2003). Herein, shape demagnetization was also used to achieve a linear response from the SV. Furthermore, a half-Wheatstone bridge arrangement was used, with one active sensor and one reference sensor covered with hard-baked photoresist, just like the INESC–MN approach (Graham, Ferreira, Freitas and Cabral, 2003). Magnetizing fields were applied in plane. A dc longitudinal bias field (in the hard axis direction) was used to polarize the magnetic beads and an orthogonal ac field (in the sensing direction) was used to modulate their magnetizations. DC bias fields between 7.5 and $9.5\,kA\,m^{-1}$ were used, together with ac orthogonal fields of $\sim 3\,kA\,m^{-1}$ rms at 40 Hz.

The laboratory at Standford University detects particles after a label solution as dried out and particles remained settled over the sensor. A later stage, particles are dissolved back in water and are washed away. This contrasts with the approach followed at INESC–MN, where particle and biomolecular recognition measurements are all performed in liquid.

In a further conception of the system (Li, Wang and Sun, 2004), the Stanford group used smaller $0.3 \times 1.5\,\mu m^2$ (active area) sensors for the detection of 16-nm Fe_3O_4 magnetic nanoparticles (Sun and Zeng, 2002). The experimental setup was similar to the previous one, but in this one a dc bias field of $6.4\,kA\,m^{-1}$ was applied transversely to the sensor (in the sensing direction) to polarize the nanoparticles and ac field of $\sim 8\,kA\,m^{-1}$ at a frequency f of 208 Hz was applied perpendicular to plane, similarly to GMR sensors. Measurements were performed at $2f$. In this study, a nanoparticle monolayer was patterned over the sensor surface using a polyethilenimine mediated self-assembly method (Sun *et al*., 2002).

More recently, a collaborative work between the John Hopkins University and NVE resulted in a platform that uses serpentine or meander SV sensors in a full-Wheatstone bridge arrangement on chip (Anguelouch, Reich, Chien and Tondra, 2004). These meander lines were 4 μm wide on a 6 μm pitch, comprising active sensing areas of $100 \times 100\,\mu m^2$ or $200 \times 200\,\mu m^2$. Two of the bridge resistors were laid out as interlaced meander lines and served as the sensing elements, while the remaining sensors were covered by a protective layer 6 μm and served as compensating elements. DC currents of 1 mA were used for detection of 5 and 30 μm length ferromagnetic nanowires. These nanowires have the potential to be used as biomolecular labels and for cell manipulation (Reich *et al*., 2003).

2.5 Magnetic tunnel junction (MTJ) sensor

These devices are based on the spin-dependent tunneling of electrodes across an insulator that separates two ferromagnetic layers. As with GMR sensors, the electron tunneling through an insulating barrier depends on the relative orientation of the magnetizations of the magnetic layers (Moodera, Kinder, Wong and Meservey, 1995).

Just, the same way as SVs, MTJs can be fabricated to have a linear response. In this case, which is the most suitable for biosensing applications, the transducer output is given by:

$$\Delta V = -\left(\frac{1}{2}\right)\left(\frac{\Delta R}{R}\right)_S I \left(\frac{RA}{Wh}\right)\frac{\langle H_{\text{labels}}\rangle}{H_k} \qquad (5)$$

In equation (5), symbols hold the same meaning as for GMR and SV sensors, while *RA* represents the MTJ resistance area product. A transfer curve for the MTJ sensor is shown in Figure 8.

Of the magnetoresistive sensor family, MTJ sensors show the highest values of the magnetoresistance ratio, ∼50 to 70% for AlOx barrier junctions (Wang, 2004) and, recently, >200% for MgO tunnel barriers (Parkin *et al*., 2004; Yuasa *et al*., 2004).

MTJ based biosensors have been recently proposed (Schotter *et al*., 2002; Freitas *et al*., 2004; Wang *et al*., 2005) and magnetic label detection has been demonstrated (Shen, Liu, Mazumdar and Xiao, 2005; Cardoso *et al*., 2006).

A group from Brown University (Shen, Liu, Mazumdar and Xiao, 2005), fabricated $2 \times 6\,\mu m^2$ MTJ sensors to detect single superparamagnetic M-280 Dynabeads. The sensor was operated in an ac bridge configuration (1 V rms at 8 kHz bias voltage), and the sensor response was read using a lock-in amplifier. Two external dc applied fields in the sensing direction ($1.2\,kA\,m^{-1}$) and perpendicular to the sensing direction ($1.6\,kA\,m^{-1}$) were applied such that the MTJ sensor operated in the most sensitive and linear region of the transfer curve.

Recently, INESC–MN demonstrated the detection of 250-nm-diameter magnetic labels (Nanomag-D) using a sensing unit comprised of a AlOx barrier MTJ in series with a hydrogenated amorphous silicon (a-Si:H) thin-film diode (TFD) (Cardoso *et al*., 2006). This sensing unit is the basis for an MRAM-like biosensor as was previously proposed (Baselt *et al*., 1998), and a 16×16 MTJ-diode matrix was already fabricated (this will be further discussed in Section 5).

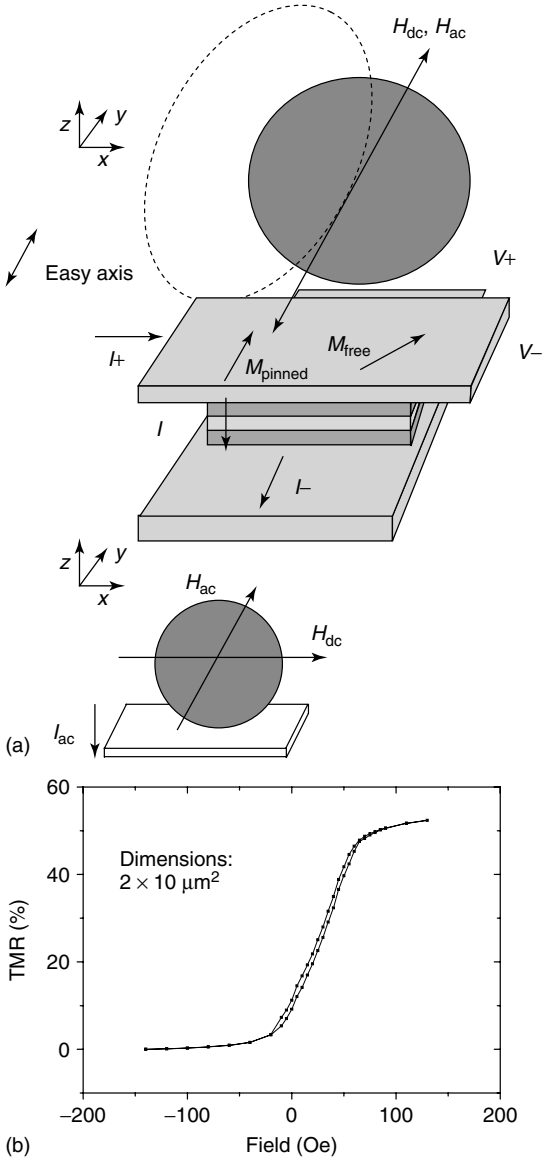

Figure 8. (a) Schematic showing a magnetic tunnel junction sensor geometry, current flow, voltage measurement points, and used external magnetic excitation field directions (larger scheme, INESC; smaller schemes, Brown). (b) Typical sensor transfer curve, $10 \times 2\,\mu m^2$ (F. Cardoso, INESC MN, 2006).

2.6 Detection of magnetic labels

In magnetic biosensing applications, it is important to quantify the number of labels that are being detected in order to determine the number of biomolecular recognition events.

In the calculation of the response of a magnetoresistive sensor to the presence of magnetic labels it is usually assumed that the sensing layers respond to an average field $\langle H_{label}\rangle$, rather than to the inhomogenous local field they create (Tondra, Porter and Lipert, 2000). In fact, a good agreement was obtained between analytical calculations, assuming this average field, and micromagnetics simulations (Li and Wang, 2003). Furthermore it is assumed that the sensing layers rotate coherently with $\langle H_{label}\rangle$, as described by the Stoner–Wohlfarth model (Stoner and Wohlfarth, 1948). Here, the sensing layers correspond to the exchanged-bias NiFe layer in planar Hall sensors; the GMR multilayers; or the free layers of the SVs and MTJs.

Although, several analytical models have been developed according to the type of sensor and to the particular detection

methods, they all consider the assumptions made in the preceding text together with the dipole field approximation in SI.

$$\boldsymbol{H}_{\text{label}}(\boldsymbol{r}) = \frac{\left(\frac{3(\boldsymbol{m}\cdot\boldsymbol{r})\boldsymbol{r}}{r^5} - \frac{\boldsymbol{m}}{r^3}\right)}{4\pi} \tag{6}$$

Here, it is assumed that the magnetic moment $\boldsymbol{m}$ of the label is located at its center, and $\boldsymbol{r}$ is the distance between the label center and the point of the sensor where the field is calculated.

The dipole field in equation (6) is inhomogeneous at the sensing layer, and consequently, the sensor response depends on the position of the magnetic label with respect to the sensor (Figure 9a). In bipolar response transducers, such as AMR rings and GMR sensors, labels adjacent to the transducer also contribute to a change in resistance, though this effect is relevant only for labels few micrometers apart

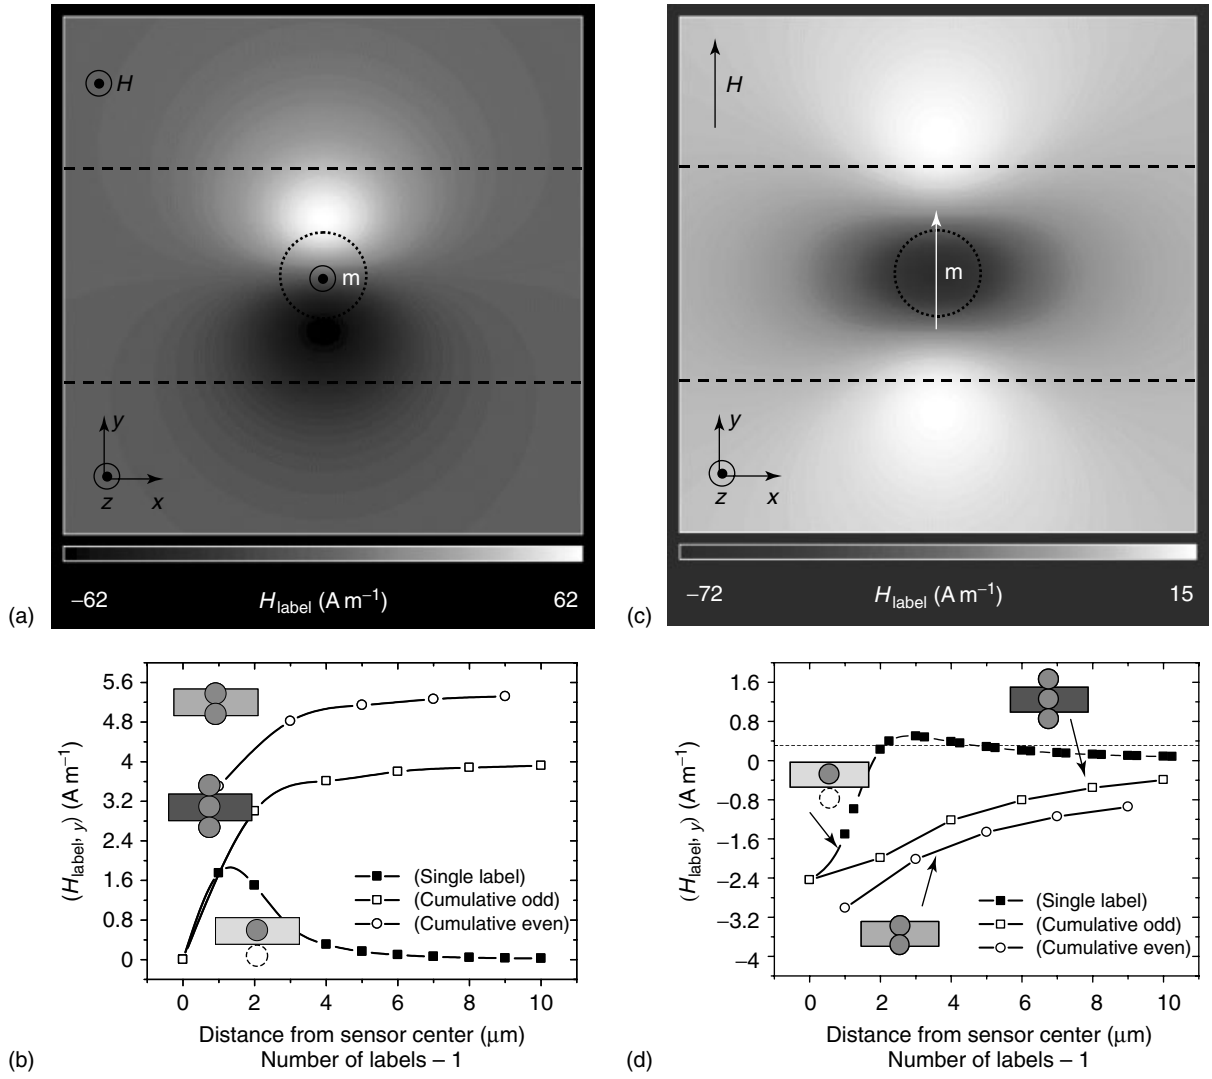

Figure 9. (a) Inhomogenous magnetic field created by a 2-μm microsphere, which shows a magnetization of 0.48 kA m^{-1} under a 1.2 kA m^{-1} external magnetizing field applied perpendicular to the plane of the sensor; 2.5-μm high sensor and particle outlines are shown in dashed lines. (b) Magnetic field created by a single label at varying distances from the center of the sensor (solid squares); also shown are the fields created by multiple labels placed on a row in two distinct arrangements (open squares and open circles) over a spin-valve sensor (the number of labels in the arrangements is indicated in the horizontal axis); fields are averaged over a $2.5 \times 40\,\mu\text{m}^2$ spin-valve trace. (c) Inhomogenous magnetic field created by a 2-μm microsphere under a 1.2 kA m^{-1} external magnetizing field applied in plane in the spin valve sensing direction. (d) Magnetic field created by a single label at varying distances from the center of the sensor and the fields created by multiple labels placed on a row in two distinct arrangements: a label at the center of the sensor and additional adjacent labels (cumulative odd); two labels over the sensor and additional labels on both sides (cumulative even).

(Figure 9a right). On the other hand, for transducers with a unipolar response such planar Hall sensors, SVs, and MTJs, adjacent labels can even have an opposite contribution to the field created by the labels on top of the sensing structures (Figure 9b). In these devices, particular care must be taken on the surface functionalized area and the estimation of the number of detected labels.

In addition, as will be discussed in Section 3, labels show usually a paramagnetic behavior, that is, they only possess a magnetic moment in presence of an externally applied magnetic field. As such, the magnetic moment of the label can be given in SI by $\boldsymbol{m} = \chi \boldsymbol{H}/V$, where χ is the susceptibility per label, $\boldsymbol{H}$ is the total applied field and V is the volume of the label.

Models have utilized several magnetizing field conditions, where the only requirement is that the induced moment on the labels gives rise to magnetic-field components in the sensing directions of the transducer (see previous sections on sensors). Nevertheless, these models only take into account the externally applied field as the magnetizing field.

It has been experimentally observed that even in the absence of an externally applied field $\mathbf{H_{ext}}$ magnetic label detection is possible. This can be attributed to either the sense current, that itself creates a magnetizing field $\boldsymbol{H_j}$ (Ejsing *et al*., 2005), or to magnetostatic field created by the magnetic layers of the sensors $\boldsymbol{H_m}$ (Ferreira, Feliciano, Graham and Freitas, 2005a). In reality, most of the times, it is the combination of the several different fields $\boldsymbol{H} = \boldsymbol{H_{ext}} + \boldsymbol{H_j} + \boldsymbol{H_m}$ that magnetizes the labels (Ferreira, Feliciano, Graham and Freitas, 2005a).

Although, the possibility to detect magnetic labels without the need of external field is advantageous, as it simplifies the experimental setup and measurement protocols, care must be taken when designing sensors and implementing the optimum detection method.

At INESC–MN a study was made on the detection of 250-nm-diameter magnetic labels using $2 \times 6\,\mu m^2$ top pinned SV sensors. These sensors were fabricated with the structure Ta 30 Å/NiFe 30 Å/CoFe 25 Å/Cu 26 Å/CoFe 25 Å/MnIr 60 Å/Ta 30 Å/TiW (N) 150 Å and showed a linear range roughly between -2.5 and $1.5\,kA\,m^{-1}$ at 8-mA sensor bias current. Values for $\boldsymbol{H_j}$ and $\boldsymbol{H_m}$, averaged along the sensitive direction of the SV (smaller dimension) and at a distance of $\sim$300 nm from the sensing layer, were $\langle H_y^j \rangle \sim -0.18\,kA\,m^{-1}$ per mA sense current and $\langle H_y^m \rangle \sim -1.0$–$1.7 \sin\theta$ (field in kA m), with θ the angle between the magnetization of the free layer and the sense current direction (for $\theta = 90^\circ$ the sensor is in the minimum resistance state as the pinned are free layers are parallel) (Bertram, 1994). As a consequence, the intensities of the several fields were comparable (Ferreira, Feliciano, Graham and Freitas, 2005a). Table 1 shows the intensities for these fields for three conditions:

Table 1. Magnetic fields acting on a 250-nm particle located on top of a spin-valve sensor ($2 \times 6\,\mu m^2$). The distance between the center of the label and the sensing layer is $\sim$300 nm. External uniform magnetic fields $\boldsymbol{H_{ext}}$ were applied in the sensing direction (y axis in Figure 9) and magnetostatic fields $\boldsymbol{H_m}$ and the field created by an 8-mA sense current $\boldsymbol{H_j}$ were averaged along the smaller dimension of the sensor. The total magnetic field $\boldsymbol{H}$ was also calculated for the three conditions presented.

	Magnetic fields ($kA\,m^{-1}$)		
H_{ext}	−1.20	0	1.20
$\langle H_y^m \rangle$	−0.56	−1.43	−2.31
$\langle H_y^j \rangle$	−1.44	−1.44	−1.44
$\langle H_y \rangle$	−3.20	−2.87	−2.55

In fact, for the external applied fields considered in Table 1, the resulting total magnetic fields acting on the labels are always negative with respect to the y axis of Figure 9 (i.e., opposite to the pinned layer magnetization direction). This means that in all these cases the stray magnetic fields created by the labels contribute to a decrease in the resistance of the transducer (see subsequent text).

The existence of magnetostatic fields had further consequences on sensor operation when using an ac external excitation field: a dc external bias field was required for optimum sensor operation (Ferreira *et al*., 2005c; Ferreira *et al*., 2006) (see Figure 10).

Without considering the effect of magnetostatic fields, an ac excitation field results in the induction of a magnetic moment in the same direction and consequently, the stray fields of the labels at the sensing layer oppose the applied field. The labels then shield the sensor from the external field, resulting in a decrease of the peak-to-peak signal or the rms output (see sensor transfer curve in Figure 10a top). Figure 10(a) in the bottom shows the rms signals obtained for a $2.5\,\mu m^2 \times 80\,\mu m^2$ spin-valve sensor with a 25% sensor coverage of 250 nm particles, by applying a dc bias and different ac excitation fields. It is observed that the sensor output increases with the magnitude of the ac field up to a maximum, where the ac field is large enough to surpass the linear regime of the sensor and move into the saturation regions.

On the other hand, when considering magnetostatic fields the induced magnetic moment of the labels is always negative, resulting in a decrease of the resistance of the sensor for all applied fields. As a consequence, the peak-to-peak signal window is shifted to lower resistances, while maintaining the magnitude of the signal in the linear region of the transfer curve. This results in a small or near zero variation of the rms signals in this regime (Figure 10b top). Applying a dc bias signal results in an increase of the sensor output to labels (25% sensor coverage) up to a

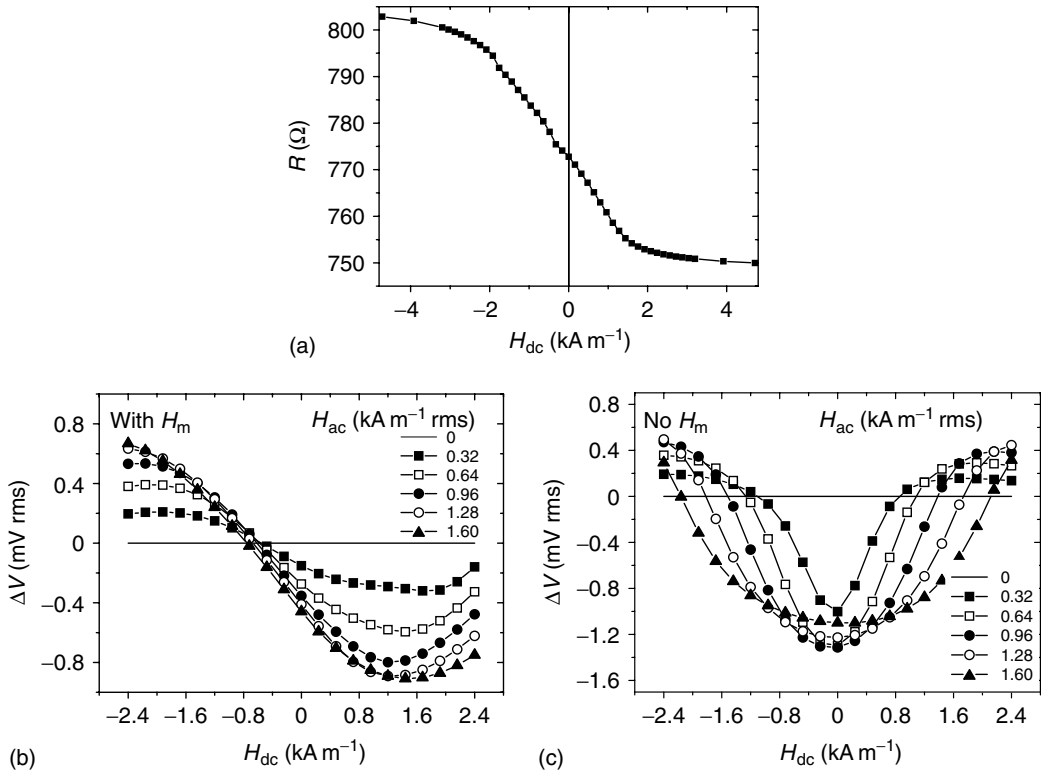

Figure 10. (a) Spin valve sensor transfer curve. (b) Sensor output (AC excitation field +DC bias field) calculated. Without taking into account sensor magnetostatic fields. (c) Sensor output (AC excitation field +DC bias field) calculated taking into account6) sensor magnetostatic fields.

maximum field where the ac excitation field goes deep into the saturation regions (Figure 10b bottom).

Finally, in order to be sensitive only to the external magnetizing field (or at least be the dominant magnetizing field) low sense currents may be used and sensors may be designed and fabricated with synthetic free (SF) and synthetic antiferromagnetic (SAF) pinned layers, such that magnetostatic fields are minimized (Guedes, Mendes, Freitas and Martins, 2006). In these conditions, the dc bias external field is no longer necessary for ac detection (see Figure 11).

2.7 Sensor performance

In sensing applications, the figure of merit to be considered is the signal-to-noise ratio (SNR), although the absolute signal is also important as the highest the signal is the lesser is the requirement for amplification steps and simpler is the detection apparatus. For instance, in earlier INESC–MN studies single magnetic microspheres were detected by simply measuring the dc voltage drop across a spin-valve resistor using a common multimeter (Graham *et al*., 2002).

For defining sensor performance is also necessary to consider the application for which the sensor is designed, that is, either it is required the detection of a great number of labels with a considerable dynamic range (number of particles to be detected) or one targets for single label and single biomolecular recognition detection (Graham, Ferreira and Freitas, 2004). As such, sensor geometry is something to take into account, not only for dynamic range (as will be discussed further in Section 5) but also in terms of sensitivity.

As sensors respond to the average field created by the labels on the sensing layer it is natural to expect that sensor sensitivity to a single label improves as the dimensions of the sensor are made comparable to those of the label (Tondra, Porter and Lipert, 2000).

On the other hand, sensor sensitivity in the broader sense depends on the magnetoresistance ratio of the bulk magnetoresistive material, on the sensor geometry (which can be used to obtain a linear response through shape demagnetizing fields) and on externally applied bias fields (which can also be used to linearize the sensors).

Here, the SNRs of the several magnetoresistive sensors are determined taking into account the detection of a single 2-μm microsphere (Freitas *et al*., 2004) and the noise levels obtained in the linear regime of the sensor. Table 2 shows

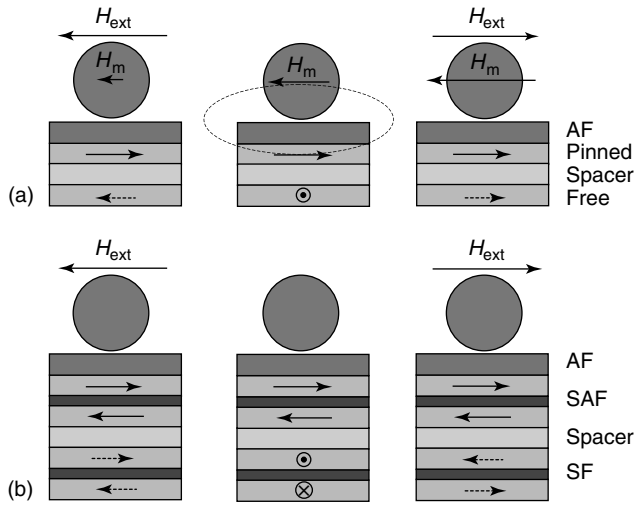

Figure 11. (a) Cross-section schematic of a top pinned spin-valve sensor showing the effects of the magnetostatic fields created by the ferromagnetic layers of the sensor. Three conditions are considered: with the external magnetic field applied in the negative direction (opposite to the magnetization of the pinned layer), without external magnetic field and with the external field applied in the positive direction (direction of the magnetization of the pinned layer). (b) Cross-section schematic of a spin-valve sensor with synthetic free (SF) and synthetic antiferromagnetic (SAF) layers. When these layers are compensated the resulting magnetostatic fields are null and labels respond only to the external magnetizing fields.

a comparison of the performance of the different types of magnetoresistive sensors mentioned in the preceding text, with respect to the signal-to-noise ratio. The magnetic properties shown are typical for these sensors and the sensor size was chosen for optimal single 2-μm microsphere under a magnetizing field of $1.2\,\mathrm{kA\,m^{-1}}$ (moment of $2 \times 10^{-15}\,\mathrm{J\,T^{-1}}$). Thermal or Johnson noise was calculated from $\sqrt{4k_bTR}$, where k_b is the Boltzmann constant ($1.38 \times 10^{-23}\,\mathrm{J\,K^{-1}}$), T is the absolute temperature (taken as 300 K) and R is the resistance of the transducer. In addition, the noise for the MTJ sensors with AlOx or MgO barriers was calculated from the summation of the thermal and shot noise $\sqrt{(4k_bTR + 2IeR^2)}$, where I is the sense current and e is the charge of the electron (1.6×10^{-19}C) (Raquet, 2001; Almeida *et al*., 2006). Finally, the minimum detectable field and the SNR was calculated for the minimum noise of these magnetoelectronic devices.

One can observe from Table 2 that due to its highest magnetoresistance ratio, the MgO barrier MTJ transducers show the highest sensitivity and consequently, highest signal per label, followed by AlOx MTJs, SVs, GMR sensors, AMR rings, and planar Hall crosses. On the other hand, for low resistance tunnel junctions (as shown), the minimum noise level is comparable to the noise levels of the other transducers, this then results in a smaller minimum detectable field and a higher SNR.

Note that in this table, the sense current was kept constant at 1 mA. Some of the sensor performances relations may differ if different currents are applied through the sensors, as the different sensors show distinct limits of operation. As an example, MTJ sensors show a decrease in tunneling magnetoresistance (TMR) with increasing sensing currents (voltage bias) and there is an increase in shot noise; while for SVs, 10-mA currents can be applied, increasing the sensor response to a single label by a factor of 10, while maintaining mostly the same thermal noise level.

MgO barrier based MTJ transducers show the promise of being the most sensitive of spintronic transducers ever, being capable of detecting magnetic fields in the picotesla range. This may enable the detection of single 10-nm magnetic particles and, consequently, of single biomolecular interactions. This shows that magnetoresistive biochips have the potential to become useful tools for molecular biology.

3 MAGNETIC LABELS

Different kinds of magnetic labels have been used in magnetic biosensing applications, ranging from nanometer to micrometer sized particles (Pankhurst, Connolly, Jones and Dobson, 2003) and nanowires (Reich *et al*., 2003). In addition, ferromagnetic, paramagnetic, or superparamagnetic labels have been chosen according to the application, transduction mechanism, and assay type.

Several ferromagnetic materials, such as Fe, Co, Ni, and their alloys, and ferrimagnetic materials, such as γ-Fe_2O_3 (maghemite) and Fe_3O_4 (magnetite), have been used in magnetic particle preparation. Nevertheless, their magnetic properties depend, not only on the material used but also on the label size. For instance, large labels, of micrometer dimensions or more, usually present a multidomain structure, as this represents a minimum magnetic energy of the system. Nevertheless for smaller labels (below the micrometer range), the energy is minimum in a single-domain state rather than including domain walls. As such, the response of these particles to an applied magnetic field is a large hysteresis loop (see Figure 12). Multidomain magnetic particles, on the other hand, show a narrow hysteresis loop, as domain walls require a smaller energy to move. Both multi- and single-domain particles show a nonzero magnetization under no applied field, and as such they are called *remanent magnetic particles*.

Smaller particles or labels, with dimensions of the order of tens of nanometers or less, have a magnetocrystalline and shape anisotropy energy that are in the order of or

Table 2. Comparison of the performance of different magnetoresistive sensors used for the detection of magnetic labels, including magnetic tunnel junctions with AlOx and MgO barriers. Typical magnetic properties for these sensors were used, and sensor geometries were chosen for the detection of a single 2-μm magnetic label of magnetization of $0.48\,\mathrm{kA\,m^{-1}}$. t* represents the magnetic sensing layer thickness. Remaining symbols are as detailed in previous sections for each of the sensor types. The field created by the label in the AMR sensor case was averaged in an annulus of radius and height of 1 μm. For the remaining sensors the label field was averaged in a squared area. The thermal noise is shown for the different sensors, while for MTJ sensors the presented noise is the summation of the thermal and shot noise (see text for details). The signal-to-noise ratio was obtained dividing the signal per 2-μm microsphere, ΔV, by the noise.

Sensor type	Width (μm)	Height (μm)	t^* (nm)	R_{sq} (Ω cm) RA (Ω μm^2)	$\Delta R/R$ (%)	H_k (kA m^{-1})	S (V T^{-1}A^{-1})
AMR ring	$r_{ext} = 1.5$ $r_{int} = 0.5$	1	20	10.5	1.5	14.5	27
Planar Hall	2.5	2.5	30	7	1.5	2.4	17
GMR	2.5	2.5	72	2.8	10	2.4	93
Spin valve	2.5	2.5	5	20	8	2.4	265
MTJ AlOx	2.5	2.5	5	80	25	2.4	531
MTJ MgO	2.5	2.5	5	150	150	2.4	5968

Sensor type	I (mA)	$\langle\mu_0 H_{label}\rangle$ (μT)	ΔV (μV)	Thermal noise/shot noise (nV Hz$^{-0.5}$)	$\langle\mu_0 H_{label}\rangle_{min}$ (nT)	SNR
AMR ring	1	60	1.6	0.7	27	2200
Planar Hall	1	28	0.5	0.3	20	1400

Spin valve	1	28	7.4	0.6	2.2	13 000
MTJ AlOx	1	28	15	0.5	1.0	29 000
MTJ MgO	1	28	170	0.8	0.1	220 000

smaller than the thermal energy (Kittel, 1996). The particles are superparamagnetic and show no remanent moment. These labels show a nonhysteretic behavior with an applied magnetic field, which is a signature of superparamagnetism (Figure12).

Under an externally applied field, magnetic labels align with the field but after the field is removed the magnetization of the particles relaxes. Relaxation occurs through two mechanisms, Néel (1955) and Brownian (Debye, 1929), and the predominance of one of the mechanism over the other depends on label size.

Néel relaxation is related to superparamagnetism, as the magnetic moment of a label fluctuates thermally inside the particle (Figure 13a), and it is characterized by the relaxation time τ_N:

$$\tau_N = \tau_0 \exp\left(\frac{\Delta E}{k_B T}\right) \tag{7}$$

In equation (7), τ_0 is usually taken as 1 to 100 ps (Brown, 1963), ΔE is the energy barrier to the moment reversal and includes the magnetocrystalline and shape anisotropies. K_B is the Boltzmann constant and T is the absolute temperature (K). Néel relaxation is dominant for particles with sizes smaller than 10–20 nm.

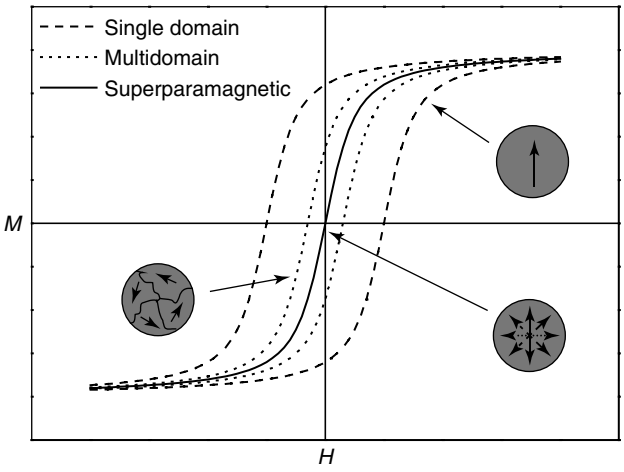

Figure 12. Magnetization versus applied field curves for single domain, multidomain and superparamagnetic labels.

Larger magnetic particles have a relaxation time τ_N in the order of tens or hundredths seconds and thus exhibit remanence. Nevertheless, their magnetization relaxes through

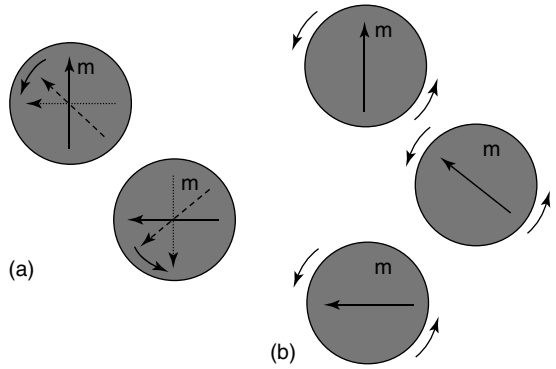

Figure 13. (a) Néel relaxation mechanism (dominant for superparamagnetic particles): labels magnetic moment, rotates with thermal energy without being accompanied by label rotation. (b) Brownian relaxation mechanism (more relevant in single-domain and multidomain particles): labels magnetic moment, relaxes together with the rotation of the whole label in the carrier liquid.

the Brownian rotation of the whole label in the carrier liquid (Figure 13b). The moment is fixed within the particle. It is characterized by the time constant τ_B:

$$\tau_B = \frac{4\pi\eta r^3}{k_B T} \tag{8}$$

Here η is the viscosity of the carrier liquid (e.g., for water, $0.001\,\mathrm{N\,s\,m^{-2}}$) and r is the hydrodynamic radius of the label.

It is these distinct magnetic properties that are used in the different biosensing approaches. Volume assays are based on Brownian relaxation of nanoparticles in solution. When labels recognize a particular analyte in solution, through probe biomolecules immobilized on the particles surfaces, their hydrodynamic radius increases. As a consequence, the ac susceptibility peak of the solution shifts to lower frequencies (Connolly and St. Pierre, 2001; Astalan *et al*., 2004; Chung *et al*., 2004).

SQUIDs, on the other hand, have been used to distinguish between surface-immobilized magnetically labeled biomolecules and particles free in solution (Kötitz *et al*., 1997; Chemla *et al*., 2000). In these cases, after removal of an applied field, surface-bond labels only show a relatively slow Néel relaxation, while unbound free-in-solution labels relax mainly via the Brownian mechanism and are distinguished by the transducers.

The remaining surface-based assays are based on the detection of magnetic stray fields created by the labels bound to the surface through the biomolecular recognition between target and probe biomolecules. Here, ∼10-nm superparamagnetic labels are used, or more frequently larger >50 nm to micrometer sized labels. The larger labels are comprised of smaller superparamagnetic labels dispersed in or coated with a polymer, metallic or oxide layer, and show a paramagnetic or a nonremanent behavior.

In magnetoresistive bioassays, magnetic labels should comply with certain requisites: have a high saturation magnetization (made of materials like Fe, Co, Ni, and their alloys) so that the signal per particle is the maximum possible; show material stability over time (like iron oxides); be biocompatible and nontoxic (like iron oxides); be monodispersed and do not cluster, that is, be superparamagnetic; show low unspecific adsorption to undesired biomolecules and surfaces; and ideally, each particle should label or tag a single biomolecule. In addition, material stability and biocompatibility requisites should apply to the encompassing matrix or the coating.

The technology of magnetic particles for biosensing applications involves several fields of knowledge, namely, inorganic and organic chemistry, materials science, and molecular biology. In fact, magnetic properties are as important as suitable coating and biomolecule functionalization chemistries.

At INESC–MN, several particles of diameters ranging from 50 nm up to 2.8 µm were studied (Ferreira, Graham, Freitas and Cabral, 2003; Freitas *et al*., 2004). Table 3 shows some of the magnetic properties of the labels tested by INESC–MN and other research laboratories.

As a notice, 130 and 250 nm (Nanomag-D) particles and 2-µm microspheres (Micromer-M) do not show a pure paramagnetic behavior at low applied fields as they do not fit the Langevin equation in this regime (Freitas *et al*., 2004).

$$M = M_S\left[\coth(gH) - \frac{1}{(qH)}\right] \tag{9}$$

In equation (9), M is the magnetization of the label, M_S is its saturation magnetization, H is the applied field and $q = \mu_0 m_p / k_B T$, where μ_0 is the magnetic permeability in vacuum and m_p is the average moment of each nanoparticle that comprises the label.

These labels show an increased magnetic susceptibility near zero, which may be the consequence of interacting smaller nanoparticles that comprise the larger ones (Figure 14).

4 BIOMOLECULAR FUNCTIONALIZATION

A magnetoresistive sensing platform can only be used for biosensing after it has been functionalized with biomolecules. This issue is as important as the magnetic transducers themselves, and implies a great control on surface and label functionalization biochemistries and assay protocols.

Table 3. Properties of several magnetic labels used in magnetoresistive biosensing platforms. Data was obtained by vibrating sample magnetometry at INESC–MN, unless indicated otherwise.

Label	Manufacturer	Diameter (nm)	Magnetization kA m^{-1})[a]	Susceptibility[b]	Material[c]
4SP NiFe powder[d]	Novamet	3300	5	4.2	$Ni_{70}Fe_{30}$(~100%)

[a]Magnetization per particle at an excitation field $\boldsymbol{H}$ of 1.2 kA m^{-1}.
[b]Average susceptibility for $1 < |\boldsymbol{H}| < 4$ kA m^{-1}.
[c]FeOx represents γ-Fe_2O_3 and Fe_3O_4. % values represent the magnetic content of the particles (data from supplier).
[d]Magnetization and susceptibility values were taken from magnetization curves shown on Rife *et al*. (2003).
[e]Magnetization values were estimated from data shown in Schotter *et al*. (2004) admitting a constant susceptibility from 0 to 40 kA m^{-1}.

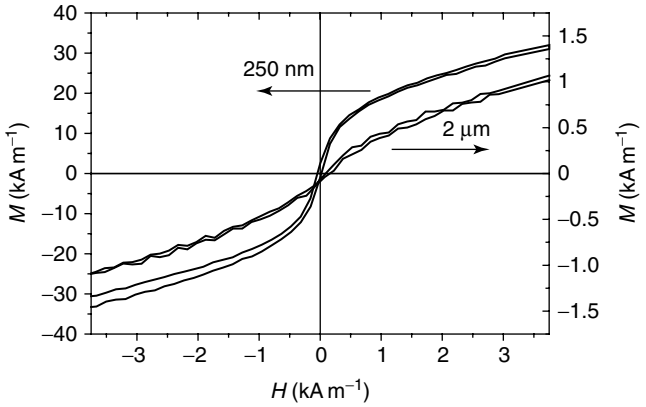

Figure 14. Magnetization curves for 2-µm microspheres and 250-nm-diameter nanoparticles in the low field regime. It is observed an increased magnetic susceptibility near zero applied field and, in particular, for smaller particles. Pure paramagnetic behavior is represented by a dashed line.

Currently, several protocols for the functionalization of nucleic acids and proteins (including antibodies and enzymes) have been developed. These methods depend on the biomolecule but also on the surface to be functionalized. Most common biochip surfaces include glass (Joos, Kuster and Cone, 1997), silicon dioxide (Chrisey, Lee and O'Ferrall, 1996), gold (Bamdad, 1998), and polymers (Fixe, Dufva, Telleman and Christensen, 2004a).

Generally, surface derivatization protocols for glass or silicon dioxide (as done in INESC–MN) consist of the following steps: activation; silanization; cross-linking; and probe biomolecule immobilization.

The activation step, may or may not be necessary, and consists in formation of reactive hydroxyl groups at the biochip surface (Figure 15a); for that several cleaning and oxidizing procedures have been developed (Cras, Rowe-Taitt, Nivens and Ligler, 1999). Nevertheless, in magnetoresistive biochip applications mild conditions are required not only for cleaning but also for all derivatization protocols. As such, low salt solutions, and weak acids or weak bases should be used; otherwise both surface as sensors may be corroded (Freitas *et al*., 2004).

The silanization protocol involves the use of trialkoxy silane derivatives containing an organic functional group such as an amine (Weetall, 1976). A silane molecule, such as triaminopropyltriethoxysilane (APTES) reacts with the hydroxyl (–OH) groups on the surface leaving amino groups available to react further (Figure 15b).

After silanization, usually a crosslinker is used to enable the covalent binding of two distinct chemical entities that are unreactive toward each other (e.g., amino $-NH_2$ and thiol –SH groups) (Figure 15c). A crosslinker serves another important purpose: it provides a physical spacer that gives a larger mobility and freedom to the immobilized biomolecules. This greater accessibility is important to facilitate biomolecular recognition. In fact, it has been shown that hybridization efficiency depends on the cross-linker size, as larger spacers enable an easier access of target molecules to the surface-immobilized probes (Southern, Mir and Shchepinov, 1999).

Cross-linking molecules are designated by homobifunctional, if they present identical reactive groups at the each end of the spacer (e.g., glutaraldehyde) or, on the other hand, they are called by heterobifunctional if they have distinct functional groups (like *N*-[ε-maleimidocaproyloxy]sulfosuccinimide ester or sulfo-EMCS) (Figure 15c). In bioarray applications, heterobifunctional cross-linkers are preferred as they diminish the potential for multipoint reactions.

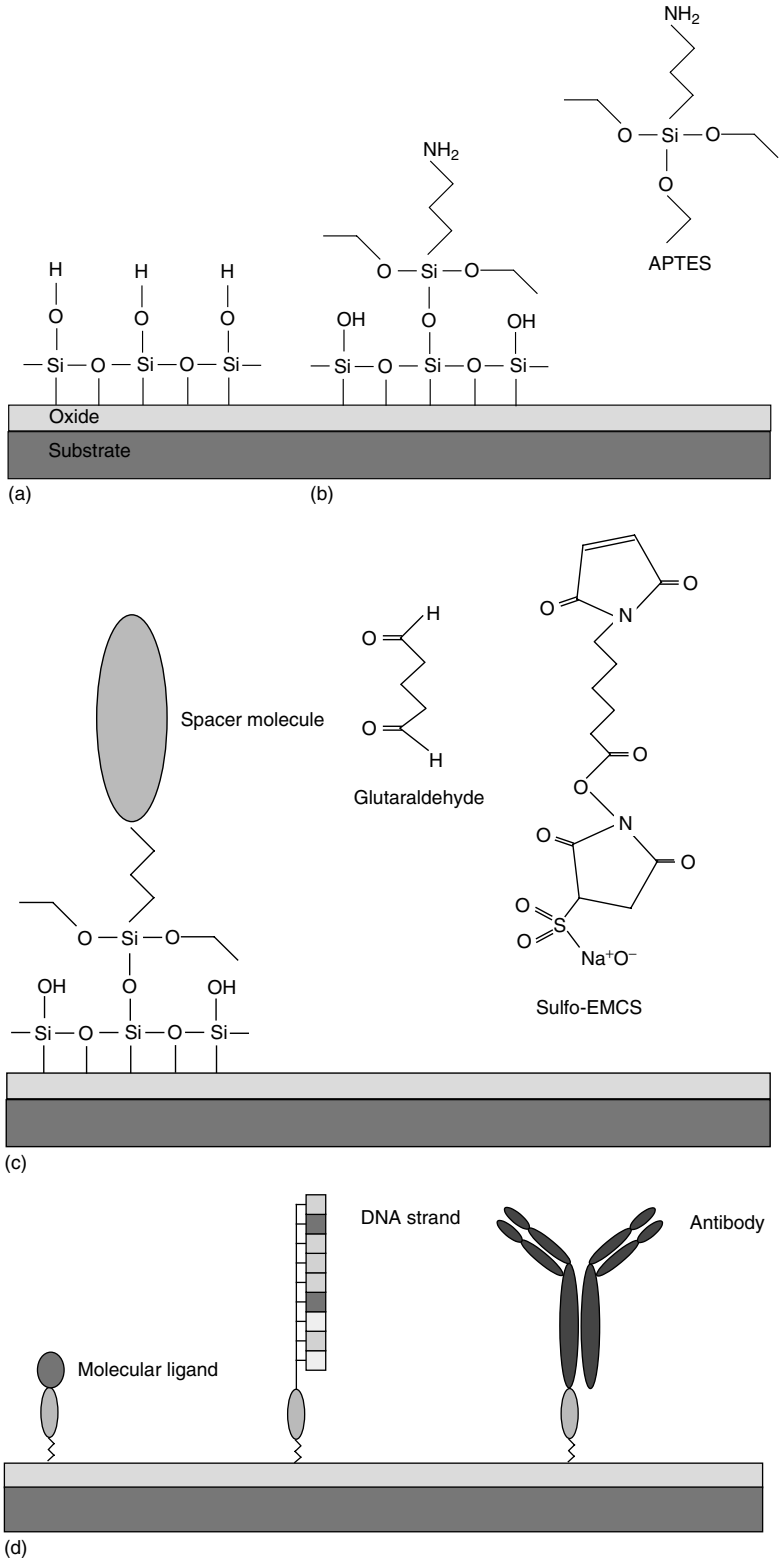

Figure 15. Oxide surface biochemical functionalization protocol: (a) Surface activation: formation of hydroxyl groups on the surface; (b) Silanization (formation of reactive amino groups) using a 3-aminopropyltriethoxysilane (APTES) solution; (c) Crosslinking with spacer molecules such as glutaraldehyde and sulfo-EMCS; and (d) Probe biomolecule (nucleic acids, proteins, etc.) immobilization to the surface through the covalent reactions between functional groups in the molecules and the cross-linkers.

Finally, probe–biomolecule immobilization can also be done using distinct protocols, depending on the biomolecule, functional groups of the spacer and the surface type. Usually, DNA probes modified at one end with an amino, carboxylic (–COOH) or thiol group are covalently bound to the cross-linker molecules (Figure 15d). In case of proteins, unreacted functional groups of aminoacid residues are used for the same end.

Biofunctionalization of gold surfaces (Bamdad, 1998) is also one of the most common approaches as the protocols are relatively straightforward. Thiolated biomolecules, such as DNA strands modified at one end with a thiol or a thiolated spacer, bind to the gold surface forming a self-assembled monolayer (SAM).

Polymer functionalization may be similar to other surfaces such as glass or silicon oxide, involving activation, amination of the surface, crosslinking, and probe immobilization (Fixe, Dufva, Telleman and Christensen, 2004a). Nevertheless, by using native functional groups in the polymer, such as methyl esters groups in poly(methylmetacrylate) (PMMA), probe immobilization can be done in on-step (Fixe, Dufva, Telleman and Christensen, 2004b). This has great advantages over traditional methods, as it is both labor time and reagent-cost saving.

Again, probe biomolecule immobilization chemistries must be optimized for each case, and in biochip applications mild conditions should be used. The surface density of bound probes is an important parameter, as low surface coverage will yield low biomolecular interaction rates and, consequently, low detection signals. High surface density of probes, on the other hand, may result on biomolecular steric hindrance and consequently low biomolecular interaction rates and detection signals may be observed. In addition, probe immobilization protocols should lead to a well-defined probe orientation accessible to the target for recognition; should be thermally and chemically stable; and finally, should be reproducible.

A bioarray is a two-dimensional set of distinct biological probes. These are designed to enable an analysis of several components in the same assay in a parallel fashion. For instance, DNA microarrays may be used to investigate the expression of genes of an ill tissue and compared it with the case of a healthy one; or they may be used to screen a particular genetic mutation related to a hereditary disease. Usually, in designing a bioarray, there is redundancy of probes (i.e., each probe is represented in several places on a chip) for statistical purposes; and both positive and negative controls are included to assess the good functioning of the assay and to determine the background noise.

Currently, there are several ways to produce a bioarray. One of the approaches is by on-chip synthesis of oligonucleotides, which uses a combination of microelectronic photolithographic techniques and combinatorial chemistry (Pease *et al*., 1994). Although, this method allows the fabrication of highly dense arrays, representing more than 100 000 genes in an area of $1.28 \times 1.28\,\mathrm{cm}^2$, the procedure is costly and time consuming, and is not applicable to proteins; these aspects prevent then a widespread use of the system (http://www.affymetrix.com). The present technology enables the fabrication of probe regions with feature sizes of $\sim 10\,\mu\mathrm{m}$.

The most common method to make DNA or protein arrays is the immobilization of pre-synthesized DNA strands and protein solutions, respectively, using devices called *microspotters* (http://www.arrayit.com), which enable the immobilization of up to 100 000 different biomolecules represented in a glass slide (Ramsay, 1998; Okamoto, Suzuki and Yamamoto, 2000). A typical biomolecule spot size is $\sim 50-100\,\mu\mathrm{m}$, but improving technologies are rapidly reaching smaller sizes, even to the nanometer scale using techniques such as dip-pen nanolithography (Demers *et al*., 2002) and supramolecular nanostamping (Yu *et al*., 2005).

Alternative methods of probe immobilization include the use of electric fields (http://www.nanogen.com), which enable much shorter probe immobilization times in comparison with the previous methods (Heller, 1996; Fixe *et al*., 2003), and the potential use of magnetic fields for biomolecular patterning (Yellen, Hovorka and Friedman, 2005).

Label functionalization protocols are similar to the ones referred in the preceding text for chip surface functionalization and, consequently, should also comply with the same requirements: mild-conditions surface biochemistries; reproducibility; thermal and chemical stability; nontoxic surface properties; and suitable biomolecular surface density.

The chemistry will depend then on the surface or coating of the particles: silica, gold, polymer, or other (del Campo, Sen, Lellouche and Bruce, 2005; Bao and Krishan, 2005; Nishibiraki *et al*., 2005; Joshi, Li, Wang and Sun, 2004) and on the biomolecule to be functionalized. This later one is related to the bioassay to be performed and the detection scheme. As such, magnetic labels may be functionalized with target molecules (e.g., analyte DNA) or with a detector biomolecule (e.g., antibody or another protein) (see Sections 5 and 6).

5 DETECTION SCHEMES AND CHIP ARCHITECTURES

Until recently, magnetoresistive biochips were being developed mostly for DNA hybridization detection in applications concerning biological warfare agent detection (Edelstein *et al*., 2000; Miller *et al*., 2001) and diagnostics of

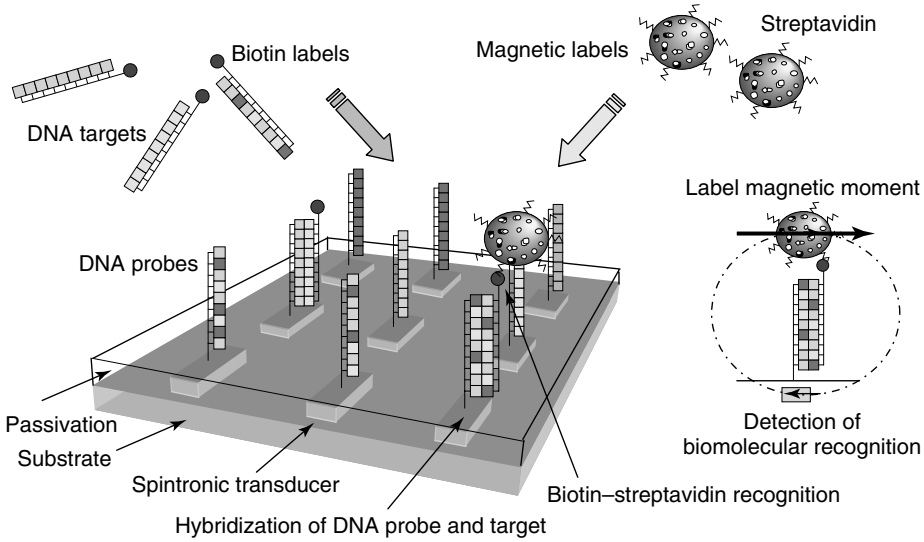

Figure 16. Post-hybridization detection method. Spintronic biochips functionalized with DNA probes are incubated usually for several hours with DNA targets labeled with a biotin reporter molecule. After hybridization has occurred, streptavidin-coated magnetic labels are dispensed over the chip. The streptavidin proteins recognized biotin molecules available where hybridization occured. Finally, magnetic labels bound to hybridized sites are detected by spintronic transducers that sense the labels stray fields.

cystic fibrosis (Graham, Ferreira and Freitas, 2004; Lagae *et al*., 2005).

Two hybridization detection strategies have been followed, the post-hybridization detection method and the magnetic-field-assisted detection method.

In the post-hybridization detection method (followed by both the NRL; the University of Bielefeld; and INESC–MN), target biomolecules are labeled with a small reporter biomolecule called *biotin*. After hybridization occurs with the probe DNA strands immobilized on the chip surface, a solution of magnetic labels is dispensed over the chip. These labels are coated with a detector protein called *streptavidin* that recognizes the reporter biotin molecules that tag the hybridized DNA targets. Subsequently, the stray field created by the magnetic labels is detected with the use of on-chip magnetoresistive sensors, indicating that hybridization has occurred (Figure 16).

In this method, the analyte solution is dispensed over the chip and the biotinylated DNA targets diffuse, passively, in solution until finding their complementary probe molecules at the chip surface. This way, hybridization times alone take usually from 3 to 12 h, which limits these systems to applications or assays were response times are not crucial.

In order to overcome this limitation, a detection method based on magnetic-field-assisted hybridization was developed at INESC–MN. In this method, DNA targets are labeled with magnetic labels and are transported to probe immobilized sensor sites by on-chip current carrying conductors that generate local magnetic-field gradients. The close proximity of target and probe biomolecules accelerates then the rate at which biomolecular recognition reactions happen. This way hybridization is detected almost in real time (Figure 17).

Using different designs, comprised of tapered on-chip conductors (Graham *et al*., 2002; Lagae *et al*., 2002; Figure 18a) or u-shaped current lines (Ferreira *et al*., 2005a; Figure 18b) enabled the detection of hybridization between complementary DNA strands in times of less than 5 min (Graham *et al*., 2005) and 30 min (Ferreira *et al*., 2005b). These systems show the potential to be used in the rapid detection of biological warfare agents, in pathogen identification or in clinical diagnostics in the point of care.

Another variant of the magnetic-field-assisted hybridization method involves the use of enzymatic cleavage of the magnetic labels bound after hybridization has occurred (Lagae *et al*., 2005). After release, labels can be detected by moving them over the sensor by alternatively applying current through tapered line structures adjacent to the sensor (Lagae *et al*., 2002) (Figure 19).

These magnetoresistive DNA chips (Freitas *et al*., 2004) have then 'evolved' in order to 'fit' with the biological requirements of the bioassays and their applications. One of such requirements is the probe-functionalized area, which, typically, has been defined by microspotting of the chip surface above the sensing elements.

The initial BARC chip from NRL (Baselt *et al*., 1998) was comprised of eight sensing zones, each containing eight GMR sensor traces of dimensions of $5 \times 80\,\mu m^2$. Each sensing zone was $\sim$250 µm in diameter and was functionalized with a particular DNA probe (Edelstein *et al*., 2000; Miller *et al*., 2001). Since magnetic labels were only

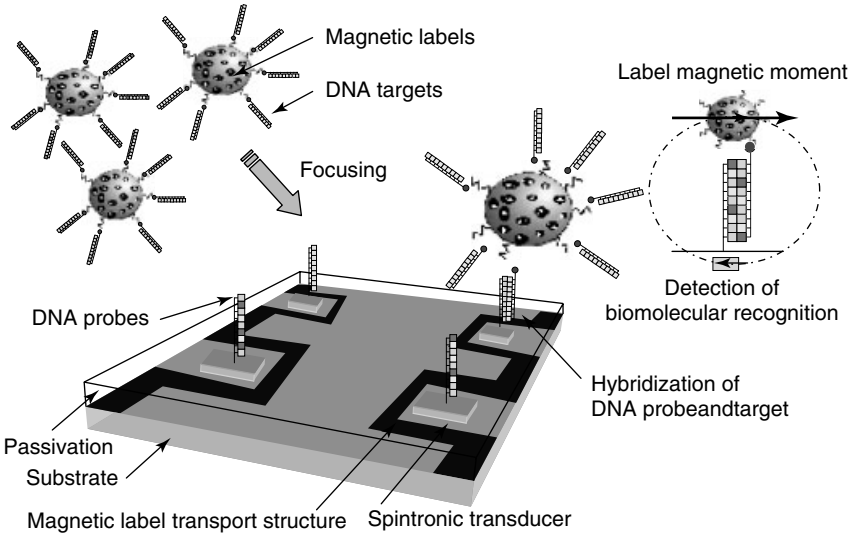

Figure 17. Magnetic-field-assisted hybridization and detection. Spintronic biochips functionalized with probe DNA are incubated with magnetically labeled DNA targets. On-chip current carrying conductors that create local magnetic-field gradients are used to attract the magnetically labeled molecules to functionalized sensing regions. The proximity of target and probe molecules accelerates the hybridization reaction rate, enabling faster hybridization times and the detection of biomolecular recognition in almost real time.

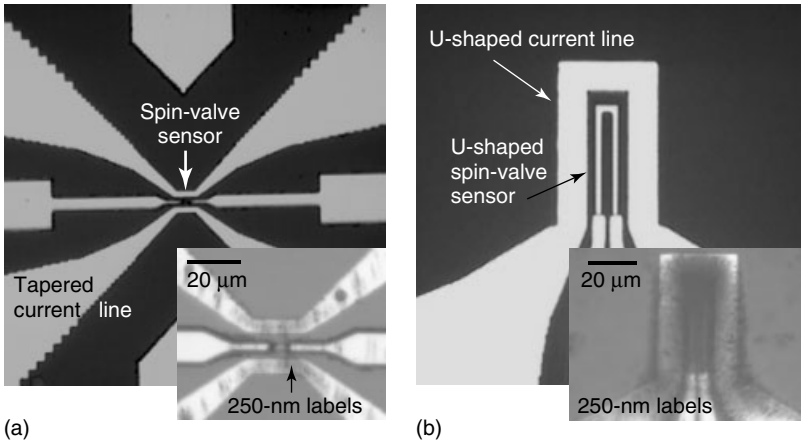

Figure 18. Optical microscope photographs of different magnetic-field guiding lines developed at INESC–MN. (a) Tapered current conductors create a maximum field gradient at the region nearest to a spin-valve sensor; inset: current passing through both top and bottom lines attract 250-nm particles closer to a $2 \times 6\,\mu m^2$ spin-valve sensor. (b) U-shaped current conductors used in combination with external magnetic fields are used to create an oscillatory magnetic-field gradient that focus labels in the inside of the line were a $2.5 \times 80\,\mu m^2$ u-shaped spin-valve sensor was fabricated; inset: 250-nm labels are concentrated at the sensing region.

detectable over or adjacent to the GMR sensors, the effective biomolecular recognition sensing area was relatively small ($\sim$10% or less) in comparison with the total functionalized area. In this case, for low DNA target concentration, target molecules could hybridize in $\sim$90% of the functionalized area and not being detected.

A later version of the BARC chip (Rife *et al.*, 2003) was designed to overcome this limitation, as the GMR sensors were fabricated in a serpentine shape that comprised a diameter of $\sim$200 μm and, consequently, fitted better the functionalized area (even so the sensing area was $<$70% of the total area with probe DNA). At the same time the number of sensing areas in the latest chip increased from 8 to 64.

One aspect to take into account is that an increase in the probe immobilized area corresponds to an increase in the biological sensitivity of the system, as the highest is the number of probe biomolecules on the surface the highest is the possibility to capture a complimentary target biomolecules that diffuses in the analyte solution being tested.

As such, an increase of the sensing area to fit the functionalized area resulted in the overall increase of the

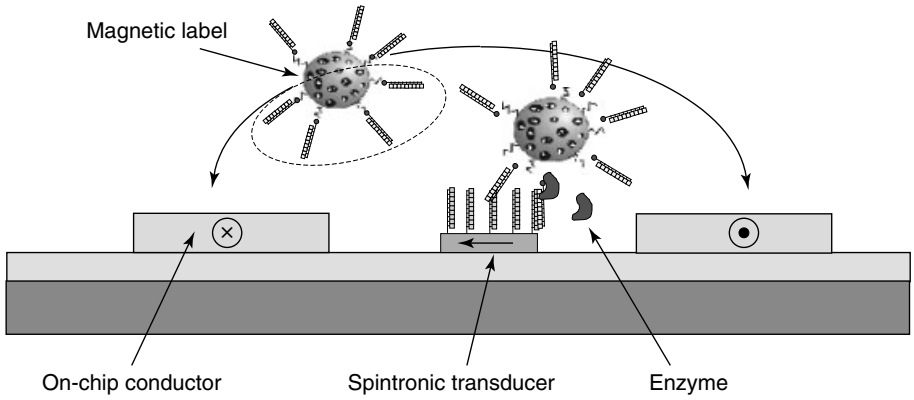

Figure 19. Variant of the magnetic-field-assisted hybridization method. After hybridization occurred, enzymes are used to cleave bound magnetic labels. Labels are then moved back and forth across the sensor using on-chip current conductors, enabling label detection.

biological sensitivity of the system. With the increase of the sensor size, the dynamic range of operation of the sensor also increases, that is, the number of magnetic labels that can be detected increases, and consequently the number of detectable biomolecular interactions also increases. Nevertheless, the sensitivity to lower number of particles or to single particles diminishes. Thus, in sensor design a compromise has to be made with respect to biological sensitivity and dynamic range with the single label sensitivity (Figure 20).

The group at the University of Bielefeld have also followed the strategy of fitting the sensor size to the probe immobilized area. In their case, they fabricated spiral-shaped GMR sensors with a diameter of 70 µm in order to fit DNA spots of 100 µm in diameter. A first version of the chip included 30 sensing elements, with half of them being used

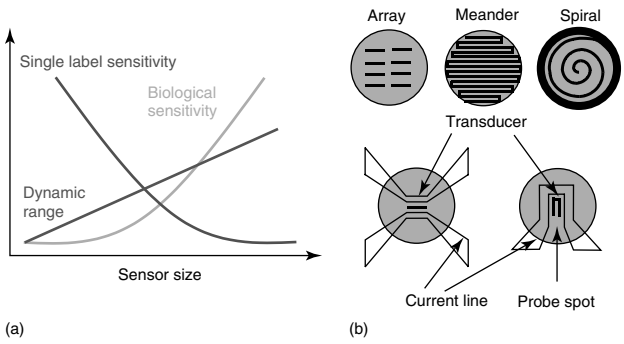

Figure 20. (a) Diagram showing the dependence on sensor size of biological sensitivity of the system, single label sensitivity and sensor dynamic range; a compromise must be found for this variables depending on the sensor and the application. (b) Different strategies for fitting the sensor size to the probe functionalized area: array of sensors and meander (NRL); and spiral sensor (University of Bielefeld). Using on-chip current conductors overcomes the large difference between sensor size and probe area by focusing the magnetically labeled targets at the sensing sites.

for reference purposes (Schotter *et al*., 2002). In a later version, where the magnetoresistive sensing platform was compared favorably with a fluorescence-based system, the chip included 206 spiral GMR sensors, with 6 of them being used as references.

Alternatively, the INESC–MN group, started to target single label detection by fabricating smaller $2 \times 6\,\mu m^2$ SV sensors (Graham *et al*., 2002), and the potential for the detection of single biomolecular recognition events (Graham, Ferreira and Freitas, 2004). These sensors had a small dynamic range of ∼200 nanoparticles of 250 nm in diameter (Graham *et al*., 2005), which seems reasonable for applications where it is necessary to distinguish between a yes or no answer more than a quantitative value. Examples of such assays are the distinction between different mutations in the same gene, including single nucleotide polymorphisms (SNPs), or the assessment of differences in the splicing of mRNA (splice-site mutations), or even the detection of a single pathogenic microorganism (see following section).

At a later stage a chip was designed to quantify differences in gene expression of an ill tissue versus a healthy one. In this case, a larger dynamic range was necessary and as a consequence larger $2.5 \times 80\,\mu m^2$ u-shaped SV sensors were fabricated (24 sensors per chip). These sensors allowed the detection up to a maximum of ∼3200 nanoparticles of 250 nm in diameter (Ferreira *et al*., 2005b).

These sensors have a very small sensing region when comparing to a typical probe spot size of 100 µm, and the comparison is even more unfavorable when considering the smaller $2 \times 6\,\mu m^2$ SVs. Nevertheless, these limitations are overcome by the use of on-chip biomolecular transport and focusing systems.

As a final note with respect to chip architecture, single sensor proof-of-concept studies from several research laboratories and more developed biochip sensing platforms all show a design limitation. These platforms comprised a small

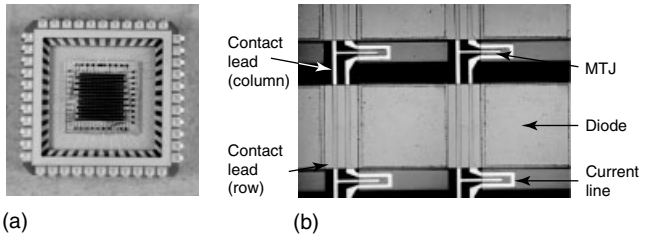

Figure 21. (a) Matrix of 256 magnetic tunnel junction (MTJ) sensing elements fabricated at INESC–MN (chip mounted on a chip carrier). (b) Photograph showing four sensing elements of the matrix. Each sensing element is addressed using thin-film diodes of amorphous-silicon. Also shown are the row and column contacts and u-shaped current lines for the focusing of magnetically labeled targets.

number of sensing elements (INESC–MN, 24 sensors; NRL, 64 serpentines; and University of Bielefeld, 200 transducers), and a further increase in the number of sensing elements is accompanied by a prohibitively large number of contacts and an off-chip multiplexing circuitry increasingly complex. These designs limit the number of different probes that can be immobilized and, consequently, the number of different analytes that can be screened in a single sample.

Recently though, a fully scalable biosensing platform was proposed and fabricated, based on a structure of a switching element and a magnetic transducer previously studied at INESC–MN for MRAM applications (Sousa, Freitas, Chu and Conde, 1999). A first prototype of a 16×16 matrix was fabricated, comprising as a sensing unit, a hydrogenated amorphous silicon (a-Si:H) TFD in series with a MTJ with a linear response (Cardoso *et al*., 2006) (Figure 21). This system can potentially be expanded to 10 000 or more sensing elements, and consequently, thousands of analytes could be analyzed simultaneously.

6 BIOASSAYS AND DETECTION RESULTS

The bioassays that have been developed concern the detection of oligonucleotides (short DNA strands) or of structural antigens from pathogenic microorganisms.

The BARC chip was used in the detection of biological warfare agents such as: *Bacillus anthracis*; *Yersinia pestis*, *Brucella suis*, *Francisella tularensis*, *Vibrio cholarae*, *Clostridium botulinum*, and *Campylobacter jejuni*. Here, DNA strands 30 nucleotides (or bases) long that represent specific bacterium, were immobilized on gold pads fabricated on top of the sensitive areas, and the chip was interrogated with a particular complementary DNA target (Edelstein *et al*., 2000; Miller *et al*., 2001).

The biochip from the University of Bielefeld, on the other hand, used polymerase chain reaction (PCR) amplified probe DNA sequences 1 kb (kilo-bases) long. The chip was immobilized with probes that were complimentary or not to a particular DNA target. The noncomplimentary probe was used to assess the background signals. In this work, a comparison with traditional fluorescence methods was made, showing that the magnetoresistive platform was more sensitive at low probe DNA concentrations (Schotter *et al*., 2004).

At INESC–MN, and within the scope of an European project, work has been focused on the development of diagnostic chips, using as a model disease cystic fibrosis (Freitas *et al*., 2004; Lagae *et al*., 2005). Cystic fibrosis is a genetic disease characterized by mutations in the cystic fibrosis conductance regulator (CFTR) gene which is localized in the chromosome 7 (Collins, 1992). Presently, more than 1000 mutations have been described (Cystic Fibrosis Mutation Database, http://www.genet.sickkids.on.ca/cftr), and their prevalence among populations varies according to race and geographical distribution. The majority of these mutations consist of variations in a small number of nucleotides of the DNA, frequently a single nucleotide is either replaced by another base, inserted, or deleted (SNPs). For instance the most common mutation, F508del, refers to the deletion of 3 nucleotides that corresponds to the deletion of a phenylalanine aminoacid at the position 508 in the CFTR protein.

Two approaches are being followed for the diagnostics of cystic fibrosis: one corresponds to screening the messenger RNA (mRNA) resulting from the transcription of the mutated CFTR gene; the other one corresponds to the analysis of genes (others than the CFTR genes) whose expression is consistently increased or diminished in cells and tissues with cystic fibrosis than in healthy ones (Clarke, Braz and Amaral, 2004).

With respect to the first approach, a study was made using the post-hybridization detection method (Graham, Ferreira and Freitas, 2004; Freitas *et al*., 2004). Here, the chip surface was immobilized with a 50-mer (50 nucleotide long) DNA probe that corresponds to the region of the gene where the F508del mutation occurs. The chip was further interrogated with PCR products either complementary to the probe or not. The noncomplementary target used was related to a proto-oncogene. Typical obtained signals are shown in Figure 22.

Later on, the same probe and targets were used in magnetic-field hybridization experiments, and hybridization times of less than 5 min were observed using the magnetoresistive biochip platform with on-chip tapered conductors (Graham *et al*., 2005). In addition, it was shown that by repeating the biomolecular recognition experiment on the same chip, an increased hybridization signal was detected,

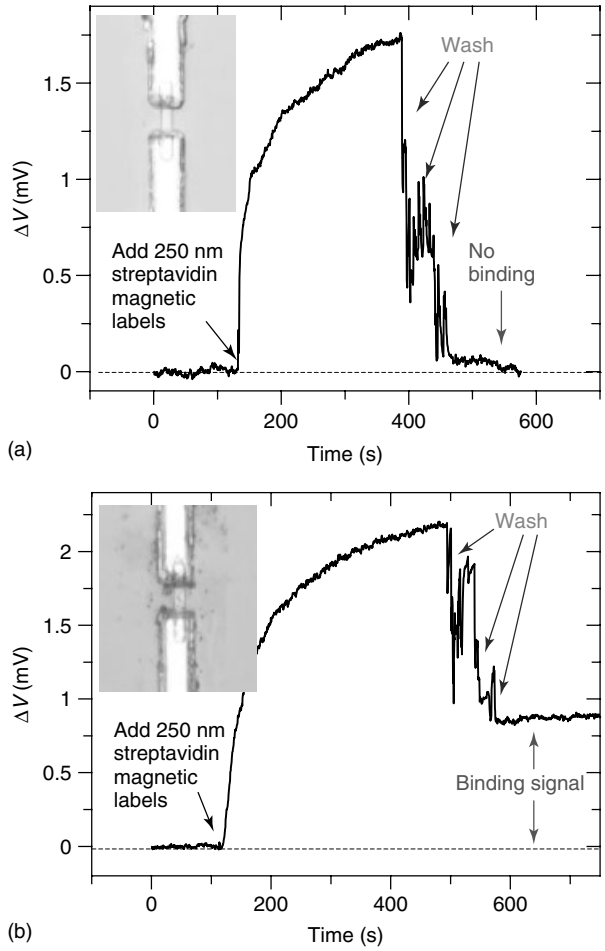

Figure 22. Post-hybridization detection experiments on chips functionalized with 50 oligomers representing the DNA sequence that spans the region where the most common in cystic fibrosis occurs. (a) The chip was incubated overnight with a biotinylated noncomplementary 75 nucleotide long target that represents the proto-oncogene *rac1*; after hybridization was attempted, streptavidin-coated magnetic labels of 250 nm in diameter were dispensed over the chip for 5 min and a change in sensor response was observed due to the presence of labels; after the chip was washed and unbound labels removed the signal returned to the baseline indicating that no hybridization occured. Inset: picture showing a $2 \times 6\,\mu m^2$ spin valve clear of particles. (b) In this case, the chip was incubated with complementary target (96 oligonucleotides) labeled with biotin reporter molecules; after introducing labels into the chip for 5 min and washing the signal did not returned to zero, indicating that hybridization between the complementary molecules occured. Inset: picture showing labels bound to the sensor surface as a result of DNA–DNA recognition.

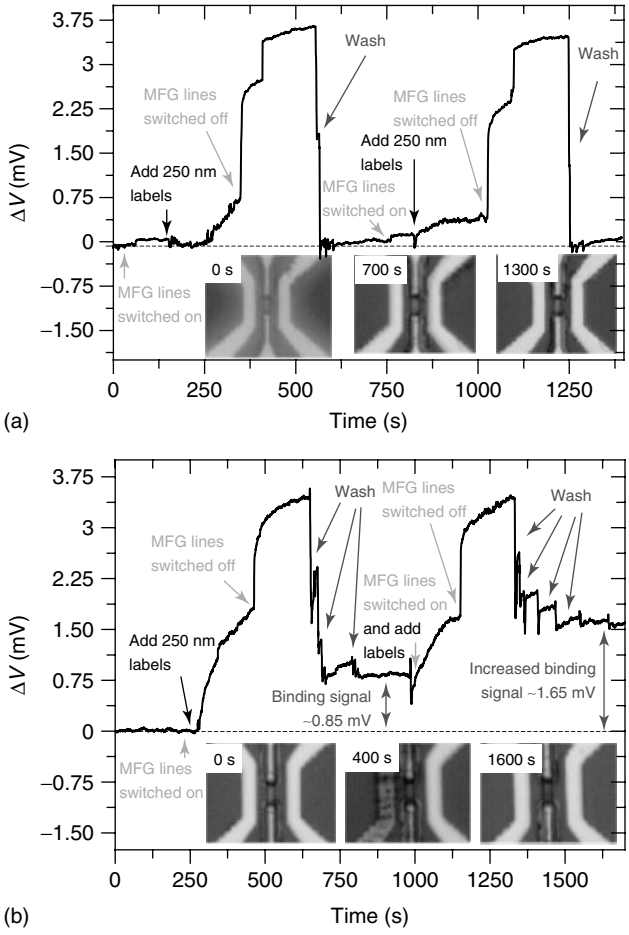

Figure 23. Magnetic-field-assisted hybridization and simultaneous detection experiments. The chips were functionalized with a cystic fibrosis-related DNA probe and were incubated with magnetically-labeled noncomplementary or complementary targets. (a) Noncomplementary targets functionalized to magnetic nanoparticles were concentrated at sensing sites using magnetic-field guiding lines with a tapered design; after ~5 min unbound labels were washed away and the signal returned to zero; later on the experiment was repeated. Insets: pictures taken from the sensor at different times during experimentation showing that no particles bound to the surface. (b) In this case, the same experiment was done for magnetically labeled complementary targets; after particle focusing and washing a residual signal was obtained indicating biomolecular recognition; later on after a second focusing step an increased signal was observed which corresponded to an increased number of hybridization events.

corresponding to an increased extension of the hybridization reaction (Figure 23).

Concerning the second approach, a new chip based on u-shaped spin-valve sensors and on u-shaped current lines for magnetic-field-assisted hybridization was used. Here, the same chip surface was spotted with distinct 50-mer probe sequences that correspond to genes that are either overexpressed or subexpressed in diseased tissues in comparison with healthy ones. A further control gene (whose expression does not change) was also spotted onto the chip. During experimentation, magnetically labeled target DNAs were focused simultaneously at 8 to 16 sensors by local magnetic filed gradients created by the u-shaped lines (Ferreira *et al*., 2005b), and hybridization signals were measured in

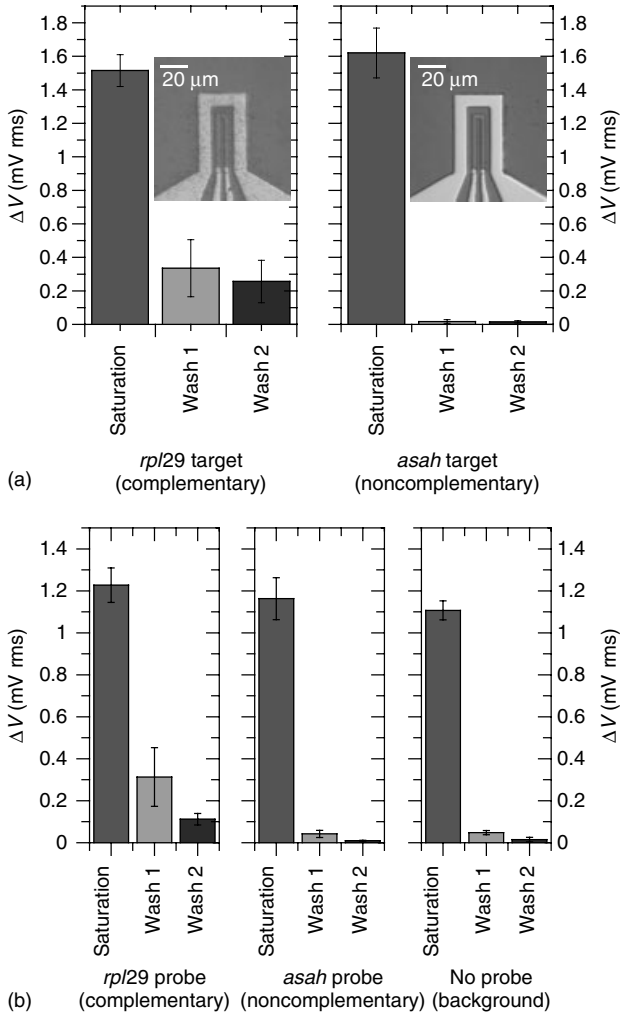

Figure 24. Magnetic-field-assisted hybridization and simultaneous detection experiments using u-shaped current lines and $2.5 \times 80\,\mu m^2$ u-shaped spin valves. (a) Spintronic biochips were functionalized with a 50-mer single-stranded DNA molecules that correspond to a gene that was found to be upregulated (*rpl29*) in cystic fibrosis-related cell lines vs healthy cell lines; in this case complementary (*rpl29*) and noncomplementary (*asah*) magnetically-labeled targets were focused for ∼15 min before washing; chips were further washed a second time with a more stringent solution to further remove weakly or unspecific bound labels; statistical data is presented for six monitored sensors. Insets show pictures for complementary and noncomplementary testing experiments. (b) Chips were functionalized with both DNA probes corresponding to upregulated (*rpl29*) and down-regulated (*asah*) genes and tested with a *rpl29* magnetically labeled target; focusing occured for about 30 min at nearly half focusing current. In these charts, saturation represents the sensor responses to labels just before washing.

less than 30 min (Ferreira *et al*., 2005c). Typical statistical results obtained are shown in Figure 24.

Furthermore, a recent study realized with 250-nm-diameter magnetic labels has shown that this platform is sensitive to particle concentrations down to 1 pM. This corresponds

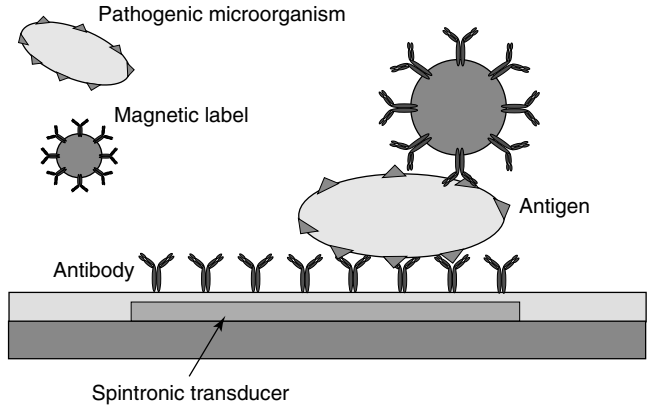

Figure 25. Schematic showing detection strategy for the detection of whole cells of pathogenic microorganisms. A sensor surface, functionalized with antibodies against a particular microorganism such as *Salmonella*, is incubated with a testing solution. In the case that the pathogen is present, the antigens present at its membrane surface are recognized by the surface bound antibodies. Later, magnetic labels functionalized with antibodies for the same microorganism bind to it, indicating its presence by measurement of the stray field of the labels.

to DNA target concentrations of 500 pM, which compares favorably with traditional DNA assays (μM concentrations). In addition, this system presents a dynamic range of at least 2 orders of magnitude, thus making these magnetoresistive DNA chips attractive for fast diagnostics of genetic diseases (Ferreira *et al*., 2006).

More recently, at INESC–MN the same biochip platform was used for the detection of pathogenic microorganisms in water (Martins *et al*., 2005). In this case, the chip surface was functionalized with antibodies against *Salmonella* species and was incubated with a solution containing viable *Salmonella* cells. Subsequently, the chip was interrogated with magnetic labels functionalized with the same antibody against the pathogen, which bound to the immobilized cells forming a 'sandwich'-like structure (see Figure 25). This showed that the chip could also successfully be used as an immunoassay, just by changing the chip surface biomolecular functionality.

7 CONCLUSIONS

Spintronics or magnetoelectronics is, in general terms, the study of devices whose operation is based not only in the electron charge like in regular electronic devices but also the electron spin (Prinz, 1998). The understanding of the underlying physics, together with advances in material science and in microelectronic processing have given rise to numerous devices that changed, are changing, and will change the day-to-day life of mankind. Such devices include

for instance, sensors in hard-disk readheads, which enable the access to practically all of man's knowledge in digital form. Among various sensing applications in position devices or in air-lock braking systems (ABS) in automobiles, magnetoelectronic devices are being developed for memories (MRAMs) and novel semiconducting hybrid devices such as spin transistors. More recently, spintronic sensors are finding new applications in the ever-growing field of biomedicine and biotechnology (Freitas *et al*., 2006).

Spintronic biochips and biosensors are presently being developed by a number of research groups and companies worldwide and they hold the promise of becoming important tools for the rapid, sensitive, high-throughput and low-cost detection of biomolecular recognition, such as in diagnostics and in the detection of pathogenic microorganisms. Its applications can span areas ranging from medicine to biotechnology and from environmental studies to the quality monitoring of beverages and food products.

Although, future seems bright a number of challenges still need to be addressed, such as thorough studies of biological assays, including the assessment of the sensitivity, the specificity, and the positive predictive and the negative predictive values of the tests. Furthermore, of quite importance is the integration of the detection platform with sample treatment procedures and data-analysis system. In this respect, hybrid systems combining magnetoresistive sensors and microfluidics are being developed (Tamanaha, Whitman and Colton, 2002; Ferreira *et al*., 2004) with the ultimate goal of fabricating a lab-on-chip system for complete sample analysis (Ahn *et al*., 2004). Finally, the simplicity of operation and the direct electronic read-out of biomolecular recognition events are pushing forward the development of portable spintronic biochip platforms that can be used at the point of care (Piedade *et al*., 2006).

ACKNOWLEDGMENTS

INESC–MN work presented in this paper was supported by the following Portuguese national projects: POCTI/BIO/34459/99, POSC/EEA-ESE/58523/2004, and POCTI/CTM/59411/2004; the the European projects CF CHIP-QLK3-CT-2001-01982, SNIP2CHIP-NMP4-CT-2005-016833, and BIOMAGSENSE-NMP4-CT-2005-017210; and also by Fundação Calouste Gulbenkian. 1 INTRODUCTION

Magnetic particles (MPs) exist in our environment in greater amounts than is commonly noticed. Huge masses of sediments contain iron oxide particles of terrigenous material. A small number of these particles are formed from magnetosomes, which are special organelles of bacteria. Recent investigations have revealed interesting details of the factors governing the size and formation of these biogenic MPs (Schüler and Frankel, 1999; Scheffel *et al*., 2006).

The properties of biogenic MPs are particularly favorable for certain applications such as a heat source in local magnetic hyperthermia (see Section 4). Nevertheless, their general use in medicine and biology is restricted owing to the fact that their growth cannot be easily controlled. Moreover, their content of bacterial proteins, if not completely removed, causes problems for their medical application. Many methods have, therefore, been developed to artificially prepare particles with properties suitable for particular applications. One of the first preparation methods, chemical precipitation of particles from a mixture of a ferrous and a ferric salt reacting at a basic $pH > 8$, was described in 1938 and used for the investigation of magnetic microstructures (Elmore, 1938). This wet method of preparing an aqueous suspension of nanoparticles was later followed by a dry powder preparation, using the thermal decomposition of iron pentacarbonyl (Andrä and Schwabe, 1955). Very recently, laser evaporation has also been applied to the highly efficient production of dry iron oxide nanoparticles (Kurland *et al*., 2007). During the last few decades, different synthetic techniques have been developed, a comprehensive review of which was done by Tartaj *et al*. (2003). The most common technique, however, is still the chemical precipitation developed by Elmore, leading to well-controlled superparamagnetic particles of typically 10 nm diameter. Attempts to increase the particle diameter has generally led to broader size distributions. In order to prepare larger particles with a narrow size distribution, a separation of the nucleation stage from further particle growth has been tried. Sun and Zeng (2002) were particularly successful at this, producing well-defined particle diameters. An alternative method, used for the preparation of barium ferrite particles, is the glass crystallization method, which has recently been adapted to γ-Fe_2O_3 nanopowders (Müller, Hergt, Zeisberger and Gawalek, 2005). The mean particle size can be controlled by the parameters of the annealing procedure. In spite of these successes, further systematic investigations for optimizing preparation techniques are necessary in order to provide nanoparticles with tailored magnetic properties.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

Medical applications of magnetic powders have been known since ancient times (Häfeli, 1998), but many of these were based on superstition and irrational ideas. It is only in the last couple of decades that the scientific use of artificially prepared MPs in medicine and biology has taken off. Important medical applications include their use as contrast media, vascular occlusion agents, localized heating sources in hyperthermia and thermoablation, targeted drug and radiation sources, transfectant (magnetofection) agents, and agents to purify and separate distinct cell populations. In the sections that follow, these topics will be covered in more detail.

Another application of MPs that can only be touched upon owing to space limitations is their natural use, for example, as sensing elements in living beings. Four decades ago, the existence of biogenic magnetite as tooth capping in a primitive sea mollusc was discovered by Lowenstam (1962). Later, magnetic iron-oxide particles were found in many different animal species. Recent reports have focused on the biophysical mechanism of magnetic sensing, which is assumed to be strongly connected with MPs in higher organisms (Kirschvink and Gould, 1981; Kobayashi and Kirschvink, 1995). The role of other MPs, such as the iron cores of ferritin, is also omitted in this chapter. Interested readers should refer to Meldrum, Heywood and Mann (1992).

2 MAGNETIC LABELING OF CELLS AND BIOMOLECULES

Magnetic labeling of cells and biomolecules can be accomplished with the use of magnetic carriers, henceforth referred to as MPs. Magnetic labeling has found extensive application in life science research, clinical diagnostics, and therapeutics. MPs can have a hydrophobic or affinity ligand immobilized on their surface or can possess ion-exchange groups that act as linkers. These specific surface structures make MPs useful in the processing of a wide variety of test samples for analysis (= samples). Samples include crude cell lysates, whole blood, plasma, ascites fluid, milk, whey, urine, cultivation media, wastes from the food and fermentation industry as well as many others (Safarik and Safarikova, 2004). When the sample and MPs are mixed and allowed to incubate for some time, the target compound (i.e., analyte) binds to the MPs and the magnetic complex that is formed can be easily and rapidly removed from the sample using an appropriate magnetic separator (see Section 2.2). After washing out the contaminants, the isolated target compound can be separated and used for further work. This process is termed *positive isolation*, that is, the direct isolation of the desired compound (Figure 1a). Magnetic separation can also be used to remove unwanted compounds from a heterogeneous suspension. In this approach, the MP-bound compound is discarded and the remaining target compounds of interest recovered. This process is termed *negative isolation* (Figure 1b).

The advantages of magnetic separation far outweigh their disadvantages, as summarized in Table 1. Magnetic separation is simple to perform and flexible compared to conventional separation methods.

2.1 Magnetic carriers

Most MPs are based on inorganic magnetic materials, primarily iron oxides. For their use in biotechnology, these MPs are either coated with or embedded into matrix materials such as polymers and silica and are then typically referred to as *composite particles*. The first applications of coated MPs began in the 1970s and included enzyme immobilization, radioimmunoassay, specific cell binding, and affinity chromatography (Pouliquen, 2001). In 1978, Kronick *et al*. reported the first use of MPs for cell separation (Kronick, Campbell and Joseph, 1978). In 1979, John Ugelstad of Norway made the first uniform monosized polystyrene spheres (Ugelstad and Mork, 1980) and developed them within a few years into a highly successful commercial product, namely, monosized composite particles (Dynabeads®) (Ugelstad *et al*., 1992). Critical to their success was that Dynabeads® are superparamagnetic, which means that they can be easily resuspended once the magnetic field is removed, with no residual magnetism.

Dynabeads® are currently available in diameters of 1, 2.8, and 4.5 μm. These large-sized particles have the disadvantage that they have limited surface area per weight. Nonporous spherical beads of 50-nm diameter contain a 20 times larger surface area than 1-μm beads of the same weight; making the beads porous further adds to their surface area. Decreasing the size of MPs to 50 nm, as was done by Miltenyi (Safarik and Safarikova, 1999), will theoretically allow for a larger number of functional groups, and the binding of increased amounts of ligands, for example, antibodies. MPs of such small particle size, however, will require high-gradient magnetic fields for separation (Miltenyi, Muller, Weichel and Radbruch, 1990). Such high gradients typically exceed $100\,\mathrm{T\,m^{-1}}$.

Most applications utilize composite magnetic nano- or microparticles with sizes between 50 nm and 10 μm, although even very large MPs that are 800 μm in diameter have been used for the magnetic separation of α amylases from porcine pancreas, starch-degrading enzymes, and wheat germ (Teotia and Gupta, 2001). The largest and earliest commercial provider of MPs in the micrometer range is Dynal Biotech (bought by Invitrogen in 2005) and in the nanometer range it is Miltenyi Biotec. However, there are many smaller

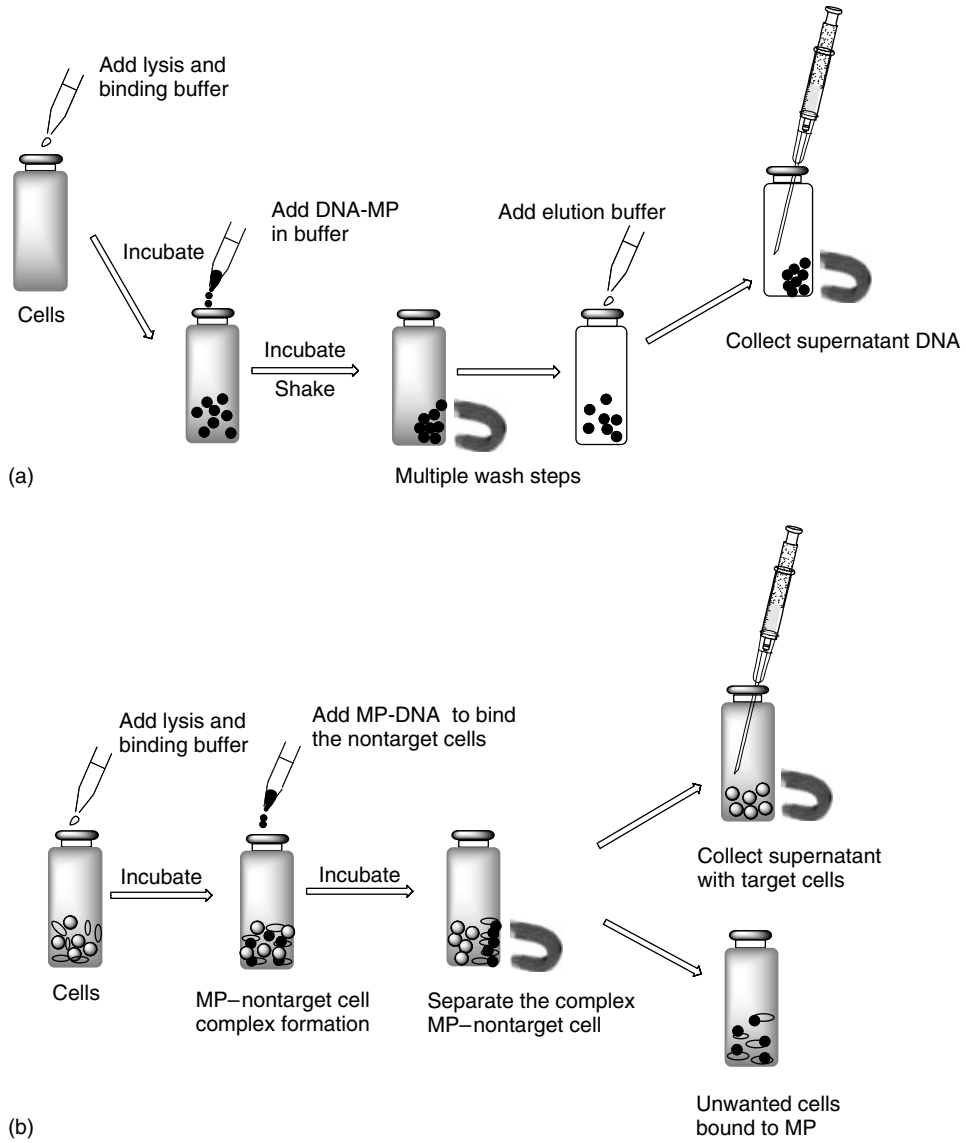

Figure 1. (a) The *positive isolation* of genomic DNA starts with the lysis and binding of DNA under nondenaturing conditions, followed by the addition of MPs with specific affinity ligands. After multiple wash steps, the purified DNA is obtained. (b) The *negative isolation* of bacterial cells begins with the addition of MPs with affinity to the nontarget cells. Bound MPs are then attracted by a magnet and the untouched target cells collected from the supernatant. Magnetic separation is indicated by the symbol of a horseshoe magnet.

companies that provide products for magnetic separation and specialty applications as well as appropriate (super)magnetic particles.

For magnetic separation, different materials can be used to prepare MPs. A partial list of matrix materials includes synthetic polymers such as poly (ethyl-2-cyanoacrylate) and poly (styrene-*co*-maleic anhydride); biopolymers such as dextran and albumin; and porous glass. The magnetic components include inorganic magnetic materials such as the iron oxides magnetite Fe_3O_4, maghemite γ-Fe_2O_3, and mixtures thereof. Metallic iron, cobalt, nickel, and alloys thereof can also be used. Since the largest use of these materials is *in vitro*, biocompatibility is not of major concern in the choice of materials.

In addition to size, structure, magnetic moment, and (superpara)magnetic properties, the most important MP parameters are surface charge, surface hydrophobicity or hydrophilicity, porosity, and the type and density of reactive surface groups. Chemically reactive groups on the surface are used for covalent immobilization of affinity ligands and target biomolecules. They must remain stable under varied temperature and pH conditions, must be correctly oriented, and must have low nonspecific binding even in complex sample types. Choosing relevant chemical groups and spacers,

Table 1. General advantages and disadvantages of magnetic cell separation using magnetic particles (MPs).

Advantages	Disadvantages
• Simple method with very few handling steps • All the steps can take place in a single test tube. No necessity for excessive instruments or equipment • Separation can be directly performed on crude samples • Total separation time can be shortened by combining the disintegration and separation steps • Magnetic absorbents can be removed easily owing to their magnetic properties • Useful for large-scale separations • Magnetic separation is usually gentle on the target proteins or peptides • Large commercial availability of MP and MP separation kits	• Insufficient and/or ineffective resuspension of the MP pellets after washing and elution steps may result in: –Lower yields –Lower purity of the separation product compared to other purification methods • Magnetic component in positive selection may interfere with subsequent procedures

adding blocking agents, and carrying out post-immobilization modifications allows for the preparation of highly specific MPs. For example, immobilization of oligonucleotides is normally achieved by introduction of specific chemical groups at the end of the oligonucleotides, thus retaining functional activity. NH_2 groups or SH groups are often used for direct covalent coupling to the MP surface, while the introduction of a biotin molecule at the 5′ or 3′ end of the oligonucleotide is used in combination with MPs coated with streptavidin. The strong streptavidin–biotin bond is temperature stable (up to 80 °C) and can withstand alkaline treatments (0.15 M NaOH), features which make streptavidin MPs a versatile tool in molecular biology (Bosnes *et al*., 1997).

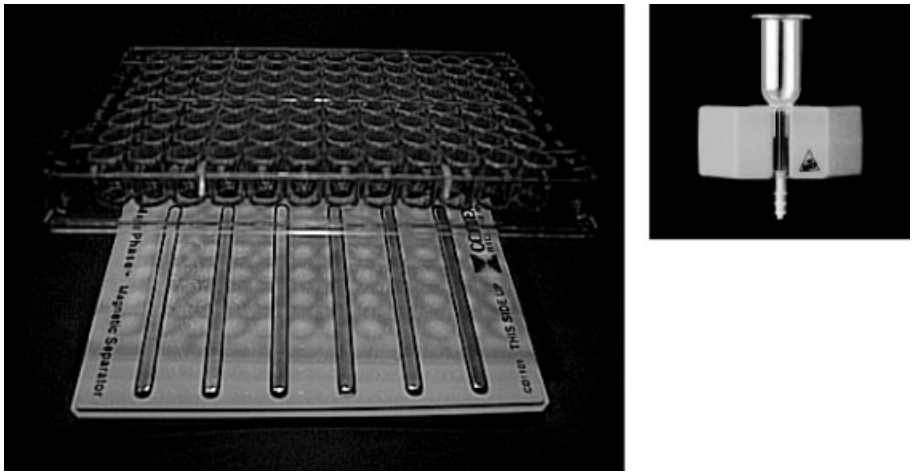
Nonspecific binding of analytes to MPs during magnetic separations can be a problem. Additional preclearing steps are often carried out, particularly when extracting proteins and peptides from crude samples. By studying the characteristic MP properties such as type (hydrophilic/hydrophobic, nonporous/macroporous), size, and functional group for use of appropriate ligands, Korecka *et al*. determined the reaction conditions required to develop immobilized magnetic enzyme reactors (IMERs). These enzyme reactors consist of the immobilized proteolytic enzymes trypsin, chymotrypsin, papain, and neuraminidase immobilized on MPs (Korecka *et al*., 2005). The strategy adopted in getting minimal nonspecific sorption of proteins and peptides, without the need for any additional preclearing steps before studying heterogeneous proteins and/or glycoproteins, was the use of different MP matrix materials. The optimal materials chosen included hydrophilic cellulose and alginate, and hydrophobic polystyrene, poly(NIPAM) and poly(HEMA-*co*-GMA) (Korecka *et al*., 2005).

2.2 Magnetic separators

Magnetic separations have been used in various areas such as molecular biology, biochemistry, immunochemistry, enzymology, analytical chemistry, and environmental chemistry (Safarik and Safarikova, 2004). Magnetic separations with MPs have also been successfully studied for a wide variety of applications such as the detoxification of blood-borne toxins of humans (Mertz *et al*., 2005), the separation of pathogenic bacteria from food and environmental samples (Rotariu *et al*., 2005), and the extraction of surfactants from water (Safarikova *et al*., 2005).

Magnetic separation techniques generally consist of two steps. In the first step, solid phase affinity MPs with specific target recognition capabilities are mixed with the sample and selectively bind to the target in the sample. In the second step, the target–MP complex formed is captured by a magnetic field and removed from the separation medium. Magnetic fields for separation can be produced by permanent magnets or electromagnets. The shape and magnitude of magnetic fields determine where and how quickly the MPs separate in any given vessel. The magnetic field gradient and magnitude play important roles in separation and their product determines the strength of the magnetic force that acts on any given MP. The higher the relative force densities, the more quickly a given magnet can separate the MPs, and the smaller the MPs can be.

Magnetic separators may be either batch-wise driven or continuous driven, and one may chose between the two on the basis of the desired application. Commercially available laboratory-scale batch magnetic separators are usually made from magnets embedded in disinfectant-proof material.



(a) (b)

Figure 2. Commercially available magnetic separators. (a) The 96-well plate laboratory-scale batch-type magnetic separator from Cortex Biochem pulls the magnetically labeled samples to the bottom of the plate, close to the long stripe-shaped NdFeB magnets. (b) The MiniMACS separator from Miltenyi Biotec is a lab scale HGMS separator, designed for extracting animal and plant cells, bacteria, viruses, cellular organelles, and molecules such as mRNA. It is designed for the positive selection of up to 10^7 labeled cells, from up to 2×10^8 unseparated cells.

The batch-type separators have racks constructed for separations and some also have a removable magnetic plate to facilitate easy washing of separated MPs (Figure 2). Other examples of batch-type magnetic separators include holders for Eppendorf microtubes, standard test tubes, and centrifugation cuvettes (Safarik and Safarikova, 2004). Simple magnet blocks in these holders typically generate field gradients in the order of 1–6 T m^{-1} across the diameter of standard 15–50-ml laboratory test tubes with wall thicknesses of 1–2 mm.

The magnetic force acting on a pointlike magnetic dipole moment m is described by the formula

$$F = m\nabla|B| \tag{1}$$

where the total magnetic dipole moment of the MPs is the result of volume magnetization of the magnetic component included in the MPs, M:

$$m = V_{\mathrm{m}}\, M \tag{2}$$

and where V_{m} is the total volume of the magnetic material in the MPs. The magnetic component is free to rotate in space (together with the MPs), and its magnetization is induced by the external magnetic field of strength H:

$$M = \Delta\chi H \tag{3}$$

where $\Delta\chi$ is the effective magnetic susceptibility of the magnetic component relative to medium. In an isotropic, weakly diamagnetic medium such as water, and for diluted MP suspensions with no free magnetic component in the solution, magnetic fields H and B differ only by a constant, the magnetic permeability of vacuum μ_0:

$$B = \mu_0 H \tag{4}$$

Combining the last four formulas and applying them to the special case of time-independent, magnetostatic fields, as is the case in the just described magnetic separators, one obtains the magnetic force acting on an MP as

$$F_{\mathrm{m}} = V_{\mathrm{m}}\Delta\chi\frac{\nabla B^2}{2\mu_0} \tag{5}$$

For small Reynolds numbers (i.e., $Re_{\mathrm{particle}} < 0.1$) the magnetic drift velocity can be derived from equation (5) when the sedimentation and buoyancy force can be neglected. Thus, the magnetic drift velocity v_{m} can be defined as

$$v_{\mathrm{m}} = \frac{V_{\mathrm{m}}\Delta\chi}{f}\frac{\nabla B^2}{2\mu_0} \tag{6}$$

where $f = 3\pi\eta D$ is the Stokes drag coefficient, η is the viscosity, and D is the MP diameter (Zborowski, 1997). The direction of the magnetic force is orthogonal to the magnetic flux.

Flow-through separations can be useful when the separation of large volumes of samples is desired or when separation involves nanosized MPs. Flow-through magnetic separations are usually carried out using a high-gradient magnetic separator (HGMS), in which optimally designed

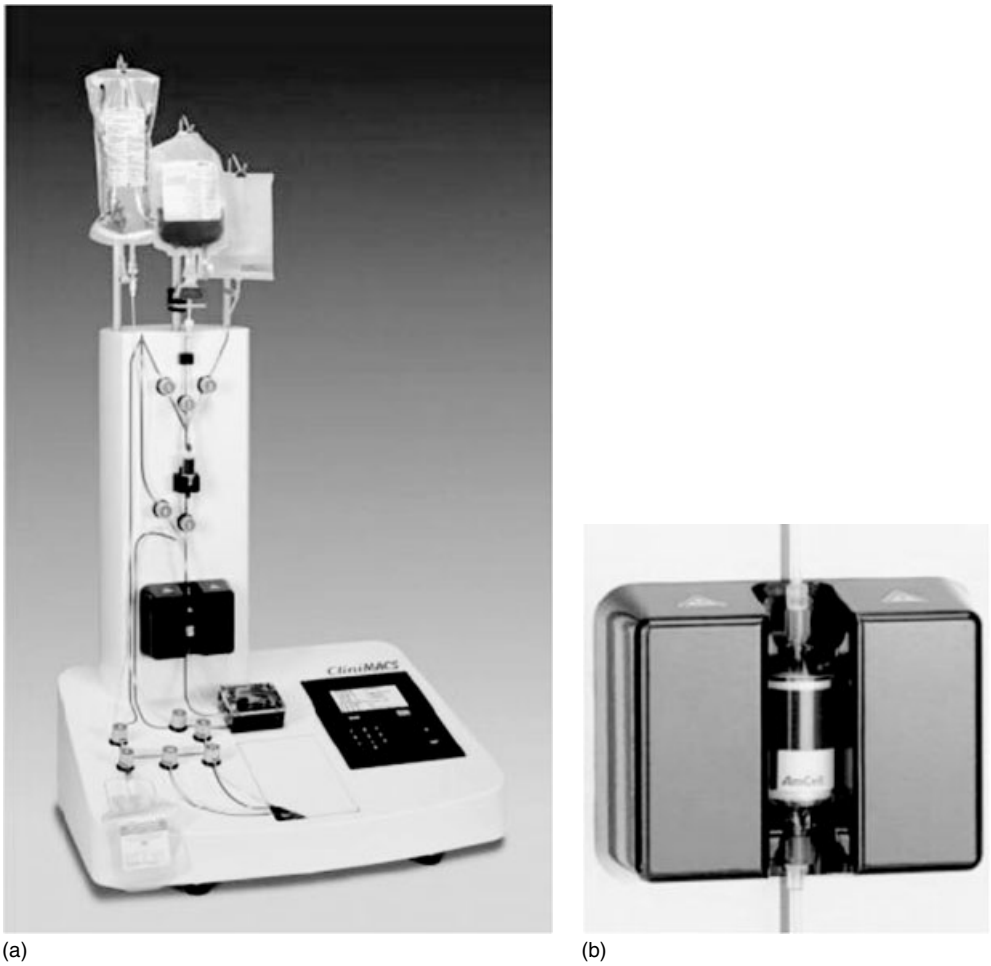


Figure 3. (a) The CliniMACS® instrument from Miltenyi Biotec with installed tubing set is a commercially available automated cell selection device, based on the HGMS principle. It enables the operator to perform large-scale magnetic cell selection in a closed and sterile system. (b) The CliniMACS® magnetic separation device (with separation column in the middle) consists of two strong permanent NdFeB magnets.

magnetic circuits generate gradients from 10 to 100 T m^{-1} across 15–50-ml test tubes (Hatch and Stelter, 2001). HGMS for laboratory-scale use consists of a column of densely packed fine magnetic grade stainless steel wool or small steel balls that is placed between the poles of a strong magnet. The MP suspension is pumped through the column and the MPs are retained within the matrix. The MPs are then recovered by gentle vibration of the column after removal of the magnetic field (Safarik, Ptackova and Safarikova, 2001). HGMSs create magnetic field gradients that can be used to attract much smaller and less magnetic MPs than those required for conventional magnetic separation techniques. The most frequently used HGMS application is the labeling of cells with submicron-sized MPs and their successful separation and/or extraction (Thomas *et al*., 1993).

The separation of pathogenic microorganisms, biological cells, or chemical compounds can be accomplished with the help of antibody-coated MPs. This separation technique is known as *immunomagnetic separation* (IMS). Current standard IMS devices use 1–8 µm MP for test volumes of 1 ml. By increasing the sample size, the sensitivity of the IMS process can be improved such that even the lowest amounts of pathogens can be extracted. A flow-through immunomagnetic separator has been designed and tested to process large volumes of samples (>50 ml) (Rotariu *et al*., 2005). The preliminary results show that between 70 and 113 times more *Escherichia coli* O157 can be recovered when compared with the standard 1-ml method.

The fast and simple handling of samples and the ability to deal with large sample volumes are major advantages of magnetic separation techniques and make them amenable to automation. The CliniMACS® system (Figure 3), marketed by Miltenyi Biotech in Europe since 1997, is an automated magnetic cell selection device based on the HGMS principle.

It enables the operator to perform large-scale magnetic cell selection of CD34, CD133 (AC133), and CD14 positive cells from human peripheral blood and bone marrow in a closed and sterile system (Campbell *et al*., 2005). CD34 and CD133 are protein complexes presented on the surface of hematopoetic and endothelial cells, and CD14 is a protein complex expressed and secreted by myeloid cells. The first commercial automated magnetic cell selection device is the Isolex 300i marketed by Baxter. It received European regulatory approval in 1995 and was also approved by the U.S. Federal Drug Administration (FDA) in 1999, for clinical selection of $CD34^+$ positive cells. A more detailed review of the MACS system and its applications has been recently published (Apel *et al*., 2006).

2.3 Magnetic isolation of proteins and DNA molecules

Magnetic isolation relies on the affinity and interaction between the MPs and the target compounds. To get the highest yields with low nonspecific binding and short separation times, appropriate ligands can be coupled to the MP with specific affinity toward the target compound(s). These MPs are added to the analysis sample, where they bind the target compounds. This method is called the *direct method*. In the *indirect method*, the affinity ligands are added to the solution or suspension without MPs being present. After binding with the target compound and forming a ligand–analyte complex, the entire complex is captured by the MPs (Safarik and Safarikova, 2004).

Magnetic separation produces superior yields of the isolates with shorter separation times. Risoen *et al*. purified two recombinant DNA binding proteins, oncoprotein Myb, and full-length yeast TFIIIA, directly from an *E. coli* cell lysate, in a single step with high purity and recovery (Risoen, Struksnes, Myrset and Gabrielsen, 1995). Holschuh *et al*. have accomplished purification of antibodies from up to 100 l of cell culture supernatant, with protein A–coated MP, called *MagPrep*^{R} *Protein A* (Merck Biosciences). The MPs were coated with 3-(2,3-epoxypropoxy)-propyltrimethoxysilane for the direct covalent immobilization of protein A. Using this technique, magnetic separation results in a similar yield and purity of product as a conventional column, but is much faster (Holschuh and Schwammle, 2005).

Various separation kits are commercially available and can be used for applications such as protein isolation, protein screening, immunoassays, purification of immunoglobulins, immunoprecipitation, and human cell separation for clinical diagnostics and research. The *geneMAG-DNA/Bacteria* kit (Chemicell, Germany) can serve as an example for these novel, simple, and highly efficient tools in molecular biology. After lysing the bacteria, adding the MPs, incubating, and washing, genomic DNA can be efficiently extracted from bacteria with magnetic silica beads (Figure 1a).

Even MPs without linker compounds can be used to separate and screen biomolecules. Magnetic separation of amino acids, using gold/iron oxide composite nanoparticles has been reported (Kinoshita *et al*., 2005). Gold firmly combines with mercapto-containing biomolecules, thus enabling the binding of functional biomolecules without the use of a special linker molecule for each different application. The sulfur-containing amino acids cystine and methionine connect to gold through Au–S bonds and can then be selectively picked up by MPs. Similarly, aspartic acid and glutamic acid have been adsorbed relatively well onto monolithic iron oxide particles, possibly owing to the presence of carboxyl groups found on these molecules (Kinoshita *et al*., 2005).

The literature is full of examples of successful extractions of cells, bacteria, enzymes, proteins, and nucleic acids as reviewed in detail by Safarik and Safarikova (2004). Table 2 gives some examples of the biologic substances that can be isolated and/or purified by magnetic separation techniques.

2.4 Magnetic gene transfection

Nucleic acids form the building blocks for living systems and are responsible for all the processes taking place within the cells. Introducing nucleic acids in a controlled and defined manner opens up an opportunity to influence the processes within living cells. One of the most effective ways to transport nucleic acids is gene therapy, where a 'normal' gene is inserted into the genome to replace an 'abnormal' disease-causing gene. This is normally done with a carrier molecule called a *vector*, which delivers the therapeutic gene to the target cells.

The most effective vectors are viruses that have been genetically altered to carry normal human DNA. After the death of Jesse Gelsinger, however, who died within two days of being injected with adenoviral vectors during a phase I clinical gene therapy trial for a life-threatening enzyme deficiency, more research efforts have focused on developing a nonviral gene transfer system, thus reducing the potential biological risks associated with viral vectors (Somia and Verma, 2000).

Irrespective of the type of vector (viral or nonviral/synthetic), the low efficiency of gene transfer poses a significant challenge in gene transfection, since the transfer process for vectors to target cells is, to a large extent, diffusion controlled (Plank *et al*., 2003b). In addition, the lack of selectivity creates a subsequent need for local targeting to achieve an effective dose at the target cells and to avoid any untoward

effects at nontarget sites. The susceptibility to *in vivo* degradation further reduces the efficiency of gene transfer.

Microparticles, especially MPs, as carriers of DNA can overcome many of these challenges and may help in delivering sustained, therapeutic concentrations of DNA. Frequent dosing regimens and protection of DNA from serum components is possible with the use of biodegradable, biocompatible polymers that are inert, safe, and do not compromise the bioactivity of the DNA. The use of MPs for gene transfection has been termed *magnetofection* by Plank *et al*. (2003a) and comprises the application of a magnetic field in order to drive the magnetic vector toward the target cells or retain it in the target tissue. Preparation of magnetic vectors can be accomplished by linking nucleic acids or nucleic acid vectors to magnetic nanoparticles (Figure 4) using physical (e.g., polyelectrolyte mediated), chemical (e.g., covalently linked), and biological (e.g., biotin–streptavidin, antigen–antibody bound) means (Plank *et al*., 2003b).

Moving to MPs significantly improves the transfection rates not only through magnetically forced contact (Mah *et al*., 2002; Scherer *et al*., 2002) (Figure 4), but also by increasing the plasmid concentration (Hughes, Galea-Lauri, Farzaneh and Darling, 2001). Gersting *et al*. (2004) compared the efficiency of magnetofection with that of standard transfection methods and found that the level of transgene expression resulting from magnetofection was 400-fold higher when compared with dendrimer- or poly(ethyleneimine) (PEI)-mediated transfection (polyfection) and 2500-fold higher when compared with lipofectamine-mediated transfection (lipofection) (Hirao *et al*., 2003). *PolyMAG100* (Chemicell) is one of the commercially available MP preparations for high-efficiency nucleic acid delivery in research. It consists of 100-nm-sized magnetic nanoparticles that are mixed with the nucleic acid to be transfected in a one-step procedure. Magnetic transfection with this reagent is rapid and efficient, uses low vector doses and thus less expensive transfection reagents, has higher transfection rates (percentage of cells transfected), and results in increased levels of transgene expression even with short incubation times. Figure 5 shows a typical example of magnetic transfection efficiency in endothelial cells.

Magnetic gene transfection is being studied with great fervor and holds great promise for gene delivery. One advantage over other methods is that an MP does not need

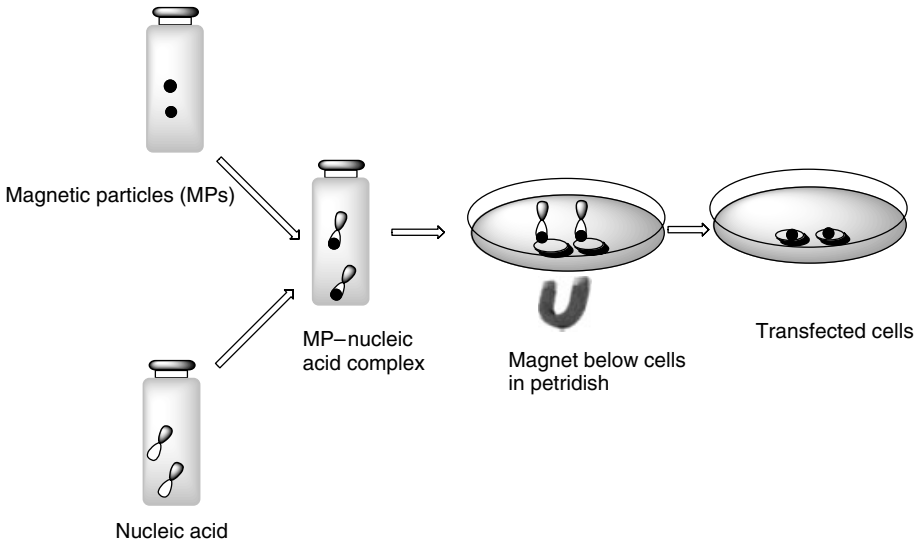

Figure 4. Magnetic transfection uses a magnetic force to guide the gene vectors associated with MPs in close contact with the target cells. Very high vector doses can thus be reached in the cells within a few minutes.

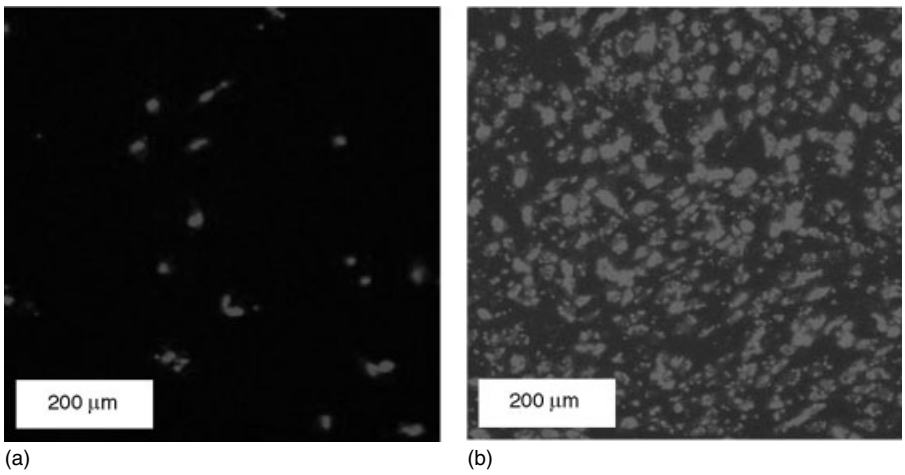

Figure 5. Primary human umbilical vein endothelial cells positioned on the MagnetoFACTOR plate were incubated for 15 min with a Cy3 fluorescence-labeled antisense-oligonucleotide complexed with (a) the transfection reagent Effectene^{TM} (Qiagen) or (b) Effectene^{TM} plus the magnetofection reagent CombiMAG (Chemicell), followed by further cultivation in cell culture medium for 24 h. (Data kindly provided by F. Krötz, Ludwig-Maximilians University, Munich.)

receptors or membrane-bound proteins to enter the cells, which makes it possible to also transfect cells that are not normally susceptible to it (Scherer *et al*., 2002). Some recent examples of magnetic gene transfection are given in Table 3.

3 THERAPEUTIC APPLICATIONS OF MAGNETIC CARRIERS

3.1 Introduction

The application of MPs as a medical means to cure diseases dates back to ancient times when pulverized magnetite was utilized to treat different external as well as internal illnesses (Häfeli, 2006a). It was, however, not until the middle of the last century that this idea enjoyed a renaissance with the proposal to treat cancer using local hyperthermia via the heating of MPs exposed to alternating magnetic fields (Gilchrist *et al*., 1957). Whereas this therapeutic modality is described in more detail in Section 4, the initial sections deal primarily with MPs as carriers of drugs.

The delivery of drugs to specific preidentified targets within the body, maximizing the drug concentration in the target and minimizing toxic effects in nontarget tissue, is known as *targeted drug delivery*. Two known mechanisms of drug delivery with carrier systems include passive and

Table 4. General advantages and disadvantages of the magnetic targeting approach.

Advantages	Disadvantages
• Increased and very high drug concentrations are possible in the target region, organ, and suborgan, as compared to other systemic passive or active targeting approaches • Very low drug concentrations are seen in other body parts • Side effects and toxicity are much reduced or missing • Total amount of drug use can be decreased substantially • Local capillary diffusion of drugs is maximized • Extravasation of MPs into interstitial/extravascular space is possible and has been reported in several investigations • Magnetic targeting supports the EPR effect • MPs can be targeted away from the RES	• Treatment depth (e.g., deep body targeting) is limited owing to rapid magnetic field fall-off • Production of defined, directed magnetic fields and field gradients can be a challenge • Magnet-induced agglomeration of MPs can lead to clogging (embolizations) of small blood vessels

EPR: enhanced permeation and retention.

active targeting. In passive targeting, the final biodistribution of the carriers is determined by the physical properties of the particles. For example, the ability of some colloids to be taken up by the reticuloendothelial system (RES), especially in the liver and the spleen, has made them the vectors of choice for passive drug targeting to these organs. In active targeting, the final biodistribution is determined by the way the receptors on specific cells and organs recognize the carriers. In order to facilitate binding to target cells, the carriers are engineered to contain target-specific ligands, such as antibodies, peptide sequences, sugar moieties, charge, and other specific molecular entities.

In addition to passive and active targeting, a third targeting option is magnetic drug delivery. Magnetic drug delivery is a physical method of delivering nano- or microsized MPs, possibly loaded with a drug, to a target organ or region. Like the other two methods, magnetic drug delivery has both advantages and disadvantages. Table 4 lists them in a comprehensive form. Combinations of all three methods are also possible and are under investigation.

3.2 Mechanism of magnetic drug delivery

Magnetic drug delivery uses external magnets to produce or to orient a magnetic moment in MPs, to guide drug-loaded

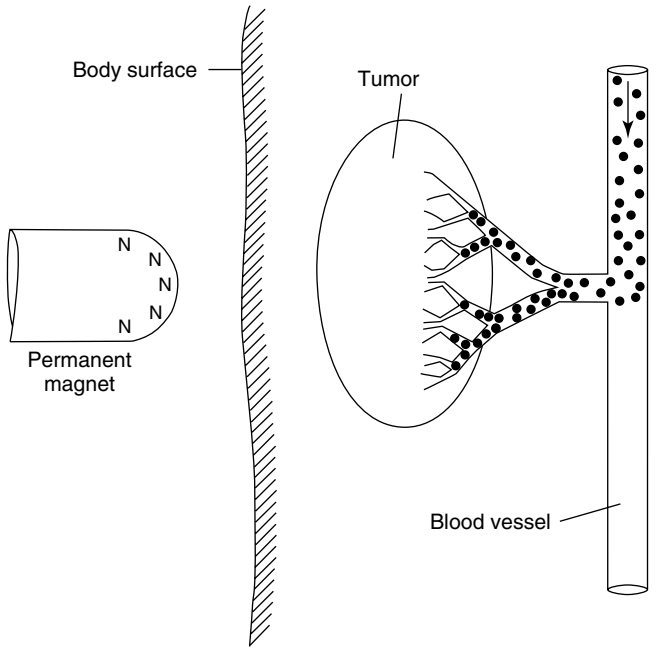

Figure 6. Principle of magnetic drug targeting. The magnetic carriers are administered into the vascular system of a patient and then 'pulled' toward the target organ, in this case a tumor. Blood flow within the capillary bed of the tumor is too weak to overcome the magnetic forces and magnetic particles get trapped within the target organ.

MPs to a target organ, and to hold them there for a controlled treatment period (Figure 6). Treatment can then be accomplished in a number of ways. These include slow release of a chemotherapeutic drug from the MPs, local irradiation from MPs containing radioactive β emitters, and locally induced hyperthermia from MPs in an alternating magnetic field.

In magnetic drug targeting, particle size is the most important parameter with respect to biodistribution, toxicity, magnetic responsiveness, and even drug release kinetics. On the one hand, smaller particles can reach a larger volume of the patient because they can enter smaller blood vessels. Particles with a diameter of less than 50 nm (see Figure 7a and b), especially with the help of magnetic forces, can even pass the fenestrations of capillary walls and, in this way, reach most of the cells in the human body. On the other hand, smaller particles experience a dramatically reduced magnetic force because the magnetic moment in a magnetic field gradient decreases with decreasing particle diameter (see equation (6)). As a result, the magnetic forces induced in superparamagnetic particles (smaller than about 50 nm) are not likely to overcome the Stokes drag and the collisions with red blood cells in the bloodstream (Grief and Richardson, 2005). These theoretical calculations have not been supported in practice. In particular, experimental studies have provided evidence that superparamagnetic particles in the bloodstream can be concentrated or prevented from clearance by magnetic forces. This seeming contradiction might be explained by an agglomeration tendency that MPs experience in a magnetic field with magnetic moments much larger than the ones of isolated units (see equation (6)). This phenomenon is illustrated by the clusters in Figure 7(c), which may disintegrate as soon as the field is switched off and can then pass through the narrow blood vessels of the vascular system.

The earliest experiments utilizing magnetic forces on MPs were carried out with particle sizes well above the superparamagnetic range. One of the earliest studies concerned a magnetic selection procedure of Kupffer cells (Rous and Beard, 1934). In this investigation, particles of milled γ-Fe_2O_3 (diameter $\leqslant 1\,\mu m$) were taken up by the Kupffer cells and could then be manipulated with a pair of horseshoe magnets.

The most common method of producing a magnetic field and field gradient capable of attracting MPs is through the use of permanent magnets or electromagnets. The strongest permanent magnets available today are rare-earth magnets made from NdFeB, a material that has only been known since 1983 (Kirchmayr, 1996). Small-sized NdFeB button magnets of the best grade with sizes of 1.0 cm diameter and 0.5 cm thickness are able to stop MPs up to 2.5 cm from their surface, although this is always dependent on the MPs as well. It has been reported that, using a larger, 2.5-cm-wide and 7.5-cm-thick NdFeB magnet, magnetic iron particles coated with carbon could be stopped within defined liver regions up to 14 cm away (Johnson *et al*., 2002). The strongest electromagnets are superconducting magnets that can be bought in easy-to-use electrically cooled configurations and produce 12 or more teslas from a barrel-sized, laboratory-compatible instrument (JASTEC: Japan Superconductor Technology) or 2.2 T from a tonguelike desktop system (Takeda *et al*., 2007) (Figure 8). A superconducting system from Stereotaxis Inc, St. Louis, MO, USA was approved by the U.S. FDA in 2003 and is now available to direct catheters with a small magnetic tip to otherwise difficult or even impossible-to-reach areas in the brain or heart. It is easy to imagine how useful such systems would be for drug delivery, (micro)surgical procedures, electrical interventions, or ablation catheter procedures. More recently, Stereotaxis developed a permanent magnet system termed *Niobe*^{TM} for the same applications (Ernst *et al*., 2004). Two outer permanent magnets align a third small magnet integrated in the tip of a mapping and ablation catheter along its magnetic field lines. By changing the orientation of the outer magnets, the orientation of the magnetic field lines also change, thereby allowing navigation of the ablation catheter. In combination with an automated advancer system, this novel technique is the first to allow for complete remote catheter ablation.

(b) Monosized oleic acid–coated lipophilic magnetite nanoparticles prepared by the iron pentacarbonyl decomposition method (Hyeon *et al*., 2001). (c) Clusters of iron oxide particles prepared by a wet chemical precipitation procedure and subsequent coating done with carboxymethyldextran. (Courtesy C. Oestreich, Institute of Ceramic Materials, Freiberg University of Mining and Technology.) (d) Magnetic biodegradable composite poly(lactide-*co*-glycolide) microspheres incorporating the magnetite particles shown in (a) (Zhao, Gagnon and Häfeli, 2007).

Two other methods can produce strong, local, and directed magnetic fields that can be used to accumulate MPs in a target organ. The first method consists in placing small magnets internally as unipolar probes next to the target organ, such as in a diseased intracerebral artery (Alksne, Fingerhut and Rand, 1966). The second method is to implant a ferromagnetic object, such as a seed, stent, wire, or needle, in the target area and then to place the patient in a strong external magnetic field (Iacob, Rotariu, Strachan and Häfeli, 2004). Magnetized magnetic meshes were able to accumulate large amounts of 2-µm or 370-nm particles, even at $5\,\mathrm{cm\,s^{-1}}$ flow rates, while nonmagnetized control wires attracted no particles at all (Yellen *et al*., 2005). Interestingly, the magnetic fields do not need to exceed 0.1 T according to the authors of this study. One disadvantage of both procedures, however, is their invasiveness, since a ferromagnetic element or magnet must first be placed inside the patient.

Although many magnetic drug delivery investigations were reported (see the following text), not much quantitative information is known about the targeting efficiency of the MPs. The reason for this is that most people are interested in the success of an attempted therapy and therefore generally are more interested in the biodistribution of the delivered drug than the carrier (MP) distribution. One of the few reported targeting efficiency studies used the old technique of radiolabeled MPs in combination with γ camera or single photon emission computed tomography (SPECT) imaging. A preliminary *in vivo* investigation tested the binding stability and magnetic targeting ability of ^{90}Y-labeled iron–carbon particles of sizes 1–5 µm (Yu *et al*., 2002). Eleven mCi of ^{90}Y-MP was administered intra-arterially into the hepatic artery of a swine. Blood samples taken following the administration showed that less than 3% of the total injected activity had escaped into the blood supply 30 min after the administration. A γ-camera image taken 24 h after the injection using the Bremsstrahlung emission associated with ^{90}Y qualitatively showed a single source of emission in the region of the liver where the ^{90}Y-MP had been targeted with a strong permanent magnet. Even 72 h after the injection, more than 85% of the injected activity was still present at the target location (unpublished data). In addition to these radioactive measurements, and histological

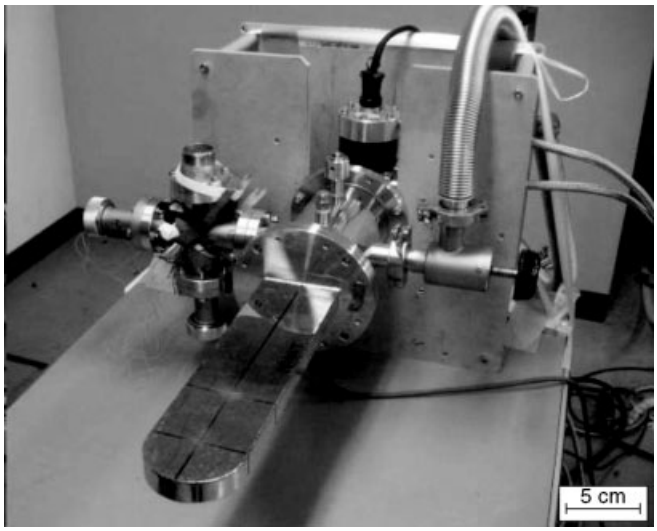

Figure 8. Tonguelike magnet system producing fields of 2.2 T.

methods and magnetic resonance imaging (MRI) for the detection of the MPs, which are at best semiquantitative, some efforts have been made in recent years to develop new and improved tools for quantitative *in vivo* measurements. These methods include magnetorelaxometric measurements (Eberbeck, Wiekhorst, Steinhoff and Trahms, 2006) and X-ray or neutron-spectroscopy measurements (Brunke *et al*., 2006). Both techniques are very promising, but have, to this point, been applied only to feasibility studies and not to complete magnetic targeting studies.

More studies are still needed to give information about the distribution of MPs *in vivo*. It would be especially useful if it was possible to simulate and predict magnetic targeting efficiency, once the MPs, magnet, and blood flow parameters are known. What is clear, however, is that there will always be some loss of the injected MPs into the blood circulation as compared to local application of a drug where there is none. The distribution of the drug-carrying MPs throughout the target organ, however, may be much better. Also, it has been shown that intra-arterial application of MPs is able to deliver much more of the drug to the target tissue than intravenous injection. Intra-arterial injection prevents the MPs from being filtered immediately by fixed macrophages in the liver and lungs.

3.3 Magnetic drug delivery systems (microspheres, nanospheres, liposomes)

The most commonly used magnetic drug delivery systems include magnetic microspheres (see Figure 7d), nanospheres, and liposomes filled with drugs or containing drugs bound to their surface. The MPs contained in these drug delivery systems are often grouped according to size. At the lower end, we have the ferrofluids, which are colloidal iron oxide solutions. Encapsulated MPs in the range of 10–500 nm are usually called *magnetic nanospheres* and any MPs of just below 1–100 µm are magnetic microspheres. Magnetic liposomes, which are phospholipid vesicles incorporating a magnetic compound, are also included when speaking about magnetic carriers. The materials for the preparation of MPs include both nonbiodegradable materials, such as ethyl cellulose and the synthetic polymers polymethylmethacrylates (PMMAs) and polystyrene, and biodegradable materials, such as albumin, phospholipids, starch, poly(lactic acid), dextran, polyalkylcyanoacrylates, and polyethylene imines (Schütt *et al*., 1997).

The amount and nature of the magnetic component incorporated into the MPs is an important material consideration. Today, materials with higher magnetic susceptibility and magnetization compared to the aforementioned iron oxides (Gupta and Gupta, 2005) are being investigated and developed to increase the magnetic response of MPs to an applied magnetic field further. Riffle at Virginia Tech in the United States and Bönnemann at the Max Planck Institute in Germany, for example, are independently and with different methods spearheading the development of oxidation-proof nanocobalt particles (Bönnemann *et al*., 2003; Riffle *et al.,* 2003). Similarly, passivated nanoiron is being developed by Materials Modifications Inc. in the United States (Williams and Kotha, 2003). The alloy Fe_3Co has also recently been prepared by Hütten at the University of Bielefeld in Germany in the form of highly uniform nanoparticles, with excellent size control between 1 and 11 nm (Hütten *et al*., 2005).

Smaller nanosized MPs containing up to a 100% of the magnetic material can be made with methods such as the decomposition of iron pentacarbonyl precursors. Typically, however, the MPs must be protected from agglomeration, oxidation, and further reactions, and coating materials such as detergents and longer-chain fatty acids are thus introduced or are already present during the synthesis.

Importantly, magnetic drug delivery systems follow the same rules as other pharmaceutical drug delivery devices. For example, magnetically delivering a chemotherapeutic drug to a tumor alone does not eradicate it. The drug must first be released from the particles in order to be efficacious. Furthermore, the particles have to follow the same strict rules regarding sterility, nonimmunogenicity, nontoxicity, and biocompatibility as any other invasive drug delivery systems.

MPs consisting of iron, nickel, or cobalt can be cytotoxic owing to the production of positively charged metal ions. Magnetite, maghemite, and superparamagnetic iron oxide nanoparticles coated and stabilized with hydrophilic polymers, however, have been found to be quite thermodynamically stable under physiological conditions and

not to exert obvious toxic effects. Pharmacokinetic studies of small magnetite nanoparticles destined for MRI (Weissleder *et al*., 1989) have shown that the magnetite nanoparticles are taken up by the cells of the RES and are transported intracellularly to lysosomes, where they slowly oxidize at low pH and are then recycled by the body (Lawaczeck *et al*., 1997). Within 20–40 days, up to 60% of the iron is recovered in red blood cells, as determined using radiolabeled ^{59}Fe. On the basis of these studies, magnetic nanoparticles have been approved as MRI contrast agents.

Recent discussions have centered on toxic effects of (magnetic) nanoparticles in humans after inhalation. Rodent models have shown that the potential problematic effects of such particles include the induction of asthma, inflammation, and even cancer (Nel, Xia, Madler and Li, 2006). Some of these effects might be due the fact that particles smaller than 100 nm are not exhaled, but are almost completely retained in the alveoli (Kreyling, Semmler and Möller, 2006). For this reason, acute effects can rapidly turn into chronic effects. Although many effects seen in rodents do not develop in humans, it is still prudent to carefully monitor all health effects from nanoparticles.

3.4 Magnetic drug delivery systems for chemotherapy

Many tumors, especially those of pancreas, liver, lung, stomach, brain, and head and neck, are untreatable because of inaccessibility, inoperability, lymph node infiltration, and the unacceptably high risk of toxicity to nearby organs. Magnetic drug delivery is able to concentrate the drugs in a tumor once it has been outlined by imaging methods such as MRI and computerized, single photon emission, and positron emission tomography. For magnetic drug delivery, the tumor must be accessible through the arterial system and have a good blood supply. The magnetic delivery method promises longer survival, fewer side effects, and shorter and less toxic treatments.

The era of drug-filled microspheres started with the use of albumin MPs filled with the anticancer drug doxorubicin (adriamycin) (Widder, Senyei and Ranney, 1979). As is typical for many other MPs, maximum magnetite contents of up to 50 wt% were reported. The era of albumin particles was followed by that of MPs made from many different matrix materials incorporating or adsorbing just about any chemotherapeutic drugs imaginable. The drugs tested *in vitro* or *in vivo* included mitomycin C (Kato *et al*., 1980, 1981), camptothecin, ara-C, tumor necrosis factor (TNF-α), paclitaxel, mitoxanthrone, 5-fluorouracil (5-FU), and dactinomycin, just to name a few (Häfeli, 2006b).

The application of drug-filled MPs by intravenous injection is not ideal, because it results in substantial dilution of MPs throughout the body and in the successive MP uptake by the RES, particularly in the spleen, liver, and lungs. As a result, typically only a threefold increase in MP concentration is reached in the target location with the attached magnet compared to the contralateral side of the body with no magnet as was shown, for example, with dactinomycin-filled magnetic nanoparticles (Ibrahim, Couvreur, Roland and Speiser, 1983). Approximately twofold enhancement between the effect of activated and non-activated electromagnets was seen when another group targeted gliomas in rats (Pulfer and Gallo, 1998; Pulfer, Ciccotto and Gallo, 1999). Even the intravenous injection of MPs very close to the tumor only marginally increases MP uptake, as shown in one of the first well-controlled patient trials with 14 patients using the drug 4′-epidoxorubicin adsorbed onto MPs with an anhydroglucose coating (Lübbe *et al*., 1996; Lübbe, Alexiou and Bergemann, 2001). Most of the drug was released over 30 min after injection, and the system was shown to be nontoxic. However, it was also not very effective, probably owing to the small particle size (about 100 nm) and the not so strong magnets used.

A better way to inject drug-filled MPs and achieve more effective magnetic targeting is intra-arterial injection proximal to the tumor. The first animal trials using this injection technique involved the delivery of MPs to a distinct area of a rat's tail (Widder, Morris, Howard and Senyei, 1981; Widder *et al*., 1983). It resulted in the delivery of 200 times more drug to the target area compared to what could be achieved through intravenous application of the same amount of free drug (Senyei, Reich, Gonczy and Widder, 1981). The company FeRx further improved on this method by employing MPs made of carbon-coated pure iron with a diameter of 1 to 5 µm. Their MPs are the most magnetic particles ever used *in vivo*. The drug doxorubicin was adsorbed to the carbon coating and then slowly released at the tumor site, as seen in a clinical phase I trial performed between 2001 and 2004 in patients with primary liver cancer (hepatocellular carcinoma or HCC) (Goodwin, 2000; Johnson *et al*., 2002). X-ray and magnetic resonance images such as those in Figure 9 confirmed excellent particle retention in the liver tumors upon employing an 8-cm-long and 2.5-cm-diameter NdFeB magnet.

Only one other clinical trial has been described in the literature. This trial used ferrocarbon particles of about 100 nm diameter that within minutes adsorbed about 2 wt% of the anticancer drug carminomycine (Kuznetsov *et al*., 1997). The authors report that more than a hundred patients have received this treatment in different Russian hospitals since 1990. Unfortunately, the clinical results were not reported in

Figure 9. Postdosing angiogram (a) and MRI (b) after magnetic targeting with doxorubicin-loaded MTC by FeRx Inc.

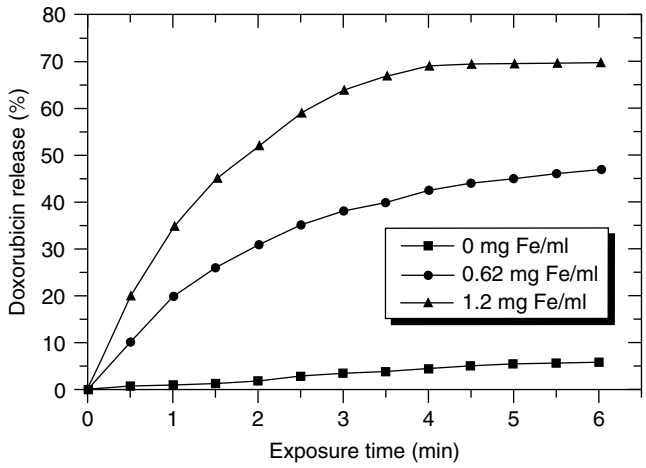

Figure 10. Dependence of doxorubicin release from magnetoliposomes with various concentrations of ferrocolloid. The results are mean values from four independent measurements. (Reprinted with permission M. Babincova *et al*., copyright 2002, Elsevier.)

a very detailed manner and the definitive treatment outcome is still unclear.

To date magnetic liposomes sized like nanoparticles have yet to be used clinically. There are, however, ongoing animal experiments using magnetoliposomes that incorporate paclitaxel (Zhang *et al*., 2005). Although the incorporation of large amounts of magnetite into liposomes is more difficult than into nanoparticles, up to 25 wt% of magnetite has been recently enclosed into dipalmitoylphosphatidylcholine liposomes that also contained crystal violet as a model drug (Koneracka *et al*., 2005). Another group made similar magnetoliposomes, without any drugs, to be used for hyperthermia treatment (Gonzales and Krishnan, 2005).

Most drug release from MPs occurs passively, by desorption from and diffusion out of the MP matrix. The main driving forces are pH, osmolarity (of the blood), and concentration differences between the MPs and the blood/tissue. One group investigated the active release of chemotherapeutic drugs upon local heating using an alternating current (AC) magnetic field with a frequency of $\sim$1 MHz (Babincova *et al*., 2002). Their doxorubicin magnetoliposomes made with 8-nm magnetic oxide particles released the drug upon irradiation. Depending on the ferrocolloid concentration in the magnetoliposomes and the length of the exposure to the alternating magnetic field, significant amounts of doxorubicin were released (see Figure 10). The release of drug seemed to be owing to local heating of the liposomal membrane, which has a phase transition temperature of 42 $^{\circ}$C. Similar results have been reported *in vivo* (Viroonchatapan *et al*., 1998). In particular, upon placement in an alternating electromagnetic field, the tumor temperature could be kept at 42 $^{\circ}$C despite blood flow and the entrapped 5-FU was almost completely released within the next hour.

Overall, as already described in an excellent review (Gupta and Hung, 1994), different chemotherapeutic drugs have already been combined with MPs made from different matrices, and many new ones will likely become available in the future. Magnetic targeting of solid animal tumors has been shown to enhance the tumor drug concentration two to several hundred times. It is hoped that the use of more magnetic and more uniform MPs will further extend the indication of such particles to lung, pancreas, and breast cancer and move them into clinical trials.

3.5 Magnetic drug delivery systems for radiotherapy

The biggest challenge in the use of radioactive isotopes for the killing of cancer cells is the delivery of a sufficiently high radiation dose without harming the surrounding tissue. MPs that incorporate radioisotopes either in the matrix or

bound to the surface can be used to address this challenge (Häfeli, 2001a). The advantage of this method over the external beam therapy typically used in radiation oncology departments is that the local dose can be very high, resulting in improved tumor cell eradication, and that it can be given in one application rather than in the standard six weeks of daily radiotherapy. Different radioisotopes can be used to treat different treatment ranges (Häfeli, 2001b). The β emitter ^{90}Y, for example, will irradiate up to a range of 12 mm in tissue while ^{131}I will irradiate only up to 2.4 mm. Unlike chemotherapeutic drugs, the radioactivity is not released. Instead, the radioactive MPs are delivered to and held at the target site and from there irradiate the area within the specific treatment range of the isotope. Once the MPs are no longer radioactive, they ideally biodegrade, as is the case with poly(lactic acid) or gelatin microspheres.

Initial experiments in mice have shown that intraperitoneally injected radioactive poly(lactic acid) based MPs could be concentrated near a subcutaneous tumor in the belly area above which a small magnet had been attached (Häfeli *et al*., 1997). The dose-dependent irradiation from the β emitter ^{90}Y-containing MPs resulted in the complete disappearance of more than half of the tumors. To improve the magnetic targeting efficiency, magnetic targeted carriers (MTCs; from FeRx), which are more magnetically responsive iron–carbon particles, have been recently radiolabeled with isotopes such as ^{188}Re (Häfeli, Pauer, Failing and Tapolsky, 2001), ^{111}In (Häfeli, 2004), ^{90}Y, and ^{125}I (Yu *et al*., 2002), but have yet to be tested.

Enhancement of tumor cell kill without harming the patient can also be achieved by combining drug delivery with internally given radioactive isotopes or external radiation. Gelatin MPs with metronidazole, an efficient sensitizer of hypoxic mammalian cells to the effects of radiation, have been prepared and shown to release the drug in a defined way (Leucuta, 1986). Such a slow drug release over a few hours sensitizes even normally radioresistant cancer cells, lowers the overall radiation dose necessary for successful treatment, and prevents side effects.

Internal radiotherapy may soon be feasible not only with β and γ emitters, but also with short-range auger emitters given that tat peptides have recently been shown to penetrate cell membranes and shuttle MPs inside cells (Lewin *et al*., 2000). For this purpose, MPs must be able to penetrate the cell surface efficiently. Tat peptide, a positively charged peptide, has been shown to induce the internalization of therapeutic agents such as radioactively complexed ^{99m}Tc and ^{188}Re (Polyakov *et al*., 2000) and superparamagnetic iron oxides known as *tat-CLIO* (tat-cross-linked iron oxides) (Wunderbaldinger, Josephson and Weissleder, 2002). Weissleder's group, who developed the tat-CLIO, was able to accumulate the tat-CLIO intracellularly in a highly specific manner (Wunderbaldinger, Josephson and Weissleder, 2002).

Overall, the advantages of local radiation treatment using magnetically delivered MPs are similar to those of magnetically delivered chemotherapy. In addition, there is no resistance formation, the doses can be planned in advance using treatment software, the treatment range and therefore also the range of expected toxicity is well known, and the targeting success can be imaged and possibly altered with commonly used nuclear medicine techniques.

3.6 Other magnetic drug targeting applications

Magnetic drug delivery can be used to deliver not only chemotherapeutic, radioactive, peptide, and hyperthermia drugs, but also antiinfective, blood-clot-dissolving, anti-inflammatory, antiarthritic, photodynamic therapy, and paralysis-inducing drugs. The magnetic delivery of genes, another successful example, has already been reviewed in Section 2 of this chapter.

One of the most successful examples in this group of drug targeting applications is the preparation of magnetite coated with the blood-clot-dissolving drug urokinase (Inada *et al*., 1987) or streptokinase (Torchilin *et al*., 1988), which was used to dissolve surgically induced thrombi in the carotid arteries of a dog (Torchilin *et al*., 1988). The control side received no special treatment while the experimental side had a magnet attached above it. One hour after the procedure, streptokinase bound to the surface of MPs was injected into the animal at a dose 10 times lower than the normal, non-MP-bound streptokinase dose. The side without the magnet completely occluded within 4 h, while the side with the magnet returned to initial blood flow after about 30 min and appeared completely open at histological examination (Figure 11).

The magnetic drug delivery potential is enormous, especially for highly potent – and thus also potentially very toxic – drugs. Many organs and systems in the body can be targeted. For most applications, it is obvious that systemic effects can be minimized or completely eliminated while the sought-after effect is enhanced. A good example is the magnetic delivery of the curare-like drug diadonium to the limbs of cats (Kharkevich, Alyautdin and Filippov, 1989), during which their limbs became paralyzed with only slight respiratory depression.

3.7 Magnetic particles that exert therapeutic effects by embolization

Under the influence of a magnetic field, MPs align in chains and eventually agglomerate. Depending on particle size and shape, this can lead to embolization (clogging) of the blood

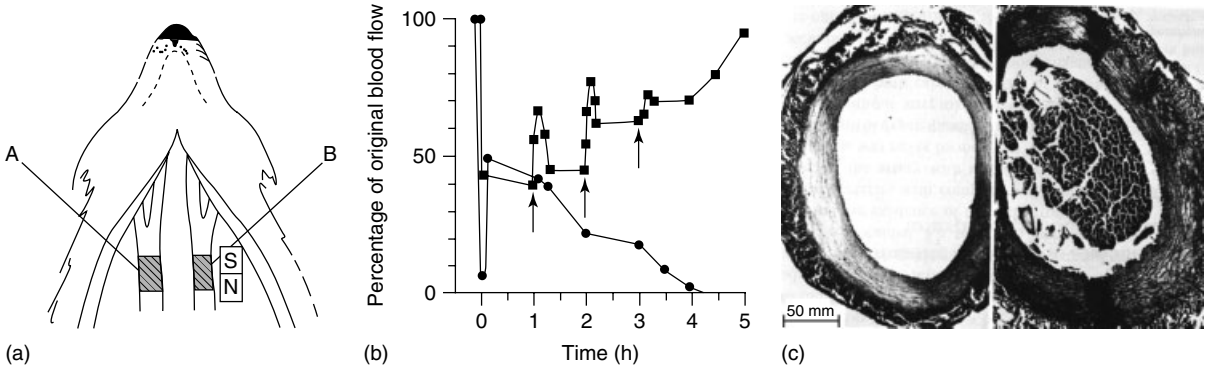

Figure 11. Magnetically driven thrombolysis with streptokinase-coated magnetite particles is possible by placing a magnet close to the area of the vascular flap in the carotid artery (a). Blood flow resumed in the targeted artery within 4 h, while the nontargeted carotid artery was completely clogged (b and c) (Torchilin *et al*., 1988).

vessels and especially of the small capillaries 7–10 µm in diameter. This accumulation of particles alone can be used to starve the target tissue of oxygen, producing hypoxia and inducing necrosis. The first embolization applications in the 1960s and 1970s included the occlusion of cerebral and renal aneurysms (Alksne, Fingerhut and Rand, 1966; Hilal, Michelsen, Driller and Leonard, 1974; Roth, 1969) and were followed by the occlusion of the feeding vessels of carcinomas. Rand *et al*. described the technique of injecting a mixture of liquid silicone and microspheres of carbonyl iron into the intraparenchymal vascular bed followed by intravascular vulcanization without heat transfer from the outside (Mosso and Rand, 1973). The ferrosilicone was retained in the required position by a strong magnetic field generated by a superconducting coil. Another successful example of cancer embolization therapy is the magnetic accumulation of a so-called 10–30-µm-diameter iron sponge in viscous solution in rabbit tumors (Sako *et al*., 1982).

To maximize efficacy, embolization therapy is generally used in combination with a second treatment approach such as radiotherapy, chemotherapy, or hyperthermia. This was shown in the 1970s when Rand *et al*. continued their above-described investigations (Snyder and Rand, 1975) with needle-shaped γ-Fe_2O_3 particles and introduced additional radiofrequency (RF) heating to more than 55 °C on the renal surface of rabbits (Rand, Snyder, Elliott and Snow, 1976; Rand, Snow, Elliott and Snyder, 1981; Rand, Snow and Brown, 1982). In this way, total coagulation necrosis of a renal cancer model was achieved, possibly more as a result of the hyperthermic treatment than because of the occlusion. The treated animals survived the procedures and the exposure to both magnetic fields and ferromagnetic compounds without evidence of ill effects. The combination of embolization and hyperthermia and its medical use is still being pursued (Mitsumori *et al*., 1994, 1996; Moroz, Jones and Gray, 2002).

3.8 Summary

Owing to space constraints, this section about the therapeutic applications of magnetic carriers could only cover a limited sampling of the literature. The interested reader is directed to a much more complete and in-depth review of the field (Häfeli, 2006b). Magnetic drug delivery covers a wide area of applications, with a lot of research currently being performed worldwide. None of the applications, with the exception of several magnetic hyperthermia trials (Gneveckow *et al*., 2005), have reached the clinical trial stage yet. Preclinical animal research, however, is being performed in the areas of magnetic gene delivery, tumor targeting, rheumatoid arthritis treatment, and blood detoxification. This ongoing work, in combination with enormous advances in the field of magnetic nanoparticle synthesis and analytical characterization methods, is expected to lead to new and successful clinical uses of magnetic carriers.

4 MAGNETIC PARTICLE HYPERTHERMIA

4.1 Principles of magnetic particle hyperthermia

The application of heat as a traditional healing method has been known for a long time. Soon after the discovery that the metabolism of tumor cells is more susceptible to high temperatures than that of normal cells, views on how hyperthermia could be used for tumor therapy emerged. Besides whole body hyperthermia where the systemic temperature has to be carefully controlled to, for example, 41.8 °C (Robins *et al*., 1997), there is a spectrum of ways of local intracorporal heat generation using focused microwave radiation, capacitive or inductive coupling of RF fields, implanted electrodes, focused ultrasound, or lasers. For the clinical state of the

art of hyperthermia in oncology, see the review given by Falk and Issels (2001). As an alternative therapy, magnetic particle hyperthermia (MPH) is a method where MPs are deposited in tumor tissue with subsequent heating by means of an external alternating magnetic field. For biomedical applications, the vast number of known magnetic materials is strongly restricted by the demand of biocompatibility (e.g., nontoxicity, sufficient chemical stability in bioenvironment, appropriate circulation time in blood, and finally, harmless biodegradability). Although attempts to use metallic iron particles, spinel ferrites, as well as special magnetic alloys for MPH have been made, the majority of investigations is focused on the magnetic iron oxides Fe_3O_4 (magnetite) and γ-Fe_2O_3 (maghemite). These materials are well tolerated by the human body. At present, a variety of approved types of magnetic iron oxide particles for specific contrast enhancement in nuclear MRI are available on the market (cf. Section 5). However, these relatively small, superparamagnetic particles are not well suited for MPH owing to insufficient heating power. Besides localized heat generation, the application of magnetic nanoparticles offers the possibility of a self-limitation of the temperature enhancement by using a magnetic material with suitable Curie temperature (e. g., Rand, Snow, Elliott, Haskins, 1985).

Since there is no strict borderline between tolerable and mortal temperatures, both on the systemic as well as the cellular level, there is a range of temperature elevation considered to be therapeutically useful. With increasing temperature, different mechanisms of cell damaging occur and accordingly two therapy modalities were conceived: Treatments at temperatures of 42–45 °C for up to few hours – commonly denoted as *hyperthermia* – need to be combined with other assisting toxic agents (mostly irradiation or chemotherapy) for reliable damage of tumor cells. In contrast, thermoablation aims at the thermal killing of all tumor cells by applying temperatures in excess of at least 50 °C in the tumor region for exposure times of at least a few minutes. Though these short treatment times and reliable tumor damage seem advantageous, there is the risk of critical systemic side effects such as a shock syndrome due to sudden release of large amounts of necrotic tumor material and major inflammatory response (Moroz, Jones and Gray, 2002).

In addition to the therapeutically useful tumor heating effect of MPs, the alternating magnetic field can also cause an unwanted nonselective heating of healthy tissue due to the generation of eddy currents. According to the induction law, the latter is proportional to the square of $(H{\cdot}f{\cdot}D)$, where H is field amplitude, f is the frequency, and D is the induced current loop diameter. The induction heating of iron oxide nanoparticles is practically negligible, but with the specific electrical conductivity of tissue ($0.6\,\Omega^{-1}\,m^{-1}$) the critical current density for irreversible cell damaging (in the order of $20\,mA\,cm^{-2}$, e.g., Siegenthaler, 1994) may be reached in macroscopic loops of the patient's body. Experimentally, Brezovich (1988) found for a loop diameter of about 30 cm that a *test person had a sensation of warmth, but was able to withstand the treatment for more than one hour without major discomfort* if the product $H{\cdot}f$ was below $4.85 \times 10^8\,A\,m^{-1}\,s^{-1}$. Depending on the diameter of the exposed body region and the seriousness of the illness, this critical product may be exceeded. For instance, for the first commercially developed equipment for treatment of human patients, a frequency of 100 kHz and a field amplitude up to $18\,kA\,m^{-1}$ was reported (Gneveckow *et al*., 2004).

4.2 Loss processes in magnetic particle systems

The generation of heat by magnetic substances in an external alternating magnetic field may be caused by several physical loss processes. The main mechanism of heat production with magnetic nanoparticles is associated with hysteresis occurring during reversal of the magnetization. With decreasing particle size, the energy barriers for magnetization reversal decrease and hysteresis is increasingly influenced by thermal fluctuations. In addition to hysteresis, in fluid suspensions of MPs viscous losses may arise owing to particle rotations induced by the external alternating magnetic field. Particles can be immobilized by adhesion, for example, to cell membranes and tissue surfaces, or by uptake by fibroblasts. Free rotations are thus suppressed, while the still possible oscillations lead to complex loss contributions. In comparison to magnetic losses, eddy current induced heating of small MPs is negligibly small. The often used term *inductive heating* in biomedical literature for MP heating is thus misleading.

4.2.1 Hysteresis losses

Hysteresis losses are represented in a well-known manner by the area of hysteresis loops (e.g., Bertotti, 1998). Below a critical particle size, domain walls do not exist and the simplest process of magnetization reversal is the uniform mode (Stoner and Wohlfarth, 1948). In this case, for an ensemble of randomly oriented, noninteracting, ellipsoidal, uniaxial single-domain particles, hysteresis loss energy density is given by twice the anisotropy energy density K. It may be enhanced by a factor of 4 if particle axes are aligned with the external field. Besides the simple model of uniform magnetization reversal, there are different theoretical models dealing with more complicated magnetization distributions (e.g., curling, buckling, fanning; see, e.g., Aharoni, 1996; Hubert and Schäfer, 1998), which are described in terms of the micromagnetic theory (Kronmüller and Fähnle, 2003). For cubic magnetite crystals, Butler and Banerjee (1975)

derived from theoretical estimations an upper limit of about 80 nm for the single-domain size range, which increases considerably with tetragonal particle elongation. The same order of magnitude is obtained from micromagnetic calculations (Fabian *et al*., 1996) considering more sophisticated magnetization patterns like the so-called flower and vortex states. For further recent theoretical and experimental results from literature, see **Magnetization Configurations and Reversal in Small Magnetic Elements, Volume 2**. Experimentally, for magnetite crystals in the mean diameter range above about 50 nm, the coercivity and remanence was found to decrease with increasing particle size d according to an empirically well established $d^{-0.6}$ power law (Heider, Dunlop and Sugiura, 1987), which implies a decrease of hysteresis losses in the multidomain size range. A strong decrease in coercivity with increasing particle size in the range 30–100 nm measured for maghemite was interpreted by Eagle and Mallinson (1967) as an indication for a nonuniform reversal mode. Since, on the other hand, magnetite particles with size below about 25 nm become superparamagnetic (see the following text), a maximum of hysteresis losses may be expected for single-domain iron oxide particles with a mean diameter of close to 30 nm.

However, for utilization of the full hysteresis loop for heat generation, alternating field amplitudes well above the coercivity field are needed, which imposes strong technical demands on the magnetic field generator. For instance, with a 15 kW 400 kHz AC generator in a coil for treatment of breast cancer (Hilger, Hergt and Kaiser, 2005) using field amplitudes of not more than 10 kA m^{-1}, one is restricted to minor loops. The large coercivities of acicular maghemite particles (typically 50 kA m^{-1}) used for magnetic recording are rarely of value for medical heating problems. In general, for single-domain particles with nearly rectangular hysteresis loop, one may expect only minor values of hysteresis losses for field amplitudes below the effective anisotropy field. By comparing different types of MPs with respect to their suitability for hyperthermia (Hergt *et al*., 1998), it was shown that hysteresis losses of different types of magnetite particles may differ by orders of magnitude in the range 1–10 kA m^{-1} of field amplitudes owing to differences of particle size, shape, and microstructure. As an illustration, Figure 12 shows the dependence of hysteresis loss on field amplitude for different classes of magnetic iron oxide particles (e.g., a typical sample m6.3 prepared by chemical precipitation, a sample BASF1 of acicular particles for recording applications, and magnetosomes synthesized by bacteria) in comparison with the theoretical curve for a Stoner–Wohlfarth (SW) system. Though the mean particle diameters of about 30 nm – as determined by transmission electron microscopy – for all samples are in the single-domain range, there are considerable deviations between the experimental results of different particle types

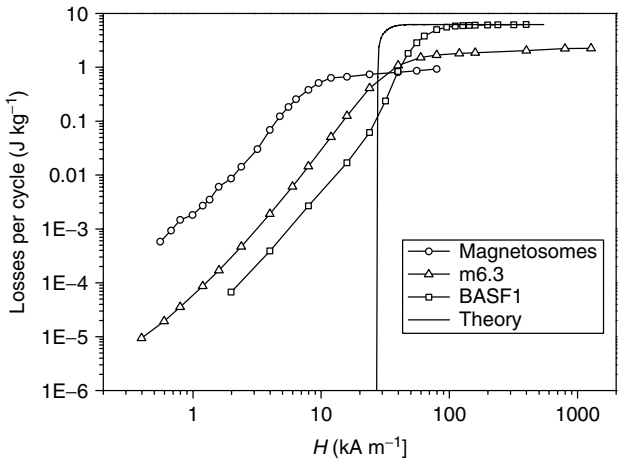

Figure 12. Dependence of hysteresis losses per cycle on field amplitude for different types of magnetic nanoparticles (a chemically precipitated sample m6.3 (Dutz *et al*., 2007), bacterial magnetosomes (Hergt *et al*., 2005), and a sample of commercial magnetic recording particles BASF1) in comparison with the theoretical curve for randomly oriented Stoner–Wohlfarth (SW) particles. The SW coercivity is adjusted to that of BASF1. (Reprinted with permission Hergt R. Hiergeist *et al*., copyright 2005, Elsevier.)

and SW theory. In particular, experimental results for low field amplitudes generally show a third-order power law for the amplitude dependence of hysteresis losses, which is known as the so-called *Rayleigh law* for multidomain objects if the motion of domain walls is hindered by pinning centers (e.g., Kronmüller and Fähnle, 2003). Many magnetite and maghemite powders in a broad size range of about 10 nm up to 100 nm were investigated (Dutz *et al*., 2007) but in no case the high specific losses at low amplitudes of bacterial iron oxide magnetosomes shown in Figure 12 were met.

4.2.2 Thermal relaxation effects

With decreasing particle volume V, the energy barriers impeding the reversal of the magnetic moments decrease and the probability of spontaneous jumps of the magnetization due to thermal activation processes increases. As a consequence, loss energy per cycle derived from hysteresis loops becomes smaller than calorimetrically measured loss data if the characteristic time of measurement τ_m is larger than the relaxation time of the particle system. For the simple case of two stable states separated by a barrier that is proportional to the anisotropy energy KV, the so-called Neél relaxation time of the system is determined by the ratio of KV to the thermal energy kT (Néel, 1949):

$$\tau_N = \tau_o \exp[KV/(kT)] \quad (\tau_o \sim 10^{-9}\text{s}) \tag{7}$$

A critical particle volume V_c may be defined by $\tau_N(V_c) = \tau_m$. For a measuring frequency of 300 kHz and a magnetic anisotropy energy density of 10^4 J m^{-3} (for magnetite

particles of ellipsoidal shape with an aspect ratio of 1.4), the critical diameter is about 20 nm. Below the critical size, the relaxation effects cause remanence, coercivity as well as hysteresis losses to vanish. This transition to the so-called superparamagnetism (for details see **Superparamagnetic Particles, Volume 4**) occurs in a narrow size range. The frequency dependence of the relaxation of the particle system may be well investigated by measuring spectra of the complex susceptibility, the imaginary part $\chi''(f)$ of which is related to the loss power density P according to (e.g., Landau and Lifshitz, 1960)

$$P(f, H) = \mu_o \pi \chi''(f) H^2 f \tag{8}$$

where $\chi''(f)$ may commonly be described by the well-known expression (see e.g., Delaunay, Neveu, Noyel and Monin, 1995)

$$\chi''(f) = \chi_o \phi/(1+\phi^2), \quad \phi = f\tau_N,$$
$$\chi_o = \mu_o M_S^2 V/(kT) (M_S : \text{saturation magnetization}) \tag{9}$$

According to these equations, at low frequencies ($\phi \ll 1$), that is, in the superparamagnetic regime, losses increase with the square of frequency while for $\phi \gg 1$ losses approach a frequency-independent saturation value $P = \mu_o \pi H^2 (\chi_o/\tau)$. At the transition between these two regimes, the spectrum of the imaginary part of the susceptibility has a peak that is related via equation (7) to the anisotropy energy KV. The very strong size dependence of the relaxation time according to this equation leads to a very sharp maximum of the loss power density in dependence on particle size (Hergt *et al*., 1998; Hergt, Hiergeist, Hilger and Kaiser, 2002). Accordingly, a remarkable output of heating power occurs only for particle systems with narrow size (and anisotropy) distribution. The effect of size distribution on loss power density was elucidated theoretically by Rosensweig (2002).

In addition to Neél relaxation, which is related to the reversal of magnetic moments inside the particles, a second relaxation path is possible in liquid suspensions: the so-called Brownian relaxation is due to particle reorientation, which becomes essential if the magnetic moment direction is strongly coupled to the particle itself, for example, by a large value of the magnetic anisotropy, combined with easy particle rotation due to a low viscosity η of the suspension liquid. For spherical particles with the hydrodynamic radius r_h (which due to, e.g., particle coating may be essentially larger than the radius of the MP core), the relaxation time is given by

$$\tau_B = 4\pi\eta r_h^3/(kT) \tag{10}$$

which was first derived by Debye (1929) for rotational polarization of molecules. The loss power density for Brown relaxation is given by introducing equation (10) instead of equation (7) into equations (9) and (8). In the general case, if both Néel and Brown relaxation are present, an effective relaxation time may be used according to

$$\frac{1}{\tau_{\text{eff}}} = \frac{1}{\tau_N} + \frac{1}{\tau_B} \tag{11}$$

A general treatment of the relaxation in ferrofluids based on a Fokker–Planck equation was given by Shliomis and Stepanov (1994).

The role of Brown relaxation may be estimated from the measured susceptibility spectra shown in Figure 13 (Hergt *et al*., 2004a). By comparing the experimental data points measured for the fluid suspension with the data of the same particles immobilized in gel, the effect of Brown relaxation becomes clear. The low frequency peak of χ'' for the liquid suspension represents Brown losses. It has vanished after immobilization of the particles in gel. Consequently, a considerable reduction of specific heating power may be expected when particles circulating in blood adhere to tumor cells or enter a cell by (typically) endocytosis. However, the results of Figure 13 show that this detrimental effect may be avoided by choosing a suitable frequency of the external magnetic field well above the Brown peak. The experimental data points may be satisfyingly approximated (full and dashed line) by combining equations (7–11) with the experimental size distribution determined by electron microscopy (for details see Hergt *et al*., 2004a). The loss power density calculated by equation (8) is well confirmed by calorimetric measurements, which give a specific loss power (SLP) of 600 W per gram maghemite in a field of 400 kHz and 11 kA m^{-1}. There, the loss power density given in (W cm^{-3}) is related to the measured SLP (W g^{-1}) by the mass density $\rho = 4.8$ g cm^{-3} of maghemite. In medical literature, the SLP is often denoted as *specific absorption rate* (SAR).

4.2.3 *Viscous losses*

Losses related to viscous friction of rotating MPs in a liquid suspension are not restricted to the above case of superparamagnetic particles. In general, a rotating magnetic field H exerts a torque moment $T = \mu_o M_R H V$ onto a particle, which may be regarded as a permanent magnet (M_R means its remanent magnetization) rotating in a liquid of viscosity η. In the steady state, the viscous drag in the liquid $12\pi\eta V f$ is counteracted by the magnetic torque T and the loss energy per cycle is simply given by $2\pi T$. In steady state, the minimum field amplitude H needed to sustain stationary rotation is related to the frequency according to the balance

$$12\pi\eta f = \mu_o M_R H \tag{12}$$

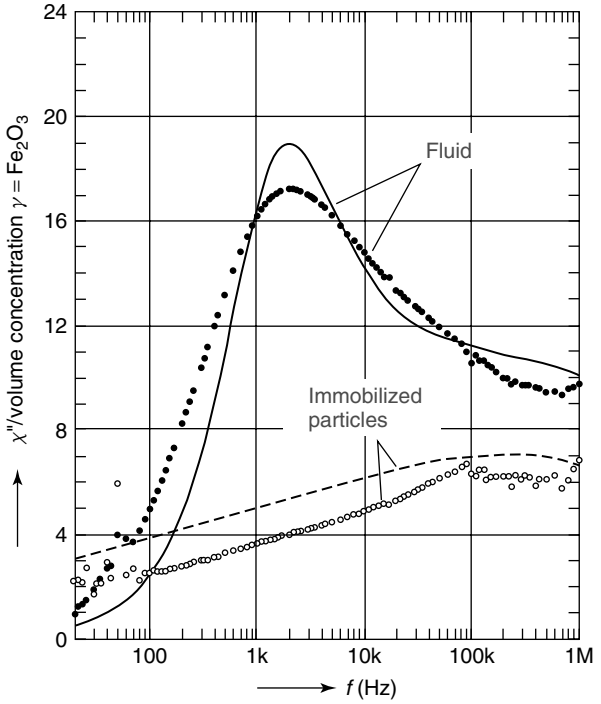

Figure 13. Imaginary part of the specific susceptibility as a function of frequency. Experimental results of an aqueous maghemite ferrofluid and of the same particles immobilized in gel are plotted (dots) in comparison with calculated spectra (full and dashed line). (Reprinted with permission Hergt R. Hiergeist *et al*., copyright 2004, Elsevier.)

For example, for an aqueous suspension (viscosity $\eta = 10^{-3}$ Pa·s) of magnetite ($M_R \approx 2.3 \times 10^5$ A m^{-1}), the minimum necessary field is 10 kA m^{-1} at a frequency of 70 kHz. For the latter AC-field parameters, the SLP given by $24\pi^2\eta f^2/\rho$ is about 240 W g^{-1}.

The effect of viscous losses was clearly demonstrated in experiments with relatively large (some 100 nm) crushed magnetite particles suspended in aqueous sol containing commercial gelatin, which is stiff below about 30 °C and a liquid at temperatures higher than 35 °C (Hiergeist *et al*., 1999). On heating above the melting point, the SLP increases by nearly an order of magnitude up to 200 W g^{-1} at a field amplitude of 6.5 kA m^{-1} and a frequency of 410 kHz.

4.3 Physical limitations of magnetic particle hyperthermia

The amount of nanoparticles necessary to increase the tissue temperature by MPH depends strongly on the SLP of the applied nanoparticles. In particular, for systemic delivery of nanoparticles (in contrast to local intratumorally injection), for instance, by means of antibody targeting (e.g., Suzuki, Shinkai, Kamihira and Kobayashi, 1995), the expected target concentration is very low (smaller than 1 mg of magnetite per cm^3 of tumor tissue) and, consequently, SLP must be rather high. For a quantitative estimation of the demand of SLP, one has to consider that the intratumoral temperature elevation is a result of the balance of two competing processes: Heat generation within magnetic nanoparticles is counteracted by heat depletion into surrounding tissue due to blood perfusion and heat conduction. In general, this needs the consideration of the so-called bioheat equation (e.g., Nyborg, 1988). However, if there are no large vessels in the immediate neighborhood of the tumor, the problem reduces to the solution of the heat conductivity equation (Andrä *et al*., 1999). As a result, in nearly steady state, for an approximately spherical tumor of radius r one gets a correlation between the size of the particle containing volume (i.e., the tumor size), the particle concentration c within it, the temperature elevation ΔT, and the SLP:

$$\Delta T = \frac{SLP \cdot c \cdot r^2}{(3\lambda)} \tag{13}$$

where λ is the thermal conductivity of body tissue, which is similar to that of water. As an important result, the demand of SLP increases with decreasing tumor size according to an inverse power law r^{-2}. Considering, for instance, thermoablation ($\Delta T = 15$ K) using a typical ferrofluid ($SLP < 100$ W g^{-1} of iron oxide) in tissue concentrations of about 10 mg cm^{-3} (provided by intratumoral injection), it follows from equation (13) that the diameter of the heated tissue region must not be smaller than 1 cm even if the tumor should be considerably smaller. In the case of antibody targeting only a low concentration of magnetic material may be achieved in the tumor region and a reasonable temperature elevation may be expected only for relatively large tumors (for details see Hergt, Hiergeist, Hilger and Kaiser, 2002; Hergt and Andrä, 2006). A volume reduction would demand a considerable increase of SLP according to equation (13). In particular, a significant temperature increase for isolated tumor cells that take up MPs cannot be expected. As stated by Rabin (2002), thermal effects on the cellular level are negligible as far as there is no macroscopic heating of cells within the tissue. Insofar, there is no reason to differentiate extracellular macroscopic heating and 'intracellular hyperthermia', which was claimed to be a particularly effective way for damaging tumor cells by some authors (e.g., Bacri *et al*., 1997; Jordan *et al*., 1999).

It should be pointed out that the scenario discussed is 'best case'. In practice, tumor shape deviates considerably from being spherical, and a homogeneous filling of tumor tissue by MPs will rarely be achievable. Consequently, the demand of heating power may be considerably larger than

expected from the above given estimations. In addition, for an optimum choice of particles with sufficient SLP, one has to take into account the limitation for the product $H{\cdot}f$ discussed in the preceding text (Section 4.1). The favorable combination of AC-field amplitude and frequency depends strongly on the type of particles provided for the therapy. For particles with mean size in the superparamagnetic regime, the frequency dependence of losses is mainly determined by the imaginary part of the susceptibility given in equation (9). On the contrary, for ferromagnetic particles, the frequency dependence of hysteresis losses is linear. The dependence of magnetic losses on field amplitude obeys a square law for superparamagnetic particles as given in equation (8) compared to a third-order power law for larger ferromagnetic particles in the Rayleigh regime. It is reasonable that for particles with hysteresis losses within the validity range of the Rayleigh regime one should favor the field amplitude against frequency in the limiting product $H{\cdot}f{\cdot}\mathrm{D}$.

It follows from the discussion of loss mechanisms given earlier – and is confirmed empirically – that the SLP of different types of magnetic nanoparticles may differ by orders of magnitude. The most important parameter is the mean particle size in combination with a narrow size distribution. For superparamagnetic particles, there is a steep decline in SLP with decreasing particle size (Hergt *et al*., 2004b). Insofar, the occasionally used very small particles below about 10 nm mean diameter are not the optimum choice for effective tumor heating. A maximum of SLP is expected for single-domain particles in the diameter range between the multidomain and the superparamagnetic regime, while, however, the coercivity should be not too high. As a confirmation, a very large value of SLP of nearly $1000\,\mathrm{W\,g^{-1}}$ at an AC-field amplitude of $10\,\mathrm{kA\,m^{-1}}$ and a frequency of 410 kHz was found by Hergt *et al*. (2005) for bacterial magnetosomes having a mean diameter of the magnetite crystals of about 35 nm (cf. Figure 12).

In addition to mean particle diameter, the particle size distribution has a strong effect on the value of the SLP as discussed in Section 4.2. As an experimental confirmation, by magnetic fractionation a high-SLP fraction with a mean core diameter of 18 nm that delivered $400\,\mathrm{W\,g^{-1}}$ (at 410 kHz and $11\,\mathrm{kA\,m^{-1}}$) could be gained from a commercial ferrofluid (Hergt *et al*., 2004b). A similar value of SLP of $600\,\mathrm{W\,g^{-1}}$ was found for magnetite particles with mean diameter of 15 nm, which owing to a special preparation procedure show a rather narrow normal size distribution instead of a commonly observed log-normal distribution (Hergt *et al*., 2004a).

In general, the mean particle concentration and especially inhomogeneities within the particles may affect the magnetic properties. The remanence of ferromagnetic particle ensembles decreases with increasing packing density owing to dipole–dipole interactions. As a consequence, the hysteresis losses decrease as well. The situation is more complicated in the case of superparamagnetic particles. Agglomerated clusters (see, e.g., Figure 7c) tend to behave like weak ferromagnetic bodies. The mean concentration in fluids, however, is usually low and the mean distance between particles too large to cause measurable modifications of magnetic properties.

Another important factor determining magnetic losses is the effective magnetic anisotropy. Considering the relatively small crystal anisotropy of the ferrimagnetic iron oxides in the order of some kilojoules per cubic meter (e.g., McCurrie, 1994), even relatively small deviations from isometric shapes lead to remarkable shape anisotropy and a wide spread of relaxation times. Moreover, magnetic anisotropy may be considerably influenced by the particle coating (Berkowitz *et al*., 1975), which is necessary for stabilization of the suspension as well as for coupling of functional groups. Finally, the coating may have a direct influence on the SLP if there is a contribution of Brown relaxation losses.

Considering all factors that may influence SLP, it is difficult to estimate a theoretical limit for the SLP of magnetic nanoparticles but it seems very questionable whether the above cited value of $1000\,\mathrm{W\,g^{-1}}$ may be exceeded by more than an order of magnitude. If this could be achieved, treatment of tumors whose diameter is a few millimeters using MPH would need a particle concentration of only $1\,\mathrm{mg\,cm^{-3}}$ in tissue. However, it is open at present whether such a concentration may be really attained by targeting with antibody-functionalized MPs.

To summarize, a good knowledge of structural and magnetic properties of magnetic nanoparticles is a prerequisite for designing particle systems with large SLP for hyperthermia or thermoablation. The manifold methods available for magnetic nanoparticle preparation has been recently reviewed (Tartaj *et al*., 2003).

4.4 Biomedical results of magnetic particle hyperthermia

4.4.1 Results with animals and cell cultures

Gilchrist *et al*. (1957) performed the first basic animal experiments with MPH, taking into account not only physical aspects of particle magnetism but also how the process could be technically implemented. Work performed since then in cell cultures and animals such as mice, rats, rabbits, dogs, and pigs are summarized in a review (Moroz, Jones and Gray, 2002). The conclusion of this experimental work is that temperature elevations sufficient for tumor degradation may be realized in animal experiments under tolerable systemic particle concentrations. Successful tumor cell killing was proved by histological evaluation of treated tissue. Although

many specific questions of MPH could be cleared in those experiments, the posttreatment survival rates – if at all determined – were rather scattered and predictions of successful human therapy will still need to be shown. The best survival rates of 87.5% in rats with no tumor regrowth within three months were reported by Yanase *et al*. (1998a). These authors also reported on observations of an antitumor immunity induction by MPH using magnetite cationic liposomes (Yanase *et al*., 1998b). Successful tumor control using magnetoliposomes coated with antibody fragments was reported (Le *et al*., 2001). For more detailed information, see the review given by Hergt and Andrä (2006).

Research on MPH was also supplemented by a lot of *in vitro* experiments using cell cultures. The main purpose of these experiments was the testing of the biocompatibility of coated magnetic iron oxides and investigation of interactions of magnetic nanoparticles with different cell species in aqueous suspension. Nanoparticle coatings used for MPH are mainly dextran, carboxydextran, citrate, polyethylene glycol, or starch. Toxicity of various coatings was studied, for example, by Häfeli and Pauer (1999). Several authors (cf. Moroz, Jones and Gray, 2002) have shown the differences of the cellular uptake of magnetic nanoparticles for different cell types as well as particle coatings by *in vitro* experiments. A very specific cellular uptake was achieved by coupling tumor-specific monoclonal antibodies on a polyethylene glycol coating of magnetite particles (Suzuki, Shinkai, Kamihira and Kobayashi, 1995). After incubation with BM314 cells, 90-pg magnetite per tumor cell was detected, which was four times that of the unlabeled control. However, much more specific antibody labeling is necessary to achieve MP enrichment in tumor tissue to meet the requirements of MPH. Chan, Kirpotin and Bunn (1993) have compared survival fractions of human lung adenocarcinoma cells following heating using water bath and MPH. They concluded that cancer cell damage was purely due to thermal effects. Being in accordance with theoretical considerations of Rabin (2002), this result contradicts the repeated claim of biomedical literature (e.g., Jordan *et al*., 1999) that 'intracellular hyperthermia' is a particularly effective way of tumor cell damaging.

To summarize, animal and cell culture experiments clarified some essential preconditions for human therapy.

4.4.2 Application to human patients

Although Gilchrist *et al*. (1957) were very optimistic about application of their new method in humans – and since then promising reports have repeatedly appeared in public media – almost half a century passed before first trials with humans were announced (Gneveckow *et al*., 2005). Provided suitable magnetic nanoparticles are available, the most critical problem to be solved is the reliable particle delivery to tumors, which may be achieved mainly in two different ways: first, injection of the particle suspension directly into the tumor or, secondly, a remote application in the blood vessel system followed by targeted delivery to the tumor. The latter may be performed, in principle, by labeling of MPs with tumor-specific antibodies or by particle guidance by means of inhomogeneous magnetic fields. At present, only direct injection is under practical consideration. The key problem of direct injection is the realization of an adequate particle distribution in the tumor tissue. Since the temperature elevation caused by the external alternating magnetic field is mainly confined to tissue regions containing MPs in sufficient concentration, the tissue distribution of the applied particle suspension should fit the tumor shape in the ideal case. However, there are serious practical difficulties in achieving this situation. Matching an infiltrative growing tumor, such as a glioblastoma, with a magnetic nanoparticle suspension seems difficult. On the basis of high-resolution imaging of the tumor shape, the physician has to realize a sufficiently homogeneous coverage of the tumor by the particle suspension avoiding excessive involvement of the healthy tissue. Even for a globular, well-bounded tumor, homogeneous injection is difficult owing to the tissue inhomogeneity, which causes the injected suspension to spread irregularly out of the tumor into the normal tissue, which is softer and differently textured compared to the relatively dense tumor tissue. To avoid these difficulties, a very slow infiltration and/or repeated multisite injections have been recommended (Jordan *et al*., 1997), although the latter bears the danger of needle track implantation or local tumor spread, as pointed out by Moroz, Jones and Gray (2002). It is therefore indispensable to check the particle distribution after injection by suitable diagnostic means, including sonography, radiography, or MRI. With knowledge of the spatial distribution of MPs and the particle concentration in tissue as well as the SLP of the applied particle type, one may estimate the temperature increase using the physical principles discussed earlier (Section 4.3, equation (13)). By measuring the local temperature increase using temperature sensors (e.g., optical fiber sensors) introduced into the tumor tissue, it is possible to control heating by adjustment of field amplitude and duration of the field exposure. A technically advanced hyperthermia and thermoablation system for clinical application was recently reported (Gneveckow *et al*., 2004) and clinical trials on the feasibility and tolerability of MPH are ongoing (Gneveckow *et al*., 2005).

For improving the site specificity of MPH, the labeling of MPs with target-specific ligands (e.g., antibodies) was suggested. Although often mentioned in the literature, only preliminary results of this appealing method have been published. They are restricted to *in vitro* experiments with cell cultures (Suzuki, Shinkai, Kamihira and Kobayashi,

1995) or *in vivo* experiments with animals using intratumoral injection (Shinkai *et al*., 1999; Le *et al*., 2001). The targeting efficiency, that is, the concentration enhancement on the tumor site in comparison to the systemic particle level and the content in organs of the reticuloendothelial system (RES), was not thoroughly investigated for remote (e.g., intravenous) particle application. The expected concentrations are so low that achieving a useful heating effect would need a considerable enhancement of the specific heating power of magnetic nanoparticles as discussed earlier.

The enrichment of magnetic nanoparticles in a target region of the body by application of external magnetic fields is in principle possible as shown by several authors. The method, however, suffers from the limitation that the center of attraction for the particles cannot be positioned within the body with extracorporeal magnets. After theoretically modeling magnetically targeted drug delivery, Grief and Richardson (2005) concluded that this method 'is appropriate only for targets close to the surface of the body'. Further, since magnetic attraction is proportional to the magnetic moment of the particles, superparamagnetic particles develop insufficient forces for magnetic targeting. On the other hand, for larger single-domain particles, there is the tendency of agglomeration with the hazard of unintended embolization. However, it is also possible to take advantage of embolization and use it for arterial embolization hyperthermia (for a review see Moroz, Jones and Gray 2002).

To summarize, MPH promises highly selective cancer therapy provided some practical problems of controlled particle delivery are solved.

5 MAGNETIC NANOPARTICLES FOR DIAGNOSTIC IMAGING

5.1 Contrast enhancement in magnetic resonance imaging

5.1.1 Introduction

One of the most valuable and widely used imaging methods in medical diagnostics is MRI. Though the diagnostic potential of conventional MRI is immense and a variety of different contrast modes are well established, further improvements of the method have been pursued in the last years by the application of magnetic nanoparticles for contrast enhancement based on functional site specificity. Since there are several introductory books and excellent review papers on MRI (e.g., Oppelt, 1998), only a short summary of the principles of the method is provided, so that the role of magnetic nanoparticles for enhancing the diagnostic value of MRI can be understood.

In MRI, the nuclear magnetic moment of protons is used as a sensitive probe of the chemical neighborhood of protons in different tissues and organs of the human body. Nuclear moments are aligned by means of an external magnetic bias field (commonly 0.2–3 T) and precession of the spins is excited by transverse RF pulses at the proton resonance frequency of about 43 MHz T^{-1} (NMR: nuclear magnetic resonance). After applying the pulse sequence, the induced magnetization decays and the longitudinal (T_1) and transverse (T_2) relaxation times of the precessing nuclear magnetic moments show tissue-specific differences that are used to generate image contrast. Imaging is performed by controlling external field gradients so that the resonance condition is fulfilled only in a restricted local region, and then scanning the resonant volume over the body part to be imaged. Magnetic response signals are detected by pick-up coils. The 'read-out' of the decaying magnetization is performed at defined delay after the end of excitation pulses. In this way, the tissue-specific differences of the relaxation times T_1 and/or T_2 may be used for construction of the so-called T_1- or T_2-weighted images showing optimal contrast of special tissue features. In practice, for optimization of tissue contrast, a variety of different pulse sequences (e.g., the widely applied 'spin echo' methods) may be used. For details, the specialized literature should be consulted (e.g., Mansson and Bjornerud, 2001).

5.1.2 Nuclear magnetic relaxation

In general, relaxation of the excited nuclear spins to equilibrium is stimulated by fluctuations of the local magnetic field due to random thermal agitation of the surrounding medium. The longitudinal relaxation is governed mainly by spin–lattice interactions, while transversal relaxation is related to spin–spin interactions, which are sensitive to local inhomogeneities of the magnetic field. In addition to random fluctuations of the local magnetic field, 'dephasing' of the excited spin system is caused by temporally constant inhomogeneities of the magnetic bias field. This latter dephasing contribution may be corrected by the so-called echo techniques.

The tissue-specific differences of relaxation times T_1 and T_2 bearing the main contrast information may be additionally influenced by paramagnetic or superparamagnetic contrast media supplied to the patient's blood vessels, to single organs, or parts thereof. Target-specific contrast enhancement may either rely on natural physiological enrichment processes or may be mediated by special ligand tags (e.g., tumor-specific antibodies) coupled to the contrast agents. Consequently, those substances may be used as markers in physiological processes and owing to their site specificity one may detect pathological deviations or malfunctions of organs.

In general, the change of relaxation times is proportional to the concentration of contrast agents in the sample volume and, accordingly, for characterizing the ability of those agents for imaging enhancement one uses the so-called 'relaxivity', which is the change in the inverse of T_1 or T_2 per unit concentration measured in ($s^{-1}\,mol^{-1}$). Commonly, both T_1 and T_2 are reduced by usual contrast agents and for good image contrast the pulse sequence used for imaging has to be chosen adequately (see, e.g., Bulte and Brooks, 1997). Of course, contrast agents approved for clinical use must show sufficient biocompatibility and the temporal biodistribution (e.g., circulation time in blood, elimination from organs) is essential to obtain useful contrast.

5.1.3 Paramagnetic contrast agents

One established group of contrast media are paramagnetic metal-ion chelates (e.g., Gd-DTPA, a chelating agent containing diethylenetriaminepentaacetic acid). The chelation of the strong paramagnetic Gd^{3+} ion is necessary to avoid toxicity effects of free ions, though in this way the 'contact area' to the bulk water protons – and correspondingly the relaxivity – is considerably reduced. In theoretical models for explaining the effect of MRI contrast agents on proton spin relaxation, one differentiates inner- and outer-sphere relaxation, which determines the 'transmission' of the paramagnetic fluctuations toward the bulk neighborhood of the contrast molecule. The inner sphere is the first coordination sphere of the metal ion, the chelation of which commonly leaves room for only one water molecule. This water molecule is in rapid exchange with the bulk water molecules via the outer sphere, which is the next shell of water molecules surrounding the chelate. The coupling of the proton spin relaxation with the paramagnetic relaxation is described by the Solomon–Bloembergen–Morgan theory. For details, see the book edited by Merbach and Toth (2001) on the chemistry of contrast agents for medical MRI. The theory relates the observed relaxation rate enhancement to microscopic time constants characterizing diffusion of proton spins, electron spin relaxation, and rotational correlation of proton and electron spin.

Present experimental investigations aim at the development of improved Gd chelates with enhanced relaxivity and site preference for targeting of special epitope binding sites (e.g., tumor antigens). The size of Gd-based water-soluble macromolecules may be adjusted for optimum contrast depending on vascular distribution dynamics and the targeting area. For instance, Winter *et al*. (2005) investigated lipid-encapsulated perfluorocarbon nanoparticle contrast agents functionalized with different new Gd chelates for the sensitive and specific detection and localization of fibrin and molecular signatures of angiogenesis. The special molecular design of the relatively large paramagnetic constructs (about 200 nm in diameter) ensures, with a paramagnetic load of about 50 000 gadolinium ions, very high relaxivity per particle in the order of $10^6\,s^{-1}\,m\,mol^{-1}$. In order to guarantee sufficient accumulation at the target area, site-specific contrast agents should circulate longer than the common blood-pool MR agents. Accordingly, adequate chemical stability of the Gd complexes in physiological environment ought to be provided for minimizing toxic side effects.

5.1.4 Magnetic nanoparticles as contrast agents

Local magnetic fields much larger than those due to paramagnetic ions are caused by superparamagnetic particles of the magnetic iron oxides (maghemite and magnetite). The most important parameter in determining the destiny of such particles after introduction into the vascular system (e.g., elimination by phagocytosis or extravasation into interstitial compartment) is the mean size of the particles. Small objects below about 10 nm diameter may leak from blood vessels and distribute in the extracellular fluid (therefore occasionally termed *ECF agents*). Agents that are normally prevented from extravasating to the healthy brain by the blood–brain barrier are suitable, for instance, to trace various neuropathological deviations. A prolonged intravascular circulation time of the so-called blood-pool agents with a diameter range of 10–50 nm ensures great utility in MR angiography. Enhanced uptake of particles in cancerous tissue related to the tumor angiogenesis (e.g., Folkman, 1985) may lead to an initial contrast enhancement after contrast agent application, providing an improved sensitivity for carcinoma detection. Further examples are enrichments at thrombi or the detection of arteriosclerotic plaques. Since particle elimination by phagocytosing cells is most effective in a medium size range of 50–150 nm, the group of contrast agents in this size range and with a circulation time in the order of hours addresses diagnostic needs for organs of the RES (e.g., liver, spleen, bone marrow, lymphatic system). In contrast, site-specific MRI contrast agents should have a long circulation time, which is a prerequisite for sufficient accumulation on a specific target site. A special group is the contrast agents for diagnostics of the gastrointestinal tract: mainly relatively large particles of 0.3–3 µm, which must be protected by suitable coatings against rapid excretion. For an overview on biomedical indications of contrast agent application including many recent references, see, for instance, La Conte, Nitin and Bao (2005).

The useful particle diameters discussed earlier comprise the magnetic oxide core plus an organic coating (e.g., dextran), which is necessary for stabilizing the aqueous particle suspensions against particle aggregation. The coating is

the boundary to the physiological environment and accordingly it is important for possible interactions with proteins (e.g., immunoglobulins of the blood plasma). For instance, hydrophilic coatings like dextran help prevent particle elimination by macrophages. The coating may be functionalized by bioactive molecular groups such as tumor-specific antibodies for receptor-specific targeting.

Important particle parameters for the relaxivity are core magnetization, mean size of the magnetic core, and size distribution. While in the case of paramagnetic contrast agents inner-sphere contributions are particularly important for the relaxivity, magnetic nanoparticles create considerable local fluctuating field gradients and interact with proton nuclear spins by dipolar interaction in the outer-sphere diffusion range. The classical outer-sphere relaxation theory was improved by different authors (for a review, see, e.g., Bulte and Brooks, 1997; Muller *et al*., 2001) taking into account the dynamics of the core magnetization. For superparamagnetic particles with a core diameter in the order of 10 nm, the dependence of relaxivity on the magnetic field was introduced by the Langevin function. In general, the existing different theoretical models rely on various microscopic parameters (mainly elementary time constants), which are rarely accessible by experimental means. Consequently, the uncertainties allow for some fitting freedom. Theoretical predictions are often checked experimentally by measuring the so-called NMRD (nuclear magnetic resonance dispersion) profiles, which is the dependence of proton relaxation rate on the magnetic field. Fitting the observed field dependence of T_2 relaxivities at high fields is only successful if a 'susceptibility term' corresponding to a linear nonsaturating component in the particle magnetization is taken into account. This term may be explained by a 'paramagnetic' surface of the nanoparticles. On the other hand, in the low field range (roughly below 0.1 T), the observed dispersion of the longitudinal relaxivity may be only explained by taking into account the anisotropy energy of the particles, which determines the Néel relaxation of the particle moment (see, e.g., Muller *et al*., 2001). The T_2 shortening by strongly magnetized spheres was treated by Gillis, Moiny and Brooks (2002) using computer simulation, taking into account partial refocusing by echo pulse sequences. For small particle sizes (up to about 30 nm), relaxivity increases with the square of the diameter in agreement with the outer-sphere theory. For larger particles above 30 nm, the relaxivity remains constant in the static dephasing regime while the relaxivity decreases for different types of echo sequences with increasing core size (cf. Figure 10.6 in the review by Muller *et al*., 2001).

While experimental investigations are usually carried out on well-defined dilute aqueous suspensions, modifications are expected for particles in dense tissue, where particles could get stuck or adhere to cell surfaces, for example, in a tumor. The effect of clustering of magnetic nanoparticles in water suspensions was investigated by Roch, Gossuin, Muller and Gillis (2005). Recently, relaxivities of several paramagnetic and superparamagnetic substances in blood as well as in water were compared by Coroiu and Cristea (2005). Data on commercially available superparamagnetic iron oxide–based contrast media are compiled in a review paper of Taupitz, Schmitz and Hamm (2003). There, an overview on several medical applications of superparamagnetic contrast media is given. The contrast change due to magnetic nanoparticles may be positive or negative for 'T_1 weighting' depending on particle concentration and the choice of the pulse sequences used for imaging, while for 'T_2-weighting' negative contrast generally arises (e.g., Bulte and Brooks, 1997). At high local particle concentrations, artifacts may arise, which mask all finer image details. This problem is relevant for assessment of the particle enrichment on a target site for MPH since at present relatively high therapeutic particle concentrations are needed.

More complicated types of nanoparticles are under development for tumor diagnostics and therapy. For instance, Kopelman *et al*. (2005) describe photodynamic nanoparticles consisting of a polyacrylamide core combined with photosensitizer and MP MRI contrast agent. One promising goal in MPH is the combination of diagnostics and therapy by using the same magnetic nanoparticles for contrast enhancement and hyperthermia. In addition, the integration of controlling the increase of tumor temperature under hyperthermia as demonstrated by Carter *et al*. (1998) and on-line checking of tumor damage by MRI would be important steps toward establishment of magnetic particle hyperthermia as a reliable tumor therapy.

5.2 Magnetic particle imaging (MPI)

When Lauterbur published his seminal paper (Lauterbur, 1973), he did not specifically restrict it to magnetic resonance but more generally described 'image formation by induced local interactions'. A recent approach in applying this idea is magnetic particle imaging (MPI), which was proposed by Gleich (2003) and further described by Gleich and Weizenecker (2005) and Trabesinger (2005). The principle of the method is based on highlighting a small region within a larger surrounding volume by marking with MPs and taking advantage of their specific magnetization curve. The large difference between the strongly nonlinear magnetization dependence of MPs as a function of the magnetic field and the magnetization of tissue, which is proportional to the field, can be utilized for medical applications. The particle magnetization as a function of the magnetic field

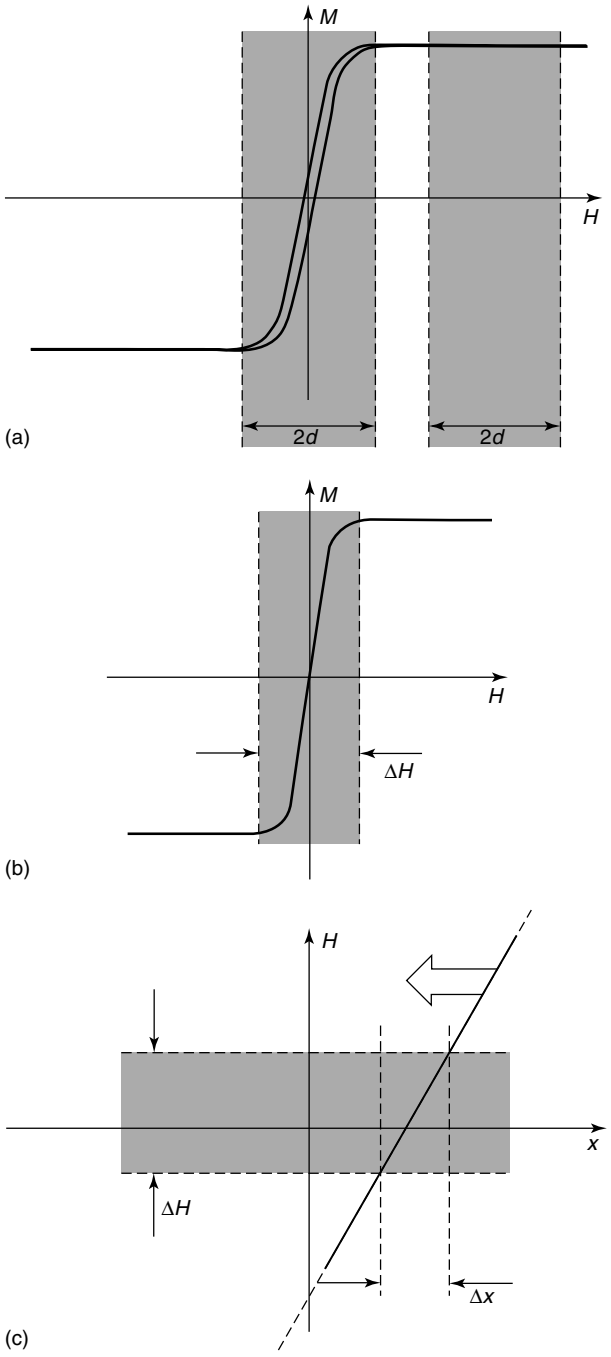

Figure 14. Two variants of magnetic particle imaging (MPI): (a) An alternating modulation field of the amplitude d (gray region) is superimposed on a selection field, which is realized by a field gradient slowly moving across the investigated volume; only if the selection field is nearly zero, the exposed particles respond with harmonics of the modulation frequency. (b) A strong magnetic field with high gradient $\mathrm{d}H/\mathrm{d}x$ is quickly moved across the examined volume; all those particles that experience the field range ΔH of their steep change of magnetization (gray region) respond with a single remagnetization pulse; the spatial resolution Δx (c) is determined by the magnitude of the field gradient $\mathrm{d}H/\mathrm{d}x$ and the field range ΔH of steeply changing particle magnetization.

may coarsely be subdivided into three different sections: for high strengths of positive and negative fields, there are two regions where the magnetization is almost constant (saturation) while in a restricted field region near zero the magnetization changes steeply with the field (Figure 14). This latter small field range (selection field) is moved by either one of two scanning procedures across the examined volume. In the first variant of MPI, an AC magnetic field with small amplitude (modulation field) is superimposed on the slowly moving selection field and causes only those particles that are exposed to the selection field to respond with harmonics of the modulation frequency, which can be selectively measured. The second variant of MPI uses a strong field with high gradient that is moved with high speed across the examined volume, thereby switching the magnetization of all particles in the small region where the actual field is about zero. In both variants, the actual position of the selection field must be known and, at the same time, the responding stray field of the particles has to be detected by suitable means, for example, by pick-up coils carefully compensated with respect to the externally applied fields.

The general operability of MPI was demonstrated by Gleich and Weizenecker (2005) with an array of small holes of 0.5 mm diameter filled with an undiluted, commercially available MRI contrast agent (Resovist®, Schering Ag, Berlin, Germany) containing magnetic oxide particles with a magnetic core well below 100 nm. The holes could be clearly resolved.

For medical applications of MPI, the regions of interest have to be marked selectively, for example, by methods of drug targeting, including the labeling of magnetic carriers and the guidance of the labeled particles to the corresponding sites. Even with the moderate resolving power demonstrated in the initial experiments mentioned earlier, the novel concept may provide the possibility to develop relatively cheap scanners that can be adapted to particular applications. An interesting feature of MPI is its use of harmless radio waves that can pass through the body without significant attenuation.

6 CONCLUSIONS AND PERSPECTIVES

Microparticles can easily pass through the narrow capillary blood vessels of humans. Nanoparticles that are still smaller with a diameter of below 50 nm can even squeeze through the fenestrations of blood vessels and, in this way, can reach most of the cells in the human body. Nanoparticles are therefore predestined to act as carriers for drugs and other agents. Making micro- or nanoparticles magnetic gives them even more favorable properties including the following:

- Their magnetic stray field enhances the contrast in MRI and can also act as source for other contrast mechanisms such as MPI.
- Their magnetic moment generates forces and torques after the application of external magnetic fields. In this way, retention and guidance of MPs can be realized.
- Their magnetic core exhibits losses in alternating or rotating magnetic fields, which leads to temperature increase in MPs. Thus they can act as localized heat sources and produce direct effects such as hyperthermia and thermoablation or indirect effects such as an enhanced rate of chemical reactions.

Together with the fact that magnetic fields in the low frequency region penetrate human tissue without significant attenuation, these particular properties make MPs unique tools for diagnosis and therapy. Despite numerous applications in technology, medicine, and biology, there is still immense research going on in this field, as judged by the large increase in relevant articles over time. Current investigations comprise the synthesis of large amounts of MPs with narrow size distributions and high magnetic susceptibilities, the optimization of magnetic targeting and the magnets to use, and the increasing the particles' heat production for magnetic hyperthermia. Magnetosomes grown in magnetotactic bacteria hold the record in specific heat production for magnetic hyperthermia, and several research groups are trying to learn from these microorganisms and apply natural processes to laboratory techniques.

1 INTRODUCTION

More than 70 years ago it was realized that in simple ferromagnetic metals such as Fe, Co, and Ni, current is carried by spin-polarized electrons because of a significant spin-dependent scattering of the majority ('up') and minority ('down') spin-polarized electrons (Mott and Jones, 1936). Many of the magnetotransport properties of these elements and their alloys can be understood within a 'two-current' model in which the electrical current is comprised of independent up- and down-spin currents. It took more than half a century, however, before it was appreciated that these currents can be manipulated in inhomogeneous magnetic systems comprising magnetic and nonmagnetic regions so as to modify the flow of current in these systems and thereby their resistance. Examples include magnetic multilayers composed of alternating thin magnetic and nonmagnetic layers such as Fe/Cr, Co/Ru, and Co/Cu (Baibich *et al*., 1988; Parkin, More and Roche, 1990; Parkin, Bhadra and Roche, 1991) and granular magnetic alloys composed of immiscible magnetic and nonmagnetic metals such as Co and Cu (Berkowitz *et al*., 1992; Chien, 1995). These systems exhibit very large changes in resistance at room temperature in response to magnetic fields as the magnetization directions of neighboring magnetic layers or regions are changed. This phenomenon is often referred to as *giant magnetoresistance* (GMR) (Parkin, 1994, 1995; Fert and Bruno, 1994; Gijs and Bauer, 1997; Mathon, 1991; Levy, 1994; Parkin *et al*., 2003; Barthélémy *et al*., 2002; Parkin, Li and Smith, 1991).

The largest GMR effects are found in Co/Cu multilayers (Parkin, 1993) with changes in resistance exceeding 100% at room temperature. However, these large effects are found in multilayers in which the individual Co and Cu layers are ultrathin – just two to three atomic layers thick – because GMR arises largely from spin-dependent scattering, not within the interior of the magnetic layers ('bulk' scattering, as Mott had considered; Mott and Jones, 1936) but rather from the interfaces between the individual layers ('interface' scattering; Parkin, 1993). The relative importance of interface scattering as compared to bulk scattering was a topic of considerable debate in the early days of GMR but now it is generally agreed that the contribution of spin-dependent scattering from a magnetic interface layer is perhaps 100 times that from an interior magnetic layer. This is very

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

important technologically because of the need to minimize and control the influence of long-range magnetic dipolar fields emanating from the magnetic component.

GMR has found one extremely important application in the form of a highly sensitive magnetic recording read head for magnetic hard disk drives (see Parkin *et al*., 2003). The GMR effect in magnetic multilayers is not suitable for sensors but can be engineered to create useful devices through several concepts of 'spin engineering' (Parkin *et al*., 2003). In particular, one important concept is fixing the direction of the magnetic moment of individual magnetic layers in a thin-film device by the phenomenon of exchange bias (Meiklejohn and Bean, 1956; Nogués and Schuller, 1999): exchange bias is a magnetic exchange interaction at the interface between a ferromagnet and an antiferromagnet, which can lead to a unidirectional exchange anisotropy in the ferromagnet. This interaction can be so large that the magnetic hysteresis loop of a ferromagnetic film can be shifted from zero field by an 'exchange bias' field which can exceed 1 T or more in magnitude. A second important concept is the use of oscillatory interlayer exchange coupling of 3d transition-metal (TM) ferromagnetic layers through intermediate nonmagnetic layers of the 3d, 4d, and 5d TMs and the noble metals, Cu, Ag, and Au (Parkin, More and Roche, 1990; Parkin, 1991). All these nonmagnetic metals exhibit a long-range indirect interlayer exchange coupling, which oscillates between ferro- and antiferromagetic coupling. By using specific thicknesses of these nonmagnetic metals, which give rise to antiferromagnetic coupling, artificial antiferromagnetic (AAF) thin-film structures that have zero or small net magnetic moment, and consequently, significantly reduced magnetic dipolar fields can be created. These concepts are illustrated in Figure 1. Figure 1(d) shows the basic structure of the most commonly used GMR read head device today. The device, a 'spin valve', contains a reference magnetic electrode formed from an exchange biased AAF separated by a thin Cu layer (second layer from the top), ∼20 Å thick, from the sensing layer which is typically formed from a soft ferromagnetic alloy with the insertion of a very thin interface layer for enhanced interface scattering. The AAF layer universally contains an ultrathin ruthenium layer just 5–10 Å thick to provide the antiferromagnetic coupling layer. These devices act, in some ways, like a valve, where the flow of current through them is modified by applying a magnetic field.

In the past two decades since the discovery of GMR and oscillatory interlayer coupling in TM systems, the magnitude of the GMR signal exhibited by spin-valve structures has changed very little. The resistance of such structures is typically about 10–15% higher when the sensing and reference magnetic moments are antiparallel (AP) as compared to that when they are parallel (P) to one another. Partly for this reason, interest has been renewed in the past decade in devices based not on spin-dependent diffusive scattering but rather on spin-dependent tunneling through an ultrathin dielectric layer forming a tunnel barrier. These structures are the focus of this review.

2 FUNDAMENTALS OF MAGNETIC TUNNEL JUNCTIONS (MTJs)

The essential element of a magnetic tunnel junction (MTJ) is a sandwich of two thin ferro- or ferrimagnetic layers separated by a thin insulating spacer layer which forms a tunnel barrier. When a bias voltage is applied across the barrier, finite current flows through the junction because of quantum-mechanical tunneling. This means that a distinctive property of an MTJ, compared to spin valves, but common to any tunneling device, is the exponential dependence of the tunneling current on the thickness of the tunnel barrier (Simmons, 1963). From a device perspective, this is very interesting, since the resistance of an MTJ can be varied over many orders of magnitude simply by varying the thickness of the dielectric spacer layer. This allows tuning of the device resistance depending on the application. On the other hand small variations in this layer thickness, perhaps due to subtle variations in a deposition process, can lead to large changes in the device resistance. Moreover, for many device applications, it is the signal-to-noise ratio in the frequency range of interest that determines the sensitivity of the MTJ device (Nowak, Weissman and Parkin, 1999). The main sources of noise in an MTJ are Johnson noise, which scales with the square root power of the resistance of the device, and shot noise, which increases with the square root power of the current through the device. Thus, for many high-frequency applications, which require that the resistance of the MTJ must be very low (on the order of ∼20 Ω), the tunnel barrier must be very thin – just a few atomic layers thick. This is a considerable challenge.

In MTJs, the magnitude of the tunneling current depends on the relative orientation of the magnetization direction of the two ferromagnetic metal layers. The tunneling magnetoresistance (TMR) is defined as:

$$TMR = \frac{I_{\max} - I_{\min}}{I_{\min}} \tag{1}$$

where $I_{\max}$ and $I_{\min}$ are the maximum and minimum currents, respectively, that flow through the barrier. For MTJs with conventional ferromagnetic metals (Ni, Fe, Co), the current flow is maximized (minimized) when the magnetization directions of the two ferromagnetic layers are parallel (antiparallel) to each other.

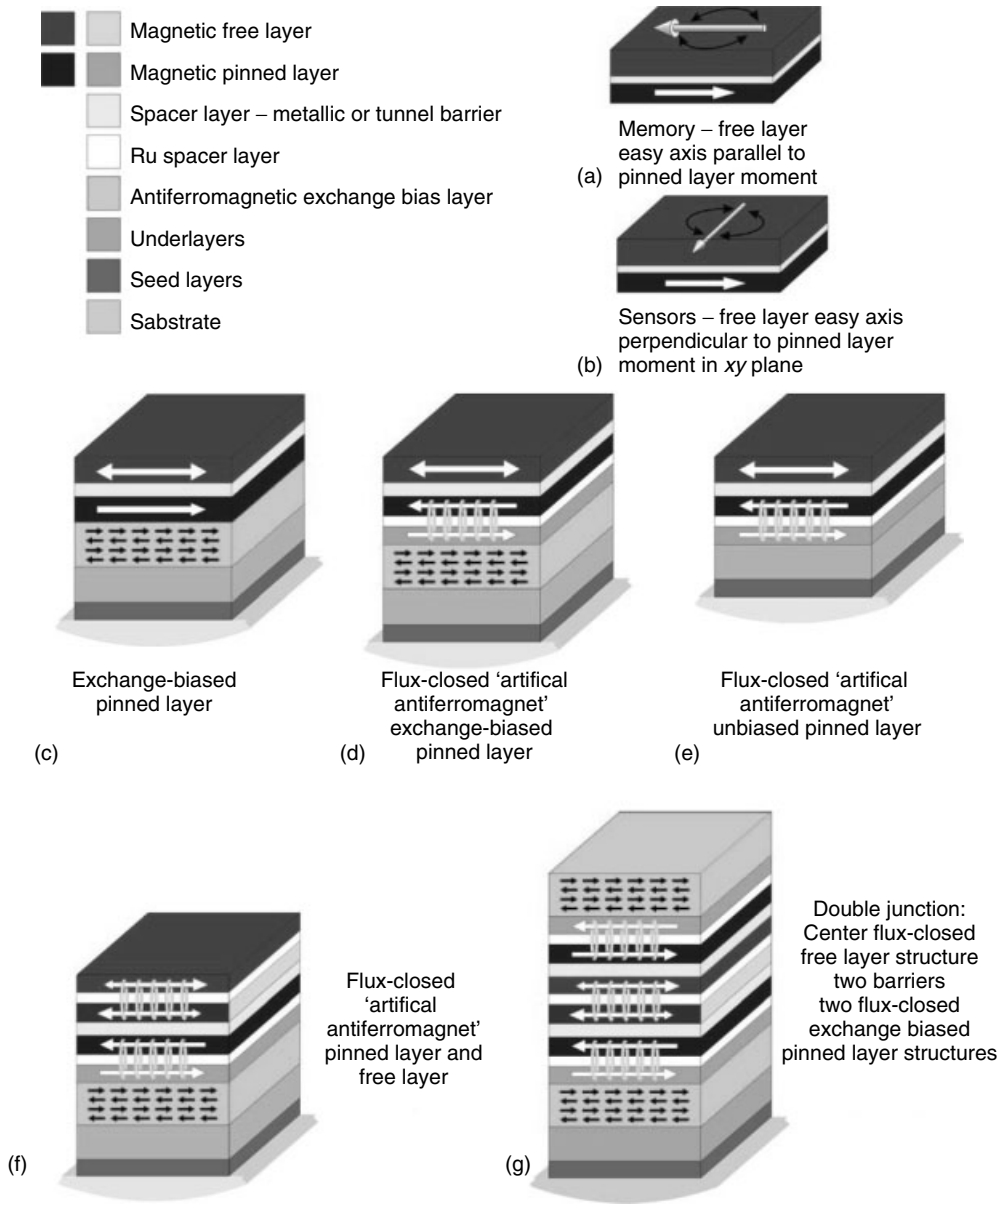

Figure 1. Spin-engineered magnetic devices. (a,b) The easy axis of the 'free' ferromagnetic layer in a magnetoresistive device is oriented based on the purpose for which it is engineered. Field sensor devices such as read heads rely on a free layer with an easy axis at right angles to the moment of the 'pinned' layer. Impinging magnetic fields will rotate the moment away from this middle position and the sensor resistance changes. On the other hand, MR devices designed for use in memory applications will have a free layer easy axis parallel to that of the pinned layer. (c) A very basic GMR/TMR stack consisting of a pinned ferromagnetic layer magnetically locked by exchange bias to the interfacial field of an antiferromagnetic layer, and a simple ferromagnetic free layer. The 'spin valve' is such a stack using a conducting spacer layer between the ferromagnetic layers. (d) In this case the pinned layer is in fact an element consisting of a pair of ferromagnetic layers antiferromagnetically coupled through a ruthenium (Ru) spacer layer; the lower layer in this artificial antiferromagnet is pinned via exchange bias as in (c). This flux closure increases the pinned layer magnetic stability and reduces coupling to the free layer. (e) Pinned element consists of an AF-coupled pair of ferromagnetic layers acting as a single 'hard' layer. There is no exchange bias layer to discourage rotation of the pinned element. (f) Both the pinned and free elements consist of AF-coupled pairs. (g) A double-tunnel junction. All ferromagnetic elements consist of AF-coupled pairs. There are two pinned ferromagnets, both exchange biased by antiferromagnetic layers. Spin filtering occurs both as current tunnels from the first pinned layer to the free element and again as it tunnels from the free element to the second pinned element. Figure 2. Schematic illustration of the tunneling process. The densities of states for the left and right electrode are shown for (a) parallel and (b) antiparallel configuration. The horizontal arrows represent the electron spin direction. The bottom panel shows the corresponding magnetization configuration of the MTJ.

The origin of tunnel magnetoresistance was first described by Julliere (1975) using a simple transport model. This model makes two important assumptions. First, the electrons do not change their spin direction during the tunneling process. Second, the tunneling current is carried by two independent conductance channels whose carriers are the electrons with spin up and down. The total current is then the sum of the current of the two independent channels within the two-current model (McGuire and Potter, 1975; Mott, 1936, 1964; Fert and Campbell, 1968) which, as mentioned in the preceding text, can account for the GMR (Baibich *et al*., 1988; Valet and Fert, 1993) effect and which has also proved valid to describe anisotropic magnetoresistance (Smit, 1951; Campbell, Fert and Jaoul, 1970; Banhart, Ebert and Vernes, 1997). In the two-current model, the conduction electrons are generally assumed to originate from the free electron–like s bands. The localized d or f states act as scattering centers. By contrast, in MTJs we take the localized d- or f-state electrons as the carriers responsible for the tunneling currents.

Figure 2 shows a simplified density of states (DOS) of an MTJ when the magnetization directions of the two ferromagnetic metals are (a) parallel and (b) antiparallel to each other. The DOS of each electron spin in the ferromagnetic electrode is shifted against the other because of the exchange splitting caused by the internal magnetic field (Mott, 1964; O'Handley, 1999). In Figure 2, the DOS of the ferromagnetic metals are weak ferromagnets, that is, the number of electrons at the Fermi energy is larger for the majority states as compared to the minority states. A bias voltage is applied across the barrier to generate tunneling current; here the voltage is applied such that the electrons tunnel through the barrier from the left to the right electrode. The tunneling current is predominantly carried by the electrons whose states are near the Fermi energy (Duke, 1969; Wolf, 1989). In order to conserve the spin during the tunneling process, the electron that travels from one spin state on the left electrode must be accepted by the same unfilled spin state on the right electrode. Consequently, the number of electrons that can tunnel through the barrier is limited by the number of filled states on the left electrode and the number of the unfilled states on the right electrode.

The tunneling current that flows through the junction for the parallel (I_P) and antiparallel (I_{AP}) states can be expressed as:

$$I_P \propto N_\uparrow^L N_\uparrow^R + N_\downarrow^L N_\downarrow^R$$
$$I_{AP} \propto N_\uparrow^L N_\downarrow^R + N_\downarrow^L N_\uparrow^R \tag{2}$$

where $N_{\uparrow\downarrow}^{L,R}$ are the density of majority ($\uparrow$) and minority ($\downarrow$) spin states at the Fermi energy for the two ferromagnetic electrodes (L and R). Equation (2) shows that the current for the AP state is suppressed compared to that of the P state. This difference in the current is the origin of the TMR effect.

From equations (1) and (2), the TMR ratio is written as

$$TMR = \frac{I_P - I_{AP}}{I_{AP}} = \frac{2P_L P_R}{1 - P_L P_R} \tag{3}$$

Here, $P_i \equiv \frac{N_\uparrow^i - N_\downarrow^i}{N_\uparrow^i + N_\downarrow^i}$, i = L, R is the spin polarization of the left (L) or right (R) ferromagnetic electrodes. As evident from equation (3), the TMR ratio is proportional to the spin polarization P_i of the ferromagnetic electrodes. Methods to experimentally determine the magnitude and sign of the spin polarization are discussed later.

A more accurate theoretical description of the TMR effect was given by Slonczewski (1989). His model included the effect of the insulator on the TMR effect, where the tunneling current was assumed to depend on the barrier height and width of the insulator. The ferromagnetic electrodes were treated within the free electron approximation with two separate bands for each spin direction (Stearns, 1977). Since the insulator possesses finite barrier height and width, the electron wave function from the ferromagnetic electrodes can penetrate inside the insulator. Consequently, an additional factor of the spin polarization arises from the interface between the insulator and the ferromagnetic electrode. The effective spin polarization becomes

$$P_{\mathrm{EFF}} = P_i A (-1 < A < 1) \tag{4}$$

where A is a constant that depends on the barrier height and width of the insulator as well as the DOS of the ferromagnetic electrode. Julliere's model ($P_{\mathrm{EFF}} = P_i$) is recovered when the barrier height or the width becomes infinite, that is, for a perfect insulator. Interestingly, Slonczewski's model predicts that the effective spin polarization can be negative at low barrier height ($A < 0$). This indicates that the spin polarization in MTJs is not an intrinsic property of the ferromagnetic metals, but depends both on the electrode and the barrier characteristics.

Although Slonczewski's model does not take into account other complications such as the multiband structure of the ferromagnetic electrodes and the complex band structure of the insulator, or the electron–electron interactions, spin-wave emission and absorption, and inelastic tunneling processes, nevertheless, it provides a reasonable basis for an appreciation of spin-dependent tunneling in MTJs. In order to include band structure effects, one needs to perform first-principle electronic structure calculations, such as the density function theory. However, even using such an elaborate method, it is difficult to predict the TMR ratio precisely in a quantitative way, since it is known that the tunneling current also depends on defects and impurities inside the barrier as well as on the roughness of the interface layer, which are difficult to include even in numerical calculations.

The first successful MTJ was prepared by Julliere (1975). The MTJ consisted of Fe/Ge/Co, where the semiconducting Ge acted as an insulating barrier. A conductance change as high as ∼14% was observed at 4.2 K. After Julliere's initial discovery, other barriers, such as nickel oxide (NiO) (Maekawa and Gafvert, 1982), gadolinium oxide (GdO_x) (Nowak and Rauluszkiewicz, 1992), and aluminum oxide (AlO_x) (Suezawa, Takahashi and Gondo, 1992; Miyazaki, Yaoi and Ishio, 1991), were explored over a period of nearly 20 years, with the observation of modest TMR effects of up to several percent at room temperature. In 1995, two groups reported TMR ratios of about 10% at room temperature, using an amorphous aluminum oxide barrier and Fe–Co electrodes (Moodera *et al.*, 1995; Miyazaki and Tezuka, 1995). These results sparked much interest in MTJs, largely due to their promising applications in recording read heads for hard disk drives and in novel magnetic random access memories (MRAMs), as discussed later in this chapter.

Most work in this period of time used amorphous aluminum oxide tunnel barriers, which had been extensively studied for Josephson junction superconducting devices. A method of forming the tunnel barrier in which a few monolayers of aluminum metal were first deposited and then were subsequently oxidized, either thermally using molecular oxygen or reactively using atomic oxygen, had been successful in creating high-quality tunnel barriers with very low leakage currents (Rowell, Gurvitch and Geerk, 1981; Mallison, Miller and Kleinsasser, 1995). In MTJs, it is not only the formation of a tunnel barrier without pinholes that is important for the observation of large TMR signals, but also the preparation of high-quality interfaces between the barrier and the electrodes which preserve the magnetic integrity of the surface layers of the ferromagnetic electrodes. Thus, the magnitude of the TMR ratio highly depends on the detailed preparation method of forming the tunnel junction. The observed increase in the TMR ratio over the past decades owes much to the improvements in these methods.

Magnetron sputtering methods are typically used for deposition, including the ferromagnetic electrodes as well as the insulator layer. To form the junction, it is ideal to grow the MTJ *in situ* since the interface between the insulator and the ferromagnetic metals needs to be extremely clean to maintain the polarization of the tunneling electrons. For exploring new materials and refining MTJ device structures it is very useful to use a *in situ* shadow masking technique to pattern first, the bottom ferromagnetic electrode, second, the tunnel barrier and third, the top ferromagnetic counterelectrode. Thus MTJs, which, unlike spin-valve structures, require patterned top and bottom electrodes to pass current through the device for testing purposes, can be prepared quickly and efficiently without using conventional lithography methods, which would otherwise be needed. Figure 3 shows a schematic illustration of a magnetron sputtering system with an *in situ* computer-controlled system for placing a sequence of shadow masks onto any 1 of 20 substrates. A shadow mask, here formed from a thin metal sheet (black layer), is

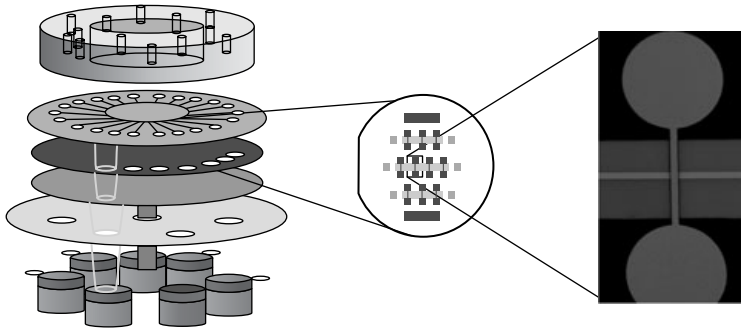

Figure 3. Schematic illustration of magnetron sputtering with a shadow mask (black plate) technique introduced. The middle panel shows the deposited MTJs. Scanning electron microscopy image of the junction is shown in the right panel.

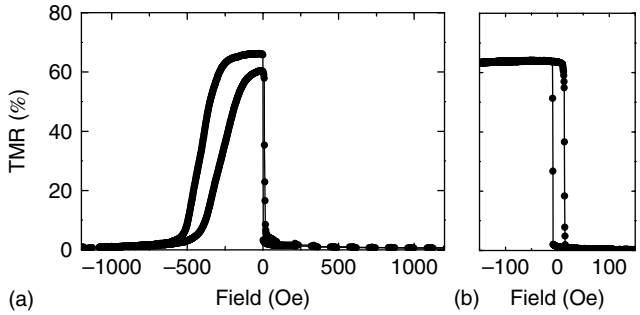

Figure 4. TMR ratio plotted against the applied magnetic field for an MTJ consisting of 50 TaN | 50 Ta | 150 IrMn | 35 $Co_{70}Fe_{30}$ | 22 Al | 10 $Co_{70}Fe_{30}$ | 65 $Co_{59.5}Fe_{25.5}Zr_{15}$ | 50 TaN | 50 Ta | (units in Å). inserted between the target (bottom layer) and the substrate (second layer from the top) to define the deposited structure. Typically, three different shadow masks are used to form, respectively, the bottom electrode, the insulator, and the top electrode, although many more masks can be used for the definition of more complex structures or for the use of isolation pads. Using shadow masking techniques the junction size is limited by the apertures within metal masks, which are typically on the order of 25–100 μm, and, in sputtering systems by the sputter gas pressure and the distance from the source to the substrate. It is interesting to recall that shadow masking techniques were used in the 1960s for the manufacture of microelectronic devices including transistors with dimensions as small as ∼10 μm (Brody and Page, 1968; Brody, 1996). Shadow masks, often termed *stencil masks*, can be formed from silicon nitride membranes with dimensions as small as 10 nm and have been used to successfully define metal nanowires on this length scale (Deshmukh *et al*., 1999). Clogging of the apertures prevents the deposition of significant amounts of material.

In AlO_x-based MTJs, the AlO_x layers are usually formed either by depositing an aluminum layer followed by a subsequent oxidation, or by depositing Al in an oxygen atmosphere. The oxidation of the ultrathin Al layer, typically 6–15-Å thick, needs to be optimized to achieve a high TMR ratio. Excess oxidation of the Al layer leads to oxidation of the bottom ferromagnetic metal, which significantly influences the spin polarization of the interface states that contribute to tunneling. Deficient oxidation creates local electrically conducting paths (pinholes) in the insulator and degrades the quality of the barrier. Such pinholes are believed to provide conductive channels that are not spin polarized. A number of oxidation methods have been used to optimize the oxidation of the ultrathin Al layer. Plasma oxidation of the Al layer has been commonly used, since the optimum oxidation time to obtain high TMR ratio is usually faster compared to thermal oxidation. It has been found that annealing the MTJ typically increases the TMR ratio by improving the quality of the interfaces between the insulator and the ferromagnetic metal.

In a few years after 1995 the TMR of MTJs increased rapidly with values of up to ∼60% for MTJs with CoFe electrodes and up to ∼70% for MTJs with amorphous ferromagnetic electrodes formed by incorporating small amounts (10–25 at.%) of glass forming elements such as B, Zr, or Hf in the CoFe alloy. Interestingly, the magnitude of the TMR signal was found to be rather insensitive to the ferromagnetic electrode material (Parkin *et al*., 1999). Figure 4 shows a plot of TMR versus applied magnetic field for an MTJ with an AlO_x barrier and ferromagnetic electrodes formed from CoFe (lower electrode) and an amorphous ferromagnetic alloy (upper electrode) which shows a TMR of about 70% at room temperature. This is the maximum value of TMR which has yet been reported at room temperature for MTJs using an AlO_x barrier (Parkin unpublished; Wang *et al*., 2004; Sakuraba *et al*., 2005).

MTJs with other barrier materials, such as titanium oxide (TiO_2) (Bibes *et al*., 2003), aluminum nitride (AlN) (Sharma *et al*., 2000; Yoon *et al*., 2004), tantalum oxide (TaO_x) (Sharma, Wang and Nickel, 1999), strontium titanium oxide

(STO) (de Teresa *et al*., 1999a,b), and magnesium oxide (MgO) (Bowen *et al*., 2001; Faure-Vincent *et al*., 2003) have also been studied. TiO_2 barrier has found its way into application as a magnetic recording read head (Mao *et al*., 2006) owing to its ultralow resistance–area product. TaO_x and STO have been reported to show an inverse or negative TMR ratio, which will be briefly discussed in the following section.

The basic origin of TMR lies in the degree of spin polarization P of the tunneling current in the MTJ device. For many years this was considered to be related to the fundamental electronic structure of the ferromagnetic electrodes and, in particular, to the degree of spin polarization of the DOS at the Fermi energy of the electrodes. Similar to the two-current model of transport in ferromagnetic metals, the tunneling current in an MTJ device may be considered to be composed of independent majority and minority spin-polarized currents. Assuming that these currents are proportional to the corresponding spin-polarized DOS in the emitting and receiving magnetic electrodes, the TMR can be defined as $TMR = P_1P_2/(1-P_1P_2)$ where $P_{1,2}$ are the spin polarizations of the DOS of the two magnetic electrodes (Julliere, 1975; Meservey and Tedrow, 1994). In this simple model the TMR is determined solely by the electronic structure of the magnetic electrodes and is insensitive to the tunnel barrier properties. It has become clear recently that this model is much too simple and that the properties of the tunnel barrier and its interface with the magnetic electrodes are extremely important in determining the degree of spin polarization of the tunnel current and, consequently, the TMR, as discussed in the following sections.

3 INFLUENCE OF CHEMICAL BONDING ON SPIN-POLARIZED TUNNELING

It is well known in metal–insulator–metal (MIM) tunneling structures that the tunneling characteristics are strongly influenced by the electronic structure of the metal interface layers (Wolf, 1989). Similarly, in MTJs the interface electronic structure and the nature of the bonding between the ferromagnet (F) and the insulator are clearly very important. Indeed, it was long postulated that the positive sign (majority spin electrons) of the polarization of the tunneling current from Co and Ni ferromagnetic electrodes reflects the predominant tunneling of the more delocalized conduction band electrons with sp character rather than the more localized electrons with d character, even though the DOS near the Fermi energy of the latter is considerably higher (Stearns, 1977). Slight variations in the nature of the bonding between Fe and Co and oxygen in alumina tunnel barriers have been calculated to affect both the magnitude and sign of the polarization of the tunneling current (Tsymbal, Oleinik and Pettifor, 2000; Oleinik, Tsymbal and Pettifor, 2000). Unfortunately, the role of oxygen bonding is difficult to probe experimentally because of the ease of formation of TM oxides many of which are nonferromagnetic or antiferromagnetic.

An interesting system in which to explore the role of oxygen bonding on spin-dependent tunneling is TM alloys formed from Fe, Ni, and Co diluted with nonmagnetic elements, in conjunction with tunnel barriers which do and do not contain oxygen. Figure 5(a,b) compiles results on alloys of Co–Pt and Co–V with tunnel barriers formed from Al_2O_3 and AlN (Kaiser *et al*., 2005). The figure includes measurements of the spin polarization of the tunneling current measured by superconducting tunneling spectroscopy (STS) in ferromagnet-insulator-superconductor (FIS) junctions formed by replacing one of the ferromagnetic electrodes in an MTJ with a superconducting (S) layer of Al. Analysis of the voltage dependence of the conductance of such structures at temperatures well below the superconducting transition temperature of Al ($\sim$2 K) allows the direct determination of the tunnel current polarization (Meservey and Tedrow, 1994). The figure shows that for Al_2O_3 barriers the tunneling spin polarization (TSP) decreases rapidly when Co is diluted with V but hardly changes at all when Co is diluted with up to 50% Pt. When the Al_2O_3 barrier is replaced with AlN then the results are quite different. For the case of V the TSP now decreases more slowly as the Co is diluted with V but for the case of Pt the TSP decreases more quickly with increasing Pt concentration.

These results can be rationalized on the basis of the different strength of the chemical bonds formed between the metal electrodes and O or N in the barrier as illustrated schematically by the cartoon in Figure 5(c). Assuming that the tunneling process is highly localized in nature and that the tunneling current may vary significantly between neighboring atomic sites in the metal interface layer, the net tunneling current comprises currents tunneling from individual Co and Pt or V atoms. If we conjecture that these currents are directly related to the strength of the local chemical bonds formed at the interface with the tunnel barrier, then since Pt forms a much weaker bond with oxygen than Co does, we conclude that the tunneling current from Co–Pt alloys for alumina tunnel barriers will be dominated by tunneling from the Co atoms. If we further assume that the current from the Co component is spin polarized and that from Pt (or V) is not then we can model the dependence of the spin polarization of the tunneling current on the Co–Pt and Co–V concentrations, as shown in Figure 5(a,b). For Co–Pt/Al_2O_3 the experimental measurements can be fit with such a model if the probability of tunneling from Co is about 3.5 times higher than that from Pt. Perhaps coincidentally, this is nearly

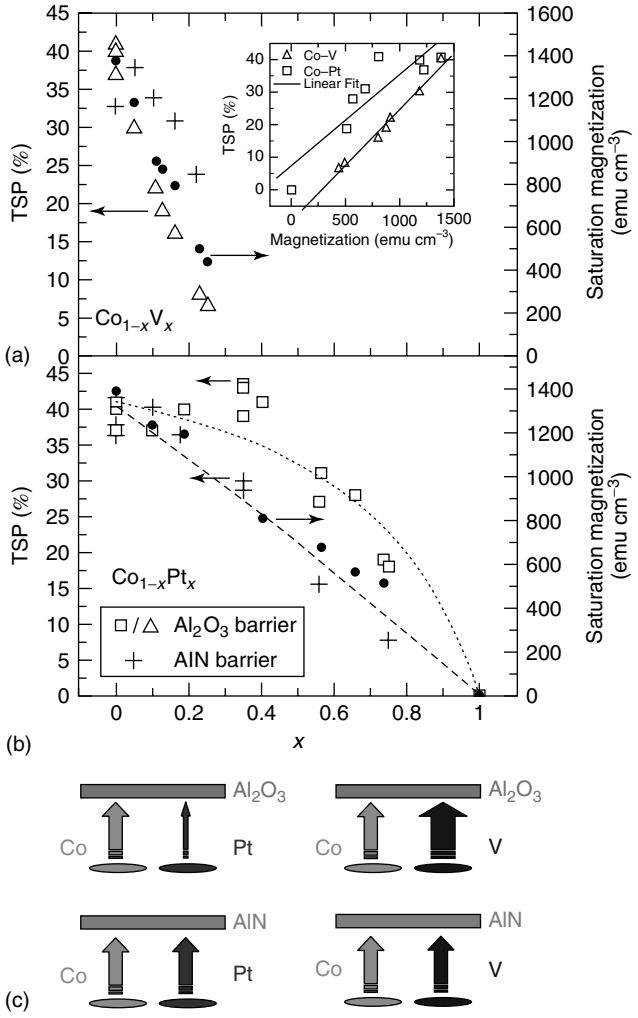

Figure 5. (a)Tunneling spin polarization at 0.25 K and magnetization at 5 K for (a) $Co_{1-x}V_x$ and (b) $Co_{1-x}Pt_x$ alloys as a function of the V and Pt atomic functions. The results show a tunneling probability from Pt sites that is ∼3.8 times lower than from Co sites for the case of Al_2O_3 barriers (dotted line) and ∼1.1 times lower for the case of AlN barriers (dashed line) (Kaiser *et al*., 2005). (c) Schematic representation of the relative magnitude of the tunneling currents from the constituent elements in Co–Pt and Co–V alloys for tunneling for Al_2O_3 and AlN tunnel barriers.

the same ratio as that of the strength of the Co–O to Pt–O bonds (as inferred from heat of enthalpies).

By contrast with Pt, V forms a much stronger bond with O than does Co so the same model would predict a fast decrease of TSP as the Co is diluted with V since the (non-spin-polarized) tunneling current from V would increase rapidly (faster than in proportion to the V concentration). This is as observed in Figure 5(a,b).

As mentioned above when $Al_2O_3$is substituted by AlN the dependence of TSP on Pt and V concentrations is quite different but the results are consistent with a model in which the local tunneling probability is related to the local chemical bonding. The bonding of Co, Pt, and V with nitrogen is quite weak so the TSP is then diluted approximately in proportion to the Pt and V concentrations, as is found experimentally (see Figure 5). These results suggest that the magnitude of the TSP and, consequently, the TMR can be strongly modified by 'chemically engineering' the bonding at the interfaces between the ferromagnetic electrodes and the tunnel barrier.

4 INFLUENCE OF WAVE-FUNCTION SYMMETRY ON SPIN-POLARIZED TUNNELING

The influence of the chemical bonds formed at the ferromagnet/insulator interface on the magnitude of the tunneling current can be described in terms of a tunneling matrix element. The tunneling current is proportional to the DOS multiplied by the corresponding tunneling matrix element. Similarly, the tunneling matrix elements will also be strongly influenced by the symmetry of the wave functions of the conduction band states in the ferromagnet. The electronic wave functions decay into the tunnel barrier evanescently with a decay length that depends on the symmetry of the wave functions. Thus states with a more delocalized character will decay less quickly into the tunnel barrier and so have a corresponding larger tunneling matrix element. This means that if the majority and minority spin-polarized conduction band states in the ferromagnet have significantly different symmetries then these states will decay at different rates across the tunnel barrier leading to an increased (or decreased) spin polarization of the tunneling current. Thus the tunnel barrier can act as a spin filter. This scenario was predicted for MTJs formed from single crystalline Fe/MgO/Fe sandwiches oriented in the (100) direction (Butler *et al*., 2001; Mathon and Umerski, 2001), where the Fe is bcc and the MgO simple cubic and the two lattices are rotated with respect to each other by 45° to allow for a nearly perfect epitaxial relationship.

Theoretical calculations of the electronic DOS at zero temperature in the Fe/MgO/Fe(100) system by Butler *et al*. (2001) are shown in Figures 6 and 7. Figure 6 shows the dependence of the transmission of electrons through a tunnel barrier composed of eight MgO (100) layers as a function of their in-plane momentum $k_{\|} = k_x + k_y$ parallel to the Fe/MgO/Fe interface. Results are shown for the majority and minority electron channels, for P orientation of the Fe layer magnetizations (a and b, respectively), and for electron transmission for AP orientation of the Fe moments (c). The most obvious feature is that the transmission probability is much higher in the majority than in the minority channel by about 3 orders of magnitude. This clearly shows that the

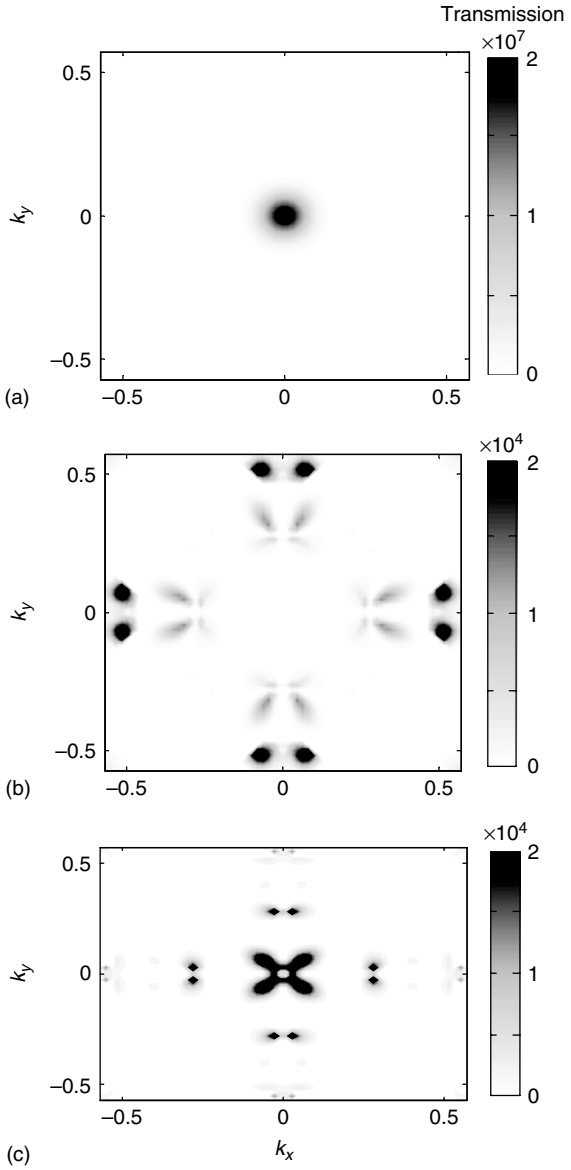

Figure 6. Majority (a), minority (b), and antiparallel (c) conductance versus the crystal momentum in the film plane for a (100) Fe/8 ML MgO/Fe structure (Butler *et al*., 2001). (American Physical Society.)

MgO barrier strongly spin filters the majority spin-polarized electrons even when just a few atomic layers thick. The origin of this spin-filtering effect is revealed by comparing the transmission probability of electrons in the various majority and minority bands at the Fermi energy. Figure 7 shows the calculated DOS for electrons incident from the left electrode for the individual majority and minority spin-polarized conduction bands. There is one majority spin-polarized band with Δ_1 symmetry, that is, with s angular momentum character that decays very slowly across the MgO barrier compared to the other majority spin-polarized

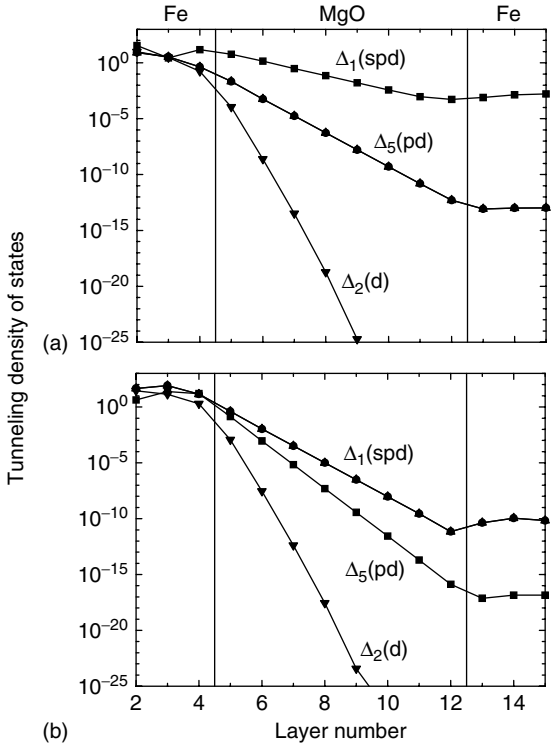

Figure 7. Tunneling density of states (TDOS) of the (a) majority and (b) minority channels at $k_\parallel = 0$ from Fe(100)/8 ML MgO/Fe(100) (Butler *et al*., 2001). (American Physical Society.)

bands and all the minority bands, which have predominant p and d wave-function symmetry. One can interpret this simplistically as the higher tunneling probability for the electrons in the more extended s-wave character states compared to the less extended p and d character states.

A second important feature shown in Figure 6 is the very different $k_\parallel$ dependence of the electron transmission probability in the majority and minority bands. In the majority band the electron transmission is very high close to the center of the Brillouin zone at $k_\parallel = 0$. This corresponds to that expected for free electrons incident on a thick tunnel barrier for which the electron transmission is decreased rapidly away from the forward direction because of an effective increase in the barrier thickness through which the electrons propagate. Note that the half-angle of the cone of the forward transmitted electrons increases as the barrier thickness is decreased. By contrast the $k_\parallel$ dependence of the transmission in the minority channel is quite unlike the simple free electron case and the transmission near the forward direction is very weak. Again this reflects the different wave-function symmetries in these channels.

In summary, for coherent tunneling of electrons through a single crystalline MgO(100) tunnel barrier, in which the electron momentum parallel to the interface is conserved,

very high TMR is expected, owing to the preferential transmission of majority spin-polarized electrons in the Δ_1 band. Fe Δ_1 states, which are highly spin polarized at the Fermi energy, couple with MgO Δ_1 evanescent states at $k_\parallel = 0$. The coupling between these states is very sensitive to details of the Fe–MgO interface. When the surface Fe layer is oxidized this coupling is calculated to be significantly weakened leading to a weakened spin-filtering effect (Zhang, Butler and Bandyopadhyay, 2003), namely, a tunneling matrix element effect.

Following the theoretical predictions of very high TMR values in (100) Fe/MgO/Fe a number of groups attempted to prepare single crystalline epitaxial thin-film Fe/MgO/Fe sandwiches and, although highly perfect structures were prepared, only modest TMR values were obtained for several years (Klaua *et al*., 2001; Bowen *et al*., 2001; Faure-Vincent *et al*., 2003; Mitani, Moriyama and Takanashi, 2003). In 2001 Parkin *et al*. used magnetron sputter deposition techniques to successfully prepare highly (100) textured, exchange biased MTJs with MgO(100)-oriented tunnel barriers which exhibited very high TMR values exceeding 180% (Parkin *et al*., 2004; Butler and Gupta, 2004). Nearly identical MTJ structures with amorphous alumina barriers exhibited much lower TMR values of ∼70%. These results are consistent with the theoretical predictions of Butler *et al*. (2001). With slight modifications of the structure reported in Parkin *et al*. (2004) even higher TMR values of more than 350% at room temperature and nearly 600% at helium temperatures are obtained, as discussed in Parkin (2006). These structures are useful technologically both because they are formed at room temperature using simple sputter deposition techniques and also because they are prepared on amorphous substrates – here an amorphous SiO_2 layer formed on Si(100). Other groups have obtained similar results in highly textured MTJs prepared on silicon oxide in closely related structures (Djayaprawira *et al*., 2005) with reported values of more than 450% TMR at room temperature (Ikeda *et al*., 2006).

A cross-section transmission electron micrograph of a typical MTJ is shown in Figure 8. Underlayers of TaN/Ta are deposited first on the SiO_2 substrate; they form a template on which grows a highly (100)-textured fcc antiferromagnetic exchange bias layer of $Ir_{76}Mn_{24}$. Subsequently, a reference ferromagnetic electrode of $Co_{70}Fe_{30}$is deposited, which is bcc and grows (100) oriented. The MgO barrier is formed by first depositing a thin layer of Mg, ∼4–6 Å thick, followed by the reactive sputter deposition of Mg in an ArO_2 plasma (∼2% oxygen) to form MgO. The Mg underlayer is used to prevent oxidation of the underlying ferromagnetic electrode but this layer is converted to MgO by the reactive oxygen introduced into the sputter chamber during the deposition of the MgO layer. Finally, a counterferromagnetic

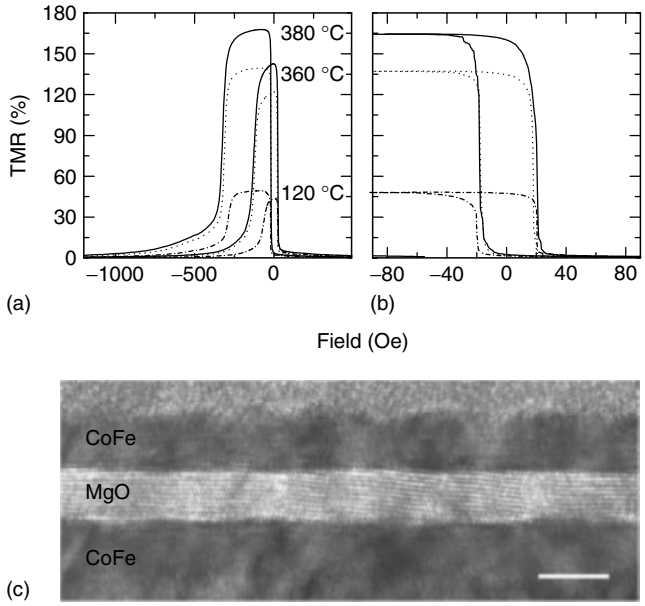

Figure 8. (a) Plots of TMR versus field for MTJs with structures of 100 TaN/250 IrMn/8 $Co_{84}Fe_{16}$/30 $Co_{70}Fe_{30}$/29 MgO/150 $Co_{84}Fe_{16}$/100 Mg. The corresponding final anneal temperature T_A, after which the data is measured at room temperature, is shown in the figure. (a) and (b) The major and minor loop, respectively. electrode is formed from a nominally amorphous alloy of $[Co_{70}Fe_{30}]_{80}B_{20}$. The TMR of this structure, as deposited, is modest (∼60–80% at room temperature) but on annealing at temperatures of up to 450 °C the TMR is significantly increased to values of more than 350% at room temperature (see Figure 8) (Parkin *et al*., 2004).

Giant TMR values have also been reported by Yuasa *et al*. (2004) in single crystal Fe/MgO/Fe(100) MTJs prepared by molecular-beam epitaxy on MgO(100) single crystalline substrates. Figure 9 shows the dependence of the TMR ratio measured at 20 and 293 K on the thickness of the MgO barrier. As predicted by theoretical calculations (Butler *et al*., 2001; Mathon and Umerski, 2001), the TMR ratio increases as the MgO thickness is increased. This is attributed to the suppression of the un-spin-polarized states in the Fe band contributing to the tunnel current at large MgO thicknesses. Surprisingly, the TMR ratio oscillates with the MgO thickness, with an oscillation period of 0.3 nm. This oscillation was interpreted as a consequence of coherent tunneling across the barrier, although the detailed mechanism is still under investigation.

Faure-Vincent *et al*. (2002) and Katayama *et al*. (2006) have studied the interlayer exchange coupling between the

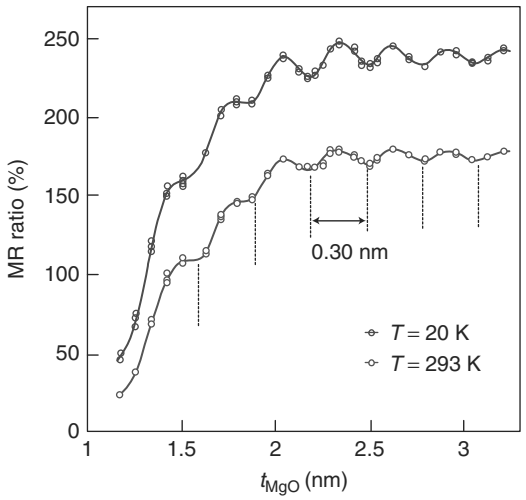

Figure 9. Tunnel magnetoresistance of Fe(001)/MgO(001)/Fe(001) junctions. MR ratio at $T = 293$ and 20 K (measured at a bias voltage of 10 mV) versus t_{MgO} is plotted. (Reprinted with Permission from S. Yuasa *et al*. Copyright 2004, Nature Publishing Group.)

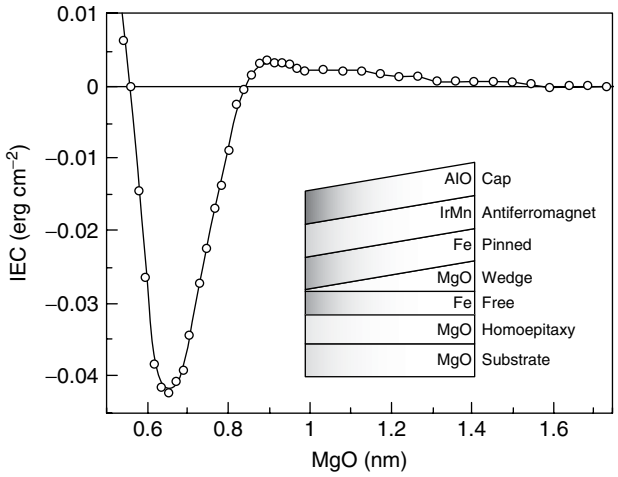

Figure 10. Interlayer exchange coupling versus MgO thickness measured for Fe(001)/MgO(001)/Fe(001) junctions. The thickness of the Fe free layer is 15 nm. Inset shows the cross section of the sample (Katayama *et al*., 2006). (American Physical Society.)

two ferromagnetic layers across an MgO barrier. When the spacer layer between the two ferromagnetic layers is a nonmagnetic metal, it is known that the exchange coupling oscillates with the thickness of the spacer layer between ferromagnetic and antiferromagnetic coupling (Parkin, More and Roche, 1990; Parkin, 1991). This coupling is mediated by the conduction electrons in the spacer layer, which is reminiscent of RKKY coupling (Bruno and Chappert, 1991; Bruno, 1995). When an insulating spacer layer is used, it is predicted that the exchange coupling is ferromagnetic and that it decays exponentially with the spacer thickness. Figure 10 shows the measured interlayer exchange coupling in MTJs consisting of a single crystal Fe/MgO/Fe. Interestingly, the exchange coupling is antiferromagnetic when the MgO thickness is in the range of 0.5–0.8 nm. From first-principle calculations, it was concluded that the coupling was mediated by oxygen vacancy states located within the MgO barrier (Zhuravlev, Tsymbal and Vedyayev, 2005).

5 RELATIONSHIP OF TUNNELING MAGNETORESISTANCE TO TUNNELING SPIN POLARIZATION

The fundamental origin of TMR is the spin polarization of the tunneling current. Therefore, the measurement of the magnitude and sign of the TSP is very important for further understanding of TMR (Julliere, 1975). The spin polarization can be probed by a variety of techniques such as photoemission (Feder, 1985; Dedkov, Rüdiger and Güntherodt, 2002), point-contact Andreev reflection (Soulen *et al*., 1998) and STS (Meservey and Tedrow, 1994). Photoemission experiments determine the unweighted DOS at the Fermi energy and, therefore, for the 3d TM ferromagnets, are sensitive mainly to the contribution of the d electrons, whereas most of the tunneling current is due to electrons from the more extended sp bands (Gadzuk, 1969). Andreev reflection measures the magnitude (but not the sign) of the polarization of electrons at a diffusive interface between the ferromagnetic metal and a superconductor, whereas MTJs involve electrons tunneling across a thin dielectric layer. The STS technique uses a superconducting electrode (S) in the presence of a large magnetic field to detect both the magnitude and the sign of the spin polarization of current tunneling from a ferromagnetic electrode (F) at the Fermi energy across an insulating layer (I) in FIS junctions. Thus, STS is the technique most closely related to spin-dependent tunneling in MTJs.

Figure 11 illustrates the superconducting DOS in a magnetic field as well as the conductance of a FIS junction. Note that the Zeeman splitting of the quasiparticle states due to the applied magnetic field parallel to the surface of the superconducting counterelectrode displaces the spin-up and spin-down DOS peaks of the superconductor by $2\mu_B H$. Thus the conductance curve in the presence of a magnetic field has four peaks with the peak height being asymmetric with respect to zero bias. Note that the inner two peaks are due to predominantly one spin component of the tunneling electrons from the ferromagnetic electrode, either spin up or spin down. The degree of the asymmetry between these two peaks is a measure of the TSP from the ferromagnet.

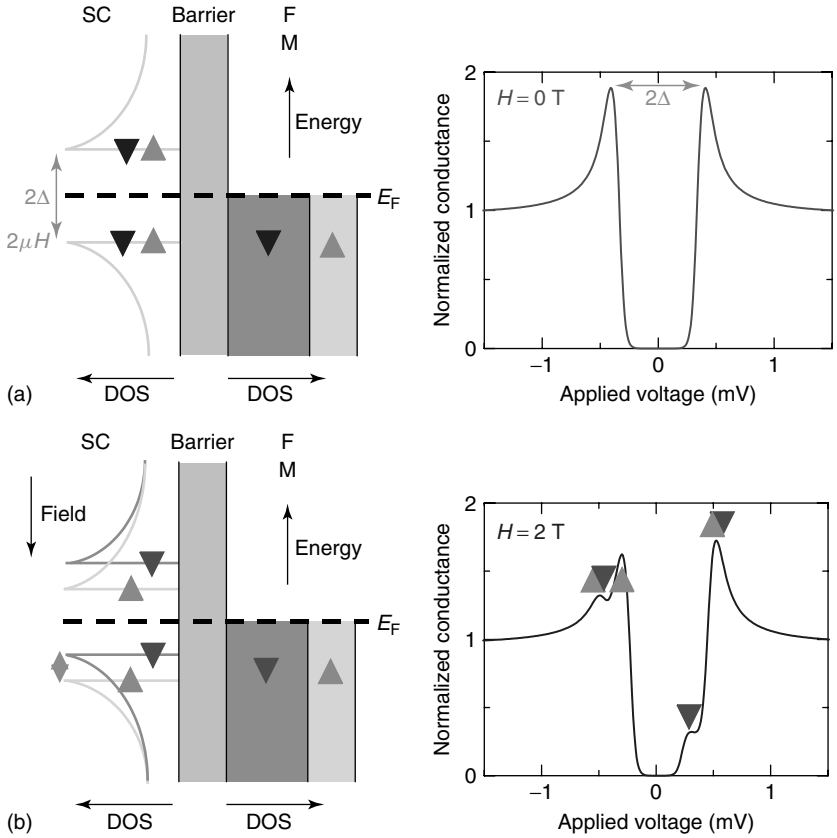

Figure 11. Superconductor–insulator–ferromagnet tunneling at zero magnetic field (a) and at 2 T (b). The figures on the left illustrate the DOS of a BCS superconductor and a ferromagnetic metal. The figures on the right show the theoretical normalized conductance from such a junction.

The STS technique was first developed by Meservey and Tedrow using aluminum superconducting electrodes (Meservey and Tedrow, 1994) and has been applied to many ferromagnetic and ferrimagnetic metals including the 3d TMs and many of their alloys (Kaiser *et al*., 2005), the rare-earth (RE) metals (Meservey and Tedrow, 1994) and RE–TM alloys (Kaiser, Panchula and Parkin, 2005). Al has been widely used ever since this early work because Al has a low spin-orbit scattering, a high superconducting critical field (∼4 T), and readily forms an insulating barrier (Al_2O_3). However, the measurements must be made at low temperatures (<0.4 K) since the superconducting critical temperature of Al is typically below ∼2.5 K. It is possible to use other superconducting electrodes. Using NbN superconducting electrodes STS measurements can be made at higher temperatures (∼1.2 K) without the need for a ^{3}He cryostat (Yang *et al*., 2006).

For many years, the determination of TSP was based simply on using four values of the conductance at the four nominal peak positions (Meservey and Tedrow, 1994; Tedrow and Meservey, 1973). This method tends to overestimate the polarization, thereby requiring a more accurate method of analysis (Worledge and Geballe, 2000). Later, spin-orbit scattering and orbital depairing in the superconductor were taken into account by using the DOS derived by Maki (1964).

Meservey and Tedrow determined the TSP of Co, Fe, and Ni as well as alloys of these elements (Meservey and Tedrow, 1994; Paraskevopoulos, Meservey and Tedrow, 1977). Results are shown in Figure 12 together with TSP data from Monsma and Parkin (2000) and the magnetic moments per atom from the Slater–Pauling curves (Cullity, 1972). Monsma and Parkin's values of TSP are slightly higher than those of Meservey and Tedrow's; this can be attributed to improved sample preparation. Ni and Ni-rich alloys appear to have low TSP values as compared to Fe- and Co-rich alloys, but this is likely due to problems in creating a high-quality interface with aluminum oxide tunnel barriers. Indeed, recent experiments have found TSP values for Ni that are much higher and similar to those of Co and Fe (Nadgorny *et al*., 2000; Kim and Moodera, 2004).

The TSP is measured to be positive for Co, Fe, and Ni as well as for all their alloys. This is not consistent with the spin-polarized DOS in the bulk band structure of Co and Ni at the Fermi energy in which the density of filled states is higher for minority spin-polarized electrons. Moreover, an

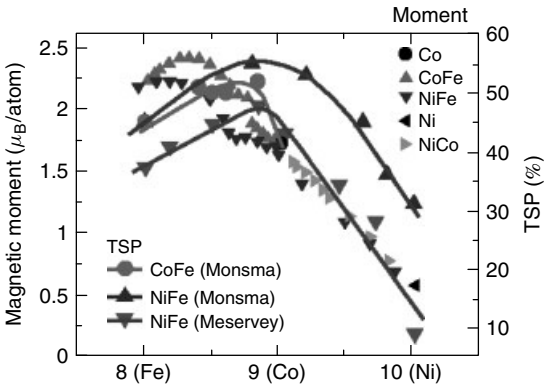

Figure 12. Tunneling spin polarization and magnetic moment per atom for different Co–Fe and Ni–Fe alloys. TSP data from Meservey and Monsma are shown for comparison with the Slater–Pauling curves (Monsma and Parkin, 2000; Cullity, 1972). (American Physical Society.)

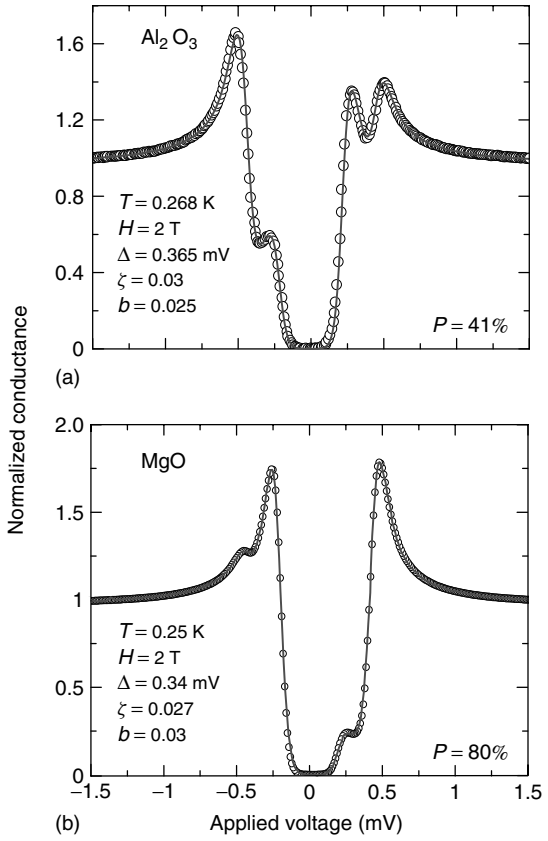

Figure 13. Conductance versus bias voltage curves (symbols) and fits (solid lines) from the structure of (a) AlSi/AlO_x/Co and (b) $Co_{70}Fe_{30}$/MgO/AlSi. The measurements were taken at ∼0.25 K in a field of 2 T applied in the plane of the films. The values for the TSP were extracted by fitting the data curves with the following fitting parameters indicated in the figure: superconducting gap Δ, depairing parameter ζ, and spin-orbit parameter b.

approximately linear relationship between magnetic moment per atom and spin polarization was found by Paraskevopoulos *et al*. who measured the spin polarization of ferromagnetic alloys comprising Ni diluted with the paramagnetic elements Cr, Cu, Mn, and Ti (Paraskevopoulos, Meservey and Tedrow, 1977). Since magnetization and spin polarization have very different physical origins, such a simple proportionality would be surprising. Indeed, for Ni alloys, this relationship appears to be derived from the decreasing tendency of oxidation of Ni as impurities are added to the metal. Indeed, with improved deposition techniques, and vacuum deposition systems with much lower base pressures, the TSP of Ni, Fe, Co, and their alloys has steadily increased over the years since the early measurements in the 1970s. Moreover, as discussed in Section 3 the dependence of the TSP on the magnetic moment of Co and Fe alloys is very sensitive to the diluent (Kaiser *et al*., 2005).

Using conventional amorphous alumina tunnel barriers TSP values of up to ∼55% (Monsma and Parkin, 2000) are found for conventional 3d ferromagnets, such as CoFe, but using highly textured crystalline MgO tunnel barriers TSP values of more than 85% (Parkin *et al*., 2004) can be achieved for otherwise the same ferromagnet, as illustrated in Figure 13. Such TSP values rival those previously observed only with half-metallic ferromagnets (Parker *et al*., 2002).

The magnitude and the sign of the TMR are strongly influenced by the electrode and tunnel barrier materials as well as the barrier/ferromagnet interface structure and chemistry. A particularly interesting example is that of the work by de Teresa *et al*. (1999b) who studied the magnetotransport properties of MTJs with one ferromagnetic electrode formed from a single crystalline thin film of the perovskite, $La_{1-x}Sr_xMnO_3$, which is nominally a majority spin-polarized half-metal, an epitaxial tunnel barrier formed from $SrTiO_3$, and a counterelectrode formed from a conventional 3d TM, cobalt. As shown in Figure 14, this MTJ device exhibits a negative TMR at zero bias, that is, the resistance is lowest when the $La_{1-x}Sr_xMnO_3$ and the Co moments are antiparallel to each other. Since the manganite is known to have only majority spin-polarized electrons at the Fermi energy (Park *et al*., 1998), de Teresa *et al*. concluded, therefore, that the polarization of the empty Co states into which the electrons tunnel across the $SrTiO_3$ barrier in the AP configuration must be predominantly *minority* spin polarized. This is exactly the opposite sign of polarization for electrons tunneling to and from Co through amorphous alumina tunnel barriers. de Teresa *et al*. argue that the $SrTiO_3$ barrier preferably favors tunneling of electrons with d character rather than the s character as in alumina because of the d character provided by the Ti. This interpretation is subject to some debate. For example, Oleinik, Tsymbal, and Pettifor (2002) suggest that

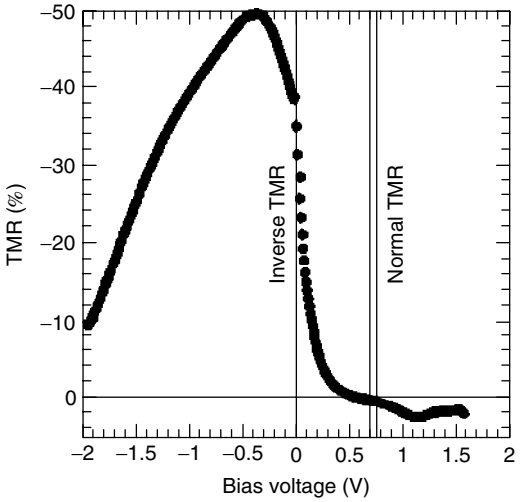

Figure 14. Bias dependence of the TMR ratio in Co/STO/LSMO tunnel junction. (Reprinted with permission de Teresa *et al*. copyright 1999, AAAs.)

the inversion of the TMR sign could be due to the formation of moments on the Ti atoms in the $SrTiO_3$ barrier which they calculate are exchange coupled antiparallel to the Co moments in the electrode. Another possibility is that defects in the tunnel barrier can give rise, through resonant tunneling, to an inversion of the TMR, as calculated by Tsymbal *et al*. (2003). Indeed, Sharma, Wang, and Nickel (1999) using composite tunnel barriers formed from bilayers of Ta_2O_5/Al_2O_3, and $Ni_{80}Fe_{20}$ electrodes, report a voltage dependence of TMR similar to that of de Teresa *et al*. They find negative TMR values, albeit small values of just a few percent, for electrons tunneling into the $NiFe/Ta_2O_5$ interface, which they find is strongly dependent on the oxidation time used to form the barrier, perhaps indicating the role of defects.

Another interesting system with regard to the relationship between TMR and TSP is tunnel junctions formed with RE–TM alloys, in particular, ferrimagnetic alloys formed from Co and Fe, and the RE metal Gd. In these alloys, which are amorphous, the TM moments are aligned antiparallel to that of Gd. These alloys show both negative and positive TSP, depending on their composition, and, the temperature, as shown in Figure 15 (Kaiser, Panchula and Parkin, 2005). This behavior that can be understood from the stronger temperature dependence of the magnetization of the RE subnetwork compared to that of the TM subnetwork, and the larger RE moment compared to the TM moment at low temperatures. Thus, there is a compensation temperature where the RE and TM subnetwork magnetizations exactly balance and the alloy has a zero net magnetization. Correspondingly, there is a compensation composition of the alloy at a given temperature where the net moment goes through zero as the RE/TM ratio is varied. As the temperature or composition

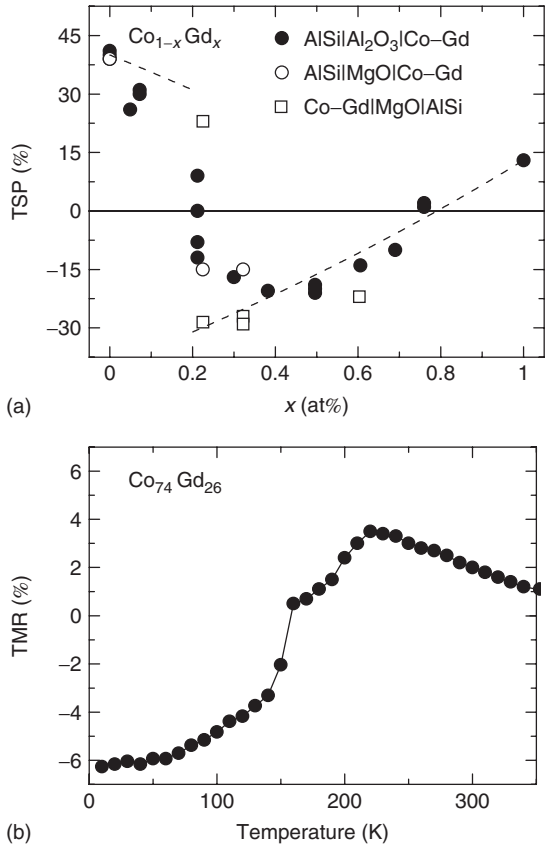

Figure 15. (a) TSP for Co–Gd alloys with various compositions. The line is a fit to the data. (b) TMR versus temperature for an MTJ with a $Co_{70}Fe_{30}$ electrode and a 50-Å thick $Co_{74}Gd_{26}$ counterelectrode (Kaiser, Panchula and Parkin, 2005). (American Physical Society.)

is varied through the corresponding compensation point, the sign of the TSP changes but the magnitude of the TSP is observed to be substantial at the compensation point when the net moment of the alloy goes to zero. This illustrates that a magnetic material can, in principle, have zero magnetization but a finite spin polarization, clearly proving that the two quantities are not related to one another in any simple way.

By inserting a thin CoFe layer at the interface between a CoFeGd alloy and a MgO tunnel barrier, large negative TMR values of $\sim -50\%$ can be achieved at room temperature (Kaiser and Parkin, 2006). The high negative spin polarization, as well as the tunable coercivity, amorphous structure, and low uniaxial anisotropy of RE–TM alloys make them promising candidates for use in MTJ-based devices, such as flux-closed double-tunnel junctions for MRAM memory cells (Kaiser and Parkin, 2006).

The Julliere relationship shown in equation (3) indicates that the magnitude of the TMR ratio diverges when the spin polarization of the ferromagnetic electrode approaches 100%. This is one of the reasons why half-metallic ferromagnets

have been of considerable interest in recent years. There are several classes of half-metals, as discussed in **Half-metals, Volume 4**, which can be both minority spin polarized, as, for example, magnetite (Fe_3O_4) (Walz, 2002; Ziese, 2002), and majority spin polarized, as, for example, $La_{1-x}Sr_xMnO_3$, mentioned in the preceding text. MTJs with $La_{1-x}Sr_xMnO_3$ electrodes and $SrTiO_3$ (and $CaTiO_3$) barriers have been demonstrated to show very high TMR values, exceeding ∼1000% (Sun *et al*., 1998; Bowen *et al*., 2003), but only at low temperatures. Though the Curie temperature of $La_{1-x}Sr_xMnO_3$ is close to or just above room temperature (depending on the oxygen concentration and the Sr dopant concentration), the TSP has a much stronger dependence than the magnetization, and typically falls to zero at about half the Curie temperature, for reasons which are not fully understood.

Recently, several groups have reported substantial TMR ratios in MTJs formed with Heusler alloy electrodes (Park *et al*., 1998; Webster, 1969; Kubler, Williams and Sommers, 1983; Galanakis, Dederichs and Papanikolaou, 2002). Heusler alloys are a large class of ternary intermetallic compounds with the chemical formula X_2YZ, which have been predicted to be half-metallic. Sakuraba *et al*. (2005) have fabricated Co_2MnSi/AlO_x/CoFe MTJs, which display a TMR ratio of 70% at room temperature, which is comparable to the highest TMR ratios reported in MTJs with TM electrodes and AlO_x tunnel barriers. They have successfully grown highly oriented Co_2MnSi layers on single crystal MgO substrates. Theoretical calculations predict that Co_2MnSi with the $L2_1$ crystal structure can achieve nearly 100% spin polarization, but chemical disorder or the formation of other crystal structures, such as B2 and A2, can significantly affect the spin polarization (Galanakis, Dederichs and Papanikolaou, 2002; Picozzi, Continenza and Freeman, 2004). Therefore, in addition to providing a clean interface between the ferromagnetic electrode and the insulator, the highly textured $L2_1$-ordered Co_2MnSi was essential to finding a high TMR ratio.

A number of other reports on MTJs using various Heusler alloys have been reported including alloys such as Co_2MnAl (Sakuraba *et al*., 2006a), Co_2FeSi (Gercsi *et al*., 2006), $Co_2FeAl_{0.5}Si_{0.5}$ (Tezuka *et al*., 2006a,b), and $Co_2Cr_{0.6}Fe_{0.4}Al$ (Marukame *et al*., 2007). It is interesting to note that the TMR ratio is very sensitive to the temperature in many MTJs with Heusler alloy electrodes. It is interesting that this is similar to the case of MTJs with manganite electrodes. For example, Sakuraba *et al*. (2006a) find that an MTJ formed with a Co_2MnAl electrode and a MgO barrier displays a TMR ratio of 570% at 4 K, but that this is more than eight times higher than its room-temperature value (see Figure 16). The large TMR ratio at low temperature indicates that Co_2MnAl is nearly half-metallic. In addition, bias-voltage-dependent conductance measurements revealed that the energy gap (Δ) between the Fermi level and the bottom of the minority spin conduction band is only ∼10 meV (Sakuraba *et al*., 2006b), which is more than two times smaller than the thermal fluctuation energy at room temperature (26 meV). The drop of the TMR ratio at the temperature is thus associated with thermal mixing of the spin state of the

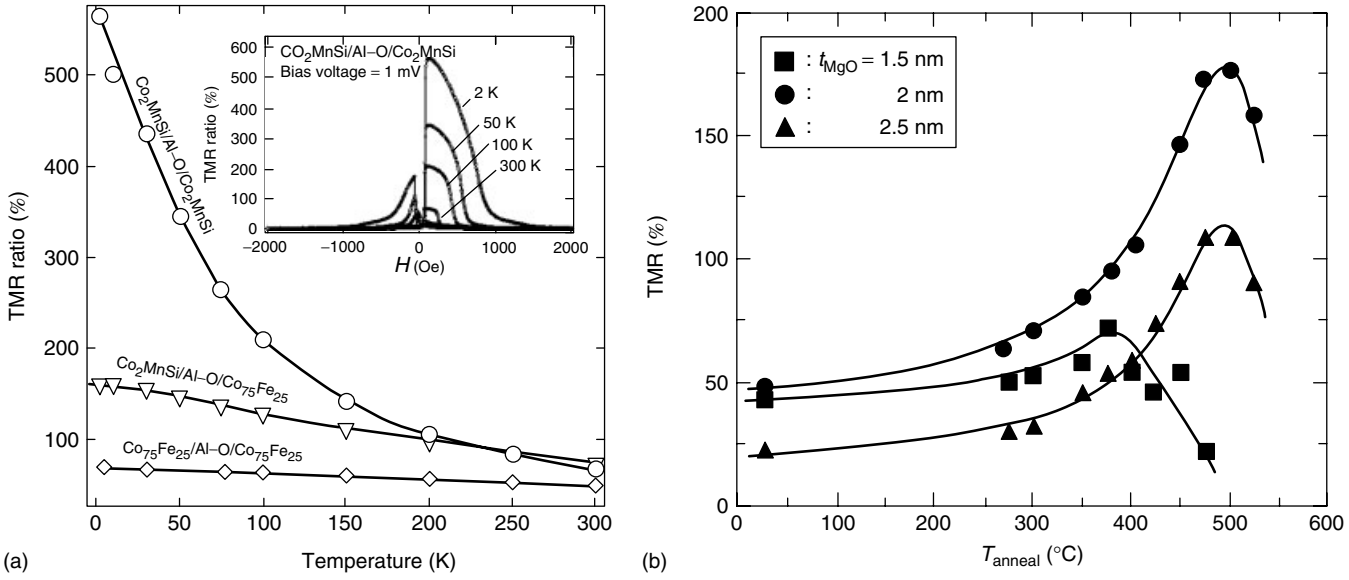

Figure 16. (a) Temperature dependence of the TMR ratio for $Co_2MnSi/Al-O/Co_2MnSi$ MTJ. TMR curves at the corresponding temperature are shown in the inset. All measurements were conducted under an applied bias voltage of +1 mV (Sakuraba *et al*., 2006a). (b) Annealing temperature dependence of TMR measured at RT for an MTJ consisting of 30-nm $Co_2FeAl_{0.5}Si_{0.5}/t_{MgO}$ MgO/5-nm $Co_2FeAl_{0.5}Si_{0.5}$/3-nm $Co_{75}Fe$/15-nm $Ir_{22}Mn_{78}$/Ta (Tezuka *et al*., 2006b). (American Physical Society.)

electrons, which thereby obscures the half-metallic nature of the Heusler alloy. Increasing the energy gap Δ by varying the composition of the Heusler alloy leads to half-metallic behavior at higher temperatures. Indeed, TMR values exceeding $\sim$100% at room temperature have recently been reported by several groups (Tezuka *et al*., 2006b; Marukame *et al*., 2007). The highest TMR values to date at room temperature have been reported in MTJs with $L2_1$-$Co_2FeAl_{0.5}Si_{0.5}$ full Heusler alloys for both electrodes and a MgO tunnel barrier (Tezuka *et al*., 2006b).

6 TEMPERATURE AND BIAS VOLTAGE DEPENDENCE OF TMR

In many MTJs the magnitude of the TMR decreases strongly with increasing temperature. There are several possible mechanisms that can be responsible for such an effect including thermally excited magnons in the ferromagnetic electrodes, thermal excitation of magnetic impurities or defects in the tunnel barrier or at the electrode/barrier interfaces, and thermal variations of the electronic structure at elevated temperatures. These effects give rise to a decrease in the interfacial magnetization and, thereby, the spin polarization (MacDonald, Jungwirth and Kasner, 1998; Shang *et al*., 1998; Moodera, Nowak and van de Veerdonk, 1998; Bratkovsky, 1998). A strong temperature dependence of the TMR is often related to a poor quality of the interface between the ferromagnetic electrode and the tunnel barrier. Since the most commonly used tunnel barriers are oxides, small amounts of excess oxygen, for example, oxygen physisorbed on the surface of the oxide barrier before deposition of the ferromagnetic electrode, can result in oxidation of ferromagnetic metal electrodes. Since oxides of Ni and Co are antiferromagnetic, and several oxides of Fe are antiferromagnetic, any oxidation of the electrode is likely to lead to a decrease in the spin polarization of the tunneling current. This is likely to be strongly temperature dependent because of the comparatively low Neel temperatures of the antiferromagnetic oxides. 'Loose' spins can readily depolarize the tunneling current.

It is interesting to note that the temperature dependence of the tunneling current is usually much weaker in the P as compared to the AP alignment of the magnetic electrodes as shown in Figure 17. In the case of MgO tunnel barriers, the temperature dependence of the junction resistance for P alignment of the ferromagnetic electrodes is almost negligible compared to that of Al_2O_3 barriers. In both barriers, most of the increase in the TMR at lower temperatures is due to the increase in the resistance of the AP state.

Most MTJs show a substantial decrease of TMR as the bias voltage is increased. Zhang *et al*. (1997) proposed that this was due to inelastic scattering by magnon excitations at the ferromagnet/insulator interface. When hot electrons tunnel from one electrode across the insulating barrier into the opposing ferromagnet/insulator interface, they may lose their energy by emitting a magnon, which may result in flipping of the electron's spin. More magnons are created with increasing bias voltage, resulting in reduced TMR values. The energy dependence of the spin polarization of the DOS in the ferromagnetic electrodes due to details of their band structure, especially the magnitude of the exchange splitting and the energy width of the exchange split bands, will also reduce the TMR at high bias (Moodera, Nowak and van de Veerdonk, 1998).

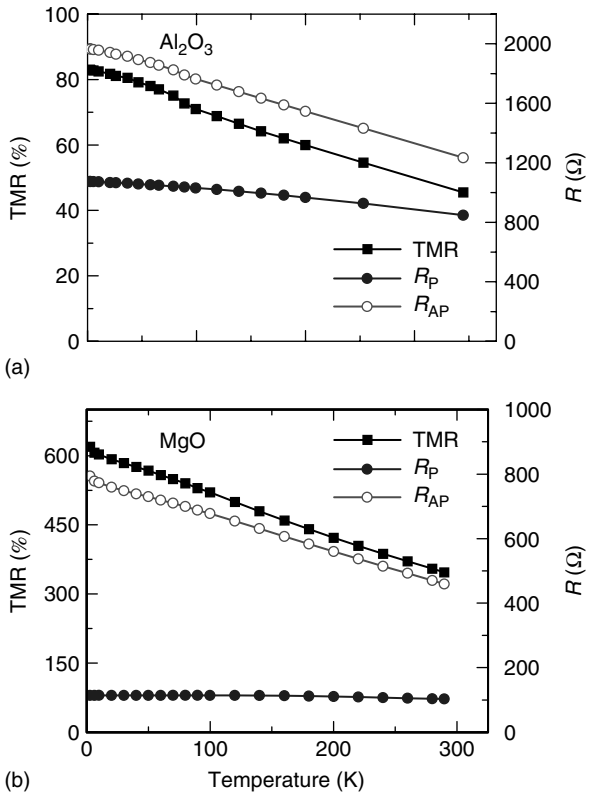

Figure 17. (a) Temperature dependence of TMR, parallel (R_P) and antiparallel (R_{AP}) resistance of (a) Ta/IrMn/CoFe/26 AlO_x/CoFe and (b) Ta/IrMn/CoFe/MgO(100)/CoFe.

Ding *et al*. (2003) reported the absence of a zero-bias anomaly and an almost constant TMR with bias voltage for spin-polarized electron tunneling between a Co(0001) surface and an amorphous magnetic tip across a vacuum barrier using a scanning tunneling microscopy technique. The zero-bias anomaly, very often observed in planar tunnel junctions with insulator barriers, was therefore attributed to defect scattering from localized states in the barrier, rather than to magnon creation or spin excitations at the interfaces (Zhang and White, 1998; Tsymbal, Mryasov and LeClair, 2003). Planar

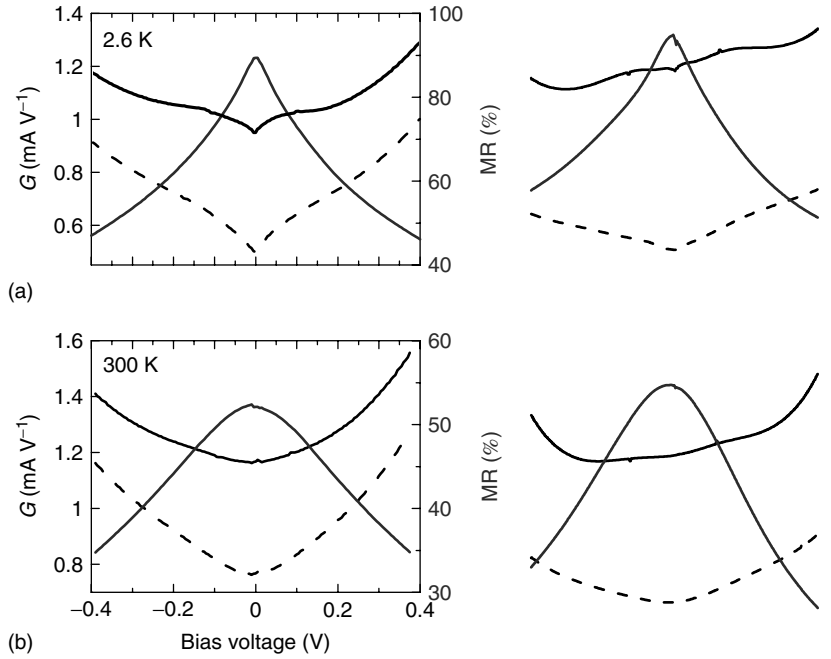

Figure 18. Conductance and TMR curves for MTJs with AlO_x barrier measured at (a) 2.6 K and (b) room temperature.

tunnel junctions often contain significant defects within the barrier and at its interfaces which can lead to significant decreases in the effective tunneling barrier height (Rippard, Perrella and Buhrman, 2001).

The bias voltage dependence of TMR should be symmetric with regard to positive and negative voltages when the magnetic electrodes are identical, and the barrier is symmetric in shape. Figure 18 shows typical bias voltage dependences of TMR and conductance for Al_2O_3 (left panels) and MgO (right panels) barriers at 2.6 K and room temperature. The Al_2O_3 barrier shows a symmetric bias dependence while the MgO does not, which may be due to the different growth methods (Al_2O_3: plasma oxidation, MgO: reactive sputtering). At low temperatures, both barriers display zero-bias anomalies in the P configuration but MgO does not show as prominent a zero-bias anomaly as Al_2O_3 in the AP configuration. Also the prominent broad valleys in conductance at $\sim$0.27 V are shown for P configuration in MgO barrier; these may be ascribed to the coherent tunneling of certain symmetries as mentioned in the preceding text.

The TMR of MTJs decreases with increased voltage and temperature. This is thought to be due to inelastic tunneling from phonons and magnons at the interface between the ferromagnetic electrode and the insulator, and impurities both at these interfaces and within the interior of the tunnel barrier, which may result in flipping of the electron spin and so a decrease in the spin polarization of the tunneling electrons. The predominant elastic tunneling, where incident electrons from one electrode tunnel through the barrier without loss of energy to the opposite electrode, gives rise to a significant background of the conductance versus voltage curve. It is thus important to clarify the relationship between the tunnel conductance and the interface structure of an MTJ. Inelastic electron tunneling spectroscopy (IETS), is the measurement of $\mathrm{d}^2I/\mathrm{d}V^2$ versus V and was first developed by Jaklevic and Lambe (1966). This is a very sensitive spectroscopic technique, which has been used to study the electronic structure of chemical compounds and complexes incorporated within insulating barriers, as well as the detailed electronic nature of interfaces within MIM tunnel junctions. The observation of both the vibrational as well as electronic spectra (defects, impurities, magnons, and phonons) has been carried out. Higher-order derivatives of the conductance versus voltage curves often reveal peaks at energies corresponding to those of the inelastic tunneling channels, where incident electrons lose energy inside the tunnel barrier or at the barrier/electrode interfaces.

A typical measurement is shown in Figure 19 for both Al_2O_3 and MgO barriers. The IETS signal from the AP configuration compared to the P configuration is large and more sensitive to the spin-dependent scattering, indicating that the spin-flip inelastic excitations are dominant for the AP configuration. In case of Al_2O_3, typical phonon spectra of the Al (33 mV) and the Al–O longitudinal optical (LO) modes (20 and 120 mV) were observed as shown in Figure 19(a). For MgO barriers in Figure 19(b), typical phonon spectra for the MgO optical (O) phonon at 27 mV (Klein *et al.*, 1973) and the MgO LO surface mode at 83 mV (Plesiewicz

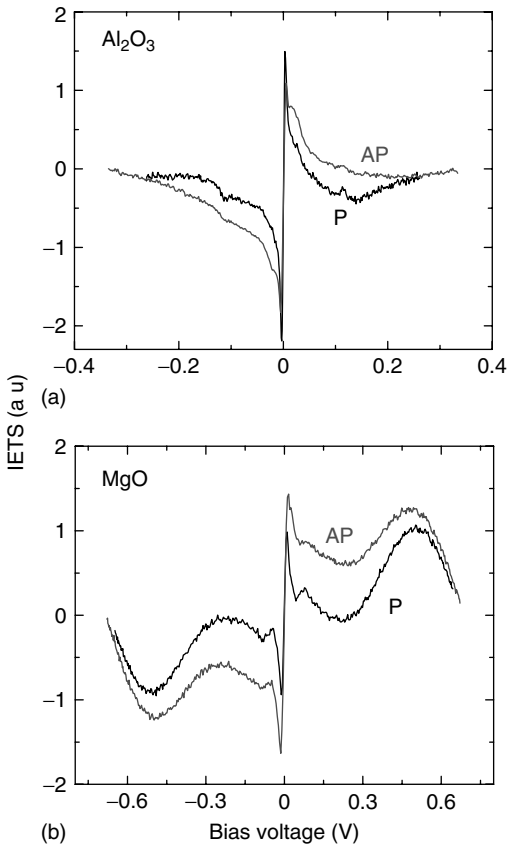

Figure 19. (a) Inelastic tunneling spectroscopy (IETS) of (a) CoFe/AlO_x/CoFe and (b) CoFe/(100)MgO/CoFe measured at 2.8 K.

and Adler, 1986) were observed. Huge peaks around zero bias from both orientations result from magnon excitations, which are reported to be absent with nonmagnetic electrodes (Moodera, Nowak and van de Veerdonk, 1998; van de Veerdonk, Moodera and de Jonge, 1999; Han *et al*., 2001). The broad peaks appearing around 500–600 mV have never been observed in the MTJs with Al–O tunnel barriers. The high-energy peaks reveal the information on the wave-function-dependent conductance channels in MgO that are related to the opening of the additional conduction channels when the applied bias is higher than the band edge of that spin Δ_x band (Ando *et al*., 2005).

7 SPIN-DEPENDENT TUNNELING IN OTHER SYSTEMS

When a tunnel barrier is itself a ferromagnetic insulator the tunnel barrier height will be different for spin-up and spin-down electrons. This means that the tunneling current will be spin filtered since the probability of tunneling is extremely sensitive to the barrier height. This is a very efficient method for polarizing current even when the metal electrodes are nonmagnetic and is of interest for spin injection into semiconductors without the need for ferromagnetic metal electrodes. However, it has so far been difficult to create MTJs with useful properties because of the difficulty of independently setting the magnetic moment direction of the insulating barrier and that of one of the metallic electrodes, which is required to observe a TMR effect. One recent example is that of Leclair *et al*. (2002) who reported a TMR ratio of more than 100% at 7 K in an MTJ with a barrier formed from EuS with one nonmagnetic electrode formed from Al and one ferromagnetic electrode formed from Gd. However, the magnetic switching characteristics of this device were quite poor. Moreover, since EuS has a very low Curie temperature, well below room temperature, this material is not useful for applications at room temperature and above.

Finally, we briefly discuss spin-dependent tunneling in granular systems. Owing to the quantized nature of electron charge, a tunneling current is associated with a series of events in which individual electrons tunnel across a barrier. Consequently, Coulomb interaction of electrons can significantly influence the tunneling process. Consider a double barrier tunnel junction, where the electron has to first tunnel through the first barrier and land on a middle electrode before tunneling through the second barrier. Suppose that the middle electrode is temporarily occupied by the preceding electrons that tunneled through the first barrier. In order for the next electron to tunnel through the first barrier, it has to overcome the charging energy associated with the Coulomb interaction with the other electrons placed in the middle electrode. This effect is called *Coulomb blockade*, in which the Coulomb interaction 'blocks' the electron from tunneling through a barrier. The magnitude of this charging energy is inversely proportional to the size of the middle electrode. Consequently, it is possible to trap a single electron in the middle 'island' (electrode) by reducing the island size such that the charging energy exceeds the thermal fluctuation energy. Double-tunnel junction devices capable of trapping a single electron in the middle island are typically called *single electron transistors*, since the middle island can act as a gate, which controls the tunneling current between the two barriers. Intensive efforts have been made to create useful single electron transistors, in particular, by using semiconductor quantum dots.

The Coulomb blockade effect has been observed in tunnel junctions using ferromagnetic granular nanoparticles as the middle islands (Mitani *et al*., 1998; Zare-Kolsaraki, Hackenbroich and Micklitz, 2002). Granular nanoparticles can be formed, for example, by cosputtering aluminum and gold in an oxygen atmosphere (Barsadeh *et al*., 1994), which results in segregated gold particles embedded in the

aluminum oxide matrix since gold is inert to oxygen. Typical diameter of the nanoparticles is in the range of a few nanometers with a relatively large distribution. A number of groups have reported observation of the Coulomb blockade effect via nanoparticles embedded in an insulating matrix.

Coulomb blockade is a pure charge effect of the electrons. Recently, the role of the spin degree of freedom on single electron tunneling has attracted great interest. In particular, much theoretical work has been carried out on the prediction of the TMR ratio for the case of single electron tunneling (Barnas and Fert, 1998; Takahashi and Maekawa, 1998). Experimentally, Yakushiji *et al*. have reported oscillations of the TMR ratio with the bias voltage across the barrier in MTJs with Co nanoparticles embedded in an AlO_x layer (Yakushiji *et al*., 2005). Interestingly, the TMR ratio was observed to oscillate between −10 and 15% when the voltage was increased from 0 to ∼0.2 V. This oscillation was attributed to an oscillation of the position of the Fermi level lying between either the majority or the minority spin states which are discretized due to the geometrical confinement of the nanoparticle.

Spin accumulation occurs frequently in magnetic/nonmagnetic hybrid systems. For example, when electron flows from a nonmagnetic layer to a ferromagnetic layer, electrons whose spin direction are opposite to the magnetization direction of the ferromagnetic layer will be reflected from the layer. Consequently, electrons with a certain spin direction will pile up at the interface of the magnetic/nonmagnetic layer. This effect can occur, for example, in current perpendicular to the plane (CPP) GMR devices.

8 CONCLUSION

Spin-dependent tunneling junctions have a long history dating back to more than 30 years but it is only in the past decade that MTJs with significant values of TMR at room temperature have been fabricated. A detailed understanding of the relationship of the TMR and the corresponding spin polarization of the tunneling current to the ferromagnetic and tunnel barrier materials forming the MTJ is developing. It is clear that it is not simply the electronic structure of the ferromagnetic electrode that determines the magnitude of the spin-dependent tunneling. Rather the spin polarization of the tunneling current can be strongly modified by tunneling matrix elements that themselves depend on chemical bonding at the ferromagnet/tunnel barrier interface and also on the symmetry of the conduction band wave functions. This means that magnetic metals which are only weakly magnetic can give rise, by suitable wave function or chemical bond engineering, to highly spin-polarized currents. Conversely, strongly magnetic metals may give only very weakly spin-polarized tunnel currents. An important conclusion is that the TSP is not related in any simple way to the magnetization of the magnetic electrodes. For example, RE–TM ferrimagnetic electrodes with no net magnetic moment can give rise to highly spin-polarized tunneling current (Miyazaki and Tezuka, 1995).

MTJs have a promising future both as highly sensitive field sensors and as magnetic memory storage elements (Parkin *et al*., 2003). By contrast with metallic spin-valve sensors whose magnetoresistance is limited to 10–20% at room temperature there is no theoretical limit to the TMR of MTJs. Whilst the very high TMR of >350% at room temperature observed with crystalline MgO tunnel barriers is very attractive for sensing and memory applications it seems likely that new materials with even higher magnetoresistance values will be found in the future which could have even wider technological applications.

Spin Angular Momentum Transfer in Magnetoresistive Nanojunctions

Jonathan Z. Sun
IBM T.J. Watson Research Center, Yorktown Heights, NY, USA

1 INTRODUCTION

Spin-angular momentum transfer (or spin transfer for short) concerns the influence of a spin-polarized current on its host magnetic conductor. This phenomenon originates from the exchange of angular momentum between a spin-polarized current and the magnetization – a concept that has been developing over the years (Berger, 1978, 1984, 1988, 1992, 1996; Hung and Berger, 1986; Bazaliy, Jones and Zhang, 1998), which resulted in the theoretical prediction of the spin-current-induced magnetic excitation and reversal (Slonczewski, 1989, 1996), and its quantitative experimental verification (Katine *et al*., 2000; Albert, Katine, Buhrman and Ralph, 2000).

A sketch for the basic concept of spin-transfer effect is shown in Figure 1. The lower left corner of the figure presents a two-ferromagnet layered spin-valve structure. A current passes through the left ferromagnet (F1) and becomes spin polarized. When it passes through the second, thinner ferromagnet on the right (F2), the spin polarization of the current may have to change direction, depending on the relative alignment of the magnetization between F1 and F2. This is illustrated at the upper left of the figure. Here N denotes a nonmagnetic conductor, or in the case of a magnetic tunnel junction (MTJ), the N between F1 and F2 could also be a tunnel barrier.

In essence, it is the repolarization process that causes F2 to experience an effective torque. This spin-current-induced torque, or spin torque for short, appears along the same direction as the damping torque experienced by the precessing F2. The spin torque can either be in the same direction as the damping or in the opposite direction, depending on the direction of current flow and the relative spin orientation between F1 and F2. When the spin torque is in the direction opposite to the damping of F2, the magnetization would amplify any deviation from its equilibrium state. When the spin torque is sufficiently strong, this amplification process can cause F2 to precess with an ever-increasing cone angle going past $\pi/2$, eventually settling into the opposite direction, causing a complete magnetic reversal. The situation for reversed current direction is a bit more complex, but the net spin torque on F2 remains proportional to the current, and the reversal process remains essentially the same.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

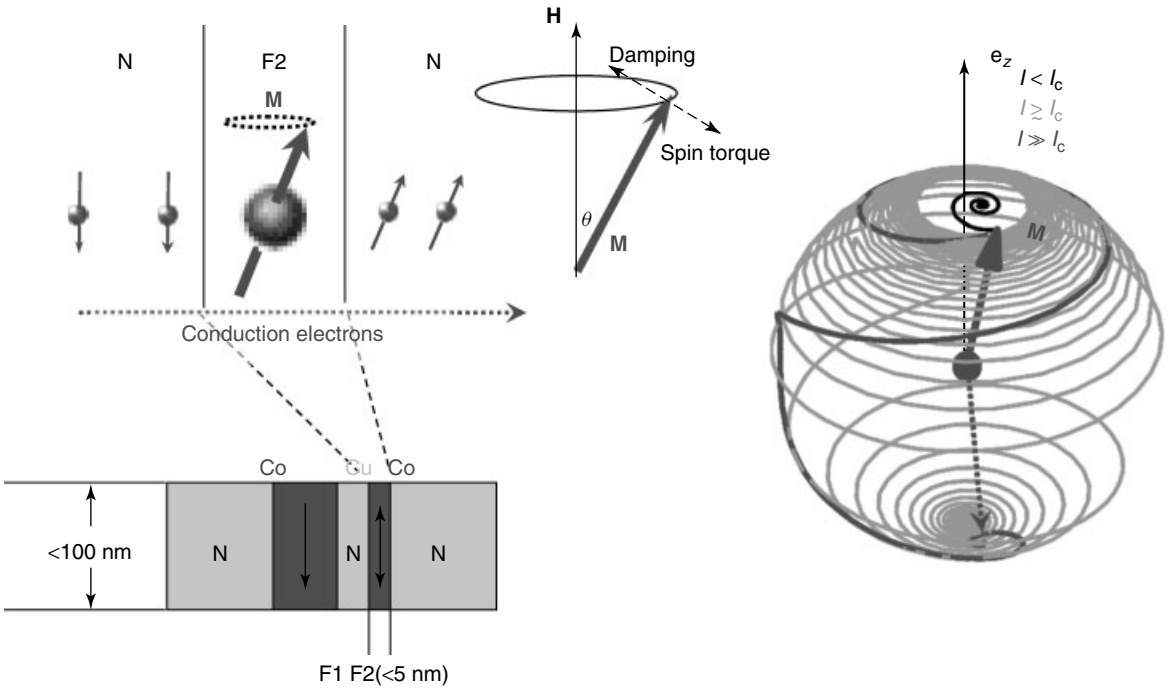

Figure 1. An illustration of the spin-torque-related dynamics for a macrospin. A uniaxial anisotropy is assumed along the $\mathbf{e}_z$ axis, as is an applied magnetic field **H**.

The presence of a spin torque affects the magnetotransport problem at many levels. The spin torque is, first of all, microscopic and quantum mechanical in nature. The collective effect of a spin-polarized current brings a torque on the ferromagnetic conductor carrying the current. The response of the ferromagnet to this torque would in turn affect the current transport, making it in general a complex coupled system. Fortunately, in most cases, the timescales are quite different between the magnetodynamics of the ferromagnet (which tends to be around the ferromagnetic resonance frequency or of the order of tens to hundreds of picoseconds) and that of the spin-polarized electronic transport process, which involves spin-flip lifetimes of the order of several picoseconds or less (Levy, 2002). This allows for an effective separation of the two processes, and a meaningful definition of a spin torque when used in the context of a description of the magnetodynamics of the ferromagnet, with the torque strength characterizable by phenomenological parameters such as the spin polarization of the current and the instantaneous angle between the two ferromagnets (F1 and F2 in Figure 1). These phenomenological parameters can in principle be derived from first-principle transport theories. The same set of parameters can also be used as input for the description of the (slower) magnetodynamics of the ferromagnet electrodes. For detailed analysis of the relationship between the spin torque and the microscopic transport properties of given materials systems, readers are referred to more advanced discussions presented in Bazaliy, Jones and Zhang (1998); Slonczewski (1996, 1999, 2002), Stiles and Zangwill (2002a,b), Bauer, Tserkovnyak, Huertas-Hernando and Brataas (2003), Stiles, Xiao and Zangwill (2004), Waintal, Myers, Brouwer and Ralph (2000), and Polianski and Brouwer (2004).

Here we focus on the macroscopic consequences of spin torque. We present a brief description of the magnetodynamics of a macrospin as it experiences the action of a spin torque. We then survey a series of experiments on the effect of spin torque, including the observation of an instability threshold current for spin-torque-induced magnetic precession and reversal, and a spin-torque-driven amplification of thermal fluctuation.

2 ZERO-TEMPERATURE MACROSPIN DYNAMICS

A macrospin model treats a nanomagnet with the assumption that its internal magnetic degrees of freedom are frozen. The only relevant parameters are the total magnetic moment **m** and the magnetic anisotropy energy $U(\theta, \varphi)$, where θ and φ are the polar-coordinate angles of **m**. The physical shape of the nanomagnet is relevant only in that its related shape demagnetization energy contributes to the total anisotropy energy function $U(\theta, \varphi)$.

2.1 Macrospin dynamics and the presence of a spin-torque term

The macrospin dynamics without the presence of a spin torque is well described by the classical Landau–Lifshitz–Gilbert (LLG) equation (Lifshitz and Pitaevskii, 1981)

$$\left(\frac{1}{\gamma}\right)\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = \mathbf{m}\times\mathbf{H} - \left(\frac{\alpha}{\gamma m^2}\right)\mathbf{m}\times\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} \qquad (1)$$

Here $\mathbf{m}$ is the magnetic moment of the macrospin, $\gamma = g\mu_\mathrm{B}/\hbar \approx 2\mu_\mathrm{B}/\hbar$ is the gyromagnetic ratio, and α is the LLG damping coefficient. The first term in equation (1) describes the magnetic-field-induced torque on a magnetic moment $\mathbf{m}$. The second term describes damping.

When a spin-polarized current passes through a ferromagnetic electrode that is $\mathbf{m}$, $\mathbf{m}$ will attempt to repolarize the current in the direction of its magnetization, $\mathbf{n}_m$. In the process, some of the angular momentum from the electron spins will be absorbed by $\mathbf{m}$. This exerts a net torque on $\mathbf{m}$.

For a nanomagnet $\mathbf{m}$ within which magnetization is uniform, the transverse component of spin torque is (Slonczewski, 1996)

$$\Gamma = -g\left(\mathbf{n}_m, \mathbf{n}_\mathrm{s}\right)\left[\frac{\hbar}{(2e)}\right]\left(\frac{\eta I}{m^2}\right)\left(\mathbf{n}_\mathrm{s}\times\mathbf{m}\right)\times\mathbf{m} \qquad (2)$$

where $\mathbf{n}_m$ is the unit vector direction of $\mathbf{m}$, $\mathbf{n}_\mathrm{s}$ is the direction of spin polarization of the incoming current, and $\eta = \left(I_\uparrow - I_\downarrow\right)/\left(I_\uparrow + I_\downarrow\right)$ is the spin-polarization factor, where $I_\uparrow$ and $I_\downarrow$ are the majority and minority spin-polarized currents with their polarization axis $\mathbf{n}_\mathrm{s}$ defined by the polarizing magnet (F1 in Figure 1). $g\left(\mathbf{n}_m, \mathbf{n}_\mathrm{s}\right)$ is a numerical prefactor that describes the angular dependence of the efficiency of spin-angular momentum transfer, originating from the dependence of net spin polarization of the current on the relative orientation of the two ferromagnets. Because the net spin polarization depends on the exact arrangements of the electrodes, so does $g\left(\mathbf{n}_m, \mathbf{n}_\mathrm{s}\right)$ (Slonczewski, 1996; Stiles and Zangwill, 2002a; Waintal, Myers, Brouwer and Ralph, 2000). For all-metal spin valves, the detailed angular dependence of $g\left(\mathbf{n}_m, \mathbf{n}_\mathrm{s}\right)$ is model dependent, and is microscopically never an angle-independent quantity. Its macroscopic form as seen in real materials systems relates to the angular dependence of magnetoresistance (MR), and is to be established experimentally.

The case of a constant $g\left(\mathbf{n}_m, \mathbf{n}_\mathrm{s}\right) \equiv 1$ describes a spin current whose polarization is independent of the relative angle, and the macrospin simply redirects the spin-current polarization direction, and in the process completely absorbs its transverse angular momentum. For simplicity of discussion, on a semiquantitative level, we assume a constant $g\left(\mathbf{n}_m, \mathbf{n}_\mathrm{s}\right)$, and use equation (2) as the basic interaction that enters the magnetodynamics equation for the motion of the macrospin. The LLG equation (Lifshitz and Pitaevskii, 1981) with the spin-torque term therefore is

$$\left(\frac{1}{\gamma}\right)\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = \mathbf{m}\times\left[\mathbf{H} - (\alpha/m)\,\mathbf{m}\times\left(\mathbf{H} + \frac{\eta\hbar I}{2em\alpha}\mathbf{n}_\mathrm{s}\right)\right] \qquad (3)$$

Equation (3) can also be viewed as a local constitutive equation for magnetodynamics studies including the nanomagnet's internal degrees of magnetic freedom. Together with an exchange-stiffness term, the vector field equation then describes the dynamics of the nanomagnet in continuous medium limit, a special case of which is when the nanomagnet is a thin film with thickness much smaller than the lateral dimensions and the exchange length. In this case, the in-plane degrees of magnetic freedom can be taken into account by replacing $\mathbf{H} \to \mathbf{H} + (D/2\mu_\mathrm{B})\,\nabla^2\mathbf{n}_m$, where $\nabla^2 = \partial_x^2 + \partial_y^2$ with x, y being the in-plane position coordinates, D the exchange-stiffness constant, and $\mathbf{n}_m = \mathbf{M}/M$ the local direction of magnetization $\mathbf{M}$ at point (x, y).

2.2 Threshold current for magnetic amplification

For simple geometries and under a macrospin approximation, equation (3) can be linearized and solved for its stability boundary. For a thin, free-layer nanomagnet in a collinear geometry, with its uniaxial anisotropy field's easy axis aligned to that of the field applied in the film plane, and the easy-plane anisotropy sharing its easy plane with the film plane, this gives a stability threshold current I_c of (Slonczewski, 1996; Sun, 1999, 2000a)

$$I_\mathrm{c} = \left(\frac{2e}{\hbar}\right)\left(\frac{\alpha}{\eta}\right)m\left(H + H_k + 2\pi M_\mathrm{s}\right) \qquad (4)$$

Here α is the LLG damping coefficient, $m = (abt)\,M_\mathrm{s}$ is the total magnetic moment of the free layer, with a, b as its lateral dimensions and t its thickness. M_s is the saturation magnetization of the free layer (F2). H_k is the uniaxial anisotropy field.

Equation (4) gives a current threshold, above which the *linearized* LLG equation becomes unstable over time, and a net gain of precession cone angle results. While comparing with experimental results, however, effects of large cone-angle precession often need to be carefully taken into account, since the development of an initial cone-angle increase as dictated by a linear stability threshold may not necessarily lead to complete magnetic reversal (Sun, 2000a). Although in many simple geometries, such as systems with uniaxial-only anisotropy or thin-film nanomagnets with a strong easy-plane anisotropy due to demagnetization and a

moderate in-plane uniaxial anisotropy, oftentimes the linear stability threshold does lead to the reversal of the magnetic moment.

There are several other factors that determine the experimentally observable switching current, making the simple stability threshold expression equation (4) insufficient. Chief among these factors is finite temperature. Other uncertainties include the relatively poor knowledge of the actual LLG damping coefficient for a particular device structure, and that of the exact spin-polarization value η. Detailed calculations for specific spin-transport models would give rise to additional angular dependences of spin torque as a function of the relative orientation between F1 and F2. The damping coefficient α may also become angle dependent, especially for large-angle dynamics.

A simple way of comparing equation (3) with experiment is to examine the intercept-to-slope ratio of the experimentally observed threshold boundary $I_c(H)$, defined as $R_{IS} = I_c(0)/(\mathrm{d}I_c/\mathrm{d}H)$. For equation (4), $R_{IS} = H_k + 2\pi M_s$. Early experimental data, mostly measured quasistatically over the timescale of less than a few milliseconds, appears to consistently underestimate the value of R_{IS}, by almost an order of magnitude (Sun *et al.*, 2003; Sun, Kuan, Katine and Koch, 2004). This is because equation (4) represents the zero-temperature stability threshold. With finite temperature, additional thermal agitation is present, making the apparent threshold current lower and also causing it to give a differently shaped $I_c(H)$, resulting in smaller R_{IS} (Sun, Kuan, Katine and Koch, 2004), as will be discussed later.

2.3 Size consideration: why is spin torque most visible only in nanomagnets?

There are two known mechanisms that can cause interaction between a magnetic moment and a transport current: current-induced magnetic field (the Oersted field) and spin-polarized current-induced spin torque. A current-induced magnetic field for a wire of radius r would give a relation between the maximum field (usually around the surface of the wire) and the current passing through the wire I. From Maxwell's equations, the relation is $I = (c/2)\,rH$ (in Gaussian units, c is the speed of light). A spin valve of similar lateral size ($2r$) would have a spin-torque threshold current of the order (following equation (4)) of $I_c \approx (H + H_k + 2\pi M_s)\left(4r^2 t\right) M_s\,(\alpha/\eta)\,(2e/\hbar)$. The spin-torque threshold is proportional to r^2, and the Oersted field–related current is (for a given threshold field, such as the anisotropy field H_k) proportional to r. Thus, at large dimensions, the threshold from the Oersted field is the lower threshold. The crossover point is roughly (for high-moment thin films like cobalt with $H \sim H_k \ll 2\pi M_s$)

$$r_c \sim \left(\frac{c\hbar}{4e}\right)\left(\frac{\eta}{\alpha}\right)\left(\frac{1}{M_s t}\right)\left(\frac{H_k}{2\pi M_s}\right) \tag{5}$$

which gives for 30-Å-thick cobalt, an $r_c \sim 0.04\,\mu\mathrm{m}$, assuming a spin-polarization factor of $\eta \approx 0.1$, a damping coefficient $\alpha \approx 0.01$, and $H_k \sim 100\,\mathrm{Oe}$. Thus, a practical crossover dimension for a pillar-structured, cobalt-based spin valve is of the order of $2r_c \sim 0.1\,\mu\mathrm{m}$, below which the spin-torque effect is more significant. For larger spin polarization or for free-layer materials with different moment and anisotropy, the crossover dimensions may be larger. For example, spin-transfer-induced magnetic switching has been observed in MTJs with sizes around $0.1 \times 0.2\,\mu\mathrm{m}^2$ (Pakala *et al.*, 2005; Kubota *et al.*, 2005a).

3 EARLY EXPERIMENTAL EVIDENCE OF SPIN-CURRENT-INDUCED MAGNETIC EXCITATION

Spin-torque-induced magnetic excitation has been experimentally observed in many different systems. Earlier experiments (Berger, 1978, 1984, 1988), for example, illustrate the effect of a carrier electron's spin-angular momentum on abrupt magnetic domain walls. Slonczewski (1996) predicted the presence of a spin torque from spin-polarized current in a metallic magnetic multilayer geometry. Experiments show current-induced magnetic excitation in point-contact junction on giant-magnetoresistance (GMR) multilayers (Tsoi *et al.*, 1998, 2000; Myers *et al.*, 1999), and magnetic switching in highly spin-polarized manganite junctions (Sun, 1999). These experiments reveal the sometimes dramatic effect of the spin torque, leading to the quantitative, experimental observation of the spin-transfer-induced magnetic reversal (Sun, 1999), and the eventual unambiguous experimental demonstration (Katine *et al.*, 2000) of the reversal and magnetic excitation effects in lithographically defined nanomagnet spin-valve junctions.

Tsoi *et al.* (1998) showed that magnetic excitation can be the result of bringing a point-contact tip made of silver in contact with a multilayered Cu|Co|Cu|Co . . . thin film. The current density under the point contact is high enough to exceed the spin-torque excitation threshold. As a consequence, an excitation and reversal of magnetic moment results – most likely only for the first cobalt layer. This manifests itself as a step in the point-contact junction's current–voltage (IV) characteristics. The threshold voltage (or current, since the junction is basically a linear resistor with only small nonlinear deviations) varies linearly with

the magnetic field, which is applied perpendicular to the film surface and is large enough to overcome the easy-plane demagnetization field of cobalt (which is about $4\pi M_s \approx 17.6\,\text{kOe}$). This linear dependence of threshold current on applied field is consistent with equation (4), although in this geometry the threshold refers to the generation of spin waves irradiating away from the point contact, as analyzed by Slonczewski (1999). The spin-wave radiation through exchange-stiffness coupling contributes to a finite intercept of the threshold current versus magnetic-field line, which was also subsequently confirmed by experiments (Rippard, Pufall and Silva, 2003).

Another possible interpretation of this data is the presence of a voltage threshold for spin-wave (magnon) emission at a certain energy, with the voltage threshold determined by the Zeeman splitting, $V_c \approx (g\mu_B/e)\,H$. Why these two apparently different interpretations may have some intrinsic relationship remains an intriguing subject (Sun *et al*., 2005).

Another form of the point contact onto magnetic layers was done by Myers *et al*. (1999). In this experiment, a special substrate with a SiN membrane was used, with a nanometer-size hole lithographically fabricated into the SiN membrane. The magnetic multilayers were then deposited on one side of the wafer, and the metal point contact (copper in this case) was deposited *in situ* on the other side, forming a metallic constriction contact through the SiN hole, and thus a point-contact junction. There, they not only observed signatures of magnetic excitation, but also observed current-induced, hysteretic magnetic reversal.

Earlier, current-induced magnetic reversal was observed in manganites-based all-oxide trilayer magnetic junctions. The junction is $1 \times 2\,\mu\text{m}^2$ in size, although the actual current path is likely to be much smaller, perhaps of the order of several hundred angstroms. Later, more systematic measurements of junctions with similar behavior were carried out, as the junction switching behavior was found to be consistent with a spin-transfer-induced magnetic reversal process (Sun, 1999, 2000b). The phenomena in these manganite-based junctions occur only in a small fraction of junctions prepared. The phenomenon is likely to have originated from interface-inhomogeneity-related current paths, and the switching occurs only for those junctions where the interface inhomogeneity is at the right place with the right size. These particular junctions, while rare, did switch with a well-defined threshold current (Sun, 1999), whose value showed a systematic dependence on applied magnetic field, in ways consistent with a simple spin-angular momentum transfer model (Slonczewski, 1996; Sun, 1999).

Other experiments during this period explored the interplay between spin-polarized current and the magnetic-field-driven reversal in nanomagnet electrodes. An example was the work by Wegrowe *et al*. (1999), where an electroplated Ni wire, 80 nm in diameter and about 500 nm in length was used. The experiment demonstrated a shift in the threshold magnetic field for a resistance-field hysteresis loop when a $10^7\,\text{A cm}^{-2}$ pulsed current was present. The change of threshold field was about 100 Oe at 0.15 mA of current pulse, larger than any induced magnetic field the current could generate. The authors argue that the spin-polarized current affects the magnetic reversal threshold field.

The quantitative proof of a spin-transfer-induced magnetic reversal was shown in all-metal current-perpendicular (CPP) spin-valve nanomagnets in 1999 by Katine *et al*. (2000) and Albert, Katine, Buhrman and Ralph (2000). Their experiments used electron-beam lithography to define a CPP spin-valve nanopillar, about 100 nm across in lateral dimension. An example of one such junction device is given in Figure 2.

A clear signature of magnetic reversal was seen, driven by current with a threshold current density around $\text{mid}-10^7\,\text{A cm}^{-2}$. The threshold current demonstrated the characteristic linear dependence on applied magnetic field with a slope consistent with spin-transfer model prediction (Katine *et al*., 2000; Albert, Katine, Buhrman and Ralph, 2000).

4 MAGNETOTRANSPORT OF A SPIN-VALVE-BASED SPIN-TRANSFER JUNCTION

4.1 Quasistatic magnetoresistance properties

For a spin-valve-based magnetic junction, its MR response to the combined effect of an applied magnetic field H and a bias current I shows distinctively different response regions that can be readily identified in the (I, H) parameter space.

Such MR measurement is usually taken in a quasistatic setup (with measurement response time at 1 ms or slower). A dc-bias current is applied to the junction. Often the junction resistance is measured by an ac lock-in method by superimposing a small ac current on top of the dc bias. This method is particularly useful when the junction MR is only a small percentage of the resistance. In a typical quasistatic measurement in our lab, the bias current is stepped at a rate around $0.1-1\,\text{mA min}^{-1}$, while the magnetic-field sweep rate (if swept) is of the order of $100-1000\,\text{Oe min}^{-1}$.

Generally speaking, the resistance response is hysteretic against both applied-field sweep and bias-current sweep. The values of the switching threshold current I^+ and I^-, corresponding to the resistance high-to-low and low-to-high switching thresholds, are functions of the applied magnetic field and the current history.

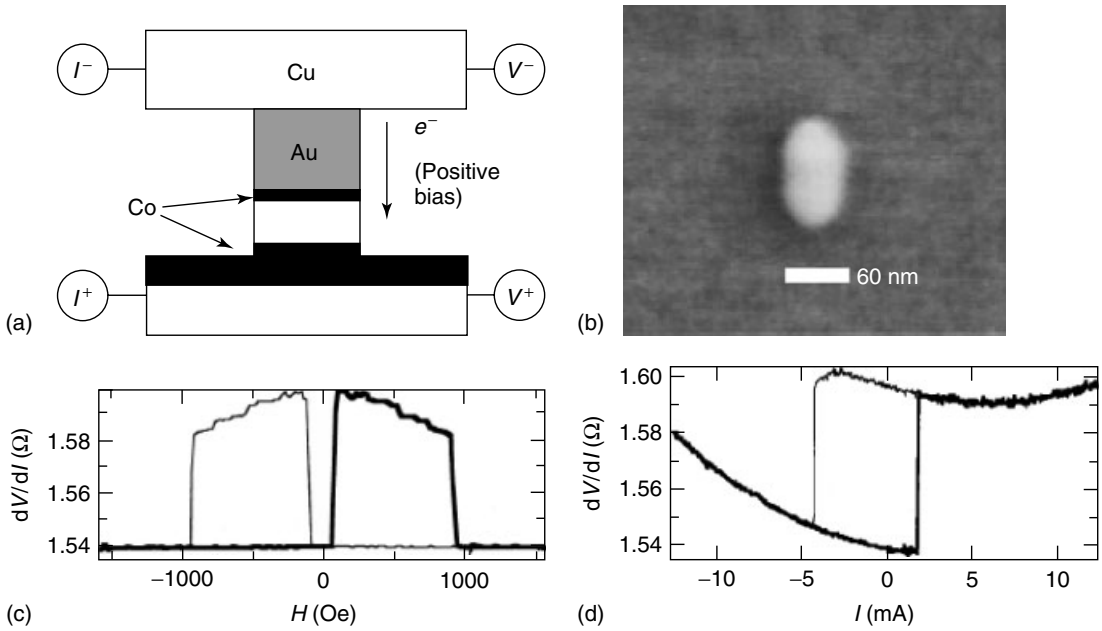

Figure 2. Current-induced reversal of magnetization in a current-perpendicular spin valve. The first definitive proof of current-induced magnetic switching was shown by Katine *et al*. (2000) in 1999 using a structure similar to the one shown in (a). The lateral size of the junction range from the earlier 120 nm or so in diameter (Katine *et al*., 2000) to the later geometry of $70 \times 120\,\mathrm{nm}^2$ (Albert, Katine, Buhrman and Ralph, 2000), as shown in the scanning electron micrograph (SEM) in (b). The resistance versus magnetic field sweep is shown in (c), and the resistance versus bias-current sweep is shown in (d). Resistance corresponds to $\mathrm{d}V/\mathrm{d}I$ measured using a lock-in detection method with an ac-bias current superimposed on the dc-bias current. (Reused with permission from F.J. Albert, J.A. Katine, R.A. Buhrman and D.C. Ralph, *Applied Physics Letters*, **77**, 3809 (2000). Copyright 2000, American Institute of Physics.)

Figure 3 describes the basic experimental observations of the hysteretic current and field dependence of the junction resistance. This phase diagram is a simplified version from Kiselev *et al*. (2003). Note that this phase diagram is obtained with quasistatic measurements, and hence it is not a simple stability boundary but a thermal-activation-determined transition-rate boundary. In principle, the exact position of the lines as well as their shape depend on the system temperature and the measurement speed, as discussed later.

There are generally three types of behaviors observed from these experimental switching boundary phase diagrams. The first corresponds to the region that shows hysteretic switching between parallel and antiparallel states, those represented by the area P/AP in Figure 3(a). The second region shows a large amount of telegraph noise, often involving two-level fluctuations, signaling thermally activated transitions between two metastable states (Myers *et al*., 2002; Urazhdin, Birge, Pratt and Bass, 2003). These two states could be two orbits of persistent precession, or they could be between two stable points, or they could be between one stable point and one orbit of persistent precession. A third type of behavior is usually observed in the high-field, high current density region, where continuous magnetic precession at microwave frequency is present. This can be accompanied by a reversible step in a junction's IV curve. It appears in $\mathrm{d}V/\mathrm{d}I$ measurement as a peak, whose amplitude and width depend on the step's shape as well as measurement conditions.

A direct correspondence between these quasistatically measured $R(H)$ phase diagrams and microwave emission characteristics was established experimentally (Kiselev *et al*., 2003). Most features observed experimentally can be found in monodomain LLG models (Sun, 2000a; Li and Zhang, 2003; Bazaliy and Jones, 2004; Grollier *et al*., 2003; Valet, 2004, private communications; Özyilmaz *et al*., 2003), as direct comparisons were made in a magnetic field perpendicular to the junction film surface geometry (Kiselev *et al*., 2004). There are, however, some features observed in the relatively high bias region that were not accounted for by the simple monodomain LLG model (Kiselev *et al*., 2003). More recent experiment has further probed the nature of these dynamic excitations beyond the monodomain limit (Kiselev *et al*., 2004). Modeling of these behaviors, in general, requires numerical treatment of the LLG equation. Comparison of such numerical simulation (e.g., see Lee *et al*. (2004)) and experiment (Kiselev *et al*., 2003) gives satisfactory agreement to the leading order.

In general, the regions outside the hysteretic P/AP part involve steady-state or chaotic dynamic motion, often in large amplitudes. As such, the exact behavior is

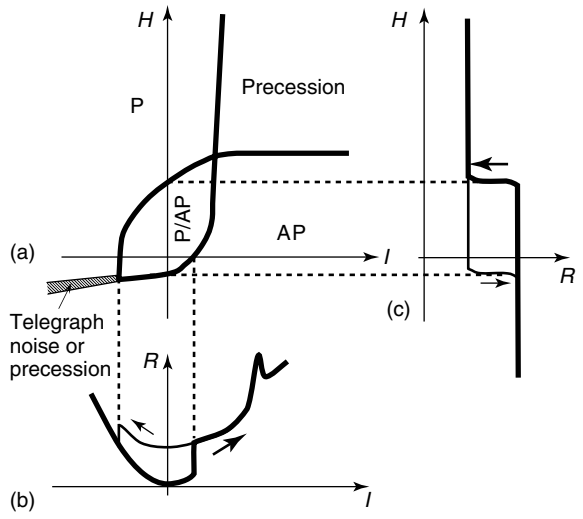

Figure 3. A sketch of the phase diagram of a spin-transfer device. (a) The phase diagram in (I, H) space. P designates 'parallel' state and AP, antiparallel. P/AP is the hysteresis region. The curvatures of the phase boundaries shown here are a result of finite temperature effect that is discussed later. (b) A horizontal cut of the phase space, showing a current-induced resistance switch. (c) A vertical cut of the phase space, showing a magnetic-field-induced resistance switch. The difference between the precessional states on the upper right region of (a) and the telegraph noise/precession states on the lower left region of (a) is not fundamental. The nanomagnet may exhibit either a persistent precessional state or a telegraph noise state, depending on the relative strength between the spin torque, the effective anisotropy field experienced by the nanomagnet, which includes the effect of applied field, as well as the effect of temperature in relation to these magnetic energy scales.

sensitive to factors beyond simple macrospin models. Factors such as the exact shape of the nanomagnet, the uniformity (or lack of uniformity) of the spin current passing through, and the magnetic boundary conditions imposed on the nanomagnet all contribute to determining the nature of the dynamics. The internal magnetic degrees of freedoms are also involved, giving rise to various modes of spin-wave excitations, further complicating the behavior.

At very high current densities (above $10^8\,\mathrm{A\,cm^{-2}}$, e.g., for typical Co|Cu structures with 30 Å or so Co), spin transfer can even amplify the magnetic inhomogeneities in a single-layer, thin- film nanomagnet, be it initially structural and static in nature or thermal and dynamic. The process involves spin diffusion current in the lateral direction parallel to the film surface, which couples magnetization of the film surfaces from different locations and amplifies the angular deviation from equilibrium. This has been theoretically described (Polianski and Brouwer, 2004; Stiles, Xiao and Zangwill, 2004) and experimentally observed (Özyilmaz *et al*., 2004).

4.2 Time-dependent magnetoresistance during magnetic reversal

The response of a nanomagnet to spin torque is dynamic. This can be investigated by time-resolved transport measurements. Time-dependent measurement also directly answers the question of spin-torque switching time and its dependence on the conditions of the driving current, which is important for applications.

Spin-transfer-induced magnetic reversal follows a different type of dynamics than magnetic-field-driven reversal. For spin-valve-based spin-transfer devices, direct measurement of the switching speed of spin-transfer junctions is nontrivial because of the small signal level involved. For CPP spin valves, even at lateral sizes of 100 nm or below, the junction resistance still is less than 10 Ω or so, and the MR change is even smaller – usually only about 3∼5% of the total junction resistance. This results in an MR-related voltage signal typically below 0.1 mV. Dynamic calculations (Sun, 2000a) give the generic timescale of the precession to be around $(2\pi M_s)\,\gamma \sim 50$–$100$ ps for cobalt, and places the precessional-reversal time in the order of 1∼10 ns.

Most switching dynamics measurements were performed at ambient temperature. One earlier experiment probed the switching speed as a function of driving current amplitude (Koch, Katine and Sun, 2004). Owing to the small MR signal level on top of the large primary signal from the current step, an elaborate signal averaging sequence was devised to extract the time-dependent evolution of the junction voltage related to magnetic reversal. With proper averaging, the output voltage difference can be normalized to reflect the ensemble-averaged reversal probability, which is presented in Figure 4(a). The corresponding switching speed as a function of the drive current amplitude is shown in Figure 4(b) on a linear scale, and on a log-linear scale in Figure 4(c).

Two points are noted for the data shown in Figure 4(b–c). First, at the high-speed limit, the dependence of τ^{-1} on bias current I is linear. Second, in the subthreshold, large-τ regime, this linearity gives way to a curved onset which turns out to be exponentially dependent on the bias current as shown in Figure 4(c). The linear τ^{-1} versus I dependence stems from spin-transfer angular momentum conservation, and the curved onset relates to thermal activation. Both can be adequately described by the spin-transfer dynamics with thermal noise. In addition, the quasistatically measured I_c on the same sample under the same environment is more than a factor of 2 less than the threshold current observed in Figure 4(b). The difference is due to the different timescales of the two measurements.

This experiment only reveals the envelope of the switching junction's voltage response in time. The detailed oscillation in the voltage related to magnetic precession is sensitive

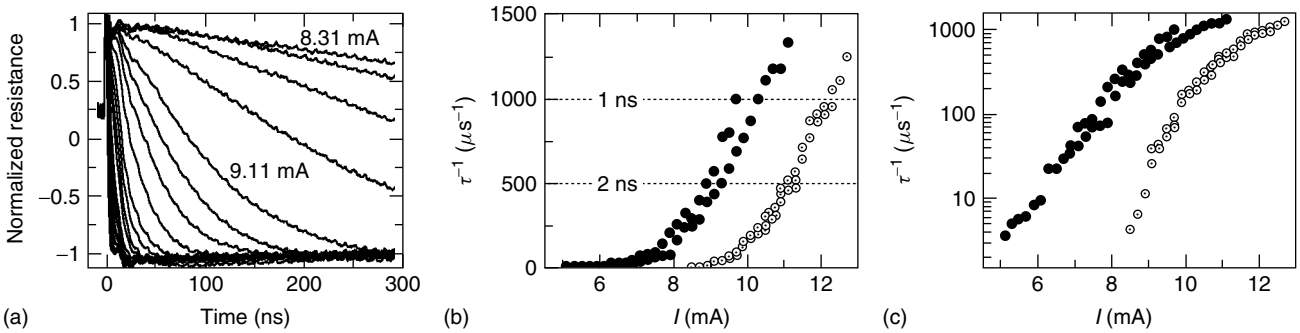

Figure 4. (a) Time-dependent switching probability. (b) Switching speed τ^{-1} extracted from (a). Horizontal dashed lines with labels indicate the switching speed corresponding to a reversal time of 1 and 2 ns, respectively; (c) Switching speed plotted on log-linear scale. Open and closed circle symbols represent the switching threshold on the positive and the negative current step of the junction. (Reproduced from J. Sun *et al*., 2004, with permission from the International Society for Optical Engineering (SPIE). © 2004.)

to the initial condition which is thermally randomized and smeared out. A more recent experiment by Krivorotov *et al*. reveals not only the envelope of the switching junction's dynamic voltage output but also the actual oscillation that reflects the dynamic precession accompanying the reversal (Krivorotov *et al*., 2005). This was done by using a junction with a noncollinear magnetic moment arrangement between the fixed and the free layers. At sufficiently large angles (around 45°), it introduces a distinctive initial condition for the precession dynamics upon the presence of a step-function driving current, thus preserving the phase information of the oscillations upon multitrace average. This way, they directly observed the effect of spin current on the damping characteristics of the nanomagnet by relating the oscillation envelope to the spin-current amplitude.

5 FINITE TEMPERATURE MACROSPIN DYNAMICS

A simple macrospin finite temperature dynamic model for spin-transfer-induced switching was first described in Sun, Kuan, Katine and Koch (2004) and Koch, Katine and Sun (2004), which capture the essentials with an analysis of a collinear geometry between the macrospin's direction and that of the spin-polarized current. A more careful analysis of the model on the basis of the Fokker–Plank equation formalism can be found in Li and Zhang (2004a) and Apalkov and Visscher (2005a).

5.1 Review of the zero-temperature model

Define a macrospin with its magnetic moment $\mathbf{m}$ having a direction described by a unit direction vector $\mathbf{n}_m = \mathbf{n}_m(\theta, \varphi) = \sin\theta\sin\varphi\mathbf{e}_x + \sin\theta\cos\varphi\mathbf{e}_y + \cos\theta\mathbf{e}_z$, where θ and φ are direction angles in a polar-coordinate system. The moment $\mathbf{m}$ is situated in a combined energy potential of $U = U(\theta, \varphi)$ that includes all energy conserving torques experienced by $\mathbf{m}$. The normalized gradient of U, expressed in terms of $\mathbf{H}_{\text{eff}} = (1/m)\,\nabla U(\theta, \varphi)$ includes terms of the applied magnetic field $\mathbf{H}$, a uniaxial anisotropy whose strength can be characterized by a uniaxial anisotropy field H_k, and an easy-plane anisotropy field that could be used to describe a macrospin in thin-film geometry, experiencing the demagnetization effect from the flat thin-film geometry. Here the operator $\nabla = \mathbf{e}_\theta\,(\partial/\partial\theta) + \mathbf{e}_\varphi\,(1/\sin\theta)\,(\partial/\partial\varphi)$, with unit vectors $\mathbf{e}_\theta$ and $\mathbf{e}_\varphi$ denoting the direction of rotation for θ and φ, respectively. Note that except for the applied field $\mathbf{H}$, $\mathbf{H}_{\text{eff}}$ here is in general not a simple magnetic-field vector but a function of the angular position of $\mathbf{m}$.

The precession dynamics of the macrospin $\mathbf{m}$ under the potential well U in the classical limit can be described by the phenomenological LLG equation

$$\left(\frac{1}{\gamma}\right)\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = \mathbf{m}\times\left[\mathbf{H}_{\text{eff}} - \left(\frac{\alpha}{m}\right)\mathbf{m}\times\mathbf{H}_{\text{eff}}\right] \tag{6}$$

As was shown for equation (3), adding the spin-torque term of equation (2) gives

$$\left(\frac{1}{\gamma}\right)\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = \mathbf{m}\times\left[\mathbf{H}_{\text{eff}} - \left(\frac{\alpha}{m}\right)\mathbf{m}\times(\mathbf{H}_{\text{eff}} + \mathbf{H}_{\text{s}})\right] \tag{7}$$

where $\mathbf{H}_{\text{s}} = I\eta\,(\hbar/2e)\,(1/m\alpha)\,\mathbf{n}_{\text{s}}$ is the spin-angular momentum transfer term. For simplicity $g = 1$ is assumed while using equation (2).

Examine the simple case when only an applied magnetic field $\mathbf{H}$ is present in $\mathbf{H}_{\text{eff}}$, and $\mathbf{H}$ and $\mathbf{H}_{\text{s}}$ are collinear. In this simple limit

$$\left(\frac{1}{\gamma}\right)\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = \mathbf{m}\times\left[\mathbf{H} - \left(\frac{\widetilde{\alpha}}{m}\right)\mathbf{m}\times\mathbf{H}\right] \tag{8}$$

with $\widetilde{\alpha} = \alpha + \hbar\eta I/(2emH) = \alpha(1 + I/I_c)$, where $I_c = (2e/\hbar)(\alpha/\eta)(abtM_s)H_a$, a special case of the threshold current as defined in equation (4). This reveals the role of spin-polarized current I: it modifies the effective damping coefficient of the nanomagnet. When the effective damping α becomes negative, the nanomagnet will amplify disturbances away from its equilibrium position, resulting in a magnetic instability, leading to a magnetic reversal.

For more general situations, since $\mathbf{H}_{\text{eff}}$ contains the angular position (θ, φ) of $\mathbf{m}$, a full stability analysis of equation (7) is required. This, in the small cone-angle limit $(\theta \ll \pi)$, can be done analytically with a linearized equation (7), as was done in Sun (2000a) When averaged over a timescale longer than the natural precession period $\Omega_K = \gamma H_k$, it gives an effective damping coefficient of $\widetilde{\alpha} = \alpha + \hbar\eta I/[2em(H + H_k + 2\pi M_s)]$ that describes the average cone-angle evolution $\langle\theta(t)\rangle$. Here, the uniaxial anisotropy field H_k and the orthogonal easy-plane anisotropy term are included. A thin-film demagnetization-related easy-plane anisotropy energy is assumed, therefore $M_s = m/v$, where $v = abt$ is the volume of the nanomagnet. The resulting instability threshold when $\widetilde{\alpha} = 0$ is just equation (4) $|I_c| = (1/\eta)(2e/\hbar)m\alpha(H + H_k + 2\pi M_s)$. This threshold current $I_c(H)$ depends linearly on the applied field H. It should have an intercept-to-slope ratio of $H_k + 2\pi M_s$. Experimental results (Sun *et al*., 2003), however, suggest that the actual slope-to-intercept ratio falls well below, and finite temperature effect plays an important role.

The effect of finite temperature on the macrospin system's response to a spin-transfer excitation is twofold. First, it affects the average precession motion of the macrospin by adding thermal agitation, resulting in finite probabilities for thermal activation over the magnetic energy barrier. Secondly, it adds a thermally distributed initial condition to the macrospin.

5.2 Finite temperature LLG equation

Following the approach of Brown (1963) and Grinstein and Koch (2003), a Langevin random field $\mathbf{H}_L$ can be added to the effective magnetic-field term $\mathbf{H}_{\text{eff}}$. $\mathbf{H}_L$ relates to the system temperature T as $H_{L,i} = \sqrt{2\alpha k_B T/\gamma m}\, I_{\text{ran},i}(t)$, $(i = x, y, z)$; where $I_{\text{ran}}(t)$ is a Gaussian random function with the first two moments of $\langle I_{\text{ran}}(t)\rangle = 0$ and $\langle I^2_{\text{ran}}(t)\rangle = 1$. Each of the x, y, z components has its own uncorrelated $I_{\text{ran}}(t)$. Without the spin-transfer effect, the finite temperature LLG equation with a Langevin random field reads

$$\left(\frac{1}{\gamma}\right)\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = \mathbf{m} \times \left[\mathbf{H}_{\text{eff}} + \mathbf{H}_L - \left(\frac{\alpha}{m}\right)\mathbf{m} \times \mathbf{H}_{\text{eff}}\right] \quad (9)$$

which describes the dynamics of a macrospin $\mathbf{m}$ sitting in a potential well $U(\theta, \varphi)$, with a thermally activated motion and a finite lifetime of staying inside the potential well, namely, a thermal lifetime τ approximately following the Boltzmann statistics of

$$\tau = \tau_0 \exp\left(\frac{\Delta U}{k_B T}\right) \quad (10)$$

where ΔU is the potential barrier height as seen from the local minimum in which $\mathbf{m}$ fluctuates, and $\tau_0 \sim 1/\gamma H_k$ is the reciprocal attempt frequency. Equation (9) should work well when $\Delta U/k_B T \gg 1$. The thermal-activation lifetime equation (10) is determined once a system is defined by equation (9) and an energy landscape $U(\theta, \varphi)$, represented in equation (9) by $\mathbf{H}_{\text{eff}}(\theta, \varphi) = (1/m)\nabla U(\theta, \varphi)$.

5.3 Finite temperature LLG equation with spin torque: amplified thermal activation

Spin-transfer excitation adds an additional torque. Similar to equation (7), after including the spin-transfer torque and assuming the spin-polarized current carries no entropy flow into the macrospin, equation (9) reads

$$\left(\frac{1}{\gamma}\right)\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = \mathbf{m} \times \left[\mathbf{H}_{\text{eff}} + \mathbf{H}_L - \left(\frac{\alpha}{m}\right)\mathbf{m} \times (\mathbf{H}_{\text{eff}} + \mathbf{H}_s)\right] \quad (11)$$

with $\mathbf{H}_s$ representing the spin-transfer torque related contribution, as defined in equation (7).

It is instructive to look at a special case when $\mathbf{H}_s$ and $\mathbf{H}$ are both collinear to the easy axis of the uniaxial anisotropy term $\mathbf{H}_k$ inside $\mathbf{H}_{\text{eff}}$, and the easy-plane anisotropy is zero. In this case and for small cone angle $\theta \ll 1$, the effect of $\mathbf{H}_s$ is simply to modify $\mathbf{H}_{\text{eff}} \to \widetilde{\mathbf{H}}_{\text{eff}} = (H_k + H + H_s)\mathbf{n}_s = (H_k + H)\left(1 + \frac{H_s}{H_k + H}\right)\mathbf{n}_s = \left(1 + \frac{H_s}{H_k + H}\right)\mathbf{H}_{\text{eff}}$. Thus, one can rewrite equation (11) in the form of equation (9)

$$\left(\frac{1}{\gamma}\right)\frac{\mathrm{d}\mathbf{m}}{\mathrm{d}t} = \mathbf{m} \times \left[\mathbf{H}_{\text{eff}} + \mathbf{H}_L - \left(\frac{\widetilde{\alpha}}{m}\right)\mathbf{m} \times \mathbf{H}_{\text{eff}}\right] \quad (12)$$

where $\widetilde{\alpha} = \left[1 + H_s/(H_k + H)\right]\alpha = (1 + I/I_c)\alpha$, with $I_c = (2e/\hbar)(\alpha/\eta)(abtM_s)(H + H_k)$, another special case of equation (4).

Equation (12) is a mathematically equivalent description of a macrospin system as equation (9) with the same amplitude of $\mathbf{H}_L$. This then suggests that $H_{L,i} = \sqrt{2\alpha k_B T/\gamma m}\, I_{\text{ran},i}(t)$ remains valid for this hypothetical macrospin's LLG equation (12). However, in equation (12), the damping coefficient α is replaced by $\widetilde{\alpha}$. To maintain $H_{L,i}$, it means the macrospin would see a fictitious temperature $\widetilde{T}$, such that $\widetilde{\alpha}\widetilde{T} = \alpha T$.

Since equation (12) is equivalent to a macrospin situated at temperature $\widetilde{T}$ with damping $\widetilde{\alpha}$, one may further deduce that the thermal-activation lifetime of the system can also be expressed in the form of equation (10), with its temperature rescaled to $\widetilde{T}$, that is,

$$\tau = \tau_0 \exp\left(\frac{\Delta U}{k_{\mathrm{B}}\widetilde{T}}\right) = \tau_0 \exp\left[\frac{\Delta U}{k_{\mathrm{B}}T}\left(\frac{\widetilde{\alpha}}{\alpha}\right)\right]$$
$$= \tau_0 \exp\left[\frac{\Delta U}{k_{\mathrm{B}}T}\left(1 - \frac{I}{I_{\mathrm{c}}}\right)\right] \tag{13}$$

This conclusion of a linearly current-dependent apparent temperature can be directly compared with experiment done in subthreshold driving current ($|I| < I_{\mathrm{c}}$).

More rigorous theoretical treatments that give equation (13) can be found in Li and Zhang (2004a) and Visscher and Apalkov (2005). The energy distribution of a macrospin under spin-current excitation is calculated by Apalkov and Visscher (2005b).

Equation (13) is the basic function that determines the shape of the quasistatically measured magnetic switching phase boundary as illustrated in Figure 3. The increase in switching rate as $H \to H_k$ and/or as $I \to I_{\mathrm{c}}$ gives rise to the increased slope, making the experimentally observed intercept-to-slope ratio well below what is expected from zero temperature $I_{\mathrm{c}}(H)$ (Sun *et al.*, 2003; Sun, Kuan, Katine and Koch, 2004), as illustrated in Figure 5. The overall shape of this quasistatic switching boundary is consistent with what is observed experimentally (Kiselev *et al.*, 2003), which is illustrated in Fig.3. The boundary here corresponds to observing a switching event during a period of τ. The expression can be readily derived from equation (13) to be

$$I(H) = I_{\mathrm{c}}(H)\left[1 - \frac{1}{(1 - H/H_k)^2}\left(\frac{k_{\mathrm{B}}T}{\Delta U}\right)\ln\left(\frac{\tau}{\tau_0}\right)\right] \tag{14}$$

In addition to measuring the averaged switching speed versus switching current as shown in Figure 4, a direct measurement of the apparent threshold current can also be done using a pulsed current bias. These experiments (Pakala *et al.*, 2005; Yagami, Tulapurkar, Fukushima and Suzuki, 2004, 2005) verify the description of equation (14) and also provide a quick estimate of the zero-temperature threshold current without requiring full dynamic measurements down to the nanosecond level.

5.4 Thermally distributed initial condition

In the simple collinear geometry, the initial condition of the macrospin system under spin-transfer excitation is most important when the spin-transfer excitation is large – such as when it is near or exceeding the zero-temperature threshold current I_{c}. In this case, when the spin-transfer current is applied suddenly at time t_0, it will result in a fairly quick magnetic reversal. The switching time required at zero temperature is estimated to be (Sun, 2000a)

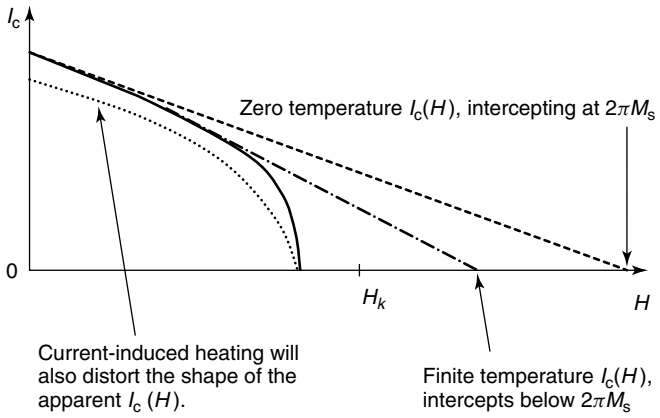

Figure 5. The effect of finite temperature and quasistatic measurement. The quasistatic measurement over a laboratory timescale τ allows an appreciable amount of probability for the nanomagnet to thermally switch out of its lowest potential well, completing a magnetic reversal. The closer to H_k and/or I_{c}, the more pronounced this thermal activation becomes, causing the observed switching boundary to curve below that of the zero temperature $I_{\mathrm{c}}(H)$, and giving an artificially low intercept on the field axis. The Joule heating of the device is often more significant for MTJs than for spin valves. In such cases, the apparent switching boundary may become further distorted, as illustrated here by the thick dotted line.

$$\tau^{-1} = \frac{\alpha\gamma}{m\ln(\pi/2\theta_0)}(H + H_k + 2\pi M_{\mathrm{s}})\left[(I/I_{\mathrm{c}}) - 1\right]$$
$$= \frac{\eta(\mu_{\mathrm{B}}/e)}{m\ln(\pi/2\theta_0)}(I - I_{\mathrm{c}}), \quad (I > I_{\mathrm{c}}) \tag{15}$$

with θ_0 being the initial deviation of $\mathbf{m}$ from its easy-axis direction. The last step in equation (15) reveals angular momentum conservation. A finite temperature brings a thermally distributed θ_0. Thus the precise switching speed will vary from measurement to measurement. At the same time, the thermal agitation during the course of reversal will add some uncertainty to the exact speed and trajectory of the reversal. This disturbance is likely to be small compared to the large cone-angle motion involved in these reversal events as long as $\Delta U/k_{\mathrm{B}}T \gg 1$.

To see the consequence of a thermally distributed initial θ_0, examine a special case with $U(\theta,\varphi) = \Delta U\left(\sin^2\theta + h_p\sin^2\theta\cos^2\varphi - 2h\cos\theta\right)$, where $\Delta U = mH_k/2$ is the uniaxial anisotropy energy constant, $h_{\mathrm{p}} = 4\pi M_{\mathrm{s}}/H_k$ is the easy-plane anisotropy field in dimensionless unit, and $h = H/H_k$ is the applied field, assuming a collinear

geometry between $\mathbf{H}$ and $\mathbf{H}_k$. Assume further a small thermal fluctuation amplitude when $\Delta U/k_{\mathrm{B}}T \gg 1$. In such limit, the main effect of finite temperature on delay τ is through the initial angular position of θ, which in the limit of $\Delta U/k_{\mathrm{B}}T \gg h_{\mathrm{p}} \gg 1$ gives a switching speed based on the ensemble-averaged switching time as (Sun, Kuan, Katine and Koch, 2004)

$$\langle\tau\rangle^{-1} \approx \frac{\eta\mu_{\mathrm{B}}}{me}\left[\frac{\ln\left(4\pi^2 h_{\mathrm{p}}\right)}{\pi\ln\left(\Delta U/k_{\mathrm{B}}T\right)}\sqrt{\frac{1+h}{h_{\mathrm{p}}}}\right](I - I_{\mathrm{c}}) \quad (16)$$

In this particular limit, the ensemble-averaged switching speed has a current-dependence slope that is directly dictated by the thermal-activation-induced initial angle. This is true only if there are no transient disturbance fields during the application of the current pulse. Such transient fields would create a sudden rotation of the effective easy-axis direction, and in effect create a nonzero and nonthermal initial angle θ_0, dictating the speed of the spin-transfer switch.

Summarizing the temperature-dependence results discussed so far, we conclude

$$\langle\tau\rangle^{-1} \approx \begin{cases} \tau_0^{-1}\exp\left[-\frac{\Delta U}{k_{\mathrm{B}}T}(1-h)^2\left(1-\dfrac{I}{I_{\mathrm{c}}}\right)\right], \\ \qquad \text{when} \quad (I \ll I_{\mathrm{c}}) \\ \left(\dfrac{\eta\mu_{\mathrm{B}}}{me}\right)\left[\dfrac{\ln\left(4\pi^2 h_{\mathrm{p}}\right)}{\pi\ln\left(\Delta U/k_{\mathrm{B}}T\right)}\sqrt{\dfrac{1+h}{h_{\mathrm{p}}}}\right](I - I_{\mathrm{c}}), \\ \qquad \text{when} \quad (I \gg I_{\mathrm{c}}) \end{cases} \quad (17)$$

Equation (17) describes the experimental observation presented in Figure 4: a linear dependence of switching speed and drive current amplitude above a switching threshold current I_{c}, and a log-linear dependence below the threshold.

The dependence of thermal-activation dwell time as a function of bias current on the spin valve was also directly probed by a set of careful experiments by Krivorotov *et al.* (2004), which confirmed the linear current-dependence factor in the exponential.

In the dynamic switch region ($I > I_{\mathrm{c}}$), the slope of switching speed versus drive current reflects angular momentum conservation. The product $(I - I_{\mathrm{c}})\langle\tau\rangle$ is also an important figure of merit for the possible application of this two-terminal switch as a memory element.

Recently two other experiments have revealed a similar set of relationships between the pulse-width and pulse-height dependences for a spin-current-driven magnetic switch (Tulapurkar *et al.*, 2005; Kaka *et al.*, 2005). A generally similar behavior is reported, although these experiments measure the magnetic switching probability in the long-time limit, including switching events that may occur after the removal of the pulsed driving current. Therefore, the statistics for the switching probability of the nanomagnet should be somewhat different from equation (17).

6 SPIN-TRANSFER SWITCHING IN MAGNETIC TUNNEL JUNCTIONS

Another class of magnetoresistive two-terminal devices is the so-called magnetic tunnel junction. Publications on MTJ research date back to the 1970s (Julliere *et al.*, 1975; Suezawa and Gondo, 1987; Maekawa and Gäfvert, 1982). Theoretical work published as early as 1989 described the MTJ's MR and also predicted a spin-current-induced magnetic excitation (Slonczewski, 1989). In the 1990s, on the experimental front, sizable room-temperature MR was observed in a relatively simple ferromagnet–oxide–ferromagnet stack structure (Moodera, Kinder, Wong and Meservey, 1995; Miyazaki and Tezuka, 1995). Since then, AlO_x-barrier-based MTJs have been successfully optimized for both low RA recording head and higher impedance devices for magnetic random access memory (MRAM) applications. More recently, explorations of MgO as a crystalline tunnel barrier material led further to dramatic improvements in MTJ's performance, both in terms of the magnitude of MR (Parkin *et al.*, 2004; Yuasa *et al.*, 2004; Djayaprawira *et al.*, 2005) and in terms of a successful reduction of the junction-specific resistance–area product (the RA).

For an MTJ to show spin-transfer-induced switching effect, it has to meet some fairly stringent requirements. For most experimental situations, the junction is required to support a tunnel current of the order of $10^7\,\mathrm{A\,cm^{-2}}$ across the tunnel barrier. This can be done only with junctions having high tunnel conductance as well as reasonable tunnel barrier breakdown voltage. At the same time, the junction has to be lithographically patterned down to around 200 nm in size to avoid having excess amount of total current, as discussed earlier. It turns out that these requirements are similar to those of recording-head applications of MTJ, where such properties are desirable for handling signal-to-noise ratio concerns and for compatibility with existing read-out electronics. To a large extent, it is the technology development surrounding the recording-head application that brought us to the age of spin-transfer switching in MTJs.

Spin-transfer-induced magnetic switching in MTJs was first unambiguously observed by Huai *et al.* (2004). Independently, Fuchs *et al.* (2004) also published their work on spin-transfer switching of MTJs. These experiments used AlO_x-based tunnel barriers. The junctions used in Huai *et al.* (2004) had MRs ranging 1–20%, for RAs in the range of $0.5–10\,\Omega\mu\mathrm{m}^2$. The junction stack was of the type

‖ substrate SiO_2 |PtMn|CoFe|Ru|CoFe| Al_2O_3 |CoFe|NiFe‖. The junctions were patterned using deep UV photolithography with resist trimming, followed by Ar ion-mill etch, to about $0.1 \times 0.2\,\mu m^2$ in size. Junctions in Fuchs *et al.* (2004) were patterned, using electron-beam lithography and ion milling, down to a size of $40 \times 130\,nm^2$. For Fuchs *et al.* (2004), because their free layer is predominantly permalloy ($Ni_{81}Fe_{19}$), the junctions were superparamagnetic at ambient temperature. They varied junction temperature to investigate the effect of spin-transfer torque on magnetic switching as the free layer moves across its superparamagnetic transition.

Recently a new tunnel barrier, MgO, was being explored as a superior barrier for MTJs, because it provides much larger tunnel magnetoresistance (TMR) than that achieved with AlO_x-based MTJs. Crystalline MgO was predicted to allow for extremely high TMR values if interfaced with (001)-textured Fe surfaces (Butler *et al.*, 2001; Mathon and Umerski, 2001). This is related to the directional electronic states that are highly spin polarized in the direction perpendicular to the interface of a (001)Fe|(100)MgO|(001)Fe stack. Such large TMR effects have now been experimentally observed (Yuasa *et al.*, 2004; Parkin *et al.*, 2004) as materials and device refinements are underway to further improve the junction characteristics (Ikeda *et al.*, 2005).

An example of spin-transfer-induced magnetic switching in an MgO-based MTJ is shown in Figure 6. The free layer for the junction shown here is composed of 2 nm of CoFeB (Assefa *et al.*, 2006). A current-induced switching is seen between these two branches both at positive and at negative currents. Here positive current designates the direction where electrons tunnel from the free layer into the fixed layer. It is clear the magnetic-field-induced switch and the current-induced switch in this case resulted in exactly the same change in low-bias junction resistance. One may therefore conclude that the current-induced magnetic switching is a complete magnetic reversal, resulting in the same final magnetic state as the one achieved by magnetic-field-induced reversal. The junction shown here is nominally $50 \times 100\,nm^2$ in size. The junction dynamic resistance R_J was measured with a lock-in detection of an ac sine-wave signal, 10 μA in rms amplitude at 331 Hz, superimposed on the dc-bias current. When measuring $R_J(H)$, the field sweep speed was about $2\,Oe\,s^{-1}$. When measuring $R_J(I)$, the bias current varies with a speed of around $0.01\,mA\,s^{-1}$. The switching boundaries thus measured are determined by assisted thermal activation, as described by the first equation in equation (17).

Spin-transfer-induced magnetic switching in MTJs is in many aspects very similar to that in all-metal spin valves. A relationship similar to that in equation (4) exists, which describes the instability current threshold (Slonczewski,

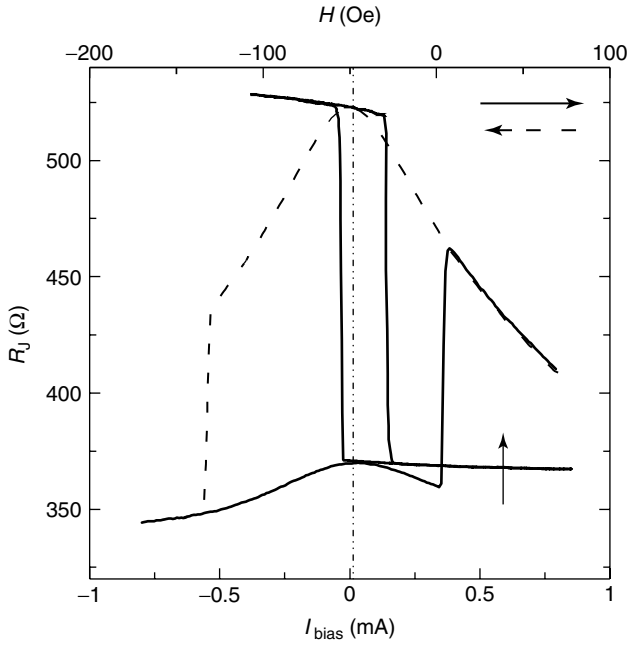

Figure 6. An example of an MTJ undergoing spin-transfer-induced magnetic switching. The solid and dash-dot lines represent the two branches of the MTJ's dynamic resistance $R_J = dV/dI$, measured as a function of a dc-bias current. To illustrate the relationship between the current-induced switching and magnetic switching, a low-bias magnetoresistance versus magnetic-field curve is shown as the faint solid line for comparison. The vertical dashed line here represents the bias magnetic field at which the current sweep for junction dynamic resistance is taken. (Data is related to work in Assefa *et al.* (2006).) The junction shown here is $0.05 \times 0.10\,\mu m^2$ in size. (Reproduced from J.Z. Sun *et al.*, 2006, *Journal of Res. And Dev*, with permission from IBM. © 2006.)

2005). In a stack containing an MTJ, the spin polarization of the tunnel current is usually determined by the spin-dependent tunnel matrices. Since a tunnel barrier usually has much higher RA than the corresponding spin-valve resistance, it tends to determine the transport current and the amount of spin polarization, while the resistances from the rest of the stack structure and that from the leads do not affect the spin-polarization current through the free layer as much as they did in an all-metal spin valve. However this difference is only quantitative. With very low RA tunnel junctions, the spin-dependent conductances from the rest of the pillar do come into play, in ways similar to that of an all-metal spin valve.

Another important issue is the bias dependence of the tunnel current's spin polarization, and its relationship with the bias dependence of the junction TMR. The bias-dependent TMR is relevant to spin transfer because both phenomena relate to the spin-dependent tunnel matrices. The spin current relating to the spin transfer of an MTJ is determined by the initial states of the tunneling electrons involved

(Slonczewski, 2005). This relates to the efficiency of conversion between the total charge current and the spin current responsible for spin torque on the free layer. The TMR of an MTJ, on the other hand, depends on both the initial and the final state densities of the tunnel electrons. It is commonly observed experimentally that an MTJ's TMR decreases upon increasing the bias (Lu *et al*., 1998; Sun *et al*., 1998; Zhang, Levy, Marley and Parkin, 1997).

Experimentally, it was shown early on that at bias currents sufficient to induce spin-transfer switching, the TMR value is significantly diminished from its low-bias value. This, however, does not appear to significantly diminish the ability of the MTJ to produce spin-transfer switching (Fuchs *et al*., 2004). More recently, the same group reported (Fuchs *et al*., 2005a) the observation of a rather constant spin-polarization factor of the tunnel current over the bias range enclosing spin-transfer switching, unlike the TMR value of the same MTJ which shows significant bias dependence over the same bias range. These seem to suggest that empirically, the spin-transfer-related spin-polarization efficiency of an MTJ is much less bias dependent than its TMR and is not significantly diminished at high bias.

It has also been experimentally shown that a correlation exists between the value of the low-bias TMR and the threshold current for a spin-transfer switching (Diao *et al*., 2005).

As in their spin-valve cousins, MTJ-based spin-transfer switching was also most often observed in quasistatic measurements. This is not surprising as quasistatic switching threshold currents are usually lower than dynamic thresholds, and MTJ devices have less tolerance for high current density bias than spin valves. Experimentally, it has been observed that a thermally activated switching process nearly identical to those described in the previous section (Koch, Katine and Sun, 2004; Sun, Kuan, Katine and Koch, 2004; Yagami, Tulapurkar, Fukushima and Suzuki, 2004) is at play. This can be quantitatively verified by careful measurements of the statistically averaged switching threshold current as a function of the current pulse width used to switch the junction (Pakala *et al*., 2005; Kubota *et al*., 2005b; Hosomi *et al*., 2005).

To access deterministic switching requires larger current density than necessary for thermal-activation-assisted switching. MTJs tend to have lower breakdown current density than spin valves. Therefore, spin-transfer switching experiments on MTJs were first done in the thermal-activation-assisted region. Further improvement in MTJ materials will make it easier access the precessional switching process. These would require improvements of the tunnel barrier strength for providing larger breakdown current densities. More importantly, this will require magnetic anisotropy engineering for the magnetic free layer so as to eliminate the dominating effect of shape-induced easy-plane anisotropy in threshold current (Sun, 2000a). The same requirements will be necessary for successful demonstration and application of MTJ in producing persistent magnetic precessions necessary for the generation of microwave emissions.

In the meantime, a convenient way of estimating the equivalent zero-temperature switching current threshold is to use an extrapolated value of the threshold current as a function of the switching time in the thermal-activation regime (Pakala *et al*., 2005; Diao *et al*., 2005) This is equivalent to using the deviation from log-linear behavior in Figure 4(c) as a way of estimating I_{c0}. The accuracy of this estimate, however, will depend on the details of the switching layer's magnetic properties, especially its uniaxial anisotropy barrier height compared to $k_B T$. In simplistic single-domain models, it is the value of $\Delta U / k_B T$.

Another important factor to be considered for MTJ-based (and to a lesser degree, for spin-valve-based) spin-transfer switching is Joule heating induced by the current. Estimates for the amount of current-induced Joule heating in a typical metallic spin valve run from less than 20 K (Krivorotov *et al*., 2004) to about 50 K (Deac *et al*., 2005). A tunnel junction on the other hand, because of its larger RA value, dissipates more power, resulting in more heating (Fuchs *et al*., 2005b). This effect could introduce an additional term in the current dependence of equation (13) through a current-dependent temperature T. It modifies the appearance of the phase boundaries and equation (14). The net effect of this heating is to tilt the apparent switching boundary $I(H)$ for large I, as illustrated in Figure 5, as also seen in experiments (Krivorotov *et al*., 2004; Fuchs *et al*., 2005a,b).

7 POSSIBLE APPLICATIONS

Spin-transfer-induced magnetic excitation and magnetic reversal is a relatively new phenomenon that dominates magnetic behavior for junction devices only in high current density transport and below about 0.1 μm in lateral size. As the critical dimensions of the modern day electronic devices shrink below this length scale, the spin-transfer mechanism becomes important in several aspects. It may be used for localized write addressing of a magnetic random memory element or it could be used for on-chip generation of tunable microwave radiation. The mechanism also affects the operation of a magnetic hard-disk's read heads.

A two-terminal spin valve or MTJ that can be current switched between two stable resistance states constitutes a memory element. To integrate such a memory element into existing CMOS circuit technologies, some basic device

requirements must be met. Chief among them are three items: the device impedance, the voltage swing between the two stable states, and the threshold current required to switch the device. Switching speed and its relationship and trade-off with switching current are also important.

To be integrable, the current density required for device switching must be comparable to what a typical CMOS circuit of comparable density can supply. If this were supplied by a MOSFET transistor, it usually is of the order of $0.5-1\,\mathrm{mA}\,\mu\mathrm{m}^{-1}$ channel width for the transistors. This determines the upper limit of the switching current. Diode selection could in principle allow for higher current density, although there are additional concerns over impedance (mis)match and uniformity of device characteristics over large numbers of junctions and diodes.

The other constraint on the junction switching current is that it has to be sufficient to switch a nanomagnet that has the thermal stability to retain its remanent state at room temperature. For this, one needs a magnetic anisotropy energy $U_k = (1/2)mH_k$ of the order $40-60\,k_\mathrm{B}T$. It turns out that the high-speed switching threshold current I_c in equations (17) and (4) can be directly related to this uniaxial anisotropy energy in the form (Sun, 1999, 2000a), $I_\mathrm{c} \approx (2e/\hbar)\,(\alpha/\eta)\,U_k$. This, depending on the damping α and spin-polarization factor η, places $I_\mathrm{c} \approx 10-100\,\mu\mathrm{A}$ for $U_k \sim 60\,k_\mathrm{B}T$.

Present-day spin-transfer switching junction devices typically involve a quasistatic switching current of the order of $0.1-1\,\mathrm{mA}$ for a device cross- sectional size of around $50-100\,\mathrm{nm}$. This places the quasistatic switching threshold current density in the order $10^6\,\mathrm{A\,cm}^{-2}$. To be useful for CMOS integration, at least another order-of-magnitude reduction is necessary. The high-speed switching threshold, as shown earlier, can be significantly higher (by perhaps a factor of 2–5 depending on device structure details).

Existing low-impedance ($1-10\,\Omega\,\mu\mathrm{m}^{-2}$) MTJs can support a transport current of the order $10^7\,\mathrm{A\,cm}^{-2}$ before barrier-related breakdown. Such current density is sufficient to demonstrate spin-transfer effect. In 2005, SONY Corporation presented the first successful implementation of a CMOS-integrated MTJ switch using spin-transfer as the switching mechanism (Hosomi *et al*., 2005). In this device, switchings of up to 10^{12} cycles were demonstrated at a write-pulse width of around 20 ns, although write-success probability still needs improvement.

A large part of the threshold current of a present-day spin-transfer device comes from the easy-plane demagnetization field because of the thin film geometry. This type of anisotropy does not contribute to thermal stability, yet since the spin-transfer excitation involves significant out-of-film-plane precession, this easy-plane anisotropy significantly increases the spin-transfer switching current. One possibility of reducing the switching current of the spin-transfer devices, therefore, is to reduce or eliminate this easy-plane anisotropy from the system (Sun, 2000a). This can be seen by generalizing equation (4) to include an additional uniaxial anisotropy term in the form of

$$I_\mathrm{c} = \left(\frac{2e}{\hbar}\right)\left(\frac{\alpha}{\eta}\right) m\left(H + H_k + \mid 2\pi M_\mathrm{s} - H_\mathrm{p} \mid\right) \qquad (18)$$

where $\mid 2\pi M_\mathrm{s} - H_\mathrm{p} \mid$ is the combined anisotropy field corresponding to an anisotropy energy expression of equation (1) in Sun (2000a), with the perpendicular anisotropy energy prefactor $K_\mathrm{p} = (1/2)\,m\left(4\pi M_\mathrm{s} - H_\mathrm{p}\right)$. When $K_\mathrm{p} > 0$, an easy-plane anisotropy results. For $K_\mathrm{p} < 0$, this anisotropy term becomes uniaxial with its axis perpendicular to the film surface (and therefore perpendicular to the usually shape-defined in-plane uniaxial anisotropy noted here as H_k). A sizable, perpendicular anisotropy component H_p can be achieved by the careful engineering of the free-layer's interface magnetism, or by controlling its stress field (for materials with large magnetostriction coefficient), or a combination of both. These propositions are theoretically feasible but are likely to raise significant material and fabrication challenges before they can be successfully implemented in a manufacturable fashion.

The threshold current as expressed in relations such as equations (4) and (18) provides only an order-of-magnitude estimate for the switching current necessary for memory circuit operation. To achieve sufficiently fast and deterministic switching, the drive current has to be above the threshold, sometimes by a significant amount. The switching speed versus switching time trade-off is well captured by the curves presented in Figure 4. This trade-off is described by the linear current-dependence in second equation in equation (17). For the $50 \times 100 \times 3\,\mathrm{nm}^3$ cobalt nanomagnet presented in Figure 4, the figure of merit for $(I - I_\mathrm{c})\,\langle\tau\rangle$ is about 8 pC.

For finite temperature operation as a memory element, the collinear switching is unlikely to be the best geometry, as the initial condition of the switch will depend sensitively on thermal distribution. A noncollinear arrangement between the 'free'-layer nanomagnet's orientation and that of the spin-polarized current may be desirable. At the same time, it may be helpful to add, through layout design, a current-induced magnetic field as a transient 'tipping' field to create a nonequilibrium initial state when switching the nanomagnet.

In addition to possible applications as a bistable resistor for memory circuits, spin-transfer devices have also been explored for potential use as compact, on-chip microwave oscillators (Rippard *et al*., 2004). Experiment has demonstrated tunable microwave output from spin-transfer-based magnetic junction structures whose frequencies range from

1 to 20 GHz and whose full-width-half-maximum power linewidth is at least 1000 times below its center frequency. Phase locking between magnetic precession–induced microwave oscillation and additional input tune has also been demonstrated (Rippard *et al*., 2005). Future work in this area is likely to be aimed at reducing the current density required for microwave generation, at increasing the device impedance, and more importantly its output signal amplitude, as well as at the reduction of required external bias magnetic field.

Spin transfer also affects the performance of magnetic read heads in modern hard drives (Covington, Rebei, Parker and Seigler, 2004; Covington *et al*., 2005; Zhu *et al*., 2004). There it can act as a negative influence, at times amplifying thermal and other magnetic noises of the read head, causing stability problems and raising concerns over the signal-to-noise ratio and dynamic characteristics.

Spin-transfer-related magnetic excitation has also been observed to move magnetic domain walls in narrow ferromagnetic wires (Yamaguchi *et al*., 2004; Kläui *et al*., 2005; Saitoh, Miyajima, Yamaoka and Tatara, 2004; Yamanouchi, Chiba, Matsukura and Ohno, 2004; Vernier *et al*., 2004; Grollier *et al*., 2003). In fact, the interaction between spin-polarized current and a ferromagnetic domain wall has been one of the first areas where a spin-angular momentum transfer process was considered (Berger, 1978, 1984). Recent experiments demonstrated unambiguous presence of a spin-torque term in the cause of domain wall motion under applied current. This mechanism (Li and Zhang, 2004b; Tatara and Kohno, 2004; Thiaville, Nakatani, Miltat and Suzuki, 2005; Waintal and Viret, 2004; Zhang and Li, 2004), if harnessed with sufficiently low current density, could have significant implications for memory devices as well.

In short, for applications in integrated circuits, the spin-transfer device has to have lower threshold current density – by at least another order of magnitude than what is demonstrated in all-metal spin valves, and it has to have much larger voltage output than the demonstrated values of several hundred microvolts in spin valves. The recently demonstrated spin-current switchable MTJ devices may prove effective as spin switches that are impedance-matched to CMOS transistors. The switching current density, even in MTJs, remains too high. Various strategies are being proposed for the improvement of spin-transfer devices.

One proposal for reducing the current required to switch a nanomagnet was presented by Berger (2003). For a free nanomagnet sandwiched in between two oppositely fixed magnetic polarizer layers, Berger predicted a sizable enhancement of the spin-transfer effect and an approximately sixfold net reduction of the threshold current.

Several recent experiments (Jiang *et al*., 2004) seem to confirm the existence of this enhancement, although quantitative comparison with model results is yet to be made.

Some recent work has further explored this three-magnetic-layer structure in combination with an MTJ, in which one side of the ferromagnetic (FM) free layer in the middle is interfaced with the FM fixed layer through a tunnel barrier (Fuchs *et al*., 2005b). In this case, the magnetic alignment between the fixed and the free layer on the spin-valve side is seen to affect the spin-transfer threshold current for the free-layer reversal, either to reduce the threshold when the two fixed layers are antiparallel or to increase the threshold when they are parallel. Furthermore, the authors have used this extra degree of freedom in the structure to investigate the effect of junction stack heating, using the apparent magnetic switching field of the free layer as a measure for the free-layer temperature through the thermal-activation model.

8 CONCLUDING REMARKS

In this chapter, we have described how spin-transfer-induced magnetic excitation has been demonstrated both in all-metal spin-valve magnetic nanojunctions and in MTJs. The spin-torque effect can generate persistent magnetic precession as well as complete reversal of a nanomagnet moment's orientation, depending on the details of the bias current and field environment. The main effect of spin torque is to oppose or assist the effective magnetic damping of the nanomagnet, absorbing part of the spin current depending on the relative direction of the nanomagnet moment with respect to the spin-polarization direction and the current flow direction of the spin current. The spin-torque-related effects become most visible when the magnetic junction is small – approximately below 200 nm in lateral dimensions and a film thickness of less than 5 nm in the case of cobalt, for example, macrospin dynamics capture the main experimental features well. It is a good starting point to the quantitative understanding of these new magnetodynamics. For more quantitative and detailed understanding, finite wavelength magnetic excitation has to be carefully taken into account. This in most cases can only be done numerically. Finite temperature problems of micromagnetics with the presence of a spin torque remains a challenge.

Spin torque has important implications for solid-state device applications. For MRAM, it can be used to locally write address a nanomagnet bit by passing an electrical (or spin) current through the particular nanomagnet. This write operation will not disturb the neighboring nanomagnet bit, as it is easier to localize the write current path than is if the write operation were done through current-induced magnetic field. It may also be possible to use spin-transfer junction in its

persistent precession mode, acting as an extremely compact tunable microwave generator. Spin transfer and spin torque also affect the performance of the read heads in magnetic disk drives. In this case, the challenge is to avoid the amplification of thermal (and other) noises present in the read head by the spin-transfer excitation.

The current density required for spin-torque effect to result in magnetic reversal and persistent precession is still a bit too high for ready integration with CMOS technology. The threshold current density is, for the moment, limited mostly by the thin-film shape-determined easy-plane anisotropy $4\pi M_s$. Reduction or elimination of this energy could reduce the threshold current, although the materials and processing challenges associated with this proposition is significant.

The signal voltage output from spin-valve-based spin-transfer junctions is too low. These are all-metal-based junctions with very low impedances which made their integration with CMOS difficult. MTJs, with their much wider range of impedances, seem to have a much better future as spin-transfer switching (or oscillation) devices for circuit integration. This will become feasible once the spin-transfer excitation current density is reduced to a level compatible with MTJs with the desired impedance.

There are relatively stringent requirements on the switching current for reversing a nanomagnet if the nanomagnet is to avoid entering its superparamagnetic state. For room-temperature data retention of the nanomagnet state, the corresponding switching threshold current has been estimated to be of the order of 10–100 μA depending on the choice of material parameters.

Spin-transfer in High Magnetic Fields and Single Magnetic Layer Nanopillars

Andrew D. Kent
New York University, New York, NY, USA

1 INTRODUCTION

Spin transfer is a newly discovered interaction between itinerant electrons and the background magnetization of a ferromagnet, first predicted by Slonczewski (1996) and Berger (1996). This interaction is remarkable in many respects, some of which have been discussed in previous chapters in this volume. From a fundamental perspective, it acts contrary to conventions in condensed matter physics. The large number of conduction electrons in a metal ($n \simeq 10^{22}$ electrons/cm^3) typically determines the characteristics of electrons or quasiparticles at the Fermi surface, which in turn determine the material's thermodynamic and transport characteristics. The ratio of the number of electrons at the Fermi surface to those in the Fermi sea at 4 K is $kT/E_F = 10^{-4}$ for a metal. A ferromagnetic (FM) metal has different numbers of up- and down-spin electrons in the Fermi sea. The up-spin electrons are those whose magnetic moment align with the magnetization and are known as *majority electrons*. The excitations for spin-up and spin-down quasiparticles are distinct, as are their conductivities, which is the basis for the phenomena of giant magnetoresistance (GMR). However, through the spin-transfer interaction, electrons at the Fermi surface change the characteristics of the Fermi sea, leading to excitations of the background magnetization and even magnetization reversal. So there is a role reversal: a small number of electrons at the Fermi surface influence the entire background charge configuration.

The phenomena of spin transfer is distinct from that associated with the flow of charge currents and the magnetic fields that result from such flows; the Oersted fields (Figure 1). Spin transfer is predicted and is found to lead to fundamentally new types of magnetic excitations. For instance, a dc spin current has been shown to lead to steady-state precession of the magnetization at gigahertz frequencies (Kiselev *et al.*, 2003; Rippard *et al.*, 2004). A steady-state charge current cannot produce a steady-state precession –illustrating, perhaps most clearly, that new physics is needed to understand the influence of a spin current on the background magnetization. Of particular interest, spin transfer is leading to new insights into the injection, diffusion, and coherence of electron spins in materials. In addition, many questions about the microscopic theory of the interactions remain open to further study, both from the theoretical and experimental view points (Zhang, Levy and Fert, 2002; Shapiro, Levy and Zhang, 2003; Levy and Zhang, 2004; Brataas, Bauer and Kelly, 2006; Stiles and Miltat, 2006).

Spin-current-induced magnetic excitations in single magnetic layer and bilayer nanopillars are discussed in this chapter. In contrast with earlier chapters, which focus on

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 5: *Spintronics and Magnetoelectronics*. ISBN: 978-0-470-02217-7.

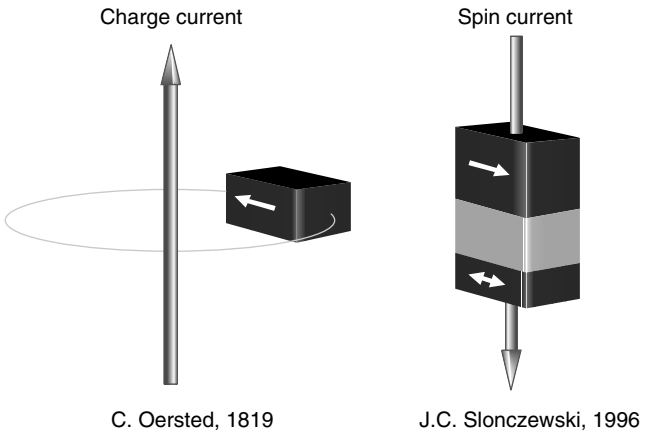

Figure 1. Oersted discovered in 1819 that a charge current produces a magnetic field which acts on a magnet. The interaction predicted by Slonczewski (1996) is distinct and is associated with the flow of spin current directly through a ferromagnetic layer. In the illustration, this is a thick 'fixed' magnetic layer and a thin 'free' layer, a prototype spin-transfer structure.

low-field switching and precession, we emphasize phenomena that occur at high current and magnetic field.

We begin with an outline of the Slonczewski model. We then present high-field experiments that reveal hysteresis in current and magnetic field sweeps in magnetic bilayers. These experiments suggest that even in very large magnetic fields a spin current may induce a complete reversal of the thin magnetic layer to align antiparallel (AP) to the applied field – that is, to a state of maximum magnetic energy. This is consistent with the Slonczewski model within a single domain or macrospin picture. We then review experiments on single magnetic layer structures that require physics beyond the macrospin model. These experiments illustrate that spin transfer can create nonuniform spin-wave excitations. The most elementary samples that exhibit spin-transfer effects thus consist of just a single thin magnetic layer, not two magnetic layers. Nonuniform spin-wave excitations are also seen in traditional bilayer structures, which experiment reveals to have a rich phase diagram of current-induced excitations. We conclude with a summary and perspectives on spin transfer.

2 SPIN-TRANSFER INTERACTION

In Slonczewski's model, spin-angular momentum is transferred to the background magnetization when the spin current enters the ferromagnet – within the first few atomic layers Stiles and Zangwill (2002). The transverse component of spin current is filtered by the FM layer and, by conservation of angular momentum, there is a back reaction on the magnetization. Absorption of the transverse component of spin-angular momentum by the background magnetization is the fundamental origin of the spin-transfer torque.

In magnetic nanopillars that consist of a thick and thin magnetic layer separated by a nonmagnetic (NM) layer, the thick (fixed) layer polarizes the current and dynamics is usually induced in the thin (free) layer. The magnetization of the free layer can be described by the Landau–Lifshitz–Gilbert (LLG) equation with an additional term. In a macrospin model, which assumes that the two layers are uniformly magnetized:

$$\frac{\mathrm{d}\hat{m}}{\mathrm{d}t} = -\gamma \hat{m} \times \vec{H}_{\mathrm{eff}} + \alpha \hat{m} \times \frac{\mathrm{d}\hat{m}}{\mathrm{d}t} + \gamma a_{\mathrm{J}} \hat{m} \times (\hat{m} \times \hat{m}_P) \quad (1)$$

$\hat{m}$ and $\hat{m}_P$ are unit vectors in the direction of magnetization of the free and fixed magnetic layers, respectively. The first term on the right leads to precession of the magnetization about the effective field, $\vec{H}_{\mathrm{eff}}$, γ is the gyromagnetic ratio. The second term on the right is the damping term, where α is the Gilbert damping constant. The last term is due to spin transfer. The vector cross product, $\hat{m} \times (\hat{m} \times \hat{m}_P)$, is in the direction of spin angular momentum transverse to the free layer magnetization and in the plane containing $\hat{m}$ and $\hat{m}_P$. To see this explicitly, note that:

$$\hat{m} \times (\hat{m} \times \hat{m}_P) = (\hat{m} \cdot \hat{m}_P)\hat{m} - \hat{m}_P \quad (2)$$

The prefactor of the spin-transfer term, a_{J}, depends on the current, the spin polarization of the current, P, and the angle between the free and pinned magnetic layers Θ, $a_{\mathrm{J}} = \frac{\hbar I}{eMV} g(P, \Theta)$ (Slonczewski, 1996). Here I is the charge current and g is a function of the polarization P that increases with Θ. V is the volume of the magnetic element. An increase in a_{J} with an increase in the angle has been found in a number of different approaches to modeling the spin-transfer effect (Bauer, Tserkovnyak, Huertas-Hernando and Brataas, 2003; Stiles and Zangwill, 2002; Waintal, Myers, Brouwer and Ralph, 2000; Shapiro, Levy and Zhang, 2003). Spin-current-induced torques of the form $b_{\mathrm{J}} \hat{m} \cdot \hat{m}_P$ are also possible, where b_{J} is proportional to the current (Zhang, Levy and Fert, 2002). This has the form of torque due to a magnetic field in a direction $\hat{m}_P$, with a magnitude proportional to the current. This term and the spin-torque term define a basis in the plane orthogonal to $\hat{m}$ and, therefore, an arbitrary torque on the magnetization can always be decomposed into these two terms. There is experimental evidence for this interaction, which is found to be somewhat smaller in magnitude than the spin-torque term (Zimmler *et al.*, 2004). However, this term does not, by itself, lead to magnetization dynamics distinct from that of Oersted fields,

so we emphasize magnetization dynamics associated with the spin torque in this chapter.

The effective magnetic field, $\vec{H}_{\rm eff}$, in equation (1) is the vector sum of the applied field, $\vec{H}$, and the anisotropy fields. Studies are typically conducted on thin elements with an asymmetric shape, approximating a rectangle or ellipse. In this case, the effective field is given by

$$\vec{H}_{\rm eff} = \vec{H} + H_{\rm a}(\hat{m}\cdot\hat{x})\hat{x} - 4\pi M_{\rm s}(\hat{m}\cdot\hat{z})\hat{z} \qquad (3)$$

Here $H_{\rm a}$ is an anisotropy field that accounts for the asymmetric shape of the element ($H_{\rm a} = 2K/M_{\rm s}$, where K is in the uniaxial anisotropy constant) and $4\pi M_{\rm s}$ characterizes the easy-plane anisotropy. $H_{\rm a}$ ($\sim$0.1 T) is typically much smaller than $4\pi M_{\rm s}$ ($\sim$1 T).

In equilibrium, the magnetization is aligned with the effective magnetic field. The spin-transfer torque competes with damping and, at a threshold current, leads to excitation of the magnetization. This is illustrated in Figure 2. Deviation of the free layer magnetization direction from the effective field leads to precession of the magnetization about the field at an angular frequency $\omega = \gamma H_{\rm eff}$. The damping torque acts to bring the magnetization back into alignment with the effective field. If the pinned layer magnetization is also parallel (P) to the effective field, then the spin-transfer torque and damping are collinear. In this case, the spin-transfer torque can enhance or oppose the damping torque depending on the sign of the current. In the latter case, excitation of the magnetization occurs, which may drive the free layer magnetization into a precessional state (PS) or new static configuration.

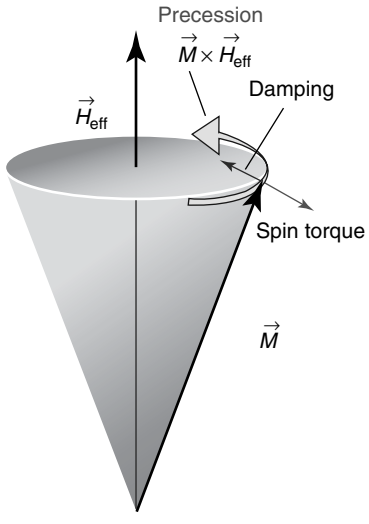

Figure 2. Schematic of magnetization dynamics with a spin-transfer torque. In large fields, when the pinned layer magnetization, effective field, and applied field are parallel, the spin-transfer torque is collinear with the damping. Instabilities occur when the spin torque opposes and exceeds the damping torque.

3 HIGH-FIELD STUDIES OF BILAYERS

Studies in large magnetic fields applied perpendicular to the layers provide insight into the physics of spin transfer. For fields greater than the layer demagnetization field ($4\pi M_{\rm s}$), the Zeeman energy ($E = -M_{\rm s}H$) becomes the dominant term in the magnetic energy and, in equilibrium, the magnetization is aligned with the applied field. In this limit (i.e., assuming that $H \gg H_{\rm a}$), there is axial symmetry about the field direction, and the precession is circular, with the precession frequency increasing linearly with the applied field.

Initial point-contact experiments on magnetic multilayers were conducted in high perpendicular fields (Tsoi *et al*., 1998, 2000; Myers *et al*., 1999) (Figure 3a). A peak structure in the differential resistance ($\mathrm{d}V/\mathrm{d}I$) versus current graph was observed and interpreted as the onset of current-induced excitation of long wavelength ($k \simeq 0$) spin waves (Tsoi *et al*., 1998, 2000; Slonczewski, 1999) (Figure 3a). Subsequent experiments have focused on nanopillar structures (Figure 3b), in which the magnetic bilayers, such as Co/Cu/Co layered films, are patterned down to the 100-nm lateral scale (Katine *et al*., 2000; Grollier *et al*., 2001, 2003; Albert, Katine, Buhrman and Ralph, 2000; Albert *et al*., 2002; Sun *et al*., 2002, 2003). Spin-transfer torque studies on pillar devices (PDs) are usually conducted with small magnetic fields applied in the layer plane. In the low-field regime, a hysteretic jump in the differential resistance was observed (Figure 3b). These experiments provide clear evidence for current-induced magnetization switching (Katine *et al*., 2000; Grollier *et al*., 2001, 2003; Albert, Katine, Buhrman and Ralph, 2000; Albert *et al*., 2002; Sun *et al*., 2002, 2003; Urazhdin, Birge, Pratt and Bass, 2003). Hence, the effect of the spin-polarized current on the magnetization seemed to be quite distinct in the low- and high-field regimes; at low fields, switching is observed, whereas high-field data is interpreted in terms of spin-wave excitations. Current-induced hysteretic magnetization reversal was only observed at low *in-plane* fields in nanopillar devices.

3.1 Experiments on nanopillar junctions

Nanopillar junctions were used to study current-induced magnetization dynamics in large fields and currents in Özyilmaz *et al*. (2003). The layer structure was |3-nm Co| 10-nm Cu|12-nm Co|300-nm Cu| 10-nm Pt| and the typical lateral size of the sample was $90 \times 140\,\mathrm{nm}^2$. The thin Co layer has a lower coercivity and is the 'free' layer in the device. The thick Co layer is the 'fixed' layer in the device and acts to set up a spin-polarized current in the intervening Cu layer. The inset in Figure 4 shows a sketch of the PD. Details of fabrication and transport properties at low in-plane

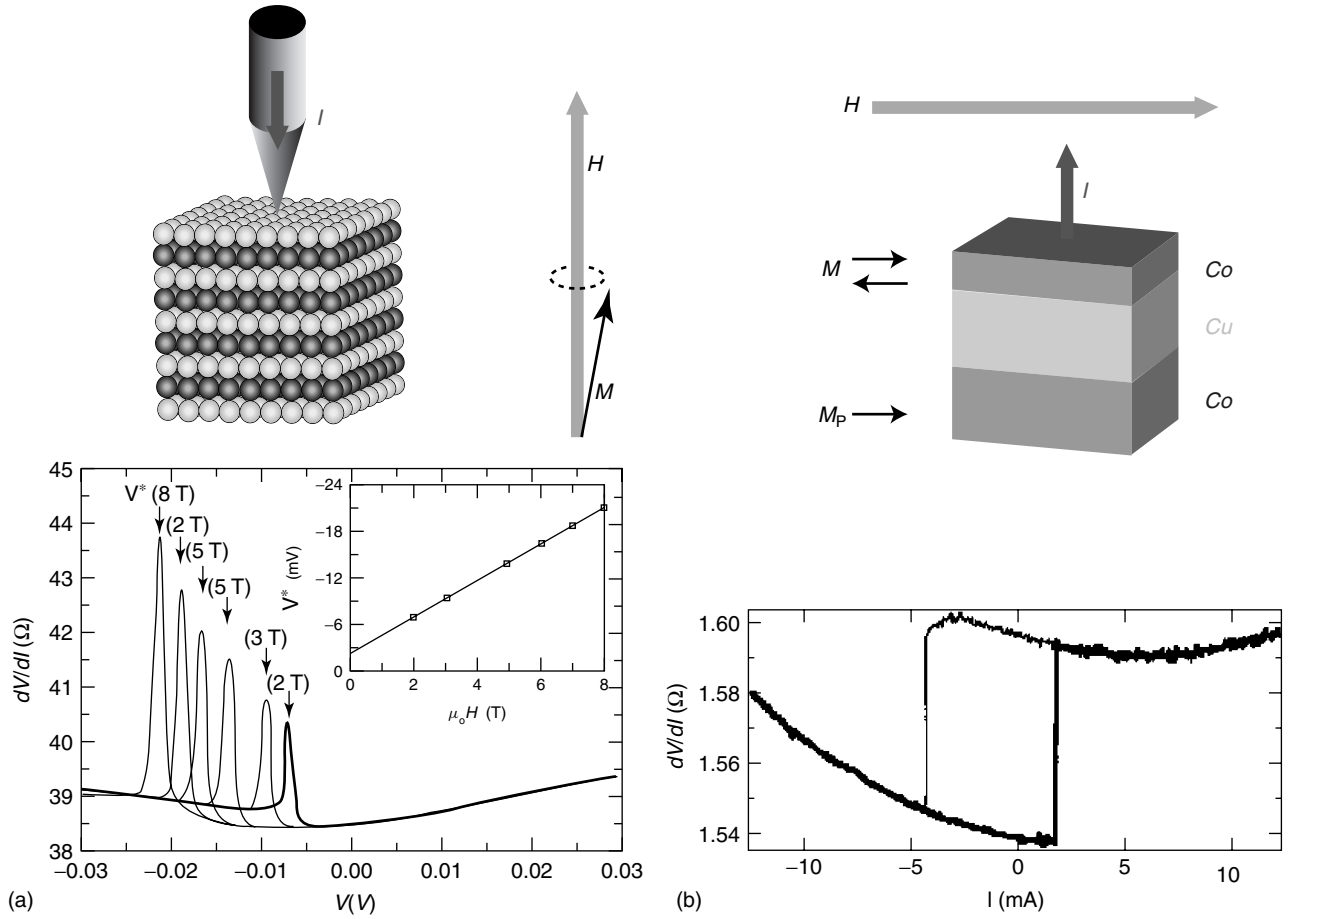

Figure 3. Spin-transfer experiments. (a) Initial studies were conduced using mechanical point contacts to magnetic multilayers. In high fields perpendicular to the plane, peaks in differential resistance were observed and interpreted as the onset spin-wave excitations. (b) Experiments on magnetic bilayer thin-film elements patterned into nanopillars showed the first evidence for current-induced magnetization reversal in small in-plane applied magnetic fields. (Reprinted with permission of Tsoi *et al*. copyright 1998, American Physical Society.)

fields can be found elsewhere (Sun *et al*., 2003). Transport measurements were conducted in a four-point measurement configuration at 4.2 K to minimize the effect of thermal fluctuations on the magnetization dynamics. Positive current bias is defined such that electrons flow from the thin to the thick layer.

A typical magnetoresistance (MR) measurement with in-plane magnetic fields is shown in Figure 4(a). The device exhibits a clean transition between a low-resistance and high-resistance state corresponding to P and AP alignment of the magnetization of the two Co layers. The MR of this sample is 5.4% at 4.2 K. Owing to magnetostatic interactions between the layers, the high-resistance state is reached before the sign of H is reversed, which is typical of pillars in which both magnetic layers are patterned.

Figure 4(b) shows dV/dI versus I with the applied field perpendicular to the film. Here the applied field ($H = 2.2$ T) is larger than the demagnetization field of the Co thin layer ($4\pi M_s \approx 1.5$ T). The sweep to negative currents is shown as the dashed line in the figure. An abrupt change in resistance occurs only for one current direction. In addition, the onset of this change in resistance is sharp and takes place at a critical current, I_c ($j_c \approx 2.3 \times 10^8 \mathrm{A\,cm^{-2}}$). The signature is a peak in the differential resistance. In simultaneous dc measurement (shown in an inset of Figure 4b), this feature corresponds to a steplike increase of the dc voltage. The parabolic increase in the background resistance for both directions of the current is due to increased electron scattering at high current densities.

In earlier reports, the peak structure in the differential resistance of point contacts was attributed to the excitation of a uniform precession of the free layer (Tsoi *et al*., 1998, 2000; Slonczewski, 1999). However, this picture does not explain the data on nanopillars for several reasons. First, the resistance change is large. This can be seen by either looking at the change of slope in the dc voltage at the critical current I_c or by comparing the differential resistance for I greater

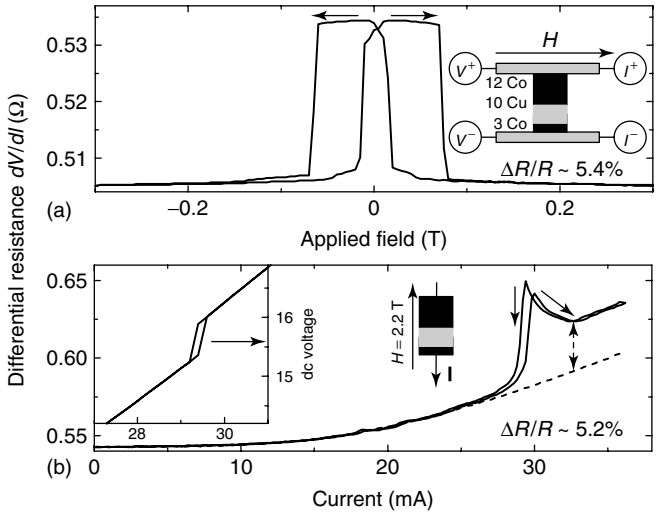

Figure 4. (a) $\mathrm{d}V/\mathrm{d}I$ versus H for in-plane fields and small bias currents. The inset show the sequence of the layers (in nm) and the four-point measurement geometry. The lateral dimensions of the sample are $90 \times 140\,\mathrm{nm}^2$. (b) $\mathrm{d}V/\mathrm{d}I$ versus I of the same device in an applied perpendicular field of $H = 2.2\,\mathrm{T}$. Differential resistance $\mathrm{d}V/\mathrm{d}I$ was measured by means of a phase-sensitive lock-in technique with a 100-μA modulation current at $f = 800\,\mathrm{Hz}$ added to a dc bias current. The dc voltage was recorded simultaneously. At a critical current, a peak structure occurs in the differential resistance. The dotted line shows $\mathrm{d}V/\mathrm{d}I$ at negative currents, for which the peak structure is absent. The inset shows the simultaneous dc voltage measurement. (Reprinted with permission of Özyilmaz *et al*. copyright 2003, American Physical Society.)

than I_c with the differential resistance at the same current value but with opposite polarity at which the abrupt change in resistance is absent. Either comparison shows a change in resistance of about 5%, similar to the GMR value of the same device (Figure 4a). Therefore, an explanation in terms of a small deviation of the free layer magnetization from its P alignment with respect to the static layer is not sufficient to explain the observed resistance change. With the measurement of a resistance change comparable to the GMR effect, it seems plausible to assume that even at high fields the spin-transfer effect can produce a full reversal of the magnetization. Second, the change in device resistance is hysteretic, occurring at higher current density for increasing current (Figure 4b). The excitation of small amplitude spin waves would decay rapidly on the timescale of such measurements and thus appear reversible in such $I-V$ measurements. Further, as we show in the following text, this interpretation is consistent with micromagnetic modeling.

The critical current for excitations has a nonmonotonic dependence on the applied perpendicular field. This is shown in Figure 5. At low fields, the critical current decreases with increasing applied fields (Figure 5a). While at fields greater than 1.5 T, the critical current increases with applied field (Figure 5b). In addition, at high fields, the current sweeps are hysteretic, particularly above 2 T. The magnetic field dependence of the critical current is summarized in Figure 6(a), in which the differential resistance is plotted in grayscale. Here the current is swept up from 20 to 36 mA, while the magnetic field is held constant for each current sweep. For subsequent current sweeps, the field is raised from 0.34 to 2.7 T in steps of 5 mT. In this grayscale plot, a critical current I_c separates the 'applied field-current bias' plane into two regions. Below the critical current, the device remains in its low-resistance state, in a P or nearly P magnetization state. Above the critical current, the magnetization of the device is in a higher resistance state, in which the relative orientation of the magnetization of the two layers deviates strongly from a P configuration.

The critical current for decreasing current is shown as the dashed line in this figure. As noted in the preceding text, for fields greater than 1.4 T, the critical current increases with applied magnetic field. In this region, the current hysteresis, ΔI_c, also generally increases with increasing field. (There is a deviation from this behavior between 2.0 and 2.4 T, in which ΔI_c actually decreases. We suspect this to be due to the onset of nonuniform excitations.) While below 1.2 T, the critical current decreases linearly with applied magnetic field. In this field region ($1.1\,\mathrm{T} \rightarrow 0.35\,\mathrm{T}$), the hysteresis is near the limit of our experimental resolution. The resistance jumps for both regions are similar in magnitude, that is, close to the GMR value.

The general features of the data can be understood on the basis of the LLG equations with the spin-torque term, equation (1). In the large-field regime ($H > 4\pi M_s$), we neglect the in-plane magnetic anisotropy and take $\vec{H}_{\mathrm{eff}} = H - 4\pi M_s(\hat{m}\cdot\hat{z})\hat{z}$. In this case, there is axial symmetry and the equations of motion can be greatly simplified. Initially, both layers are parallel to the applied field and the z component of the free layer magnetization satisfies (neglecting terms of order α^2):

$$\frac{\mathrm{d}m_z}{\gamma\,\mathrm{d}t} = (1 - m_z^2)[\alpha(H - 4\pi M_s m_z) - a_J] \qquad (4)$$

It is clear that an initial state $m_z = 1$ aligned with the applied field in the z direction will become unstable when $a_J > \alpha(H - 4\pi M_s)$. The threshold current, $a = \alpha(H - 4\pi M_s)$ increases with increasing applied field, as observed in experiment. More generally, this relation illustrates that the critical current for the onset of magnetic excitations is proportional to the ferromagnetic resonance (FMR) frequency, $\omega = \gamma(H - 4\pi M_s)$. This follows because the spin-transfer torque competes with the damping torque, which is proportional to the precession frequency. The critical current is also predicted to be zero when $H = 4\pi M_s$.

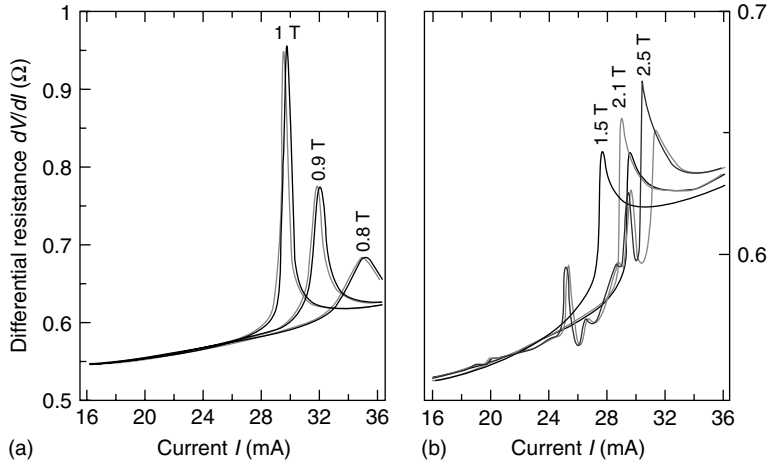

Figure 5. dV/dI versus I at several applied perpendicular fields, acquired both for increasing and decreasing current sweeps. (a) Low-field regime: here the critical current decreases with increasing field. (b) High-field regime: the critical current increases with the magnetic field and clear hysteresis is observed sweeping up and down in current.

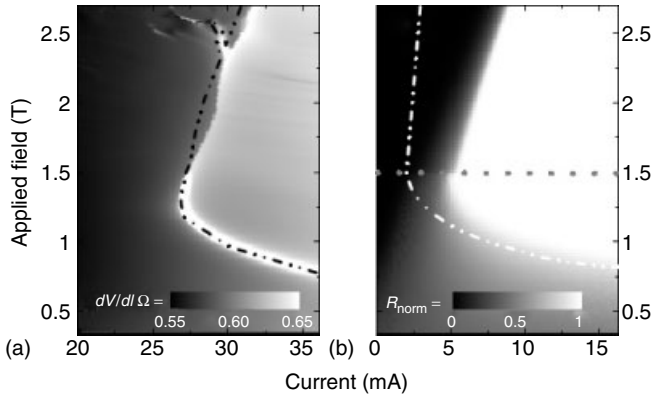

Figure 6. (a) Magnetic field dependence of dV/dI versus I. The grayscale represents the differential resistance of the junction. Light color corresponds to high resistance and dark to low resistance. The dashed line shows the position of the jump in resistance for downsweep of the bias current. (b) Micromagnetic simulations of the experiment as described in the text. (Reprinted with permission of Özyilmaz *et al*. copyright 2003, American Physical Society.)

A solution with magnetization antiparallel to the effective field ($m_z = -1$) occurs for $a_J > \alpha(H + 4\pi M_s)$ and corresponds to a static magnetization ($(d\hat{m}/dt) = 0$). In this case, the spin torque leads to a state of maximum magnetic energy of the free layer. Similar high-energy states have also been observed in numerical studies for the field in-plane geometry (Sun, 2000; Li and Zhang, 2003). As a_J increases with Θ, the transition between a precessing state with $|m_z| < 1$ and $m_z = -1$ occurs rapidly with increasing current and is hysteretic. For example, hysteresis occurs when $a_J > \alpha(H + 4\pi M_s)$ for $\hat{m}\cdot\hat{m}_P = -1$, while at the same current $a_J < \alpha(H - 4\pi M_s)$ when $\hat{m}\cdot\hat{m}_P = 1$. In addition, for increasing applied field, the transition occurs at a higher current and the width of the hysteresis increases.

It is important to note that the hysteresis here is a characteristic of the spin-transfer interaction. Hysteresis in ferromagnets is typically associated with magnetic anisotropy or dipolar interactions that result in local minima in the energy (Hubert and Schäfer, 1998). In large applied fields, however, there is only one minimum in the energy, when the magnetization and field are aligned. Here the hysteresis is due to the angular dependence of the spin-torque interaction. The spin torque per unit angle for small deviations of the layer magnetizations from collinear is largest in the AP state and therefore starting in an AP state and reducing the current results in a lower critical current than starting in a P state and increasing the current.

Figure 6(b) shows the result of integration of the equation (1) under the conditions approximating the experiment ($P = 0.4$ for Co and $\alpha = 0.007$ (Schreiber *et al*., 1995)). The device resistance is plotted in grayscale versus I and H and is computed from the angle between the fixed and free layers using the analytic expression: $R_{norm} = (R(\theta) - R(0))/(R(\pi) - R(0)) = (1 - \cos^2(\theta/2))/(1 + \cos^2(\theta/2))$ (Wang, Zhang and Levy, 1996; Bauer, Tserkovnyak, Huertas-Hernando and Brataas, 2003; Shapiro, Levy and Zhang, 2003). For $H < 4\pi M_s$ (below the horizontal dashed line in the figure) the pinned layer magnetization tilts into the plane and thus the pinned layer and effective field are no longer collinear. In this case, there are PSs of the magnetization, with the projection of $\hat{m}$ on $\hat{m}_P$ decreasing with increasing current. The average resistance is plotted below this line. The dashed–dotted line shows the transition to a low-resistance state for decreasing currents, that is, starting with the layers initially antiparallel.

Qualitatively, there is a good correspondence between the data and the model. The model captures the general features in the data, including the high-field region of increasing critical current with increasing applied field and the low-field region ($H < 1.4\,\mathrm{T}$) in which the critical current increases with decreasing field. It is now straightforward to understand why the critical current is a nonmonotonic function of field. This follows because the critical current is proportional to the FMR frequency which itself is a nonmonotonic function of applied field. The FMR frequency for magnetization in the film plane is given by the Kittel equation, $\omega = \gamma\sqrt{H_\mathrm{a}(H_\mathrm{a} + 4\pi M_\mathrm{s})}$ (Kittel, 1996). When a field is applied perpendicular to the plane, the FMR frequency decreases until the applied field is sufficient to orient the magnetization in the field direction, when $H = 4\pi M_\mathrm{s}$. Further increase of the field leads to an increasing resonance frequency and a linear dispersion of the critical current with applied magnetic field –the critical current follows the same trend.

There are also clear discrepancies between the data and the model. In particular, the model predicts significantly lower critical currents (factor of ∼5) and greater hysteresis than observed in the experiment. The latter is perhaps not surprising as we have assumed single domain dynamics in the model and likely the relaxation to the low-energy magnetic state occurs via nonuniform magnetic states of the free layer. In more recent experimental studies, the critical current is found to be within a factor of ∼2 of the model, likely reflecting the improvements in sample quality, both layer structure and lithography (Chen *et al*., 2006a,b).

MR measurements at fixed current bias also show hysteresis at high fields. Figure 7 shows MR measurements at fixed and large current bias. There are five field regions bounded by H_1, H_2, H_3, and H_4, which depend on current bias. For fields, $H_1 < H < H_2$, the field is sufficient to lead to P alignment of the layer magnetizations. In the next region ($H_2 < H < H_3$), PSs driven by the spin current become possible and a gradual and *reversible* transition from P to AP alignment takes place. In the interval $H_3 < H < H_4$. The layers are in an AP state. At the boundary H_4, a reversible but sharp transition from AP back to P configuration takes place. The width of the hysteresis depends on the current bias and the polarity of the applied field. In general, it increases with increasing current bias.

This behavior is distinct from that of point contacts (Tsoi *et al*., 1998, 2000). It is also different from the characteristics found when large in-plane fields are applied to PDs (Katine *et al*., 2000; Grollier *et al*., 2003). In the latter case, a large plateau in the MR with intermediate resistance R_int value ($R_\mathrm{P} < R_\mathrm{int} < R_\mathrm{AP}$) was observed. The resistance plateau was attributed to a precessing spin-wave state in between P and AP alignment. From Figure 7, it is clear that in the field perpendicular geometry there is not a large plateau in the MR. In comparison to point-contact

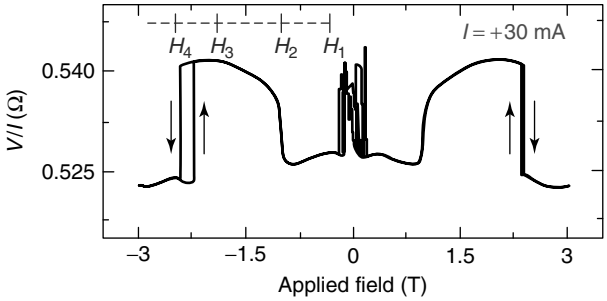

Figure 7. Magnetoresistance measurement at large positive applied bias current. For fields greater than $|H_1|$, there is a low-resistance state with parallel alignment of the layer magnetizations. In the field range $|H_3| > |H| > |H_2|$, current-induced torques lead toward antiparallel alignment through PS states. For $|H| > |H|$, the layers are forced back to a parallel alignment. The transition to parallel alignment is abrupt and hysteretic, whereas the gradual transition starting at H_2 is reversible. (Reprinted with permission of Özyilmaz *et al*. copyright 2003, American Physical Society.)

experiments (Tsoi *et al*., 1998, 2000), high bias currents in PDs appear to lead to a complete magnetization reversal even at high magnetic fields. In addition, there is a recent report that an energy-threshold mechanism explains spin-transfer-induced magnetic excitations in nanopillars in the field perpendicular geometry, based on temperature dependent studies of the critical current (Tsoi *et al*., 2004). However, a reduction in the critical current with increasing temperature is naturally explained within the standard model of spin-transfer model as a result of thermal fluctuations of the magnetization (see Li and Zhang, 2004). Finally, these results and analysis suggest that the main peak in $\mathrm{d}V/\mathrm{d}I$ in large perpendicular magnetic fields marks the end, not the onset of magnetization dynamics. Recent high-frequency studies in the field perpendicular geometry are consistent with this interpretation (Kiselev *et al*., 2004).

3.2 Phase diagram for magnetic excitations in the field perpendicular geometry

The phase diagram for magnetic excitations in the field perpendicular geometry is intricate even within the macrospin approximation. This can be seen with a simple form for the angular dependence of the spin torque proposed in Li and Zhang (2004),

$$\tau_\mathrm{ST} = \frac{a_\mathrm{J}}{1 + \eta\hat{m}\cdot\hat{m}_\mathrm{P}}\hat{m} \times (\hat{m} \times \hat{m}_\mathrm{P}), \tag{5}$$

with the single parameter η characterizing the angular dependence of the torque and with $a_\mathrm{J} = (\hbar I P/2eM_\mathrm{s}V)$ (i.e., with the angular dependence removed from this factor). Note that angular variations of the torque in equation (5) closely

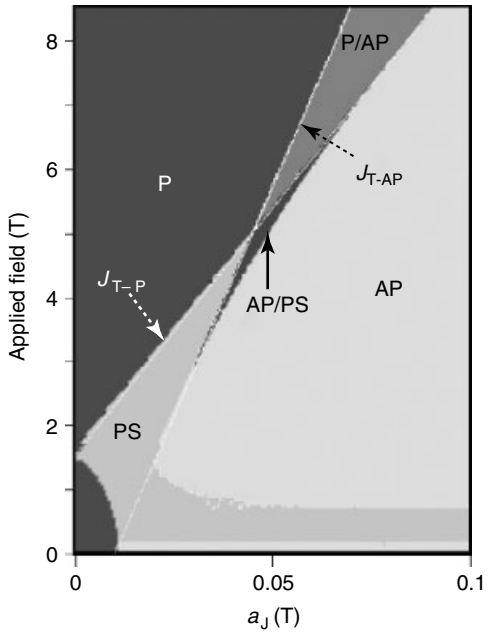

Figure 8. Phase diagram of a nanopillar in the field perpendicular geometry for $\eta = 0.3$, $\alpha = 0.01$, and $4\pi M_s = 1.5\,\mathrm{T}$, with a small (0.1 T) in-plane uniaxial anisotropy. The labels refer to parallel (P), antiparallel (AP), and precessional states (PS). The threshold current density for instability of the P state, J_{T-P}, and the AP state, J_{T-AP}, are indicated.

match those given by Slonczewski (1996). (For example, $\eta = 0.45$ here corresponds to a polarization, $P = 0.2$, in Slonczewski (1996)). This form of the torque was also chosen because it permits a greater degree of analytical analysis of spin-torque-induced magnetization dynamics.

A phase diagram computed using this form of the spin torque and the effective field given in equation (3) is shown in Figure 8. For fields greater than $4\pi M_s$, the P state becomes unstable at a threshold current given by

$$J_{T-P} = \frac{2e\alpha}{\hbar P}(1+\eta)M_s t(H - 4\pi M_s) \tag{6}$$

leading to a PS. Here t is the free layer thickness. Further increase in the current results in the free layer switching to an AP state. On decreasing the current, the AP becomes unstable and switches back to a PS or P state when

$$J_{T-AP} = \frac{2e\alpha}{\hbar P}(1-\eta)M_s t(H + 4\pi M_s) \tag{7}$$

As mentioned in the preceding text, hysteresis is associated with the angular dependence of the spin-transfer torque; the fact that the torque is larger in the AP state ($\eta > 0$).

J_{T-P} and J_{T-AP} are equal and cross when $H_c = 4\pi M_s/\eta$. However, hysteresis appears at a smaller field, corresponding to the lowest field at which the AP/PS region appears in the phase diagram. Within this model, η can be determined from experiment, from the lowest field at which hysteresis occurs. For example, on the basis of the data shown in Figure 6, η must be greater than 0.3. This implies that, for a constant current, the derivative of the torque with respect to the angle between the layers for small deviations from collinear alignment is approximately a factor of 2 larger for the AP state than the P state. This is close to that found in measurements by Smith *et al*. of the angular dependence of the spin torque in GMR read heads (Smith, Katine, Childress and Carey, 2005).

Recent experiments give a critical current threshold in semiquantitative agreement with equations (6) and (7). The main discrepancy is in the intercept of the threshold boundary, as is the case for the data presented in Figure 6. This discrepancy may reflect the fact that the macrospin model greatly underestimates the principal mode frequency in the field perpendicular geometry because of finite size effects (McMichael and Stiles, 2005; Kakazei *et al*., 2004). As the critical current is proportional to the mode frequency, this changes the intercept of the threshold current versus field, resulting in a greater threshold current at a given field. However, this does not change the slope of the threshold current versus field, which is set by the gyromagnetic ratio, γ. It would clearly be of interest to conduct full micromagnetic simulations to better understand the experimentally determined phase diagrams and the breakdown of the macrospin approximation in the high-field limit. Simulations of this sort have already been conducted for small in-plane magnetic fields (Lee *et al*., 2004; Montigny and Miltat, 2005). High-frequency experiments, like those reported in Kiselev *et al*. (2003) and Rippard *et al*. (2004), would also shed light on magnetization dynamics in the high-field limit.

4 SINGLE MAGNETIC LAYER EXCITATIONS

4.1 Background

It is of interest to study the most elementary sample or device that exhibits current-induced excitations. The concept proposed by Slonczewski requires two magnetic layers, one which serves to polarize the current and the second which responds to the polarized current (Slonczewski, 1996). This bilayer structure is also considered necessary for a more practical reason. The magnetic state of the layers is inferred from resistance measurements. The layer that polarizes the current also serves as a reference layer, and changes in magnetization are detected through the GMR effect. Therefore, a sample with only a single magnetic layer would seem to preclude

both the excitation as well as the detection of magnetic excitations. Nonetheless, experiments have demonstrated current-induced excitations in electrical transport studies, sometimes with characteristics quite similar to those seen in traditional bilayer structures. Further, recent theory suggests that the same spin-transfer interaction responsible for reversal and excitations in bilayers leads to magnetic instabilities in structures that contain only a single magnetic layer.

The spin-transfer interaction requires a component of spin-angular momentum transverse to the direction of the background magnetization of the ferromagnet. Slonczewski and Berger considered a one-dimensional model in a macrospin approximation. In this case, two magnetic layers are needed for the spin-transfer interaction –the interaction is present when the magnetizations of the layers are noncollinear. However, going beyond the macrospin and one-dimensional transport model, it is found that only one magnetic layer is needed to have a nonzero spin-torque interaction. In this case, fluctuations in the magnetization direction transverse to the current direction are allowed. This coupled with spin diffusion parallel to the layer interfaces leads to a transverse component of spin at the FM interface and magnetic excitations. This is the basis for single-layer excitations.

Polianski and Brouwer (2004) first proposed a model for single-layer magnetic excitations. They emphasized that the spin-filtering characteristic of ferromagnets is the fundamental cause of the spin-transfer torque. Spin filtering occurs whenever a current crosses a NM/FM interface. For example, in a pillar that consists of a NM/FM/NM structure in a current perpendicular to the plane (CPP) geometry, spin currents flow at the interfaces and there is spin accumulation at both FM/NM interfaces, on either side of the FM (Figure 9). Fluctuations in the magnetization direction of the FM combined with spin diffusion parallel to the NM/FM interface lead to a transverse component of spin at the interface and a spin-transfer torque (Figure 10). At each interface, these torques act to align the magnetization along the direction of the spin accumulation. In a structure that has mirror symmetry about the center of the magnetic layer, the resulting torques are of equal magnitude but are opposite in direction and cancel each other. However, if the mirror symmetry is broken, the torques acting on each NM/FM interface have different magnitudes. In this case, Polianski and Brouwer (2004) and Stiles, Xiao and Zangwill (2004) predict that an unpolarized current can induce spin-wave instabilities and generate spin-wave excitations with wave vectors in the film plane. Instabilities occur when the current bias is such that the direction of the larger spin accumulation is antiparallel to the direction of the magnetization of the FM. This leads to a specific prediction for the dependence of the excitations on current polarity. Polianski and Brouwer (2004) studied the case of a thin FM where the magnetization does not

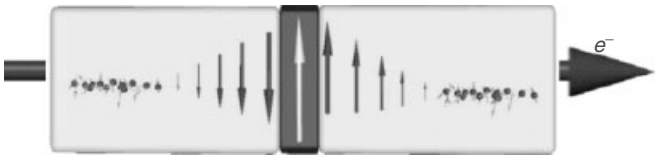

Figure 9. Electron current flow through a single ferromagnetic layer leads to spin accumulation on either side of the ferromagnet, that is, a magnetization is induced in the contacts to the layer.

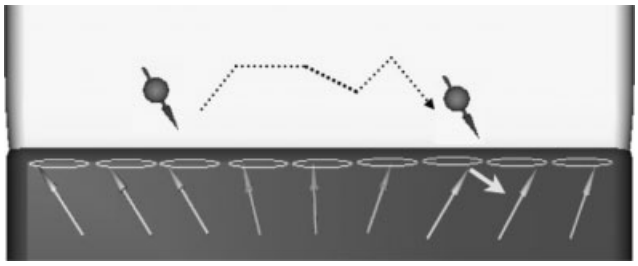

Figure 10. Mechanism of spin-wave generation proposed in Polianski and Brouwer (2004). Spin diffusion of down-spin reflected electrons are shown as dashed lines. This results in a spin torque that enhances the spin-wave amplitude. The torque on the background magnetization is shown as a white arrow. have any spatial variation along the current flow direction. Here, the break in symmetry requires asymmetric contacts. Stiles, Xiao and Zangwill (2004) relaxed this requirement and allowed the magnetization to vary along the current flow direction, which also breaks the mirror symmetry. In either case, in ideal asymmetric junctions, current-induced excitations are predicted to occur for only one current polarity and are expected to be absent in perfectly symmetric structures. Both groups made predictions on how single-layer instabilities depend on parameters such as the current bias polarity, the FM layer thickness, the degree of asymmetry of the single-layer junction, and the applied field.

4.2 Experiments

In order to study spin transfer, high current densities must be injected into the ferromagnet. This has been achieved in three different geometries: (i) lithographically patterned point-contact junctions, (ii) mechanical point contacts, and (iii) nanopillar junctions. The first technique was pioneered at Cornell University and has been used in many types of studies. In fact, in initial spin-transfer experiments in bilayer films subject to high current densities, samples with only one magnetic layer were also studied (Myers *et al*., 1999). Here, high current densities were achieved by means of lithographically patterned point contacts (Figure 11a). Mechanical point contacts were used in studies of magnetic

Symmetric junctions are fabricated by addition of a Pt layer (dashed box).

multilayers (Tsoi *et al*., 1998) and employed by Ji, Chien and Stiles (2003) to study single FM layers (Figure 11b). The first studies of single FM layer nanopillar junctions, illustrated in Figure 11(c), were done by Özyilmaz, Kent, Rooks and Sun (2005) and are discussed in detail in the following text.

These distinct sample geometries place different boundary conditions on the current and magnetization. In point-contact methods, the current density is very high at the contact and thus also highly nonuniform. This nonuniformity creates a situation in which a single magnetic layer may act as its own reference and polarizing layer. The region removed from the contact and experiencing a lower current density serves this function. The experiments of Ji, Chien and Stiles (2003) are performed on relatively thick FM layers (300 nm of Co) that allow for spatial variations of the magnetization along the current direction, or longitudinal excitation of the magnet. The excitation envisioned in this experiment is illustrated schematically in Figure 11(b). The authors propose that magnetic excitations localized near the contact result in a nonuniform magnetization in the film. They suggest that the added resistance of the contact is associated with a longitudinal excitation of the magnetization–essentially, a domain wall forms near the contact. This mechanism is similar to that operative in bilayers. The phenomena observed are in fact quite similar to those discussed in previous sections. Increases in resistance and peaks in differential resistance are observed that disperse to higher current as the magnetic field increases.

Nanopillar junctions have several key advantages in the study of spin-transfer excitation of single magnetic layers. First, the current density is uniform across the nanomagnet interface and thus there is no *a priori* spin-polarizing reference magnetic layer to generate a transverse component of spin or lead to resistance changes; these effects must come from the same magnetic layer through which the current passes. Second, there is the possibility of creating excitations that are transverse to the current flow direction. In particular, very thin magnetic layers can be realized in which the creation of longitudinal excitations would be energetically very costly. Excitations can also be studied as a function of layer thickness. This geometry is thus well suited to explore the basic physics of spin transfer in single magnetic layers. We thus focus on such experiments in this article.

4.2.1 Single-layer nanopillar devices

Experiments on PDs were conducted by Özyilmaz, Kent, Rooks and Sun (2005). Junctions ∼50 nm in diameter were fabricated by means of a nanostencil mask process (Sun *et al*., 2002), which has been used earlier for spin-transfer torque studies in Co/Cu/Co bilayer spin valves (Sun *et al*., 2003; Özyilmaz *et al*., 2003). To study the thickness dependence of single-layer excitations, a nanostencil mask process was combined with an *in situ* wedge growth mechanism. With this approach, PDs were fabricated with a single Co layer of continuously varied thickness across a single wafer. As shown in Figure 11(c), structures fabricated by means of an undercut template are intrinsically asymmetric due to the requirement of an inert bottom electrode surface, usually Pt, on top of which the pillar structure is grown. Here, asymmetry refers to the spin-accumulation pattern generated within the PD with respect to the Co-layer position. The strong asymmetry due to the choice of Pt as bottom electrode is removed by inserting a second Pt layer. Therefore, the study of spin transfer in symmetric single-layer structures requires the 'capping' of the pillar with a Pt layer, as indicated in Figure 11(c).

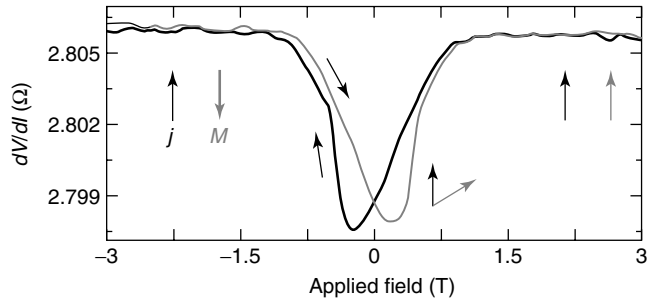

Figure 12. Typical $\mathrm{d}V/\mathrm{d}I$ versus H data at zero dc bias and 4.2 K. The junction size is $50 \times 50\,\mathrm{nm}^2$ and $t \approx 17\,\mathrm{nm}$. An increase in junction resistance ($\sim$0.1%) is observed when j and M are collinear. (Reprinted with permission Özyilmaz *et al*. copyright 2004, American Physical society.)

Junctions with an FM layer thickness varying from 2 to 17 nm and lateral dimensions from $30 \times 60\,\mathrm{nm}^2$ up to $70 \times 140\,\mathrm{nm}^2$ have been studied as a function of bias current and applied field. The range of Co-layer thicknesses covers both, the case where the thickness t is smaller than the exchange length l_{ex} of Co and the case where the thickness is comparable to the latter ($t \geq l_{\mathrm{ex}}$). All junctions in this thickness range exhibit single-layer excitations. To confirm that the excitations are caused by asymmetric contacts, the experiments were repeated with symmetric PDs with a stack sequence of |PtRh 15 nm|Cu 10 nm|Co 10 nm|Cu 10 nm|Pt 15 nm|.

A typical MR measurement of a single-layer junction at zero dc bias is shown in Figure 12. The resistance R has its minimum when the magnetization M lies in the thin-film plane, that is, when M is orthogonal to $\hat{j}$. It gradually increases with applied field which tilts the magnetization vector out of the thin-film plane. Once the applied field exceeds $4\pi M_{\mathrm{s}}$, M is parallel to $\hat{j}$ and the resistance saturates at its maximum. From this, it is clear that the MR is sensitive enough to register (*field-induced*) changes of relative orientation of $\hat{j}$ and M. MR can also be used to detect *current-induced* changes of the magnetization, as we show in the following text.

A typical $I(V)$ curve for an asymmetric single-layer PD is shown in Figure 13. Here $\mathrm{d}V/\mathrm{d}I$ versus I is plotted for fields $H = 1.5, 2, 2.5$, and 3.1 T for a $30 \times 60\,\mathrm{nm}^2$ junction with $t \approx 8\,\mathrm{nm}$. At fields above the demagnetization field ($H > 1.5\,\mathrm{T}$), we observe anomalies in the form of small dips at negative current polarity only. Note that in the field perpendicular geometry the onset of these excitations always leads to a (small) decrease in resistance, which is opposite to what has been observed in both point-contact experiments (Myers *et al*., 1999; Ji, Chien and Stiles, 2003) and bilayer PDs. We discuss this further in the following text.

To distinguish these excitations from the parabolic background resistance, we plot $\mathrm{d}^2V/\mathrm{d}I^2$, which is sensitive to abrupt features in $\mathrm{d}V/\mathrm{d}I$. Plotted in grayscale as a function

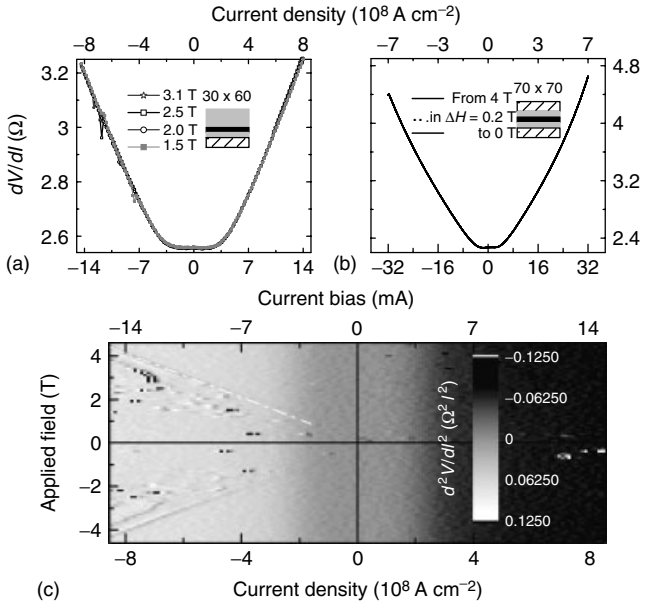

Figure 13. $\mathrm{d}V/\mathrm{d}I$ versus I at constant fields. (a) Asymmetric junction ($30 \times 60\,\mathrm{nm}^2$, $t \approx 8\,\mathrm{nm}$) with Pt as bottom electrode. For $H > 4\pi M_{\mathrm{s}}$ dips are observed at negative bias only. (b) Symmetric junction ($70 \times 70\,\mathrm{nm}^2$, $t \approx 10\,\mathrm{nm}$) with Pt on either side of the Co layer ($t \approx 10\,\mathrm{nm}$). $I(V)$ curves at different field values overlap fully. (c) Phase diagram for current-induced excitations in single-layer junctions; same junction as in Figure 13(a). $\mathrm{d}^2V/\mathrm{d}I^2$ is plotted in grayscale. of the applied field and the current bias, it represents a phase diagram for single-layer excitations. An example of such a plot is shown in Figure 13(c). Here, the current is swept from -15 to $+15$ mA, while the magnetic field is held constant for each current sweep. For subsequent sweeps, the field is stepped from -4.6 to $+4.6$ T in 100 mT steps. The 'current bias–applied field' plane segregates into two regions separated by a straight line, which we associate with the critical current I_{c} for single-layer excitations. For fields with $H > 4\pi M_{\mathrm{s}}$, excitations only occur for negative current polarities. At negative current bias, excitations are absent below the critical current, whereas above the critical current many modes are excited. I_{c} shows a linear dependence on the applied field and can be extrapolated approximately to the origin. Dividing I_{c} by the *nominal* junction area A, we estimate the field dependence of the critical current density $j_{\mathrm{c}} = bH$ with $b \approx 1.9 \times 10^8\,\mathrm{A\,cm^{-2}\,T^{-1}}$. We obtain a more accurate estimate for j_{c} by multiplying I_{c} with the junction resistance $R \approx 2.55\,\Omega$, which is equivalent to dividing by an *effective* junction area: $j_{\mathrm{c}} \propto I_{\mathrm{c}}R = \beta H$ with $\beta \approx 8.8 \times 10^{-3}$ ($\mathrm{A\Omega\,T^{-1}}$).

A better way to distinguish the small features of current-induced excitations from the varying background resistance

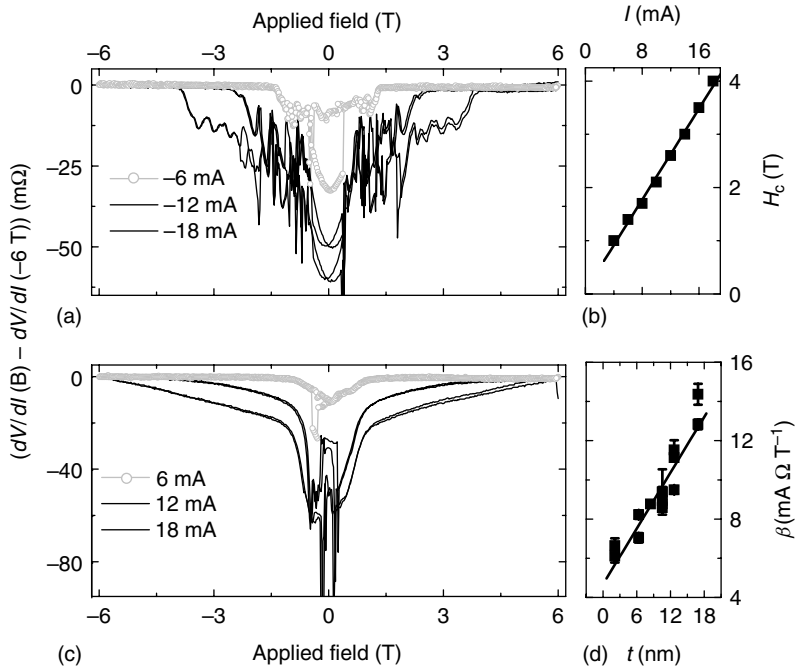

Figure 14. (a) dV/dI versus H at negative current bias. The zero dc bias field sweep of this junction is shown in Figure 13. (b) Current bias dependence of the critical fields above which excitations are not observed. (c) dV/dI versus H for positive current bias; excitations are absent. (d) Thickness dependence of the 'critical currents'. Here, the slope β of I_cR is plotted as a function of Co-layer thickness t. (Reprinted with permission Özyilmaz *et al*. copyright 2004, American Physical society.)

is to fix the latter. This can be done by keeping the current constant and sweeping the applied field instead. Here, an example of such a measurement is given in Figure 14(a) and (c). Field sweeps at fixed negative current bias are shown in Figure 14(a), whereas Figure 14(c) shows the MR at fixed positive currents. The strongest evidence for current-induced excitations in single-layer junctions comes from the comparison of these two figures. As shown in Figure 14(c), excitations at fields $H > 4\pi M_s$ are absent in the field traces. However, high current densities at positive bias gradually increase the applied field at which the differential resistance saturates. This effect cannot be attributed solely to the presence of additional (Oersted) fields related to the charge current and is not yet fully understood.

There is a dramatic change in the field traces if one applies a negative current bias to the junction. For each fixed current value, there is now a critical field H_c, above which the resistance remains constant. However, below H_c, the observation of peaks and dips indicates the presence of many (current-induced) excitations. H_c is a linear function of the bias current and shifts to higher values as one increases the current. As can be seen in Figure 14(b), the linear fit of the critical fields can once more be extrapolated to the origin. Hence, in both field sweeps at fixed currents and current sweeps at fixed fields one obtains a linear dependence of the critical parameter on the running variable, that is, $j_c = bH$ and $H_c = cj$. For a particular Co-layer thickness, the slopes b and c are equivalent, that is, $b \cong c^{-1}$. From Figure 14(b) and the nominal junction area A, we estimate the current density dependence of $H_c = cj$ with $c \approx 5.2 \times 10^{-9}\,\mathrm{T\,A^{-1}\,cm^{-2}}$. Using the junction resistance $R \approx 2.80\,\Omega$ as an approximation for the effective junction area, we obtain $H_c \propto \zeta(IR)$ with $\zeta \approx 73.8\,\mathrm{T/(A\Omega)}$. Note that for $H < 4\pi M_s$ there are large changes in the hysteresis for both current polarities. This effect cannot be explained by the interaction of the Oersted fields with magnetic domain configurations at fields $H < 4\pi M_s$. In fact, recent experiments show current-induced switching in a single layer, reflecting the domain structure in low fields even in these deep submicron magnetic elements (Özyilmaz and Kent, 2006). Related studies also indicate MR when switching between domain configurations of permalloy single magnetic layers (Urazhdin, Chien, Guslienko and Novozhilova, 2006).

The thickness dependence of these excitations has also been studied and the results are summarized in Figure 14(d). For all thicknesses, the observed boundary in the 'current bias/applied field plane' can be extrapolated close to the origin. Here we only plot the slope β of the field dependence of I_cR ($\propto j_c$) as a function of Co-layer thickness t. We observe an *increase* in β with increasing t, $\Delta\beta/\Delta t \approx 0.48 \pm 0.05\,\mathrm{m\Omega\,T^{-1}\,nm^{-1}}$. The critical currents increase by approximately a factor of 2 as one increases the Co-layer

thickness t from 2 to 17 nm. Over the same thickness range, the junction resistance R increases only by ≈25% (not shown).

To clarify the origin of these excitations, we have repeated these experiments in symmetric single-layer PDs. An example of current sweeps at fixed fields in these structures is shown in Figure 13(b). Here, the current is swept from +32 to −32 mA in a $70 \times 70\,\mathrm{nm}^2$ junction. In magnetic fields up to 4 T, features such as dips or peaks are absent in the current-voltage characteristics. Also, field sweeps at fixed current do not exhibit any of the strong polarity dependence observed in asymmetric PDs. To summarize, in symmetric junctions, current-induced excitations are absent up to $j \leq 7 \times 10^8\,\mathrm{A\,cm^{-2}}$.

The plots in Figures 13(c) and 14 make it appear that beyond a threshold current the excitations occur randomly as a function of I and H. However, this reflects the data sampling in Figure 13(c), which is too coarse to capture the pattern of excitations. Data taken at smaller field intervals reveal a regular pattern of excitations beyond the threshold (Figure 15). The data were obtained with a $30 \times 60\,\mathrm{nm}^2$ junction with $t \simeq 10$ nm. Here, we plot the second derivative of the signal in grayscale. The plot reveals distinct branches of current-induced excitations for currents $|I| > |I_c(H)|$. These new features only occur over a limited field range, δH. Within each narrow field region, excitations shift to higher currents with decreasing applied fields. This behavior is opposite to the applied field dependence of the onset of the single-layer excitations. This pattern likely reflects the discrete spin-wave spectrum in such elements. Recently, the theory presented in Polianski and Brouwer (2004) has been extended beyond the critical current for spin-wave instabilities (Adam, Polianski and Brouwer, 2006) – and this approach seems promising toward explaining single-layer characteristics and the data in Figure 15.

Generally, experimental results and theoretical predictions are in good agreement. Both models give the correct current polarity, magnitude, and thickness dependence of j_c in asymmetric structures. For the current polarity, strong spin-flip scattering at the Pt/Cu interface effectively forces the spin accumulation at the Pt/Cu interface to zero. This leads to a smaller spin accumulation at the Cu/Co interface facing the Pt bottom electrode. Excitations are therefore expected at negative current when the large spin accumulation is in a direction opposite to that of the magnetization, as observed. The theory also predicts a decrease in resistance upon magnetization excitation, as observed. This is counterintuitive because one might expect that the creation of spin-wave excitations leads to additional energy dissipation and therefore resistance. However, when the layer is excited and its magnetization is nonuniform, additional conduction channels are opened. Qualitatively, this is because electron spins reflected from the layer interface can diffuse back to the layer and be transmitted through a region with a different magnetization orientation. Alternatively stated, the nonuniformly magnetized layer leads to a smaller spin accumulation than a uniform magnetization and thus a lower resistance.

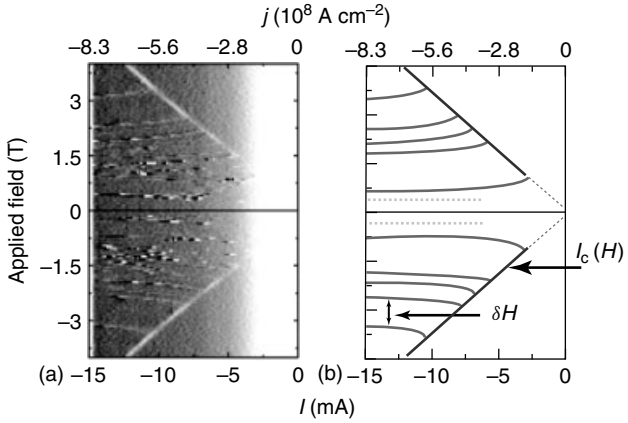

Figure 15. Phase diagram of current-induced excitations in a $30 \times 60\,\mathrm{nm}^2$ junction at negative current. Smaller field steps reveal the applied field dependence of additional features. (a) Grayscale plot of the second derivative as a function of applied field and current bias. (b) The excitation boundaries are retraced to render the pattern clear. For $|I| > |I_c(H)|$ additional features are observed. Each additional feature takes place in a narrow field range, δH. The features shift to higher currents with decreasing applied field value.

In terms of the current magnitude for the excitations, Polianski and Brouwer (2004) studied the case where **M** does not have any spatial variation along the direction parallel to the current $\hat{\mathbf{j}}$. Stiles, Xiao and Zangwill (2004) extended this model by allowing **M** to vary along $\hat{\mathbf{j}}$. For this case, excitations are expected to occur independent of current polarity even in *symmetric* PDs. However, the predicted critical currents are much larger ($j_c > 10^{10}\ \mathrm{A\,cm^{-2}}$) than for the asymmetric case. For example, for an asymmetric junction with $t \approx 17$ nm, the necessary *positive* current densities ($j_c > 2.5 \times 10^9\,\mathrm{A\,cm^{-2}}$) far exceed the value which can be sustained by existing PDs. The linear dependence of j_c on H can be explained by both models. However, the (near) zero intercept of j_c is somewhat peculiar, as the expectation is that the relevant field is the internal field in the layer or $H - 4\pi M_s$. With this reasoning, the critical current intercept should be for $H = 4\pi M_s$. There are two possible explanations for the near zero field intercept. The first is associated with the shape and finite size of the pillar junction. The principle spin-wave modes in such a disk are nonuniform and have a frequency greater than that of an extended thin film, $\omega = \gamma(H - 4\pi M_s)$. This can be seen in micromagnetic calculations of the dependence of the mode frequency on magnetic field (McMichael and Stiles, 2005). For a disk geometry, the frequency of the

modes can also be found analytically (Kakazei *et al*., 2004). A second possible explanation is that the critical current observed may not correspond to small amplitude excitations of the magnetization. As in the case of bilayers discussed in Section 3, large amplitude excitations occur at higher current densities, resulting in a smaller intercept.

The increase in the critical current j_c with increasing Co-layer thickness t is in agreement with theoretical predictions. An *increase* in j_c with increasing t is expected because of an increase in the (bulk) damping (Polianski and Brouwer, 2004; Stiles, Xiao and Zangwill, 2004). According to Stiles, Xiao and Zangwill (2004), in thicker films ($t \gtrapprox l_{ex}$), the variation of $\mathbf{M}$ along $\hat{\mathbf{j}}$ introduces an additional source of asymmetry. This should activate a competing effect, which by itself would *decrease* j_c with increasing t. However, to determine which effect would dominate, details of layer structure and junction geometry need to be considered. For the device geometry considered and for Co-layer thicknesses up to $t \sim 17\,\text{nm}$ ($t > l_{ex}$), the dominant source of the current-induced excitations appears to be the asymmetry of the leads.

In sum, these studies have established that magnetic excitations occur in single-layer asymmetric junctions and are absent in symmetric junctions at similar current densities. The current density for excitations in asymmetric junctions increases with Co-layer thickness. While these experiments demonstrate current-induced excitations in single layers, there are outstanding issues regarding the nature of the excitations. For instance, it is important to know whether they correspond to dynamical excitations. In this regard, it is of interest to study the high-frequency response associated with these excitations. Such studies would also shed light on the nature of the nonuniform modes that are excited. It would also be of interest to examine nanopillar structures with thicker Co layers to examine the onset of longitudinal excitations.

4.3 Bipolar excitations in bilayer nanopillars

The physics of single-layer or nonuniform spin-wave excitations is also relevant to the more widely studied bilayer structures. Bilayer nanopillars generally have asymmetries in the spin-accumulation pattern either due to asymmetric contacts or due to differences between the two magnetic layers in the device. Thus, asymmetries in the spin accumulation across the layers can induce nonuniform magnetic excitations. Therefore, in such structures, nonuniform and uniform current-induced excitation may compete, resulting in a rich phase diagram of magnetic excitations as well as distinct bilayer resistance states. This has been observed in experiments (Özyilmaz, Kent, Rooks and Sun, 2005) and explained in a recent theory (Brataas, Tserkovnyak and Bauer, 2006).

The consequences of single-layer excitations in asymmetric bilayer nanopillars, which consist of a thick ('fixed') and a thin ('free') magnetic layer, are outlined here. It is important to recall that current-induced excitations have been observed for only one polarity of the current at high field (see Section 3), nominally because of the asymmetry in the layer structure. This observation is considered to be clear evidence for physics associated with a spin-transfer torque –as opposed to the effects of charge-current-induced magnetic fields. In addition, the lowest resistance state was always considered to be the static state of P alignment of the layer magnetizations.

Single-layer excitations modify this picture. For sufficiently large current densities, anomalies in $\mathrm{d}V/\mathrm{d}I$ at high fields occur *independent* of current polarity, which decrease the junction resistance. The bipolarity of the excitations and the *decrease* in resistance cannot be understood in terms of spin-transfer-torque-induced single domain dynamics. These results show that high current densities can induce excitations of the magnetization independent of current polarity and relative alignment of the magnetizations of the two magnetic layers. Further, the results illustrate that at high currents the nanopillar resistance can be lower than that of a state of P magnetic alignment. Finally, modifying the contact geometry, by making the contacts more symmetric, is shown to suppress such excitations, consistent with theory (Chen *et al*., 2006a).

4.3.1 Experiments

The layer structure studied is illustrated schematically in Figure 16. The samples studied have lateral dimensions $\sim 50 \times 50\,\text{nm}^2$ and consist of a Pt 15 nm|Cu 10 nm|Co 3 nm|Cu 10 nm|Co 12 nm|Cu 300 nm multilayer.

Figure 17(a) shows typical measurements of $\mathrm{d}V/\mathrm{d}I$ versus I in large applied fields ($B \gg B_{\text{demag}} \sim 1\,\text{T}$). Current-induced excitations (peaks in $\mathrm{d}V/\mathrm{d}I$) appear to occur at positive current bias. However, a more careful look at the current sweeps reveals the presence of excitations even at negative currents (Figure 17b). Here, we observe anomalies in $\mathrm{d}V/\mathrm{d}I$ in the form of *dips*. These dips correspond to decreases in the differential resistance of about 0.5%. These excitations shift to higher currents with increasing field. They may be distinguished from the parabolic background resistance by plotting the second derivative in grayscale as a function of current bias and applied field. From this plot (Figure 17d), it is clear that the excitations depend approximately linearly on the applied field for both polarities of current.

Peaks in $\mathrm{d}V/\mathrm{d}I$ at positive currents are known to be related to magnetization excitations. In Section 3, we have discussed how their position indicates the critical current, I_c, necessary to switch the free layer magnetization into the

high-resistance AP state. However, excitations at negative currents are unexpected. In the P configuration, negative currents are expected to suppress any deviation of the free layer from P alignment with the fixed layer. In particular, in large applied fields, the layer magnetizations should therefore remain in the P state. In addition, we observe dips instead of peaks in $\mathrm{d}V/\mathrm{d}I$, indicating that excitations at negative currents decrease the junction resistance. However, within a single domain model, GMR should lead to an increase in the junction resistance whenever the layer magnetizations deviate from the P alignment.

At positive currents in a single domain model in which the thick-layer magnetization remains fixed, there are no further excitations once the AP state is achieved, that is, once $I > I_c$, after the main peak in $\mathrm{d}V/\mathrm{d}I$ (see Figure 8). However, there is structure in $\mathrm{d}V/\mathrm{d}I$ beyond the main peak, again in the form of dips in $\mathrm{d}V/\mathrm{d}I$. The results are shown in Figure 18. Here, we plot the differential resistance as a function of current for selected applied fields, $0.7\,\mathrm{T} < B < 4.7\,\mathrm{T}$. We observe both peaks *and* dips in $\mathrm{d}V/\mathrm{d}I$. However, at fields $B > 1\,\mathrm{T}$, dips occur only for $I > I_c(H)$. Also, most current sweep traces show multiple dips in $\mathrm{d}V/\mathrm{d}I$. The field dependence of these excitations is best seen when the second derivative $\mathrm{d}^2V/\mathrm{d}I^2$ is plotted in grayscale as a function of current bias and applied field (Figure 18a). Such a plot reveals two boundaries, which can be best distinguished at fields with $B > 1.5\,\mathrm{T}$. The first boundary (B) represents the currents $I_c(H)$ at which the free layer switches into the AP state. Note that in many samples we also observe additional peaks in $\mathrm{d}V/\mathrm{d}I$ for $I < I_c(H)$ (region A). These peaks coincide with small upward jumps of the junction resistance (not shown), which we associate with transitions between PSs (Kiselev *et al*., 2004).

At higher currents, the plot reveals a second boundary (C). The latter marks the critical currents $I_+(H)$ above which we observe dips in $\mathrm{d}V/\mathrm{d}I$. The current bias and field dependence of these additional excitations is nontrivial, but the observed features are both stable and reproducible. A good demonstration of the latter is their applied field dependence. The latter is best described by first considering cuts parallel to the current axis of the plots (Figure 18, dashed–dotted line) and then cuts parallel to the field axis (dotted line). In the first case, the applied field is constant.

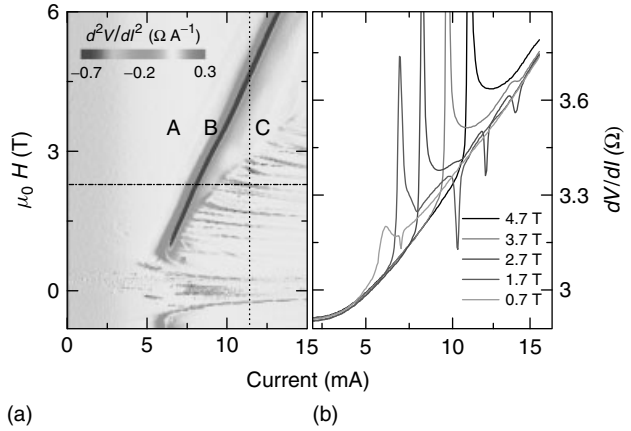

Figure 18. (a) Plot showing $\mathrm{d}^2V/\mathrm{d}I^2$ versus current and applied field. Dips in differential resistance after the main peak in $\mathrm{d}V/\mathrm{d}I$ (labeled B) are visible and correspond to boundary C. *A* labels the region where peaks in $\mathrm{d}V/\mathrm{d}I$ with $\Delta R/R$ much smaller than the GMR value are observed. Now, as we increase the current, we cross several branches corresponding to distinct excitations. At each of these crossings, we observe dips in $\mathrm{d}V/\mathrm{d}I$. From cuts parallel to the field axis (constant current bias), we see that each excitation exists only in a very narrow field range, that is, they have a weak dependence on magnetic field. Note that these excitations have a very similar structure to those observed in single magnetic layers (Figure 15). Also, here the excitations shift to lower currents as we increase the applied field. In addition, different branches of excitations are separated by narrow stripes of high-resistance regions. We suspect that these gaps reflect the quantization of transverse spin-wave modes in these small elements. As in the case of excitation of single magnetic layers, current-induced excitation can also be characterized by performing field sweeps at fixed current bias. Such measurements were reported in Özyilmaz, Kent, Rooks and Sun (2005).

We now discuss an interpretation of these results in terms of spin-wave instabilities that are expected in the presence of strong asymmetries in the longitudinal spin accumulation (Polianski and Brouwer, 2004; Stiles, Xiao and Zangwill, 2004). The necessary condition for such instabilities is that the current bias has to be such that the sum of the longitudinal spin accumulation on either side of the FM layer, that is, the net spin accumulation, is in the direction opposite to that of the magnetization (Polianski and Brouwer, 2004; Stiles, Xiao and Zangwill, 2004).

We have modeled the spin-accumulation pattern in our bilayer junctions using the two-current model, with the spin-dependent bulk and interface resistances of Yang *et al*. (1995) in the limit in which the spin-diffusion length is much larger than the layer thicknesses ($\lambda_{\mathrm{sf}} \to \infty$). Figure 16 shows that in the P state at negative current bias the spin accumulation about the thick layer is asymmetric; the net spin accumulation is in the direction opposite to that of the magnetization. According to the condition governing spin-wave instabilities in single layers (Polianski and Brouwer, 2004; Stiles, Xiao and Zangwill, 2004), this accumulation pattern can excite nonuniform spin-waves in the thick layer.

To explain the new region of excitations at currents beyond $I_+(H)$, that is, excitations at positive current bias in the AP state, we also consider the spin accumulation in this case (Figure 16, AP state graph). From this we see that the switching of the free layer has an important effect on the spin accumulation pattern at the fixed layer. The sign of the net spin accumulation changes as the system is switched by the current from the P state into the AP state. Therefore, excitations of the fixed layer now require a *positive* current bias. This is in agreement with the experimental observation. From this we conclude that dips in $\mathrm{d}V/\mathrm{d}I$ at *both* positive and negative currents are caused by excitation of the thick magnetic layer. While at positive currents these excitations could be associated with uniform excitations of the fixed layer, the pattern of the excitations matches well the nonuniform excitations found in single layers (Özyilmaz *et al*., 2004). Similar features at high positive currents have been observed in permalloy nanopillars. Narrow peaks are seen in the voltage spectrum at gigahertz frequencies at these 'dips' in differential resistance, which are consistent with the excitation of the thicker layer in the nanopillar (Kiselev *et al*., 2005). A longitudinal spin accumulation in the direction opposite to that of the magnetization on both sides of this layer seems to be the most likely cause for these excitations.

A detailed theory that explains the experiments presented in the preceding text is in Brataas, Tserkovnyak and Bauer (2006). A schematic phase diagram this theory provides is shown in Figure 19. Here, layer 1 is the thin ferromagnet and layer 2 is the thick ferromagnet. At zero current, the layers are aligned in the large magnetic field. Applying a positive current first produces a macrospin instability of layer 1,

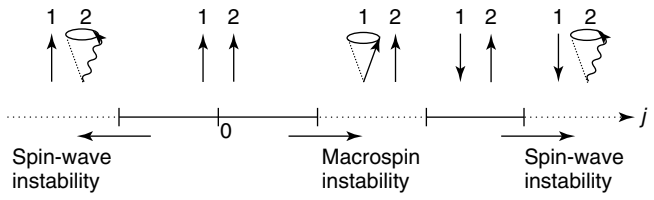

Figure 19. Phase diagram for thin (1) and thick (2) ferromagnet, starting in a parallel configuration, as a function of current. (Reprinted with permission Brataas *et al*. copyright 2006, American Physical Society.)

leading to a reversal of magnetization in the layer. A further increase in the current leads to a spin-wave instability in FM2. For negative currents, a spin-wave instability of the thick layer (FM2) is predicted. The slope of the phase boundaries with respect to applied field ($\mathrm{d}J_c/\mathrm{d}H$) are in semiquantitative agreement with the experiments (Brataas, Tserkovnyak and Bauer, 2006). Further, in the model asymmetries in the spin diffusion to the left and right of the ferromagnets are the main origin of the short wavelength spin-wave excitations of the magnetization. Subsequently, we have prepared nanopillar samples with identical top and bottom leads with respect to spin diffusion, by inserting a thin Pt layer in the right Cu leads shown in Figure 16 (Chen *et al*., 2006a). In these structures, bipolar excitations are suppressed and no excitations are observed beyond the main peak in $\mathrm{d}V/\mathrm{d}I$, confirming theoretical predictions. This result is also of importance in applications of spin transfer since a macrospin response is usually desirable.

5 SUMMARY AND OUTLOOK

The discovery of spin transfer in 1996 has led to rapid advances in the understanding of the influence of spin currents on magnetization dynamics. Spin currents have been shown to lead to nonequilibrium magnetization dynamics, including magnetization reversal, precession, and the excitation of nonuniform spin-wave modes. The resulting phenomena are clearly quite distinct from the action of charge currents or Oersted fields on ferromagnets.

This has been highlighted in this article by emphasizing experimental results on nanopillars in the high-field and high-current limit. In particular, spin currents in magnetic bilayer nanopillars have been shown to lead to magnetic hysteresis in high fields. Micromagnetic modeling shows that sufficient spin current results in a state of maximum magnetic energy, with the field and magnetization antiparallel. This modeling also shows that hysteresis may result from the angular dependence of the spin-torque interaction – distinct from the usual origin of hysteresis in magnets, namely, magnetic anisotropy and the dipole interaction.

Spin transfer also results in intriguing new phenomena in nanopillars with only a single magnetic layer. Here, current-induced excitations lead to a decrease in resistance. These excitations have been shown to be associated with an asymmetry of the contact configuration to the magnetic layer, as predicted by theory. A spin current may therefore excite nonuniform modes of a nanomagnet. The exact nature of the excitations is a topic of active investigation. Explaining such nonuniform magnetic excitations requires physics beyond the macrospin and one-dimensional transport models. It requires coupling micromagnetic and three-dimensional spin-transport calculations, a challenging but important problem. Finally, we have shown evidence for nonuniform excitations in the traditional bilayer nanopillar structures. Results illustrate that the resistance of a nanopillar may be lower than that with the layer magnetizations aligned; the P state. A lower resistance state is realized at high currents, with the onset of nonuniform spin-wave excitations. The contacts to the pillar again play an important role in these excitations.
