The effect of both interdot exchange and magnetostatic interaction has been considered from static and dynamic point of view, with a particular application to the Pt/Co/Pt simple case exhibiting out-of-plane anisotropy. The present storage density record in perpendicular magnetic recording media has been obtained for a thin CoPtCr film patterned by a Ga FIB. The advantage of the nucleation free magnetization reversal was underlined in some particular cases.

The most promising methods for patterning magnetic films will be certainly obtained by combining bottom-up and top-down techniques. For example, arrays of quasi-monodisperse short nanopillars ($t = 50–250$ nm) of iron with small diameter ($a = 10–14$ nm) have been prepared by combining chemical vapor deposition and scanning tunneling microscopy (Wirth, von Molnar, Field and Awschalom, 1999; Wirth, Anane and von Molnar, 2000). Nanopillars are perpendicularly magnetized, thanks to the shape anisotropy. This is a model system to study thermally activated magnetization reversal in ultrasmall entities.

Fundamental studies on fast magnetization reversal dynamics in isolated or coupled nanomagnetic systems are still needed for a better understanding of the properties of isolated or coupled nanoelements. Nanomagnetism and spinelectronics are exciting topics that will surely lead to sounding applications. For that purpose, combined patterning techniques are required for targeting ultimate spatial resolution and imagine ingenious designs.

ACKNOWLEDGMENTS

The authors wish to thank T. Aign, V. Repam R. Hyndman and A. Mougin for their active contributions on the subject, H. Bernas and J. Gierak for enlightening discussions on the physics of irradiation, and P. Metaxas for his critical reading of the manuscript. This work has been partly supported by the *Nanodynamag* project sponsored by the French Minister for Research.

Chemical Synthesis of Monodisperse Magnetic Nanoparticles

Chao Wang and Shouheng Sun
Brown University, Providence, RI, USA

1 INTRODUCTION

Nanometer size particles display many properties, which are both quantitatively and qualitatively different from their respective bulk materials and from the discrete atomic or molecular species from which they are derived. Novel properties arise from the large fraction of atoms that reside on the surface of the particles and from the finite number of atoms within each particle. Recently the study of finite size effects of metal nanoparticles has intensified with the promise of uncovering the evolution of material properties with particle size and harnessing novel properties in new materials and devices. Magnetic storage technology is advancing rapidly toward its scaling limits. Thin granular films of ferromagnetic nanoparticles formed by sputter deposition are already the basis of conventional rigid magnetic storage media hard drives. Progress in magnetic recording density are due, in part, to the development of media with finer and finer grain magnetic films (Weller, 2000). The study of nanoscale magnetic domains are of both fundamental and pressing technical interest as the grain size of advanced recording media is rapidly shrinking to dimensions where magnetic properties depend strongly on nanoparticle grain size.

A magnetic nanoparticle with size below 20 nm is usually in a 'single magnetic domain', within which all the spins align in one direction and magnetization reversal occurs in the case of free particles through rotation. An energy barrier, ΔE, between two orientations of the magnetization determines the relaxation in each orientation, and is proportional to the particle volume, V, and the particle's anisotropy constant, K (Morrish, 1965; Unruh and Chien, 1996). As the particle size decreases to a level that the ΔE becomes comparable to thermal energy (k_BT), the orientation of magnetic polarization in each particle begins to fluctuate randomly. The particle becomes superparamagnetic. Such size dependent nanomagnetism has stimulated tremendous interest recently with the hope to map the scaling limits of magnetic storage technology and understand spin-dependent transport phenomena in nanoscale devices.

Numerous physical and chemical methods have been employed to produce magnetic nanoparticles. These include sputtering, metal evaporation, ball milling, electrodeposition,

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

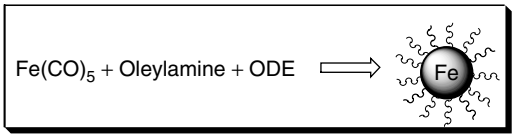
and solution phase chemistry synthesis, among which the solution phase synthesis has been seen as the most promising approach for preparing monodisperse magnetic nanoparticles. It is known that solution phase chemistry can offer an important homogenous nucleation step and facilitates the controlled growth of the nuclei suspended in the solution. As a result, magnetic nanoparticles with various monodisperse sizes and shapes have been prepared. Furthermore, magnetic nanoparticles prepared in this solution phase chemistry can be readily stabilized against particle aggregation or oxidation with a layer of robust organic or inorganic coating. The stabilized nanoparticle dispersion can be deposited on a solid substrate and the solvent is allowed to evaporate. By controlling the concentration of the particle dispersion and the solvent evaporation rate, 2D or 3D self-assembled magnetic nanoparticle superlattices can be formed. The magnetic properties of these nanoparticles can be tuned from superparamagnetic to ferromagnetic and the well-controlled magnetic nanoparticle arrays have shown spin-dependent tunneling (Black, Murray, Sandstrom and Sun, 2000) and can support high-density magnetization reversal transitions (Sun *et al*., 2000). Previous synthesis, characterization, and potential applications of the monodisperse magnetic nanoparticles have been well documented in several reviews (Green, 2005; Willard *et al*., 2004; Cushing, Kolesnichenko and O'Connor, 2004; Park *et al*., 2005; Huber, 2005). In this chapter, we focus on the most recent progress in the synthesis of magnetic nanoparticles, especially the synthetic work from our group, with controlled size, shape, composition, and magnetic properties. The control on nanoparticle shapes allows achieving texture and magnetic alignment of each particle in a self-organized nanoparticle assembly for ultrahigh density magnetic recording (DMR) and high-performance permanent magnetic applications.

2 SYNTHESIS OF Co AND Fe NANOPARTICLES

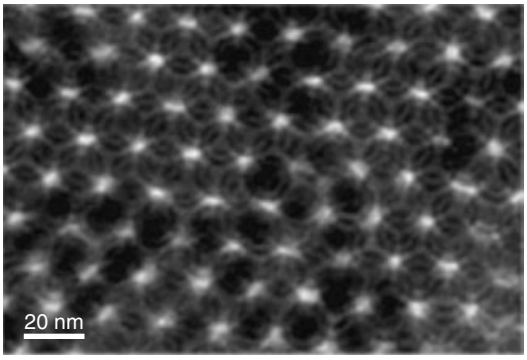
These two kinds of metallic nanoparticles are often synthesized by thermal decomposition of metal–organic complexes in the presence of stabilizing surfactants. Metal–organic complexes, especially metal carbonyl and metal alkene complexes are thermally unstable. Upon heating, they can decompose to give metal atoms and release small ligand, CO, or alkene. The metal atoms can aggregate to form nuclei. With the deposition of more metal atoms over the existing nuclei, metal nanoparticles are formed. Such decomposition chemistry has become a reliable approach for the production of monodisperse Co and Fe nanoparticles owing to the fast decomposition of the precursors and formation of magnetic nuclei.

Cobalt nanoparticles are prepared by thermal decomposing $Co_2(CO)_8$ in the presence of lipid-type surfactants. Fast nucleation is achieved by injection of $Co_2(CO)_8$ into hot ($\sim$200 °C) solution containing oleic acid/trialkylphosphine (R_3P) (Sun and Murray, 1999), oleic acid/trialkylphosphine oxide (R_3PO) (Puntes, Krishnan and Alivisatos, 2001; Bao, Beerman, Pakhomov and Krishnan, 2005). The surfactant combination in, for example, trialkylphosphine and oleic acid, is employed to control particle growth, stabilize the particles, and prevent Co oxidation. Trialkylphosphine reversibly coordinates neutral Co surface sites, slowing but not stopping particle's growth, that is it cannot prevent the particles from eventually growing to undispersable aggregates at high temperature when used alone. Oleic acid, when employed alone, is an excellent stabilizing agent due to the formation of cobalt oleate on the particle surface, but this strong binding to the particle surface during the synthesis prevents the particle from controlled growth. The combination of trialkylphosphine/oleic acid produces a tight ligand shell, which allows the particles to grow steadily while protecting them from aggregation and oxidation. $Co(\eta^3\text{-}C_8H_{13})(\eta^4\text{-}C_8H_{12})$ is another precursor that is commonly used to make Co nanoparticles. Under 3 bar dihydrogen atmosphere, its decomposition in anisole at 150 °C in the presence of a mixture of oleic acid and oleylamine leads to monodisperse Co nanoparticles (Dumestre *et al*., 2003).

Fe nanoparticles have been synthesized by thermal decomposition of iron pentacarbonyl (Green, 2005). Oleic acid is used for nanoparticle stabilization owing to the formation of iron oleate on the nanoparticle surface. Monodisperse Fe nanoparticles obtained from this process, however, do not have good crystallinity due to the complexity of the decomposition of $Fe(CO)_5$ under these synthetic conditions. Nonetheless, reductive decomposition of $Fe[N(SiMe_3)_2]_2$ at 150 °C under H_2 in the presence of hexadecylamine and oleic acid leads to the formation of monodisperse Fe nanoparticles with good crystallinity (Dumestre *et al*., 2004). The Fe nanoparticles synthesized under these conditions are very air sensitive and are difficult to characterize under normal conditions. A recent report shows that monodisperse Fe nanoparticles can be made and stabilized in both organic and phosphate buffered saline. The synthesis is outlined in Figure 1(a). The synthesis uses thermal decomposition of $Fe(CO)_5$ in octadecene (ODE) at 180 °C in the presence of oleylamine (Peng, Wang, Xie and Sun, 2006). Figure 1(b) shows the transmission electron microscopic (TEM) image of 13-nm Fe nanoparticles. Structural characterization of the nanoparticles shows that amorphous Fe_3O_4 produced by natural oxidation of Fe nanoparticles cannot protect the metallic Fe core from deep oxidation. But the desired stabilization is achieved by controlled oxidation of the as-synthesized nanoparticles using an oxygen transferring agent



(a)



(b)

$(CH_3)_3NO$. This controlled oxidation gives core/shell structured Fe/Fe_3O_4 in which crystalline Fe_3O_4 has inverse spinel structure while Fe is amorphous. The thickness of the shell is tuned by controlling the amount of $(CH_3)_3NO$ added into the reaction mixture. Magnetic measurements of the 2.5-nm/5-nm Fe/Fe_3O_4 nanoparticles show that they are superparamagnetic with magnetic moment reaching 61.6 emu g^{-1} particles (90.6 emu g^{-1} [Fe]) and is stabilized at 56.2 emu g^{-1} after the dispersion is exposed to air for over 8 h. In contrast, the as-synthesized nanoparticles start to aggregate only after 2 h and completely oxidized within 8 h.

3 SYNTHESIS OF MAGNETIC IRON OXIDE NANOPARTICLES

Magnetic iron oxide included in this review are mainly cubic spinel structured MFe_2O_4. This oxide represents a well-known and important class of iron oxide materials where oxygen forms an fcc close packing, and M^{2+} and Fe^{3+} occupy either tetrahedral or octahedral interstitial sites. By adjusting the chemical identity of M^{2+}, the magnetic configurations of MFe_2O_4 can be molecularly engineered to provide a wide range of magnetic properties. Owing to this structural versatility, nanometer-scale MFe_2O_4 materials have been among the most frequently chosen systems for studies of nanomagnetism and have shown great potential for many important technological applications, ranging from information storage and electronic devices to medical diagnostics and drug delivery.

Iron oxide nanoparticles are commonly prepared by co-precipitation of M^{2+} and Fe^{3+} ions by a base, usually NaOH, or $NH_3{\cdot}H_2O$ (Kang, Risbud, Rabolt and Stroeve, 1996; Fried, Shemer and Markovich, 2001). This precipitation method is suitable for mass production of magnetic MFe_2O_4 ferrofluids, but it requires careful adjustment of the pH value of the solution for particle formation and stabilization, and it is difficult to control sizes and size distributions, particularly for particles smaller than 20 nm. An alternative approach to monodisperse iron oxide nanoparticles is via high-temperature organic-phase decomposition of an iron precursor, for example, decomposition of $FeCup_3$ (Cup: *N*-nitrosophenylhydroxylamine, $C_6H_5N(NO)O^-$), (Rockenberger, Scher and Alivisatos, 1999) or decomposition of $Fe(CO)_5$ followed by oxidation to Fe_2O_3 (Hyeon *et al*., 2001; Guo, Teng, Rahman and Yang, 2003; Redl, Cho, Murray and O'Brien, 2003). The latter process has recently been extended to the synthesis of monodisperse cobalt ferrite ($CoFe_2O_4$) nanoparticles (Hyeon *et al*., 2002).

An improved synthesis of MFe_2O_4 nanoparticles involves high-temperature (up to 300 °C) reaction between metal acetylacetonate and a 1,2-alkanediol in the presence of oleic acid and oleylamine. When pure iron acetylacetonate, for example, Fe(acac)3, is used for the reaction, monodisperse magnetite Fe_3O_4 nanoparticles are prepared (Sun and Zeng, 2002; Sun *et al*., 2004). If a different metal acetylacetonate precursor $M(acac)_2$ is added to the mixture of $Fe(acac)_3$ and 1,2-alkanediol, MFe_2O_4 nanoparticles (with M = Co, Mn) are obtained (Sun *et al*., 2004). The size of the oxide nanoparticles is controlled by varying the reaction temperature or changing reactant concentration (Xie *et al*., 2006). Alternatively, with the smaller nanoparticles as seeds, larger monodisperse nanoparticles up to 20 nm in diameter can be synthesized by seed-mediated growth (Sun and Zeng, 2002; Sun *et al*., 2004). Figure 2 shows the TEM images of 16-nm Fe_3O_4 nanoparticles made from the seed-mediated growth (Sun and Zeng, 2002).

Magnetic measurements of the Fe_3O_4 nanoparticles indicate that the particles are superparamagnetic at room temperature. Figure 3 shows the hysteresis loops of 16-nm Fe_3O_4 nanoparticles measured at both 10 K and at room temperature. It can be seen that the particles are ferromagnetic at 10 K with a coercivity of 450 Oe (Figure 3a). At room temperature there is no hysteresis (Figure 3b). The saturation magnetization, σ_s, is dependent on the size of the particles. For example, σ_s for 16-nm Fe_3O_4 nanoparticles is 83 emu g^{-1}, close to the value of 84.5 emu g^{-1} measured from the commercial magnetite fine powder. For particles smaller than 10 nm, however, σ_s is smaller under same field strength.

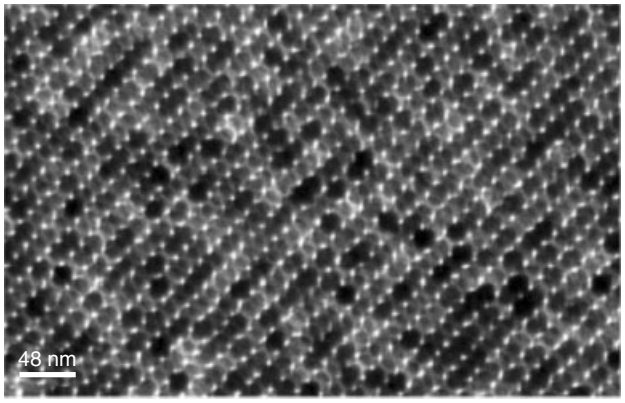

Figure 2. TEM bright field image of a self-assembled array of the 16-nm Fe_3O_4 nanoparticles. (Adapted from Sun and Zeng, 2002.)

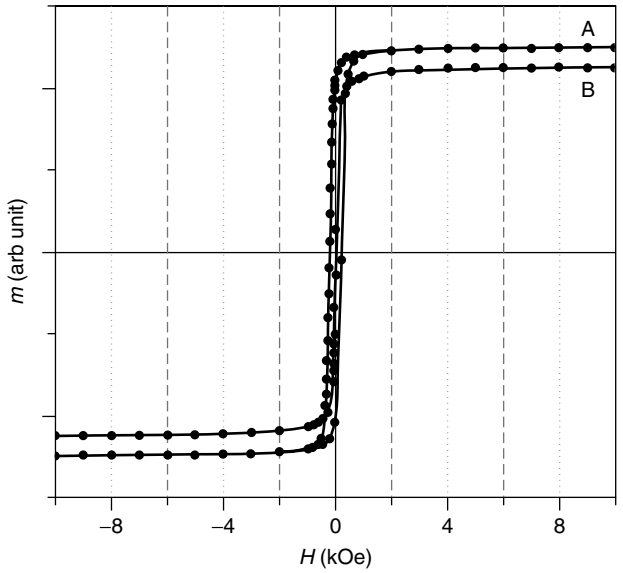

Figure 3. Hysteresis loops of the 16-nm Fe_3O_4 nanoparticle assembly measured at (A) 10 K and (B) 300 K. (Adapted from Sun *et al*., 2004.)

This is likely due to the thermal fluctuation and surface spin canting of the small nanoparticles (Morales *et al*., 1999).

The magnetic properties of the MFe_2O_4 nanoparticles can be tuned by M in the structure. Figure 4 shows the hysteresis loops of 16-nm $CoFe_2O_4$ nanoparticles measured at both 10 K and 300 K. The coercivity of the assembly is about 500 Oe at 300 K, but reaches 20 kOe at 10 K, much larger than that of the 16-nm Fe_3O_4 nanoparticles (450 Oe at 10 K), indicating that the incorporation of the Co cation in the Fe–O matrix greatly increases the magnetic anisotropy of the materials. Such anisotropy enhancement of $CoFe_2O_4$ versus Fe_3O_4 has also been observed in films deposited from aqueous solution (Kim *et al*., 2003). In contrast, the incorporation of Mn cation in the Fe–O matrix reduces the

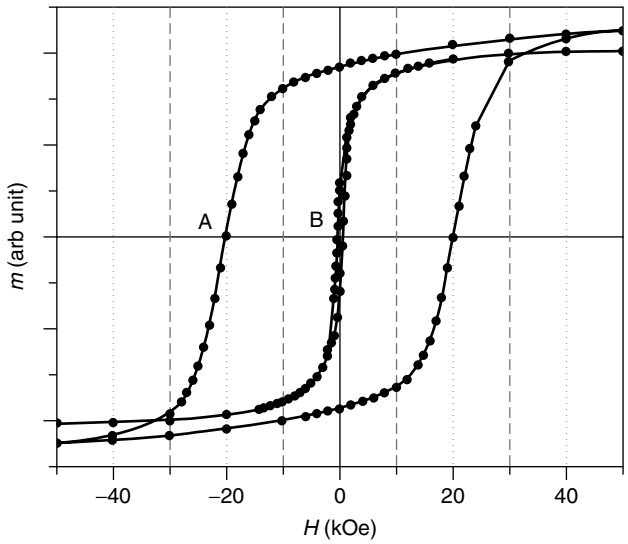

Figure 4. Hysteresis loops of the 16-nm $CoFe_2O_4$ nanoparticle assembly measured at (A) 10 K and (B) 300 K. (Adapted from Sun *et al*., 2004.)

magnetic anisotropy of the materials as the 14-nm $MnFe_2O_4$ nanoparticles shows an Hc of only 140 Oe at 10 K.

4 SYNTHESIS OF ALLOY NANOPARTICLES

Chemically prepared FePt nanoparticles have generated great interest recently because of their ease of synthesis, chemical stability, and potential applications in high-density data storage (Sun *et al*., 2000) and high-performance permanent magnets (Zeng *et al*., 2002). The particles are commonly synthesized via simultaneous decomposition of iron pentacarbonyl, $Fe(CO)_5$, and reduction of platinum acetylacetonate, $Pt(acac)_2$ (Sun *et al*., 2000; Sun, 2006). Oleic acid and oleyl amine are proven to be a good ligand combination for FePt particle stabilization. The composition of the FePt nanoparticles is tuned by varying the molar ratio of $Fe(CO)_5$ and $Pt(acac)_2$. Note that not all the $Fe(CO)_5$ contributes to the FePt formation during the synthesis. $Fe(CO)_5$ has a low boiling point (103 °C). At reaction temperature of 298 °C, $Fe(CO)_5$ is actually in the vapor phase. The formation of this vapor phase results in the slow decomposition of $Fe(CO)_5$ at a rate that matches with the reduction rate of $Pt(acac)_2$. The FePt nanoparticles are formed in a shorter period of time. Therefore, the consumption of $Fe(CO)_5$ can not be completed on this synthetic time scale. As a result, 0.5 mmol of $Fe(CO)_5$ and 0.5 mmol of $Pt(acac)_2$ yield $Fe_{38}Pt_{62}$, while 1.1 mmol of $Fe(CO)_5$ and 0.5 mmol of $Pt(acac)_2$ lead to $Fe_{56}Pt_{44}$ nanoparticle materials. The FePt particle size can be tuned

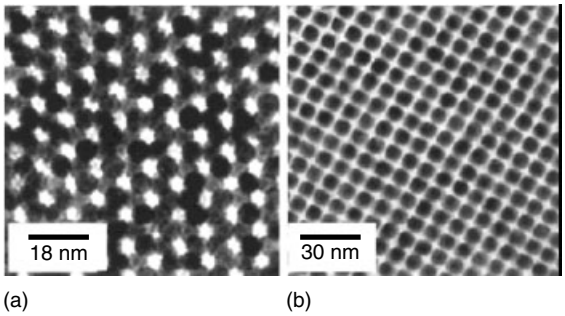

Figure 5. TEM micrographs of (a) a 3D assembly of 6-nm as-synthesized $Fe_{50}Pt_{50}$ particles and (b) a 3D assembly of 6-nm $Fe_{50}Pt_{50}$ sample after replacing oleic acid/oleyl amine with hexanoic acid/hexylamine (Sun *et al*., 2000).

from 3 to 10 nm by first growing 3-nm monodisperse seed particles *in situ* and then adding more reagents to enlarge the existing seeds to the desired size (Sun *et al*., 2000). Figure 5 gives TEM images of the 6-nm FePt nanoparticles prepared from the seed-mediated growth of 4-nm FePt nanoparticles.

The one-step decomposition/reduction method described above can yield high quality FePt nanoparticles with controlled composition but fail to produce particles larger than 4 nm unless the seed-mediated growth method is used, which gives larger FePt particles but without accurate control on Fe, Pt composition at different sizes. To overcome this synthetic problem, a diol-less one-step synthesis is developed (Chen, Liu and Sun, 2004). The lack of the diol from the reaction mixture slows down the nucleation rate, allowing more metal precursor to deposit around the nuclei formed in the solution and leading to the formation of larger particles. The size of the particles is tuned by controlling the molar ratio of stabilizers to $Pt(acac)_2$ and heating conditions. A ratio of at least 8 is needed to make FePt nanoparticles larger than 6 nm in this one-pot reaction. It is also found that, at the fixed stabilizers:$Pt(acac)_2$ ratio of 8, both heating rate and interim heating temperature are important in making FePt particles with tunable sizes. Heating rate of $\sim$15 °C/min. and interim heating temperature of 240 °C yields 6-nm FePt, while the rate of $\sim$5 °C/min. and heating temperature of 225 °C leads to 9-nm FePt. The composition of the particles is controlled by varying the molar ratio of $Fe(CO)_5$ and $Pt(acac)_2$. Under the reported reaction conditions, $Fe(CO)_5/Pt(acac)_2$ ratio of 2 gives 6-nm $Fe_{53}Pt_{47}$ and 9-nm $Fe_{44}Pt_{56}$ nanoparticles. Thermal annealing and magnetic studies show that an assembly of large (6 nm or above) FePt nanoparticles can withstand higher temperature (650 °C) annealing without noticeable particle sintering. Room-temperature coercivity of an assembly containing discrete FePt dots can reach as high as 1.3 T, a value that is suitable for hard magnetic applications.

The mechanism for the formation of FePt nanoparticles in this one-pot, diol-less reaction is given in Figure 6 (Chen, Liu and Sun, 2004). The Pt-rich nuclei (a) are formed from the reduction of $Pt(acac)_2$ either at temperature >200 °C or by Fe atoms from the decomposed $Fe(CO)_5$, or by both. More Fe atoms coat over the existing Pt-rich nuclei, forming larger clusters (b). Exposing these clusters to air leads to formation of Pt-rich $FePt/Fe_3O_4$. Heating the clusters (b) to refluxing at 300 °C results in atomic diffusion and formation of fcc structured FePt nanoparticles (c). In the presence of the excess of $Fe(CO)_5$, the extra Fe continues to coat over (c), giving core/shell structured FePt/Fe that is further oxidized to $FePt/Fe_3O_4$ (d). The intermediate and product structures proposed in Figure 6 have been separated and characterized (Chen, Liu and Sun, 2004).

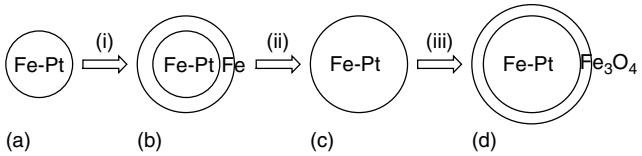

Figure 6. Schematic illustration of the mechanism for the formation of FePt nanoparticles via Fe, Pt diffusion. (i) Fe coating; (ii) Fe, Pt interface diffusion; (iii) Fe coating, then oxidation. (Adapted from Chen, Liu and Sun, 2004.)

Stable CoFe nanoparticles are important for high magnetic moment applications. Such particles can be synthesized by co-decomposition of $Fe(CO)_5$, and $Co(\eta^3\text{-}C_8H_{13})(\eta^4\text{-}C_8H_{12})$ or $Co[N(SiMe_3)_2]_2$ (Desvaux *et al*., 2005). The precursors are reacted under 3 bar H_2 pressure in toluene at 150 °C in the presence of 1 equivalent of hexadecylamine and 1 equivalent oleic acid. The solid product separated from the reaction mixture contains monodisperse CoFe nanoparticles, as shown in the scanning electron microscopy (SEM) image (Figure 7). superconducting quantum interference devices (SQUID) measurements show a ferromagnetic behavior at room temperature with a saturation magnetization (Ms)

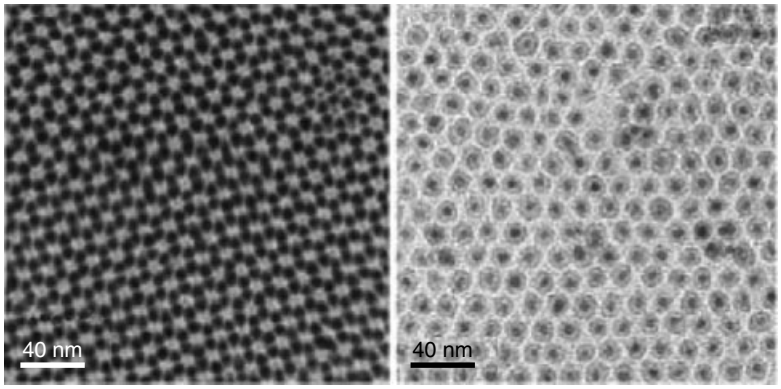

Figure 8. TEM bright field images of core/shell $Fe_{58}Pt_{42}/Fe_3O_4$ nanoparticles with core/shell being (a) 4-nm/0.5-nm and (b) 4-nm/2-nm (Zeng *et al*., 2004).

reaching as high as $183\,Am^2\,kg^{-1}$(CoFe). To improve the air-stability of the nanoparticles, the array is annealed under argon at 500 °C for 30 min. After annealing, the particles adopt the body centered-cubic structure. Furthermore, the annealing results in the formation of a carbon shell around the surface of the particles, protecting the particles from fast oxidation (no noticeable change in the magnetic properties after two weeks of exposure to air). Magnetic measurements of the annealed assembly show an improved magnetization values, $Ms = 220\,Am^2\,kg^{-1}$(CoFe), close to the bulk CoFe values, $Ms = 245\,Am^2\,kg^{-1}$(CoFe).

5 SYNTHESIS OF BIMAGNETIC CORE/SHELL STRUCTURED NANOPARTICLES

Magnetic core/shell nanoparticles can be categorized as those with magnetic core coated with a layer of a nonmagnetic, antiferromagnetic, or ferro/ferri-magnetic shell. A nonmagnetic coating is used routinely for magnetic core stabilization and surface functionalization for biomedical applications. An antiferromagnetic coating over a ferromagnetic core leads to exchange bias (a shift of the hysteresis loop along the field axis) and improvements in the thermal stability of the core (Skumryev *et al*., 2003). Compared with these two different types of core/shell systems, a bimagnetic core/shell one, where both core and shell are strongly magnetic (ferro- or ferri-magnetic) is magnetically more interesting owing to their potential in electromagnetic and permanent magnetic applications (Zeng *et al*., 2002; Carpenter, Calvin, Stroud and Harris, 2003). In such a system, the intimate contact between the core and shell leads to effective exchange coupling and therefore cooperative magnetic switching, facilitating the fabrication of nanostructured magnetic materials with tunable properties.

$FePt/Fe_3O_4$ nanoparticles represent a good example of bimagnetic core/shell structures (Zeng *et al*., 2004). They are prepared by coating the existing FePt nanoparticles with Fe_3O_4 shell in a condition similar to the synthesis of Fe_3O_4 nanoparticles. For example, the 4-nm $Fe_{58}Pt_{42}$ nanoparticles are made by the combination of reduction of $Pt(acac)_2$ and decomposition of $Fe(CO)_5$ in octyl ether solvent (Sun *et al*., 2000). These 4-nm FePt nanoparticles are then used as seeds and mixed with $Fe(acac)_3$ and 1,2-hexadecanediol, oleicacid, and oleylamine in phenyl ether solvent. Fe_3O_4 coating is achieved by heating the mixture (Zeng *et al*., 2004). By controlling the material ratio of $Fe(acac)_3$ to FePt nanoparticle seeds, the Fe_3O_4 shell thickness can be readily tuned. Figure 8(a) and (b) shows two TEM images of the core/shell structured $Fe_{58}Pt_{42}/Fe_3O_4$ nanoparticles with the darker region in the center being 4-nm $Fe_{58}Pt_{42}$ and the lighter ring being 0.5 nm (Figure 8a) and 2-nm Fe_3O_4 (Figure 8b).

The $Fe_{58}Pt_{42}/Fe_3O_4$ core/shell nanoparticles are ferromagnetic at low temperatures but superparamagnetic at room temperature (Zeng *et al*., 2004). The particles with 0.5-nm Fe_3O_4 shell have an H_c of 5 kOe, while those with 3-nm shell have an H_c value of only 1.4 kOe. The large H_c value of the core/shell nanoparticles originates from low-temperature hard magnetic properties of the $Fe_{58}Pt_{42}$ core –the coercivity of the as-synthesized 4-nm $Fe_{58}Pt_{42}$ nanoparticles is 5.5 kOe at 10 K. Fe_3O_4 is magnetically a much softer material, with 10 K H_c ranging from 200 Oe for 4 nm to 450 Oe for 16 nm nanoparticles. However, in the $Fe_{58}Pt_{42}/Fe_3O_4$ system, the magnetic behaviors of $Fe_{58}Pt_{42}$ and Fe_3O_4 are not distinguishable, and the hysteresis loops measured at 10 K show smooth change of magnetization with applied field,

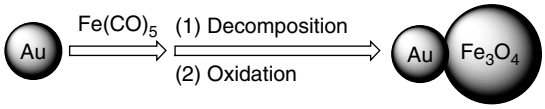

Figure 9. Schematic illustration of the synthesis of dumbbell-like Au–Fe_3O_4 nanoparticles. (Adapted from Yu *et al*., 2005.)

suggesting that the $Fe_{58}Pt_{42}$ core and the Fe_3O_4 shell are in intimate contact and are exchange coupled. Therefore, the magnetization directions of both core and shell switch coherently under an external magnetic field. The exchange-coupled FePt/Fe_3O_4 nanoparticles can be used as building blocks to form hard magnetic nanocomposites with enhanced magnetic properties (Zeng *et al*., 2004).

6 SYNTHESIS OF DUMBBELL-LIKE NANOPARTICLES

Dumbbell-like magnetic nanoparticles have two nanoparticles in intimate contact with one being magnetic. Owing to the epitaxial connection between these two units, the dumbbell structure can be considered as a nanoscale junction. In such a system, the electronic structures of both metal and metal oxide are modified by electron transfer across the interface, leading to the enhancement in chemical and physical properties at the nanoscale interface. The dumbbell-like Au–Fe_3O_4 nanoparticles with both Au and Fe_3O_4 in nanometer sizes are prepared via the decomposition of $Fe(CO)_5$ over the surface of the Au nanoparticles, as illustrated in Figure 9 (Yu *et al*., 2005). The Au nanoparticles are either synthesized *in situ* by injecting $HAuCl_4$ solution into the reaction mixture or pre-made using a modified synthetic procedure. Mixing Au nanoparticles with $Fe(CO)_5$ in 1-octadecene solvent in the presence of oleic acid and oleylamine and heating the mixture to reflux ($\sim$300 °C) followed by room temperature oxidation leads to dumbbell-like Au–Fe_3O_4 nanoparticles. The size of the Au particles is tuned by controlling the temperature at which the $HAuCl_4$ is injected, or by controlling the $HAuCl_4$/oleylamine ratio. The size of the Fe_3O_4 particles is controlled by adjusting the ratio between $Fe(CO)_5$ and Au. More $Fe(CO)_5$ leads to larger Fe_3O_4 nanoparticles. Au–Fe_3O_4 particles with Au up to 8 nm and Fe_3O_4 up to 20 nm have been synthesized.

Figure 10(a) and (b) shows two TEM images of the dumbbell-like Au–Fe_3O_4 nanoparticles with Fe_3O_4 at around 14 nm and Au at 3 and 8 nm, respectively. Figure 10(c) is the high angle annular dark field scanning transmission electron microscopy (HAADF-STEM) image of several dumbbell nanoparticles. In Figure 10(c), the Au particles are

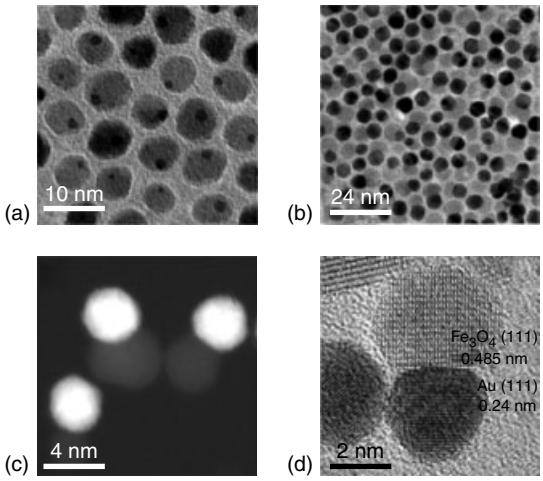

Figure 10. TEM and STEM images of the dumbbell-like Au–Fe_3O_4 nanoparticles: (a) TEM image of the 3–14-nm Au–Fe_3O_4 particles; (b) TEM image of 8–14-nm Au–Fe_3O_4 particles; (c) HAADF-STEM image of 8–9-nm Au–Fe_3O_4 particles; and (d) HRTEM image of one 8–12-nm Au–Fe_3O_4 particle (Yu *et al*., 2005).

imaged as brighter dots. Figure 10(d) is a typical high resolution TEM (high resolution transmission electron microscopy (HRTEM)) image of a dumbbell particle with Fe_3O_4 at 12 nm and Au at 8 nm. The lattice fringes in each of the particles correspond to atomic planes within the particle, indicating that both particles are single crystals. The distance between two adjacent planes in Fe_3O_4 is measured to be 0.485 nm, corresponding to (111) planes in the inverse spinel structured Fe_3O_4 and that in Au is 0.24 nm, resulting from a group of (111) planes in fcc structured Au.

The interface communication between the nanoscale Au and Fe_3O_4 leads to the change of magnetization behaviors of the Fe_3O_4 nanoparticles, especially for those smaller than 8 nm (Yu *et al*., 2005). Figure 11 shows the hysteresis loops measured at room temperature for Au–Fe_3O_4 particles with Au being 3 nm and Fe_3O_4 14 nm (Figure 11a) and 6 nm (Figure 11b), respectively. Like Fe_3O_4 nanoparticles, the dumbbell particles are superparamagnetic at room temperature. The 3–14-nm dumbbell particles show loops similar to the 14-nm Fe_3O_4 nanoparticles with saturation moment reaching 80 emu g^{-1} (Figure 11a), a value that is close to the related Fe_3O_4nanoparticles due to the negligible weight percentage of 3-nm Au in the composite. The 3–6-nm dumbbell particles, however, show a loop of slow increase in moment with the field up to 5 T (Figure 11b), while the pure 6-nm Fe_3O_4 nanoparticles are magnetically saturated within 1 T. It seems that interfacial interactions between Au and Fe_3O_4 make the small magnetic nanoparticles difficult to achieve saturation.

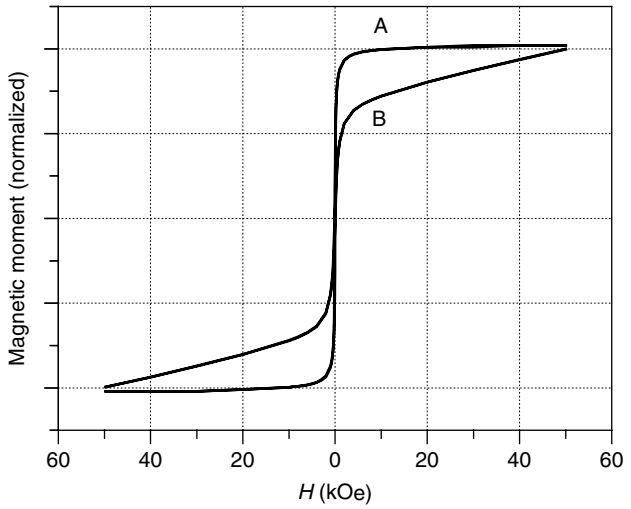

Figure 11. Hysteresis loops of $Au-Fe_3O_4$ particles measured at room temperature: (A) 3–14-nm $Au-Fe_3O_4$ and (B) 3–6-nm $Au-Fe_3O_4$ particles (Yu *et al*., 2005).

7 SHAPE-CONTROLLED SYNTHESIS OF MAGNETIC NANOPARTICLES

The shape is one of the most important factors in determining the structural, physical, and chemical properties of a nanoparticle and an assembled array of the particles. Shape-controlled synthesis of nanoparticles has become a recent focus, as different shapes of the particles can introduce electronic, optical, and magnetic properties that are different from those observed in their spherical counterparts (Burda, Chen, Narayanan and El-Sayed, 2005; Jun, Choi and Cheon, 2006). Shape-controlled synthesis and assembly of magnetic nanoparticles can induce crystal orientation and further magnetic alignment of each nanoparticle in an assembly –a key requirement for various magnetic applications.

Solution phase synthesis has shown great success in controlling the monodispersity of the nanoparticle shapes. Nearly monodisperse cobalt nanorods are synthesized by thermal decomposition of $[Co(\eta^3\text{-}C_8H_{13})(\eta^4\text{-}C_8H_{12})]$ in the presence of a mixture of hexadecylamine (HDA) and aliphatic acid (Dumestre *et al*., 2003). Using octanoic acid (C8) results in the formation of shorter and wider rods (Figure 12a). The lauric acid (dodecanoic acid, C12) leads to cobalt nanorods with an approximate size of 5:85 nm (Figure 12b). With stearic acid (octadecanoic acid), the longer nanorods are obtained.

The shape of the $MnFe_2O_4$ nanoparticles is controlled by the amount of stabilizers added to the reaction mixture during the synthesis of $MnFe_2O_4$ nanoparticles (Sun *et al*., 2004; Zeng, Rice, Wang and Sun, 2004). A reaction of 2 mmol of $Fe(acac)_3$ and 1 mmol of $Mn(acac)_2$, with 10 mmol of

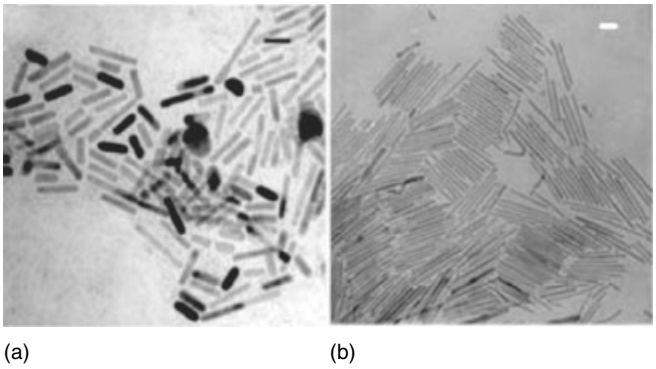

Figure 12. TEM micrographs of nanorods synthesized using hexadecylamine and (a) octanoic acid and (b) lauric acid (Dumestre *et al*., 2003).

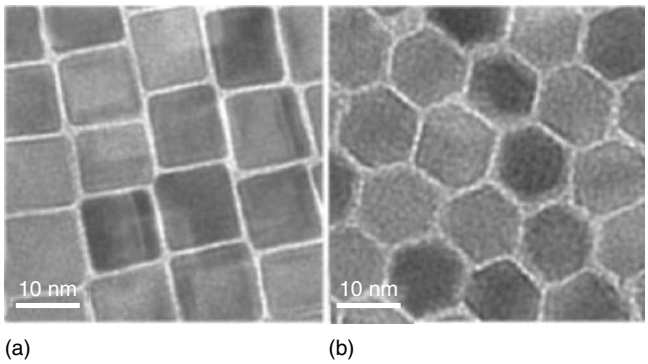

Figure 13. TEM images of the as-synthesized (a) 12-nm cube-like and (b) 12-nm polyhedron-shaped $MnFe_2O_4$ nanoparticles (Zeng, Rice, Wang and Sun, 2004).

1,2-hexadecandiol in the presence of 6 mmol of oleic acid, 6 mmol of oleyl amine and 20 ml of benzyl ether gives 12-nm $MnFe_2O_4$, while similar reaction in 22 ml or 25 ml of benzyl ether yields 10 nm or 8 nm particles, respectively (Zeng, Rice, Wang and Sun, 2004). When the surfactant/$Fe(acac)_3$ ratio is smaller than 3:1, the particles are nearly spherical with no well-defined facets. Increasing the ratio to 3:1 yields cube-like particles. If the particles are prepared using the seed-mediated growth as in the synthesis of Fe_3O_4 nanoparticles (Sun and Zeng, 2002), polyhedron-shaped particles are obtained. Figure 13 shows the representative TEM images of the $MnFe_2O_4$ nanoparticles with different morphologies, with (a) being cube-like and (b) polyhedron-shaped particles.

Self-assembly of these shaped particles can lead to crystal orientation of each particle in a self-assembled superlattice (Zeng, Rice, Wang and Sun, 2004). Controlled evaporation of the carrier solvent from the hexane dispersion ($\sim 2\,mg\,mL^{-1}$) of the particles shown in Figure 13 lead to $MnFe_2O_4$ nanoparticle superlattices. Figure 14(a) shows the superlattice assembly from the cube-like particles, whereas

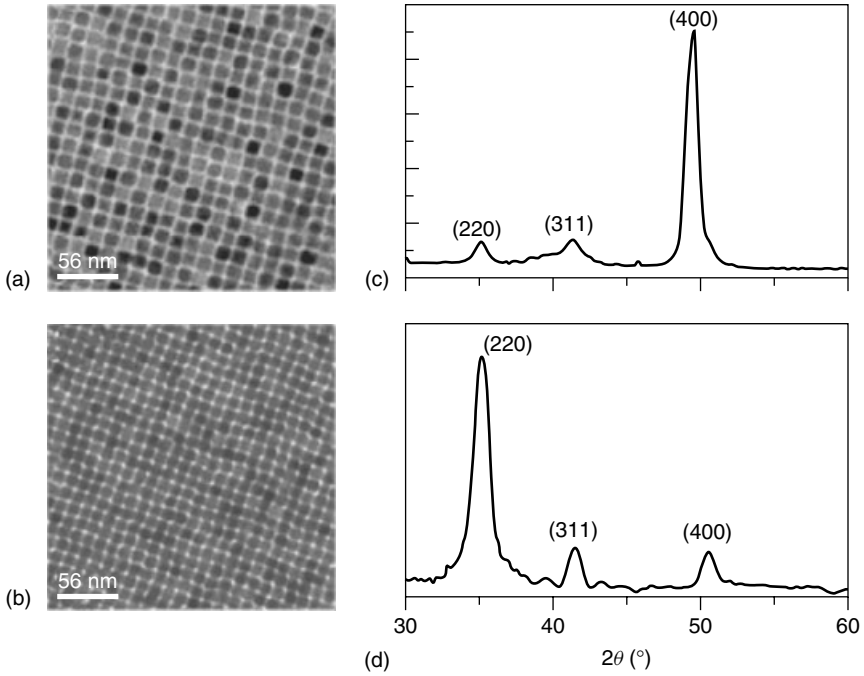

Figure 14. TEM images of 12-nm $MnFe_2O_4$ nanoparticle superlattices of (a) cubelike and (b) polyhedron-shaped nanoparticles. XRD (Co K$a\lambda = 1.788965$ Å) of (c) cubelike and (d) polyhedron-shaped nanoparticle superlattice on Si(100) substrates (Zeng, Rice, Wang and Sun, 2004).

Figure 14(b) is the assembly from the polyhedron-shaped particles. Both assemblies have the cubic packing. But the different shapes possessed by each group of the particles affect the crystal orientation of individual particles within the superlattices. X-ray diffraction (XRD) pattern of the self-assembled cube-like particles shows an intensified (400) peak (Figure 14c) while the XRD of the polyhedron-shaped particle assembly reveals a strong reflection of (220) (Figure 14d). These are markedly different from that of a 3D randomly oriented spinel structured $MnFe_2O_4$ nanoparticle assembly, which shows a strong (311) peak. These indicate that each of the cube-like particles in the cubic assembly has preferred crystal orientation with {100} planes parallel to the Si substrate while for the polyhedron-shaped particle assembly, the {110} planes are parallel to the substrate.

Nearly monodisperse FePt nanocubes are synthesized by controlled mixing of reactants and heating. (Chen *et al.*, 2006) The cubic nanoparticles are produced by first mixing olecid acid and $Fe(CO)_5$ with benzyl ether/octadecene solution of $Pt(acac)_2$ and heating the mixture to 120 °C for about 5 min. before oleylamine is added and the mixture is heated at 205 °C for 2 h (Chen *et al.*, 2006). It is believed that the nanocubes are formed from the growth of the cubic Pt-rich nuclei generated during the initial stage of the reaction, as the -COOH does not have a strong tendency to bind to Pt as the surface energy of crystallographic planes of a fcc Pt crystal generally follow the trend of $(111) < (100)$. In a kinetic growth process, the Fe-rich species prefer to deposit on the (100) plane, leading to the formation of cubes. If oleylamine is added first, sphere-like FePt nanoparticles are separated. This indicates that the amine reacts with Pt, forming stable $Pt{-}NH_2$- complex and hindering the nucleation process. The uniform FePt nanocubes must be derived from atomic diffusion between Pt-rich core and Fe-rich shell in a process that is similar to what is described in Figure 6 (Chen, Liu and Sun, 2004).

Controlled evaporation of the carrier solvent from the hexane dispersion ($\sim$2 mg mL^{-1}) of the nanocubes yields a $Fe_{50}Pt_{50}$ nanocube superlattice array, as shown in Figure 15(a) (Chen *et al.*, 2006). This assembly pattern is energetically favored as it gives the maximum van der Waals interaction energy arising from face–face interactions in short distance of the cube assembly (Korgel, Fullam, Connolly and Fitzmaurice, 1998). The interparticle distance is around 4–5 nm, close the simple thickness addition of the cube coating layer (2–2.5 nm, the length of oleate or oleylamine). Selected area electron diffraction (SAED) of the assembly in Figure 15(a) exhibits four bright (200) spots that are linked by a four-fold symmetry, as shown in Figure 15(b). The (111) diffraction ring is very weak in this diffraction pattern. These indicate that the assembly in Figure 15(a) is (100) textured. The textured cubic assembly is further revealed by a small angle diffraction of the assembly (Figure 15c). This is markedly different from that of a 3D

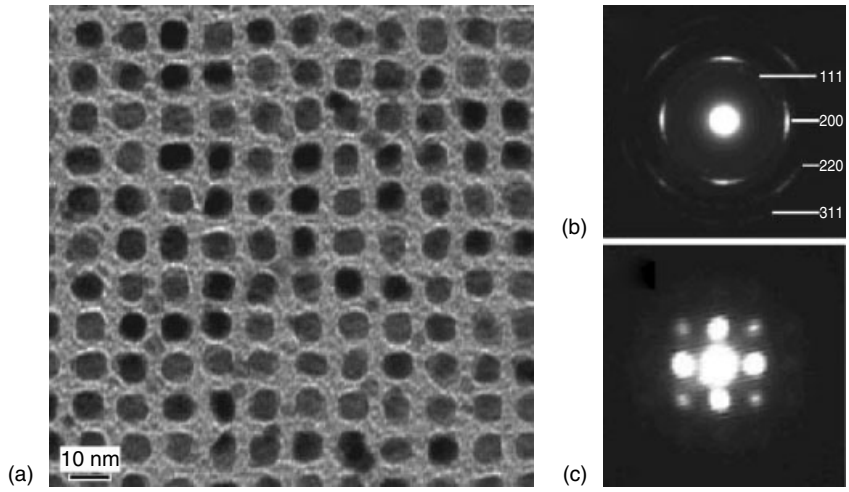

Figure 15. (a) TEM image of a multilayer assembly of 6.9-nm $Fe_{50}Pt_{50}$ nanocubes; and (b) SAED of the assembly in (a), and (c) small angle diffraction of the assembly in (a) (Chen *et al*., 2006).

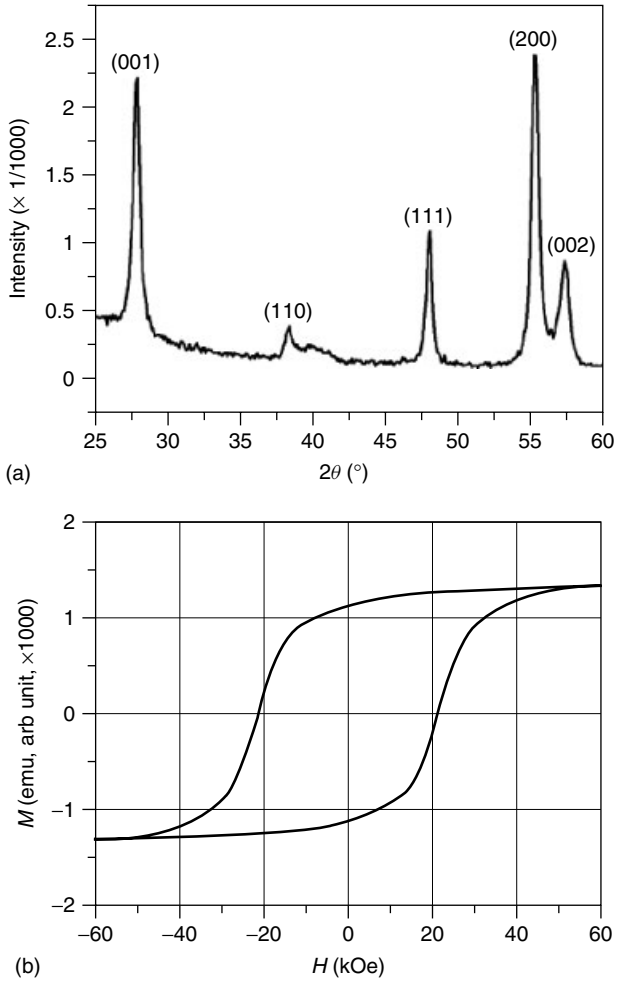

Figure 16. (a) XRD of thermally annealed FePt nanocube assembly on a Si surface, and (b) room temperature in-plane hysteresis loop of the FePt nanocube assembly in (a) (Chen *et al*., 2006).

randomly oriented FePt nanoparticle assembly with a strong (111) peak, indicating that each nanocube in the assembly has a preferred crystal orientation with {100} planes parallel to the substrate. Thermal annealing of the FePt nanocube superlattice induces FePt structure transformation from fcc to fct (Chen *et al*., 2006). The XRD pattern of the annealed assembly (675 °C under Ar for 1 h) has two strong (001) and (200) peaks, as shown in Figure 16(a). The narrowed peaks indicate the particle growth during the annealing process. However, the peak intensity is different from that of the spherical FePt nanoparticle assembly, which shows only one strong (111) peak (Sun *et al*., 2000). This indicates that (001) planes in the thermally annealed FePt nanocube array distribute equally in parallel and perpendicular directions to the substrate. Figure 16(b) is the room-temperature hysteresis loop of the annealed FePt nanocube assembly with coercivity at 22 kOe. The loop is exact the same in both parallel and perpendicular direction of the assembly, confirming what is concluded from the XRD analysis in Figure 16(b).

8 CONCLUSIONS

It is now well accepted that fabrication of ordered nanomagnet arrays with controlled magnetic alignment is an important goal in achieving high-density information storage and high-performance permanent magnets. Many experimental results have shown that solution phase chemistry is a versatile method for preparing monodisperse magnetic nanoparticles and nanoparticle superlattice array with controlled magnetic properties. With the shape-induced texture in the assembly, it is possible to align magnetic easy axis of each nanoparticle in a self-assembled superlattice structure. When this is

achieved, solution phase chemical synthesis will evolve as a new alternative for the fabrication of the advanced magnetic nanostructures for ultrahigh DMR and magnetic energy storage applications.

Nanoimprint Technology for Patterned Magnetic Nanostructures

Stephen Y. Chou
Princeton University, Princeton, NJ, USA

1 INTRODUCTION

Patterned magnetic nanostructures (PMNs) open up great opportunities for building a broad spectrum of revolutionary magnetic devices, such as magnetic random accessible memories, quantized magnetic disks ('bit-patterned media'), new sensors, new actuators, and drug delivery, to name a few; for understanding the fundamentals of micro-/nanomagnetics; and for revolutionizing the magnetic data storage industry. The properties of a magnetic material depend upon the size, shape, spacing, orientation, and composition of the grains inside the material, as well as the material components between the grains. By patterning a magnetic material, we introduce a new, unique, and powerful way to control each of these parameters, thus creating new magnetic properties, including properties unachievable by conventional fabrication approaches (e.g., thin-film deposition).

Obviously, the realization of the PMNs' potential critically hinges upon our ability in patterning, particularly the patterning resolution, pattern-shape variety, critical dimension control, patterning area, and alignment of patterning. Furthermore, it also critically depends on the patterning throughput and cost, which dictate the commercialization potential of a PMN device and the R&D cycle time.

Among available patterning methods, nanoimprint lithography (NIL) has, in the author's view, the unique combination of ultrahigh pattern resolution ($\sim$2 nm), broad pattern variety (2D and 3D), large printing area ($>10\,\mathrm{cm}^2$), and high throughput and low cost (Chou, Krauss and Renstrom, 1995; Chou, Krauss and Kong, 1996; Chou *et al*., 1997; Guo, Krauss and Chou, 1997; Krauss and Chou, 1997; Sun, Zhuang, Zhang and Chou, 1998; Tan, Gilbertson and Chou, 1998; Wu *et al*., 1998; Heidari, Maximov, Sarwe and Montelius, 1999; Lebib *et al*., 1999; Wang, Sun, Chen and Chou, 1999; Bailey *et al*., 2000; Li, Chen and Chou, 2001; Haisma, Verheijen, vandenHeuvel and vandenBerg, 1996). Hence, NIL is playing a key role in today's development and commercialization of PMNs. For example, large-area photolithography has a resolution of $\sim$1 μm. The state-of-the-art lithography tools for semiconductor industry have a 60-nm resolution (half-pitch size), 1 in.^{2} single exposure area, and a price tag of over $40 M per tool. Electron- and ion-beam lithography and scanning probe lithography have excellent patterning resolution ($\sim$10 nm), but are low in throughput and high in cost, and therefore are more suitable for direct

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

writing of small areas (e.g., a few square millimeters) and for making of NIL masks. Interference lithography (IL) can produce nanostructures over a large area (Anderson, Horwitz and Smith, 1983; Yen *et al*., 1992), but it cannot compete with NIL in terms of feature size, yield, and throughput. Self-assembly is low cost and is potentially high throughput (some methods have long pattern formation times), but have very limited pattern variety, small domain size (no long-range order), and random pattern location. Guided self-assembly can alleviate some of the shortcomings of self-assembly, but is still limited (Chou and Zhuang, 1999; Chou, Zhuang and Guo, 1999).

The invention and development of nanoimprint have intertwined with that of PMNs and quantized magnetic disks (QMDs). One of the key motivations in developing nanoimprint is to find an economical viable manufacturing method for PMNs and QMDs.

As to PMN development, the idea of use of lithography to separate magnetic disk tracks (so-called discrete track or patterned media) was proposed in 1963 (Shew, 1963) and that to separate bits in 1987 (Lambert, Sanders, Patlach and Krounbi, 1987; Lambert *et al*., 1989). However, these concepts have nothing to do with the utilization of single magnetic domain (hence their unique properties), which is the key foundation of QMD that was proposed in 1993 (Chou, Wei, Krauss and Fischer, 1994). (Note: today's terminology of 'patterned media' refers to 'patterned media with single-domain bits'.)

Experimentally, the study of the patterned magnetic structures by lithography can be traced back to 1985, when the effects of patterning on the multidomain formation in magnetic structures with lateral dimension of several tens of micrometers were studied, followed by a number of other investigations on the similar structures (Ruhrig, Bartsch, Vieth and Hubert, 1990; Cosimini *et al*., 1988; Lo *et al*., 1985; Corb, 1988). But, only multidomain structures were observed. In 1988, magnetic structures with sub-250-nm feature size patterned by electron beam lithography (EBL) were reported by two groups (Ozimek, 1985; Smyth *et al*., 1991; Gibson, Smyth, Schultz and Kern, 1991). In 1993, the observation of single-domain formation in the patterned bars using magnetic force microscopy (MFM), switching of the bars using an MFM tip, and angle dependence of switching field were reported (Lederman, Gibson and Schultz, 1993; Gibson and Schultz, 1993). The patterned Co and Fe rectangles were studied (New, Pease and White, 1994, 1995a,b). In 1993, QMDs based on lithographically patterned magnetic nanostructures were proposed (Chou, Wei and Fischer, 1994; Chou, Wei, Krauss and Fischer, 1994), the fabrication and study of a QMD with a density of 65 Gbit in.$^{-2}$ using EBL were reported in 1994 (Krauss, Fischer and Chou, 1994). Yet, the QMD was regarded as being of only academic interest, because there was no viable manufacturing in 1993. To solve manufacturing problem for QMDs and other PMNs, NIL – a low-cost, high-throughput nanofabrication technology – was proposed and demonstrated in 1994 (Chou, Krauss and Renstrom, 1995, 1996).

After 1995, PMN research began to spread rapidly because of (i) application of nanofabrication technology to magnetics; (ii) availability of scanning MFM, allowing us for the first time to image and manipulate the magnetic domain structures with great precision; and (iii) invention of NIL, a sub-10-nm resolution, high-throughput, low-cost, manufacturing technology that makes commercialization of PMN-based memories and sensors economically viable. Examples of later work in different methods of fabricating patterned media include ion beam irradiation (Chappert *et al*., 1998; Terris *et al*., 1999; Albrecht, Rettner, Best and Terris, 2003), IL (Farhoud *et al*., 1999; Ross *et al*., 2001), self-assembly (Zhukov *et al*., 2003) and diblock copolymers (Thurn-Albrecht *et al*., 2000; Park, Chaikin, Register and Adamson, 2001; Asakawa *et al*., 2002; Naito *et al*., 2002; Abes, Cohen and Ross, 2003), and porous alumina (Nielsch *et al*., 2002; Yasui, Imada and Den, 2003; Castano *et al*., 2004). Nanoimprint has been used to fabricate discrete track disks (Wachenschwanz *et al*., 2005) and QMDs (Chou, 1997).

Today, QMDs (bit-patterned media) have been placed on the magnetic disks road map as one of the possible approaches to high density, and on the same roadmap, NIL is the manufacturing method.

2 PRINCIPLE AND CAPABILITY OF NANOIMPRINT LITHOGRAPHY

2.1 Principle

NIL patterns nanostructures by physical deformation of a deformable material using a mold, creating a thickness contrast in the material; rather than by changing the local chemical properties of the material using radiation (Figure 1) (Chou, Krauss and Renstrom, 1995, 1996). After imprinting, which involves material flow, a residual material layer often exists, which may need, depending on applications, to be removed by anisotropic etching (e.g., reactive ion etching, RIE), that etches vertically much faster than it does laterally. The imprinted material can serve as a resist for subsequent processing which will be removed after processing, or as a functional structure of a device that will stay as a part of the device. For simplicity, we call the imprinted materials in either case 'resists'.

An imprint process starts at the design and fabrication of a nanoimprint mold (mask), followed by the use of the mask to imprint patterns into a material (resist) on a substrate.

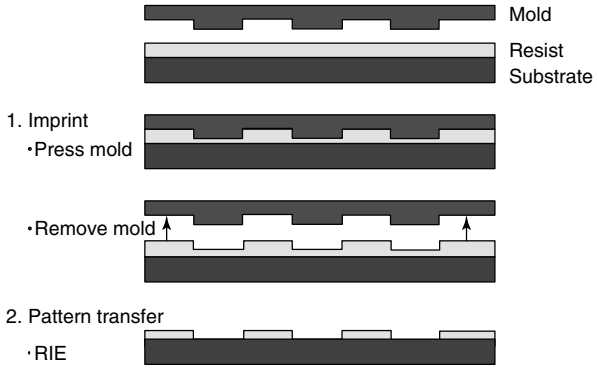

Figure 1. Schematic of nanoimprint lithography process. (1) Imprinting using a mold to create a thickness contrast in a resist; and (2) pattern transfer using anisotropic etching to remove residue resist in the compressed areas (Chou, Krauss and Renstrom, 1995, 1996).

2.2 NIL capabilities

Because it is based on a different fundamental principle, NIL has many advantages over conventional lithography, particularly in resolution, high pattern-transfer fidelity, 3D patterning, lager area (full wafer if needed), high throughput, and low cost.

2.2.1 Resolution

Since NIL is not based on the modification of the chemical structure of a resist by radiation, its resolution is not limited by the factors that limit the resolution of conventional lithography: wave diffraction, scattering and interference in a resist, backscattering from a substrate, and the chemistry of resist and developer. In fact, photocurable NIL has demonstrated 6-nm half-pitch grating with nearly atomic smooth edges imprinted into a resist (Figure 2) (Austin *et al*., 2004, 2005) and thermal NIL has demonstrated arrays of 10-nm-diameter dots separated by 40 nm (400 dots/in.^{2}) (Figure 3) (Chou *et al*., 1997). Yet, these features are not the limits of NIL, but the limits of our ability in making the features on the molds; NIL can achieve even smaller features if a mold can be made, as pointed out in the original NIL papers (Chou, Krauss, and Renstrom, 1995, 1996). Recently, imprinting of 2-nm-wide lines using carbon nanotubes as a mold was reported (Hua *et al*., 2006).

2.2.2 High pattern transfer fidelity

NIL has been demonstrated to have high fidelity in pattern transfer, accurately reproducing original mold patterns and maintaining smooth vertical sidewalls in the imprint resist. For example, repeated imprinting of static random access memory (SRAM) patterns (metal layer) of 20-nm half-pitch showed a standard deviation of 1.3 nm in the variation

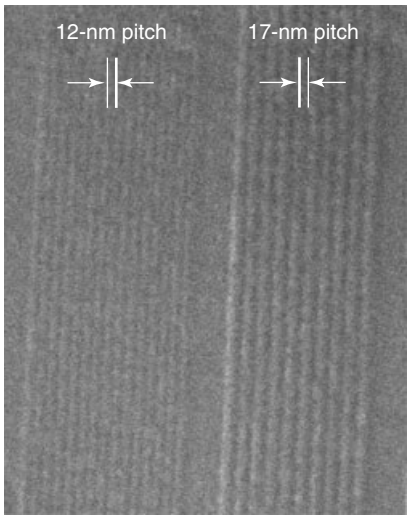

Figure 2. SEM micrograph of imprinted resist grating with a minimum 6-nm half-pitch. (Reproduced from Austin *et al*., 2004, with permission from the American Physical Society. © 2004.)

of the imprinted feature width (Figure 4) (Austin *et al*., 2005). High-aspect-ratio patterns with smooth sidewalls on the mold are transferred to the resist faithfully (Figure 5), unlike in conventional lithography, which can produce sloped sidewalls and line edge roughness, because of a Gaussian shape of the light profile, light scattering, and other noise.

2.2.3 3D patterning

The third unique feature of NIL is 3D patterning, rather than the 2D patterning as in conventional lithography. 3D features are very desirable for certain applications such as microwave circuits and microelectromechanical systems (MEMS). For example, the T-gate for microwave transistors has a narrow footprint for high-frequency operation, but a wide top for lower resistance. Fabrication of a T-gate often requires two EBL steps: one for the footprint and one for the wide top. Each electron beam exposure could take over 2 hours to pattern a single 4-in. wafer. With NIL, the entire 4-in. wafer can be patterned in one step in less than 10 s. Figure 6 shows a 40-nm T-gate fabricated by a single NIL step and lift-off of metal (Li, Chen and Chou, 2001).

2.2.4 Large patterning area

The NIL exposure area (area patterned in a single step) can be much larger that the exposure field of a conventional photolithography stepper ($\sim$1 in.^{2}) because NIL does not require high precision optics or a well conditioned monochromatic light source. Today, full 4 or 8 in. wafers are routinely imprinted at once over a full wafer. When Air Cushion Press^{TM} is used (discussed in Section 3), excellent imprint uniformity has been achieved (Figure 7) (Gao *et al*., 2006).

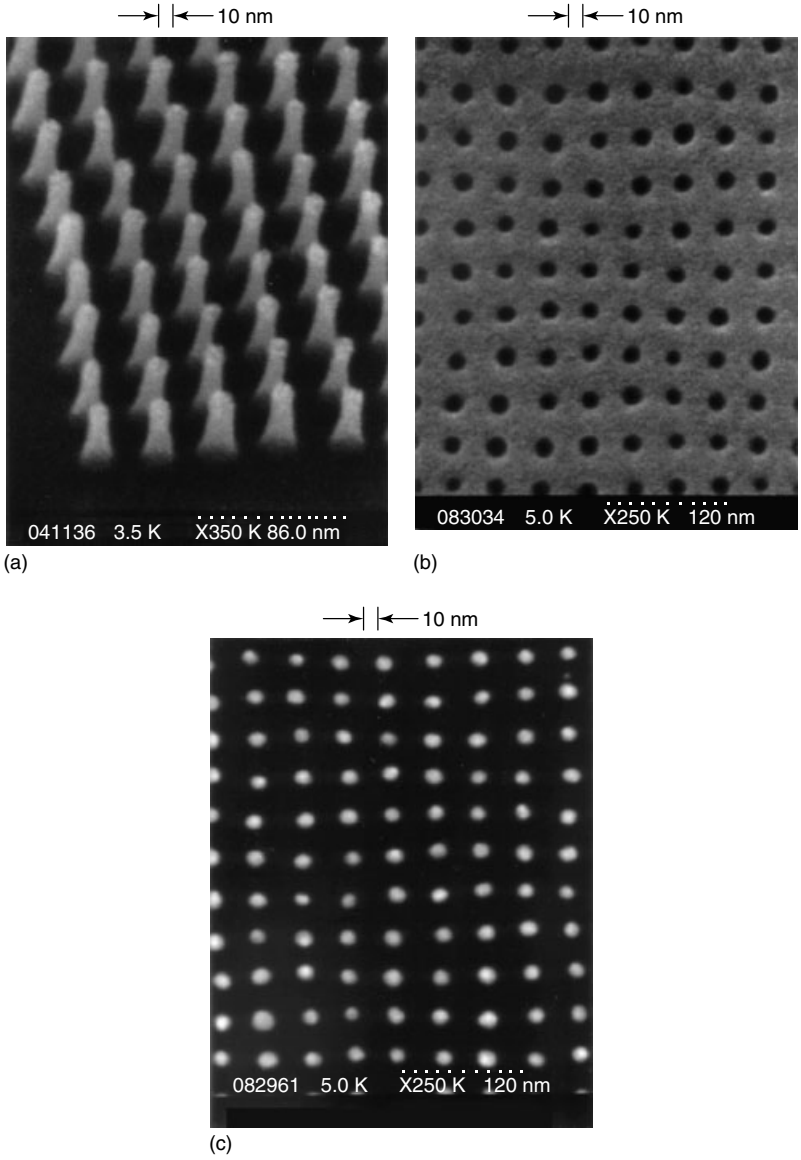

Figure 3. SEM micrographs of a dot array of 10 nm diameter and 40-nm period and hence 400G dots/in.^{2} by nanoimprint lithography and lift-off of metals. (a) A SiO_2 mold with 10-nm minimum diameter pillars with a 40-nm period which are 60 nm tall, after being used 12 times; (b) a top view of 60-nm-deep holes imprinted into PMMA which have a 10-nm minimum diameter and a period of 40 nm; and (c) a top view of 10-nm minimum diameter metal dots with a period of 40 nm, formed by imprinting into PMMA and a lift-off process. (Reproduced from Chou *et al*., 1997, with permission from IEEE. © 1997.)

2.2.5 High throughput and low cost

NIL is high throughput and low cost, because of its ability to do full-wafer-scale parallel fabrication without complicated and expensive optics systems and laser sources (Wu *et al*., 1998; Yu, Wu, Chen and Chou, 2001; Li, *et al*., 2003; Yu *et al*., 2003).

2.2.6 Self-cleaning

It has been observed, since the day one of nanoimprint development, that NIL is a self-cleaning process (Wu *et al*., 1998). That is, the dust on the mold is being cleaned every time the mold imprints a wafer. The mold release agent on the mold makes dust weakly bound to the mold, while the resist acts like a glue to the dust, taking it away from the mold. A 'dirty' mold will become completely clean after just a few imprints.

2.3 Various forms of nanoimprint

The principle of NIL can be implemented through a variety of approaches. *Thermal NIL* uses a resist material that

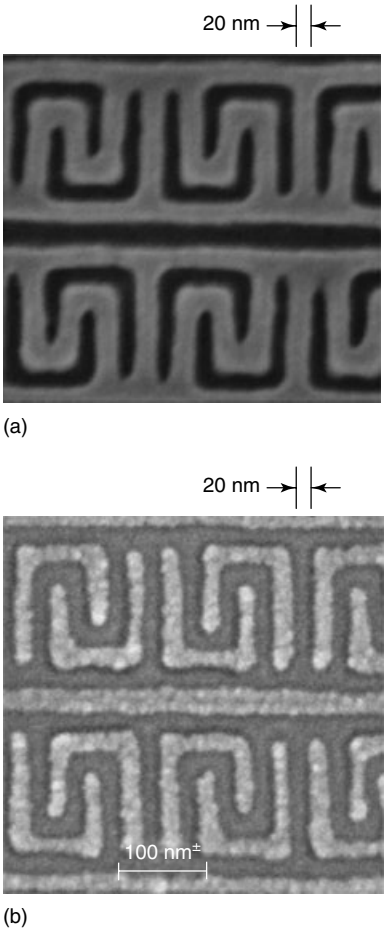

Figure 4. SEM image of 20-nm half-pitch resist pattern for SRAM metal contacts fabricated by NIL. (Reproduced from Austin *et al*., 2004, with permission from the American Physical Society. © 2004.)

is either thermoplastic or thermal curable (Chou, Krauss and Renstrom, 1995; Chou, 1998b, 2001). During a thermal imprint process, a thermoplastic material starts as a solid film, becomes a viscous liquid when its temperature is raised higher, than its glass transition temperature (T_g), and returns to a solid when its temperature is brought below T_g. This solid-liquid-solid process is reversible and repeatable for an infinite number of cycles. The imprint is performed when a resist is in its liquid state. A thermoset material is originally in a liquid form and becomes solid (cured) when heated to a certain temperature for a certain duration. This curing process is irreversible. *Photo* (*or UV*)*-NIL* uses a photocurable material as resist (Haisma, Verheijen, vandenHeuvel and vandenBerg, 1996; Chou, 2001). Like a thermal-curable material, a photo-curable material is initially in liquid form, but it is cured photochemically by photons (light) rather than heat, which is also an irreversible process. *Step-and-flash imprint lithograph* (*SFIL*) is a photo-NIL process in which drops of a resist liquid are dispensed and imprinted on one single die area at a time. This process is repeated as the imprint mold is 'stepped' from die to die across the wafer, repeating the resist drop and imprint cycle (Bailey *et al*., 2000).

Thermal NIL needs to heat an imprinted area to a temperature higher than the initial temperature for a period of time (can be as short as 100 ns). In principle, UV-NIL is carried out without a change in temperature; in reality photocuring in UV-NIL can cause local heating. Each of the methods has its own advantages and shortcomings and has its own well-suited applications. In the following text, we will discuss some commonly shared properties and then compare the pros and cons.

2.4 Pros and cons of different forms of NIL

The biggest advantage of thermal NIL is that it allows both mold and substrate to be opaque, necessary in some processes and materials systems. Thermoplastic NIL also allows the use many off-the-shelf materials as imprinting resists, making it easier to implement when sophisticated NIL resists are unavailable. In fact, thermoplastic NIL was the first form of nanoimprint to be introduced. The major disadvantage of thermal NIL is that the temperature change during the imprint process makes precision alignment difficult. The temperature change also can make demolding (i.e., the separation of the mold from the substrate) difficult because of the stress created by the differences in the thermal expansion coefficients of the mold, substrate, and resist. An opaque mold and substrate can make the viewing of alignment marks during overlay more difficult, although thermal NIL can use transparent molds or opaque mold with transparent alignment windows.

In comparison, the primary advantage of Photocurable NIL is the constant temperature during imprint, provided that heating from the photoradiation can be removed. A photocurable NIL needs either a transparent mold or substrate.

In all curable NIL (either photo or thermal), where a resist is initially in liquid form, the viscosity of the resist can be formulated in order of that of wafer (a few centipoise). A low viscosity allows excellent flow of the resist during the imprint, which is important when the pattern density varies significantly over the areas or the patterns are large and deep (e.g., 50 μm diameter features and 60 μm deep). In contrast, a thermoplastic resist often has a high viscosity ($\sim$300–3000 cP) even at temperatures significantly higher the resist's glass transition temperature. The reasons are that a curable NIL resist consists of oligomers and monomers, while a thermoplastic NIL resist is composed of long-chain polymers (high temperature allows them to slip by each other to deform). In some curable resist materials, additives (e.g., small particles) can drastically increase the viscosity.

Another form of nanoimprint, which may be in some sense more powerful, is to directly imprint a functional

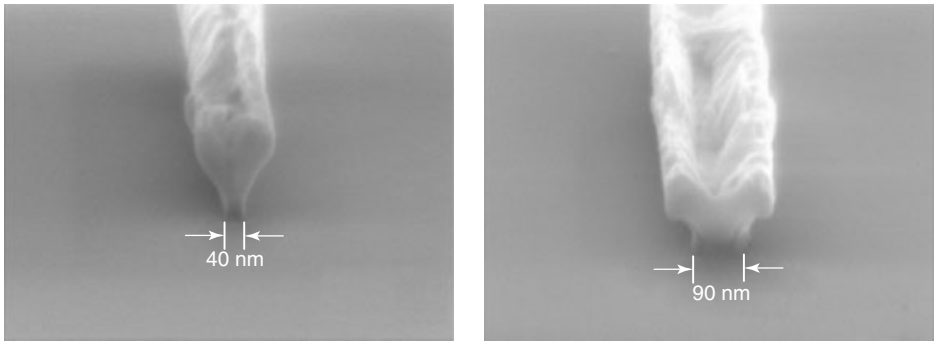

Figure 6. 3D patterning. SEM micrograph of two T gates of 40-nm and 90-nm footprint, respectively, fabricated by a single NIL and a lift-off of metal (Li, Chen and Chou, 2001; Li, Chen, Zhang and Chou, 2003).

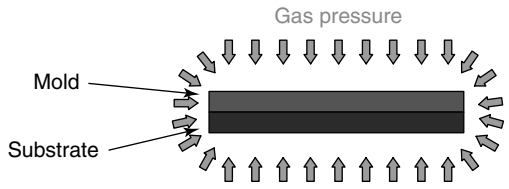

Figure 7. Schematic of Air Cushion Press™ (ACP) nanoimprint principle (Gao *et al*., 2006; Chou, 2002).

material. The functional material could be a curable material or thermoplastic, or hard solid materials such as silicon, which melt into liquid during an imprinting (Li, Chen and Chou, 2001; Chou, 2002). Sub-10-nm resolution is also demonstrated in the direct imprint (Chou, 2002).

3 KEY ISSUES IN NIL

Regardless of which particular form of nanoimprint is being used, the following issues are fundamentally important for achieving good nanoimprinting: mold, material system, pressing methods, imprint pressure uniformity, resist materials dispensing methods, vacuum, demolding, and alignment. These issues (except alignment) are discussed in the following text.

3.1 NIL masks (molds), materials, and fabrication

In principle, any material harder than the imprint resist can serve as a mold material. However, in practice, a mold material is determined by the requirements of the imprint method used, the mold material strength and durability, the ease of mold fabrication, and users' own understanding and preference of mold materials. In many cases, multiple layers of materials are used to gain more advantages.

3.1.1 Transparency to UV

In UV-NIL, unless the substrate is transparent, the mold material(s) must be transparent to UV light in order to cure the imprint resist. In thermal NIL, either transparent or opaque mold materials can be used, and a transparent mold or substrate are needed when direct heating of the resist by a lamp or laser is used. A laser can be used for ultrafast thermal imprinting (<200 ns) without much heating of the mold (Xia *et al*., 2003). A common transparent mold material used in NIL molds is fused quartz.

3.1.2 Material strength and durability

The second issue to consider in mold materials is the material's strength and durability in withstanding repeated

imprints. Quartz is hard and brittle, so to improve a quartz mold for imprinting, a thin layer of SiNx (Li, Chen, Zhang and Chou, 2003), which is known to be stronger and more durable, can be added to the surface of the mold. Other choices for good mold surfaces are SiC and diamond-like carbon films.

3.1.3 Mold fabrication

The most common way to fabricate a mold is to select a mold substrate deposited with a suitable mold surface, then use EBL to pattern a resist, followed by etching to transfer the patterns in the resist into the mold (Chou *et al*., 1997; Krauss and Chou, 1997). Sometimes a lift-off process is used to pattern a harder etching mask material (e.g., chromium) after EBL exposure to improve the etching mask durability.

Currently the feature size of EBL patterns are limited to $\sim$10 nm, the pitch to $\sim$35 nm, and the area for such size and pitch to several square millimeters. The size and pitch limitations are due to electron scattering in the EBL resist and mold substrate. The area limitation is due to the resist exposure dose requirement, which makes the writing of several square millimeters take several hours, and the writing of a much larger area becomes impractical technically and economically. Furthermore, most EBL tools write one $\sim$100 by 100 μm^2 field at a time and stitch different fields together. The stitching has an error in 10–30-nm range, depending on EBL tool. Therefore, the patterns in different fields might not be coherent. To solve the stitching error, a new approach is to move the stage while keep the electron beam fixed during writing, however, this introduces other errors.

To overcome the drawback of EBL in large-area periodic patterns, IL (Flanders, Shaver and Smith, 1978) has been extensively used to make NIL molds (Wu *et al*., 1998; Yu, Wu, Chen and Chou, 2001; Yu and Chou, 2004). The advantage of IL is the capability of fabricating periodic patterns (e.g., gratings and grids) over a large area (e.g., 6 in. wafer) in a parallel fashion, giving high throughput at relatively low cost. The pitch of the grating by IL is given by $\lambda/(2\sin\theta)$. When the interference half angle of the beams, θ, is near 90°, the pitch is near half of the wavelength, λ. However, at such small pitch, the process latitude is very small and the yield is very low, increasing the cost significantly. A high-yield and low-cost approach is to use IL to make a master mold and use NIL to make replicas (daughter molds) and manufacturing. For examples, the uniform gratings in Figure 6 were imprinted using a mold fabricated by IL.

3.1.4 Mold fabrication compatibility

Another important consideration in mold fabrication is to use materials that can be fabricated rather easily. For example, metal is more ductile than hard dielectric materials, but it is very hard to etch metal into patterns of high aspect ratio and vertical sidewalls. In practice, good molds with high-aspect-ratio intrusions and vertical sidewalls are made in dielectric materials such as SiO_2 or fused quartz.

3.1.5 Mold release agents

To separate a mold from an imprinted structure without damage and without much force, mold release agents are needed. The mold release agent can be applied by directly coating the mold or by mixing it into the imprint resist. Often both methods are used in parallel, since good commercial NIL resist always have certain mold release agents. All the mold release agents have fluorine side chains, which significantly reduce the intermolecular interaction between the mold and the imprinted resist. Mold release agents that are directly coated on the mold often have a linking group at the end of the molecular chain which attaches the molecule to the mold, as in a self-assembled monolayer. The mold release agents are often perfluorinated surfactants.

3.2 NIL materials (resists)

The materials used for NIL can be classified into three groups according to their processing properties: thermoplastic, thermocurable, and photocurable. In general, each class of material consists of five components: (i) backbone materials (e.g., polymers, oligomers, monomers); (ii) solvents (including monomers); (iii) plasticizers (for thermoplastic) and initiators (curable); (iv) mold release agents; (v) others (compatibilizers, lubricants, and other stabilizers). Clearly, there are tremendous possibilities in formulating these NIL resists, and commercial resist companies guard their formulas like the 'CocaCola recipe'. An enormous amount of research and testing is required to find a good resist formulation.

3.2.1 Thermoplastic materials (resists)

Thermoplastic materials have a characteristic glass transition temperature, T_g, below which the material is solid and above it, a viscous liquid. The backbone materials in thermoplastic materials are a mixture of linear chain polymers, with no cross-links between different chains. As the temperature is raised above the glass transition temperature, the polymer chains can slip by each other to flow, becoming a viscous liquid. The viscosity lowers as the temperature becomes higher, but does not become as low as that of a monomer-based resist. Many solvents can be used, including certain

monomers. Plasticizers are used to lower the T_g of the resist. The mold release agents in thermoplastic materials, similar to those used in curable materials, are often polysiloxane and perfluorinated surfactants.

3.2.2 Photo (UV)-curable and thermocurable materials

These materials are initially in a liquid state and become solid when irradiated with the proper dose of photons (so-called photocuring) or when heated to a certain temperature for a certain duration (so-called thermocuring). The backbones of curable materials consist of a mixture of monomers and oligomers. Again the solvents include monomers. Examples of UV and other radiation initiators for cross-linking are benzophenone, 2-hydroxy-2-methyl-1-phenyl-1-propanone, and 1-hydroxydhexyl phenyl ketone. Examples of thermal initiators are benzyl peroxide (BPO) and azobisisobutyronitrile (AIBN). Sometimes, additional additives are used to facilitate the lubrication between the mold and the substrate, so that the mold can be moved during alignment without excessive friction.

3.3 Imprinting pressure and uniformity

To deform a resist on a substrate by a mold, the mold and the substrate must be pressed toward each other to have contact. To achieve good imprint uniformity, the pressure should be not only uniform everywhere across the imprint area but also sufficiently high to create the necessary deformation in either the mold, the substrate, or both to make their surfaces conform. The latter requirement is due to the fact that a mold or a substrate initially might not be flat, but warped. In order to make the mold and substrate conform, the imprint pressure in many applications is much higher than that needed for pressing a mold into a resist.

There are several methods used for pressing the mold into the substrate, including solid parallel-plate press (SPP), Air Cushion Press^{TM} (ACP), one-sided air cushion press, and electrical force-assisted NIL (EFAN) (Liang *et al*., 2005). Clearly, for high yield – key to viable manufacturing – ACP is the key.

3.3.1 Solid parallel-plate press (SPP)

One commonly used pressing method for imprint is SPP (Figure 8). SPP, which is simple to construct, is often used in home-built NIL tools as well as many commercial NIL machines. However, SPP suffers several drawbacks: (i) Any roughness, nonflatness, or dust on the surface of a press plate (Figure 8b) and/or the backside surface of the wafer and the

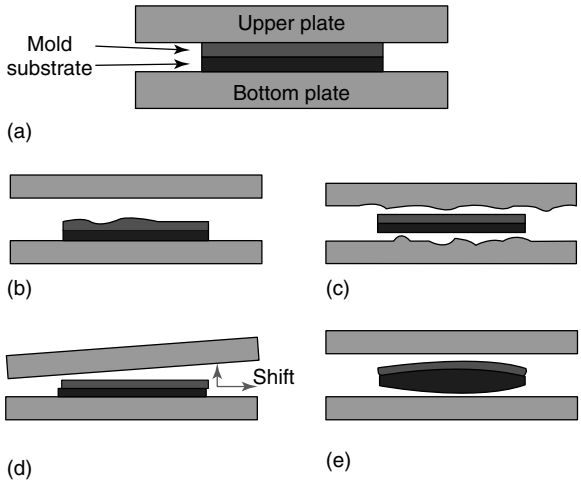

Figure 8. Schematics of solid parallel-plate press (SPP) nanoimprint process and drawbacks: (a) ideal SPP; (b) nonparallelism between plates; (c) imperfect plate surfaces; (d) uneven mold/substrate backside; and (e) curved sample surfaces (Gao *et al*., 2006).

mold (Figure 8c) will cause nonuniform pressure distribution that results in imprint nonuniformity and local high pressure points that will damage the mold and/or substrate. (ii) The two press plates may not be perfectly parallel with each other (Figure 8d), and hence assert shear and/or torque forces, causing relative shift and/or rotation between the mold and substrate. (iii) If either the mold and/or substrate has curved surfaces, SPP could not bring all mold and substrate surfaces into contact, leaving a large fraction of the wafer area unimprinted (Figure 8e). (iv) In SPP, because a constant force is applied between the two plates to provide the desired pressure, if the mold and substrate surfaces are in contact only at a point or in a small area, an enormous pressure can be generated at this contact point or area, causing damages to the mold or substrate. (v) The parallel plates of SPP have large thermal mass, making isothermal NIL take long processing time.

3.3.2 Air cushion press (ACP)

To improve pressure uniformity, yield, and thermal imprint speed, and to overcome the aforementioned issues, a new technique, air cushion press (ACP) (Figure 9) has been developed (Chou, 2002; Gao *et al*., 2006). ACP utilizes a gas (or fluid) to press the mold and substrate against each other in a chamber. ACP has a number of advantages over SPP: (i) ACP uses conformable gas (or fluid) layers to eliminate any direct contacts between the solid plates and samples (mold and/or substrate), hence removes any effects related to the imperfection of the solid plates. (ii) Because the pressurized gas is conformal to the mold and substrate,

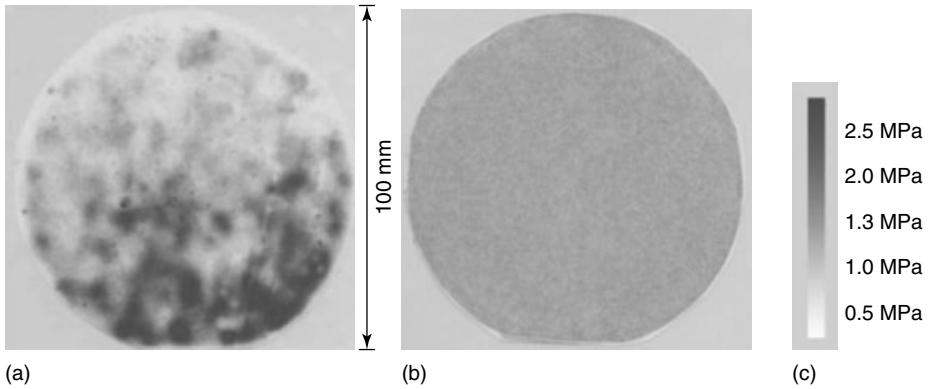

Figure 9. (a) and (b) Pressure distribution across a 100-mm-diameter imprint field when a 1.38 MPa nominal pressure is applied using SPP and ACP, respectively. (c) Pressure versus color intensity calibration chart (Gao *et al*., 2006).

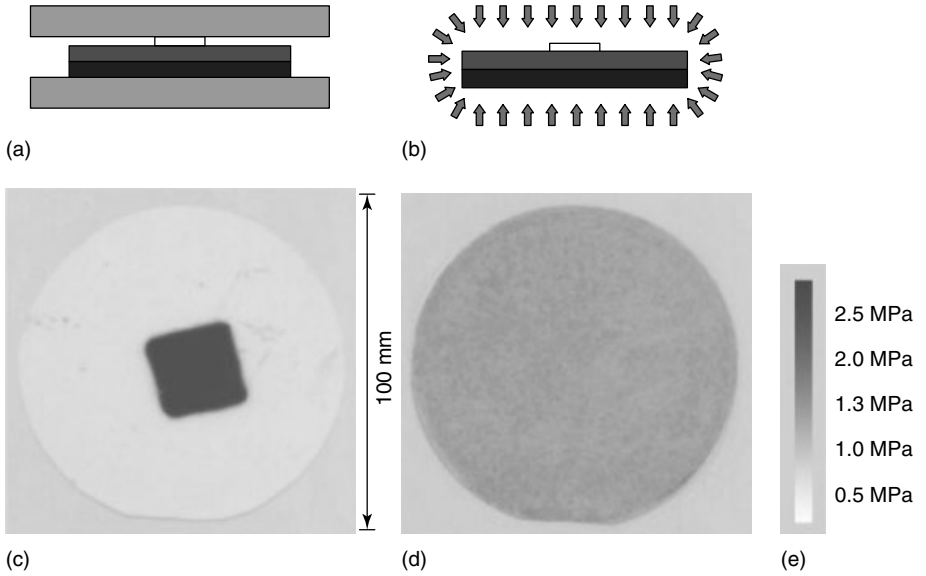

Figure 10. (a) and (b) Schematics of experimental setups for studying the effects of backside dust/topology in SPP and ACP, respectively. (c) and (d) Pressure distributions across a 100-mm-diameter imprint field with 0.1-mm-high paper piece inserted, when a 1.38 MPa nominal pressure is applied using SPP and ACP, respectively. (e) Pressure versus color intensity calibration chart (Gao *et al*., 2006).

regardless of their backside shapes or any dust particles on the backside, the pressure will be uniform everywhere over the entire imprint area. (iii) Isotropically applied gas pressure eliminates lateral shift or rotation between the mold and substrate, reducing damage to the mold and prolonging mold lifetime. (iv) Because a pressurized gas has much smaller thermal mass than a solid plate, it speeds up the heating and cooling of samples and shortens the thermal imprint time by orders of magnitude (e.g., ACP can complete the nanoimprint process in seconds rather than in tens of minutes as in SPP).

The pressure distribution of SPP and ACP over an imprint field of 100 mm diameter was investigated by placing a pressure-sensitive film between a mold and a substrate, both of which are 100-mm-diameter prime silicon wafers of 0.5 mm thickness, with flat featureless front surfaces and unpolished backsides (Gao *et al*., 2006). The pressure-sensitive film consists of a layer of microencapsulated color-forming material and a layer of color-developing material. A pressure applied to the film will break the microcapsules. As a result, the local density of broken microcapsules is determined by the local pressure, and different broken microcapsule densities will, in turn, yield different color intensities on the film. A higher pressure causes a higher density of broken microcapsules, and thus a stronger color. SPP is carried out with a solid parallel-plate nanoimprinter, and ACP is performed using a Nanonex NX-1000 nanoimprinter.

Figure 10 shows the imprint pressure distributions over 100 mm-diameter mold and wafer in both SPP and ACP, measured by pressure-sensitive films when a nominal

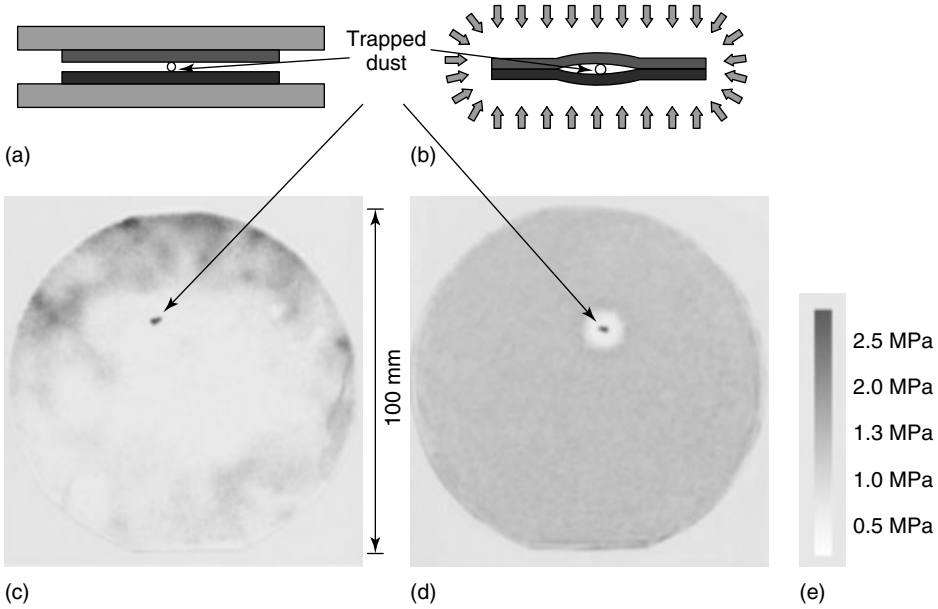

Figure 11. (a) and (b) Schematics of experimental setups for studying the effects of trapped dust in SPP and ACP, respectively. (c) and (d) Pressure distributions across a 100-mm-diameter imprint field with 0.1-mm-high paper dust trapped, when a 1.38 MPa nominal pressure is applied using SPP and ACP, respectively. (e) Pressure versus color intensity calibration chart (Gao *et al*., 2006).

pressure of 1.38 MPa (or 200 psi) is applied. In the imprint by SPP (Figure 10a), the pressure is generated by applying a constant force of 1.13×10^4 N, which corresponds to a nominal average pressure of 1.38 MPa (200 psi) over the 100-mm-diameter mold and substrate. However, the pressure-sensitive film measurement shows that the actual pressure in SPP varies tremendously across the wafers, from below 0.5 MPa (areas of lightest color) to above 2.5 MPa (areas of strongest color), showing a pressure variation over a factor of 5 across the 100-mm-diameter nanoimprint field. Furthermore, Figure 10(a) shows that the lower half of the film has a much higher average pressure than the upper half. This is due to the nonparallelism between the two pressing plates. The film also exhibits isolated local domains with strong colors with light colors over their surroundings, caused by the surface imperfections of pressing plates and wafers.

In contrast, in ACP, when the same nominal pressure of 1.38 MPa (200 psi) is supplied by a gas, the pressure-sensitive film exhibits a uniform color across the entire nanoimprint field (Figure 10b), indicating a uniform imprint pressure and complete immunity to the problems suffered by SPP.

To further study the effects of dust or topology on the backside of the mold or substrate on imprint pressure uniformity, we place a piece of 'large artificial dust', made of paper of $2.6 \times 2.6\,\text{cm}^2$ area and 0.1 mm thickness, on the backside of the mold. We then apply a 1.38 MPa nominal pressure using both SPP and ACP methods (Figure 11a and b). Clearly, in SPP (Figure 11c) under the backside-dust conditions, all the applied force is concentrated under the 'large artificial dust', with a pressure reading well above 2.5 MPa (the upper bound of the measurement range of the pressure-sensitive film), while the area surrounding the dust area has almost no imprint pressure (the pressure is below the 0.5 MPa lower bound of the pressure-sensitive film). In contrast, in ACP (Figure 11d) under the same condition, the 'large artificial dust' has no effects on the imprint pressure, which remains uniform across the entire 100-mm-diameter imprint field.

To study the effects of the dust trapped between the mold and the substrate on pressure distribution in both SPP and ACP, we place a 'small artificial dust particle', which is a triangular shaped paper piece with an in-plane dimension of 1 mm and height of 0.1 mm, between the mold and the pressure-sensitive film. Again, the same nominal pressure of 1.38 MPa is applied in the two different pressing methods (Figure 12a and b). In Figure 12(c), in SPP under this trapped-dust condition, the dust has a global effect on the pressure distribution across the entire 100-mm-diameter imprint field, causing distinct variations in pressure and contact. More than 60% of the imprint field around the dust site shows poor contact and a pressure below 0.5 MPa, while an extremely high pressure is applied on the dust site. On the other hand, in ACP under the same condition, the effects of dust on the pressure distribution are localized to a small area (Figure 12d). The affected area is limited to a circle 6 mm in radius, because of local wafer deformation. The pressure distribution outside this circle remains uniform.

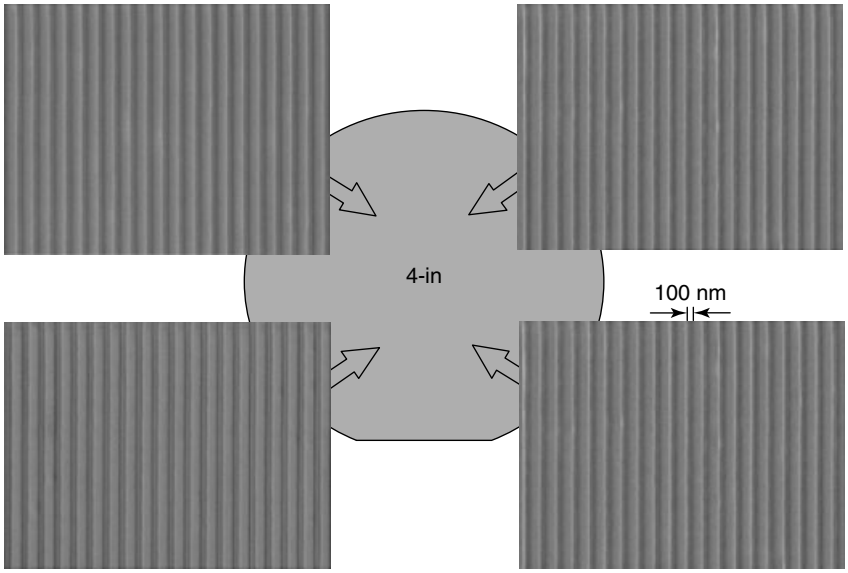

Figure 12. SEM image of uniform grating over an entire 4-in. wafer imprinted by ACP (Gao *et al*., 2006).

3.4 NIL resist dispensing methods and vacuum environment

There are two major ways of dispensing a resist on a substrate: a thin-film deposition by spinning (or spray) or droplet dispensing. For thin-film deposition, during imprint the mold needs to displace the resist from the protrusions of the molds to the valley of the mold, and from areas of high pattern density to areas of low pattern density.

For droplet dispensing, during an imprint a mold presses the droplet into a thin film while filling up the trenches in the mold. The flow of the resist liquid can remove some of the air between the mold and the substrate. If the volume of the remaining air is not too large, it can be completely absorbed into the resist (Liang, Tan, Fu and Chou, 2006). In this way, the imprint can be done without a vacuum chamber without air bubbles formed in the resist. However, as our study has indicated (Liang, Tan, Fu and Chou, 2006), complete absorption of air bubbles takes such a long time that for practical imprint conditions air bubbles exist and the throughput will be also very low. Hence, a vacuum environment is in general needed for both types of resist dispensing methods.

3.5 Mold separation

To have a good separation of the mold from an imprinted pattern, in addition to having good mold release agents, which reduce the bonding of the mold and the resist, one needs to reduce the stresses between the mold and the resist. Furthermore, the demolding can be much easier (i.e., demolding force is much smaller) if the demolding starts from a small area and propagates gradually into other areas.

4 CONTROL OF MAGNETIC NANOSTRUCTURE PROPERTY BY PATTERNING

In the demagnetized state, a thin-film or a bulk magnetic material is magnetically divided into many small regions called *domains*. Each magnetic domain, typically containing a number of polycrystalline grains, is spontaneously magnetized, but with a random magnetization direction, so that the material as whole has no net magnetization and the total energy (which is the sum of magnetostatic energy, exchange energy, crystalline anisotropy energy, magnetorestriction energy, and Zeeman energy) is minimized (Cullity, 1972). Since there are many local energy minima, each of them corresponding to a number of magnetic configurations, the exact magnetic domain configuration in a thin film or bulk material is rather unpredictable.

However, the situation is drastically different when a magnetic material is patterned into a size smaller than or comparable to a single-domain size (Cullity, 1972). In this case, each PMN contains only one or a few magnetic domains; the size, shape, and orientation of each domain become *well defined and predetermined by the pattern shape and materials*. The unique features of a PMN are attributed to new interplay among different energy terms, in particular between the magnetostatic energy and exchange energy, for minimizing the total free energy.

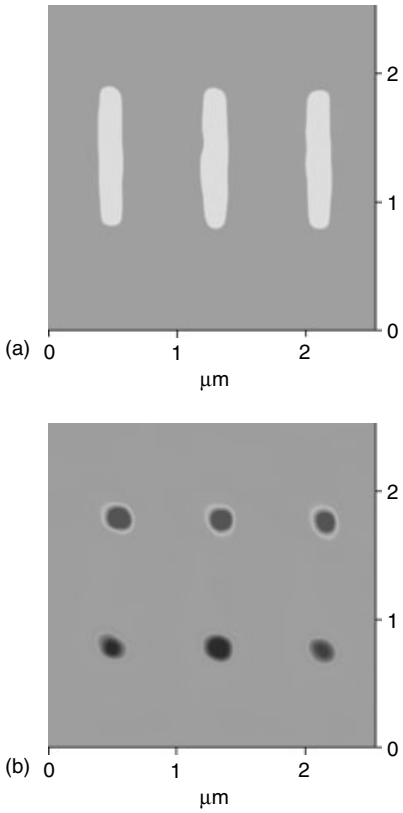

Figure 13. The atomic force microscopy (a) and magnetic force microscopy (b) of three single-domain nickel bars that are 100 nm wide, 1 μm long, and 35 nm thick. The grey dots represents attractive force between tip and sample and the black dots repulsive force.

4.1 Spontaneous formation of single domain

The first important property of a PMN is that a single domain can be formed spontaneously without an applied magnetic field, meaning the structure becomes a magnetic dipole on its own as soon as it is fabricated. This is a consequence of interplay between the magnetostatic energy and exchange energy. When the width of a patterned magnetic structure is less than the domain-wall size, the formation of multiple domains within that width requires very high energy, as it is required that the magnetization rotates to the opposite direction over a shorter distance than in the normal case. On the other hand, if all magnetic domains are aligned in the same direction (i.e., ferromagnetism) forming a single domain, there will be net magnetic poles, giving magnetostatic energy. The only way to reduce the magnetostatic energy is to break the material into multiple domains to cancel out magnetic poles. But, as indicated earlier, because of the small width of the patterned structure, formation of such multiple domains requires much higher energy. Hence the energy minimum is a single magnetic domain.

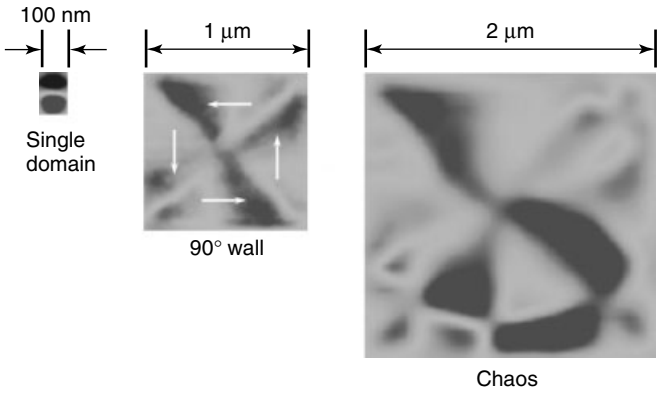

Figure 14. MFM images of magnetic domains in cobalt squares (35 nm thick) as their sizes are reduced from 2 μm to 100 nm. The gray represents attractive force between tip and sample and the black repulsive force. As the size reduces, the multidomain structure becomes single domain as shown on the left (100 nm bar) that has a south pole and a north pole.

Consider a patterned magnetic cube of a size of L. The magnetostatic energy for a single-domain cube of a side of L is proportional to its volume (L^3), and the domain-wall energy is proportional to area (L^2). Hence, the total energy of a multiple-domain cube (sum of the magnetostatic and exchange energy) is approximately proportional to $L^{2.5}$ (Cullity, 1972). Therefore, there is a critical size below which the single-domain state has the lowest energy, but above which the multiple-domain state has the lowest energy. This critical size, determined by the magnetization and exchange constant of a material, is about 100–300 nm in a thin film.

4.2 Control of domain configurations using shape

The magnetization direction in a single domain and in a multidomain PMN can be controlled well by the shape of the structure. In a single domain, the stable magnetization is always along the long axis of the structure, to reduce the demagnetization field and lower the total energy. Figure 13 shows both atomic force microscopy (AFM) and MFM images of Ni bars which are 1 μm long, 100 nm wide, and 35 nm thick. The MFM image exhibits only two opposite magnetic poles at the two ends of the bars – characteristic of a single magnetic domain.

In a multidomain PMN, the magnetization at the edges tends to be parallel to the edge to avoid free magnetic poles for lowering the magnetostatic energy (the surface pole density is equal to the discontinuity of the magnetization normal to the surface). Figure 14 shows MFM images of magnetic domains in cobalt squares (35 nm thick) as their sizes are reduced from 2 to 100 μm. At 2 μm, the domain configuration is chaos. At 1 μm, it has four well-defined closure domains.

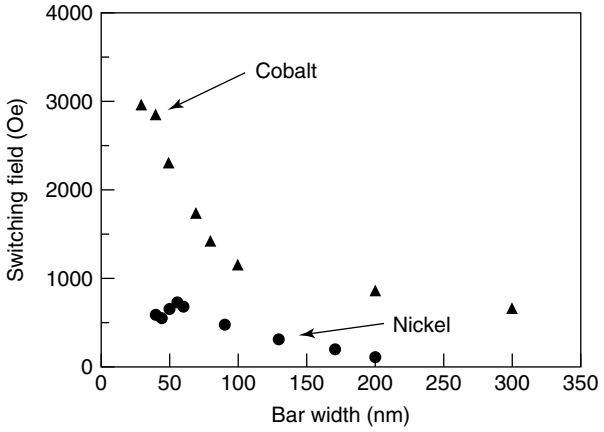

Figure 15. Experimental switching field of isolated Ni and Co bars versus bar width. The bar width was measured using SEM. The bars are 1 μm long and 35 nm thick.

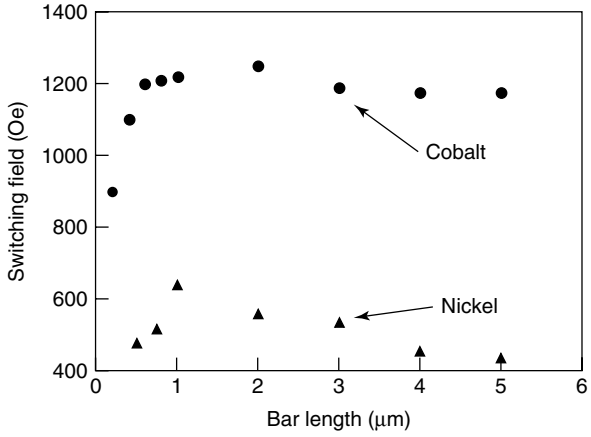

Figure 16. Experimental switching field of isolated Ni and Co bars versus bar length. The bars are 100 nm wide and 35 nm thick.

4.3 Effects of bar width on magnetic domain switching field

Another key property of PMN is that the coercivity – the magnetic field needed to switch the magnetization direction – can be controlled by changing the structure's size and shape anisotropy. This is again a consequence of the interplay between the magnetostatic energy and the exchange energy.

To investigate this property in PMN, we fabricated nickel and cobalt bars of 35 nm thickness and different width and shape anisotropies using EBL, thermal evaporation, and lift-off. Thermal evaporation, instead of sputtering, eliminates crystalline anisotropy in the materials that could mask the shape anisotropy effect. Vibrating sample magnetometer measurements show that the unpatterned thin-film samples fabricated with the bar samples have a coercivity of 50 Oe for Co and 25 Oe for Ni, and have near-zero crystalline anisotropy.

The switching fields of isolated Co and Ni bars with a 1 μm length and 35 nm thickness as a function of the bar width were measured by using an external field and MFM and are shown in Figure 15 (Chou, Wei, Krauss and Fischer, 1994; Kong and Chou, 1996). For Co bars, the switching field increases monotonically with reduction of the bar width, reaching 3000 Oe at 30 nm width. The switching field is 60 times higher that of the unpatterned thin film. For the Ni bars, the switching field first increases with decreasing bar width, reaches a maximum switching field of 740 Oe (30 times higher than that of the thin film) at a bar width of 55 nm, then decreases slightly with further reduction of the bar width. The decrease is likely due to the fact that thermal energy becomes comparable to magnetization switching energy (Cullity, 1972). The Ni bar-width dependence is similar to that of Permalloy bars studied elsewhere (Smyth *et al.*, 1991). Furthermore, the MFM shows that for 1-μm bar length and 35 nm thickness, the critical width to form single domains is 300 nm for Co and 150 nm for Ni, respectively.

4.4 Effects of bar length on magnetic domain switching field

The effects of bar length on Co and Ni bars with a fixed bar width and thickness (100 and 35 nm, respectively) were also investigated. Unlike the bar-width dependence, the switching field of the single-domain bars was found to first increase with the bar length, then decrease after reaching a peak (Figure 16). The peak switching field and the corresponding bar length are 640 Oe and 1 μm for Ni, and 1250 Oe and 2 μm for Co, respectively. Furthermore, the switching field of Ni bars decreases with the increase of the bar width much faster than that in Co bars. The length dependence observed here does not fit the Stoner–Wohlfarth model, which predicts a *coherent* switching, meaning the switching field of a bar should monotonically increase with the shape anisotropy (therefore with the bar length) (Stoner and Wohlfarth, 1948).

The nonmonotonic length dependence suggests that different bar lengths have different switching mechanisms. For short bars (<1 μm) in which the bar length is comparable to domain-wall size, all spins would rotate more or less in a same fashion, leading to a quasicoherent switching. For long bars in which the bar length is significantly longer than the domain wall, the exchange force is not strong enough to keep all spins rotating in the same direction. In this case, the domain reversal occurs at the ends of the bar where demagnetization field is the strongest, and the reversal propagates through the entire bar, leading to an incoherent switching. As Co has a much stronger exchange force than that in Ni,

Co bars should have a longer crossover length than that in Ni, consistent with experimental results.

Although the switching speed of PMN has not yet been measured, it is expected that coherent switching has time scale of 1 ns and incoherent switching should be the bar length divided by the domain propagation speed.

5 QUANTIZED MAGNETIC DISKS (PATTERNED MEDIA) AND NANOIMPRINT MANUFACTURING

QMDs (patterned media), based on fundamentally different principles of data storage than current methods, have many distinguished advantages to achieve high storage density (Chou, Wei, Krauss and Fischer, 1994). This approach is regarded as one of two recent candidates to replace the current method (vertical media) of magnetic data storage (the other one is thermal-assisted storage). QMDs are intended for a data storage density of 300 Gbit in.$^{-2}$ or higher. However, the issue of manufacturability has been raised since the conception of QMD. In fact, the drive to manufacture QMD was one of the reasons to develop NIL (Chou, Krauss and Renstrom, 1995; Chou, Krauss and Kong, 1996). Today, it has been widely accepted that NIL is the best technology for the manufacture of QMD. Here we discuss the advantages of QMD and NIL manufacturing.

The ultimate storage density of a magnetic disk is related to the magnetic recording media, write head, read head, positioning and servo, and signal processing. Although they are intricately related, the most important of all is the recording media, which dictates the requirements of all others. A good media will relax the requirements. The following discussion focuses on a new medium.

5.1 Factors limiting storage density in conventional magnetic media

The present magnetic media is a continuous, thin, magnetic film supported by a rigid, nonmagnetic disk. The film consists of many tiny, polycrystalline grains with a rather broad distribution in size and shape and a random distribution of crystallization direction. The magnetization orientation of these grains is also random until a magnetic field created by a write head aligns the magnetization of a tiny patch of these grains. The data is represented by the magnetic moment, area, size, and location of this patch.

Four factors limit the storage density capacity in a thin-film media. The first is the 'superparamagnetic limit'. Because of the statistical nature in the size and easy-magnetization axis

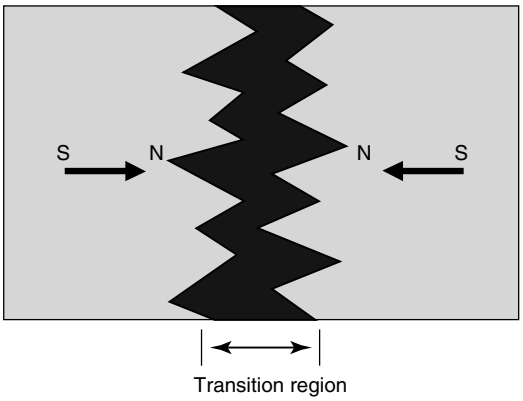

Figure 17. Schematic of transition region between two bits for the conventional magnetic recording media.

of polycrystalline grains in a magnetic media, the intrinsic signal-to-noise ratio (SNR) of a magnetic signal roughly equals the number of grains in each bit. To reduce bit size while keeping the same SNR requires a reduction of the grain size. But, when each grain becomes too small and weakly coupled to its neighboring grains by the exchange force, the energy to switch the magnetization of a grain can become less than the thermal energy. Should that happen, thermal energy will wipe out the written data. For an isolated sphere, the superparamagnetic limit will be reached when the diameter is below 9 nm. To maintain an acceptable SNR, namely 1000 grains, the superparamagnetic limit for longitudinal recording gives a maximum data density of $\sim$150 Gbit in.$^{-2}$, insufficient to meet our needs.

The second limiting factor is the transition width between two neighboring bits of opposite magnetization. The nature of ferromagnetism, that is, the positive exchange integral, (which occurs only in a few elements such as Co, Ni, and Fe) favors the case of all magnetization aligned in the same direction. When one bit is placed next to another bit with an opposite magnetization, a transition region, called a *domain wall*, must be formed to keep exchange energy reasonable. Certainly the spacing between two bits cannot be smaller than the domain-wall size. Furthermore, to lower the total energy, the interplay between the magnetostatic force and the exchange force makes the transition region between two bits have a random zig-zag shape (so-called Neel spikes), as shown in Figure 17. The zig-zag pattern not only increases the effective width of a transition region, but also creates noise in the reading signal (since the reading head, having a straight-line shape, averages the positive and negative magnetic charges in the zig-zags). The effective transition region for today's conventional medium is 10–30 nm.

The third factor is the 'side tracks'. The magnetic field distribution of a write head is not perfectly uniform and the magnetic media has quasilinear response to the magnetic

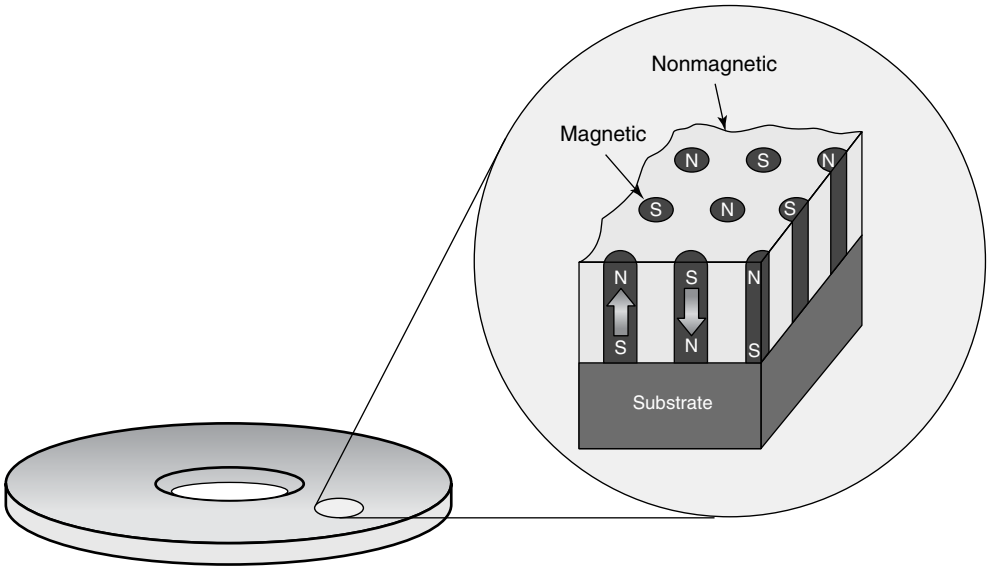

Figure 18. Schematic of a quantum magnetic disk which consists of patterned, single-domain, magnetic structures uniformly embedded in a nonmagnetic disk.

field; the fringing field at the sides of a tip pole in a write head writes two parallel tracks of useless noise next to the data (called *sidetracks*). The hysteresis loop of a conventional magnetic media has a finite slope. Since the sidetracks could erase previously written data, extra space between two data tracks must be reserved for the sidetracks, limiting data packing density.

The fourth factor is the 'tracking'. Conventional magnetic media does not automatically provide a tracking signal since a physical boundary does not always exist between two neighboring bits (it exists only between two bits of opposite magnetization). Hence, writing or reading a bit is a 'blind' process. The head first locates special codes (tacking marks) written at the beginning part of each data section, then calculates the movement between the head and disk to get the nominal bit location. Therefore, the accuracy of the disk rotation and servo will impose another limit on data density. Furthermore, much real estate area and time are wasted in writing the tracking marks, which currently use about 20% of the total disk area and are expected to be more for higher data density where tracking is more crucial.

5.2 Concept of quantized magnetic disks

All of the limitations listed in the last section can be removed or alleviated if the continuous, thin-film media is abandoned and replaced by a new media, QMDs. QMDs have prefabricated, discrete, single-domain magnetic elements uniformly embedded in a nonmagnetic disk (Figure 18) (Chou, Wei, Krauss and Fischer, 1994). Each single-domain element has a uniform, well-defined shape, a prespecified location, and most importantly, a discrete magnetization that is magnetized without an applied magnetic field and has only two possible stable states: equal in magnitude but opposite in direction. The spontaneous formation of a single domain is due to the small size and the shape anisotropy (as discussed in Section 4.2). Each magnetization direction of a single-domain element represents a single bit of binary information. A QMD of a vertical magnetization uses pillars and a longitudinal magnetization uses bars. The magnetic field needed to switch the magnetization direction can be controlled by engineering the element's size and shape anisotropy (discussed in Section 4) (Chou, Wei, Krauss and Fischer, 1994).

QMDs have many advantages over conventional disks, such as spontaneous self-quantization of each bit's magnetization and a quantized writing process to reduce requirements of write head and position accuracy; small, smooth, isolated transition region allowing high data packing density and near-zero transition noise; built-in tracking, which makes for precision tracking and positioning of write/read heads and overcomes the superparamagnetic limit.

The idea of storing one bit of information in a tiny single-domain magnetic particle could have been conceived when single-domain structure was observed (Kittel, Galt and Campbell, 1950) or when single-domain particles were used in making recording tapes. The theory of coherent switching of a single-domain particle has been discussed in the celebrated paper by Stoner and Wohlfarth (note that switching the patterned single-domain element is usually incoherent). Many other behaviors of single-domain structures were

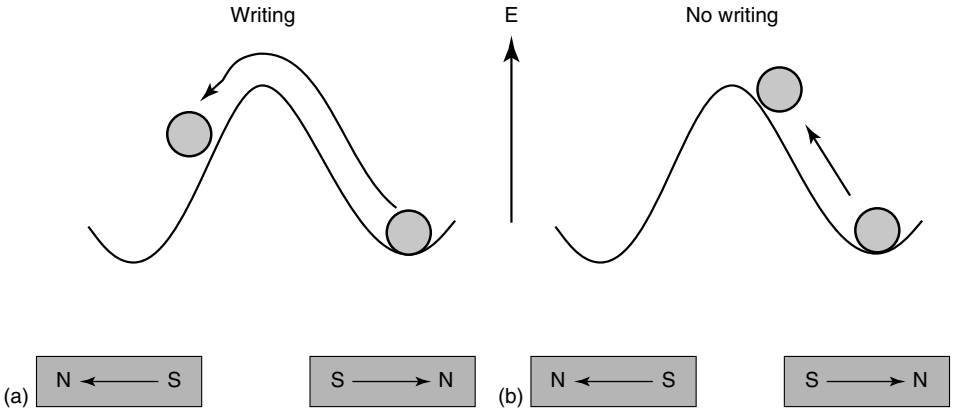

Figure 19. Schematic illustrating that the quantized switching process of a single-domain structure is like moving a ball over a hill. (a) The ball, once over a hill, will roll to another state by itself; and (b) once the drive force is removed, the ball, before reaching the top of the hill, will roll back to the original state.

theoretically investigated by Aharoni (1986, 1990, 1991). However, a number of unique properties of single-domain elements as a storage element in QMDs were not explored until 1992 when two advanced technologies became available. One is the nanofabrication technology that enables us to precisely engineer the shape, size, location, orientation, and composition of a single-domain magnetic particle (Chou, Wei and Fischer, 1994; Chou, Wei, Krauss and Fischer, 1994; Fischer, Wei and Chou, 1993). The other is magnetic force microscopy that allows us to image and manipulate the magnetic properties of each individual single-domain particle. Recently, the advent of imprint lithography has brightened the commercial potential of QMDs.

5.2.1 Overcome superparamagnetic limits

In a conventional disk, one bit is represented by approximately 1000 weakly coupled polycrystalline grains. In a QMD, each bit is stored in one discrete element that is isolated from other elements, but inside the element polycrystalline grains are strongly coupled by the exchange force behaving more like a large single magnetic grain. Therefore, the volume and switching energy for the QMD elements are much greater than that of a single grain in a conventional disk, allowing significant reduction of bit size without reaching the superparamagnetic limit. Finally, for a given material volume, a larger shape anisotropy in the QMD elements can lead to a larger switching field, allowing further increase in data density (Cullity, 1972).

5.2.2 Discrete magnetization and quantized writing process

Since each bit in a QMD spontaneously magnetizes itself without an applied field and has only two opposite stable magnetization states, the write process in a QMD is quantized with three unique features. First, in contrast to conventional disks where the magnetic moments, area, and location of each bit must be precisely defined by a write head, in QMDs these are already defined when the disk is fabricated. Thus, the writing process in a QMD is a simple flip of the magnetic direction of a discrete singledomain bit. A write head either writes the entire bit perfectly or it does not write the bit at all. Second, each bit in a QMD can be written perfectly with a write field smaller than the size of the bit (Suriono and Chou, 1996a,b). Third, a minor overlap of the writing field with a nearby bit perturbs the magnetic moment of the bit. Once the overlapping writing field is removed, the bit returns to its original magnetic state. Clearly, the quantized writing in a QMD greatly relaxes the requirements on write head design and position accuracy, and significantly avoids the writing errors and sidetracks (all of these advantages lead to a higher data storage density).

The quantized writing process in a QMD is analogous to moving a ball between two valleys separated by a mountain (each valley represents one of the two energy minima) (Figure 19). Once the ball is pushed from one valley over the top of the mountain, it will roll down to the other valley on its own (perfect writing). But, if the ball is released before being pushed over the top, it will go back its original valley (no writing).

The quantized writing property of QMDs has been demonstrated experimentally using a magnetic force microscope tip (MFM) (Chou, 1997; Kong, Shi, Krauss and Chou, 1997; Kong, Zhuang and Chou, 1997; Kong *et al.*, 1998) and theoretically using micromagnetic simulation (Suriono and Chou, 1996a,b). The magnetic field of an MFM tip splits, at the tip point, into two halves: one pointing in one direction and another in opposite direction. As the tip moves from one end of a single-domain bar to the other end, the overlap between

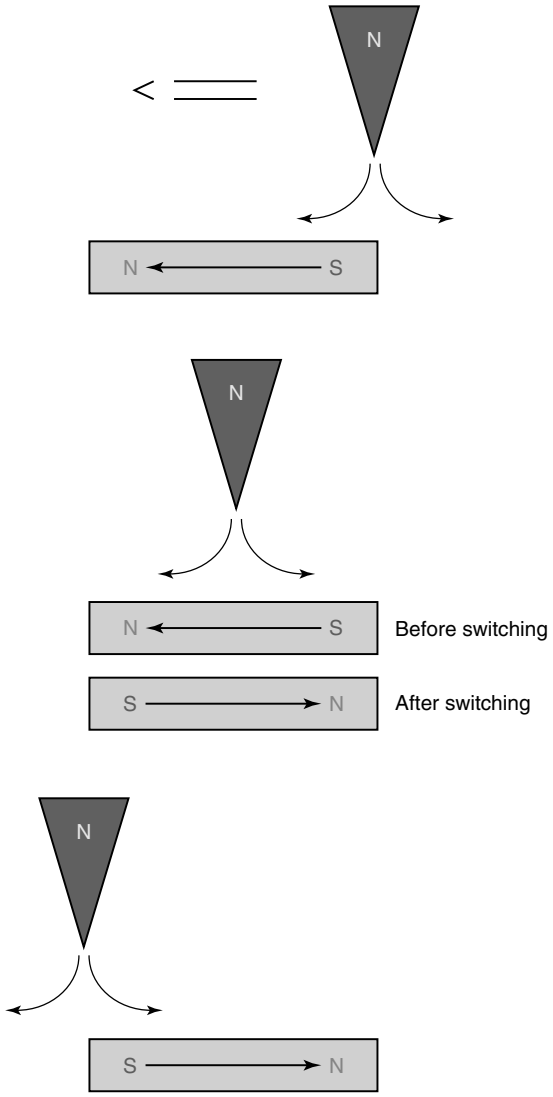

Figure 20. Schematic of the QMD writing process using an MFM tip.

the bar and the field in one moving direction decreases and the overlap between the bar and in the opposite direction increases (Figure 20). If the bar can be switched with a magnetic field of a size smaller than that of the bar, then the magnetization direction of the single-domain bar will be changed before the MFM tip reaches the other end of the bar. In this case, the magnetic images of the bar will display two poles with identical magnetizations. This is because for a single-domain bar, no magnetic charge can be seen anywhere except at the two ends of the bar. At the end where scanning starts, the MFM sees one pole before the bar is switched and at the finishing end, the MFM sees another pole after being switched. Since the magnetization switches much faster than the MFM scanning speed, the MFM image cannot tell the occurrence of the switch until the tip reaches the other end.

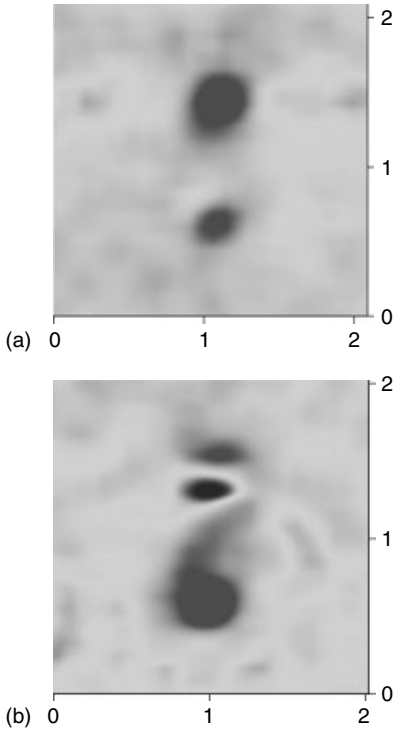

Figure 21. (a) MFM image in which the poles at the two ends of the bar have identical polarization, confirming that the magnetization of the single-domain bar is switched by the MFM tip having a field of a size smaller than that of the bar. (b) MFM image in which the switching occurs when an MFM tip is near the end of the scan, the MFM image has a perfect north pole at the starting end of the bar, but, at the finishing end, only half of a south pole (before the switching) and half of a north pole (after the switching). (Reproduced from Chou *et al*., 1997, with permission from IEEE. © 1997.)

The magnetic MFM image of a single-domain bar in Figure 21(a) shows that the poles at the two ends of the bar indeed have the identical polarization, confirming that the magnetization of the single-domain bar is switched by the MFM tip with a field size smaller than that of the bar.

When using a weaker switching field, a larger overlap between the switching field and the bar is required. Figure 21(b) shows that switching occurs when an MFM tip is near the end of a scan, therefore the MFM image has a perfect north pole at the starting end of the bar, but, at the finishing end it has only half of a south pole (before the switching) and half of a north pole (after the switching). The weaker switching field can be achieved by either reducing the amount of magnetic material on an MFM tip during the tip fabrication or increasing the space between the MFM tip and the bar.

Writing of a 20 Gbit in.$^{-2}$ longitudinal QMD using a MFM tip is shown in Figure 22(a) and (b) (Kong, Zhuang and Chou, 1997). Clearly, the writing process is quantized and

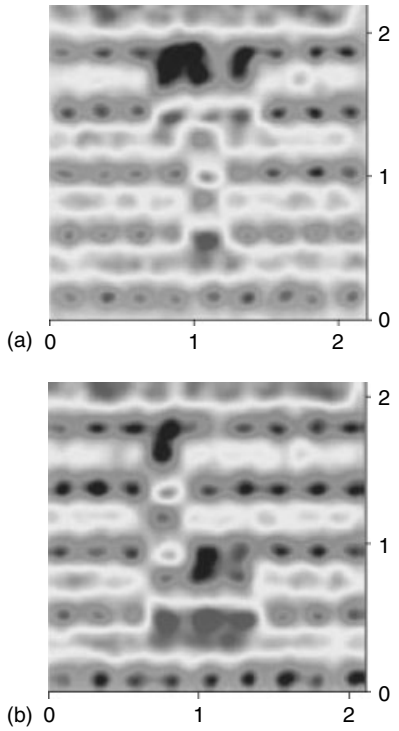

Figure 22. Writing of a 20-Gbit in.$^{-2}$ longitudinal QMD using a MFM tip. The light gray represents attractive force between the tip and the sample and the dark gray repulsive force (Kong *et al*., 1998).

perfect. The write experiments were done using two MFM tips: the writing tip with a large magnetic moment and the reading tip with very small magnetic moment (so that it would not flip the magnetization of the bar). Before writing, the magnetization of all the bars was aligned in the same direction. During the writing process, the writing tip was lifted up and then was moved to one end of a bar. The end of the bar initially had a magnetic pole opposite to that of the MFM writing tip. The actual writing process was simply to lower the writing tip, making the tip closer to the bar. It was found that when the separation between the tip and bar was less than 5 nm, the writing tip could perfectly flip the magnetization direction of the bar *without* flipping the neighboring bars, at a data density of 20 Gbit in.$^{-2}$ for longitudinal QMDs (equivalent to 80 Gbit in.$^{-2}$ for vertical QMDs). After writing one bar, the MFM writing tip was raised up and moved to write other bars. This process was continued until all the desired bars were written. After writing, the reading tip was used to nondestructively image the written pattern.

It should be pointed out that the MFM tip does not have a well-defined field distribution, and that the MFM does not have any feedback to track the exact tip movement leading to a poor positioning accuracy of MFM (about 1% of the scanning window size). Also, the switching field of

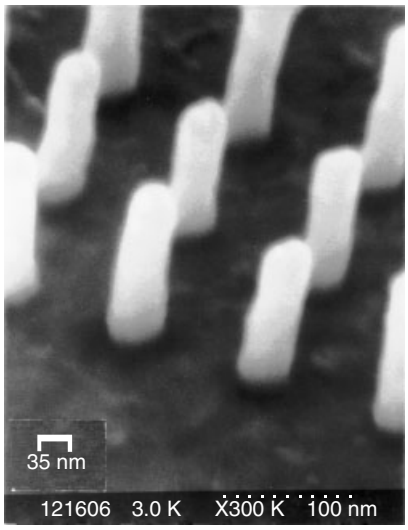

Figure 23. SEM image of Ni pillar array of 35 nm diameter, 120 nm height, and 100 nm spacing. The density is 65 Gbit in.$^{-2}$ and the aspect ratio is 3.4 (Chou, Wei, Krauss and Fischer, 1994).

each bar is not exactly the same due to the fabrication imperfection and magnetostatic interaction between the bars. However, even under these circumstances, the 7.5 Gbit in.$^{-2}$ longitudinal QMD can be written perfectly. This clearly demonstrates the advantage of quantized writing process of QMD in ultrahigh density recording. In other words, this property of the QMDs relaxes the requirement of the writing field and can increase tolerance toward the errors due to head positioning and fringing field.

5.2.3 Cut-off interbit exchange force, small and smooth transition, less noise

Since the exchange force has an effective range less than 10 nm, a thin layer of nonmagnetic material between two neighboring bits in a QMD can completely cut off the exchange force between the bits, leading to a 'transition region' that is much smaller than the transition region in a thin-film magnetic media where each grain is more or less coupled by exchange force. Furthermore, the nonmagnetic materials, patterned by a nanofabrication technique, can have very smooth and straight edges (Figure 23), giving a much quieter reading signal than that in a thin-film media where the transition regions have a zig-zag shape.

5.2.4 Built-in tracking marks, precise tracking

In a QMD, since each discrete bit is a single domain isolated by nonmagnetic materials and is spontaneously magnetized, a variation in the magnetic field always exists between neighboring bits regardless of the polarization of each bit

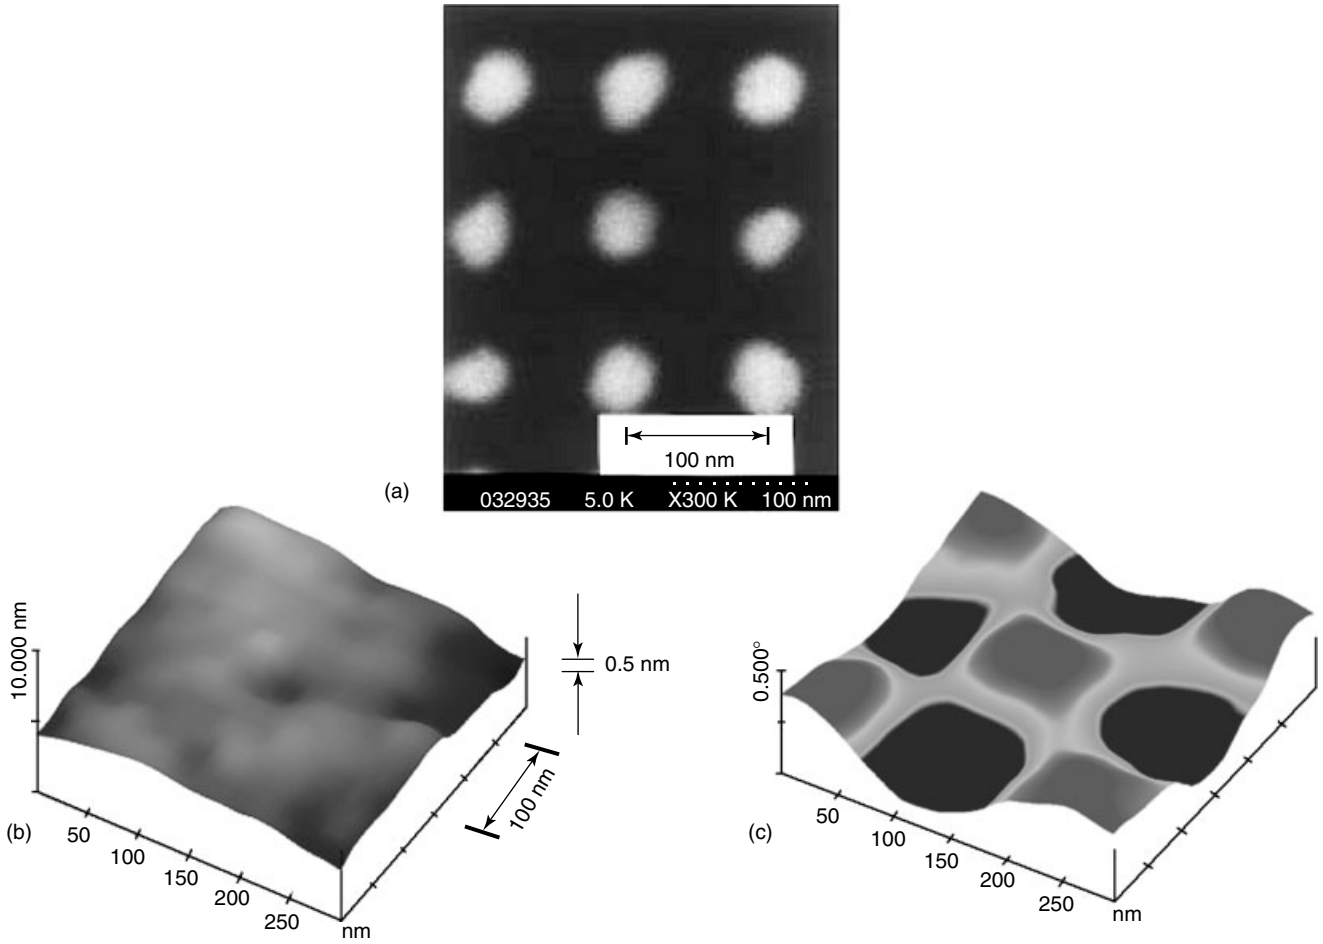

Figure 24. (a) SEM image, (b) tapping mode atomic force microscopy image (TMAFM) image, and (c) MFM image of 3×3 bits of a QMD with 65-Gbit in.$^{-2}$ density. The grey patches represents attractive force between tip and sample and the black patches repulsive force in (c). Each bit consists of a nickel pillar uniformly embedded in 200-nm SiO_2 with 50 nm diameter (aspect ratio of 4) and 100 nm period. The TMAFM image shows a very smooth surface with a roughness of 0.5-nm rms. The MFM image shows an alternating pattern of magnetization directions for each bit (Chou, Wei, Krauss and Fischer, 1994).

(Figure 24). This provides a signal for tracking each bit. In other words, in a QMD drive, discrete single-domain elements automatically provide a 'landmark'; each bit can be physically 'seen' prior to writing or reading, allowing much more precise tracking than the 'blind tracking' in a conventional disk and therefore higher data density.

5.3 Nanoimprint manufacturing of quantized magnetic disks (bit-patterned media)

A variety of structures for the implementation of QMDs have been proposed (Chou, 1997; Chou, Shi and Kong, 1997). These structures can be classified as flat surface and grooved surface. The grooved surface QMDs have grooves for the isolation of different bits unfilled on the surface. But the grooved surface QMDs have a dimension much smaller than a flying head and hence will not affect the flying. In either structure, nanoimprint will be most likely used to pattern a dielectric material and the magnetic layers will be subsequently deposited into the patterned dielectrics, since etching of metal nanostructures is well known to be very difficult. After the magnetic material deposition, for flat surface QMDs, a polishing method will be used to planarize the surface, while for grooved surface QMDs, no polishing is needed, since the groove is sufficient to break a film into discrete single magnetic domains (Chou, Shi and Kong, 1997; Chou, 1998a; Chou, 1999).

In patterning a dielectric structure for QMDs, there are again two choices: indirect or direct patterning. In indirect patterning, first nanoimprint is used to pattern a resist layer and then the resist layer is transferred into a dielectric material underneath. For direct patterning, a nanoimprint technique can directly pattern a curable dielectric material.

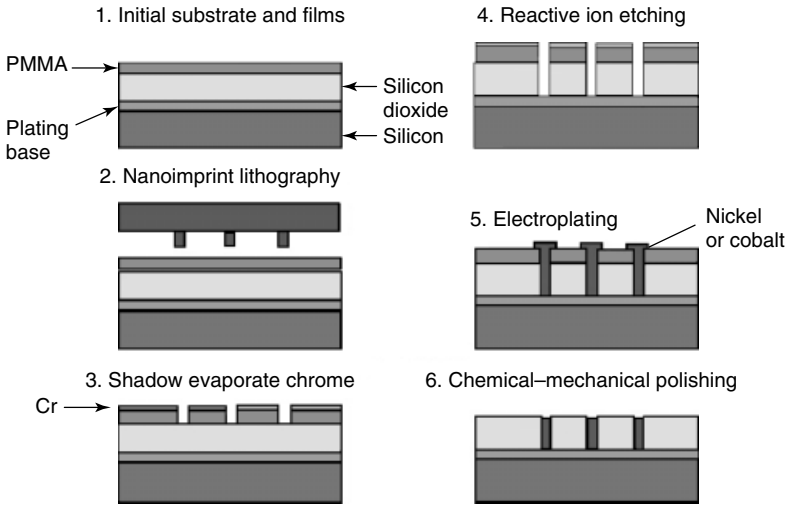

Figure 25. Schematic of the QMD fabrication process. (Reproduced from Wu *et al*., 1998, with permission from the American Institute of Physics. © 1998.)

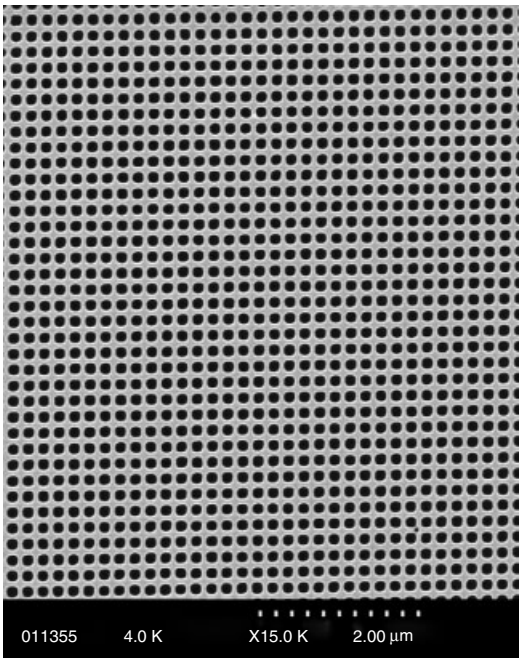

Figure 26. SEM picture of a 190-nm-period square via array on PMMA fabricated by single NIL using a pillar daughter mold. (Reproduced from Wu *et al*., 1998, with permission from the American Institute of Physics. © 1998.)

As an example, Figure 25 shows a QMD fabrication process (Wu *et al*., 1998). First, a thin metal plating base was deposited on a silicon wafer, then a SiO_2 film, followed by a 200-nm-thick NIL resist film (e.g., polymethylmethacrylate, PMMA). The SiO_2 layer is the nonmagnetic layer; its thickness determines the final height of the nickel pillars. The PMMA serves as the NIL resist. Second, pillar NIL mold was used to pattern a via array in the PMMA film using NIL. Then O_2 RIE was used in the NIL for pattern transfer, which anisotropically etched the via array into the entire PMMA thickness. Third, a 20-nm Cr layer was evaporated at a glancing angle on the top of the PMMA to provide an additional mask for etching the SiO_2. Fourth, CHF3 RIE etched the via array into the SiO_2 and stopped at the plating base. The etching had a pressure of 2 mTorr, a power of 150 W, and a CHF3 gas flow of 15 sccm. During the final several seconds of the etching, O_2 was added into the plasma to remove the passivating layer produced in the etching process on the bottom and sidewall of the SiO_2 vias, which can affect the uniformity of the subsequent electroplating. Fifth, nickel was electroplated through the holes. Finally, chemical–mechanical polishing (CMP) was used to remove the excess nickel from the top of the SiO_2 layer to achieve a smooth surface.

Figure 26 shows a 190-nm-period hole array patterned in PMMA using NIL by a daughter QMD mold. Figure 27(a), the electroplating is uniform. To examine the sidewall of the nickel pillars, SiO_2 was removed (Figure 27b). The nickel sidewall seems to conform to the SiO_2 template and no voids were found. For a uniform area of $4 \times 4\,cm^2$ and a density of $18\,Gbit\,in.^{-2}$, the total number of bits of a QMD is 45 Gbit. To make a smooth top surface, extra nickel above the SiO_2 surface was polished away using CMP. After CMP, the QMD's nonflat top surface became nearly flat. An AFM image indicates that the roughness is about 4 nm (Figure 28b). The roughness can be reduced by using an improved CMP process.

Longitudinal QMDs with densities up to $30\,Gbit\,in.^{-2}$ using NIL. The fabrication involves NIL in a 140-nm-thick PMMA layer on a silicon substrate and a lift-off of 1.5-nm Cr and 32-nm Co films evaporated thermally. As shown in

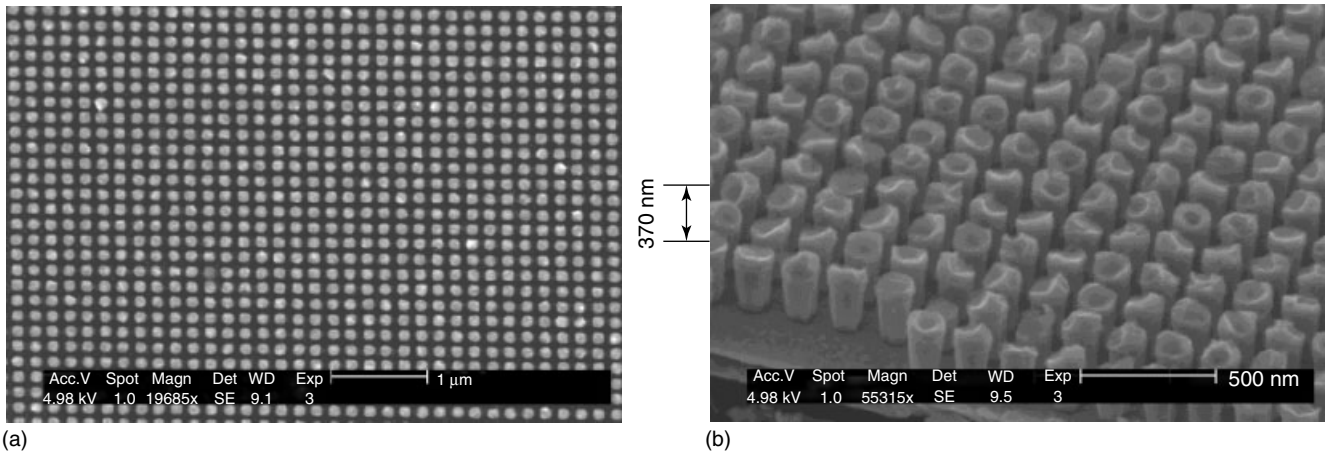

Figure 27. SEM pictures of an 18 Gbit in.$^{-2}$ large area perpendicular QMD fabricated using NIL. Each bit is an electroplated pillar. (a) Top view. (b) The SiO_2 was stripped off in order for the Ni pillars to be seen more clearly.

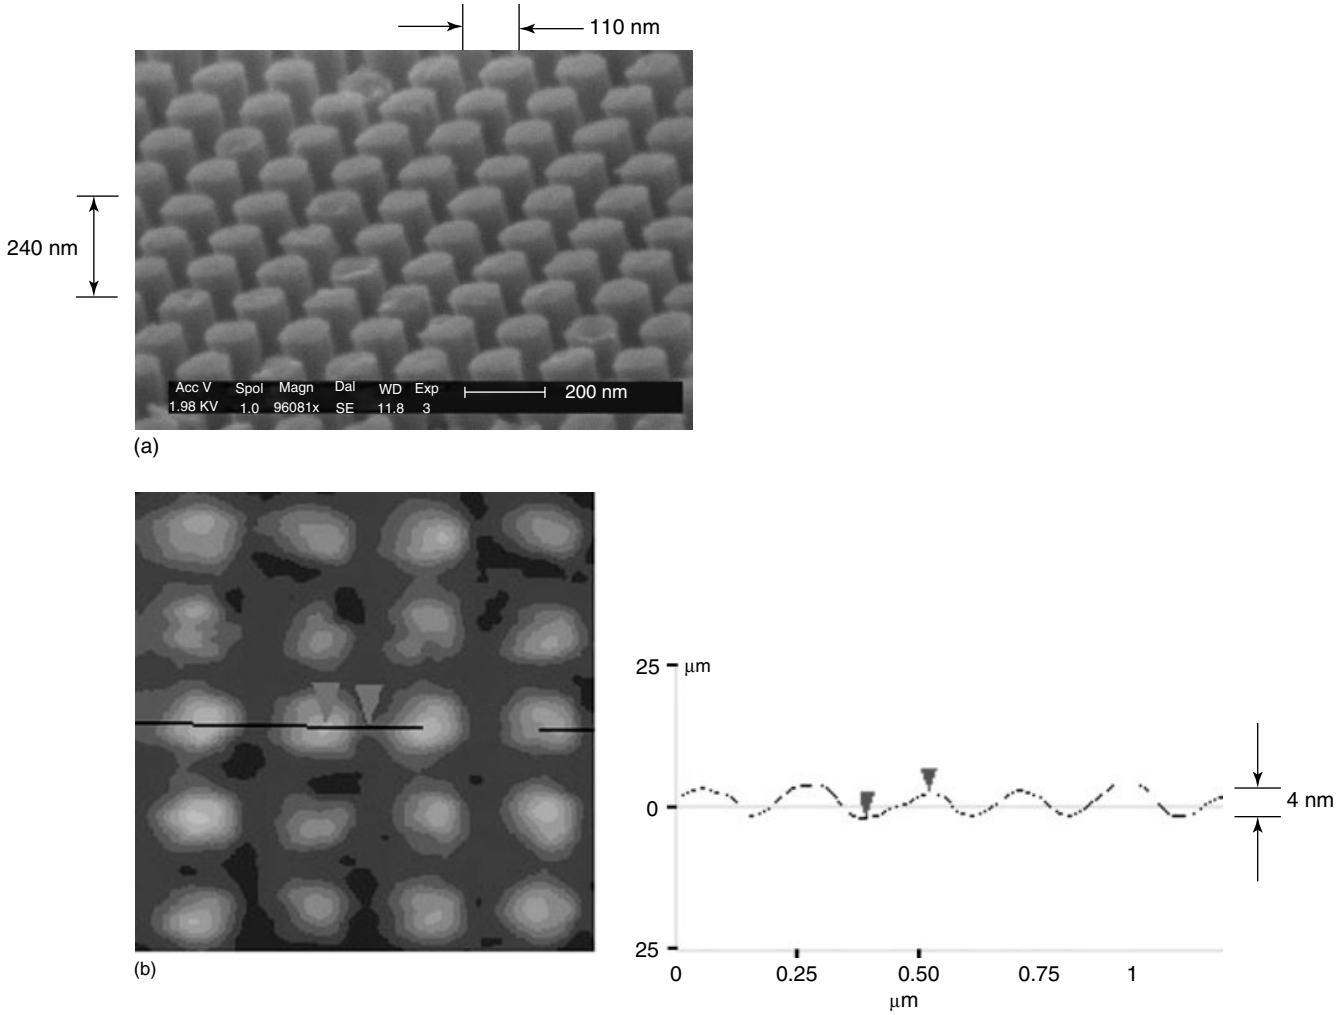

Figure 28. (a) SEM picture of an 18 Gbit in.$^{-2}$ large area perpendicular QMD fabricated using NIL. Each bit is an electroplated pillar. The SiO_2 was stripped off in order for the Ni pillars to be seen more clearly. (b) AFM image of the 18 Gbit in.$^{-2}$ large area perpendicular QMD. The image shows a surface roughness of 4 nm. (Reproduced from Wu *et al*., 1998, with permission from the American Institute of Physics. © 1998.)

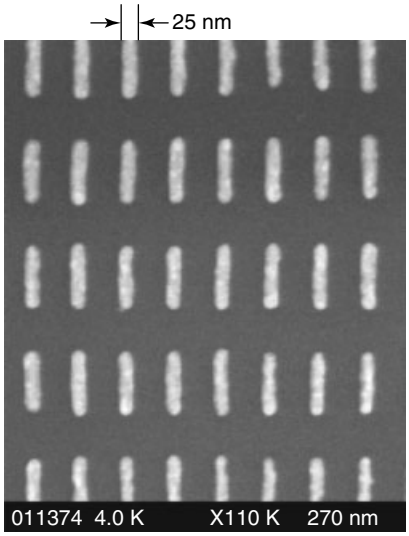

Figure 29. SEM picture of a 30 Gbit in.$^{-2}$ large area longitudinal QMD fabricated using NIL.

Figure 29, each bit is a bar 25 nm wide, 140 nm long, and 75 nm apart. MFM observations indicated that all the Co bars in the QMDs were single domains. Each bar clearly shows two opposite magnetic poles: one dark pole representing the attractive tip–bar interaction and one bright pole representing the repulsive interaction (Figures 13 and 22).

Clearly, the QMDs' density in the examples provided earlier are limited by our mold-making ability. In fact, the use of NIL to make 400G dots/in.^{2} of metal dots (Figure 3c) has been in demonstrated in 1996.

5.4 Future development of QMDs

From the discussions in the preceding text, it becomes clear that the future of QMD hinges upon our ability to make the NIL molds that not only have sub-40-nm pitch dots over a large area (at least 0.5 in. in diameter) but are also in concentric form. The rest of the NIL process has been clearly demonstrated. A promising approach to fabricate the NIL molds of QMDs is a guided self-assembly.

6 SUMMARY

We believe that nanoimprint technology is an enabling platform manufacturing technology that will impact a broad spectrum of fields. Patterned magnetic structures offer great opportunities for revolutionary magnetic materials and devices in data storage, sensors, and actuators. Nanoimprint technology is essential to the manufacturing and thus commercialization of QMD (patterned media) and other pattern magnetic structures. To accelerate the process of reaching such potential, we need to solve one of the key technological challenges in nanoimprint manufacturing of pattern media, namely, the making of the nanoimprint molds. We believe the solution comes from the combination of several innovative nanopatterning technologies. The next 5 years will be a very exciting period in both nanoimprint technology and PMNs.

ACKNOWLEDGMENTS

I thank many of my former students and postdocs who have made contributions to the work presented here, in particular, Paul Fischer, Peter Klaus, Linshu Kong, Mike Austin, Wei Wu, Bo Cui, Hua Tan, Wei Zhang, and He Gao. I also thank Patrick Murphy and Michelle Ward for grammatical editing, Linshu Kong, and Xiao-gan Liang for preparing the figures. I acknowledge ONR (Larry Cooper) and DARPA (Jan Alexande, Gernot Pomrenke, Fabian W.R. Pease, Christie Marrian, and Dave Patterson) for their partial support to the work presented here.

Growth of Magnetic Materials using Molecular Beam Epitaxy

James N. Eckstein
University of Illinois, Urbana, IL, USA

1 INTRODUCTION

Even though metals, semiconductors, and complex oxides are very different materials, molecular-beam epitaxy (MBE) has been adapted to grow films of them all (Cho and Arthur, 1975; Ploog, 1982; Eckstein and Bozovic, 1995).[2] The hallmark of MBE is the very accurate control of the synthesis process, and in practice this means control at the atomic layer level. Also, as the word 'epitaxy' implies, the growth of one layer should be in registration somehow with the layer below. Often growth occurs under ultrahigh vacuum (UHV) conditions, although sometimes carrier gases or a large overpressure of a volatile component is used. Sometimes, atomic beams are used, while in other cases, molecular beams are employed and only a part of the incident flux is destined to be incorporated in the growing layer. In many cases, accurate atomistic assembly is used for putting together devices, which depend critically on thicknesses of layers. In other cases, new aggregate phenomena can be found in samples containing interfaces that mediate charge, spin, strain, and other important factors that control electronic and magnetic properties.

The kinds of materials grown by MBE also span a wide range of structural and molecular complexity. Single component metallic films are structurally the simplest, since the total dose of atoms per unit area just determines the thickness of the layer grown, although faceting and roughening are interesting complications that often control the properties exhibited by such layers. The growth of soluble alloys is similar to the growth of single component films, but the details of how this works depend on the properties of the components, such as their vapor pressure, as well as the chemical factors that *lead to* the equilibrium phase diagram. MBE growth, however, is carried out far from thermal equilibrium. The most complex materials grown by MBE are those containing many atomic constituents and distinct atomic sites within the unit cell. Complex oxides are the most studied of such complex materials grown by MBE, and each unit cell may contain more than four different metal atom constituents located in distinct sites along with corresponding oxygen ions. Even with this diversity of materials, there are common features of the use of MBE to

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

grow magnetic materials of these types. This chapter covers these materials classes, summarizing the development of the growth processes and the results obtained.

2 MAGNETIC FILMS

Growth of films of magnetic metals using MBE began in the early 1980s. Load locked chambers with UHV base pressures, equipped with substrate heaters and *in situ* diagnostics such as reflection high energy electron diffraction (RHEED) were employed to grow transition-metal and rare-earth magnetic films. A number of different substrates and buffer layers were used in this work. The magnetic metals studied include rare-earth magnets, transition-metal magnets, and multilayer and device structures involving them. In this section, we describe representative results showing the most important advances in creating and understanding novel magnetism in artificial metallic structures. We begin with a description of MBE of rare-earth superlattices, and then discuss superlattices involving 3d transition metals that give rise to giant magnetoresistivity (GMR). Then we discuss the use of ferromagnetic materials as injectors of spin-polarized charge into semiconducting devices. This includes a variety of magnetic materials that are compatible with semiconductor film growth. We finish with a discussion of magnetic oxides, including the famous colossal magnetoresistive manganites. These materials have very large values of spin polarization, and magnetic tunnel junctions made with them have given the largest values of tunneling magnetoresistance observed so far.

3 MOLECULAR-BEAM EPITAXY OF METALLIC MAGNETIC FILMS

Because metal surfaces are reactive, MBE of metal films is done in UHV systems to avoid contamination. A schematic diagram of such a system is shown in Figure 1. Typical values of base pressure reported for the growth of metal films are less than 5e–10 Torr, with many groups reporting measured base pressures less than 1e–10 Torr. This requires a chamber having metal sealed valves and flanges that can be baked (typically to $>150\,^{\circ}\mathrm{C}$), a carefully designed load locked system with external substrate outgassing and adequate pumping to maintain the vacuum, including cryopanels for use during growth. Such systems are usually equipped with ion pumps, cryopumps, and titanium sublimation pumps, and the pumping speed seen by the chamber is in the range of $1000\,\mathrm{l\,s^{-1}}$.

The sources used in metal film MBE are either thermal effusion cells, capable of operating at temperatures as high as $1800\,^{\circ}\mathrm{C}$ (depending on the details of the cell), or electron beam evaporators that are used for elements that have to operate at higher temperatures. For magnetic films, elements such as manganese, copper, and most of the rare-earth atoms can be evaporated from conventional sources. Elements such as chromium, iron, cobalt, nickel, yttrium, and lanthanum require a higher temperature and often are evaporated from special 'high-temperature' cells. More refractory elements, such as the 4d and 5d transition-metal elements require evaporation from electron beam evaporators. Careful outgassing of sources prior to and during the baking of a system is important to obtaining the best vacuum possible.

Samples on which films are grown are held on a manipulator that incorporates the possibility of heating or cooling the sample and may also incorporate substrate rotation, which is used to obtain more uniform growth. Surface diagnostic tools are also usually incorporated for the measurement of structural, chemical, and even magnetic properties. The most common of these techniques is RHEED (Braun, 1999). It is well suited for MBE because it is surface sensitive and does not block the atomic or molecular beams used for growth. A RHEED system consists of a monoenergetic, focused electron beam with energy typically between 5 and 50 keV that is directed at a glancing angle toward the substrate; the electron beam diffracts from the growing surface and the diffraction pattern is characteristic of the surface lattice. On the opposite side of the chamber a phosphor screen displays the diffraction pattern, and this is often recorded in real time as growth occurs. The crystalline state of the surface can be monitored in this way. It provides a quantitative measure of surface flatness, the density, and structure of three-dimensional nanograins that sometimes emerge at heterointerfaces, and the gradual relaxation of lattice strain. Some systems incorporate tools for *in situ* chemical analysis, such as X-ray photoelectron spectroscopy (XPS) or Auger electron spectroscopy. Also, Magnetic properties of surface layers can be monitored if secondary electron microscopy with polarization analysis (SEMPA) is used (Scheinfein *et al*., 1990).

For metal films, the choice of substrate can be a complicating factor. In semiconductor MBE, the substrate is usually the same material or very similar to the film. In metal epitaxy, this is usually not the case. It is necessary to find a substrate, that is, chemically and structurally compatible with the metal film being grown. Sometimes the substrate must be an insulator, and in other cases metallic films are grown on semiconductor films that already incorporate an epitaxial device layer structure that, together with the metal film, forms the basis for an electronic or spintronic device. For devices, the most commonly used substrates for metal epitaxy have been the insulators, sapphire and magnesium oxide, as well as the semiconductors, silicon and gallium arsenide. Significant issues of chemical compatibility arise when some

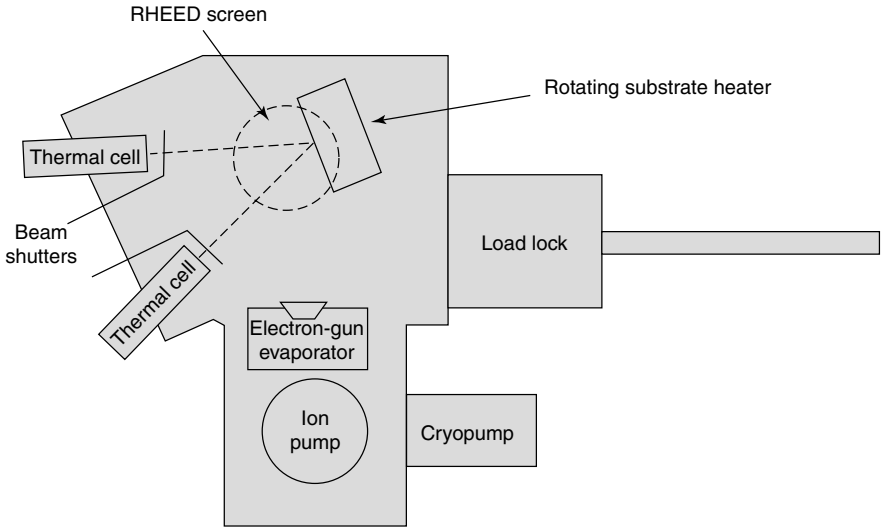

Figure 1. Schematic diagram of a typical MBE system for the growth of metallic films.

metal films are grown on sapphire. In particular, rare-earth atoms react with sapphire, removing oxygen and introducing a layer of partially oxidized rare-earth hexa-aluminate. This can be avoided by using a 'buffer layer' which is relatively stable in contact with both the sapphire as well as rare-earth atoms. Kwo and coworkers (1985b) reported that niobium provides such a buffer. It does not chemically react very rapidly with sapphire at temperatures below about 1300 °C. It grows on $(11\bar{2}0)$ sapphire with the in-plane orientation shown in Figure 2. The niobium film is oriented in the (110) direction. Niobium films grown by MBE at moderate temperatures (800–900 °C) are very flat. By annealing in UHV at somewhat higher temperatures (1300 °C) even smoother surfaces are obtained at the expense of reducing the sapphire at the interface. Figure 3(a) shows a niobium surface grown at 850 °C. The surface is covered with unit-cell-high terraces, but the direction of the terraces is not uniform. By annealing the film at 1300 °C for 20 min this changes. Figure 3(b) shows the surface that results, exhibiting fewer and more uniformly spaced terraces. Such surfaces provide a good substrate for the growth of rare-earth films.

The question of what growth conditions lead to the best metallic films and superlattices was addressed by Flynn (1988). He recognized that in many metal systems experience showed that the best growth happened over a rather narrow range of temperature. He observed that the activation energies for bulk diffusion and for surface diffusion are often proportional to the melting temperature for many elements. For a wide range of metals, the activation energy of bulk diffusion is found to be about $16\,kT_M$, while the activation energy of surface diffusion is found to be $3.5\,kT_M$, where T_M is the melting temperature and k is Boltzmann's constant. In order to quench bulk diffusion

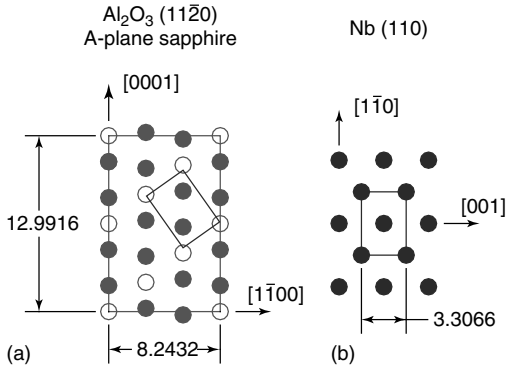

Figure 2. The orientation of Nb grown on a-plane sapphire is illustrated. (a) The position of the aluminum sites on an a-plane surface is shown. The solid circles are occupied and the open circles are vacant. The orientation of Nb atoms in a 110 plane is shown in (b), with a surface net unit cell shown outlined in the rectangle. This rectangle orients on the sapphire surface as shown in (a).

at an interface, over the time a film is grown but enable surface diffusion to adequately transport adatoms to adjacent step edges, only a limited range of temperatures may satisfy these criteria. Since a typical terrace size is about 100 unit cells wide, the required rate of surface diffusion, active only during the time an atom is on the surface and not yet buried, can be determined. By comparing these two rates, Flynn found that growth temperature should be about 3/8 times the melting temperature. In particular, this means that it should be very difficult to make structures, like superlattices, with components having very different melting temperatures. This model works well for elemental metals, but not so well for complex compounds, such as oxides. The reasons for this are numerous. For one, the phase diagrams of multicomponent systems can change with temperature. In addition, the

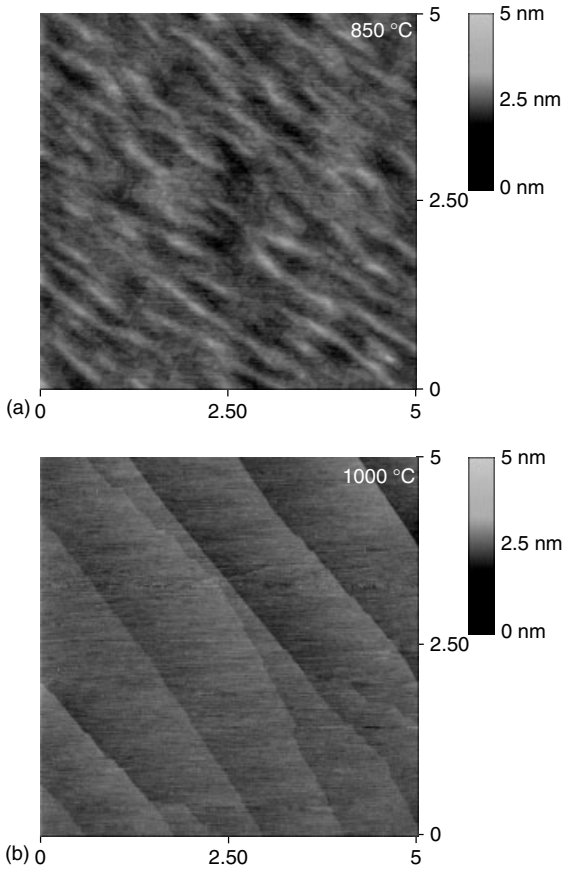

Figure 3. Surface morphology of Nb films grown by MBE. (a) An atomic force micrograph of a Nb film grown at 850 °C and removed from the growth chamber. (b) A micrograph of a similar film grown at the same temperature, but then annealed at 1300 °C.

mobility of different atoms, ions or submolecular species that diffuse on a surface during the growth of a complex material can be very different, and no simple relationship exists between the melting point of a compound and the activation energy for diffusion rates of all surface species present during growth. On the other hand, the underlying idea that a competition between bulk and surface diffusion governs the range of temperature that is optimum is still the case, even though the complexity of both bulk and surface diffusion makes it more difficult to extract a single optimum growth temperature for more complex materials.

4 MOLECULAR-BEAM EPITAXY OF RARE-EARTH MAGNETIC MULTILAYERS

Rare-earth metals exhibit phase diagrams with interesting magnetic structures in bulk samples. They crystallize into close-packed phases, either hcp or fcc (excepting samarium), and the conduction band in most of them is due to delocalization of two 6s and one 5d electrons. The 4f electrons are localized on the resulting 3^+ ions, and both their spin and their orbital angular momenta contribute to the ionic magnetic moment since the 4f orbital motion is not strongly coupled to the crystal field as the d electrons are in transition metals. The number of 4f electrons increases from zero in lanthanum (and yttrium and scandium which are electronically similar to lanthanum) to the filled 4f shell containing 14 electrons in lutetium. The 4f electrons interact with the delocalized s−d bands and this leads to an indirect coupling of the 4f angular momenta via indirect exchange. This coupling, also known as RKKY for Ruderman, Kittel, Kasuya, and Yoshida, is strongly dependent on Fermi surface properties, such as the Fermi wave vector in different directions (Kittel, 1987). It is weaker than direct exchange, which leads to magnetism in transition metals such as iron, and because it is weaker, the magnetic ordering temperatures of the rare-earth elements that do order tend to be lower. The elements gadolinium through thulium, all of which are hcp, have a low-temperature ferromagnetic phase. For terbium through thulium there is a higher-temperature antiferromagnetic phase that consists of close-packed planes with in-plane ferromagnetic alignment, and a temperature-dependent twist angle that rotates the direction of magnetic moment orientation in a spiral fashion around the *c* axis as one moves in the *c*-axis (0001) direction. Gadolinium has the highest Curie temperature, 289 K, and does not exhibit a higher-temperature spiral antiferromagnetic order, while dysprosium has a Neel temperature of 179 K below which the spiral order appears, and a Curie temperature of 89 K at which temperature a first-order transition to ferromagnetic order occurs. Two excellent reviews of the properties and discoveries found in rare-earth magnetic superlattices have been written by Majkrzak and collaborators (1991) and by Rhyne and Erwin (1995).

An early demonstration of the ability of MBE to make magnetic metallic films with new properties emerging because of layer-by-layer control of the composition was the work done studying superlattices containing layers of magnetic rare-earth atoms separated by nonmagnetic yttrium atoms. The atomic size of yttrium is close to that of gadolinium and dysprosium, and superlattices containing these atoms can be assembled with only moderate strain and with atomic plane accuracy. The superlattice results summarized subsequently were made possible by the discovery that sapphire could be used as a substrate, as long as an intervening layer of niobium was grown to chemically isolate the rare-earth atoms from the substrate Al_2O_3 (Kwo *et al.*, 1985b). Previously, Greene and coworkers found that rare-earth atoms underwent a chemical reaction with sapphire at temperatures required

for epitaxial growth (Greene *et al*., 1985). At around the same time, Durbin and coworkers showed that smooth (110)-oriented niobium films and niobium–tantalum superlattices could be grown epitaxially on a-plane sapphire substrates (Durbin *et al*., 1981). Since niobium does not react significantly with either Al_2O_3 or rare-earth atoms at the temperature ranges used for epitaxial growth, it provides chemical isolation between the rare-earth superlattice and the sapphire substrate. The niobium 110 surface can be viewed as having a distorted triangular structure on which the hexagonal close-packed rare-earth lattice orients.

The first rare-earth superlattice system studied was the Gd–Y system by Kwo and coworkers (1985a, 1987). The growth was carried out in a MBE system having a nominal base pressure of 3×10^{-11} Torr. The substrate was heated to improve the epitaxy, but the growth of the superlattice was carried out at 220 °C in order to avoid vertical diffusion. A thick Y layer was grown on top of (110) niobium to isolate the superlattice from the niobium lattice. On top of this, superlattices were grown of different numbers of Gd and Y atomic planes per supercell. Gadolinium was chosen for this work since it has the simplest magnetic phase diagram of the ferromagnetic rare-earth elements. The most important finding is illustrated in Figure 4 taken from Kwo *et al*. (1987). The supercell consists of a Y slab and a Gd slab. The Y slab had a variable number of Y planes and the Gd slab had either 4 or 10 Gd planes per slab. They observed an oscillatory dependence of the magnetic order that emerged below the Gd Curie temperature depending on the number of Y planes in each supercell. The oscillation appeared to be independent of the number of Gd planes per slab. The Gd slabs from supercell to supercell aligned either antiferromagnetically or ferromagnetically with respect to each other depending on the Y slab thickness. This result was explained in terms of RKKY coupling of the Gd spins through the nonmagnetic Y slabs. In fact, the separation leading to the first maximum of remnant magnetization was about seven Y layers, and this is in quantitative agreement with simple model of RKKY coupling through the Y slab as shown in Figure 4(c). The coupling is predicted to be antiferromagnetic for three Y layers and ferromagnetic for seven.

Superlattices of Dy and Y were grown and studied by Flynn, Salamon, and coworkers (Borchers *et al*., 1987). This system is more complicated than Gd–Y, because of the spiral magnetic order that exists in Dy between 89 and 179 K (Majkrzak *et al*., 1991). In addition, the basal plane strain is large enough to be important in this system. Since the superlattices were grown on Y films (on top of (110) niobium) that were thick enough to be relaxed, the Dy slabs were in a tensile strain of 1.6% due to the lattice mismatch between Y and Dy. If the superlattices are sufficiently perfect,

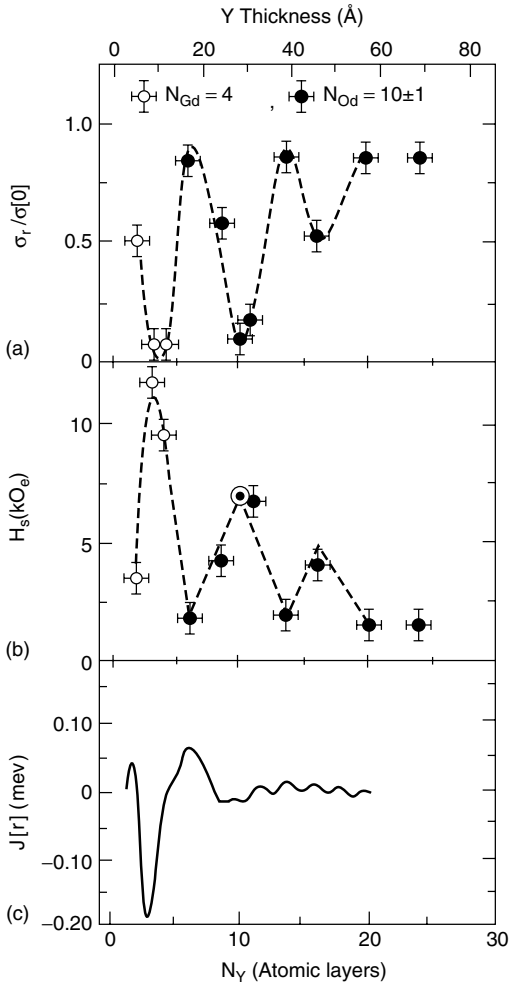

Figure 4. Magnetic characterization of Gd:Y superlattices from Kwo *et al*. (1987). Superlattices were grown in two series, with either 4 or 10 Gd layers/supercell. In each series, films with different Y layer thicknesses were grown. (a) The ratio of the magnetic remanence to the magnetization extrapolated from high field back to zero field. The authors point out that this normalizes the sample volume and makes film-to-film comparisons quantitatively possible. (b) The saturation field which behaves oppositely to the normalized magnetic remanence. (c) A calculated exchange interaction between two Gd planes separated by a Y slab of variable thickness. The sign of the exchange interaction suggests that the low remanence observed at the first minimum in (a) is due to an antiferromagnetic coupling at that Y thickness. (Reproduced from Kwo *et al*., 1987, with permission from the American Physical Society. © 1987.)

the layer architecture engineered into the film may influence the magnetic structure that naturally emerges, due to both exchange and magnetoelastic effects. The question is how the pitch of the superlattice interferes with the pitch of the magnetic spiral. The spiral magnet order exists naturally in single-phase Dy samples, and does not exist at all in single-phase Y samples. Whether the pitch of the superlattice somehow 'stabilizes' the spiral phase and prevents the

formation of the uniformly magnetized ferromagnetic phase is also complicated by the strain the Dy slab is under.

Superlattices with different layer thicknesses were grown and studied by measuring their magnetic moment as well as by neutron scattering (Salamon *et al*., 1986). In each supercell, the Dy slabs were around 15 atomic layers thick and the Y slabs ranged from 5 to about 40 in different samples. The most obvious difference between bulk Dy and these superlattices was the absence of the first-order transition to the ferromagnetic structure in the superlattices at low temperatures. Starting from the spiral ordering temperature around 180 K and extending to 10 K a spiral magnetic structure was also observed in the superlattice films. This was studied with neutron diffraction, which can distinguish magnetic order from atomic order. The length scale of magnetic order sets a minimum linewidth to magnetic superlattice reflections that are caused by the spiral order. Surprisingly, the spiral structure extended from one Dy slab to neighboring Dy slabs, even though the material connecting the Dy slab was nonmagnetic Y. Figure 5 shows magnetic superlattice reflections surrounding the 0002 structure peak. It is clear that the spiral order persists down to 10 K and that the linewidth of the magnetic peaks decreases as the temperature is reduced. On the basis of these data, it is possible to infer that the length scale of magnetic structure correlation extends through more than five superlattice periods. This means that the spiral magnetic order extended from the magnetic Dy layer into and through the nonmagnetic Y layers, although the degree of coupling through nonmagnetic Y layers was reduced for thicker Y layers. The spiral angle shift per plane was found to be constant at about 50° in the Y slabs, and Rhyne and Erwin and coworkers suggested that a spiral spin density wave was *induced* in the Y slab by proximity to the Dy layers (Erwin *et al*., 1987). This wave would then carry the spin order information between the Dy slabs. The pitch of the proximity induced spiral magnetization in the Y layer provided evidence that Y has an incipient conduction electron SDW. Alternatively, Majkrzak has suggested that introducing a finite thickness spiral order in the Dy slabs may naturally introduce spiral coupling via asymmetric strain and the RKKY interaction (Majkrzak *et al*., 1991).

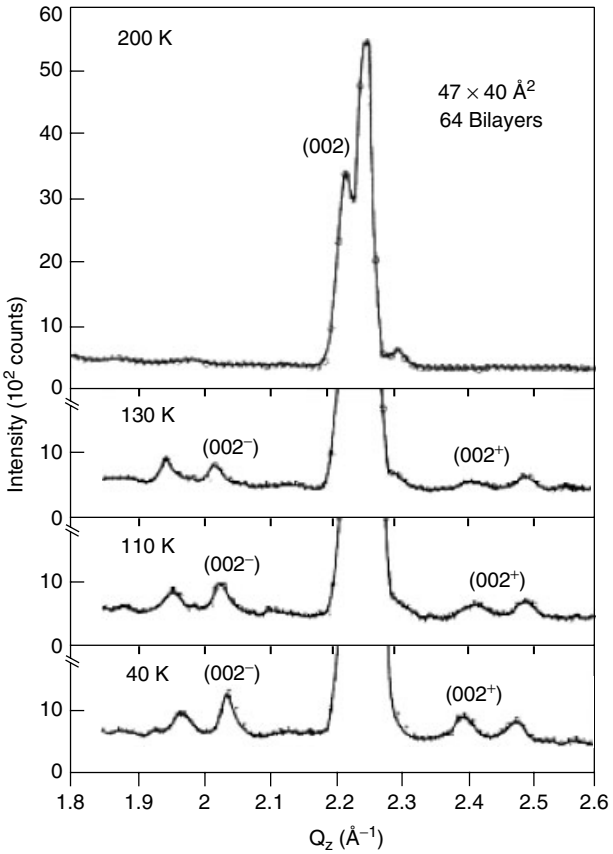

Figure 5. Magnetic reflections obtained in neutron scattering from Dy:Y superlattice from Borchers *et al*. (1987). In each supercell, the Dy layer is nominally 4.7 nm thick and the Y layer is 4.0 nm thick. The principle magnetic satellites are labeled 002− and 002+ and they emerge below the magnetic ordering temperature. Similar reflections are obtained from a single-phase Dy film in the helimagnetic phase. (Reproduced from Borchers *et al*., 1987, with permission from the American Institute of Physics.)

5 TRANSITION-METAL MULTILAYERS AND SUPERLATTICES: GIANT MAGNETORESISTANCE

Superlattices containing different magnetic transition metals have also been made by MBE. The motivation for this work has largely been to study and optimize the phenomena of 'giant magnetoresistance', in which electronic transport is strongly affected by the relative magnetic orientation of different ferromagnetic layers.[21] The underlying physics is that differences in spin-polarized density of states in two parts of a sample, magnetized in different directions, leads carrier scattering and thus resistance. If an applied magnetic field reorients the magnetization of one of the two parts, so that they become pointed in the same direction, then the magnetic scattering is eliminated and the resistance is reduced. This shows up as a negative magnetoresistance. This effect has been studied in polycrystalline as well as single crystal material, in samples with very smooth interfaces as well as in samples with rough interfaces between different layers. MBE-grown samples with controllable interface roughness have allowed a systematic investigation of the role of interface characteristics. In practical terms, the phenomena of GMR and the related tunneling magnetoresistance involving

samples made with transition metals are so robust that exquisite sample perfection is not required (Parkin, Bhadra and Roche, 1991). Excellent devices can be made with polycrystalline samples. This section reviews work done growing and studying transition-metal multilayers by MBE. For more information the reader is referred to excellent reviews by Farrow (1998) and Etienne and Massies (1993).

The 3d transition metals exhibit a wide range of magnetic properties, ranging from strong, high-temperature ferromagnetism in Co, Fe, and Ni, to antiferromagnetism in Cr and Mn, to paramagnetism in Ti, V, Cu, and Zn. The Fermi surface of ferromagnetic transition metals and alloys is significantly polarized, between 35 and 46% (Soulen *et al*., 1998). Since transport is controlled by the properties of the Fermi surface, the degree of Fermi surface spin polarization determines the amount of spin scattering that occurs in a GMR device.

In a typical GMR device, two ferromagnetic films are separated by a paramagnetic or antiferromagnetic film. Typical ferromagnets used have been Co, Fe, Ni, and permalloy (an alloy of Ni and Fe). The paramagnetic film has been Cu, V, or Au, and Cr has been used as an antiferromagnetic spacer layer. Because of the way in which RKKY changes the sign of exchange energy as a function of how far two spins are from each other, the spacing between two ferromagnetic layers and the relative direction of the spins in the two FM layers in a ferromagnet–paramagnet–ferromagnet trilayer together determine whether carriers that propagate from one interface to the other will be strongly scattered.

The earliest demonstration of GMR was reported by Baibich *et al*. (1988) who found that very large magnetoresistance could be obtained in (001)-oriented Fe/Cr superlattices if the thickness of the Cr layers was chosen correctly. The growth of the superlattice on top of (001) GaAs was monitored using RHEED. This showed that a critical thickness of Fe was required for the subsequent superlattice to grow crystallographically ordered. The growth conditions were UHV (background pressure of 5e–11 Torr) and the substrate temperature was kept near room temperature. The growth rates employed were typical of MBE, around 0.5 to 1 A s^{-1}.

The magnetization of the Fe slabs earlier had been found to be antiferromagnetically ordered for thin enough Cr layers (Grunberg *et al*., 1986). The magnetization was in plane, but oppositely directed in adjacent iron slabs. Evidence for this is shown in Figure 6, where M versus H curves of samples with different Cr thicknesses are compared. The important thing to note is the difference in the shape of the $M(H)$ curves for samples in which the Cr layer is thin, for example, see the curve for the sample with 9-Å-thick Cr slabs. For thicker Cr layers, the $M(H)$ curves show ferromagnetic behavior. The data for the larger Cr slabs, show that the magnetization shifts direction when a relatively small coercive field is applied. For thinner Cr layer thicknesses, this is not the case. Instead, a very large applied field is required to align all of the Fe magnetic moments. This was interpreted as being due to a zero-field antiparallel alignment (antiferromagnetic) of neighboring Fe slab magnetic moments for the 9-Å samples. In order to pin this down, spin flip neutron scattering was done on a sample with a thin Cr layer. For an antiferromagnet spin alignment, a 'half-order' magnetic reflection should be seen due to the doubling of the magnetic periodicity compared to the structural periodicity in the growth direction. In fact, that is what was observed, as shown in Figure 7. This reflection is sensitive to applied magnetic field; it can be eliminated

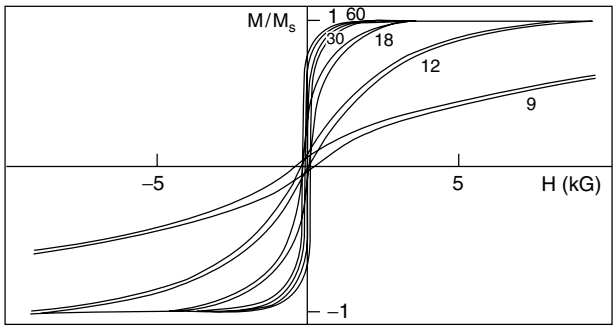

Figure 6. Magnetization curves at 4.2 K for different iron chromium superlattices. The number next to each curve indicates the thickness of the chromium layer in angstroms, while the thickness of the iron layer is 30 Å for each superlattice. For the curve labeled 60, the thickness of the iron layer was 60 Å. (From Baibich *et al*., 1988.)

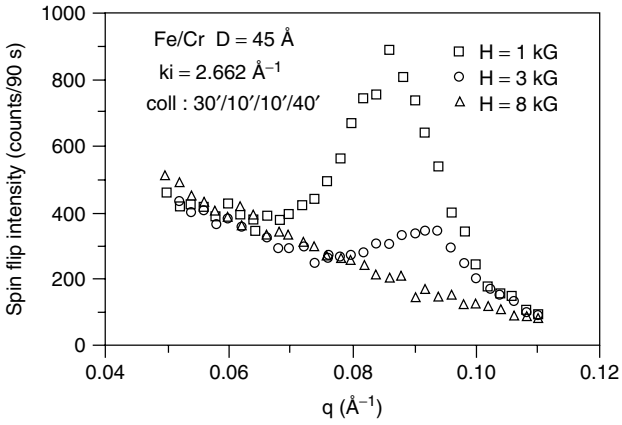

Figure 7. Neutron scattering from iron chromium superlattice with 30 Å iron layer and 15 Å chromium layer/supercell at 1.6 K. The film had 20 supercells. The magnetic reflection with periodicity equal to twice the structural periodicity is sensitive to applied field, indicating a spin flip transition leading to ferromagnetic slab alignment occurs for less than 1 T applied field. (Reproduced from Barthélémy *et al*., 1990, with permission from the American Physical Society. © 1990.)

by applying a large enough field to make all the Fe spins point in the same direction (Barthélémy *et al*., 1990). As shown in the figure, this observation was taken as evidence for ferromagnetic ordering of the superlattice by flipping the spins with a large enough applied field. At zero field, these spins had been slabwise antiferromagnetically aligned because of the slab-to-slab RKKY exchange interaction.

For samples with antiferromagnetically aligned Fe slab spins, the resistance depended strongly on magnetic field. This is shown in Figure 8, where the resistance is shown as a function of applied magnetic field for three different superlattices. Each of these samples had supercells containing the same Fe slab thickness, namely, 30 Å. They differed in Cr slab thickness. The largest effect was observed for the sample with 9-Å Cr slab thickness. Here, the resistance changed by almost a factor of two when a magnetic field large enough to align all of the Fe spins was applied. This was the discovery of GMR.

Following this work, GMR was investigated in samples with improved interfacial flatness. The results indicate substantial subtlety in the factors that influence GMR. For example, if (001) Fe/Cr superlattices with very flat interfaces are studied, a different phenomenology emerges. The underlying antiferromagnetism in the Cr slab apparently gives rise to a surface magnetization and net exchange coupling between Fe slabs that shifts for every Cr layer grown. This was discovered by Unguris, Celotta, and Pierce (1991) who used SEMPA to probe the surface of a Cr wedge grown on a flat Fe surface. In bulk Cr, which is bcc, it is *approximately true* that the magnetization of the body-centered atom

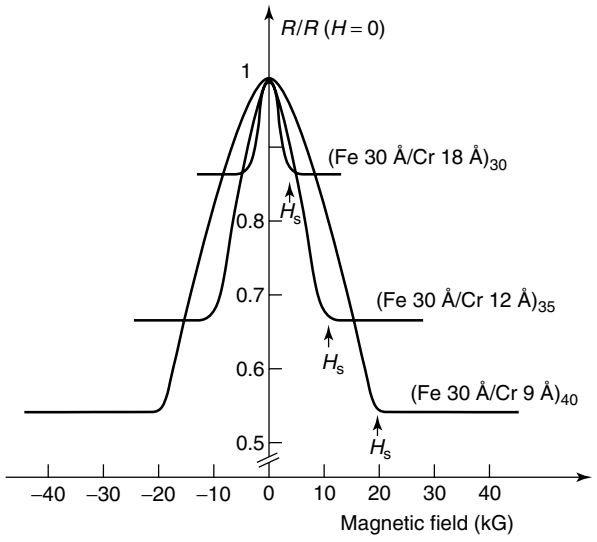

Figure 8. Dependence of in-plane resistance of superlattice on applied in-plane magnetic field. The sensitivity is largest for the thinnest chromium layer, which has quiescent antiparallel spin alignment of adjacent iron slabs. (From Soulen *et al*., 1998.)

is opposite to the magnetization of the corners. In fact, this picture is modulated by a spin density wave that has a periodicity of about 21 unit cells (Fawcett, 1988; Zabel, 1999). Unguris, Celotta, and Pierce (1991) observed an oscillation in the direction of the coupling between the Fe slabs that had a period of approximately one Cr unit cell. This was interrupted by an oscillation phase slip at relatively thick intervals, typically 20, 40, and 60 monolayers of Cr, similar to the periodicity of the bulk Cr spin density wave. This short period effect was not seen in samples having interfaces with several monolayer roughness, as evidenced by streakier RHEED patterns. (For a discussion of the use of RHEED in measuring surface roughness see Section 8 below.) Clearly, the phenomenon of GMR depends in detail on how the magnetic influence occurs at the interface to the Cr layer. The short period oscillation was attributed to the rotation of the interface magnetization direction caused by the antiferromagnetism and spin density wave present in the (001) Cr film. Observing the short period oscillations requires samples with the flatness that so far only MBE has made possible.

6 SPIN INJECTION FROM METALLIC FERROMAGNETS INTO SEMICONDUCTORS

Another area of research in which magnetic materials grown by MBE have made significant contribution is the injection of spin-polarized current into semiconductor structures. Spin injection and control of spin currents is a central component of the larger topic of spintronics. This is a wide-ranging field and includes the study of devices that sense magnetic fields by measuring spin-polarized currents, such as in magnetic tunnel junctions, as well as devices that use the spin degree of freedom to perform quantum information manipulation. In such quantum devices, spins or spin systems should be prepared in a coherent initial state, undergo time evolution in a controlled environment interacting with other quantum degrees of freedom, and then be interrogated by projecting out a final state quantum number. An important component of this is the ability to deliver a single electron with a specified spin state, at the right moment into a circuit embedded in a semiconductor heterostructure. So, highly precise injection of spins into semiconductors is required. In this section, we describe experiments working toward this goal.

Early work aimed to obtain as transparent a contact as possible between a semiconductor conduction channel and a permalloy ferromagnetic injector, $Ni_{0.8}Fe_{0.2}$ (Hammar, Bennett, Yang and Johnson, 1999; Lee *et al*., 1999). This was done in Hammar, Bennett, Yang, and Johnson (1999) by choosing the semiconductor InAs, which is known to not

have a Schottky barrier. In Fawcett (1988) and Zabel (1999) a small barrier between the permalloy and InAs channel was preserved by the processing, but the contact was very transmissive and nonrectifying. In both cases, a good connection between the carriers in the two different materials was obtained. The device geometry consisted of two magnetic films connected by a two-dimensional electron gas in the semiconductor. The spin injection in both experiments was small, and the change in interface resistance between the magnetic layer and the semiconductor was of order 1%. The reason for this small response was identified by Schmidt and coworkers who pointed out that for transmissive contact metallurgy between a ferromagnetic metal and a diffusive semiconductor, the degree of spin polarization injected into the semiconductor is less than the polarization of the ferromagnet by a factor equal to the ratio of the semiconductor conductivity to the ferromagnet conductivity (Schmidt *et al*., 2000). Since a metallic ferromagnet has many times the carrier density of a semiconductor, this factor is very small and accounts for the small injection efficiency observed in these two experiments. A solution to this problem was proposed by Rashba (2000) who considered a spin injection system in which the transport from the ferromagnetic metal into the semiconductor was due to weak tunneling. In this case, the small contact conductance effectively substitutes for the ferromagnet's large conductivity and results in much more efficient spin-polarized current injection. In practice, that barrier can be obtained from an epitaxial insulator or from an intrinsic Schottky contact.

The growth and properties of Fe films on GaAs substrates has been recently reviewed by Wastlbauer and Bland (2005). They discuss the formation of the interface between Fe and GaAs studied in experiments that systematically examine the role of temperature, substrate reconstruction, and surface stoichiometry on diffusion and interface compound formation. Since the chemistry of Fe–Ga bonding is different from Fe–As bonding, it is no surprise that the overall nature of the crystalline growth of the Fe to GaAs interface is different when the surface is predominantly terminated in Ga or As. The formation of Fe–As bonds is energetically more favorable than Fe–Ga bonds (Thibado *et al*., 1996). This leads to two-dimensional formation of the Fe film on the As-terminated GaAs surface. STM studies have shown that growth of submonolayer Fe on As-rich surfaces happens via two-dimensional nucleation and growth, followed by layer-by-layer growth of Fe on the resulting surface (Kneedler *et al*., 1997). Quite a different scenario occurs on Ga-terminated surfaces. There, the relative energetic cost of Fe–Ga bonds leads to the formation of three-dimensional grains, which coalesce when the Fe coverage exceeds five monolayers (Chambers *et al*., 1986; Xu *et al*., 1999; Monchesky, Heinrich, Urban and Myrtle, 1999; Moosbühler, Bensch, Dumm and Bayreuther, 2002). For thicker films, the surface shows a persistent As composition as seen by XPS during growth (Kneedler *et al*., 1997). A subsequent detailed investigation of the role of temperature on As and Ga surface segregation using Auger electron spectroscopy discovered diffusion and segregation of both atoms, with the diffusion of As occurring at much lower temperatures (Sano and Miyagawa, 1991). At the interface, a chemical reaction occurs between the Fe and GaAs. Studies by (Filipe, Schuhl and Galtier, 1997) suggest that a compound with composition $Fe_3Ga_{2-x}As_x$ forms at the interface.[43] This was correlated with a careful examination of the Fe–Ga–As chemical phase diagram, and interfaces annealed to high temperatures showed the growth of this phase occurring. The magnetic properties of this material are reduced compared with metallic Fe, so formation of such reacted interfacial layers can be expected to reduce the performance of spin injection. Other studies showed that growth at reduced temperatures leads to a reduced thickness of reacted interface material, but growth as low as – 15 °C still shows several monolayers of such material forms, presumably limited by bulk diffusion (Schultz *et al*., 2002).

With Fe layers grown on AlGaAs, spin injection has been obtained using both Schottky contacts as well as Al_2O_3 tunnel barriers. The first report of large spin injection from Fe into GaAs used a naturally occurring Schottky barrier and was monitored via the degree of circular polarization in the electroluminescent light. Zhu and coworkers grew Fe on top of GaAs and obtained about 2% circular polarization of the resulting electroluminescence at room temperature (Zhu *et al*., 2001). They studied the effects of different termination of the GaAs surface and found that similar luminescence polarization was obtained in all cases they studied, As and Ga stabilized surfaces. van 't Erve and coworkers (2004) compared the spin injection efficiency using intrinsic Schottky barrier with amorphous Al_2O_3 barrier. They also measured the spin injection by analyzing the circular polarization state of the electroluminescence signal. They found that spin injection occurred for both devices, but the electroluminescence signal was more than 10 times as large for the Schottky device. The luminescence signal is observed from polarized electron and unpolarized hole recombination. They suggested that the reduced emission efficiency with the grown oxide barrier was due to an enhanced rate of electron–hole recombination caused by localized states at the Al_2O_3 to AlGaAs interface. Another study looking at factors that increase the magnitude of luminescence found that either growing the Fe layer at low temperatures or introducing a very thin intervening Al layer on top of the GaAs leads to increased electroluminescence intensity (Chye, Huard, White and Petroff, 2002). They interpreted this as being due to a

reduced degree of interface compound formation. The degree of magnetic order on an atomic scale controls the magnetization of the injected current, and growth procedures that lead to a cleaner, more magnetically distinct interface appear to improve the degree of spin polarization injected across a barrier.

Other interesting candidates for ferromagnetic injectors are materials that should have completely spin-polarized bands, half-metals. In metallic systems, Heusler alloys are thought to be half-metallic, and several groups have investigated the growth of different Heusler alloys on GaAs and performed spin-injection experiments with their samples. Several groups have grown such samples on different III–V compounds and alloys. The earliest work was reported by Dong *et al*. (1999) who grew single crystal Ni_2MnGa on GaAs. They used a very thin interfacial buffer layer consisting of Sc0.3Er0.7As on top of which the magnetic alloy was grown. They obtained a somewhat reduced Curie temperature, 320 K instead of the bulk value of 376 K, but this could have been due to the film thickness – it may have been thin enough to reduce the magnetic order. Another Heusler alloy, Co_2MnGe was grown on GaAs by Ambrose, Krebs, and Prinz (2000). They grew the compound on annealed GaAs, using individual flux monitors to control stoichiometry, at a moderately low temperature, ∼175 °C, and obtained films with room-temperature ferromagnetism but unusual magnetic anisotropy that was attributed to substrate strain. Later, Dong and coworkers (2005) obtained a measure of spin injection on a sample using Co_2MnGe as the spin current injector. They obtained about 13% circular polarization of electroluminescent emission at 2 K, which corresponds to a spin polarization of 0.27. This is shown in Figure 9 along with a TEM image of the interface. At room temperature the polarization disappeared. Since the Curie temperature of this material is 905 K, the bulk is strongly magnetic at room temperature. It was suggested that some interface chemistry leads to degraded spin polarization at the junction and this becomes more noticeable as the temperature rises. In addition, control of the composition is required for this compound to form. There is a rather wide range of solubility of vacancies and antisite substitutions, so that single crystal films can be grown even without sub 1% relative composition control. But the effect of composition on resulting magnetic properties and the stability of the interface to GaAs are currently being investigated. A simpler Heusler alloy with good structural stability at the GaAs interface was investigated by Kawaharazuka *et al*. (2004). They used Fe_3Si, which is considered to be a Heusler alloy, but which is not completely characterized as a half-metal at this point in time, although as a Heusler alloy it is expected to be half-metallic. They found observable spin injection even at room temperature in electroluminescence.

7 MBE GROWTH OF DILUTE MAGNETIC SEMICONDUCTORS

Dilute magnetic semiconductors (DMS) are nominally insulating phases when undoped, into which magnetic impurities are alloyed at concentrations relatively high compared with typical 'dopant' densities. The most studied systems are based on II–VI and III–V parent phases. Magnetic impurities from the 3d transition metals have most commonly been used. The dopant atoms can do three things depending on the semiconductor. First, they introduce a local magnetic moment because the d electrons remain localized on the dopant site. Secondly, they can introduce band carrier doping if the valence of the impurity differs from the nominal valence of the site on which it sits. Finally, at a sufficiently high density, the impurity atoms give rise to an impurity band in which the Fermi energy can lie and which can mediate conduction.

In II–VI systems, zinc and cadmium telurides and selenides, as well as zinc oxide have been doped with Cr, Mn, and Co (Hou *et al*., 2006; Slobodskyy *et al*., 2004; Mofor *et al*., 2005; Buyanova *et al*., 2006; Nielsen *et al*., 2006; Saeki, Matsui, Kawai and Tabata, 2004). The nominal valence of the transition metal in these systems is 2+, so that no carrier doping occurs. For example, in the case of Co-doped ZnO, ionic absorption bands indicate a fingerprint for +2 valence (Pacuski *et al*., 2006). Since the impurity valence

is the same as the valence of the site on which it substitutes, the 'dopant' density can be very large, ∼50%. With such a large density, the Curie temperature is expected to be large. Indeed, in such systems, a $T_C >$ room temperature is found (Hou *et al*., 2006; Mofor *et al*., 2005; Nielsen *et al*., 2006; Saeki, Matsui, Kawai and Tabata, 2004).

In III–V systems, the transition-metal 3d dopant atom tends to reside on the group-III site and ionizes to a valence of 2+. This means that it introduces hole carriers as well as a magnetic moment. The fact that it has a different charge transfer means that it introduces a large energy cost and this limits the density at which it can be incorporated in equilibrium to a relatively small value. The earliest work used InAs doped with Mn (Munekata *et al*., 1989; Ohno *et al*., 1992). Later, GaAs was doped with Mn (Ohno *et al*., 1996; Hayashi *et al*., 1997) and by introducing a post-growth anneal, a Curie temperature as high as 174 K has been obtained (Ku *et al*., 2003). An excellent review of the work on III–V-based DMS by a large number of researchers is provided by Jungwirth *et al*. (2006).

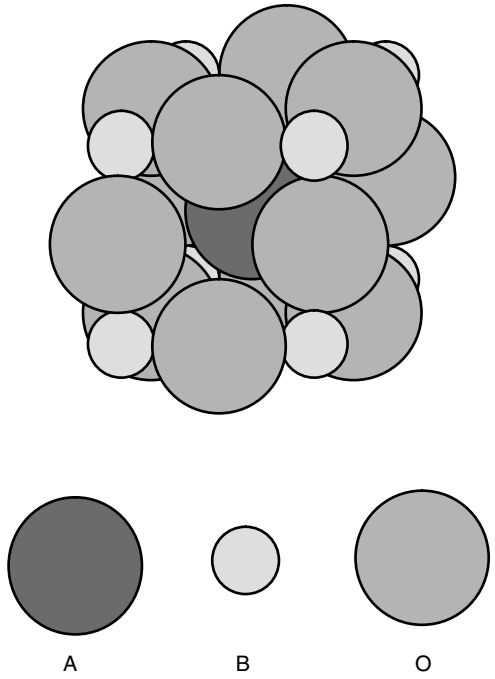

Figure 10. A ball and stick model of the atomic positions in a single unit cell of a simple cubic perovskite ABO_3. The B atom is a transition metal and is sixfold coordinated with oxygen atoms. The B-atom d orbitals hybridize with the oxygen 2p orbitals to give the states near the Fermi energy. The B-atom coordination is octahedral. In this picture to complete an octahedra around the lower right-hand B atom, three oxygen atoms should be added, one below, one to the right, and one out in front. The octahedra are corner-sharing. In real phases, such as manganites, other factors such as Jahn–Teller level splitting and charge localization in Mott–Hubbard split bands can lead to substantial distortions of the cubic structure shown.

8 MBE GROWTH AND PROPERTIES OF PEROVSKITE MAGNETIC OXIDE FILMS AND DEVICES

Perovskite manganites exhibit a rich set of potentially useful physical properties, controlled by composition, magnetic field, temperature, and other factors. These properties, along with their interesting underlying collective physics, have motivated considerable work. The basic perovskite composition can be represented as ABO_3, where A and B are different metal atom sites, and often the A site is an alloyed mixture of two different species. A ball and stick model of the undistorted perovskite structure is shown in Figure 10. The B atom is bonded covalently to six oxygen atoms in octahedral coordination, forming BO_3 molecular orbitals. Solid lines show one such octahedron. Adjacent octahedra are connected by corner-sharing each of the oxygen atoms, and the A atom fits in the space between the octahedra. The cube size is mainly determined by the size of the oxygen orbitals, although the size and valence of the A and B atoms also influence lattice size to a lesser degree. Typically, the cube size is between 3.8 and 4.0 Å. Many different kinds of materials have this structure, ranging from simple insulators, to insulators with very high dielectric constants, to superconductors and the colossal magnetoresistive manganites. In real materials the high symmetry shown in the figure is broken by various (collective) distortions, including Jahn–Teller bond length distortions of the BO_3 unit and cell-to-cell rotation of the octahedra, and these distortions play important roles in determining the electronic and magnetic properties.

The electronic structure of a perovskite phase is mainly derived from the BO_3 molecular orbital. The A site atoms ionize and transfer charge to the BO_3 bands. The valence band is mainly oxygen in character and the conduction band has B-atom character. Insulators like $SrTiO_3$ have a filled valence band and an empty conduction band. The oxygen ions are each charged 2−, the Sr ion is 2+ and the Ti ion is 4+. In conducting perovskites, the Fermi energy lies in the BO_3 band. The most studied manganite is the alloy $La_{1-x}A_xMnO_3$, where A is an alkaline earth, Sr or Ca. When A is Sr, the alloy is often referred to as LSMO, while if A is Ca the alloy is referred to as LCMO. The occupancy of the conduction band per Mn ion is equal to $4 - x$. When the Sr content is zero there are four d electrons, while for $SrMnO_3$ there are three d electrons. Figure 11(a) shows a schematic representation of the energy structure of the molecular orbitals and the occupancy for $LaMnO_3$. Because of the crystal field, the e_g orbitals have a higher energy than

the t_{2g} orbitals. The core t_{2g} spins are strongly coupled by the on-site exchange interaction. These spins align and form an essentially classical core spin. The core electrons are not strongly coupled to neighboring sites. On the other hand, the e_g states are more strongly coupled and they are itinerant in the ferromagnetic phase.

Manganites have a rich assortment of magnetic states, as Figure 11(b) shows (Chmaissem *et al*., 2003). The superexchange interaction between Mn ions occurs through an intermediate oxygen atom and is antiferromagnetic. The ferromagnetic exchange interaction between sites is due to 'double exchange', where the itinerant bandwidth is maximized for ferromagnetic spin alignment – it is more likely and therefore on average easier for an electron to hop to neighboring sites when the core spins are pointed in the same direction. Ferromagnetic exchange is quenched if the e_g electrons are immobilized. For randomly oriented core spins, magnetic scattering dramatically reduces the conductivity. Thus a metal–insulator transition (MIT) should also occur at the magnetic phase transition. However, this is not the complete picture of the MIT, as first pointed out by Millis, Littlewood, and Shraiman (1995). Strong charge-to-lattice coupling is also involved, and this amplifies the change in resistance that occurs when the material becomes magnetic. For $x = 0.35$ the Curie temperature is the largest and the material should become a half-metal, that is, have only one spin band present. This is because both the e_g and t_{2g} states for the minority spin electrons are shifted up in energy by the strong on-site exchange energy. Ideally this would lead to a completely spin-polarized MnO_3 band in the absence of parasitic effects, and this has been a strong motivation for using these manganite phases for various 'spintronic' devices.

To see how the transport and magnetization are tied together, Figure 12 shows the resistance versus temperature for a thin film of $x = 0.3$ LSMO grown by MBE on a (100) $SrTiO_3$ substrate. The MIT occurs at 350 K where the magnetization rises from zero as the temperature is lowered. The resistance drops by about two orders of magnitude and becomes as low as 40 μΩ-cm. This is one of the lowest residual resistivity values obtained for manganite phases (O'Donnell *et al*., 2000a; Coey, Viret and von Molnár, 1999).

Several groups have used MBE techniques to grow manganite films and devices. Figure 13 shows a schematic and a photograph of one such system. Samples are grown on heated substrates in a system with a base pressure of 1×10^{-9} Torr. Typical growth temperatures range from 650 to 720 °C. RHEED is used to monitor the surface during growth. The system employs thermal effusion cells for all elements used, including the transition metals Mn, Cr, Ti, Cu, Zn, Au, and Al. It also has trivalent cations La, Dy, and Bi, divalent cations Ba, Sr, and Ca and it is equipped with an ozone beam for oxidation (Johnson *et al*., 1990). In order to handle the gas flow, the system is pumped by approximately $1000\,l\,s^{-1}$ capacity turbomolecular pumping. Ozone is generated by a

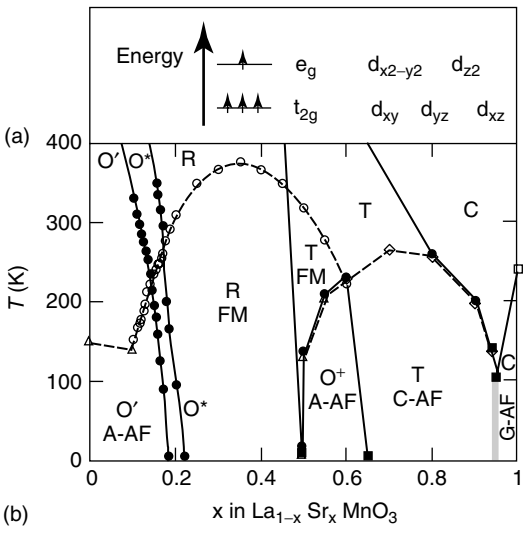

Figure 11. Electronic and magnetic structure of manganite alloys is controlled by filling the MnO_3 states. (a) A schematic representation of the energy levels. (b) Structural and magnetic phase diagram of $La_{1-x}Sr_xMnO_3$. The magnetic phases are antiferromagnetic (AF) or ferromagnetic (FM), and the AF phases are A, C, or G type, which describes the arrangement of core spins. A type has (100) FM sheets with the magnetization of alternating layers oppositely directed. G-type AF has every Mn–O–Mn bond AF, while the C-type AF structure has a more complicated spatial arrangement of spins. O+ and O′ denote orthorhombic phases in which Jahn–Teller distortions are incoherent and coherent, respectively. C, T, and R denote cubic, tetragonal, and rhombohedral phases. Figure 13. Schematic diagram and photograph of oxide MBE system capable of atomic layer-by-layer growth of complex oxides. The system has 13 metal atom effusion cells, an ozone beam, turbomolecular pumping, load lock and preparation chambers, and RHEED to monitor the film growth.

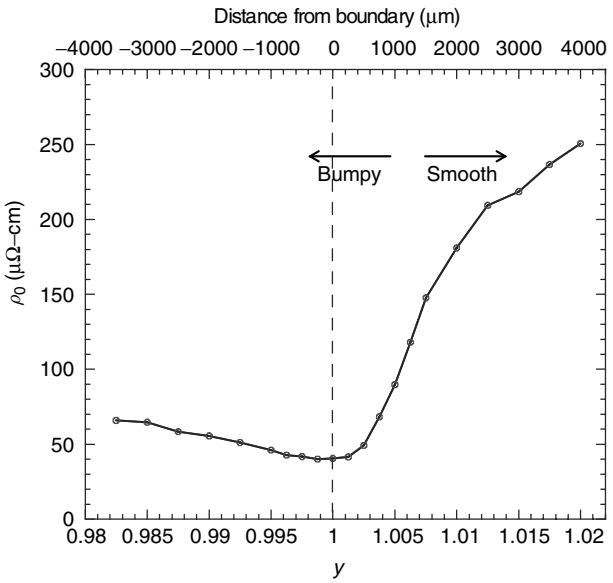

Figure 14. Residual resistivity of $(La_{1-x}Sr_x)_yMnO_3$ samples. The parameter y describes the A site to B site composition ratio. For stoichiometric LSMO $y = 1$, but single-phase material grows by MBE over a wide range of y. For Mn excess, $y < 1$ and the residual resitivity is only weakly dependent on y. For Mn deficiency, the residual resistivity is strongly dependent on y.

silent discharge using a commercial unit capable of producing 3% ozone in oxygen. The ozone is distilled on cold silica gel in a glass still. An hour of accumulation provides enough ozone for more than 10 h of growth. After accumulation, the vapor over the silica gel is pumped with a mechanical pump to a pressure of 100 mTorr, and the ozone used in the growth is drawn from the vapor flowing to the pump. The flow into the growth chamber is controlled by a manually operated needle valve, and reproducible ozone flow is obtained by monitoring the MBE system pressure. Ozone is injected from a tube about 5 in. from the substrate position. The beam expands with an angle of about 10°. Ozone is much more effective at oxidizing metals than molecular oxygen. While the ozone system is relatively simple to build, care must be taken in operation due to the danger of explosion. Too much ozone accumulation and too high a pumping manifold pressure are conditions that may lead to explosion, and consultation with an expert is advised before using such a system. Other groups use atomic oxygen beams generated by microwave discharge (Locquet and Machler, 1992).

Composition control is a very important aspect of manganite film growth. During growth using codeposition, molecular beams provide the dose of atoms to grow each monolayer. We denote the ratio of La + Sr surface composition to Mn surface composition y. This strongly controls the electronic properties of a film of LSMO as shown in Figure 14 where residual resistivity is plotted versus y. Residual resistivity is a measure of carrier scattering. The data show that excess Mn does not lead to much increase in residual resistivity, however, excess La + Sr does. This is also the case for LCMO. Furthermore, the growth dynamics are very different in these two cases. For films slightly rich in La, a smooth surface is obtained, but if the film is rich in Mn, a dramatic proliferation of step edges results. This is shown in the two AFM images in Figure 15. A change in composition of only 1 part in 1000 is enough to change between the surface structures shown. In order to obtain both a smooth surface as well as the lowest residual resistivity, the composition must be precisely controlled. Fortunately, RHEED provides a clear indication of these two regimes, and composition control at the 1/1000 level is possible using this as a diagnostic of surface composition. Figure 16 shows the RHEED patterns observed from these two kinds of surfaces. Figure 16(b) is from a smooth surface, such as shown in the Figure 15(a). Figure 16(a) shows the diffraction pattern obtained from a bumpy surface. Both of these images are obtained with the electron beam in the ⟨100⟩ direction, along the Mn−O bond direction. Figure 16(a) shows the emergence of elevated half-order streaks, which also show up in the diffraction pattern observed along the 110 azimuth. This implies a surface having k-space rods as shown in the inset to Figure 16(d).

Since the electrical and morphological properties of the surface are so sensitive to composition, it is important to control this very accurately. RHEED can provide notice that the bumpy smooth boundary has been crossed, and small corrections can be made to correct for this, but such control is possible only as a refinement to a control scheme that is accurate to the 1% level. RHEED can provide an accuracy increase to 0.1% or better, but it is not able to obtain 0.1% accuracy on its own. In order to get this, it is necessary to use *in situ* flux monitors. Quartz crystal microbalance growth rate monitors are useful if independent measurements of different sources can be made. Atomic absorption spectroscopy is also capable of providing accurate flux monitoring (Klausmeier-Brown, Eckstein, Bozovic and Virshup, 1992). However, to regularly obtain the required accuracy it is necessary to regularly calibrate the *in situ* flux monitors in some way. A convenient method for doing this is to grow a measurement film on a substrate containing only low-mass elements such as BeO, MgO, Si, and so on. If the film is thin enough, it can be analyzed in a particularly simple way by Rutherford backscattering (RBS) analysis (Chu, Mayer and Nicolet, 1978). For sufficiently thin films, each element in the film gives rise to an isolated peak, and the integral of the peak is proportional to surface density time the scattering cross section, which is element specific but available in tables. This is shown in Figure 17. The substrate signal is at lower energy and provides a reliable measure of

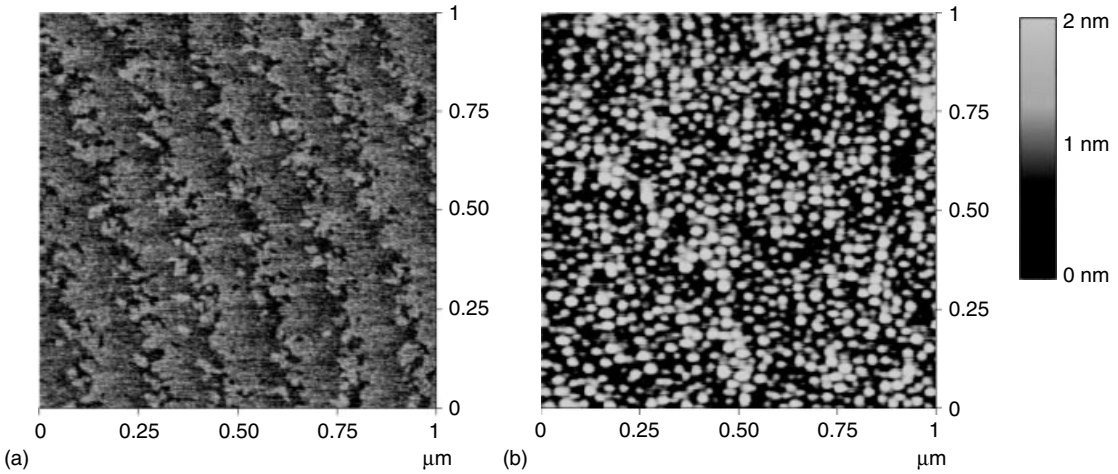

Figure 15. Besides the residual resistivity, the metal atom ratio, $y = ([La] + [Sr])/[Mn]$, also controls the surface morphology. The left panel shows an AFM image of an atomically flat film, exhibiting terracing that has y slightly greater than 1. The second image showing a very bumpy surface is for a film with $y = 0.99$. A small excess of Mn causes step-edge proliferation, leading to growth of a bumpy surface. This is also visible in RHEED, where the smooth surface shows a small reflection spot, while the bumpy surface exhibits streaks and extra reflections indicating a composition-driven surface reconstruction.

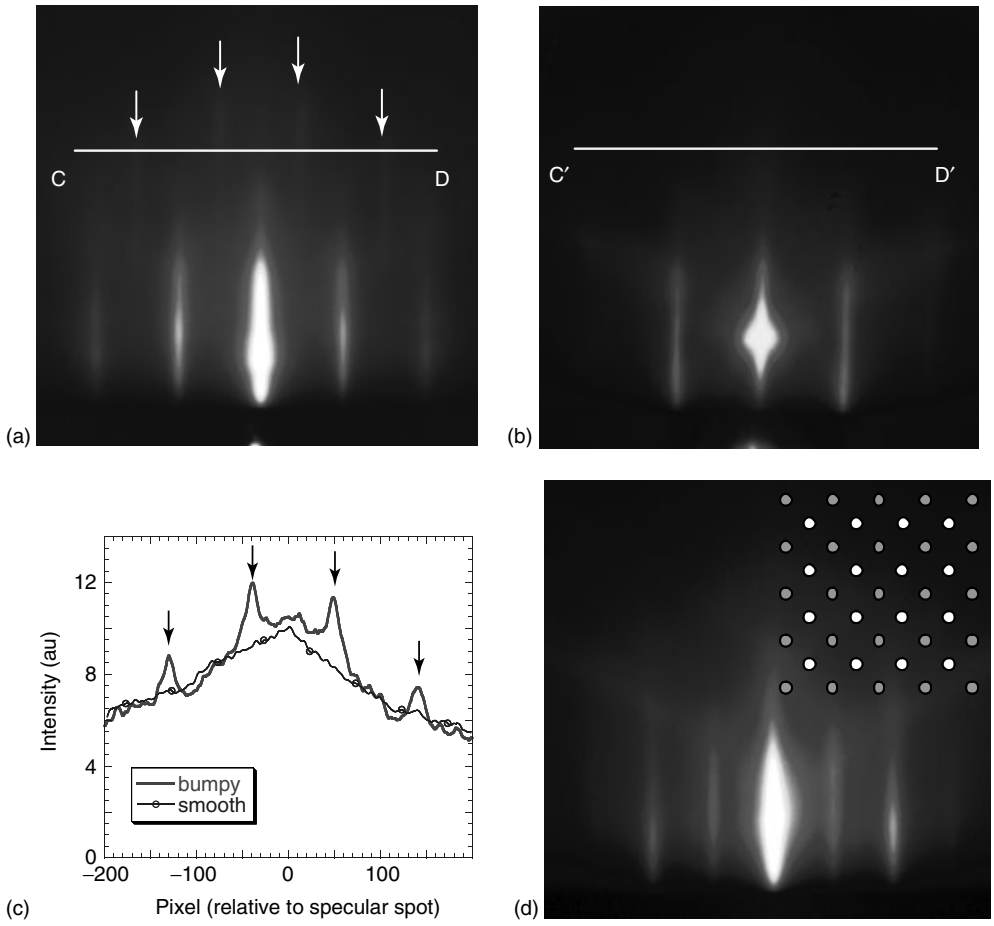

Figure 16. RHEED patterns from the *bumpy* and *smooth* regions from an LSMO sample grown on STO. (a) Bumpy region; ⟨100⟩ direction. (b) Smooth region; ⟨100⟩ direction. (c) Intensity profiles across lines CD and C′D′. Arrows indicate position of the elevated half-order streaks. (d) Bumpy region; ⟨100⟩ direction. Inset shows schematic of k-space rods because of surface reconstruction.

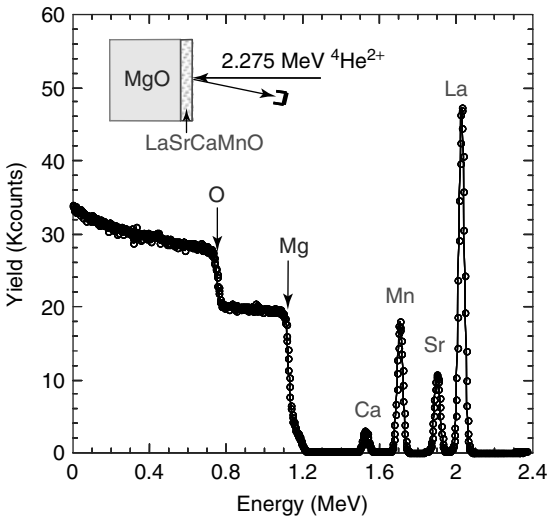

Figure 17. RBS spectrum of a thin film of La–Sr–Ca–Mn–O grown on top of MgO. Since all of the film constituent atoms are heavier than Mg and the film is thin enough, they show up as isolated peaks on a zero background.

the time-integrated beam current. With that knowledge, it is possible to reproducibly calibrate the real-time flux monitor sensors and obtain absolute composition control at the 1% level.

The ground state of the manganite oxides ($La_{0.67}A_{0.33}MnO_3$ where A = divalent dopant) is ferromagnetic and very nearly half-metallic. That is, the conduction electrons are nearly 100% spin polarized. Experiments indicate that the spin polarization, $P = (n_\uparrow - n_\downarrow)/(n_\uparrow + n_\downarrow)$ (where $n_\uparrow, n_\downarrow$ are the density of states for spin $+1/2$ and spin $-1/2$ electrons respectively), is at least 0.83, compared with 0.42 for the canonical ferromagnet, iron (Viret *et al.*, 1997; Soulen *et al.*, 1998; O'Donnell *et al.*, 2000b). These materials thus offer an interesting tool for scientists – a solid-state source of highly (possibly 100%) spin-polarized electrons in a system which is structurally, chemically, and epitaxially compatible with many other interesting perovskite oxide materials. Applications include spin-valve type magnetic tunnel junctions for disk drive read heads, spin-injection devices, and spin-polarized electron tunneling spectroscopy of high T_C superconductors (Viret *et al.*, 1997; O'Donnell *et al.*, 2000b; Sun, Abraham, Roche and Parkin 1998; Obata, Manako, Shimakawa and Kubo, 1999; Kwon *et al.*, 1998; Koller *et al.*, 1998; Stroud *et al.*, 1998). Many applications of these materials involve heteroepitaxy between manganite phases and other perovskite oxide compounds. Here, we discuss fundamental questions regarding manganite growth as it relates to heterostructure applications and describe the growth of films for 'colossal magnetoresistance' spin-valve sensors. The observations and conclusions also apply to other manganite heteroepitaxy problems as well.

The epitaxial growth architecture of a typical spin-valve device consists of a base layer of LSMO, $x = 0.35$, 100 nm thick. On top of this a thin layer of four or five unit cells of $SrTiO_3$or $CaTiO_3$ is grown. This is followed by the growth of a top LSMO film 50 nm thick. The growth of the insulating barrier, especially the interfacial layers, is just as critical as the growth of the manganite electrodes. Indeed, most speculation regarding the rapid loss of magnetoresistance in colossal magnetoresistance magnetic tunnel junctions with increasing temperature has focused on barrier and interfacial disorder (structural, magnetic, and/or compositional). By comparing RHEED oscillations before and after the growth of the insulating barrier one can see that even starting from an atomically flat base electrode, disorder can nucleate in the barrier heteroepitaxy and propagate into the top electrode. The result is a decrease in both the magnitude of the tunneling magnetoresistance, and the temperature at which the magnetoresistance vanishes. A zero bias anomaly in the tunneling conductance at low temperatures of the form predicted by Altshuler, Aronov and Lee (1980) for electron–electron interaction induced renormalization of the density of states in a disordered metal has been observed (O'Donnell *et al.*, 2000b). $SrTiO_3$, $CaTiO_3$, and $LaAlO_3$ barriers were investigated. Of the three, $CaTiO_3$ grows the best as judged by the RHEED image of the barrier surface and RHEED oscillations during barrier growth. For the growth of the insulating barrier, the substrate temperature was decreased by 90 °C in constant ozone pressure for the first two interfacial layers to quench interdiffusion, then increased by 90 °C for the remainder of the barrier growth, then decreased again by 90 °C for the initial layers of the manganite counter electrode. Five unit cell barriers give a typical tunneling conductance of $5 \times 10^{-7}\Omega^{-1}\,\mu m^{-2}$ in tunnel junctions with an area of $200\,\mu m^2$. The tunneling conductance varies exponentially with barrier thickness with each unit cell decreasing the conductance by roughly a factor of 12. The interfacial $La_{1-x}Sr_xO/CaO$ layer between the terminating MnO_2 plane of the manganite and the TiO_2 plane of the $CaTiO_3$ barrier is deposited in a layer-by-layer mode with composition 1/2 ($La_{1-x}Sr_xO$) +1/2 (CaO). The interfacial plane donates electrons to the adjacent MnO_2 plane. In a simple ionic picture, growing this mixed composition at the interface maintains a constant Mn^{4+}/Mn^{3+} ratio of x:$(1-x)$. If the interfacial layer is not doped in this way at the atomic layer level, the Mn^{4+}/Mn^{3+} ratio of the interfacial MnO_2 plane will be increased, effectively increasing the local doping level.

The films were processed into trilayer spin valves using a device geometry that eliminates the effect of resistive voltage drop from transport in the manganite layer. The device architecture is shown in Figure 18(a) and (b). Current

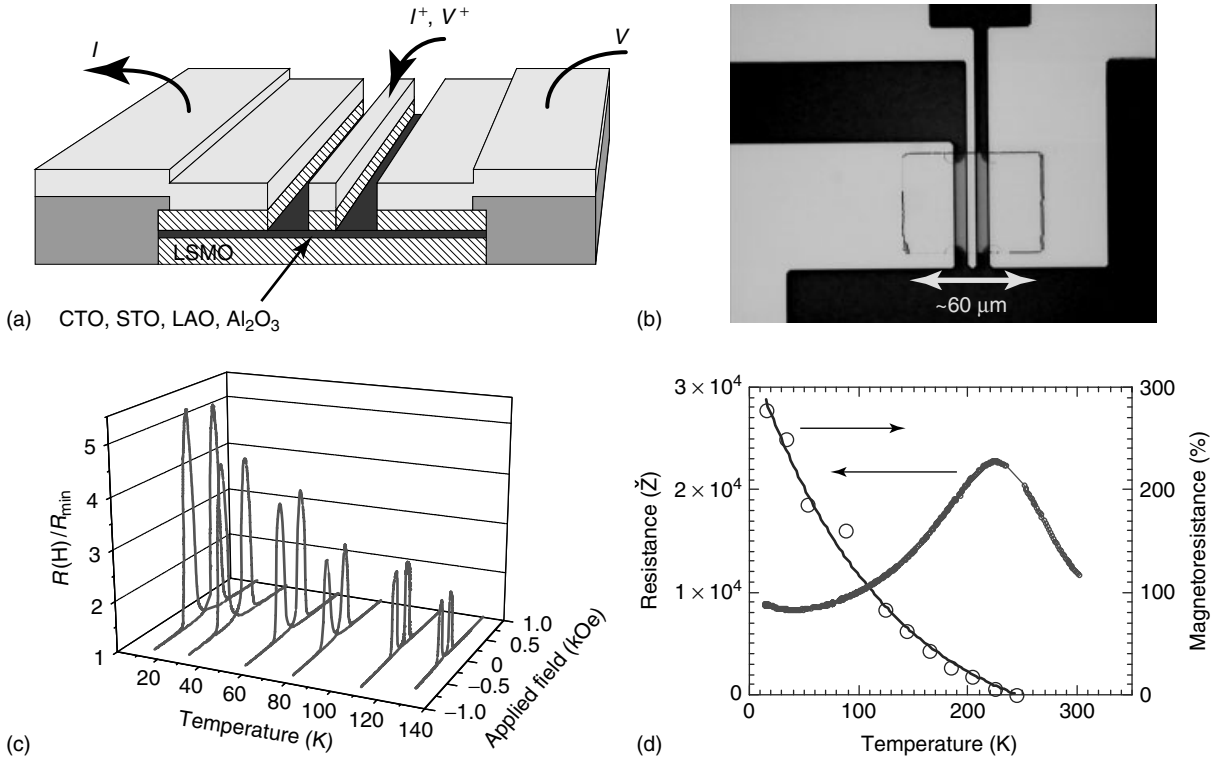

Figure 18. (a) and (b) Schematic view of a spin-valve device. An LSMO injector electrode on top provides spin-polarized carriers to tunnel into a similar LSMO base electrode. The measured tunneling magnetoresistance is shown in (c) as a function of applied field for different temperatures. The maximum measured in this experiment was 450% at 15 K. (d) Dependence of TMR on temperature. How the TMR depends on temperature. It falls faster than the bulk magnetization predicts, indicating nanoscale quenching of the magnetic order above 100 K.

is injected from the top electrode and extracted from the left electrode. A third electrode 'upstream' of the injector measures the base film voltage. The current transfer length, η is many micrometers long. It is equal to $\eta = \sqrt{R_C/R_S}$, where R_C is the specific tunneling resistance (units $\Omega\,\mathrm{cm}^2$) and R_S is the base layer two-dimensional sheet resistance (units Ω/square). This design serves two purposes. First, the use of a third electrode provides a measurement of the voltage across the barrier, without introducing any significant voltage drop from current flowing in the plane. The resistance of the junction is high, so that the series film resistance is a small correction, and this design allows a direct measurement of the tunneling voltage without the need for fine lithography. The second advantage is the large shape anisotropy introduced for one of the two electrodes, namely, the top one. This provides a different coercive field for the two electrodes and leads to a wider range of applied field in which the antialigned configuration occurs. The tunneling magnetoresistance is shown in the lower two panels of Figure 18. In the lower left panel, curves are shown for different temperature that trace out the hysteretic junction resistance as a function of applied field. Defining $\mathrm{TMR} = R_{\mathrm{ANTI}}/R_{\mathrm{ALIGN}}$ the maximum TMR was 4.5. The TMR decreased with temperature more rapidly than the temperature dependence of the bulk magnetization would predict. This was attributed to a reduced magnetization just at the interface, due to the scattering introduced by the barrier.

This hypothesis was investigated by Kavich and coworkers using resonant X-ray magnetocircular dichroism (Kavich *et al*., 2005; Freeland *et al*., 2006). This followed a study by Park *et al*. (1998) using spin resolved photoemission to measure the top layer spin polarization. Samples with two unit cells of $SrTiO_3$, grown on top of a manganite film were studied. The X rays were tuned across the Mn L edge and the dependence of magnetic scattering on energy and temperature was measured also as a function of incident angle. The results from several angles allowed the extraction of a magnetization profile as a function of depth. A second sample was also analyzed which had an interfacial layer of $LaMnO_3$. The use of such an interfacial layer to 'protect' the surface magnetization had been suggested by Yamada and coworkers and studied using optical harmonic generation, sensitive to the abruptness of the magnetic profile (Yamada *et al*., 2004). Figure 19 shows the magnetization profile inferred from the XMCD measurements, showing a substantial drop in surface magnetization as a function of temperature.

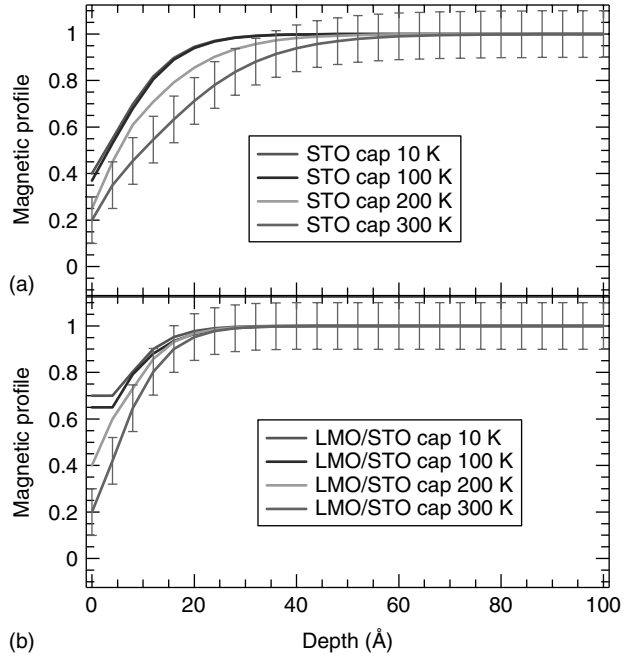

Figure 19. Magnetization profile as a function of depth for different temperatures as shown in the legends. (a) Magnetization profile for a film of LSMO, $x = 0.35$, capped with two unit cells of $SrTiO_3$ (STO). (b) Magnetization profile for a sample with two unit cells of $LaMnO_3$ between the LSMO and the STO cap. Both samples show a significant drop-off in the interface magnetization as the temperature rises. The low-temperature behavior of the LMO/STO cap sample indicates a better surface polarization.

MBE also provides a method to assemble samples with a fixed average composition, but with nanoscale organization of the atomic constituents. Early work aimed at making superlattices, having the same average composition as the highest T_C alloy ($x \sim 0.33$), but with each plane either $LaMnO_3$ or $SrMnO_3$ was carried out by Salvador *et al.* (1999). They were able to use laser-based MBE to construct superlattices consisting of alternating layers of LMO and SMO, keeping the average $x = 0.26$. They observed a systematic reduction of T_C with increasing slab thickness. They attributed this to increasing charge localization in the constituent slabs as the slab thicknesses became larger. Bhattacharya and coworkers have extended this work using MBE. Digital superlattices maintaining an average composition of $x = 0.33$ were grown, starting with samples with one unit cell of SMO and two unit cells of LMO. Resistive transitions spanning the range of superlattice pitches from 1:2 to 5:10 were grown and their properties measured. Figure 20 shows resistance versus temperature for an alloy with composition $x = 0.33$ as well as digital superlattices in this range. For the thinnest slabs, the digital superlattice reduces doping disorder and a lower residual resistivity is observed. Comparable $R(T)$ is also observed for the 2:4 sample, although a reduced

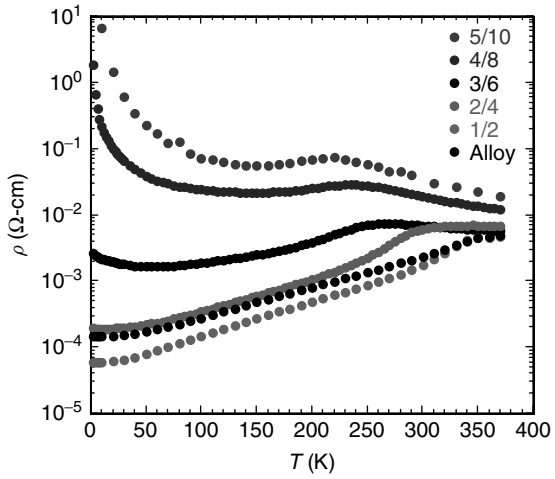

Figure 20. Resistance versus temperature for five digital superlattices, showing the emergence of charge localization as the layer thicknesses are made larger. The 1/2 digital superlattice has a lower resistivity than the random alloy of the same composition.

T_C was observed. When the slab thickness increased to 3:6 and higher, the T_C continued to drop and the low-temperature resistivity developed a strong upturn, indicating localization. These results indicate that new phase behavior can be tuned by accurate atomic-scale synthesis.

Complex oxides provide a rich set of materials with wide-ranging properties that have been observed in bulk samples. These phases provide the starting point for efforts to obtain new materials properties resulting from interaction between different materials at carefully prepared interfaces. The length scales of interactions between complex oxides at such interfaces in likely to be small, typically several unit cells at most. This places a high premium on careful atomistic growth. MBE provides this kind of control and the potential for new phenomena to emerge in cleverly engineered samples.

1 INTRODUCTION

The relatively new field of spin electronics (or spintronics) deals with physical systems where the device functionality is not only determined by the charge of electrons (holes) but also by the spin of the carriers (for a review see Prinz, 1998). Whereas the charge has been exploited in electronic devices for more than a century, it was not until 1988 when the door to the technical application of the spin was opened–although already in 1936 Mott realized that up and down spins in a metallic ferromagnet have different mobilities (Mott, 1936). The giant magnetoresistance (GMR) effect, which was discovered by the groups of Grünberg (Binasch, Grünberg, Saurenbach and Zinn, 1989) and Fert (Baibich *et al*., 1988), refers to the observation that the resistance of a ferromagnet–nonferromagnet–ferromagnet multilayer system is much larger when the ferromagnetic layers are magnetized in opposite directions. Three years later, the group of Parkin (Dieny *et al*., 1991) presented magnetic read-heads incorporating spin valves which are based on the GMR effect. Since then, besides a continuous improvement of magnetic sensors, magnetic memory devices were also proposed and demonstrated, like the magnetic random access memory (MRAM) cell.

On the basis of the pioneering proposal of (Datta and Das, 1990) to replace the emitter and collector in a field effect transistor (FET) by ferromagnetic electrodes, a number of concepts have been presented since then (for a review see Prinz, 1998). A first bipolar spin transistor involving ferromagnetic emitter and collector, sandwiched between a nonmagnetic area in a trilayer geometry, was proposed and demonstrated by Johnson (1993, 1995). In a planar geometry, the injection of a spin-polarized current into a semiconductor is a key issue (Ohno *et al*., 1999), followed by the preserving of the spin state and its manipulation (Awschalom and Kikkawa, 1999).

At the basis of most spintronics devices are the ferromagnetic contacts or layers which act as polarizers (or analyzers) for the carriers. Getting beyond the typical spin polarization of about 50% – that can be reached using alloys of Fe, Co, and Ni (Monsma and Parkin, 2000) – will dramatically enhance the performance of memory devices and will be crucial for spin transistors. Consequently, it is highly desirable to obtain a large degree of polarization at the Fermi level. The ideal case of 100% spin polarization is a property of a special class of materials, the so-called half-metallic ferromagnets (HMFs). They are characterized by a metallic behavior of the majority-spin electrons and a semiconducting behavior of the minority-spin

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. ISBN: 978-0-470-02217-7.

electrons (de Groot, Mueller, van Engen and Buschow, 1983); for a review see Pickett and Moodera (Pickett and Moodera, 2001). A number of compounds were found to be half metallic through band-structure calculations, such as CrO_2 (Schwarz, 1986), Mn_2VAl (Weht and Pickett, 1999), the Mn-containing perovskite $La_{1-x}Sr_xMnO_3$, where the spin polarization was determined via spin-resolved photoemission measurements (Park *et al*., 1998) and scanning tunneling spectroscopy (Wei, Yeh, Vasquez and Gupta, 1998), and many more.

A special class of materials, the so-called Heusler alloys (HAs) (Heusler, Starck and Haupt, 1903), came into focus when de Groot *et al*. showed *theoretically* that a number of Mn-based HAs are half-metals (de Groot, Mueller, van Engen and Buschow, 1983). On the basis of the theoretical results, the unusual magneto-optical properties of PtMnSb were explained by the extreme asymmetry of the electronic properties of spin-up and spin-down electrons (de Groot, Mueller, van Engen and Buschow, 1984). HAs, which are named after Heusler, are primarily defined by their crystal structure. The half-HAs XYZ and the full-HAs X_2YZ have a $C1_b$ and $L2_1$ crystal structure, respectively, where X and Y are transition metals and Z out of the group III, IV, or V elements. The alloys crystal structure consists of four interpenetrating lattices with lattice parameters that are within the realm of common compound semiconductors. Hence, the fact that they are lattice-matched to many compound semiconductors, have a compatible crystal structure (face-centered cubic), and show high Curie temperatures (Oxely, Tebble and Williams, 1963), makes them especially promising candidates for spintronics devices.

Epitaxial layers of stoichiometric HAs have been grown on various semiconductor surfaces using d.c. (Kelekar and Clemens, 2004) and r.f. (Caballero *et al*., 1997) sputtering, pulsed-laser deposition (PLD) (Wang *et al*., 2005b) from bulk HA targets, as well as molecular-beam epitaxy (MBE) (Dong *et al*., 2001). Besides the crystallinity, stoichiometry, and smoothness of the layers, also the local ordering of the constituents has to be achieved for the HAs to be half metallic. There are several ways to determine disorder, such as X-ray diffraction (XRD), the measurement of the magnetic moments, as well as the electrical resistance. The most critical issue for the efficient injection of spin-polarized carriers into a semiconductor is the control of the atomic arrangement at the interface with the HA. For instance, for many years the formation of a magnetically dead layer at the Fe/GaAs interface has prevented spin injection. The key advantage of MBE over alternative preparation techniques such as sputter deposition, chemical vapor deposition, or PLD is the ability to monitor *in situ* the growth and determine the structure of the material. A classical example for the need for MBE in magnetism is the field of GMR systems and interlayer exchange coupling in magnetic multilayers (Farrow, 1998). Thus, MBE is the method of choice for the precise control of the growth of epitaxial single-crystal magnetic material/semiconductor heterostructures.

2 HEUSLER ALLOYS – AN OVERVIEW

HAs are intermetallic phases with a particular composition and crystal structure. They are named after Friedrich Heusler, who found that compounds containing two parts of copper, one part of manganese, and one part of aluminum are ferromagnetic, although their atomic constituents are not ferromagnetic (Heusler, Starck and Haupt, 1903; Heusler and Richarz, 1908). As will be explained in the subsequent text, it is not only the half-metallic properties of some HAs that sparked interest in these compounds but also more importantly their ability to be grown epitaxially on compound semiconductors, since interfaces are determining to a great deal the capability to inject a spin-polarized current into a semiconductor.

2.1 Structural properties

HAs consist of four interpenetrating face-centered cubic sublattices, where the atoms of the species X_1, X_2, Y, and Z, are at the positions (0,0,0), ($\frac{1}{2},\frac{1}{2},\frac{1}{2}$), ($\frac{1}{4},\frac{1}{4},\frac{1}{4}$), and ($\frac{3}{4},\frac{3}{4},\frac{3}{4}$), respectively (Persson, 1929). Thus, type Y and Z atoms are surrounded by eight X atoms. In case of the full-HAs X_2YZ with the $L2_1$ crystal structure, all positions are filled, whereas in the half-HAs XYZ with $C1_b$ crystal structure, the X_1 sublattice is empty. This empty sublattice makes the half-HAs prone to disorder due to exchanges with the filled sublattice. The crystal structures are illustrated in Figure 1. The atoms of the species X are transition metals such as Ni, Co, Fe, Pd, Pt, Cu, Mn, Rh, Ru; the Y atoms another transition metal like Mn, Ni, Fe, Co, Ti, V, Cr; and Z a group III, IV, or V element such as Al, Ga, In, Si, Ge, Sn, As, or Sb. It should be noted that if both X_2 and Y are empty, the zincblende structure of III–V compound semiconductors is formed, which is advantageous for epitaxial growth on semiconductor surfaces.

Ziebeck and Webster (1974), Webster (1971) were the first to synthesize full-HAs containing Co. Ishida and collaborators (Ishida, Akazawa, Kubo and Ishida, 1982; Ishida, Fujii, Kashiwagi and Asano, 1995; Fujii, Sugimura, Ishida and Asano, 1990) proposed that compounds of the type Co_2MnZ, where Z stands for Si or Ge, are also half-metallic ferromagnets–a new class of materials that will be explained in Section 3. Also HAs of the type Fe_2MnZ were found

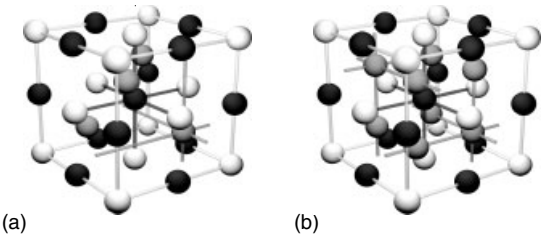

Figure 1. Crystal structures of half XYZ (a) and full X_2YZ (b) Heusler alloys. The X atoms are dark-gray, the Y atoms black and the Z atoms light-gray.

numerically to be half-magnetic metals (Fujii, Ishida and Asano, 1995). Contrary hereto, Brown *et al*. (Brown, Neumann, Webster and Ziebeck, 2000) have shown that there is a finite very small spin-down density of states at the Fermi level instead of an absolute gap by using polarized neutron diffraction. This is in agreement with the *ab initio* calculations of Kübler *et al*. for Co_2MnAl and Co_2MnSn compounds (Kübler, Williams and Sommers, 1983).

2.2 Magnetic properties

The magnetic coupling in HAs is complicated and far from being completely understood. Thus, we will restrict ourselves to a very brief summary of the most important results. The ternary alloys of the form X_2YZ and XYZ are typical local moment systems with Y the local moment material. It has been suggested that the coupling of the local moments in HAs originates from the indirect Ruderman–Kittel–Kasuya–Yosida (RKKY) type interaction; however, also other models are successfully applied (Picozzi, Continenza and Freeman, 2002). Moreover, the sole exchange via itinerant electrons is unrealistic due to the localization of the magnetic moments to the Mn atomic sites (Kübler, Williams and Sommers, 1983). It is rather believed that, due to the presence of two of the transition metals, at least some band-like contribution is also involved. Nevertheless, the resulting saturation magnetization in dependence of the constituent atoms is well understood. On the basis of *ab initio* calculations, Galanikis *et al*. showed that the total spin magnetic moment M (per formula unit in μ_B) of a Heusler alloy scales linearly with the number of the valence electrons Z, such that $M = Z - 24$ for the full-HAs and $M = Z - 18$ for the half-HAs (Galanakis, Dederichs and Papanikolaou, 2002b). For example, a half-Heusler system with 18 valence electrons per formula unit is nonmagnetic. On the basis of this well-known Slater–Pauling behavior (Kübler, 1984) it can be further deduced that the maximum magnetic moment of a half Heusler is $5\,\mu_B$, and that of a full-Heusler alloy $7\,\mu_B$.

The situation in half-HAs is illustrated by taking NiMnSb as an example (Otto *et al*., 1989a,b). It was found experimentally that the magnetic moments are present on the Mn atoms. As the distance between the local moments is too large for the direct exchange interaction to be efficient, some authors propose that the coupling occurs via itinerant holes in the Sb-5p valence band (Otto *et al*., 1987). In full-HAs, the X atoms primarily determine the lattice constant, whereas the Z atoms (group III, IV or V atoms) mediate the interaction between the d states of the local moment atoms Y (Kübler, Williams and Sommers, 1983; Reitz and Stearns, 1979). The local moment atoms do not interact directly; however, an interaction with the d states of the X atoms delocalizes their occupied d states, resulting in delocalized electrons moving in a common d band. Nevertheless, the magnetization is localized to the Y atom in case of Mn, as the minority-spin electrons (as defined locally) are excluded from the Mn 3d shell. According to Kübler *et al*. the magnetic order is sensitive depending on the occupation of the mediating p–d hybrid states–a fact that accounts well for experiments by Webster (1971) in which this occupation was varied by alloying. Depending on the coupling, the magnetic properties range from weakly antiferromagnetic in case of Pd_2MnIn to strongly ferromagnetic in case of Co_2MnSn.

The lattice constants and magnetic properties of some common HAs (bulk crystals) are listed in Table 1 (for reference see also Webster and Ziebeck, 1988).

3 HALF-METALLIC FERROMAGNETS

On the basis of band-structure calculations on the half-HAs NiMnSb and PtMnSb, de Groot and coworkers (de Groot, Mueller, van Engen and Buschow, 1983) claimed to have found a new class of materials. The so-called HMFs are characterized by one spin subband being metallic, whereas the Fermi level falls into a gap of the other subband–that is, the current-carrying electrons at the Fermi level are 100% spin polarized. This unusual behavior attracted a lot of attention since then, as HMFs are ideally suited for spintronics. Owing to various problems that will be discussed in the subsequent text, it was not until 1998 that the half-metallic character of a film was directly measured (Park *et al*., 1998).

3.1 Properties

After de Groot's discovery of a spin-splitted band structure in two Mn-based half-HAs, a number of theoretical papers followed proposing half-metallic behavior for Fe_3O_4 (magnetite) (Yanase and Shiratori, 1984), rutile-type CrO_2

a: lattice spacing (Å); m_{fu}: magnetic moment per fu (formula unit); T_C and T_N: Curie (FM = ferromagnet) and Néel (AFM = antiferromagnet) temperature in K, respectively.

(Schwarz, 1986), full-HAs (Ishida, Fujii, Kashiwagi and Asano, 1995), perovskite manganites (Pickett and Singh, 1996), double perovskites (Kobayashi *et al*., 1998), diluted magnetic semiconductors (DMS) (Ogawa, Shirai, Suzuki and Kitagawa, 1999), and others.

The degree of spin polarization P at the Fermi level is usually defined by

$$P = \frac{N_\uparrow - N_\downarrow}{N_\uparrow + N_\downarrow} \tag{1}$$

where N_σ are the density of states at the Fermi level for the respective spin-σ band. The band structure of a HMF, illustrated in Figure 2(c), shows a spin polarization at E_F of 100%. For comparison, the band structures for a normal (a) and a ferromagnetic (b) metal are also shown.

What characterizes a half-metal? First and foremost, the definition of a half-metal as a system that is metallic for one spin and semiconducting for the other, leads to a complete spin polarization at the Fermi level. Also, there exists a gap for spin-flip (Stoner continuum) excitations due to the structure of the minority band (Irkhin and Katsnel'son, 1994). Further, an integer value of the spin moment is usually central for half-metallicity, as is the unusual combination of metallic conductivity and vanishing high-field susceptibility (Eschrig and Pickett, 2001). For example, the magnetization per functional unit of NiMnSb is $4\,\mu_B$ consisting of $3.8\,\mu_B$ for Mn and $0.2\,\mu_B$ for Ni. The reasoning behind the integer-spin criterion is that, as consequence of the gap in one of the spin bands and as the sum of electrons in the two spin states is an integer, the number of spin-up or spin-down electrons is an integer too. Their difference has an integer value, corresponding to the spin moment in units of μ_B. The integer-spin criterion is a necessary, yet not sufficient requirement for half-metals.

A more advanced classification of half-metals was introduced by Coey and Venkatesan according to their electronic and magnetic properties (Coey and Venkatesan, 2002). Five classes of half-metallic materials (HMM) are distinguished: half-metals that have metallic (I) or nonmetallic (II) conductivity, metals (III), semimetals (IV), and semiconductors (V). The subgroups X_A and X_B further denote the character of the spin-up electrons at the Fermi level, that is, A for itinerant (localized in case of nonmetallic half-metals) and B for the respective case in the spin-down band. A good indication for a type (I) HMM is metallic conductivity together with the integer-spin rule. Examples for the different types of HMM are: (II) Fe_3O_4 (magnetite); (III) $La_{0.7}Sr_{0.3}MnO_3$; (IV) $Tl_2Mn_2O_7$ (Singh, 1997); and (Ga,Mn)As (V). Type (III) $La_{0.7}Sr_{0.3}MnO_3$ is considered a transport half-metal that actually shows a finite density of states in both spin channels, however, concerning conduction only one type of spin channel is involved (Nadgorny *et al*., 2001). The half-metallic HAs belong to the type (I) HMM, and can be of subgroup A (e.g., NiMnSb) or B (e.g., Mn_2VAl).

3.2 Origin of the band gap in half-metals

Let us start by having a look at ordinary ferromagnets, which are in general not half-metals. Co, for instance, has fully spin-polarized d-bands with a filled spin-up $3d$ band and only spin-down electrons at the Fermi level. However, the Fermi level also crosses the unpolarized $4s$ band, resulting in both spin-up and spin-down electrons at the Fermi level. In order to reach full spin polarization at the Fermi level, it is necessary to reorder the $3d$ and $4s$ bands by hybridization, pushing the bottom of the $4s$ band above E_F or depressing the Fermi level in the d band below the bottom of the $4s$ band. Consequently, all half-metals contain more than one element.

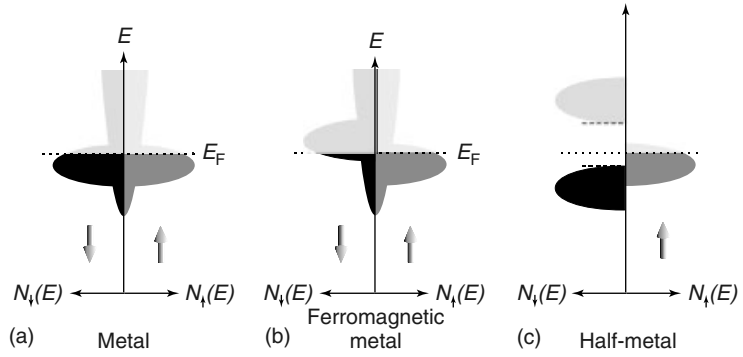

Figure 2. Spin-dependent density of states $N(E)$ of a normal metal (a), a ferromagnetic metal (b) and a half-metallic material (c) [type (I_B)]; E_F is the Fermi level. The normal metal (a) shows an equal number of electrons of spin up and spin down at E_F (at 0 K). A ferromagnetic metal (b) shows a spin polarization of the carriers at E_F. In contrast, half-metallic ferromagnets show a gap in one of the spin channels (at 0 K), that is, 100% spin-polarized carriers.

In the case of the half-HAs, the gap basically arises from the covalent hybridization between the lower-energy d states of the high-valent transition-metal-atom like Ni or Co and the higher-energy d states of the lower-valent TM atom, leading to the formation of bonding and antibonding bands with a gap in between. The bonding hybrids are localized mainly at the high-valent TM atom site while the unoccupied antibonding states are localized mainly at the lower-valent TM atom site (Galanakis, Dederichs and Papanikolaou, 2002a).

In the case of the full-HAs, each Y atom has eight X atoms as first neighbors instead of four as in the half Heuslers. Thus, the hybridization between X and Y spin-down electrons, that decreases the Y-spin moment in XYZ Heuslers, becomes even more pronounced. The X atoms are ferromagnetically coupled to the Y-spin moments and they possess a spin moment significantly smaller than that of the Y atom. The sp atom Z has a very small negative moment which is one order of magnitude smaller than the X moment. The negative sign of the induced sp moment characterizes most of the studied full- and half-HAs with very few exceptions. Both half- and full-Heusler compounds follow the Slater–Pauling curve. For an in-depth discussion of the band gap formation due to hybridization the reader is referred to Galanakis, Dederichs and Papanikolaou (2002b).

Theoretical investigations suggest that, although the half-HAs have more likely a high degree of disorder, the consequences of this disorder on the spin polarization at the Fermi level are not that drastic, since the half-HAs exhibit a larger gap with respect to the full ones (Galanakis, Dederichs and Papanikolaou, 2002b). Also, as is the case for NiMnSb, a few percent of disorder induces states in the gap that do not necessarily destroy the half-metallicity (Orgassa, Fujiwara, Schulthess and Butler, 2000).

3.3 Measurement of the spin polarization

We will briefly review the methods for measuring the spin polarization of a half-metal: point-contact Andreev reflection (PCAR) (Soulen *et al*., 1998; Upadhyay, Palanisami, Louie and Buhrman, 1998), magnetic tunnel junctions (MTJs) (Jullière, 1975), spin-resolved photoemission (Park *et al*., 1998), point-contact tunneling into a ferromagnet (Garcia, Munoz and Zhao, 1999), and tunneling into a superconducting film (Meservey and Tedrow, 1994). For further reading, please refer to Coey and Chien (2003). Interestingly, it was not until 1998 that the half-metallic property of a thin film was experimentally confirmed when Park *et al*. were measuring the band gap in the spin-down band of manganese perovskite by a surface sensitive technique. In fact, it is a real challenging task to determine the difference between spin-up and spin-down carriers in thin films. In many cases, this is due to interface and surface problems (Galanakis, Ležaić, Bihlmayer and Blügel, 2005), such as Sb segregation in case of NiMnSb (Wojcik *et al*., 2002), where the half-metallic properties were already confirmed in 1990 by spin-polarized positron annihilation that has an information depth of 40 μm (Hanssen and Mijnarends, 1986), that is, not for thin films. It has to be noted that different values for the spin polarization for a particular system are not only the result of experimental shortcomings, but may also be due to the probing of different electron states, for example, comparing photoemission and tunneling measurements.

3.3.1 *Magnetic tunnel junctions – MTJs (Jullière, 1975)*

As the tunneling probability between two ferromagnetic contacts depends on the relative magnetization of the contacts, a tunnel-junction geometry can be used to extract information about the spin polarization. However, the experimentally accessible property is the magnetoresistance (*MR*), that is, the relative difference between the resistivities of the parallel and the antiparallel magnetization configuration, which is critically depending on the interface states and barrier properties. Thus, the commonly extracted spin polarization P using Jullière's simple relationship $MR = 2P^2/(1 + P^2)$ is rather a measure of a specific device than an intrinsic material property. An in-depth discussion of spin-dependent tunneling in MTJs can be found in Tsymbal, Mryasov and LeClair (2003).

3.3.2 *Point-contact tunneling into a ferromagnet (Garcia, Munoz and Zhao, 1999)*

As in case of MTJs, the tunneling between two ferromagnetic leads in a point-contact geometry, that is, either between two tips, a tip and a surface or in a lateral point-contact structure involving a nanoconstriction, allows for the measurement of the *MR*; and the extraction of a value for the spin polarization P. Although the contacts may be difficult to control, the method is very straightforward and permits for the measurement of P as a function of temperature. The temperature dependence of P, especially the commonly observed fast decay with temperature, gives a valuable insight into the imperfections of the material system. The limitations of the method lie foremost in the preparation and reproducibility of the experiment.

3.3.3 *Tunneling into a superconducting film (Meservey and Tedrow, 1994)*

As in MTJs, a thin-film structure has to be fabricated, however, now a superconducting film is replacing one of the ferromagnetic films. Owing to the high critical field and

the well-controlled oxide in the metal–metal oxide system, the material of choice for the electrode is Al. However, this requires a working temperature below 2.5 K. A magnetic field is applied to the junction to spin split the quasi particles in the superconductor and to saturate the magnetization of the ferromagnet. The tunneling probability is proportional to the convolution of the densities of states of the superconductor and the ferromagnet, resulting in four conductance peaks. From the four conductances, the spin polarization P can be deduced.

The PCAR technique makes use of the fact that for an electron to tunnel into a superconductor, a pairing electron is required to form a Cooper pair. The process is only possible for an electron approaching the interface from the metal side, when a hole is reflected back in the opposite spin band of the metal. In case of a non-ferromagnetic electrode ($P = 0$), the conductance is doubled in the energy range of the superconducting gap, as all tunneling electrons can find partners of opposite spin to form a Cooper pair. In case of a half-metallic electrode with $P = 1$, no electrons are available for forming a Cooper pair and the tunneling current is completely suppressed. The analysis is based on the Blonder–Tinkham–Klapwijk model of Andreev reflections (Blonder, Tinkham and Klapwijk, 1982). By using the procedure described in Soulen *et al*. (1998) and Mazin (1999), the spin polarization P can be extracted from the measured conductance–voltage characteristics using $G(0)/G_n = 2(1 - P)$, with $G(0)$ and G_n the conductance at zero and high bias voltage, respectively. When interface or surface states are present, the entire conductance curve has to be modeled in order to extract P. In general, PCAR can be applied to a variety of samples and sample configurations (foils, thin films, bulk crystals). The limitations of PCAR for the determination of the spin polarization stem from the complexity of the system. Besides the influence of the type of transport regime–ballistic or diffusive–on P, also a dependence on the effective potential barrier at the interface Z has to be taken into account (Woods *et al*., 2004).

3.3.4 Spin-resolved photoemission (Park et al., 1998)

By using a spin-resolving detector for photo-excited electrons, the spin asymmetry of the emitted electrons is a direct measure of the spin polarization P. The information depth is only 5–10 Å which makes the method prone to surface contamination. The energy resolution is comparably low. The complete band structure can be probed by performing angle-resolved measurements for different wave vectors.

It has to be noted that, in principle, the thermally activated mixing of spin-up and spin-down spins limits half-metallic ferromagnetism to zero temperature (Dowben and Skomski, 2004). At finite temperatures, the spin-down density of states is no longer vanishing. Other sources of reduced spin polarization for bulk half-metals are, besides experimental deficiencies, crystal defects, interfaces, and surfaces. For example, whereas the MnSb-terminated surface of NiMnSb has a very high spin polarization similar to the half-metallic bulk crystal, the Ni-terminated surface exhibits a vanishing spin polarization (Galanakis, 2004).

3.4 Candidate materials

Half-metallic characteristics have been studied primarily in ternary compounds, such as spinels and HAs; however, also a simple oxidelike CrO_2 is a half magnet. We restrict the following discussion to HAs for two reasons. First, they hold the promise for epitaxial growth on compound semiconductor surfaces, and second, they have a large energy gap within the spin-down band structure. The calculated value for Co_2MnSi, for instance, is about 0.4 eV (Ishida, Masaki, Fujii, and Asano, 1998), which would be sufficient for providing 100% spin polarization at room temperature ($k_BT \sim 25$ meV). Other half-metals, such as CrO_2 or $La_{0.7}Sr_{0.3}MnO_3$, exhibit a high degree of spin polarization at low temperatures, but suffer from low Curie temperatures (<500 K) and thus low magnetization at room temperature. HAs, for which half-metallic behavior is predicted for a significant number of half (Galanakis, Dederichs and Papanikolaou, 2002a) and full (Galanakis, Dederichs and Papanikolaou, 2002b) systems, are very promising candidates for realizing 100% spin polarization at room temperature. Indeed, half-metallic behavior could be confirmed experimentally for many *bulk crystals*. Here, non-HAs will only be listed for reference and only materials will be discussed that are potentially interesting for forming heterostructures with semiconductors.

Table 2 gives an overview of the theoretically predicted half-metallic compounds for which experimental spin-polarization data exist. So far, CrO_2 has been among the highest degree of spin polarizations measured. It is a ferromagnetic metal with a $T_C = 387$ K, but despite the fact that this compound is commonly used in videotapes and cassettes, it is metastable (Ji *et al*., 2001). Moreover, the problem with most of the half-metallic oxides is their low Curie temperature ($T_C < 500$ K). Thus, the spin polarization measured from MR in a point contact is strongly temperature dependent, and it becomes negligible at room temperature.

3.5 Applications of half-metals

Half-metals with their inherent spin polarization of ideally 100% can be potentially used for a large variety of

applications. As the current tunneling out of a ferromagnetic material is spin polarized, the largest polarization is obtained with half-metals. This way they can, for example, act as the polarized current source as well as the analyzing filter in spin transistors (Johnson, 1995) or scanning tunneling microscopes (STMs) for the imaging of magnetic domains. Ferrimagnetic half-metallic STM tips may even solve the problem of the perturbation of the sample magnetization due to the tip's stray field (van Leuken and de Groot, 1995).

However, the potential applications of half-metals are not limited to spin-polarized contacts. For PtMnSb, an unusually large Kerr rotation of 2.5° at 720 nm was observed which may be useful for new optical applications (van Engen, Buschow, Jongebreur and Erman, 1983). The half-metallic properties also lead to a small plasma frequency, which enhances the Kerr effect (Antonov *et al*., 1997). Moreover, half-metals will be useful in multilayer spin-valve systems, as the very large difference in the density of states for the two spin directions leads to very high differences in the low and high resistance path. For a band gap of 1 eV, one can expect MR ratios exceeding 80% (Johnson *et al*., 1996). Also for magnetic tunneling junctions that are at the heart of the MRAM cell, where higher tunneling magnetoresistance (TMR) ratios are desired, half-metals are predicted to outperform the competing materials based on theory (Lu *et al*., 1996; Viret *et al*., 1997; Mukhopadhyay and Das, 2006).

4 EPITAXIAL GROWTH OF HEUSLER ALLOYS

The magnetic properties of ferromagnetic contacts, such as the magnetic anisotropy or the degree of spin polarization, are largely influenced by the crystal structure and orientation of the films. Although polycrystalline films can be used for a number of applications, especially also for small electronic structures, they are not the first choice for spintronics applications. The epitaxy of metals on semiconductors, that is, the growth of single-crystalline metal films with a defined crystalline relationship to the substrate, has been an intensive area of research for quite some time and it is well documented in the literature (Sands *et al*., 1990). Although perfect layers of epitaxial, elemental ferromagnets can be grown on semiconductors, these contacts suffer from a small spin polarization, which is on the order of 50% at best. The first half-metal that was theoretically (de Groot, Mueller, van Engen and Buschow, 1983) and experimentally (Hanssen, Mijnarends, Rabou and Buschow, 1990) investigated was the half-Heusler alloy NiMnSb. Epitaxial growth was achieved on GaAs (van Roy, de Boeck, Brijs and Borghs, 2000), as the crystal structure is very closely related to the zincblende structure of GaAs, and NiMnSb shows a lattice mismatch of 4.4% with GaAs. In the following, we will briefly discuss the growth techniques relevant for the epitaxial growth of HAs, followed by a review of epitaxial HA-semiconductor hybrid systems (for a review, see also Palmstrøm, 2003).

4.1 Growth techniques

4.1.1 Sputter deposition

The sputter deposition of magnetic films is quite common in the magnetic device industry, as it offers the advantages of high deposition rates and large sample throughput, low cost, and stoichiometric equality of sputter target and grown layer. The most common sputter gas is Ar, which is kept at pressure in the range from 10^{-3} to 10^{-1} Torr during growth. The background pressure in the growth chamber prior to growth is commonly not better than 10^{-8} Torr, although ultrahigh vacuum (UHV) sputter systems are employed too. The substrates are commonly degreased and subsequently outgassed in vacuum. The films are then sputtered from bulk HA targets at typical r.f. sputter powers between 10 and 100 W or d.c. powers of 30 W, while the substrate is kept at temperatures between room temperature and 500 °C.

So far, mostly polycrystalline HAs were grown and structurally and magnetically characterized. Some of the high quality HA films grown on semiconductors are:

Full-HAs, Co_2MnGe on MgO(100) (Yamamoto *et al*., 2006) and Al_2O_3 *a* plane with suitable metal seed layers (Geiersbach, Bergmann and Westerholt, 2002); Co_2MnSi on GaAs (Singh *et al*., 2006); on glass (Raphael *et al*., 2001); on MgO(100) and Al_2O_3 *a* plane with suitable metal seed layers (Geiersbach, Bergmann and Westerholt, 2002; Singh *et al*., 2004); on thermally oxidized Si (Kim, Kwon and Kim, 2004); on MgO(100), $SrTiO_3$(100), Si(100), Si(111), and SiO_2 with a V seed layer (Kämmerer *et al*., 2003), $Co_2MnSi/AlO_x/Co_{75}Fe_{25}$ MTJs (Sakuraba *et al*., 2005a); Co_2MnSn on MgO(100) and Al_2O_3 *a* plane with suitable metal seed layers (Geiersbach, Bergmann and Westerholt, 2002); $Co_2(Cr,Fe)Al$ on GaAs(001) (Hirohata *et al*., 2005b), thermally oxidized Si (Inomata, Okamura, Goto and Tezuka, 2003), MgO(001) (Kelekar and Clemens, 2004; Marukame *et al*., 2005; Matsuda *et al*., 2006), AlO_x (Inomata, Okamura and Tezuka, 2004; Conca *et al*., 2005), and on *a*-plane Al_2O_3 (Jakob *et al*., 2005); Co_2MnAl on Cr-buffered MgO(001) (Sakuraba *et al*., 2005b), thermally oxidized Si (Kim, Kwon and Kim, 2004); Cu_2MnAl on MgO(100) (Geiersbach, Bergmann and Westerholt, 2002); (Bach, Westerholt and Geiersbach, 2002), thermally oxidized Si (Kim, Kwon and Kim, 2004); Ni_2MnIn on InAs (von Oehsen *et al*., 2005).

Half-HAs: NiMnSb on glass (Caballero *et al*., 1997), Cu and NiFe for multilayers (Caballero *et al*., 1998), Al_2O_3(0001) (Bobo *et al*., 1997), MgO with Mo buffer layer (Ristoiu *et al*., 2000a; Ristoiu, Nozieres and Ranno, 2000b), GaAs (Debernardi, Peressi and Baldereschi, 2003; Debernardi, Peressi and Baldereschi, 2005); NiMnSb/PtMnSb superlattices (Mancoff *et al*., 1999); NiMnGa on silicon cantilevers (Wuttig, Craciunescu and Li, 2000); and PtMnSb on MgO(001) and W(001) (Kautzky and Clemens, 1995); on Al_2O_3(0001) (Kautzky and Clemens, 1995; Bobo *et al*., 1997); and PtMnSb/CuMnSb multilayers (Watanabe, Takanashi and Fujimori, 1991).

4.1.2 Pulsed laser deposition (PLD)

The PLD method involves the evaporation of a solid target in a (ultra) high-vacuum chamber by means of high-energy laser pulses. The strong absorption of the laser radiation by the target surface leads to its rapid evaporation. The evaporated material is highly exited and ionized, forming a plasma plume of high energetic species (10–100 eV/ion). The ablated material is then deposited onto the heated substrate surface to allow for surface diffusion. Typically, excimer lasers are used as the emitted wavelengths are absorbed by a number of target materials. Other commonly employed laser types are CO_2 lasers, Q-switched Nd:YAG lasers, and also femtosecond lasers. The PLD targets are much smaller than sputtering targets. In order to avoid memory effects,

the laser is scanned over the target surface. One important feature of the PLD technique is that the stoichiometry of the target is transferred to the growing film–a result of the extremely fast heating rate of the target due to the pulsed-laser irradiation. Also, as the evaporated species have a high energy, the growth temperatures can be kept lower compared to other methods, allowing for overgrowth of sensitive device structures. Furthermore, by controlling the number of pulses, the film growth can be controlled down to the atomic level. Contrary to sputter deposition, the background pressure during growth can be kept in a range where *in situ* electron probes, like (differentially pumped) reflection high-energy electron diffraction RHEED, can be employed.

For the growth of HAs, the only requirement is that a large enough bulk target can be synthesized. So far, the following HAs have been deposited onto semiconductor surfaces: Co_2MnX (X = Si, Ga, Ge, Sn, SbSn) on Si, GaAs, and InAs (Valerio *et al*., 2005; Grigorescu *et al*., 2005); Co_2MnSi on GaAs (Autric, Valerio and Grigorescu, 2005), Al_2O_3 (*a* plane) (Stadler *et al*., 2005), GaAs (001) (Wang *et al*., 2005a,b; Stadler *et al*., 2005) and Si_3N_4 (Stadler *et al*., 2005); NiMnSb on Si and InAs (Giapintzakis *et al*., 2002a,b), Si(100) (Zhu, Lu, Lai and Ding, 2005) and InSb (Gardelis *et al*., 2004; Autric *et al*., 2004).

4.1.3 Molecular beam epitaxy (MBE)

MBE has proven its strengths in many fields of research and development of (opto-)electronic structures and devices over the past decades. Materials systems for spintronics will be no exception, as the requirement of perfect interfaces is even tighter than in case of conventional electronics (Prinz and Krebs, 1981). In solid-source MBE, ultrapure elemental materials are evaporated from effusion cells in an UHV chamber onto a heated substrate where they react. Cell shutters in combination with rather low growth rates, as well as *in situ* growth monitoring by RHEED, allows for ultimate precision in materials growth. One big advantage over the other methods is that reactive semiconductor surfaces can be properly prepared under UHV conditions, rendering them smooth and free of oxides prior to the HA growth. Furthermore, the homoepitaxial growth of a buffer layer in the III–V chamber guarantees ideal starting conditions, before the sample can be transferred to a separate metal MBE chamber in order to avoid cross-contamination.

The following HAs have been grown on semiconductor surfaces (for a review see Palmstrøm, 2003). Full-HAs: Ni_2MnGa on GaAs(001) (Dong *et al*., 2000, 2001; Lund *et al*., 2002); Ni_2MnGe on GaAs(001) (Dong *et al*., 2001; Lund *et al*., 2002; Lu *et al*., 2003); Ni_2MnAl on GaAs(001) (Lund *et al*., 2002; Dong *et al*., 2003); Ni_2MnIn on InAs(001) (Dong *et al*., 2001; Xie *et al*., 2001, 2005); Co_2MnGe on AlGaAs/GaAs (Dong *et al*., 2005); Co_2MnGe on GaAs(001) (Ambrose, Krebs and Prinz, 2000a,b, 2001) and Ge(111) (Tsui *et al*., 2006); Co_2MnAl on GaAs (Chen, Basiaga, O'Brien and Heiman, 2004; Heiman *et al*., 2005); Co_2MnGa on GaAs (Heiman *et al*., 2005; Hickey *et al*., 2005; Holmes and Pepper, 2002); Co_2FeSi on GaAs(001) (Hashimoto, Herfort, Schönherr and Ploog, 2005a,b); $Co_2(Cr_{1-x}Fe_x)Al$ on GaAs (Hirohata *et al*., 2005a,b); Fe_2AlSi on GaAs(001) (Hong *et al*., 1991); and Fe_3Si on GaAs(001) (Liou *et al*., 1993) and GaAs(113)A (Herfort, Schönherr and Ploog, 2003; Herfort, Schönherr, Friedland and Ploog, 2004; Muduli, Herfort, Schönherr and Ploog, 2005a; Muduli *et al*., 2005b,c).

Half-*HAs:* NiMnAl on MgO(001) (Hassdorf *et al*., 2003); and NiMnSb on (In,Ga)As/InP (Bach *et al*., 2003a,b; Heinrich *et al*., 2004; Koveshnikov *et al*., 2005), GaAs(001) (van Roy, de Boeck, Brijs and Borghs, 2000) and GaAs(111)A and B (van Roy *et al*., 2003).

4.2 Epitaxial growth on semiconductor surfaces

Epitaxial growth has many advantages: control and monitoring of growth, defined surfaces, perfect interfaces, correct stoichiometry. This way, in the early days of ferromagnetic-semiconductor hybrid systems (Prinz, 1990), metastable bcc (body-centered cubic) Co was synthesized on GaAs(110) (Prinz, 1985). Molecular-beam epitaxy methods, and to a limited extend also sputter deposition and PLD, have been used to grow good quality magnetic single-crystal HA films on GaAs and Si substrates. The structural properties of the films are commonly characterized by RHEED, XRD, transmission electron microscopy (TEM), and anti ferro magnet (AFM).

One prerequisite for epitaxial growth of thin films on a substrate is, besides a similar crystal structure, that both lattice constants are closely matched. In a few cases or in case of certain large misfit-systems, a coincidence lattice can be formed (Trampert and Ploog, 2000). For Co_2FeSi/GaAs, the lattice constants of bulk Co_2FeSi (5.658 Å) and GaAs (5.653 Å) differ by 0.08%, which can be considered as a small lattice mismatch allowing for epitaxial growth. Figure 3 shows the lattice parameters for selected HAs and semiconductor substrates.

Typically, the MBE growth of HAs starts with preparing a defined GaAs template in a separate III–V growth chamber using standard GaAs growth techniques. For the HA growth, the substrate is transferred in UHV into the metal deposition chamber. As arsenic can act as a contaminant for HAs, this chamber is kept As free. The metallic constituents are then codeposited from high-temperature effusion cells, where the evaporation rates can be controlled via the cell temperatures and are adjusted by measuring the beam-equivalent pressure

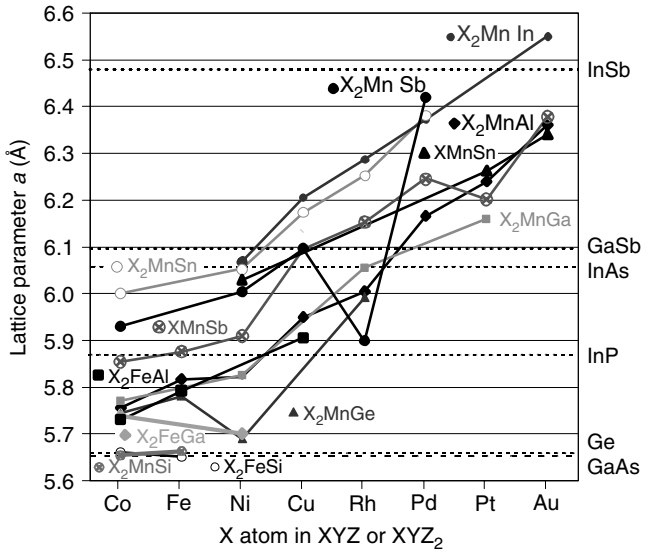

Figure 3. Full- and half-Heusler alloy (XYZ and X_2YZ) lattice parameters as a function of the atom species X, along with the lattice constants of semiconductors (horizontal lines).

using a Bayard–Alpert ionization gauge. *In situ* RHEED, together with *ex situ* XRD and AFM, are used to determine the growth mode, epitaxial relationship, lattice constants, strain, stoichiometry, and smoothness of the films. The structural properties of the heterostructure, and especially the interface quality, can further be studied by high-resolution transmission electron microscopy (HRTEM).

The material system that is best investigated in terms of growth is the half-Heusler alloy NiMnSb (see reference Turban *et al*., 2002a,b,c and references therein). A common observation is that the number of defects is lower for higher growth temperatures. This observation is generally true for inert surfaces, like MgO, however, fatal for III–V semiconductors, as interface reactions will play a critical role. As a consequence, a trade-off has to be made between interface and crystal film quality. Different from the growth of III–V materials where the stoichiometry is as result of the sticking coefficient of the group III species (within limits), HAs have a wide compositional phase field. Hence, the growth is not self-regulating and the individual fluxes have to be adjusted very precisely (Palmstrøm, 2003). Table 3 gives an overview of epitaxially grown HAs on semiconductor surfaces, listing growth temperatures, orientations, seed layers, structural, as well as magnetic properties, if available. No information about atomic disorder is given in the Table. As mentioned in the preceding text, epitaxial growth is a necessary ingredient for perfect interfaces; however, atomic disorder still remains a problem in HAs with consequences for their potential application as half-metallic contacts.

4.3 Characterization of an epitaxially grown Heusler alloy: Co_2FeSi/GaAs

We are now going to discuss some details of the epitaxial growth of a full-Heusler alloy system on GaAs by MBE (Hashimoto, Herfort, Schönherr and Ploog, 2005a). Co_2FeSi has the cubic $L2_1$ crystal structure and the lattice constant of the bulk is 5.658 Å, which is closely lattice-matched to GaAs (5.653 Å), yielding a lattice mismatch as small as 0.08%. $Fe_{3-x}Co_xSi$ shows a high stability of the cubic fcc phase over a wide compositional range ($0 < x < 2.15$), which can be used to control the magnetic properties, for example, magnetic anisotropy and magnetic moment.

According to the Slater–Pauling rule ($m = N_V - 24$, with N_V the number of valence electrons), a magnetic moment of $6\,\mu_B$ per f.u. (formula unit) and a Curie temperature of over 1000 K can be expected based on the number of valence electrons (see preceding text). Indeed, Wurmehl *et al*. confirmed the magnetic moment and measured a Curie temperature of 1100 K, making Co_2FeSi the half-metallic ferromagnet exhibiting the highest Curie temperature, and with the largest magnetic moment reported for full-HAs (Wurmehl *et al*., 2006). Recent calculations of the surface band structure of Co_2MnSi predict a stable, half-metallic Mn-terminated surface (Hashemifar, Kratzer and Scheffler, 2005). If applicable this would make Co_2FeSi indeed an excellent candidate for spintronics.

Prior to the metal growth, perfect GaAs surfaces were prepared by depositing a 100 nm-thick GaAs buffer layer in a separate III–V growth chamber. The growth conditions were chosen to obtain the As-terminated $c(4 \times 4)$ reconstruction of GaAs(001). By cooling the samples down to 420 °C under As_4 pressure, the formation of macroscopic defects on the surface during subsequent metal deposition can be prevented (Schönherr, Nötzel, Ma and Ploog, 2001). The transfer of the samples into the As-free metal chamber occurs under UHV conditions at a base pressure of $5 \cdot 10^{-10}$ Torr.

The first step for growing stoichiometric Co_2FeSi was to optimize the growth conditions for the binary alloy $Co_{0.66}Fe_{0.34}$ (bcc structure). The atomic composition of the $Co_{0.66}Fe_{0.34}$ layers was determined by measuring the film's lattice constant by XRD, and by determining the deviations from the data documented in the literature. In the next step, for obtaining the ternary alloy Co_2FeSi, Si was codeposited keeping the Fe and Co fluxes constant at the optimized values for $Co_{0.66}Fe_{0.34}$. For finding the optimum growth conditions, the growth temperature was varied from 100 to 400 °C. As the growth temperatures are comparably low, a small growth rate of about 0.1 nm min^{-1} was chosen not to compromise the crystal quality. As a free parameter, the temperature of the silicon cell (T_{Si}) was varied from 1280 to 1335 °C to obtain stoichiometric Co_2FeSi. The atomic composition of

Structural properties: rocking curve width refers to either the (004) or (220) reflection. 'X' denotes that high-resolution X-ray data are available, however, no numbers for the width of certain reflections are given. lattice param.: lattice parameter; HRTEM: high-resolution transmission electron microscopy study of the interface quality. Magnetic properties: magnetization values are given in emu cm^{-3}, emu g^{-1} or magnetic moment per formula unit (fu). The spin-polarization values, obtained at a certain temperature, or at an unspecified low temperature (LT), are given in the last column. For comparison, also a magnetoresistance (MR) value is listed for $Co_2CrFeAl$.
MBE: molecular-beam epitaxy; PLD: pulsed-laser deposition; sputter: sputter deposition; film orient.: film orientation; growth temp.: growth temperature.

Co_2FeSi was determined by high-resolution X-ray diffraction (HRXRD), monitoring the perpendicular lattice mismatch ($\Delta a/a$) of the films using the $Co_2FeSi(004)$ reflection.

4.3.1 Structural properties of epitaxial films (Hashimoto, Herfort, Schönherr and Ploog, 2005a)

The growth was monitored *in situ* using RHEED. The RHEED pattern observed during the growth of Co_2FeSi is rather spotty at growth temperatures below 100 °C. With increasing growth temperatures, the RHEED pattern gradually transforms into sharp streaks with Kikuchi lines and a Laue circle, indicating the required two-dimensional growth mode and a well-ordered single-crystal surface.

The structural properties of the films were examined *ex situ* by HRXRD using Cu K_α radiation with a Ge(220) monochrometer and a triple-bounce analyzer crystal. Figure 4 shows ω-2θ XRD curves of the $Co_2FeSi(004)$ reflection

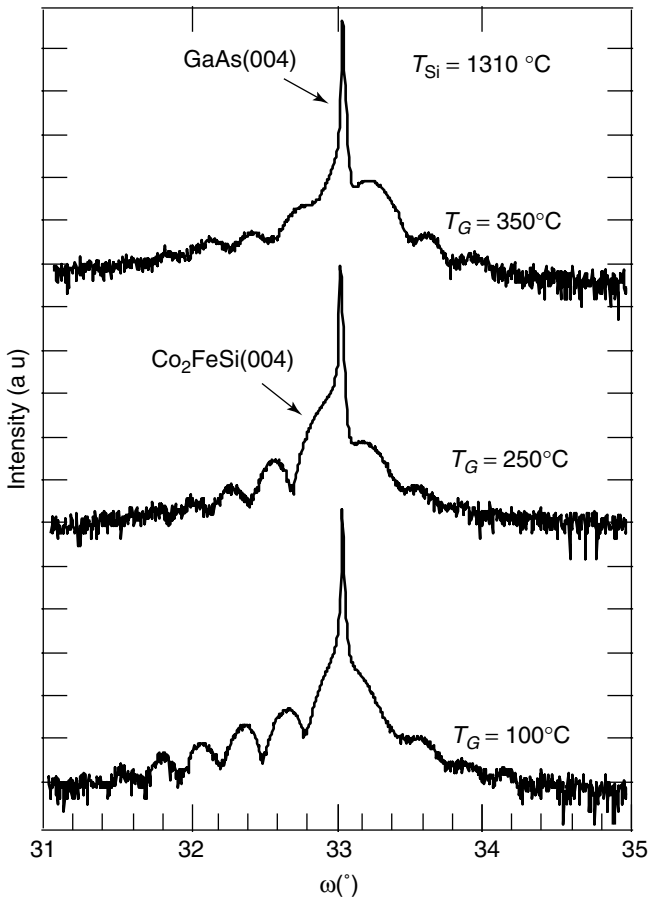

Figure 4. High-resolution X-ray diffraction ω-2θ scans for stoichiometric Co_2Fe_2Si/GaAs(001) films around the $Co_2FeSi(004)$ reflection for three growth temperatures from 100 to 350 °C. The metal effusion cell temperatures were the same for all three films.

of stoichiometric Co_2FeSi films grown at different growth temperatures (100, 250 and 350 °C). For low growth temperatures, higher order interference fringes are found (up to fifth order) – a fingerprint of high crystal quality, interface perfection, as well as smooth surfaces. At a growth temperature of 250 °C, the number of interference fringes decreases – a sign of a beginning crystal or interface degradation. At the high growth temperature, the main diffraction peak is broadened and also shifted to a larger reflection angle – most likely a sign of an interfacial reaction. This speculation was confirmed by a wide-range ω-2θ scans, showing an additional peak at around $\omega = 17.3^\circ$, which can be ascribed to the $(Co,Fe)_2As(110)$ reflection. It is worth noting that the growth temperature at which an interfacial compound is formed is much higher than that of Fe, Co or FeCo on GaAs, which makes Co_2FeSi much more suitable for device applications than these ferromagnetic metals.

The atomic ordering of the film can be studied by analyzing additional X-ray deflections, namely the (002) and (113) reflections. For the $L2_1$ structure, three types of reflections are allowed (Webster and Ziebeck, 1988): (i) h, k, l are all odd (e.g., (113) reflection); (ii) h, k, l are all even and $h + k + l = 4n + 2$ (e.g., (002) reflection); and (iii) h, k, l are all even and $h + k + l = 4n$ (e.g., (004) reflection), where n is an integer and h, k, l are the Miller indices of the diffracting plane. Type (iii) are the fundamental reflections which are not influenced by disorder and the other two are the order-dependent superlattice reflections. Type (i) reflections are reduced to zero in the limit of complete disorder between Si and Fe sublattices, which lead to the reduction of the crystal symmetry to the B2 (CsCl) structure. Type (ii) reflections, on the other hand, are reduced to zero in the limit of complete disorder between all three sublattices resulting in a further reduction of the crystal symmetry to the A2 (bcc) structure.

From the ω-2θ curve around the $Co_2FeSi(002)$ reflection and the reciprocal space map around the $Co_2FeSi(113)$ reflection of a stoichiometric Co_2FeSi film (thickness: 18.5 nm, grown at 100 °C), it was found that the two superlattice reflections of the $L2_1$ structure show interference fringes. This is an indication of long-range atomic order in the structure even for low growth temperatures. These reflections are also observed for Co_2FeSi films grown at different Si cell temperatures, that is, different Si compositions, and different growth temperatures. To precisely determine the ordering parameter, further HRXRD measurements and analysis are necessary, accompanied by electrical resistance measurements, which largely depend on the concentration of defects and impurities in the film. Further, the perfectly oriented vertical fringes indicate that the epitaxially grown Co_2FeSi layers are fully strained.

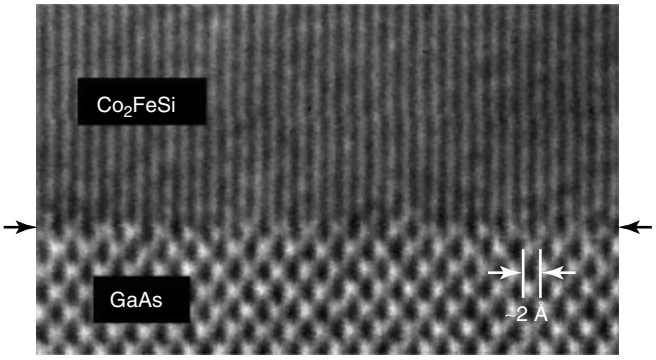

Figure 5. High-resolution cross-sectional transmission electron microscopy image of a perfect Co_2FeSi/GaAs interface. The growth temperature was 100 °C. The GaAs $d\{220\}$ lattice spacing of 2 Å is indicated below.

HRTEM is a powerful tool for studying the structural properties of the interface in great detail. Figure 5 shows a HRTEM (phase contrast) image of the Co_2FeSi/GaAs interface (Hashimoto *et al*., 2006). The abrupt interface of the Co_2FeSi layer grown at 100 °C and the GaAs substrate is indicated by arrows. A perfect matching of the Co_2FeSi(220) and GaAs(220) atomic planes across the interface is observed, that is, the Co_2FeSi layer is coherently strained. For films grown at higher temperatures, sharp interfaces are no longer observed. Already at a growth temperature of 200 °C, a 1–2 monolayer thick interlayer is found resulting from interfacial reactions.

4.3.2 Magnetic properties of epitaxial films

The magnetic properties of Co_2FeSi/GaAs heterostructures were investigated using a superconducting quantum interference device (SQUID) magnetometer. The in-plane magnetic anisotropy was determined at room temperature by applying an external magnetic field along the [110], [1$\bar{1}$0] and [100] directions.

Films grown at temperatures below 200 °C exhibit an easy axis along the [110] direction, a hard axis along [1$\bar{1}$0] and an intermediate hard axis along [100]. Along [110], square-like hysteresis loops with a small coercive field of 4.5 Oe are found. The saturation magnetization M_s of stoichiometric films is $1250 \pm 120\,\mathrm{emu\,cm^{-3}}$, which is indeed very close to the bulk value of Co_2FeSi ($1124\,\mathrm{emu\,cm^{-3}}$ at 295 K). This observation is another hint that the stoichiometric composition determined from the lattice constant is correct. The saturation magnetization decreases with increasing growth temperature, which is consistent with the proposed alteration of the interface due to chemical reactions. For the samples grown at 350 °C, the magnetization curves become more rounded and the angular-dependent difference becomes less pronounced. The previously observed uniaxial anisotropy almost disappears and the underlying cubic magnetocrystalline anisotropy dominates, turning the ⟨100⟩ direction into the easy direction.

Further, by fitting the magnetization curves along the [1$\bar{1}$0] direction with the following expression for the magnetic field as a function of magnetization (Dumm *et al*., 2000):

$$H(m) = 2K_1^{\mathrm{eff}}\frac{(2m^3 - m)}{M_s} + 2K_u^{\mathrm{eff}}\frac{m}{M_s} \qquad (2)$$

values for the cubic magnetocrystalline anisotropy term K_1^{eff} and the uniaxial anisotropy term K_u^{eff} were obtained; m is the normalized magnetization component. It was found that K_u^{eff}reaches a maximum for films grown at 200 °C, and has smaller values for growth below and above that temperature.

To study the influence of the surface and bulk part of the film on the magnetic properties, the effective anisotropy constants can be decomposed into volume $K_{u,1}^{\mathrm{vol}}$ and interface $K_{u,1}^{\mathrm{int}}$ contributions in the following way:

$$K_{u,1}^{\mathrm{eff}} = K_{u,1}^{\mathrm{vol}} + \frac{K_{u,1}^{\mathrm{int}}}{d} \qquad (3)$$

where d is the thickness of the film (Dumm *et al*., 2000). For Co_2FeSi films grown at 100 °C, K_1^{eff} is independent of d, indicating that K_1^{eff} is a volume related term, whereas K_u^{eff} is linearly dependent on 1/d. From curve fitting, K_u^{vol} is found to be almost zero and $K_u^{\mathrm{int}} = (7.3 \pm 0.9) \times 10^{-2}\,\mathrm{erg\,cm^{-2}}$, demonstrating that K_u^{eff} is a purely interface-related term as is observed in other FM/SC systems too. The value of K_u^{int} is in between those of Fe (Brockmann *et al*., 2000) and $Fe_{0.34}Co_{0.66}$ (Dumm *et al*., 2000) on GaAs: 1.2×10^{-1} and $2.6 \times 10^{-2}\,\mathrm{erg\,cm^{-2}}$, respectively. Furthermore, K_u^{int} can be expected to be larger for higher growth temperatures. In general, the uniaxial in-plane magnetic anisotropy observed in FM/SC systems is anticipated to have its origin in an anisotropic bonding at the interface (Sjöstedt, Nordström, Gustavsson and Eriksson, 2002). The quality of the interface is improved up to a growth temperature of slights below 200 °C above which interfacial reactions become limiting. Thus, it can be concluded from the analysis of the in-plane magnetic anisotropy that the optimum growth temperature for obtaining a perfect interface is below 200 °C.

5 SPIN INJECTION FROM HEUSLER ALLOYS INTO SEMICONDUCTOR HETEROSTRUCTURES

As discussed in the preceding text, spin injection into a semiconductor is key to many spintronics device ideas (de Boeck *et al*., 2002). Semiconductor-based spintronics will

potentially offer greater functionality than metal spintronics, as the electronic properties of the systems can be easily tuned in contrast to metals, and the integration with the traditional semiconductor electronics seems feasible. For instance, it was demonstrated that spin-relaxation times in GaAs can be controlled by an electric field (Sandhu, Heberle, Baumberg and Cleaver, 2001). However, the electronic excitation of spin-polarized carriers in semiconductors like GaAs or Si is still a great challenge, whereas efficient room-temperature electric spin injection in metals has been a reality for quite some time. It is even commercially employed in all-metal magnetic read-heads, making use of the GMR effect (Baibich *et al*., 1988; Binasch, Grünberg, Saurenbach and Zinn, 1989). It was not until 1999 when highly efficient spin injection into nonmagnetic GaAs was demonstrated using magnetic semiconductors as spin aligners (Fiederling *et al*., 1999; Ohno *et al*., 1999). Moreover, it was found that the spin-relaxation times in semiconductors can be orders of magnitude larger than momentum or energy relaxation times of the electron (Kikkawa and Awschalom, 1998). Another ingredient for semiconductor spintronics, the controlled manipulation and preservation of the spin over lateral distances of 100 µm and more, was reported the same year in bulk GaAs (Awschalom and Kikkawa, 1999). Recently, using simple, undoped GaAs quantum wells in connection with dynamic quantum dots, coherent spin-transport lengths approaching 1 mm seem possible (Stotz, Hey, Santos and Ploog, 2005).

5.1 Spin injection into semiconductors – an overview

The concept of a semiconductor-based spintronics device, involving spin injection, manipulation by an electrostatic gate via spin-orbit coupling, and spin detection, was introduced by Datta and Das (1990). The initial step is the efficient, electrical injection of spins into the semiconductor. Although spin injection has already been reported by Aronov and Pikus (1976), no convincing results on realizing a Datta- and Das-type device by using metal or metal alloy Ohmic contacts (e.g., NiFe) on semiconductors (e.g., InAs) have been presented (Monzon and Roukes, 1999; Gardelis *et al*., 1999; Filip, Hoving, Jedema and van Wees, 2000). Initially, it was believed that the spin-polarized electrons in the ferromagnetic metals are preserving their spin upon entering the semiconductor via an Ohmic contact. Schmidt and coworkers later realized that the conductivity mismatch in the Ohmic contact between the metal and the semiconductor might present a fundamental obstacle for spin injection (Schmidt *et al*., 2000). For a review of this topic, see also Schmidt (2005).

One way around the conductivity mismatch problem is to replace the Ohmic metal injector by a magnetic semiconductor, such as BeMnZnSe, GaMnAs, or ZnMnSe (Fiederling *et al*., 1999; Ohno *et al*., 1999; Jonker *et al*., 2001). This way, the relative resistance difference of the spin channels is larger as compared to metal injectors, and it can be further increased by a spin polarization close to 100%. In this case, the resistance of the materials plays no longer a role, as the spin-injection efficiency is always unity (Schmidt, 2005), and very large spin polarizations – up to 83% – have been reported (Jonker *et al*., 2001). It should be noted that, despite the success, the practical applicability of dilute magnetic semiconductor contacts is limited to low temperatures (still well below room temperature) and/or high magnetic fields.

A second approach to the conductivity mismatch problem is to use tunnel contacts for spin injection (Rashba, 2000), since the tunneling process is spin dependent and the tunnel contact can have a high impedance. This way, ferromagnetic metallic contacts with their advantages of simple fabrication and superior magnetic properties entered the arena again. Spin polarizations P of around 30–40% were reached in the following Schottky tunnel contact systems: Fe/GaAs, $P = 2\%$ observed between 25 and 300 K (Zhu *et al*., 2001); Fe/AlGaAs, $P = 32$ and 30% at 90 and 240 K, respectively (Hanbicki *et al*., 2002, 2003); Fe/AlGaAs, $P = 30\%$ at 2 K (Adelmann *et al*., 2005); epitxaxial MnAs/GaAs, $P = 6\%$ at 80 K (Ramsteiner *et al*., 2002); Fe/InAs, $P = 12\%$ at 6.5 K and an external magnetic field of 10 T (Ohno *et al*., 2003); and Fe_3Si/GaAs, $P = 10\%$ at 25 K (Kawaharazuka *et al*., 2004). The last system is of great importance as Fe_2FeSi marks a step into the direction of epitaxial-HAs (almost lattice-matched to GaAs).

One alternative to Schottky barriers is the use of Al_2O_3 as an insulating tunneling barrier: (Co, Fe, and NiFe)/Al_2O_3/AlGaAs, $P = 0.8\%$ for Co, 0.5% for Fe, and 0.2% for NiFe at room temperature (Manago and Akinaga, 2002); Fe/Al_2O_3/AlGaAs, $P = 40\%$ at 5 K (best case, 30% typical) (van't Erve *et al*., 2004); NiMnSb/Al_2O_3/Al, $P = 28\%$ (Tanaka, Nowak and Moodera, 1999); and CoFe/AlO_x/AlGaAs, $P = 24\%$ at 80 K and 12% at room temperature (van Dorpe *et al*., 2003). However, it will be extremely difficult to increase the spin polarization of these systems due to the preparation-related issues and the electronic properties of the Al_2O_3-metal interface.

Crystalline MgO, on the other hand, holds great promises as a barrier material since in CoFe/MgO(001), the majority electron states decay slowly in the MgO barrier as evanescent states, whereas the minority electron states decay rapidly (Zhang and Butler, 2004). The resulting high-tunneling spin polarization was experimentally verified to be 85% using superconducting tunneling spectroscopy (Parkin *et al*., 2004).

Recently, the group of Parkin reported spin-polarization values of 57% at 100 K and 47% at room temperature in FeCo/MgO(001)/GaAs (Jiang *et al*., 2005; Jiang, Wang, Shelby and Parkin, 2006). By further analyzing their data in combination with time-resolved Kerr rotation and differential reflectivity measurements, an even higher injection efficiency of 70% for temperatures from 10 K up to room temperature was claimed (Salis *et al*., 2005).

However, it has to be noted that tunneling junctions can only be used for spin injection in reverse bias. In a standard planar Datta–Das–type device geometry where the tunnel junctions are in series, it is not feasible to both inject and detect the spins this way (Schmidt, 2005).

Figure 6 illustrates the different schemes for spin injection into a semiconductor. In the general case of an Ohmic, ferromagnetic metal electrode (a), the spin-injection efficiency is very limited due to conductance mismatch. The situation is improved, if a half-metallic electrode is used (b); however, interface effects may drastically reduce the efficiency. A solution for the conductance mismatch problem is tunneling barrier, separating the half-metallic or ferromagnetic electrode and the semiconductor (c).

5.2 Detection of spin polarization by light-emitting diodes

A common approach for detecting (small) spin polarizations in direct band gap semiconductors, such as GaAs, are quantum well based light-emitting diodes (LEDs) (Fiederling *et al*., 1999; Ohno *et al*., 1999; Jonker *et al*., 2001). Spin-LEDs have been used for obtaining most of the spin-injection data presented in the previous section. Owing to the optical selection rules for radiative recombination, the spin polarization of the electrons can be extracted by analyzing the polarization of the emitted electroluminescence (EL). In the quantum well, two types of holes exist, heavy holes (HH) and light holes (LH), which both may recombine with electrons and emit photons with positive and negative helicity. In the general case, the EL spectra do not yield the spin polarization in a straightforward way. However, in the special case of quantum wells, the heavy- and light-hole states are no longer degenerated because of confinement and/or strain effects. If the heavy- and light-hole bands are separated by an energy at least several times the thermal energy, it becomes possible to spectrally resolve the heavy-hole emission. In the so-called Faraday geometry, where the spin orientation and light propagation direction are both perpendicular to the plane of the LED's quantum well, the selection rules are very simple. As a consequence of the fact that the spin carried away by the photon is ± 1, a spin-up electron can only recombine with a $+3/2$ HH (σ_+ emission) and a spin-down electron only with a spin $-3/2$ HH (σ_- emission), respectively. The circular polarization of the emitted light, P_{circ}, is now simply given by $(I_+ - I_-)/(I_+ + I_-)$, where I_+ and I_- are the peak intensities of the σ_+ and σ_- components, respectively (Jonker *et al*., 2001). P_{circ}, and the spin polarization of the electrically injected carriers, $P_{\mathrm{spin}} = (n_\uparrow - n_\downarrow)/(n_\uparrow + n_\downarrow)$, are equal in case of free exciton emission from an AlGaAs/GaAs/AlGaAs quantum well structure ($n_\downarrow$ and $n_\uparrow$ are the number of electrons of the respective spin orientation) (Jonker *et al*., 2000). As the injected electrons spend a certain amount of time in the semiconductor heterostructure before they recombine in the quantum well, the measured spin polarization is only a lower bound of the real spin polarization in the semiconductor. Thus, for a correct interpretation of the EL measurements, spin-relaxation processes have to be taken into account (Malinowski *et al*., 2000). The EL measurements are usually carried out in a temperature-controlled cryostat that is placed in a superconducting magnet. Details about a typical spin-LED setup can be found in (Ramsteiner, 2003).

5.3 Spin injection from Heusler alloys into semiconductors

To achieve the goal of efficient spin injection at room temperature, ideal half-metallic contacts with high Curie temperatures are the material system of choice, as conductivity

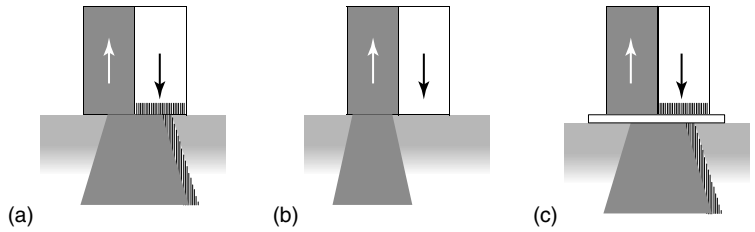

Figure 6. Schemes of spin injection into a semiconductor: (a) Ohmic (diffusive) contact between ferromagnetic metal and semiconductor. The spin-injection efficiency is very limited; (b) (Ohmic) contact between half-metal and semiconductor. Although the half-metallic film is fully spin polarized, the spin polarization at the interface may be significantly lower; (c) Tunnel barrier (Schottky barrier, insulating oxide barrier) between ferromagnetic metal and semiconductor shows an enhanced spin-injection efficiency.

mismatch for 100% spin-polarized systems may not be an issue. So far, only a few spin-LED systems involving HAs have been fabricated and characterized.

The full-HA Co_2MnGa has been deposited by MBE onto the GaAs spin-LED structure (Hickey *et al*., 2005). The InGaAs quantum well was located 300 nm below the surface and the HA was in contact with an AlGaAs layer, forming a Schottky barrier. The growth of the III–V material and metal film was carried out in two separate chambers, requiring that the GaAs device was capped with As prior to the transfer into the metal chamber. Note that instead of a film with the ideal Heusler alloy stoichiometry Co_2MnGa, a film with the composition $Co_{2.4}Mn_{1.6}Ga$ was grown. The spin polarization of the injected electrons was determined to $P = 13\%$ at 5 K; and P disappears already at 20 K. The spin polarization, determined at 6 K by the PCAR technique employing a Nb tip, yielded a transport spin polarization of about 50%. The authors attribute the discrepancy between the measured transport spin polarization and the spin injection to interfacial disorder.

Another full-Heusler system, Co_2MnGe, was also grown by MBE on a AlGaAs spin LED involving a GaAs quantum well (Dong *et al*., 2005). The spacing and intensities of the RHEED streaks suggest that Co_2MnGe grows in the (001) orientation and an $L2_1$-like crystal structure (Dong *et al*., 2003). The maximum steady-state spin polarization measured at 2 K was 13%, while the injected spin polarization was calculated to be 27% based on a calibration of the spin detector using Hanle effect measurements. In both experiments, an otherwise identical Fe electrode control structure was grown (spin polarization 40% at 2 K). Compared to this structure, the spin polarization injected from Co_2MnGe decays more rapidly with increasing temperature and despite the Curie temperature of 905 K, Co_2MnGe structures show no spin polarization at room temperature (compared to 15% at room temperature for Fe structures). Due to the small gap for minority spins in the calculated band structure of Co_2MnGe and the slight disorder observed in TEM, the lack of half-metallic behavior is not too surprising. Consequently, HAs with a larger minority-spin gap, such as Co_2MnSi, may be more effective injectors.

5.4 What next? Necessary experiments and device concepts

First of all, magnetic materials with a close to 100% spin polarization will definitely be crucial for future spintronic devices. This does not necessarily mean that spin polarizations of 100% are absolutely required, although they are intriguing. So far, the race for the best spin injection material is still too close to call. The future success of HAs largely depends on the ability to control disorder and on a theoretical treatment of the complex problem of disordered interfaces at nonzero temperature that is absolutely necessary.

However, once the problem of spin injection is solved, there is a multitude of new device concepts on the horizon (Zutic, Fabian and Das Sarma, 2004). Especially the spin transport in inhomogeneous semiconductors, like p-n junctions, holds great promises (Das Sarma, Fabian, Hu and Zutic, 2001). In a recent study of p-n junctions in which nonequilibrium spins are introduced into one (or both) regions (p and n), it was shown that the spin be transported (under an external bias) through the space-charge region separating the p and n regions. Moreover, the spin gets amplified when crossing the space-charge region. Other phenomena that have been demonstrated are the increase of an effective spin diffusion range in the p–n junction, the possibility of generating spin current in a spin-polarized solar cell, and an all-electronic control of spin (spin capacitance effect) (Zutic, Fabian and Erwin, 2006).

6 CONCLUSIONS

The future of advanced spintronic devices, like the spin transistor, relies on the efficient spin injection from a ferromagnet into a semiconductor, the scattering-free transport, manipulation, and detection of the spin-polarized current. These tough requirements make it necessary to use a growth method for the epitaxial single-crystalline magnetic film/semiconductor heterostructures that allows for extremely precise control of the growth process. In general, MBE has proven to be the method of choice when perfect interfaces and access to the structural properties of the growing film are required. HAs on III–V compound semiconductor surfaces are very promising combinations of ferromagnetic and semiconducting materials. They combine the ability to be grown epitaxially and to yield Curie temperatures well above room temperature. Moreover, some of them are most likely half-metallic ferromagnets with a degree of spin polarization of, or at least close to 100%. One caveat, however, is the inevitable problem of atomic disorder in these ternary material systems, as they exhibit a structural instability due to the fairly broad free-energy minimum. Thus, before spin transistors will become a reality, a number of problems have to be addressed in a joint effort of materials science, physics, and device engineering. The most prominent being the need to understand in detail, and consequently improve, the spin-injection probability from the ferromagnet into the unpolarized semiconductor.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the numerous contributions of J. Herfort, H.-P. Schönherr, A. Trampert and the other colleagues mentioned in the references to the experimental work summarized here. This work was in part sponsored by the Bundesministerium für Bildung und Forschung of the Federal Republic of Germany.

Crystal Growth of Magnetic Materials

Günter Behr and Wolfgang Löser
Leibniz Institute for Solid State and Materials Research, Dresden, Germany

1 INTRODUCTION

Magnetic materials cover a very wide range of substances starting from pure elements to intermetallic compounds and oxides up to molecular magnets. Magnetic materials are usually applied as polycrystalline (often textured) bulk solids or as thin films. The main purpose for studying single crystals is to provide unique physical data for understanding the bulk properties of magnetic materials or selected constituent phases as a function of their crystallographic orientation and composition. This is of outmost importance for optimization of production routes of textured transformer sheets, anisotropic hard magnets, or textured thin films, because the relevant parameters can only be derived from the single-crystalline specimens. Another important aspect is the study of magnetization processes, which depend sensitively on the stoichiometry, impurity content, and density of structural defects (apart from grain boundaries) and require well-prepared single crystals. Complex crystallographic structures or magnetic ordering of compounds, which are constituents of the magnetic materials, are preferably studied on single-crystalline specimens of various sizes. In polycrystalline or multiphase samples, many of these features inferred from X-ray or neutron diffraction patterns are often hidden because of disturbing reflections from accompanying phases. Single crystals with an optimum orientation are suitable only for special commercial purposes such as magnetostrictive materials for high-performance devices.

Generally, despite the numerous publications on properties of single-crystal specimens of magnetic metals, alloys and compounds, information about crystal growth methods and the appropriate process parameters is often scarce. Therefore, in this chapter, special emphasis is devoted to the various methods for single-crystal preparation of magnetic materials and the appropriate process parameters. One particular concern is the tight correlation between the growth method applied and the alloy phase diagram, which provides decisive information for the choice of operating temperature, feed rod composition, and other growth conditions. Some fundamental aspects and more details about the growth methods themselves can be found in the excellent handbooks (Wilke and Bohm, 1988; Hurle, 1994). Owing to the wide spectrum of existing magnetic materials and the abundance of previous measurements, we can only refer to some particularly important examples of properties determined from single crystals. We refer to the other chapters of this comprehensive handbook and previous textbooks (e.g., Kneller, 1962) for more details on measured magnetic quantities.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 3: *Novel Techniques for Characterizing and Preparing Samples*. © 2007 John Wiley & Sons, Ltd. ISBN: 978-0-470-02217-7.

2 PHASE DIAGRAMS AND CHOICE OF GROWTH METHODS

The growth methods, applicable to a specific magnetic material are determined by the desired size and degree of perfection of the single crystal and also by the phase diagram of the alloy system or in the case of flux growth, even by multicomponent phase diagrams, which involve possible solvents.

Among the various magnetic materials we can differentiate between pure elements (iron, rare earths), alloys (Fe–Si, Fe–Ni), binary (FePt, $TbFe_2$, Y_2Fe_{17}) or quasibinary solid solution compounds ($Dy_{1-x}Tb_xFe_2$), and multicomponent compounds ($Nd_2Fe_{14}B$) or oxides (RMn_2O_5). As different as the materials themselves, are the phase diagrams of the alloys. Within this section, we therefore can only show a few typical examples of phase diagrams important for magnetic materials and discuss their consequences for crystal growth with special emphasis on growth from the melt.

Figure 1 displays the phase diagram of the Fe–Si system. It not only contains an element with a solid-state transformation Fe (other examples are Dy, Gd) but also shows Fe–Si solid solutions (for transformer sheets) and ordered intermetallic compounds such as the congruent melting binary compound FeSi.

Pure iron crystallizes on cooling the liquid at 1538 °C as the bcc δ phase. At 1394 °C it transforms into the fcc γ phase and subsequently at 912 °C into the bcc α phase, which has same crystal structure as the δ phase. Finally, a ferromagnetic ordering transition takes place at 770 °C. This sequence of phase transitions doesn't allow the growth of perfect single crystals (growth from the melt results in a well-pronounced substructure). Therefore, for single-crystal growth of pure Fe a method has to be used which operates below the lower transition temperature (912 °C). In contrast, the Fe–Si solid solutions at concentrations >3.8 at% Si undergoes no phase transformation and therefore can be grown directly from the melt by different methods like Bridgman growth, zone melting in a crucible, floating zone (FZ) melting, and Czochralski (CZ) growth. The same statement holds for the intermetallic compound FeSi. In those cases, only the desired dimensions, purity, and physical perfection of the crystals decide about the preferred method for crystal growth.

The phase diagram Fe–Pt (Figure 2) exhibits complete solid solubility of the fcc γ-(Fe,Pt) phase at elevated temperatures apart from the small Fe-rich region (<5 at% Pt). The crystal growth from the melt of the γ-(Fe,Pt) phase can be accomplished by various growth methods (Bridgman growth, CZ, FZ). However, depending on the composition the γ-(Fe,Pt) crystal can undergo different ordering transitions. For example, around 50 at% Pt the tetragonal γ_2-FePt phase forms below 1300 °C via a solid-state ordering process from the disordered γ-(Fe,Pt) crystal. A growth directly from the melt of the ordered γ_2-FePt

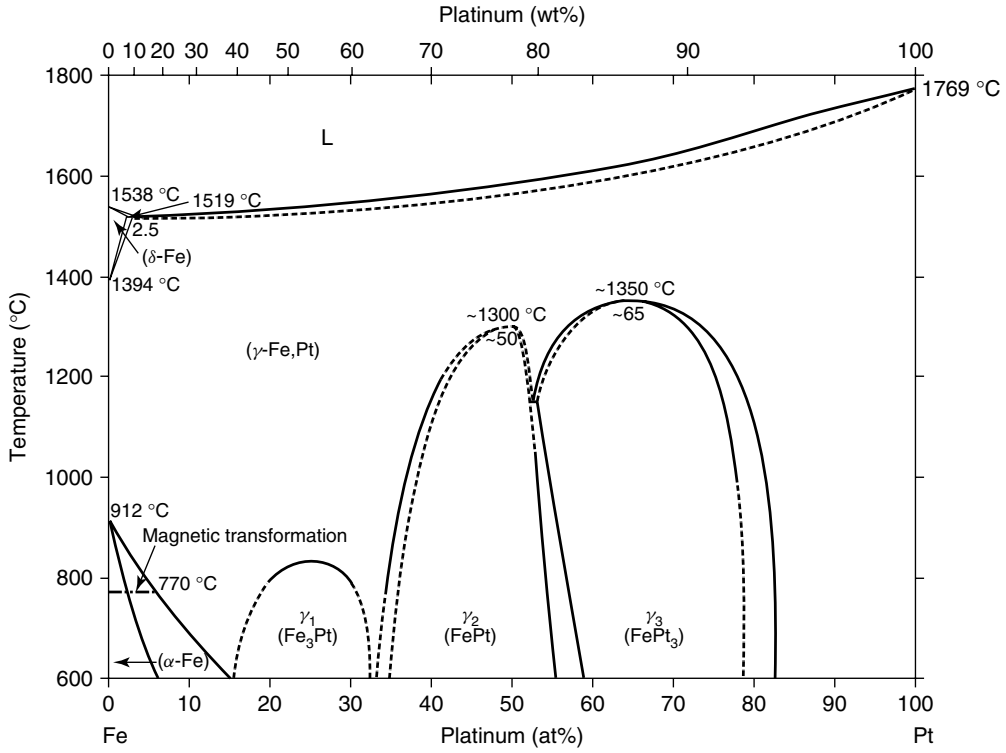

Figure 2. Phase diagram Fe–Pt. (Reprinted with permission of ASM International®. All rights reserved. www.asminternational.org.)

phase, which is interesting for magnetic recording media, is not possible. Single crystals of γ_2-FePt can be prepared by a strain-anneal treatment below the ordering temperature as described in Section 4.2.1.

In the Fe–Tb system (Figure 3) all binary phases melt incongruently, that is, by formation of a new solid phase and a melt of different composition. For example, heating the $Fe_{17}Tb_2$ phase to 1312 °C the reaction $Fe_{17}Tb_2 = \gamma\text{-Fe} + L$ takes place. This means that the phase $Fe_{17}Tb_2$ cannot coexist with a stoichiometric melt of the same composition. Direct growth of $Fe_{17}Tb_2$ is possible from a melt of a composition within the so-called primary crystallization field ranging from 17 to 21 at% Tb. The use of a FZ method is favorable with a liquid zone composition in this range. Because Tb in this case acts as a solvent, the method is known as *traveling solvent floating zone* (TSFZ) method.

Similar relations can be found in the phase diagram of Nd–Fe–B. This system is interesting because of the anisotropic magnetic phase $Nd_2Fe_{14}B$ (Φ), which has outstanding importance in permanent magnetic materials. A binary section at a Nd:B ratio of 2:1 is shown in (Figure 4). Crystal growth by TSFZ appears to be preferable due to the high sensitivity of the neodymium to oxidization and reactions with crucible materials. A detailed description is given in Section 4.2.2.

3 METHODS OF CRYSTAL GROWTH

The phase diagrams of the alloy systems of magnetic materials can show different types of phase formation (see Section 2): congruent melting compounds, peritectically melting compounds, and phases, which are not in equilibrium with the melt. As a result, quite different techniques must be used for single-crystal growth. Each method provides crystals of a characteristic size and morphology, chemical purity, and crystalline perfection.

Two main approaches can be used for the growth of magnetic single crystals, namely, the growth from a solid or a liquid phase. A growth from the gaseous phase was also used for selected materials but does not play an important role. The smallest samples, often used for a crystal-structure analysis, are simply obtained from arc melted alloy ingots. Their size may be only a few tens of micrometers, but can even reach nearly 1 mm. In order to perform magnetic, electrical, or other physical measurements single crystals with dimensions of several millimeters are needed. Still higher requirements on dimensions are valid for crystals with commercial applications (cf. Section 4.3.2). For preparation of such 'big' single-crystalline samples specific crystal growth techniques are employed. A short description of growth methods along with some details

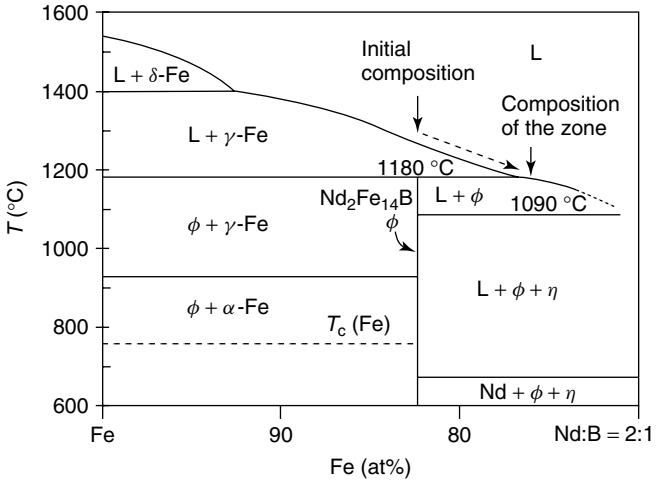

Figure 4. Binary section of the Fe–Nd–B phase diagram at a Nd:B ratio of 2:1. The pathway of melt composition during FZ crystal growth of $Nd_2Fe_{14}B$ from a stoichiometric feed rod is shown schematically (cf. Section 4.2.2). (Reproduced from G. Schneider *et al.*, 1986, with permission from Carl Hanser Verlag GmbH & Co. © 1986.)

related to the crystal growth of magnetic materials is given in the following text. The fundamentals of crystal growth and detailed information about the methods can be found in the excellent handbooks (Wilke and Bohm, 1988; Hurle, 1994).

3.1 Crystal growth from the solid phase

One possible method to grow relatively large and very pure single crystals of phases which do not coexist with the melt, for example, α-Fe, α-Gd, and α-Dy (cf. phase diagram Figure 1 for Fe), is the growth from a solid phase by a recrystallization technique. Annealing of a polycrystalline sample at elevated temperature below the phase transition leads to coarsening of crystallites by grain growth. In order to enhance the grain growth process, which is driven by the reduction of grain boundary energy, internal stress, and entropy of disorder, a controlled deformation of the sample prior to annealing can be carried out which increases the density of defects (strain-anneal technique). This process was first described for aluminum by Sauveur (1912). Furthermore, annealing in a temperature gradient improves the formation of large and perfect grains. The purity of the material plays a crucial role in this process. At elevated temperatures, impurities can segregate to grain boundaries and therefore lower their mobility. Details about the crystal growth of iron and some rare-earth metals will be given in Section 4.1.1.

3.2 Flux growth

The flux growth method is crystal growth from a melt in which the constituents of the material to be grown are dissolved. The most important advantage of using a flux is that the process temperature can be below the melting point of the desired single crystal. As a result, appropriate crucible materials can by easily found and, as for chemical vapor transport, high-temperature phase transitions, or incongruent melting can be circumvented. Therefore, the technological effort can be reduced compared with the plain melt growth methods. The main shortcomings of the method are the degraded purity of the grown crystals (due to incorporation of the flux material) and their small size. The principal problem to be solved in this method is the choice of the solvent. The properties desirable for the solvent are:

1. The compound to be grown is the only stable solid phase in the flux under growth conditions.
2. The solubility of the components of the crystal to be grown should not be too low and should decrease with falling temperature.
3. The melting point of the flux material must be much lower than the stability limit of the crystal to be grown.
4. A very low solubility of the solvent elements in the grown crystal is desirable (at least incorporated elements should not affect the measured properties).
5. A crucible material must exist, which does not react with and is not wetted by the melt solution.
6. The viscosity of the solution should be low, preferably in the range $10^{-3}-10^{-2}$ Pa s.
7. The solidified residual melt should be easy to separate from the grown crystals.

Single crystals of multiferroic compounds, for example, $RMn_{2-x}Fe_xO_5$ and $RMn_{2-x}Co_xO_5$ oxides (R = Y, Tb, Ho) have been grown from a PbO/PbF_2 flux. The solubility of the different components in the flux can be roughly estimated from binary phase diagrams. Unfortunately, the multicomponent phase diagrams in most cases have not been studied yet. Platinum is a good candidate as the crucible material for PbO/PbF_2 fluxes.

The growth process must be performed in a well-defined atmosphere (oxygen partial pressure) in a furnace with a good thermal stability and well controlled temperature. Chamber furnaces with a controllable atmosphere usually meet the requirements. The weight ratio between solvent and growing material varies in a wide range depending on the multinary phase diagram of the complex systems. The crystal growth takes place with slow cooling of the furnace. After heating to a maximum temperature and waiting for equilibrium the temperature is slowly decreased with a rate of a few degrees per hour. Spontaneous nucleation occurs first and one has to control the number of nuclei in order to obtain only a few large single crystals during subsequent growth. In order to minimize the number of growing nuclei, a temperature oscillation technique during the starting phase of the cooling can be used (Scheel and Elwell, 1972). A typical programmable temperature–time regime for the flux growth is shown in Figure 5. Depending on the crystal/solvent system, either variable cooling rates with a constant linear growth rate or a constant cooling rate or a maximum stable growth rate can be applied during crystallization. A detailed description is given by Scheel and Elwell (1972). The residual solvent can be removed from the crystals by treating samples in different etching solutions, which do not dissolve the crystals, or by crucible rotation in the hot stage to remove the solvent from the crystals grown at the bottom or at the walls of the crucible. Another variant called *flux creep method* applied for the growth of Sm–Fe crystals will be described in Section 4.2.3.

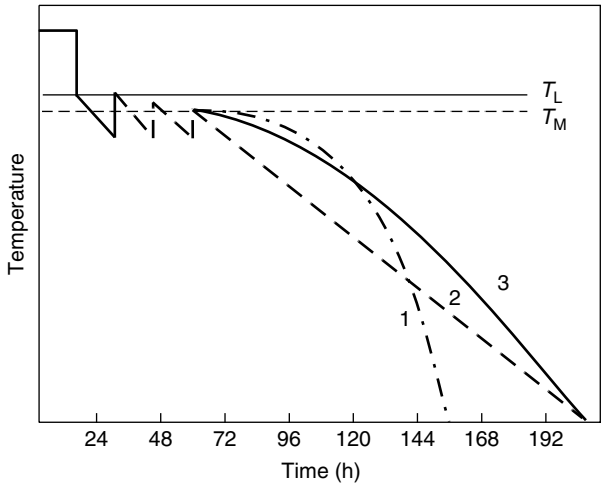

Figure 5. Typical temperature program for flux growth with a temperature oscillation in the metastable region below the liquidus temperature T_L around the melting point T_M: 1–constant linear growth, 2–constant cooling rate, 3–maximum stable growth rate. (Reproduced from Scheel *et al*., 1972, with permission from Elsevier. © 1972.)

A second method to produce single crystals from a melt solution of the components is the traveling solvent method. An alloy consisting of the components of the compound to be grown and the solvent forms the liquid zone, which is moved through the material at a very low rate. The use of a seed for growing oriented crystals is possible. Other details related to the crystal growth of refractory compounds from the flux can be found in the comprehensive review of Gurin and Korsukova (1983) who analyzed the complete process. The crucible-less TSFZ method is described together with the FZ method due to the similarity of the methods.

3.3 Crystal growth from the melt

Samples needed for crystal-structure investigations can be usually very small with a size of a few tens of micrometers. Such small single-crystal fragments of about $40 \times 45 \times 15\,\mu m^3$ can be extracted from polycrystalline arc melted and heat treated samples if the phase diagram allows this synthesis of the compound. The elements are melted in a water-cooled copper heart in purified argon at a pressure of about 0.6 bars. The melting procedure must be repeated several times in order to improve the alloy homogeneity. For further homogenization and grain coarsening the samples can be subjected to an annealing treatment with an annealing temperature as close as possible to the stability limit of the phase. Finally, single-crystalline specimens can be cut out of large grains of the button.

A growth from the melt of elemental components is the most common approach to prepare big single crystals of intermetallic magnetic compounds. In order to decide which particular method can be used, an exact knowledge of the phase diagram, the partial pressures of the components at the melting temperature, and the reactivity of the melt with the crucible material and the environmental atmosphere is necessary. The following methods for crystal growth of magnetic materials from the melt are used depending on their phase stability and melting temperature: FZ melting, horizontal FZ melting with levitation in a cold crucible, vertical container zone melting, CZ method, Bridgman–Stockbarger, and Tamann–Stöber method. The main advantage of the growth from the melt is an opportunity to obtain large single crystals (up to several cubic centimeters), which can be analyzed by various techniques including magnetic and electrical transport measurements for particular crystallographic directions. In principle, crystals can be grown from the melt of all compounds which are stable up to the melting point and which melt congruently or even incongruently with a melt composition not too far from the compound stoichiometry. The basic concept to be considered in all methods of directional solidification from a melt is the morphological stability of the solid–liquid phase boundary connected with constitutional supercooling (Rutter and Chalmers, 1953).

A possible instability of the moving solid/liquid interface is caused by the formation of a steady state boundary layer with alloy component enrichment near the interface due to deviations of the crystal stoichiometry from the melt composition described by the distribution coefficient $k = c_S/c_L < 1$ (or $k < 1$) determined from the solidus (c_S) and the liquidus (c_L) concentration of the equilibrium phase diagram (cf. Section 2). Constitutional supercooling occurs if $G_L < m{\cdot}G_C$, where G_L is the temperature gradient in the liquid near the solid/liquid interface, G_C is the solute concentration gradient in the steady state diffusion boundary layer of the liquid phase, and m is the liquidus slope in the equilibrium phase diagram. In the steady state conditions of unidirectional solidification, with a planar solid/liquid interface, this gradient is (Tiller, Jackson, Rutter and Chalmers, 1953):

$$G_C = \frac{(1-k)}{k}\cdot N_\infty \cdot \frac{V}{D} \tag{1}$$

where N_∞ is the solute concentration in the melt far from the solid/liquid interface, V is the growth rate, and D is the solute diffusion coefficient in the melt. Because of the lack of exact experimental data for melts of the various magnetic materials the simple approach of equation (1) seems to be appropriate to describe the phenomenon. Any unstable solid/liquid interface leads to a cellular growth with undesired second phase formation. While k and D are fixed by the alloy system a high-temperature gradient G_L must be realized by the design of the crystal growth facility. Moreover, the pulling rate V must be chosen to be as low as necessary to guarantee a stable growth. The various demands discussed, can be fulfilled using one of the wide variety of growth methods.

The Tamann–Stöber method is characterized by melting the material in a vertical crucible. The crucible is located in a temperature zone with a gradient so that on slow cooling the melt at the bottom of crucible crystallizes first. For a convenient seed selection the bottom of the crucible usually ends in a rounded tip with a small radius of curvature. This method is also referred to as vertical gradient freezing (VGF) method. The Bridgman technique uses a relative translation of the crucible containing a completely molten material to an axial temperature gradient in a furnace. In the crystal growth of magnetic materials, mainly vertical configurations shown in Figure 6 are used. The temperature gradient near the solid/liquid interface can be made more stable and steeper applying the vertical Stockbarger configuration consisting of two furnaces with different temperature levels divided by an adiabatic loss zone as illustrated in Figure 7. The crucible is moved into the temperature gradient zone with a velocity, which must be controlled very well.

A problem of general interest in all crucible methods is the choice of the crucible material. It must be chemically inert with respect to the melt, should not be wetted by the melt, and should have a thermal expansion coefficient less than the crystal itself. Depending on the material to be grown graphite, graphite covered with boron nitride, alumina, boron nitride, quartz, and Al_2O_3-supported silica as well as open or welded molybdenum and tantalum crucibles are used. Melts of metallic magnetic materials usually react with oxygen, and oxides contaminate the crystal and disturb the grain selection and growth process. Therefore, an inert atmosphere

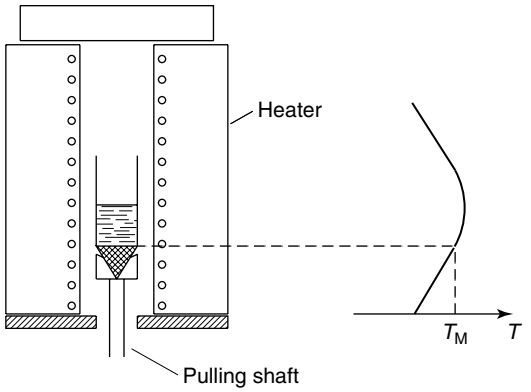

Figure 6. Vertical Bridgman method and related temperature profile. (Reproduced from G. Behr *et al*., 2000, with permission from Springer-Verlah GmbH. © 2000.)

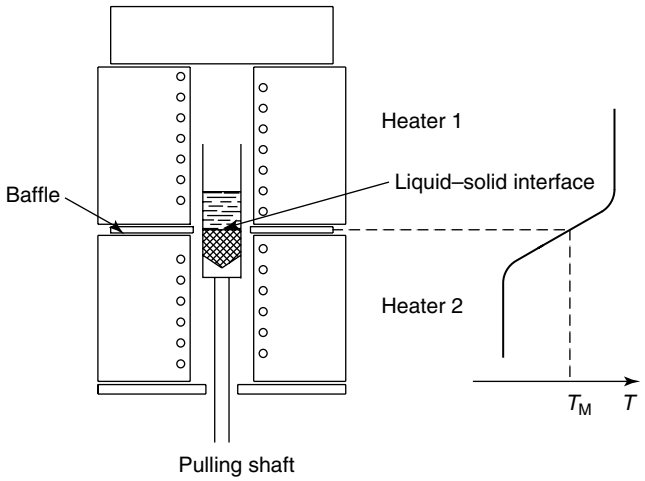

Figure 7. Vertical Stockbarger configuration and related temperature profile. (Reproduced from G. Behr *et al*., 2000, with permission from Springer-Verlah GmbH. © 2000.)

of purified argon or helium and in some cases high vacuum conditions must be realized in the growth chamber.

CZ growth by crystal pulling from a melt contained in a crucible is a widely used method in research and industry. It is schematically illustrated in Figure 8. The apparatus consists of the following components: (i) a crucible, which can be rotated, (ii) the upper pulling shaft, which enables a rotation and has a stable velocity, (iii) the heater, and (iv) a vacuum containment. Seed crystals are used if available. The choices of the crucible material and the atmosphere have to meet the same requirements as discussed for the Bridgman method. To avoid contamination from crucible material CZ growth of magnetic materials is often carried out using a tri-arc or tetra-arc configuration with a water-cooled copper hearth in an atmosphere of argon. It can also be applied in a scull-like configuration, where a

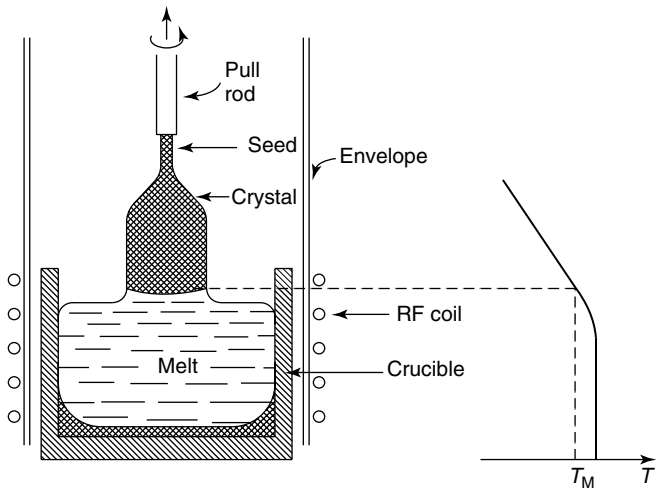

Figure 8. Czochralski method of the crystal growth and related temperature profile. (Reproduced from G. Behr *et al*., 2000, with permission from Springer-Verlah GmbH. © 2000.)

skull of unmelted material remains between the cold-copper hearth and the melt. To avoid any contact with the crucible for refractory and highly reactive materials like rare earths and rare-earth-containing compounds, radiofrequency (RF) inductive heating in a Hukin-type copper cold crucible is also utilized.

A common procedure to allow the growth of only one crystallite in all pulling methods is the bottleneck technique. Starting from a polycrystalline seed, the diameter of the growing crystal is reduced to a minimum followed by enlarging the diameter to the normal rod size. In the narrow part of the crystal only a few or sometimes one single crystallite can propagate. Otherwise, a growth process without seed can be performed starting with the polycrystalline material, which provides many small seeds for further growth.

Zone melting originally described by Pfann (1952) for purification of metals has been widely developed and used as a commercial growth technology in the past 50 years. In this method, only a relatively narrow zone of a cylindrical rod is molten and the zone travels from one end of the rod to the other one. It can be realized as a horizontal or vertical arrangement in containers or as crucible-free zone melting (FZ). The FZ method is normally preferred for refractory and highly reactive materials for which no crucible material is available.

A variety of zone melting techniques evolved with horizontal and vertical configurations, single and multiple heating zones (Pfann, 1988). The most common technique is to use a long horizontal crucible or boat to contain the material. A seed crystal is placed at one end and a molten zone is produced so that the end of the seed is just melted. The zone is then traversed away from the seed along the

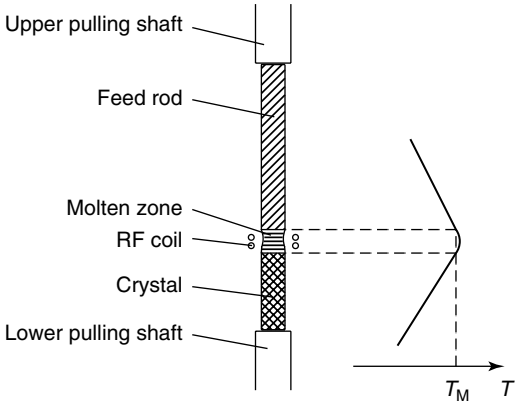

Figure 9. Floating zone (FZ) method and related temperature profile. (Reproduced from G. Behr *et al*., 2000, with permission from Springer-Verlah GmbH. © 2000.)

length of the boat. This method can lead to contamination from the boat and thus the system has been turned through 90° to give a vertical FZ. In this case, the molten material is prevented from falling down by surface tension. The molten zone is traversed up or down along the rod. In this form, it is a crucible-less technique of crystal growth and is called *floating zone technique* schematically shown in Figure 9.

There are different possibilities to heat the zone. In the past, the heat was often supplied to the molten zone using specially shaped RF coils. Apart from RF heating, halogen lamps, arc discharge, electron beam, and laser heating have been used in FZ techniques (Feigelson, 1985). In the case of RF heating, the coils are usually a single or double turn and the electromagnetic field couples directly to the material. This makes it easy to design different coil forms to obtain the correct shape of the growing interface so that a proper crystal is obtained. The main limitation of the RF heating is the necessity of electrical conductivity of the melts. For some materials with insufficient electrical conductivity at low temperatures a preheater is often used.

The use of arc discharge or halogen lamps has been very successful in growing plenty of different materials. Either an elliptical horizontal or vertical optical mirror configuration can be used, where the arc or halogen lamp is at one focus of the mirror and the FZ is at the other one. The growth usually proceeds inside a transparent holder so that gas supplies can be used to operate under inert, oxidizing, or reducing atmosphere. Thus, this method can be summarized as a moving melt zone method in which the crystal rotation is optional. It is distinguished by a small melt volume and usually relatively large temperature gradients.

Commercial systems with optical (radiation) heating specially designed for FZ growth are available only from the following companies: NEC (single- and double-ellipsoid mirror furnaces), Crystal Systems, Inc. (four-mirror furnace) in Japan, MPEI (open vertical ellipsoid configuration with aperture) in Russia, GERO in Germany and Cyberstar in France (single- and double-ellipsoid mirror furnaces). Mainly elliptical mirrors are used to focus the light from one or several lamps onto the sample. The light sources mostly used are either tungsten halogen lamps of 0.3–1.5 kW maximum power or xenon arc discharge lamps up to 10 kW for high power requirements. In all cases, lamp bulbs made of fused quartz are employed.

A disadvantage of mirror furnaces is the fact that temperature measurements during growth are quite difficult. A noncontact measurement of the sample temperature by pyrometer is virtually impossible due to the much higher level of light reflected versus radiation emitted from the sample. Feedback control of image furnaces is quite uncommon; in the case of FZ growth, the zone is usually controlled by visual observation of the sample and manual regulation of the power.

Three typical apparatuses for FZ growth are shown in Figure 10. The shape and stability of the molten zone play an important role in FZ melting. The molten zone is hanging free, between the two rods, and its length is limited to approximately the rod diameter for diameters up to 10 mm used for crystal growth of most magnetic materials. To maintain a convex solid/melt interface, which is necessary for proper grain selection (especially for the growth of peritectic melting compounds with small growth velocities, see also Section 4.7), the optical systems are preferable to RF heating due to the strong energy absorption at the surface. The RF power, by contrast, penetrates into the material depending on its electrical resistivity and the frequency of the RF generator applied.

In case of intermetallic compounds special attention has to be paid to the gas purity in the growth chamber. A common way is the use of purifying systems with heated titanium, zirconium, or alloys of these elements. The gas purity can be controlled by measuring cells with ZrO_2 as sensor material.

Two special features connected with the crystal growth of magnetic materials, especially with rare-earth-containing compounds, silicides and borides, should be mentioned.

First, the purity of the constituent components plays a key role in the growth process especially of intermetallic compounds because oxide particles hinder the grain selection very severely. The metals used for preparation of magnetic materials often do not compete with the high purity of semiconductors. Special attention has to be paid for the purity of rare-earth elements. In some commercially available materials undefined oxygen contents are present and sometimes up to about 1% tantalum is present as a relic of the preparation process. The choice of the appropriate supplier is of principal significance. In some cases purification

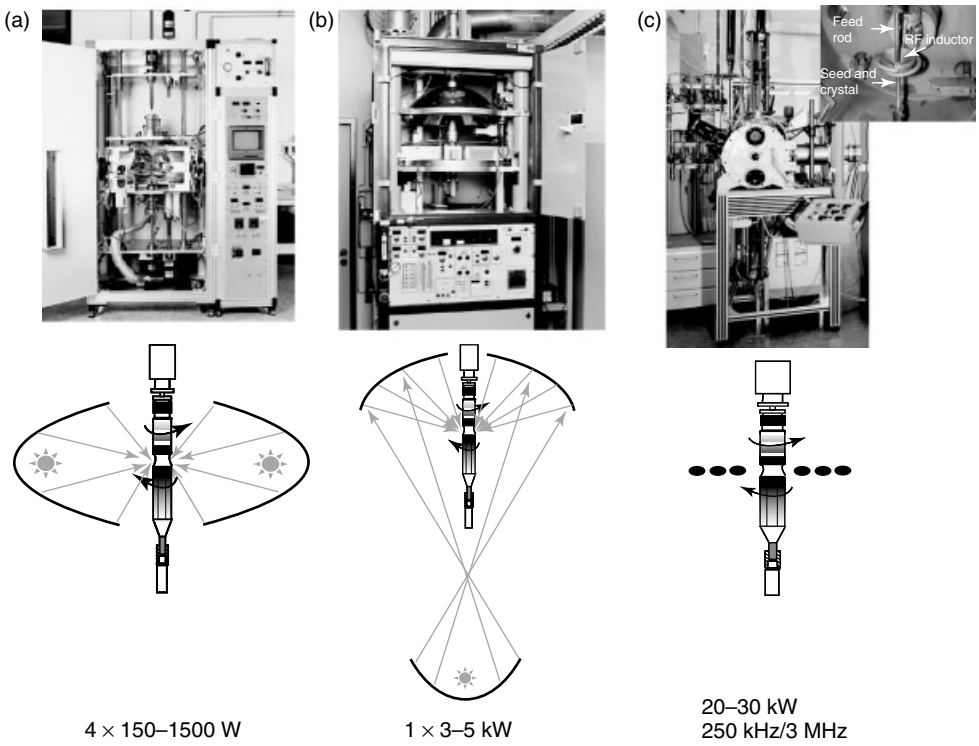

Figure 10. FZ crystal growth equipment with the quadro-mirror horizontal optical heating (CSI Japan) (a), double mirror vertical optical heating (MPEI Moscow) (b), and horizontal RF heating (IFW Dresden) (c).

by distillation or electromigration is possible and should be applied. The best results in growing of special rare-earth-containing intermetallic compounds were achieved using rare earths from the noncommercial supplier Ames Laboratories.

Secondly, silicothermic or borothermic reactions of oxygen traces with silicon or boron can arise. The reactions have the desired effect of melt refining but also shift the composition and therefore must be taken into account during preparation. The consideration of the oxygen content in materials is described, for example, in Behr *et al*. (1985).

The silicothermic and borothermic reactions of all oxide traces in the materials follow the scheme

$$\mathrm{MeO}_x + (2 + x/2)\mathrm{Si} = \mathrm{MeSi}_2 + x/2\mathrm{SiO}_2 \quad \text{or}$$

$$\mathrm{MeO}_x + (2 + 2x/3)\mathrm{B} = \mathrm{MeB}_2 + x/3\mathrm{B}_2\mathrm{O}_3 \qquad (2)$$

$$\mathrm{SiO}_2 + \mathrm{Si} = 2\mathrm{SiO} \quad \text{and} \quad \mathrm{B}_2\mathrm{O}_3 + \mathrm{B} = 3\mathrm{BO} \qquad (3)$$

Complete evaporation of SiO takes place in vacuum at temperatures above 1000 °C and for BO above 1500 °C. During growth in an argon atmosphere these temperatures change to 1400 °C and about 1600 °C.

One typical preparation route of starting materials and of feed rods for FZ melting and the TSFZ method is the follows:

First, special attention has to be paid to obtain suitable starting materials. This includes an overall purity not less than 3N and especially a low content of oxygen (often not specified by manufacturers). To reduce the oxygen contamination for rare-earth elements bulk material is favorable.

Second, the materials must be stored and handled under clean conditions mainly in glove boxes operating with purified argon, and all melting processes should proceed under purified argon or helium gas.

The alloying of compounds is possible in arc-melting facilities. Compounds with less reactive components can be melted in crucibles, too. For crystal growth by FZ or by TSFZ techniques feed rods of good homogeneity are necessary. The most effective method to obtain such rods is the use of a Hukin-type cold crucible equipped with a casting mould (see Figure 11). In this case the elements and the hot melt do not contact the crucible but levitate inside the water-cooled crucible. The melt is very effectively stirred by the electromagnetic force generated from the coil connected with HF generator (in the shown case 100 kHz, 50 kW, Hüttinger, Germany). After alloying the melt is cast into a water-cooled copper mould with 6 or 8 mm diameter. As long as the melt crystallizes radially, no macrosegregation is observed and the feed rods exhibit excellent homogeneity along the axis.

Figure 11. Hukin-type cold crucible equipped with a casting mould.

4 CRYSTAL GROWTH OF SELECTED MAGNETIC MATERIALS

4.1 Crystal growth of soft magnetic alloys

The free energy of a ferromagnetic crystal depends on the orientation of the spontaneous magnetization relative to the crystal axis. This phenomenon is known as the *magnetocrystalline anisotropy* and is displayed in the orientation dependence of the magnetization. Therefore, single crystals of magnetic materials are necessary to investigate this dependence in detail.

4.1.1 Pure metals

The 3d metals Co, Ni, Fe, and 4f metals Gd, Tb, Dy, and Ho (highest magnetic moment) are typical representatives of soft magnetic metals.

Both pure cobalt and nickel melt below 1500 °C and do not exhibit crystallographic phase transformations above 450 °C. So crystal growth can be realized directly from the melts in crucibles by Bridgman technique, CZ growth, and by zone melting in crucibles or as FZ melting.

Nickel and cobalt had been grown using Bridgman–Stockbarger technique by da Andrade and Henderson (1951) and by Šestak (1957). Alumina crucibles were used and the growth process was carried out in a hydrogen-containing atmosphere.

Better crystal perfection can be achieved by using methods with a free growing surface. Cobalt and cobalt-rich Co–Fe alloy crystals were grown by Bachmann and Wakiyama (1975) using CZ growth under argon atmosphere. The crucible consisted of alumina and was surrounded by a RF heated carbon susceptor isolated by an alumina shield. The equipment was installed in a quartz tube with flowing argon atmosphere ($1.5\,\mathrm{l\,min^{-1}}$) purified by a Ti getter. A ⟨0001⟩ oriented seed was used for pulling Co single crystals with a rate of $2.5\,\mathrm{cm\,h^{-1}}$ using the bottle-neck technique. The grown crystals were several centimeters long and up to 1 cm in diameter. To maintain the hcp cobalt structure a fast cooling rate of about $20\,\mathrm{K\,min^{-1}}$ in the vicinity of the martensitic transformation M_s (420 °C) was applied. From the same author (Bachmann, 1973) an apparatus was designed for electron beam FZ growth in a vacuum of 2×10^{-8} mbar. The apparatus can be used at a Bridgman or CZ mode, too.

Hayashi, Ono and Komatsu (1978) reported the growth of cobalt single crystals from 4N cobalt material by an electron beam FZ method using pulling rates of $0.4–0.7\,\mathrm{mm\,min^{-1}}$. About 70% of the samples were striation free single crystals the rest had one or two grain boundaries along the growth axis. By spontaneous nucleation and grain selection two preferential directions of crystallization were observed, along the ⟨0001⟩ axis and another about 60° inclined to the ⟨0001⟩ axis. As reported, striation free crystals could be grown at slow growth rates $<1\,\mathrm{mm\,min^{-1}}$ only. The same authors reported the growth of nickel single crystals by the FZ method (Hayashi and Komatsu, 1979). They used 4N nickel rods with a diameter of 5 mm as starting material for FZ growth with RF heating under flowing argon atmosphere and in vacuum with electron beam heating. The pulling rates were chosen to 0.2 and $1\,\mathrm{mm\,min^{-1}}$. With both heating methods two preferred orientations of the crystals near ⟨100⟩ and near ⟨111⟩ were found. The deviation from these orientations is slightly more severe in using the electron beam FZ method.

As concluded from the Fe–Si phase diagram (Figure 1) after crystallization from the melt pure iron exhibits two phase transitions that renders it impracticable to produce high-quality single crystals directly from the melt. But, iron is one of the very well investigated examples for preparation of highly perfect single crystals by a strain-annealing technique. For the growth high-purity iron is required, which can be achieved by the following tedious procedure:

Vapor-deposited high-purity iron was prepared in several steps with special care to avoid all electrically active elements. At first, commercial iron powder was dissolved in hydrochloric acid to prepare ferrous chloride. Next, the solution was evaporated and $FeCl_2 \cdot 4\ H_2O$ crystals were formed, which were subsequently dehydrated at 773 K to $FeCl_2$. The impurity content of nickel is high and the product has a low bulk density. The next step is vacuum distillation over lumpy sponge iron to separate the nickel from the ferrous chloride. The evaporation temperature of $FeCl_2$ is 973 K, the reduction temperature of sponge iron is 1023 K and the condensation temperature is 673–773 K. The separation of nickel on the sponge iron is due to the more negative free reaction enthalpy of $FeCl_2$ compared to $NiCl_2$, and results in Ni contents <1 wt ppm. Vacuum was used to increase the evaporation rate of $FeCl_2$ and to ensure a clean atmosphere. This process step, combining distillation with a heterogeneous chemical reaction, is referred to as *exchange distillation*. It leads to condensed $FeCl_2$ with a high density and permits a larger amount of material to be used and a more constant evaporation rate in the subsequent reaction to be achieved.

Ferrous chloride is proportioned by sublimation within a temperature range of 873–950 K from a container made of pure iron. The extrapolation of the vapor pressure of the compound, which is known between 950 K (melting point) and 1285 K (boiling point), gives vapor pressures of about 100–1500 Pa within the temperature range of 873–950 K. To ensure practical deposition rates of pure iron of 28–280 nm s^{-1}, a higher amount of ferrous chloride can be offered by increased evaporation temperatures or by increasing the evaporation rate. The reduction of the ferrous chloride was performed with hydrogen in a quartz tube of 80 mm diameter. The iron produced during the reduction process was deposited on a resistance-heated pure iron wire of 1 mm diameter.

The typical experimental conditions were described in Weise and Owsian (1976). The rods of up to 15 mm diameter and up to 300 mm length are compact. The measured density was 7875.5 kg m^{-3}, which is very close to the theoretical value. The optimum conditions are achieved for deposition rates greater than 0.14 µm s^{-1} and deposition temperatures above 1273 K. The residual resistivity ratio $r_{293\,K}/r_{4.2\,K}$ is about 3000. More details about the morphology and the defect structure as well as the properties like density, coercivity, and the residual resistivity ratio have been given by Weise and Owsian (1976). The impurity content of the prepared highly pure Fe was measured by spark source mass spectrography, gas hot extraction, and carrier gas fusion methods. The main impurity elements (with contents in wt ppm) were: Ta (13), Cu (5), Ni (2), Mo (<2), Ga (1), Zr (1), C (10), O (9), N (6), H (<6), and Cl (2). All other trace elements were below 1 wt ppm.

The crystal growth of ultrahigh-purity and doped iron by the strain-anneal technique contains the following process steps:

1. The deposited rods of high-purity (or doped) iron were subjected to a FZ process.
2. The zone floated material 13 mm in diameter contains large elongated grains which don't allow homogeneous deformation. Therefore, the material was annealed around the $\alpha-\gamma$ transformation temperature to destroy this microstructure. By radius hammering with one intermediate annealing procedure (840 °C for 2 h followed by quenching in water) it was formed to 4-mm-diameter rods with a degree of plastic deformation of about 70%.
3. The rods were annealed for recrystallization to a fine grained microstructure in a horizontal quartz furnace at 800 °C under purified hydrogen atmosphere.
4. The optimum critical deformation, about 1.5% for pure iron up to 3% for Ni-doped iron (enhancement of deformation energy in the grains), was realized by stretching at room temperature with a constant strain rate of about 10 µm s^{-1}.
5. The last step is the crystal growth in a temperature gradient, which is realized in a vertical tube furnace with a hermetic outer quartz tube and flowing argon or purified hydrogen atmosphere. The prepared 4-mm-diameter iron rod is placed inside the heated copper tube and heated to maximal 890 °C. The feed is pulled town through the temperature gradient of maximal 50 K cm^{-1} with a pulling rate of about 10 mm h^{-1}.

With this technique it is possible to grow single crystals from pure iron with a length of 100 mm and a diameter of 4–6 mm. However in many cases the rod contains–two to six crystals in a bamboo like morphology. By adding 10–20 ppm of nickel the growth becomes less perfect, but 200–500 ppm Ni stabilize the growth. The effect of different types of substitutional and interstitial impurities on the deformation created microstructure as well as the mobility of grain boundaries is different. The different behavior during grain growth is much more dependent on the microscopic dislocation substructure than on the macroscopic microstructure. In all cases a different amount of misoriented parasitic grains is observed, the origin of which is mainly the rod surface. The lowest density of parasitic grains was found in carburized nickel doped iron crystals.

Shimizu *et al*. (2001) discovered superconductivity in ε-iron transformed from α-iron under a pressure of 16–30 GPa. In their study they could not find a superconducting transition to zero values in 'normal' iron. Only after using pure iron like in the above described single-crystal growth experiments the superconducting transition to zero resistivity at about 2 K

could be demonstrated as described by Jaccard *et al*. (2002) and Holmes *et al*. (2004).

Crystals of most of the transition-metal elements were grown by chemical vapor transport, too. Due to their small dimensions these crystals are of value only for special purposes and a detailed description will not be given.

Single crystals of rare-earth elements with high purity and perfection are difficult to grow due to two main reasons:

1. The rare-earth elements react with oxygen and with practically with all crucible materials.
2. The magnetic rare-earth elements dysprosium, gadolinium, and terbium exhibit a phase transformation from a high-temperature phase with cubic bcc crystal structure to a low-temperature phase with hexagonal hcp structure. Because this transition takes place at temperatures less than 100 K below the melting point this transformation cannot be avoided by rapid quenching.

In the past there were many attempts to grow pure single crystals of rare earths. So Behrendt in 1958 reported the growth of Dy crystals (Behrendt, Legvold and Spedding, 1958), by a Bridgman technique under vacuum atmosphere in a tantalum crucible. The problem is the large amount of tantalum from the crucible material incorporated in the crystal. The Dy–Ta phase diagram (see Massalski, Okamoto, Subramarian and Kacprzak, 1990) displays a significant solubility of Ta in the rare-earth melt. All grown crystals exhibit many grains, what could be attributed to the fcc to hcp phase transition at high temperature. Nevertheless, samples cut from individual grains could be used for measurements of anisotropic magnetic properties.

Really large single-crystalline grains were obtained by Nigh (1963) using the following strain-anneal method. The sample was melted under argon in an arc furnace. The resulting 8-mm-thick and 30-mm-diameter buttons had a high degree of crystal orientation. Grain growth was accomplished by annealing the button at temperatures somewhat below the melting point of the respective rare earths. The annealing took place in a vacuum furnace hanging at a thin tungsten wire. It was possible to anneal Gd and Tb in vacuum, but an argon atmosphere was required for Dy and Ho to reduce distillation. To illustrate this procedure we report here results on Gd. The largest crystals were obtained by annealing at 1050 °C for 12 h followed by an increase of temperature by 50 K increments every 12 h up to a maximum of 1200–1225 °C (the fcc/hcp phase transition temperature of Gd is 1235 °C). The best results were obtained with the specimen near the top of the heater in a temperature gradient of approximately 25 K cm^{-1}. A similar technique has applied in growing Dy crystals. For Dy and Ho annealing in a temperature gradient for one single temperature level was applied.

Sousa *et al*. (1985) reported measurements on zone refined crystals with dimension of $10 \times 1 \times 1$ mm^3 and with a resistivity ratio of 15. The crystals were obtained by a FZ process followed by a zone annealing process at a temperature below the solid-state phase transition by Fort (1991a). The author describes the FZ growth in an ultrahigh vacuum (UHV)-rated RF induction heating FZ facility reconstructed from a commercially available high vacuum RF FZ apparatus (Metals Research Ltd., Royston). The starting materials are obtained from Rare Earth Products Ltd. (REP), Widnes, UK, or the Materials Preparation Center, Ames Laboratories, Iowa State University, USA. The rods for float zoning were cast in a cold boat system using RF heating, which is capable of melting metals under UHV conditions (Fort, Jones, Beaudry and Gschneidner, 1981). The FZ growth was carried out under an argon atmosphere purified to better than 1 ppm of all impurity gases. The sample was also degassed in vacuum under UHV conditions by running a hot (not molten) zone along the rod. The growth of Dy crystals from REP starting metal, which was further purified by resublimation under UHV conditions, was carried out under 0.7 bar argon with a growth rate of 42 mm h^{-1} followed by an annealing pass (with reduced power) at approximately 1470 K. Overall, however, any strain induced by cooling through the bcc–hcp transformation at 1653 K did not significantly impair the crystal quality. Crystals obtained from attempts using metal as received from REP were less successful as they are smaller and generally showed considerable substructure on X-ray examination. By the same procedure Ho crystals were grown without subsequent annealing pass.

Fort (1991b) reported crystal growth attempts by solid-state recrystallization on rare-earth metal elements and rare-earth alloys, which adopt the hexagonal close-packed crystal structure. The procedure involved annealing ingots, which had been strained by fast cooling from the melt. A heat treatment recipe of annealing for at least 40–60 h at a temperature equivalent to 85% of the absolute melting temperature or 95% of any hcp–bcc transformation temperature (whichever was the lower one) was deduced to lead to the most extensive grain growth. The potential advantages of solid-state crystal growth over melt growth for these materials are: the experimental simplicity, the improved quality of crystals prepared, and the lower volatilization losses for materials with high vapor pressure.

4.1.2 Fe-based alloys

One of the most important magnetic materials is the widely used electrical steel or silicon electrical steel. It is an iron-based steel containing from 3- to 4.5-wt% silicon. It is usually used in the form of cold-rolled strips less than 2 mm thick, which are called *laminations* when packed together.

The assembled laminate cores are used in transformers and stators and rotors of electric motors. To improve the magnetic properties grain-oriented electrical steel is used. Therefore, it is of interest to study the electrical and magnetic properties of the corresponding single crystals.

As far as the silicon concentration in this alloy is >1.9 wt% Si the δ to γ to α transformations of the pure iron disappear and a direct crystallization from the melt becomes possible (see Fe–Si phase diagram Figure 1). Therefore, all methods of crystal growth from the melt can be used to obtain single crystals.

Ringpfeil, Wiesinger and Fischer (1962) reported the growth of Fe-(2.5–4)wt%Si crystals by the Bridgman technique in alumina crucibles under flowing hydrogen (ca. 3 mbar pressure) with growth rates from 10 to 60 mm h^{-1}.

Vaněk and Kadečková (1979) reported the RF (360 kHz) FZ growth of Fe-3wt%Si crystals 13 mm in diameter in a hydrogen atmosphere. The molten zone was moved downwards at rates of 7–120 mm h^{-1} with (30 rpm) and without rotation of the lower part. Striations from inhomogeneities in the silicon concentration start to form at rates >21 mm h^{-1} and are well developed at high growth rates. The formation of striations does not depend on rotation of the feed rod. Vaněk, Kadečková, Jurisch and Löser (1983) achieved Fe-3wt%Si crystals 7 mm in diameter by FZ melting with both electron beam and RF heating with growth rates of 60 and 120 mm h^{-1}.

Ringpfeil, Wiesinger and Fischer (1962) reported the growth of Fe–Ni and other soft magnetic alloys. Since the Fe–Ni phase diagram displays a solid solution of the γ-Fe(Ni) phase above about 7 up to 100 mol% Ni (see Massalski, Okamoto, Subramarian and Kacprzak, 1990) this phase can easily be grown from the melt by a Bridgman technique using alumina crucibles.

More detailed orientation dependent magnetic measurements are shown in standard textbooks (Kneller, 1962).

4.2 Crystal growth of hard magnetic alloys

4.2.1 FePt, CoPt, and FePd compounds with large magnetocrystalline anisotropy

Ferromagnetic ordered alloys with the $L1_0$ crystal structure, FePd, FePt, and CoPt, have drawn much attention as promising materials for ultrahigh dense magnetic storage media due to their large magnetocrystalline anisotropy (Maykov *et al*., 1989). The anisotropic crystal field in single crystals causes a large magnetocrystalline anisotropy constant K_u as well as anisotropic magnetostriction. Since K_u is a measure for the achievable recording data density its precise determination is practically important. Multivariants, twin boundaries, and residual stress, surface and interface anisotropies cause barriers to evaluate the precise K_u for $L1_0$-type Fe–Pt thin films and nanoparticles. Therefore, $L1_0$-type bulk single crystals in a single-variant state are necessary for the accurate evaluation of K_u of these ordered alloys. Furthermore, the investigation of the temperature dependence of the magnetocrystalline anisotropy is meaningful for heat-assisted magnetic recording techniques, because the switching field governed by K_u can be reduced by heating during writing processes.

In order to investigate the magnetic properties associated with crystallographic orientations, single crystals of FePd and CoPt have been grown by the Bridgman technique (Maykov *et al*., 1989; Tanaka, Ichitsubo and Koiwa, 2001) and the FZ method under a purified He atmosphere (Shima *et al*., 2004a,b, 2005). Single crystals of $Fe_{60}Pt_{40}$ have been grown with the FZ method as well (Inoue *et al*., 2006). The equiatomic phases undergo a transition from a disordered fcc to an ordered tetragonal $L1_0$ phase. Since the symmetry of the ordered phase is lower than that of the disordered one, there are three variants of the ordered phase. In the absence of any external field, all three variants are formed with an equal probability, resulting in a twinned structure. The application of external stress or a magnetic field during the ordering processes leads to the preferential formation of a favorably oriented variant (Tanaka, Ichitsubo and Koiwa, 2001; Yermakov and Maykov, 1989).

Accordingly, single-variant $Fe_{48}Pd_{52}$ single crystals were prepared by a compressive stress method (Shima *et al*., 2004a). Single-crystalline samples with disordered fcc structure were received after homogenization of FZ grown crystals at 1473 K for 24 h in an evacuated quartz tube and quenching into ice water. The crystalline orientation was determined by the electron backscattering pattern method and the back reflection Laue method. The disordered fcc $Fe_{48}Pd_{52}$ single crystal was cut into a cube with six crystallographic equivalent {001} planes. The heat treatment for ordering under the compressive stress along the [100] direction was carried out using a Mo implement. The specimen was fixed between Mo plates and the temperature was increased up to 973 K followed by a slow cooling with the rate of 3 K min^{-1}. The difference in the thermal expansion coefficients between the Mo plate and the specimen causes the compressive stress. The back reflection Laue patterns for the ordered $L1_0$ $Fe_{48}Pd_{52}$ exhibited clear spots indicating that the *c* axis is selectively aligned.

Figure 12 shows the magnetization curves along the *c* and *a* axis in the ordered $L1_0$ $Fe_{48}Pd_{52}$ at 4.2 K (Shima *et al*., 2004a). The easy axis of magnetization is the *c* axis. On the contrary, there is no difference in the magnetization curves along the [100] and the [010] directions of the disordered fcc $Fe_{48}Pd_{52}$. The uniaxial magnetocrystalline anisotropy

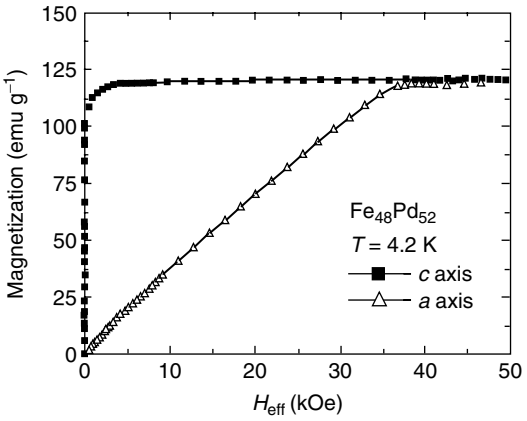

Figure 12. The magnetization curves of $L1_0$ $Fe_{48}Pd_{52}$ showing the difference between the *c* and the *a* axis. (Reproduced from Shima *et al*., 2004, with permission from Elsevier. © 2004.)

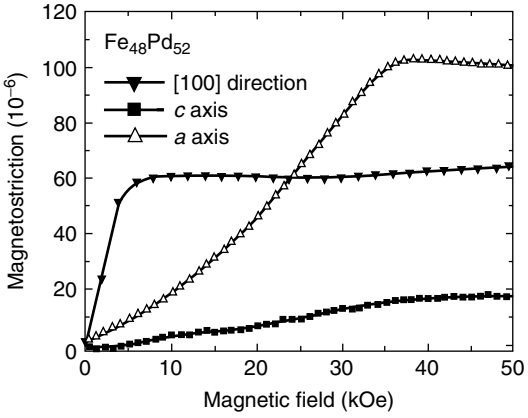

Figure 13. The longitudinal magnetostriction curves along the *c* and the *a* axis in the $L1_0$ $Fe_{48}Pd_{52}$ and the [001] direction in fcc $Fe_{48}Pd_{52}$. (Reproduced from Shima *et al*., 2004, with permission from Elsevier. © 2004.)

constant at 4.2 K becomes $K_u = 2.5 \times 10^6\,\mathrm{J\,m^{-3}}$, but there is some variance in the values of various authors (cf. Yermakov and Maykov, 1989; Shima *et al*., 2004a). The uniaxial magnetocrystalline anisotropy becomes weaker at higher Pd concentrations. As shown in Figure 13 the longitudinal magnetostriction increases with external magnetic field in analogy with the magnetization curves (Shima *et al*., 2004a).

The value of the magnetostriction constant λ_{100} in the disordered fcc $Fe_{48}Pd_{52}$ is 60×10^{-6}. In the ordered $L1_0Fe_{48}Pd_{52}$ sample the value $\lambda_a = 100 \times 10^{-6}$ along the *a* axis is larger, whereas the value of $\lambda_c = 20 \times 10^{-6}$ along the *c* axis is smaller than λ_{100}.

Single crystals of $Co_{100-x}Pt_x$ ($x = 45$, 50, and 55) were similarly prepared by the FZ method (Shima *et al*., 2005). The heat treatment for homogenization was carried out at 1473 K for 48 h. The $L1_0$-type $Co_{100-x}Pt_x$ in a single-variant state was obtained by a heat treatment under uniaxial compressive stress. A compressive stress of 20–25 MPa was applied along one of the ⟨001⟩ directions in the fcc-type $Co_{100-x}Pt_x$. The *c* axis, which becomes the easy magnetic axis, aligns parallel to the compressive stress direction. Both the *a* and *c* axes elongate with increasing Pt concentration, whereas the axial ratio *c*/*a* has a minimum value of 0.976 at $x = 50$, resulting in the largest tetragonal distortion (Shima *et al*., 2005). The magnetization curve along the *c* axis is immediately saturated under an effective magnetic field of less than $80\,\mathrm{kA\,m^{-1}}$ (1 kOe). In contrast, a very high magnetic field of 1.11×10^5 kA m^{-1} (140 kOe) is necessary for saturation along the *a* axis. The coercive force H_c observed in the magnetization curves along the *c* and *a*-axes are, respectively, about $32\,\mathrm{kA\,m^{-1}}$ (0.4 kOe) and $64\,\mathrm{kA\,m^{-1}}$ (0.8 kOe), and much smaller than that in the multivariant $L1_0$-type Co–Pt alloys. The uniaxial magnetocrystalline anisotropy constant K_u at 298 K exhibits the largest value of $4.5 \times 10^6\,\mathrm{J\,m^{-3}}$ for $x = 50$.

$L1_0$-type $Fe_{60}Pt_{40}$ single crystals in the single-variant state have been prepared in a similar way (Inoue *et al*., 2006). It should be noted that $Fe_{50}Pt_{50}$ bulk single crystals in a single-variant state are difficult to obtain because $Fe_{50}Pt_{50}$, probably the most desirable substance for recording media, has a high ordering temperature, and hence preparation at high temperature is necessary, which induces recovery and recrystallization.

Large magnetocrystalline anisotropy between the magnetization curves along the *c* and *a* axes is observed in the single-variant $Fe_{60}Pt_{40}$ single crystals. The magnetization curve along the *c* axis is easily saturated below $398\,\mathrm{kA\,m^{-1}}$ (5 kOe), while the saturation along the *a* axis is achieved above the high magnetic field of about 8.75×10^3 kA m^{-1} (110 kOe). The values of the coercivity H_c along the *c* and *a* axes are about $36\,\mathrm{kA\,m^{-1}}$ (0.45 kOe) and $28\,\mathrm{kA\,m^{-1}}$ (0.35 kOe), respectively. The value of H_c along the *c* axis is much smaller than that of $L1_0$-type Fe–Pt bulk alloy in the multivariant state, and also than in thin films and the nanoparticles. The values of anisotropy constants, at 5 K are evaluated to be $K_1 = 7.4 \times 10^6\,\mathrm{J\,m^{-3}}$, $K_2 = 0.13 \times 10^6\,\mathrm{J\,m^{-3}}$, and $K_u = 6.9 \times 10^6\,\mathrm{J\,m^{-3}}$, respectively (Inoue *et al*., 2006). The present values of $K_1 + K_2$ and K_u are larger than those of $L1_0$-type FePd (Shima *et al*., 2004b) and CoPt (Shima *et al*., 2005) single crystals in the single-variant state. That is, the $L1_0$-type $Fe_{60}Pt_{40}$ alloy has large magnetocrystalline anisotropy constants despite the deviation from the equiatomic composition. The second-order magnetocrystalline anisotropy constant K_1 and the uniaxial magnetocrystalline anisotropy constant K_u monotonically decrease with increasing temperature, while K_2 is almost independent of T. However, both K_1 and K_u keep a large value up to 298 K, being $6 \times 10^6\,\mathrm{J\,m^{-3}}$ and $5.5 \times 10^6\,\mathrm{J\,m^{-3}}$, respectively.

Finally, we remark that apart from these compounds with large magnetocrystalline anisotropy prospective for magnetic storage media, single crystals of invar alloys $Fe_{75}Pt_{25}$, $Fe_{72}Pt_{28}$, and $Fe_{72}Ni_3Pt_{25}$ have also been grown by the Bridgman–Stockbarger technique. Elastic constants of the compounds in the presence of an external magnetic field have been determined for single-crystalline samples with the ultrasonic pulse echo technique (Kawald *et al*., 1989).

4.2.2 *Crystal growth of $R_2Fe_{14}B$ compounds for high-performance permanent magnets*

Compounds of $R_2Fe_{14}B$, where R stands for rare earths including Y, have attracted much attention after discovering the outstanding permanent magnetic properties in ternary Nd–Fe–B alloys, which are based on the formation of a new phase $Nd_2Fe_{14}B$ (Sagawa *et al*., 1984). A brief overview on crystal growth activities of $R_2Fe_{14}B$ compounds and their intrinsic properties determined is given by Franse and Radwanski (1996).

Small single-crystalline samples of $Nd_2Fe_{14}B$ were simply obtained by Hukin-type cold-crucible induction melting of alloys from high-purity elements (Nd: 99.9%, Fe: 99.99%, B: 99.99%). Crystals (0.3 mm in diameter) were observed to grow in shrinkage cavities obtained after slow cooling of the melt under vacuum (Givord, Li and Moreau, 1984). From the intensities of Laue photographs of these single-crystalline samples the tetragonal structure of the $Nd_2Fe_{14}B$ phase was revealed. In this structure, Nd atoms are distributed on two crystallographic sites of low symmetry, whereas Fe atoms occupy six different sites. Large single crystals for studies of fundamental magnetic properties are difficult to grow for the following reasons: (i) the compound does not melt congruently (cf. Figure 4 in Section 2), (ii) the rare earths have a high affinity to oxygen and their melts are quickly covered by an oxide film, and (iii) the melt reacts with most crucible materials. In the cold-crucible method the melt is levitated by inductive forces within the split water-cooled Cu-crucible and melt-crucible contact is effectively avoided. Indeed, Givord, Li and Delabathie (1984) succeeded in growing 3-cm-long $Nd_2Fe_{14}B$ and $Y_2Fe_{14}B$ bars of 1 cm^2 cross section by a CZ method from a Nd-rich $Nd_{15}Fe_{77}B_8$ melt in a Hukin-type cold-crucible facility (cf. Section 3.3). The values of the magnetic ordering temperatures, 573 K for $Y_2Fe_{14}B$ and 595 K for $Nd_2Fe_{14}B$, are similar. From the $Nd_2Fe_{14}B$ crystal a cube of $4.5 \times 4.5 \times 4.3$ mm^3 was cut for magnetization measurements. As shown in Figure 13 the large uniaxial anisotropy observed in $Nd_2Fe_{14}B$ at 300 K favors the *c* axis (Givord, Li and Delabathie, 1984). However, below 135 K, an easy direction is stabilized, which is at an angle θ with respect to the *c* axis (inset to Figure 14). At higher temperatures, the reorientation of the magnetization toward the *c* axis results from the relative decrease of crystal-field interactions with respect to exchange interactions, which favor a collinear arrangement of Nd and Fe moments.

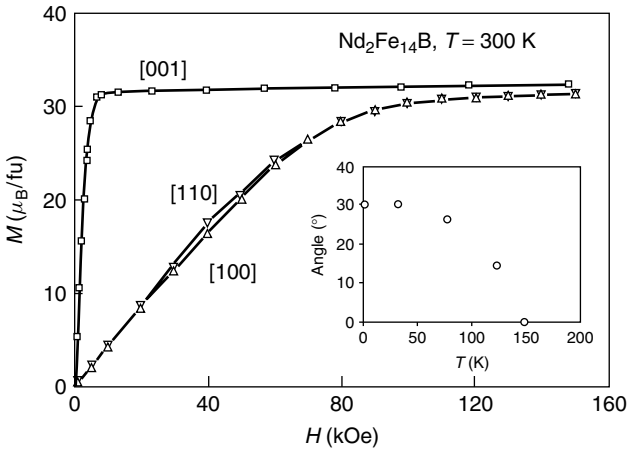

Figure 14. Field dependence of the magnetization at 300 K in $Nd_2Fe_{14}B$. Inset: temperature dependence of the angle Θ between the easy magnetization direction and the *c* axis. (Reproduced from Givord *et al*., 1984, with permission from Elsevier. © 1984.)

More details about the growth of $Nd_2Fe_{14}B$ single crystals between 5 and 10 mm diameter and >1 cm length by the cold-crucible CZ method are provided by Swets (1986). Special care was devoted to avoiding oxygen. The crucible was contained in a quartz walled chamber flushed with high-purity Ar, which was further purified by passing over Ti at 800 °C and through a Ga–In–Al bubbler at room temperature. Even under these circumstances an oxide layer was initially formed on the melt surface. It was 'skimmed off' with a quartz rod from the top of the growth chamber. Because of the peritectic formation of $Nd_2Fe_{14}B$, Nd-rich melts and slow growth velocities are favorable. Beyond a pulling rate of >5 mm h^{-1} Nd-rich phases were precipitated. The preferred growth direction for polycrystalline seeds is either along the *a* axis or the [110] direction, whereas a *c* axis oriented crystals can be grown with a single-crystalline seed with the respective the *c* axis orientation. The cold-crucible CZ technique was also used by Koon *et al*. for the growth of $R_2Fe_{14}B$ (R = Y, Nd, Tb) with 5 mm h^{-1} (Koon, Das, Rubinstein and Tyson, 1985).

$Nd_2Fe_{14}B$, $Y_2Fe_{14}B$ as well as R_2Fe_{17} crystals were grown with the tri-arc CZ method (Sinnema, Verhoef, Menovsky and Franse, 1987). In the method the skull of the material prevents the contact of the melt with the water-cooled Cu crucible. A Ti getter has been used to purify the Ar atmosphere; a titanium button was melted by a tetra arc that burns continuously during the growth process. Pulling rates of 3 mm h^{-1} similar as in FZ melting (cf. Hirosawa *et al*., 1986) were applied. In case of $Nd_2Fe_{14}B$ the crystal was

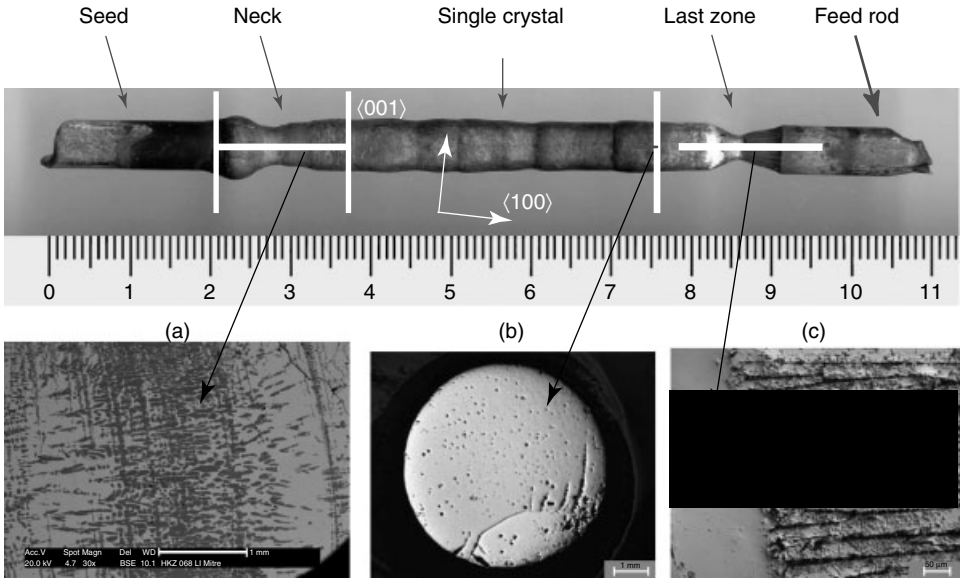

Figure 15. $Nd_2Fe_{14}B$ single-crystal FZ grown from a stoichiometric feed rod (top). Crystal orientations with respect to the rod axis are indicated. Longitudinal sections of initial part of the crystal: $Nd_2Fe_{14}B + Fe$ (dark) (a), cross section of the $Nd_2Fe_{14}B$ crystal (b), and last part with frozen zone: $Nd_2Fe_{14}B$ + Nd-rich phases (dark) (c). (Reproduced from I. Mazilu, PhD Thesis, 2006.)

grown with a stoichiometric seed from the $Nd_{15}Fe_{77}B_8$ melt, whereas a tungsten tip was utilized as seed for the $Y_2Fe_{14}B$. Laue photographs taken from different places proved that the mosaic structure in the $Nd_2Fe_{14}B$ crystal is $<1^\circ$. The bars contained a few large single-crystalline grains with a maximum size of $1\,cm^3$.

Single crystals of a series of $R_2Fe_{14}B$ (R = rare earth except of Sm) were grown by the FZ method with an infrared imaging furnace under purified Ar atmosphere (Hirosawa *et al*., 1986). This technique turned out to be very effective for $R_2Fe_{14}B$ crystal growth but also for related $R_2Co_{14}B$ compounds (Hiroyoshi *et al*., 1987). The typical dimensions of single crystals grown by this technique are several millimeters in diameter. Because $Nd_2Fe_{14}B$ (as well as related compounds) forms by a peritectic reaction, the TSFZ technique (cf. Section 3.3) is appropriate where the feed rod and the seed are of stoichiometric composition, whereas the FZ is off-stoichiometric. It can be generated by placing a small disk of (Nd,B)-rich composition between seed and feed rod and melting it together with its adjacent parts.

Alternatively, an off-stoichiometric zone can be established by progressive growth from a stoichiometric feed rod. This is shown for a FZ growth experiment with optical heating. In the initial stage of the growth process primary, γ-Fe dendrites along with the peritectic $Nd_2Fe_{14}B$ phase (Figure 15a) grow from the melt in agreement with the phase diagram. In this way, the melt composition in the zone is continuously enriched in Nd and B until it encountered the primary solidification range where the single $Nd_2Fe_{14}B$ phase grows (Figure 15b). The composition difference between the stoichiometric crystal and the frozen zone, which also contains Nd-rich phases, is illustrated in Figure 15(c).

For the whole series of FZ grown $R_2Fe_{14}B$ single crystals the temperature dependence of the saturation magnetization from 4.2 K to magnetic ordering temperatures, the magnetocrystalline anisotropy field H_A (Hirosawa *et al*., 1986; Hiroyoshi *et al*., 1986) and the anisotropy constants K_{u1}(Hirosawa *et al*., 1985) have been measured. Spin-reorientation processes similar to $Nd_2Fe_{14}B$ have been detected and the angle of easy axis of magnetization direction from the c axis has been measured for $Ho_2Fe_{14}B$, $Er_2Fe_{14}B$, $Tm_2Fe_{14}B$ compounds (Hirosawa *et al*., 1986). The coupling scheme of the $R_2Fe_{14}B$ compounds leads to ferromagnetism for light rare earths (Y, Ce, Nd, Pr, Sm) but ferrimagnetism for heavy rare earths (Er, Tb, Gd, Ho, Dy, Tm) with obvious differences in the magnetic behavior. For heavy rare-earth-containing compounds, the partial compensation between Fe and R sublattice magnetization leads to a positive thermal coefficient of the saturation magnetization in some restricted temperature range. As shown by Hirosawa *et al*. (1986) (Figure 16) the value of magnetocrystalline anisotropy field H_A of $Nd_2Fe_{14}B$ is not the largest among the $R_2Fe_{14}B$ compounds at room temperature and may be enhanced by alloying with other rare earths such as Tb or Dy. In fact Dy is utilized for improving permanent magnetic properties of $Nd_2Fe_{14}B$-based materials.

Mechanical properties were studied in uniaxial compression tests with $2 \times 2 \times 5\,mm^3$ samples from big CZ grown crystals crystallographically oriented with the (001) plane at an angle of 45° to the cuboid axis (Kuhrt *et al*., 1991). The

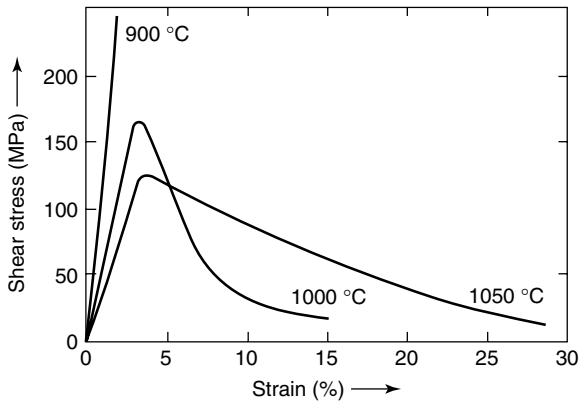

Figure 17. Compressive shear stress–strain curves of $Nd_2Fe_{14}B$ single crystals at 900, 1000, and 1050 °C, at strain rates of 5×10^{-5} s^{-1}. (Reproduced from Kuhrt *et al*., 1991, with permission from the American Inst.)

stress–strain curves at elevated temperatures 900–1050 °C of single-crystalline samples are shown in Figure 17. Substantial ductility of $Nd_2Fe_{14}B$ crystals occurs only at appreciably higher temperatures and lower strain rates than those generally used in the die-upsetting process (typically 700–800 °C) (Lee, 1985). The results support the assumption that it is not the plasticity of the $Nd_2Fe_{14}B$ phase, but other mechanisms such as grain boundary sliding combined with anisotropic grain growth that allow the microcrystalline Nd–Fe–B alloys to be so easily deformed and crystallographically textured.

The detailed oxidation and corrosion mechanisms of commercial rare-earth hard magnets are still a current research topic. Studying single crystals the different behavior of commercial polycrystalline materials and the $Nd_2Fe_{14}B$

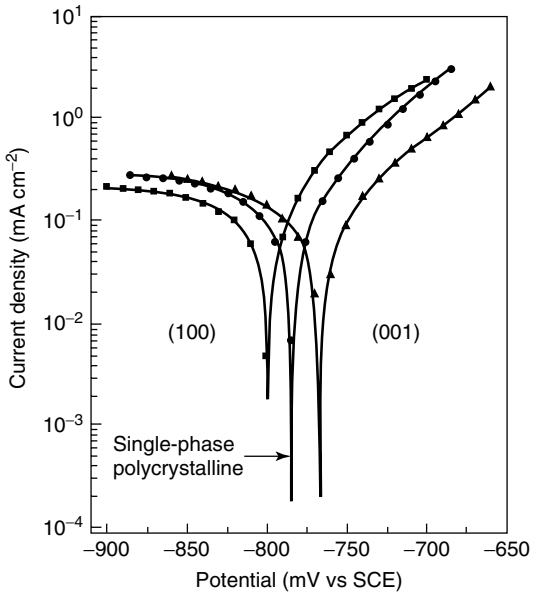

Figure 18. Potentiodynamic polarization curves recorded close to the corrosion potential U_{corr} in 0.1 M sodium sulphate solution (ph = 5) at 730 rpm at the surfaces of a $Nd_2Fe_{14}B$ single crystal which are in plane with the crystallographic (100) plane or with the (001) plane; comparative curve for polycrystalline $Nd_2Fe_{14}B$ with random grain orientation. (Reproduced from Rada *et al*., 2006, with permission from Elsevier. © 2006.)

phase itself can be distinguished. An anisotropic corrosion behavior on the two surface planes of a $Nd_2Fe_{14}B$ single crystal, namely, (100): a plane parallel to the *c* axis and (001): a plane perpendicular to the *c* axis was recently reported (Figure 18), which corresponds to the behavior of highly textured sintered Nd–Fe–B magnets (Rada *et al*., 2006). It is interesting to note that the (100) plane displaying the most active dissolution tendency in aqueous environment is identical with the (100) plane (perpendicular in *a* axis [100] direction) of preferred growth of the single crystal.

By means of calibrated dynamic secondary ion mass spectrometry (SIMS) using Cs^+ primary ions an upper limit for the oxygen content $c_O = 0.006 \pm 0.002$ at% in the single-crystalline $Nd_2Fe_{14}B$ matrix was determined, which is at least 1 order of magnitude lower than in polycrystalline samples. Another striking difference is the oxygen uptake, which depends on processing and sample handling in cast polycrystalline samples, whereas $Nd_2Fe_{14}B$ single crystals are much less sensitive (Oswald *et al*., 2005).

4.2.3 Crystal growth of other rare earth–transition metal compounds

In this section crystal growth attempts and selected magnetic properties of other classes of rare earth–transition metal intermetallic compounds prospective for the development of

permanent materials are briefly reported, which were studied in the past years but did not attract such an outstanding commercial interest like $Nd_2Fe_{14}B$.

R_2T_{17} (T = Fe, Co) compounds are distinguished by the combination of their large values of magnetic moments, high Curie temperatures, large anisotropy, and a strong coupling of magnetic moments of rare earths and transition metals. Moreover, exiting phenomena like a first order magnetic transition have been reported (Sinnema, Franse, Menovsky and Radwanski, 1986; Garcia-Landa *et al*., 1995; Garcia-Landa, Algarabel and Ibarra, 1997). For the crystal growth of R_2Fe_{17} and R_2Co_{17} compounds the same methods as for $Nd_2Fe_{14}B$ can be applied (Sinnema, Verhoef, Menovsky and Franse, 1987). Sinnema *et al*. reported the growth of R_2Fe_{17} (R = Y, Dy, Er, Ho), R_2Co_{17} (R = Y, Dy, Er, Nd, Pr, Gd, Tb), and also substitutional compounds such as $Ho_2Co_{14}Fe_3$ by the modified tri-arc CZ method (Sinnema, Verhoef, Menovsky and Franse, 1987) described in Section 4.2.2. Different from ternary systems, most binary R–T phase diagrams are known (Massalski, Okamoto, Subramarian and Kacprzak, 1990). Many R_2T_{17} compounds melt congruently or almost congruently. Compounds such as Tb_2Fe_{17} (cf. Figure 3 in Section 2), Sm_2Fe_{17} and Nd_2Fe_{17} are formed peritectically (Massalski, Okamoto, Subramarian and Kacprzak, 1990), and the composition difference between the compound and the peritectic melt increases in this sequence, which aggravates the crystal preparation. The crystals congruent melting R_2T_{17} compounds can easily be grown with relatively high pulling rates of $30\,mm\,h^{-1}$ (Sinnema, Verhoef, Menovsky and Franse, 1987). This is about 1 order of magnitude faster than for $Nd_2Fe_{14}B$ crystal growth. As-cast materials of the same alloy or W tips were used as seeds and rotated with 33 rpm during the growth. The compounds display either the hexagonal Th_2Ni_{17}-type structure (Y_2Fe_{17}, Dy_2Fe_{17}, Er_2Fe_{17}, and Tb_2Co_{17}) or the rhombohedral Th_2Zn_{17}-type structure (Nd_2Co_{17}, Gd_2Co_{17}, and Pr_2Co_{17}). The preferred growth direction was often close to the *c* axis with typical orientation deviations of the order of 10°. The crystals grown by the tri-arc method were of high quality and the magnetic transitions are very sharp (Sinnema, Verhoef, Menovsky and Franse, 1987). Crystal growth with volatile elements like Sm_2Fe_{17} or Yb_2Fe_{17} was not possible by this method. From the single crystals the crystallographic structure, the lattice constants of various R_2Fe_{17} and R_2Co_{17} compounds (Sinnema, Verhoef, Menovsky and Franse, 1987) and their fundamental magnetic properties (Garcia-Landa, Algarabel and Ibarra, 1997; Thang *et al*., 1998) were determined. As shown in Figure 19 for Er_2Fe_{17} (Sinnema, Verhoef, Menovsky and Franse, 1987) the magnetic easy direction is in the basal plane of the hexagonal unit cell, different from the uniaxial magnetic behavior of $Nd_2Fe_{14}B$. Substituted $Tb_2Fe_{17-x}Si_x$

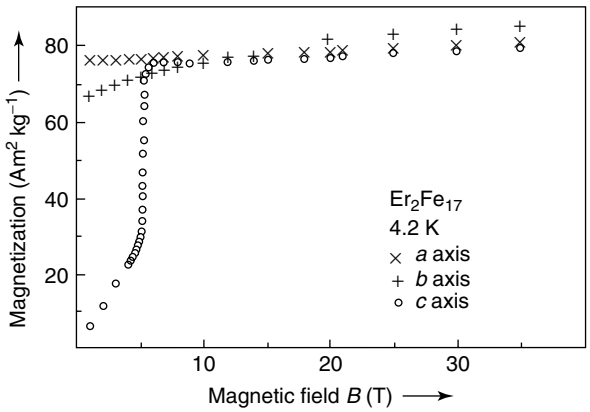

Figure 19. Magnetization curves of Er_2Fe_{17} measured in magnetic fields up to 35 T. The very sharp magnetic transition in the *c* axis illustrates the high quality of the single crystal. (Reproduced from Sinnema *et al*., 1987, with permission from Elsevier. © 1987.)

($x = 0–3.3$) single crystals were grown by a CZ method, too (Du *et al*., 1998). Oriented Er_2Fe_{17} seeds with rotation rates 30 rpm and relatively high growth velocities of $12–15\,mm\,h^{-1}$ were utilized. The substitution of Si for Fe leads to the reduction of lattice parameters and a significant increase of the Curie temperature from 413 to 526 K.

Alternatively, Dy_2Fe_{17} (Coelho, Mohan, Gama and Kronmüller, 1996) and substituted $Sm_2(Fe_{1-x}Al_x)_{17}$ (Kato *et al*., 1995) compounds were also grown with the Bridgman method. High pressures (1 MPa) of Ar and BN coated alumina crucibles were utilized for the growth of substituted $Sm_2(Fe_{1-x}Al_x)_{17}$ single crystals (Kato *et al*., 1995). Some amounts of A1 were found to be transferred from the crucible to the sample, due to an appreciable reaction between Al_2O_3 and Sm. The angle between the magnetization direction and the *b* axis increases linearly with increasing Al fraction *x* (Ono *et al*., 1998).

RCo_5 and related R–Co compounds

Among the intermediate phases which cobalt forms with rare earth the $SmCo_5$ and Sm_2Co_{17} are of importance for permanent magnetic materials (Strnat *et al*., 1967). The series of intermetallic compounds RCo_5 crystallizes in the $CaCu_5$-type hexagonal structure. The Curie temperatures and the magnetocrystalline anisotropy of these compounds are rather high and can reach 747 °C and $1 \times 10^7\,J\,m^{-3}$, respectively, for $SmCo_5$ (Strnat *et al*., 1967; Alameda, Givord, Lemaire and Lu, 1981). Because of the volatile character of Sm single crystals are difficult to achieve. Single crystals of Y_2Co_{17} and YCo_5 were grown by a FZ method (Hoffer and Strnat, 1967). The magnetization curves in the principal crystallographic directions were measured in the temperature range 20–300 K (Hoffer and Strnat, 1967) and down to

4.2 K (Alameda, Givord, Lemaire and Lu, 1981). Different from the Y_2Co_{17}, which exhibits an easy plane, YCo_5 is a uniaxial ferromagnet where the *c* axis is the easy magnetic axis and displays no detectable basal plane anisotropy. At 4.2 K the anisotropy constant can reach $K_1 = 7.38 \times 10^6\,\mathrm{J\,m^{-3}}$ and shows weak temperature dependence because of the high Curie temperature 704 °C of YCo_5 (Alameda, Givord, Lemaire and Lu, 1981). Single crystals of the ferrimagnet $DyCo_5$ were grown by the Bridgman method using the BN coated crucible technique (Ohkoshi *et al*., 1977). A magnetic study revealed the rotational-type spin-reorientation phenomenon that occurs in single crystals of $DyCo_5$.

Single crystals of other RCo_2 (R = Gd, Ho) and $HoNi_2$ Laves phases were achieved by slow cooling ($20\,\mathrm{K\,h^{-1}}$) of the melt and by the Bridgman method (Gignoux, Givord and Lemaire, 1975). Crystal-field parameters have been determined from the magnetization variation in intense magnetic fields up to $1.03 \times 10^4\,\mathrm{kA\,m^{-1}}$ (130 kOe).

RT_{12}-type compounds

Fe-rich rare-earth compounds crystallizing in the tetragonal $ThMn_{12}$ (*I*4/*mmm*) structure type are of interest as potential permanent magnet materials (Buschow, 1991). The pure RFe_{12} compound does not exist for any of the rare earth, however, the $ThMn_{12}$ structure can be stabilized in pseudobinary compounds $RFe_{12-x}M_x$ with M = Ti, V, Cr, Mo, W, or Si for values of $x \sim 1.0$. Single crystals of Er(Fe_{11}Ti), Lu(Fe_{11}Ti) (Andreev *et al*., 1988), and Dy(Fe_{11}Ti) (Hu, Li, Coey and Gavigan, 1990) have been prepared. The large Dy(Fe_{11}Ti) crystals, 40 mm long and 5 mm in diameter, have been grown by the tri-arc CZ method. The magnetic structure and the corresponding easy magnetic moment direction in the $RFe_{12-x}M_x$ compounds is governed by the Fe sublattice anisotropy and the R sublattice anisotropy. The Fe sublattice anisotropy favors an easy magnetization direction parallel to the *c* axis and the corresponding K_1 value has about the same magnitude as in $R_2Fe_{14}B$ and $R_2Fe_{14}C$ compounds. However, the crystal field induced by the rare-earth sublattice in $RFe_{12}M$ differs drastically from that found in $RFe_{14}B$ and $R_2Fe_{14}C$, both in sign and magnitude. This may be seen, for instance, by comparing the magnetic structures of $Dy_2Fe_{14}B$ and $DyFe_{11}Ti$. The former compound is a normal ferrimagnet with the magnetic moments oriented along the *c* direction at all temperatures $T < T_C$. By contrast, $DyFe_{11}Ti$ is a ferrimagnet with $M||c$ only in the limited temperature range $200\,\mathrm{K} \leq T \leq T_C = 534\,\mathrm{K}$. Below 200 K two spin reorientations occur, as can be derived from the results of magnetic measurements of Hu, Li, Coey and Gavigan (1990) shown in Figure 20. The magnetic moment is parallel to the [100] direction below 58 K and parallel to the *c* axis above 200 K.

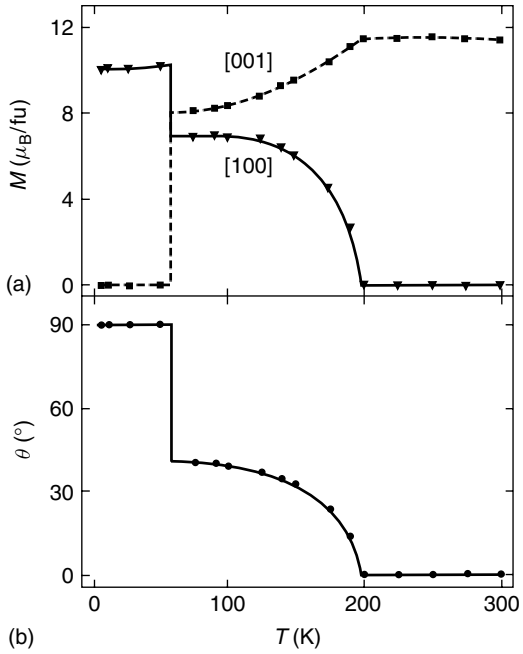

Figure 20. Temperature dependence of the magnitude and the orientation of the spontaneous magnetization M_s obtained from a $DyFe_{11}Ti$. (a) Components of M_s along [100] and [001]. (b) Angle between M_s and the *c* axis. (Reproduced from B.P. Hu *et al*., 1990, with permission from the American Physical Society.)

At temperatures between the two spin-reorientation transitions (first order at 58 K and second order at 200 K) the spin structure is canted. A slight variance between results of magnetic measurements on single crystals by various authors may be due to different concentrations (Wu *et al*., 1998). Indeed, in single crystals of $Tb(Fe,Ti)_{12}$ grown by the cold-crucible CZ technique a segregation of titanium along the crystal axis was quantified by chemical analysis (Wu *et al*., 1998). An effective macrosegregation coefficient of titanium $k_{\mathrm{eff}} = 0.92$ was derived by fitting the experimental data of crystals grown at $5\,\mathrm{mm\,h^{-1}}$ from a melt with $Tb_{1.2}Fe_{10.61}Ti_{1.39}$ starting composition shown in Figure 21. From their experimental results Wu *et al*. have defined the pseudobinary phase diagram around the $Tb(Fe,Ti)_{12}$ phase as peritectic. This peritectic reaction causes a complex of α-Fe and $TiFe_2$ as a nonhost phase with a high titanium fraction of 25 at%. To avoid this, the optimum Tb-rich melt composition $Tb_{1+\delta}Fe_{12-x}Ti_x$ with $\delta = 0.20$ was experimentally determined. Using high-quality single-crystalline samples with no nonhost phase impurities the reliable spin-reorientation transition temperature $T_{SR} = 290 \pm 3\,\mathrm{K}$ for $TbFe_{11}Ti$ in three main crystallographic directions was confirmed. From a series of $Tb(Fe,Ti)_{12}$ compounds it has been revealed that T_{SR} is strongly reduced with increasing Ti fraction in the samples.

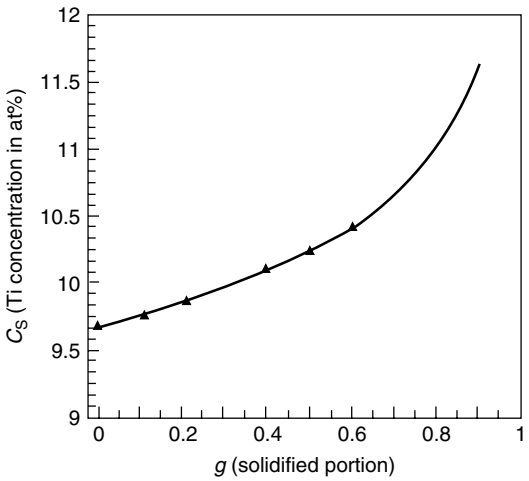

Figure 21. Titanium concentration (symbols) determined at different positions of the single crystal grown from the starting material of $Tb_{1.2}Fe_{10.61}Ti_{1.39}$ and theoretically fitting result (solid line) by $k_{\text{eff}} = 0.92\,g$ defined as in text. (Reproduced from G.H. Wu *et al.*, 1998, with permission from Elsevier. © 1998.)

R_3T_{29}-type compounds

Other novel classes of iron-based metastable intermetallic compounds, $R_3(Fe,M)_{29}$ and their nitrides $R_3(Fe,M)_{29}N_y$ (M = Ti, V, Cr, and Mo), were extensively investigated for potential application as permanent magnets (Cadogan *et al.*, 1994). The new family of $R_3(Fe,M)_{29}$ possesses the monoclinic $Nd_3(Fe,Ti)_{29}$-type structure and can be considered as an intermediate structure consisting of the 1:12 structure and the 2:17 structure at the ratio of 1:1. Like the iron-based intermetallic compounds of 2:17 and 1:12, a marvelous improvement in the Curie temperature, for example, from $T_C = 486\,K$ for $Sm_3(Fe,Ti)_{29}$ to $T_C = 750\,K$ $Sm_3(Fe,Ti)_{29}N_y$, and a drastic modification in anisotropy take place upon the introduction of interstitial atoms of C, and especially N, in 3:29 compounds. This is connected with a considerable lattice expansion (Cadogan *et al.*, 1994). Accurate determination of the crystallographic structure as well as the anisotropic magnetic properties of the $R_3(Fe,M)_{29}$ compounds require the preparation of single crystals (Courtois *et al.*, 1998a,b). The $Nd_3(Fe,Ti)_{29}$ phase is metastable. A solid-state heat treatment at temperatures typically around 1000 °C, followed by water quenching, is required to obtain compounds, which possess the 3:29 structure at room temperature. However, it is known that in the case of heavy rare-earth compounds a crucial shift in composition is needed to stabilize the binary R_2Fe_{17} compounds. Therefore it is possible to prepare $R_3(Fe,M)_{29}$ single crystals by a solid-state transformation of a $R_2(Fe,M)_{17}$ single crystal whose actual chemical composition is $R_3(Fe,M)_{29}$.

Following this route a $Y_2(Fe,V)_{17}$ single crystal (hexagonal Th_2Ni_{17}-type structure) with a chemical composition close to $Y_3(Fe,V)_{29}$ was grown under an argon atmosphere using the cold-crucible CZ method (Courtois *et al.*, 1998a). A cylindrical seed 0.5 mm in diameter with a length side parallel to the *c* axis of the 2:17 hexagonal structure was placed at the end of a head rotating with 5 rpm. The pulling rate was $22\,mm\,h^{-1}$. The $Y_2(Fe,V)_{17}$ single crystal obtained was subsequently sealed in a quartz tube under an argon atmosphere and annealed at 1015 °C for three days, followed by water quenching.

Powder X-ray diffraction showed the expected monoclinic cell, but single crystal X-ray data exhibited hexagonal symmetry. This discrepancy has been resolved by performing magnetization measurements on the crystal, which showed hexagonal symmetry with significant in-plane anisotropy. These observations have been quantitatively analyzed by considering that the crystal is, in fact, twinned. The magnetization was measured in applied fields up to $\mu_0 H = 7\,T$ in the temperature range $5\,K < T < 300\,K$. Over the whole temperature range investigated, the [001] axis of the $CaCu_5$ cell (which corresponds to the [102] axis of the $Nd_3(Fe,Ti)_{29}$ monoclinic cell) is the hardest magnetization direction and the spontaneous magnetization lies in the plane perpendicular to this axis (Courtois *et al.*, 1998a,b).

In a similar way, a novel $Y_3(Fe,Cr)_{29}$ single crystal with the $Nd_3(Fe,Ti)_{29}$-type structure has been successfully prepared (Yang *et al.*, 1999). $Y_2Fe_{15}Cr_2$ single crystals with a Th_2Ni_{17}-type structure were grown with growth rates of $15–25\,mm\,h^{-1}$ and a rotation rate of 30 rpm using the CZ method. Crystals were subjected to a heat treatment at 1000 °C for four days followed by quenching in water, which resulted in a 3:29 structure. The lattice parameters of the crystal are $a = 1.0645\,nm$, $b = 0.8455\,nm$, $c = 0.9678\,nm$, and $\beta = 97.462°$, respectively. The Curie temperature 410 K is similar to $T_C = 439\,K$ of the $Y_3(Fe,V)_{29}$ single crystal (Courtois *et al.*, 1998a). From the magnetization curves measured along the easy and hard direction it was concluded that the hard magnetic direction is [102] and that the crystal keeps a planar anisotropy from 1.5 to 293 K. The magnetocrystalline anisotropy constants at 1.5 K are $K_1 = -0.87 \times 10^6\,J\,m^{-3}$ and $K_2 = 0.19 \times 10^6\,J\,m^{-3}$.

Sm_xFe_y and miscellaneous compounds

In this section, we briefly review a few other attempts of crystal growth of hard magnetic materials. As mentioned earlier crystal growth of several compounds containing volatile elements is difficult or impossible. In some cases the so-called flux method can be applied to reduce the operating temperatures (as discussed in Section 3.2).

In the case of Fe–Sm compounds a Sm self-flux was successfully applied to grow crystals, which cannot be prepared otherwise (Samata *et al.*, 1998; Samata, Sakamoto, Yashiro and Nagata, 2001). After arc melting an appropriate amount of rare earth (Sm) and iron the button (∼30 g) was

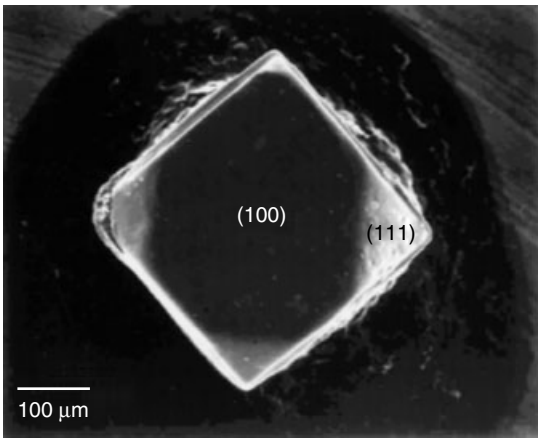

Figure 22. A SEM image of an as-grown Sm_6Fe_{23} crystal. The large square plane and the small triangular planes are the (100) and (111) planes, respectively. (Reproduced from Samata *et al*., 2001, with permission from Elsevier. © 2001.)

placed in a BN coated alumina or yttria crucible. The crucible was further sealed in a quartz ampoule with Ar gas after evacuation to 6.7×10^{-2} Pa (5×10^{-5} Torr). The mixture was heated over the dissolution temperature (900–1050 °C) using an electric furnace. After being held at that temperature for 0.5–6 h, it was cooled with 0.1–4 K h^{-1} to 700–850 °C, and then the quartz ampoule was cooled to room temperature by turning off the electric furnace. One special feature of this flux-creep-up method is that the flux creeps up the inner wall of the crucible during the crystal growth (Samata, Sakamoto, Yashiro and Nagata, 2001). Since the Sm flux around the crystal was easily oxidized into oxide powder in a few days, crystals could be removed easily from the bottom of the crucible without applying any mechanical strain. The crystallization of various intermetallic compounds is possible by adjusting the growth condition. Crystals of $SmFe_2$, $SmFe_3$ (Samata, Sakamoto, Yashiro and Nagata, 2001), Sm_6Fe_{23} (Samata, Sakamoto, Yashiro and Nagata, 2001; Samata *et al*., 2001), and $Nd_6Fe_{13-x}Al_{1+x}$ (Samata *et al*., 2001) were grown using this technique. In the latter case a Nd(Al)-rich flux was utilized. A scanning electron microscopy (SEM) image of a flux-grown Sm_6Fe_{23} crystal is shown in Figure 22.

Since the chemical composition of the mixture in the crucible changes in accordance with the creep-up of the flux, this method may be promising for both, the search for new phases and the crystal growth of known materials. In particular, $SmFe_7$ is a new phase (Samata *et al*., 1998; Samata, Sakamoto, Yashiro and Nagata, 2001) crystallizing in the tetragonal structure (space group $P4_2/mmm$) with a significantly large spontaneous magnetization 136 emu g^{-1} at 293 K, high $T_C = 608$ K, and huge magnetocrystalline anisotropy constants $K_1 + K_2 = -6.9 \times 10^6$ J m^{-3} at 293 K (Samata *et al*., 1998), which are comparable with those of $Nd_2Fe_{14}B$.

With this promising method also crystals of Al-substituted compounds $Sm(Fe_{1-x}Al_x)_2$, $Sm(Fe_{1-x}Al_x)_3$, $Sm_6(Fe_{1-x}Al_x)_{23}$, and $Sm(Fe_{1-x}Al_x)_7$ were grown and their magnetic properties were investigated (Samata, Kasai, Taniguchi and Nagata, 2003). The saturation magnetization of all compounds decreases by Al substitution. In the $Sm(Fe_{1-x}Al_x)_3$ and $Sm(Fe_{1-x}Al_x)_7$ systems, the anisotropy field is decreased with the Al substitution, while, in the cubic $Sm(Fe_{1-x}Al_x)_2$ and $Sm_6(Fe_{1-x}Al_x)_{23}$ systems, it is increased significantly. The Curie temperature of these compounds seems to be dependent on the average distance between the Fe nearest-neighbor atoms.

Flux methods have been utilized for crystal growth of various other magnetic compounds, too, which cannot be mentioned in this report.

4.3 Crystal growth of high-magnetostrictive compounds

4.3.1 Binary RFe_2 compounds

Heavy rare-earth elements, R = Tb and Dy, display the largest known magnetostrictions (∼1%), however, only at cryogenic temperatures (Clark, 1980). Among the various magnetostrictive materials RFe_2 Laves phase compounds exhibit huge (up to 10^{-3}) magnetostrictive strain at room temperature, which is important for technological reasons (Clark, Tamagawa and Belson, 1972). Among the RFe_2 compounds single crystals of $TbFe_2$, $ErFe_2$, and $TmFe_2$ exhibit [111] as the easy magnetization direction, whereas for $DyFe_2$ and $HoFe_2$ the easy magnetization direction is [100]. The room-temperature magnetostriction constants λ_{111}, for $TbFe_2$, $ErFe_2$, and $TmFe_2$ single crystals, and λ_{100} for $DyFe_2$, $HoFe_2$ single crystals as function of a magnetic field in the easy magnetization direction are shown in Figure 23 (Clark, 1980). The highly anisotropic magnetostriction reveals the importance of grain orientation in achieving high magnetostriction with two beneficial effects (i) the increase of the magnetostriction constant ($\lambda_s \approx 0.6\ \lambda_{111}$ in an isotropic polycrystal) and (ii) the lower internal losses at grain boundaries.

Various attempts of single-crystal growth of RFe_2 compounds are described by McMasters, Holland and Gschneider (1978). Small single crystals of $TbFe_2$, $DyFe_2$, and $ErFe_2$ have been prepared by the Bridgman technique using tungsten crucibles. However, the crucible-sample interface contained dendrites of the contamination product, which seriously limited the size of the crystals. Other crucible materials led to even more crucible contamination.

Single crystals of $HoFe_2$ and $Ho_{1-x}Tb_xFe_2$ compounds have been prepared by a tri-arc CZ technique described in

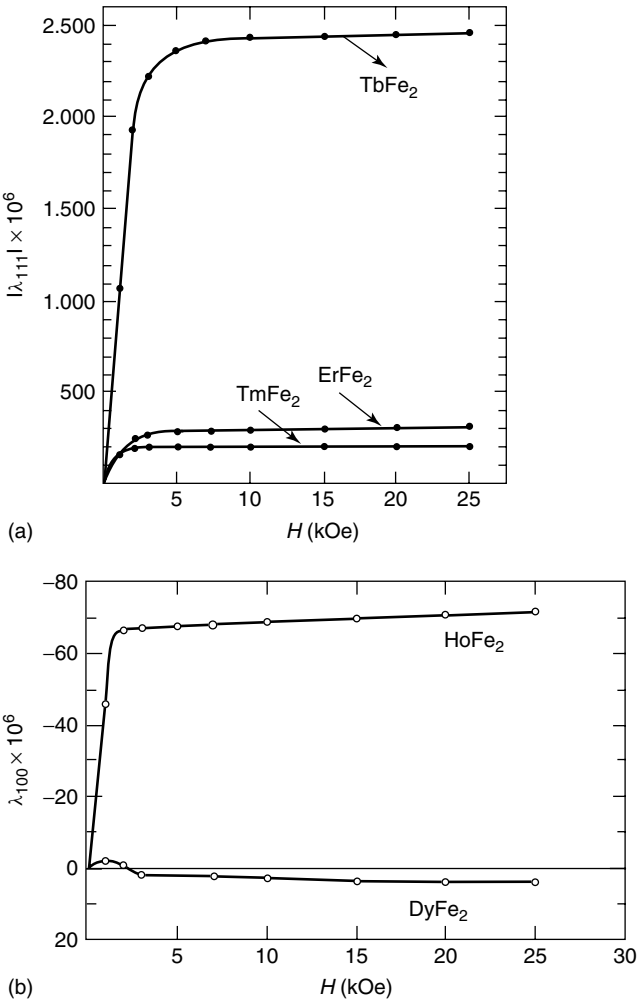

Figure 23. Room-temperature magnetostriction $|\lambda_{111}|$ for $TbFe_2$, $ErFe_2$ and $TmFe_2$ single crystals (a). For $TbFe_2$, $\lambda_{111} > 0$; for $ErFe_2$, and $TmFe_2$, $\lambda_{111} < 0$ is valid. Room-temperature magnetostriction λ_{100} for $DyFe_2$, $HoFe_2$ single crystals (b). (Reproduced from Clark, 1980, with permission from Elsevier. © 1980.)

Section 3.3 (Milstein, Koon, Johnson and Williams, 1974). Master alloy compositions 1% rich in rare earths were utilized in order to suppress Fe-rich phases. Preferable results were obtained with single-crystalline seeds rotated with 40–80 rpm at a pull rate 5 mm h^{-1}. However, suppression of spontaneous nucleation of second grains and beneficial effects on crystal quality were achieved by counterrotation of hearth of the tri-arc facility with 50–75 rpm. The growth atmosphere employed was Ar gas purified by gettering over a Ti sponge at red heat, which passed through a molecular sieve held at −78 °C. High-quality crystals of up to 1 cm in diameter and some centimeter in length have been grown. Electron probe and physical measurements, in particular, anisotropy data measured on spheres ground from different portions of the boules proved the uniform composition over some centimeters length, the absence of second phase and second grains, and the small strains in the samples.

However, this technique leads only to favorable results for congruent or nearly congruent melting compounds with moderate or low vapor pressures at their melting temperatures. More recently, a cold-crucible CZ technique was applied for the crystal growth of $NbFe_2$, $HoFe_2$, $Tb_{0.27}Dy_{0.73}Fe_x$ ($x = 1.9$, 1.95) (Terfenol-D) (Bi, Abell and Ford, 1996). In contrast to the tri-arc method, melting is accomplished by RF (350 kHz) induction heating in a Hukin-type vertical cold crucible (cf. Section 3.3). The contact between the crucible and the melt of ∼50-g mass is eliminated by levitation in an electromagnetic field. The process proceeds under a 0.2 MPa Ar atmosphere. A tungsten rod is used as a seed rotating with 5 rpm for crystal growth of $HoFe_2$, and Terfenol-D with 28 mm h^{-1} pull rate. The crystal boules 10 mm in diameter and ≥20 mm in length consist of a couple of large grains and the perfection of Terfenol-D crystals suffers from twin boundaries and needle-shaped Widmannstaetten precipitates of $(Tb/Dy)Fe_3$.

A horizontal levitation zone melting technique was developed by McMasters, Holland and Gschneider (1978) at Ames Laboratory, which circumvents crucible reactions of the reactive melt. Principal problems which had to be solved for a successful crystal were (i) reduction of the ripples of the output signal of the 25 kW RF generator (200–550 kHz), which are detrimental for the control of the molten zone in crystal growth (ii) the appropriate arrangement of the copper tube for best levitation in this open boat configuration (iii) designing of the pancake shaped work coil in order to achieve a narrow molten zone and steep temperature gradients, and (iv) proper adjustment of the conditions for levitating the zone, which are different for each material. The growth proceeds in a quartz tube evacuated and backfilled with a protective He/Ar gas mixture, which could vary from 0.13 MPa to 0.5 MPa.

The single-crystal growth of $TbFe_2$ is described here as an example since it encompasses most problems associated with other substances of this family (McMasters, Holland and Gschneider, 1978). The compound $TbFe_2$ is formed by a peritectic reaction $L + TbFe_3 \leftrightarrow TbFe_2$ at 1187 °C and the peritectic horizontal extends from 75 at% ($TbFe_3$) to 55 at% Fe (cf. Tb–Fe phase diagram Figure 3 in Section 2). At the Tb-rich side a eutectic reaction between $TbFe_2$ and Tb occurs at 847 °C and 27 at% Fe. $TbFe_{1.98}$ feed rods 9 mm in diameter and 75 mm in length were prepared by arc melting from high-purity elements. At about 10-mm distance from the end the feed rod was cut and a 3-mm-thick disk with composition $Tb_{45}Fe_{55}$ was placed between the two pieces. Finally the three pieces were welded together. The $Tb_{45}Fe_{55}$ section is melted and the molten zone passed along the rod at a rate of 0.8 mm h^{-1}. The slow rate of this TSFZ growth process is necessary since it proceeds below the peritectic temperature

and involves diffusion of the stoichiometric composition $TbFe_2$ across the molten zone. The success of the crystal growth process, which takes place under a gettered 0.4 MPa Ar atmosphere to minimize evaporation, depends on the stability of the molten zone and the solid-liquid interface shape. Zoned samples contained single-crystalline sections of about 15 mm length ($\sim$1 cm^3). At the bottom because of incomplete levitation a thin polycrystalline layer occurred, which is removed from the crystal like other polycrystalline parts. The method was also successfully utilized for the growth of smaller crystals of $TmFe_2$ (Abbundi and Clark, 1978), $DyFe_2$, and $Tb_{0.27}Dy_{0.73}Fe_2$ and also 1–2 cm^3 large crystals of Nd, Pr, and γ-Ce (McMasters, Holland and Gschneider, 1978). The latter rare-earth crystals were grown with considerable higher rates of 3–6 mm h^{-1} in conjunction with a strain-anneal technique (cf. Section 4.1.1).

4.3.2 *Quasibinary $Dy_{1-x}Tb_xFe_2$ compounds (Terfenol)*

The RFe_2 compounds possess unusually large magnetostriction strains and also a high magnetic anisotropy. For certain magnetostrictive applications high strains at low fields are necessary. In these cases, a low magnetic anisotropy is important in order to maximize domain wall mobility and easy domain rotation at low fields. RFe_2 compounds with different rare earths can display room-temperature anisotropy constants of opposite sign (cf. Table 7 in Clark (1980)). This makes it possible to tailor compounds with optimum magnetostriction and low anisotropy. Studies by Clark (1980) have demonstrated that the pseudobinary compound $Tb_{1-x}Dy_xFe_2$, known as *Terfenol-D*, has a significantly reduced magnetic anisotropy. The room-temperature magnetostriction constant $\lambda_{111} \approx 1600 \times 10^{-6}$ of single crystals at the compensation region $x \approx 0.73$ is still high in comparison with $\lambda_{111} \approx 2450 \times 10^{-6}$ of the binary $TbFe_2$. Because of its high magnetostriction in low external magnetic fields the $Tb_{0.27-0.30}Dy_{0.73-0.70}Fe_2$ compounds in the last years became outstanding candidates for applications such as sonar devices (Abbundi and Clark, 1978). Accordingly, preparation, microstructure, and physical properties of this particular compound have been widely investigated. The Laves phase $(Tb,Dy)Fe_2$ compound has a $MgCu_2$ structure type, its magnetic easy axis is the $\langle 111 \rangle$ direction and the magnetostrictive strain along this direction is 16.6 times larger than that along the $\langle 100 \rangle$ direction. Considering this huge magnetostrictive anisotropy and the hindrance to magnetic domain processes of inhomogeneity, boundaries, impurities, and so on, Tb–Dy–Fe single crystals with a minimum amount of defect structure and impurity content which are oriented along the $\langle 111 \rangle$ crystal axis are desirable not only as subjects of fundamental research but as material with optimum magnetostriction characteristics for the applications itself.

As already discussed in the foregoing section, there are three common crystal growth techniques, which one might consider for producing aligned grains and possibly single crystals of Terfenol-D, (i) Bridgman growth, (ii) CZ growth, and (iii) FZ solidification. Methods (i) and (ii) both require the alloy to be held in a container material which could lead to contamination, whereas no container is required in method (iii). FZ solidification also has another advantage as a steady state process in which the composition of the solid freezing from the zone must equal the composition of the solid being fed into the zone. In the FZ method RF induction heating (McMasters, Verhoeven and Gibson, 1986; Verhoeven, Gibson, McMasters and Baker, 1987) as well as optical heating (Mei, Okane, Umeda and Zhou, 1997; Mei, Yoshizumi, Okane and Umeda, 1997) was applied. Maximum 8 mm rod diameters can be achieved because the surface tension limits the size of the zone with a typical length of 8–10 mm. In the case of the induction furnace an electromagnetic force also contributes to zone stability.

Indeed, Terfenol-D crystals have been grown by the vertical FZ method with a pancake RF induction coil (450 kHz) from $Tb_{0.27}Dy_{0.73}Fe_x$ $(1.9 < x < 1.975)$ (McMasters, Verhoeven and Gibson, 1986), and $Tb_{0.3}Dy_{0.7}Fe_x$ (Verhoeven, Gibson, McMasters and Baker, 1987) feed rods typically 10 mm in diameter and 200 mm in length prepared by arc melting from >99.97 wt% pure elements. The binary Dy–Fe and Tb–Fe phase diagrams (Massalski, Okamoto, Subramarian and Kacprzak, 1990) are quite similar and in both systems the RFe_2 compound melts peritectically. It is reasonable to assume that the isopleth of interest in the ternary Dy–Tb–Fe system would be a quasibinary diagram, which would appear nearly identical to the Dy–Fe diagram. A schematic ternary Dy–Tb–Fe phase diagram along with the resulting composition profile of growing cells is given by Mei, Okane, Umeda and Zhou (1997).

For a steady state at the growth front one would require a rare-earth concentration beyond the liquidus composition at the RFe_2 peritectic temperature in order to grow pure RFe_2 without formation of a primary RFe_3 phase. The $TbFe_3$ phase was detected in the center of the $TbFe_2$ dendrites. FZ experiments with $Tb_{0.27}Dy_{0.73}Fe_2$ alloys have shown that for growth rates in excess of 125 mm h^{-1}, the Terfenol-D compound grows directly from the melt as a primary phase. Considering that for both Dy–Fe and Tb–Fe binary alloys the RFe_2 compound melts incongruently it is likely to assume that the Terfenol-D compound also melts incongruently, but it is stabilized kinetically and grows above the peritectic temperature by a metastable congruent reaction (McMasters, Verhoeven and Gibson, 1986). In all cases, the microstructures contained a second, darkly etching phase as

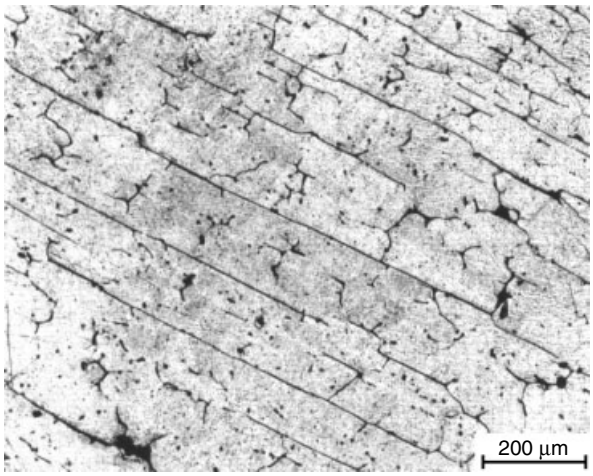

Figure 24. Cellular microstructure of Terfenol-D single crystals. (Reproduced from Mei *et al*., 1997, with permission from Elsevier. © 1997.)

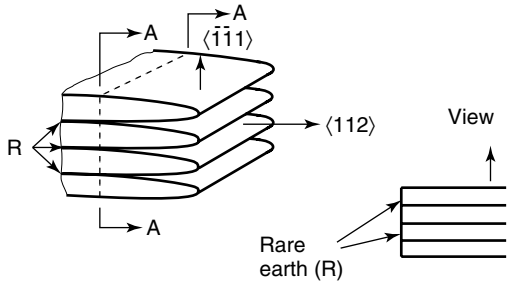

Figure 25. Schematic view of a dendrite growth front. (a) Three-dimensional view. (b) Transversal view along A–A. (Reprinted with permission of ASM International®. All rights reserved. www.asminternational.org.)

shown in (Figure 24). The dark phase was examined by scanning electron microscopy, scanning Auger microscopy and optical microscopy, and it was shown to be pure rare-earth metal. These results demonstrate that in this alloy system the eutectic reaction at the base of the cells or dendrites occurs by a divorced eutectic reaction mode for the rate of solidification 125–500 mm h^{-1} employed in FZ melting. The pure RFe_2 compound is extremely brittle but structures of RFe_2 + eutectic, while still brittle, are much less subject to breakage upon handling. Therefore crystals often are prepared from Fe-depleted RFe_x feed rods ($x < 2$). The ductile second phase consisting of pure rare-earth metal forms as an interconnected skeleton network, which probably accounts for the reduction of brittleness found for alloys of $x = 1.9$ versus alloys of $x \approx 2$. It has been demonstrated that FZ solidification with induction heating (450 kHz) in alloys of $Tb_{0.27}Dy_{0.73}Fe_x$ ($x = 1.9 - 1.975$) produces samples with essentially no macrosegregation along the axis in crystals over 18 cm length. The term *single crystal* for Terfenol-D is often used for aligned multigrain structures consisting of primary dendrites or cells of the RFe_2 compound with rare-earth metal in the intercellular/interdendritic regions (cf. Figure 23). However, it was reported that the desired ⟨111⟩ crystal was not obtained even using a seed technique. On the other hand, ⟨112⟩ and ⟨110⟩ oriented twinned crystals (Figure 25) were easily produced due to the preferred growth of the Tb–Dy–Fe alloy (Verhoeven, Gibson, McMasters and Baker, 1987). The ⟨112⟩ orientation is 19.5° tilted with respect to the desired ⟨111⟩ direction and $\lambda_{112} = 94\%\ \lambda_{111}$. The twinning in the crystals is harmful to their magnetostrictive properties because of its hindrance to magnetization process.

In the induction furnace it is difficult to obtain ⟨111⟩ oriented crystals even with seed crystals, because the liquid interface is a little concave to the melt. The direct driving force of twinning seems to be the growth rate. The rate dependence of the twinning was studied and ⟨111⟩ oriented Tb–Dy–Fe single crystals (6 mm diameter; 100 mm length) were successfully grown in an optical image zone melting furnace from a master alloy $Tb_{0.3}Dy_{0.7}Fe_{1.90}$ (Mei, Yoshizumi, Okane and Umeda, 1997). An ideal seed is an oriented Tb–Dy–Fe single crystal, which is usually obtained by cutting from a twinless crystal. Another simple method was found to grow the ⟨111⟩ twinless crystals directly from the twinned seed crystals (Mei, Yoshizumi, Okane and Umeda, 1997). One seed crystal was cut from the ⟨112⟩ oriented twinned 'single' crystal with the originally lateral (111) planes as its upper face. The perpendicular ⟨111⟩ direction was easily determined owing to the sheetlike morphology of the twinned crystals. Along this direction, both of the twinned parts and parent parts exhibited the same {111} planes, and the obtained ⟨111⟩ twinned seed had its original twin planes perpendicular to the following growth direction. From the ⟨111⟩ oriented seed crystals, ⟨111⟩ oriented twinless $Tb_{0.3}Dy_{0.7}Fe_{1.90-1.95}$ single crystals were successfully grown at rates of 3–15 mm h^{-1} in the image furnace. These rates are considerably constrained compared to the growth of the twinned crystals with ⟨112⟩ orientation cited above.

Recently, the growth of ⟨113⟩ orientated crystals (10 mm diameter; 50 mm length) with a horizontal crystal growth furnace with induction heating was accomplished with a ⟨113⟩ oriented seed crystal by carefully controlling the temperature gradients and the growth rates between 30 and 240 mm h^{-1}, which are well beyond that for growth of ⟨111⟩ oriented crystals (Zhang, Gao, Zhou and Shi, 2004). The magnetostrictive properties are superior to the specimens with ⟨112⟩ oriented twinned 'single' crystals.

Alternatively, Terfenol-D crystal growth was carried out in Bridgman furnaces. Arc-cast fingers were placed in quartz crucibles with 2–2.5 cm diameter and directional solidified from bottom to top (Verhoeven, Gibson, McMasters and Baker, 1987). The heat was supplied by an induction coil (450 kHz) and the temperature gradient was produced by placing the round bottom of the crucible on a water-cooled pedestal. Growth rates of 200–250 mm h^{-1} were employed. The solidification front was dendritic with planar-sheet morphology. The sheet faces are parallel to {111} planes, the primary growth direction lies along the ⟨112⟩ direction and grains are aligned within 5–10° of the growth axis. Similar to the FZ crystals a rare-earth phase (Tb + Dy) is placed between the sheets, but the alignment of the sheet dendrites into parallel arrays is not always obtained for the Bridgman crystals. Crystals were also grown from induction cast $Tb_{0.3}Dy_{0.7}Fe_{1.9}$ alloy rods in a Bridgman furnace with $A1_2O_3$ crucibles at 30–3600 mm h^{-1} pulling rates (Mei, Yoshizumi, Okane and Umeda, 1997). Contamination from Al_2O_3 crucible material and atmosphere was severe. A significant rare-earth loss along the axial direction was observed even at high growth rates of 600 mm h^{-1}. A change of the preferred growth direction from ⟨112⟩ to ⟨110⟩ was observed for lower growth rates (<60 mm h^{-1}) (Mei, Okane, Umeda and Zhou, 1997; Mei, Yoshizumi, Okane and Umeda, 1997).

Owing to very low growth rates of single crystals, both the FZ and the modified Bridgman method are not economical for volume production. Therefore, a crystal growth technique for the production of large diameter drivers and for mass production of smaller diameter elements within one heat was developed by ETREMA Products, Inc., Ames (Iowa). It is based on a modified Bridgman technique (Snodgrass and McMasters, 1997). Terfenol-D alloy is melted in a ceramic crucible, and then poured via a hole in the bottom of the crucible into preheated molds. The molds are withdrawn from secondary furnace sections in a standard Bridgman manner. As the material is solidified, the rate of withdrawal and the direction of heat flow are controlled to produce crystallographically aligned drivers of Terfenol-D. This method is capable of producing drivers as large as 65 mm in diameter and lengths as great as 175 mm. For rods <50 mm, the system can produce aligned drivers of 250 mm in length. The system is also capable of producing several smaller rods (<28 mm diameter) simultaneously.

4.3.3 *Ni_2MnGa-based ferromagnetic shape memory alloys*

Ferromagnetic shape memory alloys (FSMAs) moved from a hypothetical new class of active materials, to join piezoelectric and magnetostrictive materials, upon observation of a 0.2% magnetic-field-induced strain at 265 K in a single crystal of Ni_2MnGa by Ullakko *et al*. (1996). By comparison, piezoelectric materials show strains of the order 0.1% (Haertling, 1999) and the leading magnetostrictive material, Terfenol-D, shows a field-induced strain of about 0.24% (Cullen, Clark and Hathaway, 1990). The magnetic alloy exhibiting a martensitic phase transformation allows control of large displacements by application of a magnetic field at constant temperature. Ni_2MnGa is a Heusler alloy, $L2_1$, having a cubic lattice with $a = 5.822$ Å in the high-temperature phase. The martensitic transformation temperature is near 276 K. The low-temperature phase evolves from the parent phase by a diffusionless, displacive transformation that gives a tetragonal structure, $a = b = 5.90$ Å, $c = 5.44$ Å. The properties of Ni–Mn–Ga samples sensitively depend on the alloy composition (Chernenko, Cesari, Kokorin and Vitenko, 1995). Compositions slightly off the Heusler stoichiometry are chosen in order to render alloys having Curie temperatures greater than the martensite transformation temperature, which in turn was to be greater than room temperature.

Crystals were grown by the Bridgman technique (Ullakko *et al*., 1996; Chernenko, Cesari, Kokorin and Vitenko, 1995; Murray *et al*., 2000; Sozinov, Likhachev, Lanska and Ullakko, 2002) as described in by Murray *et al*. (2000). Master alloys from high-purity nickel, manganese, and gallium were arc melted into buttons and then drop cast into a chilled copper mold. The as-cast ingots were placed in alumina crucibles and heated to 1350 °C for 1 h to allow homogenization before withdrawing the sample from the heat zone at a rate of 5 mm h^{-1}. In order to minimize evaporation of the Mn during crystal growth, the furnace was backfilled to a positive pressure of 6.83×10^5 Pa with purified argon after the chamber and sample had been degassed at 1350 °C under vacuum. A typical single-crystal boule measured 1 cm in diameter and 5 cm in length. After Laue orientation, several samples were cut from the crystal boule by electric spark erosion.

Usually, after a martensitic phase transition multiple variants of martensite form within a single crystal of the parent high-temperature phase. Afterwards, that multivariant state can be transformed into a nearly single variant of martensitic phase by an appropriate mechanical treatment. In this way nearly single-variant martensitic samples were prepared where the full field-induced strain can be exploited. Strains of 6% associated with the crystallographic distortion by application of a field of 320 kA m^{-1} (4 kOe) to a single-variant sample from an off-stoichiometric $Ni_{47.4}Mn_{32.1}Ga_{20.5}$ crystal were reported (Murray *et al*., 2000). Electron probe microanalysis of this crystal showed the composition to vary along the boule axis with Mn content increasing and Ga content decreasing in the growth direction. A very large 10% strain was achieved for a $Ni_{48.8}Mn_{29.7}Ga_{21.5}$ single crystal grown with 30 mm h^{-1}, after homogenization at 1253 K and aging

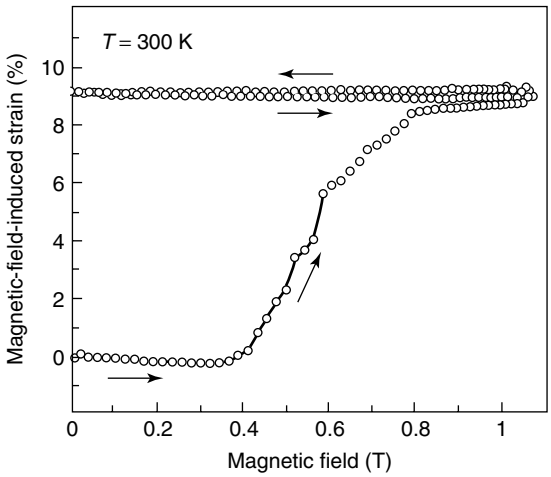

Figure 26. Field-induced strain of a single-variant sample of orthorhombic seven-layer phase in the $Ni_{48.8}Mn_{29.7}Ga_{21.5}$ alloy at 300 K measured perpendicular to the magnetic field applied along the [100] direction. (Reproduced from A. Sozinov *et al*., 2002, with permission from the American Institute of Physics. © 2002.)

at 1073 K (Sozinov, Likhachev, Lanska and Ullakko, 2002). The Curie temperature is about $T_C = 368$ K. The martensitic transformation starts at 337 K (M_s) and is completed at 333 K (M_f) during cooling. At lower temperatures, starting at 245 K, the magnetic susceptibility increased, indicating the intermartensitic transformation. By X-ray studies it was found that the crystal structure of the first high-temperature martensitic phase is nearly orthorhombic and has lattice parameters of $a = 0.619$ nm, $b = 0.580$ nm, and $c = 0.553$ nm at ambient temperature. Seven-layer modulation along the $(110)[1\bar{1}0]_p$ system was observed. The crystal structure of the second martensite is tetragonal with lattice parameters of $a = b = 0.547$ nm, and $c = 0.660$ nm ($c/a = 1.207$) at 200 K and $a = b = 0.551$ nm and $c = 0.654$ nm ($c/a = 1.187$) at ambient temperature. Figure 26 shows the results of the field-induced strain measurements of the alloy at ambient temperature. The magnetic field was applied parallel to the a axis. The maximum strain achieved in the first cycle at the field of 1.05 T is $\varepsilon_{MSM} = 9.5\%$. This value is lower than the crystallographic limit $e_0 = (1-c/a) = 10.66\%$ expected for complete transformation between two single variants.

4.4 Crystal growth of magnetocaloric materials

The magnetocaloric effect is a change in the temperature of a magnetic solid in response to a changing magnetic field. The magnetocaloric effect is intrinsic to all magnetic materials and is due to the coupling of the magnetic sublattice with the magnetic field, which changes the magnetic part of the entropy of a solid (Pecharsky and Gschneidner, 1999). This process has been used for about 70 years to achieve very/ultra low temperatures in small volumes by a process known as *adiabatic demagnetization refrigeration* (Gschneidner and Pecharsky, 1999). The magnetocaloric effect can be measured directly or it can be calculated indirectly from the measured magnetization or field dependence of the heat capacity. The range of operating temperatures of various classes of substances such as $PrNi_5$, pure rare earths (Pr, Nd, Er, Tm, Dy), rare-earth-containing intermetallic compounds (RAl_2, GdPd, RNi_2) depends on the magnetic phenomena utilized for the magnetocaloric effect. Gd, Gd_5Si_4, and Ge-substituted compounds $Gd_5(Si_xGe_{1-x})_4$ operate near room temperature. The giant magnetocaloric effect of the latter compound results from a simultaneous first order magnetostructural transformation and a structural transition from a paramagnetic monoclinic high-temperature phase into a ferromagnetic orthorhombic phase (Pecharsky and Gschneidner, 1999). Single crystals of magnetocaloric substances are exploited for details of crystallographic structures, the magnetic order, and anisotropic material properties.

The single crystals of Gd (Tishin, Gschneidner and Pecharsky, 1999) and Dy (Chernyshov *et al*., 2005), which were prepared from high-purity polycrystalline metals via a strain-anneal process (cf. Section 4.1.1), were studied over broad temperature (T) and magnetic field (H) intervals and have revealed peculiarities of magnetothermal properties especially in the vicinities of the magnetic ordering temperatures. When the magnetic field vector is parallel to the a axis of a crystal, the refined H–T phase diagram of Dy is more complicated than previously thought, and it contains several new phases (Chernyshov *et al*., 2005).

The crystal growth of $Gd_5(Si_xGe_{1-x})_4$, which is of considerable interest for practical application, is hampered by the high melting point of the compounds (>2073 K) and the reactivity of both the rare-earth metal and silicon at these temperatures. Moreover, the phase diagram near the $Gd_5(Si_xGe_{1-x})_4$ region at high temperatures is not well known. Single crystals of the monoclinic $Gd_5(Si_xGe_{1-x})_4$ compound were synthesized only recently by the Bridgman method in a conical tipped tungsten crucible (Lograsso, Schlagel and Pecharsky, 2005). The as-cast $Gd_5(Si_xGe_{1-x})_4$ ingot was electron beam welded under vacuum into the crucible for crystal growth. The ingot was heated in a tungsten-mesh resistance furnace under a pressure of 8.8×10^{-5} Pa up to 1273 K and held at this temperature for 1 h to degas the crucible and furnace chamber. The chamber was then backfilled to a pressure of 3.4×10^4 Pa with high-purity argon. The ingot was then heated to 2273 K and held at this temperature for 1 h to allow thorough mixing before withdrawing the sample from the heat zone at 4 mm h^{-1}. Tungsten crucibles

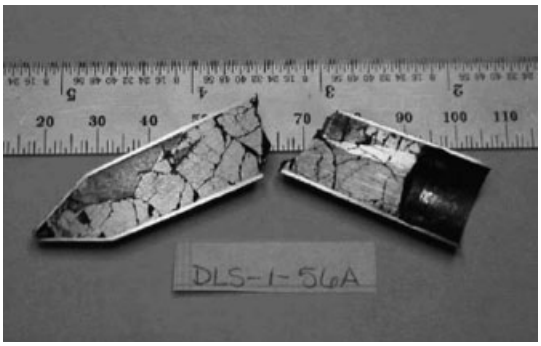

Figure 27. Longitudinal section of a typical as-grown $Gd_5Si_2Ge_2$ ingot. The ingot is comprised of three to four single crystals and is severely cracked along the entire length. (Reproduced from Lograsso *et al*., 2005, with permission from Elsevier. © 2005.)

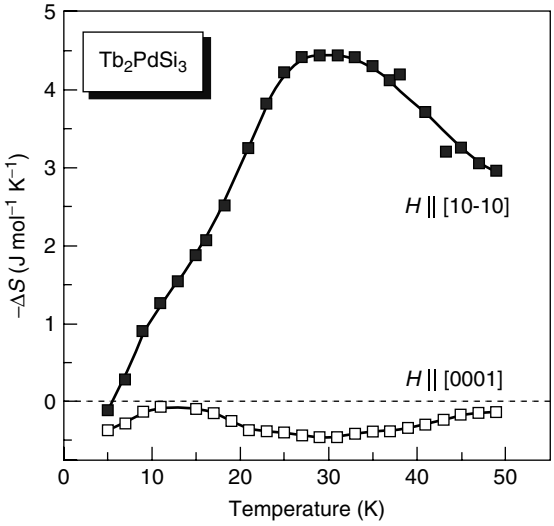

Figure 28. Entropy change by increasing the applied magnetic field from 0 to 4×10^3 kA m^{-1} (50 kOe), as derived from magnetization data as a function of temperature for Tb_2PdSi_3. (Reproduced from S. Majumdar *et al*., 2000, with permission from the American Physical Society. © 2000.)

were found to be inert, that is, no formation of tungsten silicides or germanides were observed, but slight solubility of W in molten $Gd_5(Si_xGe_{1-x})_4$ resulted in the precipitation of pure W dendrites in the bulk alloy and along the crucible wall, leading to mechanical bonding between crucible and ingot. Upon cooling the $Gd_5Si_2Ge_2$ ingot was severely cracked (Figure 27) due to the mismatch of thermal expansion between specimen and crucible (Lograsso, Schlagel and Pecharsky, 2005). Overall, the bulk crystal solidified in the monoclinic phase with a slight increase in lattice parameters reflecting the slight increase in Si:Ge ratio along the ingot. The temperature $T_C = 261$ K of the magnetostructural transformation increased by approximately 10 K. The large values of the magnetocaloric effect in specimens taken from the start of crystal growth slightly decreased over the length. No evidence was found for the solidification of second phases. Magnetization measurements using a $Gd_5(Si_{1.95}Ge_{2.05})$ single crystal with the magnetic field applied along three crystallographic directions [001], [010], and [100] were carried out. The giant magnetocaloric effect is maximum in the vicinity of T_C. The H–T phase diagrams were constructed for the $Gd_5(Si_{1.95}Ge_{2.05})$ single crystal with field along the three directions and a small anisotropy was observed, which is correlated with the nature of the crystalline anisotropy (Tang *et al*., 2003).

On the other hand, significant anisotropy of the magnetocaloric effect was derived from magnetization measurements in Tb_2PdSi_3 single crystals grown by the FZ method (Majumdar *et al*., 2000). The Tb_2PdSi_3 compound exhibits a hexagonal AlB_2-type structure and undergoes a paramagnetic–antiferromagnetic transition at $T_N = 23$ K. From the entropy change $-\Delta S$ shown in Figure 28 a large anisotropy is emphasized in the sense that the observed magnetocaloric effect over a wide T range in the vicinity of T_N is large for a [10-10] direction, in sharp contrast to relatively smaller values for [0001] direction. This implies that, if the present material could be used for magnetic refrigeration at low temperatures, one may have a relatively better cooling power if the magnetic field H is applied along a [10-10] direction of the crystal (in the basal plane of the hexagonal unit cell) instead of [0001] the perpendicular c axis. Another noteworthy point is that the sign of $-\Delta S$ is essentially positive for the former direction, whereas it is negative for the latter.

The utilization of anisotropic materials was subject of a recent theoretical study, too (Lima, Gschneidner and Pecharsky, 2004). The results indicated that using single domain magnetic materials it is theoretically possible to increase the efficiency of magnetic refrigeration up to 65% for a device operating at low temperature and utilizing $TbAl_2$.

4.5 Selected intermetallic compounds for spintronics

Spin-polarized transport in magnetic materials is beginning to play an important role in the development of magnetoelectronic devices. Half-metallic (HM) ferromagnetic materials have recently drawn intense interest due to their potential use in this field (see contributions in Vol. 5 of this Handbook).

Investigation of single crystals are usually used to verify theoretically predicted magnetic effects and properties since it is believed that they represent the least disturbed structure of a compound and its intrinsic properties. There are only a few publications about the growth of single crystals in this group of materials. The ferromagnetic shape memory compound Ni_2MnGa plays an important role (Schlagel, Wu,

Hang and Lograsso, 2000) (cf. Section 4.3.3) as do the compounds Co_2MnX (X = Si, Ge) (Cheng *et al*., 2001) due to their high Curie temperatures and the predicted high spin polarization.

Cheng *et al*. (2001) reported the growth of both Co_2MnSi and Co_2MnGe high-quality crystals. The magnetic moment per formula unit of 5.1 μ_B well agrees with the known predictions and confirmes the semimetallic nature of these materials. Cheng started from the pure elements (better 3N purity), which were melted together by arc melting under argon atmosphere. The compound was homogenized by turning and remelting the boule. The crystal growth proceeded using the tri-arc Czochalski method. Using small seed crystals from a previous experiment, single crystals about 6 mm in diameter and 30–40 mm in length were grown at 7 mm h^{-1} with a seed rotation of 15 rpm opposite to the rotation of the hearth of the tri-arc facility. The temperature of the melt, measured by optical pyrometry, was raised to about 1523 K before immersing the starting seed. Slices of both crystals were annealed at 1073 K for nine days followed by water quenching. The crystals are single phase and single crystalline with an orientation near [100].

Single crystals of the full-Heusler compound $Co_2Cr_{0.6}Fe_{0.4}Al$ were grown by the FZ technique by the authors. Firstly, starting materials (purity better than 3N) are mechanically or chemically treated, to remove oxide films often present on metal pieces in spite of highly pure conditions of storage. Then all the materials are initially melted in an arc-melting furnace on a water-cooled Cu plate under purified argon atmosphere. The resulting master alloy is remelted in a Hukin-type cold crucible with RF induction heating and cast into a copper mould with a cylindrical cavity. The cylindrical rod produced, typically 6 mm in diameter and 60–80 mm in length, is used for FZ crystal growth as a feed rod.

The single-crystal growth was accomplished by vertical FZ techniques with optical heating (see Figure 10) at a growth rate of 12 mm h^{-1}. Axially symmetric counterrotation of crystal (30 rpm) and feed rod (10 rpm) was employed. The crystals shown in Figure 29 were single crystalline over the whole diameter for the last 20 mm. They were oriented by Laue technique and cut for magnetic measurements.

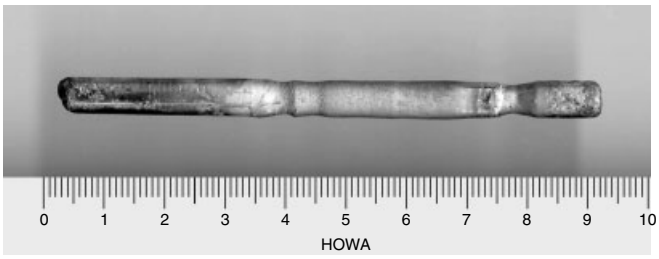

Figure 29. $Co_2Cr_{0.6}Fe_{0.4}Al$ single crystal grown by FZ method. (Courtsey of G. Behr, IFW Dresden, 2005.)

4.6 Crystal growth of multiferroic materials

Multiferroics, sometimes called *magnetoelectrics*, possess two or more switchable properties (order parameters) such as electrical polarization, magnetization, or strain (Smolenski and Chupis, 1982; Schmid, 1994a,b). Although a number of materials exhibit both ferroelectricity and (anti)ferromagnetism, there is not always a substantial coupling between them. In contrast, in most cases ferroelectricity and magnetic ordering exclude each other (Khomskii, 2006). Of practical interest is the potential to control (i) the spontaneous electric polarization by a magnetic field or (ii) the magnetization by an electric field through magnetoelectric coupling. These materials may have a perspective for future device applications such as electrically recorded magnetic media.

Magnetoelectric effects have been studied in some multiferroics since the late 1960s. In general, the applied magnetic field results in a small modulation of the spontaneous polarization. Why and under which circumstances a large coupling should come about is a major open question, but this problem has proved difficult to tackle owing to the lack of materials that show such strong coupling (Hur *et al*., 2004a). Recently, some compounds with huge magnetoelectric effects have been found among Mn oxides: in $HoMnO_3$, ferromagnetic ordering can be switched on and off by an electrical voltage (Lottermoser *et al*., 2004), and $TbMn_2O_5$ exhibits a practical value for magnetically controlling a ferroelectric polarization, which can be continuously tuned by a magnetic field between two states with opposite direction (Hur *et al*., 2004a).

4.6.1 Magnetic and ferroelectric phases of the family of RMn_2O_5 compounds

In comparison to the family of the hexagonal manganites $RMnO_3$ (R = Ho-Lu), the number of investigations on RMn_2O_5 single crystals (R = Y, Bi, or a rare-earth element) is scarce. In spite of the detailed studies of selected RMn_2O_5 compounds, little is actually known about the detailed interplay of ferroelectricity and magnetism in RMn_2O_5, primarily owing to its chemical and structural complexity (Saito and Kohn, 1995; Golovenchits, Morozov, Sanina and Sapozhnikova, 1992). According to the authors (Chapon *et al*., 2004) the emergence of ferroelectricity is a consequence of magnetic frustration between nearest and next-nearest Mn^{4+} neighbors in an antiferromagnetic square lattice.

RMn_2O_5 belongs to the orthorhombic space group *Pbam* at room temperature. Upon cooling below 50 K it displays a sequence of magnetic and electric phase transitions the nature of which is a result of the interplay of magnetic exchange interactions among Mn^{3+}, Mn^{4+}, and R^{3+} spins (if the R^{3+} ion is magnetic) and the lattice polarization (Sanina, Sapozhnikova, Golovenchits and Morozov, 1988; Kagomiya and Kohn, 1998). Mn spins order at the antiferromagnetic Neel temperature T_{N1} of about 40 K. According to earlier neutron diffraction studies, magnetic moments of Mn^{3+} and Mn^{4+} ions form a helical magnetic structure below $T_{N1} = 39 - 45$ K (Wilkinson *et al*., 1981; Kagomiya, Kimura, Noda and Kohn, 2001; Hur *et al*., 2004a).

The technological potential of most of the known magnetoelectric compounds is limited by (i) the small magnitude of the observed effects and (ii) by the low operating temperatures (<100 K). The rather low values of the ferroelectric Curie temperature T_C and the spontaneous polarization with respect to typical ferroelectrics seem to indicate a weak nature of the ferroelectricity of RMn_2O_5, which is induced by an ordering process differing from that of typical ferroelectrics (Kato, Kohn and Ishikawa, 1997).

However, operating temperatures might be increased by an appropriate substitution of Mn by other transition metals T = Fe, Co, as was shown by Shim *et al*. (2004). The small magnitude of magnetoelectric effects observed so far has been overcome in some recently investigated compounds of RMn_2O_5 (Fiebig, 2005). A significant magnetodielectric effect, that is, a change of the dielectric constant ε in an applied magnetic field, was reported near a unique commensurate–incommensurate magnetic transition in (Tb, Dy, Ho)Mn_2O_5, which is intricately coupled with a dielectric transition. In particular, the magnetodielectric effect for $DyMn_2O_5$ is more than 100% (along the crystallographic *b* axis) in a broad temperature range below T'_N if the magnetic field is applied along the *a* axis of the crystal (Hur *et al*., 2004b). This 'colossal magnetodielectric' (CMD) effect demonstrates a new kind of an intriguing interplay between spin and lattice degrees of freedom being active in RMn_2O_5. It provides an important means to tune dielectric properties with external magnetic fields (Hur *et al*., 2004a).

In $TbMn_2O_5$, a reversal of the electric polarization in a magnetic field of the order of 1 T has been observed below the antiferromagnetic ordering at $T_{N1} = 38$ K, including a memory effect with remnant states (Hur *et al*., 2004a). The behavior is reproducible throughout many cycles. This effect can be used to set the polarization in a controlled way with a magnetic field. In ferroelectric YMn_2O_5 crystals, a strong enhancement of the electrical polarization can be achieved by application of large magnetic fields of about 20 T (Kadomtseva *et al*., 2003).

The unit cell parameters of the RMn_2O_5 phase differ significantly from those in the adjacent regions of the bivariant equilibrium in the corresponding thermodynamic phase diagrams (Fedorova, Titova, Golikov and Balakirev, 2003). The fact that the unit cell can be varied with the chemical composition of the initial components indicates the existence of a sizable region of homogeneity of this substance both with respect to metal components and oxygen. No further studies in this direction have been reported, although a possible strong effect of the crystal composition and corresponding point defect structure on physical properties can take place similar to those of superconducting cuprates (Liang and Lin, 2002; Gorina *et al*., 1998).

4.6.2 Thermodynamics and crystal growth of RMn_2O_5 compounds

The study of the phase diagrams of R–Mn–O (R = Y, Tb, and Ho) systems as function of temperature, composition, and the oxygen partial pressure p_{O_2} is of great importance for controllable single-crystal growth of RMn_2O_5. The previous studies were mainly focused on subsolidus phase diagrams at low oxygen pressures ($p_{O_2} = 0.02 - 0.1$ MPa) (Balakirev and Golikov, 2003; Munoz, Alonso, Martinez-Lope and Martinez, 2004; Kitayama *et al*., 2002; Fu, Huebner, Trubelja and Stubican, 1994). Systematic studies at elevated oxygen pressures are missing, but are extremely important for RMn_2O_5 phase formation, since at lower p_{O_2} the decomposition reaction proceeds at high temperatures:

$$RMn_2O_5 \Longleftrightarrow RMnO_3 + \frac{1}{3}Mn_3O_4 + \frac{1}{3}O_2 \qquad (4)$$

An increase of the decomposition temperature of RMn_2O_5 with increasing p_{O_2} is expected and has been confirmed by Fu, Huebner, Trubelja and Stubican (1994). This behavior of RMn_2O_5 is evident since the high oxygen pressure favors the stabilization of the high oxidation states of manganese, Mn^{4+} and Mn^{3+}. Oxygen pressures of more than 20 MPa seem to be overstated for the synthesis of RMn_2O_5 compounds, since heat treatment of $LaMn_2O_5$ and $SmMn_2O_7$, which can not be synthesized at 0.02 MPa, at these pressures show higher Mn mean oxidation states of 3.56+ and 3.63+, respectively. That corresponds to an increased oxygen concentration with respect to the stoichiometry (Munoz *et al*., 2004).

The polycrystalline materials of RMn_2O_5 (R = Y, Tb, Ho) can be synthesized by conventional solid-state reactions at around 1100 °C in air for 48–72 h. La and Nd systems require higher pressures p_{O_2} at these temperatures (Kitayama *et al*., 2002). But, since RMn_2O_5 materials show strongly anisotropic properties (Hur *et al*., 2004a; Fiebig, 2005) the studies are preferably carried out on single-crystalline samples oriented in an appropriate way. In this case, the

effects of minor phases, grain size and grain boundaries are excluded and the intrinsic behavior of the crystal lattice can be studied. Therefore, availability of single crystals of several tens of cubic millimeter size, high purity, and structural perfection is of great importance.

Single crystals of RMn_2O_5 compounds have been grown by a flux technique (cf. Section 3.2) at various solvent compositions (Wanklyn, 1972; Sanina, Sapozhnikova, Golovenchits and Morozov, 1988; Golovenchits, Morozov, Sanina and Sapozhnikova, 1992).

Rare-earth manganites have been grown firstly from Bi_2O_3 and from PbO/Bi_2O_3 solvents (Tamura, Sawaguch and Kikuchi, 1965). These fluxes attack Pt crucibles severely, and since Bi^{3+} is similar in size and charge to R^{3+}, it tends to replace R^{3+} in the crystal lattice up to several at% (Wanklyn, 1972; Sanina, Sapozhnikova, Golovenchits and Morozov, 1988). Better RMn_2O_5 crystals of higher purity have been grown from PbO/PbF_2 flux, which is less corrosive and does not show a noticeable solubility of the solvent elements in the RMn_2O_5 phase (Wanklyn, 1972). Single crystals of RMn_2O_5 of several cubic millimeters in size grown from $PbO/PbF_2/B_2O_3$ flux in a Pt crucible have been reported by Wanklyn (1972). Afterwards the same technology was repeated by almost all other groups for preparing single crystals of RMn_2O_5 compounds (Kagomiya *et al*., 2003; Inomata and Kohn, 1996; Gardner, Wilkinson, Forsyth and Wanklyn, 1988; Kobayashi *et al*., 2004a,b; Doi and Kohn, 1992; Kagomiya and Kohn, 1998; Kato, Kohn and Ishikawa, 1997; Koyata and Kohn, 1997; Koyata *et al*., 1996) and with small variations in the growth parameters (Golovenchits, Morozov, Sanina and Sapozhnikova, 1992; Sanina, Sapozhnikova, Golovenchits and Morozov, 1988). The flux was usually held at 1280–1300 °C for 10–15 h at ambient oxygen pressure and then slowly cooled down to 950–1000 °C. Crystals grow in the form of black pellets or cubes with a typical size of 0.5–5 mm (Hur *et al*., 2004a). No characterization of the crystal perfection, inclusions of other phases and crystal purity were reported so far.

There are only a few reports about doping of $RMn_{2-x}T_xO_5$ polycrystalline materials (Shim *et al*., 2004; Munoz *et al*., 2002) and to our knowledge nothing about doping of the single crystals.

4.7 Crystal growth activities of less-common magnetic alloys

Numerous multicomponent intermetallic rare earth–transition metal compounds with interesting magnetic properties have only minor practical interest and therefore we can cite only a few recent examples of crystal growth activities.

In 1994 intermetallic R–T borocarbides, RT_2B_2C (R = rare-earth elements, Sc, Y, or La; T = Ni, Pd) were discovered (Nagarajan *et al*., 1994). Depending on the rare-earth component the compounds with the tetragonal body-centered $ThCr_2Si_2$-type crystallographic structure can exhibit magnetic ordering, superconductivity, or an interesting interplay of both phenomena. Because of the high melting temperatures (>1500 °C) and the extreme reactivity of the melts with oxygen and practically all known crucible materials the crystal growth of these compounds is rather challenging. So far two methods of crystal growth were successfully applied. Crystals grown by the Ni_2B-flux method provide a basis for the determination of several anisotropic physical properties of quaternary RNi_2B_2C but suffer from the relatively small size and imperfections arising from the flux (Cho *et al*., 1995; Rathnayaha *et al*., 1997). For some of the compounds the FZ methods were applied for the growth of bulk crystals typically 6 mm in diameter and up to 40 mm in length (Takeya, Hirano and Kadowaki, 1996; Takeya, Kadowaki, Mirata and Mirano, 1996; Behr *et al*., 1999; Souptel *et al*., 2005; Behr and Löser, 2005). The $TbNi_2B_2C$ compound displays antiferromagnetic ordering below $T_N = 14$ K. The relevant pseudobinary section TbB_2C_2–$TbNi_2B_2C$–$TbNi_4B$ of the quaternary phase diagram with a peritectic temperature of $T_p = 1518$ °C is shown in Figure 30 (Behr *et al*., 1999). The incongruent melting of the RNi_2B_2C compound implies that the phase is only formed from the off-stoichiometric FZ composition. This corresponds to a TSFZ method in a stable growth process and limits the pulling velocities to $<2\,mm\,h^{-1}$. If stoichiometric feed rods are used, the initial part of the crystal contains inclusions of the TbB_2C_2 primary phase before the composition of the FZ gradually approaches the composition in the primary solidification range of $TbNi_2B_2C$ (Figure 31).

Single crystals of ternary R_2PdSi_3 (R = Ce, Gd, Tb, Dy, Ho, Er, Tm) compounds, which display hexagonal AlB_2-type structures, where successfully prepared both by the tri-arc CZ method (Saha *et al*., 1999, 2000) as well as by FZ methods in Ar atmosphere (Graw *et al*., 2000; Mazilu *et al*., 2005). The challenges for crystal growth are similar to the above-mentioned RNi_2B_2C compounds; however, the compounds are congruent melting and therefore enable higher growth velocities of $5–10\,mm\,h^{-1}$ (Graw *et al*., 2000; Mazilu *et al*., 2005). The compounds exhibit various types of incommensurate magnetic orderings, metamagnetic transitions, and a giant negative magnetoresistance if the critical temperatures are approached (Saha *et al*., 1999, 2000; Majumdar *et al*., 2000).

The availability of high-quality single crystals of R_2PdSi_3 compounds (R = Ce, Gd, Tb, Dy, Ho, Er, Tm) made it possible to study in more detail the magnetic properties of compounds of the same crystallographic structure but for

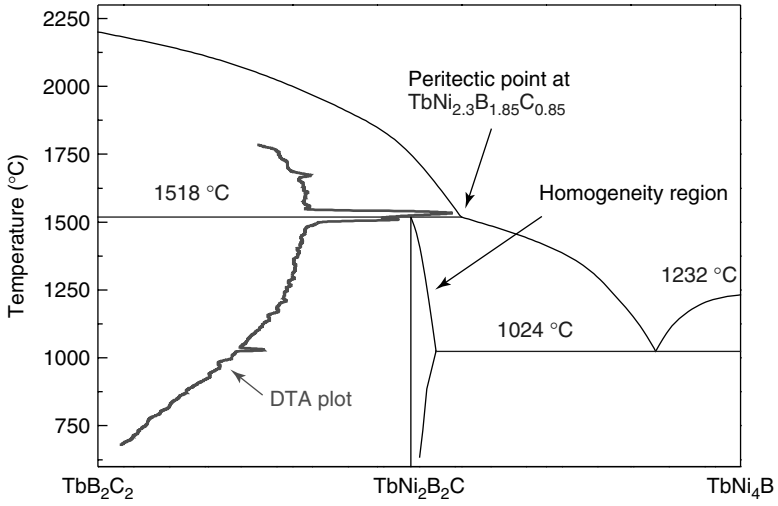

Figure 30. Tb–Ni–B–C phase diagram section TbB_2C_2–$TbNi_2B_2C$–$TbNi_4B$ relevant for $TbNi_2B_2C$ crystallization processes. Superposed is a differential thermal analysis (DTA) heating plot. (Courtesey of H. Bitterlich IFW, Dresden, 2000.)

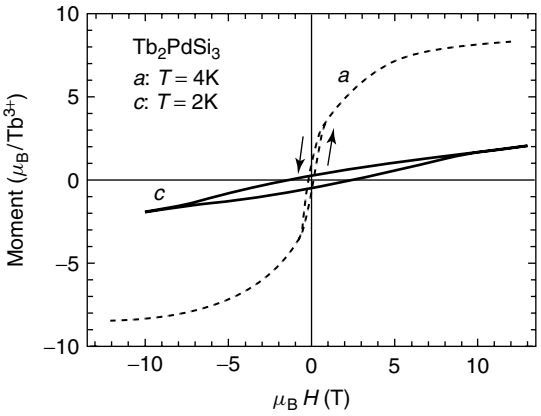

Figure 32. Tb_2PdSi_3 single-crystal magnetization data at $T = 2\,K$ for the c direction and at 4 K for the a direction well below the ordering temperature ($T_N = 23.6\,K$). (Reproduced from Frontzek *et al*., 2006, with permission from Elsevier. © 2006.)

rare-earth elements with different shapes of the 4f orbital (Frontzek *et al*., 2006). Investigations on these single crystals yielded anisotropic magnetic behavior in all substances, surprisingly even for the Gd compound, which is an S-state ion. In the high-temperature regime the magnetocrystalline anisotropy is dominated by the lowest order crystal electric field (CEF) term B_{02}. At lower temperatures CEF terms of higher order induce deviations from the Curie-Weiss law. Still, the B_{02} term dominates the CEF for Tb_2PdSi_3 and Er_2PdSi_3 and determines the magnetic easy direction in the ordered state, too (Figures 32 and 33). In contrast, the magnetic easy and magnetic hard directions in the ordered state are determined by higher order terms for Dy_2PdSi_3 and Ho_2PdSi_3. This leads to the crossing of the magnetic easy and hard direction in the paramagnetic state far above the Neél temperature in both compounds. The low ordering temperatures also indicate a delicate balance of magnetic exchange interaction and CEF.

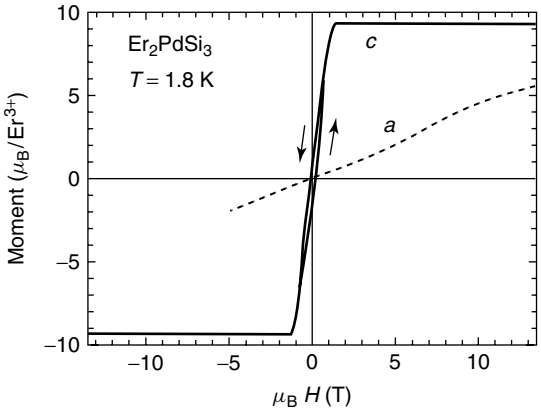

Figure 33. Er_2PdSi_3 single-crystal magnetization data at $T = 1.8$ K well below the ordering temperature ($T_N = 7$ K). (Reproduced from Frontzek *et al*., 2006, with permission from Elsevier. © 2006.)

5 CONCLUSIONS

In this chapter, we have summarized the crystal growth methods, single-crystal growth attempts, and some characteristic measurements of magnetic properties of various classes of magnetic materials: soft magnetic pure metals and alloys, highly anisotropic compounds for high-density magnetic recording media, rare earth–transition metal compounds for high-performance permanent magnets, highly magnetostrictive intermetallic compounds and FSMAs for magnetomechanical applications, magnetocaloric materials, selected intermetallic compounds for spintronics, multiferroic materials, and some other less-common magnetic compounds. The main purpose of single-crystalline specimens is to carry out measurements of intrinsic properties of magnetic materials or their constituent phases as a function of the crystallographic orientation and composition, but complex crystallographic structures or magnetic ordering of compounds and magnetization processes can also be revealed. Single crystals with optimum orientation of magnetostrictive materials and FSMAs are even prospective for commercial applications in high-performance devices.

It was shown in various examples for crystal growth of magnetic materials how phase diagram features of the alloy system, the required size of the single-crystalline specimen and its physical and chemical perfection determine the choice of the appropriate growth method and appropriate process parameters. For example, if a compound is formed by a peritectic reaction, slower growth rates are applied for crystal growth than for congruent melting compounds. In case of solid-state transformations below the melting temperature, high-quality crystals cannot be prepared directly from the melt, but strain-anneal techniques of the as-grown samples are required. Other important issues are the melt reactivity with crucible materials and the environmental gas, and volatile elements. Here container-less growth techniques (FZ melting) and special flux techniques, which operate at reduced temperature, can be useful. However, there are still a number of magnetic systems from which 'highly desirable' single crystals cannot be prepared or only with insufficient quality. In this case, single crystals with substituted elements of the same class of compounds (with the same crystallographic structure) turned out to be helpful to reveal important anisotropic magnetic features. Novel techniques, phase diagram studies as well as new ideas on growth processes are necessary for further progress in single-crystal preparation of some well-known and prospected new magnetic materials.

ACKNOWLEDGMENTS

The authors would like to express their gratitude to H. Bitterlich, M. Frontzek, A. Gebert, G. Graw, W. Gruner, I. Mazilu, S. Oswald, M. Rada, R. Scharfenberg, D. Souptel, and A. Teresiak for providing experimental data, text contributions, and helpful discussions. We thank S. Müller-Litvanyi, R. Müller, and S. Pichl for their engaged work in crystal characterization, J. Werner and J. Stöhr for technical assistance during the preparation of the manuscript, and T. Woodcock for carefully reading the text. The financial support of the Deutsche Forschungsgemeinschaft within the SFB 463 'Rare-Earth Intermetallics: Structure, Magnetism, and Transport' is grateful acknowledged.

Amorphous Alloys

Hywel A. Davies and Michael R.J. Gibbs
University of Sheffield, Sheffield, UK

1 INTRODUCTION AND BACKGROUND

Amorphous alloys, also frequently referred to as *metallic glasses*, *noncrystalline alloys*, or *glassy alloys*, are metallic materials that are devoid of long-range atomic order. They can be produced by several different techniques, most of which involve rapid solidification from the liquid or gaseous state. However, other, very different routes, including (i) mechanical alloying of crystalline precursor materials, either elemental or partly prealloyed; (ii) mechanical milling of prealloyed crystalline precursors; (iii) high energy ion or neutron bombardment of crystalline alloys; (iv) electroless deposition from solution; or (v) electrodeposition from solution, have been successfully employed to produce amorphous alloys.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

This overview is concerned specifically with soft ferromagnetic amorphous alloys. It is restricted very largely to material produced in ribbon forms by rapid solidification from the liquid state, except for, where necessary for the purposes of comparison, brief mention of materials produced by other routes. These soft ferromagnetic glassy alloy ribbon materials, often described by their trade names 'METGLAS®' or 'VITROVAC®', together with the nanocomposite ultrasoft magnetic 'FINEMET®' and 'VITROPERM®' alloys and the nanocrystalline melt spun rare earth (RE)–iron–boron-based hard magnetic alloys, having the trade name 'MQP®', are among the most successful examples of the commercial exploitation of rapid solidification technology in the production of advanced alloys.

The first explicit report of a ferromagnetic amorphous alloy was for sputter-deposited thin-film Co–Au by Mader and Nowick (1965), following the earlier theoretical prediction of amorphous ferromagnetism (Gubanov, 1960). The first reported ferromagnetic melt-quenched glassy alloys were $Pd_{12}Co_{68}Si_{20}$ (Tsuei and Duwez, 1966) and $Fe_{83}P_{10}C_7$ (Duwez and Lin, 1967), produced by a piston and anvil splat-quenching technique. The discovery of other, more favorable, ferrous alloy glass-forming compositions, particularly those based on (Fe, Co, Ni)SiB, and the demonstration of the excellent soft magnetic properties of alloy glasses after annealing to remove the quenched-in stresses (Luborsky *et al*., 1975) stimulated rapid growth of scientific and technological interest in the materials. With the utilization of the single-roll melt-spinning technique for producing thin ribbon in extended lengths (Liebermann and Graham, 1976; Kavesh, 1978), the pace of development accelerated greatly in the late 1970s and 1980s. A key step in the commercial exploitation of metallic glasses, pioneered by Allied Chemical in the United States, was the development of the planar flow casting (PFC) process (Narasimhan, 1979), which

facilitated the continuous casting of glassy alloy ribbon in uniform widths up to 300 mm and with good thickness tolerance down to as low as 15 μm but, more typically, 25–30 μm. This led to the use of FeSiB-based glassy alloys for the cores of toroidally wound distribution transformers, typically of capacity 25 kVA, on the basis of significantly lower core losses and exciting currents than for the long entrenched Fe-3wt%Si crystalline materials (Smith, 1993; Hasegawa, 2004). Similarly, very low magnetostriction CoFeSiB-based alloy glass ribbons have been widely exploited, where very high permeabilities μ and low coercivities H_c are required, as in small high-frequency transformers, inductors, and chokes, in competition with the commercially established Fe–80Ni crystalline permalloys. Another major application of the alloy glass ribbons has been for security tags in stores and libraries. These aspects of the magnetic properties and applications are discussed in Sections 7 and 8.

Amorphous FeSiB- and FeZrB-based alloys with, in the former case, small additions of Cu and Nb are also used in ribbon forms as precursors for the evolution by heat treatment of exceptionally low H_c and high μ nanocomposite structures (Yoshizawa, Oguma and Yamauchi, 1988; Suzuki *et al*., 1990). These are based on a 70/30 vol% mix of Fe–Si or Fe nanocrystallites in an untransformed residual amorphous matrix. This class of alloys is reviewed by Herzer in **Soft Magnetic Materials – Nanocrystalline Alloys, Volume 4**.

In the early 1980s, a variant of melt spinning, involving the casting of a fine stream (typically ~100 μm diameter) of glass-forming alloy melt into a rotating bath of water, was adopted in the production of amorphous ferromagnetic round section wire (Ohnaka, Fukusako and Ohmichi, 1982). These wires, because of their particular cylindrical geometry and magnetic domain structure, can have magnetic hysteresis characteristics substantially different from those of amorphous alloy ribbons of the same compositions. Even finer glassy alloy filaments, with diameters down to below 5 μm and known as *microwires*, can be produced by a variant of the Taylor wire process (Taylor, 1924). Here, the molten alloy, encased within a viscous molten silicate glass jacket, is drawn down by a continuous process and vitrified by water quenching. The stress induced by the differential thermal contraction of the alloy core and silicate sheath during solidification also imparts unique magnetic characteristics. These amorphous wires and microwires can be exploited for practical devices such as magnetic field or stress sensors. The processing and magnetic properties of such wires are reviewed by Vazquez in **Advanced Magnetic Microwires, Volume 4**.

Recently, several multicomponent ferromagnetic alloys have been shown to be glass forming at low rates of cooling such that they can be vitrified in thicknesses >1 mm (Inoue, 1997, 2000). This class of alloys, which offers the possibility of producing soft magnetic cores in a wide range of shapes by direct casting from the melt, is reviewed by Inoue *et al*. in **Soft Magnetic Bulk Glassy and Bulk Nanocrystalline Alloys, Volume 4**.

2 FORMATION AND GENERAL CHARACTERISTICS OF GLASSY ALLOYS

2.1 Glass-forming criteria and structure

A noncrystalline solid formed by continuous cooling from the equilibrium liquid state is known as a *glass* in the classical sense of the word. Such vitrification necessitates cooling to below the glass transition temperature T_g at a rate that is sufficiently high to avoid the development of the long-range order that characterizes the crystalline state. It is unlikely that a *pure* metal could be vitrified to a stable glass from the liquid state, and additions of one or more solute elements are required in order to render the glass resistant to crystallization at room temperature and above. The structure, after vitrification, can be described (Polk, 1972) as a dense random packing of hard spheres. However, it is not entirely random and retains a significant degree of *short-range* order (SRO), both topological and chemical, from the equilibrium liquid state. The chemical SRO was first explicitly demonstrated experimentally by Sadoc and Dixmier (1976) for a CoP alloy, on the basis of atomic pair correlation functions, derived from Fourier transforms of neutron and X-ray diffraction data; the results clearly showed the absence of P–P pairs at the distance expected from the P atom diameter. The SRO can be enhanced or modified by elevated temperature annealing of the glassy structure, as is evident from the fact that this causes mechanical embrittlement in certain compositions, particularly Fe-based alloys (Davis, 1976). This evidently results from reduction in quenched-in 'free volume' through short-range diffusive displacements, particularly of the small metalloid atoms. The effects of annealing on magnetic properties, especially including field and stress annealing, provide further evidence of changes in the local order (Luborsky and Walter, 1977a,b); in fact, such field and stress annealing evidently result in *directional* chemical ordering of the metal–metalloid bonds.

In addition to thermally stabilizing the glassy state, the additions of suitable solute elements in appropriate concentrations to a base metal are a prerequisite for increasing the glass-forming ability (GFA) such that the glassy phase can be produced in tractable and useful section thicknesses. Thus, the GFA can be expressed either as the critical cooling rate for glass formation R_c or the minimum thickness of fully

glassy phase x_c that can be formed by a particular quenching process (Davies, 1978, 1983). The aim in rendering an alloy readily glass forming (RGF) is to depress the liquidus temperature T_l to a level well below the weighted mean melting temperature for the pure component elements or of the pure base metal and any intermediate high-melting-point compound phase. Here, we define an RGF composition as one having an $R_c \leq 10^6\,\mathrm{K\,s^{-1}}$, which corresponds to a fully glassy phase having a section thickness formed by chill block melt spinning of $>15-20\,\mu\mathrm{m}$. Hence, compositions at or near deep eutectics, such as those that commonly occur in late transition metal–metalloid (LTM–Met) systems, are generally RGF. Examples of deep eutectics in ferromagnetic binary alloy systems include (Fe, Co, or Ni)–(P or B), with eutectic compositions at approximately 20 wt% Met, and these are all RGF. The NiP and NiB alloy glasses are essentially nonmagnetic at room temperature because their Curie temperatures T_C are close to, or below, ambient. Examples of RGF binary ferromagnetic LTM–Met alloys with T_C well above room temperature are Fe-(15–25)at%B and Co-(16–25)at%P.

Addition of a second LTM and/or of a second or more metalloid element tends to enhance the GFA by further depressing the liquidus temperature and preferably also by increasing T_g. A corollary of this is that the composition range for RGF tends to be widened. Examples of such multicomponent ferromagnetic alloy glasses are $Fe_{40}Ni_{40}B_{20}$, $Fe_{78}Si_9B_{13}$, and $Co_{75}Fe_4Si_5B_{16}$. An example of the influence on GFA of Si additions to FeB alloys is given in Figure 1, where some isometrics for various values of critical ribbon thickness of glassy phase x_c, accurately determined from magnetic coercivity measurements, are plotted for the FeBSi ternary system (Luborsky, Reeve, Davies and Liebermann, 1982). This clearly shows how the composition range for RGF of ~14–22 at%B for the binary Fe–B alloys, centered approximately about the eutectic at ~17 at%B, is substantially widened on substitution of Si. The maximum GFA corresponds to a ternary eutectic at $Fe_{75}Si_{10}B_{17}$ with x_c being about 42 μm for ribbon spun on a Cu roll and ~60 μm when spun on a steel roll, for which the thermal contact with the melt is better because of a higher surface temperature.

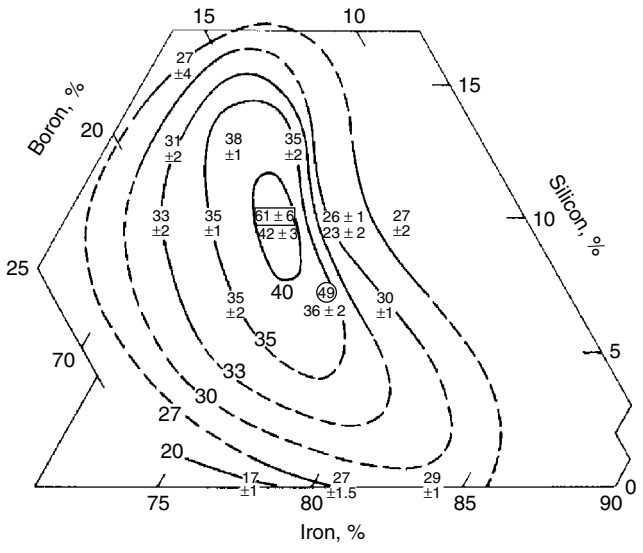

Figure 1. Critical mean thickness determined for various amorphous Fe–B–Si alloys all cast onto a 250-mm-diameter OFHC copper wheel except: cast onto a 300-mm-diameter tool steel roll; ○ cast onto a 76-mm-diameter OFHC copper roll. (Reproduced from Luborsky *et al*., 1982, with permission from IEEE. © 1982.)

Binary alloy systems of the LTM metals Fe, Co, and Ni with the early transition metals (ETMs) Zr, Hf, and Nb from periods 5 and 6 also manifest deep eutectics, generally in the range 8–15 at% ETM; and thus they are RGF. A metalloid element such as B can be added to further enhance the GFA. Examples are $Co_{90}Zr_{10}$ (Nose and Masumoto, 1980) and $Co_{82}Nb_{12}B_6$ (Inoue, Kobayashi, Nose and Masumoto, 1980), which, as for many of the LTM–Met alloys, are soft ferromagnetic at room temperature.

Many of the binary alloys systems of RE metals and of yttrium with LTMs show deep eutectics on the RE-rich side of the system in each case and several have been shown to be RGF by melt spinning, centered approximately about the eutectic composition. Examples of ferromagnetic melt-quenched glassy alloys of the RE–LTM type are Gd-(33–55)at%Co and Gd-(32–50)at%Fe (Fukamichi, Kikuchi, Masumoto and Matsuura, 1979; Buschow, 1979). These are magnetically harder than the LTM–Met and LTM–ETM alloys because of the local anisotropy induced by the RE metals (Coey, 1978). The coercivity level can be manipulated by adjusting the alloy composition. Amorphous RE–TM alloys of interest for magneto-optic recording applications tend, however, to cover different ranges of composition such that they need to be produced by sputter deposition (Grundy, 1980). Because of the absence of the long-range order characteristic of the crystalline state, amorphous alloys do not manifest magnetocrystalline anisotropy and the LTM–Met type can have very high μ and low H_c. Nevertheless, the directionally random chemical order that exists in alloy glasses in the as-quenched state leads to random anisotropy (Alben, Becker and Chi, 1978) . Marked magnetic anisotropy can be induced by the application of a uniaxial stress or a magnetic field during elevated temperature annealing, where significant local atomic diffusion can occur. The degree of strain-induced anisotropy is influenced by the magnitude of the saturation magnetostriction λ_s. These aspects of induced anisotropy are discussed in greater detail in a later section of this chapter. As for all magnetic materials, shape anisotropy also has an influence on the magnetic properties.

The absence of a microstructure in a metallurgical sense, that is, no crystal boundaries that normally act to pin domain walls, also promotes magnetic softness. Moreover, the noncrystalline structure results in high electrical resistivity, typically in the range 100–200 μΩcm, compared, for instance, to values in the range 30–50 μΩcm for crystalline Fe–Si and Fe–Ni permalloys, which favors their application for mains and high-frequency transformers and other devices.

2.2 Strength, deformation, and embrittlement

As a consequence of the absence of crystalline order in the structure, lattice dislocations, which are present in all crystalline metals, are no longer a consideration. Such mobile dislocations in crystalline metallic materials result in yield strengths or elastic limits that are only a fraction of the theoretical values, which correspond to the stresses required to break the interatomic bonds. The yield strengths of metallic glasses typically range between $\sim E/30$ and $\sim E/50$, where E is the Young's modulus (Davis, 1976; Kimura and Masumoto, 1983); thus, they approximate in each case the corresponding theoretical cohesive strength. Fracture strengths of Fe–Met alloy glasses range between ~2.2 and ~4 GPa (the value for $Fe_{78}B_{10}Si_{12}$, for instance, is 3.4 GPa) (Kimura and Masumoto, 1983), but a compressive strength in excess of 5000 MPa was recently recorded for a $Co_{43}Fe_{20}Ta_{5.5}B_{31.5}$ bulk glass (Inoue *et al.*, 2003). It should be borne in mind that values of E for alloy glasses are lower than those of equivalent crystalline alloys, typically by ~20–40% for Fe-based alloys, for example; this reflects the slightly larger mean interatomic distances in the glass than in the crystal, consistent with a lower atomic packing density. The ultrahigh strengths of metallic glasses are also reflected in very high microhardness, for instance, typically ~900–1000 H_v for Fe–Met and Co–Met-type ferromagnetic alloy ribbons but somewhat lower for corresponding Ni–Met-based glasses.

At temperatures well below T_g and at high values of stress τ, where $\tau > \mu/50$ (μ is the shear modulus), metallic glasses deform heterogeneously by a highly localized shear mechanism. The shear bands are thought to be extremely narrow –a few nanometers wide (Donovan and Stobbs, 1981). The fact that they can be revealed by metallographic etching of a deformed cross section indicates that the chemical SRO is locally modified by the shearing process. When deformed in pure tension, most Fe-, Co-, and Ni-based alloy glasses in their as-cast state fail by a single shear displacement at the yield stress, which is usually slightly above the limit of proportionality, on a plane ~55° to the applied stress (Kimura and Masumoto, 1983). In bending, which is a mixture of tensile and compressive straining, the compressive component stabilizes the material against tensile failure, and Fe-, Co-, and Ni–Met-type alloy glass ribbons in their as-cast state (unless the total metalloid element concentration is high) can generally be bent back on themselves to a true tensile strain of unity on the outer surface, through the occurrence of multiple shearing. Thus, in such cases, the toughness of the material can be described as high. However, on annealing at elevated temperatures, for instance, to relieve the quenching stresses and thus optimize the soft magnetic properties, Fe–Met-based glasses undergo irreversible embrittlement, prior to crystallization (Davis, 1976; Luborsky and Walter, 1976). The particularly detrimental role of P in promoting embrittlement was demonstrated by Luborsky and Walter (1976). It is interesting that Ni-based LTM–Met glasses, in contrast, tend not to embrittle in the glassy state prior to crystallization, particularly if the metalloid concentration is <20 at% (Lewis, Ward and Davies, 1979) and P is avoided as an alloying element. Progressive substitution of Ni by Fe results in a transformation from a nonembrittling to an embrittling regime, depending on the metalloid species and concentration (Ward, Hunger, Lewis and Davies, 1979).

The embrittlement phenomenon in metallic glasses is not clearly understood. It results from subtle changes in the chemical SRO associated with structural relaxation, that is, the removal by annealing of excess free volume quenched during the vitrification. All Fe-based LTM-Met metallic glasses are characterized by ductile–brittle transitions at a temperature T_{db}, by analogy with crystalline Fe and other bcc metals. In the as-cast state, T_{db}, for technologically important Fe–Met alloys glasses, for instance, $Fe_{78}Si_9B_{13}$, is below ambient temperature, whereas on annealing at elevated temperature, T_{db} increases, largely irreversibly, to above ambient temperature.

At low stresses, or as the temperature approaches T_g, metallic glasses deform by homogeneous flow or creep and, at sufficiently low stresses, the flow is Newtonian viscous, that is, the strain rate is proportional to stress (Spaepen and Taub, 1983). This is a common feature of many noncrystalline materials, pitch being a classical example.

3 FUNDAMENTAL MAGNETIC PROPERTIES

3.1 Magnetic moment

The dependence of saturation moment per TM atom, determined at 4.2 K, on the TM content for $LTM_{80}B_{20}$ and

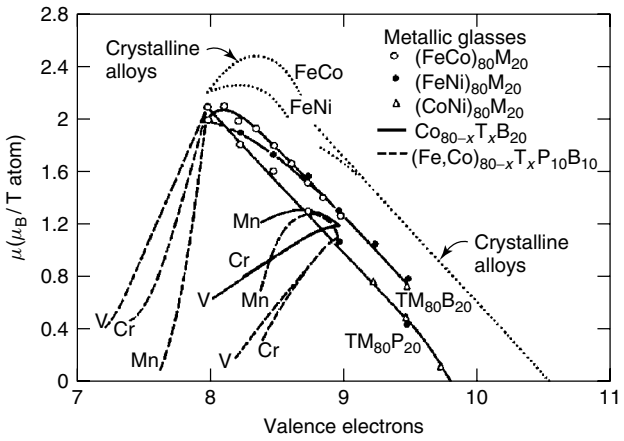

Figure 2. Variation of magnetic moment per transition-metal atom in crystalline and amorphous alloys as a function of number of valence electrons n_v. The values $n_v = 8$, 9, and 10 correspond to Fe, Co (or $Fe_{0.5}Ni_{0.5}$), and Ni respectively. (Reproduced from R.C. O'Handley, 2000. © 2000 John Wiley & Sons Inc.)

$LTM_{80}P_{20}$ glassy alloys (O'Handley, 2000) is given in Figure 2 (LTM in this case indicates Fe, Co, and/or Ni). The corresponding variations of moments for crystalline alloys are included as dotted lines. The displacement of the data for the glassy $LTM_{80}B_{20}$ alloys, relative to the Slater–Pauling curve, is consistent with data for crystalline (LTM)B and $(LTM)_2B$ compounds and alloys (O'Handley, 2000). Relatively large magnetic moments are achieved in a wide range of glassy alloys based on Fe, Co, Ni. The lower moments than for the corresponding crystalline alloys are not only consistent with the concentration(s) of the nonmagnetic metalloid atom(s), B and/or P in the present case, but also commonly including Si, which are added to promote vitrification by rapid quenching. Hence, the influence of the absence of a long-range order in the glassy alloys on the magnetic moment per LTM atom is considered to be negligible (O'Handley, 2000). The effects of the ETM solute substitutions, exemplified in Figure 2 by Cr, Mn, and V, can be rationalized on the basis of the virtual-bound-state model (O'Handley, 2000).

The saturation moment per TM atom increases with increasing TM:Met ratio for both Fe-based (FeB and FeP) and Co-based (CoB, CoB, CoZr) alloy glasses and extrapolates to values only slightly lower than those for bcc Fe and hcp Co, respectively (O'Handley, 2000).

3.2 Curie temperature

The dependence of the Curie temperature T_C on the LTM content for glassy $(FeNi)_{80}B_{20}$, $(FeCo)_{80}B_{20}$ alloys and for various other amorphous alloy systems is shown in Figure 3 (O'Handley, 2000). The T_C data for FeNi and FeCo crystalline alloys are summarized by the dotted lines. The compositional dependence of T_C for the glassy alloys is not as amenable to theoretical analysis as is the case for that of the magnetic moment. Although the shape of the dependences for the amorphous FeNi-based alloy systems is broadly similar to that for the crystalline FeNi system, the maxima in the glassy alloy curves are displaced to lower valence electron to atom ratios.

The influence on T_C of a wide range of TM and platinum group metal solute substitutions for Fe in $FeSi_{10}B_{12}$ metallic glasses, up to concentrations x of ∼10 at%, were investigated by Donald, Kemeny, and Davies (1981). The dependence of T_C on x was generally linear or nearly linear and the values of dT_C/dx are plotted against the group number of the solute in Figure 4.

It is interesting to note that the shapes and positions of the curves bear a much closer resemblance to that for $Ni_{100-x}M_x$ binary crystalline alloys than to that for $Fe_{100-x}M_x$ alloys (see Donald, Kemeny and Davies, 1981). This suggests that the majority subband in Fe-based glasses is full, due to the hybridization of the s–p states of the metalloid with the d orbitals of the TMs, as is the case for crystalline Ni. Also, the approximately 12-fold atomic coordination in the glassy state for the Fe-based glass bears a much closer resemblance to that in crystalline fcc Ni than to that in bcc Fe.

The magnitude of T_C for LTM–Met glasses is also strongly influenced by the metalloid element concentration and, especially in Co-based alloys, by the metalloid species. In FeB glassy alloys, T_C increases from ∼510 °C at 12 at%B to ∼750 °C at 28 at%B (Hasegawa and Ray, 1978). In contrast, for Co–Met binary alloy glasses, T_C decreases with increasing metalloid content at a rate of approximately 50 °C per at% metalloid, though CoP alloys have substantially lower T_C values than CoB alloys at any given metalloid concentration, clearly indicating the strong influence of the local atomic environment on this parameter (O'Handley, 1983). However, the concentration ranges over which measurements are possible for these Co-based binary alloy glasses, and indeed for most other Co-based glassy alloys, is limited because T_C is higher than the crystallization temperature T_x.

It should be borne in mind that T_C for a glassy alloy is not absolutely fixed and depends on the structural state of the glass. Generally, T_C increases by typically ∼10 K, when the as-cast glassy structure is relaxed, evidently because of subtle changes in, topological and chemical, short-range atomic order (Chen, Sherwood, Leamy and Gyorgy, 1976).

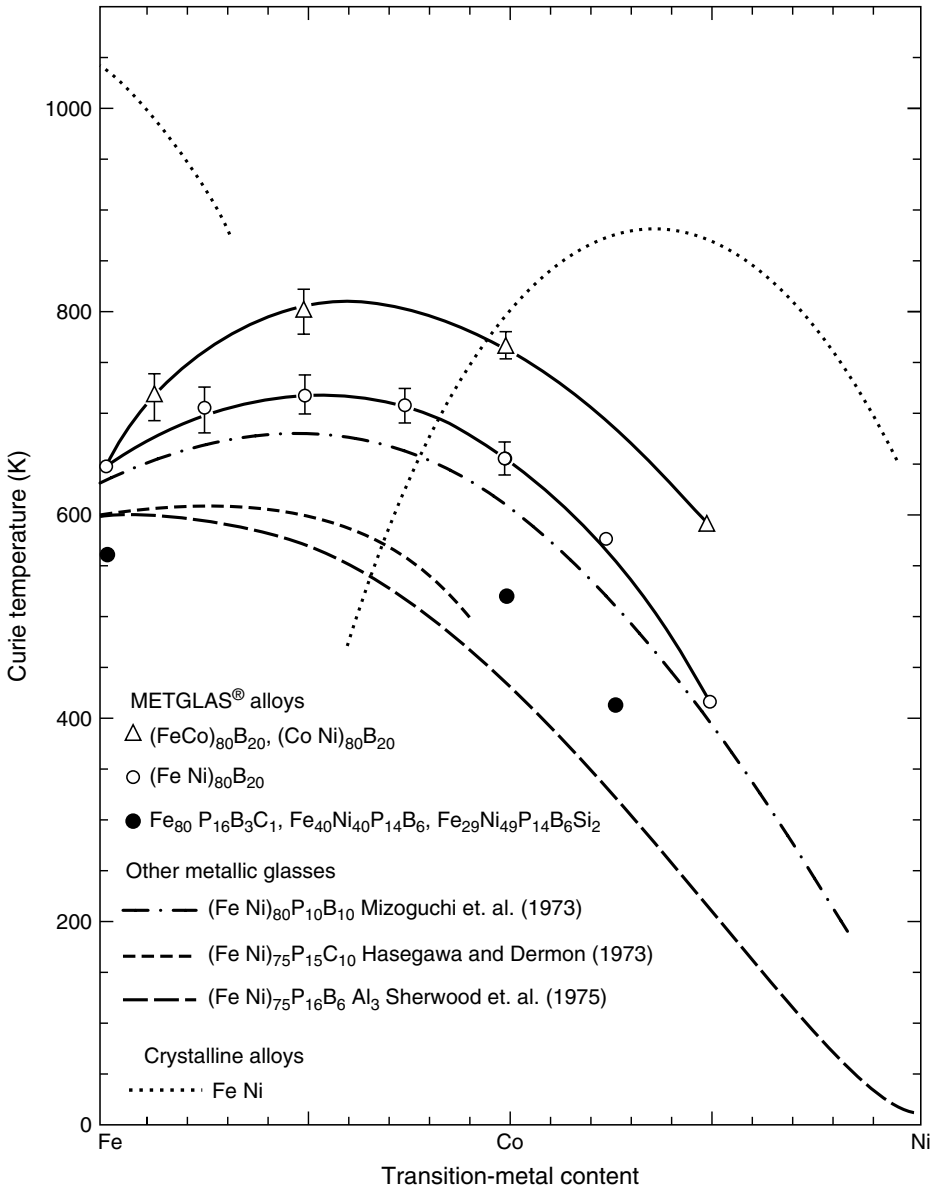

Figure 3. Variation of Curie temperatures of TM–B alloys with transition-metal content. Solid line over (FeNi)B data is a mean-field fit. Dotted lines show trends for crystalline FeNi alloys. (Reproduced from R.C. O'Handley, 2000. © 2000 John Wiley & Sons Inc.)

The influence of composition on the saturation magnetostriction of Fe-, Ni-, and Co-based alloy glasses is discussed in Section 6.

4 PROCESSING OF METALLIC GLASSES

4.1 Requirements for metallic glass formation

The alloy compositional factors that favor glass formation in metallic systems have been outlined in the previous section, in the context of ferromagnetic alloys. As indicated, alloys with compositions at, or close to, eutectics are RGF. A useful empirical parameter for predicting whether or not an alloy is RGF, which we assume rather arbitrarily, though for sound practical reasons, to be a composition which can be completely vitrified at a cooling rate $\dot{T} \leq 10^6\,\mathrm{K\,s^{-1}}$, is ΔT^* (Donald and Davies, 1978), which is given by

$$\Delta T^* = \frac{T_\mathrm{l}^\mathrm{mix} - T_\mathrm{l}}{T_\mathrm{l}^\mathrm{mix}} \tag{1}$$

Equation 1 represents the fractional departure of the liquidus temperature T_l from the simple rule of mixtures melting

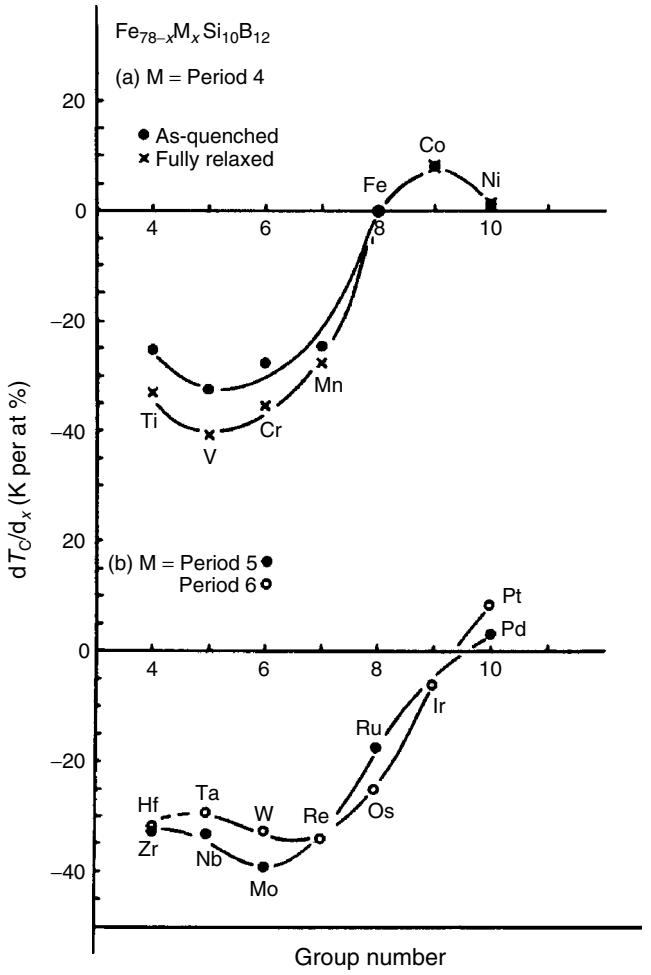

Figure 4. Variation of dT_C/dx (where x is the concentration of solute metal M) with group number (i.e. the number of outer d + s electrons) of M for dilute additions of (a) period 4 solutes (shown also are values of dT_C/dx for samples which have been relaxed fully), and (b) periods 5 and 6 solutes, to glassy $FeSi_{10}B_{12}$-based alloys. (Reproduced from Donald *et al*., 1981. © 1981, with permission from IOP Publishing Ltd.)

temperature T_l^{mix} where $T_l^{mix} = \Sigma x_i T_m^i \cdot x_i$ and T_m^i are the mole fraction and melting point, respectively, of the ith component of an alloy of n component elements. Some adjustment is required for systems where intermediate phases with exceptionally high congruent melting points occur. It was shown in a survey of numerous binary and ternary alloys that, with a few exceptions, compositions that were RGF had values of $\Delta T^* > 0.2$ (Donald and Davies, 1978). This was subsequently used to identify RGF compositions in several systems (Holt, Ankeny and Cline, 1980).

Another useful empirical approach for predicting RGF in metallic systems, first proposed by Giessen (1982) for binary alloys, is based on two parameters: the excess negative enthalpy of mixing ΔH_m and the component atomic radius ratio r_A/r_B, where A and B represent the smaller and larger atomic species, respectively. Two-dimensional maps for two series of binary alloy systems, based on Ni and on Zr, with ΔH_m and r_A/r_B axes, gave satisfactory delineation between RGF and non-RGF systems, with the former group being concentrated in the regime having coordinates of high ΔH_m and low r_A/r_B. This principle has been incorporated by Inoue and coworkers to formulate a set of rules for bulk metallic glass formation (having critical cast rod diameters >0.5 mm) with the additional requirement that the alloys should have at least three components (Inoue, 1997).

Numerous Fe-, Co-, and Ni-based bulk glass-forming alloys, generally with several solute metal additions to minimize the melting temperature, have now been demonstrated (Inoue, 2000; also, see **Soft Magnetic Bulk Glassy and Bulk Nanocrystalline Alloys, Volume 4**.)

The process of rapid quenching for vitrification is illustrated in Figure 5 by the time–temperature–transformation (T–T–T) curves for three extreme examples, pure Ni and two easy glass-forming alloys, $Pd_{82}Si_{18}$ and $Pd_{77.5}Si_{16.5}Cu_6$. The T–T–T curves indicate, in each case, the time required effectively for the start of crystallization as a function of temperature. Glass formation occurs when the cooling rate exceeds a critical value R_c, such that it bypasses the nose of the T–T–T curve, as shown. In the general case, the lower the T_l relative to T_g, the narrower the gap between T_l and T_g, the more rapid the increase in melt viscosity with increasing undercooling below T_l and, consequently, the nose of

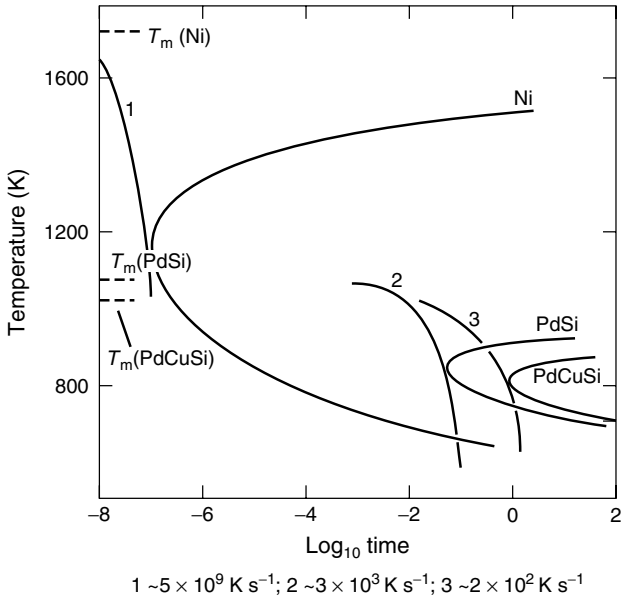

Figure 5. Computed T–T–T curves corresponding to a fraction crystal of 10^{-6} for Ni, $Pd_{82}Si_{18}$, and $Pd_{77.5}Cu_6Si_{16.5}$. Also indicated are the critical cooling curves required to effectively avoid crystallization.

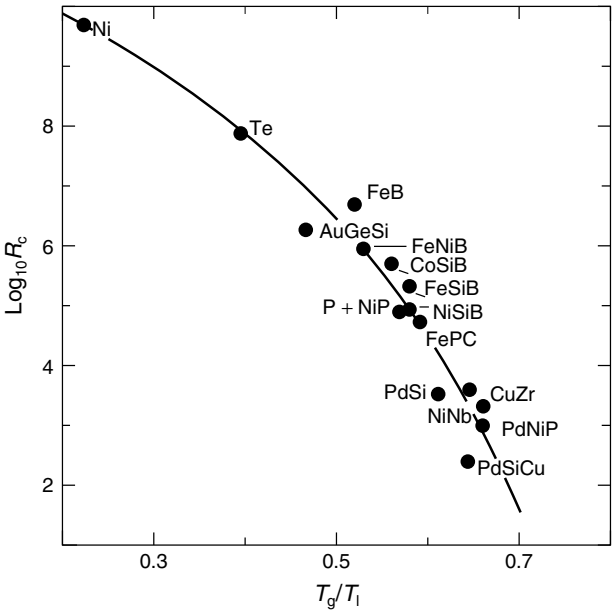

Figure 6. Theoretically predicted values of the critical cooling rate for glass formation (R_c) as a function of the reduced glass temperature T_g/T_l (actual compositions of the alloys are $Fe_{83}B_{17}$, $Au_{77.8}Ge_{13.8}Si_{8.4}$, $Fe_{41.5}B_{17}$, $Co_{75}Si_{15}B_{10}$, $Fe_{79}Si_{10}B_{11}$, $Ni_{75}Si_8B_{17}$, $Pt_{60}Ni_{15}P_{25}$, $Fe_{80}P_{13}C_7$, $Cu_{60}Zr_{40}$, $Ni_{62.4}Nb_{37.6}$, $Pd_{40}Ni_{40}P_{20}$, $Pd_{77.5}Si_{16.5}Cu_6$, $Pd_{82}Si_{18}$).

the T–T–T curve is moved to progressively longer times. Thus, R_c decreases with increasing T_g/T_l (Turnbull, 1969; Davies and Lewis, 1975). Predicted values of R_c, based on theories of crystal nucleation and growth and of transformation kinetics and involving several simplifying assumptions (Uhlmann, 1972; Davies, 1976), are plotted against T_g/T_l in Figure 6 for several glass-forming alloys, including ferromagnetic LTM–Met alloys based on Fe, Co, and Ni–Fe, as examples. The predicted values of R_c for the latter are in the range 10^5–10^6 K s^{-1}, in good agreement with corresponding experimentally estimated values. Correlation between R_c and T_g/T_l for bulk alloy glass formers is less satisfactory, partly because of high melt viscosities above T_l for these very low T_l alloys (Davies, 1995) and the greater influence of heterogeneous nucleants (Lewis and Davies, 1977).

4.2 Thermal stability of metallic glasses

The thermal stability of a glassy alloy, measured by its T_g, or in cases where the glass transition is masked by the devitrification event, the crystallization temperature T_x, is of particular interest and relevance for soft magnetic alloys, since they must generally be annealed at elevated temperature to remove quenched-in stresses, in order to optimize the magnetic properties, and, in some cases, to develop a specific anisotropy. Globally, T_g (or T_x) has been shown to scale satisfactorily with the cohesive energy, measured, for instance, by the molar heat of sublimation ΔH_s for a wide range of glass-forming alloys (Donald and Davies, 1978); the larger the ΔH_s, the higher the T_g, as would be expected for a phenomenon related to atomic diffusivity. Accordingly, ferromagnetic alloy glasses based on Fe, Ni, and Co generally have values of T_g or T_x that are intermediate between those of the glasses based on or containing large concentrations of refractory metals, such as CoTa and those based on the noble metals, such as AuSi.

A more detailed investigation of the influence of composition on the T_x of Fe-, Ni-, and Co-based metallic glasses was undertaken by Donald and Davies (1980). The measured T_x values for a broad series of glassy alloys based on Fe, Ni, and Co, with a constant metalloid content of 10 at% Si + 12 at% B and with substitutions of other metals from period 4, including Cr, Mn, Ti, V, and the noble metal Cu, and also including binary intermixtures of Fe, Ni, and Co, are plotted against valence (s + d) electron to atom ratio in Figure 7. There is a remarkably smooth correlation for the alloys containing Fe, Ni, and Cr, which are characterized by having very similar hard sphere atomic diameters. Additionally, size effect contributions to the thermal stability are associated with the Mn, Ti, and V substitutions, whose atomic diameters are significantly different from the Fe and Ni, while Cu rapidly destabilizes both the Fe- and Ni-based glasses. However, for the Ni–Co-based alloys and the Co–Fe-based alloys containing up to 15 at% Fe, T_x follows a separate half loop, the reason for which has not yet been established. The effects of other metals from periods 5 and 6 were also studied (but are not included here) and these showed a clear correlation with the atomic size difference from those of Fe and Ni. The additional increment in T_x over and above that due to conduction electron density is approximately proportional to the second power of the fractional difference in diameter between solvent and solute metal atoms.

These data provide guidelines for predicting the safe maximum temperatures for annealing of ferromagnetic glassy alloy of various compositions.

4.3 Thermal requirements for rapid solidification

The aim for all rapid solidification processes is to bring the melt into intimate thermal contact with a cool and thermally conducting heat sink, generally at a high relative velocity, in order to promote efficient and uniform melt spreading to a thin section or subdivision into small droplets. The higher the R_c for an alloy, the smaller the section thickness or the droplet diameter must be, that is, the smaller the length of the heat path should be.

The cooling rate in the melt is also dependent on the efficiency of heat transfer h across the interface with the

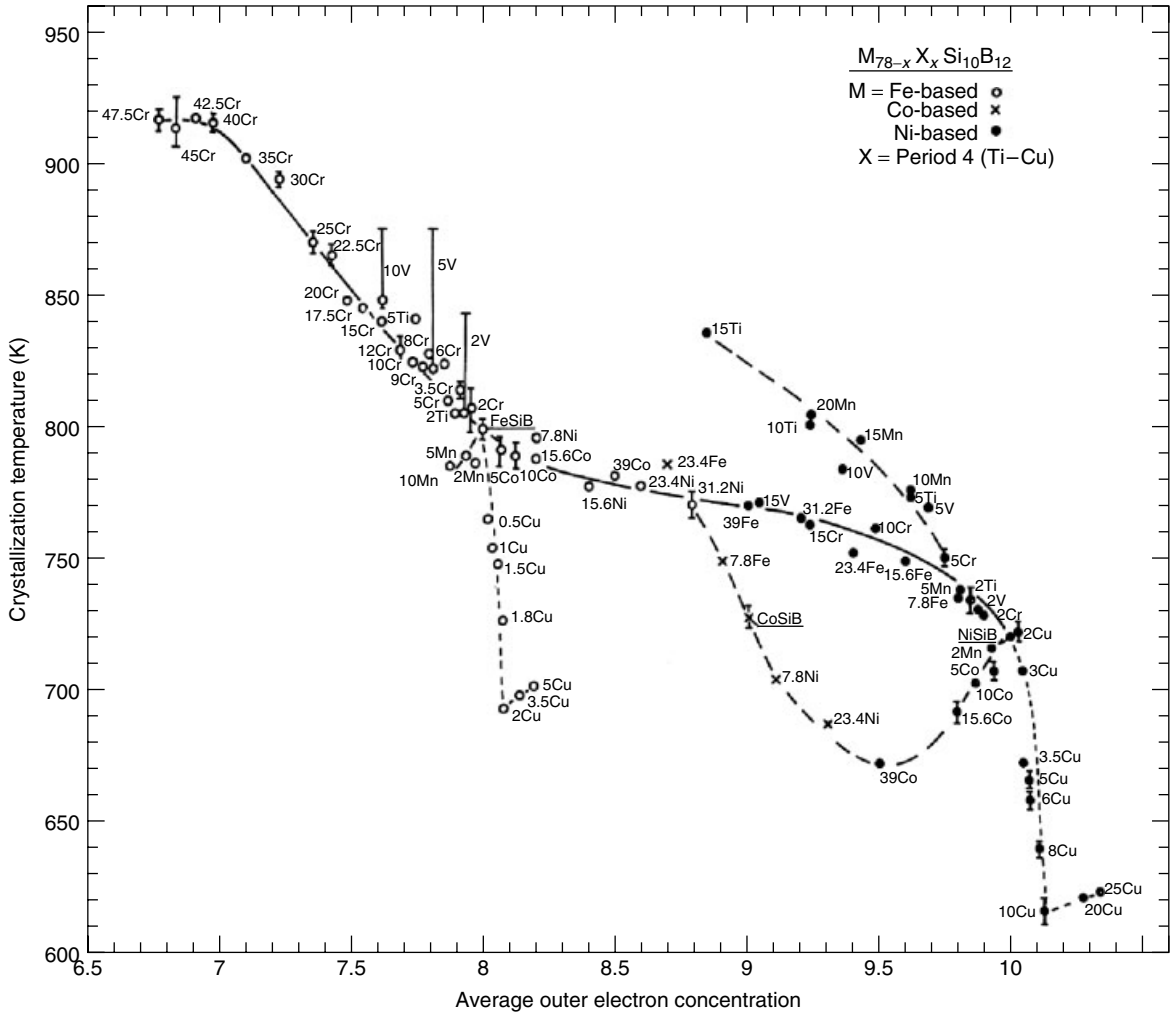

Figure 7. Variation of crystallization temperature with outer (d and s) electron concentration *e/a*, of the constituent transition elements for Fe- and Ni-based glassy alloys containing period 4 alloying additions (Donald and Davies, 1980).

heat sink. In the absence of interfacial resistance to heat flow and for a highly conducting heat sink, that is, ideal cooling conditions, $\dot{T}$ is determined by the thickness x and the thermal conductivity of the melt section, with $\dot{T}$ being proportional to x^{-2}. For melt spinning of ribbon, for instance, h has been estimated experimentally to be $\sim 10^5\,\mathrm{Wm^{-2}\,K^{-1}}$ (Warrington, Davies and Shohoji, 1982), with a spread of $\sim \pm 5\,\mathrm{Wm^{-2}\,K^{-1}}$ between alloys. This is a very high value for a metal-casting process, principally because a new clean melt surface is continually being created at the interface with the roll and intimate physical contact is being maintained. Figure 8 shows the computed variation of $\dot{T}$ with x for $h = 10^5\,\mathrm{Wm^{-2}\,K^{-1}}$, for the ideal cooling limit, computed for an RGF alloy $Fe_{40}Ni_{40}P_{14}B_6$ (Davies, 1978, 1983). For $x < \sim 10\,\mu\mathrm{m}$, $\dot{T} \propto x^{-2}$, that is, Newtonian (interface control) conditions prevail, but, as x increases, the cooling regime progressively approaches ideal, since the heat transfer is increasingly controlled by the thermal resistance of the liquid medium. Thus, for example, a ribbon of thickness $10\,\mu\mathrm{m}$ is predicted to cool at $\sim 2 \times 10^6\,\mathrm{K\,s^{-1}}$ and a 100-μm-thick ribbon at $10^5\,\mathrm{K\,s^{-1}}$. The data in Figure 8 can be combined with those given in Figure 6 to yield a plot of approximate maximum thickness of glassy phase that can be melt spun to ribbon x_c versus T_g/T_l (Figure 9).

5 LIQUID STATE PROCESSING OF METALLIC GLASSES

5.1 Ribbon casting

5.1.1 Chill block melt spinning (free jet)

A jet of molten alloy is ejected under pressure through a circular orifice at the base of a crucible and impinges onto

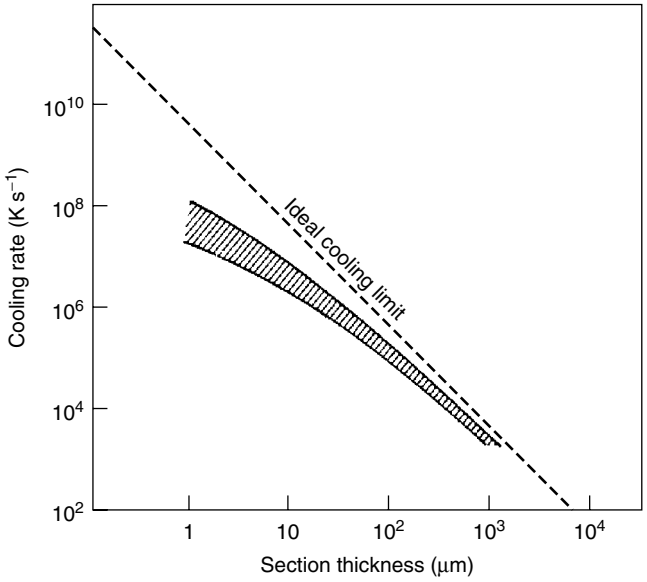

Figure 8. Cooling rate $\dot{T}$ as a function of section thickness x, computed for the glass-forming alloy $Fe_{40}Ni_{40}P_{14}B_6$ and based on experimentally derived values of heat transfer coefficient (cross hatched area) and on ideal cooling, that is, no interface resistance (dashed line), for chill block melt spinning. Unidirectional cooling of a rectangular section to one heat sink is assumed.

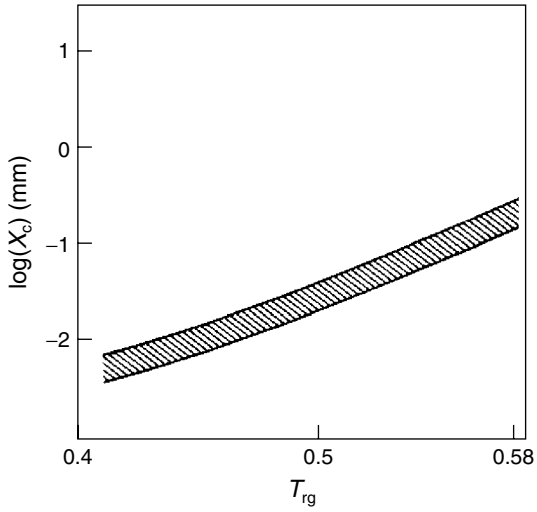

Figure 9. Predicted range of maximum section thickness of glassy alloy phase versus the reduced glass temperature $T_{rg} = T_g/T_l$.

the circumferential surface of a rapidly rotating roll (typical linear velocity: 20 m s^{-1}; Liebermann and Graham, 1976). The roll is generally fabricated from Cu or, preferably, a highly conducting Cu alloy such as Cu-1wt%Cr, which is harder and more wear resistant than pure Cu. An elongated puddle is established at the point of impingement, from which a thin ribbon is continuously extracted and solidified

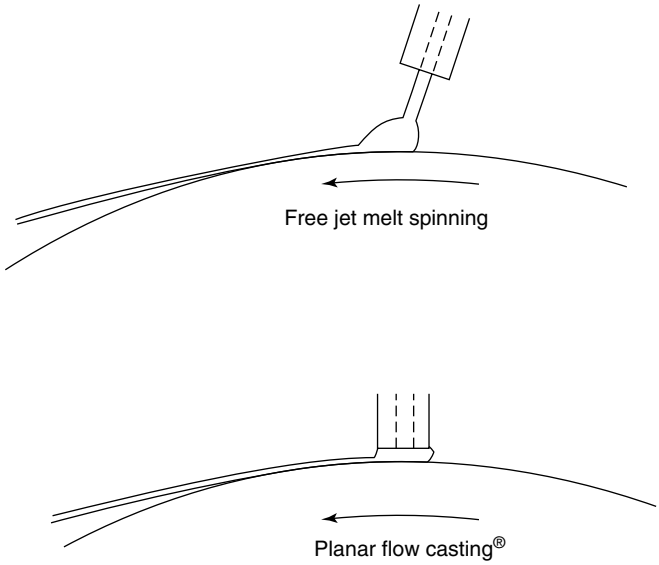

Figure 10. Nozzle configuration for free jet melt spinning and planar flow casting.

(Figure 10). This then parts from the roll surface well downstream of the puddle. The higher the roll speed V_r, the shorter the puddle and the smaller the ribbon thickness x. In this process, the puddle is also able to spread laterally since it is unconstrained. Thus, the ribbon width w is also a function of V_r.

It has been shown (Kavesh, 1978) that:

$$x \propto \frac{Q^m}{V_r^n} \tag{2}$$

where Q is the flow rate of melt and m and n are constants which depend on melt composition and roll material. Ideally, $n = 0.75$ and $m = 1 - n$ but, in practice, n varies between ~0.65 and ~0.85 (Vincent and Davies, 1982). Similarly (Kavesh, 1978),

$$w \propto \frac{Q^m}{V_r^n} \tag{3}$$

Thus, V_r principally influences x while Q has a greater influence on w.

In practice, w is limited to 4–5 mm by instability of the puddle, while the limit on x tends, in practice, to be ~80 μm, beyond which it becomes nonuniform. However, the maximum thickness of amorphous phase equates to x_c, which is governed by R_c and the interfacial heat transfer coefficient h.

5.1.2 Planar flow casting (PFC)

In this process, the nozzle tip is in close proximity to the roll surface (the typical gap size is 0.3–0.5 mm) and the

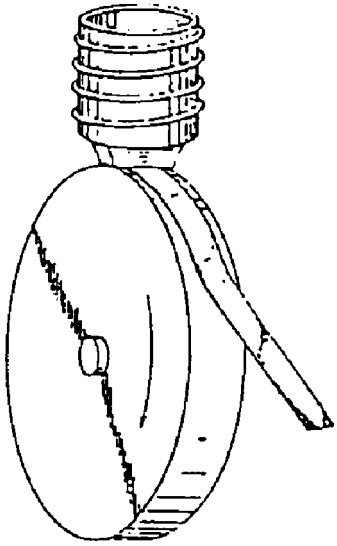

Figure 11. Schematic of the planar flow casting process.

melt is streamed through a rectangle-shaped slot nozzle (Narasimhan, 1979). Since the puddle is now constrained between the nozzle tip and the roll (Figure 10), convergence of the stream through capillary forces is prevented and a ribbon of width equal to the slot length can be cast (Figure 11). Thus, in principle, there is no limit to the width of the strip that can be cast, although, in practice, there are engineering limitations related to the uniformity of gap that can be achieved for a long slot. The melt flow rate is given by $Q = wV_r x$ (ignoring thermal contraction). Since w is now constant, then, for constant Q, x is proportional to V_r^{-1}. Because the puddle is constrained, in addition to facilitating the production of ribbon of width >4 mm, the process also gives a more uniform ribbon thickness than the free jet variant, since oscillations or vibrations of the puddle are reduced in amplitude.

On the basis of Bernoulli's equation, the ribbon thickness x can be shown to be given (Fiedler, Mühlbach and Stephani, 1984) by

$$x = \left(\frac{g}{b}\right)^c \frac{b}{v}\left(\frac{2p}{\rho}\right)^{1/2} \tag{4}$$

where b is the slot breadth, p is the pressure at the slot, ρ is the density of the liquid, g is the nozzle tip/roll gap, and c is a constant ≈1/3. An analysis of casting conditions for glassy alloy strip ($Fe_{40}Ni_{40}B_{20}$) was also made by Takayama and Oi (1979).

A significant problem with both free jet and PFC ribbon are the gas pockets (air pockets, if casting is in air) that are entrapped between the melt and the roll surface during casting. These cause roughness on the roll contact surface of the ribbon and thus reduce the packing fraction in a wound core and can adversely influence H_c (Kronmüller, 1981). They can also act as centers where localized crystallization may occur during casting or where premature crystallization may occur during subsequent annealing. The gas pockets can be eliminated by casting in reduced pressures, particularly in a helium atmosphere (Todd *et al*., 1999), though this is not economically viable for commercial production. Clearly, for extended operations, the roll must be internally water cooled to avoid overheating of the substrate; however, for laboratory-scale samples of ribbon, this is not generally necessary. PFC is now used for all commercial production of soft magnetic glassy alloys, and ribbon widths up to 300 mm are routinely produced.

5.1.3 Stacking of ribbons

The severe embrittlement of Fe-based LTM–Met metallic glasses at the temperatures required for effective annealing out of quenched-in stresses, in addition to the small thickness of the cast ribbon (~25 μm for METGLAS® 2605SC, for instance), results in difficulties in handling, punching, and stacking of individual laminations for the construction of a conventional transformer yoke. Thus, the ribbon is toroidally wound, prior to annealing, in commercial distribution transformers, which typically have a capacity of ~25 kVA for 110/120 V output voltage systems (Smith, 1993). However, for large power transformers, toroidally wound cores are less practicable than a stacked configuration. In an attempt to overcome this limitation and also to improve the packing density, the hot rolling of stacks of 5–10 ribbons was investigated. Although this material, known as Powercore®, improved the stacking density and had good magnetic properties without additional annealing (Smith, 1993), it has proved, as for annealed ribbon, to be very brittle and difficult to cut (Hasegawa, 2003). Nevertheless, stacked cores have been fabricated by cutting segments of large METGLAS® wound cores and used as the pole piece magnets for magnetic resonance imaging equipment (Hasegawa, 2003).

5.2 Production of metallic glass powder

5.2.1 Pulverization of melt spun ribbon

The most efficient and widely applicable method of producing ferromagnetic LTM–Met amorphous alloy powders for consolidation into magnetic cores is the fragmentation of melt spun glassy alloy ribbon into a flaky powder having platelet-shaped particles, using, for example, a ball mill or a hammer mill. This has the advantage that a much wider range of compositions can be efficiently fully vitrified in

bulk quantities by melt spinning onto a solid heat sink than is possible by atomization processes. It is advantageous for pulverization, though not a prerequisite, if the ribbon is either intrinsically brittle in the as-cast state or can be embrittled by annealing at temperatures well below T_g or T_x. The size of the platelets, which has an influence on the magnetic properties of the pressed cores (Hasegawa, Hathaway and Chang, 1985; Raybould and Tan, 1985), is controlled by the milling parameters and time.

Various consolidation techniques have been investigated for amorphous ferromagnetic alloy powders, including explosive compaction (Cline and Hopper, 1977; Hasegawa and Cline 1985), gas-gun compaction (Morris, 1982), isostatic pressing (Hasegawa, Hathaway and Chang, 1985), vacuum hot pressing or cold pressing (Raybould and Tan, 1985), and warm extrusion (Kawamura, Takagi and Akai, 1988). In some cases, an insulating ceramic binder was employed to reduce AC losses and to increase the roll-off frequency. Annealing of compacts to reduce any residual stresses that are present is important, particularly for cold consolidated materials. Surprisingly, it was reported (Raybould and Tan, 1985) that variations in consolidate density between 80 and 90% of the theoretical density had no significant effect on the magnetic properties; in particular, consolidation to intermediate densities was found to be amenable to mass production techniques.

5.2.2 *Fluid atomization*

These processes involve the breakup of a molten alloy stream into small droplets by a high-velocity fluid, either liquid or gas, or, in some cases, a combination of liquid and gas (see review by Miller, 1983). The higher the velocity of the quenchant, the smaller the mean droplet diameter d_p, and thus the higher the mean $\dot{T}$. Gas atomization generally employs N_2 or Ar, though He gives higher $\dot{T}$ because of its higher thermal conductivity. Liquid atomization usually employs water, which is a more efficient atomizer and coolant than a gas. Water-atomized powder generally consists largely of irregular shaped particles, which enhances the strength of a compacted core. $\dot{T}$ for gas atomization is usually $<10^4\,\mathrm{K\,s^{-1}}$, even for the finest particles, though ultrasonic gas nozzles can increase $\dot{T}$ up to $10^5\,\mathrm{K\,s^{-1}}$ for 20-μm particles (Miller, 1983). $\dot{T}$ for water-atomized powder particles is frequently in the range 10^5–$10^6\,\mathrm{K\,s^{-1}}$ and up to 80% of glassy phase has been reported for sub–20-μm powder particles of $Fe_{69}Si_{17}B_{14}$ and $Fe_{74}Si_{15}B_{11}$ alloys (Yamaguchi and Narita, 1978). Gas–liquid atomization, typically using argon and water, has been reported as yielding fully amorphous sub-20-μm particles for $Fe_{75}Si_{10}B_{15}$ and $Fe_{81.5}Si_{14.5}B_4$, alloys (Miller, 1983).

5.2.3 *Centrifugal atomization*

In the variant of this process developed by Pratt and Whitney (Miller, 1983), the melt stream impinges on a concave-shaped disc rotating at extremely high velocity (typically 150 000 rpm). This accelerates the melt to close to the rim speed and atomizes it directly to very fine droplets at the disc edge. These are quenched by helium gas jets. The process was reported as having been used to produce amorphous powder for several ferromagnetic FeSiB alloys. The powder has a narrow particle size distribution, though the particles are spherical and thus not well suited to compaction to solid bodies.

5.2.4 *Other atomization techniques*

Spark erosion, which is essentially the electrical discharge machining process, has been successfully employed to produce a wide range of ferromagnetic alloy powders (Berkowitz, Walter and Wall, 1981). The powder is formed during the discharge when local melting or vaporization of the electrodes occurs, which then condenses and solidifies in the dielectric fluid; $\dot{T}$ is reported as being up to $10^6\,\mathrm{K\,s^{-1}}$ for 20-μm particles. Particles are spherical and range in size from a few submicrometers up to 50 μm.

Electrohydrodynamic atomization (Perel, Mahoney, Duwez and Kalensher, 1980) involves the use of a very high electric-field gradient generated at the tip of a heated capillary nozzle containing molten alloy. A gradient of the order of 1 MV $\mathrm{cm^{-1}}$ is produced by applying a potential of typically 10 kV between the melt and electrode in close proximity with the nozzle. When the electrostatic forces overcome the surface tension of the melt, an extremely fine droplet is omitted and solidified as a spherical particle. Particle diameters are typically ~0.1 μm and amorphous $Fe_{40}Ni_{40}P_{14}B_6$ powder has been successfully produced.

The disadvantage of both these techniques is that production rates are only of the order of grams per hour.

6 INDUCED MAGNETIC ANISOTROPY AND MAGNETOSTRICTION

The absence of macroscopic magnetocrystalline anisotropy in amorphous ferromagnetic alloys means that other sources of anisotropy may dominate in these materials. In general, induced magnetic anisotropies in amorphous ferromagnets have energy densities of the order of 10^2–$10^3\,\mathrm{J\,m^{-3}}$ and can have their absolute magnitude and direction controlled by postproduction thermomechanical treatment. These treatments include annealing in the presence of a magnetic field, annealing under load or the introduction by annealing of

a surface layer of devitrified material (Thomas and Gibbs, 1992).

Figure 12(a) emphasizes, in a schematic representation, that in zero applied field, neighboring magnetic moments align parallel to one another because of the quantum-mechanical exchange interaction and also, in general, make some angle θ_0 with the nearest-neighbor bond direction. The angle θ_0 is defined from the *local* anisotropy symmetry in an amorphous ferromagnet. It has remained unclear as to whether this local symmetry has the same or similar form to crystalline materials that may appear on devitrification, such as bcc iron. The case where all moments are perfectly collinear in the induced easy axis direction in the demagnetized state is an ideal one in amorphous ferromagnets. There is strong evidence (Kronmüller, 1979; Pankhurst, Betteridge, Jiang and Gibbs, 1994; Wildes *et al*., 2004) of moment noncollinearity (θ_0 varying spatially about some mean value, usually related to a dominant anisotropy direction) in the ferromagnetic ground state. The degree of noncollinearity may vary with imposed thermal history, but is never absent. It is surprising that this is equally the case in alloys containing RE or TM atoms, the former being intuitively more likely to show such an effect due to the more localized moment on such atoms.

In these amorphous structures, where *a priori* no two atomic environments are topologically or chemically equivalent, there can be a distribution in magnitude and direction of the local anisotropy and exchange interactions. Where the exchange is weak, the moments follow the local anisotropy vector, and where the exchange is strong the local anisotropy can be spatially averaged out. This noncollinearity can directly impact on technical applications. We consider later in this chapter sensors that rely on magnetization by pure and coherent rotation of the moments for maximum response. The noncollinearity affects the response, especially at low fields.

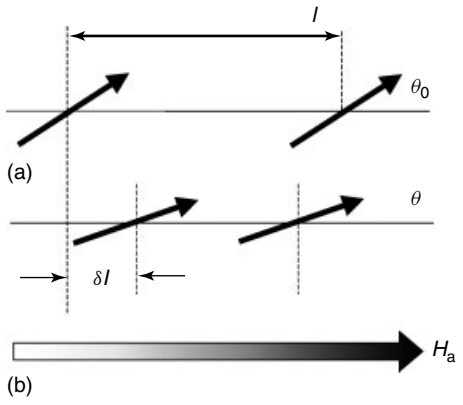

Figure 12. A schematic illustration of the effect of a magnetic field on two neighboring dipole moments in an amorphous ferromagnet (a) in zero applied field and (b) in a field applied as indicated, with rotation of the dipoles toward the field direction and a concomitant change in bond length from the magnetostriction.

Figure 12(b) represents schematically the effect of changes in bond length when the magnetization direction rotates on the application of an external magnetic field. The *total* magnetic contribution to the free energy includes contributions from exchange, anisotropy, and magnetoelastic effects. The exchange contribution to the magnetic part of the free energy causes the moments to remain parallel, and the Zeeman term promotes rotation toward the applied field direction. The moment rotation depicted can therefore in general result in a change in bond length, δl, as the magnetization rotates. Such a field-induced strain is known as *Joule magnetostriction*, and the inverse (Villari) effect is that a mechanical strain in the material (intrinsic or extrinsic) can change the ease with which the magnetization may rotate in a given field. This field-induced strain introduces the magnetoelastic contribution to the free energy.

The measurement of anisotropy and magnetoelastic properties in amorphous ferromagnets presents challenges from the point of view of the extreme magnetic softness of the alloys, and also their standard thin-ribbon geometry. This whole area has been comprehensively reviewed (Squire, 1994). Bonding to other materials must be avoided as this can lead to stress-induced anisotropy as the bond cures. The thin section (typically 25 μm) and nonuniform cross section (a legacy of the rapid solidification processing) lead to further practical difficulties. The dilatometric method has proved to be the most robust and insightful technique (Squire, 1994).

6.1 Induced magnetic anisotropy

We consider this topic within the context of samples from which the stresses arising from the casting process have been removed by a simple thermal treatment (typically 30 min at $T_x - 50\,^{\circ}\mathrm{C}$, where T_x is the temperature of the onset of crystallization as determined in slow-scan-rate differential scanning calorimetry, for example). It can further be assumed that for all the data discussed the samples have remained fully amorphous as determined by X-ray diffraction and the maintenance of magnetic softness. The latter may be a more sensitive guide than the former in amorphous ferromagnets.

The first method of introducing a uniaxial magnetic anisotropy of controlled magnitude and direction is to perform an isothermal anneal in the presence of a saturating magnetic field at a temperature below the ferromagnetic Curie temperature of the alloy. Alternatively, the sample may be cooled slowly (say $10\,\mathrm{K\,min^{-1}}$) down through the Curie temperature to ambient. Field annealing drives a rearrangement of the topological and chemical short-range structure

of the amorphous alloy to produce a material with directionally ordered metal–metal and metal–metalloid pairs. The resulting anisotropy constant for this uniaxial anisotropy, K_u, depends on both annealing time and temperature. An easy axis is induced in the direction of the annealing field, which is retained when the material is cooled to ambient temperature in the presence of the field. The kinetics of the development of the easy axis has been shown to obey a two-level model (Gibbs, Evetts and Leake, 1983; Kronmüller *et al*., 1985; Kronmüller, 1983) where, for a field anneal at a given temperature, the anisotropy constant of a material approaches a maximum value. This value is annealing temperature dependent when the anisotropy is induced owing to two-ion interactions, and temperature independent when it is induced owing to single-ion anisotropy (Callen and Callen, 1963, 1965). Thus, K_u is temperature independent in single-TM alloys (e.g., Fe-based alloys) and temperature dependent in two- or three-TM alloys (e.g., Fe–Ni or Fe–Co alloys). Figure 13(a) and (b) illustrates such data (Thomas and Gibbs, 1992).

It is important to note that the introduction of anisotropy from an applied field can take place at any temperature below the Curie temperature (it is driven by thermal activation), and effects can take place at temperatures that are a little removed from ambient. In the region of a domain wall, the magnetization distribution can act on the local topology and chemical order to produce a profile to the local easy axis, which matches the magnetization profile in the domain wall. This pins the domain wall and reduces the initial permeability, an effect known as *disaccommodation*. This possibility must be taken into account in lifetime predictions of properties in these materials, but, because it is a thermally activated process, equilibrium is reached even if there is an initial transient response in the permeability.

Annealing under a tensile load has been studied in Co-rich (low magnetostriction $-\lambda_s \approx 10^{-8}$) amorphous alloys. The induced anisotropy has two components, K_{an} arising from an anelastic response of the materials and K_{pl} arising from the plastic response (Nielsen, 1985). It is significant that both components are nonzero at the composition for which the magnetostriction (and hence the basic strain magnetostriction coupling) is zero. The anelastic component can be recovered by a second zero-applied-stress anneal. At low anneal temperatures, the easy direction is parallel to the applied stress, turning orthogonal to the applied stress at higher temperatures. This is viewed as arising from the competition between the anelastic and plastic components of the strain. At high annealing temperatures, $|K_i|_{max}$ can reach $800\,J\,m^{-3}$ (Gibbs, 1990).

There have been studies (Vázquez, Ascasibar, Hernando and Nielsen, 1987) on the simultaneous application of a tensile stress and a transverse magnetic field on ribbon

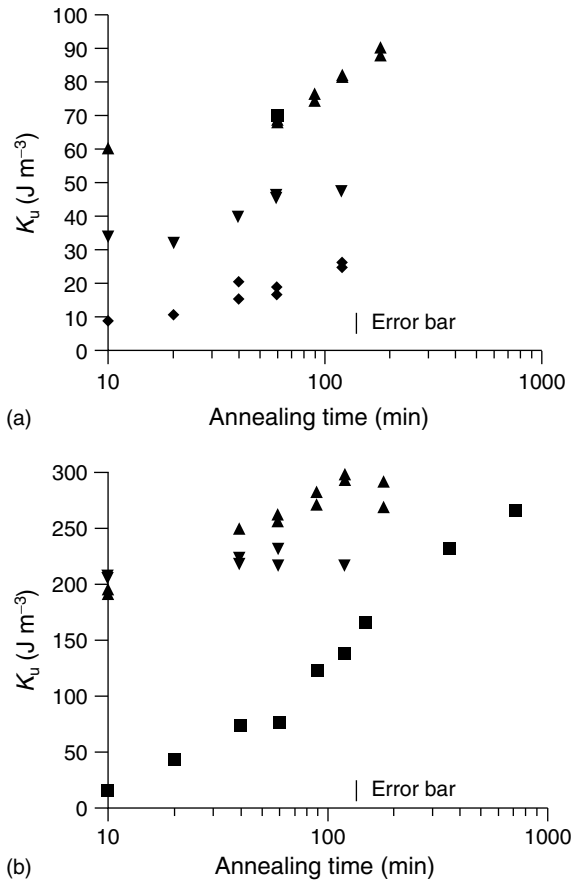

Figure 13. (a) Anisotropy constant, K_u, versus anneal time for METGLAS®2605S2 for different annealing temperatures (squares 420 °C, triangles 400 °C, inverted triangles 350 °C, diamonds 250 °C). (b) Anisotropy constant, K_u, versus anneal time for VAC®0040 for different annealing temperatures (squares 250 °C, triangles 300 °C, inverted triangles 350 °C, diamonds 370 °C).

samples; in this case, $|K_i|_{max} = 1100\,J\,m^{-3}$. It was proposed that the applied stress enhanced the field annealing effect as the sum of a tensile stress anneal and a transverse field anneal was less than that of the combined stress-field anneal.

A third method of introducing a uniaxial anisotropy in amorphous alloys is to precipitate surface crystallinity in Fe-based magnetostrictive ($\lambda_s \approx 10^{-6}$) alloys (Hang Nam and Morrish, 1981). The easy direction is perpendicular to the ribbon plane and $|K_i|_{max}$ can reach $6000\,J\,m^{-3}$ as the thickness of the surface crystalline layer increases (Herzer and Hilzinger, 1986). The mechanism proposed is that the crystalline surface layer, which is of higher density than the amorphous underlayer, will place the underlayer in biaxial compression. In a material of positive magnetostriction, this will bring the easy axis in the amorphous material to lie perpendicular to the ribbon plane, dominating the shape anisotropy in this direction.

6.2 Magnetostriction

Fe-based amorphous alloys have saturation magnetostriction constants, λ_s, in the range $20 - 30 \times 10^{-6}$. If Fe and Ni are present in equal proportions, the value of λ_s is reduced to around 10×10^{-6}. The basic mechanisms of magnetostriction in amorphous alloys have been extensively discussed (O'Handley, 1987). Figure 14 summarizes the composition dependence of λ_s in the (Fe, Co, Ni)B alloy system (O'Handley, 1978). The ability to smoothly vary the saturation magnetostriction by compositional control makes amorphous ferromagnetic alloys very attractive in device development.

Magnetostrictive strain, λ_i in a direction i in a material can be defined by

$$\lambda_i = \frac{1}{c_{ij}} \frac{\partial E_K}{\partial \varepsilon_i} \tag{5}$$

where ε_i is the strain in the direction i, c_{ij} is the appropriate elastic constant, and E_K is the anisotropy energy density. The topological disorder prevents simple macroscopic summation of the microscopic λ_i. Amorphous alloys, which may be taken as topologically isotropic to first order, have nonzero λ_i. This summation problem has been addressed (Furthmüller, Fähnle and Herzer, 1987), with each 'structural unit' characterized by a unique uniaxial anisotropy, and the magnetostrictive strain can be calculated using equation 5. The units are mechanically coupled (the solid is dense and contiguous) and the macroscopic strain manifests itself by elastic strain transfer from unit to unit. The summation is nonzero due to the anisotropic elastic properties of the 'structural units'.

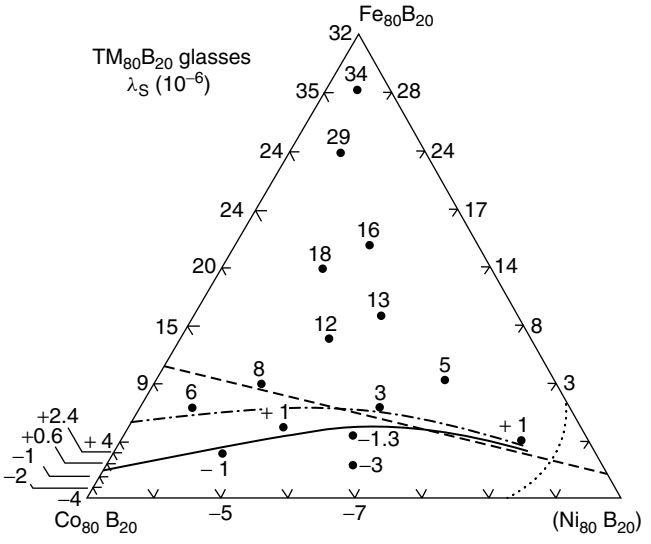

Figure 14. Saturation magnetostriction at room temperature for amorphous $(FeCoNi)_{80}B_{20}$ alloys. Solid line shows course of zero magnetostriction compositions and dashed line shows predictions based on the split band model. (Reproduced from R.C. O'Handley, 2000. © 2000 John Wiley & Sons Inc.)

The engineering magnetostriction, λ_e, is defined as the difference in magnetostrictive strain in a given direction in a sample before and after the application of a magnetic field (Bucholtz, Koo, Dandridge and Sigel, 1986). For amorphous alloys, λ_s is assumed to be isotropic, and therefore λ_e can be written as

$$\lambda_e = \frac{3}{2}\lambda_s \sin^2\theta \tag{6}$$

where θ is the angle through which the magnetization has rotated away from the easy axis direction in which it lay in zero applied field.

The basic model for magnetization by coherent moment rotation in amorphous alloys (Livingston, 1982) can be developed to deduce a number of important parameters related to the magnetostriction. If a magnetic field H rotates the magnetization through an angle θ, the magnetization M in the direction of the field is given by

$$M = M_s \cos\theta = M_s \frac{H}{H_a} \quad (H \leq H_a) \tag{7}$$

where M_s is the saturation magnetization and H_a the anisotropy field. In terms of the anisotropy constant

$$H_a = \frac{2K_u}{\mu_0 M_s} \tag{8}$$

Considering equations (6) and (7), the strain λ_e in the field direction is given by

$$\lambda_e = \frac{3\lambda_s}{2}\left(\cos^2\theta - \frac{1}{3}\right) = \frac{3\lambda_s}{2}\left(\frac{H^2}{H_a^2} - \frac{1}{3}\right) \tag{9}$$

The magnetomechanical coupling constant, d, is defined by

$$d = \frac{d\varepsilon}{dH} = \frac{3\lambda_s H}{H_a^2} \qquad d_{max} = \frac{3\lambda_s M_s}{2K_u} \tag{10}$$

If a longitudinal stress, σ, is applied to an amorphous ferromagnet of nonzero magnetostriction, then there is a magnetoelastic contribution to the free energy given by

$$E_{me} = -\frac{3}{2}\lambda_s \sigma \cos^2\theta \tag{11}$$

The anisotropy field is reduced to

$$H_{a\sigma} = \frac{2K_u - 3\lambda_s\sigma}{\mu_0 M_s} \tag{12}$$

The total strain in the field direction, ε, is the sum of elastic and magnetostrictive terms, hence

$$\varepsilon = \frac{\sigma}{E_s} + \frac{3\lambda_s}{2}\left(\frac{H^2}{H_{a\sigma}^2} - \frac{1}{3}\right) \tag{13}$$

where E_s is the Young's modulus in a saturating magnetic field. Equation (9) states that the effective Young's modulus is magnetic field dependent – the so-called ΔE effect.

$$\frac{\Delta E}{E_s} = \frac{9\lambda_s^2 E H^2}{M_s H_{a\sigma}^3} \tag{14}$$

The magnetomechanical coupling factor, k, related to the fractional energy transfer between magnetic and mechanical energy, important in transducer applications, is given by

$$k = d\left(\frac{EM_s}{H_{a\sigma}}\right)^{\frac{1}{2}} = \left[1 + \frac{M_s H_{a\sigma}^3}{9\lambda_s^2 E_s H^2}\right]^{-\frac{1}{2}} \leq 1 \tag{15}$$

For certain Fe-rich amorphous alloys (e.g., METGLAS® 2605SC), $k = 0.98$ and $(\Delta E/E_s) \geq 10$ have been achieved, which implies that outstanding sensor and actuator properties should be available from these materials (Squire and Gibbs, 1989).

Figure 15 shows the engineering magnetostriction data corresponding with the anisotropy data shown in Figure 13. It is important to note that the engineering magnetostriction reaches a saturation value at a given time and temperature before the anisotropy has saturated. Saturation of the engineering magnetostriction comes about from rotational reorientation of the local 'structural units', whereas the appropriate directional order has to reach saturation (requiring long-range diffusional processes) before the anisotropy can saturate (Thomas and Gibbs, 1992).

Figure 16 shows the ΔE effect in METGLAS®2605SC as a function of the field annealing angle (Squire and Gibbs, 1989). E/E_s is not unity at zero field, reflecting the moment noncollinearity discussed earlier. The maximum reduction in modulus (~80%) occurs in fields that are only five times the ambient field of the earth, demonstrating the extreme magnetic softness and outstanding magnetomechanical properties of appropriately treated material.

The basics (Livingston, 1982), and a more advanced treatment (du Trémolet de Lacheisserie, 1982), of magnetoelasticity in amorphous ferromagnetic alloys have been reviewed in the literature. A comprehensive phenomenological model for magnetization, magnetostriction, and ΔE effect has also been published (Squire, 1990). This model takes explicit account of the moment noncollinearity discussed earlier in the chapter.

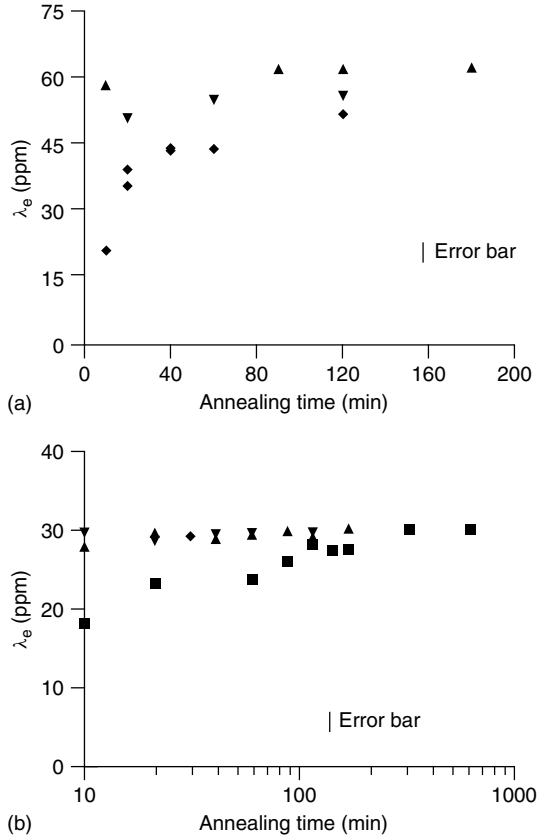

Figure 15. (a) Engineering magnetostriction, λ_e, versus anneal time for METGLAS®2605S2 for different annealing temperatures (squares 420 °C, triangles 400 °C, inverted triangles 350 °C, diamonds 250 °C). (b) Engineering magnetostriction, λ_e, versus anneal time for VAC®0040 for different annealing temperatures (squares 250 °C, triangles 300 °C, inverted triangles 350 °C, diamonds 370 °C).

7 PERMEABILITY, MAGNETIC LOSSES, AND TRANSFORMER APPLICATIONS

The combination of zero magnetocrystalline anisotropy and low induced anisotropies in amorphous ferromagnetic alloys, with the absence of features (e.g., grain boundaries) for domain wall pinning produces materials with relative permeabilities of up to 10^5 after optimized heat treatment. The structural disorder of the alloys also gives rise to electrical resistivities around three times larger than in comparable crystalline magnetic materials.

If as-cast material is taken, accepting some loss of permeability from the effect of cast-in stress, with its excellent mechanical properties, then high-grade, flexible magnetic shielding can be provided (Smith, 1982). The magnetic and mechanical advantages over crystalline Ni–Fe-based shielding products can be considerable.

At power frequencies (50–400 Hz), the drive for greener energy supply has worked in favor of amorphous alloys. The lower saturation magnetization caused by the greater solute content than for Si steel can be tolerated as cores are now designed not to be driven to such high levels of magnetization. The frequency dependence of eddy current loss is usually taken as $\propto f^n$ with $n = 2$ for common crystalline materials such as Si–Fe, but $n = 1.5$ in amorphous ferromagnetic materials. It should be borne in mind, however, that, to a significant degree, the smaller losses for the Fe-based amorphous alloys are due to smaller strip thickness than for the silicon steel, which results in significantly smaller eddy current losses. It has been shown that Hi–B silicon steel strip of thickness 100 µm, manifests lower AC losses that are only slightly larger than 25-µm-thick amorphous alloy. It is implicit that, at the 25-µm thickness level, the Fe–Si alloy would have significantly lower losses than the amorphous alloy due to its much smaller λ_s. The level of harmonic distortion caused by loads on transformer cores significantly affects the total loss. The lower core loss in amorphous alloys offers much reduced higher harmonics, and therefore lower overall losses (Hasegawa, 2004). As frequency rises to the airborne transformer range (400 Hz), the losses in amorphous alloy cores are one-fifth of those in grain-oriented silicon steel. For design purposes, ample data on permeability and loss as a function of frequency may be found on the manufacturers' websites (METGLAS® Products, www.metglas.com; Vacuumschmelze, www.vacuumschmelze.de).

While the resistivity of amorphous alloys is much higher than that of their crystalline counterparts, further improvement may be obtained by producing powder cores. Powderform amorphous material may be produced directly by powder atomization or by grinding up of ribbon material. The increased brittleness of annealed ribbon can aid in this process. In the kilohertz operating range, losses can be comparable with N–Zn ferrites (Hasegawa, Hathaway and Chang, 1985). The highest densities after dynamic compaction are around 90% (Hasegawa, Hathaway and Chang, 1985); however, increased stress on the core material lowers the permeability (Hasegawa, 2003).

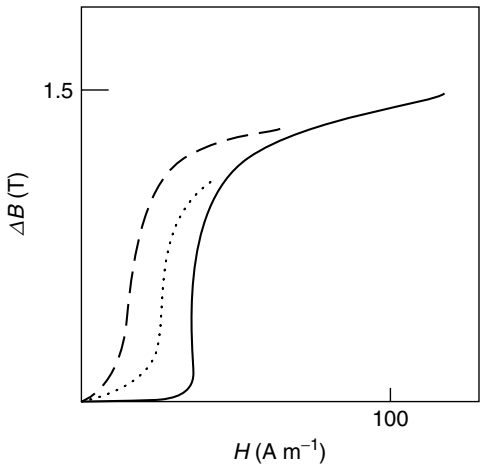

Figure 17. The pulse reversal curve of three toroids of VAC®6030 (solid line) in as-received state, (dotted line) slow cooled ($2^\circ\,s^{-1}$) from above the Curie point to ambient, and (dashed line) fast cooled ($100^\circ\,s^{-1}$) from above the Curie point to ambient. The pulse was at a rate of 300 T $(ms)^{-1}$.

Switched-mode power supplies (SMPS), operating at 10–200 kHz, require low loss and high-saturation induction, and for high-power SMPS there is an advantage from the low losses and high-saturation induction of amorphous alloys. Ferrite cores that are electrically insulating, but have low saturation induction have been used. The amorphous ferromagnets have much higher induction, and sufficient resistivity to offer better overall performance.

Magnetic switching using a saturable inductor has been known for over 50 years, but interest was rekindled with the advent of amorphous alloy cores (Smith, 1982). Pulse characteristics have been studied (Jones, 1982, 1983). The pulse response for a core of Co-based (low magnetostriction) alloy is shown in Figure 17.

Careful postprocessing of the core can give a pulse response close to ideal (Sheard, Gibbs and Avery, 1989).

8 SENSORS

It is the combination of magnetic softness and high magnetomechanical coupling that has led to numerous suggestions for sensors based on amorphous alloys. The application of amorphous alloy ribbons (Hernando, Vázquez and

Barandiaran, 1988; Hasegawa, 2004) for sensors has been comprehensively reviewed.

In terms of market penetration, the leader is electronic article surveillance of consumer products (Herzer, 2003). In this application, a length of amorphous alloy is packaged together with a piece of semihard magnet strip. The latter is incorporated for activation and deactivation. Sensing is by harmonic or acoustomechanical means. The very square loop possible with carefully treated amorphous ferromagnets, coupled with high yield strength and electrical resistivity, makes them the material of choice for the harmonic system. It is usually a Co-based low magnetostriction material that is used. The acoustomechanical system relies on mechanical resonance in the sensing layer and on the ΔE *effect*. Fe-based, high-magnetostriction amorphous alloys are used in this case. The unit cost in both cases is low, and the market penetration is high.

A range of magnetometry devices has been proposed on the basis of modulation of fibre-optic interferometers (Dandridge *et al*., 1980; Bucholtz *et al*., 1987) and shear wave propagation (Squire and Gibbs, 1988; Kilby, Squire and Willcock, 1993). The fiber-optic route using ribbon-form amorphous alloy was shown to have problems both with frequency response (Brugel, Gibbs and Squire, 1988a) and high sensitivity to bonding (Brugel, Gibbs and Squire, 1988b). The shear wave option has generated a sensitivity of 0.1 nT/$\sqrt{\text{Hz}}$. This is in the range where there are application windows, and several devices are close to commercialization.

Stress or strain sensing via changes in susceptibility has been demonstrated. There are significant advantages in using negative magnetostriction amorphous alloy ribbons, and a figure of merit (FOM) of 10^4 can be achieved (Barandiaran and Gutierrez, 1997). The degradation caused by bonding has been addressed (Wun-Fogle *et al*., 1987), and with a viscous bond, limiting application to AC strain detection, an FOM of $>2 \times 10^5$ was achieved. A semiconductor strain gauge has an FOM of $\sim$250 by comparison.

If the constraint of bulk magnetic material (in this case ribbon) can be relaxed, then thin-film deposition may be used to advantage. Amorphous ferromagnetic films derived from commercial METGLAS® alloy targets have been used in conjunction with microbridges and membranes to produce pressure sensors with FOM up to 2×10^5 (Gibbs *et al*., 1996; Karl *et al*., 2000). The potential for further application and integration within the microelectromechanical systems (MEMS) has been discussed (Gibbs, Hill and Wright, 2004). Thin-film technology overcomes many of the drawbacks of bonding, and a microstrain sensor using amorphous $(Fe_{90}Co_{10})_{78}Si_{12}B_{10}$ sputtered on to a soft glass substrate, demonstrated an FOM of 1.2×10^5 (Shin, Inoue and Arai, 1999).

The high magnetomechanical coupling also implies that there could be highly efficient transfer of sound waves into electrical signals (hydrophonics) using amorphous alloy cores. Scrolls of METGLAS®2605SC have been shown to demonstrate an optimum effective magnetomechanical coupling coefficient of 0.75 (maximum is 1). Very low bias fields were required (Rees, Gibbs and Pace, 1989; Rees *et al*., 1992).

Soft Magnetic Materials – Nanocrystalline Alloys

Giselher Herzer

1 INTRODUCTION

It is well known that the microstructure, noticeably the grain size, essentially determines the hysteresis loop of a ferromagnetic material. Figure 1 gives an example for the variation of the coercivity H_c over the whole range of structural correlation lengths starting from atomic distances in amorphous alloys over grain sizes, D, in the nanometer regime up to macroscopic grain sizes. The permeability shows an analogous behavior being essentially inversely proportional to H_c. The $1/D$ dependence of coercivity for large grain sizes (cf. Pfeifer and Radeloff, 1980) reflects the conventional rule that good soft magnetic properties require very large grains ($D > 100\,\mu m$). Thus, the reduction of particle size to the regime of the domain wall width increases the coercivity H_c toward a maximum, controlled by the anisotropies present. Accordingly, fine particle systems have been mostly discussed as hard magnetic materials (cf. Luborsky, 1961). Lowest coercivities, however, are again found for smallest structural correlation lengths like in amorphous alloys ('grain size' of the order of atomic distances) and in nanocrystalline alloys for grain sizes $D < 20\,nm$. The extraordinary D^6 dependence of coercivity at small grain size moreover demonstrates how closely soft and hard magnetic behavior actually can be neighbored. Indeed, the soft magnetic alloys are only one manifestation of the novel and extraordinary magnetic properties that can be realized by establishing structural features on the nanometer scale. Thus, nanocrystalline microstructures are also of high interest in order to enhance the properties of rare-earth hard magnets (cf. Buschow, 1997).

The decrease of coercivity in nanocrystalline soft magnetic materials has to be well distinguished from superparamagnetic phenomena, that is, the well-known decrease of coercivity in small, isolated, or weakly coupled particles due to thermal excitation (Kneller, 1969; Luborsky, 1961). In the present case, we consider small ferromagnetic crystallites well coupled by exchange interaction that results in low coercivity and, unlike superparamagnetic particles, in a simultaneously high permeability.

The most prominent example of soft magnetic nanocrystalline materials are devitrified glassy Fe–Cu–Nb–Si–B alloys introduced by Yoshizawa, Oguma and Yamauchi (1988). The material reveals an ultrafine microstructure of bcc Fe–Si with grain sizes of 10–15 nm embedded in an amorphous minority matrix. This particular microstructure enables a unique combination of the low losses, high permeability, and low magnetostriction achieved by permalloys and Co-based amorphous alloys, but with a saturation magnetization up to 1.3 T–much higher than either of these materials can conventionally offer. The material was produced by crystallization of an amorphous Fe–Si–B alloy with small additions of Cu and Nb, a hitherto somewhat unusual combination which proved to be the key for the

particular ultrafine grain structure and the associated soft magnetic properties.

The work of Yoshizawa *et al*. stimulated an intensive research for alternative alloy compositions. Thus, low-magnetostrictive nanocrystalline Fe–(Cu)–Zr–B alloys (Suzuki *et al*., 1990, 1991a,b) or Fe–Hf–C thin films (Hasegawa and Saito, 1991) have been established which exhibit a still higher saturation magnetization up to 1.7 T due to the higher Fe content in the alloy. Still, the outstanding soft magnetic properties of the original alloy system could not be reached. Interestingly, as a kind of precursor, the first example for soft magnetic behavior in the nanocrystalline state was given by O'Handley *et al*. (1985) for a devitrified glassy *cobalt*-based alloy. However, the soft magnetic properties were inferior to the amorphous state and, thus, not very attractive, which at present seems to be typical for cobalt-based nanocrystalline materials. Indeed, the most promising properties so far have been found in *iron*-based alloys on which we will focus this article. Table 1 summarizes some examples and their magnetic properties in comparison with conventional soft magnetic alloys.

We continue in Section 2 with a review of the *random anisotropy model* which provides the theoretical background for the soft magnetic properties observed in nanocrystalline and amorphous materials. This is followed in Section 3 by an overview of the most important alloy systems and their basic characteristics. Section 4 provides the experimental complement of Section 2 and discusses the various magnetic anisotropy contributions ultimately relevant for the soft magnetic properties in optimized nanocrystalline alloys. Concluding remarks are found in Section 5.

2 RANDOM ANISOTROPY MODEL

The basic conditions for good soft magnetic properties generally are a low or vanishing magnetic anisotropy constant K, which is a measure for the energy density needed to rotate the magnetization vector out of its energetically preferred orientation (magnetic easy axis). The most important contribution, the *magnetocrystalline* anisotropy, is related to the symmetry of the local atomic structure. For bcc-FeSi 20 at%, the constituent phase in nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$, the magnetocrystalline anisotropy constant is about $K_1 = 8.2\,\mathrm{kJ\,m^{-3}}$ (Gengnagel and Wagner, 1961), which is orders of magnitude too large in order to explain by itself the low coercivity ($H_c < 1\,\mathrm{A\,m^{-1}}$) and high permeability ($\mu_i \approx 10^5$) observed in the nanocrystalline material.

The key to understanding the soft magnetic properties in nanocrystalline materials is to recognize that the microstructure leads to a distribution of magnetic anisotropy axes randomly varying their orientation on a scale smaller than the domain wall width. The smoothing action of ferromagnetic exchange interaction, thus, impedes the magnetization

to follow the easy axes of the individual grains. The effective anisotropy constant for the magnetization process will therefore be an average over several grains and, hence, be reduced in magnitude. This makes the essential difference to large grained materials where the magnetization follows the randomly oriented easy axis of each grain and, accordingly, the magnetization process is controlled by the full local magnetocrystalline anisotropy.

The degree to which the local magnetocrystalline anisotropies are finally averaged out has been successfully addressed in terms of the so-called random anisotropy model (Herzer, 1989, 1990) which was originally developed in order to explain the soft magnetic properties of amorphous ferromagnets by Alben, Becker and Chi (1978). We review in this section the basic concepts of this model as well as its extensions (Herzer, 1995, 2005a; Suzuki, Herzer and Cadogan, 1998b) to multiphase systems with mixed random and uniform anisotropies.

2.1 Basic concepts

The random anisotropy model starts from a microstructure characterized by a distribution of magnetic anisotropy axes randomly varying their orientation over the scale of the grain size, D. The interplay between exchange and anisotropy energy is basically described by the following free energy density

$$\phi = A \sum_{i=x,y,z} (\nabla m_i)^2 + K_1 \, f_K(\underline{m} \cdot \underline{u}) + \ldots \qquad (1)$$

where A is the exchange stiffness, $\underline{m}$ is the direction of the magnetization vector, K_1 is the local magnetocrystalline anisotropy constant, and f_K is a dimensionless function describing the angular variation of the anisotropy energy density with respect to a local symmetry axis denoted by $\underline{u}$.

It is evident from equation (1) that the exchange energy density scales as A/L^2 if the magnetization changes its orientation on a length scale L, for example, by following the easy axes of the local magnetic anisotropies. Consequently, the exchange energy would exceed the local anisotropy energy (i.e., $A/L^2 > K_1$) if the magnetization followed the local anisotropy variations on a scale smaller than

$$L_0 = \varphi_0 \sqrt{A/K_1} \qquad (2)$$

where φ_0 is a dimensionless parameter in the order of 1. This *basic* ferromagnetic correlation length represents the characteristic minimum scale below which the direction of the magnetization cannot vary appreciably. It, for example, determines the order of the domain wall width for grains larger than L_0. Typical values are $L_0 \approx 5$–10 nm for Co-based and $L_0 \approx 20$–40 nm for Fe-based alloys. Accordingly, both amorphous ($D \approx$ atomic scale) and nanocrystalline alloys ($D \approx 5$–20 nm) fall into the regime where the structural correlation length D is smaller than L_0 and where the local randomly oriented anisotropies are, hence, averaged by the smoothing effect of exchange interaction.

The magnetic anisotropy relevant to the magnetization process for $D < L_0$ is given by the average of the anisotropy energy density over the volume $V_{ex} = L_{ex}^3$ defined by a correlation length L_{ex}, where the magnetization direction

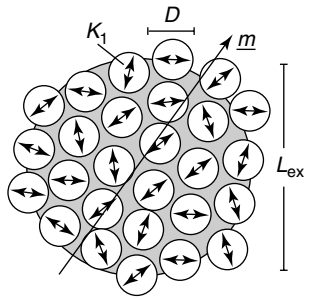

Figure 2. Schematic representation of the random anisotropy model for grains embedded in an ideally soft ferromagnetic matrix. The double arrows indicate the randomly fluctuating anisotropy axis, the hatched area represents the ferromagnetic correlation volume determined by the exchange length L_{ex} within which the orientation $\underline{m}$ of the magnetization is constant.

is kept constant by exchange interaction. The situation is schematically sketched in Figure 2. The average over the randomly oriented anisotropies of the $N = (L_{ex}/D)^3$ grains in the exchange-coupled volume is determined by statistical fluctuations. The average anisotropy constant $\langle K_1 \rangle$, hence, scales down as (cf. Appendix)

$$\langle K_1 \rangle = \frac{K_1}{\sqrt{N}} = K_1 \cdot (D/L_{ex})^{3/2} \tag{3}$$

The resulting easiest magnetic axis of the N grains is randomly oriented from one region of exchange-coupled grains to the other. The magnetization will follow these easy axes and the exchange energy consequently scales as $A/{L_{ex}}^2$. Accordingly, the average total free energy density with respect to the homogeneously magnetized state becomes

$$\langle \phi \rangle \approx A \cdot (\alpha/L_{ex})^2 - \tfrac{1}{2}\beta\,|K_1| \cdot (D/L_{ex})^{3/2} \tag{4}$$

where the dimensionless parameters α and β are basically related to the effective average angle between the easiest axes of the exchange-coupled regions and to the symmetry of the random anisotropy axis, respectively (cf. Herzer, 2005a).

The minimum of $\langle \phi \rangle$ with respect to L_{ex} is given for

$$L_{ex} = \varphi_0 \sqrt{A/\langle K_1 \rangle} \tag{5}$$

with $\varphi_0 = \alpha\sqrt{8/(3\beta)}$. The resulting exchange length L_{ex}, thus, follows from the *basic* exchange length L_0 as defined in equation (2) by self-consistently substituting the average anisotropy constant $\langle K_1 \rangle$ for the local anisotropy constant K_1. This renormalization accounts for the fact that the scale on which the exchange interaction dominates expands at the same time as the anisotropy is averaged out and, hence, the local anisotropies are averaged out even more efficiently. Combining equations (3) and (5) finally yields

$$\langle K_1 \rangle = K_1 \cdot (D/L_0)^6 \tag{6}$$

This final result is essentially based on statistical and scaling arguments and, therefore, is not limited to uniaxial anisotropies (as may be anticipated from Figure 2 or from the original work of Alben *et al.*) but also applies for cubic or other symmetries. The prefactors α, β, and φ_0 remain open parameters within this scaling analysis. Their theoretical determination would require a by far more complex micromagnetic analysis of the problem. Yet, all these parameters can be ultimately combined in a single material constant, which is given by the basic exchange length L_0, that is, the critical scale below which the averaging mechanism becomes effective. It is therefore more appropriate to write down the final result in the rationalized form of equation (6) involving the ratio D/L_0 rather than in the explicit form found in the original literature (cf. Alben, Becker and Chi, 1978; Herzer, 1990) involving all the individual material parameters and, in particular, more or less arbitrary prefactors.

The most significant feature predicted by the random anisotropy model is the strong variation of $\langle K_1 \rangle$ with the sixth power of the grain size. In typical nanocrystalline Fe-based alloys with grain sizes in the order of 10–15 nm, that is, $D \approx L_0/3$, the local magnetocrystalline anisotropy of $K_1 \approx 10^5\,\mathrm{J\,m^{-3}}$ is thus reduced by 3 orders of magnitude toward a few joules per cubic meter, which is small enough to enable superior soft magnetic behavior. Correspondingly the renormalized exchange length, L_{ex}, expands into the micrometer regime and is almost 2 orders of magnitude larger than the basic exchange length L_0 ($\approx$40 nm). High-resolution Kerr effect studies of nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ indeed reveal very wide domain walls of about 2 µm in thickness, indicative of the low effective anisotropy of the material (Schäfer, Hubert and Herzer, 1991).

2.2 Multiphase systems and mixed anisotropies

The preceding arguments were based on a single phase system. In real materials, however, we deal with various structural phases. In typical soft magnetic nanocrystalline materials, the randomly oriented crystallites of about 10 nm in size are embedded in an amorphous matrix. The latter is made up again of structural units with magnetic easy axes randomly fluctuating on the much smaller scale of atomic distances. Moreover, real materials reveal additional anisotropies, such as magnetoelastic- and field-induced anisotropies, which are uniform on a scale much larger than the exchange length. Such long-range anisotropies ultimately determine the soft magnetic properties of optimized nanocrystalline alloys where the contribution of the random anisotropies tends to become negligible. The original model

has been extended correspondingly (Herzer, 1995, 2005a; Suzuki, Herzer and Cadogan, 1998b).

2.2.1 *Average anisotropy*

The average anisotropy constant $\langle K \rangle$ of a *coupled* multiphase system with anisotropies randomly oriented on a scale smaller than a magnetic correlation length L_{ex} can be described by (Herzer, 2005a)

$$\langle K \rangle = \sqrt{K_u^2 + \sum_\nu x_\nu \beta_\nu^2 K_{1,\nu}^2 \cdot (D_\nu / L_{ex})^3} \qquad (7)$$

where K_u denotes a uniaxial anisotropy, which is *uniform* on a scale much larger than L_{ex}. The random contributions are represented by the local anisotropy constants $K_{1,\nu}$, the grain sizes D_ν, and the volume fractions x_ν of the individual structural phases labeled by the index ν. The result includes a grain size distribution if the term *structural phase* is used in a more general sense for all grains with the same $K_{1,\nu}$ and the same grain size D_ν. The parameters β_ν mainly involve conventions used for defining the anisotropy constants for different symmetries but also include some statistical corrections in the order of 10–20%. Numerical simulations for single phase systems result in $\beta \approx 1$ for uniaxial and $\beta \approx 0.4$ for cubic symmetry. The rather distinct value of β for the *cubic* case is largely a consequence of common conventions for the anisotropy energy. The latter result in $\Delta\phi_K = |K_1|/3$ for cubic and $\Delta\phi_K = |K_1|$ for uniaxial anisotropies, where $\Delta\phi_K = \phi_K^{max} - \phi_K^{min}$ is the difference of the anisotropy energy density between the hardest and easiest axis. The average anisotropy constant $\langle K \rangle$ in equation (7) is defined as the difference between the maximum and minimum of the average anisotropy energy density. For a single phase system with $K_u = 0$, it is related to $\langle K_1 \rangle$ as introduced in equation (3) by $\langle K \rangle = \beta \langle K_1 \rangle$.

The above result is valid as long as the average number of *coupled* grains $N_\nu = x_\nu (L_{ex}/D_\nu)^3$ is larger than one for each individual phase. For the derivation it is only necessary to assume that the magnetization is parallel within a volume defined by a correlation length L_{ex}, without specifying the precise coupling mechanism. This reduces the problem to adding up random anisotropies which can be done analytically using statistical concepts and/or by straightforward micromagnetic simulations (cf. Herzer, 2005a).

If the coupling mechanism is dominated by *exchange interaction*, the correlation length L_{ex} is self-consistently related to the total average anisotropy constant $\langle K \rangle$ by

$$L_{ex} = \varphi \sqrt{A / \langle K \rangle} \qquad (8)$$

where φ is a prefactor in the order of unity.

In the general case, the average anisotropy $\langle K \rangle$ has to be determined from equations (7) and (8) by numerical iteration. Explicit solutions can be obtained in the limiting cases of a vanishing or dominating macroscopic anisotropy K_u. The results are

$$\langle K \rangle = \left(\sum_\nu x_\nu \sqrt{\beta_\nu \left| K_{1,\nu} \right|} \left(D_\nu / L_{0,\nu} \right)^3 \right)^2 \qquad (9)$$

for $K_u = 0$, and

$$\langle K \rangle \approx K_u + \tfrac{1}{2} \textstyle\sum_\nu x_\nu \sqrt{\beta_\nu \left| K_{1,\nu} \right| K_u} \left(D_\nu / L_{0,\nu} \right)^3 \qquad (10)$$

if the uniform anisotropy is dominating over the random contributions. The latter is accompanied by a change of the scaling behavior of the random anisotropy contribution from D^6 to D^3. In the above relations

$$L_{0,\nu} := \varphi_{0,\nu} \sqrt{A / K_{1,\nu}} \quad \text{with} \quad \varphi_{0,\nu} := \varphi / \sqrt{\beta_\nu} \qquad (11)$$

define the *basic* exchange lengths related to the *local* anisotropies of the individual structural phases (cf. equation (2)). These length scales should not be confused with the *renormalized* exchange length L_{ex} of equation (8), which is self-consistently related to the *average* anisotropy $\langle K \rangle$. The corresponding prefactors have been estimated to be about $\varphi_0 \approx 1.5$ for cubic and $\varphi_0 \approx 1.7$ for uniaxial symmetry, respectively.

Figure 3 illustrates the competition of a uniform uniaxial anisotropy K_u and the average random anisotropy $\langle K_1 \rangle$ as obtained by numerical simulations (Herzer, 2005a). For small K_u the easiest magnetic axis is dominated by the random anisotropy. Accordingly, the easiest axes reveal a large angular dispersion from one region of exchange-coupled grains to the other. However, as K_u approaches and finally exceeds the average random anisotropy contribution $\langle K_1 \rangle$, the easiest magnetic axis is rotated toward the macroscopic anisotropy axis and the angular dispersion of the easiest axis disappears more and more.

Figure 4 illustrates the expected grain-size dependence of the average random anisotropy for the material parameters of optimized nanocrystalline Fe–Si–B–Nb–Cu alloys (Herzer, 2005b). We have included the contribution of the random atomic scale anisotropy of the amorphous matrix as well as the case of a small uniform anisotropy K_u here.

In the absence of long-range anisotropies, the average anisotropy $\langle K \rangle$ scales with D^6 down to grain sizes of about 5 nm. Although the atomic scale anisotropy of the amorphous phase in this simulation is almost 2 orders of magnitude higher than that of the bcc crystallites, its average contribution is virtually negligible for $D > 5$ nm since the structural anisotropies are fluctuating on the much shorter

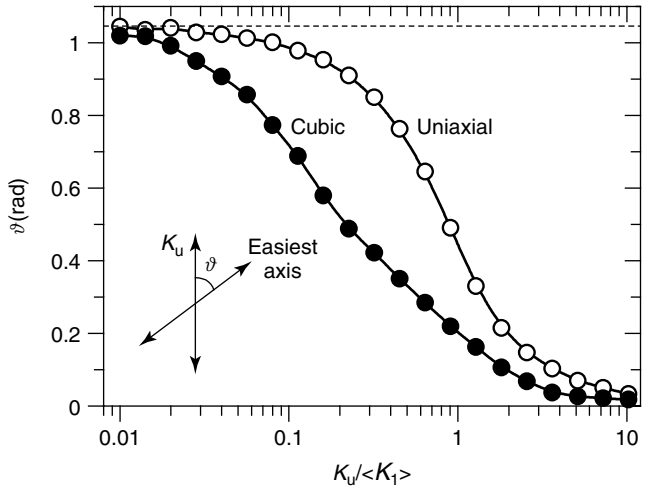

Figure 3. Average orientation of the easiest magnetic axis for a system of randomly oriented particles with average anisotropy constant $\langle K_1 \rangle = K_1/N^{1/2}$ and a superimposed, uniform uniaxial anisotropy K_u (full symbols: randomly oriented cubic grains; open symbols: uniaxial grains, dashed line: limit for $K_u = 0$).) (With permission from *Properties and Applications of Nanocrystalline Alloys from Amorphous Precursors*, Idzikowski, B. Svec, P. and Miglierini, M. (Eds), The Random Anisotropy Model, pp 15–34, 2005.)

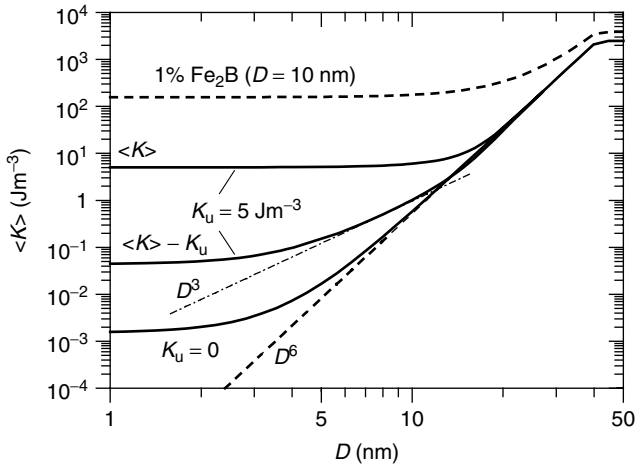

Figure 4. Theoretical estimate of the average anisotropy $\langle K \rangle$ for a system of randomly oriented crystallites of bcc $Fe_{80}Si_{20}$ ($K_1 = 8.2\,\mathrm{kJ\,m^{-3}}$) with grain size D and embedded in an amorphous matrix with a volume fraction $x = 0.75$. The atomic scale anisotropy constant of the amorphous phase was assumed as $K_1 = 430\,\mathrm{kJ\,m^{-3}}$ which is the value for Fe_2B and which can be looked upon as an upper bound. The exchange stiffness constant was assumed as $A = 6 \times 10^{-12}\,\mathrm{J\,m^{-1}}$ which is the experimental value for nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$. (Reprinted from *J. Magn. Magn. Mat.* **294**, G. Herzer, Anisotropies in Soft Magnetic Nanocrystalline Alloys, pp 99–106, 2005, with permission from Elsevier.)

scale of atomic distances ($D_{\mathrm{am.}} \approx 0.5\,\mathrm{nm}$). In this regime where the contribution of the bcc crystallites is dominating, equation (7) simplifies drastically and $\langle K \rangle$ becomes

$$\langle K \rangle := \beta \langle K_1 \rangle = \beta K_1 \cdot x_{\mathrm{cr}}^2 (D/L_0)^6 \qquad (12)$$

This result corresponds to exchange-coupled crystallites diluted in an ideally soft magnetic matrix. The only modification made over the original single phase model is the inclusion of the crystalline volume fraction x_{cr}. The statistical precondition for the averaging mechanism, that is, $N > 1$, then becomes $D < L_0/x_{\mathrm{cr}}^{1/6}$. This means that the critical grain size below which exchange interaction starts to suppress the local anisotropies is somewhat enhanced owing to the dilution effect.

The random anisotropy of the amorphous matrix becomes only visible for very small grain sizes below about 5 nm, resulting in a grain size independent anisotropy. However, this theoretical minimum value of $\langle K \rangle$ and the related coercivity ($H_c \sim 0.001\,\mathrm{A\,m^{-1}}$) are so small that the situation shown for smallest grain sizes in Figure 4 remains academic.

In real materials, whether amorphous or nanocrystalline, the minimum anisotropy is ultimately determined by more long-range anisotropies. To illustrate this more realistic situation, we have assumed the presence of a small uniform anisotropy $K_u = 5\,\mathrm{J\,m^{-3}}$. As can be seen from Figure 4, the average anisotropy constant $\langle K \rangle$ is almost totally determined by K_u for grain sizes below about 10–15 nm. The grain-size dependence of the random contribution, that is, $\delta K = \langle K \rangle - K_u$, changes from a D^6 dependence to a D^3 dependence, and finally, gets grain size independent due to the random anisotropy of the amorphous phase. The latter is larger than that for the case $K_u = 0$, because the maximum value for the renormalized exchange length is limited by $L_{\mathrm{ex}} = \varphi(A/K_u)^{1/2}$. As a consequence, the random anisotropies of the amorphous phase are less effectively averaged out.

A very small volume fraction of an additional crystalline phase with significantly higher anisotropy can finally change the picture totally. This is illustrated in Figure 4 assuming a 1% fraction of Fe_2B precipitates ($K_1 = 430\,\mathrm{kJ\,m^{-3}}$) with 10 nm grain size. The example explains at least qualitatively the finding in experiment that Fe_2B precipitates can significantly degrade the soft magnetic properties even though the grain size of the bcc crystallites remains unchanged.

2.2.2 *Grain coupling*

Adding up anisotropies is only one aspect of extending the random anisotropy model to multiphase systems. Another most challenging problem is how to relate the effective

exchange stiffness constant A to the local material parameters. It is intuitively clear that A has to be ultimately understood as an effective average value on the scale of the exchange length. However, as demonstrated by experiment (cf. Section 4.1.2), it is not a simple volume average. It is rather determined by the 'weakest link' in the exchange chain, which, for example, is the amorphous intergranular phase in typical nanocrystallized materials (Herzer, 1989). Hence, A should result from some kind of 'inverse averaging' of the local exchange constants. The most promising approach to the problem so far has been proposed by Suzuki and Cadogan (1998a). They consider the situation where the magnetization changes its orientation over the scale of the exchange length $L_{ex} \propto (A/\langle K\rangle)^{1/2}$. Like in a domain wall, the average tilting between neighboring spins is then approximately inversely proportional to L_{ex}, that is, proportional to $1/A^{1/2}$. The key argument of Suzuki *et al.* is that the local tilting angle should increase if the local exchange interaction becomes weaker and vice versa. Accordingly they assume the local tilting angle to be proportional to $1/A_{loc}^{1/2}$, where A_{loc} is the local exchange stiffness. The effective exchange stiffness, hence, can be calculated by averaging the local tilting angles. The result is

$$\frac{D+\delta}{\sqrt{A}} = \frac{D}{\sqrt{A_{cr}}} + \frac{\delta}{\sqrt{A_{am}}} \tag{13}$$

where D is the grain size, δ is the intergranular spacing, and A_{am} and A_{cr} denote the exchange stiffness constants of the amorphous matrix and the crystallites, respectively. Although physically very reasonable, this model is a rather phenomenological approach limited to the typical two-phase structure of nanocrystallized materials where the crystalline phase is completely surrounded by the amorphous phase. A more rigorous micromagnetic treatment including extensions to multiple phases or to situations like incomplete wetting of the crystallites by the amorphous matrix still provides a most challenging theoretical task.

For the derivation of equation (7), it is only necessary to assume that the magnetization is parallel within a volume defined by a correlation length L_{ex} without specifying the precise coupling mechanism. The coupling mechanism hereby has not necessarily to be exchange interaction but could also be dipolar interaction. In the latter case, 'L_{ex}' should be understood as *magnetic correlation length*, which is not necessarily proportional to $1/\langle K\rangle^{1/2}$ like it is for exchange interaction. Dipolar interactions, without any doubt, become increasingly important when the exchange interaction between the crystallites is largely interrupted, for example, when the amorphous intergranular phase becomes paramagnetic at elevated temperatures (cf. Section 4.1.2). The proper incorporation of dipolar interactions into the concepts of the random anisotropy model still provides another basic theoretical challenge for future investigations.

2.3 Coercivity and permeability

For pure random anisotropies averaged out by exchange interaction, coercivity H_c and initial permeability μ_i are directly related to the average anisotropy constant $\langle K\rangle$ by

$$H_c = p_c \frac{\langle K\rangle}{J_s}; \quad \mu_i = p_\mu \frac{J_s^2}{\mu_0 \langle K\rangle} \tag{14}$$

where J_s is the average saturation magnetization of the material and p_c and p_μ are dimensionless prefactors in the order of unity. These relations have been originally derived for coherent magnetization rotation in conventional fine particle systems (cf. Bozorth, 1951). In the regime $D < L_{ex}$, however, they also apply for domain wall displacements (Herzer, 1990). Accordingly, coercivity and permeability are expected to vary with grain size as $H_c \propto D^6$ and $\mu \propto 1/D^6$.

However, if the magnetization process is controlled by more long-range anisotropies, the theoretical description of H_c and μ_i gets more complex, similar to the case in conventional soft magnetic materials. For domain wall displacements, the coercivity is then determined by anisotropy fluctuations δK according to

$$H_c \approx \frac{1}{2J_s}\left|\overline{\frac{\partial \gamma_W}{\partial x}}\right|_{max} \approx \frac{\delta K}{J_s}\frac{L_{ex}}{\lambda} \tag{15}$$

where $\gamma_W = 4(A\langle K\rangle)^{1/2}$ is the domain wall energy, L_{ex} is the exchange length as introduced in equation (8), and λ is the fluctuation length of the effective anisotropy.

For large grains, $D > L_{ex}$, we have $\lambda \approx D$ and $\delta K \approx K_1$, such that equation (15) yields $H_c \propto K_1^{1/2}/D$, that is, the well-known $1/D$ dependence of coercivity in conventional soft magnetic materials.

In the regime $D < L_{ex}$, the effective contribution of the random magnetocrystalline anisotropies to the magnetization process is an average over the volume of the exchange length L_{ex}. Accordingly, the wavelength of the effective anisotropy fluctuations is given by the exchange length itself, that is, $\lambda \approx L_{ex}$, and the fluctuation amplitude is $\delta K = \langle K\rangle - K_u$. The coercivity, thus, is $H_c \sim (\langle K\rangle - K_u)/J_s$ and we expect for H_c the grain-size dependence shown in Figure 4 for $\langle K\rangle - K_u$. The most significant feature hereby is the transition from a D^6 to a D^3 law as K_u starts to dominate.

The preceding discussion assumed that the superimposed uniaxial anisotropy is perfectly uniform. This is rather the exception than the rule in reality, mostly due to internal

mechanical stresses and/or surface defects. The typical fluctuation wavelengths λ are much larger than L_{ex} and range from a few to about 100 µm. Such K_u fluctuations ultimately provide the limiting factor for the soft magnetic properties in amorphous and optimized nanocrystalline alloys. The result is a grain size independent contribution, $H_c \propto K_u^{1/2}/\lambda$, which finally dominates over the random microstructural anisotropies. This is the case in amorphous alloys and in optimized nanocrystalline Fe–Cu–Nb–Si–B alloys for grain sizes below about 15–20 nm.

Permeability μ behaves even more complex if we deal with a dominating long-range anisotropy K_u. In particular, it depends sensitively on the angle between applied magnetic field and macroscopic anisotropy direction. If the sample is magnetized perpendicular to the K_u axis, μ is determined by magnetization rotation and, hence, is inversely proportional to the total anisotropy, that is, $\mu \propto 1/\langle K \rangle$. It is, thus, grain size independent although coercivity may simultaneously vary proportional to D^3. If magnetized parallel to the uniform anisotropy axis μ is determined by domain wall pinning and we expect permeability to vary inversely proportional to H_c again, that is, $\mu \propto 1/\delta K$.

3 ALLOY SYSTEMS AND BASIC CHARACTERISTICS

The most suitable method to synthesize nanocrystalline alloys with attractive soft magnetic properties is controlled crystallization from the amorphous state. The amorphous precursor material is prepared either as a thin film by sputtering techniques or, more typically, as a ribbon by rapid solidification from the melt. A typical nanocrystalline structure with good soft magnetic properties occurs if the amorphous state is crystallized by the primary crystallization of bcc Fe, before intermetallic phases like Fe–B compounds may be formed. Both an extremely high nucleation rate and a slow growth of the crystalline precipitates are needed in order to obtain the nanoscaled microstructure. However, such a crystallization characteristics is rather the exception than the rule and needs an appropriate alloy design which promotes the nucleation of bcc Fe, retards the grain growth, and simultaneously inhibits the formation of intermetallic phases. The requirement of a good glass-forming ability puts further constraints on the accessible alloy compositions.

3.1 Fe–Cu–Nb–Si–B alloys

The most attractive soft magnetic properties in the nanocrystalline state are found for compositions like $Fe_{bal.}Cu_{0.5-1}Nb_{2-3}Si_{12-16}B_{6-9}$. The basic alloy design corresponds to that of a typical Fe–Si–B metallic glass. The alloys have a good glass-forming ability and are easily accessible by rapid solidification as originally amorphous ribbons, typically 20 µm thick. The nanocrystalline state is achieved by a subsequent heat treatment above the crystallization temperature. The desired crystallization characteristics is provided by the combined addition of Cu and Nb.

Figure 5 shows a typical example for the evolution of the microstructure and the soft magnetic properties with the annealing temperature. Accordingly, annealing of $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ at temperatures between about 500 and 600 °C leads to the primary crystallization of ultrafine bcc $Fe_{\sim 80}Si_{\sim 20}$ grains with typical grain sizes of 10–15 nm. The bcc grains are randomly oriented and embedded in a residual amorphous matrix which occupies about 20–30% of the volume and separates the crystallites at a distance of about 1–2 nm. This nanocrystalline structure is the basis

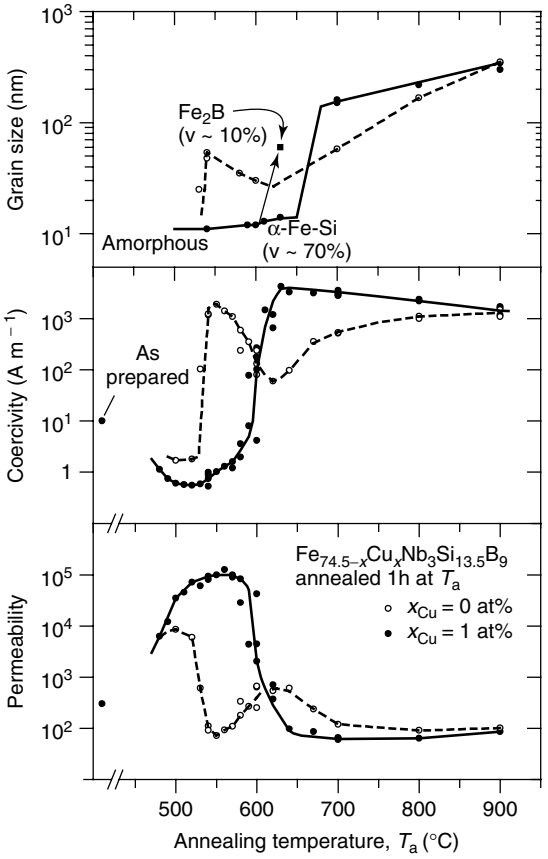

Figure 5. Average grain size, coercivity, and initial permeability of $Fe_{74.5-x}Cu_xNb_3Si_{13.5}B_9$ ($x = 0, 1$ at%) as a function of the annealing temperature. (Reprinted from *Handbook of Magnetic Materials*, Vol 10, Buschow, K.H.J, Nanocrystalline Soft Magnetic Alloys, Elsevier Science B.V., pp 415–462, 1997, with permission from Elsevier.)

for the excellent soft magnetic properties indicated by the high values of the initial permeability of about 10^5 and correspondingly low coercivities of less than $1\,A\,m^{-1}$. The magnetic properties and the underlying microstructure are relatively insensitive to the precise annealing conditions within a wide range of annealing temperatures, T_a, of about $\Delta T_a \approx 50-100\,^{\circ}C$. They develop in a relatively short period of time (about 10–15 min) and do not much alter even after prolonged heat treatment of several hours (cf. Yoshizawa and Yamauchi, 1991a). Only annealing at more elevated temperatures above about 600 °C leads to the precipitation of small fractions of boride compounds like Fe_2B or Fe_3B with typical dimensions of 50–100 nm, while the ultrafine grain structure of bcc Fe–Si still persists. Further increase of the annealing temperature above about 700 °C finally yields grain coarsening. Both the formation of Fe borides and grain coarsening deteriorates the soft magnetic properties significantly.

For comparison, Figure 5 includes the data for a $Fe_{74.5}Nb_3Si_{13.5}B_9$ alloy. The crystallization behavior of this Cu-free alloy is quite different and leads to a severe degradation of the soft magnetic properties as typically observed for conventional amorphous alloys. The average grain size is relatively large and shows a distinct variation with the annealing temperature. The crystallization of the Cu-free alloy is furthermore characterized by the almost simultaneous formation of bcc Fe–Si and Fe–B compounds, while the addition of already a few tenth at% of Cu leads to two clearly separated crystallization stages (Kataoka *et al*., 1989a; Herzer and Warlimont, 1992).

The formation of the particular nanocrystalline structure is essentially related to the combined addition of Cu and Nb (or other group IV to VI elements) and their low solubility in bcc Fe–Si: copper enhances the nucleation of the bcc grains while niobium impedes coarsening and, at the same time, inhibits the formation of boride compounds. The microstructure evolution is schematically illustrated in Figure 6 and can be described as follows:

In the early stage of annealing, prior to the primary crystallization of bcc Fe–Si, the phase separation tendency between Cu and Fe leads to the formation of Cu-rich clusters with a diameter of a few nanometer (Hono *et al*., 1992). These Cu clusters directly serve as heterogeneous nucleation sites for the Fe–Si primary crystals (Hono, Ping, Ohnuma and Onodera, 1999). The consequence is an extremely fine nucleation of bcc Fe–Si crystallites at a high rate which subsequently grow in a diffusion controlled process as the annealing proceeds further. As the bcc Fe–Si phase forms, Nb and B are excluded from the crystallites because of their low solubility in bcc Fe–Si and, hence, are enriched in the residual amorphous matrix. At the same time, effectively all Si tends to be partitioned into the bcc Fe–Si phase (Herzer, 1991; Hono *et al*., 1992). The enrichment with B

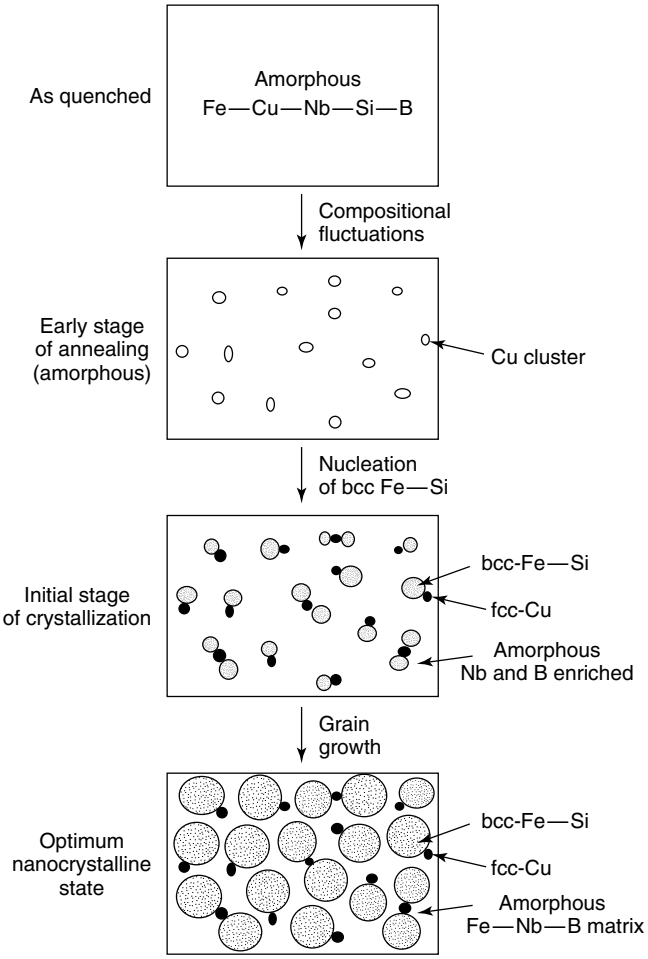

Figure 6. Schematic illustration of the formation of the nanocrystalline structure in Fe–Cu–Nb–Si–B alloys based on atom probe analysis results and transmission electron microscopy observations by Hono *et al*. (1992, 2000), Hono, Ping, Ohnuma and Onodera (1999).

and, in particular, with Nb increasingly stabilizes the residual amorphous matrix and, thus, hinders coarsening of the bcc grains. The presence of Nb also inhibits the formation of Fe boride compounds. The transformation finally ceases in a metastable two-phase microstructure of bcc Fe–Si embedded in an amorphous Fe–Nb–B matrix.

Figures 7 and 8 show the Curie temperatures T_C and the room-temperature magnetization J_s of Fe–Cu–Nb–Si–B alloys in the amorphous and in the nanocrystalline state. The precipitation of the bcc Fe–Si phase is clearly manifested in a significant increase of the Curie temperature T_C from 250 to 320 °C in the original amorphous state to about 600–740 °C after nanocrystallization. The residual amorphous matrix is ferromagnetic. Its Curie temperature and saturation magnetization, however, are clearly different from that of the amorphous precursor which reflects the discussed change in composition.

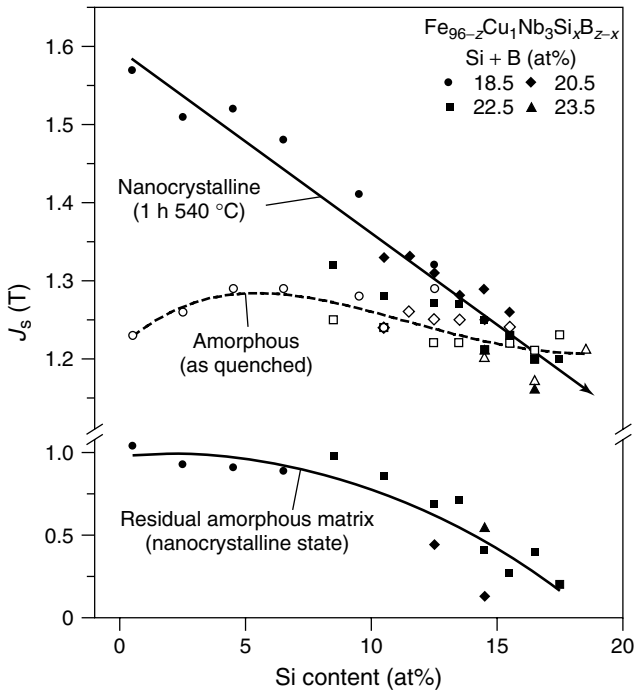

Figure 8. Room-temperature saturation magnetization, J_s, of $Fe_{96-z}Cu_1Nb_3Si_xB_{z-x}$ in the as quenched amorphous (open symbols) and nanocrystalline state after annealing 1 h at 540 °C (solid symbols, upper part). The lower part of the figure shows the local magnetization of the residual amorphous matrix in the nanocrystalline state (note the change in the axis scale). (Reprinted from *Handbook of Magnetic Materials*, Vol 10, Buschow, K.H.J, Nanocrystalline Soft Magnetic Alloys, Elsevier Science B.V., pp 415–462, 1997, with permission from Elsevier.)

Figures 9 and 10 show the crystalline fraction and the Si content of the crystallites as evaluated from thermomagnetic investigations by comparison with literature data for α-Fe–Si (Herzer, 1989, 1991). X-ray investigations of Ueda, Ikeda and Minami (1994) give comparable results. The crystalline fraction is mainly determined by the boron content and independent of the Si content. Both the crystalline fraction and the average grain size decreases with increasing boron content. This indicates that the boron plays a similar role as Nb in retarding the grain growth. The local Si content in the bcc grains is considerably larger than the average Si content of the alloy. For the high Si-content alloys the composition of the bcc grains is close to stoichiometric Fe_3Si which results in a DO_3 superlattice structure (Müller, Mattern and Illgen, 1991).

The transformation to the nanocrystalline state can be approximately described by the reaction

$$\text{Fe–Cu–Nb–Si–B} \longrightarrow x_{\text{cr}}\alpha - \text{Fe}_{1-y}\text{Si}_y + (1 - x_{\text{cr}})(\text{Fe}_{1-a}\text{Nb}_a)_n\text{B} \qquad (16)$$

which allows to estimate the crystalline fraction x_{cr} and the local atomic compositions by balance of atomic concentrations. A reasonable fit of the experimental data is obtained with $n \approx 2.2$, indicating that the nucleation and growth of the bcc grains proceeds until the residual amorphous matrix is enriched with boron such that its composition is close to stoichiometric $(Fe_{1-a}Nb_a)_2B$. In nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$, for example, the crystalline volume fraction is about 70% and the local compositions are close to $Fe_{\sim 80}Si_{\sim 20}$ in the bcc crystallites and $Fe_{\sim 60}Nb_{\sim 10}B_{\sim 30}$ in the residual amorphous matrix, respectively.

The effect of copper in enhancing the nucleation density, in a way, is unique. Gold is the only element which has been verified to have a comparable effect on the crystallization behavior (Kataoka, Matsunaga, Inoue and Masumoto, 1989b). Niobium can be substituted by other group V or VI refractory elements, like Cr, V, Mo, W, or Ta which act similarly on the crystallization process and on the magnetic properties (Yoshizawa and Yamauchi, 1991b). Like for Nb, the atomic volumes of these refractory elements are larger than that of Fe which reduces the diffusion coefficients and, thus, stabilizes the amorphous matrix and slows down the kinetics of grain coarsening (Müller and Mattern, 1994). Accordingly the efficiency of these elements for grain-size

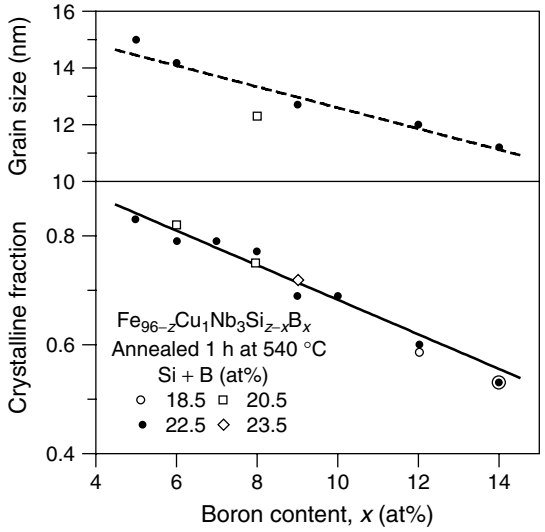

Figure 9. Average grain size and crystalline fraction in nanocrystalline $Fe_{96-z}Cu_1Nb_3Si_xB_{z-x}$ alloys versus the boron content. The solid line is the crystalline fraction calculated from the balance of atomic concentrations according to the reaction given by equation (16) with $n = 2.2$. refinement increases in the order of their atomic volumes, that is, Cr < V < Mo ≈ W < Nb ≈ Ta. Finest grain structures and superior magnetic properties require a certain minimum amount (typically 2–3 at%) of the elements Nb or Ta. More recent investigations by Ohnuma *et al*. (2000) indicate that the grain-size refinement and, hence, the soft magnetic properties can be optimized further by mutually adjusting the Cu and Nb content such that the Cu clustering occurs just before the onset of primary crystallization.

Another aspect of alloy design is that good soft magnetic properties require not only a small grain size but at the same time the absence of boron compounds. The required separation between the primary crystallization of bcc Fe and the precipitation of Fe–B compounds not only is determined by Cu and Nb but also needs a low or moderate boron content in order to minimize the driving force for the formation of boride compounds. On the other hand, Fe–Si–B metallic glasses require a certain minimum amount of B as well as minimum content of (Si + B), for the sake of glass-forming ability. This is one of the reasons that superior soft magnetic properties are only found for relatively low boron contents in the range 5–10 at% and correspondingly high Si contents of about 12–16 at% (cf. Figure 11).

Further aspects of alloy design and microstructure of the Fe–Cu–Nb–Si–B system can be found, for example, in the reviews of Herzer (1997), Yoshizawa (1999) and Hono and Ohnuma (2002).

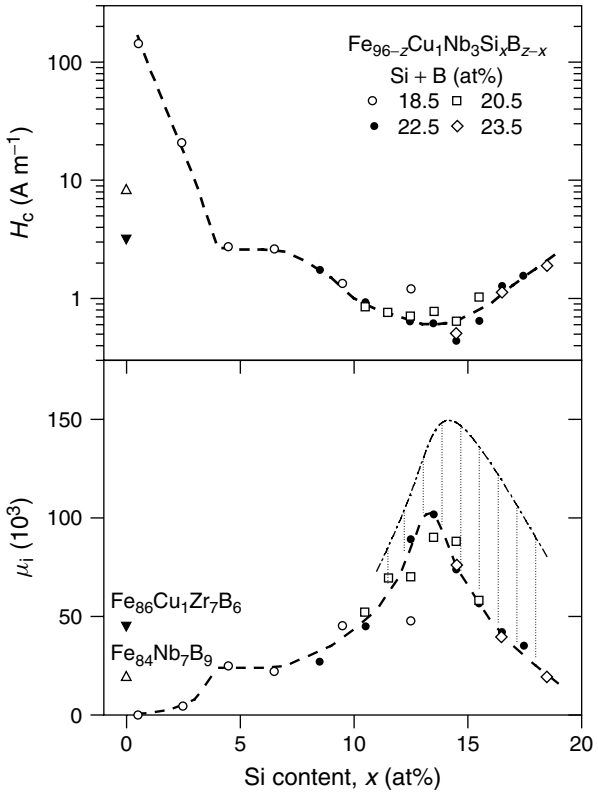

Figure 11. Coercivity, H_c, and initial permeability, μ_i, of nanocrystalline $Fe_{96-z}Cu_1Nb_3Si_xB_{z-x}$ annealed 1 h at 540 °C versus the Si content. The shaded area in the permeability plot represents the technological progress made since the introduction of the material around 1990.

3.2 Further alloy compositions

A major driving force in the search for further alloy compositions was to increase the saturation magnetization which, in the optimized compositions around $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$, is limited to about $J_s \approx 1.2-1.3$ T due to the high Si content in the bcc grains. An appreciable increase of J_s, thus, requires a nanocrystalline structure which essentially consists of pure α iron. The major problem hereby is to find appropriate amorphous precursor compositions with both sufficient glass-forming ability and the necessary crystallization characteristics.

As, for example, shown in Figure 8, the saturation magnetization in the $Fe-Cu_1Nb_3Si_xB_{z-x}$ system increases up to about 1.6 T if the Si content is reduced by replacing it with boron. However this benefit is finally accompanied by a severe degradation of the soft magnetic properties (cf. Figure 11) since the higher boron content favors the formation of boron compounds. In order to obtain a homogeneous nanocrystalline bcc structure with good soft magnetic properties, it is ultimately necessary to keep the boron content at a moderate level below about 10 at%. However, a corresponding reduction of the boron content at low Si contents, for the sake of glass-forming ability, is only possible if other good glass-forming elements are added simultaneously. Such elements which extend the glass-forming range at low Si and B contents are group IVa to VIa transition metals. The glass-forming range is the widest for Hf containing alloys and decreases in the order of Zr > Nb ≈ Ta > Mo ≈ W > V > Cr. The most stable amorphous phase is, thus, obtained in alloys containing refractory metals with large atoms and low d-electron concentrations, that is, particularly Zr, Hf, Nb, and Ta. These elements at the same time are very effective in suppressing the formation of the undesired boride compounds.

Accordingly, high iron content $Fe-(Cu_1)-M_{\sim 7}B_{2-9}$ alloys with M = Hf, Zr, Nb, and/or Ta have been found to exhibit both a more or less sufficient glass-forming ability and the necessary crystallization characteristics in order to give a nanocrystalline structure with good soft magnetic properties, low magnetostriction, and a high saturation induction up to 1.7 T (Suzuki *et al*., 1990, 1991a,b, 1993). Yet glass-forming ability and castability still remain a major problem with these alloys. Thus, the Nb containing alloys which yield reasonable properties, like, for example, $Fe_{84}Nb_7B_9$, are located at the border of the glass-forming range (Suzuki, Makino, Inoue and Masumoto, 1994) which makes them most difficult to produce, in particular, on larger scale. The glass-forming ability is considerably improved with the addition of Zr or Hf. However, the strong oxygen reactivity of either of the two elements is a severe problem and requires a good protecting casting atmosphere. Moreover, the compositions with the highest saturation magnetization of $J_s = 1.6-1.7$ T, like $Fe_{91}Zr_7B_2$ are again located at the border of the glass-forming range. The preparation of Fe–M–B thin ribbons by rapid solidification, thus, requires substantially more effort than necessary for the more conventional Fe–(Cu,Nb)–Si–B compositions and, therefore, is presently still limited to smaller quantities.

In the Fe–M–B alloy system, the addition of copper is not necessarily required in order to yield a nanocrystalline structure with reasonable magnetic properties. Quenched-in compositional fluctuations in the amorphous state due to a relatively low glass-forming ability and the enhanced concentration of refractory elements insoluble in α-Fe are considered as a possible explanation (Suzuki, Makino, Inoue and Masumoto, 1994). Still, the addition of Cu again promotes the primary nucleation of the bcc Fe and enhances the soft magnetic properties significantly.

It should be finally mentioned that the spectrum of accessible nanocrystalline systems can still be considerably expanded by thin-film sputtering techniques. One example are Hf carbide dispersed nanocrystalline Fe–Hf–C films crystallized from the amorphous state (Hasegawa and Saito, 1991; Hasegawa, Kataoka and Fujimori, 1992). They combine good thermal stability, good high-frequency properties in the megahertz range with low magnetostriction, and high saturation induction of $J_s = 1.7$ T which can be even increased up to 2.0 T by multilayering these films with Fe. Another example are (Fe,Co,Ni)–(Si,B)–(F,O,N) granular alloy films (cf. Fujimori, 1995) which, at a saturation induction of about 1 T, possess a uniquely high electrical resistivity of 10^3-10^4 μΩcm which makes them a possible candidate for future high-frequency devices.

4 ANISOTROPIES AND SOFT MAGNETIC PROPERTIES

Figure 11 summarizes the soft magnetic properties of typical nanocrystalline Fe-based alloys. Lowest coercivities ($H_c \approx 0.5-1$ A m^{-1}) and highest permeabilities ($\mu \approx 10^5$) are found around the originally proposed compositions, that is, $Fe_{\sim 74}Cu_1Nb_3Si_{13-16}B_{6-9}$. Figure 12 compares the properties with other near-zero magnetostrictive alloys. Accordingly, nanocrystalline materials offer a unique combination of a high saturation induction and a high permeability.

The soft magnetic properties found in the optimized compositions can be only partially understood by the grain-size effect. They are ultimately determined by the competition of magnetocrystalline, magnetoelastic, and annealing-induced anisotropies as well as by the ribbon quality (i.e., impurities, surface roughness, oxide layers, etc.). Thus, the degradation of the soft magnetic properties shown in Figure 11

for decreasing Si contents is a consequence of the simultaneously increasing magnitudes of the saturation magnetostriction, the field-induced anisotropy, and the local magnetocrystalline anisotropy constant. At very low Si contents, the simultaneously enhanced boron content additionally promotes the precipitation of boride compounds even after optimized annealing. The degradation toward high Si contents results from an increasing grain size due to the simultaneously decreasing boron content and from the enhanced tendency for the formation of silicon oxide layers. At very high Si contents, finally, the correspondingly low boron content reduces the glass-forming ability which additionally promotes coarse-grained crystalline precipitations already in the as-cast state. On the basis of the theoretical background given in Section 2, we will now discuss in more detail the various magnetic anisotropy contributions relevant for the soft magnetic properties.

4.1 Magnetocrystalline anisotropy

4.1.1 Grain-size effect

Figure 13 shows the coercivity H_c and the initial permeability μ_i of various nanocrystallized alloys as a function of the grain size D. The relatively broad scatter of the data is mainly related to the circumstance that the experimental variation of the grain size cannot be performed in a straightforward manner. It inevitably requires variations of the alloy composition and/or the annealing conditions which changes both the volume fraction and composition of the precipitated crystallites and the residual matrix. As a consequence, the local magnetocrystalline anisotropy constant, K_1, and the exchange interaction, A, between the grains change simultaneously. Nonetheless, the D^6 dependence predicted by the random anisotropy model seems to provide a good guiding principle through most of the coercivity and permeability data for grains smaller than $L_0 \approx 40$ nm.

However, there are also systematic deviations from the simple D^6 law. The major reasons are (i) precipitates of highly anisotropic compounds like Fe_2B and/or (ii) more long-range anisotropy contributions which are uniform on a scale much larger than the exchange length.

The formation of Fe_2B compounds can indeed drastically deteriorate the soft magnetic properties while the grain size of the bcc crystallites may remain unchanged (cf. Figures 5 and 13). The effective hardening caused by the Fe_2B precipitates already at smallest volume fractions is related to their relatively large size of 50–100 nm and, in particular, to their large magnetocrystalline anisotropy constant, K_1, of about 430 kJ m^{-3} which is orders of magnitude higher than that of the bcc crystallites. As demonstrated in Figure 14, the good soft magnetic properties of the nanocrystalline bcc structure are largely recovered when $K_1(Fe_2B)$ passes through zero

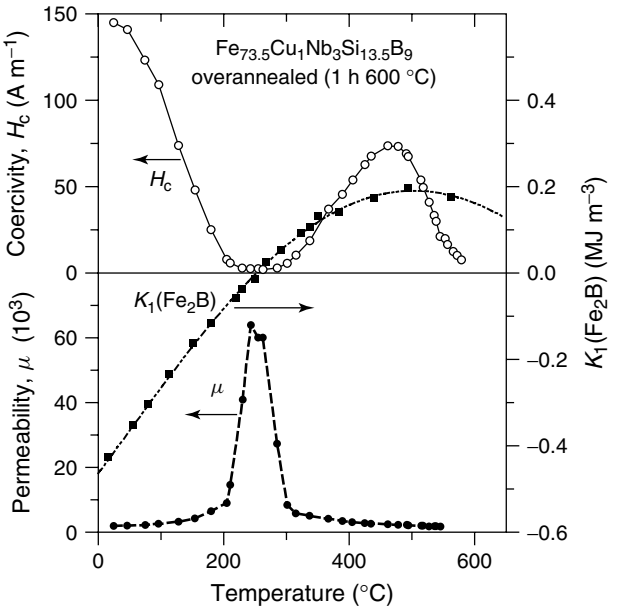

Figure 14. Temperature dependence of coercivity, H_c, and initial permeability, μ_i, of overannealed nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ with slight traces of Fe_2B, whose magnetocrystalline anisotropy constant K_1 (cf. Iga, Tawara and Yanase, 1966) is included in the figure. Figure 15. Characteristic hysteresis loops in the nanocrystalline state. The average grain sizes for the examples shown are about 25 nm for $x_{Nb} = 1.5$ at% and 12 nm for $x_{Nb} = 3$ at%, respectively. (Reprinted from *J. Magn. Magn. Mat.*, **157/158**, G. Herzer, Nanocrystalline Soft Magnetic Materials, 133–136, 1996, with permission from Elsevier.)

at 250 °C. This particular temperature dependence allows to detect even smallest amounts of borides, hardly visible by more direct structural investigations, and thus provides a most sensitive tool in order to separate whether an eventual degradation of the soft magnetic properties arises from too large bcc grains or from hard precipitates.

Long-range anisotropies lead to modified or vanishing grain-size dependence for small grain sizes. Relevant to this are magnetoelastic anisotropies, creep- or field-induced anisotropies and/or shape anisotropies which control the magnetization process when the random magnetocrystalline anisotropy is sufficiently averaged out. Thus, it is evident from Figure 13 that the soft magnetic properties of nanocrystalline Fe–Cu–Nb–Si–B alloys become basically grain size independent for grain sizes below 15–20 nm. Suzuki, Herzer and Cadogan (1998b) confirm this behavior for the coercivity of Fe–Cu–M–Si–B (M = IVa to VIa metal) alloys while they find a $H_c \propto D^3$ law, for example, for nanocrystalline $Fe_{91}Zr_7B_2$ with grain sizes $D \approx 12$–18 nm.

Figure 15 shows some typical hysteresis loops for $D < L_0$. In the regime of the D^6 law, the hysteresis loops reveal a high remanence to saturation ratio J_r/J_s. An example with $J_r/J_s \approx 0.95$ is given in Figure 15 by the sample with $D \approx 25$ nm. Such an isotropic remanence enhancement toward $J_r/J_s = 1$ is another characteristic feature when exchange interaction starts to dominate over anisotropy. The phenomenon is of particular interest for tailoring isotropic, nanoscaled hard magnets (cf. Buschow, 1997). However, the effect disappears at smaller grain sizes where more long-range anisotropies dominate over the averaged random anisotropies. Figure 15 includes a typical example (sample with $D = 12$ nm) with a remanence ratio around 0.5. The latter clearly indicates that the magnetization process is dominated by a distribution of uniaxial anisotropies which are uniform on a scale much larger than the exchange length.

Figure 16 shows typical domain patterns found for small grain sizes below 15 nm. The wide regular domains as well as typical stress patterns provide further evidence for the dominance of more uniform anisotropies in such optimized samples. Only high-resolution optical Kerr microscopy still reveals irregular magnetization patches within the wide domains (Flohrer, Schäfer, Polak and Herzer, 2005). A corresponding example is given in Figure 16(c). These magnetization patches are fluctuating on a scale of a few micrometers which is in the order of the renormalized exchange length L_{ex}. They arise from the residual contribution of the random magnetocrystalline anisotropies and reflect the angular dispersion of the easiest magnetic axis from one region of exchange-coupled grains to the other. Accordingly, these patches are found to be more pronounced, the more the random anisotropies contribute to the total magnetic anisotropy and, vice versa, they tend to disappear, the more long-range anisotropies dominate. Comparable magnetization patches are virtually invisible in soft magnetic amorphous alloys due

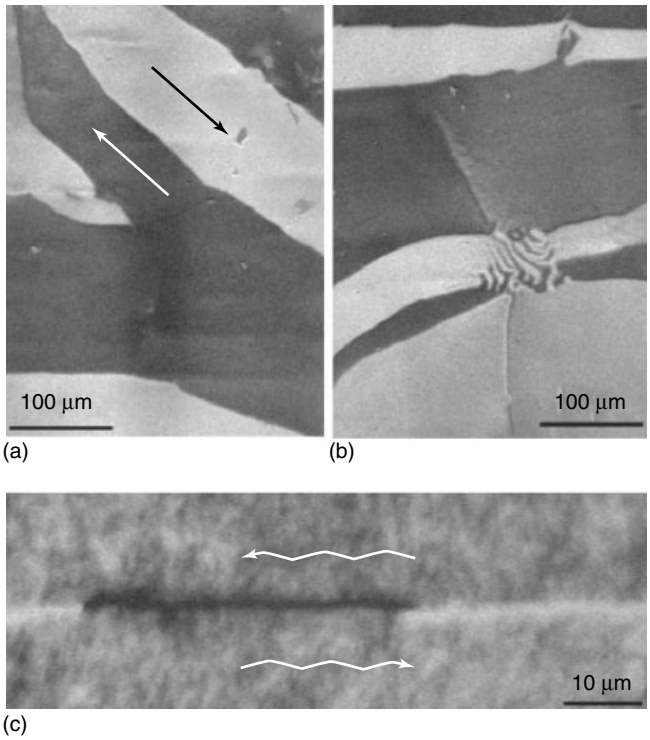

Figure 16. Magnetic domains observed in nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{16}B_7$ (annealed 1 h 540 °C). Examples for regular wide domains (a), rare zones with stress patterns (b) and a high-resolution image of a domain wall (c) are shown. The high-resolution image (c) also exemplifies the patchy magnetization fluctuations typically observed within the wide domains. (By courtesy of R. Schäfer, IFW Dresden.)

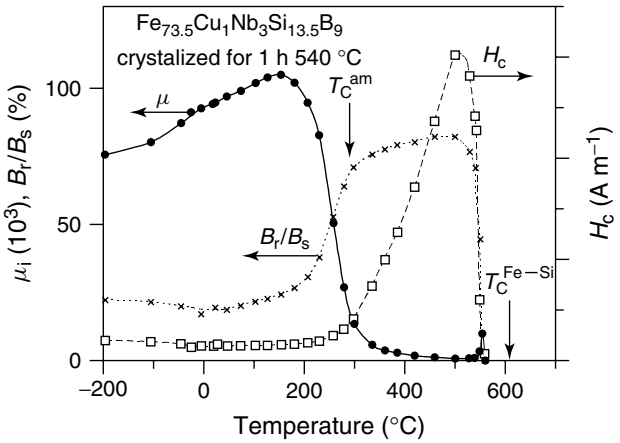

Figure 17. Initial permeability, μ_i, coercivity, H_c, and remanence to saturation ratio, B_r/B_s, of nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ (annealed 1 h at 540 °C + 4 h at 350 °C in a transverse magnetic field) versus the measuring temperature (measuring frequency f = 50 Hz). The arrows indicate the Curie temperatures of the residual amorphous matrix (T_C^{am} = 291 °C) and the bcc grains (T_C^{FeSi} = 607 °C), respectively. (Reprinted from *Scr. Metall. Mater.*, **33**, G. Herzer, Soft Magnetic Nanocrystalline Materials, 1741–1756, 1995, with permission from Elsevier.)

to the extremely small contribution of the averaged random anisotropies.

In summary, it appears that, like in amorphous metals, the average random anisotropy of optimized nanocrystalline alloys like $Fe_{bal.}Cu_{0.5-1}Nb_{2-3}Si_{12-16}B_{6-9}$ is negligibly small and that the soft magnetic properties are predominantly controlled by more long-range uniaxial anisotropies like magnetoelastic and annealing-induced anisotropies. Yet, unlike soft magnetic amorphous metals, there are still situations where the random magnetocrystalline anisotropy becomes significant even for smallest grain sizes. The most prominent example is the temperature dependence of the soft magnetic properties which will be discussed in the following.

4.1.2 Grain coupling

The suppression of magnetocrystalline anisotropy requires that the randomly oriented grains are ferromagnetically coupled by exchange interaction. Consequently, if the exchange interaction is reduced, the local anisotropies will be less effectively averaged out and the soft magnetic properties will degrade.

The crucial role of the exchange interaction becomes most evident from the temperature dependence of the magnetic properties (Herzer, 1989) which is shown in Figure 17. The exchange coupling between the bcc grains mainly occurs via the intergranular amorphous matrix. The latter has a much lower Curie temperature than the bcc grains (cf. Figure 7). As a consequence, the intergranular coupling is largely reduced as the measuring temperature approaches the Curie temperature T_C^{am} of the amorphous matrix and the soft magnetic properties degrade correspondingly. Simultaneously, as shown in Figure 18, the domain structure simultaneously changes from wide domains to a pattern of small, irregular domains (Schäfer, Hubert, and Herzer, 1991; Flohrer, Schäfer, Polak and Herzer, 2005). These features are basically reversible and, thus, are not connected with irreversible, microstructural changes during the measurement.

The particular example shown in Figure 17 reveals a small uniaxial anisotropy ($K_u \approx 6\,J\,m^{-3}$) transverse to the ribbon axis induced by magnetic field annealing. In the low temperature regime, this induced anisotropy dominates over the averaged magnetocrystalline anisotropy, as indicated by the small remanence to saturation ratio B_r/B_s. However, when approaching T_C^{am}, the random anisotropies rapidly increase due to the reduced grain coupling and take over the control of the hysteresis loop. As a consequence, the remanence to saturation ratio steeply increases around 250 °C. From the theoretical analysis of the interplay between random and uniform anisotropies (cf. Figure 3) we expect this transition to

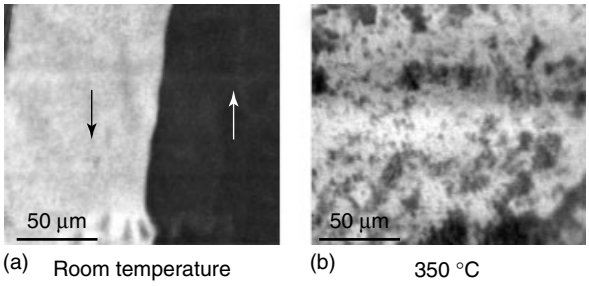

Figure 18. Transition from wide domains at room temperature to a patchy domain pattern at 350 °C for nanocrystalline $Fe_{73}Cu_1Nb_3Si_{16}B_7$ with a small field-induced anisotropy $K_u \approx 3\,J\,m^{-3}$. (Reprinted from *Acta mater.*, **53**, Flohrer, S., Schäfer, R., Polak, Ch. and Herzer. G., Interplay of Uniform and Random Anisotropy in Nanocrystalline Soft Magnetic Alloys, pp 2937–2942, 2005, with permission from Elsevier.)

occur at $K_u \approx 0.5\langle K_1\rangle$ for cubic crystallites. Accordingly, the increase of B_r/B_s is shifted toward higher temperatures with increasing magnitude of the induced anisotropy. Thus, for a sample with $K_u \approx 30\,J\,m^{-3}$, the remanence starts to increase significantly only at about 450 °C and wide domains can be still observed beyond temperatures of 500 °C (Flohrer, Schäfer, Polak and Herzer, 2005). Yet, the temperature dependence of H_c, being mainly determined by the random anisotropies, remains essentially comparable to that of a low K_u sample.

Above T_C^{am} the coercivity reaches a maximum with increasing measuring temperature and, finally, decreases toward zero together with the remanent magnetization. Interestingly, the latter occurs at a temperature (560 °C) below the Curie temperature (607 °C), of the bcc grains. This indicates the transition to superparamagnetic behavior which has been confirmed by a more detailed analysis of Lachowicz and Slawska-Waniewska (1994). Hernando and Kulik (1994) showed that the maximum of H_c shifts toward T_C^{am}, and that, H_c increases by one order of magnitude as the intergranular distance is increased from $\delta \approx 1$–2 nm to $\delta \approx 5$ nm. Simultaneously the onset temperature for superparamagnetic behavior decreases and approximately coincides with T_C^{am} for $\delta \approx 13$ nm.

The whole results for the magnetic behavior above the Curie point, T_C^{am}, of the amorphous matrix indicate that the grain coupling is largely, but not completely, interrupted above T_C^{am} and still persists to higher temperatures. Yet, the precise coupling mechanism for $T > T_C^{am}$ is still under discussion. Both exchange penetration through the thin, paramagnetic intergranular layer (Hernando and Kulik, 1994) and dipolar interactions (Herzer, 1995) provide reasonable explanations in order to interpret the experimental findings. In any case, the strength of the coupling decreases with increasing temperature due to the simultaneous decrease of the magnetization in the bcc grains. Consequently, the soft magnetic properties keep on degrading even above T_C^{am} until thermal energy dominates and the system gets superparamagnetic.

The temperature dependence of the magnetic properties demonstrates that it is important to maintain an efficient exchange coupling between the grains by appropriate alloy design such that the Curie temperature of the residual amorphous matrix is clearly higher than application temperatures. Thus, for example, too high additions of Nb (or comparable elements), although favorable for grain refinement, can be disadvantageous because they decrease the Curie temperature of the matrix considerably (Yoshizawa and Yamauchi, 1991a). Similarly, reduced grain coupling due to a low Curie temperature of the intergranular phase also provides one of the explanations for the minor soft magnetic properties in nanocrystalline Fe–Zr–B alloys (cf. Slawska-Waniewska *et al.*, 1994) or Fe–Hf–C thin films (Hasegawa, Kataoka and Fujimori, 1992).

Figure 19 finally shows the temperature dependence of the permeability in comparison with other soft magnetic materials. In highly permeable crystalline alloys, like permalloy (80% NiFe), the magnetocrystalline anisotropy constant K_1 is adjusted to zero by alloying and annealing which, however, is effective only for a certain temperature. Thus, the temperature dependence of K_1 yields a pronounced variation of the soft magnetic properties around the temperature where K_1 is zero (cf. Pfeifer, 1992). In particular, the drop of permeability toward lower temperatures (because of $K_1 > 0$) can be a problem for certain applications like, for example, magnetic cores for ground fault interrupters. In

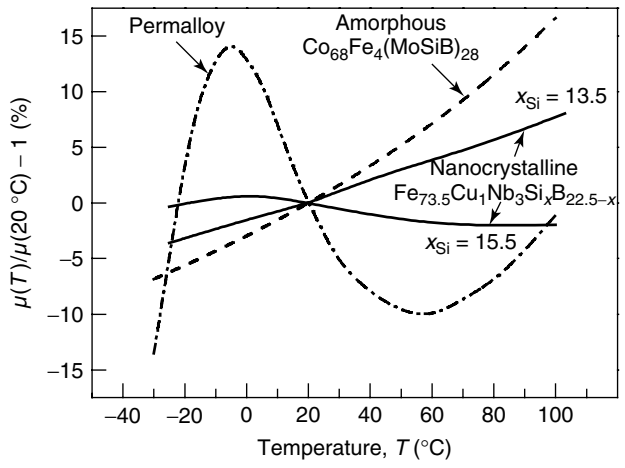

Figure 19. Relative change of the initial permeability normalized to its room-temperature value versus the typical range of application temperatures for highly permeable soft magnetic materials. All examples have been transverse field annealed and reveal an initial permeability in the range $\mu_i \approx 70 \times 10^3 - 90 \times 10^3$.

comparison, in nanocrystalline and amorphous materials, the magnetocrystalline anisotropy is averaged out by exchange interaction which is effective over a large temperature range. Accordingly the magnetic properties vary smoothly in both materials. In amorphous alloys, the behavior is mainly determined by induced anisotropies whose magnitude decreases and, thus, the permeability typically increases with increasing temperature. This mechanism also applies to nanocrystalline materials but is opposed by the reduction of the intergranular coupling at higher temperatures. Accordingly, the permeability runs through a maximum at an intermediate temperature, T_{max}. The latter depends on the details of the annealing conditions as well as on the alloy composition–though the physical mechanisms are still under investigation. Depending on T_{max}, the permeability may thus be found to increase, to decrease, or to be even largely temperature independent over the range of application temperatures.

4.2 Saturation magnetostriction

Apart from a low or vanishing magnetocrystalline anisotropy, another basic requirement for excellent soft magnetic properties is the absence of magnetostriction in order to minimize magnetoelastic anisotropies

$$K_\sigma = -\tfrac{3}{2}\lambda_s\sigma \tag{17}$$

arising from internal or external mechanical stress, σ. For example, even stress-relieved toroidal wound cores may still reveal internal stresses of a few MPa. In the amorphous state the material reveals a high positive saturation magnetostriction of $\lambda_s \approx +23 \times 10^{-6}$, typical for Fe-based amorphous alloys. The associated magnetoelastic anisotropy of about $K_\sigma \approx 50\,\mathrm{J\,m^{-3}}$, thus, limits the achievable initial permeability to typically $\mu_i \approx 10^4$.

It is the actual highlight of nanocrystalline Fe-based alloys that the phases formed on crystallization can lead to low or vanishing saturation magnetostriction, λ_s. Figure 20 summarizes the situation in the Fe–Cu–Nb–Si–B system. The decrease of λ_s is ultimately responsible for the simultaneous increase of the initial permeability upon the formation of the nanocrystalline state (cf. Figure 5).

While λ_s is fairly independent of the composition in the amorphous state (cf. Herzer, 1991), it depends sensitively on the Si content in the nanocrystalline state, passing through zero at low and at high Si concentrations around 16 at%. Still, the maximum permeability is not necessarily found for the $\lambda_s \approx 0$ compositions, but for Si contents around 13 at% (cf. Figure 11) due to the impact of the other anisotropy contributions.

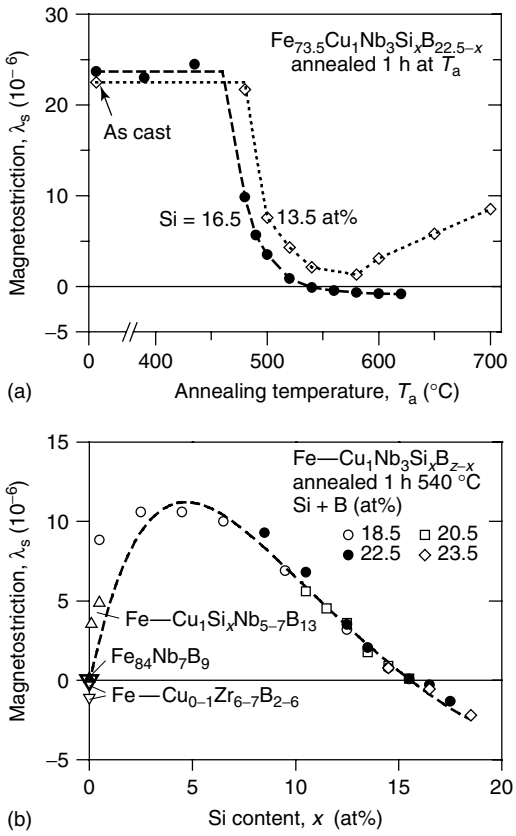

Figure 20. The saturation magnetostriction, λ_s, of Fe–Cu–Nb–Si–B alloys: (a) Influence of the annealing temperature, T_a and (b) influence of the Si content in the nanocrystalline state. The figure includes the data for Fe–Nb–B (solid up triangle) and Fe–(Cu)–Zr–B alloys (open down triangles) from Suzuki *et al.* 1991, 1993. (Reprinted from *Handbook of Magnetic Materials*, Vol 10, Buschow, K.H.J., Nanocrystalline Soft Magnetic Alloys, Elsevier Science B.V., pp 415–462, 1997, with permission from Elsevier.)

The detailed behavior of λ_s can be understood from the balance of magnetostriction among the structural phases present in the nanocrystalline state, that is, (Herzer, 1991)

$$\lambda_s \approx x_{cr} \cdot \lambda_s^{FeSi} + (1 - x_{cr}) \cdot \lambda_s^{am} \tag{18}$$

where x_{cr} is the crystalline volume fraction, and λ_s^{FeSi} and λ_s^{am} denote the local magnetostriction constants of the α-Fe–Si grains and the residual amorphous matrix, respectively. The composition dependence essentially reflects the compositional variation of λ_s found for polycrystalline α-$Fe_{100-x}Si_x$ (cf. Yamamoto, 1980). Thus, near-zero magnetostriction in nanocrystalline Fe-based alloys requires a large crystalline volume fraction with negative magnetostriction in order to compensate the high positive value of the amorphous Fe-based matrix. This is achieved either by a high Si content in the bcc grains ($\lambda_s^{FeSi} \approx -6 \times 10^{-6}$ for α-$Fe_{80}Si_{20}$), like in

the Fe–Cu–Nb–Si–B system, or if the grains consist of pure α-Fe ($\lambda_s^{Fe} \approx -4 \times 10^{-6}$) like in Fe–Zr–B alloys (Suzuki *et al*., 1991a,b) or Fe–(Si)–Hf–C thin films (Hasegawa, Kataoka and Fujimori, 1992). For the low Si-content alloys it is further important to have a low boron concentration in order to obtain a large crystalline fraction and to suppress the formation of boride compounds which yield a positive contribution to λ_s (cf. the increase of λ_s in Figure 20a at elevated annealing temperatures where such boride compounds are formed).

An important point to stress is that the superposition of the local magnetostriction constants to zero really results in stress insensitivity of the magnetic properties like in amorphous Co(Fe)-based alloys. This is again a consequence of the smoothing effect of exchange interaction for structural correlation lengths much smaller than the domain wall width. Thus, the nanoscale fluctuations in magnetoelastic anisotropy associated with the locally varying magnetostrictions are randomly averaged out which results in a single isotropic magnetostriction coefficient. The situation contrasts with that for large grained crystalline systems, where an average zero saturation magnetostriction does not generally imply stress insensitivity of the hysteresis loop. Thus, the small grain size is also a decisive factor for the magnetostriction: although it does not directly influence the value of λ_s, it opens a new way in order to achieve isotropically low magnetostriction by combining the properties of different structural phases with the help of exchange interaction.

4.3 Annealing-induced anisotropies

So far magnetic anisotropies have been discussed as a rather disturbative factor for the soft magnetic properties. However, if properly controlled, they also can be a powerful tool in order to tailor the shape of the hysteresis loop according to the demands of various applications. Like, for example, in amorphous materials, this can be realized in nanocrystalline materials by either magnetic field annealing or tensile stress annealing which both yields a uniform uniaxial anisotropy.

4.3.1 Magnetic field–induced anisotropies

Magnetic field annealing induces a uniaxial anisotropy with an easy axis parallel to the direction of the magnetic field applied during the heat treatment. The anisotropy formation is related to directional atomic ordering along the direction of the local magnetization in order to minimize spin-orbit coupling energy (cf. Néel, 1954; Fujimori, 1983). Figure 21 shows some typical examples for the hysteresis loops and the corresponding impedance permeability as obtained after characteristic heat treatments.

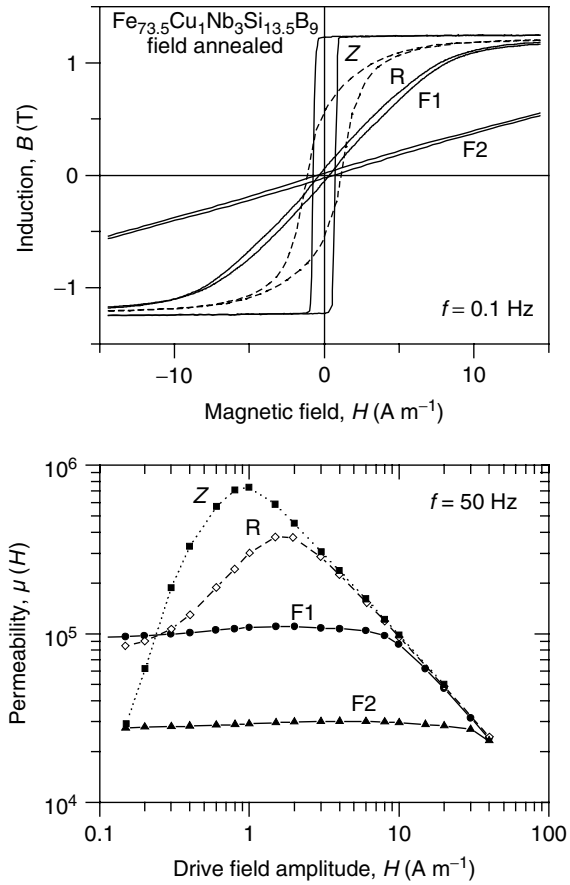

Figure 21. Quasistatic hysteresis loops and 50 Hz permeability of nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ annealed for 1 h at 540 °C without (R) and with a magnetic field applied parallel (Z) and transverse (F2; $K_u \approx 20\,J\,m^{-3}$, $\mu \approx 30 \times 10^3$) to the magnetic path. Sample F1 ($K_u \approx 6\,J\,m^{-3}$, $\mu \approx 100 \times 10^3$) was first crystallized at 540 °C and subsequently transverse field annealed at 350 °C. (Reprinted from *Handbook of Magnetic Materials*, Vol 10, Buschow, K.H.J., Nanocrystalline Soft Magnetic Alloys, Elsevier Science B.V., pp 415–462, 1997, with permission from Elsevier.)

The *flat-shaped* loops (F1, F2) are obtained by transverse field annealing, that is, by inducing a uniaxial anisotropy perpendicular to the ribbon axis. The magnetization process is determined by rotation of the magnetization vectors from the easy direction toward the ribbon axis. This results in a permeability, μ, practically constant up to ferromagnetic saturation which by

$$\mu = \frac{J_s^2}{2\mu_0 K_u} \tag{19}$$

is directly related to the induced anisotropy energy constant, K_u.

The *rectangular* loop (Z) results after longitudinal field annealing. The uniaxial anisotropy is parallel to the ribbon axis and, thus, the magnetization process is dominated by

180° domain wall displacements. Highest maximum permeabilities can be achieved this way. Since the domain wall energy is proportional to the square root of K_u, low induced anisotropies in this case facilitate domain refinement which results in good dynamic properties like reduced anomalous eddy current losses (cf. Petzold, 2002; Flohrer *et al*., 2006).

The *round* loop (R) results after conventional annealing without magnetic field. The magnetization process is a mixture of magnetization rotation and domain wall displacements. Characteristic features of the round loop are a high initial and high maximum permeability. Still, annealing without magnetic field does not mean that there are no induced anisotropies. The latter are always induced along the local direction of the spontaneous magnetization within a ferromagnetic domain as long as the annealing temperature is lower than Curie temperature. One should therefore more precisely speak of *magnetization-induced* instead of *field-induced* anisotropies. A magnetic field during annealing just aligns the magnetization which leads to a uniform anisotropy. Correspondingly, zero field annealing yields a distribution of uniaxial anisotropies reflecting the domain structure during the heat treatment. The remanence to saturation ratio of around 50%, typical for randomly oriented uniaxial anisotropies, indicates that these randomly induced anisotropies are fluctuating on a scale larger than the exchange length and, hence, control the soft magnetic properties at small grain sizes. These induced anisotropy fluctuations can be reduced by rotating field annealing which results in a significantly reduced coercivity and an enhanced remanence (Ito and Suzuki, 2005). Similarly, the field annealed samples typically reveal a smaller coercivity than the samples annealed without field which can be understood from the simpler domain configuration due to the more homogeneously induced anisotropy. Correspondingly, proper transverse field annealing allows higher initial permeabilities than obtained by the conventional heat treatment without a magnetic field.

The almost perfectly rectangular- or flat-shaped hysteresis loops after field annealing indicate that the field-induced anisotropy clearly dominates over the residual contributions from magnetocrystalline and magnetoelastic anisotropies. Still, the induced anisotropy constant, K_u, can be tailored small enough in order to achieve highest permeabilities (e.g., $K_u \approx 6\,\mathrm{J\,m^{-3}}$ and $\mu \approx 100\,000$ as for the F1 loop shown in Figure 21). Figure 22 summarizes the dependence of K_u on the annealing condition and on the alloy composition for nanocrystalline Fe–Cu–Nb–Si–B alloys annealed in a transverse magnetic field.

If the material is nanocrystallized first without applied field and subsequently field annealed at lower temperatures, the resulting induced anisotropy depends on the field annealing temperature, T_a, and the annealing time, t_a, but less sensitively than, for example, in amorphous alloys (cf. Yoshizawa and Yamauchi, 1990). The dependence of K_u on the annealing conditions (cf. Figure 22a) allows to tailor hysteresis loops with different levels of permeability as exemplified by the F1 and F2 loops shown in Figure 21. Linear, low remanence hysteresis loops with highest permeabilities up to $\mu \approx 200 \times 10^3$ ($K_u \approx 3\,\mathrm{J\,m^{-3}}$) can be achieved in this manner. Only if the induced anisotropies fall below about $K_u \approx 2\text{–}4\,\mathrm{J\,m^{-3}}$ the random magnetocrystalline anisotropies start dominating again which is indicated by nonlinear hysteresis loops with high remanence (Herzer, 2005b). In comparison, amorphous Co-based alloys still show a low remanence and a linear hysteresis loop for induced anisotropies of $K_u \approx 0.5\,\mathrm{J\,m^{-3}}$ and even smaller values because of their virtually negligible magnetocrystalline anisotropy.

If the field annealing is performed during nanocrystallization, the induced anisotropy reaches a maximum value which is relatively insensitive to the precise annealing conditions and, thus, corresponds to the equilibrium value characteristic for the alloy composition (Herzer, 1994a). As shown in

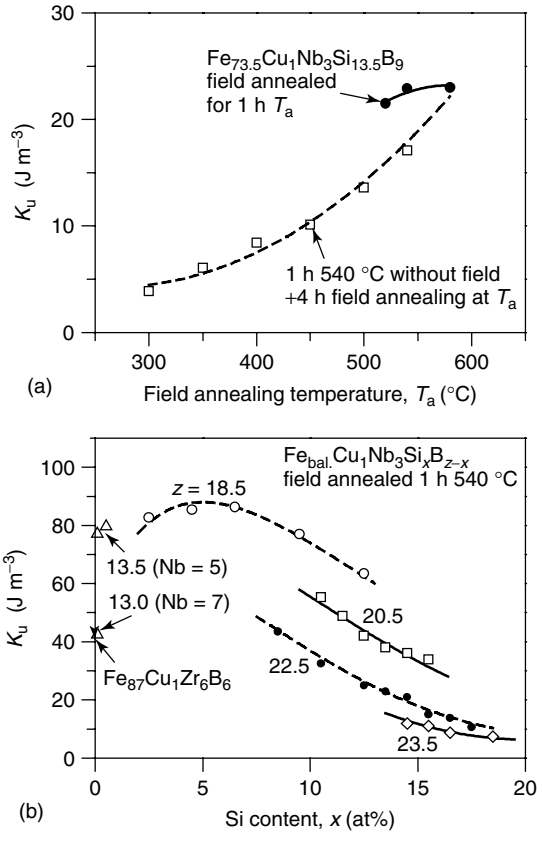

Figure 22. Field-induced anisotropy, K_u, in nanocrystalline Fe–Cu–Nb–Si–B alloys: (a) Influence of the annealing conditions and (b) role of the composition in the nanocrystalline state. (Reprinted from *Handbook of Magnetic Materials*, Vol 10, Buschow, K.H.J., Nanocrystalline Soft Magnetic Alloys, Elsevier Science B.V., pp 415–462, 1997, with permission from Elsevier.)

Figure 22(b), the induced anisotropy energy decreases with increasing metalloid contents and, in particular, with increasing Si/(Si + B) ratio. Accordingly, the lowest anisotropy energies and, thus, the highest permeabilities are found for the high Si-content alloys. The effect of the copper and niobium concentration on K_u is only minor as long as both elements are chosen such that a homogeneous nanocrystalline structure is formed. However, the influence of niobium or other refractory elements on K_u can become significant for alloy compositions with very low silicon and correspondingly high boron contents. Such compositions tend to reveal traces of boride compounds which may significantly contribute to K_u. The latter is supported by the decrease of K_u upon reducing the boron content and increasing the Nb or Zr content which suppresses the formation of such compounds.

The anisotropy induced by a magnetic field applied during nanocrystallization primarily originates from the bcc grains (Herzer, 1994a) and can be understood from the directional ordering of Si-atom pairs (cf. Sixtus, 1970). In particular, the decrease of K_u with increasing Si content is related to the simultaneously increasing long-range order (DO_3 superlattice structure) of the bcc grains. Thus, the necessary degrees of freedom for an induced directional ordering are reduced as the composition of the grains approaches completely ordered Fe_3Si where the lattice sites for the Fe and Si atoms are entirely determined by chemical interactions (cf. Néel, 1954). This mechanism is the key factor that nanocrystalline Fe–Cu–Nb–Si–B alloys exhibit lowest induced anisotropies and, hence, highest permeability despite of their high saturation magnetization.

The mechanisms of anisotropy formation also determine the thermal aging of the soft magnetic properties. Thus, thermal aging can be basically understood as the formation or reorientation of induced anisotropies along the local magnetization directions at application temperatures. The reduced degrees of freedom for anisotropy formation due to the superlattice structure and the high Curie temperature allow to stabilize low anisotropies, that is, high permeabilities, at annealing temperatures much higher than it is possible for amorphous alloys or permalloys. This essentially reduces the kinetics for anisotropy changes at application temperatures. In comparison with amorphous metals, the thermal stability is additionally improved by the more stable crystalline structure. As a consequence, nanocrystalline alloys exhibit an excellent thermal stability of their soft magnetic properties surpassing by far that of amorphous alloys and even that of permalloys (Herzer, 1997). This allows higher continuous service temperatures up to 150 °C.

The tremendous practical impact of field-induced anisotropies is evident. Their understanding is ultimately the key for the reproducible control of the soft magnetic properties. By appropriate choice of alloy composition and annealing conditions, transverse field annealing of nanocrystalline Fe–Cu–Nb–Si–B alloys, thus, allows to induce anisotropies in the range of $K_u \approx 3$–$100\,\mathrm{J\,m^{-3}}$. This corresponds to initial permeabilities of about $\mu_i \approx 10^4$–2×10^5 which perfectly covers the need of applications like common mode chokes or earth leakage circuit breakers (Petzold, 2002). More recent investigations try to expand the property spectrum of nanocrystalline alloys toward lower permeabilities in the order of several hundreds to several thousands as they are useful, for example, for energy storage chokes or current transformers. This can be achieved by adding Co and/or Ni, which like in amorphous metals (cf. Fujimori, 1983), significantly enhances the field-induced anisotropy due to pair ordering of Fe and Co or Ni atoms. Yoshizawa *et al*. (2003), for example, showed that the field-induced anisotropy in nanocrystalline $Fe_{78.8-x}Co_xCu_{0.6}Nb_{2.6}Si_9B_9$ ($x = 0$ to 78.8) is enhanced from $\sim 100\,\mathrm{J\,m^{-3}}$ at $x = 0$ to $\sim 600\,\mathrm{J\,m^{-3}}$ at $x = 50$. Ni has a similar effect on K_u like Co, but the coercivity increases drastically for Ni concentrations above about 10–15 at%. Yet, with the combined addition of Co and Ni like in $Fe_{66.8-x}Co_xNi_{10}Cu_{0.8}Nb_{2.9}Si_{11.5}B_8$ (Herzer and Otte, 2004), one can obtain similarly high field–induced anisotropies but with only about half the amount of Co, that is, at lower raw material cost. In any case, the drawback of increasing the field-induced anisotropy either by reduction of the metalloid contents (cf. Figure 11) or by adding Co and/or Ni is a disadvantageous increase of saturation magnetostriction. Müller *et al*. (1996), for example, showed that the saturation magnetostriction of nanocrystalline $Fe_{73.5-x}Co_xCu_1Nb_3Si_{15.5}B_7$ and $Fe_{86-y}Co_yZr_7B_6Cu_1$ alloys increases from near zero to maximum values of about $\lambda_s \approx 20$ ppm (for $x = 30$ at%) and $\lambda_s \approx 40$ ppm (for $y = 60$ at%), respectively, when substantial amounts of Co are added.

4.3.2 Creep-induced anisotropies

Annealing under tensile stress causes an anelastic or plastic deformation of the material and, as a consequence, an easy or hard magnetic axis along the stress axis. The basic characteristics of this creep-induced anisotropy in Fe–Cu–Nb–Si–B alloys (Kraus *et al*., 1992; Herzer, 1994b; Hofmann and Kronmüller, 1996) are essentially the same as they are well known from amorphous alloys.

Figure 23 shows some typical hysteresis loops after crystallization under tensile stress. The creep-induced anisotropy constant is proportional to the tensile stress σ_a applied during annealing, that is,

$$K_u = -\tfrac{3}{2} k \sigma_a \qquad (20)$$

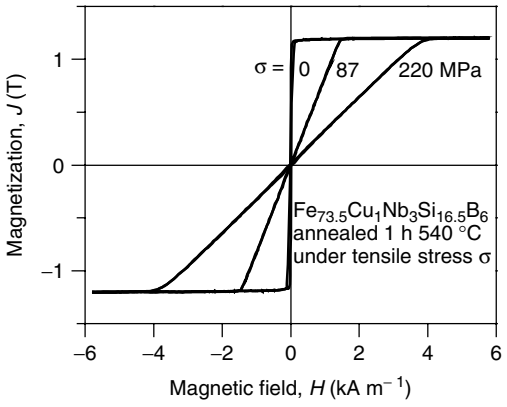

Figure 23. Dc-hysteresis loops of $Fe_{73.5}Cu_1Nb_3Si_{16.5}B_6$ nanocrystallized by annealing for 1 h at 540 °C under tensile stress σ. (Reproduced by permission of IEEE, Creep Induced Magnetic Anisotropy in Nanocrystalline Fe–Cu–Nb–Si–B Alloys, G. Herzer (1994) © 1994 IEEE.)

The anisotropy parameter k is a dimensionless proportionality constant being introduced in formal analogy to the magnetostriction constant in equation (17). By definition $k > 0$ denotes a magnetic easy axis parallel to the stress axis while $k < 0$ denotes a magnetic hard axis, that is, an easy plane perpendicular to the stress axis.

Figure 24 depicts the variation of the creep-induced anisotropy with the annealing temperature, T_a and the composition (Herzer, 1994b). The decrease of k for $T_a \geq 480\,^{\circ}C$ coincides with the transformation from the amorphous to the nanocrystalline state which is completed for $T_a \geq 500\,^{\circ}C$. The creep-induced anisotropy in the amorphous state is comparable to that typically observed in other amorphous alloy systems. However, upon devitrification, its absolute value significantly increases. Within the range where the nanocrystalline state is formed, the anisotropy induced during crystallization is fairly insensitive to the annealing time and temperature and, thus, corresponds to an equilibrium value mainly determined by the Si concentration. In particular, the magnetic hard ribbon axis ($k < 0$) observed for high Si contents turns over to an easy ribbon axis ($k > 0$) for alloys with Si concentrations below about 10 at%. An anisotropy of similar order of magnitude can also be induced in samples previously crystallized without stress. However, in this case the induced anisotropy is more sensitive to the annealing temperature since the kinetics of anisotropy formation is considerably slower (cf. Hofmann and Kronmüller, 1996).

The comparison of Figures 20 and 24 reveals that the variation with annealing temperature or alloy composition, in a way, is similar for both the creep-induced anisotropy parameter, k, and the saturation magnetostriction, λ_s, respectively. However, there are also significant differences. In particular, both quantities pass through zero at different Si concentrations. As a consequence, a strong creep-induced

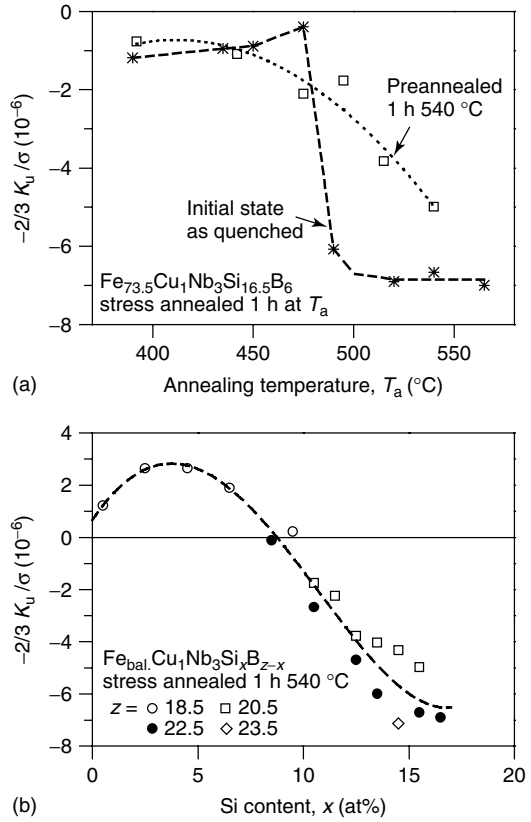

Figure 24. Creep-induced anisotropy parameter, $k = -2/3 \cdot K_u/\sigma$, of Fe–Cu–Nb–Si–B alloys: (a) Influence of the annealing conditions and (b) role of the composition in the nanocrystalline state. (Reprinted from *Handbook of Magnetic Materials*, Vol 10, Buschow, K.H.J., Nanocrystalline Soft Magnetic Alloys, Elsevier Science B.V., pp 415–462, 1997, with permission from Elsevier.)

anisotropy is found for the near-zero magnetostrictive compositions. It appears that the equilibrium value of the anisotropy parameter k differs from the saturation magnetostriction λ_s only by the lack of the positive contribution from the amorphous matrix. A closer analysis of the experimental data indeed confirms that the normalized anisotropy parameter k/x_{cr} (x_{cr} is the crystalline volume) approximately equals to the local saturation magnetostriction constant, λ_s^{FeSi}, of the bcc-FeSi grains (Herzer, 1994b). This suggests that the creep-induced anisotropy in the nanocrystalline state mainly originates from the local magnetoelastic anisotropy of the bcc grains due to an elongation induced by the stress annealing. The mechanism was confirmed by Ohnuma *et al.* (2003a,b) who directly showed by means of transmission X-ray diffractometry that the lattice spacing of the Fe(Si) nanocrystallites is elongated along the stress direction after the stress annealing. The amorphous matrix itself gives only a minor contribution to the anisotropy energy. This can be understood from (i) the comparably low magnitude of the creep-induced magnetic anisotropy generally observed in amorphous alloys

which (ii) in the nanocrystalline state is still weighted by the relatively small volume fraction of the amorphous matrix.

Creep-induced anisotropies, in principal, allow to tailor linear hysteresis loops by annealing under controlled tensile stress. The advantage over field annealed Co-doped alloys is that one can combine low magnetostriction and high anisotropies. Alves *et al*. (2002, 2005), for example, have prepared toroidally wound cores of near-zero magnetostrictive nanocrystalline $Fe_{74.5}Cu_1Nb_3Si_{15.5}B_6$ with induced anisotropies up to about $K_u \approx 2000\,J\,m^{-3}$ (i.e., $\mu \approx 300$) by (i) continuously annealing the material for a short time (10–60 s) at elevated temperatures around 650 °C under a tensile stress of 270 MPa and (ii) subsequently winding toroidal cores. However, the practical application of this technique is most challenging due to the severe embrittlement after nanocrystallization.

Yet, the practical impact of creep-induced anisotropy in nanocrystalline materials often is of more disturbative nature. For example, thin SiO_2 layers give rise to small tensile stresses during the anneal treatment which yield an unwanted creep-induced anisotropy perpendicular to the ribbon plane and, thus, a degradation of the soft magnetic properties even for zero-magnetostrictive compositions (cf. del Real, Prados, Conde and Hernando, 1994). This is a particular problem for the nanocrystalline material, since its creep-induced anisotropy is more than one order of magnitude larger than, for example, in near-zero magnetostrictive, amorphous Co-based alloys. The uncontrolled formation of such oxide layers contributes to the decrease of permeability toward high Si contents (cf. Figure 11) where both the creep-induced anisotropy and the driving force for the formation of a SiO_2 layer are particularly large.

5 CONCLUSIONS

The key to the soft magnetic properties of nanocrystalline alloys is that their structural correlation length is much smaller than the ferromagnetic exchange length. Thus, similar to the case of amorphous metals, the local magnetocrystalline anisotropies are randomly averaged out owing to the smoothing effect of exchange interaction. This averaging mechanism also applies to the fluctuations of magnetoelastic anisotropy associated with the local magnetostriction coefficients of the individual structural phases. The result is an isotropic magnetostrictive behavior characterized by a single magnetostriction coefficient λ_s which vanishes for particular compositions like nanocrystalline $Fe_{73.5}Cu_1Nb_3Si_{15.5}B_7$. For such optimized compositions, the contribution of magnetocrystalline and magnetoelastic anisotropies is ultimately negligible and the soft magnetic properties are largely determined by field-induced anisotropies which play a tremendously important role in tailoring the hysteresis loop according to the requirements of the application.

Lowest coercivities ($H_c \approx 0.5$–$1\,A\,m^{-1}$) and highest permeabilities ($\mu \approx 10^5$) are found around the originally proposed compositions, that is, $Fe_{\sim 74}Cu_1Nb_3Si_{13-16}B_{6-9}$ which are commercially available under the trade names FINEMET® (cf. Hitachi Metals Ltd, 1993) and VITROPERM® (cf. Vacuumschmelze GmbH, 1993). The soft magnetic properties are comparable with the excellent properties possessed by established materials such as permalloys or Co-based amorphous alloys. The advantages, however, are a higher saturation induction of about 1.2–1.3 T and a significantly better thermal stability of the soft magnetic properties allowing higher continuous service temperatures up to 150 °C. Similar to amorphous metals, the production inherent low thickness around 20 µm and a high electrical resistivity around 115 µΩcm minimize eddy current losses in nanocrystalline ribbons. Accordingly, the frequency dependence of permeability and the core losses of nanocrystalline Fe–Cu–Nb–Si–B alloys are comparable to those of amorphous Co-based alloys and surpass by far the properties of conventional materials, even that of ferrites, over the whole frequency range up to several 100 kHz. A corresponding comparison is given in Figure 25. The combination of high saturation magnetization and high permeability together with good high-frequency behavior, low losses, and the good thermal stability allows reductions in the size and weight of magnetic components used in, for example, switched mode power supplies or telecommunications.

Apart from its technical performance the material is based on the inexpensive raw materials iron and silicon. The

amorphous precursor material for the Fe–Cu–Nb–Si–B alloys, is furthermore easily accessible by rapid solidification from the melt – a well-established technique for large-scale production of amorphous metals.

The combination of the above factors has rendered the nanocrystalline solution competitive, not only with amorphous Co-based alloys but also with classical crystalline alloys and ferrites. The consequence is a steadily increasing level of applications in magnetic cores for ground fault interrupters, common mode chokes and high-frequency transformers. Figure 26 shows some typical examples. The worldwide production rate meanwhile approaches an estimated 1000 tons/year and with increasing trend. The only drawback of the nanocrystalline materials appears to be the embrittlement that occurs upon crystallization, which requires final shape annealing and, thus, restricts application mainly to toroidally wound cores.

The second family of near-zero magnetostrictive, nanocrystalline alloys based on $Fe_{\sim 84-91}(Cu_1)-(Zr,Nb)_{\sim 7}B_{2-9}$ appears even more interesting due to their still higher saturation magnetization up to 1.7 T. However, their application so far is limited to smaller quantities. One of the major reasons is that they require a much more sophisticated production technology due to their limited glass-forming ability and or the oxygen reactivity of the Zr addition.

APPENDIX

The objective of this appendix is to illustrate in some more detail how random anisotropies are averaged out. We start with a simple analytical model calculation and subsequently generalize the results to uniaxial and cubic anisotropies oriented randomly over all spherical angles.

The way how anisotropies are averaged can be illustrated by a simplified planar model where we assume that the magnetization vector and the anisotropy axes are lying in a plane. In order to keep the model three dimensional, we still allow the in-plane anisotropy axes to fluctuate along the coordinate perpendicular to the plane. This simple approach may be physically justified for a typical ribbon shaped sample where the large out-of-plane demagnetizing factor forces the magnetization mainly into the ribbon plane. Accordingly, the local anisotropy energy density of an individual grain is assumed to be

$$\phi_{\mathrm{K}}^{(i)}(\theta) = K_1 \sin^2(\theta - \psi_i) \tag{A1}$$

The angle ψ_i denotes the orientation of the local easy axis and is randomly fluctuating from grain to grain. The angle θ describes the orientation of the magnetization which is assumed to be constant on a scale $L_{\mathrm{ex}} > D$. Further model assumptions are that each grain has the same size D and the same local anisotropy constant K_1. The average anisotropy energy density over the volume $V_{\mathrm{ex}} = L_{\mathrm{ex}}^3$ can then be evaluated as

$$\begin{aligned}\overline{\phi}_{\mathrm{K}}(\theta) &= \frac{1}{V_{\mathrm{ex}}} \int_{V_{\mathrm{ex}}} K_1 \sin^2(\theta - \psi(\underline{x}))\, \mathrm{d}^3x \\ &= K_1 \frac{1}{N} \sum_{i=1}^{N} \sin^2(\theta - \psi_i) \\ &= k_N \sin^2(\theta - \Psi_N) \\ &\quad + \frac{K_1 - k_N}{2}\end{aligned} \tag{A2}$$

with

$$k_N = K_1 \cdot \sqrt{\frac{1}{N} + \frac{1}{N^2} \sum_i \sum_{j(\neq i)} \cos\left(2(\psi_i - \psi_j)\right)} \qquad \text{(A3)}$$

In the last step of equation (A2), the sum over the $N = (L_{ex}/D)^3$ coupled grains has hereby been rewritten as one anisotropy expression with magnitude k_N and orientation Ψ_N using trigonometric relations. The calculation is illustrated in Figure A1.

If we look at a statistical ensemble with independent sets of each N coupled grains, both Ψ_N and k_N are still random numbers. In a more physical picture this means that the easiest orientation Ψ_N of N coupled grains is randomly fluctuating on the scale of L_{ex} from one exchange-coupled region to the neighboring one. Similarly the anisotropy constants k_N are fluctuating around an average value

$$\langle k_N \rangle = \frac{\beta K_1}{\sqrt{N}} \qquad \text{(A4)}$$

with a standard deviation

$$\sigma_K := \sqrt{\langle k_N^2 \rangle - \langle k_N \rangle^2} = \eta \cdot \langle k_N \rangle \qquad \text{(A5)}$$

The fluctuations arise from the second expression under the square root in equation (A3), that is, from the sum over all anisotropy cross terms between grains at different sites. Their relative orientation $(\psi_i - \psi_j)$ is a *random phase* and the individual anisotropy cross terms therefore largely cancel. The parameters β and η involve higher order angular moments like $\langle \cos^{2n}(\psi_i - \psi_j) \rangle$ originating from the anisotropy fluctuations within the ensemble. Numerical simulations yield $\beta \approx 0.90_{\pm 0.04}$ and $\eta \approx 0.50_{\pm 0.05}$ for an ensemble with 2000 statistical independent sets of each $N(= 2 - 2^{19})$ grains. The simulations show that the results apply already for an ensemble with statistically independent sets of only two coupled grains.

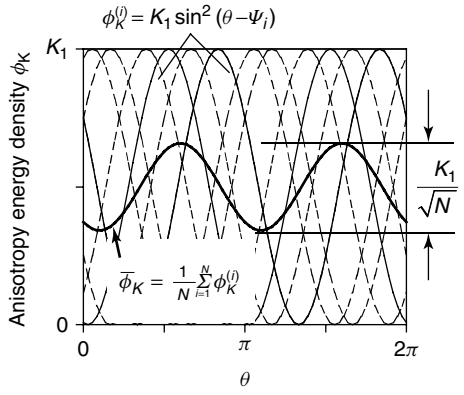

Figure A1. Local and randomly averaged anisotropy density ϕ_K as a function of the magnetization direction θ.

While the angular dependence of the anisotropy expressions given in equations (A1–A3) is specific to the above model, numerical simulations show that the relations for the ensemble averages, that is, equations (A4) and (A5), also apply very well for uniaxial or cubic anisotropies oriented randomly over all spherical angles. If the average anisotropy constant $\langle k_N \rangle$ in equation (A4) is understood as the difference between the maximum and minimum of the average anisotropy energy density, we accordingly find $\beta \approx 1.06_{\pm 0.03} (\eta \approx 0.31_{\pm 0.05})$ for uniaxial and $\beta \approx 0.393_{\pm 0.003} (\eta \approx 0.22_{\pm 0.03})$ for cubic anisotropies, respectively. The indicated errors arise from the finite ensemble size which was about 4000 statistical independent sets of N coupled grains. The rather distinct value of β for the *cubic* case is largely a consequence of common conventions for the anisotropy energy. The latter result in $\Delta\phi_K = |K_1|/3$ for cubic and $\Delta\phi_K = |K_1|$ for uniaxial anisotropies where $\Delta\phi_K = \phi_K^{max} - \phi_K^{min}$ is the difference of the anisotropy energy density between the hardest and easiest axis.

Figure A2 demonstrates that in the general case the energy surface of randomly oriented *coupled* grains no longer has the high symmetry exhibited by a pure uniaxial or cubic anisotropy. This is unlike our simplified model calculation, where the angular dependence is the same for the local and averaged anisotropy.

Random *uniaxial* anisotropies can be largely characterized analytically. The anisotropy energy density can be written as $\phi_K = \underline{m} \cdot \underline{\underline{K}}_1 \cdot \underline{m}$, where $\underline{\underline{K}}_1$ is a symmetric second rank tensor with zero trace and $\underline{m} = \underline{M}/M_s$ is the normalized magnetization vector. The average over the N coupled grains assumes the magnetization $\underline{m}$ to be constant and, hence, simply results in $\langle \phi_K \rangle_N = \underline{m} \cdot \underline{\underline{K}}_N \cdot \underline{m}$ with $\underline{\underline{K}}_N$ being still a symmetric second rank tensor with zero trace. The eigenvectors of the anisotropy tensors $\underline{\underline{K}}$ define the anisotropy axis and the eigenvalues the anisotropy constants. In a coordinate system defined by its eigenvectors, $\underline{\underline{K}}_N$ can always be represented as

$$\underline{\underline{K}}_N = k_N \cdot \begin{bmatrix} u & 0 & 0 \\ 0 & 1-2u & 0 \\ 0 & 0 & u-1 \end{bmatrix} \qquad \text{(A6)}$$

The coordinates have been hereby chosen such that the x axis is defined by the magnetic hardest and the z axis by the easiest axis. The anisotropy constant k_N denotes the energy difference between the hardest and easiest direction and, hence, is positive by definition. For a single grain we would simply have $k_1 = |K_1|$, while for N grains the ensemble average is given by $\langle k_N \rangle = \beta |K_1| / N^{1/2}$ with $\beta \approx 1.06$ as just discussed. The parameter u describes the symmetry and,

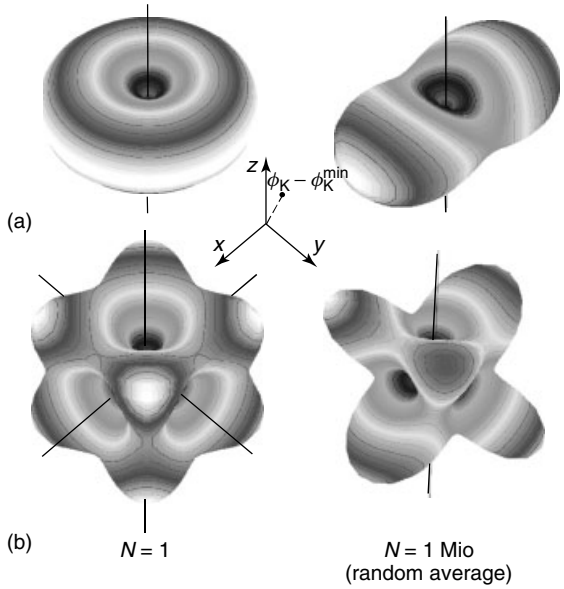

Figure A2. Energy surfaces for (a) uniaxial and (b) cubic anisotropies. The distance from the origin corresponds to the anisotropy energy difference $\phi_K - \phi_K^{min}$ for a certain orientation of the magnetization vector. The scale of each plot is different and adopted to the maximum energy difference. The thin black lines indicate the easiest magnetic axes.

with the above choice of the coordinate axis, is restricted to the range $1/3 \leq u \leq 2/3$. The boundaries $u = 1/3$ and $u = 2/3$ correspond to a magnetic easy axis with a hard plane and a magnetic hard axis with an easy plane, respectively. In the more traditional notation, this distinction is made by the sign of K_1, where $K_1 > 0$ corresponds to $u = 1/3$. However for N coupled grains, we find from our numerical simulations that u is distributed around an average value given by $\langle u \rangle \approx 0.50$ with a standard deviation of $\sigma_u \approx 0.07$, no matter if we start from an easy ($u = 1/3$) or a hard axis ($u = 2/3$). As illustrated in Figure A2 we thus deal with three preferred axes, perpendicular to each other, corresponding to a minimum, a saddle point and a maximum of the anisotropy energy.

For *cubic* anisotropies the corresponding arguments would involve the more complicated analysis of a fourth rank tensor which still has to be done. We can therefore only discuss the still somewhat preliminary numerical results. For one single *cubic* grain we have three easy axes along the $\langle 100 \rangle$ directions and four hard axes along the $\langle 111 \rangle$ directions for $K_1 > 0$ and vice versa for $K_1 < 0$. However, this distinction gets lost for randomly oriented grains. A random energy surface produced by a set of N grains with $K_1 > 0$ can always be reproduced by another set of N grains with $K_1 < 0$. The random average, thus, again breaks the high original symmetry and ultimately results in only one easiest axis and one hardest axis forming an average angle of about 50° with each other. Yet, there are a number of intermediate easy and hard directions which still remind one of the original cubic symmetry. These various easy axes typically form an angle of about $80–90^\circ$ with each other and their energies are relatively close together, differing only by about 10–20%.

Soft Magnetic Bulk Glassy and Bulk Nanocrystalline Alloys

1 INTRODUCTION

Since the first synthesis of a ferromagnetic amorphous alloy was achieved in a vacuum deposited Co–Au system in 1965 (Mader and Nowick, 1965), a large number of Fe- and Co-based ferromagnetic amorphous alloys have been developed in the order of Fe–P–C (Duwez and Lin, 1967), Fe–P–B (Yamauchi and Nakagawa, 1971), (Fe, Co, Ni)–P–B (Hasegawa, 1972), (Fe, Co)–P–B–Al (Sherwood *et al*., 1975), (Fe, Co, Ni)–B–Si (Masumoto, Kimura, Inoue and Waseda, 1976), (Fe, Co, Ni)–B (O'Handley, Hasegawa, Ray and Chou, 1976), (Fe, Co, Ni)–(Cr, Mo, W)–C (Inoue, Masumoto, Arakawa and Iwadachi, 1978), (Fe, Co, Ni)–Zr (Nose and Masumoto, 1980), (Fe, Co, Ni)–Hf (Inoue, Kobayashi and Masumoto, 1980a), and (Fe, Co, Ni)–(Zr, Hf, Nb)–B (Inoue, Kobayashi, Nose and Masumoto, 1980b) systems. Furthermore, good soft magnetic properties have been reported simultaneously by three different research groups for Fe–P–C (Chen, 1974; Fujimori, Masumoto, Obi and Kikuchi, 1974), Fe–P–B (Egami, Flanders and Graham, 1975), and (Co, Fe)–B–Si (Kikuchi, Fujimori, Obi and Masumoto, 1975) systems between 1974 and 1975. The (Fe, Co)–P–B and (Fe, Co)–B–Si amorphous alloys have been used as soft magnetic materials named *METGLAS*. Subsequently, there had been no data on the synthesis of new soft magnetic amorphous alloys for almost 15 years between 1981 and 1995, though Fe–B–Si–Nb–Cu (FINEMET) (Yoshizawa, Oguma and Yamauchi, 1988), Fe–Zr–B (Suzuki *et al*., 1990), and Fe–M–B (M = Zr, Hf, Nb) (NANOPERM) (Makino, Inoue and Masumoto, 1995) nanocrystalline alloys were developed as a new type of soft magnetic material. It is well known that the Fe- and Co-based amorphous alloys described previously required a high cooling rate above $10^5\,\mathrm{K\,s^{-1}}$ and the resultant melt-spun alloys have been limited to a small thickness range less than about 50 μm (Chen, 1980; Masumoto, 1982; Liebermann, 1993). If we can find a new Fe- or Co-based soft magnetic alloy with much higher glass-forming ability (GFA), the resultant bulk amorphous alloys are expected to extend their field of application as soft magnetic materials. Since 1995, a new class of Fe- and Co-based glassy alloys with a supercooled liquid region beyond 50 K before crystallization and a high GFA have been found, and bulk glassy alloys (BGAs) have been synthesized in a thickness range of up to 6 mm by the copper mold casting method (Inoue, Zhang, Itoi and Takeuchi, 1997a; Inoue, Zhang and Takeuchi, 1998c; Inoue, 2000).

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

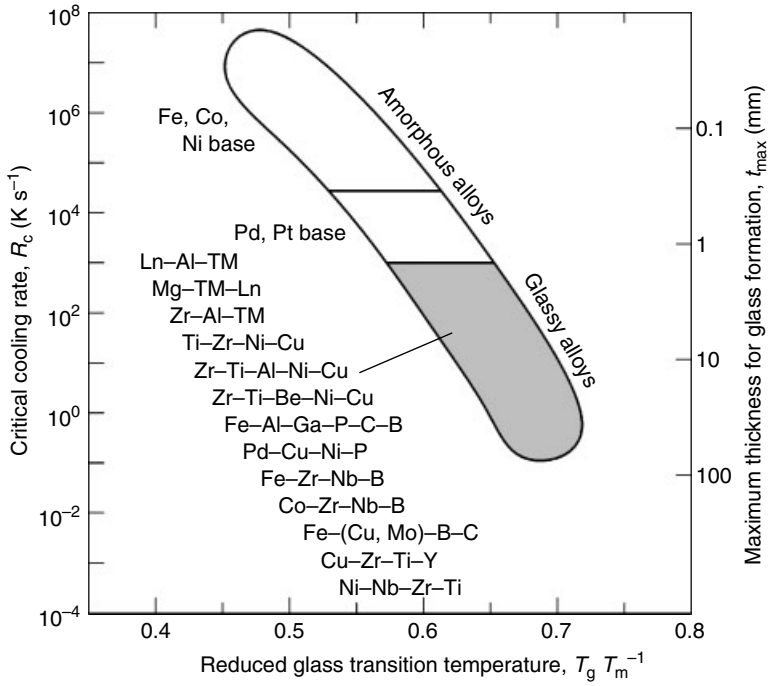

Figure 1. Relationship between critical cooling rate (R_c) for glass formation, maximum sample thickness (t_{max}) for glass formation, and reduced glass transition temperature ($T_gT_m^{-1}$; T_g and T_m are glass transition and melting temperatures, respectively) for bulk glassy alloys. The data for ordinary amorphous alloys, which require high cooling rate for glass formation, are also shown for comparison. Ln: lanthanide metal; TM: VI–VIII group transition metal.

Figure 1 shows the relationship between the critical cooling rate (R_c), the maximum sample thickness (t_{max}) for glass formation, and the reduced glass transition temperature ($T_gT_m^{-1}$; here, T_g and T_m are the glass transition and the melting temperatures, respectively) for amorphous and glassy alloys reported to date (Inoue, 1995, 1997, 1998; Inoue, Takeuchi and Zhang, 1998b,c). The lowest R_c is as low as $0.10\,K\,s^{-1}$ (Inoue and Nishiyama, 1997) for the $Pd_{40}Cu_{30}Ni_{10}P_{20}$ alloy and t_{max} reaches a value as large as approximately 100 mm. It is also noticed that the recent improvement of GFA reaches 6–7 orders for R_c and 3–4 orders for t_{max}. There is a clear tendency for GFA to increase with increasing $T_gT_m^{-1}$. Figure 2 shows the relationship between R_c, t_{max}, and the temperature interval of a supercooled liquid (ΔT_x) defined by the difference between T_g and the crystallization temperature (T_x) (Inoue, 1995, 1997, 1998; Inoue, Takeuchi and Zhang, 1998b,c). One can see a clear tendency for GFA to increase with increasing ΔT_x. The value of ΔT_x exceeds 100 K for several glassy alloys in Zr–Al–Ni–Cu(–Pd) and Pd–Cu–Ni–P systems.

It is generally known that a variety of BGAs have been synthesized using various solidification methods such as water quenching, copper mold casting, high-pressure die casting, and so on, for the past 17 years since 1988. Table 1 summarizes typical BGA systems and the calendar years when their alloy systems were reported. The alloy components can be classified into nonferrous and ferrous alloy systems. When we look at the features of the alloy components in more detail, they can be classified into five groups as summarized in Figure 3. The first group consists of early transition metals (ETMs: IV–VI group transition metals in the periodic table) or lanthanide metals (Ln), Al, and late transition metals (LTMs: VIII group transition metals) as exemplified by Zr–Al–(Ni, Cu) (Inoue, Zhang and Masumoto, 1990) and Ln–Al–(Ni, Cu) (Inoue, Zhang and Masumoto, 1989) systems. The second group is composed of LTMs, ETMs, and metalloids that are typical for Fe–(Zr, Hf, Nb)–B (Inoue, Koshiba, Zhang and Makino,1998a) and Co–(Zr, Hf, Nb, Ta)–B (Itoi and Inoue, 1998) systems. The third group is exemplified by the Fe–(Al, Ga)–metalloid system (Inoue and Gook, 1995) and the fourth group is expressed by Mg–Ln–LTM (Inoue, Ohtera, Kita and Masumoto, 1988) and ETM–Be–LTM (Peker and Johnson, 1993) systems. However, the Pd–Cu–Ni–P (Inoue, Nishiyama and Matsuda, 1996a) and Pd–Ni–P (Drehman and Greer, 1984) systems (group V) are composed of only two kinds of group elements (LTMs and metalloids), and hence are different from the alloys belonging to the four previous groups, which are made up of a combination of three types of group elements. All the alloys belonging to groups

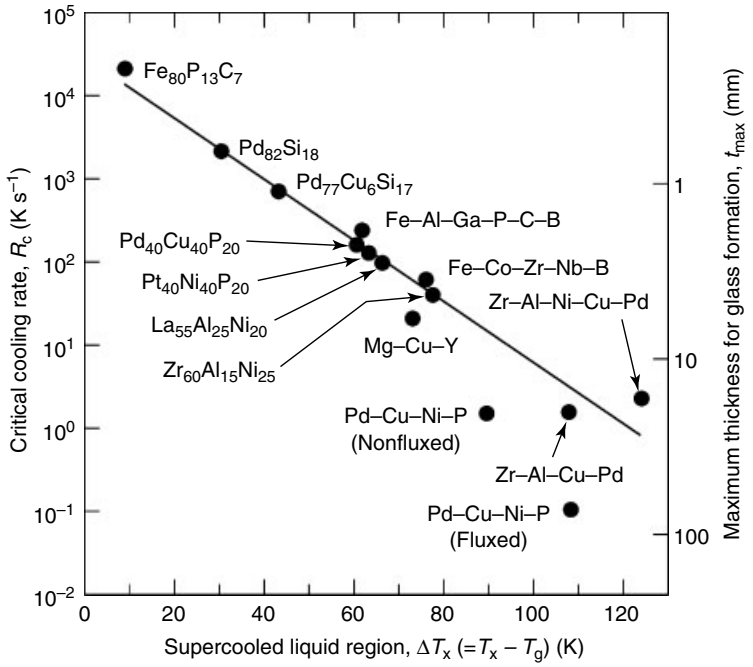

Figure 2. Relationship between critical cooling rate (R_c) for glass formation, maximum sample thickness (t_{max}) for glass formation, and temperature interval of supercooled liquid region ($\Delta T_x = T_x - T_g$; T_x and T_g are crystallization and glass transition temperatures, respectively) for bulk glassy and ordinary amorphous alloys.

Table 1. Bulk glassy alloy systems and calendar years when details about each alloy system were first published.

Nonferrous alloy systems	Years	Ferrous alloy systems	Years

Cu–(Zr, Hf)–Ti	2001		
Cu–(Zr, Hf)–Ti–(Y, Be)	2001		

I–IV have three simple rules of alloy formation which can be stated as (i) multicomponent – consisting of three or more elements, (ii) significant atomic size mismatch of 12% or more, and (iii) negative heats of mixing (Inoue, 1995, 2000; Inoue, Zhang and Takeuchi, 1997b). It has subsequently been reported that the alloys with the three empirical rules can have a new structure that has the following features: a higher degree of dense random packed atomic configurations, new local atomic configurations, and long-range homogeneity with attractive interactions as summarized in Figure 4 (Inoue, 1995, 2000; Inoue, Zhang and Takeuchi, 1997b). It is also summarized that the multicomponent alloys with such a new structure can suppress the nucleation reaction of a crystalline phase and have difficulty of atomic rearrangements leading to the suppression of the growth reaction of a crystalline phase, as shown in Table 2.

2 ALLOY SYSTEMS AND STRUCTURE

Table 3 shows examples of the soft magnetic BGAs and their properties. The soft magnetic BGA systems are also classified into five groups as exemplified by (i) Fe–(Al, Ga)–metalloid (Inoue and Gook, 1995), Fe–(Cr, Mo)–Ga–metalloid (Shen and Schwarz, 1999), and Fe–Ga–metalloid (Shen, Koshiba, Mizushima and Inoue, 2000b); (ii) (Fe, Co)–(Zr, Hf, Nb, Ta)–B (Inoue, Koshiba, Zhang and Makino, 1998a; Itoi and Inoue, 2000); (iii) (Fe, Co)–Ln–B (Inoue and Zhang, 1999); (iv) Fe–(Cr, Mo, W)–C–B (Pang, Zhang, Asami and Inoue, 2001); and (v) (Fe, Co)–B–Si–(Zr, Nb) (Inoue and Shen, 2002; Inoue, Shen and Chang, 2004) systems.

As the most important alloy systems in which Fe-based BGAs are obtained, one can list the Fe–M–B (M = Zr, Hf, Nb, Ta) and Fe–Co–Ln–B systems. Atomic configurations in these alloy systems were examined using anomalous and ordinary X-ray scattering techniques (Imafuku *et al*., 1999, 2000; Matsubara *et al*., 2000), in comparison with ordinary Fe–Cr–B and Fe–Co–B amorphous alloys, which require a high cooling rate above $10^5\,\mathrm{K\,s^{-1}}$ for glass formation. On the basis of the radial distribution function data, the atomic distance and coordination numbers of each constituent atomic pair are summarized for Fe–(Zr or Nb)–B and Fe–Co–Ln–B glassy alloys in Tables 4 and 5, respectively. On the basis of the data generated by the structural analysis, local atomic configuration models of the Fe-based glassy alloys are shown in Figure 5. The construction of a network of atomic configurations consisting of triangle prisms, which are connected with each other through glue atoms comprising Zr, Nb, or a lanthanide metal, is a feature of this type of glassy alloys. Such a linkage structure is an important factor for stabilization of the supercooled liquid in the Fe–M–B type glassy alloys. The crystallization behavior of the Fe–Nb–B (Imafuku *et al*., 1999) and Fe–Co–Ln–B

(Inoue and Zhang, 1999) glassy alloys was also examined. It has been recognized that the primary crystalline phase is a metastable complex fcc $(Fe, Nb)_{23}B_6$ phase with a large lattice parameter of 1.1 nm and a unit volume consisting of 96 atoms and including icosahedral clusters. As is evident from the distinct difference in the atomic configurations between the glassy phase and the primary crystalline phase, the necessity of long-range atomic configurations to construct the primary crystalline phase with a large unit volume from the glassy phase causes retardation of the crystallization reaction. This mechanism is concluded to be one of the reasons for the stability of the supercooled liquid and the formation of BGAs.

3 THERMAL STABILITY AND SOFT MAGNETIC PROPERTIES

When the ferrous alloys summarized in Table 1 are chosen, one can detect a large supercooled liquid region beyond 50 K before crystallization on the differential scanning calorimetry (DSC) curve. In the case of Fe–Al–Ga–P–C–B system, BGAs in a cylindrical rod form are produced in the diameter range of up to 2.5 mm by the copper mold casting method (Inoue, 1997). It has also been confirmed that there is no distinct difference in T_g, ΔT_x, and crystallization behavior among the BGA cylinders with different diameters ranging from 0.5 to 2.5 mm. Figure 6 shows the outer morphology and the surface appearance of the cast Fe–Al–Ga–P–C–B bulk glassy cylinders (Inoue, Shinohara and Gook, 1995). The BGAs possess good soft magnetic properties combined with a rather large saturation magnetization (I_s) of 1.23 T. It has been confirmed that the coercivity (H_c) is less than $5\,A\,m^{-1}$ in an optimum annealed state. The use of the $Fe_{70}Al_5Ga_2P_{9.65}C_{5.75}B_{4.6}Si_3$ alloy enables us to produce a

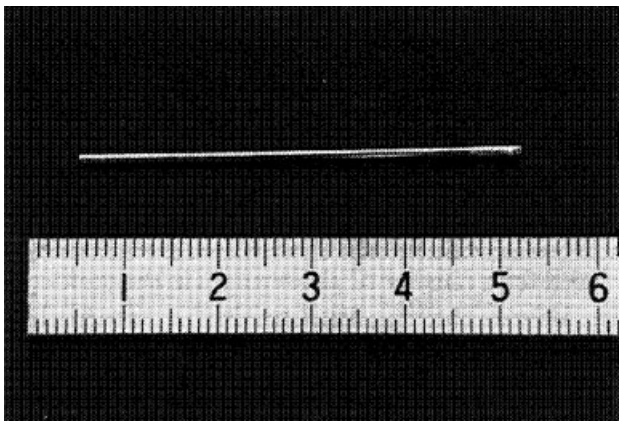

Figure 6. Outer morphology and surface appearance of a cast $Fe_{73}Al_5Ga_2P_{11}C_5B_4$ glassy alloy cylinder with a diameter of 1 mm.

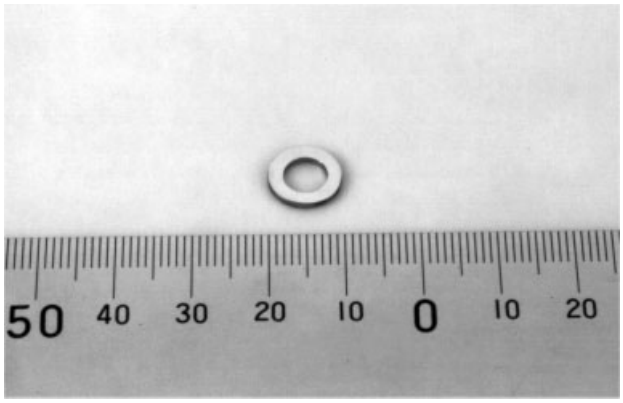

Figure 7. Outer morphology and surface appearance of a cast $Fe_{70}Al_5Ga_2P_{9.65}C_{5.75}B_{4.6}Si_3$ glassy alloy ring with a thickness of 1 mm, an outer diameter of 10 mm, and an inner diameter of 6 mm.

ring-shaped glassy alloy with a thickness of 1 mm, an outer diameter of 10 mm, and an inner diameter of 6 mm, as shown in Figure 7 (Mizushima, Ikarashi, Makino and Inoue, 1999a). The ring-shaped alloy shows the same DSC curve as that for the melt-spun glassy sheet with a thickness of 20 μm. The magnetization curves also show that the ring-shaped alloy has an I_s of 1.2 T, which is the same as that for the melt-spun sheet. Very interestingly, H_c and maximum permeability (μ_m) of the ring-shaped alloy are $2.2\,A\,m^{-1}$ and 110×10^3, respectively, which are far superior to those for the same ring-shaped sample ($3.7\,A\,m^{-1}$ and 27×10^3, respectively) made from the melt-spun glassy sheet, as shown in their $B-H$ hysteresis curves in Figure 8. Such a significant enhancement of the soft magnetic properties of the cast ring–shaped sample is presumably due to the formation of a well-arranged domain structure along the circumference. It has more recently been reported that the use of $Fe_{65}Co_{10}Ga_5P_{12}C_4B_4$ alloy without Al leads to an increase in I_s in a cast cylindrical rod form with a diameter up to 2 mm (Shen, Kimura, Inoue and Mizushima, 2000a; Shen, Koshiba, Mizushima and Inoue, 2000b).

A similar large supercooled liquid region beyond 60 K was found to be obtained in a wide composition range of 0–53 atom % of Co and 0–28 atom % of Ni in a completely different alloy system of $(Fe, Co, Ni)_{70}Zr_{10}B_{20}$ (Inoue, Zhang, Itoi and Takeuchi, 1997a). This glassy alloy system also shows good soft magnetic properties as is evident from high permeability, more than 20×10^3 at 1 kHz, and small saturation magnetostriction constant (λ_s), less than 15×10^{-6}. Furthermore, it is noticed that nearly zero λ_s is obtained in the Co-rich composition range, as shown in Figure 9. By choosing an appropriate alloy composition in the Fe–Co–Ni–Zr–Nb–B alloy series, BGAs have been produced in the diameter range of up to 6 mm by the copper mold casting process, exemplified in Figure 10.

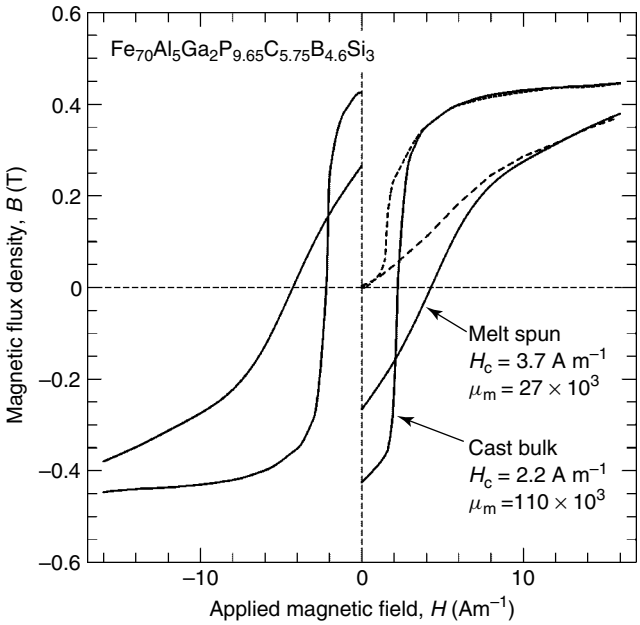

Figure 8. $B-H$ hysteresis loop, coercivity (H_c) and maximum permeability (μ_m) of cast ring-shaped $Fe_{70}Al_5Ga_2P_{9.65}C_{5.75}B_{4.6}Si_3$ glassy alloy, together with the data on a similar alloy made by stacking melt-spun sheets with a thickness of approximately 20 μm.

The increase of B content to 30 atom % in the (Fe, Co, Ni)$_{62}$Nb$_8$B$_{30}$ alloy series causes a further extension of the supercooled liquid region to more than 80 K in the (Fe, Co)-rich alloy composition range (Inoue, Zhang, Koshiba and Itoi, 1999b). Figure 11 shows the compositional dependence of ΔT_x in melt-spun (Fe, Co, Ni)$_{62}$Nb$_8$B$_{30}$ glassy alloys. It is seen that the Co-rich $Co_{40}Fe_{22}Nb_8B_{30}$ alloy shows a large supercooled liquid region at 81 K (Inoue, Itoi, Koshiba and Makino, 1999a). The Fe- and Co-based glassy alloys with 20–30 atom % of B exhibited a high electrical resistivity of 2.2–2.4 μΩ m and hence we expected to obtain good high-frequency permeability. Figure 12 shows the permeability of the melt-spun Fe- and Co-based glassy alloys with 20 atom % of B and 30 atom % of B, together with the data of commercial Fe- and Co-based amorphous sheet samples. It is clearly seen that the Fe- and Co-based glassy alloys possess much better high-frequency permeability as is evidenced form high permeability of 7×10^3 at a high frequency of 1 MHz.

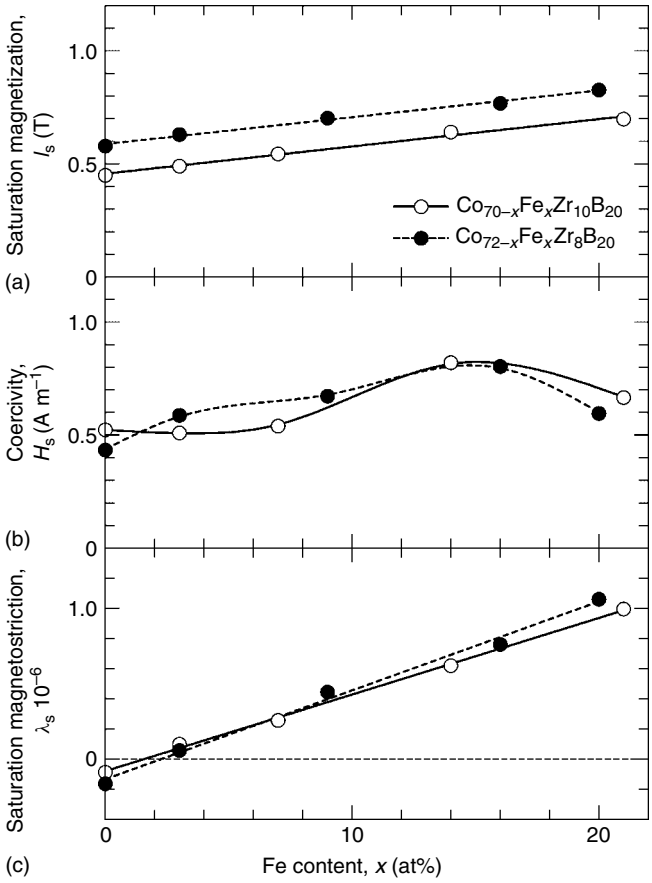

Figure 9. (a) Saturation magnetization (I_s), (b) coercivity (H_c), and (c) saturation magnetostriction constant (λ_s) as a function of Fe content for glassy $Co_{70-x}Fe_xZr_{10}B_{20}$ and $Co_{72-x}Fe_xZr_8B_{20}$ alloys subjected to annealing for 600 s at 800 K.

4 CONSOLIDATED BULK ALLOYS

In addition to BGAs synthesized by copper mold casting (Inoue, Shinohara and Gook, 1995) and thick glassy sheets prepared by controlling the wheel speed in the melt-spinning process (Mizushima, Makino, Yoshida and Inoue, 1999b), an Fe-based BGA can be produced by the consolidation technique (Inoue, Yoshida, Mizushima and Makino, 2001). When we consider the Fe–Al–Ga–metalloid alloy, a fully dense BGA was produced at the pressing temperature of 703 K, which is the lowest processing temperature as compared with those for the other Fe-based

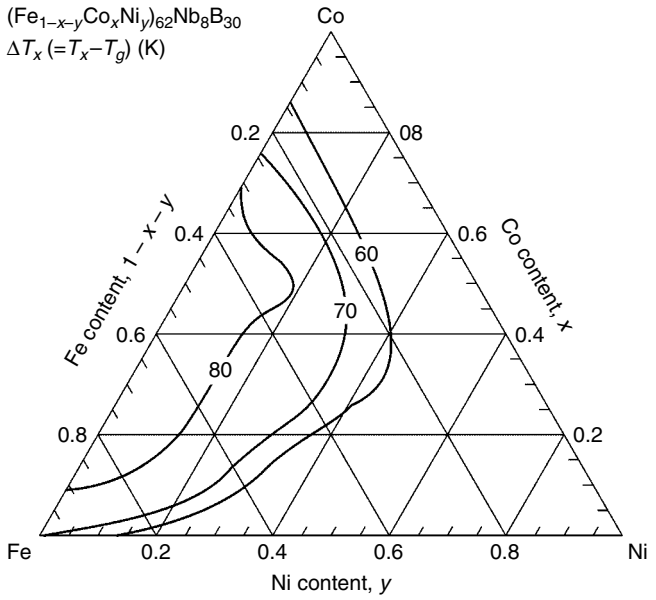

Figure 11. Compositional dependence of supercooled liquid region ($\Delta T_x = T_x - T_g$; T_x and T_g are crystallization and glass transition temperatures, respectively) for $(Fe_{1-x-y}Co_xNi_y)_{62}Nb_8B_{30}$ glassy alloys.

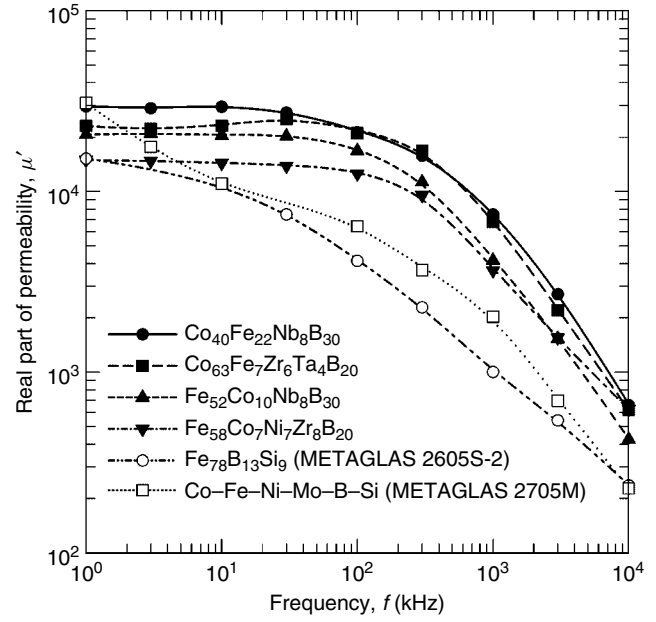

Figure 12. Frequency (f) dependence of the real part of complex permeability (μ') for melt-spun Fe- and Co-based glassy alloys. The data of commercial $Fe_{78}B_{13}Si_9$ and Co–Fe–Ni–Mo–B–Si amorphous alloys are also shown for comparison.

glassy alloys. Figure 13 shows the outer morphology and the surface appearance of Fe–Al–Ga–P–C–B–Si BGAs prepared by the warm consolidation technique. Figure 14

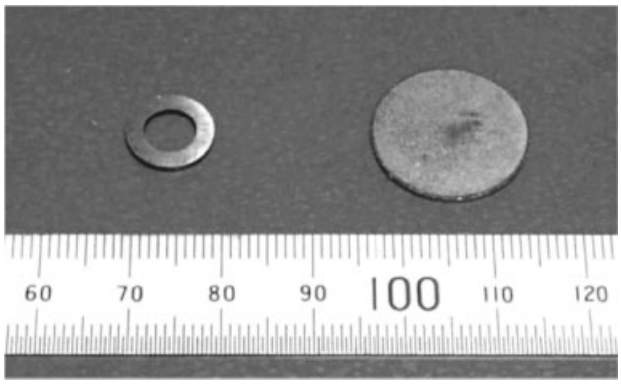

Figure 13. Outer morphology and surface appearance of bulk glassy $Fe_{70}Al_5Ga_2P_{9.65}C_{5.75}B_{4.6}Si_3$ alloys with a thickness of 1 mm prepared by warm consolidation for 480 s at 703 K under an applied pressure of 570 MPa.

shows the change in the magnetic flux density (B_{800}) under an applied magnetic field of 800 A m^{-1} (H_c), the initial permeability (μ_i) at 1 kHz, and the core loss ($W_{5/50}$) at 0.5 T (5 kOe) and 50 Hz with annealing temperature for the Fe–Al–Ga–P–C–B–Si consolidated BGAs (Inoue, Yoshida, Mizushima and Makino, 2001). The consolidated BGA exhibits a rather high B_{800} of 1.17 T, rather low H_c of 12 A m^{-1}, rather high μ' of 2.5×10^3, and low $W_{5/50}$ of 0.11 W kg^{-1}. Table 6 summarizes the soft magnetic properties of the consolidated Fe–Al–Ga–P–C–B–Si BGA, together with the data of the other consolidated Fe-based bulk glassy (Fe–Co–Ni–Hf–Nb–B and Co–Fe–Zr–B) and amorphous (Fe–B–Si) alloys. It is noticed that the Fe–Al–Ga–metalloid bulk alloy exhibits much better soft magnetic properties compared with the other Fe-based bulk glassy and amorphous alloys. The much better soft magnetic properties are presumably due to the formation of a BGA with truly full density. It is believed that if the soft magnetic properties can be improved slightly, the consolidated BGA will surely be used as a practical soft magnetic material.

5 BULK NANOCRYSTALLINE ALLOYS

The BGAs in Fe–B–Si–(Nb or Zr) systems are very attractive as a new type of soft magnetic bulk alloy because of their high I_s, exceeding 1.5 T (Inoue and Shen, 2002; Inoue, Shen and Chang, 2004). Recently, a cast amorphous alloy cylinder with a diameter of 0.5 mm was formed in the Fe–B–Si–Nb–Cu system by copper mold casting (Inoue, Shen and Ohsuna, 2002). The amorphous Fe–B–Si–Nb–Cu alloy cylinder exhibits a multistage crystallization process in which the first stage is due to the precipitation of the bcc-Fe phase and the following stages are attributed to the transition of bcc-Fe + amorphous to bcc-Fe + $Fe_{23}B_6$ + Fe_2B +

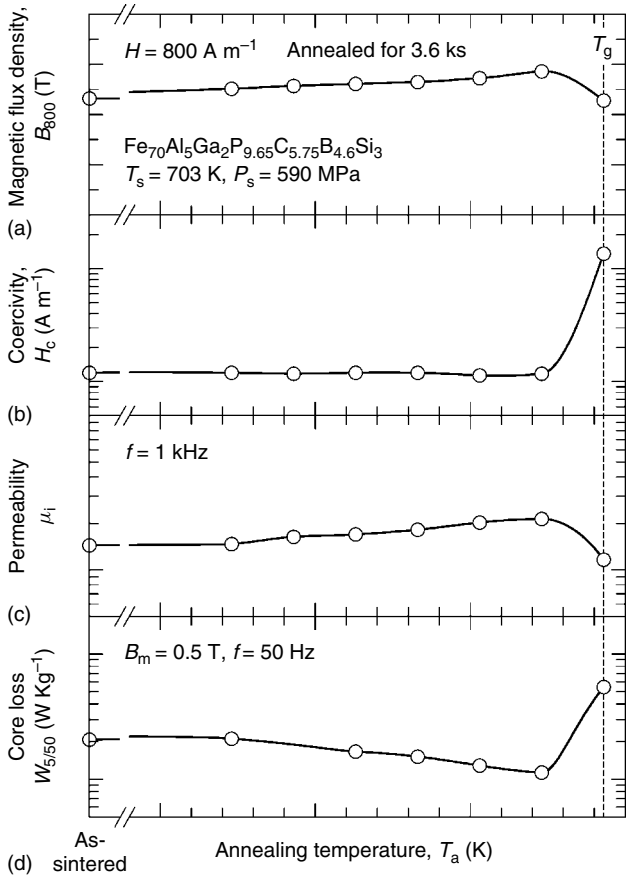

Figure 14. Changes in (a) magnetic flux density (B_{800}) at 800 A m^{-1}, (b) coercivity (H_c), (c) initial permeability (μ_i) at 1 kHz, and (d) core loss ($W_{5/50}$) at 0.5 T (5 kOe) and 50 Hz with annealing temperature (T_a) for bulk glassy $Fe_{70}Al_5Ga_2P_{9.65}C_{5.75}B_{4.6}Si_3$ alloy prepared by warm consolidation for 480 s at 703 K under an applied pressure of 570 MPa. The vertical dashed line indicates the glass transition temperature (T_g) of the alloy.

$Fe_3Si + Fe_2Nb$ phases. Figure 15 shows the bright- and dark-field transmission electron microscopy (TEM) images and the selected-area electron diffraction pattern of the $Fe_{72.5}B_{12.5}Si_{10}Nb_4Cu_1$ cast cylinder with a diameter of

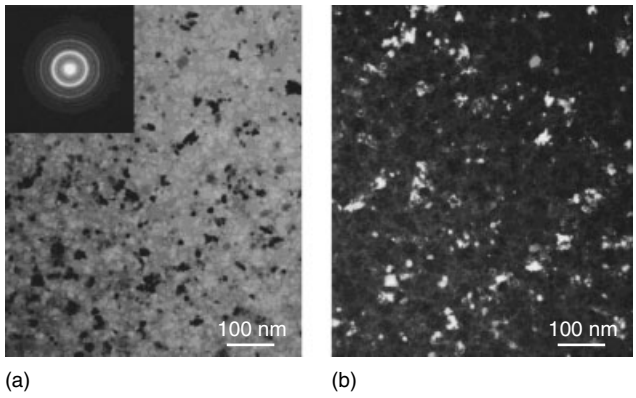

Figure 15. (a) Bright- and (b) dark-field transmission electron microscopy images and selected-area electron diffraction pattern of cast $Fe_{72.5}B_{12.5}Si_{10}Nb_4Cu_1$ amorphous alloy cylinder with a diameter of 0.5 mm annealed for 300 s at 883 K.

0.5 mm annealed for 300 s at 883 K, which is a temperature between the first (T_{x1} = 841 K) and the second ($T_{x2} \approx$ 940 K) crystallization temperatures. It is seen that bcc-Fe grains with a size of approximately 10 nm disperse homogeneously in the remaining amorphous phase matrix. The nanobeam energy-dispersive spectroscopy (EDS) reveals that the Si element is enriched in the bcc-Fe phase, while the Nb element is rejected. A similar tendency is also obtained in the $Fe_{73.5}B_9Si_{13.5}Nb_3Cu_1$ melt-spun alloy (FINEMET) (Hono, Inoue and Sakurai, 1991; Hono *et al.*, 1992). The decrease in Si content and the increase in Nb content in the remaining amorphous phase cause an increase in the thermal stability of the remaining amorphous phase in conjunction with the nanoscale bcc-Fe particles. Table 7 summarizes the thermal stability and soft magnetic properties of the nanocrystalline $Fe_{72.5}B_{12.5}Si_{10}Nb_4Cu_1$ alloy cylinder consisting of the mixed bcc-Fe and amorphous phases obtained by annealing the cast amorphous alloy cylinder. The data of the nanocrystalline $Fe_{73.5}B_9Si_{13.5}Nb_3Cu_1$ melt-spun alloy (FINEMET) are also presented for comparison (Yoshizawa, Oguma and Yamauchi, 1988). It is noticed that the nanocrystalline alloy cylinder exhibits good soft magnetic properties, that is, a high I_s

Table 6. Magnetic flux density (B_{800}) at 800 A m^{-1}, coercivity (H_c), maximum permeability (μ_m), initial permeability (μ_i) at 1 kHz and core loss ($W_{5/50}$) at 0.5 T (5 kOe) and 50 Hz of bulk glassy $Fe_{70}Al_5Ga_2P_{9.65}C_{5.75}B_{4.6}Si_3$ alloy prepared by warm consolidation for 480 s at 703 K under an applied pressure of 570 MPa. The data of other bulk glassy ($Fe_{56}Co_7Ni_7Hf_8Nb_2B_{20}$ and $Co_{56}Fe_{16}Zr_8B_{20}$) and amorphous ($Fe_{78}B_{13}Si_9$) alloys prepared by the same consolidation technique are also shown for comparison.

	B_{800} (T)	H_c (A m^{-1})	μ_m (10^3)	μ_i at 1 kHz (10^3)	$W_{5/50}$ (W kg^{-1})

Table 7. First crystallization temperature (T_{x1}), saturation magnetization (I_s), coercivity (H_c), and initial permeability (μ_i) at 1 kHz of cast $Fe_{72.5}B_{12.5}Si_{10}Nb_4Cu_1$ alloy cylinder with a diameter (d) of 0.5 mm annealed for 300 s at T_a. The data of melt-spun $Fe_{72.5}B_{12.5}Si_{10}Nb_4Cu_1$ and $Fe_{73.5}B_9Si_{13.5}Nb_3Cu_1$ (FINEMET) alloys with thicknesses (t) of 40 and 18 mm, respectively, are also shown for comparison.

	t or d (mm)	T_a (K)	T_{x1} (K)	I_s (T)	H_c (A m^{-1})	μ_i at 1 kHz (10^3)
$Fe_{72.5}B_{12.5}Si_{10}Nb_4Cu_1$ (bulk)	0.5	883	841	1.21	1.8	32
$Fe_{72.5}B_{12.5}Si_{10}Nb_4Cu_1$ (melt-spun)	0.040	883	841	1.23	0.71	80
$Fe_{73.5}B_9Si_{13.5}Nb_3Cu_1$ (melt-spun) (Yoshizawa *et al*., 1988)	0.018	823	775	1.24	0.53	100

of 1.21 T, a low H_c of 1.8 A m^{-1}, and a high μ_i of 32×10^3 (Inoue, Shen and Ohsuna, 2002). One can notice clearly the achievement of good soft magnetic properties in the nanocrystalline structure state even for the bulk alloy cylindrical rod form.

6 ORIGIN OF LOW COERCIVITY OF GLASSY ALLOYS

6.1 Coercivity of amorphous and glassy alloys

In crystalline materials, H_c is determined by dislocations and grain boundaries. In amorphous materials these defects do not exist. Nevertheless, the observed H_c has values of the order of magnitude 0.5–10 A m^{-1}. The origins of H_c have been identified and discussed (Kronmüller, 1981a,b). In the order of increasing importance in amorphous alloys these are:

1. Intrinsic fluctuations of exchange energies and local anisotropy (10^{-4}–0.1 A m^{-1}), H_c^i.
2. Clusters of chemical short-range ordered regions (<0.1 A m^{-1}), H_c^{SO}.
3. Surface irregularities (<0.5 A m^{-1}), H_c^{surf}.
4. Volume pinning of domain walls by defect structures in magnetostrictive alloys (1–10 A m^{-1}), H_c^{σ}.

The observed H_c is considerably larger than the expected ones for intrinsic fluctuations or short-range ordered regions. The typical value for the contribution of the surface irregularities H_c has been estimated to be 0.5 A m^{-1} for Fe-based amorphous alloys and thus represents one of the limiting factors for H_c of the amorphous alloys (Kronmüller, 1981a; Kronmüller and Gröger, 1981). It is therefore suggested that inhomogeneities exist in amorphous alloys, acting as strong pinning centers for domain walls. These pinning centers were found to correspond to stress sources.

Stress sources are supposed to have their origin in the partial instability of the free volume below the melting point. The free volume may exist in dispersed form as agglomerates in the melt off. By a relaxation of the atomic network, the vacancy clusters may collapse, thus generating planar defects, which act as stress sources (Kronmüller *et al*., 1979; Kronmüller, 1980, 1981b). Figure 16 shows a model for the formation of the quasi-dislocation dipole (QDD)-type defects in amorphous alloys by agglomeration of vacancy-type point defects (Kronmüller, 1979, 1981b). The QDDs are characterized by the dipole width (D), the dipole length (L), and an effective Burgers vector ($\boldsymbol{b}$).

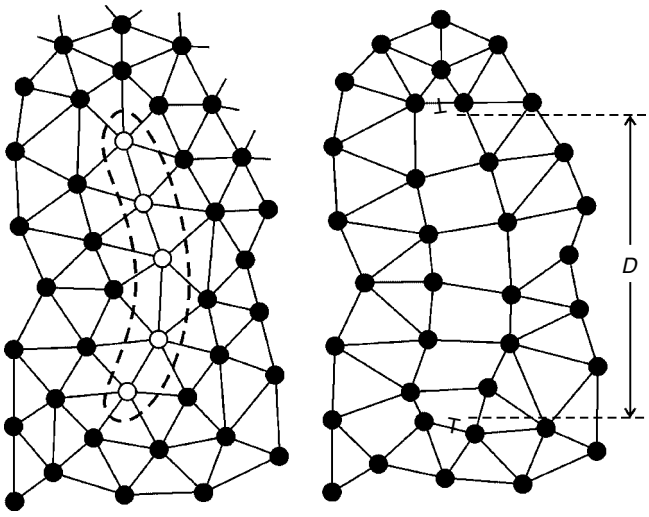

Figure 16. Schematic two-dimensional model for formation of quasi-dislocation dipoles in amorphous alloys by agglomeration of vacancy-type point defects in planar regions. The quasi-dislocation dipole is characterized by dipole width (D), dipole length (L) perpendicular to the drawing plane, and an effective Burgers vector ($\boldsymbol{b}$).

The coercivity of a random distribution of the QDD-type defects of density ρ_d is given as (Kronmüller, 1981a,b; Kronmüller and Gröger, 1981)

$$H_c^{\sigma} = \frac{12G\Delta V}{\sqrt{30F\delta}} \sqrt{\pi \rho_d \ln\left(\frac{\pi d}{2\delta}\right)} \frac{\lambda_s}{I_s} \qquad (1)$$

where G is the shear modulus, $\Delta V = DLb$ corresponds to the local volume contraction due to the QDDs, F is the domain-wall area, δ is the domain-wall thickness, and d is the domain width. The factor of $\ln\{\pi d(2\delta)^{-1}\}$ in equation (1) takes into account the statistical fluctuations

due to the $\pi d(2\delta)^{-1}$ independent positions of the domain wall within the domain width. Numerical calculations based on equation (1) predict values of the right order of magnitude for H_c in magnetostrictive alloys, while measurements of the temperature dependence of $H_c I_s \lambda_s^{-1}$, which should correspond to $\delta^{-1/2} \propto K^{1/4}$ (where K is the effective anisotropy energy density), in a number of Fe-based amorphous alloys have provided convincing proof for the existence and role of the QDDs (Kronmüller, 1981a,b; Kronmüller and Gröger, 1981).

If G, F, δ, and d are independent of the alloy system, H_c^σ can be written as

$$H_c^\sigma \propto \Delta V \sqrt{\rho_d} \frac{\lambda_s}{I_s} \tag{2}$$

Figure 17 shows H_c as a function of $\lambda_s I_s^{-1}$ for the melt-spun glassy Fe–(Al, Ga)–(P, C, B, Si, Ge) alloys and ordinary amorphous alloys with a thickness of 20–35 μm subjected to annealing (Bitoh, Makino and Inoue, 2003). Here, the contribution of the surface irregularities to H_c is assumed to be 0.5 A m^{-1} (Kronmüller, 1981a; Kronmüller and Gröger, 1981). It should be noted that the glassy Fe–(Al, Ga)–(P, C, B, Si, Ge) alloys exhibit lower H_c than the ordinary amorphous alloys with the same $\lambda_s I_s^{-1}$. The gradient of the H_c versus $\lambda_s I_s^{-1}$ plot for the glassy alloys is smaller than

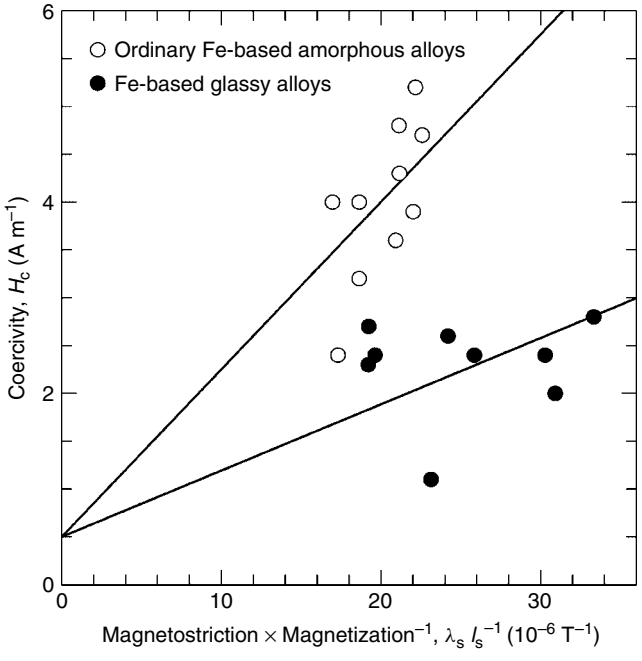

Figure 17. Coercivity (H_c) after annealing as a function of saturation magnetostriction constant and saturation magnetization ($\lambda_s I_s^{-1}$) for melt-spun Fe-based glassy alloys with a thickness of 20–35 μm and ordinary amorphous alloys. Contribution of surface irregularities to H_c is assumed to be 0.5 A m^{-1}.

that for the ordinary amorphous alloys. This result indicates that $\Delta V \rho_d^{1/2}$ of the glassy alloys is approximately 0.4 times that of the ordinary amorphous alloys; that is, ρ_d and/or ΔV of the glassy alloys are much smaller than those of the ordinary amorphous alloys. Here, the decrease of ΔV means the decrease in the pinning force due to the elastic stress (Kronmüller, 1981a,b; Kronmüller and Gröger, 1981). It should be noted that ΔV and ρ_d strongly depend on the quenched-in free volume described in the preceding text. Table 8 shows the mass density (ρ) of the typical Fe-based glassy and ordinary amorphous alloys (Bitoh, Makino and Inoue, 2004). It should be noted that the differences of ρ between the crystalline and the glassy or amorphous phases ($\Delta\rho_c$) of the glassy alloys (0.06–1.11%) are much smaller than those of the ordinary amorphous alloys (2.64–2.94%).

6.2 Magnetization process and low coercivity of glassy alloys

The magnetization curve of amorphous or glassy ferromagnetic alloys is similar to that of the crystalline materials in many aspects. In the low magnetic field (H) region, the magnetization process is governed by domain-wall movement. Sufficiently above the anisotropy field (H_K), the alloy is homogeneously magnetized. Further magnetization is due to an alignment of microscopic inhomogeneous spin states around inhomogeneities of the atomic network. In this so-called field range of approach to ferromagnetic saturation, the field dependence of magnetization is described fairly well by (Kronmüller, 1979, 1981b; Kronmüller *et al.*, 1979)

$$I = I_s - \Delta I(H) + \Delta I_{para}(H) \tag{3}$$

where the last term in equation (3) describes the increase of magnetization due to the so-called spin-wave paraprocess and

$$\Delta I(H) = \frac{a_p}{H^p} \tag{4}$$

Since the effect of intrinsic inhomogeneities on $\Delta I(H)$ is negligibly small (Kronmüller, 1979), the inhomogeneity term ($a_p H^{-p}$) is due to spin inhomogeneities induced by the magnetoelastic interactions between the elastic stress (σ) and the magnetization. Equation (4) may be attributed to certain types of stress sources as follows (Kronmüller *et al.*, 1979; Kronmüller, 1979, 1980, 1981b):

$$\text{point-like defects}: \ \sigma \propto r^{-3} \longrightarrow H^{-1/2}$$

$$\text{quasi-dislocation dipoles}: \ \sigma \propto r^{-2} \longrightarrow H^{-1}$$

$$\text{isolated quasi-dislocations}: \ \sigma \propto r^{-1} \longrightarrow H^{-2}$$

where r is the distance from the stress center.

Table 8. Mass densities (ρ) of as-quenched and annealed glassy ($Fe_{77}Al_{2.14}Ga_{0.86}P_{8.4}C_5B_4Si_{2.6}$ and $Fe_{73}Al_5Ga_2P_{11}C_5B_4$) or amorphous ($Fe_{80}B_{20}$ and $Fe_{78}B_{13}Si_9$) samples and crystalline samples (mother alloys). T_c and T_g are Curie and glass transition temperatures, respectively.

	Annealing condition	ρ^a (kg m^{-3})	$\Delta\rho_r{}^b$ (%)	$\Delta\rho_c{}^c$ (%)

	Crystal (mother alloy)	7588	–	–
$Fe_{78}B_{13}Si_9$	As-quenched	7179	–	2.94
	653 K ($\approx 0.95T_c$) for 7.2 ks	7195	0.22	2.72
	Crystal (mother alloy)	7390	–	–

[a]Relative error $\approx 0.02\%$.
[b]$\Delta\rho_r = (\rho_{\text{annealed}} - \rho_{\text{as-quenched}})/\rho_{\text{as-quenched}}$.
[c]$\Delta\rho_c = (\rho_{\text{crystal}} - \rho_{\text{amorphous}})/\rho_{\text{amorphous}}$.

The range of spin inhomogeneities is governed by the so-called exchange length (Kronmüller, 1979; Kronmüller *et al*., 1979)

$$L_H = \sqrt{\frac{2A}{HI_s}} \tag{5}$$

where A is the exchange stiffness constant. The role of L_H is most clearly demonstrated by the field dependence of the inhomogeneity terms due to dislocation dipoles. If D is smaller than L_H, the magnetization detects a dipole; however, for $L_H < D$, the magnetization detects the two opposite monopoles (dislocations) of the dipole separately, and a H^{-2} low is measured. Therefore, it is possible to obtain the mean dipole width, which is given for $\langle D\rangle = L_H(H_t)$, by the transition field (H_t) from the H^{-1} law to the H^{-2} law. The length of the effective Burgers vector ($\boldsymbol{b}$) can be evaluated from the coefficient (a_2) of the H^{-2} term (Kronmüller, 1979; Kronmüller *et al*., 1979).

Figure 18 shows I as a function of H^{-1} for the melt-spun Fe–(Al, Ga)–(P, C, B, Si) glassy alloys with a thickness of 25–30 μm (Bitoh, Makino and Inoue, 2004). The H^{-1}–power law behavior of $\Delta I(H)$ is observed for all the alloys in the range of $20 \lesssim (\mu_0 H)^{-1} < 40$–$50\,T^{-1}$ (20–$25 < \mu_0 H \lesssim 50$ mT, where μ_0 is the permeability of a vacuum). In the higher magnetic field range, $\Delta I(H)$ of the glassy alloys obeys the H^{-2} power law (Bitoh, Makino and Inoue, 2004). These results indicate that the QDD-type defects are the main sources of the elastic stress.

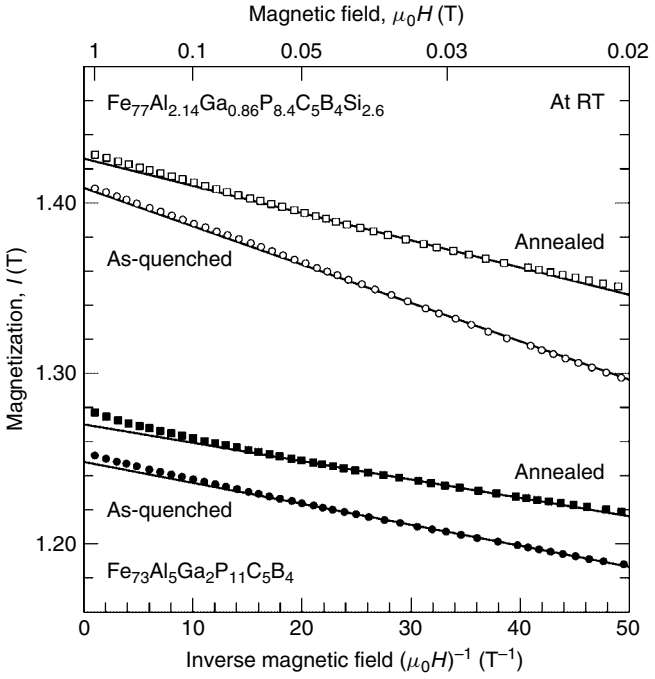

Figure 18. Magnetization (I) as a function of inverse magnetic field ($(\mu_0 H)^{-1}$) of as-quenched and annealed (for 600 s at $0.97T_g$; T_g is glass transition temperature) melt-spun glassy $Fe_{77}Al_{2.14}Ga_{0.86}P_{8.4}C_5B_4Si_{2.6}$ and $Fe_{73}Al_5Ga_2P_{11}C_5B_4$ alloys.

The analysis of the magnetization curves yields the following results: that is, both the Fe–(Al, Ga)–(P, C, B, Si) glassy alloys and the Fe–B(–Si) amorphous alloys have almost the

same $\langle D \rangle$ ($\approx$14 nm), b ($\approx$0.05 nm), and δ ($\approx$80 nm) values (Bitoh, Makino and Inoue, 2004). It can be considered that all the alloys also have almost the same value for G. The QDD-type defects are formed by the agglomeration of vacancy-type point defects in planar regions. Therefore, ρ_d is proportional to $\Delta\rho_c \Delta V^{-1}$ because $\Delta\rho_c$ denotes the amount of the free volume in the amorphous or glassy alloys. Let us further consider that L is proportional to $\langle D \rangle$. Then all the alloys have almost the same ΔV. Under these assumptions, H_c^σ can be expressed as follows:

$$H_c^\sigma = p_c(F, d)\sqrt{\Delta\rho_c}\frac{\lambda_s}{I_s} \tag{6}$$

where p_c, the prefactor, depends on F and d. Figure 19 shows the observed $H_c^\sigma I_s \lambda_s^{-1}$ as a function of $(\Delta\rho_c)^{1/2}$. This figure clearly shows that $H_c^\sigma I_s \lambda_s^{-1}$ is proportional to $(\Delta\rho_c)^{1/2}$. The prefactor of the annealed alloys is approximately 0.4 times smaller than that of the as-quenched ones. It is considered that F is increased by the structural relaxation (Schroeder, Schäfer and Kronmüller, 1978). These results suggest that low ρ_d, which corresponds to low density of the domain-wall pinning centers, is the origin of the low H_c of the Fe–(Al, Ga)–(P, C, B, Si) glassy alloys.

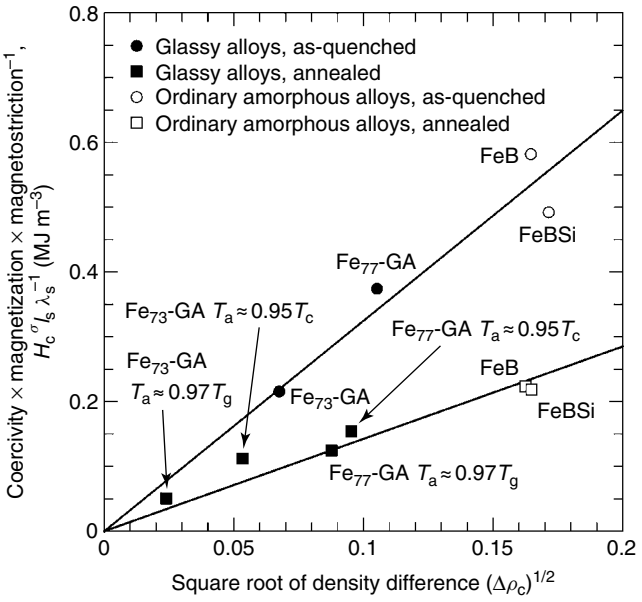

Figure 19. Coercivity times saturation magnetization divided by saturation magnetostriction constant ($H_c^\sigma I_s \lambda_s^{-1}$) as a function of square root of density differences ($(\Delta\rho_c)^{1/2}$) between crystalline and amorphous phases. Fe_{73}-GA: $Fe_{73}Al_5Ga_2P_{11}C_5B_4$; Fe_{77}-GA: $Fe_{77}Al_{2.14}Ga_{0.86}P_{8.4}C_5B_4Si_{2.6}$; FeB: $Fe_{80}B_{20}$; FeBSi: $Fe_{78}B_{13}Si_9$; T_a: annealing temperature; T_c: Curie temperature; T_g: glass transition temperature.

7 APPLICATIONS AND FUTURE TRENDS

Table 9 summarizes the advantages and disadvantages of soft magnetic properties, comparing those of Fe- and Co-based ordinary amorphous alloys. Advantages to be noted are (i) much higher GFA leading to the formation of thicker sheets and plates, larger diameter wires, and thick rings, (ii) higher electrical resistivity of 2.2–2.4 μΩ m at room temperature, (iii) more homogeneous glassy structure without clusters for crystal nucleation, (iv) appearance of a large supercooled liquid region before crystallization, (v) lower H_c, (vi) higher μ_i, (vii) intentional arrangement of domain-wall structure caused by control of casting and/or cooling condition, (viii) better high-frequency μ_i, (ix) good microforming ability in the supercooled liquid region, and (x) warm consolidation into a highly dense bulk form.

Because of these unique advantages, the soft magnetic glassy alloy powder (Liqualloy™) has already been developed as a core material for choke coils used in switching-mode power supplies. The choke coil is one of the largest components in a current switcher, and has been an obstacle to the creation of smaller units. When current is passed through a choke coil, inductance is lowered due to direct current (DC) magnetic saturation in the core material, the degree of which is commonly referred to as its DC superposition characteristic. Previously, the main core material used was ferrite, popular because of its low cost, but a major drawback of this material was its low DC magnetic saturation point. The demand for smaller choke coils is strong, and Fe-based metallic materials that are not easily subject to DC magnetic saturation have steadily come into use. However, the metallic core materials have a high degree of core loss, which leads to less efficient switching power supplies owing to heat generation in the core or power dissipation. The Fe-based magnetic glassy alloys exhibit rather high I_s, low core losses, and high electrical resistivity, simultaneously. It is difficult to produce the ordinary amorphous alloy powder with low GFA, because high-pressure gas atomization or mechanical grinding of melt-spun tapes must be used. Since the glassy alloys also have high GFA and good corrosion resistance, the glassy alloy powder can be produced easily by water atomization, which reduces manufacturing costs remarkably. Figure 20 shows the core loss (W) at 100 kHz, which is a typical operational frequency of the switching-mode power supplies with a Fe–Cr–P–C–B–Si glassy alloy dust core (Koshiba, 2003). The mixture of the near spherical glassy powder (98 mass %) with diameters ranging from 350 to 800 μm, reign for the electrical insulation of each powder and the lubricant were molded into a toroidal shape by applying a static pressure. The molded core was annealed for 3.6 ks at 763 K in a nitrogen atmosphere. The data of the commercial dust cores made of pure Fe, sendust (Fe–Al–Si), and Mo

Table 9. Advantages and disadvantages of soft magnetic properties, comparing those of Fe- and Co-based ordinary amorphous alloys.

Advantages	Disadvantages
Much higher glass-forming ability	Higher material cost
Higher electrical resistivity	Lower saturation magnetization
More homogeneous glassy structure	
Appearance of a large supercooled liquid region	
Lower coercivity	
Higher initial permeability	
Intentional arrangement of domain-wall structure	
Better high-frequency permeability	
Good microforming ability	
Warm consolidation into a highly dense bulk form	

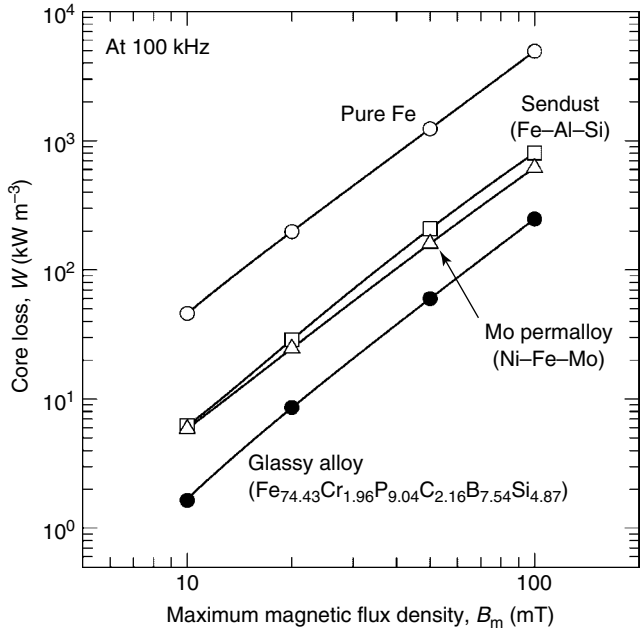

Figure 20. Core loss (W) at 100 kHz of glassy alloy ($Fe_{74.43}Cr_{1.96}P_{9.04}C_{2.16}B_{7.54}Si_{4.87}$) dust core as a function of maximum magnetic flux density (B_m). The data for commercial dust cores are also shown for comparison.

permalloy (Ni–Fe–Mo) are also shown for comparison in Figure 20. The core loss of the glassy alloy dust core is considerably lower than that of the commercial ones. The low core loss and excellent DC superposition characteristics of the glassy alloy dust core will contribute to highly efficient switching.

On the other hand, the disadvantages are (i) higher material cost due to the necessity of using special solute elements to obtain an increase in GFA and (ii) lower I_s due to the addition of larger amounts of solute elements. In particular, the lower I_s for soft magnetic glassy alloys is a serious obstacle to future use in power transformers. Consequently, a great deal of time and effort have been devoted to increasing I_s, though there exists a trade-off between the decrease in the solute contents for an increase in I_s and the increase in the solute content for an increase in GFA. However, owing to the attractive properties described earlier, it is strongly believed that the present soft magnetic BGAs will become practical magnetic materials in the near future.

Advanced Soft Magnetic Materials for Power Applications

Anthony J. Moses
Cardiff University, Cardiff, UK

1 INTRODUCTION

Electrical steels are traditional, mature magnetic materials that are in an ongoing state of incremental development. They comprise over 97% of the volume of all soft magnetic materials currently produced, amounting to a value of around £5000 million per annum. This represents around 1% of all steel production and amounts to over 8 million tonnes per annum. Coupled to this, over 5% of all the electrical energy we generate is consumed as iron losses when electrical steels are used as the magnetic core of electrical equipment, mainly motors and transformers. This costs the UK economy alone around £800 million per year, apart from the considerable detrimental effect on the environment as the by-product of generation of this wasted energy (Moses, 2002).

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

Recently, soft magnetic iron composite cores produced by powder metallurgy routes are finding some niche applications. Their 3-D characteristics, physical shapes, and magnetic properties are very different to those of electrical steel which are produced in thin sheet form. Hence, it is important to include composite material here to recognize the possible option for using this form of material for a growing range of medium frequency applications, in particular. It should also be pointed out that development continues on other important magnetic materials such as soft ferrites and iron–cobalt alloys which are used in small volume, but critical, power applications. These are not covered here but reviews can be found elsewhere, for example, (Buschow, 1995; Fish, 1989; Boll, 1978). In this article, the reference to material properties, characterization, and so on, refer specifically to *electrical steels* rather than to the *soft magnetic composite* (SMC) materials unless otherwise stated because of their far greater importance in today's context.

Nonoriented and grain-oriented electrical steels are produced in strip form up to over 1 m in width, and normally between 0.1 and 0.65 mm in thickness. Silicon is added to increase the electrical resistivity, which in turn reduces losses under ac magnetization. Silicon does, however, reduce the saturation magnetization and can cause brittleness but it does beneficially reduce the magnetostriction and crystal anisotropy. The materials are produced by conventional steel making followed by a complex series of thickness reduction by hot and cold rolling together with annealing and coating to develop the desired magnetic and mechanical properties (Moses, 1990). The coating on grain-oriented and nonoriented steel must be uniform in thickness and sufficiently thin to minimize the building factor of assembled cores.

Grain-oriented steel contains around 3% silicon (weight) and comprises a strong [001](110) texture with grains up to 10 mm in diameter, which are developed by a critical secondary recrystallization process. The grain-oriented material has losses and permeability several times better than those of nonoriented steel when magnetized along its rolling direction which is the predominant direction of the ⟨100⟩ axes of the grains. The properties of grain-oriented silicon steel depend on the strongly anisotropic magnetic characteristics of iron and some of its alloys which tend to cause low loss and high permeability when magnetized along ⟨100⟩ directions of individual grains or crystals. Because of its texture, the domain structure mainly comprises antiparallel bar domains separated by 180° walls in the demagnetized state. Grain-oriented material is also referred to as *Goss textured steel* named after its prime developer, N.P. Goss, and should not be confused with other grain-oriented steels such as [001](100) textured or *Cubex* material which has been produced only in small quantities (Moses, 1990).

Nonoriented steel is an iron alloy with up to 3% silicon which has a mainly isotropic, random texture with grains around 10–100 μm in diameter and a very complex domain structure. They are far cheaper than grain-oriented material, and magnetic properties are reasonably uniform (isotropic) in all directions in the plane of the strip. They are broadly divided into two groups: fully processed, where the magnetic properties are fully developed by the manufacturer, and semiprocessed, where the user gives the material a final anneal after assembly or forming to complete the development of the magnetic properties. The material is covered with a nonmagnetic coating which not only has to provide electrical insulation between layers or turns in assembled cores but also needs to be of a form to give suitable punching or welding characteristics.

The magnetic properties of electrical steels depend on the static domain structure and the manner in which various types of domain walls move under the influence of ac fields. In practice, the domain structure is more complicated than the idea pattern in a well-oriented grain of steel as referred to earlier (Shilling and Houze, 1974). Much of the present understanding of the properties of electrical steel has been developed from the knowledge of static and dynamic domain structures observed on the surface of electrical steel. Figure 1 shows a typical pattern in grain-oriented material compared with the far more complicated structure typical of nonoriented steel (Hubert and Schafer, 1998).

Conventional grain-oriented (CGO) steel was developed during the 1950–1960s based on the Armco Steel Inc. process for secondary recrystallization. In the 1970s, Nippon Steel Corporation used a modified technology and production route to produce so-called high permeability, grain-oriented (HGO) steel with a better distribution of well-oriented, larger

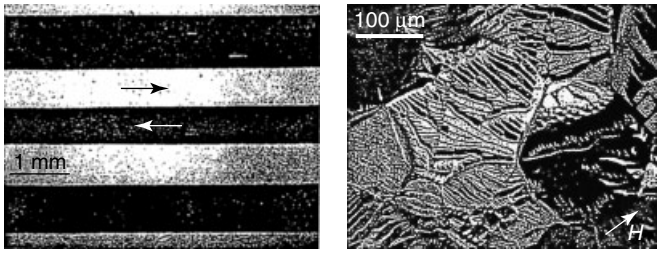

Figure 1. Typical static domain images in (a) grain-oriented and (b) nonoriented electrical steel. (Reproduced from Hubert *et al*., 1998. With permission from Springer-Verlag GmbH. © 1998.)

grains, up to around 10 mm in diameter compared with around 0.3 mm for CGO steel. Such large grains normally have wide domains and higher associated losses when magnetized, but a high-stress coating is applied to ensure that the benefit of better orientation is realized (Moses, 1990). The coating process is complex. A thin layer of magnesium oxide is first applied which reacts with the steel surface at high temperatures to produce a glass film or *Forsterite* layer (Mg_2SiO_4 glass film). A phosphate layer is applied later in the production process to produce the necessary surface electrical insulation and also to induce a high surface tensile stress along the rolling direction of the steel strip which in turn changes the static domain structure in a beneficial manner to cause a significant improvement in the stress sensitivity of the magnetic properties (Moses, Pegler and Thompson, 1972).

A further improvement in losses is achieved by additional surface treatment in grain-oriented, *domain-refined steels* (Kubota, Fujikura and Ushigami, 2000). Here, a beneficial surface stress is induced by either laser or mechanical treatment to cause further refinement, or narrowing, of the mean width of static domains with a corresponding reduction in loss. Such material normally cannot be stress-relief annealed after domain refining treatment because the beneficial surface stress is then removed.

2 LOSSES IN ELECTRICAL STEELS

Micro and macro eddy currents occur due to domain wall motion in soft magnetic materials subjected to ac magnetization. This produces the internal heating commonly referred to as *iron loss*. Traditionally, the loss is divided into three components, namely, *hysteresis*, *classical eddy current*, and *anomalous* (*excess*) *loss*. For commercial grading, these losses are quantified in terms of power ($W\,kg^{-1}$), but the same quantities are expressed, often for scientific research,

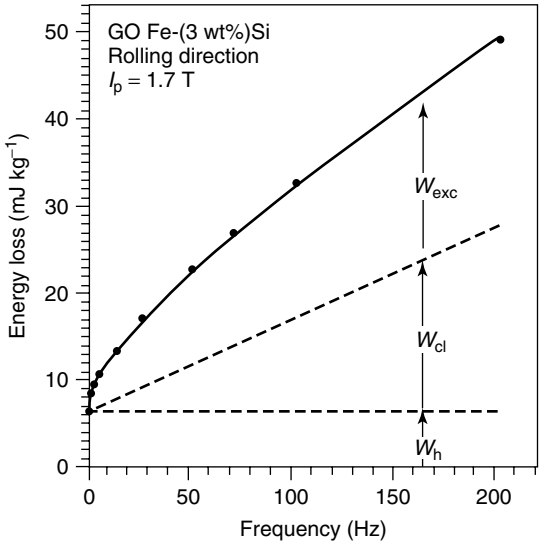

Figure 2. Energy loss per cycle as a function of magnetizing frequency in grain-oriented electrical steel at 1.7 T. (Reproduced from F. Fiorillo, 2004, with permission from TU Bergakademie Freiberg. © 2004.)

as energy components in J kg^{-1} to represent the energy loss per cycle of magnetization.

Figure 2 shows the traditional way of expressing the measured variation of these energy loss components with magnetizing frequency at a fixed sinusoidally time varying flux density of peak value $\hat{B}$ (Fiorillo, 2004).

As can be seen from Figure 2, hysteresis loss per cycle is independent of frequency. It cannot be calculated theoretically from first principles but is proportional to the area enclosed by the static $B-H$ loop. From measurements on many different types of material, it is found to depend mainly on the composition, nature, and distribution of impurities, texture, grain size, and internal stress. It is associated with the pinning of domain walls at imperfections in the material, so high-purity material will have relatively low hysteresis loss. Domain wall motion, particularly in grain-oriented materials, is also impeded close to lamination surfaces by factors such as roughness and coating-induced stress. The following empirical equation is often quoted for the total hysteresis power loss at a given magnetizing frequency f.

$$P_h = K_h f \left(\hat{B}\right)^x \tag{1}$$

where $\hat{B}$ is the peak flux density, and K_h and x are parameters that depend on the material factors referred to earlier as well as the specific magnetizing conditions.

The classical eddy current power loss in a thin lamination at magnetizing frequency f is calculated from

$$P_e = \frac{K_c \left(\hat{B} f d\right)^2}{\rho} \tag{2}$$

where K_c is a material-dependent constant, d is the lamination thickness, and ρ is its electrical resistivity. It should be noted that this commonly used equation assumes constant permeability, that is, a linear $B-H$ curve, which is true only at low induction in silicon iron. It assumes no skin effect which implies a low ratio of the product of permeability and frequency to resistivity, and it assumes sinusoidally time varying flux throughout the thickness of the lamination (Brailsford, 1966). Noting that approximations are made when deriving equation (2), it still shows the need for thin, high-resistivity laminations to minimize P_e.

The measured loss such as that shown in Figure 2 is always greater than the sum of P_h and P_e by an amount P_a, the anomalous loss, which is attributed to loss mechanisms occurring during domain wall motion. Many experimental studies have been carried out in attempts to identify and quantify the causes of P_a in electrical steels. Undoubtedly, mechanisms such as domain wall bowing, wall nucleation and annihilation, nonuniform wall mobility, and nonrepetitive wall motion from cycle to cycle contribute to the cause of the anomalous loss. A commonly used equation for estimating the anomalous loss under sinusoidal flux is written as, (Bertotti, 1998),

$$P_a = 8.8\sqrt{\sigma G S V_o}\left(\hat{B} f\right)^{3/2} \tag{3}$$

where σ is the conductivity, S is the cross-sectional area of the material, and G and V_o are parameters which are material and magnetization dependent. The numerical constant allows for waveform dependence of the expression (e.g., for a triangular waveform, it assumes a value of 8).

The components depicted in Figure 2 could be written in terms of energy loss per cycle as

$$P/f = C_0 + C_1 f + C_2 f^2 \tag{4}$$

where C_0, C_1, and C_2 are constant for a given flux density and frequency. Equation 4, of course, represents the loss variation of the components with frequency as shown in Figure 2. In nonoriented, low silicon alloys, at 50 Hz, the hysteresis loss accounts for 30–60% of the total loss, P_e accounts for 40–60%, and P_a accounts for 10–20% depending on the magnitude of flux density. In high-silicon materials, P_h becomes relatively higher. In grain-oriented materials, hysteresis loss drops from around 33 to 25%

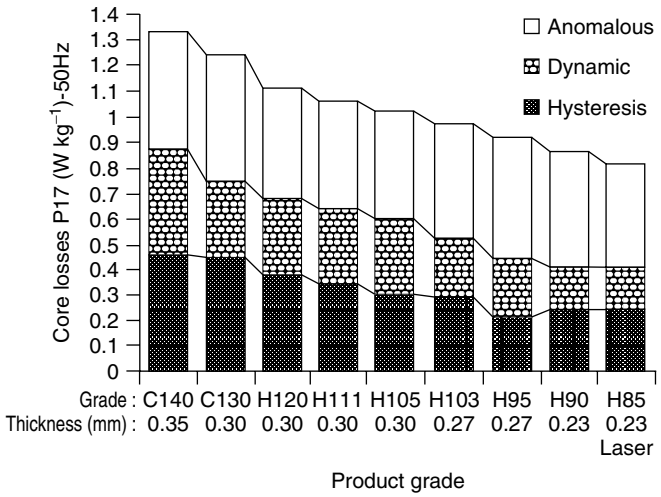

Figure 3. Evolution of best-grade commercial grain-oriented electrical steel. (Reproduced from S. Fortunati, with permission from TU Bergakademie Freiberg.)

of the total as the thickness is decreased from 0.35 to 0.23 mm, whereas the anomalous loss component increases from around 33 to 49%, although its absolute value only drops by about 10% as seen in Figure 3 (Fortunati, 2004).

3 FACTORS AFFECTING MAGNETIC PROPERTIES OF ELECTRICAL STEELS

Many factors affect the domain structure of electrical steel, which in turn controls the magnetic properties. In the previous section, it was pointed out that impurities, lamination thickness, composition, frequency, and peak flux density affect the loss components. In any engineering application, the iron loss in a magnetic core can be as much as 40% greater than that extrapolated from laboratory tests on laminations of the same grade of steel from which the core is assembled. This deterioration is defined and measured as the core *building factor* whose origin and importance is described elsewhere (Moses, 1984). In this section, effects of some of the parameters that directly affect the magnetic properties of the steel are briefly outlined.

3.1 Magnetizing flux density and frequency

The variation of loss with both flux density and frequency is well characterized under sinusoidal flux conditions and is well understood from the basic knowledge of domain activity. Equations (1–4) give a good indication of the parameters controlling the rate of increase of loss which occurs with increasing flux density or frequency. These equations cannot give quantitative values and are unreliable for prediction under extreme or complex magnetization conditions, so laboratory measurements of material loss characterization are needed for design and performance prediction of advanced machine cores. However, loss and permeability measurements on electrical steels magnetized at the increasingly higher frequencies and flux densities demanded by users requires complex, expensive equipment with skilled operators in order to obtain reproducible, reliable data.

3.2 Stress and temperature

Mechanical stress can have either a beneficial or an adverse effect on the properties of electrical steels (Moses and Phillips, 1978). Figure 4 shows the variation of loss and magnetostriction with stress at 50 Hz in grain-oriented steel when magnetized along its rolling direction at 1.5 T, 50 Hz. It

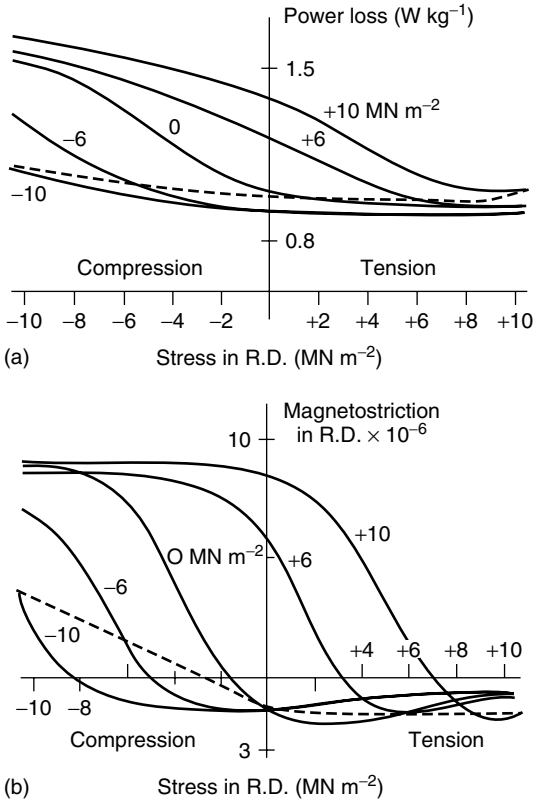

Figure 4. Variation of loss and magnetostriction with stress applied along the rolling direction of grain-oriented electrical steel. (Reproduced from A.J. Moses *et al*., 1978, with permission from IEEE. © 1978.)

should be noted that the magnetostriction, that is, the change of dimensions of the steel, which occurs with change of magnetization, is an important parameter in some applications, because it is the primary cause of acoustic noise output from static electrical equipment. Tension and compression indicated on the graph refers to stress applied along the rolling direction with different values of transverse stress simultaneously applied. For example, when no transverse stress is present (the curve labeled 0 on graph), both magnetostriction and power loss rise rapidly with compressive stress applied along the rolling direction, whereas tensile stress applied along the same direction has comparatively little effect. The characteristics change significantly when transverse stress is simultaneously applied. For example, a high transverse compressive stress of −10 MPa considerably reduces the sensitivity of loss and magnetostriction to longitudinal compression, whereas a transverse tensile stress makes the magnetic properties far worse.

The presence of mechanical stress introduces magnetoelastic energy into the material, and domains are redistributed even in the demagnetized state to minimize the free magnetic energy again. Domains in electrical steel tend to line up in ⟨100⟩ directions closest to a tensile stress direction or furthest from a compressive stress direction which is the reason for the large detrimental effect of compressive stress or the small effect of tensile stress applied along the magnetizing direction seen in Figure 4.

Because of the complex domain structure and the random nature of building stress in magnetic cores, it is impossible to calculate the effect of stress on the magnitude of loss, permeability, or magnetostriction. The results in Figure 4 also indicate that it is over simplistic and even misleading to say that compressive stress will seriously degrade the magnetic properties of grain-oriented material. Although this is often the case in practice, the importance of stress direction and whether it is unidirectional or not should be noted in any practical core assembly.

The coating applied to the surface of grain-oriented steel reduces the sensitivity of the magnetic properties to compressive stress (Moses, Pegler and Thompson, 1972). High permeability steel has lower stress sensitivity partly because of the specially chosen *high-stress coating*. The coating-induced stress in grain-oriented material effectively causes the stress sensitivity curves of the type shown in Figure 4 to shift to the right due to a large tensile component along the rolling direction. These stress sensitivity characteristics can be qualitatively estimated from the predicted reorganization of the magnetic domain structure, which occurs to minimize the total free energy in response to the introduction of the induced magnetoelastic energy. The magnitude of the magnetoelastic energy relative to other magnetic free energy sources determines the form and the nature of stress sensitivity under any given magnetization conditions. In theory, the magnetoelastic energy depends on the magnitude of the stress, its direction relative to ⟨100⟩ directions of individual grains and the magnitude of the saturation magnetostriction constants (λ_{100} and λ_{111}). These constants change with composition in such a way that the stress sensitivity of loss and magnetostriction drops with increasing silicon content to a minimum at around 6.5% (weight) silicon.

Magnetic properties such as loss, permeability, and magnetostriction of electrical steel are temperature sensitive to varying degrees (Nakaoka *et al*., 2005). Saturation magnetization drops with increasing temperature until it reaches zero at the Curie point, which varies with silicon content and is 770 °C in alloy-free iron. The domain structure which determines the magnetic properties is partly established according to the magnitudes of the magnetocrystalline anisotropy constants, electrical resistivity, and magnetostriction constants, all of which are temperature sensitive (Chen, 1958).

The losses drop by a few percent as the temperature rises from ambient to 100 °C (Bullingham, 1971), but the permeability also falls (Jenkins, 2004). In grain-oriented material, the effectiveness of the stress-inducing coating drops with increasing temperature, so the stress sensitivity of loss, magnetostriction, and permeability will increase. If the temperature is reduced below ambient, the magnetic properties do not change, but reports suggest that at cryogenic temperatures the losses increase significantly (Nakata *et al*., 1992). This is possibly due to microstructural changes, which particularly affect the hysteresis.

3.3 Losses under distorted magnetization

Both nonoriented and grain-oriented electrical steels are being used in increasing quantities in applications where they are magnetized under nonsinusoidal flux conditions. Harmonic components in the flux density waveform increase the losses considerably. The loss, P_{d}, occurring under such conditions can be analyzed as a Fourier sum of contributions from each set of flux density and field harmonic component present as

$$P_{\mathrm{d}} = \pi n f \sum_{n=1}^{\infty} \hat{B}_n \hat{H}_n \sin \phi_n \tag{5}$$

where $\hat{B}_{\mathrm{n}}$ and $\hat{H}_{\mathrm{n}}$ are the peak values of the nth harmonic components of flux density and field respectively, and ϕ_{n} is the time phase angle between corresponding harmonics of the b and h waveforms. This inherent frequency dependence of the harmonic losses indicates the advantage of high-resistivity, thin-gauge material when flux distortion is present.

In typical transformer and rotating machine applications, flux distortion can be responsible for half of the additional core losses included in the machine building factor or around 10–20% of the total core loss depending on geometry, assembly, and nominal flux density.

The more widespread use of electronically generated voltage sources to excite rotating machines in variable-speed drive systems is of increasing interest and importance. For example, in *pulse width modulation (PWM)* drive systems, machine core losses can increase by 50% or more because of the very high order harmonics present (Boglietti, Ferraris, Lazzari and Profumo, 1991). Figure 5 shows the influence of material thickness and silicon content on losses under PWM conditions in nonoriented steels (Moses and Leicht, 2005). The harmful effect of reducing the waveform modulation index from 1.0 to 0.5 shown in Figure 5 is important in variable-speed drive systems where such a range is often used in practice. The beneficial influence of using thinner-gauge or higher-resistivity steel can also be appreciated.

3.4 Rotational losses

Magnetization commonly rotates in the plane of parts of laminations assembled in electrical machine cores and is claimed to increase stator losses in some cases by up to 25% (Werner, 1991). The process, commonly referred to as *rotational* or $2-D$ magnetization, has been known and studied for many years (Moses, 1992b). It is rare for any part of a machine core to be magnetized under *pure rotational flux*, which we define as a magnetization condition when the flux density vector, B_r, at a point in a lamination is constant in magnitude and rotates at constant speed, ω. The rotational loss, P_r, can be written as

$$P_r = \frac{1}{T}\int_o^T \left\{ h_x \frac{db_x}{dt} + h_y \frac{db_y}{dt} \right\} dt \qquad (6)$$

where T is the magnetization period, h_x and h_y, db_x/dt and db_y/dt are orthogonal components of instantaneous tangential component of surface field and spatial rates of change of flux density, respectively. Figure 6 shows typical variation of rotational loss with flux density in grain-oriented and nonoriented silicon steels compared to characteristics under sinusoidal, unidirectional flux density along the rolling direction (Zurek, 2005). The rotational loss of the nonoriented steel is seen to be up to three times higher than that under the same magnitude of unidirectional (ac) flux. The difference for the grain-oriented material is far less but still significant. In general, it is found that the ratio of rotational loss to ac loss becomes higher as material texture or anisotropy increases (Arabi and Moses, 1984). The reduction of rotational loss at high flux density occurs because of fewer and fewer domain walls existing as the material approaches saturation.

Rotational losses can be analyzed in terms of hysteresis, eddy current, and excess loss components in order to study the influence of factors such as grain size, thickness, composition, and so on, which generally play very similar roles as under ac conditions. Likewise, the effect of flux harmonics, stress, and temperature on P_r follows similar trends as with unidirectional magnetization. Domain observations (Ledingham, Broadbent and Radley, 1989) demonstrate that rotational magnetization is very complex compared to unidirectional processes. It should be noted that the magnetization process is quite different under ac magnetization compared to rotational conditions, so care must be taken if attempting to infer or predict rotational loss from the value under unidirectional magnetization. Indeed, materials with

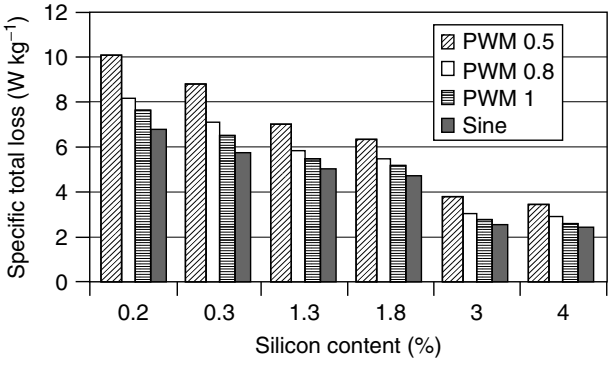

Figure 5. Effect of thickness and silicon content of nonoriented electrical steel on losses under PWM conditions at 1.5 T (peak) and 50 Hz (first harmonic). (Reproduced from Moses *et al*., 2005, with permission from the American Institute of Physics. © 2005.)

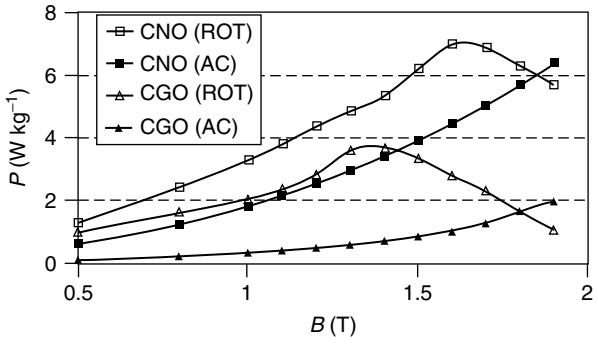

Figure 6. Variation of rotational loss (ROT) with flux density in nonoriented (CNO) and grain-oriented (CGO) electrical steel and comparison with corresponding ac losses (AC) when magnetized along rolling directions.

the 'best' magnetic properties under unidirectional magnetization need not necessarily be better than others under rotational conditions.

It is debatable whether it would be more useful for engineering applications to characterize materials under a *pure rotational field* as the reference magnetization condition than *pure rotating flux density* as is generally the case today. The research community is striving to characterize materials at very high flux densities but there are questions over the practical relevance to normal machine applications where rotational levels are generally far lower (Moses, 2004a).

3.5 High-silicon steels

Addition of silicon to steel is attractive as it increases electrical resistivity, hence reducing the eddy current losses; it reduces magnetostriction to around zero at 6.5% Si, hence tending to reduce acoustic noise of machines; it reduces the sensitivity to mechanical stress and reduces the magnetocrystalline anisotropy, hence improving the usability of the steel. However, these benefits have to be weighed up against the disadvantages of lower saturation magnetization and permeability, and most important, as far as production and operation are concerned, increased brittleness, which makes the material very difficult to manufacture and process.

Various processes have been tried over the years to produce steel containing up to around 6.5% silicon (Moses, 1992a). The method that was eventually commercialized in 1993 involves adding silicon to strips already containing around 3% silicon to increase the content to 6.5% by a chemical vapor diffusion process (Takada, Abe, Masuda and Inagaki, 1988). Here, combining the beneficial effects of silicon addition with thinner gauge (around 0.1 mm) gives low core loss at 6.5% silicon in a sufficiently ductile, nonoriented product. A comparison between flux density produced by a 50 Hz, 800 A m^{-1} field (B8), magnetostriction, and losses at various flux density/frequency combinations is shown in Table 1. Typical data for Mn–Zn ferrite and iron-based amorphous materials are included for comparison. Under some magnetizing conditions, the high-silicon alloy is seen to have the lowest core loss, but for any particular application many other factors must of course be taken into account when selecting a material.

Another attraction of high-alloy electrical steel is the possibility of creating a resistivity gradient through the thickness of the sheet by controlling the concentration of silicon or the additional alloying element. This phenomenon has been demonstrated and quantified in the laboratory using several techniques, for example, diffusion from silicon-bearing coatings (Moses and Thursby, 1983). Even under sinusoidal flux conditions, it is claimed that concentration gradients can lead to loss reductions of 50% or more (Barros Lorenzo, Ros-Yanez, De Wulf and Houbaert, 2004). High-silicon steel with controlled silicon gradient is today commercially produced using the CVD process by JFE in Japan, and large scale development to produce similar material by a hot dipping process is well advanced in Europe (Houbaert, 2004).

A further potential advantage of the material with a silicon concentration gradient is the anticipated improved performance under PWM conditions. PWM magnetizing waveforms contain low magnitude, but very high frequency harmonics. For example, a typical waveform might comprise a dominant 50 Hz component with a modulation index of 15 giving flux harmonics around 35 and 15% of the fundamental, clustered around frequencies of 1.5 and 3.0 kHz, respectively. These high-harmonic components, although small in magnitude, produce additional close-to-surface eddy currents, which, in theory, can be reduced by the presence of a resistivity gradient where the resistivity is highest at the surface. This effect has been demonstrated in the laboratory where the relative increase in loss under PWM conditions compared to sinusoidal magnetization has been found to be lower in material with a resistivity gradient. The relative effect depends on the annealing conditions which control the gradient profile (Anayi, Moses and Jenkins, 2003).

High-silicon steels are finding niche markets in high-frequency applications up to around 20 kHz, in cores subjected to distorted flux where losses or acoustic noise in conventional electrical steel may become excessive. If the material is to be used to its full technical potential as an important component in energy saving systems, development of the expensive and complex siliconizing processes is necessary to ensure that consistently uniform magnetic and mechanical properties are achieved.

4 OPTIMIZATION OF MAGNETIC PROPERTIES

The losses and permeability of the best grades of electrical steels have improved considerably over the last decades as, for example, shown in Figure 7 (Gunther, Abbruzzese, Fortunati and Ligi, 2005). Much of the improvement has been incremental and apart from achieving greater product consistency, it is possible that there is little scope for further improvement of the CGO materials (Jenkins, 2004).

A major challenge with nonoriented steels has been to simultaneously optimize losses and permeability in the same material. Generally speaking, low alloy content and small grain size are necessary to achieve high permeability, whereas low loss is normally achieved in steel with high alloy content and large grain size.

Table 1. Comparison of magnetic properties of typical core materials for medium-frequency power applications.

				Core loss (W kg^{-1}) at given B/f combination					
Material	Thickness (mm)	B8 (T)	Magnetostriction n ($\times 10^{-7}$) (1 T/400 Hz)	1 T, 50 Hz	1 T, 400 Hz	0.1 T, 10 kHz	0.05 T, 20 kHz	0.2 T, 5 kHz	Maximum permeability
6.5% Si–Fe (nonoriented)	0.10	1.25	0.1	0.7	7.3	9.7	9.1	12	18 000
	0.30	1.30	0.1	0.5	10	24.5	18	25.5	25 000
3% Si–Fe (nonoriented)	0.10	1.47	7.8	0.8	8.6	13.3	–	16.5	12 500
	0.35	1.50	7.8	0.7	14.4	33	30	38	18 000
3% Si–Fe (grain oriented)	0.10	1.85	−0.5	0.7	7.2	18	13.2	19.5	24 000
	0.35	1.93	−0.5	0.4	12.3	46	48.5	49	94 000
Amorphous (Fe–B) ribbon	0.03	1.38	27	0.13	1.5	4	3.8	4	300 000
Ferrite (Mn–Zn)	n/a	0.37	21	–	–	–	3	3	12 000

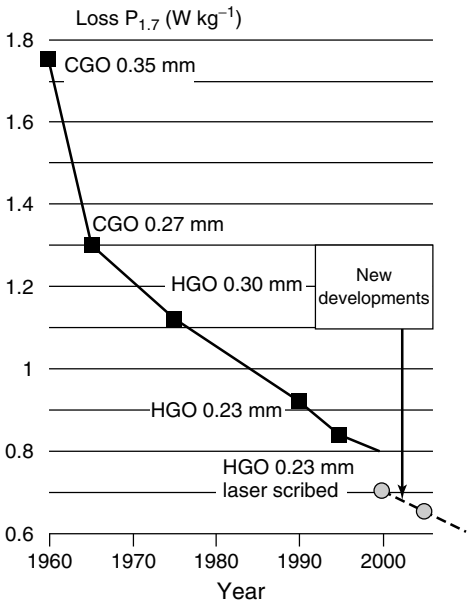

Figure 7. Recent improvements in grain-oriented electrical steels. (Reproduced from K. Gunther *et al*., 2005, with permission from Verlag Stahleisen GmbH. © 2005.)

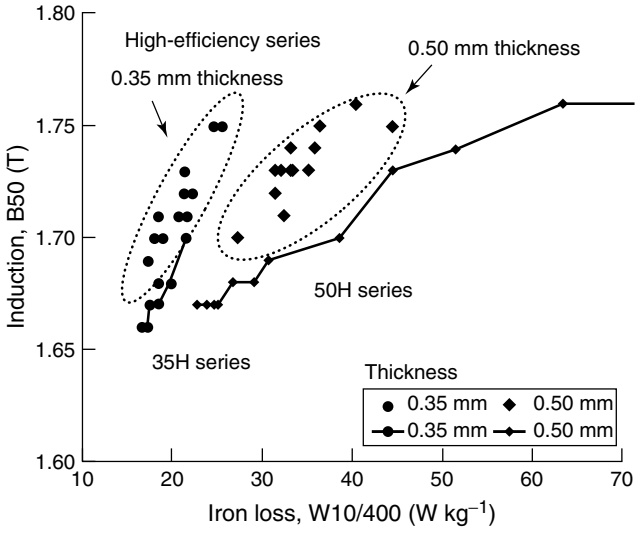

Figure 8. Magnetic properties of high efficiency, nonoriented silicon steels. (Reproduced from T. Kubota, 2005, with permission from Verlag Stahleisen GmbH, Düsseldorf, Germany. © 2005.)

Figure 8 illustrates a typical set of characteristics of commercial nonoriented steels which have been developed to have high permeability and low loss in the same products. The steel makers have achieved this by greater texture control made possible with the advent of cleaner steel produced with the aid of improved desulfurization, decarburization, and vacuum degassing (Kubota, 2005). Such findings have led to it now becoming well established that texture control for enhancement of magnetic properties is as important in nonoriented steels as in grain-oriented steels.

Reduction of thickness is an option to reduce eddy currents, and technology has already been established for commercial production of grain-oriented material, 0.1 mm thick. This usually involves rerolling strips from a thicker gauge, which, combined with other necessary extra processing, makes the material cost effective only for special applications. It is quite feasible to produce nonoriented steel even thinner but cost becomes a more major component, so it is normally restricted to high alloy grades. It is well known that for a given composition, there is an optimum thickness and optimum average grain size that gives minimum loss. The optimum condition is related to the ratio of eddy current loss to hysteresis loss. However the optimum condition depends on the form of magnetization, for example, it will vary with peak flux density, frequency, and harmonic content of the flux waveform.

The challenge of competition at power frequency from iron-based amorphous ribbon was one reason for the trend to the development of thinner grades of electrical steel. Figure 9 (Kubota, Fujikura and Ushigami, 2000) shows how the move to thinner steels, in this case 0.23–0.15 mm, can be combined with other advances to develop thin grade material whose magnetic properties can potentially surpass those of iron-based amorphous materials. Domain refining is combined with large grains to reduce hysteresis loss. Reduced density

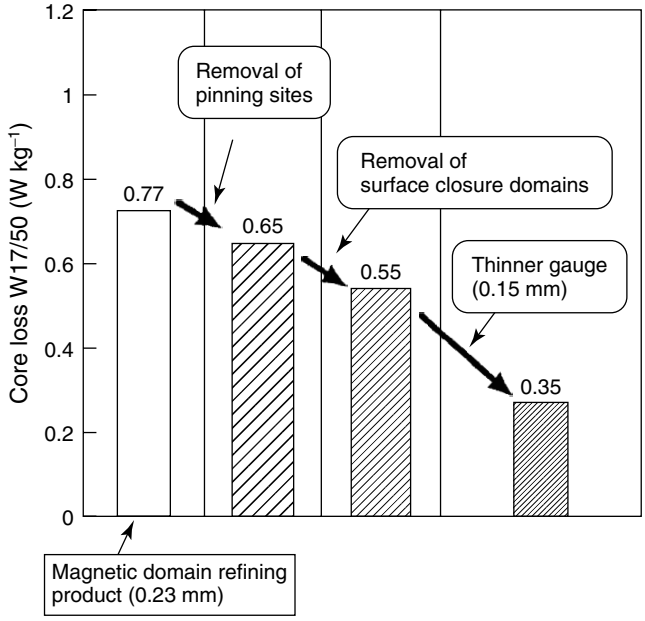

Figure 9. Future prospects for low loss grain-oriented silicon steel. (Reproduced from Kubota *et al*., 2000, with permission from Elsevier. © 2000.)

of defects in cleaner steels leads to removal of pinning sites and consequently lower hysteresis loss. Removal of surface closure domains by surface treatment has a similar effect. The reduced thickness itself reduces the eddy current component of loss.

In contrast to the focus on thickness reduction, there are incentives for assessing the possibility of developing thick materials which are attractive to core manufacturers because of benefits in core handling and assembly. If various major technical challenges in the production process can be overcome, it may be feasible, by appropriate processing, to increase the permeability of thick material without experiencing the anticipated increase in loss (Fortunati, 2004).

Another area where there is scope for development of grain-oriented steels is improvement in the complex interface between the coating and the steel. So-called surface pinning of domain walls, for example, which is believed to increase eddy current losses by 20% or more, is very much influenced by the nature of this interface. The influence of the disturbed layer close to the surface becomes proportionately more important as its thickness relative to the sheet thickness decreases. This is probably the reason why the anomalous loss shown in Figure 2 becomes a more significant contribution in thin-gauge material. There is scope for modification of the surface topology and the coating on grain-oriented steel to attempt to reduce their contribution to the anomalous loss. The steel surface needs to be as smooth as possible and near-surface oxidation should be minimal to cut down surface domain wall pinning or drag.

A further opportunity lies with the development of glassless coatings for grain-oriented steel (Ushigami, Nakayama, Arai and Kubota, 2004). These would remove many close-to-surface magnetic problems completely, as well as improve the mechanical punching quality. In the case of domain-refined steels, there is scope for better scribing by laser or other surface treatment.

4.1 Recent developments

Development of electrical steels is market driven. The main technological driving forces are to reduce losses and lower magnetostriction. All manufacturers are striving to improve the production process of both nonoriented and grain-oriented steels. It is now possible, with the availability of cleaner steels, to improve texture control, even of nonoriented steels, using elements other than silicon or aluminum. For example, manganese or tin additions can result in high permeability combined with low losses. This approach would enable the steel manufacturer to produce other combinations of desirable properties for specific applications such as low loss and very high mechanical strength (Kubota, 2005). This builds on comprehensive work carried out in the 1960s on a wide composition range of single crystals of mainly iron-based alloys to identify optimum combinations of resistivity and magnetic saturation (Foley *et al*., 1970). Today's better steel production technology does enable this prior knowledge to be exploited.

An ongoing problem in producing grain-oriented steel is that improved texture is associated with larger grain size implying higher losses without the aid of stress-inducing coatings. However, it is now becoming more feasible to reduce grain size while maintaining good orientation. One recent attempt is to introduce chromium to reduce power loss but at the expense of reduced saturation and permeability (Huppi, 1996).

An area of great interest is the introduction of *low slab reheat* in the production process for grain-oriented material (Fortunati, 2004). This route is compact and time saving, and offers the opportunity to develop new thin or thick products with a sharp Goss texture. Normal practice requires a very high slab temperature prior to hot rolling to allow the formation of precipitates essential in the Goss secondary recrystallization process. Not only is the high-temperature process energy demanding but it can also cause other technical problems (Jenkins, 2004; Gunther, Abbruzzese, Fortunati and Ligi, 2005).

A process that would significantly reduce manufacturing cost of all electrical steels is *thin strip casting*. If casting direclty from the melt to hot rolling thickness is successfully implemented, it will result in an enhanced produce with the extra benefit of the complete elimination of the high costs of continuous casting, slab reheating, and hot rolling (Gunther, Abbruzzese, Fortunati and Ligi, 2005).

Another major achievement to aim for in the production of grain-oriented steel is the replacement of the high-temperature box anneal, in which the secondary recrystallization process occurs, by a continuous annealing process. The continuous process has been demonstrated on the laboratory scale as being technically feasible and is claimed to have many benefits making it, together with strip casting, the most innovative route for future generations of grain-oriented steel products (Fortunati, 2004).

Major advances in coating technology for nonoriented steels have been made over the last few years (Lindenmo, Coombs and Snell, 2000). These have mainly been in the areas of the use of more environmentally suitable materials, better uniformity of coating composition and thickness, as well as improved punching and welding characteristics. Combined, these not only improve the basic magnetic properties of the steel but also the building factors of machine cores.

Although not directly a material property, it should be noted that different grades of fully processed, nonoriented

material have different sensitivities to deterioration of magnetic properties during material processing by the core builder, which in some applications needs to be offset against the magnetic benefits high alloy content brings (Schoppa, Schneider and Wuppermann, 2000).

5 LOSS PREDICTION

Several approaches have been developed in attempts to predict losses of electrical steel laminations magnetized uniformly at a known sinusoidal flux density under ideal laboratory conditions. The present status of some methods for predicting losses in electrical steel laminations is summarized in this section. To consider the even greater challenge of predicting losses of assembled electrical machine cores rather than sheets or strips of material under ideal conditions, factors such as localized magnetization, stress, and temperature need to be taken into account. These are described elsewhere (Moses, 2004b).

Most methods of predicting losses of laminations under given magnetizing conditions depend on knowledge of dc $B-H$ characteristics, conductivity, and thickness of the material. In order to quantify the frequency dependence of the loss, at least one value of loss at a given flux density and magnetizing frequency is needed as a reference condition. It is only possible to predict losses empirically because of the complex material-structural factors, which determine the magnitude of the hysteresis component of loss, in particular.

A widely used approach is a statistical theory of domain wall displacement based on a concept of *magnetic objects* whose activity, together with the db/dt variation in a lamination, is used in the loss prediction (Bertotti, 1988). The *magnetic objects* are defined as regions of one or more domain walls that move in a correlated fashion during ac magnetization. The energy loss, P_p, predicted under sinusoidal magnetization using this approach can be written as

$$P_\mathrm{p} = K_\mathrm{h}\hat{B}f + \frac{\pi^2}{6}\sigma d^2(\hat{B}f)^2 + 8.8\sqrt{\sigma GSV_\mathrm{o}}\left(\hat{B}f\right)^{3/2} \quad (7)$$

This is closely related to equations (1–3). The first term represents the hysteresis, where the loss per cycle is assumed to be independent of frequency. The second term is calculated from Maxwell's equations assuming homogeneous, isotropic, linear material. The third term is calculated from the *Bertotti–Fiorillo* model using a dynamic Preisach approach which simulates the excess loss by a finite switching rate of hypothetical magnetic dipoles (Bertotti, 1988). Measured or known values of loss at two frequencies are needed to calculate the terms V_o and K_h for a given material and magnetizing conditions. The term G is a geometrical factor introduced in the theory related to the eddy current density around moving domain walls (Bertotti, 1998).

The same approach can be used to predict loss under non-sinusoidal conditions provided the skin effect is negligible (Fiorillo and Novikov, 1990). A further refinement enables the same concept to be used to develop a general equation to represent losses under highly distorted flux conditions such as those occurring in devices operated under *PWM* excitation without reference to loss under sinusoidal magnetization. However, again the method neglects the skin effect and the influence of minor $B-H$ loops which may occur under distorted flux waveforms, so the range of application is restricted (Kaczmarek, Amar and Protat, 1996). The loss under such distorted flux can be written as

$$P_\mathrm{d} = K_\mathrm{h}\hat{B}f + \frac{2\sigma d^2\left(\hat{B}\right)^2}{3m\Sigma\tau} + 4\sqrt{\frac{2\sigma SGV_\mathrm{o}}{m\sqrt{\Sigma\tau}}}\left(\hat{B}\right)^{3/2} \quad (8)$$

where S is the cross-sectional area of the lamination, m is its density, τ is a wave-shape-dependent constant, and G and V_o are the material-dependent parameters that can be calculated from measurement of loss under two sine wave magnetization conditions.

It is claimed that the loss separation and analysis using the concept of *magnetic objects* is a natural and general consequence of the magnetization process (Fiorillo, 2004). The approach apparently gives a good measure of relative differences in loss versus frequency characteristics of various materials, but use as a tool for loss prediction over the wide range of magnetization conditions experienced in machine cores needs to be fully demonstrated. Also, some doubt in the approach exists because of the question over the validity of the assumption of constant hysteresis loss per cycle (Ban, 1998).

Another approach is to obtain a voltage-driven solution of the diffusion equation using a history-dependent hysteresis model (Zirka, Moroz, Marketos and Moses, 2002). A transplantation method is used together with a model for simulation of excess loss from the Landau–Lifshitz–Gilbert equations for magnetic viscosity. Apart from the material thickness and conductivity, the only other necessary input data is a family of first-order dc $B-H$ reversal curves and one reference value of loss at a given frequency and peak flux density, for example, 1.5 T, 50 Hz. A novel feature is the use of a parameter enabling accurate reproduction of the frequency dependence of the excess loss. The model is claimed to include constants which can be directly related to the material microstructure and it is claimed to predict losses in nonoriented and grain-oriented material to within 2% of the measured values (Marketos, Moroz, Moses and Zirka, 2002).

A similar approach based on the viscosity principle is to use a dynamic hysteresis model together with a 2-D magnetic potential finite element formulation. This models static $B-H$ loops, traditional eddy currents, and anomalous loss. It has been used to predict the $B-H$ trajectory and hence the losses for an electrical steel lamination with PWM excitation. Good agreement with experimental results has been claimed (Leonard, Marketos, Moses and Lu, 2006).

Other methods are based on predicting loss at a given flux density, magnetizing frequency, and waveform from prior measurements taken over a specified range of magnetizing conditions on Epstein strips, single sheets, or wound toroidal cores. Artificial neural networks have been used for this purpose to predict loss or permeability of toroids wound from grain-oriented steel with uncertainty typically less than 5% over a wide magnetization range (Moses and Leicht, 2004). This approach would be of maximum utility if it were combined with a method to go a stage further and predict localized losses in machine cores. It does require a large amount of training data over a wide range of magnetization conditions, compositions, and thicknesses to make it of any real practical use.

A recently developed *mathematical approach* is based on linear relationships found experimentally between loss measured under sinusoidal flux density and that under PWM waveforms with a given total harmonic distortion (THD) at the same fundamental frequency (Moses and Leicht, 2005). Again, as with neural network approaches, a series of measurement data under sinusoidal flux conditions is necessary as a starting point. However, the formation of the polynomial linear equations linking loss under PWM conditions to that under more readily accessible sinusoidal conditions for a given material composition and thickness avoids the need to produce data under the complex waveforms.

6 IRON POWDER CORE MATERIAL

There is an increasing interest in SMC materials because of the demand for miniaturization of cores for power electronic applications. For very high-frequency operation, ferrite cores are the main option based on cost and performance in spite of their low saturation magnetization and permeability. However for dc, and increasingly medium frequency, operation, there is growing use of cores formed by compacting iron, silicon iron, and other iron alloy powders. The compositions of commercial composite cores are essentially similar to those of common conventional bulk materials but each has a broader range of potential applications due to the possibility of true 3-D electromagnetic design and higher frequency operation than is feasible using even thin laminations.

Grain size, sintering temperature, and the degree of porosity need to be carefully controlled in order to optimize structure-sensitive properties such as maximum permeability and low coercive force. The dc magnetic properties of hot-pressed, high-purity, atomized iron powder compacts can be as good as or better that those of conventional high-purity iron (Moyer, McDermott, Topolski and Kearney, 1980). Such sintered products are not normally suitable for *ac applications* since eddy currents will normally be excessive. However for *dc applications,* the careful control of sintering conditions, in particular, leads to products with high permeability and low coercivity which could satisfy growing demands for tighter specifications and complex core shapes for electromagnetic actuators for use in transport and industrial sectors (Taylor, Mingard and Bell, 1998).

During the 1990s, advances in powder production and powder metallurgy, in general, drew more attention to magnetic powder cores suitable for *ac applications* because of their potential for use in novel 3-D topologies for electrical rotating machines offering performance or cost advantage over conventional laminated cores. Magnetic powder parts, today, are produced from high-purity powder particles each covered by insulating organic or inorganic coatings, which cause a barrier to global eddy current paths under ac magnetization. The coated powder particles, typically of 0.1-mm diameter, are mixed with less than 1% volume of binding material prior to conventional compaction into near-final-shape components. This is followed by low temperature (typically 150 °C) curing to cross-link the resin binder and produce high mechanical strength. The binding material acts as a lubricant in the pressing process and increases the mechanical strength of the composite core. Often a final anneal at 300–500 °C is carried out to develop the best combination of strength and magnetic properties. Such materials are referred to as *soft magnetic composites* or sometimes, although misleadingly, *bonded iron cores.*

The insulating coating on the powder particles in SMCs eliminates particle-to-particle eddy current paths hence minimizing eddy current losses, but it reduces the permeability and to a small extent the saturation magnetization. Internal stress caused by particle deformation during compaction is the main cause of dominant hysteresis loss in SMCs but a subsequent anneal can reduce this. Care is needed in compaction and annealing to avoid breaking down the particle coatings, otherwise eddy current loss increases.

The choice of the alloying element controls the resistivity of the individual powder particles, hence the local eddy current loss. Low resistivity material is used for dc applications but alloys with inherent high resistivity are needed to minimize eddy current loss for high-frequency operation. Permeability and coercivity are structure sensitive and

depend on factors such as powder size and shape, porosity, purity, and internal stress just as for sintered materials. Generally the permeability of a bulk SMC can be expressed as (Yanagimoto, Majima, Sunada and Aikawa, 2004)

$$\mu \propto \frac{B_s^n}{aK + b\sigma\lambda} \tag{9}$$

where B_s is the saturation induction, λ is the magnetostriction, K is an anisotropy factor, σ is the internal stress; a, b, and n are constants whose values depend on the material. The internal compaction stress in metallic powder cores is much higher than in ferrites and tends to dominate over the anisotropy. Fine powder can lead to composites with constant permeability/frequency characteristics and lower loss at high frequency than course powder, but the course powder composites generally have higher permeability and saturation induction.

Powder shape and size affects the final magnetic properties of an SMC and many combinations have been tried. One interesting approach for making high-performance SMCs has been demonstrated using anisotropic properties of elongated particles pressed by a conventional powder metallurgical process. The particles, up to over 5 mm long, are either coated or uncoated for ac and dc use, respectively (Bularzik, Krause and Kokal, 1998). Figure 10 shows the variation of core loss with flux density and frequency of such coated powder compacts compared with that of phosphorus- and silicon-bearing steel laminations. Figure 10(a) shows that even at 60 Hz, where the eddy current loss of the powder core is only 5% of the total compared to 50% in nonsilicon steel, the material could be efficient in power frequency applications such as PWM systems where high harmonic flux is present. The low eddy current loss of the powder core makes its high-frequency loss lower than that of the high-silicon material as can be seen in Figure 10(b). The loss characteristics do depend on the particle size and the ratio of their length to width/thickness as well as on the material density, which in turn depends on the thickness of the insulating coating. As with most SMCs, the compact needs to be annealed to reduce the high hysteresis loss caused by pressing-induced strain within particles without thermally breaking down the particle coating. The material, although apparently technically feasible, has not been produced commercially.

Figure 11 shows the variation of loss with frequency in other types of annealed and unannealed SMCs compared to that of a pure iron grade 1018 lamination with the same loss at 0.5 T, 50 Hz (Persson, Jansson, Jack and Mecrow, 1995). At magnetizing frequencies higher than 300 Hz, the loss of the laminated steel exceeds that of the SMCs. In general, SMCs are competitive in performance with laminated steels in the frequency range from 50 Hz to 100 kHz. In another

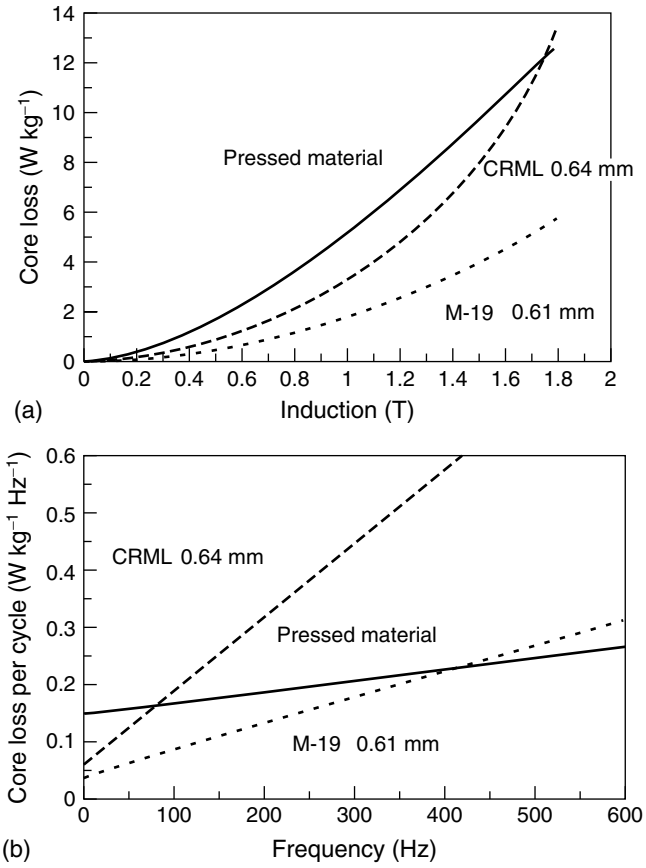

Figure 10. Loss variation with flux density (a) and frequency (b) of pressed iron powder material compared to that of phosphorous (CRML) and silicon (M-19) bearing steels at 60 Hz. (Reproduced from J.H. Bularzik *et al*., 1998, with permission from EDP Sciences. © 1998.)

example, it is quoted that the loss of coated iron powder composites is normally significantly higher than that of electrical steel at magnetizing frequencies up to around 1 kHz, but in the range 10–100 kHz it is considerably less (Goldman, 1995). Unfortunately, the permeability is not high at any magnetizing frequency and more development is needed to overcome this problem if the material is to make an impact in a wider range of electrical machine applications (Persson, Jansson, Jack and Mecrow, 1995).

Table 2 compares dc $B-H$ data of two iron SMCs from different sources with lamination materials (West, 1998). This illustrates the much larger permeability of conventional steel compared with that of the SMCs, and shows that the difference does drop at high flux density. Table 3 compares losses of similar materials with that of a higher-specification nonoriented steel over a wide frequency and flux density range (West, 1998). For the 'degraded' lamination, the performance data includes an allowance to estimate the degradation of the lamination properties when built into a

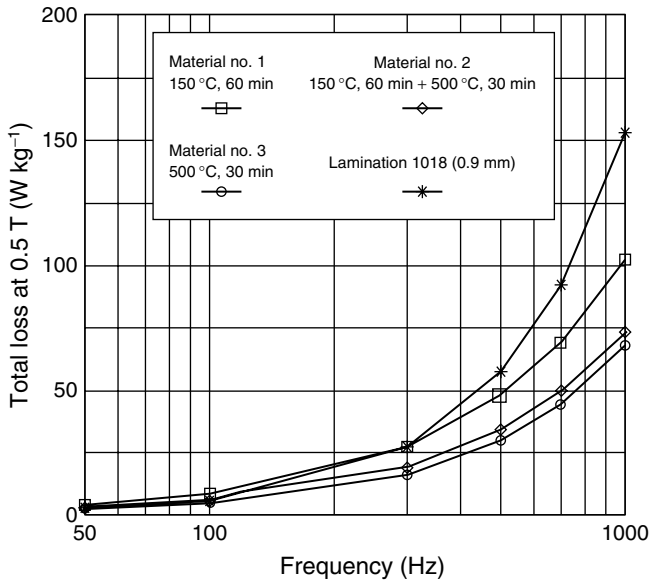

Figure 11. Comparison of losses of insulated powder and laminated steel. (Reproduced from M. Persson *et al*., 1995, with permission from IEE Publishing. © 1995.)

Table 2. Comparison of dc fields (A m^{-1}) to produce given flux density in SMC powder cores with those of typical electrical steel laminations.

Flux density	1 T	1.5 T	1.75 T	2 T

Accucore	1.4	4.8	10.7	n/a
Typical laminations	0.1	0.4	5	n/a

core due to punching shorts and rotational loss. It is perhaps more practicable to use these 'degraded' lamination figures rather than ideal laboratory data when comparing lamination performance with that of SMCs. At 400 Hz, the loss of one SMC is comparable with that of the high-grade lamination.

It can be appreciated from this snapshot comparison of permeability and losses that if SMCs are to compete with laminations in electrical machine applications, their 3-D properties must be exploited, since magnetic characteristics of laminations at low to medium frequency are generally better. Hence, the main advantage of such powder parts is the possibility for machine designers to fully exploit 3-D flux paths in machine topologies aimed at producing cores with unique electromagnetic properties combined with low material and manufacturing costs, good dimensional tolerances, and satisfactory temperature stability (Jansson, Persson, Jack and Mecrow, 1996). The magnetic and thermal properties are claimed to be isotropic and therefore very suitable for such 3-D topologies (Jansson and Persson, 1998).

Figure 12 shows an example where the 3-D versatility of the SMC is used in the design of a complex three phase claw pole, brushless motor incorporating permanent magnet material together with the SMC to optimize a complex, magnetically efficient, flux path where use of laminations would be impracticable (Viarouge, 2004).

It is interesting to note that the acoustic noise output of powder cores can be less than that of equivalent laminated assemblies (Cros, Perin and Viarouge, 2002). Another potential advantage of SMCs is that an integrated approach to the design of electrical machine core and windings can be taken to facilitate manufacturing as well as to increase the scope for novel topologies due to thermal as well as electromagnetic options. End-of-life recycling also becomes more convenient as it is easier to separate copper and iron powder parts when an SMC is used. It is important when comparing the effectiveness of SMC cores with that of a conventional lamination assembly, for any machine core application, that full use is made of the novel features and opportunities offered by SMC parts, which would not be realized fully by direct substitution of one for another.

Loss predictions in powder cores should be made with due regard to the very different structure compared to electrical steels, in particular, the 3-D nature of the materials, which makes equation 2 invalid and the eddy current path in the material more complex. A monotonic decrease of resistivity

with annealing temperature and variation of eddy currents with core size has been postulated to be due to the breakdown of surface insulation (Saito, Takemoto and Iriyama, 2005). It is assumed that two kinds of eddy currents are present as illustrated in Figure 13: firstly, circulating within the individual insulated particles and secondly, circulating around clusters of particles.

Any model for predicting the ac magnetic properties of SMCs must take account of the frequency dependent skin depth and the two eddy current mechanisms referred to earlier. Until now, no empirical approach has been reported which will take these accounts into effect. To make consistently accurate predictions of losses in SMC cores over a wide magnetizing range, models capable of accounting for core shape and size dependence of eddy current loss in complex geometries will be needed. It has not been necessary for these to be included in the development of models for predicting losses in thin laminations because of their 2-D nature.

One approach to loss prediction in SMCs assumes losses can be separated into hysteresis and eddy current components. The eddy current loss is separately calculated by finite element analysis (FEA) for a homogeneous isotropic core with known resistivity and combined with a Steinmetz model which estimates the basic hysteresis component (Nord, Pennander and Jack, 2004). Unexplained size dependence of eddy current loss was observed in the eddy current simulation, which might be related to the micro and macro eddy current paths being followed simultaneously at some frequencies. The FEA approach does lead to close agreement between measured and predicted results but the calculations depend on fitting arbitrary material constants into the expression for the hysteresis component, so the physical basis of the approach is not clear.

1 INTRODUCTION

Binary and ternary intermetallic compounds between rare-earth (RE) elements, such as samarium (Sm) and neodymium (Nd) with transition metals (TMs), like cobalt (Co) and/or iron (Fe), and with boron (B) have become the basis for a wide spectrum of RE permanent-magnet materials. A large number of phases have been synthesized, exhibiting different stoichiometries and a variety of crystal structure types since the 1970s. In many cases, their physical properties turned out to be of the high technical importance and these compounds are manufactured on an industrial scale. The Sm–Co phases, which also show a variety of crystal structure types, have been studied for more than 40 years and have recently become of interest for the high-temperature permanent-magnet applications. Belonging to another family of phases, which has been intensively studied for more than 20 years, are the $RE_2TM_{14}B$ (Herbst, 1991) and $RETM_{12-x}X_x$ with X = Ti, V, Si (Buschow, 1988).

The unique magnetic properties of the RE series from lanthanum to lutetium plus yttrium result from the incomplete filling of the 4f shell. The 4f orbitals are rather compact and well localized on the atom and there are both spin and orbital contributions to the magnetic moment. The orbital moment leads to the behavior of uniaxial magnetocrystalline anisotropy, which is indispensable for the development of magnetic hysteresis. Magnetic interactions between the localized 4f electrons are weak and the RE metals themselves have low Curie temperatures. By combining them with one of the ferromagnetic 3d elements where the magnetic 3d electrons occupy the outermost orbitals of the atom and interact strongly, it is possible to combine the advantages of 4f and 3d magnetism. The particular RE element needed for uniaxial anisotropy is determined by the symmetry of the site it occupies in the crystal structure. High-performance magnets are based on compounds of the magnetic light RE (Pr, Nd, Sm) for anisotropy and a 3d TM element (Co, Fe) for high magnetization and high Curie temperature. The most promising phases are $SmCo_5$, $Sm_2(Co,Fe)_{17}$, $Nd_2Fe_{14}B$ and $Sm_2Fe_{17}N_3$.

Up to now a large number of RE–TM intermetallic compounds are known and have been investigated intensively by many authors. The complex interactions of the 3d and 4f electrons lead to a wide range of intermetallics with different stoichiometries and variable RE elements that modify the magnetic properties of the 3d TM and 4f RE elements. Basic concepts related to the intrinsic magnetic properties of the 3d-rich RE–TM intermetallic compounds are summarized

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

in various review articles (Franse and Radwanski, 1993; Buschow, 1986). Buschow (1977) surveys the physical properties, composition, and crystal structure of intermetallic compounds formed between RE elements and 3d transition elements. Apart from binary compounds the results of pseudobinary series are also considered. The magnetic properties determined by the exchange interactions involving 4f as well as 3d electrons, are discussed together with experimental results available on magnetovolume effects and various resonance techniques such as nuclear magnetic resonance (NMR) and the Mössbauer effect.

However, the excellent intrinsic properties, such as large magnetocrystalline uniaxial anisotropy, high saturation magnetization and Curie temperature are not the only prerequisite for high-quality permanent magnets. The coercive field, remanence and maximum energy product depend also sensitively on microstructural properties such as grain size, particle shape, grain boundary type, and the distribution of secondary phases. Magnetic and microscopic investigations of permanent magnets show that microstructural features affect the magnetic properties of permanent magnets in a characteristic manner (Fidler, Knoch, Kronmueller and Schneider, 1989; Rabenberg, Fidler and Bernardi, 1992; Hirosawa and Tsubokawa, 1990; Khlopkov *et al*., 2004; Gutfleisch *et al*., 2006; Kronmüller, Durst and Sagawa, 1988). In addition to these experimental studies, the theoretical treatment of microstructural effects is beneficial for the improvement of permanent magnets. The theoretical background for the study of magnetization processes in ferromagnetic materials is the continuum theory of micromagnetics (Brown, 1963, 1978). Micromagnetic calculations show that microstructural effects considerably deteriorate the coercive field of single hard magnetic particles and grains (Schrefl, Schmidts, Fidler and Kronmuller, 1993; Kronmüller, 1987; Kronmüller and Schrefl, 1994; Schmidts and Kronmüller, 1991). Besides the magnetic behavior of the individual particles and grains also the intergrain interactions determine the magnetic properties of nucleation-controlled hard magnetic materials (Martinek and Kronmueller, 1990; Pastushenkov, Forkl and Kronmueller, 1991; Fukunaga and Inoue, 1992). Static computational micromagnetics of demagnetization processes in nanoscaled permanent magnets (Fischer and Kronmüller, 1996) quantitatively predicts experimental results (Manaf, Buckley and Davies, 1993). The expansion and pinning behavior of magnetic domains strongly depends on the intrinsic properties of the various phases and precipitates in the multiphase magnets, such as in the $Sm(Co,Cu)_5/Sm_2(CoFe)_{17}$-type magnets (Goll, Kronmuller and Stadelmaier, 2004; Streibl, Fidler and Schrefl, 2000; Scholz *et al*., 2003; Hadjipanayis *et al*., 2000).

A combination of the intrinsic properties of the material, such as saturation polarization J_s, magnetic exchange, and magnetocrystalline anisotropy of various phases and the influence of the microstructure on the magnetization reversal process governs the hysteresis properties of the magnets. The intergranular structure between the grains plays a significant role determining the magnetic properties, thus a detailed understanding of the microstructure and grain boundaries is necessary. The microstructural features directly influence magnetic domain structures, which are a result of the occurrence of magnetic stray fields. The direct observation of microstructure and magnetic domain structure leads to a deeper insight of the reasons for coercivity of RE magnets. Advanced analytical methods, such as high-resolution electron microscopy, force microscopy, position sensitive 3D-atom probe and other techniques have been used to study RE magnets. Modeling of magnetic materials is performed at various levels and becomes more important as computer power is improved. Nowadays, numerical 3D-micromagnetic simulations of the magnetization reversal process incorporate realistic microstructures. Advanced analytical investigations and future simulations should be able to predict optimal microstructures and properties for given hard and soft magnetic materials (Fidler and Schrefl, 2000). Special emphasis of the present review is laid on the discussion of the extrinsic magnetic hysteresis properties that are related to the microstructure of the various types of RE permanent magnets. The crystal structures of the most important RE–Co and RE–TM–B compounds as basis for permanent magnets are described in Chapter 2 "Crystal structures and magnetic properties of RE-Co intermetallics" and Chapter 3 "Crystal structures and magnetic properties of RE-TM-B intermetallics", whereas Chapter 4 "Microstructure and coercivity of rare-earth permanent magnets", describes the role of microstructure on the hysteresis properties, such as coercive field and energy density product of Sm–Co and Nd–Fe–B-based permanent magnets.

2 CRYSTAL STRUCTURES AND MAGNETIC PROPERTIES OF RE–Co INTERMETALLICS

The large values of coercivities of RE–Co and RE–(Co,Fe)–B intermetallics derive from the uniaxial magnetocrystalline anisotropy. The RE atoms provide most of the magnetocrystalline anisotropy, while the magnetization arises principally from the TM sublattice. Investigations of magnetization and anisotropies of promising candidates for permanent-magnet materials by Strnat and coworkers led to the discovery of large magnetocrystalline anisotropies of $RECo_5$ compounds with the hexagonal $CaCu_5$ crystal structure (Hoffer and Strnat, 1966, 1967; Strnat *et al*., 1967). For

these compounds in which the 4f shell has a nonzero orbital magnetic moment, theoretical analyses demonstrated that the behavior of the RE ion under the combined influence of the exchange and crystalline electric field controls the easy magnetization direction and accounts for much of the large uniaxial anisotropy (Buschow, van Diepen and de Wijn, 1974; Sankar *et al*., 1975; Hummler and Faehnle, 1996)

The metallic phases present in the Sm–Co-based permanent magnets are all derivative of the binary intermetallic phases appearing in the Sm–Co binary phase diagram. For the understanding of the metallurgical behavior and the magnetic properties of these magnets, it is therefore essential to understand the alloying behavior and crystal structure of the compounds appearing in the Sm–Co binary system. The difference between the atomic radii of the Sm atom (0.1994 nm) and the Co atom (0.1383 nm) precludes, according to the Hume–Rothery rules (Cahn, 1996) any significant solid solubility between the two types of atoms. This results in the appearance of a series of intermetallic compounds in the binary phase diagram for different ratios of the Sm–Co concentrations. The phases that are important for Sm–Co-type magnets appear in the region of high Co concentration. The Sm–Co_5 phase occurs at 83.3 at% of Co and Sm_2Co_{17} phase occurs at 89.5 at% of Co. The Co-rich side of the Sm–Co binary phase diagram shows that both phases, $SmCo_5$ and Sm_2Co_{17}, exhibit no solubility at room temperature although some solubility region can be observed at higher temperature above 800 °C (Strnat, 1988; Buschow and van der Goot, 1968). Besides this fact also the Sm_2Co_7 phase has to be taken into account in the preparation of single-phase $SmCo_5$ alloys. The homogeneity range for $SmCo_5$ phase at 1200–1300 °C has been reported to exist between about 14.5 and 17 at% of Sm (Buschow and van der Goot, 1968). Almost no solubility of excess Sm exists in the $SmCo_5$ phase even at higher temperature. In the case of the Sm_2Co_{17} phase a homogeneity range is obtained toward an excess of Sm at higher temperature, while almost no solubility of excess Co can be observed at any temperature. This behavior is explained in terms of the crystallographic structure considerations for both phases.

Several other RE–TM lattices are derived from $RETM_5$ by judicious replacement of RE and TM atoms (Buschow, 1971). These include the $RETM_2$ (cubic Laves phase; $MgCu_2$-type) structure formed by the extremely magnetostrictive compounds (Clark, 1993), the $RETM_3$ (rhombohedral; $PuNi_3$-type) structure, the $RETM_{12}$ (tetragonal; $ThMn_{12}$-type) structure characterizing a class of magnetically anisotropic materials such as $REFe_{10}TM_2$ (de Boer, Ying-Kai, de Mooij and Buschow, 1987; de Mooij and Buschow, 1988) and the rhombohedral RE_2TM_{17} (Th_2Zn_{17}-type) structure. Representatives of the rhombohedral RE_2TM_{17} class include the hard-magnet compound Sm_2Co_{17} including the interstitial nitride phase $Sm_2Fe_{17}N_3$ exhibiting a large high Curie temperature ($T_C \approx 750$ K), a large room-temperature magnetization, and uniaxial anisotropy (Coey and Sun, 1990).

According to the binary Sm–Co phase diagram six ordered intermetallic compounds: $SmCo_2$, $SmCo_3$, Sm_2Co_7, Sm_5Co_{19}, $SmCo_5$, Sm_2Co_{17} appear in the composition range 67–89 at% Co: (Massalski, 1990). The crystal structure of the binary Sm–Co phases are summarized in Table 1. The Sm_2Co_7 and $SmCo_5$ exist as hexagonal structures with the $P6_3/mmc$ and the $P6/mmm$ space group symmetries, respectively. The Sm_2Co_{17} phase occurs in two modifications, as the rhombohedral structure ($R\bar{3}m$ symmetry) and the hexagonal structure ($P6/mmc$ symmetry).

Other RE elements form also isomorphic structures of type $CaCu_5$. This $RECo_5$ structure is formed by the two types of layers one formed solely of Co atoms and another mixed layer formed by RE and Co. This layer stacks in a hexagonal sequence giving a unit cell as shown in Figure 1.

The $RECo_5$ structure of $CaCu_5$ is a result of an ordered substitution of Co atoms by RE atoms in the hexagonal close-packed (hcp) Co structure (Khan, 1973). Hexagonal close-packed structures are formed by the alternate stacking of layers in two different positions ABABAB. . .. By replacing three Co atoms, which form an almost equilateral triangle, by an RE atom the $RECo_5$ structure is formed. This transformation is described by

$$\begin{aligned} 3\mathrm{Co(B)} + 5\mathrm{Co(A)} \quad &\Rightarrow \quad 2\mathrm{Co(B)} + 3\mathrm{Co(A)} + \mathrm{RE(A)} \\ &\quad -1\mathrm{Co(B)} \\ &\quad -2\mathrm{Co(A)} \\ &\quad +1\mathrm{RE(A)} \\ \equiv \mathrm{RECo_5} \end{aligned} \tag{1}$$

As a result of this substitution the interlayer distance diminishes with respect to the pure hcp structure. The change of the interlayer distance is explained by the different atomic radii of the various RE elements. The normal shrinkage with increasing atomic number inside the series is found, corresponding to a smaller radio of the involved RE atom. This explains the different tendency of the various RE atoms to form disordered stacking sequences and leading to planar stacking faults and twin boundaries.

The crystal structures from the $SmCo_2$- until the $SmCo_5$-phase are closely related with each other and are based on a regular stacking of two kinds of layers, one is a layer of $SmCo_2$-Laves phase structure and the other is that of $SmCo_5$. For compounds between $RETM_5$ and TM, a fully ordered structure is derived from the 1:5 compound by replacing some RE atoms with TM-atom pairs. The two-index formula for the expected compositions was derived by Stadelmaier (1984):

$$\mathrm{RE}_{m-n}\mathrm{TM}_{5m+2}$$

where m is the number of $RETM_5$ units making up the new structure, and n is the total number of RE atoms being replaced.

From the technical point of view only compounds with a Curie temperature exceeding 400 °C are of interest. From the possible Sm–Co binaries, this is only fulfilled for Sm_2Co_7, Sm_5Co_{19}, $SmCo_5$ and Sm_2Co_{17} (Strnat, 1988). In view of their richer cobalt content and, hence, higher magnetization the RE_2Co_{17} compounds were also heavily investigated as hard-magnet materials. The light RE members of the series have the rhombohedral Th_2Zn_{17} structure, which is closely related to the $CaCu_5$ structure. In contrast to the $RECo_5$ series, the cobalt sublattice in the RE_2Co_{17} phases is characterized by basal plane rather than uniaxial anisotropy, and the total anisotropy is lower (Radwanski, Franse and Sinnema, 1985). The size difference between the Sm and Co atoms makes the solubility of additional Sm in this structure difficult. Pairs of Co atoms, on the other hand, can substitute Sm in the $SmCo_5$ structure to some extent. The substitution of Sm atoms occurs when pairs of Co atoms forming dumbbells replace the Sm position. When Sm atoms are randomly substituted by Co pairs, a disordered Co-rich phase sometimes referred as an $SmCo_7$ structure of type $TbCu_7$ ($P6/mmm$) is formed (Khan, 1973). When 22% of the Sm atoms have been substituted by Co pairs, the $TbCu_7$ structure becomes unstable and a phase separation occurs into the two nearest phases, $SmCo_5$ and Sm_2Co_{17} structures.

The Sm_2Co_{17} in its two modifications is the result of the ordered substitution of 1/3 of the Sm by two Co atoms lying above and below the former Sm position (Figure 2). If the stacking for the mixed planes follows an ABABA. . . hexagonal sequence, the Th_2Ni_{17} structure is formed. If the stacking follows an ABCABC. . . sequence, the Th_2Zn_{17}

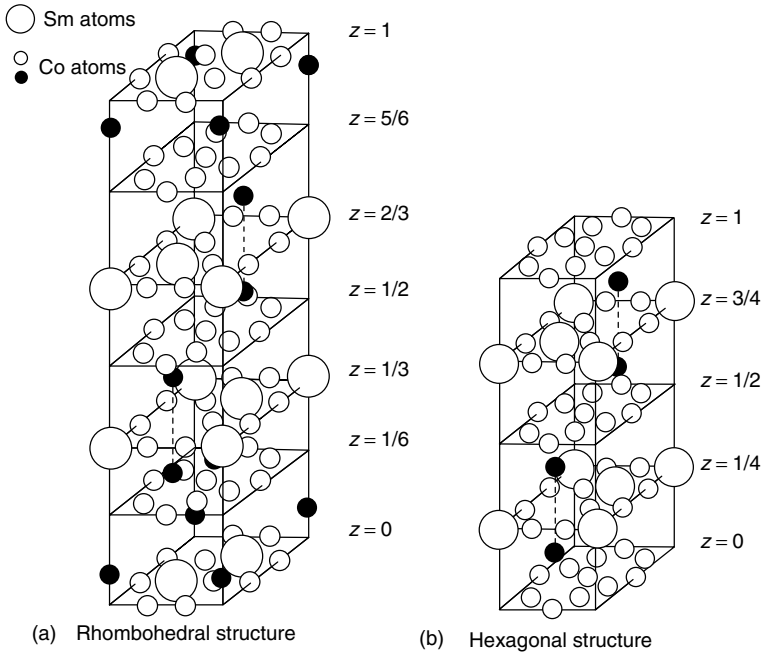

Figure 2. Sm_2Co_{17} structures. (a) rhombohedral, hR19, Th_2Zn_{17}structure type, $a = 0.8395\,\text{nm}$, $c = 1.2216\,\text{nm}$, $R\bar{3}m$ and (b) hexagonal, hP38,Th_2Ni_{17} structure type, $a = 0.8360\,\text{nm}$, $c = 0.8515\,\text{nm}$, $P6_3/mmc$.

structure is formed (Figure 3). In order to compare the structures $SmCo_5$, $SmCo_7$, Sm_2Co_{17}-R and Sm_2Co_{17}-H, the lattice parameters of each structure is related to each other according (Figure 4).

$$c_{1:5} = c_{1:7} = \frac{1}{3}c_{2:17\text{R}} = \frac{1}{2}c_{2:17\text{H}} \tag{2}$$

$$a_{1:5} = a_{1:7} = \frac{1}{\sqrt{3}}a_{2:17\text{R}} = \frac{1}{\sqrt{3}}a_{2:17\text{H}} \tag{3}$$

With the random substitution of Sm atoms by Co pairs a linear increase of the c parameter is found while the a parameter reduces slightly (Khan, 1973). In the $RECo_5$, structure the RE atoms give the main contribution to the valence electron density. As more Sm atoms are substituted by Co pairs the number of valence electrons reduces, while the reduced volume of the cell increases. The order transformation that leads to the Sm_2Co_{17} structure can be viewed as result of the better packing obtained by the Sm_2Co_{17} structure compared to the corresponding disordered $TbCu_7$-type structure.

The occurrence of a particular stacking sequence determines the stable phase at room temperature in the SmCo-magnets and therefore has important significance on the magnetic properties of the magnet. It has been found by Khan (1973) and Ray (1986) that in the Sm–Co binary phase diagram, Sm_2Co_{17} hexagonal Th_2Ni_{17} does not really occur even at high temperatures and instead a $TbCu_7$ disordered structure is formed.

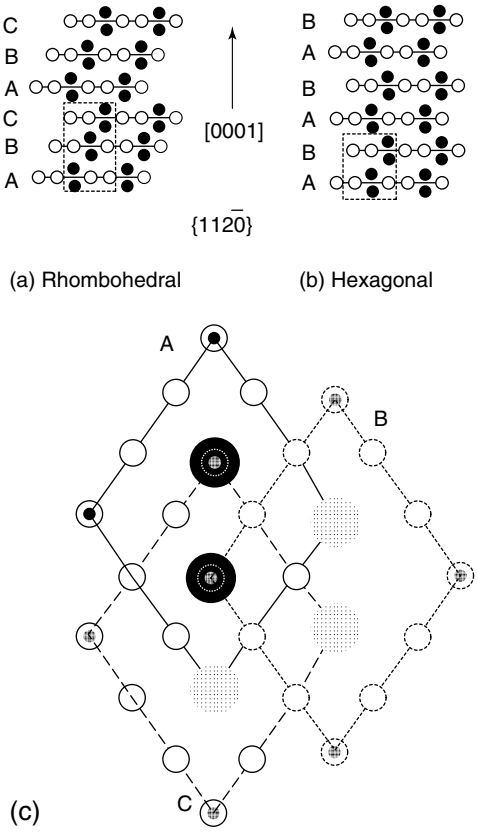

Figure 3. Stacking sequences for the (a) Th_2Zn_{17} type structure, (b) Th_2Ni_{17} structure. (c) A view along the c direction showing the different stacking positions.

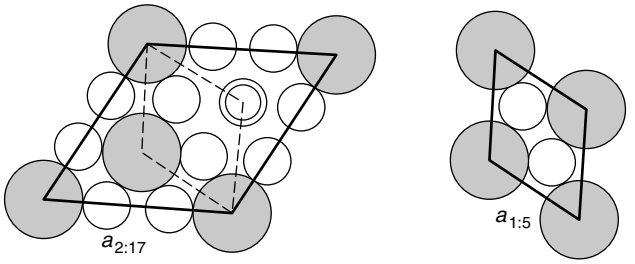

Figure 4. Basal plane of the unit cells of $SmCo_5$ and the Sm_2Co_{17} crystal structures.

The occurrence of a particular stacking sequence in a layer structure is explained in terms of energetic differences between two stacking configurations. Blandin, Friedel and Saada (1966) have shown that long-range oscillatory forces occur in metallic crystals that are related to the valence electron density. For a closed-packed structure, the different modifications only differ in the order of stacking of identical layers. This allows considering only the energy difference between closed-packed layers in different stacking environments. The difference between the energies should be enough to determine the stable stacking sequence.

Any mistake in the stacking sequence of an otherwise perfect ordered Sm_2Co_{17} layer structure will lead to a stacking fault and changes the crystallographic dependent properties around the fault. In Sm_2Co_{17}-R structure, the stacking planes are the (0001)-basal planes. When one layer of the basic structural unit is missing from the normal sequence, an intrinsic stacking fault is formed as shown in Figure 5. From the stacking fraction, the intrinsic stacking fault leads to the appearance of a hexagonal sequence of one unit cell height running as a platelet with normal parallel to the *c* axis. If instead of a missing layer, the stacking fault originates from the addition of one layer of the basic structural unit to the normal sequence, an extrinsic stacking fault is formed as shown Figure 6. In this case, the extrinsic stacking fault can lead to the formation of a hexagonal sequence running perpendicular to the c direction. Coherent twinning formed by a multiple shearing operation on the (0001) plane with the displacement vector $\frac{1}{3}\left[10\bar{1}0\right]$ also occurs, which leads to a hexagonal platelet (Figure 7).

Efforts to improve the magnetic properties of the Sm_2Co_{17} drove to the use of different substitutions for part of the Co and Sm in the magnet. To understand the effect of the substitutions in the magnetic properties of the magnet, an understanding of the anisotropy and magnetization mechanism of the Sm_2Co_{17} magnet is necessary. In $SmCo_5$ magnets the Co sublattice gives an important contribution to the total magnetic anisotropy, favoring the easy-axis anisotropy of the structure. In the case of Sm, the RE sublattice contributes significantly to the easy-axis anisotropy observed.

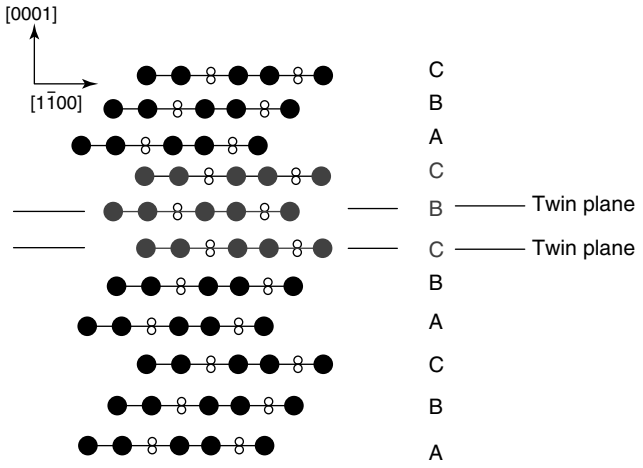

Figure 5. Intrinsic stacking fault formed by the missing of one A layer. It should be noted that, in this case, a hexagonal sequence CBC is formed with one unit cell height (Estevez-Rams, 1996).

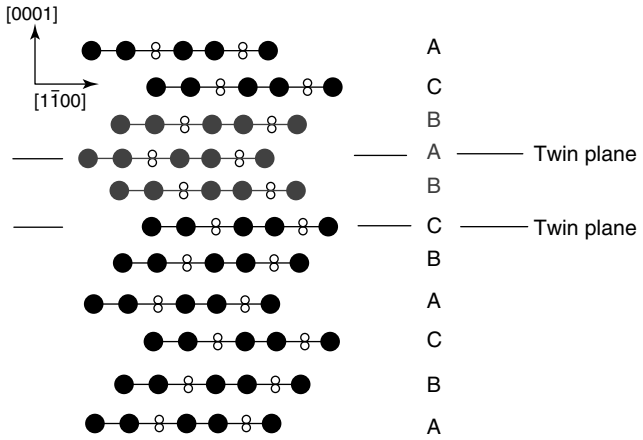

Figure 6. Extrinsic stacking fault formed by the addition of a B layer. In this case also a hexagonal stacking sequence BAB is formed (Estevez-Rams, 1996).

As temperature rises the Co contribution prevails since Sm sublattice contribution is rapidly diminished with temperature. The formation of the previously described dumbbells by substituting Sm by Co pairs, the easy-axis anisotropy decreases owing to the dumbbell contribution to easy plane anisotropy. The Sm sublattice is responsible for a strong contribution to the uniaxial anisotropy in Sm_2Co_{17} (Kumar, 1988).

Iron has been used to improve the saturation magnetization of the Sm_2Co_{17} magnets. One Fe atom is thought to preferentially substitute one Co at the dumbbell site (Perkins and Fischer, 1976; Nagamine, Rechenberg and Ray, 1990). The increased substitution of Co by iron results in a precipitation of a Co–Fe phase and in a loss of coercivity (Perry and Menth, 1975). It is also known that Sm_2Fe_{17} has an

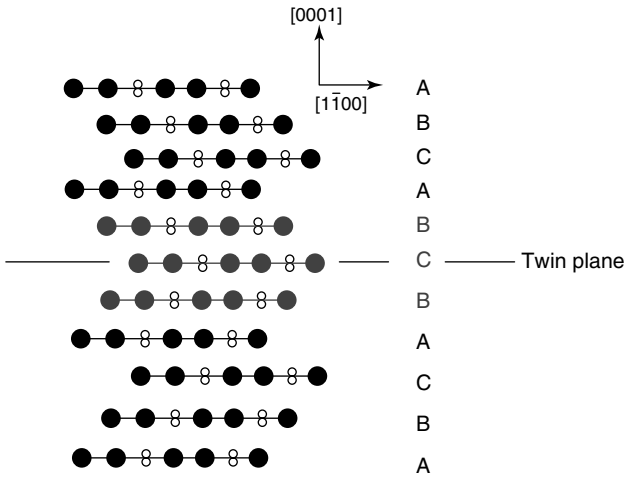

Figure 7. Coherent twinning formed by a mirror operation over a C layer. This defect also leads to a hexagonal sequence BCB (Estevez-Rams, 1996).

easy-plane anisotropy (Kumar, 1988). The Fe in the dumbbell site has a strong negative exchange interaction, which also causes a large expansion of the *c* axis with Fe content (Ray, 1986). The addition of a small amount of Zr has been found to favored a higher amount of Fe without the precipitation of the Co–Fe phase detrimental for the magnetic properties (Ojima, Tomizawa, Yoneyama and Hori, 1977). There is an on-going discussion about the exact behavior of Zr in the Sm_2Co_{17} magnets. Although it has been argued that Zr enters substituting the Sm, it is somehow accepted that Zr is substituting Co, but the exact Co position where Zr goes is still subject to discussion. Rabenberg *et al*. (1991) argues, based on extended X-ray-absorption fine-structure spectroscopy that Zr goes to the mixed plane substituting the 12j Co position. On the other hand, Ray has argued that in Fe-doped Sm_2Co_{17} magnets, Zr-vacancy pairs substitute the Fe–Fe dumbbells, based on size considerations (Ray, 1986) and in indirect evidence from Mössbauer spectroscopy (Nagamine, Rechenberg and Ray, 1990). Neutron and X-ray experiments directly support this idea showing a preference of Zr for the 6c dumbbell site (Ying-chang *et al*., 1985). Satyanarayana, Fujii and Wallace (1982) reported an alloy of $Sm_2Co_{17}Zr_1$ having the 2:17-H hexagonal modification with lattice parameters $a = 0.8558\,\text{nm}$ $c = 0.8123$ which corresponds to an interlayer distance of 0.2031 nm. This interlayer distance is below the same value for the rhombohedral structure in the Sm_2Co_{17}-R. The substitution of the Co–Co dumbbell site by a pair of Zr-vacancies will reduce the overall interlayer distance in spite of the larger size of the Zr atom compared with the Co one. The distance of the Co dumbbell from the mixed layer is influenced by the interaction between the Co pair. A Zr-vacancy pair will lie closer to the mixed plane and a smaller interlayer distance should be expected. From the analysis already made of the stability of the Sm_2Co_{17} hexagonal and rhombohedral modification, the diminishing of the interlayer distance could well explain the transformation from the rhombohedral to the hexagonal structure upon the addition of Zr. The influence of Zr in the valence electron concentration and the modification of the Fermi surface and band structure could also influence the observed behavior. In commercial Sm_2Co_{17}-type magnets, a platelet phase enriched in Zr appears upon a lengthily heat treatment precipitated inside the Sm_2Co_{17} rhombohedral matrix (Mishra *et al*., 1981). Fidler and Skalicky (1982) have indexed such phase as the hexagonal Sm_2Co_{17} structure with Zr substitution. This hexagonal structure agrees with the former analysis and appears as a result of the energetic favoring of the hexagonal stacking. The later being a result of the reduction of the interlayer distance with the substitution of the dumbbell site by Zr-vacancy pairs according to Ray proposal. Zr substitution also increases the anisotropy field (Satyanarayana, Fujii and Wallace, 1982), which is a further evidence that Zr could be substituting the Co dumbbell. The Co pair is responsible for favoring the easy plane anisotropy in the Sm_2Co_{17} structure (Kumar, 1988).

Cu improves the coercivity of the Sm_2Co_{17} magnets inducing the precipitation of a fine scale microstructure formed by cells of Sm_2Co_{17}-R surrounded by a $SmCo_5$ wall (Livingston and Martin, 1977). The improvement in coercivity is associated to a pinning mechanism on the cell walls (Nagel, 1979). Cu is considered to be completely soluble in $SmCo_5$ and an isostructural $SmCu_5$ is known (Nishida and Uehara, 1974; Katayama and Shibata, 1973). Others have reported a decomposition into two 1:5 structures (Hofer, 1970). Careful studies of the phase diagram for the ternary Sm–Co–Cu system were carried out by Perry (1977), who demonstrated that Cu stabilizes the $SmCo_5$ structure changing the peritectic line for the $SmCo_5$ to a eutectic one. He also found that Cu inhibits the appearance of Sm_2Co_{17} phases. Little solubility of Cu in this structure is also been shown. The destabilization of the Sm_2Co_{17} structures with Cu can be a result of the transformation of the band structure and valence electron density upon the addition of Cu in the Sm_2Co_{17} material. The binary phase diagram of Fe–Cu and Co–Cu shows little to no solubility of Cu in Co and Fe. The later, has been taken as indication that the atoms of Cu and Fe have a repulsive interaction.

Real Sm_2Co_{17} magnets are complex system formed by at least five components and with a complicated metallurgical behavior. Figure 8 shows a heavily faulted rhombohedral $Sm_2(Co,Fe)_{17}$ matrix phases. The magnetic properties of these magnets strongly depend on the composition and processing conditions of the alloy. Morita and coworkers

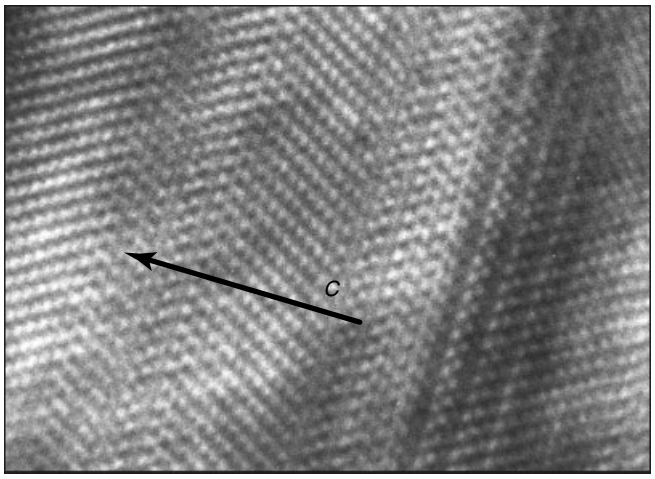

Figure 8. TEM images showing the heavily faulted regions within the rhombohedral $Sm_2(Co,Fe)_{17}$ matrix phase in a $Sm(Co,Fe,Cu,Zr)_{7.5}$ hard-magnet material.

have studied the $Sm(Co, Cu, Fe)_z$ and $Sm(Co, Cu, Fe, Zr)_z$ phase diagrams (Morita, Umeda and Kimura, 1987). According to their result, it is obvious that with the increase of Zr the homogeneity range of the Th_2Ni_{17} hexagonal structure increases. The extension of the homogeneity range for the 2:17 phase in both sides of the stoichiometry 10.5 at% Sm, while observing that with the increase of Sm, the Th_2Ni_{17} structure transforms to the disordered $TbCu_7$. At the solutionizing temperature the alloy is in a disordered $TbCu_7$ state. This state is a complex state retaining the $R\bar{3}m$ symmetry but with random occupation of dumbbell sites by TM pairs, Zr-vacancy pairs and excess Sm atoms. Such metastable state can be retained by a sufficiently quick cooling from the solutionizing temperature in order to avoid the segregation of more energetically favorable equilibrium phases upon cooling. The step aging allows the precipitation of a 1:5 cell boundary phase enriched in Cu, while precipitating a Zr-rich platelet phase believed to be a Th_2Ni_{17} hexagonal structure. The cell phase is a Sm_2Co_{17}-R, Th_2Zn_{17}, Fe enriched phase. The platelet phase and the cell boundary phase are believed to be formed cooperatively, acting the platelets as diffusion path for the Cu. The binary phase diagram shows no solubility of Co in Fe this indicates an unfavorable mixing enthalpy for both atoms and a repulsion interaction. We therefore believe that the platelet Th_2Ni_{17} phase where Fe dumbbell pairs are substituted by Zr-vacancy pairs can effectively act as diffusion path. The platelet cell c parameter was determined by Fidler, Skalicky and Rothwarf (1983) to be 0.8 nm. In the rhombohedral structure, were Fe–Fe pairs occupy the dumbbell site, the repulsive interaction between Fe atoms and Cu atoms impedes an effective diffusion of Cu.

3 CRYSTAL STRUCTURES AND MAGNETIC PROPERTIES OF RE–TM–B INTERMETALLICS

Besides the binary phases also ternary RE–TM intermetallic compounds are candidates for hard magnetic phases. Considerable technological interest has centered on $RE_2Fe_{14}B$ compounds because of their excellent intrinsic properties, such as saturation magnetization and magnetocrystalline anisotropy over Sm–Co materials. Practically magnets with energy products up to the $450\,kJ\,m^{-3}$ ($\approx 56,7$ MG Oe) range, have been prepared from melt-spun (Lee, Brewer and Schaffel, 1985; Croat, 1989) and sintered (Sagawa *et al*., 1987; Kaneko and Ishigaki, 1994; Rodewald, Wall, Katter and Uestuener, 2002) alloys. The spectrum of applications for Nd–Fe–B magnets continues to expand. On the scientific side, the existence of an entire $RE_2Fe_{14}B$ series has stimulated a great deal of research on their properties and the physics underlying those properties (Herbst, 1991).

The ternary Nd–Fe–B phase diagram was investigated by Schneider, Henig, Petzow and Stadelmaier (1986) following investigations of Stadelmaier, Elmasry, Liu and Cheng (1984) and Matsuura *et al*. (1985). The original nominal composition for the preparation of $Nd_2Fe_{14}B$-based sintered permanent magnet is $Nd_{15}Fe_{77}B_8$ (Sagawa *et al*., 1984a,c) which is richer in Nd than the stoichiometric composition of the hard magnetic phase $Nd_2Fe_{14}B$. This composition lies in the liquid plus $Nd_2Fe_{14}B$ plus $Nd_{1+\varepsilon}Fe_4B_4$ region. The crystal structure of $Nd_2Fe_{14}B$ is a tetragonal phase belonging to space group $P4_2/mnm$ with crystal parameters $a = 0.88$ nm and $c = 1.21$ nm whose crystallographic unit cell is shown in Figure 9 (Fuerst, Herbst and Alson, 1985; Herbst, Croat and Yelon, 1985). The excess of Nd in the starting material is provides the liquid Nd-rich phase at sintering temperature which enables the densification of the magnet by liquid phase sintering process. The phase forms an intergranular nonmagnetic phase during the cooling process, which magnetically decouples the $Nd_2Fe_{14}B$ grains. According the ternary phase diagram a third phase is formed which is $Nd_{1+\varepsilon}Fe_4B_4$($P4_2/ncm$, tP328, $a = 0.7117$ nm, $c = 3.507$ nm). This phase is detrimental to the hard magnetic properties of the magnet due to the further reduction of remanence and originating strong internal demagnetizing stray fields.

Comparable hard magnetic properties can be also obtained with $Pr_2Fe_{14}B$, but the Nd compound has received more attention as a magnet material, because it has higher saturation magnetization leading to higher remanence and energy density product. Table 2 compares the saturation magnetization J_s, anisotropy field H_A, easy direction of magnetocrystalline anisotropy and Curie temperature T_C of the $RE_2Fe_{14}B$

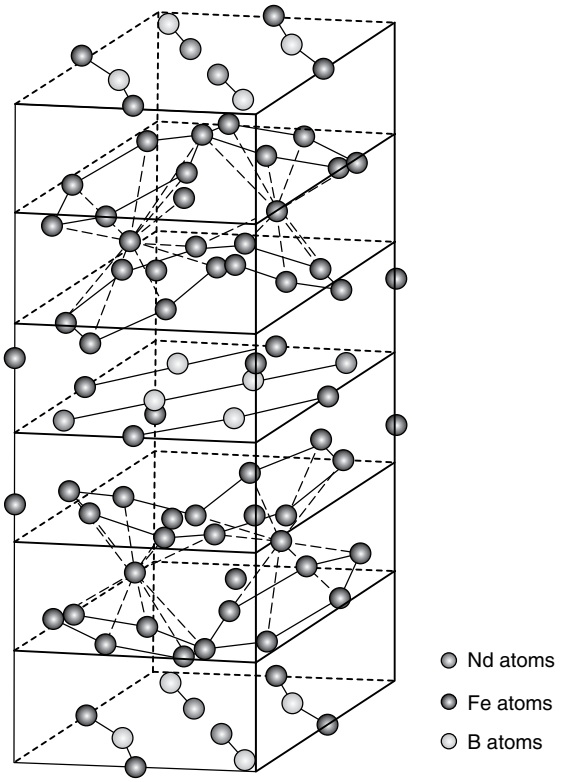

Figure 9. Crystal structure of the $Nd_2Fe_{14}B$ phase (tetragonal, $P4_2/mnm$ tP68).

Table 2. Intrinsic magnetic properties of $RE_2Fe_{14}B$-compounds at room temperature (Herbst, 1991).

Alloy	J_s(T)	H_A(kA m^{-1})	Anisotropy direction	T_c(K)
$La_2Fe_{14}B$	1.38	1600	[001]	530
$Ce_2Fe_{14}B$	1.17	2080	[001]	424
$Pr_2Fe_{14}B$	1.56	6000	[001]	565
$Nd_2Fe_{14}B$	1.60	5840	[001]	585
$Sm_2Fe_{14}B$	1.52	>12000	<100>	616
$Gd_2Fe_{14}B$	0.89	1920	[001]	661
$Tb_2Fe_{14}B$	0.70	17600	[001]	620
$Dy_2Fe_{14}B$	0.71	12000	[001]	598
$Ho_2Fe_{14}B$	0.81	6000	[001]	573
$Er_2Fe_{14}B$	0.90	640	<100>	554
$Tm_2Fe_{14}B$	1.15	640	<100>	541
$Yb_2Fe_{14}B$	1.20		[001]	524
$Lu_2Fe_{14}B$	1.17	2080	[001]	535
$Y_2Fe_{14}B$	1.41	2080	[001]	565
$Th_2Fe_{14}B$	1.41	2080	[001]	481

compounds (Herbst, 1991). It is obvious that all, except the Sm, Er, and Tm compounds show easy-axis anisotropy at room temperature.

In addition to the similarities with simpler TM-metalloid materials, many structural parallels exist between $RE_2Fe_{14}B$ and other RE–TM systems. Analogies with the hexagonal $CaCu_5$ structure characterizing the permanent-magnet compound $SmCo_5$ and a variety of other RE–TM phases include the hexagonal arrays of Fe atoms in $R_2Fe_{14}B$ are the cognates of the TM arrays in $RETM_5$. Both form hexagonal prisms enclosing the RE atoms. Givord, Li and Moreau (1984) have emphasized that the B and Fe sites of $RE_2Fe_{14}B$ correspond to the TM and RE sites, respectively, in $RETM_5$. Given the similarities of $RETM_5$ and $RE_2Fe_{14}B$ on the one hand and of $RETM_5$ and RE_2TM_{17} on the other, it is not surprising that many parallels exist between $RE_2Fe_{14}B$ and RE_2TM_{17}, especially the presence of hexagonal TM nets surrounding RE atoms in each structure.

The $RE_2Fe_{14}B$ structure has been found to form with yttrium, thorium, and all the rare-earth elements except europium and radioactive promethium (Herbst, 1991). Lattice parameter measurements show that the effect of the lanthanide contraction, the decrease in the radii of the trivalent lanthanide ions with increasing atomic number, is apparent in the decrease of the *c*lattice parameter through the RE (La–Lu) series. As the atomic number increases, the addition of another electron to the 4f shell does not completely screen the larger nuclear charge, and the radius of the RE ion contracts. The crystallographic work on $Nd_2Fe_{14}B$ and neutron studies indicate that the nuclear position parameters change minimally through the series. Only two families of $Nd_2Fe_{14}B$-type compounds are known in which Fe or B is totally replaced by another element, namely, $RE_2Co_{14}B$ (Buschow, van Noort and de Mooij, 1985) and $RE_2Fe_{14}C$ (de Boer *et al.*, 1988). Partial substitution of RE, Fe, or B with maintenance of the $RE_2Fe_{14}B$ structure is possible with many other elements, and $RE_2Fe_{14}BH_C$ and $RE_2Co_{14}BH_x$ interstitial hydride series exist (Cadogan and Coey, 1986; Gutfleisch and Harris, 1996).

4 MICROSTRUCTURE AND COERCIVITY OF RARE-EARTH PERMANENT MAGNETS

Magnetic materials and their applications have been known for many centuries. Nowadays permanent magnets are used in numerous domestic and professional appliances such as consumer electronics, computer peripherals, and telecommunications. The growing demand for miniaturization in modern technology requires the further development of permanent magnets. Smaller and stronger permanent magnets allow the construction of small devices by replacing electromagnets or less powerful permanent magnets.

The increase in applications of permanent magnets goes hand in hand with the discovery and development of progressively more powerful permanent magnets during this century. The most common figure of merit for the performance of a permanent magnet is the maximum energy density product $(BH)_{max}$, which is proportional to the magnetic field that is produced outside a unit volume of magnetic material. Thus $(BH)_{max}$ is a measure for the potential to reduce the size and weight of a magnetic device. The greater $(BH)_{max}$ the smaller the magnet to produce a field of a given value. The enormous reduction in the size of permanent magnets achieved owing to the discovery of new classes of materials that exhibit increasing $(BH)_{max}$ values. The resulting magnetic field in the air gap H_{ag} is direct proportional to the volume of the magnet V_m and the stored energy density product $(B_m \cdot H_m)$ and indirect proportional to the volume of the air gap V_{ag} according to

$$H_{ag} \approx \sqrt{\frac{V_m \cdot (B_m \cdot H_m)}{\mu_0 \cdot V_{ag}}} \tag{4}$$

A magnet should be shaped for the most efficient use in such a way that its operating point is close to the $(BH)_{max}$ point. It is evident that the increase of the energy density product reduces besides the volume also the weight of the permanent magnet-containing device, and new designs of static, such as charged beam guiding systems, and dynamic devices are possible.

Besides the Curie temperature, the energy density product, also the remanence that determines the maximum flux density within the air gap of a magnetic circuit and the coercive field are necessary to distinguish and describe different permanent-magnet materials. For practical applications also the temperature coefficients of the remanence and the coercive field are important parameters, which considerably vary in different types of magnets. The RE–intermetallic phases with a high uniaxial magnetocrystalline anisotropy, such as $SmCo_5$, Sm_2Co_{17} and $Nd_2Fe_{14}B$ are the basis for high-performance RE magnets (Strnat *et al*., 1967; Sagawa *et al*., 1984a; Croat, Herbst, Lee and Pinkerton, 1984b; Herbst, 1991). Sm–Co magnets exhibit the highest coercive fields ${}_JH_C$ and $Nd_2Fe_{14}B$-based magnets show the highest value of remanence B_r and energy density product $(BH)_{max}$, obtained so far. RE magnets are divided into the group of the so-called single-phase, nucleation-controlled magnets, based on the $SmCo_5$ or $Nd_2Fe_{14}B$ hard magnetic phases, and into the group of domain wall pinning controlled, multiphase magnets. Two-phase magnets, which are nowadays also used in high-temperature advanced power applications consist of a continuous $Sm(Co,Cu)_{5-7}$ cellular precipitation structure within a $Sm_2(Co,Fe)_{17}$ matrix phase. Nanocrystalline RE magnets exhibit microstructures of single-phase, two-phase, and multiphase character, in which the inhomogeneous magnetization behavior near the intergranular regions creates remanence enhancement. Table 3 compares the magnetocrystalline anisotropy K_1 and saturation polarization J_s together with the maximum theoretical energy density product $(BH)^{th}_{max}$ and Curie temperature of the most important RE–intermetallic compounds for hard magnets.

Table 3. Comparison of the magnetocrystalline anisotropy K_1, saturation polarization J_s, the maximum theoretical energy density product $(BH)^{th}_{max}$, and Curie temperature T_C of the most important rare-earth–intermetallic compounds for hard magnets.

Hard phase	K_1(MJ m^{-3})	J_s(T)	(BH^{th}_{max}) (kJ m^{-3})	T_C(°C)
$Nd_2Fe_{14}B$	4.9	1.61	516	310
$Sm_2Fe_{17}N_3$	8.9	1.54	472	477
$SmCo_5$	17.0	1.05	219	727
Sm_2Co_{17}	3.9	1.30	336	916

In Hoffer and Strnat (1966) discovered a new family of magnetic materials for permanent magnets that showed an extremely high magnetocrystalline anisotropy, an important requirement for obtaining a high coercivity. The new family of material based on $RECo_5$ was the first family of the RE–intermetallic magnets. For the $RECo_5$, the most important representative was $SmCo_5$. In RE–intermetallic magnets the RE provides mainly the magnetocrystalline anisotropy necessary for achieving high coercivities, while the TM mainly raises the magnetization. A second family of RE–TM magnets was soon discovered being the main representative Sm_2Co_{17}. The increase of Co in the Sm_2Co_{17} compared with the $SmCo_5$ compound had the advantage of raising the magnetization, but the crystalline anisotropy lacked behind the $SmCo_5$, efforts were then directed to raise the coercivity of magnets based on such compound in order to increase the $(BH)_{max}$ energy product. The coercivity was improved by a time consuming and complex heat treatment, after the addition of minor amounts of Cu and Zr that also allowed the raise of the magnetization by the substitution of part of the Co by Fe. A review on Sm–Co-based permanent-magnet material based on RE–Co is given by Strnat (1988) and Kumar (1988). The expensiveness of Co together with the scarcity of Sm led to efforts toward the substitution of both elements, Fe was the best candidate due to its larger contribution to magnetization than Co. This leads in 1983 to the discovery of a new family of materials showing large magnetocrystalline anisotropy and therefore good candidates for permanent magnets. The new material discovered by Sagawa *et al*. (1984b,c), Croat, Herbst, Lee and Pinkerton (1984a,b), and Hadjipanayis, Hazelton and Lawless (1983) was based in the ternary compound $Nd_2Fe_{14}B$

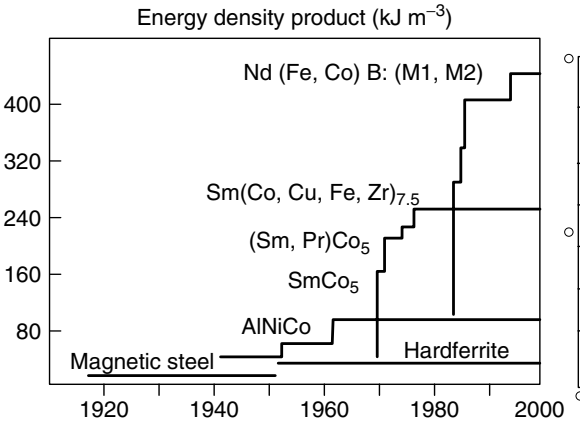
and large energy products, higher than 360 kJ m^{-3} at room temperature, was achieved in 1984. Nowadays the maximum energy density product of $Nd_2Fe_{14}B$-based permanent magnets have been gradually increased to values exceeding 450 kJ m^{-3} (Kaneko, 2000; Rodewald, Wall, Katter and Uestuener, 2002, 2003; Khlopkov *et al*., 2004). Figure 10 shows the increase of the maximum energy density product together with the increase of coercive field achieved during the last 100 years. It should also be noted that the low Curie temperature of the $Nd_2Fe_{14}B$ hard magnetic phase strongly determines the maximum application temperature of the magnet.

The characteristic property of permanent magnets is the magnetic 'hardness', the extent to which the material retains its magnetization in opposing fields. A measure for the magnetic hardness is the coercive field $_JH_C$, which has been drastically increased by the invention of the RE-based permanent magnets (Figure 10). To obtain a large energy product, both a high coercive field and a high spontaneous magnetization are required. Magnetic hardening is either obtained by shape anisotropy or by magnetocrystalline anisotropy. Permanent magnets up to the beginning of this century had consisted mainly in magnetic steels containing cobalt, carbon, tungsten additives and exhibited a low coercivity and low-energy products. In 1930, the Alnico magnets with $(BH)_{max}$ were introduced, made mainly of a combination of nickel, cobalt, and aluminum while in 1950 the ferrites were developed with a lower coercivity than the Alnico magnets but also at a lower production cost. The magnetic hardness of Alnico magnets (Enz, 1982; Kneller, 1962) originates from shape anisotropy. They are based on the precipitation of elongated ferromagnetic FeCo particles in a less magnetic AlNi matrix. The magnetocrystalline anisotropy of Ba hexaferrites (Rathenau, 1953) is considerably larger than the shape anisotropy of Alnicos. Because of their high coercive field and their low price, they are the most commonly used magnets nowadays. A disadvantage of the ferrites is their small spontaneous magnetization. Excellent candidates for high-quality magnets are RE–TM compounds where the RE component accounts for the high magnetocrystalline anisotropy and the TM provides a high magnetization. Sintered magnets based on Sm–Co compounds show excellent magnetic properties (Strnat, 1988). Because of the higher content of cobalt, the spontaneous magnetization also increases and therefore the energy density product of Sm_2Co_{17}-based magnets is even higher than the one of $SmCo_5$ magnets. $Nd_2Fe_{14}B$-based magnets exhibit a large uniaxial anisotropy as well as a high spontaneous magnetization that leads to the largest energy density products measured so far.

The direction of magnetization of a permanent magnet can be reversed either continuously, through coherent or incoherent rotation processes, or discontinuously, through dynamic domain processes. The coercivity is determined by the easiest of these processes. In modern RE permanent magnets, the magnetization rotation is impeded by the magnetocrystalline anisotropy. The nucleation field (Stoner and Wohlfarth, 1948)

$$H_{nuc} = \frac{2K_1}{J_s} \tag{5}$$

determines the maximum coercivity. As the coercive field of a real magnet is limited by the fact that the grain diameter exceeds the theoretical single-domain diameter, it is clear that the magnetization reversal process is controlled by the nucleation and expansion of reversed magnetic domains and not by rotation processes only.



Magnet	Year	$_JH_c$ (kA m^{-1})	T_c (°C)
Magnetic steel	1890	1	
AlNiCo	1955	100	850
Hardferrite	1960	200	450
Sm Co 1:5	1975	3000	720
Sm Co 2:17	1982	2000	820
Nd Fe B	1990	1500	310

Figure 10. Historical development of the maximum energy product $(BH)_{max}$ and the coercive field $_JH_c$ in permanent-magnet materials since 1900. The low Curie temperature T_C of the $Nd_2Fe_{14}B$ limits the maximum operating temperature of Nd–Fe–B-type magnets.

The coercive field of the so-called nucleation-controlled magnets, such as $SmCo_5$ and $Nd_2Fe_{14}B$-type, is well-described by the universal relation (Kronmüller, 1987; Sagawa and Hirosawa, 1987)

$$\mu_0 H_c = \mu_0 \frac{2K_1}{J_s}\alpha - N_{eff} J_s \tag{6}$$

The first and second terms of equation (3) represent modified magnetocrystalline and demagnetizing fields, where α and N_{eff} correspond to microstructural parameters that describe the effect of the microstructure on these effective fields and which in turn may depend on the intrinsic material parameters. The parameter α mainly describes the reduction of the nucleation field due to lattice defects or the disorder at the grain surfaces (Kronmüller and Fähnle, 2003), whereas N_{eff}, accounts for the effective demagnetizing factor by internal enhanced stray fields at the grain edges and corners. Both effects lead to a reduction of H_c.

If the coercive field obeys the condition

$$|{}_J H_c| \geq \frac{1}{2 \cdot \mu_0} \cdot J_r \tag{7}$$

the maximum energy density product depends only on the remanence J_r assuming a perfectly squared demagnetization curve of the magnet, and is given by:

$$(B \cdot H)_{max}^{theor.} = \frac{1}{4 \cdot \mu_0} \cdot J_r^2 \tag{8}$$

In this case, the residual flux density $B_r = J_r$ is expressed as the following equation:

$$J_r = J_s \cdot \frac{\rho}{\rho_0} \cdot V_{hm} \cdot F_{hm} = J_s \cdot \frac{\rho}{\rho_0} \cdot V_{hm} \cdot \cos\theta \tag{9}$$

where, J_s is the saturation magnetization of the hard magnetic phase (1.61 T), V_{hm} and F_{hm} are the volume fraction and the degree of alignment of the hard magnetic grains, respectively. In order to enhance J_r and therefore the energy density product, it is necessary to avoid pores and to densify the magnets up to the theoretical value ρ_0, increase the volume fraction V_{hm} and achieve a high degree of alignment F_{hm}. The theoretical value of the maximum energy product of $Nd_2Fe_{14}B$-based magnets is calculated to be $516\,kJ\,m^{-3}$ (64 MG Oe) assuming 100% perfect alignment and 100% volume fraction of the hard phase. The origin of this magnetic property lies in the $Nd_2Fe_{14}B$ ternary tetragonal compound as a main phase. In addition, according to the ternary Nd–Fe–B phase diagram this magnet also contains a certain amount of $Nd_{1.1}Fe_4B_4$-phase and an Nd-rich phase, which is essential for sintering with liquid phase. In order to densify the magnets up to the theoretical density, it is very important to control the composition of magnets thus generating sufficient amount of liquid phase at sintering. Furthermore, controlling the volume fraction of the constituent phases is indispensable for enhancing the residual flux density (B_r) and to keep the intrinsic coercivity (${}_J H_c$) stable.

4.1 Nucleation-controlled rare-earth magnets

The coercive field of $SmCo_5$- and $Nd_2Fe_{14}B$-based magnets is determined by the high uniaxial magnetocrystalline anisotropy as well as the magnetostatic and exchange interactions between neighboring hard magnetic grains. The long-range dipolar interactions between misaligned grains are more pronounced in large-grained magnets, whereas exchange coupling reduces the coercive field in small-grained magnets. The basic microstructural feature of polycrystalline $SmCo_5$- or $Nd_2Fe_{14}B$-based magnets is the individual hard magnetic grain with its size, shape, and orientation parameters. The ideal microstructure of the so-called single-phase magnets consists of aligned single-domain hard magnetic particles. Strictly speaking, in reality these magnets show a complex, multiphase microstructure with various types of intergranular phases according to their phase diagram and phase relations. The amount of each phase and their distribution within polyphase materials are perhaps the most complex of the microstructural parameters. The occurrence of the multiphase microstructure is one of the reasons why the coercive field of the magnets according to the magnetocrystalline anisotropy field of the hard phase, such as $30.7\,MA\,m^{-1}$ for $SmCo_5$ and $6.05\,MA\,m^{-1}$ for $Nd_2Fe_{14}B$, is never reached in practice.

The microstructure of single-phase, anisotropic $SmCo_5$-type magnets consists of grains oriented parallel to the alignment direction. Most of the $SmCo_5$ grain interiors show a low defect density. The grain diameter exceeds the theoretical single-domain size and is in the order of 5–10 µm. Besides $SmCo_5$-grains also grains with densely packed, parallel stacking faults perpendicular to the hexagonal c axis are observed. Such basal stacking faults correspond to a transformation of the $SmCo_5$-crystal structure into the Sm-rich Sm_2Co_7 and Sm_5Co_{19} structure types. Using high-resolution electron microscopy together with X-ray microanalysis, the different polytypes and structural modifications of these Sm-rich phases are characterized. Incoherent precipitates with diameters up to 0.5 µm were identified as Sm_2O_3- or CaO-inclusions. In $SmCo_5$-type sintered magnets, the coercivity is determined by the nucleation field of reversed domains which is lower than the coercive field of a magnetically saturated particle with a single-domain structure and nucleation by the expansion field of the reversed domains. The nucleation of reversed domains takes place in regions

with low magnetocrystalline anisotropy. RE-rich precipitates mainly deteriorate the ${}_{\mathrm{J}}H_{\mathrm{c}}$ of the final magnet. The reason for the formation of these phases is due to the addition of a RE-rich sintering aid phase before the sintering process. The coercivity can be improved by adding small amounts of TM powders or TM oxides. Transmission electron micrographic (TEM) studies shows that the chemical composition, the size distribution and the impurity content (oxygen content) of the starting powder material are important factors for the magnetic properties of $SmCo_5$-type sintered magnets. For lower cost magnets samarium is partly substituted by a mixture of cerium-mischmetal elements or for improved magnetic properties by praseodymium, thus three groups of $SmCo_5$-type sintered magnets are distinguished, (CeMM,Sm)Co_5 with low J_{s}, and $(BH)_{\max}$, $SmCo_5$ with high ${}_{\mathrm{J}}H_{\mathrm{c}}$ and (Pr,Sm)Co_5 with high $(BH)_{\max}$ values. Microstructural investigations on sintered magnets of the type (CeMM,Sm)Co_5 and (Pr,Sm)Co_5 showed similar results as in the case of $SmCo_5$ sintered magnets. The corresponding X-ray spectra of the different phases showed a mixture of RE elements due to their ratio of the nominal composition of the magnet.

High-performance $Nd_2Fe_{14}B$-based permanent magnets are produced with different composition and various processing techniques, which influence the complex, multiphase microstructure of the magnets, such as size and shape of grains, the orientation of the easy axes of the grains, and the distribution of phases. Formation and distribution of the phases are determined by the composition of the magnets and the annealing treatment. Especially grain size and the alignment of the grains strongly depend on the processing parameters. Grain sizes in the range between 10 and 500 nm are obtained by melt-spinning, mechanical alloying, and the HDDR (hydrogenation-disproportionation-desorption-recombination) process (Harris, 1992). Sintered and hot worked magnets exhibit grain sizes above 1 µm. The powder metallurgical sintering route is the most important preparation technique for RE permanent magnets and consists of the following production steps: melting of the alloy under vacuum, crushing, milling, alignment in magnetic field, pressing, sintering, annealing, machining, and coating.

The processing route of the magnet strongly influences the grain size and grain size distribution. The coercive field in sintered magnets strongly depends on the sintering parameters, such as temperature and time. Nanocrystalline and submicron magnets are obtained by the melt-spinning route, or by mechanically alloying, or by the HDDR process (Harris, 1992; Cadogan and Coey, 1986). Hot pressing and die upsetting of Nd–Fe–B ribbon materials reveals a densely packed, anisotropic magnetic material. Platelet-shaped grains with diameters less than 1 µm are observed by TEM-investigations. The degree of orientation of the platelets, which are stacked transverse to the press direction

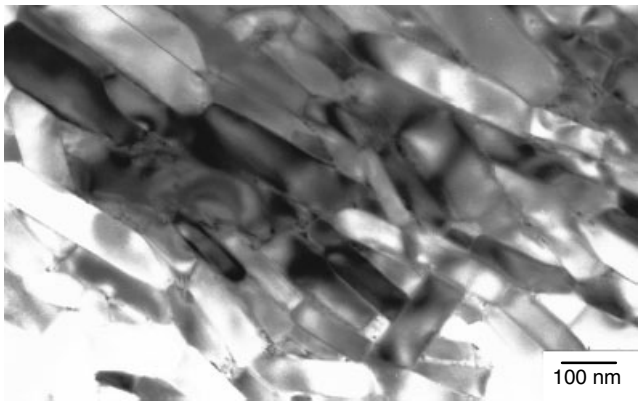


Figure 11. Microstructure of a melt-spun MQ3-type $Nd_{14}Fe_{72}Co_7B_6Ga_1$ magnet ($J_{\mathrm{r}} = 1.32\,\mathrm{T}$, ${}_{\mathrm{J}}H_{\mathrm{c}} = 1241\,\mathrm{kA\,m^{-1}}$).

with the easy c axes perpendicular to the face of each grain, determines the remanence and coercive field of the magnet (Mishra, 1987). The degree of alignment, size and shape of the grains, and the intergranular regions within the ribbons control the macroscopic magnetic properties. Die upsetting modifies the spheroidal grains after hot pressing to platelets as shown in the TEM images of Figure 11. Misaligned grains, which are clearly visible, deteriorate the remanence. The c axis for each grain runs perpendicular to the straight elongated edge. Nd-rich phase is found among the platelet-shaped grains as a fine layer between the straight edges or as pockets at the end of the platelets or between the misaligned and aligned grains. On the other hand, the magnets with a lower remanence show a microstructure with more equiaxed grains. In most of the melt-spun magnets regions with abnormally grown, large grains were found. Some of these grains were fully developed, platelet-shaped grains.

Substituent and dopant elements influence the microstructure, coercivity, and corrosion resistance of advanced (Nd,S1)-(Fe,S2)-B:(M1,M2) magnets. The replacement of the Nd-rich intergranular phase by secondary phases formed after doping by M1 and M2 type elements improves the corrosion resistance, especially in large-grained magnets. The multicomponent composition of the magnets leads to the formation of nonmagnetic and soft magnetic phases. Generally, two types of substituent elements, which replace the RE element or the transition element sites in the hard magnetic phase, and two types of dopant elements are distinguished (Fidler and Schrefl, 1996). Substituent elements mainly change the intrinsic properties such as spontaneous magnetic polarization, Curie temperature, and magnetocrystalline anisotropy. Depending on the type, the dopant elements, which show a low solubility within the hard magnetic phase, form additional intergranular rare-earth-containing or boride phases. These phases change the coupling behavior between the hard magnetic grains. Nonmagnetic intergranular

phases eliminate the direct exchange interaction and also reduce the long-range magnetostatic coupling between the hard magnetic grains; both effects lead to an increase of the coercive field. On the other hand, the decrease of the volume fraction of the hard magnetic phase within the magnet decreases the remanence. Insufficient temperature stability and poor corrosion resistance are the main factors limiting applications of $Nd_2Fe_{14}B$-based magnets. Secondary non-magnetic phases, which replace the Nd-rich intergranular phase, considerably improve the corrosion resistance and are of great technological interest.

Nd–Fe–B-based permanent magnets with a composition close to $Nd_{15}Fe_{77}B_8$ exhibit a complex multiphase microstructure. According to the ternary phase diagram at least three equilibrium phases occur, the hard magnetic $Nd_2Fe_{14}B$ phase, the boride phase $Nd_{1+\varepsilon}Fe_4B_4$ and the low melting Nd-rich phase. Other phases, such as Fe-rich and Nd oxides, and pores are found depending on the composition and processing parameters. Selected substituent elements replace the Nd atoms (S1 = Dy,Tb) and the Fe atoms (S2 = Co,Ni,Cr), respectively, in the hard magnetic phase and considerably change intrinsic properties, such as the spontaneous polarization, the Curie temperature and the magnetocrystalline anisotropy. The formation of intermetallic, soft magnetic Nd-(Fe,S2) phases, such as the Laves type $Nd(Fe,S2)_2$-phase, deteriorate the coercivity of the magnets. If dopant elements M1 or M2 are added to Nd–Fe–B, in some cases the coercivity is increased and the corrosion resistance is improved. This is the case, if the Nd-rich intergranular phase is replaced by other phases, such as $AlNd_6Fe_{13}$ and Nd_3Co. Our previous, systematic TEM-studies performed on sintered, melt-spun, mechanically alloyed, and hot worked magnets have shown that two different types of dopants can be distinguished independently of the processing route. Both types influence the microstructure in a different way (Bernardi, Fidler and Fodermayr, 1992; Bernardi and Fidler, 1994). Type 1 dopants (M1 = Al, Cu, Ga) form binary M1–Nd or ternary M1–Fe–Nd phases, and Type 2 dopants (M2 = Ti, Zr; V, Mo; Nb, W) form binary M2–B or ternary M2–Fe–B phases. The processing route of the magnet strongly influences the grain size and grain size distribution. The coercive field in sintered magnets strongly depends on the sintering parameters, such as temperature and time. Nanocrystalline and submicron magnets are obtained by the melt-spinning route, or by mechanically alloying, or by the HDDR process (Nakayama *et al*., 1994; Buschow, 1988; Gutfleisch and Harris, 1996). Hot pressing and die upsetting of Nd–Fe–B ribbon materials reveals a densely packed, anisotropic magnetic material. Platelet-shaped grains are observed by TEM-investigations. The degree of orientation of the platelets, which are stacked transverse to the press direction with the easy *c* axis perpendicular to the face of each grain, determines the remanence and coercive field of the magnet.

Nd–Fe–B sintered magnets possessing outstanding magnetic properties have developed into a major permanent-magnet material in the 20 years since their invention. The drastic increase of the energy density product of newly developed $Nd_2Fe_{14}B$-based magnets enabled the invention of many new applications of permanent magnets. In the conventional powder metallurgical sintering process it is very important to keep the processing atmosphere either in a vacuum or in an inert gas because RE elements such as Nd, Pr, and Dy, which are essential for fabrication of Nd–Fe–B magnets are easily oxidizable. Several authors have reported to obtain $Nd_2Fe_{14}B$-based magnets with energy density product $>440\,kJ\,m^{-3}$ (Kaneko, 2000; Fidler, Sasaki and Estevez-Rams, 1999; Rodewald, Wall, Katter and Uestuener, 2002, 2003) by keeping the oxygen content low (Sagawa *et al*., 1987), using the powder mixing technique (Otsuki, Otsuka and Imai, 1990), increasing the magnetizing field and reducing the pressure during compaction (Endoh and Shindo, 1994) or using the rubber isostatic pressing (RIP) technique to improve the orientation of the particles in the green compact to obtain sintered magnets with perfect orientation. The increasing demand for highest energy density magnets ($>400\,kJ\,m^{-3}$), especially for voice coil motors in hard disc drives and for magnetic circuits for magnetic resonance imaging devices, needs an efficient manufacturing process for $Nd_2Fe_{14}B$ sintered magnets with improved energy density product. A new technology–RIP–has been developed by Sagawa and Nagata (1993) and Sagawa, Nagata, Itatani and Watanabe (1994) to improve the orientation of the particles in the green compact to obtain sintered magnets with perfect orientation. RIP is one of the key technologies to approach for the theoretical limit, 64 MG0e at room temperature, of the magnets based on $Nd_2Fe_{14}B$. In RIP, magnet powder is subjected to such a strong ulsed field just before the compaction that the powder in the rubber mold is thoroughly oriented. Then the powder is compacted isostatically, while the orientation is completely held. In the conventional die pressing that uses no rubber molds, the pressure applied to the powder is uniaxial. The uniaxial pressure tends to disturb the orientation of the particles during the pressing. To prevent this orientation disturbance, the powder has to be subjected to a strong magnetic field throughout the pressing. This is one of the reasons why a pulsed field cannot be adopted for the conventional die pressing. The high orientation of the magnet produced by RIP is attributed to the application of a strong pulsed field that dissolves the agglomeration of the magnet powder particles, and then, impulsively orients the particles by isostatic pressing that holds the orientation high during the pressing. The misalignment of the hard magnetic grains with a diameter of 2–5 μm is in the best case in the order $<14\,^{\circ}C$.

The oxygen content of the magnets has to be reduced from values of 4000–6000 ppm to a value <1000 ppm. A high oxygen content is one limiting factor to decrease the Nd-content in order to improve the volume fraction of the hard magnetic phase. The squareness of the demagnetization curve and the coercive field drastically decreases as abnormal grain growth (AGG) of the $Nd_2Fe_{14}B$ grains occurs (Rodewald, Wall, Fernengel and Rodewald, 1997).

Remanence and energy product increase with decreasing Nd-content, whereas the coercive field shows its highest value at a high Nd-content. In the case when the oxygen content of the magnets was determined to be in the order of 4000–6000 ppm, a large part of the Nd was bound in the stable phase Nd_2O_3 phase. This is the why below 14 at% Nd density and hard magnetic properties of the magnets drastically deteriorated in magnets with a high oxygen content. On the contrary, low oxygen content can cause the AGG and lower the magnetic properties. The influence of oxygen on the hard magnetic properties is more complex. Kim, Camp and Stadelmaier (1994) reported that a controlled doping with oxygen improved grain alignment and resulted in an increase in remanence, coercivity, and loop squareness. One possibility to improve the alignment factor is to optimize the alignment field and/or pressure during transverse pressing. Even the sintering process influences the degree of alignment of the grains (Chin *et al*., 1988). On the other hand, several authors (Fernengel *et al*., 1996; Sagawa, Nagata, Itatani and Watanabe, 1994) found that isostatic die pressing ($\theta = 11$–$14\,^{\circ}$C) yields highest alignment followed by the transverse field die pressing (18–20 °C) and the axial field die pressing (25–27 °C). The demagnetization curve of an optimized magnet with $(BH)_{max} > 430\,kJ\,m^{-3}$ and a low oxygen content and a composition of $Nd_{13.5}Fe_{bal}B_{5.95}Cu_{0.03}Al_{0.7}$ is shown in Figure 5 and the corresponding TEM image is shown in Figure 6. The magnets produced were sintered between 960 and 1100 °C. The sintering temperature was varied to get optimum density (7.5–7.6 g cm^{-3}) and $(BH)_{max}$. The density of the samples and the remanence increased with increasing sintering temperature keeping the sintering time constant (3 h), while the squareness of the demagnetization curve only partly increased and drastically decreased as AGG of the $Nd_2Fe_{14}B$ grains occurred (Livingston, 1996). AGG of the $Nd_2Fe_{14}B$ grains occurred preferentially in magnets with low oxygen content. The oxygen content strongly affects the AGG and the magnets with higher oxygen content have the higher critical temperatures at which the AGG occurs. Figure 6 shows that the microstructure mainly consists of $Nd_2Fe_{14}B$ grains of several microns in diameter. Only a few Nd-rich phases are found as intergranular phases, especially at grain boundary junctions.

Numerical micromagnetic simulations have shown that the grain boundary phases influence the coercive field significantly (Süss, Schrefl and Fidler, 2000). The finite element simulations confirm the experimental results that nonmagnetic Nd-rich phases at grain boundary junctions increase the coercive field. Microstructural studies have characterized the complex multiphase microstructure of $Nd_2Fe_{14}B$-based permanent magnets (Fidler and Knoch, 1989). Two types of grain boundaries have been found in sintered magnets. Depending on the composition, both, grain boundaries free of any intergranular phase and also Nd-rich phases separating hard magnetic grains have been identified. Figure 12 shows a typical grain boundary junction, with only a thin layer of intergranular phase. In doped sintered magnets, the dopant element is partly dissolved in the hard magnetic phase. In the case where the solubility of the dopant is low at the sintering temperature (Nb, Mo, Zr), precipitates are formed. Dopants also form new intergranular phases and influence the wetting of the liquid phase and the smoothness of the surface $Nd_2Fe_{14}B$-grains during sintering and therefore affect the coercivity. Intergranular phases change the coupling behavior of the hard magnetic grains. Distorted grain boundary phases with reduced magnetocrystalline anisotropy favor the formation of reversed domains. The composition of these phases can be influenced by substituent and dopant elements (Bernardi, Fidler and Fodermayr, 1992). For a perfect microstructure the calculated coercive fields agree well with the Stoner–Wohlfarth theory (Stoner and Wohlfarth, 1948). The most misoriented grain, which has the largest angle between the easy axis and the alignment direction, determines the coercive field. The coercive field decreases with increasing misalignment. The values of the calculated coercive field are about 5–10% smaller than the values predicted by the Stoner–Wohlfarth theory. For sintered magnets, the measured thickness of the nonmagnetic grain boundary

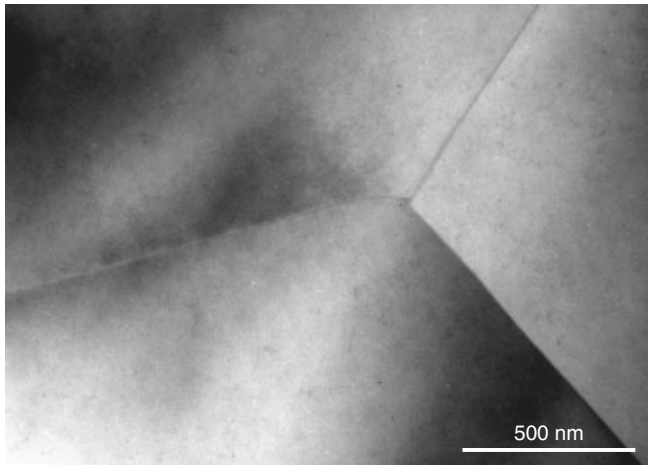

Figure 12. TEM image showing a grain boundary junction of a high energy density $Nd_{13.5}Fe_{bal}B_{5.95}Cu_{0.03}Al_{0.7}$ sintered magnet with $(BH)_{max} = 432\,kJ\,m^{-3}$, $J_r = 1.51\,T$ and ${}_JH_c = 755\,kA\,m^{-1}$.

phase varies between zero and several nanometer. This reduced magnetocrystalline anisotropy decreases the coercive field considerably, from 3200–900 kA m^{-1}, for example. The reduction of the magnetocrystalline anisotropy reverses the dependence of the coercive field on the degree of alignment (Martinek and Kronmueller, 1990). Bachmann, Fischer and Kronmüller (1998) observed a similar behavior of the coercivity on the degree of alignment for nanocrystalline magnets. The coercive field increases as the misalignment angle is changed from 8 to 16 °C misorientation. The Foucault TEM image of Figure 13 clearly shows the nucleation of reversed domains close to grain boundaries. Figure 14 compares the nucleation process for two different degrees of alignment. The micromagnetic simulations are in good agreement with the results obtained by Lorentz electron microscopic investigations (Figure 13). The isosurfaces represent the reversed nucleus. In the well-aligned sample, higher demagnetizing field initiates the nucleation of reversed domains in the defect region. The simulations are in agreement with experimental data that show a slight increase of coercivity with misalignment for Dy-free Nd–Fe–B magnets, whereas a decrease of the coercive field with increasing misalignment is observed in highly coercive, Dy-containing Nd–Fe–B magnets (Kim, Camp and Stadelmaier, 1994). The coercive field of Nd–Fe–B sintered magnet increases with increasing Nd-content (Hirosawa and Kaneko, 1998). The simulations show that the presence of the Nd-rich phase significantly changes the exchange and the magnetostatic interactions. As a consequence, the nucleation of reversed domains is suppressed.

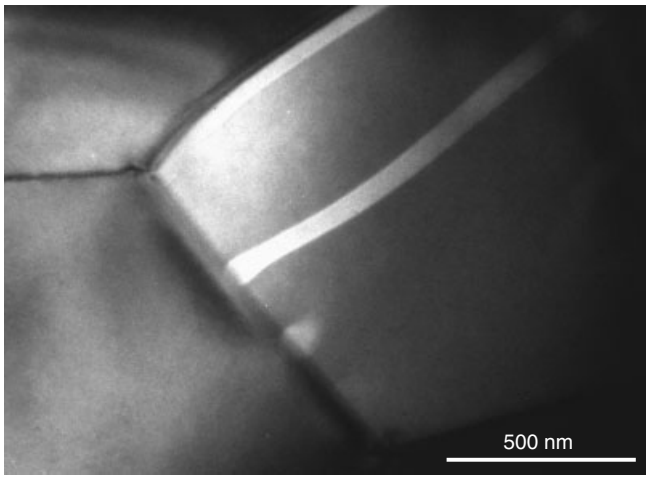

Figure 13. Foucault TEM image showing the domain nucleation at grain boundaries. Sintered $Nd_{13.5}Fe_{bal}B_{5.95}Cu_{0.03}Al_{0.7}$ magnet with $(BH)_{max} = 432\,kJ\,m^{-3}$, $J_r = 1.51\,T$ and ${}_JH_c = 755\,kA\,m^{-1}$.

4.2 Pinning controlled Sm(Co,Cu,Fe,Zr)$_{7.5-8}$ magnets

Alloys of Sm(Co, Cu, Fe, Zr)$_z$ are typically prepared by melting the respective constituents by low-frequency induction heating under an inert gas cover (Ray and Millott, 1971). Typical initial composition of the constituent elements is 10–12 Sm at%, 55–71 Co at%, 15–25 Fe at%, 3–5 Cu at%, 1–3 Zr at% for conventional applications and 11–13 Sm at%, 59–79 Co at%, 0–10 Fe at%, 8–14 Cu at%, 2–4 Zr at% for high-temperature applications (Ray, 1986).

A complex production process, which involves sintering, homogenizing, isothermal aging, and annealing, results in the formation of a cellular precipitation structure, which acts as pinning centers for magnetic domain walls (Fidler, Skalicky and Rothwarf, 1983; Livingston and Martin, 1977; Mishra *et al.*, 1981; Rabenberg, Mishra and Thomas, 1982; Nagel, 1979). The compact is first sintered between 1190 and 1210 °C in order to obtain a full dense alloy trying, at the

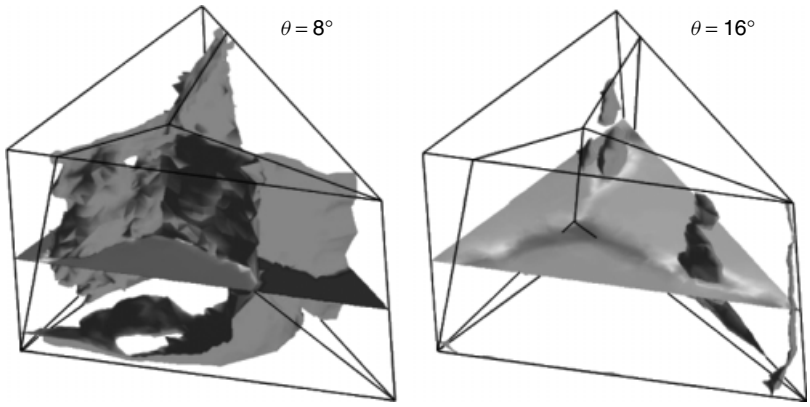

Figure 14. Numerical finite element micromagnetic simulation of the nucleation of reversed domains at a grain boundary junction in an $Nd_2Fe_{14}B$-based sintered magnet in dependence of the misalignment θ of the grains. The isosurfaces represent the regions where J_z/J_s and <0.7 and the nucleation process of reversed domains will start.

same time, to avoid excessive grain growth because of their negative effect in mechanical properties. Typical grain size is up to 50 µm. A solutionizing treatment is carried on to get a fully homogenized single-phase sample at a sufficiently high temperature and then is rapidly quenched in order to avoid phase segregation during cooling. The step aging or slow cooling heat treatment is performed at a lower temperature to obtain the precipitation of the cell boundary phase and the well formation of the continuous cell structure that accounts for the coercivity of the magnet. The two-phase magnet compound with the nominal composition $Sm(Co,Cu,Fe,Zr)_{7.5-8}$ is the best choice for high-temperature applications permanent magnets with operating temperatures above 300 °C, because of its high magnetocrystalline anisotropy, the strong domain wall pinning behavior and the high Curie temperature (Strnat, 1988; Hadjipanayis *et al*., 2000; Chen *et al*., 1998). The microstructure, which consists of the $Sm_2(Co,Fe)_{17}$ cell matrix phase, the $Sm(Co,Cu)_{5-7}$ cell boundary phase and the Zr-rich lamella phase, develops mainly during the isothermal aging (Tang *et al*., 2001). The formation of a fine cellular precipitation structure is a necessary precondition for high permanent-magnet properties at elevated temperatures, because of its behavior as pinning centers for the magnetic domain walls. However, the compositions of the distinct phases and the elemental profiles also have an even higher influence on the magnetic properties. The diffusional redistribution of the various elements during the heat treatment results in a characteristic microchemistry (Fidler *et al*., 2002; Goll, Kronmuller and Stadelmaier, 2004; Hadjipanayis *et al*., 2000; Goll, Kleinschroth, Sigle and Kronmüller, 2000). As all of the elements are placed on regular crystallographic sites, there is only diffusion of vacancies, which is very slow compared to interstitial diffusion. There are two main diffusional processes: Cu segregates to the 1:5 cell boundary phase and Fe segregates to the 2:17 matrix phase (Ray, Soffa, Blachere and Zhang, 1987). As the cell size of the precipitation structure increases with the duration of the isothermal aging, it is necessary to decrease the temperature when the desired cell size has been obtained. Diffusion continues during the following slow cooling and the subsequent annealing at 400 °C, but with a reduced rate because of the lower temperatures. Even the solutionized samples may have a microstructure and microchemistry, which have a strong influence on the duration and the profile of the heat treatment. Cu clusters within the solid solution that enabled a higher Cu diffusion rate and allowed the samples to be quenched directly after the isothermal aging (Perkins and Strässler, 1977a). The TEM images of Figure 15 show the typical cellular and lamellar precipitation structures, A high-resolution nanoprobe TEM investigation shows that the Fe content within the cell matrix phase is higher than the nominal content, which confirms that Fe mainly segregates to the

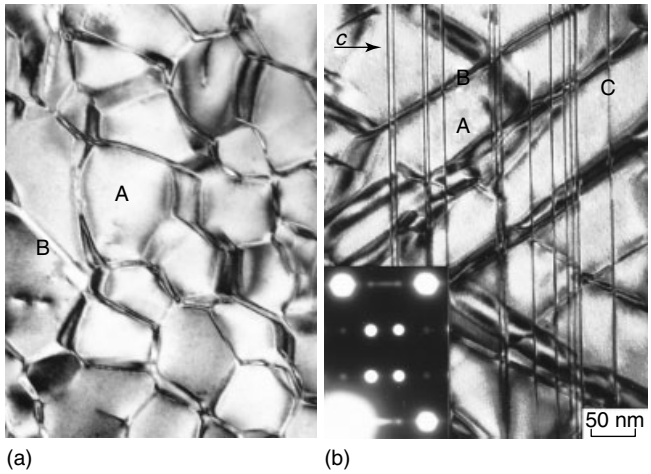

Figure 15. TEM images showing rhombic, cellular precipitation structure of a sintered Sm(Co,Cu,Fe,Zr)7.5 magnet. Views (a) parallel and (b) perpendicular to the alignment direction c. Cell boundary phase $Sm(Co,Cu)_{5-7}$ (A), cell matrix phase $Sm_2(Co,Fe)_{17}$ (B).

2:17 phase. A higher Fe/Co ratio decreases the anisotropy constant K_1 (Perkins and Strässler, 1977b) and increases the spontaneous polarization (Ray, 1984). The Zr content within the cell matrix phase lies between 1.0 and 2.4 at%. A high Zr concentration is found in the platelet phase perpendicular to the *c* axis, which presumably acts as diffusion path for the distribution of elements during the annealing procedure (Ray, 1990; Ray, Soffa, Blachere and Zhang, 1987; Rabenberg *et al*., 1991).

The magnetization reversal mechanism in Sm(Co, Fe, Cu, $Zr)_z$ magnets has been attributed to domain wall pinning at the $Sm(Co, Cu)_{5-7}$ cell boundaries (Durst, Kronmueller and Ervens, 1988a,b). Various experimental investigations, such as Kerr effect microscopy (Livingston, 1975), Lorentz electron microscopy (Fidler, 1982), analysis of initial magnetization curves (Livingston, 1981), and measurements of the irreversible susceptibility (Liu and Hadjipanayis, 1999) confirmed this assumption. Theoretical considerations (Kronmüller, 1987; Kronmüller and Fähnle, 2003) and numerical micromagnetic simulations (Streibl, Fidler and Schrefl, 2000; Scholz *et al*., 2003) reveal the details of these complex magnetization reversal processes. The Lorentz micrograph of Figure 16 shows the domain wall pinning at the continuous cell boundary phase $Sm(Co,Cu)_{5-7}$ at the remanent state at room temperature. The coercivity is determined by the difference and the gradient of the domain wall energy (Livingston and Martin, 1977; Livingston, 1996, 1981) and by the magnetoelastic coupling energy between domain wall stresses and lattice deformation strains (Fidler, 1982). The exchange constant A and the anisotropy constant K_1 of the cell boundary phase are mainly determined by

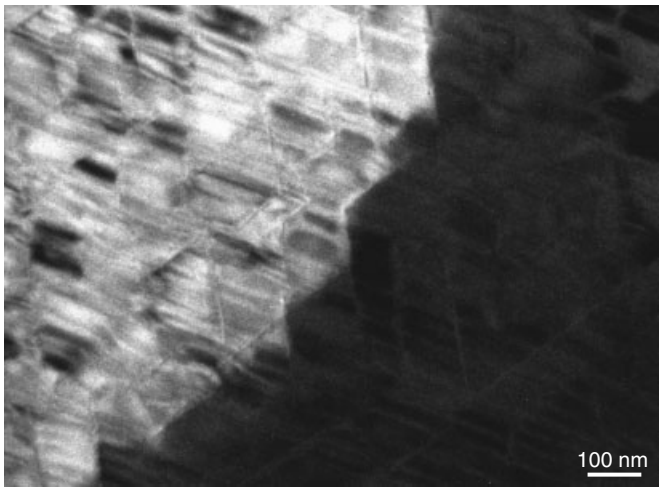

Figure 16. Foucault TEM image showing the domain pinning at the continuous cellular precipitation structure in a $Sm(Co,Cu,Fe,Zr)_z$ sintered magnet for high-temperature applications.

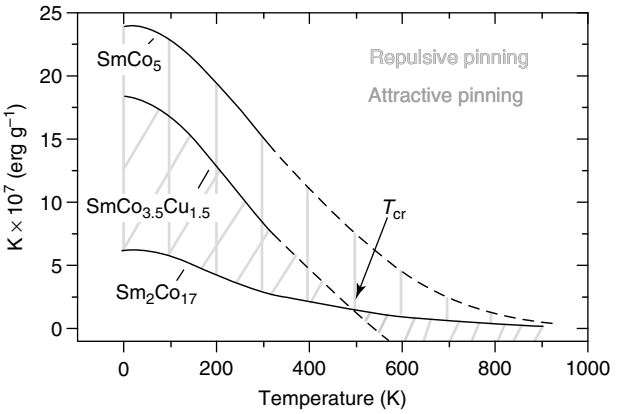

Figure 17. Temperature dependence of the anisotropy coefficients K_1 of the $Sm_2(Co,Fe)_{17}$ and $Sm(Co, Cu)_5$ phases (Tang *et al*., 2001). The coercivity of $Sm(Co,Fe,Cu,Zr)_z$ permanent magnets is determined by the gradient in domain wall energy between the different phases, which is proportional to the difference of the magnetocrystalline anisotropy constants ΔK_1. Because of the different temperature dependences of the two phases ΔK_1 is strongly dependent on the operating temperature of the magnet. (Reprinted with permission W. Tang *et al*., copyright 2001, Elsevier.)

the Cu concentration (Fidler *et al*., 2002; Goll, Kronmuller and Stadelmaier, 2004). In more detail, the different crystal structures and magnetic properties of the cell matrix and the cell boundary phase give rise to a gradient in the domain wall energy, which originates the pinning effect. There are two types of possible domain wall pinning processes. As Cu mainly segregates in the $Sm(Co, Cu)_{5-7}$ phase, the magnetocrystalline anisotropy of this phase can be tailored by the Cu content of the magnet (Lectard, Allibert and Ballou, 1994). The anisotropy constant K_1 of the cell boundary phase is either higher (low Cu concentration) or lower (high Cu concentration or high temperatures) than that of the cell matrix phase (Figure 17). As a result it is energetically favorable for a magnetic domain wall to either stay in the cell boundary phase ('attractive' domain wall pinning because of lower domain wall energy) or just inside the cells ('repulsive' domain wall pinning because of higher domain wall energy). If the cell boundary thickness is larger than the domain wall width which itself depends indirectly on the square root of K_1 the coercive field is given by Kronmüller (2000) and Kronmüller, Durst and Sagawa (1988):

$$\mu_0 H_c = \mu_0 \frac{1}{J_s \cos \psi_0} \left| \frac{d\gamma\,(z)}{dz} \right|_{max} - N_{eff} J_s \qquad (10)$$

N_{eff} denotes the effective demagnetizing factor, ψ_0 the angle between the applied field and the easy axis, z is the direction normal to the cell boundary wall and $d\gamma(z)/dz$ denotes the maximum slope of the wall energy. In the more typical case, where the boundary thickness becomes narrower than the domain wall width, the complex influence of geometrical and intrinsic magnetic parameters on the coercive field has to be determined using numerical micromagnetic simulations. Finite element reveal that the cell boundary width has a strong influence on the coercivity (Scholz *et al*., 2003). This suggests that, if an improved heat treatment resulted in larger cells with thicker cell boundaries, a higher coercivity could be achieved. A minimum thickness of 10 nm is necessary for coercivities above 1000 kA m^{-1}. Repulsive pinning enables larger coercivities than attractive pinning. For a thickness of more than 40 nm of the intercellular phase, the pinning behavior is lost again, because the domain wall sweeps through the whole intercellular phase and reverses its magnetization. As a result the unreversed cells remain until nucleation starts the reversal of their magnetization. In the case of repulsive domain wall pinning, a minimum thickness of the intercellular phase is required, too. As the thickness of the intercellular phase increases, the energy barrier becomes wider and this mechanism becomes more and more difficult. It has been shown that with increasing temperature the coercivity mechanism changes from repulsive to attractive pinning. The nucleation mechanism was found to be dominant above the Curie temperature of the cell walls (Kronmüller and Fähnle, 2003).

Recently a new series of magnets with H_c up to 1050 kA m^{-1} at 400 °C has been developed (Hadjipanayis *et al*., 2000; Chen *et al*., 1998). These magnets have low temperature coefficients of H_C and a straight line B versus H (extrinsic) demagnetization curve up to 550 °C. High Cu-, low Fe- and a higher Sm-concentration were found to contribute to high coercivity at high temperatures. In low Cu samples the magnetocrystalline anisotropy values of the 1:5

and the 2:17 phases cross at a certain temperature, which does not happen in high Cu samples. However, as a large part of the magnet consists of the 1:5 phase, the saturation polarization s strongly decreases in high Cu-containing samples. The actual domain wall pinning process in high Cu-containing magnets is rather complicated and varies from repulsive to attractive, depending on whether the magnetocrystalline anisotropy in the Cu-containing 1:5 cell boundary phase is lower or higher than in the 2:17 cell matrix phase, respectively. The shape and the thickness of the cell boundary phase and the elemental profiles across the phase determine the coercivity H_c.

4.3 Nanocrystalline, composite $Nd_2Fe_{14}B/(\alpha\text{-}Fe,Fe_3B)$ and other novel rare-earth magnets

The increasing demand for powders for bonded magnets leads to the development nitrided Sm–Fe and nanocrystalline Nd–Fe–B materials. The RE_2Fe_{17} compounds have low Curie temperatures and exhibit planar magnetic anisotropy. Substitutions or additions are needed to raise T_C and to change the magnetocrystalline anisotropy. Almost any substitution will raise T_C, but recent attention has focused on Al and Ga which also induce uniaxial anisotropy when present in modest amounts in Sm_2Fe_{17}. However, the most effective way of increasing T_C of RE_2Fe_{17} and modifying its anisotropy is to use interstitial additions (B, C, N). Interstitial modification, especially with nitrogen, has added a new dimension to the compounds that can be considered from RE permanent magnets. Besides raising T_C of iron-rich intermetallics, largely through the effect to lattice expansion (6%), interstitial atoms also control the magnetocrystalline anisotropy. Since 1990, there have been extensive studies of interstitial 2:17, 3:29, and 1:12 compounds containing nitrogen and carbon in the structures (de Boer *et al.*, 1988), but the interstitial compound that exhibits the most favorable combination of intrinsic magnetic properties remains is $Sm_2Fe_{17}N_3$ with $T_C = 470\,^{\circ}C$ (Coey and Sun, 1990). Mechanical alloying and HDDR of $Sm_2Fe_{17}N_3$ give high coercivity and good loop shape, but have so far only yielded isotropic material. The main disadvantage of nitrided powders is the dissociation at high temperature (about 600 °C) according to the reaction:

$$Sm_2Fe_{17}N_3 \rightarrow 2SmN + Fe_4N + 13\alpha\text{-}Fe \qquad (11)$$

Another useful family are the pseudobinaries Sm $(Fe_{12-x}M_x)$ where M = Ti, V, Si, which crystallize in the tetragonal $ThMn_{12}$ structure (Buschow, 1988; de Boer, Ying-Kai, de Mooij and Buschow, 1987; de Mooij and Buschow, 1988). The best of them show T_C and magnetic anisotropy similar to those of $Nd_2Fe_{14}B$, but with somewhat lower magnetization. These compounds can also be improved by interstitial modification with nitrogen or carbon.

Nanocrystalline, single-phase $Nd_2Fe_{14}B$ magnets with isotropic alignment show an enhancement of remanence that is attributed to intergrain exchange interactions, which enhance the remanence by more than 40% when compared with the remanence of noninteracting particles, if the grain size is in the order of 10–30 nm. Numerical micromagnetic calculations have revealed that the interplay of magnetostatic and exchange interactions between neighboring grains influence the coercive field and remanence considerably (Kneller and Hawig, 1991; Schrefl, Fidler and Kronmüller, 1994). Numerical micromagnetic simulation shows a large volume fraction of an inhomogeneous polarization distribution near grain boundaries in small-grained, isotropic, single-phase magnets, leading to an increase of the remanence and a decrease of the coercive field. Exchange interactions between neighboring soft and hard grains in nanocrystalline, composite magnets lead to remanence enhancement of isotropically oriented grains (Davies *et al.*, 1993; Mccallum, Kadin, Clemente and Keem, 1987; Coehoorn, de Mooij and de Waard, 1989; Hadjipanayis and Gong, 1988; Ding, Mccormick and Street, 1993; Goll, Seeger and Kronmüller, 1998). Soft magnetic grains in two- or multi-phase, composite permanent magnets cause a high polarization, and hard magnetic grains induce a large coercive field provided that the particles are small and strongly exchange coupled. The coercive field shows a maximum at an average grain size of less than 15–20 nm. Intergrain exchange interactions override the magnetocrystalline anisotropy of the $Nd_2Fe_{14}B$ grains for smaller grains, whereas exchange hardening of the soft phases becomes less effective for larger grains. The magnetization distribution at zero applied field for different grain sizes, clearly shows that the remanence enhancement and energy product increases with decreasing grain size and increases with increasing α-Fe content. Owing to the competitive effects of magnetocrystalline anisotropy and intergrain exchange interactions, the magnetization of the hard magnetic grains significantly deviates from the local easy axis for a grain size $D \leq 20$ nm. As a consequence coercivity drops, since intergrain exchange interactions help overcome the energy barrier for magnetization reversal. With increasing grain size the magnetization becomes nonuniform, following either the magnetocrystalline anisotropy direction within the hard magnetic grains or forming a flux closure structure in soft magnetic regions. Neighboring α-Fe and Fe_3B grains may make up large continuous areas of soft magnetic phase, where magnetostatic effects will determine the preferred direction of the magnetization. The large soft

magnetic regions deteriorate the squareness of the demagnetization curve and cause a decrease of the coercive field for $D > 20\,\text{nm}$. A vortex-like magnetic state with vanishing net magnetization will form within the soft magnetic phase, if the diameter of soft magnetic region exceeds 80 nm. Many of the fully dense permanent-magnet materials, especially those that are sintered, are very hard and brittle, and machining them to their final shape is often tedious. The reduction of production handling and assembly costs led to an interest in bonded magnets, which are made by consolidating a magnet powder with a polymer matrix. While machining is easy, the production processes also frequently allow parts to be made directly to their final dimensions. Thermosetting binders, such as epoxy resin, are employed for use in compression-molded magnets, thermoplastic binders like nylon for injection-molded magnets, and elastomers such as rubber are used for extruded magnets. The major drawback to bonded magnets is the reduction in their magnetic properties, relative to those that are 100% dense with magnetic material.

1 HISTORICAL REVIEW OF PERMANENT MAGNET MATERIALS

Permanent magnets have been attracting the attention of mankind since more than a thousand years. The application of lodestone, a fine mixture of ferrimagnetic magnetite (Fe_3O_4) and antiferromagnetic maghemite (γ-Fe_2O_3), in geomancy and in compasses by Chinese experts is well documented (Livingston, 1996). Since the coercivity H_{cJ} of lodestone amounts to only several $1\,kA\,m^{-1}$, these magnets had to be handled very carefully. Since the sixteenth century, needle-shaped strips of iron–carbon alloys with coercivities H_{cJ} of approximately $4\,kA\,m^{-1}$ were used by sailors of European countries. In the beginning of the nineteenth century, tungsten steel or cobalt–chromium steels were developed. These magnetic materials enable the manufacture of horseshoe magnets with maximum energy densities of about $8\,kJ\,m^{-3}$ (O'Handley, 2000).

In 1932, Mishima reported the hard magnetic properties of Fe–Al–Ni–Co alloys (Mishima, 1932), which are denoted by the tradename *Alnico*. The coercivity H_{cJ} of these magnets is determined by shape anisotropy. During a heat treatment at temperatures in the range 750–850 °C, a precipitation of ferromagnetic elongated α-(Fe,Co) rods in a Ni–Al-enriched matrix occurs by spinodal decomposition. Isotropic Alnico magnets achieve coercivities H_{cJ} in the range of $0.5–150\,kA\,m^{-1}$ and maximum energy densities between 8 and $80\,kJ\,m^{-3}$. In order to achieve anisotropic Alnico magnets, a texture in the polycrystalline microstructure was induced by directional solidification. Subsequent annealing in a magnetic field resulted in precipitation of elongated α(Fe,Co) rods parallel to the magnetic field (De Voss, 1969). Anisotropic Alnico magnets achieve coercivities H_{cJ} between 0.5 and $170\,kA\,m^{-1}$ and maximum energy densities between 40 and $75\,kJ\,m^{-3}$, see Figure 1. Single-crystal Alnico 5 magnets have a maximum energy density of $80\,kJ\,m^{-3}$, owing to the optimized alignment of the α(Fe,Co) precipitates.

In 1952, Went *et al*. detected the hard magnetic properties of the hexagonal ferrites based on $MeO{\cdot}6Fe_2O_3$, Me: Ba, Sr, Pb (Went, Rathenau, Gorter and Van Oosterhaut, 1952). The coercivity of the hexaferrites is due to a strong magnetocrystalline anisotropy, which aligns the magnetic moments of the Fe ions parallel to the hexagonal axis. In order to reverse the polarization of a magnet, in principle, a reversed magnetic domain must be nucleated in each grain by the external field. The coercivities of isotropic Ba hexaferrites range from 210 to $270\,kA\,m^{-1}$. Within a unit cell, a third of the magnetic moments of the 24 Fe^{3+} ions are aligned antiparallel to the remaining Fe^{3+} ions, so that a small

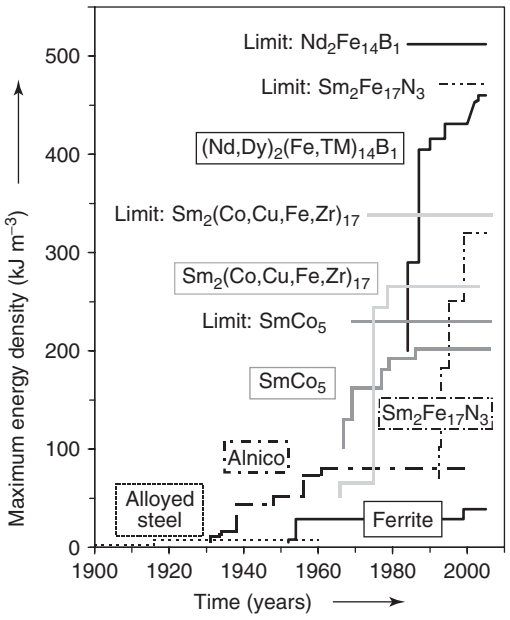

Figure 1. Progress in the maximum energy density of permanent magnets. For RE–TM magnet materials, the theoretical limits are indicated.

remanent polarization results. The maximum energy densities of isotropic $BaO{\cdot}6Fe_2O_3$ range between 6.5 and 9 kJ m^{-3}.

The uniaxial anisotropy of the hexaferrites enables the production of anisotropic magnets by powder metallurgy. After calcination, the material is milled to a fine alloy powder. The powder particles can be aligned by a magnetic field, compacted, and sintered to dense magnets. The coercivities of anisotropic Ba hexaferrites range between 130 and 340 kA m^{-1}. Owing to the increased magnetic polarization, much higher maximum energy densities between 20 and 30 kJ m^{-3} result, see Figure 1.

Even for these well-known magnetic materials, an essential improvement in the magnetic properties has been achieved lately. By a partial substitution of Sr by La and of Fe by Co, the remanent polarization and the coercivity could be increased by 4.4 and 7.5% respectively (Ogata *et al*., 1999).

In 1966, Strnat noticed the magnetocrystalline anisotropy of the rare earth (RE)–cobalt compounds $RECo_5$ (Hoffer and Strnat, 1966). The RE metals comprise the elements with the atomic numbers 58 (cerium) to 71 (lutetium), in which the 4f orbitals are filled with electrons. Owing to similar chemical properties, Y and La are also often included. Fortunately, these metals are rather abundant. For instance, the concentration of Ce in the earth's crust amounts to 46 ppm and is as available as the common metals Co (23 ppm), Sn (40 ppm), Pb (16 ppm), or Mg (15 ppm), (Vendel, 1984). Within the RE metals, Nd (24 ppm), Sm (6.5 ppm), and Dy (5 ppm) are rather abundant, see Figure 2.

In particular, the $SmCo_5$ compound has a very strong magnetocrystalline anisotropy. Hence, it was thought that anisotropic magnets should be prepared by powder metallurgy, similar to the production of the anisotropic hexaferrites. However, the RE–Co alloy powders are very sensitive to oxidation, and it took 3 years before Das succeeded in the preparation of anisotropic $SmCo_5$ magnets by powder metallurgy (Das, 1969). The coercivity of sintered $SmCo_5$ magnets is determined by nucleation of reversed domains, similar to the hexaferrites, but ranges between 1500 and 2400 kA m^{-1}. As a consequence of the high magnetic polarization, which results from the ferromagnetically coupled Co and RE^{3+} moments, the maximum energy densities amount to 160 up to 200 kJ m^{-3}, see Figure 1.

Since the concentration of Co atoms in the RE_2Co_{17} compounds is increased, a higher magnetic polarization results. However, the high saturation polarization of the RE_2Co_{17} compounds could not be exploited for increasing the maximum energy density of sintered magnets, since most of the RE_2Co_{17} compounds had a planar anisotropy. Only Sm_2Co_{17} and Er_2Co_{17} compounds have a uniaxial anisotropy (Ray and Strnat, 1972). On the basis of the Sm_2Co_{17} compound, Ojima *et al*. prepared magnets with a maximum energy density of 240 kJ m^{-3} and a coercivity of 500 kA m^{-1} (Ojima, Tomizawa, Yoneyama and Hori, 1977), which is too small for technical applications. Hence, another route for achieving strong coercivities had to be developed. By partial substitution of Co by Fe, Cu, and Zr and an appropriate heat treatment, a cellular microstructure of $Sm_2(Co,Fe)_{17}$ cells in a $Sm(Co,Cu)_5$ matrix could be achieved (Mishra *et al*., 1981). Since the intrinsic magnetic properties of these phases differ, magnetic domain walls are pinned at the phase boundaries. Hence, the pinning force determines the coercivity of such multiphase $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets (Fidler and Skalicky, 1982; Katter *et al*., 1996a,b; Katter, 1998). The coercivities H_{cJ} of sintered $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets can be tailored to meet the requirements of an application and range between 800 and 2100 kA m^{-1}. The maximum energy densities vary between 200 and 240 kJ m^{-3}, see Figure 1.

By increasing the Co content at the expense of the Fe concentration and by adjusting the Cu concentration $Sm_2(Co,Cu,Fe,Zr)_{17}$, magnets with a coercivity H_{cJ} of about 700 kA m^{-1} at a temperature of 500 °C were developed (Liu *et al*., 1999; Walmer *et al*., 2000a,b; Goll, Sigle, Hadjipanayis and Kronmüller, 2000; Zhang *et al*., 2000). With an appropriate coating, such magnets can be applied at high temperatures up to 550 °C.

Because of the successful application of RE–Co magnets, RE–Fe alloys were examined for intermetallic compounds with superior hard magnetic properties. Besides alloying and powder metallurgy (Sagawa *et al*., 1984a,b), the alternative processing route of rapid solidification or melt spinning,

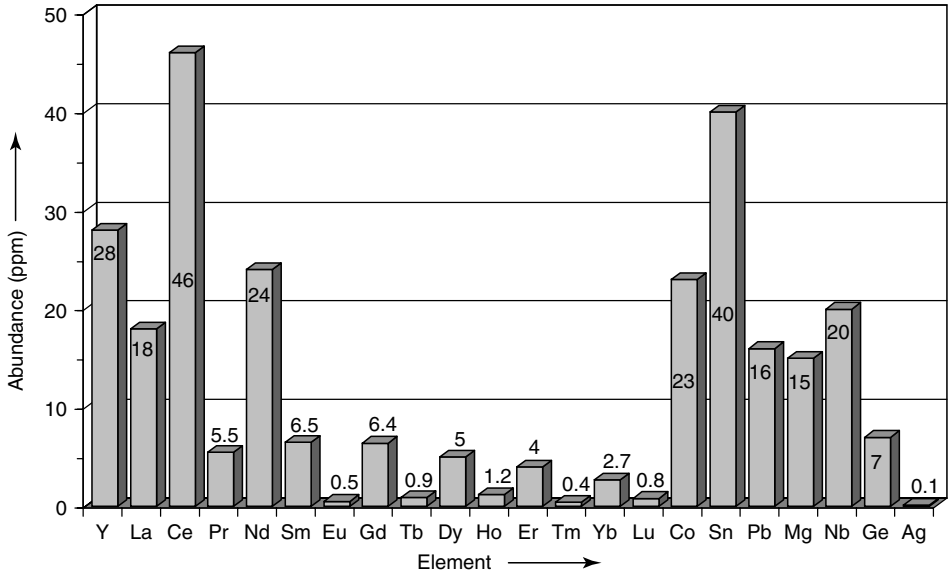

Figure 2. Abundance of rare-earth metals in comparison to some commercial metals.

respectively, has been investigated (Koon and Das, 1981; Croat, 1981a,b; Croat *et al*., 1984a,b; Hadjipanayis, Hazelton and Lawless, 1983, 1984). The efforts resulted in the development of different production routes for Nd–Fe–B magnets on the basis of the hard magnetic $Nd_2Fe_{14}B$ compound. The crystallographic positions of the different atoms in this new unit cell and their magnetic moments were determined exactly by neutron diffraction (Herbst, Croat, Pinkerton and Yelon, 1984). In this compound, the Nd atoms can be replaced by any other RE atom that influences the intrinsic magnetic properties (Sagawa *et al*., 1984; Herbst and Yelon, 1985). By a partial substitution of Nd by Dy, the coercivity of (Nd,Dy)–Fe–B magnets can be increased due to the enhanced magnetocrystalline anisotropy of the $Dy_2Fe_{14}B$ compound (Sagawa *et al*., 1984; Rodewald, 1985). Hence, the coercivities of Nd–Fe–B magnets can be adjusted to the application and now range between 950 and 2860 kA m^{-1}, the maximum energy densities being extend from 415 to 225 kJ m^{-3}, see Figure 1.

Some years later, promising hard magnetic properties were also detected in novel interstitial RE–Fe–N and RE–Fe–C compounds, the properties of which are presented by J. M. D. Coey in a separate chapter of this handbook (See also **Dilute Magnetic Oxides and Nitrides, Volume 4**).

The various production technologies for Nd–Fe–B magnets by powder metallurgy and their impact on the hard magnetic properties are presented in Section 2. In 2003, about 25.290 tons of Nd–Fe–B magnets were produced by powder metallurgy globally (Luo, 2004). Additional informations on the status of the magnet industry are presented in **Current Status and Future Development of the Magnetic Materials Industry in China, Volume 4**. The magnetizing behavior and the temperature stability of sintered Nd–Fe–B magnets are reviewed in Sections 3 and 4. A lot of research and development activities have been focused on the improvement of the corrosion behavior of sintered Nd–Fe–B magnets, which is decisive for many applications. The basic results and the progress in RE–TM magnet materials are summarized in Section 5. In many applications, the RE–TM magnets also experience mechanical stress besides magnetic stress. Some basic mechanical properties of sintered RE–TM magnets are compiled in Section 6. Some conclusions on the exploitation of the intrinsic magnetic properties of the different RE–TM compounds by commercial RE–TM magnet grades or by paramount laboratory magnets finish this review.

2 PRODUCTION OF SINTERED RE–TM MAGNETS BY POWDER METALLURGY AND THE IMPACT ON THE PROPERTIES

Most of the RE magnets with a high remanent polarization J_r or a strong coercivity H_{cJ}, respectively, are produced by powder metallurgy on a large scale in many shapes and dimensions. The processing route of RE–TM magnets starts with alloying. The alloys are melted from RE metals, transition metals (TMs), master alloys, and specific additions in vacuum induction furnaces since the RE metals are very sensitive to oxidation, in particular, at high temperatures.

An alternative processing route is the calciothermic reduction. RE oxides, TM powders, additions, and a reducing

agent, for instance, Ca hydride, are intensively mixed and compacted. During heating in a sealed container up to 1200 °C, the Ca metal evaporates and reduces the RE oxides to small RE particles, which immediately start to alloy with the TM and the additions, respectively (Herget, 1985). Finally, an RE–TM alloy powder in a matrix of Ca oxide results. After cooling to room temperature, the Ca oxide and excess Ca metal are separated from the alloy powder by leaching. Qualitatively, the calciothermic reaction and the leaching process can be described by equations (1) and (2), according to Herget (1985):

$$7.5Nd_2O_3 + 72Fe + 0.133Fe_{40}B_{60} + 22.5Ca \longrightarrow Nd_{15}Fe_{77}B_8 + 22.5CaO \quad (1)$$

$$Ca + CaO + 2H_2O \longrightarrow 2Ca(OH)_2 \quad (2)$$

The cast ingots or the calciothermic alloy powders have a multiphase polycrystalline microstructure. The hard magnetic $Nd_2Fe_{14}B$ grains are in equilibrium with Nd-rich constituents and some $Nd_{1.1}Fe_4B_4$ grains (Matsuura *et al.*, 1985). The magnetic moments of the $Nd_2Fe_{14}B$ grains are aligned parallel to the tetragonal axis by strong crystalline electric fields and hence are distributed randomly. In order to achieve a well-defined texture, powder metallurgy is applied. The alloys are crushed and milled to a fine alloy powder, see Figure 3. The powder particles must consist of single crystals or fragments thereof. In general, alloy powders with a particle size in the range between 3 and 5 µm meet this condition very well. For the production of anisotropic magnets, there exist different routes, which determine the magnetic properties, the dimensional tolerances, and the processing costs. After compaction of the alloy powders by different pressing technologies, the green parts are sintered to compact magnets. At sintering temperature, the fraction of the Nd-rich constituents is melted, so that liquid-phase sintering occurs and magnets with a density of approximately 98% of the theoretical density can be achieved. Afterward, a heat treatment is applied in order to optimize the microstructure with respect to the coercivity H_{cJ} of the magnets. Finally, the magnets are machined to dimensions, according to customer specifications, see Figure 3.

The maximum energy density is determined by the remanent polarization J_r and the reversible permeability μ_{rev}, see equation (3):

$$(BH)_{max} = \frac{J_r^2}{4 \cdot \mu_o \cdot \mu_{rev}} \quad (3)$$

In order to achieve a high maximum energy density, the remanent polarization and the reversible permeability have to be optimized. The remanent polarization J_r is determined

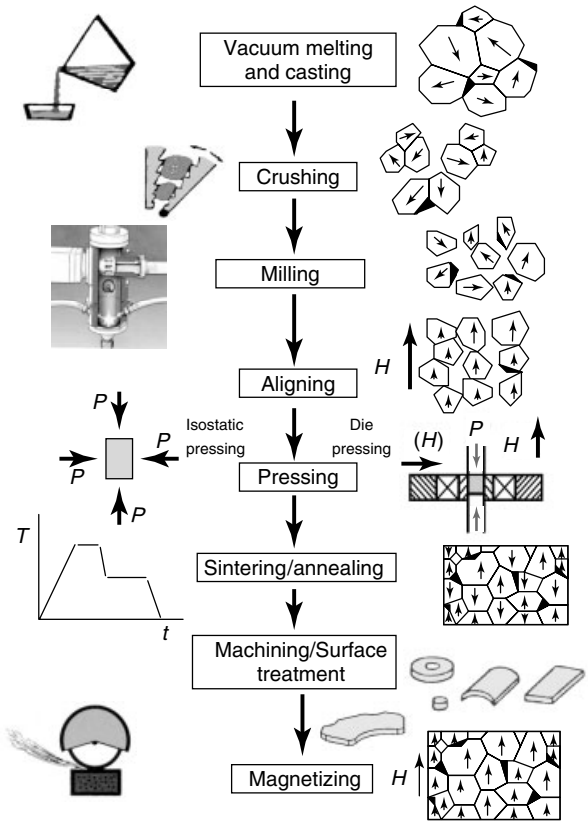

Figure 3. Processing of anisotropic RE magnets by powder metallurgy.

by equation (4):

$$J_r(20\,^\circ C) = J_s(20\,^\circ C) \cdot \frac{\rho}{\rho_0} \cdot (1 - V_{nonmag}) \cdot 0.01 \cdot f_\varphi \quad (4)$$

where $J_s(20\,^\circ C)$, ρ/ρ_0, V_{nonmag}, and f_φ denote the saturation polarization of the $Nd_2Fe_{14}B$ compound at 20 °C, the density related to the theoretical density of the alloy, and the fraction of nonmagnetic constituents and the alignment coefficient respectively.

The alignment coefficient is defined by Fernengel *et al.* (1996)

$$f_\varphi = (100\% \cdot \cos\varphi) \quad \text{with} \quad \varphi = \arctan\left(2\frac{J_{r\perp}}{J_{r\parallel}}\right) \quad (5)$$

and represents the average misalignment angle φ of the grains with respect to the easy axis, see Figure 4. The precondition is a cylindrical symmetrical distribution of the misaligned grains. Magnets pressed isostatically or in an axial magnetic field, respectively, meet this precondition fairly well. For magnets pressed in a transverse magnetic field (see Section 2.3), the perpendicular components of the remanent polarization $J_{r\perp}$ parallel or transverse to the pressing direction are different. Hence, for transversely

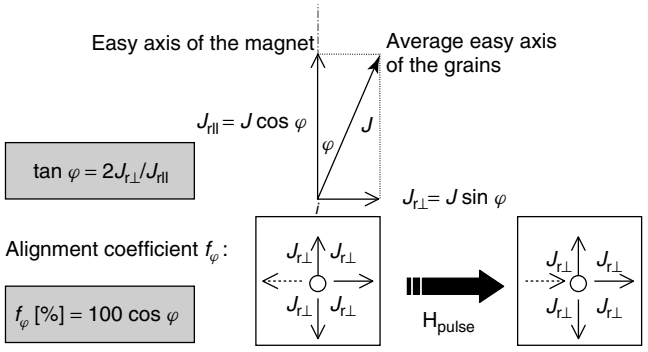

Figure 4. Schematic representation of the distribution of the components $J_{r\perp}$ of the magnetic polarization after magnetizing an anisotropic magnet perpendicular to its easy axis and definition of the alignment coefficient f_φ. Precondition is a homogeneous axial distribution of the misaligned grains, such as in cold isostatically pressed magnet blocks, axial field die pressed, or rubber isostatically pressed net-shaped magnets.

pressed magnets, two alignment coefficients have to be distinguished. The alignment coefficients can be easily determined from the remanent polarization measured parallel $J_{r\|}$ and perpendicular $J_{r\perp}$ with respect to the easy axis of an anisotropic magnet by a pair of Helmholtz coils after appropriate magnetization (Fernengel *et al.*, 1996).

The impact of different processing routes on the magnetic properties is reviewed in detail.

2.1 Cold isostatic pressing of magnet blocks (CIP)

For the production of big blocks, the alloy powder is sealed in a mold, aligned by a magnetic field, and pressed isostatically. Since the pressure increases homogeneously from all directions, the alignment of the powder particles is not disturbed significantly during compaction, see Figure 5. The isostatically pressed blocks are sintered to >98% of the theoretical density. Hence, isostatically pressed blocks have an excellent texture and achieve a high remanent polarization J_r. The alignment coefficient f_φ ranges between 96 and 99%. After sintering, the magnet blocks are annealed in order to optimize the coercivity.

Figure 6 gives the demagnetization curves $J(H)$ and $B(H)$ of isostatically pressed Nd–Fe–B magnets with a high remanent polarization at different temperatures. At room temperature, the typical remanent polarization and the coercivities amount to 1.46 T and 955 kA m^{-1} for H_{cJ} or to 915 kA m^{-1} for H_{cB}, respectively. With a recoil permeability of 1.03, a maximum energy density of 415 kJ m^{-3} results for this commercial magnet grade VACODYM® 722 HR.

Isotatically pressed blocks of $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets achieve remanent polarizations of 1.12 or 1.10 T with

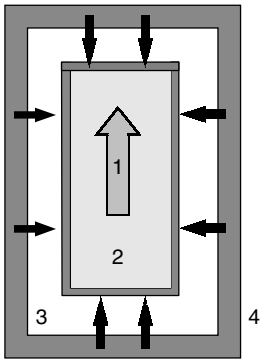

Figure 5. Principle of cold isostatic pressing of large magnet blocks: (1) alignment field, (2) alloy powder, (3) mold, (4) pressure container. Dimensions up to 105 mm in diameter and approximately 300 mm in length can be produced.

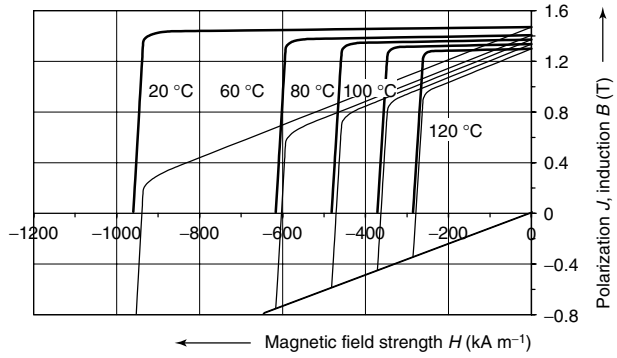

Figure 6. Demagnetization curves $J(H)$ and $B(H)$ of isostatically pressed Nd–Fe–B magnet blocks, grade VACODYM 722 HR, depending on the temperature. The typical magnetic properties at room temperature amount to $J_r = 1.46$ T, $H_{cJ} = 955$ kA m^{-1}, $(BH)_{max} = 415$ kJ m^{-3}.

coercivities H_{cJ} of 800 or 2070 kA m^{-1}, respectively, which results in maximum energy densities of 240 or 225 kJ m^{-3}. The lower Co concentration in isostatically pressed blocks of $SmCo_5$ magnets results in a smaller remanent polarization of 1.01 T and a maximum energy density of 200 kJ m^{-3}. Owing to the extraordinarily strong magnetocrystalline anisotropy of the $SmCo_5$ compound, a strong coercivity H_{cJ} of >1500 kA m^{-1} results.

2.2 Net-shaped magnets by axial field die-pressing (AP)

The manufacture of parts from isostatically pressed RE magnet blocks takes a lot of machining and therefore increases the processing costs. An alternative route is the production of net-shaped parts by die-pressing. The alloy powder is filled into the cavity of a die, aligned by an axial magnetic field, and compacted, see Figure 7. Since the easy axes

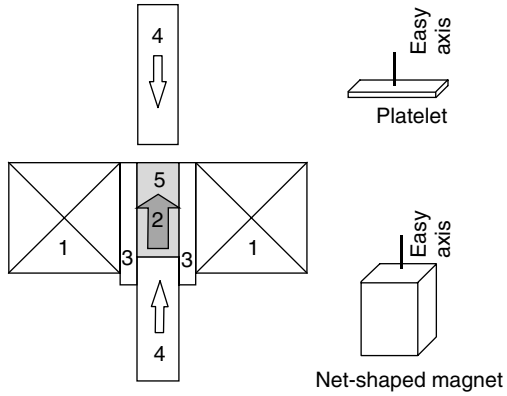

Figure 7. Principle of axial field die-pressing of large net-shaped magnets: (1) alignment coil, (2) magnetic field, (3) mold, (4) punches, and (5) alloy powder.

of the powder particles are aligned parallel to the pressing direction, the alignment is disturbed during compaction due to friction between the powder particles and the die. Hence, the remanent polarization of axial field die-pressed magnets is about 6–8% lower than isostatically pressed magnet blocks. By axial field die-pressing, a large variety of shapes with different dimensions can be manufactured economically.

Axial field die-pressed magnets based on Nd–Dy–Fe–Co–B alloys can achieve very high coercivities H_{cJ}. For instance, the typical demagnetization curves $J(H)$ and $B(H)$ at room temperature demonstrate a remanent polarization of 1.08 T and coercivities of 2.865 kA m^{-1} for H_{cJ} and 830 kA m^{-1} for H_{cB}, see Figure 8. With increasing temperature, a decrease in the coercivity H_{cJ} cannot be prevented, but at a temperature of 150 °C the coercivity H_{cJ} still amounts to 1.200 kA m^{-1}. Such magnets resist strong reversed magnetic fields even at elevated temperatures. This is a decisive benefit for many motor applications. The maximum energy density of such magnets with a strong coercivity amounts to 225 kJ m^{-3}.

Net-shaped magnets produced by axial field die-pressing from $Sm_2(Co,Cu,Fe,Zr)_{17}$ alloy powders achieve remanent polarizations and coercivities H_{cJ} in the range of 0.97–1.05 T and 2070–800 kA m^{-1}. The maximum energy density of such magnets varies between 170 and 210 kJ m^{-3}. Owing to the lower saturation polarization of the $SmCo_5$ compound, the remanent polarizations and the coercivities H_{cJ} of net-shaped $SmCo_5$ magnets amount to 0.85–0.95 T and 2400–1200 kA m^{-1}. The maximum energy densities of axial field die-pressed $SmCo_5$ magnets range between 140 and 180 kJ m^{-3}.

In general, net-shaped Sm–Co magnets are more brittle than Nd–Fe–B magnets and are sensitive to chipping, but have a superior temperature and corrosion stability.

2.3 Net-shaped magnets by transverse field die-pressing (TP)

Another possibility is the pressing of parts in a transverse magnetic field, see Figure 9. In this case, the alignment of the powder particles is not disturbed very strongly during compaction; therefore, it results in remanent polarizations similar to isostatically pressed magnet blocks. Hence, in sintered transverse field die-pressed magnets, alignment coefficients, f_φ, vary between 94 and 96% in general.

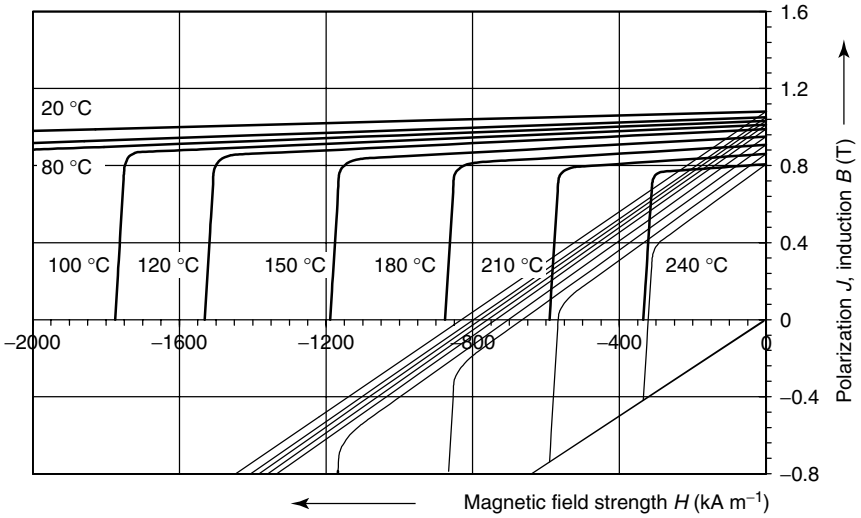

Figure 8. Demagnetization curves $J(H)$ and $B(H)$ of isostatically pressed Nd–Fe–B magnet blocks, grade VACODYM 688 AP, depending on the temperature. The typical magnetic properties at room temperature amount to $J_r = 1.08$ T, $H_{cJ} = 2865$ kA m^{-1}, $(BH)_{max} = 225$ kJ m^{-3}.

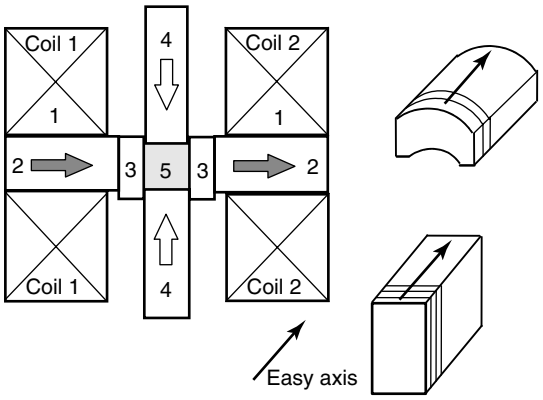

Figure 9. Principle of transverse field die-pressing of near net-shaped magnets: (1) alignment coils, (2) magnetic field, (3) mold, (4) punches, and (5) alloy powder.

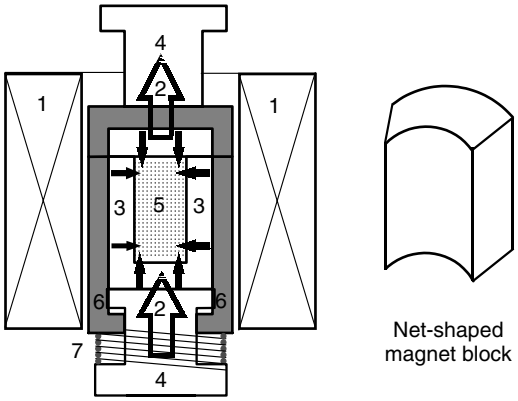

Figure 10. Principle of rubber isostatic pressing of net-shaped magnets: (1) pulse field alignment coil, (2) magnetic field, (3) thick rubber mold, (4) punches, (5) alloy powder, (6) support die, and (7) support spring.

By transverse field die-pressing, mainly rectangular blocks or near net-shaped parts are manufactured. After sintering, the blocks are cut into thin magnet plates according to customer specifications. However, near net-shaped parts may need some contour grinding before cutting. Hence, the machining costs increase in comparison to axial field die-pressed magnets.

The typical magnetic properties of transverse field die-pressed Nd–Fe–B magnets range from 1.14 up to 1.43 T for the remanent polarization and from 2865 to 955 kA m^{-1} for the coercivity H_{cJ} or from 885 to 915 kA m^{-1} for the coercivity H_{cB}, respectively, which depends on the alloy composition. Accordingly, the maximum energy densities vary between 250 and 395 kJ m^{-3}.

2.4 Net-shaped magnets by rubber isostatic pressing (RIP)

A new pressing technology, which combines the benefits of cold isostatic pressing (CIP) – an almost perfect alignment – and die-pressing net-shaped parts, is rubber isostatic pressing (RIP) (Sagawa and Nagata, 1993; Sagawa, Nagata, Watanabe and Itani, 2000; Nagata and Sagawa, 2002). The alloy powder is tapped into a thick rubber mold up to a well-defined density and then the die is closed by the upper punch. Afterwards, the powder particles are aligned by strong magnetic field pulses with a peak field strength of 2.400 kA m^{-1}. Finally, the alloy powder is compacted by axial pressing, see Figure 10. However, by the thick rubber mold, the pressing forces are diverted, so that an almost isostatic compaction occurs. Hence, near net-shaped parts with alignment coefficients comparable to isostatically pressed blocks can be manufactured.

By RIP, near net-shaped blocks with a remanent polarization of 1.47 T and a coercivity of 920 kA m^{-1} could be manufactured. The maximum energy density of such blocks amounts to 424 kJ m^{-3}, see Figure 11. Such magnets achieve alignment coefficients $f > 96\%$, which implies an average misalignment angle of $<16^{\circ}$ related to the easy axis of the magnet.

The almost perfect alignment of the grains results in strong demagnetizing local stray fields, which decrease the coercivity of such magnets (Rodewald *et al.*, 2000). Owing to the small coercivity H_{cJ}, the maximum continuous operating temperature amounts to about 60 °C for a load line $B/\mu_0 H = -2$.

2.5 Review of alternative processing routes

Besides the production of anisotropic RE–TM magnets by powder metallurgy, several alternative processing routes have been developed, in particular, for Nd–Fe–B magnets. Main objectives have been the elimination of some processing steps in order to simplify the production route and to reduce the processing costs; in particular, the handling of fine and pyrophoric RE–TM alloy powders. However, in most cases, isotropic magnet materials with inferior magnetic properties result. For the manufacture of anisotropic magnets, additional processing steps, such as hot deformation or hot rolling are needed. Besides, some alternative processing routes only enable the production of magnets with special shapes, for instance, ring magnets, thick layers, or thin films.

2.5.1 Rapid solidification and compaction of RE–TM magnets

Alloy powders for polymer-bonded magnets are produced in large quantities by rapid solidification or melt spinning

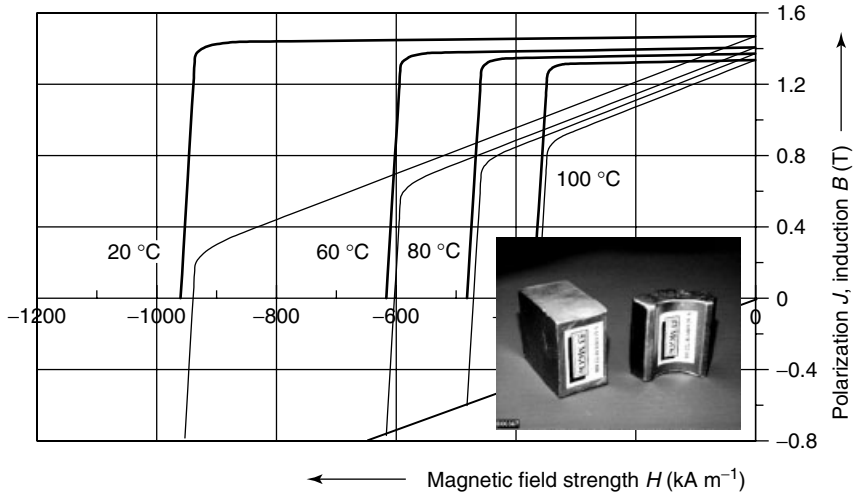

Figure 11. Demagnetization curves $J(H)$ and $B(H)$ of Nd–Dy–Fe–B magnets manufactured by rubber isostatic pressing (RIP®) at different temperatures. ®: registered trademark of Intermetallics Co. Ltd.

of Nd–Fe–B alloys. The molten alloy is chilled onto a fast rotating wheel surface, so that amorphous or submicrocrystalline ribbons with a thickness between 30 and 50 µm result (Croat *et al*., 1984). Since the easy axes of the crystals are distributed randomly, the alloy powders of such submicrocrystalline ribbons are isotropic with respect to the magnetic polarization. The remanent polarization and the coercivities of annealed and crushed alloy powders, made from Nd–Fe–B ribbons, range from 0.78 to 1.0 T and 510 to 1430 kA m^{-1}, depending on the composition of the alloy powders. The maximum energy densities, related to the theoretical density, vary from 95 to 140 kJ m^{-3}.

Compact isotropic Nd–Fe–B magnets can be manufactured by hot-pressing at temperatures of about 750 °C (Croat *et al*., 1984). The remanent polarization and the coercivities of compact isotropic hot-pressed net-shaped magnets range from 0.8 to 0.83 T for the remanent polarization, from 1440 to 1400 kA m^{-1} for the coercivity H_{cJ}, and from 112 to 120 kJ m^{-3} for the maximum energy density.

By an additional hot-deformation process at a temperature of about 750 °C, anisotropic Nd–Fe–B magnets can also be manufactured (Lee, Brewer and Schaffel, 1985). Owing to a pressure-induced anisotropic grain growth of these grains, the easy axes of which are aligned parallel to the pressing force, a texture of hot-deformed magnets is obtained (Mishra, Brewer and Lee, 1988; Li and Graham, 1990). The magnetic properties of compact anisotropic hot-deformed Nd–Fe–B magnets amount to 1.15–1.3 T for the remanent polarization, to 1600–1000 kA m^{-1} for the coercivity H_{cJ}, and to 250–340 kJ m^{-3} for the maximum energy density.

Similar principles are exploited for the production of radially aligned ring magnets by hot-backward extrusion (Yoshikawa *et al*., 1994, 1999; Grünberger, 1998). The magnetic properties of radially aligned Nd–Fe–B ring magnets strongly depend on the inner and outer diameters. Radially anisotropic Nd–Fe–B magnets with a remanent polarization between 1.08 and 1.32 T, coercivities H_{cJ} between 1990 and 1110 kA m^{-1}, and maximum energy densities between 230 and 330 kJ m^{-3} are commercially available.

2.5.2 *Gas atomization of RE–TM alloys*

Another economic route for the production of isotropic alloy powders with strong coercivities H_{cJ} is inert gas atomization (Yamamoto, Inoue and Masumoto, 1989; Lewis, Sellers and Panchanathan, 1995, 1996; Sellers *et al*., 1997; Branagan, Burch, Sellers and Hyde, 1998). The RE–TM alloy is melted by an electric arc and dispersed by a gas stream, which in general results in a wide particle size distribution (Yamamoto, Inoue and Masumoto, 1989; Lewis, Sellers and Panchanathan, 1995). The magnetic properties of the alloy powder depend on the microstructure of the particles, which can be optimized by appropriate quenching rates (Branagan, Burch, Sellers and Hyde, 1998; Kramer *et al*., 2003), subsequent heat treatments (Yamamoto, Inoue and Masumoto, 1989), or alloying additions, for instance, TiC (Branagan, Hyde, Sellers and Lewis, 1996). The research and development activities focus on the production of alloy powders with small dimensions, a narrow particle size distribution, and a submicrocrystalline microstructure in order to improve the coercivity H_{cJ} and the squareness of the demagnetization curve $J(H)$.

Commercial gas-atomized Nd–Fe–B alloy powders for the manufacture of bonded RE–TM magnets, in particular, by injection molding, with a remanent polarization and coercivity H_{cJ} of 0.73–0.76 T and 670–750 kA m^{-1} are available.

The maximum energy density of such alloy powders ranges between 80 and 92 kJ m^{-3}.

2.5.3 *Mechanical alloying and compaction of RE–TM magnets*

Mechanical alloying is a powder metallurgical processing route, originally developed for the production of oxide dispersion–strengthened materials. In general, it is well suited for the preparation of any type of nonequilibrium phases, such as amorphous or nanocrystalline materials. A powder blend consisting of elemental powders is milled in a ball mill in an inert atmosphere. Mechanical alloying was applied for the preparation of hard magnetic Nd–Fe–B powders first by Schultz, Wecker and Hellstein (1987). Elemental Nd, Fe, and B powders were milled in a ball mill in an inert atmosphere. The individual powder particles were cold worked by collisions with the balls or by friction. Heavy deformation, repeated cold welding, and fracture produced a nanocrystalline composite, which consisted of an amorphous Nd-rich phase and α-Fe crystals after prolonged milling. After a subsequent heat treatment, at a temperature between 600 and 750 °C, the hard magnetic $Nd_2Fe_{14}B$ compound was crystallized. Mechanically alloyed and heat-treated Nd–Fe–B alloy powders have a nanocrystalline microstructure. Each particle consists of many randomly aligned grains with dimensions of less than 100 nm. Similar to rapidly solidified ribbons, mechanically alloyed Nd–Fe–B alloy powders can be applied for the manufacture of polymer-bonded magnets. Typical magnetic properties of mechanically alloyed Nd–Fe–B powders amount to 0.8–0.92 T for the remanent polarization, 1200–1000 kA m^{-1} for the coercivity H_{cJ}, and 102–140 kJ m^{-3} for the maximum energy density (Schultz, Wecker and Hellstein, 1987; Bollero, Gutfleisch, Müller and Schultz, 2002).

Nanocrystalline two-phase Nd–Fe–B powders with enhanced remanent polarizations up to 1.2 T and smaller coercivities H_{cJ} in the range between 336 and 480 kA m^{-1} could be prepared by mechanical alloying and annealing (Neu and Schultz, 2001). Intensive milling of Nd–Fe–B powders, which are much easier to crush and to mill, also resulted in isotropic alloy powders with remanent polarizations and coercivities of about 0.68 T and 1.200 kA m^{-1} (Daniel, 1995).

Compact isotropic magnets can be produced by hot pressing, and an additional hot-deformation process enables the manufacture of anisotropic magnets (Schultz, Schnitzke and Wecker, 1988).

Mechanical alloying of SmF_3, Co, and Ca powders resulted after a heat treatment at a temperature between 600 and 750 °C in isotropic $SmCo_5$ powders with an extremely high coercivity H_{cJ} of 5240 kA m^{-1} (Liu, Dallimore and McCormick, 1992).

2.5.4 *Hot rolling of RE–TM magnet materials*

There are some research and development activities on the production of anisotropic RE–TM magnets directly from cast Pr–Fe–Cu–B or Nd–Fe–Cu–B alloys in order to minimize the number of processing steps. In general, cast ingots get a heat treatment at temperatures of about 1000 °C in order to homogenize the microstructure. By hot rolling such ingots, anisotropic magnet plates with a thickness up to a few millimeters have been produced (Shimoda, Akioka, Kobayashi and Yamagami, 1988, 1989; Shimoda, Akioka and Kobayashi, 1990; Hinz, Schumann, Helming and Schäfer, 1994; Rivoirard *et al*., 2000). During hot rolling, a grain refinement and an alignment occurs. Similar to the hot-deformation process, the easy axes of the grains align parallel to the deformation force and hence orientate the easy axis perpendicular to the rolling plane (Hinz, Schumann, Helming and Schäfer, 1994). Typical thickness reductions range between 75 and 95%. The optimal magnetic properties are achieved after proper annealing at temperatures between 1000 and 500 °C (Arai *et al*., 1994). In general, the magnetic properties of hot-rolled Pr–Fe–Cu–B or Nd–Fe–Cu–B magnets range between 0.9 and 1.2 T for the remanent polarization, between 800 and 1300 kA m^{-1} for the coercivity H_{cJ}, and between 120 and 290 kJ m^{-3} for the maximum energy density.

2.5.5 *Plasma spraying of RE–TM magnet layers*

A very straightforward processing route for manufacturing RE–TM magnet layers with a thickness up to some millimeters is plasma spraying. In principle, plasma spraying needs only three processing steps: alloying, crushing to an alloy powder with a particle size in the range 40–100 µm, and plasma spraying. The coarse alloy powder is melted in a gas plasma, in which the temperatures can be as high as 20 000 °C. The molten RE–TM particles are accelerated and are consolidated onto a substrate. Parts with complicated shapes can be manufactured, for instance, thin-walled hollow cylinders. The cooling rates are estimated to amount to about 10^6 K s^{-1}. Hence, amorphous or very fine crystalline microstructures result. In order to prevent oxidation, plasma spraying has to be performed in vacuum or in an inert atmosphere.

Without preheating the substrate, low coercivities of some 10 kA m^{-1} result in the as-deposited Nd–Dy–Fe–B layers, which increase substantially after appropriate annealing. The $Nd_{16}Dy_1Fe_{76}B_7$ layers have got the best magnetic properties after annealing: remanent polarizations and coercivities

H_{cJ} are in the range 0.66–0.7 T and 1210–1250 kA m^{-1}. Maximum energy densities from 80 to 82.4 kJ m^{-3} are obtained (Willson, Bauser, Liu and Huang, 2003).

Preheating the substrate to temperatures of about 600 °C, $Nd_{16}Dy_1Fe_{76}B_7$ layers achieve remanent polarizations of 0.55–0.59 T and coercivities of 960–1600 kA m^{-1}. The maximum energy densities of the almost isotropic layers amount to 44–61 kJ m^{-3} (Overfelt, Anderson and Flanagan, 1986; Rieger *et al*., 2000; Willson, Bauser, Liu and Huang, 2003).

In Nd–Fe–B plasma-sprayed layers, consolidated onto Cu substrates, which were heated to temperatures in the range 500–800 °C, some magnetic anisotropy could be obtained (Wyslocki, 1992b). Owing to the partial alignment of the $Nd_2Fe_{14}B$ grains, a remanent polarization of 0.9 T could be obtained. The very fine microstructure of the layer results in a strong coercivity H_{cJ} of 1200 kA m^{-1}. Both features, alignment of the grains and the fine microstructure, contribute to a high maximum energy density, which amounts to 180 kJ m^{-3}.

Plasma-sprayed layers, prepared form $SmCo_5$ alloy powders, achieve thin isotropic magnets with huge coercivities from 3750 up to 5400 kA m^{-1} (Kumar, Das and Wettstein, 1978). Owing to the low remanent polarizations between 0.5 and 0.56 T, maximum energy densities from 43 to 61 kJ m^{-3} are obtained.

2.5.6 *Liquid dynamic compaction of RE–TM magnet layers*

Similar to plasma spraying is the formation of RE–TM magnet layers with a thickness from 1 to 10 mm by liquid dynamic compaction. The RE–TM alloy with the final composition is melted and dispersed into small droplets by ultrasonic gas atomization. The droplet stream is consolidated onto a substrate. Growth rates up to 1 cm min^{-1} were achieved (Chin *et al*., 1986). The solidification rates were estimated to range between 100 and 1000 K s^{-1}. Owing to the almost amorphous microstructure of as-deposited Nd–Fe–B layers, only coercivities from 240 to 400 kA m^{-1} resulted. However, by annealing at temperatures between 600 and 700 °C, a fine-grained microstructure and improved magnetic properties of the isotropic layers could be achieved. Remanent polarizations and coercivities H_{cJ} of 0.53–0.7 T and 620–1250 kA m^{-1} are reported (Chin *et al*., 1986; Harada, Ando, O'Handley and Grant, 1990). The maximum energy density of these isotropic layers amount to 48–80 kJ m^{-3}.

2.5.7 *Preparation of thin RE–TM films*

For some micromechanic devices, such as miniature motors, pumps, actuators, sensors, hard magnetic films with a thickness of a few micrometers may be required. Such films can be prepared by sputtering or by laser ablation. A lot of research and development activities are going on in order to optimize the processing conditions, such as the substrate material and the temperature, the sputtering gas atmosphere, the target composition, the target–substrate distance, or even the application of a magnetic field parallel to the substrate plane (Cadieu *et al*., 1987; Parhofer, Gieres, Wecker and Schultz, 1996; Parhofer *et al*., 1998; Araki, Nakanishi and Umemura, 1999; Neu and Shaheen, 1999; Jiang and O'Shea, 2000; Castaldi, Gibbs and Davies, 2003). The films deposited onto the substrates at ambient temperatures are amorphous and need annealing at temperatures between 400 and 700 °C for crystallization. By consolidation of the sputtered material onto heated substrates, microcrystalline films can be achieved directly (Cadieu *et al*., 1987; Parhofer, Gieres, Wecker and Schultz, 1996).

About 1- to 2-μm-thick Nd–Dy–Fe–B films with a texture perpendicular to the film plane could be prepared by sputtering. In general, the magnetic properties range from 0.9 to 1.3 T for the remanent polarization, 200 to 800 kA m^{-1} for the coercivity H_{cJ}, and 150 to 190 kJ m^{-3} for the maximum energy density (Sun, Tomida, Hirosawa and Maehara, 1996; Parhofer, Gieres, Wecker and Schultz, 1996; Parhofer *et al*., 1998; Araki, Nakanishi and Umemura, 1999; Castaldi, Gibbs and Davies, 2003).

In contrast, sputtered $SmCo_5$ or $Sm_2(Co,Cu,Fe,Zr)_{17}$ films with a thickness between 1 and 2 μm crystallize with their easy axis in the film plane. The magnetic properties range from 0.6 to 0.8 T for the remanent polarization, 1000 to 1200 kA m^{-1} for the coercivity H_{cJ}, and to about 120 kJ m^{-3} for the maximum energy density (Cadieu *et al*., 1987; Neu and Shaheen, 1999).

Lately, some research and development projects have been focusing on the preparation of thin RE–TM films by pulsed-laser deposition. The thickness of such films, in general, ranges from 0.1 to 0.3 μm. The crystallization onto heated substrates with temperatures in the range 400–550 °C result in anisotropic films with a remanent polarization of about 0.6 T and a coercivity H_{cJ} of 800 kA m^{-1} for Sm–Co films (Neu *et al*., 2002b) and remanent polarizations between 0.9 and 1 T and coercivities H_{cJ} between 400 and 1000 kA m^{-1} for Nd–Fe–B films (Hannemann *et al*., 2002; Fähler *et al*., 2003; Neu *et al*., 2002a).

Isotropic Nd–Fe–B films with a thickness from about 10 to 120 μm could be prepared by high-speed pulsed-laser deposition (Nakano *et al*., 2003). The magnetic properties range between 0.4 and 0.68 T for the remanent polarization, 800 and 1200 kA m^{-1} for the coercivity H_{cJ}, and up to 77 kJ m^{-3} for the maximum energy density.

Although some improvements are to be expected by optimization of the pulsed-laser deposition, the sputtering

process seems to be more promising for the preparation of RE–TM hard magnetic films.

2.5.8 Amorphous hard magnetic RE–TM materials

In RE–Fe–Al systems, RE: Pr and Nd, there is a wide composition range for the formation of an amorphous phase, which enables the preparation of bulk amorphous alloys by conventional solidification methods (Inoue *et al*., 1996a,b; Inoue, Zhang and Takeuchi, 1997). Cylindrical rods with diameters up to 3 or 12 mm for Pr–or Nd–Fe–Al alloys respectively could be manufactured by injection casting into a Cu mold with a small pressure of 0.05 MPa or by sucking the molten alloy into a Cu mold. X-ray spectra indicate that the cylindrical rods consist of an amorphous phase. Detailed analyses of the microstructure reveal that the samples consist of Nd nanocrystals in an amorphous matrix. Indeed, the amorphous matrix contains two amorphous phases with a different composition and some short-range order (Sun *et al*., 2003).

The magnetic properties amount to 0.089 or 0.112 T for the remanent polarization, 300 or 288 kA m^{-1} for the coercivity H_{cJ}, and 13 or 19 kJ m^{-3} for the maximum energy density of $Pr_{60}Fe_{30}Al_{10}$ or $Nd_{60}Fe_{30}Al_{10}$ rods (Inoue *et al*., 1996; Inoue, Zhang and Takeuchi, 1997). The squareness of the demagnetization curve $J(H)$ depends on the diameter of the rods. This result indicates that the hard magnetic properties are sensitive to the disordered structure in the amorphous phase. There seems to be a tendency that the hard magnetic properties increase with the development of a short-range order. Annealing of cast cylinders at a temperature of 330 °C for 10 min increases the remanent polarization by about 5%, but no significant change of the coercivity H_{cJ} occurs. Heating beyond the crystallization temperature of about 510 °C results in $NdAl_2$ and $Nd_3Fe_{1-x}Al_x$ crystals in an Nd matrix. As a consequence, the hard magnetic properties decrease substantially (Inoue *et al*., 1996).

Investigation of the temperature dependence of the coercivity of $Nd_{60}Fe_{30}Al_{10}$ and of $Nd_{60}Fe_{20}Co_{10}Al_{10}$ ribbons or of cast ingots demonstrates a strong increase in the coercivity at low temperatures with a maximum between 2640 and 3200 kA m^{-1} at temperatures between 50 and 77 K (Turtelli *et al*., 2002). At temperatures below 77 K, the coercivities decrease again. The magnetization curves $J(H)$ and the linear temperature dependence of the coercivity indicate a pinning-type behavior. Probably the magnetic domain walls are pinned at the nanocrystals in the amorphous matrix (Turtelli *et al*., 2002).

In order to increase the glass-forming ability, $Nd_{60-x}Fe_{30}Al_{10}B_x$ rods, $x = 0$, 1, 3, 5, were prepared by low-pressure Cu-mold casting. For $Nd_{59}Fe_{30}Al_{10}B_1$ rods with a diameter of 1 mm, a small increase of the remanent polarization and of the maximum energy density to 0.154 T and 4.2 kJ m^{-3} results, whereas the coercivity H_{cJ} does not change significantly and amounts to 340 kA m^{-1} (Kong, Li and Ding, 2000).

By addition of B, B and Cu, or Dy to $Nd_{60}Fe_{30}Al_{10}$ alloys, the coercivity of 3-mm ingots, which were cast into a Cu mold, could be improved up to 388 kA m^{-1} for a $Nd_{41.2}Pr_{13.8}Dy_5Fe_{20}Al_{10}$ at the expense of the remanent polarization (Betancourt and Valenzuela, 2003).

However, the coercivity mechanism in amorphous RE–Fe–Al alloys is still under investigation.

3 MAGNETIZING OF RE–TM MAGNETS

After sintering, RE–TM magnets are in the thermally demagnetized state. Hence, the grains contain different magnetic domains, the dimensions of which are determined by the minimization of the magnetic stray field energy at the surface of the magnet. The magnetic domains are separated by domain walls, which can either move easily within the grains or be pinned at phase boundaries, precipitates, or planar crystal defects (Kronmüller, 1978).

Perfect magnetization of anisotropic magnets to saturation implies that all grains must be magnetized in the easy direction and no multidomain grains exist anymore. The saturation of magnets can be achieved by strong magnetic field pulses. The required magnetic field strength depends on the coercivity mechanism, the saturation polarization of the magnetic material, and the load line of the magnet or of the magnet assembly, respectively. The following coercivity mechanisms are dominant in RE–TM magnet materials with strong coercivities:

- nucleation of reversed domains in every saturated grain or
- pinning of the magnetic domain walls at phase boundaries, precipitates, or planar crystal defects.

The magnetizing curve of a magnet material from the thermally demagnetized state indicates which coercivity mechanism prevails, see Figure 12. In nucleation-type magnets, for instance, Nd–Fe–B, $SmCo_5$, or hard ferrites, the magnetic domain walls can be moved easily within the grains, so that the polarization increases steeply already in small magnetizing fields, see Figure 12(a). But, perfect saturation requires a magnetizing field strength of at least twice the saturation polarization of the magnet material (Blank, Rodewald and Schleede, 1989).

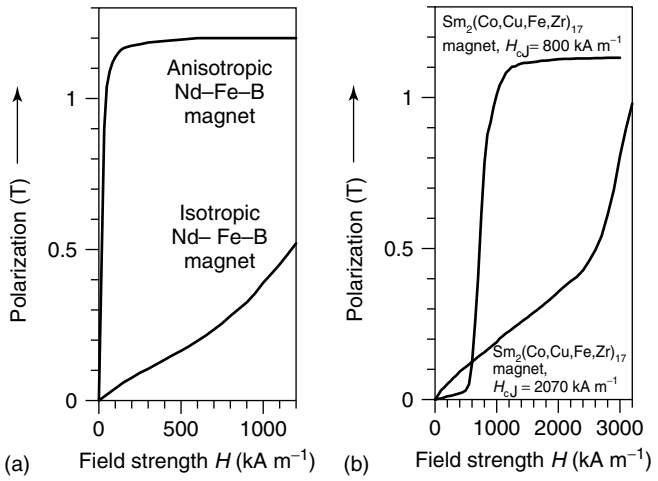

Figure 12. Principal magnetizing behavior of thermally demagnetized RE–TM magnets. (a) Nucleation-type anisotropic RE–TM magnets, for instance, Nd–Fe–B or $SmCo_5$ magnets, or isotropic RE–TM magnets, for instance, rapidly solidified Nd–Fe–B ribbons, (b) pinning-type RE–TM magnets, for instance, $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets with coercivities H_{cJ} of 800 or 2070 kA m^{-1}, respectively.

However, in isotropic Nd–Fe–B magnets, for instance, magnets made from rapidly solidified Nd–Fe–B ribbons, there is only a flat increase in the polarization from the thermally demagnetized state, see Figure 12(a). Probably only those grains, whose easy axes are aligned parallel to the magnetizing field strength, are easily saturated, whereas in all other grains the polarization must be rotated parallel to the magnetizing field. The rotation of the polarization against the magnetocrystalline fields requires strong magnetizing fields. In principle, saturation of isotropic magnets needs a magnetizing field strength similar to the anisotropy field strength.

The coercivity mechanism in nucleation-type magnets has been described by the micromagnetic theory for nucleation of reversed domains (Kronmüller, 1985, 1987; Adler and Hamann, 1985; Kronmüller, Durst and Sagawa, 1988; Sagawa and Hirosawa, 1988; Kou, Kronmüller, Givord and Rossignol, 1994) or by an empirical model for the existence and expansion of nuclei of reversed domains (Givord, Tenaud and Viadieu, 1988; Givord and Rossignol, 1996; Barthem, Givord, Rossignol and Tenaud, 2002; Givord, Rossignol and Barthem, 2003).

In pinning-type magnets, the magnetic domain walls are pinned at phase boundaries, for instance, in $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets with coercivities H_{cJ} between 500 and 800 kA m^{-1}. In order to saturate a pinning-type magnet, the domain walls must be removed from the pinning sites, which requires magnetizing fields larger than the pinning field strength, see Figure 12(b). Saturation of such magnets needs magnetizing field strengths of at least twice the coercivity H_{cJ}, see Section 3.2. Microscopic models for the coercivity mechanism of pinning-type magnets have been compiled by several authors (Durst and Kronmüller, 1987; Katter *et al*., 1996; Katter, 1998).

However, in some magnet materials, the pinning field strength is not well defined, for instance, in $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets with strong coercivities above 1600 kA m^{-1}, see Figure 12(b).

In Alnico magnets, the coercivity is determined by the shape anisotropy of the ferromagnetic Fe–Co rods in the nonmagnetic matrix. The coercivity is determined by the difference of the demagnetizing coefficient $N_|$ parallel to the easy axis and $N_\perp$ perpendicular to the easy axis of the magnet, see equation (6).

$$\mu_0 H_{cJ} = -J \cdot (N_| - N_\perp) \cdot f(q) \tag{6}$$

where $f(q)$ denotes a distribution function, which takes into account the nonideal alignment of the easy axes of the Fe–Co rods (Buschow, 1998). For the case of noninteracting uniaxial single domain particles, $f(q)$ amounts to 0.5.

For magnetization of permanent magnets, the internal magnetic field strength H_{int} in the magnet is decisive. The internal field strength is determined by the applied field strength H_{appl} and the demagnetizing field strength H_{demag} of the magnet or the magnet assembly. The demagnetizing field strength depends on the dimensions of the magnet or the load line of a magnet assembly, respectively, and the polarization of the magnet materials, see equation (7):

$$H_{int} = H_{appl} - H_{demag} = \frac{H_{appl} - 1}{\mu_0 \times N \times J} \tag{7}$$

where N denotes the demagnetization coefficient and J the polarization of the magnet material.

Most of the advanced magnets are magnetized by a short pulse field, which is achieved by discharging a capacitor bank over a Cu coil. The duration of the field pulse must last sufficiently long in order to overcome the eddy currents at the surface of the magnets, in particular, for large blocks. In general, a pulse width in the range between 5 and 10 ms is sufficient for a complete field penetration. The penetration depth λ (see equation 8) depends on the electrical resistance ρ and the permeability μ of the magnet material and the frequency f of the field pulse (Parker, 1990):

$$\lambda = \text{constant} \cdot \sqrt{\frac{\rho}{\mu \cdot f}} \tag{8}$$

In general, magnets are magnetized after assembly, since handling of not-magnetized magnets is easier and prevents

contamination by ferromagnetic particles. In addition, chipping of magnet edges due to the mutual attraction of magnet parts is avoided.

3.1 Magnetization of nucleation-type magnets

Magnetization of nucleation-type magnets, for instance, sintered anisotropic ferrites, $SmCo_5$, or Nd–Fe–B magnets, is fairly easy from the thermally demagnetized state. Since the magnetic domain walls in the individual grains can be moved easily, a polarization of about 95% of the saturation polarization results even after magnetization by a small magnetizing field strength of about 200 kA m^{-1}. However, removal of the magnetizing field strength decreases the polarization, since there is no significant coercivity. In the multidomain grains, the domain walls are moved back in order to minimize the magnetic stray field energy, see Figure 13.

Magnetization by a field strength of about 500 kA m^{-1} saturates some grains, so that some coercivity results. Such grains do not contain domain walls anymore. Since most of the grains are still multidomain grains, the demagnetization curves $J(H)$ of such partially magnetized magnets demonstrate a very poor squareness, see Figure 13.

Complete magnetization requires a strong internal field strength >1600 kA m^{-1}. In that case, every grain is saturated. There are hardly any grains that contain small reversed domains.

The coercivity of nucleation-type magnets is determined by the nucleation of reversed magnetic domains in each grain, since the grains are decoupled magnetically by nonmagnetic Nd-rich constituents. The minimal volume of such a reversed magnetic domain is proportional to the domain wall thickness cubed (Givord, Tenaud and Viadieu, 1988; Givord and Rossignol, 1996). In general, the nucleation occurs at crystal defects, where the magnetocrystalline anisotropy is reduced or at edges of grains, where strong local stray fields assist the nucleation. At edges of grains, local stray fields up to about 2.5 times the saturation polarization can occur (Adler and Hamann, 1985; Blank, Rodewald and Schleede, 1989). In order to overcome such strong local stray fields, the magnetization field strength should be at least twice the saturation of the magnet material.

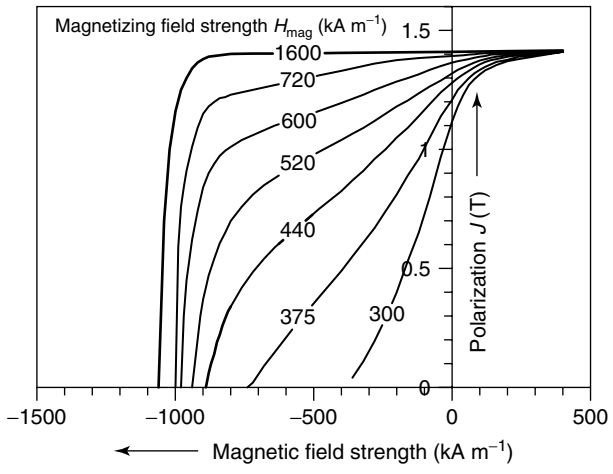

Figure 13. Magnetizing behavior of sintered Nd–Dy–Fe–B magnets. The demagnetization curves $J(H)$ were measured on different samples, each in the thermally demagnetized state, after magnetization by the indicated field strengths H_{mag}. For complete magnetization an applied field of 2000 kA m^{-1} is recommended.

There is a dominant impact of the microstructure of a magnet on the coercivity. Besides, on a strong nucleation field strength H_n, which is mainly determined by the magnetocrystalline anisotropy, the coercivity depends on local demagnetizing stray fields, which are described by an effective demagnetizing coefficient N_{eff} (Adler and Hamann, 1985; Durst and Kronmüller, 1985; Kronmüller, Durst and Sagawa, 1988; Kou, Kronmüller, Givord and Rossignol, 1994), see equation (9).

$$H_{cJ} = \frac{H_n - N_{eff}}{\mu_0 \times J} \tag{9}$$

where H_n denotes the nucleation field strength, J the polarization of the magnet material, and N_{eff} presents an effective demagnetization coefficient, which depends on the local microstructure.

3.2 Magnetization of pinning-type magnets

Magnetization of pinning-type magnets, for instance, sintered $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets with coercivities in the range 600–800 kA m^{-1}, need an internal magnetizing field strength, which is strong enough to overcome the pinning forces. If a small magnetizing field strength is applied, the magnetic domain walls are not moved and there is only a negligible increase in the polarization, see Figure 14. For internal magnetizing field strengths of about the coercive field strength, the domain walls can be pulled away from the pinning sites and the domains with a polarization parallel to the magnetic field grows significantly. Since the strength of the pinning sites may vary within the microstructure, the complete magnetization requires a magnetizing field strength of at least twice that of the coercive field strength.

Magnetization of $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets with strong coercivities in the range 1500 up to 2100 kA m^{-1} demonstrate a more heterogeneous pinning behavior. For magnetizing field strengths, which are lower than the coercivity, there is an increase in the polarization up to about a third of the remanent polarization, see Figure 15. Probably not all pinning

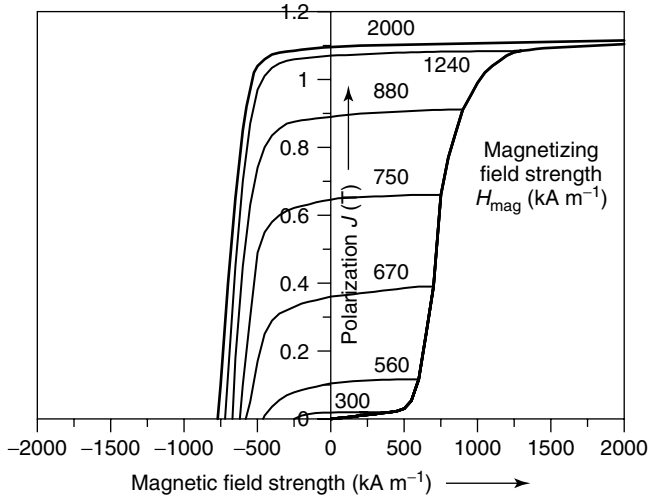

Figure 14. Magnetizing behavior of sintered $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets with a coercivity H_{cJ} of about 800 kA m^{-1}. The demagnetization curves $J(H)$ were measured on different samples, each in the thermally demagnetized state, after magnetization by the indicated field strengths H_{mag}. For complete magnetization, an applied field of 2000 kA m^{-1} is recommended.

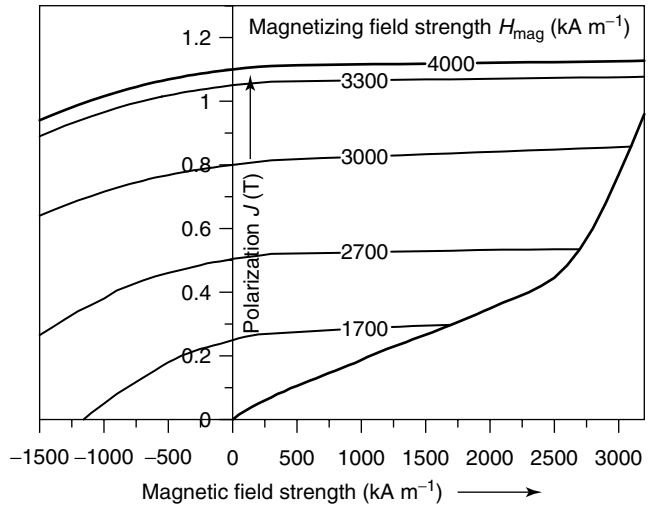

Figure 15. Magnetizing behavior of sintered $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets with a coercivity H_{cJ} of about 2070 kA m^{-1}. The demagnetization curves $J(H)$ were measured on different samples, each in the thermally demagnetized state, after magnetization by the indicated field strengths H_{mag}. For complete magnetization, an applied field of 3650 kA m^{-1} is recommended.

sites exert the same pinning strength on the magnetic domain walls. In fact, in well-annealed $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets with strong coercivities, there exist two kinds of pinning sites with different pinning strengths (Katter *et al.*, 1996). The different pinning sites were revealed by the different temperature dependences of the corresponding coercivities. Increasing the internal magnetizing field strength beyond the coercive field strength results in a strong increase in the polarization, see Figure 15. However, complete saturation of $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets requires a magnetizing field strength of at least twice the coercive field strength.

4 TEMPERATURE STABILITY OF SINTERED RE–TM MAGNETS

The magnetic properties of sintered RE magnets depend on temperature. For a proper design of magnet assemblies, their temperature dependence has to be taken into account. In particular, the maximum operating temperature of a magnet grade must not be exceeded in order to prevent degradation of a magnet assembly.

The maximum continuous operating temperature of permanent magnets depends on the temperature coefficients $TC(J_r)$ of the remanent polarization, $TC(H_{cJ})$ of the coercivity, and the load line $B/\mu_0 H$ of the magnet or the magnet assembly. In general, the maximum operating temperature T_{op} of the different permanent magnets increases proportional to the Curie temperature T_C of the magnet material, see Figure 16.

As far as the RE–TM magnets are concerned, the remanent polarization of Nd–Fe–TM–B, TM: TMs, as well as Nd–Dy–Fe–TM–B magnets, with strong coercivities $H_{cJ} > 2400$ kA m^{-1}, is larger than the remanent polarizations J_r of $SmCo_5$ or $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets, see Figure 17. But, at temperatures above 200 °C, $SmCo_5$ magnets are superior to Nd–Dy–Fe–TM–B magnets and, at temperatures above 230 °C, $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets exceed the remanent polarization of Nd–Fe–TM–B magnets. The temperature dependence of the remanent polarization is mainly determined by the Curie temperatures of the different hard magnetic compounds, $T_C(Nd_2Fe_{14}B) \cong 312$ °C, $T_C(SmCo_5) \cong 720$ °C and $T_C(Sm_2Co_{17}) \cong 820$ °C (Gutfleisch, 2000).

The temperature dependence of the coercivities of RE–TM magnets is mainly determined by the temperature dependence of the anisotropy field strength H_A. Since the anisotropy field strength of the $Nd_2Fe_{14}B$ compound, $H_A \cong 52$ kA m^{-1}, is significantly smaller than that of $SmCo_5$ compounds, $H_A \cong 320$ kA m^{-1} (Gutfleisch, 2000), the coercivity of Nd–Fe–TM–B magnets decreases more strongly with increasing temperature than the coercivity of $SmCo_5$ magnets, see Figure 18. At temperatures >150 °C, the coercivity of Sm–Co magnets exceeds the coercivities of Nd–Dy–Fe–TM–B magnets. The coercivity of the multiphase $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets is determined by pinning of the magnetic domain walls and depends only on the square root of the anisotropy field strength, which reduces the temperature dependence of the coercivity H_{cJ}.

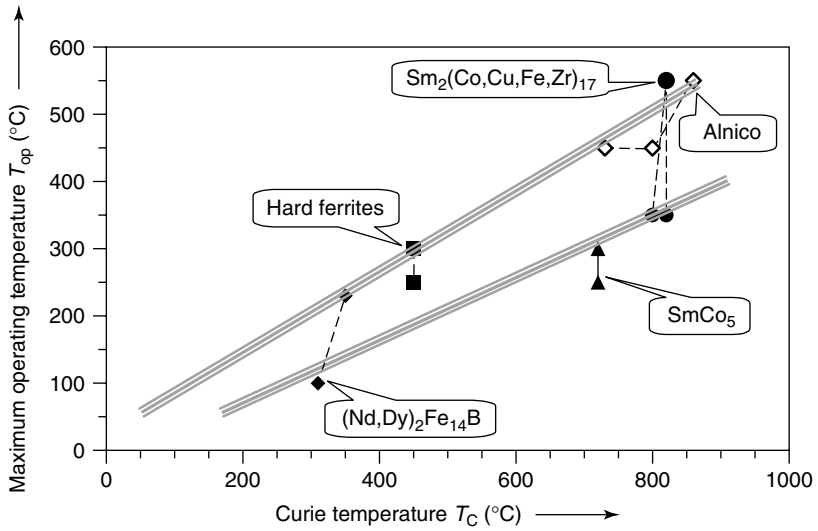

Figure 16. Maximum continuous operating temperatures T_{op} of permanent magnet materials, depending on their Curie temperatures T_C. The shaded lines indicate the lowest or highest operating temperatures, respectively, for the different permanent magnet materials.

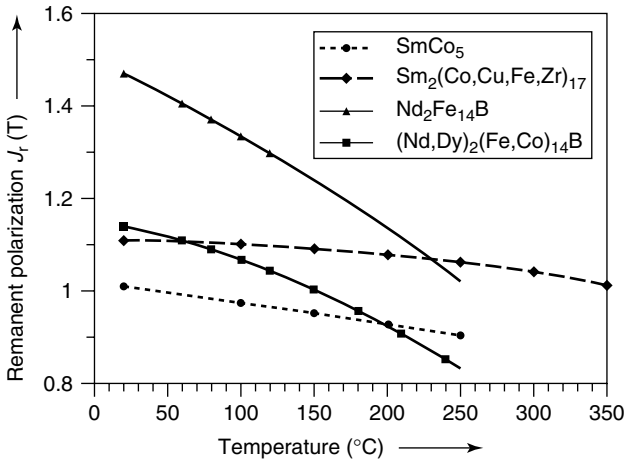

Figure 17. Remanent polarization J_r of RE–TM magnets, depending on the temperature.

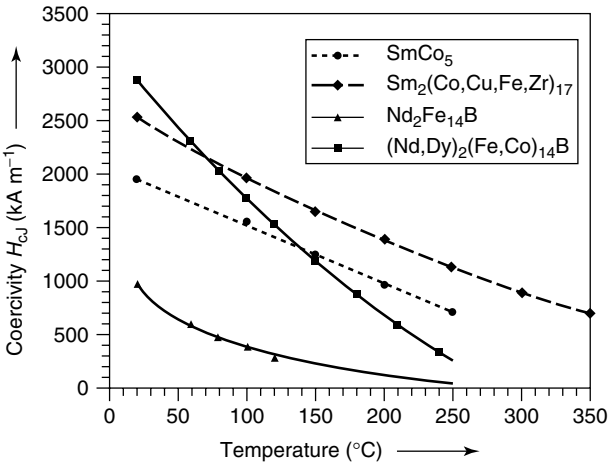

Figure 18. Coercive field strength H_{cJ} of RE–TM magnets, depending on the temperature.

As a consequence, sintered Nd–Fe–B magnets achieve maximum energy densities at 20 °C in the range 224–424 kJ m^{-3}, but, at temperatures of approximately 120 °C, sintered $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets are superior, see Figure 19.

The temperature stability of permanent magnets is determined by reversible and irreversible polarization losses. The reversible polarization changes are represented by the temperature coefficient of the remanent polarization TC(J_r).

Irreversible polarization losses are mainly caused by the temperature dependence of the coercivity H_{cJ} and the thermal aftereffect. With increasing temperature, the coercivity H_{cJ} of Nd–Fe–B magnets decreases and as a consequence the polarization of grains that have smaller coercivities may be reversed. Such irreversible polarization losses do not depend on time.

Minor polarization losses are due to the thermal aftereffect or magnetic viscosity, respectively, and depend on time logarithmically (Néel, 1951). The polarization losses due to the temperature dependence of the coercivity H_{cJ} and to the thermal aftereffect can be recovered by remagnetization.

However, polarization losses due to the deterioration of the magnet surface, for instance, by oxidation or by improper cutting and grinding (Blank and Adler, 1987) or by changes of the mircostructure due to high operating temperatures cannot be eliminated by remagnetization. The basic features that affect the temperature stability of RE–TM magnets are compiled in Table 1.

Table 1. Principle terms, which affect the temperature stability of RE–TM magnets.

Reversible polarization losses	Irreversible polarization losses	Irreversible polarization losses by microstructural changes
Reversible temperature coefficient TC(J_r)	Temperature coefficient TC(H_{cJ}) Thermal aftereffect, determined by the coefficient S_v	Surface oxidation Changes in the microstructure due to temperature

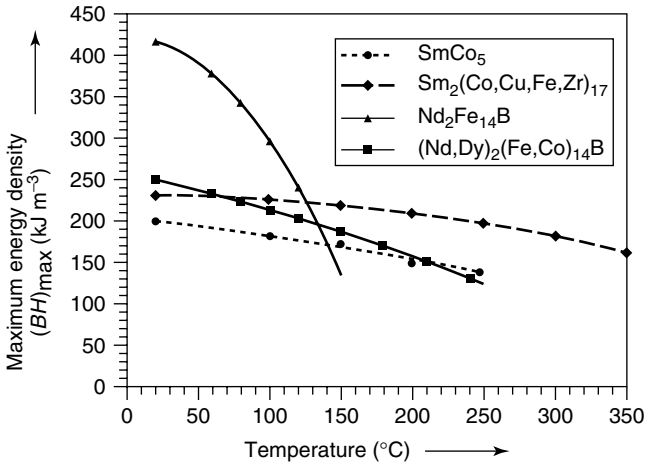

Figure 19. Maximum energy density $(BH)_{max}$ of RE–TM magnets, depending on the temperature.

4.1 Temperature coefficients of the remanent polarization J_r and of the coercivity H_{cJ}

The remanent polarization J_r and the coercivity H_{cJ} of RE magnets decrease continuously with increasing temperature. The monotonous decrease is characterized quantitatively by the temperature coefficient of the remanent polarization TC(J_r) or of the coercivity TC(H_{cJ}) respectively according to equations (10) and (11).

$$\mathrm{TC}(J_r) = \frac{J_r(T_1) - J_r(T_0)}{J_r(T_0) \cdot (T_1 - T_0)} \times 100\ \mathrm{in\%/K}$$
$$\text{for the temperature range } T_0 < T < T_1 \qquad (10)$$

$$\mathrm{TC}(H_{cJ}) = \frac{H_{cJ}(T_1) - H_{cJ}(T_0)}{H_{cJ}(T_0) \cdot (T_1 - T_0)} \times 100\ \mathrm{in\%/K}$$
$$\text{for the temperature range } T_0 < T < T_1 \qquad (11)$$

where T_0 and T_1 denote the lower and the higher temperature, very often T_0 amounts to 20 °C. $J_r(T_0)$, $J_r(T_1)$, and $H_{cJ}(T_0)$, $H_{cJ}(T_1)$ represent the remanent polarizations or the coercivities at these temperatures. The temperature coefficients describe the temperatures dependences only in small temperature ranges $T_0 < T < T_1$ fairly well. However, remanent polarizations calculated by means of the temperature coefficient TC(J_r) are a little bit smaller because the temperature dependence of the polarization is a convex graph, see Figure 20(a), whereas coercivities interpolated by means of the temperature coefficient TC(H_{cJ}) are too large, since the temperature dependence of the coercivity is a concave graph, see Figure 20(b). The deviations between the polynomial regression curves of the measurements and the interpolations by the temperature coefficients amount to <0.5% for the remanent polarization, but up to 15% for the coercivity H_{cJ}. The difference reflects the different values of the temperature coefficients. For instance, at a temperature of 120 °C, the coercivity amounts to 608 kA m^{-1} estimated by the temperature coefficient TC(H_{cJ}) and to 524 kA m^{-1} calculated by the regression polynom, see Figure 20(b). Hence, an error of about 15% results.

Typical temperature coefficients of some RE–TM magnet grades for the temperature ranges 20–100 °C and 20–150 °C are compiled in Table 2.

4.2 Irreversible polarization losses due to the temperature dependence of the coercivity H_{cJ} and the thermal aftereffect

The decrease in the coercivity H_{cJ} with increasing temperatures results in the reversal of the polarization of those grains that experience strong demagnetizing fields. The demagnetizing field strength is the sum of the applied field strength and local stray fields. Local stray fields of pores or impurities may amount to twice the polarization of the magnet material (Blank, Rodewald and Schleede, 1989). Owing to the opposite local fields, the magnetization of some grains in the magnet may be reversed, so that irreversible polarization losses result. Such irreversible polarization losses do not depend on time and occur as soon as the temperature in the magnet increases.

Irreversible polarization losses, which are caused by the temperature dependence of the coercivity, can be anticipated by an annealing treatment of the magnetized magnets or the magnetized magnet assembly. As a rule of thumb, such aging treatments for the stabilization of a magnetized magnet are performed at temperatures 10–50 K above the maximum operating temperature (Adler and Marik, 1981).

Table 2. Temperature coefficients TC(J_r) of the remanent polarization and TC(H_{cJ}) of the coercivity H_{cJ} of some RE magnet grades for the temperature ranges 20–100 °C and 20–150 °C.

Temperature range		20–100 °C		20–150 °C	
Magnet grade	(J_r in T/H_{cJ} (kA m^{-1}))	TC(J_r) (%/K)	TC(H_{cJ}) (%/K)	TC(J_r) (%/K)	TC(H_{cJ}) (%/K)
$SmCo_5$	(0.90/2400)	−0.040	−0.14	−0.045	−0.15
$SmCo_5$	(1.01/1500)	−0.040	−0.24	−0.045	−0.25
$Sm_2(Co,Cu,Fe,Zr)_{17}$	(1.12/800)	−0.030	−0.15	−0.035	−0.16
$Sm_2(Co,Cu,Fe,Zr)_{17}$	(1.10/2070)	−0.030	−0.18	−0.035	−0.19
$Nd_2Fe_{14}B$	(1.47/955)	−0.115	−0.77	–	–
$Nd_2Fe_{14}B$	(1.18/2465)	−0.085	−0.55	−0.095	−0.50
$Nd_2Fe_{14}B$	(1.08/2865)	−0.080	−0.51	−0.090	−0.46

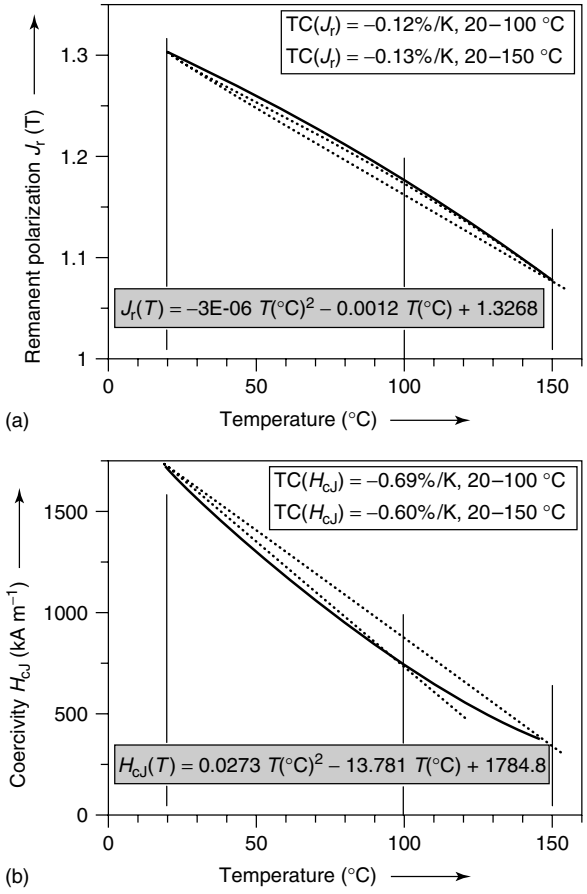

Figure 20. Temperature dependence of (a) the remanent polarization $J_r(T)$ and of (b) the coercivity $H_{cJ}(T)$ of sintered Nd–Dy–Fe–TM–B magnets. The deviation between the polynomial regression curves of the measurements and the interpolations by the temperature coefficients TC(J_r) or TC(H_{cJ}), respectively, for the different temperature intervals 20–100 °C and 20–150 °C are demonstrated.

Minor and time-dependent polarization losses may result from the thermal aftereffect or the magnetic viscosity, respectively. As soon as the sum of the external field and of internal stray fields becomes strong enough, the polarization of some grains decreases by nucleation of reversed domains. Hence, there are some multidomain grains, which contain magnetic domain walls. Even if the external magnetic field is kept constant, the domain walls can be moved by thermal activation in order to further decrease the energy of local magnetic stray fields. This results in minor decreases of the polarization dJ and is denoted as the thermal aftereffect or magnetic viscosity, respectively. Figure 21 demonstrates the principle of the aftereffect on a demagnetization curve at a constant reversed magnetic field strength.

The decrease in the polarization depends on time logarithmically and has been analyzed in detail by Néel. The

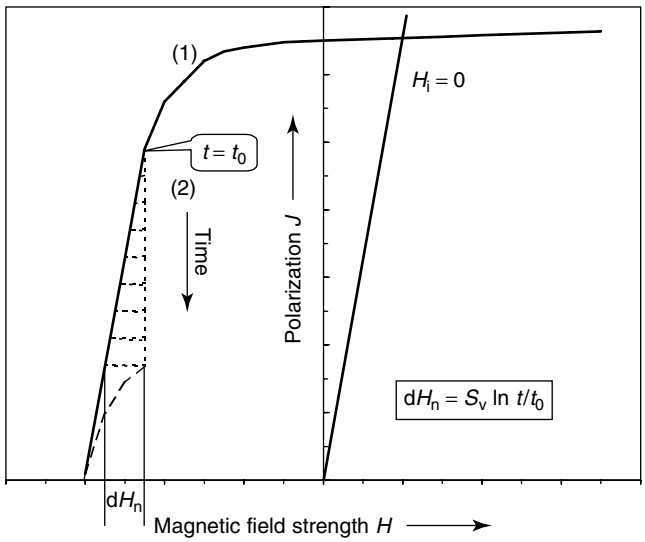

Figure 21. Procedure for the measurement of the coefficient S_v of the thermal aftereffect: (1) at first the demagnetization curve $J(H)$ is measured with a fixed sweep rate dH/dt, (2) after remagnetization of the magnet by a strong pulse field, the demagnetization curve was measured again, but, at the time $t = t_0$, the external field was kept constant and the decrease in the polarization, depending on time, was recorded.

polarization losses by the thermal aftereffect can be simulated by a small additional reversed external field dH (Néel, 1951), see equation (12):

$$dH \approx S_v \cdot \ln \frac{t}{t_0} \tag{12}$$

where S_v and dH denote the coefficient of the thermal aftereffect and the field increment that is needed for simulating the same polarization losses, t gives the time in reference to the moment at which the external magnetic field is applied and kept constant, $t_0 \approx 10^{-11}$ s, is the characteristic time for lattice vibrations (Coey, 1996). The coefficient of the thermal aftereffect is proportional to the coercivity H_{cJ} for many magnet materials. This implies that the coefficient of the thermal aftereffect decreases with increasing temperature, since the coercivities H_{cJ} decrease as well. The coefficient of the thermal aftereffect in dependence of the polarization (Street, Day and Dunlop, 1987), of the coercivity (Liu and Luo, 1990; Nishio and Yamamoto, 1993), and of the temperature has been examined by several teams (Stieler, Heiden, Kuntze and Kohake, 1984; Rodewald, 1985; Givord *et al*., 1987a,b; Singleton and Hadjipanyis, 1990). In order to determine the influence of the microstructure on the magnetic viscosity, the temperature dependence of the viscosity coefficient S_v has been examined on single-phase and multiphase nanocrystalline Nd–Fe–B or Pr–Fe–B magnets, respectively, by M. Becher *et al*. Whereas multiphase Nd–Fe–B or Pr–Fe–B magnets with a high coercivity have got high viscosity coefficients with a strong temperature dependence, exchange-coupled RE–Fe–B magnets with low coercivities have got smaller viscosity coefficients with a small temperature dependence (Becher, Seeger and Bauer, 1998).

For sintered Nd–Dy–Fe–B magnets, the coefficient of the thermal aftereffect S_v ranges from 8 to 10 kA m^{-1} at a temperature of 20 °C and decreases to about 2 kA m^{-1} at a temperature of 200 °C, probably due to the decrease in the coercivity (Rodewald, 1985). For sintered Sm–Co magnets, the coefficient of the thermal aftereffect varies between 2 and 12 kA m^{-1} and depends on the coercivity H_{cJ}.

Figure 22 gives the relative irreversible polarization losses $\Delta J_{irr}/J$, depending on the exposure time at a temperature of 130 °C in air for sintered Nd–Dy–Fe–TM–B magnets. Owing to the small coercivity and the strong temperature coefficient of the coercivity TC(H_{cJ}), such magnets experience irreversible polarization losses between 1 and 3% for small load lines, but suffer irreversible polarization losses from about 15 to 18% for a load line of $B/\mu_0 H = -0.5$. The irreversible polarization losses can be reduced by increasing the coercivity or by improving the squareness of the demagnetization curve $J(H)$ of the sintered magnets.

The irreversible polarization losses of typical Sm–Co magnets at temperatures between 100 and 200 °C amount to some percent only, due to the stronger coercivities H_{cJ} and the smaller temperature coefficient TC(H_{cJ}), see Figure 23.

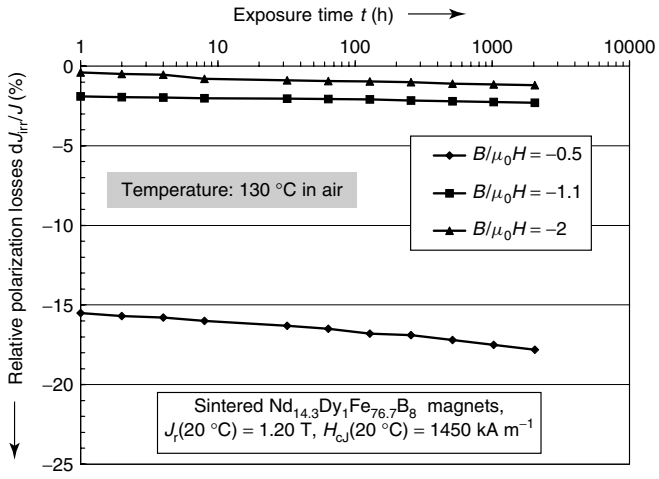

Figure 22. Irreversible polarization losses of sintered $Nd_{14.3}Dy_1Fe_{76.7}B_8$ magnets with different load lines $B/\mu_0 H$ at a temperature of 130 °C, depending on the exposure time.

In principle, the irreversible polarization losses due to the temperature dependence of the coercivity H_{cJ} and the thermal aftereffect can be recovered by remagnetization.

4.3 Irreversible polarization losses due to microstructural changes

However, irreversible polarization losses due to the deterioration of the RE–TM magnet surface, for instance, by improper cutting and grinding (Nishio, Yamamoto, Nagakura and Uehara, 1990), by oxidation (Adler and Marik, 1981; Blank and Adler, 1987) or by changes of the microstructure due to high temperatures, cannot be eliminated by remagnetization. The inset of Figure 24 demonstrates the microstructure of an oxidized surface and the impact on the demagnetization curve $J(H)$. By oxidation, the surface of the Nd–Fe–B grains is converted to a mixture of Nd oxide (hexagonal Nd_2O_3) and α-Fe (Schrey, 1986). The thickness of such a selectively oxidized surface layer may amount to some 10 nm only and hence cannot be detected by light microscopy. Only for extreme heat treatments in air, the oxidized layer increases up to the grain size of the sintered magnets.

In a demagnetizing field, the polarization of the selectively oxidized surface layer is reversed at a much lower field strength than the bulk magnet because the coercivity $H_{cJ,surf}$ ranges between 1800 and 800 kA m^{-1}, for instance, and is much lower than the coercivity of the magnet (Givord, Tenaud and Viadieu, 1986; Blank and Adler, 1987). Since the demagnetization of sintered Nd–Fe–B magnets is

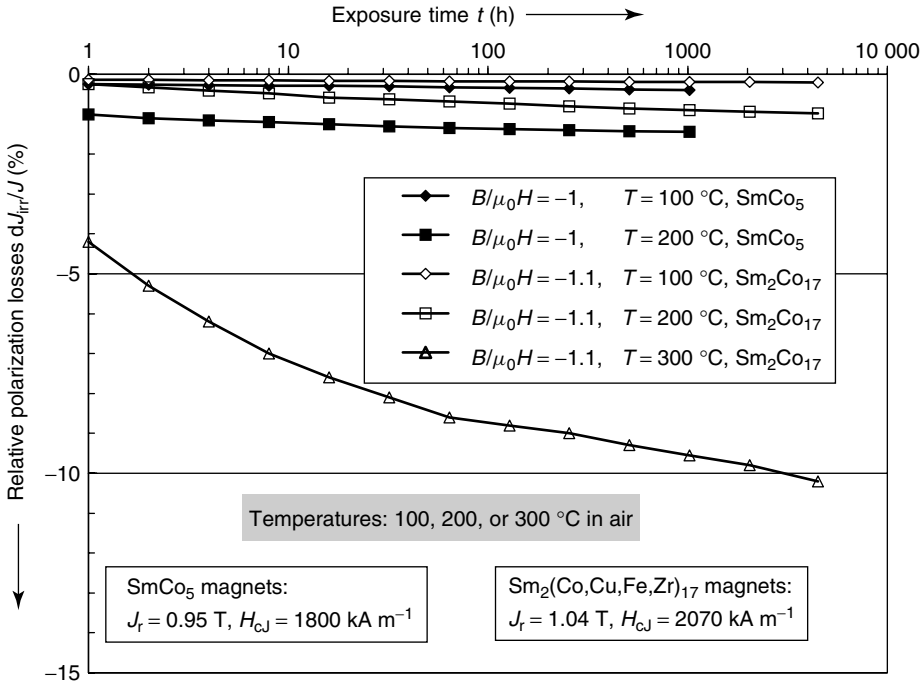

Figure 23. Irreversible polarization losses of sintered $SmCo_5$ and $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets with different load lines $B/\mu_0 H$ at different temperatures of 100, 200, and 300 °C, respectively, depending on the exposure time.

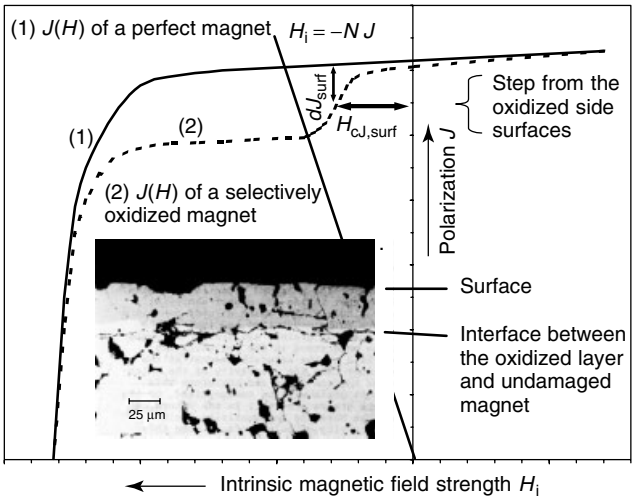

Figure 24. Influence of a selectively oxidized surface grain layer on the demagnetization curve $J(H)$ of a sintered RE–TM magnet. The enlarged microstructure of a severely oxidized layer of a Nd–Dy–Fe–B magnet after annealing in air at 500 °C for 23 h demonstrates that about one layer of grains is deteriorated.

determined by nucleation of reversed domains, not only the oxidized surface layer but the whole layer of surface grains with a thickness between 10 and 20 μm is reversed. Hence, a distinct step in the demagnetization curve $J(H)$ occurs.

The height dJ_{surf} of such a step is given by twice of the ratio of the volume V_{surf} of the reversed grain layer at the side surface to the total volume of the magnet, see equation (13):

$$dJ_{surf} = \frac{2 \cdot J_s \cdot V_{surf}}{V} = \frac{2 \cdot J_s \cdot A_{surf} \cdot d}{V} \qquad (13)$$

where J_s denotes the saturation polarization of the reversed layer, A_{surf} the area of the side surface of the magnet, d the thickness of the reversed layer, and V the total volume of the magnet.

The coefficient 2 results from the reversal of the polarization from the positive to the negative direction.

The height $dJ_{surf}/2$ is defined by the difference between the inflection point of the step in the demagnetization curve and the demagnetization curve of the unspoiled magnet. The coercivity $H_{cJ,surf}$ of the selectively oxidized surface layer is defined as the field difference between the inflection point of the step in the demagnetization curve and the ordinate, see Figure 24. The demagnetization curve has to be corrected by the demagnetizing field strength $N/\mu_0 \cdot J$.

Increasing the thickness of the selectively oxidized layer by annealing for longer times or at higher temperatures results in an increase in the height of the step dJ_{surf} and in a reduction of the coercivity $H_{cJ,surf}$ of the oxidized surface layer (Blank and Adler, 1987).

By surface treatments, the coercivity $H_{cJ,surf}$ and the height dJ_{surf} of the step can be influenced. By etching or by proper annealing, the step can almost be removed, but, after aging the magnets in air, the step may reappear.

4.4 Long-term stability of sintered Nd–Dy–Fe–B magnets

In general, the magnetic flux of sintered RE–TM magnets is constant, provided that strong temperature loads, corrosion of the magnet, and any other damages are prevented. The irreversible polarization losses due to the temperature dependence of the coercivity H_{cJ} depend on the magnet material and can be taken into account in any designed application.

The time-dependent irreversible polarization losses due to the thermal aftereffect decrease logarithmically with time. The corresponding reversed field increment can be calculated from equation (12). Then the polarization losses can be deduced from the demagnetization curves $J(H)$ of the magnet material.

Figure 25 presents measurements of the irreversible polarization losses on sintered Nd–Dy–Fe–B magnets with coercivities of 1200 or 2460 kA m^{-1}, respectively, and different load lines after aging at a temperature of 100 °C over a period of 766 days (2.1 years). The dimensions of the magnets were chosen in a way that irreversible polarization losses due to the temperature dependence of the coercive field strength are negligible. Hence, the polarization losses are mostly determined by the thermal aftereffect. After aging the Nd–Dy–Fe–B magnets for 1 year, irreversible polarization losses of about 1% result. The measurements are fairly well described by the logarithmic regression curves, see Figure 25.

With these regression equations, the irreversible polarization losses for aging periods of 3, 5, and 10 years have been calculated for example. The results are compiled in Table 3. Owing to the logarithmic time dependence, the irreversible polarization losses increase only up to <2%, provided increase in temperature beyond 100 °C, corrosion, or any other microstructural changes at the magnet surfaces are prevented.

4.5 Stability of RE–TM magnets against radiation

RE–TM magnets are often applied in focusing devices for particle beams in accelerators or in spectrometers. In such an environment, the RE–TM magnets may be exposed to γ

Table 3. Long-term irreversible polarization losses of sintered Nd–Dy–Fe–B magnets with different load lines $B/\mu_0 H$ after aging at a temperature of 100 °C in air, calculated from the regression curves in Figure 25. The regression curves are deduced from measurements over a period of 766 days (2.1 years).

Aging of Nd–Dy–Fe–B magnets at 100 °C in air	1 year	3 years	5 years	10 years
$H_{cJ} = 2460$ kA m^{-1}, $B/\mu_0 H = -0.9$	−1.03	−1.12	−1.16	−1.22
$H_{cJ} = 2460$ kA m^{-1}, $B/\mu_0 H = -0.6$	−1.04	−1.15	−1.19	−1.26
$H_{cJ} = 1150$ kA m^{-1}, $B/\mu_0 H = -6.1$	−1.20	−1.34	−1.40	−1.48

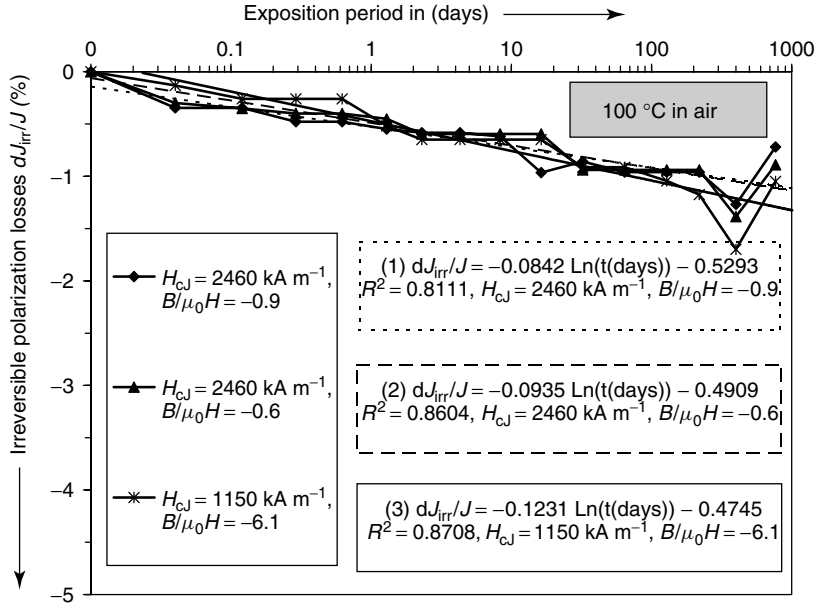

Figure 25. Long-term irreversible polarization losses of sintered Nd–Dy–Fe–B magnets with different load lines $B/\mu_0 H$ after aging at a temperature of 100 °C in air. The regression curves are deduced from measurements over a period of 766 days (2.1 years).

radiation as well as to irradiation of neutrons or other charged particles. While direct irradiation of RE–TM magnets by neutrons or charged particles may be avoided, in many cases, the magnets are often exposed to γ radiation. The effect of γ radiation from a ^{60}Co source on the magnetic properties of RE–TM magnets has been examined on five similar sets of $SmCo_5$, $Sm_2(Co,Cu,Fe,Zr)_{17}$, and Nd–Dy–Fe–B magnets at a constant temperature (Boockmann *et al.*, 1991). The magnetic properties and the load lines of the magnets amount to $J_r = 0.95\,T$, $H_{cJ} = 1800\,kA\,m^{-1}$, and $B/\mu_0 H = -0.7$ for $SmCo_5$ magnets, $J_r = 1.1\,T$, $H_{cJ} = 1400\,kA\,m^{-1}$, and $B/\mu_0 H = -0.71$ for $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets, and $J_r = 1.2\,T$, $H_{cJ} = 1520\,kA\,m^{-1}$, and $B/\mu_0 H = -0.61$ for Nd–Dy–Fe–B magnets. The magnets were supported on nonmagnetic plates with a distance of about 2 cm between every magnet, so that there was hardly any influence from the magnetic stray fields of the neighboring magnets. All magnets were exposed to γ radiation from a ^{60}Co-source emitting γ photons with energies of 1.17 and 1.33 MeV. The irradiation rate amounts to 1 krad min^{-1}. During the irradiation, the temperature was controlled by a thermocouple and could be kept constant at $(22 \pm 4)\,^{\circ}C$. After an accumulated dose of about 10 Mrad, one set of five magnets of each grade was always removed. The remanent polarization of every magnet and the demagnetization curves $J(H)$ of selected magnets were measured. The difference between the remanent polarization before and after the irradiation $dJ_{r,rad}$, related to J_r, and the standard deviations are presented in Figures 26–28 in dependence on the accumulated dose of the γ radiation.

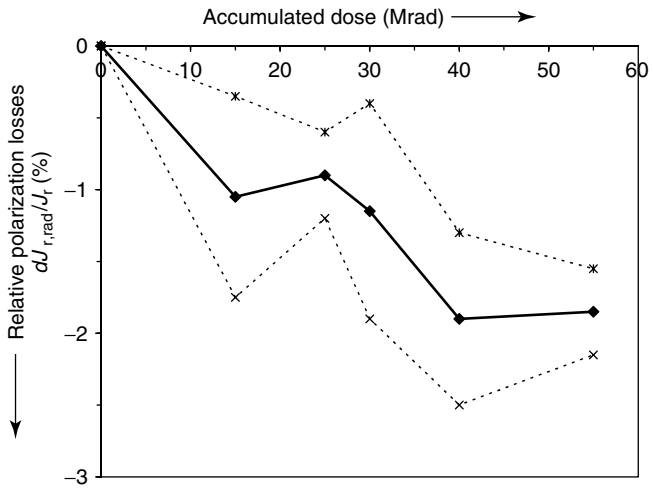

Figure 26. Dependence of the polarization losses $dJ_{r,rad}/J_r$ on the accumulated dose of γ radiation for sintered $SmCo_5$ magnets with a load line $B/\mu_0 H = -0.7$ at a temperature of about 22 °C. The data present the average of five measurements and the standard deviations.

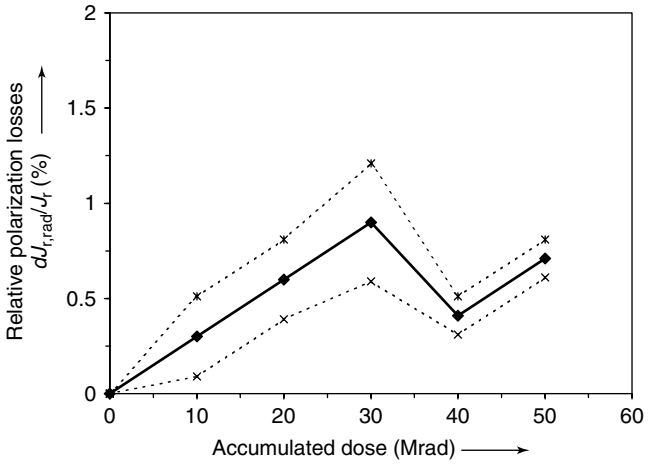

Figure 27. Dependence of the polarization changes $dJ_{r,rad}/J_r$ on the accumulated dose of γ radiation for sintered $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets with a load line $B/\mu_0 H = -0.71$ at a temperature of about 22 °C. The data present the average of five measurements and the standard deviations.

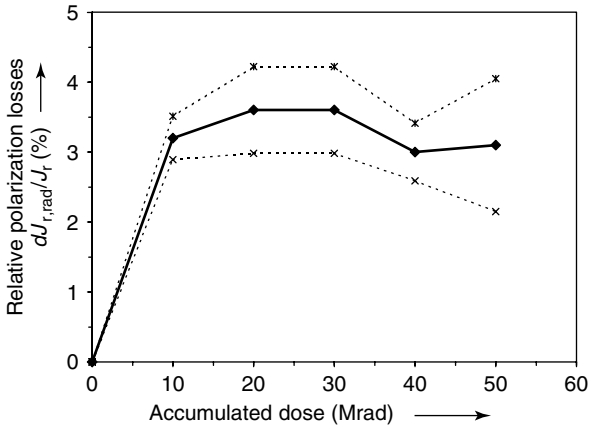

Figure 28. Dependence of the polarization changes $dJ_{r,rad}/J_r$ on the accumulated dose of γ radiation for sintered Nd–Dy–Fe–B magnets with a load line $B/\mu_0 H = -0.61$ at a temperature of about 22 °C. The data present the average of five measurements and the standard deviations.

For sintered $SmCo_5$ magnets, there seems to be a small decrease in the average remanent polarization by about 1–2%, see Figure 26. However, this was mainly caused by some oxidation at the edges of the magnets. After removal of the edges, no significant changes of the remanent polarization could be detected, which is in agreement with other results (Zeller and Nolen, 1987). The coercivity H_{cJ} of the irradiated $SmCo_5$ magnets has not been changed within an accuracy of the measurements of about 4%.

For sintered $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets, the changes in the remanent polarization $dJ_{r,rad}$ are less than 1% up to an accumulated dose of about 50 Mrad, see Figure 27.

Comparison of the demagnetization curves before and after the irradiation revealed no significant changes of the coercivity H_{cJ} within an accuracy of the measurements of about 2%.

The remanent polarization of γ-irradiated Nd–Dy–Fe–B magnets increased by about 3%, see Figure 28. The increase does not seem to depend on the accumulated dose; the origin is not known till now. A similar effect is also reported by Cost *et al*., who detected an increase in the remanent polarization of Nd–Dy–Fe–B magnets by about 0.8% after an accumulated dose of 48.8 Mrad (Cost, Brown, Giorgi and Stanley, 1987). However, Zeller *et al*. found a decrease in the remanent polarization of Nd–Fe–B magnets by about 1.5% after an accumulated γ dose of 50 Mrad and no significant changes in the remanent polarization of Nd–Dy–Fe–B magnets (Zeller *et al*., 1988). Since the coercivity H_{cJ} and the temperature stability of Nd–Fe–B magnets are inferior to Nd–Dy–Fe–B magnets, which have a stronger coercivity H_{cJ}, such polarization losses may be caused by aging due to an increase in the local temperature. In conclusion, the remanent polarization of sintered Nd–Dy–Fe–B magnets with coercivities $H_{cJ} > 1300\,\mathrm{kA\,m^{-1}}$ is not affected by γ radiation up to an accumulated dose of 50 Mrad.

Irradiation of sintered Nd–Fe–B magnets with a low coercivity of $890\,\mathrm{kA\,m^{-1}}$ and a load line $B/\mu_0 H = -0.35$ with 20 MeV protons results in polarization losses of −17% at 15 K and in almost total demagnetization after an irradiation at a temperature of 300 K. However, alloyed Nd–Dy–Fe–B magnets with a higher coercivity of $1357\,\mathrm{kA\,m^{-1}}$ and a small load line $B/\mu_0 H = -10$ experience hardly any polarization losses at room temperature even after a dose of 100 Mrad of 20 MeV protons (Talvitie *et al*., 1991). This indicates that the polarization losses may be caused by local heating in the collision cascade during irradiation, which results in the nucleation and expansion of reversed magnetic domains (Kähkönen *et al*., 1992a,b). Measurements of the demagnetization curves $J(H)$ before and after the irradiation tests by 20 MeV protons do not reveal any changes of the microstructure.

In contrast, $SmCo_5$ and $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets proved to be quite stable even after irradiation with 500 MeV protons. Polarization losses $dJ_{r,rad}$ of less than 1% were measured after irradiation by 5 Grad at a temperature of less than 120 °C (Blackmore, 1985). Remagnetization of the irradiated magnets resulted in the original magnetic properties and proved that no microstructural changes had occured.

Similar results were obtained after irradiation by 106 MeV deuterons. $SmCo_5$ and $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets did not experience significant polarization losses up to a dose of 3 Mrad, whereas Nd–Dy–Fe–B magnets were more sensitive to irradiation by 106 MeV deuterons (Zeller and Nolen, 1987).

Irradiation of Nd–Dy–Fe–B magnets with fast neutrons >0.1 MeV resulted in remanent polarization losses of about 4.5% for magnets with a coercivity $>1560\,\mathrm{kA\,m^{-1}}$ and a very small load line $B/\mu_0 H = -36$ after a total neutron fluence of 1.5×10^{16} neutrons $\mathrm{cm^{-2}}$. During irradiation, a temperature of 77 °C was measured (Brown and Cost, 1989). Nd–Dy–Fe–B magnets with lower coercivities or stronger load lines experienced much stronger polarization losses. Remagnetization after the irradiation resulted in a full recovery of the remanent polarization and an increased coercivity (Cost, Brown, Giorgi and Stanley, 1988). Hence, neutron irradiation has a similar effect on the polarization losses as a temperature load. By irradiation, nucleation of reversed domains is induced, but no changes occur in the microstructure.

$SmCo_5$ and $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets are much more stable with respect to neutron irradiation. Irradiation with fast neutrons (>0.1 MeV) up to a total fluence of 2.61×10^{18} neutrons $\mathrm{cm^{-2}}$ at a temperature of 77 °C results only in small polarization losses of less than 2% (Cost, Brown, Giorgi and Stanley, 1987). Owing to higher coercivities, $SmCo_5$ and $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets have a superior irradiation stability.

5 CORROSION BEHAVIOR OF SINTERED RE–TM MAGNETS

In many applications, RE–TM magnets are exposed to hot and humid atmospheres. In such climates, the surfaces of the RE–TM magnets may be oxidized, in particular, the RE components are preferentially oxidized.

In comparison to sintered Sm–Co magnets, Nd–Fe–B magnets are more sensitive to corrosion. As a consequence, all finished magnets get a final surface treatment. Such magnets have been applied at ambient conditions, for instance, room temperature, humidity up to 50%, no condensation of moisture, for more than 10 years in telephone transducers, without any corrosion problems.

However, in hot and humid climates, conventional Nd–Fe–B magnets, which do not contain Co additions, corrode heavily. For instance, in an accelerated test at 130 °C and 95% relative humidity, such magnets experience substantial mass losses by corrosion, whereas alloyed Nd–Dy–Fe–Co–TM–B magnets with some additions of TM: Cu, Ga, Al, and an appropriate microstructure are not affected significantly. Indeed, the weight of such magnets increases a little bit due to the formation of a passivating surface layer (Katter *et al*., 2001).

5.1 Basic principles

The microstructure of sintered Nd–Dy–Fe–B magnets consists of grains of the hard magnetic $(Nd,Dy)_2Fe_{14}B$ compound, which are separated from each other by Nd-rich constituents, in general, a Nd–Fe solid solution. Besides, there are some Nd oxides embedded or occasionally some $Nd_{1.1}Fe_4B_4$ grains may occur.

In a hot and humid climate, the Nd-rich constituents are preferentially converted to Nd hydroxides and some hydrogen is released. The hydrogen reacts immediately with the Nd-rich constituents and forms Nd hydrides. In such a hot and humid environment, Nd hydrides are not stable, react with water vapor, and are transformed into Nd hydroxides. Since this chemical reaction releases additional hydrogen, the reaction cycle continues (Katter *et al*., 2001). The microstructure of sintered Nd–Fe–B magnets and the basic constituents are presented in Figure 29.

The formation of Nd hydrides results in a strong volume increase of the Nd-rich constituents, so that cracks occur along the grain boundaries. Such microscopic cracks accelerate the corrosion. In the worst case, the surface of the sintered Nd–Fe–B magnets disintegrates. Almost white Nd oxides and grains of $Nd_2Fe_{14}B$ peel off from the surfaces of the magnets.

The corrosion rate of sintered Nd–Dy–Fe–B magnets depends on the composition of the magnet, in particular, on the electrochemical potential of the RE-rich constituents, and on the microstructure, for instance, on the fraction and on the distribution of the RE-rich phases.

By proper addition of some TMs, for instance Co, Nb, V, Mo, Cu, Ga, to the alloy, the corrosion stability of sintered Nd–Dy–Fe–B magnets can be improved substantially (Ohashi, Tawara, Yokoyama and Kobayashi, 1987; Hirosawa, Mino and Tomizawa, 1991; Kim and Camp, 1996; Grieb, 1997; Fernengel *et al*., 1999). Some of these additions transform the Nd-rich constituents into more noble intermetallic compounds, for instance, $Nd_3(Co,Cu)$, $(Nd,Dy)_5(Co,Cu,Ga)_3$, $Nd_6(Fe,Co)_{13}Ga$, see inset in Figure 29. Since the free electrochemical potentials of these compounds were determined to be about 800 mV higher than that of pure Nd metal, such Nd–Dy–Fe–Co–TM–B magnets, TM: Cu, Al, Ga, are much more stable in hot and humid climates (Katter *et al*., 2001). For such alloyed Nd–Dy–Fe–Co–TM–B magnets, the corrosion rate is substantially reduced. Depending on the total RE content, such magnets can be stable in hot and humid climates. For magnets with an appropriate total RE content, there is a passivation of the surface in the beginning and, after a prolonged exposure, the magnets start to rust similar to pure iron. However, magnets with a higher total RE concentration experience some mass losses, which depends on the exposure period in hot and humid climate (Kaszuwara and Leonowicz, 1999; Katter *et al*., 2001) or on the total RE content, if a fixed exposure period for the corrosion test is applied (Tokuhara and Hirosawa, 1991).

The sequence of the corrosion attack has been confirmed by measurements of the electrochemical potential of the constituents by scanning probe microscopy. The measurements demonstrate a correlation between the electrostatic potential and the corrosion rate. The hard magnetic $Nd_2Fe_{14}B$ grains

Nd-rich constituents	Nd(Fe)	$Nd_x(Co,TM)_y$

Figure 29. Model of the microstructure of sintered standard Nd–Dy–Fe–B magnets or alloyed Nd–Dy–Fe–Co–TM–B magnets, TM: Cu, Al, Ga. The inset indicates that the replacement of Nd-rich constituents Nd(Fe) by more noble $Nd_x(Co,TM)_y$ compounds improves the corrosion resistance substantially.

have a superior corrosion stability compared to $Nd_{1.1}Fe_4B_4$ borides or to the Nd–Fe solid solutions (Bala, Pawlowska, Szymura and Rabinovich, 1998; Schultz, El-Aziz, Barkleit and Mummert, 1999; Mummert *et al*., 2000; El-Aziz, 2003).

5.2 Typical corrosion tests

There are many different corrosion tests, in particular, in hot and humid climates at different temperatures. Other tests focus on more aggressive media, such as sulfuric acid in order to measure electrochemical potentials (Bala, Pawlowska, Szymura and Rabinovich, 1998; Schultz, El-Aziz, Barkleit and Mummert, 1999; Mummert *et al*., 2000), salt spray tests for automotive applications (Katter *et al*., 2001), seawater test for marine applications, and so on.

A very common test is the highly accelerated stress test (HAST), according to the standard IEC 68-2-66. The test samples are stored at 130 °C, 95% relative humidity, and 2.6 bar water vapor pressure. Under these conditions, no condensation of vapor occurs. The mass losses per surface area of the magnets are monitored, depending on the exposure time. Standard Nd–Fe–B magnets suffer mass losses of about 10–100 mg cm^{-2} after 10 days, whereas the mass losses of alloyed Nd–Dy–Fe–Co–TM–B magnets, TM: Cu, Al, Ga, with an improved corrosion stability amount to <1 mg cm^{-2}, see Figure 30. If some condensation occurs, such alloyed Nd–Dy–Fe–Co–TM–B magnets start to rust similar to iron.

The results of the accelerated corrosion tests could be confirmed by a long-term corrosion test in dry air with a relative humidity of about 50% over a period of 2 years. Sintered Nd–Fe–B magnets with an extremely high total RE content corrode faster than magnets with a lower RE content. The improvements were achieved by a controlled oxidation of RE-rich alloy powders in air before sintering (Ma *et al*., 1994; Kaszuwara and Leonowicz, 1999) or by addition of Co, Cu, Al, Zr, or C to Nd–Fe–B alloys (Kim and Camp, 1996; Kaszuwara and Leonowicz, 1999).

Since sintered $SmCo_5$ and $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets only contain a few isolated intergranular RE-rich constituents, they are much more stable in hot and humid climates than Nd–Dy–Fe–Co–TM–B magnets. Figure 31 compares the mass losses of alloyed Nd–Dy–Fe–Co–TM–B, $SmCo_5$, and $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets, depending on the exposure period in a HAST test. $SmCo_5$ and $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets form a passivation layer, which sometimes increases their weight. Hence, they are rather stable in such a hot and humid climate, whereas Nd–Dy–Fe–Co–TM–B magnets experience small mass losses of <1 mg cm^{-2} after 10 days and some milligram per square centimeter after an exposure period of 50 days.

By performing the stress test at 130 °C and a humidity of 100%, often denoted as pressure cooker test (PCT) or autoclave test, the corrosion stress can be accelerated by a factor of about 10. Since condensation of water vapor occurs,

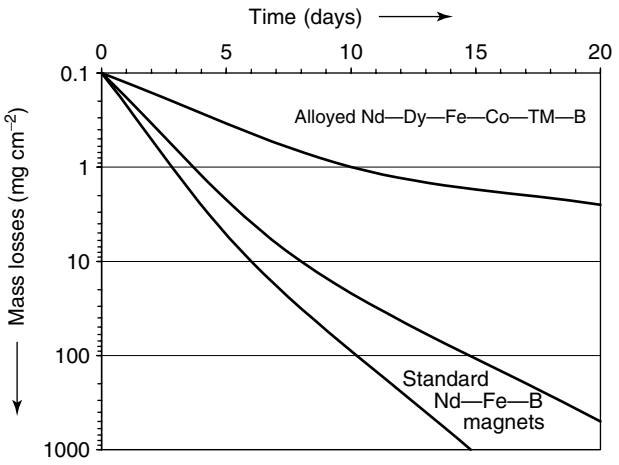

Figure 30. Mass losses per surface area of standard sintered Nd–Dy–Fe–B or alloyed Nd–Dy–Fe–Co–TM–B magnets with an improved corrosion resistance, depending on the exposure time. The highly accelerated stress test (HAST) is performed at 130 °C, 95% relative humidity, and 2.6 bar vapor pressure.

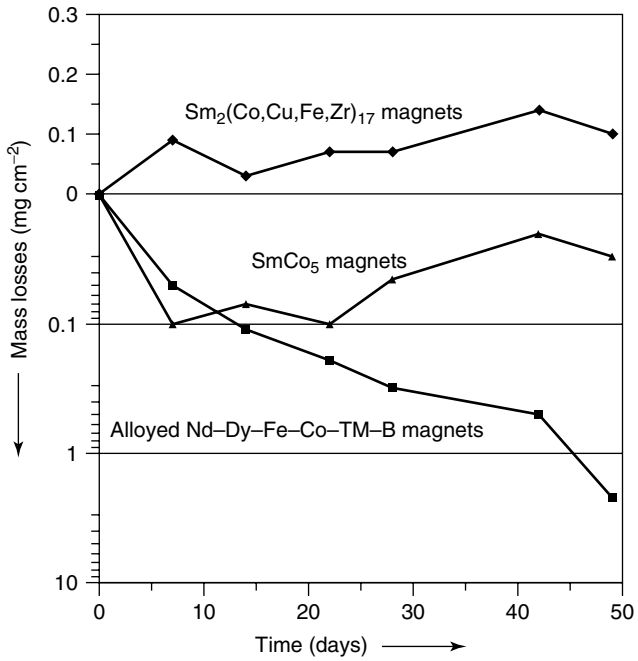

Figure 31. Comparison of mass losses per surface area of sintered $SmCo_5$, $Sm_2(Co,Cu,Fe,Zr)_{17}$, and alloyed Nd–Dy–Fe–Co–TM–B magnets in dependence on the exposure time. The highly accelerated stress test (HAST) has been performed at 130 °C, 95% relative humidity, and 2.6 bar vapor pressure.

the alloyed Nd–Dy–Fe–Co–TM–B magnets are covered with red rust after some days, but no disintegration of the magnet surface occurs (Katter *et al*., 2001).

Under salt spray conditions, according to the standard DIN 50021, the magnets are covered by red rust after an exposure time of 24 h in general.

5.3 Coating of RE–TM magnets

In applications where condensation of humidity occurs or other corrosive media exist, sintered Nd–Fe–B magnets must be protected by metallic or organic coatings. Typical commercial coatings for sintered Nd–Fe–B magnets, their color, hardness, and maximum operating temperatures are compiled in Table 4. Such coatings also facilitate the handling and cleaning of sintered magnets, for instance, for applications in clean-room workshops.

6 MECHANICAL PROPERTIES OF SINTERED RE–TM MAGNETS

Sintered RE–TM magnets are applied in many devices, for instance, motors, generators, couplings, bearings, separators, sensors, and so on in order to optimize the efficiency of the device or in order to reduce the weight or the volume of the magnet assemblies. In general, magnets operate as functional materials, but, in dynamic applications, mechanical properties may also become important.

Some mechanical properties of sintered Nd–Fe–B magnets have been examined in dependence of different processing routes (Horton, Wright and Herchenroeder, 1996; Horton *et al*., 1997), on the composition, for instance, the Co content (Rabinovich *et al*., 1996; Jiang *et al*., 2001) or different RE-rich constituents (Ohashi, Tawara, Yokoyama and Kobayashi, 1987; Otsuki, Sato and Fujiwara, 1989) or various additions of Al, Cr, Nb, Zr (Szymura, Wyslocki, Rabinovich and Bala, 1994; Rabinovich *et al*., 1996).

Besides, on the composition, the mechanical properties may also depend on the microstructure, characterized by the average grain size. There are different routes for manufacturing Nd–Dy–Fe–Co–TM–B magnets, TM: Cu, Al, Ga, with various grain sizes. For instance, Nd–Dy–Fe–TM–B magnets with various fractions of RE-rich constituents can be sintered from appropriate alloy powder blends. Owing to the different volumes of the liquid phase at the sintering temperature, the average grain size of $Nd_{12.8-x}Dy_{0.74}Fe_{bal}TM_{1.3}B_{5.6}$ magnets, TM: Co, Cu, Al, Ga, $x = 0$, 0.1, 0.3, 0.9, 1.4, 2.0, varies between 6.5 and 9.5 µm (Rodewald, Katter and Üstüner, 2004).

Another route is the sintering of $Nd_{12.9}Dy_{0.74}Fe_{bal}TM_{1.3}B_{5.6}$ magnets from alloy powders with different average particle sizes, according to Fisher sub sieve seizer (FSSS), for instance, 2.1, 2.6, 3.1, 3.5, 3.7, and 4.1 µm. By adjusted sintering conditions, dense magnets with an average grain size between 4.0 and 6.5 µm could be achieved (Rodewald, Katter and Üstüner, 2004).

The densities of the sintered magnets are controlled by the Archimedes principle. Owing to the liquid-phase sintering, Nd–Dy–Fe–TM–B magnets easily achieve densities between 7.55 and 7.6 g cm^{-3} or $\rho/\rho_0 > 99\%$, where ρ_0 denotes the density of the $Nd_2Fe_{14}B$ compound. The typical magnetic properties amount to $J_r = (1.42 \pm 0.02)$ T and $H_{cJ} = (12 \pm 1)$ kA m^{-1}. The maximum energy densities range between 360 and 400 kJ m^{-3}. The average grain

Table 4. Typical commercial surface coatings of sintered Nd–Fe–B magnets for protection against corrosion or for handling in clean rooms.

Surface	Thickness	Method	Color	Hardness	Corrosion resistance	Temperature range (°C)
Sn	>15 µm	Galvanic	Silver semibright	HV 20	Humid climate	<160

size was determined by the three circular intercept method, according to the standard ASTM E112. The following mechanical properties were determined by standardized tests: the compressive and the bending strength, the fracture toughness, the Young's modulus, and the Vickers hardness.

6.1 Compressive strength f_{comp}

In general, the compressive f_{comp} strength is determined on cubes with dimensions of approximately $5 \times 5 \times 5\,mm^3$, which are cut from sintered Nd–Dy–Fe–TM–B magnets parallel to the easy axis by diamond grinding. The ram speed of the press amounts to $0.15\,mm\,min^{-1}$. Of each batch, the measurements are performed on five samples, the averages of the results and their standard deviation are compiled in Figure 32. Overall, the compressive strength f_{comp} amounts to $(960 \pm 50)\,N\,mm^{-2}$ on the average and does not depend on the grain size of the sintered magnets within the accuracy of the measurements. These results are in fair agreement with measurements on Nd–Dy–Fe–Co–B magnets with different alloying additions of Cr, Al, Nb, or Zr, the compression strength of which ranges between 860 and $1120\,N\,mm^{-2}$ (Rabinovich *et al.*, 1996).

Measurements of the compressive strength perpendicular to the easy axis result in about 4–8% smaller values. Hence, there is only a negligible anisotropy of the compressive strength in sintered Nd–Dy–Fe–TM–B magnets.

In addition, the temperature dependence of the compressive strength of $Nd_{12.9}Dy_{0.4}Fe_{bal}TM_{1.3}B_{5.6}$ magnets, TM: Co, Cu, Al, Ga, with a high remanent polarization of 1.45 T, a coercivity H_{cJ} of $1000\,kA\,m^{-1}$, and an average grain size of 8.4 µm has been examined. On the average, the compression strength decreases by about 7%, when the temperature increases by 100 K, see Figure 33.

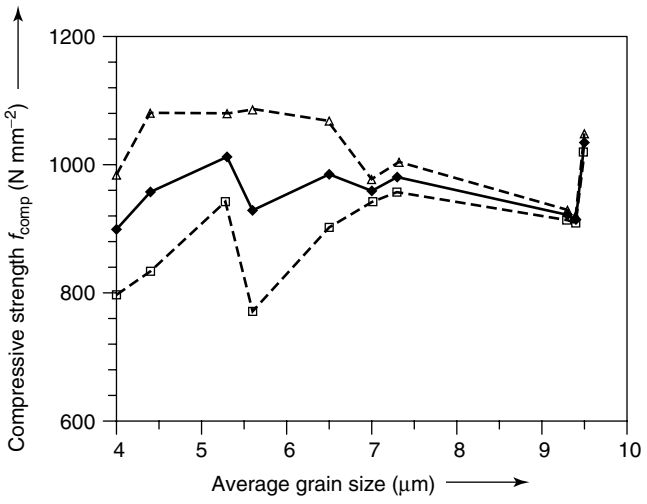

Figure 32. Compressive strength of $Nd_{12.9}Dy_{0.74}Fe_{bal}TM_{1.3}B_{5.6}$ magnets, TM: Co, Cu, Al, Ga, depending on the average grain size. The dashed graphs represent the compressive strength $f_{comp} \pm \sigma$, σ denotes the standard deviation.

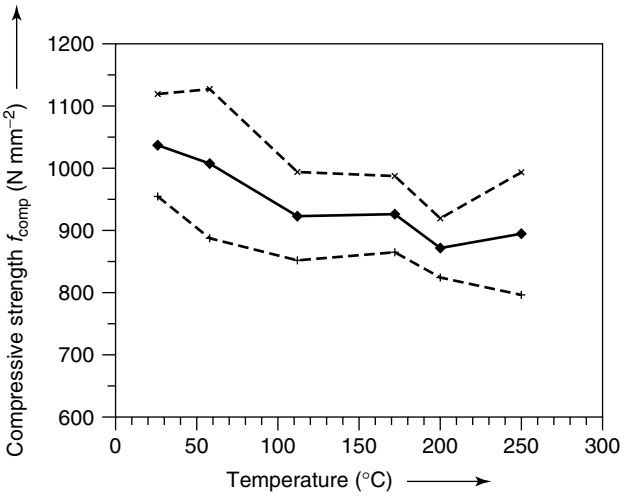

Figure 33. Compressive strength of $Nd_{12.9}Dy_{0.4}Fe_{bal}TM_{1.3}B_{5.6}$ magnets, TM: Co, Cu, Al, Ga, depending on the temperature. The dashed graphs represent the compressive strength $f_{comp} \pm \sigma$, σ denotes the standard deviation.

The compressive strength of sintered $SmCo_5$ or $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets amounts to approximately 1000 or $650\,N\,mm^{-2}$ respectively. In particular, $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets are more sensitive to compression forces and must be handled carefully in order to prevent chipping or cracks.

6.2 Bending strength f_{bend}

The bending strength f_{bend} of Nd–Dy–Fe–TM–B magnets, TM: Co, Cu, Al, Ga, was measured by the three-point bending test on bars with dimensions of approximately $5 \times 2 \times 50\,mm^3$, for instance, according to the standard ASTM 314-64, depending on the grain size. On the average, the bending strength perpendicular to the easy axis amounts to about $(330 \pm 20)\,N\,mm^{-2}$ and does not depend on the grain size of the sintered magnets within the accuracy of the measurements, see Figure 34.

There is a little anisotropy of the bending strength. In general, the bending strength perpendicular to the easy axis results in 4–10% smaller values than when it is parallel to the easy axis.

However, the bending strength of Nd–Dy–Fe–TM–B magnets, TM: Co, Cu, Al, Ga, with Co concentrations >3% or with different alloying additions of Cr, Al, Nb, or Zr, ranges only between 160 and $280\,N\,mm^{-2}$ (Rabinovich *et al.*, 1996; Jiang *et al.*, 2001).

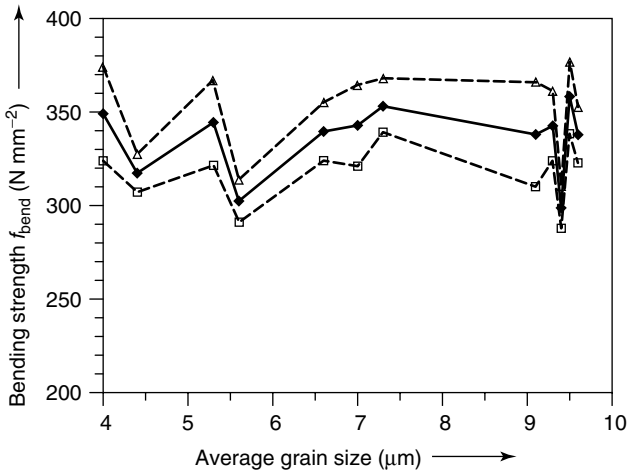

Figure 34. Bending strength of $Nd_{12.9}Dy_{0.74}Fe_{bal}TM_{1.36}B_{5.6}$ magnets, TM: Co, Cu, Al, Ga, depending on the average grain size. The dashed graphs represent the bending strength $f_{bend} \pm \sigma$, σ denotes the standard deviation.

In addition, the bending strength was examined on magnetized bars perpendicular to the easy axis, which resulted in about 10–15% smaller values. Probably the repulsive magnetic forces promote the crack formation and propagation (Rodewald, Katter and Üstüner, 2004).

Finally, the bending strength of $Nd_{12.9}Dy_{0.4}Fe_{bal}TM_{1.3}B_{5.6}$ magnets, TM: Co, Cu, Al, Ga, with a high remanent polarization of 1.45 T, a coercivity H_{cJ} of 1000 kA m^{-1} and an average grain size of 8.4 µm was examined, depending on the temperature. On the average, the bending strength decreases only by about 5%, when the temperature increases by 100 K, see Figure 35.

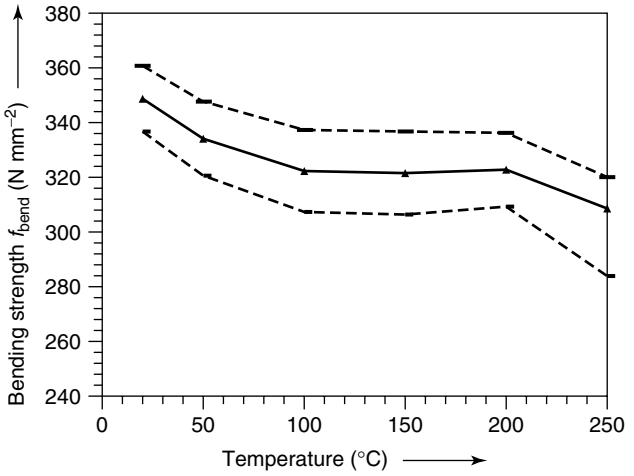

Figure 35. Bending strength of $Nd_{12.9}Dy_{0.4}Fe_{bal}TM_{1.3}B_{5.6}$ magnets, TM: Co, Cu, Al, Ga, depending on the temperature. The dashed graphs represent the bending strength $f_{bend} \pm \sigma$, σ denotes the standard deviation.

The bending strength of sintered $SmCo_5$ magnets amounts to approximately 120 N mm^{-2}, whereas the bending strength of sintered $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets ranges between 90 and 150 N mm^{-2} in general. The smaller bending strengths of Sm–Co magnets reflect rather well their high sensitivity to cracking.

6.3 Fracture toughness K_{IC}

The fracture toughness K_{IC} of $Nd_{12.9}Dy_{0.74}Fe_{bal}TM_{1.3}B_{5.6}$ magnets, TM: Co, Cu, Al, Ga, sintered of alloy powders with different average particle sizes at adjusted temperatures was examined on bars, $3 \times 6 \times 30$ mm^3, for instance, depending on the grain size. The bars had a notch of 0.2 mm in width and 3 mm in length in the middle of the bar, made by spark erosion wire cutting, in order to achieve a well-defined starting point for the cracks. The fracture force was determined by a three-point bending test according to ASTM 314-64. The cracks always started at the notch and extended symmetrically. On the average, the fracture toughness perpendicular to the easy axis amounted to (184 ± 10) N mm$^{-3/2}$. There was only a small decrease in the fracture toughness with decreasing grain size, see Figure 36. The fracture toughness K_{IC} was not affected significantly by the fraction of RE-rich constituents in the sintered magnets.

Measurements of the fracture toughness parallel to the easy axis resulted in 10–15% smaller values. Within the accuracy of the measurements there was only a small anisotropy of the fracture toughness K_{IC}.

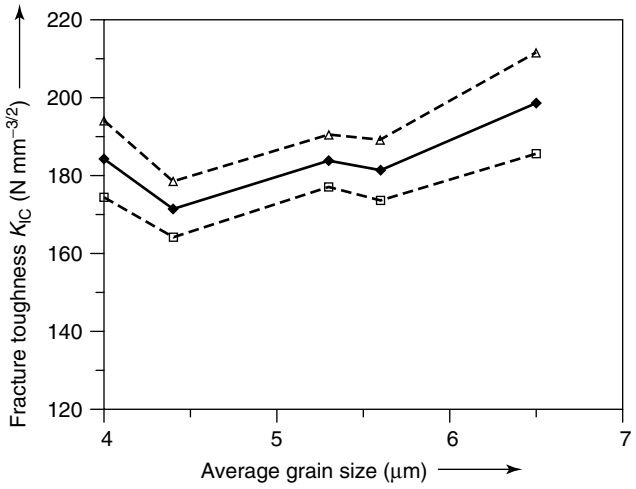

Figure 36. Fracture toughness K_{IC} of $Nd_{12.9}Dy_{0.74}Fe_{bal}TM_{1.3}B_{5.6}$ magnets, TM: Co, Cu, Al, Ga, sintered of alloy powders with different average particle sizes at adjusted temperatures, depending on the average grain size. The dashed graphs represent the fracture toughness $K_{IC} \pm \sigma$, σ denotes the standard deviation.

The fracture toughness K_{IC} was sensitive to the processing route of the magnets. The data ranged from about $60\,N\,mm^{-3/2}$ for Nd–Fe–B magnets prepared from TiC-containing gas-atomized alloy powders up to $175\,N\,mm^{-3/2}$ for sintered Nd–Fe–B magnets (Horton *et al.*, 1997). For sintered Nd–Dy–Fe–B magnets, most of the data ranged between 90 and $175\,N\,mm^{-3/2}$ (Otsuki, Sato and Fujiwara, 1989; Horton, Wright and Herchenroeder, 1996; Jiang *et al.*, 2001), whereas for Nd–Dy–Fe–Co–B magnets with a Co concentration >3%, the fracture toughness decreased to a range between 100 and $110\,N\,mm^{-3/2}$ (Jiang *et al.*, 2001).

Lately, the fracture toughness K_{IC} of $Nd_{12.9}Dy_{0.4}Fe_{bal}TM_{1.3}B_{5.6}$ magnets, TM: Co, Cu, Al, Ga, with a high remanent polarization of 1.45 T, a coercivity H_{cJ} of $1000\,kA\,m^{-1}$, and an average grain size of 8.4 µm was determined, depending on the temperature. On the average, the fracture toughness decreased by about 4–6% when the temperature increased by 100 K, see Figure 37.

The fracture toughness K_{IC} of $SmCo_5$ magnets varies between 50 and $70\,N\,mm^{-3/2}$ (Horton, Wright and Herchenroeder, 1996). Sintered $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets have an even smaller fracture toughness between 40 and $50\,N\,mm^{-3/2}$, which corroborates their sensitivity to chipping.

6.4 Young's modulus *E*

The Young's modulus E of sintered $Nd_{12.9}Dy_{0.74}Fe_{bal}TM_{1.3}B_{5.6}$ magnets, TM: Co, Cu, Al, Ga, with an average grains size of 9.8 µm was determined on bars, $3 \times 4 \times 50\,mm^3$, by ultrasound attenuation. The Young's modulus E amounted to $(160 \pm 3)\,kN\,mm^{-2}$ perpendicular to the easy axis. Measurements of the Young's modulus parallel to the easy axis yielded insignificant larger values. Within the accuracy of the measurements, there was only a negligible anisotropy of <3%.

The Young's modulus E did not seem to be very sensitive to the composition of the magnets. Data of magnets with different Co concentrations or different alloying additions of Cr, Al, Nb, or Zr, ranged between 130 and $160\,kN\,mm^{-2}$ (Szymura, Wyslocki, Rabinovich and Bala, 1994; Rabinovich *et al.*, 1996).

Measurements of the Young's modulus of sintered $Nd_{12.9}Dy_{0.74}Fe_{bal}TM_{1.3}B_{5.6}$ magnets at temperatures between 20 and 200 °C proved only a small decrease by about 2.5% when the temperature was increased by 100 K, see Figure 38.

The Young's modulus E of sintered $SmCo_5$ magnets amounted to approximately $110\,kN\,mm^{-2}$. However, the Young's modulus of sintered $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets was comparable to Nd–Dy–Fe–TM–B magnets and amounted to $150\,kN\,mm^{-2}$.

6.5 Vickers hardness HV 1

The Vickers hardness HV 1 was examined on polished surfaces of $Nd_{12.9}Dy_{0.74}Fe_{bal}TM_{1.3}B_{5.6}$ magnets, TM: Co, Cu, Al, Ga, depending on the grain size. The indenter load amounted to 10 N. There is no significant dependence of the Vickers hardness on the average grain size, see Figure 39.

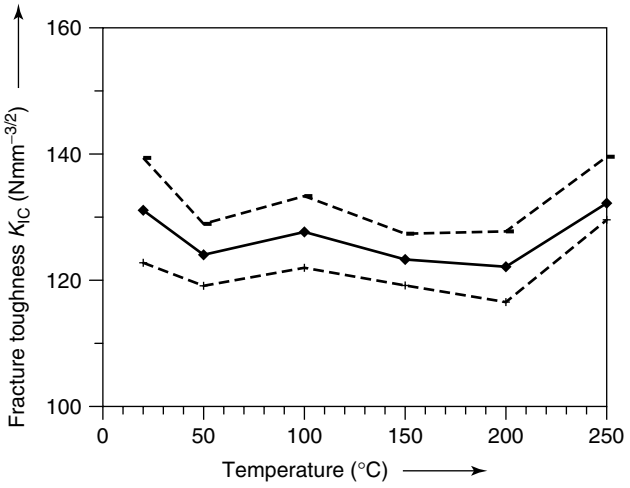

Figure 37. Fracture toughness K_{IC} of $Nd_{12.9}Dy_{0.4}Fe_{bal}TM_{1.3}B_{5.6}$ magnets, TM: Co, Cu, Al, Ga, depending on the temperature. The dashed graphs represent the fracture toughness $K_{IC} \pm \sigma$, σ denotes the standard deviation.

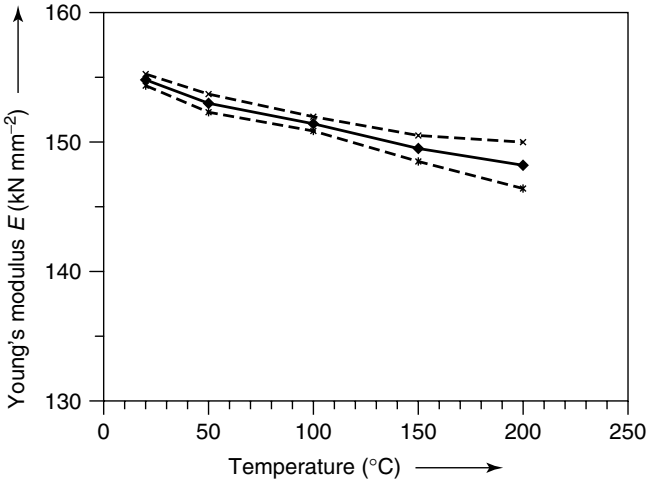

Figure 38. Young's modulus E of sintered $Nd_{12.9}Dy_{0.74}Fe_{bal}TM_{1.3}B_{5.6}$ magnets with an average grains size of 9.8 µm, depending on the temperature. The dashed graphs represent the Young's modulus $E \pm \sigma$, σ denotes the standard deviation.

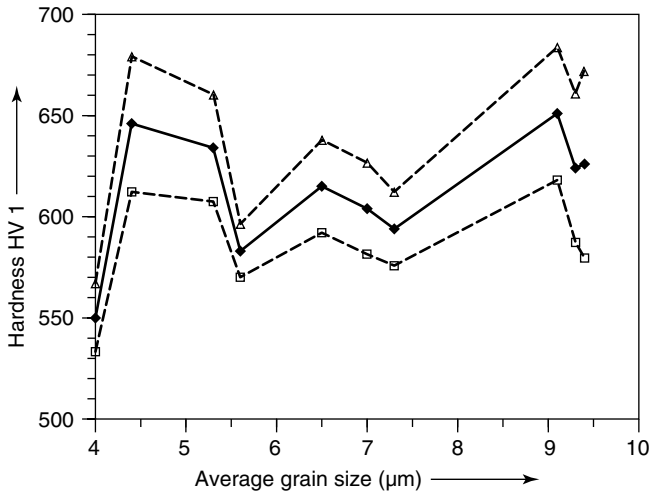

Figure 39. Vickers hardness HV 1 of $Nd_{12.9}Dy_{0.74}Fe_{bal}TM_{1.3}B_{5.6}$ magnets, TM: Co, Cu, Al, Ga, depending on the average grain size. The dashed graphs represent the Vickers hardness HV $1 \pm \sigma, \sigma$ denotes the standard deviation.

This may be due to the wide distribution of the dimensions of the grains in sintered magnets. For instance, even magnets with an average grain size of about 5 μm still contain some large grains with dimensions up to 20 μm. On the average, the Vickers hardness HV 1 amounts to (610 ± 30).

The Vickers hardness does not seem to be sensitive to the composition or to the microstructure of the magnets. Typical data range from 530 to 600 HV 1 for magnets with different RE contents (Otsuki, Sato and Fujiwara, 1989) or different Co contents (Jiang *et al.*, 2001).

The Vickers hardness HV 1 of sintered Sm–Co magnets is quite similar to Nd–Dy–Fe–TM–B magnets and amounts to 550 HV 1 for $SmCo_5$ magnets and to 640 HV 1 for $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets.

6.6 Other thermal, caloric, or electrical properties of RE–TM magnets

Additional thermal, caloric, or electrical properties of sintered RE–TM magnets can be retrieved from data sheets of magnet producers.

Very often, RE–TM magnets are glued onto soft magnetic parts, for instance, pole plates, rotor laminations of motors, casings, yokes, and so on. In particular, at increased operating temperatures, magnets with a large pole area may experience a shearing stress due to the different coefficients of the thermal expansion of the magnet and the support material. Under extreme conditions, the shearing stress may result in loosening of the bond. Hence, the coefficients of the thermal expansion should be taken into account.

For Nd–Dy–Fe–TM–B magnets, TM: Co, Cu, Al, Ga, there is a significant anisotropy of the coefficients of the thermal expansion, which range between 5 and $7.5 \times 10^{-6}\,K^{-1}$ parallel to the easy axis and between -0.5 and $-1 \times 10^{-6}\,K^{-1}$ perpendicular to the easy axis of the Nd–Dy–Fe–TM–B magnets.

For sintered Sm–Co magnets, the anisotropy of the coefficients of the thermal expansion is less pronounced. For $SmCo_5$ magnets, the coefficients of the thermal expansion amount to $7 \times 10^{-6}\,K^{-1}$ parallel and to $13 \times 10^{-6}\,K^{-1}$ perpendicular to the easy axis of the $SmCo_5$ magnets and vary from 8 to $10 \times 10^{-6}\,K^{-1}$ parallel and from 11 to $12 \times 10^{-6}\,K^{-1}$ perpendicular to the easy axis of $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets.

The thermal conductivity of sintered Nd–Dy–Fe–TM–B magnets amounts to approximately $9\,W\,m^{-1}\,K^{-1}$, which is about 11% of the thermal conductivity of iron, which amounts to $80.2\,W\,m^{-1}\,K^{-1}$, but is rather similar to the thermal conductivity of neodymium metal, which amounts to $16.5\,W\,m^{-1}\,K^{-1}$. The thermal conductivity of sintered $SmCo_5$ magnets is 10% larger than the thermal conductivity of Nd–Dy–Fe–TM–B magnets and amounts to about $10\,W\,m^{-1}\,K^{-1}$. Owing to the high Co content, the thermal conductivity of sintered $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets increases to $12\,W\,m^{-1}\,K^{-1}$, which is only 12% of the thermal conductivity of cobalt metal, which amounts to $100\,W\,m^{-1}\,K^{-1}$, but is similar to the thermal conductivity of samarium metal, which amounts to $13.3\,W\,m^{-1}\,K^{-1}$.

The specific heat of sintered RE–TM magnets is rather constant. The data range between 440 and $500\,J\,kg^{-1}\,K^{-1}$ for Nd–Dy–Fe–TM–B magnets, between 370 and $420\,J\,kg^{-1}\,K^{-1}$ for $SmCo_5$ magnets, and between 370 and $390\,J\,kg^{-1}\,K^{-1}$ for $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets. There are only minor differences to the specific heat of iron metal, $452\,J\,kg^{-1}\,K^{-1}$, or cobalt metal, $456\,J\,kg^{-1}\,K^{-1}$.

The electrical resistivity of sintered Nd–Dy–Fe–TM–B magnets ranges between 1.1 and $1.6\,\Omega\,mm^2\,m^{-1}$. In general, the electrical resistivity parallel to the easy axis is about 10–20% larger than the resistivity perpendicular to the easy axis of the Nd–Dy–Fe–TM–B magnets. There is only a small increase in the electrical resistivity of approximately $2.8 \times 10^{-2}\,\Omega\,mm^2\,m^{-1}\,K^{-1}$ in the temperature range between 20 and 100 °C.

By alloying additions to Nd–Dy–Fe–TM–B magnets, the electrical resistivity cannot be changed significantly. The electrical resistivity of Nd–Dy–Fe–TM–B magnets is about 10 times larger than the electrical resistivity of iron metal, which amounts to $0.10\,\Omega\,mm^2\,m^{-1}$.

The electrical resistivity varies between 0.5 and $0.6\,\Omega\,mm^2\,m^{-1}$ for sintered $SmCo_5$ magnets and between 0.75 and $0.85\,\Omega\,mm^2\,m^{-1}$ for sintered $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets, which is similar to the electrical resistivity

of samarium metal, $0.94\,\Omega\,mm^2\,m^{-1}$, and an order of magnitude larger than the electrical resistivity of cobalt metal, $0.06\,\Omega\,mm^2\,m^{-1}$.

7 CONCLUSIONS

Permanent magnets have become a key component in many devices. Owing to the high maximum energy density, RE–TM magnets are able to drive small motors in watches as well as strong motors in electric vehicles or huge motors for the propulsion of ships. There are miniature motors with a diameter of 1.9 mm, a length of 5 mm, which rotate at a speed of 100 000 rpm and achieve a power of 60 mW. On the other hand, there are motors with a diameter up to 3.2 m, a length up to 9.5 m, which rotate at 120 rpm. The power of such machines amounts to 5 MW and there are designs for motors with a power up to 18 MW for the propulsion of ships.

In addition, heavy and large hydraulic devices are going to be replaced by permanent magnet motors, for instance, in electronic power steering of vehicles or electronically assisted braking. In such motors, the cogging torque must be minimized. Novel and economic butterfly-shaped Nd–Dy–Fe–TM–B magnets meet such specifications.

For the design and engineering of magnet assemblies, a large variety of RE–TM magnets are commercially available. Most economic is of course the application of net-shaped parts produced by axial field die-pressing. The dimensional tolerances depend on the dimensions and on the shape of the magnets. For instance, parts with nominal dimensions up to 7 mm perpendicular to the pressing direction tolerances of ± 0.10 mm can be achieved. For larger blocks with dimensions up to 60 mm perpendicular to the pressing direction, the tolerances range between ± 0.45 and ± 0.90 mm. More precise tolerances down to ± 0.02 mm can be manufactured by grinding, but such a treatment consumes more machining time in the workshops.

Typical magnetic properties of axial field die-pressed Nd–Dy–Fe–TM–B magnets range from 1.08 to 1.36 T for the remanent polarization, 2865 to 955 kA m^{-1} for the coercivity H_{cJ}, and 225 to 350 kJ m^{-3} for the maximum energy density, see Figure 40. The maximum continuous operating temperatures range from 60 °C for magnets with a high energy density up to 230 °C for magnets with a high coercivity.

As discussed in Section 2.3, near net-shaped Nd–Dy–Fe–TM–B magnets with improved energy densities can be manufactured by transverse field die-pressing. In general, such magnets require some machining in order to meet the dimensional tolerances. Typical magnetic properties range from 1.14 to 1.43 T for the remanent polarization, 2865 to 955 kA m^{-1} for the coercivity H_{cJ}, and 250 to 395 kJ m^{-3} for the maximum energy density. The maximal continuous operating temperatures are similar to axial field die-pressed magnets.

The optimal magnetic properties and the largest parts can be produced by cold isostatic pressing of Nd–Dy–Fe–TM–B blocks. The magnetic properties range from 1.18 to 1.47 T for the remanent polarization, 2230 to 875 kA m^{-1} for the coercivity H_{cJ}, and from 270 to 415 kJ m^{-3} for the maximum energy density. The maximum continuous operating temperatures of isostatically pressed magnets range from 50 °C for magnets with the highest maximum energy density to 190 °C for magnets with the highest coercivity.

A superior temperature stability of magnet assemblies can be achieved by the application of Sm–Co magnets. For net-shaped $SmCo_5$ parts or isostatically pressed blocks, the remanent polarization varies between 0.9 and 1.01 T with coercivities H_{cJ} between 2400 and 1500 kA m^{-1} and maximum energy densities between 160 and 200 kJ m^{-3}, see Figure 40. In general, maximum continuous operating temperatures up to 250 °C can be applied.

Even higher operating temperatures up to 300 or 350 °C can be achieved for magnet assemblies of $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets. Typical magnetic properties of $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets with moderate or high coercivities range between 1.04 up to 1.12 T for the remanent polarization, 2070 or 800 kA m^{-1} for the coercivity H_{cJ}, and 205 or 240 kJ m^{-3} for the maximum energy density, see Figure 40. With respect to the temperature and corrosion stability, Sm–Co magnets are the most stable RE–TM magnets. Recently developed $Sm_2(Co,Cu,Fe,Zr)_{17}$ magnets can even be applied at temperatures up to 550°, but such

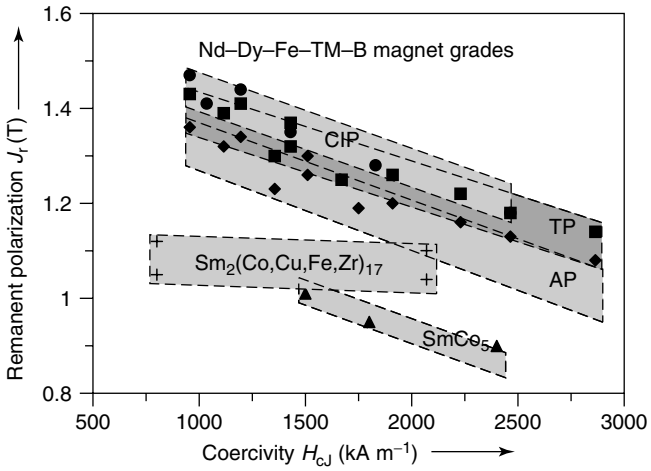

Figure 40. Remanent polarization J_r of sintered Nd–Dy–Fe–TM–B and Sm–Co magnets, depending on the coercivity H_{cJ}.

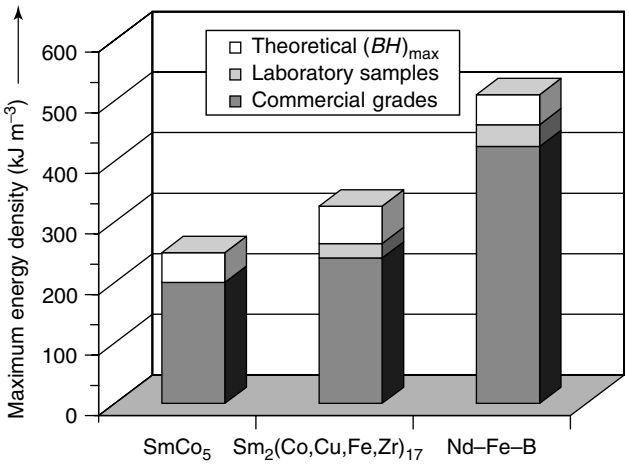

Figure 41. Exploitation of the maximum energy density of sintered RE–TM magnets based on $SmCo_5$, $Sm_2(Co,Cu,Fe,Zr)_{17}$ or $Nd_2Fe_{14}B$ compounds by commercial RE–TM magnet grades.

magnets achieve only a remanent polarization of 0.85 T and a maximum energy density of 127 kJ m^{-3} at room temperature (Walmer, 2002).

By optimization of the alloy composition, by improving the processing route, and by refining the microstructure, Nd–Dy–Fe–TM–B magnets can be tailored to meet the requirements of many different applications. As indicated in Figure 1, the maximum energy density of RE–TM magnets could be increased step by step and is now approaching the technical limits. The remanent polarization of commercial Sm–Co magnets reaches 94% of the theoretical limit and the remanent polarization of commercial Nd–Dy–Fe–TM–B magnets achieves 92% of the theoretical limit, see Figure 41.

By refined manufacturing conditions in laboratory facilities, almost ternary Nd–Fe–B magnets now achieve a remanent polarization of 1.533 T, a coercivity H_{cJ} of 784 kA m^{-1}, and a maximum energy density of 460 kJ m^{-3} (Kaneko, 2004).

Besides optimization of the processing routes of RE–TM magnets, future research and development activities should be focused on the search for new hard magnetic RE–TM compounds.

Rare-earth Nanocrystalline and Nanostructured Magnets

Melania Marinescu, Alexander Gabay and George C. Hadjipanayis
University of Delaware, Newark, DE, USA

1 INTRODUCTION

In polycrystalline anisotropic magnetic materials, the coercivity H_c is strongly dependent on the size of particles or grains. The often suggested correlation between H_c and the single domain particle size has no theoretical ground (Aharoni, 1986; Brown, 1945) and, in the case of hard-magnetic materials, it contradicts experimental observations (Grönefeld and Kronmüller, 1990). It is an empirical fact, however, that with decreasing particle size, the coercivity increases. When approaching the superparamagnetic size, which is of the order of a few nanometers in anisotropic materials, H_c decreases again because of the increasing effect of thermal fluctuations. This general dependence offers a relatively simple way to convert the high anisotropy into a high coercivity by producing materials with particles or grains of the size of tens to hundreds of nanometers.

The general equation that proved to be applicable to a vast majority of hard-magnetic materials, whose coercivity is controlled by the nucleation of reversed magnetic domains, presents the coercivity as a function anisotropy field H_A and the saturation magnetization M_s as:

$$H_c = \alpha H_A - N_{eff} M_s \quad (1)$$

where the parameters α and N_{eff} describe the effects of microstructure (including the grain size) and the local stray fields (which are also dependent on the microstructure), respectively. Theoretical derivations (Kronmüller, 1987) replace the anisotropy field from equation (1) ($H_A = 2K_1/\mu_0 M_s$) with the nucleation field (see equation (2)). On the other hand, the theoretical maximum energy product $(BH)_{max}$ (which characterizes an energy conserved by a permanent magnet with a perfectly square hysteresis loop and $H_c \geq M_s/2$) is equal to $\mu_0 M_s^2/4$ (Cullity, 1972). Table 1 shows the room-temperature intrinsic magnetic properties of some rare-earth (R) intermetallic compounds. In addition to M_s and H_A, the table includes the Curie temperature T_c, which is important for estimating a temperature stability of the permanent magnet (it is not, however, sufficient for finding the maximum operating temperature but the temperature dependence of H_A is also very important).

As it can be seen from the data in Table 1, the $Nd_2Fe_{14}B$, $Pr_2Fe_{14}B$, $Nd_2Fe_{14}C$, and $Sm_2Fe_{17}N_{2.3}$ compounds promise the highest $(BH)_{max}$ due to their high values of M_s, but the magnets based on the 2:14:1 compounds have very limited application temperature range because of their low T_c.

[a]Reference data vary because of a wide homogeneity range for the alloy.
[b]At 4.2 K.

Despite the high M_s, $Pr_2(Co_{0.53}Fe_{0.47})_{17}$ will not likely make a good magnet because of the low H_A. On the other hand, the compounds with very high H_A and modest M_s, like $SmCo_5$ and $SmCo_4B$, can potentially develop exceptionally high H_c, but not likely the record values of $(BH)_{max}$.

The most obvious way to decrease particle size is by milling. This route seems even more attractive since it may produce single crystals, which can be aligned by a magnetic field. Unfortunately, mechanical milling cannot produce particles smaller than 0.5–1 μm. Moreover, the coercivity of single crystals is very sensitive to the state of their surface. The surface of as-milled particles is always damaged and often oxidized leading to easy nucleation of domain walls and to a low H_c. Most of the contemporary nanocrystalline hard-magnetic materials are produced by either rapid solidification or high-energy mechanical milling. In the case of rapid solidification, the molten alloy is ejected onto a chilled metal surface, usually a rotating copper wheel. Depending on a quenching rate (which is usually controlled by the wheel speed) the method produces fine nanocrystalline, partially amorphous, or fully amorphous structures. Subsequent annealing may also be needed to form grains of the desired size. Melt spinning, which is the most widely used method of rapid solidification, is capable of producing both laboratory-scale and industrial-scale quantities of materials in the form of flakes or ribbons. An intensive mechanical milling diminishes the size of crystallites *inside* the particles by introducing an increasing number of lattice defects and developing subgrains. The process eventually leads to a complete destruction of a long-range atomic order. The high-energy milling which starts from several components with different composition is called *mechanical alloying*. Similar to overquenched ribbons, the amorphous powders must be annealed. Both the rapid solidification and mechanical milling/alloying can lead to metastable compounds–sometimes having better magnetic properties than the stable ones.

Most of the as-prepared nanocrystalline hard-magnetic materials are quasi-isotropic (the melt-spun $SmCo_5$ is one of the few exceptions, Li *et al*., 2002): their grains have no preferred crystallographic orientations, so the easy magnetization directions (EMDs) are oriented randomly. In this case, even if every grain has a perfectly square hysteresis loop parallel to the EMD, the magnets, as a whole, are not expected to have a remanence higher than half the saturation magnetization. However, for very small crystallites the intergranular exchange interaction can be strong enough to 'pull' the magnetization of the adjacent crystallites together (Callen, Liu and Cullen, 1977). This 'remanence enhancement' phenomenon is often used in single-phase nanocrystalline magnets (Hadjipanayis and Gong, 1988).

If the magnet consists of two phases with different magnetic properties, the exchange interaction between the

nanograins forces them to change their magnetizations in accord. The 'exchange coupling' allows us to benefit from the high coercivity of the anisotropic compounds (like those listed in Table 1) and the high magnetization of magnetically soft materials (like pure iron) combining them in one nanocomposite magnet. The potential of this phenomenon, which had been observed for the first time in melt-spun Nd–Fe–B alloys (Coehoorn, DeMooij and DeWaard, 1989), was fully understood after one-dimensional modeling (Kryukov, Manakov, Sadkov and Sakhaev, 1989; Kneller and Hawig, 1991). According to Kneller and Hawig, for an effective coupling, the size of soft magnetic grains should be less than twice the domain wall width of the hard phase. Two-dimensional (Feutrill, McCormick and Street, 1994) and three-dimensional (Fukunaga and Inoue, 1992; Schrefl, Fischer, Fidler and Kronmüller, 1994) models were later developed. The latest description of the magnetic hardening mechanism in Pr–Fe–B nanocrystalline magnets was proposed by Goll, Seeger and Kronmuller (1998) and Kronmüller and Goll (2002b).

Skomski and Coey (1993) predicted giant energy product values for certain exchange-coupled nanostructures, for example, 120 MGOe in a multilayer composed of alternating 2.4-nm hard-magnetic $Sm_2Fe_{17}N_3$ layers and 9-nm $Fe_{65}Co_{35}$ layers. Since the highest theoretical $(BH)_{max}$ for a single-phase $Nd_2Fe_{14}B$ magnet is 64 MGOe, and this value is nearly achieved by now (∼85%) in sintered magnets, it is hardly surprising that the exchange-coupled nanocomposites are sometimes referred to as the *next generation permanent magnets*. It should be noted, however, that the giant values of $(BH)_{max}$ given earlier were derived under the assumption that the hard-magnetic phase in the nanocomposite is crystallographically oriented. Obtaining texture in the magnets produced by rapid solidification requires considerable efforts even in systems where it is possible.

Another distinct group of rare-earth nanocomposite magnets is that of precipitation-hardened R–Co–Cu–Fe–Zr magnets. In these alloys, the structure of nanoscale $Sm_2(Co,Fe)_{17}$ cells develop in the bulk state through an elaborate heat treatment. Unlike most of nanocrystalline materials, these 'bulk-hardened' magnets retain alignment of the EMD for their nanophases. Also, the coercivity of these magnets is believed to be controlled by pinning of domain walls, rather than by domain wall nucleation as suggested in equation (1).

In the following sections, we review specific nanocrystalline and nanocomposite magnets. The magnets are classified according to their component phases. Within this division, we discuss separately the different preparation methods.

2 RARE-EARTH–TRANSITION METAL–METALOID-BASED NANOCRYSTALLINE MAGNETS

2.1 R–Fe–B phase diagrams and crystallization of R–Fe–B alloys

The R–Fe–B phase diagrams have been intensively studied since 1970s (Chaban *et al*., 1979; Stadelmaier, Elmasry and Cheng, 1983; Stadelmaier, Elmasry, Liu and Cheng, 1984; Matsuura *et al*., 1985; Oesterreicher, 1985; Schneider, Henig, Petzow and Stadelmair, 1986; Grieb, Henig, Schneider and Petzow, 1989; Landgraf *et al*., 1991; Givord, Nozieres, Sanchez-Lazamares and Leccabue, 1992; Knoch, Reinsch and Petzow, 1994). From the phase constitution point of view, the R–Fe–B alloys for permanent magnets are categorized according to the R content: (i) alloys with low R content that contain the $R_2Fe_{14}B$ hard-magnetic phase and a soft magnetic phase: α-Fe or Fe_3B; (ii) near stoichiometric alloys that correspond to $R_2Fe_{14}B$ single phase ($R_{11.77}Fe_{82.23}B_6$ in at%); and (iii) high R content alloys that contain the $R_2Fe_{14}B$ phase and a R-rich phase.

At a slow cooling rate, a stoichiometric $Nd_2Fe_{14}B$ alloy solidifies according to the following sequence (Schneider, Henig, Petzow and Stadelmair, 1986):

$$\text{Liquid} \xrightarrow[\text{(liquidus point)}]{1280\,^\circ\text{C}} \text{Fe} \xrightarrow[\text{(peritectic reaction)}]{1180\,^\circ\text{C}} \text{Nd}_2\text{Fe}_{14}\text{B}$$

The $Nd_2Fe_{14}B$ crystals develop around the initially formed Fe nuclei and hinder diffusion between the primary Fe crystals and the rest of the Fe-depleted liquid matrix. In this way, the as-cast $Nd_2Fe_{14}B$ ingot consists of $Nd_2Fe_{14}B$ grains, α-Fe residual crystals, and an Nd-rich phase close to the $Fe_{30}Nd_{70}$ stoichiometry.

Branagan and McCallum (1995) gave a model CCT (continuous cooling transformation) diagram for the stoichiometric $Nd_2Fe_{14}B$ alloy system showing the phase transformation upon solidification at different cooling rates (i.e., by the melt-spinning process). A vertical section of the Nd–Fe–B phase diagram along the tie line between Fe and $Nd_2Fe_{14}B$ is presented in Figure 1.

Liao and Altounian (1989) showed that $(Nd_xFe_{1-x})_{100-y}B_y$ alloy systems present a glass-forming ability for Fe content less than 87.5 at%, while the thermal stability of these alloys increases with boron concentrations and is dependent on the Nd:Fe atomic ratio.

Rapidly solidified $Nd_2Fe_{14}B$ alloys may display different microstructure features depending on the thermal history of the melt before ejection. Large superheating of the melt (above 1723 K) can prevent the early precipitation of nuclei,

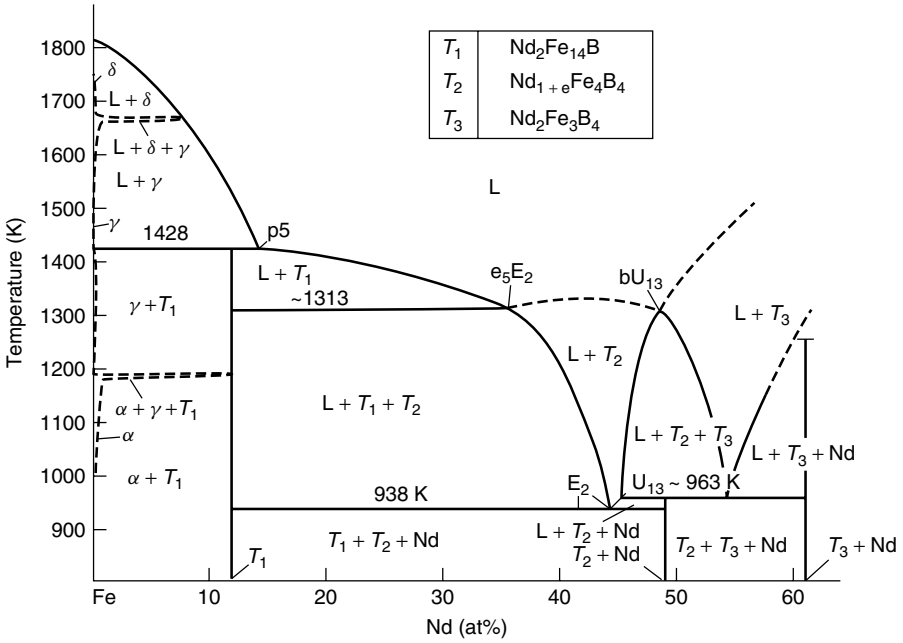

Figure 1. A vertical section of the Nd–Fe–B phase diagram along the tie line between Fe and $Nd_2Fe_{14}B$. (Reprinted with permission Branagan *et al*., copyright 1995, Elsevier.)

whereas a lower ejection temperature (1573 K) induces a nanocrystalline structure (Tang *et al*., 2003).

For each category of the R–Fe–B alloy systems, R lean, 2:14:1 stoichiometric, and R rich, the magnetic properties are different and strongly related to the grain size. For the first two categories, as the scale of the structure decreases to a certain level down to the nanometer range (but not below the critical superparamagnetic size), magnetizing-like interactions over short distances determine the enhancement of the remanence and the energy product while the coercivity may increase due to the increased density of grain boundaries.

2.2 Single-phase and R-rich nanocrystalline R–Fe–B alloys

The first studies on nanophase hard-magnetic systems were made on RFe_2 (R = Tb, Sm) alloys initially in a vitreous state, which upon crystallization develops a nanocrystalline structure with large coercivity at room temperature (Clark, 1973; Koon and Das, 1981). Hadjipanayis, Hazelton and Lawless (1983) and Croat, Herbst, Lee and Pinkerton (1984) obtained large coercivity on melt-spun Pr–Fe–B(Si) and Nd–Fe–B alloys, respectively. The large coercivity was due to the highly anisotropic $R_2Fe_{14}B$ tetragonal phase, which was produced in the nanoscale size during melt spinning or after crystallization. Coercivity of nanocrystalline $R_2Fe_{14}B$-based alloys is much larger than that of the corresponding bulk alloys, including sintered magnets. For example, melt-spun stoichiometric $Nd_2Fe_{14}B$ magnets can easily attain a coercivity of 1.15 MA m^{-1} (see Table 2) whereas the coercivity of Nd–Fe–B sintered magnets reaches only 960 kA m^{-1} (Sagawa *et al*., 1984). Table 2 summarizes the main intrinsic and extrinsic magnetic properties of $R_2Fe_{14}B$ nanocrystalline magnets. Large values of coercivity can also be obtained in the $R_2Fe_{14}C$ system, but their metallurgy is more complicated because of a phase transformation from $Nd_2Fe_{17}C_x$ to $Nd_2Fe_{14}C$ (Coehoorn, Duchateau and Demissen, 1989).

Besides melt spinning, other rapid solidification techniques like vapor deposition (Sellmyer, 1992; Fullerton *et al*., 1998), atomization (Narasimhan, Willman and Dulis, 1986), mechanical alloying (Schultz, 1990), and liquid dynamic compaction (Harada, Ando, O'Handley and Grant, 1990) have been employed for the fabrication of $R_2Fe_{14}B$ nanocrystalline magnets. By using the rapid solidification route, the nanocrystalline structure can be obtained either *in situ* by varying the cooling rate during solidification or by crystallizing the amorphous products. When using mechanical alloying, a subsequent annealing is always required to crystallize the amorphous or partially amorphous structure.

2.2.1 $R_2Fe_{14}B$ nanocrystalline ribbons obtained directly by quenching

The microstructure of the ribbons prepared by melt spinning is dependent on the quench rate (which in turn is determined by the speed of the spinning wheel). For a given composition

Table 2. Magnetic properties of $R_2Fe_{14}B$ nanocrystalline magnets.

Magnet	$\mu_0 M_s$ (T)	H_A (MA m^{-1})	T_C (°C)	H_c (MA m^{-1})	References
$Nd_2Fe_{14}B$	1.6	5.34	315	1.19	Croat, Herbst, Lee and Pinkerton (1984)

and temperature of a melt, the best combination of magnetic hysteresis parameters can be obtained in a narrow range of the wheel speed (e.g., in the case of Nd–Fe–B alloys, the optimum wheel speed is 20–21 m s^{-1}, (Pinkerton, 1987), while the Nd–Fe–B ribbons quenched at 32 m s^{-1} are entirely amorphous (Mishra, 1986)). The best magnetic properties (coercive fields) in isotropic specimens were obtained for an optimum structure of the ribbons consisting of small polyhedral $Nd_2Fe_{14}B$ crystallites surrounded by a thin (2–3 nm) shell of a paramagnetic Nd-rich phase (Croat, Herbst, Lee and Pinkerton, 1984). Though the typical average grain size d is of the order of the single domain size d_{sd}, which was reported to vary from 150 nm (Mishra, 1986) to 300 nm (Livingston, 1985), it is not necessary to have $d < d_{sd}$ (Grönefeld and Kronmüller, 1990). On the other hand, the magnetic insulation provided by the grain-boundary phase is always favorable for the high coercivities.

Remanence of a magnet consisting of randomly oriented noninteracting uniaxial grains is limited by $J_r = J_s/2$. For the single-phase $Nd_2Fe_{14}B$ ribbons with $d \leq 26$ nm the remanence may exceed $J_s/2$ because of exchange coupling between the 2:14:1 nanocrystallites (Clemente, Keem and Bradley, 1988). The absence of the Nd-rich grain-boundary phase is the other necessary condition of the remanence enhancement phenomenon. The higher remanence leads to the higher maximum energy product: $Nd_2Fe_{14}B$ ribbons with $(BH)_{max} = 150$ kJ m^{-3}, $H_c = 960$ kA m^{-1} (Clemente, Keem and Bradley, 1988) and $(BH)_{max} = 170$ kJ m^{-3}, $H_c = 800$ kA m^{-1} (Bauer, Seeger, Zern and Kronmuller, 1996) were reported. Values of J_r up to 1.42 T and $(BH)_{max} = 180.7$ kJ m^{-3} were reported in Pr–Fe–B composite ribbons with Fe-rich composition (Goll, Seeger and Kronmuller, 1998).

Since anisotropic magnets present higher values of the energy product because of the high remanence, efforts have been made to prepare anisotropic $R_2Fe_{14}B$ ribbons via the directional solidification process (melt spinning at low wheel speed) and directional solidification combined with hot deformation (twin-roller melt spinning) that leads to the formation of columnar or dendritic structures, respectively (Dadon, Gefen and Daniel, 1987; Coehoorn and Duchateau, 1988; Chin, Huang and Yau, 1992, 1993). Anisotropic Nd–Fe–B nanocrystalline alloys were produced also by splat quenching (Harada, Ando, O'Handley and Grant, 1991). Coarse columnar structures in ribbons melt spun at low wheel speed led to a low coercivity, which undermined benefits of the obtained texture. Splats with columnar dendritic structures showed sufficiently high coercivity but only modest magnetic anisotropy.

2.2.2 *$R_2Fe_{14}B$ nanocrystalline ribbons obtained by annealing of amorphous precursors*

Calorimetric studies indicate that crystallization of amorphous $Nd_2Fe_{14}B$ alloys starts at about 580 °C with some variation when other additive elements are included (Figure 2). The optimum annealing temperature for the overquenched Nd–Fe–B and PR–Fe–B ribbons, however, is much higher, 700–800 °C. The higher annealing temperature leads to the formation of an optimum microstructure for magnetic hardening; particularly it eliminates α-Fe, which is usually the first product of crystallization. Nevertheless, unless the alloy contains a significant excess of R, a small amount of the soft

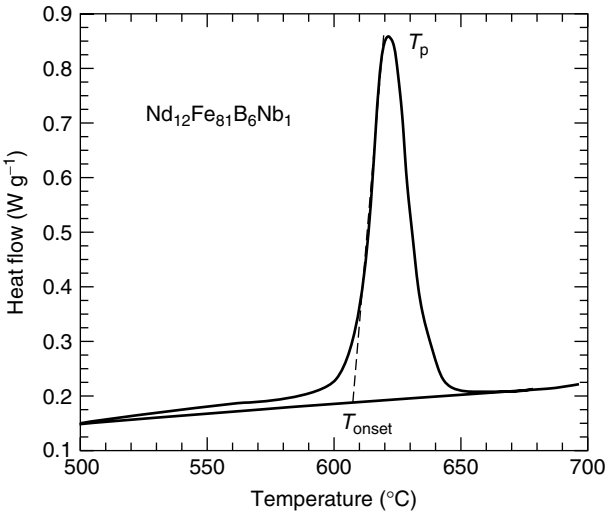

Figure 2. Calorimetric study of crystallization in amorphous $Nd_{12}Fe_{81}B_6Nb_1$ melt-spun alloy (Hadjipanayis, 1999).

magnetic phase always remains. Because of this, the magnetic properties of overquenched and subsequently annealed R–Fe–B ribbons are generally lower than those of directly quenched ribbons (Manaf, Leonowicz, Davies and Buckley, 1991). The kinetics of devitrification of overquenched $Nd_{13.5}Fe_{81.7}B_{4.8}$ and $Nd_{13.9}Fe_{78.3}B_{7.8}$ alloys has been studied by Jha, Davies and Buckley (1989). The glass-forming ability can be enhanced by the addition of TiC: the optimum wheel speed for $(Nd_{2.17}Fe_{14.17}B_{1.17})_{100-x}(TiC)_x$ was reduced as compared to the TiC-free composition (Branagan and McCallum, 1995; Branagan, Hyde, Sellers and McCallum, 1996).

The crystallization of the amorphous phase into the tetragonal $R_2Fe_{14}B$ phase and the magnetic hysteresis have been also examined in melt-spun alloys by Tao and Hadjipanayis (1984). The crystallization temperatures were found to be much higher (~650 °C) for Fe–Y–B and the heavy rare-earth alloys than in the light rare-earth Fe–R–M up to Gd (~560 °C). The crystallized samples have coercivities up to 480 kA m^{-1}. The tetragonal $La_2Fe_{14}B$ phase was found to be formed both in as-cast and crystallized melt-spun La–Fe–B alloys. This phase, however, is not stable and transforms into α-Fe and La–B upon annealing at higher temperatures (Hadjipanayis, Tao and Gudimetta, 1985).

2.2.3 *$R_2Fe_{14}B$ nanocrystalline powders*

Nanocrystalline single-phase isotropic powders can be prepared by high-energy ball milling of either single precursor alloys or several precursors with different compositions. The latter technique known as *mechanical alloying* involves a solid-state reaction between the elemental powder components, leading to the formation of composite particles with a layered morphology. In accordance with the mechanical characteristics of the starting powders and the thermodynamics of the alloy system, the reaction corresponding to the formation of 2:14:1 compound can take place during the milling or during the subsequent heat treatment (Wecker *et al*., 1994; Gong, Hadjipanayis and Krause, 1994; Chen *et al*., 1995). Coercivity values as high as $H_c = 840$ kA m^{-1} were obtained for $Nd_{15}Fe_{77}B_8$ powders (Chen *et al*., 1995). The optimum grain size of the $Nd_2Fe_{14}B$ phase was found to be about 50 nm.

Intensive milling of off-stoichiometric PR–Fe–B alloys with Dy and Zr additions lead to coercivity values as high as $H_c = 2.12$ MA m^{-1} in $Pr_{15}Dy_1Fe_{75.9}B_8Zr_{0.1}$ powders, whereas the reduction of R content and the presence of Co lead to excellent properties, $\mu_0 M_r = 0.92$ T, $H_c = 1$ MA m^{-1}, and $(BH)_{max} = 140$ kJ m^{-3}, supposedly originating from a microstructure with a mean grain size of 20 nm (Bollero *et al*., 2002).

2.3 Exchange-coupled nanocomposite R–TM–M alloys

2.3.1 *Nanocomposite α-Fe/$R_2Fe_{14}B$ alloys obtained by direct quenching*

In the early 1990s, Davies *et al*. (1992) showed that when decreasing the Nd content below 11 at% in nanocomposite $Nd_xFe_{94-x}B_6$ alloys, the α-Fe phase precipitates in an increasing amount up to 35 vol% for $x = 8$ at%. Owing to the high saturation magnetization of α-Fe and exchange coupling between the α-Fe and $N_2Fe_{14}B$ grains, this resulted in an additional enhancement of remanence, though H_c was gradually lowered. Manaf, Buckley and Davies (1993) and Manaf *et al*. 1993 reported a remanence larger than 1 T, a coercivity of 485 MA m^{-1} and $(BH)_{max} > 160$ kJ m^{-3} for the Nd-lean alloys with 8–10 at% Nd. The alloys consisted of a magnetically hard $Nd_2Fe_{14}B$ phase with an average grain size of less than 30 nm and α-Fe phase grains with an average particle grain size of less than 10 nm.

A systematic study of the two-phase α-Fe/$Nd_2Fe_{14}B$ magnets by Bauer, Seeger, Zern and Kronmuller (1996) showed that the remanence increases up to $\mu_0 M_r = 1.25$ T with increasing the content of α-Fe phase to approximately 30 vol%. This remanence value represents an enhancement of 56% as compared to that of the $Nd_2Fe_{14}B$ exchange-decoupled magnet without Fe. However, because the squareness of the hysteresis loop deteriorates with increasing α-Fe content, $(BH)_{max}$ is nearly constant for α-Fe amounts between 0 and 30 vol%, with only a weak maximum (186.4 kJ m^{-3}) at 30 vol%. In melt-spun α-Fe/$Pr_2Fe_{14}B$ magnets, Goll, Seeger and Kronmuller, (1998) obtained a pronounced maximum of $(BH)_{max}$ equal to 180.7 kJ m^{-3} for about 30 vol% of α-Fe phase. For α-Fe amounts exceeding this value, the coercivity of the magnet falls below $J_r/2$ and the $(BH)_{max}$ values start decreasing (Mendoza-Suarez, Davies and Escalante-Garcia, 2000).

The variation of the magnetic properties with the wheel speed of $Pr_xFe_{94-x}B_6$ nanocomposite ribbons with $6 \leq x \leq 10$ was studied by Mendoza-Suarez *et al*. (1999). The largest remanence enhancement was associated with the wheel speed that led to a grain size of ~30 nm for the 2:14:1 phase and of ~20 nm for the α-Fe phase. Values of the energy product as high as $(BH)_{max} = 170$ kJ m^{-3} were obtained for $x = 9$, 10 at%.

A *c*-axis orientation of the 2:14:1 phase has been observed by Jin *et al*. (2002b) (Figure 3) in the free surface of $(Pr,Tb)_2(Fe,Nb,Zr)_{14}B/\alpha$-Fe exchange-coupled nanocomposite ribbons spun at speeds below 10 m s^{-1}.

A crystallographic texture with the *c* axis perpendicular to the plane of the specimens in $Nd_{3.6}Pr_{5.4}Fe_{83}Co_3B_5$ ribbons prepared at a low wheel speed (10 m s^{-1}) has also been

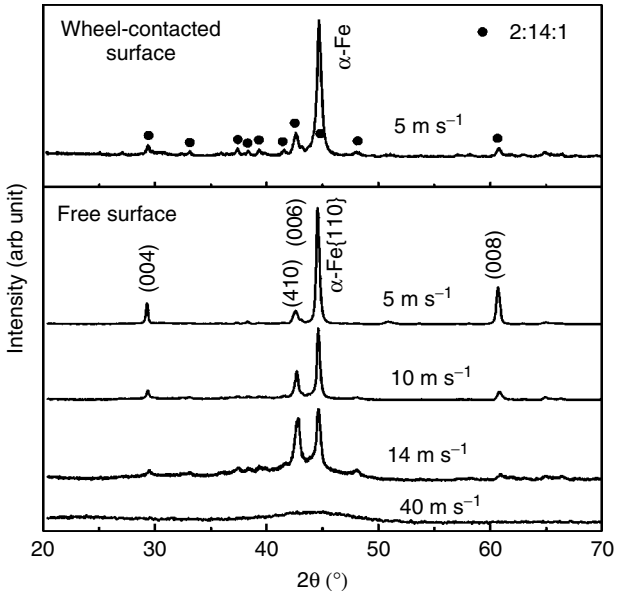

Figure 3. X-ray diffraction patterns of as-spun $Pr_7Tb_1Fe_{87}Nb_{0.5}Zr_{0.5}B_4$ ribbons indicating a trend for a *c*-axis texture of 2:14:1 phase perpendicular to the ribbon plane. (Reprinted with permission Z. Jin *et al*., copyright 2002, Elsevier.)

reported by Zhang, Guan, Yang and Zhang (2001). The orientation of the *c* axis switches to the ribbon plane for a higher wheel speed ($20\,m\,s^{-1}$) in which case, a high remanence of 0.74 M_s and a larger energy product $(BH)_{max} = 194\,kJ\,m^{-3}$ have been obtained.

2.3.2 *Nanocomposite α-Fe/$R_2Fe_{14}B$ alloys obtained by recrystallization*

In the α-Fe/$R_2Fe_{14}B$ two-phase magnets, the small size of the grains, especially those of the α-Fe phase, is essential for the intergranular exchange coupling. To avoid the overgrowth of α-Fe soft crystalline phase during annealing, high rates of heating and cooling, as well as a short isothermal stage are required. The whole annealing procedure usually lasts for only a few minutes, often seconds. This may, in particular, complicate reproducing the experimental results reported by different groups.

Most of the researchers agree that crystallization of amorphous R-lean R–Fe–B alloys occurs in several states. Among the observed metastable intermediate phases were: $R_2Fe_{23}B_3$, $RFe_{11}B_6$, and $R_3Fe_{62}B_{14}$ (Buschow, Demooij and Coehoorn, 1988); $R_3Fe_{81}B_{16}$ and $R_6Fe_{77}B_{17}$ (Gu *et al*., 1989; Gu, Shen and Zhai, 1990, 1994); R_2Fe_{17} (Linetsky, Raigorodsky and Tsvetkov, 1992); and RFe_7 (Withanawasam *et al*., 1995; Gabay *et al*., 1996).

The typical fully amorphous $Pr_8Fe_{86}B_6$ ribbons present a multistage microstructural evolution upon crystallization. From the amorphous matrix, the metastable $TbCu_7$-type phase precipitates initially and then it transforms into the metastable $Pr_2Fe_{23}B_3$ prior to the formation of $Pr_2Fe_{14}B$ and α-Fe phases (Jin *et al*., 2002a). It has been found that a more homogeneous and finer microstructure is obtained if the as-spun precursors were partially amorphous. The typical dependence of coercivity of as-spun and annealed R–Fe–B ribbons on the wheel speed is presented in Figure 4. The annealing is effective above a certain wheel speed.

Wang *et al*. (2000) studied the effect of the quenching rate during the ribbon formation, on the phase transformation and magnetic properties of $Pr_8Fe_{86}B_6$ ribbons subsequently annealed. It has been shown that the magnetic properties of the ribbons deteriorate with increasing the quenching rate followed by annealing. The directly spun ribbons present a remanence of 1.2 T and a coercivity of about $432\,kA\,m^{-1}$, whereas ribbons spun at 22 and $30\,m\,s^{-1}$ and optimally annealed show remanence values of 1.08 and 0.88 T and coercivity values of about 408 and $280\,kA\,m^{-1}$, respectively. The decrease of the magnetic hysteresis properties was attributed to the formation of coarser and more irregular microstructure.

A comprehensive study on the effect of various substitutions M (M = Cr, Nb, Ti, and Zr) for Fe, on the magnetic and structural properties of $Pr_8Fe_{84}M_2B_6$ melt-spun nanocomposites, has been done by Chen, Okumura, Hadjipanayis and Chen (2001). All these substitutions were found to make the microstructure finer and to improve the magnetic properties. The largest enhancement was obtained in Nb-substituted $Pr_8Fe_{84}Nb_2B_6$ magnets showing

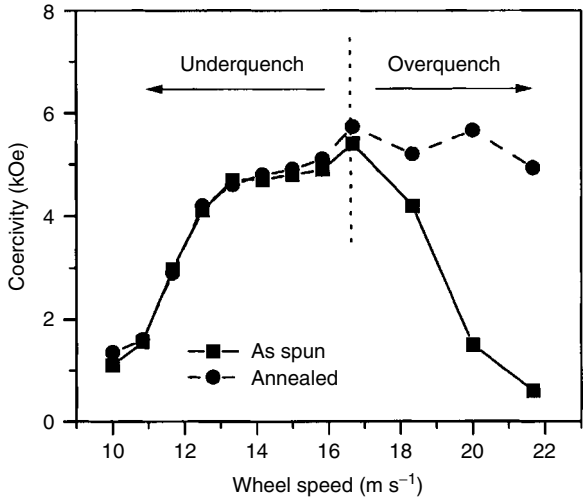

Figure 4. Coercivity of $Pr_8Fe_{86}B_6$ as a function of the wheel speed (Chen *et al*., 1999). The annealing was performed at 800 °C for 0.5–1.5 min. (Reprinted with permission Chen *et al*., copyright 1999, American Institute of Physics.)

$H_c = 518.7\,kA\,m^{-1}$, $(BH)_{max} = 143.2\,kJ\,m^{-3}$, with a grain size in the range of 10–20 nm.

Addition of Nb and Zr to $Pr_7Tb_1Fe_{88}B_4$ nanocomposite ribbons was reported (Jin *et al*., 2002b) to suppress the grain growth resulting in a large improvement of the magnetic properties with ~50% enhancement of the coercivity and a considerable increase of $(BH)_{max}$ from $441\,kA\,m^{-1}$ and $117\,kJ\,m^{-3}$ to $646\,kA\,m^{-1}$ and $162\,kJ\,m^{-3}$, respectively.

The effect of Al, Ti, or Hf additions on the magnetic properties of $Pr_{8.5}(Fe_{0.9}Co_{0.1})_{84.5}M_1B_6$ ribbons was reported by Wang and Davies (2003). In particular, the addition of Al slightly increases the coercivity whereas Ti or Hf increases the coercivity and energy product as a result of enhanced exchange coupling induced by the finer microstructure.

In contrast to the single-phase $Pr_{12}(Fe_{100-x}Co_x)_{82}B_6$ (with $x \leq 20$) nanocrystalline ribbons, which present good hard-magnetic properties ($(BH)_{max} = 220\,kJ\,m^{-3}$) by overquenching followed by annealing without any addition of grain growth inhibitor element, the two-phase Pr-lean ribbons have been found to benefit greatly with the addition of 1 at% Zr. This addition to the $Pr_{10}Fe_{84}B_6$ alloy resulted in an improved loop shape and H_c up to $550\,kA\,m^{-1}$ while $(BH)_{max}$ was increased to $140\,kJ\,m^{-3}$ compared with $80–110\,kJ\,m^{-3}$ for Zr-free ribbons (Harland and Davies, 2000).

Ga substitution for Fe was found to refine the microstructure of the $Pr_9Fe_{74}Co_{12}GaB_5$ ribbons and lead to an improvement of the magnetic properties from $J_r = 1.14\,T$ and $(BH)_{max} = 136\,kJ\,m^{-3}$ in Ga-free samples and $J_r = 1.22\,T$ to $(BH)_{max} = 177.6\,kJ\,m^{-3}$ in Ga-added samples (Zhang, Chang, Chiu and Chang, 2004). Overstoichiometric Nd–Fe–Ga–Nb–B melt-spun ribbons were studied by Bauer, Seeger and Kronmuller (1995) who reported that the coercivity is not significantly changed in samples with grain size within the range of 10 nm–1 μm.

The partitioning behavior of Co within the component phases and the Curie temperature of $Pr_2Fe_{14}B$/α-Fe nanocomposite ribbons with the nominal compositions $Pr_{9.7}Fe_{76.6}Co_{7.8}B_{5.9}$ and $Pr_{9.2}Fe_{69.4}Co_{15.4}B_{6.0}$ have been studied by Zhang *et al*. (2001a) using three-dimensional atom probe and transmission electron microscopy (TEM). It has been found that Co is dissolved uniformly, with no difference in concentration between the two component phases. For the nanocomposite samples, the Curie temperature was found to increase more rapidly with increasing overall Co content than for single-phase alloys as the Co/(Co + Fe) ratio in the 2:14:1 phase, when part of the nanocomposite system, is higher than the overall ratio.

Table 3 lists some of the best $R_2Fe_{14}B$/α-Fe nanocomposite magnets with $(BH)_{max} > 160\,kJ\,m^{-3}$.

Nanocomposite materials were also prepared in Pr–Co–Nb–B systems (Withanawasam, Panagiotopoulos and Hadjipanayis, 1996). The final microstructure consisting of a mixture of $Pr_2Co_{14}B$ and Co is formed after annealing the melt-spun ribbons through an intermediate transformation to the metastable $TbCu_7$-type structure.

2.3.3 Nanocomposite α-Fe/$R_2Fe_{14}B$ powders

Another versatile technique to produce $R_2Fe_{14}B$/α-Fe nanocomposite magnets is intensive milling of R-lean alloys or stochiometric alloys blended with different fractions of α-Fe. A 25 wt% Fe addition gave the optimum combination of the hysteresis magnetic parameters: $J_r = 1.19\,T$, $H_c = 528\,kA\,m^{-1}$, and $(BH)_{max} = 178\,kJ\,m^{-3}$ (Bollero *et al*., 2002).

Mechanically milled $Nd_{8-x}Sm_xFe_{88}B_4$ ($x = 0–2.5$) alloys have been studied by Zhang *et al*. (2004). The optimum magnetic properties of the powder milled for 5 h were achieved after annealing at 630 °C for 20 min. The reduced remanence was found to increase from 0.680 to 0.806 with increasing Sm content. Gong, Hadjipanayis and Krause (1994) obtained a remanence enhancement ($M_r/M_s = 0.60–0.68$) for R–Fe–Nb–B mechanically alloyed samples, with 5–15 at% R (R = Nd, Tb).

Neu *et al*. (1996) analyzed the influence of different additions to α-Fe/$Nd_2Fe_{14}B$ powders starting with the $Nd_8Fe_{88}B_4$ based composition. For Zr and Si addition, $\mu_0 M_r$ of approximately 1.1 T and $H_c = 320–344\,kA\,m^{-1}$ were obtained. Comparison of the magnetic properties of magnets produced by mechanical alloying of elemental powders and

Table 3. Magnetic properties of the best $R_2Fe_{14}B$/α-Fe nanocomposite magnets (ribbons).

Composition	Process route	Grain size	$\mu_0 M_r$(T)	H_c(kA m^{-1})	$(BH)_{max}$(kJ m^{-3})	References
$Pr_{8.5}(Fe_{0.8}Co_{0.2})_{86}Cu_{0.5}B_5$	Annealed	15–20 nm	10.9	583	160	Wang *et al*. (2000)

by intensive milling of precursor alloys (Neu and Schultz, 2001) showed that the latter technique is in some ways superior. The $Nd_9Fe_{77}Co_{8.5}Si_1B_{4.5}$ milled and annealed magnet had $H_c = 480\,kA\,m^{-1}$, $J_r = 1.11\,T$, and $(BH)_{max} = 147\,kJ\,m^{-3}$, if made from the precursor alloy, as compared to $H_c = 464\,kA\,m^{-1}$, $J_r = 1.07\,T$, and $(BH)_{max} = 139\,kJ\,m^{-3}$, if made from the elemental powders.

2.3.4 *Nanocomposite $Fe_3B/R_2Fe_{14}B$ alloys*

Coehoorn, DeMooij and DeWaard (1989) reported for the first time $Nd_4Fe_{78}B_{18}$ nanocomposite magnets, containing Fe_3B as the main phase and $Nd_2Fe_{14}B$ as a secondary phase, prepared by crystallization of melt-spun amorphous precursor. Because of the high boron content, an amorphous alloy is easily formed in the $Nd_2Fe_{14}B/Fe_3B$ system during melt spinning even under a relatively low wheel speed. Shen *et al*. (1994a) analyzed the thermal stability of $Nd_y(Fe_{1-x}B_x)_{100-y}$ alloys and found a very strong rise of crystallization temperature with x. In other words, boron remarkably increases the thermal stability of amorphous Nd–Fe–B alloys.

The addition of Hf and Ga in $Nd_4Fe_{76}Co_3(Hf_{1-x}Ga_x)B_{16}$ ($x = 0$, 0.5, and 1) melt-spun ribbons was found to improve the magnetic properties via improving the shape of grains. The values of remanence and coercivity of some $Fe_3B/R_2Fe_{14}B$ optimally heat-treated ribbons with various additions (Fe, Al, Si, Cu, Ga, Ag, and Au) are reported by Kanekiyo, Uehara and Hirosawa (1993), and presented in Figure 5.

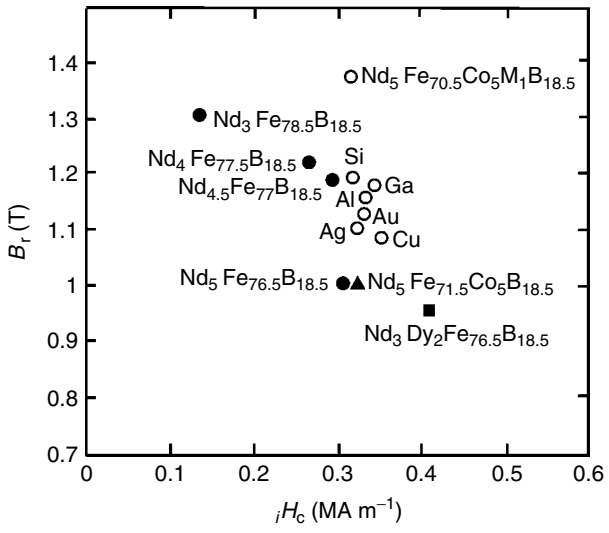

Figure 5. Remanence and coercivity of $Fe_3B/R_2Fe_{14}B$ optimally heat-treated ribbons with additions M = Fe, Al, Si, Cu, Ga, Ag, and Au (Kanekiyo, Uehara and Hirosawa, 1993).

Systematic studies on the effects of different alloying additions on Nd–Fe–B alloy with 3–5 at% Nd and 18.5 at% B have been also presented in reports of Hirosawa, Kanekiyo and Uehara (1993), Kanekiyo, Uehara and Hirosawa (1994), and Hirosawa and Kanekiyo (1996). It was found that combined additions of Co and Ga are particularly effective for improving the remanence, coercivity, and energy product. On the basis of TEM observations, it was concluded that these improvements result from a smaller grain size after the crystallization reaction. Ping, Hono and Hirosawa (1998) studied the distribution of Co and Ga atoms in $Nd_{4.5}Fe_{73}B_{18.5}Co_3Ga_1$ at various stages of crystallization. In the early stage of crystallization, Co and Ga atoms are rejected from the primary particles of the soft magnetic Fe_3B phase and are partitioned to the amorphous matrix phase. In the fully crystallized $Fe_3B/Nd_2Fe_{14}B$ nanocomposites, Co and Ga atoms are partitioned into the $Nd_2Fe_{14}B$ phase. Evidence for a slight enrichment of Ga atoms at the $Nd_2Fe_{14}B/Fe_3B$ interface has been found.

Gao, Zhu, Yang and Park (1998) found that the additions of Hf and Ga slowdown the crystallization rate in the $Nd_4Fe_{76}Co_3Hf_{0.5}Ga_{0.5}B_{16}$ amorphous alloy compared to the $Nd_4Fe_{80}B_{16}$ alloy. The optimum magnetic properties reported on annealed ribbons were $(BH)_{max} = 122.4$ and $116.8\,kJ\,m^{-3}$, respectively, while the remanence ratio M_r/M_s exceeded 0.8.

The coercivity of the nanocomposite magnets consisting of magnetically soft and magnetically hard phases is usually adjusted by varying the amount of the latter. However, in the $Fe_3B/Nd_2Fe_{14}B$ system, the room for adjustment is very small: when the Nd content exceeds 4.5 at%, the intermediate $Nd_2Fe_{23}B_3$ phase appears upon heating and it transforms into α-Fe and $Nd_1Fe_4B_4$, which are all magnetically soft. The addition of Cr extends the range for the formation of the magnetically hard $Nd_2Fe_{l4}B$ phase. Uehara *et al*. (1998) showed that in $Nd_5Fe_{77}B_{l8}$, the $Nd_2Fe_{23}B_3$ phase crystallizes along with Fe_3B from the amorphous phase and at the higher temperatures it decomposes into a mixture of α-Fe and $Nd_1Fe_4B_4$, whereas in $Nd_5Fe_{74}Cr_3B_{18}$, the $Nd_2Fe_{23}B_3$ phase breaks up into $Nd_2Fe_{l4}B$, Fe_3B, and α-Fe. According to Zhang, Matsushita and Inoue (2001), the optimum values of the magnetic properties obtained in the annealed $Nd_3Dy_{0.5}Fe_{67}Co_{9.5}B_{20}$ ribbons correspond to the four-phase structure of $Nd_2Fe_{14}B$, Fe_3B, α-Fe, and a residual amorphous phase ferromagnetic at room temperature.

An external magnetic field, applied during the annealing of melt-spun $Nd_4Fe_{73.5}Co_3Hf_{1-x}Ga_xB_{18.5}$ alloys, induced a grain refinement of about 20% and led to an increase of remanence and energy product by 30% (Yang and Park, 1995). The alloy having $x = 0.5$ exhibited $J_r = 1.25\,T$, $H_c = 225\,kA\,m^{-1}$, and $(BH)_{max} = 126.4\,kJ\,m^{-3}$. A similar effect of the magnetic field annealing was reported by Gao *et al*.

(1999) for $Nd_4Fe_{76}Co_3$ $(Hf_{1-x}Ga_x)B_{16}$ ($x = 0$, 0.5, and 1) melt-spun ribbons.

Besides the above traditional view on the $Fe_3B/R_2Fe_{14}B$ magnets, unconventional opinion exists (Li *et al*., 2004), that the hard-magnetic properties observed in these alloys may be induced in the Fe_3B phase not by the exchange interaction with the $Nd_2Fe_{14}B$ phase but rather by the partial substitution of Nd for Fe in the Fe_3B structure.

Another group of Nd–Fe–B-based nanocomposites combines the features of $Fe_3B/R_2Fe_{14}B$ and α-Fe/$R_2Fe_{14}B$. In the alloys containing approximately 9 at% Nd and 8–12 at% B, the magnetically soft metastable $Pr_2Fe_{23}B_3$ phase transforms into $Pr_2Fe_{14}B$, α-Fe, and Fe_3B by annealing at temperatures higher than 750 °C (Chen *et al*., 2003b). The phase evolution and magnetic properties of such Fe_3B/α-Fe/$R_2Fe_{14}B$ nanocomposite magnets were studied by Chang *et al*. (2002) for the $(Nd_{0.7}Pr_{0.25}La_{0.05})_xFe_{bal}Co_{10}Ti_2B_y$ alloys with $x = 4.5$–10.7 and $y = 10.9$–18.6. The best magnetic properties were obtained in the $(x, y) = (10.7, 10.9)$ alloy with $J_r = 0.8$ T, $H_c = 1.41\,MA\,m^{-1}$, and $(BH)_{max} = 104.8\,kJ\,m^{-3}$. An intrinsic coercivity $H_c > 800\,kA\,m^{-1}$, and $(BH)_{max} > 128\,kJ\,m^{-3}$ were developed in melt-spun ribbons with compositions of $(Nd_{0.95}La_{0.05})_{11}Fe_{bal}Co_{10}M_2B_{10-10.5}$ with M = Cr, V, Mo, Ti (Chang *et al*., 1999; Chang, Wang, Chang and Chen, 2000).

2.3.5 *Nanocomposite Nd–Fe carbides*

Alloys based on $R_2Fe_{14}C$ compound were also reported as a promising group of permanent magnet materials (Hellwig *et al*., 1991).

Nanocomposite Nd–Fe carbide ribbons

A study of the effect of C substitution for B on the magnetic and structural properties in nanocomposite $Nd_{10}Fe_{82}B_{8-x}C_x$ ($x = 0$, 2, 4, 5, 6, 7) ribbons in correlation with their crystallization behavior have been presented by Daniil, Okumura, Hadjipanayis and Sellmyer (2003). For $x \leq 4$, the crystallization of Nd_2Fe_{14}(B,C) and α-Fe occurs in one single stage. For $x > 4$, two structural transitions take place; the final stable structure consisting of Nd_2Fe_{14}(B,C) and α-Fe is formed from the intermediate $Nd_2Fe_{17}C_x$ and α-Fe structures. The coercivity has a maximum of $696\,kA\,m^{-1}$ for $x = 2$. With decreasing x, the formation of 2:14:1 phase is accelerated. From qualitative evaluation of X-ray diffraction (XRD) patterns it was derived that Nb and Zr additions reduce the amount of α-Fe significantly in as-spun and annealed $Nd_{10}Fe_{82}C_6B_2$ ribbons (Daniil *et al*., 2002).

Quenching of $Nd_{11}Fe_{72}Co_8(B_{0.8}C_{0.5})_9$ alloys at the optimum wheel speed allowed $(BH)_{max} = 140.5\,kJ\,m^{-3}$ (Yamamoto and Yamaguchi, 1991). Zhang, Chang, Chiu and Chang (2004) reported that ribbons with the stoichiometry $Pr_{11-x}DyFe_{72+x}Co_{10}C_4B_2$ ($x = 0$–3) consist of 2:14:1, α-Fe, 2:17 phases and a small amount of paramagnetic rare-earth 1:2 carbide. The highest values of the magnetic hysteresis parameters were obtained in $Pr_{10}DyFe_{73}Co_{10}C_4B_2$ ($B_r = 0.94$ T, $H_c = 861\,kA\,m^{-1}$).

Nanocomposite Nd–Fe carbide powders

The phase transformation and magnetic properties of mechanically alloyed $Nd_{16}Fe_{77-x}C_x$ ($x = 7$–11) and $Nd_{16}Fe_{84-x}C_{x-y}$ ($y = 0$–x and $x = 7$, 8, 9) alloys, were studied by Sui *et al*. (1996). More carbon than the stoichiometric content for $Nd_2Fe_{14}C$ was necessary to stabilize the tetragonal 2:14:1 structure. Substitution of boron for carbon can accelerate the phase transformation from $Nd_2Fe_{17}C_x$ to Nd_2Fe_{14}(C, B) and lead to an improvement of the magnetic properties. The Nd-rich phase with an fcc structure was reported to coexist with $Nd_2Fe_{14}C$ in mechanically alloyed Nd–Fe–C samples (Sui *et al*., 1996), but it was not found in melt-spun samples. The best properties were achieved in the $Nd_{16}Fe_{76}B_5C_3$ mechanically alloyed powders with $B_r = 0.71$ T, $H_c = 1.48\,MA\,m^{-1}$, and $(BH)_{max} = 91.5\,kJ\,m^{-3}$.

2.4 Bulk nanocrystalline magnets

As discussed earlier, the nanocrystalline R–Fe–B magnets are typically produced in the form of thin ribbons or fine powders. There are two exceptions to this observation: (i) the $R_xFe_{80-x-y}Co_yB_{20}$ alloys (R = Nd, Pr, Dy; $x = 3.5$–4.5; y = 10–13.5; in some reports with a small addition of Zr), which because of their remarkable glass-forming ability, can be cast into tubes or rods with 0.5–1 mm in diameter in amorphous state followed by crystallization annealing (Zhang and Inoue, 2002; Pawlik and Davies, 2003; Marinescu, Pawlik, Davies and Chiriac, 2004) and (ii) bulk nanocrystalline R–Fe–B alloys formed by room-temperature severe plastic deformation under pressure and subsequent annealing, with H_c up to $1.52\,MA\,m^{-1}$ (Popov, Gynderov and Stolyarov, 1996). As for the melt-spun R–Fe–B ribbons and intensively milled R–Fe–B powders, for most of the applications they must be consolidated before use. The most common technique is the binding of the hard-magnetic powder with a polymer or metal (usually Zn or Al). Though the nonmagnetic binder inevitably dilutes the magnetization, the bonded magnets with intermediate $(BH)_{max}$ of 80–144 $kJ\,m^{-3}$ are relatively inexpensive and can be formed into intricate net shapes (Brown, Ma and Chen, 2002). Fully dense nanocrystalline R–Fe–B magnets are commercially produced by compacting the R-rich melt-spun ribbons (≥13.5 at% R) at 700–750 °C

(Lee, 1985). Alternatively, a shock compaction can consolidate the amorphous or nanocrystalline R–Fe–B precursors without any microstructural changes (Leonowicz *et al*., 1998; Saito, 2001). Both the hot- and shock-compacted nanocrystalline magnets are isotropic.

Hot plastic deformation of R–Fe–B magnets aligns the EMDs of the 2:14:1 grains parallel to the applied pressure. This remarkable transformation can be observed in different kinds of R–Fe–B materials–cast, sintered, and so on. In the case of nanocrystalline magnets, it was first reported for hot-pressed melt-spun alloys (Lee, 1985) and later for mechanically alloyed powders (Wecker *et al*., 1994). The hot plastic deformation is usually done by either extrusion or upsetting the magnets in a loose die. The latter method is often referred to as *die upsetting*. In one of the versions of the die-upsetting technique (Yang *et al*., 1997), the hot compaction and hot deformation were performed in a single step. In the typical die-upset R–Fe–B magnets (Wecker *et al*., 1994; Leonowicz *et al*., 1994), the 2:14:1 grains are platelet shaped with a height of 50–100 nm and a diameter of 100–300 nm and the R-rich phase can be found in the form of thin grain-boundary layers. The hot-compacted specimens are isotropic while the hot-deformed ones are anisotropic due to the developed texture (Figures 6 and 7). In the model by Li and Graham (1992), the R-rich phase, which is liquid at the temperature of deformation, provides a mass transport necessary for growth of favorably oriented grains. Other studies (Grünberger *et al*., 1997) suggested that the liquid grain-boundary phase is not required for deformation and texturing, but it is rather necessary for a crack-free deformation at high strain rates. The commercially available die-upset R–Fe–B magnets have a $(BH)_{max}$ up to 360 kJ m^{-3}. The highest energy product values, up to 435.2 kJ m^{-3}, were reported for magnets made of amorphous shock-compacted precursors (Harada, Fujita and Kuji, 1996; Saito *et al*., 1998).

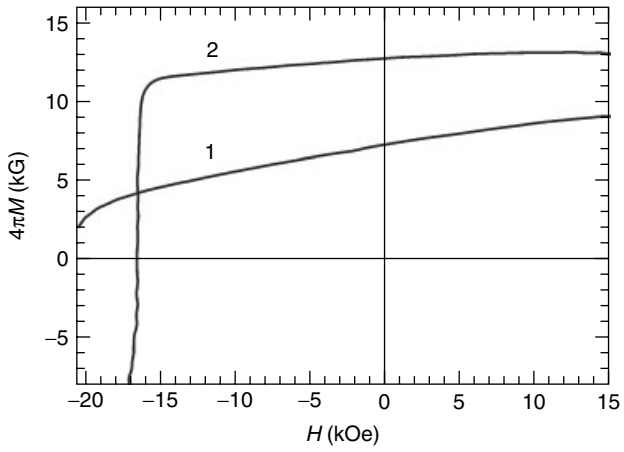

Figure 6. Demagnetization curves of hot-compacted (1) and hot-deformed (2) $Nd_{16}Fe_{77.5}Ga_{0.5}B_6$ magnets produced from intensively milled powders.

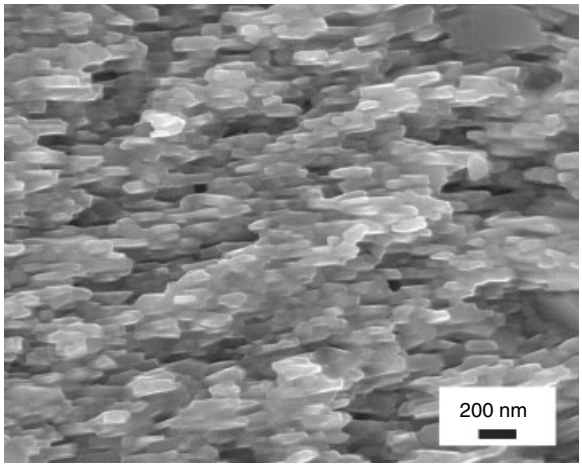

Figure 7. Elongated $Nd_2Fe_{14}B$ grains in the hot-deformed $Nd_{15.5}Fe_{77}Ga_{0.5}B_6$ magnet (scanning electron microscopy (SEM) image of the fractured surface of the magnet). Pressure had been applied in vertical direction.

While the typical R–Fe–B alloys for die upsetting contain more than 12 at% R (to provide the R-rich phase), considerable efforts were recently made to obtain *anisotropic* die-upset nanocomposites. In one of the attempts (Gabay, Zhang and Hadjipanayis, 2004), the R-rich and R-lean ribbons were blended and die upset together. The resulting magnets consisted of alternating layers of the two starting alloys arranged perpendicularly to the pressing direction (Figure 8). In the R-rich layers, the $R_2Fe_{14}B$ grains were crystallographically aligned, while the $R_2Fe_{14}B$ and α-Fe grains in the R-lean layers retained the random orientation. Though anisotropic magnets with less than 12 at% R have been obtained, their properties (see Figure 9) were far inferior to those of the traditional α-Fe-free die-upset magnets. In another recent study (Lee *et al*., 2004), die-upset anisotropic $(Nd,Pr,Dy)_2Fe_{14}B$/α-Fe magnets were reported with $(BH)_{max}$ of 336 kJ m^{-3}. The highest maximum energy product in composite magnets reported to date is $(BH)_{max} \sim 432$ kJ m^{-3} and was obtained for die-upset specimens fabricated with composite powder synthesized by coating (Liu *et al*, 2006). However, in this case, the soft magnetic phase exceeds by far the nanometer scale.

2.5 Magnetization reversal mechanism in nanostructured magnets

The magnetic hysteresis in the nanocrystalline $R_2Fe_{14}B$ alloys is difficult to model because the real microstructures are not only refined but are rather nonhomogeneous (Herbst and Croat, 1991). The pinning of domain walls at grain

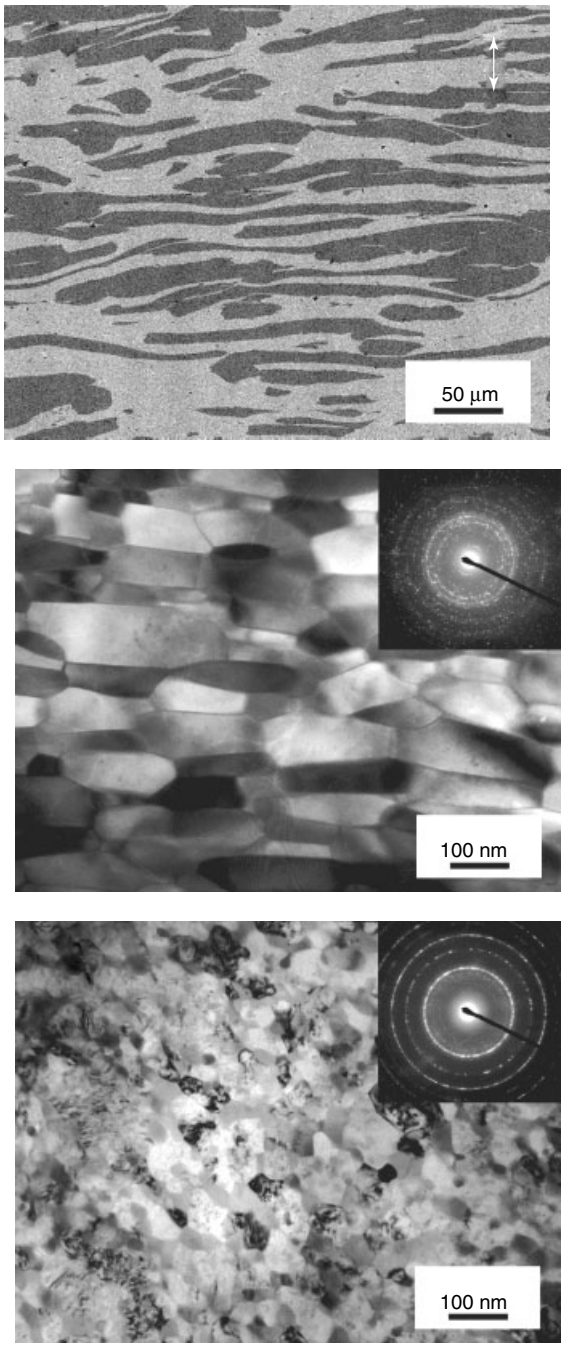

Figure 8. Microstructure of a composite magnet made from equal weight percent of $Pr_{13.5}Fe_{68}Co_{12}Ga_{0.5}B_6$ and $Pr_{3.5}Tb_1Fe_{89.5}B_6$: (a) SEM back scattered electron (BSE) image with the arrow showing the pressure direction and TEM images of areas with (b) platelet-like $R_2Fe_{14}B$ grains, (c) equiaxed $R_2Fe_{14}B$ and α-Fe grains. Figure 9. Demagnetization curves of die-upset magnet $(Pr,Tb)_{8.72}Fe_{85.04}Ga_{0.24}B_6$ made from equal weight percent of $Pr_{13.5}Fe_{80}Ga_{0.5}B_6 + Pr_{3.5}Tb_1Fe_{89.5}B_6$. The curves were measured parallel and perpendicular to the pressure direction.

boundaries has been suggested based on the shape of initial curves and field and temperature dependencies of the coercivity (Hadjipanayis, Dickerson and Lawless, 1986; Pinkerton and Van Wingerden, 1986). On the other hand, the coercivity controlled by nucleation of reversed domains has been proposed by Durst and Kronmuller (1987) based on the variation of the coercivity with temperature data. This mechanism is also supported by measurements of the initial magnetization and remanence showing that the magnetization reversal occurs by rotation of the magnetic moments of neighboring grains at a time. In later studies, the magnetization reversal process in the fine-grained magnets was explained better using the random anisotropy model (Givord and Rossignol, 1996). When the grains are smaller than 20 nm, the strong intergranular interactions lead to the formation of 'interaction domains'.

In nanocrystalline magnets without exchange coupling, H_c can be described by a modified form of equation (1) (Kronmüller, 1987; Martinek and Kronmuller, 1990):

$$\mu_0 H_c = \alpha_K \mu_0 H_N^{min} - N_{eff} J_s \qquad (2)$$

with H_N^{min} – the smallest nucleation field of reversed domains and α_K and N_{eff} – the microstructure parameters describing the variation of the magnetocrystalline anisotropy at the grain surface due to imperfections and the local demagnetizing coefficient, respectively. The microstructure parameters can be obtained by analyzing the temperature dependence of H_c. In the case of decoupled grains, the α_K parameter varies in the range $0.7 < \alpha_K < 0.9$. The exchange interaction between the magnetic moments of adjacent grains can be described by introducing the coefficient α_{ex} attached to α_K. The $\alpha_{ex}\alpha_K$ value of the exchange-coupled magnets is substantially lower than α_K of the magnets with decoupled grains. In the two-phase magnet containing 46.9% α-Fe, $\alpha_{ex}\alpha_K$ was found to be as low as 0.06 (Goll, Seeger and Kronmuller, 1998; Kronmüller and Goll, 2002b). The microstructural parameter N_{eff} is 0.1–0.16 in stochiometric and two-phase nanocrystalline magnets compared to 0.75–1

for magnets with decoupled grains (Bauer, Seeger, Zern and Kronmuller, 1996; Kronmüller and Goll, 2002b) indicating smaller internal stray fields in the exchange-coupled nanocomposites.

Micromagnetic analysis by Kronmüller and Goll (2002b) has showed three main sources of the reduction of H_c in nanocrystalline R–Fe–B magnets with the nucleation-controlled coercivity: (i) misaligned grains, (ii) imperfect grain boundaries, and (iii) exchange coupling between neighboring grains which induces cooperative demagnetization processes of clusters of grains.

3 RARE-EARTH–COBALT NANOSTRUCTURED AND NANOCRYSTALLINE MAGNETS

3.1 Bulk-hardened nanostructured R–Co magnets

The bulk-hardened (or precipitation-hardened) Sm–Co magnets were developed in the 1970s (Tawara and Senno, 1973; Ojima, Tomizawa, Yoneyama and Hori, 1977). They are also often called the *2:17* magnets after their major component, the Sm_2Co_{17} phase. These magnets are particularly attractive due to their excellent temperature stability and good corrosion resistance. However, these magnets are rather expensive because of their high-priced raw materials and typical heat-treatment processing which is long and complicated. Because of its 'bulk' nature, the magnetic hardening in the 2:17 Sm–Co alloys can be achieved in various types of materials. Sintered magnets, that is, those produced via a powder metallurgy, are anisotropic and show the best magnetic performance. Cast isotropic magnets are less expensive; they can be further crushed and used for manufacturing anisotropic polymer-bonded magnets. Recently bulk hardening has been realized in $Sm(Co,Fe,Cu,Zr)_z$ melt-spun ribbons (Goll, Kleinschroth, Sigle and Kronmuller, 2000; Yan, Bollero, Müller and Gutfleisch, 2002; Yan, Sun, Han and Shen, 2002). These ribbons can be potentially used for large-scale manufacturing of isotropic and partially anisotropic polymer-bonded magnets.

3.1.1 Crystallography and phase relations

The binary Sm–Co phase diagram depicts the coexistence of the Sm_2Co_{17} phase with another important phase, $SmCo_5$. The structures of the two compounds are related (Buschow and Van der Goot, 1968): Sm_2Co_{17} can be considered as $SmCo_5$ with one-third of the Sm atoms replaced by pairs (so-called dumbbells) of the Co atoms stretched along the [001] direction. There are two modifications of the Sm_2Co_{17} structure, both with the Co dumbbells ordered: the rhombohedral one (the Th_2Zn_{17} type) often referred to as *2:17R* and the hexagonal one (the Th_2Ni_{17} type), *2:17H*. It is the 2:17R structure that is stable at room temperature and is the primary phase of the 2:17 magnets. Random substitution of the Co dumbbells for the Sm atoms in the $SmCo_5$ structure results in the off-stoichiometric $SmCo_{5+\delta}$ structure. In the binary Sm–Co alloys, this structure is stable at high temperatures within a limited range of compositions. The addition of certain elements (most notably, Cu and Zr) greatly extends the range of the off-stoichiometric $SmCo_{5+\delta}$ structure. In Sm–Co–Zr system, this range stretches all the way to the Sm_2Co_{17} composition (Derkaoui, Valignat and Allibert, 1996). Thus, in the doped Sm–Co alloys, a third 2:17 structure exists–the hexagonal one with disordered dumbbells. Historically, this structure is known as that of the $TbCu_7$ type (Buschow and Van der Goot, 1971) or simply '1:7'. The commercial 2:17 magnets usually contain Cu, Zr, and Fe in addition to Sm and Co. The traditional way to express the magnet compositions is $Sm(Co,Fe,Cu,Zr)_z$. This approach, however, is misleading when referring to the above crystallographic relations; when forming any of the three 2:17 structures from the parent 1:5 compound a dumbbell of *two* Co, Fe, or Cu atoms, but only *one* Zr atom occupy the Sm site. Also it should be noted that because of the evaporation loss of Sm, in the 2:17 magnets prepared via a powder metallurgy, the effective z value is larger than the nominal one by 0.6–0.8 atoms (Liu *et al*., 2000).

3.1.2 Microstructure evolution

In general, the microstructure of the 2:17 magnets (Figures 10 and 11) develops in three-step processing. The alloys have to be annealed at 1150–1190 °C to form a single-phase hexagonal structure (2:17H or 1:7; Ray (1984) considered this structure as 'disordered rhombohedral'). The subsequent isothermal aging at 800–850 °C forms a submicron size microstructure consisting of the 2:17R cells surrounded by 1:5 layers.

According to Melton and Nagel, the cellular morphology minimizes the strain induced by a *c*-axis misfit between the coherent 2:17 and 1:5 structures (Melton and Nagel, 1977). It is still disputable how the cellular structure is actually formed. Livingston and Martin suggested that the cells evolve by precipitation and growth of the 2:17R particles, while the remnants of the 1:7 matrix phase form the 1:5 cell boundaries (Livingston and Martin, 1977). According to another model (Melton and Nagel, 1977), the cell boundaries arise from binding of isolated 1:5 particles during coarsening. Stadelmaier, Goll and Kronmüller (2005) who also considered the cell boundaries as precipitates compared them with the Widmannstätten pattern. In this model (Stadelmaier,

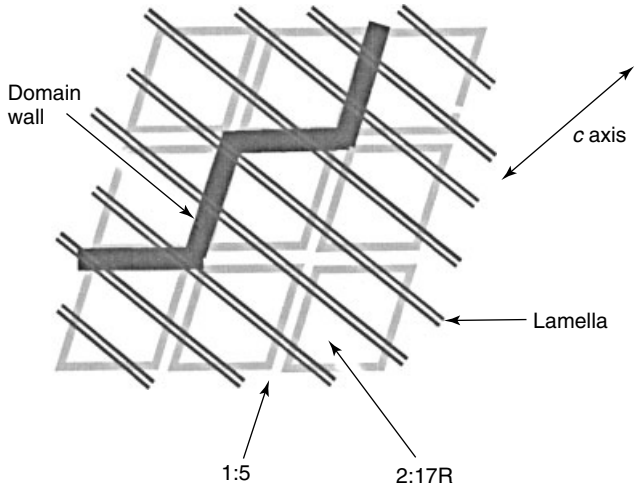

Figure 10. Schematic representation of microstructure in fully heat-treated 2:17 bulk-hardened Sm–Co magnets.

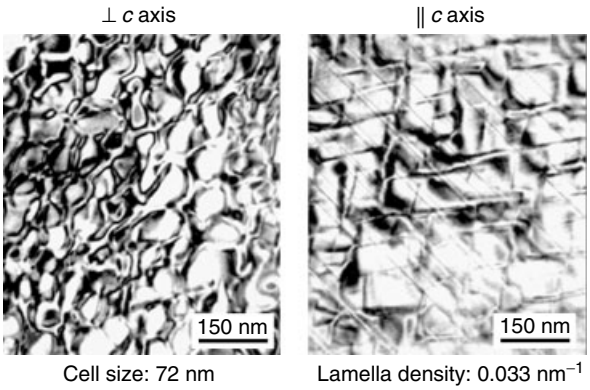

Figure 11. Typical cellular and lamellar mircostructure in 2:17 magnets along parallel and perpendicular direction to the c axis.

Goll and Kronmüller, 2005), the regular geometric pattern of the cells is caused by a low-index crystallographic interface between the 2:17 and 1:5 phases rather than by the minimum strain energy. In $Sm(Co,Fe,Cu,Zr)_z$ magnets, the 2:17/1:5 cellular structure is intersected by Zr-rich lamellae, which have been recently identified (Xiong *et al*., 2004) as $(Zr,Sm,Cu)_1(Co,Fe)_3$ with the Be_3Nb structure. After aging, the alloys have to be cooled to 350–400 °C at the rate 0.7–1 °C per min. The slow cooling is accompanied by an exchange of atoms between the phases, notably by diffusion of the Cu atoms into the 1:5 cell boundaries (Figure 12). A noticeable coercivity appears only at this stage, though for certain alloys, the aging (Yan, Bollero, Müller and Gutfleisch, 2002) or slow cooling (Tang *et al*., 2001) stages can be omitted. One should also mention that the highest concentration of Cu was found in the so-called *triple junctions*, that is the junction of three neighboring cells (Figure 12).

The above mechanism of the microstructure evolution in 2:17 magnets with heat treatment has been formulated in the early 1980s (Mishra *et al*., 1981; Fidler, Skalicky and Rothwarf, 1983). Some very recent findings (Goll, Kronmüller and Stadelmaier, 2004; Stadelmaier, Goll and Kronmüller, 2005) suggested that, opposite to the conventional view, the cell boundaries first consist of a mixture of 2:17, 2:7, and 5:19 phases, and the 1:5 structure forms only at the cooling stage.

The cellular/lamellar microstructure of the 2:17 magnets strongly depends on both the alloy composition and processing parameters. These effects were summarized in recent review by Hadjipanayis *et al*. (2000). Smaller z values in $Sm(Co,Fe,Cu,Zr)_z$ result in larger volume fraction of the 1:5 cell-boundary phase and, therefore in a smaller average cell size (Figure 13). Because the coercivity is associated with the Cu concentration in the cell-boundary phase, more Cu is required to achieve the same coercivity in the alloy with the larger volume fraction of the 1:5 phase. *Cu*, being a nonmagnetic element, decreases the magnetization of the magnet. Iron, on the contrary, increases the saturation magnetization. It also increases the average cell size (in part, probably, by stabilizing the 2:17 phase) and promotes a uniform and well-developed cellular structure. Though the cellular structure can be developed without Zr, addition of this element increases the coercivity dramatically, up to 3.20 MA m^{-1}, in the alloys with high z values. Density of the Zr-rich lamellar phase increases with Zr. It is certain that Zr assures the high-temperature single-phase structure and controls its separation into 2:17R and 1:5 during aging. The role of the lamellar phase is not that clear. It may stabilize a uniform cellular structure and/or provide diffusion paths for the Cu atoms during the slow cooling.

3.1.3 Recent advances in 2:17 magnets

Though sintered 2:17 magnets may have a room-temperature maximum energy product of more than 240 kJ m^{-3}, they are used almost exclusively for high-temperature applications (for room-temperature applications, the 2:17 magnets cannot compete with the more powerful and less expensive Nd–Fe–B magnets). However, the 2:17 magnets with the highest room temperature $(BH)_{max}$ have a weaker performance above 300 °C (Ma *et al*., 1996). During the 1990s, most of the studies in the 2:17 magnets were focused on the high-temperature properties. As a result of these concentrated efforts the maximum operating temperature of the 2:17 magnets has been increased to 450–500 °C (Liu, Chui, Dimitrov and Hadjipanayis, 1998; Chen *et al*., 1998). In general, the $Sm(Co,Fe,Cu,Zr)_z$ magnets with smaller z have better temperature stability (Figure 14, Hadjipanayis *et al*., 2000). In

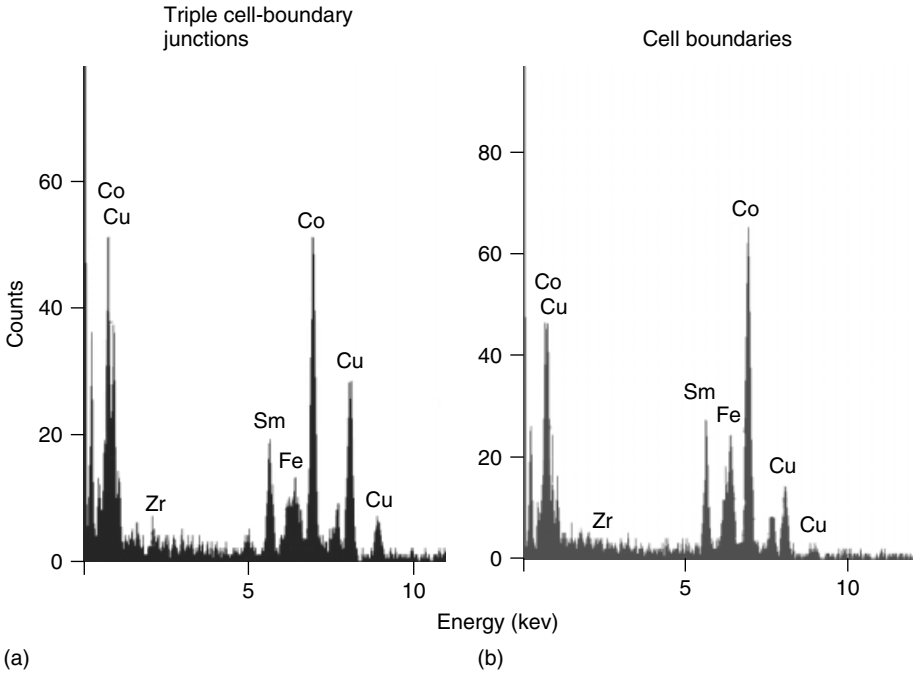

Figure 12. Nanoprobe energy dispersive X-ray (EDX) patterns of $Sm(CoCuFeZr)_z$ magnets homogenized at 1185 °C, aged at 700 °C for 24 h and followed by slow cooling to 400 °C; (a) triple cell-boundary junction, chemical composition (at%): Sm: 20.5, Cu: 29.4, Co: 37.7, Fe: 11.3, Zr: 1.1; (b) regular cell boundaries, chemical composition (at%): Sm: 13.4, Cu: 14.4, Co: 53.1, Fe: 17.8, Zr: 1.3.

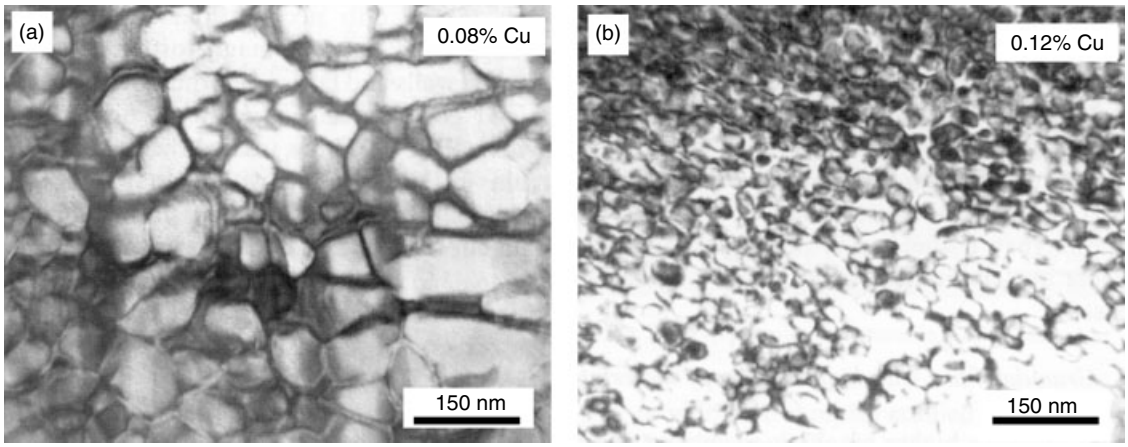

Figure 13. Effect of Cu content on cellular microstructure in $Sm(Co, Fe, Cu, Zr)_7$ (Hadjipanayis, 1999).

fact, certain 2:17 magnets show the unusual positive temperature coefficient of coercivity (Popov, Korolev and Shchegoleva, 1990).

The effect of bulk magnetic hardening in the Sm–Co–Fe–Cu–Zr alloys is not a unique feature of this system. In addition to the long-known inexpensive Ce-based magnets, there were a number of recent attempts to replace the crucial alloy components. Bulk-hardened magnets with Sm replaced by Y and Pr (Gabay, Zhang and Hadjipanayis, 2001) show a room-temperature coercivity of 640 kA m^{-1}. However, they require more Cu and Zr than the Sm-based magnets and, therefore, have inferior overall magnetic properties. Sm can also be replaced by Gd (Rong *et al*., 2004). Ti was long considered as an alternative to Zr. Recently, Sm–Co–Cu–Ti (Zhou *et al*., 2000) and Pr–Co–Cu–Ti (Zhang *et al*., 2003) magnets were found to have a significant coercivity at 400–500 °C, despite poor properties at room temperature. Similar behavior was observed when Cu in the traditional magnets had been replaced by Ni (Tang, Zhang and Hadjipanayis, 2002a). The problem with Ti and Ni is that unlike Zr and Cu they have significant room-temperature solubility in the

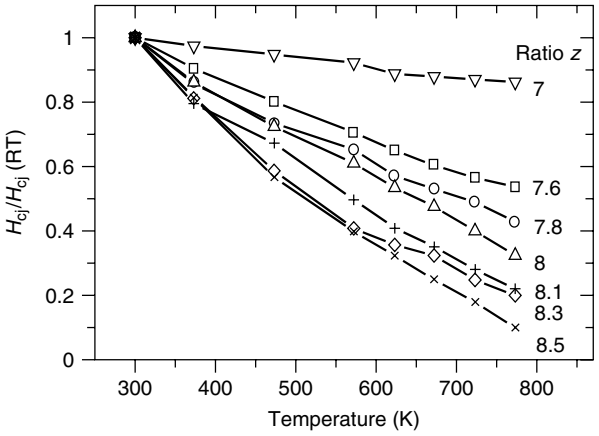

Figure 14. Temperature dependence of coercivity in $Sm(Co,Fe,Cu,Zr)_z$ magnets with different z (Hadjipanayis *et al*., 2000).

2:17R structure reducing the magnetic properties of this phase which is the primary phase in the magnets. The phenomenon of bulk magnetic hardening was even observed in the Pr–Co–Zr alloys (Gabay, Zhang and Hadjipanayis, 2000) despite the absence of Cu(Ni) and the fact that magnetocrystalline anisotropy of the main Pr_2Co_{17} phase is not uniaxial.

3.1.4 Coercivity mechanism

The predominant magnetization reversal model suggested for the 2:17 Sm–Co magnets is that of domain wall pining where the domain walls are pinned at the cell boundaries owing to a large gradient of domain wall energy (Livingston and Martin, 1977). Indeed, magnetic domain observations show that in the highly coercive 2:17 magnets, domain walls are waved and follow the cell boundaries (Figure 15). However, there is no agreement on the nature of this gradient. Figure 16 shows schematically the most typical profiles of the anisotropy constant (domain wall energy) suggested to explain the coercivity in the bulk-hardened magnets.

The profile shown in Figure 16(a) was suggested for $Sm(Co,Fe,Cu)_7$ sintered magnets (Livingston and Martin, 1977). When the domain wall energy of the cell-boundary phase is higher than that of the cell, the boundary is a repulsive pinning site–a barrier for moving domain walls. The K_1 profile shown in Figure 16(b) has been proposed for the first time by Kronmüller (1984) and was quantified later by Goll (2002) and Kronmüller and Goll (2002a). The profile was also obtained experimentally for $Sm(Co,Fe,Cu,Zr)_{7.4-7.5}$ sintered magnets (Goll, 2002; Xiong *et al*., 2004). The problem with the repulsive pinning model is that the largest difference between the higher domain wall energy of the 1:5 phase and the lower energy of the 2:17 phase must be expected at the end of the isothermal aging. The coercivity, however, appears only during the subsequent slow cooling when this difference is expected to decrease as Cu diffuses from the 2:17 cells into the 1:5 cell boundaries. To resolve this controversy, more complicated compositional profiles were suggested. According to one of the models (Yan, Gutfleisch, Gemming and Müller, 2003) the Cu-poor outer layers of the 1:5 phase result in the profile shown in Figure 16(c) and act as repulsive pinning sites. However, this model is not compatible with the experimentally determined atomic distribution within the boundary between the cell and the cell wall phases. The recent idea that the 1:5 phase itself

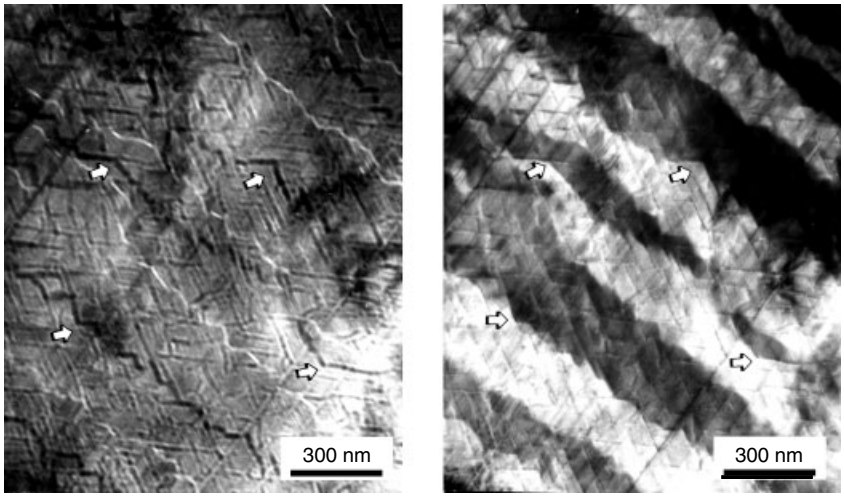

Figure 15. Typical magnetic domain structure in the fully heat-treated 2:17 Sm–Co magnets: (a) Fresnel and (b) Foucault modes of Lorentz microscopy.

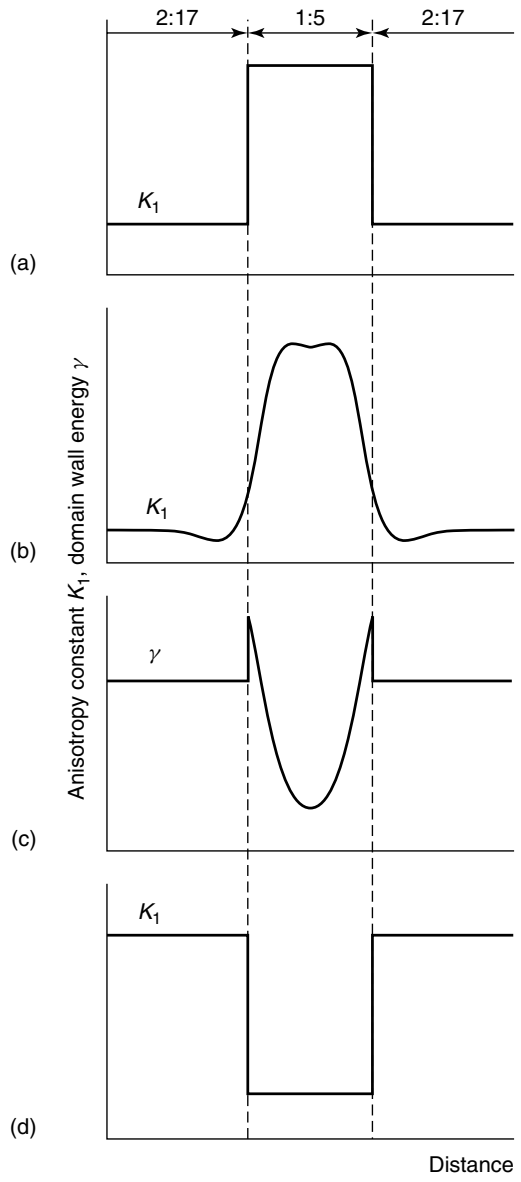

Figure 16. Profiles of the anisotropy constant K_1 or domain wall energy γ at the 1:5 cell-boundary phase as (a) suggested by Livingston and Martin (1977), (b) estimated by Goll (2002) and Xiong *et al*. (2004), (c) proposed by Yan, Gutfleisch, Gemming and Müller (2003), and (d) assumed by Liu *et al*. (2001) and Rong *et al*. (2004). (Reprinted with permission Rong *et al*., copyright 2004, American Institute of Physics.)

forms only during the slow cooling (Goll, Kronmüller and Stadelmaier, 2004; Stadelmaier, Goll and Kronmüller, 2005) may also explain why the coercivity appears only at the latter stage.

If the domain wall energy of the cell-boundary phase is lower than that in the cell, the boundary is an attractive pinning site, that is, a trap for domain walls. The attractive pinning models, in which the 1:5 phase is uniform (Figure 16d) were recently used for qualitative (Liu *et al*., 2001) and quantitative (Rong *et al*., 2004) simulations. The same experimental K_1 profile as shown in Figure 16(b) can be interpreted (Xiong *et al*., 2004) in favor of the attractive pinning, with the domain walls trapped at the Cu-rich layers of the 2:17 phase adjacent to the cell boundaries. The other model (Popov, Gaviko, Magat and Ivanova, 1990) states that attractive pinning sites appear during the slow cooling at the 2:17/1:5 interface, when the Cu atoms diffuse to the interface in order to accommodate the interphase stress.

The 2:17/1:5 interface is not the only pinning site ever considered. According to Katter *et al*., 1996, the very strong domain wall pinning in the $Sm(Co,Fe,Cu,Zr)_z$ magnets might be expected at the intersections of the 1:5 grain-boundary phase and the Zr-rich lamellar phase. However, this contribution to the coercive field is debated since the lamellar phase exists after the high-temperature treatment when the coercive field is still small.

It should be also noted that the cell-boundary $Sm(Co,Cu)_5$ phase itself is known to have a high room-temperature coercivity (Nesbitt *et al*., 1968). With increasing temperature, the domain wall energy of the 1:5 phase decreases more rapidly than that of the 2:17 phase. This means that any repulsive pinning model implies a transition to the attractive pinning at a certain elevated temperature. The 1:5 grain-boundary phase has a lower Curie temperature. At this temperature, a maximum of the coercivity is observed in the magnets with an 'anomalous' temperature dependence of H_c (Popov, Korolev and Shchegoleva, 1990; Gabay, Tang, Zhang and Hadjipanayis, 2001; Zhang *et al*., 2003). Once the grain-boundary phase becomes paramagnetic, the magnetization reversal occurs in the separated 2:17 cell either via uniform magnetization rotation or via nucleation of domain walls. It has been pointed out (Gabay, Tang, Zhang and Hadjipanayis, 2001) that, if the Cu concentration in the cell boundaries is high enough, the 2:17 cell can be magnetically separated even at room temperature (Figure 17). In such magnets, the coercivity has a 'normal' monotonic temperature dependence and it is always nucleation controlled. Neither domain wall observations nor the low initial magnetic susceptibility traditionally associated with the pinning-controlled coercivity contradict the magnetization reversal in the magnetically separated 2:17 cells. Since the cells still interact magnetostatically, the magnetic domain structure similar to the one shown in Figure 13 can be formed by interaction domains. In this case, the initial magnetic susceptibility is expected to be low, if the cells are smaller than the single domain particle size. The anomalous temperature dependence of coercivity was also reported in 2:17 melt-spun ribbons (Goll, Kleinschroth, Sigle and Kronmuller, 2000).

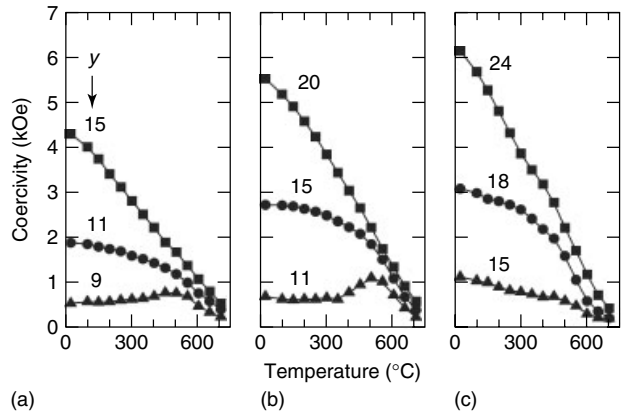

Figure 17. Temperature dependence of coercivity of the $Y_xZr_{2.5}Co_{89.5-x-y}Fe_8Cu_y$ for (a) $x = 11.5$, (b) $x = 12.5$, and (c) $x = 13.5$. (Reprinted with permission Gabay *et al*., copyright 2001, American Institute of Physics.)

3.2 Nanocrystalline R–Co magnets

3.2.1 Melt-spun R–Co magnets

Owing to their large magnetocrystalline anisotropy, $SmCo_5$ and related compounds have been obvious candidates for developing coercivity through decreasing the grain size. Melt-spun $SmCo_5$ ribbons showed coercivity values lower than that expected for a material with such a large anisotropy field (Takahashi *et al*., 1985). Since the Co-rich part of the Sm–Co phase diagram does not have a deep eutectic, the melt spinning does not lead to an amorphous structure. Most of the recent efforts in the melt-spun $SmCo_5$ were focused on solidification at relatively low speeds. The $SmCo_5$ ribbons melt spun at the wheel speed of $5–6\,m\,s^{-1}$ crystallize directionally with their EMDs preferentially laying in the ribbon plane (Ding, McCormick and Street, 1995; Li *et al*., 2002). Owing to this texture, the performance of the ribbons is comparable with that of the anisotropic sintered $SmCo_5$ magnets with the remanence, coercivity, and maximum energy product values of 0.91 T, $1.296\,MA\,m^{-1}$, and $145.6\,kJ\,m^{-3}$, respectively (Yan, Zhang, Zhang and Shen, 2000).

The $PrCo_5$ compound has a higher theoretical energy product than $SmCo_5$ because of its higher magnetization. Melt-spun Pr–Co alloys show coercivity values of more than $800\,kA\,m^{-1}$ but very poor squareness of the hysteresis loop (Morimoto, Yagi and Takeshita, 1991). Their hard-magnetic properties can be markedly improved by additions of C (Fuerst, Herbst, Murphy and Van Wingerden, 1993) or C and Ti (Branagan, Kramer, Tang and McCallum, 2000). In both cases, the additions were believed to inhibit grain growth: in the first case, by facilitating quenching, whereas in the second case, by forming TiC grain-boundary precipitates. The maximum energy product $(BH)_{max}$ of the melt-spun ribbons still did not exceed $64–72\,kJ\,m^{-3}$. The RCo_5 compounds with R = Y, Ce, Gd, Er (all having high magnetocrystalline anisotropy) were found to be even less suitable for manufacturing melt-spun permanent magnets (Fuerst, Herbst, Murphy and Van Wingerden, 1993). Although, partial Gd substitutions for Sm (Zhang W.Y. *et al*., 2001) and Pr (Meacham and Branagan, 2003) were found to be beneficial for the hard-magnetic properties.

In the Sm–Co alloys with compositions between 1:5 and 2:17, melt spinning generates the metastable '1:7' structure (which can be equally called the *Co-rich 1:5* and *Co-depleted disordered 2:17*). Since the Sm_2Co_{17} (and especially $Sm_2(Co,Fe)_{17}$) has a saturation magnetization substantially higher than that of $SmCo_5$, it seems natural to increase $(BH)_{max}$ of the $SmCo_5$ ribbons by shifting their composition toward Sm_2Co_{17}. Unfortunately, the coercivity of the melt-spun $SmCo_z$ and $Sm(Co,Fe)_z$ alloys rapidly decreases with increasing z from 5 to 8.5 (Chen *et al*., 2003a). This trend might be expected, since the anisotropy field decreases with increasing z (the anisotropy field of Sm_2Co_{17} is about one-fourth of that of $SmCo_5$). However, the major reason for the poor hard-magnetic properties of the melt-spun Sm–Co ribbons appears to be related to a coarse dendritic microstructure of the crystallized alloys (Ding, McCormick and Street, 1995; Yan *et al*., 2002). Since Crabbe, Davies and Buckley (1994) showed that melt spinning of the $Sm(Co_{0.704}Fe_{0.209}Cu_{0.061}Zr_{0.025})_{7.61}$ alloy produces a single-phase microstructure with a grain size of about 30 nm, various additions were tried to refine the microstructure of melt-spun $SmCo_z$ alloys. Carbon in combination with either Zr (Du *et al*., 2003) or Nb (Hsiao, Aich, Lewis and Shield, 2004) produces a fine 1:7 microstructure with a coercivity of $1.12–1.44\,kA\,m^{-1}$. A room-temperature coercivity of $3.08\,MA\,m^{-1}$ was reported for a B-containing melt-spun $Sm(Co,Fe,Cu,Zr,B)_{7.5}$ alloy (Makridis *et al*., 2002). It should be noted that, although the boron-added $Sm_2(Co,Fe,Mn)_{17}$ melt-spun and annealed alloys show improved temperature stability, excessive amount of B may lead to deterioration of the hard-magnetic properties because of the formation of the magnetically soft $Sm_2Fe_{14}B$ phase (Kim and Hadjipanayis, 1998).

3.2.2 Mechanically alloyed and intensively milled R–Co magnets

In contrast to the melt-spinning technique, the high-energy ball milling easily produces an amorphous $SmCo_5$ material without C or B additions. A subsequent crystallization annealing at about 600 °C leads to a uniform nanocrystalline microstructure. After milling together elemental Sm and Co, Wecker, Katter and Schultz (1991) obtained $SmCo_5$ magnets with the coercivity of $2.40\,MA\,m^{-1}$, while Liu,

Dallimore, McCormick and Alonso (1992) (they started from SmF_3, Co and Ca) achieved a coercivity of $5.20\,MA\,m^{-1}$. However, the same microstructure of RCo_5 nanograins can be realized when a single-phase RCo_5 precursor is subjected to the high-energy milling. In this case, the amorphization during milling can be accomplished in a shorter time reducing the risk of alloy oxidation and contamination by the materials of the milling media. By this route, high-performance isotropic nanocrystalline $PrCo_5$ (Chen, Meng-Burany and Hadjipanayis, 1999), YCo_5 (Tang *et al.*, 2000), and $LaCo_5$ (Okumura, Zhang and Hadjipanayis, 2002) magnets with $H_c = 1.28–1.92\,MA\,m^{-1}$ were successfully produced (Figures 18 and 19). A certain excess of R over the nominal 1:5 stoichiometry is required to obtain the maximum H_c. This fact is apparently related to the partial oxidation of the rare earth during the milling (which, of course, must be done in a protective environment, e.g., under argon).

Nanocrystalline Sm_2Co_{17} magnets also can be produced via the mechanical alloying (Wecker, Katter and Schultz, 1991). In this case, the highest reported H_c values are lower than those of $SmCo_5$ (up to $768\,kA\,m^{-1}$ has been reported by Chen, Meng-Burany, Okumura and Hadjipanayis (2000)). This is not surprising, since the nucleation-controlled coercivity of the nanocrystalline magnets is expected to be proportional to the anisotropy field H_A (Sm_2Co_{17} has a lower H_A than $SmCo_5$) reduced by the effective internal demagnetization field $N_{eff}M_s$ (Sm_2Co_{17} has a higher $N_{eff}M_s$ because of the higher M_s). In the amorphous intensively milled $SmCo_z$ ($5 < z < 8.5$) alloys, annealing at 500–650 °C leads to the formation of a metastable 1:7 phase, whose magnetic properties vary with z with values between those of $SmCo_5$ and Sm_2Co_{17}. Though the material is isotropic, the

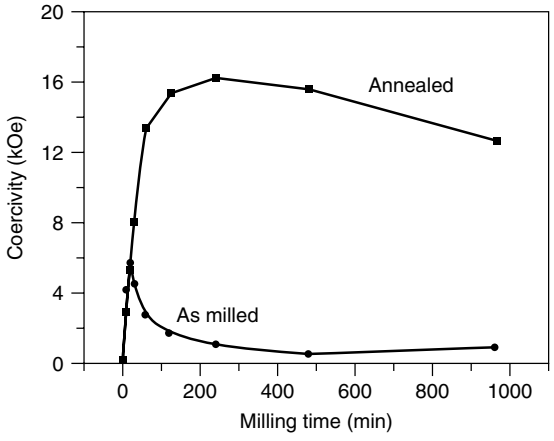

Figure 18. Coercivity of as-milled and annealed, at 800 °C for 1 min, $PrCo_5$ powders as a function of milling time. (Reprinted with permission Chen *et al.*, copyright 1999, American Institute of Physics.)

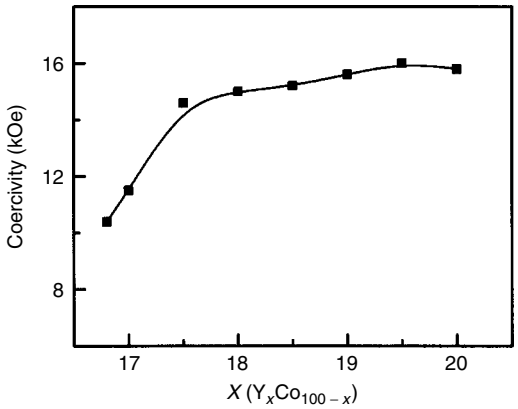

Figure 19. Coercivity of Y_xCo_{100-x} ($x = 16.8–20$) powders as a function of Y content. The powders were milled for 4 h and annealed at 950 °C for 1 min. (Reprinted with permission N. Tang *et al.*, copyright 2000, Elsevier.)

nanocrystalline structure demonstrates an enhanced remanence due to intergranular exchange coupling (Ding, Liu, McCormick and Street, 1993). Annealing at higher temperatures leads to the equilibrium 1:5 and 2:17 phases. This does not immediately lead to deterioration of the hard-magnetic properties, since the average grain size remains small. With further increase of the annealing temperature the grains coarsen and the remanence enhancement disappears. A maximum energy product of $144\,kJ\,m^{-3}$ was reported for the optimally heat-treated $Sm_{12.5}Co_{87.5}$ alloy (Ding, Liu, McCormick and Street, 1993). Similar studies performed with the Pr–Co alloys (Chen, Zhang and Hadjipanayis, 2000) also led to an increase of $(BH)_{max}$ from $72\,kJ\,m^{-3}$ for $PrCo_5$ to $94.4\,kJ\,m^{-3}$ for the alloy with 70% $PrCo_5$ and 30% Pr_2Co_{17} (at the annealing temperature of 800 °C used in that work, only the equilibrium phases could be expected).

Addition of Fe to the Sm–Co alloys leads to the formation of an additional metastable phase, bcc Co–Fe, after intensive milling (Ding, McCormick and Street, 1994). This phase remains in the microstructure after annealing at temperatures below 800 °C, that is, it may coexist with the hard-magnetic phases 1:7, 2:17, 1:5, and 2:7. The exchange-coupled nanocomposites consisting of a mixture of magnetically hard grains and magnetically soft bcc grains demonstrate even higher enhanced remanence than the single-phase alloy with hard nanograins. For mechanically alloyed and annealed $Sm_{13}(Co,Fe)_{87}$ magnets, a $(BH)_{max}$ of $160\,kJ\,m^{-3}$ has been reported (Ding, McCormick and Street, 1994).

Recently, various alloying elements were examined in an attempt to extend the temperature range of the nanocrystalline Sm–Co magnets. It was found, in particular, that the $Sm(Co,Ti,Zr,B)_7$ magnets show an increased thermal stability of the 1:7 phase (Rhen, Venkatesan, Harris and Coey, 2003).

3.2.3 Anisotropic nanocrystalline $PrCo_5$ magnets

Despite their high coercivities, the nanocrystalline magnets produced from amorphous precursors do not show high remanence and $(BH)_{max}$ values, because the EMDs of the individual crystallites are orientated randomly. In the case of Nd–Fe–B alloys, the EMDs may be almost perfectly aligned by a hot plastic deformation. Fuerst and Brewer (1993) observed a similar effect when subjecting to die-upsetting hot-compacted Pr–Co and Pr–Co–C nanocrystalline ribbons with the $PrCo_5$ as the major phase. Although imperfect, the induced texture markedly increased the remanence. For unknown reasons, the Sm–Co alloys with much higher H_c values do not develop texture during die upsetting. The optimum combination of the remanence and coercivity has been achieved for the Pr–Sm–Co–C alloys with the $(BH)_{max}$ up to 152 kJ m^{-3} (Fuerst and Brewer, 1994). Recently, Gabay, Zhang and Hadjipanayis (2005) showed that, because the intensive milling route provides better $PrCo_5$ nanocomposite magnets than melt spinning, the anisotropic die-upset magnets can be produced from intensively milled $PrCo_5$ powder using less (if any) additions. Figure 20 shows the properties of intensively milled $Pr_{0.9}Sm_{0.1}(Co_{0.98}Cu_{0.02})_5$ alloy after hot compaction and after hot deformation. Texture induced by the 75% deformation increases the remanence from 0.64 to 0.89 T and $(BH)_{max}$ from 89.6 to 133.6 kJ m^{-3}, while the coercivity decreases from 1.28 to 0.84 MA m^{-1}. The die-upset magnet consists of 1:5 and 2:17 grains with a size 20–200 nm (Figure 21). The smaller grains are more or less equiaxed, but many of the larger grains are elongated similar to those in the die-upset Nd–Fe–B magnets.

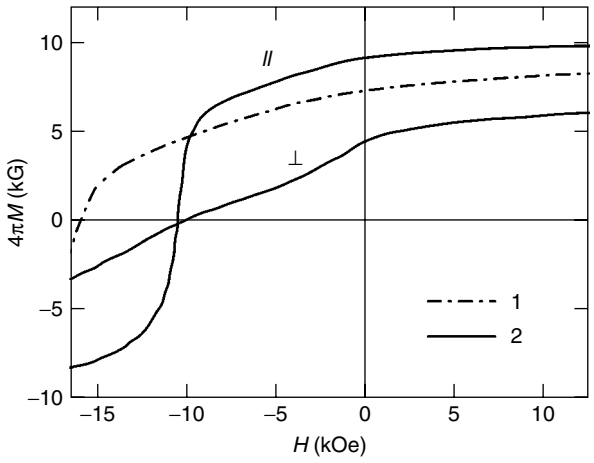

Figure 20. Demagnetization curves of hot-pressed (1) and die-upset (2) $Pr_{0.9}Sm_{0.1}(Co_{0.98}Cu_{0.02})_5$ magnets. Curves for the die-upset magnet were measured parallel and perpendicular to the pressure direction. (Reprinted with permission A.M. Gabay *et al*., copyright 2005, Elsevier.)

3.2.4 Nanocrystalline $Sm(Co,Fe,B)_5$ magnets

Boron can be used not only as an element that promotes amorphization in rapidly solidified Sm–Co alloys but also to promote the formation of Sm–Co boride structures. The $SmCo_4B$ compound, in which the B atoms replacing Co in the parent $SmCo_5$ structure are ordered along the *c* axis, has a magnetocrystalline anisotropy even higher than $SmCo_5$. This makes $SmCo_4B$ a promising candidate for nanocrystalline hard magnet. Unfortunately, the Curie temperature of $SmCo_4B$ is only 197 °C. It can be increased by additional Fe substitution for Co. Gong and Hadjipanayis (1996) achieved the coercivity of 1.28 MA m^{-1} for $SmCo_2Fe_2B$ via intensive milling and subsequent annealing. However, their melt-spinning experiments yielded H_c values lesser than 400 kA m^{-1}. On the other hand, Saito *et al*. have found that melt spinning can stabilize the disordered $SmCo_{5-x}B_x$ structure with $x < 1$ and with H_c larger than $SmCo_5$ (Saito, Takahashi and Wakiyama, 1987). There is, therefore, a possibility of optimum combination of the hard-magnetic properties in metastable $Sm(Co,Fe)_{5-x}B_x$ nanocrystalline alloys, though the realization of high $(BH)_{max}$ values is not likely to happen in these materials.

4 SAMARIUM–IRON NANOCRYSTALLINE MAGNETS

4.1 Nanocrystalline $Sm(Fe,M)_{12}$ alloys

Out of the numerous $R(Fe,M)_{12}$ compounds with the tetragonal $ThMn_{12}$ structure, only those with R = Sm and M = Ti, V, Mo, and Si possess a room-temperature magnetocrystalline anisotropy which is uniaxial and large enough

for the development of permanent magnet materials. The few studies made so far have been reported on Mo- and Si-containing alloys (Schultz and Wecker, 1988; Ding and Rosenberg, 1990), whereas the majority studies were focused on the alloys with Ti and V. Both melt spinning and high-energy milling were employed to manufacture nanocrystalline $Sm(Fe,Ti)_{12}$ and $Sm(Fe,V)_{12}$ magnets. The $SmFe_{12-x}M_x$ magnets with the desired 1:12 structure can be obtained for $x \geq 1$, if M = Ti and for $x \geq 1.5$, if M = V. This assures a higher saturation magnetization and theoretical energy product for the alloys with Ti. However, the $SmFe_{11}Ti$ compound is metastable below 1000 °C, and, therefore, relatively high annealing temperatures are required to obtain this phase in the amorphous precursors. This, in turn, results in excessive grain growth and evaporation loss of Sm (this element has a high vapor pressure). At room temperature, an H_c of 448 kA m^{-1} has been obtained for melt-spun $Sm_{1.04}Fe_{10.79}Ti_{1.17}$ (Wang *et al.*, 1990) and 624 kA m^{-1} for melt-spun $Sm_{0.95}Fe_{10}V_2$ (Pinkerton and Van Wingerden, 1989); even a higher coercivity, 936 kA m^{-1}, was reported for the mechanically alloyed $Sm(Fe,V)_{12}$ alloy (Schultz, Schnitzke and Wecker, 1990). For melt-spun ribbons, the highest coercivity values appear to be reached in alloys containing both Ti and V, with values of 816 kA m^{-1} for $Sm_{1.04}Fe_{9.88}Ti_{1.04}V_{1.04}$ (Wang *et al.*, 1990) and 960 kA m^{-1} in $SmFe_{10}TiV$ ribbons annealed in Sm atmosphere (Okada, Kojima, Yamagishi and Homma, 1990). Such an annealing technique aimed to prevent the evaporation losses of Sm is, of course, too expensive for a commercial application. In fact, despite a number of advantages (the low rare-earth content, good corrosion resistance, and reasonably high coercivity), the nanocrystalline $Sm(Fe,M)_{12}$ magnets have never been commercialized, since they have a lower remanence than the isotropic Nd–Fe–B magnets.

4.2 Nanocrystalline $SmFe_3$ and $Sm_5(Fe,M)_{17}$ alloys

The hexagonal $SmFe_3$ compound (with $PuNi_3$ structure) has a room-temperature anisotropy field of 11.20 MA m^{-1}. Wecker, Katter, Schnitzke and Schultz (1991) prepared the nanocrystalline $SmFe_3$ alloys by mechanical alloying followed by annealing and obtained a room-temperature coercivity of 840 kA m^{-1}. Further improvement has been achieved via partial Zr substitution for Sm: the melt-spun Sm–Zr–Fe with the 1:3 structure showed H_c of 1.024 MA m^{-1} (Wecker, Katter, Schnitzke and Schultz, 1991), and up to 1.184 MA m^{-1} in mechanically alloyed samples (Schultz, Schnitzke, Wecker and Katter, 1991). Unfortunately, the saturation magnetization of the $(Sm,Zr)Fe_3$ alloy does not exceed 1.05 T and the typical remanence value of the isotropic nanocrystalline 1:3 magnets is only 0.4–0.5 T.

Another Sm–Fe compound with exceptional magnetic hardness, isostructural to the hexagonal Nd_5Fe_{17}, was first discovered in sputtered Sm–Fe–Ti films (Kamprath, Liu, Hegde and Cadieu, 1988). Though it can be obtained in the binary Sm–Fe alloys (Cadieu *et al.*, 1991), partial replacement of Fe by Ti and/or V greatly favors the formation of this phase (Yang, Wang and Sun, 1997). The ternaries around $Sm_{20}Fe_{70}Ti_{10}$ (Schnitzke, Schultz, Wecker and Katter, 1990a) are the most studied alloys with the 5:17 structure. Melt-spun and mechanically alloyed nanocrystalline magnets show room-temperature H_c values up to 4.64 MA m^{-1} (Katter, Wecker, Schultz and Grössinger, 1990) and 6 MA m^{-1} (Yang *et al.*, 1994), respectively. However, similar to $SmFe_3$, the $Sm_5(Fe,Ti)_{17}$ magnets did not find practical applications because of their low saturation magnetization.

5 NANOCRYSTALLINE AND NANOCOMPOSITE RARE-EARTH–IRON NITRIDES AND CARBIDES

5.1 Magnets based on Sm_2Fe_{17} nitrides

Interstitial modification of the R_2Fe_{17} compounds dramatically changes their magnetic properties (Coey and Sun, 1990). Owing to a volume expansion of the atomic lattice caused by the absorbed N, C, or H atoms, the Curie temperature and saturation magnetization increase significantly. In Sm_2Fe_{17}, the interstitial N (or C) also induces a strong uniaxial magnetocrystalline anisotropy. The saturation magnetization of the resulting Sm_2Fe_{17} nitride is almost as high as that of $Nd_2Fe_{14}B$, whereas the anisotropy field and T_c are substantially higher (see Table 1). These excellent magnetic properties were immediately realized in high-performance isotropic magnets, both in the nanocrystalline and nanocomposite form.

A room-temperature coercivity of up to 2.40 MA m^{-1} has been obtained for mechanically alloyed Sm_2Fe_{17} powders subjected to crystallization, annealing, and subsequent nitriding at 400–550 °C in N_2 gas (Schnitzke, Schultz, Wecker and Katter, 1990b). The room-temperature remanence and $(BH)_{max}$ were equivalent to those of similarly prepared Nd–Fe–B, while their performance at the elevated temperatures was better. By lowering the Sm content from the stoichiometric 10.5–7 at% and using the same mechanical alloying–annealing–nitriding technique O'Donnell, Kuhrt and Coey (1994) obtained a nanocomposite magnet consisting of 20-nm-sized $Sm_2Fe_{17}N_3$ and α-Fe grains. Owing to

intergranular exchange interaction an enhanced remanence of 1.2 T (and a coercivity of 320 kA m^{-1}) had been achieved.

Pinkerton and Fuerst (1992) obtained H_c of 1.84 MA m^{-1} for melt-spun Sm–Fe ribbons annealed in vacuum and then in N_2 gas. To facilitate the uptake of nitrogen, the ribbons were ground down to less than 25 µm. Katter, Wecker and Schultz (1991) have pointed out that the melt-spun Sm–Fe alloys may have two crystalline modifications: the rhombohedral 2:17 structure formed at the lower quenching speeds and higher Sm concentrations and the disordered hexagonal 1:7 structure formed at higher speeds and lower Sm concentrations. The 1:7 structure can also be stabilized by Nb or Zr additions (Moukarika *et al*., 1996). The melt-spun nanocomposites consisting of fine 1:7 Sm–Zr–Fe–N grains and α-Fe grains showed a remanence of 0.99 T, a coercivity of 656 kA m^{-1}, and $(BH)_{max} = 140$ kJ m^{-3} (Hidaka, Yamamoto, Nakamura and Fukuno, 1998). Even better properties were obtained for a single-phase 1:7 structure: the melt-spun nanocrystalline $(Sm_{0.7}Zr_{0.3})(Fe_{0.8}Co_{0.2})_9B_{0.1}N_x$ alloy reportedly showed a remanence of 1.07 T, a coercivity of 784 kA m^{-1}, and $(BH)_{max} = 180.8$ kJ m^{-3} (Sakurada *et al*., 2000).

The coercivity of nitrogenated melt-spun Sm_2Fe_{17} alloys can be further improved by zinc coating (Fukunaga, Aikawa, Nagaoka and Kanai, 1996).

5.2 Magnets based on Sm_2Fe_{17} carbides

Though the effect of interstitial carbon on Sm_2Fe_{17} is similar to that of the nitrogen atoms, the number of the C atoms per formula unit after a solid–gas carburization usually does not exceed 2. This means a lesser volume expansion of the 2:17 lattice and lesser gain in the magnetic properties. Nevertheless, a coercivity of 1.856 MA m^{-1} was reported for $Sm_2Fe_{17}C_2$ obtained by annealing mechanically-alloyed Sm_2Fe_{17} powders in acetylene gas (Kuhrt *et al*., 1992). By mechanically alloying Sm, Fe, and graphite powders Geng *et al*. (2001) prepared nanocomposite magnets consisting of the Sm–Fe carbide with the disordered 1:7 structure and α-Fe. Similar to the 2:17 nitrides, these carbides are structurally unstable above 700 °C.

A simpler way of manufacturing the 2:17 carbides was found after discovering that, if Fe in Sm_2Fe_{17} was partially replaced by Ga, Si, (Shen *et al*., 1994), Al (Zhang, Cheng and Shen, 1996), Cr (Chen, Ni, and Hadjipanayis, 1998), V, Ti, Nb, and Zr (Daniel *et al*., 1998) a sufficient amount of carbon (more than 1.5 atoms per the 2:17 formula) can be introduced directly during melting. The melt-spun and annealed $Sm_2Fe_{14}Ga_3C_{\leq 2.5}$ nanocrystalline ribbons show H_c values of 1.04–1.20 MA m^{-1} (Kong *et al*., 1994; Hadjipanayis *et al*., 1995). A similar H_c value of 960 kA m^{-1} had been reported for nanocrystalline $Sm_2Fe_{15}Ga_2C_2$ prepared via mechanical milling (Cao *et al*., 1996). A small excess of Sm over the 2:17 stoichiometry increases the coercivity up to 1.76 MA m^{-1} (van Lier, Seeger and Kronmüller, 1997). Additional doping with Cu, Mo, Nb, and Zr can further improve the hard-magnetic properties of the $Sm_2(Fe,Si)_{17}C_x$, $Sm_2(Fe,Al)_{17}C_x$, and $Sm_2(Fe,Ga)_{17}C_x$ ribbons (Zhang, Zhang, Shen and Zhang, 1998; Tang *et al*., 1998a,b; Zhang *et al*., 2000). van Lier *et al*. (1998) succeeded in preparing an isotropic hot-deformed magnet with the energy product of 60.8 kJ m^{-3} from melt-spun $Sm_2(Fe,Ga)_{17}C_2$ ribbons.

5.3 Magnets based on $Nd(Fe,M)_{12}$ nitrides and carbides

Interstitial modification of the $Nd(Fe,M)_{12}$ compounds changes their intrinsic magnetic properties in a way similar to that of Sm_2Fe_{17} (Yang *et al*., 1991; Wang and Hadjipanayis, 1991).

However, even the best properties of the 1:12 nitrides (those of $NdFe_{11}TiN_x$) are inferior to the properties of $Sm_2Fe_{17}N_{2.3}$ (see Table 1). Correspondingly, nanocrystalline magnets made out of these materials show only modest performance. By nitriding melt-spun and annealed $Nd(Fe,Mo)_{12}$ ribbons in N_2 gas, room-temperature coercivities in the range of 480–640 kA m^{-1} can be obtained (Tang, Singleton and Hadjipanayis, 1993; Pinkerton, Fuerst and Herbst, 1994). The melt-spun and nitrided $Nd(Fe,M)_{12}N_x$ with M = Ti, V, W, as well as the carbides obtained by treating the $Nd(Fe,Mo)_{12}$ in methane showed worse properties (Endoh, Nakamura and Mikami, 1992; Tang, Singleton and Hadjipanayis, 1993). Nitriding mechanically alloyed $Nd(Fe,M)_{12}$ powders leads to higher H_c values (Endoh, Nakamura and Mikami, 1992). While the coercivity of $Nd(Fe,Mo)_{12}N_x$ powder was about the same–up to 640 kA m^{-1} (Gong and Hadjipanayis, 1992), higher H_c values, 720–880 kA m^{-1} were reported for $Nd(Fe,V)_{12}N_x$ (Yang, Mao and Altounian, 1996; Tang *et al*., 1998c).

Current Status and Future Development of the Magnetic Materials Industry in China

Yang Luo
Permanent Magnet Technical Committee TC-15 IEEE, Beijing, China

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

1 GENERAL SITUATION OF THE CHINESE MAGNET INDUSTRY

Commercial magnetic materials consist of two parts (IEC, 1973; Luo, 1991): soft magnetic materials (SMMs) and hard magnetic materials (HMMs). According to the material nature, magnetic materials may be metallic or nonmetallic (ferrite), crystalline, or amorphous. There are mainly two types of SMMs: soft ferrite (SF) and amorphous (or nanocrystalline) material. The three major commercially available magnets are Alnico, hard ferrite (HF), and rare-earth magnets (NdFeB, SmCo).

The output, sales value, and averaged price of SMMs (Luo, 1995; Chen, 2004; Zhou and Lu, 1999; Zhou, 2001) and HMMs (Jia *et al*., 1998; Jia, Jia and Li, 2004; Luo, 2000a,b; Zhang, 2002, 2004) produced in China during 1990–2005 are summarized in Table 1.

Output changes of both soft (SMM) and hard magnets (HMM) made in China during 1990–2005 are shown in Figure 1. Outputs of both SMMs and HMMs have been increasing every year; the only difference is in their annual growth rate. The portion between them depends on the difference in their growth rate. The averaged output growth rate of SMMs and HMMs during 1990–2005 was +16.1 and +17.6% respectively, that is, the growth rate of HMMs was higher than that of SMMs. In 1990, the percentage of SMM/T was 28.8%; it reduced to 23.3% in 1998. Then it became 29% in 2003 and dropped to 22.8 in 2004. Generally speaking, the output of SMMs is one-fourth of the total.

The output percentage of SMMs and HMMs is around one-fourth and three-fourths of the total, respectively. The ratio between the sales value of SMMs and HMMs is around 50 to 50% all the time. The sales value

($\$ \times 10^6$) of SMMs and HMMs made in China during 1990–2005 is shown in Figure 2. The portion of SMMs was >50% during 1993–1996. It became <43% during 2003–2005.

Averaged sales prices of SMMs, HMMs, and the averaged price of TMMs are summarized in Figure 3.

General speaking, the price of SMMs is much higher than that of HMMs. Although the material and processing cost for different magnets is different, it is not the deciding factor for price. The key point is that most SMMs are sold as final products or devices, but hard magnets are sold as blocks. Consequently, all magnet producers have to provide devices

Table 1. Output (tons), sales value ($\$\times 10^6$), and averaged price ($/kg) of SMM, HMM, and total magnetic materials (TMMs) made in China (1990–2005).

SMM: soft magnetic material; HMM: hard magnetic material; TMM: total magnetic material; T: magnetic materials in total; **Δ**: annual growth rate (%).

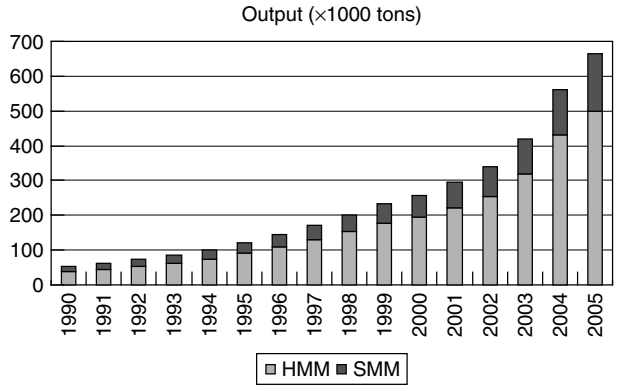

Figure 1. Output ($\times 10^3$ tons) of SMMs and HMMs made in China during 1990–2005.

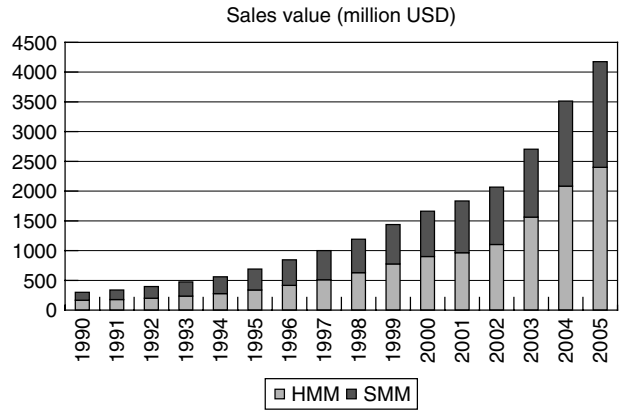

Figure 2. Sales value (million USD) of SMMs and HMMs made in China during 1990–2005.

or final products of high grade with precise tolerance to their customers to gain more added value, rather than gross blocks. This way, the needed profit can be guaranteed.

2 IMPORTANCE OF MAGNETIC MATERIALS IN MODERN COMMUNITY

Silicon-based semiconductors and magnetic materials are two of the cornerstones of the modern world economy. The importance of magnetic materials is obvious. Magnetic materials are widely used not only in computers, electronics, communication, transportation, automotives, aviation, and aerospace industries but they also penetrate into the daily lives of common people.

Whereas in the past the measure of the level of development of an industrialized country was its output of iron and steel, today this measure for a modern economy is the consumption of magnetic and other high-tech materials, since this more accurately reflects the standard of living of the citizens in each country.

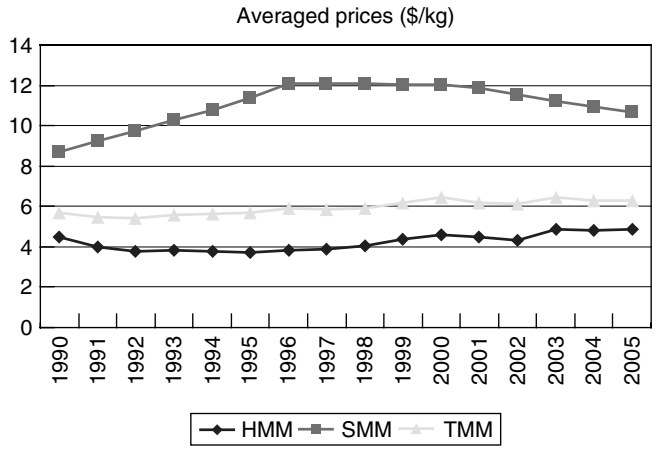

Figure 3. Averaged prices of SMMs, HMMs, and TMMs in China during 1990–2005.

In the early 1990s, the statistics showed that the consumption of magnetic materials per capita for developed countries such as the United States, Japan, and Europe was \$4.5/capita. In developing countries, such as India, this number is only \$0.25/capita, that is, 5.5% of that of developed countries. Per capita consumption in developed countries is 18 times higher than that in developing countries. The gap between developed and developing countries is so significant!

Owing to the policy of birth control, the annual growth rate of Chinese population has reduced from 2% in 1960s to less than 1% in the late 1980s. The average annual growth rate of population in China during the last 15 years since 1990 is 0.755%. The population in 2004 was 11.95% higher than that of 1990, that is, the net growth of population was 0.1398 billion. Obviously, the policy of birth control has helped in strengthening the national economy. While the annual growth rate of the sales value and per capita consumption of magnetic materials averaged was +17.85 and +14.89% respectively, the growth of both, the sales value and per capita consumption of magnetic materials, in 2004 was 11.75 and 8.06 times higher than that in 1990, respectively. The consumption value per capita in China in 1990 was \$0.217, which was only 87% of that in India. It became \$1.555 in 2004. The average annual growth rate of per capita consumption during 1990–2004 was +15.1%. On the basis of this measure, the living standard of China has improved almost seven times since 1990. This is the result of the national economic development, but the contribution of birth control policy should not be ignored. If there was no birth control and the population growth rate kept as high as 2% since 1970s, then 0.5–0.6 billion population would have been added to the current number, which is the denominator, and the per capita consumption as quotient would have been reduced by 50% or more! The situation in India will give the evidence of the importance of birth control as evidenced in another country, where the increased GDP is misappropriated by the growing population.

The population, sales value, domestic consumed value of magnetic materials (both hard and soft) made in China, and per capita consumption during 1990–2004 are listed in Table 2. The percentage of produced magnets consumed domestically is in brackets.

The average annual growth rate of population during 1990–2004 was 0.81%. It further reduced to 0.64% during 2000–2004. The average annual growth rate of the sales value of magnetic materials, its consumption domestically, and consumption per capita during the same period is +19.24, +16.034, and +15.1%, respectively. It is worth mentioning that the annual growth rate of consumption per capita since 1997–2002 was around +12.06%. In 2003 and 2004, it reached +27.8 and +26.9% respectively, which is much higher than the averaged growth rate of +15.1% during 1990–2004. The per capita consumption in 2004 reached \$1.555/capita, while it was \$0.959/capita in 2002. In other words, it has increased 62% during the last two years! The reason is obvious: sales value was significantly increased in 2003 and 2004: its annual growth rate was around +30% in 2003 and 2004, which is much higher than its averaged value of +19.24%.

The growth of consumption per capita in China during 1990–2004 is shown in Figure 4.

Population ($\times 10^9$), sales value ($\$ \times 10^9$), and domestic consumption ($\$ \times 10^9$) of magnetic materials during 1990–2004 is shown in Figure 5.

The growth rate of per capita consumption in developed countries will also continue to rise, although the growth rate will likely be quite low in comparison to that of China. If we assume a growth rate of +2% annually for developed countries (the actual annual growth rate is less then 2%), then the growth trend for developed countries will follow the dashed line in Figure 6.

It should be noted that the vertical coordinate axis in Figure 3 is logarithmic (log \$/capita), which generates a straight line under the assumption of constant growth rate. As shown in Figure 6, if the annual growth rate of per capita consumption for China averages 10, 8, or 7% instead of the current growth rate of +15%, then the logarithmic curve will cross the dashed line that represents the corresponding data for developed countries in 2021, 2028, and 2034, respectively. According to the last statistics published by the Chinese government, the annual GDP growth rate for China was 9.5% during 1985–2004. The annual economic growth rate for China will be kept around ~8% in the foreseeable future. Consequently, the gap between China and developed countries will be eliminated by 2040! In other words, the

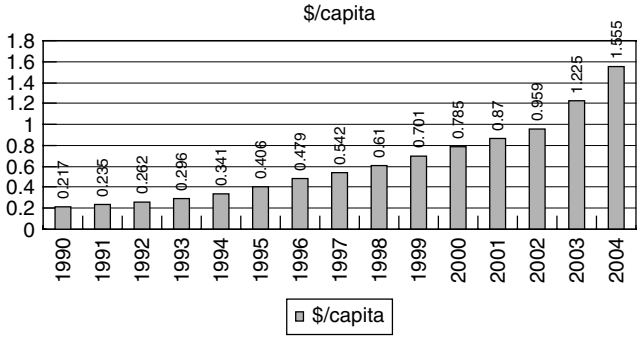

Figure 4. Per capita consumption value of magnetic materials in China (1990–2004).

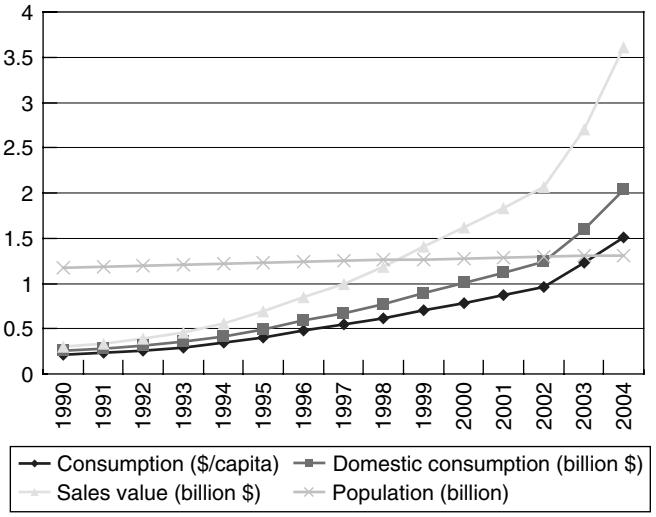

Figure 5. Population ($\times 10^9$), sales value ($\$ \times 10^9$), and domestic consumption ($\$ \times 10^9$), and consumption per capita ($/capita) of magnetic materials in China during 1990–2004.

living standard of China will be the same as that of developed countries by 2040.

A similar analysis was made by me in 2002. At that time, the cross with the dashed line representing developed countries was in 2025, 2033, and 2039, respectively. In

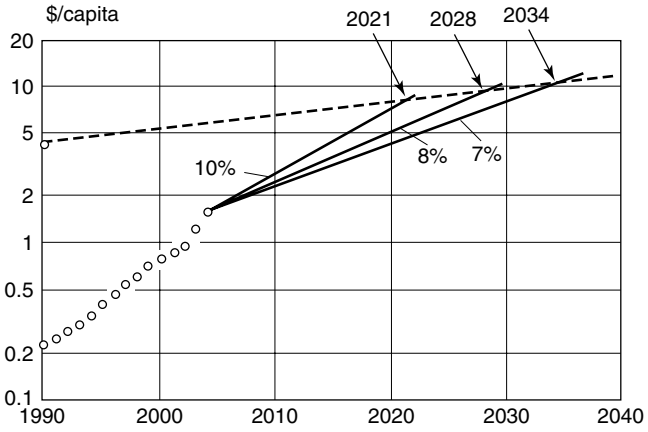

Figure 6. Changing trend of per capita consumption between China and developed countries.

fact, the time required to catch up with developed countries may be shortened by 4 years due to the unusual growth of consumption per capita during the last 2 years.

The per capita consumption value of \$1.555 means that the living standard of China has improved seven times in comparison with that in 1990; nevertheless, it is still only one-third of that of developed countries. Obviously, Chinese people still have a long way to go in order to eliminate the economic gap with developed countries completely.

The Communist Party of China announced in the 16th National Congress that within the first 20 years of the new century, a relatively comfortable life will be made possible for Chinese people, then it will take another 30 years to catch up with the developed countries in living standard. All data concerning the development of the magnet industry in China during the last decade since 1990 can be used as evidence for the reality and reasonability of such a plan.

3 SOFT MAGNETIC MATERIALS IN CHINA

All materials, which can be magnetized to saturation in a relatively low magnetic field, but lose high induction completely once the magnetic field is moved away, are called *soft magnetic materials*. Owing to historical reasons, types of magnetic materials are numerous and their branding names or grades are quite confusing. The International Electrotechnical Committee (IEC) worked on classification and technical terms of magnetic materials for many years and proposed a solution in 1973 (IEC, 1973), according to which magnetic materials are divided into two classes based on their coercive force and application: SMMs and HMMs. Each type of magnetic material can be further divided according to its nature, structural characteristics, and compositions. According to such classification, there are seven types of SMMs (Luo, 1991). Five of them are traditional metallic crystalline SMMs, namely, pure iron and low carbon steel, silicon steel, Fe–Ni (permalloy), Fe–Co, Fe–Al/Fe–Si–Al. The sixth one is nonmetallic SMM–SF. All the six SMMs mentioned earlier are crystalline materials. The final seventh type of SMMs developed in late 1960s are rapidly solidified (RS) amorphous or nanocrystalline (developed in 1980s).

Pure iron and low carbon steel and silicon steel are classified as electrotechnical steel traditionally, which are produced in mass scale and are not related to electronic materials. Thus, the traditional metallic SMMs only include Fe–Ni, Fe–Co, and Fe–Al/Fe–Si–Al alloys.

Current major commercial SMMs are SF and RS materials (Luo, 1995). As for the traditional metallic SMMs, there are Fe–Ni, Fe–Co, and Fe–Al/Fe–Si–Al alloys, which are mostly replaced either by SF or by amorphous/nanocrystalline materials, respectively. Anyway, the sales value of these metallic SMMs is a small part of the total. Consequently, SF and RS materials are solely discussed in the present paper. The traditional metallic SMMs have been ignored. Of course, this way the estimated total output and sales value of SMMs produced in China will be less than what it exactly is, but the tolerance will be less than 2% of the total.

3.1 Chinese soft ferrite industry

3.1.1 General situation

SF has developed from the study on spinel oxide started in 1947. Its permeability is high enough, the electric resistance is 10^4 times higher than that of metallic material; consequently, its power loss is much less and can be used at a higher frequency. Such materials have been commercialized since the 1950s. Now it is widely used in consumer electronics, such as radio, TV, audio, computer, and communication.

There are two groups of SF: $(Mn,Zn)Fe_3O_4$-based, that is, Mn–Zn ferrite; $(Ni,Zn)Fe_3O_4$-based, that is, Ni–Zn ferrite. The resistance of Mn–Zn ferrite $<10^2\,\Omega\,cm$, both permeability and magnetization is higher, it is used as an inductor, working at a frequency of $\sim$100 kHz. The resistance of Ni–Zn ferrite is as high as 10^4–$10^6\,\Omega\,cm$, so it can be used at higher frequencies of up to 100 kHz–100 MHz.

The production of SF in China started in the middle of 1950s. The products were of low grade, which were mainly used for radio. Both the process and the equipment were out of date. With the development of economy in China, the SF industry improved considerably. Significant progress was achieved in the 1990s, both quantitatively and qualitatively, which can be seen by the improvement in TVs,

PCs, and mobile phones made in China. The booming of the electronics sector and the involvement of foreign companies and investors has given much help in the development of the SF industry in China: TDK, FDK, Nippon-Ceramic Co., Ltd., Philips. Some companies from Taiwan have set up plants in main land either jointly or independently. The total output of SF in 2004 reached 120 000 tons. In 1980, it was 3500 tons only.

3.1.2 Current status

Producers of SF in China are estimated to be around 100. The output in 2003 was 90 000 tons, among which Mn–Zn ferrite was 60 000 tons, Ni–Zn ferrite was 25 000 tons, and the rest was about 5000 tons.

There are three types of producers: state owned, private, and foreign invested. The output of state-owned companies is 15 000 tons, which is 17% of the total; the output of private companies is 50 000 tons, that is, 55% of the total; the output of foreign-invested companies is 25 000 tons, that is, 28% of the total. The state-owned portion will be reduced, but the portion of both private- and foreign-invested companies will increase in the future.

The number, location, and production capacity of SF producers are listed in Table 3 (Chen, 2004).

The output (tons), sales value ($\$ \times 10^6$), and price ($/kg) of SF made in China during 1990–2005 are listed in Table 4.

Usually, the price of magnetic materials reduces with their output growth. However, SF seems to be an exception; its price increased continuously until 1996. The performance of products was much improved during this period. Moreover, SF is sold as devices or final products with complex shape and precise tolerance. It is quite different from HF, which is sold as gross blocks. In other words, the price of SF is

Table 3. Location, capacity (tons/year) of Chinese soft ferrite producers.

Δ: annual changing rate (%).

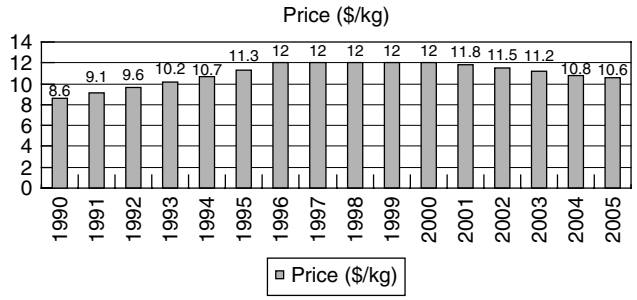

Figure 7. Price variation of soft ferrite made in China during 1990–2005.

not just the material cost, it includes partially added value for devices. Thus, the price of SF is much higher than that of HF. Starting from the new century, the promotion of the SF industry as a whole has stopped. The price has declined slightly since 2000. One can learn about this by comparison of prices of SF and HF. In order to get a higher price to guarantee the needed profit, magnet producers should make final products with high performance and higher tolerance, instead of gross blocks. Following this method, the magnet manufacturers in developed countries have been successful for years. The Chinese magnet manufacturers should also follow the same method.

The price change in SF made in China during 1990–2005 is shown in Figure 7.

The output ($\times 10^2$ tons) and sales value ($\$ \times 10^6$) of SF produced in China during 1990–2005 are shown in Figure 8.

The average annual growth rate of output and sales value of SF during the last decade was around +15.2 and +18% respectively. The growth rates of both have increased considerably during 2002–2005, which reached +28 and +25%. Curves of output and sales value are parallel in principle. The value curve exceeded the output curve due to the increase in price during 1990–1996, with an average annual growth rate of +5%. They became closer due to the reduction in price after 2000, with an average reducing rate of −2.5%.

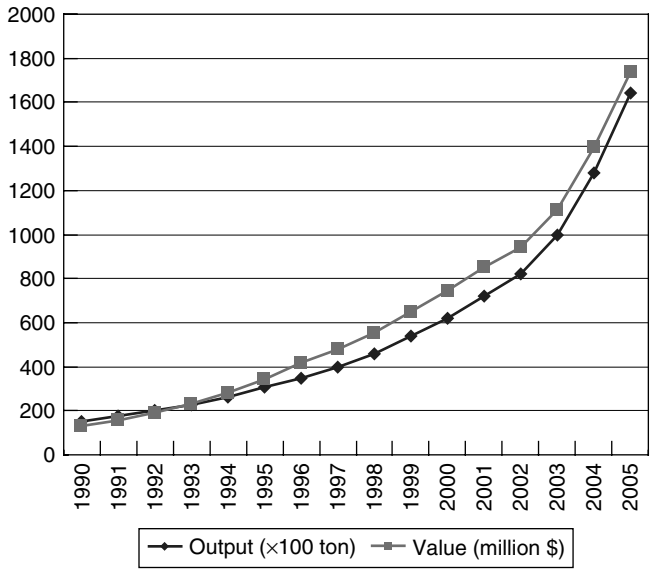

Figure 8. Output ($\times 10^2$ tons), sales value ($\$ \times 10^6$) of soft ferrite made in China.

3.2 Chinese rapidly solidified material industry

Rapidly solidification, RS, or rapidly quenching (RQ) is a technology that was developed in the late 1960s, cooling rates of which range from 10^2 to 10^{10} K s^{-1}. Many new materials with peculiar structures and excellent properties have been prepared by this technique. Structures of these materials ranged from microcrystalline (grain size of approx micrometers), nanocrystalline (grain size of approx micrometers) to amorphous (noncrystalline).

Research on amorphous metals and related RQ technology started in China in 1976, and has since spread to most universities and research institutes. From the 1980s, many metal plants have been involved in the commercialization of amorphous. As a result of R & D works, >100 grades of RS materials were developed, among which 28 grades are included in the Chinese National Standards. Different RS materials, including Fe-based (Fe ≥ 65 wt%), Co-based (Co ≥ 50 wt%), Ni-based (Ni ≥ 60 wt%), Fe–Ni-based (Fe + Ni ≥ 65 wt%), Fe–Co-based (Fe + Co ≥ 60 wt%), and Co–Ni-based (Co + Ni ≥ 60 wt%) amorphous materials have been developed and are commercially available in China now. Since both RS process and its products are quite different from the traditional metallurgy, rapidly solidification and RS materials are considered as a revolutionary development in the last century.

3.2.1 Historical review of the development of RS materials in China

In 1976, RS materials were first prepared in the laboratory. The historical development of RS materials in China is summarized as follows (Luo, 1995; Zhou and Lu, 1999; Zhou, 2001):

1976–1980, fundamental research: Studies on RQ or RS materials were started in 1967. They became quite popular in all universities and research institutes all over China in the 1970s and were commercialized in the 1980s. Some metallurgy plants were also involved in preparing RQ and RS materials. More than 100 grades RS materials were established. The commercialized RS materials included iron based (Fe > 65 wt%), cobalt based (Co > 50 wt%), nickel based (Ni > 60 wt%), iron–nickel based (Fe + Ni > 65 wt%), copper based (Cu > 70 wt%), and so on.

1981–1985, development of applied technology: In order to produce RS materials, much efforts have been made to develop the needed melt spinner or jet caster for the ribbon:

- Before 1982, jet caster with batch melt of several kilograms was developed.
- In 1983, jet caster with double ladles of 50 kg volume were developed and the width of the melt spun ribbon was 50 mm.
- In 1985, jet caster with three ladles of 50 kg capacity for each was developed and the width of melt spun ribbon was 100 mm.
- Development of 50 grades RS materials has been finished.
- Fe–Ni-based ribbon was successfully used to make induction cores for current leakage protectors. This development was invaluable for the rural area of China, where 85% of serious electric shock accidents occurred. Since Ni content in Fe–Ni amorphous ribbon is only half of that in permalloy, its price is also only half of that of permalloy. Consequently, the market demand for such materials sharply increased in the late 1980s. The success of Fe–Ni RS materials has promoted further development of production of RS materials in China. Its total output was around 10 tons in 1985.

1986–1990, building of the pilot-producing line of RS materials:

- In 1989, the melt spinner with three ladles of 100–200 kg volume was set up.
- On-line ribbon automatic catching/wounding mechanism was developed successfully.
- Fourteen sets of transformers (3–100 kVA) with amorphous ribbon cores were built and put into test.
- RS materials were used as welding material, catalyst, and construction fiber.
- Twenty-eight Stat Standards of RS materials were established and nine invention patents were issued.

1991–1995, starting pilot production of core devices:

- Pilot production of million pieces core was built up in 1993.
- c-type, r-type, o-type cores were prepared in mass scale for electronic transformer, choke, inductor, magnetic amplifier, and so on.
- Seventy-five sets of distribution transformers were built by using Fe-based RS ribbon and put into electricity net for test in comparison with that made by grain-oriented Si steel; the power loss under zero load was 60% lower. They worked stably, reliably, with lower temperature rising, and higher ability against overload.

1996–2000, further industrialization:

- In 1996, 'Engineering Center of Amorphous and Nanocrystalline Materials' was established in CISRI with the support of the Stat Science and Technology Committee.
- Producing line of Fe-based RS materials with annual output of 3000–5000 tons and an assembling line of transformer and cores was built. The ribbon width was 220 mm.

2001 – present, further development of RS industry:

The evolution of domestic melt spinner for melt spun ribbon is summarized in Table 5.

3.2.2 *Chinese amorphous and nanocrystalline materials*

RS has been included in the Stat Standard as commercial materials. The conventional RS materials are listed in the following tables as samples. Characteristics of FeCuM (M = Nb, Mo, Cr + V)SiB nanocrystalline soft magnetic alloys are listed in Table 6.

The characteristics of Fe–Ni-based, Fe-based, Co-based, and Co–Ni-based RS SMMs are listed in Tables 7–11 (Luo, 1995; Zhou and Lu, 1999; Zhou, 2001), respectively. Their major applications are also shown in these tables.

According to their nature, RS materials can be divided into two groups: SMMs and nonmagnetic materials. The nonmagnetic RS materials are used as welding, heating, and construction materials. They are also used in other minor applications, which are listed in Tables 12–14 as samples (Luo, 1995).

The SMMs include both crystalline (nanocrystalline) and noncrystalline (amorphous) materials. Amorphous or nanocrystalline materials are used for power transformers that work at several hundreds of hertz, pulse transformers, switch power sources, mutual inductors, and so on. But the main use of amorphous ribbons is for distribution power

Table 5. The evolution of melt spinner and ribbon width produced in China.

transformers working at an industrial frequency of 50–60 Hz. Output percentages of different types of RS materials made in China (1997) are shown in Figure 9. Fe–Ni-based and FeCuNbSiB are all SMMs, the former being mainly amorphous and the latter nanocrystalline. The rest are non-magnetic materials.

3.2.3 General situation of Chinese RS materials

The output (tons), sales value ($\$ \times 10^6$), and price ($/kg) of RS materials made in China during 1990–2005 are summarized in Table 15.

The annual changing rate $\Delta(\%)$ of related data is included in the Table 15. The sales price change of RS materials is shown in Figure 10.

The output of RS materials has been increasing continuously since 1990. The growth rate during the last decade has been around +20% annually. Accordingly, its price has been declining with an annual reducing rate of −5%. Now the price is only half of that of 10 years ago! The significant increase in price since 2003–2004 is the result of increase in price of raw materials. The output ($\times 10^2$ tons) and sales value ($\$ \times 10^6$) of RS materials made in China during 1990–2005 are summarized in Figure 11.

3.3 General status of Chinese soft magnets

The output (tons), sales value ($\$ \times 10^6$), and price ($/kg) of SF, RS materials, and SMMs in total (T) made in China during 1990–2005 are summarized in Table 16.

As mentioned earlier, there are two types of SMMs in China: SF and RS materials (amorphous and nanocrystalline). Also, there are some metallic soft magnetic alloys, which are very few in quantity; these have therefore been ignored in the present paper. The error in output and sales value should be less than 2% due to such ignorance.

The output of RS materials has been increasing continuously from 1% of the total in 1990 to 2.2% in 2003. This tendency would be the same in future, especially if Fe-based

ribbon is used as cores for distribution transformer. The output (tons) of both SF and RS materials made in China during 1990–2005 is shown in Figure 12.

Although the output of RS materials has been increasing continuously, its price has been reducing significantly; therefore, the percentage of its sales value is only 2% of the total. Sales value ($\$ \times 10^6$) of both SF and RS made in China during 1990–2005 are shown in Figure 13.

Prices of SF, RS materials, and averaged price for SMMs in total (averaged) made in China during 1990–2005 are shown in Figure 14.

Because of the improvement in performance, SF was sold as a final product and its price had been increasing slightly before 1997. In contrast, the price of RS materials had been declining continuously. The increase in the price in 2003–2004 was the result of the increase in price of raw materials. Since the portion of SF is about 98% of the total, the averaged price of soft magnets in total is almost the same as that of SF.

4 GENERAL STATUS OF HARD MAGNET INDUSTRY

The sales value ($\$ \times 10^9$) of SMMs, HMMs, and global TMMs during 1960–2010 is listed in Table 17.

Data of 1960–1990 are taken from (Luo, 1996), data of 2000 are actual, and the forecast of 2010 is based on actual data of 2002–2004. The annual average growth rate $\Delta(\%)$ is included in the same table. The data in the brackets are in percentage related to the total value.

Sales value of SMMs was higher than that of HMMs until the middle of 1990s. Since 1994, the sales value of hard magnets exceeded that of SMMs. It is worth noting that the averaged annual growth rate of TMMs during last 50 years has been around +6.1% (6.1075%). During the last 50 years, the average annual growth rates of SMMs and HMMs have been quite different: they have been around +3.8% (3.81248%) and +9.6% (9.5513%), respectively. Thus, every decade the value of SMM and HMM would increase 1.45 and 2.49 times, respectively. Such tendencies will continue. Consequently, the value of HMM has exceeded that of SMM since 1994. In 2010, the value of HMM is expected to be more than two times that of SMM. The change in the global sales value ($\$ \times 10^9$) of magnetic materials since 1960 is summarized in Figure 15. The changing trend of both SMMs and HMMs mentioned above can be seen clearly from Figure 15.

5 STRUCTURE CHANGE OF THE MAGNET INDUSTRY

There are four major commercially available magnets: Alnico developed in the late 1930s; HF developed in the early 1950s; first and second generation of rare-earth magnets: $SmCo_5$ (1968) and Sm_2Co_{17} (late 1970s); and third generation of rare-earth magnet developed in 1983–NdFeB.

The global output T (tons), sales price P (\$/kg), and sales value V ($\$ \times 10^9$) of Alnico, ferrite, SmCo, and NdFeB magnets since 1985–2010 are listed in Table 18. The sales values V ($\$ \times 10^9$) of each type of magnets during 1985–2010 are shown in Figure 16.

As seen in Figure 16, the value of HF is more than half of the total until 1999; till then it was the majority of the magnet market. Starting from 2000, the value of rare-earth magnet (NdFeB + SmCo) exceeded that of HF. Such tendencies would continue in the foreseeable future; consequently, rare-earth magnets would certainly be the majority of magnets sold in the twenty-first century.

Both performance and price of each type of magnets are rather different. However, we cannot evaluate each type of magnets solely by its performance or its price. The energy stored in unit volume of magnet–energy product E (kJ m^{-3})–is an important parameter in characterizing a magnet. The price of unit energy stored in a magnet is called *price performance* W (\$/J) of such magnet. The price performance W (\$/J) can be expressed by following formula:

$$W = \frac{P\rho}{E} \tag{1}$$

Where W is the price performance (\$/J), P is the price (\$/tons), ρ is the density (tons m^{-3}), and E is the energy product (kJ m^{-3}) of the magnet.

The price performance of different magnets is listed in Table 19. The densities of magnets are also included in the same table.

The market share of certain magnets could not be evaluated by its tonnage output (T) solely, but could be evaluated by the energy stored in such magnets (J). If energy stored in all magnets in total globally is J_{tot}, then J/J_{tot} (%) will be the market share of such magnets. Energy stored in a certain magnet J is expressed by the following formula:

$$J = \frac{TE}{\rho} \tag{2}$$

Where J is the total energy stored (joule), T is the tonnage output (tons), E is the energy product (kJ m^{-3}), and ρ is the density (tons m^{-3}) of the magnet.

Market shares of different magnets during 1985–2010 are listed in Table 20.

Data for 1985, 1990, and 1995 in Table 20 were referred from (Luo, 1997), the data of 2005 and 2010 are estimated on the actual data of 2002–2004.

The structure change of the global magnet market (1985–2010) is summarized in Figure 17.

Table 13. The composition (%) and applications of Ni-based and Cu-based welding materials.

Composition (at%)	T_m (°C)	T_w (°C)	σ (Mpa)	T_{work} (°C)	ρ (10^{-7} Ω-m)	Major application
$Ni_{79.5-85.5}Cr_{6-8}B_{2.75-3.5}$ $Si_{4-5}Fe_{2-4}C_{0.1-0.2}$	960–990	1040–1100	137–156	<850	8.7	Welding stainless steel and supper alloy
$Cu_{77-88}Si_{10-20}Ni_{2-3}$	830–870	900–920	205–402	<850	8.7	Welding steel/steel and steel/Cu to replace Ag-based material
$Cu_{75-79}Ni_{5-15}Si_{4-12}P_{5-10}$	560–640	700–750	98–137	<850	8.7	For welding Cu/Cu, Cu/Ag–Cd, Cu/Ag to replace Ag foil
$Cu_{80-90}Ag_{8-12}Si_{1-3}P_{2-4}$	560–640	700–750	98–137	<850	8.7	To replace Ag-based welding material

T_m: melting point; T_w: welding temperature; T_{work}: working temperature; σ: shear strength in welding area.

Table 14. Fe-based RS metallic fiber and its application.

Composition (at%)	Scale (mm)	T_{work} (°C)	η (10^{-6}/°C)	T_m (°C)	ρ (g cm^3)	Application
$Fe_{30-60}Ni_{20-40}$(Cr, Si,Mn)$_{15-30}$	Φ0.4–0.6 Length 20–35	1000–1350	17.64–18.54	1380–1420	7.72	To strengthen furnace body

η: lineal expansion coefficient.

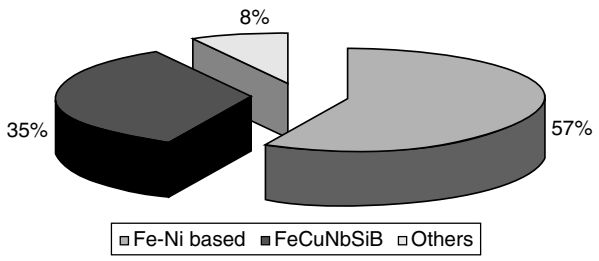

Figure 9. Output distribution of different RS materials made in China (1997).

Both vertical and horizontal coordinate axes in Figure 17 are given in logarithm because the changes in both market share J/J_{tot} and price performance W (\$/J) have covered quite big ranges: from 0.003 to 0.916 for J/J_{tot} (%) and from 0.8 to 11.4 for W (\$/J).

The market share of SmCo was 2% in 1985. Owing to strong competition from NdFeB, the market share of SmCo declined significantly since the middle of 1980s: it reduced to 1.54 and 1% in 1990 and 1995 respectively. As a result of significant reduction in the cost of both Co and Sm since 1995, the market share of SmCo has increased gradually in recent years; it was 1.1 and 1.4% in 2000 and 2005 and it will be 1.2% in 2010.

The price performance of SmCo magnet was the highest among all others: it was \$11.4/J in 1985, it reduced to \$4.7/J in 2000, and it will be \$3.2/J in 2010. It has reduced 3.5 times in comparison with that in 1985.

Market shares of different magnets changed considerably during 1985–2010: Positions of all traditional magnets, such as Alnico, HF, and SmCo are moving from upper right down toward lower left. NdFeB goes exactly in the opposite direction: moving from lower right toward upper left. Obviously, NdFeB is just like a gradually rising sun in the new century! The market share of ferrite, Alnico, and SmCo in 1985 was 91.6, 6.06, and 2.04% respectively. NdFeBs market share in 1985 was a negligible 0.3%! It has jumped to 5% in 1990, which has exceeded that of Alnico and SmCo in the same year. The market share of NdFeB was 12 and 22% in 1995 and 2000 respectively and it will be 32.8 and 47.5% in 2005 and 2010 respectively.

Alnico magnet had the majority share of the global magnet market before 1970. Since then, the market share of Alnico has been declining steadily. It dropped from 6% in 1985 to 1.8% in 2000 and it will be 0.4% or less in 2010! HF has the current majority share of the magnet market. Owing to the competition from NdFeB, its price performance has reduced gradually: It was \$0.94/J in 1985, it became \$0.96/J since the late 1980s until late 1990s due to performance improvement, then it dropped to \$0.9/J in 2000 and it will be \$0.8/J in 2010. The market share of ferrite is also shrinking: it was 91.6, 89, 84, and 75 in 1985, 1990, 1995, and 2000 respectively. It will drop to 51% by 2010.

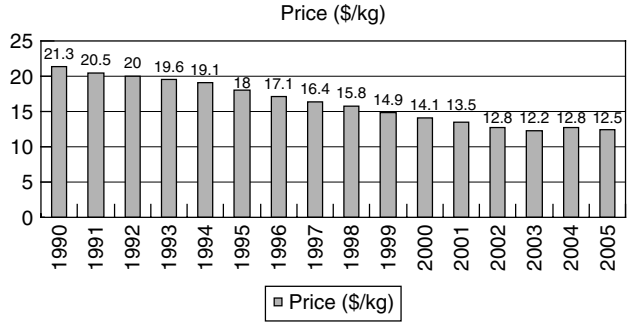

Figure 10. Price change of RS materials made in China during (1990–2005).

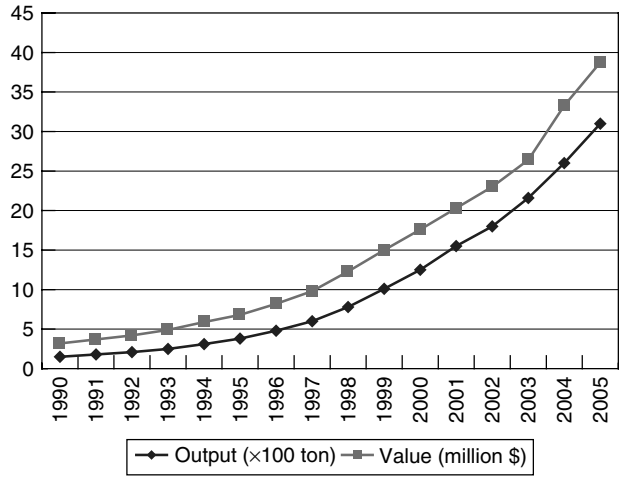

Figure 11. Output ($\times 10^2$ tons) and sales value ($\$ \times 10^6$) of RS materials made in China during (1990–2005).

The price performance of ferrite is the lowest among all magnets. It will be $0.8/J in 2010. The price performance of NdFeB was $5.83/J in 1985. It is estimated to be $1.73/J in 2010, that is, it is 2.1 times that of ferrite. In 2010, the price performance of SmCo and Alnico will be $3.23/J and $3.39/J respectively, that is, it will be 4 and 4.2 times that of ferrite.

6 GLOBAL MAGNET INDUSTRY CENTER SHIFTING

Magnets as functional materials and their development and applications are closely related to both fundamental research and booming of modern industry. Generally speaking, if half of the global total output of magnets is produced in a certain country or area, and where the research activity on magnetic materials is rather dynamic, then this country or area would become the 'Center of Global Magnet Industry'. Europe was such a center before World War II. After World War II, the Center of Global Magnet Industry shifted to the United States. Since late 1960s of last century, this center has shifted to Japan. With the beginning of the new century, the Center of Global Magnet Industry has finally shifted to China, which is evidenced by outputs of different types of magnets produced in China.

It is worth mentioning that China has a long history and tradition on magnetism and magnetic materials and their applications. There are many engineers and technicians working in the fields of magnetism and magnetic materials. Statistics showed that more than 1000 students graduated from the department of universities related to

magnetism annually. Many conferences concerning magnetism and magnetic materials are held in China every year. All of these promote the Chinese magnet industry. Tonnage outputs of magnets made in different countries in 2004 are summarized in Table 21. Distributions of NdFeB, ferrite, and Alnico magnet outputs in 2004 in different countries are summarized in Figures 18–20, respectively.

In short, outputs of different magnets made in China are the highest in the world since the beginning of the new

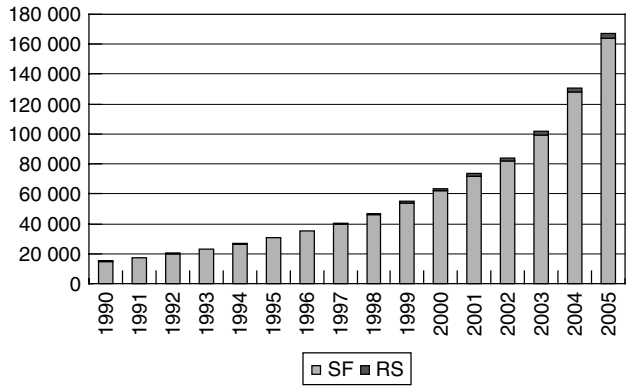

Figure 12. Output (tons) of both SF and RS materials made in China during 1990–2005.

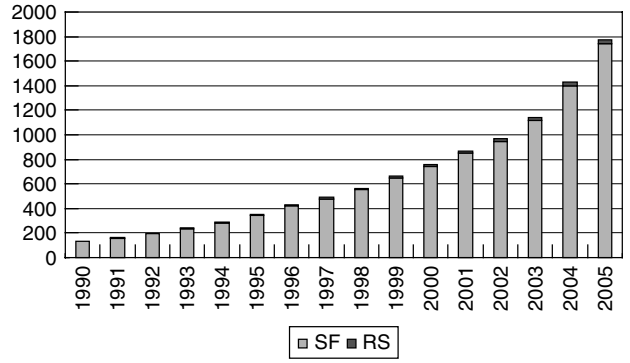

Figure 13. Sales value ($\$ \times 10^6$) of both SF and RS made in China during 1990–2005.

century. The position of China in the global magnet market will be further strengthened in the future. Discussing the position of China in the global magnet market and the future trend someone with breadth of vision in the West said that 'China would be the center of the global magnet industry in the twenty-first century. Owing to her abundant natural resources, wide territory, large population, and huge domestic market, China would keep such a position much longer than Europe, The United States of America and Japan did!' (Port Wheeler, private communication, May, 2002).

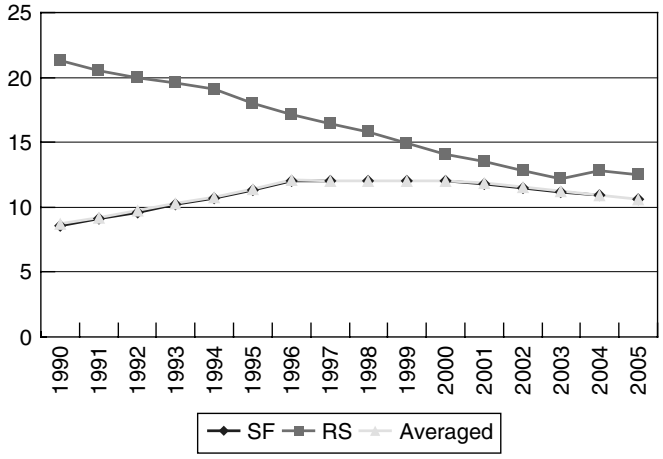

Figure 14. Price ($/kg) of SF, RS, and soft magnet in total (averaged) made in China.

Along with providing the majority of produced magnets, the Global Center of the Magnet Industry should provide magnets that are cheaper and better to all customers globally. On the basis of the abundant natural resources, huge manpower, and excellent expertise, China will surely be able to play the role of Global Center in the twenty-first century.

In view of the fact that China becomes the Center of Global Magnet Industry, there are two opinions: one is rather pessimistic, the other is quite optimistic.

The pessimist asked: 'As NdFeB magnets are so important, and are used in all high tech applications, including IT, computer, and consumer electronics, then it is hard to understand why USA and Europe agreed to stop their NdFeB magnet production?' They strongly suggested 'Do not shift all production lines to China, at least you have to keep the most advanced one for your own country!' They are afraid that China will have a monopoly in this area just as someone else has had in the past. Of course, monopoly is not good for the healthy development of the magnet industry.

The optimist said: 'Now the economy globalization becomes reality, where can make magnets better and cheaper,

then we have to shift all production activities there, it is natural and no one should complain. In fact, we have to thank China, without her contribution who can imagine that the price of sintered NdFeB magnets would drop from \$350/kg in 1983 to \$60–70/kg. Without significant price dropping of magnets, the popularization of magnet application is impossible.' I believe that the latter opinion reflects the truth and fact more than the former.

There are a lot of samples to show whether a business can be kept only due to 'strategy reason' or not. The rare-earth deposit in Mountain Pass, California, USA kept its pivotal position in the world market before the rising of the Chinese rare-earth industry until 1980s. In the late 1980s and early 1990s, there was a certain possibility for Molycorp to cooperate with China in rare-earth business in some way. But it was stopped due to 'national security', when it was clear that the mining in Mountain Pass only lost money in early 1990s. Again, it was forced to continue this business only because of 'strategic consideration'. Unfortunately, in a duration of 5 years, no single 'patriot' could be found in the United States who was willing to buy the expensive rare earth from Molycorp and refused to use rare earth from China. Finally, mining in Mountain Pass was closed in 1997. This is the result of market economy!

7 HARD MAGNET INDUSTRY IN CHINA

All materials, which can be magnetized in a magnetic field, are called *magnetic materials*. The magnetization of HMM can be kept without a magnetic field. There are three commercially available magnets: Alnico, HF, and rare-earth magnets (SmCo, NdFeB etc.). Along with fully dense sintered magnets (S), bonded magnets (B) are also being developed. Bonded ferrite magnets are the majority at the current time, but bonded NdFeB magnets are also developing rather fast. The data for bonded NdFeB(B) magnets is in two parts: Chinese domestic company made, the production of which was started from 1993, and the output of foreign joint venture companies (started from 1996). The details are discussed later. There are bonded SmCo and Alnico magnets as well, but they are very few.

The output (tons), sales value ($\$ \times 10^6$), and price (\$/kg) of different type of hard magnets made in China during 1990–2005 are summarized in Table 22.

With the development of the economy in China, her magnet industry has developed considerably since the late 1980s. Owing to excellent scientists and engineers, R & D on magnets is rather popular here. Moreover, China herself is a huge market, which absorbs all kind of magnets, from Alnico, ferrite to highest grade of SmCo and NdFeB.

8 ALNICO MAGNET INDUSTRY IN CHINA

In 1932, 25Ni10Al–Fe was discovered by Mishima in Japan (Luo, 1991). On the basis of Fe–Ni–Al, Alnico was developed. It was an Fe-based alloy, which later became a major commercial magnet in the early 1940s, especially after Neel's important work of annealing in the magnetic field (1947), which changed Alnico from an isotropic magnet to an anisotropic one. Consequently, its magnetic properties have improved considerably. Alnico magnets developed significantly in 1950s and 1960s, and their global production reached the peak value of 40 000 tons in the late 1960s.

AlNi permanent magnet was first made in Shanghai, China in 1947. Chinese Alnico magnet industry developed rather late in comparison with developed countries. However, based on inexpensive labor cost, excellent expertise, and huge domestic market, Alnico magnet industry in China developed rather fast, The total output of Alnico in China was around 1000 tons annually in 1960s. It was more than 2000 tons annually during 1970s and 1980s. The number of Alnico manufacturers was around 70. During the last decade, numerous small Alnico manufacturers were consolidated into a few big ones. Now China is at the top in the world in the production of Alnico. Although there is very serious competition from different types of magnets, such as ferrite and rare-earth magnets, due to its excellent thermal stability, Alnico is still widely used for meters (watt-hour meter, voltmeter, ampere meter, mileage meter), acoustic devices, motors, and sensors used for automobiles and motorcycles.

8.1 Current status of Alnico magnet industry in China

With the fast development of ferrite and rare-earth magnets in China during the last decade, Alnico had serious competition from them. HF took most low-cost market shares, and rare-earth magnets took market shares of high-performance products. Fortunately, Alnico kept its position in the market

due to its excellent magnetic performance. Its absolute output tonnage has increased slightly, although its output percentage has significantly reduced.

The thermal stability of different magnets is compared in Table 23.

The price of Alnico is reducing steadily. The rate of reduction in price of Alnico was quite high before 1995 ($\geq$10%), mainly due to the reduction in the cost of cobalt. The price stabilized after 1995.

The output of Alnico was almost around 2000 tons annually from 1990 until 1998. The output of Alnico increased to 3000 tons till 1999, after which it was around the same level, probably until 2005. The biggest application of produced Alnico is in the watt-hour meter. In order to save electricity, a policy of '1 Wh m for each family' was started by the Chinese government in 1998. Obviously, this policy, in fact, gave big support to the Chinese Alnico magnet industry. The Alnico output growth of 40% since 1999–2002 is the direct result of this!

The sales value of Alnico dropped significantly from $\$79.2 \times 10^6$ (1990) to $\$41.4 \times 10^6$ (1995). It was almost half of that of 1990. During the same period of time, its price dropped from \$36/kg to \$20.2/kg. The output was kept the same at around 2000 tons annually. The growth of sales value during 1998–2005 is the result of the output growth during the same period of time, because the price was kept almost the same at \$20/kg. The significant growth of sales value in 2003–2004 was mainly due to rise in both output and price, especially the increase in the price of Co.

The output ($\times$100 tons), sales value ($\$ \times 10^6$), and price (\$/kg) of Alnico made in China during 1990–2005 are shown in Figure 21.

The price of Alnico magnets declined from \$36/kg in 1990 to \$20/kg in 1998 with average annual reducing rate

of −7.63%. The price reduced slowly from $20/kg in 1998 to $19.1 in 2003 with an annual reducing rate of −0.9% (0.92513). The price was increased to $/20/kg in 2004 due to the increase in the price of raw materials in 2004. The sales value variation is similar to that of the output.

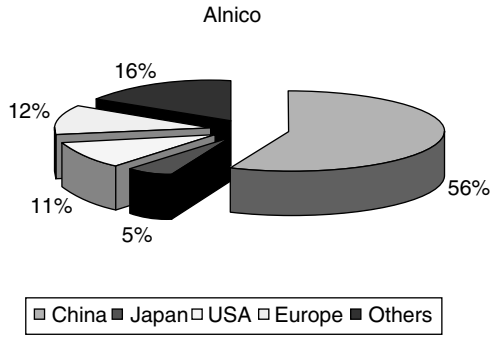

Figure 20. Distribution of global output of Alnico magnets in 2004.

8.2 Global output of Alnico magnets

The output of Alnico in Japan was 8300 tons in 1970. It reduced to 3400 tons in 1980, it became less than 2000 tons in 1990, and was only 1100 tons in 2000. The situation in the United States and Europe is similar to that in Japan. The output of Alnico magnets from 1994 to 2005 in Japan, the United States, Europe, China, others, and the global total is listed in Table 24.

The Alnico output variation in China, Japan, the United States, Europe, others, and the global total is summarized in Figure 22.

As seen in Figure 22, the output of Alnico magnets in all developed countries has been decreasing steadily during 1994–2005. China is the only exception, whose output is at the same level and has even shown certain growth during the same period. So it is follows that increase in total global output of Alnico is the same as the output of China.

The electricity system in urban areas of China was very old. Most of them were built in 1920s or 1930s of the last century, that is, before World War II. They have long been out of date and should be reconstructed immediately. Moreover, with the development of the national economy, a project of 'rural electrification' started in the middle of the 1990s. In order to save electricity, a policy of '1 Wh m for each family' was started by the Chinese government in 1998. This project concerns a population of around one billion and covers 90% territory of China. This project would last more than one decade. One can image how big the demand for magnetic materials will be in order to realize such a project as the biggest application of produced Alnico is watt-hour meter. Obviously, this project in fact provides an opportunity for the further development of the Chinese magnet industry,

including the Alnico industry. The Alnico output growth of 40% since 1999–2005 is the direct result of this!

9 HARD FERRITE INDUSTRY IN CHINA

HF, developed in the early 1950s, became major commercially available magnets in the 1960s. Their sales value exceeded that of Alnico in the early 1980s. In spite of competition from rare-earth magnets, the global output growth of HF was around +5% annually. The production of HF in developed countries becomes very difficult due to the increase in the cost of production. Now, the HF output in developed countries is only one-sixth of the global total.

Table 25. Content comparison of powder made from iron scales and oxide.

9.1 Raw materials of hard ferrite

Iron oxide has been long and widely used as a raw material for HF by major magnet manufacturers in the world. The advantage of iron oxide lies in its constant and pure chemical composition. Unfortunately, China does not have iron oxide in abundance. All the iron oxide available in China is used only for steel making. Thus, instead of iron oxide, China has to use iron scales to make HF magnets, which are waste that come from hot rolling during steel making. Steel output of China in 2004 was 270 million tons, which exceeded that of the United States and Japan put together. Obviously, China has enough iron scales to meet the increasing demand of the HF industry. Iron scales are abundant and stably available in China with a very low price.

There are at least two problems in using iron scale as raw material. First, chemical composition of iron scale is unstable and fluctuates from batch to batch, because materials processed during hot rolling always vary. Secondly, the oxidation of iron during hot rolling process is not uniform with high content of Fe_3O_4 and FeO. It took more than 20 years' R & D work by Chinese researchers and engineers to solve many theoretical and practical problems they faced while using iron scale as raw material for making HF. A unique technology of using iron scale to replace iron oxide has been developed by the Beijing General Research Institute of Metallurgy Mining (BGRIMM) successfully (Bian and Li, 2001). This process has already been put to use for mass production in China. Owing to replacement of iron oxide by iron scale, the material cost is reduced by at least one-third.

BGRIMM is the biggest producer of presintering powder of ferrite in China. BGRIMM develops most advanced kilns and its operation is fully controlled by computers. It has an annual yield capacity of 8000 tons per set. Ten kilns were built in Beijing at BGRIMM's base. Such equipment and technology has now spread to different parts of China. The composition of presintered powder produced by BGRIMM and products made by other process are compared in Table 25.

With the development of the metallurgy industry in China, more and more iron oxide made from steel plants is available. The location distribution of presintered powder makers in China is listed in Table 26. The number of BGRIMM's kiln and output of powder made by such kiln is shown in brackets in this table.

9.2 Brief review on the global sintered ferrite industry

With global economic development, the demand for magnetic materials is increasing simultaneously. The price of magnets is declining all the time. The developed countries are finding it difficult to continue the production of ferrite due to low profit margins. Thus, the shifting of the production line

Table 26. Location distribution of presintered powder makers in China.

2002	190	114 (60)	47 500 (25)	28 500 (15)
2003	200	120 (60)	50 000 (25)	30 000 (15)

to developing countries started in the 1980s. The output of HF in developed countries reached its peak value in early 1980s. Before 1985, the average annual growth rate >40%, in 1985–1990, the average annual growth rate was around 4–10%, after 1990, the average annual growth rate became negative to: −1 to −8%. Outputs of HF made in Japan, the United States, and Europe in total were only one-sixth of the global total in 2004. Total outputs in developing countries, such as China, India, and SEA are five-sixth of the global total.

The growth of global total output of HF has continued due to the increase in the global market demand. The average annual growth rate of global output of HF is more than 5%. This growth will continue in the twenty-first century.

9.2.1 Application of sintered hard ferrite

Applications of HF are quite different in different countries. There are three applications in China: acoustics (rings), motor (segments), and holding instruments (including magnet separator). The volume of used magnets for each application is changing; these are listed in Table 27 and summarized in Figure 23. Only one portion is used for application in a motor, which is expanding among other applications. Portions for acoustics and holding instrument have reduced.

9.3 Bonded ferrite magnets

Owing to the demand of refrigerator door sealing, TV tube focusing, and so on, bonded ferrite magnet was developed in the United States and Europe by mixing magnetic powder with polymer binder in the 1960s. Such bonded magnets are called *LEEP*. Later, bonded magnets with higher

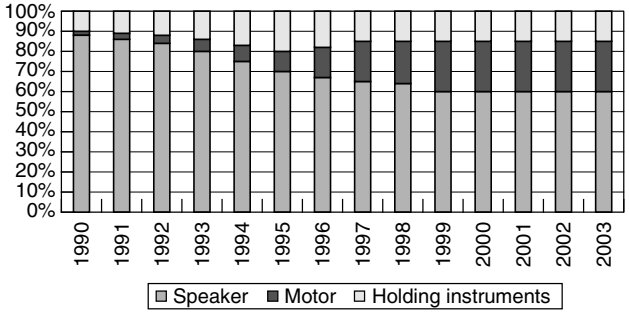

Figure 23. Percentages of hard ferrite output for different applications.

performance were developed and were called *HEEP*. On the basis of their applications and magnetic performances, Japanese bonded magnet producers divided such magnets into two groups: flexible and rigid. We follow this classification in the present paper. With the development of the electronic industry, the bonded magnet industry in China has improved considerably since the late 1980s.

9.3.1 General review on global bonded ferrite magnets

With the increase in the cost of producing bonded ferrite magnets, the industry has shifted from developed countries to developing countries including China, similar to the industries for producing other types of magnets. The use of bonded magnets in each country is different; therefore, the direction in which they develop is definitely different. For example, LEEP in Europe is mainly used as sound-damping materials for the automotive industry, in the United States, LEEP is used for advertisements, and, in Japan, it is used for medicinal purposes.

The output (tons), sales value ($\$ \times 10^6$), price ($/kg) of bonded ferrite magnets produced in China, Japan, the United States, Europe, SEA, and others during 1995–2005 are listed in Table 28. Data, except for China, are mainly taken from the publication by JABM and from discussion at the meeting of the JABM Marketing Committee (Tokyo, Japan, December 2, 2004) (JABM, 2004).

9.3.2 Bonded ferrite magnet industry in China

In the 1970s, injection equipment and technology were imported to China to produce bonded isotropic magnets mainly used for refrigerator seals and adjusting the core magnet plate for the TV tube. Since then, the producing technology, inspecting, and magnetizing equipment have been improving continuously during the 1980s. Almost 70% bonded ferrite is isotropic, whose energy products are 0.7–1 MGOe. The anisotropic bonded ferrite with energy products around 1.4–1.6 MGOe is less then 30% of the total. The forming process of anisotropic bonded ferrite requires an orientation field, which is rather expensive in comparison with that of the isotropic one. Moreover, the anisotropic magnet is used for the micromotor, which requires a magnet with special shape and precise tolerance; therefore, the price of the anisotropic bonded ferrite is much higher than that of the isotropic one. In the early 1990s, with further development of the electronic industry in China, the demand for higher-grade bonded ferrite magnets became more urgent. Such magnets require more qualified powder, which had to be imported into China in the early 1990s.

In order to solve this problem, BGRIMM developed a special grade of powder to meet the demand of bonded ferrite magnets. Now BGRIMM is able to provide powder for bonded ferrite. The specifications of the powder for bonded ferrite made by BGRIMM are listed in Table 29.

With the development of bonded ferrite magnet industry, a lot of new advanced technology and equipment has been imported into China recently. These include injection machines with orientation magnet field and automatic press with magnet field for warm compressing. Magnets prepared by calendering, rolling, and extruding have also been introduced. In order to get some idea on the price of bonded ferrite magnets, the average prices of bonded ferrite in the China market are summarized in Table 30 and are shown in Figure 24.

Preparing rigid bonded ferrite magnets in China started in 1993. Its price reduced with growth in output. Especially, its price reduced due to the replacement of the imported powder by the domestic one. The price has been stable since 2001, with improvement in the producing process. The totally averaged price of bonded ferrite magnets is the average of both flexible and rigid magnets.

10 SINTERED NdFeB PRODUCERS IN THE UNITED STATES, EUROPE, AND JAPAN

In the United States, there were three (3) NdFeB magnet producers before 1997:

Hitachi Magnets (USA): In the early 1970s, Hitachi Metals acquired former General Electric (GE) hard ferrite plant in Edmore, MI, USA. Then it expanded to China Grove, NC, where NdFeB were partly made.
CRUMAX (VAC): This was an old local magnet producer in the middle of 1990s. It was owned by YBM, it was sold to Morgan Crucible (UK) and was managed by VAC in 1999. It was fully closed in 2003.
UGIMAG (MQI): Indiana Technology was the first sintered NdFeB magnet producer in the United States. It was sold to UGIMAG in 1992, and then it was resold to MQI in 2000. Recently, its production activity has been transferred to China.

The ownership of the last two companies has changed quite frequently; nevertheless, none of them could avoid the stopping of magnet production. In fact, they had already announced the closure of their production activities in the United States by the end of 2003.

In Europe, there were four (4) sintered NdFeB magnet manufacturers:

Philips Components (UK): The production activity of this company stopped in middle of the 1990s.
VAC (Germany): The biggest producer in Europe – VAC – was sold to Morgan Crucible in 1999, and then it made a joint venture with the Chinese magnet producer, Sanhuan, in 2004.
Magnetfabrik Schramberg (Germany): This company is still working with a small output.
REOREM (Finland): This company is still working with a small output.

In Japan, there were 'five and half' (5.5) NdFeB magnet manufacturers:

Sumitomo Special Metals Co. (SSMC)
Hitachi Metals Co., Ltd. (HML)
Shin-Etsu Chemical Co.
TDK
Dowa Mining Co.: Dowa had to stop its NdFeB production in 2002 due to a sharp reduction in the sales price in the market. Dowa got the license from SSMC in the same year.
Toking Co.: Located in Sendai, Japan, it produces all kinds of magnets, including Alnico, hard ferrite, Sm-Co and NdFeB magnets, but due to patent restriction this company stopped NdFeB magnet production in early 1990s. So this company can be considered as a "half NdFeB magnet producer" solely, but not a real one.

It was announced jointly by HML and SSMC on December 18, 2003 (Jia *et al*., 1998; Jia, Jia and Li, 2004) that both companies will join together to establish a new company – 'NEOMAX Co. Ltd'. It was informed that NEOMAX is running quite well and its high-grade magnets meet the demands of newly developed applications, such as automotive motor, VCM for HDD less than 1 in., lift, and so on.

The others have had to slow down their production due to the impact from China. In order to reduce the price pressure, they are now focusing on assembling or devices making, instead of magnet production solely. Shin-Etsu Co. is in a better financial situation among all others, because it imports very cheap rare-earth concentrates from China, instead of rare-earth metal. After separation, the highly purified single rare-earth oxides can be sold in the international market at a rather high price. Shin-Etsu uses Nd oxide as starting materials to prepare Nd metal and then to make NdFeB magnets. Obviously, in this way, Shin-Etsu is in a better position than other Japanese magnet producers to compensate the reduction in magnet price.

11 OUTPUT, PRICE, AND SALES VALUE OF NdFeB MAGNETS

The output of sintered NdFeB magnets in Japan, the United States, Europe, and China during 1987–2000 was presented in my report (Luo, 2000c) at the 16th International Workshop on REM held in Sendai, Japan (September 2000). Data for China and Japan are more accurate because associations of the magnet industry in these countries publish relatively good data annually. Although there is an Association of Magnet Manufacturers in the United States, the data published by this association are definitely incomplete because some major magnet producers are not members. It is even more difficult to get data for Europe. Many participants from different countries were interested in these data and we had many interesting and important discussions during the conference.

Some Japanese experts told me that the published production of sintered NdFeB magnets in Japan is always underestimated by around 20–30% due to a number of reasons, particularly the reluctance of certain companies to provide their actual production. These experts made their estimate based on data given by master alloy producers. According to the opinion of experts from the United States and Europe, the outputs in the United States and Europe are actually 20–30% less than what is given in my table. This is because the ownership of magnet companies in the United States and Europe has changed quite frequently in last few years, thus their sales have dropped significantly and the data in my table are out of date. As for NdFeB production in China, usually they are related to blocks but not final magnets. In order to make consistency with data for other countries, data for China would have to be converted to final products, that is, the data should be reduced by 20–30% as well.

On the basis of these inputs, the tonnage outputs (tons), sales value ($\$ \times 10^8$), and price ($/kg) of sintered NdFeB magnets made in China, Japan, the United States, and Europe during 1995–2004 are reestimated and listed in Table 31.

Owing to the increased production cost in developed countries and the sharp decrease in the sales price of magnets in the international market, it will be rather difficult to continue magnet production in these countries. Consequently, the growth of production in these countries will also be rather difficult in future. The annual growth rate of the global total output of sintered NdFeB was more than +20% until 2000, it became negative in 2001 (−6%), and it again became positive after 2002 ($\geq +10\%$).

The output changes of sintered NdFeB magnet made in China, Japan, the United States, and Europe since 1995 are summarized in Figure 25. The curve with triangles in Figure 25 is related to data given by JEMA for Japan, which is −20% lower, as mentioned before. According to the data given by JEMA, the output of China exceeds that of Japan in 2000, but not in 2001. The outstanding feature in Figure 25 is the big jump in the output by China after 2002, since production in both the United States and Europe has almost stopped and 80% of global output is now concentrated in China!

The year 2001 was a 'nightmare' for global magnet industries. Owing to the global economic recession, business for both IT and computer industries was very bad. Both IT and computer industries are major customers of NdFeB magnets; consequently, the purchase of magnets dropped sharply in 2001. Statistics showed that in 2001 the output of sintered NdFeB magnets in Japan was 20% lower in comparison with that of 2000 and the sales value dropped by 36%! The situation in the United States and Europe was similar: their outputs dropped by 28 and 18%, respectively. China is the only exception in the world, where the output growth of NdFeB is continuing, although its growth rate was much reduced, from +33% (2000) to +16% (2001).

Owing to the sharp output reduction in the West, the curve of global output had declined in 2001. Owing to the reduction in the output of sintered NdFeB in Japan, China became the number one producer of sintered NdFeB in the world in 2001.

The prices in Japan, the United States, and Europe are different, but they are more or less at the same level. The price of China magnets is only half of that in western market. This is the most attractive factor of China magnets! The price changes of sintered NdFeB magnets made in China,

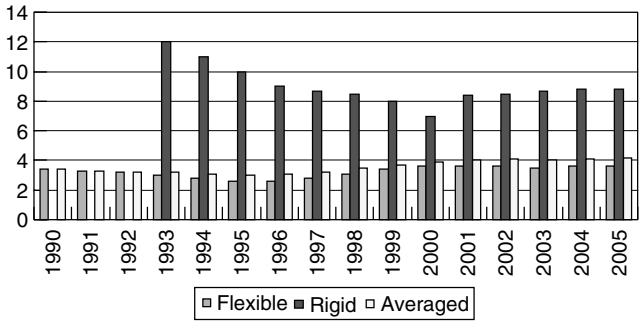

Figure 24. Price ($/kg) variation of bonded ferrite made in China (1990–2005).

Japan, the United States, Europe, and the global average are compared in Figure 26 (1995–2004).

The annual growth rate of sales value in Japan kept rather high >50% until 1990. Starting from 1991, it declined by ~20% annually. In 1992, the growth rate of sales value in Japan became negative, then it remained <20% until 1999. It declined again in 2000. In 2001, sales values of sintered NdFeB declined in all countries, the only difference being in their reducing rate: they were −36, −41, −32, and −6% for Japan, the United States, Europe, and China respectively. Since 2000, sales values in the United States and Europe have declined steadily. The sales value in Japan had increased a bit after 2001, but even in 2003, it was still much lower than its peak value of 2000.

The sales value of China in 2002 had exceeded that of 2000 with an annual growth rate of +17%. It increased even more in 2003 (with an annual growth rate of +93%) due to unusual output expansion (with annual growth rate of +109.7%), although the annual price reduction rate was around −8% (see Table 32).

Value ($\$ \times 10^8$) of NdFeB in China, Japan, the United States, Europe, and global total is shown in Figure 27.

The global total value of sintered NdFeB magnets in 2003 was still less than its peak value in 2000, in spite of its unusual increase in 2003. The same situation was seen in Japan. Its sales value in 2004 was far less than its peak value in 2000. As for China, her sales value in 2002 already exceeded that in 2000. Her sales value in 2004 was almost three times higher than that in 2000 due to her output growth of five times during the same time, although her price in 2004 was 39% less than that of 2000.

The output percentage change of sintered NdFeB made in China, Japan, the United States, and Europe during 1995–2004 is summarized in Figure 28.

Now, the output of sintered NdFeB made in China is 79.7% of the global total. The output from Japan, Europe, and the United States is 19.4, 0.9, and 0% respectively. As for the distribution of sales value, the picture is quite different: in 2004, value percentages were 63.6, 34.8, and 1.6% for China, Japan, and Europe respectively.

The gap between output and sales value is the main problem faced by the Chinese NdFeB magnet industry. The only

Value ($\$\times 10^8$)	11.835 (+8.8%)	8.44 (−29.4%)	8.634 (+2.3%)	11.593 (+34.3%)	14.124 (+21.8%)
Price ($/kg)	87 (−12%)	66.1 (−24%	57.9 (−12%)	46.1 (−20.4%)	40.9 (−11.3%)

way to solve this problem is to eliminate the technical gap that exists between China and developed countries, that is, to improve the performances of Chinese products.

It is well known that the prices of magnets are quite different, depending on their grades and performances. Generally speaking, the better the magnet, the higher its price would be. The price gap between Chinese and international magnet markets is rather big. As a sample, the averaged prices for different grades are shown in Figure 29.

The vertical coordinate axis shows magnet price ($/kg) and the horizontal coordinate axis shows energy products (MGOe) of magnet. There are two group curves: A – China market; B – international market. Each group contains two curves: one relates to 1998 and the other relates to 2003. The following are worth noting from Figure 29:

1. The price of magnets is rising with their energy products extensively. For example, now magnets with 40 MGOe can be sold for $40/kg in the Chinese market, magnets with 44 MGOe and 48 MGOe can be sold for as high as $55/kg and $80/kg respectively. Obviously, only higher-grade magnets can be sold at a better price. This is the only way to get rid off the problem of low economic efficiency (profit) of the NdFeB magnet industry in China.
2. Prices in Chinese and international markets are quite different as they belong to a different curve group. In general, the price in the Chinese market is only 65–70% of that in the international market.
3. Prices in both international and Chinese markets are reducing with time. The reducing rate in the international market seems even more than that in the Chinese market due to the price gap between them.

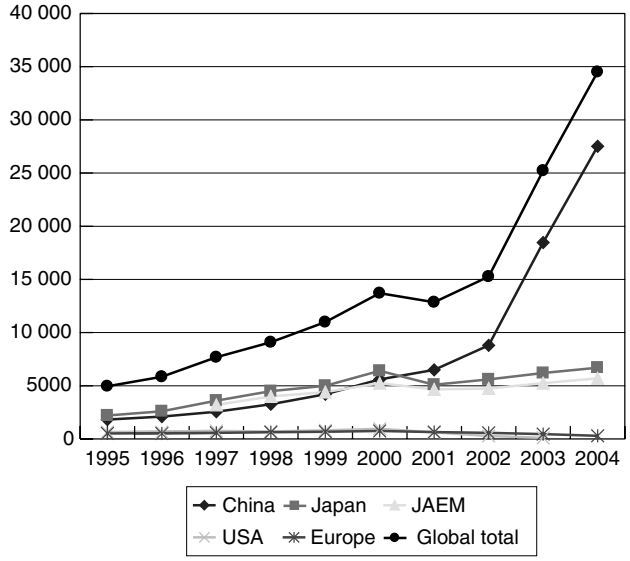

Figure 25. Output of sintered NdFeB in China, Japan, the United States, and Europe (1995–2004).

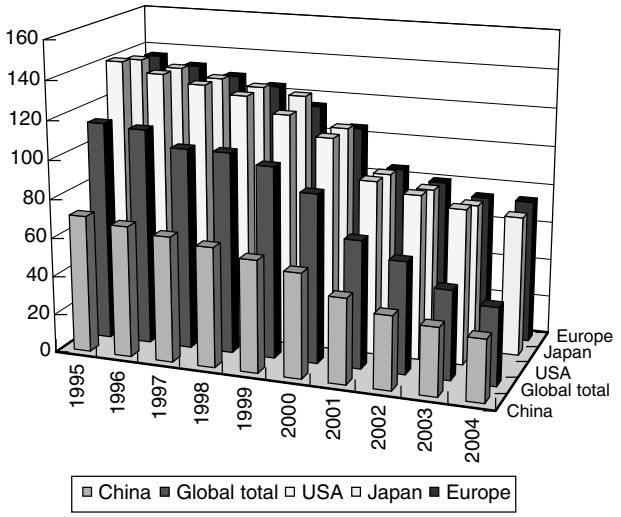

Figure 26. Sales price ($/kg) of sintered NdFeB magnets in China, Japan, the United States, Europe, and global average during 1995–2004.

Moreover, if magnet manufacturers want more value added to their magnets, they should manufacture magnets with high tolerance and accuracy, instead of block magnets, and should also do magnet assembling to make devices. This way, the magnet manufacturers in developed countries can compensate the pressure of price reduction successfully. Considering that the use of NdFeB in motor application will considerably increase in the near future, we have to focus on the development of NdFeB with high-energy products and a high coercive force, lower temperature coefficient, that is, which are suitable for motor use. In order to realize the use of NdFeB for motors more quickly, magnet manufacturers should work with motor designers and motor makers more closely.

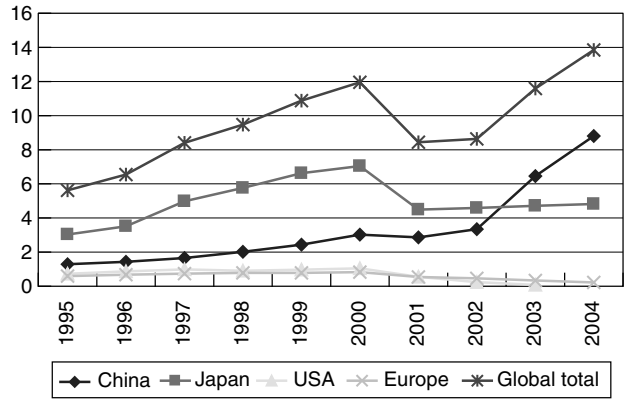

Figure 27. Value ($\$ \times 10^8$) of sintered NdFeB magnets made in China, Japan, the United States, Europe, and global total.

12 APPLICATION EXPANSION OF NdFeB MAGNETS

Since the middle of the 1990s, the market demand of NdFeB has increased so significantly that it has pushed the production expansion to a higher pace. Owing to expansion in production of NdFeB, its sales price has reduced sharply. The global economic recession has made the situation for the NdFeB magnet industry even worse; this situation may continue until 2005. On the other hand, the price reduction helps in NdFeB being used for many new applications such as motors, especially electric vehicle (EV), hybrid car, power generators, and magnetic refrigerator, whereas this was impossible earlier due to the high price of NdFeB.

In order to show the expansion of NdFeB, we take some samples from recent applications of NdFeB magnets in China.

12.1 Electric bicycle (EB)

Electric Bicycle (EB) has a permanent magnet motor (36 V/180 W) in the wheel center of bicycle and a rechargeable battery, electron monitor, with total weight ≤ 40 kg, and its speed ≤ 20 km/hr. The running distance per charge is in the range of 40–60 km. This type of EB is suitable for urban transportation in cities with population of several millions. This type of EB has been gaining popularity in south China in recent years. For example, Suzhou city with a population of half million has 180 000 EBs in the down town area. One and a half million EBs were sold in 2002. Three and a half million EBs were made in 2003. A total of around 5 million EBs were made in China in 2004.

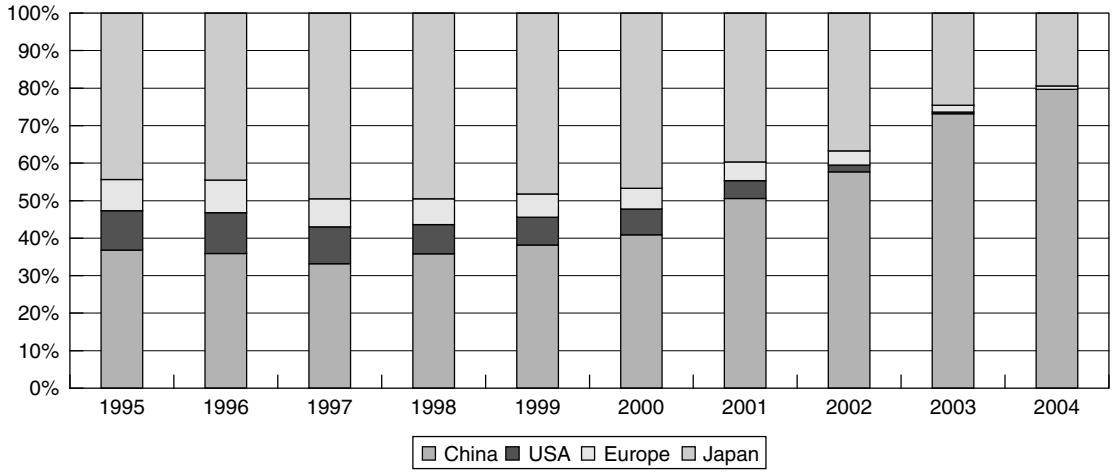

Figure 28. Output percentage change of sintered NdFeB magnets made in China, Japan, the United States, and Europe during 1995–2004.

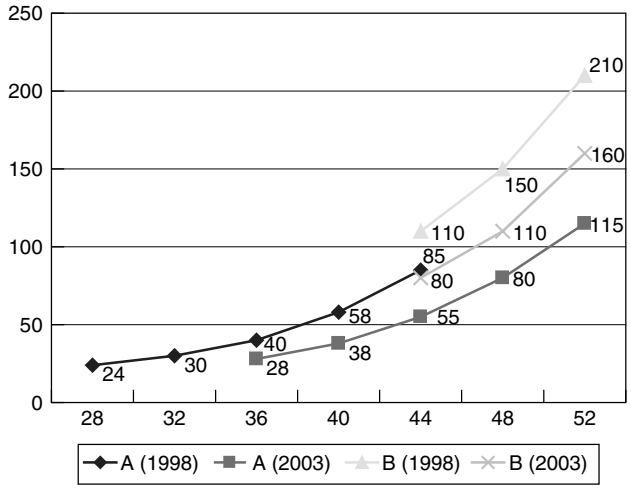

Figure 29. Average prices of sintered NdFeB depending on their grades in international (B) and China (A) market in 1998 and 2003.

The photograph of EB made in Suzhou is shown in Figure 30 as a sample.

The motor used for EB is an NdFeB magnet motor of 36 V/180 W. Three hundred and eighty grams of sintered NdFeB is used for each motor. The NdFeB that is used is of 38SH or 40H grades, the price of which is around \$38/kg. There are two types of motors: high speed and low speed, their prices are ¥350–420/pics and ¥240–280/pics, and it is \$42/pics on average. The price of EB ranges from ¥1800–2500/pics, that is, \$260/pics on average.

In order to show the value addition with product stream, we have taken data of 2003: total output of EBs is 1.5 million pieces. One thousand three hundred and thirty tons of sintered NdFeB magnets were used. It needs 653 tons of Nd_2O_3 with a value of 8.16 million USD (the price of Nd_2O_3 is \$12.5/kg). The value of used NdFeB magnets, motors, and EBs is 46.55 million USD, 147 million USD, and 910 million USD respectively. If we take the value of Nd_2O_3 as 1, then the value of the NdFeB magnet, value of NdFeB motor, and value of EB will be 6.2, 18, and 111 respectively!

Figure 30. Electric bicycle using NdFeB motor made in Suzhou.

The sharp increase in the output of EBs and used sintered NdFeB magnets is shown in Figure 31.

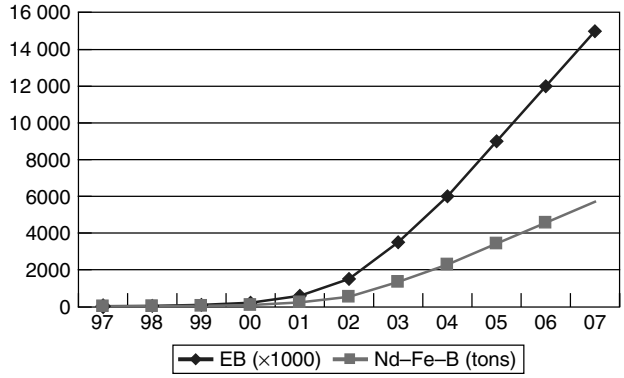

Figure 31. Output of EB ($\times 10^3$ pics) and used NdFeB magnets (tons) in China (1997–2007).

The total output of EBs will be 15 million pieces and the NdFeB magnets needed for such an application will be around 6000 tons in 2007. The annual EB output growth rate of 12 was rather high in the initial stage ($> +100\%$). It will be reduced to a normal range of within $+30\%$ annually, when the annual output reaches 15 million pieces or more.

12.1.1 Why EB has become popular in China

The EB originated in Japan, the most famous one with the trade mark PAS is made by Yamaha Co. Statistics show that in 2003 the total output of EBs in the world was 600 000 pieces. The distribution on locations is as follows:

Japan – 250 000 pieces; USA – 150 000 pieces; Europe – 100 000 pieces;

Taiwan – 100 000 pieces.

In the same year, 3.5 million EBs were made in China, which is almost six times higher than the global total! Why has the use of EBs spread so quickly in China? Some of the reasons are as follows:

1. The income of people in China is not very good as it is a developing country. The car is not affordable for every family. But, due to its low price, the EB is able to meet the needs of the common people. According to the published economic statistics in 2001, the cost of one EB (¥1800–2500/pics) is equal to the monthly income of a family in the city, or equal to the three-month income of a family in rural area. Anyway, the EB is economically available for Chinese people. Moreover, the service fee for EB is low: charging fee and depreciation of battery −¥0.9/charge. Consequently, the EB has become very popular in China recently.
2. Because of its huge population, the car did not become very popular in China, simply because of lack of oil supply and parking space. But electricity is much cheaper and easily available in China. Moreover, there is no pollution caused by using EB.
3. The people of China are used to using the bicycle to commute to various places. There is a very strong network for producing bicycles and all related parts, which can also be used for EB production. This is the reason why the EB industry has become so strong in China within the last couple of years.

12.2 Low-grade NdFeB to replace ferrite

At the end of 2003, I made a business trip to south China and visited the biggest magnet producers of bonded NdFeB (Galaxy in Chengdu), sintered NdFeB (Yunsheng in Ningbo), ferrite (DMEGC in Dongyang), and Alnico magnet (Hangzhuo Permanent Magnet Group in Hangzhuo, HPMG). I saw 'the explosion expansion of sintered NdFeB' everywhere in Zhejiang province with my own eyes, especially in the area of Ninbo city and around.

Rare-earth magnets are considered to be high-tech materials, which need high volume of investment, high technology, and highly qualified employees. But, to my surprise, what I saw in Cixi city was exactly opposite of this! There are neither big workshop buildings with modern equipment, nor are there qualified technicians. Half of the raw materials used are taken from the recycled material without any special treatment. They do not intend to make high-grade NdFeB, but only aim to replace HF. Their products are small disk magnets used as buttons for clothes, boxes, and bags. Because their magnetic force is much stronger than that of HF, such products are extremely popular among customers. Here there is mass production of NdFeB, with trucks waiting outside the plants. At one of the plants, the output of the small disk magnet per day is 12 tons, that is, $\geq$6 million pieces per day! Such products are widely used in China and abroad. The economic efficiency of such plants is much higher than that of traditional magnet producers, which make higher-grade magnets. Statistics showed that that there are 6–8 such plants in Cixi and the total annual output is $\geq$5000 tons. This is rather confusing: which way should the China NdFeB magnet industry go? Should it follow the developed countries, or should it follow Cixi?

The major applications of NdFeB magnets as high-tech and new materials are in modern high-tech industries including IT, computer, communication, automotive, and small appliances, for example, cordless tools. The total amount of magnets used for such new applications would be thousands of tons!

Therefore, the quality of products is most important for long-term development. The 'Way of Cixi' is only an appearance of certain conditions and period; it is surely not the main stream!

12.3 Application distribution of sintered NdFeB magnets

12.3.1 Distribution of sintered NdFeB magnets on applications in China

Applications of sintered NdFeB magnets in China can be divided into three groups:

1. High-tech application, such as MRI, VCM, CD pickup, CD-ROM/DVD-ROM, mobile phone, cordless tools, EB/EAV, etc.
2. Traditional application, such as speaker, magnetic separator, magnetizer including dewaxer used in oil fields and the petroleum industry.

Table 32. Output ($\times 10^3$), used NdFeB (tons), value ($\$ \times 10^8$) of NdFeB, motors, and EB (Miao, 2004).

Year	Output ($\times 10^3$pics), (Δ(%))	Used NdBeF (tons), (Price ($/kg))	Value of needed NdFeB ($\$ \times 10^6$)	Value of motor ($\$ \times 10^8$) A. P. ($42/pics)	Value of EB ($\$ \times 10^8$) A. P. ($260/pics)
1997	10	3.8 (65)	0.247	0.0042	0.026
1998	30 (200)	11.4 (62)	0.707	0.0126	0.078
1999	80 (166)	30.4 (58)	1.76	0.0336	0.208
2000	200 (150)	76 (52)	3.95	0.084	0.52
2001	580 (190)	220 (44)	9.68	0.244	1.51
2002	1500 (158)	570 (38)	21.66	0.63	3.9
2003	3500 (133)	1330 (35)	46.55	1.47	9.1
2004	6000 (71)	2280 (33)	75	2.52	15.6
2005	9000 (50)	3420 (32)	109	3.87	23.4
2006	12 000 (33)	4560 (31)	141	5.04	31.2
2007	15 000 (25)	5700 (30)	171	6.3	39

A. P.: averaged price.

Table 33. Application distribution of sintered NdFeB in China in 2003.

High-tech application MRI	360 tons	2.0%
VCM	210 tons	1.1%
CD pickup	940 tons	5.1%
DVD-ROM + CD-ROM	1500 tons (5650 tons)	8.1% (30.7%)
Mobile phone	360 tons	2.0%
Cordless tools	940 tons	5.1%
EB + EAV	1340 tons	7.3%
Traditional application Speaker	4000 tons	21.7%
Magnetic separator	2500 tons (8500 tons)	13.5% (46%)
Magnetizer (dewaxer etc.)	2000 tons	10.8%
Low-grade use (Cixi)	3000 tons	16.2%
Others	1310 tons	7.1%
Total	18 460 tons	100%

3. Low-grade uses such as magnets made in Cixi.

The distribution of used NdFeB in China (2003) is listed in Table 33 and shown in Figure 32.

The section of high-tech application is 31% of the total, considering the use for motors. This section will grow in future. The section of traditional application is 46% of the total and may reduce slightly. The use of low-grade magnets, similar to that made in Cixi, may remain steady for a certain period of time, its absolute tonnage may even increase, but its percentage would decline in the long term. In 2007, the need for sintered NdFeB magnets for EB and EAV will be 5700 and 2385 tons, respectively. The need in EB and EAV will exceed 8000 tons, and that in EV has not yet been included. It should be noted that all these demands appeared only after 1997. If the low-grade use is included, then the total demand would exceed 20 000 tons, which shows a sharp increase in the market demand for NdFeB in future!

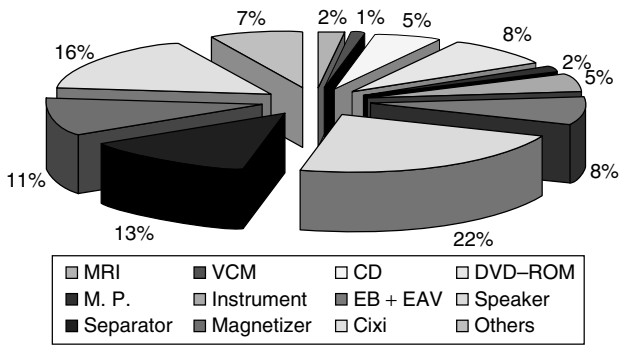

Figure 32. Application distribution of sintered NdFeB made in China (2003).

In the twenty-first century, one would see numerous improvements and growth in the NdFeB magnet industry. In particular, the next decade will see great improvement in the quality and capability of the NdFeB magnet industry in China. This will result in better and cheaper magnets for customers all over the world.

12.3.2 Application of sintered NdFeB magnets in Japan

There are three major applications of sintered NdFeB magnets in Japan: VCM, MRI, motor/generator. The portions used for certain applications vary every year. The changes during 1996–2003 are listed in Table 34 and summarized in Figure 33.

Sintered NdFeB magnets are widely used in the HDD of computers and consumer electronics. VCM is the biggest application of NdFeB magnets, but its weight percentage is reducing continuously from 57% of the total in 1996 to 35% in 2003 because the most advanced magnets with energy

Table 34. Percentage changes of used sintered magnets for certain application in Japan (1996–2003).

	VCM (%)	Motor/generator (%)	MRI (%)	Acoustics (%)	Communication (%)	Others (%)
1996	57	14	16	3	5	5
1997	58	15	14	3	6	4
1998	55	15	14	3	8	5
1999	50	20	14	3	10	3
2000	47	24	13	2	11	3
2001	43	29	16	2	9	2
2002	36	32	17	4	9	2
2003	35	34	15	8	8	2

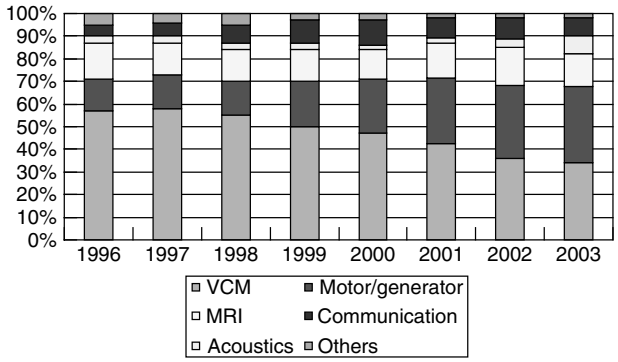

Figure 33. Percentage change of used NdFeB magnets for different applications in Japan during 1996–2003.

products ≥48 MGOe are used. Consequently, the weight per piece is much reduced. Now HDD is not only widely used for PC but is also used as a memory unit for video systems of TVs, car navigation systems, mobile phones with large memories, and so on. These 1-in. HDDs are very minute in size. The size of its VCM magnet is $3 \times 2 \times 0.8$ mm with an unsymmetrical shape, which is rather difficult to prepare.

The portion of magnets used for MRI is relatively stable; it ranges between 13 and 17%. It is not only used for medicinal purpose, but the digital MRI can also be used for quality control of agricultural products, space-orientation application, and so on (Asfour, Raoof and Fournier 2004).

The usage of small-sized magnets, such as microspeakers, pickups of CD and DVD, vibration motors of mobile phones, and audio systems for automobiles, has increased in acoustic devices and communications in recent years instead of ferrite magnets.

A remarkable increase has been observed in motor application since 1995. The driving force behind such an increase is closely related not only to improvement in performance of magnets but also to the progress in motor designs such as SPM (surface permanent magnet) type and IPM (interior permanent magnet) type by using high-performance magnets.

SPM type is mainly applied in servomotors for fabric automation and office automation, elevator lifting motor, and so on. The use of IPM type is expanding in many applications, including compressor motors. The IPM type is being increasingly used because the simple rectangular-shaped magnets can be used, which are significantly less expensive in comparison to segment magnets while preparing and assembling. IPM-type motor has been adopted by Toyota and Honda for their hybrid electric vehicle (HEV). The magnets used are 38UH grade with (BH) max = 38 MGOe, ${}_{\mathrm{i}}H_{\mathrm{c}} =$ 25 kOe, which can be used at a temperature as high as 180 °C.

13 LOCATION DISTRIBUTION OF NdFeB MAGNET MANUFACTURERS IN CHINA

The total output of sintered NdFeB magnets in China in 2004 was 27 510 tons. The magnet plant locations cover 12 provinces and Beijing–Tianjin cities. The output distribution of sintered NdFeB magnets made in China on their locations is shown in Figure 34.

In general, sintered NdFeB magnet production in China is concentrated in three areas: Zhejiang province takes the first place with 47.1% of the total output; Shanxi province takes the second place with 21.7% of the total; Beijing–Tianjin area takes the third with 11.7% of the total. The rest 19.5% of the total production is spread over nine provinces.

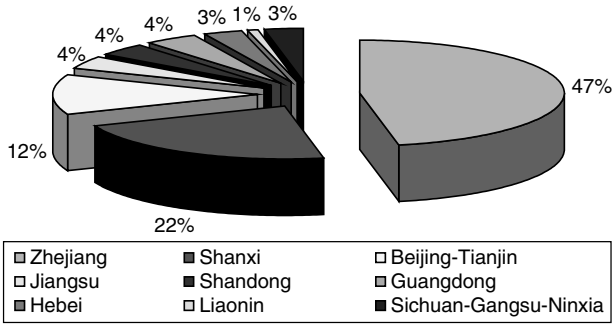

Figure 34. Location distribution of sintered NdFeB magnets made in China (2004).

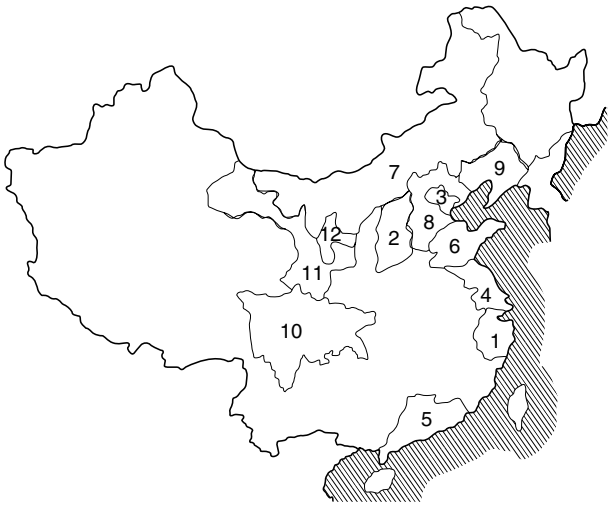

Figure 35. Location distribution of NdFeB magnet manufacturers in China. 1–Zhejiang province; 2–Shanxi province; 3–Beijing/Tianjin area; 4–Jiangsu province; 5–Kuangdong province; 6–Inner Mongolia; 7–Shiannxi province; 8–Ninxia province; 9–Gangsu province; 10–Shandong province; 11–Sichuang province; 12–Liaonin province.

Since NdFeB magnets are rather sensitive to corrosion, and it is quite hot and humid during summer in south China, the weather conditions here are unfavorable for making NdFeB magnets, especially the high-grade magnets. Thus, the NdFeB production volume in Zhejiang province is the highest, but the quality is not very good. Magnets of higher grade are produced in north China: Beijing–Tianjin area and Shanxi province (see Figure 35).

Of course, the quality of magnets depends on the process and equipment used, that is, both software and hardware used for manufacturing. The magnet plants equipped with the most advanced processes and equipment are located in the Shandong province. Therefore, the best magnets are produced there.

The actual statistical data of sintered NdFeB magnets made in China between 2003 and 2006 are given in the appendix.

APPENDIX B

B1 Development History of the China NdFeB Magnet Industry

NdFeB magnet industry appeared in China in the late 1980s, which was much later in comparison with developed countries. Although the numbers of NdFeB magnet plants were more than 100, most of them were small workshops with producing capacities of less than 5 tons/year. Plants with producing capacities $\geq$100 tons/year appeared only in early 1990s. The quality of their products was unstable and the economic efficiency of these plants was not high enough.

B1.1 1987–1996 – initial stage of the developing NdFeB magnet industry in China

'Low start point' was the character of this period because of low initial investment, all equipment was locally made and simple. Chinese engineers were forced to work out a special process to prepare NdFeB magnets by using simple hardware. Middle-grade NdFeB magnets can be prepared by using the 'Chinese process' successfully. On the whole, the NdFeB magnet industry in China was much behind compared to that in developed countries. Along with a technical gap, a big gap existed in the management and quality control systems between China and developed countries. The questions were whether to build the magnet industry in an intensive way or still keep the small-scale peasant economy? Whether to build modern quality control systems or still keep the quality systems random and out of control? Most of the owners of magnet plants in this period had some background of materials science and machinery, but none of them were familiar with the modern management and quality control systems. Owing to the huge market demand, the NdFeB magnet industry in China developed rather fast, in spite of the many difficulties that existed. Consequently, many investors who got a lot of money from other businesses looked at the NdFeB magnet industry as a better business for new investment. Thus, the second stage of development of the NdFeB magnet industry in China started.

B1.2 1997–2002 – second stage of the developing NdFeB industry in China

'Higher starting point' was the character of this stage: the volume of investment in this period was much higher than that in the initial stage. It was at least 30–50 million RMB, while it was only 1 million RMB or less in the initial stage. The biggest investment in this period reached 280 million RMB! Using the big investment, the plant built in this stage was equipped with best domestic equipment following advanced processes, some plants even imported all the equipment from Japan, Germany, and the United States. The producing capacity was usually $\geq$200 tons/year, some reaching even 2000 tons/year. The products were of middle and high grades.

The technology, including both software and hardware, and know-how are a top secret for magnet manufacturers, which they never disclose to others, especially to competitors from developing countries. But the situation dramatically changed while China became the global manufacturing center since the beginning of the new century. Equipment producers in developed countries could not find customers for their new products in their own countries. They have to seek potential customers in China now. What looked impossible a couple years ago now seemed realistic and practical. Last year, some Japanese equipment manufacturers jointly developed a new fully closed and automatic producing line for manufacturing sintered NdFeB magnets with a capacity of 500 tons of final magnets/year (equivalent to 800 tons block magnet/year). They guaranteed to make highest-grade magnets with energy products of 50 ± 2 MGOe, and oxygen content in magnet $\leqslant$ 1000 ppm. It is especially worth mentioning here that the total price of such a producing line is $\leqslant$60% of the sum of the individual equipment!

Now, an advanced producing line for high-grade NdFeB magnets is under construction. All the equipments being used are made in China. Of course, its total cost is only 1/3–1/5 of the imported one. Considering economic globalization and continuously increasing market demand for NdFeB, a new stage for the development of the NdFeB magnet industry is starting in China now.

B1.3 2003 – a new stage of the developing NdFeB magnet industry in China

The character of this stage will be 'three highs': high start point; high investment; high reward. Thus, the project will be run as follows: (i) To get the most advanced producing line by using high investment to guarantee high grade of produced magnets for special uses. (ii) To follow most advantageous processes to make magnets in an intensive way: to divide producing process into two parts–master alloy/powder production and magnet manufacturing, to reduce investment and increase economic efficiency. (iii) To run the business according to the way of capital management, in order to guarantee a high reward of investment.

In this way, the China NdFeB magnet industry would mature and would match with international standards finally. As a member of new materials, the NdFeB magnet industry in China would march forward further.

Ferrimagnetic Insulators

Victor A.M. Brabers
Eindhoven University of Technology, Eindhoven, The Netherlands

1 INTRODUCTION

Ferrimagnetism is the phenomenon that a compound shows a resultant magnetization, which originates from the antiparallel orientation of two or more nonequivalent sublattice magnetizations. This implies that ferrimagnetism can only occur in certain crystal structures consisting of two or more crystallographic nonequivalent sublattices, which are occupied by paramagnetic ions in sufficiently high concentrations. The first materials which were identified to be ferrimagnetic were the ferrites MFe_2O_4, which crystallize in the spinel structure and for which the molecular field was applied for the first time (Néel, 1948). A compound AB_2O_4 with the spinel structure contains two cation sublattices, the tetrahedral (A) and the octahedral sites (B). In Néel's theory of ferrimagnetism, the effective inter- and intra-sublattice interactions A–B, A–A and B–B are introduced, which are in fact super-exchange interactions, that is, indirect exchange via the anion p orbitals. The strength of these super-exchange interactions depends on the electronic structure of the cations, as well as on the geometry of the relative configuration of the interacting cations and the intermediate anion. In particular it appears that the antiferromagnetic A–B interaction between Fe^{3+} ions in the spinel structure is very strong, resulting in ferrimagnetic ordering with high ordering temperatures for the spinel ferrites. In addition to the spinel structure, Fe^{3+} ions can also be substituted in a number of other crystal structures, of which the most important are the garnet structure, $R_3Fe_5O_{12}$, the perovskite structure $RFeO_3$, and hexagonal structures like the magnetoplumbite structure $MFe_{12}O_{19}$ and related structures. Although a large number of 3d-metal oxide compounds may exhibit ferrimagnetic behavior at low temperatures, the focus in this paper is on oxide compounds with a high concentration of iron because of the possible applications, that is, the ferrites, which show a substantial magnetization at room temperature. The electrical resistance of ferrites is highly dependent on the chemical composition; even if a small amount of the Fe^{3+} ions is reduced to Fe^{2}, the resulting mixed valence of iron accounts for a relatively high conductivity. The electrical conductivity is usually thermally activated, which is indicative of the semiconducting or insulating nature of these materials. If there are no mixed Fe-valences, the ferrites are highly resistive materials.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

2 SPINEL FERRITES

2.1 Magnetite

The most prominent and well-known ferrimagnetic compound is magnetite, Fe_3O_4, a magnetic mineral, which is an important ore of iron and occurs abundantly in nature as octahedral spinel crystals and as a common constituent of igneous and metamorphic rocks. Magnetite is named after an old finding place, Magnesia, an ancient city in west Turkey.

A peculiar variety of natural magnetite, lodestone, exhibits a permanent magnetization and consists of oxidized and Ti-substituted magnetite. The origin of this permanent magnetization is attributed to the microstructure developed during the formation of this mineral or is supposed to be induced by the strong magnetic field caused by lightning impact (Wasilewski and Kletetschka, 1999; Mills, 2004). Because of the magnetic properties of magnetite containing rocks, magnetite is often used as a probe in geomagnetism as well as in extraterrestrial research. In particular, the research of certain characteristics of magnetite containing minerals on Mars by the Spirit Rover was designed to determine whether liquid water was present on Mars or not (Bertelsen *et al*., 2004; Morris *et al*., 2004). The analysis of Martian meteorites is also leading to the discussion whether the magnetic particles in the meteorites are magnetosomes in origin, that is, four-billion-year-old fossils of magnetotactic bacteria, indicative of ancient extraterrestrial life, or that these particles are exclusively from inorganic origin: the decomposition of Fe-rich carbonates (Weiss *et al*., 2004). The magnetic properties of a number of Martian meteorites containing magnetite are also used to probe the enhanced ancient Martian magnetic field (Collinson, 1997).

Magnetite can be met in still several other domains of sciences. In archaeology, ancient ceramics are characterized by the detection of magnetite by magnetization measurements (van Klinken, 2001), whereas mineral magnetic analysis at archaeological sites can give information about the decomposition of organic remainders, which affects the magnetism of the soil (Linford, 2004).

Recent environmental studies monitored the heavy metal pollution of surface water by the magnetism of magnetite in sediments (Desenfant, Petrovsky and Rochette, 2004); magnetite particles accumulated on pine needles are indicative of airborne pollutants (Urbat, Lehndorff and Schwark, 2004). Airborne subway particles, which consist mainly of magnetite have been shown to be highly genotoxic, partly due to the relatively high concentration in subways (Karlsson, Nilsson and Moller, 2005).

In biological and medical sciences, the magnetism of magnetite is prominently present. A few examples are as follows: Magnetotactic bacteria can orient along magnetic lines due to the magnetization of small magnetite and greigite (Fe_3S_4) particles inside these bacteria (Frankel, 2003). The navigation system over long distance of some vertebrates, like migratory birds and fishes, is supposed to be related to the magnetism of magnetite particles (Walker *et al*., 1997). The human brain contains biogenic magnetite, which triggers the dispute whether the interaction of mobile phone RF radiation with these particles may cause health problems (Cranfield, Wieser, Al Madan and Dobson, 2003). Furthermore, nanoparticles of magnetite are very effective in the study of human cancer cells for diagnosis and therapy (Zhang, Kohler and Zhang, 2002).

Although magnetite is one of the best known ferrimagnetic materials, the investigation of the physical properties is still an intriguing field and raises sometimes more problems than giving answers as is shown in the recent reviews on the Verwey transition (Brabers, 1995; Walz, 2002; Garcia and Subias, 2004). Especially for applications of magnetite in which the nanoscale structures are important (i.e., particulate magnetic media, thin films, multilayer structures etc.), the structure of the crystal surface as well as the defect structure of the reduced dimensions are decisive for the physical properties of these nanoscale structures. In both cases, the typical crystal structure of magnetite plays an important role. The room-temperature structure of magnetite is the inverted spinel structure (space group O_h^7–Fd3m). The tetrahedral A sites are occupied by one-third of the iron ions as Fe^{3+} ions and the remaining Fe ions are located on the octahedral B sites as mixed valence Fe ions with an average charge of 2.5+. Table 1 gives the coordinates of the equivalent positions of this space group as relevant for the spinel structure. The first column is the number of equivalent positions in the set, identified by a character in the second column. The third is the point symmetry of the position of each set and the last column presents the coordinates of all equivalent positions in fractions of the lattice parameter. The unit cell contains 8 'molecules' of AB_2O_4; 32 oxygen ions occupying the position e, 16 B ions in the position d, which are in the center of an oxygen octahedron and 8 A ions in the position a, which are in the center of an oxygen tetrahedron. The positions f and b are interstitial tetrahedral sites and the position c-interstitial octahedral sites. In real spinels like magnetite the closed cubic packing of the oxygen ions is disturbed by the displacement of the oxygen ions from their ideal position into a ⟨111⟩ direction, away from the central tetrahedral ions, because of the large size of the A-site ions. A measure for this displacement is the oxygen parameter u, which determines the position e of the oxygen lattice sites (Table 1). For the undisturbed structure $u = 0.375$.

Hornstra (1960) recognized that twinning in the spinel structure can occur by stacking faults in which the b and c sites are occupied instead of the a and d positions, leading to the presence of twins. The twin or antiphase boundaries are responsible for the anomalous magnetic behavior observed for single-crystalline magnetite thin films. The reduced magnetic moment as well as the nonsaturation at high fields are due to the changes in the configuration of the interacting cations across the antiphase boundary (Margulies *et al*., 1996; Heijden *et al*., 1996). Owing to the different angles between the cations, the AB interaction is strongly decreased, whereas the intra-sublattice A–A and B–B interactions are increased, reversing the dominant interaction found in

Table 1. The sets of the equivalent symmetry points of the space group $Fd3m - O_h^7$ relevant for the spinel structure. The origin is taken at the A-site and $u \approx 3/8$ (Reproduced from N.F.M. Henry *et al*., 1965, with permission from thr International Union of Crystallography. © 1965).

bulk material (Margulies *et al*., 1997). The result is a low magnetization at low fields and nonsaturation at high fields.

The second topic of interest for nanostructures, which is related to the peculiar structure of magnetite, concerns the Verwey transition at 124 K, where the cubic structure transforms into a monoclinic C_c structure. The low-temperature unit cell corresponds to the cubic spinel structure with $a\sqrt{2}.a\sqrt{2}.2a$ and additional small deformations to arrive at the monoclinic symmetry. The lattice parameters at 10 K are $a = 11.868$ Å; $b = 11.851$ Å; $c = 16.752$ Å and $\beta = 90.20^\circ$ (Iizumi *et al*., 1982). The transition was attributed by Verwey (1939) to an electronic ordering of Fe^{2+} and Fe^{3+} ions on the B sites causing a decrease in the electrical conductivity of about two orders of magnitude. A similar electronic ordering was also supposed to exist at room temperature on the (100) crystal surface, which was evidenced by magnetic-sensitive scanning tunneling microscopy (STM) through the observation of a certain structure with periodicity of 1.2 nm on a natural crystal (Wiesendanger *et al*., 1992). The reconstruction of the (100) surface $(\sqrt{2} \times \sqrt{2})$ R 45°, observed on synthetic nonstoichiometric crystals was also proposed as evidence for an electron ordering in the form of Fe^{2+}–Fe^{2+} and Fe^{3+}–Fe^{3+} pairs along the ⟨110⟩ B-site rows (Shvets *et al*., 2004). Moreover, on (100) surfaces of high-quality stoichiometric synthetic crystals a long-distance 1.2-nm corrugation has been observed in the ⟨110⟩ B-site rows, which could indicate that the surface may be a Wigner crystal rather than a Wigner glass (Koltun, Hermann, Güntherodt and Brabers, 2001; Coey, Shvets, Wiesendanger and Güntherodt, 1993). Also on (110) as well as on (111) surfaces reconstruction and peculiar structures have been observed with STM techniques (Jansen, Brabers, van Kempen, 1995; Lennie *et al*., 1996; Oda *et al*., 1998). A remarkable superstructure has been found on an oxygen-rich (111) surface with quasi-hexagonal symmetry and 4.2-nm periodicity, which is supposed to be of electronic origin. It is obvious that the surface structure of magnetite will be perceptive to modifications of the electronic structure due to the presence of the mixed valence iron ions at the B sites. The observed 4.2-nm superstructure has been suggested to be related either to a polaronic or to a charge-density wave electron-lattice instability (Berdunov, Murphy, Mariotto and Shvets, 2004b).

Besides the electronic effects, chemical effects are important as well for the surface structure of magnetite. For instance, in a reducing environment, the appearance of a phase segregation of wüstite ($Fe_{1-x}O$) is observed on a (111) Fe_3O_4 surface (Condon *et al*., 1997). Further it has to be noted that for interfaces with magnetite in thin-film structures, the surface structure can be modified in an even more complex way. Interdiffusion between the layers occurs like in MgO–Fe_3O_4 interfaces, where $MgFe_2O_4$ is formed in the entire magnetite layer at relatively low temperatures around 400 °C (Anderson *et al*., 1997). This is not surprising, since the cation exchange between octahedral and tetrahedral sites is for the magnesium ferrite system at this temperature already substantial in the bulk material (Brabers and Klerk, 1977a). For other metal ions like Cu and Mn even diffusion at 300 °C and lower temperatures is expected to go on (Brabers, 1971; Brabers and Klerk, 1977b). Moreover, from magnetic aftereffect experiments, it is evidenced that in magnetite even at room-temperature migration of iron ions takes place by mediation of cation vacancies on the B sites (Walz, 2002). Because interfaces are usually stressed due to lattice misfit and lattice defects, the stability of well-defined interfaces in which magnetite is involved might be problematical. In particular this plays an important role in spin electronics application, in which the electronic structure of magnetite at the interface has to comply with certain requirements. For example, it has been shown that the structure and the defects on the surface modifies the spin transport significantly, which in turn spoils the wanted tunneling magnetoresistance effect (Berdunov, Murphy, Mariotto and Shvets, 2004a).

It is clear that if one succeeds in constructing a spin electronic device based on magnetite films, the deterioration

of spin-polarized transport by a possible aging of the magnetite films is a major technological challenge. Because the ionic diffusion is in particular at the interface already substantial at room temperature, thermodynamically stable structures have to be fabricated to prevent aging.

2.2 The Verwey transition

An enigma concerning magnetite is the continuous discussion on the mechanism of the Verwey transition and the real electronic structure of the low-temperature phase. Around 124 K, magnetite undergoes a first-order phase transition, which was originally related to an ordering of Fe^{2+} and Fe^{3} ions on the octahedral sites (Verwey, 1939). In fact, the transition can be considered as an electronic phenomenon, because all the octahedral sites are occupied by Fe^{3+} ions, over which a number of electrons is distributed equal to half of the number of available sites. The main question is now if these electrons are localized on specific sites in the low and the high-temperature phase as well, or if these electrons are itinerant. In Verwey's picture, the structure is purely ionic. While at temperatures above the transition temperature T_v the localized electrons are rather mobile, hopping from one site to another, the electrons below T_v are frozen in rows along the $\langle 110 \rangle$ direction, resulting in an orthorhombic structure. This ordering scheme has to be modified in such a sense that the pure ionic nature of the ordering is replaced by a partial ionic ordering. On the basis of electron diffraction experiments, Zuo, Spence and Petuskey (1990) proposed an ionic charge-ordering scheme with C_c-symmetry in which a characteristic charge-density wave is present. A refined analysis of the structure with high-resolution neutron and X-ray diffraction showed a dominant $[001]_c$ charge-density wave with a secondary $[00^1/_2]_c$ modulation (Wright, Attfield and Radaelli, 2001, 2002). The four B-site sublattices in this model are split into pairs of large and small sites, indicative for charge order. However, the difference in size is small and is provided as evidence for a not complete ionic separated charge order of Fe^{2+}/Fe^{3+} ions but for apparent partial local charges of 2.4 and 2.6, with a modulation in the *c* direction. From X-ray resonant-scattering studies of the 'forbidden' reflections near the Fe–K-α absorption edge, even a complete renunciation of ionic ordering has been proposed. For the (002) reflection, no difference was observed in the energy dependence below and above T_v (Hagiwara *et al*., 1999). Similar behavior was also observed for the (006) reflection, which led Garcia *et al*. (2000) to the conclusion that all the octahedral sites must have identical anomalous scattering factors, that means there is no difference between Fe^{2+} and Fe^{3+} sites within the time window of the X-ray radiation, 10^{-16} s.

Consequently, no charge fluctuation above or charge ordering below T_v would exist. Nevertheless, the same forbidden reflections were also observed in cobalt ferrite (Subias *et al*., 2004b), in which the B sites are populated by Co and Fe ions, because of the inverse spinel structure of cobalt ferrite. This implies that Co and Fe ions, which have irrefutably a different scattering factor for the resonant diffraction, do not disturb the coherence.

With this in mind, one cannot exclude that charge disproportion on the octahedral Fe sites, leading to two distinct B-site Fe ions, will have no effect upon the resonant diffraction, which makes the conclusion about the nonexistence of the charge ordering doubtful. The finite intensity of the X-ray resonant scattering for the forbidden reflections is caused by the anisotropic environment of the resonant ions. The asymmetry of the local sites can be an intrinsic property of the crystal structure or induced by several other factors. The magnetic interactions do not play a dominant role in the resonant scattering in spinel ferrites as is shown by the results on the nonmagnetic zinc ferrite (Kanazawa, Hagiwana, Kokubun and Ishida, 2002) and the experiments on magnetite above the Néel temperature (Subias *et al*., 2004b). Besides the intrinsic anisotropy of the crystal structure (the trigonal symmetry of the B site) point defects can also contribute to the resonant scattering (Dmitrienko and Ovchinikova, 2003). Magnetite can have a highly defective structure due to the oxygen nonstoichiometry.

Subias *et al*. (2004a) reported the absence of resonant scattering for certain superstructure reflections which was taken as evidence for the absence of charge order below T_v. Although, Toyoda *et al*. (1999) observed in a similar experiment super-lattice reflections, which they took as evidence for the valence contrast between the Fe ions.

Very recently, Huang *et al*. (2006) reported O–K-edge resonant X-ray scattering experiments, which proved the existence of charge-orbital ordering vanishing abruptly above the Verwey temperature. A definitive proof of this orbital ordering in magnetite, which is also imperative for the existence of charge ordering, is given by Su *et al*. (2006), which reported an extended study of single crystal X-ray resonant scattering. This conclusion is based on the observation of the giant resonant enhancement of superstructure reflections, characteristic of the Verwey transition at all relevant absorption edges (i.e., Fe–K, Fe–L_3 and O–K) and *ab initio* band structure calculations.

The charge/orbital ordering is well described by a superstructure $a/\sqrt{2} \times a\sqrt{2} \times 2a$, with the charge modulation in the *c* direction (Su *et al*., 2006; Huang *et al*., 2006).

The use of refined anomalous scattering coefficients for the octahedral iron ions gave direct evidence for a high degree of 46% Fe^{2+}/Fe^{3+} charge order in magnetite at 90 K (Goff, Wright, Attfield and Radaelli, 2005).

A nuclear resonance study on Fe^{57} in magnetite around T_v revealed 8 A-site NMR lines and 15 B-site lines for the

low-temperature phase (Novak *et al*., 2000). According to the C_c-symmetry the number of B lines must be 16. One line coincides with the A spectrum and was indeed found in an additional NMR study (Mizoguchi, 2001). Since the nucleus acts as a probe on an atomic scale, the effect of differences in charge must be easy detectable. However, the observed B-site lines could not be split into two sets of lines on the basis of the NMR parameters like the spin–lattice relaxation time T_1 and the spin–spin relaxation time T_2. This is not consistent with the presence of Fe^{2+} because the Fe^{2+} relaxation is usually much faster, and suggests strong mixing of the $3d^5$ and $3d^6$ configurations of the B-site ions. This means that a complete ionic ordered structure is not supported by the NMR results.

A number of band structure calculations have been published for magnetite to elucidate the electronic structure above as well below T_v. Depending on the method which is used the results are diverse, as expected. The self-consistent spin-polarized augmented plane wave (APW) method with the local spin density approximation (LSDA) revealed that the majority-spin electrons are semiconducting with a sizeable energy gap, whereas the minority spin electrons are present at the Fermi energy, which indicates that the $3d^6$ electrons of the iron ions are itinerant above T_v (Yanase and Siratori, 1984; Pénicaud, Siberchicot, Sommers and Kubler, 1992). The LSDA band structure calculations render always a metallic solution without charge ordering. Zhang and Satpathy (1991) tried to obviate this problem by suggesting a three-band model Hamiltonian to describe the motion of the electrons on the B sites. However, a critical parameter for itinerant or localized character of the 3d electrons is U/t, where U is the electron–electron Coulomb interaction and t the 3d bandwidth (Hubbard, 1963, 1964a,b, 1965). Modification of the LSDA method, introducing a Coulomb interaction correction, the so-called LSDA + U method, gives indeed a stable solution with a charge ordering and an energy gap of 0.19 (Antonov *et al*., 2001) and 0.34 eV (Anisimov, Elfimov, Hamada and Terakura, 1996). Unfortunately, in both studies the orthorhombic Verwey-ordering scheme was taken as starting point, which has been shown to be unrealistic (Wright, Attfield and Radaelli, 2001). With electronic structure LSDA + U calculations based on the low symmetry monoclinic structure of magnetite, a periodic charge disproportion along the c axis was found, in agreement with the experimental X-ray structure determination (Madsen and Novak, 2005). LSDA + U calculations in the tight-binding linear muffin-tin orbital calculation scheme for the P_2/c structure of magnetite unveiled a strong charge as well as an orbital ordering for the low-temperature phase, with an energy gap of 0.18 eV. However, the obtained total 3d charge disproportion is rather small (Leonov *et al*., 2004). The results show that the charge order has a pronounced $\langle 100 \rangle$ modulation, which is not compatible with the so-called Anderson criterion. It was pointed out by Anderson (1956) that nearest-neighbor Coulomb interactions in magnetite led to a T_v higher than 10^4. The Verwey transition is exceptional in the sense that if only the Coulomb interaction is the driving force for the transition, substantial short-range order must be present in the disordered structure to explain the low $T_v = 124$ K. The octahedral sites in the spinel structure are arranged in tetrahedrons, with each site belonging to two tetrahedrons. In this arrangement, it is possible to create substantial short-range order, imposed by the Anderson criterion: the total ionic charge of the individual tetrahedrons must be constant, which means an occupation by $2Fe^{2+}$ and $2Fe^{3+}$ ions per tetrahedron.

The violation of Anderson's point charge criterion in the outcome of the LSDA + U band calculation explicitly explained by the t_{2g} orbital ordering, would lead to additional Coulomb interactions stabilizing a charge-ordered structure, which does not comply with Anderson's criterion (Jeng, Guo and Huang, 2004). From a theoretical point of view, charge order combined with orbital ordering seems to be a realistic description of the mechanism of the Verwey transition, notwithstanding the denial of any charge ordering, based on X-ray resonant scattering (Garcia *et al*., 2001). This controversy on the existence of a long-range order of different electronic states on octahedral sites has been discussed recently using a number of experimental and theoretical results (Fähnle, Kronmuller and Walz, 2005).

The electronic structure and the mechanism of the Verwey transition are important for deciding whether magnetite can be useful in spin electronics. If the material can be considered as a semimetal, there is a 100% spin polarization of the charge carriers, which is very attractive for spin electronics (de Groot and Buschow, 1986). Unfortunately, the various reports on spin-polarized photoelectron spectroscopy do not give a fixed result but show a scattering of the spin-polarization degree of the conduction electrons, which might be caused by the variation of the surface structure of the thin films used in the experiments (Morton *et al*., 2002; Dedkov, Rudiger and Güntherodt, 2002; Huang *et al*., 2002; Fonin *et al*., 2003). That the surface structure modifies indeed the photoelectron emission has been shown by the temperature dependence around T_v of the onset energy near the Fermi level at which the emission starts. Depending on the crystal plane of the single crystal and surface treatment, a gradual shift of the spectral onset energy or a small jump at T_v superimposed on an overall gradual dependence occurs (Schrupp *et al*., 2004). This implies that for certain surfaces an energy gap is formed at T_v, indicative of a clear metal–insulator transition as was earlier deduced from photoelectron spectra (Chainani *et al*., 1995). For other surfaces, the gap does not disappear at T_v but is reduced by a

step from 0.10 to 0.05 eV. A similar step and the persistence of the gap above T_v was also reported for a cleaved surface (Park *et al*., 1997). Soft X-ray photoemission experiments gave evidence of the existence of strongly bound small polarons, which supports a picture for the Verwey transition in which elastic effects (like Jahn–Teller effects) interplay with local Coulomb interactions (Schrupp *et al*., 2005). The local structure of the octahedral sites, detected by EXAFS measurements shows indeed distortions, which are in favor of this picture (Subias, Garcia and Blasco, 2005).

X-ray absorption spectroscopy (XAS) and magnetic circular dichroism (MCD) experiments, which are not so surface sensitive as photoelectron spectroscopy, proved the B-site spin moment to be noninteger, in contrast to the predicted half-metallic feature. Evidence was found for a substantial average orbital moment of the B-site iron ions, $0.33\,\mu_B$ (Huang *et al*., 2004). However, XMCD experiments, taking into account self-absorption and other spurious experimental effects reveal vanishing orbital moments and nearly integer spin values (Goering *et al*., 2005; Goering, Gold, Lafkioti and Schütz, 2006)! From the preceding discussion it might be clear that the intrinsic electronic and magnetic structure of bulk magnetite is not yet completely settled.

Additional experimental data which can give insight into this problem concern the influence of impurities on the Verwey transition (Brabers, Walz and Kronmüller, 1998) and magnetic aftereffects, caused by electronic processes (Walz, 2002). The magnetic disaccommodation (DA) spectra of highly perfect single-crystalline magnetite are shown in Figure 1 (Walz *et al*., 1982). DA is defined as the relative difference of the reciprocal susceptibility $1/\chi$ measured at two times t_1 and t_2 after the demagnetization of the sample:

$$DA = [\chi^{-1}(t_2) - \chi^{-1}(t_1)]/\chi^{-1}(t_1) \qquad (1)$$

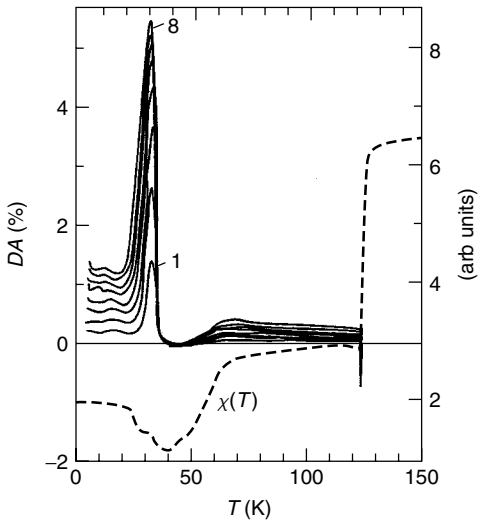

Figure 1. The isochronal disaccommodation (DA) spectra of perfect single-crystalline magnetite in the low-temperature range as measured, $t_1 = 1$ s after demagnetization and at the following times: $t_2 = 2, 4, 8, 16, 32, 64, 128$ and 180 s, yielding the curves $1, \ldots 8$, respectively. (Reproduced from Walz *et al*., 1982, with permission from Wiley-VCH. © 1982.)

The DA reflects the stabilization of the domain wall after demagnetization, which is achieved by reorientation of the local configuration, intermediate by ionic or electron transport processes. The low-temperature DA spectra in Figure 1 are most clearly structured for perfect single crystals but are modified and even complete suppressed by lattice imperfections like nonstoichiometry, mechanical stresses, impurities etc. (Walz, 2002). The conclusion is evident that the DA spectra below T_v are electronic of origin and represent intrinsic properties of bulk magnetite. A detailed analysis of the DA spectra explains the observed spectra as follows: the extended relaxation zone of logarithmic time dependence in the $4\,K < T < 30\,K$ range, together with the exponential Debye-type relaxation peak at 30 K are assigned to coherent electron tunneling processes and local electronic excitations (Walz, Weidner and Kronmüller, 1980; Walz *et al*., 1982; Kronmüller and Walz, 1980).

The 30 K peak is composed of a narrow superposition of two single Debye-type processes, as clearly indicated in the initial permeability plot in Figure 1 and which results from the thermal excitation between the doublet and singlet of the d_ε level (Kronmüller and Walz, 1980). Between 35 and 50 K, a relaxation gap occurs, accompanied by a dip in the initial susceptibility. In the 50–125 K range an extended relaxation area with logarithmic time dependency appears, which is caused by thermally activated variable range hopping processes further supported by a $T^{-1/4}$ dependence of the logarithm of the conductivity (Lenge, Kronmüller and Walz, 1984; Mott, 1990). Further evidence for the assignment to thermal activated variable range hopping was brought on by the DA spectra of electron-irradiated magnetite, which showed a splitting of the extended logarithmic relaxation zone into separated Debye processes (Walz and Kronmüller, 1990). Essential for the existence of a thermally activated magnetic relaxation is the presence of localized magnetic-anistropic species, which can reorientate under the influence of the (de)magnetization process. For the low-temperature electronic relaxation in magnetite it is obvious that Fe^{2+} ions, due to their residual orbital moment, represent such anisotropic species. Consequently, processes contributing to the DA must be linked to the electron transitions between octahedral Fe sites by means of thermal activated hopping or incoherent tunneling, which implies charge localization on the Fe^{2+}.

An interesting feature of the Verwey transition is that the transition temperature is very sensitive for the perfection

of the crystal, that is, the oxygen stoichiometry and the cation impurities. It turned out that the T_v shifting with the concentration of the cation impurity depends on the charge and the size of the substituent, as well as on the A or B site on which the substitution takes place (Brabers, Walz and Kronmüller, 1998). In Figure 2, the shifting of T_v for stoichiometric magnetite substituted with various cations is plotted against the substituent concentration. Substitution with bivalent ions (Ni, Mg, Co) on the B sites reveals a nearly identical shift with impurity concentration and even for the trivalent Ga an identical behavior is found, if the cation distribution is taken into account, one-third of Ga on B sites (Kohout *et al*., 2005). The ionic size of the impurities does fit in the range of the two and trivalent octahedral iron ions, which means that the crystal lattice is not extremely deformed by these substitutions. However, the substitution with bivalent zinc on the A sites resulted in a shift twice as large as observed for the above mentioned substitutions (Schwenk *et al*., 2000), which is also the case for Ti^{4+} on B sites and cation vacancy doping by changing the oxygen content of the crystals. In the latter cases the ratio of the concentration of the octahedral two and three valent ions is deviating from one, which seems to be more effective to retard the Verwey transition than an octahedral impurity with a similar charge as the iron ions, which leaves this ratio untouched. From these findings one could arrive at the conclusion that the charges of the B-site ions, that is, the Coulomb interactions between the B sites are the dominant driving force for the Verwey transition. Although it must be noted that the small trivalent Al ions also have a rather strong effect upon the shifting, indicating that lattice or phonon effects may play an additional role. In a first

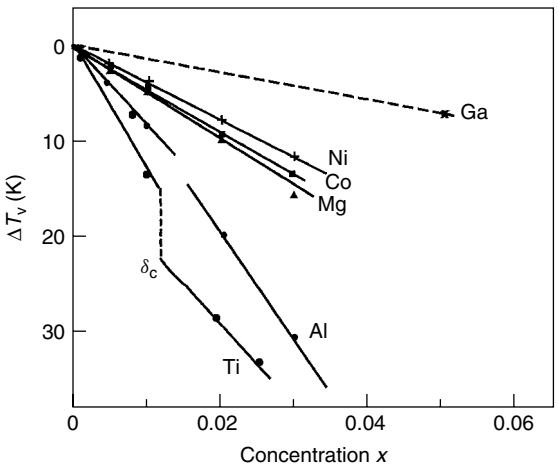

Figure 2. The shift of T_v for substituted stoichiometric magnetites $Fe_{3-x}M_xO_4$ as function of the concentration x. (Reprinted figure from Brabers *et al*., 1958, with permission from the American Physical Society. © 1958.)

approximation with a two-state mean-field model, accounting for Coulomb short- and long-range interactions only, a number of experimental results on the impurity and pressure dependence and even the value of the transition temperature were explained satisfactorily (Brabers, Walz and Kronmüller, 1999a,b, 2000). The effect of the cation substitutions on the octahedral lattice consists of a (partial) blocking of the electron exchange mechanism necessary to establish the long-range ordering scheme. The result is that a fraction of the 2+ or 3+ ions is localized, limiting the number of sites to participate in the ordering–disordering process. With the proposed model the transition temperature was calculated: $T_v = W/8\,k$ in which W represents an energy gap separating the electronic subbands of the two-state model. Taking a value of $W \sim 0.10\,eV$ (Kuipers and Brabers, 1979) one arrives at a value around 145 K, in reasonable agreement with the experimental value of 124 K. The model describes the linear T_v shifting $\Delta T_v = -\alpha x T_v$ in which x the substituent concentration M in $Fe_{3-x}M_xO_4$, T_v the Verwey temperature of the perfect magnetite crystal and $\alpha = 3$ for bivalent and trivalent substitutions on B sites or $\alpha = 9$ for Zn^{2+} on A and Ti^{4+} on B sites (Brabers, Walz and Kronmüller, 1999a). With a refinement of the model, in which the dependence of the interionic potential on the unit cell dimensions is taken into account, an expression for the pressure dependence of T_v is found (Brabers, Walz and Kronmüller, 1999b):

$$dT_v/dp = -6/7\, v/N \cdot k \tag{2}$$

v is the relative volume change at T_v and atmospheric pressure ($\Delta V/V = 6 \times 10^{-4}$); N, the number of Fe^{2+}-type ions per m^3 ($N = 1.35 \times 10^{28}\,m^{-3}$); and k, the Boltzmann constant.

The calculated value of $dT_v/dp = kGPa^{-1}$ agrees fairly well with the experimental data, which varies between -2.0 and $-5.0\,kGPa^{-1}$ for pressures up to 6 GPa.

A further refinement of the two-state mean-field model is the replacement of the two distinct levels by two bands of finite width (Brabers, Walz and Kronmüller, 2000). This provides the explanation of the discontinuity in the relation of T_v upon the impurity content at higher concentration, and also marks the transition from first to second order (Shepherd *et al*., 1991). Fitting the model parameters yields a Coulomb gap of 0.04 eV and a bandwidth of 0.01 eV, which are typical values for localized electron systems and supports a small polaronic band picture (Brabers, Walz and Kronmüller, 2000).

The IR optical conductivity is also consistent with a small-polaron nature of the charge carriers (Degiorgi, Wachter and Ihle, 1987; Pimenov *et al*., 2005). This suggests that the charge order is not only driven by electrostatic Coulomb interactions, but that elastic lattice contributions are also

relevant for the localization of the electrons on the Fe^{2+} ions and the nature of the Verwey transition. An interplay of an electron ordering with elastic lattice effects is very likely, which point of view is also put forward by Su *et al*. (2006) by introducing the Jahn–Teller distortions of the high spin Fe^{2+} ions.

2.3 Mixed spinel ferrites

A large variety of metal ions can be incorporated into the oxide spinel structure, which implies that the physical properties of the technical applied spinel ferrites like permeability, high induction, temperature and time stability, low losses and operating frequency can be tuned by a proper choice of the composition. It must be noted that spinel ferrites are usually soft magnetic, with the exception of magnetite and maghemite (γ-Fe_2O_3) in particulate media. In Table 2 some basic magnetic properties of a number of simple ferrites are given. From these data predictions can be made for the relevant magnetic properties of the mixed ferrites, useful for applications. For instance, the mixed series of the simple ferrites with $ZnFe_2O_4$ are important because of the phenomenon that the magnetization increases upon substitution as shown in Figure 3. The nonmagnetic Zn ions are located on the A sites, which results in the enhancement of the spontaneous magnetization as a consequence of the antiferromagnetic coupling between the tetrahedral and the octahedral sublattice. However, with increasing Zn concentration the Néel temperature decreases and above a concentration of $x \sim 0.5$, the antiparallel magnetic structure of the A and B sublattices is replaced by spin-canting and spin-glass structures. The spinel ferrites, which are important for applications are based on a limited number of chemical systems. The basic

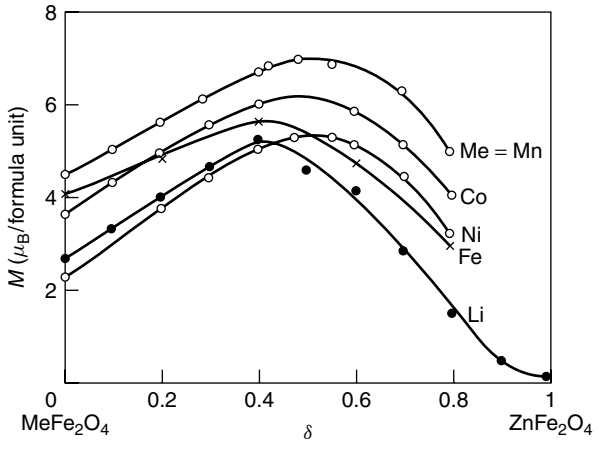

Figure 3. The magnetic moment at 0 K per formula unit of the $Me_{1-\delta}Zn_\delta Fe_2O_4$ mixed series.

composition of a soft ferrite for a specific application is first of all determined by the frequency and the power level at which the material is used. Mn–Zn ferrites are suitable up to 1 MHz for low and high power level. For frequencies above 1 MHz, the Ni–Zn ferrite system is more appropriate, because of the high electrical resistance, due to the absence of Fe^{2+}, which lowers the losses. At microwave frequencies the electrical conductivity must be very low, so that microwave ferrites are found in the Ni–Al ferrite system. An illustrative example that the choice of a basic ferrite composition for a specific application is determined by the operation frequency is given by the ferrites for deflection yokes. Because of the higher sweep frequency in high-definition *T*V and the higher resolution and the larger screen in display monitors, the original Mg–Mn ferrites are gradually replaced by the more high resistive ferrites like Mn–Mg–Zn and Ni–Zn–Cu ferrites.

Another new field in soft ferrites is the multilayer ferrite chip inductor, which consists of thin ferrite layers between silver strips which form the internal windings in the final assembly of the ferrite layer inductor. Because ferrite layers and silver strips are sintered together, low-temperature sintering is required, which limits this technique to the low-melting Ni–Zn–Cu ferrite system (Ohiai, 1997).

In addition to the basic composition, which represents only the main components of the ferrites, several types of additives are used to achieve a fine-tuning of the final properties. Depending on the objectives three types of additives can be distinguished. The first class of additives comprises of those which substitute for the main components and which control the intrinsic properties like magnetostriction, magnetic anisotropy and electrical resistance. For instance in high-permeability Mn–Zn ferrite, the presence of Fe^{2+} is essential to obtain zero magnetic anisotropy. To decrease the electrical conductivity, simultaneously with the introduction of Fe^{2+} four valent ions like Ti or Ge are substituted (Stijntjes, Klerk and Broese van Groenou, 1970). In Ni–Zn ferrites the anisotropy is tuned by the substitution of bivalent cobalt (Vogel, Gyorgy, Johnson and Sherwood, 1986). The second type concerns additives designed to segregate at the grain boundaries like Si, Zr, Ca and Ta, in order to increase the grain-boundary resistance and to reduce eddy-current losses (Otsuki, 1992; Drofenik, Žnidarsič and Zajč, 1997). Ca and Si are already present in the raw materials as impurities. In addition to the formation of the high-resistance grain boundary, Ca and Si promote the sintering of the polycrystalline ferrite by the formation of a 'glass' phase at the boundary. Sintering can be carried out at lower temperatures, preventing exaggerated grain growth. The third class of additives promotes or prevents grain growth. Grain growth is usually promoted by a liquid phase at the grain boundary by additives like CaO, SrO, V_2O_5, Nb_2O_5, Sb_2O_5, PbO, and CuO (Yan and Johnson, 1978). TiO_2 and SiO_2

sustain also the exaggerated grain growth but without a liquid phase; this effect is caused by the formation of cation vacancies and the diffusion of Ti and Si into the grains. Ta_2O_5 and ZrO_2 inhibit particle growth (Ishino *et al*., 1992). However, depending on the processing parameters like sinter temperature and atmosphere, additives can show opposing effects upon the grain growth. Ta_2O_5 dissolves in the spinel lattice above 1250 °C leading to an increased grain growth, below 1250 °C grain growth is inhibited by Ta_2O_5 segregation at the grain boundary (Žnidarsič, Limpel, Dražič and Drofenik, 1992). Similar to BaO, segregating in the solid grain boundary below 1240 °C preventing grain growth, at higher temperature a liquid phase is formed promoting grain growth (Drofenik, Besiničar and Kolar, 1984).

The properties of ferrites are not only determined by the chemical composition; the polycrystalline microstructure and the cation distribution between the tetrahedral and octahedral sites determine the properties as well. Because of the temperature dependence of the cation distribution, for example, in Mn, Mg, and Cu ferrites, the magnetic properties can vary within the range as indicated in Table 2, which is due to the differences in cation distribution, which are frozen during the cooling after the sinter process. The microstructure, that is, the nature of the grain boundary and the grain size does affect the magnetic susceptibility. Ferrites have an advantage that the electrical conductivity is lower than for metallic materials, but for high-permeability Mn–Zn ferrites it is desirable to choose compositions with some excess of iron. This excess of iron is present as Fe^{2+} and sets the magnetic anisotropy and magnetostriction to zero, which gives rise to a large secondary maximum in the permeability (Stijntjes and Roelofsma, 1986). Unfortunately, the mixed valence of the iron ion also gives rise to an increased electronic conductivity, which increases the eddy-current loss. By an appropriate ceramic processing, the grain boundaries can be oxidized preferentially, which increases the grain-boundary resistance and causes a frequency dependence of the effective conductivity (Koops, 1951), which means a reduction of the losses in the low frequency range. As will be discussed in the section on the magnetic permeability, the grain-boundary characteristics play an important role in the development of high-quality ferrites. The grain-boundary chemistry and structure of various commercial-grade Mn–Zn ferrites were investigated with high-resolution-transmission-electron-microscopy and Auger analysis. It was shown that glassy phases are present on a nanoscale in 1-MHz ferrites, while for 100-kHz ferrites no such phases are present, but only an enrichment of the grain boundary occurs with impurities like Ca, Si, Ti and Sn. Simultaneously, a 5–10-nm mosaic structure occurs near the grain boundary, with low angle tilts in the order of a few tenths of a degree (Nomura, 1992). Also, residual stresses, due to the grain-boundary structure and stresses induced by the thermal processing alter the permeability and losses, which is convincingly proved in the case of the excessive silver addition to Ni–Cu–Zn multilayer ferrite chip inductors. The deterioration of the magnetic properties is caused by the comprehensive stress, originating from silver precipitates at the grain boundary (Nakano, Momoi and Nomura, 1992).

2.4 Maghemite

An outstanding ferrite material is maghemite, γ-Fe_2O_3, which at room temperature is a metastable phase of ferric oxide. The stable α-Fe_2O_3 phase, hematite, has a corundum-type crystal structure; maghemite has a cation-deficient spinel structure $Fe[\theta_{0.33}Fe_{1.67}]O_4$, with the cation vacancies at the B sites. Maghemite can only be prepared at temperatures below 450 °C by oxidation of magnetite or dehydration of ferric hydroxides because above 450 °C γ-Fe_2O_3 transforms to the stable α-phase. Because of the low-temperature preparation, poorly crystallized particles are formed in which the

Fe^{3+} cations and the vacancies are distributed in a disordered way. An ordered structure of maghemite is also known, in which the vacancies and Fe^{3+} ions are 1:5 ordered on the B sites, forming a tetragonal structure with $a = 8.3396$ Å and $c = 24.9663$ Å. The cubic lattice parameter of the disordered structure is 8.3363 Å (Greaves, 1983). γ-Fe_2O_3 is applied in magnetic recording in the form of particulate media and as thin films. An important property for this application is the coercive force H_c. For iron-based recording particles, the H_c is increased by improving the acicular form of the particles, which increases the shape anisotropy (range of H_c 250–450 Oe). A second possibility is the increase of the magnetocrystalline anisotropy by Co^{2+} doping. The most effective way to increase H_c turned out to be the absorption of Co^{2+} in the surface of the particles, which results in materials known as surface Co-modified iron oxides ($H_c \sim 1000$ Oe). Besides the shape and the magnetocrystalline anisotropy, the surface anisotropy is another factor determining the size of the coercive force of the ferrite particles. Because of the large specific surface, the balance of the exchange interactions at the surface will be different from that in the bulk. A magnetic surface reconstruction might occur where the spin system lowers its energy by adopting a noncollinear structure at the surface. The concept of surface spin canting explains the particle size dependence of the magnetization and spin canting has been experimentally proved to exist by the nondisappearance of the second and fifth line in the Mössbauer spectra in an external longitudinal field (Coey, 1971). However, spin canting in small particles has not been restricted to the surface layer as was theoretically described by a simple mean-field model, but is a routine manifestation of the response of a uniaxial magnetic particle to an applied field. Consequently, a ferrimagnetic particle will not saturate by a large magnetic field (Pankhurst and Pollard, 1991). Experimental evidence for the spin canting throughout the particle has been given by the Mössbauer study of ^{57}Fe surface enriched γ-Fe_2O_3 particles (Parker and Berkowitz, 1991; Parker, Foster, Margulies and Berkowitz, 1993). Notwithstanding the importance of Co-modified γ-Fe_2O_3 as recording medium, the mechanism of the increase of H_c by the surface treatments is not clear. Co absorption onto the γ-Fe_2O_3 acicular particles increases the uniaxial anisotropy of the precursor particles, originally mainly due to the shape anisotropy. Since acicular γ-Fe_2O_3 particles are elongated along the $\langle 110 \rangle$ axis, the large single-ion anisotropy of Co^{2+} in the $\langle 100 \rangle$ direction should introduce a multiaxial anisotropy in the epitaxial oriented cobalt ferrite layers on the particle surface. The result has to be an anisotropic axis at the surface not collinear with those of the interior. An explanation for the observed uniaxial anisotropy of the whole particle is not found. The demagnetization field of the particle has been suggested to induce a uniaxial cobalt ferrite coating by establishing a local reorientation of the anisotropic Co^{2+} ions like in the DA phenomena. Another possibility is the migration of Co^{2+} into the lattice sites with a symmetry axis close to the field direction. The crystal defects at the surface created by the cobalt absorption have to be considered in more detail as possible explanation of the enhanced anisotropy. It has been shown that other 'chemistry' effects at the surface layer change the anisotropy as well (Slonczewski, 1992).

2.5 The magnetic permeability of polycrystalline ferrites

For designing components based on polycrystalline soft ferrites, the magnetic permeability as function of frequency, temperature, and magnetic field as well as the magnetic losses are significant factors. For polycrystalline ferrites two magnetization processes are of importance: rotation of the spontaneous magnetization in the domains and the domain wall displacement. In general the domain wall displacement gives a larger component to the permeability than the rotational process and accounts for the high permeability of a certain class of nonmicrowave ferrites. For microwave ferrites (>100 MHz) the rotational process is the dominant mechanism. On the basis of the natural spin resonance (NSR), which occurs at a resonance frequency $\omega_r = \gamma H^A$ (Landau and Lifshitz, 1935), in which H^A is the anisotropy field. A relation between the static permeability and the resonance frequency of the NSR has been derived:

$$f_r(\mu_i - 1) = \tfrac{4}{3}\gamma M_s \tag{3}$$

in which M_s represents the saturation magnetization and $\gamma = g \times e/2mc$. (Snoek, 1948).

For a series of polycrystalline $Ni_xZn_{1-x}Fe_2O_4$, the dispersion frequency in the permeability spectrum could be well explained by the NSR according to formula (3), which suggests that these ferrites are magnetized by the rotational process (Smit and Wijn, 1959).

The initial permeability of a material originating from rotational magnetization is given by:

$$(\mu_i - 1) = c \times M_s^2/K_1 \tag{4}$$

The coefficient c depends on the sign of the anisotropy ($c = \frac{1}{3}$ for positive K_1, $c = \frac{1}{2}$ for negative K_1). The rotational permeability does not depend on the microstructure of a polycrystalline ferrite, but for a large number of ferrites the permeability turned out to be linearly dependent on the grain size D. This microstructure dependence can easily be understood by the domain wall displacements if one considers the pinning effect of the grain boundaries upon the walls.

Because of the crystallographic disorder in the grain boundary and the porosity of the ceramic ferrites, domain walls are pinned at the periphery of the grain and can only bulge out when a small external field is applied. In equilibrium, the gain in field energy is in balance with the increased wall energy caused by the increased wall area and the demagnetization energy because of the magnetic poles formed on the bulged wall. By considering the demagnetization energy as the main effect, μ_i can be approximated by

$$(\mu_i - 1) \approx 20\, M_s^4 \times D/K_1^2 \times d \tag{5}$$

with d being the distance between the domain walls (Smit and Wijn, 1959).

A linear grain size dependence of the permeability was found with a simple but elegant model of spherical bulging of a domain wall, pinned to the grain boundary in a spherical grain with diameter $D = 2r$. The responding spherical bulging upon a weak magnetic field is schematically shown in Figure 4; the increased wall surface is $\pi \times (r^2 + x^2)$ and the volume of the black spherical segment is $\pi/6 \times x(3r^2 + x^2)$. Minimization of the magnetostatic energy of the reversed magnetization in this segment and the wall energy gives for the permeability:

$$(\mu_i^c - 1) = {}^3\!/_4\pi \times M_s^2 \times D/\gamma \tag{6}$$

in which γ represents the wall energy (Globus, 1977) and μ_i^c the experimental μ_i, corrected for the porosity $\mu_i^c = \mu_i \times d_x/d$, with d_x, the X-ray density and d the density of the polycrystalline material. The frequency dependence of the wall susceptibility can also be derived from the equation of motion of a unit surface of a 180° domain wall in an infinite medium (Döring, 1948)

$$m\ddot{z} + \beta\dot{z} + \alpha z = 2M_s \times H \tag{7}$$

m represents the domain wall mass, β the damping and α the restoring force per unit surface. Supposing that the damping is dominant and the response of the domain wall is linear, equation (6) can be derived for the wall permeability and for the relaxation frequency $f_o = 4\gamma/\pi\beta r^2$ (Guyot, Merceron, Cagan and Messekher, 1988). For polycrystalline $NiFe_2O_4$ a relaxation frequency proportional to $1/D^2$ was found and the maximum in the frequency dependence of the magnetic losses was found to be proportional with D_m, the mean grain size diameter (Gieraltowski and Globus, 1977). A practical impact of these findings is that the dispersion of the permeability can be shifted to higher frequencies and the magnetic losses be suppressed by tailoring the microstructure that is, lowering the grain size. Bulging of the domain wall in a weak magnetic field is a reversible process, which is supposed to cause no losses up to a critical field H_{cr} above which a sudden increase is observed. A typical example of the field dependence of the permeability for polycrystalline Ni–Zn ferrite is given in Figure 5 (Globus and Duplex, 1971). The appearance of the critical field H_{cr} is attributed to the depinning of the domain walls from the grain boundary. The result is an irreversible displacement of the domain wall with hysteresis losses (Guyot and Globus, 1973, 1977). Hysteresis losses within Globus' model are ascribed to the continuous pinning and depinning of the domain wall at the grain boundaries, which can be considered as a friction force causing an energy loss. A second contribution to the losses is proportional with the wall energy in that part of the domain wall, which is created and annihilated during the wall displacements. The same wall displacement is also related to the magnetoacoustic emission (MAE). MAE is the phenomenon when bursts of stress waves

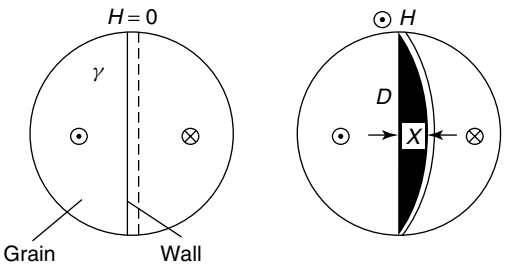

Figure 4. Schematic presentation of a domain wall pinned to the grain boundary in a spherical grain.

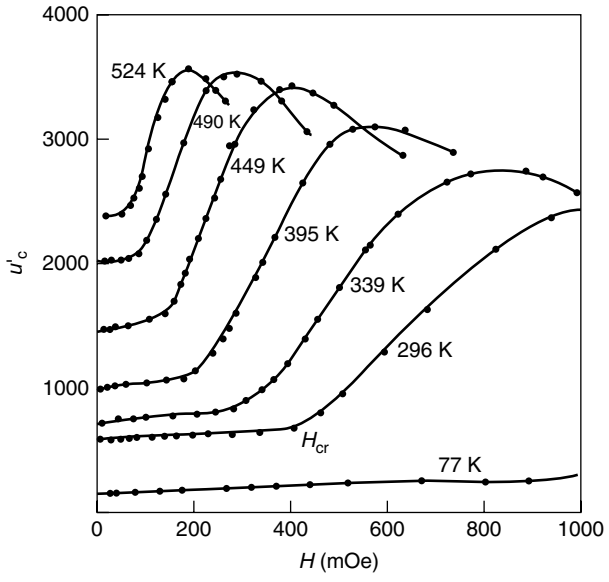

Figure 5. The permeability of polycrystalline $Ni_{0.5}Zn_{0.5}Fe_2O_4$ (grain size $D = 3.0\,\mu m$ and porosity = 0.03) as function of the measuring field H at various temperatures. (Reproduced from A. Globus *et al.*, 1971, with permission from EDP Sciences. © 1971.)

are generated during the irreversible magnetization process, originating from magnetoelastic interactions. The MAE is usually attributed to the release of magnetoelastic energy associated with the jumping of non -180° domain walls, because the displacement of a 180° wall does not change the magnetoelastic energy; the linear magnetostriction is an even function of the magnetization. In particular, for 180° domain walls, the release of the elastic energy by the creation and annihilation of these walls is supposed to cause the MAE, which can in turn be the mechanism for the hysteresis loss in ferrites (Guyot and Cagan, 1991, 1993).

The microstructure of ceramic ferrites is not only specified by the grain size, but nonmagnetic inclusions like closed pores and the finite thickness of the grain boundaries modify the physical properties significantly. In addition for the low anisotropy Mn–Zn ferrites, indications are found that also for ferrites with mainly rotational magnetization processes, a large grain size effect upon the permeability exists (Visser, Roelofsma and Aaftink, 1989). An explanation for this apparent controversy is found in the magnetic inhomogeneity of the ferrite materials.

If the demagnetizing fields caused by the nonmagnetic closed pores and the low-permeability grain boundaries are taken into consideration, the apparent μ_e for a polycrystalline matrix is given by Rikukawa (1982):

$$\mu_e = (1 - P)\mu_i/(1 + P/2) \times (1 + 0.75^{\delta}/_{D} \times \mu_i/\mu_b) \quad (8)$$

with μ_e the apparent permeability, P the porosity, δ the width of the grain boundary, D the grain size, μ_i the permeability of the grain and μ_b the permeability of the grain boundary, which is supposed to be much lower than μ_i. Since equation (8) contains only μ_i, irrelevant which mechanism is accountable for the magnetization, ferrites with rotational permeability can show a grain size effect. Most high-quality ferrites have very low porosity, which means that only low-permeability grain boundaries have to be considered which simplifies equation (8) to (Johnson, Noordermeer, Severin and Meeuwissen, 1992):

$$\mu_e = \mu_i \times D/(\mu_i\delta + D) \quad (9)$$

This is known as the nonmagnetic grain-boundary model (NMGB). The experimental results on certain polycrystalline Mn–Zn ferrites show a good fit with equation (9) as is shown in Figure 6, indicating that in these ferrites the rotational mechanism cannot be excluded. The observed decrease of the resonance frequency with increasing grain size is another point in favor of the rotational permeability for these ferrites (Visser and Johnson, 1991). However, a serious drawback of the NMGB model is that the loss factor $\mu''/(\mu')^2$ and

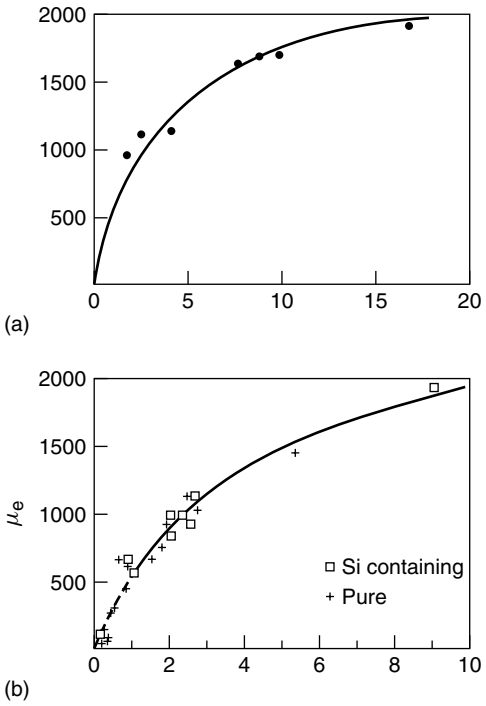

Figure 6. (a) Grain size dependence of the rotational permeability of polycrystalline $Mn_{0.68}Zn_{0.24}Fe_{2.08}O_4$. The grains contain no domain walls because of the small size of the grains. The solid curve fits equation (9) with $\mu_i = 2500$ and $\delta = 1.5$ nm. (Reprinted from Johnson *et al*., 1991, with permission from Elsevier. © 1991.) (b) Similar plot as (a) for $Mn_{0.60}Zn_{0.35}$ $Fe_{2.05}O_4$. (Reprinted from Johnson *et al*., 1992, with permission from Elsevier. © 1992.)

the temperature factor $1/\mu^2 \mathrm{d}\mu/\mathrm{d}T$ are independent of the grain size, which is not in agreement with experiment (Visser and Johnson, 1991). Both factors are strongly affected by the microstructure (Snelling, 1988). In fact the Globus wall size model and the NMGB model can be combined in a transition region, as was shown by the analysis of the permeability data of coarse-grained Mn–Zn ferrites, these models also have mutually excluding regions of validity (Visser, Johnson and van der Zaag, 1992). However, in the design of ferrites, these models are useful as guidelines to produce materials with improved properties for particular specifications.

Besides the permeability, the magnetic losses are an important quality factor of a magnetic ferrite. The magnetic loss is composed of three contributions: hysteresis losses, eddy-current loss and the residual loss, which can be represented by a total loss factor (Snelling, 1988):

$$\begin{aligned}\tan\delta_t/\mu &= \mu''/(\mu')^2 = \tan\delta_h/\mu + \tan\delta_e/\mu + \tan\delta_r/\mu \\ &= {}^4\!/_3 \nu B/\mu_o\mu^3 + \pi\mu_o d^2 f/16\rho + \tan d\delta_r/\mu \\ &= a \times B + b \times f + c \end{aligned} \quad (10)$$

with ν the Rayleigh coefficient ($\mu(H) = \mu_i + \nu H$), B the peak value of the flux density perpendicular to the cross section of a cylinder of the ferrite material with radius d, f the frequency, and ρ the bulk resistance. The coefficients a and c are the hysteresis and residual loss coefficients and are pure material properties, b is the eddy-current loss coefficient also depending on the geometry of the component.

The total power loss can be determined from the loss factor by the relation:

$$P = (\tan\delta/\mu) \times \pi \times f \times B^2/\mu_o \quad \text{Watt/m}^3 \qquad (11)$$

The eddy-current loss in ferrites is usually small compared with the total loss because of the low electrical conductivity. However to produce high-permeability Mn–Zn ferrites, which means low anisotropy, compensation by substitution of Fe^{2+}–Ti^{4+} is often used. The introduction of Fe^{2+} enhances the electrical conductivity in the grain, which increases the eddy-current loss. By a proper addition of Ca and Si to the grain boundary, a higher effective resistance in the low frequency range is obtained, which lowers the eddy-current loss again, but also the permeability according to the NMGB model.

The largest contribution to the total loss originates from the hysteresis losses, caused by the irreversible domain wall displacements, which increase with increasing amplitude of the ac field and which are determined by the wall pinning. A possibility of decreasing the hysteresis loss is to suppress the wall permeability and to promote the rotation permeability, which can be achieved by small grains in which no wall can exist or by domain wall pinning by anisotropic ions like Co^{2+} ions. Specifically, ferrites with low power losses at high frequencies are indispensable for the size reduction of power supplies operating at high frequencies. For Mn–Zn power ferrites applied up to 500 kHz, substantial improvements of the losses have been realized by simultaneous substitution with Co^{2+} and Ti^{4+} and an optimization of the thermal processing of the ceramic production by which the Ca segregates preferentially at the grain boundary. If the large Ca ion is incorporated in the grain, the lattice stresses cause additional losses (Stijntjes and Roelofsma, 1986). The hysteresis losses provoke a loss tangent proportional to the magnetic induction and the eddy-current loss a tangent proportional with frequency. The third loss contribution, the residual loss, is the remaining loss, measured at low frequencies and small field, where hysteresis and eddy-current losses are going to zero.

The residual loss is partly associated with the magnetic aftereffects due to thermally activated domain wall motions.

3 MAGNETIC IRON GARNETS

The garnet structure has been for the first time found for a series of silicates with the general formula $(A_3)_c(B_2)_a(Si_3)_d\ O_{12h}$; the space group is $O_h^{10} - Ia3d$, containing 8 'molecules' per unit cell (Menzer, 1926, 1928). There are three different cation sublattices given by the subscripts c, a and d, indicating the Wyckoff positions and which are composed of 24 dodecahedral, 16 octahedral, and 24 tetrahedral sites, respectively. The garnet structure can accommodate a large variety of cations in variable concentrations and an extended range of mixed series is known. Magnetic iron-based synthetic garnets were first synthesized by Bertaut and Forrat (1956). The prototype of the magnetic garnet is yttrium iron garnet (YIG), which can be presented by the formula $(Y_3^{3+})_c\ (Fe_2^{3+})_a\ (Fe_3^{3+})_d\ O_{12h}$. The Y^{3+} are located on the dodecahedral sublattice and the octahedral a and tetrahedral d lattices are occupied by Fe^{3+} ions. Substitution of Y^{3+} by a rare-earth (RE) ion gives a series of iron garnets all with a lattice parameter in the order of 12 Å and with remarkable temperature dependence of the saturation magnetization, as shown in Figure 7 (Bertaut and Pauthenet, 1957). The magnetization of the iron garnet is the resultant of the magnetization vectors of the three sublattice magnetizations, $M_s = M_a + M_d + M_c$, in which the iron sublattice magnetizations M_a and M_d are antiparallel and the RE sublattice M_c is parallel with M_d for the light RE (Ce, Pr, Nd) and parallel with M_a for the heavier RE ions (Eu, . . . , Yb). The antiferromagnetic coupling of the RE with the Fe^{3+} ions is weaker than between the iron ions, which results in a quick drop of the RE magnetization at low temperature. Because of the large moment of the RE ions, the RE magnetization prevails at low temperature and the Fe^{3+} magnetization at higher temperature. The result is the presence of a compensation point in the T dependence of the magnetization. For all the RE iron garnets, T_c is determined by the super-exchange interaction of the Fe^{3+} lattices and is almost identical for all the RE iron garnets ($\pm$560 K). At room temperature the complete antiparallel arrangements of the magnetizations as mentioned before occur, but at low temperatures the RE moments itself are arranged in a noncollinear structure. The point symmetry of the dodecahedral RE site is D_2, rhombic. The local symmetry on these sites is formed by three perpendicular twofold axes for which there are six different orientations possible with reference to the cubic crystal structure axis. In principle there are now six magnetic sublattices possible of which the magnetization can be canted with respect to each other. For instance, the umbrella structure has been reported for $Er_3Fe_5O_{12}$ (Hock, Fuess and Bonnet, 1991), whereas the double umbrella structure has been reported for holmium and terbium iron garnets (Hock, Fuess, Vogt and Bonnet,

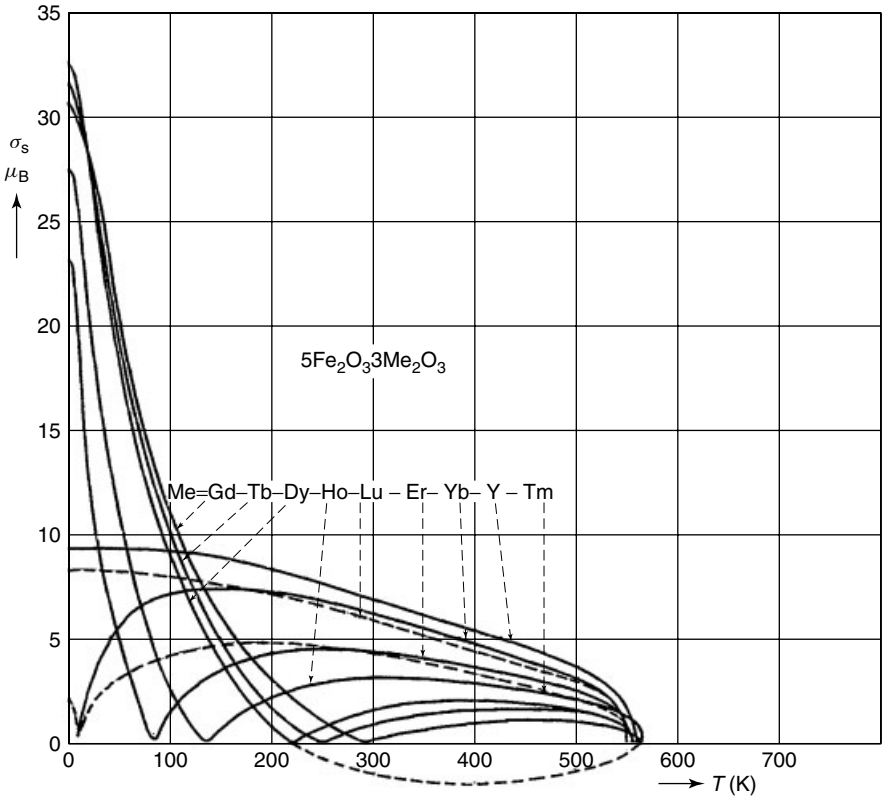

Figure 7. Spontaneous magnetization of a number of rare-earth garnets and yttrium iron garnet in μ_B per formula unit as function of temperature. (Reproduced from Bertaut *et al.*, 1957, with permission from IEE. © 1957.)

1990; Guillot, Tcheou, Marchand and Feldmann, 1984). If the resultant magnetization is directed along the ⟨111⟩ direction the magnetic moments of the RE ions are divided into two sets of three, which lie on two cones, forming the double umbrella structure. For the magnetization parallel to the ⟨100⟩ direction two of the six RE moments lie along the magnetization direction and the other four lie again on one cone, the so-called umbrella structure. The exchange interactions of the RE ions are weaker than the iron interactions, which makes it easy to change the direction of their magnetic moments, especially close to the compensation temperature. Spin orientation transitions can occur by a temperature variation or an external magnetic field. A survey of this type of transitions is given by Balestrino and Geller (1985). Iron garnets are excellent materials for microwave frequencies because of the narrow resonance line. Thin films are favorable for their magneto-optic properties. In particular the substitution of the RE ion by Bi and the iron by other metals gives the opportunity to tune the properties for special purposes. However, the substitution of iron by other magnetic or nonmagnetic metal ions lowers the Curie temperature and the spontaneous magnetization; if diamagnetic cations are involved, local canting of the Fe^{3+} magnetic moments may occur, which can generate even more magnetic phase transitions. A survey on the numerical data of the magnetic properties of RE iron garnets is given by Novak (1991).

4 HEXAGONAL FERRITES

$PbFe_{12}O_{19}$ is the archetype of a class of ferrites, which are indicated as M-type hexaferrites. These ferrites crystallize into the hexagonal magnetoplumbite structure, which is characterized by the space group $P6_3/mmc(D^4_{6h})$. The basis of this lattice is formed by a hexagonal closed packed array of oxygen ions, where in every fifth layer one-quarter of the oxygen ions is substituted by a Pb^{2+} ion. The Fe ions are located on five different interstitial sublattices, three with octahedral sites (indicated by 12k, 2a and $4f_2$), one with tetrahedral ($4f_1$) and one with bipyramidal sites (2b). The symbol of these sites includes the number of sites per unit cell. The lattice parameters of the magnetoplumbite structure are $a \approx 5.88$ Å and $c \approx 32.1$ Å. The unit cell contains two formula units. A variety of M-type ferrites can be produced by part or complete substitution of the Pb^{2+} cations by Ba^{2+}, Sr^{2+} or Ca^{2+}. The Fe^{3+} ions can be substituted by trivalent ions like Al^{3+}, Ga^{3+}, Mn^{3+}, or by a combination of divalent and four valence ions, such as Co^{2+}–Ti^{4+}.

$BaFe_{12}O_{19}$ was the first M-type ferrite employed as hard-magnetic material (Went, Rathenau, Gorter and van Oosterhout, 1952). The magnetic structure is ferrimagnetic with the magnetizations of the three sublattices 12k, 2a and 2b antiparallel with the remaining $4f_1$ and $4f_2$, which by complete alignment gives a spontaneous magnetization of $(16-8)\cdot 5 = 20\,\mu_B$ per formula unit (Gorter, 1957). The high coercive force is caused by the large uniaxial anisotropy along the *c* axis, which is caused by the hexagonal structure and the typical oxygen coordination of the bipyramidal sites (Smit and Wijn, 1959). Permanent magnets based on $BaFe_{12}O_{19}$ are produced by a ceramic technology, in which two objectives are essential. In the first place the grain size must be small (about 1 μm) in order to be a single domain to obtain high coercivity. Secondly, the grains must be aligned during a wet-pressing process by a magnetic field, in order to get an anisotropic magnet with an enhanced effective magnetization. The temperature dependence of the saturation magnetization around room temperature is high, which makes the M-type ferrites not suited for high precision applications (Shirk and Buessem, 1969). The ceramic processing of the production of permanent hexaferrite magnets plays a crucial role in the final performance of the magnets. The basic properties of the M-hexaferrites are not very distinct for the various compositions, as long as the iron concentration is high. The microstructure, that is, the grain size, alignment and the grain boundary determine to a great extent the hard-magnetic properties. The Sr-based M-ferrites have the advantage of a higher coercive force at some level of remnant magnetization, because the ceramic processing is easier to control for this composition (Cochardt, 1966). The ceramic techniques have been optimized in such a way that further improvement of the performance of the permanent ferrite magnets is very limited. However, some improvements seem still to be possible by improving the intrinsic properties by a chemical modification. An increase of the anisotropy in the Sr-based M-ferrite is possible, if Sr^{2+} and Fe^{3+} are replaced by La^{3+} and Co^{3+}, which results in a strong increase of anisotropy and coercivity, without a negative effect on the remnant magnetization (Tenaud *et al*., 2004).

Table 3. Compositions of hexagonal ferrites.

Type	Chemical formula	Short symbol
M	$BaFe_{12}O_{19}$	BaM
W	$BaMe_2Fe_{16}O_{27}$	Me_2W
Y	$Ba_2Me_2Fe_{12}O_{22}$	Me_2Y
Z	$Ba_3Me_2Fe_{24}O_{41}$	Me_2Z
X	$Ba_2Me_2Fe_{28}O_{46}$	Me_2X
U	$Ba_4Me_2Fe_{36}O_{60}$	Me_4U

Besides the M-type hexaferrites, a number of other hexaferrites exist which have strongly related crystal structures because they are built from similar crystal blocks as the M-structure (Smit and Wijn, 1959). In Table 3 the chemical formulas of the various types are given, in which Me stands for a bivalent transition-metal ion or Mg and Zn. In all these ferrites the hexagonal axis settles the magnetization in the sense that the magnetization is strongly aligned into the *c* direction, which means hard-magnetic materials. A second possibility is that the magnetization is aligned in a plane perpendicular to the *c* axis, which means high magnetic permeability in the plane but low in the other directions, the so-called ferroxplana materials. The W-, X- and Z-type compounds show uniaxial anisotropy in the *c* direction, but because of their problematic processing in the production, they are not attractive for the production of permanent magnets. The Y compounds, showing the ferroxplana behavior, are materials very well suited for high frequencies up to 1 GHz (Jonker, Wijn and Braun, 1957).

1 INTRODUCTION

The structural family of perovskites is a large family of compounds having crystal structures related to the mineral perovskite $CaTiO_3$. In the ideal form, the crystal structure of cubic ABX_3 perovskite can be described as consisting of corner sharing $[BX_6]$ octahedra with the A cation occupying the 12-fold coordination site formed in the middle of the cube of eight such octahedra. The ideal cubic perovskite structure is not very common and also the mineral perovskite itself is slightly distorted. The perovskite family of oxides is probably the best-studied family of oxides. The interest in compounds belonging to this family of crystal structures arises from the large and ever surprising variety of properties exhibited and the flexibility to accommodate almost all of the elements in the periodic system. Pioneering structural work on perovskites were conducted by Goldschmidt and coworkers in the 1920s that formed the basis for further exploration of the perovskite family of compounds (Bhalla, Guo and Roy, 2000). Distorted perovskites have reduced symmetry, which is important for their magnetic and electric properties. Owing to these properties, perovskites have great industrial importance, especially the ferroelectric tetragonal form of $BaTiO_3$.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

2 THE CRYSTAL STRUCTURE OF PEROVSKITE

If the large oxide ion is combined with a metal ion having a small radius, the resulting crystal structure can be looked upon as close-packed oxygen ions with metal ions in the interstitials. This is observed for many compounds with oxygen ions and transition metals of valence +2, for example, NiO, CoO, and MnO. In these crystal structures, the oxygen ions form a cubic close-packed (ccp) lattice with the metal ion in octahedral interstitials (i.e., the rock salt structure). Replacing one-fourth of the oxygen with a cation of approximately the same radius as oxygen (e.g., alkali, alkaline earth, or rare earth element) reduces the number of octahedral voids, occupied by a small cation, to one-fourth. The chemical formula is written as ABX_3 and the crystal structure is called *perovskite*. X is often oxygen but other large ions such as F^- and Cl^- are also possible.

The idealized cubic structure is realized, for example, in $CaRbF_3$ and $SrTiO_3$. The latter can be described as Sr^{2+} and O^{2-} ions forming a ccp lattice with Ti^{4+} ions occupying the octahedral holes created by the oxygen ions. The perovskite structure has a three-dimensional net of corner sharing $[TiO_6]$ octahedra with Sr^{2+} ions in the 12-fold cavities in between the polyhedra (see Figure 1).

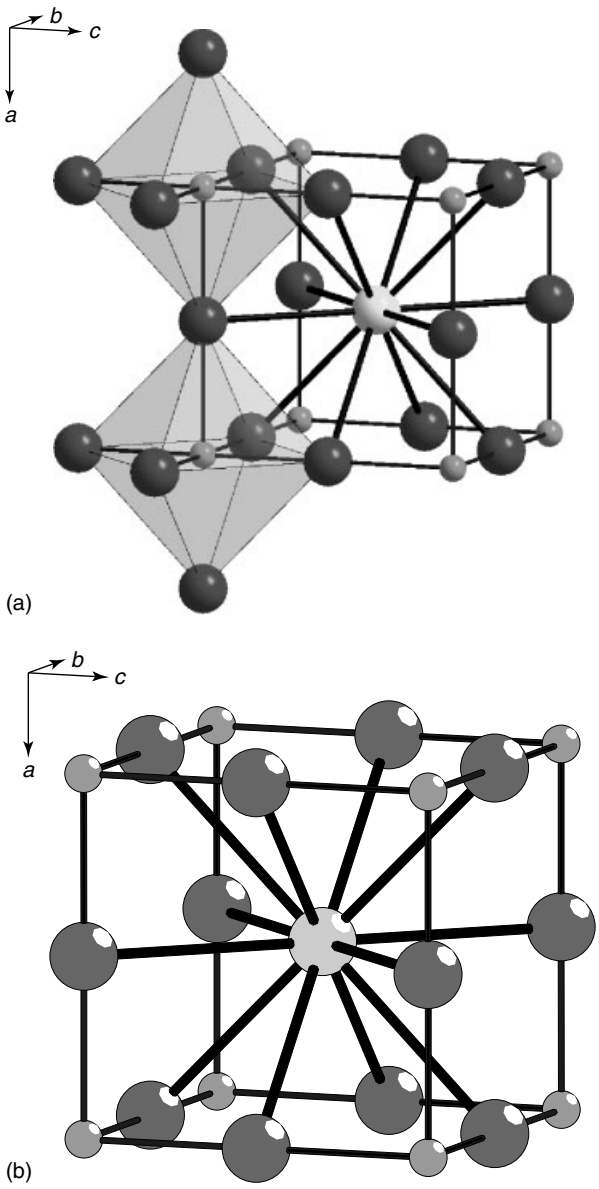

Figure 1. Outline of the ideal cubic perovskite structure $SrTiO_3$ that has (a) a three-dimensional net of corner sharing $[TiO_6]$ octahedra with (b) Sr^{2+} ions in the twelve fold cavities in between the polyhedra.

In the cubic ABX_3 perovskite structure ($a = 3.905$ Å, space group $Pm3m$, $Z = 1$), the A atoms are in Wyckoff position 1b, ½,½,½; the B atoms in 1a, 0,0,0; and the X atoms in 3d ½,0,0; 0,½,0; 0,0,½, all being special positions. If the position of the Sr^{2+} ion (A) is vacant, the remaining framework is that of the ReO_3 type. Partial occupation of the A position occurs in the cubic tungsten bronzes A_xWO_3 (A = alkali metal, $0.3 \leq x \leq 0.93$). The ReO_3 structure type can be converted to a denser packing by rotating the octahedra until a hexagonal close packing of the RhF_3 type is obtained. The void in the center has then an octahedral surrounding. If this octahedral hole is occupied we have the ilmenite structure, $FeTiO_3$. The perovskite structure is known to be very flexible, and the A and B ions can be varied leading to the large number of known compounds with perovskite or related structures. Most perovskites are distorted and do not have the ideal cubic structure.

Three main factors are identified as being responsible for the distortion: size effects, deviations form the ideal composition, and the Jahn–Teller effect. It is rare that a distortion of a certain perovskite compound can be assigned to a single effect. In most cases several factors act on the structure. As an example of the complexity, $BaTiO_3$ has four phase transitions on heating: rhombohedral ($R3m$), $-90\,^{\circ}C \rightarrow$ orthorhombic ($Amm2$), $5\,^{\circ}C \rightarrow$ tetragonal ($P4mm$), $120\,^{\circ}C \rightarrow$ cubic ($Pm3m$).

2.1 Size effects

In the ideal cubic case, the cell axis, a, is geometrically related to the ionic radii (r_A, r_B, and r_O) as described in equation (1):

$$a = \sqrt{2}(r_A + r_O) = 2(r_B + r_O) \tag{1}$$

The ratio of the two expressions for the cell length is called the *Goldschmidt's tolerance factor* t, and it allows us to estimate the degree of distortion. It is based on ionic radii, that is, purely ionic bonding is assumed, but can be regarded as an indication for compounds with a high degree of ionic bonding; it is described in equation (2).

$$t = \frac{(r_A + r_O)}{\sqrt{2}(r_B + r_O)} \tag{2}$$

The ideal cubic perovskite $SrTiO_3$ has $t = 1.00$, $r_A = 1.44$ Å, $r_B = 0.605$ Å, and $r_O = 1.40$ Å. If the A ion is smaller than the ideal value then t becomes smaller than 1. As a result, the $[BO_6]$ octahedra will tilt in order to fill space. However, the cubic structure occurs if $0.89 < t < 1$ (Wells, 1995; Müller, 1993). Lower values of t will lower the symmetry of the crystal structure. For example, $GdFeO_3$ (ICSD, 2005) with $t = 0.81$ is orthorhombic ($r_A = 1.107$ Å and $r_B = 0.78$ Å) (see Figure 2a). Also the mineral perovskite $CaTiO_3$ itself, has this structure. With values less than 0.8, the ilmenite structure is more stable.

On the other hand, if t is larger than 1 due to a large A or a small B ion then hexagonal variants of the perovskite structure are stable, for example, $BaNiO_3$ type structures. In this case, the close-packed layers are stacked in a hexagonal

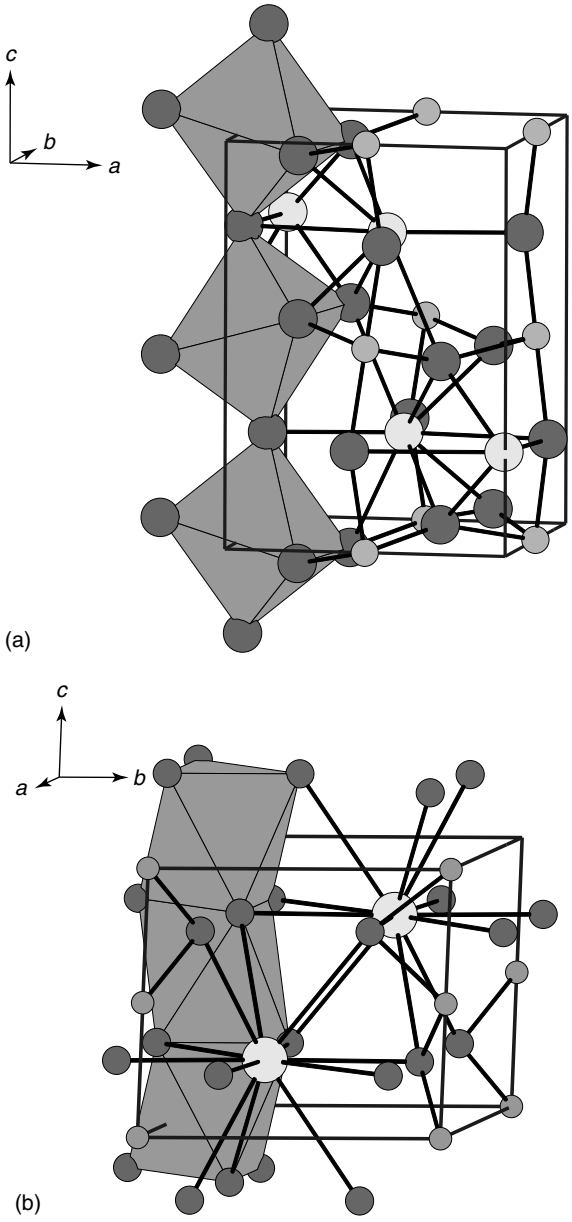

Figure 2. (a) Low values of the tolerance factor t will lower the symmetry of the crystal structure. $GdFeO_3$ with $t = 0.81$ have tilted $[FeO_6]$ octahedra and crystallize in the orthorhombic system ($r_A = 1.107$ Å and $r_B = 0.78$ Å). (b) If t is larger than 1 due to a large A or a small B ion then hexagonal variants form of the perovskite structure. The t value for $BaNiO_3$ is 1.13 ($r_A = 1.61$ Å and $r_B = 0.48$ Å).

manner in contrast to the cubic one found for $SrTiO_3$, leading to face sharing of the $[NiO_6]$ octahedra, (see Figure 2b). The t value for $BaNiO_3$ is 1.13 ($r_A = 1.61$ Å and $r_B = 0.48$ Å). Since perovskites are not truly ionic compounds and the t values also depend on the values that are taken for the ionic radii, the tolerance factor is only a rough estimate.

2.2 Changing the composition from the ideal ABO_3

An example is the family of compounds $SrFeO_x$ ($2.5 \leq x \leq 3$). The valency of the Fe ions can be changed by heating the sample in either an oxidizing or a reducing environment. As a result, the oxygen content can vary between 2.5 and 3. For example, in $SrFeO_{2.875}$ some Fe ions can be assigned to the oxidation state +3 and others to +4. The oxygen vacancies order so that FeO_5 square pyramids are formed (see Figure 3). The $SrFeO_x$ compounds are examples of defective perovskites. Their chemistry can be described according to the homologous series $A_nB_nO_{3n-1}$, $n = 2 - \infty$. Several other types of vacancy orderings are known, for example, the structures of $Ca_2Mn_2O_5$ and $La_2Ni_2O_5$ having $n = 2$ are shown in Figure 4(a–b).

2.3 Jahn–Teller effects

In some perovskites, the distortion of the structure can be assigned to Jahn–Teller active ions at the B position. For example, in $LnMnO_3$ (Ln = La, Pr, or Nb) with Mn^{3+} ions the $3d^4$ electrons divide up into $3\,t_g$ and $1\,e_g$ electron. The odd number of electrons in the e_g orbital cause an elongation of the $[MnO_6]$ octahedron.

3 SUPERSTRUCTURES RELATED TO THE PEROVSKITE STRUCTURE

If we double all three unit cell edges of the cubic perovskite structure, it is possible to occupy equivalent positions with atoms of different elements (see Figure 5). In K_2NaAlF_6, the K^+ and the F^- ions take the Ca^{2+} and the O^{2-} positions, respectively, of the perovskite. The one-to-one relation can be recognized by comparing with the doubled formula of perovskite. The comparison also shows how the octahedral Ti^{4+} position shifts into two sites for Na^+ and Al^{3+} (Müller, 1993). In kryolite, Na_3AlF_6, the Na^+ ions occupy two different positions, namely the Sr^{2+} and the Ti^{4+} positions of the doubled perovskite cell, that is, positions with coordination numbers of 6 and 12. Since this is not convenient for ions of the same size, the structure experiences some distortion.

Perovskites of the type $ACuO_{3-\delta}$ which have Cu atoms in the octahedral sites are deficient in oxygen; alkaline earth, and trivalent ions (Y^{3+}, lanthanoids, Bi^{3+}, Tl^{3+}) occupy the A site. A typical composition is $YBa_2Cu_3O_{7-x}$ with $x \approx 0.04$. These compounds are high-temperature superconductors. The structure is a superstructure of perovskite, but

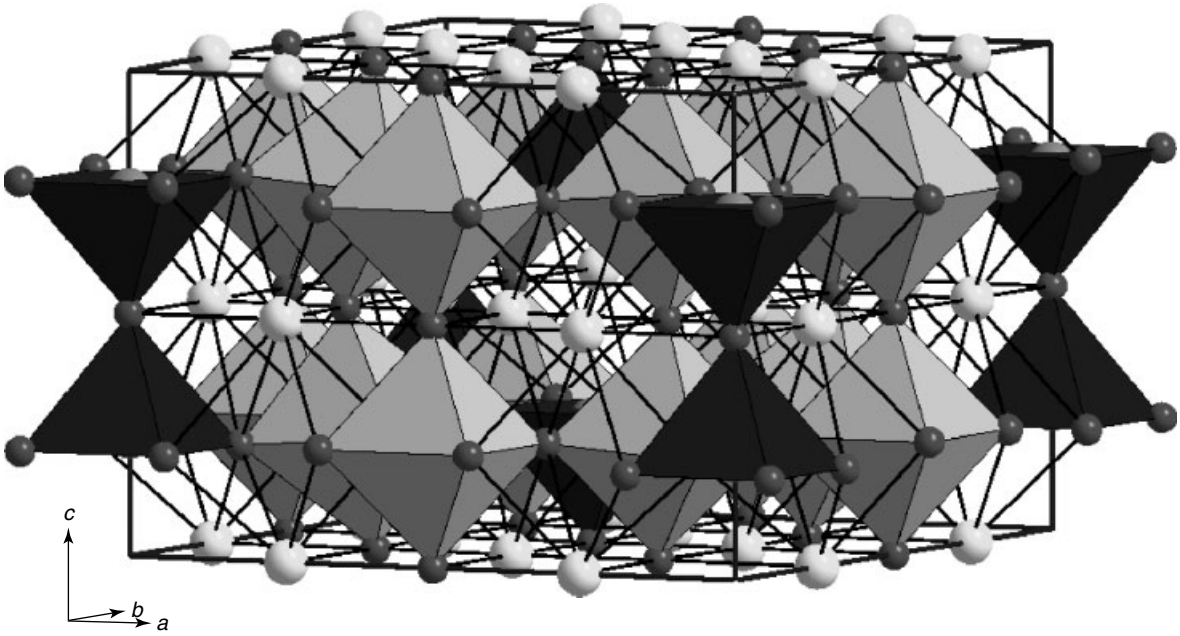

Figure 3. Ordering of oxygen vacancies in $SrFeO_{2.875}$ (=$Sr_8Fe_8O_{23}$). Fe ions are located in both square pyramids and in octahedra.

with approximately two-ninth of the oxygen positions vacant, in such way that two-third of the Cu atoms have square pyramidal coordination and one-third have square-planar coordination (see Figure 6). The cobaltite $GdBaCo_2O_{5.5}$ is another example of an oxygen-deficient perovskite-related structure where the Co^{3+} ions have octahedral and square pyramidal coordination (Frontera, Garcia-Munoz, Llobet and Aranda, 2002) (see Figure 7).

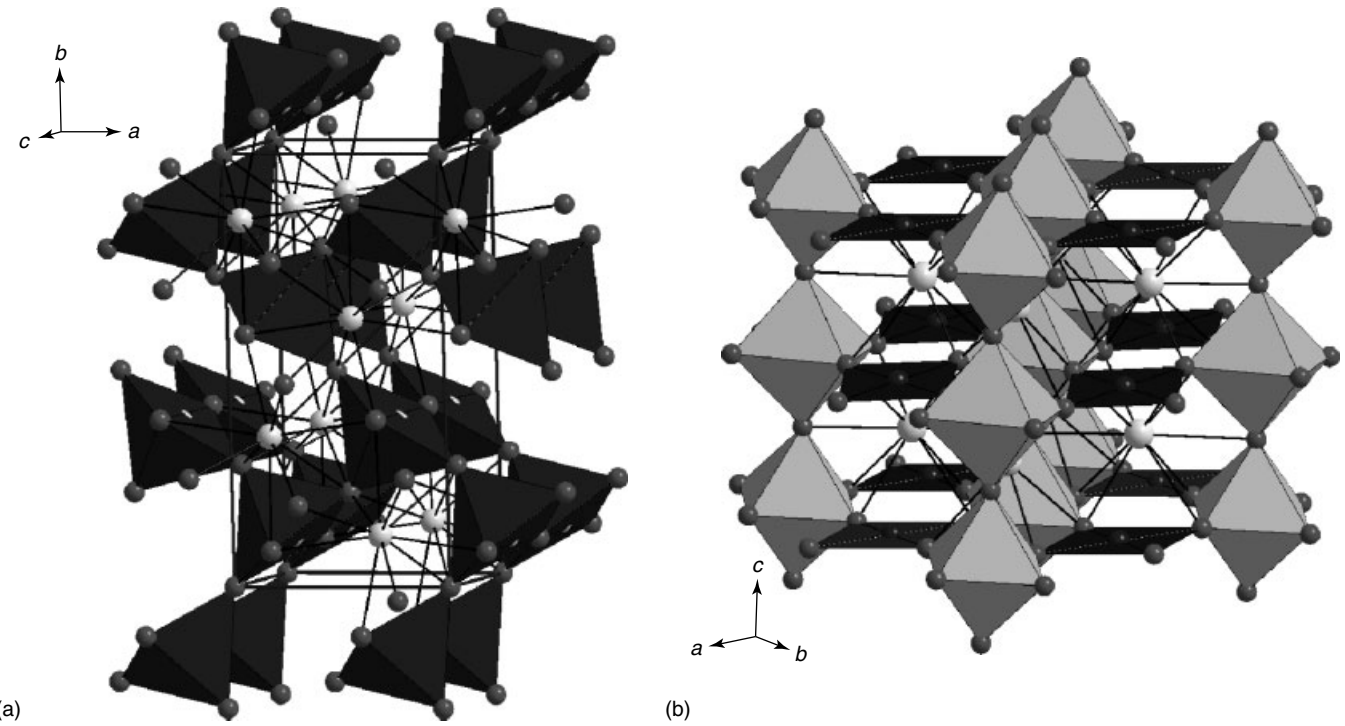

Figure 4. Ordering of oxygen vacancies in (a) $Ca_2Mn_2O_5$ having [MnO_5] square pyramides and (b) $La_2Ni_2O_5$ having [NiO_6] octahedra and [NiO_4] square planes.

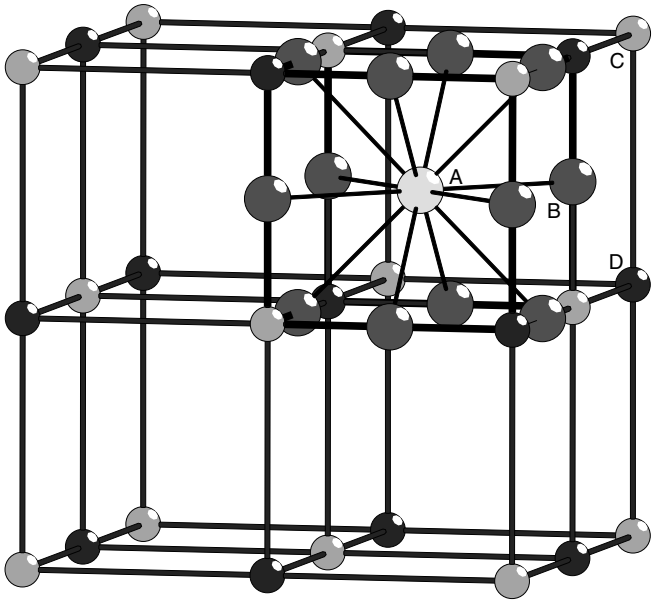

Figure 5. Superstructures of the perovskite type. If the unit cell edges are doubled, it is possible to occupy equivalent positions with atoms of different elements. The one-to-one relation can be recognized by comparing with the doubled formula of perovskite.

Structure type	Example	A(Yellow)	B(Red)	C(Green)	D(Blue)
Perovskite	$SrTiO_3$	Sr^{2+}	O^{2-}	Ti^{4+}	Ti^{4+}
Elpasolite	K_2NaAlF_6	K^+	F^-	Na^+	Al^{3+}
Kryolite	$(NH_4)_3AlF_6$	NH_4^+	F^-	NH_4^+	Al^{3+}
K_2PtCl_6	–	K^+	Cl^-	–	Pt^{4+}

Also the brownmillerite structure is an oxygen-deficient superstructure of cubic perovskite with an ordering of oxygen vacancies. Ruddlesden and Popper designed a series of homologous compounds with the general formula $AO(ABO_3)_n$, where AO represent a rock salt structure layer separating blocks of perovskite layers characterized by $n = 1, 2, 3, \ldots, \infty$. Examples are the high T_c superconductor prototype La_2CuO_4 and the 2D quantum antiferromagnet La_2NiO_4.

4 ELECTRONIC AND MAGNETIC PROPERTIES OF PEROVSKITES

Perovskites with transition metal ions (TMIs) on the B site show an enormous variety of intriguing electronic or magnetic properties. This variety is not only related to their chemical flexibility but also, to a large extent, to the complex character that TMIs play in certain coordinations with oxygen or halides (Lemmens and Millet, 2004). While magnetism

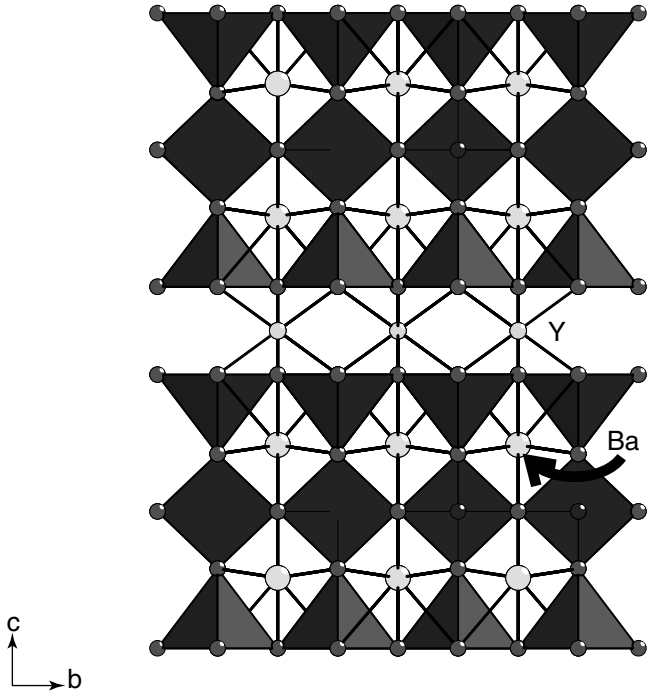

Figure 6. The high-temperature superconductor $YBa_2Cu_3O_{6.96}$. The structure is a superstructure of perovskite with approximately two-ninth of the oxygen positions vacant, in such way that two-third of the Cu atoms have $[CuO_5]$ square pyramidal coordination and one-third have square-planar $[CuO_4]$ coordination. The perovskite structure is attained by inserting oxygen atoms in between the yttrium atoms (gray) and in between the $[CuO_4]$ square planes.

and electronic correlations are usually related to unfilled 3d electron shells of the TMI, pronounced dielectric properties are connected with filled 3d electron shells. Multiferrocity, a coexistence of spontaneous ferroelectric and ferromagnetic moments, is a rare phenomenon due to the small number of low-symmetry magnetic point groups that allow a spontaneous polarization (Schmid, 1994). Nevertheless, in the presence of competing interactions (Hemberger *et al.*, 2005), canted moments (Kimura *et al.*, 2003; Higashiyama *et al.*, 2004), or in composites (Zheng *et al.*, 2004) large magneto-capacitive couplings have been reported (Fiebig, 2005).

In the following section, we will discuss examples of material properties in which transition metal perovskites and related structures prove to be outstanding. To some extent, these aspects also touch application areas, such as capacitors, transducers, actuators, sensors, and electro-optical switches.

4.1 Dielectric and ferroelectric perovskites

High dielectric permittivity (ε) or ferroelectric materials are of enormous importance as electroceramics for engineering and electronics. Perovskites, for example, titanium or

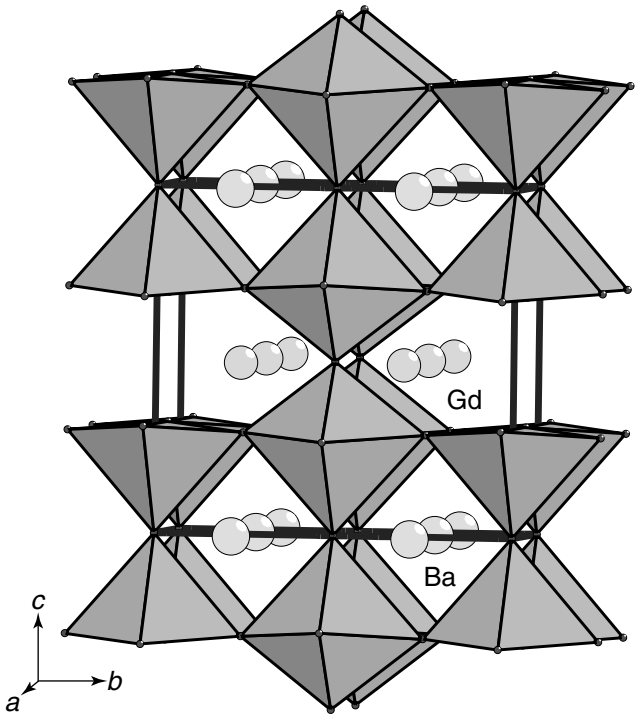

Figure 7. The cobaltite $GdBaCo_2O_{5.5}$ has a perovskite related structure were 1/12 of the oxygen atoms are missing leading to that 50% of the Co atoms have square pyramidal [CoO_5] coordination and 50% of the Co atoms have octahedral [CoO_6] coordination.

niobium perovskites, $BaTiO_3$, and $LiNbO_3$, have been intensively studied in the past (Cross and Newnham, 1987; Cross, 1987). A large ε is based on collective polar displacements of the metal ions with respect to the oxygen sublattice and is a highly nonlinear and anisotropic phenomenon. The phase transition that leads to ferroelectricity is usually described by a soft-mode model (Shirane, 1974).

To optimize dielectric and mechanical properties, several routes have been followed from the structurally simple $BaTiO_3$ via the solid solution system $Pb(Zr,Ti)O_3$ to other distinct families of materials. These routes explicitly take into account the flexibility for chemical manipulation and "docility" of the perovskites (Cross and Newnham, 1987; Cross, 1987). One of them is the relaxor ferroelectric. It is genuinely based on a multielement substituted Pb titanate ($PbTiO_3$) with the composition A(B'B")O_3 with a random occupation of the A and B sites by metal ions of different valence.

Relaxor ferroelectrics show enormously large dielectric constants, a pronounced frequency dispersion and variation of ε as function of temperature. These effects are due to slow relaxation processes for temperatures above a glass transition (Lunkenheimer, Schneider, Brand and Loidl, 2000). The length scales of fluctuating composition and spontaneous polarization are 2–5 nm, that is, the effects are based on electronic inhomogeneities and the existence of polar nanoregions. The lattice part of the response is considered to be a local softening of transverse-optical phonon branch that prevents the propagation of long-wavelength ($q = 0$) phonons. It is interesting to note that the fundamental limit, the superparaelectric state, is still not reached for such small length scales (Spaldin, 2004). Generic examples for relaxor ferroelectrics are PZT: $Pb(Zn_{1/3}Nb_{2/3})O_{3-x}PbTiO_3$ and PMN: $Pb(Mg_{1/3}Nb_{2/3})O_{3-x}PbTiO_3$, with PZT having a higher temperature scale compared to PMN.

Incipient ferroelectrics or quantum paraelectrics can be regarded as almost ferroelectric crystals (Höchli, Knorr and Loidl, 1990). Examples are $KTaO_3$ and $SrTiO_3$ (Bednorz and Müller, 1984). Pronounced quantum fluctuations of ions suppress the phase transition into the ferroelectric state and stabilize the soft transverse-optical mode. The dielectric susceptibility shows a divergence in the limit $T = 0\,K$ together with pronounced phonon anharmonicities (Bednorz and Müller, 1984). In these systems, even minor substitutions or doping can induce phase transitions into ferroelectric states. Finally, we mention perovskite-related oxides with giant dielectric constants (GDCs) where no evidence for a ferroelectric instability exists. These nonintrinsic permittivities are attributed to barrier layers and surface effects (Lunkenheimer *et al.*, 2002). Examples are $CaCu_3Ti_4O_{12}$, (Ramirez *et al.*, 2000) and the Li-ion conductor material $La_{0.67}Li_{0.25}Ti_{0.75}Al_{0.25}O_3$ (Garcia-Martin, Morata-Orrantia, Aguirre and Alario-Franco, 2005).

4.2 Magnetism and electronic correlations

Magnetism or orbital (electronic) ordering phenomena of various kinds are observed in perovskites with TMI that have unfilled 3d electron shells. Electronic correlations (Fazekas, 1999) of such 3d states are generally strong, as the ratio U_d/W of the Coulomb repulsion energy U_d versus the bandwidth W is larger compared to other electronic states, that is, they have a more local character and a tendency for insulating states or metal-insulator transitions (Imada, Fujimori and Tokura, 1998). Hopping and superexchange of these electrons takes place via oxygen sites due to the overlap of the respective wave function. Thereby, the properties and phase diagrams of a perovskite strongly depend on nonstoichiometries and, even more, on tilting or distortions of the [BO_6] octahedra. Further aspects rely on order/disorder processes of the orbital part of the 3d wave function, charge doping and charge/orbital inhomogeneous states that lead to colossal response, for example, to external magnetic fields (Tokura, 2003).

However, before considering such effects, the properties of the system are given by a hierarchy of energies based on the electronic structure, that is, the number of 3d electrons, the Hund's rule coupling, the crystalline electric field or Jahn–Teller splitting of the 3d electron states, and finally due to exchange energies.

4.3 Cuprates, Jahn–Teller distortions and high-temperature superconductors

This hierarchy of energies is well established for cuprates with Cu^{2+} in a $3d^9$ configuration. The hole in the d shell has $e_g x^2 - y^2$ symmetry and contributes to an $s = 1/2$ spin moment. The orbital moment is quenched due to the crystalline electric field of the surrounding oxygen. The e_g electron is Jahn–Teller active, that is, local or collective configurations with oxygen in distorted octahedra are energetically preferable. Extreme limits are pyramidal [CuO_5] or even a planar [CuO_4] configuration of the oxygen neighbors. Thereby, the superexchange and magnetic interactions between the $s = 1/2$ spin moments are restricted to a plane or, if building blocks are shifted by half a unit cell within the plane, to a quasi-one-dimensional path. There are numerous realizations of such low-dimensional magnetic systems as in Sr_2CuO_3 (spin chain system) or $SrCu_2O_3$ (spin ladder system) (Lemmens, Güntherodt and Gros, 2003). Owing to the small coordination number of the spin moments in one dimension and pronounced quantum fluctuations related to the small magnitude of the spin, such compounds generally do not show long-range ordering. Strong fluctuations are evident as broad maxima in the magnetic susceptibility and continua in inelastic neutron scattering.

Superexchange and electronic correlations – restricted to a two-dimensional, weakly doped plane – are the key ingredients of high-temperature superconductors. The crystal structure of the prototype and perovskite-related compound $YBa_2Cu_3O_{7-x}$ is shown in Figure 6. For $x \approx 1$, the resulting Cu^{2+} with $s = 1/2$ moments show long antiferromagnetic range ordering with a Néel temperature of more than 500 K. This high ordering temperature marks the exceptionally large energy scales and strong correlations involved in these materials. With smaller x, doping is induced that leads to a drastic drop of the Néel temperature and the onset of high-temperature superconductivity. The maximum superconducting transition temperature is $T_{cmax} = 92\,K$ for this system.

Electronic correlations are essential to understand the effect of doping. The electronic structure of cuprates in the vicinity of the Fermi level is given by an occupied low-energy and an unoccupied high-energy band, the lower and the upper Hubbard band, separated by the Coulomb repulsion energy U_d of the 3d electrons. High-temperature superconductors are charge transfer insulators, that is, the oxygen is included in this scheme as an occupied, nonbonding 2p band separated by a smaller charge transfer energy Δ from the upper Hubbard band ($\Delta < U_d$). The doping process consists of introducing a novel correlated electron state, the Zhang–Rice singlet state (Imada, Fujimori and Tokura, 1998), in the proximity of the oxygen band. This state of hybridized Cu and O character leads to a transformation from a long-range Néel state to a high-temperature superconductor. Although the number of known high-temperature superconductors seem to be large (of the order of 20 compounds), they all rely on this scheme of a doped, two-dimensional perovskite-related structure with pronounced electronic correlations (Imada, Fujimori and Tokura, 1998; Dagotto, 1994; Orenstein and Millis, 2000).

4.4 Cobaltates, spin state transitions and oxygen deficiency

If the hierarchy of energies, mentioned in the preceding text, is not well defined, the compound chooses certain ways to lift degeneracies of the electronic system. Important are spin state transitions or crossover behavior, a partial metallization of 3d electrons, or charge disproportionation of the TMI sites. Perovskites based on cobalt and vanadium serve as model systems for such effects and the resulting interplay of electronic and structural degrees of freedom. In the following text, we will discuss briefly two cobaltates to give an example for the resulting complexities.

In the cobalt perovskite $LaCoO_3$, with the same crystal structure as is shown in Figure 1, all three spin states of Co^{3+} ($3d^6$) are close to degenerate. As these states correspond to slightly different ionic radii with decreasing temperatures, a crossover of the dominant populations from high spin ($s = 2$), intermediate spin ($s = 1$) to low spin ($s = 0$) Co^{3+} $3d^6$ states takes place. This process is mainly controlled by temperature and has no evident collective character. The magnetic susceptibility shows a broad maximum and a strong decrease at low temperatures (Korotin *et al.*, 1996). The different ionic radii of the spin states also couple the electronic configurations of the TMIs only weakly to other properties of the compound.

An ordered oxygen deficiency leads to a multiplication of the unit cell volume. It also has a profound influence on the electronic and magnetic properties of the compound (Vidya *et al.*, 2004). Owing to the smaller coordination number of some TMI sites, the respective bandwidth is reduced, and with increasing electronic correlations, the tendencies for charge/orbital ordered states is enhanced. In Figure 7

the perovskite cobaltite $GdBaCo_2O_{5.5}$ is depicted. Oxygen defects form chains of $[CoO_5]$ pyramids and $[CoO_6]$ octahedra along the crystallographic *a* axis. Compared to the ideal perovskite $LaCoO_3$, the behavior is rather complex and highly collective. The phase diagram contains a metal-insulator transition and three different magnetic phases that include spin state ordering (Fauth, Suard, Caignaert and Mirebeau, 2002; Chernenkov *et al*., 2005; Plakhty *et al*., 2005).

4.5 Manganites and orbital degrees of freedom

In the manganite $(La,Sr)MnO_3$, the ratio La^{3+}/Sr^{2+} determines the oxidation state of Mn and thus the ratio Mn^{3+}/Mn^{4+}. This corresponds to the number of Mn sites with a single 3d e_g orbital occupied. Double exchange describes the situation where these states simultaneously hop via Mn^{4+} ions. The remaining $3\,t_{2g}$ electrons on each Mn ion sum up to $s = 3/2$ due to Hund's rule coupling and form a 'rigid background'. The bandwidth and charge transport are solely given by e_g state dependents on the spin and orbital orientation of the exchange partners.

As a function of composition, different magnetic ground states and orbitally/charge ordered structures are observed. These degrees of freedom react rather cooperative because of the strong interlink of the octahedra in the perovskite structure (Choi *et al*., 2005). Pronounced effects are observed in all physical quantities. However, most spectacular is the colossal magnetoresistance (CMR) at the borderline between a ferromagnetic insulating and ferromagnetic metallic phase. For a more complete treatment of this increasingly rich field of research including a discussion of relevant vanadium and titanium perovskites, we refer to reviews (Imada, Fujimori and Tokura, 1998; Tokura, 2003; Tokura and Tomioka, 1999; Salamon and Jaime, 2001; Dagotto, 2002) and recent focus issues (Keimer and Oles, 2004) of international journals.

5 SYNTHESIS

Many perovskites are synthesized by solid-state reactions giving polycrystalline samples. The starting materials are then usually simple binary oxides or pure elements made to react at relatively high temperatures. This synthesis technique involves problems due to the fact that certain starting oxides (e.g., PbO) may vaporize. The reaction temperature can be lowered by applying microwave synthesis techniques, thus minimizing the loss of volatile starting components. Hydrothermal synthesis techniques have been applied to manufacture nanopowders of, for example, $BaTiO_3$. Powders and thin films with controlled levels of dopants have been prepared with the sol–gel technique using metal alkoxides as precursors. Thin films of ferroelectrics have been successfully prepared by physical vapor deposition (PVD) or pulsed laser deposition (PLD).

During recent years, several research groups have succeeded in growing single crystals of several families of perovskite-related compounds from molten alkali carbonates or other fluxes such as hydroxides or halides. Large single crystals (>10 cm long) of manganites and other oxides have been grown by utilizing optically heated floating zone techniques with oxygen injected into the furnace around the molten zone (see Figure 8). The review (Bhalla, Guo and Roy, 2000) and references therein are referred for further aspects of synthesis techniques.

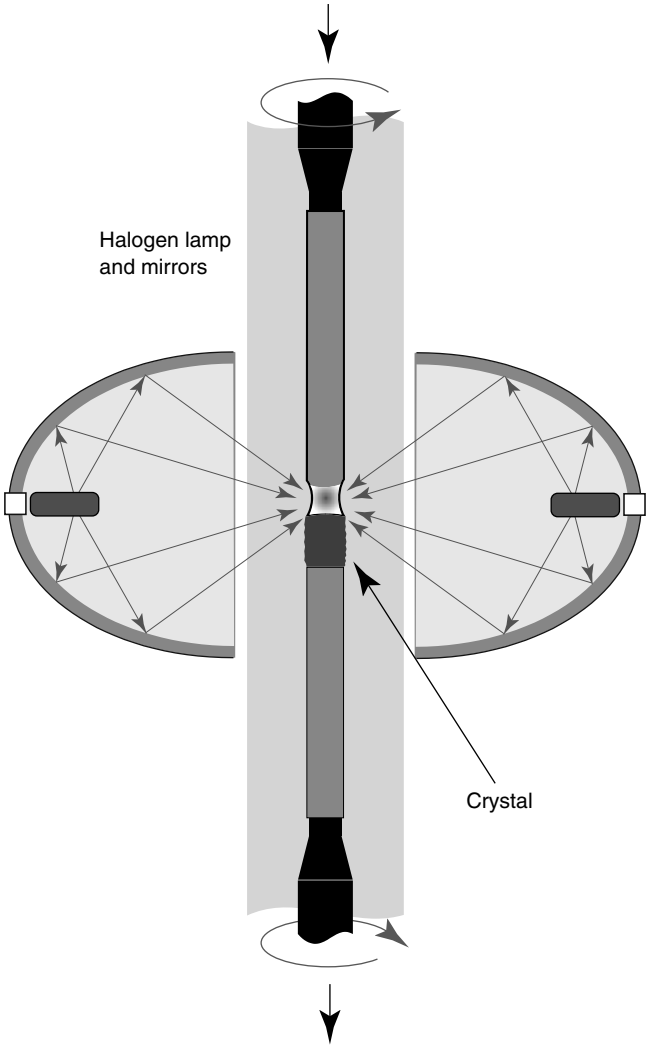

Figure 8. Outline of the principles for a floating zone mirror furnace. The crystal is grown by moving sintered powder rods through an optically heated floating zone.

Dilute Magnetic Oxides and Nitrides

John Michael David Coey and Karsten Rode
Trinity College, Dublin 2, Ireland

1 INTRODUCTION

The magnetism of oxides was long regarded as an important, but well understood and uninspiring branch of magnetism from which little that was new could be expected. The sources of magnetism in transition-metal and rare-earth oxides are the metal cations, which bear a magnetic moment due to unpaired electrons in the 3d shells, or sometimes in the 4d shell. The number of electrons per cation is integral, and the moments are well localized on the ions. The oxides are usually insulators or wide-gap semiconductors. Electrons or holes, introduced by doping or nonstoichiometry, are often trapped, and do not contribute to the conductivity.

The crystal structures of oxides are frequently based on a close-packed lattice of oxygen anions (ionic radius 140 pm) where the 3d cations occupy the octahedral interstices with six oxygen neighbors, or the tetrahedral interstices with four oxygen neighbors. The larger cations show some preference for the octahedral sites. The 4f ions have a greater coordination number, and may even take the place of an anion in the close-packed oxygen lattice.

The primary band gap E_p in 3d oxides is between the filled oxygen 2p valence band, corresponding to O^{2-} ions, and the empty conduction band of 4s character, formed from the transition-metal states. The localized 3d levels lie in the gap (see Figure 1). The magnitude of E_p decreases on moving along the 3d series from 8.1 eV for TiO_2 or 5.7 eV for Sc_2O_3 to 3.4 eV for ZnO or 4.9 eV for Ga_2O_3. The measured band gap E_g can be much less than E_p because of the possibility of p–d, or d–s transitions. A list of common 3d cations, for which a localized electron picture is appropriate is given in Table 1.

The wave functions of the 3d cations have exponentially decaying tails, which ensures that there is negligible overlap between cations which are not nearest neighbors. These neighbors share one or more common coordinating oxygen anion. Hence the magnetic exchange coupling is essentially an affair of nearest-neighbor cations, with an intervening oxygen. These are known as *superexchange interactions*.

A dilute oxide has the general formula

$$(M_xN_{1-x})O_n \tag{1}$$

where M is a magnetic cation, N is a nonmagnetic cation, n is an integer or rational fraction, and x is the magnetic doping level $0 \leq x \leq 1$, which will usually be expressed here in percent. An important limit is x_p, the percolation threshold (Stauffer, 1985), where continuous nearest-neighbor paths first appear which link M cations throughout the crystal. Below x_p there are only isolated cations, and small clusters of nearest-neighbor pairs, triplets, and so on. Above x_p there is a bulk cluster, which encompasses most of the magnetic cations. Whenever the exchange interactions only involve nearest neighbors, there is no possibility of long-range order below x_p, the percolation threshold, approximately $2/Z_0$

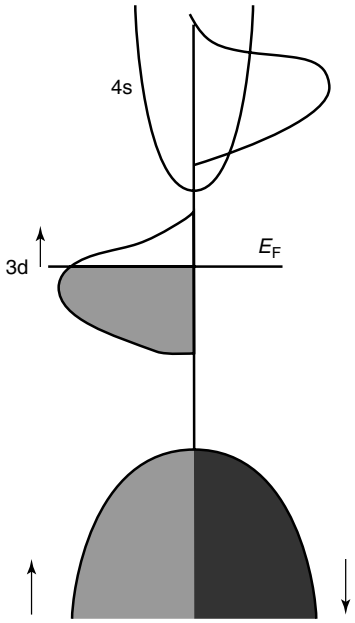

Figure 1. Generic electronic structure diagram for a 3d metal oxide.

Table 1. Charge state, electronic configuration, ionic radius in O_h coordination for common magnetic and nonmagnetic cations in oxides.

Cation	Charge state	Configuration	Ionic radius (pm)
Sc	3^+	$3d^0$	83
Ti	$3^+/4^+$	$3d^0/3d^1$	61/69
V	2^+	$3d^3$	72
Cr	3^+	$3d^3$	64
Mn	$2^+/3^+/4^+$	$3d^5/3d^4/3d^3$	83/65/53
Fe	$2^+/3^+$	$3d^6/3d^5$	82/65
Co	$2^+/3^+$	$3d^7/3d^6$	82/61
Ni	$2^+/3^+$	$3d^8/3d^7$	78/69
Cu	2^+	$3d^9$	72

(Deutscher, Zallen and Adler, 1983), where Z_0 is the cation coordination number. Depending on the structure, Z_0 lies between 6 and 12, which means that x_p is in the range 16 to 33%.

It therefore came as a surprise when a series of reports, beginning with that of Masumoto *et al*. (2001a), claimed that oxides with only a few percent of magnetic cations, usually 1–10%, were ferromagnetically ordered at room temperature. The first samples were all *thin films*. Table 2 lists some of these early reports.

These results were surprising for at least three reasons:

1. The magnetic order appears in films where the doping is far below x_p.
2. The magnetic order is ferromagnetic, whereas the superexchange in oxides is usually antiferromagnetic.
3. The films are ferromagnetic at room temperature and above, although no such dilute magnetic oxide or semiconductor, and no dilute magnetic metal had ever been found to be magnetically ordered at room temperature. (An exception is Pd, which has a greatly enhanced Pauli paramagnetism and by itself almost satisfies the Stoner criterion for the appearance of magnetism.)

In these circumstances the claims of ferromagnetism in these films were regarded with scepticism, and the conviction that high-temperature ferromagnetism must somehow be associated with a segregated impurity phase. In some of the samples, secondary phases in the form of cobalt clusters, Mn–Ga alloys or nanoparticles of Fe_3O_4 were indeed found. In other systems such a V-doped ZnO there are no known ferromagnetic phases in the ternary system. For this, and other reasons discussed below, one is led to consider the high-temperature ferromagnetism of dilute oxides and nitrides as a new and significant magnetic phenomenon.

2 MAGNETIC INTERACTIONS IN OXIDES

The principal magnetic interaction in oxides is superexchange. The coupling between the spins of two cations occurs via the intervening oxygen, as shown schematically for the $Mn^{2+} - O^{2-} - Mn^{2+}$ bond in Figure 2. The Mn has a half-filled 3d shell, so only minority-spin electron transfer from the oxygen to the manganese is possible. A 2p electron with $\downarrow$ is transferred to the Mn on the left, leaving a $2p\downarrow$ hole, which can be filled by an electron from the other Mn, provided it is $\downarrow$. Superexchange theory leads to a Heisenberg-type Hamiltonian

$$H = -2J\mathbf{S}_i \cdot \mathbf{S}_j \tag{2}$$

where the exchange constant $J = J_0 \cos^2\theta$ where θ is the superexchange bond angle and $J_0 = t^2/U$, where t is the M–O transfer integral and U is the on-site Coulomb interaction for the M ion. Typically, $t \approx 0.1$ eV and $U \approx 5$ eV. Hence the order of magnitude of the exchange constant is 2 meV or 20 K.

The expression for the Curie temperature in mean-field theory is

$$T_C = \frac{2ZJS(S+1)}{3k} \tag{3}$$

Hence, if $S = 5/2$, the largest value possible in the 3d series, and the cation coordination number $Z = 8$, we find

Table 2. Dilute ferromagnetic oxide thin films with T_C above room temperature.

Material	E_g (eV)	Doping	Moment (μ_B)	T_C (K)	Reference
GaN	3.5	Mn – 9%	0.9	940	Sonoda *et al*. (2002)

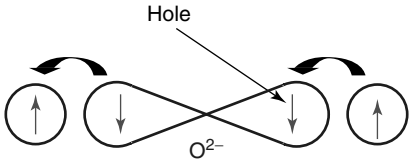

Figure 2. Superexchange interaction between ions with more than half-filled d shells via an O^{2-} anion.

$T_C \approx 800$ K. In practice, the superexchange interactions are often frustrated – the antiparallel coupling of all nearest neighbors cannot be achieved for geometric reasons imposed by the topology of the lattice. Furthermore, equation (3) is known to overestimate T_C by about 30%. In practice, the magnetic ordering temperatures of oxides do not exceed 1000 K. Hematite – α-Fe_2O_3 – has a Néel temperature of 960 K. In most cases the magnetic ordering temperatures of oxides are a few hundred kelvin, at best. When they are diluted with nonmagnetic cations, the coordination number $Z = Z_0x$ is reduced, and T_C varies as x above the percolation threshold (Figure 3).

The validity of the Heisenberg model in oxides has been amply demonstrated by fitting the exchange constants to the spin-wave dispersion relations determined by inelastic neutron scattering. Complete data sets have been obtained for Fe_2O_3, Cr_2O_3, and Fe_3O_4, among others (Samuelsen and Shirane, 1970; Samuelsen, Hutchings and Shirane, 1970; Bourdonnay *et al*., 1970). The values of the exchange constants range from -30 K to $+6$ K in α-Fe_2O_3. Negative interactions are for superexchange bonds involving the same ions, with large bond angles. Positive values are for bonds involving ions in different valence states, or near 90° bonds between ions in the same valence state.

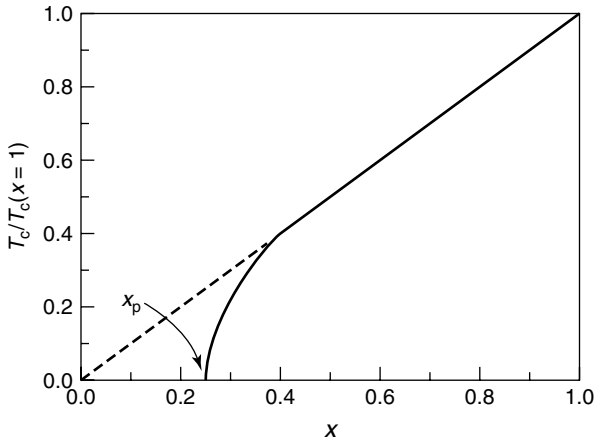

Figure 3. Variation of the magnetic ordering temperature in a dilute magnetic oxide with nearest-neighbor superexchange interactions. The dotted line is the prediction of mean-field theory for long-range interactions.

During the 1960s, a wealth of information was accumulated on the nature of the exchange interactions between different cations for different superexchange bond angles. An extensive set of rules was formulated by Goodenough (1955) and Kanamori (1959). These rules were simplified by Anderson (1963), as follows:

1. 180° exchange between half-filled orbits is strong and antiferromagnetic.
2. 90° exchange between half-filled orbits is ferromagnetic, and rather weak.
3. Exchange between a half-filled and an empty orbital of different symmetry is ferromagnetic and rather weak.

To summarize, concentrated magnetic oxides are well described in terms of the *m*-J paradigm: there are localized magnetic moments *m* on the cations, and superexchange interactions couple them together. The paradigm provides a good account of the magnetic order and the spin waves. Magnetocrystalline anisotropy in oxides is also well understood, in terms of crystal-field theory. The electric field acting on the localized electron shell of a 3d ion can be expressed as a multipole expansion where the second derivatives of the potential couple with the electric quadrupole moment of the ionic charge distribution, and the fourth derivatives with the hexadecapole moments (Hutchings, 1964). The leading term in the expansion is

$$H_{\mathrm{cf}} = \theta_2 < r_2 > A_2{}^0 \hat{\mathbf{O}}_2{}^0 \approx D\hat{\mathbf{S}}_{\mathbf{Z}}{}^2 \tag{4}$$

where $\hat{\mathbf{O}}_n{}^m$ is the Stevens operator equivalent, a method used to evaluate the matrix element of the wave function corresponding to a particular value of J (described in some detail in Hutchings (1964)). In a site with uniaxial anisotropy, $\hat{\mathbf{O}}_2{}^0$ is equivalent to $(3\mathbf{J}_{\mathbf{Z}} - J(J+1))$. θ_2 is the reduced matrix element known as the *Stevens parameter*. For the 4f series, J is a good quantum number, and the sixth order terms may need to be taken into account for ions with $J > 5/2$. Typically, the crystal-field parameter D, the zero field spin-orbit splitting of the ground state, for non-S-state ions is of order λ^2/Δ, where λ is the spin-orbit coupling and Δ is the crystal-field splitting. This ratio is of order 1 K. The small magnitude of this interactions means that an applied magnetic field of order 1 T will suffice to saturate the magnetization in a hard direction.

Nitrides are rather different, in that the ionic model does not suit them so well. The large, highly charged N^{3+} ion does not really exist. Such configurations are inevitably screened, and have a strongly covalent character. The ionic model is a plausible starting point for compounds such as RN, where R is a trivalent 4f cation, or an ion such as Ga^{3+} or Al^{3+}. In interstitial compounds such as Fe_4N, the nitrogen is in an uncharged, atomiclike state, where it is actually smaller than the surrounding iron atoms.

3 MAGNETIC PROPERTIES OF DILUTE OXIDES AND NITRIDES

First, it is useful to summarize the behavior which is normally expected from a dilute magnetic oxide. A random distribution of magnetic dopant ions is illustrated schematically in Figure 4(a). At low concentrations, most of the dopants are isolated, with no magnetic nearest neighbors, and a Curie-law susceptibility is expected.

$$\chi = \frac{\mu_0 N x g^2 \mu_{\mathrm{B}}{}^2 S(S+1)}{3kT} \tag{5}$$

As the concentration increases, there will be an increasing proportion of dimers and larger groups. The dimers and other even-membered groups have a Curie–Weiss susceptibility

$$\chi = \frac{\mu_0 N x_2 g^2 \mu_{\mathrm{B}}{}^2 S(S+1)}{3k(T-\theta)} \tag{6}$$

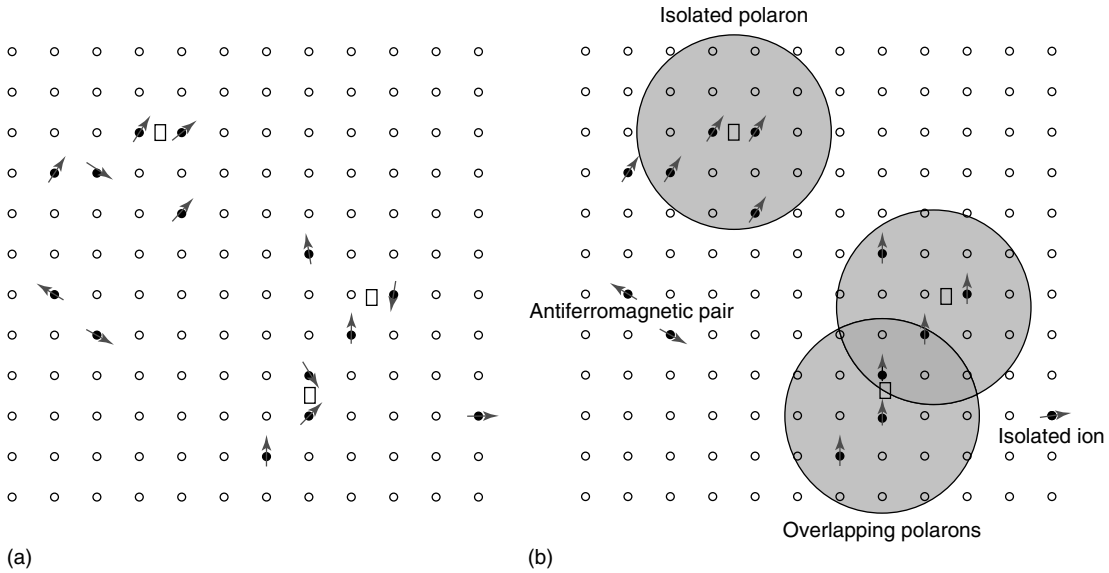

Figure 4. (a) Schematic representation of distribution of dopant ions in a dilute magnetic semiconductor. (b) The same, but with donor defects which create magnetic polarons where the dopant ions are coupled ferromagnetically.

where θ is a negative constant of order 10–100 K, which is proportional to the antiferromagnetic exchange coupling J_0. The odd-membered groups with a net moment contribute a modified Curie-law susceptibility. With all this, deviations from a linear response to an applied field of up to 1 T, for example, are only perceptible below about 10 K. The room-temperature dimensionless susceptibility is of order $10^{-3}x$. Such is the behavior normally expected of a dilute magnetic oxide. This is what is actually found in bulk crystalline materials and in well-crystallized, defect-free thin films. There are numerous examples in the literature of this 'normal' behavior, for example, Sati *et al*. (2006), Pacuski *et al*. (2006), and Rao and Deepak (2005).

We now present experimental results on the dilute oxides and nitrides, which can exhibit an anomalous ferromagnetic behavior when they are in thin-film or nanocrystalline form. The crystal structures of host materials are presented in Figure 5. Some structural details are given in Table 3, including the percolation threshold x_p and the cation site symmetry. The band gap E_g is listed, together with the high-frequency dielectric constant. The main systems will be discussed in turn.

Magnetization measurements on thin films deposited on substrates, which are the samples of most interest in the present context, present something of a challenge. There is a huge mismatch between mass of the thin-film sample – typically some tens of micrograms – and that of the substrate – which is about a thousand times greater. Commonly used substrates include sapphire (Al_2O_3), MgO, $SrTiO_3$, $LaAlO_3$, and Si. The problem is illustrated in Figure 6. The substrate presents a diamagnetic signal, which is perhaps reproducible to within 1% given the uncertainties in positioning and centering the substrate in the superconducting quantum interference device (SQUID) magnetometer, vibrating-sample magnetometer (VSM), or alternating-gradient force magnetometer (AGFM) used to measure the hysteresis loop. It is therefore practically impossible to determine the diamagnetic susceptibility of the undoped film. A Curie-law signal due to paramagnetic dopant ions can be readily detected at low temperatures, but it is difficult to measure any high-field slope that may be associated with the ferromagnetic signal. The diamagnetic susceptibility of some common substrate materials is listed in Table 4.

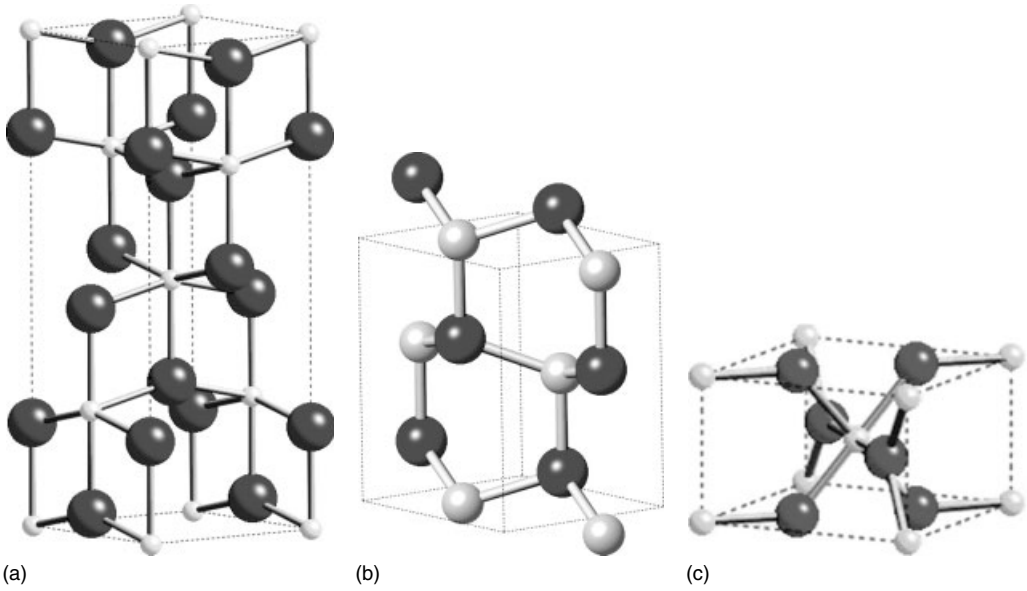

Figure 5. Crystal structures of host semiconductors: (a) TiO_2 (anatase), (b) ZnO or GaN (wurtzite), (c) SnO_2 or TiO_2 (rutile). Oxygen in dark spheres, cations in light spheres.

Table 3. Parameters for some oxides.

Material	Structure	n_c (10^{28} m^{-3})	ε	m^*/m	E_g (eV)	C	x_p
ZnO	Wurtzite	3.94	4.0	0.28	3.4	Tetrahedral	0.18
TiO_2	Anatase	2.93	9.0	1.0	3.2	Octahedral	0.25
SnO_2	Rutile	2.80	3.9	0.24	3.6	Octahedral	0.25

n_c: cation density; ε: high-frequency dielectric constant; E_g: optical band gap; C: cation coordination; x_p: cation percolation threshold.

Table 4. Diamagnetic susceptibility of some substrate materials (room temperature) $\chi = \mathrm{M/H}$ is the dimensionless SI susceptibility. To obtain the mass susceptibility (units $\mathrm{m^3\,kg^{-1}}$) divide by the density. To convert to dimensionless cgs susceptibility (emu $\mathrm{cm^{-3}}$) divide χ by 4π.

Material	Density (kg $\mathrm{m^{-3}}$)	χ (10^{-6})
Al_2O_3	3960	−19
MgO	3600	−14
$SrTiO_3$	5120	−7.1
$LaAlO_3$	6510	−18
Si	2329	−4.1
SiC	3210	−13

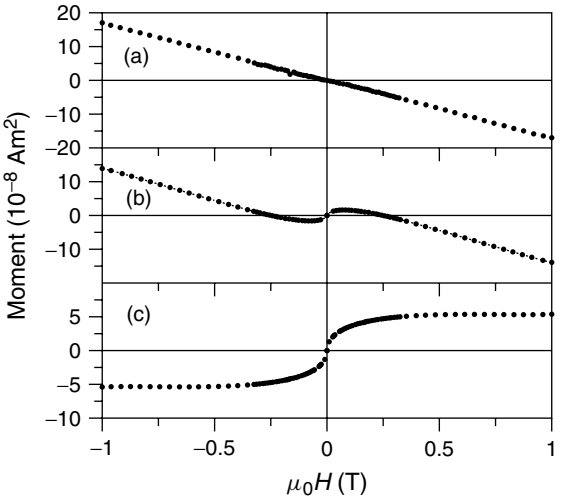

Figure 6. Data reduction for magnetization measurements on a thin film of a dilute magnetic oxide or nitride. (a) Diamagnetic substrate, (b) ferromagnetic thin film with diamagnetic substrate, (c) ferromagnetic component isolated from (b).

The measured response for a ferromagnetic thin film is shown in Figure 6(b). The magnetization appears to saturate in a field of order 1 T, and the high-field slope becomes that of the substrate, within experimental error. The procedure is then to suppose that the magnetization is indeed saturated and to subtract the high-field diamagnetic slope as the substrate correction, yielding the magnetization curve for the film shown in Figure 6(c). Typically, these 'ferromagnetic' hysteresis loops for dilute magnetic oxides exhibit little coercivity (≈ 10 mT), and a small remanence ratio ($M_\mathrm{r}/M_\mathrm{s} \approx$ 5–10%) [1]. The magnetization of the samples is often given in units of Bohr magnetons per transition metal (TM) ion by normalizing the measured magnetic moment by the number of TM ions supposedly in the sample. This unit is useful when comparing different doping concentrations and also when comparing different host materials, if the TM concentration is accurately known.

3.1 ZnO

ZnO is a promising semiconductor material with a band gap of 3.37 eV. It has a natural tendency to be n-type on account of oxygen vacancies or interstitial zinc atoms in the wurtzite structure. Recently, it has been possible to make nitrogen-doped p-type material, which opens the way to producing light-emitting diodes and laser diodes. An extensive review of the semiconducting properties of ZnO is available (Ozgur *et al*., 2005).

Various cations can replace zinc in the structure. The Co^{2+} ion gives a characteristic pattern of optical absorption in the band gap, due to crystal-field transitions of the ion in tetrahedral coordination. Studies of the magnetic properties of bulk material doped with Co (Rao and Deepak, 2005; Bouloudenine *et al*., 2005) or Mn (Alaria *et al*., 2005) show only the paramagnetism expected for isolated ions and small antiferromagnetically coupled nearest-neighbor clusters which arise statistically at a low doping level, as discussed above (Figure 5a).

The range of solid solubility of cations of the 3d series in ZnO films prepared by pulsed-laser deposition was established by Jin *et al*. (2001); solubility limits as high as 15% were found for Co, but most other cations could be introduced at the 5% level. None of these films were found to be magnetic, but following Ueda, Tabata and Kawai, (2001), who were the first to report high-temperature ferromagnetism in films doped with Co at the 10% level, there have been numerous reports of ferromagnetic moments in films doped with Co (See among others Janisch, Gopal and Spaldin, 2005; Prellier, Fouchet and Mercey, 2003; Pearton *et al*., 2004 and references therein), as well as almost every other 3d dopant from Sc to Ni (Sharma *et al*., 2003; Venkatesan *et al*., 2004b; Saeki, Tabata and Kawai, 2001; Radovanovic and Gamelin, 2003) (Figure 7). It must be emphasized that there are no reports of magnetism in undoped ZnO films,

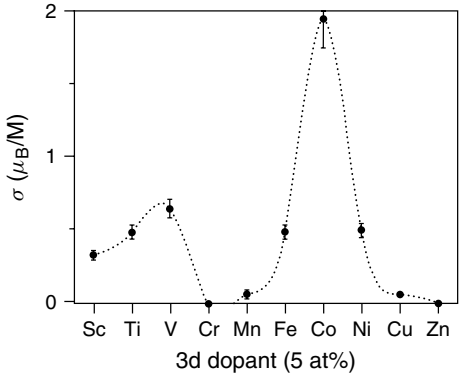

Figure 7. Magnetic moment measured at room temperature for ZnO with various 3d dopants. (Reprinted with permission M. Venkatesan *et al*., copyright 2004, Nature Publishing Group.)

however, prepared. There are also numerous counterexamples where no room-temperature moment has been found in doped films. Negative results tend to be underreported in the literature, so the observation of ferromagnetism in ZnO films is probably less prevalent than one might imagine. It is very sensitive to the deposition conditions (Ozgur *et al*., 2005). However, nanoparticles and nanorods of ZnO with cobalt and other dopants have also been found to be magnetic under certain process conditions (Martinez *et al*., 2005), although the moments per cobalt atom are an order of magnitude less than those found for the thin films, which are typically $0.1-1\ \mu_B$/Co.

Some progress has been made toward providing a systematic experimental account of the phenomenon. Narrow process windows have been delimited where ferromagnetism can be observed, depending on the deposition method – pulsed-laser deposition, sputtering, evaporation, organometallic chemical vapor deposition, and others. With Cr and Mn, for example, it is difficult to produce ferromagnetic moments in n-type material, whereas p-type samples can exhibit the symptoms (Kittilstved, Liu and Gamelin, 2006) (Figure 8). The substrate temperature required for ferromagnetism is often around 400 °C, where the films are not of the best crystalline quality. This points to a defect-related origin of the magnetism (Khare *et al*., 2006). Other evidence in this sense comes from the appearance of magnetism in Zn-doped (Halliburton *et al*., 2005; Schwartz and Gamelin, 2004), or in oxygen-deficient (Patterson, 2006) films.

The evidence that Co-doped ZnO is an intrinsically ferromagnetic semiconductor is rather sparse. No magnetoresistance has been observed at room temperature, despite the high T_C, nor is there clear evidence of an anomalous Hall effect. Magnetoresistance can, however, be observed below

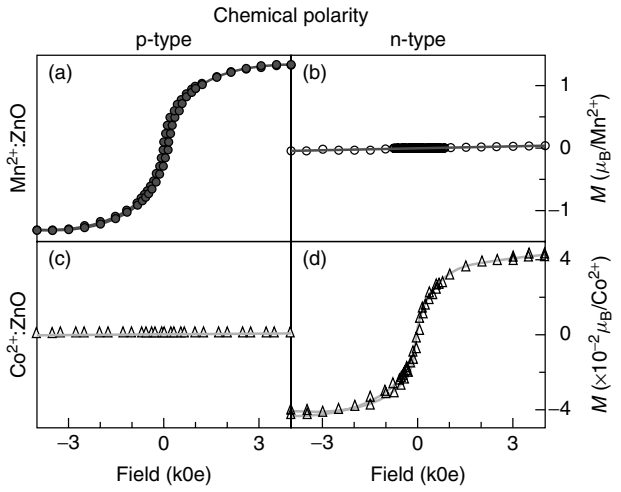

Figure 8. Development of magnetism in n-type ZnO with Co or p-type ZnO with Mn. (Reprinted with permission K.R. Kittilstved *et al*., copyright 2006, Nature Publishing Group.)

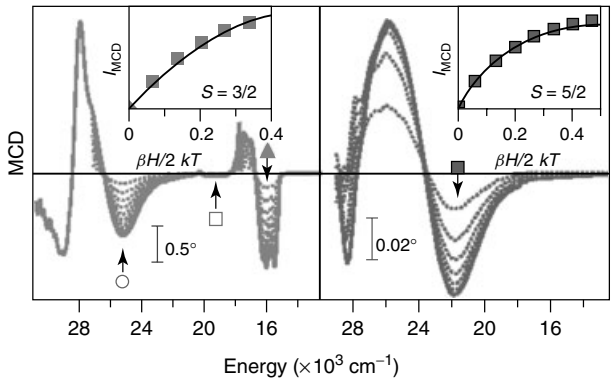

Figure 9. MCD spectra and the magnetic field dependence of the intensity of the MCD signal (insets) recorded at different energies in ZnO doped with Co (left) and Mn (right). (Reprinted with permission K.R. Kittilstved *et al*., copyright 2006, Nature Publishing Group.)

about 30 K (Stamenov *et al*., 2006). Furthermore, there is a band-edge magnetic dichroism which exhibits ferromagnetic response (Kittilstved, Liu and Gamelin, 2006; Neal *et al*., 2006), as well as a paramagnetic dichroic response from the dilute Co^{2+} ions in tetrahedral sites in the wurtzite lattice, Figure 9 (Kittilstved, Liu and Gamelin, 2006). The ferromagnetic dichroism has been observed for Ti and Co (Figure 10) and also for V and Mn doping (Neal *et al*., 2006). The interaction between the conduction electrons and the Co spins seems to be rather weak, and the magnetic properties are little influenced by changing the carrier concentration, by Al doping, for example Venkatesan *et al*. (2006).

A problem in interpreting the magnetic data for some dopants is the tendency to form ferromagnetic impurity phases, which may escape detection by X rays. For cobalt, in particular, absence of evidence cannot be taken as evidence of absence. There is a tendency for nanometric coherent cobalt precipitates to appear in the ZnO films which exhibit ferromagnetic properties (Park *et al*., 2004). An impurity-based explanation ($Mn_{2-x}Zn_xO_3$) has been advanced also for Mn-doped material (Kundaliya *et al*., 2004). For other dopants, such as vanadium, contamination by high-temperature ferromagnetic impurity phases seems improbable.

In some cases, there are features of the data which make an impurity-phase explanation untenable. These are (i) observation of a moment per transition-metal ion greater than that of any possible ferromagnetic impurity phase based on the dopant ion, and which may exceed the spin-only moment of the cation, and (ii) observation of an anisotropy of the magnetization, measured in different directions relative to the crystal axes of the film, which is not a feature of any known ferromagnetic phase at room temperature. An example is shown in Figure 11.

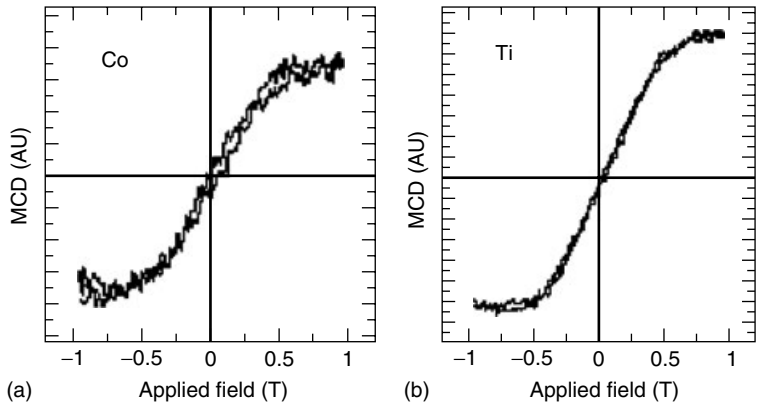

Figure 10. Magnetic field dependence of the intensity of the MCD signal recorded at the ZnO band edge. Co-doped ZnO (a) and Ti-doped ZnO (b). (Reprinted with permission Neal *et al*., copyright 2006, American Physical Society.)

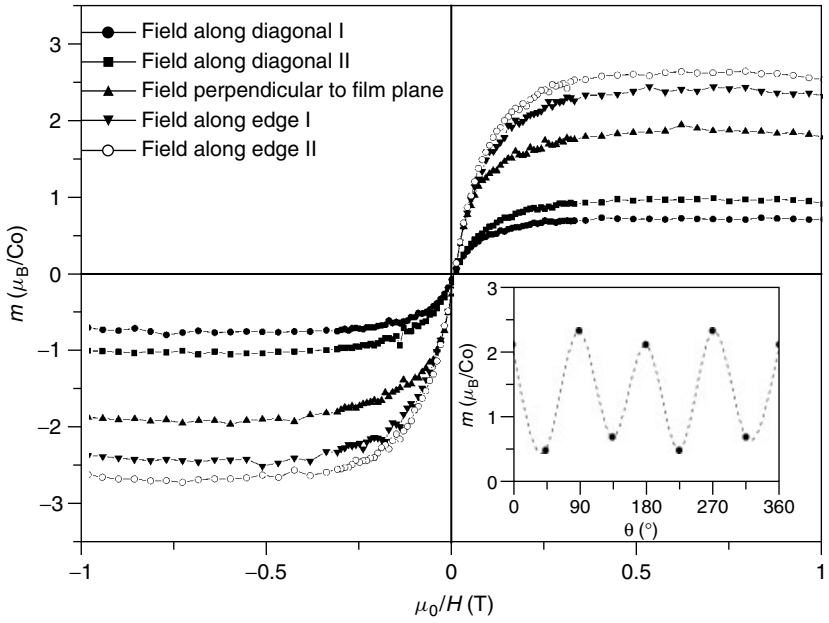

Figure 11. Anisotropy of the magnetization of a film of $(Zn_{0.95}Co_{0.05})O$.

The tunnel spin polarization of transition-metal-doped ZnO has been measured (Rode, 2006). Although poorly reproducible, these results are in line with the observation of magnetic circular dichroism (MCD) on the band edge as discussed above. The possibility of obtaining and manipulating a spin current in ZnO could be of great interest, as the spin lifetime in ZnO is rather long (Ghosh *et al*., 2005).

3.2 TiO_2

Anatase with 1–2% Co doping was the first example of high-temperature ferromagnetism in a dilute oxide film (Masumoto *et al*., 2001a). The same group reported ferromagnetism in rutile films (Masumoto *et al*., 2001b). The solubility of aliovalent Co in these oxides is low, and there is the possibility of cobalt-metal clustering (Kim *et al*., 2003; Stampe, Kennedy, Xin and Parker, 2003). But films can be prepared which are apparently free of clusters, and exhibit ferromagnetism (Shinde *et al*., 2003; Bryan, Heald, Chambers and Gamelin, 2004). Other evidence that Co-doped TiO_2 may be intrinsically ferromagnetic, and carrier mediated include electric-field modulation of the magnetization (Zhao *et al*., 2005), observation of band-edge optical dichroism (Toyosaki *et al*., 2005a), anomalous Hall effect (Toyosaki *et al*., 2004) as well as tunnel magnetoresistance (Toyosaki *et al*., 2005b).

Other cation dopants reported to make TiO_2 ferromagnetic include V (Hong *et al*., 2004) and Cr (Chambers and Farrow, 2003). It is found that highly perfect Cr-doped TiO_2 films are

not ferromagnetic, whereas films with structural defects may be (Kaspar *et al*., 2005). The Cr is trivalent in TiO_2 films, and the magnetization is highly anisotropic (Osterwalder *et al*., 2005).

TiO_2, unlike ZnO or SnO_2 is usually quite insulating in thin-film form, which indicates that delocalized, conduction electrons are not necessary for the high-temperature ferromagnetism.

3.3 SnO_2

First reports of high-temperature ferromagnetism in SnO_2 films came from Ogale *et al*. (2003), who reported a Curie temperature of 650 K and a huge moment of 7.5 μ_B/Co for films doped with 5%. Subsequently, ferromagnetism was observed for films doped with V, Cr Mn, Fe, and Ni, as well as Co, (Hong *et al*., 2005b; Coey, Douvalis, Fitzgerald and Venkatesan, 2004; Hong *et al*., 2005c), and in some of these cases the moments also exceed the cation spin-only values (Ogale *et al*., 2003; Fitzgerald *et al*., 2006). In the case of V doping, for example, the results have been shown to depend rather critically on the substrate employed (Hong *et al*., 2005c; Fitzgerald *et al*., 2006). The anisotropic magnetization and weak hysteresis found for doped ZnO or TiO_2 is also found for SnO_2. It seems to be a characteristic signature of the ferromagnetism in dilute oxides.

In the case of Fe-doped SnO_2 films, nanocrystalline Fe_3O_4 forms in some conditions, but it cannot be the complete explanation of ferromagnetism, when the moment exceeds 1.33 μ_B/Fe.

3.4 Other oxides

Room-temperature ferromagnetism has been reported in thin films of Cu_2O produced by sputtering (Kale *et al*., 2003) or electrodeposition (Liu *et al*., 2005).

Indium oxide doped with Cr is a promising system. Moments of 1.5 μ_B/Cr are found, and there seems to be little prospect of contamination of the films by ferromagnetic impurities. (CrO_2 is ferromagnetic, with $T_C = 390$ K, but T_C is reported as 900 K). An anomalous Hall signal is observed at room temperature, and the magnetism is related to the carrier concentration (Philip *et al*., 2006).

Indium tin oxide, the well-known transparent conductor is ferromagnetic when doped with Mn (Philip *et al*., 2004).

Ferromagnetic behaviour has been observed for HfO_2 doped with Fe or Co doping (Coey *et al*., 2005; Hong *et al*., 2005a). HfO_2 is an example of a material which is magnetic in thin-film form even when undoped (Coey *et al*., 2005; Venkatesan *et al*., 2004a). See the following text.

Another interesting oxide is $LaSrTiO_3$. This metallic oxide is ferromagnetic when doped with Co and also shows tunnel spin polarization (Herranz *et al*., 2006a,b).

3.5 d^0 systems

There is some evidence that it is possible to achieve ferromagnetism an *undoped* defective oxides. Thin films of HfO_2 show weakly hysteretic ferromagnetism when prepared on various substrates, with magnetizations of up to 30 k Am^{-1}. (Hong *et al*., 2005a; Coey *et al*., 2005). This is perhaps misleading, as the magnetization does not scale with substrate thickness. Typically it can be 200–400 μ_B nm^{-2}. Other systems where ferromagnetism has been reported in thin films include anatase-TiO_2 (Hong, Sakai, Poirot and Brizé, 2006), CaB_6, SrB_6 (Dorneles *et al*., 2004), and reduced powders of HfO_2 and WO_3. On the other hand, investigations of alkaline earth oxides MgO, CaO, SrO, BaO, some of which have been predicted to exhibit ferromagnetism related to the presence of cation vacancies (Elfimov, Yunoki and Sawatzky, 2002), have thus far shown no sign of being magnetic.

3.6 Nitrides

The first reports of ferromagnetism in a dilute nitride were from Sonoda *et al*., who found $T_C = 960$ K in a film of GaN doped with 9% Mn (Sonoda *et al*., 2002). Such high doping makes one wary of Ga–Mn phases, which have high Curie points. Nevertheless, Cr-doped GaN and AlN are also reported to be high-temperature ferromagnets (Park *et al*., 2002; Wu *et al*., 2003), and there are no plausible ferromagnetic impurity phases in these systems.

More striking are the reports of ferromagnetism in GaN films grown by molecular-beam epitaxy and doped with Gd. First reports, which showed $T_C > 400$ K were for films with $x = 6\%$ (Dhar *et al*., 2005a). Subsequently, films were doped with Gd at the level of 10^{16}–10^{19} atoms/cm^3, which corresponds to $2 \times 10^{-7} < x < 0.0002$, and the system appears to order ferromagnetically, with a moment per Gd atom as high as 10^4 μ_B in the most dilute films (Dhar *et al*., 2005b). Here the Gd atoms are separated by an average distance of 4.5 to 45 nm, in a matrix which is nonconducting, yet they exhibit room-temperature ferromagnetism. The Gd, whether substitutional or interstitial, creates large strains in the piezoelectric GaN matrix.

4 DISCUSSION

The experimental picture is obscured by the difficulty in reproducing some of the experimental results, and the

difficulties in characterizing defects and interface states in the thin films, as well as the difficulty in detecting small amounts (≈ 1 wt%) of secondary phases. The anomalous ferromagnetism is not a feature of highly perfect films or bulk crystalline material.

The presence of ferromagnetic nanoparticles of a second phase with a high T_C is an important factor, and possibly the complete explanation of the ferromagnetism in certain cases. Co nanoparticles are difficult to detect, but Fe and Fe_3O_4 are readily picked up by Mossbauer spectroscopy. Other high-temperature ferromagnets are spinel phases, where the antiferromagnetic interactions lead to ferromagnetic structures where the moment does not exceed $1.5\,\mu_B$/magnetic cation. High-temperature nitride ferromagnets include Mn_4N, $MnGa_2$, and $MnGa_3$. Nevertheless, it seems improbable that impurity phases can be a general explanation. In some systems, there are no plausible candidates for ferromagnetic impurities, other than ubiquitous iron introduced by careless sample handling. Other arguments were given in Section 3.1.

Insofar as it is possible to generalize from the data at hand, the characteristic features of the high-temperature ferromagnetism in dilute oxides and nitrides are as follows:

The ferromagnetism exhibits very little hysteresis. The loop in Figure 6(c) is practically the same for any of the systems we have been discussing.

The films may be insulating or semiconducting; the semiconductors are usually n-type. They may be partially compensated, semiconducting, or degenerate. Coupling between the magnetism and the conduction electrons is weak.

The moment does not depend obviously on the film thickness or doping level when $x < x_p$. It is often $100–400\,\mu_B\,nm^{-2}$. The moment per dopant ion increases as x decreases, and it may exceed the spin-only value for the ion at low concentrations.

The ferromagnetism is already present in *some* undoped films, and in all films at concentrations that lie far below the percolation threshold associated with nearest-neighbor cation coupling. T_C can be far above RT.

The magnetism is highly anisotropic, in a way unrelated to the dopant, but dependent on the film/substrate combination.

The conventional picture of magnetism in insulators or magnetic semiconductors is at a loss to account for these observations. The Curie or Néel temperatures of oxides are plotted on a histogram in Figure 12. None of them exceed the Néel point of α-Fe_2O_3, which is 960 K. The ordering temperatures in solid solutions vary as x or as $x^{1/2}$. No order is expected at room temperature when $x < 10\%$, or in insulators when $x < x_p$. The magnetic behavior we would normally expect from the m-J paradigm is a superposition of Curie-law paramagnetism for isolated ions and Curie–Weiss behavior for the small, antiferromagnetically coupled groups of two, three, or more ions. Indeed, this is what is found in well-crystallized, bulk material (Rao and Deepak, 2005), but not in the ferromagnetic thin films of interest here.

Next we consider carrier-mediated exchange. In the first generation of n-type rare-earth magnetic semiconductors such as EuS, studied in the 1960s and 1970s (Methfessel and Mattis, 1968), the carriers are electrons in the spin-split

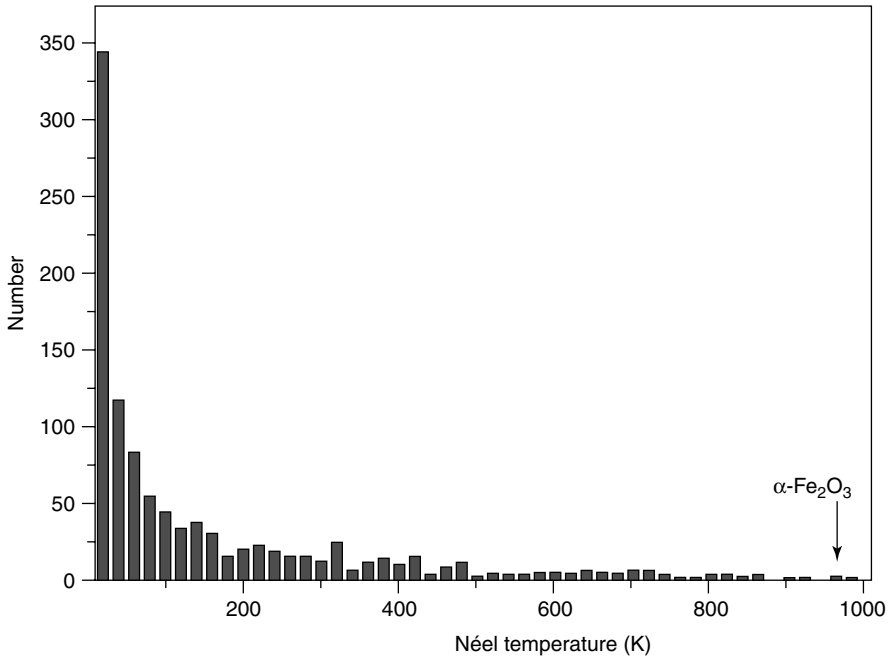

Figure 12. Histogram of the Néel temperature of a selection of magnetic oxides.

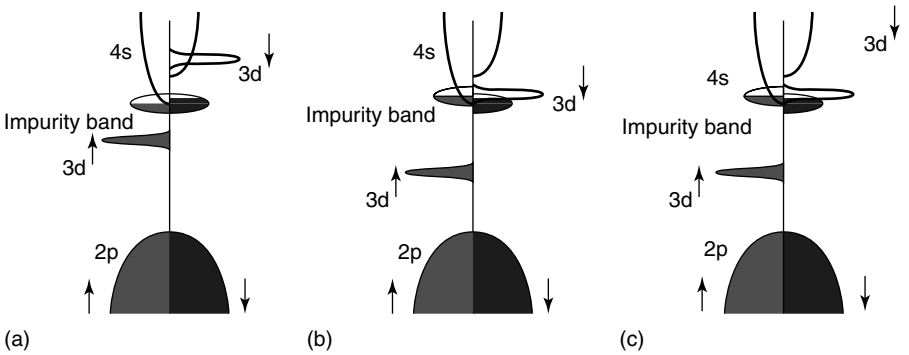

Figure 13. Spin-split impurity band model for dilute magnetic semiconductors. The electronic structure diagrams are drawn for cases where the impurity band is separated from (a), or resonant with (b and c) the d bands of the dopant.

5d/6s conduction band. In the next generation of p-type materials such as (GaMn)As, the carriers are holes in a spin-split 4p valence band. In an influential paper, Dietl *et al*. (2000) suggested that high Curie temperatures might be obtained in this way in p-type Mn-doped ZnO or GaN. These materials are usually n-type, however, and the s–d exchange interaction α is usually weaker than the p–d exchange interaction β.

A newer a model of magnetic semiconductors is one where exchange is propagated by a spin-split impurity band (Figure 13) derived from donor or acceptor defect states, which form magnetic polarons (Figure 5b). This has the virtue of yielding simple expressions for the Curie temperature when treated by molecular field theory (Coey, Venkatesan and Stamenov, 2005; Priour and Das Sarma, 2006)

$$T_{\mathrm{C}} = \left[\frac{S(S+1)s^2 x\delta}{3}\right]^{1/2} \frac{J_{\mathrm{sd}}\omega_{\mathrm{c}}}{k_{\mathrm{B}}} \tag{7}$$

Where S and s are the cation core spin and the donor spin respectively. δ is the donor or acceptor defect concentration and the cation volume fraction in the oxide $\omega_{\mathrm{c}} \approx 8\%$.

The problem is that, knowing the values of the parameters in the model, especially $J_{\mathrm{sd}} \approx 1\,\mathrm{eV}$, the predicted Curie temperatures are again of the order of 10 K, which are 1 or 2 orders of magnitude too low. The model can be modified by introducing hybridization and charge transfer from the donor orbitals to those of the dopants, but at some point in the dilute limit it has to fail, and a different approach is needed.

Small concentrations of conduction electrons do provide ferromagnetic coupling via the RKKY interaction, but an estimate of the magnitude of the magnetic ordering temperature due to this interaction is

$$T_{\mathrm{C}} \approx \frac{Z_0 n^{5/3} m^* \delta x^{1/3} J_{\mathrm{sf}}^2 S(S+1)}{(96\eth\hbar^2 n_{\mathrm{c}}^{2/3} k_{\mathrm{B}})} \tag{8}$$

The Curie temperature at elevated carrier concentrations, corresponding to about $10^{21}\,\mathrm{cm}^{-3}$, does not exceed a few tens of kelvin.

Some insight into the problem is provided by first-principles calculations for specific defects. Early calculations by Elfimov *et al*. for CaO (Elfimov, Yunoki and Sawatzky, 2002) indicated that a Ca vacancy could stabilize a moment on the adjacent oxygen ions where two holes coupled with parallel spin to form a triplet state. These extended molecular magnetic states were then shown to couple ferromagnetically to produce long-range order. A similar calculation for CaB_6 led to the prediction of defect-related ferromagnetism there too (Monnier and Delley, 2001), which has been observed in powders (Lofland *et al*., 2003) and amorphous films (Dorneles *et al*., 2004). In HfO_2, Das Pemmaraju and Sanvito (2005) have shown that an Hf vacancy induces a moment of $4\,\mu_{\mathrm{B}}$ on holes in the surrounding oxygen ions, and the coupling of these extended molecular magnetic objects is again ferromagnetic. Although no evidence of ferromagnetism in defective CaO has yet been found, the idea of oxygen-hole-related molecular magnetism has much to commend it.

Electronic defects associated with oxygen or nitrogen appear to be the most plausible source of the anomalous ferromagnetism in doped and undoped material. These holes are strongly correlated, and can form extended molecular orbitals. At least the *m* part of the *m*-J paradigm has to be revised. It is unclear whether the extended spin moments overlap sufficiently to provide the exchange necessary for high-temperature magnetism, or whether a quite different mechanism must be sought, based, for example, on elastic strain.

There have been numerous calculations in doped systems (Janisch, Gopal and Spaldin, 2005; Patterson, 2006; Gopal and Spaldin, 2006 and references therein). A critical feature in these systems is the position of the different 3d charge states relative to the primary band gap, which is difficult

to obtain accurately by density-functional theory methods. Some insight is provided by phenomenological theory (Kittilstved, Liu and Gamelin, 2006).

5 CONCLUSIONS

The magnetism of dilute magnetic oxides and nitrides is one of the most intriguing and potentially important open questions in magnetism at present. There is sufficient evidence that the observations are not, in most cases attributable to artifacts or trivial impurities. There is something to explain.

There appear to be two sources of the magnetism, defects and dopants. Both are usually necessary, but in the d^0 systems, the former suffice. The nature of the magnetic order and the coupling mechanism has to be explained, but it seems that the *m*-J paradigm for magnetism in solids is unable to encompass these materials.

On present evidence, the coupling between the 3d dopants and the conduction electrons in these systems is weak. There is evidence of intrinsic ferromagnetism, but useful magnetoresistive effects, for example, are not observed at room temperature. Applications of this new class of materials, which exhibit some sort of ferromagnetism above room temperature, optical transparency, and a wide range of transport properties ranging from degenerate semiconductor to insulator, remain to be identified.

NOTES

[1] $1\,\mathrm{Am^2} = 10^3\,\mathrm{emu}$; $1\,\mathrm{Am^2\,kg^{-1}} = 1\,\mathrm{emu\,g^{-1}}$; $1\,\mathrm{Am^{-1}} = 10^{-3}\,\mathrm{emu\,cm^{-3}}$; $1\,\mu_\mathrm{B}\ \mathrm{fu^{-1}} = 5585/\mathrm{MW\,Am^2\,kg^{-1}}$.

Heusler Alloys

Robert A. de Groot[1,2]

[1] *Radboud University Nijmegen, Nijmegen, The Netherlands*
[2] *Rijks Universiteit Groningen, Groningen, The Netherlands*

1 INTRODUCTION

In the beginning of the twentieth century, Heusler studied the magnetic properties of ternary alloys containing both transition and main-group metals (Heusler, 1903). The motivation for this work was the mysterious observation that magnetic alloys could be formed from nonmagnetic elements. (Antiferromagnetism was not discovered yet, so chromium and manganese were considered as nonmagnetic elements.) More than a century later, these alloys, named after Heusler, are still an area of active research. A number of them possess the unique property of exhibiting metallic behavior for one spin direction only. Half-metals (as these alloys have been baptized) are the ultimate materials in spintronics, where besides the charge, the spin of the electron plays an essential role – conceptually in some cases and indispensably as components of an actual device in other cases. Also, half-metals form an interesting area for fundamental research in materials science. Electronic structure calculations have played an important role in the area of half-metallic properties of Heusler alloys and beyond. Part of the reason for this is the degree of refinement these calculations have today, which make them a reliable instrument in materials science, especially in areas where little experimental data is at hand. There is hardly any direct experimental observation of half-metallicity possible. The most direct way of observing half-metallic magnetism is spin-resolved positron annihilation, an expensive measurement requiring dedicated equipment and single crystals. The possibility of extracting 100% spin-polarized electrons from a half-metal has been taken as a proof of half-metallic magnetism, but this requires electrons to cross a surface or an interface. Only recently, we have began to realize that surfaces and interfaces are distinct objects with distinct properties. They require special studies, both computationally as well as experimentally. Unfortunately, the understanding of interfaces is not nearly as advanced as that of bulk properties. This chapter follows more or less the historic developments of the half-metallic properties of Heusler alloys. This implies that computational studies form its backbone. However, experimental studies are essential and will be discussed.

Today we know two classes of alloys named after Heusler: the $C1_b$ structure and the $L2_1$ structure, sometimes referred to as the *half Heuslers* and the *full Heuslers*, respectively. Both structures are closely related with each other as well as with the zinc-blende structure. All three are based on a face centered cubic Bravais lattice. Whereas the zinc-blende structure has the 0, 0, 0 and 1/4, 1/4, 1/4 positions, the three constituents in the Heusler $C1_b$ structure occupy the 0, 0, 0; 1/4, 1/4, 1/4; and 1/2, 1/2, 1/2 positions. The full-Heusler structure is identical with the half-Heusler structure, furthermore, the element occupying the 1/4, 1/4, 1/4 position also occupies the 3/4, 3/4, 3/4

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

position. Thus, the $C1_b$ structure lacks the inversion symmetry that the $L2_1$ structure has. These differences and similarities are essential and at the same time almost sufficient to understand the quite different, rich physics of both classes of alloys.

Two groups initially studied the electronic structure of Heusler alloys independently and at the same time. NiMnSb, a half-Heusler, showed semiconducting behavior exclusively for the minority-spin direction and was baptized a 'half-metallic ferromagnet' (de Groot, Mueller, van Engen and Buschow, 1983). At the same time, several full Heuslers were studied (Kübler, Williams and Sommers, 1983), and it was noticed by these authors that for Co_2MnAl and Co_2MnSn, 'the minority-spin state density nearly vanished'. Both groups realized the consequences of controlling the electron spin in electrical conduction, an area known as *spintronics* today. Kübler remarks 'This should lead to peculiar transport properties in these Heusler alloys', while the publication of the Dutch group was delayed by half a year because of a patent application using half-metals as a source of spin-polarized electrons in a transistor containing two layers of half-metal separated by a nonmagnetic layer.

The similarities of both Heusler structures and the occurrence of half-metallic magnetism in both types of alloys suggest a common origin. These similarities are misleading, however. The origin of half-metallic magnetism in the two structures is quite distinct. Also, the defect chemistry, important for the robustness of the half-metallicity, is different, as we will see.

2 HEUSLER $C1_b$s

2.1 Nickel–manganese–antimonide

2.1.1 General

Since NiMnSb is a half-metal that has been studied for a long time, both computationally as well as experimentally, it will be treated here in detail. The band structure is shown in Figure 1 for both spin directions. The majority-spin panel shows that three bands cross the Fermi level with sizable slope. This is a consequence of the rather large bandwidths of the bands. The minority-spin direction shows an energy gap at the Fermi level with valence and conduction bands that closely resemble those of many zinc-blende semiconductors with an indirect band gap. The similarity is even more pronounced if we remove the Ni d states from the Hamiltonian (but not their interaction with the antimony and manganese states) and compare the valence band with that of GaSb (Figure 2). This observation is important. One can analyze band structures in terms of tight-binding interactions as described by Slater and Koster. An interaction between two atoms in real space contributes a cosine to the band structure in the corresponding direction of k space. The strength of the interaction determines the dispersion, while the wavelength of the cosine is determined by the inverse of the distance between the interacting atoms in real space. Therefore similarities of band structures directly reflect similarities in chemical bonding. Much of this information is lost if one considers quantities derived from Brillouin zone integrals like densities of states. So, the essential ingredients are the trivalent manganese with tetrahedral coordination interacting with the pentavalent antimony, which is also tetrahedrally coordinated (as long as no inversion center is present, even d wave functions of manganese in NiMnSb can play the same role as the odd p functions in a zinc-blende semiconductor). Whereas this interaction is direct in the zinc-blende semiconductors, it is indirect through the nickel atoms in the half Heuslers; to quote Kübler: 'a nickel *induced* Mn–Sb *covalent interaction*' (Kübler, 2000). Whereas the zinc-blende semiconductors show a band gap for 8 valence electrons, 18 electrons are required here in order to keep the nickel d shell filled. Thus, the magnetic moment of NiMnSb is

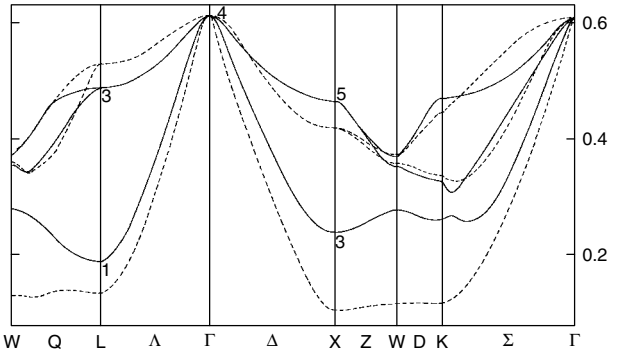

Figure 2. Valence-band structure of minority-spin (semiconducting) NiMnSb ($C1_b$ structure) where the Ni-d states were deliberately removed from the Hamiltonian (full lines). For comparison the valence-band structure of GaSb (calculated with the same method) is shown (broken lines).

$4\,\mu_B$, of which manganese carries 90%, while the remaining moment resides on the nickel atom. The interactions for the majority-spin direction are quite different. Because the manganese d states are much lower in energy as compared to the minority-spin d states, these electrons are practically degenerate with the antimony electrons they interact with. Consequently, the bandwidths are larger when compared to the semiconducting spin direction and no band gap occurs, either at the Fermi energy or in the vicinity of it. Note that this is a very different case from the strongly magnetic half-metals, the manganites with colossal magnetoresistance, or, for example, CrO_2. In these cases, the majority and minority bands are to a good approximation shifted in a ridged bandlike fashion by the exchange interaction. The Fermi level intersects the majority band while the corresponding minority band is still empty. This situation is practically determined by the valence of the ion carrying the magnetic moment only. Thus, very little influence is to be expected from disorder, surfaces, and interfaces, as long as the proper valence of the magnetic species is conserved. NiMnSb, on the other hand, requires the correct crystal structure and site occupancy, as shown in the next paragraph. Since the role of nickel is so passive, one wonders whether it is needed at all. Manganese–antimonide does exist, but it crystallizes in the nickel–arsenide structure. This structure has a deformed octahedral coordination of the metal and a trigonal prismatic coordination of the pnictide. Consequently it is not half-metallic. But manganese–antimonide in the zinc-blende structure is a half-metal, very much like nickel–manganese–antimonide. The magnetic moments are identical. So the role of nickel in NiMnSb is to stabilize it in the crystal structure with the required coordination of manganese and antimony. It is very efficient in doing so: the lattice parameter of NiMnSb is actually smaller than that of zinc-blende manganese–antimonide.

Let us return to the issue of point defects in nickel–manganese–antimonide. A proper site occupancy is essential (Helmholdt *et al.*, 1984). For example, nickel–manganese interchange deprives the manganese of its tetrahedral coordination and consequently does not show any half-metallic properties. Even a 1% interchange is enough to destroy the band gap (Orgassa, Fujiwara, Schulthess and Butler, 2000). However, such an interchange is energetically very unfavorable. It costs 2.8 eV per interchanged Ni–Mn pair, more than the heat of evaporation. Similar considerations hold for nickel–antimony interchange. This is consistent with nuclear magnetic resonance (NMR) measurements on cold-worked Heusler alloys. All investigated full Heuslers showed broadening of the manganese line, but even severe crushing in the case of NiMnSb left the NMR spectrum unaffected (Schaf, Le Dang, Veillet and Campbell, 1983). The trivalent behavior of manganese for the minority-spin direction implies that minority-spin d electrons are involved in the chemical bonds and the valence-band formation. Magnetic materials can be classified as strong magnets or weak magnets. Strong magnets are defined as magnets, where an increase in the spin-up, spin-down splitting in energy (the exchange interaction) does not lead to an increase in magnetic moment. Clearly, the magnetic moment is not limited by the strength of the exchange interaction, but by a lack of available electron states. For transition metals, this implies a full majority d shell or an empty minority d shell. In the case of a weak magnet, the moment is not determined by a lack of available states but by balancing the energy gain of magnetic moment formation (the exchange interaction) against the cost of transferring electrons from one spin direction to the opposite one (band energy). The involvement of the manganese d electron in the valence band for the minority-spin direction classifies NiMnSb as a *weak* magnet. One can force NiMnSb into becoming a strong magnet by artificially increasing the exchange interaction till the magnetic moment has obtained the value of $5\,\mu_B$, characteristic of a strong magnet in this case. The resulting band structure is shown in Figure 3. NiMnSb has evolved into a normal metal. Clearly half-metallicity and strong magnetism are mutually exclusive in NiMnSb.

2.1.2 Experimental bulk properties

A striking, but trivially proven property of half-metals is the occurrence of integral magnetic moments. This property follows directly from the fact that the number of electrons of the semiconducting spin direction and the total number of electrons are integers. This gives a direct indication of whether a compound could be a half-metal. It should be applied with caution, however. An integral magnetic moment is no proof of half-metallicity: integral magnetic

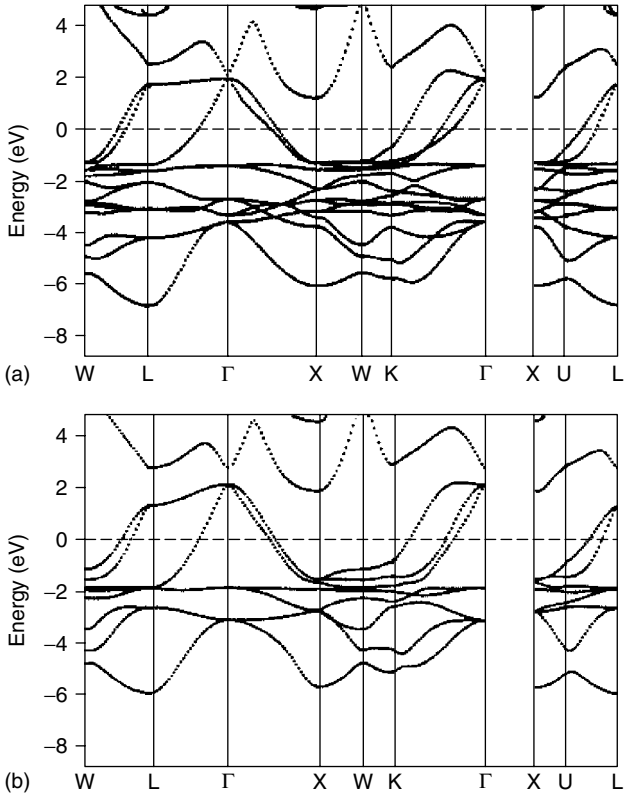

Figure 3. Band structure of NiMnSb with an artificially increased exchange splitting: (a) majority-spin channel and (b) minority-spin channel.

moments can occur accidentally within the precision of the experiment. The sulfospinel greigite is *not* half-metallic in spite of its integer magnetic moment of $2\,\mu_B$. The opposite case can also occur. An integral number of electrons (per formula unit) occurs only for an integral number of atoms. So, a nonintegral magnetic moment does *not* disprove half-metallicity if deviations from stoichiometry occur, for example, in the form of vacancies. These imperfections are more difficult to measure than a magnetic moment. (Chemical analyses of a sample will not help if the missing element is present in the sample in the form of another phase, which is frequently the case. X-ray diffraction is insensitive in detecting smaller fractions of other phases.) The magnetic moment at a low temperature for NiMnSb agrees with the expected $4\,\mu_B$.

The most direct proof of half-metallicity is provided by positron annihilation. This method measures the Fermi surfaces for the two spin directions independently and can also detect the absence of a Fermi surface for a particular spin direction. These are genuine bulk measurements. This way, the half-metallic properties of NiMnSb were confirmed experimentally to the precision of 0.01 electrons (Hanssen and Mijnarends, 1986; Hanssen, Mijnarends, Rabou and Buschow, 1990). (Another attractive feature of positron annihilation is that it can be applied on a broad range of temperatures, unlike methods such as de Haas–van Alphen or cyclotron resonance.)

Fingerprints of half-metallicity are expected to show up in transport properties like the temperature dependence of electrical resistivity, the (anomalous) Hall effect, and so on. The situation here is remarkably complex, however, and a simple consistent picture is missing. The first study specifically addressing these points is the work of Otto *et al*. for NiMnSb (as well as PtMnSb, AuMnSb, CoMnSb, and PtMnSn). In a half-metal, no spin-flip scattering (one magnon scattering) is possible. The characteristic T^2 term in the temperature dependence of resistivity at low temperatures is indeed missing for NiMnSb (as well as for PtMnSb and CoMnSb, see the following text). The normal Hall effect shows a strong linear decrease from 4 to 90 K by a factor of 7, after which it saturates. Otto explains this remarkable feature as resulting from a complex Fermi surface comprising three sheets of mixed hole/electron character. Otto *et al*. report a strong anomalous Hall effect for all cases they investigated. Assuming a degree of spin polarization of the conduction electrons that is proportional to the magnetization (both as a function of temperature), a linear behavior is observed in all systems investigated for the anomalous Hall effect divided by the normal resistivity as a function of resistivity. NiMnSb follows this trend above 97 K only. The temperature dependence of the resistivity in half-metals was reviewed and studied theoretically by Irkhin and Katsnelson. The expected temperature dependence of the resistivity is $T^{9/2}$, which has not been reported experimentally. On the other hand, these authors also considered the nonquasiparticle contribution to the temperature dependence of the resistivity and obtained $T^{\sim 1.65}$, very close to the experimentally observed $T^{3/2}$, above a temperature of 100 K (Irkhin and Katsnelson, 1994, 2002). Strong evidence exists that a transition takes place in NiMnSb, but a complete understanding is still missing. An interesting scenario considers the thermal excitation of electrons at the Fermi energy level to the bottom of the conduction band (Hordequin, Ristoiu, Ranno and Pierre, 2000). This excitation transfers a majority-spin electron to the minority-spin direction. It reduces the magnetic moment and thus the exchange splitting, lowering the activation energy for more excitations of this type. A catastrophe occurs, the bottom of the conduction band drops below the Fermi level and the half-metallic properties are lost. Basically, this is a magnetic analog of the semiconductor–metal transition as described by Falicov. Such a phase transition could happen for any half-metal, but it requires the Fermi level to be positioned asymmetrically in the band gap, closer to the conduction band for half-metals with a band gap in the minority-spin direction. More recently, evidence has been obtained that around a temperature of

90 K, a reordering of the magnetic moments occurs, with loss of the half-metallic properties (Borca *et al*., 2001). The low temperature of these transitions is somewhat unexpected. Naively one would expect the spin polarization of the conduction electrons as a function of temperature to roughly follow the magnetization. Clearly more work is needed in order to obtain a full understanding here. Why was this transition not noticed in measurements of the magnetization? How does the transition depend on details of the magnon spectrum and could it be suppressed by doping with lanthanide atoms (Attema *et al*., 2004)? Half-metals with a band gap in the majority-spin direction, an area practically unexplored till now, could greatly contribute to our understanding of finite temperature properties.

2.1.3 Surfaces and interfaces

The majority of the techniques that measure the degree of spin polarization of the conduction electrons are actually surface-sensitive techniques. It is important to have an understanding of the physical properties of the surface of NiMnSb and half-metals in general. Also, knowledge and understanding of interfaces of half-metals with semiconductors, in particular, is of importance in spintronics. Ideally, a *bona fide* energy gap exists for one spin direction in the half-metal throughout the interface into the semiconductor. Such an interface is an exception. Designing an interface that fulfills all requirements requires proper insight into the interactions at the interface. Strongly magnetic half-metals have fundamentally different surface and interface properties compared to weak magnetic half-metals. In the case of strong magnetic half-metals, the magnetic properties are essentially determined by the ion carrying the magnetic moment and its valence. As long as this valence is conserved, the half-metallic properties are conserved, even at the surface. Figure 4 shows a comparison of the surface electronic structure with the bulk for the strongly magnetic half-metal CrO_2 (van Leuken and de Groot, 1995). In both cases, remarkably little influence of the surface on the electronic properties is found. In the case of weak magnets, additional strict requirements on the structure need to be fulfilled in order to maintain half-metallic properties. These conditions are violated at the surfaces. Experimentally, spin-dependent photoemission did not show 100% polarization (Bona *et al*., 1985), but inverse photoemission (probing the empty electron states) showed a very high degree of spin polarization (Ristoiu *et al*., 2000). Photoemission is a very surface-sensitive technique. A drawback is the possibility that it does not measure the entire Brillouin zone. For this reason Andreev reflection is superior. The spin polarization obtained this way is only 60% (Soulen *et al*., 1998). Originally, Andreev reflection was not considered as a particularly surface-sensitive technique, but

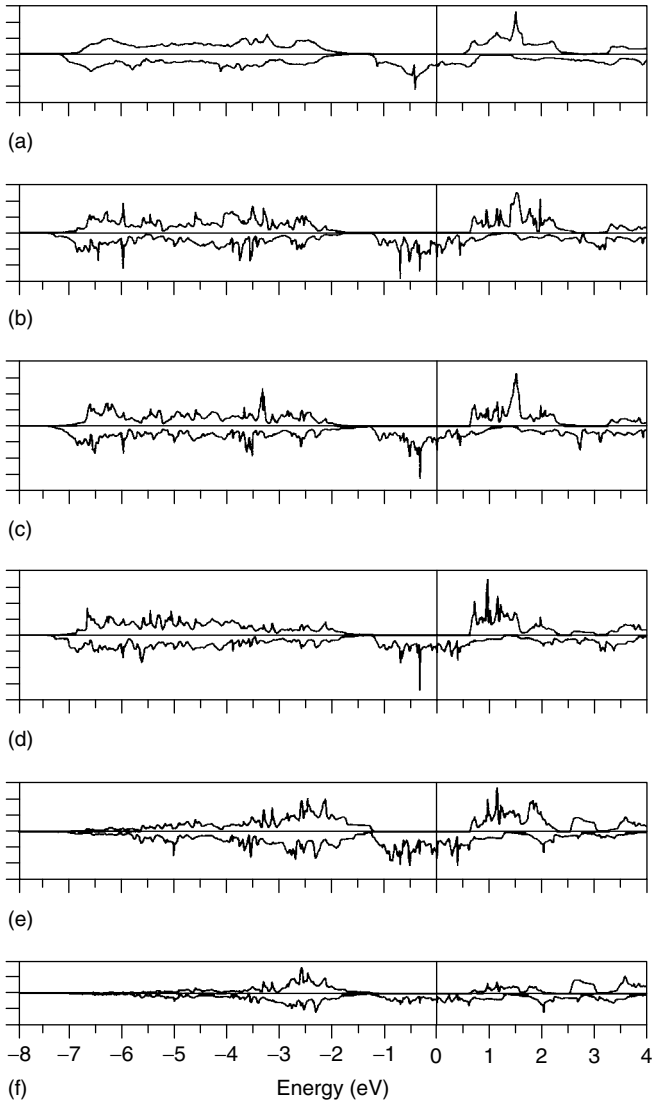

Figure 4. Comparison of the density of states of bulk CrO_2 (a) with the density of states per layer of the CrO_2(001) slab: central CrO_2 layer (b), sub-subsurface layer (c), subsurface layer (d), surface layer (e), and first vacuum layer (f). Vertical scale: 2 states per eV formula unit per division and 0.2 states per eV formula unit per division for (f).

this question is still under debate (Eschrig, Kopu, Cuevas and Schoen, 2003), and its interpretation is sometimes subtle (Auth, Jakob, Block and Felser, 2003). Electronic structure calculations on all the possible surfaces of low index (100, 110, 111) showed that none of them exhibited half-metallic surfaces, independent of the termination, and there are no reasons to assume that more complex surfaces would not interpolate between these cases (see e.g., Galanakis, 2002 for the (001) surfaces). The most detailed calculations find two metallic minority-spin surface states for the (001) surface (Jenkins and King, 2001). The same is found for the (111)

surface (Jenkins, 2004). This study also gives detailed information on the thermodynamic stability of the various (111) surfaces. An important conclusion is the stability of the antimony-terminated surface. For details we refer to the original literature.

The breakdown of half-metallicity at the surface of NiMnSb could be a reason to abolish NiMnSb and Heuslers, in general, as candidates for spin injection into semiconductors. However, it should be realized that the surface of NiMnSb is quite different from the interface with a semiconductor in view of the similarity in electronic structure between NiMnSb and III–V semiconductors. Also, the application of a strong magnetic half-metal like CrO_2 on a III–V semiconductor may very well introduce metallic behavior in the *semiconductor* for the spin direction in which the half-metal itself is semiconducting.

The properties of an interface are even more complex than those of a surface. Experimentally, few techniques are available to directly measure interface properties as compared to those available for measurements at the surface. Computationally also, the situation is much more complicated than is generally realized. Even if no lattice mismatch exists between the two materials and interdiffusion of atoms from the neighboring materials can be neglected, the number of possible interfaces is still infinite, since the lateral orientation of one material with respect to the other is undetermined. Also, the structure at the interface and its volume need to be determined. This requires a careful and very expensive structure optimization. But it should be realized that actual interfaces are not determined by thermodynamic equilibrium alone. These optimizations are essential: the value of the spin polarization of the conduction electrons at the interface can change by hundreds of percent as compared with the guessed geometry. Structural relaxations in the stacking direction can be calculated quite straightforwardly. But relaxations in the lateral directions require very large unit cells and can be performed for relatively easy cases only. An early study of interfaces of low index of NiMnSb with InP and CdS showed (de Wijs and de Groot, 2001; Figure 5) that only one interface maintained semiconducting properties for the half-metal throughout the interface into the semiconductor. It is the 111 interface where both half-metal and semiconductors are anion terminated with a displacement of the lattices with respect to each other in the lateral directions in such a way that the two anions are positioned on top of each other in the stacking direction. In the first inspection, such an interface may look unstable, but such anion–anion bonds do occur in minerals like costabite and paracostabite, which have crystal structures very much related to the interfaces described here. Minerals are stable on a geological timescale. Much can be learned from the reason for this being the only half-metallic interface. The 111 direction in NiMnSb is the only

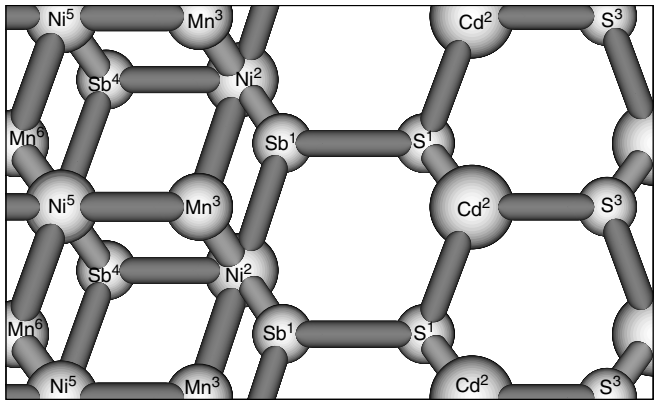

Figure 5. Structure of the half-metallic NiMnSb(111)/CdS(111) interface. The [111] axis runs horizontally, form left to right. Notice the Sb–S bond at the interface ($d_{Sb1-S1} = 2.7$ Å).

direction in which one finds layers of one element only, the 100 and 110 directions already show at least one plane with more than one component. The origin of the band gap in NiMnSb is very much like that in a III–V semiconductor, where the trivalent manganese can play a role similar to that of a trivalent metal like gallium in the corresponding semiconductor. But there is a difference between the two. In Ga–pnictide semiconductors, the contribution of Ga to the valence bands consists of 4s and 4p electrons, whereas Mn in NiMnSb contributes 4s and 3d electrons, with different main quantum numbers. Each element separately (Ga or Mn) gives a band structure with a *bona fide* band gap, *but a mixture of them does not.* The double-anion-terminated 111 interface is the only interface without anions coordinated by both transition and main-group metals. These findings are confirmed by calculations on $Ga_{(1-x)}$ Mn_xSb. The limited solubility of Mn in, for example, GaAs as known in dilute magnetic semiconductors, is not unrelated with the problems of a NiMnSb/semiconductor interface. Experimental work has been focused mainly on (100) interfaces. The best surface morphology and crystal quality was obtained for NiMnSb grown on GaAs, which was 20% deficient in antimony (van Roy *et al*., 2000, 2001). A (111) NiMnSb–GaAs B interface of good quality was realized (van Roy *et al*., 2003). This interface did not show a high degree of polarization, possibly because of the lattice mismatch.

2.2 Heusler alloys isoelectronic with nickel–manganese–antimonide

2.2.1 General

The band structures of PdMnSb and PtMnSb show strong similarities with that of NiMnSb. In PdMnSb, the Fermi energy straddles the top of the valence band. PtMnSb shows

major differences in the conduction band as compared with NiMnSb. The origin of these differences is relativistic: they originate from the mass–velocity and Darwin terms. The result is that the platinum 6s states are positioned much lower in energy than the 4s states of Ni in NiMnSb. This has a direct influence on the nature of the band gap. The direct gap for PtMnSb is very much like NiMnSb, the bottom of the conduction band at the Γ point, however, is a single degenerate band in which Pt s states contribute substantially. This possibly influences the magneto-optic Kerr effect.

The very high magneto-optic Kerr effect in PtMnSb spurred interest in this compound and in Heusler alloys, in general. The 2.5° (double) rotation at room temperature was a record (van Engen, Buschow and Jongebreur, 1983). A simple model related this observation to the half-metallic properties as the complement of the optical generation of spin-polarized electrons in semiconductors: where an optical transition with circularly polarized light from a spin-orbit split valence band generates spin-polarized electrons in the conduction band, the absorption of light from a 100% spin-polarized, spin-orbit split top of a valence band is possible for one (circular) polarization only. This uncompensated excitation gives a peak in the magneto-optic spectrum at a remarkably good position (de Groot, Mueller, van Engen and Buschow, 1984). The differences between PtMnSb and NiMnSb could be explained by the much higher position of the final state in the latter compound caused by the absence of strong scalar relativistic effects, leading to a second peak at much higher energy (Wijngaard, Haas and de Groot, 1989). On the other hand, the importance of a very small diagonal part, which enters the denominator in the expression of the Kerr effect, was stressed (Feil and Haas, 1987).

The first calculations of magneto-optical spectra based on first-principles calculations appeared in the beginning of the 1990s (Halilov and Kulatov, 1991; Kulatov, Uspenkii and Halilov, 1995). The magneto-optical properties of PtMnSb were reproduced very well. The results for NiMnSb showed a discrepancy of 0.5 eV in the position of spectral features and peaks that are more than twice as strong as compared with experiment. The latter point is of no importance, since any defects in samples and temperature reduce spectral features. A very thorough study on the background of magneto-optics in NiMnSb, PdMnSb, and PtMnSb analyzed in detail the effects of spin-orbit coupling, the magnetic moment, the degree of hybridization, the half-metallic character, the plasma frequency, and the crystal structure. This was accomplished by calculations on a large number of (sometimes hypothetical) compounds, in which these factors could be controlled separately. All factors contributed in the case of PtMnSb (Antonov *et al*., 1997). Regrettably, no analyses were made as to whether a specific part of the Brillouin zone contributed to the observed effect. Recent measurements on the (magneto-)optical properties of NiMnSb (Gao *et al*., 1999) were interpreted using the calculations of Antonov *et al*. and very good agreement was obtained. On the other hand, recent measurements on the *temperature* dependence of the Kerr effect in PtMnSb showed that there still remains an aspect to be understood: the Kerr effect increases by more than a factor of 3 on cooling down to 100 K (Carey, Newman and Wears, 2000). The diagonal part of the dielectric tensor is responsible for this unexpected result.

2.3 Other half-metals in the $C1_b$ structure

2.3.1 Slater–Pauling curves

If one plots the magnetic moment per formula unit of a large collection of compounds as a function of the number of valence electrons, many linear dependences are obtained. A unique curve with slope -1 is obtained for high electron concentrations, at the right side of what has been baptized the *Slater–Pauling* (SP) curve (Figure 6). This particular behavior is obtained if the number of majority electrons is constant; in practically all cases, this implies that the majority d bands are completely filled, for example, it is an implication of strong magnetism. The situation at the left-hand side of the SP curve is more complex. One could imagine that strong magnetism based on empty minority-spin bands is the origin. But low electron concentrations necessarily imply atoms from the left side of the transition-metal series, and the delocalized behavior of their d electrons does not favor magnetism (Kübler, 2000). An exception is found in the strongly ionic, strongly magnetic compounds like the colossal magnetoresistance materials and oxides like CrO_2. They are half-metals, but are not the subject of this chapter. Several different curves with a positive slope are found at the left side of the SP diagram, each representing a different mechanism for keeping the number of minority-spin electrons constant. One such mechanism is half-metallic magnetism.

In NiMnSb, if we were to substitute Ni with other 3d metals, the resulting compounds would follow the SP curve as long as the half-metallic magnetism persists. As mentioned before, the presence of minority-spin d electrons in the valence-band complex causes NiMnSb to be a weak magnet. Consequently, the maximal magnetic moment in a possible *series* of half-metals based on it is $4\,\mu_B$. This marks NiMnSb as the end of the series. Indeed, compounds with electron concentrations beyond NiMnSb are not half-metallic. In NiFeSb, the reduction in magnetic moment is accomplished by the occupation of minority-spin d states in the conduction band with the inevitable loss of half-metallicity. The required loss of half-metallicity and reduction of magnetic moments is energetically, more favorably realized by adopting an

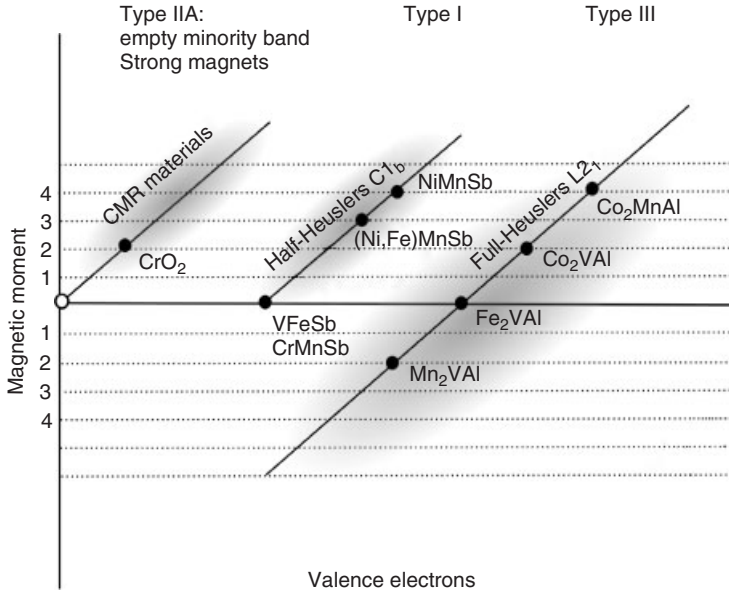

Figure 6. Slater-Pauling curves showing the relation between several classes of half-metals.

antiferromagnetic magnetic structure by doubling the unit cell (CuMnSb). A *reduction* of the electron density leads to CoMnSb calculated to be a half-metal indeed (Kübler, 1984). The band structure for the minority (semiconducting)-spin direction has hardly changed. The metallic spin direction is more strongly affected and the magnetic moment is reduced to $3\,\mu_B$. Following the SP curve, the next compound is FeMnSb. Calculations show a half-metallic electronic structure here as well (de Groot, van der Kraan and Buschow, 1986). Consequently, the magnetic moment is reduced to $2\,\mu_B$, which is quite a small moment for iron and manganese to share in a magnetic alloy. This is actually not the case. FeMnSb is a *ferrimagnet*, so $2\,\mu_B$ represents the *difference* of the moments on iron and manganese. This way, both the energy gain of the energy gap as well as the maximal gain in exchange energy can be obtained: the ferromagnetic solution can accommodate the larger moments as well, but at the expense of the energy gain associated with the band gap. This constitutes an exchange coupling mechanism unique for half-metals and is expected to occur for band gaps exceeding the exchange coupling strengths, which rarely exceed 0.1 eV. The next case is MnMnSb (this notation is used to accentuate the very different crystallographic point group symmetries of the two manganese atoms). It is a half-metallic ferrimagnet with a net moment of $1\,\mu_B$. Another way of reducing the number of charge carriers is the substitution of nickel with 4d or 5d elements like osmium, iridium, or rhodium. In these cases, the exchange interaction of the introduced elements is not strong enough to maintain half-metallic properties. Instead a rigid band like that of the Fermi energy occurs. The band gap is maintained, but the Fermi level is positioned below the top of the valence band. PtMnSn shows a similar behavior (de Groot van der Kraan and Buschow, 1986).

The results discussed in the previous paragraph are only partially confirmed experimentally, mainly because of the fact that these systems adopt different crystal structures. Experimentally a magnetic moment different from $3\,\mu_B$ is found for CoMnSb. The explanation for this discrepancy is that CoMnSb actually shows a tetragonal superstructure related to the Heusler $C1_b$ structure but with partial occupation of cobalt on the empty sites (Szytula *et al*., 1972). The situation for FeMnSb is also more complex. Partial substitution of Ni by Fe in NiMnSb leads initially to the theoretically expected behavior. But beyond 10%, a second non-half-metallic phase similar to CoMnSb shows up. No calculations have been reported on iron-substituted NiMnSb yet. Mn_2Sb does exist and is experimentally found to be a ferrimagnet with a magnetic moment of $1\,\mu_B$. However, it crystallizes in the Cu_2Sb structure, quite different from the Heusler structure. Band structure calculations in the actual structure are consistent with the magnetic properties, but do not show any sign of half-metallicity (Wijngaard, Haas and de Groot, 1992).

Potentially, other half-metals could exist by substituting both transition metals in NiMnSb. CoVSb has been seriously considered, but has been rejected on the basis of neutron scattering work (Heyne *et al*., 2005).

2.3.2 CrMnSb, half-metallic antiferromagnetism

The SP curve described in Section 2.3.1 intersects the ordinate for CrMnSb. Usually, the intersection of the SP curve

is an indication of a nonmagnetic solution. But in this particular case, we have seen that the reduction of magnetization following the SP curve is energetically more favorably realized by adopting an antiparallel ordering of the magnetic moments of the two different magnetic atoms. Following this trend toward CrMnSb, a fundamentally new type of material is encountered: There is no net magnetization, *but the conduction electrons remain completely spin polarized.* This was baptized half-metallic antiferromagnetism (de Groot, 1991). It is a situation quite distinct from traditional antiferromagnets, in which magnetization vanishes because of a symmetry operator or a spin-density wave. As a matter of fact, the half-metallic antiferromagnetism is so different from conventional antiferromagnetism, that its name is controversial. The reason we use the name is that the cancellation of the moments on *different* atoms (Cr and Mn in this case) on *different* Wyckoff positions is, nevertheless, *exact.* It follows from the requirement of integral magnetic moments for half-metals and this is zero here. Unfortunately, CrMnSb actually crystallizes in the same crystal structure as Mn_2Sb, and although it is antiferromagnetic for some range of composition it is not half-metallic. Isoelectronic VFeSb does adopt the Heusler $C1_b$ structure, but it is a nonmagnetic semiconductor. Clearly, the energy gain of having a band gap for the second spin direction exceeds the gain in exchange energy of a magnetic solution here. The half-metallic antiferromagnetic solution could be stabilized in a calculation by partially replacing the more delocalized d metal vanadium by manganese (van Leuken and de Groot, 1995). The required electron count was maintained by modifying the occupation of the main-group element: $(VFeSb)_{(1-x)}(MnFeIn)_x$. We are not aware of any attempts to synthesize this compound. A practical realization, whether as a Heusler alloy or other, would be important. Not only has it been predicted that half-metallic antiferromagnets show a novel form of superconductivity ('single-spin superconductivity') (Pickett, 1996) but also that applications of systems with 100% spin polarization without magnetization are easily imagined.

3 HEUSLER $L2_1$ STRUCTURE

The Heusler $L2_1$ structure is obtained by occupation of the remaining open position of the $C1_b$ structure by the element with cube coordination already present in this structure. This introduces an inversion center in the crystal structure and eliminates the tetrahedral coordination of the two atoms in the half-Heusler structure. The strong interatomic interaction responsible for the well-defined band gaps in the half Heuslers is forbidden by symmetry in the full Heuslers. The relation with zinc-blende semiconductors is lost, as evidenced by the distinct band gap topologies. Half-metals in the $L2_1$ show narrower bands, and a band gap opens up simply because the bandwidth is not always larger than a ligand-field splitting. This process is quite independent of the structure; a continuing decrease of interatomic interactions with respect to crystal-field and intra-atomic interactions leads through various other possible type of half-metals to magnetite in the end (Yanase and Siratori, 1984), at which point a Mott insulating state occurs. This is case 3 of half-metallicity in the classification scheme of half-metals (Fang, de Wijs and de Groot, 2002). The fact that both classes of half-metals ($C1_b$ and $L2_1$) share the *same* SP curve should not be interpreted as an indication of a common detailed mechanism in both cases; it merely reflects the fact that bonding–antibonding interactions are strongest near half-filled electron shells, independent of the specific details of these interactions. (Several different versions of the SP curves exist. Both classes of Heuslers fall only on the same SP curve if the unit of the ordinate is the average number of charge carriers per atom.)

The number of known full-Heusler alloys as well as the number of potential half-metals is larger than those for the half Heuslers. Much of the systems investigated at this moment go back to the early experimental work of Ziebeck and Webster (1974). From a computational point of view, besides the early work of Kübler, important early work came from the Japanese group (Fujii, Sugimura, Ishida and Asano, 1990; Ishida, Fujii, Kashiwagi and Asano, 1995; Fujii, Ishida and Asano, 1995). An important aspect is the occurrence of disorder in full Heuslers. The type of disorder that can occur and the influence of disorder, particularly, in connection with the integrity of the band gap is a subject of active research. There seems to be a trend that the most damaging types of disorder are also the energetically less favorable ones. This justifies some optimism in terms of applications, but the amount of disorder is not always determined by thermodynamics alone, in particular, in cases where samples are prepared at low temperatures. Annealing afterwards is sometimes difficult because of the risk of interdiffusion from or to a neighboring layer already present.

The physics of half-metals in the full-Heusler alloys is best displayed in an SP curve shown in Figure 7 (Galanakis, Dederichs and Papanikolaou, 2002). Galanakis, Dederichs, and Papanikolaou (2002) also compiled much of the experimental and computational results on full Heuslers. For this reason we will concentrate on more recent work here. Much work has been done on the alloys in the upper right corner of the SP curve. Magnetic moments are relatively large here, but more importantly, the Curie temperatures are also high. Several groups have addressed the problem of impurities in Co_2MnSi. A strong dependence on the impurity concentration was found depending on the preparation condition as inferred from residual resistance ratios (RRRs) (Raphael

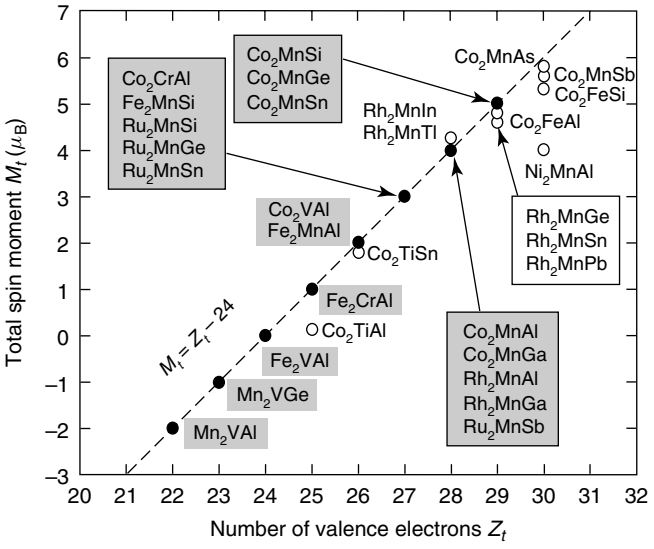

Figure 7. Calculated total spin moments for all the studied Heusler alloys. The dashed line represents the Slater–Pauling behavior. With open circles we present the compounds deviating from the SP curve.

et al., 2002). Single crystals showed an RRR of 6.5, arc melted samples 2.7, while the best films had an RRR of 1.4. Neutron diffraction on polycrystalline bulk samples showed the presence of Co–Mn disorder. Electronic structure calculations (Picozzi, Continenza and Freeman, 2004) showed a Mn antisite to be harmless, but a Co antisite induces a strong peak in the density of states at the Fermi level for the majority spin. It is considered of rather localized character, however. The effect of imperfections, strain, and impurities were investigated for Co_2MnGe, isoelectronic with the silicon analog (Carey, Block and Gurney, 2004). The effect of strain on the spin polarization of the conduction electrons was negligible up to 3%. On the other hand, the presence of impurities and, in particular, oxygen has a devastating effect. Nevertheless, Co_2MnSi showed 61% tunneling magnetoresistance at a temperature of 10 K, using an aluminum oxide barrier (Kammerer, Thomas, Huetten and Reiss, 2004). The effect decreases rather fast, but is continuous with temperature, which is explained in nonperfect interfaces.

Half-metallic behavior was predicted for Co_2CrAl, with the magnetic moment of $3\,\mu_B$ expected from the SP curve. Experimentally a magnetic moment of $1.55\,\mu_B$ was obtained, which would disprove half-metallicity (Buschow and van Engen, 1981). However, later work showed variations of the magnetic moment between 1.5 and $3\,\mu_B$. Reproducible moments in line with a half-metallicity are obtained by partially substituting Cr by Fe (Elmers *et al.*, 2003 and reference 7 therein). Electronic structure calculations proved that a low iron concentration was most effective (Miura, Nagao and Shirai, 2004). Two detailed studies of interfaces with III–V semiconductors were reported recently. Although half-metallicity was lost, a very high degree of spin polarization (estimated at ∼90% from Figure 1) was obtained for the (110) interface with GaAs – higher than (100) interfaces (Nagao, Shirai and Miura, 2004). For InP, on the other hand, the (001) surface showed more than 80% majority-spin contribution at the Fermi level (Galanakis, 2004), corresponding to over 60% spin polarization.

Finally, we consider the half-metals with low electron concentration, which are found in the lower left part of the SP curve. The half-metallic properties of Fe_2CrAl could not be confirmed experimentally. The magnetic moment derived from the saturation magnetization was $1.75\,\mu_B$ rather than the $1\,\mu_B$ expected from the SP curve. Also, the band structure did not show half-metallic properties, when calculated with the experimental lattice constant (Zhang, Bruck, de Boer and Wu, 2004).

A most interesting phenomenon, at least from a scientific point of view, occurs when following the SP curve further to the left. One step to the left of Fe_2CrAl, one arrives at Fe_2VAl, where the SP curve crosses the ordinate. Consequently, no distinction between majority spin and minority spin exists anymore, which implies either a half-metallic antiferromagnet or a nonmagnetic solution, where the preservation of the band gap along the SP curve suggests semiconducting behavior. Experimentally, it is a nonmagnetic semiconductor with exotic properties, which are outside the scope of this review. *But the SP curve continues beyond this point.* The crossing of the ordinate in the SP curve indicates a transition from half-metals with a minority-spin gap to half-metals with a majority-spin gap for Mn_2VAl (Weht and Pickett, 1999). Half-metals with a majority-spin gap are rare. Other examples are found in the double perovskites (Kobayashi *et al.*, 1998) and magnetite (Fe_3O_4), but the half-metallic properties of the latter compound are seriously challenged. The many-body physics at finite temperature of half-metals with a band gap for majority-spin electrons is distinct from that of ordinary half-metals (Irkhin and Katsnelson, 1994). The prospect of studying these differences in a series of similar chemical compounds is a challenge for the future.

Half-metals

M. Venkatesan
Trinity College, Dublin 2, Ireland

1 INTRODUCTION

Half-metallic ferromagnets are solids that are metals with a Fermi surface in one spin channel, but for the opposite spin there is a gap in the spin-polarized density of states (DOS), like a semiconductor or insulator (O'Handley, 2000). The gap may occur in either the majority or minority channel. In general, half-metals are ferromagnetic but a ferromagnet is not necessarily a half-metal. Half-metals are the extreme case of strong ferromagnets where not only $3d$ electrons are fully polarized, but also other (sp) down-spin bands do not cross the Fermi level. As a result of this, only electrons of one spin direction contribute toward conduction yielding 100% spin polarization at the Fermi energy, E_F. This unusual property could have significant implications for applications related to magnetism and spin electronics. Electrically conducting ferromagnetic materials where the conduction electrons have a high mobility and are fully spin polarized are desirable for realizing future thin-film spin electronic devices. Since the devices will probably be expected to work around and above room temperature, the new ferromagnets should have Curie temperatures in excess of 500 K. Half-metallic ferromagnetic electrodes can serve as ideal spin injectors and detectors, because they can carry current in only one spin direction under moderate voltage. They also constitute ideal components for giant magnetoresistance (GMR) and tunneling magnetoresistance (TMR) devices.

Half-metallicity yields features of the solid that are quite different from conventional ferromagnetic metals. It is not an easy property to detect experimentally, unlike superconductors, metals, semiconductors, or insulators where there is a clear indication in electrical transport. It has therefore been customary to rely on electronic structure calculations to identify half-metals. One of the features is flat high-field susceptibility at low temperature, but it is impractical to measure the intrinsic high-field susceptibility of a ferromagnet accurately to assert that it is zero. The response of a half-metal to an electric and magnetic field is quite different. There is electric conductivity, but no high-field magnetic susceptibility. The application of an external magnetic field only shifts the up- and down-spin bands by $\pm g\mu_B H$ with no change in net spin moment. Hence, the spin susceptibility vanishes, like an insulator. The best indication of a half-metal is metallic conduction in a solid with a spin moment at $T = 0$ which is *precisely an integral number of Bohr magnetons per unit cell*. In a stoichiometric compound, the number of electrons per unit cell $n = n^{\uparrow} + n^{\downarrow}$ is an integer. On account of the gap in one of the spin-polarized bands, $n^{\uparrow}$ or $n^{\downarrow}$ is also an integer. It follows that both $n^{\uparrow}$ and $n^{\downarrow}$ are integers, and so

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

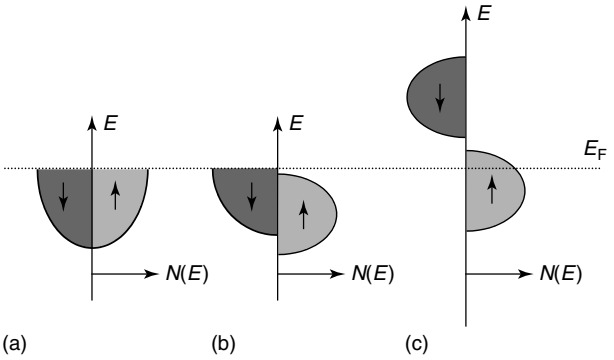

Figure 1. Schematic densities of states of (a) a normal metal, (b) a ferromagnetic metal, and (c) a half-metal.

is the difference $n^{\uparrow} - n^{\downarrow}$ which is the spin moment in units of the Bohr magneton. The integer spin moment criterion, or an extension of it to cover the case of a solid solution, is a necessary but not a sufficient condition for half-metallicity.

The schematic diagram of a normal metal, ferromagnetic metal, and half-metal is shown in Figure 1. Normal and conventional ferromagnets such as Fe, Co, Ni are not half-metals. The conduction electrons in the 3*d* ferromagnets are not fully spin polarized, even when the d band is strongly spin split, because of the simultaneous presence of 4*s* electrons at the Fermi level. Cobalt and nickel, for example, are strong ferromagnets with fully spin-polarized d bands and fully occupied majority spin states (↑ 3*d* band), and only ↓ 3*d* electrons at E_F (O'Handley, 2000). However, the Fermi level also crosses the unpolarized 4*s* band, which carries most of the current. So there are both the spin-up and spin-down densities of states present at E_F. In order to obtain only ↑ or ↓ electrons at E_F, it is necessary to reorder the 3*d* and 4*s* bands. This is done by hybridization, pushing the bottom of the 4*s* band up above E_F or depressing the Fermi level in the d band below the bottom of the 4*s* band. Therefore, all half-metals consist of more than one element – they are alloys or compounds. Most known examples are oxides, sulfides, or Heusler alloys. Some are stoichiometric compounds, others are solid solutions.

2 CLASSIFICATION OF HALF-METALS

Half-metals can be classified (Coey, Venkatesan and Bari, 2001; Coey and Sanvito, 2004) into four categories, types I–IV, as presented in Figure 2. Type IA (IB) half-metals (Figure 2a and b) only have majority (minority) spin electrons appearing at E_F. In type II half-metals (Figure 2c), the electrons lie in a band that is sufficiently narrow for them to be localized. The heavy carriers may then form polarons, where conduction takes place via electron hopping between spin-polarized sites. Type III half-metals (Figure 2d) have localized ↑ carriers and delocalized ↓ carriers or vice versa (also known as *transport half-metal*). A DOS exists for *both* subbands at E_F, but the carriers in one band have a much larger effective mass than those in the other. As far as electronic transport properties are concerned, only one sort of carriers contributes significantly to the conduction. Type IV half-metals (Figure 2f) are semimetallic – magnetically ordered semimetals with a great difference in effective masses between electrons and holes. There is a big difference between a half-metal and a semimetal. A semimetal (Figure 2e) like bismuth, graphite, or antimony is usually nonmagnetic with small and equal numbers of electrons and holes (≈ 0.01 per atom) due to a small overlap between valence and conduction bands. Table 1 summarizes the various types of half-metals in detail (Coey, Venkatesan and Bari, 2001; Coey and Sanvito, 2004).

3 HALF-METALLIC MATERIALS

In this section, we will review some materials that are claimed to be half-metals before discussing the experimental techniques needed to measure spin polarization and other half-metallic characteristics. There are two main classes of materials – oxides and Heusler alloys. The crystal structures of a few representative materials are presented in Figure 3. Table 2 summarizes the list of different types of half metallic materials with predicted spin moment per formula unit, deduced from band structure calculations, and the Curie temperature.

3.1 Oxides

3.1.1 CrO_2

Chromium dioxide crystallizes in the tetragonal rutile structure (Barry, 1999; Coey and Venkatesan, 2002) and it is the best-studied half-metal in the literature (Barry, 1999; Coey and Venkatesan, 2002). The formal electronic configuration is $(t_{2g}^2)^{\uparrow}$ for Cr^{4+}, and $2p^6$ for O^{2-} although there is some $O^{2-} \rightarrow Cr^{4+}$ charge transfer and strong mixing of oxygen hole and chromium electron states at E_F (Lewis, Allen and Sasaki, 1997; Korotin, Anisimov, Khomski and Sawatzky, 1998). Band-structure calculations (Schwarz, 1986) have shown that CrO_2 is a half-metallic system (Figure 4a) with the spin-spilt band structure of a type IA half-metal and a spin gap $\Delta_{\downarrow} > 1$ eV. The half-metallic character is maintained up to the surface (van Leuken and de Groot, 1995). The calculations generally show a t_{2g} bandwidth of 2.5–3.0 eV, with a trident structure including a narrow peak in the DOS due to the d_{xy} electrons. All the calculations and experimental

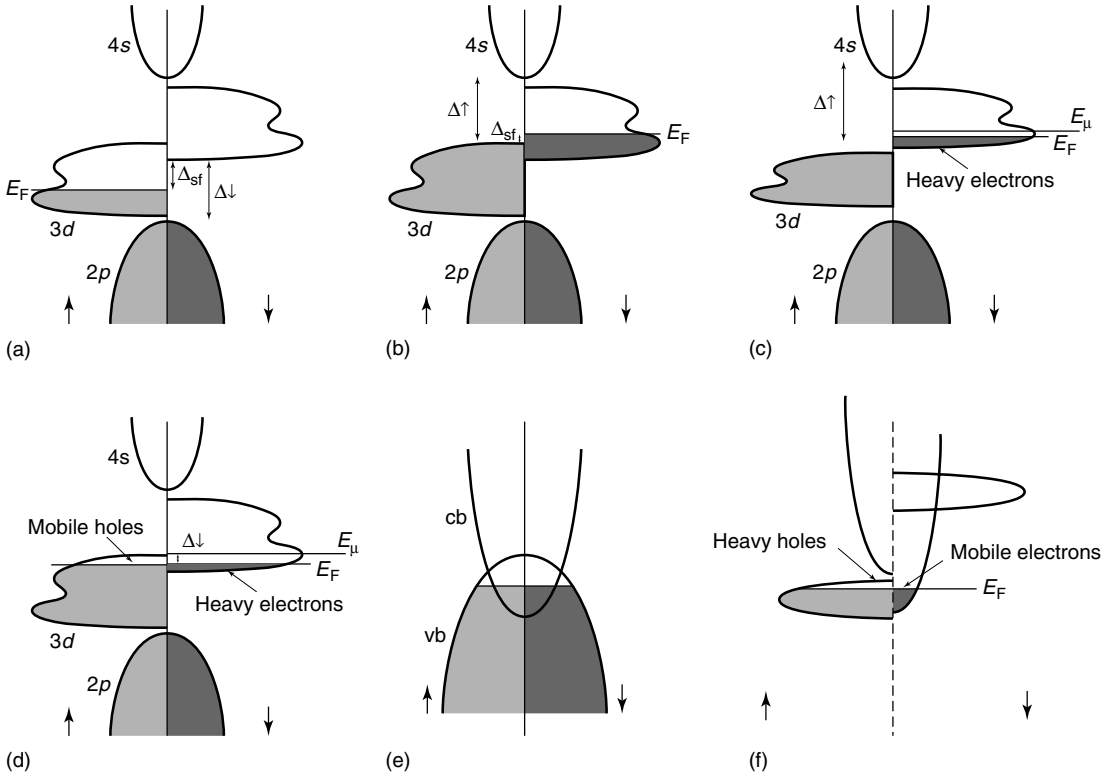

Figure 2. Schematic density of states for a half-metal. (a) Type IA with only ↑ electrons at E_F, (b) type IB with only ↓ electrons at E_F, (c) type II, (d) type III, (e) semimetal, (f) type IV, half-metallic semimetal. The symbols Δ_{sf}, $\Delta_{\uparrow,\downarrow}$, and E_μ refer to the spin-flip excitation energy, spin gap, and the mobility edge, respectively (Coey, Venkatesan and Bari, 2001; Coey and Sanvito, 2004).

Table 1. Summary of the classification of half-metals (Coey, Venkatesan and Bari, 2001; Coey and Sanvito, 2004).

Type	Density of states	Conductivity	↑ electrons at E_F	↓ electrons at E_F
1A	Half-metal	Metallic	Itinerant	None
1B	Half-metal	Metallic	None	Itinerant
IIA	Half-metal	Nonmetallic	Localized	None
IIB	Half-metal	Nonmetallic	None	Localized
IIIA	Metal	Metallic	Itinerant	Localized
IIIB	Metal	Metallic	Localized	Itinerant
IVA	Semimetal	Metallic	Itinerant	Localized
IVB	Semimetal	Metallic	Localized	Itinerant
VA	Semiconductor	Semiconducting	Few, itinerant	None
VB	Semiconductor	Semiconducting	None	Few, itinerant

results yield a low-temperature magnetic moment of $\sigma = 133\,\mathrm{Am^2\,kg^{-1}}$ corresponding to an integral moment of $2.0\,\mu_B$ per formula unit (Chamberland, 1977). The Curie temperature of CrO_2 is about 395 K. The transport properties (resistivity, magnetoresistance) exhibit a syndrome where spin-flip scattering seems to be suppressed below a temperature $\Delta \approx 0.2T_C$. This is related to spin-wave excitations and not to the spin-flip gap Δ_{sf}, which is many times greater than Δ. A series of Andreev reflection measurements (Soulen *et al.*, 1998; Ji *et al.*, 2001) have been carried out on CrO_2 – superconductor point contacts. These indicate a very high spin polarization, $P \approx 80$–96% for CrO_2 at low temperatures (<2 K).

3.1.2 Fe_3O_4

Magnetite, the most famous magnetic mineral, is a spin-polarized, Fe^{2+}–Fe^{3+} mixed-valence metal. It is the half-metal with the highest Curie temperature (860 K) among oxides. The B sites of the spinel structure (Figure 3b) are populated by an equal mixture of Fe^{3+} and Fe^{2+}, so the average B-site configuration is $(t_{2g}^3 e_g^2)^\uparrow\ (t_{2g}^{0.5})^\downarrow$. The

A sites contain oppositely magnetized $Fe^{3+}(t_{2g}^3 e_g^2)^\downarrow$ cores. The ↓ B-site electrons form small polarons which hop among the B sites (Brabers, 1995). Magnetite undergoes a metal–insulator phase transition below about 120 K in which the conductivity abruptly decreases by a factor ∼100 (Verwey, 1939). Resistivity at 120 K, where the B-site charges order, is $\sim 10^{-4}\,\Omega$m. High-quality films and crystals have a spin moment of $4.0\,\mu_B$ at this temperature, reflecting the ferrimagnetic structure of A and B sites. Magnetite is a type IIB half-metal with a spin gap in the majority DOS (Penicaud, Silberchiot, Sommers and Kubler, 1992; Zhang and Satpathy, 1991) as shown by the band structure in Figure 4(b). Despite the strong belief that magnetite should exhibit a large spin polarization owing to its half-metallicity,

Density of state for majority and minority spins in (a) CrO_2 (Lewis, Allen and Sasaki, 1997; Korotin, Anisimov, Khomski and Sawatzky, 1998), (b) Fe_3O_4 (Penicaud, Silberchiot, Sommers and Kubler, 1992; Zhang and Satpathy, 1991), (c) Sr_2FeMoO_6 (Kobayashi *et al*., 1998), and (d) Co_2CrAl (Felser, Elmers and Fecher, 2005).

no concrete manifestation has been reported as yet and the low magnetoresistance values in TMR junctions is still not properly understood.

3.1.3 $La_{0.7}Sr_{0.3}MnO_3$

Optimally doped $La_{1-x}Sr_xMnO_3$ (LSMO) is a half-metallic material and potential candidate for spin electronics applications, although LSMO ($x = 0.3$–0.4) has a Curie temperature around 360–380 K, which is probably too low for any room-temperature devices. It crystallizes into a rhombohedrally distorted perovskite structure. The substitution of Sr for La creates a mixture of Mn^{3+} $(t_{2g}^3 e_g)^{\uparrow}$ and Mn^{4+} $(t_{2g}^3)^{\uparrow}$ on the B sites of the structure (Figure 3c) (Coey, Viret and von Molnar, 1999). The hopping $e_g^{\uparrow}$ electron produces ferromagnetic coupling by double exchange. The electronic structure of LSMO, as described by band theory, is completely

spin polarized reflecting the type III, transport half-metallic behavior (Nadgorny *et al*., 2001). Electronic structure calculations on this (Nadgorny *et al*., 2001) and the isostructural phase $(La_{0:67}Ca_{0:33})MnO_3$ (Pickett and Singh, 1996) place the Fermi level slightly above the bottom of the $t_{2g}^{\downarrow}$ band. The ferromagnetic moment is consistently reported as slightly less than the $3.7\,\mu_B$ when $x = 0.3$. $(La_{0.7}Sr_{0..3})MnO_3$ is a type IIIA half-metal, with both mobile $Mn(e_g)\uparrow$ electrons and immobile $Mn(t_{2g})\downarrow$ electrons at E_F having very different mobilities for the two spins.

3.1.4 Sr_2FeMoO_6

In the ordered double perovskites $A_2BB'O_6$, the transition-metal sites are occupied alternatively by different cations B and B' (Figure 3d). Oxygen atoms bridge between B and B', forming alternating octahedra with B or B' as central atom. The double perovskite Sr_2FeMoO_6 (SFMO) crystallizes in a tetragonal structure, space group $P4_2/n$, with NaCl-type order of Fe and Mo. Here, Fe and Mo ions alternate on the B and B' sites. In all the proposed models, its electronic structure is composed of localized up-spins borne by the Fe^{3+} ($S = 5/2$) ions and a conduction band partially occupied by the single itinerant down-spin electron provided by the Mo^{5+} ions. Formal electronic configurations are Fe^{3+} $(t_{2g}^3 e_g^2)^{\uparrow}$ and $Mo^{5+}(t_{2g}^1)^{\downarrow}$, although the Mo and Fe $t_{2g}^{\downarrow}$ orbitals are strongly mixed. A half-metallic structure (Figure 4c) is predicted (Kobayashi *et al*., 1998). The compound is ferrimagnetic with $T_C = 420\,K$ and a saturation magnetic moment of $4\,\mu_B$. It is a type IB half-metal. Some good-quality films have moments approaching this value (Westerburg, Reisinger and Jakob, 2000), but moments measured in single crystals are generally lower (Tomioka *et al*., 2000) which is usually attributed to antisite disorder of Fe and Mo. X-ray magnetic circular dichroism (XMCD) (Besse *et al*., 2002) confirms the presence of a finite spin moment on Mo together with only very small orbital moments on both Fe and Mo suggesting that the predicted half-metallicity is due to a configuration with five localized d electrons forming a high-spin moment on Fe and one antiparallel delocalized electron shared between the Mo and the other sites.

3.1.5 $Tl_2Mn_2O_7$

The pyrochlore manganite $Tl_2Mn_2O_7$ is a cubic compound with an interesting electronic structure and unexpected magnetic properties (Shimakawa, Kubo and Manako, 1996; Subramanian *et al*., 1996). In a simple ionic picture, the material would be an insulator containing Mn^{4+} ($3d^3$) and Tl^{3+} ($5d^{10}$) cations. Only the former bear the magnetic moment of $3\,\mu_B$ due to a $t_{2g}^{3\uparrow}$ configuration. The thallium compound, however, is a ferromagnetic semimetal with a small number of heavy holes at the top of a narrow $\uparrow$ band of mainly Mn (t_{2g}) character and an equal number of mobile $\downarrow$ electrons in a broadband of mixed Tl ($6s$), O ($2p$), and Mn ($3d$) character (Shimakawa *et al*., 1999; Singh, 1997; Mishra and Sathpaty, 1998). The number of carriers has been estimated at 0.086 per unit cell (Imai, Shimakawa, Sushko and Kubo, 2000) or 0.005 per manganese from LSDA-LAPW calculations. Other calculations (Shimakawa *et al*., 1999; Singh, 1997; Mishra and Sathpaty, 1998) give 0.04 or 0.24 carriers per unit cell, but all agree on the ferromagnetic semimetallic structure. The mobile $\downarrow$ electrons are expected to dominate the conduction, while the heavy $\uparrow$ holes, for which the Fermi energy lies just 0.07 eV below the top of the band, will be easily localized by any impurities or disorder that may be present in the compound. $Tl_2Mn_2O_7$ can also be regarded as a half-metal insofar as the $\uparrow$ holes do not contribute significantly to the conduction; it is therefore a type IVB half-metal (Coey and Sanvito, 2004). Measurements of the Hall effect confirm the electronic structure predictions to the extent that the Hall coefficient is negative, and corresponds, in a one-band model, to 0.01–0.05 electrons per unit cell (Shimakawa, Kubo and Manako, 1996; Imai, Shimakawa, Sushko and Kubo, 2000).

3.2 Heusler alloys

Another promising class of materials for spin electronic applications is the Heusler alloys, a number of which have been predicted to be half-metallic ferromagents (de Groot, Mueller, van Engen and Buschow, 1983; Pickett and Moodera, 2001; Irkhin and Katsnel'son, 1994; Galanakis and Dederichs, 2005). The Heusler structures consist of four interpenetrating fcc sublattices, some of which may or may not be filled. Full-Heusler alloy, A_2BC, crystallizes in the $L2_1$ structure (Figure 3f) and all the sublattices are filled. Half-Heusler alloy, ABC, crystallizes in the Cl_b crystal structure (Figure 3e) and the A_1 sublattice is empty. The Cl_B structure is closely related to the zinc-blende structure. Some of these alloys exhibit very high Curie temperatures (as high as 1100 K) and integral spin moments required for half-metallicity. Both Heusler and half-Heusler compounds show the Slater–Pauling behavior (Kübler, 1984) of the binary transition-metal alloys. The total spin magnetic moment per unit cell scales with the total number of valence electrons following a simple electron counting scheme (Galanakis and Dederichs, 2005). The total number of electrons Z_t is the sum of the number of spin-up and spin-down electrons, while the total spin moment M_t is given by the difference ($Z_t = N_\uparrow + N_\downarrow$; $M_t = N_\uparrow - N_\downarrow \rightarrow M_t = Z_t - 2N_\downarrow$). The minority band contains 9 electrons for half-Heusler and 12 electrons for full-Heusler alloys. Therefore, the total spin moment is given by the relation $M_t = Z_t - 18$ (Figure 5a)

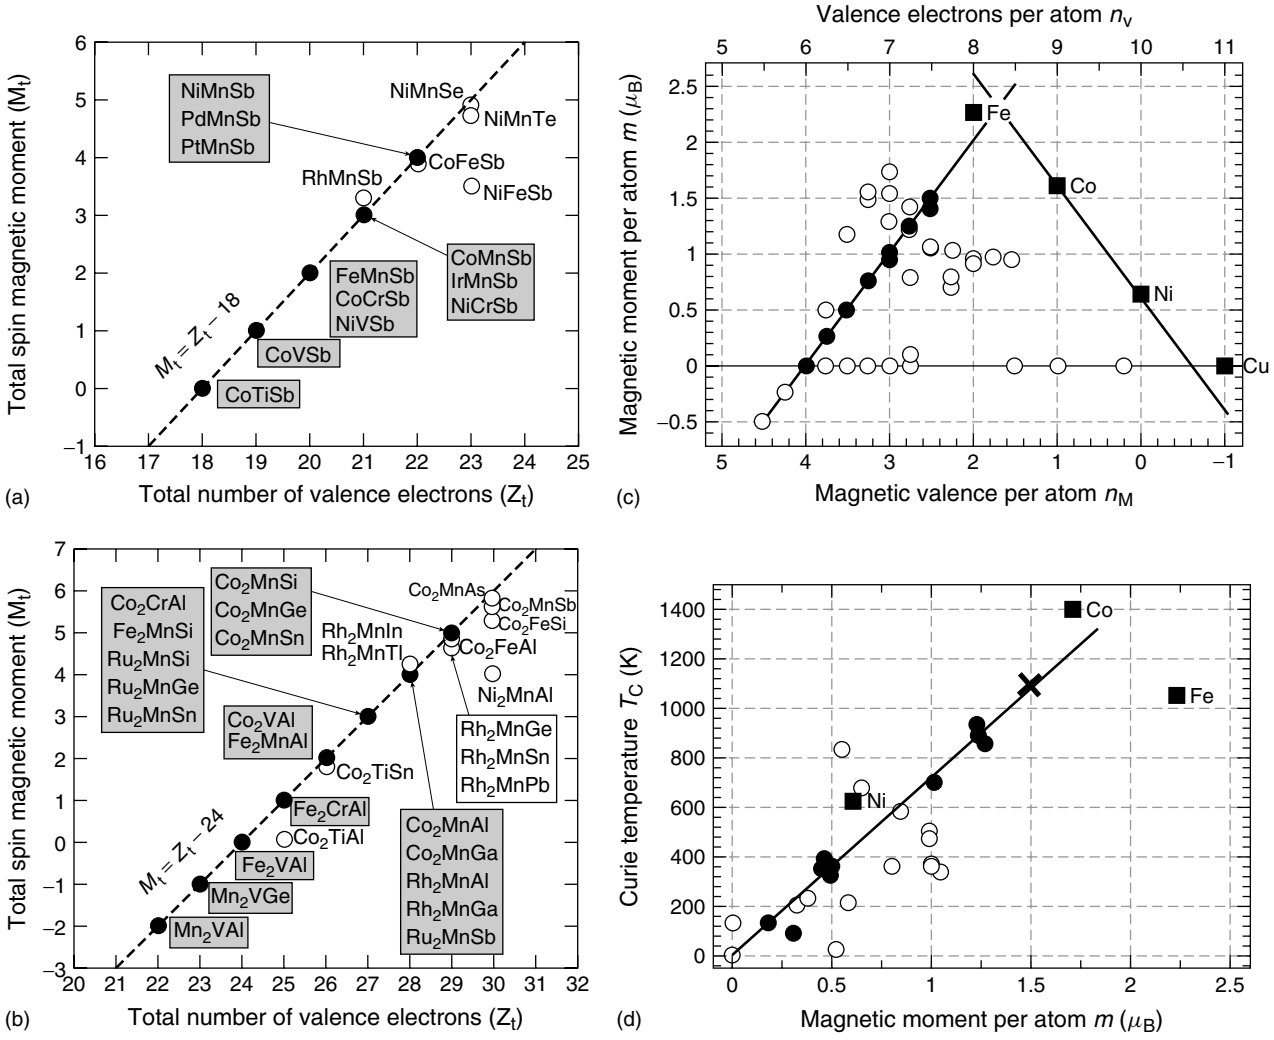

Figure 5. Calculated total spin moments for some (a) half-Heusler and (b) full-Heusler alloys. The dashed line represents the Slater–Pauling behavior (Galanakis and Dederichs, 2005). Scaling of (c) magnetic moments and (d) Curie temperature of Heusler compounds (Wurmehl *et al*., 2005). The heavy 3*d* transition metals are given for comparison. Solid symbols correspond to Co_2-based full-Heusler alloys and open symbols refer to other Heusler compounds.

or $M_t = Z_t - 24$ (Figure 5b) for the half- and full-Heusler alloys respectively (Galanakis and Dederichs, 2005). The variation of magnetic moment and Curie temperature with the number of valence electrons (Wurmehl *et al*., 2005) is shown in Figure 5(c) and (d). Typical examples that fall in this half-metallic category include the half-Heusler alloys NiMnSb (de Groot, Mueller, van Engen and Buschow, 1983), PtMnSb (de Groot, Mueller, van Engen and Buschow, 1983) and the full-Heusler alloys Co_2MnSi (Fujii, Ishida and Asano, 1995), Co_2(Cr,Fe)Al (Block *et al*., 2003; Felser, Elmers and Fecher, 2005). Theoretical calculations predict the critical dependence of magnetic properties on structure, atomic ordering, number of electrons per unit cell, and defects. Half-metallicity is sensitive to the composition and surface structure and atomic disorder (Palmstrøm, 2003).

3.2.1 NiMnSb

Many groups have intensively studied the NiMnSb alloy because of its high-spin polarization (de Groot, Mueller, van Engen and Buschow, 1983). This half-Heusler alloy has atoms ordered on three of the four sublattices of the fcc structure and crystallizes in the Cl_b structure, with the fourth remaining vacant. A self-consistent spin-polarized calculation of energy bands in NiMnSb was performed by de Groot, Mueller, van Engen and Buschow (1983), who first predicted half-metallicity in this material. In the majority spin-up band, the Mn d states are shifted to lower energies and form a common d band with the Ni d states, while in the minority spin-down band the Mn states are shifted to higher energies and are unoccupied, so that a band gap

at E_F is formed separating the occupied d bonding from the unoccupied d antibonding states. NiMnSb is a type IA half-metal with ↑ electrons of Ni(e_g) character at E_F and the calculated magnetic moment is $4\,\mu_B$ per formula unit. Presence of small quantities of other phases and modest amounts of atomic disorder can destroy the half-metallicity (Orgassa, Fujiwara, Schulthess and Butler, 1999).

3.2.2 PtMnSb

Considerable interest has focused on the half-Heusler alloy PtMnSb, which crystallizes in the Cl_B structure. Self-consistent electronic structure calculations by de Groot, Mueller, van Engen and Buschow (1983) and de Groot, Mueller, van Engen and Buschow (1984) revealed half-metallic behavior, and the spin-spilt band structure is that of a type IA half-metal. The results are very similar to those for NiMnSb. The calculated magnetic moment was again $4\,\mu_B$ per formula unit. The main contribution to the magnetic moment comes from the Mn atoms ($4\,\mu_B$), which have their minority d band shifted E_F. The partial Pt moment ($0.18\,\mu_B$) is quite small and the even smaller Sb moment ($-0.04\,\mu_B$) couples antiferromagnetically to the Mn moments. The compound shows a very large magneto-optical Kerr rotation. The Kerr rotation has a maximum in excess of 2.5° at 720 nm (van Engen, Buschow, Jongebreur and Erman, 1983). The vanishing spin-down density at E_F leads to a noncancellation of the optical transitions arising from up- and down-spin bands. The half-metallic properties also lead to a small plasma frequency enhancing the Kerr effect. The effect derives from the large spin-orbit coupling of Pt together with the large magnetic moment on Mn and the strong hybridization of Mn, Pt, and Sb orbitals.

3.2.3 Co_2MnSi

Half-metallic behavior has also been predicted for Co_2MnSi (Fujii, Ishida and Asano, 1995) in which both the cobalt and manganese atoms carry magnetic moments. The magnetic properties depend sensitively on the degree of atomic order and the conduction electron concentration. Spin-polarized band-structure calculations (Fujii, Asano and Ishida, 1984) indicate that the moments are predominantly $3d$ in origin and the shapes of the DOS for Co and Mn are similar. This ternary intermetallic full-Heusler alloy is predicted to be half-metallic with a minority spin Co $3d$ gap of 0.4 eV. In addition, Co_2MnSi is a type IB half-metal with a $T_C = 985$ K, the highest among those of all known Heusler alloys containing manganese. The saturation magnetic moment is $5\,\mu_B$ per formula unit.

3.2.4 Co_2(Cr,Fe)Al

Co_2CrAl has 27 valence electrons and is in the ordered $L2_1$ structure. Its electronic structure shows a gap for minority spin electrons at the Fermi energy. It is thus a type IA half-metal (Figure 4d). Block *et al.* (2003) have recently argued that the electron count 27.8 for the compound $Co_2Cr_{0.6}Fe_{0.4}Al$ leads to a DOS peak in the majority spin electrons due to Fermi surface nesting. The magnetization curves show the alloy to be a soft ferromagnet with a low-temperature saturated moment of $3.65\,\mu_B$ per formula unit (Felser, Elmers and Fecher, 2005; Clifford, Venkatesan, Gunning and Coey, 2004), very close to the value of $3.7\,\mu_B$ per formula unit predicted from the band-structure calculations (Block *et al.*, 2003; Felser, Elmers and Fecher, 2005). The Curie temperature of the alloy was found to be 660 K. Disorder is known to destroy the half-metallic property.

3.2.5 Mn_2VAl

Mn_2VAl has a ferrimagnetic structure with a moment of roughly $1.5\,\mu_B$ on each Mn and $-0.9\,\mu_B$ on V. The DOS within nearly 0.5 eV of the Fermi level, both above and below, is dominated by Mn t_{2g} character (Weht and Pickett, 1999). At stoichiometry, the saturation moment is reported to be $2.0\,\mu_B$ per formula unit, close to the integral value of the spin moment and the Curie temperature is 760 K (Jiang, Venkatesan and Coey, 2001). It is not a robust half-metal because any changes in stoichiometry as well as incomplete atomic order will greatly affect the structural stability and magnetic properties of the system and can eliminate the spin gap, introducing light ↓ holes at the Fermi level. The Fermi level lies exactly in the minority spin band. In the system $Mn_2V_{1+x}Al_{1-x}$, although V and Al atoms may substitute each other's sublattice, the structure remains the Heusler one from x between -0.3 and $+0.2$, with linearly varying saturation moment (Yoshida, Kawakami and Nakamichi, 1981). The ideal compound is predicted to be a type IB half-metal with Mn (t_{2g}) ↓ electrons at E_F.

3.2.6 Other half-metals

FeS_2 is a nonmagnetic semiconductor with the Fe^{2+} in a low-spin state $(t_{2g}^3)^{\uparrow}(t_{2g}^3)^{\downarrow}$ and a gap between the t_{2g} and e_g states, in agreement with the band-structure calculations (Eyert, Hock, Fiechter and Tributsch, 1998; Opahle, Koepernik and Eschrig, 1999). On the other hand, CoS_2 is an itinerant ferromagnet and the Fermi level sits on a steep slope of the DOS. On substitution of Co (∼0.1%), it becomes a ferromagnetic metal and remains ferromagnetic all the way through to CoS_2. The solid solutions are ferromagnetic with

$T_C \propto x$ and $m \approx x\mu_B$ for $x > 0.1$ in an extremely wide concentration range (Jarrett *et al*., 1968). This seems to be a robust half-metal of type IA (Mazin, 2000).

In the case of Mn_4N, where the Mn occupies an fcc lattice the DOS at E_F is zero for the Mn(I) positions and has a deep minimum at the Mn(II) position which resembles that of a half-metal (Matar, Mohn, Demazeau and Siberchicot, 1988; Fujii, Ishida and Asano, 1992). Investigations of the isostructural ferromagnetic system Fe_4N which has a high saturation magnetization ($2.2\,\mu_B$ per Fe) revealed the same result, an absence of DOS at E_F at the Fe(I) positions (Matar, Mohn, Demazeau and Siberchicot, 1988; Sakuma, 1991).

Theoretical calculations on half-metals with zinc-blende transition-metal chalcogenides and pnictides are reviewed in detail by Liu (2005). Half-metallic ferromagnetism is also achieved while doping some transition-metal atoms into the semiconductors ZnTe and CdTe. In some cases, half-metallicity is robust when these materials are subject to large deformations. Zinc-blende-type CrAs, CrSb, and MnAs are theoretically predicted to be half-metals (Akinaga, Manago and Shirai, 2000; Shirai, 2001).

4 SPIN POLARIZATION

There is no clear experimental signature or property which allows us to identify a material as a half-metal. This is in contrast to metals, semiconductors, and superconductors where there is a clear electrical signature.

Spin polarization is a measure of the ratio of the electron density for each spin at the Fermi energy, and is given by the expression,

$$P_0 = (N^{\uparrow} - N^{\downarrow})/(N^{\uparrow} + N^{\downarrow}) \tag{1}$$

where $N^{\uparrow,\downarrow}$ are the densities of states of majority ($\uparrow$) or minority ($\downarrow$) at E_F, but this parameter is not necessarily the one measured experimentally. In the case of ballistic or diffusive transport, the densities of states must be weighted by the Fermi velocity of the electrons, or its square, respectively (Mazin, 1999).

$$P_n = (\langle N^{\uparrow} v_F^{\uparrow n}\rangle - \langle N^{\downarrow} v_F^{\downarrow n}\rangle)/(\langle N^{\uparrow} v_F^{\uparrow n}\rangle + \langle N^{\downarrow} v_F^{\downarrow n}\rangle) \tag{2}$$

P_1 or P_2 may be large for transport half-metals (type III – $La_{0.7}Sr_{0.3}MnO_3$ and type IV – $Tl_2Mn_2O_7$), but P_0 can be small for the same materials. The densities of states in tunneling experiments should be weighted by the appropriate spin-dependent tunneling matrix element to give tunneling spin polarization P_T. Mazin shows that P_T is equal to P_2 in the case of a specular barrier with low transparency (Mazin, 1999). One of the major problems with the above definition is that it is only valid at 0 K – the actual value of the spin polarization drastically reduced with increasing temperature due to spin-flip processes. Another argument is that the spin polarization of a ferromagnet in a heterostructure is not simply a property of the ferromagnet alone, but it is a joint property of the materials used in the heterostructure. In epitaxial tunnel junctions, for example, the effective spin polarization depends on the barrier oxide and the applied bias. There is mounting evidence that the spin polarization in a tunnel junction is critically dependent on the interface with the barrier and can even change sign for a given ferromagnetic electrode according to the nature of the barrier (de Teresa *et al*., 1999). This leads to doubts of claims that the polarization is an intrinsic property of a material, except when $P = 100\%$.

Measuring the spin polarization poses lots of challenges. All the techniques for measuring spin polarization somehow involve extracting electrons from the surface of the material, with the chance that its inherent polarization will be modified in the process. But, until now, there are no measurements that identify a material as a half-metal without removing electrons. Several methods have been explored to measure the spin polarization of ferromagnetic metals as summarized in Figure 6. Table 3 lists a number of measurements of spin polarization for half metallic materials including elemental ferromagnets Fe, Co and Ni. The spin polarization is weighted differently in each technique. Photoemission experiments (Park *et al*., 1998) measure the unweighted spin polarization P_0 of a ferromagnet. Tedrow and Meservey's technique of spin-polarized tunneling (Meservey and Tedrow, 1994) measures the tunneling spin polarization P_t directly. Andreev reflection (Soulen *et al*., 1998; Upadhyay, Palanisami, Louie and Burman, 1998) measures the transport spin polarization directly, weighted by $v_F^{\uparrow,\downarrow}$ or its square, but is not sensitive to the sign of the polarization. Spin-polarized scanning tunneling microscopy (Bode, 2003) gives the tunneling spin polarization P_t through a vacuum barrier. In addition to these direct measurements, transport measurements in point contacts (Versluijs, Bari and Coey, 2001; Garcia, 2000) and tunnel junctions (Moodera and Mathon, 1999) with two ferromagnetic electrodes separated by a thin insulating barrier are used to determine the spin polarization indirectly through magnetoresistance measurements (Figure 6). There are several experimental difficulties in all these measurement methods and they rarely yield 100% polarization.

When the electrons are fully spin polarized, $N^{\uparrow}$ or $N^{\downarrow} = 0$ and $P_0 = P_1 = P_2 = 100\%$, but they will be different for any other polarization. For example, for $(La_{0.67}Ca_{0.33})MnO_3$ (Pickett and Singh, 1996), $N^{\uparrow}$ and $N^{\downarrow}$ are 0.58 and 0.27 states eV^{-1} fu^{-1}, respectively, and $v_F^{\uparrow}$ and $v_F^{\downarrow}$ are 0.76×10^6

and 0.22×10^6 m s^{-1}, hence $P_0 = 36\%$, $P_1 = 76\%$ but $P_2 = 92\%$. In the case of $3d$ ferromagnets in the diffusive limit, the value of P is always positive and close to 40% (Monsma and Parkin, 2000) despite the fact that the $3d^{\uparrow}$ bands are full for the strong ferromagnets cobalt and nickel, and the Fermi level lies in the $3d^{\downarrow}$ band. The positive spin polarization is actually associated with the more mobile $4s$ electrons, which are polarized by hybridization with the $3d$ states.

In the case of point contacts or tunnel junction geometry, the magnetoresistance is defined as

$$MR = \Delta R/R_{\uparrow\downarrow} = (R_{\uparrow\downarrow} - R_{\uparrow\uparrow})/R_{\uparrow\downarrow} = 2P_1P_2/(1 + P_1P_2) \quad (3)$$

where $R_{\uparrow\downarrow}(R_{\uparrow\uparrow})$ is the resistance in antiparallel (parallel) state and P_1 and P_2 are polarizations of the two electrodes. Note that MR cannot exceed 100%. Since the conductance is $G = 1/R$, $\Delta R/R$ is also equal to $(G_{\uparrow\uparrow} - G_{\uparrow\downarrow})/G_{\uparrow\uparrow}$. It is often used in conjunction with the Julliere model (Julliere, 1975) to infer the spin polarization if the electrodes are identical ($P_1 = P_2$) or if the polarization of one of them is known.

5 MEASUREMENTS OF SPIN POLARIZATION

5.1 Spin-resolved photoemission

Spin-resolved photoemission measurements (Figure 6a) directly manifest the half-metallic nature of materials (Park *et al*., 1998). For the majority (minority) spin, the photoemission spectrum showed a metallic Fermi cutoff, whereas for the minority (majority) spin, it showed an insulating gap. The spin polarization of ejected photoelectrons can be measured for different incident photon energies. This method provides a rather direct image of the spin-polarized DOS near E_F, but it lacks the necessary energy resolution ($\sim$1 meV) and requires very careful surface preparation as the photoelectrons that carry the information are coming from a thin layer at the surface. The surface or interface states may have a critical influence on the result. The measured polarization is weighted by the absorption cross section for $\uparrow$ and $\downarrow$ electrons.

The stoichiometric or near-stoichiometric ordered NiMnSb alloy, with MnSb surface termination, exhibits high polarization in normal-incidence spin-polarized inverse photoemission. The polarization at the Fermi level is 67% (Ristoiu *et al*., 2000). This is significantly higher than the polarization asymmetry of 50%, at room temperature, measured from a polycrystalline sample using spin-polarized photoemission (Bona *et al*., 1985). Careful studies (Park *et al*., 1998) on $La_{0.7}Sr_{0.3}MnO_3$ shows that the spectrum for the majority spin extends up to E_F and shows the metallic Fermi cutoff, while that for the minority spin decreases rapidly at $\sim$1 eV binding energy. The spin polarization is found to be $\sim$100%. Typical data for $La_{0.7}Sr_{0.3}MnO_3$ (Park *et al*., 1998) is shown in Figure 7(a).

5.2 Andreev reflection

Andreev reflection is a process which occurs when a current passes between a superconductor and a normal metal through a point contact (Figure 6c). For an electron to pass from a normal metal to a superconductor it must form a Cooper pair with another electron. The $\uparrow$ electrons injected from the normal metal into the superconductor must form Cooper pairs, and this is achieved by the simultaneous injection of a $\downarrow$ hole from the superconductor back into the metal. The injected current is doubled in this way for a normal metal, when the junction is biased within the superconducting gap, Δ. If a normal metal is replaced by a half-metal, Cooper pairs are unable to form since electronics of both spin are required to form a pair. For a half-metallic ferromagnet, there are no states available, and the current is then zero (Soulen *et al*., 1998; Upadhyay, Palanisami, Louie and Burman, 1998). The effect depends on the degree of spin polarization, which may be deduced from data at $T = 0$ using $P_1 = 1 - G_0/2G_n$ where G_0 is the conductance at zero bias and G_n is the conductance when the applied voltage is much greater than the energy gap. The data (Ji *et al*., 2001) for CrO_2 is presented in Figure 7(b). This technique is simple to implement – no special surface preparation is necessary and there are no limits on sample geometry. Point contact Andreev reflection (PCAR) technique, by creating a nanocontact by depositing through a nanohole made through a layer of PMMA, was recently established to measure the spin polarization of various half-metals (Clifford, 2005).

5.3 Tunnel junctions

Magnetic tunnel junctions (MTJs) generally consist of ferromagnet/insulator/ferromagnet (FIF) structures (Figure 6c). Spin-polarized tunneling in ferromagnetic junctions has been recently reviewed by Moodera and Mathon (1999). These are usually made up of thin film of ferromagnetic electrodes separated by a thin layer of insulating barrier oxide. The most important part of junction preparation is the formation of the tunnel barrier. Up to now, Al_2O_3 has been the most commonly used tunnel barrier material. Thin layers of this material are amorphous and as a result the TMR is predominantly determined by spin polarization of the ferromagnetic electrodes. However, it was recently shown that much higher TMR values can be obtained with crystalline MgO tunnel barriers (Parkin *et al*., 2004; Yuasa *et al*., 2004) as shown in Figure 8(a,b). The reason is that the tunneling matrix elements for crystalline MgO are spin dependent, so the barrier acts as an efficient *spin filter*.

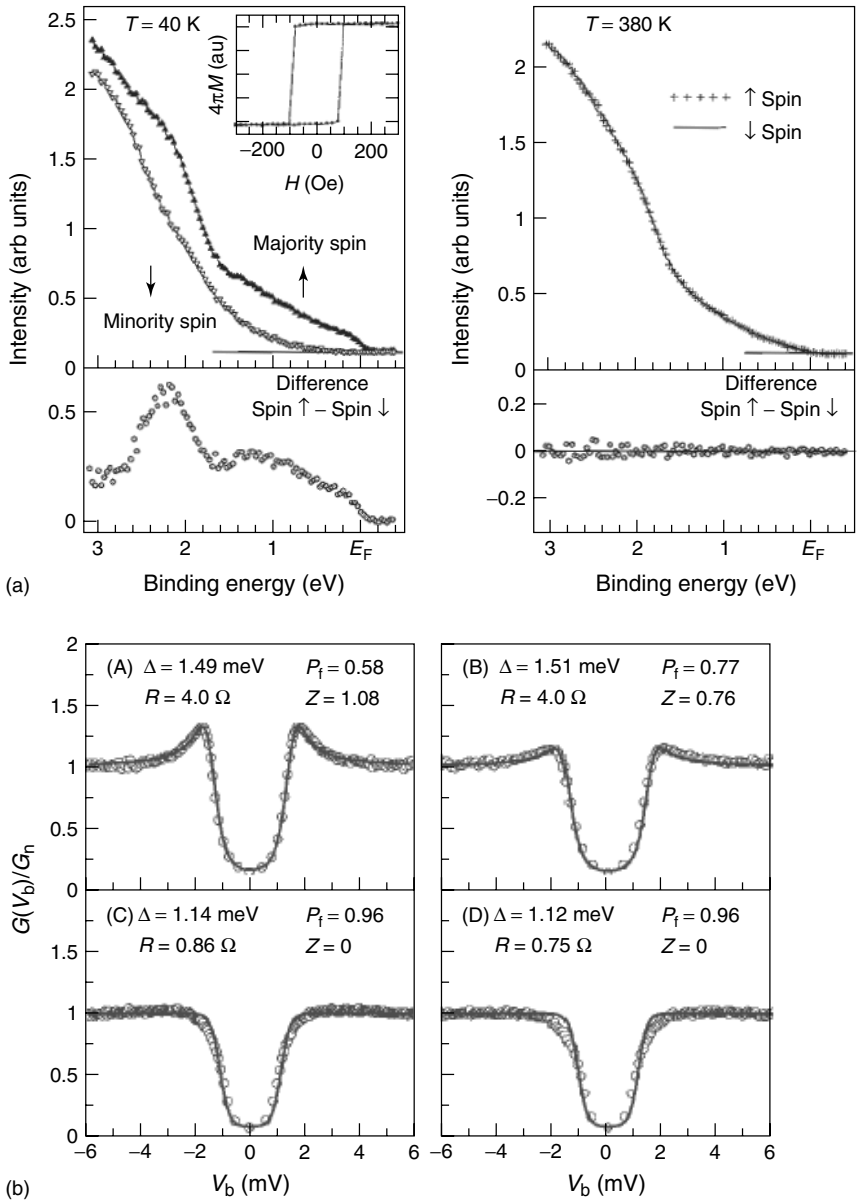

Figure 7. (a) Spin-resolved photoemission spectra of $La_{0.7}Sr_{0.3}MnO_3$ thin film (Park *et al*., 1998) and (b) normalized conductance $G(V_b)/G_n$ versus bias voltage V_b for Pb/CrO_2 point contacts at 1.85 K for different contact resistances (Ji *et al*., 2001). The solid lines are fits to the data, with the BTK model resulting in P, Z, and Δ as shown in the panel.

The magnitude of the TMR is related to the spin polarization P of the individual FM electrodes: $(R_{\uparrow\downarrow} - R_{\uparrow\uparrow})/R_{\uparrow\downarrow} = 2P_1P_2/(1 + P_1P_2)$, where $R_{\uparrow\downarrow}$ and $R_{\uparrow\uparrow}$ are the resistance of the MTJ corresponding to antiparallel and parallel orientation of the FM electrodes, respectively. For best results, the junction area should be small, so the ferromagnetic electrodes can be deposited as two perpendicular stripes using shadow masks, or else the films are patterned using a lithographic technique. The electrode shapes are chosen so that they have different switching fields, and the magnetoresistance is measured from the difference in resistance between the parallel and antiparallel configurations. While the magnetoresistance is sensitive to applied voltage, falling rapidly with increasing bias, the polarization is sensitive to temperature and decreases rapidly with increasing temperature.

5.4 Tedrow–Meservey method

Meservey and Tedrow (1994) measured the conduction electron spin polarization of magnetic metals and compounds using the Zeeman-split quasiparticle DOS in a

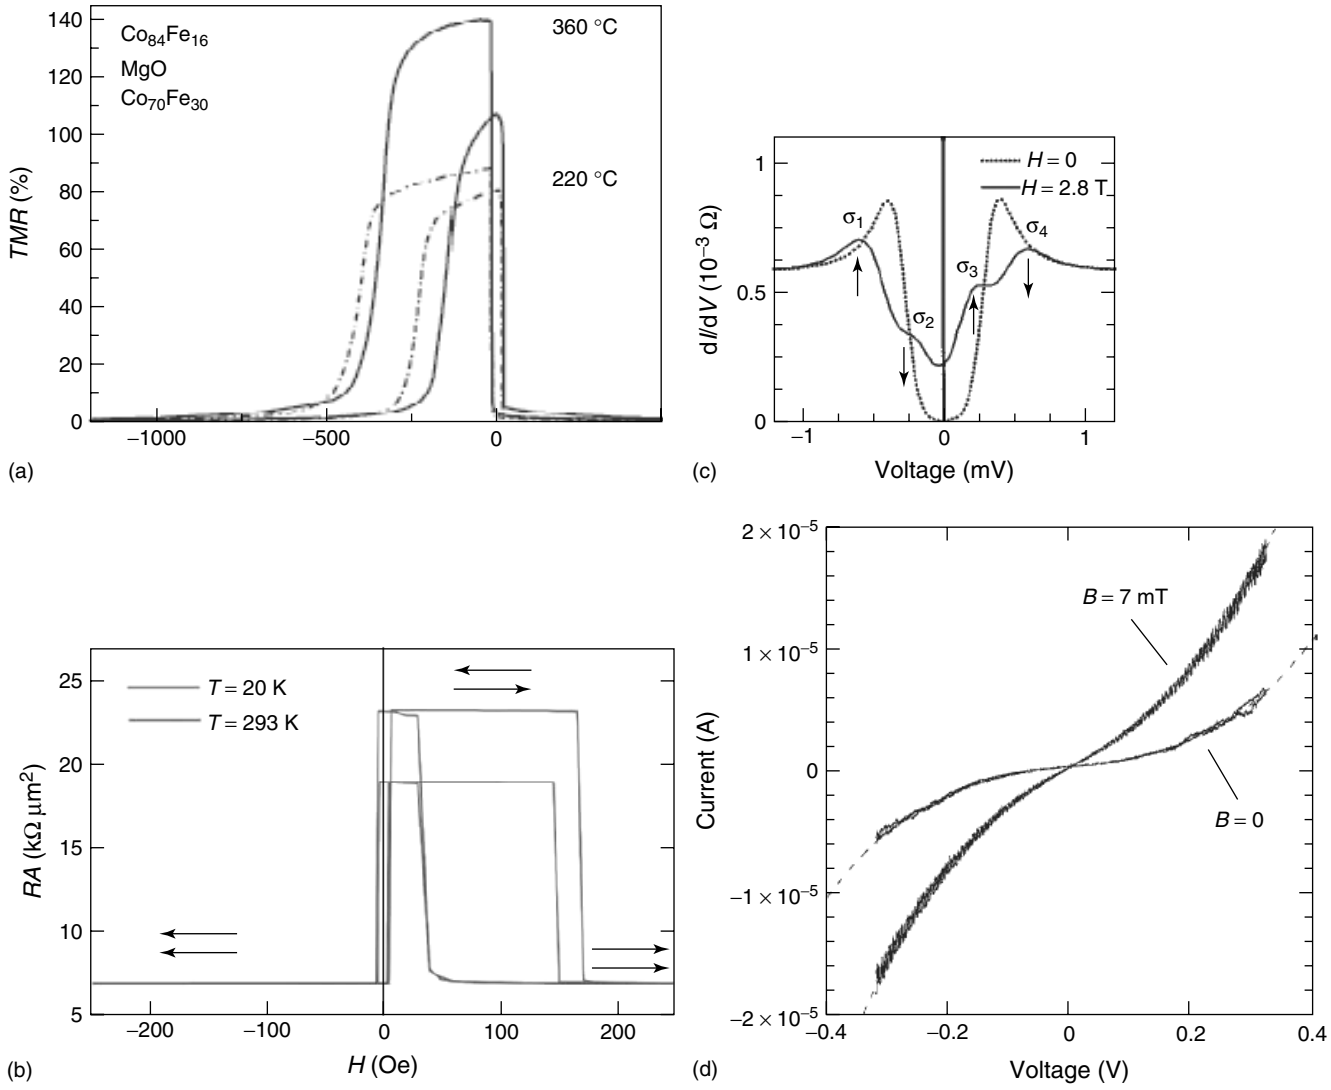

Figure 8. (a) TMR versus field for MTJs with structures (all thicknesses in Å): 100 TaN/250 IrMn/8 Co84Fe16/30 Co70Fe30/29 MgO/150 Co84Fe16/100 Mg (Parkin *et al.*, 2004). (b) Tunnel magnetoresistance of Fe(001)/MgO(001)/Fe(001) junctions (Yuasa *et al.*, 2004). (c) Spin-polarized differential tunnel conductance versus voltage in NiMnSb/Al_2O_3/Al at 0.4 K (Tanaka, Nowak and Moodera, 1999). (d) Typical magnetic field effect on a Fe_3O_4 nanocontact showing the I:V curves with and without a magnetic field (Versluijs, Bari and Coey, 2001).

superconductor. This technique involves a tunnel barrier where the second electrode is a thin layer of superconducting aluminum (Figure 6d). The superconducting electrode serves as an analyzer of the spin polarization of the tunneling current. They showed that the conduction electrons in ferromagnetic metals are spin polarized and that the spin is conserved in the tunneling process. Tunneling from a ferromagnetic film, with its unequal spin distribution at the Fermi level (E_F), into such a spin-split superconducting Al film reflects the spin polarization of the tunneling electrons coming from the ferromagnet. The superconducting transition of Al is 1.2 K, but there is a high critical field because the penetration depth in a type I superconductor can be much greater than the film thickness. Figure 8(c) compares the field dependence of dI/dV for the first reported half-metal, NiMnSb (Tanaka, Nowak and Moodera, 1999).

The normal tunneling characteristic from a ferromagnet to a superconductor in zero field is shown in Figure 8(c). It depends on the convolution of the ferromagnetic and superconducting densities of states, and the twin peaks are separated by the superconducting energy gap; for Al, $2\Delta \approx 0.25$ meV. In an applied field, the superconductor quasiparticle DOS are Zeeman split, allowing the tunnel current to be clearly resolved into spin-up and spin-down parts and the curve becomes asymmetric, as shown in Figure 8(c). The spin polarization is usually inferred from

the conductivity at the four points labeled σ_1 to σ_4, using the formula

$$P = [(\sigma_1 - \sigma_3) - (\sigma_2 - \sigma_4)] = [(\sigma_1 - \sigma_3) + (\sigma_2 - \sigma_4)] \quad (4)$$

5.5 Point contacts

Point contact phenomena, like quantum conductance, are best studied in nanocontacts formed when two macroscopic electrodes are put into contact and then slowly pulled apart. Precise control over the movements of the electrodes is desirable for the formation of a stable nanocontact. In this technique, a stable conducting contact is established between two crystallites of the ferromagnetic material, and the magnetoresistance of the contact is measured (Figure 6e). Normally, there is no method of controlling the magnetization directions in the initial contact before applying the magnetic field, so the experiment involves making many contacts and selecting those with the largest magnetoresistance. Typical data for Fe_3O_4 are illustrated in Figure 8(d) (Versluijs, Bari and Coey, 2001). A related structure is a nanowire between two spin-polarized electrodes. Provided the transfer of the electron across the contact does not interfere with its spin (the transport may be ballistic, by hopping, or by tunneling) the magnetoresistance for classical spins is still given by equation (3) (Julliere, 1975).

6 TRANSPORT PROPERTIES

In view of the difficulties in measuring P directly, it is worth exploring other experimental signatures, apart from the integral spin moment and metallic conduction, which can throw some light on half-metallicity. The transport properties of some half-metallic systems show unique features, though it is not generalized to all half-metallic systems. In conventional metallic ferromagnets, generally a T^2 dependency of the resistivity is found in the low-temperature region (Wohlfarth, 1980; Meaden, 1971). This quadratic term is usually ascribed to the electron-scattering process called *one-magnon scattering* (Mannari, 1959), where an electron undergoes a spin flip in an inelastic process involving creation or annihilation of a magnon. In half-metallic ferromagnets, spin-flip one-magnon scattering at low temperatures is not possible, because only states with one spin direction are present at E_F at $T = 0\,K$. This will lead to the absence of T^2 dependence of resistivity and to an increase in the mobility of the charge carriers. The first available magnetic scattering processes involve two magnons, which give rise to a term in the resistivity varying as $T^{9/2}$ (Kubo and Ohata, 1972). Unfortunately, such a term is very difficult to disentangle from regular scattering processes involving phonons. However, the absence of a T^2 term forms only a necessary and not sufficient condition for complete spin polarization of current carriers at low temperatures. For example, if the Fermi surfaces of spin-up and spin-down carriers are spheres with a large radius difference (in k space), magnons with wave vectors shorter than this difference do not contribute to the scattering of these current carriers, and a T^2 term cannot be observed. In addition, there is no contribution of one-magnon processes to the anomalous Hall effect ($R_s(T) \propto aT^3 + bT^4$). It follows that magnetic scattering in half-metals should be dominated by two-magnon processes. Careful studies on NiMnSb and PtMnSb (Otto *et al.*, 1989) reveal that the resistivity varies linearly with temperature below 15 K (Figure 9a,b). However, electron–electron and electron–photon scattering processes can also lead to such behavior and creates difficulty to ascribe the dependence entirely to a half-metal. The most dominant magnetic scattering processes involve two magnons, which give rise to a term in the resistivity varying as $T^{9/2}$ is reported by Kubo and Ohata (1972) based on a rigid band electronic structures of half-metals. Unfortunately, such a term is very difficult to disentangle from regular scattering processes involving phonons. Irkhin and Katsnel'son (2002) showed that the resistivity is proportional to $T^{9/2}$ for $T < T^*$ and to $T^{7/2}$ for $T > T^*$, T^* being the crossover temperature for longitudinal scattering processes. The $T^{7/2}$ behavior also plays an important role in magnetoresistance. At finite temperatures, however, it is necessary to take into account the effect of spin fluctuations, which breaks down the perfect spin polarization. In the absence of spin gaps, magnetization deviates from its saturation values as $\delta M \propto T^{3/2}$ in three dimensions. In the strong Hund's coupling limit, spin polarization of the conduction electrons are proportional to the total spin polarization. At finite temperatures, the half-metallic structure of conduction electrons breaks down and as a consequence, the rigid band approaches cannot be justified. Taking into account the nonrigid band behavior due to spin fluctuations, it was established (Furukawa, 2000) that the most dominant contribution for the low-temperature resistivity is from an unconventional one-magnon scattering process in which case the resistivity is proportional to the product of the following two quantities – magnon population δM and the DOS of the minority spin quasiparticles which should also scale as δM. Therefore, $\rho(T) \propto (\delta M)^2 \propto T^3$. This T^3 behavior is demonstrated experimentally for mixed valent manganite $La_{0.7}Sr_{0.3}MnO_3$ single crystals (Figure 9c) (Furukawa, 2000).

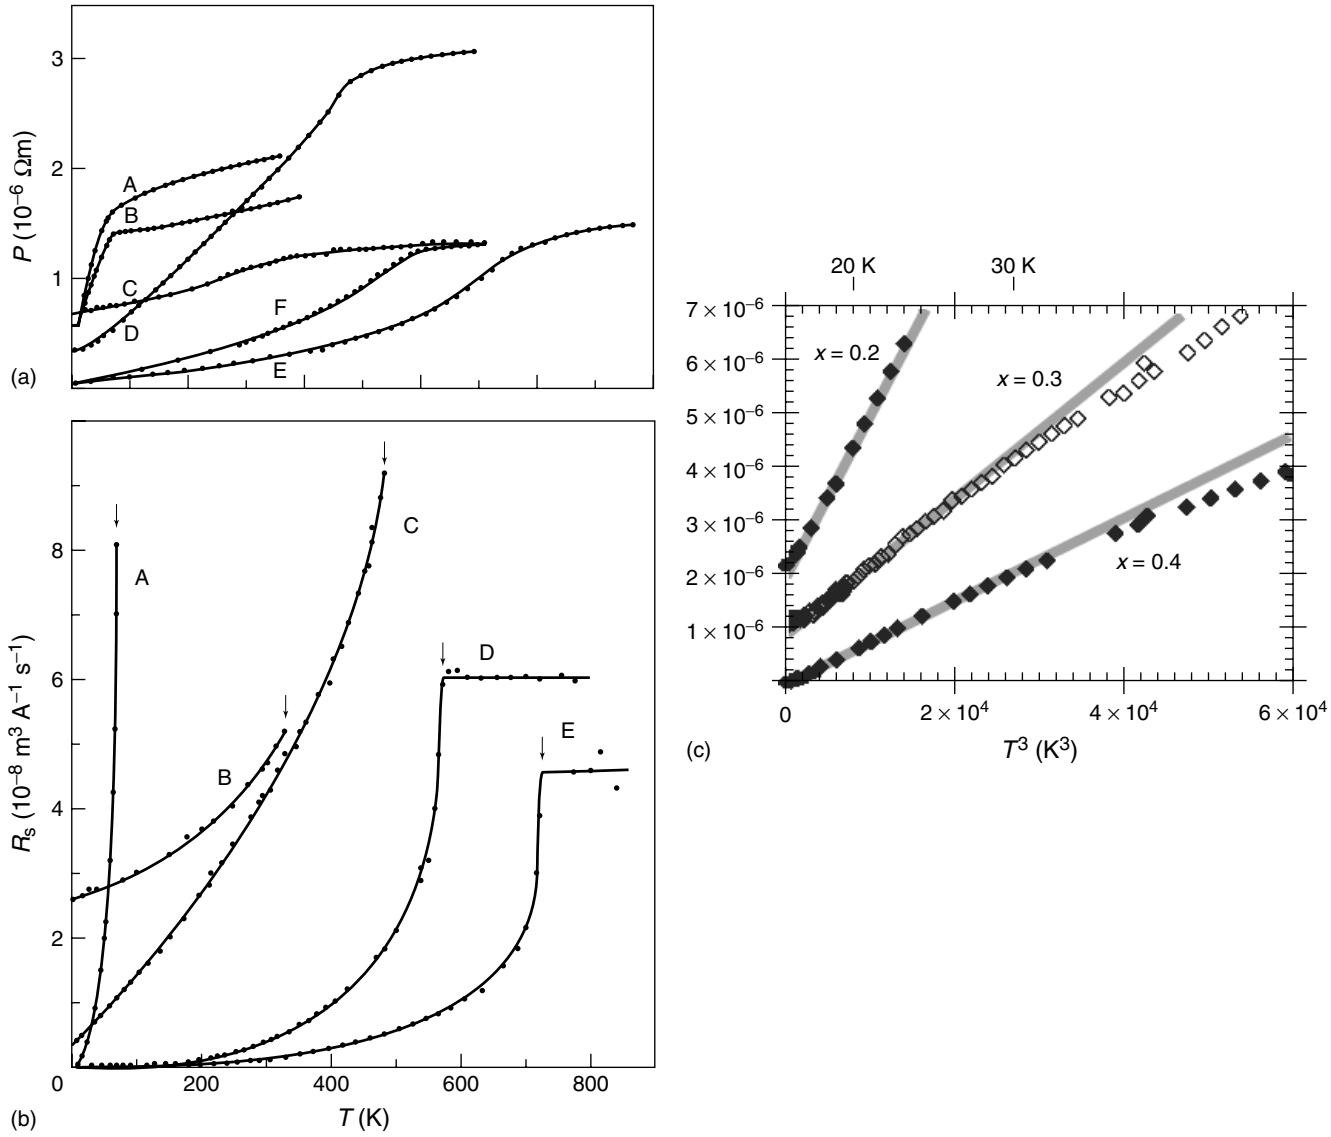

Figure 9. Temperature dependences of the (a) electric resistivity of the half-Heusler alloys TMnSb (T = Cu (A), Au (B), Co (D), Ni (E), Pt (F)) and PtMnSn (C) (Otto *et al*., 1989), (b) spontaneous Hall coefficient of TMnSb (T = Au (A), Co (C), Pt (D), Ni (E)) and PtMnSn (B) (Otto *et al*., 1989), and (c) T^3 behavior of resistivity in $La_{1-x}Sr_xMnO_3$ single crystals (Furukawa, 2000).

7 SURFACE/INTERFACE STATES

The DOS and exchange interactions at the surface/interface may be very different from those of the bulk. It was well established that spin disorder has a profound effect on the half-metallic nature (Skomski and Dowben, 2002; Dowben and Skomski, 2003). Opposite spin surface states (Jenkins and King, 2001; de Wijs and de Groot, 2001; Jenkins and King, 2002) in half-metals can develop into interface states (de Wijs and de Groot, 2001; Jenkins and King, 2002; Picozzi, Continenza and Freeman, 2003) and destroy the half-metallic behavior. The increase in the number of interfaces enhances the spin minority population, which in turn decreases the spin polarization. At finite temperature, thermally activated spin-flip scattering such as spin waves will also induce states within the gap (Dowben and Skomski, 2003). Even in an ideally prepared single crystal at zero temperature, the spin-orbit coupling will introduce states in the half-metallic gap of minority states, which are produced by spin-flip scattering of the majority states. Magnon excitations tend to decrease the polarization at low temperature for many half-metallic systems viz $La_{0.7}Sr_{0.3}MnO_3$ (Obata, Manako, Shimakawa and Kubo, 1999), CrO_2 (Coey and Venkatesan, 2002; Watts *et al*.,

2000) and NiMnSb (Borca *et al*., 2001; Hordequin, Ristoiu, Ranno and Pierre, 2000). The low-energy transverse and longitudinal optical modes (phonon modes) can couple to spin-wave modes and reduce the net magnetization in half-metals (Dowben and Skomski, 2003).

The best-studied half-metal CrO_2 with nearly 100% spin polarization possesses stoichiometric (001) surface. Calculations reveal two oxygen-derived surface states in the band gap for the minority spin direction. However, these states lie well below E_F and do not affect the half-metallicity at the surface (van Leuken and de Groot, 1995). For magnetite, the loss of half-metallicity could be due to the presence of disorder above the Verwey transition temperature ($T_V = 120\,K$), which results in smearing of the energy gap in the minority subbands. Manganites and double perovskites show nonstoichiometry surfaces which lead to surface reconstructions. In half-Heusler NiMnSb, the random disorder, in particular, Ni−Mn interchange greatly affects the half-metallic property and hence the spin polarization (Helmholdt *et al*., 1984). First-principles band theory calculations have demonstrated that antisite disorder can destroy the half-metallic character of a number of Heusler alloys (Orgassa, Fujiwara, Schulthess and Butler, 1999). Major challenges remain in controlling the composition, defects, atomic ordering both in the bulk and at the interface.

8 APPLICATION OF HALF-METALS IN SPIN ELECTRONICS

High-spin polarization half-metallic materials are promising candidates for integration into the GMR multilayers, first discovered by Fert *et al*. (Baibich *et al*., 1988), as the spins of the current carriers are predominantly aligned in the same direction (Figure 10a). They are ideal sources of spin-polarized electrons and can act as spin injectors, detectors, and magnetically controllable spin filters. The emerging science of spin electronics seeks to exploit the two separate spin channels in increasingly sophisticated electronic devices. So far, these expectations have not been fully realized in practical applications.

8.1 Spin valves

The basic element of a spin valve is two ferromagnetic layers separated by a nonmagnetic spacer (Figure 10b). The electrical resistance of the structure is low when the magnetization directions of the ferromagnetic layers are aligned parallel and high when they are antiparallel. One of the ferromagnetic layers, the free layer, switches magnetization direction close to zero field. The other layer, the pinned layer, is grown next to an antiferromagnet and its magnetization direction is pinned at low fields. Switching of the free layer at low fields, therefore, results in a transition from the parallel to antiparallel state and a change in resistance. Hence the exchange-biased spin valve is a highly sensitive magnetic field sensor and can be used in several applications. Improvements in spin valve performance (GMR, exchange field, sensitivity) are continually pursued both through the development of new materials and thin-film stacks, in particular, using high spin-polarized half-metallic electrodes, and the design of new spin valve geometries. The basic FM/NM/FM/AF spin valve has evolved into many variants (Dieny, 2004; Coehoorn, 2003). For example, dual spin valves essentially consist of three FM layers separated by two nonmagnetic spacers. The magnetization of the outer two FM layers are pinned by an AFM layer, whereas the inner FM layer is free. GMR ratios as large as 25% have been reported (Egelhoff *et al*., 1995, 1996) for these structures but the increased thickness of the structure may make it unsuitable for read-head applications. A further advance in spin valve design was the development of the synthetic antiferromagnet (SAF) (Parkin, More and Roche, 1990). The pinning fields in the SAF spin valve can be twice as large as that of the standard spin valve. Another advantage of using the SAF is that, in a patterned device, stray field created by the pinned layer on the sensing layer is reduced because of the antiparallel alignment of the two FM layers in the pinned layer. Spin valves with nano-oxide layers (NOLs) were introduced in Kamiguchi *et al*. (1999) resulting in enhanced MR ratios of up to 18%. An overwhelming amount of spin valve research has been driven by the interests of the magnetic storage industry. Less than a decade after their discovery, spin valves were introduced as sensor materials in hard disk read heads. Other applications include position, speed and velocity sensors, and electronic compasses.

8.2 Magnetic tunnel junction

The basic two terminal device is an MTJ (Figure 10c) (Moodera, Kinder, Wong and Meservey, 1995) where two ferromagnetic half-metallic electrodes are separated by a thin insulating barrier. In a configuration where the magnetic moments are aligned parallel in top and bottom half-metallic electrodes, current will pass by tunneling of the majority spin electrons. There is no tunneling event in the antiparallel configuration because spin-up electrons can only tunnel into spin-up empty states, which lead to high resistance state. The schematic band profile in TMR and GMR junctions (Mavropoulos, Ležaić and Blügel, 2005) is compared in Figure 11. This simple ideal half-metal based spin-controlled switch (MTJs) device finds interesting applications in the

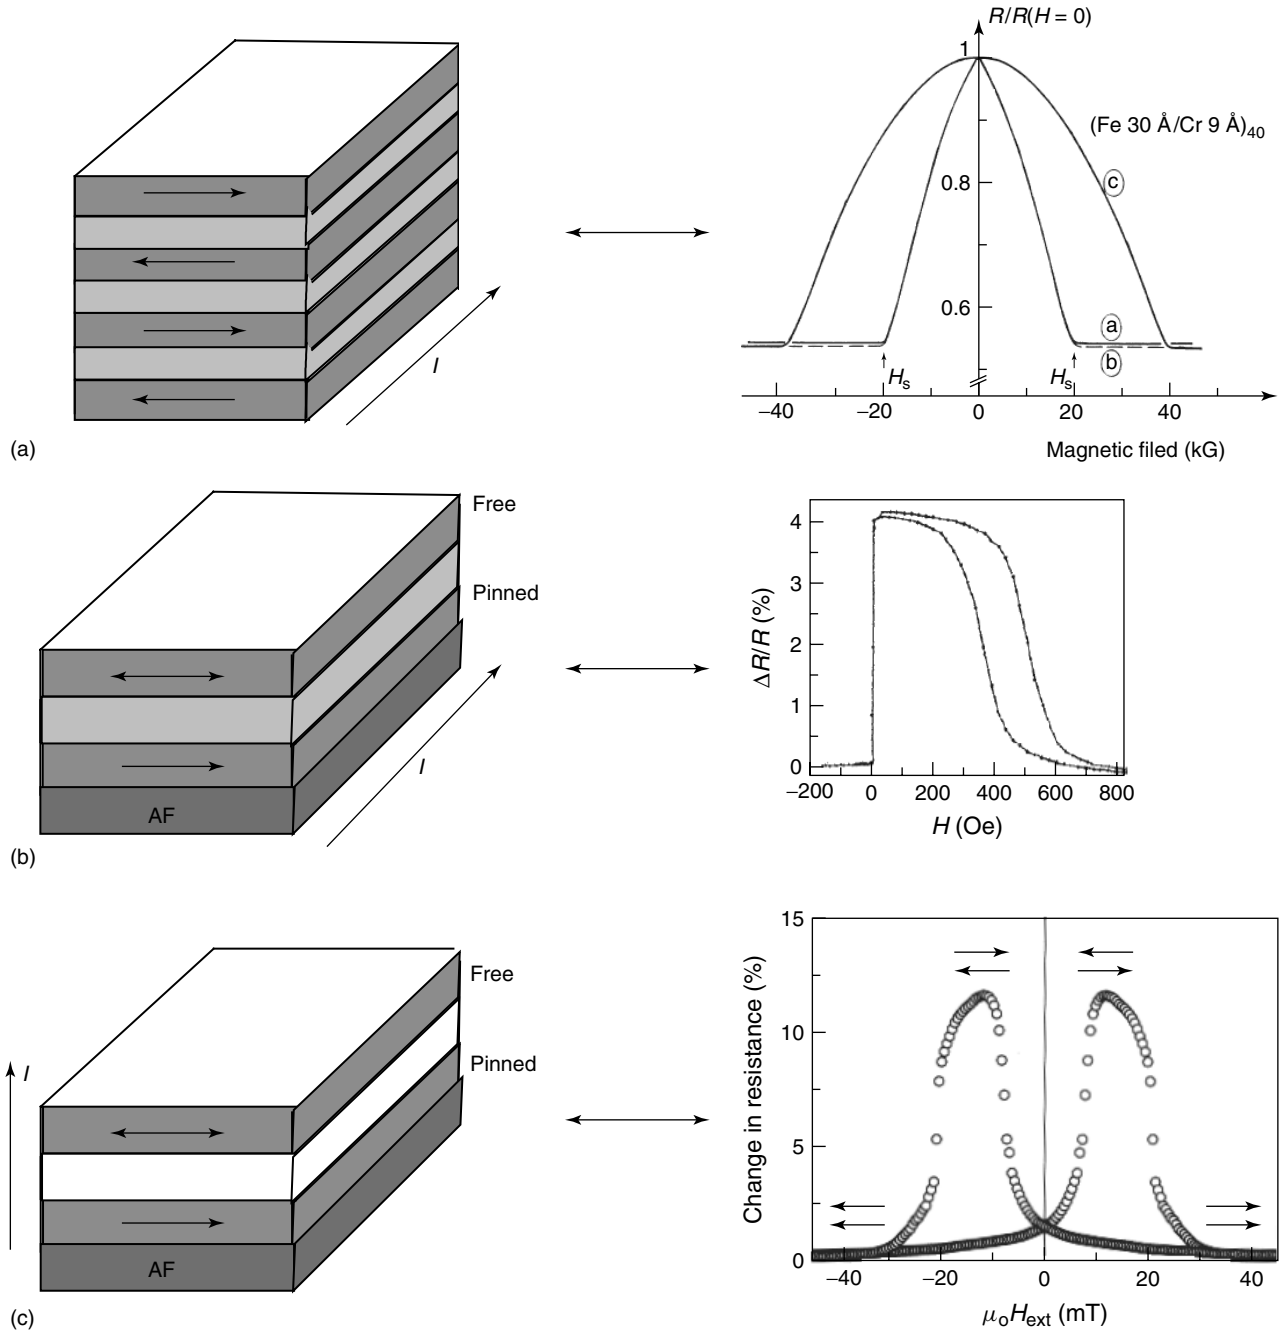

Figure 10. Schematic diagram of (a) GMR structure (Baibich *et al*., 1988), (b) spin valve (Dieny, 2004), and (c) magnetic tunnel junction (Moodera, Kinder, Wong and Meservey, 1995) and the corresponding magnetoresistance behavior.

area of magnetic memories (MRAMs) and also read heads for magnetic hard disk drives (Prinz, 1998; Wolf *et al*., 2001). These devices are nonvolatile with high speed, high density, and low power consumption. They are promising replacements for the present semiconductor RAMs. As a result, there exists a great potential market for these applications. Spin polarization measured via MTJ is the realistic limit for spin electronics applications. Moreover, the tunnel junction area is precisely controllable and so is the magnetic orientation of the two magnetic electrodes. Other applications include sensors, contactless potentiometer, and so on. A huge TMR ratio will certainly help to realize sensors with enhanced sensitivities in small field ranges.

The theoretical prediction of spin polarization in the half-Heusler (de Groot, Mueller, van Engen and Buschow, 1983) and as full-Heusler (Fujii, Ishida and Asano, 1995; Block

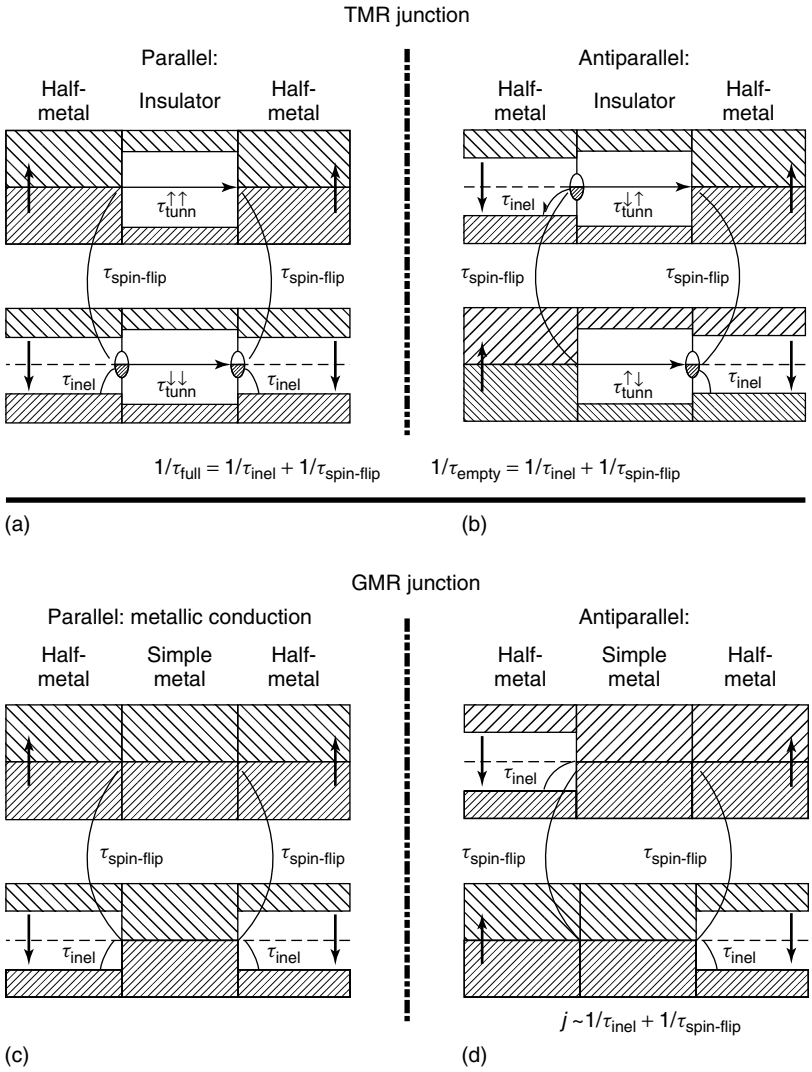

Figure 11. Schematic band picture in TMR (a and b) and GMR (c and d) junction using half-metallic electrodes. E_F is shown as a dashed line. Dark shaded, light shaded, and unshaded regions correspond to filled bands, empty bands, and band gaps respectively. Interface states contribute to the tunneling current and is controlled by the tunneling rate as shown in the figure (Mavropoulos, Ležaić and Blügel, 2005).

et al., 2003; Felser, Elmers and Fecher, 2005) alloys is currently the driving force for evaluating the potential of MTJs. Experimental attempts to realize MTJs with Heusler alloy did not yield any enhancement till recently. NiMnSb based MTJ exhibit spin polarization of 25% at 4.2 K and 9% at 300 K. Recently, MTJs based on full-Heusler alloy of type $Co_2Cr_{0.6}Fe_{0.4}Al$ showed promising results, reaching spin polarization values of 42–47% at room temperature (Marukame *et al*., 2005; Okamura *et al*., 2005). Another interesting candidate is half-metallic Co_2MnSi ($T_C = 985$ K). It was found that the temperature dependence of the spin polarization scales with the magnetic moment (Meservey, Pereskevopoulus and Tedrow, 1976) as described by the Bloch $T^{3/2}$ behavior (O'Handley, 2000) and consequently, materials with large Curie temperatures should have a high remanent spin polarization at room temperature. Recent experimental results on MTJs with $Co_{70}Fe_{30}$ and Co_2MnSi electrodes separated by a AlO_x barrier yields 66% spin polarization at 20 K (Kämmerer, Thomas, Hütten and Reiss, 2004). This value clearly exceeds that of the 3*d*-based magnetic elements or their alloys but is also well below the predicted 100%.

According to Butler, Zhang, Schulthess and MacLaren (2001), it is possible to obtain huge TMR values at room temperature in epitaxial Fe(100)/MgO(100)/Fe(100) with thick MgO tunnel barriers. This has been realized to some extent in CoFe/MgO (Parkin *et al*., 2004) and Fe/MgO/Fe (Yuasa *et al*., 2004) based MTJs. These MTJs based on MgO tunnel barrier will certainly have an immense impact on spin electronic devices operable at room temperature.

Moreover, they exhibit high temperature stability which makes them suitable for integration with CMOS circuits for MRAM applications (Parkin *et al*., 2004). In particular, Parkin *et al*. showed that these devices would have dramatic effect on MRAMs with read performance better than the current prototypes and eases the implementation of advanced MRAM architectures with ultradense cross-point random access memory (Reohr *et al*., 2002).

Half-metallic electrodes also constitute ideal components for GMR with half-metallic electrodes sandwiching a non-magnetic metal (Figure 10a). While half-metallic property of materials can be exploited fully in GMR-based junctions, the presence of interface states dramatically affect the TMR junctions as the tunneling rate is slower compared to the spin-flip rate (Mavropoulos, Ležaić and Blügel, 2005).

8.3 Spin transistor

Another proposed application of half-metal is in the *spin* MOSFET with an Si channel, MOS gate, and ferromagnetic source and drain electrodes as described by Tanaka (2005). The source/channel and drain/channel contacts, made up of half-metallic ferromagnets, are Schottky barriers, which allow for efficient spin injection and detection. The typical device structure is shown in Figure 12(a). The spin MOSFET behaves similar to Si-MOSFETs but with an additional spin-dependent transport functionality. Spin-polarized charge carriers are injected through the Schottky barrier by tunneling into the Si channel. The half-metallic drain selectively extracts the spin-polarized carriers from the channel, only when the spin configuration between the ferromagnetic source and drain is parallel. Thus, the output current depends on the relative magnetic configuration of the source and drain (Tanaka, 2005) as shown in Figure 12(b). Experiments showed that Schottky barriers can be used as spin aligners in reverse bias (Zhu *et al*., 2001; Hanbicki *et al*., 2002). However, under reverse bias, it is difficult to incorporate two Schottky barriers in series in GMR injector/detector configuration as one of them will lose its spin dependence (Schmidt, 2005).

8.4 Spin filters

A different approach to polarized spin injection is the *spin filter* (Hao, Moodera and Meservey, 1990), a tunnel barrier with different barrier heights, and therefore greatly different transmission coefficients for ↑ and ↓ electrons. Barrier heights are sufficiently different for almost fully spin-polarized currents to emerge on the far side of a barrier with unpolarized incident current. This can be realized using the

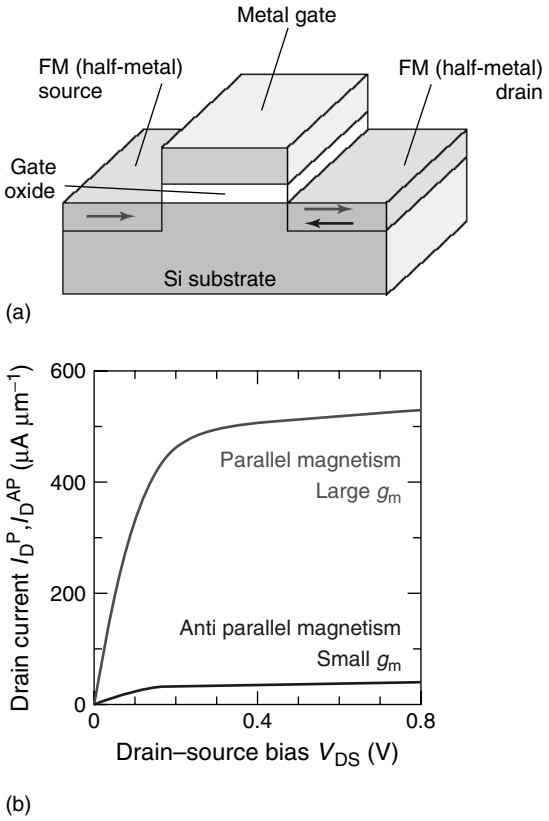

Figure 12. (a) The structure of spin MOSFET device and (b) calculated drain currents in parallel and antiparallel configurations (Tanaka, 2005).

half-metallic ferromagnetic materials with the majority spin channel with the lower resistance carries the entire current and minority channel acts as a barrier. The spin-filter effect may be used to provide a low-energy spin-polarized electron source.

9 CONCLUSIONS

The classification of half-metals is discussed taking account of both itinerant and localized electrons. For many potential applications, we need half-metals, which are compatible with semiconductors. In order to obtain useful materials operable at room temperature, it is quite important to explore new half-metallic compounds and structures through band-structure calculations and seek the highest possible Curie temperatures. The growth of high-quality single-crystalline epitaxial films of various half-metallic ferromagnets must be controlled. The effect of interfacial states on semiconductors needs to be studied in detail. Interface engineering will be critical for device operation, for example, making use of multiple reflection as in spin tunnel junctions. There are

dramatic developments in the search for new semiconductor-compatible half-metals such as Heusler alloys. However, growth temperature must be reduced to match the semiconductor integration. Studies should be focused on new half-metallic oxides and nitrides with high Curie temperature to enable them to be introduced in tunnel junctions or spin valves to attain huge TMR values at room temperature. The half-metallic oxides, nitrides, sulfides, Heusler alloys, and the novel magnetic semiconducting oxides, in the form of ultrathin films or layered samples, should be sufficient for future nanoscale applications. The ability to pattern in a subnanometer range today suggests that the role of half-metals in spin electronic applications is reaching a new stage. The difficulties in measuring the spin polarization directly forced to explore other experimental techniques to identify a half-metal, apart from an integral spin moment, metallic conduction criteria and band-structure calculations.

Superparamagnetic Particles

Steen Mørup and Mikkel Fougt Hansen
Technical University of Denmark, Kongens Lyngby, Denmark

1 INTRODUCTION

Magnetic nanoparticles have attracted much attention because of their unique magnetic properties, which, in several respects, differ considerably from those of bulk materials, and because of their many technological applications. Magnetic nanoparticles play a crucial role in information technology as they are used for data storage in, for example, hard disks in modern computers. Apart from this very important application, they are applied, for example, in ferrofluids and catalysts, for magnetic targeted drug delivery and MRI contrast imaging, and in biotechnology. Moreover, magnetic nanoparticles are commonly found in nature, including, for example, in sediments, in living organisms, and in primitive meteorites. It has been shown that a variety of different animals can navigate on the basis of a magnetic sense, which can be ascribed to magnetic nanoparticles in their bodies. The preparation, properties, and applications of magnetic nanoparticles have been the subject of several review papers (Bean and Livingston, 1959; Mørup, Dumesic and Topsøe, 1980; Mørup, 1990; Tronc, 1996; Leslie-Pelecky and Rieke, 1996; Murad, 1996, 1998; Dormann, Fiorani and Tronc, 1997; Kodama, 1999; Garcia-Palacios, 2000; Walker, Diebel and Green, 2000; Battle and Labarta, 2002; Pankhurst, Connolly, Jones and Dobson, 2003; Tartaj *et al*., 2003; Jönsson, 2004; Willard *et al*., 2004; Bansmann *et al*., 2005).

Usually, crystals of ferromagnetic and ferrimagnetic crystals spontaneously split up in magnetic domains as this reduces the magnetic energy. The domain walls, in which the spin directions gradually chance from the magnetization direction of one domain to that of the next, typically have widths of the order of 100 atomic layers. Because it costs exchange energy to form a domain wall, it is not energetically favorable to form domain walls in particles with dimension below a certain critical size. The critical size for single domain behavior is typically in the range 10–1000 nm, depending on the material.

A very significant difference between bulk materials and nanoparticles is that the magnetization direction may be unstable in magnetic nanoparticles because the thermal energy may be sufficient to overcome the energy barrier separating the easy directions of magnetization. This phenomenon, termed *superparamagnetic relaxation*, is particularly crucial in the development of high-density magnetic data storage media. The continued increase in the data storage density requires a reduction of the particle size, but the onset of superparamagnetic relaxation in very small particles makes them useless for data storage and this ultimately sets an upper limit for the density of stored data in magnetic recording media.

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

In this chapter, we discuss the properties of magnetic nanoparticles with special emphasis on superparamagnetic relaxation, and we show how a number of different experimental techniques can elucidate these phenomena. The aim of this chapter is to give an introduction to the field for nonspecialists rather than presenting a comprehensive review. In Section 2, a general introduction to magnetic relaxation phenomena in nanoparticles is given. In Section 3, we present a brief review of some of the common preparation techniques, and, in Section 4, we discuss some of the most important (nonmagnetic) characterization techniques. Section 5 deals with the most important techniques used for studies of magnetic relaxation phenomena in nanoparticles with an emphasis on studies of noninteracting particles. In Section 6, we show how the magnetic relaxation phenomena can be influenced by interparticle interactions. Finally, in Section 7, we give a brief discussion of the magnetic structure of nanoparticles, spin canting, and the related transverse relaxation.

2 MAGNETIC RELAXATION IN NANOPARTICLES

Single domain particles are characterized by two or more easy directions of magnetization, that is, directions of the magnetization, which give minimum magnetic energy. If the magnetocrystalline anisotropy is predominant, the easy directions are defined by the crystal symmetry. However, in nanoparticles, it is commonly found that other contributions to the magnetic anisotropy are more important (Mørup, Dumesic and Topsøe, 1980; Dormann, Fiorani and Tronc, 1997). For ferromagnetic and ferrimagnetic particles, shape anisotropy may be significant if the particle shape deviates from the spherical shape. The lower symmetry of the surface atoms compared to bulk can result in surface anisotropy, which may be predominant for particle sizes below about 10 nm. Furthermore, if a particle is exposed to stress, this may also result in a contribution to the magnetic anisotropy. For these reasons, the magnetic anisotropy of nanoparticles is complex, but commonly it is assumed that nanoparticles have a dominating uniaxial anisotropy with a magnetic energy given by the simple expression

$$E = KV \sin^2 \theta \tag{1}$$

where K is an effective magnetic anisotropy constant, V is the particle volume, and θ is the angle between the magnetization direction and the easy axis of magnetization. In this case, there are energy minima at $\theta = 0^\circ$ and $\theta = 180^\circ$ separated by an energy barrier of height KV. In very small particles at a finite temperature, the energy barrier may be comparable to the thermal energy, and the particles then perform superparamagnetic relaxation, that is, spontaneous fluctuations of the magnetization direction between the easy directions of magnetization. The superparamagnetic relaxation time, τ, is approximately given by the Néel–Brown expression (Néel, 1949; Brown, 1963)

$$\tau = \tau_0 \exp(KV/k_B T) \tag{2}$$

where τ_0 is typically in the range 10^{-12}–10^{-9} s, k_B is Boltzmann's constant, and T is the temperature. τ_0 depends on material parameters such as the magnetization, the magnetic anisotropy constant, the particle volume, and also weakly on temperature (Néel, 1949; Brown, 1963; Dormann, Fiorani and Tronc, 1997). Equation (2) is valid for particles that are well separated, such that interparticle magnetic interactions are negligible. The influence of interparticle interactions on the magnetic relaxation is discussed in Section 6.

Superparamagnetic relaxation can be studied using several different experimental techniques. In experimental studies, the timescale of the experimental technique is crucial. If the superparamagnetic relaxation time is longer than the timescale of the experimental technique, the magnetization appears static, but, if it is shorter, one may instead observe an average value of the magnetization. The temperature at which the superparamagnetic relaxation time is equal to the timescale of the experimental technique is called the *blocking temperature*, T_B. It is noteworthy that the blocking temperature of a sample is not uniquely defined, but, for each applied experimental technique, a related blocking temperature can be defined.

In practice, samples of superparamagnetic particles have a particle size distribution, and the magnetic anisotropy constants may also vary from particle to particle because of differences in, for example, particle size, shape, stress, and the surface state. Therefore, there will be a distribution of energy barriers, which can lead to a very broad distribution of relaxation times due to the exponential dependence of the superparamagnetic relaxation time, τ, on the energy barrier, KV. In a sample with an energy barrier distribution, the (median) blocking temperature can be defined as the temperature at which half the volume of the particulate material has relaxation times shorter than the timescale of the experimental technique and half of it has longer relaxation times.

In DC magnetization measurements, the timescale is of the order of seconds or longer. In AC magnetization measurements, one can choose the timescale by choosing the frequency. For studies of nanoparticles with short relaxation times, Mössbauer spectroscopy, with a timescale of the order of a few nanoseconds, is often used. Even shorter relaxation times may be studied by inelastic neutron scattering. The

use of these techniques for studies of magnetic relaxation in nanoparticles is discussed in Section 5. In a few studies, it has been demonstrated that muon spin relaxation (μ-SR) also can be used for studies of superparamagnetic relaxation. This technique can be used to study relaxation phenomena with frequencies in the range 10^4–10^{11} s^{-1} (Bewley and Cywinski, 1998; van Lierop, Ryan, Pumarol and Roseman, 2001; Ucko *et al*., 2001).

Below the blocking temperature, where the superparamagnetic relaxation is negligibly slow, there may still be thermal excitations, which affect the magnetic properties. For a particle with magnetic energy given by equation (1), the probability that the magnetization direction forms an angle in the range between θ and $\theta + \mathrm{d}\theta$ with the easy direction of magnetization is given by Mørup and Topsøe (1976) and Mørup (1983)

$$p(\theta)\mathrm{d}\theta = \frac{\exp(-E(\theta)/k_\mathrm{B}T)\sin\theta}{\int_0^{\pi/2}\exp(-E(\theta)/k_\mathrm{B}T)\sin\theta\mathrm{d}\theta}\mathrm{d}\theta \qquad (3)$$

Thus, even well below the blocking temperature, the magnetic properties may be influenced by fluctuations of the magnetization direction close to the easy axis. These fluctuations are uniform, that is, the magnetic moments of all the ionic spins are parallel and they have been termed *collective magnetic excitations*. Collective magnetic excitations can be described in terms of precession of the (sublattice) magnetization vector in the anisotropy field in combination with transitions between precession states with different precession angles (Mørup *et al*., 2002). In Mössbauer spectroscopy studies, the fluctuations can be considered fast compared to the timescale, and, as discussed in Section 5.3, one measures a magnetic hyperfine field, which is proportional to the average magnetization, which is given by Mørup and Topsøe (1976), Mørup (1983), and Mørup and Hansen (2005)

$$\langle M\rangle_T = M_0\langle\cos\theta\rangle_T = M_0\int_0^{\pi/2}\cos\theta\, p(\theta)\,\mathrm{d}\theta \approx M_0(1 - k_\mathrm{B}T/2\,KV) \qquad (4)$$

where M_0 is the saturation (or nonrelaxing) magnetization and the approximation is valid for $k_\mathrm{B}T \ll KV$. In inelastic neutron-scattering experiments, which have a shorter timescale, one can measure the transition energy for transitions between the precession states. This is discussed in Section 5.4.

In nanoparticles of antiferromagnetic materials, the sublattice magnetization directions may fluctuate in a way that is similar to the fluctuations of the magnetization direction of ferromagnetic and ferrimagnetic nanoparticles. Ideally, the net magnetic moment of an antiferromagnetic particle should be negligible. However, in practice, nanoparticles of antiferromagnetic materials have nonzero magnetic moments. This can be explained by uncompensated magnetic moments due to different numbers of ions with spin up and spin down at the surface and possibly also in the interior of the particles (Néel, 1961; Richardson *et al*., 1991; Kodama, 1999). It has recently been suggested that thermal excitations of the uniform mode in a nanoparticle of an antiferromagnetic material can result in a contribution to the magnetic moment (thermoinduced magnetization), which increases with increasing temperature (Mørup and Frandsen, 2004; Mørup and Hansen, 2005).

Apart from the thermally activated relaxation discussed in the preceding text, it has been suggested that quantum tunneling between the energy minima may take place (Chudnovsky and Gunther, 1988; Barbara and Chudnovsky, 1990). Since quantum tunneling is temperature independent, one should expect that it gives rise to a temperature-independent relaxation time below the temperature where the thermally activated relaxation is slow compared to quantum tunneling.

3 SAMPLE PREPARATION TECHNIQUES

Magnetic nanoparticles can be synthesized by using numerous different techniques. Here, we present a brief overview of some of the most commonly applied preparation methods and give some examples of the occurrence of magnetic nanoparticles in nature.

3.1 Chemical synthesis and thermal decomposition

Wet chemical synthesis methods are among the most-used techniques for preparation of magnetic nanoparticles (Willard *et al*., 2004). For example, nanoparticles of iron oxides, such as maghemite (γ-Fe_2O_3), magnetite (Fe_3O_4) (Jolivet, Tronc and Chanéac, 2000), and hematite (α-Fe_2O_3) (Sugimoto, Wang, Itoh and Maramatsu, 1998), are conveniently prepared by precipitation from aqueous solutions of iron salts. By varying the preparation conditions, it is possible to vary the average particle size. Thermal decomposition of, for example, (oxy)hydroxides or hydrated salts is another commonly used technique for preparation of nanoparticles (Richardson *et al*., 1991; Bødker *et al*., 2000). By varying the decomposition temperature, one can vary the average particle size. Precipitation and thermal decomposition techniques usually result in rather broad size distributions. Narrow size distributions can be obtained using the so-called inverse micelle technique (O'Conner *et al*., 2001; Willard *et al*., 2004). Thermal decomposition of, for example, $Fe(CO)_5$ in organic liquids containing appropriate surfactant molecules

can also lead to very narrow particle size distributions (Fisker *et al*., 2000; Sun *et al*., 2000), and three-dimensional ordered arrays of nanoparticles can be prepared by drying suspensions of such monodisperse particles (Bentzon *et al*., 1989).

3.2 Preparation of metallic nanoparticles by reduction

Metallic nanoparticles can be prepared by reduction of, for example, metal oxide nanoparticles in hydrogen at elevated temperatures. Often, there is a strong tendency for the particles to sinter during the reduction. Therefore, the reduction is often carried out using samples of particles, that are well dispersed on a high-surface-area support, such as silica, carbon black, alumina, or others (Topsøe, Dumesic and Mørup, 1980; Bødker, Mørup and Linderoth, 1994; Bødker *et al*., 1998). Metallic nanoparticles are very reactive and may even burn when exposed to air. Therefore, studies of their magnetic properties must be performed in a controlled environment, and sophisticated *in situ* cells have been constructed for such studies (Bødker and Mørup, 1996).

3.3 Chemical reduction using $NaBH_4$

Nanoparticles of amorphous $TM_{1-x}B_x$ alloys, where TM is a transition metal (Fe, Co, or Ni), can be prepared by reduction of the transition-metal ions in aqueous solution using $NaBH_4$ (or KBH_4). It has been shown that the boron content can be varied by changing the pH value of the solution in which the reaction takes place (van Wonterghem *et al*., 1986; Linderoth and Mørup, 1991).

3.4 Evaporation techniques

Evaporation of metals in inert atmospheres has also been used to produce nanoparticles and, by varying the gas composition and pressure, it is possible to vary the particle size (Granqvist and Buhrman, 1976). In some studies, this preparation technique has been combined with separation in a mass spectrometer such that one can select particles with a well-defined size (Billas, Becker, Chatelain and de Heer, 1993).

3.5 Ball milling

For large-scale production of nanoparticles, high-energy ball milling may be used (Koch, 1991; Suryanarayana, 2001). With this technique, one can typically reduce the crystal size to around 10–20 nm within hours. Further milling does not result in smaller particles because ball milling of very small particles also can result in growth of crystallites (Mørup, Jiang, Bødker and Horsewell, 2001). Ball-milled samples usually contain many defects, and the crystallites of nanometer size often form large agglomerates. Besides, material from the balls and vials usually contaminate the ball-milled samples. A very interesting feature of ball milling is that one can make chemical reactions by high-energy ball-milling mixtures of different materials. In this way, it appears possible to produce nanocrystals of metastable materials, which cannot be produced by traditional techniques (Koch, 1991; Suryanarayana, 2001; Principi, 2001).

3.6 Coating of nanoparticles

As discussed in Section 6, magnetic interactions between nanoparticles can have a significant influence on the magnetic relaxation. Therefore, it is often important that one is able to control the distance between the particles. Coating the nanoparticles with surfactant molecules such as oleic acid reduces the magnetic interaction, and, for antiferromagnetic particles, this may be sufficient to ensure that the interactions are negligible. For nanoparticles of ferromagnetic or ferrimagnetic materials, further separation may be necessary to reduce the interactions because of the long-range dipole interactions. In several studies, coated particles have been suspended in a liquid to form a stable suspension (a ferrofluid). One may then ideally control the strength of the interactions by diluting the liquid, and studies of the magnetic properties can be performed on frozen samples. In other studies, particles have been prepared in a matrix of polyvinyl alcohol (PVA), which is a solid at room temperature (Tronc, 1996; Tronc *et al*., 2000).

3.7 Magnetic nanoparticles in biological samples

The iron storage protein ferritin has been used in many studies of the fundamental magnetic properties of nanoparticles. Ferritin consists of a core of iron oxyhydroxide surrounded by a protein shell. It can be extracted from, for example, horse spleen, and it is commercially available. Ferritin has the advantage that the particle size distribution is relatively narrow, and the protein shell ensures that the interparticle interactions are negligible. Several different animals utilize magnetic nanoparticles for navigation. Magnetotactic bacteria contain a chain of, for example, single domain magnetite particles, which have superparamagnetic blocking temperatures well above room temperature. This chain of particles acts as a compass needle (Blakemore, 1975).

Homing pigeons have a magnetic sense, which is based on arrays of superparamagnetic nanoparticles in the tissue of the upper-beak skin. These arrays are deformed by the Earth's magnetic field and, via complex mechanisms, this enables the pigeons to navigate (Davila, Fleissner, Winklhofer and Petersen 2003).

3.8 Magnetic nanoparticles in geological samples

Nanoparticles of iron oxides and oxyhydroxides are widespread in soils and are responsible for the reddish color of, for example, tropical soils. Superparamagnetic behavior in geological samples can have important implications in studies of geomagnetism (Néel, 1949). The magnetic properties of soils have been extensively studied by, for example, Mössbauer spectroscopy (Murad, 1998; Vandenberghe *et al*., 2000).

4 CHARACTERIZATION OF NANOPARTICLES

4.1 Structural characterization

In studies of magnetic nanoparticles, it is essential that they are well characterized with respect to purity, size, shape, and so on. It is, for example, noteworthy that even tiny amounts of a strongly magnetic impurity phase may dominate the magnetization of an antiferromagnetic material.

A standard technique for characterization of nanoparticles is X-ray diffraction, which is used to identify the crystalline phases in a sample. Furthermore, this technique can also be used to estimate the particle size since the diffraction lines of nanoparticles are broadened with a line broadening that is inversely proportional to the particle size (Langford, Louër and Scardi, 2000). X-ray diffraction is less suitable for characterization of amorphous and poorly crystalline materials.

Transmission electron microscopy is another standard technique for characterization of nanoparticles. It gives information about both the particle size and the particle morphology. In studies of crystalline nanoparticles, electron diffraction can be used to determine the crystal structure. High-resolution transmission electron microscopy often allows observation of the lattice planes, and, in this way, the crystal structure can also be studied. Often, nanoparticles have a tendency to agglomerate, and it may then be difficult to obtain information on individual particles. Well-separated particles can be prepared by coating with appropriate surfactant molecules, and, by analyzing them in large numbers, one can estimate the particle size distribution. Figure 1(a) shows an example of a transmission electron microscope image of surfactant-coated amorphous Fe–C particles with a very narrow size distribution. The particles were prepared by thermal decomposition of $Fe(CO)_5$. Figure 1(b) shows the corresponding size distribution obtained from a computer analysis of an image containing about 4500 particles (Fisker *et al*., 2000).

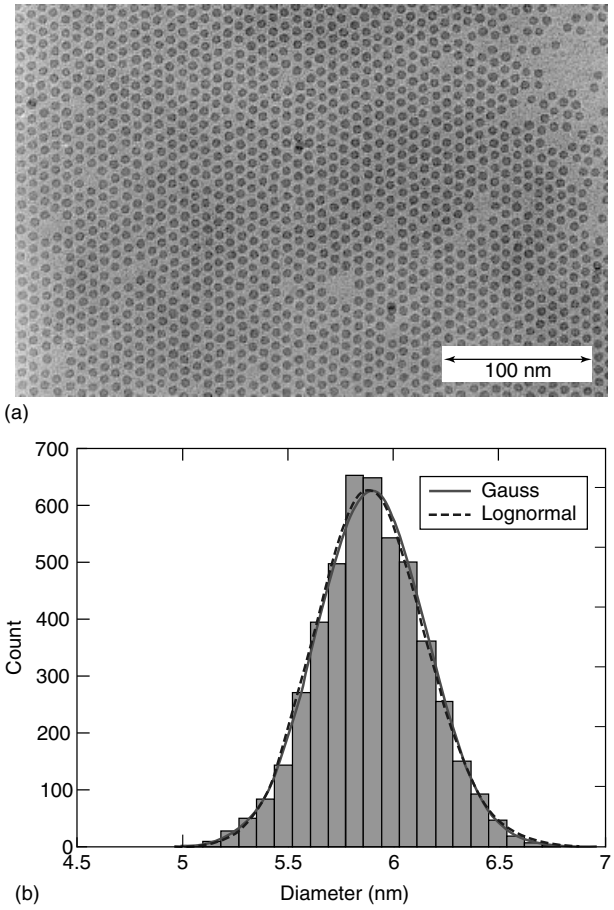

Figure 1. (a) Transmission electron microscopy image of amorphous Fe–C nanoparticles. (b) Size distribution of the same particles determined by a computer analysis of approximately 4500 particles in an image. The mean diameter is 5.9 nm with a standard deviation of 0.3 nm. (Kluwer Academic Publishers, *Journal of Nanoparticle Research* **2**(3), 2000, pp 267–277, Estimation of Nanoparticle size distributions by image analysis, R. Fisker, J.M. Carstensen, M.F. Hansen, F. Bødker, S. Mørup, figure 6, with kind permission of Springer Science and Business Media.)

Other techniques that can be employed for the morphological characterization of nanoparticles are small-angle neutron scattering (SANS) and small-angle X-ray scattering (SAXS). For samples with nearly uniform particle sizes, these techniques can give information on the size distribution and the structural and magnetic (for SANS) correlations between particles.

4.2 Particle size distributions

As discussed in Section 2, the exponential dependence of the superparamagnetic relaxation time on the energy barrier, KV, implies that the particle size distribution can have a great influence on the magnetic behavior of a sample, even for narrow size distributions. It is therefore important to know and include the particle size distribution when experimental data are analyzed. Let the number-weighted particle volume distribution be $f_{\mathrm{N}}(V)\,\mathrm{d}V$. Thus, the number of particles with volumes between V and $V+\mathrm{d}V$ is $f_{\mathrm{N}}(V)\,\mathrm{d}V$. If the signal from a particle of size V is $g(V,x)$, where x is the experimental parameter that will be varied in the measurements, the resulting signal, $G(x)$, from the entire sample is

$$G(x)=\int_0^\infty g(V,x)\,f_{\mathrm{N}}(V)\,\mathrm{d}V \tag{5}$$

Often, the normalized number-weighted or volume-weighted volume distribution is represented by a log-normal distribution

$$f_{\mathrm{LN}}(V)\,\mathrm{d}V=\frac{1}{\sqrt{2\pi}\sigma V}\exp\left(-\frac{\ln^2(V/V_{\mathrm{m}})}{2\sigma^2}\right)\mathrm{d}V \tag{6}$$

where V_{m} is the median particle volume and σ is the logarithmic standard deviation (Granqvist and Buhrman, 1976). This distribution function has been used to describe the size distribution of nanoparticles in numerous publications.

5 EXPERIMENTAL STUDIES OF NONINTERACTING MAGNETIC PARTICLES

5.1 DC magnetization measurements

When a sample of superparamagnetic particles is exposed to an applied magnetic field above the blocking temperature, the measured magnetization equals its thermal equilibrium value, that is, the particles are magnetized in a way that is similar to a paramagnetic material. However, the magnetic moments that interact with the applied magnetic field are the moments of whole particles, which can be hundreds or thousands of Bohr magnetons. This is in contrast to paramagnetic materials in which only the magnetic moments of individual ions (typically a few Bohr magnetons) interact with the field. Therefore, at a given temperature, the magnetization of a sample of superparamagnetic particles will approach the saturation value much faster than for a paramagnetic material. Often, the magnetic anisotropy energy can be considered negligible compared to the Zeeman energy, and the magnetic energy is then given by

$$E=-\boldsymbol{\mu}\cdot\mathbf{B}+KV\sin^2\theta\approx-\boldsymbol{\mu}\cdot\mathbf{B} \tag{7}$$

where $\boldsymbol{\mu}$ is the magnetic moment of the particle, $\mathbf{B}=\mu_0\mathbf{H}$ is the applied magnetic induction, and $\mathbf{H}$ is the intensity of the applied magnetic field. To ease the language in the following, we refer to $\mathbf{B}(=\mu_0\mathbf{H})$ as the applied magnetic field as it is common in the literature. The average magnetization along the applied field in thermal equilibrium is proportional to the Langevin function $L(\mu B/k_{\mathrm{B}}T)$:

$$\begin{aligned}\langle M\rangle &= M_0L(\mu B/k_{\mathrm{B}}T)\\ &\equiv M_0[\coth(\mu B/k_{\mathrm{B}}T)-k_{\mathrm{B}}T/\mu B]\end{aligned} \tag{8}$$

Thus, if the magnetization is plotted as a function of B/T, curves obtained at different temperatures should be identical in a temperature range where M_0 and μ can be considered temperature independent. This behavior is often taken as a fingerprint of a superparamagnetic sample.

In a detailed analysis of magnetization data, one has to take the particle size distribution into account. The average magnetic moment of a particle in a small applied magnetic field is $m(V,T)=\chi(V,T)VH$, where $\chi(V,T)$ is the initial magnetic susceptibility and T is the temperature. The total initial susceptibility of the sample is by definition the total magnetic moment divided by H and the total sample volume, that is,

$$\chi(T)=\frac{\int_0^\infty\chi(V,T)Vf_{\mathrm{N}}(V)\,\mathrm{d}V}{\int_0^\infty Vf_{\mathrm{N}}(V)\,\mathrm{d}V}\equiv\int_0^\infty\chi(V,T)\,f_{\mathrm{V}}(V)\,\mathrm{d}V \tag{9}$$

Here, we have defined the volume-weighted size distribution function $f_{\mathrm{V}}(V)\,\mathrm{d}V=Vf_{\mathrm{N}}(V)\,\mathrm{d}V/\int_0^\infty Vf_{\mathrm{N}}(V)\,\mathrm{d}V$, which is conveniently used in experimental studies where the sample signal is proportional to the particle volume.

When the magnetic anisotropy is not negligible, the field dependence of the magnetization deviates from the Langevin function. An analysis of the magnetization curves may then be used to estimate the magnetic anisotropy constant (Hanson, Johansson and Mørup, 1993; Respaud, 1999).

Below the blocking temperature, the magnetization curves exhibit hysteresis. It is characteristic that the coercivity decreases with increasing temperature and vanishes at the blocking temperature. The temperature dependence of the coercivity has in several cases been found to be in accordance with the expression (Bean and Livingston, 1959)

$$H_{\mathrm{c}}\approx 2\,KV(1-5\sqrt{k_{\mathrm{B}}T/KV})/\mu \tag{10}$$

Often, the superparamagnetic relaxation in samples of magnetic nanoparticles is studied by measuring the so-called zero-field-cooled (ZFC) and the field-cooled (FC) magnetization curves. A ZFC magnetization curve is obtained by cooling the sample in zero applied magnetic field from a temperature, where the entire sample shows a superparamagnetic response. Then a small field is applied and the magnetization of the sample is measured as a function of temperature during heating. The FC magnetization curve is measured as a function of increasing temperature after cooling the sample in the applied magnetic field. A typical example is shown in Figure 2. At temperatures well below the blocking temperature, the ZFC magnetization is small because the sample is not in thermal equilibrium and the magnetization directions of the particles in a small applied field are mainly governed by the randomly oriented easy directions of magnetization. With increasing temperature, first the smaller particles become superparamagnetic, and the probability of finding the particles with their magnetization directions close to that of the applied field increases, resulting in an increase in the magnetization. With further increasing temperature, more and more particles become superparamagnetic, resulting in an increasing magnetization until the net effect of the thermal energy is a decrease in the magnetization. In the FC state, the magnetization in the blocked state is preferably frozen in directions close to that of the applied field. Therefore, the magnetization is considerably larger than that in the ZFC state. The ZFC and the FC curves coincide above the bifurcation temperature, which is the temperature above which all particles are superparamagnetic.

The ZFC magnetic susceptibility curves are often modeled in the following manner: Well below the blocking temperature, the magnetic moments are frozen in random easy directions and the effect of an applied external field in this case is to slightly change the directions of minimum energy. For particles with uniaxial anisotropy and randomly oriented easy axes, a minimization of the energy yields the low-field magnetic susceptibility

$$\chi_0 = \frac{\mu_0 M_0^2}{3K} \tag{11}$$

Well above the blocking temperature, the thermal effects dominate and the susceptibility at low fields is obtained using the fact that the Langevin function fulfills $L(x) \approx x/3$ for $x < 1$. The result is

$$\chi_\infty = \frac{\mu_0 M_0^2 V}{3k_B T} \tag{12}$$

In the analyses of ZFC susceptibility curves for real samples, it is often assumed that the response of a particle of a given size is described by equation (11) for $T < T_B$ and equation (12) for $T \geq T_B$ as the effects of the particle size distribution on the relaxation time significantly smear out the assumed sharp transition between the blocked and superparamagnetic state. A typical timescale of such measurements is $\tau_m \approx 100\,\mathrm{s}$. It should be noted that the peak in the ZFC magnetization curve corresponds to the blocking temperature for a sample of particles of the same size. However, for a particle size distribution, the peak temperature can be up to a factor of 2 larger than the blocking temperature (Gittleman, Abeles and Bozowski, 1974; Chantrell, El-Hilo and O'Grady, 1991).

To elucidate the energy barrier distribution and to reveal information on interparticle interactions, it is useful to study the remanent magnetic moment after exposing the sample to different temperature and field conditions. These different conditions lead to the so-called thermoremanent magnetization (TRM), isothermal remanent magnetization (IRM), and the direct current demagnetization (DCD) magnetization. These techniques have especially been used for studies of magnetic recording media, where the stability of the remanent state after exposure to a magnetic field is essential for the ability to read the stored information. For an introduction and further references on these techniques, see Dormann, Fiorani and Tronc (1997).

Magnetic viscosity measurement is another useful technique for studies of superparamagnetic relaxation (Labarta, Iglesias, Balcells and Badia, 1993; Iglesias, Badia, Labarta and Balcells, 1996). In such measurements, one measures the approach to equilibrium magnetization as a function of time. For example, the sample can be cooled in an applied magnetic field and the field is switched off at a selected temperature. Subsequently, the time dependence of the magnetization $M(t)$ is measured as a function of time. The magnetic

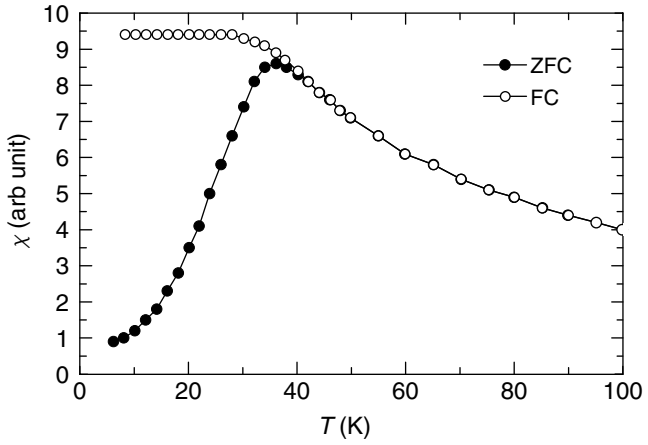

Figure 2. ZFC and FC magnetization curves measured on a ferrofluid of the Fe–C particles from Figure 1 with a concentration of 0.05 vol% in an applied field of $\mu_0 H = 0.5\,\mathrm{mT}$.

viscosity is defined as

$$S = \frac{\partial M(t)}{\partial \ln t} \tag{13}$$

In several studies, it has been found that the magnetic viscosity becomes temperature independent at very low temperatures (Zhang, Tejada, Hernandez and Ziolo, 1997; Tejada, Zhang and Chudnovsky, 1993). This has been taken as evidence for quantum tunneling. It has, however, been pointed out that if the distribution of energy barriers, ΔEs, diverges approximately inversely proportional to ΔE for $\Delta E \to 0$, this will also lead to an apparently temperature-independent relaxation time (Barbara *et al*., 1992). Both computer simulations (Kodama, Berkowitz, McNiff and Foner, 1996) and analytical calculations (Mørup, 2003) have shown that there may be energy barrier distributions due to localized magnetic defects that diverge for $\Delta E \to 0$. It can be shown that a plot of $S/k_{\mathrm{B}}T$ against $k_{\mathrm{B}}T\ln(t)$ gives information about the distribution of energy barriers (Iglesias, Badia, Labarta and Balcells, 1996). In a study of ferritin, St. Pierre *et al*. (2001) have shown experimentally that the energy barrier distribution in fact seems to diverge for $\Delta E \to 0$. The origin of such an energy barrier distribution is further discussed in Section 7.

5.2 AC magnetization measurements

The applied magnetic field intensity in the AC magnetization measurements is $H(t) = H_0 \cos(\omega t)$, where $\omega = 2\pi f$ and f is the frequency of the applied magnetic field. The response of the magnetic moments of the particles may be phase shifted compared to the applied field and is therefore conveniently described as a complex number. The complex magnetic susceptibility is written as

$$\chi_{\mathrm{AC}}(\omega, T) = \chi'(\omega, T) + \mathrm{i}\chi''(\omega, T) \tag{14}$$

where χ' and χ'' are the in-phase and out-of-phase components of the measured susceptibility, respectively. A simple expression for χ_{AC} has been given by Gittleman, Abeles, and Bozowski (1974). They wrote the time-dependent magnetic susceptibility as

$$\chi_{\mathrm{AC}}(t, T) = \chi_0 + (\chi_\infty - \chi_0) \cdot (1 - \mathrm{e}^{-t/\tau}) \tag{15}$$

where χ_0 is the magnetic susceptibility in the absence of thermal fluctuations (equation 11), χ_∞ is the equilibrium susceptibility (equation 12), and τ is the superparamagnetic relaxation time (equation 2). This expression is a good approximation to more accurate and complicated expressions for a random distribution of easy axes (Svedlindh, Jonsson and García-Palacios, 1997). By Fourier transformation, one obtains

$$\chi_{\mathrm{AC}}(\omega, T) = \frac{\chi_\infty + \mathrm{i}\omega\tau\chi_0}{1 + \mathrm{i}\omega\tau} = \frac{\chi_\infty + \chi_0(\omega\tau)^2}{1 + (\omega\tau)^2} + \mathrm{i}\frac{\omega\tau(\chi_0 - \chi_\infty)}{1 + (\omega\tau)^2} \tag{16}$$

AC susceptibility measurements have the advantage that the timescale is well defined and that it can be varied over several orders of magnitude ranging from $\sim 10^{-2}$ to 10^5 s^{-1}. The in-phase susceptibility shows a behavior similar to $\chi_{\mathrm{ZFC}}(T)$. The out-of-phase susceptibility is nonzero when the relaxation time of a significant fraction of the particles is of the order of ω^{-1} and peaks at the blocking temperature. It should be noted that, for a size distribution of particles, which is not too narrow, the out-of-phase susceptibility mirrors the distribution of superparamagnetic relaxation times (Jonsson, Mattsson, Nordblad and Svedlindh, 1997). Figure 3 shows AC susceptibility curves of samples of noninteracting and interacting γ-Fe_2O_3 nanoparticles. For the noninteracting sample, it is seen that both the in-phase and out-of-phase susceptibility curves are shifted toward higher temperatures as the frequency is increased and also that the peak height of the out-of-phase susceptibility curve depends only weakly on the frequency. The curves for the interacting sample are discussed in Section 6.

5.3 Mössbauer spectroscopy

Mössbauer spectroscopy has been widely used for studies of the magnetic properties of nanoparticles. The technique can be used for several isotopes of which the most important one, which we have also focused on here, is ^{57}Fe. An introduction to Mössbauer spectroscopy can be found in, for example, Greenwood and Gibb (1971). The technique is very sensitive to relaxation phenomena with relaxation times of the order of nanoseconds and can therefore be used for studies of relaxation phenomena that cannot be studied by, for example, AC and DC susceptibility measurements.

^{57}Fe Mössbauer spectra of bulk magnetic materials consist of one or more sextets, depending on the number of different Fe atomic sites. The distance between the lines is proportional to the magnetic field acting at the nucleus. In Mössbauer studies of magnetic nanoparticles, superparamagnetic relaxation can have a dramatic influence on the shape of the spectra, depending on the relaxation time. The timescale of Mössbauer spectroscopy, τ_{M}, is related to the Larmor precession time of the nuclear magnetic moment in the magnetic hyperfine field. In ^{57}Fe Mössbauer spectroscopy studies, τ_{M} is typically of the order of a few nanoseconds. The spectra

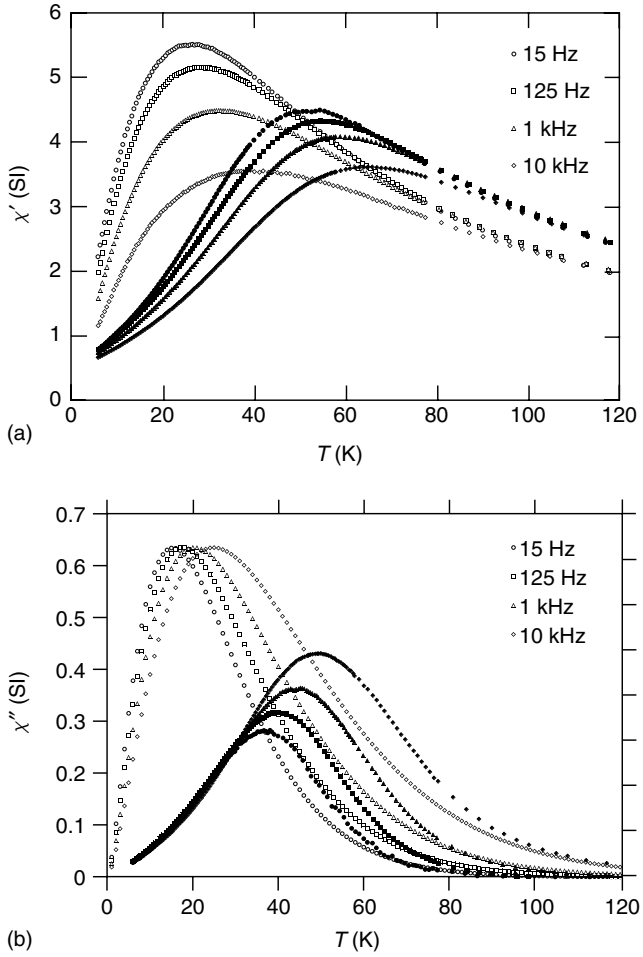

Figure 3. In-phase (a) and out-of-phase (b) AC susceptibilities versus temperature at different frequencies ranging from 15 Hz to 10 kHz for a noninteracting 0.03 vol% ferrofluid (open symbols) and an interacting 17 vol% ferrofluid (filled symbols) of 8-nm γ-Fe_2O_3 nanoparticles. (Reprinted figure from T. Jonsson, P. Nordblad, P. Svedlindh, *Phys. Rev.*, **B57**, pp 497–504 (1998).)

consist of sextets for relaxation times that are long compared to τ_M. For relaxation times close to τ_M, the lines are broadened and the magnetic splitting gradually collapses. For very short relaxation times ($<10^{-10}$ s), only a singlet or a doublet component is observed. This is illustrated in Figure 4, which shows theoretical ^{57}Fe Mössbauer spectra for different relaxation times.

Since the inevitable particle size distribution results in a broad distribution of relaxation times, the spectra of samples of magnetic nanoparticles consist of superpositions of components with different relaxation times. In nanoparticles, for which τ_0 is small compared to τ_M, a typical particle size distribution results in a very broad distribution of relaxation times at temperatures where the average relaxation time is close to τ_M. Therefore, close to the blocking temperature,

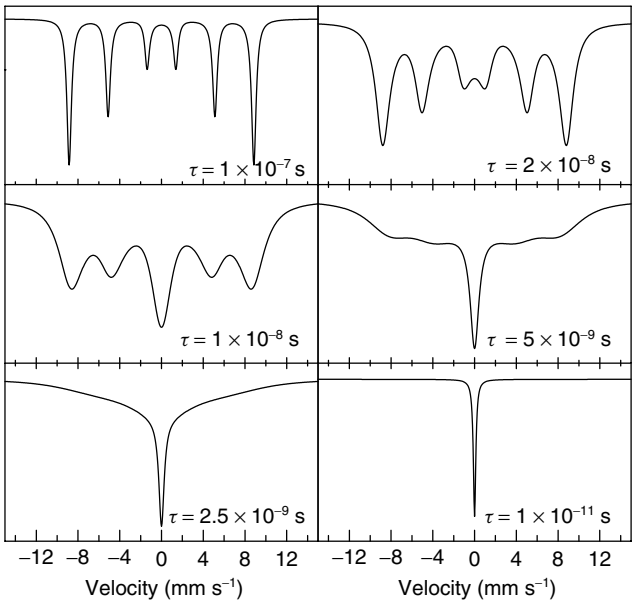

Figure 4. Theoretical Mössbauer spectra calculated for different superparamagnetic relaxation times and a hyperfine field fluctuating between ±55 T.

only a very small fraction of the particles have relaxation times close to τ_M. Thus, the spectra mainly consist of a superposition of a sextet with narrow lines, due to particles that are well below their blocking temperature ($\tau \gg \tau_M$), and a sharp central doublet or singlet, due to particles that exhibit fast superparamagnetic relaxation ($\tau \ll \tau_M$) (Kündig, Bömmel, Constabaris and Lindquist, 1966; Mørup *et al.*, 2002). Figure 5 shows Mössbauer spectra of α-Fe nanoparticles for which τ_0 is of the order of 10^{-10} s (Bødker *et al.*, 1998), and the spectra therefore mainly consist of a sextet and a doublet with relatively narrow lines. Broad components due to particles with relaxation times of the order of 10^{-8}–10^{-9} s only give a minor contribution. In nanoparticles of α-Fe_2O_3, τ_0 is of the order of 10^{-11} s (Bødker and Mørup, 2000) and, in Mössbauer spectra obtained near the blocking temperature, the contributions from particles with relaxation times of the order of 10^{-8}–10^{-9} s are barely visible. This is illustrated in the spectra of noninteracting 9-nm hematite particles shown in Section 6 (Figure 8a). In samples of nanoparticles for which τ_0 is of the order of 10^{-10}–10^{-9} s, a larger fraction of the particles have relaxation times comparable to the timescale of Mössbauer spectroscopy in a temperature range where KV/k_BT is small. This results in spectra with broadened lines around the blocking temperature. This is the case for spectra of γ-Fe_2O_3 nanoparticles with sizes of the order of 5–10 nm (Mørup, Bødker, Hendriksen and Linderoth, 1995; Frandsen *et al.*, 2004) for which $\tau_0 \approx 4 \times 10^{-10}$ s (Jonsson, Mattsson, Nordblad and Svedlindh, 1997).

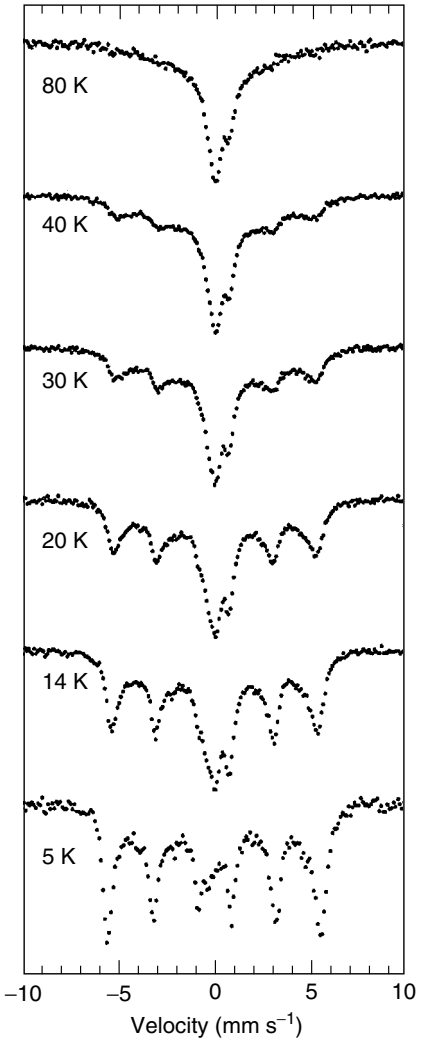

Figure 5. Mössbauer spectra of 3-nm α-Fe particles obtained at the indicated temperatures. (Reprinted from *Journal of Magnetism and Magnetic Materials*, vol 177–181, Bodker *et al.*, 'Superparamagnetic relaxation in α-Fe particles', pp 925–927 (1998), with permission from Elsevier.)

Below the blocking temperature, the magnetic hyperfine splitting of the spectra is reduced owing to collective magnetic excitations. For a particle with magnetic anisotropy energy given by equation (1), the observed magnetic hyperfine field is proportional to $\langle M \rangle$ (equation 4) and is given by Mørup and Topsøe (1976) and Mørup (1983)

$$B_{\text{obs}} \approx B_0(1 - k_{\text{B}}T/2\,KV) \tag{17}$$

where B_0 is the magnetic field acting on the nucleus in the absence of superparamagnetic relaxation. For antiferromagnetic particles, B_{obs} is proportional to the average value of the sublattice magnetizations, but can also be expressed by equation (17) (Mørup and Hansen, 2005).

Studies of the temperature dependence of the Mössbauer spectra of nanoparticles allow the parameters KV and τ_0 to be estimated. Often, the particle volume, V, is known from, for example, X-ray diffraction or transmission electron microscopy. In such cases, the magnetic anisotropy constant can be estimated. Mössbauer studies of magnetic nanoparticles of α-Fe (Bødker, Mørup and Linderoth, 1994), γ-Fe_2O_3 (Tronc, 1996), and α-Fe_2O_3 (Bødker and Mørup, 2000) have shown that the magnetic anisotropy constant increases with decreasing particle size. This has been explained by a contribution from the surface to the magnetic anisotropy, which is expected to increase with decreasing particle size.

In the presence of an applied magnetic field **B**, the magnetic energy of a ferro- or ferrimagnetic particle is given by equation (7) and, if the magnetic anisotropy is negligible, the magnetic field at the nucleus is given by

$$\mathbf{B}_{\text{obs}} \approx \mathbf{B}_0 L(\mu B/k_{\text{B}}T) + \mathbf{B} \tag{18}$$

Figure 6 shows room-temperature Mössbauer spectra of 7.5-nm maghemite nanoparticles in different applied magnetic fields (Mørup, Bødker, Hendriksen and Linderoth, 1995). It can be seen that even moderate applied fields result in a substantial splitting. The lines are relatively broad, mainly because of the distribution of magnetic moments due to the particle size distribution, which gives rise to a distribution in the values of B_{obs}. For values of $\mu B/k_{\text{B}}T$ larger than 2–3, one may use the high-field approximation $L(x) \approx 1 - x^{-1}$ and we then find

$$B_{\text{obs}} \approx B_0(1 - k_{\text{B}}T/\mu B) - B \tag{19}$$

The minus in front of the last term is because the magnetic hyperfine field in iron compounds is usually opposite to the magnetization. It can be seen from equation (19) that a plot of the induced hyperfine field, $B_{\text{ind}} = B_{\text{obs}} + B$, as a function of B^{-1} should give a straight line with intercept B_0 and slope $B_0 k_{\text{B}}T/\mu$ from which the magnetic moment of the particles can be estimated (Mørup, Dumesic and Topsøe, 1980; Mørup, 1983). When the magnetization is known, the average particle size can be estimated.

5.4 Neutron scattering

Neutron scattering is another technique that has appeared useful in studies of the magnetic properties of nanoparticles. Neutrons can be scattered by both nuclei and ionic magnetic moments. Therefore, neutron diffraction gives information not only about both the crystal structure (as X-ray diffraction) but also about the magnetic structure. Thus, one can

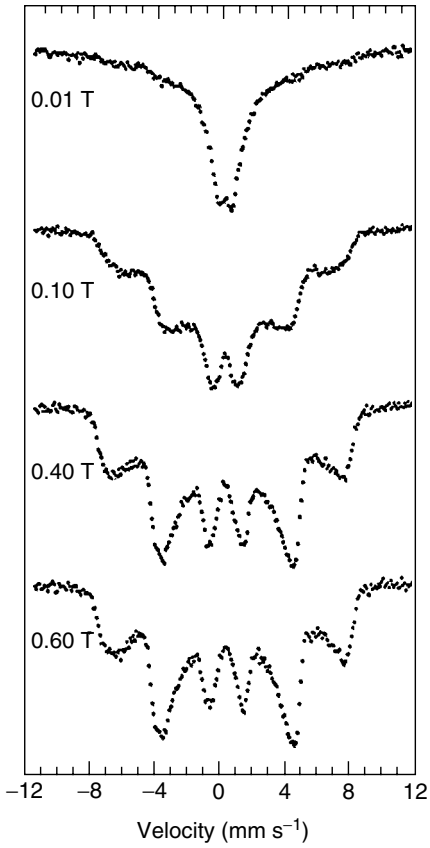

Figure 6. Mössbauer spectra of coated 7.5-nm maghemite nanoparticles obtained at 295 K with the indicated values of magnetic fields applied perpendicular to the γ-ray direction. (Reprinted figure from S. Mørup, F. Bødker, P.V. Hendriksen, S. Linderoth, *Phys. Rev.* **B52**, pp 287–294 (1995).)

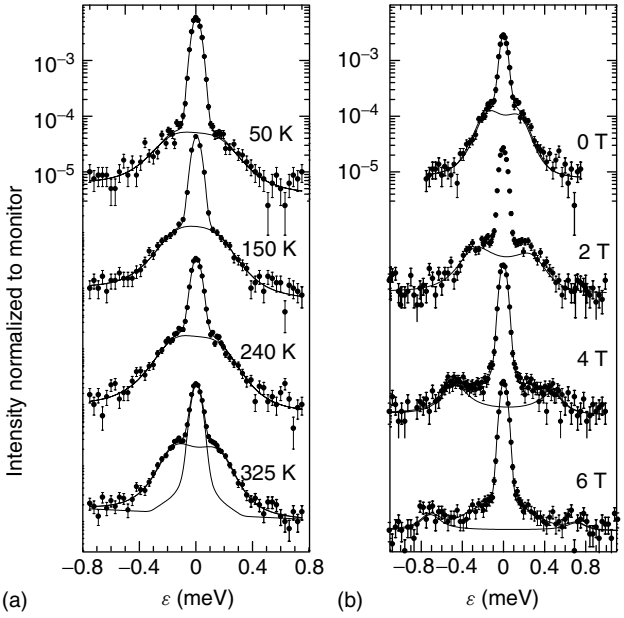

Figure 7. (a) Typical inelastic neutron-scattering data on 15-nm α-Fe_2O_3 nanoparticles obtained at zero field at the indicated temperatures. (b) Inelastic neutron-scattering data obtained at $T = 268$ K at the indicated applied magnetic fields. (Reprinted figure from M.F. Hansen, F. Bødker, S. Mørup, K. Lefmann, K.N. Clausen, P.A. Lindgärd, *Phys. Rev. Lett.* **79**, pp 4910–4913 (1997).)

study, for example, how the magnetic structure and the magnetic transition temperature of nanoparticles may depend on particle size. In a neutron diffraction study of plate-shaped nanoparticles of NiO with a thickness of a few nanometers (Klausen *et al.*, 2002), it was found that the Néel temperature was considerably lower than the bulk value, in accordance with theoretical estimates.

In inelastic neutron-scattering experiments, one analyzes the energy distribution of neutrons that are diffracted at a certain diffraction angle using a so-called triple-axis neutron spectrometer (Hansen *et al.*, 2000). By choosing a diffraction angle corresponding to a purely magnetic reflection, the energy distribution of the scattered neutrons gives information about the energy of magnetic excitations in the sample. As an example, Figure 7 shows energy scans from a triple-axis neutron spectrometer taken around the pure hexagonal (001) antiferromagnetic reflection for 15-nm hematite nanoparticles (Hansen *et al.*, 1997). The zero field scans (a) show a relatively narrow, quasielastic peak centered at zero energy transfer and two broad inelastic peaks at energy transfers around $\varepsilon \approx \pm 0.2$ meV. The width of the quasielastic peak increases with increasing temperature because of the finite lifetime of the magnetization orientations in superparamagnetic particles. Thus, the superparamagnetic relaxation time can be estimated from the line width of the quasielastic peak. Neutron scattering is sensitive to fluctuations at the timescale $10^{-14}\,\mathrm{s} > \tau > 10^{-7}\,\mathrm{s}$, that is, it is suitable for the study of superparamagnetic relaxation, which is so fast that Mössbauer spectroscopy becomes insensitive to the relaxation frequency. The inelastic peaks are caused by collective magnetic excitations and their positions correspond to the energy change associated with a transition between two neighboring precession states. The position of the inelastic peaks is at $\varepsilon = \pm\hbar\omega_{\mathrm{AF}}$, where $\omega_{\mathrm{AF}} \approx \hbar^{-1} g\mu_{\mathrm{B}}(2B_{\mathrm{A}}B_{\mathrm{E}})^{1/2}$ is the antiferromagnetic resonance frequency, g is the gyromagnetic ratio, μ_{B} is the Bohr magneton, $B_{\mathrm{A}} = K/M_{\mathrm{s}}$ is the anisotropy field, M_{s} is the sublattice saturation magnetization, and B_{E} is the exchange field (Hansen *et al.*, 1997, 2000). It can be seen that the area of the inelastic peaks increases with increasing temperature. This is due to the temperature dependence of the population of the precession states. When magnetic fields are applied, the inelastic peaks move to higher energies (Figure 7b) because the magnetization vectors precess in an effective field, which has contributions from both the anisotropy field and the applied field.

6 INTERPARTICLE INTERACTIONS

The magnetic properties of samples of nanoparticles are often strongly influenced by interparticle interactions. In particular, interactions can have a significant influence on the superparamagnetic relaxation. In some cases, the interactions result in faster relaxation and, in other cases, they result in some suppression of the relaxation. These apparently contradicting results have given rise to some debate in the literature (Hansen and Mørup, 1998; Dormann, Fiorani and Tronc, 1999). Both dipole interaction and exchange interaction between magnetic nanoparticles can be significant.

6.1 Dipole interactions

In samples with ferromagnetic or ferrimagnetic nanoparticles, the magnetic dipole interaction between neighboring particles is of the order of $E_{\mathrm{dd}} = \mu_0 \mu^2/(4\pi d^3)$, where d is the average distance between neighboring particles. If the concentration of particles is high, the interaction energy may be comparable to both the anisotropy energy and also to the thermal energy for temperatures up to about 100 K or more (Hansen and Mørup, 1998). In samples with weak interactions, the dipole fields modify the energy barriers separating the easy directions of magnetization. Dormann, Bessais, and Fiorani (1988) have proposed a model according to which the energy barriers always increase because of the dipole interactions. This model can qualitatively explain many experimental observations of suppression of superparamagnetic relaxation in samples with interparticle interactions. However, in some Mössbauer spectroscopy studies, the opposite behavior has been observed (Prené *et al*., 1994; Tronc *et al*., 1995). Simple analytical calculations (Mørup and Tronc, 1994; Hansen and Mørup, 1998) have shown that the net effect of weak dipole interactions is to reduce the average value of the energy barriers, and this can explain the increase in the relaxation frequency with increasing interaction strength. Later theoretical work has confirmed that the net effect of weak dipole interactions is to reduce the average energy barriers and thereby increase the relaxation frequency (Jönsson and García-Palacios, 2001; Iglesias and Labarta, 2004; Berkov, 1998).

In samples of ferro- and ferrimagnetic nanoparticles, it has been found that strong dipole interactions may result in a divergence of the superparamagnetic relaxation time at a finite temperature, which depends on the strength of the interactions. This has been investigated using, for example, AC magnetization measurements (Zhang, Boyd and Luo, 1996; Djurberg *et al*., 1997; Dormann *et al*., 1999). Both theoretical estimates and experimental studies have indicated that the critical temperature is of the order of $E_{\mathrm{dd}}/k_{\mathrm{B}}$ (Mørup, 1994; Hansen and Mørup, 1998). Below this critical temperature, such samples may exhibit complex nonequilibrium phenomena that are similar to those observed in spin glasses (Djurberg *et al*., 1997; Mamiya, Nakatani and Furubayashi, 1998; Jönsson, 2004). In ZFC magnetization measurements, interactions are observed to shift the peak of the curve toward higher temperatures. In AC susceptibility measurements, the peaks of the in-phase and out-of-phase susceptibility curves are typically shifted toward higher temperatures and, for strong interactions, the shape of the susceptibility curves may change significantly with frequency. In Figure 3, which shows AC susceptibility data for both noninteracting and strongly interacting γ-Fe_2O_3 nanoparticles, it is seen that the interactions shift all peaks toward higher temperatures and that the shape and height of the out-of-phase susceptibility curves have a stronger dependency on the frequency than the corresponding curves for the noninteracting particles. It is noteworthy that, because of the longer timescale of magnetization measurements compared to that of Mössbauer spectroscopy, the decrease in the relaxation time due to weak interactions may not be clearly visible in magnetization measurements (Mørup, 1994).

In summary, it is found that for weak magnetic dipole interactions the superparamagnetic relaxation time decreases with increasing strength of the interactions, but, for stronger interactions, the relaxation time increases when approaching a spin-glass-like ordered (collective) state.

6.2 Exchange interaction between nanoparticles

Because nanoparticles of antiferromagnetic materials have magnetic moments that are much smaller than those of typical ferromagnetic and ferrimagnetic particles, the magnetic dipole interaction between them is much weaker. Anyway, it has been found in several Mössbauer spectroscopy studies that interactions between antiferromagnetic nanoparticles can significantly suppress the superparamagnetic relaxation. This has been attributed to exchange interactions between surface atoms of neighboring particles (Mørup *et al*., 1983; Hansen, Bender Koch and Mørup, 2000; Bødker, Hansen, Bender Koch and Mørup, 2000; Frandsen and Mørup, 2003). As an example, Figures 8(a) and (b) show Mössbauer spectra of noninteracting and interacting 9-nm hematite particles, respectively. The particles in the two samples were from the same batch. The noninteracting particles were coated with oleic acid and suspended in heptane, whereas the interacting particles were uncoated, suspended in water, and then dried at room temperature allowing them to interact. The large differences between the spectra in Figures 8(a) and (b) show that interactions can have a substantial influence

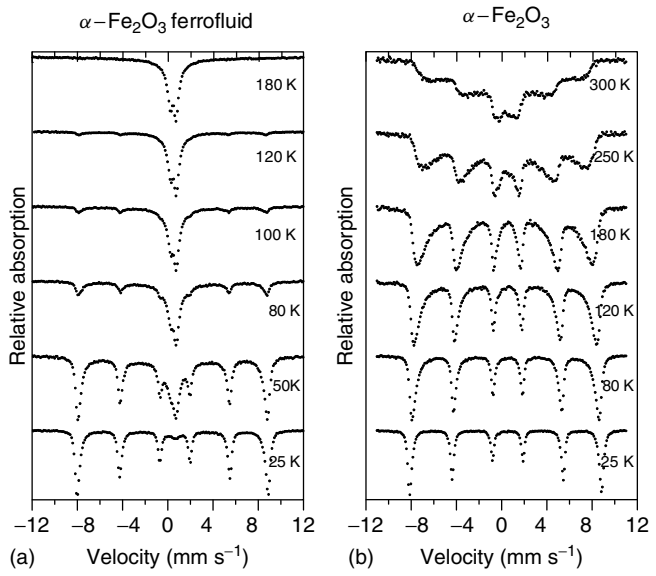

Figure 8. Mössbauer spectra obtained at the indicated temperatures of (a) noninteracting 9-nm α-Fe_2O_3 particles and (b) interacting 9-nm α-Fe_2O_3 particles. (Reprinted from the *Journal of Magnetism & Magnetic Materials*, vol 266, Frandsen *et al*., Inter-particle interactions in composites of antiferromagnetic nanoparticles, pp 36–48, 2003, with permission from Elsevier.)

on the relaxation. The observations can be explained by a simple model in which the magnetic energy of a particle, i, which interacts with its neighbors, j, is written (Mørup *et al*., 1983; Hansen, Bender Koch and Mørup, 2000; Frandsen and Mørup, 2003)

$$E_i = K V_i \sin^2 \theta - \mathbf{M}_i \cdot \sum_j K_{ij} \mathbf{M}_j \qquad (20)$$

where $\mathbf{M}_i$ and $\mathbf{M}_j$ represent the (sublattice) magnetization of the particles i and j, respectively and K_{ij} is an effective exchange coupling constant due to exchange coupling between surface atoms belonging to neighboring particles. If the first term in equation (20) is predominant, superparamagnetic relaxation may take place between the easy directions close to $\theta = 0$ and $\theta = \pi$ and, as discussed in Section 5.3, this results in spectra consisting of superimposed sextets and doublets. Strong interactions can result in an ordered (collective) state at temperatures where noninteracting particles would be superparamagnetic (Mørup *et al*., 1983; Hansen, Bender Koch and Mørup, 2000; Frandsen and Mørup, 2003). The magnetic properties may then be calculated using a simple mean-field model in which the summation in the second term in equation (20) is replaced by an average value (Mørup *et al*., 1983; Hansen, Bender Koch and Mørup, 2000; Frandsen and Mørup, 2003). Equation (20) then has a form similar to equation (7), that is, the effect of interactions is described in terms of an effective interaction field. If the interaction term in equation (20) is predominant, there is only one energy minimum. At finite temperatures, the (sublattice) magnetization then fluctuates around the direction corresponding to this energy minimum. If the fluctuations of the sublattice magnetization directions are fast compared to the timescale of Mössbauer spectroscopy, the magnetic splitting in the spectra is proportional to the average value of the magnetic hyperfine field. Variations of the magnitude and direction of the interaction field in the sample results in a distribution of magnetic hyperfine splittings, which leads to broadened sextets, like those seen in Figure 8(b), as it is also the case in spectra of superparamagnetic particles in applied magnetic fields (Figure 6). If the neighboring particles are randomly oriented, one might expect that the contributions from different neighboring particles in the summation of equation (20) partially cancel, and therefore the interaction field should be small. However, it has been shown that interacting nanoparticles of α-Fe_2O_3 nanoparticles may not be randomly oriented, but can form chains of particles with a common [001] axis. Neutron diffraction studies have shown that both structural and magnetic correlations exist across the interfaces along this direction. This can explain the substantial exchange coupling between the particles (Frandsen *et al*., 2005).

In recent studies, it has been found that exchange interactions between nanoparticles of different magnetic materials can have unexpected effects on the superparamagnetic relaxation time (Frandsen and Mørup, 2003; Frandsen *et al*., 2004). For example, the superparamagnetic relaxation of iron oxide particles was to some extent suppressed when they were mixed with nanoparticles of CoO, whereas the opposite effect was found when the iron oxide particles were mixed with nanoparticles of NiO. The studies indicate that there can be a strong exchange interaction between nanoparticles of iron oxide and nanoparticles of CoO and NiO. The different effect of mixing with CoO and NiO can be explained by differences in magnetic anisotropy of the nanoparticles of the two materials (Frandsen and Mørup, 2003; Frandsen *et al*., 2004).

7 MAGNETIC STRUCTURE AND TRANSVERSE RELAXATION IN NANOPARTICLES

Several studies have shown that the magnetic structure of nanoparticles may deviate from that of the corresponding bulk materials. Computer simulations have suggested that nanoparticles of NiO may have a complicated antiferromagnetic structure with eight sublattices instead of

the simple two-sublattice structure that is found in bulk (Kodama, Makhlouf and Berkowitz, 1997). In bulk hematite, the magnetic structure changes at the Morin temperature, $T_M \approx 263$ K. Above T_M, the sublattice magnetization is perpendicular to the [001] axis of the hexagonal structure. Below this temperature, the sublattice magnetization is parallel to this direction. However, in particles with diameters less than about 20 nm, the sublattice magnetization direction remains perpendicular to the [001] axis at all temperatures (Kündig, Bömmel, Constabaris and Lindquist, 1966; Schroeer and Nininger, 1967; Bødker and Mørup, 2000). Neutron-scattering studies have shown that the Néel temperature of NiO nanoparticles can be lowered compared to the bulk value (Klausen *et al*., 2002). It has recently been shown that interparticle interactions on powders of hematite nanoparticles can rotate the sublattice magnetization directions because of exchange coupling between differently oriented neighboring nanoparticles (Frandsen and Mørup, 2005).

In many defect-free macroscopic crystals of ferrimagnetic and antiferromagnetic materials, the spins in the sublattices are antiparallel. However, if a sample has defects in the interior, magnetic frustration may result in localized noncollinear magnetic structures. Noncollinear (canted) spin structures are commonly found in diamagnetically substituted ferrites and garnets (Coey, 1987; Dormann and Nogues, 1990). Similar spin-canting effects may be found at surfaces, and may therefore be important in nanoparticles. Experimental studies have revealed a rich variation of the dependence of spin canting on composition, temperature, particle size, and applied magnetic fields (Coey, 1971, 1987; Morrish and Haneda, 1983; Parker, Foster, Margulies and Berkowitz, 1993; Kodama, Berkowitz, McNiff and Foner, 1996; Tronc *et al*., 1998, 2000; Mørup, 2003). In particular, spin canting in maghemite (γ-Fe_2O_3) nanoparticles has been extensively studied because of their importance in magnetic data storage media.

Spin canting is conveniently studied by Mössbauer spectroscopy with large magnetic fields applied parallel to the γ-ray direction. In ^{57}Fe Mössbauer spectra, obtained in this way, the relative intensities of lines 2 and 5 in the six-line spectra are proportional to $\sin^2\theta_0/(1+\cos^2\theta_0)$, where θ_0 is the angle between the γ-ray direction and the total magnetic field at the nucleus. If the magnetic hyperfine field is large compared to the applied field, one finds that $\theta_0 \approx \theta_c$, where θ_c is the canting angle. Figure 9 shows, as an example, Mössbauer spectra of maghemite nanoparticles obtained at various temperatures with a magnetic field of 6 T applied parallel to the γ-ray direction (Tronc *et al*., 2000). In a perfect ferrimagnetic material, lines 2 and 5 would have zero intensity. The finite intensity of the lines in the spectra obtained at 9 K thus show that there is a noncollinear spin

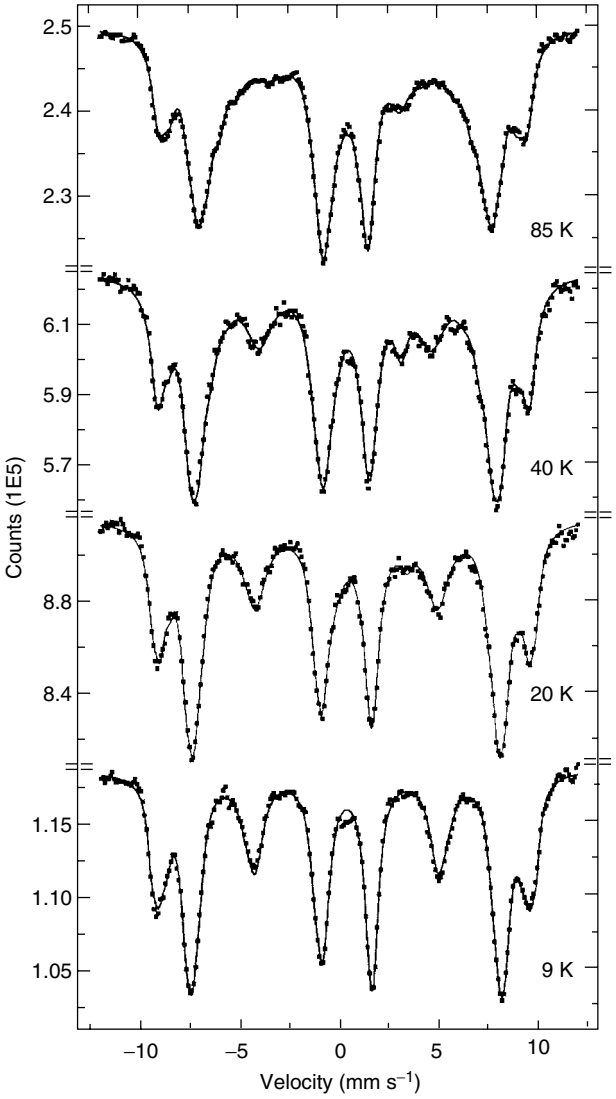

Figure 9. Mössbauer spectra of maghemite nanoparticles with a mean diameter of 2.7 nm. The spectra were obtained at the indicated temperatures with a magnetic field of 6 T applied parallel to the γ-ray direction. (Reprinted from the *Journal of Magnetism & Magnetic Materials*, vol 221, Tronc *et al*., pp 63–79, Surface-related properties of γ-Fe_2O_3 nanoparticles, 2000, with permission from Elsevier.)

structure in the sample. At higher temperatures, the intensity of lines 2 and 5 gradually disappears. This may be explained as follows: Let θ_c be the angle between a canted spin and the spin direction in defect-free environments. Owing to symmetry, a canted state with a canting angle θ_c is usually accompanied by an equivalent state with canting angle $-\theta_c$ (Mørup, 2003). The energy barriers that separate such equivalent states may be quite small and at finite temperatures there may therefore be transitions between such equivalent canted states. If the relaxation time of this so-called

transverse relaxation is of the order of nanoseconds, lines 2 and 5 in the Mössbauer spectrum are broadened (Helgason, Rasmussen and Mørup, 2006). If the transverse relaxation is fast compared to the timescale of Mössbauer spectroscopy, the nucleus only experiences the average magnetic hyperfine field, which is parallel to the applied magnetic field and the intensity of lines 2 and 5 therefore vanishes, as seen in the Mössbauer spectra in Figure 9. It has been shown that the energy barriers, ΔE, separating equivalent states with canting angles θ_c and $-\theta_c$, may have a distribution, which diverges for $\Delta E \rightarrow 0$ (Mørup, 2003). This may explain some of the observations of an apparently temperature-independent relaxation at low temperatures, discussed in Section 5.1.

In several studies, it has been assumed that spin canting is restricted to the surface, and the thickness of the canted surface layer has been calculated. However, this simple model cannot explain the irregular variation of the degree of canting with particle size (Linderoth *et al*., 1994). In fact, it has been shown that maghemite particles with similar size may have different degrees of canting, depending on the preparation method (Morales, Serna, Bødker and Mørup, 1997; Serna *et al*., 2001). This indicates that defects in the interior of the nanoparticles also can play an important role.

Extensive spin canting results in a diminished saturation magnetization. This makes the particles less useful for many applications such as data storage, biotechnology, and so on. Therefore, it is important to use preparation techniques, which lead to particles with low defect concentrations.

Novel Nanoparticulate Magnetic Materials and Structures

David J. Sellmyer, Yingfan Xu, Yucheng Sui and Ralph Skomski
University of Nebraska, Lincoln, NE, USA

1 INTRODUCTION

Magnetic nanoparticles, clusters, and particulate thin films have many present or future applications, for example, as permanent magnets, soft magnets, and sensors. However, in recent years, the most active area of research has been *magnetic recording*, and this trend is likely to continue in the foreseeable future. Magnetic recording media, such as hard disks and magnetic tapes, are widely used for data storage in computers and in audiovisual technology. Key criteria for magnetic recording media are areal density, signal-to-noise ratio, and thermal stability. Nanoparticulate thin films are ideally suited for this application because factors such as grain size, grain-size distribution, texture, magnetization, grain isolation, and film smoothness can be controlled with considerable precision. This is an important aspect of the fascinating increase in hard-disk storage density since about 1990, when thin-film media were introduced on an industrial scale. In addition, nanoparticulate thin films and related materials, such as fine particles and ferrofluids, have present or potential uses in many other areas including biomedical imaging and treatment applications.

This chapter deals with various aspects of nanoparticulate magnetic thin films and of the particles they contain. Emphasis is on magnetic recording media, due to their special importance in advanced data storage. Furthermore, we focus on the processing of nanoparticles of different shape, size, chemical composition, and texture, and on magnetic properties and phenomena directly related to the structures of interest. For information about basic magnetic phenomena, bulk properties, experimental and theoretical methods, and applications beyond magnetic recording media we refer to other articles of this handbook and to the references quoted in the following text. Similarly, structures produced from ultrathin films, such as dots and antidots, geometries created by ion-beam milling and lithography, and top-down approaches such as scanning tunneling microscopy (STM) deposition go beyond the scope of this article.

1.1 Basic concepts of magnetic recording

A key figure of merit of magnetic recording media is the areal storage density, measured in bits per square centimeter (b cm^{-2}) or bits per square inch (1 b $in.^{-2} = 6.452$ b cm^{-2}). Figure 1 shows schematically the development of the areal storage density in recent decades. Since its invention, magnetic recording has developed rapidly, competing with and often outperforming other storage media, from vinyl records and punch cards to advanced electronic and optical

Handbook of Magnetism and Advanced Magnetic Materials. Edited by Helmut Kronmüller and Stuart Parkin. Volume 4: *Novel Materials*. ISBN: 978-0-470-02217-7.

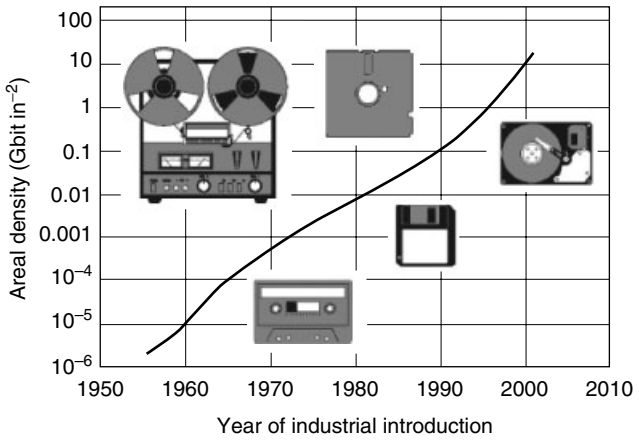

Figure 1. Increase in areal storage density since the 1950s (schematic). Modern audiovisual and data recording would be unthinkable without this development of storage media.

storage media such as CD-ROMs and flash memory. The main advantages of magnetic storage are the potential density and cost. The bit size of optical and magneto-optical media is limited by the wavelength of the used light, whereas semiconductor devices can be slow and/or volatile.

Defining an effective bit size as the square root of the inverse areal density, the progress shown in Figure 1 corresponds to a bit-size reduction from 250 µm in 1960 to 250 nm in 2000. The recent trend is likely to continue in the next few years, with terabit recording at the horizon. An upper limit to the recording density is provided by the thermal stability of the stored information, which makes it difficult to realize room-temperature magnetic recording using bit sizes smaller than several nanometers (Section 1.2).

A condition for magnetic recording is magnetic hysteresis, as epitomized by coercivity, remanence, and loop shape. In a sense, magnetic recording media are intermediate between soft and hard magnets. Typical media exhibit moderate but well-controlled coercivities. The coercivity H_c must be sufficiently large to ensure the long-time stability of the stored information, but very high coercivities complicate the recording process, because they require excessive writing fields. Very small particles obey the coherent rotation or Stoner–Wohlfarth theory, and for uniaxial anisotropy the coercivity approaches the anisotropy field $H_a = 2K_1/\mu_o M_s$. In this expression, K_1 is the first uniaxial anisotropy constant and M_s is the spontaneous magnetization. In most systems, H_c is much smaller than H_a. This is due to real-structure imperfections (Section 1.2).

The first magnetic recording medium was the magnetic wire, invented by Valdemar Poulsen in Denmark in 1898. Until the early 1940s, steel wires were used quite extensively for dictation, telephone recording, and radio broadcasting. Tape recording was pioneered in Germany, leading from a patent for iron-coated paper (!) and polymer film strips in 1928 to the first portable tape recorder (Volk, 1935). This was the starting point for various developments in sound and audiovisual magnetic recording, including the introduction of the tape cassette system in 1963 and of the VHS videocassette system in 1976.

A very important application of magnetic recording is *data storage* (Mee and Daniel, 1996; Comstock, 1999; Wood, 2000). Data storage using magnetic tapes is cheap but slow and therefore not suitable for applications where fast access is important. The first data-storage tapes, used in the United States in 1951, had bit lengths of about 200 µm and areal storage densities of the order of 0.002 Mb in.$^{-2}$. Tape storage systems range from ordinary audiocassettes to large reel-to-reel systems for mass storage. Audiocassettes were a popular choice for some home computers in the 1980s but are no longer used. By contrast, reel-to-reel and sophisticated cartridge systems continue to be used for purposes such as data backup. For example, present-day tapes have capacities of up to 320 GB.

Diskettes or *floppy disks* are a very convenient storage medium with moderate capacity. The first floppy disks, introduced in 1971, had a diameter of 8 in. and a storage capacity of 0.08 MB. Early personal computers used 51/4″ floppy disks, whereas single-sided single-density 51/4″ disks, first produced in 1976, had a capacity of 0.18 MB. The 31/2″ disk format was introduced by Sony in 1981. The widely used 31/2″ DS/HD disks, which date back to 1987, have a storage capacity of 1.44 MB and an areal density of more than 2.4 Mb in.$^{-2}$, as compared to about 0.3 Mb in.$^{-2}$ in early 51/4″ disks (1 MB in.$^{-2}$ = 0.155 GB cm^{-2}). The traditional way of producing floppy discs was to start from magnetic thin films that were isotropic in the plane. The disks were then obtained by cutting.

Today, *hard disks* are the most powerful data-storage medium for personal computers. Early hard disks, introduced by IBM in 1973, had a capacity of 30 MB but were large and cumbersome. Designed for use in data centers and large offices, they often required special power supplies and equipment racks. Since the 1980s, internal and external hard disks have been used in personal computers. The first PC hard disks had a capacity of only 5 MB, increasing to typically about 1 GB (1000 MB) in the mid-1990s and about 100 GB in 2005. This increase has been made possible by advances in magnetic nanotechnology, defining an effective bit size as the square root of bit width (track spacing) and bit length (inverse linear bit density). This underlines the role of nanostructuring in advanced magnetic recording: areal densities of 1 Mb in.$^{-2}$, 1 Gb in.$^{-2}$, and 1 Tb in.$^{-2}$ correspond roughly to bit sizes of 25 µm, 800 nm, and 25 nm, respectively. The physics of ultrahigh-density magnetic recording has recently been reviewed by Plumer, van Ek and Weller (2001).

1.2 Recording materials and limits

Early magnetic storage media used ferromagnetic 3d metals, especially iron and nickel, in the form of powders, wires, and thin films. They were soon complemented or superseded by magnetic oxides in the form of elongated small particles. Widely used oxides are γ-Fe_2O_3, CrO_2, and $BaFe_{12}O_{19}$, with typical particle lengths between 1 and 2 μm and coercivities of order of 50 mT (500 Oe). These media have the magnetization in the disk or tape plane, as contrasted to perpendicular recording. The latter, presently in a development stage, is more difficult to realize than longitudinal recording but has greater potential for ultrahigh-density recording (Wood, 2000).

The coercivity of typical magnetic particles is much smaller than the Stoner–Wohlfarth prediction $H_a = 2K_1/\mu_o M_s$. This is because real-structure imperfections give rise to incoherent magnetization reversal, even if the particle size is smaller than the critical single domain size (Skomski, 2003). Furthermore, for particle diameters larger about 20 nm, there are incoherent curling or 'vortex' modes, irrespective of the presence of imperfections. It is therefore necessary to have a sufficiently high anisotropy K_1. The leading contribution to the anisotropy involves spin-orbit coupling and crystal-field interactions. It depends on the local chemistry and on the atomic coordination of the magnetic moments and can be tuned quite easily by chemical substitutions (Skomski and Coey, 1999).

However, with decreasing particle size the coercivity increases and becomes more Stoner–Wohlfarth like. In fact, for some materials, the coercivity of small particles is actually too high for convenient writing, and coercivity tuning is more important that mere anisotropy enhancement. Aside from chemical substitutions, this may be done by exploiting the strong temperature dependence of the anisotropy and magnetization of some magnetic alloys (thermally assisted writing) and by using hard-soft composites.

An upper limit to the room-temperature areal density is given by the thermal stability of the stored information. Small hard grains of uniaxial anisotropy K_1 and volume V exhibit magnetic energy barriers $E_a = K_1 V$. When the volume is too small, thermal excitations reverse the spin direction and destroy the stored information. In a different context, this phenomenon is known as *superparamagnetism*. As analyzed by Becker and Döring (1939) and later popularized by Néel and Brown, thermally activated magnetization processes obey the Arrhenius law $\tau = \tau_o \exp(E_a/k_B T)$. In terms of the thermal stability factor $\xi = \ln(\tau/\tau_o)$, stability is achieved for volumes larger than

$$V = \xi k_B T/K_1 \tag{1}$$

Since $\tau_o \sim 10^{-10}$ s for a wide range of materials, safe information storage for more than 10 years implies $\xi \approx 60$. Room-temperature anisotropies of very hard materials are of order 10 MJ m^{-3} (Skomski and Coey, 1999), so that V cannot be made arbitrarily small. Making particles elongated, $V = b^2 t$ where the film thickness $t \gg b$, does not solve the problem, because very thin particles are susceptible to thermally activated domain formation. The domain-wall energy $\gamma = 4\sqrt{AK_1}$, where $A \sim 10$ pJ m^{-1} is the exchange stiffness, so that the energy barrier for a double wall is of order $8b^2\sqrt{AK_1}$. This energy is independent of t and means that the room-temperature bit size cannot be much smaller than about 2 nm. Exchange coupling to other phases, such as antiferromagnets, stabilizes the stored information at the expense of areal density and does not represent a viable way of overcoming the superparamagnetic limit.

The high anisotropy of materials helps to improve thermal stability and coercivity. For this reason, hard magnetic materials are increasingly used in magnetic recording, although extremely high coercivities complicate writing. A typical example is $L1_0$ materials, such as FePt. Advanced high-density recording media, characterized by more than 10 Gb in.$^{-2}$ (1.55 Gb cm^{-2}), are based on materials such as Co–Cr–Pt–B, where Pt improves anisotropy. Other classes of materials, such as rare-earth transition-metal (RE-TM) nanocomposite films are also being considered.

1.3 New magnetic recording media

Magnetic thin films have been used as recording media in hard-disk drives since about 1990. Together with the development of recording-head technology, from the early inductive read heads and magnetoresistive (MR) heads since 1990 to the recent giant magnetoresistive (GMR) heads, this has been the key factor in the enhancement of the storage density in recent years (Mee and Daniel, 1996). The head development is accompanied by a shift of emphasis from read-back signal amplitude to signal-to-noise ratio, with focus on questions such as grain-size distribution and grain-size refinement. This includes grain isolation by chemical or physical means, in order to reduce intergranular coupling.

There are several approaches forwards the development of new recording media: Sputtering is a well-established method, but it is rapidly approaching its grain size and noise limits. Another approach is to use patterned media where each grain acts as a recording bit. This has the potential to increase the recording density beyond 1 Tb in.$^{-2}$, but it is very difficult to fabricate large-area patterned media and to read and write signals on such media. A third approach is to use patterned perpendicular recording media. This makes it possible to stabilize the magnetic structure by using

elongated particles, but there are various technical challenges involved in this and all recording schemes that approach 1Tb in.$^{-2}$.

1.3.1 Sputtered media

The first generation of magnetic media for hard disks used particulate media consisting of γ-Fe_2O_3 particles dispersed in polymeric binders. The coating was spun onto the substrates, and the magnetic particles were aligned by a circumferential magnetic field before the solvents had completely evaporated. To improve the mechanical durability and to separate the recording head from the polymeric binder, aluminum oxide particles with diameters larger than the coating thickness were added. Since adequate mechanical properties require a particle volume fraction of less than 30%, relatively thick coatings are necessary. Thin coatings with good uniformity are very difficult to obtain and the nonmagnetic aluminum oxide particles degrade the signal-to-noise ration.

Today, most magnetic recording media for hard-disk drives are thin films, which are deposited by *sputtering*. The advantages of the sputtered film media over particle-coated media are their superior magnetic properties in much thinner films and smoother surfaces. Smooth surfaces allow low flying heights that reduce spacing between the head and the medium, thereby increasing the areal density. In addition, by modifying the sputtering parameters, the microstructure can be controlled and magnetic properties can be tailored to satisfy desired recording requirements. Advantageous magnetic properties of sputtered thin films are high magnetization, high anisotropy, and adjustable coercivity. In particular, the enhanced magnetization allows the use of thin recording layers without loss in read-back signal, and the high anisotropy enhances the thermal stability.

Figure 2 shows the basic structure of a thin-film medium, which consists of a substrate, an underlayer, a magnetic layer, an overcoat, and a lubricant. An Al–Mg alloy with a thick plated amorphous NiP layer is used as the substrate. The hard NiP layer allows easy polishing and provides a surface for resistance to mechanical damage. The underlayers develop a necessary texture, which controls the grain size and hexagonal *c*-axis alignment of the magnetic layer.

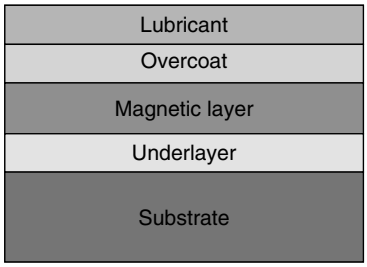

Figure 2. Basic structure of a thin-film medium.

The underlayers, Cr or body-centered cubic Cr alloys such as Cr–Mo and Cr–W, promote the epitaxial growth of magnetic layer. To reduce the grain size and orientation, an additional nucleation or seed layer is deposited before the Cr-alloy underlayer, because it is difficult to nucleate the necessary Cr texture on glass or glass-ceramic surfaces. Examples of seed-layer materials are MgO (Lee, Cheong, Laughlin and Lambeth, 1995) and AlN (Mirzamaani and Doerner, 1996).

Most *magnetic layers* for the present longitudinal recording are pseudoternary and -quaternary alloys based on hcp cobalt. Typical examples are Co–Cr–Ta, Co–Cr–Pt, Co–Ni–Pt, Co–Ta–Ni, Co–Cr–Pt–Ta, and Co–Pt–Cr–X (X = Ni, B, or Si). Another material of potential interest is Co–Cr–Pt–Ta–Nb. A key issue in magnetic recording is media noise. In thin-film media, a major consideration is transition noise, which strongly depends on the grain size and on whether the grains are exchange coupled. Reducing intergranular interactions by physically isolating or chemically segregating the grains helps reduce the media noise. The chromium yields grain boundaries that decouple the grains and improve the corrosion resistance. Elements such as Ta, B, Nb, P, Pt, W, Si, Ir, and Sm are added to Co to improve the signal-to-noise ratio by realizing optimized nanostructures. A similar effect is obtained by adjusting deposition parameters. For example, using high gas pressure to sputter Co alloy can create voided grain boundaries, which helps to isolate the grains physically (Yogi *et al*., 1990).

1.3.2 $L1_0$ alloys

Unlike most other additives, Pt enhances the magnetocrystalline anisotropy of the magnetic alloys, improving both the coercivity and the thermal stability (Ishikawa and Sinclair, 1996). Magnets with equiatomic compositions, such as FePt and CoPt, crystallize in the tetragonal CuAu(I) and $L1_0$ structure. These materials, discovered by Graf and Kussmann (1935) and Jellinghaus (1936), are characterized by very high magnetic anisotropies of several megajoule per cubic meter and have long been used as specialty permanent magnets. Recently, this fascinating class of materials has attracted considerable attention in magnetic recording. Figure 3 shows that the $L1_0$ structure consists of alternating monolayers of different atoms. The magnetic $L1_0$ magnets contain a 3d or iron-series transition-metal element, such as Fe or Co, and a 4d or 5d transition-metal element, such as Pt or Pd.

A challenge is that nearly equiatomic FePt and CoPt form both the disordered fcc and ordered $L1_0$ structure. The cubic anisotropy of the fcc is very low, and a proper heat treatment of the as-deposited fcc films is necessary to form the $L1_0$

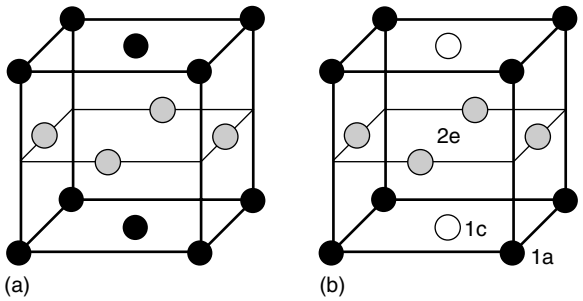

Figure 3. Structure of $L1_0$-type magnets: (a) equiatomic composition and (b) general composition (ABC_2). (Reproduced from R. Skomski *et al*., 2005, with permission from Elsevier. © 2005.)

phase. The coercivities of appropriately grown FePt films, about 2 T, are in fact too high for convenient writing. Current research aims at tuning the coercivity by methods such as random or site-specific substitutions on 1a, 1c, and 2e sites.

A promising approach is to embed CoPt and FePt particles in a nonmagnetic matrix, such as C, SiO_2, Ag, Al_2O_3, and B_2O_3. Most of these films are deposited in a multilayered film and subsequently annealed to obtain the desired nanocomposite structure. For example, the anisotropy of FePt in nanocomposite FePt:B_2O_3 films can be controlled by varying the total film thickness, initial B_2O_3 layer thickness, and the Fe concentration (Luo *et al.,* 2000). Yan *et al*. (2003) have fabricated nonepitaxially grown, double-layered FePt:C/FeCoNi thin films with excellent perpendicular anisotropy on a soft underlayer.

1.3.3 Rare-earth transition-metal compounds

A potentially important class of materials for magnetic recording is RE-TM intermetallics. By rare-earth and transition-metal substitutions it is possible to tune the properties such as magnetization, Curie temperature, and anisotropy over a wide range (Skomski and Coey, 1999). The room-temperature anisotropy of $SmCo^5$ is as high as 17 MJ m^{-3}, as compared to 0.53 MJ m^{-3} for hcp Co. This large anisotropy would allow grain sizes down to a few nanometers, without losing the thermal stability. This corresponds to areal densities in excess of 1 Tb in.$^{-2}$.

However, RE-TM films with the desired properties are usually difficult to produce, as deposited RE-TM films are amorphous and do not have large crystalline anisotropy when they are sputtered below 600 °C. This leads to unfavorably high processing temperatures during growth or post annealing, which is difficult to realize on an industrial scale. Furthermore, rare earths are very corrosive and need special care during processing. Among the considered alloys are Sm-Co and Pr-Co, and the resulting structures are granular. For example, room-temperature deposition of Pr-Co films on Cr underlayers yields essentially amorphous films with coercivities of about 30–40 mT. Subsequent annealing for 20 min at 400 °C causes the Pr-Co to crystallize, and high-resolution transmission electron microscopy (TEM) reveals grain sizes of about 10 nm. The coercivity reaches 200–800 mT, depending on film thickness and deposition conditions (Malhotra *et al*., 1996).

1.3.4 Particulate and other structured media

Advanced magnetic recording technology requires new magnetic nanostructures, such as nanoparticle-based media with great uniformity in both particle size and particle properties (Weller and Moser, 1999). This includes the limit of patterning the media so that each grain represents one bit (White *et al*., 1997). Methods to produce suitable nanostructured thin-film materials include artificial structuring, template-assisted assembly (Sun, Fullerton, Weller and Murray, 2001), and self-assembly. A comprehensive treatment of these methods goes far beyond the scope of this chapter, and we will restrict ourselves to a few examples and then address some material issues in more detail.

E-beam and focused ion-beam lithography, which work for feature sizes down to 50 nm or less, are slow and cumbersome. By contrast, optical lithography and related methods, such as laser-interference lithography (Zheng *et al*., 2001), can be used to pattern large areas; but the feature size is limited by the wavelength. Template methods, such as electrodeposition into porous anodic alumina, combine small feature sizes, and large-area processing (Sellmyer, Zheng and Skomski, 2001). They can also be used to produce structures such as nanocylinders (Section 3).

In some cases, the exchange interaction of the heavy (4d or 5d) transition-metal atoms is antiferromagnetic. This is exploited in *antiferromagnetically coupled* or AFC media, where Co-based magnetic layers are separated by ultrathin ruthenium layers (Fullerton *et al*., 2000). For some thickness, the Pauli-paramagnetic ruthenium layer yields an antiferromagnetic RKKY-type coupling between the Co layers, and the recording signal is the staggered magnetization of the structure.

One way of producing arrays of monodisperse particles is *chemical synthesis*. The nanoparticle dispersions are stabilized toward aggregation and oxidation by a layer of organic stabilizers. It is then deposited on a solid substrate and the solvent is allowed to evaporate. In the films, the grains or nanoparticles are separated by a nonmagnetic coating (Figure 4), which minimizes exchange coupling between adjacent grains. As an example, decomposition of $Fe(CO)_5$ and using polymer stabilizers is a common way to make Fe nanoparticles (see e.g., Johansson, Hanson, Hendriksen and Mørup, 1993). It is also possible to produce binary-alloy

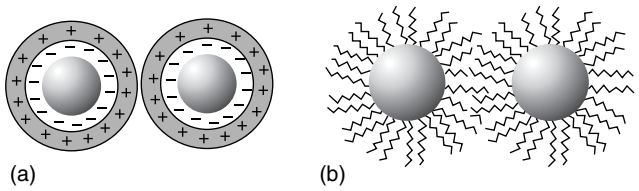

Figure 4. Chemically processed nanoparticles: (a) coating by ionic compounds and (b) steric repulsion due to long-chain surfactants. (Reproduced from David Sellmyer *et al*., Advanced Magnetic Nanostructures, Chapter 9, 2006, with permission from Springer. © 2006.)

nanoparticles, such as CoPt and FePt, but the preparation of nanoparticles with well-controlled stoichiometry is quite complicated (Sun *et al*., 2000).

2 METALLIC NANOCLUSTERS

Magnetic nanoclusters, which have diameters from 1 to 10 nm, are of great scientific and technological interest. An example are the magnetic moments of free Fe, Co, and Ni clusters whose size dependence was determined by measuring their Stern–Gerlach deflections (Bucher, Douglass and Bloomfield, 1991; Billas, Becker, Châtelain and de Heer, 1993; Apsel, Emmert, Deng and Bloomfield, 1996; Edmonds *et al*., 1999). At a low temperature of 120 K, small Fe clusters ($25 \leq N \leq 130$ atoms) have a moment of $3\,\mu_B$ per atom, as compared to the bulk value of $2.2\,\mu_B$; which is reached at about $N = 500$ atoms (Billas, Becker, Châtelain and de Heer, 1993). This moment reduction, which reflects the reduced atomic coordination of surface atoms, and other features, such as pronounced surface anisotropy, make clusters attractive for potential applications such as high-density data storage, spin electronics, memory devices, and high-performance magnetic materials.

Traditionally, CoPt and FePt nanoparticles are prepared by normal magnetron sputtering or electron beam evaporation techniques (Stavroyiannis *et al*., 1998; Yu *et al*., 1999; Bian, Sato and Hirotsu, 1999; Suzuki, Kiya, Honda and Ouchi, 2001). Here we focus on a relatively recently developed gas-aggregation technique, where magnetron sputtering is employed in the source (Haberland, Karrais, Mall and Thurner, 1992; Haberland *et al*., 1994) for the preparation of magnetic nanoclusters and of cluster-assembled nanocomposites. This cluster-deposition technique can produce a range of mean cluster sizes from 3 to 12 nm with high deposition rate (can be as high as 5 Å s^{-1}), and a well-controlled cluster size and size distribution. A major advantage is that the clusters have size dispersions much smaller than that of grains in a typical vapor-deposition system.

2.1 Cluster source and gas aggregation

The formation of metal clusters by gas aggregation, where metal atoms are either evaporated or sputtered into a cooled inert gas flow at relatively high pressure, has been well established for the last two decades. By repeated collisions with the carrier gas, the supersaturated metal vapor nucleates and forms clusters. In some cases, this method is used in combination with mass selectors or time-of-flight (TOF) spectrometers (Baker *et al*., 2000).

Sputtering-based cluster sources have three advantages: (i) they can produce a large range of mean cluster sizes from 200 to 15 000 atoms per cluster, (ii) they have a high degree of ionization, from 20 to 50%, depending on the target material, and (iii) a wide variety of elements and alloys can be used as source materials. Usually, the deposition rate is about 3 Å s^{-1} for the total flux of the cluster beam. Sputtering-based gas-aggregation sources are now widely used in laboratories and commercially available from Oxford Applied Research and Mantis Deposition.

Figure 5 shows a modern cluster-deposition system with a sputtering-based gas-aggregation source (Xu, Sun, Qiang and Sellmyer, 2003a,b). It consists of five chambers: (i) the chamber for cluster formation containing a LN_2 cooled aggregation tube with a magnetron sputter discharge, (ii) a chamber containing a quadrupole mass selection and e-beam deposit in system for particle coating, (iii) the deposition chamber with a substrate holder, (iv) a sample load-lock

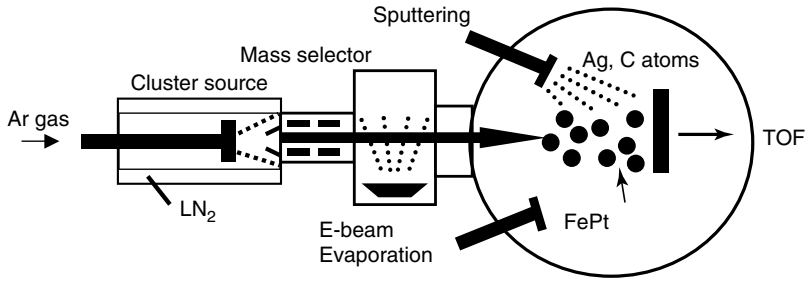

Figure 5. Cluster-deposition system (schematic). (Reproduced from D.J. Sellmyer *et al*., 2005. With permission from IEEE. © 2005.)

chamber (not shown) for rapid substrate change, and (v) a chamber (not shown) containing the TOF mass spectrometer. Briefly, the clusters are generated in the aggregation tube, go through two apertures, and are then deposited onto the substrate. The cluster size can be adjusted by varying the source parameters: gas-aggregation tube temperature, gas pressure, gases Ar to He flux ratio, magnetron power, and the condensation length in which the clusters aggregate. If a very narrow cluster size distribution is needed, the mass selector can be employed; in this case the ratio of rms diameter deviation to average diameter can be made as small as $\sigma/d \approx 3\%$. Figure 6 shows an example of Fe clusters produced with the quadruple mass selector.

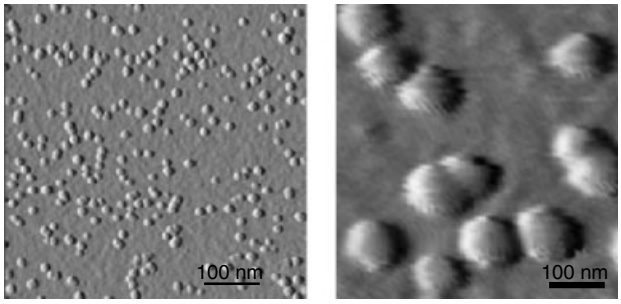

Figure 6. (a) Atomic-force (AFM) images of Fe clusters. (b) Enlarged Fe clusters with size about 8 nm.

2.2 $L1_0$ FePt and CoPt nanoclusters

This section deals with the size distribution and nanostructure of FePt and CoPt clusters prepared by the gas-aggregation technique (Xu, Sun, Qiang and Sellmyer, 2003a,b).

2.2.1 Size distribution and nanostructure of clusters

For cluster films deposited on a substrate, the determination of the structure are mostly done by using TEM. For the TEM observations, the FePt and CoPt nanoclusters are directly deposited onto carbon-coated films supported by Cu grids.

The TEM images in Figure 7 show CoPt clusters with average size of 4.9 nm ($\sigma = 0.46$ nm, $\sigma/d = 0.09$), prepared with sputtering power of 160 W (Xu, Sun, Qiang and Sellmyer, 2003a). The high-resolution image indicates that the CoPt clusters have faceted surfaces. Similar results were obtained for FePt clusters (Xu, Sun, Qiang and Sellmyer, 2003b). The cluster size follows a Gaussian distribution rather than the lognormal one observed in Fe clusters (Upward *et al*., 2000). This distinction is important but not yet understood in terms of the cluster formation mechanism.

The formation of $L1_0$-ordered FePt clusters naturally requires a high-temperature postdeposition annealing. However, postdeposition annealing leads to subsequent crystallite growth and concurring agglomeration of the clusters on the substrate. Rellinghaus, Stappert, Acet and Wassermann (2003) used a sintering oven between the cluster source and the deposition chamber, allowing preparation and thermal sintering of FePt nanoclusters in the gas phase prior to their deposition.

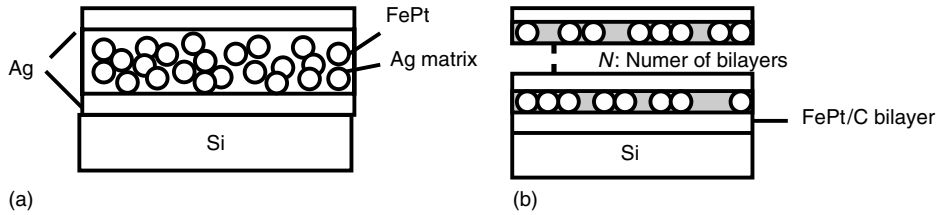

Figure 8. Cluster film structures: (a) codeposition and (b) multilayers.

2.2.2 FePt:C cluster films

For most applications, *embedded* clusters are more important than free clusters. The matrix material may be magnetic or nonmagnetic and metallic or nonmetallic. A cluster beam combined with an atomic beam from normal magnetron sputtering guns is used for matrix materials deposition, such as Ag, C, and so on. Figure 8 shows two examples: clusters embedded in matrix by codeposition (a) and isolated by a matrix via multilayers (b).

Figure 9 shows TEM images for annealed FePt:C nanocluster films prepared by the multilayer method. Alternating FePt cluster and C layers were deposited onto a Si substrate. The average FePt cluster size is about 4.5 nm, and the thickness of carbon layer was adjusted to yield C volume fractions changing from 7 to 45% (Xu, Yan and Sellmyer, 2004). The carbon serves to isolate the clusters and to avoid cluster aggregation during thermal annealing. After annealing, the FePt clusters remained well separated by the amorphous carbon, Figure 9(b).

As verified by X-ray diffraction, the grains have the $L1_0$ structure. Both in-plane and perpendicular coercivities increase with annealing temperature. A perpendicular coercivity larger than 13 kOe was achieved in the films annealed at a temperature of 700 °C for 10 min. The same method was also used to prepare dilute FePt:C cluster films with a FePt volume fraction of 5%. The low-temperature coercivity is 4.0 T, corresponding to an anisotropy field of 8.3 T. This indicates that the individual FePt particles are Stoner–Wohlfarth like.

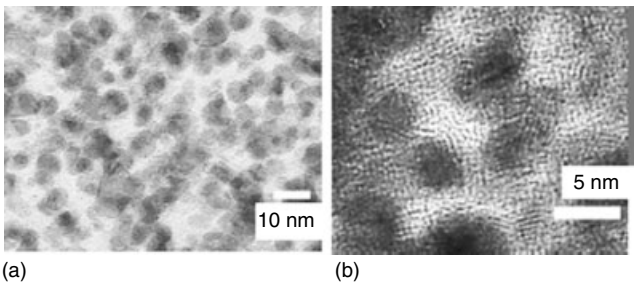

Figure 9. TEM images of FePt:C cluster film with 45 vol% C, annealed at 650 °C for 10 min. (Reproduced from Y. Xu *et al.*, 2004, with permission from IEEE. © 2004.)

3 CHEMICALLY DEPOSITED NANOPARTICLES AND NANOTUBES

There are three main bottom-up approaches in making isolated magnetic clusters: chemical reaction (molecular clusters), evaporation or sputtering and condensation (gas phase clusters), and matrix isolation (solution phase and template synthesis). Matrix isolation is the most widely used method in creating magnetic nanostructure. In this section, the main focus is on (i) the creation of nanostructures through solution processes and (ii) template synthesis.

3.1 Chemical reaction mechanisms

3.1.1 Cluster formation by solution reaction

Cluster synthesis by solution phase reaction is a thermodynamic quasiequilibrium approach and follows the well-established theory of crystal growth. It consists of three consecutive processes: supersaturation, nucleation, and growth (Murray, Kagan and Bawendi, 2000). Solvents ensure that the chemical reaction proceeds homogeneously and act as a flexible isolating matrix to keep the clusters apart. To produce monodispersed clusters, it is highly desirable that nuclei with identical size be created at the same time in supersaturated solution. In many cases, the supersaturation is technically achieved through the rapid injection of organometallic compounds into a hot solution. Either thermal decomposition or chemical reduction at the high temperature, combined with the rapid drop of processing temperature, induces a sharp nucleation followed by slow growth at low concentration.

Both the inhibition of additional nucleation during growth and the controlled growth of nuclei are important to obtain monodispersed clusters. When the concentration of growth species is lower than the specific concentration after the explosive nucleation, additional nucleation is inhibited. The organic capping agents on cluster surfaces act as a diffusion

barrier to control the growth of the nuclei. The polymeric layers covering the clusters also prevent agglomeration and oxidation, and define the minimum intercluster separation after self-assembly. Further growth, named *Ostwald ripening*, is observed in many systems at a late stage of growth. The main characteristic of Ostwald ripening is that the larger clusters keep growing at the expense of smaller ones, driven by the difference of their surface free energy. Ostwald ripening also helps to narrow the size distribution if it is properly exploited.

3.1.2 Template-mediated synthesis

If the isolating matrix is a solid nanostructure instead of a liquid, the matrix isolation approach is called *template-mediated synthesis*, rather than solution phase synthesis. A wide variety of materials covering both organics and inorganics have been built into nanostructures by template-engaged processes (Hulteen and Martin, 1997; Sellmyer, Zheng and Skomski, 2001; Sui, Skomski, Sorge and Sellmyer, 2004a; Sui *et al*., 2004b). The only requirement seems to be the proper method to load the pores with the desired materials, as long as the template is stable with respect to the nanomaterials and chemical reactions inside these pores.

Most of the work in this area is based on porous films such as anodized alumina, track-etched polycarbon, and self-assembled block copolymers (Hulteen and Martin, 1997). The common feature of these templates is nanopores having their axis perpendicular to the film plane, but pore diameters, densities, distributions, thermal and chemical stabilities, surface chemical characteristics differ from one template to another. For nanostructures deposited by electrochemical, electroless, sol–gel and electrophoretic process, the templates are involved physically rather than chemically and have a similar isolating effect for all the typical templates. For nanostructures produced by high-temperature chemical reaction – chemical vapor deposition (CVD) or hydrogen reduction – anodized alumina film becomes the only option, due to its heat resistance (Sui *et al*., 2002; Sui, Skomski, Sorge and Sellmyer, 2004a).

3.2 Magnetic clusters produced by solution phase reaction

The decomposition of organometallic precursors in an inert atmosphere (Section 3.1.1) has long been employed to produce Co, Fe, and Ni clusters (Thomas, 1966; Hoon, Kilner, Russell and Tanner, 1983), but with a relatively large size distribution. A modification of this technique, namely, the rapid injection of organometallic reagents into a hot coordinating solvent, has led to the synthesis of monodispersed clusters of transition metals and their alloys with controllable size and shape. The synthesis of FePt cluster by the combination of $Pt(acac)_2$ reduction and $Fe(CO)_5$ thermal decomposition in dioctylether under airless condition is a typical chemical synthesis via solution phase reaction (Sun *et al*., 2000). The cluster size is controlled by the explosive nucleation and the slow seed-mediated growth. For example, 10-nm FePt clusters are produced first by growing 3-nm clusters *in situ* and then adding more reagents to enlarge the existing seeds to 10 nm. The alloy composition can be adjusted by changing the molar ratio of iron carbonyl to the platinum salt. Postannealing is necessary to transform the FePt clusters from the disordered face-centered cubic to the ordered $L1_0$ structure. Following a similar recipe, clusters of both transition-metal oxides and a RE-TM alloy ($SmCo_5$) with narrow size distributions have also been synthesized. However, the low anisotropy of the Sm-Co, $0.2\,MJ\,m^{-3}$ indicates incomplete phase transformation, leaving much room for improvement by the solution phase reaction.

One of the oldest techniques for the synthesis of magnetic clusters is the precipitation of oxides from the solution. For example, Fe_3O_4 nanoparticles were produced via coprecipitation from a $FeCl_3$ and $FeCl_2$ water solution by NaOH or $NH_3{\cdot}H_2O$ base. The advantage of the precipitation reaction is that large quantities of clusters can be produced by controlling the pH value and the metal cation concentration properly. However, it is difficult to tailor the size and shape of the particles. This problem has been solved by a recently developed organic-phase synthesis approach. Either metal or oxide clusters can be generated by the decomposition of organometallic compounds in the presence of polymeric stabilizers. The type of the organometallic precursors and the solvents, the decomposition and growth condition are critical in determining whether metal or oxide clusters will be produced (Park *et al*., 2004). For example, 5-nm clusters of iron oxides are produced by the decomposition of iron-oleate complex in 1-hexadecene at 350 °C > 280 °C for 30 min. When the same iron-oleate complex is processed in trioctylamine at 380 °C, 20-nm iron cubes are synthesized. Both iron cubes and spherical iron oxide clusters have size variations of less than 4.1%, without applying size-selection process. This technique can be extended to produce monodispersed manganese ferrite and cobalt ferrite clusters also.

Magnetic clusters made by solution reaction provide not only a good opportunity to explore the basic physics and chemistry of nanomaterials, but also supply a rich source of building blocks to construct macrosystems with controlled nanostructure. Such structures are of importance, for example, in permanent magnetism (Skomski and Coey, 1999; Sellmyer, 2002). When FePt and Fe_3O_4 clusters of similar size (about 4 nm) assembled together

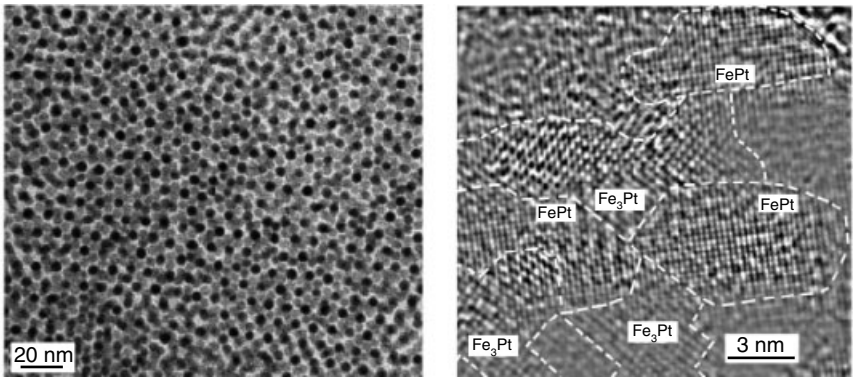

Figure 10. TEM image of binary particulate thin films: (a) FePt and Fe_3O_4 nanoparticles and (b) annealed FePt–Fe_3Pt nanocomposite. (Reprinted by permission from Macmillan Publishers Ltd: Nature 420, H. Zeng *et al*., 2002. © 2002.)

in specific mass ratio, and heated in a gas mixture (Ar + 5% H_2) at 650 °C for 1 h, the binary system is transformed into a homogeneous mixture of hard tetragonal FePt phase and a high magnetization soft Fe_3Pt phase (Zeng *et al*., 2002). Figure 10 shows typical TEM images of (a) assembled binary FePt and Fe_3O_4 nanoparticles, and (b) of the annealed FePt–Fe_3Pt nanocomposite. The latter structure exhibits effective exchange coupling between hard and soft magnetic phases to enhance the energy product of the nanocomposite.

3.3 Magnetic nanostructures created by template-mediated reaction

3.3.1 Magnetic nanotubes and one-dimensional nanocomposites

Magnetic nanostructures may be produced in a wide range of shapes, sizes, and materials (Skomski, 2003). This includes not only thin films, particles, and nanowires but also structures such as nanotubes and nanorings. Transition-metal nanotubes and nanowires have been produced by electroless or electrodeposition guided by various porous templates (Tourillon *et al*., 2000; Sellmyer, Zheng and Skomski, 2001). Nanochannels of porous alumina are used as nanoreactors to create both nanotubes and nanoparticles. However, it is difficult to tune the magnetic properties of one-dimensional structures generated by electrochemical methods. This refers, in particular, to magnetic compounds, such as intermetallics and ferrimagnetic oxides.

Nanoporous alumina templates have been loaded with a mixture of $H_2PtCl_6 \cdot 6H_2O$ and $FeCl_3 \cdot 6H_2O$ and heated in hydrogen for 1.5 h at 560 °C. This led to the formation of FePt nanotubes inside the pores of the template. Similarly, Fe_3O_4 nanotubes arrays were produced by loading the template with alcohol solution of 65% $Fe(NO_3)_3 \cdot 9H_2O$ and processing at 250 °C for 2.5 h in flowing hydrogen (Sui, Skomski, Sorge and Sellmyer, 2004a). The porous alumina film simply serves as a skeleton in which FePt or Fe_3O_4 are generated *in situ* by hydrogen reduction and shaped into nanotubes with their morphologies complementary to the nanochannels of the anodized alumina. Figure 11 shows the results of the procedure: TEM micrographs of (a) FePt and (b) Fe_3O_4 nanotubes, and hysteresis loops of (c) FePt and (d) Fe_3O_4. The magnetic properties can be explained in terms of a tubular random-anisotropy model (Sui, Skomski, Sorge and Sellmyer, *et al*., 2004a).

Hysteresis in very small particles is realized by coherent or Stoner–Wohlfarth rotation. In practice, this applies to particles with diameters of less than 5–20 nm, depending on factors such as particle shape and real structure (defect structure). In larger particles, there is a broad range of incoherent spin configurations such as spin waves and curling modes or 'vortices'. Figure 12 shows some examples for nanotubes and nanorings (Sui, Skomski, Sorge and Sellmyer, 2004a). The physical origin of these nonuniform spin states and the corresponding length scales have been reviewed by Skomski (2003, 2004), and there is also a discussion of incoherent magnetization states in nanoparticles of various shapes (Skomski, Kashyap, Sorge and Sellmyer, 2004).

The technique of chemical reactions in nanochannels can be extended to the creation of quasi-one-dimensional nanocomposites of transition metals in carbon by the combination of hydrogen reduction with carbon deposition using CVD (Sui *et al*., 2002). Figure 13 shows TEM micrograph of a composite FePt:C nanofiber. The FePt $L1_0$ clusters were formed by hydrogen reduction at 650 °C, followed by carbon deposition using C_2H_2 pyrolysis at the same temperature. The FePt:C nanocomposite exhibits a coercivity of 29.0 kOe after heating at 900 °C in nitrogen.

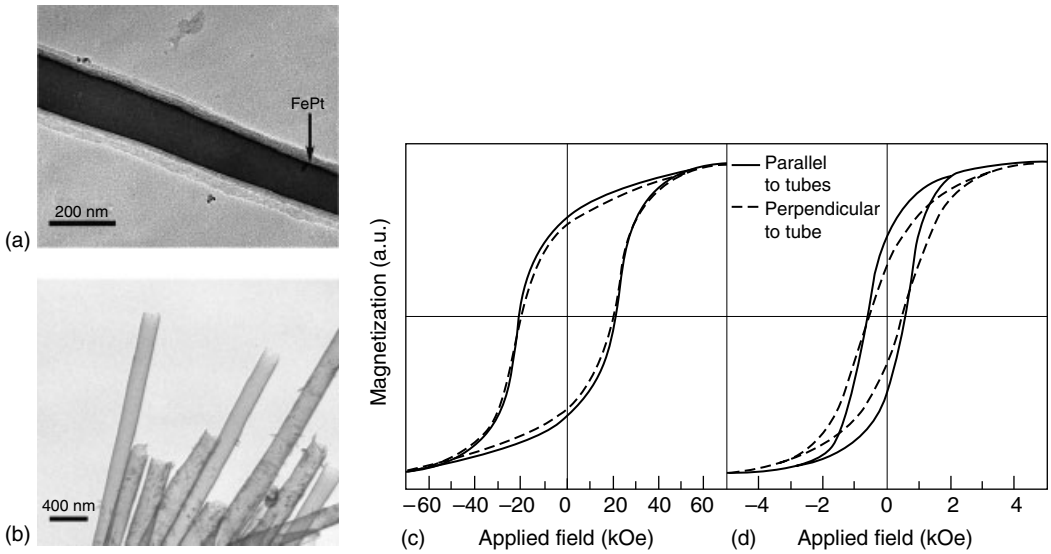

Figure 11. TEM micrographs and room-temperature hysteresis loops of magnetic nanotubes: (a) isolated FePt nanotube surrounded by alumina and (b) Fe_3O_4 nanotubes released from the matrix, (c) hysteresis of FePt and (d) Fe_3O_4. In the loops, the external field is parallel (solid lines) and perpendicular (dashed lines) to the tubes axes. (Reproduced from Y.C. 3.3.2 Template-mediated self-assembly

FePt $L1_0$ nanoparticles produced within the pores of the templates by hydrogen reduction can be extracted and capped with organic surfactants. These clusters have a relatively large size distribution. After size selection via chemical processing, clusters with average diameter of 11 nm precipitated out. Figure 14 shows a TEM image of the selected FePt cluster assembled on a copper grid with 10 nm carbon coating, which demonstrates a narrow size distribution with standard size deviation (σ/d) of about 7%. Those clusters form a suspension in hexane and behave as a liquid under the influence of capillary action.

Figure 15 depicts an alumina template with ordered pore array. The barrier layer consists of a regular hexagonal array of hemispherical cells above the pores. Two-step anodization of aluminum foils can create similar structures (Sui *et al*., 2002). The pore array of the alumina template tunes the self-assembly process when the FePt cluster suspension is drop cast over the template, and a magnetic pattern matching the hexagonal pore distribution is generated. This simple and fast technique is called *template-mediated self-assembly* (TMSA). An external magnetic field applied at the same time aligns the magnetic clusters during assembly.

The result of the TMSA process is shown in Figure 16. The images show the barrier layer after TMSA cluster suspension of FePt $L1_0$ in an external magnetic field. The

average pore diameter is 50 nm, which lead to the formation of 50-nm FePt dots arrays. The advantages of this technique over traditional self-assembly are that it can generate ordered cluster arrays up to centimeter scales or larger, and that the magnetic dots can be aligned by a magnetic field. This technique has a high potential for nanofabrication of arrays for high-density magnetic recording or other nanodevices.

4 CONCLUDING REMARKS

For two reasons, the focus of this article has been on nanoparticles and particulate thin films for recording media. Firstly, the recording industry has been the major driving force in recent magnetism research, and this trend is likely to continue in the near to medium future. Secondly, various aspects of experimental, theoretical, and industrial magnetism relevant to particulate magnets are treated in other parts of this handbook. However, it is important to keep in mind that many other present or future materials, such as soft magnets, permanent magnets, ferrofluids, and sensors, are nanoparticulate magnets. Examples are isotropic permanent magnets (Coehoorn, de Mooij and de Waard, 1989) and nanocrystalline soft magnets (Yoshizawa, Oguma and Yamauchi, 1988). Furthermore, particulate systems often combine features of nanoparticles or clusters with those of thin-film and bulk magnets (Zhou *et al*., 2004).

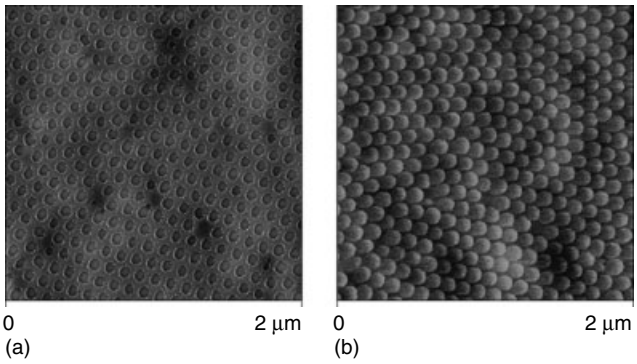

Figure 16. Self-assembled template-mediated $L1_0$ FePt: (a) atomic-force microscopy and (b) magnetic-force microscopy. Images are taken from the closed end of the pores (top side in Fig. 15). (Reproduced from Y.C. Sui *et al*., 2005, with permission from American Institute of Physics. © 2005.)

There are various methods to fabricate free and embedded ensembles of nanoparticles for magnetic recording. Key requirements for storage densities approaching 1 Tb in.$^{-2}$ are nanoparticles with well-controlled sizes, size distributions, separations, and crystalline orientations, and there has been an unprecedented search for artificial granular nanostructures that satisfy these criteria. The balance of room-temperature anisotropy and cluster or grain size is becoming increasingly important as the superparamagnetic limit is approached.

Our specific emphasis has been on cluster deposition of magnetic particles and deposition into porous templates. Chemical deposition is not as versatile as vacuum deposition technologies, such as sputtering. A combination of conventional thin-film technology and self-assembly may be a viable route to overcome these limitations.
